IMPLICIT $O(1)$ PROBE SEARCH*

AMOS FIAT† AND MONI NAOR‡

Abstract. Given a set of n elements from the domain $\{1, \cdots, m\}$, this paper investigates how to arrange them in a table of size n, so that searching for an element in the table can be done in constant time. Yao [*J. Assoc. Comput. Mach.*, 28(1981), pp. 615-628] has shown that this cannot be done when the domain is sufficiently large as a function of n.

This paper gives a constructive solution when the domain m is polynomial in n, the number of elements, as well as a nonconstructive proof for m no larger than exponential in poly (n). The authors improve upon a result of Yao and give better bounds on the maximum m for which implicit $O(1)$ probe search can be done. The results are achieved by showing the tight relationship between hashing and certain encoding problems called rainbows.

Key words. hashing, perfect hashing, spatial complexity, Ramsey theory, randomness in computation

1. Introduction. The problem addressed in this paper is that of searching a full table: A set $S \subset \{1, \cdots, m\}$ of size n is to be stored in a table T of size n, where every table entry holds a single element of S. Given $x \in \{1, \cdots, m\}$, the goal is to locate x in the table or to indicate that $x \notin S$, while probing the table as few times as possible. We assume that n and m are known to the searcher.

Yao [8] has shown that if no storage is available in addition to the table T, then there is no table organization that enables an element to be located in less than $\log n$ probes. We refer to a table organization that requires no additional storage as an *implicit* scheme. Yao's proof assumes that the domain size m is much larger than the number of elements n. This immediately raises the following two questions.

(1) For what values of m (relative to n) does an implicit $O(1)$ probe search scheme exist?

(2) Given that an implicit scheme does not exist, how much additional storage is required to ensure $O(1)$ search?

In [4] Fiat, Naor, Schmidt, and Siegel show that if $m = O(n)$, then search can be performed in $O(1)$ time without any additional storage. As for the second question, Fredman, Komlós, and Szemerédi [5] show that one probe search can be performed with $O(n\sqrt{\log n} + \log\log m)$ additional bits of storage. In [4] an $O(1)$ probe scheme is given that requires only $O(\log n + \log\log m)$ additional bits of storage.

We give an implicit $O(1)$ probe search scheme for a domain of size m that is polynomial in the number of elements n. We prove that an implicit scheme exists whenever m is bounded by $2^{\text{poly}(n)}$, based upon a probabilistic construction. It then follows from [4] that $O(\log\log m)$ additional bits are sufficient for any m.

We provide a refinement to Yao's theorem mentioned above that yields a better bound on the maximum m for which implicit $O(1)$ probe search schemes exist. Our proof technique gives a lower bound tradeoff between the number of probes and the

size of the domain that allows implicit search. In particular, if $O(1)$ probe implicit search is possible, then we can show that

$$m \leqq 2^{2^{2^{\cdot^{\cdot^{2^n}}}}}\Big\}O(1).$$

Yao's proof technique obtains a tower whose height depends on n.

These results are obtained by mean of a class of structures we call *rainbows*. A t-sequence over a set U is a sequence of length t, without repetitions, of elements in U. A (c, m, n, t)-rainbow is a coloring of all t-sequences over $\{1, \cdots, m\}$ with c colors so that for any set $S \subset \{1, \cdots, m\}$, $|S| = n$; all c colors occur in the coloring of the t-sequences over S. We show that the existence of $(c = n, m, n, t = O(1))$-rainbows is essentially equivalent to the implicit $O(1)$ probe search problem for a set of n elements chosen from the domain $\{1, \cdots, m\}$.

The relationship between rainbows and implicit $O(q)$ probe search schemes is specified by the following theorems.

THEOREM 1. *For m, n, let $c = \max(n, \log m)$. The existence of a $(c, m, n, t = O(1))$-rainbow yields an implicit $O(1)$ probe search scheme for n elements from the domain* $\{1, \cdots, m\}$.

THEOREM 2. *Given an implicit $O(1)$ probe search scheme for n elements chosen from the domain $\{1, \cdots, m\}$, we can construct an $(n, m, n, t = O(1))$-rainbow.*

To motivate rainbows, we start in § 2 by showing how they can be utilized to provide virtual memory.

Theorems 1 and 2 are proved in §§ 3 and 4. Section 5 contains a probabilistic construction for a $(c = n, m = 2^{\text{poly}(n)}, n, t = O(1))$-rainbow and an explicit construction for a $(c = n, m = \text{poly}(n), n, t = O(1))$-rainbow. Thus, by Theorem 1, we achieve the bounds claimed in the beginning of this section.

From their definition it is apparent that rainbows are related to Ramsey Theory. Indeed, the impossibility results we have are derived from Ramsey Theory are expressed in terms of Ramsey numbers.

In § 6 we show bounds on the maximal m, as a function of n, for which an $(n, m, n, t = O(1))$-rainbow exists. Thus, Theorem 2 gives bounds on m for which implicit $O(1)$ probe search schemes exist. Section 6 also discusses the connection between rainbows and colorings of the uniform hypergraph.

Section 7 deals with the relationship between the rainbow structure and other structures, called dispersers, proposed in the literature (for completely different applications). Specifically, we show that if an explicit construction for a certain kind of dispersers is possible, then we can find an explicit construction for an implicit $O(1)$ probe search scheme for m that is $n^{\log n}$. For these dispersers, Sipser [7] gave a probabilistic construction.

2. Rainbows provide virtual memory. We now show how Rainbows can be used to simulate additional memory. The virtual memory problem with parameters c, n', t, l is defined below:

Virtual memory problem.
- A set $R = \{r_1, r_2, \cdots, r_{n'}\}$, where $1 \leqq r_j \leqq m$ for $1 \leqq j \leqq n'$.
- A series of values $v_1, v_2, \cdots, v_l$, where $0 \leqq v_i \leqq c-1$ for $1 \leqq i \leqq l$.

Arrange the elements of R in an array A of size n' (putting each element of R in a different location), so that given $1 \leqq j \leqq l$, v_j can be reconstructed (decoded) quickly, via t accesses to A.

Note that we do not require anything about locating elements of R, only that they will reside somewhere in A.

The next lemma shows the relationship between this problem and the existence of rainbows.

LEMMA 1. *Given a (c, m, n, t)-rainbow $\mathscr{C}$, the virtual memory problem for parameters c, n', t, l such that $n - tl \geqq n$ can be solved.*

Proof. Divide the first $t \cdot l$ locations of the array A into blocks of size t. The elements of R should be arranged in A so that the color assigned by $\mathscr{C}$ to the jth block, i.e., to the sequence $\langle A[jt+1], \cdots, A[(j+1)t]\rangle$, is v_j. To achieve that, a greedy algorithm can be applied.

Greedy encoding.

```
• Set $U = R$.
• For $j = 1$ to $l$
    - find a sequence $s$ colored $v_j$ in $U$,
    - put the sequence $s$ in the $j$th block of $A$,
    - $U \leftarrow U \setminus s$.
• Arrange $U$ in the rest of $A$ arbitrarily.
```

Throughout the execution of the loop, the number of elements in U is $n' - jt \geqq n$. Hence there is a sequence in U colored by $\mathscr{C}$, and the find step in the algorithm always succeeds.

This arrangement means that in order to reconstruct v_j, we have to determine the color of the jth block under $\mathscr{C}$, and this can be done via t probes to A. This method is constructive if the color of a sequence under $\mathscr{C}$ can be determined effectively. □

3. Rainbows yield implicit $O(1)$ probe search. Our goal in this section is to prove Theorem 1. This section is strongly dependent on [4], which is the source of our techniques. A reader not familiar with the paper should be able to understand the major steps explained hereafter.

We note the following theorem from [4].

THEOREM 3 [4]. *n elements from the domain $\{1, \cdots, m\}$ can be arranged in a table of size n so that $O(1)$ probe search is possible, provided $O(\log n + \log\log m)$ additional bits of storage are available.*

We will concentrate on proving a slightly weaker version of Theorem 1.

THEOREM 4. *For m, n, let $c = \max(n, \log m)$. The existence of a $(c, m, n, t = O(1))$-rainbow yields an implicit $O(1)$ probe search scheme for $4n$ elements from a domain of size m.*

Later, we will show that the rainbow construction is robust in that the constants ($4n$) are irrelevant, a $(c, m, n, t = O(1))$-rainbow can be translated into another $(c^{e_1}, m^{e_2}, n^{e_3}, t' = O(1))$-rainbow for arbitrary fixed exponents e_1, e_2, $e_3 > 0$.

It now might seem trivial to prove Theorem 1, given Theorem 3. Given $4n$ elements from a domain of size m, we encode the $O(\log n + \log\log m)$ bits required by the (FNSS) scheme above by choosing $O(1)$ groups of t elements and ordering the elements in some fixed set of locations in the table as in the greedy encoding. During the search, the $O(1)$ special elements chosen for the encoding are read; if the search value is not found, then the elements are interpreted under the rainbow interpretation as representing the extra bits of storage required by the scheme in [4].

Unfortunately, moving the required elements to their position as required by the encoding ruins the original order suggested in [4]. To prove our claim, we must start afresh.

Given a set of n keys, $S \subset \{1, \cdots, m\}$. Fredman, Komlós, and Szemerédi [5] describe how to find a perfect hash function $f: \{1, \cdots, m\} \mapsto \{1, \cdots, n\}$ with the property that f is one-to-one and onto when limited to the domain S. This function requires a description of $O(\log\log m)+o(n\log n)$ bits. The description is split into $O(1)$ words of size $O(\log\log m+\log n)$ bits, plus an additional $o(n)$ words of $O(\log n)$ bits each. Evaluating the function f requires reading only $O(1)$ of these words.

We say that S is in the natural order in the table T relative to f if $T[f(x)]=x$, $x\in S$. The natural order is easy to search, given f's description. Another order that is easy to search is obtained by applying an arbitrary permutation $\tau:\{1,\cdots,n/2\}\mapsto\{1,\cdots,n/2\}$ to the first half of the table and applying τ^{-1} to the second half. (For $1\leqq i\leqq n/2$, set $T[\tau(i)]:=T[i]$; for $n/2<i\leqq n$, set $T[\tau^{-1}(i-n/2)+n/2]:=T[i+n/2]$.) The idea is that both τ and τ^{-1} are easy to compute. To compute $\tau^{-1}(i)$, simply evaluate $f(T[i])$; to compute $\tau(i)$, evaluate $f(T[i+n/2])-n/2$. As both τ and τ^{-1} can be computed with one probe to the table, search can be done by performing two probes to the table.

This is a variation of Feldman's involution trick, as presented in [2].

The method.

- Find a perfect hash FKS-function f for the $4n$ elements, as described in [5].
- Divide the elements into two sets, depending on whether $f(x)\leqq 2n$ or $f(x)>2n$.
- Encode the description of f by arranging the elements x with $f(x)\leqq 2n$ in the first half of T using the greedy encoding of § 2. By Lemma 1, this is possible.
- The arrangement defines a permutation τ of the elements in the first half of T, so organize the elements x with $f(x)>2n$ in the second half of the table as required under τ^{-1}.

Searching for an element now requires decoding $O(1)$ words of the description of the FKS-function. Each decoding requires probing the table at $O(1)$ locations. The natural order can be reestablished by appropriately computing either τ or τ^{-1}, each of which requires one probe plus $O(1)$ probes to read the [5] function description. Overall, search requires $O(1)$ probes.

4. Implicit $O(1)$ probe search yields rainbows. In this section we show that rainbows and $O(1)$ probe search schemes relate in the other direction as well; i.e., given a search scheme we show how to construct a rainbow. More specifically, we prove a refined version of Theorem 2.

THEOREM 5. *Given an implicit t-probe search scheme for n elements from the domain* $\{1,\cdots,m\}$, *an* $(n, m, n, t+2\log t)$*-rainbow can be constructed.*

Proof. The sequences are assigned colors based on simulating a search scheme. The colors $1,\cdots,n$ correspond to locations $1,\cdots,n$ in some imaginary search array. The idea is that in a t-sequence there is enough information to simulate a t probe search; i.e., given a t-sequence over $\{1,\cdots,m\}$, $e_1, e_2,\cdots,e_t$, we simulate a search for e_1 in the imaginary array, where e_{i+1}, $1\leqq i\leqq t-1$ is the element probed at Step i. Since the location probed at Step i is determined by the search value and the elements probed in Steps 1-$i-1$, we know the location in the imaginary array at each step of the simulation. The color assigned to the sequence is the last location we are to probe.

The only problem with this description is that e_1 might be probed at any of the t steps, not necessarily the last, but our sequences do not have repetitions. We can use $\log t$ bits to indicate the step number, j, at which e_1 is probed. This can be done by dedicating a pair of elements is allocated for each bit of j. If the elements are in order, they encode 0; otherwise 1. We assume that these elements are at the end of the sequence, that is, elements $e_{t+1}, e_{t+2},\cdots,e_{t+2\log t}$.

To summarize, the color assigned to the sequence

$$e_1, e_2,\cdots,e_t, e_{t+1},\cdots,e_{t+2\log t}$$

is the location of e_1 in the array for which the search is being simulated, where e_1 is encountered in the step encoded by $e_{t+1}, \cdots, e_{t+2\log t}$. Sequences that cannot be interpreted in such a fashion are colored arbitrarily.

CLAIM 1. *Given a set $S \subset \{1, \cdots, m\}$ of size n, and any color $1 \leqq c \leqq n$, there is a $t+2\log t$-sequence over S that is colored c.*

Proof. Assume that the set S is arranged in the array A so that implicit t-probe search is possible. Consider the sequence consisting of the elements probed in A when searching for $A[c]$, concatenated to $2\log t$ elements in S not appearing in the probe sequence whose order encodes the step number at which cell c is probed. This sequence is colored c, and consists only of elements in S. □

5. Rainbow construction. This section provides an explicit construction of rainbows when the number of colors $c = n$ and the length of the sequence t is a constant. We start with a construction for a domain m that is quadratic in the number of elements n (Lemma 2). The ideas behind this construction are later used in showing how to reduce a problem with domain m to another problem with domain $\sqrt{m}$ (Lemma 3). This yields an explicit recursive construction for any m that is polynomial in n (Theorem 6). Theorem 6 yields as a corollary that implicit $O(1)$ probe search scheme is possible when m is polynomial in n. We conclude the section by showing that a probabilistic construction is good even when m is exponential in n (Theorem 7).

LEMMA 2. *For any prime p, there is an explicit construction of a $(c = n,\ m = p^2,\ n = p+1,\ t = 2)$-rainbow.*

Proof. Consider a one-to-one mapping from all elements $e \in \{1, \cdots, m\}$ to pairs (x, y) such that $0 \leqq x,\ y \leqq p-1$. (For instance, $x = e \pmod p$, $y = (e-x)/p \pmod p$.) Given an element in $\{1, \cdots, m\}$, we will set its value of the mapping.

Color the sequence $\langle u, v\rangle$, $u = (x_1, y_1)$, $v = (x_2, y_2)$, with the color $(y_2 - y_1)/(x_2 - x_1) \pmod p$. If $x_2 = x_1$, then color the sequence $\langle u, v\rangle$ with the color p. We have colored all edges of the full directed graph on m vertices. Note that the sequence $\langle u, v\rangle$ is colored as the sequence $\langle v, u\rangle$; hence we can consider the coloring as that of a complete undirected graph. To prove that this is a good coloring, we need the following.

CLAIM 2. *Consider the edge induced subgraph G_i obtained by choosing all edges of color i. G_i consists of p vertex disjoint cliques of size p.*

Proof. First, note that every vertex $u = (x, y)$ has exactly $p-1$ directed edges $(u, v_j = (x_j, y_j))$ colored i, for all $0 \leqq i \leqq p$. For $i = p$, these are simply pairs (x, y_j), $y_j \neq y$; for $i < p$, the x_j and values are the $p-1$ solutions to the equation $(y_j - y)/(x_j - x) = i \pmod p$.

To show that the undirected induced subgraph consists of cliques, assume that the $\langle u, v\rangle$ and $\langle v, w\rangle$ sequences are colored i: then the $\langle u, w\rangle$ sequence must also be colored i. If $u = (x_1, y_1)$, $v = (x_2, y_2)$, and $w = (x_3, y_3)$, either $i = p$ in which case $y_1 = y_2 = y_3$ and (u, w) is also colored p or $i < p$, in which case $(y_2 - y_1)/(x_2 - x_1) = (y_3 - y_2)/(x_3 - x_2) = i \pmod p$. It now follows that $(y_3 - y_1)/(x_3 - x_1) = i \pmod p$. □

Remark. Note that all vertices u_j, $u_j = (x_j, y_j)$, belonging to the same clique in G_i, have the same value $y_j - ix_j \pmod p$. This means that we can identify the clique in G_i containing a vertex u.

We can now resume the proof of the lemma. Given a set $S \subset \{1, \cdots, m\}$ of size $n = p+1$, for all $0 \leqslant i \leqslant p$, at least two elements $u,\ v \in S$ belong to the same clique in G_i. This means that both sequences $\langle u, v\rangle$ and $\langle v, u\rangle$ are colored i.

To construct a rainbow for m polynomial in n, we use a recursive construction. We explain how to use the construction above to transform the problem from a domain of size m to a domain of size $\sqrt{m}$ by concatenating two elements to each sequence in the $\sqrt{m}$ domain.

LEMMA 3. *Given a construction of a $(c=n,\ m=p,\ n-2,\ t)$-rainbow, p a prime, a $(c=n,\ p^2,\ n,\ t+2)$-rainbow can be constructed.*

Proof. Let $\mathscr{C}_1$ be a $(p+1,\ p^2,\ p+1,\ 2)$-rainbow as described in Lemma 2, and let $\mathscr{C}_2$ be an $(n,\ p,\ n-2,\ t)$-rainbow that exists by assumption. Our goal is to construct an $(n, p^2, n, t+2)$-rainbow. Given a $t+2$-sequence $\bar{e}=e_1, e_2, \cdots, e_{t+2}$, over $\{1, \cdots, m\}$ we use e_1 and e_2 as indicators. If $e_1 > e_2$, then color $\bar{e}$ with the color assigned to (e_1, e_2) under $\mathscr{C}_1$.

Given a set $S \subset \{1, \cdots, m\}$, $|S| = n$, if all $p+1$ colors occur in the coloring of the 2-sequences over S under $\mathscr{C}_1$, then we are done. (In fact, the rainbow contains more colors than required.)

Otherwise, at least one color is missing under $\mathscr{C}_1$, but there is at least one color that appears (we assume $n \geqq 2$); therefore, there is a color i such that no pair in S is colored by $\mathscr{C}_1$ with i, but there exist $u, v \in S$ such that (u, v) is colored $i-1 \pmod{p+1}$ under $\mathscr{C}_1$.

Consider G_i, the edge induced graph defined by edges colored i and introduced above. Every element in S is in a different clique of G_i; otherwise there would have been a pair colored i. The cliques of G_i can easily be indexed as described by the remark at the end of Lemma 2.

If $e_1 < e_2$, we translate $\bar{e}$ to a t-sequence, $\bar{d}=d_1, d_2, \cdots, d_t$, over $1, \cdots, \sqrt{m}$. We color $\bar{e}$ by the color assigned to $\bar{d}$ by $\mathscr{C}_2$. Let d_j be the index of the clique of G_i containing e_{j+2}, $1 \leqq j \leqq t$, and $i-1 \pmod{p+1}$ is the color assigned to (e_1, e_2) under $\mathscr{C}_1$.

By the discussion above, it follows that for every $S \subset \{1, \cdots, m\}$, and for every $1 \leqq k \leqq c$ there is a $t+2$-sequence over S that is colored k. Thus we have described a construction for an $(n,\ p^2,\ n,\ t+2)$-rainbow. □

Since for any integer x there is a prime in $(x, 2x)$, we can apply Lemma 3 recursively, each time reducing the domain from m to $2\sqrt{m}$. Using Lemma 2 as the base case provides us for any $d \geqq 1$ with an explicit construction of an $(c=n,\ m=n^d,\ n,\ 2\lceil \log d \rceil + \lceil \log\log d \rceil)$-rainbow. Thus we have the following.

THEOREM 6. *For any domain m polynomial in the set size n there exists an $(n, m, n, O(1))$-rainbow. Given a sequence, its color can be determined in $O(1)$ time assuming modular arithmetic in unit time.*

Remark. Note that the proof implies that the existence of rainbows is a robust property, meaning that if p_1, p_2, p_3 are polynomials, and m is as a function of n such that a $(c, m, n, O(1))$-rainbow exists, then a $(p_1(c), p_2(m), p_3(n), O(1))$-rainbow exists as well.

It now follows from Theorem 1.

COROLLARY 1. *For any domain m polynomial in the set size n there exists an implicit $O(1)$ probe search scheme for which search requires $O(1)$ time, assuming modular arithmetic in unit time.*

Probabilistic constructions. We now turn to probabilistic constructions of rainbows for m that is *exponential* in n. Suppose $m = 2^{n^l}$, and consider a random coloring with n colors of all $l+2$ sequences over $\{1, \cdots, m\}$. For a set $S \subset \{1, \cdots, m\}$, $|S| = n$, the probability that a specific color is missing in the $l+2$ sequences over S is less than

$$(1-1/n)^{n(n-1)\cdots(n-l-1)}.$$

There are n colors and $\binom{m}{n}$ sets; hence the probability that there exists a set and a color such that the color is missing over the set is less than

$$\binom{m}{n} \cdot n \cdot (1-1/n)^{n(n-1)\cdots(n-l-1)} \leqq 2^{n^{l+1}} \cdot n \cdot e^{-n^{l+1}} \cdot e^{l^2 n^l} \ll 1;$$

therefore, we have the following.

THEOREM 7. *For any domain m exponential in the set size n there exists an $(n, m, n, O(1))$-rainbow.*

COROLLARY 2. *For any domain m exponential in the set size n there exists an implicit $O(1)$ probe search scheme.*

6. Bounds on rainbows. In this section we give bounds on the maximum m, as a function of n and t, for which a $(c = n, m, n, t)$-rainbow can exist. We will do that by showing the connection between rainbows and colorings of the t-uniform hypergraph. Consider a coloring of all t-subsets (subsets of size t) of $\{1, \cdots, m\}$ with c colors. Ramsey Theory tells us that there exists a function $R(n, t, c)$ such that if $m > R(n, t, c)$, then for any coloring of the t-subsets of $\{1, \cdots, m\}$ with c colors there exists a set $S \subset \{1, \cdots, m\}$ of size n such that all the t-subsets over S are colored with the same color. (See the book by Graham, Rothschild, and Spencer [6] for details on Ramsey Theory.)

THEOREM 8. *If there exists a (c, m, n, t)-rainbow and $c > t!$, then*

$$m \leqq R(n, t, t!+1).$$

Proof. Let $\mathscr{C}$ be a (c, m, n, t)-rainbow. Define a coloring of the t-subsets of $\{1, \cdots, m\}$ $\mathscr{D}$: for each subset $H \subset \{1, \cdots, m\}$ of size t consider all possible orderings of H. Each of the $t!$ possible orderings receives a color in the rainbow. Since there are more than $t!$ colors in the rainbow, we know that there is a color i, $1 \leqq i \leqq t!+1$, which none of the orderings receives. $\mathscr{D}$ colors H with the least such i. From Ramsey Theory it follows that if $m > R(n, t, t!+1)$, then there will be a set $S \subset \{1, \cdots, m\}$ of size n such that all of S subsets of size t are colored under $\mathscr{D}$ with the same color i. Hence under $\mathscr{C}$ none of the t-sequences over S are colored i, and thus $\mathscr{C}$ is not a rainbow. $\square$

How fast does $R(n, t, t!+1)$ grow? Let the tower functions $h_i(x)$ be defined as $h_1(x) = x$ and $h_{i+1}(x) = 2^{h_i(x)}$ for $i \geqq 1$. That is,

$$h_i(x) = \left.2^{2^{2^{\cdot^{\cdot^{\cdot^{2^x}}}}}}\right\}i-1.$$

The Stepping Up Lemma in [6, p. 91] yields the following: $h_{j-1}(c_1 \cdot n^2) \leqq R(n, j, 2) \leqq h_j(c_2 \cdot n)$ for some fixed c_1 and c_2. By the method of the proof of Ramsey's Theorem, increasing the number of colors from 2 to $t!+1$ does not add more than $\log t!+1$ to the height, i.e., $R(n, t, t!+1) < h_{t+\lceil\log(t!+1)\rceil}(c_2 n)$. Hence we can conclude that for a $(c \geqq t!+1, m, n, t = O(1))$-rainbow to exist we must have

$$m \leqq \left.2^{2^{2^{\cdot^{\cdot^{\cdot^{2^n}}}}}}\right\}O(1).$$

Applying Theorem 2, on the connection between rainbow and t-probe search, we get that an implicit t-probe scheme can exist only if $m < R(n, t', t'!+1)$, where $t' = t + 2\log t$. Thus, for an implicit O(1) probe search to exist we must have

$$m \leqq \left.2^{2^{2^{\cdot^{\cdot^{\cdot^{2^n}}}}}}\right\}O(1).$$

This constitutes a new proof of Yao's theorem [8] with better bounds. His bounds imply that $m < R(2n-1, n, n!)$, which grows much faster. Yao's proof has the advantage that it implies that whenever $m \geqq R(2n-1, n, n!)$, the lower bound on the search time is $\lceil \log n \rceil$. Our proof cannot give better bounds than $\Omega(\log n/\log\log n)$, since $t!+1$ must be less than n.

Any improvement on the lower bounds for rainbows would yield a better lower bound for implicit $O(1)$ probe search. Conversely, constructive implicit $O(1)$ probe search schemes for higher bounds imply better rainbow constructions. The reader can interpret this as either an optimistic or a pessimistic statement.

Undirected rainbows. We now show that the existence of rainbows is closely related to that of undirected rainbows defined as follows: *A* (c, m, n, t)*-undirected rainbow* is a coloring of all t-subsets over $\{1, \cdots, m\}$ with c colors, so that for any set $S \subset \{1, \cdots, m\}$, $|S| = n$, all c colors appear in the t-subsets over S.

Since the order itself in directed rainbows can determine $t!$ different colors, we know that $(c = t!, m, n, t)$-rainbows exist for any m and n such that $m \geqq n$. However, by Ramsey theory, this is not true for undirected rainbows. On the other hand, the next theorem shows that in order to give bounds on the maximum m for which $(c = n, m, n, O(1))$-rainbows exist, it is enough to consider undirected rainbows.

THEOREM 9. *For every t there exists a constant b_t, dependent only upon t, such that a construction for a $(c = n, m, n, t)$-rainbow yields a construction for a $(c = n, m, \lceil \log (t!) + 1 \rceil \cdot n, b_t)$-undirected rainbow.*

Proof. The idea is to provide enough information in the b_t-subset so as to simulate an ordered set. If, in addition to a t-subset, $\lceil \log (t!) \rceil$ bits are provided to determine the order in the t-subset, then the color of the subset will be the color of the corresponding t-sequence in the $(c = n, m, n, t)$-rainbow.

Let $\mathscr{C}$ be a $(c = n, m, n, t)$-rainbow. From Theorem 8 we know that $m < R(n, t, t!+1)$, and thus $m < h_{t'}(c_2 n)$ for some t', depending only on t. From the lower bound on $R(n, j, 2)$ of the Stepping Up Lemma there exists a $(2, n, m, t')$ undirected rainbow $\mathscr{A}$. Let $b_t = t + t' \cdot \lceil \log (t!) \rceil$. Define $\mathscr{C}'$, a coloring of b_t-subsets, as follows. Sort the b_t-subset and partition it into $\lceil \log (t!) \rceil + 1$ subsets of consecutive elements such that the subset of the largest elements is of size t, and all the rest are of size t'. Compute the coloring under $\mathscr{A}$ of each of the t'-subsets. Each of the $\lceil \log (t!) \rceil$ t'-subsets supplies one bit under its 2-coloring, and together those bits determine an ordering of the t-subset. The color $\mathscr{C}'$ assigns is the one $\mathscr{C}$ assigns the t-sequence, resulting from the the t-subset when it is ordered by the encoding given by the smaller subsets.

To see that $\mathscr{C}'$ is indeed a $(c = n, m, \lceil \log (t!) + 1 \lceil \cdot n, b_t)$-undirected rainbow, consider any $S \subset \{1, \cdots, m\}$ of size $\lceil \log (t!) + 1 \rceil \cdot n$. Partition S into $\lceil \log (t!) + 1 \rceil \cdot$ subsets $S_1, S_2, \cdots$, such that each S_i is of size n and all the elements of S_i are smaller than those of S_{i+1}. For any color $1 \leqq j \leqq c$, $\mathscr{C}$ colors at least one t-ordered subset of $S_{\lceil \log (t!) + 1 \rceil}$ with j. The order of this subset determines $\lceil \log (t!) \rceil$ bits $b_1, b_2, \cdots, b_{\lceil \log (t!) \rceil}$. In each subset S_i there is a t'-subset colored b_i under $\mathscr{A}$. The b_t subset of S that is the union of all these subsets is colored j under $\mathscr{C}'$. $\square$

7. Construction through dispersers. In this section we show how an explicit construction for dispersers, defined below, yields an explicit construction for rainbows with $m = n^{\log n}$. An (m, n, d, a, b)*-disperser* is a bipartite graph with m nodes on the left side, each with degree at most d, n nodes on the right side with the property that every subset of a nodes in the left side is connected to at least b of the nodes of the right side. These graphs have been used, for instance, by Ajtai, Komlós, and Szemerédi [1] and Sipser [7] to remove randomness in probabilistic algorithms. Cohen and Wigderson [3] provide a survey of constructions and applications.

Let $m = n^{\log n}$. We first show how to construct a rainbow with $\log n$ colors for such m and n, and then we show how to apply it with a $(m, n, \log^2 n, n, n/2)$-disperser to get an $(c = n, m, n, O(1))$-rainbow.

LEMMA 4. *There exists an explicit construction for a* $(c=\log n, m, n, O(1))$*-rainbow if* m *is* $n^{\text{polylog}(n)}$.

Proof. For $1 \leqq x \leqq m$ let x_i denote the ith bit of x. Consider the coloring of pairs that assigns the pair (x, y) $\min_{1\leqq i \leqq \log m} x_i \neq y_i$, i.e., the first bit in which x and y differ.

CLAIM 3. *In any set* $S \subset \{1, \cdots, m\}$ *of size* n, *the pairs must be colored with at least* $\log n$ *different colors.*

To see that the claim is true, consider organizing the elements of S in a trie, i.e., in a binary tree where each element appears as a leaf and its value is determined by the path from the root. If a node in the ith level of the trie has two children, then there is a pair $\langle x, y\rangle$, where x is a descendent of the left child and y a descendent of the right child, that is, colored i. There must be at least $\log n$ levels in which there is a node with 2 children, since each level at most doubles the number of nodes from the previous one and there are n leaves.

The claim shows that rather than having a set of size n out of a domain of size m, the problem can be reduced to that of a set of size $\log n$ from a domain of size $\log m$. If m is $n^{\text{polylog}(n)}$, then $\log m$ is polynomial in $\log n$, and hence the construction of Theorem 6 can be applied to obtain the required rainbow.

Sipser [7] gave a probabilistic construction for an $(n^{\log n}, n, \log^2 n, n, n/2)$-disperser. Given such a disperser D, we now show how to use such dispersers to amplify rainbows and construct $(c=n,\ m=n^{\log n},\ n,\ O(1))$-rainbows. Let $\mathscr{C}$ be a $(c=\log^2 n,\ m,\ n-1,\ t)$-rainbow whose existence is assured by the previous lemma and the remark following Theorem 6. Consider a coloring of $t+1$-tuples over $\{1, \cdots, m\}$ defined as follows. The first t elements are used to obtain a color $e \in \{1 \cdots \log^2 n\}$ via $\mathscr{C}$. The $t+1$st element, $v \in \{1, \cdots, m\}$ is treated as a node on the left side of D. e specifies a neighbor of v on the right side of D. The neighbor is the color of the t-tuple. Since any set of n nodes on the left side is adjacent to at least half the nodes on the right side, and since $\mathscr{C}$ is a $(\log^2 n, m, n, t)$-rainbow, it follows that for any set $S \subset \{1, \cdots, m\}$ of size n there is a set $T \subset \{1, \cdots, n\}$ of size at least $n/2$ such that we can specify in this manner any member of T. Using the construction of Lemma 2, this can be amplified to include all the n nodes on the right. This construction gives a $(c=n,\ m=n^{\log n},\ n,\ 2t+2)$-rainbow. Therefore, an explicit construction for a disperser with those parameters yields an implicit $O(1)$ probe search scheme for $m=n^{\log n}$.

No explicit construction with parameters close to the ones given in [7] is known. The best explicit construction for such expanders is given in Ajtai, Komlós, and Szemerédi [1].

8. Conclusions and open problems.

As a consequence of the results of this paper, the maximal m for which implicit $O(1)$ probe is possible lies between $2m^{\text{poly}(n)}$ and a constant height tower of powers. One obvious, open problem is to close this gap. Finding an explicit construction for rainbows with m superpolynomial in n is another obvious research direction. A different question is whether rainbows are useful for implicit data representation in other settings.

Note added in proof. Zuckerman [9] has found some constructions related to those in § 7.

Acknowledgments. We thank Noga Alon, Joel Friedman, Nati Linial, Mike Luby, Jeanette P. Schmidt, Alan Siegel, and Avi Wigderson for helpful discussions and advice and are grateful to the two anonymous referees for their diligent reading and many useful remarks.

MAINTAINING THE 3-EDGE-CONNECTED COMPONENTS OF A GRAPH ON-LINE*

ZVI GALIL† AND GIUSEPPE F. ITALIANO‡

Abstract. The problem of maintaining the 3-edge-connected components of a graph undergoing repeated dynamic modifications, such as edge and vertex insertions, is studied. This paper shows how to answer the question of whether or not two vertices belong to the same 3-edge-connected component of a connected graph that is undergoing only edge insertions. Any sequence of q query and updates on an n-vertex graph can be performed in $O((n + q)\alpha(q, n))$ time.

1. Introduction. Given an undirected graph $G = (V, E)$, and an integer $k \geq 2$, a pair of vertices $\langle u, v\rangle$ is said to be *k-edge-connected* if the removal of any $k - 1$ edges in G leaves u and v connected. This is an equivalence relationship, and we denote it by $\equiv_k$, i.e., if a pair of vertices $\langle x, y\rangle$ is k-edge-connected we write $x \equiv_k y$. The vertices of a graph G are partitioned by this relationship into equivalence classes called *k-edge-connected components*. An edge set $E' \subseteq E$ is an *edge-cut* for vertices x and y if the removal of all the edges in E' disconnects x and y. The cardinality of an edge-cut E', denoted by $|E'|$, is given by the number of edges in E'. An edge-cut E' for x and y is said to be a *minimum cardinality edge-cut* or in short a *min-edge-cut* if there is no other edge-cut E'' for x and y such that $|E''| < |E'|$. Then $x \equiv_k y$ if and only if a min-edge-cut for x and y contains at least k edges. A graph G is said to be *k-edge-connected* if all its pairs of vertices are k-edge-connected. A min-edge-cut of cardinality 1 is called a *bridge*. Similarly, a vertex set $V' \subseteq V - \{x, y\}$ is a *vertex-cut* for vertices x and y if the removal of all the vertices in V' disconnects x and y. The cardinality of a vertex-cut V', denoted by $|V'|$, is given by the number of vertices in V'. A vertex-cut V' for x and y is said to be a *minimum cardinality vertex-cut* or in short a *min-vertex-cut* if there is no other vertex-cut V'' for x and y such that $|V''| < |V'|$. Then x and y are k-vertex-connected if and only if a min-vertex-cut for x and y contains at least k vertices. A graph G is said to be *k-vertex-connected* if all its pairs of vertices are k-vertex-connected. A min-vertex-cut of cardinality 1 is called an *articulation point*.

The following theorems, due to Menger; Ford and Fulkerson; Elias, Feinstein, and Shannon (see, for instance, [17]), give another characterization of k-vertex and k-edge connectivity.

THEOREM 1.1 (Menger). *Given a graph G and two vertices x and y in G, x and y are k-vertex-connected if and only if there are at least k vertex-disjoint paths between x and y.*

THEOREM 1.2 (Ford and Fulkerson; Elias, Feinstein, and Shannon). *Given a graph G and two vertices x and y in G, x and y are k-edge-connected if and only if there are at*

least k edge-disjoint paths between x and y.

Vertex connectivity and edge connectivity problems arise naturally in many applications and have been extensively studied. Much attention has been given to the 2-vertex-connected (or biconnected) components and 2-edge-connected (or bridge-connected) components of a graph. Tarjan [32] gives optimal linear-time sequential algorithms. Tarjan and Vishkin [34] give logarithmic-time parallel algorithms. Recently, Westbrook and Tarjan [36] considered the problem of maintaining biconnected components and bridge-connected components undergoing any sequence of edge and vertex insertions. They presented algorithms that run in a total of $O(q\alpha(q,n))$ time, where q is the total number of operations, n is the number of vertices, and α is a functional inverse of Ackermann's function. As for 3-vertex-connectivity, Hopcroft and Tarjan [18] showed how to compute the triconnected components of a graph in linear time. Di Battista and Tamassia [6] showed how to maintain the triconnected components of a graph during edge insertions in a total of $O(q + n\log n)$ time[1], where q is the total number of operations performed and n is the number of vertices. Their algorithm achieves an $O(q\alpha(q,n))$ bound only in the case of an initially biconnected graph.

In the last decade there has been a growing interest in dynamic problems on graphs. In particular, much attention has been devoted to (among others) the dynamic maintenance of connected components [10], [11], [26], [28]; 2- and 3-connectivity [6], [15]; [35], [36]; transitive closure [2], [19], [20], [21], [24], [31], [37]; planarity [5], [6], [30]; shortest paths [1], [4], [9], [25], [27], [29], [37]; and minimum spanning trees [3], [8], [11], [29]. In these problems we would like to answer queries on graphs that are undergoing a sequence of updates, for instance, insertions and deletions of edges and vertices.

A problem is said to be *fully dynamic* if the update operations include both insertions and deletions of edges. On the other hand, a problem is called *partially dynamic* if only one type of update, i.e., either insertions or deletions, is allowed. The goal of a (fully or partially) dynamic graph algorithm is to update efficiently the solution of a problem after dynamic changes, rather than having to recompute it from scratch each time. Given their powerful versatility, it is not surprising that dynamic algorithms and dynamic data structures are usually more difficult to design than their static counterparts.

In this paper we study the partially dynamic problem of maintaining the 3-edge-connected components of a connected graph during edge insertions. We wish to maintain the graph under an intermixed sequence of operations of the following kinds.

Same3EdgeBlock(u,v): Return *true* if vertices u and v are in the same 3-edge-connected component. Return *false* otherwise.

InsertEdge(x,y): Insert a new edge between the two vertices x and y.

AddVertex(u,v): Add a new vertex u to the graph, and connect it to G by means of the edge (u,v).

We give algorithms that support any sequence of q *InsertEdge*, *AddVertex*, and *Same3EdgeBlock* operations on an initially connected graph with n vertices in a total of $O((n+q)\alpha(q,n))$ time. Notice that the best-known bound for the twin problem of maintaining in a partially dynamic fashion the triconnected components of a graph is $O(q + n\log n)$ [6], and the algorithms given in [6] achieve the $O(q\alpha(q,n))$ bound only in the case of an initially biconnected graph.

Our techniques combine a variety of graph properties, and data structures. We represent the 3-edge-connected components of a graph by means of a tree structure, and

[1]In this paper all the logarithms are assumed to be base two.

update and query this tree instead of the original graph. Indeed, we represent a graph G by a tree of 2-edge-connected components, each of which is itself represented as a tree of 3-edge-connected components. We then develop efficient data structures for updating this representation during edge and vertex insertions.

The remainder of the paper consists of four sections. Section 2 gives some graph-theoretical properties of k-edge-connectivity. Section 3 gives our bounds for 2-edge-connected graphs, and §4 extends these bounds to connected graphs. In §5 we list some concluding remarks.

2. Some properties of k-edge connectivity. Let $G = (V, E)$ be an undirected graph. Let $V_1, V_2, \dots, V_p$ be a partition of the vertices of $G = (V, E)$ such that if $x, y \in V_i$, $1 \leq i \leq p$, then $x \equiv_k y$. Notice that $V_1, V_2, \dots, V_p$ are not necessarily the k-edge-connected components of G since we can have $u \equiv_k v$ for $u \in V_i$ and $v \in V_j$, $i \neq j$. Let $\varphi(G) = (\varphi(V), \varphi(E))$ be the graph obtained from G by shrinking each V_i, $1 \leq i \leq p$, into one super-vertex $\varphi(V_i)$. If $e = (u, v)$ is an edge of G, $u \in V_i$, $v \in V_j$, let $\varphi(e) = (\varphi(V_i), \varphi(V_j))$ be the corresponding edge in $\varphi(G)$. Notice that $\varphi(G)$ can contain multiple edges and self-loops. For any $E' \subseteq E$, let $\varphi(E') = \{\varphi(e) | e \in E'\}$. As a consequence of this definition, $|\varphi(E')| = |E'|$ for any edge set $E' \subseteq E$. Similarly, if $x \in V_i$ we define $\varphi(x) = \varphi(V_i)$. In the sequel such a φ will be referred to as a *k-edge-connectivity obeying mapping*.

The following lemmas characterize some combinatorial properties of the k-edge-connected components of a graph.

LEMMA 2.1. *Let φ be a k-edge-connectivity obeying mapping. A set of edges E', $|E'| \leq k - 1$, is an edge-cut for x and y in G if and only if $\varphi(E')$ is an edge-cut for $\varphi(x)$ and $\varphi(y)$ in $\varphi(G)$.*

Proof. Assume $\varphi(E')$ is not an edge-cut for $\varphi(x)$ and $\varphi(y)$ in $\varphi(G)$. Thus, there is a path $\varphi(\pi)$ in $\varphi(G)$ between $\varphi(x)$ and $\varphi(y)$ containing no edges in $\varphi(E')$. Let $\varphi(e_1)$, $\varphi(e_2), \dots, \varphi(e_p)$ be the edges in $\varphi(\pi)$, and let $e_1, e_2, \dots, e_p$ be the corresponding edges in G. Clearly, $e_i \notin E'$, $1 \leq i \leq q$. However, $e_1, e_2, \dots, e_p$ does not give a path in G. Let $e_i = (u_i, v_i)$, $1 \leq i \leq q$. Denote x by v_0 and y by u_{p+1}. By definition of $\varphi(G)$, $v_i \equiv_k u_{i+1}$, $0 \leq i \leq p$. By Theorem 1.2, there are at least k edge-disjoint paths in G between v_i and u_{i+1}, $0 \leq i \leq p$. Since $|E'| \leq k - 1$, there is at least one path π_i between v_i and u_{i+1}, $0 \leq i \leq p$, containing no edges in E'. As a result, $\pi_0 \cdot e_1 \cdot \pi_1 \cdot e_2 \cdot \dots \cdot e_p \cdot \pi_p$ gives a path in G between x and y, avoiding edges of E'. Hence E' is not an edge-cut for x and y in G.

Conversely, assume E' is not an edge-cut for x and y in G. That is, there is a path $\pi = \{x = v_0, v_1, \dots, v_{q-1}, v_q = y\}$ in G containing no edges of E'. Then $\varphi(\pi) = \{\varphi(x), \varphi(v_1), \dots, \varphi(v_{q-1}), \varphi(y)\}$ gives a path between $\varphi(x)$ and $\varphi(y)$ in $\varphi(G)$ that uses no edges of $\varphi(E')$. Therefore, $\varphi(E')$ cannot be an edge-cut for $\varphi(x)$ and $\varphi(y)$ in $\varphi(G)$. □

LEMMA 2.2. *Let φ be a k-edge-connectivity obeying mapping. Let $\varphi(V_i)$ and $\varphi(V_j)$ be any two vertices in $\varphi(G)$, and let x and y be any two vertices of G, $x \in V_i$, $y \in V_j$. Given any integer h, $1 \leq h \leq k$, $\varphi(V_i)$ and $\varphi(V_j)$ are h-edge-connected in $\varphi(G)$ if and only if x and y are h-edge-connected in G.*

Proof. If $V_i = V_j$, the lemma is trivial.

Assume $i \neq j$ and let V_i and V_j be such that $\varphi(V_i) \not\equiv_h \varphi(V_j)$ in the contracted graph $\varphi(G)$. This means that there is a min-edge-cut for $\varphi(V_i)$ and $\varphi(V_j)$ in $\varphi(G)$ containing at most $h - 1$ edges. Let A be such such a min-edge-cut, $|A| \leq h - 1$. Let x be any vertex in V_i, and let y be any vertex in V_j. Let $\bar{E} = \{e \in E | \varphi(e) \in A\}$. By Lemma 2.1, $\bar{E}$ is an edge-cut for x and y in G. Since $|\bar{E}| = |A| \leq h - 1$, $x \not\equiv_h y$ in G.

Let x and y be vertices in G such that $x \not\equiv_h y$. Let $x \in V_i$, $y \in V_j$, $i \neq j$. Let E', $|E'| \leq h - 1$, be an edge-cut for x and y in G. Then by Lemma 2.1, $\varphi(E')$, $|\varphi(E')| = |E'| \leq h - 1$, is an edge-cut for $\varphi(V_i)$ and $\varphi(V_j)$ in $\varphi(G)$. Therefore, $\varphi(V_i) \not\equiv_h \varphi(V_j)$ in $\varphi(G)$. □

3. Maintaining 3-edge-connected components of 2-edge-connected graphs.

In this section we show how to maintain efficiently the 3-edge-connected components of a graph G under any sequence of the operations *InsertEdge*, *AddVertex*, and *Same3EdgeBlock*. We recall here that *InsertEdge*(x, y) adds a new edge between vertices x and y, *AddVertex*(u, v) inserts a new vertex u and connects it to vertex v, and *Same3EdgeBlock* (u, v) returns true if vertices u and v are in the same 3-edge-connected component of G, and it returns false otherwise. We consider first 2-edge-connected graphs and then generalize the results to connected graphs.

Let G be a 2-edge-connected graph with n vertices subject to *Same3EdgeBlock* and *InsertEdge* operations. In this section we do not consider *AddVertex* operations since they do not preserve G 2-edge-connected; we show how to deal with them in the next section.

For any vertex x in G, denote by $C(x)$ the 3-edge-connected component containing x. We show now how to maintain information about 3-edge-connected components of a 2-edge-connected graph G during edge insertions. Let G' be the graph obtained by contracting each 3-edge-connected component of G into a super-vertex. Notice that there can be multiple edges in G'. We use interchangeably the terms 3-edge-connected component of G and super-vertex in G'. By hypothesis G is 2-edge-connected, and by Lemma 2.2 G' is 2-edge-connected, too. As a result, any two super-vertices of G' lie on a common cycle. The following lemma states that G' consists of simple cycles such that any two of them share at most one super-vertex (see also [7], [22]).

LEMMA 3.1. *Two simple cycles of G' can intersect in at most one super-vertex.*

Proof. We proceed by contradiction. Assume there exist two different simple cycles Λ_1 and Λ_2 of G' intersecting at two super-vertices σ_1 and σ_2. Then there must be a subpath of Λ_2 between two vertices σ' and σ'' of Λ_1 (not necessarily σ_1 and σ_2) that is edge-disjoint from Λ_1. As a result, there are three edge-disjoint paths between σ' and σ'' in G'. By Theorem 1.2, $\sigma' \equiv_3 \sigma''$ in G'. By Lemma 2.2, any two vertices x and y of G such that $x \in \sigma'$ and $y \in \sigma''$ are 3-edge-connected. Consequently, σ' and σ'' cannot be 3-edge-connected components of G, a contradiction. □

LEMMA 3.2. *Each biconnected component of G' is a simple cycle.*

Proof. We proceed by contradiction. Let B be a biconnected component of G' that is not a simple cycle. This implies that there are three edges e_1, e_2, and e_3 in B that do not lie in a simple cycle. However, since two edges belong to the same biconnected component if and only if they lie in a same simple cycle, there must be a simple cycle Λ_1 containing both e_1 and e_2, and a simple cycle Λ_2 containing both e_2 and e_3. Since e_2 belongs to both Λ_1 and Λ_2, Λ_1 and Λ_2 must intersect in at least two vertices, which contradicts Lemma 3.1. □

Define $\mathcal{T}$ as the block tree of G'. We recall here that given a graph G, the block tree of G is defined as follows (see, for instance, [17]). The nodes of the block tree are partitioned into *square* and *round* nodes: square nodes correspond to the vertices of G, while round nodes correspond to the biconnected components of G. There is an edge between a square node u and a round node ρ if and only if vertex u of G is in biconnected component ρ. Also, there is an edge between a square vertex u and round vertices ρ_1 and ρ_2 if and only if u is an articulation point separating biconnected components ρ_1 and ρ_2 in G.

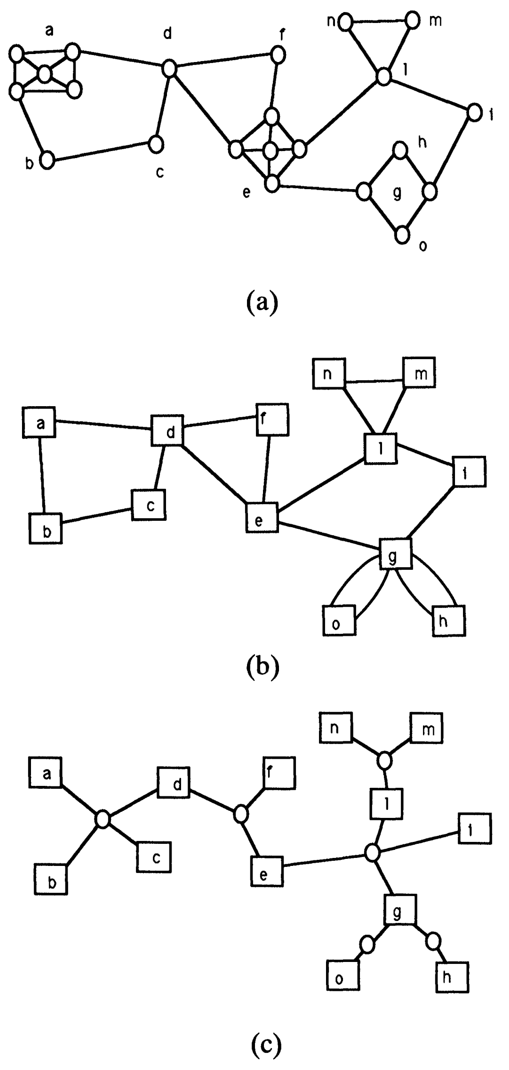

FIG. 1. (a) *A* 2*-edge-connected graph G*; (b) *the graph G'*; *and* (c) *the tree of* 3*-edge-connected components of G.*

In the following, we refer to $\mathcal{T}$ as the *tree of* 3*-edge-connected components* of G. Notice that each 3-edge-connected component of G corresponds uniquely to a super-vertex of G' and to a square node in $\mathcal{T}$. In the remainder of this section we use interchangeably the terms 3-edge-connected component of G, super-vertex of G', and square node of $\mathcal{T}$. Figure 1 shows graphs G and G', as well as the block tree $\mathcal{T}$.

We root the tree $\mathcal{T}$ arbitrarily at any square node. Edges of $\mathcal{T}$ are considered directed from children to parent. Furthermore, for each simple cycle in G', we maintain the same cyclic order of vertices in $\mathcal{T}$ (see Fig. 1). In other words, let $\sigma_1, \sigma_2, \ldots, \sigma_p$ be the vertices of G' encountered in a counterclockwise walk around around a cycle ρ. Then in $\mathcal{T}$ there is one square node σ_ℓ, $1 \leq \ell \leq p$, that is the parent of ρ, and all the children of ρ from left to right are $\sigma_{\ell+1}, \sigma_{\ell+2}, \ldots, \sigma_p, \sigma_1, \sigma_2, \ldots, \sigma_{\ell-1}$. The following corollary follows easily from Lemma 3.2 and the definition of block tree of a graph.

COROLLARY 3.3. *Let x and y be any two vertices in G, $x \not\equiv_3 y$. Let $C(x)$ and $C(y)$ be the 3-edge-connected components containing x and y, respectively. Let $\pi_{x,y}$ be the path in $\mathcal{T}$ between $C(x)$ and $C(y)$ containing vertices $C(x) = \sigma_1, \rho_1, \sigma_2, \ldots, \sigma_{q-1}, \rho_{q-1}, \sigma_q = C(y)$, $q \geq 2$ (σ_i are square nodes and ρ_i are round nodes). Then $\sigma_2, \sigma_3, \ldots, \sigma_{q-1}$ are all the articulation points separating $C(x)$ and $C(y)$ in G', and all the simple paths between $C(x)$ and $C(y)$ in G' are given by the $q-1$ simple cycles $\rho_1, \rho_2, \ldots, \rho_{q-1}$.*

Besides maintaining $\mathcal{T}$, we maintain the actual 3-edge-connected components of G as disjoint sets subject to *union* and *find* operations. The name of any such set gives a pointer to the corresponding square node in $\mathcal{T}$. For each vertex x, *find*(x)=$C(x)$ (i.e., *find*(x) returns the 3-edge-connected component containing vertex x in G). With this data structure, a *Same3EdgeBlock*(x, y) operation can be simply performed by checking whether *find*(x) = *find*(y). The *union* operations will be used to update efficiently the 3-edge-connected components during *InsertEdge* operations. We recall that using the fast set-union data structures of [33] yields that any sequence of q *union* and *find* operations on a collection of n elements can be performed in $O(q\alpha(q, n))$ worst-case time.

Let x and y be any two vertices in G such that $x \not\equiv_3 y$. Denote by $C(x)$ and $C(y)$ the square nodes in $\mathcal{T}$ corresponding to the 3-edge-connected components of x and y, respectively, and let $\pi_{x,y}$ be the path in $\mathcal{T}$ between $C(x)$ and $C(y)$. We now describe the updates needed in $\mathcal{T}$ because of the insertion of a new edge (x, y). As the following lemma shows, the path in $\mathcal{T}$ between $C(x)$ and $C(y)$ plays a crucial role in the update.

LEMMA 3.4. *Let G be a 2-edge-connected graph. After the insertion of (x, y), all the vertices of the 3-edge-connected components corresponding to square nodes in $\pi_{x,y}$ become 3-edge-connected, while there is no change in the other 3-edge-connected components of G.*

Proof. Let $V_1, V_2, \ldots, V_p$ be the 3-edge-connected components of G before the insertion of edge (x, y). Let $V'_1, V'_2, \ldots V'_q$, $1 \leq q \leq p$, be the 3-edge-connected of G corresponding to the square nodes of $\mathcal{T}$ in $\pi_{x,y}$, as they are met while going from $C(x)$ to $C(y)$ in $\mathcal{T}$. Notice that $C(x) = V'_1$ and $C(y) = V'_q$. Let $G^{new} = G \cup \{(x, y)\}$. Similarly, let $(G^{new})'$ be the graph obtained from G^{new} by contracting its 3-edge-connected components.

Consider the graph $G'_{temp} = G' \cup \{(C(x), C(y))\}$. Notice that G'_{temp} is not necessarily $(G^{new})'$. However, since any two vertices that were 3-edge-connected in G are still 3-edge-connected in G^{new}, $V_1, V_2, \ldots, V_q$ gives a partition of the vertices of G^{new} such that if $u, v \in V_i$, then $u \equiv_3 v$. Therefore, G'_{temp} can be derived from G^{new} by applying a 3-edge-connected obeying mapping φ to G^{new}: namely, $G'_{temp} = \varphi(G^{new})$.

Assume first that $C(x) = C(y)$. Since by definition no two vertices of G' are 3-edge-connected, then no two vertices of $\varphi(G^{new})$ are 3-edge-connected either. Therefore, by Lemma 2.2 there is no change in the 3-edge-connected components of G. In this case $\pi_{x,y} = \{C(x)\}$ and the lemma is trivially true.

Assume now $C(x) \neq C(y)$. By Corollary 3.3, all the simple paths between $C(x) = V'_1$ and $C(y) = V'_q$ in G' are given by $q - 1$ simple cycles $\rho_1, \rho_2, \ldots, \rho_{q-1}$ in G' such that $V'_1 \in \rho_1$, $V'_p \in \rho_{q-1}$, $\rho_{i-1} \cap \rho_i = \{V'_i\}$, $2 \leq i \leq q-1$, and $\rho_i \cap \rho_j = \emptyset$, $i \leq j-2$ or $i \geq j+2$. Each ρ_i, $1 \leq i \leq q-1$, is composed of two disjoint paths between V'_i and V'_{i+1}, say, $\rho_i^{(1)}$ and $\rho_i^{(2)}$.

Then there are three edge-disjoint paths between V'_i and V'_j, $1 \leq i < j \leq q$, in $\varphi(G^{new})$. The first is given by $\rho_i^{(1)}, \rho_{i+1}^{(1)}, \ldots, \rho_{j-1}^{(1)}$; the second by $\rho_i^{(2)}, \rho_{i+1}^{(2)}, \ldots, \rho_{j-1}^{(2)}$; and, finally, the third is given by $\rho_{i-1}^{(1)}, \rho_{i-2}^{(1)}, \ldots, \rho_1^{(1)}, (C(x), C(y)), \rho_{q-1}^{(1)}, \rho_{q-2}^{(1)}, \ldots, \rho_j^{(1)}$. Thus $V'_i \equiv_3 V'_j$.

We now show that only the vertices V_i', $1 \le i \le q$, become 3-edge-connected in $\varphi(G^{new})$. Let $\widetilde{V}$ be any vertex of G' different from V_i', $1 \le i \le q$, and let V_i, $1 \le i \le p$, be any vertex of G' different from $\widetilde{V}$. Since vertices of G' correspond to 3-edge-connected components of G, $\widetilde{V} \not\equiv_3 V_i$ in G'. We show that also $\widetilde{V} \not\equiv_3 V_i$ in $\varphi(G^{new})$. By Corollary 3.3, all the simple paths between $\widetilde{V}$ and V_i in G' are given by $p \ge 1$ simple cycles $\rho_1', \rho_2', \dots, \rho_p'$ in G' such that $\widetilde{V} \in \rho_1'$, $V_i \in \rho_p'$. Consequently, if e_1 and e_2 are the two edges of ρ_1' incident to $\widetilde{V}$, $\{e_1, e_2\}$ separates $\widetilde{V}$ and V_i in G'. Therefore, the removal of $\{e_1, e_2\}$ breaks G' into two pieces: G_1' and G_2' such that G_1' contains $\widetilde{V}$ and G_2' contains V_i. We claim that the removal of $\{e_1, e_2\}$ must leave $C(x)$ and $C(y)$ on the same side (i.e., either both in G_1' or both in G_2'). Indeed assume by contradiction that $C(x)$ and $C(y)$ are left in different sides by the removal of $\{e_1, e_2\}$. Without loss of generality, let $C(x)$ be in G_1' and $C(y)$ be in G_2'. This implies that $\{e_1, e_2\}$ is an edge-cut for $C(x)$ and $C(y)$ in G'. Since e_1 and e_2 are both incident to $\widetilde{V}$ in G', also the removal of $\widetilde{V}$ together with its incident edges disconnects $C(x)$ and $C(y)$ in G'. This implies that $\widetilde{V}$ is an articulation point whose removal disconnects $C(x)$ and $C(y)$ in G'. But by Corollary 3.3, this gives $\widetilde{V} = V_i'$, for some i, $1 \le i \le q$, contradicting our assumption. Since $C(x)$ and $C(y)$ must be either both in G_1' or both in G_2', $\{e_1, e_2\}$ still separates $\widetilde{V}$ and V_i in $\varphi(G^{new}) = G' \cup \{C(x), C(y)\}$. Consequently, $\widetilde{V} \not\equiv_3 V_i$ in $\varphi(G^{new})$.

By Theorem 1.2, all and only the vertices $V_1', V_2', \dots, V_q'$ become 3-edge-connected in $\varphi(G^{new})$, while all the remaining vertices of $\varphi(G^{new})$ stay 2-edge-connected. By Lemma 2.2 all and only the vertices of G contained in $V_1', V_2', \dots, V_q'$ become 3-edge-connected. □

Lemma 3.4 gives a way to compute $(G^{new})'$ from G'. As shown in the lemma, all the paths between V_1' and V_q' in G' are given by $q-1$ edge-disjoint simple cycles $\rho_1, \rho_2, \dots, \rho_{q-1}$ in G' such that $V_1' \in \rho_1$, $V_q' \in \rho_{q-1}$, and $\rho_{i-1} \cap \rho_i = \{V_i'\}$, $2 \le i \le q-1$. Each ρ_i is composed of two edge-disjoint paths between V_i' and V_{i+1}', say, $\rho_i^{(1)}$ and $\rho_i^{(2)}$. Furthermore, the insertion of (x, y) in G implies that all and only the vertices in V_i', $1 \le i \le p$, become 3-edge-connected in G. Therefore, $(G^{new})'$ can be computed from G' by simply shrinking all the vertices $V_1', V_2', \dots, V_q'$ into one vertex V'. This destroys the previous simple cycles ρ_i, $1 \le i \le q-1$, and creates at most $2(q-1)$ new simple cycles $\rho_i^{(1)}$ and $\rho_i^{(2)}$, $1 \le i \le q-1$, that are all incident to V' in $(G^{new})'$.

The changes in G' induce updates in $\mathcal{T}$, which is the block tree of G'. We denote by λ the least common ancestor of $C(x)$ and $C(y)$ in $\mathcal{T}$. The update causes the following transformations on the path $\pi_{x,y}$ of $\mathcal{T}$, to obtain $\mathcal{T}^{new}$, the block tree of $(G^{new})'$.

(i) Merge together all the square nodes $V_1', V_2', \dots, V_q'$ in $\pi_{x,y}$ into a new square node V'.

(ii) For each round node $\rho_i \ne \lambda$ in $\pi_{x,y}$, denote by V_i' and V_{i+1}' the two square nodes in $\pi_{x,y}$ adjacent to ρ_i. Without loss of generality, let V_{i+1}' be the parent of ρ_i in $\pi_{x,y}$. Let $a_1^{(i)}, \dots, a_s^{(i)}, V_i', b_1^{(i)}, \dots, b_t^{(i)}$, $s, t \ge 0$, be the children of ρ_i sorted from left to right. Split ρ_i into two round nodes $\rho_i^{(1)}$ and $\rho_i^{(2)}$: make $a_1^{(i)}, \dots, a_s^{(i)}$ children of $\rho_i^{(1)}$ and $b_1^{(i)}, \dots, b_t^{(i)}$ children of $\rho_i^{(2)}$. Make $\rho_i^{(1)}$ and $\rho_i^{(2)}$ children of V'. If $s = 0$ [$t = 0$], delete $\rho_i^{(1)}$ [$\rho_i^{(2)}$].

(iii) If λ is a round node, again denote by V_i' and V_{i+1}' the two square nodes in $\pi_{x,y}$ adjacent to λ. Without loss of generality, let $a_1^{(i)}, \dots, a_s^{(i)}$, V_i', $b_1^{(i)}, \dots, b_t^{(i)}$, V_{i+1}' $c_1^{(i)}, \dots, c_u^{(i)}$, $s, t, u \ge 0$, be the children of λ sorted from left to right. Split λ into two round nodes $\lambda^{(1)}$ and $\lambda^{(2)}$: make $a_1^{(i)}, \dots, a_s^{(i)}$, V', $c_1^{(i)}, \dots, c_u^{(i)}$ children of $\lambda^{(1)}$ and

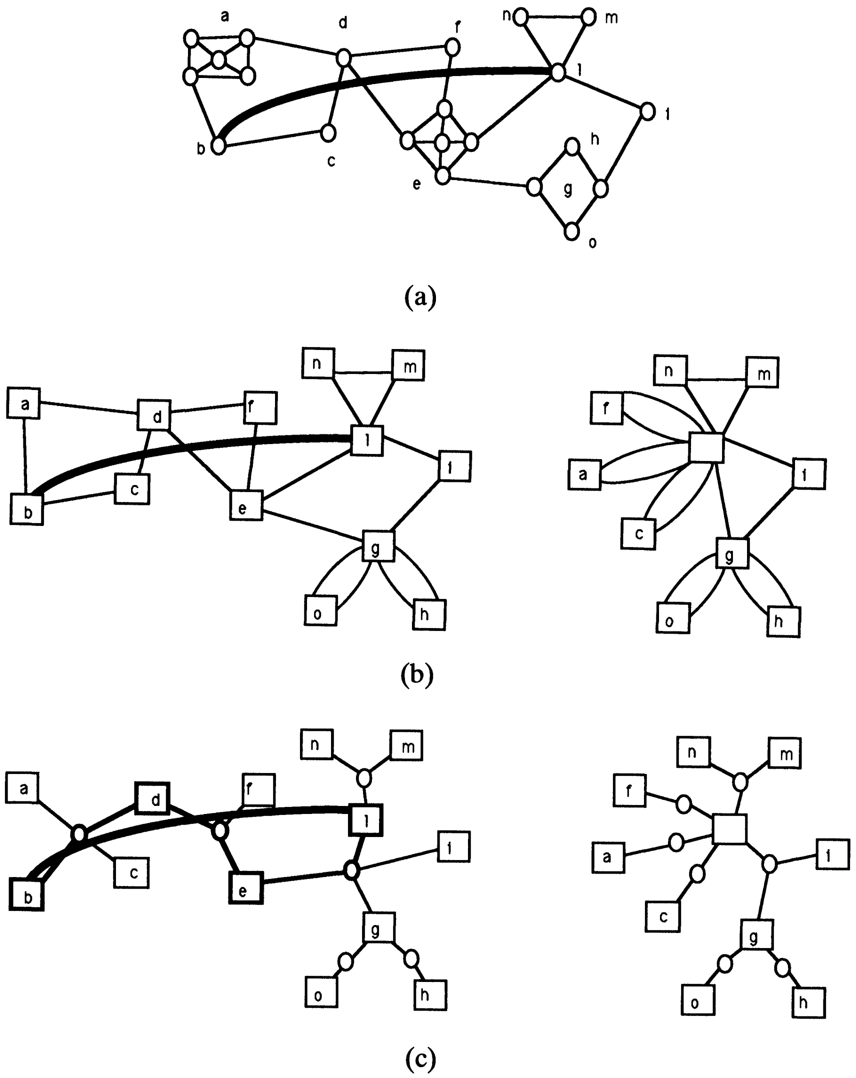

FIG. 2. (a) *G after the insertion of a new edge*; (b) *updates in the graph G' because of the new edge*; *the new G' is shown to the right*; (c) *updates in T because of the new edge*; *the path involved in the update is shown in bold*; *the new T is shown to the right.*

$b_1^{(i)}, \ldots, b_t^{(i)}$ children of $\lambda^{(2)}$. Make $\lambda^{(1)}$ child of the previous parent of λ and $\lambda^{(2)}$ child of V'. If $t = 0$, delete $\lambda^{(2)}$. Notice that since $\mathcal{T}$ is rooted at a square node, λ cannot be the root of $\mathcal{T}$ and thus must have a parent.

The sequence of above transformations, plus the actual merging of the 3-edge-connected components, is referred to in the sequel as *path compression*. Figure 2 shows the updates needed in the graph of Fig. 1, as a result of the insertion of a new edge.

To implement the above rules, we need to support the following primitives on the tree $\mathcal{T}$ during an *InsertEdge* operation:

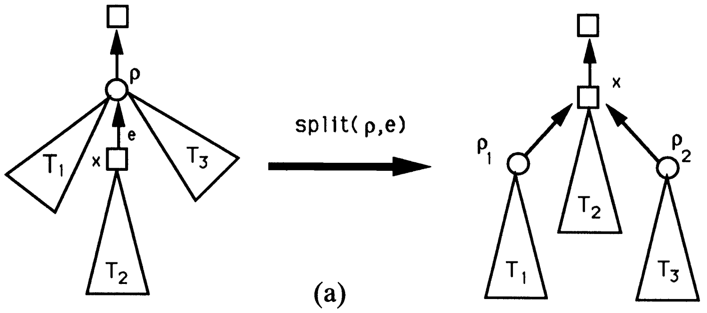
split(ρ, e): Given a round node ρ and an edge $e = (x, \rho)$, where x is a square node child of ρ, split ρ into two round nodes ρ_1 and ρ_2: the edges previously to the left [right] of

e are now incident to ρ_1 [ρ_2]. Make ρ_1 and ρ_2 children of x, and x child of the former parent of ρ (see Fig. 3(a)). If either ρ_1 or ρ_2 has no children, then delete it. Since ρ is a round node, it cannot be the root; therefore, the parent of ρ is always defined.

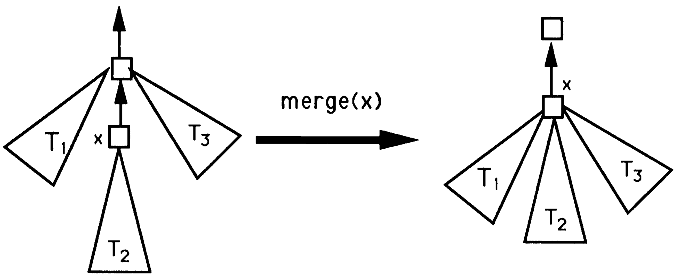
merge(v): Given a square node v, whose parent is a square node itself, contract the edge $(v, \mathit{parent}(v))$ (see Fig. 3(b)), and union the corresponding 3-edge-connected components.

parent(v): Given any (round or square) node v, return its parent.

Notice that the primitive *merge*(v) is not applicable to the tree $\mathcal{T}$ itself since in $\mathcal{T}$ each square node has a round parent. However, a *split*(ρ, e) produces two adjacent square nodes as shown in Fig. 3 and, therefore, allows a primitive *merge* to be applied in the resulting tree.



(a)



(b)

FIG. 3

We are now able to describe our implementation of an *InsertEdge*(x, y) operation. First we perform a *Same3EdgeBlock*(x, y) operation: if it returns true, then x and y are in the same 3-edge-connected component and by Lemma 3.4 nothing need be done. Otherwise, x and y are in different 3-edge-connected components. We proceed as follows. Given $\mathcal{T}$, we first locate the path $\pi_{x,y}$. Then we perform path compression on $\pi_{x,y}$ by doing *merge* operations on the square nodes of $\pi_{x,y}$ and *split* operations on the round nodes of $\pi_{x,y}$. We do this as follows. Denote by λ the least common ancestor of $C(x)$ and $C(y)$ in $\mathcal{T}$. Set $\beta = C(x)$ and $\gamma = \mathit{parent}(\beta)$. While $\gamma \neq \lambda$ repeat the following step:

If γ is a round node, then set $e = (\beta, \gamma)$ and perform *split*(γ, e). If γ is a square node, then perform *merge*(β). In both cases set $\gamma = parent(\beta)$.

Denote by β_1 the square node child of λ at which the preceding step stops. Now set $\beta = C(y)$ and repeat the same splits and merges in the path from $C(y)$ to λ. Similarly, denote by β_2 the square node child of λ in this path. If λ is a round node, then split it as shown in Fig. 4(a). Otherwise, λ is a square node; merge β_1, β_2, and λ as shown in Fig. 4(b). Notice that those two operations can be implemented by using a constant number of *merge* and *split* primitives. In the following, we refer to the update of $\mathcal{T}$ after an *InsertEdge*(u, v) operation as *CompressPath*$(u, v, \mathcal{T})$.

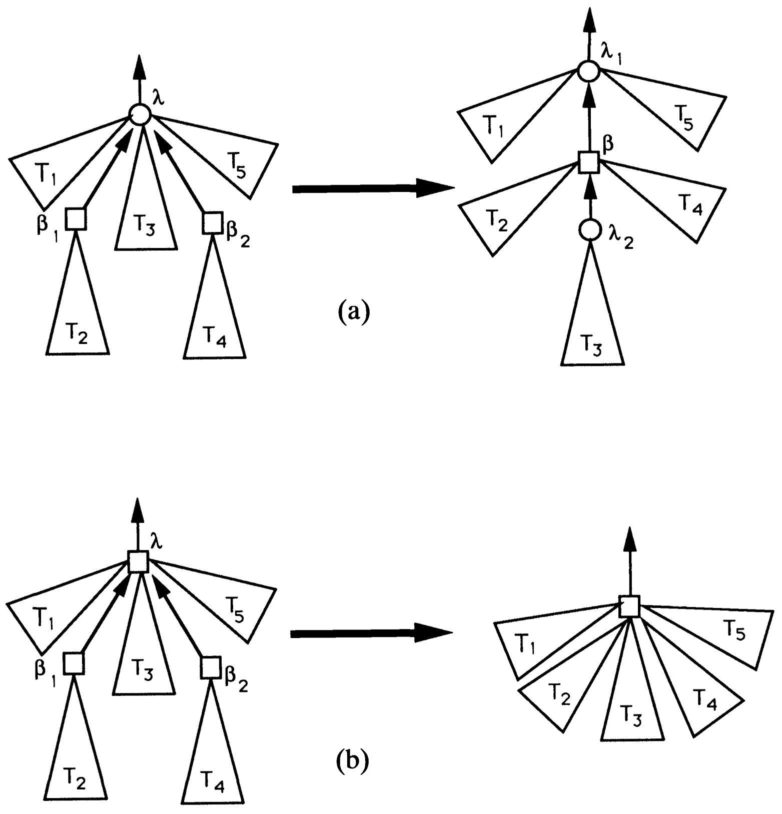


FIG. 4

The following lemma shows how to perform efficiently any sequence of *merge*, *split*, and *parent* operations.

LEMMA 3.5. *Any sequence of p merge, split, and parent primitives on a tree with n nodes requires a total of $O(p\alpha(p, n))$ worst-case time.*

Proof. To support efficiently these primitives, we use different data structures for each node of $\mathcal{T}$. We represent square nodes as *condensible nodes* [36], which enable us to merge two square nodes in $O(\alpha(p, n))$ amortized time at the price of spending $O(\alpha(p, n))$ amortized time to find the parent of a round node. The idea behind a condensible square node is to group all the sibling round nodes into disjoint sets and to maintain those disjoint sets under *union* and *find* operations. We do this as follows. By definition, the children of each square node in $\mathcal{T}$ are all round nodes. Let v be any square node in $\mathcal{T}$, with children $\rho_1, \rho_2, \ldots, \rho_\ell$, $\ell \geq 1$. We maintain a set $\mathcal{UF}(v)$ such that the name of $\mathcal{UF}(v)$ returns a pointer to v. Let ρ_i be a child of v: instead of having an edge from ρ_i to v, we have an edge from ρ_i to an item in the set $\mathcal{UF}(v)$.

We refer to [36] for the details of this method. It suffices to say that a *merge*(v) operation corresponds to a *union* between disjoint sets $\mathcal{UF}(v)$ and $\mathcal{UF}(parent(v))$, and to a *union* of the 3-edge-connected components corresponding to v and $parent(v)$. We remark here that unioning disjoint sets $\mathcal{UF}(v)$ and $\mathcal{UF}(parent(v))$ implies that the space used by the item corresponding to v in $\mathcal{UF}(parent(v))$ is left unused. This implies an $O(1)$ extra space per *merge* operation.

Finding the parent of a round node corresponds to a *find* operation. If for each square node $v \in \mathcal{T}$ we implement $\mathcal{UF}(v)$ by means of a fast set-union data structure [33], each *merge* and *parent* primitive can be supported in $O(\alpha(p, n))$ amortized time.

For splitting round nodes efficiently we use a similar data structure, which we call *expandable node*, and which allows us to split a round node and to find the parent of a square node in constant amortized time. The expandable node data structure has much the same flavor as condensible nodes, but it is based upon set-splitting data structures. We recall here that set-splitting data structures are able to perform *find* and *split* operations on disjoint sets in constant amortized time [12]. Now we group all the sibling square nodes into disjoint sets, and we maintain those disjoint sets under sequences of *split*, and *find* operations. Let ρ be any round node in $\mathcal{T}$, with children $v_1, v_2, \ldots, v_\ell$, $\ell \geq 1$. We maintain a set $\mathcal{SF}(\rho)$ containing ℓ items and such that the name of $\mathcal{SF}(\rho)$ returns a pointer to ρ. Let v_i be any child of ρ: instead of having an edge from v_i to ρ, we have an edge from v_i to the corresponding item in the set $\mathcal{SF}(\rho)$. We implement *split*(ρ, e) as follows. Let v be the square node child of ρ such that $e = (v, \rho)$, and let u be the square node parent of ρ. We perform the corresponding *split* operation in $\mathcal{SF}(\rho)$: this creates two new round nodes ρ_1 and ρ_2 and destroys ρ. To make ρ_1 and ρ_2 children of v we union $\mathcal{UF}(v)$ with two singleton sets. Finally we make v child of u by inserting an edge from u to the item of $\mathcal{UF}(u)$ that round node ρ was pointing to. Therefore, splitting a round node ρ corresponds to performing a *split* operation in $\mathcal{SF}(\rho)$ and at most two union operations involving $\mathcal{UF}(v)$. Finding the parent of a square node corresponds to a *find* operation in a set-splitting data structure.

Notice that due to the structure of $\mathcal{T}$, in which after each update every path alternates between square and round nodes, there is no interaction between condensible and expandable nodes, since only round nodes are subject to splits, and only square nodes are subject to merges. Each *merge* requires unioning two condensible nodes, while each *split* can be performed by splitting an expandable node and by performing a constant number of unions on condensible nodes. Each *parent* requires a *find* operation in either a set-union or a set-splitting data structure. Therefore, by using condensible and expandable nodes we are able to perform each sequence of p *merge*, *split*, and *parent* primitives on a tree with n nodes in a total of $O(p\alpha(p, n))$ worst-case time. $\square$

Lemma 3.5 allows us to prove the following theorem.

THEOREM 3.6. *The data structure supports any sequence of q Same3EdgeBlock and InsertEdge operations on an initially 2-edge-connected graph with n vertices in a total of $O((q + n)\alpha(q, n))$ time. The space required is $O(n)$.*

Proof. A *Same3EdgeBlock* operation consists of performing two *find* operations in disjoint sets and, therefore, can be performed in $O(\alpha(q, n))$ amortized time. As for an *InsertEdge*(x, y) operation, it requires (i) finding the path $\pi_{x,y}$ in $\mathcal{T}$, (ii) performing the merging and splitting of square and round nodes in $\pi_{x,y}$, and (iii) unioning the disjoint sets corresponding to the square nodes (3-edge-connected components) in $\pi_{x,y}$. Given $\mathcal{T}$, we can locate the path $\pi_{x,y}$ by first performing *find*(x) and *find*(y). This returns $C(x)$ and $C(y)$, the two square nodes corresponding to the 3-edge-connected components containing x and y, respectively. Then we trace the paths from $C(x)$ to the root of $\mathcal{T}$ and from $C(y)$ to the root of $\mathcal{T}$, alternating among them one edge at the time. We stop when we reach a node already visited. This requires $2|\pi_{x,y}|$ *parent* primitives in the worst case. Then we have to perform at most $|\pi_{x,y}|$ merges and splits along this path. We recall that *merge* operations union all the 3-edge-connected components in $\pi_{x,y}$. Henceforth, the whole operation can be implemented by using no more than $3|\pi_{x,y}|$ *merge*, *split*, and *parent* primitives. As a consequence of Lemma 3.5, it can be done in a total of $O(|\pi_{x,y}|\alpha(q,n))$ time.

The total time spent during a sequence of at most q *Same3EdgeBlock* and *InsertEdge* operations is, therefore, $O((q+T(n))\alpha(q,n))$, where

$$T(n) \le \sum_{(x,y)} 3|\pi_{x,y}|$$

is the total number of *merge*, *split*, and *parent* primitives performed during *InsertEdge* operations.

We prove the claimed time bound by showing that $T(n) = O(n)$. Notice that the path $\pi_{x,y}$ in $\mathcal{T}$ is a path between square node $C(x)$ and square node $C(y)$. Since any path in $\mathcal{T}$ alternates between square and round nodes, $\pi_{x,y}$ contains at least $\lceil |\pi_{x,y}|/2 \rceil + 1$ square nodes (i.e., 3-edge-connected components of G). After we perform path compression on $\pi_{x,y}$, we are left with only one square node. Consequently, the number of 3-edge-connected components of G decreases by at least $\lceil |\pi_{x,y}|/2 \rceil$. Since at the beginning G can have at most n 3-edge-connected components, and each time we perform *InsertEdge*(x,y) we decrease this number by at least $\lceil |\pi_{x,y}|/2 \rceil$,

$$T(n) \le \sum_{(x,y)} 3|\pi_{x,y}| = O(n).$$

As for the space complexity, we have to bound the size of the set-union data structures used to represent the 3-edge-connected components, and the size of the tree $\mathcal{T}$. Since each 3-edge-connected component of G consists of at least one vertex, and any two 3-edge-connected components are disjoint, the total space required by the set-union data structures used to store the 3-edge-connected components is $O(n)$. As for the size of the tree $\mathcal{T}$, we bound the number of square and round nodes in $\mathcal{T}$. Each square node of $\mathcal{T}$ uniquely corresponds to a vertex of G' (i.e., to a 3-edge-connected component of G), while each round node of $\mathcal{T}$ corresponds to a biconnected component of G'. Since we have at most $O(n)$ 3-edge-connected components in G, there can be at most $O(n)$ vertices and $O(n)$ biconnected components in G'. Therefore, there can be at most $O(n)$ square and round nodes in $\mathcal{T}$. Since $\mathcal{T}$ has at most $O(n)$ nodes, and each *merge* primitive implies an $O(1)$ extra space, $\mathcal{T}$ can be implemented using condensible and expandable nodes in $O(n)$ space as shown in [36]. □

4. Maintaining 3-edge-connected components of connected graphs. We now extend the previous result to the case of connected (but not necessarily 2-edge-connected) graphs. We start with a singleton vertex, and we would like to perform any intermixed sequence of *Same3EdgeBlock*, *InsertEdge*, and *AddVertex* operations.

In this case, we maintain the bridge-block tree $\mathcal{T}_1$ of G. We recall that each node B of $\mathcal{T}_1$ corresponds to a 2-edge-connected component of G, referred to as $graph(B)$, and each edge of $\mathcal{T}_1$ corresponds to a bridge of G. Since $graph(B)$ is a 2-edge-connected component of G, it is 2-edge-connected. We maintain for each node B of $\mathcal{T}_1$ the tree $\mathcal{T}_2(B)$ of 3-edge-connected components of $graph(B)$ as defined in the previous section.

Thus, we maintain information about the graph G by using a tree of trees. Each of these trees is rooted as follows. $\mathcal{T}_1$ is rooted arbitrarily at any node C, and $\mathcal{T}_2(C)$ is rooted arbitrarily at any square node. For each nonroot node B of $\mathcal{T}_1$, let (x_B, y_B) be the bridge in G corresponding to the edge $(B, parent(B))$ in $\mathcal{T}_1$, $x_B \in B$, $y_B \notin B$. We root $\mathcal{T}_2(B)$ at $C(x_B)$ (i.e., the square node corresponding to the 3-edge-connected component containing vertex x_B). Besides this data structure, we maintain also the 2-edge-connected components of G by using the algorithm of Westbrook and Tarjan [36].

As in the previous section, let G' be the graph obtained by shrinking each 3-edge-connected component of G into a super-vertex. Notice that this time G is not necessarily 2-edge-connected and, therefore, G' is not necessarily 2-edge-connected. However, by Lemma 2.2 there is a one-to-one correspondence between bridges of G' and bridges of G, and between 2-edge-connected components of G' and 2-edge-connected components of G. Consequently, $\mathcal{T}_1$ is the bridge-block tree of G' as well, and given any 2-edge-connected component B of G', $\mathcal{T}_2(B)$ is the block tree of B. We notice that combining $\mathcal{T}_1$ and all the trees $\mathcal{T}_2(B)$ yields a tree $\mathcal{T}$ that resembles the block tree of G'. Indeed, denote by $\mathcal{T}$ the tree obtained by plugging each tree $\mathcal{T}_2(B)$ in place of the corresponding node in $\mathcal{T}_1$: the only difference between $\mathcal{T}$ and the block tree of G' is that each bridge (u, v) of G' is represented by a simple edge (u, v) in $\mathcal{T}$, while there is a square node σ and edges (u, σ) and (σ, v) in the block tree of G'. Finally, we remark that Lemma 3.1 still holds for G'. As far as Lemma 3.2 is concerned, we have now that each biconnected component of G' consists of either a unique edge or a simple cycle.

We show how to perform the three operations. A *Same3EdgeBlock*(u, v) is carried out as follows. Find the 2-edge-connected components of G containing u and v, say, B_u and B_v by using the algorithm of Westbrook and Tarjan [36]. If $B_u \neq B_v$, then u and v are not even in a same 2-edge-connected component of G, and, therefore, they cannot be in the same 3-edge-connected component of G, and we return *false*. Otherwise, u and v are in a same 2-edge-connected component $B = B_u = B_v$ of G. We now perform *Same3EdgeBlock*(u, v) on a 2-edge-connected graph as explained in the previous section.

To support an *InsertEdge*(u, v), we first find the 2-edge-connected components of G containing vertices u and v, say, B_u and B_v. If $B_u = B_v = B$, then we perform *CompressPath*$(u, v, \mathcal{T}_2(B))$ as shown in the previous section.

If $B_u \neq B_v$, let $B_u = B_0, B_1, \ldots, B_\ell = B_v$ be the nodes in the path $\pi_{u,v}$ in $\mathcal{T}_1$ between B_u and B_v as they are met while going from B_u to B_v. Each B_i corresponds to the 2-edge-connected component $graph(B_i)$ of G. For each B_i let (x_i, y_i) be the edge in G between $graph(B_i)$ and $graph(B_{i+1})$, $0 \leq i \leq \ell - 1$. For $1 \leq i \leq \ell - 1$ define $start(B_i) = y_{i-1}$ and $end(B_i) = x_i$. Notice that for each 2-edge-connected component $graph(B_i)$, $1 \leq i \leq \ell - 1$, $start(B_i)$ $[end(B_i)]$ is the vertex to which the edge in $\pi_{u,v}$ between $graph(B_{i-1})$ and $graph(B_i)$ [between $graph(B_i)$ and $graph(B_{i+1})$] is incident to. For sake of completeness, define $start(B_0) = u$, $end(B_0) = x_0$, $start(B_\ell) = y_{\ell-1}$, and $end(B_\ell) = v$. Denote by B_λ the least common ancestor of B_u and B_v in $\mathcal{T}_1$ (see, for example, Fig. 5).

The following lemma explains the updates needed in our data structure.

LEMMA 4.1. *Let π_i be the path in $\mathcal{T}_2(B_i)$ between $C(start(B_i))$ and $C(end(B_i))$, $0 \leq i \leq \ell$. After the insertion of edge (u, v) in G, we have the following changes*:

(i) *All and only the vertices in $\cup_{0 \leq i \leq \ell} \{graph(B_i)\}$ become 2-edge-connected in G*;

(ii) *Fix i, $0 \leq i \leq \ell$. Let $u_1^{(i)}, u_2^{(i)}, \ldots, u_{q_i}^{(i)}$ be the square nodes in π_i. All and*

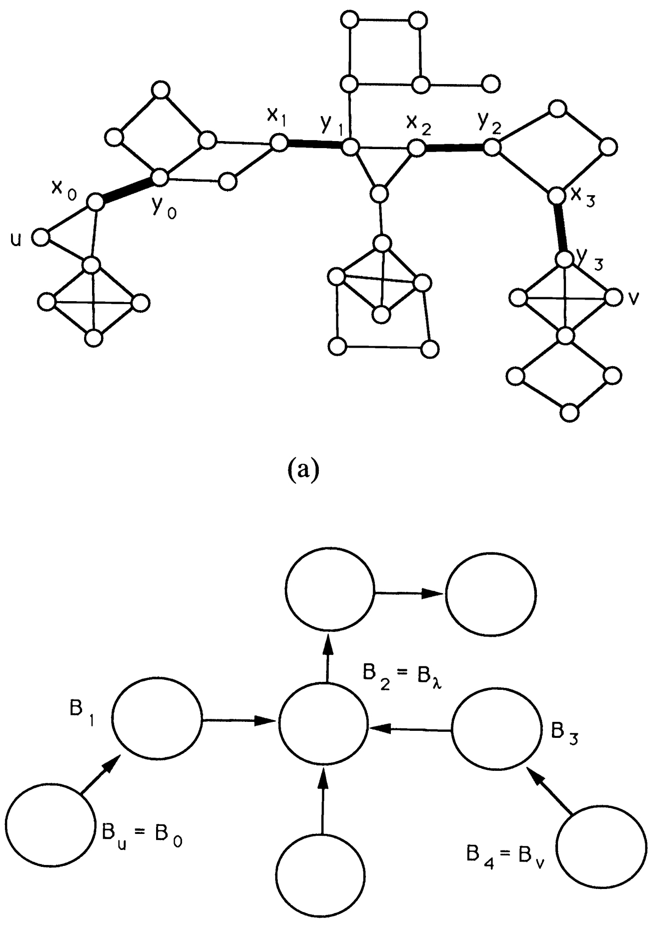

FIG. 5. (a) *A graph $G = (V, E)$ bridges between vertices u and v are in bold*; (b) *the tree of the 2-edge-connected components of G.*

only the vertices in the 3-edge-connected components of $graph(B_i)$ corresponding to $u_1^{(i)}$, $u_2^{(i)}, \ldots, u_{q_i}^{(i)}$ become 3-edge-connected in G.

Proof. Edge (u, v) introduces cycles in G that contain at least one vertex in $graph(B_0)$, $graph(B_1), \ldots, graph(B_\ell)$. Since these are the only new cycles introduced, all and only the vertices in those 2-edge-connected components become 2-edge-connected as stated in proposition (i).

The proof of proposition (ii) can be carried out along the same lines as the proof of Lemma 3.4. Let $V_{i,1}, V_{i,2}, \ldots, V_{i,p}$ be the 3-edge-connected components of $graph(B_i)$ before the insertion of edge (u, v). Let $V'_{i,1}, V'_{i,2}, \ldots, V'_{i,q}$, $1 \leq q \leq p$ be the 3-edge-connected of $graph(B_i)$ corresponding to the square nodes of $\mathcal{T}_2(B_i)$ in π_i, as they are met while going from $C(start(B_i))$ to $C(end(B_i))$ in $\mathcal{T}_2(B_i)$. Notice that $C(start(B_i)) = V'_{i,1}$ and $C(end(B_i)) = V'_{i,q}$. The insertion of edge (u, v) causes a new path outside $graph(B_i)$ between $V'_{i,1}$ and $V'_{i,q}$. By repeating the same argument given in the proof of Lemma 3.4, it can be shown that all and only the vertices of $graph(B_i)$ contained in $V'_{i,1}, V'_{i,2}, \ldots, V'_{i,q}$ become 3-edge-connected. □

Let $G^{new} = G \cup \{(u,v)\}$, and let $(G^{new})'$ be the graph obtained by shrinking the 3-edge-connected components of G^{new} into one vertex. Once again, Lemma 4.1 gives a way to compute $(G^{new})'$ from G'. Consider the 2-edge-connected components of G' obtained by shrinking the 3-edge-connected components of $graph(B_i)$, $0 \le i \le \ell$. Let us refer to them as B'_i, $0 \le i \le \ell$. For each one of them we can repeat the same argument given after Lemma 3.4. Fix i, $0 \le i \le \ell$. By definition of G' all the paths between $V'_{i,1}$ and $V'_{i,q}$ in G' are given by $q-1$ edge-disjoint simple cycles $\rho_{i,1}, \rho_{i,2}, \ldots, \rho_{i,q-1}$ in B'_i such that $V'_{i,1} \in \rho_{i,1}$, $V'_{i,q} \in \rho_{i,q-1}$, and $\rho_{i,j-1} \cap \rho_{i,j} = \{V'_{i,j}\}$, $2 \le j \le q-1$. Each $\rho_{i,j}$ is composed of two disjoint paths between $V'_{i,j}$ and $V'_{i,j+1}$, say, $\rho^{(1)}_{i,j}$ and $\rho^{(2)}_{i,j}$. Furthermore, the insertion of (u,v) in G implies that all and only the vertices in $V'_{i,s}$, $1 \le s \le p$, become 3-edge-connected in G. Therefore, in $(G^{new})'$ the vertices $V'_{i,1}, V'_{i,2}, \ldots, V'_{i,q}$ of G' have to be shrunk into one vertex V'_i. This destroys the previous simple cycles $\rho_{i,j}$, $1 \le j \le q-1$, and creates at most $2(q-1)$ new simple cycles $\rho^{(1)}_{i,j}$ and $\rho^{(2)}_{i,j}$, $1 \le j \le q-1$, that are all incident to V'_i. Furthermore, there is a new simple cycle in G' consisting of all the newly created vertices $V'_1, V'_2, \ldots, V'_\ell$ and edges $(x_0,y_0), (x_1,y_1), \ldots, (x_{\ell-1}, y_{\ell-1}), (u,v)$.

Because of Lemma 4.1 we have to perform the following updates in our data structure. First, all the nodes B_i, $0 \le i \le \ell$, have to be merged into one node B in $\mathcal{T}_1$ because all the vertices in $graph(B_0), graph(B_1), \ldots, graph(B_\ell)$ become now 2-edge-connected. This can be done by using the algorithm of Westbrook and Tarjan [36]. Second, we have to compute the tree $\mathcal{T}_2(B)$ of 3-edge-connected components of the new node $B = B_0 \cup B_1 \cup \ldots \cup B_\ell$. We compute $\mathcal{T}_2(B)$ starting from the trees $\mathcal{T}_2(B_0), \mathcal{T}_2(B_1), \ldots, \mathcal{T}_2(B_\ell)$ as follows. For $0 \le i \le \ell$, we perform *CompressPath*$(start(B_i), end(B_i), \mathcal{T}_2(B_i))$. This is correct because of condition (ii) of Lemma 4.1, and produces the new trees $\mathcal{T}_2^{new}(B_i)$, $0 \le i \le \ell$. Denote by σ_i the square node of $\mathcal{T}_2^{new}(B_i)$ which is the result of the path compression that took place in $\mathcal{T}_2(B_i)$. Notice that σ_i, $0 \le i \le \ell$, corresponds to the new vertex V'_i in $(G^{new})'$. We recall that B_λ is the least common ancestor of B_u and B_v in $\mathcal{T}_1$. As said before, all the new vertices V'_i are now in a new simple cycle of $(G^{new})'$: we create a new round node ρ, make ρ a child of σ_λ, and make $\sigma_{\lambda+1}, \ldots, \sigma_\ell, \sigma_0, \ldots, \sigma_{\lambda-1}$ children of ρ in $\mathcal{T}_2(B)$ in this order. This preserves the same order as in the new simple cycle created in $(G^{new})'$. Since σ_i, $i \ne \lambda$, is the root of $\mathcal{T}_2^{new}(B_i)$, we do not need to reroot any of these trees.

An *AddVertex*(u,v) operation inserts a new vertex u and connects it to v. We update our data structure as follows. Let B_v be the 2-edge-connected component containing v. We create a new 2-edge-connected component B_u containing only vertex u and make it child of B_v in $\mathcal{T}_1$. We initialize $\mathcal{T}_2(B_u)$ to be a tree with a singleton square root node, and initialize a new 3-edge-connected component containing only vertex u.

THEOREM 4.2. *There exists a data structure that supports any sequence of q Same3EdgeBlock and InsertEdge and n AddVertex operations in a total of $O((q+n)\alpha(q,n))$ time. The space required is $O(n)$.*

Proof. We first analyze the space complexity of our data structure. Notice that we start with a graph containing a single vertex. At the end of the sequence of operations, we end up with a graph G with at most $n+1$ vertices. Since G can have at most $O(n)$ 2-edge-connected components and bridges, $\mathcal{T}_1$ has size $O(n)$. For each 2-edge-connected component B_i of G, denote by n_i the number of vertices in B_i. Since each vertex of G is an at most one 2-edge-connected component, we have that $\sum_i n_i = n+1$. By Theorem 3.6, the tree of 3-edge-connected components of B_i has at most $O(n_i)$ nodes and edges.

As a result, all the trees in our data structure require

$$O\left(\sum_i n_i\right) = O(n)$$

space.

Each *Same3EdgeBlock* operation can be performed in $O(\alpha(q,n))$ amortized time as the following argument shows. Finding B_u and B_v, the 2-edge-connected components of G containing u and v, can be done in $O(\alpha(q,n))$ amortized time [36]. If $B_u \neq B_v$, then *Same3EdgeBlock* returns false and no further computation is required. If $B_u = B_v = B$, performing *Same3EdgeBlock* on $\mathcal{T}_2(B)$ requires $O(\alpha(q,n))$ amortized time by Theorem 3.6.

As for an *InsertEdge*(u,v) operation, the bridge-block tree can be updated in $O(\alpha(q,n))$ amortized time [36]. The update of the trees of 3-edge-connected components $\mathcal{T}_2(B_i)$, $0 \le i \le \ell$, requires

$$O\left(\ell + \sum_i |\pi_i|\right)$$

merge, *split*, and *parent* primitives. By applying exactly the same argument used in Theorem 3.6, we obtain that the total number of such primitives during any sequence of *InsertEdge* operations is $O(n)$. As a result, the total time required to perform any sequence of *InsertEdge* operations is $O((q+n)\alpha(q,n))$. Finally, each *AddVertex* operation can be performed in $O(1)$ time. □

Our data structure can be used even if we start with a nonempty graph $G_0 = (V_0, E_0)$ and allow $O(|V_0| + |E_0|)$ preprocessing.

LEMMA 4.3. *Given a graph $G_0 = (V_0, E_0)$ our data structure can be initialized in $O(|V_0| + |E_0|)$ time.*

Proof. Compute in $O(|V_0| + |E_0|)$ the 2-edge-connected components of G_0 by using the algorithm of Tarjan [32]. This gives also $\mathcal{T}_1$, the bridge-block tree of G_0, which can be initialized in $O(|\mathcal{T}_1|) = O(|V_0|)$ as a condensible and expandable nodes tree. For each 2-edge-connected component B of G_0, compute the 3-edge-connected components of B and initialize the tree of 3-edge-connected components $\mathcal{T}_2(B)$. This requires $O(|B|)$ time[16], and sums up to a total time of $O(|V_0| + |E_0|)$. □

5. Concluding remarks. In this paper we have studied the on-line maintenance of the 3-edge-connected components of an undirected graph during edge and vertex insertions. We have proposed algorithms that support any sequence of q *InsertEdge*, *AddVertex*, and *Same3EdgeBlock* operations on an initially connected graph with n vertices in a total of $O((n+q)\alpha(q,n))$ time. Recently La Poutré [23] extended this bound to unconnected graphs.

We remark that the same $O(\alpha(q,n))$ amortized bound holds also if we wish to maintain the names of the 3-edge-connected components of a graph subject to the following operations.

3EdgeBlock(x): Return the name of the 3-edge-connected component containing vertex x.

InsertEdge(x,y,A): Insert a new edge between vertices x and y and call A the new (if any) 3-edge-connected component created by (x,y).

We have been able to achieve an $O(m^{2/3})$ bound per operation for the fully dynamic maintenance of the 3-edge-connected components of a graph [13] by using techniques similar to the ones used for the fully dynamic maintenance of the 2-edge-connected components [14].

One might ask whether there is any efficient partially dynamic algorithm for maintaining on-line the k-edge-connected components of a graph, $k \geq 4$.

Acknowledgment. We are grateful to Dany Breslauer for many useful discussions.

ON THE BOUNDEDNESS OF CONSTANT-TIME-MAINTAINABLE DATABASE SCHEMES*

HÉCTOR J. HERNÁNDEZ† AND KE WANG‡

Abstract. Constant-time-maintainable database schemes are highly desirable with respect to constraint enforcement, since it is possible to determine whether any of their consistent states plus an inserted tuple is consistent in time independent of the state size. Several proper subclasses of constant-time-maintainable database schemes are known to be bounded with respect to dependencies and hence very desirable with respect to query answering. However, whether the whole class of constant-time-maintainable database schemes is bounded is not known for sure.

In this paper, it is proven that the entire class of constant-time-maintainable database schemes is bounded with respect to dependencies and thus very desirable with respect to query answering in the following cases: (1) only cover-embedded functional dependencies appear as constraints; (2) only equality-generating dependencies appear as constraints and the database scheme has a lossless join. In particular, it is shown that total projections of representative instances can be computed via unions of projections of simple chase join expressions. Since it is known how to optimize these expressions, it is possible to compute total projections optimally. These results show that the class of constant-time-maintainable database schemes is the largest class of database schemes, which are highly desirable with respect to both constraint enforcement and query answering. This class of schemes can be effectively recognized by known algorithms. The previously known largest class of database schemes with these desirable properties is the class of independent database schemes, which is a proper subclass of constant-time-maintainable schemes.

1. Introduction.

Within the *weak instance model* [H2], [Vas], the *maintenance problem* [GY], [GW], [W] of a database scheme is the following decision problem: Given a consistent state of the database scheme and a tuple to be inserted into the state, is the modified state consistent with respect to the constraints imposed on the database scheme? Database schemes for which this problem has "very fast" solutions are highly desirable in practice.

The notion of constant-time-maintainability was proposed by Graham and Wang [GW] to capture the intuition on "very fast" solutions to the maintenance problem. Informally, a database scheme is constant-time-maintainable with respect to the constraints imposed on the scheme if its maintenance problem can be solved in time independent of the state size. Therefore constant-time-maintainable database schemes are particularly desirable in a large and highly dynamic database environment. Also in such an environment, we will consider only constant-time-maintainable schemes to have fast solutions to constraint enforcement, because all other schemes are linear time lower bounded [GW], [WG]. As mentioned in [GW], constant-time-maintainability generalized the notion of independence [GY], [S1], [S2], and the class of constant-time-maintainable schemes properly contains the class of independent schemes when (1) only functional dependencies appear, (2) functional dependencies and the join dependency

of the database scheme appear, and (3) functional dependencies and inclusion dependencies appear [AC2].

Recently, the recognition problem of constant-time-maintainable database schemes was solved in several useful cases. An exponential time recognition algorithm for constant-time-maintainable database schemes was given in [GW], [W], [WG] for each of the following cases: (1) The database scheme cover embeds functional dependencies; (2) functional dependencies plus the join dependency of the database scheme appear as constraints; and (3) equality-generating dependencies appear as constraints and the database scheme has a lossless join. An efficient recognition algorithm for constant-time-maintainable database schemes was presented in [HC] when cover-embedding Boyce–Codd Normal Form is assumed. Previous work on fast constraint enforcement can be found in [BrV], [CH1], [CH2], [CH4].

In view of the importance and generality of constant-time-maintainable database schemes, this paper investigates query processing in that class of database schemes. Under the weak instance model, the *X-total projection of the representative instance* [M], [S1], [S2], [Y] of a database can be used to answer a query defined on a set of attributes X; intuitively, the representative instance of a database is an adequate and correct representation of all the information that can be logically inferred from the database using certain rules derived from the dependencies that the database must satisfy; the X-total projection of the representative instance is the set of tuples in the representative instance that do not contain missing information on X. Under this approach, it is highly desirable for query processing to have a database scheme that would allow us to compute the X-total projection of the representative instance via a predetermined relational expression that is independent of the databases. This is possible exactly when the database scheme is bounded with respect to the dependencies given [GM], [MUV].

Unfortunately, the problem of deciding whether a database scheme is bounded with respect to dependencies is conjectured to be undecidable even for the case of functional dependencies [MUV]. It has been shown that proving boundedness of database schemes with respect to dependencies is difficult even for restricted cases [C], [CH1], [CH2], [IIK], [HC], [MRW], [S2], [S3]. Therefore, defining some classes of database schemes that are general enough and obviously bounded, like the one in [CM1], or proving the boundedness of some meaningful classes of database schemes seems to be a reasonable thing to do. The two largest classes of database schemes that can be effectively recognized and have an effective construction of relational expressions for computing total projections with respect to functional dependencies are the class of independent schemes [C], [IIK], [S3] and the class of independence-reducible database schemes [CH2]. A general, sufficient condition for unboundedness of database schemes when functional dependencies are considered was presented in [CH3]. A methodology for incrementally generating bounded database schemes can be found in [CH4]. When only total projections on the universe of attributes are considered, Sagiv [S4] gave a necessary and sufficient condition for computing total projections for lossless database schemes with only tuple-generating dependencies.

The notion of boundedness has also been investigated in the context of optimization of Datalog (the language of function-free Horn-clause) programs. A Datalog program is *bounded* if it is possible to eliminate recursion from it [CGKV], [GMSV], [I], [NS]. Boundedness of Datalog programs has been shown to be undecidable in [GMSV]. Some other decidable and undecidable results on boundedness of Datalog programs are presented in [CGKV], [S4], [Var].

The class of constant-time-maintainable database schemes seems to be a subclass of bounded database schemes. Several subclasses of constant-time-maintainable database schemes are known to be bounded: Boyce–Codd Normal Form (BCNF) independent database schemes [S2], independent database schemes [C], [IIK], [MRW], [S3], γ-acyclic BCNF database schemes [CH1], split-free independence-reducible schemes [CH2], and BCNF constant-time-maintainable database schemes [HC]. However, whether the whole class of constant-time-maintainable database schemes is bounded with respect to dependencies is not known.

In this paper we prove in §4 that the entire class of constant-time-maintainable database schemes is bounded when only cover-embedded functional dependencies appear as constraints. In §5 we describe a method to construct the relational expressions that compute total projections of representative instances. In particular, we prove that unions of projections of simple chase join expressions [AC3], [C], a kind of extension joins [H1], compute the total projections of the representative instances. The construction, however, takes exponential time in the size of the database scheme. Since it is known from [AC3], [C] how to optimize these expressions to a minimal number of union and join operations, we can compute total projections optimally (in that sense). Then in §6 we show that the boundedness and construction of relational expressions obtained in §§4 and 5 also hold when only equality-generating dependencies appear as constraints and the database scheme has a lossless join. In §7 we prove that we can compute X-total projections via unions of projections of simple chase join expressions, for any X included in any relation scheme in the database when a set of functional dependencies and the join dependency of the database scheme are the constraints. In §8 we give our conclusions.

2. Definitions and notation. In this section, we give most of the notation required for the rest of this paper.

2.1. Basic definitions. We shall follow standard notation [Ma], [U] and only give some nonstandard definitions here.

We fix a finite set U to be the *universe* of attributes (or columns) and fix $\mathbf{R}$, the *database scheme*, to be a collection of relation schemes $\{R_1, \ldots, R_n\}$ whose union is U. A *database state* (or *state*) $\mathbf{r}$ on $\mathbf{R}$ is an assignment of finite relations to relation schemes of $\mathbf{R}$; we shall denote it as $\mathbf{r} =< r_1 = \mathbf{r}(R_1), \ldots, r_n = \mathbf{r}(R_n) >$. A *tableau* is a set of tuples defined on U [ASU]. For each attribute $A_j \in U$, the domain of a tableau on A_j consists of countable many variables, and constants taken from $dom(A_j)$, the *domain* of A_j. We assume that all the tableaux and states are *typed*, that is, the domains of a tableau or state on different attributes are disjoint. A *symbol* is either a constant or a variable, and we say that a symbol is *unique* if it is distinct from any other symbol appearing anywhere else. We say that a tuple $\mu[X]$, the restriction of tuple μ onto attributes X, is *total* if $\mu[A_i]$ is a constant for all $A_i \in X$, where $X \subseteq U$.

Assume T_1 and T_2 are tableaux. A *valuation function* $\theta : T_1 \rightarrow T_2$ is a function from symbols in T_1 to symbols in T_2, which is the identity on constants. A *containment mapping* $\theta : T_1 \rightarrow T_2$ is a valuation function such that $t \in T_1$, implies $\theta(t) \in T_2$.

Let $\mathbf{r} =< r_1 = \mathbf{r}(R_1), \ldots, r_n = \mathbf{r}(R_n) >$ be a state on $\mathbf{R}$. We define $T_\mathbf{r}$, *the tableau for state* $\mathbf{r}$, as follows: For each relation $r_i \in \mathbf{r}$ and for each tuple $t \in r_i$, there is a tuple s in $T_\mathbf{r}$ corresponding to it; the tuple s is defined as follows: $s[R_i] = t$, and for all $A_j \in U - R_i$, $s[A_j]$ is a unique variable in $T_\mathbf{r}$. Now, let r'_j be a relation on $R_j \in \mathbf{R}$. Then $\mathbf{r} \cup r'_j$ shall denote the state $< r_1, \ldots, r_{j-1}, r_j \cup r'_j, r_{j+1}, \ldots, r_n >$.

2.2. Dependencies and chasing. The kinds of constraints considered here are (*typed*) *equality-generating dependencies* (*egd's*), *functional dependencies* (*fd's*), and the *join dependency* (*jd*) $\bowtie \mathbf{R}$ [ABU], [BV], [F], [YP]. We shall use the term *dependencies* to refer to the above-mentioned dependencies.

Associated with each dependency there is a *dependency rule* [ABU], [BV], [F], [YP]. Given a tableau T and a set of dependencies D, we can apply their associated rules to T to infer additional information. These dependency rules are defined in [ABU], [BV], [MMS]. $CHASE_D(T)$ denotes the final tableau obtained from applying exhaustively to T the rules for the dependencies in D; $CHASE_D(T)$ is also known as the *chase of* T (with respect to D) [MMS].

Without loss of generality, we will assume in this paper that every fd has a single attribute as its right-hand side. We define the *closure* of a set of fd's F, denoted as F^+, to be the set of fd's that logically follow from F [Ma], [U]. An fd $X \rightarrow A$ is *embedded* in a relation scheme R_i if $XA \subseteq R_i$. A set of fd's F is *embedded* in $\mathbf{R}$ if each fd $X \rightarrow A \in F$ is embedded in some $R_i \in \mathbf{R}$. For a set of fd's F and a relation scheme $R_i \in \mathbf{R}$, $F|R_i$ denotes all fd's from F that are embedded in R_i. $\mathbf{R}$ is said to be *cover embedding* (or to *cover embed*) a set of fd's F if there exists a *cover* G of F, that is, $G^+ = F^+$, such that G is embedded in $\mathbf{R}$; G is said to be an *embedded cover* of F. $\mathbf{R}$ is said to *preserve* a set of fd's F if for any relation I defined on U, I satisfies F implies $\bowtie \pi_{\mathbf{R}}(I)$ satisfies F, where $\pi_{\mathbf{R}}(I)$ denotes the state $< \pi_{R_1}(I), \ldots, \pi_{R_n}(I) >$ and $\bowtie \pi_R(I) = \pi_{R_1}(I) \bowtie \cdots \bowtie \pi_{R_n}(I)$. $\mathbf{R}$ is said to have a *lossless join* with respect to a set of dependencies D if the jd $\bowtie \mathbf{R}$ logically follows from D [ABU].

2.3. Simple chase join expressions and derivation sequences. Borrowing from [C], in this subsection we define derivation sequences and simple chase join expressions, a generalization of extension joins [H1].

Given a set of fd's F, a *derivation sequence* (*ds*) of some relation scheme R_i (with respect to F) is a finite sequence of fd's $< Y_1 \rightarrow A_1, \ldots, Y_m \rightarrow A_m >, m \geq 0$, that satisfies the following conditions: For all $1 \leq j \leq m$,

- $Y_j \rightarrow A_j \in F$;
- $Y_j \subseteq R_i A_1 \cdots A_{j-1}$, and $A_j \notin R_i A_1 \cdots A_{j-1}$.

The ds is said to *cover* X if $R_i A_1 \cdots A_m \supseteq X$. A ds $< Y_1 \rightarrow A_1, \ldots, Y_m \rightarrow A_m >$ that covers X is said to be *nonredundant* if for every $Y_j \rightarrow A_j$ with $1 \leq j \leq m$, either $A_j \in X$ or $A_j \in Y_k$, for some $k > j$ (otherwise, any fd that fails to satisfy this condition is said to be *redundant*). Two ds's of R_i are said to be *equivalent* if they are identical up to permutation of the fd's in the sequences. Given a ds $< Y_1 \rightarrow A_1, \ldots, Y_m \rightarrow A_m >$ of R_i that covers X, if each fd $Y_j \rightarrow A_j$ is embedded in some relation scheme R_j, then we define the *simple chase join expression* (*simple cje*) E *for the ds* as $E = \pi_X(R_i \bowtie \pi_{Y_1 A_1}(R_1) \bowtie \cdots \bowtie \pi_{Y_m A_m}(R_m))$. Given a simple cje E and a state $\mathbf{r}$ on $\mathbf{R}$, $E(\mathbf{r})$ denotes the evaluation of E after substituting every relation scheme R_j in E with the relation $r_j \in \mathbf{r}$. It should be obvious that for every ds π_1 of R_i covering X, there is a nonredundant ds π_2 of R_i covering X (obtained by removing redundant fd's from π_1) such that the simple cje E_1 for π_1 and the simple cje E_2 for π_2 satisfy $E_2(\mathbf{r}) \supseteq E_1(\mathbf{r})$ for every state $\mathbf{r}$.

2.4. Weak instance and boundedness. Let $\mathbf{r}$ be a state on $\mathbf{R}$, let I be a relation defined on U, and let D be a set of dependencies. Then I is a *weak instance* for $\mathbf{r}$ with respect to D if $\pi_{R_i}(I) \supseteq r_i$ for each $\mathbf{R}_i \in \mathbf{R}$ and I satisfies D. $\mathbf{r}$ is said to be *consistent* with respect to D if a weak instance exists for the state with respect to D [GMV], [H2], [Vas]. The set of all consistent states for $\mathbf{R}$ with respect to D is denoted by $CONS(\mathbf{R}, D)$. $CHASE_D(T_{\mathbf{r}})$ is called *the representative instance for state* $\mathbf{r}$ (with respect to D) [M], [S1],

[S2], [Y]. The *X-total projection* of the representative instance (with respect to D) for $\mathbf{r}$, denoted $[X]_{\mathbf{r}}^{D}$, is $\{t[X] | t \in CHASE_D(T_{\mathbf{r}})$ and $t[X]$ is total$\}$.

A database scheme $\mathbf{R}$ is *bounded* with respect to a set of dependencies D if for every $X \subseteq U$, every X-total tuple in the representative instance of any consistent state $\mathbf{r}$ of $\mathbf{R}$ with respect to D can be obtained in at most k applications of rules for dependencies in D to tableau $T_{\mathbf{r}}$ for some constant $k \geq 0$ [GM], [MUV]. It has been shown in [GM], [MUV] that a database scheme is bounded with respect to D if and only if for any $X \subseteq U$, the X-total projection of the representative instance for any consistent state can be computed by a predetermined relational expression that is independent of the state.

2.5. Constant-time-maintainable and independent schemes. The *maintenance problem* (for database states) of $\mathbf{R}$ with respect to a set of dependencies D is the following decision problem: Let $\mathbf{r}$ be a consistent state of a database scheme $\mathbf{R}$ with respect to D and assume we insert a tuple t into $r_p \in \mathbf{r}$. Is $\mathbf{r} \cup \{t\}$ a consistent state of $\mathbf{R}$ with respect to D? We say that $< \mathbf{r}, t >$ is a *yes-instance* of the maintenance problem of $\mathbf{R}$ with respect to D if $\mathbf{r} \cup \{t\}$ is consistent with respect to D; otherwise, $< \mathbf{r}, t >$ is a *no-instance* of the maintenance problem of $\mathbf{R}$ with respect to D. An algorithm *solves* the maintenance problem of $\mathbf{R}$ with respect to F if for every instance $< \mathbf{r}, t >$, the algorithm returns a *yes* answer exactly when $< \mathbf{r}, t >$ is a yes-instance of the maintenance problem of $\mathbf{R}$ with respect to D. We call such an algorithm a *maintenance algorithm*.

Following [GW], we define constant-time-maintainable database schemes as follows. Suppose there is a maintenance algorithm $\mathbf{A}$ that solves the maintenance problem of $\mathbf{R}$ with respect to a set of dependencies D. Let $< \mathbf{r}, t >$ be an instance of the maintenance problem of $\mathbf{R}$ with respect to D. Assume that $\mathbf{r}$ is stored on a device that responds to requests of the form $< R_i, \Psi >$, where $R_i \in \mathbf{R}$ and Ψ is a Boolean combination of formulas of the form $A =$ 'a,' where $A \in R_i$, a is an element of the domain of A that appears in either the inserted tuple t or the tuples previously returned, as defined below. The device responds to the request $< R_i, \Psi >$ by returning, if it exists, an arbitrary tuple from $r_i \in \mathbf{r}$ that satisfies Ψ. Now, we define $\#\mathbf{A}(\mathbf{r}, t)$ to be the number of requests of the above form made by $\mathbf{A}$ on $< \mathbf{r}, t >$. We say that $\mathbf{A}$ solves the maintenance problem of $\mathbf{R}$ with respect to D in *constant time* if there is a constant integer $k \geq 0$ such that $k \geq \#\mathbf{A}$ $(\mathbf{r}, t)$ for all instances $< \mathbf{r}, t >$ of the maintenance problem of $\mathbf{R}$ with respect to D. A database scheme $\mathbf{R}$ is said to be *constant-time-maintainable* (*ctm*) with respect to D if there is a maintenance algorithm that solves the maintenance problem of $\mathbf{R}$ with respect to D in constant time [GW]. The reader should note that the definition suggests that constant-time-maintainability is cover insensitive; that is, for any two equivalent sets of dependencies, say, D_1 and D_2, $\mathbf{R}$ is ctm with respect to D_1 if and only if $\mathbf{R}$ is ctm with respect to D_2.

A database scheme is *independent* with respect to a set of dependencies D if each relation in a state satisfies its projected dependencies implies that the state is consistent with respect to D [GY], [IIK], [S2].

The following example illustrates these definitions.

Example 1. Let $\mathbf{R} = \{CAZ, CZ\}$ and $F = \{CA \to Z, Z \to C\}$. This is the classic City, Address, Zip database scheme. $\mathbf{R}$ is not independent with respect to F because $Z \to C$ is embedded in both CAZ and CZ. We now show that $\mathbf{R}$ is ctm with respect to F. Suppose that we have a consistent state $\mathbf{r}$ with respect to F and that we insert a tuple t into either the CZ relation or the CAZ relation. We now prove that we need to issue at most three requests of the above form to verify whether $\mathbf{r} \cup \{t\} \in CONS(\mathbf{R}, F)$.

Case 1. Assume $t =< c, z >$ is to be inserted into the CZ relation. To verify whether $Z \to C$ is satisfied by the updated state, we need to issue the requests $< CZ, Z =$'z'$>$

and $< CAZ, Z =$'z'$>$ to retrieve from $\mathbf{r}$ any tuple of the form $< c_1, z >$ or $< c_2, a, z >$. Then the consistency of $\mathbf{r}$ implies that the updated state is consistent if and only if none of these tuples is returned (i.e., they do not exist in $\mathbf{r}$) or the returned tuples have the constant c on column C (i.e., if one tuple is returned, then $c_1 = c$ or $c_2 = c$; if two tuples are returned, then $c_1 = c$ and $c_2 = c$).

Case 2. Assume $t =< c, a, z >$ is to be inserted into the CAZ relation. To verify if $CA \rightarrow Z$ is satisfied by the updated state, we need to issue the request $< CAZ, C =$ 'c' $\wedge A =$'a'$>$ to retrieve from $\mathbf{r}$ any tuple of the form $< c, a, z' >$; if a tuple is returned with $z' \neq z$, the updated state is not consistent with respect to F. Otherwise, we still have to check for a possible violation of $Z \rightarrow C$. To verify this, we need to issue at most two requests, as it is shown in Case 1 above.

The above discussion shows that at most three requests are required to solve the maintenance problem of $\mathbf{R}$ with respect to F. Therefore $\mathbf{R}$ is ctm with respect to F. $\square$

3. An equivalent definition of ctm schemes. It is difficult to work directly with the notion of constant-time-maintainability as it was defined above, because the notion is concerned with the existence of some kind of algorithm. To alleviate that problem, an equivalent definition of constant-time-maintainability, which is based on a specific computation, was given in [W]. We now present this alternative definition.

Assume that F is a set of fd's embedded in $\mathbf{R}$ such that $F|R_i$ is a cover of $F^+|R_i$ for every $R_i \in \mathbf{R}$. Let $\mathbf{r}$ be a state on $\mathbf{R}$ and let u be a tuple on U. We say that the pair $\tau =< v_i, X \rightarrow A >$ can *expand* u if $X \rightarrow A \in F|R_i$, v_i is a tuple in $r_i \in \mathbf{r}$ for some $R_i \in \mathbf{R}$, and $u[X] = v_i[X]$. Sometimes, we just say that v_i (or $X \rightarrow A$) can expand u if we are not concerned with the other element. Assume that $\tau =< v_i, X \rightarrow A >$ can expand u. Then $\tau(u)$, the result of expanding u by τ, is the tuple defined on U as follows: $\tau(u)$ is u, except that $\tau(u)[A]$ is $v_i[A]$ if $u[A] \neq v_i[A]$. If $\tau(u) \neq u$, we say that τ can *strictly expand* u. Let $\chi =< \tau_1, \ldots, \tau_m >$, where for $1 \leq j \leq m$, $\tau_j =< p_j, X_j \rightarrow A_j >$ and $X_j \rightarrow A_j \in F|R_l$ for some $R_l \in \mathbf{R}$, and p_j is a tuple from r_l in $\mathbf{r}$. We say that χ can (*strictly*) *expand* u if τ_1 can (strictly) expand u, and for $2 \leq j \leq m$, τ_j can (strictly) expand $\tau_{j-1}(\tau_{j-2}(\cdots\tau_1(u)\cdots))$. We also say that the sequence of fd's $< X_1 \rightarrow A_1, \ldots, X_m \rightarrow A_m >$ can (strictly) expand u in the above case.

Given a state $\mathbf{r} \in CONS(\mathbf{R}, F)$ and a total tuple v on $V \subseteq U$, let $aug_U(v)$ be the tuple on U defined as follows: $aug_U(v)[V] = v$ and for each $B \in U - V$, $aug_U(v)[B]$ is a unique variable. The *expansion computation of* v *in* $\mathbf{r}$ (with respect to F) is defined as follows [W]:

```
Let $\bar{v}$ be $aug_U(v)$.
Repeatedly expand $\bar{v}$ by a tuple in r and an fd in $F$ until either
        (i)  no more changes can be made to $\bar{v}$ or
        (ii) some constant is replaced by a different constant.
```

It was proven in [W], [WG] that the expansion computation has finite Church–Rosser-like properties, provided that for every $R_i \in \mathbf{R}$, $F|R_i$ is a cover of $F^+|R_i$, which has been assumed at the beginning of this section. In particular, the computation stops after at most $|U|$ strict expansions, and the condition (i) or (ii) on which the computation stops and the final tuple $\bar{v}$ if it stops at (i) are unique for every input $\mathbf{r}$ and v. If the expansion computation of v in $\mathbf{r}$ stops at condition (i), v is said to be *expansible in* $\mathbf{r}$ (with respect to F), and the final universal tuple $\bar{v}$ is called *the expansion of* v *in* $\mathbf{r}$ (with respect to F); otherwise, v is said to be *not expansible in* $\mathbf{r}$ (with respect to F), and we say that the expansion computation of v in $\mathbf{r}$ *reveals a contradiction*. Obviously, for any state $\mathbf{r} \in CONS(\mathbf{R}, F)$, every tuple in $\mathbf{r}$ is expansible in $\mathbf{r}$.

The following theorem gives another equivalent definition of ctm schemes, which we shall use for the rest of this paper.

THEOREM 1. *Let* $\mathbf{R}$ *be a database scheme, and let* F *be a set of* fd*'s embedded in* $\mathbf{R}$ *such that* $F|R_i$ *is a cover of* $F^+|R_i$*, for every* $R_i \in \mathbf{R}$*. Then* $\mathbf{R}$ *is* ctm *with respect to* F *if and only if for every instance* $< \mathbf{r}, u >$ *of the maintenance problem of* $\mathbf{R}$ *with respect to* $F, \mathbf{r} \cup \{u\} \notin CONS(\mathbf{R}, F)$ *implies* u *is not expansible in* $\mathbf{r}$ *with respect to* F.

Proof. See the proof of Theorem 3.3 and Definition 3.1 in [W]. (For a full proof see Thm. 4.2.3 in [WG]. The assumption that for any $R_i \in \mathbf{R}$, $F|R_i$ is a cover of $F^+|R_i$ is essential in that proof.) □

4. Ctm schemes are bounded with respect to cover-embedded fd's. Throughout this section we assume that (1) F is a set of fd's embedded in $\mathbf{R}$; (2) $F|R_i$ is a cover of $F^+|R_i$ for every $R_i \in \mathbf{R}$; and (3) every fd in F has a single attribute on the right-hand side. Any set G of cover-embedded fd's can be transformed into a set satisfying (1) and (3) above in polynomial time [BH], [GY]. The transformation into a set satisfying (2) takes exponential time in general. For any such cover F of G, $CHASE_F(T_\mathbf{r})$ and $CHASE_G(T_\mathbf{r})$ are identical up to the renaming of variables [MMS], and therefore they have identical total projections. Thus our results in this section, about boundedness, and in §5, about the computation of total projections, are actually those for cover-embedding ctm schemes.

In this section, we shall prove that the constant-time-maintainability of $\mathbf{R}$ with respect to F implies the boundedness of $\mathbf{R}$ with respect to F. We prove this fact by showing how to chase any consistent state of a ctm database scheme in a particular way. In §5, we show how to construct the relational expressions that compute the total projections of representative instances.

4.1. The expansion of r. Let $\mathbf{r} \in CONS(\mathbf{R}, F)$. We define

$$T_\mathbf{r}^* = \{\bar{u} | \bar{u} \text{ is the expansion of } u \text{ in } \mathbf{r} \text{ (with respect to } F), u \in r_i, r_i \in \mathbf{r}\},$$

where we assume that all the variables in $T_\mathbf{r}^*$ are unique. We say that $T_\mathbf{r}^*$ is the *expansion of* $\mathbf{r}$ (with respect to F). Observe that $T_\mathbf{r}^*$ is a tableau in a chase of $T_\mathbf{r}$ with respect to F. We shall prove that if $\mathbf{R}$ is ctm with respect to F, then we can obtain $CHASE_F(T_\mathbf{r})$ from $T_\mathbf{r}^*$ without equating any variable in $T_\mathbf{r}^*$ to a constant from $\mathbf{r}$. This shall imply that for any $X \subseteq U$ and for any $\mathbf{r} \in CONS(\mathbf{R}, F)$, $[X]_\mathbf{r}^F = \{t[X] | t \in T_\mathbf{r}^* \text{ and } t[X] \text{ is total}\}$. Then the boundedness of $\mathbf{R}$ with respect to F follows because every X-total tuple in $T_\mathbf{r}^*$ can be obtained by at most $|U|$ strict expansions, each being an application of an fd-rule for some fd in F. We are going to prove this claim in §4.3 by induction on the number of applications of fd-rules to the tableau. The following subsection shall constitute the basis of such proof.

4.2. Basis of the proof of the main lemma. Assume the following for the rest of this subsection:

- $\mathbf{R}$ is ctm with respect to F, where F is as assumed above,
- $\mathbf{r} \in CONS(\mathbf{R}, F)$, and

- There are two tuples $\bar{u}$ and $\bar{v}$ in $T^*_{\mathbf{r}}$, and a nontrivial fd $X \to A \in F^+|R_1$ for some $R_1 \in \mathbf{R}$ such that $\bar{u}[X] = \bar{v}[X]$ and $\bar{u}[A] \neq \bar{v}[A]$. Furthermore, we assume that $\bar{u}$ and $\bar{v}$ come from tuples u and v in $\mathbf{r}$, respectively, that is, $\bar{u}$ is the expansion of u in $\mathbf{r}$ (with respect to F) and $\bar{v}$ is the expansion of v in $\mathbf{r}$ (with respect to F).

We shall prove that both $\bar{u}[A]$ and $\bar{v}[A]$ are variables.

Let $V = \{B | B \in R_1$ and $\bar{u}[B] = \bar{v}[B]\}$; notice that $R_1 - V$ is nonempty since $A \in R_1 - V$; also observe that $X \subseteq V$ and $\bar{u}[V]$ are constants because by construction of $T^*_{\mathbf{r}}$ all the variables in $\bar{u}$ and $\bar{v}$ are distinct. Let z be a tuple on R_1 defined as follows: $z[V] = \bar{u}[V]$ and for all $B \in R_1 - V$, $z[B]$ is a unique constant. We are going to prove (1) z is expansible in $\mathbf{r}$, and hence, by Theorem 1, $\mathbf{r} \cup \{z\}$ is consistent with respect to F, and (2) $\bar{v}[A]$ and $\bar{u}[A]$ are variables.

LEMMA 1. *$z[V]$ is expansible in* $\mathbf{r}$.

Proof. This follows from $\bar{u}[V] = z[V]$ and $\bar{u}[V]$ is expansible in $\mathbf{r}$. □

We now prove that the expansion computation of $z[V]$ in $\mathbf{r}$ does not equate to a constant any unique variable on columns $R_1 - V$ of $aug_U(z[V])$. Therefore, if we replace these unique variables with the unique constants in $z[R_1 - V]$, the same expansion computation shows that z is expansible in $\mathbf{r}$.

LEMMA 2. *Let $\bar{zv}$ be the expansion of $z[V]$ in* $\mathbf{r}$. *Let $Y = \{B | B \in U$ and $\bar{zv}[B]$ is a constant$\}$. $Y \cap (R_1 - V) = \emptyset$.*

Proof. We first prove that $\bar{u}[Y] = \bar{zv}[Y] = \bar{v}[Y]$.

Let $\tau_1 = < y_1, Y_1 \to B_1 >, \ldots, \tau_l = < y_l, Y_l \to B_l >, l \geq 0$, be a sequence that can strictly expand $aug_U(z[V])$ in an expansion computation of $z[V]$ in $\mathbf{r}$. From Lemma 1, no contradiction is revealed in this expansion.

Let $z_j = \tau_j(\cdots(\tau_1(z_0))\cdots)$, for $1 \leq j \leq l$, where $z_0 = aug_U(z[V])$. It is not difficult to prove that for $0 \leq j \leq l$ and for any $C \in U$ if $z_j[C]$ is a constant, then $\bar{u}[C] = z_j[C]$. This implies $\bar{u}[Y] = \bar{zv}[Y]$. Similarly, we can prove that for $0 \leq j \leq l$ and for any $C \in U$ if $z_j[C]$ is a constant, then $\bar{v}[C] = z_j[C]$. This implies $\bar{v}[Y] = \bar{zv}[Y]$.

Now assume that there is $B \in Y \cap (R_1 - V)$. Then $B \notin V$. But since $\bar{u}[Y] = \bar{v}[Y]$, $\bar{u}[B] = \bar{v}[B]$ and thus, by definition of V, $B \in V$. This is a contradiction. □

Now we prove that z is expansible in $\mathbf{r}$, that is that $\mathbf{r} \cup \{z\} \in CONS(\mathbf{R}, F)$.

LEMMA 3. (a) *z is expansible in* $\mathbf{r}$, *and* (b) $\mathbf{r} \cup \{z\} \in CONS(\mathbf{R}, F)$.

Proof. From Lemma 2, the expansion computation of $z[V]$ in $\mathbf{r}$ does not equate to a constant any unique variable on columns $R_1 - V$ of $aug_U(z[V])$. Therefore, by replacing each unique variable of $aug_U(z[V])$ on column A, $A \in R_1 - V$, with the unique constant $z[A]$, the same sequence of expansions shows that z is expansible in $\mathbf{r}$.

Part (b) follows from part (a) above and Theorem 1. □

The following lemma says that if we can apply an fd-rule to two tuples in $T^*_{\mathbf{r}}$, then the fd-rule equates only variables.

LEMMA 4. *Let $\bar{u}$, $\bar{v}$, and A be as defined above. $\bar{u}[A]$ and $\bar{v}[A]$ are variables.*

Proof. Without loss of generality, we assume that $\bar{v}[A]$ is a constant. If $\bar{u}[A]$ is a constant, then by assumption that $\bar{u}[X] = \bar{v}[X]$ and $\bar{u}[A] \neq \bar{v}[A]$, $\mathbf{r} \notin CONS(\mathbf{R}, F)$, which is a contradiction to our assumption about $\mathbf{r}$. Hence $\bar{u}[A]$ must be a variable. Let z and V be as defined above. We now show that z and $\bar{v}$ violate the fd $X \to A$. Since $A \notin V$ (because $\bar{u}[A] \neq \bar{v}[A]$), $z[A] \neq \bar{v}[A]$ and both are constants by definition of z; thus $X \to A$ is violated by these two tuples, because $z[X] = \bar{v}[X]$ by definition of z. This implies $\mathbf{r} \cup \{z\} \notin CONS(\mathbf{R}, F)$. But this is a contradiction to Lemma 3. Therefore both $\bar{v}[A]$ and $\bar{u}[A]$ must be variables. □

4.3. Proof of main lemma. We now want to prove that in any chase of $T^*_{\mathbf{r}}$ no variable is replaced by a constant, provided the database scheme is ctm. Before proving this, we need to introduce the following notation. Let T be a tableau, and let τ be the triple $< u, v, X \rightarrow A >$, where u and v are tuples defined on U and $X \rightarrow A$ is a nontrivial fd in $F^+|R_i$, for some $R_i \in \mathbf{R}$. We say that τ is an *fd-rule for* T (with respect to F) if u and v are tuples in T and $u[X] = v[X]$. If $u[A] \neq v[A]$, we say that τ is a *strict fd-rule for* T. $\tau(T)$ denotes the tableau that results by equating $u[A]$ with $v[A]$. We say that the sequence $\tau_1, \ldots, \tau_m$ of triples of the above form is a *sequence of (strict) fd-rules for* T if τ_1 is a (strict) fd-rule for T, and for $2 \leq i \leq m$, τ_i is a (strict) fd-rule for $\tau_{i-1}(\cdots(\tau_1(T))\cdots)$.

LEMMA 5. *Let* $\mathbf{R}$ *be a* ctm *database scheme with respect to* F. *Then for all* $\mathbf{r} \in CONS(\mathbf{R}, F)$, *there is no finite sequence of* fd*-rules for* $T^*_{\mathbf{r}}$ *(the expansion of* $\mathbf{r}$*) that replaces a variable in* $T^*_{\mathbf{r}}$ *by a constant from* $\mathbf{r}$.

Proof. We prove it by induction on the length, k, of any sequence of fd-rules for $T^*_{\mathbf{r}}$.

Basis. $k = 1$. By Lemma 4, there is no sequence of fd-rules for $T^*_{\mathbf{r}}$ of length at most 1 that replaces a variable of $T^*_{\mathbf{r}}$ by a constant from $\mathbf{r}$.

Induction. $k > 1$. Assume that for all $\mathbf{r} \in CONS(\mathbf{R}, F)$, there is no sequence of fd-rules for $T^*_{\mathbf{r}}$ of length at most $k = m - 1 \geq 1$ that replaces a variable of $T^*_{\mathbf{r}}$ by a constant from $\mathbf{r}$. We show the lemma holds for $k = m$. In fact, if it does not hold for $k = m$, we can construct a consistent state $\mathbf{r}_1$ that will let us show that there is a sequence of fd-rules for $T^*_{\mathbf{r}_1}$, the expansion of $\mathbf{r}_1$, of length no more than $m - 1$ that replaces a variable in $T^*_{\mathbf{r}_1}$ by a constant from $\mathbf{r}_1$, contradicting the inductive hypothesis.

Let $\mathbf{r} \in CONS(\mathbf{R}, F)$ and let $T^*_{\mathbf{r}}$ be the expansion of $\mathbf{r}$. We assume there is a sequence of fd-rules $\tau_1 =< u_1, v_1, X_1 \rightarrow A_1 >, \tau_2 =< u_2, v_2, X_2 \rightarrow A_2 >, \ldots, \tau_m =< u_m, v_m, X_m \rightarrow A_m >$, for $T^*_{\mathbf{r}}$, in which τ_m is the first fd-rule that replaces a variable in $T^*_{\mathbf{r}}$ by a constant from $\mathbf{r}$. Without loss of generality, we further assume that each fd $X_j \rightarrow A_j$ is in F, for $1 \leq j \leq m$, and $u_m[A_m]$ is a constant and $v_m[A_m]$ is a variable. By the inductive hypothesis, all of the other fd-rules equate only variables.

We now construct a state $\mathbf{r}_1$ that shows that the sequence $\tau_1 \cdots \tau_m$ does not exist. Let us consider the first fd-rule, $\tau_1 =< u_1, v_1, X_1 \rightarrow A_1 >$, and assume without loss of generality that $X_1 A_1 \subseteq R_1$, for some $R_1 \in \mathbf{R}$. Then $u_1[X_1] = v_1[X_1]$, v_1 and u_1 are both in $T^*_{\mathbf{r}}$, and we may assume $u_1[A_1] \neq v_1[A_1]$; otherwise, $\tau_2 \cdots \tau_m$ will be a sequence of fd-rules for $T^*_{\mathbf{r}}$ of length at most $m - 1$ that replaces the variable $v_m[A_m]$ with the constant $u_m[A_m]$, contradicting the inductive hypothesis. From the inductive hypothesis, $u_1[A_1]$ and $v_1[A_1]$ are variables. Let $V = \{B | B \in R_1 \text{ and } u_1[B] = v_1[B]\}$ and let z be the (total) tuple on R_1 defined as follows: $z[V] = u_1[V]$ and $z[R_1 - V]$ are all unique constants (i.e., new constants that are not in $\mathbf{r}$). Then from Lemma 3, $\mathbf{r}_1 = \mathbf{r} \cup \{z\} \in CONS(\mathbf{R}, F)$.

We now expand every tuple in $T^*_{\mathbf{r}}$ by the tuple z (and fd's in $F^+|R_1$) as much as possible and let the final result be T'. (Note that we cannot assume that $T^*_{\mathbf{r}}$ and T' are the same, because z, which contains unique constants, is not in $\mathbf{r}$, and $T^*_{\mathbf{r}}$ is the expansion with respect to only the tuples in $\mathbf{r}$.) Furthermore, let z' be the expansion of z in the state $\mathbf{r}$, and let $T_1 = T' \cup \{z'\}$. In the following, we show that T_1 is identical to $T^*_{\mathbf{r}_1}$ up to renaming of variables and that $< \tau'_2, \ldots, \tau'_m >$ is a sequence of fd-rules for T_1 (hence for $T^*_{\mathbf{r}_1}$) that equates a variable with a constant, where $\tau'_j =< u'_j, v'_j, X_j \rightarrow A_j >, u'_j \in T_1$ originates from u_j and $v'_j \in T_1$ originates from v_j, $2 \leq j \leq m$. The proofs are stated as the following claims. (See the appendix for the proofs of these claims.)

CLAIM 1. T_1 *is the expansion of* $\mathbf{r}_1$. *That is,* T_1 *is identical to the* $T^*_{\mathbf{r}_1}$ *up to the renaming of variables.*

CLAIM 2. $u_1[A_1]$ *and* $v_1[A_1]$ *are both replaced by the constant* $z[A_1]$, *that is, the effect of the first fd-rule has been enforced when computing* T_1 *from* $T^*_{\mathbf{r}}$. *(Note that this is different from saying that* $u_1[A_1]$ *and* $v_1[A_1]$ *are equated directly in the computation of* T_1 *from* $T^*_{\mathbf{r}}$. *Thus, the expansion* T_1 *contains no repeated variables still holds.)*

In the following claim, we prove that there is a sequence of fd-rules $\tau'_1 =< u'_1, v'_1, X_1 \to A_1 >, \ldots, \tau'_m =< u'_m, v'_m, X_m \to A_m >$ for T' that is "parallel" to the sequence $\tau_1, \ldots, \tau_m$ for $T^*_{\mathbf{r}}$ in the sense that u'_j and u_j come from the same tuple in $T^*_{\mathbf{r}}$ and so do v'_j and v_j. This is intuitively correct because the computation of T' from $T^*_{\mathbf{r}}$ does not make distinct any repeated occurrences of symbols; therefore we can always apply the fd's in $\tau_1, \ldots, \tau_m$ to the corresponding tuples in T'. A formal argument is given in terms of containment mappings by the following claim.

CLAIM 3. *There are mappings $\theta_0, \ldots, \theta_{m-1}$ such that for all $0 \le j \le m-1$,*

(i) *θ_j is a containment mapping from $\tau_j(\cdots(\tau_0(T^*_{\mathbf{r}}))\cdots)$ to $\tau'_j(\cdots(\tau'_0(T'))\cdots)$;*

(ii) *θ_j satisfies the condition that any variable δ is mapped to either itself or to the unique constant from $z[R_1 - V]$ that replaced δ when we computed T', where for $1 \le l \le j$, $\tau'_l =< \theta_{l-1}(u_l), \theta_{l-1}(v_l), X_l \to A_l >$, and τ_0 and τ'_0 are defined to be such that $\tau_0(T^*_{\mathbf{r}}) = T^*_{\mathbf{r}}$ and $\tau'_0(T') = T'$.*

We now complete the proof of the lemma by showing that there is a sequence of fd-rules for T' (hence for $T_1 = T^*_{\mathbf{r}_1}$) of length no more than $m-1$ that replaces a variable by a constant. Let us consider $\tau_m =< u_m, v_m, X_m \to A_m >$ and θ_{m-1} defined as above. Recall that $u_m[A_m]$ is a constant from $\mathbf{r}$ and $v_m[A_m]$ is a variable. Since θ_{m-1} is a containment mapping, we have that $\theta_{m-1}(u_m)[X_m] = \theta_{m-1}(v_m)[X_m]$, because $u_m[X_m] = v_m[X_m]$. Then from part (ii) of Claim 3, $\theta_{m-1}(v_m)[A_m]$ must be the variable $v_m[A_m]$; otherwise $\theta_{m-1}(v_m)$ and $\theta_{m-1}(u_m)$ will violate $X_m \to A_m$, which is a contradiction to $\mathbf{r}_1 \in CONS(\mathbf{R}, F)$. Therefore, applying τ'_m to $\tau'_{m-1}(\cdots(\tau'_0(T'))\cdots)$ equates the variable $v_m[A_m]$ to the constant $u_m[A_m]$, where $\tau'_m =< \theta_{m-1}(u_m), \theta_{m-1}(v_m), X_m \to A_m >$. Then, Claims 1 and 2 and the above discussion show that $\mathbf{r}_1$ is a consistent state for which $< \tau'_2, \tau'_3, \ldots, \tau'_m >$ is a sequence of fd-rules for $T^*_{\mathbf{r}_1}$ of length at most $m-1$ that equates a variable with a constant. But this is a contradiction to the inductive hypothesis of the lemma.

This completes the induction and the proof of this lemma. □

4.4. Main theorem. The following theorem follows from the way we compute $T^*_{\mathbf{r}}$, Lemma 5, and the definition of bounded schemes.

THEOREM 2. *Let $\mathbf{R}$ be a* ctm *data base scheme with respect to F. Then $\mathbf{R}$ is bounded with respect to F.*

5. Computing $[X]^F_{\mathbf{r}}$ by simple chase join expressions. We now show that the unions of simple cje's that compute the total projections of representatives instances can be constructed in exponential time in the scheme size.

We first give a lemma stating a close relationship between the sequences of fd's used in the expansion computations and derivation sequences.

LEMMA 6. *Let $\mathbf{R}$ be a database scheme, and let F be a set of functional dependencies. Let $\mathbf{r}$ be a consistent state on $\mathbf{R}$ with respect to F and let t be a total tuple on some $R_i \in \mathbf{R}$ such that t is expansible in $\mathbf{r}$ with respect to F. If some sequence of* fd'*s $< X_1 \to A_1, \ldots, X_m \to A_m >, m \ge 0$, in F strictly expands $aug_U(t)$ in an expansion computation of t in $\mathbf{r}$ and the expanded tuple has constants on $X \subseteq U$, then $< X_1 \to A_1, \ldots, X_m \to A_m >$ is a* ds *of R_i covering X.*

Proof. The lemma follows immediately from the definitions. □

Unlike independent schemes, when ctm schemes are considered, one fd may be embedded in more than one relation scheme, as illustrated by Example 1. To deal with such a multiple embedding situation, we define for any set of attributes $W \subseteq U$

$$\downarrow W \downarrow = \cup\{\pi_W(R_j) \mid R_j \in \mathbf{R}, W \subseteq R_j\}.$$

That is, $\downarrow W \downarrow$ is the relational expression that is the union of projections on $W$ of all the relation schemes that embed $W$.

In fact, Lemma 5 and the way the expansion $T^*_{\mathbf{r}}$ was computed in the last section suggest a method to extract the relational expression that computes the total projections of representative instances. Given a consistent state $\mathbf{r}$ with respect to F and a subset $X \subseteq U$, let t be a tuple in $[X]^F_{\mathbf{r}}$. From the result of the last subsection, $t = \bar{v}[X]$ for some tuple $\bar{v}$ in $T^*_{\mathbf{r}}$, where $\bar{v}$ is the expansion of some tuple v in some $r_p \in \mathbf{r}$. From Lemma 6, let $< X_1 \to A_1, \ldots, X_m \to A_m >, m \geq 0$, be the ds of R_p covering X that strictly expands $aug_U(v)$ in the expansion computation of v in $\mathbf{r}$ with respect to F. We define the expression $E = \pi_X(R_p \bowtie\downarrow X_1A_1 \downarrow\bowtie \cdots \bowtie\downarrow X_mA_m \downarrow)$. Clearly, from the way $\bar{v}$ is computed, we have $t \in E(\mathbf{r})$. By Theorem 5 in [MUV], $E(\mathbf{r}) \subseteq [X]^F_{\mathbf{r}}$. It is not difficult to see that we can transform the expression E into a union of simple cje's for the ds $< X_1 \to A_1, \ldots, X_m \to A_m >$, in which each simple cje corresponds to a choice from the relation schemes embedding the fd's in the ds.

From the above discussion, the union of all simple cje's for all ds's of R_i's covering X produces exactly the X- total projection of representative instances. Hence we have an algorithm to compute the X-total projections for consistent states of any ctm database scheme $\mathbf{R}$ with respect to a set F of embedded fd's: For each $R_i \in \mathbf{R}$ such that $R_i^+ \supseteq X$, find all nonequivalent and nonredundant ds's of R_i covering X. The ds's are of the form $< X_1 \to A_1, \ldots, X_m \to A_m >$, $m \geq 0$, where $X_j \to A_j \in F$ for all $1 \leq j \leq m$. For each of these ds's, construct the union of simple cje's E for it as above. The union of all these E's is an expression for computing the X-total projection of representative instances. The following theorem is a consequence of the above discussion.

THEOREM 3. *Let* $\mathbf{R}$ *be a* ctm *database scheme with respect to F, where F is a set of* fd*'s embedded in* $\mathbf{R}$. *Then for any* $X \subseteq U$ *and for any consistent state* $\mathbf{r}$ *of* $\mathbf{R}$, $[X]^F_{\mathbf{r}}$, *the X-total projection of the representative instance of* $\mathbf{r}$, *can be computed with a union of projections onto X of simple* cje*'s that cover X.*

By an algorithm given in [AC3], [C], we can optimize the unions of simple cje's obtained above in polynomial time of size of these expressions. The returned expression is minimal both in the number of subexpressions and in the number of join operations [AC3], [C]. However, the algorithm given above does not suggest an efficient way of doing it, since in general, there may be an exponential number of simple cje's. As shown in [AC1], [IIK], when independent schemes are considered, for each $X \subseteq U$ and each $R_j \in \mathbf{R}$ such that $R_j^+ \supseteq X$, there is just one "maximum" simple cje of R_j covering X that has to be considered. This is not true of ctm schemes because there is no such maximum simple cje, as shown below. We usually examine all simple cje's for all the combinatorics of derivations for each $R_j \in \mathbf{R}$. Let us consider the following example.

Example 2. Let $\mathbf{R} = \{R_1(ID), R_2(IC), R_3(CD)\}$ and $F = \{I \to D, I \to C, C \to I, C \to D\}$. This is a Course-Instructor-Department database scheme. It is not difficult to see that $\mathbf{R}$ is not independent with respect to F. However $\mathbf{R}$ is ctm with respect to F; Example 1 in [HC] shows this fact. To compute the CD-total projection of representative instances, for example, we need to consider the following ds's that cover CD: the empty ds $<>$ of R_3, $< C \to D >$ and $< I \to D >$ of R_2, and $< I \to C >$ of R_1. Their corresponding simple cje's are $E_1 = R_3, E_2 = \pi_{CD}(R_2 \bowtie R_3), E_3 = \pi_{CD}(R_2 \bowtie R_1)$, and $E_4 = \pi_{CD}(R_1 \bowtie R_2)$. Observe that E_2 and E_3 are incomparable[1]. In particular, let $\mathbf{r}_1$ and $\mathbf{r}_2$ be the consistent states shown in Table 1. It is easy to verify that $E_2(\mathbf{r}_1) \supset E_3(\mathbf{r}_1)$ and $E_3(\mathbf{r}_2) \supset E_2(\mathbf{r}_2)$.

[1] E and E' are incomparable if neither $E \subseteq E'$ nor $E' \subseteq E$ holds, where $E \supseteq E'(E \supset E')$ if and only if $E(\mathbf{r}) \supseteq E'(\mathbf{r})(E(\mathbf{r}) \supset E'(\mathbf{r}))$ for every consistent state $\mathbf{r}$.

TABLE 1
States for Example 2.

$\mathbf{r}_1$				$\mathbf{r}_2$			
I	C	D	Tag	I	C	D	Tag
i	c		R_2	i	c		R_2
	c	d	R_3	i		d	R_1

The reader may also note that $< C \rightarrow D >$ and $< I \rightarrow D >$ both are minimal ds's of R_2 covering CD in the terms of [C], and both are minimal derivations of CD from R_2 in terms of [IIK], and neither is "embedded" in the other.

Then from the above we get the expression

$$R_3 \cup \pi_{CD}(R_2 \bowtie R_3) \cup \pi_{CD}(R_2 \bowtie R_1) \cup \pi_{CD}(R_1 \bowtie R_2),$$

which is equivalent to $R_3 \cup \pi_{CD}(R_2 \bowtie R_1)$.

It is interesting to note that the polynomial constructions of algebra computing X-total projections for independent schemes [AC1], [IIK], [S2] follow immediately from the uniqueness property of independent schemes and our results for ctm schemes. When independent schemes are considered, the problem of combinatorics of derivations disappears because at most one ds has to be considered for each relation scheme, and each term $\downarrow X_iA_i \downarrow$ becomes $\pi_{X_iA_i}(R_{i_j})$ for the unique relation scheme R_{i_j} that embeds the fd $X_i \rightarrow A_i$.

Alternatively, to compute the total projection $[X]^F_{\mathbf{r}}$ for ctm schemes, we may first compute the expansion $T^*_{\mathbf{r}}$ of $\mathbf{r}$ using the expansion computation as a subroutine. This way we can compute total projections in linear time (in the state size) without predetermining any relational algebra expression, assuming each strict expansion is charged one unit of time. One advantage of this alternative is that the expansion $T^*_{\mathbf{r}}$, once computed, can be used for answering all queries until state $\mathbf{r}$ is updated next time, and all we have to do for each additional query is a total projection operation on $T^*_{\mathbf{r}}$. Another advantage is the uniformity of enforcing constraints and processing queries. The expansion computation is all we need for both kinds of transactions. This method is particularly meaningful when queries are more often imposed than updates and the universe of attributes is not very large.

6. Computing $[X]_{\mathbf{r}}$ with respect to egd's. In this section, we prove that if the constraints considered is a set of egd's and the database scheme has a lossless join with respect to the constraints, then the database scheme is bounded if it is ctm. The following theorem is due to Wang and Graham [W], [WG].

THEOREM 4. *Let* $\mathbf{R}$ *be a database scheme, let D be a set of* egd'*s on U such that the scheme* $\mathbf{R}$ *has a lossless join with respect to D, and let G be the embedded* fd'*s implied by D. Then* $\mathbf{R}$ *is* ctm *with respect to D if and only if the following statements hold.*

1. *G is a cover of D;*
2. $\mathbf{R}$ *is* ctm *with respect to G.*

The following is a corollary to Theorem 4 above.

THEOREM 5. *Let* $\mathbf{R}$ *be a database scheme and let D be a set of* egd'*s on U such that the scheme* $\mathbf{R}$ *has a lossless join with respect to D. If* $\mathbf{R}$ *is* ctm *with respect to D, then*

1. $\mathbf{R}$ *is bounded with respect to D;*
2. *A relational algebra expression for computing total projections of representative instances can be constructed in exponential time in the number of attributes.*

Proof. Assume $\mathbf{R}$ is a ctm database scheme with respect to D. Let G be a cover of the embedded fd's implied by D. We can find G by enumerating all fd's and selecting those logically implied by D. From part (1) of Theorem 4 and the cover-insensitive property of total projections, for every consistent state $\mathbf{r}$ with respect to D, and for every $X \subseteq U$, $[X]_{\mathbf{r}}^{D} = [X]_{\mathbf{r}}^{G}$. Then from part (2) of Theorem 4, $\mathbf{R}$ is ctm with respect to G. Thus, the method in the last section for computing $[X]_{\mathbf{r}}^{G}$ can be used to compute $[X]_{\mathbf{r}}^{D}$ as well. Then the theorem follows from the results in that section. □

A useful case to which the above results can be applied is when D is a set of fd's and the scheme $\mathbf{R}$ has a lossless join with respect to D.

7. Computing $[X]_{\mathbf{r}}$ with respect to fd's and $\bowtie$ R. When $D = F \cup \{\bowtie \mathbf{R}\}$ is given as the constraints and X is taken from a single relation scheme, our method to compute the X-total projection with respect to a set of embedded fd's F can also be used.

The following lemma is Theorem 5 in [GW] (or Thm. 5.4.1 in [WG]).

LEMMA 7. *Let* $\mathbf{R}$ *be a* ctm *database scheme with respect to* $D = F \cup \{\bowtie \mathbf{R}\}$, *where* F *is a set of* fd*'s. Let* G *be the set of* fd*'s implied by* D. *Then* $\mathbf{R}$ *cover embeds* G.

From the above lemma, we have the following result.

THEOREM 6. *Let* $\mathbf{R}$ *be a* ctm *database scheme with respect to* $D = F \cup \{\bowtie \mathbf{R}\}$, *where* F *is a set of* fd*'s. Let* G *be the set of* fd*'s implied by* D *and let* H *be an embedded cover of* G. *Then for any* $\mathbf{r} \in CONS(\mathbf{R}, D)$, *and for any* $X \subseteq R_i, R_i \in \mathbf{R}$, $[X]_{\mathbf{r}}^{D} = [X]_{\mathbf{r}}^{H}$.

Proof. By Lemma 7, $H \cup \{\bowtie \mathbf{R}\}$ is equivalent to $F \cup \{\bowtie \mathbf{R}\}$. Since the chase process is cover insensitive, we have $[X]_{\mathbf{r}}^{D} = [X]_{\mathbf{r}}^{H \cup \{\bowtie \mathbf{R}\}}$. Then by Theorem 7 in [CM2], $[X]_{\mathbf{r}}^{H} = [X]_{\mathbf{r}}^{H \cup \{\bowtie \mathbf{R}\}}$, and the theorem follows. □

Given a set of fd's G, if $\mathbf{R}$ cover embeds G, an algorithm in [GY] can find an embedded cover H of G in polynomial time. Therefore the total projection of any set of attributes $X \subseteq R_i$, $R_i \in \mathbf{R}$, for ctm schemes with respect to fd's plus the jd $\bowtie \mathbf{R}$ can be computed by our methods in §5.

8. Conclusions. We have shown that constant-time-maintainable database schemes are bounded with respect to dependencies in the following cases: (1) only cover-embedded functional dependencies appear as constraints; (2) only equality-generating dependencies appear as constraints and the database scheme has a lossless join. Interestingly, we showed that total projections can be computed via unions of projections of simple chase join expressions. Therefore by previous results in [C], we can compute optimally the total projections of the representative instances of constant-time-maintainable database schemes. We also proved that by the same method we can compute X-total projections when a set of functional dependencies and the join dependency of the database scheme are the constraints, for any X included in some relation in the database scheme.

Within the above context, our results show that fast constraint enforcement is stronger than efficient query processing in the sense that every constant-time-maintainable scheme is bounded with respect to dependencies. Our results also showed that the class of constant-time-maintainable schemes is highly desirable with respect to query processing. Therefore the class of constant-time-maintainable database schemes is the largest class of database schemes, which is highly desirable with respect to both constraint enforcement and query processing. Importantly, this class of schemes can be effectively recognized by known methods [GW], [W], [WG]. The previously known largest class of database schemes with these desirable properties is the class of independent database schemes which is a proper subclass of constant-time-maintainable schemes.

The boundedness of constant-time-maintainable schemes was proven in the absence of the essential uniqueness property [GY], [S2] of independent schemes. As a consequence, the polynomial construction of the relational expressions that compute total projections for independent schemes with only functional dependencies [AC1], [C], [IIK], [S2], [S3] follows immediately from the uniqueness property and our construction.

Our work illustrates a more general technique to prove boundedness, and it provides more insight into characterizing boundedness.

Appendix.

A. Proofs of claims in main lemma. In this section, we present the proofs of Claims 1, 2, and 3 in Lemma 5. These proofs should be read in the context of that lemma, since we are assuming all the assumptions, definitions, and notation introduced there. First, we present a claim needed in Claims 1 and 3.

CLAIM 0. *No variables are replaced by constants from $z[V]$ when computing T' from $T^*_{\mathbf{r}}$.*

Proof. Let t_1 be a tuple in $T^*_{\mathbf{r}}$. Let $\lambda_1 =< z, W_1 \rightarrow B_1 >, \ldots, \lambda_m =< z, W_m \rightarrow B_m >$ be a sequence that can strictly expand t_1 when computing T' from $T^*_{\mathbf{r}}$; observe that the fd's are from $F^+|R_1$. Since $\lambda_1, \ldots, \lambda_m$ can strictly expand t_1 and $\mathbf{r}_1 \in CONS(\mathbf{R}, F)$, $t_1[B_l]$ is a variable (because $z[B_l]$ is a constant) for $1 \leq l \leq m$.

We claim that for $1 \leq l \leq m, B_l \in R_1 - V$. Assume otherwise. That is, assume there is B_q for some $1 \leq q \leq m$ such that $B_q \in V$. Let $Y_1 = \{B | t_1[B] = z[B]\}$. Then $Y_1 \subseteq V$ since $z[R_1 - V]$ are all unique constants. Thus $t_1[Y_1] = z[Y_1] = u_1[Y_1]$. Also, notice that $B_q \notin Y_1$, because $t_1[B_q]$ is a unique variable (and $z[B_q]$ is a constant). From a property of the chase process and the fact that t_1 and z have common values exactly on Y_1, we have $Y_1 \rightarrow B_q \in F^+|R_1$. Therefore one step of chasing $T^*_{\mathbf{r}}$ by applying the fd-rule $< u_1, t_1, Y_1 \rightarrow B_q >$ to u_1 and t_1 will equate the variable $t_1[B_q]$ to the constant $u_1[B_q]$, which is a contradiction to the inductive hypothesis. Thus the claim $B_l \in R_1 - V$ for $1 \leq l \leq m$ holds, and therefore Claim 0 is proven. □

CLAIM 1. *T_1 is the expansion of $\mathbf{r}_1$. That is, T_1 is identical to $T^*_{\mathbf{r}_1}$ up to the renaming of variables.*

Proof. Assume that T_1 is not the expansion of $\mathbf{r}_1$. Then there is a tuple $t \in T_1$ and a tuple $p \in r_l$ for some $r_l \in \mathbf{r}_1$ and an fd $Y_l \rightarrow B_l \in F|R_l$ such that $< p, Y_l \rightarrow B_l >$ can strictly expand t. Then $t[B_l]$ must be a variable; otherwise, t and p violate $Y_l \rightarrow B_l$, which is a contradiction to $\mathbf{r}_1 \in CONS(\mathbf{R}, F)$. We claim that t comes from a tuple in $T^*_{\mathbf{r}}$, and p is a tuple from $\mathbf{r}$. First, notice that t cannot be the tuple z' because z' is already the expansion of z in $\mathbf{r}_1$. Then t must come from a tuple in $T^*_{\mathbf{r}}$ (that is, $t \in T'$). Therefore, p cannot be z, because at this point we already expanded every tuple from $T^*_{\mathbf{r}}$ by z as much as possible. Therefore our claim holds. Since we are expanding $t \in T'$ by p from $\mathbf{r}$, and since by Claim 0 to obtain T' from $T^*_{\mathbf{r}}$ we have just replaced some variables with unique constants that do not appear in $\mathbf{r}$, these changes certainly will not create the possibility for new strict expansions by tuples from $\mathbf{r}$. Therefore this is a contradiction. Thus Claim 1 holds. □

CLAIM 2. *$u_1[A_1]$ and $v_1[A_1]$ are both replaced by the constant $z[A_1]$, that is, the effect of the first* fd-*rule has been enforced when computing T_1 from $T^*_{\mathbf{r}}$.*

Proof. It is not difficult to see that in the above computation of T_1, $u_1[A_1]$, and $v_1[A_1]$ are both equated to $z[A_1]$ because expanding u_1 by $< z, X_1 \rightarrow A_1 >$ will set $u_1[A_1]$ to $z[A_1]$, and expanding v_1 by $< z, X_1 \rightarrow A_1 >$ will set $v_1[A_1]$ to $z[A_1]$. Therefore Claim 2 holds. □

CLAIM 3. *There are mappings $\theta_0, \ldots, \theta_{m-1}$ such that for all $0 \leq j \leq m-1$,*

1. *θ_j is a containment mapping from $\tau_j(\cdots(\tau_0(T^*_{\mathbf{r}}))\cdots)$ to $\tau'_j(\cdots(\tau'_0(T'))\cdots)$;*
2. *θ_j satisfies the condition that any variable δ is mapped to either itself or to the unique constant from $z[R_1 - V]$ that replaced δ when we computed T',*

where for $1 \le l \le j, \tau'_l = < \theta_{l-1}(u_l), \theta_{l-1}(v_l), X_l \to A_l >$, *and* τ_0 *and* τ'_0 *are defined to be such that* $\tau_0(T^*_{\mathbf{r}}) = T^*_{\mathbf{r}}$ *and* $\tau'_0(T') = T'$.

Proof. The proof is by induction on j. □

Basis. $j = 0$. Let $t_1, t_2, \ldots, t_q$ be the tuples in $T^*_{\mathbf{r}}$; for each $t_l, 1 \le l \le q$, let t'_l be the tuple in T' that comes from t_l, that is, t'_l is t_l with possibly some of its variables replaced by the unique constants from $z[R_1 - V]$ from Claim 0. Thus it should be clear that there is a containment mapping θ_0 from $T^*_{\mathbf{r}}$ to T' given by $\theta_0(t_l) = t'_l$ for $1 \le l \le q$; and θ_0 is such that any variable δ is mapped to either itself or to the unique constant from $z[R_1 - V]$ that replaced δ when we computed T'.

Induction. We now assume that our claim is true for $j = k - 1, 1 \le k \le m - 1$. We prove it for $j = k$.

First we notice that the sequence $\tau'_1, \ldots, \tau'_k$ are fd-rules for T' from the inductive hypothesis; and therefore $\theta_{k-1}(u_k)[X_k] = \theta_{k-1}(v_k)[X_k]$. Let $T^*_{k-1} = \tau_{k-1}(\cdots(\tau_0(T^*_{\mathbf{r}}))\cdots)$ and let $T'_{k-1} = \tau'_{k-1}(\cdots(\tau'_0(T'))\cdots)$. We now derive a containment mapping θ_k from θ_{k-1} and τ_k. Since $u_k[A_k]$ and $v_k[A_k]$ must be some distinct variables δ_1 and δ_2 in T^*_{k-1} (because at the beginning of the proof of Lemma 5 we have assumed that all fd-rules except τ_m equate only variables), θ_{k-1} maps each of them to either itself or to the unique constant from $z[R_1 - V]$ that replaced it when we computed T'. There are two cases to analyze depending on whether both $\theta_{k-1}(\delta_1)$ and $\theta_{k-1}(\delta_2)$ are unique constants from $z[R_1 - V]$.

Case 1. $\theta_{k-1}(\delta_1)$ and $\theta_{k-1}(\delta_2)$ are both unique constants from $z[R_1 - V]$. Then $\theta_{k-1}(\delta_1) = \theta_{k-1}(\delta_2)$, because we only introduced at most one unique constant on each column in the construction of T'. (Then τ'_k is a trivial fd-rule for T'_{k-1} that makes no change to T'_{k-1}, i.e., $T'_k = T'_{k-1}$.) Without loss of generality, we assume the application of τ_k to T^*_{k-1} replaces δ_1 with δ_2. We define θ_k to be θ_{k-1} except that θ_k does not need to be defined for δ_1.

Case 2. Either $\theta_{k-1}(\delta_1)$ or $\theta_{k-1}(\delta_2)$ (or both) are variables. Assume without loss of generality that $\theta_{k-1}(\delta_1)$ is a variable and that we apply τ_k to T^*_{k-1} by replacing δ_1 with δ_2. Then we apply τ'_k to T'_{k-1} by replacing $\theta_{k-1}(\delta_1)$ with $\theta_{k-1}(\delta_2)$ and define θ_k to be θ_{k-1} except that θ_k does not need to be defined for δ_1.

The mapping θ_k defined above satisfies the conditions required by our claim. This completes the induction and our proof of Claim 3. □

TIGHT WORST-CASE PERFORMANCE BOUNDS FOR NEXT-k-FIT BIN PACKING*

WEIZHEN MAO†

Abstract. The bin packing problem is to pack a list of reals in (0, 1] into unit-capacity bins using the minimum number of bins. Let $R[A]$ be the limiting worst value for the ratio $A(L)/L^*$ as L^* goes to ∞, where $A(L)$ denotes the number of bins used in the approximation algorithm A, and L^* denotes the minimum number of bins needed to pack L. Obviously, $R[A]$ reflects the worst-case behavior of A. For Next-k-Fit(NkF for short, $k \geq 2$), which is a linear time approximation algorithm for bin packing, it was known that $1.7 + \frac{3}{10(k-1)} \leq R[NkF] \leq 2$. In this paper, a tight bound $R[NkF] = 1.7 + \frac{3}{10(k-1)}$ is proved.

1. Introduction. Given a finite list $L = (a_1, a_2, \ldots, a_m)$ of reals in (0, 1], and a sequence of unit-capacity bins, $B_1, B_2, \ldots$, the bin packing problem is to pack the numbers in the list into the bins such that no bin contains a total exceeding 1 and that the number of bins used is minimized.

Since the bin packing is NP-complete [9], no polynomial-time algorithm has ever been developed. A lot of effort has been made to find good approximation algorithms for the problem.

In order to evaluate and compare the quality of different approximation algorithms, we need to have a rigorous mathematical analysis of the worst-case behavior of these algorithms. Given an approximation algorithm A, and for any list L, let $A(L)$ be the number of bins used in the packing resulting when A is applied to L, and L^* be the minimum number of bins needed to pack L. The *worst-case performance bound* of the approximation algorithm A is defined to be $R[A] = \limsup \max\{A(L)/L^*\}$ as $L^* \to \infty$.

Besides those well-studied approximation algorithms such as First-Fit (FF), Best-Fit (BF), First-Fit-Decreasing (FFD), Best-Fit-Decreasing (BFD), and Next-Fit (NF) [1], [5], [6], [7], [8], there is another important algorithm called Next-k-Fit (NkF), where k is an integer greater than 1. In NkF, we process the numbers in L in turn, starting from a_1, which is placed at the bottom of the first bin B_1. Suppose that a_i is now to be packed. We look at the last k nonempty bins. If a_i does not fit into any of them, a new bin is created; otherwise, a_i will go to the lowest indexed one of these k nonempty bins into which it fits. Earlier, Johnson [7] proved that $1.7 + \frac{3}{10k} \leq R[NkF] \leq 2$. In the recent paper written by Csirik and Imreh [2], a new lower bound of $R[NkF]$ was given. They showed that $R[N2F] = 2$ and $1.7 + \frac{3}{10(k-1)} \leq R[NkF] \leq 2$ for $k \geq 3$. In this paper, we study the tight worst-case performance bound for the Next-k-Fit algorithm. Our result is the following theorem.

MAIN THEOREM.

$$R[NkF] = 1.7 + \frac{3}{10(k-1)}, \quad k \geq 2.$$

In §2, we study the upper bound proving technique for NkF bin packing. In §3, we prove an important lemma. In §4, we show the proof of the main theorem.

2. The upper bound of $R[NkF]$. It is known that $R[N2F] = 2$, and $R[NkF] \geq 1.7 + \frac{3}{10(k-1)}$ for $k \geq 3$ [2]. To prove the main theorem, all we need to do is prove the upper bound result, i.e., $R[NkF] \leq 1.7 + \frac{3}{10(k-1)}$ for $k \geq 3$. We need some careful analyses and preliminary results.

In the NkF packing of any list L, there are $NkF(L)$ nonempty bins, $B_1, B_2, \ldots, B_{NkF(L)}$. For each bin B_i, its content can be divided into k areas, $A_{i,1}, A_{i,2}, \ldots, A_{i,k}$, where $A_{i,1}$ contains all the numbers coming to B_i when B_i is the rightmost, or, in other words, the most recently created nonempty bin in the current packing, and $A_{i,2}$ contains all the numbers coming to B_i when B_i becomes the second rightmost nonempty bin, etc. Finally, $A_{i,k}$ contains all the numbers coming to B_i when B_i becomes the oldest among the k active bins and is about to be thrown away. Figure 1 shows the division for $N3F$.

To prove the upper bound, we wish to show that $NkF(L) \leq (1.7 + \frac{3}{10(k-1)})L^* + c$ for all L, where c is a constant. With the help of the following weighting function $W : (0,\ 1] \rightarrow R^+$, also shown in Fig. 2, we will find the relation between $NkF(L)$ and L^*.

$$W(\alpha) = \begin{cases} \frac{6}{5}\alpha & \text{if } \alpha \in (0,\ \frac{1}{6}]; \\ \frac{9}{5}\alpha - \frac{1}{10} & \text{if } \alpha \in (\frac{1}{6},\ \frac{1}{3}]; \\ \frac{6}{5}\alpha + \frac{1}{10} & \text{if } \alpha \in (\frac{1}{3},\ \frac{1}{2}]; \\ \frac{6}{5}\alpha + \frac{2}{5} + \frac{3}{10(k-1)} & \text{if } \alpha \in (\frac{1}{2},\ 1]. \end{cases}$$

For any number a_i in L, $W(a_i)$ is called the weight of a_i. $W(B_i)$, the weight of the bin B_i, is defined to be the sum of the weight of all numbers in B_i, i.e., $W(B_i) = \sum_{\forall a_j \in B_i} W(a_j)$. And $W(L)$, the weight of the list L, is defined to be the sum of the weight of all numbers in L, i.e., $W(L) = \sum_{\forall a_j \in L} W(a_j)$. When there is no possibility of confusion, we also use B_i to denote the sum of the numbers in bin B_i, $A_{i,h}$ the sum of the numbers in area $A_{i,h}$, and b_i the bottommost item in bin B_i.

3. A lemma.

LEMMA. *In the NkF packing of L, for $j < NkF(L)$, if $B_j < \frac{5}{6}$, then there is $l > 0$ such that either* (1) $j + l \leq NkF(L)$, *and* $\frac{6}{5}B_j + W(B_{j+1}) + \cdots + W(B_{j+l}) \geq l + \frac{6}{5}B_{j+l}$, *or* (2) $j + l = NkF(L)$, *and* $\frac{6}{5}B_j + W(B_{j+1}) + \cdots + W(B_{NkF(L)}) + 2 \geq l + \frac{6}{5}B_{NkF(L)}$.

Proof. For notational simplicity, we assume $j = 1$. Because $B_1 < \frac{5}{6}$, items in $A_{2,1}$ and $A_{3,1}$ must be greater than $\frac{1}{6}$. Consider the following cases.

Case I. If $B_1 \leq \frac{1}{2}$, then B_1 must be followed by k bins with their bottommost items greater than $\frac{1}{2}$, i.e., $b_2, \ldots, b_{k+1} > \frac{1}{2}$ (Fig. 3).

$$\begin{aligned} &\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_k) + W(B_{k+1}) \\ &\geq \tfrac{6}{5}A_{1,1} + (\tfrac{6}{5}b_2 + \tfrac{2}{5} + \tfrac{3}{10(k-1)}) + \cdots + (\tfrac{6}{5}b_k + \tfrac{2}{5} + \tfrac{3}{10(k-1)}) + \tfrac{6}{5}B_{k+1} + \tfrac{2}{5} + \tfrac{3}{10(k-1)} \\ &\geq \tfrac{6}{5}(A_{1,1} + b_2) + \tfrac{6}{5}(b_3 + \cdots + b_k) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})k + \tfrac{6}{5}B_{k+1} \\ &\geq \tfrac{6}{5} \times 1 + \tfrac{6}{5} \times \tfrac{1}{2} \times (k-2) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})k + \tfrac{6}{5}B_{k+1} \\ &\geq k + \tfrac{6}{5}B_{k+1}. \end{aligned}$$

Case II. If $\frac{1}{2} < B_1 < \frac{5}{6}$, then we consider the cases in Fig. 4.

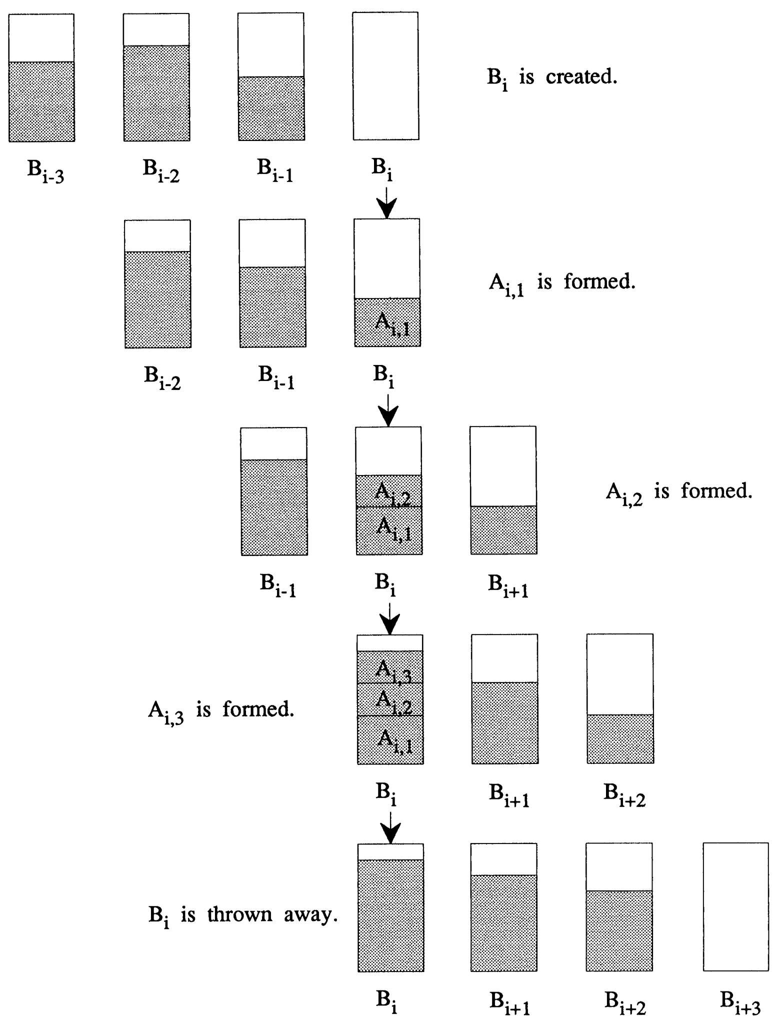

FIG. 1. *How the three areas of B_i in $N3F$ packing are formed.*

Case 1. B_2 has one item greater than $\frac{1}{2}$. We have

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2)\\
&\quad \geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{2}{5} + \tfrac{3}{10(k-1)}\\
&\quad \geq \tfrac{6}{5} \times \tfrac{1}{2} + \tfrac{2}{5} + \tfrac{6}{5}B_2\\
&\quad \geq 1 + \tfrac{6}{5}B_2.
\end{aligned}$$

Starting from now, we assume that all the items in B_2 are no greater than $\frac{1}{2}$.

Case 2. $A_{2,1} > \frac{1}{2}$. Since $A_{2,1}$ has at least two items, we assume at least one of its two bottommost items is in $(\frac{1}{6}, \frac{1}{3}]$. It is clear that B_1 is greater than $\frac{2}{3}$.

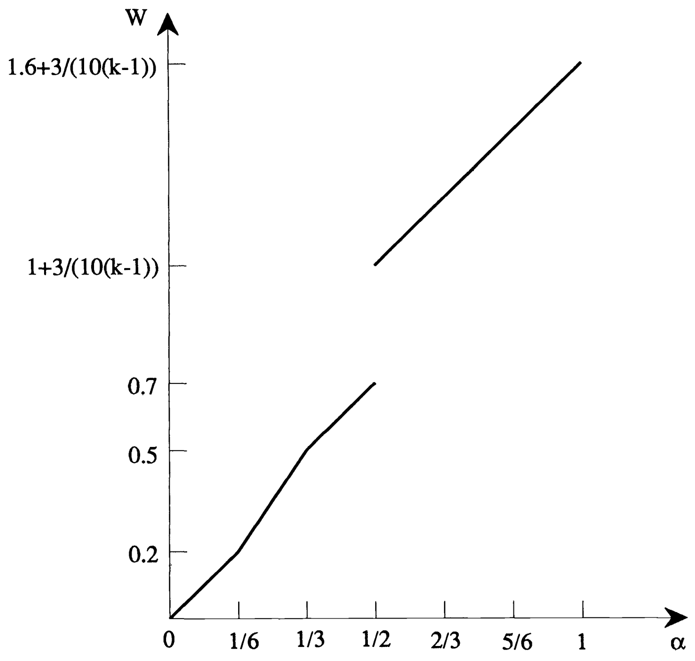

FIG. 2. *The weighting function $W(\alpha)$.*

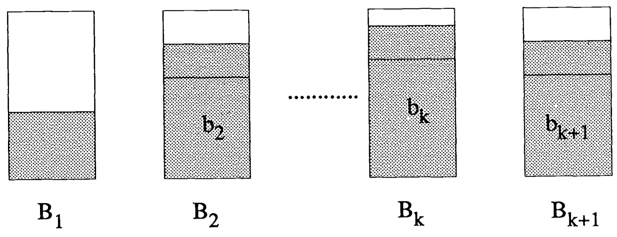

FIG. 3. *The possible packing when $B_1 \le \frac{1}{2}$.*

If the other item in $A_{2,1}$ is also in $(\frac{1}{6}, \frac{1}{3}]$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2)\\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{3}{5}(1 - B_1) - \tfrac{1}{10} + \tfrac{3}{5}(1 - B_1) - \tfrac{1}{10}\\
&\ge 1 + \tfrac{6}{5}B_2.
\end{aligned}$$

If the other item is in $(\frac{1}{3}, \frac{1}{2}]$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2)\\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{3}{5}(1 - B_1) - \tfrac{1}{10} + \tfrac{1}{10}\\
&\ge \tfrac{3}{5}B_1 + \tfrac{3}{5} + \tfrac{6}{5}B_2\\
&\ge \tfrac{3}{5} \times \tfrac{2}{3} + \tfrac{3}{5} + \tfrac{6}{5}B_2\\
&\ge 1 + \tfrac{6}{5}B_2.
\end{aligned}$$

\end{aligned}$$

If the two bottommost items of $A_{3,1}$ are in $(\frac{1}{6}, \frac{1}{3}]$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + W(B_3)\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{10} + \tfrac{1}{10} + \tfrac{6}{5}B_3 + \tfrac{3}{5}(1 - B_1) - \tfrac{1}{10} + \tfrac{3}{5}(1 - B_2) - \tfrac{1}{10}\\
&\quad\geq \tfrac{3}{5}B_1 + \tfrac{3}{5}B_2 + \tfrac{6}{5} + \tfrac{6}{5}B_3\\
&\quad\geq \tfrac{3}{5}B_1 + \tfrac{3}{5}(1 - B_1 + \tfrac{1}{3}) + \tfrac{6}{5} + \tfrac{6}{5}B_3\\
&\quad\geq 2 + \tfrac{6}{5}B_3.
\end{aligned}$$

If one of the two bottommost items is in $(\frac{1}{6}, \frac{1}{3}]$, and the other is in $(\frac{1}{3}, \frac{1}{2}]$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + W(B_3)\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{10} + \tfrac{1}{10} + \tfrac{6}{5}B_3 + \tfrac{3}{5}(1 - B_2) - \tfrac{1}{10} + \tfrac{1}{10}\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{3}{5}B_2 + \tfrac{4}{5} + \tfrac{6}{5}B_3\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{3}{5}(1 - B_1 + 1 - B_1) + \tfrac{4}{5} + \tfrac{6}{5}B_3\\
&\quad\geq 2 + \tfrac{6}{5}B_3.
\end{aligned}$$

If the two bottommost items are in $(\frac{1}{3}, \frac{1}{2}]$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + W(B_3)\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{10} + \tfrac{1}{10} + \tfrac{6}{5}B_3 + \tfrac{1}{10} + \tfrac{1}{10}\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}(1 - B_1 + \tfrac{1}{3}) + \tfrac{2}{5} + \tfrac{6}{5}B_3\\
&\quad\geq 2 + \tfrac{6}{5}B_3.
\end{aligned}$$

Case 4. $A_{2,1} > \frac{1}{2}$, with its two bottommost items in $(\frac{1}{3}, \frac{1}{2}]$, and $A_{3,1} \leq \frac{1}{2}$. In this case, we need to consider several possibilities according to the area distribution of B_3. In Fig. 5, on the right side of the vertical line are the three such possible packings that may follow the bins B_1 and B_2.

If $A_{3,1} + \cdots + A_{3,h} \leq \frac{1}{2}$, but $A_{3,1} + \cdots + A_{3,h+1} > \frac{1}{2}$, for $1 \leq h \leq k - 2$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{h+3})\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{10} + \tfrac{1}{10} + \tfrac{6}{5}B_3 + \tfrac{6}{5}(b_4 + \cdots + b_{h+2}) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})h + \tfrac{6}{5}B_{h+3}\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{5} + \tfrac{6}{5}(A_{3,1} + A_{3,h+1}) + \tfrac{6}{5} \times \tfrac{1}{2} \times (h - 1) + \tfrac{2}{5}h + \tfrac{6}{5}B_{h+3}\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{6}{5}(1 - B_1 + 1 - B_2) + h - \tfrac{2}{5} + \tfrac{6}{5}B_{h+3}\\
&\quad\geq h + 2 + \tfrac{6}{5}B_{h+3}.
\end{aligned}$$

If $A_{3,1} + \cdots + A_{3,k-1} \leq \frac{1}{2}$, but $A_{3,1} + \cdots + A_{3,k} > \frac{1}{2}$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{k+2})\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{2}{10} + \tfrac{6}{5}B_3 + \tfrac{6}{5}(b_4 + \cdots + b_{k+1}) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})(k - 1) + \tfrac{6}{5}B_{k+2}\\
&\quad\geq \tfrac{6}{5}B_1 + \tfrac{6}{5}(1 - B_1 + \tfrac{1}{3}) + \tfrac{1}{5} + \tfrac{6}{5} \times \tfrac{1}{2} + \tfrac{6}{5} \times \tfrac{1}{2} \times (k - 2) + \tfrac{2}{5}(k - 1) + \tfrac{3}{10} + \tfrac{6}{5}B_{k+2}\\
&\quad\geq k + 1 + \tfrac{6}{5}B_{k+2}.
\end{aligned}$$

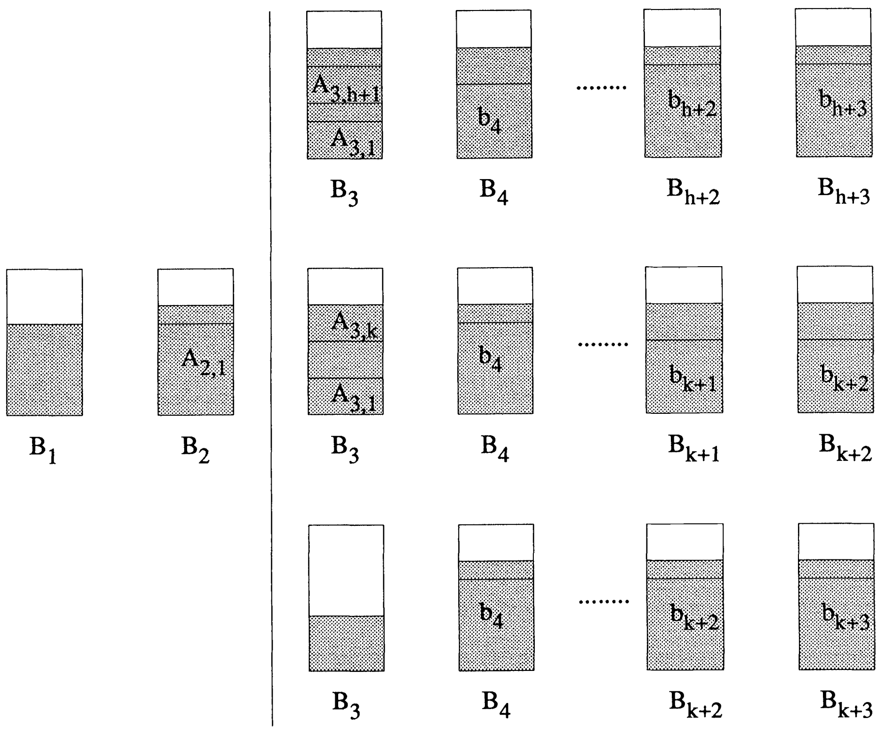

FIG. 5. *The possible packings when $A_{2,1} > \frac{1}{2}$, with its two bottommost items in $(\frac{1}{3}, \frac{1}{2}]$, and $A_{3,1} \le \frac{1}{2}$.*

If $A_{3,1} + \cdots + A_{3,k} \le \frac{1}{2}$, then

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{k+3}) \\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{1}{10} + \tfrac{1}{10} + \tfrac{6}{5}B_3 + \tfrac{6}{5}(b_4 + \cdots + b_{k+2}) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})k + \tfrac{6}{5}B_{k+3} \\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}(1 - B_1 + \tfrac{1}{3}) + \tfrac{1}{5} + \tfrac{6}{5}A_{3,1} + \tfrac{6}{5}b_4 + \tfrac{6}{5} \times \tfrac{1}{2} \times (k-2) + \tfrac{2}{5}k + \tfrac{3}{10} + \tfrac{6}{5}B_{k+3} \\
&\ge \tfrac{6}{5}(A_{3,1} + b_4) + k + \tfrac{9}{10} + \tfrac{6}{5}B_{k+3} \\
&\ge \tfrac{6}{5} \times 1 + k + \tfrac{9}{10} + \tfrac{6}{5}B_{k+3} \\
&\ge k + 2 + \tfrac{6}{5}B_{k+3}.
\end{aligned}$$

Case 5. $A_{2,1} \le \frac{1}{2}$. Let us consider the subcases in Fig. 6.

If $A_{2,1} + \cdots + A_{2,h} \le \frac{1}{2}$, but $A_{2,1} + \cdots + A_{2,h+1} > \frac{1}{2}$, where $1 \le h \le k-2$, then it is easy to prove that $W(B_2) \ge \frac{6}{5}a + \frac{2}{5}$, where a is the smallest item among $A_{2,1}, \ldots, A_{2,h+1}$. Because we know that $A_{2,1}$ and $A_{2,h+1}$ are both nonzero, so there are at least two items in these areas. Since $A_{2,1} + \cdots + A_{2,h+1} > \frac{1}{2}$, then $(A_{2,1} + \cdots + A_{2,h+1}) - a > \frac{1}{4}$. If there is one item in $A_{2,1}, \ldots, A_{2,h+1}$ in $(\frac{1}{3}, \frac{1}{2}]$, then $W(B_2) \ge \frac{6}{5}a + \frac{6}{5}((A_{2,1} + \cdots + A_{2,h+1}) - a) + \frac{1}{10} > \frac{6}{5}a + \frac{2}{5}$. Otherwise, all numbers in $A_{2,1}, \ldots, A_{2,h+1}$ are in $(\frac{1}{6}, \frac{1}{3}]$, and there are at least two of them. If there are only two numbers in $(\frac{1}{6}, \frac{1}{3}]$, then $W(B_2) \ge \frac{6}{5}a + \frac{6}{5}((A_{2,1} + \cdots + A_{2,h+1}) - a) + \frac{3}{5}(A_{2,1} + \cdots + A_{2,h+1}) - \frac{2}{10} > \frac{6}{5}a + \frac{6}{5} \times \frac{1}{4} + \frac{3}{5} \times \frac{1}{2} - \frac{2}{10} = \frac{6}{5}a + \frac{2}{5}$. If $A_{2,1}, \ldots, A_{2,h+1}$ have at least three items in $(\frac{1}{6}, \frac{1}{3}]$, then $W(B_2) \ge \frac{6}{5}a + \frac{6}{5} \times (\frac{1}{6} + \frac{1}{6}) = \frac{6}{5}a + \frac{2}{5}$. Therefore,

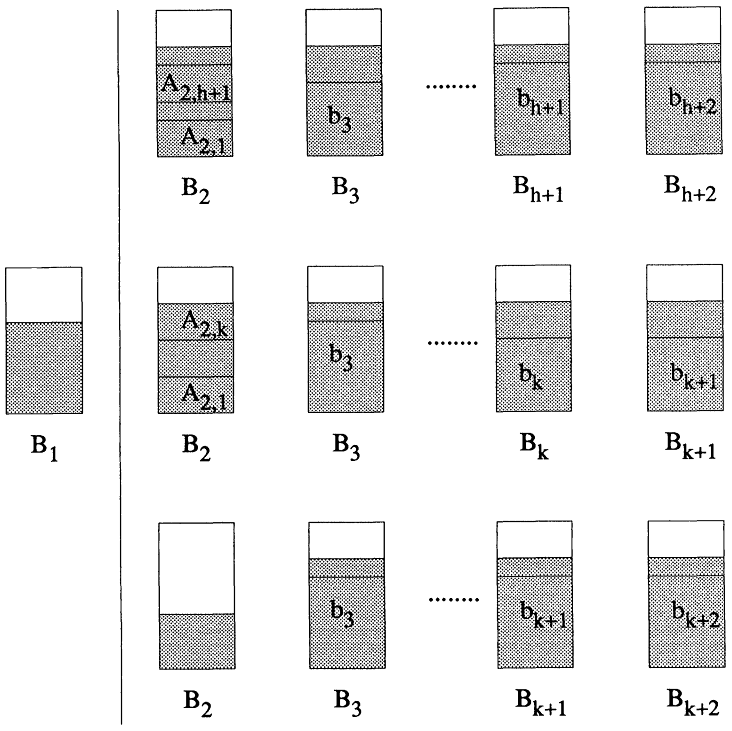

FIG. 6. *The possible packings when* $A_{2,1} \le \frac{1}{2}$.

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{h+2})\\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}a + \tfrac{2}{5} + \tfrac{6}{5}(b_3 + \cdots + b_{h+1}) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})h + \tfrac{6}{5}B_{h+2}\\
&\ge \tfrac{6}{5}(B_1 + a) + \tfrac{2}{5} + \tfrac{6}{5} \times \tfrac{1}{2} \times (h-1) + \tfrac{2}{5}h + \tfrac{6}{5}B_{h+2}\\
&\ge \tfrac{6}{5} \times 1 + \tfrac{2}{5} + \tfrac{3}{5}(h-1) + \tfrac{2}{5}h + \tfrac{6}{5}B_{h+2}\\
&\ge h + 1 + \tfrac{6}{5}B_{h+2}.
\end{aligned}$$

If $A_{2,1} + \cdots + A_{2,k-1} \le \frac{1}{2}$, but $A_{2,1} + \cdots + A_{2,k} > \frac{1}{2}$, then it is easy to prove that $W(B_2) \ge \frac{6}{5}A_{2,1} + \frac{1}{10}$. Because if $A_{2,1}$ has at least one item in $(\frac{1}{3}, \frac{1}{2}]$, then the inequality is obvious. If all the items in $A_{2,1}$ are in $(\frac{1}{6}, \frac{1}{3}]$, then there are at most two such items in $A_{2,1}$ since $A_{2,1}$ is less than $\frac{1}{2}$. So $W(B_2) \ge \frac{9}{5}A_{2,1} - \frac{1}{10} \times 2 + \frac{6}{5}(A_{2,2} + \cdots + A_{2,k}) > \frac{6}{5}A_{2,1} - \frac{1}{5} + \frac{3}{5}B_2 > \frac{6}{5}A_{2,1} - \frac{1}{5} + \frac{3}{5} \times \frac{1}{2} = \frac{6}{5}A_{2,1} + \frac{1}{10}$. Therefore,

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{k+1})\\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}A_{2,1} + \tfrac{1}{10} + \tfrac{6}{5}(b_3 + \cdots + b_k) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})(k-1) + \tfrac{6}{5}B_{k+1}\\
&\ge \tfrac{6}{5} \times \tfrac{1}{2} + \tfrac{6}{5}(A_{2,1} + b_3) + \tfrac{1}{10} + \tfrac{6}{5} \times \tfrac{1}{2} \times (k-3) + \tfrac{2}{5}(k-1) + \tfrac{3}{10} + \tfrac{6}{5}B_{k+1}\\
&\ge \tfrac{3}{5} + \tfrac{6}{5} \times 1 + \tfrac{1}{10} + \tfrac{3}{5}(k-3) + \tfrac{2}{5}(k-1) + \tfrac{3}{10} + \tfrac{6}{5}B_{k+1}\\
&\ge k + \tfrac{6}{5}B_{k+1}.
\end{aligned}$$

If $A_{2,1} + \cdots + A_{2,k} \le \frac{1}{2}$, then it is easy to prove that $W(B_2) \ge \frac{6}{5}B_2 + \frac{3}{5}A_{2,1} - \frac{1}{5}$. Because if $A_{2,1}$ has at least one item in $(\frac{1}{3}, \frac{1}{2}]$, then $W(B_2) \ge \frac{6}{5}B_2 + \frac{1}{10} = \frac{6}{5}B_2 + \frac{3}{5} \times \frac{1}{2} - \frac{1}{5} \ge \frac{6}{5}B_2 + \frac{3}{5}A_{2,1} - \frac{1}{5}$. If all the numbers in $A_{2,1}$ are in $(\frac{1}{6}, \frac{1}{3}]$, then $W(B_2) \ge \frac{9}{5}A_{2,1} - \frac{1}{10} \times 2 + \frac{6}{5}(A_{2,2} + \cdots + A_{2,k}) = \frac{6}{5}B_2 + \frac{3}{5}A_{2,1} - \frac{1}{5}$. Therefore,

$$\begin{aligned}
&\tfrac{6}{5}B_1 + W(B_2) + \cdots + W(B_{k+2}) \\
&\ge \tfrac{6}{5}B_1 + \tfrac{6}{5}B_2 + \tfrac{3}{5}A_{2,1} - \tfrac{1}{5} + \tfrac{6}{5}(b_3 + \cdots + b_{k+1}) + (\tfrac{2}{5} + \tfrac{3}{10(k-1)})k + \tfrac{6}{5}B_{k+2} \\
&\ge \tfrac{3}{5}B_1 + \tfrac{3}{5}(B_1 + A_{2,1}) - \tfrac{1}{5} + \tfrac{6}{5}(B_2 + b_3) + \tfrac{6}{5} \times \tfrac{1}{2} \times (k-2) + \tfrac{2}{5}k + \tfrac{3}{10} + \tfrac{6}{5}B_{k+2} \\
&\ge \tfrac{3}{5} \times \tfrac{1}{2} + \tfrac{3}{5} \times 1 - \tfrac{1}{5} + \tfrac{6}{5} \times 1 + \tfrac{3}{5}(k-2) + \tfrac{2}{5}k + \tfrac{3}{10} + \tfrac{6}{5}B_{k+2} \\
&\ge k + 1 + \tfrac{6}{5}B_{k+2}.
\end{aligned}$$

This ends the case analysis. If beginning with B_j (B_1 in the case analysis) there is a portion of the NkF packing which matches one of the above cases, and if we let l be the index of the last bin in that portion minus j, then $j + l \le NkF(L)$, and $\frac{6}{5}B_j + W(B_{j+1}) + \cdots + W(B_{j+l}) \ge l + \frac{6}{5}B_{j+l}$, which satisfies (1) in the Lemma. However, if the NkF packing of the list L ends without completely matching any of the above cases, i.e., $B_j, \ldots, B_{NkF(L)}$ only matches the first part of one of the cases, then we can see that no matter where the packing ends B_j is followed by $h(\ge 0)$ bins with $\frac{6}{5}B_j + W(B_{j+1}) + \cdots + W(B_{j+h}) \ge h$, then followed by $g(\ge 0)$ bins with items greater than $\frac{1}{2}$, hence each having weight greater than 1. If we let l be the index of the last bin in the packing minus j, i.e., $NkF(L) - j$, then $j + l = NkF(L)$, and $\frac{6}{5}B_j + W(B_{j+1}) + \cdots + W(B_{NkF(L)}) + 2 \ge (NkF(L) - j) + 2 \ge l + \frac{6}{5}B_{NkF(L)}$, which satisfies (2) in the Lemma.

4. Proof of the main theorem.

CLAIM 1. *For any bin B_i of items of total size 1 or less*,

$$W(B_i) \le 1.7 + \frac{3}{10(k-1)}.$$

Proof. See the proof of Lemma 1 in the work of Garey, Graham, Johnson, and Yao [4]. We note that our weighting function differs from that in the reference only by the addition of $\frac{3}{10(k-1)}$ for the items of size exceeding $\frac{1}{2}$, and there can be only one such item in B_i. So the bound in the claim exceeds the bound 1.7 in the reference by precisely this amount. □

CLAIM 2. *For any list L,*

$$W(L) \le \left(1.7 + \frac{3}{10(k-1)}\right) L^*.$$

Proof. Apply the optimal algorithm to L. We get L^* nonempty bins.

$$\begin{aligned}
W(L) &= \textstyle\sum_{i=1}^{L^*} W(B_i) \\
&\le \textstyle\sum_{i=1}^{L^*} (1.7 + \frac{3}{10(k-1)}) \qquad \text{(by Claim 1)} \\
&= (1.7 + \tfrac{3}{10(k-1)})L^*.
\end{aligned}$$
□

CLAIM 3. *For any list L, there exists a constant c such that*

$$W(L) + c \ge NkF(L).$$

Proof. Let j be the largest index of the bins in the NkF packing such that $\sum_{i=1}^{j} W(B_i) \geq j - 1 + \frac{6}{5}B_j$. Such j always exists.

If $j = NkF(L)$, then $W(L) = \sum_{i=1}^{j} W(B_i) \geq j - 1 + \frac{6}{5}B_j \geq NkF(L) - 1$. So $W(L) + 1 \geq NkF(L)$. Now assume $j < NkF(L)$. Let us consider B_j.

If $B_j \geq \frac{5}{6}$, then $\sum_{i=1}^{j} W(B_i) + W(B_{j+1}) \geq j - 1 + \frac{6}{5}B_j + \frac{6}{5}B_{j+1} \geq j + \frac{6}{5}B_{j+1}$. There exists $j + 1$, such that $\sum_{i=1}^{j+1} W(B_i) \geq j + \frac{6}{5}B_{j+1}$. This is a contradiction to the assumption that j is the largest index having the property. So the case of $B_j \geq \frac{5}{6}$ can never happen.

If $B_j < \frac{5}{6}$, and (1) in Lemma happens, then $\sum_{i=1}^{j} W(B_i) + W(B_{j+1}) + \cdots + W(B_{j+l}) \geq j - 1 + \frac{6}{5}B_j + l + \frac{6}{5}B_{j+l} - \frac{6}{5}B_j$. Therefore, $\sum_{i=1}^{j+l} W(B_i) \geq j + l - 1 + \frac{6}{5}B_{j+l}$. This is again a contradiction to the assumption that j is the largest index. So (1) in Lemma can never happen.

If $B_j < \frac{5}{6}$, and (2) in Lemma happens, then we have $\sum_{i=1}^{j} W(B_i) + W(B_{j+1}) + \cdots + W(B_{NkF(L)}) + 2 \geq j - 1 + \frac{6}{5}B_j + NkF(L) - j + \frac{6}{5}B_{NkF(L)} - \frac{6}{5}B_j$. So $W(L) + 3 \geq NkF(L)$. $\square$

Now we are prepared to prove Main Theorem.

Proof of Main Theorem.

$$\begin{aligned} R[NkF] &= \limsup \max\{NkF(L)/L^*\} \\ &\leq \lim_{L^* \to \infty}(W(L) + c)/L^* \quad \text{(by Claim 3)} \\ &\leq \lim_{L^* \to \infty}((1.7 + \tfrac{3}{10(k-1)})L^* + c)/L^* \quad \text{(by Claim 2)} \\ &= 1.7 + \tfrac{3}{10(k-1)}. \end{aligned}$$

Combining with the previous results $R[N2F] = 2$ and $R[NkF] \geq 1.7 + \frac{3}{10(k-1)}$, we have $R[NkF] = 1.7 + \frac{3}{10(k-1)}$ for $k \geq 2$.

Acknowledgment. The author wishes to thank Professor Andrew C. Yao, without whose valuable advice, constructive comments, and enthusiastic encouragement the work of this paper could never have been accomplished. And also, many thanks go to Dr. David S. Johnson, who read the first version of the paper carefully, pointed out one mistake in the proof of the lemma, and suggested the current proving style, which significantly simplifies the entire proof.

A NOTE ON THE COMPLEXITY OF A SIMPLE TRANSPORTATION PROBLEM*

GREG N. FREDERICKSON†

Abstract. Consider the problem of using a vehicle to transport k objects one at a time between s stations on a circular track. Let the cost of the transportation be the total distance traveled by the vehicle on the track. An $O(k+M(s,q))$ time algorithm is presented to find a minimum cost transportation, where $M(m,n)$ is the time to solve a minimum spanning tree problem on a graph with m edges and n vertices, and $q \leq \min\{k,s\}$ is the number of strongly connected components in an associated balanced problem. Also, the minimum spanning tree problem on a graph with m edges and n vertices is reduced to a transportation problem on a linear track with $O(m)$ stations, $O(m)$ objects, and $O(n)$ strongly connected components in $O(m)$ time.

Key words. transportation problems, robot arm motion, circular track, graph augmentation

AMS(MOS) subject classification. 68Q25

1. Introduction. Consider an undirected weighted graph with objects located at various vertices. Associated with each object is a destination vertex, to which that object is to be moved by a vehicle that traverses the edges of the graph. A fundamental problem in motion planning is to determine a minimum cost tour of the vehicle that transports all objects from their initial positions to their destinations. In the case of general graphs, the problem is NP-hard, even if the vehicle can transport only one object at a time [FHK]. Recently, attention has focused on solving this motion planning problem on very simple classes of graphs with unit capacity vehicles. Such examples have potential applications in robotics. Atallah and Kosaraju consider graphs that are simple paths and simple cycles [AK]. Frederickson and Guan consider graphs that are trees [FG1], [FG2], [FG3]. These papers distinguish between two cases, based on whether or not drops are allowed in the transportation. A *drop* is an unloading of an object at a vertex that is not its destination. If an object is dropped, its move is not immediately completed, and the object must be picked up and transported farther at some later time in the transportation.

In this note we tighten the bound of [AK] for the case of simple cycles with no drops. Whereas all possible solutions are considered in a divide-and-conquer search that is used in [AK], we quickly prune away all but a constant number of possible solutions. We also show that the asymptotic complexity of the transportation problem with no drops for either a simple path or a simple cycle is essentially the same as that of the minimum spanning tree problem (on a general graph).

For simplicity, we shall use much of the notation in [AK]. In particular, we shall refer to the underlying graph as a track, and the vertices in the graph as stations. Let k be the number of objects; s, the number of stations; and q, the number of strongly connected components once additional moves are added to yield a certain "balanced" problem. Let $M(m,n)$ be the time to solve the minimum spanning tree problem on a graph with n vertices and m edges. (Currently, the fastest known algorithm in a standard comparison-based model for finding the minimum spanning tree problem is given in [GGST], providing an upper bound on $M(m,n)$ of $O(m \log \beta(m,n))$, where $\beta(\cdot,\cdot)$ is a slowly growing function similar to the $\log^*(\cdot)$ function. In the trans-dichotomous model of Fredman and Willard, an upper bound of $O(m)$ is achieved for $M(m,n)$ in [FW].) For the case in which drops are allowed, an $O(k+s)$ time algorithm is given in [AK] for the

†Department of Computer Sciences, Purdue University, West Lafayette, Indiana 47907.

circular track and hence the linear track. For the case in which no drops are allowed, an $O(k + s \log s)$ time algorithm is given in [AK] for a circular track and an $O(k + M(s, q))$ time algorithm for a linear track (where the time is as indicated in the note added in proof in [AK]).

We make several observations about the structure of the transportation problem on a circular track with no drops that allows us to generate an $O(k + M(s, q))$ time algorithm. We also provide a simple argument that solving a transportation problem on a linear track where $k = s$ is in general no easier than solving a minimum spanning tree problem on q vertices and s edges. Thus in the sense of asymptotic complexity, the circular track problem with no drops is no harder than the linear track problem with no drops. Thus for both the case of drops and the case of no drops, restricting the graph from a circular track to a linear track will make the problem no easier.

2. A faster algorithm. In this section we derive several observations that lead to a faster algorithm. We first recall some definitions from [AK]. Let the stations be indexed from 1 to s, and the edge between stations i and $i + 1$ be denoted as interval $(i, i + 1)$. Assume that each object moves in the shorter of the two directions for it, either clockwise or counterclockwise around the cycle. Let $\phi(i)$ be the *input flux* across interval $(i, i + 1)$, defined as the number of clockwise moves in the input minus the number of counterclockwise moves in the input across interval $(i, i + 1)$.

Recall from [AK] that in any transportation, the number of clockwise moves across an interval minus the number of counterclockwise moves across an interval will be the same for all intervals. More generally, for any set of moves in which the difference across every interval is the same, this common difference is called the *flux*. By adding moves in which the vehicle carries no object, any particular value of flux can be achieved. Let ψ be the value of the flux for some set of moves. Let l_i be the length of interval $(i, i + 1)$. Let $db(\psi)$ be the cost of a minimum cost set of augmenting moves that yield a flux of ψ. The function $db(\cdot)$ represents the cost to achieve degree balance between incoming and outgoing moves at each station. Then $db(\psi) = \sum_{i=1}^{n} |(\psi - \phi(i))|\, l_i$. Note that adding moves with the "empty object" to achieve degree balance may result in more than one strongly connected component, where each component is Eulerian, and each is isolated from the others. Among all minimum-cost sets of augmenting moves that yield a flux of ψ, let q_ψ be the minimum number of strongly connected components that result from any of these augmentations. There is a minimum-cost set of augmenting moves that achieves flux ψ, creates q_ψ strongly connected components, and is of cardinality $O(k + s)$, and such a set can be found in $O(k + s)$ time. Besides the augmenting moves that achieve a particular flux, additional moves with no object are in general necessary to achieve connectivity among the components. With these additional moves a transportation can then be constructed.

We introduce some additional notation. Let c_ψ be the total length of intervals with $\phi(i) = \psi$. Then $c_\psi = \sum_{\phi(i)=\psi} l_i$. Note that $c_\psi \geq 0$ for all ψ. Let $tc(\psi)$ be the cost of a minimum cost set of augmenting moves that yield a transportation with flux ψ. The function $tc(\cdot)$ represents the *total cost* to achieve both degree balance and connectivity. Let γ be the largest value of flux for which a set of augmenting moves of overall minimum cost achieves degree balance. We note some simple relationships among these quantities in the following lemmas.

LEMMA 1. *For all values ψ of flux, $tc(\psi) \leq db(\psi) + 2c_\psi$, which holds with strict inequality if $db(\psi) < tc(\psi)$.*

Proof. The addition of the augmenting moves that achieve degree balance will leave one or more strongly connected components. If there is more than one such component, then the components are separated by intervals $(i, i+1)$ with $\phi(i) = \psi$. Adding a move in each direction across all but one such interval will yield one strongly connected component. □

LEMMA 2. *For all values ψ of flux, $db(\psi) = db(\psi - 1) - \sum_{j>\psi-1} c_j + \sum_{j\leq\psi-1} c_j$.*

Proof. Given a set of moves that achieve degree balance for flux $\psi - 1$, one can generate a set of moves that achieve degree balance for flux ψ by removing an augmenting move from each interval i for which $\phi(i) > \psi - 1$ and by adding an augmenting move for each interval i for which $\phi(i) \leq \psi - 1$. □

LEMMA 3. *The value γ satisfies the following*:

(i) $\sum_{j>\gamma-1} c_j \geq \sum_{j\leq\gamma-1} c_j$;

(ii) $\sum_{j\leq\gamma} c_j > \sum_{j>\gamma} c_j$.

Proof. Part (i) follows directly from Lemma 2 and the definition of γ. Part (ii) follows by combining the definition of γ with

$$db(\gamma + 1) = db(\gamma) - \sum_{j>\gamma} c_j + \sum_{j\leq\gamma} c_j,$$

which is obtained from Lemma 2. □

Next we note that $db(\psi)$ is a concave (upwards) function of ψ.

LEMMA 4. *The function $db(\cdot)$ is concave.*

Proof. A simple proof by induction on n establishes that functions of the form $\sum_{i=1}^{n} |a_i x - b_i|$ are concave. Note that $db(\cdot)$ is of this form. □

Let δ be the largest value of flux for which a minimum cost transportation is achieved. Then $tc(\delta) = \min_\psi\{tc(\psi)\}$. We next show that at most three values of ψ need to be considered.

LEMMA 5. *A value of ψ in the range $\gamma - 1 \leq \psi \leq \gamma + 1$ achieves the minimum value of $tc(\cdot)$.*

Proof. Suppose $\delta \geq \gamma + 2$. Then

$$\begin{aligned} db(\delta) &\leq tc(\delta - 1), \\ &\leq db(\delta - 1) + 2c_{\delta-1} \text{ (by Lemma 1)} \\ &= db(\delta) + \sum_{j>\delta-1} c_j - \sum_{j\leq\delta-1} c_j + 2c_{\delta-1} \\ &= db(\delta) + \left(\sum_{j>\gamma} c_j - \sum_{j\leq\gamma} c_j\right) - 2\sum_{j=\gamma+1}^{\delta-2} c_j. \end{aligned}$$

By the nonnegativity of c_ψ, $c_j \geq 0$ for $\gamma+1 \leq j \leq \delta-2$. But then $\sum_{j\leq\gamma} c_j - \sum_{j>\gamma} c_j \leq 0$, which contradicts Lemma 3(ii). Thus $\delta < \gamma + 2$.

Suppose $\delta \leq \gamma - 2$ and $db(\delta + 1) = tc(\delta + 1)$. Then by Lemma 4

$$db(\delta) \geq db(\delta + 1) = tc(\delta + 1).$$

Thus the cost of a solution with flux $\delta + 1$ is always at least as good as a solution with flux δ, a contradiction to the choice of δ.

Suppose $\delta \leq \gamma - 2$ and $db(\delta+1) < tc(\delta+1)$. Then

$$\begin{aligned} db(\delta) &\leq tc(\delta+1), \\ &< db(\delta+1) + 2c_{\delta+1} \text{ (by Lemma 1)} \\ &= db(\delta) - \sum_{j>\delta} c_j + \sum_{j\leq\delta} c_j + 2c_{\delta+1} \\ &= db(\delta) + \left(\sum_{j\leq\gamma-1} c_j - \sum_{j>\gamma-1} c_j\right) - 2\sum_{j=\delta+2}^{\gamma-1} c_j. \end{aligned}$$

By the nonnegativity of c_ψ, $c_j \geq 0$ for $\delta+2 \leq j \leq \gamma-1$. But then $\sum_{j\leq\gamma-1} c_j - \sum_{j>\gamma-1} c_j > 0$, which contradicts Lemma 3(i). From this and the preceding case, we may conclude that $\delta > \gamma - 2$.

Thus the above cases rule out all values ψ of flux except those in the range $\gamma - 1 \leq \psi \leq \gamma + 1$. □

The algorithm to solve the transportation problem is the following. First, compute the values of $db(\psi)$ for values of ψ from $-k$ to k, as discussed in [AK]. Next perform a scan of the values $db(\psi)$ to identify γ. Then for each of the values $\gamma-1$, γ, $\gamma+1$ of flux, solve the associated minimum spanning tree problem, using the fastest currently known algorithm. Choose from among the three transportations the solution that is of smallest total cost. Let q be $\max\{q_{\gamma-1}, q_\gamma, q_{\gamma+1}\}$.

THEOREM 1. *The time to solve a transportation problem with no drops on a graph that is a simple cycle is $O(k + M(s,q))$, where k is the number of objects, s is the number of stations, q is the maximum of number of strongly connected components in three related balanced problems, and $M(m,n)$ is the time to solve the minimum spanning tree problem on a graph with n vertices and m edges.*

Proof. By the discussion in [AK], the time to find γ is $O(k)$. The three minimum spanning tree problems can each be set up in $O(s)$ time. Since $M(s,\cdot)$ is $\Omega(s)$, the result follows. □

3. A reduction from the minimum spanning tree problem. We show how to reduce the minimum spanning tree problem to a transportation problem with no drops on a linear track. Recall from [AK] that the degree balanced version of the problem is one in which a minimum cost set of balancing moves has been added so that for any interval $(i, i+1)$ on the track, the number of moves across the interval in the clockwise direction equals the number of moves across the interval in the counterclockwise direction. Let k be the number of moves and s the number of stations. Among all such minimum-cost sets of augmenting moves, let q be the minimum number of strongly connected components that result from any of these augmentations. There is a minimum-cost set of augmenting moves that creates q strongly connected components and is of cardinality $O(k+s)$, and such a set can be found in $O(k+s)$ time.

THEOREM 2. *Let $R(k,s,q)$ be the time to solve a transportation problem with no drops on a linear track of s stations, with k moves and q components in the balanced problem. The time to find a minimum spanning tree in a graph of m edges and n vertices is $O(R(m,m,n))$.*

Proof. Let $G = (V,E)$ be a connected weighted undirected graph with m edges and $n > 3$ vertices. Without loss of generality, assume all edge weights are positive. Let W

be the largest of the edge weights. Compute the degree of every vertex. For any vertex of degree less than 3, add edges of cost $W+1$ to G to make every vertex be of degree at least 3. Once these edges have been added, if not all vertices are of even degree, introduce a new vertex with edges of cost $W+1$ to each vertex of odd degree. The resulting graph G' will have n' vertices, $n \leq n' \leq n+1$, and m' edges, $m \leq m' \leq m+3n$, and the degree of each vertex will be even and at least 4. By the choice of the cost of new edges, a minimum spanning tree of G' will be a minimum spanning tree of G, plus some edge to the new vertex if a new vertex was introduced. Given graph G', find an Euler tour of G', starting at any vertex. We denote the tour by the sequence of vertices and edges v_0, $e_1, v_1, e_2, v_2, \ldots, v'_m, e'_m, v_0$.

Given the Euler tour, we generate an instance P of a transportation problem on a linear track as follows. There will be $m'+1$ stations, one for each visit of a vertex in the Euler tour. The edge from the jth to the $(j+1)$st station will correspond to the $(j+1)$st edge in the Euler tour and thus be of cost $c(e_{j+1})$. There will be one object originating at each station. The destinations of the objects are determined as follows. Consider the rth station, and suppose it corresponds to a visit to vertex v in the Euler tour. Let the r'th station correspond to the next visit to vertex v in the Euler tour. (If there is no next visit to v, let the r'th station correspond to the first visit to v.) Then the destination of the object at station r is station r'. Since the degree of each vertex in G' is at least 4, every object will have a destination different from its originating station.

It is clear from the construction that for any vertex in G' the set of arcs in P form a cycle. It follows that there are n' strongly connected components in P. For each edge (v, w) in G' there is an edge of the same cost in the track from a station in the cycle of stations corresponding to v to a station in the cycle of stations corresponding to w.

Consider an optimal transportation Q for P. Consider the set of edges traversed by Q when no object is being carried. Any edge traversed in one direction is traversed in the other direction. The number of such edges is $n'-1$, and these edges correspond to a minimum spanning tree of G'. Thus we can solve a minimum spanning tree problem by generating an instance P, finding an optimal transportation Q for P, and extracting the edges of the minimum spanning tree from Q. Clearly, all steps other than that of finding the transportation will take $O(m')$ time. Thus the minimum spanning tree problem in G' can be solved in time $O(m' + R(m'+1, m'+1, n'))$. Assuming the monotonicity of $R(\cdot,\cdot,\cdot)$, and noting that $R(m,\cdot,\cdot)$ is $\Omega(m)$, this is $O(R(m,m,n))$. □

A LOWER BOUND ON THE SIZE OF SHELLSORT SORTING NETWORKS*

ROBERT CYPHER†

Abstract. Shellsort is a sorting algorithm that is based on a set of parameters called *increments*. Shellsort has been used both as a sequential sorting algorithm and as a sorting network. The central result of this paper is that all Shellsort sorting networks based on monotonically decreasing increments require $\Omega(N \log^2 N/ \log \log N)$ comparators. Previously, only the trivial $\Omega(N \log N)$ bound was known for this class of networks. The lower bound obtained in this paper nearly matches the upper bound of $O(N \log^2 N)$ that was proven by Pratt.

1. Introduction. Shellsort is a sorting algorithm that was first proposed by D. L. Shell in 1959 [11]. Shellsort is based on a sequence of integers $Z = z_k, z_{k-1}, \cdots, z_1$ that is called an *increment sequence*. Different increment sequences yield sorting algorithms with different complexities, so a great deal of effort has been devoted to finding the best increment sequence possible.

Given an array of items $A = A[1], A[2], \cdots, A[N]$ and an increment sequence $Z = z_k, z_{k-1}, \cdots, z_1$, Shellsort sorts the array A by performing z_j-sorts for $j = k, k-1, \cdots, 1$. A z_j-sort consists of partitioning the locations in the array A into equivalence classes modulo z_j and sorting the data in each equivalence class. Therefore, following the z_j-sort, for all i where $z_j < i \leq N$, $A[i] \geq A[i - z_j]$. It is required that $z_1 = 1$, so the z_1-sort completely sorts the file. In general, the increment sequence used for sorting N items can depend on N. However, one common technique is to define a single infinite sequence and to use, in decreasing order, those elements in this sequence that are less than N. Increment sequences that are created in this manner are said to be *uniform*.

The z_j-sorts are implemented by using *insertion sort* [5]. Insertion sort sorts a set of items by processing the items from left to right. Each item w is processed by comparing it to the items to its left until an item v is found that is smaller than w (or the list of items to the left of w has been exhausted). Item w is then inserted immediately to the right of v, and the items that were between v and w are moved one position to the right. Thus for any item w, if there are c items to the left of w that are larger than w, then $c + 1$ comparisons are required. Although insertion sort is an inefficient sorting algorithm (it requires $\Theta(N^2)$ time to sort N items in the worst case), it is used because it performs well when the data are nearly sorted. It is hoped that the z_j-sorts will be efficient because the sorts performed by the earlier increments will have left each item near its correct, sorted position.

Shellsort has been studied both as a sequential sorting algorithm and as a technique for creating sorting networks. A *sorting network* is a collection of comparators that are wired together in such a way that when a set of items is placed on the input wires, the items appear in sorted order on the output wires. A *comparator* is a device that takes two inputs and produces two outputs; the smaller input is placed on the first output and the larger input is placed on the second output. Shellsort can be used to create a sorting network by implementing each of the insertion sorts with a sorting network [5]. An example of a sorting network that performs an insertion sort is given in Fig. 1.

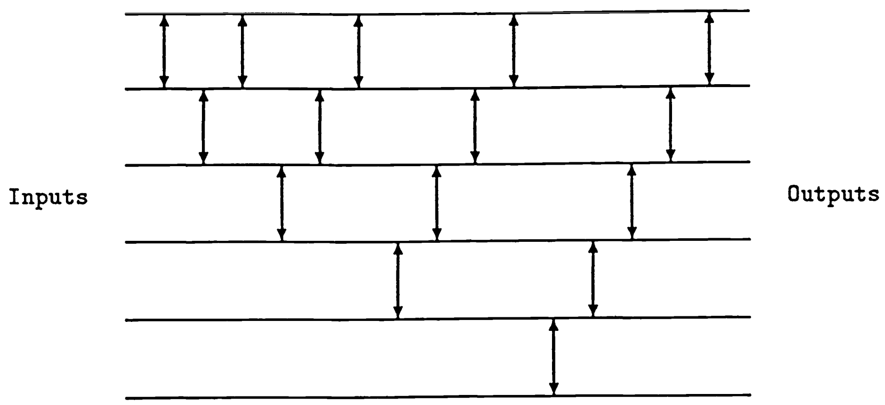

FIG. 1. *Insertion sort network. Horizontal lines represent wires, and vertical lines represent comparators. Each comparator places the smaller of its inputs on its upper output wire and the larger of its inputs on the lower output wire.*

The *size* of a sorting network is the number of comparators that it contains, and the *depth* of a sorting network is the maximum number of comparators through which an item may pass. Sorting networks are important because their nonadaptive nature allows them to be implemented directly in hardware and also because of a result due to Leighton [7]. Leighton has shown that any small-depth sorting network can be used to create a fast sorting algorithm for a bounded-degree parallel computer.

An $O(\log N)$-depth sorting network was created by Ajtai, Komlós, and Szemerédi [1]. Their sorting network is very complex, and it has an extremely large constant of proportionality associated with the $O(\log N)$ depth. A number of researchers have suggested that Shellsort might provide a simple $O(\log N)$-depth sorting network that would be practical for realistic values of N [4], [10]. This paper proves that a fundamentally new type of increment sequence will be needed if this goal is to be attained.

Two well-known results are helpful in understanding the behavior of Shellsort. First, Knuth proved that if an array is u-sorted and then it is v-sorted, it will remain u-sorted [2]. Second, from transitivity it follows that if an array is both u-sorted and v-sorted, then it is also $(u+v)$-sorted [9]. These two results suggest the use of a data structure that Pratt calls a *template* [9]. A template is a set of natural numbers that contains 0 and is closed under addition. Let $Z = z_k, z_{k-1}, \cdots, z_1$ be a sequence of increments, and let Y be the smallest template containing Z. If an array has been z_j-sorted for all j, $k \geq j \geq 1$, then it follows from the two results given above that the array is also y-sorted for each $y \in Y$. Thus templates provide a means of keeping track of all of the properties implied by the above results. Templates have been used to obtain upper bounds on the time requirements of Shellsort algorithms and on the size and depth of Shellsort sorting networks. This paper shows that templates can also be used to obtain lower bounds on the size of Shellsort sorting networks.

Shell used the increments $\lfloor N/2 \rfloor, \lfloor N/4 \rfloor, \lfloor N/8 \rfloor, \cdots, 1$. However, when N is a power of 2 this sequence requires $\Theta(N^2)$ comparisons. Modifications to Shell's increment sequence were suggested by Lazarus and Frank [6], Hibbard [3], and Knuth [5]. Papernov and Stasevich showed that Hibbard's increment sequence yields a sequential algorithm that runs in $O(N^{3/2})$ time [8]. All of the above modifications to Shell's increment sequence have the property that they are within an additive constant of a geometric sequence. Pratt proved that a large class of such nearly geometric sequences result in $\Theta(N^{3/2})$-time sequential algorithms [9]. Pratt also proposed using the uniform increment sequence consisting of all numbers of the form 2^i3^j, where i and j are integers, and he showed that these increments yield a sorting network with size $O(N \log^2 N)$ and depth $O(\log^2 N)$ [9].

Sedgewick then proposed a uniform increment sequence that yields an $O(N^{4/3})$-time sequential algorithm [10]. Although this is greater than the $O(N \log^2 N)$ sequential time required by Pratt's sequence, Sedgewick's sequence has $O(\log N)$ increments, whereas Pratt's sequence has $\Theta(\log^2 N)$ increments. The restriction to using $O(\log N)$ increments is required if an $O(N \log N)$-time algorithm is to be obtained. Incerpi then developed a uniform increment sequence with $O(\log N)$ increments that required $O\left(N^{1+\epsilon/\sqrt{\log N}}\right)$ comparisons for any $\epsilon > 0$ [4]. Finally, Weiss and Sedgewick proved that Sedgewick's sequence does require $\Omega(N^{4/3})$ comparisons in the worst case [12], [13]. In addition, Weiss and Sedgewick made a conjecture that, if true, would imply that $\Omega\left(N^{1+\epsilon/\sqrt{\log N}}\right)$ time is required by Incerpi's sequence and by any sequence $Z = z_k, z_{k-1}, \cdots, z_1$ for which $z_j = \Theta(\alpha^j)$ for some $\alpha > 1$ [12], [13].

All of the increment sequences mentioned above are monotonically decreasing. In fact, Knuth has called Shellsort the "diminishing-increment sort" [5]. Monotonically decreasing increments are natural because they sort larger sets of data as the data become increasingly ordered. Monotonically decreasing increments thus provide a smooth transition from sorting small, very unordered sets to sorting large, very ordered sets. However, this paper shows that all Shellsort sorting networks with monotonically decreasing increments are of size $\Omega(N \log^2 N / \log\log N)$. Previously, only the trivial $\Omega(N \log N)$ lower bound was known for this class of increment sequences.

Also, although the results presented here are for Shellsort sorting networks, they do provide some insight into the sequential Shellsort algorithm. In particular, many proofs of upper bounds on the sequential running time of Shellsort use templates to bound the time requirements of the insertion sorts. Such proofs ignore the adaptive nature of the sequential algorithm, so they actually imply an identical upper bound on the number of comparators in the corresponding Shellsort sorting network. Given the results of this paper, it is clear that such a proof will yield an upper bound that is $\Omega(N \log^2 N / \log\log N)$ if monotonically decreasing increments are chosen. It should be noted, however, that the $\Omega(N \log^2 N / \log\log N)$ bound applies only to the upper bound created by such a proof technique and not to the actual running time of the sequential algorithm.

This paper is organized as follows. Section 2 contains definitions and notation that are used throughout the paper, and §3 proves a connection between template costs (defined in §2) and the number of comparators that a sorting network must have. In §4, the relationship between the cost of an increment and the number of items that it adds to a template is established. Section 5 proves a lower bound on the number of elements missing from a template, §6 proves a lower bound on the total template costs of any Shellsort algorithm with monotonically decreasing increments, and §7 gives a lower bound on the number of comparators required when monotonically decreasing increments are used. Some conclusions and open problems are presented in §8.

2. Definitions and notation. The expression $\log N$ will be used to indicate $\log_2 N$. The set of nonnegative integers will be denoted by I. An *I-set* is any subset of I. Uppercase letters will be used to name I-sets, and lowercase letters will be used for arbitrary members of I-sets. An uppercase letter with the subscript $[i]$, where $i \geq 1$, will be used to indicate the ith smallest member of an I-set. For example, if Z is an I-set, then $Z_{[1]}$ is the smallest member of Z. Given a nonempty I-set Z, $\text{Min}(Z) = Z_{[1]}$, and if Z is finite, $\text{Max}(Z) = Z_{[|Z|]}$. Given an I-set Z, the *complement* of Z, written $\overline{Z}$, is $I - Z$. Given an I-set Z, a positive integer u, and an integer v, $\text{Slice}(Z, u, v) = \{z \in Z \mid z \equiv v \pmod{u}\}$.

An I-set Y is a *template* if it contains 0, it is closed under addition, and $\overline{Y}$ is finite. Given a template Y, a positive integer u, and an integer v, $\text{Lack}(Y, u, v) = |\text{Slice}(\overline{Y}, u, v)|$. The *cost of increment u with respect to template* Y, written $\text{Cost}(Y, u)$, is $\text{Lack}(Y, u, 0)$.

Let $D = d_1, d_2, \cdots, d_k$ be a finite sequence of nonnegative integers, and let Z be an I-set where $|Z| \geq k$. The *product* of D and Z, written $D \odot Z$, is $\sum_{i=1}^{k} d_i Z_{[i]}$. An integer x is said to be *representable* by the I-set Z if there exists a finite sequence of nonnegative integers $D = d_1, d_2, \cdots, d_k$ where $D \odot Z = x$. The *span* of an I-set Z, written $\text{Span}(Z)$, is the I-set consisting of the integers that are representable by Z. The *weight* of a finite sequence $D = d_1, d_2, \cdots, d_k$, written $\text{Weight}(D)$, is $\sum_{i=1}^{k} d_i$. If u is representable by Z, then $\text{Size}(Z, u)$ is the minimum of $\text{Weight}(D)$ taken over all sequences D such that $D \odot Z = u$.

We will consider the input to a Shellsort sorting network to be an array of registers $A = A[1], A[2], \cdots, A[N]$ that holds N items. Each comparator in the sorting network will be viewed as performing a compare–exchange operation on a fixed pair of registers. The compare–exchange operation compares the contents of the two registers and exchanges the contents if they are out of order. We will divide the comparators into a sequential set of *stages*, each of which performs the z-sort for a given increment z. For any I-set Z, the array A is said to be *sorted by* Z if for all $z \in Z$, A is z-sorted. For any I-set Z, Y is the *template generated by* Z if $Y = \text{Span}(Z \cup \{i \in I \mid i \geq N\})$ (it is easily verified that Y is, in fact, a template). Recall that if the array A is z-sorted for each $z \in Z$, then it must also be y-sorted for each $y \in Y$ (the integers greater than or equal to N are included in Y because the array A contains only N data items, so it must be y-sorted for all $y \geq N$).

3. Template costs and comparators.

Throughout this section let Z be an I-set, let Y be the template generated by Z, and let x be a positive integer. Also, let c be the cost of x with respect to template Y, and let L be any integer, where $1 \leq L \leq N$. We will first show that the cost of an increment with respect to a template can be used to put an upper bound on the size of the sorting network stage that performs the sort for that increment. It is easy to see that if the array A is sorted by Z, there are at most c array locations i such that $i < L$, $A[i] > A[L]$, and $i \equiv L \pmod{x}$. Therefore, when we perform the x-sort each location L will have to be compared to at most c other locations. As a result, the stage of the network that performs the x-sort requires only $O(Nc)$ comparators. Pratt used a similar argument to prove the correctness of his sorting network [9].

Of course, we are trying to prove a lower bound on the size of Shellsort sorting networks. In the remainder of this section we will show that the stage of the network that performs the x-sort does, in fact, require $\Omega(Nc)$ comparators.

LEMMA 3.1. *For any integer L, $1 \leq L \leq N$, there exists an assignment of values to the array A such that A is sorted by Z and for all i, $1 \leq i < L$, where $L - i \notin Y$, $A[i] > A[L]$.*

Proof. Let $E = \{i \mid 1 \leq i \leq L \text{ and } L - i \in Y\}$, let $F = \{i \mid 1 \leq i \leq L \text{ and } L - i \notin Y\}$, and let $G = \{i \mid L < i \leq N\}$. Assign values to A as follows. For each $E_{[i]} \in E$ let $A[E_{[i]}] = i$, for each $F_{[i]} \in F$ let $A[F_{[i]}] = i + |E|$, and for each $G_{[i]} \in G$ let $A[G_{[i]}] = i + L$ (see Fig. 2). Note that for all i, $1 \leq i < L$, where $L - i \notin Y$, $A[i] > |E| = A[L]$. Therefore, all that remains to be shown is that A is sorted by Z.

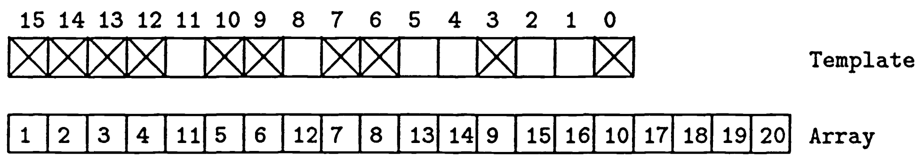

FIG. 2. *Worst-case array for Shellsort.*

Assume for the sake of contradiction that A is not sorted by Z. Then there exist i and j, where $i < j$, $A[i] > A[j]$, and $j - i \in Z$, which implies that $j - i \in Y$. Note that because $i < j$ and $A[i] > A[j]$, i and j cannot both be in E, they cannot both be in F, and they cannot both be in G. Also, $j \notin G$ because this would require that $A[j] > L$ and $A[i] \leq L$. Furthermore, $i \notin E$ because this would require that $A[i] \leq |E|$ and $A[j] > |E|$. Finally, $i \notin G$ because this would require that $i > L$ and $j \leq L$. Therefore, $i \in F$ and $j \in E$. However, $j \in E$ implies that $L - j \in Y$, and it was shown that $j - i \in Y$, so $(L - j) + (j - i) = L - i \in Y$ (because Y is a template and is closed under addition), which is a contradiction because $i \in F$ implies that $L - i \notin Y$. □

Recall that insertion sort works by performing a sequence of comparisons that insert each of the items into the list. Also, recall that insertion sort performs all of the comparisons that insert a given item into the list before performing any of the comparisons that insert the next item into the list. As a result, it is impossible for a single comparator in an insertion sort sorting network to participate in the insertion of two different items. We will use this observation to obtain a lower bound on the number of comparators required by a single stage of a Shellsort network.

THEOREM 3.2. *If A has been sorted by* Z, $x \leq N/2$, *and* $c =$ Cost(Y, x), *then at least* $Nc/24$ *comparators are needed to implement an* x*-sort of A.*

Proof. If $c = 0$, the proof is trivial. Otherwise, let $m =$ Max(Slice$(\overline{Y}, x, 0)$) (that is, m is the largest multiple of x that is not in Y). There are two cases based on the value of m.

Case 1: $m \leq 3N/4$. Let L be any integer where $3N/4 < L \leq N$. From Lemma 3.1 all c registers i, where $1 \leq i < L$ and $L - i \in$ Slice$(\overline{Y}, x, 0)$, can be such that $A[i] > A[L]$. Thus immediately before $A[L]$ is inserted it is possible that $A[L - jx] > A[L]$ for all j, where $1 \leq j \leq c$. As a result, at least c comparators are needed to insert $A[L]$ by using an insertion sort. Because there are at least $N/4$ such integers L, because c comparators are required for each L, and because no comparator can be shared by different values of L, at least $Nc/4$ comparators are needed.

Case 2: $m > 3N/4$. Let $U =$ Slice$(I, x, 0)$ (that is, U is the set of all nonnegative multiples of x), and let $V = \{i \in U \mid m/4 \leq i \leq 3m/4\}$. Let $k = m/x$, and note that $|V|$ is a function of k. Specifically, there are four cases. If $k \equiv 0 \pmod 4$, then $|V| = k/2 + 1$. If $k \equiv 1 \pmod 4$, then $|V| = \lfloor k/2 \rfloor$. If $k \equiv 2 \pmod 4$, then $|V| = k/2$. If $k \equiv 3 \pmod 4$, then $|V| = \lceil k/2 \rceil$. In any case, $|V| \geq \lfloor k/2 \rfloor$. Note that $c \leq m/x = k$, so $|V| \geq \lfloor c/2 \rfloor$. Also, note that $x \notin Y$ (because $x \in Y$ would imply that $c = 0$), $m \notin Y$, and $x \neq m$ (because $x \leq N/2$ and $m > 3N/4$), so $c \geq 2$ and $\lfloor c/2 \rfloor \geq c/3$. Therefore, $|V| \geq c/3$.

Now let $W = V \setminus Y$, and note that Max$(W) \leq 3N/4$. Because $m \notin Y$ and Y is closed under addition, for any $i \in Y$, where $i \leq m$, $m - i \notin Y$. Also, for any $i \in V$, $m - i \in V$. Therefore, for any $i \in Y \cap V$, $m - i \in \overline{Y} \cap V$. As a result, $|W| \geq |V|/2 \geq c/6$. Let L be any integer where $3N/4 < L \leq N$. From Lemma 3.1 all $|W| \geq c/6$ registers

i, where $1 \leq i < L$ and $L - i \in W$, can be such that $A[i] > A[L]$. Thus immediately before $A[L]$ is inserted it is possible that $A[L - jx] > A[L]$ for all j, where $1 \leq j \leq c/6$. As a result, at least $c/6$ comparators are needed to insert $A[L]$ by using an insertion sort. Because there are at least $N/4$ such integers L, because $c/6$ comparators are required for each L, and because no comparator can be shared by different values of L, at least $Nc/24$ comparators are needed. □

4. Efficiency of increments. At any time during the Shellsort algorithm let the *current template* be the template generated by the increments for which sorts have been performed. Before the sorts for the first increment are performed, the current template is missing $N - 1$ natural numbers, namely, $1, 2, \cdots, N - 1$. After the sort for the final increment (which must be 1) is performed, the current template contains all of the natural numbers. In this section we examine the relationship between the cost of an increment and the number of items that it adds to the current template.

For the remainder of this section let Z be an I-set, let x be a positive integer, let Y be the template generated by Z, and let c be the cost of x with respect to template Y. Also, let $Z' = Z \cup \{x\}$, and let Y' be the template generated by Z'.

THEOREM 4.1. *Given the above definitions*, $|Y' \setminus Y| \leq xc$.

Proof. Let $E = Y' \setminus Y$. Assume for the sake of contradiction that the claim is false, in which case $|E| > xc$. Therefore, there must exist a u for which $0 \leq u < x$ and $|\text{Slice}(E, x, u)| > c$. Let $F = \text{Slice}(E, x, u)$.

It will first be shown that for each $f \in F$ there exists a $t \in \text{Slice}(Y, x, u)$ where $t < f$. Let f be an arbitrary member of F, and note that $f \in E$. Therefore, f is not representable by Z, but f is representable by Z'. Let the sequence $D = d_1, d_2, \cdots, d_j$ be such that $D \odot Z' = f$. Note that if $Z'_{[i]} = x$, then $d_i > 0$ because f is not representable by Z. Let the sequence $H = d_1, \cdots, d_{i-1}, 0, d_{i+1}, \cdots, d_j$, and let $t = H \odot Z'$. Then $t < f$, t is representable by Z, and $t \equiv f \pmod{x}$. Therefore, $t \in \text{Slice}(Y, x, u)$ and $t < f$.

Now let $m = \text{Min}(\text{Slice}(Y, x, u))$. By the argument given in the previous paragraph $\text{Min}(F) > m$. For any i, $1 \leq i \leq |F|$, $F_{[i]} - m \notin Y$ because $F_{[i]} \notin Y$ and Y is closed under addition. But $F_{[i]} - m \equiv 0 \pmod{x}$, so $|F| \leq \text{Lack}(Y, x, 0) = \text{Cost}(Y, x) = c$, which is a contradiction. □

We can now outline the remainder of the lower-bound proof. We have shown in Theorem 3.2 that lower bounds on increment costs can be used to obtain lower bounds on the size of Shellsort sorting networks. We have just seen that only large increments are efficient in adding items to the current template. That is, for a given cost a large increment is capable of adding more new items to the template than will a small increment. Therefore, to obtain a small sorting network we should use large increments to add items to the template. Therefore, when using monotonically decreasing increments we should add as many items as possible to the template with the increments in the beginning of the sequence. However, we will show in Theorem 5.2 that there will always be a large number of items missing from the template. As a result, monotonically decreasing increments cannot be efficient. The remaining lemmas and theorems formalize this argument.

5. Elements missing from templates. In this section we will prove a lower bound on the number of elements missing from a template. Throughout this section let Z be a nonempty I-set with $\text{Min}(Z) > 1$ and $\text{Max}(Z) < N$, let Y be the template generated by Z, and let $x = \text{Min}(Z)$.

LEMMA 5.1. *For any k such that* $Y_{[k]} < N$, $Y_{[k]} \geq x \log k / \log(|Z| + 1)$.

Proof. Assume for the sake of contradiction that the claim is false, so there exists a k such that $Y_{[k]} < N$ and $Y_{[k]} < x \log k / \log(|Z|+1)$. Let $E = \{Y_{[i]} \mid 1 \le i \le k\}$. For each $Y_{[i]} \in E$, $Y_{[i]} < N$, so $Y_{[i]} \in \text{Span}(Z)$. Let j be such that $Y_{[j]} \in E$, and for all i, where $1 \le i \le k$, $\text{Size}(Z, Y_{[i]}) \le \text{Size}(Z, Y_{[j]})$. Let $h = \text{Size}(Z, Y_{[j]})$. Note that there are at most $(|Z|+1)^h$ integers $i \in \text{Span}(Z)$ such that $\text{Size}(Z, i) \le h$. Therefore, $k = |E| \le (|Z|+1)^h$, so $h \ge \log k / \log(|Z|+1)$ and $x \log k / \log(|Z|+1) \le xh \le Y_{[j]} \le Y_{[k]}$, which is a contradiction. □

THEOREM 5.2. *If* $1 \le |Z| < \log^2 N$, $N^{1/2} \le x \le N/\log N$, *and* $N \ge 2^{64}$, *then* $|\overline{Y}| > x \log N / 16 \log\log N$.

Proof. Let $u = \text{Max}(\overline{Y})$. Note that for all i, $u + 1 \le i \le u + x$, $i \in Y$. Therefore, $u + x \ge Y_{[x]}$ and $u \ge Y_{[x]} - x$. Because $x \le N/\log N$, $x \log x / \log(|Z|+1) < N$. Therefore, either $Y_{[x]} \ge N > x \log x / \log(|Z|+1)$ or $Y_{[x]} < N$, and from Lemma 5.1 $Y_{[x]} \ge x \log x / \log(|Z|+1)$. Thus in either case $u \ge x(\log x / \log(|Z|+1) - 1)$. Because $\log x \ge \frac{1}{2} \log N$ and $\log(|Z|+1) \le 2 \log\log N$, $\log x / \log(|Z|+1) \ge \log N / 4 \log\log N$ and $u \ge x(\log N / 4 \log\log N - 1)$. Because $N \ge 2^{64}$, $\log N / 4 \log\log N \ge 8/3$ and $(\log N / 4 \log\log N) - 1 \ge (\log N / 4 \log\log N)/2 = \log N / 8 \log\log N$. Therefore, $u \ge x \log N / 8 \log\log N$. Because Y is closed under addition and $u \notin Y$, for each i, $0 \le i \le u$, either $i \notin Y$ or $u - i \notin Y$. Therefore, $|\overline{Y}| > u/2 \ge x \log N / 16 \log\log N$. □

6. Template costs for monotonic increments. In this section we prove a lower bound on the total template costs incurred when monotonically decreasing increments are used. Throughout this section let $N \ge 2^{64}$ and let Z be an I-set where $\text{Min}(Z) = 1$ and $\text{Max}(Z) < N$. Let $k = |Z|$, where $1 \le k < \log^2 N$. Let $R_{k+1} = \emptyset$ and for all i, where $1 \le i \le k$, let $R_i = \{z \in Z \mid z \ge Z_{[i]}\}$. For all i, where $1 \le i \le k+1$, let Y_i be the template generated by R_i and let $b_i = |\overline{Y_i}|$. For all i, where $1 \le i \le k$, let $c_i = \mathit{Cost}(Y_{i+1}, Z_{[i]})$.

LEMMA 6.1. *For all* i, $1 \le i \le k$, *if* $N^{1/2} \le Z_{[i]} \le N/\log N$, *then* $c_i > (b_{i+1}/b_i - 1)(\log N / 16 \log\log N)$.

Proof. From Theorem 4.1 $c_i \ge (b_{i+1} - b_i)/Z_{[i]}$. From Theorem 5.2 $b_i > Z_{[i]} \log N / 16 \log\log N$, so $Z_{[i]} < 16 b_i \log\log N / \log N$ and $c_i > (b_{i+1} - b_i) \log N / 16 b_i \log\log N = (b_{i+1}/b_i - 1)(\log N / 16 \log\log N)$. □

LEMMA 6.2. *For any* u *and* v *where* $N^{1/2} \le Z_{[u]} < Z_{[v-1]} \le N/\log N$,

$$\sum_{i=u}^{v-1} c_i > (\log N / 16 \log\log N)(v-u)((b_v/b_u)^{1/(v-u)} - 1).$$

Proof. From Lemma 6.1

$$\begin{aligned}\sum_{i=u}^{v-1} c_i &> \sum_{i=u}^{v-1} (b_{i+1}/b_i - 1)(\log N / 16 \log\log N) \\ &= (\log N / 16 \log\log N)\left(u - v + \sum_{i=u}^{v-1} b_{i+1}/b_i\right).\end{aligned}$$

Note that

$$\prod_{i=u}^{v-1} b_{i+1}/b_i = b_v/b_u.$$

Because the arithmetic mean is always greater than or equal to the geometric mean,

$$(1/(v-u))\sum_{i=u}^{v-1} b_{i+1}/b_i \geq (b_v/b_u)^{1/(v-u)}$$

and

$$\sum_{i=u}^{v-1} b_{i+1}/b_i \geq (v-u)(b_v/b_u)^{1/(v-u)}.$$

Therefore,

$$\sum_{i=u}^{v-1} c_i > (\log N/16\log\log N)(v-u)((b_v/b_u)^{1/(v-u)}-1). \qquad \square$$

THEOREM 6.3. $\sum_{i=1}^{k} c_i \geq \log^2 N/192\log\log N$.

Proof. If $\operatorname{Max}(Z) \leq N^{1/2}$, then from Theorem 4.1

$$\begin{aligned} N-1 &= \sum_{i=1}^{k}(b_{i+1}-b_i) \\ &\leq \sum_{i=1}^{k} c_i Z_{[i]} \\ &\leq \sum_{i=1}^{k} c_i N^{1/2}, \end{aligned}$$

so $\sum_{i=1}^{k} c_i \geq (N-1)/N^{1/2} \geq \log^2 N/192\log\log N$.

If $\operatorname{Max}(Z) > N^{1/2}$, then let u and v be such that $Z_{[u]}$ is the smallest member of Z that is greater than $N^{1/2}$ and $Z_{[v]}$ is the largest member of Z that is less than or equal to $N/\log N$. There are two cases.

Case 1: $b_u \geq N^{1/2}\log^2 N$. From Theorem 4.1

$$\begin{aligned} N^{1/2}\log^2 N &\leq b_u \\ &= \sum_{i=1}^{u-1}(b_{i+1}-b_i) \\ &\leq \sum_{i=1}^{u-1} c_i Z_{[i]} \\ &\leq \sum_{i=1}^{u-1} c_i N^{1/2}, \end{aligned}$$

so $\sum_{i=1}^{u-1} c_i \geq \log^2 N$ and $\sum_{i=1}^{k} c_i \geq \log^2 N/192\log\log N$.

Case 2: $b_u < N^{1/2}\log^2 N$. Note that if $v = k$, then $b_{v+1} = N-1$, whereas if $v < k$, then because $Z_{[v+1]} > N/\log N$, $b_{v+1} \geq N/\log N - 1$. So in either case $b_{v+1} \geq N/\log N - 1 \geq N/\log^2 N$. From Lemma 6.2

$$\sum_{i=u}^{v} c_i \geq (\log N/16\log\log N)(v-u+1)((b_{v+1}/b_u)^{1/(v-u+1)}-1).$$

Let $t = v - u + 1$, and note that $t \leq k < \log^2 N$. Then

$$\begin{aligned}
&(\log N/16 \log\log N)(v-u+1)((b_{v+1}/b_u)^{1/(v-u+1)} - 1) \\
&\quad \geq (\log N/16 \log\log N)(t)((N^{1/2}/\log^4 N)^{1/t} - 1) \\
&\quad \geq (\log N/16 \log\log N)(t)(N^{1/8t} - 1).
\end{aligned}$$

Because $t(N^{1/8t}-1) = t(e^{\ln N/8t}-1)$ and $e^x = \sum_{i=0}^{\infty} x^i/i!$, $t(e^{\ln N/8t}-1) \geq t(\ln N/8t) = \ln N/8 > \log N/12$. Therefore,

$$\begin{aligned}
\sum_{i=1}^{k} c_i \geq \sum_{i=u}^{v} c_i& \\
&\geq (\log N/16 \log\log N)(t)(N^{1/8t} - 1) \\
&\geq \log^2 N/192 \log\log N. \qquad \square
\end{aligned}$$

From Theorem 6.3 it is clear that any upper bound on the sequential running time that is based on template costs and that uses monotonically decreasing increments will be at least $\Omega(N \log^2 N/\log\log N)$.

7. Network sizes for monotonic increments. This section establishes a lower bound on the size of Shellsort sorting networks when monotonically decreasing increments are used. The proof is based on Theorems 3.2 and 6.3.

THEOREM 7.1. *Shellsort sorting networks with monotonically decreasing increments require* $\Omega(N \log^2 N/\log\log N)$ *comparators to sort N items.*

Proof. It will be shown that when $N \geq 2^{64}$ at least $N \log^2 N/4608 \log\log N$ comparators are required. Let Z be the set of increments that are used, and let $k = |Z|$. Let $R_{k+1} = \emptyset$, and for all i, where $1 \leq i \leq k$, let $R_i = \{z \in Z \mid z \geq Z_{[i]}\}$. For all i, where $1 \leq i \leq k$, let Y_i be the template generated by R_i. For all i, where $1 \leq i \leq k$, let $c_i = \text{Cost}(Y_{i+1}, Z_{[i]})$. It will be assumed that for all i, where $1 \leq i \leq k$, $c_i \geq 1$ because increments that have no cost have no effect on the order of the data items. Two cases will be considered.

Case 1: $k \geq \log^2 N$. Because for each i, where $1 \leq i \leq k$, $c_i \geq 1$, from Theorem 3.2 at least $N/24$ comparators are required to perform each $Z_{[i]}$-sort. Therefore, a total of at least $\sum_{i=1}^{k} N/24 \geq N \log^2 N/24$ comparators are required.

Case 2: $k < \log^2 N$. From Theorem 3.2 at least $(N/24) \sum_{i=1}^{k} c_i$ comparators are required; from Theorem 6.3 $\sum_{i=1}^{k} c_i \geq \log^2 N/192 \log\log N$, so $N \log^2 N/4608 \log\log N$ comparators are required. $\square$

8. Conclusions and open problems. We have shown that all Shellsort sorting networks based on monotonically decreasing increments require $\Omega(N \log^2 N/\log\log N)$ comparators. This lower bound nearly matches the upper bound of $O(N \log^2 N)$ that was proved by Pratt. One open problem is the removal of the $\Theta(\log\log N)$ gap between these lower and upper bounds.

Another interesting open problem consists of removing the restriction that the increments be monotonically decreasing. Although the case of monotonically decreasing increments is an important special case, it is natural to ask if a similar lower bound applies when the increments are not monotonically decreasing. The results of §3, which establish the relationship between template costs and comparators, and the results of

§4, which bound the efficiency of increments, are independent of whether or not the increments are monotonically decreasing. However, the results of §5, which give a lower bound on the number of items missing from a template, are stated in terms of the smallest increment that has been used. As a result, if the increments are not monotonically decreasing, this lower bound is seriously weakened. In fact, a single very small increment will render the lower bound given in §5 worthless. As a result, a stronger theorem on the number of items missing from a template appears to be needed in order to address the issue of nonmonotonic increments.

Acknowledgment. I am very grateful for the helpful comments and recommendations given by the anonymous referee.

A NOTE ON POSET GEOMETRIES*

JOEL FRIEDMAN†

Abstract. This note describes how varying the geometric representation of a poset can be applied to "poset balancing." It is shown that the 1/3, 2/3 balancing property holds for a certain class of posets whose number of relations is sufficiently small, in a certain sense.

Key words. partial order, linear extension, poset balancing

AMS(MOS) subject classifications. primary 06A10; secondary 68P10

1. Introduction. Given a poset (partially ordered set) for elements x and y, let $p(x < y)$ denote the fraction of completions of the partial order to a total order in which $x < y$. Fredman's conjecture, in connection with [Fre76] (also conjectured by Linial in [Lin84]), is that any nontotal poset (i.e., poset that is not a total order) has two elements, x, y, for which $1/3 \le p(x < y) \le 2/3$. This conjecture arose in the context of studying the information theoretic bound on the complexity of sorting the elements of the poset. The nontrivial nontotal three-element poset shows this conjecture to be as optimistic as possible.

To date the conjecture is unresolved, but using convexity in geometric realizations of the posets, such as the techniques of Stanley in [Sta81], theorems have been proven with the $1/3, 2/3$ replaced by different constants. In [KS84], Kahn and Saks, proved the above conjecture with $3/11, 8/11$ as constants. In [KL88], Kahn and Linial gave a simpler proof of the conjecture with $1/(2e), (2e-1)/(2e)$ as constants (a referee has informed me that Khachian had earlier given a proof similar to that of [KL88] with constants $e^{-2}, 1-e^{-2}$).

Both proofs are based on convex geometry involving a geometric realization of S_n, the group of permutations on n objects. The point of this note is to remark that by varying the geometries one can sometimes get better results. This is definitely true when the poset has few enough relations in a certain sense. The geometries we use are suggested by the standard realization of S_n as its associated Coxeter complex (see, e.g., [Ron89]). We combine the varying geometries with the simplified technique of [KL88] to obtain improved results for such posets. In this note we prove the following theorem.

THEOREM 1.1. *For any $\epsilon > 0$ there is a C such that the following is true. Let P be a poset on $\{x_1, \dots, x_n\}$, and let a_i and b_i denote the number of elements, respectively, $>$ and $<$ than x_i in P. If for every permutation $\sigma \in S_n$ we have*

$$\sum_{i=1}^{n} \left(\frac{\sigma(i)}{a_i + 1} + \frac{n + 1 - \sigma(i)}{b_i + 1} \right) \ge Cn,$$

then P has elements x, y with $(1/e) - \epsilon \le p(x < y) \le 1/2$.

This appears as Theorem 3.6 of §3 and is proven there. This is the precise sense of P having "few enough relations" mentioned earlier. As applications we have Theorem 1.2.

THEOREM 1.2. *For any $\epsilon > 0$ there is a C such that if P either (1) has at least $C\sqrt{n}$ maximal (or minimal) elements or (2) has no chain of length $\ge 2\log_2 \log n - C$, then P has elements x, y with $(1/e) - \epsilon \le p(x < y) \le 1/2$. For any $\epsilon > 0$ and $\nu > 0$, there is a*

†Department of Computer Science, Princeton University, Princeton, New Jersey 08544.

$\mu > 0$ such that the same conclusion holds if P has some νn of its elements each unrelated to at least $(1-\mu)n$ other elements.
This appears as Theorems 3.5, 3.7, and 3.8 of §3.

We also note that other special cases of the poset $(1/3, 2/3)$ conjecture have been resolved. In [Lin84], Linial proves the conjecture for posets of width 2. In [Kom], Komlós proves that for any $\epsilon > 0$, there is a function $f_\epsilon(n) = o(n)$ such that any poset with at least $f_\epsilon(n)$ minimal elements has two elements, x, y, such that $|p(x<y) - 1/2| \le \epsilon$; here $f(n)/n$ decreases to zero exponentially fast in the inverse of some Ramsey-type function of n. Also Kahn and Saks [KS84] have conjectured that as the width of the poset tends to infinity, a $|p(x<y) - 1/2| \le o(1)$ balancing result should hold.

2. Variants of a standard model.

A standard geometric model of S_n is its associated Coxeter complex (see [Ron89]). One views this as a triangulation of the $(n-2)$-dimensional sphere. The convex polytope determined as the convex hull of the simplices of this triangulation (this polytope looks like a beachball) is a realization of S_n such that the realization of every poset is convex. Of course, there is no reason to insist that this polytope's vertices all lie on one sphere. By moving certain vertices further or closer to the center, we get different convex polytopes.

So consider n points $v_1, \ldots, v_n \in \mathbf{R}^{n-1}$ not contained in any hyperplane of dimension $n-2$. Every point $v \in \mathbf{R}^{n-1}$ can be uniquely written as

$$v = \sum \alpha_i v_i, \quad \text{with} \quad \sum \alpha_i = 1. \tag{2.1}$$

For a permutation of $\{1, \ldots, n\}$, $\sigma = \{i_1, \ldots, i_n\}$, let

$$A_\sigma = \left\{ \sum \alpha_i v_i \mid \alpha_{i_1} \ge \cdots \ge \alpha_{i_n} \right\}.$$

If U is any convex body, say, containing the v_i, then $\sigma \mapsto U_\sigma \equiv A_\sigma \cap U$ is a realization of S_n in which every poset corresponds to a convex subset of U. U_σ will be *adjacent* to U_τ, i.e., will share a facet (i.e., an $(n-2)$-dimensional face), if and only if σ and τ differ by some transposition (i,j), and in that case the facet lies on the hyperplanes H_{ij} containing $(v_i + v_j)/2$ and all v_k with $k \ne i, j$. When no confusion will occur, we will often simply refer to this facet as H_{ij}.

For future reference, the α_i's in (2.1) are called the *barycentric coordinates* of v (with respect to the v_i's). If U is the simplex spanned by the v_i's, the *barycentric distance* of v to a facet, F, of U (i.e., a simplex spanned by any $n-1$ distinct v_i's), is the barycentric coordinate of v with respect to the v_i not contained in F.

We now make some explicit calculations to describe various choices of U. For simplicity, we perform them in $\mathbf{R}^n$ restricted to the hyperplane $x_1 + \cdots + x_n = 1$. For a subset $S \subset \{1, \ldots, n\}$, let e_S be the vector that is 1 on the ith coordinate if $i \in S$ and 0 elsewhere. Let $Q = (1/n, \ldots, 1/n)$. For positive real $\theta_1, \ldots, \theta_n$, consider the collection of points

$$v_S = \theta_S e_S + \left(1 - |S|\theta_S\right) Q$$

with $\theta_S = \theta_{|S|}$, ranging over all nonempty proper subsets, S, of $\{1, \ldots, n\}$. Clearly all these vertices lie on the hyperplane $x_1 + \cdots + x_n = 1$. Let U be their convex hull.

LEMMA 2.1. *The following two conditions are equivalent*: (1) *no v_S is in the interior of U and* (2) *for all $i < j$*

$$i\theta_i \leq j\theta_j \quad and \quad (n-i)\theta_i \geq (n-j)\theta_j. \tag{2.2}$$

Proof. By symmetry the first condition is equivalent to saying that for any $|S|$, the centers of mass of the sets

$$E_{j,k} = \left\{ v_T \;\middle|\; |T \cap S| = j, |T - S| = k \right\}$$

for all k, j lie between (or on) Q and v_S. Each of these gives an inequality between $\theta_{|S|}$ and θ_{j+k}, which is exactly of the form of those of (2.2) (except when $j + k = |S|$, which is trivial), and conversely each inequality in (2.2) arises in this way. □

For future reference we note that the distance of v_S to a half plane H_{ij} is just $\theta_S/\sqrt{2}$ if exactly one of i, j are in S (and 0 otherwise); this is seen by noting that the reflection through H_{ij} merely exchanges the ith and jth coordinates. We also note some familiar choices of θ_i. The choice $\theta_i = 1/i$ and $\theta_i = 1/(n-i)$ are simplices with vertex sets $\{v_S\}$ ranging over S of respective sizes 1 and $n-1$. Choosing the v_S's to be equidistant from Q gives

$$\theta_i = \sqrt{\frac{n}{i(n-i)}}.$$

We now describe some features of varying the geometry. First, we make the observation that in any poset there exists an ordering of the elements $\sigma = \{x_1, \ldots, x_n\}$ such that $p(x_i > x_{i+1}) \geq 1/2$ for all i. We call such a σ *optimal.* Its existence follows from the fact that any tournament has a Hamiltonian path. This statement also implies that $p(x_i > x_j) > 2/3$ for all $i > j$ if P is a counterexample to Fredman's conjecture. The point to our method is that by fixing P and such an ordering we can choose the geometry best suited to the situation at hand. We will apply this to the centroid method used in [KS84] and [KL88], using the simplified technique of the latter. We explain this in the next section.

It is sometimes easier to visualize the problem and amusing, if not particularly useful, to state the poset problem in the "real-estate" terminology (see [Ron89]). Given a Coxeter complex, there are two natural notions of convexity for a subset of chambers—that of metric convexity and that of being an intersection of half-apartments. It is easy to see that these two notions are equivalent; in the case of S_n, a convex set is merely a poset, and our question is to try to find a wall that divides a given convex set P into roughly equal parts. For example, since any collection of ≥ 2 chambers is nontrivially divided by some wall, it follows by descending induction on k that for all $k \geq 2$ there is a collection of $< k$ chambers all of whose bounding half-apartments contain more than half of P; this again proves the existence of an optimal σ.

3. Centroid type arguments. We review the techniques in [KL88]. They start with the observation given below.

LEMMA 3.1. *Let C be a convex body in $\mathbf{R}^m$ such that the centroid of C has x_1 coordinate $-\alpha$ and contains points with x_1 coordinates u and $-w$, with some $u, w, \alpha \geq 0$. Then*

$$\frac{|C \cap \{x_1 \geq 0\}|}{|C|} \geq \min_{U \geq u, W \geq w} \left(\frac{1}{1 + \frac{1}{m-1} + \frac{(m+1)\alpha - W}{(m-1)U}} \right)^{m-1} \frac{1}{1 + \frac{W}{U}}. \tag{3.1}$$

Furthermore the right-hand side above is minimized at $U = u, W = w$ if $u \geq u^*$ and otherwise at $U = u^*, W = w$, where

$$u^* = \frac{wm\Big(w - \alpha(m+1)\Big)}{w + \alpha(m^2-1)}.$$

Proof. The proof is a simple argument that shows that the worst case C is a "double cone," in the spirit of Mityagin (see [Mit68]). Calculating the worst case volume ratio on this basis is easy and yields (3.1), which is essentially straight from [KL88]. Differentiating in U and W yields the second part, using the fact that $w \geq (\alpha(m+1)+u)/m$ always holds in the above situation. □

If $\alpha = 0$ in the above, the above volume ratio is at least $1/e$, which is Mityagin's result. So we can expect volume ratios close to this if α is small enough.

The argument in [KL88] is as follows. Fix a realization of S_n as in the previous section. Let σ be an optimal total order, and let c be the centroid of the poset P, where we identify P with its realization. We can assume $c \in A_\sigma$ (or else we can apply Mityagin's result), so consider c's barycentric coordinates with respect to the vertices of A_σ. If H_{ij} is a facet of A_σ with i and j related in P (i.e., either $i < j$ or $i > j$ in the partial ordering), then P itself lies to one side of H_{ij} and it easily follows that the barycentric distance of c to H_{ij} is at least $1/n$. Hence, there must exist some facet, H_{ij}, of A_σ whose barycentric distance is $\leq 1/n$ such that i, j are unrelated in P, and in particular $A_{\sigma'}$ lies in P, where σ' is σ followed by the transposition (i, j). Then we can apply Lemma 3.1 with $m = n-1, u = w = 1, \alpha = 1/(m+1)$, which gives a volume ratio $\geq 1/(2e)$.

Actually, the realization used in [KL88], [KS84], and [Sta81] is different from ours; namely, they use the cube $[0,1]^n$ with A_σ being the set $x_{\sigma(1)} \leq \cdots \leq x_{\sigma(n)}$. In this realization, when H_{ij} is a facet of A_σ, there is never any point in P that is further away from H_{ij} than one of the vertices of A_σ. If we use our realizations, then it can happen that some of P's points are further away, and we can get better results. This can be guaranteed to be the case when P is "sufficiently sparse."

More precisely, recall from the last section that the distance from a vertex v_S to is proportional to θ_S. The choice of $\theta_i = 1$ would yield a situation like the cube realization, but varying the θ_i's allows some improvement. Varying the θ_i's involves slightly different applications of Lemma 3.1, namely, those outlined in the following lemma.

LEMMA 3.2. *For any positive ϵ there is a positive $\delta = \delta(\epsilon)$ such that if, in Lemma* 3.1, *α is less than $\delta u/m$ or $\delta w/m$ in Lemma* 3.1, *then*

$$\frac{|C \cap \{x_1 \geq 0\}|}{|C|} \geq \frac{1}{e} - \epsilon.$$

Proof. This is an easy calculation. If we have $(m+1)\alpha/U \leq \delta$ for some small δ (slightly different from the δ in the statement of the lemma), then the right-hand side of (3.1) with $U = u$ is bounded below by

$$\left(\frac{1}{1 + \frac{1+\delta}{m-1} + \frac{-W}{(m-1)u}}\right)^{m-1} \frac{1}{1 + \frac{W}{u}}.$$

By substituting $t = W/u$ and differentiating, we can see that for any fixed m there is a δ making the above expression $\geq (1/e) - \epsilon$ for all positive W. On the other hand, for large m the above expression is

$$\geq \left(1+O\left(\frac{1}{m}\right)\right)e^{-(1+\delta)}e^{W/u}\frac{1}{1+\frac{W}{u}},$$

and as before we see that this is $\geq (1/e)-\epsilon$ for m sufficiently large and some positive δ (independent of m). This proves the first case of the lemma. In the second case, we write $(m+1)\alpha - W \leq -(1-\delta)W$ and proceed similarly, showing that a small enough δ yields the desired lower bound. □

Returning to the situation at hand, given a poset P fix settings of the θ_i's, consider any optimal $\sigma=(x_1,\dots,x_n)$, and let c be the centroid of P. Being interested in bounds of the form $1/e, 1-(1/e)$ or worse, we can assume that c lies in A_σ. The vertices of A_σ are v_{S_i} with $S_i=\{x_1,\dots,x_i\}$, $1\leq i\leq n-1$. Let

$$c=\sum_{i=1}^{n-1} v_{S_i}\alpha_{S_i}$$

be the barycentric representation of c in A_σ. For each i fix a set T_i that contains exactly one of x_i, x_{i+1} and with $v_{T_i}\in P$; usually we'll take T_i to be the smallest or largest such set, depending on the choice of θ_i's. T_i is any set whose elements are not $<$ any element not in T_i (in the partial order P).

COROLLARY 3.3. *If $x_i > x_{i+1}$ in P, then*

$$\alpha_{S_i}\geq \frac{1}{n-1}\frac{\theta_{T_i}}{\theta_{S_i}}.$$

If not, then for any $\epsilon>0$ we have

$$\alpha_{S_i}\geq \delta(\epsilon)\frac{1}{n-1}\frac{\theta_{T_i}}{\theta_{S_i}},$$

unless $p(x_i<x_{i+1})\geq (1/e)-\epsilon$, for $\delta=\delta(\epsilon)$ as in Lemma 3.2.

Proof. In the first case, the facet, H, of A_σ opposite v_{S_i}, bounds P, and yet there is a point of P, v_{T_i}, whose distance to H is $\theta_{T_i}/\sqrt{2}$. c's distance to H must be at least $1/(n-1)$ of T_i's distance to H. On the other hand, c's distance to H is precisely $\alpha_{S_i}\theta_{S_i}/\sqrt{2}$.

The second case follows from Lemma 3.2, with similar distance considerations. □

COROLLARY 3.4. *If*

$$\sum_{i=1}^{n-1}\frac{\theta_{T_i}}{\theta_{S_i}}\geq \frac{n-1}{\delta(\epsilon)}, \tag{3.2}$$

then there exists an i with $p(x_i<x_{i+1})\geq (1/e)-\epsilon$.

We now seek situations in which we can guarantee that (3.2) will hold for appropriate θ_i's.

THEOREM 3.5. *For any $\epsilon>0$, there is a C such that if P contains at least $C\sqrt{n}$ maximal elements, then there exists elements x, y*

$$\frac{1}{e}-\epsilon\leq p(x<y)\leq \frac{1}{2}.$$

Proof. Take $\theta_i = 1/i$ in the above. If, in the above circumstances, x_i is maximal, then taking $T_i = \{x_i\}$ gives $\theta_{T_i}/\theta_{S_i} = |S_i|$. Hence,

$$\sum_{i=1}^{n-1} \frac{\theta_{T_i}}{\theta_{S_i}} \geq \sum_{i=1}^{C\sqrt{n}} i \geq \frac{n-1}{\delta}$$

for sufficiently large C. □

More generally we have the following theorem.

THEOREM 3.6. *For any $\epsilon > 0$, there is a C such that the following is true. Let P be a poset on $\{x_1, \ldots, x_n\}$, and let a_i and b_i denote the number of elements in P that are, respectively, $>$ and $<$ than x_i. If for every permutation $\sigma \in S_n$ we have*

$$\sum_{i=1}^{n} \left(\frac{\sigma(i)}{a_i + 1} + \frac{n+1-\sigma(i)}{b_i+1} \right) \geq Cn, \tag{3.3}$$

then P has elements x, y with $(1/e) - \epsilon \leq p(x < y) \leq 1/2$.

Proof. Consider the two choices for θ_i, $1/i$ and $1/(n-i)$. Taking C to be $2/\delta(\epsilon)$, we find that if (3.3) holds, then we can apply Corollary 3.4 for one of these two choices of θ_i. □

While the condition in Theorem 3.6 requires optimizing over σ and is not entirely explicit, in many cases it is not hard to check that it holds, such as when there exist $C\sqrt{n}$ maximal elements. We give some other examples to which Theorem 3.6 can be applied.

THEOREM 3.7. *For any $\epsilon > 0$, there is a C' such that the condition (and therefore conclusion) of Theorem 3.6 holds if every chain in P has length $\leq C' + 2\log_2 \log n$.*

THEOREM 3.8. *For any $\epsilon, \nu > 0$, there is a $\mu > 0$ such that the condition (and therefore conclusion) of Theorem 3.6 holds if some νn of P's elements are each unrelated to more than $(1-\mu)n$ (possibly different) elements of P.*

Proof. For the latter theorem, each element x_i unrelated to more than $(1-\mu)n$ has both a_i and b_i less than μn. Hence, it suffices to chose μ so that ν/μ exceeds $C(\epsilon)$ of Theorem 3.6. To prove the former, let X_i be the set of nodes whose longest chain from a maximal element is of length $i+1$; for example, X_1 is the set of maximal elements. Then any two elements of any X_i are unrelated. Then, setting $n_i = |X_i|$, we have

$$\sum_{i=1}^{n} \frac{\sigma(i)}{a_i+1} \geq \sum_{i=1}^{n_1} i + \sum_{i=n_1+1}^{n_2} \frac{i}{n_1+1} + \sum_{i=n_1+n_2+1}^{n_3} \frac{i}{n_1+n_2+1} + \cdots,$$

which, within a constant, is

$$\geq n_1^2 + \frac{n_2^2}{n_1} + \frac{n_3^2}{n_2} + \cdots. \tag{3.4}$$

A similar estimate holds for the sum in (3.3) involving the b_i's. Now let k be the length of the longest chain in P. If the condition for Theorem 3.6 is not met, then the expression in (3.4) must be bounded by Cn for some constant C. Then we conclude $n_1 \leq \sqrt{Cn}$ and then $n_2 \leq (Cn)^{3/4}$ and more generally

$$n_j \leq (Cn)^{1-(1/2^j)}.$$

Now let k be the length of the longest chain in P. Applying the same argument to the sum in (3.3) involving the b_i's, we conclude that

$$n_{k+1-j} \leq (Cn)^{1-(1/2^j)}$$

for all j. Hence,

$$n = n_1 + \cdots + n_k \leq k(Cn)^{1-\frac{1}{2^{(k+1)/2}}},$$

and thus $(k+1)/2 \geq \log_2 \log n + C'$. Hence, if $k \leq C'' + 2\log_2 \log n$, Theorem 3.6 must apply. $\square$

4. Concluding remarks. There are some other possible variants on these techniques. For one thing, we can vary the θ_S's even over S's of the same size. Of course, it may no longer be true that the A_σ's all have the same volume, but if we are only interested in $1/3, 2/3$ type results we might have some room for slight variations of volume.

On some level it seems appealing to phrase the poset question in terms of finding a wall separating a convex set of chambers in a Coxeter complex into roughly equal sizes, but it is not clear if this is of any use. It is easy to see that any convex set of a general Coxeter complex on k generators has a wall separating it into sets of fractional sizes between $1/(k+1), k/(k+1)$ and that this is the best one can say. From this point of view, it is clear that for the poset problem one is making use of the special fact that most of the generators of S_n commute.

AN $O(n)$ ALGORITHM FOR DETERMINING THE SUBREGION-TREE REPRESENTATION OF A RECTANGULAR DISSECTION*

SUKHAMAY KUNDU†

Abstract. A rectangular dissection is a partition of a rectangular space R into $n \geq 1$ disjoint rectangles $\{r_1, r_2, \cdots, r_n\}$. A T_*-plan is a dissection that is obtained by repeated application of the (1) horizontal, (2) vertical, (3) left-spiral, and (4) right-spiral partitioning operations. Two common ways of representing a T_*-plan are the wall representation $w(D)$ and the subregion-tree representation $t(D)$. It is known [S. Kundu, *Comm. ACM*, 31 (1988), pp. 752–763] that these two representations are equivalent in that one can be uniquely determined from the other. This paper presents an optimal $O(n)$ algorithm for constructing $t(D)$ from $w(D)$, which improves the previous bound of $O(n^2)$ in [S. Kundu, *Comm. ACM*, 31 (1988), pp. 752–763]. The new algorithm is based on a domination relationship among the walls, which is defined here and represented by a digraph $G_w(D)$. The algorithm exploits the disjoint cycle property of $G_w(D)$ and the relationship between the tree $t(D)$ and the transitive reduction of the acyclic digraph obtained by merging the cycles of $G_w(D)$ into distinct nodes. The new method of constructing the tree $t(D)$ by means of the digraph $G_w(D)$ can be applied to an arbitrary class of dissections D that are generated by a finite family of partitioning operations that satisfies certain natural restrictions. The complexity of the algorithm remains $O(n)$ for many such families.

1. Introduction.

Let R be a rectangular space in a plane. A partition of R into $n \geq 1$ disjoint rectangles $\{r_1, r_2, \cdots, r_n\}$ is called a *dissection*. Each r_j is called a *basic region*. A dissection D is called a *T-plan* [2] if each junction point between a vertical line and a horizontal line is a T-junction. The T-plans form models for space partitioning in very-large-scale-integration (VLSI) design [10], [11] and for floor-space planning in architectural design [2]–[9]. Figure 1(a) shows a T-plan consisting of 10 basic regions. We assume that the top and the bottom horizontal lines of R extend to infinity on both the left and the right (as indicated in the figure by the broken lines), although the extensions are usually not shown. The regions outside R, which are labeled W (for west), E (for east), N (for north), and S (for south), are called the *external regions*. A wall is a maximal horizontal or vertical line segment. The set of walls of a T-plan D forms its wall representation $w(D)$; see Fig. 1(b), where each wall is written as a pair of ordered lists. Each list consists of the basic and external regions adjacent to the wall from one side and ordered from left to right or from top to bottom. A *subregion* of D is a rectangular subspace that is the union of one or more basic regions. In general, a T-plan may not have any nontrivial subregion other than R and the basic regions r_j. Since either any two nontrivial subregions of a T-plan are disjoint or one is contained in the other (with few trivial exceptions; see §2), the subregions of a T-plan D form a tree structure $t(D)$. The basic regions of D form the terminal nodes of $t(D)$, and the whole space R corresponds to the root. The tree $t(D)$ is called the *subregion tree* of D. In Fig. 1(c), the labels h and v for the intermediate nodes of $t(D)$ indicate the type of partitioning operation applied to the associated subregion.

The tree representation $t(D)$ is particularly important for a subclass of T-plans, called T_**-plans*, which are obtained by repeated application of the (1) horizontal, (2) vertical, (3) left-spiral, and (4) right-spiral partitioning operations. (See Fig. 2.) We refer to these operations as h, v, s, and S partitions, respectively. The T_*-plans that are

FIG. 1. (a) *A T-plan D consisting of* 10 *basic regions* $\{r_1, r_2, \cdots, r_{10}\}$; (b) *walls of the T-plan* D; (c) *subregion tree* $t(D)$ *of* D.

formed by only h and v partitions are called *acyclic*; others are called *cyclic*. In [7]–[9] we present several important properties of the tree representation, including the equivalence between the wall representation and the tree representation. The main contributions of this paper are the following:

(1) It provides a linear $O(n)$ algorithm for constructing the tree representation $t(D)$ of a T_*-plan D from its wall representation $w(D)$, where n is the number of basic regions in D. This is an improvement over the $O(n^2)$ algorithm given in [7]. (The algorithm for converting $t(D)$ to $w(D)$ is $O(n)$, as shown in [7].)

(2) The method developed here for constructing $t(D)$ from $w(D)$ is general. The new method is applicable to an arbitrary class of T-plans that are generated by a finite family of partitioning operations that satisfies certain natural restrictions. The complexity of the algorithm remains $O(n)$ for many such families.

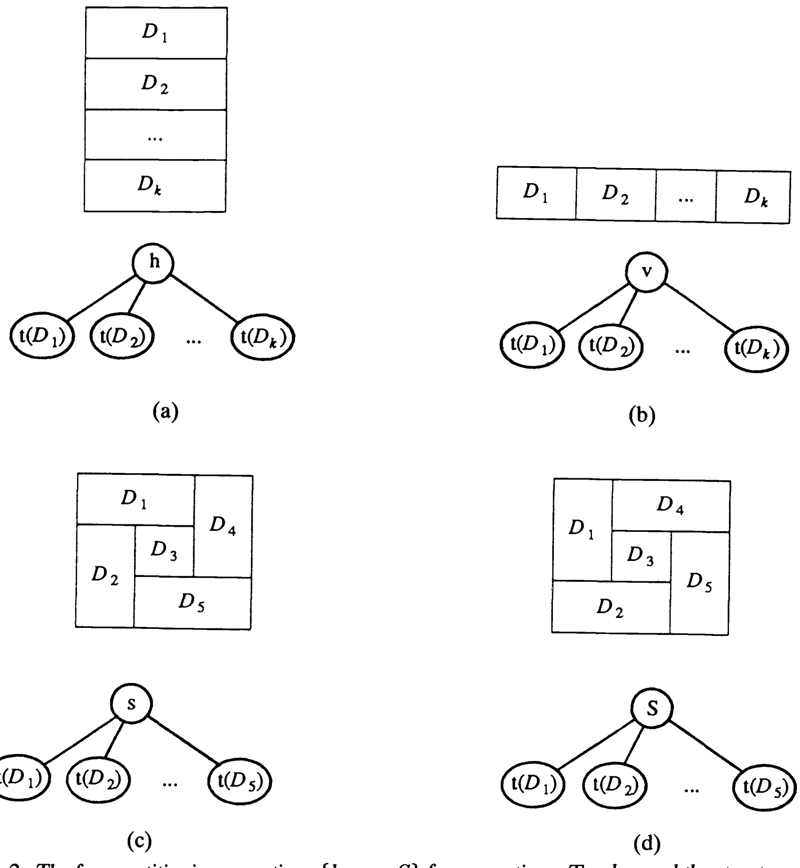

FIG. 2. *The four partitioning operations* $\{h, v, s, S\}$ *for generating a* T_**-plan and the structure of their associated subregion trees* $t(D)$; *partitioning operations*: (a) *horizontal*, (b) *vertical*, (c) *left spiral, and* (d) *right spiral.*

As a brief comparison of the new algorithm given here and the algorithm in [7], we note that the algorithm in [7] constructs the tree $t(D)$ in a top-down fashion, where a basic region r_i is processed once for every subregion containing it. This results in a computation time proportional to the sum of the path lengths in $t(D)$ from the root to the terminal nodes, which can be as much as $O(n^2)$ in the worst case and as small as $O(n \log_k n)$ in the best case. The best case occurs when the tree $t(D)$ is highly balanced and $k \geq 2$ is the minimum number of subregions created by a partitioning operator. The algorithm given here employs a more global approach using the properties of cycles in the digraph $G_w(D)$, which represents the domination properties of walls and basic regions in D (see §2). The digraph $G_w(D)$ is determined directly from the wall representation $w(D)$. The new algorithm builds the tree $t(D)$ in a top-down fashion as in [7], but it does not explicitly construct subregions of D. The two special properties of the digraph $G_w(D)$ that are exploited in the new algorithm are the following:

(1) The cycles in $G_w(D)$ correspond to the spiral partitions in D, and, moreover, no two cycles in $G_w(D)$ have a node in common. This property allows us to determine the cycles in $G_w(D)$ in linear $O(n)$ time.

(2) The transitive reduction of the acyclic graph obtained by merging each cycle of $G_w(D)$ into a distinct node has a tree structure that is isomorphic to $t(D)$ as an unordered tree. The orderings among the children of nodes in $t(D)$ are constructed by using a partial order "$<$" that is also determined from the wall representation $w(D)$. The ordering information in the wall representation $w(D)$ allows us to obtain the relevant part of the ordering "$<$", which is needed in the construction of $t(D)$, by using only $O(n)$ time.

2. Basic concepts. We denote a wall w of a T-plan by a pair of lists $w = \langle L_1, L_2\rangle$, one list for each side of the wall. For a horizontal wall (h-wall) L_1 is the list of basic regions and possibly some external regions adjacent to w from the above (north), and similarly L_2 is the list of basic regions and external regions adjacent from below (south). The regions in both L_1 and L_2 are ordered from the left to right. Likewise, for a vertical wall (v-wall) L_1 is the list of basic regions and external regions adjacent to w from the left (west) and L_2 is the list of basic regions and external regions adjacent to w from the right (east). The regions in both L_1 and L_2 are now ordered from north to south. We sometimes refer to L_1 as the first region list of w and to L_2 as the second region list. In Fig. 1(b) the horizontal walls are labeled $w_1, w_3, w_5, \cdots$, and the vertical walls are labeled $w_2, w_4, w_6, \cdots$. This odd–even labeling convention for the h-walls and v-walls is used throughout the paper. The two horizontal walls bordering the external regions N and S and the two vertical walls bordering the external regions W and E are called the *external* walls. They are also referred to as the north wall, south wall, etc. The other walls are called the *internal* walls. The four external walls are labeled w_1, w_2, w_3, and w_4, respectively. Note that each external wall is easily identified by the presence of N, S, W, and E in the first or the second region list.

We formally define the subregion tree $t(D)$ of a T_*-plan D recursively as follows. If D consists of only one basic region, region r_1, then $t(D)$ consists of a single node r_1. Otherwise, the root node of $t(D)$ that corresponds to the whole rectangular space R is labeled by one of the symbols $\pi = h, v, s$, or S, where $\pi = \pi(R)$ denotes the top-level partitioning operation applied to R. If the partition $\pi(R)$ decomposes R into k subregions $\{R_1, R_2, \cdots, R_k\}$, then the root node has k child nodes $\pi_i, 1 \le i \le k$, one for each subregion R_i. For $\pi(R) = s$ or S we have $k = 5$, and for $\pi(R) = h$ or v we have $k \ge 2$. The left-to-right ordering of the child nodes π_i is determined according to the schemas shown in Fig. 2. The subtree at each child node π_i is now determined recursively by the T_*-plan corresponding to the dissection on the subregion R_i.[1] The tree $t(D)$ is an *ordered* tree. Note that the only subregions of D for which there is no node in $t(D)$ are the ones that are formed by the union of $m, 2 \le m < k$, consecutive subregions of a k-part horizontal or vertical partition. For instance, there is no node in the tree in Fig. 1(c) corresponding to the subregion formed by the union of r_1 and r_2;

[1]We use R_i to denote both a subregion and the dissection of that subregion in D.

such a subregion may be called a *trivial* subregion. Henceforth, by subregion we shall mean a nontrivial subregion, which may be a basic region in the extreme case.[2]

We sometimes refer to an intermediate node of $t(D)$ that has the label π as a π-node. A node with the label s or S is also referred to as a *spiral* node. If R' is a subregion, then we denote by $\pi(R')$ the top-level partitioning operation of R'. The set of walls created by $\pi' = \pi(R')$ is called the *primary walls* of R' and is denoted by $w_p(\pi')$ or $w_p(R')$. We write $w_I(R')$ for the set of all internal walls of R'; $w_I(R') \supset w_p(R')$. For an h-partition π' each wall in $w_p(\pi')$ is an h-wall, and for a v-partition π' each wall in $w_p(\pi')$ is a v-wall. If π' is a spiral partition, then $w_p(\pi')$ consists of two h-walls and two v-walls.

2.1. The partial order "<". We now define a partial ordering "<" among the walls and basic regions of an arbitrary T-plan D. The partial order "<" captures the spatial (left-to-right and north-to-south) relationships among the walls and the basic regions. It is important in the determination of the left-to-right ordering of the children of the nodes in $t(D)$.

If $w = \langle L_1, L_2\rangle$ is an arbitrary wall, $r_i \in L_1$, and $r_j \in L_2$, then we let $r_i < w < r_j$. For an h-wall w the ordering $r_i < w < r_j$ represents the vertical spatial relationships, and for a v-wall the ordering $r_i < w < r_j$ represents the horizontal spatial relationships. In general, we write $x_0 < x_k$, where each of x_0 and x_k is a wall or a basic region, if there is an alternating sequence $(x_0, x_1, \cdots, x_k)$ of basic regions and walls such that $x_0 < x_1, < \cdots x_k$. In Fig. 1(a) we have the following ordering relationships among the walls and basic regions on the south side of the wall w_1:

$$w_2 < r_1 < w_6 < r_4 < w_{12} < r_5 < w_4.$$

Similarly, among the walls and basic regions on the east side of the wall w_2 we have

$$w_1 < r_1 < w_5 < r_2 < w_7 < r_3 < w_3.$$

Note that we get the same ordering "$w_2 < w_6$" by following the south side of w_1 and by following the north side of w_3. Figure 3(c) shows the partial order "<" resulting from the left-spiral operation in Fig. 3(a), where an arc (x_i, x_j) corresponds to the ordering $x_i < x_j$ such that there is no x_k with the property $x_i < x_k < x_j$. It is easy to see that "<" defines a proper partial order.

The algorithm in [7] does not make full use of the partial order "<". Instead, it uses two subpartial orders of "<", namely, $l(r_i, r_j)$ ="r_i left of r_j" and $a(r_i, r_j)$ ="r_i above r_j", both of which were originally defined in [2]. The relation $l(r_i, r_j)$ arises as the special case of the relation "<" for which each of the walls $x_{2i+1}, i \geq 0$, in the sequence $(r_i, x_1, \cdots, x_{k-1}, r_j)$ is a v-wall, and, similarly, $a(r_i, r_j)$ arises as the special case of the relation "<" for which each of the walls x_{2i+1} is an h-wall.

2.2. The wall digraph $G_w(D)$. We now define the domination relationship among the walls and basic regions in a T-plan D. In general, the domination relationship is not a partial order. The main use of the domination relationship is in the determination of the hierarchical structure of the subregions in D, i.e., the parent–child relationships in $t(D)$.

[2]The above definition of $t(D)$ easily generalizes to an arbitrary dissection D that is generated by a family of partitioning operations Π provided these partitioning operations are independent of each other in the sense that if $\sigma \in \Pi$, then for no subset $\Pi' \subseteq \Pi - \{\sigma\}$ a dissection generated by applications of Π' equals the dissection obtained by a single application of σ.

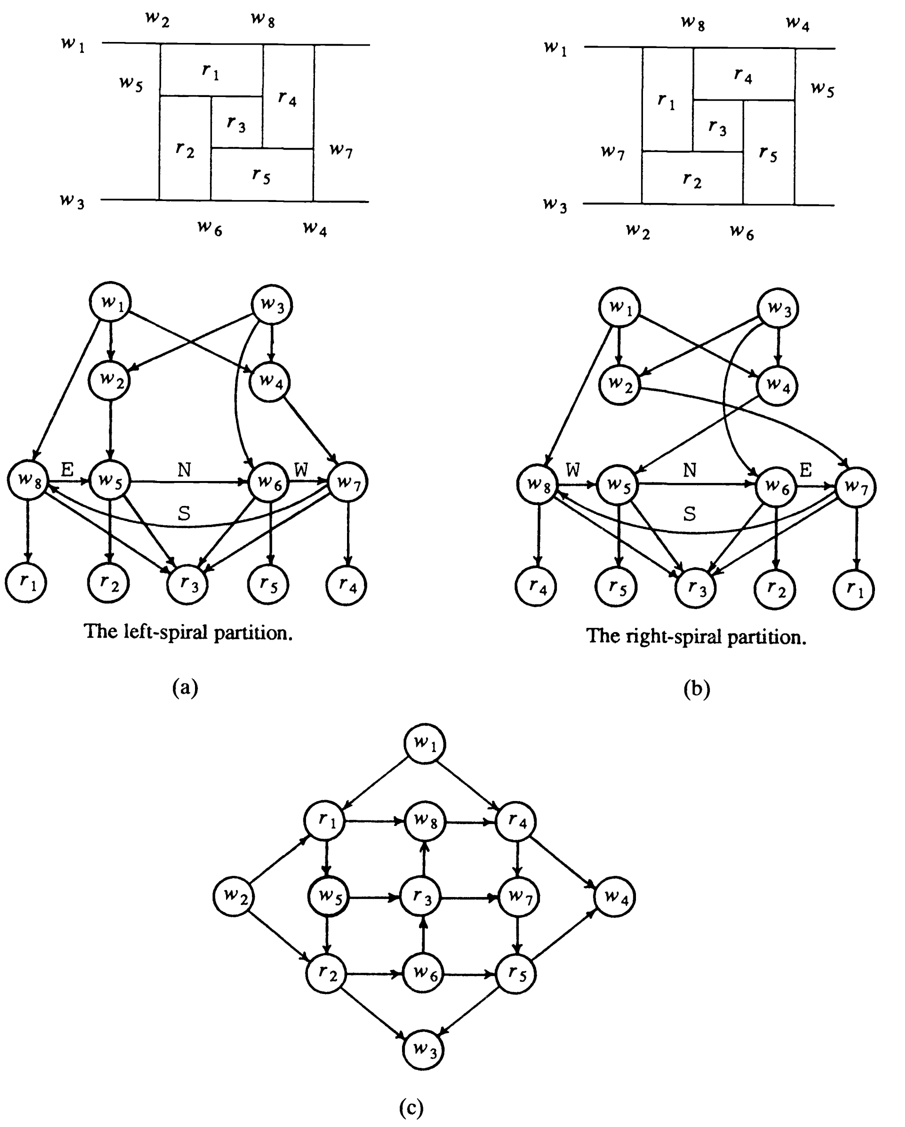

FIG. 3. *Wall graphs G_w for* (a) *left-spiral and* (b) *right-spiral showing only some of the arcs to the region vertices with the exception of r_3;* (c) *acyclic graph of the partial order "<" for the left-spiral partition.*

We say that a wall w_1 *dominates* another wall w_2 if they form a T-junction with w_2 forming the leg of the T. Put another way, if $w_1 = \langle L_{11}, L_{12}\rangle$ and $w_2 = \langle L_{21}, L_{22}\rangle$, then w_1 dominates w_2 if and only if the first members of both L_{21} and L_{22} belong to the second region lists L_{12} of w_1 or the last members of both L_{21} and L_{22} belong to the first region lists L_{11} of w_1. If w_1 is an h-wall and w_2 is a v-wall, then in the first case we say that w_1 dominates w_2 from *above* or *north* and in the second case we say that w_1 dominates w_2 from *below* or *south* (see Figs. 4(a) and (b)). Similarly, if w_1 is a v-wall and w_2 is an h-wall, then in the first case we say that w_1 dominates w_2 from *left* or *west* and in the second case we say that w_1 dominates w_2 from *right* or *east* (see Figs. 4(c) and (d)). We extend the notion of domination to that between a wall and a basic region by saying that the wall $w = \langle L_1, L_2 \rangle$ *dominates* a basic region r_i if $r_i \in L_1$ or L_2, i.e., if w is a boundary wall of r_i. If w is an h-wall, then in the first case we say that w dominates r_i from *below* or *south* and in the second case we say that w dominates r_i from *above* or *north*. The notion of domination of r_i from *left* or *west* (respectively *right* or *east*) by a v-wall is defined similarly. In Fig. 1(a) the basic region r_{10} is dominated by w_{11} from above, by w_3 from below, by w_6 from left, and by w_4 from right.

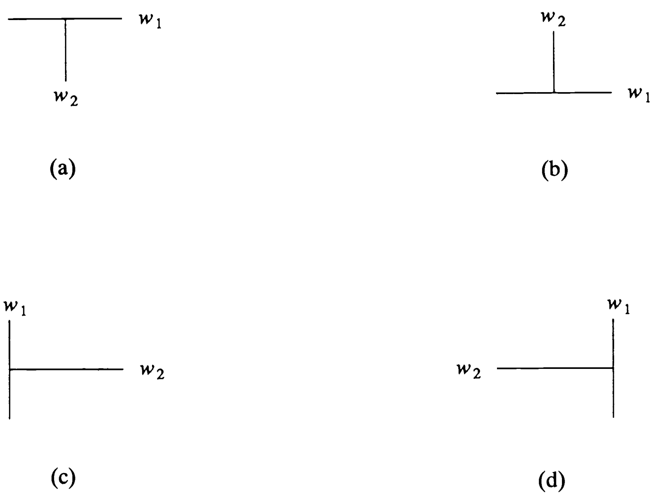

FIG. 4. *The four types of domination relationships between an h-wall and a v-wall:* (a) *the h-wall w_1 dominates the v-wall w_2 from above,* (b) *the h-wall w_1 dominates the v-wall w_2 from below,* (c) *the v-wall w_1 dominates the h-wall w_2 from the left, and* (d) *the v-wall w_1 dominates the h-wall w_2 from the right.*

We represent the domination relationships in a T-plan D as a digraph $G_w(D)$, called the *wall digraph* of D. The digraph $G_w(D)$ contains one node for each wall and basic region of D, and (w_i, w_j) or (w_i, r_j) is an arc of $G_w(D)$ if w_i dominates w_j or w_i dominates r_j. We label each arc (w_i, w_j) and (w_i, r_j) by one of the symbols $\{N, S, W, E\}$ to indicate the direction of domination by w_i. These labels are used primarily for analyzing the spiral partitions, and therefore we often show these labels only for the arcs that join two primary walls of a spiral partition. (We show in Lemma 2 in §3 that these are the only walls that belong to cycles in $G_w(D)$.) A vertex in $G_w(D)$ that corresponds to a wall is called a *wall vertex*, and a vertex that corresponds to a basic region is called a *region vertex*. The wall vertices w_1 and w_3 in $G_w(D)$, corresponding to the external north and south walls, have no incoming arcs and are the only *source nodes* in $G_w(D)$. All other wall vertices in $G_w(D)$, including w_2 and w_4, which correspond to the external west and east walls, have exactly two incoming arcs. Each region vertex r_j in $G_w(D)$ has, on the other hand, four incoming arcs and no outgoing arcs. Figure 5 shows the digraph $G_w(D)$ for the T-plan in Fig. 1(a), where we have shown only some of the arcs to the region vertices r_i, with the exception of r_1 and r_{10} to keep the diagram simple. The wall digraphs for the two spiral partitions are shown in Figs. 3(a) and (b); once again, we show only some of the arcs to the region vertices, with the exception of the central region r_3. Note that the labels of the arcs along the cycle are (N, W, S, E) for the left spiral and (N, E, S, W)

for the right spiral. We use this difference to distinguish a left spiral from a right spiral. If D has n basic regions, then the number of internal walls in D is $n-1$ and hence the digraph $G_w(D)$ has $4+(n-1)+n=2n+3$ nodes and $4+2(n-1)+4n=6n+2$ arcs. If x and y are two nodes in $G_w(D)$, we say that y is *reachable* from x if $y=x$ or there is a (directed) path from x to y.

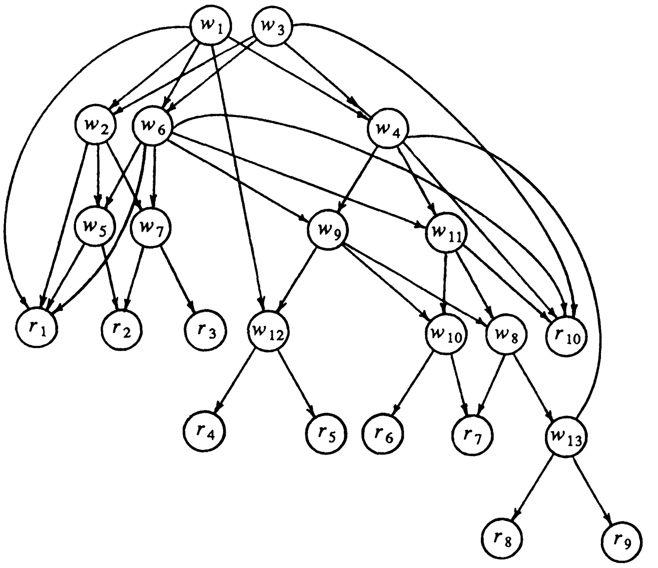

FIG. 5. *The wall graph $G_w(D)$ of the dissection in Fig.* 1(a); *to keep the diagram simple, only some of the arcs to the region vertices r_j, except for r_1 and r_{10}, are shown here.*

If a dissection D is not a T_*-plan, then the digraph $G_w(D)$ may contain cycles with an arbitrarily large number of nodes in it; some examples of such T-plans are given in Fig. 10 and in [4]. It is easy to see that if D is an acyclic T_*-plan and (w_i, w_j) is an arc in $G_w(D)$, then there is a unique subregion R' of R such that w_i is a boundary wall of R' and $w_j \in w_p(R')$; we write $R' = \rho(w_i, w_j)$. In Fig. 1(a) we have $\rho(w_6, w_9) = \{r_4, r_5, \cdots, r_{10}\}$, the subregion consisting of the basic regions $r_4, r_5, \cdots$, and r_{10}; $\rho(w_1, w_{12}) = \{r_4, r_5\}$. For the cyclic T_*-plans in Figs. 3(a) and (b), there is no such R' corresponding to the arc (w_8, w_5).

If w is an h-wall, then let

$$\delta_N(w) = \{x : x \text{ is a } v\text{-wall or a basic region dominated by } w \text{ from north}\},$$

and

$$\delta_S(w) = \{x : x \text{ is a } v\text{-wall or a basic region dominated by } w \text{ from south}\}.$$

For a v-wall w the sets $\delta_W(w)$ and $\delta_E(w)$ are defined similarly. We regard each of the sets $\delta_N(w), \delta_S(w), \delta_W(w)$, and $\delta_E(w)$ as linearly ordered according to "$<$" and refer to them as lists. The items in each list alternate between a wall and a basic region. For an h-wall w the set of nodes adjacent *from* the node w is given by adj$[w] = \{x : (w, x)$ is an arc in $G_w(D)\} = \delta_S(w) \cup \delta_N(w)$, which is a disjoint union. We thus write adj$[w] =$

$\langle \delta_S(w), \delta_N(w)\rangle$. Similarly, for a v-wall w we have adj$[w] = \langle \delta_E(w), \delta_W(w)\rangle$. For each basic region r_j, adj$[r_j] = \oslash$ by the definition of $G_w(D)$. Figure 6(a) shows the adjacency lists adj$[w]$ for the T-plan in Fig. 1(a). We use the notation adj$[w] = \langle \delta_1(w), \delta_2(w)\rangle$, where $\delta_1(w) = \delta_S(w)$ or $\delta_E(w)$ and $\delta_2(w) = \delta_N(w)$ or $\delta_W(w)$, when we do not wish to emphasize whether w is an h-wall or a v-wall. The number of arcs that are incident to a node x in $G_w(D)$ is denoted by indeg$[x]$.

$adj[w_1] = \langle \oslash, (w_2, r_1, w_6, r_4, w_{12}, r_5, w_4)\rangle$
$adj[w_2] = \langle \oslash, (r_1, w_5, r_2, w_7, r_3)\rangle$
$adj[w_3] = \langle (w_2, r_3, w_6, r_{10}, w_4), \oslash\rangle$
$adj[w_4] = \langle (r_5, w_9, r_8, w_{13}, r_9, w_{11}, r_{10}), \oslash\rangle$
$adj[w_5] = \langle (r_1), (r_2)\rangle$
$adj[w_6] = \langle (r_1, w_5, r_2, w_7, r_3), (r_4, w_9, r_6, w_{11}, r_{10})\rangle$
$adj[w_7] = \langle (r_2), (r_3)\rangle$
$adj[w_8] = \langle (r_7), (r_8, w_{13}, r_9)\rangle$
$adj[w_9] = \langle (r_4, w_{12}, r_5), (r_6, w_{10}, r_7, w_8, r_8)\rangle$
$adj[w_{10}] = \langle (r_6), (r_7)\rangle$
$adj[w_{11}] = \langle (r_6, w_{10}, r_7, w_8, r_9), (r_{10})\rangle$
$adj[w_{12}] = \langle (r_4), (r_5)\rangle$
$adj[w_{13}] = \langle (r_8), (r_9)\rangle$

FIG. 6. *Illustration of Algorithm* 1 *for the T-plan in Fig.* 1(a): (a) *adjacency lists adj*$[w]$ *for the wall vertices in the digraph* $G_w(D)$ *for the T-plan in Fig.* 1(a); (b) *formation of successive node groups by Algorithm* 1. *The walls in* (b) *are processed in the order shown in the first column*; *the root node corresponds to the node group* $L = (w_6)$.

If G is an acyclic digraph, then the *transitive reduction* of G is the (unique) minimal digraph $G' \subseteq G$ such that G' and G have the same nodes and there is a path from a node x to a node y in G if and only if there is a path from x to y in G'. If G contains cycles, then there may be more than one distinct minimal subdigraph G' as defined above. However, if no two cycles in G have a node in common, then G' is unique.

The fundamental observation behind the algorithm presented here is that if the top-level partition $\pi(R')$ of a subregion R' is an h or v partition, then the source nodes in the subdigraph $G_I(R') \subset G_w(D)$ on the internal walls and basic regions in R' (excluding the vertices for the boundary walls of R') consist of the primary walls $w_p(R')$ created by the top-level partition operation $\pi(R')$ in R'. The situation is slightly more complex if $\pi(R')$ is a spiral partition. In this case we do not have any source nodes in the subdigraph $G_I(R')$. Instead, we have a "source cycle" formed by the set of walls $w_p(R')$ such that the only arc (w_i, w_j) in $G_I(R')$ to a wall $w_j \in w_p(R')$ is from another wall $w_i \in w_p(R')$. Fortunately, the source cycles in the various $G_I(R')$ are precisely the cycles in $G_w(D)$; moreover, they are easily identified because they are disjoint from each other (see Lemma 2, §3). Identifying the subsets of nodes of the form $w_p(R')$ without constructing the subregions R' themselves is also possible by exploiting certain special properties of the wall digraph $G_w(D)$ that are described in §3.

3. Properties of wall digraph $G_w(D)$. The following lemmas summarize some of the important properties of the digraph $G_w(D)$ for a T_*-plan D. These properties form the basis of the algorithms given in §§4 and 5 for the construction of $t(D)$.

LEMMA 1. *If w_i is a boundary wall of a subregion R', then there is a path from w_i to each internal wall w_j of R'. Also, if w_i is an internal wall of R', then the paths from w_i to other vertices in $G_w(D)$ are limited to only the internal walls and basic regions of R'.*

Proof. The second part of the lemma is immediate from the fact that for any arc (w_i, w_k) from an internal wall $w_i \in w_I(R')$, w_k is necessarily an internal wall of R' and, in particular, w_k is not a boundary wall of R'. If (w_i, r_j) is an arc from the internal wall w_i of R', then r_j is necessarily a basic region of R'.

We prove the first part of the lemma by induction on the number of partition operations $m \geq 1$ applied to R'. If w_j is one of the primary walls in $w_p(R')$ created by the top-level partition operation $\pi(R')$ of R' and $\pi(R') = h$ or v, then either (w_i, w_j) is an arc in $G_w(D)$ or there is another boundary wall w_k of R' such that (w_i, w_k) and $(w_k, w_j) \in G_w(D)$. The latter occurs, for example, if R' is created by an h (respectively, v) partition and $\pi(R') = v$ (respectively, h). On the other hand, if $\pi(R') = s$ or S, then there is a path of length ≤ 4 from w_i to each primary wall $w_j \in w_p(R')$. Thus the lemma is true for $m = 1$. Now suppose that the lemma is true for subregions having fewer than $m \geq 2$ partition operations, and suppose that R' has m partition operations. If $w_j \in w_I(R') - w_p(R')$, then one of the subregions $R'' \subset R'$ created by $\pi(R')$ contains w_j as an internal wall. Let $w' \in w_p(R')$ be a boundary wall of R''. Then w' is reachable from w_i (by the case $m = 1$), and w_j is reachable from w' by the induction hypothesis. Hence there is a path from w_i to w_j. □

COROLLARY 1. *The digraph $G_w(D)$ is connected as an undirected graph.*

Proof. Each vertex in $G_w(D)$ is reachable by an undirected path from the node w_1, say. □

LEMMA 2. *If D is an acyclic T_*-plan, then $G_w(D)$ is an acyclic graph. If D is not acyclic, then each cycle of $G_w(D)$ corresponds to the set of primary walls $w_p(R')$ for some subregion R', where $\pi(R') = s$ or S, and the converse is also true. No two-cycles in $G_w(D)$ have a node in common.*

Proof. Clearly, any cycle of $G_w(D)$ involves only the wall vertices. In view of Lemma 1, if $G_w(D)$ contains a cycle that involves w_i and if w_i is a boundary wall of a subregion R', the cycle must not involve any internal wall of R'. Thus the only way that a cycle may be formed is by the boundary walls of the subregions created by a single partition, i.e., the set of primary walls $w_p(R')$ for some (R'), where $\pi(R') = s$ or S. The converse and disjointness of the cycles are now immediate. □

LEMMA 3. *Let D be an acyclic T_*-plan. If the wall w_i dominates the walls w_j and w_k from two different directions (i.e., below and above or left and right), then there is no wall w' such that there is a path from w_i to w' through w_j and a path from w_i to w' through w_k.*

Proof. Let $R_1 = \rho(w_i, w_j)$ and $R_2 = \rho(w_i, w_k)$. The subregions R_1 and R_2 lie on two different sides of the wall w_i. Since w_j is an internal wall of R_1, it follows from Lemma 1 that a path leading from the arc (w_i, w_j) cannot reach any wall that is not internal to R_1. A similar property holds for the paths leading from the arc (w_i, w_k) and the subregion R_2. This proves the lemma. □

Lemma 3 may not be true, in general, for T_*-plans containing spiral partitions. For instance, in Fig. 7(a) the wall w_{14} dominates the walls w_{17} and w_{19} from two different directions, but $p = (w_{14}, w_{17}, w_{10})$ is a path from w_{14} to w_{10} via the arc (w_{14}, w_{17}) and $p' = (w_{14}, w_{19}, w_{18}, w_5, w_6, w_{17}, w_{10})$ is a path from w_{14} to w_{10} via the arc (w_{14}, w_{19}).

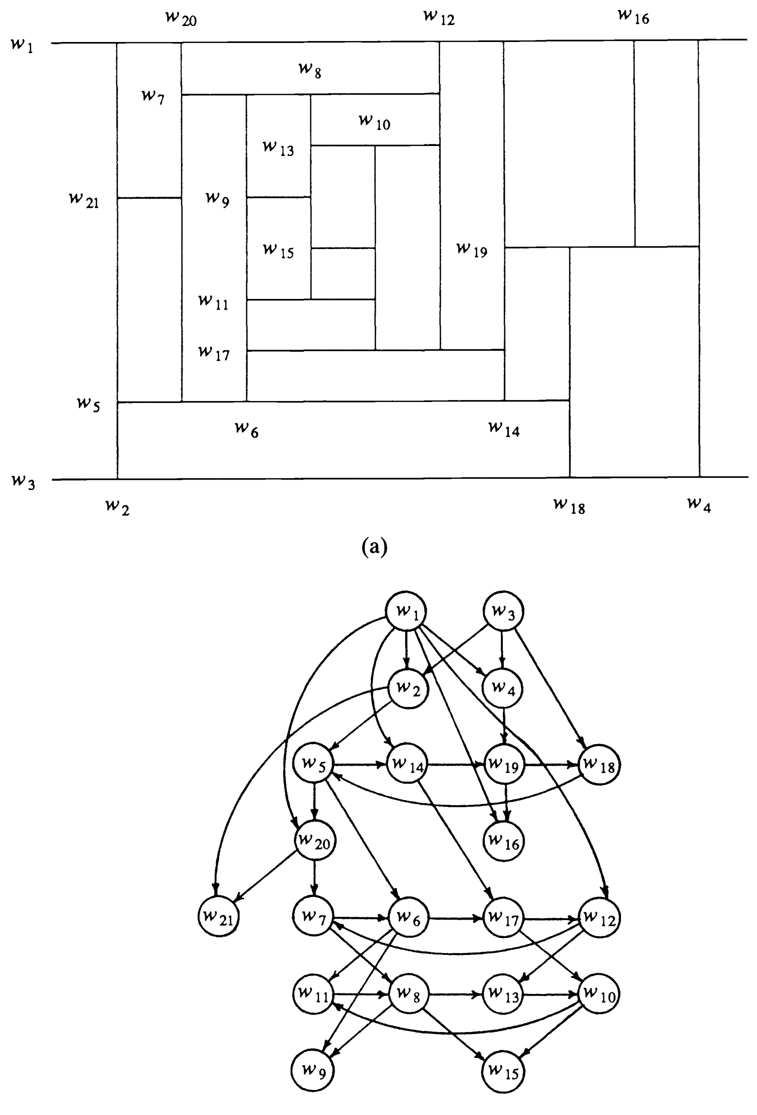

FIG. 7. (a) *A T_*-plan D with nested spiral partitions and its wall digraph $G_w(D)$*; (b) *a part of the digraph $G_w(D)$ for the T_*-plan D in* (a); *only the wall vertices and the arcs among them are shown.*

LEMMA 4. *Let D be an acyclic T_*-plan. Then the arcs in the transitive reduction of $G_w(D)$ are given by the following*:

(1) $(w_1, w_2), (w_1, w_4), (w_3, w_2)$, *and* (w_3, w_4);

(2) $(w_i, w_j) \in G_w(D)$, *where w_i is a boundary h-wall of a subregion R' such that $\pi(R') = v$ and $w_j \in w_p(R')$*;

(3) $(w_i, w_j) \in G_w(D)$, *where w_i is a boundary v-wall of a subregion R' such that $\pi(R') = h$ and $w_j \in w_p(R')$*;

(4) (w_i, r_j), *where $w_i = \langle L_1, L_2\rangle$ and $L_1 = (r_j)$ or $L_2 = (r_j)$.*

Proof. Let $G'(D)$ denotes the transitive reduction of $G_w(D)$. That the arcs in group (1) are the only arcs to w_2 and w_4 in $G'(D)$ is easily verified. Now assume that w_i is an

h-wall and $w_j \in w_p(R')$ as in (2). We need to show that there is no other path from w_i to w_j. If possible, let $p = (w_i, w_k, \cdots, w_j)$ be a path from w_i to w_j. By Lemma 3 w_k must be on the same side of w_i as w_j, and by Lemma 1 w_k must be internal to R'. If $w_k \notin w_p(R')$, then w_k is an internal wall of a subregion $R'' \subset R'$ created by the partition operation $\pi(R')$, and thus the path p cannot reach w_j, which is not internal to R''. Thus $w_k \in w_p(R')$. However, this means that the path p enters a subregion $R'' \subset R'$ following the arc (w_i, w_k) and that w_j is not an internal wall of R''. Once again, the path p cannot continue to w_j. Thus no path $p = (w_i, w_k, \cdots, w_j)$ exists, and hence $(w_i, w_j) \in G'(D)$. The proof for group (3) is similar. On the other hand, if $(w_i, w_j) \in G_w(D), w_j \notin w_p(R')$, and $w_j \neq w_2$ or w_4, then there is a subregion $R'' \subset R'$ such that w_j is an internal wall of R'' and by Lemma 1 there is a wall $w_k \in w_p(R')$ and a path from w_i to w_j via the arc (w_i, w_k). This shows that the only arcs (w_i, w_j) in $G'(D)$ are those in groups (1)–(3).

Finally, consider the arc (w_i, r_j), where $L_1 = (r_j)$ or $L_2 = (r_j)$. Let $(w_i, w_k) \in G_w(D)$. Then r_j and w_k are on two different sides of the wall w_i. If we write $\rho(w_i, w_k) = R''$, then a path leading from the arc (w_i, w_k) cannot reach any basic region that is outside R'' and hence cannot reach r_j. This shows that $(w_i, r_j) \in G'(D)$. On the other hand, if $r_j \in L_1$ and $L_1 \neq (r_j)$, then there is a wall w_j such that both the arcs (w_i, w_j) and (w_j, r_j) belong to $G_w(D)$ and hence $(w_i, r_j) \notin G'(D)$. Similar reasoning applies for the case $r_j \in L_2$ and $L_2 \neq (r_j)$. □

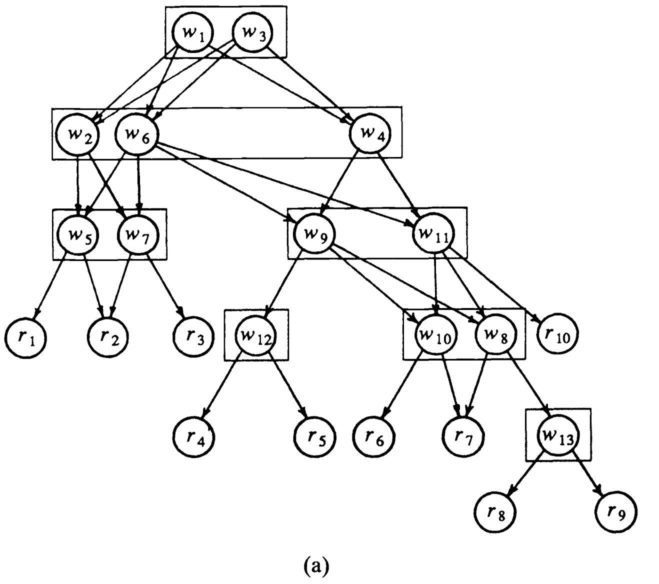
4. Construction of $t(D)$ for an acyclic T_*-plan. The following theorem shows the relationship between $t(D)$ and $G_w(D)$ for an acyclic T_*-plan D and forms the basis of Algorithm 1 for the construction of $t(D)$ from the wall representation $w(D)$.

THEOREM 1. *Let D be an arbitrary acyclic T_*-plan, and let $G_I(D) = G_w(D) - \{w_1, w_2, w_3, w_4\}$ be a subdigraph that shows the domination relationships among the internal walls and basic regions of D. Then the subregion tree $t(D)$ is isomorphic as an unordered tree to the digraph obtained from the transitive reduction of $G_I(D)$ by merging each node group of primary walls $w_p(R')$, where R' is a subregion, into a single node.*

Proof. If D consists of a single basic region, then there is nothing to prove. Suppose that D has two or more basic regions. It is easy to see that the source nodes of $G_I(D)$ are the same as the set of primary walls $w_p(R) = \{w_{j_1}, w_{j_2}, \cdots, w_{j_{k-1}}\}$, say, that are created by the top-level partition operation $\pi(R)$ corresponding to the root node of $t(D)$. By Lemma 1 it follows that the removal of nodes $w_p(R)$ from $G_I(D)$ decomposes $G_I(D)$ into k disconnected components (as an undirected graph), one for each of the subregions $\{R_1, R_2, \cdots, R_k\}$ created by $\pi(R)$. (The wall w_{j_i} may be regarded as the common boundary wall between R_i and R_{i+1}.) The connected component of $G_I(D)$ corresponding to the subregion R_j equals $G_I(R_j), 1 \leq j \leq k$. The theorem now follows by a simple induction argument applied to each R_j. □

Figure 8(a) shows the transitive reduction of the wall digraph $G_w(D)$ for the T-plan in Fig. 1(a); a part of $G_w(D)$ was shown earlier in Fig. 5. Each node group of the form $w_p(R')$ is shown here enclosed in a rectangular box. The node groups $w(R')$ are easily identified successively as follows. Initially, the external walls $\{w_1, w_3\}$ form the source nodes of $G_w(D)$. The nodes $\{w_1, w_3\}$ may be thought of as the primary walls of a hypothetical h-partition of the whole infinite plane (without any boundary lines) creating the three subregions N, S, and the area $R^+ = R \cup W \cup E$ between the walls w_1 and w_3. The removal of $\{w_1, w_3\}$ from $G_w(D)$ (see Fig. 5) gives rise to the source nodes $\{w_2, w_4, w_6\}$, which consist of the external wall $\{w_2, w_4\}$ and the node group $w_6(R) = \{w_6\}$. Here the walls $\{w_2, w_4, w_6\}$ may be thought of as the primary walls of an extended v-partition of R^+ corresponding to $\pi(R) = v$. If $\pi(R)$ were an h-partition, then $\{w_2, w_4\}$ would be the only source nodes in $G_w(D) - \{w_1, w_3\}$ and the source nodes in $G_I(D) =$

$G_w(D) - \{w_1, w_2, w_3, w_4\}$ would equal the set of primary walls $w_p(R)$. Each successive node group is obtained by removing the current node group and taking the source nodes of a connected component of the resulting digraph.[3] Figure 8(b), save the labels h and v for the nonterminal nodes, shows the tree obtained by merging each node group in the transitive reduction of $G_I(D)$ into a distinct single node. This tree is isomorphic to the tree $t(D)$ in Fig. 1(c) as an unordered tree.



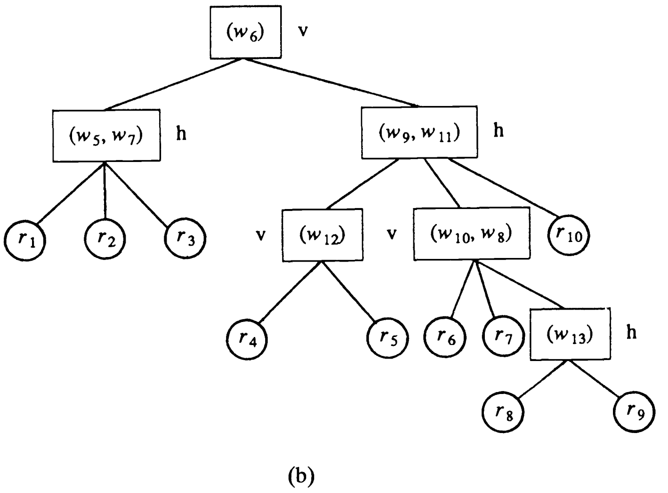


FIG. 8. (a) *The transitive reduction of $G_w(D)$ for the T-plan in Fig.* 1(a); *each node group consists of the primary walls $w_p(R')$ for some subregion R'.* (b) *The result of merging each node group $w_p(R')$ into a single node after deleting the nodes $\{w_1, w_2, w_3, w_4\}$ in the transitive reduction. The tree is identical to the tree in Fig.* 1(c) *except for the h and v labels of the nonterminal nodes.*

[3]The method of forming the successive node groups in this way may be likened to the topological sorting algorithm in [1]. It essentially amounts to computing the transitive reduction of $G_I(D)$ because of the special structure of $G_I(D)$.

To complete the construction of the tree $t(D)$, we now show how to determine the ordering of the children of each node in $t(D)$ by using the ordering "$<$" together with the digraph $G_w(D)$. We argue below the case for the root node only; the same argument holds for all other nodes of $t(D)$ as well. Let $\{R_1, R_2, \cdots, R_k\}$ be the subregions created by $\pi(R)$, in the left-to-right or top-to-bottom order, according to whether $\pi(R) = v$ or h. If w_{j_i} is the wall between subregions R_i and R_{i+1}, then $w_{j_i} < w_{j_2} < \cdots w_{j_{k-1}}$ and $w_p(R) = \{w_{j_1}, w_{j_2}, \cdots, w_{j_{k-1}}\}$. If we disconnect the node w_{j_1} from each node in $\delta_1(w_{j_1}) \subset adj[w_{j_1}]$, then in view of Lemmas 1 and 3 we have that $G_I(R_1)$ becomes isolated as one connected component and the second component consists of the union of $w_p(R)$ and $G_I(R_i), 2 \leq i \leq k$. The component $G_I(R_1)$ is identified as the one that does not contain w_{j_1}. We now complete the deletion of w_{j_1} from $G_I(R)$ by disconnecting w_{j_1} from the remaining nodes $\delta_2(w_{j_1})$ in $adj[w_{j_1}]$ and by removing w_{j_1}. This, however, causes no further decomposition of the second component into two or more components if $k \geq 2$.[4] The process now continues by first disconnecting w_{j_2} from the nodes in $\delta_1(w_{j_2})$ and isolating the component $G_I(R_2)$ as the one that does not contain w_{j_2}. The deletion of w_{j_2} is then completed by disconnecting it from the nodes in $\delta_2(w_{j_2})$ and removing w_{j_2} and so on. The last component remaining after the removal of $w_{j_{k-1}}$ is the component $G_I(R_k)$. This completes the determination of the ordering of the children of the root node, which correspond to the subregions $R_i, 1 \leq i \leq k$. In Algorithm 1 below, we determine only the source nodes in the various components R_i in the order $i = 1, 2, \cdots, k$ instead of determining the whole components R_i. This helps to minimize the computation and keep the overall computation at the level $O(n)$.

Algorithm 1 constructs the subregion tree $t(D)$ for an acyclic T_*-plan D in a top-down, breadth-first fashion by successively identifying the various node groups of the form $w_p(R')$ as described above. It assumes that the linear ordering "$<$" of each of the lists $\delta_1(w_j)$ and $\delta_2(w_j)$ has already been determined. It is from these orderings that we directly obtain the ordering $w_{j_1} < w_{j_2} < \cdots < w_{j_{k-1}}$ of the primary walls $w_p(R')$ in each node group, without having to order the set $w_p(R') = \{w_{j_1}, w_{j_2}, \cdots, w_{j_{k-1}}\}$ separately for each R' after the determination of $w_p(R')$. The advantage of using the orderings of $\delta_1(w_j)$ and $\delta_2(w_j)$ is that they can be determined for all walls w_j by using only $O(n)$ time (see §6). Algorithm 1 uses a queue Q to hold the source-node groups that have been identified but that have not been deleted yet from $G_w(D)$. In terms of the tree $t(D)$, these node groups correspond to the nodes whose children are yet to be determined. (The use of a stack instead of a queue results in constructing the tree $t(D)$ in the depth-first fashion.) Each item in Q is a pair $(p(z), L(z))$, where $p(z)$ is a pointer to the node z in $t(D)$ and $L(z)$ = the node group at z in the order "$<$". The list $L(z)$ consists of either a basic region or the set of primary walls $w_p(R')$ for some subregion R'. The pointer $p(z)$ is used for connecting the children of z to the node z. When an arc (w_i, w_j) is deleted from $G_w(D)$, we label w_j as an h-wall or a v-wall according to whether w_i is a v-wall or an h-wall. Initially, the external north and south walls (w_1 and w_3) are labeled as h-walls. The h–v labels are maintained in an array label$[w_j]$. A node in $t(D)$ is labeled h or v according to whether the walls in that node group are h-walls or v-walls.

[4]To see this, one may argue as follows. If R_2 is a basic region, then it is adjacent from both w_{j_1} and w_{j_2}. On the other hand, if R_2 is not a basic region, then the primary walls $w_p(R_2)$ of R_2 are adjacent from both w_{j_1} and w_{j_2} and all basic regions and internal walls in R_2 can be reached from w_{j_2} via the primary walls $w_p(R_2)$.

ALGORITHM 1

Construction of $t(D)$ from $w(D)$ of an acyclic T_*-plan D.

```
Input:   The set of walls $w(D)$ of an acyclic $T_*$-plan $D$.

Output:  The subregion tree $t(D)$ of $D$.
1. If there are only four walls in $w(D)$, then $D$ consists of a single basic region $r_j$
   and $t(D)$ consists of a single node $r_j$. Otherwise, for each wall $w$ determine the
   adjacency lists in the form adj$[w] = \langle\delta_1(w), \delta_2(w)\rangle$, including the ordering "<"
   in each of the lists $\delta_1(w)$ and $\delta_2(w)$. Let indeg$[w_j] = 2$ for each wall $w_j$ except
   for indeg$[w_1] = 0 =$ indeg$[w_3]$, and let indeg$[r_j] = 4$ for each basic region $r_j$.
   (Here $w_1$ is the external north wall and $w_3$ is the external south wall.)
2. Let $w_2$ and $w_4$ be the external west and east walls, respectively.
3. Remove $w_1$ and $w_3$ from $G_w(D)$, and adjust indeg$[x]$ appropriately for each
   vertex $x$ that is adjacent from one or both of $w_1$ and $w_3$.
4. (Determine the label of the root node of $t(D)$.) Let $L_0 =$ the list of the source
   nodes other than $w_2$ and $w_4$, if any. Remove the nodes $w_2$ and $w_4$, and adjust
   indeg$[x]$ for all vertices that are adjacent to one or both of $w_2$ and $w_4$. Perform
   step (a) or (b) as appropriate.
   (a) If $L_0 \neq \oslash$, then the label of the root node of $t(D)$ is $v$. In this case $L_0 \subset$
       $\delta_2(w_1)$; assume that $L_0$ is ordered according to $\delta_2(w_1)$.
   (b) If $L_0 = \oslash$, then the label of the root node of $t(D)$ is $h$; let $L_0 =$ the set of
       new source nodes after removal of $w_2$ and $w_4$. In this case $L_0 \subset \delta_2(w_2)$;
       assume that $L_0$ is ordered according to $\delta_2(w_2)$.
5. Create the root node $z$ of $t(D)$ with the associated node group $L(z) = L_0$.
   Initialize the queue $Q$ with the item $(p(z), L(z))$, where $p(z)$ is a pointer to the
   node $z$.
6. While $Q$ is nonempty do (a) and (b):
   (a) Remove the first item $(p(z), L(z))$ from $Q$.
   (b) Process each wall $w \in L(z)$ according to the order "<" in $L(z)$ as follows,
       where adj$[w] = \langle\delta_1(w), \delta_2(w)\rangle$.
       (i) For each $x \in \delta_1(w)$ reduce indeg$[x]$ by one. Let $L \subseteq \delta_1(w)$ be the list
           of new source vertices in the order as in $\delta_1(w)$.
       (ii) If $L \neq \oslash$, then create a new node $z'$ in the tree $t(D)$ with the associated
           node group $L(z') = L$; make $z'$ the current rightmost child of the node
           $z$ using the pointer $p(z)$. If $L$ is not a single basic region, then add the
           item $(p(z'), L(z'))$ to the end of $Q$ and let label$[z']$ be the same as the
           labels of the nodes in $L$ (all nodes in $L$ have the same label, $v$ or $h$).
       (iii) Repeat steps (i) and (ii) using $\delta_2(w)$ in place of $\delta_1(w)$. (In this case $L$
           is empty except when $w$ is the last item in $L(z)$; in processing $\delta_1(w)$, $L$
           is always nonempty.)
```

Fig. 6(b) illustrates Algorithm 1 and shows the various node groups L formed for the set of walls in Fig. 1(b). The final tree obtained by the algorithm is the same as that in Fig. 1(c).

5. Construction of $t(D)$ for an arbitrary T_*-plan. Suppose now that the T_*-plan D contains one or more spiral partitions. As we noted in §2, if the partition operation $\pi(R') = s$ or S, then the digraph $G_I(R') \subset G_w(D)$ on the internal walls and basic regions of R' does not contain a source node because the primary walls $w_p(R')$ form a cycle C. By Lemma 1, cycle C has the distinguishing property that no internal wall in

$w_I(R')$ dominates a wall in C. In this sense we may say that cycle C is a "source cycle" in $G_I(R')$. We determine all cycles in $G_w(D)$ by a single depth-first traversal [1] of $G_w(D)$ starting at the external north wall w_1, say. Since the region vertices have no outgoing arcs, it suffices to traverse only the arcs to wall vertices. Also, because the cycles are disjoint (Lemma 2), each cycle is formed by a back arc (w_i, w_j) and the path from w_j to w_i in the depth-first tree. We assume that the arcs (w_i, w_j) from a wall vertex w_i are processed in the depth-first search first for $w_j \in \delta_1(w_i)$ and then for $w_j \in \delta_2(w_i)$, in both cases following the ordering "$<$" in the lists $\delta_1(w_i)$ and $\delta_2(w_i)$. Figure 9(a) shows the depth-first tree for the wall digraph of the T_*-plan D in Fig. 7(a) which contains three spiral partitions, three h-partitions, and two v-partitions. Here, one of the spiral partitions is nested inside another one and the third spiral partition is disjoint from the first two. The three cycles corresponding to the spiral partitions are given by

$$\begin{aligned} C_1 &= (w_{19}, w_{18}, w_5, w_{14}), && \text{a right spiral,} \\ C_2 &= (w_7, w_6, w_{17}, w_{12}), && \text{a left spiral,} \\ C_3 &= (w_{13}, w_{10}, w_{11}, w_8), && \text{a right spiral.} \end{aligned}$$

The following theorem (similar to Theorem 1) is now easily proved by using the lemmas in §2 and is stated here without proof. Note that the special properties of $G_w(D)$, including the disjointness of its cycles, imply that the transitive reduction of $G_I(D) = G_w(D) - \{w_1, w_2, w_3, w_4\}$ is uniquely defined.

THEOREM 2. *Let D be an arbitrary T_*-plan acyclic or not. Then the subregion tree $t(D)$ is isomorphic as an unordered tree to the digraph obtained from the transitive reduction of $G_I(D) = G_w(D) - \{w_1, w_2, w_3, w_4\}$ by merging each node group $w_p(R')$, where R' is a subregion, into a single node.*

We are now ready to present Algorithm 2 for constructing the tree $t(D)$ from $w(D)$ for a general T_*-plan D that may contain one or more spiral partitions. We regard a cycle C_j as a *composite* vertex consisting of the vertices $w_i \in C_j$. For each cycle C_j we define indeg$[C_j] = 4$, which is simply the number of arcs from nodes not in C_j to the nodes in C_j. We augment the array indeg$[x]$ for the wall and region vertices x in $G_w(D)$ by adding an entry indeg$[C_j]$ for each cycle C_j in $G_w(D)$. When an arc $(w_i, w_k), w_i \notin C_j$ and $w_k \in C_j$, is deleted from $G_w(D)$, we reduce indeg$[C_j]$ by one; we say the cycle C_j is adjacent from w_i. The test $w_k \in C_j$ is performed by using an additional array cycle$[w_k]$, which gives for each wall vertex w_k the unique cycle in $G_w(D)$ containing w_k, if any (if w_k does not belong to any cycle, then we let cycle$[w_k]$ = nil). We assume that each cycle C_j is written in the *standardized* form, which is defined to be $C_j = (w_a, w_b, w_c, w_d)$, where the vertices are listed in the cyclic order and the wall vertex w_a dominates w_b from north. We define label$(C_j) = s$ or S according to whether the labels of the arcs along the cycle are (N, W, S, E) or (N, E, S, W). As in Algorithm 1, on processing an arc (w_i, w_j) we identify the wall w_j as an h-wall or a v-wall according to whether w_i is a v-wall or an h-wall.

The main difference between Algorithm 1 and Algorithm 2 lies in the processing of the vertices in a source cycle C. The processing of C [i.e., the deletion of the nodes in C from $G_w(D)$] generates five separate node lists $L_k, 1 \leq k \leq 5$, corresponding to the five regions formed by the associated spiral partition. If x is a cycle, then the test "$x < w_j$" in steps 6(c)(i) and (ii) is considered to be true if a vertex w_i belonging to the cycle x satisfies $w_i < w_j$ (in which case $w_i < w_j$ holds for all vertices w_i in the cycle x).

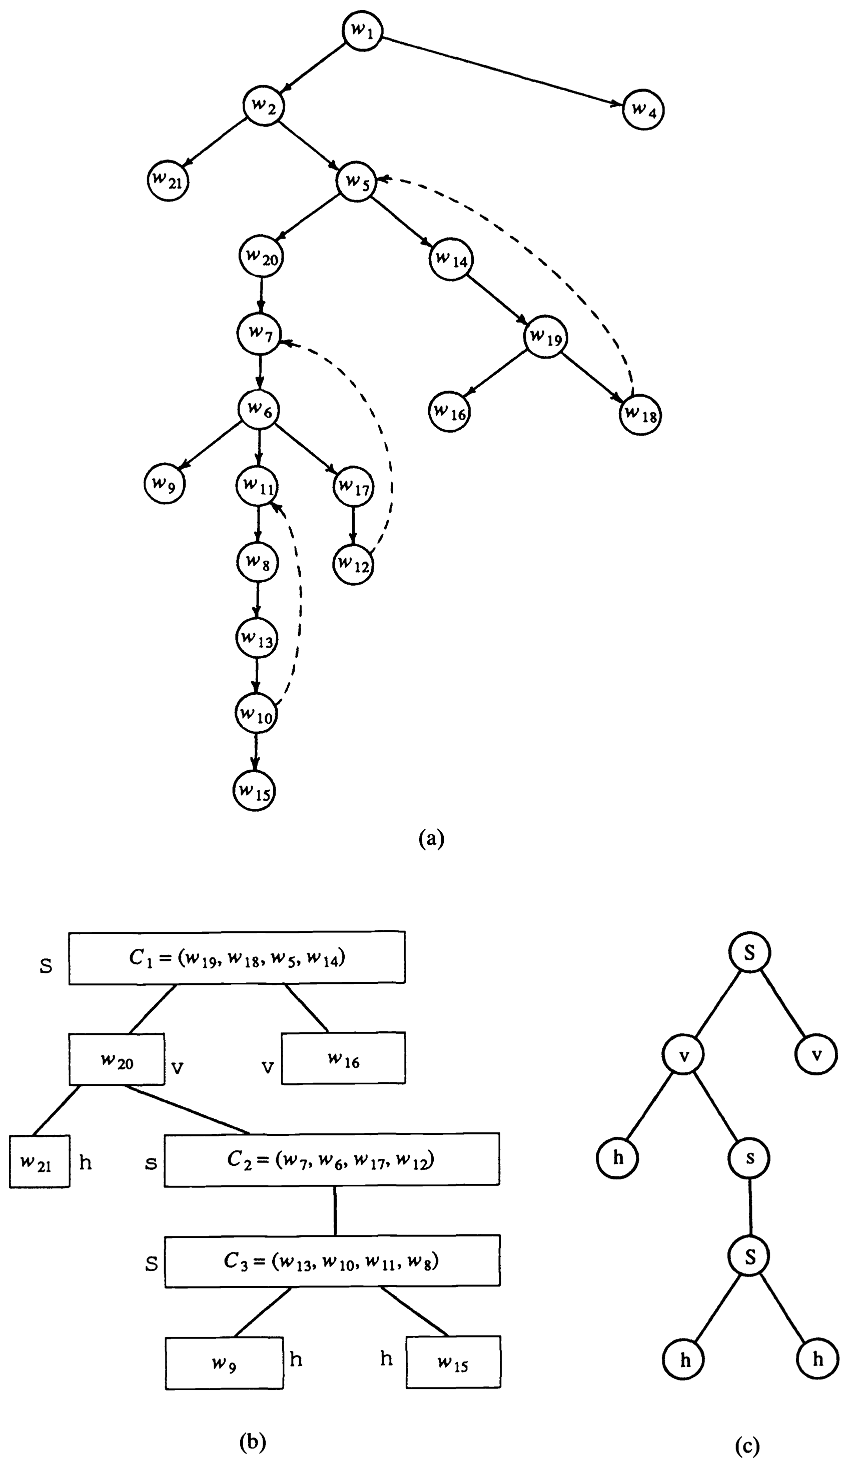

FIG. 9. *Illustration of Algorithm 2 for the T_*-plan in Fig.* 7(a): (a) *Depth-first traversal of the wall vertices of $G_w(D)$ shown in Fig.* 7(b) *with the back arcs shown in broken lines and vertex w_3 not visited*; (b) *node groups L constructed by Algorithm* 2 *corresponding to the nonterminal nodes of $t(D)$ and the arcs among them in the transitive reduction*; (c) *nonterminal nodes in the tree $t(D)$*.

ALGORITHM 2

Determination of $t(D)$ from $w(D)$ for an arbitrary T_*-plan D.

Input: The set of walls $w(D)$ of an arbitrary T_*-plan D, which may contain spiral partitions.

Output: The subregion tree $t(D)$ of D.

1. If there are only four walls in $w(D)$, then $t(D)$ consists of a single node $r_j = D$. Otherwise, for each wall w determine the adjacency lists in the form adj$[w] = \langle\delta_1(w), \delta_2(w)\rangle$, including the ordering "$<$" in each of the lists $\delta_1(w)$ and $\delta_2(w)$. Let indeg$[w_j] = 2$ for each wall w_j except for indeg$[w_1] = 0 =$ indeg$[w_3]$, and let indeg$[r_j] = 4$ for each basic region r_j.
2. Let w_1, w_2, w_3, and w_4 be the external north, west, south, and east walls, respectively. Determine the cycles C in $G_w(D)$ by a depth-first traversal starting from the node w_1. Let indeg$[C] = 4$ for each cycle, and compute the array cycle$[w_j]$ by scanning each cycle C once.
3. Remove w_1 and w_3 from $G_w(D)$, and adjust indeg$[x]$ for all vertices and cycles x that are adjacent from one or both of w_1 and w_3.
4. (Determine the label of the root node of $t(D)$.) Let $L_0 =$ the list of the source nodes other than w_2 and w_4, if any. Remove the nodes w_2 and w_4, and adjust indeg$[x]$ for all vertices and cycles x. Perform one of the steps (a)–(c) as appropriate.
   (a) If $L_0 \neq \oslash$, then the label of the root node of $t(D)$ is v. In this case $L_0 \subset \delta_2(w_1)$; assume that L_0 is ordered according to $\delta_2(w_1)$.
   (b) If $L_0 = \oslash$ and there is a wall w_i that is a source node (after removal of w_2 and w_4), then the label of the root node of $t(D)$ is h; let $L_0 =$ the set of source nodes after removal of w_2 and w_4. In this case $L_0 \subset \delta_2(w_2)$; assume that L_0 is ordered according to $\delta_2(w_2)$.
   (c) Otherwise, there is a unique source cycle $C = (w_{j_1}, w_{j_2}, w_{j_3}, w_{j_4})$, in the standard notation, with indeg$[C] = 0$. Let $L_0 = C$, and let the label of the root node of $t(D)$ be label(C).
5. Create the root node z of $t(D)$ with the associated node group $L(z) = L_0$. Initialize the queue Q with the item $(p(z), L(z))$, where $p(z)$ is a pointer to the node z.
6. While Q is nonempty do (a) and (b) or (a) and (c) as appropriate:
   (a) Remove the first item $(p(z), L(z))$ from Q.
   (b) If $L(z)$ is not the vertices of a cycle or, equivalently, if it contains only h-walls or only v-walls, then process each wall $w \in L(z)$ according to the order "$<$" by (i)–(iii), where adj$[w] = \langle\delta_1(w), \delta_2(w)\rangle$.
      (i) For each $x \in \delta_1(w)$ reduce indeg$[x]$ by one and reduce indeg$[C]$ by one, where $C =$ cycle$[x]$, if any. Let L be the new source cycle, if any, or let $L \subseteq \delta_1(w)$ be the list of new source vertices in the order as in $\delta_1(w)$.
      (ii) If $L \neq \oslash$, then create a new node z' in the tree with the associated node group $L(z') = L$; make z' the current rightmost child of the node z using the pointer $p(z)$. If L is not a basic region, then add the item $(p(z'), L(z'))$ to the end of Q and let label$[z'] =$ label(L) if L consists of a cycle; otherwise, let label$[z']$ be the same as the labels of the nodes in L (all nodes in L have the same label, h or v).

(iii) Repeat steps (i)–(ii) using $\delta_2(w)$ in place of $\delta_2(w)$. (In this case L is empty except when w is the last item in $L(z)$; in processing $\delta_1(w)$, L is always nonempty.)

(c) If $L(z) = (w_{j_1}, w_{j_2}, w_{j_3}, w_{j_4})$ is a cycle, then process the lists $\delta_1(w_{j_i})$, and $\delta_2(w_{j_i}), 1 \leq i \leq 4$, in the order "<" as shown in the table below. The processing of $\delta_1(w_{j_i})$ or $\delta_2(w_{j_i})$ means that for each x in that list, indeg[x] and indeg[C], where C = cycle[x] $\neq$ nil, are reduced by one. Moreover, if the indegree of a node or a cycle becomes zero after it is reduced by one, then that node or the nodes of that cycle are added to one of the lists $L_k, 1 \leq k \leq 5$. This is indicated in the table by "$x \rightarrow L_k$". The lists L_k are initially assumed to be empty. The final result of this step are the five lists $L_k, 1 \leq k \leq 5$. (See Fig. 3(a) with the walls w_5, w_6, w_7, and w_8 regarded as $w_{j_1}, w_{j_2}, w_{j_3}$, and w_{j_4}, respectively.) Now, create five child nodes $z_k, 1 \leq k \leq 5$, of the node z in the tree in that order, with the associated node groups $L(z_k) = L_k$. For each $L(z_k)$ that is not a basic region add to Q the item $(p(z_k), L(z_k))$, where $p(z_k)$ is a pointer to the node z_k.

(i)	The case label[z] = s	(ii)	The case label[z] = S
$\delta_1(w_{j_1})$:	$x \rightarrow L_1$	$\delta_1(w_{j_1})$:	$x \rightarrow L_4$
$\delta_2(w_{j_1})$:	if $x < w_{j_2}$ then $x \rightarrow L_2$	$\delta_2(w_{j_1})$:	if $x < w_{j_2}$ then $x \rightarrow L_3$
	else $x \rightarrow L_3$		else $x \rightarrow L_5$
$\delta_1(w_{j_2})$:	$x \rightarrow L_2$	$\delta_1(w_{j_2})$:	if $x < w_{j_3}$ then $x \rightarrow L_3$
$\delta_2(w_{j_2})$:	if $x < w_{j_3}$ then $x \rightarrow L_3$		else $x \rightarrow L_2$
	else $x \rightarrow L_5$	$\delta_2(w_{j_2})$:	$x \rightarrow L_5$
$\delta_1(w_{j_3})$:	if $x < w_{j_4}$ then $x \rightarrow L_3$	$\delta_1(w_{j_3})$	if $x < w_{j_4}$ then $x \rightarrow L_1$
	else $x \rightarrow L_4$		else $x \rightarrow L_3$
$\delta_2(w_{j_3})$:	$x \rightarrow L_5$	$\delta_2(w_{j_3})$:	$x \rightarrow L_2$
$\delta_1(w_{j_4})$:	if $x < w_{j_1}$ then $x \rightarrow L_1$	$\delta_1(w_{j_4})$:	$x \rightarrow L_1$
	else $x \rightarrow L_3$	$\delta_2(w_{j_4})$:	if $x < w_{j_1}$ then $x \rightarrow L_4$
$\delta_2(w_{j_4})$:	$x \rightarrow L_4$		else $x \rightarrow L_3$

Figures 9(b) and (c) show the results of applying Algorithm 2 to the set of walls for the T_*-plan in Fig. 7(a). We show only the various node groups formed by Algorithm 2 corresponding to $w_p(R')$ and the cycles in the wall digraph, i.e., the nonterminal nodes of the tree $t(D)$.

6. Complexity analysis. Let n be the number of basic regions in the T_*-plan D. To argue that the time complexity of both Algorithms 1 and 2 are $O(n)$, it suffices to show that for all walls $w_j \in w(D)$ the lists $\delta_1(w_j)$ and $\delta_2(w_j)$ together with their linear ordering "<" can be determined in time $O(n)$. As for the other computations, we note that the total number of of arcs in $G_w(D)$ is $O(n)$ and the various processings of each arc (for the depth-first traversal, updates to indeg[x] for the vertices and cycles x and computation of label[w_j] for the walls) take at most a constant time c, for some c. Also, the number of cycles in $G_w(D)$ is at most $n/4$. This shows that the total time required by each algorithm is $O(n)$.

We determine the ordered lists $\delta_1(w_j)$ and $\delta_2(w_j)$ for all w_j in time $O(n)$ as follows. For each basic and external region x_i let first[x_i] denote the list of walls $w_j = \langle L_1, L_2 \rangle$, in some order, such that x_i is the first member of L_1 or L_2. We define the lists last[x_i] similarly. Each of the lists first[x_i] and last[x_i] has at most four items. The lists first[x_i] and last[x_i] can be constructed by a simple scan of L_1 and L_2 for each wall $w_j \in w(D)$ and by noting the first and last items in L_1 and L_2. The time required for this is proportional to the sum of lengths of all the lists L_1 and L_2 for $w_j \in w(D)$, which equals $4n + 8$ ($8 =$ the number of times the external regions N, S, W, and E appear in the various L_1 and L_2). Table 1 shows first$[x_i]$ and last$[x_i]$ for the walls in Fig. 1(b) when the walls are processed in the order $w_1, w_2, \cdots, w_{13}$.

TABLE 1
The lists first$[x]$ *and last*$[x]$ *corresponding to the walls in Fig.* 1(b).

x	first$[x]$	last$[x]$
N	(w_1)	(w_1)
S	(w_3)	(w_3)
W	(w_1, w_2, w_3)	(w_2)
E	(w_4)	(w_1, w_3, w_4)
r_1	(w_2, w_5, w_6)	(w_5)
r_2	(w_5, w_7)	(w_5, w_7)
r_3	(w_7)	(w_2, w_6, w_7)
r_4	(w_6, w_9, w_{12})	(w_{12})
r_5	(w_4, w_{12})	(w_9, w_{12})
r_6	(w_9, w_{10}, w_{11})	(w_{10})
r_7	(w_8, w_{10})	(w_8, w_{10})
r_8	(w_8, w_{13})	(w_9, w_{13})
r_9	(w_{13})	(w_8, w_{11}, w_{13})
r_{10}	(w_{11})	(w_4, w_6, w_{11})

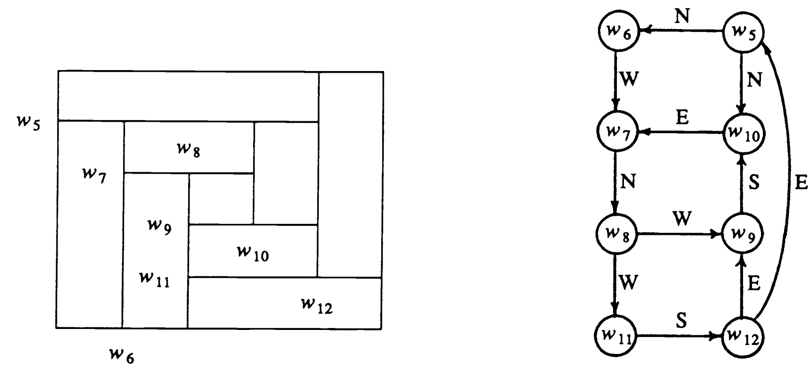
If $w_j = \langle L_1, L_2 \rangle$, then we construct the ordered list $\delta_1(w_j)$ by scanning L_1 in left-to-right order as follows. Let $L_1 = (x_1, x_2, x_3, \cdots, x_k)$ and $w_{j_i} =$ last$[x_i] \cap$ last$[x_{i+1}], 1 \leq i \leq k - 1$. Then $\delta_1(w_j) = (x_1, w_{j_1}, x_2, w_{j_2}, \cdots, w_{j_{k-1}}, x_k)$, except that we may have to remove one or both of x_1 and x_k, whichever equals an external region. The ordered list $\delta_2(w_j)$ is constructed similarly by using the list L_2 and the lists first$[x_i]$. For example, to compute $\delta_2(w_1)$ for the T_*-plan in Fig. 1(a), we start with the second list $L_2 = (W, r_1, r_4, r_5, E)$ for w_1 in Fig. 1(b) and this gives

$$(W, \text{first}[W] \cap \text{first}[r_1], r_1, \text{first}[r_1] \cap \text{first}[r_4], r_4, \text{first}[r_4] \cap \text{first}[r_5], r_5, \text{first}[r_5] \cap \text{first}[E], E)$$
$$= (W, w_2, r_1, w_6, r_4, w_{12}, r_5, w_4, E)$$

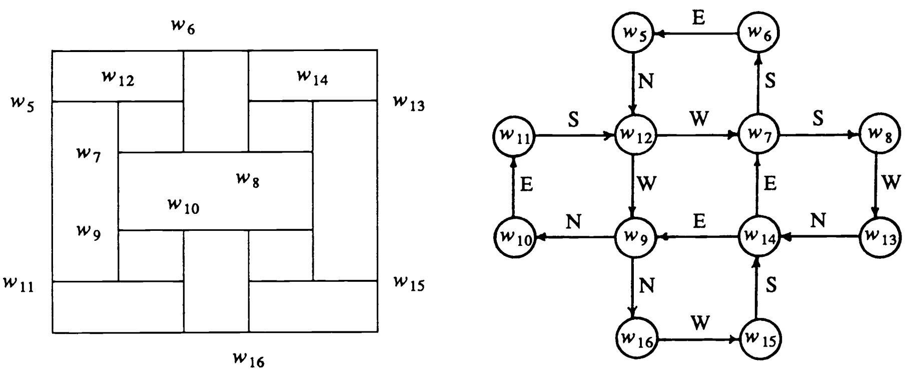
from Table 1. By removing the external regions W and E from this list, we get $\delta_2(w_1) = (w_2, r_1, w_6, r_4, w_{12}, r_5, w_4)$.

THEOREM 3. *The time complexity of each of Algorithms* 1 *and* 2 *is* $O(n)$, *where* $n =$ *number of basic regions in the* T_**-plan* D.

7. Generalization to arbitrary partitioning operators. The technique described in §§4 and 5 for the construction of the subregion tree $t(D)$ from $w(D)$ actually applies to more general classes of T-plans, namely, those generated by a finite family Π of partitioning operators that satisfy some natural conditions. If $\pi \in \Pi$ is an arbitrary partitioning operator, let D_π denote the dissection obtained by a single application of π and let $G_0(\pi) \subset G_I(D\pi)$ denote the subdigraph on the internal walls of D_π, excluding the region vertices. An operator $\pi, \pi \neq h$ or v, is called *primitive* if D_π contains no proper subregion other than a basic region. This is the same as saying that D_π cannot be obtained by combining two or more applications of other partitioning operators (in Π or otherwise). The spiral partitions are examples of primitive partitioning operators. Figures 10(a) and 10(b) show two other primitive partitioning operations $\Sigma =$ the double left spiral and $\Omega =$ the weave partition; also shown are the digraphs $G_0(\Sigma)$ and $G_0(\Omega)$.



(a)



(b)

FIG. 10. *Examples of primitive partition operations that cannot be generated by* $\{h, v, s, S\}$ *partition operations. The internal h-walls are labeled as* w_{2i-1}, *and the v-walls are labeled as* $w_{2i}, i \geq 1$: (a) *double-left-spiral partitioning operation* Σ *and its wall graph* $G_0(\Sigma)$ *on the internal walls*; (b) *weave-pattern partitioning operation* Ω *and its wall graph* $G_0(\Omega)$ *on the internal walls.*

A digraph G is called *strongly* connected if there is a directed path from each vertex to every other vertex in G. If G is not strongly connected, then a maximal strongly connected subdigraph of G is called a *strong component*. The strong components form a disjoint partition of the nodes of G. If we merge each strong component of G to a distinct vertex, then the result is an acyclic digraph. A strong component of G that corresponds to a source node in that acyclic digraph is called *source component*.

LEMMA 5. *If* $\pi \neq h$ *or* v *is a primitive partition operator, then the digraph* $G_0(\pi)$ *is strongly connected and has at least four vertices.*

Proof. Let $\{w_1, w_2, w_3, w_4\}$ be the external walls of the dissection D_π, and let C be a source component of $G_0(\pi)$. We claim that the walls in C form the internal walls of a dissection of the rectangular space R of D_π. The only way that this may be false is if there is a wall $w_j \in C$ that is dominated by a wall $w_i \in G_0(\pi) - C$. However, because C is a source component, there cannot be any w_i in $G_0(\pi) - C$ that dominates a wall $w_j \in C$. Thus the walls in C define a dissection, and hence must have $C = G_0(\pi)$ because otherwise one of the subregions of the dissection defined by C is partitioned by one or more of the remaining walls in $G_0(\pi) - C$, which contradicts that π is primitive.

Now if $C = \{w_j\}$ consists of a single wall, then $\pi = h$ or v according to whether w_j is an h-wall or a v-wall, and this is a contradiction. Finally, to show that C has at least four vertices, we simply note that $G_0(\pi)$ is a bipartite graph with each arc joining an h-wall and a v-wall. (The number of nodes in $G_0(\pi)$ may be odd or even. In Fig. 10(a) if we delete the h-wall w_9 and extend the v-wall w_{10} downward to meet with the h-wall w_{11}, then we get a variant Σ' of the double-left spiral partition, which is primitive, and there are seven nodes in $G_0(\Sigma')$.) □

For the techniques used in Algorithm 2 to work correctly for a general class of T-plans, which are obtained by the partition operators Π, we must assume that conditions (1) and (2) below hold. Condition (1) is a global property of the family Π as it relates different members of Π. Condition (2), on the other hand, constrains each individual member of Π separately. The family of operators $\Pi_0 = \{h, v, s, S\}$ for generating the T_*-plans clearly satisfies conditions (1) and (2); the same is true for the family $\Pi' = \{h, v, s, S, \Sigma, \Omega\}$.

(1) No two digraphs in the family $\{G_0(\pi) : \pi \in \Pi \text{ and } \pi \neq h, v\}$ are isomorphic as labeled digraphs (where each arc is labeled appropriately by one of the symbols in $\{N, S, W, E\}$).

(2) There is no nontrivial isomorphism of $G_0(\pi)$ to itself as a labeled digraph if $\pi \neq h$ or v.

Note that although both $G_0(\Sigma)$ and $G_0(\Omega)$ contain as a subdigraph an isomorphic copy of $G_0(s)$, this does not cause any problem in recognizing whether a particular occurrence of the subdigraph $G_0(s)$ in a wall digraph $G_w(D)$ is due to an s-partition or is due to one of the partition operators Σ and Ω. The former is the case if and only if that subdigraph $G_0(s)$ is a strong component of $G_w(D)$.

The main reason that Algorithm 2 can be extended to the general class of T-plans obtained by partition operations Π without increasing the time complexity $O(n)$ is that one can determine the strong components of the wall digraph $G_w(D)$ in time $O(n)$ [1]. As for the correctness of such an algorithm, we only need to note that Lemma 1 remains valid for the general T-plans in view of the strong-connectedness property of $G_0(\pi)$ shown in Lemma 5. This also means that Theorem 2 remains valid for the general T-plans. The role of the source cycles in Algorithm 2 is now replaced by the more general notion of source components. The details of the modification of step 6(c) in Algorithm 2 will depend on the specific partitioning operators in Π. For example, if $\pi =$ the double left spiral, then there will be nine lists L_k obtained in step 6(c).

We conclude the paper with two conjectures: (i) If π and π' are two primitive partitioning operators other than h and v, then $G_0(\pi)$ and $G_0(\pi')$ are not isomorphic as labeled digraphs. (ii) If $\pi \neq h$ or v is a primitive partition operator, then there is no nontrivial isomorphism from $G_0(\pi)$ to itself as labeled digraph. We assume here that two partitioning operators that have the same wall representation are not distinguished. For example, if the h-wall w_{13} in Fig. 10(b) is moved slightly up or down in relation to the h-wall w_5, then we do not consider the result to be a partitioning operator different from Ω. However, if we rotate the dissections in Fig. 10 by 90 degrees, then the corresponding partition operators are considered to be distinct from Σ and Ω. The h-walls now correspond to the original v-walls and vice versa. In particular, the wall representations of the new T-plans can be distinguished from those of Σ and Ω if we consider both the internal walls and the external walls (and only then). Also, the digraphs $G_0(\Sigma)$ and $G_0(\Omega)$ are distinguished from those of the new partition operators by the arc labels.

Acknowledgment. The author gratefully acknowledges the comments of the anonymous referees, which greatly helped in improving the presentation.

TALLY VERSIONS OF THE SAVITCH AND IMMERMAN–SZELEPCSÉNYI THEOREMS FOR SUBLOGARITHMIC SPACE*

VILIAM GEFFERT†

Abstract. It is shown that for each $s(n)$-space-bounded nondeterministic Turing machine recognizing a language $L \subseteq 1^*$ there exists an equivalent deterministic $O(s^2(n))$-space-bounded machine, and also a nondeterministic $O(s(n))$-space-bounded machine recognizing the complement of L, for any $s(n)$, independent of whether $s(n)$ is below $\log(n)$ or is space constructible. In other words, the Savitch [*J. Comput. System Sci.*, 4(1970), pp. 177–192] and Immerman–Szelepcsényi [*SIAM J. Comput.*, 17(1988), pp. 935–938], [*Acta Inform.*, 26(1988), pp. 279–284] theorems can be extended to any space bound $s(n)$ for languages over a single-letter alphabet.

Key words. space bounded computation, nondeterministic Turing machine, nondeterministic space, tally sets

AMS(MOS) subject classifications. 68Q15, 68Q75, 68Q05

1. Introduction.

Two of the most important results in space-bounded complexity theory, Savitch's simulation of nondeterministic space-bounded Turing machines by deterministic space-bounded machines [4] and the Immerman–Szelepcsényi proof that nondeterministic space is closed under complement [3], [6], were proved for only space bounds $s(n) \geq \log(n)$. If these facts are taken into consideration, the question of whether these two results can be extended to sublogarithmic-space bounds naturally arises. Although we do not give a complete answer, we show that for tally sets, i.e., for languages over a single-letter alphabet, the Savitch and Immerman–Szelepcsényi theorems are valid for any space bound $s(n)$, independent of whether $s(n)$ is below $\log(n)$ or is space constructible.

In fact, these two theorems are also valid for languages over the binary-tape alphabet with low information content, e.g., if there exists a constant d such that each word in L of length n contains at most $d^{s(n)}$ zeros.

The situation is much more complicated for space-complexity classes below $\log(n)$ than for those above, because we do not have enough space to count the number of reachable configurations or the length of a computation path and hence we cannot use the deterministic simulation [4] or the inductive counting method [3], [6] directly. Moreover, each machine using less than $\log(n)$ space is physically incapable of verifying that it has returned to the same input-tape position after moving its input-tape head too far, because it does not have enough space to remember a position of the input-tape head.

We shall begin in §2 by showing that the result of any computation on tally input is completely determined by the machine's behavior near the input-tape end markers. For the detailed proofs of the lemmas presented in §2 the reader is referred to [2]. Section 3 deals with the closure under complement. The construction is based on a modified version of the standard inductive counting algorithm [3], [6], which calls as its subprogram another version of the inductive counting algorithm. In §4 we shall show that the same technique can be applied to Savitch's deterministic simulation [4] as well, that is, one version of the deterministic simulation algorithm calls another one. Section 5 discusses some extensions and the fundamental difference between the methods presented here and the standard Savitch and Immerman–Szelepcsényi algorithms for $s(n) \geq \log(n)$.

2. Nondeterministic computations of tally inputs. We shall consider the standard Turing machine model having a two-way read-only input tape, a finite control, and a separate semi-infinite two-way read-write work tape. This model was introduced in [5] for studying computations requiring less than linear space. A nondeterministic Turing machine is $s(n)$-*space bounded* if all computation paths on all inputs of length n use at most $s(n)$ tape squares on the work tape.

DEFINITION 1. (a) A *memory state* of a Turing machine is an ordered triple $q = \langle r, u, j\rangle$, where r is a state of the machine's finite control, u is a string of work-tape symbols written on the work tape (not including the left end marker and blank symbols), and j is a position of the work tape head.

(b) A *configuration* is an ordered pair $k = \langle q, i\rangle$, where q is a memory state and i is a position of the input-tape head.

It is not too difficult to verify that for each $s(n)$-space-bounded nondeterministic Turing machine there exists a constant $c \geq 6$ such that the number of different memory states for inputs of length n is at most $c^{s(n)+1}$. Similarly, the number of configurations can be bounded by $nc^{s(n)+1}$ for each $n \geq 1$. Thus we have a constant c such that for each $n \geq 1$

$$\begin{aligned} &6 \leq c, \\ (1)\qquad &\text{number of memory states} \leq c^{s(n)+1}, \\ &\text{number of configurations} \leq nc^{s(n)+1}. \end{aligned}$$

Note that we need only $\Theta(s(n))$ space to remember a memory state, but we need $\Theta(s(n)+\log(n))$ space to remember a configuration. The same amounts of space are required to count the number of memory states and the number of configurations, respectively. That is why the Savitch and Immerman–Szelepcsényi algorithms can be applied only to space bounds satisfying $\log(n) \in O(s(n))$.

In particular, both the Savitch and Immerman–Szelepscényi theorems are valid if $n \leq \left(c^{s(n)+1}\right)^6$, since then the position of the input-tape head can be stored in $O(s(n))$ space, as can be a particular configuration or number of reachable configurations. Therefore, we shall now concentrate on nondeterministic Turing machines using very little space, i.e., with

$$(2)\qquad (c^{s(n)+1})^6 < n.$$

The computations taking place very close to the input-tape end markers play a dominant role for such machines when they are computing on tally inputs. In fact, the result of any computation [2] on a tally input is completely determined by computation paths not moving the input head farther than $(c^{s(n)+1})^5$ positions away from the tape end markers. To make these ideas more precise, we shall need some lemmas. For the detailed proofs of Lemmas 1, 3, and 4 the reader is referred to [2]. All proofs are based on the assumption that $(c^{s(n)+1})^6 < n$. In what follows we shall therefore assume that the input word is 1^n and that the space bound $s(n)$ satisfies $\left(c^{s(n)+1}\right)^6 < n$. Define

$$M = c^{s(n)+1}$$

to be an upper bound on the number of reachable memory states for input 1^n.

LEMMA 1 [2, Lem. 3]. *If there exists a computation path from the configuration $k_1 = \langle q_1, i\rangle$ to the configuration $k_2 = \langle q_2, i\rangle$, i.e., beginning and ending at the same position on* *the input tape, such that the input head never visits the right end marker, then the shortest computation path from $\langle q_1, i\rangle$ to $\langle q_2, i\rangle$ never moves the input head farther than M^2 positions to the right of i.*

By symmetry a similar statement holds for computation paths from $\langle q_1, i\rangle$ to $\langle q_2, i\rangle$ that never visit the left end marker.

The next lemma states that the optimal computation paths beginning and ending very close to the end markers never move the input head too far, nor do they consume too much time.

LEMMA 2. *If there exists a computation path from the configuration $k_1 = \langle q_1, i_1\rangle$ to $k_2 = \langle q_2, i_2\rangle$, where $i_1 \leq M^4 + M$ and $i_2 \leq M^4 + M$, such that the input head never visits the right end marker, then the shortest computation path from k_1 to k_2* (a) *never moves the input head more than M^5 positions away from the left end marker and* (b) *never executes more than M^6 steps. The same holds for computation paths beginning and ending closer than $M^4 + M$ positions from the right end marker.*

Proof. (a) Suppose that the rightmost configuration in the shortest computation path from k_1 to k_2 is $k = \langle q, i\rangle$, where $i > M^5$. Because $M = c^{s(n)+1} \geq c \geq 6$, by (1), we have that $M^5 - (M^4 + M) > M^2$. Since both i_1 and i_2 lie to the left of the position $M^4 + M$, we can find two configurations $k_1' = \langle q_1', M^4 + M\rangle$ and $k_2' = \langle q_2', M^4 + M\rangle$ such that the shortest computation path from k_1' to k_2' moves the input head to the position i, i.e., more than M^2 positions to the right (see Fig. 1), but this is a contradiction by Lemma 1.

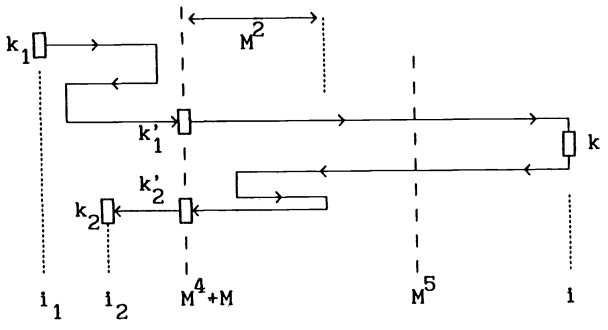

FIG. 1

(b) Furthermore, since there are at most M^6 different configurations with the input-head positions bounded by M^5, the shortest computation path from k_1 to k_2 executes at most M^6 steps. If not, some configuration would have been repeated. □

The following lemma shows that computation paths on tally inputs are position independent provided that they begin and end at least $M^2 + 1$ positions away from either end marker.

LEMMA 3 [2, Lem. 4]. *If machine A can get from configuration $\langle q_1, i\rangle$ to $\langle q_2, i + \ell\rangle$ by a computation path visiting neither of the end markers, then A can get from $\langle q_1, j\rangle$ to $\langle q_2, j + \ell\rangle$ for each j satisfying*

$$M^2 + 1 \leq j \leq n - (M^2 + 1),$$
$$M^2 + 1 \leq j + \ell \leq n - (M^2 + 1).$$

The proof uses Lemma 1 and the fact that the input head scans the same symbols (ones) everywhere along the tape with a tally input.

The following lemma asserts that the nondeterministic machine A, having a computation path that traverses the whole input from left to right (or vice versa), has one path that repeats a single loop on most of the input, beginning and ending in the same configurations at the endmarkers. *A loop of length ℓ* is a computation path starting in configuration $\langle q, i\rangle$ and ending in $\langle q, i+\ell\rangle$ for some memory state q and tape position i. Moreover, neither of the end markers is visited by the input head during this computation.

LEMMA 4 [2, Thm. 1]. *Each computation path beginning in configuration $\langle q_1, 0\rangle$ and ending in $\langle q_2, n+1\rangle$ such that the end markers are visited only in $\langle q_1, 0\rangle$ and $\langle q_2, n+1\rangle$ can be replaced by an equivalent computation path visiting the end markers only in $\langle q_1, 0\rangle$ and $\langle q_2, n+1\rangle$ such that machine A,*

(a) *having traversed s_1 input-tape positions,*

(b) *gets into a loop of length ℓ that is iterated r times and*

(c) *then traverses the rest of the input tape of length s_2*

for some s_1, ℓ, r, s_2 such that

$$\begin{aligned} &M^2+1 \le s_1 \le M^4, \\ (3)\qquad &M^2+1 \le s_2 \le M^4, \\ &1 \le \ell \le M. \end{aligned}$$

The same holds for traversals from right to left (*see also Fig.* 2).

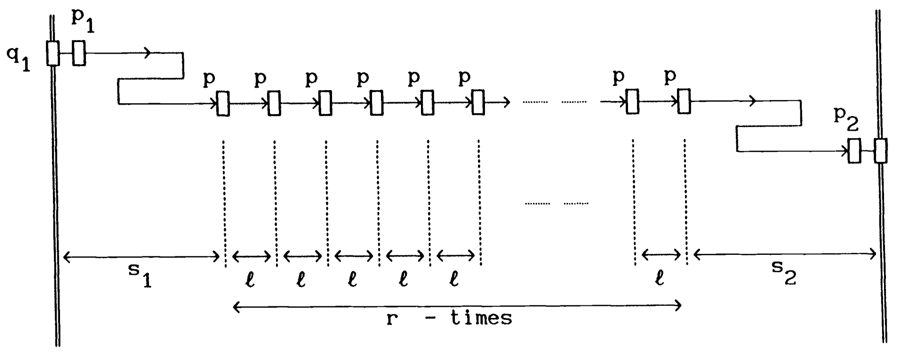

FIG. 2

A configuration is *extending* if it has used space h on the work tape and is going to use space $h+1$ on the next computation step (by rewriting the leftmost blank on the work tape by a nonblank symbol).

LEMMA 5. *For each $s(n)$-space-bounded nondeterministic Turing machine A there exists an equivalent machine A' such that for each $h = 0, \cdots, s(n)$ there exists a configuration having used exactly h space on the work tape with the input head positioned at the left end marker* (*reachable from the initial configuration*). *Moreover, A' accepts with the input head at the left end marker.*

Proof. We can replace the original machine A by a new machine A' that simulates A but that, each time A gets into an extending configuration, nondeterministically decides whether to carry on the simulation or to move the input head to the left end marker, extend the work tape space, and then halt and reject the input. Machine A' has more computation paths than does the original machine A, but all new computation paths are terminated in nonaccepting configurations, and hence both A and A' recognize the same language. A similar idea can be used for accepting configurations as well. $\square$

3. Inductive counting. The reader is assumed to be familiar with the Immerman–Szelepcsényi proofs that nondeterministic space is closed under complement for each space bound $s(n) \geq \log(n)$ [3], [6]. The idea is that if for each $s(n)$-space-bounded nondeterministic machine A we could compute d, the exact number of distinct configurations reachable from the initial configuration, then we could recognize $\overline{L(A)}$ in $s(n)$ space.

Simulate, d times, a computation of A from the very beginning along a (nondeterministically chosen) computation path, and check whether these d simulations are terminated in d different configurations in a lexicographically increasing order. This can be done in $O(s(n)+\log(n))$ space because all we have to remember is d, a variable i to count from 1 to d, a current configuration along some computation path, and the configuration resulting from the previous simulation in order to check that these d configurations are generated in increasing order so that none of them is generated twice. For the right sequence of nondeterministic guesses we shall reach d distinct configurations in increasing order and accept the input if and only if none of these d configurations is an accepting configuration.

The proof that the number of reachable configurations can be computed in space $O(s(n) + \log(n))$ is shown by induction on the number of steps. We shall present this result in a slightly modified form. The algorithm computing the number of reachable configurations is used to test whether a configuration k_2 can be reached from k_1 by a computation path executing at most $t\ell$ steps for any given k_1, k_2 and time limit $t\ell$.

To do this we need to compute d, defined as the number of configurations reachable from a configuration k_1 by computation paths executing *exactly* t steps, for any given k_1 and t.

Clearly, $d = 1$ for $t = 0$. Having computed d, we can compute d', the number of configurations reachable from k_1, by computations executing exactly $t + 1$ steps. To do this, for each target configuration k' generate the d distinct configurations reachable from k_1 in t steps in lexicographically increasing order. Verify whether, among these d configurations, there is a configuration k such that k' is reachable from k in one step, and increment d' in this case.

Now, if we want to check whether a configuration k_2 can be reached from k_1 by a computation path executing at most $t\ell$ steps, we must successively check for each $t = 0, \ldots, t\ell$ if k_2 is equal to any of the configurations reachable from k_1 in exactly t steps.

Because this algorithm will be used in several modifications on different levels, we shall present it using a more formal notation, in the form of a Boolean function test$(k_1, k_2, t\ell)$ such that (a) if a configuration k_2 is reachable from k_1 by a computation path executing at most $t\ell$ steps, then the test will return TRUE in at least one computation path and no computation path will return FALSE; (b) if k_2 is not reachable from k_1 in $t\ell$ steps, then the test will return FALSE in at least one computation and no computation will return TRUE. Note that the test may also halt the computation and reject the input returning no value if it finds that a wrong nondeterministic choice has been made.

```
1   function test($k_1, k_2, t\ell$)
2       $d' := 1$
3       for $t := 0$ to $t\ell$ do
4           $d := d'; d' := 0$
5           for each $k'$ do
6               $k_{\text{prev}} := k_{\text{zero}}$; increment := 0
7               for $i := 1$ to $d$ do
8                   $k :=$ simulation_result($k_1, t$)
9                   if $k = k_2$ then return TRUE
10                  if $k \le k_{\text{prev}}$ then reject
11                  if step($k, k'$) then increment := 1
12                  $k_{\text{prev}} := k$
13              end
14              $d' := d'$ + increment
15      end   end
16      return FALSE
17  end
```

In the algorithm above, "**for each** k' **do** ... **end**" denotes the loop that is executed for each configuration k' not using more than s space, where s is a global variable stored on a separate work tape track. k_{zero} is a constant representing a dummy configuration that lexicographically precedes any other configuration. k_{zero} is not reachable from any other configuration. simulation_result(k_1, t) is a nondeterministic function returning a configuration that is reachable from k_1 by a computation path executing exactly t steps. It simply simulates machine A from k_1 and counts the simulated steps up to t. This function may halt the entire computation and reject the input if it finds that the computation path ends, not having executed t steps. The reject procedure halts the computation and rejects the input, and Boolean function step(k, k') returns the value TRUE if and only if k' is reachable from k in one computation step.

Clearly, if we want to determine whether k_2 is reachable from k_1, it is sufficient to use test($k_1, k_2, nc^{s(n)+1}$) because the shortest computation path from k_1 to k_2 cannot enter the same configuration twice and there are at most $nc^{s(n)+1} = nM$ distinct configurations. In particular, we can test whether any of the accepting configurations is reachable from the initial configuration. It can easily be seen that all variables then require at most $O(s(n) + \log(n))$ space.

We shall now show that the space used can be reduced to $O(s(n))$ if we consider computations on the input 1^n. By the lemmas presented in §2 the actions of the nondeterministic machine on tally inputs can be understood as a combination of moves that are close to one of the end markers of the input tape (at a distance of at most M^4) together with long marches between the end markers. Moreover, these long marches can be replaces by fixed loops of lengths less than or equal to M. Space $O(s(n))$ suffices to describe these situations.

Using inductive counting, by induction on the number of times the input head hits an end marker (instead of single computation steps), we shall construct a procedure that checks whether there is a computation path connecting two configurations that have the input head positioned at the end markers. This procedure calls as its subprogram another version of the inductive counting algorithm that is used to analyze computations that are close to one of the end markers.

First, we shall show that the space $O(s(n))$ is sufficient for analysis of computations taking place entirely within positions 1 and M^5. The following modifications are required in the procedure test:

Line 5. The loop is iterated for each configuration k' not using more than s space, such that the input head is between positions 1 and M^5, where s and M are global variables stored on separate work tape tracks and M is equal to c^{s+1}.

Line 8. The function simulation_result(k_1, t) is replaced by a nondeterministic function L_simulation_result(k_1, t), which returns a configuration reachable from k_1 by a computation path executing exactly t steps, neither moving the input head to the right of M^5 nor visiting the left end marker (position 0). This procedure simulates A from k_1 and counts the simulated steps. It rejects the input (returning no configuration) if machine A moves the input head to the right of position M^5 or scans the left end marker or if the chosen computation path terminates too early, not having executed t steps.

The above modifications give function L_test($k_1, k_2, t\ell$), which checks whether configuration k_2 is reachable from k_1 by a computation executing at most $t\ell$ steps taking place entirely within positions 1 and M^5 or rejects the input because of a wrong nondeterministic decision. The procedure simply uses inductive counting to compute the number of configurations reachable by computation paths taking place between positions 1 and M^5.

Note that by Lemma 2 we can check whether configuration k_2 is reachable from k_1 by a computation path visiting neither of the end markers by the use of L_test(k_1, k_2, M^6) for each $k_1 = \langle q_1, i_1 \rangle$ and $k_2 = \langle q_2, i_2 \rangle$ such that $1 \leq i_1 \leq M^4 + M, 1 \leq i_2 \leq M^4 + M$, because the shortest computation path from k_1 to k_2 never moves the input head to the right of position M^5 nor does it execute more than M^6 steps, since both the initial and final positions are to the left of $M^4 + M$. It is not difficult to verify that L_test then uses at most $O(s(n))$ space.

Now we can easily construct function L_L_path(q_1, q_2), which checks whether there exists a computation path from memory state q_1 to q_2 beginning and ending at the left end marker such that the end markers are visited only in q_1 and q_2:

```
function L_L_path($q_1, q_2$)
    if step($\langle q_1, 0\rangle$ , $\langle q_2, 0\rangle$) then return TRUE
    for each $p_1, p_2$ do
        if step($\langle q_1, 0\rangle$ , $\langle p_1, 1\rangle$) and step($\langle p_2, 1\rangle$ , $\langle q_2, 0\rangle$) and
          L_test($\langle p_1, 1\rangle$ , $\langle p_2, 1\rangle$ , $M^6$)
        then return TRUE
    end
    return FALSE
end
```

The construct "**for each** p_1, p_2 **do** ... **end**" denotes two nested loops that are iterated for all memory states not using more than s space.

DEFINITION 2. An *R-configuration* is an ordered pair $k = \langle q, i \rangle$, where q is a memory state and i is a distance between the input-tape head and the right end marker.

Clearly, for each configuration $\langle q, i \rangle$ there exists a corresponding *R-configuration* $\langle q, n + 1 - i \rangle$, and vice versa. We introduce this notion only to have a space-efficient coding for configurations with the input head positioned close to the right end marker.

We can now design procedures R_step, R_simulation_result, R_test, and R_R_path that, by symmetry, mirror step, L_simulation_result, L_test, and L_L_path, respectively. That is, R_step(k, k') returns TRUE if and only if R-configuration k' is reachable from R-configuration k in one computation step, and R_test($k_1, k_2, t\ell$) checks whether R-configuration k_2 is reachable from k_1 by a computation path executing at most $t\ell$ steps, neither moving the input head more than M^5 positions away from the right end marker nor visiting the right end marker. For R-configurations with the input head less than $M^4 + M$ positions to the left of the right end marker, R_test(k_1, k_2, M^6) checks whether k_2 is reachable from k_1 by a computation path visiting neither of the end markers. R_R_path(q_1, q_2) checks whether there exists a path from memory state q_1 to q_2 beginning and ending at the right end marker, visiting the end markers only in q_1 and q_2.

We shall now construct a function L_R_path(q_1, q_2), which checks whether there exists a computation path from memory state q_1 to q_2 traversing the entire input from left to right such that the end markers are visited only in q_1 and q_2. By Lemma 4 it is sufficient to check whether there exist s_1, ℓ, r, s_2 satisfying (3) and a memory state p such that

(a) $\langle p, s_1\rangle$ is reachable from $\langle q_1, 0\rangle$,

(b) $\langle p, s_1 + (i+1)\ell\rangle$ is reachable from $\langle p, s_1 + i\ell\rangle$, for each $i = 0, \cdots, r-1$, and

(c) $\langle q_2, n+1\rangle$ is reachable from $\langle p, n+1-s_2\rangle = \langle p, s_1 + r\ell\rangle$ (see Fig. 2). Because the end markers are visited only in q_1 and q_2, condition (a) can be verified by using L_test($\langle p_1, 1\rangle, \langle p, s_1\rangle, M^6$) for each memory state p_1 such that $\langle p_1, 1\rangle$ is reachable from $\langle q_1, 0\rangle$ in one step. The same holds for (c), but we shall use R-configurations instead to reduce the space used.

From Lemma 3 it follows that, having verified that $\langle p, s_1 + \ell\rangle$ is reachable from $\langle p, s_1\rangle$, we have verified that $\langle p, s_1 + (i+1)\ell\rangle$ is reachable from $\langle p, s_1 + i\ell\rangle$ for each $i \geq 0$ provided that both $s_1 + i\ell$ and $s_1 + (i+1)\ell$ are at least $M^2 + 1$ positions away from either end marker. This is satisfied for each $i = 0, \cdots, r-1$, since $s_1 \geq M^2 + 1$ and $s_2 \geq M^2 + 1$ by (3) (see Lemma 4). It only remains to check whether $s_1 + r\ell + s_2 = n+1$. Note that we must store s_1, s_2 and ℓ, but not r, on the work tape. We can verify whether $(n+1-s_1-s_2) \bmod \ell = 0$ by moving the input head $s_1 + s_2$ positions to the right from the left end marker and checking whether the rest of the tape can be divided into segments of equal length ℓ. We are now ready to present the algorithm:

```
function L_R_path($q_1, q_2$)
    for each $p, p_1, p_2$ do
        for $s_1, s_2 := M^2 + 1$ to $M^4$ do
            for $\ell := 1$ to $M$ do
                if step($\langle q_1, 0\rangle, \langle p_1, 1\rangle$) and
                   L_test($\langle p_1, 1\rangle, \langle p, s_1\rangle, M^6$) and
                   L_test($\langle p, s_1\rangle, \langle p, s_1 + \ell\rangle, M^6$) and
                   R_test($\langle p, s_2\rangle, \langle p_2, 1\rangle, M^6$) and
                   R_step($\langle p_2, 1\rangle, \langle q_2, 0\rangle$) and
                   $(n + 1 - s_1 - s_2) \bmod \ell = 0$
                then return TRUE
    end end end
    return FALSE
end
```

In the algorithm "for each p, p_1, p_2 do $\cdots$ end" denotes three nested loops iterated for all memory states not using more than s space.

A similar algorithm can be used for the function R_L_path(q_1, q_2), which checks traversals from right to left.

DEFINITION 3. An *M-configuration* is an ordered pair $k = \langle q, m\rangle$, where q is a memory state and $m \in \{L, R\}$, where L and R denote the left and right end markers, respectively.

M-configurations will be used to identify configurations with the input head scanning the end markers. Combining L_L_path, R_R_path, L_R_path, and R_L_path, we obtain

```
function M_step($\langle q_1, m_1\rangle, \langle q_2, m_2\rangle$)
    return $m_1$_$m_2$_path($q_1, q_2$)
end
```

which checks whether there exists a computation path from M-configuration $\langle q_1, m_1\rangle$ to M-configuration $\langle q_2, m_2\rangle$ by visiting the end markers only in $\langle q_1, m_1\rangle$ and $\langle q_2, m_2\rangle$.

Now, using inductive counting again, we can construct a function M_test($k_1, k_2, t\ell$), which checks whether there exists a computation path from M-configuration k_1 to M-configuration k_2 such that the input head visits the end markers at most $t\ell$ times.

The algorithm uses induction not on the number of single computation steps but, rather, on the number of times the input head visits the end markers. Having computed d, the number of M-configurations reachable from k_1 by computation paths visiting the end markers exactly t times, we can compute d', the number of M-configurations reachable from k_1 by computations visiting the end markers exactly $t + 1$ times. For each target M-configuration k' generate the d distinct M-configurations reachable from k_1 by exactly t visits to the end markers and verify whether there is an M-configuration k such that k' is reachable from k by a computation path visiting the end markers only in k and k' by using the function M_step. Increment d' in this case.

We shall need some modifications in the procedure test:

Line 5. The loop is not iterated for each configuration; rather it is iterated for each M-configuration k' not using more that s space on the work tape.

Line 11. The function step(k, k') is replaced by M_step(k, k').

Line 8. The function simulation_result(k_1, t) returning a configuration reachable from k_1 by a computation executing t steps is replaced by nondeterministic function M_simulation_result(k_1, t), which returns an M-configuration reachable from M-configuration k_1 by a computation path visiting the end markers exactly t times not including k_1 itself. This procedure simulates the original machine A from k_1 and counts the number of times the head visits the end markers instead of counting single computation steps. The input is rejected and the entire computation is halted if the chosen path terminates without having visited the end markers t times. The only M-configuration returned for $t = 0$ is k_1 itself.

Clearly, M_test($k_1, k_2, 2M$) checks whether M-configuration k_2 is reachable from M-configuration k_1, since there are at most $2M$ distinct M-configurations and therefore the shortest computation path from k_1 to k_2 cannot visit the end markers more than $2M$ times. By using this it can easily be shown that M_test uses at most $O(s(n))$ space.

By Lemma 5 there is no loss of generality is assuming that the original machine A accepts with the input head at the left end marker. Therefore, it is sufficient to check whether any accepting M-configuration with the head at the left end marker is reachable from the initial M-configuration $\langle q_I, L\rangle$. However, two problems arise here. First, we do not know a priori how much space machine A is going to use. This can be overcome by testing for $s = 1, 2, \cdots$ if A is going to use at least that much space. By Lemma 5 we may assume without loss of generality that if A uses $s(n)$ space on the work tape, then for each $h = 0, \cdots, s(n)$ there exists a configuration reachable from the initial configuration that uses exactly h space *with the input head at the left end marker.* Hence it is sufficient to iterate over all M-configurations having used exactly space s with the input head at the left end marker and to check whether any of these is reachable from $\langle q_I, L\rangle$. We shall interrupt the work-tape space extension when we reach s such that no M-configuration using exactly space s at the left end marker is reachable from the initial M-configuration. Second, our strategy is based on Lemmas 1, 3, and 4 [2], i.e., on the assumption that $M^6 = (c^{s(n)+1})^6 < n$. Fortunately, if $n \leq (c^{s(n)+1})^6 = M^6$, then the STANDARD inductive counting algorithm [3], [6] uses at most $O(s(n))$ space, since then $\log(n) \in O(s(n))$. Therefore, each time the work-tape space s is extended we should check whether $M^6 = (c^{s+1})^6 < n$ and decide whether to proceed further or to switch to the standard inductive counting procedure.

Combining the ideas above, we get the following main program:

```
procedure main
    $s := 0$; $M := c$; extend := 1
    while extend = 1 and $M^6 < n$ do
        extend := 0
        for each $q$ do
            if worktape_space_used ($q$) = $s$ and
               M_test($\langle q_I, L\rangle, \langle q, L\rangle, 2M$)
            then extend := 1
        end
        $s := s + 1$; $M := c^{s+1}$
    end
    if $M^6 \geq n$ then STANDARD else begin
        for each $q$ do
            if accepting($q$) and
               M_test($\langle q_I, L\rangle, \langle q, L\rangle, 2M$)
            then reject
        end
        accept
end end
```

By the argument above we have the following theorem:

THEOREM 1. *For each $s(n)$-space-bounded nondeterministic Turing machine recognizing a language $L \subseteq 1^*$ there exists a nondeterministic $O(s(n))$-space-bounded Turing machine recognizing the complement of L for each $s(n)$, independent of whether it is below* $\log(n)$ *or is space constructible.*

4. Deterministic simulation. The same approach can be applied to Savitch's theorem [4]. Consider the deterministic version of the function test:

```
1   function test($k_1, k_2, t\ell$)
2       if $k_1 = k_2$ then return TRUE
3       if $t\ell = 1$ then return step($k_1, k_2$)
4       for each $k$ do
5           if test($k_1, k, \lfloor t\ell/2 \rfloor$) and test($k, k_2, \lceil t\ell/2 \rceil$)
6           then return TRUE
7       end
8       return FALSE
9   end
```

We have used the same function step but no nondeterministic function like simulation_result. The procedure uses $O(s(n) + \log(n) + \log(t\ell))$ *local* space, but it calls itself recursively. The depth of recursion is bounded by $\lceil \log(t\ell) \rceil$.

The basic idea of the proof is the same as it was for the nondeterministic simulation. The deterministic version of L_test will use $O(s(n))$ local space to store configurations that have input-head positions bounded by M^5. The same amount of local space is sufficient for the time limit $t\ell$ bounded by M^6. The depth of recursion for L_test is then bounded by $\lceil \log(M^6) \rceil \in O(s(n))$, which gives the total space $O(s^2(n))$. The same amount of space is sufficient for R_test and also for the deterministic recursive variant of M_test, calling M_step instead of step (cf. the deterministic function test, line 3) with $t\ell$ bounded by $2M$. Savitch's STANDARD procedure that is called in the main program also uses at most $O(s^2(n))$ space if $n \leq M^6$.

We can now establish the following theorem:

THEOREM 2. *For each $s(n)$-space-bounded nondeterministic Turing machine recognizing a language $L \subseteq 1^*$ there exists an equivalent deterministic Turing machine that is space bounded by $O(s^2(n))$ for each $s(n)$, independent of whether it is below* $\log(n)$ *or is space constructible.*

5. Conclusion. The above idea can be used not only for tally inputs but also for binary inputs with a low information content, e.g., for strings not containing too many zeros:

DEFINITION 4. A language $L \subseteq \{0,1\}^*$ is *$f(n)$-zero-bounded* if each $w \in L$ of length n contains at most $f(n)$ zeros.

THEOREM 3. *For each $s(n)$-space-bounded nondeterministic Turing machine recognizing an $f(n)$-zero-bounded language L, such that the value of $f(n)$ can be computed and stored in $O(s(n))$ space, there exists a nondeterministic $O(s(n))$-space-bounded Turing machine recognizing the complement of L and also an equivalent $O(s^2(n))$-space-bounded Turing machine that is deterministic.*

Note that we have to compute $f(n)$ by using $O(s(n))$ space only, but $s(n)$ itself need not be fully space constructible.

Proof. We state only the basic ideas for the inductive counting, since the proof is very similar to the arguments presented above. (A similar argument can be used for the deterministic simulation.)

First, compute $f(n)$, and store this value on a separate work-tape track. Accept the input if the number of zeros on the input tape exceeds $f(n)$.

Otherwise, we must simulate the original machine A. Because $f(n)$ can be stored in $O(s(n))$ space, there is a constant d such that $f(n) \leq d^{s(n)}$. Since there are at most $d^{s(n)}$ zeros on the input tape, there can be at most $c^{s(n)+1}d^{s(n)}$ so-called Z-configurations, i.e., with the head scanning a symbol zero on the input tape.

No optimal computation path enters the same Z-configuration twice, and therefore we shall consider only computation paths scanning zeros on the input tape at most $c^{s(n)+1}d^{s(n)}$ times. (In fact, the value of $c^{s+1}f(n)$ will be computed and stored on a separate work-tape track. Because s is not known at the beginning of the computation, this value is recomputed each time s is extended.)

Moreover, each Z-configuration can be stored on the work tape by using only $O(s(n))$ space because the input tape position can be coded by the number of zeros lying to the left of the current position.

Using inductive counting, we can now generate and count all Z-configurations that are reachable from the initial configuration by induction on the number of times the input head scans zero.

We must call a nondeterministic Z-configuration generator, i.e., a function Z_simulation_result(k, t) returning a Z-configuration reachable from Z-configuration k by a computation path scanning zeros on the input exactly t times.

Second, we shall need a single Z-step verifier, i.e., a function Z_step(k_1, k_2) to check whether Z-configurations k_1 and k_2 can be connected by a computation path scanning zeros only in k_1 and k_2. Such a computation path can be found only if k_1 and k_2 scan the same zero on the input tape or if they scan two adjacent zeros, i.e., two zeros separated by 1^k, for some $k \geq 0$. Return FALSE if this is not satisfied. Now consider the two adjacent zeros. (The argument for the first case is very similar—by Lemma 1—and therefore is omitted.) Compare k, the distance between these two zeros, with M^6. If $k \leq M^6$, then we shall call the standard inductive counting procedure and use the tape segment between the two zeros as its effective input, measuring off the input-head positions from the left zero. Otherwise, we shall use the strategy based on Lemma 4 (see §3, procedure L_R_path).

The basic difference from the tally input recognition is that M^6 is compared not at the beginning of the main program but each time the procedure Z_step is called to analyze computation paths between any two adjacent zeros. □

For example, the Savitch and Immerman–Szelepcsényi theorems hold for each $d^{s(n)}$-zero-bounded language, where d is a constant, if $s(n)$ is fully space constructible.

These two theorems hold for each $L \subseteq a^*b^*$ for each $s(n)$, independent of whether $s(n)$ is above $\log(n)$ or is space constructible, since there is a straightforward correspondence between L and the 1-zero-bounded language $L' = \{1^m 0 1^n; a^m b^n \in L\}$.

However, there is a very important difference between inductive counting in sublogarithmic space and the standard Immerman–Szelepcsényi result. In fact, the Immerman–Szelepcsényi algorithm for $s(n) \geq \log(n)$ can be used to generate all configurations reachable from *any* given configuration k, not only from the initial configuration. It is this fact that is needed to prove that the alternating hierarchy of $s(n)$-space-bounded machines collapses to $\Sigma_1-\text{SPACE}(s(n))$. $\Sigma_k-\text{SPACE}(s(n))$ and $\Pi_k-\text{SPACE}(s(n))$ denote the classes of languages recognizable by alternating $s(n)$-space-bounded machines making fewer than k alternations between universal and existential states with the initial state existential and universal, respectively. This is not possible in sublogarithmic space because we do not have enough space to remember the input-head position. Once we have moved the input head too far, the tape position is lost. We cannot restart, over and over again, computation paths beginning in the same configuration. On tally inputs this is possible only for a restricted set of configurations with the input-head positions close to the end markers. Fortunately, the initial configuration belongs to this set, and that is why we were able to check whether there is an accepting reachable configuration.

However, we still have that $\Pi_2 - \text{SPACE}(s(n)) - \Sigma_1 - \text{SPACE}(s(n)) \neq \emptyset$ for each $s(n)$ between $\log\log(n)$ and $\log(n)$ [7], [1]. An example [7] of a language over a single-letter alphabet in $\Pi_2 - \text{SPACE}(s(n)) - \Sigma_1 - \text{SPACE}(s(n))$ for each unbounded fully space-constructible $s(n)$ below $\log(n)$ is

$$L = \{a^n; n \leq \text{ least common multiple of } 1, \cdots, d^{s(n)}\}.$$

There exist unbounded fully space-constructible functions below $\log(n)$, e.g., $s(n) = \log(\min\{i; i \text{ does not divide } n\}) \in O(\log\log(n))$. However, none of these functions can be monotone increasing [1], [2].

Acknowledgment. The author thanks Branislav Rovan for some remarks concerning this work.

NV-SEQUENTIALITY: A DECIDABLE CONDITION FOR CALL-BY-NEED COMPUTATIONS IN TERM-REWRITING SYSTEMS*

MICHIO OYAMAGUCHI†

Abstract. In 1979 Huet and Levy introduced the class of sequential term-rewriting systems in which call-by-need computations are possible (without look-ahead) and defined the subclass called *strongly sequential systems* for which needed redexes in a given term are effectively found [chapter in *Computational Logic: Essays in Honor of Alan Robinson*, J.-L. Lassez and G. Plotkin, eds., MIT Press, Cambridge, MA, 1991]. This paper introduces a larger subclass that is a natural extension of strong sequentiality and is based on the analysis of both the left-hand sides and part of the right-hand sides (i.e., the nonvariable parts) of systems, whereas strong sequentiality is based on the analysis of left-hand sides alone. This new sequentiality is called *NV-sequentiality*. It is shown that (i) the class of NV-sequential systems properly includes the class of strongly sequential systems, (ii) there exists an algorithm for finding needed redexes for a given term when a system is NV-sequential, and (iii) it is decidable whether an arbitrary left-linear system is NV-sequential.

Key words. term-rewriting system, call-by-need computation, sequentiality, strong sequentiality, left-linear system

AMS(MOS) subject classification. 68Q50

1. Introduction.

A term-rewriting system (TRS) is a set of directed equations (called *rewrite rules*). TRSs are used as abstract interpreters of programming languages and as formula-manipulating systems in various applications, such as theorem proving, reasoning about specifications, program optimization, and transformation (see [5], [6], [9], [13]).

The notion of *call-by-need* computations has turned out to be fruitful in implementation of interpreters for (applicative) programming languages [5], [10], [21], [22]. Here a computation step is said to be call-by-need if the step is necessary to reach a normal form (or to obtain an answer). (This notion is closely related to that of *strictness*, which is important in functional programming (see [1]).) Huet and Levy [8] gave a more complete, theoretical treatment of this subject for TRSs and used the notion of sequentiality given in [11], [22] to define a subclass of TRSs for which the call-by-need computations are possible (without look-ahead). Intuitively, a TRS is said to be sequential if, for any term M that is not in normal form but can reduce to a normal form, there exists a redex in M that we need to compute to obtain to a normal form of M and this redex (which is said to be *needed*) can be determined without look-ahead. However, sequentiality was shown to be undecidable for TRSs in [8]. This undecidability stems from the undecidability of the reachability problem for TRSs. Here the reachability problem is the problem of deciding, for two terms M and N, whether there exists a reduction sequence from M to N. To overcome this difficulty a sufficient condition for sequentiality, called *strong sequentiality*, was introduced in [8]. The notion of strong sequentiality is based on the analysis of left-hand sides of rewrite rules alone. (In other words, it is similar to the sequentiality condition for the set of new rewrite rules defined under the assumption that any redex can reduce to an arbitrary term.) It was shown in [8] that needed redexes for a given term are effectively found when we consider a strongly sequential system. Moreover, whether a TRS is strongly sequential was shown to be decidable in [8]. For a refinement of the notion of strong sequentiality, see [20], and for a related result on strong sequentiality

with constructors, see [19]. For an alternative analysis of strong sequentiality and two simplified proofs of the decidability of this property, see [12].

In this paper we introduce a new notion of sequentiality that is a natural extension of strong sequentiality and is based on the analysis of both the left-hand sides and part of the right-hand sides (i.e., the nonvariable parts) of systems, whereas strong sequentiality is based on the analysis of left-hand sides alone. (In other words, this new sequentiality condition is sufficient for ensuring sequentiality under the assumption that for each rewrite rule $\alpha \to \beta$ every redex $\sigma(\alpha)$, where σ is a substitution, can reduce to any term that contains the nonvariable part of β as the prefix (or upper) part. Note that reducing $\sigma(\alpha)$ to $\sigma'(\beta)$, where σ' is another substitution, is permitted, but reducing $\sigma(\alpha)$ to any term is not permitted. Thus this new sequentiality is based on relatively more precise (or detailed) analysis than is strong sequentiality.) Henceforth this new sequentiality is called *NV-sequentiality*, which is an abbreviation of sequentiality with respect to nonvariable parts of right-hand sides.

We first show that the class of NV-sequential systems properly includes the class of strongly sequential systems and that NV-sequentiality is a sufficient condition for sequentiality. (These results show that NV-sequentiality gives a wider class of TRSs, in which call-by-need computations are possible, than does strong sequentiality.)

Next we show that for an NV-sequential system there exists a redex selection algorithm deriving normal forms from given terms whenever they possess normal forms. To show this we prove that the problem of deciding, for a term M and an occurrence (position) u, whether u is a needed redex occurrence for obtaining the normal form of M is reducible to the reachability problem for quasi-ground TRSs, which has been shown to be decidable in [4], [15], [16]. Here a TRS is a quasi-ground system if for every rewrite rule in the TRS the left-hand side is linear and the right-hand side contains no variables. Thus we obtain a redex selection algorithm for NV-sequential TRSs. The algorithm operates in polynomial time. Moreover, whether a left-linear TRS is NV-sequential is shown to be decidable. The proof of this decidability leads to a new (perhaps simplified) proof of the decidability of strong sequentiality that is different from the more algorithmic one given in [8].

This paper is organized as follows. Section 2 is devoted to standard definitions. The notions of sequentiality and strong sequentiality are explained in §3, and the definition of NV-sequentiality is given in §4. In §5 we give a redex selection algorithm for NV-sequential TRSs, and in §6 we show that NV-sequentiality is decidable.

2. Definitions. We use ϵ to denote the empty string and $\emptyset$ to denote the empty set. For a set U we let $\|U\|$ be the cardinality of U. We use $\mathbb{N}$ to denote the set of positive integers and $\mathbb{N}_0$ to denote $\mathbb{N} \cup \{0\}$.

The following definitions and notations are similar to those in [7]. Let X be a finite set of *variables*, and let F be a finite set of *operation symbols* graded by an arity function $a : F \to \mathbb{N}_0$. Let T be the set of terms constructed from X and F. That is, a term either is a variable or is of the form $fM_1 \cdots M_n$ for some $f \in F$ with arity $a(f) = n$ and $M_1, \cdots, M_n \in T$. For any M in T we define $V(M)$ as the set of variables that occur in M. A term M is called a *ground* term if $V(M) = \emptyset$ and is called a *linear* term if no variables occur more than once in M.

Let $F_n = \{f \in F | a(f) = n\}$. We define several functions on terms: For any M in T let $M = x$, where $x \in X$, or $M = fM_1 \cdots M_n$, where $f \in F_n$. Then

(i) the *size* $|M| : |x| = 1$,

$$|fM_1 \cdots M_n| = 1 + |M_1| + \cdots + |M_n|;$$

(ii) the set of *occurrences* $\mathcal{O}(M)$: $\mathcal{O}(x) = \{\epsilon\}$,

$$\mathcal{O}(fM_1 \cdots M_n) = \{\epsilon\} \cup \{iu \,|1 \leq i \leq n, u \in \mathcal{O}(M_i)\};$$

(iii) the subterm M/u at occurrence $u : x/\epsilon = x$,

$$fM_1 \cdots M_n/\epsilon = fM_1 \cdots M_n,$$
$$fM_1 \cdots M_n/iu = M_i/u, \qquad 1 \leq i \leq n;$$

(iv) $M[u \leftarrow N] \in T$, where $u \in \mathcal{O}(M)$ and $N \in T$:

$M[\epsilon \leftarrow N] = N$

$fM_1 \cdots M_n[iu \leftarrow N] = fM_1 \cdots M_{i-1}(M_i[u \leftarrow N])M_{i+1} \cdots M_n, \qquad 1 \leq i \leq n;$

(v) the *height* $h(M)$: $h(x) = 0$,

$$h(fM_1 \cdots M_n) = \begin{cases} 1 + \mathrm{Max}\{h(M_1), \cdots, h(M_n)\} & \text{if } n > 0; \\ 0 & \text{otherwise;} \end{cases}$$

(vi) the operation symbol Occ(M, u) at occurrence u:

$$\mathrm{Occ}(x, \epsilon) = x, \qquad \mathrm{Occ}(fM_1 \cdots M_n, \epsilon) = f,$$
$$\mathrm{Occ}(fM_1 \cdots M_n, iu) = \mathrm{Occ}(M_i, u), \qquad 1 \leq i \leq n;$$

(vii) sub$(M) = \{M/u|u \in \mathcal{O}(M)\}$.

The set of occurrences $\mathcal{O}(M)$ is partially ordered by the prefix ordering $u \leq v$ if and only if $\exists w$ such that $uw = v$. In this case we denote w by v/u. If $u \not\leq v$ and $v \not\leq u$, then u and v are said to be disjoint and are denoted $u|v$. If $u \leq v$ and $u \neq v$, then $u < v$.

Let $\mathcal{O}_X(M)$ be the set of variable occurrences in $\mathcal{O}(M)$, i.e., $\mathcal{O}_X(M) = \{u \in \mathcal{O}(M)|M/u \in X\}$.

A *substitution* σ is a mapping $\sigma : X \to T$, and σ is extended to a mapping from terms to terms: $\sigma(fM_1 \cdots M_n) = f\sigma(M_1) \cdots \sigma(M_n)$ for $f \in F_n$.

A TRS is a finite set E of rules $\alpha \to \beta$ such that $\alpha, \beta \in T$, and $V(\beta) \subseteq V(\alpha)$. Let $L_E = \{\alpha \,|\alpha \to \beta \in E\}$ and $R_E = \{\beta \,|\alpha \to \beta \in E\}$. For any substitution σ and $\alpha \in L_E$, $\sigma(\alpha)$ is called a *redex*. A term M reduces to N at occurrence u if and only if $M/u = \sigma(\alpha)$ and $N = M[u \leftarrow \sigma(\beta)]$ for some substitution σ and rule $\alpha \to \beta \in E$. In this case u is called the redex occurrence of the reduction. We denote this reduction by $M \overset{u}{\to}_E N$. In this notation u and E may be omitted (i.e., $M \to N$) and $\to$ is regarded as a relation over T. Let $\to^+$ and $\to^*$ be the transitive closure and the reflexive-transitive closure of $\to$, respectively. Let $\to^0$ be the identity relation, and let $\to^k = \to \cdot \to^{k-1}$ for $k > 0$. Let $\to^{(k)} = \cup_{i=0}^k \to^i$ for $k \geq 0$.

We define the size of system E by $\sum_{\alpha \to \beta \in E} |\alpha| + |\beta|$, which is denoted size$(E)$.

DEFINITION 2.1. Let $\gamma : M \overset{u_1}{\to} M_1 \cdots \overset{u_k}{\to} M_k$ be a reduction sequence. Then $v \in \mathcal{O}(M)$ is said to be *safe for* γ if there exists no $u_i, 1 \leq i \leq k$, such that $u_i \leq v$.

DEFINITION 2.2. For a term M we use $\mathcal{R}(M)$ to denote the set of redex occurrences in M, i.e., $\mathcal{R}(M) = \{u \in \mathcal{O}(M)|M/u = \sigma(\alpha)$ for some $\alpha \in L_E$ and mapping $\sigma : X \to T\}$. The minimal subset $\mathcal{MR}(M)$ of $\mathcal{R}(M)$ consists of the minimal occurrences of $\mathcal{R}(M)$ in a sense of $\leq$. For example, if $\mathcal{R}(M) = \{1, 2, 21\}$, then $\mathcal{MR}(M) = \{1, 2\}$.

DEFINITION 2.3. A term M is a *normal form* if and only if $\mathcal{R}(M) = \emptyset$. In this case M is also said to be *irreducible*. We denote the set of terms in normal form by NF_E. We use NF if E is clear in the context.

DEFINITION 2.4. A TRS E is said to be *left-linear* if every term α in L_E is linear and is said to be a *quasi-ground* system if for every rule $\alpha \to \beta$ in E, α is linear and β is a ground term. TRS E is said to be nonoverlapping if there are no critical pairs [7], [13].

Notation. For a term M let $U = \{u_1, \cdots, u_{n-1}, u_n\} \subseteq \mathcal{O}(M)$, where $u_1, \cdots, u_n$ are pairwise disjoint. We use $M[u_1 \leftarrow N_1, \cdots, u_{n-1} \leftarrow N_{n-1}, u_n \leftarrow N_n]$ to denote $(M[u_1 \leftarrow N_1, \cdots, u_{n-1} \leftarrow N_{n-1}])[u_n \leftarrow N_n]$. We also use $M[u_i \leftarrow N_i, u_i \in U]$ to denote this term.

Henceforth we will be dealing with a fixed TRS $E = \{\alpha_i \to \beta_i | 1 \leq i \leq n_0\}$ and will that E satisfies the following conditions:

(i) $L_E \cap X = \emptyset$,

(ii) E is left-linear and nonoverlapping.

Note that by (ii) E is confluent, so that if a term M can reduce to a term in normal form, then the normal-form term is unique (see [7], [9]).

3. Sequentiality and needed redex. We will first explain the notion of sequentiality. Intuitively, a TRS E is sequential if and only if for any term M not in normal form there exists a redex in M that we must compute to get to the normal form of M, and this redex can be determined without looking at the subparts of M, which are not yet computed. For a more precise explanation, we need some preliminaries.

First, a new constant symbol Ω (i.e., $a(\Omega) = 0$) will be added to the set F of operation symbols, and the augmented set of terms will be denoted by T_Ω. We denote the set of non-Ω-terms constructed from $F \cup X$ by T. Members of T_Ω will be called Ω-terms, and an irreducible Ω-term will be called an Ω-normal form. Only irreducible terms in T are said to be normal forms. Intuitively, Ω denotes the absence of information and is the least information symbol (in denotational semantics [18]).

An information ordering on T_Ω is defined as follows.

DEFINITION 3.1 [8], [18].

(i) $\Omega \leq M$ for all $M \in T_\Omega$.

(ii) For $f \in F \cup X, fM_1 \cdots M_n \leq fN_1 \cdots N_n$ if and only if $M_i \leq N_i$ for all $i, 1 \leq i \leq n$. Here $n = a(f)$ if $f \in F$, and $n = 0$ if $f \in X$.

(iii) For $f, g \in F \cup X, fM_1 \cdots M_n \not\leq gN_1 \cdots N_m$ if $f \neq g$. Note that if $M \in T$, then $M \leq N$ if and only if $M = N$. We write $M < N$ if $M \leq N$ and $M \neq N$.

By this definition, however, we can easily show the following lemma concerning the ordering $\leq$.

LEMMA 3.1. *Let $M, N \in T_\Omega$. Then the following three statements are equivalent*:

(i) $M \leq N$;

(ii) $\exists u \in \mathcal{O}(M)$ *such that* $M/u \leq N/u$ *and* $M[u \leftarrow \Omega] \leq N[u \leftarrow \Omega]$;

(iii) $M = N$ *or there exists a set* $U \subseteq \mathcal{O}(N)$ *such that occurrences in* U *are pairwise disjoint and* $M = N[u \leftarrow \Omega, u \in U]$.

The proof is straightforward, so it is omitted.

DEFINITION 3.2 [8]. For a term $M \in T$ we use M_Ω to denote the term obtained from M by replacing all variables in M by Ω, i.e., $M_\Omega = M[u \leftarrow \Omega, u \in \mathcal{O}_X(M)]$.

DEFINITION 3.3. For an Ω-term $N \in T_\Omega$ we use $\mathcal{O}_\Omega(N)$ to denote the set of Ω occurrences in $\mathcal{O}(N)$, i.e., $\mathcal{O}_\Omega(N) = \{u \in \mathcal{O}(N) | N/u = \Omega\}$.

Next we define a *normal-form predicate* nf_E as follows:

DEFINITION 3.4 [8]. For $M \in T_\Omega$, $\mathrm{nf}_E(M) = \mathrm{TRUE}$ if and only if $\exists N \in \mathrm{NF}_E$ such that $M \to_E^* N$, that is, M can reduce to a normal form. $\mathrm{nf}_E(M) = \mathrm{FALSE}$ if and only if

$\mathrm{nf}_E(M) \neq$ TRUE. We may omit the subscript E if E is clear in the context.

Note that NF_E is a monotonic predicate under the assumption FALSE $\leq$ TRUE, i.e., $M \leq N$ implies $\mathrm{NF}_E(M) \leq \mathrm{NF}_E(N)$.

Assume that $\mathrm{nf}_E(M) =$ TRUE and that M contains Ω. Then note that all Ω's in M must be eliminated in the reductions to the normal form. We now define needed redex occurrences as follows.

DEFINITION 3.5. Let $\mathrm{nf}_E(M) =$ TRUE for $M \in T_\Omega$. Then a redex occurrence $u \in \mathcal{R}(M)$ is said to be *needed for the normal form* if and only if $\mathrm{nf}_E(M[u \leftarrow \Omega]) =$ FALSE. (This definition is equivalent to that in [5].) A reduction $M \xrightarrow{u} N$ is said to be a *call-by-need* reduction (or computation) if u is needed for the normal form of M.

It has been shown that in λ-calculus the leftmost reduction for any term is call-by-need, but in TRSs the leftmost outmost reduction is usually not call-by-need (see [2], [8]).

We now consider the case for which TRS E is left-linear and nonoverlapping. Let M be an Ω-term not in normal form. If there exists a reduction sequence $\gamma : M \to^* N$ for some $N \in \mathrm{NF}_E$, then at least one outermost redex of M (i.e., M/u for some u in $\mathcal{MR}(M)$ (see Definition 2.2)) must be evaluated in γ. As a stronger result, it was shown in [8, Lemma 4.3] that there exists u in $\mathcal{MR}(M)$ needed for the normal form (i.e., M/u must be evaluated for all reduction sequences $\gamma : M \to^* N$ such that $N \in \mathrm{NF}_E$). Generally, such an occurrence u depends on the subterms $M/u', u' \in \mathcal{MR}(M)$. For example, in the case for which $E \supseteq \{f(A,B,x) \to C, f(x,A,B) \to C, f(B,x,A) \to C\}$ a needed occurrence of an Ω-term $M = f(M_1, M_2, M_3)$ depends on the contexts M_1, M_2, M_3 (e.g., if M_1, M_2, M_3 are redexes and there is no reduction sequence such that $M_3 \to^* A$ or $M_3 \to^* B$, then occurrences 1 and 2 are needed, but if $M_3 \to^* B$, then occurrence 1 may not be needed [8]).

We now explain the notion of sequentiality of the predicate nf_E. The notion is based on the assumption that there exists a needed occurrence independent of the subterms $M/u, u \in \mathcal{MR}(M)$. Let $M' = M[u \leftarrow \Omega, u \in \mathcal{MR}(M)]$, where $\mathcal{MR}(M) \neq \emptyset$. Note that $\mathrm{nf}_E(M') =$ FALSE. Then the sequentiality condition is that there exists an occurrence $u \in \mathcal{MR}(M)$ such that if $N \geq M'$ and $\mathrm{nf}_E(N) =$ TRUE, then $N/u \neq \Omega$. That is, sequentiality ensures that this occurrence u is a needed occurrence of M and that it can be determined independently of the contents of the M/v's, $v \in \mathcal{MR}(M)$. The following definition of a sequential predicate is given in [11] and [8].

DEFINITION 3.6. Let the truth values be ordered by FALSE $\leq$ TRUE. Let $\mathcal{P}$ be a monotonic predicate on T_Ω. An occurrence u of a term M is said to be an *index* of $\mathcal{P}$ in M if and only if (i) $M/u = \Omega$ and (ii) $N \geq M$ and $\mathcal{P}(N) =$ TRUE (where $N \in T_\Omega$) imply $N/u \neq \Omega$. (Note that $\mathcal{P}(M)$ is false if M has an index of $\mathcal{P}$.) We use $I(\mathcal{P}, M)$ to denote the set of indices of $\mathcal{P}$ in M. $\mathcal{P}$ is said to be *sequential at* M if and only if whenever $\mathcal{P}(M) =$ FALSE and there exists N such that $N \geq M$ and $\mathcal{P}(N) =$ TRUE, it follows that there exists an index of $\mathcal{P}$ in M.

DEFINITION 3.7 [8]. TRS E is sequential if and only if the predicate nf_E is sequential at every Ω-normal form.

Unfortunately, sequentiality of TRSs is known to be undecidable, and indices of nf_E are not computable in general [8]. A sufficient condition for sequentiality, called strong sequentiality, is given in [8]. The notion of strong sequentiality is based on the analysis of the left-hand sides of rules alone, and the contents of the right-hand sides are ignored. Precisely, strong sequentiality is defined as follows.

DEFINITION 3.8 [8]. From the set E of rewrite rules, a new reduction $\to_{\mathrm{st}}$ is defined as follows: $M \to_{\mathrm{st}} N$ if and only if $M/u = \sigma(\alpha)$ and $N = M[u \leftarrow N']$ for some

$u \in \mathcal{O}(M)$, redex $\sigma(\alpha)$ (where $\alpha \in L_E$ and $\sigma : X \to T_\Omega$), and $N' \in T_\Omega$. Note that any term N' is allowed as the right-hand-side term of the rule, and L_E is the set of left-hand-side terms of E. We define a predicate snf_E as follows: $\mathrm{snf}_E(M) = \mathrm{TRUE}$ if and only if $\exists\ N$ such that $M \to_{\mathrm{st}}^* N$ and N is in normal form; (i.e., $N \in \mathrm{NF}_E$). (Note that $\mathrm{snf}_E = \mathrm{nf}_{\mathrm{st}}$ if we denote by st the set of the new rules $\{M \to N | M \to_{\mathrm{st}} N\}$.) A TRS E is said to be *strongly sequential* if and only if snf_E is sequential at every Ω-normal form.

We will see in §4 that if a TRS E is strongly sequential, then E is sequential, and for every Ω-normal form N if an occurrence u is an index of snf_E in N, then u is also an index of nf_E in N, although these results have already been shown in [8]. Thus strong sequentiality is a sufficient condition for sequentiality, and Huet and Levy [8] showed an efficient algorithm to compute indices of snf_E in a given Ω-term. Hence by the previous arguments it follows that a needed occurrence of a given Ω-term M is efficiently computed if TRS E is strongly sequential, $\mathrm{nf}_E(M) = \mathrm{TRUE}$, and $\mathcal{R}(M) \neq \emptyset$. Moreover, it is shown in [8] that if $\mathrm{nf}_E(M) = \mathrm{TRUE}$, then every call-by-need reduction sequence from M is normalizing, i.e., reaches the normal form in finite steps. Thus we can obtain a redex selection algorithm that derives the normal form from a given term whenever it has the normal form. Also, whether a TRS is strongly sequential has been shown to be decidable [8].

As a related work, it has been shown that in left-linear and nonoverlapping TRSs if a given term has the normal form, then every sequence of parallel-outermost reductions (i.e., simultaneously rewriting all outermost redexes) from the term is normalizing (see [3], [14]).

4. NV-sequentiality. In this section we introduce a condition called NV-sequentiality, which is more general than strong sequentiality. The notion of NV-sequentiality is based on the analysis of both the left-hand sides and part of the right-hand sides (i.e., the nonvariable parts) of systems, whereas strong sequentiality is based on the analysis of the left-hand sides alone.

DEFINITION 4.1. From the set E of rewrite rules, a new reduction $\to_{\mathrm{nv}}$ is defined as follows: $M \to_{\mathrm{nv}} N$ if and only if $\exists u \in \mathcal{O}(M) \exists \alpha \leftarrow \beta \in E$ such that $M/u \geq \alpha_\Omega$ and $N = M[u \leftarrow N']$ for some N', where $N' \geq \beta_\Omega$. Note that Q is a redex of E if and only if $Q \geq \alpha_\Omega$ for some $\alpha \in L_E$, since E is left-linear. So under the reduction $\to_{\mathrm{nv}}$ any redex $Q \geq \alpha_\Omega$ can reduce to any term N' such that $N' \geq \beta_\Omega$, where $\alpha \to \beta \in E$.

Note that $\to_{\mathrm{st}} \supseteq \to_{\mathrm{nv}} \supseteq \to_E$ hold, and these reductions have the same set of redexes (and the same normal forms). Using $\to_{\mathrm{nv}}$, we now define NV-sequentiality as follows.

DEFINITION 4.2. A predicate *term* is defined as follows: $\mathit{term}(M) = \mathrm{TRUE}$ if and only if $\exists N$ such that $M \to_{\mathrm{nv}}^* N$ and $N \in T$. Note that N is a term and N does not contain Ω. A TRS E is said to be NV-sequential if and only if *term* is sequential at every Ω-normal form, that is, for any M in Ω-normal form if (i) $\mathit{term}(M) = \mathrm{FALSE}$ and (ii) there exists a term N such that $N \geq M$ and $\mathit{term}(N) = \mathrm{TRUE}$, then there exists an index of *term* in M. Note that condition (ii) is always true. So from now on we will omit (ii) from the definition of NV-sequentiality. The predicate *term* is defined over the new reduction $\to_{\mathrm{nv}}$, but it is not defined over $\to_E$.

Note. To define NV-sequentiality we used the predicate *term*. Of course, we can use a predicate similar to nf_E to define another sufficient condition for sequentiality. That is, we can define a predicate $\mathrm{nvnf}_E(M)$ as follows: $\mathrm{nvnf}_E(M) = \mathrm{TRUE}$ if and only if $\exists N \in \mathrm{NF}_E$ such that $M \to_{\mathrm{nv}}^* N$. Using this predicate, we can define a class of TRSs such that nvnf_E is sequential at every Ω-normal form. In this paper we did not adopt this definition, since it will be very difficult to obtain an (efficient) algorithm for finding indices of nvnf_E.

(We conjecture that the class of TRSs satisfying this sequentiality properly includes the class of NV-sequential TRSs.)

We will give a relationship between sequential TRSs, NV-sequential TRSs, and strongly sequential TRSs. We will show that the class of NV-sequential TRSs is included in the class of sequential TRSs and properly includes the class of strongly sequential TRSs. The following two technical lemmas are used to obtain this result.

LEMMA 4.1. *Assume that* $\mathrm{NF}_E \neq \emptyset$. *Then the following statements hold*:

(i) $\mathrm{term}(M) = \mathrm{TRUE} \Rightarrow \mathrm{snf}_E(M) = \mathrm{TRUE}$;

(ii) $\mathrm{nf}_E(M) = \mathrm{TRUE} \Rightarrow \mathrm{term}(M) = \mathrm{TRUE}$.

Proof. (i) By $\mathrm{term}(M) = \mathrm{TRUE}$ we have $M \to_{\mathrm{nv}}^* N$ for some $N \in T$, so that $M \to_{\mathrm{st}}^* N$ holds. If N/u is a redex for some $u \in \mathcal{O}(N)$, then we have a reduction $N \to_{\mathrm{st}} N[u \leftarrow N']$, where $N' \in \mathrm{NF}_E$. Hence $\mathrm{snf}_E(M) = \mathrm{TRUE}$ by repeating the above reductions. (ii) By $\mathrm{nf}_E(M) = \mathrm{TRUE}$ we have $M \to_E^* N$ for some $N \in \mathrm{NF}_E$. By $N \in T$ $\mathrm{term}(M)$ is true. □

LEMMA 4.2. *Let M be an* Ω*-normal form. Let* $\mathrm{NF}_E \neq \emptyset$. *Then the following statements hold*:

(a) $u \in I(\mathrm{snf}_E, M) \Rightarrow u \in I(\mathrm{term}, M)$;

(b) $u \in I(\mathrm{term}, M) \Rightarrow u \in I(\mathrm{nf}_E, M)$.

Proof. By Definition 3.6, $u \in I(\mathcal{P}, M)$ if and only if (i) $M/u = \Omega$ and (ii) $N \geq M$ and $\mathcal{P}(N) = \mathrm{TRUE} \Rightarrow N/u \neq \Omega$ for a predicate $\mathcal{P}$.

Proof of (a). Let $u \in I(\mathrm{snf}_E, M)$. That is, the above (i) and (ii) hold where $\mathcal{P} = \mathrm{snf}_E$. Assume that $N \geq M$ and $\mathrm{term}(N) = \mathrm{TRUE}$. Then $\mathrm{snf}_E(N) = \mathrm{TRUE}$ holds by (i) of Lemma 4.1. So $N/u \neq \Omega$ by (ii) above, where $\mathcal{P} = \mathrm{snf}_E$. Thus the above (i) and (ii) also hold in the case for which $\mathcal{P} = \mathrm{term}$.

Proof of (b). This proof is similar to that of (a), except that Lemma 4.1(ii), i.e., $\mathrm{nf}_E(M) = \mathrm{TRUE} \Rightarrow \mathrm{term}(M) = \mathrm{TRUE}$ is used (instead of Lemma 4.1(i)). □

LEMMA 4.3. *Let* TRS *E be left-linear and nonoverlapping. Let* $\mathrm{NF}_E \neq \emptyset$. *Then the following statements hold*:

(i) *E is strongly sequential* $\Rightarrow$ *E is* NV*-sequential*;

(ii) *E is* NV*-sequential* $\Rightarrow$ *E is sequential.*

Proof. Let M be an Ω-normal form.

Prooff of (i). Assume that

$$(1) \qquad \mathrm{term}(M) = \mathrm{FALSE} \text{ and } \exists N, (N \geq M) \wedge (\mathrm{term}(N) = \mathrm{TRUE}).$$

By (1) $\mathrm{snf}(M) = \mathrm{FALSE}$, since $\mathrm{term}(M) = \mathrm{FALSE}$ implies that M contains Ω and M is in Ω-normal form. Obviously, $\exists N'$ such that $(N' \geq M) \wedge (\mathrm{snf}_E(N') = \mathrm{TRUE})$. (For example, choose $N' \in T$ such that $N' \geq M$.) Hence strong sequentiality of E implies that there exists an index $u \in I(\mathrm{snf}_E, M)$. Hence by (a) of Lemma 4.2, $u \in I(\mathrm{term}, M)$. Thus E is NV-sequential.

Proof of (ii). Assume that

$$(2) \qquad \mathrm{nf}_E(M) = \text{ FALSE and } \exists N \text{ such that } (N \geq M) \wedge (\mathrm{nf}_E(N) = \text{ TRUE}).$$

We first show that $\mathrm{term}(M) = \mathrm{FALSE}$. Since M is an Ω-normal form, there is no redex in M. So $\mathrm{nf}_E(M) = \mathrm{FALSE}$ in (2) implies that M contains at least one Ω. Thus $\mathrm{term}(M) = \mathrm{FALSE}$, as claimed. Hence NV-sequentiality of E implies that there exists an index $u \in I(\mathrm{term}, M)$. So by (b) of Lemma 4.2, $u \in I(\mathrm{nf}_E, M)$. Thus E is sequential. □

We can obtain a TRS E that is NV-sequential but not strongly sequential.

Example 4.1. Let

$$E = \{f(f(a,x), f(b,y)) \to f(e,e), f(f(x,a), f(c,y)) \to f(e,e), f(d,d) \to f(e,e)\},$$

where $a, b, c, d, e \in F_0, f \in F_2$, and $x, y \in X$. Note that E is similar to that given in [8, p. 27], and E is not strongly sequential since $f(f(\Omega,\Omega), f(f(\Omega,\Omega),\Omega))$ has no index. (However, note that occurrence 22 in this term is an index of term.) We can show that E is NV-sequential. We omit the proof. (A reader who is interested in the proof may refer to the previous version of this paper [17].) A general algorithm for checking NV-sequentiality will be given in §6. □

By Lemma 4.3 and Example 4.1 we have the following theorem.

THEOREM 4.1. (i) *The class of NV-sequential TRSs properly includes the class of strongly sequential TRSs.*

(ii) *The class of NV-sequential TRSs is included in the class of sequential TRSs.*

Note. Properness of (ii) in Theorem 4.1 can be proved since NV-sequentiality is shown to be decidable in §6, but sequentiality is undecidable in general. As a concrete candidate for a sequential TRS that is not NV-sequential, we give the following TRS E_2.

Example 4.2. Let

$$E_2 = \{f(g(a,x),a) \to c, f(g(x,a),b) \to c, f(k(a),x) \to c, g(b,b) \to h(b), h(x) \to k(x)\},$$

where $a, b, c \in F_0, f, g \in F_2, h, k \in F_1$, and $x \in X$. Note that E_2 is similar to that given in [8, p. 26]. We can show that E_2 is not NV-sequential, because $f(g(\Omega,\Omega),\Omega)$ has no index of term. (Note that occurrence 2 is not an index, since $f(g(b,b),\Omega) \to_{\mathrm{nv}} f(h(b),\Omega) \to_{\mathrm{nv}} f(k(a),\Omega) \to_{\mathrm{nv}} c$.) The author thinks that E_2 is sequential, although the formal proof has not been given.

5. Redex selection algorithm. In this section we consider the problem of deciding, for an Ω-term N and an occurrence $u \in \mathcal{O}(N)$, whether u is an index of term in N, i.e., $u \in I(\text{term}, N)$. We show that this problem is decidable. From now on we call this problem the *term I-problem*.

Notation. For $N \in T_\Omega$ let $I_t(N) = I(\text{term}, N)$.

Let M be a term in T, where $\mathcal{MR}(M) \neq \emptyset$, and let TRS E be NV-sequential, where E is left-linear and nonoverlapping. Let $M' = M[u \leftarrow \Omega, u \in \mathcal{MR}(M)]$. Note that $\text{term}(M') = \text{FALSE}$ by $\mathcal{MR}(M) \neq \emptyset$. So NV-sequentiality of E ensures that some occurrence u in $\mathcal{MR}(M)$ is an index of term in M' (i.e., $u \in I_t(M')$). By Lemma 4.2(b), u is also an index of nf in M', so that u is a needed redex of M for the normal form by Definition 3.5. Let $M \xrightarrow{u}_E N$ be the call-by-need reduction. If N is reducible, i.e., $\mathcal{MR}(N) \neq \emptyset$, then we repeat the above procedure for N (instead of M) until we obtain the normal form. As was explained in §3, it is shown in [8] that if $\mathrm{nf}_E(M) = \text{TRUE}$, then every call-by-need reduction sequence from M is finite-terminating and eventually leads to the normal form. Thus, using an algorithm for deciding the above term I-problem, we can obtain a redex selection algorithm that gives a reduction sequence from a term to the normal form whenever the term can reduce to the normal form.

To obtain an algorithm for deciding the term I-problem, we need some preliminaries. The following definition is given in [8].

DEFINITION 5.1 [8]. For Ω-terms $M, N \in T_\Omega$, M and N are said to be *compatible*, written $M \uparrow N$, if and only if there exists an Ω-term Q such that $M \leq Q$ and $N \leq Q$. We write $M \uparrow\!+ N$ if $M \uparrow N$ and $M \neq \Omega$.

DEFINITION 5.2 [8]. The least upper bound of two compatible Ω-terms M and N, written $M \sqcup N$, is defined as follows:

$$\Omega \sqcup M = M \sqcup \Omega = M$$

$(fM_1 \cdots M_n) \sqcup (fN_1 \cdots N_n) = f(M_1 \sqcup N_1, \cdots, M_n \sqcup N_n)$, where $f \in F \cup X$. Note that if $M \uparrow N$, then $M \sqcup N$ is defined and $M \leq M \sqcup N$ and $N \leq M \sqcup N$.

We now define a new kind of rewrite rules associated with a TRS E as follows.

DEFINITION 5.3. For Ω-terms $M, N \in T_\Omega, M \rightarrow_\omega N$ if and only if $M/u \uparrow + \alpha_\Omega$ and $N = M[u \leftarrow \beta_\Omega]$ for some $u \in \mathcal{O}(M), \alpha \rightarrow \beta \in E$. We call this reduction an ω-reduction, and we call M/u an ω-redex.

Note. The reduction $\rightarrow_\omega$ in [8] is the same as that of Definition 5.3., except that Ω is substituted for β_Ω.

Note. Let M be an Ω-normal form. Then there is no redex $\sigma(\alpha)$ in M, where $\alpha \in L_E$ and $\sigma : X \rightarrow T_\Omega$, but M may have an ω-redex, i.e., $M/u \uparrow + \alpha_\Omega$ for some $u \in \mathcal{O}(M)$ and $\alpha \in L_E$.

We first explain a relationship between this new reduction $\rightarrow_\omega$ and $\rightarrow_{\text{nv}}$ (defined in §4). Using this relationship, we will show that the term I-problem reduces to the reachability problem for quasi-ground TRSs, which is shown to be decidable in [4], [15], [16].

LEMMA 5.1. (a) *Let $M \rightarrow_\omega \beta_\Omega$ where $M \uparrow + \alpha_\Omega$ and $\alpha \rightarrow \beta \in E$. Then there exists $M' \geq M$ such that $M' \rightarrow_{\text{nv}} Q$ for any $Q \geq \beta_\Omega$.*

(b) *Let $M \rightarrow_{\text{nv}} M'$ and $N \leq M$ where $N, M, M' \in T_\Omega$. Then either $N \leq M'$ or there exists $N' \in T_\Omega$ such that $N \rightarrow_\omega N'$ and $N' \leq M'$. (This implies that $\exists N'$ such that $N \rightarrow_\omega^* N'$ and $N' \leq M'$.)*

Proof. (a) The proof is obvious. (b) By $M \rightarrow_{\text{nv}} M'$ we have $M/u \geq \alpha_\Omega$ and $M' = M[u \leftarrow Q]$ for some $u \in \mathcal{O}(M), \alpha \rightarrow \beta \in E$, and $Q \geq \beta_\Omega$. We first consider the case where there exists $v \in \mathcal{O}(N)$ such that $v \leq u$ and $N/v = \Omega$. In this case $M[v \leftarrow \Omega] \geq N[v \leftarrow \Omega] = N$ holds, so that $M' = M[v \leftarrow M'/v] \geq N$ holds, as claimed. Next consider the case where there exists no $v \in \mathcal{O}(N)$ such that $v \leq u$ and $N/v = \Omega$. In this case, by $M \geq N$ we have

$$(3) \qquad u \in \mathcal{O}(N) \wedge \text{Occ}(M, u) = \text{Occ}(N, u) \neq \Omega.$$

Since $M/u \geq \alpha_\Omega$ and $M/u \geq N/u$, we have $N/u \uparrow \alpha_\Omega$, so that $N/u \uparrow + \alpha_\Omega$ by (3). Thus $N/u \rightarrow_\omega \beta_\Omega$ by the definition of $\rightarrow_\omega$. Let $N' = N[u \leftarrow \beta_\Omega]$. Obviously, $N \rightarrow_\omega N'$ and $N' \leq M'$ hold, since $M' = M[u \leftarrow Q] \geq M[u \leftarrow \beta_\Omega] \geq N[u \leftarrow \beta_\Omega] = N'$. □

Using this relationship between $\rightarrow_{\text{nv}}$ and $\rightarrow_\omega$, we will first give a characterization of $I_t(M)$, where M is an Ω-term. That is, we will prove Lemma 5.3, which says that for an Ω-term $M \in T_\Omega - \{\Omega\}$ an occurrence $u \in \mathcal{O}(M)$ (where $M/u = \Omega$) is no index of term, i.e., $u \notin I_t(M)$ if and only if there exist $v \in \mathcal{O}(M)$, where $v < u$, and $N \in T_\Omega$ such that $(M[u \leftarrow x])/v \rightarrow_\omega^* N$ and $N \uparrow + \alpha_\Omega$ for some $\alpha \in L_E$, where x is a variable and L_E is the set of left-hand sides of E. By using this characterization the term I-problem will be shown to be decidable. For this purpose we will need some definitions and lemmas.

DEFINITION 5.4. For Ω-terms M', M and an occurrence $u \in \mathcal{O}(M')$, if $M' \geq M \wedge M'/u = \Omega \wedge \text{term}(M') = \text{TRUE}$, then we say that M' witnesses $u \notin I_t(M)$.

The following technical lemma comprises the *if* part of Lemma 5.3.

LEMMA 5.2. *Let $M \in T_\Omega$, and let $u \in \mathcal{O}(M)$, where $M/u = \Omega$. Let $M[u \leftarrow x] \rightarrow_\omega^* N$ and $N \uparrow + \alpha_\Omega$, where x is a variable and $\alpha \in L_E$. Then $u \notin I_t(M)$.*

Proof. Let $M_1 = M[u \leftarrow x]$ and $M_1 \rightarrow_\omega^k N$ for some $k \geq 0$, where $N \uparrow + \alpha_\Omega$. We will prove this lemma by induction on k.

Basis: $k = 0$. In this case $M_1 = N \uparrow + \alpha_\Omega$. Let

$$(4) \qquad Q = M_1 \sqcup \alpha_\Omega.$$

Then $Q/u = x$ holds by $M_1/u = x$. Moreover, note that α_Ω contains no variable, so that by (4), $\exists u' \leq u$ such that $\alpha_\Omega/u' = \Omega$. Thus we have

$$(5) \qquad Q[u \leftarrow \Omega] \geq \alpha_\Omega.$$

We now show that $Q[u \leftarrow \Omega]$ witnesses $u \notin I_t(M)$, i.e., (i) $Q[u \leftarrow \Omega] \geq M$, (ii) $Q[u \leftarrow \Omega]/u = \Omega$, and (iii) $\mathrm{term}(Q[u \leftarrow \Omega]) = \mathrm{TRUE}$. Obviously, (ii) holds. Since $Q[u \leftarrow \Omega] \geq M_1[u \leftarrow \Omega] = M$ holds by (4), (i) holds. It remains to show (iii). By (5) the definition of $\rightarrow_{\mathrm{nv}}$ ensures that $Q[u \leftarrow \Omega] \rightarrow_{\mathrm{nv}} N'$ for any $N' \geq \beta_\Omega$, where $\alpha \rightarrow \beta \in E$. Thus $\mathrm{term}(Q[u \leftarrow \Omega]) = \mathrm{TRUE}$, i.e., (iii) holds, as claimed.

Induction step: $k > 0$. Let $M_1 = M[u \leftarrow x] \rightarrow_\omega M_2 = (M[u \leftarrow x])[v \leftarrow \bar{\beta}_\Omega] \rightarrow_\omega^{k-1} N$, where

$$M[u \leftarrow x]/v \uparrow\!+\, \bar{\alpha}_\Omega \quad \text{for some } v \in \mathcal{O}(M[u \leftarrow x]) \text{ and } \bar{\alpha} \rightarrow \bar{\beta} \in E.$$

Let

(6) $$Q = M[u \leftarrow x]/v \sqcup \bar{\alpha}_\Omega.$$

There are two subcases: (a) $u|v$ and (b) $v < u$. Note that $u \leq v$ is impossible by $M[u \leftarrow x]/u = x$.

Case (a): $u|v$. Note that $M_2 = (M[v \leftarrow \bar{\beta}_\Omega])[u \leftarrow x]$ and $M_2 \rightarrow_\omega^{k-1} N$. So the induction hypothesis ensures that there exists Q_1 witnessing $u \notin I_t(M[v \leftarrow \bar{\beta}_\Omega])$, i.e.,

(7) $$Q_1 \geq M[v \leftarrow \bar{\beta}_\Omega] \wedge Q_1/u = \Omega \wedge \mathrm{term}(Q_1) = \mathrm{TRUE}.$$

Using (6) and (7), we can show that $Q_1[v \leftarrow Q]$ witnesses $u \notin I_t(M)$ for Q in (6), i.e., (i) $Q_1[v \leftarrow Q] \geq M$, (ii) $Q_1[v \leftarrow Q]/u = \Omega$, and (iii) $\mathrm{term}(Q_1[v \leftarrow Q]) = \mathrm{TRUE}$. Note that $Q \geq M[u \leftarrow x]/v = M/v$ by (6) and $u|v$, so that (i) holds, since $Q_1 \geq M[v \leftarrow \bar{\beta}_\Omega] \geq M[v \leftarrow \Omega]$ by (7). Since $Q_1[v \leftarrow Q]/u = Q_1/u = \Omega$ by (7), (ii) holds. It remains to show (iii). Note that $Q_1/v \geq \bar{\beta}_\Omega$ holds by (7) and $Q \geq \bar{\alpha}_\Omega$ holds by (6), where $\bar{\alpha} \rightarrow \bar{\beta} \in E$. So the definition of $\rightarrow_{\mathrm{nv}}$ ensures that $Q \rightarrow_{\mathrm{nv}} Q_1/v$. Thus $Q_1[v \leftarrow Q] \rightarrow_{\mathrm{nv}} Q_1[v \leftarrow Q_1/v] = Q_1$ holds. Since $\mathrm{term}(Q_1) = \mathrm{TRUE}$ by (7), it follows that $\mathrm{term}(Q_1[v \leftarrow Q]) = \mathrm{TRUE}$, i.e., (iii) holds, as claimed.

Case (b): $v < u$. In this case $M[u \leftarrow x]/v = (M/v)[u' \leftarrow x]$, where $vu' = u$. By $M[u \leftarrow x]/v \uparrow\!+\, \bar{\alpha}_\Omega$, the proof of the basis case of $k = 0$ ensures that there exists Q' witnessing $u' \notin I_t(M/v)$, i.e.,

(8) $$Q' \geq M/v \wedge Q'/u' = \Omega \wedge \mathrm{term}(Q') = \mathrm{TRUE}.$$

Obviously, there exists a term M_0 in T such that $M_0 \geq M$. Let $M' = M_0[v \leftarrow Q']$. Then we can prove that M' witnesses $u \notin I_t(M)$, i.e., (i) $M' \geq M$, (ii) $M'/u = \Omega$, and (iii) $\mathrm{term}(M') = \mathrm{TRUE}$. Obviously, (i) holds, since $M' = M_0[v \leftarrow Q'] \geq M[v \leftarrow Q'] \geq M$ by (8), and (ii) holds, since $M'/u = Q'/u' = \Omega$ by (8). Moreover, since $M_0 \in T$ and $\mathrm{term}(Q') = \mathrm{TRUE}$ by (8), (iii) holds, that is , $\mathrm{term}(M') = \mathrm{term}(M_0[v \leftarrow Q']) = \mathrm{TRUE}$. □

We are now ready to prove the main lemma in this section.

LEMMA 5.3. *Let M be an Ω-term, and let $u \in \mathcal{O}(M)$, where $M/u = \Omega$. Then $u \notin I_t(M)$ if and only if there exist $v \in \mathcal{O}(M)$, where $v < u$, and $N \in T_\Omega$ satisfying the following condition*:

(9) $$M[u \leftarrow x]/v \rightarrow_\omega^* N \quad \text{and} \quad N \uparrow\!+\, \alpha_\Omega \quad \text{for some } \alpha \in L_E \text{ where } x \text{ is a variable.}$$

Proof: *if part*. Note that $M[u \leftarrow x]/v = (M/v)[u' \leftarrow x]$, where $u = vu'$. So by Lemma 5.2 there exists $M' \in T_\Omega$ witnessing $u' \notin I_t(M/v)$, i.e.,

(10) $$M' \geq M/v \wedge M'/u' = \Omega \wedge \mathrm{term}(M') = \mathrm{TRUE}.$$

It follows that there exists $Q \in T_\Omega$ such that Q witnesses $u \notin I_t(M)$, because, for example, we can take $M_0[v \leftarrow M']$ as Q, where M_0 is a term in T such that $M_0 \geq M$. (Note that $Q = M_0[v \leftarrow M'] \geq M, Q/u = M'/u' = \Omega$, and term$(Q)$ = TRUE by (10).) Hence $u \notin I_t(M)$.

Proof: *only-if part*. Since $u \notin I_t(M)$, there exists $Q \in T_\Omega$ such that

(11) $$Q \geq M \wedge Q/u = \Omega \wedge \text{ term}(Q) = \text{ TRUE}.$$

So there exists a reduction sequence

$$\gamma : Q = Q_1 \xrightarrow{u_1}_{\text{nv}} Q_2 \xrightarrow{u_2}_{\text{nv}} \cdots \xrightarrow{u_{n-1}}_{\text{nv}} Q_n,$$

where $Q_n \in T$ and u_i is the redex occurrence of $Q_i \rightarrow_{\text{nv}} Q_{i+1}, 1 \leq i < n$. In this reduction sequence γ note that there exists $u_i, 1 \leq i < n$, such that $u_i < u$, since $Q/u = \Omega$ and $Q_n \in T$. Let $j(1 \leq j < n)$ be the smallest number satisfying $u_j < u$. Let $v = u_j$, and let u' satisfy $vu' = u$. Note that

(12) $$Q/v \rightarrow^*_{\text{nv}} Q_j/v \wedge Q_j/v \geq \alpha_\Omega$$

for some $\alpha \in L_E$ and that occurrence u' is safe for this reduction $Q/v \rightarrow^*_{\text{nv}} Q_j/v$, so that $Q_j/vu' = \Omega$. Let $\bar{Q}/v = (Q/v)[u' \leftarrow x]$ and $\bar{Q}_j/v = (Q_j/v)[u' \leftarrow x]$. Then

(13) $$\bar{Q}/v \rightarrow^*_{\text{nv}} \bar{Q}_j/v \quad \text{and} \quad \bar{Q}_j/v \geq \alpha_\Omega,$$

since $\bar{Q}_j/v \geq Q_j/v \geq \alpha_\Omega$ by (12). Note that by (11)

(14) $$\bar{Q}/v = (Q/v)[u' \leftarrow x] \geq (M/v)[u' \leftarrow x] = M[u \leftarrow x]/v.$$

We can now prove that condition (9) holds, i.e., the *only-if* part. Since (13) and (14) hold, by repeatedly invoking Lemma 5.1(b) we have

(15) $$M[u \leftarrow x]/v \rightarrow^*_\omega N_1 \wedge N_1 \leq \bar{Q}_j/v \quad \text{for some } N_1.$$

By (13) and (15), $N_1 \uparrow \alpha_\Omega$ holds. So if $N_1 \neq \Omega$, then $N_1 \uparrow\!+ \alpha_\Omega$ holds, so that condition (9) holds. If $N_1 = \Omega$, then by $M[u \leftarrow x]/v \neq \Omega$ there exists $R \in T_\Omega$ such that $M[u \leftarrow x]/v \rightarrow^*_\omega R \rightarrow_\omega N_1 = \Omega$ and $R \neq \Omega$. Obviously, $R \uparrow\!+ \alpha'_\Omega$ for some $\alpha' \in L_E$. (In this case $\alpha' \rightarrow \beta' \in E$ and $\beta'_\Omega = \Omega$ for some β'.) In either case condition (9) holds. □

The following lemma is a direct consequence of Lemma 5.3.

LEMMA 5.4. *Let M be an Ω-term, where $M \neq \Omega$, and let $u \in \mathcal{O}(M)$ where $M/u = \Omega$. Then $u \notin I_t(M)$ if and only if there exist $v \in \mathcal{O}(M)$, where $v < u$, and $\beta \in R_E$ such that*

$$(M[u \leftarrow x])/v \rightarrow^*_\omega \beta_\Omega,$$

where x is a variable.

Proof. The *only-if* part obviously holds by Lemma 5.3. So consider the *if* part. Let $\gamma : M[u \leftarrow x]/v \rightarrow^*_\omega \beta_\Omega$. Let u' satisfy $vu' = u$. Then, since β_Ω does not contain x, some $v_1 \in \mathcal{O}(M[u \leftarrow x]/v)$ such that $v_1 < u'$ must be an ω-redex occurrence in γ. Thus for such a v_1

$$M[u \leftarrow x]/vv_1 \rightarrow^*_\omega N \quad \text{and} \quad N \uparrow\!+ \bar{\alpha}_\Omega$$

for some $N \in T_\Omega$ and $\bar{\alpha} \in L_E$. Hence by Lemma 5.3 $u \notin I_t(M)$ holds. □

We have shown that the condition of Lemma 5.4 is an "if and only if" condition for ensuring that a given occurrence is no index of term. Now we consider how to check this condition. We will first construct a new set $K(E)$ of rewrite rules from E such that $K(E)$ is a quasi-ground TRS, and we will show a close relationship between $\rightarrow_\omega$ and $\rightarrow_{K(E)}$. Next, using this relation, we will prove that in the condition of Lemma 5.4 $\rightarrow_\omega^*$ can be replaced by $\rightarrow_{K(E)}^*$, that is, for $M \in T_\Omega - \{\Omega\}$ an occurrence $u \in \mathcal{O}(M)$ (where $M/u = \Omega$) is no index of term, i.e., $u \notin I_t(M)$ if and only if there exists $v \in \mathcal{O}(M)$, where $v < u$, and $\beta \in R_E$ such that $M[u \leftarrow x]/v \rightarrow_{K(E)}^* \beta_\Omega$. In other words, we will show that the term I-problem is reducible to the reachability problem for quasi-ground TRSs. We now define the quasi-ground system $K(E)$ as follows.

DEFINITION 5.5. For a set E of rewrite rules we define a new set $K(E)$ of rewrite rules as follows:

$$K(E) = \{\alpha \rightarrow \beta_\Omega \mid \alpha \rightarrow \beta \in E\} \cup \{\Omega \rightarrow N \mid N \in \text{sub}(\alpha_\Omega), \alpha \in L_E\}.$$

Let $\rightarrow_{K(E)}$ be a usual reduction, i.e., $M \rightarrow_{K(E)} N$ if and only if $M/u = \sigma(\alpha)$ and $N = M[u \leftarrow \sigma(\beta)]$ for some $u \in \mathcal{O}(M), \alpha \rightarrow \beta \in K(E)$, and $\sigma : X \rightarrow T_\Omega$. We have assumed that E is left-linear, so that $K(E)$ is a quasi-ground system. We now show a relationship between $\rightarrow_\omega$ and $\rightarrow_{K(E)}$.

LEMMA 5.5. *Let $M \rightarrow_\omega M'$, where $M, M' \in T_\Omega$. Then $M \rightarrow_{K(E)}^* M'$ holds.*

Proof. By $M \rightarrow_\omega M'$ there exist $v \in \mathcal{O}(M)$ and $\alpha \rightarrow \beta \in E$ such that

$$M/v \uparrow\!+ \alpha_\Omega \quad \text{and} \quad M' = M[v \leftarrow \beta_\Omega].$$

By $M/v \uparrow\!+ \alpha_\Omega$ let $Q = M/v \sqcup \alpha_\Omega$. Note that for each $u \in \mathcal{O}_\Omega(M/v)$ (see Definition 3.3) if $u \in \mathcal{O}(\alpha_\Omega)$, then $Q/u = \alpha_\Omega/u$ holds and $Q = M/v[u \leftarrow \alpha_\Omega/u, u \in \mathcal{O}_\Omega(M/v) \cap \mathcal{O}(\alpha_\Omega)]$ by definition of $\sqcup$. Thus Q is obtained from M/v by replacing Ω at each occurrence u in $\mathcal{O}_\Omega(M/v)$ by α_Ω/u, where $u \in \mathcal{O}(\alpha_\Omega)$. Hence we have $M/v \rightarrow_{K(E)}^* Q$ by applying rewrite rules of form $\Omega \rightarrow R$, where $R \in \text{sub}(\alpha_\Omega)$. Furthermore, $Q \rightarrow_{K(E)} \beta_\Omega$ holds by $Q \geq \alpha_\Omega$. Thus $M \rightarrow_{K(E)}^* M[v \leftarrow \beta_\Omega] = M'$ holds. □

LEMMA 5.6. *Let $M \rightarrow_{K(E)} M'$ and $N \leq M$, where $M, M', N \in T_\Omega$. Then there exists $N' \in T_\Omega$ such that $N \rightarrow_\omega^* N'$ and $N' \leq M'$.*

Proof. Let v be the redex occurrence of $M \rightarrow_{K(E)} M'$. If $M/v = \Omega$, then a rule of form $\Omega \rightarrow R$ is applied. In this case $M \leq M'$ holds, so that $N \leq M \leq M'$. Thus this lemma holds if we choose $N' = N$. So consider the case for which $M/v \neq \Omega$, that is, $M/v \geq \alpha_\Omega$ for some $\alpha \in L_E$ and $M' = M[v \leftarrow \beta_\Omega]$, where $\alpha \rightarrow \beta \in E$. For $N \leq M$ if there exists $v' \in \mathcal{O}(N)$ such that $N/v' = \Omega$ and $v' \leq v$, then, obviously, $N \leq M[v \leftarrow \beta_\Omega] = M'$ holds by $N \leq M$. So this lemma holds if we choose $N' = N$.

Consider the case for which there exists no $v' \in \mathcal{O}(N)$ such that $v' \leq v$ and $N/v' = \Omega$. In this case, by $N \leq M$ we have

$$(16) \qquad v \in \mathcal{O}(N) \wedge \text{Occ}(N, v) = \text{Occ}(M, v) \neq \Omega.$$

Since $M/v \geq \alpha_\Omega$ and $M/v \geq N/v$, we have $N/v \uparrow \alpha_\Omega$, so that $N/v \uparrow\!+ \alpha_\Omega$ by (16). Hence $N/v \rightarrow_\omega \beta_\Omega$ by the definition of $\rightarrow_\omega$. So $N \rightarrow_\omega N[v \leftarrow \beta_\Omega]$ holds. By $N[v \leftarrow \beta_\Omega] \leq M[v \leftarrow \beta_\Omega] = M'$ this lemma holds. □

LEMMA 5.7. *Let $M \in T_\Omega - \{\Omega\}$ and $u \in \mathcal{O}(M)$, where $M/u = \Omega$. Then $u \notin I_t(M)$ if and only if there exist $v \in \mathcal{O}(M)$, where $v < u$, and $\beta \in R_E$ such that*

$$(M[u \leftarrow x])/v \rightarrow_{K(E)}^* \beta_\Omega,$$

where x is a variable.

Proof. The *only-if* part obviously holds by Lemmas 5.4 and 5.5. So consider the *if* part. Let $M[u \leftarrow x]/v \to^*_{K(E)} \beta_\Omega$. By Lemma 5.6 we have the following ω-reduction sequence

$$\gamma : M[u \leftarrow x]/v \to^*_\omega N \quad \text{for some } N \leq \beta_\Omega.$$

Let u' satisfy $vu' = u$. Note that N does not contain x, since β_Ω does not contain x. So some $v_1 \in \mathcal{O}(M[u \leftarrow x]/v)$, where $v_1 < u'$, must be a redex occurrence in γ. Thus for such a v_1

$$M[u \leftarrow x]/vv_1 \to^*_\omega Q \to_\omega \bar{\beta}_\Omega \quad \text{and} \quad Q \uparrow\!+ \bar{\alpha}_\Omega$$

for some $Q \in T_\Omega$ and $\bar{\alpha} \to \bar{\beta} \in E$. Hence by Lemma 5.4 we have $u \notin I_t(M)$. □

By Lemma 5.7 the term I-problem is reducible to the reachability problem for quasi-ground systems, which has been shown to be decidable in [4], [15], [16]. Thus we have the following theorem.

THEOREM 5.1. *It is decidable, for an Ω-term M and an occurrence $u \in \mathcal{O}(M)$, whether u is an index of term in M, i.e., $u \in I_t(M)$.*

Next we discuss the time complexity of algorithms for deciding the term I-problem. By Lemma 5.7, to decide whether u is an index of term in M we need the reachability tests for at most $|M| \cdot \|R_E\|$ pairs $(M[u \leftarrow x]/v, \beta_\Omega)$. Let $\mathcal{A}$ be an algorithm that takes as input a quasi-ground system E_1 and two terms M, N and decide whether $M \to^*_{E_1} N$. For example, as $\mathcal{A}$ one can consider an algorithm in [4], [15], [16]. Anyway, it will be natural to consider the input size of $\mathcal{A}$ as size$(E_1) + |M| + |N|$, where size$(E_1) = \sum_{\alpha\to\beta\in E_1} |\alpha| + |\beta|$. Let $T_\mathcal{A}(n)$ be the time needed by algorithm $\mathcal{A}$ under inputs whose size is n. (We consider $T_\mathcal{A}(n)$ as the worst-case time complexity.) Let n = size(E), and let $m = |M|$. Then, for given $u, v \in \mathcal{O}(M)$ and $\beta \in R_E$, whether $M[u \leftarrow x]/v \to^*_{K(E)} \beta_\Omega$ can be checked in the order of time $T_\mathcal{A}(n^2 + m)$, since size$(K(E)) \leq n + n^2$. So the total time required to decide whether u is an index of term in M is bounded by the order of time $mn \cdot T_\mathcal{A}(n^2 + m)$. By the preceding arguments we have the following theorem.

THEOREM 5.2. *Let E be a left-linear system, and let $M \in T_\Omega$. Let n =* size(E), *and let $m = |M|$. Let $\mathcal{A}$ be an algorithm that solves the reachability problem for quasi-ground systems and operates in time $T_\mathcal{A}(k)$ for inputs of size k. Then, using algorithm $\mathcal{A}$, we can decide whether a given occurrence u is an index of term in M in time $mn \cdot T_\mathcal{A}(n^2 + m)$.*

Since reachability for quasi-ground systems can be checked in polynomial time (see [4], [16]), we have the following corollary.

COROLLARY 5.1. *The term I-problem can be decided in polynomial time.*

Note. At each step of the call-by-need reduction sequence, we must find a needed redex. Thus consecutive searches for finding needed redexes are made, and it is important to consider how to reduce the total cost of computing needed redexes, that is, how to use useful information obtained from the search of the previous step to efficiently find a needed redex at each step. In this paper we did not consider this problem, so it will be the next step following the work of this paper.

6. Decidability of NV-sequentiality.

In this section we show that whether a left-linear TRS E is NV-sequential is decidable. For this purpose we need some lemmas and definitions. The following three technical lemmas are used later. They state properties concerning indices of term.

LEMMA 6.1. *Let $M \in T_\Omega$, and let $u, v \in \mathcal{O}(M)$, where $u \mid v$. Then $v \in I_t(M[u \leftarrow \Omega]) \Rightarrow v \in I_t(M)$.*

Proof. By the definition of indices of term, $v \in I_t(M[u \leftarrow \Omega])$ if and only if (i) $M[u \leftarrow \Omega]/v = \Omega$ and (ii) $N \geq M[u \leftarrow \Omega]$ and term$(N) =$ TRUE imply $N/v \neq \Omega$. By $u \mid v$ and (i) we have $M/v = \Omega$. Note that $N \geq M$ implies that $N \geq M[u \leftarrow \Omega]$, so that by (ii) $v \in I_t(M)$ holds □

LEMMA 6.2. *Let $M \in T_\Omega$, and let $u \in \mathcal{O}(M)$. If $I_t(M) = \emptyset$, then either $I_t(M[u \leftarrow \Omega]) = \emptyset$ or $u \in I_t(M[u \leftarrow \Omega])$.*

Proof. Assume that $I_t(M) = \emptyset$ and $u \notin I_t(M[u \leftarrow \Omega])$. Then we can show that $I_t(M[u \leftarrow \Omega]) = \emptyset$. Let $v \in \mathcal{O}(M)$ such that $M/v = \Omega$ and $u \mid v$. By $I_t(M) = \emptyset, v \notin I_t(M)$ holds, so that $v \notin I_t(M[u \leftarrow \Omega])$ holds by Lemma 6.1. Thus for all $u' \in \mathcal{O}(M[u \leftarrow \Omega])$ such that $M[u \leftarrow \Omega]/u' = \Omega$ we have $u' \notin I_t(M[u \leftarrow \Omega])$, so that $I_t(M[u \leftarrow \Omega]) = \emptyset$ holds. □

LEMMA 6.3. *If $uv \in I_t(M)$, then $v \in I_t(M/u)$.*

Proof. To the contrary, we assume that $v \notin I_t(M/u)$. Then by Lemma 5.3 we have

$$\exists w < v \exists Q \in T_\Omega \exists \alpha \in L_E$$

such that

$$(M/u[v \leftarrow x])/w \to_\omega^* Q \uparrow\!+ \alpha_\Omega.$$

By $(M/u[v \leftarrow x])/w = (M[uv \leftarrow x])/uw$ and Lemma 5.3 we have $uv \notin I_t(M)$, a contradiction. □

Next we need the following definition.

DEFINITION 6.1. Let $h_E = \text{Max}\{h(\alpha) | \alpha \in L_E\}$, i.e., h_E is the maximal height of left-hand sides of E. We omit the subscript E where confusion does not occur without it.

The following lemma says that, for a given Ω-term M, if some subterm M/u has an index of term and some Ω-term N' satisfying $N' = M[v \leftarrow \Omega]$ for some $v > u$ also has an index of term, then the existence of an index of term in M is ensured. That is, this lemma shows a kind of transitivity result on the index of term and will be used to prove the main theorem in this section, i.e., to obtain an upper bound of the least size $|M|$ satisfying $I_t(M) = \emptyset$ if such M in Ω-normal form exists. (In [12] a result similar to this lemma is called a partial transitivity result for index propagation.)

LEMMA 6.4. *Let M be an Ω-term, and let $u\delta v \in \mathcal{O}_\Omega(M)$, where $|\delta| \geq h_E$. If $u\delta \in I_t(M[u\delta \leftarrow \Omega])$ and $\delta v \in I_t(M/u)$, then $u\delta v \in I_t(M)$.*

Proof. To the contrary, we assume that $u\delta v \notin I_t(M)$. Then by Lemma 5.3

$$\exists w < u\delta v \exists Q \in T_\Omega \exists \alpha \in L_E$$

such that

(17) $$M[u\delta v \leftarrow x]/w \to_\omega^* Q \uparrow\!+ \alpha_\Omega.$$

Note that $w < u$ must hold by $\delta v \in I_t(M/u)$ and Lemma 5.3 (see Fig. 1). Without loss of generality we can assume that for every occurrence w', where $w \leq w' < u, w'/w$ is safe for the ω-reduction sequence (17). Note that by $\delta v \in I_t(M/u)$, for every occurrence w'', where $u \leq w'' < u\delta v, w''/w$ is also safe for sequence (17). Hence for a term $M[u\delta \leftarrow x]$ we have

$$M[u\delta \leftarrow x]/w \to_\omega^* Q[u\delta/w \leftarrow x].$$

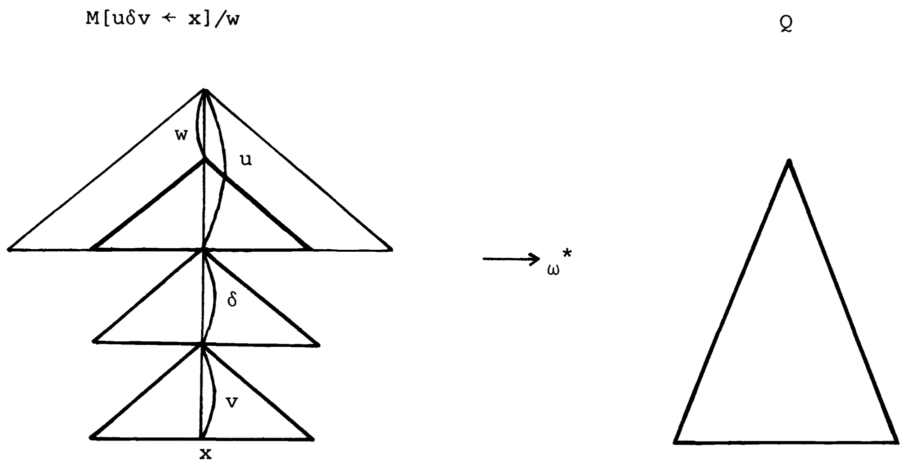

FIG. 1. *ω-reduction sequence* $M[u\delta v \leftarrow x]/w \to_\omega^* Q$.

Moreover, $Q[u\delta/w \leftarrow x] \uparrow\!\!+\ \alpha_\Omega$ holds, since $Q \uparrow\!\!+\ \alpha_\Omega$ by (17) and $|u\delta/w| > h_E$ holds. Hence $u\delta \notin I_t(M[u\delta \leftarrow \Omega])$ by Lemma 5.3, a contradiction. □

We also need the following functions, the use of which will be explained later.

DEFINITION 6.2. We define some functions on Ω-term as follows: For $M \in T_\Omega$ and $n \geq 0$

(i) $\mathcal{O}(M)_n = \{u \in \mathcal{O}(M) \mid |u| = n\}$, i.e., $\mathcal{O}(M)_n$ is the set of occurrences of M with size n.

(ii)

$$\mathrm{Pref}(M)_n = \begin{cases} M[u \leftarrow \Omega, u \in \mathcal{O}(M)_n] & \text{if } \mathcal{O}(M)_n \neq \emptyset, \\ M & \text{otherwise.} \end{cases}$$

We call $\mathrm{Pref}(M)_n$ the Ω-prefix of M with height $\leq n$. Note that $\mathrm{Pref}(M)_n \leq M$.

(iii) $\mathrm{Yield}(M)_h = \{\mathrm{Pref}(N)_h | M \to_\omega^* N\}$, where $h = h_E$ (see Definition 6.1), i.e., $\mathrm{Yield}(M)_h$ is the set of the Ω-prefixes (with height $\leq h$) of Ω-terms reachable from M under $\to_\omega$.

(iv) $\mathrm{Env}(M,u)_{2h} = \{\mathrm{Pref}(N)_{2h} \mid \exists\gamma : M[u \leftarrow \Omega] \to_\omega^* N$ such that $u \in \mathcal{O}(M)$ is safe for $\gamma\}$, where $h = h_E$, i.e., $\mathrm{Env}(M,u)_{2h}$ is the set of the Ω-prefixes (with height $\leq 2h$) of Ω-terms reachable from $M[u \leftarrow \Omega]$ by ω-reduction sequences for which occurrence $u \in \mathcal{O}(M)$ is safe. $\mathrm{Env}(M,u)_{2h}$ is undefined if $u \notin \mathcal{O}(M)$.

Example. Let $M = f(c, f(\Omega, x))$, where $f \in F_2, c \in F_0, x \in X$. Then $\mathcal{O}(M)_1 = \{1,2\}, \mathcal{O}(M)_2 = \{21,22\}$, and $\mathrm{Pref}(M)_1 = f(\Omega,\Omega)$, $\mathrm{Pref}(M)_2 = f(c, f(\Omega,\Omega))$.

Note. We can show that Yield and Env are computable functions, i.e., we can give algorithms to compute $\mathrm{Yield}(M)_h$ and $\mathrm{Env}(M,u)_h$ for a given Ω-term M and $u \in \mathcal{O}(M)$. The proof is omitted because Theorem 6.1 does not need the proof of existence of such algorithms, but simply upper bounds of $\|\mathrm{Yield}(M)_h\|$ and $\|\mathrm{Env}(M,u)_h\|$ (which are obvious).

Now we explain how to use the function Env. For this purpose we need the following definition.

DEFINITION 6.3. Two Ω-term M and N have the same environment concerning an occurrence δ (where $\delta \in \mathcal{O}_\Omega(M) \cap \mathcal{O}_\Omega(N)$) if $\mathrm{Env}(M,\delta)_{2h} = \mathrm{Env}(N,\delta)_{2h}$, where $h = h_E$.

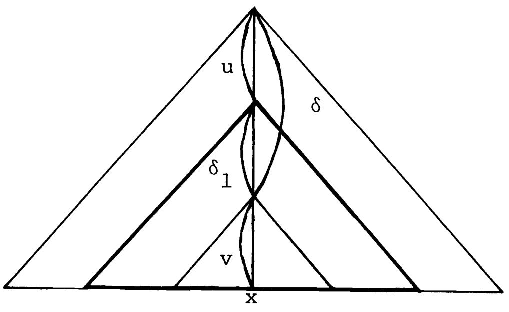

FIG. 2. $M[\delta \leftarrow Q[v \leftarrow x]]/u$.

The following lemma says that if M and N have the same environment concerning δ, then for any Ω-term Q if $M[\delta \leftarrow Q]$ has an index δv of term for some $v \in \mathcal{O}(Q)$, then $N[\delta \leftarrow Q]$ has also δv as an index of term. Thus replacement of $M[\delta \leftarrow Q]$ by $N[\delta \leftarrow Q]$ is index preserving in the above sense. This property will be used to prove the main theorem in this section, i.e., to obtain an upper bound of the least size $|M|$ satisfying $I_t(M) = \emptyset$ if such M in Ω-normal form exists.

LEMMA 6.5. *Let $M, N \in T_\Omega$ and $\delta \in \mathcal{O}_\Omega(M) \cap \mathcal{O}_\Omega(N)$, where $|\delta| = h$. Let M and N have the same environment concerning δ. Then for any $Q \in T_\Omega$ and $v \in \mathcal{O}_\Omega(Q)$*

$$\delta v \in I_t(M[\delta \leftarrow Q]) \textit{ if and only if } \delta v \in I_t(N[\delta \leftarrow Q]).$$

Proof: *if part*. To the contrary, we assume that $\delta v \notin I_t(M[\delta \leftarrow Q])$. By Lemma 5.3

$$\exists u < \delta v \exists P \in T_\Omega \exists \alpha \in L_E$$

such that

(18) $$M[\delta \leftarrow Q[v \leftarrow x]]/u \to_\omega^* P \uparrow + \alpha_\Omega.$$

If $u \geq \delta$, then $N[\delta \leftarrow Q[v \leftarrow x]]/u \to_\omega^* P \uparrow + \alpha_\Omega$, so that $\delta v \notin I_t(N[\delta \leftarrow Q])$ by Lemma 5.3, a contradiction.

So consider the case $u < \delta$. Let δ_1 satisfy $u\delta_1 = \delta$ (see Fig. 2). Without loss of generality we can assume that any $w < \delta_1$ is safe for the ω-reduction sequence (18), so that we can divide (18) into two subsequences, one of which is the subsequence with ω-redex occurrences $\geq \delta_1$ and the other of which has ω-redex occurrences disjoint from δ_1 :

(19) $$M[\delta \leftarrow Q[v \leftarrow x]]/u\delta_1 (= Q[v \leftarrow x]) \to_\omega^* P/\delta_1,$$

(20) $$M[\delta \leftarrow \Omega]/u \to_\omega^* P[\delta_1 \leftarrow \Omega].$$

Since M and N have the same environment concerning δ, by (20) we have

(21) $$N[\delta \leftarrow \Omega] \to_\omega^* P'$$

for some $P' \in T_\Omega$, where

$$\text{Pref}(P'/u)_h = \text{Pref}(P[\delta_1 \leftarrow \Omega])_h \tag{22}$$

and δ is safe for this ω-reduction sequence (21), so that $P'/\delta = \Omega$ holds. Thus by (21) we have

$$N[\delta \leftarrow \Omega]/u \to_\omega^* P'/u. \tag{23}$$

Now we combine the ω-reduction sequences (23) and (19):

$$N[\delta \leftarrow Q[v \leftarrow x]]/u \to_\omega^* (P'/u)[\delta_1 \leftarrow P/\delta_1]. \tag{24}$$

Note that $\text{Pref}((P'/u)[\delta_1 \leftarrow P/\delta_1])_h = \text{Pref}(P)_h$ holds by (22), so that

$$(P'/u)[\delta_1 \leftarrow P/\delta_1] \uparrow\!+ \alpha_\Omega$$

holds by (18). Therefore, $\delta v \notin I_t(N[\delta \leftarrow Q])$ by (24) and Lemma 5.3, which is a contradiction. □

Proof: *only-if part.* This proof is the same as the above except that M and N are interchanged. □

Now we give the last definitions needed in this section.

DEFINITION 6.4. For $n \geq 0$ we define $T_\Omega(n)$ and $\text{lg}(n)$ as follows: $T_\Omega(n) = \{M \in T_\Omega \mid h(M) \leq n\}$, i.e., $T_\Omega(n)$ is the set of Ω-terms of height $\leq n$. $\text{lg}(n) = \text{Max}\{|M| \mid M \in T_\Omega \wedge h(M) \leq n\}$, i.e., $\text{lg}(n)$ is the maximal size of Ω-terms of height $\leq n$.

DEFINITION 6.5. Let $l_0, l_1, \cdots, l_5$ be constants defined as follows: Let $l_0 = \text{Max}\{a(f) \mid f \in F\}$ (i.e., l_0 is the maximal arity of F), $l_1 = l_0^h, l_2 = \|2^{T_\Omega(2h)}\|$ (i.e., l_2 is the cardinality of subsets of $T_\Omega(2h)$), $l_3 = \|2^{T_\Omega(h)}\|, l_4 = \|T_\Omega(h)\|$, and $l_5 = \text{Max}\{|M| \mid M \in \text{NF}_E \wedge h(M) \leq h\}$, where $h = h_E$.

We are now ready to show the decidability of NV-sequentiality for left-linear TRSs. The following theorem says that to decide whether a left-linear TRS E is NV-sequential, we need to check, for only a finite number of Ω-normal forms, whether there exist indices of term. In other words, this theorem gives an upper bound of the least size $|M|$ satisfying $I_t(M) = \emptyset$ if such an Ω-term M in Ω-normal form exists.

THEOREM 6.1. *Let $L = 1 + h + l_5 + l_1 \cdot l_2 \cdot l_3 \cdot l_4$. Then a left-linear* TRS *E is* NV*-sequential if and only if for all Ω-normal form M in T_Ω such that $|M| \leq lg(L)$ and $M \notin T, I_t(M) \neq \emptyset$ holds.*

Proof: *only-if part.* If M is in Ω-normal form and $M \notin T$, then $\text{term}(M) = \text{FALSE}$, so that $I_t(M) \neq \emptyset$ by NV-sequentiality of E.

Proof: *if part.* To the contrary, we assume that there exists an Ω-normal form M such that $|M| > lg(L), M \notin T$, and $I_t(M) = \emptyset$. Here we assume that M is such an Ω-term with the least size $|M|$. By $|M| > lg(L)$ Definition 6.4 of $lg(L)$ ensures $h(M) > L$, so that $\exists v \in \mathcal{O}(M)$, such that $|v| > L$. Let

$$v = v_1 v_2, \quad \text{where } |v_2| = l_5 + 1. \tag{25}$$

Note that $|v_1| > h + l_1 \cdot l_2 \cdot l_3 \cdot l_4$.

Our goal is to show that there exists an Ω-normal form M' such that $|M'| < |M|$, $M' \notin T$, and $I_t(M') = \emptyset$. Thus this contradicts the minimality of the size of M. The

crucial point in this argument is how to construct such an Ω-term M'. We will show that $M' = M[u_0 \leftarrow M/u_1]$ for some $u_0, u_1 \in \mathcal{O}(M)$ satisfies the above required conditions:
(i) $M' \notin T$,
(ii) $|M'| < |M|$,
(iii) M' is in Ω-normal form,
(iv) $I_t(M') = \emptyset$.

The following assertion shows that if we choose u_1 so that $u_1 \leq v_1$ may hold for v_1 in (25), then $M/u_1 \notin T$, so that $M' = M[u_0 \leftarrow M/u_1]$ satisfies condition (i).

ASSERTION 6.1. *M/v_1 contains Ω.*

Proof. To the contrary, we assume that $M/v_1 \in T$. Note that M/v_1 is in normal form. By (25), $v_2 \in \mathcal{O}(M/v_1)$ and $|v_2| > l_5 = \mathrm{Max}\{|M| \mid M \in \mathrm{NF}_E \wedge h(M) \leq h_E\}$, so that we have $h(M/v_1) > h_E$. Let

$$N = (M/v_1)[u \leftarrow x, u \in \mathcal{O}(M/v_1)_{h_E}],$$

where $x \in X$. Then clearly $N \in \mathrm{NF}_E$ by $M/v_1 \in \mathrm{NF}_E$. Note that

$$(26) \qquad |N| < |M/v_1| \quad \text{and} \quad \mathrm{Pref}(N)_{h_E} = \mathrm{Pref}(M/v_1)_{h_E}.$$

Let

$$M_1 = M[v_1 \leftarrow N].$$

Then $|M_1| < |M|$ holds by (26). Note that $M_1 \notin T$ by $M \notin T$ and the assumption $M/v_1 \in T$, and M_1 is in Ω-normal form, since M is in Ω-normal form and replacement of M/v_1 by N does not produce any redex by (26). Moreover, we can show that $I_t(M_1) = \emptyset$, so that this contradicts the minimality of the size of M.

We now show that $I_t(M_1) = \emptyset$. By $I_t(M) = \emptyset$, for every $u \in \mathcal{O}_\Omega(M)$, we have $u \notin I_t(M)$, so that by Lemma 5.3

$$\exists u' < u \exists Q \in T_\Omega \exists \alpha \in L_E$$

such that

$$(27) \qquad M[u \leftarrow x]/u' \to_\omega^* Q \uparrow\!+ \alpha_\Omega.$$

Note that $u|v_1$ holds by $M/v_1 \in T$ and $M/u = \Omega$. There are two cases: (i) $u'|v_1$ and (ii) $u' < v_1$. In case (i) obviously $u \notin I_t(M_1)$ by Lemma 5.3, so consider case (ii). Let δ satisfy $u'\delta = v_1$. Without loss of generality we can assume that every occurrence δ' satisfying $\delta' < \delta$ and $u'\delta' < u$ is safe for the ω-reduction sequence (27) (see Fig. 3). We want to show that

$$(28) \qquad M_1[u \leftarrow x]/u' \quad (= M[u \leftarrow x, v_1 \leftarrow N]/u') \to_\omega^* Q' \uparrow\!+ \alpha_\Omega$$

for some $Q' \in T_\Omega$, so that $u \notin I_t(M_1)$. If any $\delta' < \delta$ is safe for the ω-reduction sequence (27), then $M/v_1 \to_\omega^* Q/\delta$ by the definition of safe, and since $M/v_1 \in \mathrm{NF}_E$ by the assumption, we have

$$M/v_1 = Q/\delta.$$

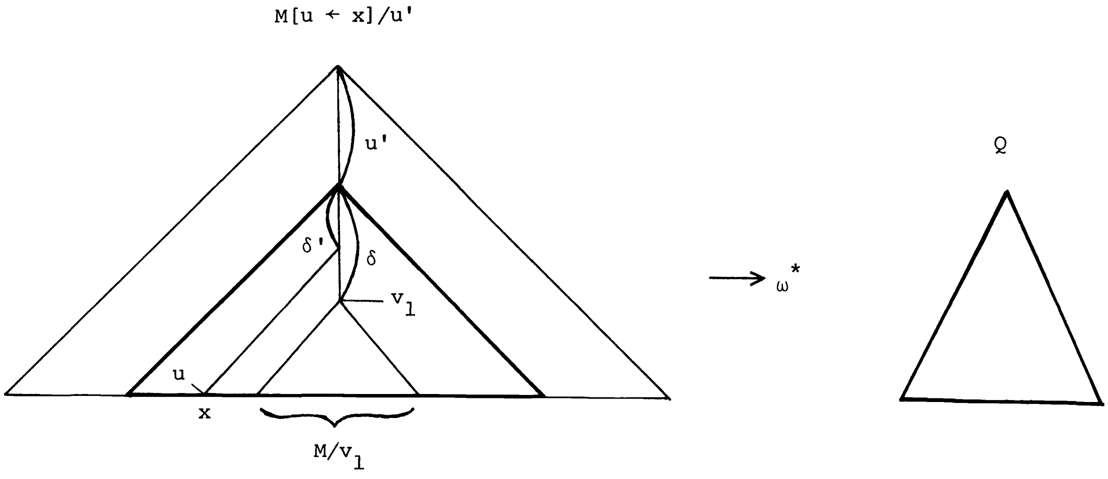

FIG. 3. *ω-reduction sequence* $M[u \leftarrow x]/u' \to_\omega^* Q$.

By replacing M/v_1 with N, we have the following sequence from (27):

$$M[u \leftarrow x, v_1 \leftarrow N]/u' \to_\omega^* Q[\delta \leftarrow N].$$

(Note that $v_1/u' = \delta$.) Then $Q[\delta \leftarrow N] \uparrow\!+\, a_\Omega$ holds, since $\mathrm{Pref}(N)_{h_E} = \mathrm{Pref}(M/v_1)_{h_E}$ by (26) and $Q \uparrow\!+\, a_\Omega$ by (27), where $Q/\delta = M/v_1$. Hence we have the above ω-reduction sequence (28), where $Q' = Q[\delta \leftarrow N]$. Otherwise, i.e., if some u'' satisfying that $u'' < \delta$ and $u'u''|u$ is an ω-redex occurrence in (27), then $\mathrm{Pref}(M/v_1)_{h_E} = \mathrm{Pref}(N)_{h_E}$ also ensures the existence of the above ω-reduction sequence (28). (In this case $Q' = Q$ holds.) Hence $u \notin I_t(M_1)$. Thus $I_t(M_1) = \emptyset$, as claimed. □

Now we explain how to choose occurrences u_0 and u_1 in $\mathcal{O}(M)$ to construct $M' = M[u_0 \leftarrow M/u_1]$. We choose u_1 satisfying $u_1 \le v_1$, so that $M' \notin T$ by Assertion 6.1.

For each occurrence u such that $u \le v_1$ and $|u| \le |v_1| - h$ we define tuple(u) as follows:

$$\mathrm{tuple}(u) = (\delta, \mathrm{env}, \mathrm{yield}, \mathrm{pref}) \in \mathbb{N}^h \times 2^{T_\Omega(2h)} \times 2^{T_\Omega(h)} \times T_\Omega(h),$$

where δ satisfies $|\delta| = h$ and $u\delta \le v_1$, env $= \mathrm{Env}(M/u, \delta)_{2h}$, yield $= \mathrm{Yield}(M/u\delta)_h$, pref $= \mathrm{Pref}(M/u\delta)_h$, and here $h = h_E$. Note that the number of different tuples is bounded by $l_1 \cdot l_2 \cdot l_3 \cdot l_4$ (see Definition 6.5).

By $|v_1| > h + l_1 \cdot l_2 \cdot l_3 \cdot l_4$ there exist

(29) $u, u' \in \mathcal{O}(M)$ such that $u < u' < v_1, |u'| \le |v_1| - h,$ and $\mathrm{tuple}(u) = \mathrm{tuple}(u')$.

Let

(30) $\mathrm{tuple}(u) = (\delta, \mathrm{env}, \mathrm{yield}, \mathrm{pref}) = \mathrm{tuple}(u'), u_0 = u\delta,$ and $u_1 = u'\delta$.

Note that $u'\delta \le v_1$, so that $M' = M[u_0 \leftarrow M/u_1]$ satisfies condition (i), $M' \notin T$, by Assertion 6.1. Our goal is to show the remaining three conditions.

Condition (ii), $|M'| < |M|$, holds, since by (29) $u < u'$, so that $|M/u_0| > |M/u_1|$ follows.

Condition (iii), that M' is in Ω-normal form, also holds. Since M is in Ω-normal form, M/u_1 is also in Ω-normal form. Moreover, since $\mathrm{Pref}(M/u_0)_{h_E} = \mathrm{Pref}(M/u_1)_{h_E} = \mathrm{pref}$ holds by (30), $M[u_0 \leftarrow M/u_1](= M')$ has no redex. Thus it remains to show condition (iv).

Proof of (iv). $I_t(M') = \emptyset$. We will show that any occurrence v in $\mathcal{O}_\Omega(M')$ is not an index of term so that $I_t(M') = \emptyset$.

Let $v \in \mathcal{O}_\Omega(M')$. Then there are two cases: (a) $v|u_0$ and (b) $u_0 < v$.

Case (a). $v|u_0$. In this case $v \in \mathcal{O}_\Omega(M)$ holds by $M' = M[u_0 \leftarrow M/u_1]$. Since $v \notin I_t(M)$, Lemma 5.3 ensures that

$$\exists w < v \exists Q \in T_\Omega \exists \alpha \in L_E \text{ such that } M[v \leftarrow x]/w \to_\omega^* Q \uparrow\!+ \alpha_\Omega. \tag{31}$$

There are two subcases: (a1) $w|u_0$ and (a2) $w < u_0$.

Case (a1). $w|u_0$. In this case $M[v \leftarrow x]/w$ is a subterm of $M'[v \leftarrow x]$, so that $v \notin I_t(M')$ by Lemma 5.3.

Case (a2). $w < u_0$. This proof is a slight generalization of that of Assertion 6.1. Let δ_0 satisfy $w\delta_0 = u_0$. Without loss of generality, we can assume that every occurrence δ' satisfying $\delta' < \delta_0$ and $w\delta' < v$ is safe for (31). We want to show that

$$M'[v \leftarrow x]/w \to_\omega^* Q' \uparrow\!+ \alpha_\Omega \tag{32}$$

for some $Q' \in T_\Omega$, so that $v \notin I_t(M')$. If any $\delta' < \delta_0$ is safe for (31), then

$$M/u_0 \to_\omega^* Q/\delta_0$$

holds. Since $\mathrm{Yield}(M/u_0)_{h_E} = \mathrm{Yield}(M/u_1)_{h_E} = \mathrm{yield}$ by (30), we have

$$M/u_1 \to_\omega^* P \quad \text{and} \quad \mathrm{Pref}(P)_{h_E} = \mathrm{Pref}(Q/\delta_0)_{h_E} \tag{33}$$

for some $P \in T_\Omega$. Hence by (33) and (31) we have

$$M[v \leftarrow x, u_0 \leftarrow M/u_1]/w \to_\omega^* Q[\delta_0 \leftarrow P].$$

(Note that $u_0/w = \delta_0$.) Then $Q[\delta_0 \leftarrow P] \uparrow + \alpha_\Omega$ holds, since $Q \uparrow + \alpha_\Omega$ by (31) and $\mathrm{Pref}(P)_{h_E} = \mathrm{Pref}(Q/\delta_0)_{h_E}$ by (33). Hence we have the sequence (32), where $Q' = Q[\delta_0 \leftarrow P]$. Otherwise, i.e., if some δ' satisfying $\delta' < \delta_0$ and $w\delta'|v$ is an ω-redex occurrence in (31), then $\mathrm{Yield}(M/u_0)_{h_E} = \mathrm{Yield}(M/u_1)_{h_E}$ (by (30)) also ensures the existence of the above ω-reduction sequence (32). (In this case $Q' = Q$ holds.) Hence $v \notin I_t(M')$, as claimed.

Case (b). $u_0 < v$. Let v' satisfy $v = u_0 v'$. Note that

$$v' \in \mathcal{O}_\Omega(M/u_1) \tag{34}$$

by $M'/u_0 = M/u_1$. Thus $u_1 v' \in \mathcal{O}_\Omega(M)$ holds. We can show the following assertion that $\delta v' \notin I_t(M/u')$. Note that $u_1 = u'\delta$ by (30). By using this result it will be shown that $v \notin I_t(M')$.

ASSERTION 6.2. $\delta v' \notin I_t(M/u')$.

Proof. To the contrary, we assume that $\delta v' \in I_t(M/u')$. Then we can show that

$$u'\delta \notin I_t(M[u'\delta \leftarrow \Omega]), \tag{35}$$

because if $u'\delta \in I_t(M[u'\delta \leftarrow \Omega])$ and $\delta v' \in I_t(M/u')$, then $I_t(M) \neq \emptyset$ would hold by Lemma 6.4, a contradiction. However, since Lemma 6.2 says that if $I_t(M) = \emptyset$, then either $I_t(M[u'\delta \leftarrow \Omega]) = \emptyset$ or $u'\delta \in I_t(M[u'\delta \leftarrow \Omega])$, and (35) ensures that

$$I_t(M[u'\delta \leftarrow \Omega]) = \emptyset. \tag{36}$$

Since $|M[u'\delta \leftarrow \Omega]| < |M|$ and $M[u'\delta \leftarrow \Omega]$ is in Ω-normal form, (36) contradicts the minimality of size of M. Thus Assertion 6.2 holds. □

Using Assertion 6.2 $\delta v' \notin I_t(M/u')$, we can show that

$$\delta v' \notin I_t(M'/u). \tag{37}$$

It follows that $u\delta v'(= v) \notin I_t(M')$ by Lemma 6.3, as claimed.

Thus it remains only to show (37). We first note that

$$\mathrm{Env}(M/u, \delta)_{2h} = \mathrm{Env}(M/u', \delta)_{2h} = \text{ env} \tag{38}$$

holds by (30). By Definition 6.3 (iv) of Env,

$$\mathrm{Env}(M/u, \delta)_{2h} = \mathrm{Env}(M/u[\delta \leftarrow \Omega], \delta)_{2h},$$

$$\mathrm{Env}(M/u', \delta)_{2h} = \mathrm{Env}(M/u'[\delta \leftarrow \Omega], \delta)_{2h}.$$

Thus $\mathrm{Env}(M/u[\delta \leftarrow \Omega], \delta)_{2h} = \mathrm{Env}(M/u'[\delta \leftarrow \Omega], \delta)_{2h}$ holds by (38), i.e., $M/u[\delta \leftarrow \Omega]$ and $M/u'[\delta \leftarrow \Omega]$ have the same environment concerning δ. Hence by Lemma 6.5 we have

$$\delta v'' \in I_t(M/u[\delta \leftarrow Q]) \quad \text{if and only if } \delta v'' \in I_t(M/u'[\delta \leftarrow Q]) \tag{39}$$

for any $Q \in T_\Omega$ and $v'' \in \mathcal{O}_\Omega(Q)$. Let $Q = M/u'\delta(= M/u_1)$, and let $v'' = v'$. Note that $v' \in \mathcal{O}_\Omega(M/u_1)$ by (34). Then (39) is

$$\delta v' \in I_t(M/u[\delta \leftarrow M/u_1]) \quad \text{if and only if } \delta v' \in I_t(M/u'[\delta \leftarrow M/u_1]). \tag{40}$$

Since $M/u'[\delta \leftarrow M/u_1] = M/u'$ and $\delta v' \notin I_t(M/u')$ by Assertion 6.2, the right-hand side of (40) is false, so that the left-hand side is false: $\delta v' \notin I_t(M/u[\delta \leftarrow M/u_1])$, i.e., $\delta v' \notin I_t(M'/u)$ by $M/u[\delta \leftarrow M/u_1] = M[u\delta \leftarrow M/u_1]/u = M'/u$. Thus (37) holds, as claimed. □

By the above arguments we have shown that any v in $\mathcal{O}_\Omega(M')$ is not an index of term, so that $I_t(M') = \emptyset$. □

Hence M' satisfies all the conditions (i)–(iv), so that we have a contradiction. Thus this theorem holds. □

Note. In the proof of Theorem 6.1 we have chosen u and u' satisfying tuple$(u) = (\delta$, env, yield, pref$) =$ tuple(u'). The sameness of the first, second, and third components (i.e., δ, env, and yield) was used in the proof of (iv), and that of the fourth component pref was used in the proof of (iii). Note that the use of the same δ's was necessary to use Lemma 6.5.

Note. Our concern was mainly to give a simplified proof of the decidability of NV-sequentiality. It remains open whether there exists an efficient algorithm to decide NV-sequentiality.

By Theorem 5.1 it is decidable whether $I_t(M) = \emptyset$ for Ω-normal form $M \in T_\Omega$. Thus by Theorem 6.1 we have the following theorem.

THEOREM 6.2. *It is decidable whether a left-linear* TRS E *is* NV-*sequential.*

ASPACE(o(log log n)) IS REGULAR*

KAZUO IWAMA†

Abstract. One of the common results of resource bounded Turing machines is the $\log\log n$ lower bound for the space usage of deterministic and nondeterministic Turing machines that accept nonregular languages. In this paper this result is extended to alternating Turing machines: It is proved that if $f(n) = o(\log\log n)$, then $f(n)$-space-bounded (off-line) alternating Turing machines can accept only regular sets. The problem has been open for a decade.

Key words. space lower bounds, alternating Turing machines

AMS(MOS) subject classifications. 68Q05, 68Q15, 68Q68

1. Introduction. One of the common results regarding resource-bounded Turing machines (TMs) [5] is that there is a nontrivial, tight lower bound, $\log\log n$, for the space usage of both deterministic TMs (DTMs) and nondeterministic TMs (NTMs) that accept nonregular languages. In this paper we extend this result to alternating TMs (ATMs); we prove that if $f(n) = o(\log\log n)$, then $f(n)$-space-bounded (off-line) ATMs can accept only regular sets. The problem was first considered by Sudborough in [11], and the $\log\log n$ lower bound was proved under the *strong definition* of space bounds (see below). In [1] the $\log\log\log n$ lower bound is proved under the *standard definition*, and the $\log\log n$ bound for *on-line* ATMs is also proved. The $\log\log n$ bound for *off-line* ATMs was once claimed to be proved [3], but the claim was later corrected [4]. Thus the problem was still open.

There are two distinct definitions of space complexity measurement for nondeterministic (and alternating) space-bounded TMs: (i) All computations must satisfy the space bound (*strong definition*). (ii) It is enough that at least one accepting computation on each acceptable string satisfies the bound (*standard definition*). For small space bounds, such as $\log\log n$, the distinction is important because we cannot use the common technique of marking off the work tape in advance and then finishing the computation as rejection if the head goes outside the bound. Definition (ii) is more reasonable according to the principle of nondeterminism (existence of a single good computation is enough) and is clearly more standard (used in most papers, e.g., [2], [7], [9]).

It should be noted that there are a number of facts that might mislead us into feeling that the lower bound that we are currently interested in can differ between NTMs and ATMs:

(1) There exists a (regular) language for which m states by deterministic finite automata (DFAs), $\log m$ states by nondeterministic finite automata (NFAs) and $\log\log m$ states by alternating finite automata (AFAs) are necessary and sufficient [2]. There also exists a (nonregular) language for which $\log n$ space by DTMs and $\log\log n$ space (standard definition) by NTMs are necessary and sufficient (see §2). Can the latter statement be extended to encompass $\log\log\log n$ space by ATMs by the analogy of finite automata?

(2) Not surprisingly, $\log\log n$ space-bounded (standard definition) ATMs are more powerful than the same space-bounded NTMs; this is demonstrated by using a rather simple language in the Appendix.

(3) Using a language similar to that of fact (2), we can also show that $\log\log n$ space-bounded (standard definition) off-line ATMs are more powerful than their on-line coun-

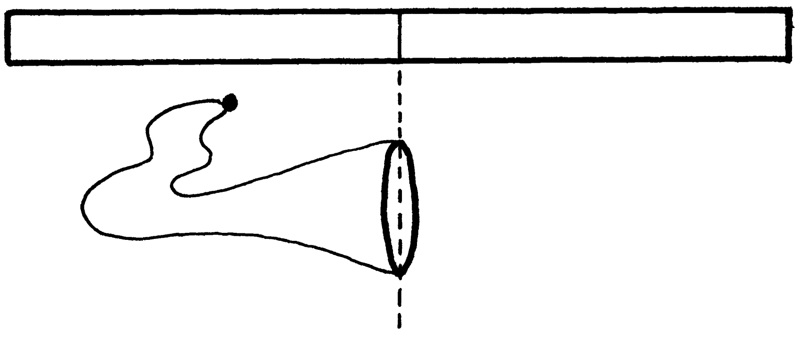

FIG. 1. *Computation subtrees.*

terparts (see Appendix). Thus we cannot rule out the possible reduction of the known $\log\log n$ lower bound for on-line ATMs.

(4) There does exist a complexity measure whose lower bound for NTMs is different from that for ATMs. In [6] it is shown that the (tight) lower bound of the reverse (or cross) complexity of single-read–write-tape TMs is $\log\log n$ for NTMs but $\log\log\log n$ for ATMs of even a single alternation and becomes as small as $\log^* n$ for general ATMs.

In this paper TMs are those machines having a read-only input tape and a read–write work tape. They are said to be *on-line* if the input head can move only from left to right (and can stay there) and *off-line* if it can move in both directions. We will call a triple (w, h, s) of the nonblank portion w of the work tape, the work-tape head position h, and the state s of the finite control a *global state*. A *configuration* consists of the input string, the input head position, and the global state. A *computation* (*tree*) P for an input x is a tree of the following structure: (i) The root is associated with the initial configuration denoted always by I_{init}. (ii) If a vertex v is associated with an existential configuration σ (i.e., its state is existential), then v has exactly one child that is one of the possible successors of σ. (iii) If a vertex v is a universal configuration, then v has the children that are the set of all possible successors of σ. The computation P is said to be *k-space bounded* if at any vertex of P at most k work-tape cells are used. P is said to be *accepting* if it is finite and all of its leaves are associated with accepting configurations. (We assume that TMs never write the blank symbol on the work tape. Then, since the length of the nonblank portion increases monotonically, "at any vertex of P" in the above definition can be replaced by "at any leaf of P" if P is an accepting computation.) An ATM M is called *$f(n)$-space bounded* if for any input string of length n that is accepted by M there is an $f(n)$-space-bounded accepting computation. Besides the (complete) computation tree described above, we often consider a *computation subtree*; its root is associated with an arbitrary (not necessarily initial) configuration, and all of its paths end (are cut forcibly) by some condition, e.g., when the input head crosses some boundary of the tape (see Fig. 1). All TMs described in this paper accept their inputs when the input heads are at the right end.

2. Basic tools. This section demonstrates two fundamental techniques that are important in proving the main theorem. Before that proof, we first take a look at how the strong and standard definitions are different in our current situation.

PROPOSITION 1 [11]. *If an* ATM *uses an unbounded number of work-tape cells under the strong definition of space usage, then it must use at least* $c\log\log n$ *cells infinitely often for some* $c > 0$.

Proof. Let M be an ATM. We can construct the NTM M' from M by replacing each universal state of M by an existential state with the same set of choices. Then, if M has a computation path Q (not the whole tree defined previously but a single path from the root to some leaf) that uses k work-tape cells, then M' has (the same) computation path Q that uses k work-tape cells for the same input. This concludes the proof since the statement is known to be true for NTMs [10]. □

Now let us return to the standard definition. We can no longer claim this proposition. First of all, we do not have to count the space usage if the above computation path Q is not accepting. Even if it is accepting (i.e., it ends with an accepting configuration), any computation *tree* of M including Q may not be accepting. In other words, "the same input" above, which must be accepted by the NTM M', is not necessarily accepted by the ATM M, and we again do not have to consider such an input when measuring the space usage of M. Furthermore, if there is an accepting computation tree of M including Q, we still cannot rule out the existence of a better computation tree for the same input.

We shall next review the convenient tool to prove small resource bounds, generally called *cut-and-paste*, by using the following well-known bounds for on-line TMs.

PROPOSITION 2. *Let* $f_1(n) = o(\log n)$, *i.e.*, $\sup(f_1(n)/\log n) = 0$, *and let* $f_2(n) = o(\log\log n)$. *Then any* $f_1(n)$*-space-bounded on-line* DTM *or* $f_2(n)$*-space-bounded on-line* NTM *can accept only a regular set.*

Proof. We shall show that if a $g_1(n)$-space-bounded DTM M accepts a nonregular language, then $g_1(n) \geq c \log n$ for an infinite number of n's and for some fixed constant c determined by M. Clearly, $g_1(n)$ is not bounded by any constant. Then one can see that there exists an arbitrary large integer k for which there is a string v such that (i) v is accepted by M, and (ii) for all strings u that are accepted by M and are shorter than v, there is a computation that uses less than k space. Intuitively, v is the shortest string that needs k space.

Recall that we are now discussing *on-line* TMs. For strings x and y let $t_{x;y}$ denote M's global state (w, h, s) that M, on the input xy, is in when its input head crosses (only once) the boundary between x and y (";" indicates the boundary). Now select an arbitrary pair of v and k mentioned above. If v is written as $v = xyz$ $(y \neq \varepsilon)$, then $t_{x;yz}$ and $t_{xy;z}$ must be different. (The reasoning is as follows: Suppose that $t_{x;yz} = t_{xy;z}$. Then one can see that (i) xz is also accepted and (ii) M also needs k space to accept xz since both xyz and xz lead M to the same accepting configuration, which determines the space usage. That contradicts the assumption that xyz is the shortest string that needs k space.) Note that if the computation is k-space bounded, $|w| \leq k$ at any boundary. Thus the number of all different triples (w, h, s) is bounded by c_1^k for a constant c_1. In order that $t_{x;yz} \neq t_{xy;z}$ for any two boundaries, $c_1^k \geq |xyz| = n$ or $k \geq c_2 \log n$ for a constant c_2.

The same argument may also be applied when M is an NTM by replacing $t_{x;y}$ with $T_{x;y}$ that is the set of all global states $t = (w, h, s)$ such that M can reach t at the boundary. Now suppose that $T_{x;yz} = T_{xy;z}$. Then we can claim that

(*) if xyz is accepted with k, but not less space, then
xz is also accepted with k, but not less, space.

(Note that (*) is equivalent to the statement that xyz is accepted with k space if and only if xz is accepted with k space. Again, recall that the space usage of a computation path is determined by that of its final configuration. If $t_{\text{init}} \xrightarrow{x} t_1 \xrightarrow{y} t_2 \xrightarrow{z} t_3$ is an accepting computation path with k space, then, since t_2 that appears in $T_{xy;z}$ on the above path is also in $T_{x;yz}$, $t_{\text{init}} \xrightarrow{x} t_2 \xrightarrow{z} t_3$ is also such a path. Note that t_1 may differ from t_2.

Conversely, suppose that $t_{\text{init}} \xrightarrow{x} t_5 \xrightarrow{z} t_6$ is a path with k' space, which means that t_5 is in $T_{x;z}$. Clearly, $T_{x;z}$ coincides with $T_{x;yz}$, and, since $T_{x;yz} = T_{xy;z}$ by the assumption, there must be t_4 that constructs the path $t_{\text{init}} \xrightarrow{x} t_4 \xrightarrow{y} t_5 \xrightarrow{z} t_6$, which clearly uses the same space. That is enough to claim the statement (*).) A crucial point is that we can get the same conclusion if the assumption $T_{x;yz} = T_{xy;z}$ is relaxed to $T^k_{x;yz} = T^k_{xy;z}$, where $T^k_{x;y}$ is the subset of $T_{x;y}$ such that $|w| \leq k$. Thus we can conclude that $T^k_{x;yz}$ should differ from $T^k_{xy;z}$ for any $y \neq \epsilon$. Now a simple evaluation of the size of the power set is enough to achieve the goal. □

It turns out that these lower bounds are tight: Let $bin(i)$ denote the string over 0 and 1 whose reverse is the binary representation of the integer i. For example, $bin(6) = 011$. Now let

$$BIN = \{\sharp bin(0)\sharp bin(1)\sharp \cdots \sharp bin(n)\sharp \mid n \geq 0\},$$

and let $\overline{BIN} = \{0,1,\sharp\}^* - BIN$. Then it is not difficult to see [5] that $\overline{BIN}$ is recognized by a $(\log n)$-space-bounded ($(\log\log n)$-space-bounded, respectively) on-line DTM (NTM, respectively).

Now we must determine how we can apply the cut-and-paste method to ATMs. If ATMs are *on-line*, we have the following answer.

PROPOSITION 3 [1]. *Let $f(n) = o(\log\log n)$. Then any $f(n)$-space-bounded on-line* ATM *M can recognize a regular set.*

Proof. We could simply extend the above proof for NTMs by replacing a computation path with a set of computation paths. The idea is that at each boundary the machine M is universally in a set S_1 of global states (corresponding to one computation tree) or is universally in set S_2 (another computation tree), and so on. Thus this extension would force us to enumerate sets of sets of global states, or we would obtain only a $\log\log\log n$ lower bound.

The following proof is considerably modified from [1] in order to prepare ourselves for the main theorem. It should be noted that $T_{x;y}$, introduced in Proposition 2, depends on x but not at all on y. To attain the same goal as before, we can develop a similar construct that does not depend on x but does depend on y. Namely, we define $S_{x;y}$ as the set of global states t, at the boundary between x and y, that is led to acceptance by y. Then it is not difficult to see that $S_{x;yz} = S_{xy;z}$ implies that xyz is accepted if and only if xz is also. A difficulty is that the claim (*) on the space usage in the proof of Proposition 2 no longer holds for the following reason: Suppose that there is an accepting computation path $t_{\text{init}} \xrightarrow{x} t_1 \xrightarrow{y} t_2 \xrightarrow{z} t_3$. Since $S_{x;yz} = S_{xy;z}$, there must be t_2 in $S_{x;yz}$. However, there may not be a computation (sub)path $t_{\text{init}} \xrightarrow{x} t_2$. (Note that $S_{x;yz}$ requires only that the machine can go to an accepting configuration *if* we assume that it is in some global state in $S_{x;yz}$ at the boundary between x and yz.) There should exist the accepting path $t_{\text{init}} \xrightarrow{x} t_1 \xrightarrow{z} t_4$, but it may need less space than before.

With this problem in mind, we define $S^k_{x;y}$ as follows: Let (t,j) be a pair of a global state and an integer. Then $S^k_{x;y}$ contains all (t,j)'s such that (i) $j \leq k$ and (ii) if M is in t at the boundary, then t leads to acceptance while using j space but does not do so while using $j-1$ space or less (i.e., there is an accepting computation subtree of the described space bound whose root is associated with the global state t and the input head being on the leftmost symbol of y). This introduction of *pairs* of a global state and space, unlike the conventional *only global states*, is important, especially for proving the main theorem.

Let P be a computation subtree of M on input xy such that its root is I_{init} and all paths end when the input head crosses the boundary between x and y. We also define

$SEC_{x;y}(P)$ as the set of all global states that M, following P, is in when it crosses the boundary. A key fact (whose proof is easy and is omitted) is that there is an accepting computation tree of k-space bound for M on input xy if and only if there is this kind of computation subtree P such that

$$SEC_{x;y}(P) \subseteq \{t \mid (t,j) \in S^k_{x;y}\}.$$

Now suppose that the ATM M accepts input xyz and uses k, but not less than k, space and that $S^k_{x;yz} = S^k_{xy;z}$. Then we can conclude by the following reasoning that (i) xz is also accepted while using k space and (ii) that it is not accepted while using less than k space: The assumption means that there is an accepting k-space-bounded computation tree for xyz. By this and the preceding fact there is a computation subtree P_0 whose root is I_{init} and all of whose paths end at the boundary between x and yz such that

$$SEC_{x;yz}(P_0) \subseteq \{t \mid (t,j) \in S^k_{x;yz}\}.$$

Note that $S^k_{x;yz} = S^k_{xy;z}$ means $S^k_{x;yz} = S^k_{x;z}$ (because both $S^k_{xy;z}$ and $S^k_{x;z}$ depend on only z), and therefore the computation subtree P_0 also satisfies

$$SEC_{x;z}(P_0) \subseteq \{t \mid (t,j) \in S^k_{x;z}\}.$$

Again by the fact ("if" part), there is an accepting computation tree of k-space bound for xz. Thus statement (i) is correct. As for (ii), we can similarly show that if xz is accepted and uses less than k space, then xyz is also.

We are now ready to carry out the same enumeration as that of Proposition 2. The number of all different (t,j)'s such that $t = (w,h,s)$ and $|w| \leq j \leq k$ is a bit larger than before, but it is still bounded by c^k for some constant c. □

3. Main result. It should be noted that the weaker $\log\log\log n$ lower bound proved in [1] can also be proved by modifying the transition matrix in [5] from $r \times r$ to $2^r \times 2^r$.

THEOREM 1. *Let $f(n) = o(\log\log n)$. Then any $f(n)$ space-bounded off-line* ATM *M can recognize a regular set.*

Proof. With the boundary between strings x and y we associate $S^k_{x;y}$ as before. This time, according to the alternation from on-line to off-line, $S^k_{x;y}$ is not a simple set but is an array such as

$$S^k_{x;y} = (S^k_{x;y}(1), S^k_{x;y}(2), \cdots, S^k_{x;y}(p)),$$

where the value p will be given later. We need a few more notations: Let P be a computation subtree whose root is associated with a global state t and an input head position τ. In what follows we often focus our attention to some boundary, say, the boundary between x and y of the input xy. If τ is on the rightmost symbol of x (leftmost symbol of y, respectively), then we say that P has *root* $(t,x;y,L)$, where L stands for the left of the boundary (respectively, $(t,x;y,R)$, where R stands for the right of the boundary). $CRS_{x;y}(P)$ denotes how many times M's input head, following P, crosses the boundary. (The number of crosses can differ according to each path of P. We take the largest value as $CRS_{x;y}(P)$.) $SP(P)$ denotes the space P uses.

Now we define $S^k_{x;y}(i)$. Suppose that i is odd. Then $S^k_{x;y}(i)$ contains all the pairs (t,j) of a global state t and an integer $j \leq k$ satisfying the following conditions: (i) There is an accepting computation subtree P (see Fig. 2) such that P has root $(t,x;y,R)$, $CRS_{x;y}(P) = i-1$, and $SP(P) = j$. (ii) There is no accepting computation subtree P such that P has the same root $(t,x;y,R)$ and the same $CRS_{x;y}(P) = i-1$ but for which

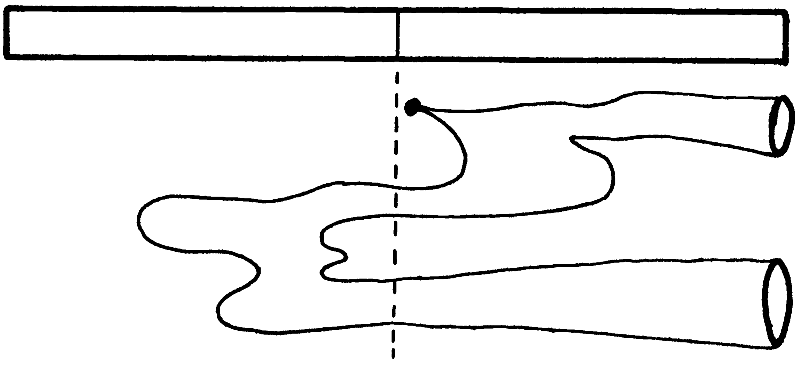

FIG. 2. *Accepting computation subtrees P to construct $S^k_{x;y}(3)$.*

$SP(P) < j$. (iii) If there is a pair (t, j') in $S^k_{x;y}(i')$ for some odd $i' < i$, then $j' > j$. If i is even, then P has root $(t, x; y, L)$ instead of $(t, x; y, R)$ and "odd" above should be replaced by "even." Intuitively speaking, the fact that (t, j) exists in $S^k_{x;y}(i)$ means that the global state t can lead to acceptance while using j space and $i - 1$ crosses *most economically*: If t can lead to acceptance while using j space and $i - 3$ (or fewer) crosses or while using $j - 1$ (or less) space and i crosses, then (t, j) does not appear in $S^k_{x;y}(i)$. Let us observe more about this. Suppose, for example, that $(a, 8)$, $(b, 3)$, and $(c, 5)$ are in $S^k_{x;y}(3)$ for global states a, b, and c. Then we know that M needs 8 space to go from global state a to acceptance. However, we cannot rule out the possibility that M needs, for example, only 5 space to do the same if we allow M to cross the boundary more: There may be a computation subtree Q such that it has root $(a, x; y, R)$ and all paths end when M crosses the boundary not from right to left (the first cross) but from left to right (the second cross) and such that $SEC_{x;y}(Q) = \{b, c\}$. If that is the case, then $(a, 5)$ should be in $S^k_{x;y}(5)$.

Thus $S^k_{x;y}$ seems to depend on both sides of the boundary, both x and y of the input xy. However, this is not desirable for attempting to apply the cut-and-paste. One can see that the proof of Proposition 3 fully depends on the fact that $S^k_{x;y}$ is determined by only the right side of the boundary. It is for this reason that the next claim is important.

CLAIM 1. *If i is odd, then $S^k_{x;y}(i)$ is determined by the right-side string y of the boundary and by $S^k_{x;y}(2), S^k_{x;y}(4), \cdots, S^k_{x;y}(i-1)$. If i is even, then $S^k_{x;y}(i)$ is determined by the left-side string x and by $S^k_{x;y}(1), S^k_{x;y}(3), \cdots, S^k_{x;y}(i-1)$.*

Proof. By the definition, $S^k_{x;y}(1)$ contains all (t_1, j_1) such that the global state t_1, which M is in when crossing the boundary from left to right, leads to acceptance while using j_1 (not less) space and never coming back to the boundary. (Note that it does not matter whether M can actually reach the boundary in t_1 from I_{init}.) Thus $S^k_{x;y}(1)$ clearly depends only on y.

Next it is shown that $S^k_{x;y}(2)$ can be constructed from x and $S^k_{x;y}(1)$. For each global state $t_2 = (w, h, s)$ ($|w| \leq k$) we construct, if there are any, all computation subtrees P_2 such that (i) P_2 has root $(t_2, x; y, L)$ and every path ends when it crosses the boundary from left to right for the first time (see Fig. 3) and (ii) $SEC_{x;y}(P_2) \subseteq \{t \mid (t, j) \in S^k_{x;y}(1)\}$, where $SEC_{x;y}(P_2)$ denotes, as before, the set of all global states M is in when it crosses the boundary. For such a subtree as P_2 we also define $SP(P_2)$ as

$$SP(P_2) = \max\{j \mid \exists t \text{ s.t. } t \in SEC_{x;y}(P_2) \text{ and } (t, j) \in S^k_{x;y}(1)\}.$$

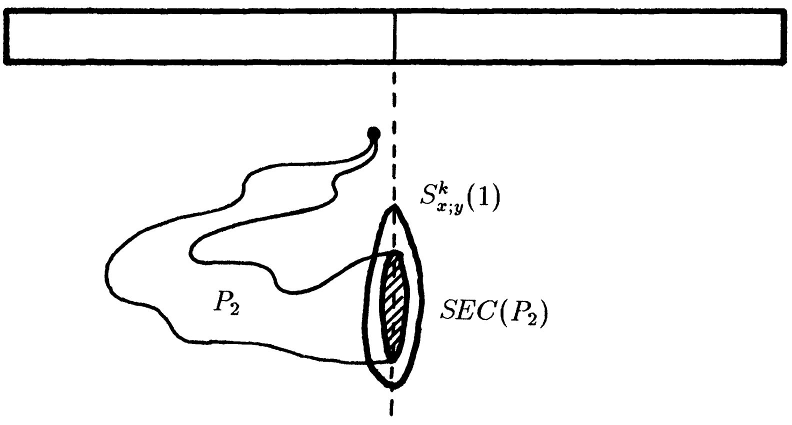

FIG. 3. *Computation subtree P_2.*

Note that there are, in general, many such P_2's for a single t_2. We select from among them one such that $SP(P_2)$ is minimum ($= j_2$) and (t_2, j_2) is included in $S^k_{x;y}(2)$. Note that we used only x and $S^k_{x;y}(1)$ for this construction.

Now suppose that we have constructed $S^k_{x;y}(1)$ through $S^k_{x;y}(i)$ for an even i. To obtain $S^k_{x;y}(i+1)$, we first let

$$\begin{aligned} MINS^k_{x;y}(i) = \{(t,j) \mid\ & (t,j) \in S^k_{x;y}(2) \cup S^k_{x;y}(4) \cup \cdots \cup S^k_{x;y}(i) \text{ and} \\ & (t,j') \notin S^k_{x;y}(2) \cup S^k_{x;y}(4) \cup \cdots \cup S^k_{x;y}(i) \text{ if } j' < j\}. \end{aligned}$$

Thus the fact that (t, j) is in $MINS^k_{x;y}(i)$ means that the global state t at the left side of the boundary (on the rightmost symbol of x) can lead to acceptance with j (but not less) space if it can cross the boundary $i-1$ *or fewer* times. Now, as before, for each global state t_{i+1} we construct all computation subtrees P_{i+1} such that (i) P_{i+1} has root $(t_{i+1}, x; y, R)$ and every path ends in acceptance directly (without coming back to the boundary) or ends when it crosses the boundary from right to left for the first time (Fig. 4) and (ii) $SEC_{x;y}(P_{i+1}) \subseteq \{t \mid (t,j) \in MINS^k_{x;y}(i)\}$. (It should be noted that $SEC_{x;y}(P_{i+1})$ includes several global states, each of which may need different crosses before ending with an accepting configuration. That is why we introduced $MINS^k_{x;y}(i)$.) $SP(P_{i+1})$ is defined as

$$\begin{aligned} SP(P_{i+1}) \;=\; & \max\{j \mid \text{(i) } \exists t \text{ s.t. } t \in SEC_{x;y}(P_{i+1}) \text{ and } (t,j) \in MINS^k_{x;y}(i) \\ & \text{or (ii) } \exists \text{ path from the root directly to acceptance while using } j \text{ space}\}. \end{aligned}$$

Among all the subtrees thus constructed, we select a subtree P_{i+1} such that $SP(P_{i+1})$ is minimum ($= j_{i+1}$). Thus obtained, (t_{i+1}, j_{i+1}) is not included in $S^k_{x;y}(i+1)$ unconditionally, however. It is included in $S^k_{x;y}(i+1)$ if (t,j), such that $t = t_{i+1}$ and $j \le j_{i+1}$, is not in $MINS^k_{x;y}(i-1)$. $MINS^k_{x;y}(i-1)$ is defined in the same way as $MINS^k_{x;y}(i)$, but $S^k_{x;y}(2) \cup S^k_{x;y}(4) \cup \cdots \cup S^k_{x;y}(i)$ is replaced by $S^k_{x;y}(1) \cup S^k_{x;y}(3) \cup \cdots \cup S^k_{x;y}(i-1)$. (Note that we do not violate the dependency of the construction. $S^k_{x;y}(i-1)$, for example, was determined by y and $S^k_{x;y}(2), \cdots, S^k_{x;y}(i-2)$.) Intuitively speaking, (t_{i+1}, j_{i+1}) is added to $S^k_{x;y}(i+1)$ if either (i) t_{i+1} absolutely needs at least i crosses before reaching accepting configurations regardless of its space usage or (ii) although it is already in, say, $S^k_{x;y}(i-3)$, we can save space if we allow it more crosses.

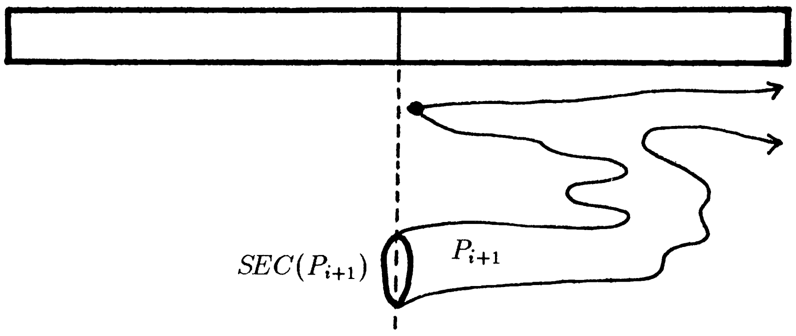

FIG. 4. *Computation subtree P_{i+1}.*

The argument is almost the same for an odd i and is therefore omitted. It may also be omitted in the formal justification of the construction. □

CLAIM 2. *If k is fixed, then:* (i) *there exists an integer i such that $S^k_{x;y}(i) = \phi$, and* (ii) *if $S^k_{x;y}(i) = \phi$, then $S^k_{x;y}(i+1) = S^k_{x;y}(i+2) = \cdots = \phi$.*

Proof. Part (i) is almost obvious by the restriction that all (t, j) in $S^k_{x;y}(i)$ satisfy $j \leq k$ and by definition (iii) of $S^k_{x;y}(i)$. (ii) If $S^k_{x;y}(i) = \phi$, then by the definition $MINS^k_{x;y}(i) = MINS^k_{x;y}(i-2)$. One can see that if some (t, j) were in $S^k_{x;y}(i+1)$, then they would also be in $S^k_{x;y}(i-1)$, which contradicts definition (iii) of $S^k_{x;y}(i)$ again. □

Now we define $S^k_{x;y}$. Fix some input string xy that is accepted by M and integer k. Then by Claim 2 the sequence $S^k_{x;y}(1), S^k_{x;y}(2), \cdots$ becomes empty at some moment and remains empty after that. Let $S^k_{x;y}(p)$ be the last member of the sequence that is not empty. Then $S^k_{x;y}$ is defined as $(S^k_{x;y}(1), S^k_{x;y}(2), \cdots, S^k_{x;y}(p))$.

CLAIM 3. *Let xyz be an input string. Then $S^k_{x;yz} = S^k_{xy;z}$ implies $S^k_{x;yz} = S^k_{xy;z} = S^k_{x;z}$.*

Proof. By Claim 1 both $S^k_{xy;z}(1)$ and $S^k_{x;z}(1)$ depend only on z, and therefore they must be the same. Then

$$S^k_{xy;z}(1) = S^k_{x;yz}(1) = S^k_{x;z}(1)$$

by the assumption. This and Claim 1 imply that $S^k_{x;yz}(2) = S^k_{x;z}(2)$ and therefore that

$$S^k_{xy;z}(2) = S^k_{x;yz}(2) = S^k_{x;z}(2).$$

We can continue this argument step by step until we get to

$$S^k_{xy;z}(p+1) = S^k_{x;yz}(p+1) = S^k_{x;z}(p+1) = \phi. \qquad □$$

CLAIM 4. *Suppose that $S^k_{x;yz} = S^k_{xy;z}$. Then if* ATM *M accepts input xyz using k, but not $k-1$ or less, space, then it also accepts xz using k, but not $k-1$ or less, space.*

Proof. The proof is very similar to the last portion of the proof of Proposition 3 (see Fig. 5). Let

$$\begin{aligned} MINS^k_{x;y} = \{(t,j) \mid\ & (t,j) \in S^k_{x;y}(i) \text{ for some odd } i \leq p \text{ and} \\ & (t,j') \notin S^k_{x;y}(i) \text{ for any odd } i \leq p \text{ if } j' < j\}. \end{aligned}$$

The definition means that if (t, j) is in $MINS^k_{x;y}$, then the global state t at the right side of the boundary can lead to acceptance with j ($\leq k$), but not with $j-1$ or less, space.

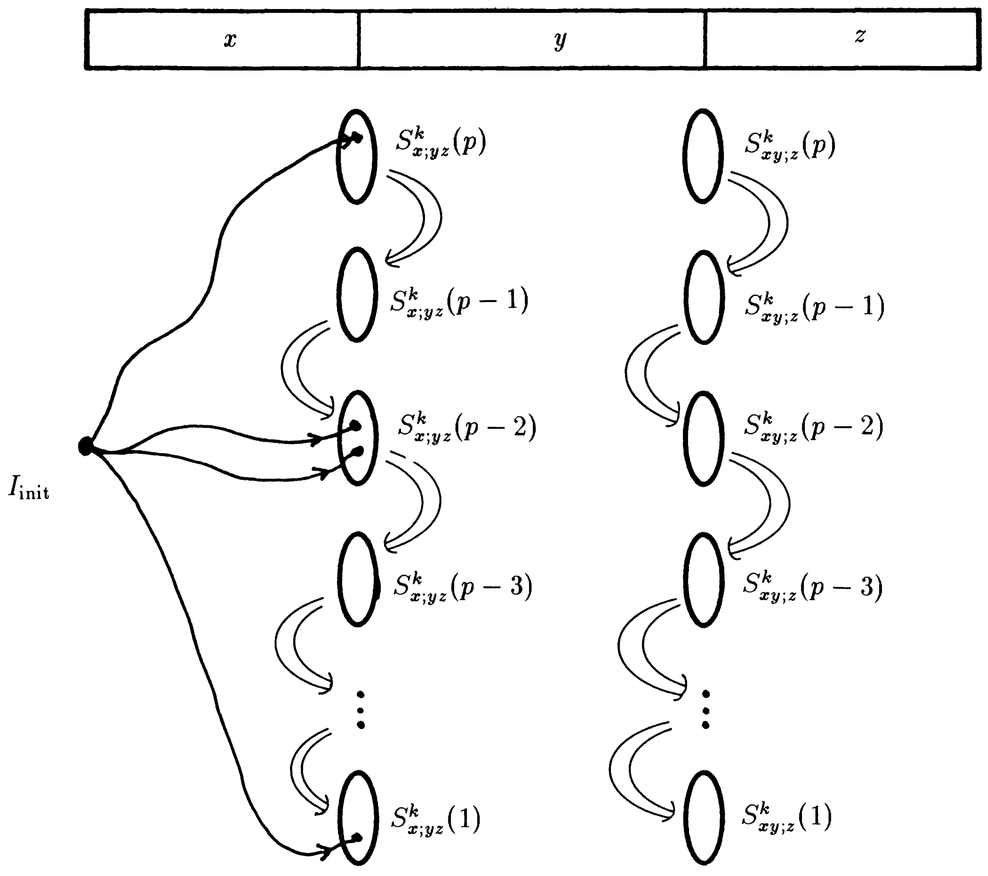

FIG. 5. *Cut-and-paste in off-line ATMs.*

Now suppose that M accepts xyz using k space. Then one can see that there is a computation subtree P_0 (having root I_{init} and for which all paths end when the input head crosses the boundary for the first time) such that

$$SEC_{x;yz}(P_0) \subseteq \{t \mid (t,j) \in MINS^k_{x;yz}\}.$$

We next consider the input xz. Since $S^k_{x;yz} = S^k_{xy;z}$, $S^k_{x;yz} = S^k_{x;z}$ by Claim 3. Then it is clear from the definition that $MINS^k_{x;yz} = MINS^k_{x;z}$. Hence the computation subtree P_0 introduced above satisfies the condition that

$$SEC_{x;z}(P_0) \subseteq \{t \mid (t,j) \in MINS^k_{x;z}\},$$

which says that xz is also accepted while using k space.

Similarly, we can show that if xz is accepted while using k' space, then xyz is also accepted while using k' space under the condition that $S^k_{x;yz} = S^k_{xy;z}$. That is enough to prove the claim. □

Now we are ready to carry out the enumeration. Suppose that $v = xyz$ is the shortest string accepted by M while using k space. Then by Claim 4 $S^k_{x;yz}$ and $S^k_{xy;z}$ must be different for any $y \neq \epsilon$. Recall that $S^k_{x;yz} = (S^k_{x;yz}(1), S^k_{x;yz}(2), \cdots, S^k_{x;yz}(p))$. Each

$S^k_{x;yz}(i)$ consists of pairs like (t, j) of a global state and an integer $\leq k$. The number of all different such pairs is bounded by c^k for a constant c, and therefore the number of all different $S^k_{x;yz}(i)$'s is bounded by 2^{c^k}. A key fact is that our construction of $S^k_{x;yz}(i)$'s guarantees that $S^k_{x;yz}(i_1)$ and $S^k_{x;yz}(i_2)$ are disjoint if i_1 and i_2 are both odd (or even). Since $S^k_{x;yz}(i)$ is a subset of the (at most) c^k different elements, it follows that

$$p/2 \leq c^k.$$

Thus the number of different $S^k_{x;yz}$ is bounded by

$$(2^{c^k})^p \leq (2^{c^k})^{2c^k} = 2^{2c^{2k}} \leq 2^{d^k}$$

for some constant d, which is enough to claim the theorem. □

Appendix. Let *EXBIN* be the language that contains strings of the form

$$\sharp u_0 \sharp v_0 \sharp u_1 \sharp v_1 \sharp \cdots \sharp u_i \sharp v_i \sharp \cdots \sharp u_n \sharp v_n \sharp\sharp u \sharp v \sharp$$

such that (i) $n \geq 0$ and $v_i = bin(i)$ (see §2 for $bin(i)$), (ii) u_i is any string over $\{0, 1\}$ and $|u_i| = |v_i|$, and (iii) for some j, $u = u_j$ and $v = v_j$. As for Theorem 2 below, a different language that is based on the prime-number theory and plays the same role as *EXBIN* is found in [3]. However, the current language would give us a more intuitive image of the difference of abilities between small space-bounded NTMs and ATMs as well as between on-line ATMs and off-line ATMs (Theorem 3).

THEOREM 2. (i) *EXBIN needs* $\log n$ *nondeterministic space (off-line).* (ii) $\log\log n$ *alternating on-line space is enough for the same language.*

Proof. (i) Intuitively, $\log\log n$ space-bounded NTMs can check conditions (i) and (ii) but not condition (iii). In what follows, every string satisfies all the conditions above except for condition (iii). Suppose that there is a k-space-bounded off-line NTM M that recognizes *EXBIN*. We focus our attention on the boundary between $\sharp u_0 \sharp bin(0) \sharp \cdots \sharp u_n \sharp bin(n) \sharp$ and $\sharp u \sharp v \sharp$ of each string. The left-side portion is determined by $u_0, u_1, \cdots, u_n$, which we denote by $left(u_0 u_1 \cdots u_n)$. Suppose that M, if it crosses that boundary in global state t from right to left (i.e., enters $left(u_0 u_1 \cdots u_n)$ from right), can come back to the same boundary (exits $left(u_0 u_1 \cdots u_n)$) in global state s. Then let $S_t(u_0 \cdots u_n)$ denote the set of all such global states s. (Note that more than one such s may exist since M is nondeterministic.) Also let

$$S(u_0 \cdots u_n) = (S_0(u_0 \cdots u_n), S_{t_1}(u_0 \cdots u_n), \cdots, S_{t_p}(u_0 \cdots u_n)),$$

where $S_0(u_0 \cdots u_n)$ is the set of all the global states s in which M can get to the boundary for the first time from I_{init}, and t_1 through t_p are all different global states in some fixed order. Note that p is bounded by c^k for some constant c.

Now suppose that $u_0 u_1 \cdots u_n \neq u'_0 u'_1 \cdots u'_n$. Then $S(u_0 u_1 \cdots u_n)$ must be different from $S(u'_0 u'_1 \cdots u'_n)$. (The reason is as follows: Suppose that $u_i \neq u'_i$. Consider two strings

$$\begin{aligned} z_1 &= left(u_0 \cdots u_i \cdots u_n) \sharp u_i \sharp bin(i) \sharp, \\ z_2 &= left(u'_0 \cdots u'_i \cdots u'_n) \sharp u_i \sharp bin(i) \sharp \end{aligned}$$

Since z_1 is in *EXBIN*, M accepts it. Then one can see that if $S(u_0 \cdots u_n) = S(u'_0 \cdots u'_n)$, then M also accepts z_2, a contradiction.) Note that the number of different $u_0 u_1 \cdots u_n$ is at least $2^{N/d}$ for some constant d and for the length N of the input. On the other hand, the number of different $S(u_0 \cdots u_n)$ is bounded by

$$(2^{c^k})^{c^k} = 2^{c^{2k}}.$$

Then to satisfy $S(u_0 \cdots u_n) \neq S(u'_0 \cdots u'_n)$ for every two strings $u_0 \cdots u_n$ and $u'_0 \cdots u'_n$, we need the condition $2^{c^{2k}} \geq 2^{N/d}$ or

$$k \geq c_1 \log N$$

for some constant c_1.

(ii) It is not difficult to see that condition (iii) can now be checked by using $\log \log n$ space. The details are omitted. □

THEOREM 3. *Let $EXBIN^R = \{x^R \mid x \in EXBIN\}$. Then* (i) *there is a* $\log \log n$ *space-bounded off-line ATM that recognizes $EXBIN^R$, but* (ii) *at least* $\log n$ *is necessary (and sufficient) to recognize the same language by on-line* ATMs.

Proof. Part (i) is obvious by Theorem 2. (ii) It is now difficult for $\log \log n$ space-bounded ATMs to check condition (iii). Again we look at the boundary between $y = \sharp v^R \sharp u^R \sharp$ and $x = \sharp bin(n)^R \sharp u_n^R \sharp \cdots \sharp bin(0)^R \sharp u_0^R$. Now recall Proposition 3. Let S be the set of all global states at the boundary between y and x that lead to acceptance. By the same line of observation as for Theorem 2 one can see that at least $2^{N/d}$ different S's, each of which corresponds to a different x above, are necessary. Suppose that a k-space-bounded on-line ATM M recognizes $EXBIN^R$. Then

$$2^{c^k} \geq 2^{N/d}$$

should be met, which implies $k \geq c_1 \log N$ for some constant c_1. □

Remark. Recall that all the results in this appendix assume the standard definition. However, they also hold under the strong definition except for the sufficient part in (ii) of Theorem 3. Under the strong definition $\log n$ is probably not sufficient since, intuitively, the on-line ATM should hold the $\sharp v^R \sharp u^R \sharp$ portion of the input in its work tape *before* it knows whether the following portion is correct (i.e., whether it is exponentially longer than $\sharp v^R \sharp u^R \sharp$).

THE COMPLEXITY OF MALIGN MEASURES*

PETER BRO MILTERSEN†

Abstract. This paper analyzes the concept of *malignness*, which is the property of probability ensembles making the average case running time equal to the worst case running time for a class of algorithms. The author derives lower and upper bounds on the complexity of malign ensembles, which are tight for exponential time algorithms, and which show that no polynomial time computable malign ensemble exists for the class of polynomial time algorithms. Furthermore, it is shown that for no class of superlinear algorithms a polynomial time samplable malign ensemble exists, unless every language in P has an expected polynomial time constructor.

Key words. average case complexity, malignness

AMS(MOS) subject classifications. 68Q15, 68Q30

1. Introduction. The average case time complexity of specific algorithms has for a number of years been an active area of research, often showing significant improvement over the worst case complexity when specific distributions of the inputs were assumed. Li and Vitányi [4] studied the Solomonoff–Levin measure $\mathbf{m}$ and found that when the inputs to any algorithm are distributed according to this measure, it holds that the algorithm's average case complexity is of the same order of magnitude as its worst case complexity. More precisely,

$$\exists c > 0 : \sum_{x\in\Sigma^n} \frac{\mathbf{m}(x)}{\sum_{y\in\Sigma^n}\mathbf{m}(y)} T_A(x) \geq c \max_{x\in\Sigma^n} T_A(x).$$

In this paper, we use the term *malign* for such a measure.

The result seems significant for the following reason: Li and Vitányi argue in [5] that the Solomonoff–Levin measure should be used as the a priori probability in Bayesian reasoning because, in a certain sense, it lies close to any recursively enumerable measure (it dominates them multiplicatively). Similarly, they argue in [4] that if inputs are given from a natural source, the result implies that with high probability the average case time will be close to the worst case time, so that no improvement is possible. This would make worst case complexity the significant way to measure the cost of computation, and average case considerations with respect to, e.g., the uniform distribution much less relevant.

However, since the Solomonoff–Levin measure is not even recursive, the result has no immediate implications for the complexity theory of average case complexity, founded by Levin in [3] and extended in [2] and [1]. In Levin's approach to average case complexity, the distribution function of the input measure is required to be polynomial time computable. Thus, it is natural to ask if some kind of time bounded version of Li and Vitányi's result can be derived.

In this paper, we analyze from a complexity-theoretic perspective the property of malignness. We restate Li and Vitányi's result and give a simple proof. It seems that the surprising property of malignness is dependent upon an exponential time pattern, which in our view makes the above interpretations less obvious. We present a number of

results that support this intuition. Our results pose a limit on the results achievable in the average case direction by the time bounded versions of the Solomonoff–Levin measure, which are also discussed in [4]. In general, they suggest that if inputs are produced by a polynomial time adversary, phenomena like the above will not arise.

2. Notation.

• We consider the fixed binary alphabet $\Sigma = \{0,1\}$. Σ^* is the set of binary strings with the usual ordering, first by length and then lexicographically, and Σ^n is the set of strings of length n. By $x-1$ we denote the string preceding x, and by $x+1$ the string following x. The empty string is denoted Λ. The length of the string x is denoted by $|x|$. $\langle\cdot,\cdot\rangle$ denotes a polynomial time bijective pairing function $\Sigma^* \times \Sigma^* \to \Sigma^*$ with polynomial time projections.

• A *measure* μ on a finite or countable set M is a function from M to the real numbers, with $\mu(x) \geq 0$ for all x. Given a subset $A \subseteq M$, we define

$$\mu(A) = \sum_{x \in A} \mu(x).$$

A *probability measure* is a measure with $\sum_{x\in M} \mu(x) = 1$. Given a measure μ on Σ^* or Σ^n, we denote by μ^* its distribution function $\mu^*(x) = \mu(\{y | y \leq x\})$. If $\mu(\Sigma^n) \neq 0$, the nth derived measure of μ is the probability measure on Σ^n defined by

$$\mu_n(x) = \frac{\mu(x)}{\mu(\Sigma^n)}.$$

• A function $f : \Sigma^* \to \boldsymbol{R}$ is called *polynomial time computable* if there exists a polynomial time Turing machine transducer, which on input $\langle x, 1^i\rangle$ produces the binary notation of a number t with

$$|f(x) - t| \leq 2^{-i}.$$

In general, if the machine runs in time at most $g(|x|, i)$, we say that f is computable in time $g(|x|, i)$.

• Our model for *algorithms* is, for concreteness, multitape Turing machines. The results are easily transferred to other models. An algorithm takes one input x, and it always halts. Algorithms cannot be effectively enumerated of course, but the Turing machines are assumed enumerated $A_1, A_2, \ldots$ such that simulation, including stepcounting, etc. of n steps of A_i on input x can be performed in time polynomial in i,$|x|$ and n.

• Given an algorithm A, we define $T_A(x), x \in \Sigma^*$ to be its running time on the binary string x. Given a function $f : \boldsymbol{N} \to \boldsymbol{N}$, we define

$$ALG(f) = \{A | T_A(x) \leq f(|x|) \text{ for all } x\text{, except a finite number}\}.$$

$$T_A^w(n) = \max_{|x|=n} T_A(x)$$

is the algorithm's worst case running time. We denote by $w_A(n)$ the lexicographically least string in Σ^n with $T(w_A(n)) = T_A^w(n)$.

$$T_A^a(\mu, n) = \sum_{|x|=n} \mu_n(x) T_A(x)$$

is the algorithm's average case running time with respect to the measure μ.

3. Malign measures. In this section malignness is defined and Li and Vitányi's result on the Solomonoff–Levin measure is presented. We give a direct proof and skip the conceptual developments of [4]. We consider the class of Turing machines, where each machine has three tapes:

- A binary input tape, infinite in one direction, with the restriction that the head can only move in this direction. Thus, the input tape is one-way, one-way infinite;
- A two-way, infinite, work tape;
- A one-way, one-way infinite binary output tape.

The input tape and the output tape are started with their heads on the first square, and a machine must be able to determine by itself when it has read its input. Now consider an acceptable enumeration $M_1, M_2, \ldots$ of the above class of Turing machines, and let U be a machine universal for the class, i.e., U will on input 1^i0t, where t is an infinite tape, halt if and only if the machine M_i on input tape t halts, and U will in that case output whatever M_i outputs.

We next consider the input tape of U filled with the results of an infinite sequence of coin tosses. The Solomonoff–Levin measure $\mathbf{m}(x)$ of a string $x \in \Sigma^n$ is then defined as the probability that U halts, outputting x. Since U of course has a nonzero probability of not halting, we have that

$$\sum_{x\in\Sigma^*} \mathbf{m}(x) < 1.$$

The Solomonoff–Levin measure was first defined rigorously (for continuous sample spaces) in [8]. Intuitively, it gives a large amount of measure to strings with lots of pattern, since these have short programs that have a high probability of appearing. Actually, it is closely tied to self-delimiting Kolmogorov complexity, since $\mathbf{m}(x) = \Theta(2^{-K(x)})$, where $K(x)$ is the self-delimiting Kolmogorov complexity of x, but we do not need this result here (see [8] for a proof, and [5] and [6] for general discussions of the properties of $\mathbf{m}$).

DEFINITION 3.1. A measure μ is malign for an algorithm A if and only if there exists a $c > 0$ such that for all sufficiently large n,

$$T_A^a(\mu, n) \geq cT_A^w(n).$$

It is malign for a class of algorithms $\mathcal{A}$ if it is malign for each $A \in \mathcal{A}$.
The following is the main result from [4] on average case complexity.

THEOREM 3.1 (Li and Vitányi). *The Solomonoff–Levin measure* $\mathbf{m}$ *is malign for all algorithms.*

Proof. Consider the following Turing machine M, of the above kind.

```
Read the prefix $1^i0$, $i \geq 0$ from the tape.
Simulate $U$ on the rest of the tape.
if $U$ halts then
        $n := |U\text{'s output}|$
        simulate $A_i$ on all inputs of length $n$, finding the lexicographically
            least worst case output, $w_{A_i}(n)$ (This may not halt.)
        output $w_{A_i}(n)$
fi
```

Assume $M = M_k$ in the above enumeration, and assume that i is the index of an algorithm, i.e., that A_i halts on all inputs. If U is started with the tape 1^k01^i0t, where U, started on t, outputs a string of length n, U will output $w_{A_i}(n)$. The events of reading 1^k01^i0 and reading t are independent. But this means that for all n,

$$\mathbf{m}(w_{A_i}(n)) \geq 2^{-k-i-2}\mathbf{m}(\Sigma^n).$$

But then

$$T^a_{A_i}(\mathbf{m}, n) \geq \frac{\mathbf{m}(w_{A_i}(n))}{\mathbf{m}(\Sigma^n)} T^w_{A_i}(n) \geq 2^{-k-i-2} T^w_{A_i}(n). \qquad \square$$

Observe that the proof uses that the worst case input to A_i of length n can be described in the following way: "The worst case input to A_i of length n." Thus $w_{A_i}(n)$ has a short description, i.e., lots of pattern. The problem with the pattern "The worst case input to A_i of length n" is that it may take at least exponential time to get from the description to the result. Thus, the pattern is computationally difficult. The main object of this paper is to establish that this is the way it has to be. In general it does not hold that inputs that are slow to process have an easy pattern. To make this more precise, we want to answer questions of the following kind: Suppose μ is malign for a class of algorithms $\mathcal{A}$. What complexity does μ have?

If the complexity of a measure is defined in a suitable way, it is our belief that natural input sources are unlikely to have exponential complexity. Indeed, we would not expect the source to have resources that are exponentially larger than the resources of the algorithm to which it supplies inputs. This motivates searching for lower bounds on the complexity of malign ensembles. As in the theory of Average-*NP* [3], [2], [1], it seems natural to take the computational complexity of the distribution function μ^* as the complexity of μ. However, if we put no further restrictions on μ, this does not seem to be the correct approach, as the following theorem shows.

THEOREM 3.2. *For each general recursive function f there exists a measure μ that is malign for $ALG(f)$ and whose distribution function μ^* is polynomial time computable.*

Proof. The idea of the proof is to let the jth digit of $\mu_n(x)$ be 1 if and only if x is the lexicographically least worst case input of A_j. In order to remain within the time bounds, we let $\mu(\Sigma^n)$ vanish rapidly. Define

$$T(x, i, t) = \min(T_{A_i}(x), t).$$

$$w(n, i, t) = \min\{y \in \Sigma^n | \forall x \in \Sigma^n : T(y, i, t) \geq T(x, i, t)\},$$

i.e., $w(n, i, t)$ is the lexicographically least worst case input of A_i of size n, when A_i is restricted to run for at most t time steps. Let g be a time constructible function with $g(n) \geq f(n)$ for all n. Define

$$v(n, i) = w(n, i, g(n)).$$

Observe that $v(n, i)$ can be computed in time $t(n, i) = q(2^n p(n, i, g(n)))$, where p and q are polynomials, by simulating A_i on all inputs of length n. Put

$$u(n) = t(n, n).$$

By choosing p and q appropriately (sufficiently large), u can be made time constructible. We can without loss of generality assume that $u(n + 1) \geq u(n) + n$. Now define

$$b(x,i) = \begin{cases} 0 & \text{if } i \le u(|x|), \\ 0 & \text{if } u(|x|) < i \le u(|x|) + |x| \quad \text{and} \quad v(|x|, i - u(|x|)) \ne x, \\ 1 & \text{if } u(|x|) < i \le u(|x|) + |x| \quad \text{and} \quad v(|x|, i - u(|x|)) = x, \\ 0 & \text{if } u(|x|) + |x| < i, \end{cases}$$

$$\mu(x) = \sum_{i=1}^{\infty} b(x,i) 2^{-i}.$$

Since $v(n,j) \in \Sigma^n$, we have

$$\mu(\Sigma^n) = \sum_{i=u(n)+1}^{u(n)+n} 2^{-i} < 2^{-u(n)}.$$

Fix an algorithm $A_j \in ALG(f)$. We have that $v(n,j) = w_{A_j}(n)$ for sufficiently large n. But then

$$b(w_{A_j}(n), u(n) + j) = 1 \quad \text{for } n \ge j$$

and, therefore,

$$\mu(w_{A_j}(n)) \ge 2^{-u(n)-j},$$

$$\mu_n(w_{A_j}(n)) = \frac{\mu(w_{A_j}(n))}{\mu(\Sigma^n)} > 2^{-j},$$

$$T^a_{A_j}(\mu, n) \ge \mu_n(w_{A_j}(n)) T_{A_j}(w_{A_j}(n)) > 2^{-j} T^w_{A_j}(n).$$

Thus μ is malign for $ALG(f)$. It remains to show that μ^* is polynomial time computable.

$$\mu^*(x) = \sum_{j<|x|} \mu(\Sigma^j) + \mu(\{y | |y| = |x| \wedge y \le x\}).$$

The ith binary digit of $\sum_{j<|x|} \mu(\Sigma^j)$ is 1 if and only if there exists an $m \in \{0, \ldots, |x|-1\}$ so that $u(m) < i \le u(m)+m$. This can be decided in time polynomial in $|x|$ and i, since u is time constructible. For the second term, observe that the ith binary digit of $\mu(\{y||y| = |x| \wedge y \le x\})$ is 1 if and only if $u(|x|) < i \le u(|x|) + |x|$ and $v(|x|, i - u(|x|)) \le x$. The inequality $u(|x|) < i \le u(|x|) + |x|$ can be checked in polynomial time and if it is found to hold, the calculation of $v(|x|, i - u(|x|))$ can be done in time

$$t(|x|, i - u(|x|)) \le t(|x|, |x|) = u(|x|) < i. \qquad \square$$

Of course, the theorem (and in particular its proof) suggests that the complexity of the measure μ itself is not particularly relevant when we are interested in properties such as being malign for a class. This is no big surprise, since we only use the derived probability measures μ_n. The time bound is achieved by letting $\mu(\Sigma^n)$ vanish very rapidly, so that the nonzero digits of $\mu(x)$ appear so late that we have a sufficient amount of time to compute them. The fact that μ is not necessarily normalized, i.e., that $\mu(\Sigma^n)$ may not be 1, thus seems to be giving us an unreasonable advantage in the computation of μ^*. If we instead look at the time required to compute the normalized $\mu^*_{|x|}(x)$, no such trick will work. It is, therefore, still reasonable to conjecture that it requires time exponential in x to compute this number, since the computation of a digit seems to require running an algorithm on all inputs of size $|x|$. Consequently, from now on we require that the measures we consider are normalized.

4. Malign ensembles.

DEFINITION 4.1. A probability ensemble (or merely ensemble) is a function $\mu : \Sigma^* \rightarrow [0,1]$, with $\mu(\Sigma^n) = 1$ for all n.

Thus, if μ is an ensemble, $\mu(x) = \mu_{|x|}(x)$ for all x.

DEFINITION 4.2. An ensemble μ is called polynomial time computable if and only if its family of distribution functions $x \rightarrow \mu^*_{|x|}(x)$ is polynomial time computable. We denote by PE the class of polynomial time computable ensembles. In general, we say that an ensemble is computable in time $f(|x|, i)$ if $\mu^*_{|x|}$ is computable in time $f(|x|, i)$, in the sense of §2.
This definition relativizes in the obvious way.

We can, through the use of essentially the same technique as in the proofs of Theorems 3.1 and 3.2, construct malign ensembles and hence provide upper bounds for the time required to compute malign ensembles for certain classes of algorithms.

THEOREM 4.1. *There exists a polynomial p so that for any time constructible function f there exists an ensemble μ, computable in time $p(2^{|x|}f(|x|), i)$ so that μ is malign for $ALG(f)$.*

Proof. Define

$$T(x, i) = \min(T_{A_i}(x), f(|x|)).$$

By our assumptions on the enumeration A_i, $T(x, i)$ can be computed in time $p_1(f(|x|), i)$, where p_1 is a polynomial, which, by the time constructibility of f, does not depend upon f. Define

$$w(n, i) = \min\{x \in \Sigma^n | \forall y \in \Sigma^n : T(y, i) \leq T(x, i)\}.$$

The function w can be computed in time $p_2(2^n, p_1(f(n), i))$, i.e., in time $p_3(2^n f(n), i)$.

$$b(x, i) = \begin{cases} 1 & \text{if } w(|x|, i) = x, \\ 0 & \text{otherwise,} \end{cases}$$

$$\mu_{|x|}(x) = \sum_{i=0}^{\infty} b(x, i) 2^{-i}.$$

μ is a probability ensemble. It can be computed in the required time because the ith binary digit of $\mu^*_{|x|}(x)$ is 1 if and only if $w(|x|, i) \leq x$. It only remains to show that it is malign for $ALG(f)$. But for this we observe that if A_j is such an algorithm, $T(x, j) = T_{A_j}(x)$ for sufficiently large $|x|$, and for these x, $b(x, j) = 1$ if x is the lexicographically least worst case input of size $|x|$ for A_j. But then

$$T^a_{A_j}(\mu, n) \geq 2^{-j} T^w_{A_j}(n)$$

for sufficiently large n. □

Of course, if $f \in 2^{\Omega(n)}$, the factor $2^{|x|}$ can be omitted from the stated time, i.e., for classes of exponential time algorithms, we can compute the ensemble almost as fast as the algorithms run.

COROLLARY 4.1. *There exists an ensemble μ, computable in time $p(2^{|x|}, i)$, where p is a polynomial, so that μ is malign for the class of polynomial time algorithms.*

Theorem 4.1 and the corollary reflect our intuition from the proof of Theorem 3.1: Malignness can be obtained if we are willing to use exponential time. By using the same technique, we can provide a recursive measure that is malign for classes of algorithms with some recursive upper bound on their running time. It won't provide us with a recursive measure for the class of all algorithms, and, as is proved below, no such thing exists. We now turn to a negative result, complementing Theorem 4.1.

THEOREM 4.2. *There is an $\epsilon > 0$ and a polynomial p, such that for all nondecreasing time constructible functions f with $f \in \Omega(p)$, there is no ensemble μ, malign for $ALG(f)$ and computable in time $f(|x|)^\epsilon h(i)$, where h is any function.*

Proof. The idea of the proof is the following: Given an ensemble μ, we can find a string y with low μ-value by binary search. We can then construct an algorithm A for which μ is not malign by making sure A runs for a long time on the input y.

Given a nondecreasing, time constructible function g, $g \in \Omega(n)$ and any function h, consider an ensemble μ, computable in time $g(|x|)h(i)$. We may assume that h is recursive, since $h(i)$ otherwise can be replaced with $\max_n T_\mu(n, i)$, which is recursive. We may furthermore assume that h is time constructible, strictly increasing, and tends to infinity, since any general recursive function is dominated by such a function. Define

$$\tilde{h}(n) = \min(\max(1, \max\{j | h(j) < \log(n)\}), n).$$

By h's time constructibility, $\tilde{h}$ can be computed in polynomial time. Furthermore, the polynomial time bound does not depend upon h. Consider the following algorithm, B:

```
input $x$
$y := \Lambda$
for $i := 1$ to $\tilde{h}(|x|)$ do
    $v_1 :=$ a $2^{-i}$-approximation to $\mu_{|x|}\{z | z < y0^{|x|-i+1}\}$
    $v_2 :=$ a $2^{-i}$-approximation to $\mu^*_{|x|}(y01^{|x|-i})$
    $v_3 :=$ a $2^{-i}$-approximation to $\mu^*_{|x|}(y1^{|x|-i+1})$
    if $v_2 - v_1 \leq v_3 - v_2$ then
        $y := y0$
    else
        $y := y1$
    fi
od
$y := y0^{|x|-|y|}$
if $x = y$ then
    idle for $q(g(|x|)\log(|x|))^2$ time steps ($q$ being specified below)
fi
```

The function q should be a polynomial such that $q(g(|x|)\log(|x|))$ is an upper bound for the running time of the algorithm when $x \neq y$. Observe that q can be picked independently of μ, g, and h. We may assume that q is of the form $q(t) = t^\alpha$. Put $\epsilon = \frac{1}{3\alpha}$. Putting $g(n) = f(n)^\epsilon$, we have that B halts on almost all inputs in time $q(\log(|x|)f(|x|)^\epsilon)^2 = \log(|x|)^{2\alpha} f(|x|)^{\frac{2}{3}}$, which is less than $f(|x|)$ for almost all $|x|$. Thus, $B \in ALG(f)$. By an easy induction, the invariant

$$\mu_{|x|}\{yz | z \in \Sigma^{|x|-i}\} \leq \left(\frac{3}{4}\right)^{i-3}$$

holds at the end of the ith cycle of the for loop, so the y found by the for loop has

$$\mu_{|x|}(y) \leq \left(\frac{3}{4}\right)^{\tilde{h}(|x|)-3}$$

We then have

$$T_B^a(n) \le \left(\frac{3}{4}\right)^{\tilde{h}(n)-3} T_B^w(n) + \sqrt{T_B^w(n)}.$$

But this is smaller than $cT_B^w(n)$, for any $c > 0$, for sufficiently large n, i.e., μ is not malign for B, which was to be proved. □

For exponential time algorithms the lower bound matches the upper bound of Theorem 4.1 within a polynomial. The theorem implies that no recursive measure is malign for the class of all algorithms and thus that the Solomonoff–Levin measure is not recursive (of course, this can be proven in more elementary ways, see [6]). For polynomial time algorithms, we have the following.

COROLLARY 4.2. *No ensemble $\mu \in PE$ is malign for the class of polynomial time algorithms.*

5. Malign ensembles for classes of fast algorithms. Corollary 4.2 still leaves something to be desired. After all, most algorithms we are likely to run will be in, e.g., $ALG(n^4)$. It still seems that exponential time is required to compute malign ensembles for such classes, even if our lower bound is much smaller. However, we are not likely to be able to prove these intuitions correct because the following theorem tells us that in order to show that superpolynomial time is necessary, we would have to prove $P \neq NP$. We are reusing the technique from the previous constructions.

THEOREM 5.1. *For all k, an ensemble $\mu \in PE^{\Sigma_2^p}$ exists, which is malign for $ALG(n^k)$.*

Proof. Put $f(n) = n^k$ in the proof of Theorem 4.1. This makes $T(x, i)$ polynomial time computable. Observe that the ith binary digit of $\mu^*_{|x|}(x)$ is 1 if and only if

$$\exists y \in \Sigma^n \, \forall z \in \Sigma^n \, [y \le x \wedge T(z, i) \le T(y, i)],$$

and this is a Σ_2^p-problem. □

It thus seems that we will have to concentrate on merely making the existence of such a PE-ensemble unlikely, instead of trying to prove that it does not exist. We will indeed do this, by deriving from it a complexity-theoretic equality that seems unreasonable, although it is a lot weaker than $P = NP$. For this, we need a result on sampling.

DEFINITION 5.1. An ensemble μ is polynomial time samplable if a polynomial time probabilistic Turing machine exists, which on input $\langle 1^n, 1^i \rangle$ produces a string of length n, $M(n, i)$ such that for all $x \in \Sigma^n$,

$$|\Pr(M(n, i) = x) - \mu_n(x)| \le 2^{-i}.$$

Thus, the polynomial time samplable ensembles are those ensembles that can be approximated as the output distributions of polynomial time probabilistic algorithms. A similar definition and an analogy to the following theorem can be found in [1]. Note that we cannot demand that the strings are produced with the exact probability, since it is easy to see that no probabilistic machine with a worst case time bound can produce a string with an irrational probability. Thus, demanding exact sampling would make the following theorem false.

THEOREM 5.2. *Every ensemble μ in PE is polynomial time samplable.*

The proof is essentially equal to the one in [1] and is, therefore, omitted. We might note that the converse result holds if and only if $P = PP$.

DEFINITION 5.2. Given a language L. An expected polynomial time constructor for L is a probabilistic algorithm that on input 1^n produces an $x \in L \cap \Sigma^n$ in expected polynomial time if one exists and otherwise fails to halt.

This is a natural generalization of the deterministic constructors defined and studied by Sanchis and Fulk in [7]. A useful equivalence is the following.

LEMMA 5.1. *Every $L \in P$ has an expected polynomial time constructor if and only if every $L \in DTIME(n)$ has one.*

Proof. Suppose every $L \in DTIME(n)$ has a constructor. Let J be a language in P. There is a constant c, such that $J \in DTIME(n^c)$. Define $\tilde{J} = \{x10^{|x|^c} | x \in J\}$. It is easy to see that $\tilde{J} \in DTIME(n)$, so, by assumption, $\tilde{J}$ has a constructor, $\tilde{C}$. By running $\tilde{C}$ on input 1^{n+1+n^c} and extracting the first n digits of the output if $\tilde{C}$ halts, we get a string in $L \cap \Sigma^n$. □

THEOREM 5.3. *Suppose a polynomial time samplable ensemble μ is malign for $ALG(f)$, where f is a time constructible function with $n \in o(f)$. Then every $L \in P$ has an expected polynomial time constructor.*

Proof. By Lemma 5.1, we need only to show that every $L \in DTIME(n)$ has a constructor. Consider the following algorithm A_L:

```
Input $x$
Decide if $x \in L$.
If it is not, halt immediately.
If it is, wait $f(n)/2$ time-steps before halting.
```

A_L is an $ALG(f)$-algorithm, so there exists a c so that $T_A^a(\mu, n) \geq cT_A^w(n)$. We will show that for sufficiently large n,

$$L \cap \Sigma^n \neq \emptyset \Rightarrow \mu_n(L \cap \Sigma^n) \geq \frac{c}{2}.$$

Assume not, i.e., $\mu_n(L \cap \Sigma^n) < c/2$. Then

$$\sum_{x \in L \cap \Sigma^n} \mu_n(x) T_A(x) < \frac{c}{2} T_A^w(n).$$

We also have that for sufficiently large n:

$$\sum_{x \in \Sigma^n \setminus L} \mu_n(x) T_A(x) \leq n.$$

But then

$$\frac{c}{2} T_A^w(n) + n \geq T_A^a(\mu, n) \geq cT_A^w(n).$$

If $L \cap \Sigma^n \neq \emptyset$, the algorithm will run for $f(n)/2$ time steps for some value of x. Therefore,

$$n \geq \frac{c}{2} T_A^w(n) \geq \frac{cf(n)}{4},$$

which is a contradiction for sufficiently large n. Let M be a polynomial time sampler for μ. By the definition of sampling, if $L \cap \Sigma^n \neq \emptyset$, then $\Pr(M(n, \lceil -\log \frac{c}{4} \rceil + n) \in L \cap \Sigma^n) \geq (c/2) - (c/4) = c/4$. Thus, running M several times on input $< 1^n, 1^{\lceil -\log \frac{c}{4} \rceil + n} >$ until an element of L is produced, is a construction of such an element in expected polynomial time. □

The following theorem (an analog to Proposition 4.1 in [7]) makes expected polynomial time constructors for all languages in P unlikely.

DEFINITION 5.3. Let RE be the class of languages L for which there exist a probabilistic Turing machine, running in time $2^{c|x|}$ on input x, rejects if $x \notin L$, and accepts with probability at least $\frac{1}{2}$ if $x \in L$.

Thus, RE is for $E = \cup_{c\geq 0} DTIME(2^{cn})$ what RP is for P. Hence, RE should be considered a rather small extension of E, and $RE = NE$, where $NE = \cup_{c\geq 0} NTIME(2^{cn})$ must be considered only slightly more plausible than $E = NE$. Actually, by standard arguments $RE = NE$ if and only if there are no tally languages in $NP - RP$.

THEOREM 5.4. *If every $L \in P$ has an expected polynomial time constructor, then $RE = NE$.*

Proof. Let L be a language in NE, and let M be a nondeterministic machine, running in time 2^{cn} and recognizing L. We can represent the nondeterministic computations of M on input x as binary strings of length at most $2^{c|x|}$, where the bits represent the nondeterministic choices of M. Denote by x_n^i the lexicographically ith string of size n. Define $f : \Sigma^* \to \mathbf{N}$ by $f(x_n^i) = 2^{cn} + i$. The function f is clearly injective, provided $c \geq 1$, which we may assume. Now consider

$$\tilde{L} = \{y \mid \exists x : |y| = f(x) \text{ and } y \text{ codes an accepting computation of } M \text{on } x\}.$$

Clearly $\tilde{L} \in P$ and has, therefore, by assumption, an expected polynomial time constructor, C. Let $p(n)$ be an upper bound on C's expected running time on inputs of size n. If we simulate C on $1^{f(x)}$ for $2p(f(x))$ time steps and accept if an element has been produced by then and reject otherwise, we have an RE-acceptor for L. □

COROLLARY 5.1. *If an ensemble $\mu \in PE$ is malign for $ALG(f)$, where f is time constructible and $n \in o(f)$, then $RE = NE$.*

Thus, if we assume $RE \neq NE$, we get a superpolynomial lower bound on ensembles malign for this class of algorithms. By making the stronger assumption that there are tally sets in NP, which cannot be recognized in subexponential randomized time, the same technique gives an exponential lower bound, essentially matching the upper bound of Theorem 4.1.

Acknowledgments. Thanks to Joan Boyar for her helpful supervision on the thesis on which this paper is based and to Sven Skyum for useful comments and suggestions. Lane A. Hemachandra and Paul M.B. Vitányi pointed out some errors in the original manuscript.

SCAN-FIRST SEARCH AND SPARSE CERTIFICATES: AN IMPROVED PARALLEL ALGORITHM FOR k-VERTEX CONNECTIVITY[*]

JOSEPH CHERIYAN[†], MING-YANG KAO[‡], AND RAMAKRISHNA THURIMELLA[§]

Abstract. Given a graph $G = (V, E)$, a *certificate* of k-vertex connectivity is an edge subset $E' \subset E$ such that the subgraph (V, E') is k-vertex connected if and only if G is k-vertex connected. Let n and m denote the number of vertices and edges. A certificate is called *sparse* if it contains $O(kn)$ edges.

For undirected graphs, this paper introduces a graph search called the *scan-first search*, and shows that a certificate with at most $k(n-1)$ edges can be computed by executing scan-first search k times in sequence on subgraphs of G. For each of the parallel, distributed, and sequential models of computation, the complexity of scan-first search matches the best complexity of any graph search on that model. In particular, the parallel scan-first search runs in $O(\log n)$ time using $C(n, m)$ processors on a CRCW PRAM, where $C(n, m)$ is the number of processors needed to find a spanning tree in each connected component in $O(\log n)$ time, and the parallel certificate algorithm runs in $O(k \log n)$ time using $C(n, m)$ processors. The parallel certificate algorithm can be employed to test the k-vertex connectivity of an undirected graph in $O(k^2 \log n)$ time using $knC(n, kn)$ processors on a CRCW PRAM. For all combinations of n, m, and $k > 3$, both the running time and the number of processors either improve on or match those of all known deterministic parallel algorithms.

This paper also obtains an online algorithm for computing an undirected graph certificate with at most $2kn$ edges, and a sequential algorithm for computing a directed graph certificate with at most $2k^2n$ edges.

1. Introduction.

Graph connectivity is one of the most fundamental properties in graph theory [4]. Given a positive integer k, an undirected (or directed) graph $G = (V, E)$ with at least $k+1$ vertices is called *k-vertex connected* if the deletion of any $k-1$ vertices leaves the graph connected (respectively, strongly connected). A *certificate* for the k-vertex connectivity of G is a subset E' of E such that the subgraph (V, E') is k-vertex connected if and only if G is k-vertex connected. Let $n = |V|$ and $m = |E|$. Note that $kn/2$ is a trivial lower bound on the number of edges in a certificate for a k-vertex connected graph. For general k, it is not obvious that there is any upper bound strictly less than m on the number of edges in a certificate for k-vertex connectivity; however, nonconstructive results of Mader imply an upper bound of $O(kn)$ for undirected graph certificates [5]. We call a certificate for k-vertex connectivity *sparse* if it has $O(kn)$ edges. For instance, a spanning tree is a sparse certificate for the 1-vertex connectivity of a connected undirected graph.

Sparse certificates have applications in diverse areas of computer science. For example, they can be used for message-efficient fault-tolerant protocols in distributed computing [20], [21]. Also, they are useful for improving existing graph k-vertex connectivity algorithms. The k-vertex connectivity of a graph can be tested in two stages. Stage 1

computes a sparse certificate of the input graph. Stage 2 applies a given k-vertex connectivity algorithm to the certificate obtained in Stage 1. Because a certificate preserves the k-vertex connectivity of the input graph, Stage 1 ensures the correctness of the test. Stage 2 can *potentially* improve the complexity of the test by reducing the size of the input to the given k-vertex connectivity algorithm.

For sequential computing, Nagamochi and Ibaraki have presented an algorithm for sparse undirected graph certificates that runs in $O(m + n)$ time [27]. For testing the k-vertex connectivity of undirected graphs, this gives sequential running times of $O(k^2n^2)$ for $k \leq \sqrt{n}$ and of $O(k^3n^{1.5})$ for $k > \sqrt{n}$ when their sparse-certificate algorithm is combined with Galil's k-vertex connectivity algorithm [17]. Independently, another sequential algorithm for k-vertex connectivity with the same complexity for $k \leq \sqrt{n}$ was reported in preliminary versions of this paper [9], [8], the stated bound being achieved in the latter [8]. It is now clear that the work of Nagamochi and Ibaraki [27] was the earlier result, although unknown to us at the time of our work.

We present an algorithm for finding sparse certificates for undirected graphs, using a new graph search procedure called the *scan-first search*. This search procedure has surprisingly efficient implementations in the parallel, distributed and sequential models of computation. Consequently, our certificate algorithm also has efficient implementations in all these three models. Below we list the complexity of scan-first search on the three models. Note that the complexity of scan-first search on each model matches the best complexity of any graph search on that model.

• **Parallel computing.** Scan-first search runs in $O(\log n)$ time using $C(n,m)$ processors on a CRCW PRAM, where $C(n,m)$ is the number of processors used to compute a spanning tree in each connected component in $O(\log n)$ time. For deterministic algorithms, Cole and Vishkin have shown [11] that $C(n,m) = O((m+n)\alpha(n,m)/\log n)$, where $\alpha(n,m)$ is the inverse of Ackerman's function and has an extremely slow growth rate [12]. For randomized algorithms, Gazit has shown [18] that $C(n,m)$ achieves the optimal bound of $\Theta((m+n)/\log n)$.

• **Distributed computing.** Scan-first search runs in $O(d\log^3 n)$ time using $O(m + n\log^3 n)$ messages, where d is the diameter of the input graph.

• **Sequential computing.** Scan-first search runs in $O(m+n)$ time.

The advantage of scan-first search over the two most well-known graph search procedures is easy to see. Depth-first search runs in optimal linear time on the sequential model [28] but has no known parallel implementation that is efficient [1], [2]. Breadth-first search runs efficiently on the sequential and the distributed models [14], [3]. However, currently the best parallel implementation is no more efficient than matrix multiplication [19].

For undirected graphs, we show that a sparse certificate can be computed by executing scan-first search k times in sequence on subgraphs of G; moreover, the resulting certificate has at most $k(n-1)$ edges, only a factor of two away from the trivial lower bound (see Theorem 2.4). Combining this result with the above implementations of scan-first search shows that the complexity of our sparse-certificate algorithm on the three models is as follows: $O(k\log n)$ time using $C(n,m)$ processors on the parallel model, $O(kn\log^3 n)$ time using $O(k(m+n\log^3 n))$ messages on the distributed model, and $O(k(m+n))$ time on the sequential model.

Consider the problem of testing an undirected graph for k-vertex connectivity. Using the method sketched above, our certificate algorithm can be used as a preprocessing step, both with Khuller and Schieber's parallel algorithm [24], and with Even's sequential algorithm [13].This gives a parallel running time of $O(k^2\log n)$ using $knC(n, \min\{kn, m\})$

processors, and sequential running times of $O(k^2n^2)$ when $k \leq \sqrt{n}$ and of $O(k^3n^{1.5})$ when $k > \sqrt{n}$.

For general k, there are no previous parallel or distributed algorithms for sparse certificates. The best previous parallel algorithm for (undirected) k-vertex connectivity, due to Khuller and Schieber [24], runs in $O(k^2 \log n)$ time and uses $knC(n, m)$ processors. For $m > kn$, our algorithm uses fewer processors than their algorithm. For dense graphs and for $k = O(1)$, our algorithm runs in $O(\log n)$ time and has a time-processor product that is within an alpha-factor of the trivial lower bound of $\Omega(n^2)$.

We also obtain the following results. For *undirected* graphs, we give an *online* algorithm that computes a certificate with at most $2kn$ edges. This algorithm is parallelized to run probabilistically in $O(\log^2 n)$ time using $mP(n, m)$ processors, where $P(n, m)$ is the number of processors needed to find a maximum matching in $O(\log^2 n)$ time with high probability. Currently, the best value known for $P(n, m)$ is $O(mn^{3.38})$ [26]. For *directed* graphs, we show that a certificate with at most $2k^2n$ edges can be computed in $O(km \max\{n, k\sqrt{n}\})$ sequential time.

The above discussion has highlighted the results of this paper. The following sections proceed to detail those results. Section 2 discusses scan-first search and the algorithm for computing undirected graph certificates in the three models. Section 3 presents the online algorithm for undirected graph certificates and its parallelization. Section 4 describes the sequential algorithm for directed graph certificates. Section 5 concludes the paper with open problems.

2. Scan-first search and sparse undirected graph certificates.

The main result of this section is that a sparse certificate for undirected k-vertex connectivity can be found by iteratively performing k scan-first searches on subgraphs of the input graph.

Section 2.1 defines scan-first search and discusses how to perform the search efficiently in the parallel, distributed, and sequential models of computation. Section 2.2 states the main certificate theorem based on scan-first search and discusses its algorithmic implications. Sections 2.3 and 2.4 prove the main certificate theorem, and §2.4 gives a generalization of the theorem.

2.1. Scan-first search.

Given a connected undirected graph and a specified vertex, a *scan-first search* in the graph starting from the specified vertex is a systematic way of marking the vertices. The main marking step is called *scan*: to scan a marked vertex means to mark all previously unmarked neighbors of that vertex. At the beginning of the search, only the specified starting vertex is marked. Then, the search iteratively scans a marked and unscanned vertex until all vertices are scanned.

A scan-first search in a connected undirected graph produces a spanning tree defined as follows. At the beginning of the search, the tree is empty. Then, for each vertex x in the graph, when x is scanned, all the edges between x and its previously unmarked neighbors are added to the tree; the edges between x and its previously marked neighbors are not added to the tree.

For an undirected graph that may or may not be connected, a scan-first search can be performed by applying the above search procedure to each connected component (as well as to each isolated vertex). The search produces a spanning forest with a spanning tree in each connected component.

Notice that scan-first search is more general than sequential breadth-first search [14]. In other words, all sequential breadth-first search trees are scan-first search trees, but some scan-first search trees are not breadth-first search trees. For example, let C be an undirected graph consisting of a five-vertex cycle x_1, x_2, x_3, x_4, x_5. Let e_i denote the edge $\{x_i, x_{i+1}\}$. Then, $C - \{e_2\}$, $C - \{e_3\}$, $C - \{e_4\}$ are the scan-first search trees of C rooted at x_1. However, $C - \{e_3\}$ is the only breadth-first search tree rooted at x_1.

```
Subroutine PARALLEL SCAN-FIRST SEARCH
Input: a connected undirected graph $G = (V, E)$ and a vertex $r$.
Output: a scan-first search spanning tree $T$ of $G$ rooted at $r$.
begin
    Find a spanning tree $T'$ of $G$ rooted at $r$;
    Assign a preorder numbering to the vertices in $T'$;
    For each vertex $v \in T'$ with $v \neq r$, let $b(v)$ denote the neighbor of $v$ in $G$ with
    the smallest preorder number;
    Let $T$ be the tree formed by the edges $\{v, b(v)\}$ for all $v \neq r$;
end.
```

FIG. 1. *Computing a scan-first search spanning tree in parallel.*

THEOREM 2.1. *For an undirected graph with n vertices and m edges, a scan-first search spanning forest can be found in $O(\log n)$ time using $C(n, m)$ processors on a* CRCW PRAM, *where $C(n, m)$ is the number of processors used to compute a spanning tree in each connected component in $O(\log n)$ time.*

Proof. Let G be the input graph. Without loss of generality, assume that G is connected. Let r be a given starting vertex in G. To prove the theorem, Fig. 1 describes an algorithm for finding a scan-first search spanning tree T of G rooted at the vertex r.

T is a scan-first search spanning tree of G rooted at r for the following reasons. T corresponds to a scan-first search in G starting at r with the preorder of T' being the scanning order. T is a spanning tree because every vertex except r has a neighbor with a smaller preorder number in T'.

T can be found in $O(\log n)$ time using $C(n, m)$ processors on a CRCW PRAM as follows. By the definition of $C(n, m)$, T' can be found in $O(\log n)$ time using $C(n, m)$ processors. By standard parallel algorithmic techniques [23], the preorder numbers and the neighbors $b(v)$ in Figure 1 can be computed in $O(\log n)$ time using $O((n+m)/\log n)$ processors. Because $C(n, m) = \Omega((n+m)/\log n)$, the total complexity is $O(\log n)$ time using $C(n, m)$ processors. □

To find a scan-first search tree on the distributed model, we use the best distributed breadth-first search algorithm currently known, that of Awerbuch and Peleg [3].

THEOREM 2.2. *For an undirected graph with diameter d, n vertices, and m edges, a scan-first search spanning forest can be found in $O(d \log^3 n)$ distributed time using $O(m + n \log^3 n)$ messages.*

Proof. The distributed breadth-first search algorithm of Awerbuch and Peleg [3] runs in $O(d \log^3 n)$ distributed time using $O(m + n \log^3 n)$ messages. We first execute their algorithm, and then modify the resulting breadth-first search forest to give a scan-first search forest within the same complexity bounds. □

THEOREM 2.3. *For an undirected graph with n vertices and m edges, a scan-first search spanning forest can be found in $O(n + m)$ sequential time.*

Proof. The proof is easy. □

2.2. The main certificate theorem and its algorithmic implications. The next theorem shows that sparse certificates for the k-vertex connectivity of undirected graphs can be computed efficiently.

THEOREM 2.4 (The main certificate theorem). *Let $G = (V, E)$ be an undirected graph and let n denote the number of vertices. Let k be a positive integer. For $i = 1, 2, \ldots, k$, let E_i be the edge set of a scan-first search forest in the graph $G_{i-1} = (V, E - (E_1 \cup \cdots \cup$

E_{i-1})). Then $E_1 \cup \cdots \cup E_k$ is a certificate for the k-vertex connectivity of G, and this certificate has at most $k(n-1)$ edges.

Theorem 2.4 has algorithmic consequences for the parallel, distributed and sequential models of computation.

THEOREM 2.5. *For an undirected graph with n vertices and m edges, a sparse certificate for k-vertex connectivity with at most $k(n-1)$ edges can be found in $O(k \log n)$ time using $C(n,m)$ processors on a* CRCW PRAM.

Proof. The proof is obtained by Theorems 2.4 and 2.1. □

The next theorem improves on the best previous parallel algorithms for testing the k-vertex connectivity of undirected graphs, namely, the algorithm in Khuller and Schieber [24] and the one in the preliminary version of this paper [10].

THEOREM 2.6. *For an undirected graph with n vertices and m edges, the k-vertex connectivity can be tested in $O(k^2 \log n)$ time using $knC(n,kn)$ processors on a* CRCW PRAM.

Proof. The k-vertex connectivity is tested in two steps. Step 1: Compute a sparse certificate for the k-vertex connectivity of the input graph via Theorem 2.5. Step 2: Apply the k-vertex connectivity algorithm of Khuller and Schieber [24] to the certificate found in the first step. Step 1 runs in $O(k \log n)$ time using $C(n,m)$ processors. Step 2 runs in $O(k^2 \log n)$ time using $knC(n,kn)$ processors. Because $knC(n,kn) \geq C(n,m)$, the total complexity is as stated. □

The main certificate theorem also gives an efficient algorithm on the distributed model of computation. For general k, the first distributed algorithm for undirected sparse certificates was presented in the preliminary version of this paper [10]. For $k=2$, Itai and Rodeh have previously given a distributed algorithm for undirected sparse certificates [21].

THEOREM 2.7. *For an undirected graph with n vertices and m edges, a sparse certificate for k-vertex connectivity with at most $k(n-1)$ edges can be found in $O(kn \log^3 n)$ distributed time using $O(k(m+n\log^3 n))$ messages.*

Proof. This proof follows from Theorems 2.4 and 2.2. For $i > 1$, notice that the diameter of G_{i-1} may increase to $\Omega(n)$. □

For sequential computation, linear-time algorithms for sparse certificates for the 2-vertex connectivity and the 3-vertex connectivity of undirected graphs have been given by Itai and Rodeh [21] and Cheriyan and Maheshwari [7], respectively. For general k, Nagamochi and Ibaraki have recently given a linear-time algorithm for sparse certificates for undirected graphs [27]. The main certificate theorem gives a slower sequential algorithm for general k.

THEOREM 2.8. *For an undirected graph with n vertices and m edges, a sparse certificate for k-vertex connectivity with at most $k(n-1)$ edges can be found in $O(k(m+n))$ sequential time.*

Proof. The proof is obtained by Theorems 2.4 and 2.3. □

For testing the k-vertex connectivity of undirected graphs, sequential running times of $O(k^2n^2)$ for $k \leq \sqrt{n}$ and of $O(k^3n^{1.5})$ for $k > \sqrt{n}$ have been reported in Nagamochi and Ibaraki [27]. The main certificate theorem gives the same sequential complexity, when combined with Even's k-vertex connectivity algorithm [13].

THEOREM 2.9. *The k-vertex connectivity of an n-vertex undirected graph can be tested in $O(k^2n^2)$ sequential time for $k \leq \sqrt{n}$ and in $O(k^3n^{1.5})$ sequential time for $k > \sqrt{n}$.*

Proof. First use Theorem 2.8 to find a sparse certificate. Then run the k-vertex connectivity algorithm of Even [13], [14]. □

COROLLARY 2.10. *For $k = O(1)$, the k-vertex connectivity of an n-vertex undirected graph can be tested in $O(n^2)$ sequential time.*

Proof. The proof follows from Theorem 2.9. □

2.3. The proof of the main certificate theorem. The main certificate theorem states that a certificate with at most $k(n-1)$ edges can be computed by successively finding the edge set E_1 of a scan-first search spanning forest of $G_0 = G$, the edge set E_2 of a scan-first search spanning forest of $G_1 = (V, E - E_1), \ldots$, the edge set E_k of a scan-first search spanning forest of $G_{k-1} = (V, E - (E_1 \cup \cdots \cup E_{k-1}))$, and taking their union $E_1 \cup \cdots \cup E_{k-1}$.

For $i = 1, \ldots, k$, let F_i denote the spanning forest computed by the ith scan-first search (i.e., F_i has edge set E_i), and let H_i denote the subgraph $(V, (E_1 \cup \cdots \cup E_i))$. See Fig. 2 for an example illustrating the definitions of G_i, F_i and H_i. Clearly, the theorem holds if H_k is k-vertex connected. To prove the theorem by contradiction, suppose that H_k is not k-vertex connected, and that G is k-vertex connected. Then there is a subset S of at most $k-1$ vertices such that $H_k - S$ is disconnected, by Menger's theorem. The next lemma shows that at least one tree of the last scan-first search forest F_k must contain vertices of two or more connected components of $H_k - S$.

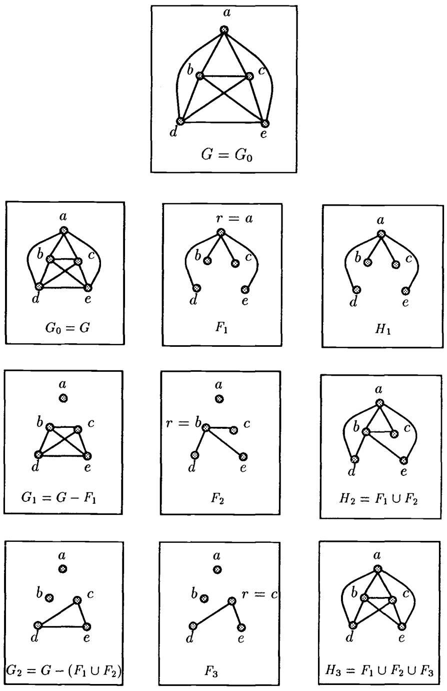

FIG. 2. *An example illustrating the definitions of G_i, F_i, and H_i when G is K_5.*

LEMMA 2.11. *Suppose that H_k is not k-vertex connected, and that G is k-vertex connected. Then the following two statements hold:*

1. *There is a subset $S \subset V$ with $|S| < k$ such that $H_k - S$ is disconnected;*
2. *F_k contains a simple tree path P_k whose two endpoints are in different connected components of $H_k - S$.*

Proof. Focus on the second statement. By the k-vertex connectivity of G, the graph $G - S$ obtained by deleting S from G is connected because S contains $k-1$ or fewer vertices. Because $H_k - S$ is disconnected and $G - S$ is connected, there exists an edge

e in G whose endpoints are in two different connected components of $H_k - S$. The edge e is not in H_k, and so is not in $E_1 \cup \cdots \cup E_{k-1}$. Hence the edge e is in $G_{k-1} = (V, E - (E_1 \cup \cdots \cup E_{k-1}))$, and so the two endpoints of e are in the same connected component of G_{k-1}. Because F_k is a scan-first search forest in G_{k-1}, the forest F_k has a spanning tree for the connected component in G_{k-1} that contains e. Therefore, F_k contains a simple tree path P_k between the two endpoints of e. This shows that the second statement holds. □

To finish the proof of Theorem 2.4, the following discussion proceeds to show that the path P_k of Lemma 2.11 cannot exist, yielding the desired contradiction.

A few definitions are in order. Let ω denote the size of S. The proof of Theorem 2.4 makes crucial use of the following indexing scheme of S. Let $s_1, \ldots, s_\omega$ denote the vertices of S such that s_i is the first vertex in $S - \{s_1, \ldots, s_{i-1}\}$ that is scanned by the ith search. Because $\omega < k$ by the first statement of Lemma 2.11, this indexing scheme is well defined and establishes a one-to-one onto correspondence between the vertices in S and the forests $F_1, \ldots, F_\omega$.

For each s_i in S, the *home component* of s_i is defined as follows. In the forest F_i, let r be the root of the tree that contains s_i. There are three cases.

Case 1. If $r \notin S$, then the home component of s_i is the connected component in $H_k - S$ that contains r.

Case 2. If $r \in S$ and $r \neq s_i$, then the home component of s_i is the home component of r.

Case 3. If $r = s_i$, then s_i has no home component.

Figure 3 illustrates the definition of home components. The next lemma shows that the definition is consistent.

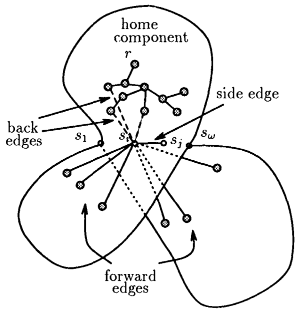

FIG. 3. *Illustration of the definitions of home components and of forward, back, and side edges (of vertex s_i).*

LEMMA 2.12. *For each $s_i \in S$, if s_i satisfies Case 1 or Case 2 of the above definition, then the home component of s_i is a connected component of $H_k - S$. If s_i satisfies Case 3, then s_i has no home component.*

Proof. The lemma is obviously true if s_i satisfies Case 1 or Case 3 of the definition. For Case 2, the lemma is shown by induction on the indices of S.

Induction Hypothesis: For all $j < i$, if s_j satisfies Case 2 of the above definition, then the home component of s_j is a connected component of $H_k - S$.

Induction Step: The goal is to show that s_i has a home component. Because s_i satisfies Case 2, the root of the tree in F_i that contains s_i is some $s_h \in S$.

CLAIM 1. $h < i$.

Proof. Note that $i \neq h$ because $s_h \neq s_i$ by the definition of Case 2. To prove this claim by contradiction, assume that $h > i$. Then, $s_h \in S - \{s_1, \ldots, s_{i-1}\}$. Moreover, because s_i is a descendant of s_h in F_i, the ith search scans the vertex s_h before s_i. Thus, the vertex s_i should not have been indexed i. This is a contradiction. Consequently, h must be smaller than i. This finishes the proof of Claim 1. □

CLAIM 2. *No tree of F_h has s_h as its root.*

Proof. To prove this claim by contradiction, assume that s_h is a root in F_h. Then the edges in G that are adjacent to s_h and are not in $F_1, \ldots, F_{h-1}$ would all be included in F_h. Consequently, s_h would be an isolated vertex in G_h. Because $i > h$ by Claim 1, s_h would be an isolated vertex in F_i. This contradicts the fact that s_i is a descendant of s_h in F_i. Therefore, s_h is not a root in F_h. This finishes the proof of Claim 2.

To show that s_i has a home component, by the definition of Case 2, it suffices to prove that s_h has a home component. If Case 1 holds for s_h, then by definition, s_h has a home component. If Case 2 holds for s_h, then by Claim 1 and the induction hypothesis, s_h has a home component. Case 3 cannot hold for s_h by Claim 2. This finishes the proof of the lemma. □

To describe the key properties of scan-first search, more definitions are needed. For each vertex $s \in S$ if s has a home component, let $hcc(s)$ denote the home component of s; if s has no home component, let $hcc(s)$ denote s itself. Moreover, for each $v \in V - S$, let $hcc(v)$ denote the connected component in $H_k - S$ that contains v.

Given a forest F_i, a *jump* of F_i is a simple tree path $Q = v_1, \ldots, v_q$ of F_i with $hcc(v_1) \neq hcc(v_q)$.

For each vertex $s \in S$, the edges incident with s in G are classified into three types as follows. The *back* edges of s are those between s and its home component. The *side* edges of s are those between s and $S - \{s\}$. The rest of the edges incident with s are the *forward* edges. Note that if s does not have a home component, then it has no back edges. Refer to Fig. 5 for an illustration of these definitions.

The next lemma shows a key property of the first scan-first search, and the following lemma, which is the critical one for the proof of the main certificate theorem, generalizes the key property to the first i scan-first searches for all $i \in \{1, 2, \ldots, \omega\}$.

LEMMA 2.13. *The following two statements are true.*

1. *Every jump of F_1 contains at least one vertex of S.*
2. *The scan-first search forest F_1 contains all the forward edges of s_1.*

Proof. To prove the first statement by contradiction, assume that F_1 has a jump $Q = v_1, \ldots, v_q$ which contains no vertices from S. Then, $v_1, v_q \in V - S$. By the definition of hcc, $hcc(v_1)$ and $hcc(v_q)$ are connected components in $H_k - S$. By the definition of a jump, $hcc(v_1) \neq hcc(v_q)$. In sum, Q is a path in H_k that connects two different connected components of $H_k - S$. Therefore, Q must contain a vertex from S, contradicting the assumption of the proof. This finishes the proof of the first statement.

To prove the second statement, note that F_1 is a tree because $G_0 = G$ is connected. Let r be the root of F_1. Then there are two cases: either $r \in S$ or $r \notin S$.

Case 1. $r \in S$. By the definition of the indexing scheme of S, $r = s_1$. When the first search scans s_1, none of the neighbors of s_1 in G have been marked. Consequently, F_1 includes all edges incident with s_1 in G, and hence the lemma holds for this case.

Case 2. $r \notin S$. Refer to Fig. 4(ii) for an illustration of this case. By definition, s_1 has a home component and $hcc(r) = hcc(s_1)$. To prove this case by contradiction, assume that there is a forward edge $e = \{s_1, x\} \notin F_1$. This can happen only if the first search marks x before it scans s_1. Focus on the tree path, say, Q of F_1 from r to x. Because e is a forward edge, $hcc(s_1) \neq hcc(x)$. Therefore, $hcc(r) \neq hcc(x)$ and the path Q is a jump of F_1. By the first statement of this lemma, Q contains a vertex $s \in S$. Because s is an ancestor of x in F_1, the first search scans s before or when it marks x. Hence the first search scans s before it scans s_1. However, this contradicts the definition of the indexing scheme of S, because s_1 should have received a higher index. This finishes the proof of case (2) of the second statement, and completes the proof of the lemma. □

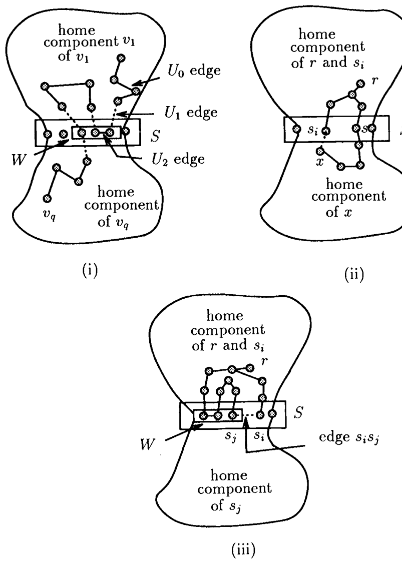

FIG. 4. *Proof of the main certificate theorem.* (i) *Proof of Claim* 3 (*in Lemma* 2.14) *and Lemma* 2.15. (ii) *Proof of Lemma* 2.13 *and Claim* 4 (*in Lemma* 2.14). (iii) *Proof of Claim* 5 (*in Lemma* 2.14).

LEMMA 2.14. *For each $i \in \{1, 2, \ldots, \omega\}$, the following statements are true.*

1. *Every jump of F_i contains at least one vertex in $S - \{s_1, \ldots, s_{i-1}\}$.*
2. *$F_1, \ldots, F_i$ contain the following edges of G :*
   (a) *All forward edges of s_i, and*
   (b) *All side edges $\{s_i, s_j\}$ with $i > j$ and $hcc(s_i) \neq hcc(s_j)$.*

Proof. This lemma is proved by induction on i as follows. The base step follows from Lemma 2.13; note that Statement 2(b) holds vacuously for $i = 1$. The induction hypothesis is that the lemma holds for $i = t$. The induction step shows that the lemma holds for $i = t + 1$. This is proved by the following three claims.

CLAIM 3. *Statement* 1 *holds for $i = t + 1$.*

To prove the above claim by contradiction, assume that F_{t+1} has a jump $Q = v_1, \ldots, v_q$ which contains no vertices from $S - \{s_1, \ldots, s_t\}$. Refer to Fig. 4(i) for an illustration. Let W be the set of vertices that are in both Q and S. Let U_0 be the set of edges in Q that each have two endpoints in $H_k - S$. Let U_1 be the set of edges in Q that each have one endpoint in W and the other endpoint in $H_k - S$. Let U_2 be the set of edges in Q that each have two endpoints in W. Observe that for all edges $\{x, y\} \in U_0$, $hcc(x) = hcc(y)$. Next, from the assumption of the proof, $W \subseteq \{s_1, \ldots, s_t\}$. Therefore, from statement 2(a) of the induction hypothesis, the edges in U_1 cannot be forward edges and hence for all edges $\{x, y\} \in U_1$, $hcc(x) = hcc(y)$. Furthermore, because the edges in U_2 are side edges, from statement 2(b) of the induction hypothesis, for all edges $\{x, y\} \in U_2$, $hcc(x) = hcc(y)$. Hence, for all vertices $x, y \in Q$, $hcc(x) = hcc(y)$. In particular, $hcc(v_1) = hcc(v_q)$, contradicting the assumption that Q is a jump. This finishes the proof of Claim 3.

CLAIM 4. *Statement* 2(a) *holds for* $i = t + 1$.

To prove the above claim, let T be the tree of F_{t+1} that contains s_{t+1} and let r be the root of T. Then there are two cases: (1) $r \neq s_{t+1}$ or (2) $r = s_{t+1}$.

Case 1. $r \neq s_{t+1}$. Refer to Fig. 4(ii) for an illustration of this case. By definition, s_{t+1} has a home component and $hcc(r) = hcc(s_{t+1})$. To prove this case by contradiction, assume that there is a forward edge $e = \{s_{t+1}, x\} \notin F_{t+1}$. This can happen only if the $(t + 1)$th search marks x before it scans s_{t+1}. From the existence of e, the tree T contains x. So T contains a tree path Q from r to x. Because e is a forward edge, $hcc(s_{t+1}) \neq hcc(x)$. Therefore, $hcc(r) \neq hcc(x)$, and Q is a jump of F_{t+1}. By Claim 3, Q contains a vertex $s \in S - \{s_1, \ldots, s_t\}$. Notice that $x \neq s$ because $x \in H_k - S$. Therefore, s is an ancestor of x in T. Consequently, the $(t + 1)$th search scans s before or when it marks x. Thus, the $(t + 1)$th search scans s before it scans s_{t+1}. Therefore, s_{t+1} should not have been indexed by $t+1$, contradicting the indexing scheme of S. This finishes the proof of Case 1 of Claim 4.

Case 2. $r = s_{t+1}$. Notice that when the $(t + 1)$th search scans s_{t+1}, none of the neighbors of s_{t+1} in G_t have been marked. So F_{t+1} includes all edges incident with s_{t+1} in G_t. Consequently, $F_1, \ldots, F_{t+1}$ include all edges incident with s_{t+1} in G and statement 2(a) holds for Case 2. This finishes the proof of Case 2 of Claim 4 and the proof of Claim 4.

CLAIM 5. *Statement* 2(b) *holds for* $i = t + 1$.

To prove the above claim, let T be the tree of F_{t+1} that contains s_{t+1}, and let r be the root of T. Then there are two cases: (1) $r \neq s_{t+1}$ or (2) $r = s_{t+1}$.

Case 1. $r \neq s_{t+1}$. Refer to Fig. 4(iii) for an illustration of this case. By definition, s_{t+1} has a home component and $hcc(r) = hcc(s_{t+1})$. To prove this case by contradiction, assume that there is a side edge $e = \{s_{t+1}, s_j\} \notin F_{t+1}$ such that $t+1 > j$ and $hcc(s_{t+1}) \neq hcc(s_j)$. This can happen only if the $(t+1)$th search marks s_j before it scans s_{t+1}. From the existence of e, the tree T contains s_j. So T contains a tree path Q from r to s_j. Notice that $hcc(r) = hcc(s_{t+1}) \neq hcc(s_j)$. Therefore, Q is a jump of F_{t+1}. Next, let W be the set of vertices that are in both S and Q. Notice that $s_j \in W$. Also, s_j is a proper descendant of all vertices in $W - \{s_j\}$, and the $(t + 1)$th search scans $W - \{s_j\}$ before it marks s_j. In sum, the $(t + 1)$th search scans $W - \{s_j\}$ before it scans s_{t+1}. Then, by the indexing scheme of S, $W - \{s_j\} \subseteq \{s_1, \ldots, s_t\}$. By the assumption of the proof, $s_j \in \{s_1, \ldots, s_t\}$. Hence, $W \subseteq \{s_1, \ldots, s_t\}$; by Claim 3, this contradicts the assumption that Q is a jump of F_{t+1}. This finishes the proof of Case 1 of Claim 5.

Case 2. $r = s_{t+1}$. This case is exactly the same as case (2) of Claim 4. This finishes the proof of case (2) of Claim 5, the proof of Claim 5, and the proof of the induction step. □

To complete the proof of the main certificate theorem, recall our assumption that H_k is not k-vertex connected, while G is k-vertex connected. Then Lemma 2.11 shows that F_k must contain a path P_k whose endpoints are in two different connected components of $H_k - S$, where S is a subset of V with $|S| < k$ whose deletion disconnects H_k. The next lemma shows that the path P_k cannot exist, using the same argument as in the proof of Claim 3 in Lemma 2.14, and thus completes the proof of Theorem 2.4.

LEMMA 2.15. *The path* P_k *of the second statement of Lemma* 2.11 *cannot exist.*

Proof. To prove the lemma by contradiction, assume that P_k exists. Let $P_k = v_1, \ldots, v_q$. Refer to Fig. 4(i) for an illustration. Because the two endpoints of P_k are in two different connected components of $H_k - S$, $hcc(v_1) \neq hcc(v_q)$ and the path P_k is a jump of F_k. Let W be the set of vertices that are in both P_k and S. Let U_0 be the set of edges in P_k that each have two endpoints in $H_k - S$. Let U_1 be the set of edges in P_k that each have one endpoint in W and the other endpoint in $H_k - S$. Let U_2 be the set of edges in P_k that each have two endpoints in W. Observe that for all edges $\{x, y\} \in U_0$, $hcc(x) = hcc(y)$. Next, because $W \subseteq S = \{s_1, \ldots, s_\omega\}$, by statement 2(a) of Lemma 2.14, the edges in U_1 cannot be forward edges and hence for all edges $\{x, y\} \in U_1, hcc(x) = hcc(y)$. Furthermore, because the edges in U_2 are side edges, from statement 2(b) of Lemma 2.14, for all edges $\{x, y\} \in U_2$, $hcc(x) = hcc(y)$. In sum, for all vertices $x, y \in P_k$, $hcc(x) = hcc(y)$. In particular, $hcc(v_1) = hcc(v_q)$, contradicting the assumption that P_k is a jump. This finishes the proof of Lemma 2.15. □

2.4. A generalization of the main certificate theorem. This section gives a generalization of the main certificate theorem, and discusses its applications.

For two distinct vertices x and y in G, the *local connectivity* of x and y, denoted $\kappa(x, y)$, is the maximum number of internally vertex-disjoint paths between x and y in G. A *certificate of local connectivity* k for G is a subset E' of E such that for every two distinct vertices x and y, $\kappa'(x, y) \geq \min\{k, \kappa(x, y)\}$, where $\kappa'(x, y)$ denotes $\kappa(x, y)$ for the subgraph (V, E'). A certificate of local connectivity k is said to be sparse if it has $O(kn)$ edges.

THEOREM 2.16 (The generalized certificate theorem). *Let $G = (V, E)$ be an undirected graph, and let n denote the number of vertices. Let k be a positive integer. For $i = 1, 2, \ldots, k$, let E_i be the edge set of a scan-first search forest in the graph $G_{i-1} = (V, E - (E_1 \cup \cdots \cup E_{i-1}))$. Then $E_1 \cup \cdots \cup E_k$ is a certificate of local connectivity k for G, and this certificate has at most $k(n-1)$ edges.*

Proof. The proof is essentially the same as that of the main certificate theorem. Let H_k be the subgraph $(V, (E_1 \cup \cdots \cup E_k))$, and let $\kappa_k(x, y)$ denote $\kappa(x, y)$ for H_k. To prove the theorem by contradiction, assume that $\kappa_k(u, w) < \min\{k, \kappa(u, w)\}$ for some two vertices $u, w \in V$ with $u \neq w$.

Although Lemma 2.11 does not apply now because it supposes that G is k-vertex connected, we first show that the two statements in Lemma 2.11 hold under the assumption that $\kappa_k(u, w) < \min\{k, \kappa(u, w)\}$ for some two vertices $u, w \in V$ with $u \neq w$. By Menger's theorem, there exist two vertices $u', w' \in V$ and a set $S \subseteq V - \{u', w'\}$ such that (1) $|S| = \kappa_k(u, w)$, (2) u' and w' are in different connected components of $H_k - S$, and (3) u' and w' are in the same connected component of $G - S$. By properties (1) and (2), there is a subset $S \subset V$ with $|S| < k$ such that $H_k - S$ is disconnected. By property (3), there exists an edge e in $G - S$ whose endpoints are in two different connected components of $H_k - S$. Clearly, the edge e is not in H_k, and hence e is in $G_{k-1} = (V, E - (E_1 \cup \cdots \cup E_{k-1}))$. So the two endpoints of e are in the same connected component of G_{k-1}. Because F_k is a scan-first search forest in G_{k-1}, the forest F_k has a spanning tree for the connected component in G_{k-1} that contains e. Therefore, F_k contains a simple tree path P_k whose two endpoints are in different connected components of $H_k - S$. This finishes the proof of the two statements in Lemma 2.11.

With the two statements in Lemma 2.11 proven, we can complete the proof of this theorem by using Lemmas 2.13, 2.14, and 2.15 to show that the above path P_k cannot exist. □

The next corollary is useful for computing the k-separators of a graph. For a positive integer k, a *k-separator* of G is a set S of k vertices such that $G - S$ has more connected components than G.

COROLLARY 2.17. *For a positive integer $k < n$ and for all $i \in \{1, \ldots, k-1\}$, G and $H_k = (V, (E_1 \cup \cdots \cup E_k))$ have the same i-separators.*

Proof. The proof is straightforward by Theorem 2.16. □

Some of the recent algorithmic research on k-connected graphs has focussed on highly efficient parallel algorithms for finding k-vertex connected components and k-separators for small k, namely, $k = 2$, 3, and 4. Theorem 2.16 and Corollary 2.17, when combined with Theorem 2.5, yield immediate improvements to several of these algorithms.

An undirected graph is said to be *bridge-connected* if for each edge the deletion of that edge leaves the graph connected. For a bridge-connected graph, Fussell and Thurimella [16] have given an algorithm for finding an open ear decomposition for each biconnected component on an $O(\sqrt{n}/\log n \times \sqrt{n}/\log n)$ mesh of trees architecture in $O(\log^3 n)$ time. We improve the running time to $O(\log^2 n)$ by first finding a sparse certificate of local connectivity 2 for the input graph, and then running their algorithm on the subgraph induced by the certificate. The main bottleneck of the original algorithm [16] is to compute, for a given spanning tree T of the input graph, the nearest common ancestor in T of all nontree edges. Note that by executing their algorithm on a sparse certificate, the worst-case number of nontree edges decreases from $\Omega(n^2)$ to $O(n)$.

THEOREM 2.18. *Let $G = (V, E)$ be a bridge-connected graph, and let n denote the number of vertices. An open ear decomposition for each biconnected component of G can be found on an $O(\sqrt{n}/\log n \times \sqrt{n}/\log n)$ mesh of trees architecture in $O(\log^2 n)$ time.*

Fussell, Ramachandran, and Thurimella [15] have given an algorithm for computing the triconnected components of an undirected graph in $O(\log n)$ time with a time-processor product of $O((m+n)\log\log n)$. We obtain the following improvement by first finding a sparse certificate of local connectivity 3 for the input graph, and then running their algorithm on the subgraph induced by the certificate.

THEOREM 2.19. *Let $G = (V, E)$ be an undirected biconnected graph, and let n and m denote the number of vertices and edges. The 3-vertex connected components of G can be found on an* ARBITRARY-CRCW PRAM *in $O(\log n)$ time with a time-processor product of $O(m\alpha(n, m) + n \log\log n)$.*

For an undirected triconnected graph, Kanevsky and Ramachandran [22] have given an algorithm for finding a compact representation of all the 3-separators. Their algorithm runs in $O(\log^2 n)$ time with a time-processor product of $O(n^2 \log^2 n)$. We obtain the following improvement in two steps. First, find a sparse certificate E' of local connectivity 4 for the input graph $G = (V, E)$. Then, for each vertex v, use the algorithm of Fussell, Ramachandran, and Thurimella [15] to find all the 2-separators of $(V, E') - \{v\}$.

THEOREM 2.20. *Let $G = (V, E)$ be an undirected triconnected graph, and let n denote the number of vertices. An $O(n^2)$ representation for all the 3-separators of G can be found on an* ARBITRARY-CRCW PRAM *in $O(\log n)$ time with a time-processor product of $O(n^2 \log\log n)$.*

The algorithm of Kanevsky and Ramachandran [22] also tests the input graph for 4-vertex connectivity in $O(\log^2 n)$ time using $O(n^2)$ processors. Note that for testing 4-vertex connectivity, our Theorem 2.6 gives a running time of $O(\log n)$ using $4nC(n, 4n) = O(n^2\alpha(n, 4n)/\log n)$ processors.

3. An online algorithm for sparse undirected graph certificates and its parallelization.

We first present a sequential online algorithm for finding sparse certificates for the k-vertex connectivity of undirected graphs. Then we parallelize the algorithm to obtain a randomized NC algorithm with a complexity independent of k.

Let $G = (V, E)$ denote the input undirected graph to our online certificate algorithm. Let n and m denote the numbers of vertices and edges of G. G is given one edge at a time; the input order $e_1, \ldots, e_m$ of the edges is arbitrary. Upon receiving an edge e_i, the online certificate algorithm must decide whether to include e_i in the final certificate $F \subseteq E$. Once an edge is included, it cannot be deleted from F at a later step; similarly, if an edge is not included, it cannot be added to F later. Initially, F is empty. Our online algorithm incrementally updates F by examining each input edge $\{v, w\}$ and including $\{v, w\}$ in F if and only if the subgraph induced by the current F has at most $k - 1$ vertex-disjoint paths between v and w.

The detailed description of our online certificate algorithm is given in Fig. 5. For an example, refer to Fig. 6. The next lemma shows that the F output by the online certificate algorithm is indeed a certificate of k-vertex connectivity.

```
Subroutine ONLINE CERTIFICATE
Input: the edges of an undirected graph $G = (V, E)$ given one at a time in an arbitrary
order $e_1, \ldots, e_m$.
Output: a sparse certificate $F \subseteq E$ for the $k$-vertex connectivity of $G$.
begin
    $F := \emptyset$;
    for $i := 1$ to $m$ do
        begin
            Let $v$ and $w$ denote the endpoints of $e_i$;
            Let $k_i$ denote the maximum number of vertex-disjoint paths between $v$
            and $w$ in $(V, F)$;
            if $k_i < k$ then $F := F \cup \{e_i\}$ else $F$ remains unchanged;
        end
end.
```

FIG. 5. *Computing a sparse certificate online.*

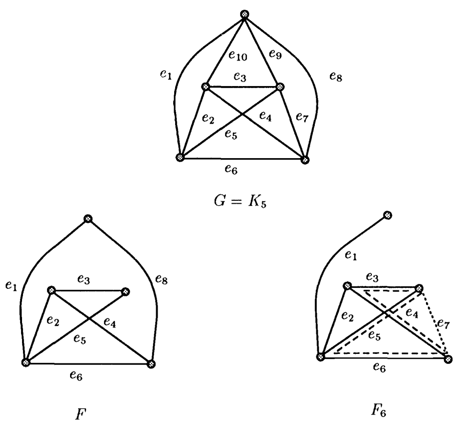

FIG. 6. *Using the online algorithm to find a certificate for 2-vertex connectivity. The edge ordering is* $e_1, e_2, \ldots, e_{10}$. *F does not contain e_7, for example, because in $F_6 = \{e_1, e_2, \ldots, e_6\}$ there are two vertex-disjoint paths between the endpoints of e_7.*

LEMMA 3.1. *If $G = (V, E)$ is k-vertex connected, then the final subgraph (V, F) is also k-vertex connected.*

Proof. To prove the lemma by contradiction, suppose that G is k-vertex connected but (V, F) is not k-vertex connected. Then, there is a set S of less than k vertices such that $(V, F) - S$ is disconnected. Let I be a connected component of $(V, F) - S$. Since $G - S$ is connected, G has an edge $\{v, w\}$ with $v \in I$ and $w \in V - (I \cup S)$. Because (V, F) has at most $|S|$ vertex-disjoint paths between v and w and because $|S| < k$, the online certificate algorithm would have added the edge $\{v, w\}$ to F when it examined $\{v, w\}$. This contradicts the assumption of the proof. Thus the lemma is true. □

Next we prove that the final F has at most $2kn$ edges by combining the following lemma with a theorem due to Mader.

LEMMA 3.2. *The final subgraph (V, F) does not contain any subgraph that is $(k+1)$-vertex connected.*

Proof. To prove the lemma by contradiction, suppose that (V, F) contains a $(k+1)$-vertex connected subgraph J. Let $e_i = \{v, w\}$ be the edge with the largest index among all the edges in J. In other words, e_i is the last edge added to J by the online certificate algorithm. Then $J - \{e_i\}$ has k vertex-disjoint paths between v and w because $J - \{e_i\}$ is k-vertex connected. Therefore, when the algorithm examined e_i, it would not have added e_i to F. This contradicts the assumption of the proof and finishes the proof the lemma. □

THEOREM 3.3 (Mader [5]). *For an integer $k \geq 1$, if an undirected graph has at least $2k - 1$ vertices and at least $(2k-1)(n-k)+1$ edges, where n denotes the number of vertices, then it contains a $(k+1)$-vertex connected subgraph.*

LEMMA 3.4. *The final F has at most $2kn$ edges.*

Proof. If $n \geq 2k - 1$, then the lemma follows from Lemma 3.2 and Theorem 3.3. If $n < 2k - 1$, then F contains at most $n(n-1)/2$ edges, which is less than $2kn$. □

The next theorem summarizes the discussion of the online certificate algorithm.

THEOREM 3.5. *Let G be an n-vertex undirected graph. Assume that the edges of G are given one at a time. Then a certificate for the k-vertex connectivity of G with at most $2kn$ edges can be computed on line in $O(k^2n)$ time per input edge.*

Proof. The correctness of the online certificate algorithm follows from Lemmas 3.1 and 3.4. As for the running time, note that for each edge e_i, the algorithm attempts to find k vertex-disjoint paths between the endpoints of e_i in (V, F). This takes time proportional to k times the size of (V, F) [14]. Therefore, the running time for examining one edge is $O(k^2n)$. □

A fast parallel version of the online certificate algorithm can be obtained by a parallel greedy method as follows. Let $E_0 = \emptyset$. For $i = 1, \ldots, m$, let E_i denote the edge set $\{e_1, e_2, \ldots, e_i\}$. For $i = 1, \ldots, m$, test in parallel whether the graph (V, E_{i-1}) has at least k vertex-disjoint paths between the endpoints of e_i. The certificate F contains exactly those edges e_i that fail the test.

Notice that the main difference in the computations executed by the above parallel algorithm and the online one is that the maximum number of vertex-disjoint paths between the endpoints of e_i is found in the subgraph (V, E_{i-1}) by the parallel algorithm and in (V, F) by the online algorithm. The next lemma shows that this difference does not affect F.

LEMMA 3.6. *The online certificate algorithm and its parallel version compute the same final F.*

Proof. For $t = 1, \ldots, m$, let F_t denote the F found by the online algorithm after it processes e_t, and let F_0 denote the empty set. Also, let C_p and C_q denote the final F computed by the parallel algorithm and the online algorithm, respectively. The goal is to show that $C_q = C_p$. Observe that $C_p \subseteq C_q$ because $F_{t-1} \subseteq E_{t-1}$ for all t. Thus, to prove the lemma by contradiction, it suffices to assume that there exists an edge $e_i = \{v, w\} \in C_q - C_p$. Then, by definition, there are at least k vertex-disjoint paths between v and w in (V, E_{i-1}) and there are less than k vertex-disjoint paths between v and w in (V, F_{i-1}). Therefore, there exists a set $S \subseteq V - \{v, w\}$ with $|S| < k$ such that (1) v and w are disconnected in $(V, F_{i-1}) - S$, and (2) there exists an edge $e_j \in E_{i-1} - F_{i-1}$ whose endpoints are in two different connected components of $(V, F_{i-1}) - S$. Notice that $j \leq i - 1$ because $e_j \in E_{i-1}$. Moreover, $e_j \notin F_j$ because $e_j \notin F_{i-1}$ and $F_j \subseteq F_{i-1}$. On the other hand, observe that (V, F_{i-1}) contains less than k vertex-disjoint paths between the endpoints of e_j. Then, because $F_{j-1} \subseteq F_{i-1}$, (V, F_{j-1}) also contains less than k vertex-disjoint paths between the endpoints of e_j. But then the online algorithm would have included e_j in F_j. This contradicts the earlier conclusion that $e_j \notin F_j$. Therefore, the assumption of the proof is incorrect and the lemma is correct. □

The next theorem summarizes the discussion of the parallelization of the online certificate algorithm. Let $P(n, m)$ denote the number of processors needed to find a maximum matching in $O(\log^2 n)$ time with high probability. Currently, the best value known for $P(n, m)$ is $O(m \cdot n^{3.38})$ [26].

THEOREM 3.7. *Given an undirected graph with n vertices and m edges, a certificate for k-vertex connectivity with at most $2kn$ edges can be found by a randomized algorithm in $O(\log^2 n)$ time using $m \cdot P(n, m)$ processors on a* CRCW PRAM.

Proof. The correctness of the above parallel algorithm follows from Lemmas 3.6, 3.1, and 3.4. As for the complexity, to test in parallel for the existence of k vertex-disjoint paths between two vertices, we use the well-known method of transforming this problem to the maximum matching problem [6]. □

4. A sequential algorithm for small certificates for directed graphs.

The main result of this section is stated in the following theorem.

THEOREM 4.1. *Let $G = (V, E)$ be a directed graph with n vertices and m edges. A certificate for the k-vertex connectivity of G with at most $2k^2 n$ edges can be found in $O(k \cdot m \cdot \max\{n, k\sqrt{n}\})$ sequential time.*

Notice that the running time of our directed graph certificate algorithm is the same as the best time complexity known for testing directed k-vertex connectivity [17]. Mader has shown an $O(kn)$ upper bound for the minimum size of a certificate for directed k-vertex connectivity [25]. For $k > 1$, our directed graph certificate algorithm is the best algorithm known for finding a certificate of size at most $n \cdot k^{O(1)}$.

Our proof of Theorem 4.1 is based on the next lemma. It allows certain edges of a vertex to be deleted without affecting the connectivity elsewhere. For a directed graph G and for every two distinct vertices $x, y \in G$, let $\kappa_G(x, y)$ denote the maximum number of internally vertex-disjoint directed paths from x to y in G.

LEMMA 4.2. *Let $G = (V, E)$ be a directed graph. Let z, u, v be vertices in G. Let e be an incoming edge of u in G. Let $H = (V, E - \{e\})$. If $\kappa_H(z, u) \geq k$ and $\kappa_G(z, v) \geq k$, then $\kappa_H(z, v) \geq k$.*

Proof. To prove the lemma by contradiction, assume that $\kappa_H(z, v) < k$. Then, to derive a contradiction by Menger's theorem, it suffices to show that for every vertex subset $S \subseteq V - \{z, v\}$ with $|S| < k$, there exists a directed path in $H - S$ from z to v.

Because $\kappa_G(z, v) \geq k$, G contains k internally vertex-disjoint directed paths $P_1, \ldots,$ P_k from z to v. Because $\kappa_H(z, v) < k$, the edge e must be in one of the P_i's. Without loss of generality, assume that e is in P_k. Let L be the subpath of P_k from u to v. Note that L is a directed path in H. Also, note that because the P_i's are internally vertex-disjoint, $P_1, \ldots, P_{k-1}$ cannot contain e and therefore remain directed paths in H.

There are two cases based on whether L and S intersect.

Case 1. $L \cap S \neq \emptyset$. Note that $|S - L| \leq k - 2$. Because $P_1, \ldots, P_{k-1}$ are internally vertex-disjoint in H, at least one of those P_i's does not contain any vertices from S, and remains a directed path from z to v in $H - S$. This is a desired contradiction and thus completes the proof of Case 1.

Case 2. $L \cap S = \emptyset$. Note that L is directed path in $H - S$ from u to v. Because $\kappa_H(z, u) \geq k$, H contains k internally vertex-disjoint directed paths $Q_1, \ldots, Q_k$ from z to u. Because $Q_1, \ldots, Q_k$ are internally vertex-disjoint and $|S| \leq k - 1$, at least one Q_j does not contain any vertices from S. Then Q_j remains a directed path from z to u in $H - S$. Therefore, the directed path formed by Q_j and L is a directed path from z to v in $H - S$. This is a desired contradiction and thus finishes the proof of Case 2. □

The next lemma uses Lemma 4.2 to compute an important subset of a desired certificate for a directed graph. In the lemma, let $G = (V, E)$ be a directed graph with n vertices and m edges. Let z be a vertex in G.

LEMMA 4.3. *Assume that $\kappa_G(z, v) \geq k$ for all $v \in V - \{z\}$. Then there exists a subgraph $H = (V, E')$ computable in $O(k \cdot m \cdot n)$ time with the following properties*:

1. *For all $v \in V - \{z\}$, $\kappa_H(z, v) = k$*;
2. *The indegree of z in H is zero*; *and*
3. *For all $v \in V - \{z\}$, the indegree of v in H is exactly k.*

Note that because of the indegree constraints, H is a minimum-size subgraph with $\kappa_H(z, v) = k$ for all $v \in V - \{z\}$.

Proof. H can be computed by the algorithm FIND-H given in Fig. 7. Note that deleting the incoming edges of z does not affect $\kappa(z, v)$. Then, the correctness of FIND-H follows directly from repeated applications of Lemma 4.2. As for the time complexity, each iteration of the do loop takes $O(k \cdot m)$ time [14]. So the total runing time is $O(k \cdot m \cdot n)$. □

```
Subroutine FIND-H
Input: a digraph $G = (V, E)$ and a vertex $z \in V$ with $\kappa_G(z, v) \geq k$ for all $v \in V - \{z\}$.
Output: a minimum-size subgraph $H = (V, E')$ with $\kappa_H(z, v) = k$ for all $v \in V - \{z\}$.
begin
    Let $E'$ be obtained from $E$ by removing all incoming edges of $z$;
    Let $v_1, v_2, \ldots, v_{n-1}$ be the vertices in $V - \{z\}$;
    for $i = 1$ to $n - 1$ do
        begin
            Find $k$ internally vertex-disjoint directed paths from $z$ to $v_i$ in the sub-
            graph $(V, E')$;
            Delete from $E'$ all incoming edges of $v_i$ except the $k$ incoming edges in
            the $k$ paths just found above;
        end
end.
```

FIG. 7. *Computing a subgraph H of Lemma* 4.3.

Our directed graph certificate combines the subroutine FIND-H and the classic k-vertex connectivity algorithm of Even [14]. The certificate algorithm computes a certificate F for the input graph G in five steps as follows.

1. Test the k-vertex connectivity of G. If G is not k-vertex connected, then let $F = \emptyset$ and stop; otherwise, continue the computation.

2. Pick k arbitrary vertices $x_1, \ldots, x_k \in V$. For all x_i and x_j with $i < j$, compute k internally vertex-disjoint directed paths in G from x_i to x_j and k internally vertex-disjoint directed paths from x_j to x_i. Let E_0 denote the set of the edges in all those paths.

3. Let G^+ be the graph constructed by adding to G a new vertex z and $2k$ new edges $(z, x_1), \ldots, (z, x_k)$ and $(x_1, z), \ldots, (x_k, z)$.

4. Use FIND-H to find a subgraph $H_1 = (V \cup \{z\}, E_1)$ for G^+ and z. Symmetrically, find a subgraph $H_2 = (V \cup \{z\}, E_2)$ for G^+ and z with respect to the *reverse* edge and path directions.

5. Let the final certificate F be $E_0 \cup E_1 \cup E_2$ without the edges incident with z.

The next two lemmas show the correctness of the above certificate algorithm.

LEMMA 4.4. *If G is k-vertex connected, then the subgraph (V, F) computed above is k-vertex connected.*

Proof. Let $C = (V, F)$. Let $C^+ = (V \cup \{z\}, E_0 \cup E_1 \cup E_2)$. Note that C^+ is the graph constructed by adding to C the vertex z and the $2k$ edges $(z, x_1), \ldots, (z, x_k)$ and $(x_1, z), \ldots, (x_k, z)$. Next, because $E_1 \cup E_2$ is included in C^+, by Lemma 4.3, $\kappa_{C^+}(z, v) \geq k$ and $\kappa_{C^+}(v, z) \geq k$ for all $v \in V$. Because E_0 is included in C, for all x_i and x_j with $i < j$, $\kappa_C(x_i, x_j) \geq k$ and $\kappa_C(x_j, x_i) \geq k$. Therefore, by the classic argument of Even for his k-vertex connectivity algorithm, (V, F) is indeed k-vertex connected. □

LEMMA 4.5. $|F| \leq 2k^2 n$.

Proof. If G is not k-vertex connected, then $|F| = 0$. Otherwise, the upper bound of $|F|$ follows from the facts that $|E_1| = |E_2| = kn$ and $|E_0| \leq k(k-1)(n-2+k)$. □

The next lemma finishes the proof of Theorem 4.1.

LEMMA 4.6. *The above certificate algorithm runs in $O(km \max\{n, k\sqrt{n}\})$ time.*

Proof. Testing k-vertex connectivity takes $O(km \max\{n, k\sqrt{n}\})$ time [14]. Computing E_0 takes $O(k^2 m \min\{k, \sqrt{n}\})$ time. By Lemma 4.3, computing E_1 and E_2 takes $O(kmn)$ time. These three steps dominate the time complexity. Therefore, the total running time is $O(km \max\{n, k\sqrt{n}\})$. □

5. Conclusions and open problems.

Designing graph search procedures that are efficient in several major models of computation is an important issue in algorithmic graph theory. We have shown that scan-first search can be performed extremely efficiently in the parallel, the distributed, and the sequential models. Based on this unusual efficiency, it is worth further research to find other applications for scan-first search.

We conclude with two open problems concerning graph connectivity. The first is whether the k-vertex connectivity of an n-vertex *directed* graph can be tested in $k^{O(1)}n^2$ sequential time. The second is whether a sparse certificate for the k-vertex connectivity of an n-vertex undirected graph can be found *deterministically* in time polylogarithmic *both* in k and n, using a number of processors polynomial both in k and n.

Acknowledgments. The authors wish to thank Martin Farach, Hillel Gazit, Samir Khuller, Sandeep Sen, and Éva Tardos for helpful discussions.

DECOMPOSING FINITE-VALUED TRANSDUCERS AND DECIDING THEIR EQUIVALENCE*

ANDREAS WEBER†

Abstract. In this paper finite-valued finite transducers are investigated in connection with their inner structure. The following results are shown: A finite-valued nondeterministic generalized sequential machine (NGSM) M can be effectively decomposed into finitely many single-valued NGSMs $M_1, \dots, M_N$ such that the transduction realized by M is the union of the transductions realized by $M_1, \dots, M_N$. Using this decomposition, the equivalence of finite-valued NGSMs is decidable in deterministic double exponential time. By reduction, both results can be generalized to normalized finite transducers.

Key words. finite transducer, valuedness, finite valued, equivalence problem

AMS(MOS) subject classification. 68Q75

Introduction. A finite transducer M is a finite automaton with output. Informally, M may be regarded as a finite directed labeled graph. The vertices and edges of that graph represent the states and transitions of M, respectively. The label of an edge is the pair of input/output words consumed/produced by the corresponding transition of M. As usual, these input words are required to have length 0 or 1. The resulting nondeterministic model for M is the normalized finite transducer (NFT) — or the nondeterministic generalized sequential machine (NGSM) if only length 1 appears. The successful computations in M are represented by those paths (called accepting) in the above graph that lead from an initial to a final state (i.e., vertex). Along the edges of such a path an input word x is "transduced" into an ouput word, which is called a value for x in M. The valuedness of M is the maximal number of different values for an input word, or is infinite, depending on whether or not a maximum exists. In the former case, M is called finite valued. M is called single valued if its valuedness is at most 1. Two finite transducers are called equivalent if the transductions (or relations) realized by them coincide, i.e., if every input word has the same set of values in both transducers.

The valuedness is a structural parameter of the transduction realized by a finite transducer that received attention in connection with the equivalence problem. This problem is undecidable for NGSMs (see [G68], [I78], [L79b], and [L83]) but decidable for finite-valued NFTs [CK86]. The equivalence problem for single-valued NFTs is PSPACE-complete (see [Sch76], [BH77], [AL78], [GI83], and [HW91]). It is decidable in polynomial time whether or not an NFT is finite valued (see [W87], [W90]). Given any fixed integer d, it can be tested in polynomial time whether or not the valuedness of an NFT is greater than d [GI83]. For further background on finite transducers we refer to Berstel's textbook [B79] and to excellent survey papers by Karhumäki (see [K86], [K87]), and Culik [C90].

The basic result of this paper is the following decomposition theorem (see §2).

(1) A finite-valued NGSM M can be effectively decomposed into finitely many single-valued NGSMs $M_1, \dots, M_N$ such that the transduction realized by M is the union of the transductions realized by $M_1, \dots, M_N$.

*Received by the editors April 2, 1990; accepted for publication (in revised form) August 22, 1991. A preliminary version of this paper appeared under the title "A decomposition theorem for finite-valued transducers and an application to the equivalence problem" in the Proceedings of MFCS 1988. A full revision was done while the author was supported by a Postdoctoral Fellowship of the Japan Society for the Promotion of Science.

†Fachbereich Informatik, Johann Wolfgang Goethe-Universität, Postfach 111 932, W-6000 Frankfurt am Main 11, Germany.

In this theorem, N is of exponential order, which is optimal in certain cases. Each M_i has double exponential size and can be constructed in double exponential time. Intuitively, the theorem (1) states that a "difficult" (i.e., finite-valued) NGSM M is equivalent to some effectively constructible "disjoint union" of "easy" (i.e., single-valued) NGSMs $M_1, \ldots, M_N$. We want to point out that the main problem for the machines $M_1, \ldots, M_N$ is that the model of a "disjoint union" does not allow any communication among them. Given an input word x, each M_i has to decide autonomously which of the values for x in M it should produce as its own value. The theorem (1) directly implies two fundamental results of [W87] and [W90]; that is, an upper bound for the valuedness of a finite-valued NGSM and a characterization of the infinite valuedness of an NGSM, which can be tested in polynomial time (see §2).

In §3 we present a combinatorial word lemma. This lemma allows to use the above decomposition theorem in order to decide the equivalence of finite-valued NGSMs. Our results are as follows.

(2) The noninclusion of transductions realized by finite-valued NGSMs (and, hence, the nonequivalence of finite-valued NGSMs) can be detected by a witness of double exponential length.

(3) The inclusion of transductions realized by finite-valued NGSMs (and, hence, the equivalence of finite-valued NGSMs) is decidable in deterministic double exponential time.

Note that (2) alone implies a deterministic triple exponential time algorithm for (3). The witness length in (2) is necessarily of exponential order [N79] and the decision problems in (3) are PSPACE-hard [GJ79], even if the NGSMs in question are single valued and have only one output symbol. It is an open problem regarding whether or not the upper bounds for the witness length in (2) and for the time complexity in (3) can be improved to bounds of exponential order (see §3).

By reduction, the results (1)–(3) can be generalized to NFTs (see §4).

A noneffective version of (1) was stated in [Sch76] without complete proof. The methods used here differ from those in [Sch76]. Another attempt to establish a proof of (1) and a (nonefficient) decision procedure for (3) failed because of a fatal proof error (see [AL78], [L79a]). Our algorithm underlying (3) is quite different from the procedure by Culik and Karhumäki [CK86] deciding the equivalence of finite-valued NFTs. The latter procedure uses an algorithm by Makanin as a "subroutine"; it is proved to be recursive by employing a generalization of the (recently confirmed) Ehrenfeucht Conjecture. As far as I know, a time analysis for this procedure does not exist.

The above-mentioned word lemma generalizes a lemma by Schützenberger [Sch76] and may be of own interest. From similar work by Lisovik (see [L79a], [L80]) it can be obtained that the theorem (1) and Schützenberger's lemma imply (2). In order to derive (2) and (3) from (1) the above-mentioned word lemma can be replaced by a "machine-oriented" approach due to Gurari and Ibarra [GI81] or by an "algebraic" approach due to Turakainen (see [T88], [T89], and §3).

Our proof of (1) is based on a classification of accepting paths. To each accepting path in an NGSM M we attach a set of specifications. Given any such specification (altogether there are exponentially many), we effectively construct an NGSM realizing nothing but all pairs of words which appear as input/output along those accepting paths in M, that have the given specification. If M is finite valued, then the thus constructed NGSMs turn out to be single valued, and the union of the transductions realized by them coincides with the transduction realized by M. In order to prove this, we work on the basis of methods and technical lemmas presented in [W87] and [W90].

In a finite transducer, instead of counting different values it is quite natural to consider only their lengths. This leads from the valuedness to another parameter called length-degree [W92a]. Indeed, variants of (1)–(3) hold true when the valuedness of an NGSM is replaced by its length-degree [W92a]. In particular, the equivalence of NFTs with finite length-degree is recursively decidable. Another result similar to (1) is published in [W92b].

The work presented in this paper and a part of its sequel as described above was recently generalized by Seidl to bottom-up finite state tree transducers [S90].

1. Definitions and notations.

1.1. General notations. We use the following notations: $\mathcal{N}$, $\mathcal{Z}$, and $\mathcal{Q}$ denote the sets of all nonnegative integers, integers, and rationals, respectively. $\mathbb{N}$ and $[m]$ denote the sets $\mathcal{N}\backslash\{0\}$ and $\{1,\dots,m\}$, respectively, $[i,j]$ denotes the set $\{t \in \mathcal{Z} \mid i \le t \le j\}$ ($m \in \mathcal{N}, i,j \in \mathcal{Z}$). Let Δ be some nonempty, finite set. $\Delta^{\le l}$ denotes the set of all words in Δ^* having length at most l ($l \in \mathcal{N}$). Let $z \in \Delta^*$ and $j \in [|z|]$, then $z(j) \in \Delta$ denotes the jth letter of z. Let $z_1, z_2 \in \Delta^*$ and $j \in [\min\{|z_1|, |z_2|\}]$. We say that z_1 and z_2 *differ at position* j if $z_1(j)$ and $z_2(j)$ are distinct. Without further mention we assume that the model of computation for all our algorithms is the deterministic random access machine (RAM) without multiplications and divisions using the uniform cost criterion (see, e.g., [AHU74]).

1.2. Finite transducers. Our model of a finite transducer is the *normalized finite transducer* (NFT). Formally, an NFT is a 6-tuple $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ where Q, Σ, and Δ denote nonempty, finite sets of states, input symbols, and output symbols, respectively, $Q_I, Q_F \subseteq Q$ denote sets of initial and final (or accepting) states, respectively, and δ is a finite subset of $Q \times (\Sigma \cup \{\varepsilon\}) \times \Delta^* \times Q$. Σ (Δ) is called the input (output) alphabet, δ is called the transition relation. Each element of δ denotes a *transition*. Of course, M is *nondeterministic*. M is called a *nondeterministic generalized sequential machine* (NGSM) if δ is a finite subset of $Q \times \Sigma \times \Delta^* \times Q$. In this paper we mainly deal with NGSMs.

The mode of operation of M is described by paths. A *path* π (of length m) is a word

$$(q_1, x_1, z_1) \dots (q_m, x_m, z_m) q_{m+1} \in (Q \times (\Sigma \cup \{\varepsilon\}) \times \Delta^*)^m \cdot Q$$

so that $(q_1, x_1, z_1, q_2), \dots, (q_m, x_m, z_m, q_{m+1})$ are transitions. π is said to lead from q_1 to q_{m+1}, to consume $x := x_1 \dots x_m \in \Sigma^*$, to produce $z := z_1 \dots z_m \in \Delta^*$, and to realize $(x, z) \in \Sigma^* \times \Delta^*$. π is called *accepting* if $q_1 \in Q_I$ and $q_{m+1} \in Q_F$. Whenever convenient we identify a transition (p, a, z, q) with the path $(p, a, z)q$ of length 1 and vice versa. We define $\hat{\delta} := \{(p, x, z, q) \in Q \times \Sigma^* \times \Delta^* \times Q \mid (x, z)$ is realized by some path in M leading from p to $q\}$. If M is an NGSM, then δ equals $\hat{\delta} \cap Q \times \Sigma \times \Delta^* \times Q$. In this case we rename $\hat{\delta}$ by δ. Let $\pi_1 = \pi_1' q_1$ and $\pi_2 = \pi_2' q_2$ be paths in M leading from p_1 to q_1 and from p_2 to q_2, respectively. If q_1 and p_2 coincide, then we define the path $\pi_1 \circ \pi_2 := \pi_1' \pi_2' q_2$. Note that the operation "$\circ$" on paths is associative.

The *transduction* (or *relation*) *realized* by M, denoted by $T(M)$, is the set of pairs (in $\Sigma^* \times \Delta^*$) realized by all accepting paths in M. The *language recognized* by M, denoted by $L(M)$, is the domain of $T(M)$, i.e., the set of words (in Σ^*) consumed by all accepting paths in M. Two NFTs are *equivalent* if the transductions realized by them coincide.

If $(x, z) \in \Sigma^* \times \Delta^*$ belongs to $T(M)$, then z is called a *value* for x in M. The *valuedness* of $x \in \Sigma^*$ in M (short form: $\mathrm{val}_M(x)$) is the number of all different values for x in M. The *valuedness* of M (short form: $\mathrm{val}(M)$) is the supremum of the set $\{\mathrm{val}_M(x) \mid x \in \Sigma^*\}$. Note that, for a given $x \in \Sigma^*$, $\mathrm{val}_M(x)$ may be infinite (see §4), whereas it is clearly finite if M is an NGSM. M is called *infinite valued* (*finite valued*, *single valued*) if its valuedness is infinite (finite, at most 1, respectively).

A state of M is called *useful* if it appears on some accepting path; otherwise, this state is called *useless*. Useless states are irrelevant to the valuedness in M. If all states of M are useful, then M is called *trim*. A state p of M is said to be *connected* with a state q of M (short form: $p \overset{M}{\longleftrightarrow} q$) if some paths lead from p to q and from q to p. An equivalence class with respect to the relation "$\overset{M}{\longleftrightarrow}$" is called a *strong component* of M.

Let $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ be another NFT. We define some local structural parameters of M and M_0: $\text{val}(\delta)$ is defined as the minimal $k_1 \geq 1$ such that, for all $(p, a, q) \in Q \times (\Sigma \cup \{\varepsilon\}) \times Q$, $\#\{z \in \Delta^* \mid (p, a, z, q) \in \delta\}$ is at most k_1. $\text{diff}(\delta, \delta_0)$ is defined as the minimal $k_2 \geq 0$ such that, for all pairs $((p, a, z, q), (\tilde{p}, a, \tilde{z}, \tilde{q}))$ of transitions in M and M_0 consuming the same $a \in \Sigma \cup \{\varepsilon\}$, $||z| - |\tilde{z}||$ is at most k_2. We set $\text{diff}(\delta) := \text{diff}(\delta, \delta)$. $\text{im}(\delta)$ is the set of ε and of all words $z \in \Delta^*$ produced by any transition of M. We set $\text{iml}(\delta) := \max\{|z| \mid z \in \text{im}(\delta)\}$.[1]

The *size* of δ, denoted by $\|\delta\|$, is defined as 1 plus the sum of $1 + |z|$ over all transitions (p, a, z, q) of M. The *size* of M, denoted by $\|M\|$, is defined as the sum of $\#Q$, $\#\Sigma$, $\#\Delta$, and $\|\delta\|$.

Note. $\text{val}(\delta) \leq \#\text{im}(\delta) \leq \min\{\|\delta\|, \#(\Delta^{\leq \text{iml}(\delta)})\}$, $\text{diff}(\delta, \delta_0) \leq \max\{\text{iml}(\delta), \text{iml}(\delta_0)\}$, and $\text{diff}(\delta) \leq \text{iml}(\delta) \leq \|\delta\| - 1$.

In the rest of this subsection we assume that $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ is an NGSM.

Let $x = x_1 \dots x_m \in \Sigma^*$ $(x_1, \dots, x_m \in \Sigma)$. The *graph of accepting paths* in M consuming x (short form: $G_M(x)$) is the directed graph (V, E) where

$$\begin{aligned} V &:= \{(q, j) \in Q \times \{0, \dots, m\} \mid \exists q_I \in Q_I \, \exists q_F \in Q_F \, \exists z_1, z_2 \in \Delta^* : \\ &\qquad (q_I, x_1 \dots x_j, z_1, q) \in \delta \;\;\&\;\; (q, x_{j+1} \dots x_m, z_2, q_F) \in \delta\}, \quad \text{and} \\ E &:= \{((p, j-1), (q, j)) \in V^2 \mid j \in [m] \;\;\&\;\; \exists z \in \Delta^* : (p, x_j, z, q) \in \delta\}. \end{aligned}$$

Note that the set of all paths in $G_M(x)$ leading from $Q_I \times \{0\}$ to $Q_F \times \{m\}$ corresponds to the set of all accepting paths in M consuming x projected to their Q- and Σ-components. Each vertex of $G_M(x)$ is situated on such a path.

Let $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ be another NGSM. Let $x = x_1 \dots x_m \in \Sigma^*$ $(x_1, \dots, x_m \in \Sigma)$. Let

$$\pi = (q_1, x_1, z_1) \dots (q_m, x_m, z_m) q_{m+1} \quad \text{and} \quad \tilde{\pi} = (\tilde{q}_1, x_1, \tilde{z}_1) \dots (\tilde{q}_m, x_m, \tilde{z}_m) \tilde{q}_{m+1}$$

be paths in M and M_0, respectively, both consuming x. We define

$$\text{diff}\,(\pi, \tilde{\pi}) := \max\{||z_1 \dots z_l| - |\tilde{z}_1 \dots \tilde{z}_l|| \mid 0 \leq l \leq m\}.$$

Note that $\text{diff}\,(\pi, \tilde{\pi})$ is at most $m \cdot \text{diff}(\delta, \delta_0)$.

1.3. Criteria for finite transducers. Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be an NFT. The following criteria (IV1) and (IV2) were introduced in [W87] and [W90][2] in order to characterize the infinite valuedness of M.

(IV1) There are useful states $p, q_1, q_2, q_3, q \in Q$ such that, for some words $u, v, w \in \Sigma^*$ and $\tilde{u}_1, \tilde{u}_2, \tilde{u}_3, \tilde{v}_1, \tilde{v}_2, \tilde{v}_3, \tilde{w}_1, \tilde{w}_2, \tilde{w}_3 \in \Delta^*$, the following holds: $\tilde{v}_1$ and $\tilde{v}_2$ have distinct lengths, $(p, u, \tilde{u}_1, q_1), (q_1, v, \tilde{v}_1, q_1), (q_1, w, \tilde{w}_1, p) \in \hat{\delta}$, $(p, u, \tilde{u}_2, q_2)$, $(q_2, v, \tilde{v}_2, q_2), (q_2, w, \tilde{w}_2, q) \in \hat{\delta}$, and $(q, u, \tilde{u}_3, q_3), (q_3, v, \tilde{v}_3, q_3), (q_3, w, \tilde{w}_3, q) \in \hat{\delta}$.

[1] $\text{iml}(\delta)$ is denoted by $\text{length}(\delta)$ in [W87] and [W90].

[2] Note that (IV1) appears as (IV3) in [W87] and as (IV1) in [W90], whereas (IV2) slightly differs from (IV2) in [W87], appears as (IV2)′ in [W90], and is equivalent to (IV2) there [W90, Lem. 2.3(i)].

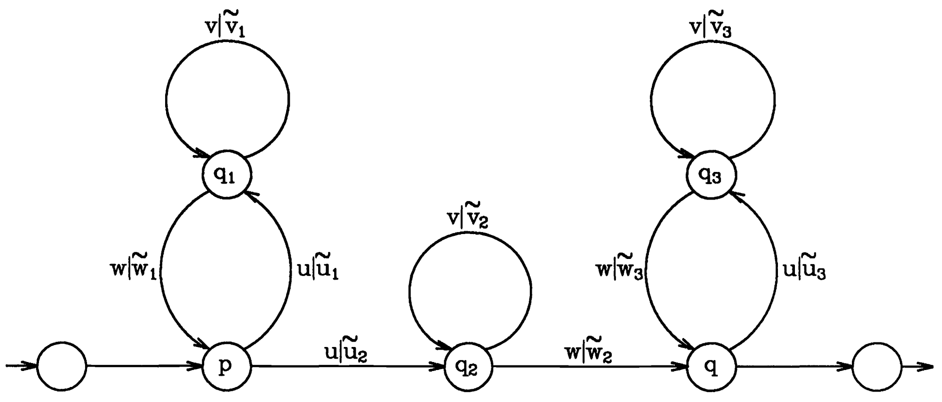

FIG. 1

(IV2) There are useful states $p, q \in Q$ such that, for some words $v \in \Sigma^*$, $\tilde{v}_1 \in \Delta^+$ and $\tilde{v}_2, \tilde{v}_3, \tilde{v}_4 \in \Delta^*$, $\tilde{v}_2$ and $\tilde{v}_3$ differ at some position $j \in [\min\{|\tilde{v}_2|, |\tilde{v}_3|\}]$, and $(p, v, \tilde{v}_1, p), (p, v, \tilde{v}_2, q), (p, v, \tilde{v}_3, q), (q, v, \tilde{v}_4, q) \in \hat{\delta}$.

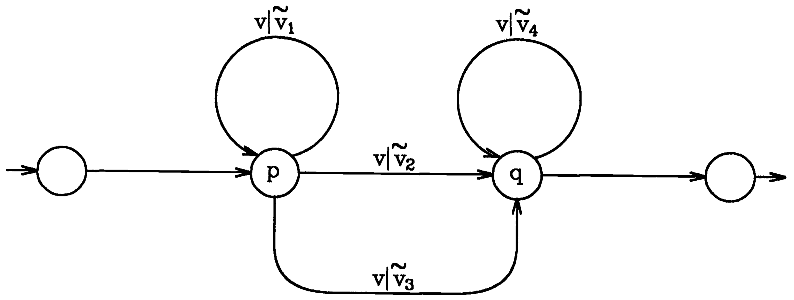

FIG. 2

1.4. Finite automata. Our model of a finite automaton is the *nondeterministic finite automaton with ε-moves* (ε-NFA). Formally, an ε-NFA is a 5-tuple $M = (Q, \Sigma, \delta, Q_I, Q_F)$ whose components Q, Σ, δ, Q_I, and Q_F have the same meaning as for an NFT $(Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ except that δ is a subset of $Q \times (\Sigma \cup \{\varepsilon\}) \times Q$. Each element of δ denotes a *transition*. M is called a *nondeterministic finite automaton* (NFA) if δ is a subset of $Q \times \Sigma \times Q$. M is called a *deterministic finite automaton* (DFA) if it is an NFA such that $\#Q_I = 1$ and $(p, a, q_1), (p, a, q_2) \in \delta$ implies $q_1 = q_2$.

A *path* π (of length m) in M is a word $(q_1, x_1) \dots (q_m, x_m) q_{m+1} \in (Q \times (\Sigma \cup \{\varepsilon\}))^m \cdot Q$ so that $(q_1, x_1, q_2), \dots, (q_m, x_m, q_{m+1})$ are transitions. π is said to lead from q_1 to q_{m+1} and to consume $x := x_1 \dots x_m \in \Sigma^*$. π is called *accepting* if $q_1 \in Q_I$ and $q_{m+1} \in Q_F$. We define $\hat{\delta} := \{(p, x, q) \in Q \times \Sigma^* \times Q \mid x$ is consumed by some path in M leading from p to $q\}$. If M is an NFA, then δ equals $\hat{\delta} \cap Q \times \Sigma \times Q$. In this case we rename $\hat{\delta}$ by δ. Let $\pi_1 = \pi_1' q_1$ and $\pi_2 = \pi_2' q_2$ be paths in M leading from p_1 to q_1 and from p_2 to q_2, respectively. If q_1 and p_2 coincide, then we define the path $\pi_1 \circ \pi_2 := \pi_1'\pi_2'q_2$. Note that the operation "$\circ$" on paths is associative.

The *language recognized* by M, denoted by $L(M)$, is the set of words consumed by all accepting paths in M. Two ε-NFAs are *equivalent* if the languages recognized by them coincide.

The *size* of M, denoted by $\|M\|$, is defined as the sum of $\#Q$, $\#\Sigma$, and $1 + \#\delta$.

2. Decomposing finite-valued NGSMs. In this section we prove the following decomposition theorem.

THEOREM 2.1. *Let M be an* NGSM, *which does not comply with any of the criteria* (IV1), (IV2). *Then, $O(2^{\mathrm{poly}\|M\|})$ many single-valued* NGSMs *$M_1, \ldots, M_N$ — each of size $O(2^{2^{\mathrm{lin}\|M\|}})$ — effectively exist such that $T(M)$ equals $T(M_1) \cup \ldots \cup T(M_N)$. In detail, let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ and $n := \#Q$, then N is at most*

$$\begin{cases} (5^{1/2} \cdot 3^{2/3})^n \cdot n^{4\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+3)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{diff}(\delta)} & \text{if } \#\Delta > 1, \\ (5^{1/2} \cdot 3^{4/3})^n \cdot n^{6\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+2)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1, \end{cases}$$

and each M_i ($i \in [N]$) has at most $2^{n\cdot(2^{n+1}+12)} \cdot (1 + \mathrm{diff}(\delta)) \cdot (2 + \mathrm{iml}(\delta))$ states and size at most $2^{n\cdot(2^{n+2}+24)} \cdot \|M\|^5$.

Using a variant of the construction for Theorem 2.1 we obtain the following theorem.

THEOREM 2.2. *Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$, n, N and $M_1, \ldots, M_N$ be as in Theorem 2.1. Then,* NFAs *$M_1', \ldots, M_N'$ — each of size $O(2^{2^{\mathrm{lin}\|M\|}})$ — effectively exist such that, for all $i \in [N]$, M_i' recognizes $\Sigma^* \backslash L(M_i)$. In detail, each M_i' ($i \in [N]$) has at most $2^{n\cdot(2^{n+1}+8)} \cdot 2^{2n^8\cdot(1+\mathrm{diff}(\delta))\cdot(2+\mathrm{iml}(\delta))}$ states (and more states than M_i) and size at most $2^{n\cdot(2^{n+2}+17)} \cdot 2^{5n^8\cdot\|M\|^2}$.*

A time analysis of the constructions for the Theorems 2.1 and 2.2 yields:

THEOREM 2.3. *Let M be an* NGSM *as in the Theorems* 2.1 *and* 2.2. *The* NGSMs *$M_1, \ldots, M_N$ and the* NFAs *$M_1', \ldots, M_N'$ of these theorems can be constructed in* DTIME $(2^{2^{\mathrm{lin}\|M\|}})$.

According to Lemma A.1 in the Appendix, the Theorems 2.1–2.3 apply to finite-valued NGSMs as well. Intuitively, Theorem 2.1 therefore states that a finite-valued NGSM M can be effectively decomposed into finitely many single-valued NGSMs. By reduction, Theorem 2.1 can be generalized to NFTs (Theorem 4.1).

Let M be an NGSM as in the Theorems 2.1–2.3. It turns out that the quite large and a little complicated NGSMs $M_1, \ldots, M_N$ and NFAs $M_1', \ldots, M_N'$ constructed for M in these theorems, while consuming the same word, need the greater part of their capability in order to carry out exactly the same "basic work." Intuitively spoken these machines are doing so because the model of a "disjoint union" of finite transducers does not allow any communication among them. The author believes that this missing communication is the main reason why $M_1, \ldots, M_N$ and $M_1', \ldots, M_N'$ are so large and complicated.

In §3 we use the Theorems 2.1–2.3 in order to decide the equivalence of finite-valued NGSMs. Here, using Lemma A.1, we state the following immediate corollaries of Theorem 2.1.

COROLLARY 2.4. *Let M be an* NGSM. *M is finite valued if and only if finitely many single-valued* NGSMs *$M_1, \ldots, M_N$ effectively exist such that $T(M)$ equals $T(M_1) \cup \ldots \cup T(M_N)$.*

COROLLARY 2.5 (see [W90, Thm. 2.1]). *Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be a finite-valued* NGSM *with n states. Then, the valuedness of M is not greater than the upper bound for N stated in Theorem* 2.1.

COROLLARY 2.6 [W90, Thm. 2.2]. *Let M be an* NGSM. *M is infinite-valued if and only if it complies with at least one of the criteria* (IV1), (IV2).

Note that, unless $n = 1$, the upper bound for the valuedness of a finite-valued NGSM stated in [W90, Thm. 2.1] is smaller than the upper bound in Corollary 2.5 and the upper bound for N in Theorem 2.1. The Theorems 4.1 and 4.2 of [W90] imply that each improvement of any of these bounds has to stop above $\#\Delta^{n^3 \cdot \mathrm{diff}(\delta)/343}$ if $\#\Delta > 1$ and at 2^{n-1} if $\#\Delta = 1$. Thus, if $\#\Delta > 1$ and $\mathrm{diff}(\delta) > 0$, all these bounds are asymptotically optimal apart from a constant factor in the exponent.

It is decidable in polynomial time whether or not an NGSM complies with (IV1) or (IV2) (see [W90, §3]). Therefore, Corollary 2.6 implies: It is decidable in polynomial time whether or not an NGSM is infinite valued [W90, Thm. 3.1].

In the rest of this section we prove the Theorems 2.1–2.3, successively.

Proof of Theorem 2.1. Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be an NGSM with n states, which does not comply with any of the criteria (IV1), (IV2). We may assume that M is trim. The set of accepting paths in M is denoted by Π. Let $Q_1, \ldots, Q_k$ be an order of the strong components of M so that for all $i, j \in [k]$ the following holds.

$$\delta \cap Q_i \times \Sigma^* \times \Delta^* \times Q_j \neq \emptyset \quad \Longrightarrow \quad i \leq j.$$

Let $n_i := \#Q_i$ $(i = 1, \ldots, k)$.

Our proof of Theorem 2.1 consists of the following steps.

(1) We define a set S of potential path specifications having cardinality at most

$$\begin{cases} 5^{n/2} \cdot 3^{2n/3} \cdot 2^{(n+3)\cdot(n-1)} \cdot n^{4\cdot(n-1)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{diff}(\delta)} & \text{if } \#\Delta > 1, \\ 5^{n/2} \cdot 3^{4n/3} \cdot 2^{(n+2)\cdot(n-1)} \cdot n^{6\cdot(n-1)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1. \end{cases}$$

(2) We define a mapping $\varphi : \Pi \longrightarrow 2^S \backslash \{\emptyset\}$, such that every $\sigma \in \varphi(\pi)$ acts as a specification of the path $\pi \in \Pi$, and the following holds: If $\pi, \pi' \in \Pi$ realize $(x, z), (x, z') \in \Sigma^* \times \Delta^*$, respectively, and if $\varphi(\pi) \cap \varphi(\pi')$ is nonempty, then z and z' coincide.

(3) For all $\sigma \in S$ we effectively construct an NGSM $\bar{M}_\sigma$ realizing the transduction $\{(x, z) \in \Sigma^* \times \Delta^* \mid (x, z) \text{ is realized by some } \pi \in \Pi \text{ so that } \sigma \in \varphi(\pi)\}$. Each $\bar{M}_\sigma$ $(\sigma \in S)$ has at most $2^{n\cdot(2^{n+1}+12)} \cdot (1 + \mathrm{diff}(\delta)) \cdot (2 + \mathrm{iml}(\delta))$ states and size at most $2^{n\cdot(2^{n+2}+24)} \cdot \|M\|^5$.

From (1)–(3) it follows that $T(M)$ equals $\bigcup_{\sigma \in S} T(\bar{M}_\sigma)$, and that each $\bar{M}_\sigma$ $(\sigma \in S)$ is single valued. Therefore, the steps (1)–(3) prove the theorem. Note that $N = \#S$ and the NGSMs $\bar{M}_\sigma$ $(\sigma \in S)$ are playing the role of $M_1, \ldots, M_N$.

In order to carry out step (1) we need the following proposition.

PROPOSITION 2.7. *Let $n = \sum_{i=1}^k n_i$, where $n_1, \ldots, n_k \in \mathcal{N}$. Then, $\prod_{i=1}^k n_i \leq 3^{n/3}$ and $\prod_{i=1}^k (n_i^2 + 1) \leq 5^{n/2}$.*

Proof. It is easy to show by induction on j that, for each $j \in \mathcal{N}$, $j^3 \leq 3^j$ and $(j^2+1)^2 \leq 5^j$. In turn, this implies: $\prod_{i=1}^k n_i \leq \prod_{i=1}^k 3^{n_i/3} = 3^{n/3}$ & $\prod_{i=1}^k (n_i^2+1) \leq \prod_{i=1}^k 5^{n_i/2} = 5^{n/2}$. $\square$

Execution of step (1). We define a set S of potential path specifications:

$$S := \bigcup_{l\geq 0} \bigcup_{1\leq i_0<\ldots<i_l\leq k} \bigcup_{0<j_1<\ldots<j_l<2^{n+1}} (Q_I \cap Q_{i_0}) \times$$
$$\prod_{\lambda=1}^{l} [\{j_\lambda\} \times Q_{i_{\lambda-1}} \times (\mathrm{im}(\delta) \cup \{z \in \Delta^* \mid |z| \leq (n^2 \cdot \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i - 1) \cdot \mathrm{diff}(\delta)\} \cup$$
$$\{(t,\tilde{p},\tilde{q}) \in \mathcal{Z} \times Q^2 \mid |t| \leq (n^2 \cdot \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i - 1) \cdot \mathrm{diff}(\delta) \ \ \& \ \ \tilde{p} \overset{\mathrm{M}}{\longleftrightarrow} \tilde{q}\}) \times Q_{i_\lambda}]$$
$$\times (Q_F \cap Q_{i_l}).$$

Using Proposition 2.7, we can prove the announced upper bound for the cardinality of S as follows.

$$\begin{aligned}
\#S &= \sum_{l\geq 0} \sum_{1\leq i_0<\ldots<i_l\leq k} \sum_{0<j_1<\ldots<j_l<2^{n+1}} \\
&\quad \#(Q_I \cap Q_{i_0}) \cdot \prod_{\lambda=1}^{l} [n_{i_{\lambda-1}} \cdot (\#(\mathrm{im}(\delta) \cup \Delta^{\leq(n^2\cdot\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i-1)\cdot\mathrm{diff}(\delta)}) \\
&\quad +(2 \cdot (n^2 \cdot \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i - 1) \cdot \mathrm{diff}(\delta) + 1) \cdot \sum_{i=1}^{k} n_i^2) \cdot n_{i_\lambda}] \cdot \#(Q_F \cap Q_{i_l}) \\
&\leq \sum_{l\geq 0} \sum_{1\leq i_0<\ldots<i_l\leq k} \sum_{0<j_1<\ldots<j_l<2^{n+1}} (\prod_{\lambda=0}^{l} n_{i_\lambda}^2) \cdot \\
&\quad \prod_{\lambda=1}^{l} [\#\mathrm{im}(\delta) \cdot \#\Delta^{\leq(n^2\cdot\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i-1)\cdot\mathrm{diff}(\delta)} \cdot 2n^4 \cdot (\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i) \cdot (1+\mathrm{diff}(\delta))] \\
&\leq \sum_{l\geq 0} \sum_{1\leq i_0<\ldots<i_l\leq k} \\
&\quad [2^{(n+1)\cdot l} \cdot (\prod_{\lambda=0}^{l} n_{i_\lambda}^2) \cdot (\#\mathrm{im}(\delta))^l \cdot 2^l \cdot n^{4l} \cdot (\prod_{\lambda=1}^{l} (\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i)) \cdot (1+\mathrm{diff}(\delta))^l \\
&\quad \cdot \begin{cases} (\prod_{\lambda=1}^{l} 2 \cdot \#\Delta^{(n^2\cdot\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i-1)\cdot\mathrm{diff}(\delta)})] & \text{if } \#\Delta > 1, \\ (\prod_{\lambda=1}^{l} n^2 \cdot (\sum_{i=i_{\lambda-1}}^{i_\lambda} n_i) \cdot (1+\mathrm{diff}(\delta)))] & \text{if } \#\Delta = 1 \end{cases} \\
&\leq 5^{n/2} \cdot 2^{(n+1)\cdot(n-1)} \cdot (\#\mathrm{im}(\delta))^{n-1} \cdot 2^{n-1} \cdot n^{4\cdot(n-1)} \cdot 3^{2n/3} \cdot (1+\mathrm{diff}(\delta))^{n-1} \\
&\quad \cdot \begin{cases} 2^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{diff}(\delta)} & \text{if } \#\Delta > 1, \\ n^{2\cdot(n-1)} \cdot 3^{2n/3} \cdot (1+\mathrm{diff}(\delta))^{n-1} & \text{if } \#\Delta = 1 \end{cases} \\
&\leq \begin{cases} 5^{n/2} \cdot 3^{2n/3} \cdot 2^{(n+3)\cdot(n-1)} \cdot n^{4\cdot(n-1)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1+\mathrm{diff}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{diff}(\delta)} & \text{if } \#\Delta > 1, \\ 5^{n/2} \cdot 3^{4n/3} \cdot 2^{(n+2)\cdot(n-1)} \cdot n^{6\cdot(n-1)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1+\mathrm{diff}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1. \end{cases}
\end{aligned}$$

Note. Proposition 2.7 implies

$$\sum_{l\geq 0}\ \sum_{1\leq i_0<\ldots<i_l\leq k}\ \prod_{\lambda=0}^{l} n_{i_\lambda}^2 = \prod_{i=1}^{k}(n_i^2+1)-1 \leq 5^{n/2}-1.$$

Execution of step (2). Let $x = x_1 \ldots x_m \in \Sigma^*$ $(x_1, \ldots, x_m \in \Sigma)$. Consider $G_M(x) = (V, E)$. Let $\mu \in \{0, \ldots, m\}$. We define $\text{set}(x, \mu) := \{q \in Q \,|\, (q, \mu) \in V\}$. $\text{set}(x, \mu)$ denotes the set of states at column μ in $G_M(x)$. Consider the uniquely determined $A_1, \ldots, A_{d+1} \in 2^Q$ and $y_1, \ldots, y_d \in \Sigma^*$ such that $x = y_1 \ldots y_d$, d is odd and the following holds (see Fig. 3).

$$\begin{array}{rll} \forall j = 1, \ldots, d+1: & A_j = \text{set}(x, |y_1 \cdots y_{j-1}|) & \& \\ \forall j = 1, \ldots, d: & j \text{ odd} \implies & \\ & |(y_1 \cdots y_{j-1})y_j| = \max\{0 \leq \mu \leq m \,|\, A_j = \text{set}(x, \mu)\} & \& \\ \forall j = 1, \ldots, d: & j \text{ even} \implies y_j \in \Sigma. & \end{array}$$

Thus, for each odd $j \in [d]$, A_{j+1} is the "last occurrence" of A_j in the sequence $\text{set}(x, 0)$, $\text{set}(x, 1), \ldots, \text{set}(x, m)$. Clearly, $d \leq 2^{n+1} - 1$. *Note*: If $x \notin L(M)$, then $d = 1$ and $A_1 = A_2 = \emptyset$.

Assume that $\pi \in \Pi$ is an accepting path consuming x and producing some $z \in \Delta^*$. We shall define the set $\varphi(\pi) \subseteq S$ of specifications of π, and we shall show that this set is nonempty.

Consider the uniquely determined paths $\pi_1, \ldots, \pi_d$ and the uniquely determined $z_1, \ldots, z_d \in \Delta^*$ and $p_1', q_1', \ldots, p_d', q_d' \in Q$ such that $\pi = \pi_1 \circ \ldots \circ \pi_d$ and, for each $j = 1, \ldots, d$, π_j realizes (y_j, z_j) and leads from p_j' to q_j' (see Fig. 3). By construction, $z = z_1 \ldots z_d$, $p_1' \in A_1 \subseteq Q_I$, $q_{j-1}' = p_j' \in A_j$ $(j = 2, \ldots, d)$, $q_d' \in A_{d+1} \subseteq Q_F$, and $\{z_j \,|\, j \in [d], \text{j even}\} \subseteq \text{im}(\delta)$. We define

$$J := \{j \in [d] \,|\, \neg(p_j' \xleftrightarrow{\text{M}} q_j')\}.$$

Let $l \in \{0, \ldots, k-1\}$ and $1 \leq j_1 < \ldots < j_l \leq d$ so that $J = \{j_1, \ldots, j_l\}$. Let $1 \leq i_0 < i_1 < \ldots < i_l \leq k$ so that $p_1' \in Q_{i_0}$, $p_{j_\lambda}' \in Q_{i_{\lambda-1}}$, $q_{j_\lambda}' \in Q_{i_\lambda}$ $(\lambda = 1, \ldots, l)$, and $q_d' \in Q_{i_l}$ (see Fig. 3). For each $j := j_\lambda \in J$ set $\tilde{n}_j := \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i$.

Let $j \in \mathbb{N}$, and let π_0 be a path in M realizing some $(y_0, z_0) \in \Sigma^* \times \Delta^*$ and leading from some $p \in Q$ to some $q \in Q$. Let $1 \leq i(p) \leq i(q) \leq k$ so that $p \in Q_{i(p)}$ and $q \in Q_{i(q)}$. Set $\tilde{n} := \sum_{i=i(p)}^{i(q)} n_i$. We define $\varphi_j(\pi_0) \in 2^{\Delta^* \cup \mathcal{Z} \times Q^2}$:

$$\begin{array}{rcl} \varphi_j(\pi_0) & := & \{z_0\}, \quad \text{if } j \text{ is even or } |z_0| \text{ is at most } (n^2 \cdot \tilde{n} - 1) \cdot \text{diff}(\delta), \text{ and else,} \\ \varphi_j(\pi_0) & := & \{(t, \tilde{p}, \tilde{q}) \in \mathcal{Z} \times Q^2 \,|\, |t| \leq (n^2 \cdot \tilde{n} - 1) \cdot \text{diff}(\delta) \quad \& \quad \tilde{p} \xleftrightarrow{\text{M}} \tilde{q} \quad \& \\ & & \exists \tilde{z} \in \Delta^* \quad \exists \text{ a path } \tilde{\pi} \text{ in } M \text{ realizing } (y_0, \tilde{z}) \text{ and leading from } \tilde{p} \text{ to } \tilde{q}: \\ & & \text{diff}(\pi_0, \tilde{\pi}) \leq (n^3 - 1) \cdot \text{diff}(\delta) \quad \& \quad t = |z_0| - |\tilde{z}|\}. \end{array}$$

We are now ready to define $\varphi(\pi) \in 2^S$:

$$\varphi(\pi) := \{p_1'\} \times \prod_{\lambda=1}^{l} [\{j_\lambda\} \times \{p_{j_\lambda}'\} \times \varphi_{j_\lambda}(\pi_{j_\lambda}) \times \{q_{j_\lambda}'\}] \times \{q_d'\}.$$

Next, we prove that $\varphi(\pi)$ is nonempty, i.e., we have to show that, for all $j \in J$, $\varphi_j(\pi_j)$ is nonempty. Let $j := j_\lambda \in J$ such that $z_j \notin \varphi_j(\pi_j)$. Then, j is odd and $|z_j|$ is greater

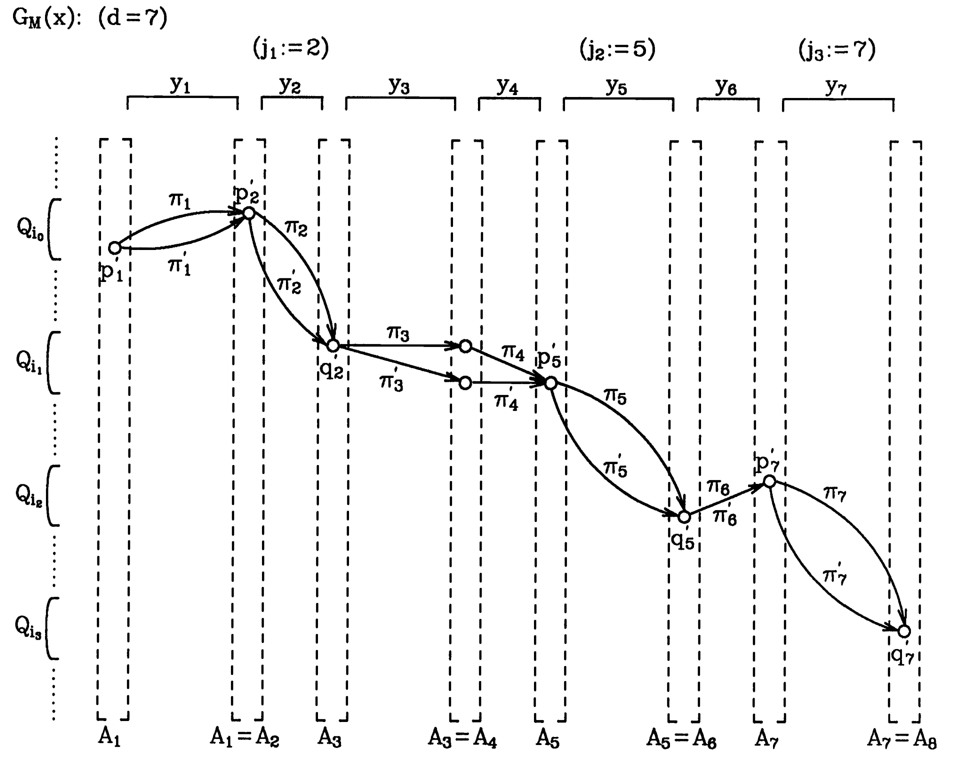

FIG. 3

than $(n^2 \cdot \tilde{n}_j - 1) \cdot \text{diff}(\delta)$. Since j is odd and $y_j \neq \varepsilon$, we can apply Lemma A.2 in the Appendix to $A := A_j = A_{j+1}$, $y := y_j$, $p' := p'_j \in A$, and $q' := q'_j \in A$, which yields

(*) There are $p, q \in A, p_1, p_2, p_3, p_4 \in Q, l_1, l_2 \geq 0$ and $z_1^{(1)}, \ldots, z_4^{(1)}, z_6^{(1)}, \ldots, z_9^{(1)} \in \Delta^*$ so that $(p, y^{l_1}, z_1^{(1)}, p_1), (p_1, y, z_2^{(1)}, p_2), (p_2, y^{l_2}, z_3^{(1)}, p) \in \delta$, $(p, y^{l_1}, z_4^{(1)}, p')$, $(q', y^{l_2}, z_6^{(1)}, q) \in \delta$ and $(q, y^{l_1}, z_7^{(1)}, p_3), (p_3, y, z_8^{(1)}, p_4), (p_4, y^{l_2}, z_9^{(1)}, q) \in \delta$.

Recall that π_j realizes (y, z_j) and leads from p' to q', and that $p' \in Q_{i_{\lambda-1}}$ and $q' \in Q_{i_\lambda}$. Select $\tilde{p} := p_1$, $\tilde{q} := p_2$, $\tilde{z} := z_2^{(1)}$, and $t := |z_j| - |\tilde{z}|$. Let $\tilde{\pi}$ be an arbitrary path realizing $(y, \tilde{z})$ and leading from $\tilde{p}$ to $\tilde{q}$. Since M does not comply with the criterion (IV1), we can apply Lemma A.3 in the Appendix to $U_1 := \bigcup_{i=1}^{i_{\lambda-1}-1} Q_i$, $U_2 := \bigcup_{i=i_{\lambda-1}}^{i_\lambda - 1} Q_i$, $U_3 := Q_{i_\lambda}$, $U_4 := \bigcup_{i=i_\lambda+1}^{k} Q_i$, $A, y, p' \in A \cap U_2$, $q' \in A \cap U_3$, the assertion (*), π_j, and $\tilde{\pi}$. Lemma A.3 implies: $\text{diff}(\pi_j, \tilde{\pi}) \leq (n^2 \cdot \tilde{n}_j - 1) \cdot \text{diff}(\delta)$. Thus, $(t, \tilde{p}, \tilde{q})$ belongs to $\varphi_j(\pi_j)$.

Assume that $\pi, \pi' \in \Pi$ are accepting paths consuming x and producing some $z, z' \in \Delta^*$, respectively, such that $\varphi(\pi) \cap \varphi(\pi')$ is nonempty. We shall show that z and z' coincide.

Consider the uniquely determined paths $\pi_1, \ldots, \pi_d, \pi'_1, \ldots, \pi'_d$ and the uniquely determined $z_1, \ldots, z_d, z'_1, \ldots, z'_d \in \Delta^*$ and $p_j^{(1)}, q_j^{(1)}, p_j^{(2)}, q_j^{(2)} \in Q$ $(j = 1, \ldots, d)$ such that $\pi = \pi_1 \circ \ldots \circ \pi_d$, $\pi' = \pi'_1 \circ \ldots \circ \pi'_d$ and, for each $j = 1, \ldots, d$, π_j realizes (y_j, z_j) and leads from $p_j^{(1)}$ to $q_j^{(1)}$ and π'_j realizes (y_j, z'_j) and leads from $p_j^{(2)}$ to $q_j^{(2)}$. By construction, $z = z_1 \ldots z_d$ and $z' = z'_1 \ldots z'_d$. We define

$$J \ := \ \{j \in [d] \mid \neg(p_j^{(1)} \xleftrightarrow{M} q_j^{(1)})\} \quad \text{and}$$

$$J' \;:=\; \{j \in [d] \mid \neg(p_j^{(2)} \overset{\mathrm{M}}{\longleftrightarrow} q_j^{(2)})\}.$$

Since $\varphi(\pi) \cap \varphi(\pi')$ is nonempty, we know: $J = J'$, $p_1^{(1)} = p_1^{(2)} =: p'_1$, $p_j^{(1)} = p_j^{(2)} =: p'_j$, $q_j^{(1)} = q_j^{(2)} =: q'_j$ $(j \in J)$, $q_d^{(1)} = q_d^{(2)} =: q'_d$. Let $l \in \{0,\dots,k-1\}$ and $1 \le j_1 < \dots < j_l \le d$ so that $J = \{j_1,\dots,j_l\}$. Let $1 \le i_0 < i_1 < \dots < i_l \le k$ so that $p'_1 \in Q_{i_0}$, $p'_{j_\lambda} \in Q_{i_{\lambda-1}}$, $q'_{j_\lambda} \in Q_{i_\lambda}$ $(\lambda = 1,\dots,l)$, and $q'_d \in Q_{i_l}$ (see Fig. 3). For each $j := j_\lambda \in J$ set $\tilde{n}_j := \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i$.

Set $j_0 := 0$, $j_{l+1} := d+1$, $q'_0 := p'_1$ and $p'_{d+1} := q'_d$. Let $\lambda \in \{0,\dots,l\}$. By construction, for some $y \in \Sigma^*$, $(q'_{j_\lambda}, y, z_{j_\lambda+1}\cdots z_{j_{\lambda+1}-1}, p'_{j_{\lambda+1}}) \in \delta$ and $(q'_{j_\lambda}, y, z'_{j_\lambda+1}\cdots z'_{j_{\lambda+1}-1}, p'_{j_{\lambda+1}}) \in \delta$. Since M does not comply with any of the criteria (IV1), (IV2), and since q'_{j_λ} is connected with $p'_{j_{\lambda+1}}$, this implies: $z_{j_\lambda+1}\cdots z_{j_{\lambda+1}-1} = z'_{j_\lambda+1}\cdots z'_{j_{\lambda+1}-1}$ (see Fig. 3).

Let $j := j_\lambda \in J$. Since $\varphi(\pi) \cap \varphi(\pi')$ is nonempty, we know that $\varphi_j(\pi_j) \cap \varphi_j(\pi'_j) \neq \emptyset$. If j is even or $|z_j|$ is at most $(n^2 \cdot \tilde{n}_j - 1)\cdot \mathrm{diff}(\delta)$, then $\{z_j\} = \varphi_j(\pi_j) = \varphi_j(\pi'_j) = \{z'_j\}$, i.e., $z_j = z'_j$. Otherwise, consider $(t, \tilde{p}, \tilde{q}) \in \mathcal{Z} \times Q^2$ so that $(t, \tilde{p}, \tilde{q}) \in \varphi_j(\pi_j) \cap \varphi_j(\pi'_j)$. Since M does not comply with any of (IV1), (IV2), and since $\tilde{p}$ is connected with $\tilde{q}$, there is exactly one $\tilde{z} \in \Delta^*$ such that $(\tilde{p}, y_j, \tilde{z}, \tilde{q}) \in \delta$. Hence, we know: $|z_j| - |\tilde{z}| = t = |z'_j| - |\tilde{z}|$, i.e., $|z_j| = |z'_j|$.

Since j is odd and $y_j \neq \varepsilon$, we can apply Lemma A.2 to $A := A_j = A_{j+1}$, $y := y_j$, $p' := p'_j \in A$, and $q' := q'_j \in A$, which yields $(*)$. Let $\tilde{\pi}$ be an arbitrary path realizing $(y, z_2^{(1)})$ and leading from p_1 to p_2. Since M does not comply with (IV1), we can apply Lemma A.3 to $U_1 := \bigcup_{i=1}^{i_{\lambda-1}-1} Q_i$, $U_2 := \bigcup_{i=i_{\lambda-1}}^{i_\lambda-1} Q_i$, $U_3 := Q_{i_\lambda}$, $U_4 := \bigcup_{i=i_\lambda+1}^{k} Q_i$, A, y, $p' \in A \cap U_2$, $q' \in A \cap U_3$, the assertion $(*)$, π_j, and $\tilde{\pi}$. Lemma A.3 implies: $||z_j| - |z_2^{(1)}|| \le (n^2 \cdot \tilde{n}_j - 1)\cdot \mathrm{diff}(\delta)$. Thus, we know in addition to $(*)$

$$(p', y, z_j, q'), (p', y, z'_j, q') \in \delta \quad \& \quad |z_j| = |z'_j| \quad \& \quad z_2^{(1)} \neq \varepsilon.$$

Since M does not comply with (IV2), this implies: $z_j = z'_j$. In summary, we have shown that z and z' coincide.

Execution of step (3). Let $\sigma \in S$. We will effectively construct an NFT $M_\sigma = (Q_\sigma, \Sigma, \Delta, \delta_\sigma, Q_{I,\sigma}, Q_{F,\sigma})$, which realizes the transduction $\{(x,z) \in \Sigma^* \times \Delta^* \mid (x,z)$ is realized by some $\pi \in \Pi$ so that $\sigma \in \varphi(\pi)\}$, and which has the property that any path in M_σ consuming ε also produces ε. It is easy to see that M_σ is equivalent to the (effectively constructible) NGSM $\bar{M}_\sigma = (Q_\sigma, \Sigma, \Delta, \bar{\delta}_\sigma, \bar{Q}_{I,\sigma}, Q_{F,\sigma})$ where

$$\begin{aligned}
\bar{Q}_{I,\sigma} &:= \{q \in Q_\sigma \mid \exists p \in Q_{I,\sigma}\colon (p,\varepsilon,\varepsilon,q) \in (\hat{\delta_\sigma})\} \quad \text{and}\\
\bar{\delta}_\sigma &:= \{(p,a,z,q) \in Q_\sigma \times \Sigma \times \Delta^* \times Q_\sigma \mid \exists r \in Q_\sigma\colon\\
&\qquad (p,a,z,r) \in \delta_\sigma \quad \& \quad (r,\varepsilon,\varepsilon,q) \in (\hat{\delta_\sigma})\}.
\end{aligned}$$

Having constructed M_σ, we prove that it works as stated above. Finally we observe that $\#Q_\sigma$ and $\|\bar{M}_\sigma\|$ are bounded as desired.

Let $l \ge 0$, $1 \le i_0 < \dots < i_l \le k$ and $0 < j_1 < \dots < j_l < 2^{n+1}$ so that $\sigma = (q_I, (j_1, p'_{j_1}, \sigma_{j_1}, q'_{j_1}), \dots, (j_l, p'_{j_l}, \sigma_{j_l}, q'_{j_l}), q_F)$ where $q_I \in Q_I \cap Q_{i_0}$, $p'_{j_\lambda} \in Q_{i_{\lambda-1}}$, $q'_{j_\lambda} \in Q_{i_\lambda}$ $(\lambda = 1,\dots,l)$, and $q_F \in Q_F \cap Q_{i_l}$. For each $j := j_\lambda \in \{j_1,\dots,j_l\}$ set $\tilde{n}_j := \sum_{i=i_{\lambda-1}}^{i_\lambda} n_i$. Define $J := \{j_1,\dots,j_l\} = J_1 \,\dot\cup\, J_2$ where $J_1 := \{j \in J \mid z_j := \sigma_j \in \Delta^*\}$ and $J_2 := \{j \in J \mid (t_j, \tilde{p}_j, \tilde{q}_j) := \sigma_j \in \mathcal{Z} \times Q^2\}$. Let $j \in J$. If $j \in J_1$, then $z_j \in \mathrm{im}(\delta)$ or $|z_j|$ is at most $(n^2 \cdot \tilde{n}_j - 1)\cdot \mathrm{diff}(\delta)$. Otherwise, $|t_j|$ is at most $(n^2 \cdot \tilde{n}_j - 1)\cdot \mathrm{diff}(\delta)$, and $\tilde{p}_j$ is connected with $\tilde{q}_j$.

By construction of φ we know: If, for some $j \in J_2$, j is even or if, for some $j \in J_1$, j is odd and $|z_j| > (n^2 \cdot \tilde{n}_j - 1) \cdot \mathrm{diff}(\delta)$ or j is even and $z_j \notin \mathrm{im}(\delta)$, then σ does not belong to $\varphi(\Pi)$. In this case we can select M_σ so that $T(M_\sigma) = \emptyset$. Let us therefore assume that, for all $j \in J_2$, j is odd and that, for all $j \in J_1$, either j is odd and $|z_j| \leq (n^2 \cdot \tilde{n}_j - 1) \cdot \mathrm{diff}(\delta)$ or j is even and $z_j \in \mathrm{im}(\delta)$.

Before we construct M_σ in detail, we explain the desired mode of operation of an arbitrary accepting path π_σ in this machine. Assume that π_σ realizes $(x, z) \in \Sigma^* \times \Delta^*$. Let $x_1, \ldots, x_m \in \Sigma$ so that $x = x_1 \ldots x_m$. Consider $G_M(x) = (V, E)$. Let $\mu \in \{0, \ldots, m\}$. We define

$$\begin{aligned} \mathrm{att}(x,\mu) &:= \{s \in Q \mid \exists r \in Q_I \, \exists z \in \Delta^* \colon (r, x_1 \ldots x_\mu, z, s) \in \delta\} \quad \text{and} \\ \mathrm{der}(x,\mu) &:= \{r \in Q \mid \exists s \in Q_F \, \exists z \in \Delta^* \colon (r, x_{\mu+1} \ldots x_m, z, s) \in \delta\}; \end{aligned}$$

$\mathrm{att}(x,\mu)$ and $\mathrm{der}(x,\mu)$ denote the set of states attainable from Q_I with $x_1 \ldots x_\mu$ and the set of states derivable to Q_F with $x_{\mu+1} \ldots x_m$, respectively. In step (2), $\mathrm{set}(x,\mu)$ was defined as the set of states at column μ in $G_M(x)$. Clearly, this set equals $\mathrm{att}(x,\mu) \cap \mathrm{der}(x,\mu)$. The reader may further recall from step (2) the definition of $A_1, \ldots, A_{d+1} \in 2^Q$ and of $y_1, \ldots, y_d \in \Sigma^*$ (where $x = y_1 \ldots y_d$ and d is odd and at most $2^{n+1} - 1$).

The path π_σ consists of five components that correspond to five components of Q_σ. Roughly spoken, the first four components of π_σ provide the index $j \in [d]$ of the word y_j currently consumed by π_σ. These components are independent of σ and z. The fifth component of π_σ guesses an accepting path $\pi \in \Pi$ realizing (x, z) and uses the basic information provided by the first four components in order to verify "on line" that σ belongs to $\varphi(\pi)$. Note that π_σ inherits z from π.

The first component of π_σ constantly contains $(A_1, \ldots, A_{2^{n+1}}) \in (2^Q)^{2^{n+1}}$, where $A_1, \ldots, A_{d+1}$ are as above and $A_{d+2}, \ldots, A_{2^{n+1}}$ are arbitrary. $(A_1, \ldots, A_{2^{n+1}})$ is guessed at the beginning of π_σ. Note that we need $A_{d+2}, \ldots, A_{2^{n+1}}$ only in order to make Q_σ "well typed."

The next three components of π_σ drive a nondeterministic process, which verifies the correctness of $A_1, \ldots, A_{d+1}$ and uses these sets in order to provide the index $j \in [d]$ of the word y_j currently consumed by π_σ. Assume that, for some $\mu \in \{0, \ldots, m\}$, π_σ has consumed $x_1 \ldots x_\mu$. Then, the second (deterministic) and third (nondeterministic) components of π_σ contain $\mathrm{att}(x,\mu)$ and $\mathrm{der}(x,\mu)$, respectively.

The fourth component of π_σ contains some $(j, \alpha) \in [d+1] \times [3]$ so that the following holds: If $\alpha = 1$, then either $j \leq d$ and π_σ can, after one transition realizing $(\varepsilon, \varepsilon)$, begin to consume the letters of y_j or π_σ guesses that $j = d + 1$ and accepts. In the latter case, of course, j is even and greater than j_l. If $\alpha \in \{2, 3\}$, then $j \leq d$. If $\alpha = 2$, then j is even and π_σ is ready to consume the only letter of y_j. If $\alpha = 3$ and j is even, then y_j has been completely consumed. If $\alpha = 3$ and j is odd, then either π_σ is ready to consume the next letter of y_j or y_j has been completely consumed, depending on the guess of π_σ. Whenever all letters of a y_j have been consumed, π_σ increments j by 1 on a transition realizing $(\varepsilon, \varepsilon)$. At the beginning of π_σ its fourth component contains $(1, 1)$. The distinction between the values 2 and 3 for α is needed in order to ensure that $|y_j| = 1$ for all even $j \in [d]$.

The second and third component of π_σ is used to check that, for each $j \in [d + 1]$, $A_j = \mathrm{set}(x, |y_1 \ldots y_{j-1}|)$ and that, for each odd $j \in [d]$, A_{j+1} is the "last occurrence" of A_j in the sequence $\mathrm{set}(x, 0), \mathrm{set}(x, 1), \ldots, \mathrm{set}(x, m)$. Therefore, these components contribute to the verification of the first and the fourth component of π_σ.

For the fifth component of π_σ we first of all need, for all $j \in J$, an NGSM $M_{\sigma,j}$ realizing the transduction

$$T_{\sigma,j} := \{(y_0, z_0) \in \Sigma^* \times \Delta^* \mid (y_0, z_0) \text{ is realized by some path } \pi_0 \text{ in } M \text{ leading from } p'_j \text{ to } q'_j \text{ so that } \sigma_j \in \varphi_j(\pi_0)\}.$$

Informally spoken, an accepting path in $M_{\sigma,j}$ simply guesses (in its first component) a path π_0 in M leading from p'_j to q'_j, realizes the same $(y_0, z_0) \in \Sigma^* \times \Delta^*$ as π_0 and verifies (on its three other components) that σ_j belongs to $\varphi_j(\pi_0)$. The verification procedure directly arises from the definition of φ_j in step (2). The detailed construction of $M_{\sigma,j}$ is given below.

The fifth component of π_σ verifies that, for some $\pi \in \Pi$ realizing (x, z), σ belongs to $\varphi(\pi)$. Following the definition of φ this component operates as follows: For all $\lambda \in \{0, \ldots, l\}$, while π_σ consumes $y_{j_\lambda+1}, \ldots, y_{j_{\lambda+1}-1}$, one after another, it guesses and verifies a path in M consuming $y_{j_\lambda+1} \ldots y_{j_{\lambda+1}-1}$, producing some $z_{j_\lambda+1}, \ldots, z_{j_{\lambda+1}-1} \in \Delta^*$, one after another, and leading from q'_{j_λ} to $p'_{j_{\lambda+1}}$ (where $j_0 := 0$, $j_{l+1} := d+1$, $q'_0 := q_I$, $p'_{d+1} := q_F$). For all $j := j_\lambda \in J$ ($\lambda \in [l]$), while π_σ consumes y_j, this component guesses and verifies an accepting path in $M_{\sigma,j}$ consuming y_j and producing some $z_j \in \Delta^*$. The index $j \in [d]$ of the word y_j currently consumed by π_σ is read from its fourth component. π_σ inherits $z = z_1 \ldots z_d \in \Delta^*$ from the combination of the above paths.

Let $j \in J$. We construct the NGSM $M_{\sigma,j} = (Q_{\sigma,0}, \Sigma, \Delta, \delta_{\sigma,j}, Q_{I,\sigma,j}, Q_{F,\sigma,j})$:

$$\begin{aligned} Q_{\sigma,0} &:= Q \times Q \times [-(n^3-1)\cdot \mathrm{diff}(\delta), (n^3-1)\cdot \mathrm{diff}(\delta)] \\ &\quad \times [0, \max\{\mathrm{iml}(\delta), 1 + (n^3-1)\cdot \mathrm{diff}(\delta)\}], \end{aligned}$$

if $j \in J_1$:

$$\begin{aligned} Q_{I,\sigma,j} &:= \{(p'_j, p'_j, 0, 0)\}, \\ Q_{F,\sigma,j} &:= \{(q'_j, q'_j, 0, |z_j|)\}, \\ \delta_{\sigma,j} &:= \{((p,p,0,\tau), a, z, (q,q,0,\tau')) \in Q_{\sigma,0} \times \Sigma \times \Delta^* \times Q_{\sigma,0} \mid (p,a,z,q) \in \delta \\ &\quad \& \quad \tau' = \tau + |z| \le |z_j| \quad \& \quad \forall \nu \in [|z|]\colon\ z(\nu) = z_j(\tau+\nu)\}, \end{aligned}$$

if $j \in J_2$:

$$\begin{aligned} Q_{I,\sigma,j} &:= \{(p'_j, \tilde{p}_j, 0, 0)\}, \\ Q_{F,\sigma,j} &:= \{(q'_j, \tilde{q}_j, t_j, \tau) \in Q_{\sigma,0} \mid \tau > (n^2 \cdot \tilde{n}_j - 1)\cdot \mathrm{diff}(\delta)\}, \\ \delta_{\sigma,j} &:= \{((p,\tilde{p},t,\tau), a, z, (q,\tilde{q},t',\tau')) \in Q_{\sigma,0} \times \Sigma \times \Delta^* \times Q_{\sigma,0} \mid (p,a,z,q) \in \delta \\ &\quad \& \quad \exists \tilde{z} \in \Delta^*\colon \quad (\tilde{p}, a, \tilde{z}, \tilde{q}) \in \delta \quad \& \quad t' = t + |z| - |\tilde{z}| \\ &\quad \& \quad \tau' = \min\{\tau + |z|, 1 + (n^3-1)\cdot \mathrm{diff}(\delta)\}\}. \end{aligned}$$

Now we are ready to construct the NFT $M_\sigma = (Q_\sigma, \Sigma, \Delta, \delta_\sigma, Q_{I,\sigma}, Q_{F,\sigma})$:

$$\begin{aligned} Q_\sigma &:= (2^Q)^{2^{n+1}} \times 2^Q \times 2^Q \times ([2^{n+1}] \times [3]) \times Q_{\sigma,0}, \\ Q_{I,\sigma} &:= \{((A_1, \ldots, A_{2^{n+1}}), B_1, B_2, (1,1), (q_I, q_I, 0, 0)) \in Q_\sigma \mid \\ &\quad (\forall 1 \le j_1 < j_2 \le 2^{n+1}\colon \quad A_{j_1} = A_{j_2} \quad \Leftrightarrow \quad j_2 = j_1 + 1 \quad \& \quad j_1 \text{ odd}) \\ &\quad \& \quad B_1 = Q_I \quad \& \quad B_1 \cap B_2 = A_1\}, \\ Q_{F,\sigma} &:= \{((A_1, \ldots, A_{2^{n+1}}), B_1, B_2, (j,1), (q_F, q_F, 0, 0)) \in Q_\sigma \mid \\ &\quad B_2 = Q_F \quad \& \quad j \text{ even} \quad \& \quad j > j_l\}, \end{aligned}$$

$$\begin{aligned}
\delta_\sigma &:= \delta_\sigma^{(1)} \cup \delta_\sigma^{(2)} \cup \delta_\sigma^{(3)}, \quad \text{where} \\
\delta_\sigma^{(1)} &:= \{(((A_1,\dots,A_{2^n+1}),B_1,B_2,(j,1),(q,q,0,0)),\varepsilon,\varepsilon, \\
&\quad ((A_1,\dots,A_{2^n+1}),B_1,B_2,(j,\alpha'),(q,\tilde{q},0,0))) \in Q_\sigma \times \{\varepsilon\} \times \{\varepsilon\} \times Q_\sigma \mid \\
&\quad (j \text{ odd} \;\Rightarrow\; \alpha' = 3) \;\;\&\;\; (j \text{ even} \;\Rightarrow\; \alpha' = 2) \;\;\& \\
&\quad (j \notin J \;\Rightarrow\; q = \tilde{q}) \;\;\&\;\; (j \in J \;\Rightarrow\; (q,\tilde{q},0,0) \in Q_{I,\sigma,j})\}, \\
\delta_\sigma^{(2)} &:= \{(((A_1,\dots,A_{2^n+1}),B_1,B_2,(j,\alpha),(p,\tilde{p},t,\tau)),a,z, \\
&\quad ((A_1,\dots,A_{2^n+1}),B_1',B_2',(j,\alpha'),(q,\tilde{q},t',\tau'))) \in Q_\sigma \times \Sigma \times \Delta^* \times Q_\sigma \mid \\
&\quad B_1' = \{s \in Q \mid \exists r \in B_1\, \exists z' \in \Delta^*\colon (r,a,z',s) \in \delta\} \;\;\& \\
&\quad B_2 = \{r \in Q \mid \exists s \in B_2'\, \exists z' \in \Delta^*\colon (r,a,z',s) \in \delta\} \;\;\& \\
&\quad B_1' \cap B_2' \notin \{A_1,\dots,A_{j-1}\} \;\;\&\;\; (j \text{ odd} \;\Rightarrow\; \alpha = \alpha' = 3) \;\;\& \\
&\quad (j \text{ even} \;\Rightarrow\; (\alpha,\alpha') = (2,3)) \;\;\&\;\; (j \notin J \;\Rightarrow\; (p,a,z,q) \in \delta \;\;\& \\
&\quad (p,\tilde{p},t,\tau) = (p,p,0,0) \;\;\&\;\; (q,\tilde{q},t',\tau') = (q,q,0,0)) \;\;\& \\
&\quad (j \in J \;\Rightarrow\; ((p,\tilde{p},t,\tau),a,z,(q,\tilde{q},t',\tau')) \in \delta_{\sigma,j})\}, \\
\delta_\sigma^{(3)} &:= \{(((A_1,\dots,A_{2^n+1}),B_1,B_2,(j,3),(q,\tilde{q},t,\tau)),\varepsilon,\varepsilon, \\
&\quad ((A_1,\dots,A_{2^n+1}),B_1,B_2,(j+1,1),(q,q,0,0))) \in Q_\sigma \times \{\varepsilon\} \times \{\varepsilon\} \times Q_\sigma \mid \\
&\quad B_1 \cap B_2 = A_{j+1} \;\;\&\;\; (j \notin J \;\Rightarrow\; (q,\tilde{q},t,\tau) = (q,q,0,0)) \;\;\& \\
&\quad (j \in J \;\Rightarrow\; (q,\tilde{q},t,\tau) \in Q_{F,\sigma,j})\}.
\end{aligned}$$

FACT 2.8. *For all $j \in J$, the* NGSM $M_{\sigma,j}$ *realizes the transduction* $T_{\sigma,j}$.

Proof.

Case 1. $j \in J_1$, i.e., $\sigma_j = z_j \in \Delta^*$. Then, we have: $T_{\sigma,j} = \{(y_0, z_j) \in \Sigma^* \times \Delta^* \mid (y_0, z_j)$ is realized by some path π_0 in M leading from p_j' to $q_j'\} = T(M_{\sigma,j})$. Note that for the first equality we have used our assumption that j is even or $|z_j| \le (n^2 \cdot \tilde{n}_j - 1) \cdot \text{diff}(\delta)$.

Case 2. $j \in J_2$, i.e., $\sigma_j = (t_j, \tilde{p}_j, \tilde{q}_j) \in \mathcal{Z} \times Q^2$. Then, we have: $T_{\sigma,j} = \{(y_0, z_0) \in \Sigma^* \times \Delta^* \mid$ there are paths π_0 and $\tilde{\pi}$ in M realizing (y_0, z_0) and $(y_0, \tilde{z})$, for some $\tilde{z} \in \Delta^*$, and leading from p_j' to q_j' and from $\tilde{p}_j$ to $\tilde{q}_j$, respectively, so that $\text{diff}(\pi_0, \tilde{\pi}) \le (n^3 - 1) \cdot \text{diff}(\delta)$, $t_j = |z_0| - |\tilde{z}|$, and $|z_0| > (n^2 \cdot \tilde{n}_j - 1) \cdot \text{diff}(\delta)\} = T(M_{\sigma,j})$. Note that for the first equality we have used our assumption that j is odd. □

The NFT M_σ works as desired above. Thus, using Fact 2.8, it is easy to establish that this NFT realizes the transduction $\{(x,z) \in \Sigma^* \times \Delta^* \mid (x,z)$ is realized by some $\pi \in \Pi$ so that $\sigma \in \varphi(\pi)\}$.

Note that, for each transition (r,a,z,s) of M_σ, either $(a,z) = (\varepsilon,\varepsilon)$ or there are $p,q \in Q$ such that (p,a,z,q) is a transition of M. Any path in M_σ consuming ε has length at most 4 and also produces ε. Of course, the construction of M_σ is effective (see Theorem 2.3 for details). The following fact states upper bounds for $\#Q_\sigma$ and $\|\bar{M}_\sigma\|$ and for some other useful parameters of $M_{\sigma,j}$ $(j \in J)$, M_σ and $\bar{M}_\sigma$.

FACT 2.9. *The following assertions are true.*

(i) $\#Q_{\sigma,0} \le 2n^8 \cdot (1 + \text{diff}(\delta)) \cdot (2 + \text{iml}(\delta))$.

(ii) *For all* $j \in J$: $\|\delta_{\sigma,j}\| \le \#Q_{\sigma,0}^2 \cdot \|\delta\|$, $\|M_{\sigma,j}\| \le \#Q_{\sigma,0}^2 \cdot \|M\| \le 4n^{16} \cdot \|M\|^5$.

(iii) $\#Q_\sigma \le 2^{n \cdot (2^{n+1}+12)} \cdot (1 + \text{diff}(\delta)) \cdot (2 + \text{iml}(\delta))$.

(iv) $\text{diff}(\bar{\delta}_\sigma) = \text{diff}(\delta_\sigma) \le \text{diff}(\delta)$, $\text{im}(\bar{\delta}_\sigma) = \text{im}(\delta_\sigma) \subseteq \text{im}(\delta)$, $\text{iml}(\bar{\delta}_\sigma) = \text{iml}(\delta_\sigma) \le \text{iml}(\delta)$, $\|\delta_\sigma\| \le \#Q_\sigma^2 \cdot (1 + \|\delta\|)$, $\|\bar{\delta}_\sigma\| \le \#Q_\sigma^2 \cdot \|\delta\|$, $\|M_\sigma\| \le \#Q_\sigma^2 \cdot (1 + \|M\|)$, $\|\bar{M}_\sigma\| \le \#Q_\sigma^2 \cdot \|M\| \le 2^{n \cdot (2^{n+2}+24)} \cdot \|M\|^5$.

(v) *Let* $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ *be another* NGSM. *Then,* $\text{diff}(\bar{\delta}_\sigma, \delta_0) \le \text{diff}(\delta, \delta_0)$.

Proof. The assertions (i) and (ii) are obvious from the definition of $M_{\sigma,j}$ $(j \in J)$. The assertions (iii)–(v) follow from the definition of M_σ and $\bar{M}_\sigma$. Note that for the proof of (iii) we apply (i) and the estimation $n^8 \le 3^{8n/3} \le 2^{5n}$ (cf. proof of Proposition 2.7). □

This completes the proof of Theorem 2.1. □

Proof of Theorem 2.2. Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ and $n = \#Q$ be as in Theorem 2.1. Let S and $M_\sigma, \bar{M}_\sigma$ $(\sigma \in S)$ be as in the proof of this theorem. The NGSMs $\bar{M}_\sigma$ $(\sigma \in S)$ are playing the role of $M_1, \ldots, M_N$ in Theorem 2.1, where $N = \#S$. Therefore, all we have to do here is to construct effectively, for each $\sigma \in S$, an NFA $\bar{M}'_\sigma$ recognizing $\Sigma^* \backslash L(\bar{M}_\sigma) = \Sigma^* \backslash L(M_\sigma)$ and having at most $2^{n\cdot(2^{n+1}+8)} \cdot 2^{2n^8\cdot(1+\text{diff}(\delta))\cdot(2+\text{iml}(\delta))}$ states and size at most $2^{n\cdot(2^{n+2}+17)} \cdot 2^{5n^8\cdot\|M\|^2}$.

Let $\sigma \in S$. Following the main lines of the construction of M_σ in step (3) of the proof of Theorem 2.1, we will effectively construct an ε-NFA $M'_\sigma = (Q'_\sigma, \Sigma, \delta'_\sigma, Q'_{I,\sigma}, Q'_{F,\sigma})$ which recognizes $\Sigma^* \backslash L(M_\sigma)$, i.e., the language $\{x \in \Sigma^* \mid$ there is no $\pi \in \Pi$ consuming x so that $\sigma \in \varphi(\pi)\}$. It is easy to see that M'_σ is equivalent to the (effectively constructible) NFA $\bar{M}'_\sigma = (Q'_\sigma, \Sigma, \bar{\delta}'_\sigma, \bar{Q}'_{I,\sigma}, Q'_{F,\sigma})$ where

$$\begin{aligned}
\bar{Q}'_{I,\sigma} &:= \{q \in Q'_\sigma \mid \exists p \in Q'_{I,\sigma} \colon (p, \varepsilon, q) \in (\hat{\delta'_\sigma})\} \quad \text{and} \\
\bar{\delta}'_\sigma &:= \{(p, a, q) \in Q'_\sigma \times \Sigma \times Q'_\sigma \mid \exists r \in Q'_\sigma \colon (p, a, r) \in \delta'_\sigma \quad \& \quad (r, \varepsilon, q) \in (\hat{\delta'_\sigma})\}.
\end{aligned}$$

Having constructed M'_σ, we will see that it works as stated above. Finally we observe that $\#Q'_\sigma$ and $\|\bar{M}'_\sigma\|$ are bounded as desired.

Let $\sigma = (q_I, (j_1, p'_{j_1}, \sigma_{j_1}, q'_{j_1}), \ldots, (j_l, p'_{j_l}, \sigma_{j_l}, q'_{j_l}), q_F) \in S$ and $J, J_1, J_2, \tilde{n}_j$ $(j \in J)$, z_j $(j \in J_1)$ and $(t_j, \tilde{p}_j, \tilde{q}_j)$ $(j \in J_2)$ be given as in step (3) of the proof of Theorem 2.1. Following this proof we also assume here that, for all $j \in J_2$, j is odd and that, for all $j \in J_1$, either j is odd and $|z_j| \le (n^2 \cdot \tilde{n}_j - 1) \cdot \text{diff}(\delta)$ or j is even and $z_j \in \text{im}(\delta)$.

We recall from step (3) of the proof of Theorem 2.1 the NGSM $M_{\sigma,j} = (Q_{\sigma,0}, \Sigma, \Delta, \delta_{\sigma,j}, Q_{I,\sigma,j}, Q_{F,\sigma,j})$ $(j \in J)$ realizing the transduction $T_{\sigma,j}$. Let $j \in J$. Using the well-known subset construction we obtain from $M_{\sigma,j}$ the following DFA $M'_{\sigma,j} = (Q'_{\sigma,0}, \Sigma, \delta'_{\sigma,j}, Q'_{I,\sigma,j}, Q'_{F,\sigma,j})$ recognizing the language $\Sigma^* \backslash L(M_{\sigma,j})$.

$$\begin{aligned}
Q'_{\sigma,0} &:= 2^{Q_{\sigma,0}}, \\
Q'_{I,\sigma,j} &:= \{Q_{I,\sigma,j}\}, \\
Q'_{F,\sigma,j} &:= 2^{Q_{\sigma,0} \backslash Q_{F,\sigma,j}}, \\
\delta'_{\sigma,j} &:= \{(B, a, B') \in Q'_{\sigma,0} \times \Sigma \times Q'_{\sigma,0} \mid \\
&\qquad B' = \{s \in Q_{\sigma,0} \mid \exists r \in B \, \exists z \in \Delta^* \colon (r, a, z, s) \in \delta_{\sigma,j}\}\}.
\end{aligned}$$

According to the definition of $T_{\sigma,j}$, $L(M'_{\sigma,j}) = \{y_0 \in \Sigma^* \mid$ there is no path π_0 in M consuming y_0 and leading from p'_j to q'_j so that $\sigma_j \in \varphi_j(\pi_0)\}$.

Before we construct M'_σ in detail we explain the desired mode of operation of an arbitrary accepting path π'_σ in this machine. Assume that π'_σ consumes $x \in \Sigma^*$. Let $x_1, \ldots, x_m \in \Sigma$ so that $x = x_1 \ldots x_m$. From step (2) of the proof of Theorem 2.1 the reader may recall the definition of $y_1, \ldots, y_d \in \Sigma^*$ (where $x = y_1 \ldots y_d$ and d is odd and at most $2^{n+1} - 1$). We further ask once again to recall the main lines of the construction of $M_\sigma = (Q_\sigma, \Sigma, \Delta, \delta_\sigma, Q_{I,\sigma}, Q_{F,\sigma})$ in step (3) of this proof.

The path π'_σ consists of five components that correspond to five components of Q'_σ. Concerning the first four components, π'_σ operates exactly as an accepting path in M_σ consuming x. In particular, the value $(j, \alpha) \in [d + 1] \times [3]$ of the fourth component of π'_σ, if $j \le d$, determines the index j of the word y_j currently consumed by π'_σ. At the beginning respectively end of π'_σ its fourth component contains $(1,1)$ respectively $(d+1,1)$. One reason for π'_σ to accept x is that at its end $d+1 \le j_l$. Let us assume here that $j_l < d+1$.

The fifth component of π'_σ verifies that there is no $\pi \in \Pi$ consuming x such that σ belongs to $\varphi(\pi)$. Following the definition of φ this component verifies that (a) or (b), depending on its guess, holds: (a) For some (guessed) $\lambda \in \{0,\dots,l\}$ there is no path in M consuming $y_{j_\lambda+1}\cdots y_{j_{\lambda+1}-1}$ and leading from q'_{j_λ} to $p'_{j_{\lambda+1}}$ (where $j_0 := 0$, $j_{l+1} := d+1, q'_0 := q_I, p'_{d+1} := q_F$). (b) For some (guessed) $j := j_\lambda \in J$ ($\lambda \in [l]$) there is an accepting path in $M'_{\sigma,j}$ consuming y_j. Of course, condition (a) is verified (as described below) while π'_σ consumes $y_{j_\lambda+1},\dots,y_{j_{\lambda+1}-1}$, one after another, and condition (b) is verified by simulating $M'_{\sigma,j}$ while π'_σ consumes y_j. The index $j \in [d]$ of the word y_j currently consumed by π'_σ is read from its fourth component.

Technically the fifth component of π'_σ contains some $(B_3,\beta) \in Q'_{\sigma,0} \times [3]$. The set $Q'_{\sigma,0}$ is needed for the simulation of $M'_{\sigma,j}$ ($j \in J$). The value for β can never decrease along π'_σ. $\beta = 2$ means that π'_σ is about to verify (a) or (b). $\beta = 1$ ($\beta = 3$) means that this verification still has to be done (is already completed, respectively). If $\beta \in \{1,3\}$, then $B_3 = \emptyset$. If $\beta = 2$, if π'_σ is about to verify (a) for $\lambda \in \{0,\dots,l\}$, and if π'_σ has consumed the prefix y of $y_{j_\lambda+1}\cdots y_{j_{\lambda+1}-1}$, then $B_3 = \{(q,q,0,0) \mid \exists z' \in \Delta^*\colon\ (q'_{j_\lambda}, y, z', q) \in \delta\}$.

Now we construct the ε-NFA $M'_\sigma = (Q'_\sigma, \Sigma, \delta'_\sigma, Q'_{I,\sigma}, Q'_{F,\sigma})$:

$$\begin{aligned}
Q'_\sigma &:= (2^Q)^{2^{n+1}} \times 2^Q \times 2^Q \times ([2^{n+1}] \times [3]) \times (Q'_{\sigma,0} \times [3]),\\
Q'_{I,\sigma} &:= \{((A_1,\dots,A_{2^{n+1}}), B_1, B_2, (1,1), (B_3,\beta)) \in Q'_\sigma \mid\\
&\quad\ (\forall 1 \le j_1 < j_2 \le 2^{n+1}\colon\ \ A_{j_1} = A_{j_2} \ \Leftrightarrow\ j_2 = j_1 + 1 \ \ \&\ \ j_1 \text{ odd})\\
&\quad\ \&\ \ B_1 = Q_I \ \ \&\ \ B_1 \cap B_2 = A_1\\
&\quad\ \&\ \ (B_3,\beta) \in \{(\emptyset,1), (\{(q_I,q_I,0,0)\},2)\}\},\\
Q'_{F,\sigma} &:= \{((A_1,\dots,A_{2^{n+1}}), B_1, B_2, (j,1), (B_3,\beta)) \in Q'_\sigma \mid\\
&\quad\ B_2 = Q_F \ \ \&\ \ j \text{ even} \ \ \&\ \ (j \le j_l \ \ \vee\ \ (B_3,\beta) = (\emptyset,3)\\
&\quad\ \vee\ \ (B_3,\beta) \in 2^{Q_{\sigma,0}\setminus\{(q_F,q_F,0,0)\}} \times \{2\})\},\\
\delta'_\sigma &:= \delta^{(4)}_\sigma \cup \delta^{(5)}_\sigma \cup \delta^{(6)}_\sigma, \text{where}\\
\delta^{(4)}_\sigma &:= \{(((A_1,\dots,A_{2^{n+1}}), B_1, B_2, (j,1), (B_3,\beta)), \varepsilon,\\
&\quad\ ((A_1,\dots,A_{2^{n+1}}), B_1, B_2, (j,\alpha'), (B'_3,\beta'))) \in Q'_\sigma \times \{\varepsilon\} \times Q'_\sigma \mid\\
&\quad\ (j \text{ odd} \ \Rightarrow\ \alpha' = 3) \ \ \&\ \ (j \text{ even} \ \Rightarrow\ \alpha' = 2) \ \ \&\\
&\quad\ [(B_3,\beta) = (B'_3,\beta') \in \{(\emptyset,1),(\emptyset,3)\} \ \ \vee\\
&\quad\ (j \notin J \ \ \&\ \ (B_3,\beta) = (B'_3,\beta') \in Q'_{\sigma,0} \times \{2\}) \ \ \vee\\
&\quad\ (j \in J \ \ \&\ \ (B_3,\beta) \in 2^{Q_{\sigma,0}\setminus\{(p'_j,p'_j,0,0)\}} \times \{2\} \ \ \&\ \ (B'_3,\beta') = (\emptyset,3))\\
&\quad\ \vee\ \ (j \in J \ \ \&\ \ (B_3,\beta) = (\emptyset,1) \ \ \&\ \ (B'_3,\beta') \in Q'_{I,\sigma,j} \times \{2\})]\},\\
\delta^{(5)}_\sigma &:= \{(((A_1,\dots,A_{2^{n+1}}), B_1, B_2, (j,\alpha), (B_3,\beta)), a,\\
&\quad\ ((A_1,\dots,A_{2^{n+1}}), B'_1, B'_2, (j,\alpha'), (B'_3,\beta))) \in Q'_\sigma \times \Sigma \times Q'_\sigma \mid\\
&\quad\ B'_1 = \{s \in Q \mid \exists r \in B_1\, \exists z' \in \Delta^*\colon\ (r,a,z',s) \in \delta\} \ \ \&\\
&\quad\ B_2 = \{r \in Q \mid \exists s \in B'_2\, \exists z' \in \Delta^*\colon\ (r,a,z',s) \in \delta\} \ \ \&\\
&\quad\ B'_1 \cap B'_2 \notin \{A_1,\dots,A_{j-1}\} \ \ \&\\
&\quad\ (j \text{ odd} \ \Rightarrow\ \alpha = \alpha' = 3) \ \ \&\ \ (j \text{ even} \ \Rightarrow\ (\alpha,\alpha') = (2,3)) \ \ \&\\
&\quad\ [(B_3,\beta) = (B'_3,\beta') \in \{(\emptyset,1),(\emptyset,3)\} \ \ \vee\ \ (j \notin J \ \ \&
\end{aligned}$$

$$\begin{aligned}
& B_3' = \{(q,q,0,0) \mid \exists\,(p,p,0,0) \in B_3\, \exists z' \in \Delta^*\colon\ (p,a,z',q) \in \delta\} \\
& \&\quad \beta = 2) \quad \vee \quad (j \in J \quad \& \quad (B_3,a,B_3') \in \delta'_{\sigma,j} \quad \& \quad \beta = 2)]\}, \\
\delta_\sigma^{(6)} \quad := \quad & \{(((A_1,\dots,A_{2^{n+1}}),B_1,B_2,(j,3),(B_3,\beta)),\varepsilon, \\
& ((A_1,\dots,A_{2^{n+1}}),B_1,B_2,(j+1,1),(B_3',\beta'))) \in Q'_\sigma \times \{\varepsilon\} \times Q'_\sigma \mid \\
& B_1 \cap B_2 = A_{j+1} \quad \& \quad [(B_3,\beta) = (B_3',\beta') \in \{(\emptyset,1),(\emptyset,3)\} \quad \vee \\
& (j \notin J \quad \& \quad (B_3,\beta) = (B_3',\beta') \in Q'_{\sigma,0} \times \{2\}) \quad \vee \\
& (j \in J \quad \& \quad (B_3,\beta) = (\emptyset,1) \quad \& \quad (B_3',\beta') = (\{(q_j',q_j',0,0)\},2)) \quad \vee \\
& (j \in J \quad \& \quad (B_3,\beta) \in Q'_{F,\sigma,j} \times \{2\} \quad \& \quad (B_3',\beta') = (\emptyset,3))]\}.
\end{aligned}$$

The ε-NFA M'_σ works as desired above. Thus, it is easy to establish that this ε-NFA recognizes the language $\{x \in \Sigma^* \mid \text{there is no } \pi \in \Pi \text{ consuming } x \text{ so that } \sigma \in \varphi(\pi)\}$. Of course, the construction of M'_σ is effective (see Theorem 2.3 for details). The following fact states upper bounds for $\#Q'_\sigma$ and $\|\bar{M}'_\sigma\|$ and for some other useful parameters of $M'_{\sigma,j}$ $(j \in J)$, M'_σ and $\bar{M}'_\sigma$.

FACT 2.10. *The following assertions are true.*

(i) $\#Q'_{\sigma,0} = 2^{\#Q_{\sigma,0}} \le 2^{2n^8\cdot(1+\mathrm{diff}(\delta))\cdot(2+\mathrm{iml}(\delta))}$.

(ii) For all $j \in J$: $\#\delta'_{\sigma,j} = \#Q'_{\sigma,0} \cdot \#\Sigma$, $\|M'_{\sigma,j}\| \le 2 \cdot \#Q'_{\sigma,0} \cdot \|M\| \le 2^{3n^8\cdot\|M\|^2}$.

(iii) $\#Q_\sigma \le \#Q'_\sigma \le 2^{n\cdot(2^{n+1}+8)} \cdot 2^{2n^8\cdot(1+\mathrm{diff}(\delta))\cdot(2+\mathrm{iml}(\delta))}$.

(iv) $\#\delta'_\sigma \le (\#Q'_\sigma)^2 \cdot (1+\#\Sigma)$, $\#\bar{\delta}'_\sigma \le (\#Q'_\sigma)^2 \cdot \#\Sigma$,
$\max\{\|M'_\sigma\|, \|\bar{M}'_\sigma\|\} \le 2 \cdot (\#Q'_\sigma)^2 \cdot \|M\| \le 2^{n\cdot(2^{n+2}+17)} \cdot 2^{5n^8\cdot\|M\|^2}$.

Proof. The assertions (i) and (ii) follow from the definition of $M'_{\sigma,j}$ $(j \in J)$ and from Fact 2.9(i). Using (i), the assertions (iii) and (iv) are obvious from the definition of M'_σ and $\bar{M}'_\sigma$. □

This completes the proof of Theorem 2.2. □

Proof of Theorem 2.3. Let $M = (Q,\Sigma,\Delta,\delta,Q_I,Q_F)$ and $n = \#Q$ be as in the Theorems 2.1 and 2.2. Let S and $\bar{M}_\sigma, \bar{M}'_\sigma$ $(\sigma \in S)$ be as in the proofs of these theorems. The NGSMs $\bar{M}_\sigma$ $(\sigma \in S)$ and the NFAs $\bar{M}'_\sigma$ $(\sigma \in S)$ are playing the role of $M_1,\dots,M_N$ in Theorem 2.1 and of $M_1',\dots,M_N'$ in Theorem 2.2, respectively, where $N = \#S = O(2^{\mathrm{poly}\|M\|})$. Therefore, all we have to do here is to show that S and each $\bar{M}_\sigma$ and $\bar{M}'_\sigma$ $(\sigma \in S)$ can be constructed in $\mathrm{DTIME}(2^{2^{\mathrm{lin}\|M\|}})$.

We recall from the proof of Theorem 2.1 the definition of $Q_1,\dots,Q_k$ and of $n_i := \#Q_i$ $(i \in [k])$. In order to prepare the construction of S and $\bar{M}_\sigma, \bar{M}'_\sigma$ $(\sigma \in S)$ we have to carry out the following procedure.

ALGORITHM 1.

1. Remove all useless states from M. Let without loss of generality M be trim.
2. Compute $Q_1,\dots,Q_k$ and $n_1,\dots,n_k$.
3. Compute $\mathrm{im}(\delta)$, $\mathrm{iml}(\delta)$, $\mathrm{diff}(\delta)$ and $(n^3-1)\cdot\mathrm{diff}(\delta)$.
4. Compute $Q_I \cap Q_i$, $Q_F \cap Q_i$ (for all $1 \le i \le k$) and $(n^2 \cdot \sum_{i=i_1}^{i_2} n_i - 1)\cdot\mathrm{diff}(\delta)$ (for all $1 \le i_1 \le i_2 \le k$).

Note that in 1 and 2 we apply depth-first search, the computation of strongly connected components and topological sort (see [AHU74]) to directed graphs attached to M. It is easy to see that Algorithm 1 can be realized in $O(\mathrm{poly}\|M\|)$ time. Using the results of Algorithm 1, all members of the set S can be generated in $O(\#S \cdot \mathrm{poly}\|M\|)$ time.

Let $\sigma \in S$. Let $\sigma = (q_I,(j_1,p'_{j_1},\sigma_{j_1},q'_{j_1}),\dots,(j_l,p'_{j_l},\sigma_{j_l},q'_{j_l}),q_F)$ and J, J_1, J_2, $\tilde{n}_j$ $(j \in J)$, z_j $(j \in J_1)$ and $(t_j,\tilde{p}_j,\tilde{q}_j)$ $(j \in J_2)$ be given as in step (3) of the proof of Theorem 2.1. We recall from there the NGSM $M_{\sigma,j} = (Q_{\sigma,0},\Sigma,\Delta,\delta_{\sigma,j},Q_{I,\sigma,j},Q_{F,\sigma,j})$

$(j \in J)$ and the NFT $M_\sigma = (Q_\sigma, \Sigma, \Delta, \delta_\sigma, Q_{I,\sigma}, Q_{F,\sigma})$. We recall from the proof of Theorem 2.2 the DFA $M'_{\sigma,j} = (Q'_{\sigma,0}, \Sigma, \delta'_{\sigma,j}, Q'_{I,\sigma,j}, Q'_{F,\sigma,j})$ $(j \in J)$ and the ε-NFA $M'_\sigma = (Q'_\sigma, \Sigma, \delta'_\sigma, Q'_{I,\sigma}, Q'_{F,\sigma})$.

In order to construct $M_{\sigma,j}$ (for all $j \in J$), M_σ and $\bar{M}_\sigma$ we may proceed as follows.

ALGORITHM 2.

1. Generate all members of $Q_{\sigma,0}$.
2. For all $j \in J$ do the following:
   (a) Generate all members of $Q_{I,\sigma,j}$ and $Q_{F,\sigma,j}$.
   (b) For all $(r,s) \in Q^2_{\sigma,0}$ and for all $(p,a,z,q) \in \delta$, decide whether $(r,a,z,s) \in \delta_{\sigma,j}$.
3. Using $Q_{\sigma,0}$, generate all members of Q_σ, $Q_{I,\sigma}$, and $Q_{F,\sigma}$.
4. Using $M_{\sigma,j}$ $(j \in J)$, decide for all $(r,s) \in Q^2_\sigma$ whether $(r,\varepsilon,\varepsilon,s) \in \delta_\sigma$, and for all $(p,a,z,q) \in \delta$ whether $(r,a,z,s) \in \delta_\sigma$.
5. Using M_σ, construct the NGSM $\bar{M}_\sigma$.

Note that in 5 we apply again depth-first search. Recall that $\#J < n$ and $\|M_{\sigma,j}\| = O(\text{poly}\|M\|)$ $(j \in J)$. It is easy to see that Algorithm 2 can be realized using $O(\#Q^2_{\sigma,0} \cdot \text{poly}\|M\|)$ time for 1–2, $O(\#Q^2_\sigma \cdot \text{poly}(2^{\|M\|}))$ time for 3–4, and $O(\text{poly}\|M_\sigma\|)$ time for 5. According to Fact 2.9, all these bounds are of order $O(2^{2^{\text{lin}\|M\|}})$.

In order to construct $M'_{\sigma,j}$ (for all $j \in J$), M'_σ and $\bar{M}'_\sigma$ we may proceed as follows.

ALGORITHM 3.

1. Using $Q_{\sigma,0}$, generate all members of $Q'_{\sigma,0}$.
2. For all $j \in J$ do the following.
   (a) Using $M_{\sigma,j}$, generate all members of $Q'_{I,\sigma,j}$, and $Q'_{F,\sigma,j}$.
   (b) Using $\delta_{\sigma,j}$, determine for all $(B,a) \in Q'_{\sigma,0} \times \Sigma$ the unique $B' \in Q'_{\sigma,0}$ so that $(B,a,B') \in \delta'_{\sigma,j}$.
3. Using $Q'_{\sigma,0}$, generate all members of Q'_σ, $Q'_{I,\sigma}$, and $Q'_{F,\sigma}$.
4. Using $M'_{\sigma,j}$ $(j \in J)$, decide for all $(r,a,s) \in Q'_\sigma \times (\Sigma \cup \{\varepsilon\}) \times Q'_\sigma$ whether $(r,a,s) \in \delta'_\sigma$.
5. Using M'_σ, construct the NFA $\bar{M}'_\sigma$.

Note that in 5 we apply again depth-first search. Recall that $\#J < n$, $\|M_{\sigma,j}\| = O(\text{poly}\|M\|)$ and $\|M'_{\sigma,j}\| = O(2^{\text{poly}\|M\|})$ $(j \in J)$. It is easy to see that Algorithm 3 can be realized using $O(\#Q'_{\sigma,0} \cdot \text{poly}\|M\|)$ time for 1–2, $O((\#Q'_\sigma)^2 \cdot 2^{\text{poly}\|M\|})$ time for 3–4, and $O(\text{poly}\|M'_\sigma\|)$ time for 5. According to Fact 2.10, all these bounds are of order $O(2^{2^{\text{lin}\|M\|}})$.

This completes the proof of Theorem 2.3. □

3. Deciding the equivalence of finite-valued NGSMs. Let M_0 and M be NGSMs with coinciding input (and output) alphabets so that M is finite valued. Applying the Theorems 2.1–2.3 to M we can construct in DTIME$(\|M_0\|^{2^{\text{poly}\|M\|}})$ a nondeterministic finite 1-turn $2N$-counter machine (see [GI81]), where $N = O(2^{\text{poly}\|M\|})$ is as in Theorem 2.1, which has $O(\|M_0\|^{2^{\text{poly}\|M\|}})$ transitions, and which recognizes the language $L_0 := \{x \in L(M_0) \mid \text{there is a value } z \text{ for } x \text{ in } M_0 \text{ so that } (x,z) \notin T(M)\}$. Applying a result of Gurari and Ibarra [GI81] to this counter machine we obtain the following.

(1) If $T(M_0)$ is not included in $T(M)$, then there is an $x \in L_0$ such that $|x|$ is of order $O(\|M_0\|^{2^{\text{poly}\|M\|}})$.

(2) It is decidable in DTIME$(\|M_0\|^{2^{\text{poly}\|M\|}})$ whether or not $T(M_0)$ is included in $T(M)$.

(1) means: Noninclusion of $T(M_0)$ in $T(M)$ can be detected by a witness of length $O(\|M_0\|^{2^{\mathrm{poly}\|M\|}})$. We remark that the bounds in (1) and (2) are rather "machine oriented." It seems lengthy to analyse them exactly.

In this section we present a combinatorial word lemma (Lemma 3.6), which yields, together with the Theorems 2.1–2.2, an exact version of (1) (see Theorem 3.1). From this and from the Theorems 2.1–2.3 a proof of (2) can be easily derived (see Theorem 3.2).

The main result of this section is the following theorem.

THEOREM 3.1. *Let M_0 and M be* NGSMs *with coinciding input* (*and output*) *alphabets so that M is finite valued. If $T(M_0)$ is not included in $T(M)$, then there is a witness $(x, z) \in T(M_0)\backslash T(M)$ such that $|x|$ is of order $O(\|M_0\| \cdot 2^{2^{\mathrm{poly}\|M\|}})$. In detail, let $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$, $n_0 := \#Q_0$, $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$, and $n := \#Q$, then $|x| < e \cdot N! \cdot n_0 \cdot \bar{n}^N$, where*

$$N \leq \begin{cases} (5^{1/2} \cdot 3^{2/3})^n \cdot n^{4\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+3)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{diff}(\delta)} & \text{if } \#\Delta > 1, \\ (5^{1/2} \cdot 3^{4/3})^n \cdot n^{6\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+2)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1 + \mathrm{diff}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1, \end{cases}$$

and $\bar{n} \leq 2^{n\cdot(2^{n+1}+8)} \cdot 2^{2n^8\cdot(1+\mathrm{diff}(\delta))\cdot(2+\mathrm{iml}(\delta))}$.

We will also show that the Theorems 2.1–2.3 and 3.1 imply the following theorem.

THEOREM 3.2. *Let M_0 and M be* NGSM*s with coinciding input* (*and output*) *alphabets so that M is finite valued. It is decidable in* DTIME $(\|M_0\|^{2^{\mathrm{poly}\|M\|}})$ *whether or not $T(M_0)$ is included in $T(M)$.*

We want to point out that the basic problem of the Theorems 3.1 and 3.2 is to verify that some $(x, z) \in T(M_0)$ does *not* belong to $T(M)$. By reduction, the Theorems 3.1 and 3.2 can be generalized to NFTs (Theorems 4.2 and 4.3). Going with the title of this section we state the following immediate corollary to Theorem 3.2.

THEOREM 3.3 (see [CK86]). *Let M_0 and M be finite-valued* NGSMs *with coinciding input* (*and output*) *alphabets. It is decidable in* DTIME $(2^{2^{\mathrm{poly}(\|M_0\|+\|M\|)}})$ *whether or not M_0 and M are equivalent.*

Note. Theorem 3.1 alone implies a

$$\mathrm{DTIME}\,(2^{\|M_0\|^{2^{\mathrm{poly}\|M\|}}}) \quad \text{and} \quad \mathrm{DSPACE}\,(\|M_0\|^{2^{\mathrm{poly}\|M\|}})$$

algorithm for the decision problem in Theorem 3.2. This algorithm just tests all

$$O(2^{\|M_0\|^{2^{\mathrm{poly}\|M\|}}})$$

candidates (x, z) with "small" $|x|$, as proposed by Theorem 3.1, on membership in $T(M_0)$ $\backslash T(M)$.

In [N79] Nozaki constructed for any given $n \geq 6$ two nonequivalent NFAs having n states and 4 input symbols such that the shortest word in the symmetric difference of the languages recognized by them has length at least $2^{n-4} + 1$. From this follows that each improvement of the upper bound for $|x|$ stated in Theorem 3.1 has to stop at $2^{n-4} + 2$, even if $\#\Delta = 1$ and M_0 and M are single valued. If $\#\Delta = 1$, then we conjecture that the upper bound for $|x|$ in Theorem 3.1 can be improved to $O(2^{\mathrm{poly}(\|M_0\|+\|M\|)})$.

Since the equivalence problem for NFAs is PSPACE-complete (see [GJ79]), the decision problems in the Theorems 3.2 and 3.3 are PSPACE-hard, even if M_0 and M are single valued and have only one output symbol. It is an open question whether these decision problems can be solved in DTIME $(2^{\mathrm{poly}(\|M_0\|+\|M\|)})$, even in the case of a unitary output alphabet.

In order to prove the Theorems 3.1 and 3.2 we first of all introduce a little Ramsey theory including an upper bound for certain Ramsey numbers (Proposition 3.4). After that, we will establish a combinatorial word lemma (Lemma 3.6), which generalizes a word lemma by Schützenberger [Sch76] (Lemma 3.5) and may be of interest. Finally, we will use the Theorems 2.1–2.3 and Lemma 3.6 in order to prove the Theorems 3.1 and 3.2, successively.

For a general background on Ramsey theory we refer to [GRS80]. Let $A \subseteq \mathbb{N}$, then $\binom{A}{2}$ denotes the set $\{B \subseteq A \mid \#B = 2\}$. Let $N \in \mathbb{N}$, then the *Ramsey number* $R(3;N)$ denotes the minimal $l \in \mathbb{N}$ having the following property.

($*$) Given any mapping $\varphi\colon \binom{[l]}{2} \longrightarrow [N]$, there is a set $A \subseteq [l]$ such that $\#A = 3$ and, for some $i \in [N]$, $\varphi(\binom{A}{2}) = \{i\}$.

By Ramsey's theorem, such an l exists. Note that every $l \geq R(3;N)$ has property ($*$) and that, for every $N' \geq N$, $R(3;N') \geq R(3;N)$. As exact values, it is only known that $R(3;1) = 3$, $R(3;2) = 6$, and $R(3;3) = 17$ (see [Be79, Chap. 19.3]). In general, $R(3;N) \geq (3^N + 3)/2$ (see [GRS80, Chap. 4.5]). Here, we need the following upper bound for $R(3;N)$.

PROPOSITION 3.4. *Let $N \in \mathbb{N}$. Then, $R(3;N) \leq 1 + N! \cdot \sum_{i=0}^{N}(1/i!) \leq \lceil e \cdot N! \rceil$.*

Proof. See [Be79, Chap. 19.3]. □

LEMMA 3.5 (Schützenberger [Sch76]). *Let Δ be some nonempty finite set. Let $z_1, z_2, z_3, z_4, z_1', z_2', z_3', z_4' \in \Delta^*$ such that $z_1z_4 = z_1'z_4'$, $z_1z_2z_4 = z_1'z_2'z_4'$, and $z_1z_3z_4 = z_1'z_3'z_4'$. Then, $z_1z_2z_3z_4 = z_1'z_2'z_3'z_4'$.*

Proof. Because of symmetry we may assume that $|z_1| \geq |z_1'|$. $z_1z_4 = z_1'z_4'$ implies that, for some $z \in \Delta^*$, $z_1 = z_1'z$ and $zz_4 = z_4'$. Thus, $zz_2 = z_2'z$ and $zz_3 = z_3'z$. In summary, we know: $z_1z_2z_3z_4 = z_1'zz_2z_3z_4 = z_1'z_2'zz_3z_4 = z_1'z_2'z_3'zz_4 = z_1'z_2'z_3'z_4'$. □

LEMMA 3.6. *Let Δ be some nonempty finite set, and let K be a nonempty finite subset of $\mathbb{N}$. Let $l \geq R(3;\#K)$, let $\varphi\colon \binom{[l]}{2} \longrightarrow 2^K\backslash\{\emptyset\}$, and let $z_{i,j} \in \Delta^*$ ($i \in K \cup \{0\}$, $j \in [l+1]$) such that, for all $1 \leq j_1 < j_2 \leq l$ and for all $i \in \varphi(\{j_1, j_2\})$,*

$$z_{0,1} \cdots z_{0,j_1} z_{0,j_2+1} \cdots z_{0,l+1} = z_{i,1} \cdots z_{i,j_1} z_{i,j_2+1} \cdots z_{i,l+1}.$$

Then, for some $i_0 \in K$, $z_{0,1} \ldots z_{0,l+1} = z_{i_0,1} \ldots z_{i_0,l+1}$.

Proof. According to the definition of $R(3;\#K)$, there are $i_0 \in K$ and $1 \leq j_1 < j_2 < j_3 \leq l$ such that $i_0 \in \varphi(\{j_1,j_2\}) \cap \varphi(\{j_1,j_3\}) \cap \varphi(\{j_2,j_3\})$. Thus, we can apply Lemma 3.5 to $z_1 := z_{0,1} \ldots z_{0,j_1}$, $z_2 := z_{0,j_1+1} \ldots z_{0,j_2}$, $z_3 := z_{0,j_2+1} \ldots z_{0,j_3}$, $z_4 := z_{0,j_3+1} \ldots z_{0,l+1}$ and $z_1' := z_{i_0,1} \ldots z_{i_0,j_1}$, $z_2' := z_{i_0,j_1+1} \ldots z_{i_0,j_2}$, $z_3' := z_{i_0,j_2+1} \ldots z_{i_0,j_3}$, $z_4' := z_{i_0,j_3+1} \ldots z_{i_0,l+1}$, which yields

$$z_{0,1} \ldots z_{0,l+1} = z_1z_2z_3z_4 = z_1'z_2'z_3'z_4' = z_{i_0,1} \ldots z_{i_0,l+1}. \qquad \square$$

Proof of Theorem 3.1. Let $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ and $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be NGSMs with n_0 and n states, respectively, so that M is finite valued. If $L(M_0) \not\subseteq L(M)$, then the well-known subset construction (see, e.g., [HU79]) applied to an NFA recognizing $L(M)$ yields a witness $(x,z) \in T(M_0)\backslash T(M)$ such that $|x|$ is smaller than $n_0 \cdot 2^n$. Thus, we may assume that $L(M_0) \subseteq L(M)$. By Lemma A.1 we can apply the Theorems 2.1 and 2.2 to M. Let $M_1, \ldots, M_N$ and $M_1', \ldots, M_N'$ be the NGSMs and NFAs, respectively, the existence of which is claimed in these theorems.

Let $M_i = (Q_i, \Sigma, \Delta, \delta_i, Q_{I,i}, Q_{F,i})$, $n_i := \#Q_i$, $M_i' = (Q_i', \Sigma, \delta_i', Q_{I,i}', Q_{F,i}')$, $n_i' := \#Q_i'$, $\bar{n}_i := \max\{n_i, n_i'\}$ $(i = 1, \dots, N)$, and let $\bar{n} := \max\{\bar{n}_1, \dots, \bar{n}_N\}$. Then, $M_1, \dots, M_N$ are single valued, $T(M)$ equals $T(M_1) \cup \dots \cup T(M_N)$, M_i' recognizes $\Sigma^* \backslash L(M_i)$ $(i = 1, \dots, N)$, and N and $\bar{n}$ are bounded as desired.

Using Proposition 3.4, the theorem follows from the assertion $(*)$.

$(*)$ If $T(M_0)$ is not included in $T(M)$ and if $(x, z) \in T(M_0) \backslash \bigcup_{i=1}^N T(M_i)$ such that $|x|$ is minimal, then $|x|$ is smaller than $(R(3; N) - 1) \cdot n_0 \cdot \prod_{i=1}^N \bar{n}_i$.

Proof of $(*)$. Let (x, z) be as in $(*)$. We assume that $|x| \geq (R(3; N) - 1) \cdot n_0 \cdot \prod_{i=1}^N \bar{n}_i$. Define $K := \{i \in [N] \mid x \in L(M_i)\}$ and $K' := [N] \backslash K$. Since $x \in L(M_0) \subseteq L(M)$, K is nonempty. Let π_0 be an accepting path in M_0 realizing (x, z). Let π_i (for all $i \in K$) and π_i' (for all $i \in K'$) be accepting paths in M_i and M_i', respectively, all consuming x. Since $|x| \geq (R(3; N) - 1) \cdot n_0 \cdot \prod_{i=1}^N \bar{n}_i$, there are at least $R(3; N)$ different prefixes $y_1, y_1 y_2, \dots, y_1 \dots y_l$ of $x = y_1 \dots y_l y_{l+1}$ and states $q_i \in Q_i$ (for all $i \in K \cup \{0\}$) and $q_i' \in Q_i'$ (for all $i \in K'$) such that the following holds.

- For each $i \in K \cup \{0\}$: Consider the uniquely determined paths $\pi_{i,1}, \dots, \pi_{i,l+1}$ in M_i consuming $y_1, \dots, y_{l+1}$, respectively, such that $\pi_i = \pi_{i,1} \circ \dots \circ \pi_{i,l+1}$. Then, each of the paths $\pi_{i,2}, \dots, \pi_{i,l}$ leads from q_i to q_i.
- For each $i \in K'$: Consider the uniquely determined paths $\pi_{i,1}', \dots, \pi_{i,l+1}'$ in M_i' consuming $y_1, \dots, y_{l+1}$, respectively, such that $\pi_i' = \pi_{i,1}' \circ \dots \circ \pi_{i,l+1}'$. Then, each of the paths $\pi_{i,2}', \dots, \pi_{i,l}'$ leads from q_i' to q_i'.

For all $(i, j) \in (K \cup \{0\}) \times [l+1]$ let $z_{i,j} \in \Delta^*$ be the word produced by $\pi_{i,j}$. Consider the mapping $\varphi \colon \binom{[l]}{2} \longrightarrow 2^K$, where for all $1 \leq j_1 < j_2 \leq l$

$$\varphi(\{j_1, j_2\}) := \{i \in K \mid z_{0,1} \dots z_{0,j_1} z_{0,j_2+1} \dots z_{0,l+1} = z_{i,1} \dots z_{i,j_1} z_{i,j_2+1} \dots z_{i,l+1}\}.$$

Since $|x|$ is minimal and $M_1, \dots, M_N$ are single valued, each $\varphi(\{j_1, j_2\})$ is nonempty. Thus, we can apply Lemma 3.6 to K, l, φ, and to $z_{i,j} \in \Delta^*$ $(i \in K \cup \{0\}, j \in [l+1])$, which yields an $i_0 \in K$ such that $(x, z) = (x, z_{0,1} \dots z_{0,l+1}) = (x, z_{i_0,1} \dots z_{i_0,l+1}) \in T(M_{i_0})$ (Contradiction!) Therefore, $|x|$ is smaller than $(R(3; N) - 1) \cdot n_0 \cdot \prod_{i=1}^N \bar{n}_i$. □

Note that in previous versions of the proof of Theorem 3.1 (see [W88]) Ramsey numbers were used only in an implicit way. We want to point out that from work by Lisovik ([L79a, Lem. 1.1], see also [L80, Thm. 1]) it can be derived that Schützenberger's lemma (Lemma 3.5) implies the above assertion $(*)$ with the upper bound $3 \cdot N! \cdot n_0 \cdot \prod_{i=1}^N \bar{n}_i$ for $|x|$. Lisovik's proof methods are basically similar to ours. The above assertion $(*)$ can be also proved using an approach due to Turakainen [T89], which is based on some results on $\mathcal{Q}$-rational languages [T88, §2]. By this alternative proof, the upper bound for $|x|$ in Theorem 3.1 can be improved to $3^N \cdot n_0 \cdot \bar{n}^N$.

Proof of Theorem 3.2. Let $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ and $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be NGSMs with n_0 and n states, respectively, so that M is finite valued. If $L(M_0) \not\subseteq L(M)$, then $T(M_0) \not\subseteq T(M)$. The above condition is decidable in DTIME $(\mathrm{poly}\|M_0\| \cdot 2^{\mathrm{lin}\|M\|})$ (see, e.g., [HU79]), so we may assume that $L(M_0) \subseteq L(M)$. By Lemma A.1 we can apply the Theorems 2.1 and 2.2 to M. Let $M_1, \dots, M_N$ and $M_1', \dots, M_N'$ be the NGSMs and NFAs, respectively, constructed by these theorems. Let $M_i = (Q_i, \Sigma, \Delta, \delta_i, Q_{I,i}, Q_{F,i})$, $n_i := \#Q_i$, $M_i' = (Q_i', \Sigma, \delta_i', Q_{I,i}', Q_{F,i}')$, $n_i' := \#Q_i'$, $\bar{n}_i := \max\{n_i, n_i'\}$ $(i = 1, \dots, N)$, and let $\bar{n} := \max\{\bar{n}_1, \dots, \bar{n}_N\}$. Then, $M_1, \dots, M_N$ are single valued, $T(M)$ equals $T(M_1) \cup \dots \cup T(M_N)$, M_i' recognizes $\Sigma^* \backslash L(M_i)$ $(i = 1, \dots, N)$, the quantities $N = O(2^{\mathrm{poly}\|M\|})$ and $\bar{n} = O(2^{2^{\mathrm{lin}\|M\|}})$ are bounded as in Theorem 3.1, and, for each $i \in [N]$, $\mathrm{im}(\delta_i)$ is included in $\mathrm{im}(\delta)$ and $\mathrm{diff}(\delta_i, \delta_0)$ is at most $\mathrm{diff}(\delta, \delta_0)$. The last two properties are stated in Fact 2.9.

Using Proposition 3.4, the assertion $(*)$ in the proof of Theorem 3.1 implies

$(\#)$ $T(M_0)$ is not included in $T(M)$ if and only if there is an accepting path π_0 in M_0 realizing some $(x, z_0) \in \Sigma^* \times \Delta^*$ and there are subsets K, K_1, K_2 of $[N]$ such that the following assertions are true.

- $K = K_1 \cup K_2$ and $K_1 \cap K_2 = \emptyset$.
- For each $i \in K$: There is an accepting path π_i in M_i and a word $z_i \in \Delta^*$ so that π_i realizes (x, z_i), $\operatorname{diff}(\pi_i, \pi_0)$ is at most $3 \cdot N! \cdot n_0 \cdot \bar{n}^N \cdot \operatorname{diff}(\delta_i, \delta_0)$, $|z_i|$ is distinct from $|z_0|$ (if $i \in K_1$) and z_i and z_0 differ at some position $j \in \min\{|z_i|, |z_0|\}$ (if $i \in K_2$).
- For each $i \in [N] \backslash K$: There is an accepting path π_i' in M_i' consuming x.

Note. $(\#)$ remains true if we omit all upper bounds for $\operatorname{diff}(\pi_i, \pi_0)$.

We will transform the assertion $(\#)$ into a simple characterization of the noninclusion at issue, which is based on graphs. For this, let us consider $K, K_1, K_2, K' \subseteq [N]$ so that $K = K_1 \cup K_2$, $K_1 \cap K_2 = \emptyset$ and $K' = [N] \backslash K$. Then, following [W90, §3], we construct the directed graph $G_{K_1,K_2} = (V, E)$ (for comments see below):

$$\begin{aligned}
V \;:=\;& Q_0 \times \prod_{i \in K_1} (Q_i \times Z_i) \times \prod_{i \in K_2} (Q_i \times (\Delta \,\dot{\cup}\, \{1,2\}) \times Z_i) \times \prod_{i \in K'} Q_i', \\
& \text{where} \quad Z_i := \{t \in \mathcal{Z} \mid |t| \le 3 \cdot N! \cdot n_0 \cdot \bar{n}^N \cdot \operatorname{diff}(\delta_i, \delta_0)\} \quad (i \in K), \\
E \;:=\;& \{((p_0, ((p_i, t_i))_{i \in K_1}, ((p_i, b_i, t_i))_{i \in K_2}, (p_i')_{i \in K'}), \\
& (q_0, ((q_i, t_i'))_{i \in K_1}, ((q_i, b_i', t_i'))_{i \in K_2}, (q_i')_{i \in K'}) \in V^2 \mid \\
& \exists a \in \Sigma \quad \exists (z_i)_{i \in K \cup \{0\}} \in \prod_{i \in K \cup \{0\}} \Delta^* : \\
& [\forall i \in K \cup \{0\} \colon (p_i, a, z_i, q_i) \in \delta_i] \quad \& \quad [\forall i \in K' \colon (p_i', a, q_i') \in \delta_i'] \quad \& \\
& [\forall i \in K_1 \colon t_i' = t_i + |z_i| - |z_0|] \quad \& \quad [\forall i \in K_2 \colon \\
& (b_i = b_i' = 1 \quad \& \quad t_i' = t_i + |z_i| - |z_0|) \quad \vee \\
& (b_i = 1 \quad \& \quad \exists j \in [|z_i|] \colon \quad b_i' = z_i(j) \in \Delta \quad \& \quad t_i' = t_i + j - |z_0| > 0) \quad \vee \\
& (b_i = 1 \quad \& \quad \exists j \in [|z_0|] \colon \quad b_i' = z_0(j) \in \Delta \quad \& \quad t_i' = t_i + |z_i| - j < 0) \quad \vee \\
& (b_i = b_i' \in \Delta \quad \& \quad t_i' = t_i - |z_0| > 0) \quad \vee \\
& (b_i = b_i' \in \Delta \quad \& \quad t_i' = t_i + |z_i| < 0) \quad \vee \\
& ((b_i, t_i) \in \Delta \times [|z_0|] \quad \& \quad b_i \ne z_0(t_i) \quad \& \quad (b_i', t_i') = (2, 0)) \quad \vee \\
& ((b_i, -t_i) \in \Delta \times [|z_i|] \quad \& \quad b_i \ne z_i(-t_i) \quad \& \quad (b_i', t_i') = (2, 0)) \quad \vee \\
& (b_i = 1 \quad \& \quad \exists j \in [|z_i|] \colon \quad t_i + j \in [|z_0|] \quad \& \quad z_i(j) \ne z_0(t_i + j) \quad \& \\
& (b_i', t_i') = (2, 0)) \quad \vee \quad (b_i = b_i' = 2 \quad \& \quad t_i = t_i' = 0)]\}.
\end{aligned}$$

The construction of G_{K_1,K_2} requires some explanation.

First of all, a path π in G_{K_1,K_2}, regarding its behavior on the Q_i- and Q_i'-components of V, yields an $(N+1)$-tuple of paths π_i in M_i $(i \in K \cup \{0\})$ and π_i' in M_i' $(i \in K')$, all consuming the same word in Σ^*. Let $z_i \in \Delta^*$ be the word produced by π_i $(i \in K \cup \{0\})$. Let $i \in K_1$. Assume that, on the Z_i-component of V, the given path π leads from $t_i \in Z_i$ to $t_i' \in Z_i$. Then, $t_i' - t_i = |z_i| - |z_0|$. Let $i \in K_2$. Assume that, on the $(\Delta \cup \{1,2\}) \times Z_i$-component of V, π leads from $(1, 0)$ to $(2, 0)$. Then, z_i and z_0 differ at some position $j \in \min\{|z_i|, |z_0|\}$. In order to verify this, the path π "guesses" a position $j \in [|z_i|]$ (or, alternatively, a position $j \in [|z_0|]$), remembers the letter $z_i(j)$ (respectively, $z_0(j)$) until the jth letter of z_0 (respectively, z_i) can be seen, and verifies that $z_i(j)$ and $z_0(j)$ are distinct.

Conversely, let us consider an $(N+1)$-tuple $((\pi_i)_{i\in K\cup\{0\}}, (\pi'_i)_{i\in K'})$ of paths in M_i and in M'_i (as above), all consuming the same word in Σ^*. Let $z_i \in \Delta^*$ be the word produced by π_i ($i \in K \cup \{0\}$). Assume that, for all $i \in K$, $\mathrm{diff}(\pi_i, \pi_0)$ is at most $3 \cdot N! \cdot n_0 \cdot \bar{n}^N \cdot \mathrm{diff}(\delta_i, \delta_0)$ and that, for all $i \in K_2$, z_i and z_0 differ at some position $j \in \min\{|z_i|, |z_0|\}$. Then, the given $(N+1)$-tuple of paths induces a path π in G_{K_1,K_2} as follows: The behavior of π on the Q_i- and Q'_i-components of V is inherited from the given paths. On the Z_i-component of V ($i \in K_1$) π leads from 0 to $|z_i| - |z_0|$. On the $(\Delta \cup \{1,2\}) \times Z_i$-component of V ($i \in K_2$) π leads from $(1,0)$ to $(2,0)$; the detailed behavior of π on this component is as above.

We define the sets $V_{I,K_1,K_2}, V_{F,K_1,K_2} \subseteq V$ as follows.

$$\begin{aligned} V_{I,K_1,K_2} &:= Q_{I,0} \times \prod_{i\in K_1} (Q_{I,i} \times \{0\}) \times \prod_{i\in K_2} (Q_{I,i} \times \{(1,0)\}) \times \prod_{i\in K'} Q'_{I,i}, \\ V_{F,K_1,K_2} &:= Q_{F,0} \times \prod_{i\in K_1} (Q_{F,i} \times Z_i\backslash\{0\}) \times \prod_{i\in K_2} (Q_{F,i} \times \{(2,0)\}) \times \prod_{i\in K'} Q'_{F,i}. \end{aligned}$$

Then, the above discussion shows that (#) implies

(§) $T(M_0)$ is not included in $T(M)$ if and only if, for some $K_1, K_2 \subseteq [N]$ with $K_1 \cap K_2 = \emptyset$, there is a path in G_{K_1,K_2} leading from V_{I,K_1,K_2} to V_{F,K_1,K_2}.

Note. $\#V \le (6\cdot N!)^N \cdot n_0^{N+1} \cdot \bar{n}^{N\cdot(N+1)} \cdot (1+\mathrm{diff}(\delta,\delta_0))^N \cdot (2+\#\Delta)^N$ and $\#E \le \#V^2$, i.e., $\#V$ and $\#E$ are of order $O(\|M_0\|^{2^{\mathrm{poly}\|M\|}})$.

We sketch an algorithm that decides according to (§) whether or not $T(M_0)$ is included in $T(M)$:

1. Construct the NGSMs $M_1, \ldots, M_N$ and the NFAs $M'_1, \ldots, M'_N$.
2. For each $K_1, K_2 \subseteq [N]$ with $K_1 \cap K_2 = \emptyset$ do the following:
   (a) Construct G_{K_1,K_2}, V_{I,K_1,K_2} and V_{F,K_1,K_2}.
   (b) Decide whether or not there is a path in G_{K_1,K_2} leading from V_{I,K_1,K_2} to V_{F,K_1,K_2}.

Note that in step 2(b) we apply depth-first search (see [AHU74]) to G_{K_1,K_2}. According to Theorem 2.3, step 1 of the above algorithm requires DTIME $(2^{2^{\mathrm{lin}\|M\|}})$. The loop in step 2 is passed 3^N times. Let $K_1, K_2 \subseteq [N]$ such that $K_1 \cap K_2 = \emptyset$, and let $G_{K_1,K_2} = (V, E)$. Step 2 for (K_1, K_2) can be realized using $O(\mathrm{poly}(\#V + \|M_0\| \cdot \|M\|^N))$ time for 2(a) and $O(\mathrm{poly}(\#V + \#E))$ time for 2(b). All these bounds are of order $O(\|M_0\|^{2^{\mathrm{poly}\|M\|}})$.

This completes the proof of Theorem 3.2. □

4. Normalized finite transducers. In this section we generalize the main results of this paper (Theorems 2.1–2.3 and 3.1–3.2) to NFTs. The outcome is stated in the Theorems 4.1–4.3.

THEOREM 4.1. *Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be a finite-valued* NFT *with n states. Then, $O(2^{\mathrm{poly}\|M\|})$ many single-valued* NFTs *$M_1, \ldots, M_N$ and ε-*NFAs *$M'_1, \ldots, M'_N$ — each of size $O(2^{2^{\mathrm{lin}\|M\|}})$ — effectively exist such that $T(M)$ equals $T(M_1) \cup \ldots \cup T(M_N)$ and M'_i recognizes $\Sigma^*\backslash L(M_i)$ ($i = 1, \ldots, N$). In detail, N is at most*

$$\begin{cases} (5^{1/2}\cdot 3^{2/3})^n \cdot n^{4\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+3)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1+\mathrm{iml}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\mathrm{iml}(\delta)} & \text{if } \#\Delta > 1, \\ (5^{1/2}\cdot 3^{4/3})^n \cdot n^{6\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+2)} \cdot (\#\mathrm{im}(\delta))^{n-1} & \\ \cdot(1+\mathrm{iml}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1. \end{cases}$$

The NFTs $M_1, \dots, M_N$, *and the* ε-NFAs $M'_1, \dots, M'_N$, *can be constructed in* DTIME $(2^{2^{\text{lin}\|M\|}})$.

THEOREM 4.2. *Let* M_0 *and* M *be* NFTs *with coinciding input (and output) alphabets so that* M *is finite valued. If* $T(M_0)$ *is not included in* $T(M)$, *then there is a witness* $(x, z) \in T(M_0)\backslash T(M)$ *such that* $|x|$ *is of order* $O(\|M_0\| \cdot 2^{2^{\text{poly}\|M\|}})$. *In detail, let* $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$, $n_0 := \#Q_0$, $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$, *and* $n := \#Q$, *then* $|x| < e \cdot N! \cdot n_0 \cdot \bar{n}^N$, *where*

$$N \leq \begin{cases} (5^{1/2} \cdot 3^{2/3})^n \cdot n^{4\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+3)} \cdot (\#\text{im}(\delta))^{n-1} & \\ \cdot(1 + \text{iml}(\delta))^{n-1} \cdot \#\Delta^{2\cdot(n^3-1)\cdot\text{iml}(\delta)} & \text{if } \#\Delta > 1, \\ (5^{1/2} \cdot 3^{4/3})^n \cdot n^{6\cdot(n-1)} \cdot 2^{(n-1)\cdot(n+2)} \cdot (\#\text{im}(\delta))^{n-1} & \\ \cdot(1 + \text{iml}(\delta))^{2\cdot(n-1)} & \text{if } \#\Delta = 1, \end{cases}$$

and $\bar{n} \leq 2^{n\cdot(2^{n+1}+8)} \cdot 2^{2n^8\cdot(2+\text{iml}(\delta))^2}$.

THEOREM 4.3. *Let* M_0 *and* M *be* NFTs *with coinciding input (and output) alphabets so that* M *is finite valued. It is decidable in* DTIME $(\|M_0\|^{2^{\text{poly}\|M\|}})$ *whether or not* $T(M_0)$ *is included in* $T(M)$.

We prove the Theorems 4.1–4.3 by reduction to the Theorems 2.1–2.3 and 3.1–3.2. For this reduction we adopt from [W90, §5] the criterion (ε-IV) and the two subsequent propositions.

Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be an NFT. The criterion (ε-IV) reads as follows.

(ε-IV) There is a useful state $q \in Q$ such that, for some word $\tilde{v} \in \Delta^+$, $(q, \varepsilon, \tilde{v}, q) \in \hat{\delta}$.

PROPOSITION 4.4 (see [W90, §5]). *Let* $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ *be an* NFT *with* n *states. Then, the following assertions are true.*

(i) *If* M *complies with* (ε-*IV*), *then some word in* $\Sigma^{\leq 2\cdot(n-1)}$ *has infinite valuedness in* M.

(ii) *If* M *complies with* (ε-*IV*), *then it is infinite valued.*

(iii) *It is decidable in* DTIME (poly$\|M\|$), *whether or not* M *complies with* (ε-*IV*).

Proof. If M complies with (ε-IV), then $(u, \tilde{u}), (w, \tilde{w}) \in \Sigma^* \times \Delta^*$ and $\tilde{v} \in \Delta^+$ exist such that uw has length at most $2 \cdot (n-1)$ and, for all $i \in \mathcal{N}$, $\tilde{u}\tilde{v}^i\tilde{w}$ is a value for uw in M. Thus, $\text{val}(M) = \text{val}_M(uw) = \infty$. This implies (i) and (ii). For assertion (iii) we refer to the proof of Theorem 5.3 in [W90]. □

PROPOSITION 4.5 (see [W90, Lem. 5.5]). *Let* $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ *be an* NFT *with* n *states, which does not comply with* (ε-IV). *Then, an* NGSM $M' = (Q, \Sigma', \Delta, \delta', Q_I, Q_F)$, *where* $\Sigma' := \Sigma \dot{\cup} \{a_0\}$, *effectively exists such that the following assertions are true.*

(i) $\text{im}(\delta') = \text{im}(\delta)$, $\text{diff}(\delta') \leq \text{iml}(\delta') = \text{iml}(\delta)$,
$\|\delta\| \leq \|\delta'\| \leq \|\delta\| + n$, $\|M\| < \|M'\| \leq \|M\| + n + 1$.

(ii) M' *has the same valuedness as* M.

(iii) $\forall m \in \mathcal{N} \quad \forall x_1, \dots, x_m \in \Sigma \quad \forall \lambda_1, \dots, \lambda_{m+1} \in \mathcal{N} \quad \forall z \in \Delta^*$:
$(a_0^{\lambda_1}x_1 \dots a_0^{\lambda_m}x_m a_0^{\lambda_{m+1}}, z) \in T(M') \implies (x_1 \dots x_m, z) \in T(M)$.

(iv) $\forall m \in \mathcal{N} \quad \forall x_1, \dots, x_m \in \Sigma \quad \forall z \in \Delta^* \quad \forall \lambda_1, \dots, \lambda_{m+1} \geq n-1$:
$(x_1 \dots x_m, z) \in T(M) \implies (a_0^{\lambda_1}x_1 \dots a_0^{\lambda_m}x_m a_0^{\lambda_{m+1}}, z) \in T(M')$.

(v) M' *can be constructed in* DTIME(poly$\|M\|$).

Proof. We construct the NGSM $M' = (Q, \Sigma', \Delta, \delta', Q_I, Q_F)$:

$$\begin{aligned} \Sigma' &:= \Sigma \dot{\cup} \{a_0\}, \\ \delta' &:= (\delta \cap Q \times \Sigma \times \Delta^* \times Q) \cup \{(p, a_0, z, q) \mid (p, \varepsilon, z, q) \in \delta\} \\ &\quad \cup \{(q, a_0, \varepsilon, q) \mid q \in Q\}. \end{aligned}$$

The assertions (i), (iii), and (v) are obvious. The assertion (iv) can be proved as Claim 2 in the proof of Lemma 5.5 in [W90]. The assertion (ii) immediately follows from (iii) and (iv). □

Proof of Theorem 4.1. Let $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ be a finite-valued NFT with n states. By Proposition 4.4(ii), M does not comply with (ε-IV). Let $M^{(1)} = (Q, \Sigma^{(1)}, \Delta, \delta^{(1)}, Q_I, Q_F)$, where $\Sigma^{(1)} := \Sigma \,\dot\cup\, \{a_0\}$, be the finite-valued NGSM of size $O(\|M\|)$ which is attached to M in Proposition 4.5. $M^{(1)}$ can be constructed in DTIME (poly$\|M\|$). Applying the Theorems 2.1 and 2.2 to $M^{(1)}$ we obtain single-valued NGSMs $M_1^{(1)}, \ldots, M_N^{(1)}$ and NFAs $M_1^{(2)}, \ldots, M_N^{(2)}$ — each of size $O(2^{2^{\mathrm{lin}\|M^{(1)}\|}})$ — such that $T(M^{(1)})$ equals $T(M_1^{(1)}) \cup \ldots \cup T(M_N^{(1)})$, $M_i^{(2)}$ recognizes $(\Sigma^{(1)})^* \backslash L(M_i^{(1)})$ ($i = 1, \ldots, N$), and N is bounded as desired. By Theorem 2.3, $M_1^{(1)}, \ldots, M_N^{(1)}$ and $M_1^{(2)}, \ldots, M_N^{(2)}$ can be constructed in DTIME $(2^{2^{\mathrm{lin}\|M^{(1)}\|}})$.

Let $i \in [N]$. We attach to $M_i^{(1)} = (Q_i^{(1)}, \Sigma^{(1)}, \Delta, \delta_i^{(1)}, Q_{I,i}^{(1)}, Q_{F,i}^{(1)})$ the NFT $M_i = (Q_i, \Sigma, \Delta, \delta_i, Q_{I,i}, Q_{F,i})$, where $Q_i := Q_i^{(1)} \times \{0, \ldots, n-1\}$, $Q_{I,i} := Q_{I,i}^{(1)} \times \{0\}$, $Q_{F,i} := Q_{F,i}^{(1)} \times \{n-1\}$, and

$$\begin{aligned}\delta_i \;:=\;& \{((p, n-1), a, z, (q, 0)) \mid a \in \Sigma,\ (p, a, z, q) \in \delta_i^{(1)}\} \cup \\ & \{((p, j-1), \varepsilon, z, (q, j)) \mid j \in [n-1],\ (p, a_0, z, q) \in \delta_i^{(1)}\}.\end{aligned}$$

We attach to $M_i^{(2)} = (Q_i^{(2)}, \Sigma^{(1)}, \delta_i^{(2)}, Q_{I,i}^{(2)}, Q_{F,i}^{(2)})$ the ε-NFA $M_i' = (Q_i', \Sigma, \delta_i', Q_{I,i}', Q_{F,i}')$, where $Q_i' := Q_i^{(2)} \times \{0, \ldots, n-1\}$, $Q_{I,i}' := Q_{I,i}^{(2)} \times \{0\}$, $Q_{F,i}' := Q_{F,i}^{(2)} \times \{n-1\}$, and

$$\begin{aligned}\delta_i' \;:=\;& \{((p, n-1), a, (q, 0)) \mid a \in \Sigma,\ (p, a, q) \in \delta_i^{(2)}\} \cup \\ & \{((p, j-1), \varepsilon, (q, j)) \mid j \in [n-1],\ (p, a_0, q) \in \delta_i^{(2)}\}.\end{aligned}$$

Obviously, $\|M_i\| \le n \cdot \|M_i^{(1)}\|$ and $\|M_i'\| \le n \cdot \|M_i^{(2)}\|$. Thus, M_i and M_i' are of size $O(2^{2^{\mathrm{lin}\|M\|}})$. Given $M_i^{(1)}$, M_i can be constructed in DTIME (poly($n + \|M_i^{(1)}\|$)). Given $M_i^{(2)}$, M_i' can be constructed in DTIME (poly($n + \|M_i^{(2)}\|$)). Thus, $M_1, \ldots, M_N$ and $M_1', \ldots, M_N'$ can be constructed in DTIME $(2^{2^{\mathrm{lin}\|M\|}})$.

Proposition 4.5 and the definition of $M_1, \ldots, M_N$ and $M_1', \ldots, M_N'$ yields for all $x_1, \ldots, x_m \in \Sigma$, $z \in \Delta^*$ and $i \in [N]$:

$$\begin{aligned}(x_1 \ldots x_m, z) \in T(M) &\iff (a_0^{n-1}x_1 \ldots a_0^{n-1}x_m a_0^{n-1}, z) \in T(M^{(1)}) \quad \& \\ (x_1 \ldots x_m, z) \in T(M_i) &\iff (a_0^{n-1}x_1 \ldots a_0^{n-1}x_m a_0^{n-1}, z) \in T(M_i^{(1)}) \quad \& \\ x_1 \ldots x_m \in L(M_i') &\iff a_0^{n-1}x_1 \ldots a_0^{n-1}x_m a_0^{n-1} \in L(M_i^{(2)}).\end{aligned}$$

From this follows that $M_1, \ldots, M_N$ are all single valued, $T(M)$ equals $T(M_1) \cup \ldots \cup T(M_N)$, and M_i' recognizes $\Sigma^* \backslash L(M_i)$ ($i = 1, \ldots, N$). □

Proof of the Theorems 4.2 and 4.3. According to Proposition 4.4, we may assume that $M_0 = (Q_0, \Sigma, \Delta, \delta_0, Q_{I,0}, Q_{F,0})$ and $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ are NFTs with n_0 and n states, respectively, so that M is finite valued and M_0 and M do not comply with (ε-IV). Define $\tilde n := \max\{n, n_0\}$. Let $M' = (Q, \Sigma', \Delta, \delta', Q_I, Q_F)$, where $\Sigma' := \Sigma \,\dot\cup\, \{a_0\}$, be the finite-valued NGSM of size $O(\|M\|)$ which is attached to M in Proposition 4.5. M' can be constructed in DTIME (poly$\|M\|$).

We attach to M_0 the NGSM $M_0' = (Q_0', \Sigma', \Delta, \delta_0', Q_{I,0}', Q_{F,0}')$ where $Q_0' := Q_0 \times \{0, \ldots, \tilde{n}-1\}$, $Q_{I,0}' := Q_{I,0} \times \{0\}$, $Q_{F,0}' := Q_{F,0} \times \{\tilde{n}-1\}$, and

$$\begin{aligned}\delta_0' \; := \; & \{((p, \tilde{n}-1), a, z, (q, 0)) \mid a \in \Sigma,\ (p, a, z, q) \in \delta_0\} \cup \\ & \{((p, j-1), a_0, z, (q, j)) \mid j \in [\tilde{n}-1] \quad \& \\ & ((p, \varepsilon, z, q) \in \delta_0 \quad \vee \quad (p, z) = (q, \varepsilon) \in Q_0 \times \Delta^*)\}.\end{aligned}$$

Note that $\|M_0'\| \leq \tilde{n} \cdot (\|M_0\| + n_0)$. M_0' can be constructed in DTIME $(\mathrm{poly}(\|M_0\| + \|M\|))$. By definition, M_0' only recognizes words of the form $a_0^{\tilde{n}-1} x_1 \ldots a_0^{\tilde{n}-1} x_m a_0^{\tilde{n}-1}$, where $x_1, \ldots, x_m \in \Sigma$.

Recall that M_0 does not comply with (ε-IV). Proposition 4.5 and the definition of M_0' yields for all $x_1, \ldots, x_m \in \Sigma$ and $z \in \Delta^*$:

$$\begin{aligned}(x_1 \ldots x_m, z) \in T(M) \quad &\Longleftrightarrow \quad (a_0^{\tilde{n}-1} x_1 \ldots a_0^{\tilde{n}-1} x_m a_0^{\tilde{n}-1}, z) \in T(M') \quad \& \\ (x_1 \ldots x_m, z) \in T(M_0) \quad &\Longleftrightarrow \quad (a_0^{\tilde{n}-1} x_1 \ldots a_0^{\tilde{n}-1} x_m a_0^{\tilde{n}-1}, z) \in T(M_0').\end{aligned}$$

This implies that $T(M_0') \subseteq T(M')$ if and only if $T(M_0) \subseteq T(M)$. Thus, Theorem 3.2 applied to M_0' and M' yields Theorem 4.3.

In order to prove Theorem 4.2, let us assume that $T(M_0)$ is not included in $T(M)$, i.e., $T(M_0')$ is not included in $T(M')$. Applying Theorem 3.1 to M_0' and M', we obtain a witness $(x', z) \in T(M_0') \backslash T(M')$ such that $|x'| < e \cdot N! \cdot (n_0 \cdot \tilde{n}) \cdot \tilde{n}^N$ and N and $\tilde{n}$ are bounded as desired. Let $x_1, \ldots, x_m \in \Sigma$ so that $x' = a_0^{\tilde{n}-1} x_1 \ldots a_0^{\tilde{n}-1} x_m a_0^{\tilde{n}-1}$. Then, by the above properties of M and M_0, $(x_1 \ldots x_m, z)$ belongs to $T(M_0) \backslash T(M)$ and $|x_1 \ldots x_m| = m \leq |x'|/\tilde{n} < e \cdot N! \cdot n_0 \cdot \tilde{n}^N$. □

A. Appendix. For the sake of completeness, we state here three lemmas from [W90], which are fundamental for our proof of Theorem 2.1.

LEMMA A.1 [W90, Lems. 2.4 and 2.3(i)]. *Let M be an* NGSM. *If M complies with at least one of the criteria* (IV1), (IV2), *then it is infinite valued.*

LEMMA A.2 [W90, Lem. 2.9]. *Let* $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ *be an* NGSM. *Let* $A \in 2^Q \backslash \{\emptyset\}$ *and* $y \in \Sigma^+$ *such that the following holds: For all* $r \in A$ *there are* $s \in A$ *and* $z \in \Delta^*$ *so that* $(r, y, z, s) \in \delta$, *and for all* $s \in A$ *there are* $r \in A$ *and* $z \in \Delta^*$ *so that* $(r, y, z, s) \in \delta$. *Let* $p', q' \in A$. *Then, the following assertion is true: There are* $p, q \in A$, $p_1, p_2, p_3, p_4 \in Q$, $l_1, l_2 \geq 0$, *and* $z_1, \ldots, z_4, z_6, \ldots, z_9 \in \Delta^*$ *so that* $(p, y^{l_1}, z_1, p_1), (p_1, y, z_2, p_2), (p_2, y^{l_2}, z_3, p) \in \delta$, $(p, y^{l_1}, z_4, p'), (q', y^{l_2}, z_6, q) \in \delta$, *and* $(q, y^{l_1}, z_7, p_3), (p_3, y, z_8, p_4), (p_4, y^{l_2}, z_9, q) \in \delta$.

LEMMA A.3 [W90, Lem. 2.10]. *Let* $M = (Q, \Sigma, \Delta, \delta, Q_I, Q_F)$ *be a trim* NGSM *with n states, which does not comply with the criterion* (IV1). *Let* $U_1, U_2, U_3, U_4 \in 2^Q$ *so that* $Q = U_1 \mathbin{\dot\cup} U_2 \mathbin{\dot\cup} U_3 \mathbin{\dot\cup} U_4$ *and, for all* $1 \leq i < j \leq 4$, $\delta \cap U_j \times \Sigma^* \times \Delta^* \times U_i = \emptyset$. *Let* $A \in 2^Q \backslash \{\emptyset\}$, $y \in \Sigma^+$, $p' \in A \cap U_2$, *and* $q' \in A \cap U_3$ *such that the assertion of Lemma* A.2 *is true. Let* $p_1, p_2 \in Q$ *be taken from this assertion. If* π *and* $\tilde{\pi}$ *are paths in M consuming y and leading from* p' *to* q' *and from* p_1 *to* p_2, *respectively, then* $\mathrm{diff}(\pi, \tilde{\pi})$ *is at most* $((\#U_1 + \#U_2) \cdot (\#U_2 + \#U_3) \cdot (\#U_3 + \#U_4) - 1) \cdot \mathrm{diff}(\delta)$. *In particular, if* $\pi, \tilde{\pi}$ *produce some* $z, \tilde{z} \in \Delta^*$, *respectively, then* $||z| - |\tilde{z}|| \leq \mathrm{diff}(\pi, \tilde{\pi}) \leq (n^2 \cdot (\#U_2 + \#U_3) - 1) \cdot \mathrm{diff}(\delta)$.

Acknowledgment. During all stages of my work on this paper Helmut Seidl acted as an inexhaustible source for useful stimulations and valuable comments. The proposals by one of the referees led to an improved presentation. I highly appreciate all this help.

ONE MORE OCCURRENCE OF VARIABLES MAKES SATISFIABILITY JUMP FROM TRIVIAL TO NP-COMPLETE*

JAN KRATOCHVÍL[†], PETR SAVICKÝ[‡], AND ZSOLT TUZA[§]

Abstract. A Boolean formula in a conjunctive normal form is called a $(k, s) - formula$ if every clause contains exactly k variables and every variable occurs in at most s clauses. The $(k, s)-$SAT problem is the SATISFIABILITY problem restricted to $(k, s)-$formulas. It is proved that for every $k \geq 3$ there is an integer $f(k)$ such that $(k, s)-$SAT is trivial for $s \leq f(k)$ (because every $(k, s)-$formula is satisfiable) and is NP-complete for $s \geq f(k) + 1$. Moreover, $f(k)$ grows exponentially with k, namely, $\lfloor 2^k/ek \rfloor \leq f(k) \leq 2^{k-1} - 2^{k-4} - 1$ for $k \geq 4$.

Key words. satisfiabilty, Boolean formula, conjunctive normal form, NP-completeness

AMS(MOS) subject classifications. 68Q15, 68Q25, 05CXX

1. Introduction.

A Boolean formula in conjunctive normal form is called a $(k, s)-$*formula* if every clause contains exactly k distinct variables and every variable occurs in at most s clauses. A $(k, s)-$formula is called a $(k, = s)-$*formula* if every variable occurs in exactly s clauses. We denote by $(k, s)-$SAT (respectively, $(k, = s)-$SAT) the SATISFIABILITY problem restricted to $(k, s)-$ (respectively, $(k, = s)-$) formulas, namely,

(k, s)–SAT	$(k, = s)$–SAT
Instance: A (k, s)–formula Φ.	Instance: A $(k, = s)$–formula Φ.
Question: Is Φ satisfiable?	Question: Is Φ satisfiable?

Tovey [T] proved that every $(3, 3)-$formula is satisfiable, but $(3, 4)-$SAT is NP-complete. Thus considering $(3, s)-$SAT as a decision problem parametrized by s, the problem is either trivial (i.e., one can output the affirmative answer without computation) for $s \leq 3$ or NP-complete for $s \geq 4$. Such a sudden jump from triviality to NP-completeness occurs for every $k \geq 3$.

THEOREM 1.1. *For every $k \geq 3$, there is an integer $f(k)$ such that*
(i) *every $(k, s)-$formula with $s \leq f(k)$ is satisfiable*;
(ii) *$(k, s)-$SAT is NP-complete for every $s \geq f(k) + 1$.*

The proof of this result, presented in §2, extends the basic ideas of the argument given by Tovey [T] for $k = 3$. The main task of this article is to derive reasonable bounds on $f(k)$. Note that obviously $f(k) = \max\{s \mid \text{every } (k, s)-\text{formula is satisfiable}\}$, and we may extend the definition of $f(k)$ to $k = 1, 2$ in this way. We will also prove the following strengthening of part (ii) of Theorem 1.1 in §2.

THEOREM 1.2. *The $(k, = s)-$SAT problem is NP-complete for every $k \geq 3$ and $s \geq f(k) + 1$.*

As a nice application of Hall's marriage theorem, Tovey [T] proved that $f(k) \geq k$ for every k. He also conjectured that every $(k, 2^{k-1} - 1)-$formula is satisfiable. The following result disproves this conjecture. It also shows, however, that the exponential upper bound 2^{k-1} is essentially best possible, apart from a factor linear in k.

THEOREM 1.3. *For every $k \geq 4$, $\lfloor \frac{2^k}{ek} \rfloor \leq f(k) \leq 2^{k-1} - 2^{k-4} - 1$.*

The lower bound given in this theorem is proved in §3. The upper bound is related to the existence of nonsatisfiable formulas. We show in §4 that every nonsatisfiable (k, ∞)–formula has at least 2^k clauses. We also show that every nonsatisfiable $(k, f(k)+1)$–formula contains more than $\log_2 f(k)$ (and hence more than $k - \log_2 k - \log_2 e$) variables that occur in exactly $f(k) + 1$ clauses. Finally, the upper bound on $f(k)$ is proved in §5.

In the subsequent sections, we use the following convention. Formulas Φ and Ψ are called SAT-*equivalent* if either both are satisfiable or both are nonsatisfiable. The number of clauses of a formula Φ that contain a variable x (positive or negative) is called the *degree* of x and it is denoted by $deg_\Phi x$. Formulas are called *disjoint* if their variable sets are disjoint. If a clause c contains a variable x, say, $c = (x^\epsilon \wedge x_1^{\epsilon_1} \wedge \ldots \wedge x_{k-1}^{\epsilon_{k-1}})$ (where $\epsilon_i \in \{1, -1\}$ and $x^1 = x$ and $x^{-1} = \neg x$), then $c - x$ is the clause $(x_1^{\epsilon_1} \wedge \ldots \wedge x_{k-1}^{\epsilon_{k-1}})$. For a real t, we denote by $\lceil t \rceil$ (respectively, $\lfloor t \rfloor$) the least integer not smaller than t (respectively, the greatest integer not exceeding t).

2. The jump. In this section, we prove Theorems 1.1 and 1.2. The following concept will play an important role.

DEFINITION 2.1. A (k, s)–formula Φ containing a variable x is called an x-implying (k, s)-formula if

(i) the variable x occurs in at most $s - 1$ clauses of Φ,
(ii) x receives the value TRUE in every satisfying truth assignment for Φ,
(iii) Φ is satisfiable.

LEMMA 2.2. *If $k \geq 3$ and s are such that an x–implying (k, s)–formula exists, then (k, s)–SAT is* NP-*complete.*

Proof. We show that k–SAT $\propto$ (k, s)–SAT, provided an x–implying (k, s)–formula exists. In our terminology, k–SAT is (k, ∞)–SAT (i.e., SATISFIABILITY restricted to formulas with exactly k variables per clause, but with an unbounded number of occurrences of variables) and it is known to be NP-complete for every fixed $k \geq 3$ [GJ].

Let Φ be an x–implying (k, s)–formula and let Ψ be an instance of k–SAT. We will show how to reduce the degrees of variables in Ψ using disjoint copies of Φ, i.e., we will construct a (k, s)–formula $\widetilde{\Psi}$ SAT-equivalent to Ψ.

Let y be a variable of Ψ that occurs in more than s clauses, say, in the clauses $c_1, c_2, \ldots, c_m,$ $m > s$ (if Ψ has no such variables, we are done). Let $\Phi_{i,j}$, $1 \leq i \leq m$, $1 \leq j \leq k-2$, be disjoint copies of the formula Φ, with the variable x of Φ being renamed as $x_{i,j}$ in $\Phi_{i,j}$ (thus each $\Phi_{i,j}$ is an $x_{i,j}$–implying (k, s)–formula, and these formulas and the formula Ψ have pairwise disjoint sets of variables).

A formula Ψ' is defined as a result of a local replacement in Ψ in the following way. The variable y is replaced by m new variables $y_1, y_2, \ldots, y_m$, where each y_i replaces y in the clause c_i (so that $y_i \in c_i$ in Ψ' if and only if $y \in c_i$ in Ψ and $\neg y_i \in c_i$ in Ψ' if and only if $\neg y \in c_i$ in Ψ). In addition, Ψ' contains the formulas $\Phi_{i,j}$, $1 \leq i \leq m$, $1 \leq j \leq k-2$ and the clauses $d_i = (y_i \vee \neg y_{i+1} \vee \neg x_{i,1} \vee \neg x_{i,2} \vee \ldots \vee \neg x_{i,k-2})$, $1 \leq i \leq m$ (the subscripts of y_i are read modulo m).

Obviously, Ψ' has fewer variables of degree greater than s. We claim that Ψ' is satisfiable if and only if Ψ is satisfiable. Suppose ϕ' : {variables of Ψ'} $\rightarrow$ {TRUE,FALSE} is a truth assignment that satisfies Ψ'. By the definition of Φ, $\phi'(x_{i,j})$ = TRUE for all $1 \leq i \leq m$ and $1 \leq j \leq k-2$. Hence the clauses $\{d_i | 1 \leq i \leq m\}$ are satisfied by the variables $\{y_i | 1 \leq i \leq m\}$. It follows that $\phi'(y_i)$ have the same value, say, $\phi'(y_i) = \phi'_y \in$ {TRUE,FALSE} for all $1 \leq i \leq m$. Then ϕ : { variables of Ψ} $\rightarrow${TRUE,FALSE} defined by

$$\phi(x) = \begin{cases} \phi'_y & \text{if} \quad x = y \\ \phi'(x) & \text{if} \quad x \neq y \end{cases}$$

is a truth assignment that satisfies Ψ. Conversely, if Ψ is satisfiable, a satisfying truth assignment for Ψ' is guaranteed by condition (iii) of Definition 2.1.

If Ψ contains more variables of degree greater than s, we repeat the construction above letting each of these variables play the role of y, until finally a (k,s)–formula $\widetilde{\Psi}$ SAT-equivalent to Ψ is obtained. Note that if Φ contains k_Φ variables and h_Φ clauses and Ψ contains k_Ψ variables of degree $\leq s$, n variables of degree greater than s (say, of degrees $m_1, m_2, \ldots, m_n$) and h_Ψ clauses, then $\widetilde{\Psi}$ contains $k_\Psi + \sum_{i=1}^n m_i(1 + k_\Phi(k-2))$ variables and $h_\Psi + \sum_{i=1}^n m_i(1 + h_\Phi(k-2))$ clauses, and it is thus constructible in polynomial time. □

LEMMA 2.3. *If $k \geq 3$ and s are such that a nonsatisfiable (k,s)–formula exists, then there exists an x–implying (k,s)–formula as well.*

Proof. Let Φ be a minimal nonsatisfiable (k,s)–formula (i.e., if C is the set of clauses of Φ, then for every $C' \subsetneq C$, $\Phi' = \bigwedge C'$ is satisfiable). Choose a variable x and a clause c which contains x (or $\neg x$). Define $\widetilde{C} = (C \setminus \{c\}) \cup \{\widetilde{c}\}$, with $\widetilde{c} = (c - x) \cup \{\widetilde{x}\}$, where $\widetilde{x}$ is a new extra variable not occurring in Φ ($\widetilde{x}$ is positive in $\widetilde{c}$). We claim that $\widetilde{\Phi}$ is an $\widetilde{x}$–implying (k,s)–formula.

Since $\widetilde{x}$ occurs in just one clause, $\widetilde{\Phi}$ obviously is a (k,s)–formula and condition (i) of Definition 2.1 holds in $\widetilde{\Phi}$ (note that $s \geq 2$ follows from the nonsatisfiability of Φ). If $\widetilde{\Phi}$ is satisfied by a truth assignment $\widetilde{\phi}$, then $\widetilde{\phi}(\widetilde{x}) = \text{TRUE}$ (otherwise $\widetilde{\phi}$ would satisfy Φ as well, contradicting the nonsatisfiability of Φ). On the other hand, it follows from the minimality of Φ that $\Phi' = \bigwedge(C \setminus \{c\})$ is satisfiable, and hence so is $\widetilde{\Phi}$. □

Proof of Theorem 1.1. Put $m = f(k)$ and the statement follows directly from Lemmas 2.2 and 2.3. □

Proof of Theorem 1.2. We will prove that (k,s)–SAT $\propto$ $(k,=s)$–SAT. Let a formula Ψ with a set C of clauses over a set X of variables be an instance of (k,s)–SAT. The purpose is to construct a $(k,=s)$–formula $\widetilde{\Psi}$ SAT-equivalent to Ψ. This can be done by adding new clauses to Ψ to complete the degrees of variables of Ψ, together with new variables that guarantee that the new clauses can always be satisfied. The explicit construction is as follows.

We begin with s disjoint copies $\Psi_1, \Psi_2, \ldots, \Psi_s$ of the formula Ψ. We use the following notation. Each formula Ψ_i has clause set $C_i = \{c_i | c \in C\}$ and variables $X_i = \{x_i | x \in X\}$, so that $x_i \in c_i$ if and only if $x \in c$ and $\neg x_i \in c_i$ if and only if $\neg x \in c$. For each $x \in X$, consider $s - deg_\Psi(x)$ formulas $\Phi_{x,1}, \Phi_{x,2}, \ldots, \Phi_{x,s-deg_\Psi(x)}$, where

$$\Phi_{x,i} = \bigwedge_{j=1}^{s} (x_j \vee y_{i,1} \vee y_{i,2} \vee \ldots \vee y_{i,k-1})$$

(the variables x_j are the same as those occurring in the formulas Ψ_j, while $y_{i,j}$ are new extra variables). Straightforwardly,

$$\widetilde{\Psi} = \bigwedge_{i=1}^{s} \Psi_i \wedge \bigwedge_{x \in X} \bigwedge_{i=1}^{s-deg_\Psi(x)} \Phi_{x,i}$$

is a $(k,=s)$–formula and it is satisfiable if and only if Ψ is satisfiable. □

3. The lower bound. In this section we prove that $f(k) \geq \lfloor \frac{2^k}{ek} \rfloor$ for all $k \geq 1$. Of course, this inequality is trivial for $k \leq 3$; and for $k \leq 7$, it follows from $f(k) \geq k$, which Tovey [T] proved. We will use the following variant of a lemma of Erdös and Lovász [EL] (frequently referred to as Lovász's Local Lemma).

LEMMA [S]. *Let $\xi_1, \xi_2, \ldots, \xi_n$ be events in a probability space* (Ω, Prob). *A graph Γ with vertex set $\xi_1, \xi_2, \ldots, \xi_n$ is called an event graph of $\xi_1, \xi_2, \ldots, \xi_n$ if its edges express dependencies between the events so that each event ξ_i is independent of any combination of events nonadjacent to ξ_i. Suppose there exist reals $\gamma_i, 0 < \gamma_i < 1, i = 1, 2, \ldots, n$ satisfying*

$$\text{Prob}(\xi_i) \leq \gamma_i \prod_{\xi_i \xi_j \in E(\Gamma)} (1 - \gamma_j)$$

for $i = 1, 2, \ldots, n$. Then

$$\text{Prob}(\neg\xi_1 \wedge \neg\xi_2 \wedge \ldots \wedge \neg\xi_n) > 0. \qquad \square$$

Set $g(k) = \lfloor \frac{2^k}{ek} \rfloor$ and consider any $(k, g(k))$–formula Φ with clauses $c_1, c_2, \ldots, c_m$ over variables $x_1, x_2, \ldots, x_n$. We prove that Φ is satisfiable.

Let $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ be a random truth assignment of the variables, i.e., $\mathbf{x}_i \in$ {TRUE,FALSE}, each $\mathbf{x}_i$ equals TRUE with probability $\frac{1}{2}$, and the random variables $\mathbf{x}_i$ are independent. Denote by ξ_j the event that c_j is not satisfied by $\mathbf{x}$. Then $\text{Prob}(\xi_j) = 2^{-k}$ for $j = 1, 2, \ldots, m$.

The graph $\Gamma = (\{\xi_i | 1 \leq i \leq m\}, \{\xi_i\xi_j | \xi_i$ and ξ_j share a variable$\})$ is an event graph for $\xi_i, 1 \leq i \leq m$. Since each variable occurs in at most $g(k)$ clauses, and each clause contains just k variables, every ξ_j has degree at most $k(g(k) - 1)$ in Γ. Put $\gamma_i = e\,\text{Prob}(\xi_i) = e2^{-k}$ for each i. By our assumptions,

$$\frac{\gamma_i}{\text{Prob}(\xi_i)} \prod_{\xi_i \xi_j \in E(\Gamma)} (1 - \gamma_j) \geq e(1 - \frac{e}{2^k})^{k(\lfloor \frac{2^k}{ek} \rfloor - 1)} > e(1 - \frac{e}{2^k})^{\frac{2^k}{e} - 1} > ee^{-1} = 1.$$

Thus

$$\text{Prob}(\neg\xi_1 \wedge \neg\xi_2 \wedge \ldots \wedge \neg\xi_n) > 0$$

follows by the local lemma. Consequently, $\Phi(\mathbf{x})$ =TRUE holds with a positive probability. This fact implies that Φ is satisfied by some suitably chosen truth assignment.

4. Nonsatisfiable formulas. In this section we prove lower bounds on two other parameters of nonsatisfiable formulas—the number of clauses and the number of variables with degree $f(k) + 1$. In the following proposition clauses are not necessarily of the same size.

PROPOSITION 4.1. *If $\Phi = \bigwedge_{i=1}^{n} c_i$, then at least $n - \sum_{i=1}^{n} 2^{-size(c_i)}$ clauses can be satisfied simultaneously (here $size(c_i)$ is the number of variables occurring in c_i).*

Proof. We use the random truth assignment as in §3 and we define random variables $\Xi_i, i = 1, 2, \ldots, n$ by

$$\Xi_i = \begin{cases} 1 & \text{if } c_i \text{ is satisfied by } \mathbf{x}, \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$\text{E}\left(\sum_{i=1}^{n} \Xi_i\right) = \sum_{i=1}^{n} \text{Prob}(c_i \text{ is satisfied}) = n - \sum_{i=1}^{n} 2^{-size(c_i)},$$

which means that at least $n - \sum_{i=1}^{n} 2^{-size(c_i)}$, clauses are satisfied by a suitable truth assignment. □

COROLLARY 4.2. *If $\Phi = \bigwedge_{i=1}^{n} c_i$ and $\sum_{i=1}^{n} 2^{-size(c_i)} < 1$, then Φ is satisfiable.*

COROLLARY 4.3. *Every nonsatisfiable (k, ∞)–formula has at least 2^k clauses.*

We remark that Corollary 4.3 is the best possible, since for every k, the formula consisting of all the 2^k possible k–clauses over variables $x_1, x_2, \dots, x_k$ is nonsatisfiable. Proposition 4.1 was actually proved in [J] (though Johnson only states the result for the case of (k, ∞)–formulas). The proof presented there is algorithmic, and we decided to include our probabilistic argument, which we believe is more transparent.

PROPOSITION 4.4. *If Φ is a nonsatisfiable (k, ∞)–formula, then at least one of its clauses shares variables with at least $\lfloor \frac{2^k}{e} \rfloor$ other clauses.*

Proof. Follows from the local lemma and is similar to the proof in §3. □

By the definition of $f(k)$, we know that nonsatisfiable $(k, f(k) + 1)$–formulas exist. We show that such formulas are rich in variables occurring in $f(k) + 1$ clauses.

THEOREM 4.5. *Let Φ be a nonsatisfiable $(k, f(k) + 1)$–formula, $k \geq 4$. Then at least $\lfloor \log_2 f(k) \rfloor + 1$ of the variables of Φ occur in $f(k) + 1$ clauses.*

Proof. Let $x_1, x_2, \dots, x_t$ be the variables that occur each in $f(k) + 1$ clauses of a $(k, f(k) + 1)$–formula Φ. We prove that Φ is satisfiable, provided $t \leq \log_2 f(k)$. The idea is to construct a $(k, f(k))$–formula Ψ SAT-equivalent to Φ by taking 2^t disjoint (and slightly modified) copies of Φ. Then Ψ is satisfiable by the definition of $f(k)$ and the satisfiability of Φ follows.

Here is the explicit construction of Ψ. For each x_i, choose a clause, say c_i, of Φ which contains x_i (respectively, $\neg x_i$). Consider t new variables $y_1, y_2, \dots, y_t$ and 2^t disjoint copies Φ_u of Φ, indexed by Boolean vectors $u = (u_1, u_2, \dots, u_t), u_i \in \{0, 1\}$. For a variable x and a clause c of Φ, let their copies in Φ_u be denoted by x^u and c^u, respectively. For each $u \in \{0, 1\}^t$, let $\widetilde{\Phi}_u$ be the formula obtained from Φ_u by replacing the occurrence of x_i^u in c_i^u by y_i (respectively, $\neg y_i$) if $u_i = 0$ (respectively, $u_i = 1$). Finally, we put

$$\Psi = \bigwedge_{u \in \{0,1\}^t} \widetilde{\Phi}_u.$$

The degrees of the variables x_i^u in Ψ drop by one compared to their degrees in Φ_u, the degrees of other variables do not change, and the degrees of the variables y_i are equal to $2^t \leq f(k)$. Thus Ψ is a $(k, f(k))$–formula. Let ϕ : {variables of Ψ} $\to$ {TRUE,FALSE} be a truth assignment that satisfies Ψ. Consider $u_\phi = (u_1, u_2, \dots, u_t)$ with $u_i = 0$ (respectively, $u_i = 1$) if $\phi(y_i)$ =FALSE (respectively, $\phi(y_i)$ =TRUE). Then no clause $c_i^{u_\phi}$ in $\widetilde{\Phi}_{u_\phi}$ is satisfied by y_i , and hence all clauses of $\widetilde{\Phi}_{u_\phi}$ are satisfied by the variables x^{u_ϕ}. Therefore, Φ is satisfiable. □

The bound given by Theorem 4.5 is probably not the best possible. On the other hand, the result cannot be extended straightforwardly to (k, s)–formulas with $s > f(k)+1$, because of the following.

PROPOSITION 4.6. *For every k, there exists a nonsatisfiable (k, ∞)–formula that contains just one variable with degree greater than $f(k)$.*

Before proving this observation, we need one auxiliary result that is also interesting on its own.

LEMMA 4.7. *The function $f(k)$ is strictly increasing.*

Proof. We prove that for every k, there exists a nonsatisfiable $(k, f(k+1))$–formula. Let Φ be a nonsatisfiable $(k + 1, f(k + 1) + 1)$–formula. Obviously, every formula obtained from Φ by deleting some variables from some clauses (while retaining the occurrences in other clauses) is nonsatisfiable. It only remains to show that one may obtain a $(k, f(k+1))$–formula in this way.

Suppose the formula Φ has a set C of clauses over a set X of variables, and let $x_1, x_2, \ldots, x_n$ be the variables of Φ that occur in $f(k+1)+1$ clauses. For $i = 1, 2, \ldots, n$, we put $C_i = \{c | c \in C \text{ and } c \text{ contains } x_i \text{ or } \neg x_i\}$ and we consider the set system $\mathcal{C} = \{C_i | 1 \le i \le n\}$. For every $A \subset \{1, 2, \ldots, n\}$, we have

$$f((k+1)+1)|A| = |\{(x_i, c) | c \in C_i \text{ and } i \in A\}| \le (k+1)|\bigcup_{i \in A} C_i|,$$

and, hence,

$$|\bigcup_{i \in A} C_i| \ge \frac{f(k+1)+1}{k+1}|A| > |A|$$

(note that $f(k+1) \ge k+1$). Using Hall's theorem, it follows that there are *distinct* clauses $c_i, i = 1, 2, \ldots, n$ such that each c_i contains either x_i or $\neg x_i$.

Now we let Ψ be a formula obtained from Φ by deleting the occurrence of x_i from c_i for $i = 1, 2, \ldots, n$ and deleting arbitrary variables from the remaining clauses, one from each. Consequently, Ψ is a nonsatisfiable $(k, f(k+1))$–formula and $f(k) < f(k+1)$ follows. □

Proof of Proposition 4.6. Suppose $k \ge 2$ (for $k = 1$, $\Phi = (x) \wedge (\neg x)$ is a desirable formula). Let Φ be a nonsatisfiable $(k-1, f(k-1)+1)$–formula with a set C of clauses over a set X of variables, and consider two disjoint copies Φ_1, Φ_2 of Φ (Φ_i has clause set $C_i = \{c_i | c \in C\}$ and variable set $X_i = \{x_i | x \in X\}$). Let y be a new extra variable. Then

$$\Psi = \left(\bigwedge_{c \in C} (c_1 \vee y) \right) \vee \left(\bigwedge_{c \in C} (c_2 \vee \neg y) \right)$$

is a (k, ∞)–formula with just one variable (namely, y) occurring in more than $f(k)$ clauses (all other variables occur in at most $f(k-1)+1 \le f(k)$ clauses). Obviously, Ψ is nonsatisfiable, since y cannot satisfy simultaneously both Φ_1 and Φ_2. □

5. The upper bound. We first present a recursive inequality for $f(k)$.

LEMMA 5.1. *For every k, we have $f(k+1) \le 2f(k)+1$.*

Proof. Let Φ be a nonsatisfiable $(k, f(k)+1)$–formula with a set C of clauses over a set X of variables. For each $c \in C$, let x_c be a new extra variable. Consider

$$\Psi = \bigwedge_{c \in C} (c \vee x_c) \wedge (c \vee \neg x_c).$$

The degrees of the variables of Φ are doubled in Ψ, while the new variables $x_c, c \in C$ have degree 2. Thus, Ψ is a $(k+1, 2(f(k)+1))$–formula. To see that it is nonsatisfiable, recall that for each clause c of Φ, $(c \vee x_c) \wedge (c \vee \neg x_c)$ is SAT-equivalent to c.

Therefore, $f(k+1)+1 \le 2f(k)+2$ and the statement follows. □

PROPOSITION 5.2. *We have $f(4) \le 6$.*

Proof. Let a, b be variables. We first construct an auxiliary $(4, 7)$–formula $\Phi_{a,b}$ such that every truth assignment satisfying $\Phi_{a,b}$ satisfies $a \Rightarrow b$. Then we use disjoint copies of this formula to reduce the degrees of variables in a nonsatisfiable $(4, \infty)$–formula in analogy to the proof of Lemma 2.2.

We put

$$\begin{aligned}\Phi_{a,b} = {} & (u \vee x \vee y \vee z) \wedge (\neg u \vee \neg x \vee \neg y \vee \neg z) \wedge (u \vee \neg x \vee v \vee w)\\ & \wedge (x \vee \neg y \vee v \vee w) \wedge (y \vee \neg z \vee v \vee w) \wedge (z \vee \neg u \vee v \vee w)\\ & \wedge (\neg a \vee b \vee \neg v \vee w) \wedge (\neg a \vee b \vee \neg v \vee \neg w) \wedge (\neg a \vee b \vee v \vee \neg w).\end{aligned}$$

It is straightforward to check that $deg_{\Phi_{a,b}} u = deg_{\Phi_{a,b}} x = deg_{\Phi_{a,b}} y = deg_{\Phi_{a,b}} z = 4, deg_{\Phi_{a,b}} v = deg_{\Phi_{a,b}} w = 7$, and $deg_{\Phi_{a,b}} a = deg_{\Phi_{a,b}} b = 3$. One can also check easily that every truth assignment satisfying $\Phi_{a,b}$ satisfies $a \Rightarrow b$ as well, and on the other hand, every truth assignment to a, b that satisfies $a \Rightarrow b$ can be extended to a truth assignment satisfying $\Phi_{a,b}$.

In the forthcoming construction, we will use copies of this formula. Let the convention be such that $\Phi_{\alpha,\beta}$ is a copy of $\Phi_{a,b}$ with a (respectively, b) being renamed as α (respectively, β), the other variables u, x, y, z, v, w of $\Phi_{a,b}$ are renamed so that these new variables do not occur in other copies of $\Phi_{a,b}$.

Finally, let Ψ be a nonsatisfiable $(4, \infty)$–formula, and suppose a variable x occurs in $n \geq 8$ clauses, say, $c_1, c_2, \dots, c_n$. We replace x by n new variables $x_1, x_2, \dots, x_n$ (x_i replaces x in c_i), and we add formulas $\Phi_{x_i, x_{i+1}}, i = 1, 2, \dots, n$ $(x_{n+1} = x_1)$. The resulting formula Ψ' is again nonsatisfiable, since any satisfying truth assignment ϕ of Ψ' would satisfy $x_i \Rightarrow x_{i+1}, i = 1, 2, \dots, n$, and ϕ would induce a truth assignment satisfying Ψ in an obvious way. Note that each variable x_i occurs in 7 clauses of Ψ'. Applying this construction to all variables of degree greater than 7 in Ψ', we finally obtain a nonsatisfiable $(4, 7)$–formula $\widetilde{\Psi}$. □

The above construction can be straightforwardly generalized to $k > 4$. This leads, however, to the upper bound $f(k) \leq 2^{k-1} - 2$, which is worse than the one in Theorem 1.3.

Proof of the upper bound of Theorem 1.3. The inequality follows by an easy induction on k, using Proposition 5.2 and Lemma 5.1. □

6. Concluding remarks.

6.1. The behavior of $f(k)$. We have defined the function $f(k)$, showed that it is strictly increasing, and proved exponential bounds for it. Undoubtedly, it would be very interesting to find an exact formula for $f(k)$, but that might be a rather tough problem. We would be satisfied whether one can eliminate the factor $\frac{1}{k}$ in the lower bound in Theorem 1.3.

Let us define the function

$$g(k) = \log_2(f(k) + 1) - k.$$

Theorem 1.3 yields

$$-\log_2 e - \log_2 k < g(k) \leq \log_2 7 - 4$$

and Lemma 5.1 implies

$$\begin{aligned} g(k+1) &= \log_2(f(k+1) + 1) - (k+1) \leq \log_2(2(f(k) + 1)) - k - 1\\ &= 1 + \log_2(f(k) + 1) - k - 1 = g(k),\end{aligned}$$

and thus $g(k)$ is monotone. Hence, the limit $g = \lim_{k \to \infty} g(k)$ exists, and therefore, we propose the following open problem.

PROBLEM. *Determine whether $g > -\infty$. Find reasonable bounds for g in case of an affirmative answer, or determine the asymptotic behavior of $g(k)$ if $g = -\infty$.*

Note that if $g > -\infty$, then $f(k)$ behaves asymptotically as 2^{k+g}, whereas if $g = -\infty$, then for every arbitrarily large positive constant M, $f(k) < 2^{k-M}$ for every $k > k_M$.

6.2. Computation of $f(k)$. Another tough problem may be to determine the exact values of $f(k)$, even for small k. We only know $f(1) = 1, f(2) = 2$ and $f(3) = 3$, but already for $k = 4$, we know nothing better than $4 \leq f(k) \leq 6$. The problem is that no bound on the size of a minimum nonsatisfiable $(4, f(4)+1)$ (and in general $(k, f(k)+1)-$ for $k \geq 4$)–formula is known.

6.3. Decision versus search. We have called the $(k, s)-$SAT problem trivial when $s \leq f(k)$. One should keep in mind that this concerns decision problems. The companion search problem (i.e., given a (satisfiable) $(k, s)-$formula with $s \leq f(k)$, find a satisfying truth assignment) is much harder. For $s \leq k$, one can find a satisfying truth assignment via matching theory, but for $k < s \leq f(k)$, no polynomial algorithm is known. This is just another example of a problem where the existence of a solution is guaranteed by a nonconstructive argument, but it is not known how difficult it is to find one. (On the other hand, in Proposition 4.1 our probabilistic approach gives exactly the same result as the polynomial search algorithm derived in [J].)

Note added in proof. Recently we became aware of a paper of Dubois [D] who was apparently the first to disprove the conjecture of Tovey. By a rather technical construction, he proves that $f(4) \leq 5$ and $f(5) \leq 10$. It then follows from our Lemma 5.1 that $f(k) \leq 11 \cdot 2^{k-5} - 1 = 2^{k-1} - 2^{k-3} - 2^{k-5} - 1$, which is better than the upper bound in our Theorem 1.3. Dubois also raised a conjecture which, in our setting, is equivalent to $\lim_{k\to\infty} \frac{f(k+1)}{f(k)} = 2$. This is strongly supported by the lower bound in our Theorem 1.3, which directly yields $\lim\,\sup_{k\to\infty} \frac{f(k+1)}{f(k)} = 2$. More precisely, it follows that for every $\epsilon > 0$, the set $A_\epsilon = \{k | \frac{f(k+1)}{f(k)} < 2 - \epsilon\}$ has zero density, i.e., $\lim_{n\to\infty} \frac{|A_\epsilon \cap \{1,2,\ldots,n\}|}{n} = 0$ (and even $\frac{|A_\epsilon \cap \{1,2,\ldots,n\}|}{n} \leq O(\frac{\log_2 n}{n})$).

A recent paper of Beck [B] provides a significant breakthrough to the decision versus search metaquestion for applications of Lovász's Local Lemma. Beck gives a polynomial search algorithm which, however, does not apply to the full range of the Local Lemma. Namely, for the restricted SATISFIABILITY problem, his method enables to find a satisfying truth assignment to a given $(k, s)-$formula if $s \leq \frac{2^{\frac{k}{48}+1}}{k} + 1$. A parallelized version of the Beck's algorithm is presented in a paper of Alon [A].

ROUNDS IN COMMUNICATION COMPLEXITY REVISITED*

NOAM NISAN† AND AVI WIGDERSON‡

Abstract. The k-round two-party communication complexity was studied in the deterministic model by [P. H. Papadimitriou and M. Sipser, *Proc. of the 14th STOC*, 1982, pp. 330–337] and [P. Duris, Z. Galil, and G. Schnitger, *Proc. of the 16th STOC*, 1984, pp. 81–91] and in the probabilistic model by [A. C. Yao, *Proc. of the 24th FOCS*, 1983, pp. 420–428] and [B. Halstenberg and R. Reischuk, *Proc. of the 20th STOC*, 1988, pp. 162–172]. This paper presents new lower bounds that give (1) randomization is more powerful than determinism in k-round protocols, and (2) an *explicit* function which exhibits an exponential gap between its k and $(k-1)$-round randomized complexity.

This paper also studies the three-party communication model, and exhibits an exponential gap in 3-round protocols that differ in the starting player.

Finally, this paper shows new connections of these questions to circuit complexity, that motivate further work in this direction.

Key words. communication complexity, information, rounds, monotone circuits

1. Introduction.

1.1. The two-party model. Papadimitriou and Sipser [14] initiated the study of how Yao's model[1] [19] of communication complexity is affected by limiting the two players to only k rounds of messages. They considered the following natural problem g_k: each of the players A and B is given a list of n pointers (each of $\log n$ bits), each pointing to a pointer in the list of the other. Their task is to follow these pointers, starting at some fixed $v_0 \in A$, and find the kth pointer. This can easily be done in k rounds and complexity $O(k \log n)$: A starts and the players alternately send the value of the next pointer. It is not clear how to use less than $n \log n$ bits if only $(k-1)$ rounds are allowed or in fact with k-rounds but player B starts. Indeed, Papadimitriou and Sipser [14] conjectured that the complexity is exponentially higher (for fixed k), namely, that there is a strict hierarchy, and proved it for the case $k = 2$. The general case was resolved by Duris, Galil, and Schnitger [4], who gave an $\Omega(n/k^2)$ lower bound on the $(k-1)$ round complexity of g_k.

It is not difficult to see that allowing randomness g_k can be solved with high probability in $(k-1)$ rounds using only $O((n/k)\log n)$ communication bits. Another $\log n$ factor in the complexity can make this a Las Vegas (errorless) algorithm. This raises the question, *What is the relative power of randomness over determinism in k-round protocols*? Without limiting the number of rounds, Mehlhorn and Schmidt [12] showed a quadratic gap between Las Vegas and Determinism, and allowing error, the gap can be exponential.

We use simple information theoretic and probabilistic arguments to strengthen the lower bound of [4] in two ways. First we improve their $(k-1)$-round deterministic lower bound on g_k to $\Omega(n)$ (for $k < n/\log n$), thus showing that randomness can be cheaper by a factor of $k/\log^2 n$ for k-round protocols. This result also provides the largest gap

[1]In fact, they and [4] considered the stronger "arbitrary partition" model, but known simulation results of [4], [6], [9], [10] allow us to use Yao's standard "fixed partition" model without loss of generality.

known for $k > \log n$ in the deterministic model — the previous one was obtained in [4] via counting arguments. The fact that the simulation of McGeoch [10] is constructive gives the same gap in the arbitrary partition model for an explicit function, resolving an open question of Duris, Galil, and Schnitger [4].

Second, we prove that the probabilistic upper bound above is not very far from optimal — we give an $\Omega(n/k^2)$ lower bound, establishing an exponential gap in the probabilistic setting between k and $(k-1)$-round protocols for an explicitly given function. The existence of such functions (with somewhat larger gap) was proven by Halstenberg and Reischuk [6], via complicated counting arguments. The only previous exponential gap for an explicit function was shown for $k = 2$ by Yao [20]. We stress the simplicity of our proof technique, in contrast to that of Halstenberg and Reischuk [6]. We have recently learned that similar techniques were used by Smirnov [16] to prove an $\Omega(n/(k(\log n)^k))$ lower bound on g_k, which is much weaker than our bound, but establish an exponential gap as well.

Finally, we use the communication complexity characterization of circuit depth of Karchmer and Wigderson [8] to establish g_k as a complete problem for monotone depth-k Boolean circuits. (This result was independently discovered by Yannakakis [18].) Thus, a simple deterministic reduction enables us to derive the monotone constant-depth hierarchy of Klawe, Paul, Pippenger, and Yannakakis [7] from the constant-round hierarchy of Duris, Galil, and Schnitzer [4]. (The reverse direction was proven in [7].) We speculate that our new probabilistic lower bound may serve to extend the monotone circuit hierarchy result to depth above $\log n$, via probabilistic reductions (as was done by Raz and Wigderson [15]).

1.2. The multi-party model. Chandra, Furst, and Lipton [2] devised the multi-party communication complexity model. Here t players $P_1, P_2, \ldots, P_t$ are trying to compute a Boolean function $g(x_1, x_2, \ldots, x_t)$, where $x_i \in \{0,1\}^{n_i}$. (Until now all work in this model considered equal length inputs, i.e., $n_i = n$ for all i.) The twist is that every player P_i sees *all* values x_j for $j \neq i$. This model turns out to capture diverse computational models. Chandra, Furst, and Lipton [2] used it to prove that majority requires super-linear length constant width branching programs. Babai, Nisan, and Szegedy [1] gave $\Omega(n/2^t)$ lower bounds for explicit functions g, and used it for Turing machine, branching program, and formulae lower bounds, as well as efficient pseudorandom generators for small space. Recently, Håstad and Goldmann [5] used the results in [1] to prove lower bounds on constant-depth threshold circuits.

We consider only the 3-player model, and within it we allow three rounds of communciation: one per player. We exhibit a function u whose complexity is $\Omega(\sqrt{n})$ if P_3 is the first to speak, but $O(\log n)$ otherwise. The proof uses properties of universal hash functions developed in [13] and [11]. It is interesting that u acts on different size arguments; $u : \{0, 1\}^{2n} \times \{0,1\}^n \times \{0, 1\}^{\log n} \to \{0, 1\}$ so $n_1, n_2 = \Theta(n)$, but $n_3 = \log n$. The following connection to circuit complexity makes such functions important. We show that improving our lower bound to $\Omega(n)$ for some explicit function g of this form would give the following size-depth trade-off: the function $f : \{0, 1\}^{\Theta(n)} \to \{0, 1\}^n$ defined by $f(x_1, x_2)_{x_3} = g(x_1, x_2, x_3)$ cannot be computed by Boolean circuits of size $O(n)$ and depth $O(\log n)$ simultaneously. This result is obtained via Valiant's [17] method of depth reduction in circuits.

2. The two-party model.

The four subsections of this section give the definitions, results, technical lemmas, and some proofs, respectively, in the two-party communication complexity model.

2.1. Definitions. Let $g : X_A \times X_B \to \{0,1\}$ be a function. The players A, B receive, respectively, inputs $x_A \in X_A$, $x_B \in X_B$. A k-round protocol specifies for each input a sequence of k messages, $m_1, m_2, \ldots, m_k$ sent alternately between the players such that at the end both know $g(x_A, x_B)$. The cost of a k-round protocol is $\sum_{i=1}^{k} |m_i|$ (where $|m_i|$ is the binary length of m_i), maximized over all inputs (x_A, x_B). Denote by $C^{A,k}(g)$ (respectively, $C^{B,k}(g)$) the cost of the best protocol in which player A (respectively, B) sends the first message, and $C^k(g) = \min\{C^{A,k}(g), C^{B,k}(g)\}$.

Let $T : X_A \times X_B \to \{0, 1\}$ be the function computed by the two players following a protocol T. We introduce randomization by allowing T to be a random variable distributed over deterministic protocols. The cost is simply the expectation of the associated random variable. We say that randomized protocol makes ϵ-error if $\Pr[T(x_A, x_B) \neq g(x_A, x_B)] \leq \epsilon$ for every input $(x_A, x_B) \in X_A \times X_B$. Denote by $C_\epsilon^k(g)$ the cost of the best k-round ϵ-error protocol for g and similarly define $C_\epsilon^{A,k}$, $C_\epsilon^{B,k}$. The case $\epsilon = 0$ (e.g., $C_0^k(g)$) denotes Las Vegas (errorless) protocols.

Finally, if we leave T a deterministic protocol and choose the input uniformly at random, we can define the ϵ-error distributional complexity $D_\epsilon^k(g)$ to be the cost of the best k-round protocol for which $\Pr[T(x_A, x_B) \neq g(x_A, x_B)] \leq \epsilon$, under this distribution. The following lemmas are useful.

LEMMA 1 [20]. *For every* g, $\epsilon > 0$ $\; D_{2\epsilon}^k(g) \leq 2C_\epsilon^k(g)$.

LEMMA 2. *For all constants* $\frac{1}{3} \geq \epsilon > \epsilon' > 0 \quad C_{\epsilon'}^k(g) = O(C_\epsilon^k(g))$.

2.2. Results. Let V_A, V_B be two disjoint sets (of vertices) with $|V_A| = |V_B| = n$ and $V = V_A \cup V_B$. Let

$$F_A = \{f_A : V_A \to V_B\}, \qquad F_B = \{f_B : V_B \to V_A\}$$

and

$$f = (f_A, f_B) : V \to V$$

defined by

$$f(v) = \begin{cases} f_A(v) & v \in V_A \\ f_B(v) & v \in V_B \end{cases}.$$

For each $k \geq 0$ define $f^{(k)}(v)$ by $f^{(0)}(v) = v$, $f^{(k+1)}(v) = f(f^{(k)}(v))$.

Let $v_0 \in V_A$. The function we will be interested in computing is $g_k : F_A \times F_B \to V$ defined by $g_k(f_A, f_B) = f^{(k)}(v_0)$.

Remark. In the following theorems note that the number of input bits to each player is $n \log n$ and that they hold for every value of k. We also note that one can make g_k a Boolean function by taking the parity of the output vertex. All our upper and lower bounds apply to this Boolean function as well.

THEOREM 1 [14]. $C^{A,k}(g_k) = O(k \log n)$.

THEOREM 2. $C^{B,k}(g_k) = \Omega(n - k \log n)$.

THEOREM 3. $C_{1/3}^{B,k}(g_k) = O((n/k) \log n)$, $C_0^{B,k}(g_k) = O((n/k) \log^2 n)$.

THEOREM 4. $C_{1/3}^{B,k}(g_k) = \Omega(\frac{n}{k^2} - k \log n)$.

Remark. At the end of the proofs of Theorems 2 and 4 we explain why the "ugly" term $-k \log n$ in these lower bounds can be essentially ignored.

In the remainder we show the completeness of g_k for monotone depth k circuits. Let $g_k = g_{k,n}$ to stress that each player gets n vertices.

DEFINITION. For a Boolean function h define $L^d(h)$ to be the size of the minimal *monotone formula* of depth d and unbounded fanin that computes h. Define $LS^d(k, n)$ to be the maximum of $L^d(h)$ over all functions h that can be computed by monotone circuits of unbounded fanin depth k and total size n. Define $LF^d(k, n)$ to be the maximum of $L^d(h)$ over all functions h that can be computed by a formula of depth k and fanin n at each gate.

THEOREM 5.

$$\log LS^d(k,n) \le C^d(g_{k,n}) \le \log LF^d(k,n).$$

The left inequality was proven in [7], and allowed them to deduce a lower bound on g_k from their circuit lower bound. The right inequality was independently discovered by Yannakakis [18]. It allows us to recover the tight hierarchy theorem of [7] from the lower bound on g_k.

Let h_k be the complete function for depth k-circuits, i.e., an alternating and-or tree of depth k and fanin $n^{1/k}$ at each gate.

COROLLARY (see Klawe et al. [7]). Any monotone circuit of depth $k - 1$ for h_k requires size $2^{\Omega(n^{1/k}/k)}$.

2.3. Probability, measure, and information theory. Let Ω be a finite set (universe), $X \subseteq \Omega$. Denote by $\mu(X)$ the *density* of X in Ω, $\mu(X) = |X|/|\Omega|$. Let $P : X \to [0, 1]$ a probability distribution on X, and $x \in X$ a random variable distributed according to P. The probability of any event $Y \subseteq X$ is denoted $\Pr_P[Y]$, and the subscript P is usually omitted. For $y \in X$, we write $\Pr[\{y\}] = P_y$. Then the *entropy* $H(P) = H(x) = \sum_{y\in X} P_y \log P_y$. The *information* on X (relative to Ω), is $I(x) = \log|\Omega| - H(x)$. If P is the uniform distribution U on X, then $H(x) = \log|X|$, and $I(x) = -\log \mu(X)$.

The following lemmas will be useful to us.

LEMMA 3. *Let $x = (x_1, x_2, \dots, x_m)$ be a random variable (so $\Omega = \Omega_1 \times \Omega_2 \times \cdots \times \Omega_m$ and x_i distributed over Ω_i), then $I(x) \ge \sum_{i=1}^m I(x_i)$.*

The next lemma (from [15]) shows that if $I(x)$ is very small, one can get good bounds on the probability of any event under P in terms of its probability under the uniform distribution U.

LEMMA 4 [15]. *For $Y \subseteq X$, let $q = \Pr_U[Y]$. Assume*

$$\Delta = \sqrt{\frac{4I(x)}{q}} \le \frac{1}{10}.$$

Then

$$|\Pr_P[Y] - q| \le q\Delta.$$

LEMMA 5. *If*

$$X = \Omega = \{0,1\},\ I(x) \le \delta \le \frac{1}{4},$$

then

$$\left|P_0 - \frac{1}{2}\right|,\ \left|P_1 - \frac{1}{2}\right| \le 2\sqrt{\delta}.$$

2.4. Proofs.

Proof of Theorems 1 *and* 3. $C^{A,k}(g_k) \leq k \log n$ follows easily, since in round t the right player knows $f(v_{t-1}) = v_t$ and can send these $\log n$ bits to the second player.

The idea in beating the deterministic $\Omega(n)$ lower bound when the wrong player B starts is as follows: First B chooses a random subset $U \subseteq V_B$ with $|U| = 10n/k$, and sends to A $\{f_B(u) : u \in U\}$. Now it is A's turn and they start sending each other $v_1, v_2, \ldots$ as above, but lagging one round "behind schedule." However, with probability $\geq 2/3$, one of the v_i's will be in U, which allows them to save two rounds, and "finish on time." This gives $C_\epsilon^{B,k}(g_k) = O((k + n/k)\log n)$. This algorithm can be made Las Vegas with an extra factor of $O(\log n)$ in the complexity.

Proof of Theorems 2 *and* 4. Let $f = (f_A, f_B) \in F_A \times F_B$ be the input. Let T' be a deterministic k-round protocol for g_k in which B sends the first message. Note that at any round $t \geq 1$, if it is B's turn to speak, then $v_{t-1} = f^{(t-1)}(v_0) \in V_A$, and vice versa. It will be convenient to replace T' by a protocol T in which in any round $t \geq 1$, we replace the message m by the message (m, v_{t-1}). By induction on t, this is always possible for the player whose turn it is. In particular, it implies that $\geq \log n$ bits are sent per round. Thus, if T' uses C bits, T uses $\leq C + k \log n$ bits. We will assume T uses $\epsilon n/2$ bits, (ϵ will be chosen later) and obtain a contradiction.

Every node z of the protocol tree T can be labeled by the rectangle $F_A^z \times F_B^z$ of inputs arriving at z. By the structure of T, if z is at level $t \geq 1$ (the root is at level 0), then $v_0, v_1, \ldots, v_{t-1}$ are determined in $F_A^z \times F_B^z$.

We shall assume the input is chosen uniformly at random from $F_A \times F_B$, so in fact we shall bound from below the distributional complexity. Thus the probability of arriving at z is $\mu(F_A^z \times F_B^z)$, and given that the input arrived at z, it is uniformly distributed in $F_A^z \times F_B^z$. The main lemma below intuitively shows that if the input arrived at z and the rectangle at z has nice properties, then with high (enough) probability the input will proceed to a child w of z, which is equally nice. Nice means that both F_A^z, F_B^z are large enough and that the player *not* holding v_{t-1} has very little information on $v_t = f(v_{t-1})$.

Denote by c_z the total number of bits sent by the players before arriving at z. Assume without loss of generality that A speaks at z. Let f_A^z and f_B^z be random variables uniformly distributed over F_A^z and F_B^z, respectively. Recall that T uses $\leq \frac{\epsilon}{2} n$ bits, and let δ satisfy $\delta = \text{Max}\,\{4\sqrt{\epsilon}, 400\,\epsilon\}$. Define z to be *nice* if it satisfies:

1. $I(f_A^z) \leq 2c_z$,
2. $I(f_B^z) \leq 2c_z$,
3. $I(f_B^z(v_{t-1})) \leq \delta$.

MAIN LEMMA. If z is nice, and w a random child of z, then $\Pr[w \text{ not nice}] \leq 4\sqrt{\epsilon} + \frac{1}{n}$.

Proof. Assume A sends bits at z. Let a_w be the length of the message, which leads to the child w. Thus, $c_w = c_z + a_w$ for all children w of z. We will now give upper bounds separately on the probability of each of the three properties defining nice being false at a random child w.

Claim 1. $\Pr[I(f_B^w) > 2c_w] = 0$.

Proof. B sent nothing, so $\forall\, w$ $F_B^w = F_B^z$ and

$$I(f_B^w) = I(f_B^z) \leq 2c_z < 2c_w. \qquad \square$$

Claim 2. $\Pr[I(f_A^w) > 2c_w] \leq \frac{1}{n}$.

Proof. A child w is chosen with probability $\mu(F_A^w)/\mu(F_A^z)$. Also note that the for every w $a_w \geq \log n$ (by our assumption on the protocol) and they satisfy Kraft's inequality $\sum_w 2^{-a_w} \leq 1$ (where the sum is over all children of z). Thus we have

$$\Pr[I(f_A^w) > 2c_w] \leq \Pr[\mu(F_A^w) < 2^{-2c_w}]$$
$$\leq \Pr[\mu(F_A^w)\big/\mu(F_A^z) < 2^{-2a_w}] \leq \tfrac{1}{n}\sum_w 2^{-a_w} \leq \frac{1}{n}. \qquad \square$$

Claim 3. $\Pr[I(f_A^w(v_t)) > \delta] \leq 4\sqrt{\epsilon}$.

Proof. We may assume now that $I(f_A^w) \leq 2c_w \leq \epsilon n$. The random variable f_A^w is a vector of random variables $f_A^w(v)$ for all $v \in V_A$. Thus, by Lemma 3, $\sum_{v\in V} I(f_A^w(v)) \leq I(f_A^w) \leq \epsilon n$. So if v_t was chosen *uniformly* from V_A, $\Pr_U[I(f_A^w(v_t)) > \delta] \leq \frac{\epsilon}{\delta}$ by Markov's inequality. But $v_t = f_B^z(v_{t-1})$, so v_t is distributed with $I(v_t) = I(f_B^z(v_{t-1})) \leq \delta$ as we assumed z was nice. By Lemma 4 (and our choice of δ),

$$\Pr[I(f_A^w(v_t)) > \delta] \leq \frac{\epsilon}{\delta}\left(1 + \sqrt{\frac{4\delta}{\epsilon/\delta}}\right) \leq 4\sqrt{\epsilon}. \qquad \square$$

Now we can conclude the proofs of Theorems 2 and 4 from the main lemma. Consider any *nice* leaf ℓ of the protocol tree T, labeled by an answer (0 or 1). Say A spoke on the last round k. Then $I(v_k) = I(f_B^\ell(v_{k-1})) \leq \delta$. So by Lemma 5, even if the algorithm gives one bit (say, parity) of the answer, it is correct with probability $\leq \frac{1}{2} + 2\sqrt{\delta}$.

Conclusion of Theorem 2. Take $\epsilon = 10^{-4}$. The root of T is nice, so by the main lemma and induction we have a positive probability ($\geq 2^{-k}$) of reaching a nice leaf, contradicting the fact that the protocol never errs. This proves only $C^{B,k}(g_k) = \Omega(n - k\log n)$, since we augmented an arbitrary T' to a nice protocol T.

Getting rid of the $-k\log n$ term, achieving the lower bound $C^{B,k}(g_k) = \Omega(n)$ (which is stronger when $k \geq \frac{n}{\log n}$) requires a more delicate argument that we sketch below. The idea is to follow the same steps of the proof with the following changes.

(1) We stay with the original protocol T', as we cannot afford the players sending $\log n$ bits per round as in the nice protocol T.

(2) We still fix the vertex v_{t-1} by the player sending the message at round t, but avoid paying $\log n$ bits for this information by removing this vertex from our universe. Thus, the information I is measured relative to a smaller set of pointers at every round.

(3) We prove a weaker main lemma, which is clearly sufficient in the deterministic case, namely, that every nice node z has at least one nice child w. The details are left to the interested reader.

Conclusion of Theorem 4. Pick $\epsilon = 10^{-4}\cdot k^{-2}$. Thus the probability of not reaching a nice leaf is $\leq k\frac{1}{25k} = \frac{1}{25}$, and the probability that the protocol answers correctly is less than $\frac{1}{25} + (\frac{1}{2} + \frac{2}{5\sqrt{k}}) < 0.95$. Thus we get from Lemmas 1 and 2 that $D_{1/20}^{B,k}(g_k) = \Omega((n/k^2) - k\log n)$.

This bound is $\Omega(n/k^2)$ for all $k < (n/\log n)^{1/3}$. For larger k one can use the trivial lower bound k, which applies to every k-round protocol. Note that when $k \geq n^{1/3}$ this trivial bound is larger than n/k^2.

Proof of Theorem 5. As mentioned above, the left inequality was proven in [7], so we prove only the right inequality. The proof is based on the Karchmer and Wigderson characterization of circuit depth in terms of communication complexity, which can be stated as follows. For every monotone function h on n variables with minterms $\text{Min}(h)$ and maxterms $\text{Max}(h)$ define a communication search problem $R_h^m \subset \text{Min}(h) \times \text{Max}(h) \times [n]$ in which player A gets a minterm $S \in \text{Min}(h)$, player B gets a maxterm $T \in \text{Max}(h)$, and their task is to find an element in $S \cap T$. Then monotone formulae for h and protocols for R_h^m are in 1-1 correspondence via the simple syntactic identification of $\vee$ gates with player A's moves and $\wedge$ gates with player B's moves. In particular, depth corresponds to the number of rounds and logarithm of the size to the communication complexity.

In view of the above, all we need to give now is a reduction from computing $g_{k,n}$ to the computation of R_h^m for some function h, which has a depth k formula of fanin n at each gate. Once this is done, the players can solve R_h^m and hence, $g_{k,n}$ in d rounds and $\log LF^d(k,n)$ communication by simulating the guaranteed depth d circuit for h.

Let h be defined by a formula that is a complete n-ary tree of depth k, alternating levels of $\vee$ and $\wedge$ gates (say, with $\vee$ at the root), and distinct n^k variables at the leaves. The players agree on a fixed labeling of the nodes of this tree in which the root is labeled v_0, the children of every $\vee$ gates labeled by V_B, and children of every $\wedge$ gate labeled by V_A. Let f_A and f_B be the inputs to players A, B, respectively. Player A constructs sets S_i of nodes from the ith level inductively as follows. S_0 contains the root. If level i contains $\vee$ gates, then for every gate in S_i labeled v he adds to S_{i+1} the unique child of this gate labeled $f_A(v)$. If level i contains $\wedge$ gates, then for every gate in S_i he adds all its children to S_{i+1}. In a similar way (exchanging the roles of gates) player B constructs his sets T_i. It is easy to verify that S_k is a minterm of h, T_k is a maxterm of h, and that they intersect at a unique leaf whose label is $f^{(k)}(v_0)$. This completes the reduction, and hence the proof. $\square$

3. The three-party model. Let $g : \{0,1\}^{n_1} \times \{0,1\}^{n_2} \times \{0,1\}^{n_3} \to \{0,1\}$ be a function. Players P_1, P_2, P_3 are given (x_2, x_3), (x_1, x_3), (x_1, x_2), respectively, with $x_i \in \{0,1\}^{n_i}$ and compute g from this information by exchanging messages according to a predetermined protocol. We consider only 3-round protocols in which each player speaks once. Let $M^i(g)$ denote the communication complexity when player P_i speaks first (and then the other two in arbitrary order), and $M^s(g)$ the complexity when they all speak simultaneously (an oblivious protocol). Clearly, for all $i \in \{1,2,3\}$ $M^i(g) \leq M^s(g)$.

Let $u : \{0,1\}^{2n} \times \{0,1\}^n \times \{0,1\}^{\log n} \to \{0,1\}$ be the following function. Interpret the first string x_1 as a 2-universal hash function (see Carter and Wegman [3]) h, mapping $\{0,1\}^n$ to itself, the second string x_2 as an argument y to h, and the third x_3 as an index $j \in [n]$. Then, $u(h,y,j) = h(y)_j$. The next two theorems exhibit an exponential gap between 3-round protocols that differ in the order in which players speak.

THEOREM 6. $M^1(u) = M^2(u) = O(\log n)$.

THEOREM 7. $M^3(u) = \Omega(\sqrt{n})$.

Proof of Theorem 7. We first recall a fundamental lemma from [11] regarding the distribution of hash values given little information on the hash function and the argument.

LEMMA 6 [11]. *Let $H = \{h : I \to O\}$ be a collection of universal hash functions from domain I into range O. Let $A \subset I$, $B \subset O$, $C \subset H$ and $p = |B|/|O|$. Then*

$$|\Pr[h(x) \in B \mid x \in A, h \in C] - p| \leq \sqrt{p|H|/(|A||C|)}.$$

Restrict the value of j to be $j \in [\sqrt{n}]$. Thus, we consider $h : \{0,1\}^n \to \{0,1\}^{\sqrt{n}}$, which is still a universal hash function. Assume $M^3(u) \leq \sqrt{n}/5$. This means that there is a new protocol (independent of j) to compute $z = h(y)$ in which P_3 sends $\sqrt{n}/5$ bits, and then players P_1 and P_2 can compute each bit of z separately, using altogether $n/5$ bits.

Let (h, y) be chosen uniformly at random. Simple averaging shows that there are messages m_1, m_2, m_3 of P_1, P_2, P_3, respectively, which under this distribution, satisfy $\Pr[m_1] \geq 2^{-n/4}$, $\Pr[m_2] \geq 2^{-n/4}$, and $\Pr[m_3] \geq 2^{-\sqrt{n}/4}$. As m_1 corresponds to a subset C of all hash functions (inputs to P_1), and m_2 corresponds to a subset A of all inputs to P_2, we can use Lemma 6 with $|H|/|C| \leq 2^{n/4}$, $1/|A| \leq 2^{-3n/4}$, $B = \{z\}$ and $p = 2^{-\sqrt{n}}$ to obtain

$$\Pr[h(y) = z \mid m_1, m_2, m_3] \leq 2^{\sqrt{n}/4} \Pr[h(y)$$

$$= z \mid m_1, m_2] \leq 2^{\sqrt{n}/4} \cdot 2^{-\sqrt{n}/2} = 2^{-\sqrt{n}/4} < 1.$$

Let $f : \{0,1\}^m \to \{0,1\}^n$ be an arbitrary function, and for any $m' < m$ define

$$g_f : \{0,1\}^{m'} \times \{0,1\}^{m-m'} \times \{0,1\}^{\log n} \to \{0,1\} \text{by} g_f(x_1, x_2, x_3)$$

$$= f(x_1 \circ x_2)_{x_3},$$

where $\circ$ denotes concatenation. The next theorem gives the relationship of size-depth trade-offs in circuits to 3-round oblivious protocols.

THEOREM 8. *If f above can be computed by a circuit of fan-in 2, size $O(n)$, and depth $O(\log n)$, then $M^s(g_f) = O(n/\log\log n)$.*

Proof of Theorem 8. Let $f : \{0,1\}^m \to \{0,1\}^n$ be computed by a circuit C of size $O(n)$ and depth $O(\log n)$. By a result of Valiant [17], there are $s = O(n/\log\log n)$ wires in C, $e_1, e_2, \ldots, e_s$ with the following property. For every input $x \in \{0,1\}^m$, and every $j \in [n]$, $f(x)_j$ is determined by the values $e_1(x), \ldots, e_s(x)$ on these wires, together with the values of x_i, $i \in S_j$ with $|S_j| \leq \sqrt{n}$. To compute g_f, note that P_3 has access to $x = (x_1 \circ x_2)$ (which is the input to f) and, therefore, can compute the values on the wires. P_2 and P_3, now knowing $j = x_3$, exchange the necessary bits in S_j to complete the computation of $f(x)_j$.

Acknowledgments. We are grateful to the referees for careful reading and many valuable suggestions.

RECURSIVE STAR-TREE PARALLEL DATA STRUCTURE*

OMER BERKMAN† AND UZI VISHKIN†‡

Abstract. This paper introduces a novel parallel data structure called the recursive star-tree (denoted "*-tree"). For its definition a generalization of the $*$ functional is used (where for a function $f * f(n) = \min\{i | f^{(i)}(n) \leq 1\}$ and $f^{(i)}$ is the ith iterate of f). Recursive *-trees are derived by using recursion in the spirit of the inverse Ackermann function.

The recursive *-tree data structure leads to a new design paradigm for parallel algorithms. This paradigm allows for extremely fast parallel computations, specifically, $O(\alpha(n))$ time (where $\alpha(n)$ is the inverse of the Ackermann function), using an optimal number of processors on the (weakest) concurrent-read, concurrent-write parallel random-access machine (CRCW PRAM).

These computations need only constant time, and use an optimal number of processors if the following nonstandard assumption about the model of parallel computation is added to the CRCW PRAM: an extremely small number of processors each can write simultaneously into different bits of the same word.

Applications include finding lowest common ancestors in trees by a new algorithm that is considerably simpler than the known algorithms for the problem, restricted domain merging, parentheses matching, and a new parallel reducibility.

Key words. parallel algorithms, parallel data structures, lowest common ancestors

C.R. subject classification. F. 2. 2

1. Introduction.

The model of parallel computation used in this paper is the concurrent-read, concurrent-write (CRCW) parallel random-access machine (PRAM). We assume that several processors may attempt to write at the same memory location only if they are seeking to write the same value (the so-called Common CRCW PRAM). We use the weakest Common CRCW PRAM model, in which only concurrent writes of the value one are allowed. Given two parallel algorithms for the same problem, one is *more efficient* than the other if (1) primarily, its time–processor product is smaller and (2) secondarily (but important), its parallel time is smaller. An *optimal* parallel algorithm is an algorithm whose time–processor product matches the sequential complexity of the problem (which in this paper is always linear). A *fully parallel* algorithm is a parallel algorithm that runs in constant time and uses an optimal number of processors. An *almost fully parallel* algorithm is a parallel algorithm that runs in time $\alpha(n)$ (the inverse of the Ackermann function) while using an optimal number of processors.

The notion of a fully parallel algorithm represents an ultimate theoretical goal for designers of parallel algorithms. Research on lower bounds for parallel computation (see references later) indicates that for nearly any interesting problem this goal is not achievable. These same results also preclude almost fully parallel algorithms for the same problems. Therefore, any result that approaches this goal is somewhat surprising.

The class of doubly logarithmic optimal parallel algorithms and the challenge of designing such algorithms is discussed in [BBG$^+$89]. The class of almost fully parallel algorithms represents an even stricter demand.

There is a remarkably small number of problems for which there exist optimal parallel algorithms that run in $o(\log\log n)$ time. These problems include (a) OR and AND of n bits; (b) finding the minimum among n elements, where the input consists of integers in the domain $[1, \cdots, n^c]$ for a constant c (see [FRW84]); (c) $\log^{(k)} n$ coloring of a cycle, where $\log^{(k)}$ is the kth iterate of the log function and k is constant [CV86b]; (d) some probabilistic computational geometry problems [Sto88]; (e) matching a pattern string in a text string, following a preprocessing stage in which a table based on the pattern is built [Vis91].

Not only is the number of such upper bounds small, there is evidence that for almost any interesting problem an $o(\log\log n)$-time optimal upper bound is impossible. We mention time lower bounds for a few very simple problems. Clearly, these lower bounds apply to more involved problems. For brevity, only lower bounds for optimal speed-up algorithms are stated: (a) parity of n bits, for which the time lower bound is $\Omega(\log n/\log\log n)$, following from the lower bound of [Has86] for circuits in conjunction with the general simulation result of [SV84] or from [BH87]; (b) finding the minimum among n elements, for which the lower bound is $\Omega(\log\log n)$ on a comparison model [Val75]; (c) merging two sorted arrays of numbers, for which the lower bound is similar to (b) [BH85].

The main contribution of this paper is a parallel data structure called a *recursive *-tree*. This data structure also provides a new paradigm for parallel algorithms. There are two known examples for which tree-based data structures provide a "skeleton" for parallel algorithms: (1) balanced binary trees, where the depth of such a tree with n leaves is $\log n$, and (2) "doubly logarithmic" balanced trees, where the depth of such a tree with n leaves is $\log\log n$ (each node of a doubly logarithmic tree, whose rooted subtree has x leaves, has $\sqrt{x}$ children). Balanced binary trees are used in the prefix-sums algorithm of [LF80] (perhaps the most heavily used routine in parallel computation) and in many other logarithmic-time algorithms. [BBG$^+$89] shows how to apply doubly logarithmic trees for guiding the flow of the computation in several doubly logarithmic algorithms (including some previously known algorithms). Similarly, the recursive *-tree data structure provides a new pattern for almost fully parallel algorithms.

To be able to list results obtained by application of *-trees, we define the following family of extremely slow-growing functions. Our definition is direct. A subsequent comment explains how this definition leads to an alternative definition of the inverse Ackermann function. For a more standard definition see [Tar75]. We note that such a direct definition is implicit in several "inverse-Ackermann-related" serial algorithms (e.g., [HS86]).

The inverse-Ackermann function. Consider a real function f. Let $f^{(i)}$ denote the ith iterate of f. (Formally, we denote $f^{(1)}(n) = f(n)$ and $f^{(i)}(n) = f(f^{(i-1)}(n))$ for $i > 1$.) Next, we define the $*$ (pronounced "star") functional that maps the function f into another function $*f$: $*f(n) = \min\{i \mid f^{(i)}(n) \leq 1\}$ (we consider only functions for which this minimum is well defined). (The function $\log^*$ will thus be denoted $*\log$.)

We define inductively a series I_k of slow-growing functions from the set of integers that are larger than 2 into the set of positive integers: (i) $I_1(n) = \lceil n/2 \rceil$ and (ii) $I_k = *I_{k-1}$ for $k \geq 2$. The first three in this series are familiar functions: $I_1(n) = \lceil n/2 \rceil$, $I_2(n) = \lceil \log n \rceil$, and $I_3(n) = *\log n$. The inverse Ackermann function is $\alpha(n) = \min\{i \mid I_i(n) \leq i\}$.

Comment. Ackermann's function is defined following [HS86] as follows: $A_1(n) = 2n$ and $A_k(n) = A_{k-1}^{(n)}(1)$ for $k \geq 2$.

Note that I_k is actually the inverse of the kth recursion level of A, the Ackermann function, namely, $I_k(n) = \min\{i \mid A_k(i) \geq n\}$ or $I_k(A_k(n)) = n$. The definition of $\alpha(n)$ is equivalent to the more often used (but perhaps less intuitive) definition: $\min\{i \mid A_i(i) \geq n\}$.

*Applications of recursive *-trees*.

1. *The lowest-common-ancestor* (LCA) *problem*. Suppose a rooted tree T is given for preprocessing. The preprocessing should enable a single processor to process quickly queries of the following form: Given two vertices u and v, find their lowest common ancestor in T.

Results. (i) Preprocessing is in $I_m(n)$ time and uses an optimal number of processors. (The space complexity here and throughout the paper is linear unless otherwise specified.) Queries will be processed in $O(m)$ time, that is, $O(1)$ time for constant m. A more specific result is (ii) almost fully parallel preprocessing and $O(\alpha(n))$ time for processing a query. These results assume that the Euler tour of the tree and the level of each vertex in the tree are given. Without this assumption the time for preprocessing is $O(\log n)$ with an optimal number of processors, and each query can be processed in constant time. For a serial implementation the preprocessing time is linear and a query can be processed in constant time.

Our algorithm for the LCA problem is new and is based on an approach that is completely different from the serial algorithm of Harel and Tarjan [HT84] and the simplified and parallelizable algorithm of Schieber and Vishkin [SV88]. Its serial version is considerably simpler than these two algorithms. Specifically, consider the Euler tour of the tree and replace each vertex in the tour by its level. This gives a sequence of integers. Unlike previous approaches, the new LCA algorithm is based only on an analysis of this sequence of integers. In particular, answering an LCA query converts to finding the minimum over some range $[i, i+1, \cdots, j]$ of the sequence of levels. (We define the range-minima problem formally and discuss previous results for it in §3.) This provides another interesting example of the quest for parallel algorithms also enriching the field of serial algorithms. Algorithms for quite a few problems use an LCA algorithm as a subroutine. We mention some: (1) strong orientation [Vis85]; (2) computing an open ear decomposition and st-numbering of a biconnected graph [MSV86] (also, [FRT89] and [RR89] use as a subroutine an algorithm for st-numbering and thus also the LCA algorithm); (3) approximate string matching on strings [LV89] and on trees [SZ89] and retrieving information on strings from their suffix trees [AIL$^+$88].

2. *The all-nearest-zero-bit problem*. Let $A = (a_1, a_2, \cdots, a_n)$ be an array of bits. For each bit a_i find the nearest-zero bit both to its left and right.

Result. The algorithm is almost fully parallel.

A similar problem is considered in [CFL83], where the motivation is circuits.

3. *The parentheses-matching problem*. Suppose a legal sequence of parentheses is given. For each parenthesis find its mate.

Result. Assuming the level of nesting of each parenthesis is given, we have an almost fully parallel algorithm. Without this assumption $T = O(\log n / \log\log n)$ if an optimal number of processors is used.

Parentheses matching in parallel is considered in [AMW89], [BSV88], [BV85], and [DS83]. We are putting the algorithm for parentheses matching into a later paper [BV91] to keep the present paper to a reasonable length.

4. *Restricted-domain merging*. Let $A = (a_1, \cdots, a_n)$ and $B = (b_1, \cdots, b_n)$ be two

nondecreasing lists whose elements are integers drawn from the domain $[1, \cdots, n]$. The problem is to merge them into a sorted list.

Result. The algorithm is almost fully parallel.

Merging in parallel is considered in [Van89], [BH85], [Kru83], [SV81], and [Val75]. We presented the merging algorithm in another paper [BV90], where it is implemented on the less powerful concurrent-read, exclusive-write (CREW PRAM) model with the same bounds, and the restricted-domain limitation is somewhat relaxed by using unrelated techniques.

5. *Almost fully parallel reducibility*. Let A and B be two problems. Suppose that any input of size n for problem A can be mapped into an input of size $O(n)$ for problem B. Such a mapping from A to B is an *almost fully parallel reducibility* if it can be realized by an almost fully parallel algorithm.

Given a convex polygon, the *all-nearest-neighbors* (*ANN*) problem is to find for each vertex of the polygon its nearest (Euclidean) neighbor. Using almost fully parallel reducibilities, we prove the following lower bound for the ANN problem: Any CRCW PRAM algorithm for the ANN problem that uses $O(n \log^c n)$ (for any constant c) processors needs $\Omega(\log \log n)$ time. We note that this lower bound is proved in [SV90] by using a considerably more involved technique.

Fully parallel results. For our fully parallel results we introduce the CRCW-bit PRAM model of computation. In addition to the above definition of the CRCW PRAM, we assume that a few processors can each write simultaneously into different bits of the same word. Specifically, in our algorithms this number of processors is very small and never exceeds $O(I_d(n))$, where d is a constant. Therefore, the assumption strikes us as quite reasonable from the architectural point of view. We believe that the cost for implementing a step of a PRAM on a feasible machine is likely to absorb implementation of this assumption at no extra cost. Nevertheless, we do not advocate adopting the CRCW-bit PRAM as a theoretical substitute for the CRCW PRAM.

Specific fully parallel results.

1. *The lowest-common-ancestor problem*. The preprocessing algorithm is fully parallel if we assume that the Euler tour of the tree and the level of each vertex in the tree are given. A query can be processed in constant time.

2. *The all-nearest-zero-bit problem*. The algorithm is fully parallel.

3. *The parentheses-matching problem*. If we assume that the level of nesting of each parenthesis is given, the algorithm is fully parallel.

4. *Restricted-domain merging*. The algorithm is fully parallel.

Results 3 and 4 are not explicitly given in [BV91] and [BV90]. However, they can be derived from the series of fast algorithms in these papers in a fashion similar to the way the fully parallel algorithm of §4.4 in the current paper is derived from the series of algorithms of Lemma 4.2.1 below.

We elaborate on where our fully parallel algorithms use the CRCW-bit new assumption. The algorithms work by mapping the input of size n into n bits. Then, given any constant d, we derive a value $x = O(I_d(n))$. The algorithms proceed by forming n/x groups of x bits each. Informally, our problem is then to pack all x bits of the same group into a single word and solve the original problem with respect to an input of size x in constant time. This packing is exactly where our almost fully parallel CRCW PRAM algorithms fail to become fully parallel and the CRCW-bit assumption is used. We believe that it is of theoretical interest to determine ways of avoiding such packing and thereby get fully parallel algorithms on a CRCW PRAM without the CRCW-bit assumption and suggest this as open problem.

A repeating motif in the present paper is putting restrictions on the domain of problems. This is the case for the all-nearest-zero-bit problem and the restricted-domain merging problem. Perhaps our more interesting applications concern problems whose input domain is *not explicitly restricted*. This is the case for the LCA problem and the parentheses-matching problem. However, as part of the design of our algorithms for these respective problems, we identified a few subproblems whose input domains are restricted: The level of vertices in the Euler tour is the restricted input for the LCA subproblem, and the level of nesting of each parenthesis is the input for the parentheses-matching subproblem. The Euler tour and prefix sums (by which the level of nesting is computed) are basic techniques for trees and arrays, respectively. A lower bound on their running times is $\Omega(\log n/\log\log n)$. One of the aims of this paper is to determine the added difficulty of each of the two problems, LCA and parentheses matching, beyond the use of these basic (and simple) techniques.

The rest of this paper is organized as follows. Section 2 describes the recursive *-tree data structure, and §3 recalls a few basic problems and algorithms. In §4 the parallel algorithms for LCA and the all-nearest-zero bit are presented. A sequential version of the LCA algorithm, which is considerably simpler than the parallel version, is also outlined. The almost fully parallel reducibility is presented in §5, and §6 discusses how to efficiently compute the functions used in this paper.

2. The recursive *-tree data structure. Let n be a positive integer. We define inductively a series of $\alpha(n) - 1$ trees. For each m, $2 \leq m \leq \alpha(n)$, a balanced tree with n leaves, denoted $BT(m)$, is defined. For a given m, $BT(m)$ is a recursive tree in the sense that each of its nodes holds a tree of the form $BT(m-1)$.

The base of the inductive definition (*see Fig.* 1). We start with the definition of the *-tree $BT(2)$. $BT(2)$ is simply a complete binary tree with n leaves.

Number of children per node	Number of leaves per node	Level of the tree
$I_1^{(0)}(n)/I_1^{(1)}(n) = 2$	$I_1^{(0)}(n) = n$	1
$I_1^{(1)}(n)/I_1^{(2)}(n) = 2$	$I_1^{(1)}(n) = \frac{n}{2}$	2
$I_1^{(2)}(n)/I_1^{(3)}(n) = 2$	$I_1^{(2)}(n) = \frac{n}{4}$	3
0	1	$*I_1(n) + 1$ $= I_2(n) + 1$ $= \log n + 1$

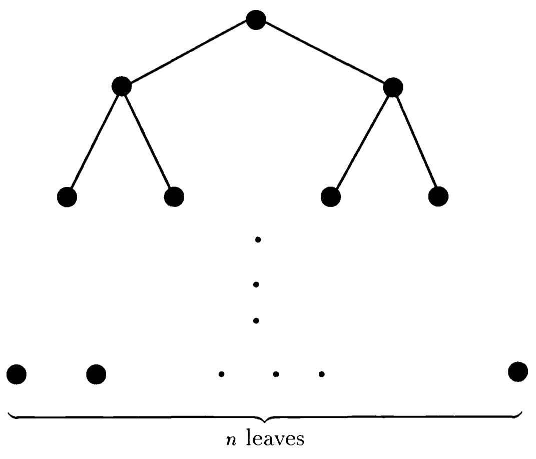

FIG. 1. *A BT (2) tree.*

The inductive step (*see Fig.* 2). For $m, 3 \leq m \leq \alpha(n)$, we define $BT(m)$ as follows. $BT(m)$ has n leaves. The number of levels in $BT(m)$ is $*I_{m-1}(n) + 1$ ($= I_m(n) + 1$). The root is at level 1, and the leaves are at level $*I_{m-1}(n) + 1$. Consider a node v at level $1 \leq l \leq *I_{m-1}(n)$ of the tree. Node v has $I^{(l-1)}_{m-1}(n)/I^{(l)}_{m-1}(n)$ children (we define $I^{(0)}_{m-1}(n)$ to be n). The total number of leaves in the subtree rooted at node v is $I^{(l-1)}_{m-1}(n)$. We refer to the part of the $BT(m)$ tree described so far as the *top recursion level* of $BT(m)$ (denoted $TRL-BT(m)$ for brevity). In addition, node v recursively contains a $BT(m-1)$ tree. The number of leaves in this tree is exactly the number of children of node v in $BT(m)$.

Number of children per node	Number of leaves per node	Level of the tree
$I^{(0)}_{m-1}(n)/I^{(1)}_{m-1}(n)$	$I^{(0)}_{m-1}(n) = n$	1
$I^{(1)}_{m-1}(n)/I^{(2)}_{m-1}(n)$	$I^{(1)}_{m-1}(n)$	2
$I^{(2)}_{m-1}(n)/I^{(3)}_{m-1}(n)$	$I^{(2)}_{m-1}(n)$	3
0	1	$*I_{m-1}(n) + 1$ $= I_m(n) + 1$

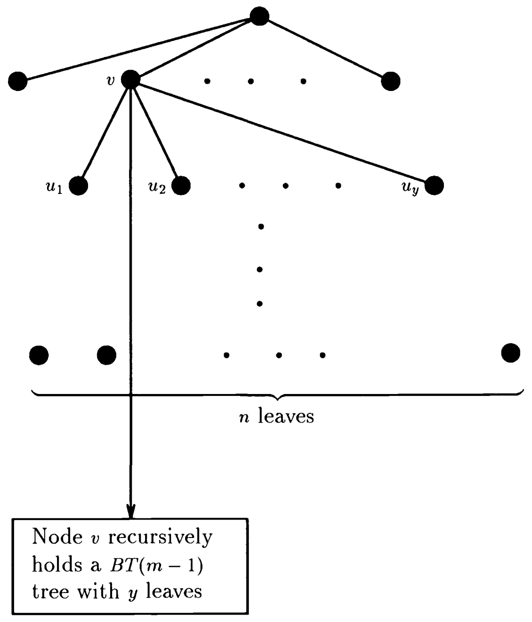

FIG. 2. *$BT(m)$—mth recursive $*$—tree.*

There is one key idea that enables our algorithms to be as fast as they are. When the mth tree $BT(m)$ is used to guide the computation, *we invest $O(1)$ time on the top recursion level for $BT(m)$*! Since $BT(m)$ has m levels of recursion, this leads to a total of $O(m)$ time.

Similar computational structures have appeared in a few contexts. See [AS87] and [Yao82] for generalized range-minima computations, [HS86] for Davenport–Schinzel sequences, and [CFL83] for circuits.

3. Basics. We need the following problems and algorithms.

The Euler-tour technique. Consider a tree $T = (V, E)$ rooted at some vertex r. The Euler-tour technique enables us to compute several problems on trees in logarithmic time and optimal speedup (see also [TV85] and [Vis85]). The technique is summarized below.

Step 1. For each edge $(v \to u)$ in T we add its antiparallel edge $(u \to v)$. Let H denote the new graph. Since the in-degree and out-degree of each vertex in H are the same, H has an Euler path that starts and ends in the root r of T. Step 2 computes this path into a vector of pointers D of size $2|E|$, where for each edge e of H, $D(e)$ gives the successor edge of e in the Euler path.

Step 2. For each vertex v of H we do the following. Let the outgoing edges of v be $(v \to u_0), \cdots, (v \to u_{d-1})$. Then $D(u_i \to v) := (v \to u_{(i+1) \bmod d})$ for $i = 0, \cdots, d-1$. Vector D now represents an Euler circuit of H. The "correction" $D(u_{d-1} \to r) :=$ end-of-list (where the out-degree of r is d) gives an Euler path that starts and ends in r.

Step 3. In this step we apply list ranking to the Euler path. This results in ranking the edges so that the tour can be stored in an array. Similarly, we can find for each vertex in the tree its distance from the root. This distance is called the *level* of vertex v. These and other applications of list ranking appear in [TV85]. This list ranking can be performed in logarithmic time with an optimal number of processors by the method of [AM88], [CV86a], or [CV89].

Comments.

1. In §4 we assume that the Euler tour is given in an already ranked form. There we systematically replace each edge (u, v) in the Euler tour by the vertex v. We then add the root of the tree to the beginning of this new array. Suppose a vertex v has l children. Then v appears $l + 1$ times in our array.

2. We note that while advancing from a vertex to its successor in the Euler tour, the level may either increase by one or decrease by one.

Finding the minimum for restricted-domain inputs. Given an array $A = (a_1, a_2, \cdots, a_n)$ where each a_i is an integer between 1 and n, find the minimum value in A.

Fich, Ragde, and Wigderson [FRW84] gave the following parallel algorithm for the restricted-domain minimum-finding problem. It runs in $O(1)$ time with n processors. We use an auxiliary vector B of size n, which is all zero initially. Processor $i, 1 \leq i \leq n$, writes one into location $B(a_i)$. Now the problem is to find the leftmost one in B. Partition B into $\sqrt{n}$ equal-size subarrays. For each such subarray find in $O(1)$ time, using $\sqrt{n}$ processors, whether the subarray contains a one. Apply the $O(1)$ time algorithm of Shiloach and Vishkin [SV81] for finding the leftmost subarray of size $\sqrt{n}$ containing a one, using n processors. Finally, reapply this latter algorithm for finding the index of the leftmost one in this subarray.

Remark 3.1. This algorithm can be readily generalized to yield $O(1)$ time for inputs between 1 and p^c, where $c > 1$ is a constant, as long as $p \geq n$ processors are used.

Range-minima problem. Given an array $A = (a_1, a_2, \cdots, a_n)$ of n real numbers, preprocess the array so that for any interval $[a_i, a_{i+1}, \cdots, a_j]$ the minimum over the interval can be retrieved in constant time by using a single processor.

We show how to preprocess A in constant (to be precise, $O(1/\epsilon)$) time with $n^{1+\epsilon}$ processors and $O(n^{1+\epsilon})$ space for any constant ϵ. The preprocessing algorithm uses the following naive parallel algorithm for the range-minima problem. Allocate n^2 processors to each interval $[a_i, a_{i+1}, \cdots, a_j]$, and find the minimum over the interval in constant time, as in [SV81]. This naive algorithm runs in constant time and uses n^4 processors and n^2 space.

The preprocessing algorithm. Suppose some constant ϵ is given. The output of the preprocessing algorithm can be described by means of a balanced tree T with n leaves, where each internal node has $n^{\epsilon/3}$ children. The root of the tree is at level one, and the leaves are at level $3/\epsilon+1$. Let v be an internal node, and, let $u_1, \cdots, u_{n^{\epsilon/3}}$ be its children. Each internal node v has the following data:

1. $M(v)$, the minimum over its leaves (i.e., the leaves of its subtree);
2. For each $1 \leq i < j \leq n^{\epsilon/3}$ the minimum over the range $\{M(u_i), M(u_{i+1}), \cdots, M(u_j)\}$.

This requires $O(n^{2\epsilon/3})$ space per internal node and a total of $O(n^{1+\epsilon/3})$ space.

The preprocessing algorithm advances through the levels of the tree in $3/\epsilon$ steps, starting from level $3/\epsilon$. At each level each node computes its data by using the naive range-minima algorithm. Each internal node uses $n^{4\epsilon/3}$ processors and $O(n^{2\epsilon/3})$ space, and the whole algorithm uses $n^{1+\epsilon}$ processors, $O(n^{1+\epsilon/3})$ space, and $O(3/\epsilon)$ time.

Retrieval. Suppose we wish to find the minimum, MIN(i,j), over an interval $[a_i, a_{i+1}, \cdots, a_j]$. Let LCA$(a_i, a_j)$ be the lowest common ancestor of leaf a_i and leaf a_j in the tree T. There are two possibilities.

(i) LCA(a_i, a_j) is at level $3/\epsilon$. The data at LCA(a_i, a_j) give MIN(i,j).

(ii) LCA(a_i, a_j) is at level $< 3/\epsilon$. Let x be the number of edges in the path from a_i (or a_j) to LCA(a_i, a_j) (i.e., LCA(a_i, a_j) is at level $3/\epsilon + 1 - x$). Using the tree T, we can represent interval $[i,j]$ as a disjoint union of $2x - 1$ intervals whose minima were previously computed. Formally, let $r(i)$ denote the rightmost leaf of the parent of a_i in T, and, let $l(j)$ denote the leftmost leaf of the parent of a_j in T. MIN$[i,j]$ is the minimum among three numbers.

1. MIN$[i, r(i)]$. The data at the parent of a_i give this information.
2. MIN$[l(j), j]$. The data at the parent of a_j give this information.
3. MIN$[r(i)+1, l(j)-1]$. Advance to level $3/\epsilon$ of the tree to get this information recursively.

Complexity. Retrieval of MIN(i,j) takes constant time: The first and second numbers can be looked up in $O(1)$ time. Retrieval of the third number takes $O(3/\epsilon - 1)$ time.

Below we review previous results for the range-minima problem. This review is appropriate since the main technical effort of §4 is a parallel algorithm for an instance of the range-minima problem. [GBT84] gives a linear time algorithm for preprocessing that allows constant-time query retrieval. We discuss these results further in Remark 4.1. An $O(\log\log n)$-time optimal parallel preprocessing algorithm for the range-minima problem is given in [BSV88]. The following generalization of the range-minima problem is considered in [Yao82] and [AS87]. The input array A contains semigroup elements, and a query over the range $[i,j]$ requests the product $a_i \cdot a_{i+1} \cdot \cdots \cdot a_j$, where "$\cdot$" is the semigroup product operator. Both papers give a sequential algorithm for the problem that runs in $O(n\alpha(n))$ time and allows $O(\alpha(n))$ time for query retrieval. In addition, they show that $\Omega(\alpha(n))$ is needed if only linear time is allowed for preprocessing. [AS87] also gives a tradeoff between the sequential time needed for preprocessing and the time for answering a query. The algorithm we give for our instance of the range-minima problem (given in §4) benefits from this approach. However, a serial implementation of our preprocessing algorithm needs only linear time.

4. LCA algorithm.

The input to this problem is a rooted tree $T = (V, E)$. Let $n = 2|V| - 1$. We assume that we are given a sequence of n vertices $A = [a_1, \cdots, a_n]$, which is the Euler tour of the input tree, and that we know for each vertex v its level, LEVEL(v), in the tree.

Recall the range-minima problem defined in §3. Below we give a simple reduction from the LCA problem to a restricted-domain range-minima problem, which is an instance of the range-minima problem in which *the difference between each two successive* *numbers for the range-minima problem is exactly one*. The reduction takes $O(1)$ time and uses n processors. An algorithm for the restricted-domain range-minima problem is given later, implying an algorithm for the LCA problem.

4.1. Reducing the LCA problem to a restricted-domain range-minima problem. Let v be a vertex in T. Denote by $l(v)$ the index of the leftmost appearance of v in A and by $r(v)$ the index of its rightmost appearance. For each vertex v in T it is easy to find $l(v)$ and $r(v)$ in $O(1)$ time with n processors by using the following (trivial) observations: $l(v)$ is where $a_{l(v)} = v$ and $\text{LEVEL}(a_{l(v)-1}) = \text{LEVEL}(v) - 1$; $r(v)$ is where $a_{r(v)} = v$ and $\text{LEVEL}(a_{r(v)+1}) = \text{LEVEL}(v) - 1$. The claims and corollaries below provide guidelines for the reduction.

CLAIM 1. *Vertex u is an ancestor of vertex v if and only if $l(u) < l(v) < r(u)$.*

COROLLARY 1. *Given two vertices u and v, a single processor can find in constant time whether u is an ancestor of v.*

COROLLARY 2. *Vertices u and v are unrelated (namely, neither is u an ancestor of v nor is v an ancestor of u) if and only if either $r(u) < l(v)$ or $r(v) < l(u)$.*

CLAIM 2. *Let u and v be two unrelated vertices. (By Corollary 2 we may assume without loss of generality that $r(u) < l(v)$.) Then the* LCA *of u and v is the vertex whose level is minimal over the interval $[r(u), l(v)]$ in A.*

The reduction. Let $\text{LEVEL}(A) = [\text{LEVEL}(a_1), \text{LEVEL}(a_2), \cdots, \text{LEVEL}(a_n)]$. Claim 2 shows that after we perform the range-minima preprocessing algorithm with respect to $\text{LEVEL}(A)$, a query of the form $\text{LCA}(u, v)$ becomes a range-minimum query. Observe that the difference between the level of each pair of successive vertices in the Euler tour (and thus each pair of successive entries in $\text{LEVEL}(A)$) is exactly one and therefore the reduction is to the restricted-domain range-minima problem as required.

Remark 4.1. In [GBT84] it is observed that the problem of preprocessing an array so that each range-minimum query can be answered in constant time (this is the range-minima problem defined in §3) is equivalent to the LCA problem. It gives a linear-time algorithm for the former problem by using an algorithm for the latter. This does not look very helpful: We know to solve the range-minima problem on the basis of the LCA problem, and, conversely, we know to solve the LCA problem on the basis of the range-minima problem. Nevertheless, using the restricted-domain properties of our range-minima problem, we show that this cyclic relationship between the two problems can be broken and thereby lead to a new algorithm.

4.2. The restricted-domain range-minima algorithm. Below we define a restricted-domain range-minima problem that is slightly more general than the problem for LEVEL (A). The more general definition enables recursion in the algorithm below. The rest of this section shows how to solve this problem.

The restricted-domain range-minima problem. We are given an integer k and an array $A = (a_i, a_2, \cdots, a_n)$ of integers, such that $|a_i - a_{i+1}| \leq k$. In words, the difference between each $a_i, 1 \leq i < n$, and its successor a_{i+1} is at most k. The parameter k need not be a constant. Preprocess the array $A = (a_1, a_2, \cdots, a_n)$ so that any query $\text{MIN}[i, j]$, $1 \leq i < j \leq n$, requesting the minimum element over the interval $[a_i, \cdots, a_j]$, can be processed quickly with a single processor.

Comment 1. We make the simplifying assumption that $\sqrt{k}$ and all other quantities needed in the paper are always integers. For example, $\log n$ and $n/\log n$ are assumed to be integers. This implies that the root of $BT(3)$ with n leaves has $n/\log n$ children, each with *exactly* $\log n$ leaves in its rooted subtree. To demonstrate that handling the general case is only a matter of technicality let us consider as an example the *-tree

$BT(3)$. When $BT(3)$ is used in the algorithm below with, say, r leaves, we need to store at each internal node an array that contains all leaves of the node. The space is thus $O(r)$ per level and $O(r \log^* r)$ overall. We sketch how to treat general r: The number of children of the root of $BT(3)$ will be $\lceil r/\log r \rceil$, each with $\lceil \log r \rceil$ leaves. This implies that additional $O(r/\log r)$ space is needed for all nodes at level 2 of the tree. At level 3 the additional space needed is $O(\lceil r/\log r \rceil \cdot \lceil \log \log r \rceil)$. Overall, the additional space required is linear. To facilitate memory access we will allocate to each level of $BT(3)$ an additional $O(r)$ space, which is more than is actually needed. This will double the space and number of processors needed by our algorithms but will not change the complexity in terms of "big Oh."

Comment 2. In case the minimum in the interval is not unique, find the minimum element in $[a_i, \cdots, a_j]$ whose index is smallest ("the leftmost minimum element"). Throughout this section, whenever we refer to a minimum over an interval we always mean the leftmost minimum element. Finding the leftmost minimum element (and not just the minimum value) will serve us later.

We start by constructing recursively a series of $\alpha(n) - 1$ parallel preprocessing algorithms for our range-minima problem.

LEMMA 4.2.1. *The algorithm for $2 \leq m \leq \alpha(n)$ runs in cm time, for some constant c, using $nI_m(n) + \sqrt{k}n$ processors and $o(nI_m(n))$ space. The preprocessing algorithm results in a table. With this table any range-minimum query can be processed in cm time with one processor. In addition, the preprocessing algorithm finds explicitly all prefix minima and suffix minima. Therefore, there is no need to do any processing for prefix-minima or suffix-minima queries.*

Our optimal algorithms, whose efficiencies are given in Theorem 4.3.1, are derived from this series of algorithms. We describe the series of preprocessing algorithms. We give first the base of the recursive construction and later the recursive step.

The base of the recursive construction (*the algorithm for $m = 2$*). To provide intuition for the description of the preprocessing algorithm for $m = 2$ we present first its output and how the output can be used for processing a range-minimum query.

Output of the preprocessing algorithm for $m = 2$:

(1) For each consecutive subarray $a_{j \log^3 n+1}, \cdots, a_{(j+1)\log^3 n}$, $0 \leq j \leq n/\log^3 n - 1$, we keep a table. The table enables constant-time retrieval of any range-minimum query within the subarray.

(2) We have array $B = b_1, \cdots, b_{n/\log^3 n}$, consisting of the minimum in each subarray.

(3) We have a complete binary tree $BT(2)$, whose leaves are $b_1, \cdots, b_{n/\log^3 n}$. Each internal node v of the tree holds an array P_v with an entry for each leaf of v. Consider prefixes that span between $l(v)$, the leftmost leaf of v, and a leaf of v. Array P_v has the minima over all these prefixes. Node v also holds a similar array S_v. For each suffix that spans between a leaf v and $r(v)$, the rightmost leaf of v, array S_v has its minimum.

(4) We have two arrays of size n each; one contains all prefix minima and the other contains all suffix minima with respect to A.

Remark. The reason behind the (seemingly arbitrary) grouping of array A into subarrays of $\log^3 n$ elements each is as follows: The main part of the preprocessing algorithm for $m = 2$ (which is given below) deals with constructing output element (3). To maintain processor count within our desired bounds, the input to this part (which is array B) must be of size $O(n/\log^3 n)$.

LEMMA 4.2.2. *Let m be 2. Then $I_m(n) = \log n$. The preprocessing algorithm runs in 2c time for some constant c using $n \log n + \sqrt{k}n$ processors and $o(n \log n)$ space. Retrieval of a query* MIN$[i, j]$ *takes 2c time with one processor.*

How does one retrieve a query MIN$[i,j]$ in constant time? There are two possibilities.

(i) a_i and a_j belong to the same subarray (of size $\log^3 n$). MIN(i,j) is computed in $O(1)$ time by using the table that belongs to the subarray.

(ii) a_i and a_j belong to different subarrays. Let right(i) denote the rightmost element in the subarray of a_i and let left(j) denote the leftmost element in the subarray of a_j. MIN$[i,j]$ is the minimum among three numbers:

1. MIN$[i$,right$(i)]$, the minimum over the suffix of a_i in its subarray;
2. MIN[left$(j),j]$, the minimum over the prefix of a_j in its subarray;
3. MIN[right$(i)+1$, left$(j)-1$].

The retrieval of the first and second numbers is similar to possibility (i) above. Denote $i_1 = \lceil i/\log^3 n\rceil + 1$ and denote $j_1 = \lceil j/\log^3 n\rceil - 1$. Retrieval of the third number is equivalent to finding the minimum over interval $[b_{i_1}, \cdots, b_{j_1}]$ in B, which is denoted MIN$_B[i_1, j_1]$.

Let x be the lowest common ancestor of b_{i_1} and b_{j_1}, let x_1 be the child of x that is an ancestor of b_{i_1}, and let x_2 be the child of x that is an ancestor of b_{j_1}. MIN$_B[i_1, j_1]$ is the minimum of two numbers:

1. MIN$_B[i_1, r(x_1)]$, the minimum over the suffix of b_{i_1} in x_1 (we obtain this from S_{x_1});
2. MIN$_B[l(x_2), j_1]$, the minimum over the prefix of b_{j_1} in x_2 (we obtain this from P_{x_2}).

How to find x, x_1, and x_2 in constant time remains to be shown. It is observed in [HT84] that the lowest common ancestor of two leaves in a complete binary tree can be found in constant time with one processor. (The idea is to number the leaves from 0 to $n-1$. Given two leaves i_1 and j_1, it suffices to find the most significant bit in which the binary representation of i_1 and j_1 are different in order to get their lowest common ancestor.) Thus x (and thereby also x_1 and x_2) can be found in constant time. Constant-time retrieval of the MIN(i,j) query follows.

The preprocessing algorithm for $m = 2$.

Step 1. Partition A into subarrays of $\log^3 n$ elements each. Allocate $\log^4 n$ processors to each subarray, and apply the preprocessing algorithm for range minima given in §3 (for $\epsilon = \frac{1}{3}$). This uses $\log^4 n$ processors and $O(\log^3 n \log^{1/3} n)$ space per subarray and $n \log n$ processors and $o(n \log n)$ space overall.

Step 2. Take the minimum in each subarray to build array B of size $n/\log^3 n$. The difference between two successive elements in B is at most $k \log^3 n$.

Step 3. Build $BT(2)$, a complete binary tree whose leaves are the elements of B. For each internal node v of $BT(2)$ we keep an array. The array consists of the values of all leaves in the subtree rooted at v. So the space needed is $O(n/\log^3 n)$ per level and $O(n/\log^2 n)$ for all levels of the tree. We allocate to each leaf at each level $\sqrt{k}\log^2 n$ processors, and the total number of processors used is thus $\sqrt{k}n$.

Step 4. For each internal node find the minimum element over its array. If the minimum element is not unique, the leftmost one is found. We apply the constant- time algorithm mentioned in Remark 3.1. Consider an internal node of size r. After subtracting the first element of the array from each of its elements, we get an array whose elements range between $-kr\log^3 n$ and $kr \log^3 n$. The size of the range, which is $2kr\log^3 n + 1$, does not exceed the square of the number of processors, which is $r\sqrt{k}\log^2 n$, and the algorithm of Remark 3.1 can be applied.

Step 5. For each internal node v we compute P_v (S_v is computed similarly). That is, for each leaf b_i of v we need to find MIN$_B[l(v), i]$ (the minimum over the prefix of b_i

in v). For this, the minimum among the following list of (at most) $\log n + 1$ numbers is computed. Denote the level of v in the binary tree by level (v). Each level l, level $(v) < l \leq \log n + 1$, of the tree contributes (at most) one number. Let u denote the ancestor at level $l-1$ of b_i. Let u_1 and u_2 denote the left and right children of u, respectively. If b_i belongs to (the subtree rooted at) u_2, then level l contributes the minimum over u_1. If b_i belongs to u_1, then level l does not contribute anything (actually, level l contributes a large default value so that the minimum computation is not affected). Finally, b_i is also included in the list. This minimum computation can be done in constant time with $\log^2 n$ processors by the algorithm of [SV81]. Note that all prefix minima and all suffix minima of B are computed (in the root) in this step. We note that since $BT(2)$ is a complete binary tree, node u (the ancestor at level $l-1$ of b_i) can be easily found in constant time with one processor ([HT84]).

Step 6. For each a_i we find its prefix minimum and its suffix minimum with respect to A in constant time by using one processor. Let b_j be the minimum representing the subarray of size $\log^3 n$ containing a_i. The minimum over the prefix of a_i with respect to A is the minimum between the prefix of b_{j-1} with respect to B and the minimum over the prefix of a_i with respect to its subarray.

This completes the description of the recursion base: Items (1), (2), (3), and (4) of the output were computed (respectively) in steps 1, 2, 5, and 6 above. The complexity of the recursion base is specified by $O(1)$ time by using $n \log n + \sqrt{k}n$ processors and $o(n \log n)$ space. Lemma 4.2.2 follows.

The recursion step. The algorithm is presented in a way similar to that of the recursion base.

Output of the mth preprocessing algorithm.

(1) For each consecutive subarray $a_{jI^3_m(n)+1}, \cdots, a_{(j+1)I^3_m(n)}$, $0 \leq j \leq n/I^3_m(n) - 1$, we keep a table. The table enables constant-time retrieval of any range-minimum query within the subarray. (The notation $I^3_m(n)$ means $(I_m(n))^3$, where $I_m(n)$ is defined earlier.)

(2) We have array $B = b_1, \cdots, b_{n/I^3_m(n)}$, consisting of the minimum in each subarray.

(3) We have $TRL\text{–}BT(m)$, the top recursion level of (the recursive *-tree) $BT(m)$, whose leaves are $b_1, \cdots, b_{n/I^3_m(n)}$. Each internal node v of $TRL-BT(m)$ holds an array P_v and array S_v with an entry for each leaf of v. These arrays hold (as in the binary tree for $m = 2$) prefix minima and suffix minima with respect to the leaves of v.

(4) Let $u_1, \cdots, u_y$ be the children of v, an internal node of $TRL-BT(m)$. Denote by MIN(u_i) the minimum over the leaves of node u_i, $1 \leq i \leq y$. Each such node v has recursively the output of the $(m-1)$th preprocessing algorithm with respect to the input MIN$(u_1), \cdots$, MIN(u_y).

(5) We have two arrays of size n each; one contains all prefix minima and the other contains all suffix minima with respect to A.

How can we retrieve a query MIN$[i, j]$ in cm time? We distinguish two possibilities.

(i) a_i and a_j belong to the same subarray (of size $I^3_m(n)$). MIN(i, j) is computed in $O(1)$ time by using the table that belongs to the subarray.

(ii) a_i and a_j belong to different subarrays. Again, let right(i) denote the rightmost element in the subarray of a_i, and let left(j) denote the leftmost element in the subarray of a_j. MIN$[i, j]$ is the minimum among three numbers:

1. MIN$[i$,right$(i)]$;
2. MIN$[$left$(j), j]$;
3. MIN$[$right$(i) + 1$,left$(j) - 1]$.

The retrieval of the first and second numbers is similar to possibility (i) above. Denote $i_1 = \lceil i/I_m^3(n) \rceil + 1$, and denote $j_1 = \lceil j/I_m^3(n) \rceil - 1$. Retrieval of the third number is equivalent to finding the minimum over interval $[b_{i_1}, \cdots, b_{j_1}]$ in B, which is denoted $\text{MIN}_B[i_1, j_1]$.

Let x be the lowest common ancestor of b_{i_1} and b_{j_1} in $TRL-BT(m)$, let $x_{\beta(i_1)}$ be the child of x that is an ancestor of b_{i_1}, and let $x_{\beta(j_1)}$ be the child of x that is an ancestor of b_{j_1}. $\text{MIN}_B[i_1, j_1]$ is (recursively) the minimum among three numbers:

1. $\text{MIN}_B[i_1, r(x_{\beta(i_1)})]$, the minimum over the suffix of b_{i_1} in $x_{\beta(i_1)}$ (we obtain this from $S_{x_{\beta(i_1)}}$);

2. $\text{MIN}_B[l(x_{\beta(j_1)}), j_1]$, the minimum over the prefix of b_{j_1} in $x_{\beta(j_1)}$ (we obtain this from $P_{x_{\beta(j_1)}}$);

3. $\text{MIN}_B[r(x_{\beta(i_1)}) + 1, l(x_{\beta(j_1)}) - 1]$ (this will be recursively derived from the data at node x).

The first two numbers are precomputed in $TRL–BT(m)$. The recursive definition of the third number implies that $\text{MIN}_B[i_1, j_1]$ is actually the minimum among $4(m-1)-2$ precomputed numbers and can thus be done in $\overline{c_1}m$ time for some constant $\overline{c_1}$. Below we show how to find the nodes x, $x_{\beta(i_1)}$, and $x_{\beta(j_1)}$ in constant time with one processor. This (together with the recursive definition of $BT(m)$) implies that over the retrieval procedure finding these nodes takes $\overline{c_2}m$ time for some constant $\overline{c_2}$ when one processor is used . We choose $c > \overline{c_1} + \overline{c_2}$, and the retrieval time is then cm, as required.

We first note that for each leaf of $TRL-BT(m)$, finding the child of the root that is its ancestor needs constant time if one processor is used: Recall that the number of leaves of $TRL-BT(m)$ is $n/I_m^3(n)$, its root has $(n/I_m^3(n))/I_{m-1}(n/I_m^3(n))$ children, and each of these children has $I_{m-1}(n/I_m^3(n))$ leaves. Thus the ancestor of a leaf b_i, $1 \le i \le n/I_m^3(n)$, of $TRL–BT(m)$ is the $\lceil i/I_{m-1}(n/I_m^3(n)) \rceil$th child of the root. Given two leaves of $TRL–BT(m)$, consider their ancestors among the children of the root. If these ancestors are different, we are done. Suppose these ancestors are the same.

Observe that for $TRL–BT(m)$ the same subtree structure is replicated at each child of the root. As part of the preprocessing algorithm we build one table with respect to this generic subtree structure. For each pair of leaves u and v of the generic subtree structure, we compute three items into a table: (1) their lowest common ancestor w; (2) the child f of w that is an ancestor of u; (3) the child g of w that is an ancestor of v. Since each child of the root has $I_{m-1}(n/I_m^3(n)) \le I_{m-1}(n)$ leaves, the size of the table is only $O(I_{m-1}^2(n))$.

How the table is computed remains to be shown. Consider an internal node w of the generic subtree structure, and suppose that its rooted subtree has r leaves. At node w each pair of leaves u, v is allocated to a processor. The processor determines in constant time if w is the LCA of u and v. This is done by finding whether the child of w that is an ancestor of u, denoted f, and the child of w that is an ancestor of v are different. If they are different, then w, f, and g are as required for the table. The number of internal nodes of the generic subtree is $O(I_{m-1}(n))$, and each has at most $I_{m-1}(n)$ leaves. Thus the number of processors needed for computing the table is $O(I_{m-1}^3(n))$.

The preprocessing algorithm for m. Inductively, we assume that we have an algorithm that preprocesses the array $A = (a_1, a_2, \cdots, a_n)$ for the range-minima problem in $c(m-1)$ time, using $nI_{m-1}(n) + \sqrt{k}n$ processors and $o(nI_{m-1}(n))$ space, where c is a constant, and that after this preprocessing any $\text{MIN}[i, j]$ query can be answered in $c(m-1)$ time. We construct an algorithm that solves the range-minima problem in $c_1 + c(m-1)$ time for some constant c_1, using $nI_m(n) + \sqrt{k}n$ processors and $o(nI_m(n))$ space. We have already shown that a query can be answered in $c_2 m$ time with one processor for some constant c_2. Selecting initially $c > c_1$ and $c > c_2$ implies that the algorithm runs in cm

time, using $nI_m(n) + \sqrt{k}n$ processors and $o(nI_m(n))$ space, and that a query can be answered in cm time.

Step 1. Partition A into subarrays of $I_m^3(n)$ elements each. Allocate $I_m^4(n)$ processors to each subarray, and apply the preprocessing algorithm for range minima given in §3 (for $\epsilon = \frac{1}{3}$). This uses $I_m^4(n)$ processors and $O(I_m^3(n)I_m^{1/3}(n))$ space per subarray and $nI_m(n)$ processors and $o(nI_m(n))$ space overall.

Step 2. Take the minimum in each subarray to build array B of size $n/I_m^3(n)$. The difference between two successive elements in B is at most $kI_m^3(n)$.

Step 3. Build $TRL-BT(m)$, the upper level of a $BT(m)$ tree whose leaves are the elements of B. The definition of $TRL-BT(m)$ implies that each internal node of $TRL-BT(m)$, whose rooted tree has r leaves, has $r/I_{m-1}(r)$ children. For each such internal node v of $TRL–BT(m)$ we keep an array. The array consists of the values of the r leaves of the subtree rooted at v. $TRL–BT(m)$ has $*I_{m-1}(n/I_m^3(n)) + 1 \leq I_m(n) + 1$ levels and thus at most $I_m(n)$ internal levels (where internal levels exclude the leaves but include the root). So the space needed is $O(n/I_m^3(n))$ per level and $O(n/I_m^2(n))$ for all levels of $TRL-BT(m)$. We allocate to each leaf at each internal level $1 + \sqrt{k}I_m^2(n)$ processors, and the total number of processors used is thus $n/I_m^2(n) + \sqrt{k}n$ (which is less than $nI_m(n) + \sqrt{k}n$).

Step 4.1. For each internal node of $TRL-BT(m)$ find the minimum over its array. The difference between the minimum value and the maximum value in an array never exceeds the square of its number of processors, and we apply the constant-time algorithm mentioned in Remark 3.1 as in Step 4 of the recursion-base algorithm.

Step 4.2. We focus on internal node v having r leaves in $TRL-BT(m)$. Each of its $r/I_{m-1}(r)$ children contributes its minimum, and we preprocess these minima by using the assumed algorithm for $m - 1$. The difference between adjacent elements is at most $kI_{m-1}(r)I_m^3(n)$. Thus this computation takes $c(m - 1)$ time using $r + \sqrt{kI_m^3(n)}\,r$ processors. (To see this, simplify $(r/I_{m-1}(r))I_{m-1}(r) + \sqrt{kI_{m-1}(r)I_m^3(n)} \cdot (r/I_{m-1}(r))$, the processor count term for this problem, into $r + \sqrt{kI_m^3(n)}\,r/\sqrt{I_{m-1}(r)}$, which is less than $r + \sqrt{kI_m^3(n)}\,r$ processors.) This amounts to $n/I_m^3(n) + \sqrt{kI_m^3(n)}\,n/I_m^3(n)$ per level or a total of $n/I_m^2(n) + \sqrt{k}n/\sqrt{I_m(n)}$ processors, which is less than $n/I_m^2(n) + \sqrt{k}n$.

Step 5. For each internal node v we compute P_v (S_v is computed similarly). That is, for each leaf b_i of v we need to find $\text{MIN}_B[l(v), i]$, the minimum over the prefix of b_i with respect to the leaves of node v. For this, the minimum among the following list of at most $*I_{m-1}(n) + 1 = I_m(n) + 1$ numbers is computed: Each level l, level$(v) < l \leq I_m(n) + 1$, of the tree contributes (at most) one number. Let u denote the ancestor at level $l - 1$ of b_i, and let $u_1, \cdots, u_y$ denote its children, which are at level l. Suppose $u_j, j > 1$ is an ancestor of b_i. We take the prefix minimum over the leaves of $u_1, \cdots, u_{j-1}$. This prefix minimum is computed in the previous step (by the assumed algorithm for $m - 1$). If u_1 is the ancestor of b_i, then level l contributes a large default value (as in Step 5 of the recursion-base algorithm). Finally, b_i is also added to the list. This minimum computation can be done in constant time by using $I_m^2(n)$ processors (by the algorithm of [SV81]). Note that (1) all prefix minima and all suffix minima with respect to B are computed (in the root) in this step, and (2) given a leaf b_i in $TRL-BT(m)$, finding a node w that is both a child of the root and an ancestor of b_i in constant time was solved in the context of the query retrieval. Node u is found similarly.

Step 6. For each a_i we find its prefix minimum and its suffix minimum with respect to A by using one processor in constant time. This is similar to Step 6 of the recursion base.

This completes the description of the recursive step: Items (1), (2), (3), (4), and (5) of the output were computed (respectively) in steps 1, 2, 5, 4.2, and 6 above.

Complexity of the recursive step. In addition to application of the inductively assumed algorithm, Steps 1 through 6 take constant time and use $nI_m(n) + \sqrt{k}n$ processors and $o(nI_m(n))$ space. This totals cm time if $nI_m(n) + \sqrt{k}n$ processors and $o(nI_m(n))$ space are used. Together with Lemma 4.2.2, Lemma 4.2.1 follows.

From recursion to algorithm. The recursive procedure in Lemma 4.2.1 translates easily into a constructive parallel algorithm in which the instructions for each processor at each time unit are available. For such translation, issues such as processor allocation and computation of certain functions need to be taken into account. Since $TRL-BT(m)$ is balanced, allocating processors in the algorithm above can be done in constant time if the following functions are precomputed: (a) $I_m(x)$ for $1 \leq x \leq n$ and (b) $I^{(i)}_{m-1}(x)$ for $1 \leq x \leq n$ and $1 \leq i \leq I_m(x)$. Let us illustrate how processor allocation is done in Step 3 above. We use $n/I^2_m(n) + \sqrt{k}n$ processors. The processors are partitioned into $I_m(n)$ groups of $n/I^3_m(n) + \sqrt{k}n/I_m(n)$ processors each. Each group is allocated to one level. Within a level, the processors in its group are partitioned equally among the nodes of the level. This will provide a sufficient number of processors to each node. Some processors are superfluous and simply remain idle. These same functions suffice for all other computations above. The functions are computed and stored in a table at the beginning of the algorithm. Section 6 discusses their computation.

4.3. The optimal parallel algorithms. In this subsection we show how to derive a series of optimal parallel algorithms from the series of algorithms described in Lemma 4.2.1. Theorem 4.3.1 gives a general tradeoff result between the running time of the preprocessing algorithm and the retrieval time. Corollary 4.3.1 emphasizes results in cases for which the retrieval time for a query is constant. Corollary 4.3.2 points at an interesting tradeoff instance in which the retrieval time bound is increased to $O(\alpha(n))$ and the preprocessing algorithm runs in $O(\alpha(n))$ (i.e., it become almost fully parallel).

THEOREM 4.3.1. *Consider the range-minima problem where k, the bound on the difference between two successive elements in A, is constant. For each $2 \leq m \leq \alpha(n)$ we present a parallel preprocessing algorithm that runs in time $O(I_m(n))$ and uses an optimal number of processors and optimal linear space. Query retrieval time is $O(m)$ if one processor is used.*

COROLLARY 4.3.1. *When m is constant the preprocessing algorithm runs in $O(I_m(n))$ time if $n/I_m(n)$ processors are used. Retrieval time is $O(1)$ if one processor is used.*

COROLLARY 4.3.2. *When $m = \alpha(n)$ the preprocessing algorithm runs in $O(\alpha(n))$ time if $n/\alpha(n)$ processors are used. Retrieval time is $O(\alpha(n))$ if one processor is used.*

We describe below the optimal preprocessing algorithm for m as per Theorem 4.3.1.

Step 1. Partition A into subarrays of $I^2_m(n)$ elements each, allocate $I_m(n)$ processors to each subarray, and find the minimum in the subarray. This can be done in $O(I_m(n))$ time. Put the $n/I^2_m(n)$ minima into an array B.

Step 2. Out of the series of preprocessing algorithms of Lemma 4.2.1, apply the algorithm for m to B, where k', the difference between two successive elements of B, is $O(I^2_m(n))$. This takes $O(m)$ time if $\sqrt{k'}\,n/I^2_m(n) + n/I_m(n)$ processors and $o(n/I_m(n))$ space are used. This can be simulated in $O(m)$ time by using $n/I_m(n)$ processors and $o(n/I_m(n))$ space.

Step 3. Preprocess each subarray of $I^2_m(n)$ elements so that a range-minimum query within the subarray can be retrieved in $O(1)$ time. This is done by using the following parallel variant of the range-minima algorithm of Gabow, Bentley, and Tarjan (GBT) [GBT84].

Range minimum: a parallel variant of the GBT *algorithm*. Consider the general range-minima problem as defined in §3, with respect to an input array $C = (c_1, c_2, \cdots, c_n)$. We overview a preprocessing algorithm that runs in $O(\sqrt{n})$ time using $\sqrt{n}$ processors, so that a range-minimum query can be processed in constant time.

(1) Partition array C into $\sqrt{n}$ subarrays $C_1, \cdots, C_{\sqrt{n}}$, each with $\sqrt{n}$ elements.

(2) Apply the GBT linear time serial algorithm separately to each C_i, taking $O(\sqrt{n})$ time and using $\sqrt{n}$ processors.

(3) Let $\overline{c_i}$ be the minimum over C_i. Apply the GBT algorithm to $\overline{C} = (\overline{c_1}, \cdots, \overline{c_{\sqrt{n}}})$ in $O(\sqrt{n})$ time, using a single processor.

It should be clear that any range-minimum query with respect to C can be retrieved in constant time by at most three queries with respect to the tables built by the above applications of the GBT algorithm. The complexity of the preprocessing algorithm is specified by $O(I_m(n))$ time if $n/I_m(n)$ processors are used. Retrieval of a range-minimum query takes $O(m+1)$ time, which is $O(m)$ time if one processor is used. Theorem 4.3.1 follows.

4.4. The fully parallel algorithms. Consider the restricted-domain range-minima problem in which k, the bound on the difference between adjacent elements, is constant. In this subsection we present a fully parallel preprocessing algorithm for the problem on a CRCW-bit PRAM that provides for constant time processing of a query. Theorem 4.4.1 gives the general result achieved in this subsection, including tradeoff among parameters. Corollary 4.4.1 summarizes the fully parallel result.

Let d be an integer $2 < d \leq \alpha(n)$. The model of parallel computation is the CRCW-bit PRAM with the assumption that up to $I_d(n)$ processors may write simultaneously into different bits of the same memory word.

THEOREM 4.4.1. *The preprocessing algorithm takes $O(d)$ time if n processors and linear space are used. Retrieval of a query* MIN(i, j) *takes $O(d)$ time if one processor is used.*

Remark. Theorem 4.4.1 represents a tradeoff between the time for the preprocessing algorithm and query retrieval, on one hand, and the number of processors that may write simultaneously into different bits of the same memory word, on the other.

COROLLARY 4.4.1. *For a constant d the algorithm is fully parallel and query retrieval can be done in constant time with one processor.*

Step 1. Partition A into $n/I_d(n)$ subarrays of $I_d(n)$ elements each. For each subarray find the minimum in $O(1)$ time and $I_d(n)$ processors. For this we apply the constant-time algorithm mentioned in Remark 3.1 as in Step 4 of the recursion-base algorithm. Put the $n/I_d(n)$ minima into an array B. The difference between two successive elements in B is at most $kI_d(n)$.

Step 2. Out of the series of preprocessing algorithms of Lemma 4.2.1 apply the algorithm for d to B, where k', the difference between two successive elements of B, is $O(I_d(n))$. This takes $O(d)$ time when $\sqrt{k'}\, n/I_d(n) + n$ processors and $o(n)$ space are used and can be simulated in $O(d)$ time by using n processors and $o(n)$ space.

Suppose we know to retrieve a range-minimum query within each of the subarrays of size $I_d(n)$ in constant time. It should be clear how a query MIN(i, j) can then be retrieved in $O(d)$ time. Theorem 4.4.1 would follow. Thus it remains to show how to preprocess the subarrays of size $I_d(n)$ in constant time such that a range-minimum query within a subarray can be retrieved in constant time. These subarrays are preprocessed in Steps 3.1, 3.2, and 3.3.

Step 3.1. For each subarray subtract the value of its first element from each element of the subarray. Observe that after this subtraction the value of the first element is zero and the difference between each pair of successive elements remains at most k. Step 3.2

constructs a table with the following information: For any $I_d(n)$-tuple $(c_1, \cdots, c_{I_d(n)})$, where $c_1 = 0$ and the difference between each pair of successive c_i values is at most k, the table has an entry. This entry gives all $I_d(n)(I_d(n) - 1)/2$ range minima with respect to this $I_d(n)$-tuple.

Step 3.2. All n processors together build a table. Each entry of the table corresponds to one possible allocation of values to the $I_d(n)$-tuple. The entry provides all $I_d(n)(I_d(n) - 1)/2$ range minima for this allocation. Observe that the number of possible allocations is $(2k(I_d(n) - 1) + 1)^{I_d(n)-1}$. To see this we note that each element in an $I_d(n)$-tuple assumes an integer value in the range $[-k(I_d(n) - 1) \cdots k(I_d(n) - 1)]$. Our table will have $y \geq (2k(I_d(n) - 1) + 1)^{I_d(n)-1}$ entries. It will be more convenient to defer the statement of the exact value for y to the comment below. By using n processors (or even fewer) the table can be built in $O(1)$ time. We sketch below how the table is built. Consider any integer x in the range $[1, y]$, and suppose x is given in binary representation. We break the binary (i.e., bit) representation of x into $I_d(n) - 1$ bit strings of equal length. Each of these bit strings should be long enough to represent integers in the range $[-k(I_d(n) - 1), k(I_d(n) - 1)]$ (namely, a range of $2k(I_d(n) - 1) + 1$ integers). (It is enough to have $\lceil \log(2k(I_d(n) - 1) + 1) \rceil$ bits in each bit string and therefore a total of $(I_d(n) - 1)(\lceil \log(2k(I_d(n) - 1) + 1) \rceil)$ bits for representing the original value of x. So $y = 2^{(I_d(n)-1)(\lceil \log(2k(I_d(n)-1)+1) \rceil)}$.) These integers are then put in an array X (of size $I_d(n) - 1$). It is easy to see that for any $I_d(n)$-tuple (whose first entry is fixed to zero) for which the difference between any two consecutive locations is at most k, there exists an integer x in the range $[1, y]$ whose array X is equal to locations 2 to $I_d(n)$ in the $I_d(n)$-tuple. For each entry x, $1 \leq x \leq y$, in our table we compute separately each range minimum with respect to array X of x. Given a range $[i, j]$ the minimum over $[X_i \cdots X_j]$ is done in constant time with $(j - i)^2$ processors by the algorithm of [SV81]. Since $I_d(n) \leq \log^* n$, the n available processors are more than enough for the necessary computations above.

Step 3.3. The only difficulty is to identify the table entry for our $I_d(n)$-tuple, $c_1, \cdots, c_{I_d(n)}$, since once we reach the entry the table already provides the desired range minimum. We allocate to each subarray $I_d(n)$ processors. For each subarray we have a word in our shared memory with $(I_d(n) - 1)\lceil \log(2k(I_d(n) - 1) + 1) \rceil$ bits. Processor $i, 1 < i \leq I_d(n)$, writes c_i (which is an integer from $[-k(I_d(n) - 1) \cdots k(I_d(n) - 1)]$) starting in bit number $(i - 2)\lceil \log(2k(I_d(n) - 1) + 1) \rceil$ of the word belonging to its subarray (bit zero is the least significant). As a result, this word has a sequence of integers from the range $[-k(I_d(n) - 1), k(I_d(n) - 1)]$ that yields the desired entry in our table. Note that exactly $I_d(n)$ processors write to different bits of the same memory word. Theorem 4.4.1 follows.

4.5. The all-nearest-zero-bit problem. The following corollary of Theorems 4.3.1 and 4.4.1 is needed for §5.

COROLLARY 4.5.1. *The all-nearest-zero-bit problem is almost fully parallel. On the* CRCW-*bit* PRAM *the all-nearest-zero-bit problem is fully parallel.*

Proof. Recall that the algorithm for the restricted-domain range-minima problem computes all suffix minima. Recall also that if the minimum over an interval is not unique, the leftmost minimum is found. Thus if we apply the restricted-domain range-minima algorithm (with the difference between successive elements at most one) with respect to A, then the minimum over the suffix of entry $i + 1$ gives the nearest zero to the right of entry i. Thus the all-nearest-zero bit is actually an instance of the restricted-domain range-minima problem (with the difference between successive elements at most one). It follows that the almost fully parallel and the fully parallel algorithms for the latter apply for the all-nearest-zero-bit problem as well. □

4.6. A simple sequential LCA algorithm. In this subsection we outline a sequential variant of the restricted-domain range-minima problem for which k, the difference between adjacent elements, is one. Together with the reduction of §4.1, this gives a sequential algorithm for the LCA problem.

We first describe two preprocessing procedures for the range-minima problem: (i) Procedure I takes $O(n \log n)$ time for an input array of length n. No assumptions are needed regarding the difference between adjacent elements. (A similar procedure is used in [AS87].) (ii) Procedure II takes exponential time. After each of these preprocessing procedures, query retrieval takes constant time. Second, the sequential linear-time range-minima algorithm is described. Finally, we show how to retrieve a range-minimum query in constant time.

Procedure I. Build a complete binary tree whose leaves are the elements of the input array A. Compute (and keep) for each internal node all prefix minima and all suffix minima with respect to its leaves.

Procedure I clearly runs in $O(n \log n)$ time. Given any range $[i, j]$, the range-minimum query with respect to $[i, j]$ can be processed in constant time, as follows. (1) Find the lowest node u of the binary tree such that the range $[i, j]$ falls within its leaves. This range is the union of a suffix of the left child of u and a prefix of the right child of u. The minima over the suffix and prefix were computed by Procedure I. (2) The answer to the query is the minimum among these two minima.

Procedure II. We use the assumption that the difference between any two adjacent elements of the input array A is exactly one. A table similar to the table built in Step 3 of §4.4 is built as follows. We assume without loss of generality that the value of the first element of A is zero (since otherwise we can subtract from every element in A the value of the first element without affecting the answers to range-minima queries). Then the number of different possible input arrays A is 2^{n-1}. The table will have a subtable for each of these 2^{n-1} possible arrays. For each possible array the subtable will store the answer to each of the $n(n-1)/2$ possible range queries. The time to build the table is $O(2^n n^2)$, and $O(2^n n^2)$ space is needed.

The linear-time range-minima preprocessing algorithm follows.

• For each of the subsets $a_{i \log n+1}, \cdots, a_{(i+1)\log n}$ for $0 \leq i \leq n/\log n - 1$, find its minimum and apply Procedure I to an array of these $n/\log n$ minima.

• Separately, for each of the subsets $a_{i \log n+1}, \cdots, a_{(i+1)\log n}$ for $0 \leq i \leq n/\log n - 1$, do the following. Partition each such subset into smaller subsets of size $\log\log n$, and find the minimum in each smaller subset; apply Procedure I to these $\log n/\log\log n$ minima.

• Run Procedure II to build the table required for an (any) array of size $\log\log n$. For each of the subsets $a_{i \log\log n+1}, \cdots, a_{(i+1)\log\log n}$ for $0 \leq i \leq n/\log\log n - 1$, identify its subtable.

The time (and space) for each step of the preprocessing algorithm is $O(n)$.

Consider a query requesting the minimum over a range $[i, j]$. We show how to process it in constant time. The range $[i, j]$ can easily be presented as the union of the following (at most) five ranges: $[i, x_1]$, $[x_1+1, y_1]$, $[y_1+1, y_2]$, $[y_2+1, x_2]$, and $[x_2+1, j]$, where (1) $[i, x_1]$ (and $[x_2+1, j]$) falls within a single subset of size $\log\log n$—its minimum is available in its subtable, (2) $[x_1+1, y_1]$ (and $[y_2+1, x_2]$) is the union of subsets of size $\log\log n$ and falls within a single subset of size $\log n$—its minimum is available from the application of Procedure I to the subset of size $\log n$, and (3) $[y_1+1, y_2]$ is the union of subsets of size $\log n$—its minimum is available from the first application of Procedure I. So the minimum over range $[i, j]$ is simply the minimum of these five minima.

5. Almost fully parallel reducibility. We demonstrate how to use the $*$-tree data structure for reducing a problem A to another problem B by an almost fully parallel algorithm. We apply this reduction for deriving a parallel lower bound for problem A from a known parallel lower bound for problem B.

Given a convex polygon with n vertices, the *all-nearest-neighbors* (*ANN*) problem is to find for each vertex of the polygon its nearest (Euclidean) neighbor.

THEOREM 5.1. *Any* CRCW PRAM *algorithm for the* ANN *problem that uses* $O(n \log^c n)$ (*for any constant* c) *processors needs* $\Omega(\log \log n)$ time.

Proof. We give below an almost fully parallel reduction from the problem of merging two sorted lists of length n each to the ANN problem with $O(n)$ vertices. This reduction together with the following lemma imply the theorem.

LEMMA 5.1. *Merging two sorted lists of length n each by using* $O(n \log^c n)$ (*for any constant* c) *processors on a* CRCW PRAM *requires* $\Omega(\log \log n)$ time.

A remark in [SV90] implies that Borodin and Hopcroft's [BH85] lower bound for merging in a parallel comparisons model can be extended to yield the lemma.

Proof of Theorem 5.1 (*continued*).

The reduction (*see Fig*. 3). Let $A = (a_1, a_2, \cdots, a_n)$ and $B = (b_1, b_2, \cdots, b_n)$ be two increasing lists of numbers that we wish to merge. Assume, without loss of generality, that the numbers are integers and that $a_1 = b_1$, $a_n = b_n$. (The lower bound for merging assumes that the numbers are integers.) Consider the following *auxiliary* problem: For each $1 \leq i \leq n$ find the minimum index j such that $b_j > a_i$. The position of a_i in the merged list is $i + j - 1$, and therefore an algorithm for the auxiliary problem (together with a similar algorithm for finding the positions of the b_i numbers in the merged list) suffices for the merging problem.

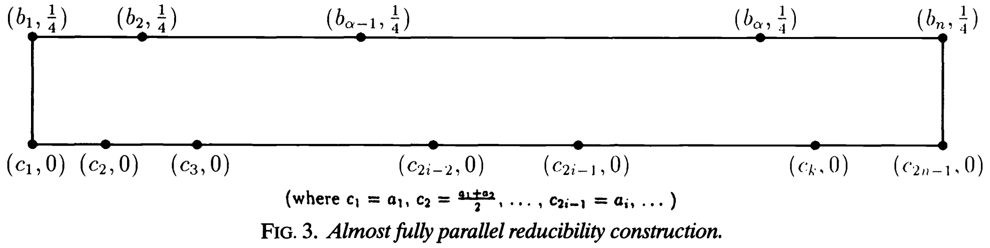

FIG. 3. *Almost fully parallel reducibility construction.*

We give an almost fully parallel reduction from the auxiliary problem to the ANN problem with respect to the following convex polygon. Let $(c_1, c_2, \cdots, c_{2n-1}) = (a_1, (a_1 + a_2)/2, a_2, (a_2 + a_3)/2, \cdots, a_{n-1}, (a_{n-1} + a_n)/2, a_n)$. The numbers $c_1, c_2, \cdots, c_{2n-1}$ form an increasing list. The convex polygon is $(c_1, 0), (c_2, 0), \cdots, (c_{2n-1}, 0), (b_n, \frac{1}{4}), (b_{n-1}, \frac{1}{4}), \cdots, (b_1, \frac{1}{4})$.

In [SV90] a similar construction is given, and the lower-bound proof then follows by (nontrivial) Ramsey theoretic arguments.

Let $D[1, \cdots, 2n-1]$ be a binary vector. Each vertex $(c_l, 0)$ finds its nearest neighbor with respect to the convex polygon (by using a "supposedly existing" algorithm for the ANN problem) and assigns the following into vector D.

```
If the nearest vertex is of the form$(b_k, \frac{1}{4})$
Then $D(l) := 0$
Else $D(l) := 1$
```

Next we apply to vector D the almost fully parallel algorithm for the nearest-zero-bit problem of §4.5. Finally, we show how to solve our auxiliary problem with respect to every element a_i. We break into two cases concerning the nearest neighbor of $(a_i, 0)$ $(= (c_{2i-1}, 0))$.

Case (i). The nearest neighbor of $(a_i, 0)$ is a vertex $(b_\alpha, \frac{1}{4})$. Then the minimum index j such that $b_j > a_i$ is either α or $\alpha + 1$. A single processor can determine the correct value of j in $O(1)$ time.

Case (ii). Otherwise, then $D(2i - 1) = 1$. The nearest-zero computation gives the smallest index $k > 2i - 1$ for which $D(k) = 0$. Let the nearest neighbor of $(c_k, 0)$ be $(b_\alpha, \frac{1}{4})$. Then $j = \alpha$ is the minimum index for which $b_j > a_i$. $\square$

6. Computing various functions. We need to compute certain functions in our algorithms. For each $2 < m \leq \alpha(n)$ we need $I_{m-1}^{(i)}(n)$ for all $1 \leq i \leq I_m(n)$. Fortunately, the function parameters that we are actually concerned with are small relative to n. For instance, to compute $I_3(n) = \log^* n$, it is enough to compute $\log^* (\log\log n)$ since $\log^* n = \log^* (\log\log n) + 2$.

We show only how to compute $I_m(n)$ for each $2 \leq m \leq \alpha(n)$. Computation of $I_{m-1}^{(i)}(n)$ for $2 < m \leq \alpha(n)$ and all $1 \leq i \leq I_m(n)$ is similar. Our computation works by induction on m.

The inductive hypothesis. Let $x = \log\log n$. We know how to compute the following values in $O(m - 1)$ time by using $o(n/\alpha(n))$ processors: (1) $I_{m-1}(n)$ and (2) $I_{m-1}(y)$ for all $1 \leq y \leq \log\log n$.

We show the inductive claim (the claim itself should be clear) by assuming the inductive hypothesis. The inductive base is given later. First, we describe (informally) the computation of $I_m(x)$ in $O(1)$ (additional) time using $o(n/\alpha(n))$ processors. Consider all permutations of the numbers $1, \cdots, x$. The number of these permutations is (much) less than n. The idea is to identify a permutation that provides the sequence $[x, I_{m-1}(x), I_{m-1}^{(2)}(x), \cdots, I_{m-1}^{(k)}(x) = 1, \cdots]$. So if $I_{m-1}(p_i) = p_{i+1}$ for all $0 \leq i \leq k - 1$, we conclude that $I_m(x) = k$. We can check this condition in $O(1)$ time with x processors per permutation by using the ability of the CRCW PRAM to find the AND of x bits in $O(1)$ time. The total number of processors is $o(n/\alpha(n))$. We make two remarks: (1) Computing $I_m(y)$ for all $1 \leq y \leq \log\log n$, the rest of the inductive claim, in $O(1)$ time with $o(n/\alpha(n))$ processors is similar; (2) there are easy ways for finding all permutations in $O(1)$ time by using the number of available processors.

We finish by showing the inductive base. We compute $\log n$ in $O(1)$ time and with $o(n/\alpha(n))$ processors as follows. If n is given in a binary representation, then the index of the leftmost one is $\log n$. Following [FRW84], this can be computed in $O(1)$ time by using as many processors as the number of bits of a number. By iterating this we obtain $\log^{(2)} n$. Finally, we find $\log y$ for all $1 \leq y \leq \log\log n$. The number of processors used for this computation is $o(n/\alpha(n))$.

Acknowledgments. We are grateful to Pilar de la Torre and to Baruch Schieber for fruitful discussions and helpful comments.

APPROXIMATE BOYER–MOORE STRING MATCHING*

JORMA TARHIO† AND ESKO UKKONEN†

Abstract. The Boyer–Moore idea applied in exact string matching is generalized to approximate string matching. Two versions of the problem are considered. The k mismatches problem is to find all approximate occurrences of a pattern string (length m) in a text string (length n) with at most k mismatches. The generalized Boyer–Moore algorithm is shown (under a mild independence assumption) to solve the problem in expected time $O(kn(1/(m-k)+(k/c)))$, where c is the size of the alphabet. A related algorithm is developed for the k differences problem, where the task is to find all approximate occurrences of a pattern in a text with $\leq k$ differences (insertions, deletions, changes). Experimental evaluation of the algorithms is reported, showing that the new algorithms are often significantly faster than the old ones. Both algorithms are functionally equivalent with the Horspool version of the Boyer–Moore algorithm when $k = 0$.

Key words. string matching, edit distance, Boyer–Moore algorithm, k mismatches problem, k differences problem

1. Introduction.

The fastest known exact string matching algorithms are based on the Boyer–Moore idea [BoM77], [KMP77]. Such algorithms are "sublinear" on the average in the sense that it is not necessary to check every symbol in the text. The larger the alphabet and the longer the pattern, the faster the algorithm works. In this paper we generalize this idea to approximate string matching. Again the approach leads to algorithms that are significantly faster than the previous solutions of the problem.

We consider two important versions of the approximate string matching problem. In both, we are given two strings, the *text* $T = t_1t_2 \ldots t_n$ and the *pattern* $P = p_1p_2 \ldots p_m$ in some alphabet Σ, and an integer k. In the first variant, called the *k mismatches problem*, the task is to find all occurrences of P in T with at most k mismatches, that is, all j such that $p_i = t_{j-m+i}$ for $i = 1, \ldots, m$ except for at most k indexes i.

In the second variant, called the *k differences problem*, the task is to find (the endpoints of) all substrings P' of T with the edit distance at most k from P. The edit distance means the minimum number of editing operations (the differences) needed to convert P' to P. An editing operation is either an insertion, a deletion, or a change of a character. The k mismatches problem is a special case with the change as the only editing operation.

There are several algorithms proposed for these two problems; see, e.g., the survey [GaG88]. Both can be solved in time $O(mn)$ by dynamic programming [Sel80], [Ukk85b]. A very simple improvement giving $O(kn)$ expected time solution for random strings is described in [Ukk85b]. Later, Landau and Viskin [LaV88], [LaV89], Galil and Park [GaP89], Ukkonen and Wood [UkW90] have given different algorithms that consist of preprocessing the pattern in time $O(m^2)$ (or $O(m)$) and scanning the text in worst-case time $O(kn)$. For the k differences problem, $O(kn)$ is the best bound currently known if the preprocessing is allowed to be at most $O(m^2)$. For the k mismatches problem Kosaraju [Kos88] gives an $O(n\sqrt{m}\ \text{polylog}(m))$ algorithm. Also see [GaG86], [GrL89].

We develop a new approximate string matching algorithm of Boyer–Moore type for the k mismatches problem and show, under a mild independence assumption, that it processes a random text in expected time $O(kn(1/(m-k) + (k/c)))$ where c de-

†Department of Computer Science, University of Helsinki, Teollisuuskatu 23, SF-00510 Helsinki, Finland.

notes the size of the alphabet. A related but different method is (independently) developed and analyzed in [Bae89a]. We also give an algorithm for the k differences problem and show in a special case that its expected processing time for a random text is $O(c/(c-2k)kn(k/(c+2k^2)+(1/m)))$. The preprocessing of the pattern needs time $O(m+kc)$ and $O((k+c)m)$, respectively. We have also performed extensive experimental comparison of the new methods with the old ones, showing that Boyer–Moore algorithms are significantly faster, for large m and c in particular.

Our algorithms can be considered as generalizations of the Boyer–Moore algorithm for exact string matching because they are functionally identical with the Horspool version [Hor80] of the Boyer–Moore algorithm when $k = 0$. The algorithm of [Bae89a] generalizes the original Boyer–Moore idea for the k mismatches problem.

All these algorithms are "sublinear" in the sense that it is not necessary to examine every text symbol. Another approximate string matching method of this type (based on totally different ideas) has recently been given in [ChL90].

The paper is organized as follows. We first consider the k mismatches problem for which we give and analyze the Boyer–Moore solution in §2. Section 3 develops an extension to the k differences problem and outlines an analysis. Section 4 reports our experiments.

2. The k mismatches problem.

2.1. Boyer–Moore–Horspool algorithm. The characteristic feature of the Boyer–Moore algorithm [BoM77] for exact matching of string patterns is the right-to-left scan over the pattern. At each alignment of the pattern with the text, characters of the text below the pattern are examined from right to left, starting by comparing the rightmost character of the pattern with the character in the text currently below it. Between alignments, the pattern is shifted from left to right along the text.

In the original algorithm the shift is computed using two heuristics: the match heuristic and the occurrence heuristic. The *match* heuristic implements the requirement that after a shift, the pattern has to match all the text characters that were found to match at the previous alignment. The *occurrence* heuristic implements the requirement that we must align the rightmost character in the text that caused the mismatch with the rightmost character of the pattern that matches it. After each mismatch, the algorithm chooses the larger shift given by the two heuristics.

Since the patterns are not periodic on the average, the match heuristic is not very useful. A simplified version of the method can be obtained by using the occurrence heuristic only. Then we may observe that it is not necessary to base the shift on the text symbol that caused the mismatch. Any other text character below the current pattern position will do as well. Then the natural choice is the text character corresponding to the rightmost character of the pattern as it potentially leads to the longest shifts. This simplification was noted by Horspool [Hor80]. We call this method the Boyer–Moore–Horspool or the BMH algorithm.

The BMH algorithm has a simple code and is in practice better than the original Boyer–Moore algorithm. In the preprocessing phase the algorithm computes from the pattern $P = p_1p_2\dots p_m$ the shift table d, defined for each symbol a in alphabet Σ as

$$d[a] = \min\{s \mid s = m \text{ or } (1 \leq s < m \text{ and } p_{m-s} = a)\}.$$

For a text symbol a below p_m, the table d shifts the pattern right until the rightmost a in $p_1 \dots p_{m-1}$ becomes above the a in the text. Table d can be computed in time $O(m+c)$, where $c = |\Sigma|$, by the following algorithm.

ALGORITHM 1. BMH-preprocessing.

```
for $a$ in $\Sigma$ do $d[a] := m$;
for $i := 1, \ldots, m-1$ do $d[p_i] := m - i$.
```

The total BMH method [Hor80] including the scanning of the text $T = t_1 t_2 \ldots t_n$ is given below.

ALGORITHM 2. The BMH method for exact string matching.

```
call Algorithm 1;
$j := m$;                                   {pattern ends at text position $j$}
while $j \le n$ do begin
    $h := j; i := m$;                       {$h$ scans the text, $i$ the pattern}
    while $i > 0$ and $t_h = p_i$ do begin
        $i := i - 1; h := h - 1$ end;       {proceed to the left}
    if $i = 0$ then report match at position $j$;
    $j := j + d[t_j]$ end                   {shift to the right}
```

2.2. Generalized BMH algorithm. The generalization of the BMH algorithm for the k mismatches problem will be very natural: for $k = 0$ the generalized algorithm is exactly as Algorithm 2. Recall that the k mismatches problem asks for finding all occurrences of P in T such that in at most k positions of P, T and P have different characters.

We have to generalize both the right-to-left scanning of the pattern and the computation of the shift. The former is very simple; we just scan the pattern to the left until we have found $k+1$ mismatches (unsuccessful search) or the pattern ends (successful search).

To understand the generalized shift it may be helpful to look at the k mismatches problem in a tabular form. Let M be a $m \times n$ table such that for $1 \le i \le m, 1 \le j \le n$,

$$M[i,j] = \begin{cases} 0 & \text{if } p_i = t_j, \\ 1 & \text{if } p_i \ne t_j. \end{cases}$$

There is an exact match ending at position r of T if $M[i, r-m+i] = 0$ for $i = 1, \ldots, m$, that is, there is a whole diagonal of 0's in M ending at $M[m,r]$. Similarly, there is an approximate match with $\le k$ mismatches if the diagonal contains at most k 1's. This implies that any successive $k+1$ entries of such a diagonal have to contain at least one 0.

Assume then that the pattern is ending at text position j and we have to compute the next shift. We consider the last $k+1$ text characters below the pattern, the characters $t_{j-k}, t_{j-k+1}, \ldots, t_j$. Then, suggested by the above observation, we glide the pattern to the right until there is at least one match in $t_{j-k}, t_{j-k+1}, \ldots, t_j$. The maximum shift is $m-k$. Clearly this is a correct heuristic: A smaller shift would give an unsuccessful alignment because there are at least $k+1$ mismatches, and a shift larger than $m-k$ would skip over a potential match.

Let $d(t_{j-k}, t_{j-k+1}, \ldots, t_j)$ denote the length of the shift. The values of $d(t_{j-k}, \ldots, t_j)$ could be precomputed and tabulated. This would lead to quite heavy preprocessing of at least time $\Theta(c^k)$. Instead, we apply a simpler preprocessing that makes it possible to compute the shift on-the-fly with small overhead while scanning.

In terms of M the shifting means finding the first diagonal above the current diagonal such that the new diagonal has at least one 0 for $t_{j-k}, t_{j-k+1}, \ldots, t_j$.

For example, consider table M in Fig. 1, where we assume that $k = 1$. We may shift from the diagonal of $M[1, 1]$ directly to the diagonal of $M[1, 3]$, as this diagonal contains the first 0 for characters $t_3 = a, t_4 = a$. Hence $d(a, a) = 2$ for the pattern *abbb*. Also note that t_4 alone would give a shift of 3 and t_3 a shift of 2, and $d(t_3, t_4)$ is the minimum over these component shifts.

$$

$$\longrightarrow$$

FIG. 1. *Determining of shift* ($k = 1$).

In general, we compute $d(t_{j-k}, \ldots, t_j)$ as the minimum of the component shifts for each $t_{j-k}, \ldots, t_j$. The component shift for t_h depends both on the character t_h itself and on its position below the pattern. Possible positions are $m - k, m - k + 1, \ldots, m$. Hence we need a $(k + 1) \times c$ table d_k defined for each $i = m - k, \ldots, m$, and for each a in Σ, as

$$d_k[i, a] = \min \{s | s = m \text{ or } (1 \leq s < m \text{ and } p_{i-s} = a)\}.$$

Here the values greater than $m - k$ are not actually relevant. Table d_k is presented in this form, because the same table is used in the algorithm solving the k differences problem.

Table d_k can be computed in time $O((m + c)k)$ by a straightforward generalization of the BMH-preprocessing, which scans $k + 1$ times over P, and each scanning creates a new row of d_k.

A more efficient method needs only one scan, from right to left, over P. For each symbol p_i encountered, the corresponding updates are made to d_k. To keep track of the updates already made, we use a table *ready*$[a]$, a in Σ, such that *ready*$[a] = j$ if $d_k[i, a]$ already has its final value for $i = m, m - 1, \ldots, j$. Initially, *ready*$[a] = m + 1$ for all a, and $d_k[i, a] = m$ for all i, a. The algorithm is as follows.

ALGORITHM 3. Computation of table d_k.

```
1.    for $a$ in $\Sigma$ do ready$[a] := m + 1$;
2.    for $a$ in $\Sigma$ do
3.        for $i := m$ downto $m - k$ do
4.            $d_k[i, a] := m$;
5.    for $i := m - 1$ downto 1 do begin
6.        for $j :=$ ready$[p_i] - 1$ downto $\max(i, m - k)$ do
7.            $d_k[j, p_i] := j - i$;
8.        ready$[p_i] := \max(i, m - k)$ end
```

The initializations in steps 1–4 take time $O(kc)$. Steps 5–8 scan over P in time $O(m)$ plus the time of the updates of d_k in step 7. This takes time $O(kc)$ as each $d_k[j, p_i]$ is updated at most once. Hence Algorithm 3 runs in time $O(m + kc)$.

We now have the following total method for the k mismatches problem.

ALGORITHM 4. Approximate string matching with k mismatches.

```
1.  compute table $d_k$ from $P$ with Algorithm 3;
2.  $j := m$;                                   {pattern ends at text position $j$}
3.  while $j \le n + k$ do begin
4.      $h := j; i := m; neq := 0$;             {$h$ scans the text, $i$ the pattern}
5.      $d := m - k$;                           {initial value of the shift}
6.      while $i > 0$ and $neq \le k$ do begin
7.          if $i \ge m - k$ then $d := \min(d, d_k[i, t_h])$;
                                        {minimize over the component shifts}
8.          if $t_h \ne p_i$ then $neq := neq + 1$;
9.          $i := i - 1; h := h - 1$ end;       {proceed to the left}
10.     if $neq \le k$ then report match at position $j$;
11.     $j := j + d$ end                        {shift to the right}
```

2.3. Analysis. First recall that the preprocessing of P by Algorithm 3 takes time $O(m + kc)$ and space $O(kc)$. The scanning of T by Algorithm 4 obviously needs $O(mn)$ time in the worst case. The bound is strict for example for $T = a^n, P = a^m$.

Next we analyze the scanning time in the average case. The analysis will be done under the random string assumption which says that individual characters in P and T are chosen independently and uniformly from Σ. The time requirement is proportional to the number of the text-pattern comparisons in step 8 of Algorithm 4. Let $C_{loc}(P)$ be a random variable denoting, for some fixed c and k, the number of such comparison for some alignment of pattern P between two successive shifts, and let $\bar{C}_{loc}(P)$ be its expected value.

LEMMA 1.

$$\bar{C}_{loc}(P) < \left(\frac{c}{c-1} + 1\right)(k+1).$$

Proof. The distribution of $C_{loc}(P) - (k+1)$ converges to the negative binomial distribution (the Pascal distribution) with parameters $(k+1, 1-(1/c))$ when $m \to \infty$, because $C_{loc}(P) - (k+1)$ is the number of matches until we find the $k+1$st mismatch; the probability of the mismatch is $1 - (1/c)$. As the expected value of $C_{loc}(P)$ increases with m, the expected value $(k+1)/(c-1)$ of this negative binomial distribution (see, e.g., [Fel65]) would be an upper bound (and the limit as $m \to \infty$) of $\bar{C}_{loc}(P) - (k+1)$. This, however, ignores the effect of the fact that after a shift of length $d < m - k$ we know that at least one and at most $k+1$ of characters $P_{m-d-k}, \ldots, P_{m-d}$ will match. Hence to bound $\bar{C}_{loc}(P) - (k+1)$ properly, it surely suffices to add $k+1$ to the above bound that gives

$$\bar{C}_{loc}(P) - (k+1) < \frac{k+1}{c-1} + k + 1,$$

and the lemma follows. □

Let $S(P)$ be a random variable denoting the length of the shift in Algorithm 4 for pattern P and for some fixed k and c when scanning a random T. Moreover, let P_0 be a pattern that repeatedly contains all characters in Σ in some fixed order until the length of P_0 equals m. Then it is not difficult to see that P_0 gives on the average the minimal shift, that is, the expected values satisfy $\bar{S}(P_0) \leq \bar{S}(P)$ for all P of length m. Hence a lower bound for $\bar{S}(P_0)$ gives a lower bound for the expected shift over all patterns of length m (cf. [Bae89b]).

LEMMA 2. $\bar{S}(P_0) \geq \frac{1}{2}\min(c/(k+1), m-k)$. *Moreover,* $\bar{S}(P_0) \geq 1$.

Proof. Let $t = \min(c-1, m-k-1)$. Then the possible lengths of a shift are $1, 2, \ldots, t+1$. Therefore,

$$\bar{S}(P_0) = \sum_{i=0}^{t} Pr(S(P_0) > i),$$

where $Pr(A)$ denotes the probability of event A. Then

$$Pr(S(P_0) > i) = \left(\frac{c-i}{c}\right)^{k+1}$$

because for each of the $k+1$ text symbols that are compared with the pattern to determine the shift (step 8 of Algorithm 4), there are i characters not allowed to occur as text symbols. Otherwise the shift would not be $> i$. Hence

$$\bar{S}(P_0) = \sum_{i=0}^{t} \left(1 - \frac{i}{c}\right)^{k+1},$$

which is clearly ≥ 1, because $t \geq 0$ as we may assume that $c \geq 2$ and that $k < m$.

We divide the rest of the proof into two cases.

Case 1. $m - k < c/(k+1)$. Then $t = m - k - 1$, and we have

$$\begin{aligned}\bar{S}(P_0) &\geq \sum_{i=0}^{m-k-1} \left(1 - \frac{k+1}{c} \cdot i\right) \\ &= m - k - \frac{k+1}{c} \cdot \frac{(m-k-1)(m-k)}{2} \\ &\geq (m-k)\left(1 - \frac{k+1}{c} \cdot \frac{m-k}{c}\right) \geq \frac{1}{2}(m-k).\end{aligned}$$

Case 2. $m - k \geq c/(k+1)$. Then $t \geq \lceil c/(k+1) \rceil - 1$, and we have

$$\begin{aligned}\bar{S}(P_0) &\geq \sum_{i=0}^{\lceil \frac{c}{k+1} \rceil - 1} \left(1 - \frac{i}{c}\right)^{k+1} \geq \sum_{i=0}^{\lceil \frac{c}{k+1} \rceil - 1} \left(1 - \frac{k+1}{c} \cdot i\right) \\ &= \left\lceil \frac{c}{k+1} \right\rceil - \frac{k+1}{c} \cdot \frac{1}{2} \cdot \left\lceil \frac{c}{k+1} \right\rceil \left(\left\lceil \frac{c}{k+1} \right\rceil - 1\right) \\ &\geq \left\lceil \frac{c}{k+1} \right\rceil \left(1 - \frac{1}{2} \cdot \frac{k+1}{c} \cdot \frac{c}{k+1}\right) = \frac{1}{2}\left\lceil \frac{c}{k+1} \right\rceil. \qquad \square\end{aligned}$$

Consider finally the total expected number $\bar{C}(P)$ of character comparisons when Algorithm 4 scans a random T with pattern P. Let $f(P)$ be the random variable denoting the number of shifts taken during the execution, and let $\bar{f}(P)$ be its expected value. Then we have

$$\bar{C}(P) = \bar{f}(P) \cdot \bar{C}_{loc}(P).$$

To estimate $\bar{f}(P)$, we let S_i be a random variable denoting the length of ith shift. At the start of Algorithm 4, P is aligned with T such that its first symbol corresponds to the text position 1, and at the end P is aligned such that its first symbol corresponds to some text position $\leq n-m+k+1$, but the next shift would lead to a position $> n-m+k+1$. Hence new shifts are taken until the total length of the shifts exceeds $n-m+k$. This implies that $f(P)$ equals the largest index Φ such that

$$\sum_{i=1}^{\Phi} S_i \leq n-m+k.$$

Assume now that the different variables S_i are independent, that is, the shift lengths are independent; note that this simplification is not true for two successive shifts such that the first one is shorter than $k+1$. Then all variables S_i have a common distribution with expected value $\bar{S}(P) \geq \bar{S}(P_0)$. Under this assumption,

$$\left\{ \sum_{i=1}^{\Phi} S_i \right\}$$

is, in fact, a *pure renewal process* within interval $[0, n-m+k]$ in the terminology of [Fel66, Chap. XI]. Then the expected value of Φ is $(n-m+k)/\bar{S}(P)$ for large $n-m+k$ (see [Fel66, p. 359]). Hence

$$\bar{f}(P) = O\left(\frac{n-m+k}{\bar{S}(P_0)}\right),$$

and by Lemma 2,

$$\bar{f} = O\left(\max\left(\frac{k+1}{c}, \frac{1}{m-k}\right) \cdot (n-m+k)\right).$$

Recalling finally that $\bar{C}(P) = \bar{f}(P) \cdot \bar{C}_{loc}(P)$ and applying Lemma 1, we obtain that

$$\bar{C}(P) \leq O\left(\max\left(\frac{k+1}{c}, \frac{1}{m-k}\right)(n-m+k)\left(\frac{c}{c-1}+1\right)(k+1)\right),$$

which is

$$O\left(\frac{nk^2}{c} + \frac{nk}{m-k}\right) \quad \text{as } n >> m.$$

Hence we have the following.

THEOREM 1. *The expected running time of Algorithm* 4 *is* $O(nk((k/c)+1/(m-k)))$, *if the lengths of different shifts are mutually independent. The preprocessing time is* $O(m+kc)$, *and the working space is* $O(kc)$.

Removing the independence assumption from Theorem 1 remains open.

3. The k differences problem.

3.1. Basic solution by dynamic programming.

The *edit distance* [WaF75], [Ukk85a] between two strings, A and B, can be defined as the minimum number of editing steps needed to convert A to B. Each editing step is a rewriting step of the form $a \rightarrow \epsilon$ (a deletion), $\epsilon \rightarrow b$ (an insertion), or $a \rightarrow b$ (a change) where a, b are in Σ and ϵ is the empty string.

The *k differences problem* is, given pattern $P = p_1 p_2 \ldots p_m$ and text $T = t_1 t_2 \ldots t_n$ and an integer k, to find all such j that the edit distance (i.e., the number of differences) between P and some substring of T ending at t_j is at most k. The basic solution of the problem is by the following dynamic programming method [Sel80], [Ukk85b]: Let D be an $m+1$ by $n+1$ table such that $D(i,j)$ is the minimum edit distance between $p_1 p_2 \ldots p_i$ and any substring of T ending at t_j. Then

$$D(0,j) = 0, \quad 0 \le j \le n;$$
$$D(i,j) = \min \begin{cases} D(i-1,j)+1, \\ D(i-1,j-1) + \textbf{if } p_i = t_j \textbf{ then } 0 \textbf{ else } 1, \\ D(i,j-1)+1. \end{cases}$$

Table D can be evaluated column-by-column in time $O(mn)$. Whenever $D(m,j)$ is found to be $\le k$ for some j, there is an approximate occurrence of P ending at t_j with edit distance $D(m,j) \le k$. Hence j is a solution to the k differences problem.

3.2. Boyer–Moore approach. Our algorithm contains two main phases: the scanning and the checking. The scanning phase scans over the text and marks the parts that contain all the approximate occurrences of P. This is done by marking some entries $D(0,j)$ on the first row D. The checking phase then evaluates all diagonals of D whose first entries are marked. This is done by the basic dynamic programming restricted to the marked diagonals. Whenever the dynamic programming refers to an entry outside the diagonals, the entry can be taken to be ∞. Because this is quite straightforward we do not describe it in detail. Rather, we concentrate on the scanning part.

The scanning phase repeatedly applies two operations: mark and shift. The shift operation is based on a Boyer–Moore idea. The mark operation decides whether or not the current alignment of the pattern with the text needs accurate checking by dynamic programming and in the positive case marks certain diagonals. To understand the operations we need the concept of a minimizing path in table D.

For every $D(i,j)$, there is a *minimizing arc* from $D(i-1,j)$ to $D(i,j)$ if $D(i,j) = D(i-1,j)+1$, from $D(i,j-1)$ to $D(i,j)$ if $D(i,j) = D(i,j-1)+1$, and from $D(i-1,j-1)$ to $D(i,j)$ if $D(i,j) = D(i-1,j-1)$ when $p_i = t_j$ or if $D(i,j) = D(i-1,j-1)+1$ when $p_i \ne t_j$. The costs of the arcs are 1, 1, 0, and 1, respectively. The minimizing arcs show the actual dependencies between the values in table D. A *minimizing path* is any path that consists of minimizing arcs and leads from an entry $D(0,j)$ on the first row of D to an entry $D(m,h)$ on the last row of D. Note that $D(m,h)$ equals the sum of the costs of the arcs on the path. A minimizing path is *successful* if it leads to an entry $D(m,h) \le k$.

A *diagonal* h of D for $h = -m, \ldots, n$, consists of all $D(i,j)$ such that $j - i = h$. As any vertical or horizontal minimizing arc adds 1 to the value of the entry, the next lemma easily follows.

LEMMA 3. *The entries on a successful minimizing path are contained in* $\le k+1$ *successive diagonals of D.*

Our marking method is based on the following lemma. For each $i = 1, \ldots, m$, let the *k environment* of the pattern symbol p_i be the string $C_i = p_{i-k} \ldots p_{i+k}$, where $p_j = \epsilon$ for $j < 1$ and $j > m$.

LEMMA 4. *Let a successful minimizing path go through some entry on a diagonal h of D. Then for at most k indexes,* $i, 1 \le i \le m$, *character* t_{h+i} *does not occur in k environment* C_i.

Proof. Column $j, h+1 \le j \le h+m$, of D is called *bad* if t_j does not appear in C_{j-h}. The lemma claims that the number of the bad columns is $\le k$. Let M be the path in the lemma. Let R be the set of indexes, $j, h+1 \leq j \leq h+m$, such that path M contains at least one entry $D(i,j)$ on column j of D. If M starts or ends outside diagonal h, then the size of R can be $< m$. Then, however, M must have at least one vertical arc for each index j missing in R because M crosses diagonal h. Therefore, $\mathit{vert}(M) \geq m - \mathit{size}(R)$, where $\mathit{vert}(M)$ is the number of vertical arcs of M.

By Lemma 3, M must be contained in diagonals $h-k, h-k+1, \ldots, h+k$ of D. Hence for each j in R, path M must enter some entry on column j restricted to diagonals $h-k, \ldots, h+k$, that is, some entry $D(i-k,j), \ldots, D(i+k,j)$. Then if j is bad, the first arc in M that enters column j must add 1 to the total cost of M. Because such an arc enters a new column, it must be either a diagonal or a horizontal arc; note that with no restriction on generality we may assume that the very first arc of M is not a vertical one. Hence the number of bad columns in R is $\leq \mathit{cost}(M) - \mathit{vert}(M)$, where $\mathit{cost}(M)$ is the value of the final entry of M.

Moreover, there can be $m - \mathit{size}(R)$ additional bad columns as every column outside R can be bad. The total number of the bad columns is, therefore, at most $m - \mathit{size}(R) + \mathit{cost}(M) - \mathit{vert}(M) \leq \mathit{cost}(M) \leq k$. □

Lemma 4 suggests the following marking method. For diagonal h, check for $i = m, m-1, \ldots, k+1$ if t_{h+i} is in C_i until $k+1$ bad columns are found. Note that to get minimum shift $k+1$ (see Fig. 2) we stop already at $i = k+1$ instead of at $i = 1$. If the number of bad columns is $\leq k$, then mark diagonals $h-k, \ldots, h+k$, that is, mark entries $D(0, h-k), \ldots, D(0, h+k)$.

For finding the bad columns fast we need a precomputed table $\mathit{Bad}(i,a), 1 \leq i \leq m, a \in \Sigma$, such that

$$\mathit{Bad}(i,a) = \textbf{true} \quad \text{if and only if } a \text{ does not appear in } k \text{ environment } C_i.$$

Clearly the table can be computed by a simple scanning of P in time $O((c+k)m)$.

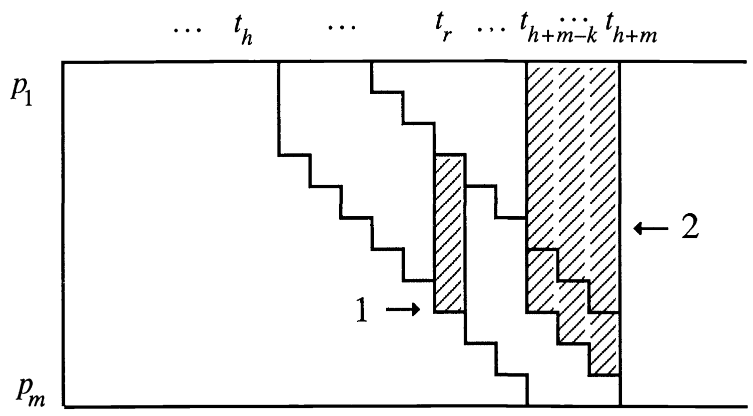
After marking we have to determine the length of shift; that is, what is the next diagonal after h around which the marking should eventually be done? The marking of heuristic ensures that all successful minimizing paths that are properly before diagonal $h+k+1$ are already marked. Hence we can safely make at least a shift of $k+1$ to diagonal $h+k+1$.

This can be combined with the shift heuristics of Algorithm 4 of §2 based on table d_k. So we determine the first diagonal after h, say, $h+d$, where at least one of the characters $t_{h+m}, t_{h+m-1}, \ldots, t_{h+m-k}$ matches with the corresponding character of P. This is correct because then there can be a successful minimizing path that goes through diagonal $h+d$. The value of d is evaluated as in Algorithm 4, using exactly the same precomputed table d_k. Note that unlike in the case of Algorithm 4, the maximum allowed value of d is now m, not $m-k$, as the marking starts from diagonal $h-k$, not from h. Finally, the maximum of $k+1$ and d is the length of the shift.

In practice, the marking and the computation of the shift can be merged if we start searching for the bad columns from the end of the pattern.

Figure 2 illustrates marking and shifting. For $r = h+m, h+m-1, \ldots, h+k+1$ we check whether or not t_r appears among the pattern symbols corresponding to the shaded block 1 (the k environment). If $k+1$ symbols t_r that do not appear are found, entries $D(0, h-k), \ldots, D(0, h+k)$ are marked. Simultaneously we check what is the next diagonal after h containing a match between P and $t_{h+m-k}, \ldots, t_{h+m}$ (shaded block 2). The next shift is to this diagonal but at least to diagonal $h+k+1$.

We get the following algorithm for the scanning phase.



$\ldots\ t_h\ \ldots\ t_r\ \ldots\ t_{h+m-k}\ \ldots\ t_{h+m}$
p_1
p_m
$\leftarrow 2$
$1 \rightarrow$

FIG. 2. *Mark and shift* ($k = 2$).

ALGORITHM 5. The scanning phase for the k differences problem.

```
1.  compute table Bad and, by Algorithm 3, table $d_k$ from $P$;
2.  $j := m$;
3.  while $j \leq n + k$ do begin
4.      $r := j; i := m$;
5.      $bad := 0$;                    {bad counts the bad indexes}
6.      $d := m$;                      {initial value of shift}
7.      while $i > k$ and $bad \leq k$ do begin
8.          if $i \geq m - k$ then $d :=\min(d, d_k[i, t_r])$;
9.          if $Bad(i, t_r)$ then $bad := bad + 1$;
10.         $i := i - 1; r := r - 1$ end;
11.     if $bad \leq k$ then
12.         mark entries $D(0, j - m - k), \ldots, D(0, j - m + k)$;
13.     $j := j + \max(k + 1, d)$ end
```

The loop in steps 7–9 can be slightly optimized by splitting it into two parts such that the first one handles $k + 1$ text characters and computes the length of shift, and the latter goes on counting bad indexes (a similar optimization also applies to Algorithm 4).

Algorithm 5 has the drawback that it marks all diagonals when $k > (m - 1)/2$, and hence it is useful only for $k \leq (m - 1)/2$. Its marking accuracy can be improved for larger k at cost of losing the minimum shift of $k + 1$. This is achieved by replacing line 7 by

```
7'.         while $i > 0$ and $bad \leq k$ do begin
```

and lines 11–13 by

```
11'.    if $bad \leq k$ then begin
12'.        mark entries $D(0, j - m - k), \ldots, D(0, j - m + k)$;
13'.    $j := j + \max(k + 1, d)$ end
14'.    else $j := j + \max(\min(k + 1, i + 1), d)$ end
```

3.3. Analysis. The preprocessing of P requires $O((k+c)m)$ for computing table *Bad* and $O(m+kc)$ for computing table d_k. As $k<m$, the total time is $O((k+c)m)$. The working space is $O(cm)$.

The marking and shifting by Algorithm 5 takes time $O(mn/k)$ in the worst case. The analysis of the average case is similar to the analysis of Algorithm 4 in §2. Let $B_{loc}(P)$ be a random variable denoting, for some fixed c and k, the number of the columns examined (step 9 of Algorithm 5) until $k+1$ bad columns are found and the next shift will be taken.

Obviously, $B_{loc}(P)$ corresponds to $C_{loc}(P)$ of Lemma 1. For the expected value $\bar{B}_{loc}(P)$ we show the following rough bound.

LEMMA 5. *Let* $2k+1<c$. *Then*

$$\bar{B}_{loc}(P) \le \left(\frac{c}{c-2k-1}+1\right)(k+1).$$

Proof. The expected value of $B_{loc}(P)-(k+1)$ can be bounded from above by the expected value of the negative binomial distribution with parameters $(k+1,q)$, where q is a lower bound for the probability that a column is bad. Recall that column j is called bad if text symbol t_j does not occur in the corresponding k environment. As the k environment is a substring of P of length at most $2k+1$, it can have at most $2k+1$ different symbols. Therefore, the probability that a random t_j does not belong to the symbols of a k environment is at least $(c-(2k+1))/c$. Hence we can choose $q=(c-(2k+1))/c$.

The negative binomial distribution would then give for $\bar{B}_{loc}(P)-(k+1)$ an upper bound $(2k+1)(k+1)/(c-(2k+1))$. However, the shift heuristic implies that after a shift of length $<m$ we know that at least one and at most $k+1$ columns will not be bad. Hence to bound $\bar{B}_{loc}(P)-(k+1)$ properly, we have to add $k+1$ to the above bound, which gives

$$\bar{B}_{loc}(P)-(k+1) \le \frac{(2k+1)}{c-(2k+1)}(k+1)+k+1,$$

and the lemma follows. □

Let $S'(P)$ be a random variable denoting the length of the shift in Algorithm 5 for pattern P and for some fixed k and c. When scanning a random T, the special pattern P_0 again gives the shortest expected shift, that is, $\bar{S}'(P_0) \le \bar{S}'(P)$ for all P of length m. Lemma 6 gives a bound for $\bar{S}'(P_0)$.

LEMMA 6. $\bar{S}'(P_0) \ge \frac{1}{2}\min(c/(k+1), m)$.

Proof. Let $t=\min(c-1, m-1)$. Then the possible lengths of a shift are $1,2,\ldots,t+1$; note that a shift actually is always $\ge k+1$ according to our heuristic, but the heuristic can be ignored here, as our goal is to prove a lower bound. Therefore,

$$\bar{S}'(P_0)=\sum_{i=0}^{t} Pr(S'(P_0)>i).$$

If $0 \le i \le m-k-1$, then

$$Pr(S'(P_0)>i)=\left(\frac{c-i}{c}\right)^{k+1}$$

because for each of the $k+1$ text symbols that are compared with the pattern to determine the shift (step 8 of Algorithm 5), there are i characters not allowed to occur as the text symbols. This is exactly as in the proof of Lemma 2. A slight difference arises when $m - k \leq i \leq m - 1$. Then

$$Pr(S'(P_0) > i) = \left(\frac{c-1}{c}\right)^{m-i} \cdot \frac{c-i+1}{c} \cdot \frac{c-i+2}{c} \cdot \ldots \cdot \frac{c-m+k+1}{c}$$

because now the number of forbidden characters is i for the $m - i$ last text symbols and $i - 1, i - 2, \ldots, i - (m - k - 1)$ for the remaining $k + 1 - (m - i)$ text symbols, listed from right to left. But also in this case,

$$Pr(S'(P_0) > i) \geq \left(\frac{c-i}{c}\right)^{k+1}.$$

Hence

$$\bar{S}'(P_0) \geq \sum_{i=0}^{t} \left(1 - \frac{i}{c}\right)^{k+1}.$$

The rest of the proof is divided into two cases which are so similar to the cases in the proof of Lemma 2 that we do not repeat the details. If $m < c/(k+1)$, then $\bar{S}'(P_0) \geq \frac{1}{2}m$. If $m \geq c/(k+1)$, then $\bar{S}'(P_0) \geq \frac{1}{2}\lceil c/(k+1)\rceil$. □

As the length of a shift is always $\geq k + 1$, we get, from Lemma 6,

$$\begin{aligned} \bar{S}'(P) &\geq \bar{S}'(P_0) \\ &\geq \max\left(k+1, \min\left(\frac{c}{2(k+1)}, \frac{m}{2}\right)\right) \\ &= \min\left(\max\left(k+1, \frac{c}{2(k+1)}\right), \max\left(k+1, \frac{m}{2}\right)\right) \\ &\geq \frac{1}{2}\min\left(k+1+\frac{c}{2(k+1)}, \frac{m}{2}\right). \end{aligned}$$

The number of text positions at which a right-to-left scanning of P is performed between two shifts is again

$$O\left(\frac{n-m}{\bar{S}'(P)}\right) = O\left(\frac{n-m}{\bar{S}'(P_0)}\right).$$

This can be shown as in the analysis of Algorithm 4. Note that for Algorithm 5 we need not assume explicitly that the lengths of different shifts are independent. They are independent as the length of the minimum shift is $k + 1$.

Hence the expected scanning time of Algorithm 5 for pattern P is

$$O\left(\bar{B}_{loc}(P) \cdot \frac{n-m}{\bar{S}'(P)}\right).$$

When we apply here the upper bound for $\bar{B}_{loc}(P)$ from Lemma 5 and the above lower bound for $\bar{S}'(P)$, and simplify, we obtain our final result.

THEOREM 2. *Let* $2k + 1 < c$. *Then the expected scanning time of Algorithm* 5 *is*

$$O\left(\left(\frac{c}{c-2k}\right) \cdot kn \cdot \left(\frac{k}{c+2k^2} + \frac{1}{m}\right)\right)$$

The preprocessing time is $O((k+c)m)$, and the working space $O(cm)$.

The checking of the marked diagonals can be done after Algorithm 5 or in cascade with it in which case a buffer of length $2m$ is enough for saving the relevant part of text T. The latter approach is presented in Algorithm 6, which contains a modification of Algorithm 5 as its subroutine, function *NPO*.

ALGORITHM 6. The total algorithm for the k differences problem.

```
 1.        function NPO; begin                 {the next possible occurrence}
 2.        while $j \le n + k$ do begin
 3.            $r := j; i := m; bad := 0; d := m;$
 4.            while $i > k$ and $bad \le k$ do begin
 5.                if $i \ge m - k$ then $d := \min(d, d_k[i, t_r]);$
 6.                if $Bad(i, t_r)$ then $bad := bad + 1;$
 7.                $i := i - 1; r := r - 1$ end;
 8.            if $bad \le k$ then goto out;
 9.            $j := j + \max(k + 1, d)$ end;
10.  out: if $j \le n + k$ then begin
11.            $NPO := j - m - k;$
12.            $j := j + \max(k + 1, d)$ end
13.        else $NPO := n + 1$ end;

14.       compute tables $Bad$ and $d_k$;
15.       $j := m;$
16.       for $i := 0$ to $m$ do $H_0[i] := i;$
17.       $H := H_0;$
18.       $top := \min(k + 1, m);$             {$top - 1$ is the last row with the value $\le k$}
19.       $col := NPO;$
20.       $lastcol := col + m + 2k - 1;$
21.       while $col \le n$ do
22.           for $r := col$ to $lastcol$ do begin
23.               $c := 0;$
24.               for $i := 1$ to $top$ do begin
25.                   if $p_i = t_r$ then $d := c;$
26.                   else $d := \min(H[i-1], H[i], c) + 1;$
27.                   $c := H[i]; H[i] := d$ end;
28.               while $H(top) > k$ do $top := top - 1;$
29.               if $top = m$ then report match at $j$;
30.               else $top := top + 1$ end;
31.           $next := NPO;$
32.           if $next > lastcol + 1$ then begin
33.               $H := H_0;$
34.               $top := \min(k + 1, m);$
```

```
35.             col := next end
36.         else col := lastcol +1;
37.         lastcol := next +m + 2k − 1 end
```

The checking phase of Algorithm 6 evaluates a part of D by dynamic programming (see §3.1). Because entries on every diagonal are monotonically increasing [Ukk85a], the computation along a marked diagonal can be stopped, when the threshold value of $k+1$ is reached, because the rest of the entries on that diagonal will be greater than k. Algorithm 6 implements this idea in a slightly streamlined way. Instead of restricting the evaluation of D exactly on the marked diagonals, (which could be done, of course, but leads to more complicated code), we evaluate each *column* of D that intersects some marked diagonal. Each such column is evaluated from its first entry to the last one that could be $\leq k$. This can be easily decided using the diagonalwise monotonicity of D [Ukk85b]. The evaluation of each separate block of columns can start from a column identical to the first column of D (H_0 in Algorithm 6; H stores the previous as well as the current column under evaluation). For random strings, this method spends expected time of $O(k)$ on each column (this conjecture of [Ukk85b] has recently been proved in [ChL92]). Hence the total expected time of the checking phase remains $O(kn)$.

Asymptotically, steps 22–37 of Algorithm 6 are executed very seldom. Hence except for small patterns, small alphabets and large k's, the expected time for the checking phase tends to be small, in which case the time bound of Theorem 2 is valid for our entire algorithm.

3.4. Variations. Each marking operation before the next shift takes time $O(m)$ in the worst case. At the cost of decreased accuracy of marking we can reduce this by limiting the number of the columns whose badness is examined. The time reduces to $O(k)$ when we examine only at most ak columns for some constant $a > 1$. If there are not more than k bad columns among them, then the diagonals are marked. This variation appealingly has the feature that the total time of marking and shifting reduces to $O(n)$ in the worst case. Of course, the gain may be lost in the checking phase, as more diagonals will be marked.

On the other hand, the accuracy of the marking heuristic, which quite often conservatively marks too many diagonals in its present form, can be improved by a more careful analysis of whether or not a column is bad. Such an analysis can be based, at the cost of longer preprocessing, on the observation that two matches on successive columns of D can occur in the same minimizing path only if they are on the same diagonal.

In Algorithm 6, the width of the band of columns inspected is $m+2k$. The algorithm works better for small alphabets and short patterns, if a wider width is used, because that will reduce reinspection of text positions during the scanning phase. If the width is at least $2m+k$, then we can in the case of a potential match make a shift of $m+1$, which guarantees that no text position is reinspected in that situation.

4. Experiments and conclusions. We have tested extensively our algorithms and compared them with other methods. We will present results of a comparison with the $O(kn)$ expected time dynamic programming method [Ukk85b] which we found to be the best in practice among the old algorithms we have tested [JTU90].

Table 1 shows total execution times of Algorithm 4 and 6 and the corresponding dynamic programming algorithms $DP1$ (the k mismatches problem) and $DP2$ (the k differences problem). Preprocessing, scanning, and checking times are specified for Algorithm 6, as well as preprocessing times for Algorithm 4. In our tests, we used random

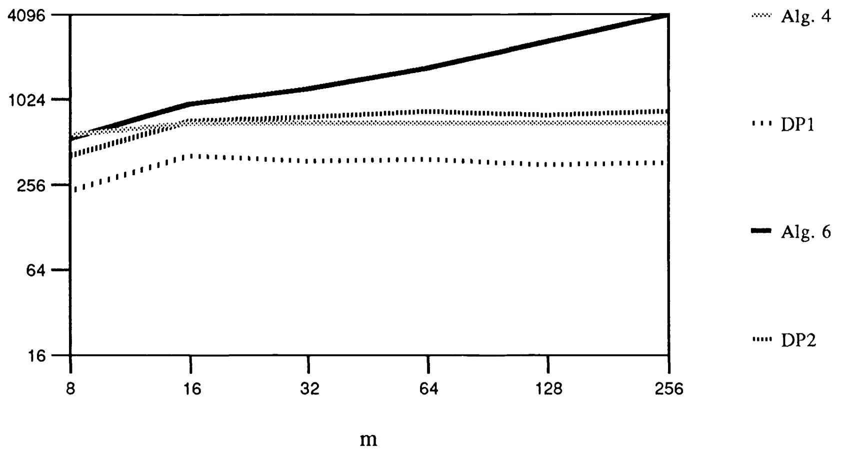


FIG. 3. *Total times for $k = 4$ and $c = 2$.*

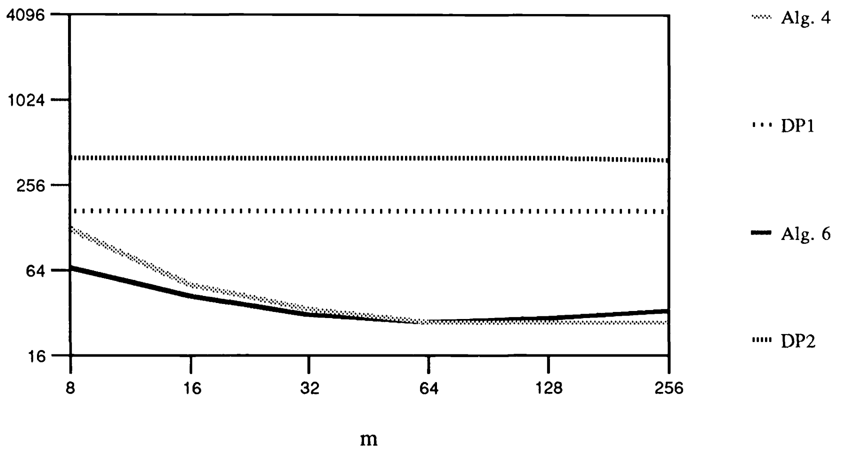

FIG. 4. *Total times for $k = 4$ and $c = 90$.*

patterns of varying lengths and random texts of length 100, 000 characters over alphabets of different sizes. The tests were run on a VAX 8800 under VMS. In order to decrease random variation, the figures of Table 1 are averages of ten runs. Still more repetitions should be necessary to eliminate variation, as can be seen in the duplicate entries of Table 1 corresponding to different test series with the same parameters.

Figures 3–6 have been drawn form the data of Table 1. Figures 3 and 4 show the total execution times when $k = 4$ and m varies for alphabet sizes $c = 2$ and 90. Figures 5 and 6 show the corresponding times when $m = 8$ and k varies for alphabet sizes $c = 4$ and 30.

Our algorithms, as all algorithms of Boyer–Moore type, work very well for large alphabets, and the execution time decreases when the length of the pattern grows. An increment of the error limit k slows down our algorithms more than the dynamic programming algorithms. Observe also that the Boyer–Moore approach is relatively better

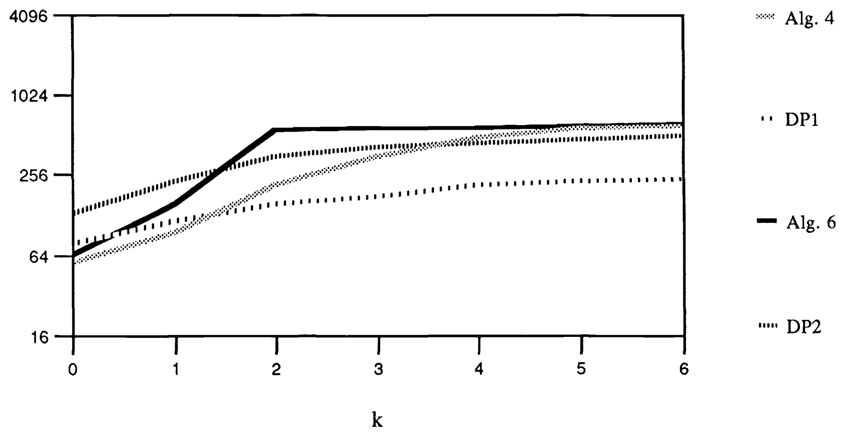

FIG. 5. *Total times for $m = 8$ and $c = 4$.*

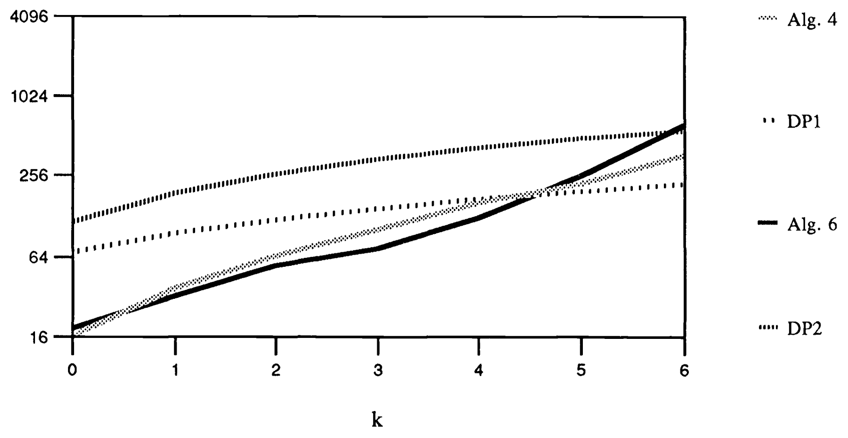

FIG. 6. *Total times for $m = 8$ and $c = 30$.*

in solving the k differences problem than in solving the k mismatches problem.

Our methods turned out to be faster than the previous methods; when the pattern is long enough ($m > 5$), the error limit k is relatively small and the alphabet is not very small ($c > 5$). Results of the practical experiments are consistent with our theoretical analysis. Devising a more accurate and complete theoretical analysis of the algorithms is left as a subject for further study.

TWO PROBABILISTIC RESULTS ON MERGING*

WENCESLAS FERNANDEZ DE LA VEGA[†], SAMPATH KANNAN[‡], AND MIKLOS SANTHA[†]

Abstract. This paper contains two probabilistic results about merging two sorted lists of sizes n and m with $m < n$. This paper designs a probabilistic algorithm, which in the worst case is significantly faster than any deterministic one in the range $1.618 < n/m \leq 3$. This paper extends it into a simple general algorithm that performs well for any ratio n/m. In particular, for $n/m > 1.618$ it is significantly faster than binary merge. This paper also proves an average case lower bound for a widely studied class of merging algorithms, when $1 < n/m < \sqrt{2}+1$.

Key words. merging, randomized algorithm, information theory, lower bound

AMS(MOS) subject classifications. 68Q20, 68Q25

1. Introduction. Merging is one of the basic problems in theoretical computer science. Given two sorted lists $A = \{a_1 < \ldots < a_m\}$ and $B = \{b_1 < \ldots < b_n\}$, the task consists of sorting the union of the two lists. We assume that the $m+n$ elements are distinct and $m \leq n$. The merging is performed by pairwise comparisons between items in A and items in B. The measure of complexity of a merging algorithm is the number of comparisons made by the algorithm, and the complexity of the merging problem is the complexity of the best merging algorithm. As usual, we can speak of worst case and average case complexity.

The worst case complexity of the merging problem is quite well studied. Let $C(m,n)$ denote this complexity with input lists of sizes m and n. When $m = 1$, merging degenerates into binary search whose complexity is $\lceil \log_2(n+1) \rceil$. The case $m = 2$ was completely solved by Graham [7] and Hwang and Lin [5]; their result is

$$C(2,n) = \lceil \log_2 7(n+1)/12 \rceil + \lceil \log_2 14(n+1)/17 \rceil.$$

The exact complexity is also known when the sizes of the two lists are not too far apart. For $m \leq n \leq \lfloor 3m/2 \rfloor$ we have

$$C(m,n) = m+n-1,$$

and the optimal algorithm is the well-known tape-merge (two-way merge). This result was obtained by Stockmeyer and Yao [10] and by Christen [2], after it was observed by several people for $m \leq n \leq m+4$. The best known algorithm—binary merge—which gives satisfactory results for all values of m and n is due to Hwang and Lin [6]. Let N denote the set of nonnegative integers. Set $n/m = 2^t x$, where $t \in N$ and $1 < x \leq 2$ are uniquely determined, and let $BM(m,n)$ denote the complexity of binary merge. Then

$$BM(m,n) = \lfloor (t+x+1)m \rfloor - 1,$$

and Hwang and Lin have also shown that

$$BM(m,n) \leq \lceil L(m,n) \rceil + m,$$

where $L(m, n) = \log_2 \binom{m+n}{m}$ is the lower bound from information theory. This means that if the ratio n/m goes to infinity, then the relative extra work done by binary merge is $o(C(m, n))$. As the relative extra work might be significant for ratios n/m of constant order, it is important to look for improvements in this case.

Several algorithms were proposed, which in some range for n/m perform better than binary merge. Let us say that merging algorithm A_1 with running time $T_1(m, n)$ is *significantly* faster for some fixed ratio n/m than merging algorithm A_2 with running time $T_2(m, n)$, if $T_2(m, n) - T_1(m, n) = \Omega(m)$. The merging algorithm of Hwang and Deutsch [4] is better than binary merge for small values of m, but not significantly faster. The first significant improvement over binary merge was proposed by Manacher [8]; he improved it for $n \geq 8m$ by $31m/336$ comparisons. It was further improved by Christen [1], who designed an ingenious but quite involved merging algorithm. It is better than binary merge if $n > 3m$, it uses at least $m/4$ fewer comparisons if $n \geq 4m$, and asymptotically it uses at least $m/3 - o(m)$ fewer comparisons when n/m goes to infinity. On the other hand, this algorithm is worse than binary merge when $n < 3m$.

In the first part of this paper we propose a simple probabilistic algorithm for merging. The algorithm will at some points flip a (biased) coin, and its next step will depend on the result of the coin toss. The algorithm is quite simple, and works well for all values of m and n. It is significantly faster than binary merge for $n/m > (\sqrt{5} + 1)/2 \approx 1.618$. To the best of our knowledge, binary merge is the best algorithm known for $n/m \leq 3$, thus our probabilistic algorithm is significantly faster than any deterministic one in this range.

In the second part of the paper we prove a nontrivial average case lower bound for a widely studied class of merging algorithms called *insertive* algorithms, defined as follows: During the run of a merging algorithm, we will say that an element a of a list is *active* if a has been compared to at least one element of the other list, but a's exact position in the other list has not been determined. We will call a merging algorithm *insertive* if there is no more than one active element in the smaller list at any time. Apart from this constraint the algorithm can be arbitrary. Many merging algorithms such as repeated binary search, tape merge, and binary merge are insertive. We can establish the lower bound for ratios n/m in the interval $(1, \sqrt{2}+1)$ which are bounded away by a constant from the endpoints of the interval. More precisely, we will prove that if $(1 + \eta) \leq n/m \leq (\sqrt{2} + 1 - \eta)$ for some constant $\eta > 0$, then every insertive merging algorithm makes on the average at least a constant factor more comparisons than the information theoretic lower bound. We were unable to extend the lower bound for constant ratios $n/m \geq \sqrt{2} + 1$. When $n/m \to \infty$, then the result of Hwang and Lin also implies that the information theoretic lower bound and the actual complexity are asymptotically equal.

The rest of the paper is organized as follows: In §2.1 we describe our algorithm. The analysis of its complexity will be done in §2.2 and we also prove there that the particular bias of the coin in the algorithm was optimally chosen. In §3 we prove the average case lower bound result for insertive algorithms. Finally, in §4 we mention some open problems. Throughout the paper the logarithm function in base 2 will be denoted by log, and in the natural base by ln.

2. The probabilistic algorithm.

2.1. Description of the algorithm. For this section let $s = (\sqrt{5} - 1)/2 \approx 0.618$, and $r = (\sqrt{2} - 1 + \sqrt{2}s)^2 \approx 1.659$. These numbers play a considerable role in the algorithm and in its analysis. The heart of the algorithm MERGE is the probabilistic procedure PROBMERGE, which merges two already sorted lists, where the longer list contains more than $(1+s)$-times, but at most $2r$-times as many elements as the shorter one. The intuition underlying PROBMERGE is described below. We know that if $n \le \lfloor 3m/2 \rfloor$, then the tape merge algorithm is best possible. Given two sorted lists A and B as before, the tape merge algorithm can be thought of as inserting the a's in order in list B. At each stage the next a to be inserted is compared with the first "eligible" element in B. If, however, B is a list of length $2m$, then it might be better to compare the next a to be inserted with the second eligible b (since, on average, there are two b's between every two consecutive a's). However, the deterministic algorithm that tries to do this turns out to be no better than tape merge. Its worst case complexity is also $3m-1$. A natural idea is to try to compare the next a to be inserted with either the first or the second eligible element in B, the decision being made probabilistically. In fact this is our algorithm.

We will use sentinel elements in the algorithm. They make the description simpler for the price of a little loss of efficiency.

Procedure PROBMERGE
Input: $A = \{a_1 < \ldots < a_m\}$ and $B = \{b_1 < \ldots < b_n\}$, where $1+s < n/m \le 2r$, and sentinel elements $b_0 = -\infty$, $b_{n+1} = b_{n+2} = \infty$.
Output: The merged list.

```
• $p := \begin{cases} s & \text{if } 1+s < n/m \le 2+s \\ \sqrt{n/m} - 1 & \text{if } 2+s < n/m \le 2r \end{cases}$   $\left\{ \begin{array}{l} \textit{the choice of the} \\ \textit{probability value} \end{array} \right\}$
• $i := 1; j := 1$ $\{i$ indexes $A$, $j$ indexes $B\}$
• **while** $i \le m$ **do**
    – with probability $1-p$ compare $a_i$ with $b_j$
        * **if** $a_i < b_j$ **then** $i := i+1$ $\{b_{j-1} < a_i < b_j\}$
        * **else** $j := j+1$
    – with probability $p$ compare $a_i$ with $b_{j+1}$
        * **if** $a_i < b_{j+1}$ **then**
            · compare $a_i$ with $b_j$
            · **if** $a_i < b_j$ **then** $i := i+1$ $\{b_{j-1} < a_i < b_j\}$
            · **else** $i := i+1; j := j+1$ $\{b_j < a_i < b_{j+1}\}$
        * **else** $j := j+2$
• **end**
```

The general algorithm MERGE uses PROBMERGE as a subroutine. Given lists A and B of size m and $n > (1+s)m$, respectively, the algorithm calls PROBMERGE directly if $n \le rm$. Otherwise it picks a uniformly spaced sublist C of B. The spacing between the elements of C is 2^t, where t is the unique integer such that cardinality of C is between rm and $2rm$. The algorithm first merges A with C probabilistically. This determines for each a in A a list of $2^t - 1$ b's into which a should be inserted. The insertion is done deterministically by binary search and takes t steps. Let us observe that MERGE actually coincides with the procedure PROBMERGE while $n \le 2rm$.

Algorithm MERGE
Input: $A = \{a_1 < \ldots < a_m\}$ and $B = \{b_1 < \ldots < b_n\}$, where $(1+s) < n/m$. For $r < n/m$ set $m = 2^t xm$, $t \in N$, $r < x \le 2r$.
Output: The merged list.

1. If $n/m \le r$ then PROBMERGE(A, B).
2. Let $C = \{c_1 < \ldots < c_{\lceil xm \rceil}\}$ be the sublist of B, where $c_k = b_{(k-1)2^t+1}$ for $k = 1, \ldots, \lceil xm \rceil$, and define sentinel elements $c_0 = -\infty$, $c_{\lceil xm \rceil + 1} = \infty$.
3. PROBMERGE(A, C).

4. For $i = 1, \ldots, m$ let $0 \leq j_i \leq \lceil xm \rceil$ be such that $c_{j_i} < a_i < c_{j_i+1}$.
5. For $i = 1, \ldots, m$ insert a_i by binary search into the list $\{b_{(j_i-1)2^t+2} < \cdots < b_{j_i 2^t}\}$.

2.2. Analysis of the algorithm. We would like to analyze the expected number of comparisons made by the algorithm PROBMERGE. Let $T(m, n)$ be this number when the input of the procedure is two lists of size m and n, respectively, $1 + s < n/m \leq 2r$, and let p be the probability value defined inside the procedure.

THEOREM 2.1. *We have*

$$T(m,n) \leq \begin{cases} sn + (1+s)m & \text{if } 1 + s < n/m \leq 2 + s, \\ 2\sqrt{nm} & \text{if } 2 + s < n/m \leq 2r. \end{cases}$$

Proof. The outcome of the procedure uniquely determines m nonnegative integers $k_1, \ldots, k_m$, where k_i is the number of b's between a_{i-1} and a_i. As the list B contains n elements, $\sum_{i=1}^m k_i \leq n$. The procedure puts the a's into B one by one. Let f_k be the expected number of comparisons to put an a into B, when the number of b's between a and its predecessor in A is k. f_k does not depend on the index of the element being inserted. Then

$$T(m,n) = \max_{\substack{k_1, \ldots, k_m \\ \sum_{i=1}^m k_i \leq n}} \sum_{i=1}^m f_{k_i}.$$

Thus we are interested in the values f_k. If $k \geq 2$, then after the first comparison the element a jumps over two b's with probability p, and jumps over one b with probability $1 - p$. This means that we get the following recurrence relation for f_k:

$$f_k = (1-p)f_{k-1} + pf_{k-2} + 1,$$

with the initial conditions

$$f_0 = 2p + 1(1-p) = p + 1,$$

$$f_1 = 3p(1-p) + 2((1-p)^2 + p) = -p^2 + p + 2.$$

By standard technique, the solution of this linear recurrence is

$$f_k = \frac{k}{p+1} + \frac{p^3 + p^2 - p}{(p+1)^2}(-p)^k + \frac{2p^2 + 4p + 1}{(p+1)^2}.$$

This tells us that

$$\sum_{i=1}^m f_{k_i} = \sum_{i=1}^m \frac{k_i}{p+1} + \frac{p^3 + p^2 - p}{(p+1)^2} \sum_{i=1}^m (-p)^{k_i} + \frac{2p^2 + 4p + 1}{(p+1)^2} m.$$

The term $\sum_{i=1}^m \frac{k_i}{p+1}$ is always bounded from above by $\frac{n}{p+1}$. If $p = s$, we have $p^3 + p^2 - p = 0$, and the result follows. If $p > s$ (when $2 + s < n/m$), we have $p^3 + p^2 - p > 0$, and $\sum_{i=1}^m (-p)^{k_i}$ is maximized by choosing $k_i = 0$. Simple arithmetic gives the result also in this case. □

The global algorithm MERGE calls PROBMERGE with two lists of size m and $\lceil mx \rceil$ and then makes n binary searches, each in a list of size $2^t - 1$. Applying Theorem 2.1, we immediately get the following result.

THEOREM 2.2. *Let $E(m,n)$ denote the expected number of comparisons made by* MERGE. *For $n/m \leq r$ set $n/m = x$, $t = 0$, and for $n/m > r$ set $n/m = 2^t x$, $t \in N$, $r < x \leq 2r$. Then*

$$E(m,n) \leq \begin{cases} (t + sx + 1 + s)m + 1 & \text{if } (1+s) < x \leq 2+s, \\ (t + 2\sqrt{x})m + 1 & \text{if } 2+s < x \leq 2r. \end{cases}$$

COROLLARY 2.1. *The algorithm* MERGE *is significantly faster than binary merge for any fixed ratio $n/m > 1 + s$.*

Proof. With the notation of Theorem 2.2 we have

$$BM(m,n) - E(m,n) \geq \begin{cases} (x - sx - s)m - 3 & \text{if } (1+s) < x \leq 2, \\ ((1-s) - x(s - 1/2))m - 3 & \text{if } 2 < x \leq 2+s, \\ (2 - \sqrt{x})^2 m/2 - 3 & \text{if } 2+s < x \leq 2r. \end{cases}$$

This difference is $\Omega(m)$. □

Let us point out an interesting special case of the above result. When $n = 2m$, PROBMERGE merges the two lists with less than $2.855m$ expected comparisons, whereas the best known deterministic algorithm [6] performs $3m - 2$ comparisons.

Some more calculation also yields a relation between the expected running time of MERGE and the information theoretic lower bound.

COROLLARY 2.2. $E(m,n) - L(m,n) \leq 0.471m$.

We also claim that the probability value p was optimally chosen in the procedure PROBMERGE. Let $T_p(m,n)$ be the expected number of comparisons made by PROBMERGE when the probability $0 \leq p \leq 1$ is taken as a variable. Let us observe that we have just analyzed $T_s(m,n)$ and $T_{\sqrt{n/m}-1}(m,n)$ in Theorem 2.1. For the purpose of this analysis let us permit any input lists such that the ratio n/m is at least 1. The following theorem gives optimal choices for the probability value for all ranges of n/m.

THEOREM 2.3. *For every p, for every large enough m and n, we have*

$$T_p(m,n) \geq \begin{cases} T_0(m,n) & \text{if } 1 \leq n/m \leq 1+s, \\ T_s(m,n) & \text{if } 1+s \leq n/m \leq 2+s, \\ T_{\sqrt{n/m}-1}(m,n) & \text{if } 2+s \leq n/m \leq 4, \\ T_1(m,n) & \text{if } 4 \leq n/m. \end{cases}$$

Proof. We will examine the function $T_p(m,n)$ according to two cases.

Case 1. $p \geq s$. For $k_1 = \ldots = k_{m-1} = 0$ and $k_m = n$, the expected number of comparisons made by the procedure PROBMERGE is

$$U_p(m,n) = \left(\frac{n/m}{p+1} + p + 1\right) m + \frac{p^3 + p^2 - p}{(p+1)^2}((-p)^n - 1).$$

By definition, for every p, m, n we have $U_p(m,n) \leq T_p(m,n)$. We claim that for every large enough m and n, for every $p \neq s$, we have

$$T_s(m,n) < U_p(m,n) \quad \text{if} \quad 1+s < n/m \leq 2+s,$$

and that for every large enough m and n, for every $p \neq \sqrt{n/m} - 1$, we have

$$T_{\sqrt{n/m}-1}(m,n) < U_p(m,n) \quad \text{if} \quad 2+s \leq n/m.$$

Let us define the functions $V(p) = (\frac{n/m}{p+1} + p + 1)m$ and $D(p) = \frac{p^3+p^2-p}{(p+1)^2}((-p)^n - 1)$. Then $U_p(m,n) = V(p) + D(p)$. We will first prove the claim for the function $V(p)$ rather than the function $U_p(m,n)$. Its derivative is $V'(p) = (\frac{-n/m}{(p+1)^2} + 1)m$, and it is easy to check that the function $V(p)$ takes its global minimum in the set of real numbers at the point $\sqrt{n/m} - 1$. Moreover, $V(p)$ is an increasing function for $p \geq \sqrt{n/m} - 1$. Thus the minimum of the function $V(p)$ in the interval $[s, 1]$ is at the point s, if $\sqrt{n/m} - 1 \leq s$, and is at the point $\sqrt{n/m} - 1$, if $\sqrt{n/m} - 1 \geq s$. If we observe that $\sqrt{n/m} - 1 \leq s$ if and only if $n/m \leq 2 + s$, then the claim follows for the function V.

If $\sqrt{n/m} - 1 \geq s$ then for every p, we have $V(p) - V(\sqrt{n/m} - 1) = \Omega(m)$, while $D(\sqrt{n/m} - 1) - D(p) \leq |D(\sqrt{n/m} - 1)| + |D(p)| = O(1)$. This implies the claim for $U_p(m,n)$ when $\sqrt{n/m} - 1 \geq s$, and a similar argument works when $\sqrt{n/m} - 1 \leq s$.

In conclusion, we have shown that for every p in the interval $[s, 1]$, for every large enough m and n,

$$T_p(m,n) \geq T_s(m,n) \quad \text{if} \quad n/m \leq 2+s,$$

and similarly, for every p, for every large enough m and n,

$$T_p(m,n) \geq T_{\sqrt{n/m}-1}(m,n) \quad \text{if} \quad n/m \geq 2+s.$$

Case 2. $p \leq s$. We will show that for every p in the interval $[0, s]$, for every large enough m and n,

$$T_p(m,n) \geq T_0(m,n) \quad \text{if} \quad n/m \leq 1+s,$$

and similarly, for every p, for every large enough m and n,

$$T_p(m,n) \geq T_s(m,n) \quad \text{if} \quad n/m \geq 1+s.$$

This clearly implies the theorem. The function $U_p(m,n)$ that we use is when $k_1 = \dots k_{m-1} = 1$ and $k_m = n - m + 1$. This is because, in this range for p, $p^3 + p^2 - p$ is negative. For these choices of k_i we get,

$$U_p(m,n) = \left(\frac{-p^3 + 3p + 1 + n/m}{p+1}\right)m + \left(\frac{p^3+p^2-p}{(p+1)^2}\right)((-p)^{n-m+1} + p).$$

Once again we break up $U_p(m,n)$ into its two terms which we call $V(p)$ and $D(p)$. Thus $V(p) = (\frac{-p^3+3p+1+n/m}{p+1})m$ and $D(p) = (\frac{p^3+p^2-p}{(p+1)^2})((-p)^{n-m+1} + p)$. As before, we concentrate on $V(p)$, $D(p)$ being $O(1)$. We compute the derivative $V'(p)$ of $V(p)$ with respect to p:

$$V'(p) = \left(\frac{-2p^3 - 3p^2 + 2 - n/m}{(p+1)^2}\right)m.$$

Note that $V'(p)$ is a decreasing function in the range $[0, \infty]$. This means that the minimum value for $V(p)$ for p in the range $[0, s]$ is attained either at 0 or at s. $V(0) =$

$m(n/m+1)$ and $V(s) = m((1+s)+sn/m)$. It is easy to see that $V(s) - V(0)$ decreases as n/m increases. At $n/m = (1+s)$, $V(s) = V(0)$. This proves both statements of the claim at the beginning of case 2. □

Thus while $n/m \leq (1+s)$, our probabilistic procedure gives deterministic tape-merge as a special case. In the range $1+s \leq n/m \leq 2+s$ the best choice is the constant $p = s$. For $n/m > 2+s$, the best choice grows with n/m until 1, when the procedure (obviously) degenerates into a deterministic one. There is no reason to use PROBMERGE for large values of n/m; MERGE is significantly faster when $n/m > 2r$. In fact that is how r is chosen.

3. The lower bound. In this section we will prove the following theorem.

THEOREM 3.1. *For every $\eta > 0$ there exists $\epsilon > 0$ such that for every large enough m and n with $(1+\eta)m \leq n \leq (\sqrt{2}+1-\eta)m$, every insertive merging algorithm makes at least $(1+\epsilon)L(m,n)$ comparisons on the average.*

Proof. The proof depends on the following Unbalance Lemma.

UNBALANCE LEMMA. *Let T denote a binary decision tree with k leaves, let the set of internal nodes be $\{D_1, \ldots, D_{k-1}\}$, and let d_j be the number of leaves of the subtree with root D_j. Let us suppose that for some $J \subseteq \{1, 2, \ldots, k-1\}$, the subset of nodes $\{D_j : j \in J\}$ satisfies the following conditions:*

(i) *There exists $\epsilon_1 > 0$ such that $\sum_{j \in J} d_j \geq \epsilon_1 k \log k$.*

(ii) *There exists $\epsilon_2 > 0$ such that for every $j \in J$, the answer probabilities (fraction of leaves in left and right subtrees) at the node D_j lie outside the interval $(1/2 - \epsilon_2, 1/2 + \epsilon_2)$. Then, the average path length of T is at least*

$$(1 + \epsilon_1 \epsilon_2^2) \log k.$$

Proof. The average path length of T is

$$L(T) = \frac{1}{k} \sum_{1 \leq j \leq k-1} d_j.$$

Let p_j denote the answer probability at D_j. The information in T is

$$I(T) = \sum_{1 \leq j \leq k-1} d_j H_j,$$

where $H_j = p_j \log 1/p_j + q_j \log 1/q_j$ is the entropy function. Elementary information theory [9] tells us that we have necessarily

$$I(T) = k \log k.$$

For every j, we obviously have $H_j \leq 1$, and Taylor's formula gives $H_j \leq 1 - \epsilon_2^2$ for $p_j \leq 1/2 - \epsilon_2$. Thus we obtain

$$\sum_{j \notin J} d_j + \sum_{j \in J} d_j (1 - {\epsilon_2}^2) \geq k \log k,$$

and finally

$$L(T) \geq (1 + \epsilon_1 {\epsilon_2}^2) \log k. \qquad \square$$

Let us fix some insertive algorithm, and let T be the binary decision tree associated with this algorithm. Let the internal nodes of T be $D_1, \ldots, D_{k-1}$, where $k = \binom{m+n}{m}$.

Since the average running time of the algorithm is the average path length of T, it will suffice to prove that the assumptions of the Unbalance Lemma are fulfilled for some subset of the nodes and for some proper ϵ_1 and ϵ_2. To begin, notice that there is a bijection between the outcomes of a merging algorithm and the set Z of words containing precisely m letters a and n letters b. For any word $w \in \{a, b\}^*$, let $|w|_a$ and $|w|_b$ denote, respectively, the number of occurrences of a and b in w.

It follows from the hypothesis that for some sufficiently small $\zeta > 0$ we have

$$1/2 + 3\zeta < n/(m+n) < 1/\sqrt{2} - 3\zeta.$$

Let $c_3 > 0$ be an appropriate constant to be specified later. For any $m \le i \le n$ and $w \in Z$, let *decomp*(w, i) denote the decomposition $uvxy = w$, where the factors u, v, x, y have the following lengths:

- $|u| = i - 3c_3$,
- $|v| = |x| = 3c_3$,
- $|y| = m + n - i - 3c_3$.

Let us denote by Z_i the set of words $w \in Z$ such that *decomp*(w, i) satisfies the following conditions:

1. $vx = (bba)^{c_3}(abb)^{c_3}$,
2. for every decomposition $y = y'y''$, where $|y'| = l$; and for every decomposition $u = u''u'$, where $|u'| = l$, we have

$$(1/2 + \zeta)l - c_2 \le |y'|_b, |u'|_b \le (1/\sqrt{2} - \zeta)l + c_2,$$

where $c_2 > 0$ is an appropriate constant also to be specified later. We will define a subset of nodes satisfying the assumptions of the Unbalance Lemma using the sets Z_i. First we prove two claims about these sets.

CLAIM 1. *There exists a constant $\epsilon_3 > 0$ such that for all $m \le i \le n$ we have*

$$|Z_i| \ge \epsilon_3 |Z| .$$

Proof. Let w be a random element of Z, and let $m \le i \le n$. The first requirement is obviously satisfied by w with constant probability. We will show that under this hypothesis, the conditional probability that $|y'|_b$ falls outside the interval $((1/2 + \zeta)l - c_2, (1/\sqrt{2} - \zeta)l + c_2)$ is less then 0.48 . As the second requirement is symmetrical in $|y'|_b$ and $|u'|_b$, this will imply the claim. We shall (rather crudely) bound this probability by the sum $\sum_{1 \le l \le |y|} s(l)$, where $s(l)$ denotes the probability that the left factor of y of length l violates the second requirement. Clearly $s(l) = q(l) + r(l)$, where $q(l)$ is the probability that the left factor of y of length l contains less than $(1/2 + \zeta)l - c_2$ occurrences of b's, and $r(l)$ is the probability that the same left factor contains more than $(1/\sqrt{2} - \zeta)l + c_2$ occurrences of b's. Let us recall Hoeffding's bound [3] about sampling without replacement.

LEMMA (Hoeffding's bound). [3] *Let us suppose that we have an urn that contains $M + N$ letters, N of which are b's and M of which are a's. Let $p = N/(M + N)$. We are sampling the urn without replacement. Let X_j be the $0 - 1$ valued random variable which is 1 if and only if at the jth trial we get a letter b. Let $S_{i,p} = \sum_{j=1}^{i} X_j$. Then for every $\delta > 0$ we have*

$$P[S_{i,p} \ge (1 + \delta)ip] \le \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{ip},$$

and similarly, for every $0 < \gamma \leq 1$ *we have*

$$P[S_{i,p} \leq (1-\gamma)ip] \leq \left(\frac{e^{\gamma}}{(1+\gamma)^{1+\gamma}}\right)^{ip}.$$

We will use Hoeffding's bound in the following way: set $N = n - 4c_3$ and $M = m - 2c_3$ (recall that $4c_3$ is the number of b's and $2c_3$ is the number of a's in vx). Let $p = N/(M+N)$. Then for large enough m, we have:

$$1/2 + 2\zeta < N/(M+N) < 1/\sqrt{2} - 2\zeta.$$

Let $q(l)$ (respectively, $r(l)$) be the probability that in a random w which satisfies the first condition, the left factor of y of length l contains more (fewer) occurrences of b than the second condition permits. Then

$$q(l) < P[S_{l,1/\sqrt{2}-2\zeta} \geq (1/\sqrt{2} - \zeta)l],$$

and

$$r(l) < P[S_{l,1/2+2\zeta} \leq (1/2+\zeta)l].$$

Hoeffding's bound implies that there exists a constant $0 < \xi < 1$ which depends only on ζ such that

$$q(l), r(l) < \xi^l.$$

Let $c_1 = c_1(\xi)$ be an integer such that

$$\sum_{l=c_1}^{\infty} \xi^l < 0.24.$$

Now, as a function of c_1 we choose c_2 large enough that $q(l) = r(l) = 0$, whenever $l \leq c_1$. Hence

$$\sum_{1 \leq l \leq |y|} s(l) < 2\sum_{l=c_1}^{\infty} \xi^l < 0.48\,. \qquad \square$$

We are now ready to choose the constant c_3 as a function of c_2 such that the following Claim becomes true. Let $c_3 = c_2/((3/\sqrt{2}) - 2 - 3\zeta)$.

CLAIM 2. *Let* $w \in Z_i$ *for some* $m \leq i \leq n$, *and let* $uvxy = decomp(w,i)$. *Let* z *be a nonempty prefix of* xy (*a suffix of* uv) *such that either the letter which follows* (*precedes*) z *in* w *is an* a, *or there is no more* a *in* w *after* (*before*) z. *Then we have*

$$(1/2+\zeta) \leq |z|_b/|z| \leq (1/\sqrt{2} - \zeta).$$

Proof. We show the upper bound. If z is a prefix of x, then $|z|_b/|z| = 2/3$. Otherwise this fraction is maximized when the corresponding prefix of y contains the most possible b's. If this prefix is of length l, we have

$$|z|_b/|z| \leq \frac{2c_3 + (1/\sqrt{2} - \zeta)l + c_2}{3c_3 + l} = 1/\sqrt{2} - \zeta. \qquad \square$$

We can now define a subset of the nodes of T which satisfies the conditions of the Unbalance Lemma. For every couple (w, i) such that $m \le i \le n$ and $w \in Z_i$, we first define an internal node $V(i, w)$ of T. Let $uvxy = decomp(w, i)$, and let $h = h(w, i)$ be such that a_h is the first instance of a in x (thus $h - 1$ is the number of instances of a in uv). If on the path of T corresponding to w the comparisons involving a_{h-1} precede those involving a_h, then let $V(w, i)$ be the node of the decision tree at which the first comparison involving a_h takes place. Otherwise let $V(w, i)$ be the node at which the first comparison involving a_{h-1} takes place. Finally let

$$J = \{j : D_j = V(w, i) \text{ for some } w \in Z_i\}.$$

We now show that the two conditions of the Unbalance Lemma are met by the nodes whose indices are in J. First we will show that

$$\sum_{j \in J} d_j \ge \sum_{m \le i \le n} |Z_i|.$$

On the right-hand side every word $w \in \bigcup_{m \le i \le n} Z_i$ is counted with multiplicity t_w, where

$$t_w = |\{i : w \in Z_i\}|.$$

If $i \ne i'$, then $V(w, i) \ne V(w, i')$, because $|h(w, i) - h(w, i')| > 1$. Thus the leaf corresponding to w is counted on the left-hand side at least t_w times. Therefore by using Claim 1 we get

$$\sum_{j \in J} d_j \ge \epsilon_3 m \binom{m+n}{m} = \epsilon_1 k \log k.$$

We now turn to the second condition of the Unbalance Lemma. Let $D_j = V(w, i)$ for some $w \in Z_i$, and let us suppose without loss of generality that the comparisons involving a_{h-1} precede those involving a_h. Let a_{h+r} denote the leftmost right neighbour of a_h which has already been treated when the comparisons involving a_h begin at D_j. (If there is no such element we set $r = m - h + 1$.) Let us further suppose that a_{h-1} and a_{h+r} are separated by s occurrences of b for some $s \ge 1$, which we denote by $b_e, \dots, b_{e+s-1}$. Let us observe that $s/(r+s) = |z|_b/|z|$ for some initial segment z of xy, where z satisfies the conditions of Claim 2. Therefore we have

$$1/2 + \zeta \le s/(r+s) \le 1/\sqrt{2} - \zeta.$$

The comparison at D_j is $a_h : b_{e+l-1}$ for some $1 \le l \le s$. Let $p(r, s, l) = Pr[a_h > b_{e+l-1}]$ denote the answer probability at D_j. Among the leaves of $V(w, i)$, the relative rankings of the sets $\{a_h, \dots, a_{h+r-1}\}$ and $\{b_e, \dots, b_{e+s-1}\}$ are all equally represented. For any word belonging to the leaves of D_j, the relative rank of a_h within the pooled set is at least l if and only if $a_h > b_{e+l-1}$. Thus we have

$$p(r, s, l) = \frac{s(s-1)\dots(s-l+1)}{(r+s)(r+s-1)\dots(r+s-l+1)}$$

We claim that for every l, the answer probability $p(r, s, l)$ falls outside the interval $(1/2 - \epsilon_2, 1/2 + \epsilon_2)$, for $\epsilon_2 = \min\{\zeta, 1/2 - (1/\sqrt{2} - \zeta)^2\}$. We prove this in two cases according to the value of l. If $l = 1$, then $p(r, s, 1) = s/(r+s) \ge 1/2 + \zeta$. If $l \ge 2$, then we have

$$p(r, s, l) \le \left(\frac{s}{r+s}\right)^2 \le (1/\sqrt{2} - \zeta)^2,$$

which means that the second condition of the Unbalance Lemma is also satisfied. We now set $\epsilon = \epsilon_1\epsilon_2^2$. The conclusion of the Unbalance Lemma gives exactly what we wanted to prove. □

4. Open problems. We have shown how to make significant improvements upon the tape merge algorithm when the ratio n/m is at least the golden ratio. An interesting open question is the value of the smallest ratio n/m where a significant improvement — probabilistic or deterministic — can be obtained. Although the lower bounds in [2], [10] hold only for deterministic algorithms, we conjecture that not even a probabilistic algorithm can achieve improvements over tape merge for ratios less than the golden ratio.

It would be interesting to design other, more complex probabilistic algorithms. Generalizing our average case lower bound for arbitrary merging algorithms also remains open.

Acknowledgments. Thanks are due to Charles Delorme for his most valuable assistance. We would also like to thank Russell Impagliazzo for his help in simplifying the analysis of the probabilistic algorithm.

OPTIMAL RANDOMIZED ALGORITHMS FOR LOCAL SORTING AND SET-MAXIMA*

WAYNE GODDARD[†], CLAIRE KENYON[‡], VALERIE KING[§], AND LEONARD J. SCHULMAN[¶]

Abstract. Randomized algorithms for two sorting problems are presented. In the local sorting problem, a graph is given in which each vertex is assigned an element of a total order, and the task is to determine the relative order of every pair of adjacent vertices. In the set-maxima problem, a collection of sets whose elements are drawn from a total order is given, and the task is to determine the maximum element in each set. Lower bounds for the problems in the comparison model are described and it is shown that the algorithms are optimal within a constant factor.

1. Introduction. In this paper we study two sorting problems. The first is the *local sorting* problem: given a graph in which each vertex is assigned an element of a total order, one must determine the relative order of every pair of adjacent nodes. This problem restricts to standard sorting when the graph is complete, but in general its complexity depends on the graph selected. The second problem is *set-maxima*, where the task is to identify the maximum element in each of a collection of sets drawn from a total order. Set-maxima was investigated in [1], [3], and [5]. Local sorting appears to be new, although a restricted version was suggested in [6].

We present randomized algorithms for these problems and measure their complexity in the comparison (decision-tree) model. In that model, one pays only for comparisons between elements of the total order. The algorithms use random bits to help determine which comparisons will be made, but their outcomes must be correct. The complexity of the algorithm is thus the expected number of comparisons made on a worst-case input. We obtain information-theoretic lower bounds for both problems and show that our algorithms attain these bounds.

The output of a local-sorting algorithm is exactly an acyclic orientation of the graph G. Thus an information-theoretic lower bound on the complexity of local sorting, even for randomized algorithms, is given by the logarithm of the number, $\alpha(G)$, of acyclic orientations of the graph G. We present an algorithm that is optimal for all graphs—it makes an expected $\Theta(\log \alpha(G))$ comparisons.

We derive an estimate of $\alpha(G)$ in terms of the degrees, $\{d_v\}$, of the vertices $\{v\}$ of G: specifically $\log \alpha(G)$ is $\Theta(\sum_{v \in G} \log(d_v + 1))$. Thus the number of comparisons

our algorithm makes contrasts with the $\Theta(\sum_{v\in G} d_v)$ comparisons made by the naive algorithm, which examines all edges.

Closely related to local sorting is the *set-sort* problem: sort each of a family of possibly overlapping sets. Set-sort is equivalent to locally sorting the graph in which each set induces a clique. We also observe that local sorting may be thought of as a special case of set-maxima (where every set is a pair).

One application of local sorting is to the *element uniqueness problem on a graph*: given a graph G with each vertex assigned an element of a total order, are all pairs of adjacent values distinct? Manber and Tompa [7] introduced this question and showed that $\log \alpha(G)$ comparisons are necessary for this decision problem. Up to a constant factor, this is the bound achieved by our local sorting procedure (which can identify every equality).

The second problem we study, set-maxima, was introduced in [3], where an argument of Fredman was presented showing that, given m sets over an n-element universe, at most $\binom{m+n-1}{n-1}$ arrangements of maxima are possible. We in fact observe an information-theoretic lower bound of $\Omega(n\log(m/n)+n)$, matching this limitation.

We describe a randomized algorithm for set-maxima that performs an expected $O(n\log(m/n)+n)$ comparisons. By the above this is optimal in terms of n and m.

Local sorting provides a reasonable solution to the *partial order verification* problem suggested by A. Yao [10]: given a directed graph G with elements of a total order at each of the n vertices, verify that the orientation of every edge agrees with the order. But it is best to reduce the problem to set-maxima. In the reduction each set consists of the immediate predecessors of a vertex of the graph. Our set-maxima algorithm yields an optimal $O(n)$-comparison algorithm for this problem.

Deterministic algorithms are known for a few special cases of set-maxima. Komlós [5] made use of a reduction to set-maxima when he solved the *minimum spanning tree verification* problem. His deterministic algorithm finds the tree edge of largest weight in every simple cycle containing exactly one nontree edge. It solves this instance of set-maxima in $O(n\log(m/n))$ comparisons, where n and m are the number of tree and nontree edges. Then it verifies that the every nontree edge is greater than the appropriate maximum. We have been informed of an $O(m+n)$-time implementation of this algorithm by Tarjan [9].

Recently Bar-Noy, Motwani, and J. Naor [1] gave a deterministic algorithm that uses $O(n)$ comparisons when the n sets are the hyperplanes in a projective geometry. They also gave an $O(n)$-comparison algorithm for the case where n sets are chosen randomly, so that each element appears in each set with probability $p(n)$.

This paper has three main sections: the first deals with local sorting, the second with set-maxima, and some open problems are discussed in the third.

2. Local sorting. At the heart of our approach to local sorting is the *limited-degree* algorithm (§2.1) whose complexity, $O(n\log(\Delta+1))$, is a function only of the number n of vertices and the maximum degree Δ of a graph G (where Δ may be a function of n). However, the maximum degree of G is too crude a measure of its complexity for local sorting. A more accurate measure is the logarithm of $\mathcal{D}(G)$, defined by:

$$\mathcal{D}(G) = \prod_{v\in G}(d_v+1),$$

where d_v is the degree of v in G. In §2.3 we show that $\log \mathcal{D}(G)$ is $\Theta(\log \alpha(G))$, which is a lower bound on the complexity of local sorting. In §2.2 we describe a *reduction* procedure that alters the graph so that we can achieve the optimal $\Theta(\log \mathcal{D}(G))$ comparisons with several applications of the limited-degree algorithm.

We present our results under the assumption that the values at the vertices are distinct. Minor modifications suffice to cover the more general case where equalities are allowed, and "local sorting" includes reporting the equalities as such.

2.1. The limited-degree local sorting algorithm. We show here how to sort locally in a graph with vertex set X ($|X| = n$) and maximum degree Δ. The idea is to take a series of increasingly large random samples of the vertices and partially order each sample using the information given by the partial order on the previous sample.

We produce a series of samples $R_k, R_{k-1}, \ldots, R_0 = X$ (where k will be defined later). Starting with R_k, we then:

- Partially order each R_i so that it is *locally sorted to radius* 2^{2i}.

By this we mean that the relative order of vertices in R_i is known if, as measured in G, they are within distance 2^{2i} of each other. The end result is that $R_0 = X$ is locally sorted to radius 1, as called for.

Algorithm. We choose the samples as follows. We let $R_0 = X$. Then we randomly choose R_i from within R_{i-1} by taking elements independently with probability p_i/p_{i-1}. Thus the sample R_i has expected size np_i. (The descending sequence p_i will be specified later.)

We continue until k such that R_k has expected size $O(1)$. This we then sort using an expected $O(1)$ comparisons.

The main part of the algorithm is an iterative process in which the partial order on R_i is used to obtain the requisite partial order on R_{i-1}. The R_i are used as "signposts" for the two parts of this process. Let B_x^r denote the set of vertices of distance at most r from vertex x. Proceed as follows.

Step 1. *For each $x \in R_{i-1}$ do:*

- *Find the rank of x in $R_i \cap B_x^{2^{2i-1}}$ using a binary search.*

Any two elements of R_i in $B_x^{2^{2i-1}}$ are within a distance of 2^{2i} of each other—so, since R_i is locally sorted to distance 2^{2i}, their relative order is already known (i.e., $R_i \cap B_x^{2^{2i-1}}$ has been totally ordered). This allows us to find x's rank with a binary search.

Step 2. *For each $x \in R_{i-1}$ do:*

- *Determine C_x, the set of all $y \in R_{i-1} \cap B_x^{2^{2i-2}}$ that have the same rank as x with respect to $R_i \cap B_x^{2^{2i-2}}$.*

Note that for y in $B_x^{2^{2i-2}}$, $B_y^{2^{2i-1}}$ contains $B_x^{2^{2i-2}}$. (See Fig.2.1.) Thus C_x can be constructed using no further comparisons.

Step 3. *For each pair $x, y \in R_{i-1}$ do:*

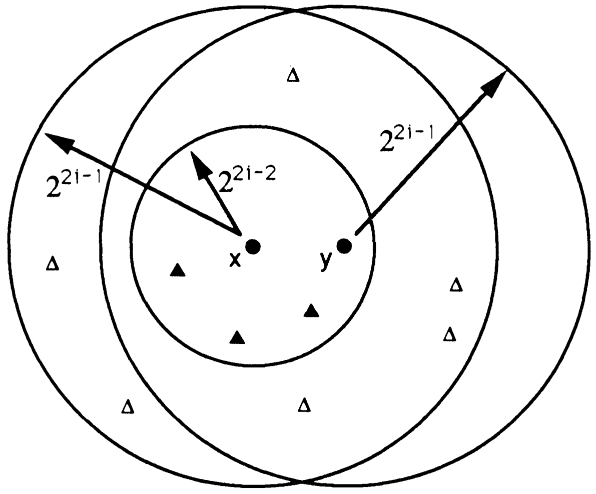
- *If $x \in C_y$ and $y \in C_x$ then compare x and y.*

If either $x \notin C_y$ or $y \notin C_x$ while x and y are at most distance 2^{2i-2} apart, then there is at least one intervening signpost (element of $R_i \cap B_x^{2^{2i-2}}$ or $R_i \cap B_y^{2^{2i-2}}$ whose value is between x and y), and therefore their relative order is known. Thus Step 3 is sufficient to determine for each $x \in R_{i-1}$ the relation between it and every element of $R_{i-1} \cap B_x^{2^{2i-2}}$. In other words Step 3 locally sorts R_{i-1} to radius 2^{2i-2}.

Analysis. How many comparisons do we use?

Step-by-step analysis. For each $x \in R_{i-1}$, the number of comparisons in Step 1 is at most $\log |B_x^{2^{2i-1}}|$ which, by our assumption on the degrees, is at most $2^{2i-1} \log(\Delta + 1)$. Thus the expected number of comparisons for the whole of Step 1 is at most

$$np_{i-1} 2^{2i-1} \log(\Delta + 1). \tag{2.1}$$



(▲, △ : signposts for x ; ▲ : signposts determining C_x)

FIG. 2.1. *y is a candidate for C_x.*

Step 2 involves no comparisons.

We bound the number of comparisons in Step 3 by $\frac{1}{2}\sum_{x\in R_{i-1}} |C_x|$, since each $x \in R_{i-1}$ is involved in at most $|C_x - \{x\}|$ comparisons. The following lemma provides a bound on the conditional expectation of $|C_x|$ given R_{i-1}.

LEMMA 2.1. *For any R_{i-1} and any $x \in R_{i-1}$, the expected size of C_x is at most $2p_{i-1}/p_i$.*

Proof. Consider first the set B^+ consisting of those elements of $B_x^{2^{2i-2}} \cap R_{i-1}$ greater than x. Then let z^+ be the smallest element of $B^+ \cap R_i$, and note that $B^+ \cap C_x$ consists of those elements of B^+ less than z^+. Each element of B^+ is in R_i with probability $p = p_i/p_{i-1}$. Hence (as this is a Bernoulli process), if B^+ were infinite, $|B^+ \cap C_x| + 1$ would have a geometric distribution with parameter p and thus expected value $1/p$. The finiteness of B^+ only reduces this value.

Now define B^- and z^- analogously (so that $E(|B^- \cap C_x|) < (1-p)/p$). As $C_x = (B^+ \cap C_x) \cup (B^- \cap C_x) \cup \{x\}$, it follows that $E(|C_x|) < 1 + 2(1-p)/p$. □

Thus the expected number of comparisons in Step 3, given *any* particular R_{i-1}, is bounded by $|R_{i-1}|p_{i-1}/p_i$. Therefore the expected number of comparisons for Step 3 is at most the expectation (ranging over R_{i-1}) of this bound, which is

$$p_{i-1}/p_i E(|R_{i-1}|) = np_{i-1}^2/p_i. \tag{2.2}$$

Definition of the parameters. A good choice of the $\{p_i\}$ is obtained by balancing the costs (2.1) and (2.2). This requires $2^{2i-1}\log(\Delta+1) = p_{i-1}/p_i$. Solving for p_i in terms of p_{i-1} and noting that $p_0 = 1$, this leads us to choose

$$p_i = \frac{1}{(\log(\Delta+1))^i 2^{i^2}}.$$

The value k is chosen such that $E(|R_k|) = O(1)$. For this it is sufficient that $k = \left\lceil \sqrt{\log n} \right\rceil$.

Total number of comparisons. Substituting this choice of p_i into bounds (2.1) and (2.2) and summing, it follows that the expected number of comparisons in going from R_i to R_{i-1} is at most

$$\frac{n}{(\log(\Delta+1))^{i-2}2^{i^2-4i+1}}.$$

Therefore the expected number of comparisons in going from R_k to R_1 is at most

$$\sum_{i=2}^{k} \frac{n}{(\log(\Delta+1))^{i-2}2^{i^2-4i+1}} \leq n \sum_{i \geq 2} 2^{-i^2+4i-1} < 13n.$$

(This bound is independent of Δ: this is possible because Δ determined the size of R_1.) Thus the overall number of comparisons is dominated by the transition from R_1 to R_0, and we have the following theorem.

THEOREM 2.2. *The limited-degree local sorting algorithm requires*

$$E(\textit{comparisons}) \leq 4n \log(\Delta+1) + 13n$$

on a graph with n vertices and maximum degree Δ.

As an example, if the degree of every vertex is polylogarithmic in n, then the procedure runs in $O(n \log\log n)$ comparisons.

2.2. A reduction for arbitrary graphs. In this subsection we show how to sort locally an arbitrary graph in $O(\log \mathcal{D}(G))$ comparisons. This is achieved through a reduction to the limited-degree case. In the reduction we transform G into a new graph H in which every edge of G is represented exactly once and each vertex of G is represented several times. H is constructed such that locally sorting each component of H with the limited-degree algorithm represents an efficient way of locally sorting G. Our reduction is deterministic and requires no comparisons.

Given a graph G, first discard all isolated vertices. Then let U_0 be the set of vertices of degree 1, and $G_0 = G - U_0$. We define U_i and G_i inductively for $i \geq 0$ by: U_i is the set of vertices of degree at most $a_i = 2^{2^i} - 1$ in G_{i-1}, and $G_i = G_{i-1} - U_i$. Halt when G_i is the null graph.

We now consider the graph whose vertex set is $U_i \cup N_{i-1}(U_i)$ (where $N_{i-1}(U_i)$ denotes the set of neighbors of U_i in G_{i-1}), and whose edges are the edges that are interior to U_i or that connect U_i to $N_{i-1}(U_i)$. In that graph, some vertices of $N_{i-1}(U_i)$, the "red" vertices, have degree at most a_i. Others have degree higher than a_i: we split each of these into several "green" vertices each retaining between $a_i/2$ and a_i of its originator's edges. (The coloring will be used in the analysis.) Let H_i be this new graph. An example is shown in Fig. 2.2.

We now apply the limited-degree local sorting algorithm (§2.1) to each H_i. This is equivalent to locally sorting G.

THEOREM 2.3. *Given any graph G, the local sorting algorithm uses an expected $O(\log \mathcal{D}(G))$ comparisons.*

Proof. Let $h_i = |H_i|$. The maximum degree of H_i is at most a_i. Thus we require an expected $O(\sum_i h_i \log(a_i+1))$ comparisons to sort H locally. We separate the contributions to $\eta = \sum_i h_i \log(a_i+1)$ into the contribution of the vertices in $\bigcup U_i$, the contribution of the red vertices, and that of the green vertices. (Note that $\log(a_i+1) = 2^i$.)

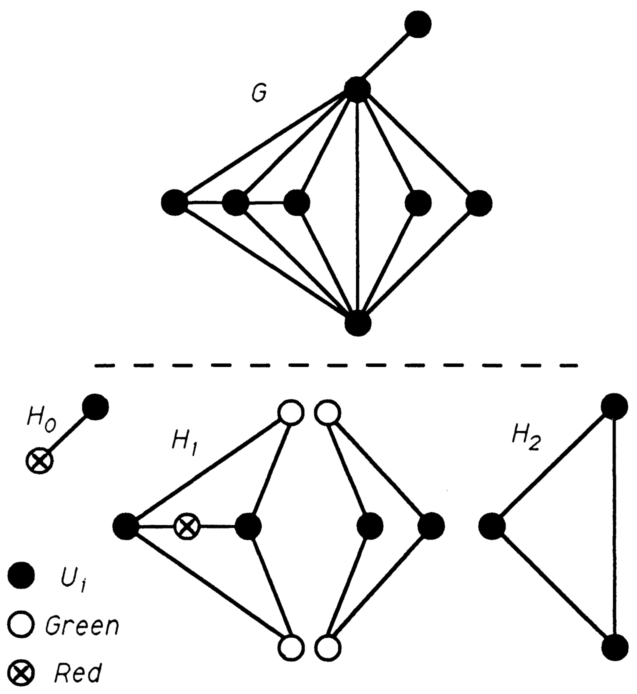


FIG. 2.2. *Example of the graph reduction.*

Every nonisolated vertex v of G shows up, perhaps lacking some of its original edges, in just one U_i. For each $j < i$, $N_{j-1}(U_j)$ may contain vertices corresponding to v: either several green vertices, or just one red vertex. Note that $i \leq \lceil \log\log(d_v + 1)\rceil$.

Consider a vertex v' in U_i, derived from v in G. As v was *not* chosen for U_{i-1}, its degree d_v must exceed a_{i-1}. Therefore $\log(d_v + 1) \geq \log(a_{i-1} + 1) = \frac{1}{2}\log(a_i + 1)$. Thus the contribution of $\bigcup U_i$ to η is at most $2\log\mathcal{D}(G)$.

A vertex v of G has at most one red vertex derived from it in each $N_{i-1}(U_i)$ for $j \leq \lceil \log\log(d_v + 1)\rceil - 1$. Hence its total red contribution is at most

$$\sum_{j=1}^{\lceil \log\log(d_v+1)\rceil - 1} 2^j \leq 2\log(d_v + 1).$$

Therefore the contribution of the red vertices is at most $2\log\mathcal{D}(G)$.

The green vertices of H_i are adjacent only to vertices of U_i. Further, green vertices of H_i are of degree at least $a_i/2$, whereas those of U_i are of degree at most a_i. Thus there are at most $2|U_i|$ green vertices, and their contribution is at most twice that from $\bigcup U_i$.

Combining all the above, it follows that $\eta \leq 8\log\mathcal{D}(G)$. □

Set-sort. Using the concavity of the log function, we can conclude from the above that if G has m edges, then our local sorting algorithm uses $O(n\log((2m + n)/n))$ comparisons. Applying this to the set-sort problem, we obtain the following corollary.

COROLLARY 2.4. *Let $S_1, S_2, \ldots, S_m$ be sets from a totally ordered universe of size n. Then these sets can be sorted using an expected $O(n\log(\sum_j |S_j|^2/n))$ comparisons.*

2.3. The acyclic orientations of a graph. In this subsection we provide an estimate of the number $\alpha(G)$ of acyclic orientations of a graph G, based solely on the degrees of the vertices of G. The upper bound is due to Manber and Tompa [7]. (The parameter α has also been studied, for instance, in [8].)

Define

$$\mathcal{F}(G) = \prod_{v \in G} f(d_v + 1),$$

where d_v is the degree of v in G, and $f(x) = (x!)^{1/x}$.

THEOREM 2.5. *For any graph G,*

$$\sqrt{\mathcal{D}(G)} \le \mathcal{F}(G) \le \alpha(G) \le \mathcal{D}(G).$$

In particular, $\log \mathcal{D}(G) = \Theta(\log \alpha(G))$.

Proof. The proof that $\alpha(G) \le \mathcal{D}(G)$ is in [7]. For positive integral x, $\sqrt{x+1} \le f(x+1)$, hence $\sqrt{\mathcal{D}(G)} \le \mathcal{F}(G)$. Now we show that $\mathcal{F}(G) \le \alpha(G)$.

The proof is by induction on the number of vertices of G. The case of a single vertex is trivial.

Let v be a vertex of minimum degree δ. If $\delta = 0$, then $\alpha(G) = \alpha(G - v)$ and $\mathcal{F}(G) = \mathcal{F}(G - v)$; so hereafter we assume that $\delta \ge 1$. We prove first that

$$\alpha(G) \ge (\delta + 1)\alpha(G - v). \tag{2.3}$$

Take any acyclic orientation $\mathcal{A}$ of $G - v$ and look at v's neighbors N in G. If N is totally ordered by $\mathcal{A}$, then there are $\delta + 1$ ways of extending $\mathcal{A}$ to an acyclic orientation of G (by choosing v's rank with respect to N); otherwise there are even more ways to extend $\mathcal{A}$.

The next thing to notice is that

$$\mathcal{F}(G) = \mathcal{F}(G - v) f(\delta + 1) \left(\prod_{v \in N} \frac{f(d_v + 1)}{f(d_v)} \right),$$

where $\{d_v\}$ indicate degrees in G (each greater than or equal to δ). It can be shown that $f(x + 1)/f(x)$ is monotone decreasing for positive integral x. Therefore

$$\mathcal{F}(G) \le \mathcal{F}(G - v) f(\delta + 1) \left(\frac{f(\delta + 1)}{f(\delta)} \right)^{\delta}.$$

Thus from inequality (2.3) above and the induction hypothesis, we find that

$$\alpha(G) \ge (\delta + 1)\mathcal{F}(G - v) \ge \mathcal{F}(G) \frac{(\delta + 1)(f(\delta))^{\delta}}{(f(\delta + 1))^{\delta + 1}} = \mathcal{F}(G). \qquad \square$$

The bounds on $\alpha(G)$ are the best possible of the form $\prod_v g(d_v)$. The lower bound is attained by any disjoint union of cliques. For the upper bound consider $G = K(a, b)$ with $b \gg a$: here $\alpha(G) \sim a!(a + 1)^b$. (We would like to thank Mark Haiman for discussions on this point.) The latter graphs also disprove the upper bound $\prod_v \max\{2, d_v\}$ claimed in [6].

Conclusion. The results of this section establish the following theorem.

THEOREM 2.6. *For any graph G, the local sorting algorithm uses an expected*

$$\Theta(\log \alpha(G)) = \Theta \left(\sum_{v \in G} \log(d_v + 1) \right)$$

comparisons and is optimal up to a constant factor.

3. Set-maxima. One can use the set-sort algorithm to solve set-maxima; this is fine when the sets are very small, but it is inefficient for large sets. The key idea in handling large sets is a *reduction* process: take a random sample, partially sort it, and then use this to reduce the sizes of the sets. Another useful idea is a generalization of set-maxima (called *t-maxima* in this paper), in which one must find and sort the t largest elements in each set.

In §3.1 we discuss our approach to set-maxima, and in §3.2 we provide the algorithm for t-maxima. In §3.3 we analyze the algorithm and show that for $t = O(1)$ it uses an expected $O(n \log(m/n) + n)$ comparisons, where m is the number of sets and n the size of the universe. This we show is optimal as a function of m and n.

3.1. The approach to set-maxima. In this subsection we outline the set-maxima algorithm. Assume we have sets $S_1, S_2, \dots, S_m$ in a universe X of size n. Our general strategy for set-maxima can be summarized in three stages.

1. Choose a random sample R, and determine for each set S_i a "representative" r_i which is the maximum sample point in that set.
2. Determine for each set S_i the reduced set S_i' formed by discarding those elements less than the representative.
3. Solve set-maxima on the reduced system.

Observe that the maximum element in the reduced set is the same as that in the original set.

Implementation of Stage 2 if *R* is sorted. We look here at an efficient implementation of Stage 2 when the sample R has been sorted. Define for each x the "dual" set

$$T_x = \{ r_j : x \in S_j \}.$$

To determine the reduced sets we need to determine the relationship between x and r_j for all j and $x \in S_j$. This is equivalent to finding for each x, the set $\{ r_j : r_j \in T_x \,\&\, r_j < x \}$.

We perform a "doubling" search, rather than a binary search, to find the interval of T_x in which x lies: One compares x with the elements of T_x of ranks $1, 2, 4, \dots, 2^l$ from the bottom, until an element greater than x (if it exists) is found, and then performs a binary search in the interval $[2^{l-1}, 2^l)$ to find where x lies.

A doubling search is more efficient than an ordinary binary search because the average x is likely to be smaller than most of the representatives, and thus near the bottom of T_x.

Example. Let m be $\Theta(n \log^c n)$. We solve set-maxima as follows. First we take a random sample R where each element of X is chosen independently with probability $1/\log n$. Then we sort R, achieving Stage 1. It can then be shown that the expected size of each reduced set is $O(\log n)$, and thus that the doubling searches of Stage 2 take a total of $O(n \log\log n)$ comparisons. (Proofs omitted.) We then use an expected $O(n \log\log n)$ comparisons to apply the set-sort algorithm to the reduced sets, determining their maxima. Thus the entire procedure requires an expected $O(n \log\log n) = O(n \log(m/n))$ comparisons.

Generalization. It appears that the $O(n \log\log n)$ comparisons of the example is the best one can do with a completely sorted sample. However, if m is small this quantity is $\omega(n \log(m/n))$, and so, in general, we cannot afford to sort the sample completely. We therefore must handle Stage 2 differently. We note that for most $x \in X$, the search of T_x ends after x has been compared with only the smallest elements of T_x. This motivates an extension of set-maxima.

DEFINITION. In the *t-maxima* problem, one is given a set system and a parameter t, and one must find and sort the t largest elements of each set. The *t-minima* problem is defined analogously.

It is this level of generality that proves robust in our recursion.

We implement Stage 2 as follows. We first invoke u-minima on the $\{T_x\}$ to find and sort the u smallest elements in each T_x. (The parameter u will be specified later.) We then attempt for each x the doubling search of T_x as before. But we are able to complete the doubling search only when x is smaller than the uth smallest element of T_x. We set aside the few "bad" x's for which the doubling searches fail, and handle them separately.

3.2. The set-maxima algorithm. In this subsection we present the full set-maxima algorithm. Given an element x and a set A containing x, we say that the rank (bottom-rank) of x in A is the number of elements not less than (not greater than) x.

We are given a universe $\mathcal{X}$ of n elements from some total order; and $S_1, S_2, \ldots, S_m$, subsets of $\mathcal{X}$. We will assume that $m \geq 2n$.

The algorithm **Large** is defined below, recursively for X, $S_1, S_2, \ldots, S_m$ subsets of the universe, and a parameter $t \geq 16$. **Large** solves t-maxima on the collection $\{X \cap S_j\}_{j \leq m}$. **Small** is defined analogously for t-minima.

We call the procedure **Large** $(16, \mathcal{X}, \{S_j\}_{j \leq m})$ to solve the set-maxima problem on $\mathcal{X}$ and $S_1, S_2, \ldots, S_m$.

```
Large(t, X, {S_j}_{j≤m}):
    If |X| ≤ 16 then sort X.
    Else
Step 1. Let R be the sample generated by choosing each x ∈ X independently with
    probability 1/t.
    Do Large(t, R, {S_j}). For 1 ≤ j ≤ m, let r_j be the element of rank t in R ∩ S_j, or
    −∞ if there is no such element.
```

The call to **Large**$(t, R, \{S_j\})$ finds the t largest sample elements in each set S_j. Then, rather than taking the representative to be the maximum sample element in each set, we choose the tth largest value. This is so that each reduced set contains at least t elements, if the original set started with that many.

The implementation of Stage 2 has three steps:

Step 2A. *For each* $x \in X$, *let* $T_x = \{r_j : S_j \ni x\}$. *Do* **Small**$(mt^3/n, R, \{T_x\}_{x \in X})$. This finds and sorts the mt^3/n smallest elements in each T_x.

Step 2B. *For each* $x \in X$, *compare* x *with the element* τ_x *of* T_x *of rank* mt^3/n *from the bottom. If* $x > \tau_x$, *then put* x *in* Y.

If $x \leq \tau_x$, *then do a doubling search on the sorted portion of* T_x : *compare* x *to the elements of* T_x *of bottom-ranks* $2^0, 2^1, \ldots$ *until you find* x *is less than some element of bottom-rank* $2^k \leq mt^3/n$. *Then perform a binary search in the interval between* 2^{k-1} *and* 2^k *until* x *is placed among the elements of* T_x.

If x is high up in T_x, specifically, greater than the element of bottom-rank mt^3/n, it is placed aside in Y. Otherwise a doubling search is performed. After this we know for each S_j the subset S_j^1 consisting of the $x \in S_j \cap (X - Y)$ which are at least as big as the representative r_j.

Step 2C. *Do* **Large**$(t, Y, \{S_j\})$.

This yields for each S_j the subset S_j^2 consisting of the t largest elements in $S_j \cap Y$ (if there are that many). By combining S_j^1 and S_j^2, we obtain for each S_j the reduced set S'_j, which contains its t largest elements (if S_j had that many originally).

Step 3. *Let* $S'_j = \{x \in S_j \cap (X - Y) : x \geq r_j\} \cup \{$*largest t elements of* $S_j \cap Y\}$.
Apply the set-sort algorithm (*cf. Corollary* 2.4) *to the sets* $\{S'_j\}_{j \leq m}$.

Step 3 sorts each reduced set, and yields the t largest elements in each $S_j \cap X$, as required.

3.3. Analysis. We analyze the expected number of comparisons performed during the procedure **Large**$(t, X, \{S_j\}_{j \leq m})$. All comparisons occur in Steps 2B and 3, and in the recursive calls.

Comparisons in Steps 2B and 3. For $1 \leq j \leq m$ let $\rho(r_j)$ denote the rank of r_j in $S_j \cap X$.

The number of comparisons needed for each element $x \in X$ in Step 2B is the cost of searching for the interval in which x lies and, if one is found, the cost of locating x within the interval. Thus, Step 2B requires at most

$$\sum_{x \in X} 2 \log (|\{ j : r_j \leq x,\ x \in S_j \cap X \}|)$$

comparisons. But $\sum_{x \in X} |\{ j : r_j \leq x,\ x \in S_j \cap X \}|$ is equal to $\sum_j |\{ x \in S_j \cap X : x \geq r_j \}|$, the sum of the ranks of the representatives. Hence, by the concavity of the log function, Step 2B requires at most

$$2n \log \left(\sum_j \rho(r_j)/n \right) \tag{3.1}$$

comparisons.

In Step 3, the m sets S'_j have size at most $t + \rho(r_j)$. Therefore the set-sort algorithm (cf. Corollary 2.4) takes at most

$$c_0 n \log \left(\sum_j (t + \rho(r_j))^2 / n \right) \tag{3.2}$$

comparisons, for c_0 a constant.

To compute the expectations of expressions (3.1) and (3.2), we determine the following upper bounds.

LEMMA 3.1. *$E(\rho(r_j)) \leq t^2$ and $E((t + \rho(r_j))^2) \leq 2t^4$.*

Proof. If $S_j \cap X$ were infinite, then $\rho(r_j)$ would be the rank of the tth sample element in that set. Elements are in the sample independently with probability $1/t$; so we would have a Bernoulli process, and $\rho(r_j)$ would be given by the sum of t independent geometric random variables with parameter $1/t$. For a geometric random variable Z with parameter p, $E(Z) = 1/p$ so that $E(\rho(r_j)) \leq t^2$. Further, $E(Z^2) = (2-p)/p^2$ and therefore a simple calculation shows that $E((t + \rho(r_j))^2) \leq 2t^4$. □

Because of the concavity of logarithms, we thus have that the expected sum of expressions (3.1) and (3.2) is at most

$$2n \log((mt^2)/n) + c_0 n \log((2mt^4)/n) \leq cn \log(mt/n),$$

with $c = 4 + 4c_0$, since $m \geq 2n$.

Full analysis. Let $f(t, n, m)$ denote the average cost of **Large**$(t, X, \{S_j\})$, including recursive calls, when X and $\{S_j\}$ are the worst possible inputs such that $|X| = n$ and the number of subsets is m. We will show by induction on n that for $m \geq 2n$ and $t \geq 16$

$$f(t, n, m) \leq 2cn \log(mt/n). \tag{3.3}$$

This is true for $n \leq 16$: then $t \geq n$, while the sort of X takes at most $dn \log(n)$ for d a small constant.

So assume that $n > 16$. Then, examining all stages of the algorithm, we see that $f(t, n, m)$ satisfies the following equation:

$$f(t,n,m) \leq cn \log(mt/n) + E(f(t,|R|,m)) + E(f(mt^3/n,|R|,n)) + E(f(t,|Y|,m)),$$

where the expectations are taken over the distribution of the sample R.

By induction and because $n \log 1/n$ is concave, we may write:

$$\begin{aligned} f(t,n,m) \leq cn \log(mt/n) &+ f(t, E(|R|), m) \\ &+ f(mt^3/n, E(|R|), n) + f(t, E(|Y|), m). \end{aligned}$$

LEMMA 3.2. *$E(|R|) = n/t$ and $E(|Y|) \leq n/t$.*

Proof. The first part of the lemma is obvious. To prove the second part, we note that $x \in Y$ if and only if x is greater than at least mt^3/n values r_j for which $S_j \ni x$. Thus $(mt^3/n)|Y| \leq |\{(x,j) : x \geq r_j, x \in S_j\}| = \sum_j \rho(r_j)$. Hence $E(|Y|) \leq mt^2/(mt^3/n) = n/t$. □

The equation bounding f can now be formulated as

$$f(t,n,m) \leq cn \log(mt/n) + 2f(t, n/t, m) + f(mt^3/n, n/t, n). \tag{3.4}$$

Observe that if $m \geq 2n$ and $f(t', n', m')$ is one of the terms on the right-hand side of (3.4), then $t' \geq t$ and $m' \geq 2n'$.

Thus, by our inductive hypothesis (3.3),

$$\begin{aligned} f(t,n,m) &\leq cn \log(mt/n) + 2(2c(n/t)\log(mt^2/n)) + 2c(n/t)\log(mt^4/n) \\ &\leq cn \log(mt/n)(1 + 8/t + 8/t) \\ &\leq 2cn \log(mt/n), \end{aligned}$$

since $t \geq 16$ and $m \geq 2n$.

THEOREM 3.3. *Let m sets be given from a totally ordered n-element universe, with $m \geq 2n$, and a parameter $t \geq 16$. Then the expected number of comparisons required by the t-maxima algorithm is $O(n \log(mt/n))$. In particular, for all m we solve set-maxima in*

$$\Theta(n \log(m/n) + n)$$

expected comparisons, which is optimal as a function of n and m.

We established the upper bound above. Here is the lower bound. (Note that for $m \geq n$, $\Theta(\log(mt/n)) = \Theta(\log(mt^2/n))$.)

THEOREM 3.4. *If mt^2 is $O(n^2)$, then there exist collections of m sets such that*

$$\Omega(n \log(mt^2/n) + n)$$

comparisons are required for t-maxima.

Proof. If one set contains all elements, then $n-1$ comparisons are necessary. On the other hand, one may partition the universe into blocks of size B and arrange $\Theta(nB/t^2)$ sets of size t such that t-maxima forces each block to be sorted. This requires $\Omega(n \log B)$ comparisons. □

4. Open questions. We list below some questions we have encountered.

(1) What about deterministic algorithms? No nontrivial deterministic algorithm for local sorting is known other than on dense graphs, where one might as well totally sort the elements. The same is true of set-maxima with the exception of the restricted set systems discussed in [5] and [1].

(2) Can the time complexity of the set-maxima and local sorting algorithms (currently polynomial) be brought into line with their comparison model complexity?

(3) We have shown that there exist collections of m sets for which the information-theoretic lower bound for set-maxima matches the complexity of our algorithm. However, some collections of m sets have fewer arrangements of maxima. Is there a set-maxima algorithm that does better on such collections? We do not know of a simple characterization of the number of possible arrangements of maxima for an arbitrary collection of sets.

(4) A fourth question is raised by our local sorting algorithm, which makes comparisons between distant elements of the graph in order to finally determine the local order relationships. Is this necessary? Specifically: Is there a local sorting algorithm that uses $\Theta(\log \alpha(G))$ comparisons but never compares elements over a distance greater than some constant *comparison horizon* h? Our algorithm, modified so that $E(|R_k|) = n/\log n$, needs $h(n) = \sqrt{\log\log n}$. The question is particularly intriguing because our algorithm actually makes rather few long-distance comparisons (e.g., only linearly many beyond distance 4).

We know only that $h = 1$ is not sufficient. This answers a question of Linial [6]. Consider a bipartite graph where all values in one color class are greater than those in the other: all edges must be checked in order to certify this.

(5) A combinatorial question is that of obtaining better upper and lower bounds on $\alpha(G)$.

Acknowledgments. The authors would like to thank Michael Sipser for many discussions and considerable advice. Further, they would like to thank Michelangelo Grigni, Mark Haiman, Russell Impagliazzo, and Mauricio Karchmer for helpful discussions.

A MONTE-CARLO ALGORITHM FOR ESTIMATING THE PERMANENT*

N. KARMARKAR[†], R. KARP[‡], R. LIPTON[§], L. LOVÁSZ[¶], AND M. LUBY[1]

Abstract. Let A be an $n \times n$ matrix with 0-1 valued entries, and let $\text{per}(A)$ be the permanent of A. This paper describes a Monte-Carlo algorithm that produces a "good in the relative sense" estimate of $\text{per}(A)$ and has running time $\text{poly}(n)2^{n/2}$, where $\text{poly}(n)$ denotes a function that grows polynomially with n.

Key words. permanent, matching, Monte-Carlo algorithm, algorithm, bipartite graph, determinant

1. Introduction. Let A be an $n \times n$ matrix with 0-1 valued entries, $\det(A)$ denote the determinant of A, and $\text{per}(A)$ denote the permanent of A. The marked contrast between the computational complexity of computing $\det(A)$ versus that of computing $\text{per}(A)$, despite the deceiving similarity between the two tasks, has baffled researchers for years. One of the reasons for interest in computing $\text{per}(A)$ is that A can be viewed as the adjacency matrix of a bipartite graph, $H = (X, Y, E)$, where X corresponds to the rows in A, Y to the columns in A, and $A_{ij} = 1$ if there is an edge between X_i and Y_j. The quantity $\text{per}(A)$ is exactly the number of perfect matchings in H.

It is well known that $\det(A)$ can be computed in $\text{poly}(n)$ time. On the other hand, the fastest algorithm known for computing $\text{per}(A)$ runs in $n2^n$ time [20]. Solid grounds for arguing that computing $\text{per}(A)$ is an inherently difficult problem were first provided in [21], which shows that the problem is $\#P$-complete. One implication of this result is that if $P \neq NP$, then there is no $\text{poly}(n)$ time algorithm for computing $\text{per}(A)$.

Because of the apparent nonexistence of a $\text{poly}(n)$ time algorithm for computing $\text{per}(A)$ exactly, we focus our attention on finding an algorithm that produces a good estimate of $\text{per}(A)$ and has a small running time. An (ϵ, δ) *approximation algorithm* for $\text{per}(A)$ is a Monte-Carlo algorithm that accepts as input A and two positive parameters ϵ and δ. The output of the algorithm is an estimate Y of $\text{per}(A)$, which satisfies

$$\Pr[(1-\epsilon)\text{per}(A) \leq Y \leq (1+\epsilon)\text{per}(A)] \geq 1 - \delta.$$

The papers [9], [15], [16] discuss (ϵ, δ) approximation algorithms for counting problems in greater detail. We develop an (ϵ, δ) approximation algorithm for $\text{per}(A)$, which runs in $2^{n/2}\frac{1}{\epsilon^2}\log(\frac{1}{\delta})\text{poly}(n)$ time. For fixed ϵ and δ, the running time of the approximation algorithm is essentially the square root of the running time for the fastest known algorithm that computes $\text{per}(A)$ exactly.

In [3], [10], [11] (ϵ, δ) approximation algorithms for $\text{per}(A)$ are given which run in $\text{poly}(n)$ time in the special case when each row and column in A contains at least $n/2$ $1's$. The report [13], which appeared during the final revision of this paper, gives an

(ϵ, δ) approximation algorithm for per(A), which runs in time $O(c^{\sqrt{n}\log^2(n)}\epsilon^{-2}\log(\frac{1}{\delta}))$. Whether or not there is an (ϵ, δ) approximation algorithm for per(A), which runs in poly(n) time for general A, is still an open problem.

2. Some general considerations regarding (ϵ, δ) approximation algorithms. Suppose we would like to estimate some quantity Q and have available a stochastic experiment whose output is a random variable X such that $\mathrm{E}[X] = Q$ and $\mathrm{E}[X^2]$ is finite. Suppose further that we can repeat this experiment as many times as we wish, and that the outcomes of the successive trials will be independent and identically distributed, with the same distribution as X. Let X_i be the outcome of the ith trial. A straightforward application of Chebyshev's inequality shows that, if we conduct N trials, where $N = (\mathrm{E}[X^2]/\mathrm{E}[X]^2)(1/\epsilon^2\delta)$ then $(\sum_{i=1}^{N} X_i/N)$ gives an (ϵ, δ) approximation to Q.

We can improve the dependence of the number of trials on δ using a well-known trick. Setting $\delta = \frac{1}{4}$, we find that, if $N = (4\mathrm{E}[X^2]/\mathrm{E}[X]^2)(1/\epsilon^2)$, the probability is at least $\frac{3}{4}$ that the average of the N trials will lie within ϵ of Q. To obtain an (ϵ, δ)-approximation algorithm, we repeat such an N-sample experiment K times, where K is an odd integer greater than a suitable constant c times $\log(1/\delta)$, and take as our estimator of Q the median of the estimators produced by the K experiments of N samples each. Let us say that the outcome of a N-sample experiment is *good* if it lies within ϵ of Q. Then the median of the K outcomes will be good whenever the majority of the K outcomes are good. Using the fact that the outcomes are independent and identically distributed, and that each outcome has probability at least $\frac{3}{4}$ of being good, standard bounds on the tail of the binomial distribution [5] reveal that the median is good with probability at least $1 - \delta$. Thus, the number of trials required for an (ϵ, δ) approximation to Q is

$$O\left(\frac{\mathrm{E}[X^2]}{\mathrm{E}[X]^2}\frac{1}{\epsilon^2}\log\left(\frac{1}{\delta}\right)\right).$$

3. The Godsil/Gutman estimator of per(A). The discussion of the last section shows how an (ϵ, δ)-algorithm for approximating a quantity Q can be constructed from any computable stochastic experiment whose outcome is a random variable Y such that $\mathrm{E}[Y] = Q$ and $\mathrm{E}[Y^2]$ is finite. The efficiency of the algorithm will be based on the computational difficulty of performing the stochastic experiment, and on the ratio $\mathrm{E}[Y^2]/\mathrm{E}[Y]^2$. The rest of the paper is devoted to studying two particular stochastic experiments for estimating per(A). The first of these, which we call the Godsil/Gutman estimator, was suggested in [8], but no analysis of the number of trials needed for an (ϵ, δ) approximation algorithm was provided; the second one is a variant of the Godsil/Gutman estimator, which has a smaller second moment and thus leads to a more efficient algorithm.

The Godsil/Gutman estimator is defined as follows:

```
(1) An $n \times n$ matrix $B$ is formed from $A$ as follows:
        For all $i, j$, $1 \le i, j \le n$,
        If $A_{ij} = 0$ then $B_{ij} \leftarrow 0$
        Elseif $A_{ij} = 1$ then randomly and independently choose $B_{i,j} \in \{-1, 1\}$,
            each choice with probability $\frac{1}{2}$.
(2) $Y \leftarrow (\det(B))^2$.
```

This stochastic experiment can be executed in poly(n) time.

In §4 we introduce some technical language that is appropriate for all of the following analysis. Section 5 concerns the Godsil/Gutman estimator; we show that $\mathrm{E}[Y] =$ per(A) and derive an upper bound on $\mathrm{E}[Y^2]$. Then, in §6, we present a refinement of the Godsil/Gutman estimator, show that it is unbiased, and derive an upper bound on its second moment.

4. Terminology. Let P be the set of all $n!$ permutations of $1, \ldots, n$. For all $\sigma \in P$, let $\operatorname{sgn}(\sigma) = -1^t$, where t is the number of transpositions to form σ.

Let $P(A) \subseteq P$ be the set of all permutations σ such that for $i = 1, \ldots, n$, $A_{i,\sigma(i)} = 1$. Then, $\operatorname{per}(A) = \sum_{\sigma \in P(A)} 1 = |P(A)|$. For each $\sigma \in P(A)$, for $i = 1, \ldots, n$, we label $\langle i, \sigma(i) \rangle$ with the symbol σ. Let $P^2(A) = P(A) \times P(A)$. For each $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle \in P^2(A)$, let $G(\dot{\sigma})$ be the unlabelled graph where there is an unlabelled node for each $\langle i, j \rangle$ which is labelled with either or both of σ_1, σ_2, and where there is an edge between two distinct nodes $\langle i, j \rangle$ and $\langle i', j' \rangle$ if and only if $i = i'$ or $j = j'$. Each connected component of $G(\dot{\sigma})$ is an isolated node or an even length cycle. For each cycle in $G(\dot{\sigma})$, designate one of the nodes in the cycle as the root of the cycle. Let $D = \{G(\dot{\sigma}) : \dot{\sigma} \in P^2(A)\}$. For each graph $G \in D$, let $c(G)$ be the number of cycles in G. For each $G \in D$, let

$$\dot{\mathrm{eq}}(G) = \{\dot{\sigma} \in P^2(A) : G(\dot{\sigma}) = G\}.$$

PROPOSITION 4.1. $|\dot{\mathrm{eq}}(G)| = 2^{c(G)}$.

Proof. Let $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle \in \dot{\mathrm{eq}}(G)$. Each isolated node in G is labelled with both σ_1 and σ_2. Let c be a cycle in G. If the label of the root in c is σ_1, then every node at an even distance from the root in c must be labelled σ_1 and every node at an odd distance from the root in c must be labelled σ_2. The case when the root is labelled σ_2 is symmetric, interchanging the roles of σ_1 and σ_2. Thus, for each cycle there are two possible labellings and the total number of labellings of all cycles is then $2^{c(G)}$. □

Let $D' = \{G \in D : c(G) = 0\}$.

PROPOSITION 4.2.

(1) $G(\langle \sigma_1, \sigma_2 \rangle) \in D' \Leftrightarrow \sigma_1 = \sigma_2$.

(2) $G(\langle \sigma_1, \sigma_1 \rangle) = G(\langle \sigma_2, \sigma_2 \rangle) \Leftrightarrow \sigma_1 = \sigma_2$.

(3) $|D'| = \operatorname{per}(A)$.

(4) *For all* $G \in D'$, $|\dot{\mathrm{eq}}(G)| = 1$.

5. Analysis of the Godsil/Gutman estimator.

THEOREM 5.1. $\mathrm{E}[Y] = \operatorname{per}(A)$.

Proof. For each $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle \in P^2(A)$, let

$$x(\dot{\sigma}) = \prod_{k=1}^{2} \left(\operatorname{sgn}(\sigma_k) \prod_{i=1}^{n} B_{i,\sigma_k(i)} \right).$$

Then, since $\det(B) = \sum_{\sigma \in P(A)} \operatorname{sgn}(\sigma) \prod_{i=1}^{n} B_{i,\sigma(i)}$,

$$Y = (\det(B))^2 = \sum_{\dot{\sigma} \in P^2(A)} x(\dot{\sigma}) = \sum_{G \in D} \sum_{\dot{\sigma} \in \dot{\mathrm{eq}}(G)} x(\dot{\sigma})$$

$$= \sum_{\dot{\sigma} = \langle \sigma_1, \sigma_1 \rangle \in P^2(A)} x(\dot{\sigma}) \qquad (1)$$

$$+ \sum_{G \in D - D'} \sum_{\dot{\sigma} \in \dot{\mathrm{eq}}(G)} x(\dot{\sigma}). \qquad (2)$$

For each $\dot{\sigma} = \langle \sigma_1, \sigma_1 \rangle \in P^2(A)$, $x(\dot{\sigma}) = 1$ independent of the values chosen for B. Thus, part (1) is equal to $\operatorname{per}(A)$ because the number of terms in the sum is $|P(A)| = \operatorname{per}(A)$. We show that the expected value of part (2) is equal to zero as follows. Fix $G \in D - D'$ and $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle \in \dot{\mathrm{eq}}(G)$. We show that $\mathrm{E}[x(\dot{\sigma})] = 0$, thus showing that the expected value of every term in part (2) is zero. Because $G \in D - D'$, G contains at least one cycle. Let $\langle i,j\rangle$ be some node in some cycle of G. Because either $\langle i,j\rangle$ is labelled with σ_1 and not with σ_2 or vice versa, $x(\dot\sigma)$ can be written as $y(\dot\sigma)B_{i,j}$, where $y(\dot\sigma)$ does not contain $B_{i,j}$. Because $B_{i,j}$ is independent of $y(\dot\sigma)$,

$$\mathrm{E}[x(\dot\sigma)] = \mathrm{E}[y(\dot\sigma)]\mathrm{E}[B_{i,j}].$$

Because $\mathrm{E}[B_{i,j}] = 0$, $\mathrm{E}[x(\dot\sigma)] = 0$. □

THEOREM 5.2.

$$\frac{\mathrm{E}[Y^2]}{\mathrm{E}[Y]^2} = \frac{\sum\limits_{G\in D} 6^{c(G)}}{\sum\limits_{G\in D} 2^{c(G)}}.$$

Proof.

$$\mathrm{E}[Y]^2 = (\mathrm{per}(A))^2 = \sum_{\langle\sigma_1,\sigma_2\rangle\in P^2(A)} 1 = \sum_{G\in D}\ \sum_{\langle\sigma_1,\sigma_2\rangle\in \dot{\mathrm{eq}}(G)} 1 = \sum_{G\in D} 2^{c(G)},$$

where the last equality is from Proposition 4.1. Let $P^4(A) = P(A) \times P(A) \times P(A) \times P(A)$. For each $\ddot\sigma = \langle\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle \in P^4(A)$, let

$$x(\ddot\sigma) = \prod_{k=1}^{4}\left(\mathrm{sgn}(\sigma_k)\prod_{i=1}^{n} B_{i,\sigma_k(i)}\right).$$

Then,

$$Y^2 = (\det(B))^4 = \sum_{\ddot\sigma\in P^4(A)} x(\ddot\sigma)$$

and

$$\mathrm{E}[Y^2] = \sum_{\ddot\sigma\in P^4(A)} \mathrm{E}[x(\ddot\sigma)].$$

Let ODD $= \{\ddot\sigma \in P^4(A)$: there is some $\langle i,j\rangle$ which is labelled with an odd number of labels from $\{\sigma_1,\sigma_2,\sigma_3,\sigma_4\}\}$, and let EVEN $= P^4(A) -$ ODD. For each $\ddot\sigma \in$ ODD, there is some $\langle i,j\rangle$ such that $x(\ddot\sigma)$ can be written as $y(\ddot\sigma)B_{i,j}$, where $y(\ddot\sigma)$ does not contain $B_{i,j}$. Thus, $\mathrm{E}[x(\ddot\sigma)] = \mathrm{E}[y(\ddot\sigma)]\mathrm{E}[B_{i,j}]$. Because $\mathrm{E}[B_{i,j}] = 0$, $\mathrm{E}[x(\ddot\sigma)] = 0$. For each $\ddot\sigma \in$ EVEN, for each row $i = 1,\dots,n$, either there is a j such that $\langle i,j\rangle$ is labelled with all four of $\{\sigma_1,\sigma_2,\sigma_3,\sigma_4\}$ or there is a j and a $j' \neq j$ such that $\langle i,j\rangle$ is labelled with exactly two of $\{\sigma_1,\sigma_2,\sigma_3,\sigma_4\}$, and $\langle i,j'\rangle$ is labelled with the other two. Let $G(\ddot\sigma)$ be the graph where there is a node for each $\langle i,j\rangle$ such that $\langle i,j\rangle$ is labelled with at least one of $\{\sigma_1,\sigma_2,\sigma_3,\sigma_4\}$. There is an edge between two distinct nodes $\langle i,j\rangle$ and $\langle i',j'\rangle$ if and only if $i = i'$ or $j = j'$. Then, $\{G(\ddot\sigma) : \ddot\sigma \in \text{EVEN}\} = D$, where D is as previously defined. For each $G \in D$, define

$$\ddot{\mathrm{eq}}(G) = \{\ddot\sigma \in \text{EVEN} : G(\ddot\sigma) = G\}.$$

We claim that $|\ddot{\mathrm{eq}}(G)| = 6^{c(G)}$. The reasoning is similar to that used for the proof of Proposition 4.1. Let $\ddot\sigma = \langle\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle \in \ddot{\mathrm{eq}}(G)$. Each isolated node in G is labelled with all four of $\{\sigma_1,\sigma_2,\sigma_3,\sigma_4\}$. For each cycle c in G, the root of c and every node at an even distance from the root must be labelled with the same two elements of $\{\sigma_1, \sigma_2, \sigma_3, \sigma_4\}$ and every node at an odd distance from the root must be labelled with the remaining two. Thus, there are $\binom{4}{2} = 6$ possible labellings of each cycle, and consequently a total of $6^{c(G)}$ labellings.

It is not hard to see that for each $\ddot{\sigma} \in$ EVEN, $x(\ddot{\sigma}) = 1$ independent of the values chosen for the entries in B. This fact rests on the following two observations:

• For any two permutations σ and τ, $\mathrm{sgn}(\sigma\tau) = \mathrm{sgn}(\sigma)\cdot \mathrm{sgn}(\tau)$ and $\mathrm{sgn}(\sigma^{-1}) = \mathrm{sgn}(\sigma)$. Hence $\prod_{k=1}^{4} \mathrm{sgn}(\sigma_k) = \mathrm{sgn}(\prod_{k=1}^{4} \sigma_k) = \prod_{k=2}^{4} \mathrm{sgn}(\sigma_1^{-1}\sigma_k)$. It follows from the definition of EVEN that, if each of the three permutations $\sigma_1^{-1}\sigma_k, k = 2, 3, 4$ is written in the usual cycle notation as a product of disjoint cycles, then the cycles occurring will correspond to the cycles of even length in $G(\ddot{\sigma})$, and each cycle will occur in exactly two of the three permutations $\sigma_1^{-1}\sigma_k$. Thus, if each of these cycles is expressed in a standard way as a product of transpositions, then each transposition will occur an even number of times. It follows that $\prod_{k=1}^{3} \mathrm{sgn}(\sigma_1^{-1}\sigma_k) = 1$, and hence $\prod_{k=1}^{4} \mathrm{sgn}(\sigma_k) = 1$;

• Each factor in the product$\prod_{k=1}^{4} \prod_{i=1}^{n} B_{i,\sigma_k(i)}$ occurs an even number of times, and thus the product is equal to 1.

Thus, $\mathrm{E}[Y^2] = \sum_{\ddot{\sigma}\in \mathrm{EVEN}} 1 = \sum_{G\in D} 6^{c(G)}$. Since $\mathrm{E}[Y]^2 = \sum_{G\in D} 2^{c(G)}$, the proof is complete. □

COROLLARY 5.3. *The Godsil/Gutman estimator yields an* (ϵ,δ)*- approximation algorithm for estimating* $\mathrm{per}(A)$ *which runs in time* $\mathrm{poly}(n)3^{n/2}\frac{1}{\epsilon^2}\log(\frac{1}{\delta})$.

Proof. Each evaluation of the estimator can be performed in time $\mathrm{poly}(n)$. Also,

$$\frac{\mathrm{E}[Y^2]}{\mathrm{E}[Y]^2} = \frac{\sum\limits_{G\in D} 6^{c(G)}}{\sum\limits_{G\in D} 2^{c(G)}} \leq \max_{G\in D} 3^{c(G)} \leq 3^{n/2},$$

where the previous inequality follows because there are at most $n/2$ cycles in any $G \in D$. □

6. A better estimator and its analysis.

We now present a variant of the Godsil/Gutman estimator which yields a more efficient (ϵ, δ)-approximation algorithm for $\mathrm{per}(A)$. Let

$$w_0 = 1, \quad w_1 = -\frac{1}{2} + \frac{\sqrt{3}}{2}i, \quad w_2 = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$$

be the three cube roots of unity. If $y = a + bi$ is a complex number, then $\overline{y} = a - bi$ is the complex conjugate of y.

The estimator is computed as follows.

```
(1) An $n \times n$ matrix $B$ is formed from $A$ as follows:
    For all $i, j,\ 1 \leq i, j \leq n$,
    If $A_{i,j} = 0$ then $B_{i,j} \leftarrow 0$
    Elseif $A_{i,j} = 1$ then randomly and independently choose
        $B_{i,j} \in \{w_0, w_1, w_2\}$, each choice with probability $\frac{1}{3}$.
(2) $Z \leftarrow \det(B)\overline{\det(B)}$.
```

This estimator can be evaluated in $\mathrm{poly}(n)$ time.

THEOREM 6.1.

$$\mathrm{E}[Z] = \mathrm{per}(A).$$

Proof. The proof is similar to the proof of Theorem 5.1. For each $\dot\sigma = \langle \sigma_1, \sigma_2 \rangle \in P^2(A)$, let

$$x(\dot\sigma) = \mathrm{sgn}(\sigma_1)\mathrm{sgn}(\sigma_2) \prod_{i=1}^{n} B_{i,\sigma_1(i)} \overline{B}_{i,\sigma_2(i)}.$$

Then,

$$\begin{aligned} Z &= \det(B)\overline{\det(B)} = \sum_{\dot\sigma \in P^2(A)} x(\dot\sigma) \\ &= \sum_{\dot\sigma = \langle \sigma_1, \sigma_1 \rangle \in P^2(A)} x(\dot\sigma) && (3) \\ &\quad + \sum_{G \in D - D'} \sum_{\dot\sigma \in \dot{\mathrm{eq}}(G)} x(\dot\sigma). && (4) \end{aligned}$$

For each $\dot\sigma = \langle \sigma_1, \sigma_1 \rangle \in P^2(A)$, $x(\dot\sigma) = 1$ independent of the values chosen for B. Thus, part (3) is equal to per(A). Showing that the expected value of part (4) is equal to zero is very similar to the corresponding portion of the proof in Theorem 5.1. The observation needed is again that for any $\langle i, j \rangle$, $\mathrm{E}[B_{i,j}] = 0$. □

THEOREM 6.2.

$$\frac{\mathrm{E}[Z^2]}{\mathrm{E}[Z]^2} = \frac{\sum_{G \in D} 4^{c(G)}}{\sum_{G \in D} 2^{c(G)}}.$$

Proof. The proof follows exactly the outline of the proof of Theorem 5.2. We only note the differences here.

For each $\ddot\sigma = \langle \sigma_1, \sigma_2, \sigma_3, \sigma_4 \rangle \in P^4(A)$, let

$$x(\ddot\sigma) = \left(\prod_{k=1}^{2} \mathrm{sgn}(\sigma_k) \prod_{i=1}^{n} B_{i,\sigma_k(i)} \right) \left(\prod_{k=3}^{4} \mathrm{sgn}(\sigma_k) \prod_{i=1}^{n} \overline{B}_{i,\sigma_k(i)} \right).$$

Then, $\mathrm{E}[Z^2] = \sum_{\ddot\sigma \in P^4(A)} \mathrm{E}[x(\ddot\sigma)]$. From the definitions in the proof of Theorem 5.2,

$$P^4(A) = \mathrm{ODD} \cup \mathrm{EVEN} = \mathrm{ODD} \cup \bigcup_{G \in D} \ddot{eq}(G).$$

For $\ddot\sigma \in$ ODD there is some $\langle i, j \rangle$ such that $x(\ddot\sigma)$ can be written as $y(\ddot\sigma)B_{i,j}$ or as $y(\ddot\sigma)\overline{B}_{i,j}$, where in either case $y(\dot\sigma)$ contains neither $B_{i,j}$ nor $\overline{B}_{i,j}$. Because $\mathrm{E}[B_{i,j}] = \mathrm{E}[\overline{B}_{i,j}] = 0$, $\mathrm{E}[x(\ddot\sigma)] = 0$. For each $G \in D$ we further partition $\ddot{\mathrm{eq}}(G)$ as follows:

$$\begin{aligned} \ddot{\mathrm{eq}}'(G) = \ & \{\ddot\sigma \in \ddot{\mathrm{eq}}(G) : \text{in each cycle } c \text{ in } G \text{ the root of } c \text{ is} \\ & \text{labelled with exactly one of } \{\sigma_1, \sigma_2\} \text{ and with exactly} \\ & \text{one of } \{\sigma_3, \sigma_4\}\}. \end{aligned}$$

Because there are four possible labellings for each cycle in G, $|\ddot{\text{eq}}'(G)| = 4^{c(G)}$. For each $\ddot{\sigma} \in \ddot{\text{eq}}'(G)$, for each node $\langle i,j\rangle$ in G there are an equal number of occurrences of $B_{i,j}$ and $\overline{B}_{i,j}$ in $x(\ddot{\sigma})$. Thus, $x(\ddot{\sigma}) = 1$ independent of the values chosen for B, and $\mathrm{E}[x(\ddot{\sigma})] = 1$. For each $\ddot{\sigma} \in \ddot{\text{eq}}(G) - \ddot{\text{eq}}'(G)$, there is some node $\langle i,j\rangle$ in G such that $B_{i,j}$ occurs twice in $x(\ddot{\sigma})$ and $\overline{B}_{i,j}$ does not occur at all. Thus, $x(\ddot{\sigma})$ can be written as $y(\ddot{\sigma})B_{i,j}^2$, where $y(\ddot{\sigma})$ contains no occurrences of $B_{i,j}$ or $\overline{B}_{i,j}$. Then, $\mathrm{E}[x(\ddot{\sigma})] = \mathrm{E}[y(\ddot{\sigma})]\mathrm{E}[B_{i,j}^2]$. Because $\mathrm{E}[B_{i,j}^2] = 0$, $\mathrm{E}[x(\ddot{\sigma})] = 0$.

Putting this together, $\mathrm{E}[Z^2] = \sum_{G\in D} 4^{c(G)}$, and thus

$$\frac{\mathrm{E}[Z^2]}{\mathrm{E}[Z]^2} = \frac{\sum_{G\in D} 4^{c(G)}}{\sum_{G\in D} 2^{c(G)}}. \qquad \square$$

COROLLARY 6.3. *The estimator Z yields an (ϵ,δ)-approximation algorithm for estimating* $\mathrm{per}(A)$ *which runs in time* $\mathrm{poly}(n)2^{n/2}\frac{1}{\epsilon^2}\log(\frac{1}{\delta})$.

Proof. Each evaluation of the estimator can be performed in time $\mathrm{poly}(n)$. Also,

$$\frac{\mathrm{E}[Z^2]}{\mathrm{E}[Z]^2} = \frac{\sum_{G\in D} 4^{c(G)}}{\sum_{G\in D} 2^{c(G)}} \le \max_{G\in D} 2^{c(G)} \le 2^{n/2},$$

where the previous inequality follows because there are at most $n/2$ cycles in any $G \in D$. $\square$

It is natural to consider a generalization of the above two algorithms, in which $B_{i,j}$ is set equal to zero when $A_{i,j} = 0$, and to a random kth root of unity whenever $A_{i,j} = 1$. The Godsil/Gutman estimator corresponds to the case $k = 2$, and the algorithm of the present section, to the case $k = 3$. Theorem 3 holds for all integers $k \ge 2$, and Theorem 4 holds for all integers $k \ge 3$. However, choosing k greater than 3 appears to give no reduction in the variance of the estimator.

7. Some special cases.

We have introduced two unbiased estimators of $\mathrm{per}(A)$: the Godsil/Gutman estimator Y and a second estimator Z which refines the Godsil/Gutman technique by using cube roots of unity. We showed that

$$\frac{\mathrm{E}[Y^2]}{\mathrm{E}[Y]^2} = \frac{\sum_{G\in D} 6^{c(G)}}{\sum_{G\in D} 2^{c(G)}}$$

and

$$\frac{\mathrm{E}[Z^2]}{\mathrm{E}[Z]^2} = \frac{\sum_{G\in D} 4^{c(G)}}{\sum_{G\in D} 2^{c(G)}}.$$

We then obtained an upper bound of $3^{n/2}$ on $\mathrm{E}[Y^2]/\mathrm{E}[Y]^2$ and an upper bound of $2^{n/2}$ on $\mathrm{E}[Z^2]/\mathrm{E}[Z]^2$ using the trivial observation that, for all G, $c(G) \le \frac{n}{2}$. Although this bound seems terribly pessimistic, the following example shows that there are cases in which it is close to the truth. Let n be even and let A be the $n \times n$ matrix such that for $i = 1, \dots, \frac{n}{2}$, $A_{2i-1,2i-1} = A_{2i-1,2i} = A_{2i,2i-1} = A_{2i,2i} = 1$ and all other entries in A are zero. For the first algorithm the expected number of trials before there is even one trial where $Y \neq 0$ is $\Omega(2^{n/2})$, and for the second algorithm it is $\Omega((\frac{3}{2})^{n/2})$. There is a lot of room between $3^{n/2}$ and $2^{n/2}$ and between $(\frac{3}{2})^{n/2}$ and $2^{n/2}$; we are not sure which bound is closer to the worst case behavior for the respective algorithms.

Despite this bad example, we suspect that in most situations, these bounds are far too pessimistic, since $c(G)$ will "typically" be much smaller than $n/2$. As one heuristic indication of this phenomenon we note that, if $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle$, where σ_1 and σ_2 are independent random permutations, then $c(G(\dot{\sigma}))$ will be close to $\ln(n)$ with very high probability.

In this section we analyze a concrete example in which the bounds of $3^{n/2}$ for the Godsil/Gutman algorithm and $2^{n/2}$ for its refinement are provably too pessimistic: the $n \times n$ matrix C in which every element is equal to 1. The permanent of this matrix is, of course, $n!$.

Let the random variable Y be the estimator produced by the Godsil/Gutman algorithm applied to the matrix C, and let Z be the estimator produced by the refinement given in §6 applied to the matrix C. Our main result is as follows.

THEOREM 7.1. *In the particular case of the $n \times n$ matrix C,*

$$\frac{\mathrm{E}[Y^2]}{\mathrm{E}[Y]^2} \leq \frac{(n+1)(n+2)}{2} \quad \textit{and} \quad \frac{\mathrm{E}[Z^2]}{\mathrm{E}[Z]^2} \leq n+1.$$

Proof. Since the two estimators are unbiased, $\mathrm{E}[Y] = \mathrm{E}[Z] = n!$. In order to discuss the second moments of Y and Z we require a definition: for any permutation σ of $\{1, 2, \dots, n\}$, let $d(\sigma)$ be the number of cycles of length greater than one in the permutation σ.

We know from Theorems 5.2 and 6.2 that $\mathrm{E}[Y^2] = \sum_G 6^{c(G)}$ and $\mathrm{E}[Z^2] = \sum_G 4^{c(G)}$. We note that, for any $\dot{\sigma} = \langle \sigma_1, \sigma_2 \rangle$, $c(G(\dot{\sigma})) = d(\sigma_1^{-1}\sigma_2)$. Combining this with the fact that $|\dot{\mathrm{eq}}(G)| = 2^{c(G)}$ we find that $\sum_{G \in D} 6^{c(G)} = \sum_{\langle \sigma_1, \sigma_2 \rangle \in P^2(A)} 3^{d(\sigma_1^{-1}\sigma_2)}$. In the case of the complete graph, $P(A)$ is equal to P, the set of all permutations of $\{1, 2, \dots, n\}$, and thus $\mathrm{E}[Y^2] = \sum_{\langle \sigma_1, \sigma_2 \rangle \in P^2} 3^{d(\sigma_1^{-1}\sigma_2)}$. Since each permutation σ can be written as $\sigma_1^{-1}\sigma_2$ in exactly $n!$ ways, the right-hand side reduces to $n! \sum_{\sigma \in P} 3^{d(\sigma)}$. Similarly, we obtain $\mathrm{E}[Z^2] = n! \sum_{\sigma \in P} 2^{d(\sigma)}$. But it follows from [17] (solution to Exercise 3.12, p. 203) that $\sum_{\sigma \in P} 3^{d(\sigma)} \leq \frac{(n+2)!}{2}$ and $\sum_{\sigma \in P} 2^{d(\sigma)} \leq (n+1)!$. Hence, $\mathrm{E}[Y^2]/\mathrm{E}[Y]^2 \leq (n+2)(n+1)/2$ and $\mathrm{E}[Z^2]/\mathrm{E}[Z]^2 \leq n+1$. $\square$

It follows that, in the special case of the matrix C, a quadratic number of trials of the Godsil/Gutman Monte-Carlo algorithm, or a linear number of trials of our refinement of the Godsil/Gutman algorithm, are sufficient for an (ϵ, δ)-approximation.

In a preliminary version of this paper we conjectured that similar claims hold true for almost all $n \times n$ zero-one matrices. This was established in [9], where it was shown that, for almost every 0, 1 matrix, $O(n\omega(n)\epsilon^{-2})$ independent trials, using the estimator of §6, suffice to obtain an $(\epsilon, \frac{1}{4})$ approximation to the permanent. Here $\omega(n)$ is any function tending to infinity as $n \to \infty$. It was previously known that [12], combined with [7] or [19], yields a polynomial-time (ϵ, δ) approximation algorithm for the permanent of a random zero-one matrix of arbitrary density. However, Jerrum's result, based on the algorithm of §6, gives a better running time than these methods.

8. Comments, generalizations, refinements. For both algorithms presented here, once the values of B have been chosen, the value of the estimator can be computed exactly in $\mathrm{poly}(n)$ time. In the second algorithm, this requires that $\sqrt{3}$ be represented symbolically. The symbol $\sqrt{3}$ will not appear in the final answer, which is an integer.

Both Monte-Carlo algorithms can easily be modified to estimate $\mathrm{per}(A)$ when the entries in A are allowed to be arbitrary positive numbers. However, in this case there is an issue with precision; the estimators cannot be computed exactly in $\mathrm{poly}(n)$ time, although they can be closely approximated. The modification for the Godsil/Gutman estimator is to randomly choose

$$B_{i,j} \in \left\{\sqrt{A_{i,j}}, -\sqrt{A_{i,j}}\right\},$$

each choice with probability $\frac{1}{2}$. The modification for the second estimator is to randomly choose

$$B_{i,j} \in \left\{\sqrt{A_{i,j}}w_0, \sqrt{A_{i,j}}w_1, \sqrt{A_{i,j}}w_2\right\},$$

each choice with probability $\frac{1}{3}$. In both cases, the expected value of the estimator is $\mathrm{per}(A)$ and the upper bounds on the number of trials to guarantee an (ϵ, δ) approximation algorithm stated in Corollaries 5.3 and 6.3 still apply, assuming that at each trial the estimator is computed exactly. The analysis would have to be modified to allow for truncation error.

Each of our Monte-Carlo algorithms consists of $O(\log(\frac{1}{\delta}))$ phases, with each phase consisting of some number N of independent trials. We required that each phase be an $(\epsilon, \frac{1}{4})$ approximation algorithm. Our analysis of the upper bound on the number of trials to guarantee this property was based on Chebyshev's inequality, and thus the analysis still holds if trials are pairwise independent. Consider running the first Monte-Carlo algorithm with a fixed ϵ and δ. As it is written it requires $\Theta(3^{\frac{n}{2}}n^2)$ random bits per phase in total, i.e., n^2 random bits per trial to randomly choose the values for B. This can be reduced to $O(n^3)$ random bits per phase using standard methods of generating pairwise independent unbiased random bits [1], [6], [18].

9. Open questions.

(1) Is there an (ϵ, δ) approximation algorithm for $\mathrm{per}(A)$ which runs in $\mathrm{poly}(n)$ time? One possible approach to solving this problem is based on the observation that the trials within a phase need only be pairwise independent, rather than completely independent. The result of each phase is $\sum_{i=1}^{\ell} Y_i/\ell$ where ℓ, the number of trials, is exponential in n. Pairwise independence permits the ℓ samples to be generated using only $O(n^3)$ random bits. Perhaps the rule for generating the samples from the random bits can be designed so that the quantity $\sum_{i=1}^{\ell} Y_i$ can be computed directly and efficiently from the random bits, without the need to calculate the result of each trial explicitly. Similar ideas have been used successfully in other contexts [1], [2], [6], [4], [14], [18].

(2) Is there a deterministic algorithm with running time $o(2^n)$, which accepts as input A and ϵ and which outputs Y such that

$$(1-\epsilon)\,\mathrm{per}(A) \leq Y \leq (1+\epsilon)\,\mathrm{per}(A)?$$

LIMITING NEGATIONS IN CONSTANT DEPTH CIRCUITS*

MIKLOS SANTHA† AND CHRISTOPHER WILSON‡

Abstract. It follows from a theorem of Markov that the minimum number of negation gates in a circuit sufficient to compute any Boolean function on n variables is $l = \lfloor \log n \rfloor + 1$. It can be shown that, for functions computed by families of polynomial size, $O(\log n)$ depth and bounded fan-in circuits (NC^1), the same result holds: on such circuits l negations are necessary and sufficient. In this paper it is proven that this situation changes when polynomial size circuit families of constant depth are considered: l negations are no longer sufficient. For threshold circuits it is proven that there are Boolean functions computable in constant depth (TC^0) such that no such threshold circuit containing $o(n^\epsilon)$, for all $\epsilon > 0$, negations can compute them. There is a matching upper bound: for any $\epsilon > 0$, everything computable by constant depth threshold circuits can be computed by constant depth threshold circuits using n^ϵ negations asymptotically. There are also tight bounds for constant depth, unbounded fan-in circuits (AC^0): $n/\log^r n$, for any r, negations are sufficient, and $\Omega(n/\log^r n)$, for some r, are necessary.

Key words. circuit complexity, monotone circuits, negation gates

AMS(MOS) subject classifications. 68Q15, 68Q10, 94C10

1. Introduction. Although extensively studied, not very much is known about the circuit complexity of Boolean functions. The results are especially few concerning lower bounds. While it is conjectured that NP-complete problems cannot be computed with circuits of less than exponential size, the best-known lower bounds are linear with small constants. In striking opposition to this situation, important progress has been made recently on monotone circuits. In his famous result Razborov [15] has proved a super-polynomial lower bound on the monotone circuit complexity of an appropriate clique function. Later this lower bound was strengthened to exponential size by Alon and Boppana [5]. In another development, Tardos [16] pointed out that there are even problems in P whose monotone circuit complexity is exponential, thus proving that negation may be exponentially powerful.

Of course, we would like to extend Razborov's lower bound result to the general model. As this seems to be at the moment quite elusive, a natural intermediate step is the study of circuits with a limited number of negations. If negations are also permitted in the circuit, then we should not restrict the study just to monotone functions. But if we consider also nonmonotone functions in our investigations, then before the study of lower bounds there is an even more basic question: can a given function be computed at all with a limited number of negations?

This question was answered by Markov [12] without any complexity theoretical considerations. He defined for any Boolean function $f : \{0,1\}^n \to \{0,1\}^m$, the *inversion* complexity $inv(f)$ of f as the minimum number of negation gates contained in a circuit which computes f. Let $f = (f_1, \dots, f_m)$, and let $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ be two Boolean vectors in $\{0,1\}^n$. By definition let $x \le y$ if $x_i \le y_i$ for $i = 1, \dots, n$. The ordered pair (x, y) is a *gap* for f if $x < y$ and for some j, $1 \le j \le m$, $f_j(x) > f_j(y)$. Let $x_1 < \cdots < x_r$ be an increasing sequences of Boolean vectors in $\{0,1\}^n$. The *decrease* of f on the sequence $x_1, \dots, x_r$ is the number of indices i such that (x_i, x_{i+1}) is a gap for f. Finally the *decrease* $dec(f)$ of f is the maximum decrease over all increasing sequence

of Boolean vectors. The result of Markov establishes a precise relationship between the inversion complexity of f and its decrease.

THEOREM 1.1 (MARKOV'S THEOREM) [12]. *For every Boolean function f we have*

$$inv(f) = \lfloor \log(dec(f)) \rfloor + 1.$$

Because the length of any increasing sequence of n-dimensional Boolean vectors is at most $n + 1$, by Markov's theorem $\lfloor \log n \rfloor + 1$ negations are sufficient to compute any Boolean function on n variables. On the other hand, it is easy to find a very simple function f for which there exists an increasing sequence of vectors with n gaps. Thus, for some functions $\lfloor \log n \rfloor + 1$ negations are also necessary.

In this paper we will study what remains true of this necessary and sufficient condition when restrictions are imposed on the size and depth of the circuits computing f. The restriction we will impose on the size of the circuits is polynomial size. Thus, the question we would like to answer is the following: Let $f : \{0,1\}^* \rightarrow \{0,1\}^*$ be a Boolean function that can be computed by a family of polynomial size circuits. Is it true that f can also be computed with a family of polynomial size circuits that contain at most $\lfloor \log n \rfloor + 1$ negations?

It turns out that the answer strongly depends on whether any restriction is put on the depth of the circuits. If f can be computed in polynomial size and depth $d(n)$, where $d(n) = \Omega(\log n)$, then the answer is *yes* (Theorem 2.3): f can be computed in the same order of depth with $\lfloor \log n \rfloor + 1$ negations, even if the underlying model has bounded fan-in. This result is implicitly contained in an early survey paper of Fischer [7], where he also considers circuits with limited negation.

Our results on the other hand show that the answer is *no* for constant depth circuits. In the case of threshold circuits we show that there exists a function computable in constant depth which cannot be computed in constant depth on threshold circuits using $o(n^\epsilon)$, for all $\epsilon > 0$, negations (Corollary 3.3). We also establish a matching upper bound on the number of negations sufficient for constant depth (Theorem 3.7): For any $\epsilon > 0$, every function which can be computed in constant depth on a family of threshold circuits can be computed in constant depth by threshold circuits with n^ϵ negations asymptotically. The method will give us a sublinear bound on the number of negations needed for AC^0 circuits (Theorem 4.1): For any r, every Boolean function computable in constant depth can also be computed in constant depth with at most $n/\log^r n$ negations. This is the best bound we can obtain (Corollary 4.4): There is a (multi-output) function computable in constant depth that cannot be computed in constant depth with $o(n/\log^r n)$, for all $r > 0$, negotiations.

The tight lower bounds of Corollary 3.3 and Corollary 4.4 are obtained from trade-off results between depth and number of negations in constant depth. Theorem 3.2 says that depth d threshold circuits for NEG (see the definition in §2) require $d(n+1)^{1/d} - d$ negations, and Theorem 4.3 claims that any circuit family computing NEG in depth d has $\Omega(n/\log^{d+3} n)$ negations. We can also prove that depth d threshold circuits for *PARITY* have $d(\lceil n/2 \rceil)^{1/d} - d$ negations. However, we are not able to obtain a tight lower bound on the number of negotiations required by a constant depth *AND/OR* circuit for a *single valued* function (*NEG* has n outputs). See §5 for more comments on this problem.

Let us mention at this point a result of Okolnishnikova [13] and Ajtai and Gurevich [2] related to our Theorem 3.2: There exists a monotone function that can be computed with polynomial size, constant depth circuits, but can not be computed with monotone, polynomial size, constant depth circuits.

A trade-off result between depth and randomness was obtained for the st-connectivity problem by Raz and Wigderson [14]. They have shown that in every polynomial size,

$O(\log n)$ depth circuit family, in which all the negations are placed on the input variables, at least a constant fraction of them should be negated.

The paper is organized as follows. After some preliminaries, §2 contains a short outline of the proof of the already known result about circuits with $\Omega(\log n)$ depth. Section 3 deals with upper and lower bounds for constant depth threshold circuits. Section 4 derives upper and lower bounds for unbounded fan-in *AND/OR* circuits. Finally, in §5 we conclude and mention some open problems.

2. Preliminaries. We will use standard notions from circuit complexity theory, for which the reader is referred, e.g., to Wegener's book [18]. We will also use some conventions throughout the paper. When it is not otherwise specified, we will deal with circuits on n variables. Let x denote the Boolean vector $(x_1, \dots, x_n)$, and $x - x_i$ the vector $(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$. We often identify the vector x with the word $x_1 \cdots x_n$. For $w \in \{0,1\}^*$, the *weight* of w is the number of ones in w, denoted by $|w|$. If f is a one-output Boolean function, then $\bar{f}$ is the negation of f.

Throughout the paper there may be nonintegral indices which should, in fact, be rounded to an appropriate integer. This has not been done for the sake of legibility and is in any case straightforward.

Two circuits are *equivalent* if they compute the same function. A circuit is *monotone* if it does not contain any negation gates. Ignoring uniformity considerations, for $i \geq 0$, the classes NC^i and AC^i are defined to be the set of functions computable by polynomial size, $O(\log^i n)$ depth circuit families with bounded and unbounded fan-in, respectively.

Another important class of circuits we examine is that of threshold circuits. By definition, for $k = 0, \dots, n$, the kth *threshold* function $T_k(x) = 1$ if and only if $|x| \geq k$. The class TC^i is defined to be the class of functions computed by a family of polynomial size, $O(\log^i n)$ depth circuits consisting of negations and gates that compute threshold functions. It is known that $NC^i \subseteq AC^i \subseteq TC^i \subseteq NC^{i+1}$. An especially interesting problem recently has been that of separating these classes when $i = 0$. It is known that $AC^0 \subset TC^0$ [9], but whether the containment $TC^0 \subseteq NC^1$ is proper is still an open problem. In [8] it is shown that depth 2 threshold circuits are weaker than depth 3 threshold circuits. In [20] it is shown that depth k monotone threshold circuits are weaker than depth $k+1$ monotone threshold circuits for any k.

The *sorting* function $S(x)$ and the *exact* function $E(x)$ are closely related to threshold functions. By definition $S(x) = (T_1(x), \dots, T_n(x))$, and $E(x) = (E_0(x), \dots, E_n(x))$, where $E_k(x) = 1$ if and only if $|x| = k$. Indeed, $S(x)$ is the simultaneous computation of all the nontrivial threshold functions, $E_n(x) = T_n(x)$, and $E_k(x) = T_k(x) \wedge \bar{T}_{k+1}(x)$ for $0 \leq k \leq n-1$. These functions will be extensively used as well as the function NEG, defined by $NEG(x_1, \dots, x_n) = (\bar{x}_1, \dots, \bar{x}_n)$.

Let $\mathcal{C}$ be the class of functions computed by a class of families of polynomial size circuits, and let $g(n)$ be a function from the natural numbers to the natural numbers. Then $\mathcal{C}_{g(n)}$ is the set of functions that can be computed by a circuit family in the class that contains at most $g(n)$ negation gates. The class $\mathcal{C}_0$ will be denoted *mon-$\mathcal{C}$*; this is the set of functions computable by a monotone circuit family in the class. By the *type* of a circuit we mean bounded fan-in, unbounded fan-in, or threshold. The following facts are well known.

FACT 2.1 (Valiant [17], Ajtai, Komlós, and Szemerédi [3]). *The sorting function $S(x)$ is in mon-NC^1.*

FACT 2.2 (Ajtai and Ben-Or [1], Wegener, Wurm, and Yi [19]). *For every $t \geq 0$, the threshold function $T_{\log^t n}(x)$ is in mon-AC^0.*

The importance of the function NEG lies in the fact that it incorporates all the "non-monotone" information we need to compute any function by a circuit. This is expressed in the following completeness lemma.

LEMMA 2.1 (Completeness Lemma). *Let C be a class of functions computed by families of polynomial size circuits of the types described above, such that the allowable depth of the circuit families is closed under multiplication by a constant. Let $g(n)$ be a function on the natural numbers. Then we have*

$$C_{g(n)} = C \quad \textit{if and only if } NEG \in C_{g(n)}.$$

Proof. The implication is straightforward from left to right. The other direction is implied by the following well-known result (see, e.g., Wegener [18]): For every circuit C of size s and depth d, there exists a monotone circuit C' of the same type, of size at most $2s$ and depth d which is equivalent to C, when the output of $NEG(x)$ is also given as input to C'. □

The function NEG can easily be computed by a monotone AC^0 circuit from the outputs of the sorting function and the exact functions. This is stated in the following lemma, which shares some ideas with the theory of slice functions (again, see [18]).

LEMMA 2.2. *For $1 \leq i \leq n$, we have*

$$\bar{x}_i = \bigvee_{k=0}^{n} (T_k(x - x_i) \ \wedge \ E_k(x)).$$

Proof. First we claim that for any $1 \leq i \leq n$, $\bar{x}_i = T_{|x|}(x - x_i)$. If $\bar{x}_i = 1$, then the number of ones in $x - x_i$ is $|x|$ and $T_{|x|}(x - x_i) = 1$. On the other hand, if $\bar{x}_i = 0$, then the number of ones in $x - x_i$ is $|x| - 1$ and $T_{|x|}(x - x_i) = 0$. The result follows since $E_k(x) = 1$ if and only if $k = |x|$. □

Fischer [7] constructed a circuit that contains only $\lfloor \log n \rfloor + 1$ negations, and computes the exact function, when the inputs are already sorted. The size of the circuit is polynomial, and its depth is $O(\log n)$. This enabled him to compute the exact functions by a polynomial size circuit family containing $\lfloor \log n \rfloor + 1$ negations. The depth of his circuit family depended on the circuit depth of the sorting function, which was at that time still an open problem. Today, it is known (Fact 2.1) that threshold functions can in fact be computed in *mon-*NC^1. This means that Fischer's result implicitly implies the following theorem.

THEOREM 2.3. *For every circuit family of polynomial size and depth $d(n)$, there exists an equivalent circuit family of the same type, also of polynomial size and depth $d(n) + O(\log n)$, which contains only $\lfloor \log n \rfloor + 1$ negations.*

COROLLARY 2.4. *For all $k \geq 1$, we have*

(i) $NC^k_{\lfloor \log n \rfloor + 1} = NC^k$,

(ii) $AC^k_{\lfloor \log n \rfloor + 1} = AC^k$,

(iii) $TC^k_{\lfloor \log n \rfloor + 1} = TC^k$.

This method of computing NEG in $NC^1_{\lfloor \log n \rfloor + 1}$ can be viewed as a constructive (and efficient) implementation of Markov's result. This, to some extent, was foreshadowed by Akers [4]. An analysis of his method reveals that NEG can be computed using few negotiations in $O(\log n)$ depth using threshold circuits; that is, $TC^1_{\lfloor \log n \rfloor + 1}$.

3. Bounds for threshold circuits.

3.1. Lower bounds. Here we shall prove that it is impossible to compute *NEG* on a depth d threshold circuit that uses fewer than $d(n+1)^{1/d} - d$ negotiations. In the proof of this lower bound we will concentrate on inputs that are integers in unary notation. These inputs are sequences of n bits with the ones preceding the zeros. When we say that j is the input value, we mean that $1^j 0^{n-j}$ is the input string.

With each gate g in a circuit we associate a satisfying set $I_g \subseteq \{0, \dots, n\}$ such that gate g outputs 1 if and only if input $j \in I_g$. For example, the satisfying set of x_i is $[i, n]$, that of $\bar{x}_5 \vee x_{10}$ is $[0, 5) \cup [10, n]$, and that of $x_5 \wedge \bar{x}_{10}$ is $[5, 10)$.

Let $I \subseteq \{0, \dots, n\}$. We define j as a *right boundary* of I if $j \in I$ and $j + 1 \notin I$. The value j is a right boundary of a gate of a circuit if it is a right boundary of the satisfying set of the gate, and j is a right boundary of a circuit if it is the right boundary of some of its gates. For example, the unique right boundary of $\bar{x}_i$ is $i - 1$. In what follows, it is important to count the number of right boundaries of a circuit since these are the inputs where it behaves nonmonotonically. First we will note that the only way to create new right boundaries is by the use of negotiations.

LEMMA 3.1. *Let C be a circuit of any type whose gates are either negations or monotone functions. Suppose that gate g is a monotone function of its input gates. Then any right boundary of g is a right boundary of at least one of its input gates.*

Proof. Let us suppose that $g = f(g_1, \dots, g_r)$, where f is a monotone function and $g_1, \dots, g_r$ are the input gates to g. We claim that if j is not a right boundary of g_i, for $1 \le i \le r$, then j is not a right boundary for g either. This is true since $g_i(j) \le g_i(j+1)$, for $1 \le i \le r$, implies $g(j) \le g(j+1)$ by the monotonicity of f. □

THEOREM 3.2. *Let C be a circuit computing NEG on inputs of size n. Suppose that C has depth d, uses ν negations, and has gates that are either negations or arbitrary monotone functions. Then $\nu \ge d(n+1)^{1/d} - d$.*

Proof. For $0 \le i \le d$, let level i of the circuit consist of all gates whose longest path to an input is of length i. Level 0 consists of inputs and constants, and thus only presents the single right boundary n. The circuit must eventually create n other right boundaries. Our bound will follow by showing that added depth can create only few right boundaries if insufficient negotiations are available.

Observe what happens when a node is negated. If gate g has k right boundaries and satisfying set $[i_1, i_2) \cup [i_3, i_4) \cup \cdots \cup [i_{2k-1}, i_{2k})$, then $\bar{g}$ has satisfying set $[0, i_1) \cup [i_2, i_3) \cup \cdots \cup [i_{2k}, n]$. This creates up to k new right boundaries. By the previous lemma, no other type of gate can create new right boundaries. Thus, if up to some level the gates present altogether t right boundaries and at the next level μ gates are negated, this next level creates at most $t\mu$ new right boundaries. This gives a total of $t(1+\mu)$ possible right boundaries up to the next level.

For $i = 1, \dots d$ let ν_i be the number of negations at level i, where $\sum_{i=1}^{d} \nu_i = \nu$. By the above, the circuit can create at most $\prod_{i=1}^{d}(1 + \nu_i)$ right boundaries. This product is maximized when $\nu_i = \nu/d$. Since we must have $(1 + \nu/d)^d \ge n + 1$, it follows that $\nu \ge d(n+1)^{1/d} - d$. □

Similarly we can prove that if C is a circuit computing *PARITY* that satisfies the conditions of Theorem 3.2, then $\nu \ge d(\lceil n/2 \rceil)^{1/d} - d$. As threshold gates are monotone, the following corollary is immediate.

COROLLARY 3.3. *Let $g(n) = o(n^\epsilon)$ for all $\epsilon > 0$. Then*

1. $NEG,\ PARITY \notin TC^0_{g(n)}$;
2. $TC^0 \neq TC^0_{g(n)}$.

Notice that these results did not put any restrictions on the size of the circuit. Even exponentially many monotone gates are of little use without enough negations. We can state something strong about depth as well. For example, no family of threshold circuits of depth $(\log n)^{1-\epsilon}$, $\epsilon > 0$, with $2^{\log^\epsilon n}$ negations can compute *NEG* or *PARITY*. Furthermore, Corollary 3.3 immediately implies that $NC^1_{\text{poly-log}}$ properly contains $TC^0_{\text{poly-log}}$.

COROLLARY 3.4. *Let $g(n) \geq \log n$ and for all $\epsilon > 0, g(n) = o(n^\epsilon)$. Then $TC^0_{g(n)} \neq NC^1_{g(n)}$.*

It is interesting to compare Corollary 3.4 to the result in [20] showing that *mon-TC^0* is properly contained in *mon-NC^1*. Corollary 3.4 can also be generalized to show a separation of NC^1 and TC^0 restricted to, say, $\log\log n$ negations. This generalization does not subsume the result in [20].

THEOREM 3.5. *Let $0 < f(n) \leq \lfloor \log n \rfloor + 1$. If for all $\epsilon > 0$, $g(n) = o(2^{\epsilon f(n)})$, then*

$$NC^1_{f(n)} - TC^0_{g(n)} \neq \emptyset.$$

Proof. Let $k = n/2^{f(n)-1}$ and consider the function

$$e(x) = (x_0 \wedge \bar{x}_k) \vee (x_{2k} \wedge \bar{x}_{3k}) \vee \cdots \vee (x_{n-k} \wedge \bar{x}_n)$$

(x_0 by default is 1). This can be viewed as a function on $\frac{n}{k} = 2^{f(n)-1}$ inputs, so by Theorem 2.3 is in $NC^1_{f(n)}$. Following the proof of Theorem 3.2, $e(x)$ has $\frac{n}{2k}$ right boundaries. Thus, any depth d threshold circuit with ν negations computing $e(x)$ must have $(1 + \nu/d)^d \geq \frac{n}{2k} = 2^{f(n)-2}$ or $\nu \geq d2^{(f(n)-2)/d} - d$. This is not possible under the assumption on $\nu = g(n)$ in the statement of the theorem. □

3.2. Upper bounds. We have seen that not everything computable in TC^0 can be computed using $o(n^\epsilon)$, for all $\epsilon > 0$, negations. The question arises naturally: how many negations are sufficient to give full power to TC^0? We can show that the lower bounds derived above for threshold circuits are essentially optimal.

Our main tool will be the computation of the exact function in constant depth on a threshold circuit. Since this is just two levels away from *NEG*, it is evident that we cannot compute it in depth $d-2$ using less than $d(n+1)^{1/d} - d$ negations. We will show how to compute it in depth $3d + O(1)$ using no more $dn^{1/d} - d + 1$ negations. Hence, the upper and lower bounds are nearly tight.

LEMMA 3.6. *Let $d \geq 1$ be an integer. There exists a depth $3d+O(1)$ and size $O(n^{1+(1/d)})$ family of threshold circuits with $dn^{1/d} - d + 1$ negations computing the exact function E.*

Proof. Set $x_0 = 1$ for the sake of convenience. We will assume that the input has been sorted as $x_1 \geq x_2 \geq \cdots \geq x_n$. This can be done in depth 1 on a threshold circuit, and this is the only place that we need threshold gates. The rest of the circuit will consist of negotiations and unbounded fan-in *AND*/*OR* gates.

The circuit we describe will have d layers, each layer will consist of several levels. Let us define the functions F_i^k for $0 \leq k \leq d$ and $0 \leq i < n^{k/d}$:

$$F_i^k = 1 \Leftrightarrow in^{(d-k)/d} \leq |x| < (i+1)n^{(d-k)/d}.$$

The construction we describe is iterative. One layer of the circuit will use $n^{1/d} - 1$ negations in transforming the $\{F_i^k\}_{i=0}^{n^{k/d}-1}$ into the $\{F_i^{k+1}\}_{i=0}^{n^{(k+1)/d}-1}$. Clearly, the F_i^d are the desired outputs E_i, so long as we add $E_n = x_n$. The base case is simple as there is only one possible i: $i = 0$. We let $F_0^0 = \bar{x}_n$.

Given the F_i^k for $0 \leq i < n^{k/d}$, the following describes how to construct the F_i^{k+1} for $0 \leq i < n^{(k+1)/d}$ in constant depth.

(k,1) For $0 \leq i < n^{k/d}$ and $0 \leq j < n^{1/d}$ compute

$$G^k_{i,j} = F^k_i \wedge x_{in^{(d-k)/d}+jn^{(d-k-1)/d}}.$$

(k,2) For $0 \leq j < n^{1/d}$ compute $H^k_j = \bigvee_{i=0}^{n^{k/d}-1} G^k_{i,j}$.
(k,3) For $1 \leq j < n^{1/d}$ compute $\bar{H}^k_j$.
(k,4) For $0 \leq j \leq n^{1/d} - 2$ compute $I^k_j = H^k_j \wedge \bar{H}^k_{j+1}$. Let $I^k_{n^{1/d}-1} = H^k_{n^{1/d}-1}$.
(k,5) For $0 \leq i < n^{k/d}$ and $0 \leq j < n^{1/d}$ compute $F^{k+1}_{in^{1/d}+j} = I^k_j \wedge G^k_{i,0}$.
We can describe when the functions above are satisfied.
(1) $G^k_{i,j} = 1$ if and only if $in^{(d-k)/d} + jn^{(d-k-1)/d} \leq |x| < (i+1)n^{(d-k)/d}$.
(2) $H^k_j = 1$ if and only if there exists i $(1 \leq i < n^{k/d})$ $in^{(d-k)/d} + jn^{(d-k-1)/d} \leq |x| < (i+1)n^{(d-k)/d}$.
(3) $\bar{H}^k_j = 1$ if and only if there exists i $(1 \leq i < n^{k/d})$ $in^{(d-k)/d} \leq |x| < in^{(d-k)/d} + jn^{(d-k-1)/d}$.
(4) $I^k_j = 1$ if and only if there exists i $(1 \leq i < n^{k/d})$ $in^{(d-k)/d} + jn^{(d-k-1)/d} \leq |x| < in^{(d-k)/d} + (j+1)n^{(d-k-1)/d}$.
(5) $F^{k+1}_{in^{1/d}+j} = 1$ if and only if $(in^{1/d} + j)n^{(d-k-1)/d} \leq |x| < (in^{1/d} + j + 1)n^{(d-k-1)/d}$, as desired.

The steps (k,4), (k,5), and ($k+1$,1) are all computed by $\wedge$ gates, so they can be combined into one level. This yields a circuit for the $E_i = F^d_i$ of depth $3d + O(1)$. The number of negations needed is $1 + d(n^{1/d} - 1)$. The size bound follows from observing that steps (k,1) and (k,5) use $n^{k/d}n^{1/d} = n^{(k+1)/d}$ gates. The sum $\sum_{k=1}^d n^{(k+1)/d}$ is clearly $O(n^{(d+1)/d})$. □

THEOREM 3.7. *For every $\epsilon > 0$, we have asymptotically*

$$TC^0_{n^\epsilon} = TC^0.$$

Proof. Choose d so that $1/d < \epsilon$. For this d we have that $dn^{1/d} \leq n^\epsilon$ asymptotically. From Lemma 3.6 we can compute E in constant depth using asymptotically less than n^ϵ negotiations. From Lemma 2.2, we see that $\bar{x}_i = \bigvee_{k=0}^n (T_k(x - x_i) \wedge E_k(x))$. The Completeness Lemma then implies the result. □

4. Constant depth AND/OR circuits. In this section we show that AC^0 remains invariant under a restriction to some sublinear number of negations: $n/\log^r n$ negations, for any r, are sufficient. Furthermore, this bound is tight.

The upper bound follows from the construction used in the previous section.

THEOREM 4.1. *Let $r \geq 0$ and $g(n) = n/\log^r n$. Then we have*

$$AC^0_{g(n)} = AC^0.$$

Proof. We will break the input up into n/N groups, each of size $N = 4\log^{2r} n$. According to Fact 2.2, T_N is in *mon-AC^0*. Thus we can sort any group $y_1, \ldots, y_N$ in monotone constant depth and polynomial (in n) size.

As we have seen in the proof of Lemma 3.6, we can compute E from $y_1 \geq \cdots \geq y_N$ in constant depth using *AND/OR* gates and $2\sqrt{N}$ negations. The thresholds can be applied again to find $\bar{y}_i = \bigvee_{k=0}^N (T_k(y - y_i) \wedge E_k(y))$, as per Lemma 2.2. The total number of negations used will be $2\sqrt{N}(n/N) = n/\log^r n$. The result then follows from the Completeness Lemma. □

DEFINITION. The *sensitivity on* a string w of the single valued function f, $s(f, w)$, is the number of neighbors w' of w differing in exactly one bit such that $f(w) \neq f(w')$. The *sensitivity* of f, $s(f)$, is the average over $w \in \{0,1\}^n$ of $s(f, w)$.

There have been several papers in recently relating the sensitivity of a Boolean function to its Fourier transform [10], [11]. To show a matching lower bound to Theorem 4.1, we make use of the following application of these results to AC^0 functions.

LEMMA 4.2 [11]. *If f is computed by a circuit family of depth d, then* $s(f) = 0(\log^{d+3} n)$.

THEOREM 4.3. *Let $\{C_n\}$ be a depth d circuit family which computes $NEG(x)$ with $\nu(n)$ negotiations. Then $\nu(n) = \Omega(n/\log^{d+3} n)$.*

Proof. Let us suppose on the contrary that there is depth d circuit family $\{C_n\}$ which computes $NEG(x)$ with $\nu(n) \neq \Omega(n/\log^{d+3} n)$ negotiations. By Lemma 4.2 there exists a constant $c > 0$ such that for every n, for every function f which is computed at some gate of C_n,

$$s(f) < c \log^{d+3} n.$$

Our hypothesis implies that there exists n such that

$$\nu(n) < n/(c \log^{d+3} n).$$

Let n be such an integer, and let $f_1, \dots, f_k$, $k \leq \nu(n)$ be the outputs of the negation gates of C_n.

Given a string w, we say a bit of w is sensitive to f if changing that bit changes the output of f on w. Otherwise, that bit is insensitive to f. It follows that there is a string w, which has a bit insensitive to all $f_1, \dots, f_k$. This is because

$$\begin{aligned} E[s(f_1, w) + \cdots + s(f_k, w)] &= E[s(f_1, w)] + \cdots + E[s(f_k, w)] \\ &\leq k c \log^{d+3} n < n, \end{aligned}$$

where E indicates the expectation of an event over all strings w of length n uniformly distributed.

Let w be a string whose jth bit is insensitive to all $f_1, \dots, f_k$. Obtain w' by changing this bit. We can suppose that $w_j = 0$ and $w_j{}' = 1$, which implies $w < w'$. Since the bit is insensitive, we have for all i, $f_i(w) = f_i(w')$. Thus, between w and w' the outputs of all negation gates of C_n are constant. This implies that no gate of C_n can take a greater value on w than on w'. However, C_n computes $\bar{x}_j$, so on input w it outputs $\bar{w}_j = 1$ and on w' it outputs $\bar{w}'_j = 0$. This is impossible if no negation gate changes. □

COROLLARY 4.4. *If $g(n) = o(n/\log^r n)$ for all r, then $AC^0 \neq AC^0_{g(n)}$.*

5. Conclusions and open problems. Let us say a few words about the uniformity of our circuits. In fact all of them are uniform. Indeed, while the earlier circuits of Valiant [17] and Ajtai and Ben-Or [1] of, respectively, Fact 2.1 and Fact 2.2 are probabilistic, the later constructions of Ajtai, Komlós and Szemerédi [3] and Wegener, Wurm, and Yi [19] are already uniform. The circuits of Fact 2.2 can also be constructed uniformly using Theorem 4.1 of [6].

Although the upper bound of Theorem 4.1 and the lower bound of Theorem 4.3 were matching, the lower bound held only for a multivalued function. An intriguing problem is to find out the exact number of negations necessary and sufficient to compute every single-valued function in AC^0. We can show a weaker lower bound for some single valued function. Let the problem *EXISTODD*, defined on $x_1, \dots, x_n$, be

$$(x_1 \wedge \bar{x}_2) \vee (x_3 \wedge \bar{x}_4) \vee \cdots \vee (x_{n-1} \wedge \bar{x}_n)$$

(if n is odd, then the formula will be $\cdots \vee (x_{n-2} \wedge \bar{x}_{n-1}) \vee x_n$). Since *EXISTODD* on inputs of the form $1^j 0^{n-j}$ is equivalent to *PARITY*, the proof technique of Theorem 3.2 works for this function. Clearly, *EXISTODD* is in AC^0 but it is not in $AC^0_{g(n)}$ if, for all $\epsilon > 0$, $g(n) = o(^\epsilon)$.

Another direction is where we started our reasoning: can we find lower bounds with limited negations, without any restriction on the depth? For example, can we prove Razborov type results for circuits containing a few (say, a constant number of) negations?

Acknowledgments. The authors would like to thank Noam Nisan for pointing out the use of Lemma 4.2 in deriving the lower bound for AC^0.

AVERAGE TIME ANALYSIS OF CLAUSE ORDER BACKTRACKING*

KHALED M. BUGRARA† AND PAUL WALTON PURDOM, JR.‡

Abstract. Backtracking algorithms solve problems by selecting a variable and assigning each possible value to the variable. The resulting subproblems are simplified and solved recursively. Simple backtracking selects variables in a fixed order. Clause order backtracking selects variables from the first nontrivial clause that has not yet been satisfied. Formulas are given for the average time used by clause order backtracking when solving random CNF satisfiability problems, where the problem sets have v variables, t clauses, and a probability p of a literal being in a clause. The average time for clause order backtracking is always less than that for simple backtracking. It leads to polynomial time under many conditions where simple backtracking uses exponential average time. Cases where clause order backtracking uses average time less than v^n (in the limit of v going to infinity) include $p < 1/(2v)e^{[(n-1)\ln v - \ln t]/t}$ and $p > \sqrt{[\ln t + (\ln v)/2]/v}$. (The second result needs a slight increase in the coefficient of $\ln t$ when t increases faster than $v^{\ln v}$.)

1. Constraint satisfaction and backtracking.

Many interesting problems require determining whether a set of constraints on variables with discrete values can be satisfied. Let $R_1(x_1, \ldots, x_v), \ldots, R_t(x_1, \ldots, x_v)$ be a set of relations and $x_1, \ldots, x_v$ be a set of variables, where each variable has a finite set of possible values. A constraint satisfaction problem consists of determining whether the variables can be set in a way that makes all of the relations *true*. Such problems can be quite difficult even when each relation is simple. For example, if each relation is a clause, then the constraint satisfaction problem becomes the classical Conjunctive Normal Form (CNF) satisfiability problem. Many special forms of the constraint satisfaction problem are NP-complete [3], [6], [12].

Searching is one common way to solve constraint satisfaction problems. The basic idea of searching is to choose a variable and generate subproblems by assigning each possible value to the variable. In each subproblem the relations are simplified by plugging in the value of the selected variable. If any subproblem has a solution, then the original problem has a solution. Otherwise, the original problem has no solution. The subproblems are solved by applying the technique recursively. *Simple search algorithms* stop the recursion when all variables have values. They use exponential time when used to find all solutions.

If any relation of a constraint satisfaction problem is always *false*, then the problem has no solution. *Backtracking* improves over plain search by immediately reporting no solution for problems with a false relation. Often this short cut saves a huge amount of time. Backtracking can take either exponential or polynomial average time, depending on the set of problems being solved [1], [11].

Simple backtracking has a fixed order for selecting variables. Sometimes it wastes time by assigning values to variables that do not appear in the problem. Even when the original problem uses all the variables, some of the simplified subproblems may use

only a few of them. For problems with a few short clauses simple backtracking *frequently* assigns values to absent variables.

Clause order backtracking reports no solution if the problem has a relation that is always *false*. Otherwise, it selects the first relation that is not always *true*. For the first variable that affects the value of this relation, each possible value is plugged in, the predicate simplified, and the resulting subproblem is solved by recursive application of the algorithm. Each solution of the subproblem (along with the the partial assignments of values that lead to the subproblem) gives a solution to the original problem. If the original problem has no nontrivial relations, then every assignment of values to the remaining variables results in a solution.

The following is a precise statement of the version of the algorithm that we analyze. This version is tailored for CNF satisfiability problems. The algorithm finds every solution to the given CNF problem, but it reports the solutions in a compressed form. A clause is always *false* if and only if it is empty (contains no literals). A clause is a *tautology* if and only if it contains a variable and its negation. A tautological clause always evaluates to *true*.

Clause Order Backtracking Algorithm for CNF problems.

1. If the CNF problem has an empty clause, return with an empty set of solutions, and charge one time unit.
2. If the first remaining clause of the CNF problem is a tautology, then remove it from the problem. Repeat this part of the step as long as it applies. If there are no clauses, then return with the current assignment of values to the variables as a solution (each assignment of values for the remaining unset variables results in a solution) and charge one time unit.
3. Let k be the number of unset variables in the first remaining clause. (Step 1 ensures that $k \geq 1$, and Step 2 ensures that each variable occurs in at most one literal of the clause.) For j starting at 1 and increasing to at most k, generate the jth subproblem by setting the first $j-1$ variables of the clause so that their literals are *false* and setting the jth variable so that its literal is *true*. Use the assignment of values to simplify the CNF problem (remove each false literal from its clause and remove from the problem each clause with a true literal). Apply the algorithm recursively to solve the simplified problem. If setting the first $j-1$ literals of the first remaining clause to *false* results in some clause being empty, then stop generating subproblems. The set of solutions for the original problem is the union of the set of solutions for the subproblems. If the loop stops with $j = h$, then charge $h + 1$ time units.

The cost in time units has been defined to be the same as the number of nodes in the backtrack tree generated by the algorithm. The actual running time of the algorithm depends on how cleverly it is implemented, but a good implementation will result in a time that is proportional to the number of nodes multiplied by a factor that is between 1 and tv, where v is the number of variables and t is the number of clauses.

The backtrack tree includes nodes for determining that the first remaining clause is empty. The computation associated with these nodes can be done quickly. In the analysis we briefly consider the effect of not charging for these nodes (giving an upper limit of k time units for Step 3). A cost of up to $k + 1$ units at Step 3 is natural when comparing the algorithm with simple backtracking, but a limit of k units is more natural when comparing the algorithm with unit clause backtracking. (Unit clause backtracking selects variables from clauses of length one when possible.)

Figure 1 illustrates the counting of nodes. Each internal node is labelled with the variable that is set at the corresponding point in the computation, the left branch corresponds to setting the variable to *false*, and the right branch corresponds to setting it to *true*. The first clause, $c_1 = x \vee y$, contributes nodes 1, 2, and 3. The second clause, $c_2 = x \vee z$, contributes nodes 4 and 5. Node 6 represents the solution $\{x = \textit{false}, y = \textit{true}, z = \textit{true}\}$. When x is *true*, both the first and second clauses are satisfied, but the third clause, $c_3 = \bar{x} \vee \bar{z}$ contributes nodes 7 and 9. Node 8 represents the set of solutions with $\{x = \textit{true}, z = \textit{false}\}$. All values of y are permitted at node 8. If the predicate had a fourth clause, $c_4 = x \vee \bar{y}$, then the predicate would be *false* at node 4 and clause c_2 would contribute only node 4. Nodes 5 and 6 would not be in the tree. With the three clause problem of Fig. 1, nodes 3, 5, and 9 would not be charged for using the alternate charging method of the previous paragraph.

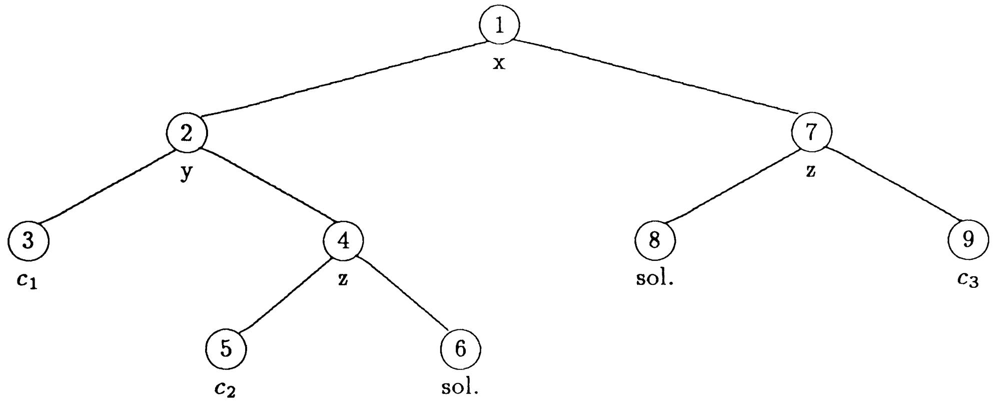

FIG. 1. *The backtrack tree for the predicate consisting of the three clauses* $c_1 = x \vee y$, $c_2 = x \vee z$, $c_3 = \bar{x} \vee \bar{z}$.

2. Probability model. The *random clause model* generates random CNF satisfiability problems using a set of v variables. A random clause is formed by independently selecting each of the $2v$ literals with probability p. A random predicate is formed by independently forming t random clauses.

In this model some variables may not occur in a particular problem. Some clauses may be empty. Some clauses may be tautologies. Some clauses may be duplicates of others. Each of these features may be considered to be a defect in the model, since problems initially given to a satisfiability algorithm are not likely to have them. However, these defects are not as important as it may at first appear because most of the features do occur in the subproblems that are produced by searching algorithms. The model has the advantage that the distribution of clauses does not change much when setting a variable. This leads to a relatively easy analysis. As a result more satisfiability algorithms have been analyzed with this model than with any other. The problems generated by this model can be either easy or hard (for the algorithms that have been analyzed so far) depending on how the parameters are set [2], [4], [5], [7], [8], [9], [10], [11]. The model is useful for comparing strengths and weaknesses of various satisfiability algorithms.

3. Discussion of results. This section discusses the the average time performance of clause order backtracking and compares it with that of other satisfiability algorithms. The following sections contain the detailed derivation of the results.

A contour plot of the performance for problems with one hundred variables is given in Fig. 2. A similar plot for fifty variables is given in [9]. The line that runs from the left side to the right side shows for each t, the value of p that leads to the largest average number of nodes. The remaining contours denote constant running time and are as follow. The outer contour in Fig. 2 shows the conditions where the average number of nodes per problem is 100. Each contour inward shows the conditions where the average number of nodes per problem is a factor of 100 larger. Thus, the contours show the conditions where the average number of nodes per problem is v, v^2, v^3, and v^4. The actual average running time is bounded by a low degree polynomial times the average number of nodes, where the details of the polynomial depend on just how cleverly one programs the algorithm.

The average number of nodes for clause order backtracking is never more than the average number of nodes for the version of simple backtracking that reports every solution. Under many conditions, clause order backtracking is much faster, but when pv is small and t/v is large the improvement is not important. (This is the lower right region of Fig. 2.) The comparison with simple backtracking [11] implies that the average number of nodes for clause order backtracking is bounded by v^n for large v when

$$(1) \qquad \frac{t}{v} > \frac{\ln 2 - n(\ln v)/v}{-\ln(1-e^{-pv})} \quad \text{and} \quad pv < \ln 2,$$

and also when

$$(2) \qquad \frac{t}{v} > \frac{pt[2\ln 2 - n(\ln v)/v]}{(\ln 2)\ln(1+pt/\ln 2) + pt\ln[1+(\ln 2)/pt]} \quad \text{and} \quad pv > \ln 2,$$

provided $pv/\ln v$ goes to zero.

There are additional cases where clause order backtracking is fast. Under most of these conditions the average number of solutions per problem is exponential. The reason that clause order backtracking is able to run in polynomial time and report every solution is that solutions are reported in compressed form. When the algorithm reports a solution, it often does not assign values to all the variables. Any truth assignment to the remaining variables is a solution.

For small p we show that the average number of nodes is no more than v^n when

$$(3) \qquad p \le \frac{1}{2v} e^{[(n-1)\ln v - \ln t - O(1)]/t}.$$

This limit approaches $1/(2v)$ when t grows faster than a constant times $\ln v$. This result corresponds to the fact that in Fig. 2 the contours all remain above $p = 1/(2v)$. The result in (3) is better than the one in (1) when

$$(4) \qquad \frac{t}{v} \le 0.743 < \frac{\ln 2}{-\ln(1-e^{-1/2})}.$$

For large p we show that the average number of nodes is no more than v^n when

$$(5) \qquad p \ge \sqrt{\frac{(1+\delta)\ln t + (\ln v)/2}{v}},$$

for any $\delta > 0$ and large v. When $\ln[(\ln t)/(\ln v)] < \ln v$ (i.e., when $t < v^{\ln v}$), δ can be replaced with zero. This result corresponds to the upper branch of the contours in

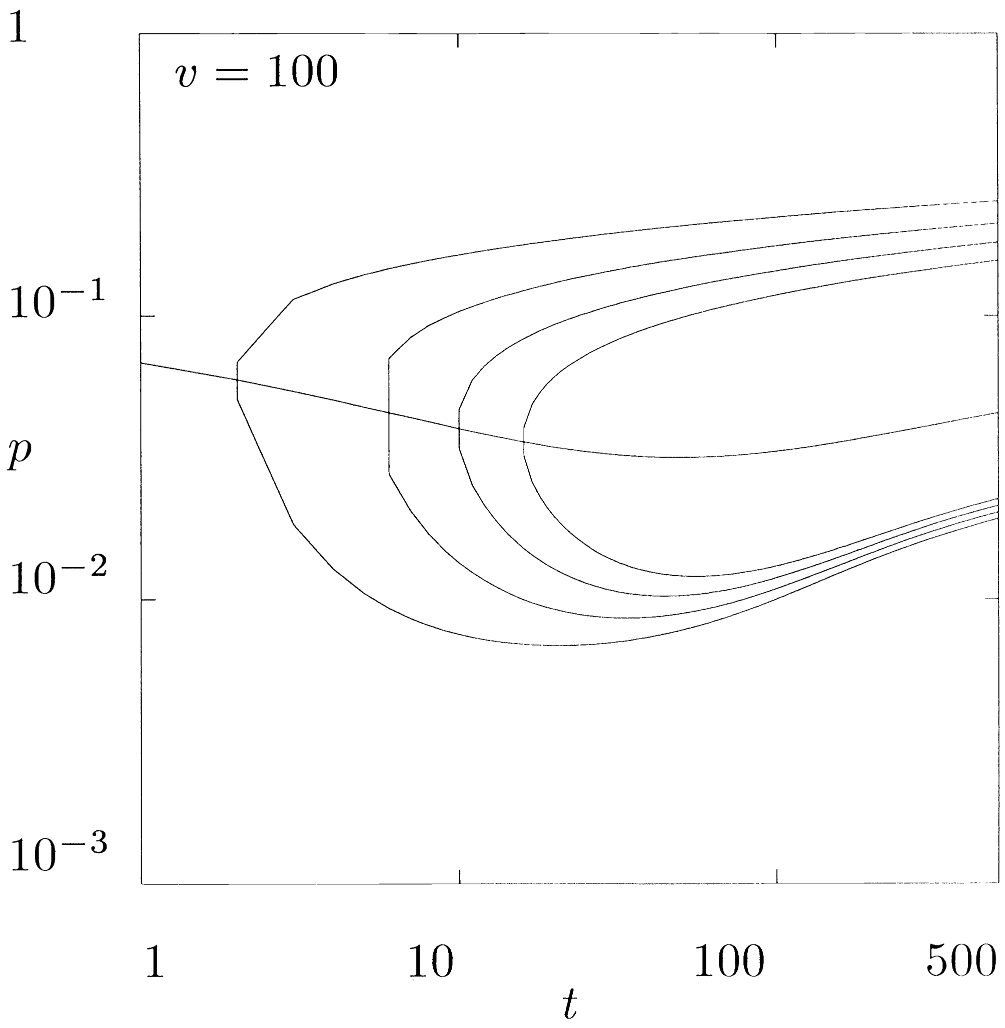

FIG. 2. *The outer contour shows for each t the value of p that results in an average of* 100 *nodes. Proceeding inward, contours for an average of* 100^2, 100^3, *and* 100^4 *are also shown. The line from the left side to the right side shows for each t which value of p results in the largest average number of nodes. Consecutive points on a contour are connected by a straight line.*

Fig. 2. Iwama's counting algorithm [7] for satisfiability has an average number of nodes bounded by v^n when

$$p > \sqrt{\frac{\ln t - \ln n}{v}}. \tag{6}$$

This is quite similar to (5), but somewhat better. Exact calculations for particular cases [9] confirm the suggestion of these upper bound calculations, i.e., Iwama's algorithm is faster for large p. (It is slow for small p.) Iwama's algorithm provides a count of the number of solutions, but does not give the solutions. When p is above the bound in (5) clause order backtracking quickly provides a complete list of solutions (in compressed form).

Equations (3) and (5) show that for all p we have polynomial average time when

$$t < 2(n-1) - O([\ln \ln v]/\ln v). \tag{7}$$

Other algorithms are known to be faster for small t, but none of them report all solutions. For example, the upper bound for the pure literal rule algorithm [10] is better than the upper bound for clause order backtracking for small t. (Comparing upper bounds does not always show which algorithm is best, but the measurements in [9] suggest that the upper bounds are close to the true values.) Comparing (3) with (28) of [10] shows that for small p, the pure literal rule algorithm has a better upper bound for

$$t < 2(nv \ln v)^{1/2}. \tag{8}$$

Equation (18) of [10] shows that the pure literal rule has a better upper bound for large p when

$$t < \frac{n-2}{\ln 2} \ln v \left[1 + O\left(\frac{1}{v}\right)\right]. \tag{9}$$

The fastest analyzed algorithm [5] for small t combines the unit clause rule, the pure literal rule, and resolution to eliminate variables that occur no more than two times. The use of resolution results in polynomial average time when t is below $v^{2/3}$ so long as p is not too large (when p is too large for this result, Iwama's algorithm is fast).

Among the analyzed satisfiability algorithms that report all solutions, clause order backtracking is one of the fastest. Selecting short clauses before long clauses would clearly improve the speed but complicate the analysis. A version of clause order backtracking where unit clauses are selected before longer clauses has been partly analyzed [9], but it is significantly faster than simple clause order backtracking only when pv is small. Resolution-based algorithms are much faster than clause order backtracking for small t and some values of p. For some applications the fact that they do not report all solutions is a disadvantage. Clause order backtracking runs in low degree polynomial average time for both large and small p. Only intermediate values of p lead to problems that are difficult for the algorithm.

4. Analysis. In the analysis, we associate clauses with nodes in the backtrack tree in a way that is equivalent to that described in §1 but different in detail. The backtrack tree always has a root. Each variable that is set when processing a clause results in two nodes, one for setting it to *true* and one for setting it to *false*. Thus, in Fig. 1, this way of counting associates node 1 with the root; nodes 2, 7, 3, and 4 with clause c_1; nodes 5 and 6 with clause c_2; and nodes 8 and 9 with clause c_3.

We now derive a sum that gives the average number of nodes generated by clause order backtracking. First, we consider the probability that the first clause attempts to contribute j nodes to the all false branch of the search tree (the branch where all variables are set to *false*). Then, we consider the probability that the first clause contributes zero nodes to the branch. (This happens when the first clause is a tautology.) Next, we consider the probability that the clauses following the first clause frustrate its attempt to contribute j nodes (by becoming *false* before j variables have been set). Finally, we use the fact that the probabilities are the same on all branches to obtain the sum for the average number of nodes.

The probability that a clause contains the first variable appearing positively but not negatively is $p(1-p)$. The probability that the first variable appears as either positive or negative, but not both is $2p(1-p)$. The probability that a clause contains k literals and the clause is not a tautology is

$$\binom{v}{k}2^k(p-p^2)^k(1-p)^{2v-2k} = \binom{v}{k}2^k p^k(1-p)^{2v-k}. \tag{10}$$

Suppose i variables are set to *false*. The probability that a random clause contains no true literals, contains k unset literals, and is not a tautology is

$$\binom{v-i}{k}2^k p^k(1-p)^{2v-i-k}. \tag{11}$$

The probability that such a clause contains its first true literal when j of its variables have been set to *false* is 2^{-j} (provided $j \le k$). Let $a_j(i)$ be the probability that a random clause is not a tautology, that it contains no true literals initially, and that it first contains a true literal after setting the first j of its previously unset variables. Summing (11) times 2^{-j} gives

$$a_j(i) = \sum_{k \ge j}\binom{v-i}{k}2^{k-j}p^k(1-p)^{2v-i-k} \quad \text{for } j \ge 1. \tag{12}$$

This is the probability that the first clause attempts to contribute j nodes to the all false branch of the backtrack tree.

The probability that a clause contains no true literals and is not a tautology is

$$\sum_k \binom{v-i}{k}2^k p^k(1-p)^{2v-i-k} = (1-p)^v(1+p)^{v-i}. \tag{13}$$

Let $a_0(i)$ be the probability that a random clause evaluates to *true* after i of its variables have been set to *false*. Any clause meets these conditions except those considered in (13). Thus,

$$a_0(i) = 1-(1-p)^v(1+p)^{v-i}. \tag{14}$$

This is the probability that a clause is skipped in Step 2 of the algorithm, and thus contributes zero nodes to the all false branch of the backtrack tree.

A clause evaluates to *false* if it contains only false literals. It cannot contain true or unset literals. The probability that a clause contains no such literals in $(1-p)^{2v-i}$. Thus, the probability that a clause evaluates to *false* is

$$1-(1-p)^{2v-i}. \tag{15}$$

Consider a particular predicate and a particular node in the associated backtrack tree. Let n be the number of clauses that contribute nodes to the path from the root to the selected node. (These are the clauses that are skipped in Step 2 and those that are used in Step 3 of the algorithm.) Let j_m be the number of nodes that the mth clause contributes to the path. Then $j_m \ge 0$ for $1 \le m < n$, and $j_n \ge 1$. Let s_m be the number of nodes contributed before those of the mth clause. That is,

$$s_m = \sum_{1 \le k < m} j_k. \tag{16}$$

Consider a particular set of j_m's and the set of all predicates that generate backtrack trees with that set of j_m's. Assume that each set variable is assigned the value *false*. The mth clause must contribute j_m nodes to the all false branch, with s_m variables having already been set. The remaining $t - n$ clauses (those that are not associated with any m) must not be *false* after $s_{n+1} - 1$ variables have been set. If all these conditions are met, then the backtrack tree has a node for both values of the last literal: one value results in the current clause containing a true literal, while the other value results in each literal of the current clause being either *false* or *unset*. Let $B(n, j_1, \ldots, j_n)$ be the probability that the backtrack tree for a random predicate contains a node where the mth clause contributes j_m (for $1 \le m \le n$) nodes to the path and where the last set variable makes the nth clause *true*. Since each condition pertains to one clause, and each clause is independently selected,

$$B(n, j_1, \ldots, j_n) = [1 - (1-p)^{2v - s_{n+1} + 1}]^{t-n} \prod_{1 \le m \le n} a_{j_m}(s_m). \tag{17}$$

The a_{j_1} factor in this formula gives the probability that the first clause of a random predicate contributes j_1 nodes, the a_{j_2} factor gives the probability that the second clause contributes j_2 nodes, etc. The $[1-(1-p)^{2v-s_{n+1}+1}]^{t-n}$ factor gives the probability that the clauses that have not contributed nodes have not previously evaluated to *false*. If you consider node 5 in Fig. 1, it was reached by the first clause contributing two nodes (nodes 2 and 4), the second clause contributing one node (node 5). To reach node 5 it was also necessary for the remaining clauses (clause c_3 in this case) not to evaluate to *false* at node 4. If the noncontributing clauses were not *false* at node 4, then they could not have been *false* at any of the earlier nodes on the path. The factor $a_2(0)$ gives the probability that the first random clause will contribute two nodes, and the $a_1(2)$ factor gives the probability that the second clause will contribute one node (even though two variables have already been set). The factor $[1-(1-p)^4]^1$ gives the probability that the one remaining clause does not evaluate to *false* even though two variables have been set at the parent of node 5.

Equation (17) gives the probability that the tree has a node with the specified characteristics. In particular, the last variable has been set so that its literal in the selected clause evaluates to *true*. With the same probability the tree has a node where that variable is set so that the literal evaluates to *false*. Thus, the average number of nodes corresponding to a particular $j_1, \ldots, j_n$, with each variable being assigned any preselected value (such as *false*), is $2B(n, j_1, \ldots, j_n)$.

In the random clause model each branch of the backtrack tree has the same probability. There are 2^i branches that have i variables set. Also each backtrack tree has a root node. Thus, the expected number of nodes in the backtrack tree is

$$N(t) = 1 + \sum_{1 \le n \le t} \sum_{j_1 \ge 0} \cdots \sum_{j_{n-1} \ge 0} \sum_{j_n \ge 1} 2^{s_{n+1}+1} B(n, j_1, \ldots, j_n). \tag{18}$$

The initial 1 counts the root of the backtrack tree, and the remaining terms count the nodes on level s_n for $1 \le s_n \le v$. Using $b_j(i) = 2^j a_j(i)$ and (17), equation (18) can be written as

$$N(t) = 1 + 2 \sum_{1 \le n \le t} \sum_{j_1 \ge 0} \cdots \sum_{j_{n-1} \ge 0} \sum_{j_n \ge 1} [1-(1-p)^{2v-s_{n+1}+1}]^{t-n} \prod_{1 \le m \le n} b_{j_m}(s_m). \tag{19}$$

5. Recurrence equation. The number of terms needed to evaluate $N(t)$ with (19) increases rapidly with t and v. We now derive a recurrence equation that is quicker to evaluate. Define

(20)
$$N(t,i) = 1+2\sum_{1\le n\le t}\sum_{j_1\ge 0}\cdots\sum_{j_{n-1}\ge 0}\sum_{j_n\ge 1}[1-(1-p)^{2v-i-s_{n+1}+1}]^{t-n}\prod_{1\le m\le n} b_{j_m}(i+s_m).$$

Note that $N(t) = N(t,0)$.

Giving separate consideration to the $n = 1$ case in (20) results in

$$N(t,i) = 1+2\sum_{j\ge 1}[1-(1-p)^{2v-i-j+1}]^{t-1}b_j(i)$$
$$+2\sum_{2\le n\le t}\sum_{j_1\ge 0}\cdots\sum_{j_{n-1}\ge 0}\sum_{j_n\ge 1}[1-(1-p)^{2v-i-s_{n+1}+1}]^{t-n}\prod_{1\le m\le n} b_{j_m}(i+s_m).$$

Giving separate consideration to the j_1 sum results in

$$N(t,i) = 1+2\sum_{j\ge 1}[1-(1-p)^{2v-i-j+1}]^{t-1}b_j(i)$$
$$+2\sum_{j} b_j(i)\sum_{2\le n\le t}\sum_{j_2\ge 0}\cdots\sum_{j_{n-1}\ge 0}\sum_{j_n\ge 1}$$
$$[1-(1-p)^{2v-i-j-s'_{n+1}+1}]^{t-n}\prod_{2\le m\le n} b_{j_m}(i+j+s'_m),$$

where $s'_k = s_k - j$. Now replace n by $n+1$, m by $m+1$, j_i by j_{i-1}, and s'_{i+1} by s_i. As a result, the new s_i is the sum of the new j_1 through j_n, and

(21)
$$N(t,i) = 1+2\sum_{j\ge 1}[1-(1-p)^{2v-i-j+1}]^{t-1}b_j(i)$$
$$+\sum_{j} b_j(i)\sum_{1\le n\le t-1}\sum_{j_1\ge 0}\cdots\sum_{j_{n-1}\ge 0}\sum_{j_n\ge 1}$$
$$2[1-(1-p)^{2v-i-j-s_{n+1}+1}]^{t-n-1}\prod_{1\le m\le n} b_{j_m}(i+j+s_m).$$

The part of (21) to the right of the second $b_j(i)$ is $N(t-1,i+j)-1$, so N obeys the recurrence equation

$$(22)\quad N(t,i) = 1+2\sum_{j\ge 1}[1-(1-p)^{2v-i-j+1}]^{t-1}b_j(i) + \sum_{j} b_j(i)[N(t-1,i+j)-1].$$

Simplifying, we get

$$(23)\quad N(t,i) = 1+b_0(i)[N(t-1,i)-1]$$
$$+\sum_{j\ge 1} b_j(i)\{2[1-(1-p)^{2v-i-j+1}]^{t-1}+N(t-1,i+j)-1\}.$$

Equation (20) gives the boundary condition $N(0,i) = 1$.

With (23), the average time can be computed in time $O(tv^2)$. Figure 2 shows the results of calculations for $v = 100$.

The recurrences in this paper were checked by comparing their solutions with the actual number of nodes generated by programs for the algorithms. Each recurrence was solved algebraically for $1 \le t \le 3$, $1 \le v \le 3$ using Macsyma. (A modification of (23) was checked for $1 \le t \le 6$, $1 \le v \le 6$, $tv \le 12$.) Also, each of the 2^{2tv} SAT problems was generated and solved with a program that counted the number of nodes that were generated. A problem with i literals has probability $p^i(1-p)^{2tv-i}$. Multiplying the count by the probability and summing over all problems gives a formula for the average number of nodes. (This formula is a polynomial in p with integer coefficients.) The formulas generated from the recurrences were identical with the ones generated by the programs.

6. Related recurrences. The number of nodes that results when a clause of length k is allowed to contribute at most k nodes can be obtained by replacing $2a_{j_n}$ in the previous derivations with $a_{j_n} + a'_{j_n}$, where a' is defined by (12) with the $k = j$ term omitted from the sum. Let $T(t,i)$ be the solution to

(24)

$$T(t,i) = 1 + \sum_{j\ge 1}[1-(1-p)^{2v-i-j+1}]^{t-1}\,[b_j(i)+b_{j+1}(i)] + \sum_j b_j(i)\,[T(t-1,i+j)-1],$$

with boundary condition $T(0,i) = 1$. The average number of nodes for the alternate counting method is $T(t) = T(t,0)$.

The recurrence for the number of solutions (in compressed form) is given by (23) with the constant term dropped. Let $S(t,i)$ be the solution to

$$S(t,i) = \sum_j b_j(i)S(t-1,i+j), \tag{25}$$

with the boundary condition $S(0,i) = 1$. The average number of solutions is given by $S(t) = S(t,0)$.

7. Comparison with simple backtracking.

THEOREM 1. *The average number of nodes generated by simple backtracking is greater than or equal to the average number of nodes generated by clause order backtracking for any distribution where the probability of a predicate is not changed by permuting the variable names in a single clause.*

Proof. Consider an arbitrary node q in a possible backtrack tree. Refer to this node with a string of T's and F's, where the ith symbol says which way to set the ith variable. (The important point is that the node can be described without reference to which variables are set on the path to the node.) For each predicate P consider whether or not node q occurs in the clause order backtrack tree for P. If node q does not occur, it is either because one of the clauses used to determine the order of assigning values to variables becomes *false* or because one of the other clauses becomes *false*. For the comparison between clause order backtracking and simple backtracking, construct a predicate P' in the following way. If node q does not occur in the clause order backtrack tree for P, then P' is the same as P. Otherwise, let k be the number of variables on the path from the root to node q, let v_i be the ith variable set by clause order backtracking on the path from the root to q, and let c_i be the clause that introduced v_i into the clause order backtrack tree. Form predicate P' from P by making the following change in variable names in the indicated clauses. For i from 1 to k, interchange variable names v_i and i in all clauses after c_i. For any node q, this mapping from P to P' is well defined, each P' is the image of a unique P, and P and P' have the same probability in the model for generating random clauses. Finally, if node q occurs in the clause order backtrack tree for P, then it also occurs in the simple backtrack tree for P'. Summing over all predicates P, we find that the probability of node q occurring in the clause order backtracking tree is no larger than the probability of it occurring in the simple backtracking tree. (For most distributions the node is less likely to be in the clause order tree, because a node q that does not appear in the clause order backtrack tree for P may still appear in the simple backtrack tree for P'.) $\square$

8. Asymptotics. Let $U(t)$ be an upper bound on $N(t,i)-1$ so that $U(t) \geq N(t,i)-1$ for $0 \leq i \leq v$ and $t \geq 0$. Since all the coefficients in (23) are positive

$$N(t,i)-1 \leq b_0(i)U(t-1)+\sum_{j\geq 1} b_j(i)\{2[1-(1-p)^{2v-i-j+1}]^{t-1}+U(t-1)\}. \tag{26}$$

Using

$$\sum_{j\geq 1} b_j(i) = 2p(v-i)(1-p)^v(1+p)^{v-i-1}, \tag{27}$$

and

$$1-(1-p)^{2v-i} \geq 1-(1-p)^{2v-i-j+1} \qquad \text{for } j \geq 1 \tag{28}$$

gives

$$\begin{aligned} N(t,i)-1 \leq{} & [1-(1-p)^v(1+p)^{v-i}]U(t-1) \\ & +2p(v-i)(1-p)^v(1+p)^{v-i-1}\{2[1-(1-p)^{2v-i}]^{t-1}+U(t-1)\}, \end{aligned}$$

which can be written as

$$\begin{aligned} N(t,i)-1 \leq{} & 4p(v-i)(1-p)^v(1+p)^{v-i-1}[1-(1-p)^{2v-i}]^{t-1} \\ & +\{[2p(v-i)-1-p](1-p)^v(1+p)^{v-i-1}+1\}U(t-1). \end{aligned} \tag{29}$$

Replacing the i's on the right side of (29) with the value that maximizes each part and replacing two factors of $(1+p)^{-1}$ with 1 gives

$$N(t,i)-1 \leq 4pv(1-p^2)^v[1-(1-p)^{2v}]^{t-1}+\{1+[2pv-1](1-p^2)^v\}U(t-1), \tag{30}$$

where we have assumed that $2pv-1$ is nonnegative. (When $2pv-1$ is negative, a slight modification of the current derivation shows that $N(t,i)$ is small, so that case is not considered further.)

Now let $U(t)$ be the solution to the recurrence

$$U(t) = 4pv(1-p^2)^v[1-(1-p)^{2v}]^{t-1}+\{1+[2pv-1](1-p^2)^v\}U(t-1), \tag{31}$$

with boundary condition $U(0)=0$. Equation (31) and the boundary for (23) imply that $U(t)$ is an upper bound on $N(t,i)-1$. Let $a = 1+(2pv-1)(1-p^2)^v$ and $b = 1-(1-p)^{2v}$. Then,

$$U(t) = 4pv(1-p^2)^v\frac{a^t-b^t}{a-b}. \tag{32}$$

Since $(a^t - b^t)/(a-b) = a^{t-1} + a^{t-2}b + a^{t-3}b^2 + \cdots + ab^{t-2} + b^{t-1}$, $a \geq b \geq 0$, and $a \geq 1$, we have

$$U(t) \leq 4ptv(1-p^2)^v a^{t-1}. \tag{33}$$

Also,

$$U(t) \leq \frac{4pv(1-p^2)^v}{a-b} a^t. \tag{34}$$

Figure 3 shows the contours from the approximation

$$N(t,i) \leq 1 + \frac{4pv(1-p^2)^v}{1+p} \frac{[1+(2pv-1)(1-p^2)^v/(1+p)]^t - [1-(1-p)^{2v}]^t}{(2pv-1)(1-p^2)^v/(1+p)+(1-p)^{2v}}. \tag{35}$$

This approximation is (32) modified by including the $(1+p)^{-1}$ factors that were dropped in deriving (32). When (35) gives a small result, it appears to have the main features of the real results (except in the lower right region where p is small and t is large). The $(1+p)^{-1}$ factors that are included in (35) but omitted from (32) have a noticeable effect in the upper part of Fig. 3, but the following derivations show that the factors are not significant when $v^{1/2}$ is large.

The right side of (35) is large when a is above 1, and it is small when a is near 1. Thus, it is small when pv is near 1/2 (so that $2pv - 1$ is small) and when p^2v is large (so that $2pv(1-p^2)^v$ is small). When p is larger than v^{-1} but smaller than $v^{-1/2}$, the bound is exponentially large (provided t is not small).

9. The small p case. From (33) we obtain

$$N(t,i) \leq 1 + 4ptv(1-p^2)^v[1+(2pv-1)(1-p^2)^v]^t. \tag{36}$$

When p is small, the $(1-p^2)^v$ term is not important. Replacing it with the upper limit of 1 gives

$$N(t,i) \leq 1 + 4ptv(2pv)^t. \tag{37}$$

The number of nodes is no more than v^n when

$$v^n \geq 1 + 4ptv(2pv)^t. \tag{38}$$

Rearranging and taking logarithms gives

$$\ln(2pv) \leq \frac{n \ln v - \ln(4ptv) - O(v^{-n})}{t}. \tag{39}$$

Since $p \leq 1$, the number of nodes is no more than v^n when

$$p \leq \frac{1}{2v} e^{[(n-1)\ln v - \ln t - O(1)]/t}. \tag{40}$$

10. The large p case. From plugging in the values of a and b into (34) we obtain

$$N(t,i) \leq 1 + \frac{4pv(1-p^2)^v}{(2pv-1)(1-p^2)^v + (1-p)^{2v}} [1+(2pv-1)(1-p^2)^v]^t. \tag{41}$$

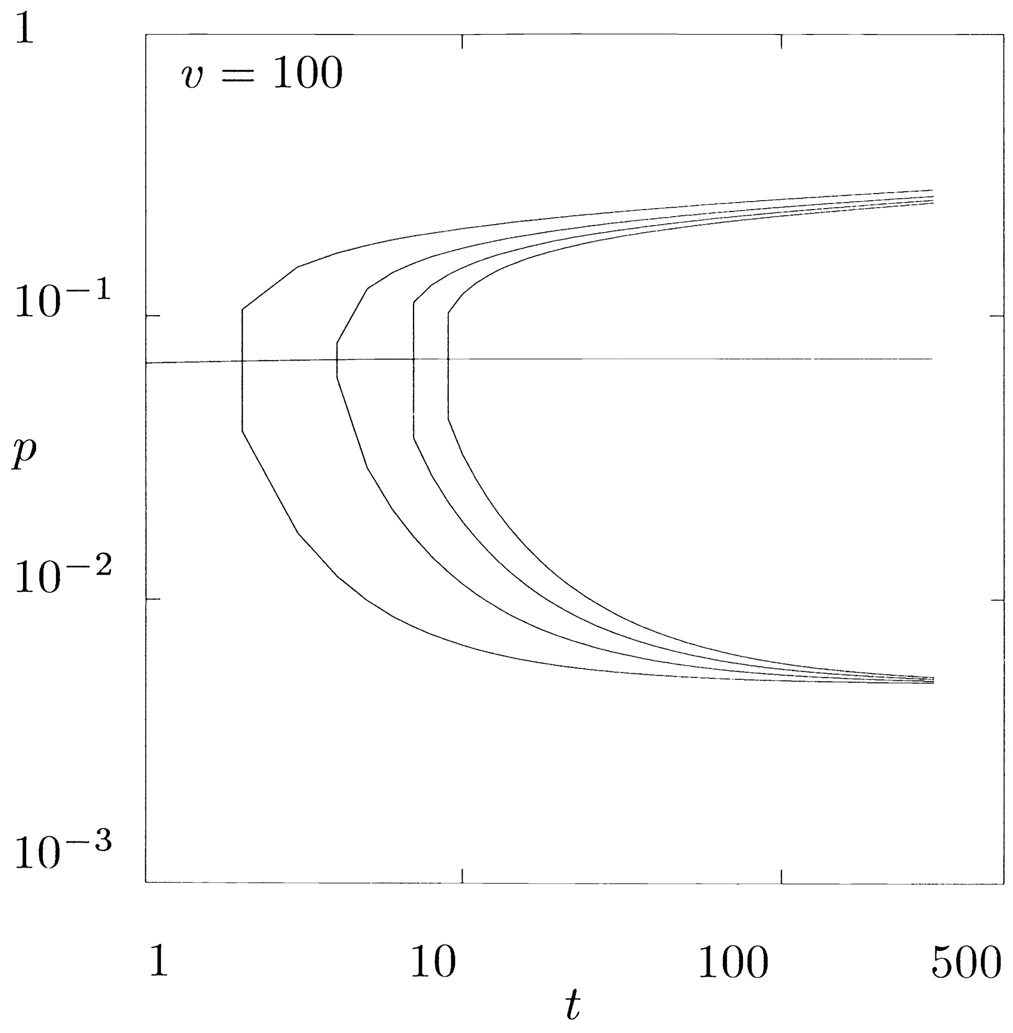

FIG. 3. *The contours for the approximation to the average number of nodes.*

Dropping terms in a way that leads to an even large bound gives

$$\begin{aligned}N(t,i) &\le 1 + \frac{4pv(1-p^2)^v}{(2pv-1)(1-p^2)^v}[1+2pv(1-p^2)^v]^t\\ &\le 1 + \frac{2}{1-1/(2pv)}[1+2pv(1-p^2)^v]^t\\ &\le 1 + \left[1+O\left(\frac{1}{pv}\right)\right][1+2pv(1-p^2)^v]^t.\end{aligned}$$

The number of nodes is no more than v^n when

(42) $$v^n \ge 1 + 2\left[1+O\left(\frac{1}{pv}\right)\right][1+2pv(1-p^2)^v]^t.$$

Writing this as $v^n - 1 \geq 2[1 + O(1/(pv))][1 + 2pv(1-p^2)^v]^t$ and taking logarithms gives $[n \ln v - \ln(1 - v^{-n})]/t \geq \ln[1 + 2pv(1-p^2)^v] + \ln 2 + \ln[1 + O(1/(pv))]$, which can be written as

$$e^{[n \ln v - O(1)]/t} - 1 \geq 2pv(1-p^2)^v. \tag{43}$$

Expanding the exponential in a power series gives

$$\frac{n \ln v}{2ptv}\left[1 + O\left(\frac{n \ln v}{t}\right)\right] \geq (1-p^2)^v. \tag{44}$$

Taking logarithms gives

$$\ln p + \ln t + \ln v - \ln \ln v - O\left(\frac{n \ln v}{t}\right) \leq v \ln(1-p^2). \tag{45}$$

Dividing by v and replace $\ln(1-p^2)$ with $-p^2 - O(p^4)$ gives

$$p^2 \geq \frac{\ln p + \ln t + \ln v - \ln \ln v}{v} - O(p^4) - O\left(\frac{n \ln v}{tv}\right). \tag{46}$$

For any $\delta > 0$ and large v, (46) is satisfied by

$$p \geq \sqrt{\frac{(1+\delta)\ln t + (\ln v)/2}{v}}. \tag{47}$$

When $\ln[(\ln t)/(\ln v)] < \ln v$ (i.e., when $t < v^{\ln v}$), the bound on p is also satisfied with $\delta = 0$.

To obtain conditions where the average time is barely exponential (bounded by $(1+\epsilon)^v$ for small positive ϵ), replace $n \ln v$ with ϵ in (3) and (46).

Acknowledgment. We wish to thank the referees for their careful reading of the paper and their helpful suggestions.

FACTORING RATIONAL POLYNOMIALS OVER THE COMPLEX NUMBERS*

CHANDERJIT BAJAJ†, JOHN CANNY‡, THOMAS GARRITY§, AND JOE WARREN¶

Abstract. NC algorithms are given for determining the number and degrees of the factors, irreducible over the complex numbers **C**, of a multivariate polynomial with rational coefficients and for approximating each irreducible factor. NC is the class of functions computable by logspace-uniform boolean circuits of polynomial size and polylogarithmic depth. The measures of size of the input polynomial are its degree, coefficient length, number of variables (d, c, and n, respectively). If n is fixed, we give a deterministic NC algorithm. If the number of variables is not fixed, we give a random (Monte-Carlo) NC algorithm in these input measures to find the number and degree of each irreducible factor.

After reducing to the two-variable, square-free case, we apply the classical algebraic geometry fact that the absolute irreducible factors of $(P(z_1, z_2) = 0)$ correspond to the connected components of the real surface (or *complex* curve) $P(z_1, z_2) = 0$ minus its singular points. In finding the number of connected components of the surface $P = 0$, the surface is projected to the the z_2-plane. The singular points of $P(z_1, z_2)$ lie over the projection's critical values. The inverse image of a grid isolating the critical values in the z_2-plane lifts to a one-dimensional real curve skeleton on the surface $(P = 0)$ whose number of connected components is precisely the number of connected components of $P = 0$ minus its singular points. The connectivity of this curve skeleton is constructed symbolically using Sturm sequences associated with the various polynomials defining these maps. Given the number of irreducible factors and their degrees, the actual factors can be reconstructed using the recent result of Neff [*Proceedings of the* 31*st Annual Symposium on Foundations of Computer Science*, pp. 152–162] on finding zeros of one-variable polynomials in NC.

1. Introduction.

Factoring polynomials is a basic problem in symbolic computation with applications as diverse as theorem proving and computer-aided design. Our goal is to approximate the factors, irreducible over the complex numbers, of a multivariable polynomial with rational coefficients in deterministic NC with respect to the polynomial's degree and coefficient size, assuming that the number of variables is fixed. Further, if the number of variables is not fixed, we will find the number of irreducible factors and each of their degrees in random NC with respect to the polynomial's degree, coefficient size and number of variables. The key is that this is a topological problem, not an algebraic one. We will show that the number of irreducible factors is exactly equal to the number of connected components of a certain semialgebraic set.

Since factoring is held as a touchstone problem in computer algebra, there have been a number of recent successes in factoring various types of polynomials over different fields. Methods for factoring polynomials with rational coefficients over the rational numbers are well known. Kaltofen [16] and Lenstra, Lenstra, and Lovasz [20] establish that factoring polynomials in a fixed number of indeterminates over the field of rational numbers **Q** is in polynomial time.

For factoring rational polynomials over **C**, Noether [23], Davenport and Trager [6], and Heintz and Sieveking [13] each give methods that require time exponential in the

degree of the input polynomial. DiCrescenzo and Duval [7] and Duval [8] give geometric methods of factorization based on algebraic geometry. Kaltofen [15] describes an NC method for testing whether a rational polynomial is irreducible over **C**. The method involves computing approximate roots and their corresponding minimum polynomials. The first polynomial time algorithm for factoring over **C** seems to have been given by Chistov and Grigoryev [4]. Until recently, it has been an open problem whether approximating the factors, irreducible over **C**, of a rational polynomial is in NC. Kaltofen [18], using techniques quite different from ours, has also derived an algorithm for approximating these factors in NC.

Recall that NC is the class of functions computable by log-space uniform Boolean circuits of polynomial size and polylogarithmic depth. Thus the running time of an NC algorithm will be polylogarithmic, allowing a polynomial number of processors that work in parallel. Given a polynomial P with rational coefficients, the input size is measured by the number of variables n degree d coefficient size c and the number of nonzero ooefficients s. We show that the general problem of computing number and degrees of the factors is in random NC in these measures, in the Monte-Carlo sense (definitely fast, probably correct). If the number of variables is fixed, or if the polynomial P is dense, we give a deterministic NC solution for also approximating the irreducible factors. Finally, if the polynomial is represented as a straight-line program of length p our algorithm runs in random NC plus the time to evaluate the polynomial at an integer point. By the parallelization result of Valiant et al. [27], any straight-line program of size p and degree d can be converted into an equivalent program of polynomial size, and polylogarithmic depth in d and p, which can be evaluated in NC. Although this result applies to the real number model, it extends easily to bit complexity since every node of the SLP represents a polynomial in the input variables and constants. If we have a bound on the degree of these polynomials, this also bounds the size of any intermediate coefficient when we evaluate the program numerically.

However, the conversion to a low-depth straight-line program is itself not in NC, and seems intrinsically sequential because of constant evaluation, which is P-complete. So we cannot run our algorithm in random NC for straight-line program polynomials unless we are given a program of low depth.

The paper can be divided into two main parts. In the first part, in §§2 and 3 we show how to find the number and the degree of the irreducible factors of a two-variable, square-free polynomial with rational coefficients. In the second main part, in §§4 and 5, we show how to reduce the general case of a multivariable polynomial to a two-variable, square-free polynomial, and then how to approximate the actual irreducible factors.

In §2, we recall a fact of the classical algebraic geometry: namely, that the number of factors of a two-variable, square-free polynomial $P(z_1, z_2)$ is precisely the number of connected components of the real, two-dimensional surface $P = 0$ minus the singular points of P. This is the key, allowing us to translate the original algebraic problem of factoring to the topological one of finding connected components of a special semi-algebraic set. Section 3, the technical heart of the paper, finds the number of these connected components. The two-dimensional surface $P(z_1, z_2) = 0$, lying in $\mathbf{C}^2$ or equivalently $\mathbf{R}^4$, can be projected to the z_2 plane, with a finite number of critical values. The singular points of the surface lie over critical points of the projection. In §3.1, the projection is described. In §3.2, we create a grid of horizontal and vertical lines in the z_2-plane with the property that inside each box of the grid there is at most one critical point of the projection. The inverse image of this grid on the surface $P(z_1, z_2) = 0$ forms a curve skeleton. By Theorems 3 and 4, the number of connected components of this curve skeleton will be precisely the number of connected components of $P(z_1, z_2) = 0$ minus its singular points. Since this curve skeleton is a graph, if we can compute its adjacency matrix in NC, we can find the number of connected components in NC. Section 3.3 shows how to find this matrix by using sign sequences of various Sturm sequences, all of which, by Theorem 6, can be computed in NC. This will give the number of irreducible factors of a two-variable square-free polynomial with rational coefficients. We will see that the degree of each factor has already been determined, by applying Bezout's theorem.

In §4, we show how to reduce the problem of factoring a multivariable polynomial with rational coefficients to that of factoring a square-free, two-variable polynomial. All we do is note that the proof of Bertini's theorem in [21] actually describes an algorithm that runs in NC. Finally, in §5, using the recent wonderful result of Neff [22] that the roots of a one-variable rational polynomial can be approximated in NC, we actually show how to approximate the irreducible factors.

2. Connectivity and factorization.

2.1. Preliminaries. Let $P_i(z_1, \ldots, z_n) \in \mathbf{C}[z_1, \ldots, z_n]$ for $i = 1, \ldots, k$ be polynomials with complex coefficients in n variables. Let $V(P_1, \ldots, P_k)$ denote the set of common zeros of these polynomials in $\mathbf{C}^n$

$$V(P_1, \ldots, P_k) = \{z \in \mathbf{C}^n | P_i(z) = 0,\ i = 1, \ldots, k\}.$$

This is an example of an *algebraic* set. For a single polynomial P, the set $S = V(P)$ is called a *hypersurface*. A hypersurface S is said to be *irreducible* if the zero set of the polynomial $P(z_1, \ldots, z_n)$ is irreducible over $\mathbf{C}$. More generally, an algebraic set is irreducible if it cannot be expressed as a finite union of proper algebraic subsets. An irreducible algebraic set is called a *variety*.

For the rest of the paper, we assume that P is square-free (irreducible factors have multiplicity one). Note that if the original P is not square-free, we may compute the square-free part of P by computing

$$P/GCD\left(P, \frac{\partial P}{\partial z_1}\right),$$

where P is monic in z_1. This computation may be performed in NC using the greatest common divisor algorithm of [1].

The key observation in §2.2 will be that there is a fundamental relationship between the *singular* points of an algebraic set and its irreducible components.

DEFINITION. Let $S = V(P)$ be a hypersurface with P a square-free polynomial. The set of *singular points* of S, denoted $Sing(S)$, is defined by

$$Sing(S) = S \cap V\left(\frac{\partial P}{\partial z_1}, \ldots, \frac{\partial P}{\partial z_n}\right). \qquad (1)$$

For example, an irreducible algebraic plane curve has at most a finite number of singular points. More generally, the singular set can be defined for any algebraic set, but we will not give a definition here. Intuitively, the singular points of an algebraic set are the points where the set is not smooth (smooth points have neighborhoods diffeomorphic to some $\mathbf{C}^k$) or where tangent lines are ill-defined.

2.2. Topology of zero sets of reducible polynomials. This section is the key to translating the algebraic problem of factoring to the topological problem of counting connected components.

Removing the singular set from an algebraic set may split it into several connected components. Here connectivity is equivalent to pathwise connected in the usual (metric) topology. As the following theorems show, these components correspond exactly to the irreducible components of the curve.

THEOREM 2.1. *The set S is irreducible if and only if $S - Sing(S)$ is connected.*

THEOREM 2.2. *The irreducible components of set S are exactly the closures of the connected components of $S - Sing(S)$.*

Both theorems are extremely classical and are consequences of the next two lemmas.

LEMMA 2.3. *Let the set S have distinct irreducible components $S_1, S_2, \dots, S_k$. Then for any i and j, $S_i \cap S_j \subseteq Sing(S)$.*

For hypersurfaces, this is a straightforward calculation. For the general case, this is Theorem 6 in [26, Chap. 2, §2].

LEMMA 2.4. *If S is irreducible, and Y is any proper algebraic subset of S, then $S - Y$ is connected.*

This is Corollary 4.16 of [21].

3. Computing connected components. We have reduced the problem of finding the number of irreducible factors of $P(z_1, z_2)$ to the problem of counting the number of connected components of the surface $V(P) - Sing(V(P))$. In the first part of this section, we discuss an algorithm for counting the number of connected components. We then discuss how the algorithm can be executed in parallel.

3.1. Projecting to the plane. In this subsection, we treat the algebraic set $V(P(z_1, z_2))$ as a branched cover of the z_2 plane, showing that there will only be a finite number of critical values (which will be defined in a minute) and, more importantly, that the singular points of P must lie over critical values. In §§3.2 and 3.3, we will construct a grid, isolating the critical values, in the z_2 plane whose inverse image on $V(P)$ will be a graph with the same number of connected components as $V(P) - Sing(V(P))$. This reduces the problem to constructing the adjacency matrix of this graph.

We express the complex coordinates z_1 and z_2 in terms of their real and imaginary parts: $z_1 = x_1 + y_1\mathbf{i}$ and $z_2 = x_2 + y_2\mathbf{i}$. The polynomial $P(z_1, z_2) = P(x_1, y_1, x_2, y_2)$ can also be expressed in terms of its real and imaginary parts: $P(x_1, y_1, x_2, y_2) = P_1(x_1, y_1, x_2, y_2) + P_2(x_1, y_1, x_2, y_2)\mathbf{i}$. Thus, $V(P)$ can be expressed as the two-dimensional real surface $V(P_1, P_2)$ in $\mathbf{R}^4$. Let $\pi : \mathbf{R}^4 \to \mathbf{R}^2$ be the projection map that takes those points (x_1, y_1, x_2, y_2) lying on $V(P_1, P_2)$ and maps them to (x_2, y_2). By a change of variables, we can assume that $P(z_1, z_2)$ has a z_1^d term, where d is the degree of P, implying that P does not have any factors univariate in z_2. Thus, π must be finite-to-one everywhere.

DEFINITION. If $F : \mathbf{R}^n \to \mathbf{R}^m$ is a differentiable map, $p \in \mathbf{R}^n$ is a *critical point* of F if the Jacobian dF of F is not surjective at p. The image of a critical point is a *critical value*.

In complex algebraic geometry, the critical points are called *ramification points* and the critical values, *branch points*. A point that is not a critical point is called a *regular point*, and the preimage of a *regular value* consists of regular points only.

This projection map has only a finite number of critical points.

LEMMA 3.1. *There are only a finite number of critical points in the projection map π from the surface $V(P_1(x_1, y_1, x_2, y_2), P_2(x_1, y_1, x_2, y_2))$ to the (x_2, y_2) plane.*

This lemma can be stated more precisely.

LEMMA 3.2. *The critical points of the projection map π are the points in the intersection of $V(P)$ and the surface $\frac{\partial P_1}{\partial z_1}$.*

The proofs of both lemmas are contained in §§4 and 5 in [19, Chap. 2]. The critical values of the projection map are the zeros of the one variable polynomial $R(z_2) = Res_{z_1}(P, \frac{\partial P}{\partial z_1})$. This expression is frequently referred to as the *discriminant*.

Note that the singular points of the polynomial P, the points where both partial derivatives vanish, must be contained in the critical points.

3.2. Reduction to curve skeleton. In this subsection we reduce the problem of finding the number of connected components of $V(P(z_1, z_2)) - Sing(V(P))$, which is the number of irreducible factors of P, to finding the number of connected components of a real one-dimensional curve skeleton (or graph) on the surface $V(P) - Sing(V(P))$.

In §3.1 we showed that the projection map π from $V(P)$ to the z_2 or (x_2, y_2) plane has only a finite number of critical values. Let G be a grid of a finite number of horizontal and vertical lines in the (x_2, y_2) plane, so that each critical value is in at most one cell of the grid. For now, we assume such a grid exists. We will give more details about how to construct such a grid later in this section. For now, the key point is that G isolates the critical values of the projection map.

Let K be the inverse image of the grid G on the surface $V(P)$. Note that K is one dimensional and, since no critical values lie on G, lies on $V(P) - Sing(V(P))$. K can be interpreted as defining a graph whose vertices are those points on K lying over the vertices of the grid G. Two vertices in this graph are adjacent if their corresponding points on K are connected.

The following two theorems will show that the number of connected components of the curve skeleton K is the same as the number of connected components of $V(P) - Sing(V(P))$. Theorem 3 will also yield the degree of each irreducible factor of $P(z_1, z_2)$.

THEOREM 3.3. *The number of vertices of the curve skeleton K, over any vertex of the grid G, in each connected component of $V(P) - Sing(V(P))$ is exactly the degree of that component.*

Proof. Let $P(z_1, z_2) = \Pi Q_i(z_1, z_2)$, where each Q_i is an irreducible factor of P. Each connected component of $V(P) - Sing(V(P))$ is of course $V(Q_i) - Sing(V(P))$, for some i.

A vertex of the grid G is a point a in the z_2 plane. The inverse image of this vertex is given by the zeros of the one-variable polynomial $P(z_1, a)$. The inverse image in each component are the zeros of $Q_i(z_1, a)$. By the Fundamental Theorem of Algebra, each component will have exactly degree of Q_i points, which is also the degree of the component. We do not have to worry about multiple roots of these polynomials since the grid G does not pass through any critical values. $\square$

THEOREM 3.4. *Any path in $V(P) - Sing(V(P))$ connecting two points in K is homotopic (i.e., can be continuously deformed) to a path in K.*

Proof. Let σ be a path in $V(P) - Sing(V(P))$ connecting two points of K. By slightly deforming σ, we can assume that the projection of σ by π misses any critical values in the z_2 plane. In each cell of the grid G, deform the path $\pi(\sigma)$ to the actual grid G, so that the area swept out by the deformation does not contain any critical values. This is possible since each cell will contain at most one critical value. Since the area swept out by the deformation does not contain a critical value, the deformation can be lifted to $V(P) - Sing(V(P))$. Thus the path σ can be continuously deformed to a path on the skeleton K. $\square$

We next describe the actual construction of the grid G. In the last section we show that the critical points of the projection map π are the points in $V(P, \frac{\partial P}{\partial z_1})$. Then the critical values are the zeros of the one variable polynomial,

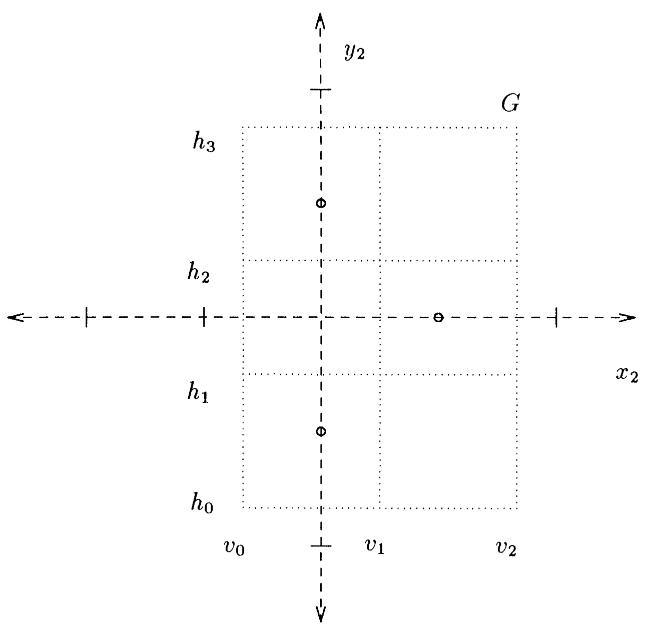

FIG. 1. *A grid plane whose cells contain at most one critical point.*

$$R(z_2) = Res_{z_1}\left(P, \frac{\partial P}{\partial z_1}\right), \tag{2}$$

where $Res_{z_1}(P, Q)$ is the resultant of the polynomials of P and Q treated as one-variable polynomials in z_1. The edges of G are chosen to be parallel to the x_2 and y_2 axes.

The vertical edges are the lines $x_2 = v_i$ with the $(v_0 < v_1 < \cdots)$ real constants chosen so that the open interval (v_i, v_{i+1}) contains at most one of the distinct real components of the complex zeros of $R(z_2)$. The horizontal edges are the lines $y_2 = h_i$ with the $(h_0 < h_1 < \cdots)$ real constants chosen so that the open interval (h_i, h_{i+1}) contains at most one of the distinct imaginary components of the complex zeros of $R(z_2)$. Figure 1 illustrates this situation where $R(z_2) = (z_2 - 1)(z_2 + \mathbf{i})(z_2 - \mathbf{i})$.

The lines of G form rectangular cells in the z_2 plane, intersecting in vertices. Note that each cell in the grid contains at most one critical value.

The grid G may now be used to construct the curve skeleton K directly on $V(P)$. In fact K, the inverse image of G under the projection π onto the z_2 plane is the one-dimensional curve $V(P) \cap \pi^{-1}(G)$. As described earlier, the vertices of this graph are the points on $V(P)$ lying over each vertex (v_k, h_l) in G. These points are the complex roots of the univariate polynomial $P(z_1, v_k + \mathbf{i}h_l)$. The edges of the graph correspond to algebraic curve segments of K. Figure 2 illustrates three curve segments over two vertices s and t of the grid G, adjacent on a vertical grid line. The curve segments have been projected onto the x_1y_2 plane.

Thus to find the number of connected components of $V(P) - Sing(V(P))$, we must find the number of connected components of the graph K. To determine the connectivity of K, we need only the adjacency information between points of K, not the actual curve segments. We will next describe a fast parallel method for computing this adjacency information.

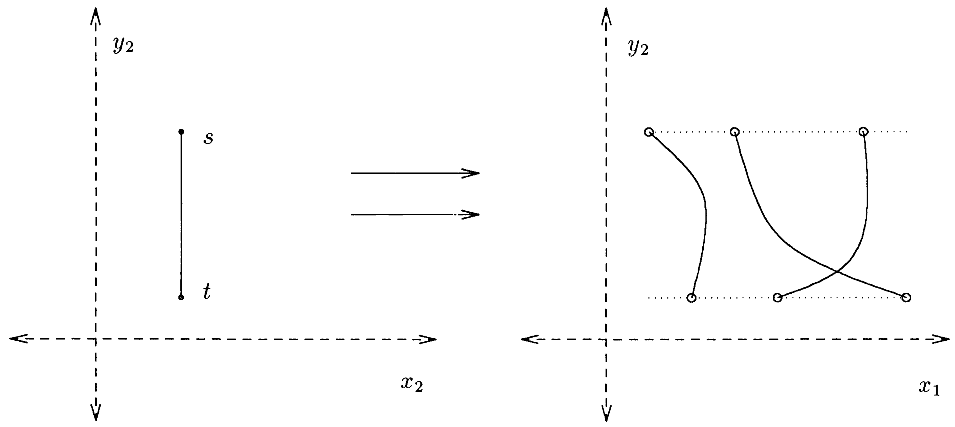

FIG. 2. *Curve segments on S joining vertices of K.*

3.3. Construction of curve skeleton. In this section we show how to construct the adjacency matrix for the curve skeleton K in NC with respect to the degree of the polynomial and the coefficient size. The key will be the symbolic representation by sign sequences of roots of various polynomials, allowing us to keep track of the order of the roots, which will be needed for the matrix.

In §3.3.1, we quickly review Sturm sequences for one-variable polynomials and then give a generalization for multivariable polynomials. In §3.3.2, we show explicitly how to construct the adjacency matrix of the curve skeleton.

3.3.1. Sturm sequences. Sturm sequences are classical. Let $p(x)$ be a one-variable polynomial. Consider the following sequence $p_0(x), \ldots, p_n(x)$ of polynomials:

$$\begin{aligned} p_0 &= p \\ p_1 &= dp(x)/dx \\ &\vdots \quad \vdots \\ p_k &= q_{k-1}p_{k-1} - p_{k-2} \\ &\vdots \\ &p_n \end{aligned} \tag{3}$$

where p_k is simply the negative of the remainder obtained by dividing p_{k-2} by p_{k-1}. Since $p(x)$ is a polynomial, the last term p_n must be a constant. If $p(x)$ is square-free, p_n must be nonzero. Sturm sequences can be computed in NC [1].

The importance of Sturm sequences lies in that they provide an easy way of determining how many real roots a polynomial has between two points.

THEOREM 3.5. *Let $p(x)$ be a univariate real polynomial with Sturm sequence $(p_0(x), \ldots, p_n(x))$. Let a and b be real numbers that are not roots of $p(x)$. Then the number of real roots of $p(x)$ between a and b is equal to the number of sign changes in the sequence $(p_0(a), \ldots, p_n(a))$ minus the number of sign changes in the sequence $(p_0(b), \ldots, p_n(b))$.*

The proof can be found in many places, such as [14, Chap. 6].

We will also need the following multivariable version of Sturm sequences. Let Σ be a collection of rational polynomials $(p_1, \ldots, p_m)$ in n variables.

THEOREM 3.6. *Let $p_1(x_1, \ldots, x_n) = 0, \ldots, p_m(x_1, \ldots, x_n) = 0$ be a system of rational coefficient polynomial equations having a finite number of solution points. Denote the l real solution points not at infinity as $\alpha_j \in \mathbf{R}^n, j = 1, \ldots, l$. Let $q_1(x_1, \ldots, x_n), \ldots, q_k(x_1, \ldots, x_n)$ be a set of polynomials. Then the set of sign sequences of $q_1(\alpha_j), \ldots, q_k(\alpha_j), j = 1, \ldots, l$ can be computed in* NC *if m is fixed.*

This theorem is a corollary of Lemma 2.4 in [3].

3.3.2. Parallel adjacency calculation. We now discuss how to compute the grid G in the z_2 plane and the adjacency information for K in NC with respect to the degree of the original polynomial and the coefficient size.

Let $R(z_2)$ be the polynomial whose zeros are the critical values of the projection map from $V(P)$ to the z_2 plane, defined by (2). Without loss of generality, we assume that $R(z_2)$ is square-free (if not, make it so). We write $R(z_2)$ in terms of its real and imaginary parts:

$$R(x_2, y_2) = R_1(x_2, y_2) + \mathbf{i}R_2(x_2, y_2).$$

The complex zeros of R are at the simultaneous real zeros of R_1 and R_2. Let

$$U(x_2) = Res_{y_2}(R_1, R_2), \qquad H(y_2) = Res_{x_2}(R_1, R_2). \tag{4}$$

The real zeros of U contain the x_2-coordinates of the critical values and the zeros of H contain the y_2-coordinates. Again, we ensure that U and H are square-free.

Since U is square-free, the solutions v_i to the equation

$$\frac{dU(x_2)}{dx_2} = 0 \tag{5}$$

generate vertical lines that separate the critical points. Likewise, the solutions h_i to the equation

$$\frac{dH(y_2)}{dy_2} = 0 \tag{6}$$

generate horizontal lines that separate the critical points. Finally, if A is a constant so that all roots of both U and H are greater than $-A$ and less than A, then the grid G will consist of the lines from (5) and (6) and

$$x_2 = \pm A$$

$$y_2 = \pm A.$$

This gives a symbolic description of G. We next use this description of the grid with Sturm sequences to compute the adjacency information for graph of the curve skeleton K.

We describe a method for computing this adjacency information in the x_2 direction in G. The y_2 direction is similar. Let (v_i, h_j) and (v_i, h_{j+1}) be two adjacent vertices in G. These vertices lie on the grid line $x_2 = v_i$. Over each of these vertices lies d points in $V(P)$. These points form the vertices of K. In $\mathbf{R}^4$, the intersection of $x_2 = v_i$ and

$V(P)$ define d algebraic curve segments in K. These curve segments form the edges in K, joining pairs of vertices in K, each lying over a distinct grid vertex.

We do not explicitly attempt to construct and follow the curve segments. Instead, we symbolically compute the adjacency information. Project $(V(x_2 - v_i) \cap V(P))$ onto the x_1y_2-plane via resultants. As shown in the next section, this projection can be chosen so that only nodal singularities are introduced into the curve. To determine adjacency information, we need only locate and detect the relative position of these nodes with respect to the vertices of K, since at each node the order of vertices changes. Since we are interested in nothing more than the relative order of these points, these calculations can be done via Sturm sequences. For example, in Fig. 3, denote the endpoints of the segment (v_i, h_j) and (v_i, h_{j+1}) by s and t. Over s, assume that there are four vertices s_1, s_2, s_3, and s_4 in K. Likewise, over t there are four vertices t_1, t_2, t_3, and t_4. The projected curve segments link the s_i to the t_j and the position of the nodes determines which s vertices are connected to which t vertices.

Specifically, consider the three polynomials:

$$T(x_1, x_2, y_2) = Res_{y_1}(P_1, P_2).$$

$$\frac{dU(x_2)}{dx_2} \tag{7}$$

$$N(x_2, y_2) = Res_{x_1}(T, \tfrac{\partial T}{\partial x_1}).$$

$V(T)$ is the projection of $V(P)$ to x_1, x_2, y_2 space. Allowing x_1 and y_2 to be free variables for $\frac{dU(x_2)}{dx_2}$, the intersection of $V(\frac{dU(x_2)}{dx_2})$ with $V(P)$ yields curves lying in planes parallel to the x_1y_2 plane and through the vertical grid lines.

Now allow y_2 to be a free variable for $\frac{dU(x_2)}{dx_2}$, the points on $V(N, dU/dx_2)$, restricted to the line $x_2 = v_i$, are the images of the nodes of $V(T)$ projected to the y_2 axis. Thus, allowing x_1 to be a free variable, $V(N, dU/dx_2)$ consists of lines in the x_1y_2 plane, parallel to the x_1 axis, containing nodes of the projected plane curve (the dotted horizontal lines in Fig. 3).

Compute the sign sequences of the following polynomials at the common zeros of the system (7):

- The Sturm sequence of dU/dx_2.
- The Sturm sequence of dH/dy_2.
- The Sturm sequence with respect to y_2 of $N(x_2, y_2)$.
- The Sturm sequence with respect to x_1 of $\frac{\partial T}{\partial x_1}$.

By Theorem 3.6, these sign assignments can be computed in NC with respect to the size of the input polynomials.

To compute adjacencies for K we proceed as follows: As y_2 increases, the number of sign alternations of the Sturm sequence for dH/dy_2 increases monotonically. We first sort all the sign assignments according to the number of sign alternations in this Sturm sequence within each sign assignment. This partitions all the zeros of (7) into classes according to y_2 coordinate. Each of these classes provides adjacency information for a particular slice $y_2 = h_i$.

Next we sort within each class according to the number of sign alternations of the Sturm sequence of dU/dx_2. This gives us a collection of classes that lie on the same horizontal grid segment between two adjacent vertical grid lines.

Then sort within classes according to number of sign alternations of the Sturm sequence of $N(x_2, y_2)$. The sign assignments with a zero correspond to the image in the (x_2, y_2) plane of the nodes of the curve seqments.

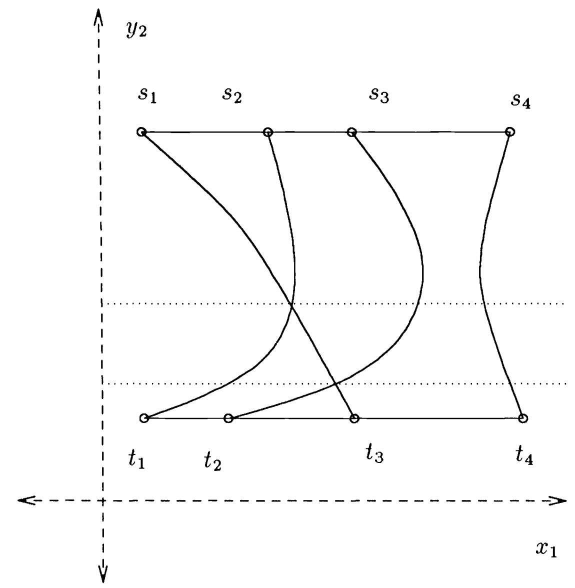

FIG. 3. *Effect of nodes on adjacency calculations.*

Finally, we sort the sign assignments according to number of alternations of the Sturm sequence of $\partial T/\partial x_1$. This orders the points with the same x_2, y_2-coordinates along lines parallel to the x_1 axis. One of these sign assignments will have a zero assignment to the polynomial $\partial T/\partial x_1$, and this is the sign assignment of the node point itself. From the position of this sign assignment in the ordering, we infer the relative position of the node point along the dotted line and therefore among the branches of the curve in K. In Fig. 3, we are ordering the points along the dotted lines.

To generate the graph K, we label the d vertices of K over a given gridpoint with $1, \ldots, d$. These labels come from the x_1 ordering of the corresponding points in K. Each node can be represented as a permutation (an exchange of two adjacent elements) of the indices of the curve branches that cross at the node. To determine the permutation as we move in y_2 past k nodes, we compose the permutations of the nodes. The composition can be done in NC by composing adjacent (in y_2 ordering) permutations, then composing adjacent pairs of these, etc. The final permutation gives the change in ordering from one gridpoint to the next and provides the d edges joining corresponding vertices of K.

One performs similar calculations to compute adjacency information in the horizontal direction.

3.3.3. Projections introducing only nodal singularities. We need to prove the assumption used in the §3.3.2 that a smooth space curve defined by the intersection of two surfaces can be projected to a plane curve with at worst nodes as singularities. The following is no doubt well known.

LEMMA 3.7. *Let C be a space curve defined by the intersection of two algebraic surfaces. Then we can choose a projection map in* NC *with respect to the degrees of the polynomials defining the surfaces so that the image of C is a plane curve with at worst ordinary nodes as singularities.*

Proof. Recall that a projection is defined as follows: choose a point p off of both the curve C and a plane P. Let q be any point on C. Then the unique line defined by p and

q intersects the plane P in exactly one point. The projection maps q to this intersection point.

By [21, pp. 132–135] or [12, Th. IV.3.10], a point will give rise to a nonnodal projection if it lies on a multisecant of the curve (i.e., a secant intersecting the curve in more than two places), a tangent of the curve, or a secant with coplanar tangent lines. In these references, it is shown that the set of nonnodal projection points forms a proper algebraic subset. It can be checked that the polynomials defining this algebraic set are bounded by the degrees of the polynomials defining the surfaces. Thus by [25], and using arguments similar to those that will be given for Theorems 4.2 and 4.3 in §4, we can, in NC with respect to the degrees of the polynomials defining the surfaces, choose a point of projection.

One technical note is needed. Both [21] and [12] work over the complex numbers. But a proper algebraic subset of $\mathbf{C}^n$ cannot contain all of the underlying real points. Thus we are indeed guaranteed a good point of projection.

4. Reduction to bivariate factorization. All of the previous work depended on the original polynomial being in two variables. In this section we show how to reduce the problem of factoring a multivariable polynomial to the two-variable case.

There have been a number of papers giving reductions from multivariate to bivariate factorization. The first appeared in Heintz and Sieveking [13], and made use of Bertini's theorem, as will we. This was a randomized irreducibility test that worked for sparse multivariate polynomials. The idea was extended to factorization in [10]. In [16] a reduction was given which is in deterministic polynomial time if the number of variables is fixed, or if the polynomials are dense. Kaltofen [17] later gave a different randomized reduction for the sparse case. These randomized reductions work for polynomials represented as straight-line programs as well as sparse polynomials. An NC reduction for the dense case was given in [15].

For the complex case, we give a new randomized reduction that requires fewer bits per random coefficient $O(\log d)$ than the previous methods $O(d)$ for [17] and $O(d^2)$ for [10]. Thus our reduction also runs in deterministic NC if the number of variables is fixed, or if the polynomials are dense. For sparse polynomials, the reduction is in random NC in the degree d number of variables n coefficient size c and number of nonzero terms s. For straight-line program polynomials, the parallel running time is the sum of a polylogarithmic function of measures d, n, c, plus the time to evaluate the polynomial at an integer point.

Given a polynomial $P(x_1, \ldots, x_n)$, we assume that it is square-free. We wish to develop a constructive version of Bertini's theorem, which states that the intersection of an irreducible variety with a generic plane will be an irreducible plane curve. Luckily the proof given in Mumford as Theorem 4.17 in [21] is constructive. Next we describe algebraically the set of intersecting planes that violate Bertini's theorem and then, using Schwartz's lemma [25], show how to choose an intersecting plane satisfying Bertini's theorem.

We use the following theorem (which is Theorem 4.17 in [21]).

THEOREM 4.1. *Let $X \subset \mathbf{P}^n$ (complex projective n-space) be an r-dimensional projective variety and let $M^{n-r-1} \subset \mathbf{P}^n$ be a linear space disjoint from X. Let $p : X \to \mathbf{P}^n$ be the projection from M and let*

$$B = (x \in \mathbf{P}^r \mid p \text{ not smooth over } x)$$

so that

$$(X - p^{-1}B) \to \mathbf{P}^r - B$$

is a finite-sheeted covering space. Let $l \subset \mathbf{P}^r$ be any line that meets B transversely. Then

$$p^{-1}(l - l \cap B) \to l - l \cap B$$

is also a connected covering space, hence p^{-1} is an irreducible curve.

In fact by Corollary (4.18) in [21], the above line l can be chosen so that $p^{-1}(l)$ will intersect the variety X transversely. For our case, X will be an irreducible hypersurface $V(P(x_0, \dots, x_n))$, where $P(x_0, \dots, x_n)$ is the homogenized version of a polynomial $P(x_1, \dots, x_n)$. Thus $V(P(x_0, \dots, x_n))$ is the projective closure of the affine hypersurface $V(P(x_1, \dots, x_n))$. Then M^{n-r-1} will be for us simply a point off of $V(P(x_0, \dots, x_n))$.

Following [21], we will find three points that span the plane $p^{-1}(l)$. The first point, p_0 will be the point of projection. Any point off of the hypersurface $V(P(x_0, \dots, x_n))$ will work.

As in the theorem, let B be the set of points, in the hyperplane $\mathbf{P}^{n-1}$, over which the projection from p_0 is not smooth. In our terminology, B is the set of critical values. We now need to find a line l in the hyperplane $\mathbf{P}^{n-1}$ that is transverse to B. But this is easy. In $\mathbf{P}^{n-1}$, choose a point p_1 off of B and then project B from this point to some $\mathbf{P}^{n-2}$. Let B' be the critical values in $\mathbf{P}^{n-2}$ of this projection map, and let our third point p_2 be a point off of B'. The line l will be defined by the points p_1 and p_2 and the plane $p^{-1}(l)$ will be spanned by p_0, p_1, and p_2. Again, the justification for these choices is in [21].

The following choices must be made. First we must find a point p_0 off of a degree ($d = \deg P$) hypersurface in $\mathbf{P}^n$. Then we must find a point p_1 off of B, which is a degree $d(d-1)$ hypersurface in $\mathbf{P}^{n-1}$. Note that the degree of B is $d(d-1)$ since it is given by the resultant of the polynomial P and some first partial of P. Finally we must find the point p_2 off of the set B', which is a hypersurface of degree $d(d-1)(d(d-1)-1)$ in $\mathbf{P}^{n-2}$. Luckily it is not hard to choose points off of a proper algebraic set. Further, since the set of bad points is a proper algebraic set, we can assume, even though the statement of the above theorem is for projective space, that we are in an affine space $\mathbf{C}^n$ (i.e., we can dehomogenize, since we will be losing only the points on the hyperplane at infinity, which is a proper algebraic subset of degree one).

THEOREM 4.2. *Let $P(x_1, \dots, x_n)$ be an irreducible polynomial of degree d. Let E be a finite subset of $\mathbf{C}$. Then the probability that the bivariate polynomial $Q(x, y)$ defining the plane curve, given by the intersection of $V(P)$ by a plane spanned by three points in E^n, is reducible is less than $(d^4 - 2d^3 + d^2 + d + 1)/|E|$, where $|E|$ is the cardinality of E.*

Proof. We make use of Schwartz's lemma [25] that the number of points in the set E^n (E a finite subset of $\mathbf{C}$) that lie in an algebraic set $Z \subset \mathbf{C}^n$ of degree d is at most $d|E|^{n-1}$.

The set of points off of which we want to choose our three points is the union of $V(P)$, B, B', and the hyperplane at infinity; hence, has degree $d + d(d-1) + d(d-1)(d(d-1)-1)$, which is $d^4 - 2d^3 + d^2 + d + 1$. The result follows. □

COROLLARY 4.3. *Let $P(x_1, \dots, x_n)$ be a polynomial of degree d with k irreducible, distinct factors. Let E be a finite subset of $\mathbf{C}$. Then the probability that the bivariate polynomial $Q(x, y)$ defining the plane curve given by the intersection of $V(P)$ by a plane spanned by three points in E^n does not have k factors with corresponding degrees is less than $d^4 - 2d^3 + d^2 + d + 1/|E|$.*

This follows because the points can be chosen exactly as in Theorem 4.2.

In order to achieve a probability of failure less than ϵ, we make sure that the following holds true: $|E| > d^4 - 2d^3 + d^2 + d + 1/\epsilon$. Choosing integer values for elements of E therefore requires $(4 \log d + \log \frac{1}{\epsilon})$ bits. For a deterministic algorithm, we take $|E| = d^4 - 2d^3 + d^2 + d$.

Finally, note that by Bertini's theorem almost every reduction to two variables will work. Thus if we do not fix the number of variables, our algorithm will run in random (Monte-Carlo) NC.

5. Factorization information.

We now want to approximate each factor of the polynomial $P(z_1, \dots, z_n)$, which is possible due to the recent work of Neff [22] on approximating the roots of a one-variable polynomial with rational coefficients in NC. The arguments used are very straightforward, so we will only sketch the proof.

Let our polynomial $P(z_1, \dots, z_n) = \prod P_i(z_1, \dots, z_n)$, where each P_i is irreducible of degree d_i. We can assume, after a change of coordinates, that P and the P_i are monic in the variable z_n. There are then $(\frac{(d_i+n)!}{(d_i)!(n)!} - 1)$ unknown coefficients for each P_i. We will now determine how to approximate these coefficients by solving an associated system of linear equations: $AX = B$, where A will be an integral invertible matrix, X will be a column vector of coefficients for P_i, and B will be a column vector of algebraic numbers.

Let $a_1, a_2, \dots, a_{n-1}$ be integers. Using [22], approximate the roots of the one-variable polynomial $P(a_1, a_2, \dots, a_{n-1}, z_n)$. Assume for a moment that we can determine which roots are associated with which irreducible factor P_i and can thus approximate the one-variable polynomial $P_i(a_1, a_2, \dots, a_{n-1}, z_n)$. Then given an integer a_n, we can approximate the algebraic number $b = P(a_1, a_2, \dots, a_{n-1}, a_n)$. By choosing $(\frac{(d_i+n)!}{(d_i)!(n)!} - 1)$-tuples of integers $(a_1, a_2, \dots, a_{n-1}, a_n)$ and treating the coefficients of the P_i as unknowns, we can approximate the coefficients by solving a linear system $AX = B$. Here B is the column vector of the algebraic numbers b from the various $P_i(a_1, a_2, \dots, a_{n-1}, a_n)$ and A is the square matrix arising from evaluating all monomials of degree d_i in n variables at the points $(a_1, a_2, \dots, a_{n-1}, a_n)$. We must choose our tuple so that the matrix A is invertible, but this is clearly no problem.

There is one difficulty with this method. We do not yet know how to determine which roots of $P(a_1, a_2, \dots, a_{n-1}, z_n)$ are associated to which factor P_i. We do know how to do this in the two-variable case. For a polynomial $P(z_1, z_2) = \prod P_i(z_1, z_2)$, we can determine which roots of $P(a_1, z_2)$ are associated to which factors P_i, since this is precisely the information that is contained in the connectedness of the earlier constructed curve skeleton, provided that we choose the point a_1 to be on the grid in the z_1 plane, which we can do by enlarging the grid. The general case is now easy. Given two tuples $(a_1, a_2, \dots, a_{n-1})$ and $(b_1, \dots, b_{n-1})$, intersect $P(z_1, \dots, z_n) = 0$ with the plane parallel to the z_n axis containing the points $(a_1, a_2, \dots, a_{n-1}, 0)$ and $(b_1, \dots, b_{n-1}, 0)$. This reduces the problem of associating roots of P to the two-variable case, which we can do. Of course, we cannot intersect $P(z_1, \dots, z_n) = 0$ with any plane, but this is not a true difficulty. In the previous section we have an algebraic description of the planes that do not intersect $P(z_1, \dots, z_n) = 0$ correctly. Thus we simply must choose our $(n-1)$ tuples so that resulting planes perform properly.

Acknowledgments. We would like to thank Jim Renegar for his comments and discussion of this work. We would also like to thank the referee for many suggestions for improving the exposition of the paper. An earlier version of this work was presented at ISSAC '89, in Portland, Oregon.

OPTIMAL STOCHASTIC ALLOCATION OF MACHINES UNDER WAITING-TIME CONSTRAINTS*

E. G. COFFMAN, JR.†, LEOPOLD FLATTO†, AND PAUL E. WRIGHT†

Abstract. The nonpreemptive scheduling of $n \geq 1$ stochastic jobs is considered to minimize the expected number of parallel machines needed to meet given waiting-time constraints. The number of machines available is unlimited. The running times of the jobs are denoted $T_1, \ldots, T_n$ and are taken to be independent samples of an exponentially distributed random variable T with mean 1. Job waiting times are to be bounded stochastically by a nonnegative random variable W, independent of $T_1, \ldots, T_n$. At time zero, a timer is started with an initial value W, and job scheduling begins. When the timer expires, all jobs still waiting for a machine are assigned to available machines. Only the distributions of W and the job durations $T_1, \ldots, T_n$ are known to the scheduler in advance.

A scheduling policy is defined which is proven to be optimal when W has an exponential distribution, and is asymptotically optimal as $n \to \infty$, when W is a constant (hard-deadline). In the exponential case, an explicit formula for the cost function is derived. The uniqueness question is also resolved. The paper concludes with a partial analysis of the general hard-deadline problem, which leads to a policy that we think is optimal. A proof of optimality, however, remains an open problem.

1. Introduction.

We consider the nonpreemptive scheduling of $n \geq 1$ stochastic jobs so as to minimize the expected number of parallel machines needed to meet given waiting-time constraints. The number of machines available is unlimited. The running times of the jobs are denoted $T_1, \ldots, T_n$ and are taken to be independent samples of a random variable T.

Job waiting times are to be bounded stochastically by a nonnegative random variable W, independent of T, with distribution $C(t)$. Thus at time zero a timer is started with the initial value W and job scheduling begins. To simplify terminology, we equip the timer with a bell which rings when the interval W expires. When the bell rings, all jobs not currently running and still waiting are assigned to available machines. We emphasize that, except when W is a constant, the value of the timer is not available to the scheduling policy before the bell rings; but its distribution is known. Similarly, job lengths are also not known in advance, but their common distribution is known. The problem is to find, within the class of nonpreemptive policies, a policy which minimizes the expected cost, with cost defined as the number of distinct machines used throughout a schedule.

The analysis of later sections suggests that this *machine minimization* problem is quite difficult for general distributions of T and W. A similar, but more precise statement can be made about the corresponding combinational optimization problem, where the values of $T_i, 1 \leq i \leq n$ and W are all given in advance and the maximum number of machines used throughout a schedule is to be minimized. This problem is strongly NP-complete, a result which follows easily from the strong NP-completeness of one-dimensional bin-packing [1].

This paper simplifies the general problem by assuming that T has an exponential distribution. In the usual way, this allows us to formulate a Markov decision process without having to include elapsed job running times as part of the state variable. For convenience we take the mean of the distribution as the time unit, $E(T) = 1$. For general

$C(t)$, the optimization problem remains difficult. However, for $C(t)$ also exponential, we give in §§3 and 4 a complete characterization of optimal policies.

In particular, it is shown that, for some $1 \leq k \leq n$, the following policy is optimal. The policy begins by assigning jobs to k machines. Thereafter, until the bell rings, jobs are run only on these machines; whenever a machine finishes a job, it is assigned a waiting job, if any. If there are any jobs still waiting when the bell rings, then all such jobs are assigned to new machines. This is called the *constant-k* policy; it is analyzed for general $C(t)$ in §2 in preparation for the results of later sections. Note that the cost of any constant-k schedule is simply the maximum of k and the number of unfinished jobs when the bell rings.

Section 5 treats the hard-deadline model, where W is a known constant. This section first shows that the best constant-k policy is asymptotically optimal as $n \rightarrow \infty$. A Bellman equation is then developed for the general case. Numerical evidence and partial results derived from the Bellman equation suggest the structure that an optimal policy is likely to have. We present such a policy, but a proof of its optimality has so far eluded us.

In the context of stochastic scheduling theory, machine minimization relates to the *makespan minimization problem*, where the system of machines is assumed fixed and the latest job finishing time is to be minimized in expected value. The latter problem has been studied extensively under a variety of assumptions, including machines of different speeds, precedence constraints among jobs, and different distributions for the T_i (see [2], [3], [4], [5] and the references therein for the literature on this problem). The model here concerns the complementary, equally important problem of allocating resources to meet customer demands on waiting times.

In addition to the usual job-shop applications cited in the literature of stochastic scheduling theory, there are equivalent problems in computer/communication system design. For example, at a network node the machines become channels or trunks, and W bounds the message delay prior to the start of transmission. Machine minimization also falls within the theory of stochastic real-time scheduling. A distinctive feature of the model here is that job running times are not known in advance. Also, the waiting time constraint is imposed on the delays prior to being assigned machines, rather than the job finishing times.

2. The constant-k policy. This section assumes a general clock-time distribution $C(t) = Pr\{W \leq t\}$. For given n and $k, 1 \leq k \leq n$, let $F(n,k)$ denote the expected cost incurred by the constant-k policy. Then $F(n) = \min_{1 \leq k \leq n} F(n,k)$ denotes the expected cost incurred by a best constant-k policy. Recall that the constant-k policy initially assigns k of the given n jobs to k machines. Of the remaining $m = n - k$ jobs, let R count those that will eventually be served before the bell rings. When the bell rings, there still remain $m - R$ jobs requiring $m - R$ new machines, in addition to the k already in use. Thus, the total number M of machines used by the constant-k policy is given by $M = m - R + k = n - R$, so that

$$F(n,k) = E[M] = n - E[R]. \tag{2.1}$$

In particular, when $k = n$, we have $R = 0$ so that $F(n,n) = n$.

The distribution for R is denoted by $\pi_i = Pr\{R = i\}, 0 \leq i \leq m = n - k$. For $i < m, Pr\{R = i|W = t\}$ is simply the probability that, in a Poisson process with rate k, i events occur in $[0,t)$. Thus, we have a mixture of truncated Poisson distributions

$$\pi_i = \begin{cases} \displaystyle\int_0^\infty e^{-kt}\frac{(kt)^i}{i!}dC(t), & 0 \le i < m, \\ \displaystyle\int_0^\infty \sum_{j\ge m} e^{-kt}\frac{(kt)^j}{j!}dC(t), & i = m. \end{cases} \tag{2.2}$$

Introduce the Laplace transform $\hat{c}(s) = \int_0^\infty e^{-st}dC(t)$ and rewrite (2.2) as

$$\pi_i = \begin{cases} p_i - p_{i+1}, & 0 \le i < m, \\ p_m, & i = m, \end{cases}$$

with

$$p_i = \int_0^\infty \sum_{j\ge i} e^{-kt}\frac{(kt)^j}{j!}dC(t) = \sum_{j\ge i}\frac{(-k)^j}{j!}\hat{c}^{(j)}(k), \tag{2.3}$$

where $\hat{c}^{(j)}(k)$ is the jth derivative of $\hat{c}(s)$ evaluated as $s = k$. We have

$$\begin{aligned} \mathbf{E}[R] &= \sum_{i\ge 0} i\pi_i = \sum_{i=0}^{m-1} i(p_i - p_{i+1}) + mp_m = \sum_{i=1}^{m} ip_i - \sum_{i=1}^{m}(i-1)p_i \\ &= \sum_{i=0}^{m} p_i, \end{aligned}$$

so (2.1) and (2.3) give

$$F(n,k) = n - \sum_{i=1}^{m}\sum_{j\ge i}\frac{(-k)^j}{j!}\hat{c}^{(j)}(k). \tag{2.4}$$

This formula simplifies when C is a completely monotone distribution or the difference of two such distributions. In this case, C has a density $c(t)$ that can be expressed as

$$c(t) = \int_0^\infty e^{-ts}d\alpha(s) \tag{2.5}$$

for some (signed) measure $\alpha(s)$ which is finite on $[0,\infty)$. Since $\int_0^\infty c(t)dt = 1$, the measure $\alpha(s)$ must satisfy $\int_0^\infty d\alpha(s)/s = 1$. As an example of (2.5) we observe that weighted sums of exponentials (hyperexponential distributions) are completely monotone. In this case $\alpha(s)$ consists of a sequence of point masses, one for each exponential.

From (2.5) we get

$$\begin{aligned} \int_0^\infty e^{-kt}t^j c(t)dt &= \int_0^\infty\int_0^\infty e^{-(k+s)t}t^j dt\, d\alpha(s) \\ &= \int_0^\infty \frac{j!}{(k+s)^j}d\alpha(s); \end{aligned}$$

so by (2.3), $\sum_{i=1}^{m} p_i$ becomes

$$\begin{aligned}\sum_{i=1}^{m}\sum_{j\geq i}\int_0^\infty e^{-kt}\frac{(kt)^j}{j!}c(t)dt &= \int_0^\infty \sum_{i=1}^{m}\sum_{j\geq i}\frac{k^j}{(k+s)^{j+1}}d\alpha(s)\\ &= \int_0^\infty \sum_{i=1}^{m}\left(\frac{k}{k+s}\right)^i\frac{d\alpha(s)}{s}\\ &= \int_0^\infty k\left[1-\left(\frac{k}{k+s}\right)^m\right]\frac{d\alpha(s)}{s^2}.\end{aligned}$$

Then (2.4) reduces to

$$F(n,k) = n - k\int_0^\infty \left[1-\left(\frac{k}{k+s}\right)^{n-k}\right]\frac{d\alpha(s)}{s^2}. \tag{2.6}$$

Note that $1/s^2$ in the integrand causes no difficulties, by virtue of the integrability condition on the measure and the fact that the bracketed term vanishes at $s = 0$.

In general, little insight is provided by (2.4); the computation of $F(n)$ becomes a numerical problem. However, useful information is available from the asymptotic behavior of $F(n,k)$ as $n \to \infty$. Asymptotic estimates can be obtained without reference to (2.4), using only elementary properties of the Poisson distribution. We need the following intuitive, preliminary result.

LEMMA 2.1. *Let $a(\lambda)$ be any function satisfying $a(\lambda)/\lambda \to \mathcal{B}, 0 < \mathcal{B} < \infty$ as $\lambda \to \infty$. Let Y_λ denote a Poisson random variable with parameter λ, and define $\overline{Y}_\lambda$ as Y_λ truncated at $a(\lambda)$, i.e., $\overline{Y}_\lambda = \min\{Y_\lambda, a(\lambda)\}$. Then as $\lambda \to \infty$,*

$$\mathbf{E}[\overline{Y}_\lambda] \sim \begin{cases}\lambda & \text{if } \mathcal{B} \geq 1,\\ a(\lambda) & \text{if } \mathcal{B} \leq 1.\end{cases} \tag{2.7}$$

Proof. If $\mathcal{B} < 1$, choose $\varepsilon > 0$ so that $a(\lambda) < \lambda(1-\varepsilon)$ for all λ sufficiently large. On the set $\{|Y_\lambda - \lambda| < \lambda\varepsilon\}, \overline{Y}_\lambda = a(\lambda)$. Thus, since $\mathbf{E}[\overline{Y}_\lambda] \leq \min\{\lambda, a(\lambda)\} = a(\lambda)$, we have for all λ sufficiently large,

$$a(\lambda)Pr\{|Y_\lambda - \lambda| < \lambda\varepsilon\} \leq \mathbf{E}[\overline{Y}_\lambda] \leq a(\lambda).$$

But $\lim_{\lambda\to\infty} Pr\{|Y_\lambda - \lambda| < \lambda\varepsilon\} = 1$ is a standard property of the Poisson distribution, so (2.7) follows for $\mathcal{B} < 1$.

If $\mathcal{B} > 1$ choose ε so that $a(\lambda) > \lambda(1+\varepsilon)$, and if $\mathcal{B} = 1$ choose ε so that $a(\lambda) > \lambda(1-\varepsilon)$, for all λ sufficiently large. Then in either case $\overline{Y}_\lambda \geq \lambda(1-\varepsilon)$ when $|Y_\lambda - \lambda| < \lambda\varepsilon$, so that

$$\lambda(1-\varepsilon)Pr\{|Y_\lambda - \lambda| < \lambda\varepsilon\} \leq \mathbf{E}[\overline{Y}_\lambda] \leq \lambda,$$

and (2.7) follows for $\mathcal{B} > 1$ as above.

THEOREM 2.1. *For any constant $0 < \theta \leq 1$,*

$$\lim_{n\to\infty}\frac{F(n,\lfloor n\theta\rfloor)}{n} = 1 - \left\{\theta\int_0^{(1-\theta)/\theta} tdC(t) + (1-\theta)\left[1 - C\left(\frac{1-\theta}{\theta}\right)\right]\right\}. \tag{2.8}$$

Proof. From (2.1)

$$\frac{F(n,k)}{n} = \int_0^\infty \left[1 - \frac{\mathbf{E}[R|W=t]}{n}\right] dC(t). \tag{2.9}$$

For $k = \lfloor n\theta \rfloor, [R|W=t]$ is a Poisson random variable with parameter $\lfloor n\theta \rfloor t$ truncated at $n - \lfloor n\theta \rfloor$. By Lemma 2.1, as $n \to \infty$,

$$\frac{\mathbf{E}[R|W=t]}{n} \sim \begin{cases} \theta t & \text{if } t \le \dfrac{1-\theta}{\theta}, \\ 1-\theta & \text{if } t \ge \dfrac{1-\theta}{\theta}. \end{cases} \tag{2.10}$$

Let $n \to \infty$ in (2.9). Since $0 \le \mathbf{E}[R|W=t] \le n$, the dominated convergence theorem along with (2.10) implies (2.8). □

The expression for

$$L(\theta) \equiv \lim_{n\to\infty} \frac{F(n, \lfloor n\theta \rfloor)}{n}$$

is easy to minimize if $C(t)$ has a continuous density $c(t), t \ge 0$. In this case, let $\theta = 1/(1+u)$ and set

$$\hat{L}(u) = L\left(\frac{1}{1+u}\right), u = \frac{1-\theta}{\theta}, 0 \le u < \infty.$$

Then (2.8) becomes

$$\hat{L}(u) = 1 - \frac{1}{1+u}\int_0^u t\, dC(t) - \frac{u}{1+u}[1 - C(u)], \tag{2.11}$$

where $\hat{L}(0) = \hat{L}(\infty) = 1$ and $\hat{L}(u) > 0$ for all $u \ge 0$. We are assuming that $C(t)$ has a continuous derivative $C'(t) = c(t)$ for $t \ge 0$, so

$$\hat{L}'(u) = \frac{1}{(1+u)^2}\left(\int_0^u tc(t)dt - [1 - C(u)]\right). \tag{2.12}$$

Now $\int_0^u tc(t)dt$ is monotone increasing from zero to $\mathbf{E}[W]$ and $1 - C(u)$ is monotone decreasing from 1 to zero. Hence $\hat{L}(u)$ has a unique minimum at $u = u_0$, where $\hat{L}'(u_0) = 0$. The above analysis leads to the following consequence of Theorem 2.1.

COROLLARY 2.1. *If W has a continuous density* $c(t)$, *then* $L(\theta)$ *has a unique minimum at* $\theta_0 = 1/(1+u_0)$, *where* u_0 *is the solution to*

$$\int_0^{u_0} tc(t)dt = [1 - C(u_0)]. \tag{2.13}$$

Hence, by (2.8),

$$L(\theta_0) = C\left(\frac{1-\theta_0}{\theta_0}\right) = C(u_0).$$

For distributions C without continuous densities, it may still be possible to obtain $\inf_{0\le\theta\le 1} L(\theta)$. An important example, to which we return in §5, occurs when W is a constant.

Trivially, the constant=k policy supplies the upper bound $E(n) \le F(n, \lfloor n\theta_0 \rfloor)$, where θ_0 minimizes $L(\theta)$ and $E(n)$ is the expected cost of an optimal policy. This fact is exploited in §5, where the asymptotic optimality of the constant-k policy is proved for the case of constant clock times.

3. Exponential clock. This section shows that optimal policies are constant-k policies when W is exponentially distributed. We let $\mu > 0$ be the parameter of the distribution, $C(t) = 1 - e^{-\mu t}, t \ge 0$. Before getting into the analysis we introduce two problem reductions.

First, it is easy to see that we may confine ourselves to policies that always assign a waiting job, if any, to a processor that has just completed a job, i.e., there is always an optimal policy in the class defined by this property. This observation applies no matter what clock and service time distributions are assumed. But under our exponential assumptions, if we ignore events with probability zero (in particular, simultaneous job completions), it is clear that this "replenishing" property is in fact mandatory in an optimal policy whenever there are two or more waiting jobs. If there is only one job waiting at the time some processor completes a job, then the waiting job can be assigned to this processor immediately or at any subsequent time no later than W.

Our second observation exploits the memoryless property of the exponential distributions for W and T, and it states that the decisions of an optimal policy can be restricted to job completion times. Furthermore, for the Markov decision process underlying our optimization problem, a sufficient state is (n, k), where n is the number of unfinished jobs and k is the number of jobs currently assigned to processors. Based on this fact, it is easy to develop a Bellman equation for the cost $E(n, k)$ of an optimal policy starting in state (n, k). When in state $(n, k), 1 \le k < n$, either initially or at some job completion time, an optimal policy can assign a waiting job to an available machine and then proceed optimally, or it can wait until the next job departure or until the bell rings, whichever comes first. As part of the first choice, the term "proceed optimally" includes those situations where $j > 1$ jobs are allocated before continuing to run jobs in state $(n-j, k+j)$. If the second choice is made, a job will depart first with probability $k/(k + \mu)$, while the bell will ring first with probability $\mu/(k + \mu)$. If a job leaves first, then the machine on which the completion occurs is replenished with a waiting job, if any. Then for any given $n \ge 1$ we can write

$$\begin{aligned} &E(n,k) = \min\left\{E(n,k+1), \frac{k}{k+\mu}E(n-1,k) + \frac{\mu n}{k+\mu}\right\}, \qquad 1 \le k < n < \infty \\ &E(n,n) = n, \end{aligned} \tag{3.1}$$

where the first and second terms in braces account for the first and second choices, respectively. A routine induction on $n - k$ shows that (3.1) has a unique solution for any $n \ge 1$. The cost of an optimal policy is computed from $E(n) = \min_{1\le k\le n} E(n, k)$.

With respect to (3.1) the following terminology is useful. We say that state (n, k) is *stable* if and only if

$$E(n,k) = \frac{k}{k+\mu}E(n-1,k) + \frac{\mu}{k+\mu}n < E(n,k+1). \tag{3.2}$$

That is, an optimal policy in state (n,k) must continue running jobs in that state. State (n,k) is *unstable* if and only if

$$E(n,k) = E(n,k+1) < \frac{k}{k+\mu}E(n-1,k) + \frac{\mu}{k+\mu}n, \tag{3.3}$$

so that an optimal policy must assign at least one more job before continuing to run jobs. State (n,k) is *semistable* if and only if

$$E(n,k) = E(n,k+1) = \frac{k}{k+\mu}E(n-1,k) + \frac{\mu}{k+\mu}n, \tag{3.4}$$

so an optimal policy in state (n,k) has both of the above options.

It is appropriate to define the state (n,n) as stable, since no new assignments are possible in this state. Note also that (3.2) and $E(n,n) = n$ imply that $(n, n-1), n > 1$ is stable, i.e., the worst possible cost $(n > 1)$ is never incurred unless forced by the bell.

Our objective is a result (Theorem 3.1) that not only determines an optimal policy, but also decides the uniqueness question and classifies each state as stable, semistable, or unstable. For this purpose we need three lemmas. The existence of an optimal constant-k policy follows easily from the first lemma, as the second lemma will show.

LEMMA 3.1. *If $k \le n-1$ and state (n,k) is stable or semistable, then $(n-1,k)$ is stable.*

Proof. The result is immediate for $k = n-1$; so assume that $k < n-1$. We first observe that (3.2), (3.4), and the assumptions of the lemma imply

$$E(n,k) = \frac{k}{k+\mu}E(n-1,k) + \frac{\mu}{k+\mu}n \le E(n,k+1). \tag{3.5}$$

From the Bellman equation (3.1),

$$E(n,k+1) \le \frac{k+1}{k+1+\mu}E(n-1,k+1) + \frac{\mu}{k+1+\mu}n. \tag{3.6}$$

Now substitute the right-hand side of (3.6) in (3.5) and rearrange to obtain

$$E(n-1,k+1) \ge \frac{1}{(k+1)(k+\mu)}[k(k+1+\mu)E(n-1,k) + \mu n]. \tag{3.7}$$

But $n > E(n-1,k)$. So on substitution into (3.7), we get $E(n-1,k+1) > E(n-1,k)$, which means that $(n-1,k)$ is stable. □

Next, we relate $E(n,k)$ to $F(n,k)$, defined in §2 for the constant-k policy. Observe that $E(n,k) \le F(n,k)$ for all n and k, by definition of $E(n,k)$.

LEMMA 3.2. (a) *If (n,k) is stable or semistable, then $E(n,k) = F(n,k)$, and, furthermore, the constant-k policy is the unique optimal policy among those policies which begin running jobs in state (n,k).*

(b) *Conversely, if $E(n,k) = F(n,k)$, then (n,k) is either stable or semistable.*

(c) $E(n,k) = \min_{k\le j\le n} F(n,j)$.

Proof. To prove part (a), consider an optimal policy for any fixed n. Clearly, the policy must begin by running some subset of $l > 1$ jobs, where the corresponding state (n,l) is stable or semistable. Thereafter, provided the bell does not ring, the next state transition will occur at a job completion and have the form $(n,l) \to (n-1,l)$, where we have accounted for the fact that the machine just finishing a job is replenished. But state

$(n-1, l)$ is stable by Lemma 3.1, so the policy must continue running jobs in this state with one fewer waiting job. Repeating this reasoning shows that the decisions of the given optimal policy must be precisely those of a constant-k policy with $k = 1$. Part (a) follows easily. For part (b), we may assume that $k < n$. We are assuming $E(n, k) = F(n, k)$, so we can write

$$\frac{k}{k+\mu}E(n-1,k)+\frac{\mu}{k+\mu}n$$
$$\geq E(n,k) = F(n,k) = \frac{k}{k+\mu}F(n-1,k)+\frac{\mu}{k+\mu}n \geq \frac{k}{k+\mu}E(n-1,k)+\frac{\mu}{k+\mu}n,$$

and hence

$$E(n,k) = \frac{k}{k+\mu}E(n-1,k)+\frac{\mu}{k+\mu}n.$$

But this means (n, k) is stable or semistable so part (b) is proved.

For part (c) we may again assume $k < n$. Define the integer l such that $E(n, k) = E(n, k+1) = \cdots = E(n, l) < E(n, l+1)$ where $k \leq l < n$. Thus (n, l) is stable. By part (a),

$$E(n,k) = E(n,l) = F(n,l) \geq \min_{k\leq j\leq n} F(n,j). \tag{3.8}$$

For fixed n and $k \leq j \leq n$, let $F(n, j)$ attain its minimum at $j = j_0$. One possible policy starting out from state (n, k) is to transit to (n, j_0) and then apply the *constant-*j_0 policy. The expected cost of this policy is $F(n, j_0)$, so that

$$E(n,k) \leq F(n,j_0) = \inf_{k\leq j\leq n} F(n,j). \tag{3.9}$$

Inequalities (3.8) and (3.9) give $E(n, k) = \min_{k\leq j\leq n} F(n, j)$ as desired. □

To deal with the uniqueness problem, we analyze an explicit formula for $F(n, k)$. Choosing $\alpha(s)$ of (2.5) to have unit mass concentrated at $s = \mu$, so as to obtain the density $c(t) = \mu e^{-\mu t}, t \geq 0$, we find easily from (2.6),

$$F(n,k) = n - \frac{k}{\mu}\left[1-\left(\frac{k}{k+\mu}\right)^{n-k}\right], \qquad 1 \leq k \leq n. \tag{3.10}$$

Let

$$k_n = \max\{1 \leq k \leq n : F(n,k) = F(n)\} \tag{3.11}$$

denote the largest value of k for which $F(n, k)$ attains its minimum as a function of k with n held fixed. From (3.10), we obtain $F(n, k) < F(n, n)$ for $1 \leq k \leq n-1$, so that $k_n < n$ for $n > 1$.

LEMMA 3.3. *For fixed n, $F(n, k)$ is unimodal in k and attains its minimum at either one or two consecutive values of k, i.e., at just k_n, or at just k_n and $k_n - 1$.*

Proof. Replace k in (3.10) by the continuous variable x, $1 \leq x \leq n$, and with n fixed, write $F(x) = n - f(x)/\mu$, where

$$f(x) = x\left[1-\left(\frac{x}{x+\mu}\right)^{n-x}\right]. \tag{3.12}$$

We show that $f''(x) < 0$ and hence $F''(x) > 0, 1 \leq x \leq n$; the lemma then follows easily. Let $h(x) = (n-x)\log x/(x+\mu)$ so that $f(x) = x[1-e^{h(x)}]$. To prove that $f''(x) < 0$, it is enough to show that $2h'(x) + xh''(x) > 0$ in

$$f''(x) = -e^{h(x)}[2h'(x) + x(h'(x))^2 + xh''(x)].$$

Routine calculations give

$$2h'(x) + xh''(x) = \frac{(n-x)\mu^2}{x(x+\mu)^2} - 2\left\{\log\left(1 - \left[\frac{\mu}{x+\mu}\right]\right) + \frac{\mu}{x+\mu}\right\}.$$

The first term is clearly nonnegative for $1 \leq x \leq n$, and the bracketed term is negative, since $\log(1-z) + z < 0$ for $z = \mu/(x+\mu) < 1$. Thus $f''(x) < 0$ and $F''(x) > 0$, $1 \leq x \leq n$. □

We are now in position for the main result.

THEOREM 3.1. (a) *For any* $n \geq 1$,

$$(3.13) \qquad E(n,k) = \begin{cases} F(n,k) & \text{if } k \geq k_n, \\ F(n,k_n) & \text{if } k \leq k_n. \end{cases}$$

(b) (n,k) *is stable for* $k \geq k_n$ *and unstable for* $k \leq k_n - 2$. *If, for fixed* n, $F(n,k)$ *has a unique minimum at* $k = k_n \geq 2$, *then* $(n, k_n - 1)$ *is also unstable; otherwise it is semistable.*

(c) *If, for fixed* n, $F(n,k)$ *has a unique minimum at* k_n, *then the constant-k policy with* $k = k_n$ *is the unique optimal policy. Otherwise there are exactly two optimal policies, viz, the constant-k policies with* $k = k_n$ *and* $k = k_n - 1$.

Proof. Part (a) follows directly from Lemmas 3.2 and 3.3. To prove part (b), we may assume that $k < n$. For $k \geq k_n$, we have $E(n,k) = F(n,k) < F(n,k+1) = E(n,k+1)$. Here (n,k) is stable for $k \geq k_n$. For $k \leq k_n - 2, E(n,k) < F(n,k)$. By Lemma 3.2(a), (n,k) is thus unstable. Similarly, if $F(n,k)$ attains a unique minimum at k_n, then $E(n,k_n-1) < F(n,k_n-1)$, and so (n,k_n-1) is also unstable. Otherwise, $E(n,k_n-1) = F(n,k_n-1)$ and by Lemma 3.2(b) (n,k_n-1) is either stable or semistable. As $E(n,k_n-1) = E(n,k_n)$, we conclude that (n,k_n-1) is semistable.

For part (c), we observe that the initial states for which $E(n)$ is attained must either be stable or semistable. Hence by part (b) and Lemma 3.2(a), the only optimal policies executing initially in these states are the corresponding constant-k policies.

4. Analysis of k_n. This section studies k_n as a function of both n and μ. We begin by fixing μ and describing the behavior of k_n as n increases.

THEOREM 4.1. k_n *is an increasing function of* n.

Proof. State (n,k_n) is stable and, by Lemma 3.1, so is $(n-1,k_n)$. It follows from Theorem 3.1(b) that $k_n \geq k_{n-1}$. □

Corollary 2.1, together with a uniform version of Theorem 2.1, furnishes asymptotic estimates for the present model. With $C(t) = 1 - e^{-\mu t}, t \geq 0$, these results imply that as $n \to \infty, k_n \sim \mu/(\mu + x(\mu))n$ and $E(n) \sim [1 - e^{-x(\mu)}]n$, where $x(\mu)$ is the unique positive root of $e^x - x - 1 = \mu$. We do not present the details of the proof, as a more detailed analysis is possible for this case which yields the following stronger result.

THEOREM 4.2. *As* $n \to \infty$,

$$(4.1) \qquad k_n = \frac{\mu}{\mu + x(\mu)}n + O(1)$$

and

$$E(n) = [1 - e^{-x(\mu)}]n + O(1). \tag{4.2}$$

Proof. For given n, k_n is the largest k for which

$$H(n,k) \equiv \mu[n - F(n,k)] = k\left[1 - \left(\frac{k}{k+\mu}\right)^{n-k}\right], \qquad 1 \le k \le n,$$

attains its maximum. Let $H(n, n\theta) = nf_n(\theta)$, where $k = n\theta$ and

$$f_n(\theta) = \theta\left[1 - \left(1 + \frac{\mu}{n\theta}\right)^{n(\theta-1)}\right], \qquad 0 < \theta \le 1.$$

Then k_n may be expressed as $k_n = n\theta_n + O(1)$, where $f_n'(\theta_n) = 0$ defines θ_n.

Write

$$f_n(\theta) = \theta\left[1 - e^{n(\theta-1)\log(1+(\mu/n\theta))}\right],$$

and then expand $\log(1 + (\mu/n\theta))$ in powers of $\mu/(n\theta)$. It is easily verified that, for any constant $\gamma, 0 < \gamma < 1$,

$$f_n(\theta) = f(\theta) + O\left(\frac{1}{n}\right), \quad f_n'(\theta) = f'(\theta) + O\left(\frac{1}{n}\right) \tag{4.3}$$

uniformly on $[\gamma, 1]$, where

$$f(\theta) = \theta[1 - e^{-h(\theta)}], \quad h(\theta) = \mu(\theta^{-1} - 1). \tag{4.4}$$

Differentiation formulas give $f'' > 0$ on $(0, 1]$ with $f'(0+) > 0$, and $f'(1) < 0$. Hence $f'(\theta) = 0$ has a unique root in $(0, 1]$, say, at θ_*. Choose $0 < \gamma < \theta_*$. By (4.3), for n sufficiently large, $0 < \gamma < \theta_n$ and $f'(\theta_*) - f'(\theta_n) = O(1/n)$. An application of the mean value theorem to f' then gives $\theta_n = \theta_* + O(1/n)$; so from $k_n = n\theta_n + O(1)$, we get $k_n = n\theta_* + O(1)$. By (4.4), $\theta_* = \mu/[\mu + h(\theta_*)]$; so

$$f'(\theta_*) = 1 - e^{-h(\theta_*)} + \theta_* h'(\theta_*)e^{-h(\theta_*)} = 1 - \left(1 + \frac{\mu}{\theta_*}\right)e^{-h(\theta_*)} = 0 \tag{4.5}$$

implies $e^{h(\theta_*)} - h(\theta_*) - 1 = \mu \Rightarrow h(\theta_*) = x(\mu)$. Together with $k_n = n\theta_* + O(1)$, this proves (4.1).

Substituting $k_n = n\theta_* + O(1)$ into (4.3) shows that

$$H(n, k_n) = nf_n\left(\frac{k_n}{n}\right) = nf_n\left(\theta_* + O\left(\frac{1}{n}\right)\right) = n\left[f(\theta_*) + O\left(\frac{1}{n}\right)\right];$$

so

$$\begin{aligned} E(n) &= n - \frac{1}{\mu}H(n,k_n) = \left[1 - \frac{f(\theta_*)}{\mu}\right]n + O(1) \\ &= \left[1 - \frac{\theta_*}{\mu}(1 - e^{-h(\theta_*)})\right]n + O(1). \end{aligned} \tag{4.6}$$

By (4.5), $1 - e^{-h(\theta_*)} = \mu e^{-h(\theta_*)}/\theta_*$; so on substitution into (4.6) we prove (4.2). □

Finally, we describe k_n as a function of μ. For $n = 1, 2$, we readily check that $k_n(\mu) = 1$; so we assume $n > 2$. First, we need the following property of

$$H(n,k,\mu) = k\left[1 - \left(\frac{k}{k+\mu}\right)^{n-k}\right].$$

LEMMA 4.1. *For given n and $1 \le k \le n-2$, the equation $H(n,k,\mu) = H(n,k+1,\mu)$ has exactly one root. Denoting this root by μ_k, we have*

$$H(n,k,\mu) > H(n,k+1,\mu), \qquad 0 < \mu < \mu_k,$$
$$H(n,k,\mu) < H(n,k+1,\mu), \qquad \mu > \mu_k.$$

Proof. Let $H'(n,k,\mu)$ denote the derivative with respect to μ. Then

$$H'(n,k,\mu) = \left(\frac{k}{k+\mu}\right)^{n-k+1}(n-k) > 0. \tag{4.7}$$

From the formulas for H and H',

$$H(n,k,0) = 0, \quad H(n,k,\infty) = k, \quad H'(n,k,0) = n-k. \tag{4.8}$$

We conclude that $D(n,k,\mu) = H(n,k,\mu) - H(n,k+1,\mu), 1 \le k \le n-2$, is positive for all μ sufficiently small and negative for all μ sufficiently large. Let μ_k denote the smallest zero of D. Then $D(n,k,\mu) > 0, 0 < \mu < \mu_k$, and it remains to show that $D(n,k,\mu) < 0, \mu > \mu_k$. For $\mu > \mu_1$, the function $(x+\mu_k)/(x+\mu)$ is strictly increasing in $x > 0$; so

$$\frac{H'(n,k+1,\mu)}{H'(n,k+1,\mu_k)} = \left(\frac{k+1+\mu_k}{k+1+\mu}\right)^{n-k} > \left(\frac{k+\mu_k}{k+\mu}\right)^{n-k+1} = \frac{H'(n,k,\mu)}{H'(n,k,\mu_k)}.$$

Also $D(n,k,\mu) > 0$ on $(0,\mu_k)$ implies $D'(n,k,\mu_k) \le 0$, which means

$$H'(n,k+1,\mu_k)/H'(n,k,\mu_k) \ge 1;$$

so

$$H'(n,k+1,\mu) > \frac{H'(n,k+1,\mu_k)}{H'(n,k,\mu_k)}H'(n,k,\mu) \ge H'(n,k,\mu),$$

whereupon an integration yields $D(n,k,\mu) < 0$ for $\mu > \mu_k$. □

THEOREM 4.3. *Let $\mu_k, 1 \le k \le n-2$, be defined as in Lemma 4.1, and define $\mu_0 = 0, \mu_{n-1} = \infty$. Then $\mu_0 < \mu_1 < \mu_2 < \cdots < \mu_{n-2} < \mu_{n-1}$ and in $(\mu_{k-1}, \mu_k), 1 \le k \le n-1$, we have $k_n(\mu) = k$, i.e., as μ increases, $k_n(\mu)$ increases from 1 to $n-1$ and assumes all intermediate values.*

Proof. Fix n and let $1 \le k \le n-1, 0 < \mu < \infty$. Since $F(n,k,\mu) = n - H(n,k,\mu)/\mu$, we conclude from (3.10) and (4.8) that $F(n,1,\mu) < F(n,2,\mu) < \cdots < F(n,n-1,\mu)$ for all μ sufficiently small, and $F(n,1,\mu) > F(n,2,\mu) > \cdots > F(n,n-1,\mu)$ for all μ sufficiently large. Thus, $k_n(\mu) = 1$ and $k_n(\mu) = n-1$ for all μ sufficiently small and large, respectively. This gives $F(n,1,\mu) < \min_{2 \le k \le n-1} F(n,k,\mu)$ for μ sufficiently small and the reverse inequality for μ sufficiently large. Let $\hat{\mu}_1$ be the smallest μ for which

$F(n,1,\mu) = \min_{2\leq k\leq n-1} F(n,k,\mu)$, so that $k_n(\mu) = 1, 0 < \mu < \hat{\mu}_1$. By Lemma 3.3 we must then have $F(n,1,\hat{\mu}_1) = F(n,2,\hat{\mu}_1) < \cdots < F(n,n-1,\hat{\mu}_1)$. Together with Lemma 4.1, this implies $\hat{\mu}_1 = \mu_1$ and $F(n,1,\mu) > F(n,2,\mu), \mu > \mu_1$, and thus for $\mu > \mu_1$, that k rendering $F(n,k,\mu)$ smallest will be at least 2, and exactly 2 near μ_1. Repeating the above reasoning yields the theorem. □

We remark that for given n and $\mu \in (\mu_{k-1}, \mu_k), F(n,j,\mu)$ assumes a minimum at $j = k$ only. For such μ, the constant-k policy is the only optimal policy. For $\mu = \mu_k, 1 \leq k \leq n-2, F(n,j,\mu)$ assumes a minimum at $j = k, k+1$. In this case, there are exactly two optimal policies, viz the constant-k and $k+1$-policies.

5. Constant clock. It is easy to anticipate that the constant-clock case is likely to be more difficult than the exponential-clock case. We only have to observe that (n,k) is no longer a sufficient state for the Markov decision process; with a constant clock we need in addition to (n,k) an indication of how long the clock has to run, or equivalently, how long it has already run. However, we can describe the asymptotic behavior of an optimal policy. We do this by proving a lower bound on the expected cost incurred by any policy, and then observing that the expected cost of the best constant-k policy converges to this lower bound as $n \to \infty$. Thus, while the constant-k policies are not optimal in general, they are asymptotically optimal in the above sense.

After the asymptotic result we will present conjectures and partial results for the general problem. The analysis will identify what lies at the heart of the open optimization problem. This material is further motivated by the fact that the numerical evaluation of the Bellman equation (see (5.6)) gives convincing evidence that the conjectures are true.

A lower bound. Let $C(t)$ be an arbitrary distribution, and define the function

$$\Phi(u) = \frac{C(u) - \int_u^\infty t\,dC(t)}{1+u}, \qquad u \geq 0. \tag{5.1}$$

It is easy to see that $\Phi(u)$ is bounded and positive for all u sufficiently large, so $\sup_{u\geq 0} \Phi(u) > 0$. The result below is our sole generalization to other than exponential service times.

THEOREM 5.1. *Let the distribution of T have a monotone nondecreasing hazard-rate function, and assume as before that $E[T] = 1$. Then $E(n)/n \geq \sup_{u\geq 0} \Phi(u)$.*

Proof. Let M denote the maximum number of processors used throughout the schedule. An area argument yields the inequality

$$\sum_{i=1}^{n} T_i \leq MW + \sum_{i=1}^{K} T_i',$$

where $K \leq M$ is the number of active machines just before the bell rings, and where the $T_i', 1 \leq i \leq K$, denote the residual times of the jobs running on these machines ($\sum_{i=1}^K T_i'$ is defined to be zero when $K = 0$). Taking expectations,

$$n = E\left[\sum_{i=1}^{n} T_i\right] \leq E[MW] + E\left[\sum_{i=1}^{K} T_i'\right]. \tag{5.2}$$

To simplify (5.2), we prove next that

$$E\left[\sum_{i=1}^{K} T_i'\right] \leq E[K],$$

a result that would be trivial if K were independent of T_i' for all i. But the inequality is easy to prove in any case. Let $\mathcal{X}(A)$ be the indicator function of event A, and define $\mathcal{X}_k = \mathcal{X}(K = k), 0 \le k \le n$. Also, let $T_i'', 1 \le i \le K$, be the elapsed time of the job whose remaining time is T_i'. Then

$$(5.3)\qquad E\left[\sum_{i=1}^{K} T_i'\right] = E\left[\sum_{k=1}^{n} \mathcal{X}_k \sum_{i=1}^{k} T_i'\right] = \sum_{k=1}^{n}\sum_{i=1}^{k} E[\mathcal{X}_k T_i']$$

and

$$E[\mathcal{X}_k T_i'] = EE[\mathcal{X}_k T_i' | \mathcal{X}_k, T_i''] = E[\mathcal{X}_k E(T_i' | \mathcal{X}_k, T_i'')].$$

But given T_i'', T_i' is independent of $\mathcal{X}_k$; so $E[\mathcal{X}_k T_i'] = E[\mathcal{X}_k E(T_i' | T_i'')]$. Also, $E[T_i' | T_i''] \le E[T] = 1$, since T's distribution is hazard-rate-nondecreasing. Then $E[\mathcal{X}_k T_i'] \le E[\mathcal{X}_k]$, whereupon substitution into (5.3) gives

$$E\left[\sum_{i=1}^{K} T_i'\right] \le \sum_{k=1}^{K} kE[\mathcal{X}_k] = E[K],$$

as desired.

Since $K \le M$, we can now return to (5.2) and write

$$(5.4)\qquad n \le E[MW] + E[M] = E[M(W+1)].$$

But for any $u \ge 0$, we have

$$(5.5)\qquad \begin{aligned} E[M(W+1)] &= E[M(W+1)\mathcal{X}(W \le u)] + E[M(W+1)\mathcal{X}(W > u)] \\ &\le (1+u)E[M] + n\int_u^{\infty} (1+t)dC(t). \end{aligned}$$

The desired bound on $E(n) = E[M]$, valid for optimal schedules, follows easily from (5.1), (5.4), and (5.5). □

It follows at once from Theorem 5.1 that $E(n) \le n$ is bounded from below by a linear function of n for all n sufficiently large. Returning to our exponential service-time distribution, we can now prove the optimality result promised earlier.

THEOREM 5.2. *Let the clock time be a constant s. Then the constant-k policy is asymptotically optimal in the sense that, with*

$$k = \left\lfloor \frac{n}{1+s} \right\rfloor,$$

$$\frac{n}{1+s} \le E(n) \le F(n,k) = \frac{n}{1+s} + o(n) \text{ as } n \to \infty.$$

Proof. The lower bound follows from Theorem 5.1. The asymptotic expression for $F(n,k)$ is obtained directly from Theorem 2.1, since the right-hand side of (2.8) equals $1/(1+s)$ when $\theta = 1/(1+s)$. □

The general problem. Assuming a constant clock time, and exponentially distributed service times T with $E[T] = 1$, a Markov decision process can be defined on the set of states (n, k, s), where n and k have their earlier meanings and where s is the time remaining on the clock. Define $E(n, s) = \min_{1\leq k\leq n} E(n, k, s)$ as the expected cost incurred by an optimal policy in scheduling n jobs with s time units on the clock and all machines initially available. $E(n, k, s)$ can be computed from the following Bellman equation:

(5.6)
$$E(n,k,s) = \inf_{0\leq t\leq s}\left\{e^{-kt}E(n,k+1,s-t) + \int_0^t ke^{-ku}E(n-1,k,s-u)du\right\}, \qquad k < n,$$
$$E(n,n,s) = n.$$

The second of these equations is obvious. The recurrence in the first equation is derived as follows. In state (n, k, s) the scheduler must choose one of a continuum of actions $P_t, 0 \leq t \leq s$. P_t means: Begin the k jobs on k machines at time zero. If none of these jobs finishes by time t, then start a new job on a $(k+1)$th machine and proceed optimally thereafter. If at least one job finishes by time t, say this occurs first at time u, then replenish the just finishing machine with a new job and proceed optimally thereafter. The expected number of machines used under P_t is the expression inside the brackets of (5.6). Minimizing over t yields the cost of the optimal policy.

The following elementary properties of $E(n, k, s)$ are intuitive and easily derived from the Bellman equation. We omit the proofs.

LEMMA 5.1. (a) $E(n, k, 0) = n, E(n, k, \infty) = k$.

(b) *$E(n, k, s)$ is nondecreasing in k for fixed n and s, strictly increasing in n for fixed k and s, and strictly decreasing in s for fixed n and $k < n$.*

Graphs of $E(n, k, s)$ suggested by numerical evaluations of the Bellman equation are sketched in Fig. 1. The key properties of the curves in Fig. 1 are expressed in the following assertion.

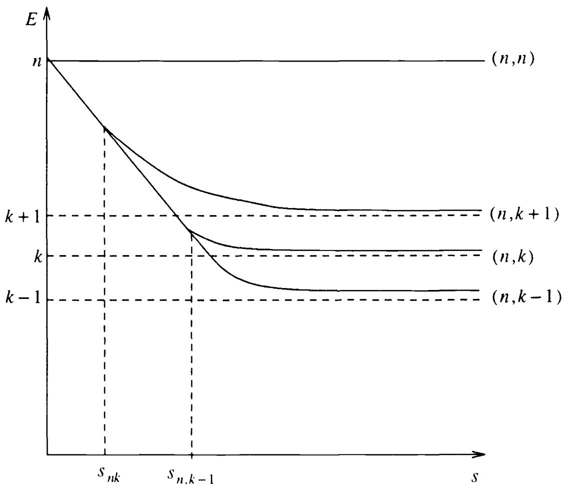

FIG. 1. *Graph of $E(n, k, s)$.*

CONJECTURE. *For each $n > 1$ there exist nonnegative numbers $s_{nk}, 1 \leq k \leq n-1$, such that*

(5.7) $E(n, k+1, s) = E(n, k, s), s \leq s_{nk}$; $E(n, k+1, s) > E(n, k, s)$, $s > s_{nk}$, (5.8) $$s_{n,n-1} < s_{n,n-2} < \cdots < s_{n1}.$$

Since a state in which $k = n-1$ must be stable, as in §3, we have $s_{n,n-1} = 0$. Unfortunately, we have been unable to prove this assertion; it remains a conjecture supported by numerical evaluations of (5.6). The remainder of this section proves the following result, which shows how (5.7) and (5.8) determine the structure of an optimal policy.

THEOREM 5.3. *The relations in* (5.7) *and* (5.8) *imply*

(5.9) $$s_{n-1,k} < s_{n,k}, \quad 1 \le k \le n-2,$$

and hence the following structure of an optimal policy.

Let the initial state have $n > 1$ jobs to be scheduled, an unlimited number of machines available, and a clock time s such that $s_{nk} < s \le s_{n,k-1}$ for some $1 \le k \le n-1$. Then assign jobs to k machines and start running jobs in state (n, k, s). Continue running jobs in any given state until one of the following three events occur: (1) *The bell rings: in this case assign the $n-k \ge 0$ waiting jobs to new machines.* (2) *A machine completes a job in some state (n', k', s'), $k' < n'$; in this case replenish the machine and continue in state $(n'-1, k', s')$.* (3) *A state (n', k', s'), $k' < n'$, is reached in which the remaining clock time has reduced to $s' = s_{n'k'}$; in this case assign a waiting job to a new machine and continue in state $(n', k'+1', s')$.*

We remark that (2) is a direct consequence of Theorem 5.3 and (3) a direct consequence of the assertion made in (5.7), (5.8).

Before proving the theorem, we need a preliminary result. Define

(5.10) $$B(n,k,s) = e^{ks}E(n,k+1,s) - \int_0^s ke^{k\tau}E(n-1,k,\tau)d\tau.$$

Introducing $B(n,k,s)$ into (5.6) gives

(5.11) $$E(n,k,s) = E(n,k+1,s) - e^{-ks}\left[B(n,k,s) - \inf_{0\le t\le s} B(n,k,t)\right].$$

LEMMA 5.2. *The relations in* (5.7) *and* (5.8) *imply that $E(n,k,s)$ is continuously differentiable with respect to s for all $1 \le k < n < \infty$ and $0 < s < \infty$. In addition,*

(5.12) $$E'(n,k,s) + kE(n,k,s) \le kE(n-1,k,s),$$

with equality for $s \ge s_{nk}$.

Proof. The proof is by induction on $n-k$, the number of waiting jobs. The assertions of the lemma are readily verified for $n-k \le 1$; so assume $n-k \ge 2$. Differentiating (5.10) we get

(5.13) $$B'(n,k,s) = e^{ks}[E'(n,k+1,s) + kE(n,k+1,s) - kE(n-1,k,s)].$$

In view of (5.11), we may rewrite (5.7) as

(5.14) $$B'(n,k,s) < 0 \text{ for } s < s_{nk}, \text{ and } B(n,k,s) > B(n,k,s_{nk}) \quad \text{for } s > s_{nk},$$

so that $B'(n,k,s_{nk}) = 0$. Then (5.13), (5.14), and the inductive hypothesis give

(5.15) $$E'(n,k,s) \le -kE(n,k,s) + kE(n-1,k,s) \quad \text{for } s \le s_{nk},$$

with equality at $s = s_{nk}$, where $E'(n, k, s)$ is interpreted as a left derivative at $s = s_{nk}$. By (5.11) and (5.14),

$$E(n,k,s) = E(n,k+1,s) - e^{-ks}[B(n,k,s) - B(n,k,s_{nk})]$$
$$= E(n,k,s_{nk})e^{-k(s-s_{nk})} + \int_{s_{nk}}^{s} ke^{-k(s-\tau)}E(n-1,k,\tau)d\tau, \qquad s \geq s_{nk}.$$

Differentiating, we get

$$(5.16) \qquad E'(n,k,s) = -kE(n,k,s) + kE(n-1,k,s), \qquad s \geq s_{nk},$$

where $E'(n, k, s)$ is interpreted as a right derivative at $s = s_{nk}$. The lemma follows from (5.15) and (5.16). □

Proof of Theorem 5.3. From (5.12) and (5.13) we obtain for $0 \leq s \leq s_{n-1,k}$,

$$B'(n,k,s) = e^{ks}[E'(n,k+1,s) + kE(n,k+1,s) - kE(n-1,k+1,s)]$$
$$\leq e^{ks}[(k+1)E(n-1,k+1,s) - (k+1)E(n,k+1,s)]$$
$$+[kE(n,k+1,s) - kE(n-1,k+1,s)]$$
$$= e^{ks}[E(n-1,k+1,s) - E(n,k+1,s)] < 0.$$

Thus $B(n, k, s)$ is strictly decreasing for $0 < s \leq s_{n-1,k}$, and we conclude from (5.11) that $s_{nk} > s_{n-1,k}$.

Finally, it is easily seen that the relations in (5.7)–(5.9) imply the optimality of the policy given in the theorem. □

6. Final remarks. The main contributions have been a solution to the stochastic machine minimization problem under exponential assumptions, a detailed analysis of the constant-k policy, and a proof that this policy is asymptotically optimal in the case of exponential service and hard deadlines. The most tantalizing open problem is finding a proof of the optimality of the policy defined in Theorem 5.3 for hard deadlines. The optimality of the constant-k policy for distributions $C(t)$ with nonincreasing hazard rates is also a conjecture worth investigating. However, in addition to more general distributional assumptions, there are many other interesting avenues of further research, e.g., machines of different speeds, and jobs with precedence constraints are useful extensions of the structure of the problem.

A special case of some importance is the assumption of constant service times. Here, it can be proved that the constant-k policy is optimal for all clock-time distributions. In general, the analysis is in the same spirit as that in §§3 and 4. However, the peculiarities of the problem and the greater generality of the result alter and extend the arguments in certain ways. As a result, a comprehensive analysis is well beyond the scope of this paper. The authors plan to include this analysis in a future publication.

AN ON-LINE SCHEDULING HEURISTIC WITH BETTER WORST CASE RATIO THAN GRAHAM'S LIST SCHEDULING*

GÁBOR GALAMBOS† AND GERHARD J. WOEGINGER‡

Abstract. The problem of on-line scheduling a set of independent jobs on m machines is considered. The goal is to minimize the makespan of the schedule. Graham's List Scheduling heuristic [R. L. Graham, *SIAM J. Appl. Math.*, 17(1969), pp. 416–429] guarantees a worst case performance of $2 - \frac{1}{m}$ for this problem. This worst case bound cannot be improved for $m = 2$ and $m = 3$. For $m \geq 4$, approximation algorithms with worst case performance at most $2 - \frac{1}{m} - \varepsilon_m$ are presented, where ε_m is some positive real depending only on m.

AMS(MOS) subject classifications. 90B35, 90C27

1. Introduction.

We consider the problem of on-line scheduling a list $\{J_1, \ldots, J_n\}$ of n jobs nonpreemptively on m identical machines $\{M_1, \ldots, M_m\}$. Each job J_i has a fixed processing time p_i. The jobs may be processed in any order. Our goal is to minimize the makespan, i.e., the maximum completion time over all jobs in a schedule. This problem obviously is NP-hard. So we are interested in heuristics that produce "rather" good approximate solutions. The quality of a heuristic H is measured by its worst case ratio

$$R^H(m) = \limsup\{C^H(L)/C^*(L) : L \text{ is a list of jobs}\}, \tag{1}$$

where $C^H(L)$ denotes the makespan produced by the heuristic on m machines and the list L of jobs and $C^*(L)$ denotes the corresponding makespan in some optimum schedule. The jobs are given to us *on-line*, that means we get the jobs one by one and must immediately decide by which machine the job is processed. Once a job is assigned to its machine, we are not allowed to move the job to another machine.

In 1969, Graham [2] suggested a simple heuristic to solve this on-line problem, *List Scheduling* (*LS* for short). This heuristic always assigns a job to the machine that has the minimum load at the moment. Graham showed that *LS* constructs a schedule with makespan at most $2 - \frac{1}{m}$ times the optimum makespan. Until now there was no heuristic known with better worst case ratio. This was mentioned as an open problem by Faigle, Kern, and Turán [1].

In this paper, for $m \geq 4$ machines we present a heuristic that has a slightly better worst case performance guarantee than *LS*. Contrary to the simple formulation of Graham's heuristic, the behaviour of our heuristic depends on the number m of machines and the processing time of the job that has to be scheduled next. Thus, by exploiting more information than *LS* does, we are able to improve on the antique $2 - \frac{1}{m}$ worst case bound. For the average performance, numerical tests indicate that the gain in the worst case ratio is *not* paid by a loss in the average performance. For $m = 2$ and $m = 3$, List Scheduling cannot be beaten, as its worst case bounds are best possible. For $m \geq 4$, no on-line heuristic can guarantee a better worst case performance than $1 + \sqrt{2}/2 \approx 1.707$.

The paper is organized as follows. Section 2 deals with lower bounds for on-line scheduling algorithms. Section 3 gives a number of basic definitions and presents our heuristic. Section 4 gives the worst case analysis of the heuristic and the discussion in §5 finishes the paper.

2. Lower bounds for on-line scheduling.

2. Lower bounds for on-line scheduling. All we do in this section is to prove the following theorem. This result is also contained in the discussion of [1].

THEOREM 2.1. *There is no on-line scheduling algorithm with worst case guarantee better than*

(i) $3/2$ *for* 2 *machines*,
(ii) $5/3$ *for* 3 *machines*,
(iii) $1+\sqrt{2}/2$ *for* $m \geq 4$ *machines.*

Proof. Claims (i) and (ii) are easily proved by using the list $\mathcal{L}_2 = \langle 1,1,2\rangle$ for $m=2$ and the list $\mathcal{L}_3 = \langle 1,1,1,3,3,3,6\rangle$ for $m=3$. The exact arguments are analogous to those used for $m \geq 4$ and omitted.

For $m \geq 4$, we consider a sequence consisting of m times a job of length 1, followed by m times a job of length $1+\sqrt{2}$ and ending with a single job of length $2+2\sqrt{2}$. If the algorithm puts two or more of the jobs with length 1 on the same machine, it does not get any other job. It produced a makespan of 2, whereas the optimum makespan is only 1 and we are finished. Otherwise, it puts one job with length 1 on every machine. If in the following the algorithm puts two or more of the jobs with length $1+\sqrt{2}$ on the same machine, we are finished again. Instead of an optimum makespan $2+\sqrt{2}$, it came up with a $3+2\sqrt{2}$ makespan. Consequently, every machine gets one job with processing time 1 and one with processing time $1+\sqrt{2}$ job. But now the single final job completes the proof. □

3. Some definitions and the heuristic.

3. Some definitions and the heuristic. We will denote by C^* the makespan in the optimal schedule and by C^H the makespan in the schedule constructed by our heuristic. As the algorithm gets the jobs one by one, the values of C^* and C^H vary during the algorithm. To simplify notation, we will identify each job with its length. The *load* L_i of a machine M_i is the sum of processing times over all jobs assigned to it. When we describe the algorithm, we will use $L^{\max}$ to denote the maximum load and $L^{\min}$ to denote the minimum load over all machines.

We assume that $m \geq 4$ holds (as for $m \leq 3$ List Scheduling cannot be beaten). To define the algorithm, we introduce two real numbers $\alpha(m)$ and $\beta(m)$, where $0 \leq \alpha(m) \leq 1/3$ and $1 \leq \beta(m) \leq 5/4$ holds. Moreover, we will assume that $(\beta(m)+1)/\beta(m)^3 > \alpha(m)+1$ holds. These two numbers depend on m and their exact value will be specified later. To simplify presentation we write α and β instead of $\alpha(m)$ and $\beta(m)$. For nonnegative reals x, y we define the symmetric relation

$$x \sim y \quad \Longleftrightarrow \quad \frac{y}{\beta} \leq x \leq \beta y, \tag{2}$$

and we say that in this case x is *similar* to y. For S a set of nonnegative reals, we say that $\sim(S)$ holds, if and only if every two elements in S are similar (equivalently we can say, $\sim(S)$ holds if and only if the smallest and the largest elements of S are similar to each other).

Before we present our heuristic, we want to give the reader some intuition of the underlying ideas. We begin with recapitulating the analysis of List Scheduling. Let $L_1 \leq L_2 \leq \ldots \leq L_m$ be the loads of the machines and let x be a new job to be scheduled.

We use $C^* \geq (\sum L_i + x)/m \geq L_1 + x/m$ and $C^* \geq x$ to derive

$$L_1 + x \leq C^* - x/m + x \leq \left(2 - \frac{1}{m}\right) C^*. \tag{3}$$

This inequality is tight if $C^* = x$ holds and all L_i are equal. To reach a better worst case performance, we must avoid at least one of these two conditions. We have no influence on the length of job x, consequently we try to keep the L_i as "unequal" as possible. To measure "unequality" of loads we apply the similarity relation introduced above. Unfortunately, it is not always possible to keep the loads unequal (for example if the first m jobs to be scheduled all have equal length). To circumvent this difficulty, we use a threshold α; if the quotient of smallest load to largest load is less than α, the next job may be put on the smallest machine. If α is chosen appropriately (with respect to β and m), we will show that after such actions the ratio C^H/C^* is not too large.

Finally, we are ready to present our heuristic called *Refined List Scheduling* (*RLS* for short).

```
(1) Reorder the machines such that $L_1 \leq L_2 \leq \ldots \leq L_m$ holds.
    Let $x$ be a new job given to the algorithm.
(2) If $\not\sim (L_1 + x, L_2, L_3, \ldots, L_m)$ then put $x$ on $M_1$ and goto (1).
(3) Else if $L_1 > \alpha L_m$ then put $x$ on $M_2$ and goto (1).
(4) Else if $L_1 \leq \alpha L_m$ then
    (4.1) Put $x$ on $M_1$.
    (4.2) While $L^{\min} \sim L^{\max}$ do: put all new jobs on $M_1$.
    (4.3) Goto (1).
```

The heuristic terminates when no more jobs are given to it. Observe that new jobs are given to the algorithm only in steps (1) and (4.2). In step (4.2) M_1 generally is *not* the machine with minimum load anymore; the heuristic is putting jobs on M_1 until it has the maximum load.

4. The worst case analysis. In this section we will derive a sequence of claims and lemmas that lead to a number of different worst case bounds. Having derived all these bounds, we will fix the values of α and β so as to minimize the maximum of all these bounds.

LEMMA 4.1. *Each time the heuristic reenters step* (1), $\not\sim (L_1, \ldots, L_m)$ *holds.*

Proof. The proof is a simple inductive argument. When the heuristic reenters step (1) the first time, there is only one nonempty machine and the claim follows. If the heuristic last performed step (2), the claim holds by definition; if it last performed step (3), the claim holds by induction, as step (3) does not increase $L^{\min} = L_1$. If it reenters from step (4), $L^{\min} \not\sim L^{\max}$ holds. □

LEMMA 4.2. *When the heuristic leaves step* (2), *the inequality*

$$(L_1 + x)/C^* < (2m - 2 + \beta)/(m - 1 + \beta) \tag{4}$$

holds.

Proof. By Lemma 4.1, before x was assigned to M_1 the machine loads were not similar. This implies

$$C^* \geq \left(\sum L_i + x\right)/m > \frac{1}{m}(m - 1 + \beta)L_1 + x/m, \tag{5}$$

where the first inequality follows from averaging over all loads and the second inequality uses $L_i \geq L_1$ for $i = 1 \ldots m-1$ and $L_m > \beta L_1$. Using $C^* \geq x$, we simply derive the claimed result. □

LEMMA 4.3. *When the heuristic leaves step* (3), *the inequality*

$$(L_2 + x)/C^* < \Big(m + (m-2)\beta - (m-1)\alpha\Big)/(m-1) \tag{6}$$

holds.

Proof. As L_2 is the second smallest load, it is less or equal to the average value of the $m-1$ largest loads. This gives

$$L_2 \leq (L_2 + \ldots + L_m)/(m-1) \leq (mC^* - L_1 - x)/(m-1). \tag{7}$$

Moreover, we show that

$$L_1 + x \leq \beta C^* \tag{8}$$

by considering the following two cases. If $L_2 > C^*$, $L_1 + x < C^*$ must hold (again by the standard averaging argument) and this implies the inequality because of $\beta \geq 1$. On the other hand, if $L_2 \leq C^*$ holds, we may use that $L_1 + x$ and L_2 are similar and derive the inequality. The two displayed inequalities together with $L_1 > \alpha L_m \geq \alpha C^*$ lead to

$$\begin{aligned} L_2 + x &\leq (mC^* - L_1 - x)/(m-1) + x \\ &= mC^*/(m-1) - L_1 + (L_1 + x)(m-2)/(m-1) \\ &< C^*\Big(m + (m-2)\beta - (m-1)\alpha\Big)/(m-1), \end{aligned} \tag{9}$$

and the proof is complete. □

LEMMA 4.4. *If $L^{\min} \sim L^{\max}$ holds in step* (4.2), *then*

$$L^{\max}/C^* \leq m\beta/(m-1+\beta). \tag{10}$$

Proof. By load averaging, $C^* \geq \sum L_i/m$ holds. Now we simply use $L_i \geq L^{\max}/\beta$ for $i \leq m-1$ and finish the proof. □

LEMMA 4.5. *Assume the algorithm enters step* (4). *Denote by a_i the job assigned last to machine M_i. Then for every $i \geq 2$, $a_i \geq (1-\alpha\beta^2)L_i$ must hold.*

Proof. Assume the contrapositive. Then we consider that machine M_j with $a_j < (1-\alpha\beta^2)L_j$ that got its a_j latest among all these contradicting machines. The job a_j was not assigned during step (2), as step (2) assigns jobs to only the smallest machine and by assumption

$$L_j - a_j > \alpha\beta^2 L_j \geq \alpha\beta L_m \geq L_1 \tag{11}$$

holds. Therefore, a_j was treated either in step (3) or in step (4). We will distinguish between these two cases. We typify loads at the moment before a_j is assigned by a prime, loads without prime concern the moment cited in the formulation of the claim. The two moments are typified analogously. Finally, in our arguments we will use a machine M_d with $M_1 \neq M_d \neq M_j$.

First we scrutinize the step (3) case. In this case, M_j must have been the second smallest machine when a_j was assigned to it. The only possible smaller machine at this moment is M_1. Moreover by the definition of M_j, no other machine received a job between the primed and the unprimed moment. At the primed moment, L'_j and L'_d are similar, and at the unprimed moment the loads are similar again. This means $\beta L'_j \geq L'_d$ and $\beta L'_d \geq L'_j + a_j$ and we derive

$$(\beta^2 - 1)L'_j \geq a_j. \tag{12}$$

At the primed moment $L'_1 > \alpha L^{\max}$ holds, at the unprimed moment $L_1 \leq \alpha L^{\max}$ holds. The load of M_1 does not decrease between these two moments, thus $L^{\max}$ must increase. The only possibility for this is $L^{\max} = L'_j + a_j$. This gives $L_1 \leq \alpha(L'_j + a_j)$. In addition, $L'_1 + a_j \geq L'_j/\beta$ holds, since the two numbers are similar. These two facts together with $L_1 \geq L'_1$ imply

$$(\alpha + 1)a_j \geq \left(\frac{1}{\beta} - \alpha\right) L'_j. \tag{13}$$

But now the two displayed inequalities contradict the assumption $(\beta + 1)/\beta^3 > \alpha + 1$.

Next we examine the step (4) case. As the heuristic entered step (4), $L_1 \leq \alpha L^{\max} \leq \alpha\beta L_j$ holds. At the primed moment, $L'_j \sim L'_1$ implies that $L'_1 \geq (L_j - a_j)/\beta$ holds. Using $L_1 \geq L'_1$, this leads to

$$a_j \geq (1 - \alpha\beta^2)L_j, \tag{14}$$

and our proof is complete. □

LEMMA 4.6. *When the heuristic leaves step* (4.2), *then*

$$L^{\max}/C^* \leq \beta^2/(2 - 2\alpha\beta^2) + 1. \tag{15}$$

Proof. Let a_i, $1 \leq i \leq m$ denote the last job assigned to M_i before the heuristic enters the while-loop (hence, a_1 is equal to x). As $L_1 + x \sim L_m$, we have $L_1 + x \geq L_m/\beta$. Together with Lemma 4.5 and $L_1 \leq \alpha L_m$, this gives

$$a_i \geq \left(\frac{1}{\beta} - \alpha\beta\right) L_m \tag{16}$$

for all $1 \leq i \leq m$. Finally, we define y to be the last job assigned to machine M_1 before the heuristic leaves step (4.2) and note that after this assignment $L^{\max}$ is the load of machine M_1.

We distinguish two cases. If $y \geq (\frac{1}{\beta} - \alpha\beta)L_m$ holds, we use the pigeon hole principle: There are $m + 1$ jobs with length greater or equal $(\frac{1}{\beta} - \alpha\beta)L_m$, hence the optimum schedule must put two of them on the same machine. This gives $C^* \geq (\frac{2}{\beta} - 2\alpha\beta)L_m$. Using $C^* \geq y$ and the fact that $L^{\max} - y \sim L_m$ we have

$$L^{\max} \leq \beta L_m + y \leq \beta^2 C^*/(2 - 2\alpha\beta^2) + C^*. \tag{17}$$

Otherwise, if $y < (\frac{1}{\beta} - \alpha\beta)L_m$ holds, we derive in an analogous way that $C^* \geq (\frac{1}{\beta} - \alpha\beta)L_m + y$ and $C^* \geq y$. This gives

$$L^{\max} - C^* \leq (\beta - \frac{1}{\beta} + \alpha\beta)L_m \leq (\beta^2 - 1 + \alpha\beta^2)L^{\min}. \tag{18}$$

But now $L^{\min} \leq C^*$ and $\beta^2 - 1 + \alpha\beta^2$ is smaller or equal to $\beta^2/(2 - 2\alpha\beta^2)$, if $0 \leq \alpha \leq 1/3$ and $1 \leq \beta \leq 5/4$. So we end in all cases with the claimed bound. □

THEOREM 4.7. *For $m \geq 4$, the worst case performance of RLS is less than or equal to $2 - \frac{1}{m} - \varepsilon_m$, with ε_m some small positive real depending on m.*

Proof. Summarizing, Lemmas 4.2, 4.3, 4.4, and 4.6 give the following worst case bounds. In each inequality C^* denotes the momentary optimum makespan:

$$(19)\qquad (L_1 + x)/C^* < (2m - 2 + \beta)/(m - 1 + \beta),$$

$$(20)\qquad (L_2 + x)/C^* < \Big(m + (m-2)\beta - (m-1)\alpha\Big)/(m-1),$$

$$(21)\qquad L^{\max}/C^* \leq m\beta/(m - 1 + \beta),$$

$$(22)\qquad L^{\max}/C^* \leq \beta^2/(2 - 2\alpha\beta^2) + 1.$$

Let us examine the worst case performance of *RLS*. A worst case situation occurs after some job x was assigned to its machine. This happens either in step (2), in step (3), in the middle of step (4), or in the end of step (4); the four inequalities above give upper bounds on the worst case ratios in these four scenarios. Consequently, our goal is to minimize for each $m \geq 4$ the maximum over the four right-hand side values under the restrictions

$$(23)\qquad 0 \leq \alpha \leq 1/3, \qquad 1 \leq \beta \leq 5/4, \qquad (\beta + 1)/\beta^3 > \alpha + 1.$$

We denote this minimum (that is an upper bound on the worst case ratio of *RLS*) by $R^{RLS}(m)$. First, it is easy to see that for $\beta \leq 2$, the right-hand side of (21) is less than or equal to the right-hand side of (19) and so we need not consider it in the optimization problem. For the remaining three values, we derive by using standard calculus that the minimum is taken if all three values are equal. Some substitutions lead to

$$(24)\ \beta^4(2m-3) + 2\beta^3(m^2 - 2m + 2) + \beta^2(4m - m^2 - 3) - 2\beta(m-1) = 2(m-1)^2.$$

For $m \leq 3$ this equality does not have a feasible solution. For each $m \geq 4$, this equality has a solution with $1 < \beta < 5/4$, since its value taken for $\beta = 1$ is negative and its value for $\beta = 5/4$ is positive. The solutions for some small values of m are stated in the third column of Table 1. As m tends to infinity, β tends from below to the positive real root of $2\beta^3 - \beta^2 - 2 = 0$. The restriction $(\beta + 1)/\beta^3 > \alpha + 1$ that was essential in the proof of Lemma 4.5, is of no consequence for the minimization problem.

Finally, we determine from the right-hand side of inequality (19) the value of $R^{RLS}(m)$. As $\beta > 1$ holds, we have $R^{RLS}(m) < 2 - \frac{1}{m}$. This means that *RLS* beats the worst case performance of List Scheduling for $m \geq 4$. Table 1 summarizes some of the results of this section. $\square$

5. Discussion. In this paper we derived an on-line algorithm that beats Graham's List Scheduling in the measure of worst case performance (for $m \geq 4$ machines). For two or three machines, the worst case guarantee of List Scheduling is optimal.

However, asymptotically our analysis did not improve the heuristic LS, since ε_m tends to zero as m tends to infinity. So the first open problem is at hand. Are there on-line scheduling algorithms with worst case ratio smaller than $2 - \delta$ for all m and some fixed $\delta > 0$? Secondly, the following question may be interesting as well. For four machines, we gave a lower bound of 1.7071 and an upper bound of 1.7447. How can we narrow the gap between these two bounds?

Acknowledgement. We thank Hannes Hassler and Hans Kellerer for valuable discussions, and we thank Wolfgang Gutjahr for pointing out an error in an earlier version of this paper.

THEORETICAL ASPECTS OF VLSI PIN LIMITATIONS*

ROBERT CYPHER†

Abstract. This paper presents a formal model of the pin requirements of a parallel computer. This model is then used to obtain bounds on the pin requirements of different parallel machines and on the tradeoffs between pins and time. Specifically, two new bounds are established on the relationship between pin requirements and the time needed to sort or permute data. This paper also gives new lower bounds on the pin requirements of mesh-connected, cube-connected-cycles, shuffle-exchange, and Ajtai–Komlós–Szemerédi (AKS) computers, and it gives new upper bounds on the pin requirements of shuffle-exchange and AKS computers. All of these bounds are tight to within a constant factor. Finally, the bounds on pin requirements are used to prove a tight lower bound on the time required to implement the AKS sorting algorithm on a shuffle-exchange or cube-connected-cycles computer.

Key words. pin limitations, VLSI theory, parallel sorting

1. Introduction. An enormous number of different interconnection networks have been proposed for distributed-memory parallel computers. These networks differ in both their ability to support various algorithms and in their hardware costs. One useful measure of hardware cost is the area required when the entire parallel computer is laid out on a single sheet of silicon. This measure has been well studied, and the very-large-scale integration (VLSI) area requirements of many interconnection networks are known. Also, tradeoffs between area and time for problems such as permuting and sorting data have been established [28], [29].

Actual parallel machines are typically laid out on a number of separate chips, each of which has a limited number of pins through which connections can be made to other chips. In some cases the number of pins available per chip is a more serious limitation than the amount of area available per chip [6], [10], [11], [15], [25]. As a result, the pin requirements of a parallel computer are another important measure of its cost. Many researchers have studied pin requirements but a theory comparable to that relating to VLSI area requirements has not been created.

A large amount of research has been devoted to studying the pin requirements of switch-based interconnection networks. For example, the pin requirements of the Omega network were studied by Ciminiera and Serra [6]; Snir [25]; Franklin and Dhar [10]; Franklin, Wann, and Thomas [11]; McMillen and Siegel [20]; Knauer, O'Neill, and Huang [15]; and Szymanski [27]. Other switch-based networks studied include the crossbar [10], [11], [27], the augmented data manipulator [20], and various partial concentrators [7]. Snir introduced a general model for VLSI pin requirements [25] and proved matching upper and lower bounds on the pin requirements of Omega networks, two-dimensional mesh-connected computers, and trees. Snir also proved a lower bound on the pin requirements of shuffle-exchange computers, which was subject to certain restrictions, and an upper bound on the pin requirements of mesh-connected computers of arbitrary dimension [25].

*Received by the editors April 29, 1991; accepted for publication (in revised form) January 7, 1992. A preliminary version of this work was presented at the 6th MIT Conference on Advanced Research in VLSI, Cambridge, Massachusetts, April 1990. This research was supported in part by a National Science Foundation Graduate Fellowship.

†Department K54/802, IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, California 95120.

A number of researchers have studied different but related problems. Ullman defined the notion of "flux" to capture the amount of locality in a network and he showed the importance of this measure to sorting and artificial intelligence problems [31]. Li and Maresca introduced a parallel computer called the "polymorphic torus" and compared this machine to mesh-connected computers and hypercubes in terms of flux and performance [19]. They introduced the notion of the flux–time product, and they calculated this product for a number of machines and algorithms. Hong and Kung studied the input/output complexity of the fast Fourier transform and other problems [14], and Aggarwal and Vitter studied the input/output complexity of the fast Fourier transform and of permuting and sorting problems [1].

Three types of results are presented in this paper. First, two new lower bounds on the tradeoffs between pin and time requirements for permuting and sorting data are proved. These lower bounds are analogous to the AT^2 (where A is chip area and T is time) lower bounds that have been established for the VLSI area model. These lower bounds apply to all interconnection networks, so they provide an objective measure of the cost/performance tradeoffs of an interconnection topology.

Second, new lower and upper bounds on the pin requirements of various types of parallel computers are proved. Specifically, tight lower bounds on the pin requirements of mesh-connected computers of arbitrary (constant) dimension [21], cube-connected-cycles computers [22], shuffle-exchange computers [26], and Ajtai–Komlós–Szemerédi (AKS) computers [2], [18] are proved, as are tight upper bounds on the pin requirements of shuffle-exchange computers and AKS computers. The lower bound for mesh-connected computers extends a lower bound proved by Snir for two-dimensional mesh-connected computers [25]. The upper bound for shuffle-exchange computers solves an open problem posed by Snir [25], and the lower bound for shuffle-exchange computers generalizes a lower bound proved by Snir [25]. The bounds on AKS computers show that the AKS computer is suboptimal in terms of pin and time requirements for permuting and sorting data. This result is unexpected, because the AKS computer has been proved to be optimal in terms of the VLSI area model [3].

Third, the AKS sorting algorithm is proved to require $\Theta(\log^2 N)$ time to sort N items when it is implemented on an N-processor cube-connected-cycles or shuffle-exchange computer. Previously it was unknown whether the AKS sorting algorithm could be used to obtain an optimal $O(\log N)$-time sorting algorithm for these types of computers. Surprisingly, this bound on the running time of the AKS algorithm makes critical use of the bounds on pin requirements proved earlier in the paper.

The remainder of this paper is organized as follows. Section 2 presents a formal model of the VLSI pin requirements of a parallel machine. Section 3 reviews some previously known results for the pin requirements of parallel computers. Lower bounds on the time and pin requirements for permuting and sorting are presented in §4. Sections 5–8 contain results for mesh-connected computers, cube-connected-cycles computers, shuffle-exchange computers, and AKS computers, respectively. Finally, bounds on the time required to implement the AKS sorting algorithm on cube-connected cycles and shuffle-exchange computers are presented in §9.

2. The VLSI-pin-requirements model. A distributed-memory parallel machine M will be viewed as an undirected graph $M = (V, E)$, where the nodes V represent processors and the edges E represent communication links. Each communication link can transmit one word in unit time. The parameter $N = |V|$ will be the number of processors in M, and the parameter C will be the number of chips to which M is partitioned. It will be assumed throughout that $4 \leq C \leq N$. To minimize the pin requirements for

M, the N processors must be assigned to the C chips so that no chip has a large number of wires connecting the processors on the chip with the processors off the chip. The only restriction in assigning processors to chips will be that each chip has fewer than $N/2$ processors. This restriction is a result of the limited area of a chip, and it prevents the trivial solution of assigning all the processors to a single chip, which requires 0 pins. The above notions are formalized below.

Given any positive integer I, let $[I] = \{0, 1, \cdots, I-1\}$. Let $M = (V, E)$ be an undirected graph. The collection of sets $P = P_0, \cdots, P_{k-1}$ is a *partition* of M if the following properties hold:

1. For each $i \in [k]$, $P_i \subset V$.
2. $\bigcup_{i\in[k]} P_i = V$.
3. For each $i \in [k]$ and $j \in [k]$, where $i \neq j$, $P_i \bigcap P_j = \emptyset$.

The sets $P_0, \cdots, P_{k-1}$ will often be referred to as *chips*. Given a set $S \subseteq V$, the *boundary* of S in M, written Bound(S, M), is the set of edges in E connecting vertices in S with vertices not in S. The *girth* of M partitioned by P, written Girth(M, P), is $\max_{i\in[k]} |\text{Bound}(P_i, M)|$.

A partition $P = P_0, \cdots, P_{k-1}$ of M is *legal* if $\max_{i\in[k]} |P_i| < |V|/2$ and $k \leq C$. The pin requirements of M will be denoted by the parameter Q, where Q is the minimum, over all legal partitions P of M, of Girth(M, P). Given a problem to be solved, the parameter T is the minimum, over all algorithms for the problem, of the algorithm's time requirements on M.

3. Known results. This section briefly reviews some lower and upper bounds on the pin requirements of parallel computers that are either known or that follow directly from known results.

3.1. Mesh-connected computers. The N processors in a d-dimensional mesh-connected computer [21] may be thought of as being arranged in a d-dimensional array. Each side of the array is of length u, where $u = N^{1/d}$ is an integer. The position of each processor in the array is specified by a unique integer vector of the form $(a_{d-1}, \cdots, a_0)$, where $0 \leq a_i < u$ for all i, $0 \leq i < d$. Mesh-connected computers can be defined either with or without wraparound connections. In a mesh-connected computer *without* wraparounds, each processor $(a_{d-1}, \cdots, a_0)$ is connected to the at most $2d$ processors of the form $(a_{d-1}, \cdots, a_{i+1}, a_i \pm 1, a_{i-1}, \cdots, a_0)$, provided that they exist. In a mesh-connected computer *with* wraparounds, each processor $(a_{d-1}, \cdots, a_0)$ is connected to $2d$ processors of the form $(a_{d-1}, \cdots, a_{i+1}, (a_i \pm 1) \bmod u, a_{i-1}, \cdots, a_0)$.

An upper bound on the pin requirements of mesh-connected computers can be obtained by viewing the processors as forming a d-dimensional cube and partitioning the cube into (nearly) cubical blocks with (approximately) N/C processors each. The number of pins required by this partition is based on the surface-to-volume ratio of the cubical blocks and is given in the following theorem due to Snir [25].

THEOREM 3.1. *If M is a d-dimensional mesh-connected computer with or without wraparounds and if d is a constant, then $Q = O((N/C)^{(d-1)/d})$.*

The following theorem, proved by Snir [25], shows that the above bound is the best bound possible when $d = 2$. However, Snir's proof technique makes critical use of a property that is unique to the case $d = 2$ (namely, that a single chip cannot receive processors from opposite faces of the cube) and does not generalize to higher values of d.

THEOREM 3.2. *If M is a 2-dimensional mesh-connected computer with or without wraparounds, then $Q = \Omega((N/C)^{1/2})$.*

3.2. Hypercube computers. A hypercube computer [21], [24] consists of $N = 2^n$ processors, each of which has a unique label in the range 0 through $N - 1$. Each pair of processors i and j are connected if and only if the binary representations of i and j differ in exactly one bit position.

An upper bound on the pin requirements of a hypercube can be obtained by partitioning the hypercube into smaller dimensional hypercubes with (approximately) N/C processors each. Each processor will then be connected to $O(\log N - \log(N/C)) = O(\log C)$ processors[1] on different chips, so $Q = O(N \log C/C)$. This result, which is very natural and has been discovered by several researchers [13], [19], [24], is stated in the following theorem.

THEOREM 3.3. *If M is a hypercube computer with N processors, then it holds that $Q = O(N \log C/C)$.*

This partition into smaller dimensional hypercubes can be shown to be optimal by using the following lemma (called an *isoperimetric inequality*) proved by Hart [12]. For any nonnegative integer i, let $h(i)$ denote the number of ones in the binary representation of i. For example, $h(0) = 0$ and $h(23) = 4$. Also, for any positive integer s, let $g(s) = \sum_{i=0}^{s-1} h(i)$.

LEMMA 3.4. *Let $M = (V, E)$ be a hypercube computer with N processors, and let $S \subseteq V$, where $|S| = s > 0$. Then $|\mathrm{Bound}(S, M)| \geq s \log N - 2g(s)$.*

In order to use Lemma 3.4 to prove that the upper bound given by Theorem 3.3 is optimal, we will need the following bound on the value of $g(s)$.

LEMMA 3.5. *For all integers $s \geq 1$, $g(s) \leq s \lceil \log s \rceil /2$.*

Proof. All integers in the range 0 through $s - 1$ can be represented with $\lceil \log s \rceil$ bits. In the sequence $0, 1, \cdots, s - 1$, the jth bit, $0 \leq j < \lceil \log s \rceil$, appears periodically as 2^j zeros followed by 2^j ones. Because the jth bit first appears as 2^j zeros, it has the value one for at most half of the integers in the sequence $0, 1, \cdots, s - 1$. Thus $g(s) = \sum_{i=0}^{s-1} h(i) \leq s \lceil \log s \rceil /2$. $\square$

Combining Lemmas 3.4 and 3.5 yields the following theorem.

THEOREM 3.6. *If M is a hypercube computer with N processors, then it holds that $Q = \Omega(N \log C/C)$.*

Proof. Let $P = P_0, \cdots, P_{k-1}$ be any legal partition of M, let $s = \max_{i \in [k]} |P_i|$, and let j be such that $|P_j| = s$. Note that $k \leq C$, so the average size of the sets P_i is at least N/C and $s \geq N/C$. Also, because P is a legal partition of M, $s < N/2$. Let $f(x) = x(\log N - \lceil \log x \rceil)$. From Lemmas 3.4 and 3.5 $|\mathrm{Bound}(P_j, M)| \geq f(s)$. There are two cases. If $N/4 \leq s < N/2$, then $\log N - \lceil \log s \rceil \geq 1$ and $f(s) \geq N/4 = \Omega(N \log C/C)$. Otherwise, $N/C \leq s < N/4$ and $\log N - \log s \geq 2$, so $\log N - \lceil \log s \rceil \geq \log N - \log s - 1 \geq (\log N - \log s)/2$. Let $e(x) = x(\log N - \log x)/2$. Then the derivative $e'(x) = (\ln N - \ln x - 1)/2 \ln 2$, so when $\ln x < \ln N - 1$, $e'(x) > 0$. Thus $f(s) = s(\log N - \lceil \log s \rceil) \geq e(s)$ and $e(s)$ is minimized when $s = N/C$, at which point $e(s) = (N/2C)(\log C) = \Omega(N \log C/C)$. Thus in either case $Q \geq |\mathrm{Bound}(P_j, M)| \geq f(s) = \Omega(N \log C/C)$. $\square$

3.3. Cube-connected-cycles computers. A cube-connected-cycles (CCC) computer [22] consists of $N = n2^n$ processors, where $n = 2^m$ for some integer m. Each processor has a unique label of the form (r, c), where $0 \leq r < 2^n$ and $0 \leq c < n$. Let $a \oplus b$ denote the bitwise exclusive OR of a and b. Each processor (r, c) is connected to processor $(r \oplus 2^c, c)$ through a *cube edge* and to processors $(r, (c \pm 1) \bmod n)$ through *lateral edges*.

[1]Throughout this paper $\log N$ will denote the base 2 logarithm of N and $\ln N$ will denote the natural logarithm of N.

Snir [25] proved tight lower and upper bounds on the pin requirements of Omega networks, which are multistage switch-based interconnection networks. Snir's upper bound is based on a partition of an Omega network into a collection of smaller Omega networks. By associating each switch in an Omega network with a pair of processors that are connected by a cube edge in a CCC, Snir's upper bound on the pin requirements of an Omega network can be used to obtain an upper bound on the pin requirements of a CCC. In fact, the resulting partition of a CCC is similar to partitions given by a number of authors, including Hong and Kung [14]; Knauer, O'Neill, and Huang [15]; and Aggarwal and Vitter [1]. The pin requirements of this partition of a CCC are given in the following theorem.

THEOREM 3.7. *If M is a cube-connected-cycles computer with N processors, then $Q = O(N/C \log(4N/C))$.*

It should be noted that Snir's lower bound on the pin requirements of an Omega network does not imply a similar lower bound on the pin requirements of a CCC, because each switch in an Omega network must be assigned to a single chip, whereas a pair of processors in a CCC that are connected by a cube edge can be assigned to different chips.

One interesting consequence of Theorems 3.6 and 3.7 is that if $C = N^x$, where $0 < x < 1$ is a constant, then the pin requirements of a hypercube are a factor of $\Omega(\log^2 N)$ greater than those of a CCC even though the degree of a hypercube is only a factor of $\Theta(\log N)$ greater than the degree of a CCC.

4. Lower bounds for permuting and sorting.

Having defined the VLSI-pin-requirements model, we are able to establish bounds on relationships among the parameters N, C, Q and T. In this paper we will focus on the permutation and sorting problems. For both problems it is assumed that N items are to be permuted or sorted and that each item consists of a constant number of words. The only operations that are allowed to be performed on items are duplication of the item and examination of the item's destination or key value, so algorithms that encode the contents of an item are prohibited. Also, it is assumed that each processor originally holds one item and that after the permutation or sort each processor again holds one item. When an average-case time analysis is used, it is assumed that all of the $N!$ different permutations or orderings of the sort keys are equally likely. In the permutation problem only the time spent permuting the data is counted; the time spent determining how to accomplish the permutation is ignored. The following theorems establish lower bounds on the time and pin requirements of permuting and sorting. Theorem 4.1 is closely related to a lower bound on the input/output complexity of permuting and sorting that was obtained by Aggarwal and Vitter [1] and to a lower bound on area that was proven by Vuillemin [32].

THEOREM 4.1. *If M is a parallel machine with N processors and if T is the average- or worst-case time required to permute or sort N items on M, then $TCQ = \Omega(N)$.*

Proof. The lower bound for the average-case time analysis will be proved here. The lower bound for the worst case follows immediately from the lower bound for the average case. View M as a graph $M = (V, E)$, and let $P = P_0, \cdots, P_{C-1}$ be any legal partition of M. Let $j \in [C]$ be such that for all $i \in [C]$, $|P_j| \geq |P_i|$, and let $S = P_j$. Note that the average size of the sets P_i is at least N/C so $|S| \geq N/C$. Also, because P is a legal partition of M, $|S| < N/2$.

Note that for any permutation or sort, if k items must be sent from processors in S to processors outside of S, then the time required for that permutation or sort is at least $k/|\text{Bound}(S, M)|$. Also, to implement all $N!$ of the different permutations or sorts, a total of $|S|(N - |S|)(N - 1)!$ items must be sent from processors in S to processors outside of S. Because $N/C \leq |S| < N/2$, $|S|(N-|S|)(N-1)! > (N/2C)N!$. Therefore, the total time required to implement all $N!$ different permutations or sorts is at least $N!(N/2C|\text{Bound}(S,M)|)$, and the average time required for a permutation or sort is at least $N/2C|\text{Bound}(S,M)|$. Because $Q \geq |\text{Bound}(S,M)|$, it follows that $T \geq N/2CQ$ and $TCQ = \Omega(N)$. □

Although Theorem 4.1 gives an important lower bound on the time and pin requirements for permuting and sorting, a tighter lower bound can be obtained in some cases. This other lower bound is proved in the following theorem.

THEOREM 4.2. *If M is a parallel machine with N processors and if T is the average- or worst-case time required to permute or sort N items on M, then* $TCQ \log Q/\log C = \Omega(N)$.

Proof. The lower bound for the average-case time analysis will be proved here. The lower bound for the worst case follows immediately from the lower bound for the average case. If $4 \leq C < 256$, then from Theorem 4.1 $TCQ = \Omega(N)$, which implies that $TCQ \log Q/\log C = \Omega(N)$. Therefore, it will be assumed that $C \geq 256$.

The idea of the proof is that at most TCQ items can move between chips in time T. Thus if it could be shown that on the average $\Omega(N)$ items each have to visit $\Omega(\log C/\log Q)$ chips, then TCQ would have to be $\Omega(N \log C/\log Q)$, which implies that $TCQ \log Q/\log C = \Omega(N)$. This argument can be used if the processors are fairly evenly distributed among the chips, but it fails if many of the processors are assigned to a small number of chips. However, in that case an argument like the one used in Theorem 4.1 can be used to obtain the desired result. Thus a two-case analysis will be used on the basis of how evenly the processors are assigned to the chips.

View M as a graph $M = (V,E)$, and let $P = P_0, \cdots, P_{C-1}$ be any legal partition of M. Without loss of generality, assume that for all $i,j \in [C]$ if $i < j$, then $|P_i| \geq |P_j|$. Let $s = |P_0|$, and for each i, where $1 \leq i \leq s$, let y_i be the number of chips having at least i processors (see Fig. 1). More formally, $y_i = C$ if $|P_{C-1}| \geq i$, and $y_i = \min\{j \in [C] \mid |P_j| < i\}$ otherwise. Note that

$$\sum_{i=1}^{s} y_i = N.$$

(This follows from the fact that a chip with j processors will be counted in exactly j of the y_i's.) Let k be the smallest integer such that

$$\sum_{i=1}^{k} y_i \geq N/2.$$

The definition of k is illustrated in Fig. 2, where the area of the shaded region consisting of the first k rows is at least $N/2$. Two cases will be considered on the basis of the value of y_k.

First, consider the case for which $y_k \geq C^{1/2}$. Let Wires(P,M) be the set of all edges in E that connect nodes that are in different sets in P, and for any $i,j \in V$ let WireDist(i,j,P,M) be the minimum, over all paths between i and j in M, of the number of edges in the path that are in the set Wires(P,M). Then, for an item to go from processor i to processor j it must cross at least WireDist(i,j,P,M) wires between chips. Note that given any processor i and any distance d, at most $Q^d + 1$ chips contain a processor j such that WireDist$(i,j,P,M) \leq d$. In particular, for any processor i at most $\lfloor C^{1/4} + 1 \rfloor$ chips contain a processor j such that WireDist$(i,j,P,M) \leq \log C/4 \log Q$.

Let R be a set consisting of k of the processors from each chip, or all of the processors from a chip if the chip has fewer than k processors. For example, the shaded region in

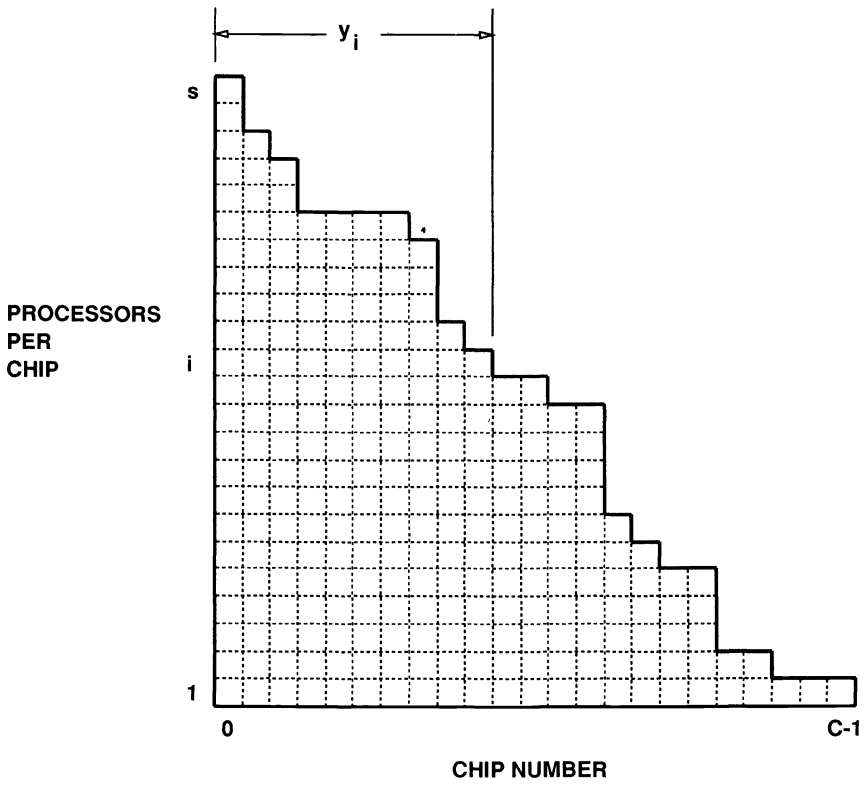

FIG. 1. *Number of processors per chip as a function of chip number. Each square represents one processor.*

Fig. 2 is such a set R. Note that

$$N \geq |R| = \sum_{i=1}^{k} y_i \geq N/2.$$

It is clear that $ky_k \leq |R|$, so $k \leq |R|/y_k \leq N/C^{1/2}$. As a result, for any positive integer z any set of z chips can contain at most $zk \leq zN/C^{1/2}$ processors in R. If we set $z = \lfloor C^{1/4} + 1 \rfloor$ and recall that $C \geq 256$, it follows that for any processor i there are at most $\lfloor C^{1/4} + 1 \rfloor N/C^{1/2} \leq (C^{-1/4} + C^{-1/2})N \leq 3N/8$ processors $j \in R$ such that WireDist$(i, j, P, M) \leq \log C/4 \log Q$. Therefore, for any given processor i there are at least $|R| - 3N/8 \geq N/8$ processors $j \in R$ such that WireDist$(i, j, P, M) > \log C/4 \log Q$.

As a result, the sum over all $N!$ permutations or sorts of the total number of times that items must move between chips to implement the permutation or sort is at least $(\log C/4 \log Q)(N/8)(N)(N-1)! = (N \log C/32 \log Q)N!$. However, only CQ items can move between chips in unit time, so the total time required to implement all $N!$ permutations or sorts is at least $N!(N \log C/32CQ \log Q)$ and the average time required to implement a permutation or sort is at least $N \log C/32CQ \log Q$. Therefore, $T \geq N \log C/32CQ \log Q$, and $TCQ \log Q/ \log C = \Omega(N)$.

Next, consider the case for which $y_k < C^{1/2}$. Notice that

$$\sum_{i=1}^{k-1} y_i < N/2,$$

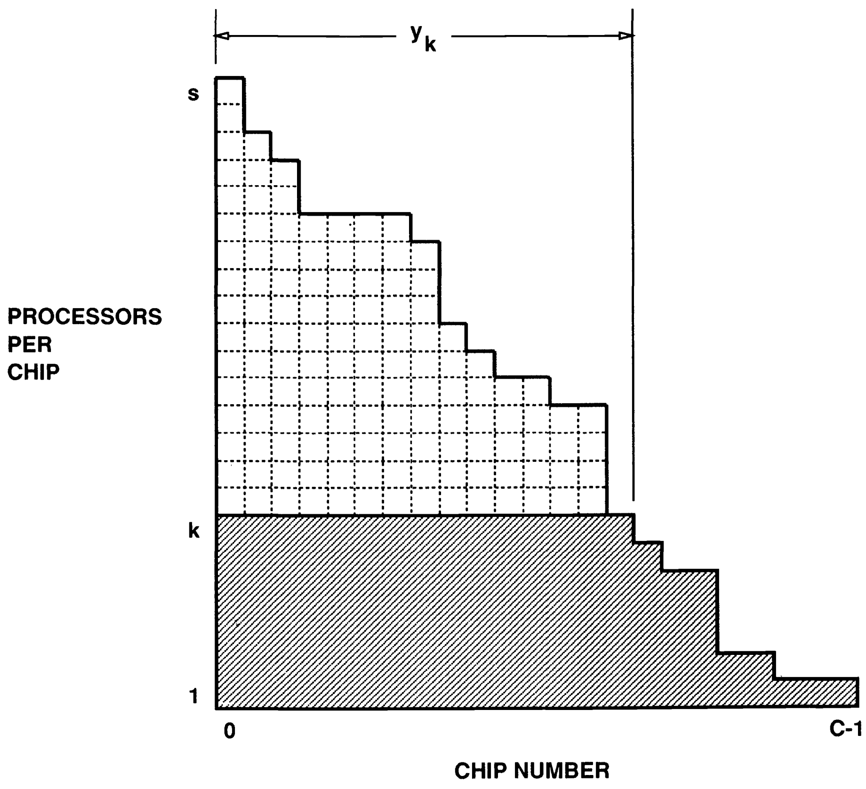

FIG. 2. *Number of processors per chip as a function of chip number. The value k is the smallest integer such that the lowest k rows contain at least half of the processors. The shaded region shows the $N/2$ or more processors considered when $Y_k \geq C^{1/2}$.*

so

$$\sum_{i=k}^{s} y_i \geq N/2,$$

as is illustrated in Fig. 3. However, for each i where $k \leq i \leq s$, $y_i < C^{1/2}$. Therefore,

$$N/2 \leq \sum_{i=k}^{s} y_i < \sum_{i=k}^{s} C^{1/2} = (s-k+1)C^{1/2},$$

so $s-k+1 > N/2C^{1/2}$. Because $k \geq 1$, $s > N/2C^{1/2}$.

Now let $S = P_0$. To implement all $N!$ of the different permutations or sorts, a total of $|S|(N-|S|)(N-1)! = s(N-s)(N-1)!$ items must be sent from processors in S to processors outside of S. Because $N/2C^{1/2} < s < N/2$, $s(N-s)(N-1)! > (N/4C^{1/2})N!$. Therefore, the total time required to implement all $N!$ different permutations or sorts is at least $N!(N/4C^{1/2})/|\text{Bound}(S,M)|$, and the average time required for a permutation or sort is at least $(N/4C^{1/2})/|\text{Bound}(S,M)|$. Because $Q \geq |\text{Bound}(S,M)|$, $T \geq N/4C^{1/2}Q$ and $TCQ/\log C \geq NC^{1/2}/4\log C \geq N/4$, so $TCQ\log Q/\log C = \Omega(N)$. □

Notice that the stronger lower bound is obtained by using Theorem 4.1 when $C = O(Q)$ and by using Theorem 4.2 when $Q = O(C)$. A natural question is whether or not

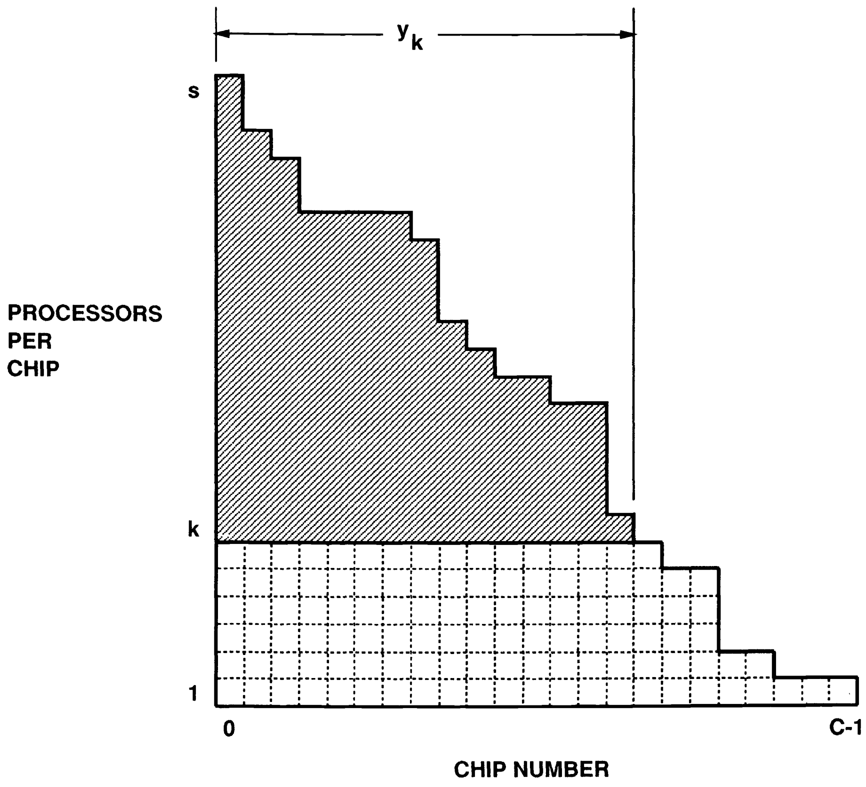

FIG. 3. *Number of processors per chip as a function of chip number. The value k is the smallest integer such that the lowest k rows contain at least half of the processors. The shaded region shows the $N/2$ or more processors considered when $Y_k < C^{1/2}$.*

these lower bounds are the strongest possible. In §6 it will be shown that for the average- and worst-case permutation problems and for the average-case sorting problem, when $C = O(Q)$ the lower bound given by Theorem 4.1 can be attained and when $Q = O(C)$ the lower bound given by Theorem 4.2 can be attained. It is unknown whether a stronger lower bound exists for the worst-case sorting problem.

5. *d*-Dimensional mesh-connected computers. The definition of a d-dimensional mesh-connected computer and an upper bound on its pin requirements were given in §3. A tight lower bound on the pin requirements of a two-dimensional mesh-connected computer was given in §3. In this section a tight lower bound on the pin requirements of a d-dimensional mesh-connected computer will be proved for any positive constant d. The lower bound is based on the following definitions and lemmas.

For the remainder of this section let $M = (V, E)$ be a d-dimensional mesh-connected computer (with or without wraparounds), where d is a constant, and let $u = N^{1/d}$. Given a set $S \subseteq V$ and an integer $k \in [d]$, Proj(S, k) is obtained by setting the kth coordinate of each vector in S to 0 and removing duplicates. More formally, Proj$(S, k) = R$, where $y = (y_{d-1}, \cdots, y_0) \in R$ if and only if $y_k = 0$ and $\exists x = (x_{d-1}, \cdots, x_0) \in S$ such that for all $i \in [d]$, where $i \neq k$, $x_i = y_i$. Given a set $S \subseteq V$ and integers i and k where $k \in [d]$, Slice(S, k, i) consists of those vectors in S for which the kth coordinate equals i. More formally, Slice$(S, k, i) = R$, where $y = (y_{d-1}, \cdots, y_0) \in R$ if and only if $y \in S$ and $y_k = i$. Given a set $S \subseteq V$ and an integer $k \in [d]$, Intersect(S, k, u) consists of those vectors $y \in \text{Proj}(S, k)$ for which all u of the vectors obtainable from y by setting the kth coordinate to a value in $[u]$ are also in S. More formally, $\text{Intersect}(S, k, u) = R$, where $y = (y_{d-1}, \cdots, y_0) \in R$ if and only if $y_k = 0$ and for all $i \in [u]$, $\exists x = (x_{d-1}, \cdots, x_0) \in S$ such that $x_k = i$ and for all $j \in [d]$, where $j \neq k$, $x_j = y_j$. Finally, for any $(x, y) \in E$, $\text{Dim}((x, y)) = k$ if and only if $x = (x_{d-1}, \cdots, x_0)$ and $y = (y_{d-1}, \cdots, y_0)$ and $x_k \neq y_k$.

LEMMA 5.1. *Given a nonempty set $S \subseteq V$,*

$$\sum_{j \in [d]} |\text{Proj}(S, j)| \geq d s^{(d-1)/d},$$

where $s = |S|$.

Proof. The proof is by induction on d. The basis is $d = 1$, in which case the claim is that $|\text{Proj}(S, 0)| \geq 1$, which follows immediately from the fact that S is nonempty. The induction hypothesis is that the lemma holds for all $d < a$, and it will be shown that the induction hypothesis implies that the lemma holds for $d = a$. Assume that $d = a$. For all $i \in [u]$ let $S_i = \text{Slice}(S, a-1, i)$ and let $s_i = |S_i|$. Note that $\sum_{i \in [u]} s_i = s$. Also, note that for each $j \in [a-1]$

$$|\text{Proj}(S, j)| = \sum_{i \in [u]} |\text{Proj}(S_i, j)|.$$

Therefore,

$$\sum_{j \in [a-1]} |\text{Proj}(S, j)| = \sum_{j \in [a-1]} \sum_{i \in [u]} |\text{Proj}(S_i, j)| = \sum_{i \in [u]} \sum_{j \in [a-1]} |\text{Proj}(S_i, j)|,$$

and, because each of the sets S_i is contained in an $(a-1)$-dimensional cube, the induction hypothesis yields

$$\sum_{i \in [u]} \sum_{j \in [a-1]} |\text{Proj}(S_i, j)| \geq \sum_{i \in [u]} (a-1) s_i^{(a-2)/(a-1)} = (a-1) \sum_{i \in [u]} s_i s_i^{-1/(a-1)}.$$

Let $h \in [u]$ be such that for each $i \in [u]$, $s_h \geq s_i$. Then

$$(a-1) \sum_{i \in [u]} s_i s_i^{-1/(a-1)} \geq (a-1) s_h^{-1/(a-1)} \sum_{i \in [u]} s_i = (a-1) s_h^{-1/(a-1)} s.$$

It has been shown that

$$\sum_{j \in [a-1]} |\text{Proj}(S, j)| \geq (a-1) s_h^{-1/(a-1)} s.$$

However, $|\text{Proj}(S, a-1)| \geq s_h$, so

$$\sum_{j \in [a]} |\text{Proj}(S, j)| \geq s_h + (a-1) s_h^{-1/(a-1)} s.$$

Let $f(x) = x + (a-1) x^{-1/(a-1)} s$. The derivative $f'(x) = 1 - x^{-a/(a-1)} s$ equals 0 when $x = s^{(a-1)/a}$, and the second derivative $f''(x) = (a/(a-1)) x^{(1-2a)/(a-1)} s$ is positive when $x = s^{(a-1)/a}$, so $f(x)$ is minimized when $x = s^{(a-1)/a}$. Therefore,

$$\sum_{j \in [a]} |\text{Proj}(S, j)| \geq s^{(a-1)/a} + (a-1)(s^{(a-1)/a})^{-1/(a-1)} s = a s^{(a-1)/a},$$

which completes the inductive step. □

LEMMA 5.2. *For any nonempty set $S \subseteq V$ and any integer $k \in [d]$, let $E_{k,S} = \{(x, y) \in \text{Bound}(S, M) \mid \text{Dim}((x, y)) = k\}$. Then for any $k \in [d]$, $|E_{k,S}| \geq |\text{Proj}(S, k)| - |\text{Intersect}(S, k, u)|$.*

Proof. Let $R = \text{Proj}(S, k) \setminus \text{Intersect}(S, k, u)$. Note that $|R| = |\text{Proj}(S, k)| - |\text{Intersect}(S, k, u)|$. For any $x \in R$ let $V_x = \{y \in V \mid \text{Proj}(\{y\}, k) = \{x\}\}$. Then there must exist a $y = (y_{d-1}, \cdots, y_0) \in V_x$ and a $y' = (y_{d-1}, \cdots, y_{k+1}, y_k + 1, y_{k-1}, \cdots, y_0) \in V_x$ where either $y \in S$ and $y' \notin S$ or $y \notin S$ and $y' \in S$. Therefore, for each $x \in R$ there exists an edge $(y, y') \in E_{k,S}$, where $y \in V_x$ and $y' \in V_x$. Note that for any $x \in R$ and $x' \in R$, if $x \neq x'$, then V_x and $V_{x'}$ are disjoint. Therefore, the edges in $E_{k,S}$ corresponding to distinct elements of R are distinct. As a result, $|E_{k,S}| \geq |R| = |\text{Proj}(S, k)| - |\text{Intersect}(S, k, u)|$. □

THEOREM 5.3. *If M is a d-dimensional MCC with or without wraparounds and if d is a constant, then $Q = \Omega((N/C)^{(d-1)/d})$.*

Proof. Let $P = P_0, \cdots, P_{C-1}$ be any legal partition of M. Let $j \in [C]$ be such that for all $i \in [C]$, $|P_j| \geq |P_i|$, and let $S = P_j$. Note that $N/C \leq |S| < N/2$. From Lemma 5.2

$$\begin{aligned}|\text{Bound}(S, M)| &\geq \sum_{k\in[d]} (|\text{Proj}(S, k)| - |\text{Intersect}(S, k, u)|) \\ &= \sum_{k\in[d]} |\text{Proj}(S, k)| - \sum_{k\in[d]} |\text{Intersect}(S, k, u)|.\end{aligned}$$

From Lemma 5.1

$$\sum_{k\in[d]} |\text{Proj}(S, k)| \geq d|S|^{(d-1)/d}.$$

Note that for any $k \in [d]$, $|\text{Intersect}(S, k, u)| \leq |S|/u$, so

$$\sum_{k\in[d]} |\text{Intersect}(S, k, u)| \leq d|S|/u.$$

Therefore,

$$\begin{aligned}|\text{Bound}(S, M)| &\geq d|S|^{(d-1)/d} - d|S|/u \\ &= d|S|^{(d-1)/d}(1 - |S|^{1/d}/N^{1/d}) \\ &> d(N/C)^{(d-1)/d}(1 - 1/2^{1/d}) \\ &= \Omega((N/C)^{(d-1)/d}).\end{aligned}$$

Because $Q \geq |\text{Bound}(S, M)|$, it follows that $Q = \Omega((N/C)^{(d-1)/d})$. □

It should be noted that Bollobás and Leader have proved isoperimetric inequalities (lower bounds on the number of neighbors that a set of nodes must have) for d-dimensional meshes both with and without wraparounds [4], [5]. However, those isoperimetric inequalities characterize a set that has a minimal number of neighbors without quantifying the number of neighbors, and as a result they do not provide a bound such as the one proved in Theorem 5.3.

6. Cube-connected-cycles computers. The definition of a CCC computer and an upper bound on its pin requirements were given in §3. By combining the lower bounds of Theorems 4.1 and 4.2 with published algorithms for permuting and sorting on a CCC computer, it is possible to prove tight lower bounds on the pin requirements of a CCC computer. The following lemma is due to Preparata and Vuillemin [22].

LEMMA 6.1. *The average- and worst-case times required to permute N items on an N-processor cube-connected-cycles computer are $O(\log N)$.*

The following lemma was proven by Reif and Valiant [23].

LEMMA 6.2. *The average-case time required to sort N items on an N-processor cube-connected-cycles computer is $O(\log N)$.*

THEOREM 6.3. *If M is a cube-connected-cycles computer with N processors, then $Q = \Omega(N/C \log(4N/C))$.*

Proof. Let T be the worst-case time required to permute N items on M. From Lemma 6.1 $T = O(\log N)$. We will consider two cases based on the relative values of C and N. First, consider the case $C \leq N^{1/2}$. In this case note that $\log(4N/C) = \Omega(\log N)$. From Theorem 4.1 $TCQ = \Omega(N)$, so $Q = \Omega(N/C \log N) = \Omega(N/C \log(4N/C))$.

Next, consider the case $C > N^{1/2}$. In this case note that $\log C = \Omega(\log N)$. From Theorem 4.2 $TCQ \log Q / \log C = \Omega(N)$, so $Q \log Q = \Omega(N \log C / C \log N) = \Omega(N/C)$. If $Q < 4N/C$ then $\log Q = O(\log(4N/C))$ and $Q = \Omega(N/C \log(4N/C))$. Otherwise, $Q \geq 4N/C$, so $Q = \Omega(N/C)$ and $Q = \Omega(N/C \log(4N/C))$. □

We will now show that the CCC computer is capable of matching the lower bounds for the average- and worst-case permutation problems and for the average-case sorting problem given by Theorems 4.1 and 4.2. Recall that the stronger lower bound is obtained by using Theorem 4.1 when $C = O(Q)$ and by using Theorem 4.2 when $Q = O(C)$.

THEOREM 6.4. *If M is a cube-connected-cycles computer with N processors and if T is the average-case time required to permute or sort N items on M or the worst-case time required to permute N items on M, then either*

$$C = O((N/\log N)^{1/2})$$

and

$$C = O(Q) \quad \textit{and} \quad TCQ = O(N)$$

or

$$C = \Omega((N/\log N)^{1/2})$$

and

$$Q = O(C) \quad \textit{and} \quad TCQ \log Q / \log C = O(N).$$

Proof. First, consider the case $C = O((N/\log N)^{1/2})$. From Theorem 6.3

$$\begin{aligned} Q &= \Omega(N/C \log(4N/C)) \\ &= \Omega(N/(N/\log N)^{1/2} \log N) \\ &= \Omega((N/\log N)^{1/2}) \\ &= \Omega(C), \end{aligned}$$

so $C = O(Q)$. From Lemmas 6.1 and 6.2 $T = O(\log N)$. From Theorem 3.7 $Q = O(N/C \log(4N/C))$. Therefore, $TCQ = O(N \log N / \log(4N/C))$. Because $C = O((N/\log N)^{1/2})$, $\log(4N/C) = \Omega(\log N)$. Therefore, $TCQ = O(N)$.

Next, consider the case $C = \Omega((N/\log N)^{1/2})$. If $f(x) = x/\log x$, then the derivative $f'(x) = (\ln^{-1} x - \ln^{-2} x)\ln 2$ and $f'(x) > 0$ when $x \geq 3$. But $4N/C \geq 4$, so $f(4N/C)$ is maximized when $4N/C$ is largest. From Theorem 3.7

$$\begin{aligned} Q &= O(N/C\log(4N/C)) \\ &= O(f(4N/C)) \\ &= O((N\log N)^{1/2}/\log(N\log N)^{1/2}) \\ &= O((N/\log N)^{1/2}) \\ &= O(C). \end{aligned}$$

Because $f(4N/C) \geq 2$ and $Q = O(f(4N/C))$, it holds that $\log Q = O(\log f(4N/C)) = O(\log(4N/C))$. Therefore, $Q\log Q = O(N/C)$. From Lemmas 6.1 and 6.2 $T = O(\log N)$. Because $C = \Omega((N/\log N)^{1/2})$, $\log C = \Omega(\log N)$. As a result, $TCQ\log Q/\log C = O(N)$. □

7. Shuffle-exchange computers. This section contains tight lower and upper bounds on the pin requirements of shuffle-exchange computers [26]. A shuffle-exchange computer has $N = 2^n$ processors, each of which has a unique label in the range 0 through $N - 1$. For any integer i, where $0 \leq i < N$, let $(i_{n-1}, \cdots, i_0)$ denote the n-bit binary representation of i. Let $a \oplus b$ denote the bitwise exclusive OR of a and b, and for any integers i and j, where $0 \leq i < N$, $0 \leq j < n$, let $\text{Comp}(i,j) = i \oplus 2^j$. For any integer i, where $0 \leq i < N$, let $\text{Shuffle}(i,n) = (i_{n-2}, \cdots, i_0, i_{n-1})$, let $\text{Unshuffle}(i,n) = (i_0, i_{n-1}, \cdots, i_1)$, and let $\text{Exch}(i) = \text{Comp}(i,0)$. In a shuffle-exchange computer each processor i is connected to processor $\text{Exch}(i)$ by an *exchange edge* and to processors $\text{Shuffle}(i,n)$ and $\text{Unshuffle}(i,n)$ by *shuffle edges*.

The lower bound on the pin requirements of a shuffle-exchange computer is based on the following lemma due to Stone [26].

LEMMA 7.1. *The worst-case time required to permute N items on an N-processor shuffle-exchange computer is* $O(\log N)$.

Combining Lemma 7.1 with Theorems 4.1 and 4.2 yields the following theorem, which generalizes a result obtained by Snir [25]. The proof is identical to the proof of Theorem 6.3 and will not be repeated here.

THEOREM 7.2. *If M is a shuffle-exchange computer with N processors, then* $Q = \Omega(N/C\log(4N/C))$.

The following theorem solves an open problem posed by Snir [25]. The proof is based on results obtained by Leighton in creating an optimal area layout of the shuffle exchange [17].

THEOREM 7.3. *If M is a shuffle-exchange computer with N processors, then* $Q = O(N/C\log(4N/C))$.

Proof. First, note that if N/C is less than some constant k, then $\log(4N/C) = O(1)$ and the theorem holds from any assignment of nearly equal numbers of processors to each chip. Therefore, in the remainder of the proof it will be assumed that N/C is larger than any given constant k. To obtain an optimal area layout of the shuffle exchange, Leighton divided the processors into two sets, one that contained $O(N/\log N)$ processors and will be called the *exceptional processors* and another that contained the remainder of the processors and will be called the *regular processors* [17]. (In Leighton's terminology, the exceptional processors include processors in degenerate necklaces, processors for which the longest block of zeros has length less than $\log n - \log\ln n - 1$ or greater than $2 \log n$, and processors for which there is no distinguished node for the piece of the necklace containing the processor.) Leighton then defined a $\log N \times O(N/\log N)$ grid of nodes, and he gave rules for placing the regular processors on this grid.

A similar grid of nodes will be used here. For any regular processor i let Col(i) be what Leighton referred to as the distinguished node of the (basic, primary, or secondary) piece of the necklace containing processor i. Also, for any regular processor i let Row(i) be the row of Leighton's grid that contains processor i. Then create a $\log N \times O(N/\log N)$ grid of nodes, where the rows are numbered $0, \cdots, \log N - 1$ and the columns are numbered with all of the possible values of the function Col(i). Next, place each regular processor i in row Row(i) and column Col(i) of this grid. The following properties of this grid follow immediately from the properties of Leighton's grid.

• At most three processors are assigned to each node of the grid.

• For all but $O(N/\log N)$ regular nodes i, Col(Shuffle(i, n)) $=$ Col(i) and Row(Shuffle(i, n)) $=$ Row(i) $- 1$.

• For all but $O(N/\log N)$ regular nodes i, Col(Unshuffle(i, n)) $=$ Col(i) and Row(Unshuffle(i, n)) $=$ Row(i) $+ 1$.

• For all but $O(N/\log N)$ regular nodes i, Col(Exch(i)) $=$ Comp(Col(i), Row(i)) and Row(Exch(i)) $=$ Row(i).

This grid will be used to partition the processors onto C chips. The idea is to create an initial partition of the processors P' such that each group in the initial partition is very small and the total number of edges that cross partition boundaries is also small. A final partition of the processors P is obtained by merging groups in the initial partition until no more than C groups remain.

The initial partition P' is based on the observation that when the regular processors of a shuffle-exchange computer are assigned to the $\log N \times O(N/\log N)$ grid defined above, a similarity between their connections and the connections of a CCC computer becomes apparent. As a result, the optimal partition of a CCC computer given in Theorem 3.7 can be used to obtain a good partition of the regular nodes in a shuffle-exchange computer. Let $x = \lfloor (\log(4N/C))/2 \rfloor$, and let $y = 2^x$. Note that $x = \Theta(\log(4N/C))$ and $y = \Theta((N/C)^{1/2})$. For each regular processor i let Band(i) $= \lfloor \text{Row}(i)/x \rfloor$, and if Col($i$) $= j = (j_{n-1}, \cdots, j_0)$ then let Vert(i) $= k = (k_{n-1}, \cdots, k_0)$, where for all h, $0 \leq h < n$, $k_h = 0$ if $\lfloor h/x \rfloor =$ Band(i) and $k_h = j_h$ otherwise. The partition P' is formed by assigning each exceptional processor to its own group and by assigning regular processors i and j to the same group if and only if Band(i) $=$ Band(j) and Vert(i) $=$ Vert(j). Then each group of this partition has at most $3xy = O((N/C)^{1/2} \log(4N/C)) = O(N/C \log(4N/C))$ processors and the size of the boundary of each group is at most $O(N/C \log(4N/C))$. Also, there are at most $O((N/\log N)(\log N/\log(4N/C))) = O(N/\log(4N/C))$ shuffle edges that are not local to a group of processors and at most $O(N/\log N) = O(N/\log(4N/C))$ exchange edges that are not local to a group of processors. Let the constant a be such that there are at most $aN/\log(4N/C)$ edges that are not local to a group of processors.

Next, the groups defined by partition P' are arbitrarily divided into three classes with the only restriction being that each class contains fewer than $N/2$ processors. The final partition P is then created by merging groups in the partition determined by P', subject to the restriction that only groups in the same class can be merged. Specifically, a greedy procedure is used to merge groups defined by partition P', all of which are in the same class, until a cluster (collection of groups) is obtained that has a boundary of $4aN/C \log(4N/C)$ or more edges, or until the class is empty. Because the groups in the initial partition are so small, each cluster will have a boundary of at most $O(N/$

$C \log(4N/C))$ edges. Also, because there are at most $aN/\log(4N/C)$ edges that are not local to a group in the initial partition and because all but three of the clusters have a boundary of at least $4aN/C \log(4N/C)$ edges, there are at most $C/4 + 3 \leq C$ clusters. Finally, each cluster has fewer than $N/2$ processors. Thus the partition P, which is defined to consist of these clusters, is legal, and $Q \leq \text{Girth}(M, P) = O(N/C \log(4N/C))$. □

Following the original appearance of Theorem 7.3 [8], Koch et al. showed an embedding of an N-processor shuffle exchange into an $O(N)$-processor butterfly with constant load and congestion [16]. That embedding, combined with a similar embedding of a butterfly into a cube-connected-cycles computer and Theorem 3.7, could be used to obtain an alternative proof of Theorem 7.3.

The following lemma proves that when $C = N^{1/2}$ the upper bound on Q given in Theorem 7.3 can be achieved without assigning more than $N^{3/4}$ processors to any one chip. Although this result will not be needed in this section, it will be used in §9. The proof is omitted because it is identical to the proof of Theorem 7.3, except that $N^{1/4}$ classes of $O(N^{3/4})$ processors each are used instead of three classes of fewer than $N/2$ processors each.

LEMMA 7.4. *If M is a shuffle-exchange computer with N processors, then it is possible to partition M onto $C = N^{1/2}$ chips with $O(N^{3/4})$ processors per chip and with $O(N^{1/2}/\log N)$ pins per chip.*

8. AKS computers.

Ajtai, Komlós, and Szemerédi created a sorting network for N items that has $O(N \log N)$ comparators and $O(\log N)$ depth [2]. The constants of proportionality hidden in the $O(N \log N)$ and $O(\log N)$ bounds are extremely large, so the network is not useful in practice. However, this network, which will be called the *AKS network*, is of great theoretical interest because all previously known sorting networks required $\Omega(\log^2 N)$ depth. As a result, the AKS network has been important in answering a number of questions about parallel sorting.

We will define a parallel computer, called the *AKS computer*, that is based on the AKS network. We begin with an AKS network for sorting r items, where $r = \Theta(N/\log N)$. This network receives r input lines from the left and produces the sorted items on r output lines on the right. The network consists of $\Theta(r \log r)$ comparators that are arranged in $d = \Theta(\log r)$ columns. The AKS computer is created by forming an $r \times d$ array of $rd = N$ processors. Each processor (i, j), where $0 \leq i < r$ and $0 \leq j < d$, is connected to processors $(i, (j+1) \bmod d)$ and $(i, (j-1) \bmod d)$ by horizontal connections. Also, each processor (i, j) is connected to processor (i', j) by a vertical connection if and only if wires i and i' are connected by a comparator in column j of the AKS network (see Fig. 4). Thus an AKS computer is basically an AKS network with processors instead of comparators and with wraparound connections between the input and output lines.

One notable application of the AKS computer was obtained by Leighton, who showed that an AKS computer with N processors can sort N items in $O(\log N)$ time [18]. Leighton's technique consists of performing sorts of r items in a pipelined manner plus performing four fixed permutations of the N items. Leighton proposed adding additional connections to implement these permutations, but they could also be performed on the AKS computer defined above without sacrificing the $O(\log N)$-time performance of the sort. This can be done by breaking each of the fixed permutations of N items into permutations of the r items located in the same column of the computer, followed by permutations of the $O(\log r)$ items located in the same row of the computer, followed by permutations of the r items located in the same column of the computer. This breaking

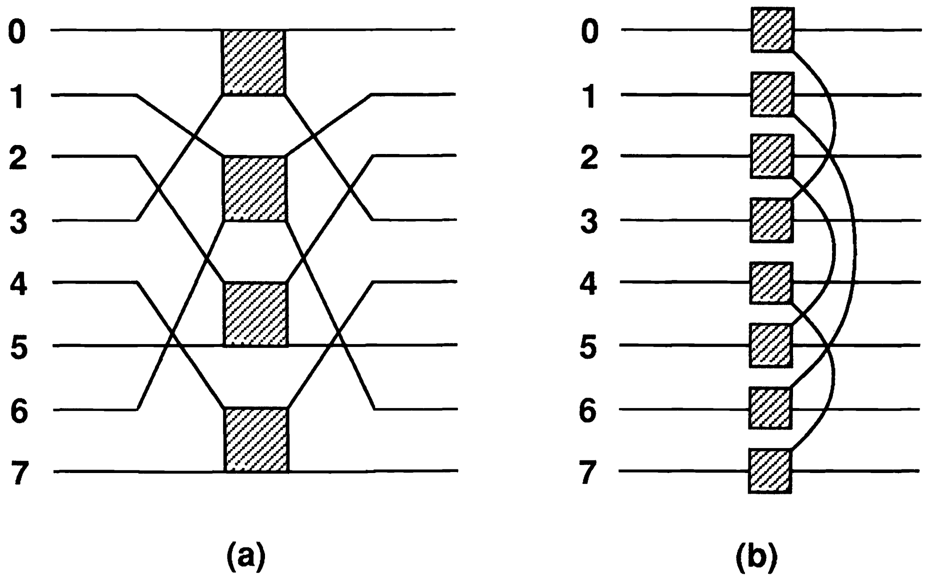

FIG. 4. *Relationship between* (a) *a column in the* AKS *network and* (b) *a column in the* AKS *computer.*

of a permutation into smaller permutations can be accomplished by using the Hall–Konig marriage theorem [33]. The permutations within rows can be implemented by simply using the horizontal connections to shift each item to its destination in $O(\log r)$ time. The permutations within columns can be implemented by sorting the items within each column according to their destination row. Of course, these sorts can also be pipelined and thus can be implemented in $O(\log r)$ time. This $O(\log N)$-time algorithm for sorting N items on an N-processor AKS computer will be called the Leighton–AKS algorithm.

The AKS network has been used to obtain minimum-area VLSI sorters. Bilardi and Preparata demonstrated that the N-input AKS sorting network has $O(N^2)$ area [3] (in the word model), and Leighton used this result and the Leighton–AKS algorithm to show that an $O(N^2/\log^2 N)$-area VLSI sorter that sorts N items in $O(\log N)$ time could be created [18]. This result matches the lower bound for sorting of $AT^2 = \Omega(N^2)$ proved by Thompson [30]. Thus despite its complex pattern of comparisons, the AKS computer requires the minimum possible amount of area for a VLSI sorter that operates in $O(\log N)$ time. In this section we will show that despite the optimality of the AKS computer from an area perspective, the AKS computer is suboptimal from a VLSI-pin-requirements perspective.

The detailed structure of an AKS computer is quite complicated and will not be repeated here. Instead, a few key characteristics of the AKS computer will be reviewed. First, recall that an AKS computer with N processors has the structure of an AKS sorting network for sorting $r = \Theta(N/\log N)$ items. The columns in an AKS computer are grouped into $\log r + 1$ stages. All of the connections from processors in stage i, where $0 \leq i \leq \log r$, are to processors in stages $i-1 \bmod (\log r+1)$, i, and $i+1 \bmod (\log r+1)$. The processors in each stage are located in r different rows, and connections between processors in different stages link processors that lie in the same row.

Each stage (except the first) is divided into three substages. During each substage the processors are partitioned into a number of groups, and comparisons are performed only within groups. Within each stage (except the first) the first and third substages use one partition, and the second substage uses a different partition. These partitions can be defined with the help of a complete binary tree having r leaves. Each node of the binary tree is assigned a natural interval in the range $0, \cdots, r-1$, where the root is given the entire interval, and the left and right children of a node are assigned the left and right halves, respectively, of that node's interval. We will use these overlapping natural intervals to define a partition of $0, \cdots, r-1$ into disjoint subintervals. More specifically, the nodes of the binary tree occupy $\log r + 1$ levels with the root being in level 0 and the leaves being in level $\log r$. During each stage i, $0 \le i \le \log r$, the nodes at level i of the tree are assigned their entire natural intervals, and nodes at level $i - j$, $1 \le j \le i$, are assigned two intervals, each of which is α^{-j} as long as the node's natural interval, located at each end of the node's natural interval ($\alpha \ge 8$ is a constant set to 100 in the original AKS paper [2]). The nodes at each level other than level 0 actually receive slightly less than their entire intervals, because the nodes at lower numbered levels have priority (see Fig. 5).

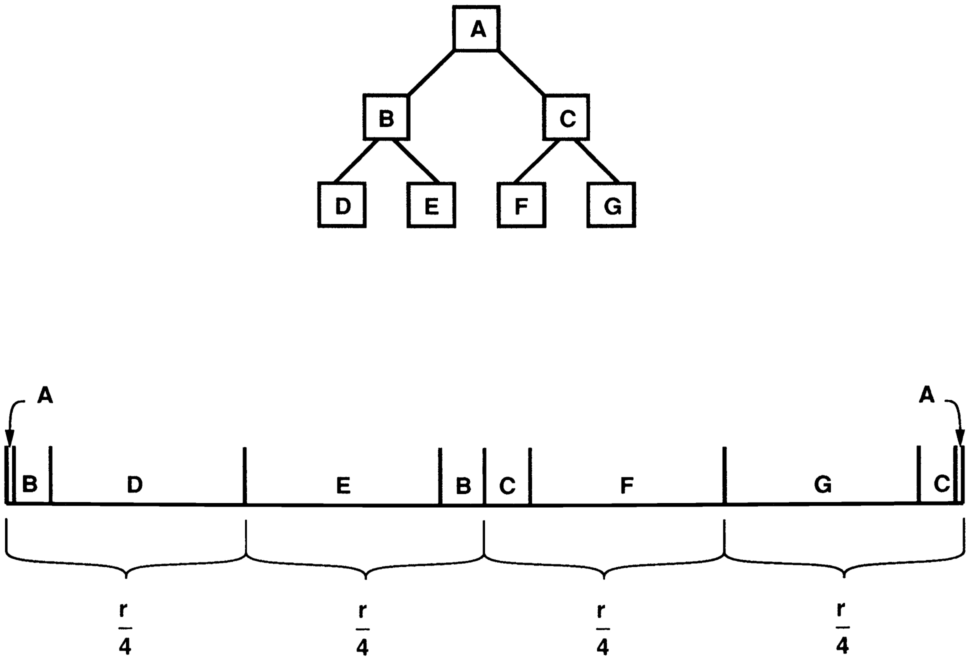

FIG. 5. *Binary tree and associated intervals for stage $i = 2$.*

This binary tree is then divided into triangles of three nodes each. During the first and third substages of a stage the binary tree is divided into triangles with apexes at even levels (see Fig. 6), but during the second substage of a stage the binary tree is divided into triangles with apexes at odd levels (see Fig. 7). During each substage the processors are partitioned by rows according to the intervals contained in the triangles in the binary tree. In the first stage all of the rows of processors lie in a single group.

Within each of the groups of a partition, an operation called a *nearsort* is performed. The details of the nearsort will be ignored, but two properties of the nearsort will be needed. First, comparisons are performed only within groups. Second, each group is divided into an upper half and a lower half, and a set of comparisons is performed of

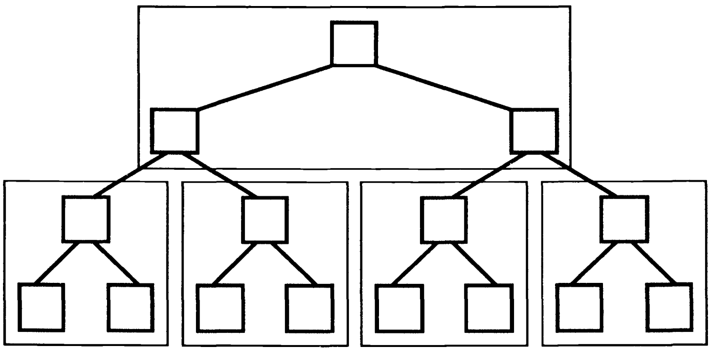

FIG. 6. *Division of binary tree for first and third substages.*

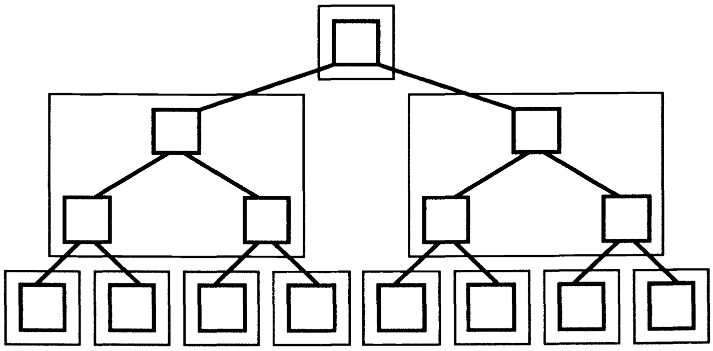

FIG. 7. *Division of binary tree for second substage.*

the two halves, which form a bipartite expander graph with parameters $((1-\epsilon)/\epsilon, \epsilon, \gamma)$, where $0 < \epsilon < \frac{1}{7}$ and $\gamma > 1$ are constants ($\epsilon = 10^{-9}$ in the original AKS paper [2]). A bipartite expander graph with $2w$ nodes and with parameters (x, y, z) has degree at most z, and yet for each set S consisting of wy or fewer nodes of one partite set, at least $x|S|$ nodes have connections to nodes in S. Such a set S will be said to be *expanded* by a factor of x. The above properties of the AKS computer will be used to prove upper and lower bounds on the pin requirements of AKS computers.

THEOREM 8.1. *If M is an AKS computer with N processors, then it holds that $Q = O(N \log C/C \log N)$.*

Proof. Recall that the processors can be viewed as forming a rectangular array with $r = \Theta(N/\log N)$ rows. If $C \geq r$, then $\log C = \Theta(\log N)$ and the claim is that $Q = O(N/C)$, which is trivially accomplished by assigning roughly equal numbers of processors to each chip. If $C < r$, then let $c = 2^{\lfloor \log C \rfloor}$ and partition the r rows of processors into c sets each containing r/c adjacent rows (it is assumed that r is a power of 2). It will be shown that this partition is legal and has only $O(N \log C/C \log N)$ pins per chip. First, note that all horizontal connections are local to chips, so only vertical connections require pins. Next, note that stages $0, \cdots, \log c$ contribute only $O(r \log c/c)$ processors to each chip, and thus they contribute only $O(r \log c/c)$ pins to each chip.

Now consider the processors in stages $\log c + 1, \cdots, \log r$. In the binary tree that determines the partitions used by the AKS network, the natural intervals of the nodes at levels $\log c + 1, \cdots, \log r$ lie entirely within the blocks of r/c rows that are assigned to single chips. As a result, only levels $0, \cdots, \log c$ (which will be called the *upper levels*) correspond to processors that will require pins for their vertical connections. There are at most kr/c (where k is a constant determined by the AKS network) processors per chip in the upper levels during stage $\log c + 1$, at most kr/ck' (where $k' > 1$ is a constant determined by the AKS network) processors per chip in the upper levels during stage $\log c + 2$, and, in general, at most $kr/c(k')^{i-1}$ processors per chip in the upper levels during stage $\log c + i$, where $1 \leq i \leq \log r - \log c$. Therefore, there are a total of at most $O(r/c)$ processors per chip in the upper levels during stages $\log c + 1, \cdots, \log r$ combined and at most $O(r/c) + O(r \log c/c) = O(N \log C/C \log N)$ pins per chip. Finally, the partition is legal because $c \geq 4$ and each chip has at most N/c processors. $\square$

We will now prove a matching lower bound on the pin requirements of an AKS computer. Our proof will require a number of definitions. First, let r be such that an AKS computer with N processors has the connections of an AKS sorting network with r inputs. Recall that $r = \Theta(N/\log N)$. Let α and ϵ be constants given by the AKS network construction as defined above. Let β be the maximum number of processors in any single row and stage of an AKS computer. Let $k_1 = \log(4/\epsilon)$, and let k_2 be such that an AKS computer with N processors requires at most $k_2 \log N$ time to sort N items by using the Leighton–AKS algorithm. Let k_3 be such that for any parallel computer, if T is the worst-case time required to sort N items, then $TCQ \geq k_3 N$ (see Theorem 4.1). Let $k_4 = (k_2 + 1)^4 + 2^{4k_1}$, let k_5 be such that $r \leq k_5 N/\log N$, and let $k_6 = \min(1/16\beta, 1/k_5, k_3/k_2k_4k_5)$. Note that α, β, ϵ, k_1, k_2, k_3, k_4, k_5, and k_6 are constants. Also, notice that $\alpha \geq 8$, $\beta \geq 1$, $0 < \epsilon < 1/7$, $(1-\epsilon)/\epsilon > 6$, $k_1 \geq 4$, $k_4 \geq 2^{16}$, and $k_6 \leq 1$.

The following lemmas will be helpful in obtaining the lower bound on Q.

LEMMA 8.2. *If M is an AKS computer with N processors and if P is a legal partition of M onto C chips, then either* $\mathrm{Girth}(M, P) \geq k_6 r \log C/C$ *or* $C > k_4$.

Proof. Assume for the sake of contradiction that the claim is false, in which case $C \leq k_4$ and $\mathrm{Girth}(M, P) < k_6 r \log C/C$. Let T be the time required to implement the Leighton–AKS algorithm on M. Because $Q \leq \mathrm{Girth}(M, P)$, $TCQ \geq k_3 N$, and $T \leq k_2 \log N$, it follows that

$$\begin{aligned} \mathrm{Girth}(M, P) &\geq k_3 N/TC \\ &\geq k_3 N/k_4 k_2 \log N \\ &\geq k_3 r/k_2 k_4 k_5 \\ &\geq k_6 r \\ &\geq k_6 r \log C/C \end{aligned}$$

which is a contradiction. $\square$

LEMMA 8.3. *If M is an AKS computer with N processors and if P is a legal partition of M onto C chips, then either* $\mathrm{Girth}(M, P) \geq k_6 r \log C/C$ *or each chip contains processors from at most $r/C^{1/2}$ different rows of the AKS computer.*

Proof. Assume for the sake of contradiction that the claim is false, in which case $\mathrm{Girth}(M, P) < k_6 r \log C/C$ and there exists some chip x that contains processors from more than $r/C^{1/2}$ different rows. We will classify each row of the AKS computer according to how many of the processors in that row are assigned to chip x. Let a row of processors be a *full row* if all of the processors in that row are assigned to chip x, let a row of processors be a *partial row* if some but not all of the processors in that row are assigned to chip x, and let a row be an *empty row* otherwise. First, we will show that there are fewer than $k_2 r \log C/C$ full rows. This is true because if there are at least $k_2 r \log C/C$ full rows, then chip x must contain at least $k_2 N \log C/C$ processors. Because the items from chip x can be moved to other chips in $k_2 \log N$ time by using the Leighton–AKS algorithm, chip x must have at least $N \log C/C \log N \geq r \log C/k_5 C \geq k_6 r \log C/C$ pins, which would imply that $\text{Girth}(M, P) \geq k_6 r \log C/C$, which would be a contradiction. Therefore, there are fewer than $k_2 r \log C/C$ full rows.

Because chip x contains processors from more than $r/C^{1/2}$ different rows, there must be more than $r/C^{1/2} - k_2 r \log C/C$ partial rows. But from Lemma 8.2 $C > k_4 \geq 2^{16}$ so $C^{1/4} - k_2 \geq 1$, $\log C \leq C^{1/4}$ and $(\log C)/C \leq 1/C^{3/4}$. Therefore, $r/C^{1/2} - k_2 r \log C/C \geq (r/C^{3/4})(C^{1/4} - k_2) \geq r/C^{3/4} \geq r \log C/C$. But chip x must have at least one pin per partial row because the processors in each row are connected in a cycle. Therefore, $\text{Girth}(M, P) \geq r \log C/C \geq k_6 r \log C/C$, which is a contradiction. $\square$

THEOREM 8.4. *If M is an AKS computer with N processors, then it follows that $Q = \Omega(N \log C/C \log N)$.*

Proof. Assume for the sake of contradiction that there exists a legal partition $P = P_0, \cdots, P_{C-1}$ of M onto C chips such that $\text{Girth}(M, P) < k_6 r \log C/C$. Note that from Lemma 8.2 $C > k_4$.

Consider an arbitrary stage i of the AKS computer, where $1 \leq i \leq \frac{1}{2} \log C - k_1$. If i is even, let $j = 1$, and if i is odd, let $j = 2$. As was discussed earlier, the processors in each substage of each stage are partitioned with the use of a binary tree. In the first substage of each stage the nodes in the binary tree are divided into triangles with apexes at even levels, and in the second substage of each stage they are divided into triangles with apexes at odd levels. Thus in substage j of stage i the nodes in the binary tree are divided so that each node in level i of the binary tree forms its own group. The natural interval for each node in level i of the binary tree has size $r/2^i$. Although each node in level i does not receive all of its natural interval (part of the interval is taken by nodes at lower numbered levels), it does receive at least

$$1 - \sum_{h=1}^{i} (2/\alpha)^h \geq 1/2$$

of its natural interval (because each level $i - h$, $1 \leq h \leq i$, takes a fraction of at most $(2/\alpha)^h$ of the natural interval of a node at level i). Let the intervals assigned to nodes at level i of the binary tree be called *primary intervals*, and let the upper and lower halves of a primary interval be called *half intervals*. Because $1 \leq i \leq \frac{1}{2} \log C - k_1$ and because each node at level i receives at least half of its natural interval, each primary interval contains at least $r/2^{i+1} \geq r(4/\epsilon)/2C^{1/2} = 2r/C^{1/2}\epsilon$ rows and each half interval contains at least $r/C^{1/2}\epsilon$ rows.

Now consider an arbitrary primary interval y and an arbitrary chip P_x, $0 \leq x < C$. Let V be the set of processors in P_x that are in substage j of stage i, and let W be the set of processors in V that are in rows associated with primary interval y. Let S be the set of rows in the AKS computer that contain one or more processors in W. Note that from Lemma 8.3 $|S| \leq r/C^{1/2}$. Each row in set S will be called a *complete row* if and only if all of the processors in that row that are in substage j of stage i are in P_x. Let U be the set of rows in S that are complete. There are two cases:

Case 1: $|U| \geq |S|/2$. In this case let U_1 and U_2 be the subsets of U contained in the upper and lower half intervals of y, respectively. Assume without loss of generality that $|U_1| \geq |U_2|$. Because $|U_1| \leq |S| \leq r/C^{1/2}$ and the half interval containing U_1 has at least $r/C^{1/2}\epsilon$ rows, U_1 consists of at most a fraction of ϵ of the rows in the half interval, and as a result the rows in U_1 are expanded by a factor of $(1 - \epsilon)/\epsilon$ (that is, they are connected to at least $|U_1|(1 - \epsilon)/\epsilon$ rows in the lower half interval). However, at most $|S|$ rows in the lower half interval contain processors in W, so there are at least $(|U_1|(1-\epsilon)/\epsilon) - |S| > (|S|/4)(6) - |S| = |S|/2$ vertical connections between processors in W and processors not in P_x. Therefore, chip P_x must have at least $|S|/2$ pins for the processors in W, which is an average of at least $1/2\beta$ pins per processor in W.

Case 2: $|U| < |S|/2$. In this case there are at least $|S| - |U| \geq |S|/2$ horizontal connections between processors in W and processors not in P_x. Therefore, chip P_x must have at least $|S|/2$ pins for the processors in W, which is an average of at least $1/2\beta$ pins per processor in W.

Thus in either case chip P_x must have at least $1/2\beta$ pins per processor in W. Because the chip P_x and primary interval y were chosen arbitrarily and because there are at least $r/2$ processors in substage j of stage i that are in some primary interval, there must be a total of at least $r/4\beta$ pins required by the processors in substage j of stage i. Note that $C > k_4 \geq 2^{4k_1}$, so $\frac{1}{2}\log C - k_1 \geq \frac{1}{4}\log C$. Because i is an arbitrary stage in the range $1 \leq i \leq \frac{1}{2}\log C - k_1$, there are a total of at least $\frac{1}{4}(\log C)(r/4\beta) = r\log C/16\beta \geq k_6 r \log C$ pins and some chip has at least $k_6 r \log C/C$ pins. Therefore, $\mathrm{Girth}(M, P) \geq k_6 r \log C/C$, which is a contradiction. As a result, for any legal partition P, $\mathrm{Girth}(M, P) \geq k_6 r \log C/C$, which implies that $Q = \Omega(N \log C/C \log N)$. □

An immediate consequence of Theorem 8.4 is that an AKS computer is suboptimal with respect to its TCQ product for the worst-case sorting problem. To show this, we will need the following lemma proved by Cypher and Plaxton [9].

LEMMA 8.5. *The worst-case time required to sort N items on an N-processor cube-connected-cycles or shuffle-exchange computer is* $O(\log N(\log\log N)^2)$.

Now let T be the worst-case time required to sort N items, and consider the case for which $C = N^{1/3}$. In this case for an AKS computer $T = \Theta(\log N)$ and $Q = \Theta(N^{2/3})$, so $TCQ = \Theta(N \log N)$. In contrast, for a cube-connected-cycles or shuffle-exchange computer $T = O(\log N(\log\log N)^2)$ and $Q = O(N^{2/3}/\log N)$, so $TCQ = O(N(\log\log N)^2)$. As a result, the TCQ product of an AKS computer is suboptimal for the worst-case sorting problem.

9. AKS algorithm lower bound.

In this section we will prove a lower bound on the running time of the AKS sorting algorithm when it is implemented on a cube-connected-cycles or shuffle-exchange computer. This lower bound is based on the bounds for the pin requirements of the AKS, cube-connected-cycles, and shuffle-exchange computers presented earlier.

THEOREM 9.1. *If M is a cube-connected-cycles or shuffle-exchange computer with N processors, then the time required to sort N items on M by using the AKS algorithm is* $\Omega(\log^2 N)$.

Proof. The proof follows from Theorems 3.7 and 8.4 and Lemma 7.4 with the parameter C set to $N^{1/2}$. From Theorem 3.7 and Lemma 7.4 the pin requirements of M are $Q = O(N/C \log(4N/C)) = O(N^{1/2}/\log N)$. The AKS network with N inputs can be viewed as being the data-flow graph for the AKS algorithm, where each comparator in the network represents a comparison operation in the graph and each link in the network represents the transmission of a data value from one comparison to another. Any time T implementation of the AKS algorithm on M will require that this data flow graph be mapped to M with at most T nodes of the graph being assigned to each processor and at most T edges of the graph lying on each communication link of M. Note that the ith largest item, $0 \leq i < N$, must be moved to processor i, which is the processor that originally had the ith input. This corresponds to the existence of wraparound edges in the data-flow graph. Thus a time T implementation of the AKS algorithm will also define a partition of an $O(N \log N)$ node AKS network (with wraparounds) onto $N^{1/2}$ chips with girth at most $QT = O(TN^{1/2}/\log N)$. From Lemma 7.4 and the proof of Theorem 3.7 each chip contains at most $N^{3/4}$ processors from M. Therefore, when $T = O(\log^2 N)$ the resulting partition of the AKS network (with wraparounds) is legal. However, from Theorem 8.4 an $O(N \log N)$ node AKS network (with wraparounds) that is legally partitioned onto $N^{1/2}$ chips must have a girth of at least $\Omega(N^{1/2} \log N)$. Thus $TN^{1/2}/\log N = \Omega(N^{1/2} \log N)$ and $T = \Omega(\log^2 N)$. $\square$

It is quite easy to attain the lower bound given in Theorem 9.1. The AKS sorting algorithm performs $O(\log N)$ stages of comparisons, where the pattern of the comparisons is fixed. As a result, each stage can be implemented by first permuting the data items so that items that need to be compared are in connected processors. Because these permutations are fixed, each of them can be implemented in $O(\log N)$ time on a cube-connected-cycles or shuffle-exchange computer [22], [26]. This implementation yields the following theorem.

THEOREM 9.2. *If M is a cube-connected-cycles or shuffle-exchange computer with N processors, then the time required to sort N items on M by using the AKS algorithm is $O(\log^2 N)$.*

GAP THEOREMS FOR DISTRIBUTED COMPUTATION*

SHLOMO MORAN† AND MANFRED K. WARMUTH‡

Abstract. Consider a bidirectional ring of n identical processors that communicate asynchronously. The processors have no identifiers, and hence the ring is called anonymous. Each processor receives an input letter, and the ring is to compute a function of the circular input string. If the function value is constant for all input strings, then the processors do not need to send any messages. On the other hand, it is proven that any deterministic algorithm that computes any nonconstant function for anonymous rings requires $\Omega(n \log n)$ bits of communication for some input string. Also exhibited are nonconstant functions that require $O(n \log n)$ bits of communication for every input string. The same gap for the bit complexity of nonconstant functions remains even if the processors have distinct identifiers, provided that the identifiers are taken from a large enough domain.

When the communication is measured in messages rather than bits, the results change. A nonconstant function that can be computed with $O(n \log^* n)$ messages on an anonymous ring is presented.

Key words. distributed algorithms, networks, asynchronous, message complexity, bit complexity, ring of processors, lower bounds, gap theorem

1. Introduction. There has been an extensive amount of research on studying computation on a ring of n asynchronous processors. The ring topology is in a sense the simplest distributed network that produces many typical phenomena of distributed computation. In this model the processors may communicate by sending messages along the links of the ring, which are either unidirectional or bidirectional. All the messages sent reach their targets after a finite, but unpredictable and unbounded delay. Numerous algorithms [ASW88], [DKR82], [P82] have been found for this *asynchronous ring* model. All these algorithms require the transmission of $\Omega(n \log n)$ bits. This is not surprising in view of the results of this paper. We establish a gap theorem for asynchronous distributed computation on the ring which says that either the function computed is constant and no messages need to be sent, or the function is nonconstant and there is an input string requiring $\Omega(n \log n)$ bits.

In our model there is no leader among the processors. All processors receive a letter from some input alphabet as their input and run the same deterministic program, which may depend on the ring size. We first treat the case where the ring is unidirectional and the processors have no identifiers (the anonymous model of [ASW88]). Then we show that the lower bound holds also for bidirectional anonymous rings, and for rings of processors with distinct identifiers, provided the set of possible identifiers is sufficiently large. Note that in the anonymous ring without a leader it is necessary that the processors "know" some bound on the ring size. Otherwise the processors cannot determine when to terminate [ASW88].

Let us contrast the anonymous ring with the model of a ring with a leader (which is also the initiator of the algorithm). If we assume unidirectional communication, then any nonconstant function that depends on the input of any processor other than the input of leader requires $\Omega(n)$ bits. In the bidirectional case, there are simple nonconstant

functions for any bit complexity $\Theta(b(n))$. If $b(n) \geq n^2$, such a function is achieved using nonconstant size input alphabet. We now show how to achieve such a function with $b(n) < n^2$. In this case the input letters are bits. The input to the ring is denoted as an n-bit cyclic string ω, the ith bit ω_i of ω being the input letter of the ith processor. Using a crossing sequence argument on pairs of links we can show that the following function is a nonconstant function of bit complexity $\Theta(b(n)) : f(\omega) = 1$ if and only if ω contains a palindrome of

$$2\left\lceil\sqrt{b(n)}\right\rceil + 1$$

bits centered at the leader (the same function was first described in [MZ87], where it was used for a similar purpose). Thus there is no gap for rings with a leader. Our gap theorem for anonymous rings clearly quantifies the price we have to pay for having no distinguished processor.

In the model where there is a leader but the size of the ring is unknown, a different sort of "gap" has been found by Mansour and Zaks [MZ87]. They showed that a language is accepted in this model in $O(n)$ bit complexity if and only if it is regular, and every nonregular language requires $\Omega(n \log n)$ bits. These results of [MZ87] are analogous to the classical results for one-tape Turing machines [T64], [H68]. Note that the bit complexity of nonregular language coincides with the bit complexity required for computing the size of the ring. As discussed above, if the size of the ring is known, then for any bit complexity, there is a language with that complexity on rings with a leader.

The lower bound of $\Omega(n \log n)$ for anonymous rings proven here does not hold if one counts *messages* (of arbitrary length) instead of bits. In fact, we show in this paper that if the input alphabet is of size at least n, then there are simple nonconstant functions that can be computed in $O(n)$ messages, for arbitrary ring size. Considering the message complexity is more interesting in the case when the input alphabet is of constant size, independent of the ring size n. In [ASW88] a nonconstant function was presented that is computable in $O(n)$ messages on an anonymous ring when the inputs are bits. However, this function is only defined for rings of odd size. It is easy to find similar functions for rings whose sizes are not divisible by some fixed integer. When the smallest nondivisor of the ring size is large, the ring contains more inherent symmetry, and it is hard to find nonconstant functions of low message complexity. We exhibit a nonconstant function with binary inputs for arbitrary ring size that can be computed[1] in $O(n \log^* n)$ messages. For some values of n, a matching lower bound of $O(n \log^* n)$ was proven for computing any nonconstant function [DG87]. The lower bound assumes that the input alphabet is finite.

Our lower bound proofs rely heavily on the asynchronous nature of the computation. We use the fact that the result of a computation must be independent of the specific delay times of the links, and impose certain delays on the links that assure that $\Omega(n \log n)$ bits are sent. In contrast, on synchronous anonymous rings, the Boolean *AND* can be computed with $O(n)$ bits [ASW88], and $\Omega(n)$ is also a trivial lower bound for an arbitrary nonconstant function.

Our research opens many challenging problems concerning gap theorems in distributed computation. Given an asynchronous network of anonymous processors, define the *distributed bit* (*message*) *complexity* of the network to be the smallest bit (message) complexity of a nonconstant function when computed on that network. Intuitively, this complexity measures the minimum effort needed to coordinate the processors of the net-

[1]The function $\log^* n$ grows very slowly (≤ 5 for $n \leq 2^{65536}$). It is the number of iterations of the function $\log_2$ required to get the value n down to 1 or below.

work in any sensible way.[2] This coordination should be more difficult if the network is highly symmetric. What parameters of the network correspond to this complexity? How does this complexity depend on the connectivity, diameter, or other properties of the network? Our results show that the distributed bit complexity of a ring of n processors is $\Theta(n \log n)$. The distributed bit complexity of the torus was recently shown to be linear in the number of processors [BB89].

In the next section we summarize the model of computation. We first prove the $\Omega(n \log n)$ lower bound on the bit complexity for unidirectional rings with no identifiers (§3), and then we generalize the result to bidirectional rings (§4) and to rings with identifers (§5). In the last section we show that for each n, there are nonconstant functions that can be computed on a ring of n anonymous processors by algorithms of $O(n \log n)$ bit complexity and $O(n \log^* n)$ message complexity. The latter function is defined by interleaving de Bruijn sequences of various lengths. We also show there that if we allow the alphabet size to be $\Omega(n)$, then there is a nonconstant function (defined uniformly for all ring sizes) of linear message complexity.

The Gap Theorem with distinct identifiers assumes that the identifiers are chosen from a set of double exponential size. Similar theorems for small identifier sets are considered in a subsequent paper [BMW91]. Also Gap Theorems for probabilistic models have been recently shown in [AAHK89].

2. The model. Our computational model is a ring R of n processors, $p_1, p_2, \ldots, p_n$. The processors are *anonymous*, i.e., they do not have identifiers, and they run the same deterministic program which may depend on the ring size. In particular, the program of p_i does not depend on its index i. Consecutive processors (as well as the last processor p_n and the first processor p_1) are connected by communication *links*, and thus each processor has two *neighbors*. A processor can distinguish between its two neighbors; one is called the *left* and the other one the *right* neighbor. An *orientation* of the ring is a particular assignment of left and right to the links of each processor. If the notions of left and right of all processors are consistent, then we say the ring is *oriented*. In the *bidirectional* ring connected processors can send and receive messages to and from both neighbors, respectively. In the *unidirectional* ring we assume that the ring is oriented and that messages can only be sent to the right and received from the left, that is, messages can only travel in one direction around the ring.

We assume that messages are encoded as nonempty bit strings. The messages sent along a fixed direction of a link arrive in the order in which they were sent. The communication is *asynchronous*, meaning that messages arrive with an unpredictable but finite delay time. We assume that any nonempty subset of the processors may wake up spontaneously and start running the algorithm. Processors that do not wake up spontaneously are awakened upon receiving a message from a neighbor.

In our model, the input of each processor is a letter of an arbitrary alphabet I, i.e., the functions have the domain I^n. We shall assume that I contains the letter 0. An *execution* of an algorithm on a unidirectional or bidirectional ring consists of (i) an input assignment to each processor, (ii) in the case of a bidirectional ring an orientation of the ring, and (iii) a combined schedule of how the algorithm is run at each processor. The schedule includes wake up times for each processor, the exact times for each step taken by the individual runs of the algorithm and times for when each message was sent and received. The schedule has to satisfy the requirements of asynchronous ring computations, as described above.

[2]This complexity might also depend on the size of the input alphabet over which the functions are defined.

An algorithm *computes* a function f (which is defined for a particular ring size[3] n) if for every input string ω in I^n and each execution on the ring labeled with ω every processor outputs $f(\omega)$. For any nonconstant function f there is a string $\omega \in I^n$ such that $f(\omega) \neq f(0^n)$. For any algorithm that computes f we say for convenience that if the input is ω (respectively, 0^n), then all processors running AL reach an *accepting* (respectively, *rejecting*) state.

Note that functions computed on a ring without a leader must be invariant under circular shifts of the input string and in case of (unoriented) bidirectional ring also under reversal of the input string [ASW88]. The *bit* (*message*) *complexity* of any algorithm is the maximal number of bits (messages) sent over all possible executions of this algorithm. The bit (message) complexity of a function f is the minimal possible bit (message) complexity of any algorithm that computes f. The bit (message) complexity of a given network is the minimal possible bit (message) complexity of any nonconstant function when computed on that network. The lower bound we prove on the bit complexity of bidirectional rings also holds when the bidirectional rings are oriented. All algorithms presented in this paper are for unidirectional rings. We discuss how they can be converted to algorithms of similar bit and message complexities that work on unoriented bidirectional rings.

Proof method for the lower bounds. We consider an arbitrary algorithm AL that computes a nonconstant function on a ring of size n, and we construct executions of AL on lines of processor of various lengths. By cutting and pasting such executions we get an execution of AL on a ring of size n in which at least $cn \log n$ bits are sent for some constant c independent of n. We first present the lower bound for the unidirectional case since it helps us understand the more complicated bidirectional case.

3. The lower bound for unidirectional rings.

THEOREM 1. *The bit complexity of a unidirectional ring of n anonymous processors is* $\Omega(n \log n)$.

The proof of Theorem 1 will follow from some lemmas given below. We will give lower bounds on the worst case complexity of any algorithm AL that accepts some string $\omega \in I^n$ and rejects 0^n. The first lemma (which holds for both the unidirectional and bidirectional case) is similar to Theorem 5.1 of [ASW88]. We repeat its proof here to make the paper more self-contained. Since the function value is independent of the delay times of the asynchronous computation, we may choose any delay times for the proofs: we assume that the ring is oriented, all processors start at time zero, internal computation at a processor takes no time, and links are either *blocked* (very large delay) or are *synchronized* (it takes exactly one time unit to traverse the link). For the lemma below we assume that all links are synchronized. Intuitively, this keeps the execution symmetric and causes the most messages to be sent.

LEMMA 1. *Let AL be an algorithm for a unidirectional or bidirectional ring of n processors. If AL rejects 0^n and accepts $0^z \cdot \tau$ for some τ, then AL requires at least $n\lceil z/2 \rceil$ messages on input 0^n.*

Proof. Consider the synchronized execution of AL with input string 0^n. Since all processors have the same input letter and run the same algorithm, at any given time all the processors are in the same state of the algorithm. Hence, at least one message is sent by each processor at each integral time until some time T at which no message is sent. From then on the processors are inactive because no new messages are received. Thus

[3]In §6 (the last section) and only in that section we present algorithms for computing nonconstant functions that are defined for more than one ring size. In that case we give the algorithm the ring size as an argument.

the processors terminate at time T after sending at least nT messages altogether. Now consider a second execution with input string $O^z \cdot \tau$. If $T < \lceil z/2 \rceil$, then the processor $p_{\lceil z/2 \rceil}$ is in the same state of the algorithm at time step T in both executions. Thus in both cases $p_{\lceil z/2 \rceil}$ terminates with the same result, which is a contradiction. We conclude that at least $n\lceil z/2 \rceil$ messages are sent in the execution with 0^n as the input string. □

Consider an execution of the algorithm AL on ring R with ω as input string and all links synchronized. The sequence of messages sent by an anonymous processor in such an execution is uniquely determined[4] by its input letter and the sequence of messages received by the processor, which we call the "history" of the processor. Suppose all processors terminate before some time t. For $0 \leq s \leq t$ and for $1 \leq i \leq n$, we define the *history* $h_i(s)$ as the string $m_i(1)L \cdots Lm_i(r_s)$, where L is a separating symbol, and $m_i(1), \ldots, m_i(r_s)$ are the messages (nonempty bit strings) received by p_i until (and including) time s, in chronological order. Note that r_s might be smaller than s. $H_i = h_i(t)$ is the *total history* of p_i in this execution. Since the messages are nonempty bit strings, the total length of H_i is less than twice the number of bits received by p_i. Thus, a lower bound on the bit complexity of AL is implied by a lower bound on the sum of the lengths of the total histories of the processors in a certain execution of AL. The lower bound on the sum of the lengths will follow from the fact that during a certain execution of AL the number of distinct histories of the processors is $\Omega(n)$, and therefore the lemma below implies the $\Omega(n \log n)$ bound.

LEMMA 2. *Let $H_1, \ldots, H_l$ be l distinct strings over an alphabet of size $r > 1$. Then $|H_1| + |H_2| + \cdots + |H_l| \geq (l/2)\log_r(l/2)$.*

Proof. Represent the H_i with an order r-ary tree, such that each H_i corresponds to a path from the root to an internal node or a leaf of the tree. In the tree each leaf is responsible for some H_i. Assume the overall length of the strings H_i is minimized and the leaves at the lowest level of the tree are as far to the left as possible. Then in the corresponding tree each leaf and each internal node is responsible for some H_i. Furthermore, all but possibly one internal node have out-degree r, and hence at least half of all nodes are leaves. The lemma is implied by the fact that the average height of the leaves in an r-ary tree with v leaves is at least $\log_r v$. □

Outline of the proof of Theorem 1. An execution of AL is constructed for which either Lemmas 1 or 2 implies the lower bound of $\Omega(n \log n)$ bits. In the first case a processor accepts an input string that contains $\log n$ consecutive zeros. Thus Lemma 1 implies that $\Omega(n \log n)$ messages are required for input 0^n. In the second case there will be an execution with more than $n - \log n$ processors with distinct histories and Lemma 2 gives an $\Omega(n \log n)$ bits lower bound.

Let k be an integer such that all the processors have terminated before time $t = kn$ in the synchronized execution of AL on ω, and let C be a line of kn processors, denoted by $p_{1,1}, p_{2,1}, \ldots, p_{n,1}, p_{1,2}, \ldots, p_{n,k}$. Informally, C consists of k copies of the ring R of n processors that were cut at the link $p_n - p_1$ and then concatenated to form one line of kn processors. Thus, processor $p_{i,j}$ in C corresponds to the processor p_i in the jth copy of R. We make C a ring by connecting $p_{n,k}$ with $p_{1,1}$ by a link which is blocked. Note that even though every processor in C acts as if it is on a ring, the block on the link $p_{n,k} - p_{1,1}$ makes the global behavior of C to be that of a line of processors.

Let ω^k be the input string to C, where $p_{i,j}$ receives the input letter ω_i, and consider the execution of AL on C in which all links are synchronized except for the block on the link $p_{n,k} - p_{1,1}$. For $0 \leq s \leq t$, the histories $h_{i,j}(s)$ and $H_{i,j}$ of the processor $p_{i,j}$

[4]This does not hold for arbitrary executions. In this paper we only need to consider histories of specific executions.

in C (with input string ω^k) are defined similarly to the histories of the processors in R (with input ω) given above. Recall that all processors of R terminate at time $t-1$ or before. Using an argument similar to the "shifting scenario" argument of [FLM85], we show that p_n and $p_{n,k}$ act alike.

LEMMA 3. *Processor $p_{n,k}$ in C accepts.*

Proof. Recall that C consists of k identical copies of R. Assume for a moment that there is no block on the link $p_{n,k}-p_{1,1}$. It is easy to see that in that case $h_{i,j}(s)=h_i(s)$ for all i,j and for $0 \leq s \leq t$. If we now restore the block on $p_{n,k}-p_{1,1}$, then by time s, the block can only effect the s leftmost processors. Thus at time $t-1$ processor $p_{n,k}$ has exactly the same history that p_n has at time $t-1$ and $p_{n,k}$ accepts because p_n does so. □

Next, we define a subsequence $\bar{C}$ of C such that all of its processors have distinct histories at the end of the execution. First we use C to construct a directed graph, G, and the construct $\bar{C}$ from G.

The vertices of G are the processors of C, and there is a directed edge from p to q if q is the rightmost processor having the same history as the processor to the right of p. It is easy to see that there is exactly one edge leaving every processor except the last processor, $p_{n,k}$, and that G contains no cycles. Thus, G is a directed tree rooted at $p_{n,k}$. $\bar{C}$ is now the sequence of processors on the unique path that starts at $p_{1,1}$ and ends at $p_{n,k}$.

LEMMA 4. *No two processors of $\bar{C}$ have the same history in the execution on C.*

Proof. The first processor in $\bar{C}, p_{1,1}$, is the only processor that receives no messages during the execution described above, due to the block on the link entering it. For the other processors the lemma follows from the fact that for each history H there is at most one rightmost processor p in C with $H_p = H$. □

Let the sequence of processors $\bar{C}$ defined above be $\bar{C} = (p_{i_1,j_1},\ldots,p_{i_m,j_m})$, and let τ be the input string $\omega_{i_1}\cdots\omega_{i_m}$ of length m. We now run AL on $\bar{C}$ with all links synchronized except for the link $p_{i_m,j_m}-p_{i_1,j_1}(=p_{n,k}-p_{1,1})$ which is blocked.

LEMMA 5. *In the execution of AL on $\bar{C}$ with input string τ, the history of processor $p_{i_l,j_l}(1 \leq l \leq m)$ of $\bar{C}$ is the same as the history of p_{i_l,j_l} in the corresponding execution of AL on C with input string ω^k. In particular, processor $p_{i_m,j_m}(=p_{n,k})$ of $\bar{C}$ accepts.*

Proof. This follows by a "cut and paste" argument, using the way $\bar{C}$ is constructed from C : $p_{1,1}(=p_{i_1,j_1})$ clearly has the same history in both executions, and the history of any other processor p in both executions is completely determined by its input letter and the history of the preceding processor. □

COROLLARY 1. *For any $1 \leq l \leq m$, the number of bits received by l distinct processors of $\bar{C}$ in the execution described above is at least $(l/4)\log_3(l/2)$.*

Proof. Let P be a set of l processors in $\bar{C}$, and let $p \in P$. By Lemma 5, the history of p in the execution of $\bar{C}$ is the same as its history in the execution of C. This implies, by Lemma 4, that no two processors in P have the same history. Thus, by Lemma 2, the sum of the lengths of the histories of the processors in P is at least $(l/2)\log_3(l/2)$. The corollary follows from the observation made earlier, that this sum is less than twice the number of bits received by these processors. □

Proof of Theorem 1. Let τ' be the first n letters of $\tau \cdot 0^n$. Let $m' = \min(\{m,n\})$ (recall that $|\tau| = m$). Consider an execution of AL on R with input string τ', in which the first m' processors have exactly the same history as the first m' processors in the execution of $\bar{C}$ on τ described above, and no message sent by the remaining processors is ever received. We distinguish two cases, depending on the length m of $\bar{C}$.

Case $m \leq n - \log n$. By Lemma 5, τ' will be accepted by at least one processor in R. Since τ' ends with $\log n$ zeros, Lemma 1 guarantees that $\Omega(n \log n)$ messages are required for the input string 0^n and the theorem holds.

Case $m > n - \log n$. By Corollary 1, the total number of bits received by the first m' processors is $(m'/4)\log_3(m'/2)$, which is $\Omega(n \log n)$. This completes the proof of Theorem 1. □

4. The lower bound for bidirectional rings. The proof of the gap theorem for bidirectional rings follows the same general outline. However, the corresponding "cut and paste" construction is more subtle, and requires a more careful analysis.

THEOREM 1′. *The bit complexity of a bidirectional ring of n anonymous processors is $\Omega(n \log n)$. This bound holds even if the ring is oriented.*

Proof. Let AL be an algorithm for an oriented bidirectional ring R of size n that accepts ω and rejects 0^n and consider a synchronized execution of AL on ω. The history of a processor p_i at time s in such an execution is a string $h_i(s) = d_i(1)m_i(1) \cdots d_i(r_s)m_i(r_s)$, where $d_i(j)$ is either R (for right) or L (for left), and the $m_i(j)$'s are the distinct messages (nonempty bit strings) received by p_i up to (and including) time s, in chronological order; $m_i(j)$ is received from direction $d_i(j)$, and when two messages arrive at the same time, we assume that the left one is received before the right one. Note that the length of H_i is at most two times larger than the number of bits received by p_i.

Assume that AL accepts ω in less than t time units, where $t = nk$. For each positive integer $b \leq k$, define a line D_b of $2nb$ processors as follows: Let C_b be a line $(p_{1,1}, p_{2,1}, \ldots, p_{n,b})$ of nb processors, and let C_b' be the line obtained by replacing each $p_{i,j}$ in C_b by $p_{i,j}'$. D_b is constructed by connecting the last processor $p_{n,b}$ of C_b with the first processor $p_{1,1}'$ of C_b'. As before make D_b a ring by connecting $p_{n,b}'$ to $p_{1,1}$ via a blocked link.

For each $b \leq k$, we construct a particular execution, E_b, of AL on D_b with input string ω^{2b}. Again internal computation of a processor takes no time, and a message requires exactly one unit to traverse a link. A processor is *blocked* at time s if it receives no messages at time s or later. In execution E_b we impose the following schedule: $p_{1,1}$ and $p_{n,b}'$ are blocked at time 1, $p_{2,1}$ and $p_{n-1,b}'$ are blocked at time 2, and in general at time s $(1 \leq s \leq bn)$, the s leftmost and the s rightmost processors of D_b are blocked. Since $p_{1,1}$ and $p_{n,b}'$ are blocked at time 1 and since the execution is synchronized, no message sent on the link $p_{n,b}' - p_{1,1}$ is ever received and thus D_b acts as a line of processors.

The following stronger version of Lemma 3 states that at the end of the execution E_b, the history of the sth leftmost [rightmost] processor in D_b is equal to that of the corresponding processor in the synchronized execution of AL on R after $s - 1$ time units. □

LEMMA 6. *Let $p_{i,j}$ $[p_{i,j}']$ be the sth leftmost [rightmost] processor in $D_b (1 \leq s \leq bn)$, and let $h_{i,j}$ $[h_{i,j}']$ denote the history of processor $p_{i,j}$ $[p_{i,j}']$ in execution E_b. Then $h_{i,j}(t) = h_i(s-1)$ $[h_{i,j}'(t) = h_i(s-1)]$ and in the execution E_k on D_k, both $p_{n,k}$ and $p_{1,1}'$ accept.*

Since every n consecutive processors in D_b correspond to the n processors of R, Lemma 6 implies the following.

COROLLARY 2. *Let R' be any set of n consecutive processors in D_b. Then the sum of the lengths of the histories in E_b is not larger than the sum of the lengths of the histories of the processors in the synchronized execution on R.*

Similar to the proof for the unidirectional case, we associate with the sequence D_b described above an undirected graph as follows: The vertices are the processors in

$D_b = C_b \cdot C'_b$. There is an edge between each processor p in C_b and the rightmost processor in C_b which has the same history as the right neighbor of p, and there is an edge between each processor p' in C'_b and the leftmost processor in C'_b, which has the same history as the left neighbor of p'. We also add an extra edge between the leftmost processor in $C'_b, p'_{1,1}$, and the rightmost processor of $C_b, p_{n,b}$. It is easily observed that this graph is an undirected tree. Let $\overline{C_b}$ be the path in that tree from $p_{1,1}$ to $p_{n,b}$, and $\overline{C'_b}$ be the path from $p_{n,b}$ to $p'_{n,b}$. $\overline{D_b}$ is the concatenation $\overline{C_b} \cdot \overline{C'_b}$.

LEMMA 7. *There is an execution $\overline{E_b}$ on $\overline{D_b}$ in which every processor has the same history as it has in the execution E_b on D_b.*

Proof. Consider two processors, p and q, that are adjacent on $\overline{D_b}$ but not on D_b. Now let $\hat{D}$ be the line obtained from D_b by connecting p and q with a link e, and deleting all the processors between p and q. We now define an execution $\hat{E}$ and $\hat{D}$ in which the histories of all the processors in $\hat{D}$ are the same as the corresponding histories in the execution E_b on D_b.

Assume without loss of generality that in E_b, p sends a message to its right neighbor before it receives a message from it. Then the execution $\hat{E}$ is initiated by simulating the execution E_b on the processor p and the processors to its left, and delaying the computations in all other processors. Such a simulation is possible since no processor to the left of p ever receives a message from a processor to the right of p (here we use the fact that the link between $p'_{n,b}$ and $p_{1,1}$ is blocked). Continue the simulation as long as p sends messages to its right neighbor without receiving a message from it, up to a point where p receives message from its right neighbor. At this point, continue the execution $\hat{E}$ by making a similar simulation on q and the processors to its right. This procedure can be repeated until the desired execution $\hat{E}$ is constructed.

Once the execution $\hat{E}$ is constructed, select in $\hat{D}$ two processors that are adjacent in $\overline{D_b}$ but not in $\hat{D}$, connect them by a link as above, and repeat the procedure above. By repeating this for every link in $\overline{D_b}$, we get the desired execution $\overline{E_b}$. □

The construction of $\overline{C_b}$ and $\overline{C'_b}$ guarantees that no two processors in $\overline{C_b}$ and no two processors in $\overline{C'_b}$ have the same history in the execution $\overline{E_b}$ on $\overline{D_b}$ described above. Hence no three processors in $\overline{D_b}$ have the same history in $\overline{E_b}$. This implies, by Lemma 2, that the number of bits received by any l distinct processors in $\overline{D_b}$ is larger than $(l/8)\log_4(l/4)$.

Let m_k be the length of $\overline{D_k}$ (recall that k is defined by the equality $t = nk$). In the case where $m_k \leq n$ we can pad $\overline{D_k}$ with $n - m_k$ processors that receive input zero. As in the proof Theorem 1, the messages sent by these $n - m_k$ never reach their target. According to Lemma 6, $p_{n,k}$ accepts, and hence by Lemma 7 the corresponding processor in $\overline{D_k}$ accepts too. By distinguishing two cases depending on whether $m_k \leq n - \log n$ or not, we can complete the proof of Theorem 1′ as in Theorem 1, provided that $m_k \leq n$.

However, if $m_k > n$, then we cannot proceed as in the unidirectional case. If we "cut" the n leftmost processors of $\overline{D_k}$, then the nth processor does not receive the proper messages from the right, and the proof requires modification. This is where we use the histories $\overline{E_b}$ for $b < k$.

LEMMA 8. *Let m_b be the length of $\overline{D_b}$, and let $m_0 = 0$. For any b such that $1 \leq b \leq k$, either the last n processors of C_b or the first n processors of C'_b contain at least $(m_b - m_{b-1})/2$ distinct histories in E_b.*

Proof. For notational convenience assume that processor lines with subscript 0 are empty. For a line Q let $|Q|$ denote the number of processors in it. Recall that D_b is obtained by inserting a line of $2n$ processors between the left half, C_{b-1}, and the right half, C'_{b-1}, of D_{b-1}. Since $m_b = |\overline{D_b}| = |\overline{C_b}\,\overline{C'_b}|$ and $m_{b-1} = |\overline{D_{b-1}}| = |\overline{C_{b-1}}\,\overline{C'_{b-1}}|$, either

$$|\overline{C_b}| - |\overline{C_{b-1}}| \geq \frac{m_b - m_{b-1}}{2}$$

or

$$|\overline{C'_b}| - |\overline{C'_{b-1}}| \geq \frac{m_b - m_{b-1}}{2}.$$

Assume without loss of generality that the former is the case. It suffices to show that the last $(m_b - m_{b-1})/2$ processors of $\overline{C_b}$ are the last n processor of C_b. Observe that $\overline{C_b}$ is constructed by taking a prefix of $\overline{C_{b-1}}$ and appending it with a sequence of distinct processors from the last n processors of C_b. Thus the processors at position $|\overline{C_{b-1}}| + 1$ through position $|\overline{C_b}|$ of the line $\overline{C_b}$ must be from the last n processors of C_b. □

We are now ready to prove the Theorem 1′ for the remaining case that $m_k > n$ (recall that $t = kn$). Let b be the smallest integer such that $m_b > n$. Clearly either $m_b - m_{b-1} \geq n/2$ or $n/2 < m_{b-1} \leq n$.

In the former case by Lemma 8 there are n consecutive processors in D_b, which have at least $n/4$ distinct histories the lower bound follows from Lemma 2 and Corollary 2. In the second case, let τ be the string composed of the concatenation of the input letters to the processors in $\overline{D_{b-1}}$. Then $n/2 < m_{b-1} = |\tau| \leq n$. Consider the execution on a line with input string $\tau \cdot 0^{n-|\tau|}$ consisting of the execution $\overline{E_{b-1}}$ on the first m_{b-1} processors, and assume that the remaining processors are never awakened. Since this execution has more than $n/2$ distinct histories, the result follows. This completes the proof of Theorem 1′. □

5. Lower bounds for rings with identifiers.

5. Lower bounds for rings with identifiers. Interestingly, the gap remains for rings with identifiers if the set of possible identifiers is large enough relative to the ring size n. Now the algorithm AL that each processor runs is given two inputs, a symbol of the input alphabet and an *identifier* of the processor. Different processors must receive distinct identifiers. An *execution* of an algorithm includes a labeling of the ring with distinct identifiers in addition to an assignment of an input symbol to each processor, an orientation of the ring, and a combined schedule of how the algorithm is run at each processor. The function value may only depend on the labeling of the processors with input symbols and must be invariant over all labelings of the ring with distinct identifiers, all orientations, and all possible schedules. The *bit* (*message*) *complexity* of an algorithm is again the maximal number of bits (messages) sent over all possible executions of this algorithm and the bit (message) complexity of a function f is the minimal possible bit (message) complexity of any algorithm that computes f. Note that this notion of complexity is worst case over all possible labelings of the ring with distinct identifiers.

To prove the lower bound of $\Omega(n \log n)$ on the bit complexity for rings with identifiers we make the following simplifying assumptions. Assume that AL rejects 0^n and accepts an input string ω, as before. Let $\sum$ denote the set of letters in the string $0 \cdot \omega$. Observe that the function computed by AL is nonconstant even for input strings over the restricted input alphabet $\sum^n$. For each $a \in \sum$ let $e(a)$ be an encoding of a by at most $\log n + 2$ bits. For a specific execution of AL, in which all the input letters are from $\sum$, define $eh_i(s)$, the *extended history* of the processor p_i at time s in this execution, to be a string $e(a)t_i(1)d_i(1)m_i(1) \cdots t_i(r_s)d_i(r_s)m_i(r_s)$, where a is the input of p_i in this execution, the $d_i(j)s$ and the $m_i(j)s$ are, as before, directions and messages, and the $t_i(j)s$ are either I if the corresponding message was received by p_i, or O if it was sent by it.

THEOREM 2. *The bit complexity of a bidirectional oriented ring of n processors with distinct identifiers is $\Omega(n \log n)$, provided that the set of identifiers that can be assigned to the processors is large enough.*

Proof. Assume that there is an algorithm AL of bit complexity[5] $o(n \log n)$ computing a nonconstant function, and let Z be the set of possible identifiers, with $|Z| \geq n2^{n^n}$. Let $\boldsymbol{H}_z$ be the set of possible extended histories that can occur at a processor with identifier $z \in Z$ when AL is executed on an input from $\sum^n$. Then the definition of extended history implies that the program of a processor with identifier z in executions on input from $\sum^n$ is uniquely determined by $\boldsymbol{H}_z$, and hence that if $\boldsymbol{H}_z = \boldsymbol{H}_{z'}$, then two processors with identifiers z and z' behave identically in all executions on inputs from $\sum^n$. Since, apart from the $\log n + 2$ bits required to encode the input, the length of the extended history of a processor is at most three times the number of bits received or sent by that processor, the assumption on the bit complexity of AL implies that the set of all possible extended histories $\boldsymbol{H} = \cup_{z \in Z} \boldsymbol{H}_z$ is of cardinality $o(2^{n \log n}) = o(n^n)$.

Denote $z \equiv_{AL} z'$ if $\boldsymbol{H}_z = \boldsymbol{H}_{z'}$. The relation $\equiv_{AL}$ partitions Z into at most $2^{|\boldsymbol{H}|} = o(2^{n^n}) = o(|Z|/n)$ equivalence classes, where all the processors in each class behave identically on inputs from $\sum^n$. Thus, there must be n distinct identifiers in Z that belong to the same equivalence class. By restricting the identifiers to this equivalence class, the proof of the anonymous class implies a lower bound of $\Omega(n \log n)$ on the bit complexity of AL, which contradicts the assumption. □

6. Functions computable with a small number of messages. In [ASW88] a nonconstant function was presented that is computable in $O(n)$ messages and $O(n \log n)$ bits. That function is the characteristic function for the subset of $\{0, 1\}$, which consists of all cyclic shifts pattern $0(01)^*$. The pattern requires that the ring size n is odd. As we will show here, for any nondivisor k of n there are similar patterns that can be recognized in $O(kn)$ messages and $O(kn + n \log n)$ bits. Since for any ring size n there is a nondivisor of size $O(\log n)$ this leads to a nonconstant function defined for all ring sizes with message and bit complexity $O(n \log n)$. This shows that the $\Omega(n \log n)$ bounds on the bit complexity given in the previous sections are tight.

As the main result of this section we exhibit a function with "almost linear," i.e., $\Omega(n \log^* n)$, message complexity, and this function is defined for arbitrary ring size. The lower bound proven in [DG87] for specific ring sizes matches this upper bound. The upper bounds proven in this section assume alphabets of constant size at least two. In fact, we show that if the alphabet size is at least n, then there are nonconstant functions that can be computed with $O(n)$ messages. (The $\Omega(n \log^* n)$ lower bound of [DG87] assumes constant alphabet size.)

All algorithms presented in this section work on the unidirectional ring and output one if and only if the input is a cyclic shift of a string Θ. It is easy to derive bidirectional versions of these algorithms working on bidirectional rings of arbitrary orientation such that the message complexity increases by at most a factor of two. Recall that algorithms working on unidirectional rings assume that the ring is oriented and they only receive messages from the left and send messages to the right. Let U be such an algorithm. In the bidirectional version each processor runs two noninteracting versions of U, one that receives messages from the left neighbor and sends messages to the right neighbor, and a second one that receives messages from the right neighbor and sends to the left neighbor. Here left and right refer to the local orientation of the processor. The local orientations between processors do not have to be consistent with each other. After both algorithms terminate each processor outputs one if and only if one of the algorithms outputs one. It is easy to see that the bidirectional version computes one if and only if the input string or the reverse of the input string is a cyclic shift of Θ.

[5]We write $f(n) = o(g(n))$ if $\lim_{n \to \infty} f(n)/g(n) = 0$.

To get an easy introduction to the unidirectional algorithms presented in this section, we will first present a simple generalization of an algorithm of [ASW88], which is also used in our algorithm. This generalization, which we call *NON-DIV*, is defined for two parameters: the ring size n, and an integer k which does not divide $n (n > k)$. It accepts the (cyclic shifts of) the pattern $\pi = 0^{n \bmod k}(0^{k-1}1)^{\lfloor n/k \rfloor}$. The message complexity of *NON-DIV* is $O(kn)$ and its bit complexity is $O(kn + n \log n)$. Algorithm *BRUIJN*, the second algorithm described, follows the same outline as *NON-DIV* but it is used to recognize more complicated patterns. Finally, *BRUIJN* is used iteratively in Algorithm *STAR* for recognizing a pattern in $O(n \log^* n)$ messages.

```
ALGORITHM NON-DIV(k, n):
%% it is assumed that $n \bmod k = r \neq 0$. %%
FOR all $n$ processors in parallel DO
N1. Set your status to passive and send your bit to the right neighbor. Forward $k+r-3$
    bits received from the left to the right and wait until you receive $k + r - 2$ bits
    from the left.
N2. Let $\Psi$ be the concatenation of the $k + r - 2$ bits received from the left with your
    own bit ($\Psi$ contains $k + r - 1$ bits).
    IF $\Psi$ is not a cyclic substring of $\pi = 0^r(0^{k-1}1)^{\lfloor n/k \rfloor}$ THEN send a zero-message
    and terminate with output zero.
    IF $\Psi = o^{k+r-1}$ THEN send a size-counter message with count one to the right
    and change your status to active.
    Wait for a message from the left.
    %% This must be either a zero-message or a size-counter. %%
N3. IF the message receives is a zero-message THEN forward it and terminate with
    output zero.
    IF the message received is a size-counter THEN
        IF your status is passive THEN increment the size-counter by one and forward
        it to the right.
        ELSE (i.e., your status is active):
        IF the value of the size-counter is $n$ THEN send a one-message to the right and
        terminate with output one.
        ELSE send a zero-message to the right and terminate with output zero.
    ELSE (The message received must be either one-message or a zero-message)
N4. Forward the message you received and terminate with output zero if it was a zero-
    message and with output one otherwise.
```

We sketch below a proof that *NON-DIV* indeed recognizes the string $\pi = 0^r(0^{k-1}1)^{\lfloor n/k \rfloor}$, where $r = n \bmod k$.

Case 1. The input string contains a substring of length $k + r - 1$ which is not a substring of π. Then the processor with the rightmost bit of this substring will initiate a *zero-message* in Step N2, and will never forward a *size-counter*. This latter fact means that no *size-counter* will make a complete traversal of the ring, and hence that no *one-message* can be initialized. The *zero-messages* (possibly more than one) produced in Step N2 will eventually cover the whole ring and all processors will output zero.

Case 2. This case is the complement of Case 1. Thus no *zero-message* will be initiated in Step N2. A simple case analysis shows that in this case the input string must contain a substring of $k + r - 1$ successive zeros, and that it contains exactly one such substring if and only if the input string is a cyclic shift of π. This means that at least one *size-counter* will be initiated in Step N2, and exactly one *size-counter* will be initiated if and only if the input string should be accepted. The proof is completed by observing that output one is obtained only if some *size-counter* traverses the whole ring which is only possible if exactly one such counter was initiated. If more than one *size-counter* is initiated, then eventually some processor will generate a *zero-message* and all processor will output zero.

Each processor sends at most $2k$ messages in an execution of *NON-DIV*, so that the total number of messages is $O(kn)$. Counters cost at most $\lfloor \log n \rfloor + 1$ bits, so the total bit complexity of *NON-DIV* is $O(kn + n \log n)$.

Now it is easy to derive an algorithm computing a nonconstant function of $O(n \log n)$ bit complexity uniformly for all ring sizes: First each processor determines the smallest nondivisor of k of the ring size n and then runs *NON-DIV*(k, n). Since k is $O(\log n)$ we get an algorithm for a nonconstant function whose bit complexity matches the lower bounds of the previous sections.

LEMMA 9. *There is a nonconstant function for binary input alphabet defined for all ring sizes n with bit complexity $O(n \log n)$ on the unidirectional ring.*

Before proceeding we note that if the input alphabet has size at least n, then there are nonconstant functions of $O(n)$ message complexity: let $\sigma_0, \ldots, \sigma_{n-1}$ be n letters of the alphabet. The cyclic shifts of $\sigma = \sigma_0\sigma_1 \cdots \sigma_{n-1}$ can be accepted as follows. Send your input letter to your right neighbor as in Step N1 of *NON-DIV*, and concatenate the letter received with your own letter as in N2 to form Ψ; if Ψ is not of the form $\sigma_i\sigma_{i+1 \bmod n}(i = 0, \ldots, n-1)$, then initiate a *zero-message* and terminate with output 0. The pattern $\Psi = \sigma_{n-1}\sigma_0$ initiates a counter message. Thus we have:

LEMMA 10 (Hans Bodlaender). *If the input alphabet is of size at least n, then the distributed message complexity of ring n processors is $O(n)$.*

The above lemma can be generalized to alphabet size ϵn for arbitrary positive constant ϵ. Moreover, a similar technique can be used to show a linear distributed message complexity of other networks, provided the alphabet size is linear in the network size.

The final goal of this section is to present an algorithm called *STAR*(n) that computes a nontrivial function in $O(n \log^* n)$ messages for arbitrary ring size n. So far we have shown that if n is not divisible by some integer $k = O(\log^* n)$, then *NON-DIV*(k, n) is such an algorithm. However, it is much harder to find algorithms of low message complexity if n has no small nondivisors.

STAR(n) recognizes patterns based on the classical de Bruijn Sequences [B46]. A *de Bruijn Sequence* β_k is a sequence of 2^k bits with the property that each binary string of length k occurs in β_k exactly once as a cyclic substring [B46]. For each $k \geq 1$ there are such sequences (see, e.g., [E79]). From now on assume that β_k denotes a fixed such sequence with the property that its first k bits are zeros, and that the first zero is barred. That means that our input alphabet has three letters $0, 1$, and $\bar{0}$, which we call bits for simplicity. We discuss later how to get the corresponding results for the two-letter case.

One way to construct a de Bruijn sequence β_k is the following: start with $\bar{0}0^{k-1}$; bit i for $(k + 1 \leq i \leq 2^k)$ is one if the string of length k formed by the bits $i - k + 1, i - k + 2, \ldots, i - 1$ appended by a one does not appear yet in the sequence; otherwise bit i is zero. The sequences for $k = 1, 2, 3, 4$ are $\bar{0}1, \bar{0}011, \bar{0}0011101, \bar{0}000111101100101$, respectively.

We will use prefixes of strings in $(\beta_k)^*$ to construct patterns recognizable with a small number of messages. Note that in these prefixes, each new copy of β_k starts with $\bar{0}$. Let $\pi_{k,n}$ (for $k \leq n$) be the first n bits of $(\beta_k)^n$. For example, $\pi_{3,21} = \bar{0}0011101\bar{0}0011101\bar{0}0011$. The Algorithm *STAR* (n) will essentially recognize cyclical shifts of a word formed by interleaving a number of patterns of the form $\pi_{k',n'}$, for various choices of k' and n'.

At times the algorithm checks whether the parts of the input string fulfill a local condition of legality with respect to some $\pi_{k',n'}$, which we define now. Let $\Theta = \Theta_0 \cdots \Theta_{n-1}$ be a cyclic string of length n representing the input of the n processors. Then Θ_i is *legal* with respect to $\pi_{k,n}$ if the k bits to the left of Θ_i appended with Θ_i produces a string that occurs as a cyclic substring in $\pi_{k,n}$. The following lemma shows that if all bits of Θ are legal with respect to $\pi_{k,n}$, then this string must be equal to $\pi_{k,n}$ or a close relative thereof.

Let τ be any bit string and σ be a cyclical substring in τ. A bit b is called a *successor* of σ in τ if σb is a cyclical substring of τ. Let the last k bits of a string $\alpha_0, \alpha_1, \ldots, \alpha_{l-1}$ of length $l \geq k$ be the string $\alpha_{l-k}, \alpha_{l-k+1}, \ldots, \alpha_{l-1}$. Let ρ be the last k bits of $\pi_{k,n}$. Every length k cyclic substring $\sigma \neq \rho$ of $\pi_{k,n}$ has exactly one successor in $\pi_{k,n}$. However there might be two successors of ρ in $\pi_{k,n}$. Clearly $\bar{0}$ is always a successor. If $n > 2^k$ then $\pi_{k,n}$ contains β_k as substring and ρ has b as a successor in $\pi_{k,n}$, where b is the unique successor of ρ in β_k. Now $b \neq 0$ if and only if and $n \neq 0 \bmod 2^k$.

LEMMA 11. *Assume all n bits of an input string Θ are legal with respect to $\pi_{k,n}$ and let ρ consist of the last k bits of $\pi_{k,n}$. If $n = 0$ mod 2^k then Θ is a cyclic shift of $(\beta_k)^{n/2^k}$. If $n \neq 0$ mod 2^k then Θ contains $\rho\bar{0}$ at least once as a cyclical substring and $\rho\bar{0}$ occurs exactly once if and only if Θ is a cyclical shift of $\pi_{k,n}$.*

Proof. If $n = 0 \bmod 2^k$, then $\pi_{k,n} = (\beta_k)^{n/2^k}$. Thus, $\pi_{k,n}$ and β_k have the same set of cyclical substrings of length k and each such substring has the same unique successor in $\pi_{k,n}$ and in β_k. Since all bits of Θ are legal with respect to $\pi_{k,n}$ we conclude that if $n = 0 \bmod 2^k$, then Θ must be a cyclic shift of $(\beta_k)^{n/2^k}$.

If $n \neq 0 \bmod 2^k$, then by the legality assumption the successors of all cyclical substrings of length k of Θ are uniquely determined, except for ρ, which has two successors: $\bar{0}$ and the successors of ρ in β_k. Thus after each occurrence of ρ the current copy of β_k is completed or it is cut off at ρ and a new copy of β_k is begun with the $\bar{0}$. The definition of ρ implies that the subword of β_k beginning with $\bar{0}$ and ending with ρ has length $n \bmod 2^k$ and equals $\pi_{k,n\mathrm{mod}2^k}$. Thus Θ must be a cyclical shift of a string of length n of the form $(\beta_k + \pi_{k,n\mathrm{mod}2^k})^*$. Now the second half for the claim follows easily. □

If the ring size n is not divisible by $k = 1 + \log^* n$ then *STAR*(n) simply calls *NON-DIV*(k, n). However if $n = 0 \bmod (1 + \log^* n)$ then the algorithm recognizes a complicated pattern $\Theta^{(n)}$ which we will now describe. Let $n' = n/(1 + \log^* n)$. $\Theta^{(n)}$ is a string in the language $F = (\#\{\bar{0}, 0, 1\}^{\log^* n})^{n'}$ over the four letter alphabet $\{0, 1, \bar{0}, \#\}$ containing $l(n)$ "interleaved" de Bruijn Sequences, where $l(n)$ is defined as follows: let $k_0 = 1$ and $k_{i+1} = 2^{k_i}$; $l(n)$ is the minimum i such that k_i does not divide n'. Note that $\log^* n$ is the minimum i such that $k_i \geq n$, and hence $l(n) \leq \log^* n$.

For all strings Θ in F, let $\Theta[i]$ (for $1 \leq i \leq \log^* n$) be the concatenation of the n' bits which are the ith letters to the right of the $\#$ letters. For example, $\Theta[1]$ consists of the bits to the right of the $\#$ letters, and $\Theta[\log^* n]$ consists of the bits to the left of the $\#$ letters. $\Theta^{(n)}$ is the string in F with the following properties:

(1) $\Theta^{(n)}[i] = \pi_{k_{i-1},n'}$, for $1 \leq i \leq l(n)$; and

(2) $\Theta^{(n)}[i]$ contains only zeros for $l(n) + 1 \leq i \leq \log^* n$.

As a rough outline, Algorithm *STAR* (n) first checks in Step S0 whether the input Θ is in F. Note that if this is true, then there are exactly n' processor with input $\#$. These processors check in loop i of Step S1 whether $\Theta[i]$ is a cyclic shift of $\pi_{k_{i-1},n'}$. To do this for $\Theta[l(n)]$ Step S2 is needed as well.

```
ALGORITHM $STAR(n)$.
S0. IF $n \neq 0 \bmod (\log^* n + 1)$ THEN call $NON\text{-}DIV(k,n)$, for $k = \log^* n + 1$,
    to recognize cyclic shifts of $0^{n \bmod k}(0^{k-1}1)^{n/k}$.
    ELSE
      BEGIN
      Send your input to your right neighbor, forward $log^*n$ inputs, and wait for $1+$
    $\log^* n$ inputs.
      IF the number of # signs you have received is not exactly one THEN send a
    zero-message to the right and terminate with output zero.
      %% If no processor initiates a zero-message in the previous statement then
    there are $n'$# signs in the input, all of which are exactly $1 + \log^* n$ apart. Each of
    processor with input # denotes the $\log^* n$ bit string between itself and the previ-
    ous processor with input # as $b_1 \cdots b_{\log^* n}$.%%
      IF your input is # and $b_{l(n)+1}b_{l(n)+2} \cdots b_{\log^* n}$ contains a letter other than 0 or
    if $b_i = \bar{0}$, for $1 < i \leq l(n)$, and $b_{i-1} \neq \bar{0}$ THEN send a zero-message to the right
    and terminate with output zero.
      END
    %% For the remaining part of the algorithm whenever any processor receives
    a zero-message (one-message) it forwards it and terminates with output zero (re-
    spectively, one). Furthermore we only address processors with input #. All other
    processors always only forward the messages they receive and terminate as de-
    scribed above. %%

S1. For $i := 1$ to $l(n)$ DO
    BEGIN
    IF $i = 1$ THEN all processors are initiators.
    ELSE you are an initiator if your bit $b_{i-1}$ equals $\bar{0}$.
    %% The initiators are $k_{i-1}(1 + \log^* n)$ apart.%%
    IF you are an initiator
    THEN start an input collection message by sending your bit $b_i$ to the right.
    IF you are an initiator THEN do the following once and ELSE to it twice:
        Append your bit $b_i$ to the input collection message received and forward it.
    %% The second input collection message received by each initiator processor has
    length $2k_{i-1}$. The concatenation of the second halves of all these messages con-
    stitute $\Theta^{(n)}[i]$ and the same holds for the first halves.%%
    IF you are an initiator and any of the bits in the second half of the last message is
    not legal with respect to $\pi_{k_{i-1},n'}$ THEN initiate a zero-message.
      %% Note that $2^{k_{i-1}} = k_i$ divides $n'$ for all $i$ except $i = l(n)$. %%
      END

S2.   IF your last message contains $\rho\bar{0}$ as a substring, where $\rho$ consists of the last
      $k_{l(n)-1}$ bits of $\pi_{k_{l(n)-1},n'}$
      THEN send a size-counter with count one to the right.
      IF you receive a size-counter and did not start a size-counter
      THEN increment it and forward it.
      ELSE IF the received size-counter equals $n'$
      THEN send a one-message to the right.
      ELSE Send a zero-message.
END
```

LEMMA 12. *For all ring sizes $n = 0 \bmod (\log^* n + 1)$, Algorithm STAR$(n)$ recognizes cyclic shifts of $\Theta^{(n)}$ in $O(n \log^* n)$ messages.*

Proof.

Case 1. A *zero-message* was generated in Step S0. That is either (i) the input string Θ is not in $F = (\#\{\bar{0}, 0, 1\}^{\log^* n})^{n'}$, or (ii) for some processor with input $\#$ one of the bits $b_{l(n)+1}, \ldots, b_{\log^* n}$ is not 0, or (iii) for some such processor $b_i = \bar{0}$ and $b_{i-1} \neq \bar{0}$ for some $1 \leq i \leq l(n)$. In any of the above three cases the input string is not a cyclical shift of $\Theta^{(n)}$ and the processor which generated a *zero-message* will not forward any *size-counter*. Hence no *size-counter* will traverse the whole ring, and no processor will initiate a *one-message*. We conclude that in this case all the processors will eventually output zero.

Case 2. Case 1 does not hold and for some $1 \leq i \leq l(n)$, $\Theta[i]$ contains a bit which is not legal with respect to $\pi_{k_{i-1},n'}$. Assume i is minimum. We first claim that all initiators of loop i are $k_{i-1}(1+\log^* n)$ apart. This clearly holds for $i = 1$. If $i > 1$ then in loop $i-1$ all bits of $\Theta[i-1]$ were legal with respect to $\pi_{k_{i-2},n'}$. Recall that $n' = 0 \bmod k_{i-1}$ and that $2^{k_{i-2}} = k_{i-1}$. Thus Lemma 11 implies that $\Theta[i-1]$ is a cyclic shift of $(\beta_{k_{i-2}})^{n/k_{i-1}}$ and all occurrences of $\bar{0}$ in $\Theta[i-1]$ are k_{i-1} apart. This guarantees that the claim holds for $i > 1$ as well.

Since all initiators are properly spaced the second input collection message the initiators receive are exactly $2k_{i-1}$ long. Thus the second halfs of these messages form $\Theta[i]$ and the same holds for the first halves. Each initiator can check whether the bits in the second half are legal with respect to $\pi_{k_{i-1},n'}$ since it knows the preceding substrings of length k_{i-1}. By the above choice of i one of the bits must be illegal and thus some initiator will start a *zero-message*. Thus in Case 2 all processors correctly output zero.

Case 3. Case 1 does not hold and for $1 \leq i \leq l(n)$, all bits of $\Theta[i]$ are legal with respect to $\pi_{k_{i-1},n'}$. Since all bits of $\Theta[l(n)]$ are legal with respect to $\pi_{k_{i-1},n'}$ and $n' \neq 0 \bmod k_{l(n)}$, Lemma 11 guarantees that there is at least one occurrence of $\rho\bar{0}$ in $\Theta[l(n)]$, where ρ consists of the last $k_{l(n)-1}$ bits ρ of $\pi_{k_{l(n)-1},n'}$. Thus there will be at least one initiator that has $\rho\bar{0}$ as a substring in its *second input collector* message and these initiators will start *size-counters*. As for *NON-DIV* if more than one counter is initiated then this eventually causes a *zero-message* and all processors terminate with output zero. Only if exactly one counter travels around the whole ring, a *one-message* is initiated and all processors output one. The correctness of *STAR*(n) in Case 3 follows again from Lemma 11 which assures us that exactly one counter is initiated in Step S3 if and only if $\Theta[l(n)]$ is a cyclic shift of $\pi_{k_{l(n)-1},n'}$.

It is easy to see that Algorithm *STAR* sends $O(n \log^* n)$ messages in Step S0. In Step S1 each loop costs $O(n)$ messages and there are $l(n) = O(\log^* n)$ iterations. In Step S2 only $O(n)$ messages are sent. $\square$

Note that $\Theta^{(n)}$ might use up to four letters. To recognize similar strings $\Theta'^{(n)}$ over a binary input alphabet we encode the ith letter $(1 \leq i \leq 4)$ by $1^i 0^{5-i}$. If $n \neq 0 \bmod 5$ then $\Theta'^{(n)} = 0^{n \bmod 5}(0^4 1)^{n/5}$ and otherwise $\Theta'^{(n)}$ equals $\Theta^{n/5}$, using the five bit encoding for all letters. It is easy to see that for all ring sizes $\Theta'^{(n)}$ can also be recognized in $O(n \log^* n)$ messages.

THEOREM 3. *There is a nonconstant function for binary input alphabet defined for all ring sizes n with message complexity $O(n \log^* n)$ on the unidirectional ring.*

Acknowledgment. The authors thank Hans Bodlaender for pointing out Lemma 10, Gerhard Buntrock for many useful discussions, and an anonymous referee for numerous and insightful comments which helped to clarify and improve the presentation of this paper.

ON LANGUAGES WITH VERY HIGH SPACE-BOUNDED KOLMOGOROV COMPLEXITY*

RONALD V. BOOK† AND JACK H. LUTZ‡

Abstract. It is shown that if a language recognizable in exponential space is bounded truth-table reducible in polynomial time to a language with very high space-bounded Kolmogorov complexity, then it is bounded truth-table reducible in polynomial time to a sparse language.

There are a number of corollaries, including the following:

(a) no language with very high space-bounded Kolmogorov complexity is $\leq_{btt}^{P}$-hard for NP, unless P = NP;

(b) no language with very high space-bounded Kolmogorov complexity is $\leq_{btt}^{P}$-hard for the class of languages accepted in exponential time.

Key words. Kolmogorov complexity, bounded truth-table reducibility, exponential space, sparse sets

AMS(MOS) subject classifications. 68Q15, 03D15

1. Introduction.

In complexity theory a great deal of attention has been given to sparse languages and to properties of languages efficiently reducible to sparse languages (see, for example, [KL82], [Ma82], [OW91], [Wa87]). Such languages are considered to have very low information content. A number of results in this area have improved our understanding of the structure of complexity classes and resource-bounded reducibilities.

The subject of this paper is the class of languages that are bounded truth-table (or Turing) reducible in polynomial time to languages with essentially maximal information content. Specifically, it is shown (Theorem 3.1) that any language recognizable in exponential space that is bounded reducible in polynomial time to a set with very high space-bounded Kolmogorov complexity must be bounded reducible in polynomial time to a sparse set. Using a recent result of Ogiwara and Watanabe [OW91], this implies that no language with very high space-bounded Kolmogorov complexity can be $\leq_{btt}^{P}$-hard for NP, unless P = NP; similar results are given for other classes.

From the proof of the main result, other conclusions can be made. For example, Watanabe [Wa87] has shown that the class of languages recognizable deterministically in exponential time (denoted E) is not included in the class of languages that are bounded truth-table reducible in polynomial time to sparse languages; we can conclude that no language with very high space-bounded Kolmogorov complexity can be $\leq_{btt}^{P}$-hard for E.

Languages with very high space-bounded Kolmogorov complexity are very complex in the sense that each such language has essentially maximal information content. It is known that almost every language has space-bounded Kolmogorov complexity of this magnitude. The results presented here provide evidence that the information in languages with very high space-bounded Kolmogorov complexity is encoded in such a way that very little of it can be retrieved in a computationally useful way.

2. Preliminaries. For the most part our notation is standard, following that used by Balcázar, Díaz, and Gabarró [BDG88], [BDG90].

All *languages* here are sets $A \subseteq \{0,1\}^*$. A language S is *sparse*, written $S \in \mathrm{SPARSE}$, if there is a polynomial q such that $\|S_{\leq n}\| \leq q(n)$ for all n, where $S_{\leq n}$ denotes $S \cap \{0,1\}^{\leq n}$. We write REC for the set of all recursive languages.

A $\leq^{\mathrm{P}}_{k-tt}$*-reduction* of language A to language B is a pair (f,g) of polynomial time computable functions such that for each $x \in \{0,1\}^*$, the following hold:

(i) $f(x) = (f_1(x), f_2(x), \ldots, f_k(x))$ is an ordered k-tuple of strings;

(ii) $g(x) : \{0,1\}^k \to \{0,1\}$ is a Boolean function;

(iii) $[\![x \in A]\!] = g(x)([\![f_1(x) \in B]\!][\![f_2(x) \in B]\!] \cdots [\![f_k(x) \in B]\!])$, where $[\![\phi]\!]$ is the truth value of ϕ (i.e., $[\![\phi]\!] =$ **if** ϕ **then** 1 **else** 0).

We write $A \leq^{\mathrm{P}}_{btt} B$ if for some k, $A \leq^{\mathrm{P}}_{k-tt} B$.

Given a polynomial time-bounded reducibility $\leq^{\mathrm{P}}_{\mathrm{r}}$ and a class C of languages, we write $\mathrm{P_r(C)}$ for

$$\{A | (\exists C \in \mathrm{C}) \text{ such that } A \leq^{\mathrm{P}}_{\mathrm{r}} C\}.$$

For example, $\mathrm{P}_{btt}(\mathrm{C}) = \cup_{k>0} \mathrm{P}_{k-tt}(\mathrm{C})$.

We use the following notation for exponential complexity classes:

$$\mathrm{E} = \mathrm{DTIME}(2^{\mathrm{linear}}); \mathrm{ESPACE} = \mathrm{DSPACE}(2^{\mathrm{linear}}).$$

A property of natural numbers holds *infinitely often* (i.o.) if it holds for infinitely many $n \in \mathbb{N}$, and holds *almost everywhere* (a.e.) if it holds for all but finitely many $n \in \mathbb{N}$.

3. Main result. The main technical result of this paper is the following: any language in ESPACE that is bounded truth-table reducible in polynomial time to a set with high space-bounded Kolmogorov complexity must be bounded truth-table reducible in polynomial time to some sparse set. In the next section we show that this result yields a variety of corollaries.

Given a machine M, a function $t : \mathbb{N} \to \mathbb{N}$, a language $L \subseteq \{0,1\}^*$, and a natural number n, the t-*space-bounded Kolmogorov complexity* of $L_{\leq n}$ relative to M is defined as

$$KS^t_M(L_{\leq n}) = \min\{|\pi| \; |M(\pi, n) = \chi_{L_{\leq n}} \text{in } t(2^n) \text{ space}\}.$$

Thus, $KS^t_M(L_{\leq n})$ is the length of the shortest string π such that M on input (π, n) outputs the $(2^{n+1}-1)$-bit characteristic string of $L_{\leq n}$ and halts while using no more than $t(2^n)$ workspace. This quantity is often interpreted as the "amount of information" that is contained in $L_{\leq n}$ and is "accessible" by means of computations that use at most $t(2^n)$ workspace.

Well-known simulation techniques show that there exists a universal machine U that is optimal in the sense that for each machine M there is a constant c such that for all t, L, and n, we have

$$KS^{ct+c}_U(L_{\leq n}) \leq KS^t_M(L_{\leq n}) + c.$$

Hence, we fix an optimal machine U and omit it from the notation. (See [BDG90] or [LV90] for additional discussions of Kolmogorov complexity.)

The main result involves languages with essentially maximal information content, that is, languages B such that for every polynomial q, $KS^q(B_{\leq n}) > 2^{n+1} - 2n$ almost everywhere. (Notice that for every language A, $KS^n(A_{\leq n}) < 2^{n+1}+c$ for some absolute constant c; this justifies the phrase "essentially maximal.")

THEOREM 3.1. *Let $A \in$ ESPACE, and let $k > 0$ be an integer. Suppose that there is a language B such that $A \leq^{\mathrm{P}}_{k-tt} B$ and, for every polynomial q, $KS^q(B_{\leq n}) > 2^{n+1} - 2n$ almost everywhere. Then there exists a sparse set S such that $A \leq^{\mathrm{P}}_{k-tt} S$.*

Before proceeding with the proof of Theorem 3.1, we provide some notation and terminology.

First, suppose that for some languages C and D and some functions f and g, $C \leq^{\mathrm{P}}_{k-tt} D$ via (f, g). Define $\tilde{f}$ as follows: for each string $x \in \{0,1\}^*$ and each $i, 1 \leq i \leq k$, $\tilde{f}_i(x) = f_i(x)10^{|x|}$. Note that for each $x \in \{0,1\}^*$ and $i, 1 \leq i \leq k$,

$$(3.1) \qquad |\tilde{f}_i(x)| > |x|.$$

For each $L \subseteq \{0,1\}^*$, define $\tilde{L}$ by

$$\tilde{L} = \{\tilde{f}_i(x) | x \in \{0,1\}^*, 1 \leq i \leq k, f_i(x) \in L\}.$$

Notice that $C \leq^{\mathrm{P}}_{k-tt} D$ via (f, g) implies that $C \leq^{\mathrm{P}}_{k-tt} \tilde{D}$ via $(\tilde{f}, g)$.

Second, some terminology will be convenient. For $n \in \mathbb{N}$, an *n-assignment* is a partial function α from $\{0,1\}^{\leq n}$ into $\{0,1\}$. (Thus, an n-assignment is also an m-assignment for all $m \geq n$.) A language $C \subseteq \{0,1\}^*$ *satisfies* an n-assignment α if $\alpha(x) = [\![x \in C]\!]$ for all $x \in$ dom α. Two n assignments α and β are *consistent* with one another if there exists a language $C \subseteq \{0,1\}^*$ such that $\tilde{C}$ satisfies both α and β. For an n-assignment α and $x \in \{0,1\}^*$, let $\alpha\tilde{f}(x)$ denote the string $\alpha(\tilde{f}_1(x)) \dots \alpha(\tilde{f}_k(x)) \in \{0,1\}^k$. (Note that $\alpha\tilde{f}(x)$ is defined if and only if $\tilde{f}_1(x), \dots, \tilde{f}_k(x) \in$ dom α.) A string $x \in \{0,1\}^*$ *forbids* an n-assignment α if $\alpha\tilde{f}(x)$ is defined and $g(x)\alpha\tilde{f}(x) \neq [\![x \in A]\!]$. (This implies that if $A \leq^{\mathrm{P}}_{k-tt} \tilde{C}$ via $(\tilde{f}, g)$ and x forbids α, then $\tilde{C}$ does not satisfy α.) An *n-assignment to* $\tilde{f}(x)$ is an n-assignment α such that dom $\alpha = \{\tilde{f}_1(x), \dots, \tilde{f}_k(x)\} \subseteq \{0,1\}^{\leq n}$. Finally, fix an "end-marker" \$ and, for each $n \in \mathbb{N}$ and n-assignment α, let

$$x(\alpha, n) = \begin{cases} \text{the lexicographically first string } x \in \{0,1\}^{\leq n} \text{ that forbids} \\ \text{some } n-\text{assignments to } \tilde{f}(x) \text{ that is consistent} \\ \text{with } \alpha, \text{ if such an } x \text{ exists,} \\ \$, \quad \text{if no such } x \text{ exists.} \end{cases}$$

Now we turn to the proof of Theorem 3.1.

Proof. Assume that the result is false, that is, assume that $A \in \mathrm{ESPACE} - {}^{\mathrm{P}}_{k-tt}(\mathrm{SPARSE})$. Let f and g be functions such that $A \leq^{\mathrm{P}}_{k-tt} B$ via (f, g). We will show that there is a polynomial r such that

$$(3.2) \qquad KS^r(B_{\leq n}) < 2^{n+1} - 2n \quad \text{i.o.,}$$

thus contradicting the hypothesis.

Let us briefly sketch the argument. For each $n \in \mathbb{N}$, we define a finite tree T_n whose vertices at each level include partial specifications of all languages $\tilde{C}$ such that $A \leq^{\mathrm{P}}_{k-tt} \tilde{C}$ via $(\tilde{f}, g)$. In particular, $\tilde{B}$ will satisfy some leaf of T_n. For a randomly selected language $C \subseteq \{0,1\}^*$, let $\mathcal{E}_l$ be the event that $\tilde{C}$ satisfies some vertex at depth $\geq l$ in T_n. The trees T_n will be constructed so that the probability $\Pr(\mathcal{E}_l)$ decays exponentially as l increases. It will follow by the algorithmic construction of T_n that $KS(C_{\leq n})$ is small for all C such that $\widetilde{C}$ satisfies some vertex that is deep in T_n, thus guaranteeing that $KS(C_{\leq n})$ is small for infinitely many n. The quantitative details will be such that (3.2) holds.

Construction of the trees. For each $n \in \mathbb{N}$, define a tree T_n as follows. Each vertex of each T_n is an n-assignment. The tree T_0 consists of a single vertex, the empty 0-assignment α_ϕ. (That is, dom $\alpha_\phi = \phi$.) The tree T_{n+1} is constructed from T_n by attaching subtrees to zero or more of the leaves of T_n. The vertices of T_n are the *old vertices* of T_{n+1}. The *new vertices* of T_{n+1} are introduced recursively as follows. Let α be a leaf of T_n or a new vertex of T_{n+1}. If $x(\alpha, n+1) = \$$, then α is a leaf of T_{n+1}. Otherwise, the immediate successors of α in T_{n+1}, when they exist, are those $(n+1)$-assignments β such that β is consistent with α, dom $\beta = (\text{dom}\ \alpha) \cup \{\widetilde{f}_1(x(\alpha, n+1)), \ldots, \widetilde{f}_k(x(\alpha, n+1))\}$, and $x(\alpha, n+1)$ does not forbid β.

General properties of T_n. (a) It is clear that, for each vertex α of T_n, dom $\alpha \subseteq W_n \cap \widetilde{W}_n$, where $W_n = \{0,1\}^{\leq n}$.

(b) Note that each vertex of each T_n has at most $2^k - 1$ immediate successors. Also, along any path from the root of T_n to a leaf of T_n, the domain of each vertex is a proper subset of the domain of its immediate successors, so the depth of T_n is at most $\|\{0,1\}^{\leq n}\| = 2^{n+1} - 1$. Thus, each T_n is a finite tree.

(c) By hypothesis $A \in$ ESPACE, and f and g were assumed to be computable in polynomial time. Thus, the trees T_n can be constructed and traversed in space polynomial in their depth.

The key property of the trees T_n is best understood in probabilistic terms. Fix $n \in \mathbb{N}$ and consider the random experiment in which a set $S \subseteq \{0,1\}^{\leq n}$ is chosen probabilistically according to the uniform distribution on all such sets. For each n-assignment α, let F_α be the event that $\widetilde{S}$ satisfies α, and let $F_{\alpha+}$ be the event that $\widetilde{S}$ satisfies some immediate successor of α in T_n. (If α is not an interior vertex of T_n, then $F_{\alpha+} = \phi$. We emphasize that it is S, not $\widetilde{S}$, which is chosen according to the uniform distribution.) The key property of our construction is the following.

Local property. For each interior vertex α of T_n,

$$\Pr(F_{\alpha+}|F_\alpha) \leq 1 - 2^{-k}. \tag{3.3}$$

Proof of the local property. Assume that α is an interior vertex of T_n, and let $x = x(\alpha, m)$, where m is the least integer such that $x(\alpha, m) \neq \$$. (Note that $m \leq n$.) By the construction of T_n, there is an n-assignment β such that β is consistent with α, dom $\beta = (\text{dom}\ \alpha) \cup \{\widetilde{f}_1(x), \ldots, \widetilde{f}_k(x)\}$, and β is not an immediate successor of α in T_n (because x forbids β). Since β is consistent with α, there exists a set $S_0 \subseteq \{0,1\}^{\leq n}$ such that $\widetilde{S_0}$ satisfies both α and β.

Note that dom α and dom β are subsets of $W_n \cap \widetilde{W}_n$, where $W_n = \{0,1\}^{\leq n}$. Define $h : W_n \cap \widetilde{W}_n \to W_{n-1}$ by $h(u10^i) = u$ for all $u10^i \in W_n \cap \widetilde{W}_n$. Note that $F_\alpha = \{S | S \cap h(\text{dom}\ \alpha) = S_0 \cap h(\text{dom}\ \alpha)\}$ and $F_\beta = \{S | S \cap h(\text{dom}\ \beta) = S_0 \cap h(\text{dom}\ \beta)\}$. Let

$$G = \{S | S \cap (h(\text{dom}\ \beta) - h(\text{dom}\ \alpha)) = S_0 \cap (h(\text{dom}\ \beta) - h(\text{dom}\ \alpha))\}.$$

Then G and F_α are independent events whose intersection is F_β, so that $\Pr(F_\beta|F_\alpha) = \Pr(G)$. Since $\|h(\text{dom}\ \alpha)\| \leq \|h(\text{dom}\ \beta - \text{dom}\ \alpha)\| \leq \|\text{dom}\ \beta - \text{dom}\ \alpha\| \leq k$, it follows that $\Pr(f_{\alpha+}|F_\alpha) \leq 1 - \Pr(F_\beta|F_\alpha) = 1 - \Pr(G) = 1 - 2^{-\|h(\text{dom}\beta) - h(\text{dom}\alpha)\|} \leq 1 - 2^{-k}$. □

For each $l \in \mathbb{N}$, let $\mathcal{E}_l$ be the event that $\widetilde{S}$ satisfies some vertex at depth l in T_n. (The set S is still chosen uniformly, with n fixed.) Write $T_n(l)$ for the set of all interior nodes of T_n at depth l.

Claim. For all

$$l \in \mathbb{N}, Pr(\mathcal{E}_l) \leq (1-2^{-k})^l. \tag{3.4}$$

Proof. The local property (3.3) yields

$$\begin{aligned} Pr(\mathcal{E}_{l+1}) &= \sum_{\alpha \in T_n(l)} Pr(F_{\alpha+}) \\ &= \sum_{\alpha \in T_n(l)} Pr(F_{\alpha+} \cap F_\alpha) \\ &= \sum_{\alpha \in T_n(l)} Pr(F_{\alpha+}|F_\alpha) Pr(F_\alpha) \\ &\leq (1-2^{-k}) \sum_{\alpha \in T_n(l)} Pr(F_\alpha) \\ &\leq (1-2^{-k}) Pr(\mathcal{E}_l). \end{aligned}$$

It follows inductively that for all $l \in \mathbb{N}$,

$$Pr(\mathcal{E}_l) \leq (1-2^{-k})^l. \qquad \square$$

For each $n \in \mathbb{N}$, define a path $\beta_{n,0}, \ldots, \beta_{n,J(n)}$ from the root of T_n to a leaf of T_n by the following recursion. First, $B_{n,0} = \alpha_\phi$. For the recursion step, for each interior vertex α of T_n, let $x(\alpha) = x(\alpha, m)$, where m is the least integer such that $x(\alpha, m) \neq \$$. Assume that a path $\beta_{n,0}, \ldots, \beta_{n,j}$ in T_n has been defined so that $\beta_{n,j}$ is an interior node of T_n and $\beta_{n,j}\tilde{f}(x) = [\![f_1(x) \in B]\!] \ldots [\![f_k(x) \in B]\!]$ for each $x = x(\beta_{n,i}), 0 \leq i < j$. (Note that this hypothesis is satisfied vacuously when $j = 0$.) Then $\beta_{n,j+1}$ is the unique n-assignment such that $\beta_{n,j+1}$ is consistent with $\beta_{n,j}$, dom $\beta_{n,j+1} = (\text{dom } \beta_{n,j}) \cup \{\widetilde{f_1}(x), \ldots, \widetilde{f_k}(x)\}$, and $\beta_{n,j+1}\tilde{f}(x) = [\![f_1(x) \in B]\!] \cdots [\![f_k(x) \in B]\!]$, where $x = x(\beta_{n,j})$. (Recall that (f, g) is a $\leq^{\mathrm{P}}_{k-tt}$-reduction of A to B, so this implies that $g(x)(\beta_{n,j}\tilde{f}(x)) = [\![x \in A]\!]$. It follows that x does not forbid $\beta_{n,j+1}$, so that $\beta_{n,j+1}$ is indeed an immediate successor of $\beta_{n,j}$ in T_n.)

For each $n \in \mathbb{N}$, let $\beta_n = \beta_{n,J(n)}$. A routine induction shows that for every $n \in \mathbb{N}$, $\widetilde{B}$ satisfies β_n.

For each $n \in \mathbb{N}$, let $S_{n,1}, \ldots, S_{n,I(n)}$ be the lexicographic enumeration of all sets $S \subseteq \{0,1\}^{\leq n}$ such that $\widetilde{S}$ satisfies some vertex α of T_n whose depth in T_n is at least dn, where

$$d = \frac{3}{k - \log(2^k - 1)}. \tag{3.5}$$

Note that this is precisely an enumeration of $\mathcal{E}_{dn}$, so that from (3.4) we have

$$\begin{aligned} \log I(n) &= 2^{n+1} - 1 + \log Pr(\mathcal{E}_{dn}) \\ &\leq 2^{n+1} - 1 + d \cdot n \cdot \log(1 - 2^{-k}) \\ &= 2^{n+1} - 3n - 1. \end{aligned} \tag{3.6}$$

By hypothesis $A \in$ ESPACE, and f and g were assumed to be computable in polynomial time. Thus, the trees T_n can be constructed and traversed in space polynomial in their depth. Thus, there is a machine M such that, if $1 \leq i \leq l(n)$ and i is written in binary, then $M(i, n)$ outputs the $(2^{n+1} - 1)$-bit characteristic string of $S_{n,i}$ using workspace polynomial in 2^n. Since $\widetilde{B}$ satisfies each β_n, it follows by (3.6) that there is a polynomial r' such that $KS_M^{r'}(B_{\leq n}) \leq 1 + \log I(n) \leq 2^{n+1} - 3n$ for all $n \in D$, where $D = \{n \in \mathbb{N} | J(n) \geq dn\}$. Then, by the optimality of the universal machine, there exists a polynomial r and a constant c such that

$$(3.7) \qquad KS^r(B_{\leq n}) \leq 2^{n+1} - 3n + c$$

for all $n \in D$.

To prove that (3.2) holds, it will be sufficient to show that the set D is infinite.

Claim. D is infinite.

Proof. Let $B' = \cup_{n \geq 0} \beta_n^{-1}(\{1\})$. Since $\widetilde{B}$ satisfies each β_n, it is clear that $B' \subseteq \widetilde{B}$. Fix a strictly increasing polynomial s such that $|\widetilde{f}_i(x)| \leq s(|x|)$ for all $x \in \{0,1\}^*$ and $1 \leq i \leq k$. Then

$$(3.8) \qquad B'_{\leq n} \subseteq \beta_{s(n)}^{-1}(\{1\})$$

for all $n \in \mathbb{N}$. To see that this is true, let $y \in B'_{\leq n}$. Then $y = \widetilde{f}_i(x)$ for some $x \in \{0,1\}^*$ and $i, 1 \leq i \leq k$. By (3.1), $|x| < n$, so that $|\widetilde{f}_j(x)| \leq s(n)$ for all $j, 1 \leq j \leq k$. Since $x(\beta_{s(n)}, s(n)) = \$$, x does not forbid any $s(n)$-assignment to $\tilde{f}(x)$ that is consistent with $\beta_{s(n)}$. It follows that $y = \widetilde{f}_i(x)$ is not in (dom β_{m+1}) $-$ (dom β_m) for any $m \geq s(n)$. Since $y \in B' = \cup_{m \geq 0} B_m^{-1}(\{1\})$. It follows that $y \in \beta_{s(n)}^{-1}(\{1\})$, confirming (3.8).

We have already noted that $(\tilde{f}, g)$ is a $\leq_{k-tt}^{\mathrm{P}}$-reduction of A to $\widetilde{B}$. In fact, $(\tilde{f}, g)$ is a $\leq_{k-tt}^{\mathrm{P}}$-reduction of A to B'. To see this, fix $x \in \{0,1\}^*$, let $n = |x|$, and let $m = s(s(n))$. Let β'_m be the unique m-assignment such that β'_m is consistent with β_m, dom β'_m = (dom β_m) $\cup \{\widetilde{f}_1(x), \ldots, \widetilde{f}_k(x)\}$, and $\beta'_m(\widetilde{f}_i(x)) = 0$ for each $i, 1 \leq i \leq k$, such that $\widetilde{f}_i(x) \notin$ dom β_m. Since $x(\beta_m, m) = \$$, x does not forbid β'_m. Since $\beta'_m \tilde{f}(x)$ is defined, it follows by (3.8) that

$$\begin{aligned}
[\![x \in A]\!] &= g(x)(\beta'_m \tilde{f}(x)) \\
&= g(x)(\beta'_m(\widetilde{f}_1(x)) \cdots \beta'_m(\widetilde{f}_k(x))) \\
&= g(x)([\![\widetilde{f}_1(x) \in B'_{\leq s(n)}]\!] \cdots [\![\widetilde{f}_k(x) \in B'_{\leq s(n)}]\!]) \\
&= g(x)([\![\widetilde{f}_1(x) \in B']\!] \cdots [\![\widetilde{f}_k(x) \in B']\!]),
\end{aligned}$$

confirming that $A \leq_{k-tt}^{\mathrm{P}} B'$ via $(\tilde{f}, g)$. By assumption, $A \notin \mathrm{P}_{k-tt}(\mathrm{SPARSE})$ so that we have

$$(3.9) \qquad \|B'_{\leq n}\| > k \cdot d \cdot s(n) \quad \text{i.o.}$$

On the other hand,

$$(3.10) \qquad \|\mathrm{dom}\, \beta_{s(n)}\| \leq k \cdot \mathrm{depth}(\beta_{s(n)}) = k \cdot J(s(n)).$$

By (3.8), (3.9), and (3.10), $J(s(n)) > d \cdot s(n)$ for infinitely many n. Since s is strictly increasing, it follows that the set D is infinite.

Since D is infinite, (3.2) follows from (3.7). This completes the proof of Theorem 3.1. □

Consider the reducibility specified by the pair (f, g) in the proof of Theorem 3.1. What properties were used? Time as such played no role. Another measure of computation such as space or time-space could have been used; for example, $\leq_{k-tt}^{\mathrm{PSPACE}}$ could have been used instead of $\leq^{\mathrm{P}}_{k-tt}$. The fact that the reducibility was specified by deterministic machines plays no role except for the fact that both f and g are functions; another mode of computation could have been used as long as functions are used to specify the reducibility. The hypothesis that $A \in$ ESPACE, combined with the fact that f and g could be computed in polynomial time, allowed the trees T_n to be constructed and traversed in space polynomial in their depth. In each case the corresponding result would hold and the proof would be essentially the same as that of Theorem 3.1.

4. Applications. We develop some applications of Theorem 3.1. In each case we consider languages satisfying the lower bounds on the space-bounded Kolmogorov complexity of the language. In order to eliminate the repetition of awkward phrases, we introduce a new definition.

The class HIGH is the collection of all languages B that for every polynomial q, satisfy $KS^q(B_{\leq n}) > 2^{n+1} - 2n$ almost everywhere.

As noted in §3, if a language is in HIGH, then it has essentially maximal information content.

Almost every language is in HIGH. This follows from the fact [Ma71] that RAND $\subset$ HIGH, where RAND is the set of *algorithmically random languages* as defined by Martin-Löf [Ma66]. Martin-Löf showed that almost every language is in RAND. In fact, the inclusion of RAND in HIGH is proper since almost every recursive language is in HIGH [Lu92], while no recursively enumerable (hence, no recursive) language is in RAND. On the other hand, HIGH $\cap$ ESPACE $= \phi$, that is, no language recognized by a machine that uses workspace $O(2^{cn})$ for any $c > 0$ is in HIGH.

Recall that Theorem 3.1 shows that for every integer $k > 0$, P_{k-tt}(HIGH) $\cap$ ESPACE $\subseteq \mathrm{P}_{k-tt}$(SPARSE).

The following result shows that it is highly unlikely that any language in HIGH is $\leq^{\mathrm{P}}_{btt}$-hard for many of the classes studied in structural complexity theory. Recall that the reducibility $\leq^{\mathrm{P}}_{btt}$ is transitive.

THEOREM 4.1. *Let K be any class chosen from* {PSPACE, NP, PP, $\mathrm{C_{=}P}$, $\mathrm{MOD_2P}$, $\mathrm{MOD_3P}, \ldots$}. *If there is a language in* HIGH *that is $\leq^{\mathrm{P}}_{btt}$-hard for K, then $K =$* P.

Proof. Ogiwara and Watanabe [OW91] have shown that if there is a sparse set that is $\leq^{\mathrm{P}}_{btt}$-hard for NP, then P = NP. Later, Ogiwara and Lozano [OL91] extended that result so that it holds for the other choices of K. Theorem 3.1 shows that if there is a language $A \in$ HIGH such that A is $\leq^{\mathrm{P}}_{btt}$-hard for any such class K, then there is a sparse set S such that S is $\leq^{\mathrm{P}}_{btt}$-hard for K. Hence, $K =$ P. □

Thus, Theorem 4.1 shows that for any class K chosen from {PSPACE, NP, PP, $\mathrm{C_{=}P}$, $\mathrm{MOD_2P}$, $\mathrm{MOD_3P}, \ldots$}, if P $\neq K$, then no language in HIGH can be $\leq^{\mathrm{P}}_{btt}$-hard for K. A similar consequence holds for E = DTIME(2^{linear}) with no unproven hypothesis.

THEOREM 4.2. *No language in* HIGH *is $\leq^{\mathrm{P}}_{btt}$-hard for* E.

Proof. Watanabe [Wa87] has shown that no sparse set is $\leq^{\mathrm{P}}_{btt}$-hard for E, so by Theorem 4.1 no language in HIGH is $\leq^{\mathrm{P}}_{btt}$-hard for E. □

The main theorem was stated in terms of a fixed integer k that bounds the number of queries. Instead, we could consider a function $k(n) = O(\log n)$ that is computable in polynomial time and replace the fixed integer k with the function $k(n)$ to obtain a bound on the number of queries. Thus, $\mathrm{P}_{k(n)-tt}$(HIGH) $\cap$ ESPACE $\subseteq \mathrm{P}_{k(n)-tt}$(SPARSE). In addition, the proof of the main theorem allows us to conclude that P_m(HIGH) $\cap$ ESPACE $\subseteq \mathrm{P}_m$(SPARSE) and

$$\mathrm{P}_{(\log n)-dtt}(\mathrm{HIGH}) \cap \mathrm{ESPACE} \subseteq \mathrm{P}_{(\log n)-dtt}(\mathrm{SPARSE}).$$

The results have been stated in terms of languages reducible to languages with extremely high space-bounded Kolmogorov complexity. No such language is in ESPACE. However, the proof of the main theorem yields a bound on the Kologogorov complexity of languages to which languages in ESPACE can be reduced, and this bound allows us to make additional conclusions.

COROLLARY 4.3. *For every* $A \in \mathrm{ESPACE} - \mathrm{P}_{btt}(\mathrm{SPARSE})$, *there exists a polynomial* r *such that for all languages* B, *if* $A \leq^{\mathrm{P}}_{btt} B$, *then* $KS^r(B_{\leq n}) < 2^{n+1} - 2n$ *i.o.*

Corollary 4.3 implies that hard languages have unusually low Kolmogorov complexity. Moreover, the fact that the polynomial r is fixed enables us to strengthen Theorem 4.1 as follows.

THEOREM 4.4. (a) *If* $\mathrm{P} \neq \mathrm{NP}$, *then there is a* fixed *polynomial* q *such that every* $\leq^{\mathrm{P}}_{btt}$-*hard language* H *for* NP *has space-bounded Kolmogorov complexity* $KS^q(H_{\leq n}) < 2^{n+1} - 2n$ *i.o.*

(b) *There is a* fixed *polynomial* q *such that every* $\leq^{\mathrm{P}}_{btt}$-*hard language* H *for* E *has space-bounded Kolmogorov complexity* $KS^q(H_{\leq n}) < 2^{n+1} - 2n$ *i.o.*

Proof. (a) If $\mathrm{P} \neq \mathrm{NP}$, then there exists a language $A \in \mathrm{NP} - \mathrm{P}_{btt}(\mathrm{SPARSE})$ [OW91]. Fix q for A as in Corollary 4.3. Then every $\leq^{\mathrm{P}}_{btt}$-hard language H for NP satisfies $A \leq^{\mathrm{P}}_{btt} H$, while $KS^q(H_{\leq n}) < 2^{n+1} - 2n$ i.o.

(b) The proof is the same as for (a) except that we fix $A \in \mathrm{E} - \mathrm{P}_{btt}(\mathrm{SPARSE})$ [Wa87]. □

COIN-FLIPPING GAMES IMMUNE AGAINST LINEAR-SIZED COALITIONS*

NOGA ALON† AND MONI NAOR‡

Abstract. Perfect information coin-flipping and leader-election games arise naturally in the study of fault tolerant distributed computing and have been considered in many different scenarios. This paper answers a question of Ben-Or and Linial by proving that for every $c < 1$ there are such games on n players in which no coalition of cn players can influence the outcome with probability greater than some universal constant times c. (Note that this paper actually proves this statement only for all $c < \frac{1}{3}$, but since its universal constant is bigger than 3 the above is trivial for $c \geq \frac{1}{3}$.) This paper shows that a random protocol of a certain length has this property and gives an explicit construction as well.

Key words. fault tolerance, distributed computing, perfect information games, coin-flipping, leader election

AMS(MOS) subject classifications. 68C05, 05B25, 90D99

1. Introduction.

A fundamental problem of fault tolerant distributed computing is that of n processors wishing to agree on a random value. The problem becomes nontrivial when some of the processors are faulty. The problem has been considered in many different scenarios, depending on the assumptions made on the type of communication between the processors, the kind and number of faults, and the power of the adversary. See the surveys of Chor and Dwork [9] and Ben-Or, Linial, and Saks [6]. In the present paper we consider it in the natural model formulated by Ben-Or and Linial [5] (whose formal description is given in the next subsection): the processors have complete information, (i.e., the communication type is a public broadcast channel), the processors take turns broadcasting some random values and the outcome is a function of all the bits that were sent. The adversary is assumed to be computationally unlimited. The problem is to design protocols where the influence on the outcome of any set of faulty processors not exceeding a certain size is bounded.

A closely related problem is that of leader election: the processors take turns broadcasting messages. At the end of the protocol, as a function of the bits transmitted, one processor is considered the leader. The problem is to design protocols that have the property that for any coalition of faulty processors whose size does not exceed a certain threshold, the probability that a member of the coalition be elected is bounded.

Unlike the Byzantine case, where the exact thresholds for achieving an agreement were known [9], [10], for the perfect information scenario a gap existed: it was known that $n/2$ cheaters (out of n players) can completely control the protocol, yet the best known protocol [12], [1] (improving the one in [5]) has the property that only sets of cheaters of size less than $n/3 \log n$ have influence bounded away from 1.

In this paper we resolve this problem and show that there are protocols where even a linear number of cheaters have only bounded influence. We first show in §2, via a *probabilistic construction*, the existence of an election protocol that can tolerate up to $\frac{1}{3}n$ cheaters (i.e., the elected leader will not be faulty with some nonzero probability). Then, in §3, we show an *explicit construction* that works for a smaller (yet linear in n) threshold. This easily gives coin-flipping protocols with a similar behavior.

Our proofs combine probabilistic arguments with an iterative procedure based on the pseudorandom properties of projective and affine planes. The analysis requires a study of a game that we call faulty baton passing, which is performed in each iteration of the procedure.

1.1. Preliminaries, background, and results. A *perfect-information coin-flipping game* of n players is a rooted tree T whose leaves are labeled by zero or 1 and whose internal vertices are labeled by the names of the players. In addition, each internal vertex v is associated with a probability distribution D_v on its children. Starting from the root, the player whose name labels the current vertex v chooses one of its children according to the distribution D_v, and the game proceeds to the chosen child. When a leaf is reached the game ends and its value is the label of the leaf. Note that the same player may have to make more than one choice in a game. It is sometimes assumed that the tree T is binary and that the probability distribution associated with each internal vertex is the uniform distribution on its two children. This makes no essential difference, and hence we use here the more general definition.

Let N denote the set of players. We say that a player $I \in N$ plays *fairly* if he makes his choice randomly (according to the corresponding probability distribution) whenever it is his turn to make a choice in the course of the game.

Let p_1^T be the probability of reaching a leaf labeled 1 if all players play fairly. T is a *fair* game if $p_1(T) = \frac{1}{2}$. For a subset S of the set of players N, let $p_1^T(S)$ denote the probability of reaching a 1-leaf when the coalition S plays the optimal strategy trying to maximize the probability of reaching a 1-value. Here we assume that all the other players play fairly and that each player in S knows exactly which other players are in S. The *influence* $I_1^T(S)$ *of* S *towards* 1 *in the game* T is defined by $I_1^T(S) = p_1^T(S) - p_1^T$. The influence $I_0^T(S)$ of S towards zero in T is defined similarly and the (*total*) *influence* $I(S) = I^T(S)$ is defined by $I(s) = I_1^T(S) + I_0^T(S)$. Therefore, $I(S)$ measures the capability of S to control the game, and a game is robust if $I(S)$ is small for every relatively small S. In [5] it is proved that for every perfect-information coin-flipping game T of a set N of n players, where p_1^T is bounded away from zero and 1, and for every $k \leq n$ there is a subset $S \subset N$ of cardinality k whose influence $I(S)$ is at least $\Omega(k/n)$. In the same paper the authors construct a fair game of n players in which the influence of each set of k players, where $k \leq O(n^{\log_3 2})$ is at most $O(k/n)$. Improving the estimates of Saks [12], together with the main result of [11], Ajtai and Linial [1] showed that there is a fair game on n players in which the influence of each set of $k \leq n/3 \log n$ is at most $O(k/n)$. These results lead to the following problem, raised in [5], and referred to as the most outstanding problem in this area in some of the more recent papers on the subject.

Problem (see [5] and [1]). Are there fair perfect-information coin-flipping games of n players in which for every $k \leq n$ the influence of every set of k players is at most $O(k/n)$? In particular, are there such games in which there is no set of size $o(n)$ whose influence is $1 - o(1)$?

In the present paper we show that the answer to both questions is "yes." We first present a probabilistic proof of existence of such games. Afterwards we describe, for every positive $c < 1$, an explicit construction of perfect-information coin-flipping fair games of n players in which there is no set of cn players whose influence exceeds $O(c)$. (Note that the construction works only for all positive real $c < C$, where C is some absolute positive constant; but since the multiplicative constant in the expression $O(c)$ can be adjusted, this implies the result for all $c < 1$.)

Our results are better formulated in terms of leader-election games. A *leader-election game* of n players is a rooted tree T whose vertices are labeled by the names of the players, and each internal vertex v is associated with a probability distribution D_v on its children. Starting from the root, the player whose name labels the current vertex v chooses one of its children according to the distribution D_v, and the game proceeds to the chosen child. When a leaf is reached the game ends and the chosen leader is the label of this leaf.

For a subset S of players, let $p^T(S)$ denote the probability that a leader from S is chosen, when the coalition S plays the optimal strategy trying to maximize the probability of such a choice, (and when all other players play fairly). For a constant $\delta > 0$ and for $t \leq n$ let us call, following [12], a leader-election game T *δ-robust against t-cheaters* if $p^T(S) \leq \delta$ for any subset S of at most t players. Let $t(n, \delta)$ denote the maximum t such that there exists a leader-election game of n players that is δ-robust against t cheaters. From any leader-election game T we can construct its associated coin-flipping fair game $C(T)$ obtained by letting the chosen leader flip a coin and decide the value of the game. Thus, formally, $C(T)$ is the game obtained from the tree T by adding to each leaf v of T two children labeled zero and 1, and by associating v with the uniform distribution on these two children. It is obvious that for a subset S of players, the influence of S towards zero or towards 1 in $C(T)$ is precisely $p^T(S)/2$. Therefore, the existence of robust leader-election games implies the existence of robust coin-flipping games. This leads naturally to the problem of estimating $t(n, \delta)$.

In [12] Saks constructed a leader-election game that is δ-robust against $c(\delta)n/\log n$ cheaters, for any $0 < \delta < 1$, where $c(\delta)$ is a positive constant depending only on δ. This shows that $t(n, \delta) > c(\delta)n/\log n$. Answering a question raised in [12] we show that in fact $t(n, \delta) > \Omega(\delta n)$ for all $0 < \delta < 1$. Moreover, for any $\epsilon < \frac{1}{3}$ there is a $\delta < 1$ such that $t(n, \delta) > \epsilon n$. As noted in [12] there is a simple argument that shows that $t(n, \delta) < n/2$ for all $\delta < 1$. It would be interesting to close the gap between the two constants $\frac{1}{2}$ and $\frac{1}{3}$ here.

Our best lower bounds (in terms of the constants) for $t(n, \delta)$ are obtained by probabilistic arguments, described in the next section. However, we also give an explicit construction of leader-election games of n players that are δ-robust against $\Omega(\delta n)$-cheaters.

2. The existence of robust games. Let T be a full binary rooted tree of depth d. Put $N = \{1, \ldots, n\}$, and let us label each internal vertex v of T, randomly and independently, by a number in N chosen according to a uniform distribution on N. Observe that T is a leader-election game of n players. Our first result in this section is the following theorem, which demonstrates the existence of very robust leader-election games.

THEOREM 2.1. *Let T be the leader-election game chosen randomly as above. Then, the probability that there is a set $S \subset N$ of cardinality ϵn, where $\epsilon < \frac{1}{3}$, such that $p^T(S)$ is at least*

$$\epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} + \gamma$$

does not exceed

$$\binom{n}{\epsilon n} \frac{\epsilon((1/2) + (3\epsilon/2))^d}{\gamma^2}.$$

In particular, there is an n-player leader-election game T of depth $O(n)$ in which for any set of $\epsilon n \leq \frac{1}{4} n$ players $p^T(S) \leq \epsilon + 12\epsilon^{3/2}$.

Note that even if all players in an n-players leader-election game play fairly, then for every ϵ (which is an integral multiple of $1/n$) there is a set S of ϵn players such that the leader is chosen among the members of S with probability of at least ϵ. This shows that the last estimate for $p^T(S)$ in the theorem above is sharp, up to the additive lower order term $12\epsilon^{3/2}$.

The theorem is proved by deriving estimates on the expectation and variance of the value of $p^T(S)$ in a randomly chosen leader-election game. Then, using Chebyshev's inequality it is shown that with the required probability there is no set S where $p^T(S)$ is larger than the bound in the theorem. A similar strategy is used in the proof of the main result of [4].

First we establish the following two lemmata.

LEMMA 2.2. *Let Y, Z be two independent random variables with equal expectations $E(Y) = E(Z) = E$ and equal variances* $\mathrm{Var}(Y) = \mathrm{Var}(Z) = \sigma^2$. *Let $\epsilon \leq 1$ be a positive constant and let X be the random variable defined as $(Y+Z)/2$ with probability $1-\epsilon$ and* $\mathrm{Max}\{Y, Z\}$ *with probability ϵ. Then*

$$E(X) = E + \frac{\epsilon}{2}E(|Y-Z|) \leq E + \frac{\epsilon\sigma}{\sqrt{2}} \tag{1}$$

$$\mathrm{Var}(X) \leq \sigma^2\left(\frac{1}{2} + \frac{3\epsilon}{2}\right). \tag{2}$$

Proof. Observe that $\mathrm{Max}(Y, Z) = (Y+Z)/2 + |Y-Z|/2$. By Jensen's inequality

$$E(|Y-Z|) \leq \sqrt{E((Y-Z)^2)} = \sqrt{\mathrm{Var}(Y-Z)} = \sqrt{\mathrm{Var}(Y) + \mathrm{Var}(Z)} = \sqrt{2}\sigma.$$

Hence,

$$E(X) = (1-\epsilon)E + \epsilon\left(E + \frac{1}{2}E(|Y-Z|)\right) = E + \frac{\epsilon}{2}E(|Y-Z|) \leq E + \frac{\epsilon}{2}\sqrt{2}\sigma.$$

Thus (1) holds.

To prove (2) observe, first, that by the Cauchy–Schwarz inequality, for every two random variables T, F,

$$(E(TF) - E(T)E(F))^2 = (E((T-E(T))(F-E(F))))^2 \leq \mathrm{Var}(T)\mathrm{Var}(F).$$

(This is simply the well-known fact that the absolute value of the correlation factor of two random variables is at most 1.) Taking $T = Y+Z$, $F = |Y-Z|$ we get

$$|E((Y+Z)|Y-Z|) - E(Y+Z)E(|Y-Z|)| \leq \sqrt{\mathrm{Var}(Y+Z)\mathrm{Var}(|Y-Z|)} \leq 2\sigma^2. \tag{3}$$

By the definition of X:

(4)
$$E(X^2) = (1-\epsilon)\frac{E(Y^2) + E(Z^2) + 2E(YZ)}{4}$$
$$+\epsilon\frac{E(Y^2) + E(Z^2) + 2E(YZ)}{4} + 2\frac{\epsilon}{4}E((Y+Z)|Y-Z|) + \frac{\epsilon}{4}E(|Y-Z|^2)$$
$$= \frac{E(Y^2) + E(Z^2) + 2E^2}{4} + \frac{\epsilon}{2}E((Y+Z)|Y-Z|) + \frac{\epsilon}{4}E(|Y-Z|^2).$$

Also, by (1),

$$(5)\qquad \begin{aligned} E(X)^2 &= E^2 + \epsilon E\, E(|Y-Z|) + \frac{\epsilon^2}{4}(E(|Y-Z|))^2 \\ &= E^2 + \frac{\epsilon}{2}E(Y+Z)E(|Y-Z|) + \frac{\epsilon^2}{4}(E(|Y-Z|))^2. \end{aligned}$$

Subtracting (5) from (4) we obtain

$$\begin{aligned} \operatorname{Var}(X) &= E(X^2) - (E(X))^2 \\ &= \frac{E(Y^2)+E(Z^2)-2E^2}{4} + \frac{\epsilon}{2}(E((Y+Z)|Y-Z|) - E(Y+Z)E(|Y-Z|)) \\ &\quad + \frac{\epsilon}{4}E(|Y-Z|^2) - \frac{\epsilon^2}{4}(E(|Y-Z|))^2. \end{aligned}$$

In view of (3), the last quantity is at most

$$\begin{aligned} &\frac{\operatorname{Var}(Y)+\operatorname{Var}(Z)}{4} + \frac{\epsilon}{2}2\sigma^2 + \frac{\epsilon}{4}E(|Y-Z|^2) \\ &= \frac{\sigma^2}{2} + \epsilon\sigma^2 + \frac{\epsilon}{4}2\sigma^2 = \sigma^2\left(\frac{1}{2}+\frac{3}{2}\epsilon\right), \end{aligned}$$

completing the proof of (2). □

In order to state the next lemma we need some more notation. Let T be, as before, a full binary rooted tree of depth d, whose vertices are labeled randomly and independently by the elements of $N = \{1,\dots,n\}$. Let $a < 1$ be a positive number, and let us choose, for every leaf v of T randomly and independently, a weight $w(v)$, where $w(v) = 1$ with probability a and $w(v) = 0$ with probability $1-a$. Let $S \subset N$ be a fixed subset of cardinality $|S| = \epsilon n$. Define a weight function $w_{a,S}$ on the vertices of T as follows. If v is a leaf of T, then $w_{a,S}(v) = w(v)$. If u is an internal vertex of T and v_1, v_2 are its two children, then

$$\begin{aligned} w_{a,S}(u) &= \operatorname{Max}\{w_{a,S}(v_1), w_{a,S}(v_2)\} \quad \text{if } u \text{ is labeled by an element of } S, \quad \text{and} \\ w_{a,S}(u) &= \frac{w_{a,S}(v_1)+w_{a,S}(v_2)}{2} \quad \text{otherwise.} \end{aligned}$$

Obviously, for fixed S, a, and for every fixed vertex v of T, $w_{a,S}(v)$ is a random variable whose value depends on the random choices of the labels of the internal vertices of T and on the random choices of the weights $w(v)$ of the leaves of T.

LEMMA 2.3. *Let v be a vertex of T whose distance from the leaves is h. Then the expectation and the variance of the random variable $w_{a,S}(v)$ satisfy*

$$\begin{aligned} E(w_{a,S}(v)) &\le a + \epsilon\frac{\sqrt{a}}{\sqrt{2}}\sum_{i=0}^{h-1}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{i/2} \le a + \epsilon\frac{\sqrt{a}}{\sqrt{2}(1-\sqrt{(1/2)+(3\epsilon/2)})}, \\ \operatorname{Var}(w_{a,S}(v)) &\le a\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^h. \end{aligned}$$

Proof. We apply induction on h. For $h = 0$ the expectation and the variance of $w_{a,S}(v)$ are a and $a(1-a)$, respectively, and hence both inequalities hold. Assuming the result holds for all $h' < h$, let u be a vertex of distance h from the leaves, $h > 1$. Let v_1 and v_2 be the two children of u. Since the label of u is in S with probability ϵ, and since $w_{a,S}(v_1)$ and $w_{a,S}(v_2)$ are two identically distributed independent random variables, we can apply Lemma 2.2 with $X = w_{a,S}(u)$, $Y = w_{a,S}(v_1)$, $Z = w_{a,S}(v_2)$. By the induction hypothesis this gives

$$\begin{aligned} E(w_{a,S}(u)) &\le E(w_{a,S}(v_1)) + \frac{\epsilon}{\sqrt{2}}\sqrt{\operatorname{Var}(w_{a,S}(v_1))} \\ &\le a + \epsilon\frac{\sqrt{a}}{\sqrt{2}}\sum_{i=0}^{h-2}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{i/2} + \frac{\epsilon}{\sqrt{2}}\sqrt{a}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{(h-1)/2} \\ &= a + \epsilon\frac{\sqrt{a}}{\sqrt{2}}\sum_{i=0}^{h-1}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{i/2}. \end{aligned}$$

Similarly, by Lemma 2.2 and by the induction hypothesis,

$$\begin{aligned} \operatorname{Var}(w_{a,S}(u)) &\le \operatorname{Var}(w_{a,S}(v_1))\left(\frac{1}{2}+\frac{3\epsilon}{2}\right) \\ &\le a\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{h-1}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right) = a\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{h}. \end{aligned}$$

This completes the proof. □

Returning, now, to our randomly chosen leader-election game given by the randomly labeled tree T of depth d, let us fix a set S with $S = \epsilon n$, where $\epsilon < \frac{1}{3}$, and let us estimate the probability that for this specific set S, the inequality

$$p^T(S) > \epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} + \gamma$$

holds. For every vertex v, let T_v denote the subtree of T rooted at v. If the leader-election game is played on T_v, then the probability that a leader from S is chosen, when the coalition S plays the optimal strategy trying to maximize the probability of such a choice, is $p^{T_v}(S)$. Obviously, if v is a leaf of T, then $p^{T_v}(S)$ is 1 if the label of v is in S and is zero otherwise. More interesting is the case that v is an internal vertex of T and u and w are its two children. It is not too difficult to check that in this case:

$$\begin{aligned} p^{T_v}(S) &= \operatorname{Max}\{p^{T_u}(S), p^{T_w}(S)\} \quad \text{if } v \text{ is labeled by an element of } S, \quad \text{and} \\ p^{T_v}(S) &= \frac{p^{T_u}(S) + p^{T_w}(S)}{2} \quad \text{otherwise.} \end{aligned}$$

Therefore, the random variables $p^{T_v}(S)$ are defined exactly as the random variables $w_{a,S}(v)$ discussed in Lemma 2.3, where here $a = \epsilon$. It follows that the expectations and variances of these random variables satisfy the bounds appearing in this lemma (with $a = \epsilon$). In particular, when we let v be the root of T we conclude that the expectation and the variance of $p^{T_v}(S) = p^T(S)$ satisfy

$$\begin{aligned} E(p^T(S)) &\le \epsilon + \epsilon\frac{\sqrt{\epsilon}}{\sqrt{2}}\sum_{i=0}^{d-1}\left(\frac{1}{2}+\frac{3\epsilon}{2}\right)^{i/2} \\ &\le \epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})}, \end{aligned}$$

and

$$\mathrm{Var}(p^T(S)) \le \epsilon \left(\frac{1}{2} + \frac{3\epsilon}{2}\right)^d .$$

Combining this with Chebyshev's inequality we obtain the following.

LEMMA 2.4. *Let S be a fixed set of $\epsilon n < \frac{1}{3}n$ players, and let T be the leader-election game chosen randomly as above. Then, for every positive γ, the probability that*

$$p^T(S) \ge \epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} + \gamma$$

does not exceed

$$\frac{\epsilon((1/2) + (3\epsilon/2))^d}{\gamma^2}.$$

Proof of Theorem 2.1. By Lemma 2.4, for every fixed subset of players S of cardinality $|S| = \epsilon n < \frac{1}{3}n$, the probability that $p^T(S)$ exceeds

$$\epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} + \gamma$$

does not exceed

$$\frac{\epsilon((1/2) + (3\epsilon/2))^d}{\gamma^2}.$$

Since the number of choices for S is $\binom{n}{\epsilon n}$, the desired result follows. □

Theorem 2.1 shows that for every ϵ that satisfies

$$\epsilon + \frac{\epsilon^{3/2}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} < 1,$$

there is a $\delta < 1$ such that $t(n, \delta) \ge \epsilon n$; i.e., there are leader-election games on n players which are δ-robust against ϵn-cheaters. This does not suffice to prove the existence of such a δ for ϵ, which is, e.g., at least $\frac{1}{4}$. Still, we can modify the proof to show that such a δ exists for every $\epsilon < \frac{1}{3}$. To do so, we first need one of the simple properties of the *baton-passing game.* The baton-passing game, first analyzed in [12], is a leader-election game where a leader is chosen by passing a baton among the players. Initially the baton is held by an arbitrary player, and each player that receives the baton picks (randomly) a player that has not been selected so far and passes the baton to him. The leader is the last person to hold the baton. As was already mentioned, in any leader-election game T of n players there is a coalition S of at most $\lceil n/2 \rceil$ players such that $p^T(S) = 1$, i.e., S can guarantee a leader from the coalition. The baton-passing game shows that this is sharp. This is because if there are n players, and S is a set of less than half of them, then there is a positive (though exponentially small) probability that whenever a player not in S has to pass the baton and there are still yet unselected players from S he chooses a player from S. If this happens, the chosen leader will not be in S. We have thus proved the following simple lemma.

LEMMA 2.5. *For every integer m there is a leader-election game G of m players such that $p^G(S) < 1$ for each set S of less than $m/2$ players.*

COROLLARY 2.6. *For every $\epsilon < \frac{1}{3}$ there is a $\delta < 1$ such that for every n there is an n-players leader-election game that is δ-robust against ϵn-cheaters.*

Proof. Given $e < \frac{1}{3}$ let us choose small positive constants $a = a(\epsilon)$ and $\gamma = \gamma(\epsilon)$ such that

$$a + \epsilon \frac{\sqrt{a}}{\sqrt{2}(1 - \sqrt{(1/2) + (3\epsilon/2)})} + \gamma < \frac{1}{2}.$$

Next choose a sufficiently large integer h so that

$$\binom{n}{\epsilon n} \frac{a((1/2) + (3\epsilon/2))^h}{\gamma^2} < 1.$$

Finally choose a sufficiently large $m = m(\epsilon, a)$ so that

$$\sum_{i \geq m/2} \binom{m}{i} \epsilon^i (1 - \epsilon)^{m-i} \leq a.$$

Let T be a full binary rooted tree of depth h, and let us choose, for each *internal* vertex of T, randomly and independently, a label in the set of players $N = \{1, \ldots, n\}$. For each leaf v of T we choose, randomly an independently (with repetitions) a (multi) set M_v of m members of N. Consider the following leader-election game represented by T. Starting at the root, the player whose name labels the current vertex chooses randomly one of its two children, and the game proceeds to the chosen child. When a leaf v is reached, a leader is chosen by playing the baton-passing game among the players in M_v. Observe that by Lemma 2.5, for every coalition S of ϵn players, if, during the game, the set M_v corresponding to the chosen leaf contains less than $m/2$ members of S, then the probability that the leader will be chosen from S is bounded away from 1 (i.e., is less than 1 by a constant depending on m, which depends only on ϵ (and $a = a(\epsilon)$) and is independent of the total number of players n.) Thus, to complete the proof, it suffices to bound away from 1 the probability that the coalition S will succeed in reaching a leaf whose set contains more than $m/2$ members of S. However, by the inequalities used in defining the quantities m, a, γ, and h, and by applying Lemma 2.3 and repeating the arguments used in the proofs of Lemma 2.4 and Theorem 2.1 we conclude that there is a tree T such that for every set S of cardinality ϵn the above probability is at most $\frac{1}{2}$. This completes the proof. □

Remark. The constant $\frac{1}{3}$ can be probably increased a bit by a more careful analysis in the proof of Lemma 2.2. This would not suffice, however, to close the gap between this increased constant and $\frac{1}{2}$. We suspect that for every $\epsilon < \frac{1}{2}$ there is a $\delta < 1$ such that for every n there are leader-election games of n players that are δ-robust against ϵn players. This remains open.

As mentioned in the introduction, robust leader-election games supply robust coin-flipping games by allowing the leader choose the random bit. Therefore, as a simple consequence of Theorem 2.1 and Corollary 2.6, we obtain the following.

THEOREM 2.7. (i) *There are fair n-players coin flipping games of depth $O(n)$ such that the influence of every set of $\epsilon n \leq \frac{1}{4} n$ players towards zero or towards* 1 *is at most $\frac{1}{2}\epsilon + 6\epsilon^{3/2}$.*

(ii) *For every $\epsilon < \frac{1}{3}$ there are fair n-players coin-flipping games such that the influence of every set of ϵn players towards zero or towards* 1 *is bounded away from $\frac{1}{2}$.*

This theorem solves the problem mentioned in the introduction. Its proof, as well as that of Theorem 2.1, is probabilistic, and hence supplies no explicit construction of the corresponding robust games. In the next section we describe explicit constructions of leader-election games and coin-flipping games that are immune against linear-sized coalitions.

3. Explicit construction. In this section we show how to explicitly construct coin-flipping games where the influence of any set which is smaller than some linear threshold is bounded away from 1. We use the idea put forth by Bracha [7] in the Byzantine context of forming virtual players from committees of actual players. Say that a committee is good if it has a certain ratio of good players to bad players. The advantage of an assignment to committees is that the ratio of good committees to bad committees can be much better than the ratio of good players to bad players.

Recall that baton passing is the game analyzed by Saks [12] and Ajtai and Linial [1], where a leader is chosen by passing a baton among the players. Initially the baton is held by some arbitrary player and each player that receives the baton picks a player that has not been selected so far and gives him the baton.

In our scheme, the committees formed play baton passing. When a committee gets the baton it elects a leader (recursively) and decides on the next committee to get the baton. The leader of the last committee to hold the baton is the global leader.

The advantage our game has over baton passing is that the bad players do not know in advance which committees will elect good leaders and which bad leaders. Thus, though the percentage of bad leaders is high, a bad leader does not necessarily choose a committee that elects a good leader (which is the optimal strategy in baton passing).

The committees are assigned using an affine plane: each player corresponds to a point in the plane and a committee is a line.

In the next subsection we analyze the variant of the baton-passing game that is relevant to our scheme: a good player might turn bad when he receives the baton. (This corresponds to the case that a good committee elects a bad leader.) In §3.2 we discuss the properties of the assignment to committees by affine planes. Finally in §3.3 we analyze the resulting construction.

3.1. Faulty baton passing. In this subsection we analyze the baton-passing game when even the good players have a certain probability ϵ of becoming faulty. We call this variant the faulty baton-passing game. The game itself is identical to the usual baton passing, and only the behavior of the good players differs.

In the regular baton-passing game the best strategy for the bad participants is to select a good player to receive the baton. By the moment reflection argument [1] (or by induction as in [12]) this is the best strategy in the faulty baton-passing game as well. Thus we can assume that whenever a bad participant has the baton he selects a good participant to receive it, and a good participant that becomes faulty also selects a good participant to receive the baton.

We would like to find bounds on the function $f(s,t) = f_\epsilon(s,t)$ defined as follows. $f(s,t)$ is the probability of the baton to end at a bad player (and *not* at a good one that becomes faulty), starting from a good player when there are s (as yet unselected) good players, t (as yet unselected) bad players, and a good player has probability ϵ of becoming faulty when he gets the baton. (It is important that it not be known in advance whether a good player would become faulty when he will receive the baton.)

We assume $0 \leq \epsilon < \frac{1}{4}$. Clearly, $f(0,t) = 1\,\forall t \geq 1$ and $f(s,0) = 0\,\forall s \geq 0$. From the bad players strategy,

$$(6) \qquad \forall s,t, \geq 1 \quad f(s,t) = \frac{s+\epsilon t}{s+t} \cdot f(s-1,t) + \frac{t-\epsilon t}{s+t} \cdot f(s-1,t-1).$$

LEMMA 3.1. *For all* $s,t \geq 0$, $0 \leq \epsilon < \frac{1}{4}$,

$$f(s,t) \leq 8 \cdot \frac{(t \log_2(t+1))^{\frac{1}{1-4\epsilon}}}{(s+1)^{1-\epsilon}}. \tag{7}$$

Proof. We apply induction on $s+t$. The assertion holds for ($s=0, t\geq 1$) and for ($t=0$, $s \geq 0$). For $t=1$ and $s \geq 1$ from (6) we have

$$f(s,1) = \frac{s+\epsilon}{s+1} \cdot f(s-1,1) = \frac{s+\epsilon}{s+1} \cdot \frac{s-1+\epsilon}{s} \cdots \frac{1+\epsilon}{2} \cdot f(0,1)$$
$$\leq e^{-(1-\epsilon)(\frac{1}{s+1}+\frac{1}{s}+\ldots+\frac{1}{2})} \leq e^{-(1-\epsilon)\int_2^{s+2} \frac{1}{x}dx} \leq \frac{2^{1-\epsilon}}{(s+1)^{1-\epsilon}}.$$

Assume now that $t \geq 2$, $s \geq 1$. Then by (6) and the induction hypothesis it suffices to show that

$$\frac{s+\epsilon t}{s+t} \cdot \frac{(t\ln(t+1))^{\frac{1}{1-4\epsilon}}}{s^{1-\epsilon}} + \frac{t-\epsilon t}{s+t} \cdot \frac{((t-1)\ln t)^{\frac{1}{1-4\epsilon}}}{s^{1-\epsilon}} \leq \frac{(t\ln(t+1))^{\frac{1}{1-4\epsilon}}}{(s+1)^{1-\epsilon}},$$

i.e., that

$$\frac{t-\epsilon t}{(s+t)s^{1-\epsilon}} \cdot ((t-1)\ln t)^{\frac{1}{1-4\epsilon}} \leq (t\ln(t+1))^{\frac{1}{1-4\epsilon}} \left(\frac{1}{(s+1)^{1-\epsilon}} - \frac{s+\epsilon t}{(s+t)s^{1-\epsilon}}\right).$$

Multiplying by $(s+1)^{1-\epsilon}s^{1-\epsilon}(s+t)$ we conclude that it suffices to prove that

$$\begin{aligned} &(t-\epsilon t)(s+1)^{1-\epsilon} \cdot ((t-1)\ln t)^{\frac{1}{1-4\epsilon}} \\ &\leq (t\ln(t+1))^{\frac{1}{1-4\epsilon}}(s^{1-\epsilon}(s+t) - (s+\epsilon t)(s+1)^{1-\epsilon}). \end{aligned} \tag{8}$$

Notice that

$$s^{1-\epsilon}(s+t) - (s+\epsilon t)(s+1)^{1-\epsilon} = s^{1-\epsilon}\left(s+t-\left(1+\frac{1}{s}\right)^{1-\epsilon}(s+\epsilon t)\right)$$
$$\geq s^{1-\epsilon}\left(s+t-\left(1+\frac{1}{s}\right)(s+\epsilon t)\right) = s^{-\epsilon}(s(t-1)-\epsilon st-\epsilon t).$$

Since $t \geq 2$, the right-hand side is at least $s^{-\epsilon}(s(t-1)-4\epsilon s(t-1)) > 0$, and thus by (8) it suffices to show that

$$\frac{(t-\epsilon t)(s+1)^{1-\epsilon}s^{\epsilon}}{s(t-1)-\epsilon st-\epsilon t} \leq \left(\frac{t\ln(t+1)}{(t-1)\ln t}\right)^{\frac{1}{1-4\epsilon}}. \tag{9}$$

But the left-hand side of (9) is at most

$$\frac{(t-\epsilon t)(s+1)}{s(t-1)-\epsilon st-\epsilon t} = \frac{st-\epsilon st+t-\epsilon t}{st-\epsilon st-s-\epsilon t} = 1 + \frac{s+t}{st-\epsilon st-s-\epsilon t} \tag{10}$$
$$= 1 + \frac{s+t}{s(t-1)-\epsilon st-\epsilon t} \leq 1 + \frac{s+t}{s(t-1)-4\epsilon s(t-1)}$$
$$= 1 + \frac{s+t}{s(t-1)(1-4\epsilon)} \leq 1 + \frac{1}{(t-1)(1-4\epsilon)} + \frac{2}{s(1-4\epsilon)}.$$

Since $\ln\left(1+\frac{1}{t}\right) \geq \frac{1}{2t}$ for all $t \geq 2$ we have

$$\begin{aligned}(11)\qquad \frac{t}{t-1}\cdot\frac{\ln(t+1)}{\ln t} &= \left(1+\frac{1}{t-1}\right)\left(1+\frac{\ln\left(1+\frac{1}{t}\right)}{\ln t}\right)\\ &\geq \left(1+\frac{1}{t-1}\right)\left(1+\frac{1}{2t\ln t}\right) \geq 1+\frac{1}{t-1}+\frac{1}{2t\ln t}.\end{aligned}$$

By (9), (10), and (11) it suffices to show that

$$\left(1+\frac{1}{t-1}+\frac{1}{2t\ln t}\right)^{\frac{1}{1-4\epsilon}} \geq 1+\frac{1}{(t-1)(1-4\epsilon)}+\frac{2}{s(1-4\epsilon)}.$$

By Bernoulli's inequality,

$$\left(1+\frac{1}{t-1}+\frac{1}{2t\ln t}\right)^{\frac{1}{1-4\epsilon}} \geq 1+\frac{1}{(t-1)(1-4\epsilon)}+\frac{1}{2t\ln t(1-4\epsilon)}.$$

Therefore, it suffices to check that

$$1+\frac{1}{(t-1)(1-4\epsilon)}+\frac{1}{2t\ln t(1-4\epsilon)} \geq 1+\frac{1}{(t-1)(1-4\epsilon)}+\frac{2}{s(1-4\epsilon)},$$

i.e., that

$$(12)\qquad s \geq 4t\ln t.$$

But for s, t satisfying $s \geq 1$ that violate (12) we have

$$(s+1)^{1-\epsilon} \leq s+1 \leq 2s \leq 8t\ln t \leq 8\,(t\log_2 t)^{\frac{1}{1-4\epsilon}},$$

and thus for this case (7) is trivial (as its right-hand side is greater than 1), completing the proof. □

3.2. Amplification via affine planes. In this subsection we describe a pseudorandom property of projective planes which is applied in [2], [3] and show how affine planes have a similar property. Affine planes better fit our purposes here. The property we need can be proved by an eigenvalue argument; here we present a more direct proof, as in [3].

LEMMA 3.2 [2], [3]. *Let $\mathcal{P} = (P, L)$ be a projective plane of order p with a set P of $n = p^2+p+1$ points and a set L of n lines. If $A \subset P$, $|A| = \epsilon n$, then*

$$\sum_{\ell\in L}\left(|\ell\bigcap A| - \epsilon(p+1)\right)^2 = \epsilon(1-\epsilon)p\cdot n.$$

Proof. Clearly

$$(13)\qquad \sum_{\ell\in L}|\ell\bigcap A| = (p+1)|A| = (p+1)\epsilon n.$$

Also by double counting the number of ordered triples (ℓ, a, b) where $\ell \in L$, $a, b \in A$, $a \neq b$ we get

$$|A|(|A|-1) = \epsilon n(\epsilon n-1) = \sum_{\ell\in L}|\ell\bigcap A|(|\ell\bigcap A|-1) = \sum_{\ell\in L}|\ell\bigcap A|^2 - \sum_{\ell\in L}|\ell\bigcap A|.$$

Thus

$$\sum_{\ell\in L}|\ell\bigcap A|^2 = \epsilon n(\epsilon n-1)+(p+1)\epsilon n = \epsilon n(\epsilon n+p). \tag{14}$$

The two equations (13), (14) enable us to compute for each polynomial $q(x)$ of degree at most two the sum $\sum_{\ell\in L} q(|\ell\bigcap A|)$. In particular,

$$\begin{aligned}\sum_{\ell\in L}(|\ell\bigcap A|-\epsilon(p+1))^2 &= \sum_{\ell\in L}(|\ell\bigcap A|^2-2\epsilon(p+1)|\ell\bigcap A|+\epsilon^2(p+1)^2)\\ &= \epsilon n(\epsilon n+p)-2\epsilon(p+1)(p+1)\epsilon n+n\epsilon^2(p+1)^2\\ &= \epsilon n(\epsilon n+p-\epsilon(p+1)^2)=\epsilon n(p-\epsilon p)=\epsilon(1-\epsilon)pn,\end{aligned}$$

completing the proof. □

COROLLARY 3.3. *Let $\mathcal{A}=(\bar P,\bar L)$ be an affine plane of order p, obtained by deleting a line from the projective plane of that order. Put $m=p^2=|\bar P|=|\bar L|$ and recall that each $\ell\in\bar L$ has p points. Suppose that $A\subset\bar P$, $|A|=\epsilon m$, and suppose that $\delta>0$. Then*

$$\left|\left\{\ell\in\bar L:\left|\ell\bigcap A\right|\ge(\epsilon+\delta)\cdot p\right\}\right|\le\frac{\epsilon(p^2+p+1)}{\delta^2 p}\le\frac{\epsilon}{\delta^2}(\sqrt{m}+2).$$

Proof. Let $x=|\{\ell\in\bar L:|\ell\bigcap A|\ge(\epsilon+\delta)\cdot p\}|$. Embed $\mathcal{A}$ in the projective plane or order p, $\mathcal{P}=(P,L)$. Observe that $|A|/(p^2+p+1)=\epsilon p^2/(p^2+p+1)$, and hence $(|A|/(p^2+p+1))(p+1)=\epsilon p^2(p+1)/(p^2+p+1)\le\epsilon p$. By Lemma 3.2,

$$\sum_{\ell\in\bar L}\left(|\ell\bigcap A|-\frac{|A|}{p^2+p+1}(p+1)\right)^2\le\epsilon p(p^2+p+1).$$

Each line among the x defined above contributes to the left-hand side at least δ^2p^2. Thus $x\delta^2p^2\le\epsilon p(p^2+p+1)$, implying the desired result. □

Remark. For every $p=2^k$ there is an affine plane of order p. Our algorithm uses the planes of order 2^{2^k}. Note that the number of points in a plane of order 2^{2^k} is equal to the number of points in one line of a plane of order $2^{2^{k+1}}$. This is used for recursive application of the algorithm.

Remark. The first author has suggested previously using projective planes as a construction meeting some of the requirements of [7]. (See [9] for details.) As we shall see, unlike the Byzantine case, for our purposes it is not essential that the size of the committees be small (logarithmic in n).

Remark. The construction is an instance of graphs called *dispersers* that have many other applications. (See [8] for an extensive survey of constructions and applications.) There are several other constructions of dispersers that can be used for our purposes.

3.3. The construction. We are now ready to present the construction in detail. We can assume without loss of generality that n is of the form 2^{2^j}: otherwise, let $n'=2^{2^{\lceil\log\log n\rceil}}$ and make each of the n participants play the role of $\lfloor\frac{n'}{n}\rfloor$ or $\lceil\frac{n'}{n}\rceil$ in a game of n' participants. The ratio of bad players has not increased by more than $\frac{1}{n}$.

The scheme is as follows: form committees by treating each player a as a point $a\in\bar P$ in the affine plane $\mathcal{A}=(\bar P,\bar L)$ of order $2^{2^{j-1}}$. Each committee ℓ corresponds to a line $\ell\in\bar L$, i.e., a player a is in committee ℓ if and only if $a\in\ell$.

```
• Set $m \leftarrow$ threshold.
• If $n \le m$, then choose leader by baton passing. Otherwise,
    (1) Construct committees via affine planes.
    (2) $\ell \leftarrow$ first committee.
    (3) Repeat
        (a) Let $\ell$ choose a leader recursively;
        (b) Let the leader of $\ell$ choose a committee $\ell'$ as yet unselected;
        (c) $\ell \leftarrow \ell'$;
until there are no unselected committees.
    (4) The leader of the last chosen committee $\ell$ is crowned as the leader of all players.
```

The value of threshold is a function of ϵ. We let it be the smallest number of the form 2^{2^r}, where r is an integer, such that $2^{2^r} \geq \left(\frac{1}{\epsilon}\right)^{100}$. (Note that for this choice $\left(\frac{1}{\epsilon}\right)^{100} \leq m \leq \left(\frac{1}{\epsilon}\right)^{200}$.)

Observe that the total amount of work done by each player is polynomial in n, since at each stage of the recursion every two players are together in exactly one committee.

The next theorem implies that no set smaller than some linear threshold can control the leadership.

THEOREM 3.4. *There are $\mu, c > 0$ such that $\forall 0 < \epsilon < \mu$ the protocol specified above with an appropriately chosen threshold (as a function of ϵ) is $c\epsilon$ robust against ϵn cheaters.*

To prove this theorem we need the following two lemmas.

LEMMA 3.5. *Suppose that our procedure has the property that with $\sqrt{n} = 2^{2^k}$ participants, for every set of $(\epsilon + \delta)\sqrt{n}$ bad participants, the probability that a bad leader is elected is at most $f = f(\epsilon+\delta)$. Then for $n = 2^{2^{k+1}}$ participants, for every set of ϵn bad participants the probability that one of the bad participants is elected is at most*

$$\frac{8(t\log_2(t+1))^{\frac{1}{1-4f}}}{(s+1)^{1-f}} + f, \tag{15}$$

where $s+t+1 = n$ and $t = \lfloor \frac{\epsilon}{\delta^2}(\sqrt{n}+2) \rfloor$.

Proof. Call a committee good if it has at most $(\epsilon + \delta)\sqrt{n}$ bad participants and bad otherwise. By Corollary 3.3 there are at most $t = \frac{\epsilon}{\delta^2}(\sqrt{n}+2)$ bad committees.

To compute a lower bound on the probability that the last committee is good we can use the analysis of Lemma 3.1 of the faulty baton-passing game: assume that a bad committee is completely bad and that a good committee has probability f to elect a bad leader (i.e., to turn bad). These assumptions clearly only increase the probability of ending in a bad committee. Thus by Lemma 3.1 the probability of ending in a bad committee is at most

$$\frac{8(t\log_2(t+1))^{\frac{1}{1-4f}}}{(s+1)^{1-f}}.$$

If we end in a good committee, then by the hypothesis the conditional probability to end in a bad leader is at most f. Hence the result. □

LEMMA 3.6. *There are $\mu, c > 0$ such that $\forall 0 \leq \epsilon \leq \mu$, $\forall 0 \leq k$ when the protocol is executed with $M_k = m^{2^k}$ players and threshold m chosen as the smallest number of the form 2^{2^r} which is bigger than $\left(\frac{1}{\epsilon}\right)^{100}$, for any set of at most $\epsilon_k \cdot M_k$ bad players, p_k; the probability that a bad leader is elected is at most f_k. Here $\epsilon_k = \epsilon + \sum_{i=k}^{\infty}\left(1/m^{0.01}\right)^{2^i}$ and $f_k = c\epsilon + \sum_{i=1}^{k}\left(1/m^{0.03}\right)^{2^i}$.*

Proof. Apply induction on k. In case $k = 0$ the protocol degenerates to (nonfaulty) baton passing with ϵ_0 bad players. $\epsilon_0 = \epsilon + \sum_{i=0}^{j} \left(1/m^{0.01}\right)^{2^i} \leq 3\epsilon$. Choose μ to be small enough so that $\mu \leq 1/(1800 \log(1/\mu))$. Thus, from the analysis of baton passing in [1], there exists a positive c such that if $3\epsilon m \leq m/3 \log m$, then the probability of electing a faulty player is at most $c \cdot \epsilon = f_0$. Since μ satisfies $\mu \leq 1/(1800 \log(1/\mu))$, the condition above holds, by the choice of m.

Assume that the statement of the lemma holds up to k; we will show that it holds for $k+1$. Given M_{k+1} players with at most ϵ_{k+1} fraction of bad ones, define $\delta = \epsilon_k - \epsilon_{k+1} = (1/M_k)^{0.01}$. By the induction hypothesis and the previous lemma, the probability of electing a bad leader when executing the protocol with M_{k+1} players of whom at most ϵ_{k+1} fraction are bad is at most

$$p_k \leq f_k + \frac{8(t \log_2(t+1))^{\frac{1}{1-4f_k}}}{(s+1)^{1-f_k}},$$

where $s + t + 1 = M_{k+1}$ and $t = \lfloor \frac{\epsilon_{k+1}}{\delta^2} (\sqrt{M_{k+1}} + 2) \rfloor$, where δ is as above. Therefore,

$$t = \left\lfloor \frac{\epsilon_{k+1}}{\delta^2} \left(\sqrt{M_{k+1}} + 2\right) \right\rfloor \leq \epsilon_{k+1} \left(M_{k+1}\right)^{0.01} \left(\sqrt{M_{k+1}} + 2\right) \leq \left(M_{k+1}\right)^{\frac{2}{3}}.$$

Note that $f_k = c\epsilon + \sum_{i=0}^{k} (1/m^{0.03})^{2^i} \leq 3\epsilon c$. We choose μ small enough so that $3\epsilon c \leq 3\mu c < \frac{1}{100}$. Thus we get that

$$p_k \leq f_k + \frac{8(t \log_2(t+1))^{\frac{1}{1-4f_k}}}{(s+1)^{1-f_k}} \leq f_k + \frac{16((M_{k+1})^{\frac{2}{3}} \log M_{k+1})^{\frac{1}{1-4f_{k+1}}}}{(M_{k+1})^{1-f_{k+1}}}$$

$$\leq f_k + \frac{16((M_{k+1})^{\frac{2}{3}} \log M_{k+1})^{\frac{100}{96}}}{(M_{k+1})^{0.99}} \leq f_k + \left(\frac{1}{M_{k+1}}\right)^{0.03} = f_{k+1}. \qquad \square$$

Theorem 3.4 now follows, since by the last lemma, p_j, the probability that a bad leader is elected when the protocol is executed with $n = m^{2^j}$ players,

$$\epsilon_j = \epsilon + \sum_{i=j}^{\infty} \left(\frac{1}{m^{0.01}}\right)^{2^i}$$

fraction of whom are bad, is at most $f_j \leq 3c\epsilon$. Thus this probability is certainly at most $3c\epsilon$ if the fraction of bad players is only ϵ. $\square$

Observe that by adjusting the constant c in this theorem so that it would be bigger than $1/\mu$ we can allow ϵ to be any positive real smaller than 1. We thus have the following.

COROLLARY 3.7. *There is a positive constant* c *such that for every* $0 < \epsilon < 1$ *our protocol with an appropriately chosen threshold* (*as a function of* ϵ) *is* $c\epsilon$ *robust against* ϵn *cheaters.*

Remark. We chose to end the recursion by the baton-passing game. Alternatively, we could have ended when the size of the committee is small enough, say $\log \log \log n$: for each possible protocol for that size of the type considered in §2 and of depth, say, $100 \log \log \log n$ an equal number of committees can be allocated that will elect its leader accordingly. By the analysis of §2 most protocols are good, and thus most good committees will elect a good leader.

Remark. As already mentioned we suspect that for every $\epsilon < \frac{1}{2}$ there is a $\delta < 1$ such that for every n there are coin-flipping and leader-election games that are δ-robust against ϵn cheaters. (The results of §2 show that for every $\epsilon < \frac{1}{3}$ there is such a δ.) It is obvious that the validity of the above statement for leader-election games implies its validity for coin-flipping games. The converse is not obvious, but is true. Combining our technique with some of the ideas of [13] concerning slightly random sources, we can prove the equivalence of these two statements. The details will appear somewhere else.

Note added in proof. R. B. Boppana and B. O. Narayanan (*The biased coin problem*, to appear) have recently extended the main result of [4]. Combining their technique with our method here it is possible to settle the question mentioned in the last remark and show that indeed for every $\epsilon < \frac{1}{2}$ there is a $\delta < 1$ such that for every n there are coin-flipping and leader-election games that are δ-robust against ϵn cheaters.

ON THE ZONE THEOREM FOR HYPERPLANE ARRANGEMENTS*

HERBERT EDELSBRUNNER†, RAIMUND SEIDEL‡, AND MICHA SHARIR§

Abstract. The zone theorem for an arrangement of n hyperplanes in d-dimensional real space says that the total number of faces bounding the cells intersected by another hyperplane is $O(n^{d-1})$. This result is the basis of a time-optimal incremental algorithm that constructs a hyperplane arrangement and has a host of other algorithmic and combinatorial applications. Unfortunately, the original proof of the zone theorem, for $d \geq 3$, turned out to contain a serious and irreparable error. This paper presents a new proof of the theorem. The proof is based on an inductive argument, which also applies in the case of pseudohyperplane arrangements. The fallacies of the old proof along with some ways of partially saving that approach are briefly discussed.

1. Introduction. A set H of n hyperplanes in d-dimensional space $\mathbf{R}^d$ decomposes $\mathbf{R}^d$ into open cells of dimension d (also called d-faces) and into relatively open faces of dimension k between 0 and $d-1$. These cells and faces define a cell complex which is commonly known as the *arrangement* $\mathcal{A}(H)$ of H. We define the *complexity of a cell in* $\mathcal{A}(H)$ to be the number of faces that are contained in the closure of the cell.

For a hyperplane b (not necessarily in H) the *zone of* b is defined to be the set of all cells in $\mathcal{A}(H)$ that intersect b. Define the *complexity of a zone* to be the sum of the complexities of the cells in the zone. A fundamental result on hyperplane arrangements is presented in the following theorem.

ZONE THEOREM. *Any zone in any arrangement of n hyperplanes in $\mathbf{R}^d$ has complexity $O(n^{d-1})$.*

Various algorithmic and combinatorial applications of this theorem appear throughout the computational and combinatorial geometry literature [6]. For the case $d = 2$ a number of different and fairly straightforward proofs are known, following paradigms such as induction [5]; sweep [3], [11]; tree construction [8]; and Davenport–Schinzel sequences [9]. Only the sweep proof was extended to three and higher dimensions. However, this generalization turned out to be too sweeping. The authors of this paper discovered an irreparable error in that proof, which left the zone theorem unproven for dimensions $d > 2$.

This paper presents a new proof of the general zone theorem. It is based on a relatively straightforward inductive argument whose simplicity fosters confidence that this time the proof is actually correct. The new proof does not exploit the "straightness" of hyperplanes and thus it applies also to arrangements of pseudohyperplanes [4]. The validity of the zone theorem for such arrangements had been considered an open question.

Section 2 contains the new proof. Explanations of why the old sweep-based proof fails and of how it can be partially saved are presented in the appendix.

A few bibliographical remarks: After the incorrectness of the old sweep proof of the zone theorem was announced, we soon learned of two partial proofs of the theorem, one by Houle [13] dating back to 1987, and the other by Matoušek [15]. They showed that the zone theorem is correct if the complexity of a cell is defined to be just the number of its facets, i.e., the number of $(d-1)$-dimensional faces contained in the cell's boundary. In the terminology of the following section, they showed that $z_1(n,d) = O(n^{d-1})$. Interestingly, Houle and Matoušek's proofs methods are virtually identical, and in essence are also the same as the saved version of the sweep proof presented in the appendix. Attempts to adapt this proof method to the general zone theorem have failed so far.

2. The new proof. For a d-polyhedron P let $g_k(P)$ denote the number of faces of P of *codimension* k (i.e., dimension $d-k$). For a hyperplane b and a set of hyperplanes H in $\mathbf{R}^d$, let $Zone(b;H)$ denote the set of cells in the arrangement $\mathcal{A}(H)$ that intersect b, and for $0 \le k \le d$ let $z_k(b;H)$ denote $\sum_{C\in Zone(b;H)} g_k(\bar{C})$, where $\bar{C}$ denotes the topological closure of C. Finally, for $n > 0$, $d > 0$, and $0 \le k \le d$, let $z_k(n,d)$ denote the maximum of $z_k(b;H)$ over all hyperplanes b and all sets H of n hyperplanes in $\mathbf{R}^d$. Our goal is to prove the following.

THEOREM 2.1. *$z_k(n,d) = O(n^{d-1})$ for each $d > 0$ and $0 \le k \le d$. In particular, for all $n > 0$, $d > 0$, and $0 \le k < d$, we have*

$$z_k(n,d) \le c_k \binom{d-1}{k}\binom{n}{d-1} + 2^k \sum_{k\le j<d-1} \binom{j}{k}\binom{n}{j},$$

where $c_0 = 1$, and $c_k = \frac{3}{4}(6^k + 2^k)$ for $k > 0$.

As will be explained in §3, the constant can be slightly improved to $c_k = \frac{2}{3}6^k + \frac{3}{4}2^k$.

First note that, for any fixed k, $z_k(b;H)$ achieves its maximum when b and H are in generic position, i.e., every k hyperplanes in $H \cup \{b\}$ intersect in a $(d-k)$-flat, for $1 < k \le d+1$. This can be proved using a standard perturbation argument: translating b slightly can only enlarge $Zone(b;H)$ and displacing a hyperplane of H by a small amount can only increase the complexities of the cells in $Zone(b;H)$ through vertex truncation or the actions dual to vertex pulling or pushing (see [12, pp. 78–83]).

Next note that Theorem 2.1 does not state an explicit upper bound for the number of vertices in a zone. However, it is easily seen that in the generic case $z_d(b;H) \le \frac{2}{d} z_{d-1}(b;H)$ holds, since in the generic (i.e., simple) case every vertex of a d-polyhedron P is incident to d edges, and each edge of P is incident to at most two vertices. Therefore we obtain from Theorem 2.1 the bound

$$z_d(n,d) \le \frac{2}{d} z_{d-1}(n,d) \le \frac{2}{d} c_{d-1} \binom{n}{d-1}.$$

The most important ingredient for our proof of Theorem 2.1 is the following lemma.

LEMMA 2.2. *For all $d > 1$, $0 \le k < d$, and $n > k$ we have*

$$z_k(n,d) \le \frac{n}{n-k}\left(z_k(n-1,d) + z_k(n-1,d-1)\right). \qquad (1)$$

Proof. Let H be a set of n hyperplanes in $\mathbf{R}^d$, and let b be some other hyperplane. Because of the remarks above we assume that the hyperplanes in $H \cup \{b\}$ are in generic position. A face f in $\mathcal{A}(H)$ of codimension k now lies in exactly k hyperplanes of H

and is part of the boundary of 2^k cells of $\mathcal{A}(H)$. More than one of these cells can lie in *Zone*$(b; H)$, and thus the contribution of the face f to $z_k(b; H)$ can be larger than one. In order to have entities that contribute at most one to the count $z_k(b; H)$, we define a *border* of codimension k to be a pair (f, C), where f is a face of codimension k in $\mathcal{A}(H)$ and C is a cell that has f on its boundary. Thus $z_k(b; H)$ counts all borders of codimension k in *Zone*$(b; H)$, i.e., borders (f, C) for which C is in *Zone*$(b; H)$.

Now let h be some hyperplane in H, and let H/h be $\{j \cap h | j \in H\backslash\{h\}\}$. Note that H/h forms a $(d-1)$-dimensional arrangement of $n-1$ "hyperplanes" within h. Consider the expression

$$z_k(b; H\backslash\{h\}) + z_k(b \cap h; H/h).$$

We claim that it is at least as large as the number of borders (f, C) of codimension k in *Zone*$(b; H)$, for which f is not contained in h. Note that every such border is equal to or contained in a border in *Zone*$(b; H\backslash\{h\})$. Our strategy is thus to consider borders in this latter zone, and analyze what happens to them when h is added back to H. So let (f, C) be a border of codimension k in *Zone*$(b; H\backslash\{h\})$.

Case 1. $h \cap C = \emptyset$. The border (f, C) gives rise to exactly one border of codimension k in *Zone*$(b; H)$, namely, itself.

Case 2. $h \cap C \neq \emptyset$ but $h \cap f = \emptyset$. Let h_f be the (open) halfspace bounded by h that contains f, and let $C' = C \cap h_f$. If C' intersects the base hyperplane b, then (f, C) gives rise to one border of codimension k in *Zone*$(b; H)$, namely, (f, C'); otherwise it gives rise to no border in *Zone*$(b; H)$.

Case 3. $h \cap C \neq \emptyset$ and $h \cap f \neq \emptyset$. Let h' and h'' be the two open halfspaces bounded by h and let $C' = C \cap h'$ and $C'' = C \cap h''$. If only one of C' and C'' intersect b (say, C'), then (f, C) gives rise to one border of codimension k in *Zone*$(b; H)$, namely, $(f \cap h', C')$. However, if both C' and C'' intersect b, then (f, C) gives rise to two borders in *Zone*$(b; H)$, namely, $(f \cap h', C')$ and $(f \cap h'', C'')$. But in that case $C \cap h$ is part of *Zone*$(b \cap h; H/h)$ and $(f \cap h, C \cap h)$ is a border of codimension k in *Zone*$(b \cap H; H/h)$. (Note that, in generic position, the border $(f \cap h, C \cap h)$ uniquely determines the border (f, C).)

Since all borders (f, C) of codimension k in *Zone*$(b; H)$ for which f is not contained in h must arise as described in the three cases, it follows that the number of such borders is at most $z_k(b; H\backslash\{h\}) + z_k(b \cap h; H/h)$, as claimed. But from this we can conclude that

$$(n-k) z_k(b; H) \leq \sum_{h \in H} \left(z_k(b; H\backslash\{h\}) + z_k(b \cap h; H/h) \right),$$

since every border (f, C) of codimension k in *Zone*$(b; H)$ is counted in the sum $n-k$ times, once for each hyperplane h that does not contain f. From this last inequality the statement of the lemma follows immediately. $\square$

The recurrence of Lemma 2.2 is a bit unwieldy. However, it becomes more manageable by putting $z_k(n, d) = \binom{n}{k} w_k(n, d)$, for $n \geq k$, which transforms the recurrence (1) into

$$w_k(n, d) \leq w_k(n-1, d) + w_k(n-1, d-1),$$

for all $d > 1$, $0 \leq k < d$, and $n > k$. By iterating this new recurrence on the first summand one obtains

$$w_k(n, d) \leq w_k(k, d) + \sum_{k \leq m < n} w_k(m, d-1), \tag{2}$$

valid again for all $d > 1$, $0 \le k < d$, and $n > k$.

Proving the asymptotic version of Theorem 2.1 is now an easy induction on d. The base case $z_k(n, 2) = O(n)$ for $k = 0, 1, 2$ is proved separately using any one of the proofs offered in [3], [5], [8], [9] (or also in Lemma 2.3).

Now let $d > 2$ and assume inductively that $z_k(m, d-1) = O(m^{d-2})$, for all $k \le d-1$ (where the constant of proportionality depends on k and d). Then $w_k(m, d-1) = O(m^{d-2-k})$, and thus by (2)

$$w_k(n,d) = w_k(k,d) + \sum_{k \le m < n} O(m^{d-2-k}),$$

which implies $w_k(n,d) = O(n^{d-1-k})$, thereby showing that $z_k(n,d) = O(n^{d-1})$, provided $k \le d-2$. When $k = d-1$ this approach yields only an $O(n^{d-1}\log n)$ bound. However, one can now establish the desired $z_k(n,d) = O(n^{d-1})$ for $k = d-1$ and $k = d$ as follows: Euler's relation states that for any cell C in an arrangement the sum $\sum_{0 \le k \le d}(-1)^{d-k} g_k(\overline{C})$ evaluates to 0 or 1, depending on whether C is bounded (see [12, pp. 130–140]). Thus it follows that in $\mathbf{R}^d$ for any set H of $n \ge d$ hyperplanes and any hyperplane b in generic position

$$\sum_{0 \le k \le d} (-1)^{d-k} z_k(b; H) \ge 0.$$

Recalling that $z_d(b;H) \le \frac{2}{d} z_{d-1}(b;H)$, we obtain the relation

$$(3) \qquad \left(1 - \frac{2}{d}\right) z_{d-1}(b;H) \le z_{d-1}(b;H) - z_d(b;H) \le \sum_{0 \le k \le d-2} (-1)^{d-k} z_k(b;H).$$

But as $d > 2$ and we have proven already that $z_k(b;H) \le z_k(n,d) = O(n^{d-1})$ for $0 \le k \le d-2$, and since $z_d(b;H) \le \frac{2}{d} z_{d-1}(b;H)$, relation (3) yields that $z_k(b;H) = O(n^{d-1})$ holds for all k. As this is true for any H and b in generic position and since it suffices to consider only generic position we can conclude that $z_k(n,d) = O(n^{d-1})$ for $0 \le k \le d$. This completes the proof of the asymptotic version of Theorem 2.1.

The proof for the more exact, nonasymptotic version follows the same inductive scheme, except that we will use a slightly different method for dealing with the case $k > d-2$. First we need a few small lemmas. Recall that when arguing about $z_k(n,d)$ we need only to consider simple arrangements with the zone-producing hyperplane b in generic position.

LEMMA 2.3. $z_1(n, 2) \le 6n$.

Proof. Of course this is just the Zone Theorem for arrangements of lines in the plane, and we could refer to a number of different proofs ([3], [5], [8], [9]; in fact, [3] gives a slightly better bound—see §3). For the sake of completeness, however, we include here yet a different proof.

Let H be a set of n lines in the plane, and let b be some other line. Without loss of generality we assume that $H \cup \{b\}$ is in generic position (no three lines intersect, but every two do), and we assume that b is "horizontal." We need to show that the sum of the edges of the cells in $\mathit{Zone}(b;H)$ is at most $6n$.

Since no line in H is parallel to the horizontal line b, it makes sense to talk about the left bounding edges and the right bounding edges of a cell. It suffices to show that the total number of all left bounding edges of the cells in $\mathit{Zone}(b;H)$ is at most $3n$. This is clearly true when H is empty. So let h be the line in H that intersects b furthest to the right. By induction the total number of left bounding edges of the cells in

Zone$(b; H\backslash\{h\})$ is at most $3n-3$. The addition of h to the arrangement formed by $H\backslash\{h\}$ can increase this number at most by 3. $\square$

LEMMA 2.4. *For any set H of n hyperplanes and any hyperplane b in generic position in $\mathbf{R}^d$ with $d > 2$ we have*

$$z_{d-3}(b; H) \geq 2^{d-3}\binom{d-1}{2}\binom{n}{d-1} + 2^{d-3}\binom{d-2}{1}\binom{n}{d-2}.$$

Proof. Assuming generic position of a set H of n hyperplanes and an additional hyperplane b, every 2-face in the $(d-1)$-dimensional arrangement induced by H in b derives from a 3-face in $\mathcal{A}(H)$ that is in the boundary of 2^{d-3} cells of $\mathcal{A}(H)$, all of which are in *Zone*$(b; H)$. It now suffices to observe that in a simple $(d-1)$-dimensional arrangement of n hyperplanes the number of 2-faces is

$$\sum_{0\leq i\leq 2}\binom{d-1-i}{2-i}\binom{n}{d-1-i} \geq \binom{d-1}{2}\binom{n}{d-1} + \binom{d-2}{1}\binom{n}{d-2}$$

(see [6, p. 7]). $\square$

LEMMA 2.5. *For all $d > 2$ and for all $n > d-1$ we have*

$$\binom{d-1}{2} z_{d-1}(n,d) \leq 3(d-2)z_{d-2}(n,d) - 6\cdot 2^{d-3}\left[\binom{d-1}{2}\binom{n}{d-1} + \binom{d-2}{1}\binom{n}{d-2}\right].$$

Proof. Lemma 2.4 implies that it suffices to show the validity of the inequality

$$\binom{d-1}{2} z_{d-1}(b; H) \leq 3(d-2)z_{d-2}(b; H) - 6z_{d-3}(b; H),$$

for any set H of n hyperplanes in $\mathbf{R}^d$ and any hyperplane b in generic position (recall that it suffices to consider only generic position).

Since in a simple arrangement of $n > d-1$ hyperplanes in $\mathbf{R}^d$ every face is pointed (i.e., has a vertex) it suffices to show that for any pointed simple d-polyhedron P with $d > 2$, the inequality $\binom{d-1}{2} f_1 \leq 3(d-2)f_2 - 6f_3$ holds, where $f_i = g_{d-i}$ is the number of i-dimensional faces of P.

Let F_3 be the set of three-dimensional faces of P, and for a 3-face $c \in F_3$ let $e(c)$ denote the number of edges of c and let $s(c)$ denote the number of 2-faces of c. For $j = 1, 2$ let $I_{j,3}$ denote the number of pairs (X, Y) so that Y is a 3-face of P, and X is a j-face of Y.

Because of the simplicity of P every 1-face is contained in $\binom{d-1}{2}$ faces of dimension 3, and thus $I_{1,3} = \binom{d-1}{2} f_1$. Similarly $I_{2,3} = (d-2)f_2$. On the other hand $I_{1,3}$ can also be expressed as $\sum_{c\in F_3} e(c)$, and $I_{2,3}$ as $\sum_{c\in F_3} s(c)$. Euler's relation in any three-dimensional pointed polyhedron with e edges and s facets implies the inequality $e \leq 3s-6$. Hence,

$$\binom{d-1}{2} f_1 = \sum_{c\in F_3} e(c) \leq \sum_{c\in F_3}(3s(c)-6) = 3I_{2,3} - 6f_3 = 3(d-2)f_2 - 6f_3,$$

as asserted. $\square$

We now have everything ready to give a complete inductive proof of our main Theorem 2.1, which claims that for each $d > 0$ the following holds for all $n > 0$ and for each $0 \leq k < d$:

$$z_k(n,d) \le Z_k(n,d) \equiv c_k \binom{d-1}{k}\binom{n}{d-1} + 2^k \sum_{k\le j<d-1} \binom{j}{k}\binom{n}{j}, \tag{4}$$

where $c_0 = 1$, and $c_k = \frac{3}{4}(6^k + 2^k)$ for $k > 0$. For $k > 1$ it is easy to check that $c_k = 6(c_{k-1} - 2^{k-2})$ with $c_1 = 6$.

We first dispose of a few easy cases. The bound (4) is trivially correct when $d = 1$. So assume $d > 1$ and consider $n < k < d$. In this case the bound $Z_k(n,d)$ in (4) evaluates to 0, which is correct since there cannot be any face with codimension k when there are fewer than k hyperplanes.

Finally we can dispose of the case $n = k < d$ since in an arrangement of $k < d$ hyperplanes in generic position there is exactly one face of codimension k and it is in the boundary of 2^k cells, all of which are intersected by the zone hyperplane. Thus $z_k(k,d) = 2^k \le Z_k(k,d)$, as desired. From now on we will thus assume that $d > 1$ and $n > k$.

Applying the binomial product identity $\binom{A}{B}\binom{C}{A} = \binom{C}{B}\binom{C-B}{A-B}$ to each term on the right side of (4), and using the substitution $z_k(n,d) = \binom{n}{k} w_k(n,d)$ as before, we can rewrite (4) equivalently as

$$w_k(n,d) \le W_k(n,d) \equiv c_k \binom{n-k}{d-1-k} + 2^k \sum_{k\le j<d-1} \binom{n-k}{j-k}.$$

We can now prove the bounds (4) by induction on d. For the base case $d = 2$ Lemma 2.3 implies that indeed $z_1(n,2) \le 6n = Z_1(n,d)$; the fact that $z_0(n,d) \le n+1 = Z_0(n,d)$ is trivial.

Now let $d > 2$ and assume inductively that for $0 \le k < d-1$ and for all $m \ge k$ the bounds $z_k(m,d-1) \le Z_k(m,d-1)$ and therefore also the equivalent bounds $w_k(m,d-1) \le W_k(m,d-1)$ hold.

Recall that for $0 \le k < d$, and $n > k$ Lemma 2.2 implies the inequality (2)

$$w_k(n,d) \le w_k(k,d) + \sum_{k\le m<n} w_k(m,d-1).$$

Clearly $w_k(k,d) = z_k(k,d)$ and hence $w_k(k,d) = 2^k$. Thus employing our inductive assumption and exploiting the binomial identities $\binom{A}{0} = 1$ and $\sum_{0\le i<A}\binom{i}{B} = \binom{A}{B+1}$ if $B \ge 0$, we obtain

$$\begin{aligned}
w_k(n,d) &\le 2^k + \sum_{k\le m<n} W_k(m,d-1)\\
&= 2^k + \sum_{k\le m<n}\left[c_k\binom{m-k}{d-2-k} + 2^k \sum_{k\le j<d-2}\binom{m-k}{j-k}\right]\\
&= 2^k + \left[c_k\binom{n-k}{d-1-k} + 2^k \sum_{k\le j<d-2}\binom{n-k}{j+1-k}\right]\\
&= c_k\binom{n-k}{d-1-k} + 2^k \sum_{k\le j<d-1}\binom{n-k}{j-k} = W_k(n,d),
\end{aligned}$$

as desired.

Thus we have established for all $n > k$ the desired $w_k(n,d) \leq W_k(n,d)$ and equivalently $z_k(n,d) \leq Z_k(n,d)$—however, only for $0 \leq k < d-1$. For $k = d-1$ our inductive assumption does not hold.

To prove the desired bound for $k = d-1$ we proceed as follows. We need only consider the case $n > k = d-1$. We just proved that

$$z_{d-2}(n,d) \leq Z_{d-2}(n,d) = c_{d-2}(d-1)\binom{n}{d-1} + 2^{d-2}\binom{n}{d-2}.$$

Plugging this in the inequality

$$z_{d-1}(n,d) \leq \frac{1}{\binom{d-1}{2}}\left[3(d-2)z_{d-2}(n,d) \; -6\cdot 2^{d-3}\binom{d-1}{2}\binom{n}{d-1} \right. \\ \left. -6\cdot 2^{d-3}\binom{d-2}{1}\binom{n}{d-2}\right]$$

of Lemma 2.5 yields the desired

$$z_{d-1}(n,d) \leq \tfrac{1}{\binom{d-1}{2}}\left[3(d-2)c_{d-2}(d-1)\binom{n}{d-1} + 3(d-2)2^{d-2}\binom{n}{d-2} \right. \\ \left. -6\cdot 2^{d-3}\binom{d-1}{2}\binom{n}{d-1} - 6\cdot 2^{d-3}(d-2)\binom{n}{d-2}\right] \\ = 6(c_{d-2} - 2^{d-3})\binom{n}{d-1} = c_{d-1}\binom{n}{d-1} = Z_{d-1}(n,d).$$

This completes the induction on d and the proof of Theorem 2.1.

3. Remarks. First let us point out that our proof of the zone theorem does not exploit the "straightness" of hyperplanes per se, but only the restricted kinds of intersection patterns that are possible amongst hyperplanes. Thus the proof applies equally well to arrangements of pseudohyperplanes which can be modeled combinatorially by oriented matroids (see [4]).

For the two-dimensional case Bern et al. [3] prove the slightly stronger bound of $z_1(n,2) \leq \frac{11}{2}n$, which is tight up to an additive constant in the worst case. Using this bound as an induction basis in our proof yields a slightly better value for the constants c_k, namely, $c_k = \frac{2}{3}6^k + \frac{3}{4}2^k$ for $k > 0$.

The definition of a zone that we use in this paper is slightly different from definitions used before. We define $Zone(b; H)$ to be the set of all cells in the arrangement $\mathcal{A}(H)$ that intersect the hyperplane b, and the cells were defined to be open sets. Previously the zone used to be defined as the set of all cells *whose closure intersects b*. Let us call this set $Czone(b; H)$. Note that in degenerate cases $Czone(b; H)$ can be substantially more extensive than $Zone(b, H)$. Nevertheless the $O(n^{d-1})$ upper bound also applies to the sum of the complexities of the cells in $Czone(b; H)$. This can most easily be seen by observing that $Czone(b; H) = Zone(b^+; H) \cup Zone(b^-; H)$, where b^+ and b^- are two hyperplanes parallel to b, one on each side of b and sufficiently close to b.

Deriving the exact value of $z_k(n,d)$ looks like a fairly challenging problem. For a start, tight lower bounds on $z_k(n,3)$ are desired.

Finally, we remark that the proof techniques of this paper, in particular Lemma 2.2, bear some similarity to the so-called combination lemma techniques; see [7], [10], [16].

It would be interesting to see to what extent it can be generalized and applied to related discrete geometry problems. Recent successful applications have been achieved by Aronov et al. [1], who derive bounds on the sum of squares of cell complexities in a hyperplane arrangement, by Aronov and Sharir [2], who prove bounds on the complexity of the zone of a convex or fixed-degree algebraic hypersurface in a hyperplane arrangement, and by Houle and Tokuyama [14], who give bounds on the complexity of the zone of a flat in a hyperplane arrangement.

4. Appendix: Why the sweep proof fails in the general case and how it can be partially saved. In this appendix we first show what is wrong with the old sweep-based proof of the zone theorem as presented in [11] or [6], and then we show how the sweep approach can be used to still prove the zone theorem in the three-dimensional case, and a weak version of the theorem in the general d-dimensional case, which counts only facets.

Before we get to the details of the old proof let us change the problem slightly: Firstly we rename the base plane b of the previous sections h, and secondly we could the number of faces bounding the cells in $\mathcal{A}(H \cup \{h\})$ that lie on one side of h and have a facet in h. In the generic case (which we can again assume without loss of generality), even if we ignored the faces contained in h, this number, for at least one side of h, would be at least half the complexity of the zone of h in $\mathcal{A}(H)$ as defined in §1.

Choose a coordinate system so that h is the hyperplane $x_d = 0$ and consider the cells above h (in the half-space $x_d > 0$) that have a facet in h. Call these cells and their faces *active*. As above, when we count the active faces we will count a face once for each active cell it bounds. We therefore continue to use the notion of borders, and define 2^{d-k} *k-borders* (f, C) for each k-face f, one for each cell C it bounds. Call a k-border (f, C) *active* if and only if cell C is active.

4.1. The notion of a chain. The basic idea of the sweep proof is to move a hyperplane h_t continuously over the active cells. Think of $t \geq 0$ as the time and define $h_t : x_d = t$. So $h_0 = h$ and h_t moves upwards as t increases. At any point in time t the cross section of $\mathcal{A} = \mathcal{A}(H)$ within h_t is an arrangement defined by n hyperplanes in $\mathbf{R}^{d-1}$, which we denote as $\mathcal{A}_t$.

Let us index the vertices of $\mathcal{A}$ above h as $v_1, v_2, \ldots, v_m$ and define points in time u_i so that $v_i \in h_{u_i}$ for $1 \leq i \leq m$. We assume that $0 = u_0 < u_1 < u_2 < \ldots < u_m < u_{m+1} = \infty$. Unless $t = u_i$ for some i, $\mathcal{A}_t$ is a simple arrangement. If $t = u_i$ then exactly d of the hyperplanes defining $\mathcal{A}_t$ meet in a common point, and otherwise the hyperplanes are in a generic position. Let t and t' be so that $u_{i-1} < t < u_i < t' < u_{i+1}$ for some $1 \leq i \leq m$ and call the transition from $\mathcal{A}_t$ to $\mathcal{A}_{t'}$ an *elementary step.* Ignoring the positional differences of the hyperplanes in $\mathcal{A}_t$ and $\mathcal{A}_{t'}$, the only combinatorial difference between the two arrangements is that a $(d-1)$-simplex in $\mathcal{A}_t$ reverses its orientation in $\mathcal{A}_{t'}$. This is illustrated in Fig. 4.1, which shows three cross sections of an arrangement of three planes in $\mathbf{R}^3$.

Let $h_1, h_2, \ldots, h_d$ be the hyperplanes (in $\mathbf{R}^d$) that intersect at v_i. The faces of $\mathcal{A}$ that intersect h_t are the same as the faces that intersect $h_{t'}$, except for a group of faces that have v_i as their topmost vertex (they intersect h_t but not $h_{t'}$) and another group of faces that have v_i as their bottommost vertex (they intersect $h_{t'}$ but not h_t). For each $1 \leq k \leq d$, we *identify* a k-face f in the first group with a k-face f' in the second group if f and f' span the same k-flat. Similarly, we identify the k-borders (f, C) and (f', C') if f and f' are identified and C and C' lie on the same side of each hyperplane that contains f and f'. The identification effectively defines equivalence classes of faces and borders. We call an equivalence class of k-borders a *k-chain,* for $1 \leq k \leq d$. For example, a

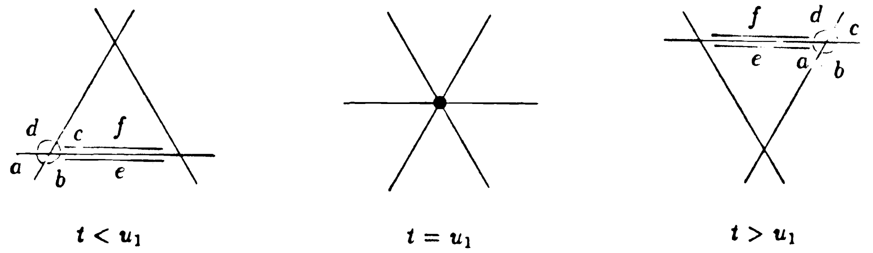

FIG. 4.1. *The triangle defined by three lines (the cross sections of three planes) changes orientation as h_t sweeps through the vertex where the three planes meet.*

1-chain is a sequence of 1-borders (sided edges) on a line, a 2-chain is a sequence of 2-borders in a common 2-flat, and so on and so forth. Figure 4.1 shows the cross sections of four 1-chains (the four-sided versions of a sequence of edges) and of two 2-chains in a three-dimensional arrangement.

4.2. 2-chains do not necessarily die. The sweep proof of the zone theorem hinges on the claim that whenever we sweep through an active vertex there is at least one chain that dies. A chain is said to be *dead* at time t if it contains no further active borders, that is, all borders of the chain that intersect some $h_{t'}$ with $t' > t$ are inactive. Since the number of chains is $O(n^{d-1})$, this claim implies the Zone Theorem. We show below that, unfortunately, this claim is incorrect starting in dimension $d = 3$.

For a vertex v call the cell for which v is the topmost vertex the *cell below* v, and consider the three types of elementary steps shown in Fig. 4.2. In type 1 the 3-chain whose first cell is the cell below v dies. Indeed, every 3-chain has only one active cell, namely, its first cell. In type 2 the 1-chain labeled a dies. This is because all future 1-borders of this 1-chain lie on an edge of a triangular cone disjoint from h and their associated cells lie inside this cone. We now demonstrate that in type 3 the 2-chain labeled ϵ does not die, contrary to the claim in [11].

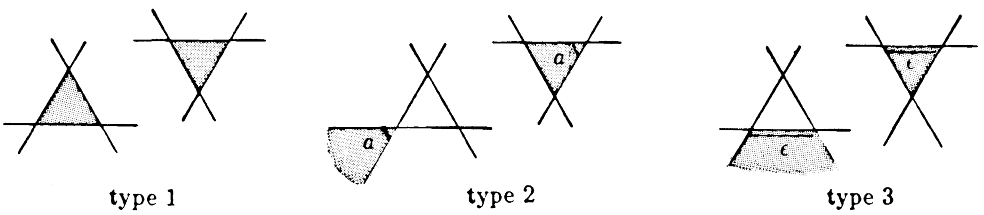

FIG. 4.2. *We distinguish three types of elementary steps associated with a vertex v in a three-dimensional arrangement. For each type the cross section of the active cell is shaded. In type 1 the cell below v is active, in type 2 the cell below v shares an edge with the active cell, and in type 3 the cell below v shares a 2-face with the active cell. Elementary steps where more than one cell bounded by v are active are decomposed into instances of the three basic types.*

The example that we use consists of four planes, h_1, h_2, h_3, h_4. We choose $h_1 : x_1 = 0$, $h_2 : x_2 = 0$, and $h_3 : x_1+x_2+x_3 = 1$. Now choose h_4 so that it meets the line $h \cap h_3$ at a point with negative x_2-coordinate and so that the central triangle (the 2-face that lies in h_3 and in front of h, h_1, and h_2) lies just slightly behind h_4. In Fig. 4.3 only the lines of intersection of h_4 with h and h_3 are shown. Of the three shaded 2-borders, which belong to a 2-chain, the first and the third are active and the middle one is inactive. Indeed, the middle 2-border is within the dead cone defined by h_1, h_2, h_3, but the third 2-border is not. When we sweep through vertex $v = h_1 \cap h_2 \cap h_3$ we have type 3 as shown in Fig. 4.2, but the 2-chain labeled e does not die.

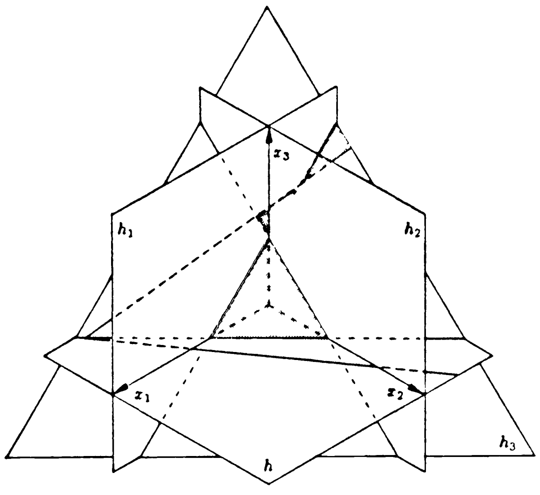

FIG. 4.3. *The shaded* 2*-borders (they face the observer) belong to a* 2*-chain. The first and the third* 2*-borders are active, the middle one is inactive.*

4.3. Fixing the sweep proof in three dimensions. In spite of the fact that in type 3 no chain dies we can still argue that the zone theorem is correct for $d = 3$ using the sweep approach and the type classification illustrated in Fig. 4.2. The reason is that 1-chains still die and 2-chains are linked to 1-chains in elementary steps of the sweep.

At time $t = 0$. $\mathcal{A}_0$ is a two-dimensional arrangement defined by n lines. Because we assume generic position it consists of $\nu_0 = \binom{n}{2}$ vertices, $\epsilon_0 = n^2$ edges, and $\phi_0 = \binom{n}{2} + n + 1$ 2-faces (see, e.g., [6, p. 7]). So we have $4\nu_0$ 1-borders each starting a 1-chain, $2\epsilon_0$ 2-borders each starting a 2-chain, and ϕ_0 cells each starting a 3-chain. All these 1-borders, 2-borders, and cells are active.

Type 1. Recall that in this case the cell below the vertex v that is swept over is active. The corresponding 3-chain dies. So type 1 can occur at most ϕ_0 times. Indeed, it occurs exactly once for each bounded 2-face in $\mathcal{A}_0$ and therefore exactly $\gamma_1 = \phi_0 - 2n = \binom{n}{2} - n{+}1$ times. Each time an elementary step is of type 1 we encounter a new active 0-border, and, respectively, three active 1-borders and 2-borders no longer intersect h_t.

Type 2. Here, the cell below v shares an edge with the active cell. One 1-chain on the corresponding line dies and a new active 2-border is encountered. Since there are only $4\nu_0$ 1-chains, this type can occur only $\gamma_2 \leq 4\nu_0$ times. Besides the new active 2-border we also encounter two new active 1-borders and one new 0-border at v.

Type 3. Here, the cell below v shares a 2-face with the active cell. The number of active 2-borders that intersect h_t decreases by one. Type 3 thus occurs $\gamma_3 \leq 2\epsilon_0 + \gamma_2 - 3\gamma_1 \leq 2n^2 + \binom{n}{2} + 3n - 3$ times because there are $2\epsilon_0$ active 2-borders initially, we get one more at each occurrence of type 2, and $3\gamma_1$ 2-faces disappear in elementary steps of type 1. Notice that we encounter one new active 1-border and one new active 0-border.

We count the active borders when they are encountered by h_t. Initially, we have $4\nu_0$ 0-borders, $2\epsilon_0$ 1-borders, and ϕ_0 2-borders, all active and all in h. We also have $4\nu_0$ 1-chains each starting with an active 1-border, and $2\epsilon_0$ 2-chains each starting with an active 2-border. So we get

$$4\nu_0+\gamma_1+\gamma_2+\gamma_3 \le 4\binom{n}{2}+\binom{n}{2}-n+1+4\binom{n}{2}+2n^2+\binom{n}{2}+3n-3 = 7n^2+O(n)$$

active 0-borders,

$$2\epsilon_0+4\nu_0+2\gamma_2+\gamma_3 \le 2n^2+4\binom{n}{2}+8\binom{n}{2}+2n^2+\binom{n}{2}+3n-3=\frac{21n^2}{2}+O(n)$$

active 1-borders, and

$$\phi_0+2\epsilon_0+\gamma_2 \le \binom{n}{2}+n+1+2n^2+4\binom{n}{2}=\frac{9n^2}{2}+O(n)$$

active 2-borders. This proves the zone theorem for $d=3$.

What kind of upper bounds does this yield for $z_k(n,3)$? Note that here we are counting the borders just on one side of the plane h, but we include the borders contained in h. Thus to get good bounds for $z_k(n,3)$ from the above bounds, we need to subtract the borders contained in h, multiply by two, and subtract the borders that intersect h. Doing this yields the bounds $z_1(n,3)\le 6n^2+O(n)$, $z_2(n,3)\le 15n^2+O(n)$, and $z_3(n,3)\le 10n^2+O(n)$. Note that the coefficients of the n^2 terms agree with the corresponding coefficients of Theorem 2.1 as proved in §2. Thus, with the improved coefficients mentioned in §3, we have better bounds than those derived above.

4.4. The sweep proof for facets. The fix of the sweep proof described in §4.3 does not extend beyond three dimensions. For example, in dimension $d=4$ the sweep links 1-chains with 3-chains and 2-chains with other 2-chains. Since 1-chains still die we can bound the number of active 3-borders, but currently we are not able to bound the number of active k-borders, $k\le 2$, using the sweep approach. Below we show how to bound the number of active $(d-1)$-borders for arbitrary dimension d.

As before, let H be a set of n hyperplanes in generic position and let $h\notin H$ be the hyperplane $x_d=0$. There are $\sum_{i=0}^{d-1}\binom{n}{i}$ active $(d-1)$-borders in h, and initially, there are $2\sum_{i=1}^{d-1} i\binom{n}{i}$ $(d-1)$-chains, each starting with an active $(d-1)$-border. We encounter a new active $(d-1)$-border at an elementary step if and only if it is of the type that the cell below the passed vertex shares (only) an edge with the active cell. However, in this case a 1-chain on the shared edge dies. So this type of elementary step can occur at most $2^{d-1}\binom{n}{d-1}$ times, once for each 1-chain. It follows that there are at most

$$\sum_{i=0}^{d-1}\binom{n}{i}+2\sum_{i=1}^{d-1}\binom{n}{i}+2^{d-1}\binom{n}{d-1}=(2^{d-1}+2d-1)\binom{n}{d-1}+O(n^{d-2})$$

active $(d-1)$-borders.

The bound given here implies the bound $z_1(n,d)\le(2^d+2d-2)\binom{n}{d-1}+O(n^{d-2})$, which in terms of its leading coefficient is substantially worse than the bound for $z_1(n,d)$ given in Theorem 2.1.

LINEAR-PROCESSOR NC ALGORITHMS FOR PLANAR DIRECTED GRAPHS I: STRONGLY CONNECTED COMPONENTS*

MING-YANG KAO†

Abstract. Finding strongly connected components is a fundamental step in many algorithms for directed graphs. In sequential computation this problem has an optimal linear-time algorithm. In parallel computation, however, it remains an open problem whether polylogarithmic time and a *linear* number of processors are sufficient for computing the strongly connected components on a parallel random-access machine. This paper provides the first nontrivial partial solution to the open problem: for a planar directed graph of size n the strongly connected components can be computed deterministically in $O(\log^3 n)$ time with $n/\log n$ processors. The algorithm runs on a parallel random-access machine that allows concurrent reads and concurrent writes in its shared memory and, in case of a write conflict, permits an arbitrary processor to succeed.

1. Introduction.

A directed graph is *strongly connected* if for all vertices u and v there exists a pair of directed paths from u to v and from v to u. A *strongly connected component* in a directed graph is a maximal strongly connected subgraph. The problem of finding strongly connected components is of fundamental importance in graph theory. In sequential computation this problem has optimal linear-time algorithms [2], [9]. In parallel computation on parallel random-access machines (PRAMs) the best current algorithm is based on matrix multiplication and for an n-vertex graph requires $O(\log^2 n)$ time if $n^{2.376}$ processors are used [7], [11], [16].

The total number of operations performed by an algorithm can be estimated from the product of its running time and its processor count. Thus there is a substantial complexity gap between the optimal sequential algorithms and the best current PRAM algorithm for strongly connected components. In view of this gap it is important to ask whether polylogarithmic time and a *linear* number of processors are sufficient for computing strongly connected components. This paper provides the first nontrivial partial solution to this open problem: for a planar directed graph of size n the strongly connected components can be computed deterministically in $O(\log^3 n)$ time with $n/\log n$ processors. The algorithm runs on a PRAM that allows arbitrary concurrent reads and concurrent writes (CRCWs) in its shared memory and, in case of a write conflict, permits an arbitrary processor to succeed.

A natural approach to computing strongly connected components is to iteratively contract directed cycles into single vertices. At the end of this contraction process the strongly connected components become single vertices. Then the strongly connected components are obtained by undoing the contractions and expanding each single vertex back to an original strongly connected component.

For this contraction process to be efficient it is necessary to find directed cycles efficiently. Unfortunately, it is in general very expensive to find directed cycles. In this

paper the planar strongly connected component algorithm focuses on *cycle* faces; a cycle face in an embedded planar directed graph is one whose boundary forms a directed cycle. Note that given an embedded planar directed graph of size n, the cycle faces can be identified in $O(\log n)$ time with $n/\log n$ processors.

The concentration on cycle faces is coupled with useful observations about *compact* strongly connected components; a compact strongly connected component is one that encloses no other components. Observe that if a compact strongly connected component consists of more than one vertex, then this component contains a cycle face. Also observe that the contraction of a cycle face preserves the compactness of strongly connected components. Therefore, when cycle faces are iteratively contracted, all compact strongly connected components eventually become single vertices. If the strongly connected components do not enclose one another, then this face-contraction process can indeed compute the strongly connected components.

There are three major difficulties associated with the above process of contracting cycle faces. First, contracting cycle faces in general creates new cycle faces. The contraction process as described may take more than a polylogarithmic number of iterations. The number of iterations in the planar strongly connected component algorithm is limited by using an edge-cutting technique to compute and contract large neighborhoods of cycle faces. Edge cutting and vertex contraction are combined with a vertex-expansion technique and an orientation structure of primal and dual planar directed graphs. This combination of techniques has also led to the first linear-processor NC algorithm for computing directed spanning trees in strongly connected planar directed graphs [17].

Second, an embedded planar directed graph generally contains nested strongly connected components. It is possible that a planar directed graph has no cycle faces, but not every strongly connected component is a single vertex. Therefore, the face-contraction process is not enough for contracting all strongly connected components into single vertices. To flatten the nesting of strongly connected components, the component algorithm uses edge cutting and vertex contraction to manipulate the nesting. The manipulation is effected through the interaction between graphic and topological structures of planar directed graphs and is guided by a forestlike construct of the topological nesting of strongly connected components.

Third, although it is easy to see that the contraction of a cycle face preserves the compactness of strongly connected components, the contraction of more complex sets incurs complicated changes in the structure of planar directed graphs. To manage and analyze these changes, the component algorithm works with structures and properties of planar directed graphs that are invariant under vertex contraction.

This paper is organized as follows. Section 2 provides basic definitions of and facts about planar directed graphs, and §3 describes their orientation structures. Section 4 analyzes topological nestings of planar strongly connected components, §§5 and 6 discuss edge cutting and vertex contraction, respectively, and §7 details how to flatten the nesting of strongly connected components. Section 8 gives the planar strongly connected component algorithm, and §9 concludes with open problems.

2. Basics of planar directed graphs.

A *planar* directed graph is one that can be embedded on a plane such that the edges intersect only at common endpoints [4], [5], [14], [23]. An *embedded* planar directed graph is one with a given planar embedding.

Remark. The planar strongly connected component algorithm uses only spherical embeddings, but its analysis uses planar embeddings.

2.1. Canonical graphs. A *bridge* of a directed graph is an edge whose removal increases the number of undirected connected components in that graph.

A *canonical* graph is a planar directed graph that is connected, has at least one vertex, and may have multiple edges but contains no loop edges and no bridges.

Most discussions in this paper focus on canonical graphs for the following reasons. Permitting a planar graph to have multiple edges but no loop edges, except in the analysis of contraction invariants in §6.2, makes the effects and invariants of vertex contraction manageable. The planar strongly connected component algorithm works with planar graphs and their duals. Because bridges are duals of loop edges, they are also removed from planar graphs soon after they appear. Note that removing the bridges of a directed graph does not alter its strongly connected components.

2.2. Faces, boundaries, orientations, and cycle faces. Let G be an embedded canonical graph. If the vertices and edges of G are deleted from its embedding plane, then the plane is divided into disconnected regions. Exactly one of the regions is infinite; all others are finite. Each region is called a *face* of G. The infinite region is called the *external* face; the finite regions are called the *internal* faces.

Let f be a face of G. The *boundary* of f, denoted by $\mathcal{B}(f)$, is the set of edges and vertices surrounding f. Because G is connected and bridgeless, $\mathcal{B}(f)$ is connected and bridgeless. Thus if $\mathcal{B}(f)$ contains edges, it can be arranged into a unique edge-simple undirected cycle by having an observer stay inside f and walk around $\mathcal{B}(f)$ once. This cycle is called the *boundary* cycle of f.

Let d be a boundary edge of f. The *orientation* of d with respect to f is defined as follows:

• Case (1): f is the external face. The edge d is *positive* (respectively, *negative*) with respect to f if it points in the counterclockwise (respectively, clockwise) direction on the boundary cycle of f.

• Case (2): f is an internal face. The edge d is *positive* (respectively, *negative*) with respect to f if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of f.

A *cycle* face is one with a directed boundary cycle. A cycle face is *positive* (respectively, *negative*) if its boundary edges are all positive (respectively, negative).

2.3. Subfaces, orientations, and cycle subfaces. Let G be an embedded canonical graph. Let f be a face of G. A *subface* g of f is a vertex-simple undirected subcycle of the boundary cycle of f.

For an edge d of g the *orientation* of d with respect to g is defined to be the same as the orientation of d with respect to f.

A *cycle* subface is one that is a directed cycle. A cycle subface is *positive* (respectively, *negative*) if its edges are all positive (respectively, negative).

A graph with no cycle faces may still have cycle subfaces. The nonexistence of cycle subfaces is crucial for obtaining desired structures of planar graphs. The planar strongly connected component algorithm works with subfaces instead of faces.

2.4. Holes, boundaries, orientations, cycle holes, and subholes. Let G be an embedded canonical graph. Let B be a connected subgraph of G with at least one vertex. If the vertices and edges of B are removed from the embedding plane of G, then the plane is divided into disconnected regions. Exactly one of the regions is infinite; the others are all finite. Each region is called a *hole* of B. The infinite region is called the *external* hole; the finite regions are called the *internal* holes.

The *content* of a hole is the set of vertices and edges in that hole. An *empty* (respectively, *nonempty*) hole is one whose content is empty (respectively, nonempty). Note that an empty hole of B is a face of G.

Let X be a hole of B. The *boundary* of X, denoted by $\mathcal{B}(X)$, is the set of vertices and edges surrounding X. Because B is connected, $\mathcal{B}(X)$ is connected. Thus if $\mathcal{B}(X)$ contains at least one edge, it can be arranged into a unique undirected cycle by having an observer stay inside X and walk around $\mathcal{B}(X)$ exactly once. This cycle is called the *boundary* cycle of X. It may not be edge-simple because $\mathcal{B}(X)$ may not be bridgeless.

Let d be a boundary edge of X. The *orientation* of d with respect to X is defined as follows:

• Case (1): X is the external hole of B. The edge d is *positive* (respectively, *negative*) with respect to X if it points in the counterclockwise (respectively, clockwise) direction on the boundary cycle of X.

• Case (2): X is an internal hole of B. The edge d is *positive* (respectively, *negative*) with respect to X if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of X.

A *cycle* hole is one with a directed boundary cycle. A cycle hole is *positive* (respectively, *negative*) if its boundary edges are all positive (respectively, negative).

A *subhole* Z of X is a vertex-simple undirected subcycle of the boundary cycle of X. For an edge d on Z the *orientation* of d with respect to Z is defined to be the same as the orientation of d with respect to X.

2.5. Combinatorial embeddings and data structures. Let G be a canonical graph. Algorithmically, a planar embedding of G is encoded by the boundary of its external face and the clockwise cyclic order of the edges incident with each vertex. Such an encoding is called a *combinatorial* planar embedding of G. Topologically, a planar embedding is uniquely specified by its corresponding combinatorial embedding.

The cyclic edge incidence in a combinatorial embedding is further encoded by the following data structure: for each vertex there is a doubly linked circular list consisting of the edges incident with that vertex in the clockwise order. These lists can be used to efficiently trace the boundary cycles of the faces of G. They can also be used to trace the boundary cycles of the holes of a connected subgraph.

Given a canonical graph of size n, a combinatorial planar embedding can be computed in $O(\log n)$ time with $n \log\log n/\log n$ processors on a deterministic arbitrary-CRCW PRAM [24].

3. Planar orientation. This section describes orientation structures of primal and dual planar directed graphs.

3.1. Dual planar directed graphs. Let G be an embedded canonical graph. The *dual* of G, denoted by $\tilde{G}$, is the embedded canonical graph constructed below:

• For each face f in G there is a vertex, denoted by $\tilde{f}$, in $\tilde{G}$ that corresponds to f. The vertex $\tilde{f}$ is called the *dual* of f.

• For each edge d in G there is an edge, denoted by $\tilde{d}$, in $\tilde{G}$ that corresponds to d. The edge $\tilde{d}$ is called the *dual* of d and is determined as follows. Let f_1 and f_2 be the two faces in G that share d as a boundary edge. If d is positive (respectively, negative) with respect to f_1, then $\tilde{d}$ is a directed edge from $\tilde{f}_1$ to $\tilde{f}_2$ (respectively, from $\tilde{f}_2$ to $\tilde{f}_1$).

• The planar embedding of $\tilde{G}$ is derived from that of G as follows. For each face f of G the vertex $\tilde{f}$ is placed inside f. For each edge d of G the edge $\tilde{d}$ is obtained by turning d counterclockwise 90°.

Note that the above planar embedding may not be unique because its external face is not unique. For the purposes of this paper any planar embedding that fits this construction is suitable.

Also note that the dual of the dual of G is the same as G with all edge directions reversed. Consequently, each vertex in G also corresponds to a face in $\tilde{G}$. In particular, a source (respectively, sink) in $\tilde{G}$ corresponds to a positive (respectively, negative) cycle face in G.

3.2. Primal-dual orientations. The following theorems are crucial to the planar strongly connected component algorithm. Some of them have been highlighted in §1.

LEMMA 3.1 (Folklore). *Let G be an embedded canonical graph. If the two endpoints of an edge d are in the same strongly connected component of G, then the two endpoints of $\tilde{d}$ are in different strongly connected components of $\tilde{G}$.*

Proof. Because the two endpoints of d are in the same strongly connected component of G, there is a vertex-simple directed cycle C in G that contains d. C divides the plane into two regions. Let Δ_{in} and Δ_{out} be the sets of faces of G in the internal hole and the external hole of C, respectively. Let $\tilde{C}$ be the set of edges in $\tilde{G}$ that are the duals of the edges of C. Let $\tilde{\Delta}_{\text{in}}$ and $\tilde{\Delta}_{\text{out}}$ be the sets of vertices of $\tilde{G}$ that are the duals of the faces in Δ_{in} and Δ_{out}, respectively. Observe that by the definition of a dual graph one of the two endpoints of $\tilde{d}$ is in $\tilde{\Delta}_{\text{in}}$ and the other is in $\tilde{\Delta}_{\text{out}}$. For the remainder of the proof, it suffices to show for all vertices $u \in \tilde{\Delta}_{\text{in}}$ and $v \in \tilde{\Delta}_{\text{in}}$ that u and v are not in the same strongly connected component of $\tilde{G}$. By the definition of a dual graph if C is clockwise (respectively, counterclockwise), then the edges in $\tilde{C}$ all point from $\tilde{\Delta}_{\text{in}}$ to $\tilde{\Delta}_{\text{out}}$ (respectively, from $\tilde{\Delta}_{\text{out}}$ to $\tilde{\Delta}_{\text{in}}$). By this unidirection of $\tilde{C}$ no strongly connected component of $\tilde{G}$ contains both a vertex from $\tilde{\Delta}_{\text{in}}$ and one from $\tilde{\Delta}_{\text{out}}$. □

THEOREM 3.2. *Let G be an embedded canonical graph. Then G is strongly connected if and only if $\tilde{G}$ is acyclic.*

Proof. The proof has two directions. One is to show that if G is strongly connected, then $\tilde{G}$ is acyclic. Because G is strongly connected, the endpoints of all edges of G are in the same strongly connected component of G. By Lemma 3.1 the two endpoints of each edge of $\tilde{G}$ are in different strongly connected components of $\tilde{G}$. Thus no strongly connected component of $\tilde{G}$ can contain any edge, i.e., $\tilde{G}$ is acyclic.

The other direction is to show that if G is not strongly connected, then $\tilde{G}$ is not acyclic. Because G is not strongly connected, there is a strongly connected component S in G such that the edges between S and $G - S$ all point from S to $G - S$. Because $G - S$ cannot be empty, either there are vertices in the external hole of S or there are vertices in internal holes of S. These two cases are symmetric, and so it suffices to discuss the case for which there are vertices in the external hole of S. Let U be the set of these vertices. Because G is connected, there are edges between S and U. Let D be the set of these edges. Let $\tilde{D}$ be the set of dual edges of D in $\tilde{G}$. Because D contains all edges around the boundary of the external hole of S and because this boundary is connected, $\tilde{D}$ forms a undirected cycle in $\tilde{G}$. By the unidirection of D the cycle $\tilde{D}$ is a directed one. Thus $\tilde{G}$ is not acyclic. □

COROLLARY 3.3. *Let G be an embedded canonical graph with more than one vertex. If G is strongly connected, then G contains at least one positive face and one negative face.*

Proof. Note that $\tilde{G}$ has at least two vertices. Also, $\tilde{G}$ is acyclic by the strong connectivity of G and Theorem 3.2. Thus $\tilde{G}$ has at least one sink and one source. Because G contains more than one vertex, a source (respectively, sink) in $\tilde{G}$ corresponds to a positive (respectively, negative) face in G. Therefore, G contains at least one positive face and one negative face. □

4. Planar topology.

This section analyzes topological nestings of strongly connected components.

4.1. Enclosure, compactness, indices, and enclosure forests.

Let G be an embedded canonical graph. Let S and T be two strongly connected components of G. S *encloses* T if T is in an internal hole of S. S *immediately* encloses T if S encloses T and no other strongly connected component both encloses T and is enclosed by S.

A *compact* strongly connected component is one that does not enclose any strongly connected components.

The *index* of a noncompact strongly connected component S is the number of noncompact strongly connected components immediately enclosed by S.

The *enclosure forest* of G, denoted by $\mathcal{F}(G)$, is constructed as follows:

- Each strongly connected component of G is a vertex in $\mathcal{F}(G)$.
- There is a directed edge in $\mathcal{F}(G)$ from S to T if and only if S immediately encloses T.

LEMMA 4.1. *The following statements are true:*

1. *$\mathcal{F}(G)$ is a directed forest.*
2. *The compact strongly connected components of G are the leaves of $\mathcal{F}(G)$.*
3. *The noncompact strongly connected components of G are the internal vertices of $\mathcal{F}(G)$. The index of a noncompact strongly connected component S in G is the number of nonleaf children of S in $\mathcal{F}(G)$.*

Proof. The proof is straightforward. □

The strongly connected component algorithm focuses on converting the index-0 and index-1 strongly connected components of G into compact ones. The next theorem confirms that there are enough noncompact components of these two indices.

THEOREM 4.2. *Let G be an embedded canonical graph. If not all strongly connected components of G are compact, then more than half of the noncompact strongly connected components are of index* 0 *or* 1.

Proof. This theorem follows from Lemma 4.1 and the fact that if a rooted tree has at least two vertices, then more than half of the internal vertices have zero or one nonleaf child each. □

4.2. Cycle faces and compact strongly connected components.

The next lemma was used in §1.

LEMMA 4.3. *Let G be an embedded canonical graph. Let S be a compact strongly connected component of G with more than one vertex. Then S contains the boundary of a cycle face of G.*

Proof. S can be regarded both as a subgraph of G and as a strongly connected component. By its strong connectivity the subgraph S is an embedded canonical graph. Because S has more than one vertex, by Corollary 3.3 the subgraph S contains at least one positive face and one negative face. If the external face of the subgraph S is a cycle face, then the subgraph S has at least one internal cycle face; otherwise, the subgraph S has at least two internal cycle faces. Because the strongly connected component S is compact in G, an internal face of the subgraph S is also a face in G. Thus at least one of the cycle faces in the subgraph S is a cycle face in G. □

4.3. Structures of singular compact strongly connected components.

The reason for focusing on index-0 and index-1 components is that the strongly connected components enclosed by them have useful structures and thus can be efficiently separated. Some of these structures are analyzed below.

Let G be an embedded canonical graph. A compact strongly connected component S of G is *inward* (respectively, *outward*) *singular* if there is no directed path from a noncompact strongly connected component to S (respectively, from S to a noncompact strongly connected component).

LEMMA 4.4. *Let T be a strongly connected component of G. Let X be a hole of T that contains no noncompact strongly connected components. Then every strongly connected component in X is a singular compact strongly connected component in G.*

Proof. Let S be a compact strongly connected component in X. To prove the lemma by contradiction, assume that S is not singular. Then there are two directed paths P and Q with P going from S to a noncompact strongly connected component in G and Q going from a noncompact strongly connected component to S in G. Because all noncompact strongly connected components in G are outside X, P, and Q go through T. Consequently, S and T are in the same strongly connected component, contradicting the condition that S is in X. □

4.4. Structures of index-0 strongly connected components.

LEMMA 4.5. *Let G be an embedded canonical graph. For each index-*0 *strongly connected component S of G, every strongly connected component in the internal holes of S is a singular compact strongly connected component.*

Proof. This lemma follows from Lemma 4.4 and the fact that an internal hole of an index-0 component contains only compact strongly connected components. □

4.5. Structures of index-1 strongly connected components. Let G be an embedded canonical graph. Let S be a strongly connected component of G. Let X be a hole of S in G. The following notations are used for analyzing index-1 components in this and other sections:

- $\mathcal{E}_X(S)$ is the set of edges between S and the vertices in X.
- $\mathcal{E}_{\text{in}}(S)$ is the set of edges between S and the vertices in its internal holes.
- $\mathcal{E}_{\text{ns}}(S)$ is the set of edges in $\mathcal{E}_{\text{in}}(S)$ except those between S and the singular compact strongly connected components immediately enclosed by S.

LEMMA 4.6. *Let S be an index-*1 *strongly connected component of G. Let X be the internal hole of S that contains a noncompact strongly connected component. The following statements are true:*

1. *Every strongly connected component in the internal holes of S except possibly X is a singular compact strongly connected component.*
2. *The edges in $\mathcal{E}_{\text{ns}}(S)$ either all point from S or all point to S.*

Proof. The first statement follows from Lemma 4.4 and the fact that no internal hole of S except X contains a noncompact strongly connected component.

The second statement is proved as follows. Let T be the unique noncompact strongly connected component immediately enclosed by S. It suffices to show the following property: for each edge $d \in \mathcal{E}_{\text{ns}}(S)$, d can be extended into a directed path between S and T such that if d points to (respectively, from) S, then that path goes from T to S (respectively, from S to T). Because S and T are different strongly connected components, this extension property ensures that $\mathcal{E}_{\text{ns}}(S)$ cannot contain two edges with one pointing to S and the other pointing from S.

The edge d is extended as follows. Let $d = u \to v$. There are two cases: either $u \in S$ or $v \in S$. Because these two cases are symmetric, only the case of $u \in S$ is described. If $v \in T$, then d itself is already a directed path from S to T. Thus, without loss of generality, assume that $v \notin T$. Then v is in some nonsingular compact strongly connected component R immediately enclosed by S. Because R is nonsingular, there is a directed path P from R to some noncompact strongly connected component. Because S is of index 1, the noncompact strongly connected components of G except S and T are either outside S or inside T. Thus P goes through either S or T. Because d goes from S to R and because S and R are different strongly connected components, P cannot go through S and must go through T. Then the edge d, a directed path in R, and a subpath of P together form a directed path from S through R to T. □

5. Edge cutting and vertex expansion. This section describes a procedure called CutSegment that cuts edges in an embedded canonical graph. CutSegment is coupled with another procedure called ExpandVertex that eliminates undesirable large-degree vertices. These two procedures are extremely simple but, surprisingly, together reveal very useful structures of planar directed graphs: *clusters*, *territories*, and *chambers*. These procedures and structures are detailed in §5.1 through §5.5, respectively.

5.1. ExpandVertex. The three structures exposed by CutSegment subtly depend on the nonexistence of vertices with degree greater than three. For this reason, a vertex of degree four or more is called a *large-degree* vertex.

A useful operation for eliminating large-degree vertices is to replace each of them by a positive face or a negative face. This operation is called *vertex expansion*. An example of vertex expansion is shown in Fig. 1. The procedure ExpandVertex in Algorithm 1 details how to expand vertices into negative faces.

ALGORITHM 1. *Procedure for expanding large-degree vertices into negative faces.*

```
Procedure ExpandVertex
Input: an embedded canonical graph $G$ and a set $U$ of large-degree vertices.
Output: $G$ with each vertex in $U$ expanded into a negative face.
begin
    for each vertex $u \in U$ do
        begin
            1. Let $d_1, \ldots, d_s$ be the edges incident with $u$ in the counterclockwise order.
            2. Create $s$ copies of $u$, namely, $u_1, \ldots, u_s$.
            3. Replace the $u$-end of each $d_i$ by $u_i$.
            4. Link the vertices $u_i$ into a counterclockwise directed cycle, i.e., $u_1 \rightarrow$
               $u_2 \rightarrow \cdots \rightarrow u_{s-1} \rightarrow u_s \rightarrow u_1$.
        end.
    return $G$ with the above changes.
end.
```

By symmetry a procedure for expanding large-degree vertices into positive faces can be obtained by reversing the orientations in ExpandVertex.

THEOREM 5.1. *The following statements are true:*

1. *The output graph of* ExpandVertex *is an embedded canonical graph and has the same strongly connected components as the input graph does.*

2. ExpandVertex *runs in* $O(\log n)$ *time with* $n/\log n$ *processors for an input graph of size* n.

Proof. The first statement is straightforward. As for the second statement, ExpandVertex can be performed in a straightforward manner with fundamental techniques, including prefix computation [18], [19], and list ranking [3], [7], [15]. □

5.2. CutSegment. Let G be an embedded canonical graph. Let g be a noncycle subface of G. The *positive* (respectively, *negative*) *breakpoints* of g are the following vertices:

• the local sources and sinks of g;

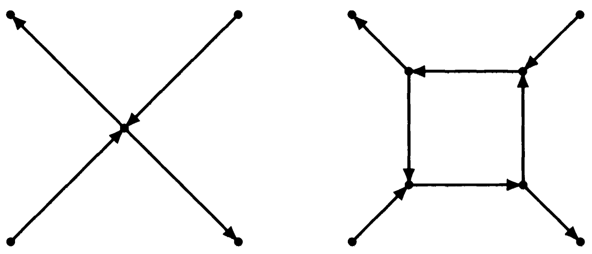

FIG. 1. *Example of expanding a large-degree vertex into a negative face.*

• the vertices shared by g and positive (respectively, negative) subfaces.

Remarks. Cycle subfaces are not assigned breakpoints. A vertex may be a breakpoint for a noncycle subface but not for another.

A *segment* of g is the subpath of g between two consecutive breakpoints with the same orientation. Observe that a segment is a directed path. In light of this, a *positive* (respectively, *negative*) segment P of g is one with the following properties.

• The segment P is between two consecutive positive (respectively, negative) breakpoints of g.

• Every edge of P is a positive (respectively, negative) edge of g.

With the above definitions Algorithm 2 details the procedure CutSegment.

ALGORITHM 2. *Procedure for edge cutting.*

```
Procedure CutSegment
Input: an embedded canonical graph $G$ and two symbolic parameters $x$ = "first" or
"last" and $y$ = "positive" or "negative."
Output: $G$ without the $x$ edge of each $y$ segment.
begin
    1. Find all $y$ breakpoints of $G$.
    2. Find the $x$ edge of each $y$ segment in $G$.
    3. Delete from $G$ all the edges found above.
    4. return $G$.
end.
```

Figure 2 provides an example for CutSegment.

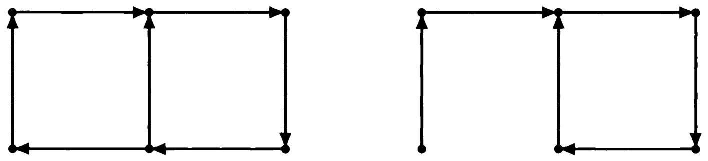

FIG. 2. *Example of cutting the first edge of each positive segment.*

LEMMA 5.2. *Let G be an embedded canonical graph of size n. The following can be computed in $O(\log n)$ time with $n/\log n$ processors:*

1. *the subfaces of G with their orientations,*
2. *the positive (or negative) subfaces of G, and*

3. *the positive* (*or negative*) *breakpoints of the noncycle subfaces of G.*

Proof. Observe that the subfaces of a face f are just the biconnected components of $\mathcal{B}(f)$. Similarly, the subfaces of G are the face boundaries of the subgraphs that are induced by the biconnected components of G. On the basis of these observations, the subfaces of G can be computed in a straightforward manner in $O(\log n)$ time with $n/\log n$ processors. This computation uses optimal algorithms for planar connectivity [14], planar biconnectivity [14], list ranking [3], [7], [15], and prefix computation [18], [19]. Once the subfaces of G are obtained, it is straightforward to identify the cycle subfaces of G and the breakpoints of the noncycle subfaces in $O(\log n)$ time with $n/\log n$ processors. □

THEOREM 5.3. CutSegment *runs in $O(\log n)$ time with $n/\log n$ processors for an embedded canonical graph of size n.*

Proof. Let G be the input graph to CutSegment. By symmetry it suffices to prove the case of deleting the first edge of each positive segment. The subfaces and the positive breakpoints of G are obtained by means of Lemma 5.2. The first edges of the positive segments are simply the positive edges outgoing from positive breakpoints on the subfaces. These edges can be easily found and deleted in $O(\log n)$ time with $n/\log n$ processors. Thus CutSegment runs within the stated complexity. □

5.3. Clusters. Let G be an embedded canonical graph. Two positive (respectively, negative) subfaces h_1 and h_2 of G are *linked* if there is a sequence of positive (respectively, negative) subfaces $g_1, \dots, g_s$ such that $h_1 = g_1$, $h_2 = g_s$, and for $1 \le i \le s-1$, g_i and g_{i+1} share at least one vertex.

A *positive* (respectively, *negative*) *cluster* of G is a maximal set of positive (respectively, negative) subfaces that are linked.

LEMMA 5.4. *Let G be an embedded canonical graph of size n. Then the positive* (*or negative*) *clusters of G can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The positive (respectively, negative) subfaces of G are computed by means of Lemma 5.2. Then the positive (respectively, negative) clusters can be found in $O(\log n)$ time with $n/\log n$ processors by using an optimal parallel algorithm for planar connectivity [14]. □

The following lemma gives a preliminary analysis of CutSegment(G, first, positive). Similar lemmas for the other parameter combinations can be obtained by symmetry.

LEMMA 5.5. *The following statements are true:*

1. *A cluster of G is contained in a strongly connected component of G.*
2. CutSegment(G, *first, positive*) *contains every positive cluster of G.*
3. CutSegment(G, *first, positive*) *has no edges outgoing from positive clusters.*
4. *If the degree of a vertex u is at most three in G, then the outdegree of u is at most one in* CutSegment(G, *first, positive*).

Proof. The statements are proved as follows.

Statement 1. This statement follows from the fact that a cluster consists of linked directed cycles.

Statement 2. By definition a positive subface has no positive breakpoints and thus no positive segments. Thus no edge of a positive subface is cut, and every positive cluster is in CutSegment(G, first, positive).

Statement 3. Let d be an edge from a positive cluster Φ of G to a vertex not in Φ. It suffices to show that d is cut in CutSegment(G, first, positive). Let $d = u \rightarrow v$ with $u \in \Phi$ and $v \notin \Phi$. Let g_t and g_b be the two noncycle subfaces that contain d such that d is positive on g_t and negative on g_b. Let P_t be the positive segment of g_t that contains d.

Then d is cut in CutSegment(G, first, positive) because u is a positive breakpoint and d is the first edge of P_t.

Statement 4. There are two cases based on whether u is on a positive subface of G or not.

• Case (1): u is on a positive subface g. The statement is trivially true if the outdegree of u is at most one in G. Thus, without loss of generality, assume that the outdegree of u is two or three in G. Then, because u has at most three incident edges in G and at least two of them are outgoing, u has exactly two outgoing edges and one incoming edge. Exactly one of the outgoing edges is not on any positive subface and thus is an outgoing edge from the positive cluster containing g. By the third statement of this lemma that edge is cut.

• Case (2): u is not on a positive subface. This case is further divided into subcases. Let Case (i_1, i_2, i_3) denote the case that the degree, indegree, and outdegree of u in G are i_1, i_2, and i_3, respectively. The statement is trivially true for $i_3 \leq 1$. Thus it suffices to discuss Cases (2,0,2), (3,1,2), and (3,0,3).

– Case (2,0,2). Let $d_1 = u \rightarrow v_1$ and $d_2 = u \rightarrow v_2$ be the two edges adjacent with u. Let g_t and g_b be the noncycle subfaces that contain d_1 and d_2 such that d_1 is positive on g_t and negative on g_b. Let P_t be the positive segment of g_t that contains d_1. Let P_b be the positive segment of g_b that contains d_2. The edge d_1 is cut in CutSegment(G, first, positive) because it is the first edge of P_t. Similarly, d_2 is cut.

– Case (3,1,2). Let $d_1 = u \leftarrow v_1$, $d_2 = u \rightarrow v_2$, $d_3 = u \rightarrow v_3$ be the edges adjacent with u in the clockwise order around u. Let $g_{1,2}$, $g_{2,3}$, $g_{3,1}$ be the noncycle subfaces that contain, respectively, d_1 and d_2, d_2, and d_3, and d_3 and d_1. Let $P_{2,3}$ be the positive segment of $g_{2,3}$ that contains d_2. Let $P_{3,1}$ be the positive segment of $g_{3,1}$ that contains d_1 and d_3. The edge d_1 may or may not be cut in CutSegment(G, first, positive), depending on whether v_1 is a positive breakpoint of $g_{3,1}$. The edge d_2 is cut because it is the first edge of $P_{1,2}$. The edge d_3 is not cut because it cannot be the first edge of $P_{3,1}$.

– Case (3,0,3). Let $d_1 = u \rightarrow v_1$, $d_2 = u \rightarrow v_2$, $d_3 = u \rightarrow v_3$ be the edges adjacent with u in the clockwise order around u. Let $g_{1,2}$, $g_{2,3}$, $g_{3,1}$ be the noncycle subfaces that contain, respectively, d_1 and d_2, d_2 and d_3, and d_3 and d_1. Let $P_{1,2}$ be the positive segment of $g_{1,2}$ that contains d_1. Let $P_{2,3}$ be the positive segment of $g_{2,3}$ that contains d_2. Let $P_{3,1}$ be the positive segment of $g_{3,1}$ that contains d_3. The edge d_1 is cut in CutSegment(G, first, positive) because it is the first edge of $P_{1,2}$. Similarly, d_2 and d_3 are cut. □

5.4. Territories. Let G be an embedded canonical graph that has no large-degree vertices except possibly in positive clusters. A *territory* of a positive cluster of G is a vertex subset as defined by the procedure in Algorithm 3.

ALGORITHM 3. *Procedure for computing the positive territories.*

```
Procedure ComputePositiveTerritories
Input: an embedded canonical graph $G$ with no large-degree vertices except possibly in
positive clusters.
Output: the positive territories of $G$.
begin
  1. Let $G_c$ = CutSegment($G$, first, positive).
  2. Let $G_d$ = CutSegment($G$, last, positive).
  3. for each positive cluster $\Phi$ of $G$ do
       begin
         3-1. Let $C_c(\Phi)$ be the connected component in $G_c$ that contains $\Phi$.
```

```
        3-2. Let $\mathcal{C}_d(\Phi)$ be the connected component in $G_d$ that contains $\Phi$.
        3-3. Let $\mathcal{S}(\Phi)$ be the subgraph of $G$ induced from the vertices shared by
             $\mathcal{C}_c(\Phi)$ and $\mathcal{C}_d(\Phi)$.
        3-4. Let $\mathcal{T}(\Phi)$, the territory of $\Phi$, be the connected component in $\mathcal{S}(\Phi)$
             that contains $\Phi$.
    end.
  4. return all $\mathcal{T}(\Phi)$ computed above.
end.
```

For brevity a territory of a positive cluster is called a *positive* territory. A *negative* territory is defined by substituting "negative" for "positive" in the above definition.

Territories are the key neighborhoods of directed cycles contracted in the planar strongly connected component algorithms. The following analysis focuses on positive territories. A similar analysis for negative territories can be obtained by symmetry.

The next theorem provides the basis for contracting territories in the planar strongly connected component algorithm.

THEOREM 5.6. *The following statements are true:*

1. *$\mathcal{C}_c(\Phi)$, $\mathcal{C}_d(\Phi)$, and $\mathcal{T}(\Phi)$ exist.*

2. *Each connected component in G_c (or G_d) contains at most one positive cluster of G. Consequently, distinct positive clusters have disjoint territories.*

3. *Each $\mathcal{T}(\Phi)$ is connected and is in the strongly connected component of G that contains Φ.*

Proof. The statements are proved as follows.

Statement 1. The existence of $\mathcal{C}_c(\Phi)$ follows from Lemma 5.5(2) and the connectivity of Φ. By symmetry $\mathcal{C}_d(\Phi)$ exists. The existence of $\mathcal{T}(\Phi)$ readily follows from that of $\mathcal{C}_c(\Phi)$ and $\mathcal{C}_d(\Phi)$.

Statement 2. By symmetry it suffices to show the statement for G_c. To prove by contraction, assume that G_c contains an undirected vertex-simple path $P = u_1, \dots, u_s$ between two distinct positive clusters Φ_1 and Φ_2 of G with $u_1 \in \Phi_1$ and $u_s \in \Phi_2$. Without loss of generality, further assume that the internal vertices of P are not in any positive cluster of G.

Because u_2 is not in Φ_1, by Lemma 5.5(3) the edge of P between u_1 and u_2 points from u_2 to u_1. Similarly, the edge of P between u_{s-1} and u_s points from u_{s-1} to u_s. Therefore, P has at least three vertices, and at least one internal vertex u_i of P is a local source of P. By the vertex-simplicity of P the outdegree of u_i is at least two in G_c. On the other hand, because u_i is not in any positive cluster of G, the degree of u_i is at most three in G by the degree condition of G. Thus by Lemma 5.5(4) the outdegree of u_i in G_c is at most one. This contradicts the above conclusion that the outdegree of u_i is at least two in G_c.

Statement 3. The connectivity of $\mathcal{T}(\Phi)$ is required by the definition of a territory. For the remainder of the proof, by Lemma 5.5(1) it suffices to show that $\mathcal{C}_c(\Phi)$ (respectively, $\mathcal{C}_d(\Phi)$) contains a directed path P from each vertex u to Φ (respectively, from Φ to each vertex u). By symmetry it suffices to prove this claim only for $\mathcal{C}_c(\Phi)$. Let $P = v_1, \dots, v_s$ be an undirected path in $\mathcal{C}_c(\Phi)$ with $v_1 = u$ and $v_s \in \Phi$ such that P is vertex-simple and intersects with Φ only at v_s. The goal is to show that P is a directed path.

If $s = 1$, then P is obviously a directed path. So, without loss of generality, assume that $s > 1$. Then by the second statement of this theorem $v_1, \dots, v_{s-1}$ are not in any positive cluster of G. By the degree condition of G the degrees of $v_1, \dots, v_{s-1}$ are at most three in G. Because v_{s-1} is not in Φ, by Lemma 5.5(3) the edge of P between v_{s-1} and v_s points to v_s. Furthermore, by Lemma 5.5(4) the outdegree of v_{s-1} in $\mathcal{C}_c(\Phi)$ is at most one. Because v_{s-1} already has an edge pointing to v_s, the edge of P between v_{s-2} and v_{s-1} points to v_{s-1}. Repeating this argument inductively shows that P is indeed a directed path. □

THEOREM 5.7. *Let n be the size of G. The positive territories of G can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The complexity of the procedure in Algorithm 3 is analyzed as follows. Steps 1 and 2 are computed by means of Theorem 5.3. To start Step 3 the positive clusters of G are computed by means of Lemma 5.4. Then Steps 3-1–3-4 can be computed in $O(\log n)$ time with $n/\log n$ processors. These four steps use Theorem 5.6(2) and an optimal parallel algorithm for planar connectivity [14]. Thus the positive territories can be computed with the stated complexity. □

The next theorem is crucial for analyzing the contraction procedures of the planar strongly connected component algorithm.

THEOREM 5.8. *Let g be a noncycle subface in G. Let P be a directed subpath of g that has at least one internal vertex and consists of positive edges of g. If the endpoints of P are in positive territories of G but its internal vertices are not, then the endpoints of P are in different positive territories.*

Proof. Let $P = p_1, \ldots, p_s$. To prove by contradiction, assume that p_1 and p_s are in the same positive territory $\mathcal{T}(\Phi)$. It suffices to show $P \subseteq \mathcal{T}(\Phi)$, contradicting the condition that the internal vertices of P are not in any positive territory.

Because the internal vertices of P are not in any positive territory of G, they are not in any positive cluster of G. Because P is a directed path, the internal vertices of P are not local sources or sinks on g. Thus the internal vertices of P are not positive breakpoints for g. Furthermore, because g is a noncycle subface and P is positive on g, the path P is a subpath of a positive segment Q of g.

Let $Q = q_1, \ldots, q_t$. After the first edge of Q is cut, the path $Q_c = q_2, \ldots, q_t$ remains in G_c. Because the path $P_c = p_2, \ldots, p_s$ is a subpath of Q_c, the path P_c is connected to p_s in G_c. Because $p_s \in \mathcal{T}(\Phi) \subseteq \mathcal{C}_c(\Phi)$, the path P_c is in $\mathcal{C}_c(\Phi)$. The vertex p_1 is also in $\mathcal{C}_c(\Phi)$ because $p_1 \in \mathcal{T}(\Phi) \subseteq \mathcal{C}_c(\Phi)$. Thus P is in $\mathcal{C}_c(\Phi)$. By symmetry P is also in $\mathcal{C}_d(\Phi)$. Consequently, P is in $\mathcal{S}(\Phi)$. Because P is connected to $\mathcal{T}(\Phi)$, the path P lies in $\mathcal{T}(\Phi)$. □

5.5. Chambers. Let G be an embedded canonical graph. Let S be a strongly connected component in G with more than one vertex. A *chamber* of S is a nonempty hole X of S with the following properties:

- The edges in $\mathcal{E}_X(S)$ either all point from S or all point to S.
- X is a cycle hole.

Remark. As shown by Lemma 4.6, index-1 components hold a unidirectional property very similar to the first property above. In fact, a key stage of the planar strongly connected component algorithm is to derive chambers from index-1 components.

The edges in $\mathcal{E}_X(S)$ are called the *chamber* edges of X. The chamber X is *inward* (respectively, *outward*) if the edges in $\mathcal{E}_X(S)$ all point to X (respectively, all point to S). The chamber X is *positive* (respectively, *negative*) if it is a positive (respectively, negative) hole.

Note that if the chamber edges of X can be found efficiently, then these edges can be cut to efficiently separate S from the content of X. This section discusses how to use CutSegment to find the chamber edges of G. The discussion focuses on positive outward chambers. The first part of the discussion assumes that G has no large-degree vertices. The second part allows G to have large-degree vertices.

5.5.1. Chamber edges of graphs without large-degree vertices.

THEOREM 5.9. *Let G be an embedded canonical graph with no large-degree vertices. Let Δ be the set of biconnected components in* CutSegment(G, *first, positive*) *that each contain at least two edges. Then each component in Δ is a directed cycle. Moreover, Δ consists of the positive subfaces in G and the boundary cycles of positive outward chambers.*

Proof. This theorem is based on the following claims:

1. CutSegment(G, first, positive) contains all positive subfaces and all boundary cycles of positive outward chambers of G.

2. A vertex-simple undirected cycle in CutSegment(G, first, positive) is either a positive subface of G or the boundary cycle of a positive outward chamber.

3. Two distinct vertex-simple undirected cycles cannot share a vertex in the graph CutSegment(G, first, positive).

With the above claims the theorem is shown as follows. If a biconnected component of CutSegment(G, first, positive) contains more than one edge, then that component contains at least one vertex-simple undirected cycle. By the third claim, that component contains exactly one such cycle. By the second claim, that cycle is a positive subface or the boundary cycle of a positive outward chamber of G. Conversely, by the first claim CutSegment(G, first, positive) preserves the positive subfaces and the boundary cycles of the positive outward chambers in G. These cycles are preserved in the biconnected components of CutSegment(G, first, positive) that each contain more than one edge.

Claim 1. The claim for positive subfaces follows from Lemma 5.5(2). The claim for chambers is proved as follows. Let X be a positive outward chamber in G. Let C be the boundary cycle of X. Because G has no large-degree vertices, C is vertex-simple. Assume by symmetry that X is an internal hole of a strongly connected component. Then C is a clockwise-directed cycle and the chamber edges of X are inside C. Because the chamber edges point to C, the heads of the chamber edges divide C into directed subpaths. Let d_1 be a chamber edge. Let d_2 be the chamber edge next to d_1 in the clockwise order on C. Let P be the subpath of C from the head of d_1 to the head of d_2. Observe that because d_1 points to C, the edge d_1 and the path P are contained in a positive segment Q. Because d_1 precedes P in Q, the boundary edges of X in P cannot be the first edge of Q and thus cannot be cut in CutSegment(G, first, positive).

Claim 2. Let C be a vertex-simple undirected cycle in G. It is equivalent to show that if C is neither a positive subface nor the boundary cycle of a positive outward chamber, then at least one edge of C is deleted in CutSegment(G, first, positive). There are two cases based on whether C is a directed cycle or not.

- Case (1): C is not a directed cycle. Then there is a local source on C with two outgoing edges. Because G has no large-degree vertices, by Lemma 5.5(4) CutSegment deletes at least one of these two edges.

- Case (2): C is a directed cycle but is neither a positive subface nor the boundary cycle of a positive outward chamber. There are two subcases based on whether C runs clockwise or counterclockwise. Assume by symmetry that C runs clockwise. Because C is not a positive subface, C encloses some edges. In particular, there is an edge d_1 incident with C and inside C. Because C is not the boundary cycle of a positive outward chamber of G, there is an edge residing inside C and pointing from C. Without loss of generality, assume that d_1 points from a vertex u of C. Let d_2 and d_3 be the two edges on C with d_2 entering u and d_3 leaving u. Because G has no large-degree vertices, the edges d_i are the only edges incident with u in G. Observe that d_1 and d_3 are on a noncycle subface and d_3 is the first edge of a positive segment of that subface. Thus d_3 is cut in CutSegment(G, first, positive).

Claim 3. To prove by contradiction, assume that there are two vertex-simple undirected cycles C_1 and C_2 in CutSegment(G, first, positive) that share at least one vertex. Because G has no large-degree vertices, C_1 and C_2 share at least one edge. By the second claim C_1 and C_2 are directed cycles. There are three cases: (1) both C_1 and C_2 run clockwise, (2) both C_1 and C_2 run counterclockwise, or (3) C_1 and C_2 are in the opposite directions. Because these three cases are symmetric, only Case (1) is discussed. Because C_1 and C_2 share at least one edge, one cycle is inside the other. Assume by symmetry that C_2 is inside C_1. Then C_1 is not a positive subface. Also, the internal hole of C_1 is not a positive outward chamber because C_2 violates the unidirectional property of that hole as a chamber. These two conclusions contradict the second claim. □

THEOREM 5.10. *Let G be an embedded canonical graph with no large-degree vertices. Let n be the size of G. The procedure in Algorithm* 4 *computes the chamber edges of positive outward chambers of G in $O(\log n)$ time with $n/\log n$ processors.*

ALGORITHM 4. *Procedure for computing the chamber edges of positive outward chambers of graphs without large-degree vertices.*

```
Procedure ComputePOCE
Input: an embedded canonical graph $G$ with no large-degree vertices.
Output: the chamber edges of positive outward chambers in $G$.
begin
    1. Let $G_c$ = CutSegment($G$, first, positive).
    2. Let $\Delta$ be the set of biconnected components of $G_c$ that contain at least two edges
       each.
    3. Delete from $\Delta$ the positive subfaces of $G$.
    4. Find the chamber edges of the positive outward chambers of $G$, whose boundary
       cycles are now in $\Delta$.
    5. return all edges computed at Step 4.
end.
```

Proof. The correctness of ComputePOCE follows directly from Theorem 5.9. As for its complexity, Steps 1–4 of the procedure can be performed in $O(\log n)$ time with $n/\log n$ processors as follows. Step 1 is performed by means of Theorem 5.3. Step 2 uses an optimal parallel algorithm for planar biconnectivity [14]. Step 3 is performed by means of Lemma 5.2(2). To collect the desired chambers edges, Step 4 uses list ranking and prefix computation to process the doubly linked circular lists of the combinatorial embedding of G. Thus the total complexity of ComputePOCE is as stated. □

5.5.2. Chamber edges of graphs with large-degree vertices.

THEOREM 5.11. *Let G be an embedded canonical graph that may have large-degree vertices. Let G' be the graph constructed by expanding each large-degree vertex of G into a negative face. The following statements are true:*

1. *G' is an embedded canonical graph with no large-degree vertices.*

2. *The chamber edges of the positive outward chambers of G' are originally the edges incident with the large-degree sinks of G and the chamber edges of the positive outward chambers of G.*

Proof. The first statement is obtained by straightforward observation. To prove the second statement, observe that G and G' have the same strongly connected components. Also, each strongly connected component has the same nonempty holes in G and G'. Let S be a strongly connected component in G. Let X be a nonempty hole of S in G. Let S' and X' be the versions of S and X in G'. Observe that $\mathcal{E}_X(S)$ and $\mathcal{E}_{X'}(S')$ consist of the same edges with the same directions to or from S and S'.

These observations permit the second statement to be proved by showing that the positive outward chambers of G' are originally the external holes of the large-degree sinks of G and the positive outward chambers of G. This claim follows directly from the following case analysis on $\mathcal{B}(X)$ for the second property of a chamber.

If $\mathcal{B}(X)$ contains no large-degree vertices, then $\mathcal{B}(X') = \mathcal{B}(X)$. Otherwise, vertex expansion inserts new positive edges into $\mathcal{B}(X)$. There are three cases.

• Case (1): If $\mathcal{B}(X)$ consists of a large-degree vertex, then X' is the external hole of S' and is a positive one.

• Case (2): If X is a positive hole, then X' is also a positive hole.

• Case (3): If X has more than one boundary vertex but is not a positive hole, then X' is not a positive hole. □

THEOREM 5.12. *Let G be an embedded canonical graph. Let n be the size of G. The procedure in Algorithm 5 computes the chamber edges of positive outward chambers of G in $O(\log n)$ time with $n/\log n$ processors.*

ALGORITHM 5. *Procedure for computing the chamber edges of positive outward chambers.*

```
Procedure ComputePositiveOutwardChamberEdges
Input: an embedded canonical graph $G$.
Output: the chamber edges of positive outward chambers in $G$.
begin
    1. Let $G'$ be the graph constructed by expanding each large-degree vertex of $G$ into
       a negative face.
    2. Let $D'$ be the set of the chamber edges of positive outward chambers of $G'$ com-
       puted by the procedure in Algorithm 4.
    3. Let $D$ be the set of edges in $G$ that correspond to those in $D'$ and are not the
       edges incident with the large-degree sinks of $G$.
    4. return the edges in $D$.
end.
```

Proof. The correctness of the procedure follows from Theorems 5.10 and 5.11. As for its complexity, Steps 1 through 3 of the procedure can be performed in $O(\log n)$ time with $n/\log n$ processors as follows. Step 1 is performed by means of Theorem 5.1(2). Step 2 is performed by means of Theorem 5.10. Step 3 is performed by identifying the sinks of G in $O(\log n)$ time with $n/\log n$ processors. Thus the total complexity of the procedure is as stated. □

The above discussion has described how to compute the chamber edges of positive outward chambers. The chamber edges of the other groups of chambers can be similarly computed on the basis of the symmetry summarized in Table 1.

6. Vertex contraction.

Throughout this paper vertex contraction always satisfies the following specifications:

• Vertex contraction keeps all multiple edges and deletes all loop edges that it creates.

• Vertex contraction contracts only connected vertex subsets of strongly connected components.

Note that deleting all loop edges simplifies contracted strongly connected components. Keeping all multiple edges maintains crucial contraction invariants. In particular, each uncontracted edge keeps a unique identity because its link remains unchanged, whereas its endpoints may be altered by contraction.

TABLE 1
Symmetry for computing chamber edges.

Chambers		Vertex Expansion	CutSegment		Discarded Edges
positive	outward	negative faces	first	positive	sinks
positive	inward	negative faces	last	positive	sources
negative	outward	positive faces	first	negative	sinks
negative	inward	positive faces	last	negative	sources

Also note that contracting only connected vertex subsets preserves planarity. Contracting only subsets of strongly connected components preserves the strongly connected components.

In fact, the planar strongly connected component algorithm contracts only territories and vertex subsets expanded from large-degree vertices. Theorem 5.6(3) ensures that a territory satisfies the second specification above. The vertex subset expanded from a large-degree vertex clearly satisfies the second specification.

The detailed discussion of vertex contraction is divided into four parts. Section 6.1 gives the definition of a planar embedding induced by vertex contraction, §6.2 discusses contraction invariants, §6.3 describes contraction procedures, and §6.4 analyzes contraction effects.

6.1. Planar embeddings induced by vertex contraction. Let G be an embedded canonical graph. Let B be the subgraph induced by a connected vertex subset of a strongly connected component of G. Let G' be the graph constructed from G by contracting B into a vertex B'. If B consists of at most one vertex, then G' and G are the same. Otherwise, a planar embedding for G' is specified as follows:

• For every vertex $u \notin B$ the clockwise cyclic order of the edges incident with u is the same in G and G'.

• The edges around each nonempty hole X of B stay together around B', and their clockwise cyclic order around B' is the same as their cyclic order around the boundary cycle of X in the negative direction of X.

• All uncontracted edges on the boundary of the external face of G remain on that of G' and have the same orientations with respect to both external faces.

• If B contains a boundary vertex of the external face of G, then B' is on the boundary of the external face of G'.

In general, such a planar embedding is not unique. For the purposes of this paper any planar embedding that fits this construction is suitable.

THEOREM 6.1. *Given an embedded canonical graph of size n, a planar embedding induced by contracting a disjoint family of connected vertex subsets can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The edges around a new vertex of G' are collected by processing the doubly linked circular lists of the combinatorial embedding of G. The computation takes $O(\log n)$ time and $n/\log n$ processors and uses optimal parallel algorithms for list ranking [3], [7], [15], prefix computation [18], [19], tree contraction [1], [6], [9], [12], [17], [20], and planar connectivity [14]. □

6.2. Contraction invariants. The next four lemmas describe contraction invariants for subfaces, paths, holes, and subholes. The lemmas for subfaces, paths, and subholes are false if multiple edges are not kept.

To prove the invariant lemmas, note that the above definition of vertex contraction is not directly suitable for analyzing contraction invariants because it permits many structural changes to occur simultaneously. This difficulty is resolved by observing that vertex contraction can be done by performing a sequence of contracting a nonloop edge and deleting a loop edge. The planar embedding induced by contracting a nonloop edge is constructed by topologically shrinking that edge into a single vertex. The planar embedding induced by deleting a loop edge is constructed by simply deleting that loop.

The proofs of the invariant lemmas are obtained by straightforward induction based on direct observations about the effects of deleting a single loop edge and contracting a single nonloop edge. For contracting a connected vertex subset there may be several sequences of contracting and deleting edges. Different sequences may result in different planar embeddings. These planar embeddings all satisfy the definition of vertex contraction, and thus every sequence of deletions and contractions suffices for proving the invariant lemmas.

6.2.1. Subface invariants. Let G be an embedded canonical graph. Let G' be a contracted version of G. Let g be a subface in G. Let D be the set of edges of g. Let D' be the set of edges in D that remain in G'.

LEMMA 6.2. *There is a face g' in G' such that the subfaces of g' can be partitioned into two collections Δ_{new} and Δ_{old} with the following properties:*

1. *The subfaces in Δ_{new} contain no edges from D'.*
2. *The subfaces in Δ_{old} consist of exactly the edges in D', and each edge in D' has the same orientation with respect to g and g'.*

Proof. See the above discussion. □

6.2.2. Path invariants. Let G be an embedded canonical graph. Let G' be a contracted version of G. Let g' be a subface in G'. Let P' be a subpath of g' whose internal vertices are original vertices in G.

LEMMA 6.3. *P' originally is a subpath of a subface g in G, and each edge of P' has the same orientation on g and g'.*

Proof. See the above discussion. □

6.2.3. Hole invariants. Let G be an embedded canonical graph. Let G' be a contracted version of G. Let S and T be two strongly connected components in G. Let S' and T' be the versions of S and T in G'.

LEMMA 6.4. *The following statements are true:*

1. *The content of an internal hole of S' is the union of the contents of some internal holes of S.*
2. *The content of the external hole of S' is the union of the contents of the external hole of S and possibly some internal holes of S.*
3. *Distinct holes of S' do not share the content from the same hole of S.*
4. *If S does not enclose T, then S' does not enclose T'.*
5. *If S is compact, then S' is compact.*
6. *If S has exactly one nonempty internal hole, then S' either is compact or has exactly one nonempty internal hole.*

Proof. See the above discussion. □

6.2.4. Subhole invariants. Let G be an embedded canonical graph. Let G' be a contracted version of G. Let S be a strongly connected component in G. Let X be the external hole of S. Let S' and X' be the versions of S and X in G'. Let D be the set of boundary edges of X. Let D' be the set of edges in D that remain in G'.

LEMMA 6.5. *The subholes of X' can be partioned into two collections Δ_{new} and Δ_{old} with the following properties:*

1. *The subholes in Δ_{new} contain no edges from D'. These subholes are all subfaces in G', and each of them has the same orientation in both contexts.*

2. *The subholes in Δ_{old} consist of exactly the edges in D', and each edge in D' has the same orientation with respect to X and X'.*

Proof. See the above discussion. □

6.3. Contraction procedures. The planar strongly connected component algorithm uses three high-level procedures for vertex contraction: ContractPositive, ContractNegative, and ContractBoth.

ContractPositive is described in Algorithm 6.

ALGORITHM 6. *Procedure for contracting positive subfaces.*

```
Procedure ContractPositive
Input: an embedded canonical graph $G$.
Output: an embedded canonical graph that is a contracted version of $G$ with no positive
subfaces.
begin
    repeat
        1. Expand into a negative face each large-degree vertex of $G$ that is not on any
           positive subfaces.
        2. Contract each positive territory of $G$ into a single vertex.
        3. Contract back into single vertices the vertices in $G$ that are duplicates of the
           vertices expanded at Step 1.
    until $G$ has no positive subfaces.
    return the resulting $G$.
end.
```

ContractNegative is obtained by reversing all orientations in the description of ContractPositive. ContractBoth is simply the composition of ContractNegative and ContractPositive, i.e., ContractBoth(G) = ContractNegative(ContractPositive(G)).

Note that the output specifications of these procedures contain some subtleties that are prone to overexpectations and may result in mistaken theorems or proofs. In particular, although the output graph of ContractNegative has no negative subface, it may have positive subfaces even if its input graph has no positive subfaces. Consequently, ContractBoth(G) may have positive subfaces or even compact strongly connected components that contain positive subfaces.

The following analysis focuses on ContractPositive. A similar analysis for ContractNegative can be obtained by symmetry.

The next lemma examines the size of G at different steps of ContractPositive and measures the progress made by an iteration of the repeat loop in ContractPositive.

LEMMA 6.6. *At a given iteration of the repeat loop in* ContractPositive *let G_0 be the input graph to Step* 1. *For $i \in \{1,2,3\}$ let G_i be the output graph from Step i. Let n be the initial size of G. For $i \in \{0,1,2,3\}$ let n_i be the size of G_i and let β_i be the number of positive clusters in G_i. The following statements are true:*

1. $n_i \leq 5n$ *for* $i \in \{0,1,2,3\}$.

2. $\beta_3 \leq \beta_0/2$.

Proof. The first statement is obtained by induction by using the fact that $n_1 \leq 5n_0$, $n_2 \leq n_1$, and $n_3 \leq n_0$. To prove the second statement, it suffices to show that $\beta_1 = \beta_0$, $\beta_2 \leq \beta_1/2$, and $\beta_3 \leq \beta_2$ as follows.

$\beta_1 = \beta_0$. This is true because Step 1 does not create, destroy, split, or merge positive clusters.

$\beta_2 \leq \beta_1/2$. It suffices to show that each positive subface in G_2 contains at least two contracted positive territories of G_1. To prove by contradiction, assume that there is a positive subface g_2 in G_2 that contains at most one contracted positive territory of G_1. If g_2 contains no contracted positive territory of G_1, then g_2 is a positive subface in G_1, contradicting the fact that every positive cluster of G_1 is contracted at Step 2. Thus, without loss of generality, assume that g_2 contains exactly one vertex u that is a contracted positive territory of G_1. Consider g_2 as a path P_2 from u to u. By Lemma 6.3 the path P_2 is originally a positive subpath P_1 of a noncycle subface in G_1 such that the endpoints of P_1 are in positive territories of G_1 but its internal vertices are not. Because G_2 has no loop edges, P_1 has at least one internal vertex. By Theorem 5.8 the endpoints of P_1 are in different positive territories of G_1, contradicting the proof assumption that g_2 contains only one contracted positive territory of G_1.

$\beta_3 \leq \beta_2$. By Lemma 6.2 each negative face created by vertex expansion at Step 1 remains unchanged, becomes a collection of smaller negative subfaces, or disappears altogether in G_2. Step 3 in effect contracts these remaining negative subfaces. Contracting a negative subface does not create new positive subfaces and may merge old positive clusters. Therefore, the desired inequality is true. □

THEOREM 6.7. ContractPositive *correctly computes an embedded canonical graph that is a contracted version of the input graph with no positive subfaces. The procedure runs in* $O(\log^2 n)$ *time with* $n/\log n$ *processors for an input graph of size* n.

Proof. Steps 2 and 3 of ContractPositive ensure that the output graph is a contracted version of the input graph. Moreover, the output graph is an embedded canonical graph because vertex contraction preserves connectivity and bridgelessness. The termination condition of the repeat loop ensures that the output graph contains no positive subfaces.

Because G has at most n positive clusters, by Lemma 6.6(2) in $\lceil \log_2(n+1) \rceil$ iterations of the repeat loop G has no positive cluster and thus no positive subface. For the remainder of the proof, the following analysis shows that Steps 1 through 3 and the termination condition can all be done in $O(\log n)$ time with $n/\log n$ processors. Step 1 is performed by means of Theorem 5.1(2) and Lemmas 5.2(2) and 6.6(1). Next, by Theorem 5.1(1) and by the effect of vertex expansion the graph produced by Step 1 is an embedded canonical graph with no large-degree vertices except possibly in positive clusters. Thus Step 2 can be performed by means of Lemma 6.6(1) and Theorems 5.7 and 6.1. Step 3 is performed by means of Theorem 6.1 and an optimal parallel algorithm for planar connectivity [14]. The termination condition is tested by means of Lemmas 5.2(2) and 6.6(1). □

6.4. Contraction effects. Section 6.4.1 examines the effects of vertex contraction on compact strongly connected components. Section 6.4.2 analyzes the effects on singular components and their contracted versions, *singular* vertices. These components and vertices are closely related to index-0 and index-1 components. Section 6.4.3 details the effects on strongly connected components that each have exactly one nonempty internal hole. These components can be derived from index-1 components.

6.4.1. Effects of contraction on compact components.

THEOREM 6.8. *Let G be an embedded canonical graph. Then every compact strongly connected component of G becomes a single vertex in* ContractBoth(G).

Remark. This theorem is false if the loop edges created by contraction are kept.

Proof. Let G_1 = ContractPositive(G). Let G_2 = ContractNegative(G_1). Let S be a compact strongly connected component in G. Let S_1 and S_2 be the versions of S in G_1 and G_2. Let X_1 and X_2 be the external holes of S_1 and S_2. The goal is to show that S_2 is a single vertex. To prove by contradiction, assume that S_2 is not a single vertex. Then S_1 is also not a single vertex.

S_1 can be regarded both as a subgraph of G_1 and as a strongly connected component. Because S is compact in G, by Lemma 6.4 the component S_1 is compact in G_1. Thus every internal subface of the subgraph S_1 is an internal subface of G_1 with the same orientation in both contexts. Similarly, the boundary of the external face of the subgraph S_1 is the boundary of the external hole of the component S_1 with the same orientation in both contexts.

Because the subgraph S_1 is strongly connected and has at least two vertices, by Corollary 3.3 it has at least one positive face and one negative face. Because G_1 has no positive subface, the subgraph S_1 has no internal positive subface and thus no internal positive face. Therefore, the external face of the subgraph S_1 is a positive one, i.e., X_1 is a positive hole. By symmetry X_2 is a negative hole because G_2 has no negative subface. Then because G_2 is contracted from G_1, by Lemma 6.5(2) $\mathcal{B}(X_2)$ contains no edge from $\mathcal{B}(X_1)$. Next, by Lemma 6.5(1) each subhole Z of X_2 is also a subface in G_2 with the same orientation in both contexts. Consequently, Z is a negative subface in G_2, contradicting the fact that G_2 = ContractNegative(G_1). □

6.4.2. Effects of contraction on singular components and vertices. An *inward* (respectively, *outward*) *singular* vertex is one such that there is no directed path from any directed cycle to that vertex (respectively, from that vertex to any directed cycle). Singular vertices and components are related by means of the following theorem.

THEOREM 6.9. *Let G be an embedded canonical graph. Then every inward (respectively, outward) singular compact strongly connected component of G becomes an inward (respectively, outward) singular vertex in* ContractBoth(G).

Proof. By symmetry it suffices to prove the theorem for the inward case. Let G' = ContractBoth(G). Let S be an inward singular compact strongly connected component in G. Let S' be the version of S in G'. Because S is compact in G, by Theorem 6.8 S' is a single vertex in G'. To prove by contradiction, assume that S' is not an inward singular vertex in G'. Then G' contains a directed path from a directed cycle C' to the vertex S'. Consequently, by Theorem 6.8 C' must be part of a noncompact strongly connected component T in G. Furthermore, there is a directed path from T to S in G because vertex contraction preserves reachability. This contradicts the condition that S is an inward singular component in G. □

The reason for working with singular vertices is as follows. For computing the strongly connected components it is useful and easy to determine whether a vertex is a source or a sink or neither. If a vertex is a source or a sink, it is a strongly connected component by itself. Note that a source is inward singular and a sink is outward singular. Moreover, if the sources are removed, new sources may appear, and if the sinks are removed, new sinks may appear. The inward singular vertices are exactly the sources created by iteratively removing sources, and the outward singular vertices are exactly the sinks created by iteratively removing sinks. The iterative process of removing sources and sinks can be parallelized by means of the following theorem.

THEOREM 6.10. *Let G be an embedded canonical graph. Let $\tilde{G}$ be the dual of G. Let D be the set of edges in G incident with the outward and inward singular vertices. Let $\tilde{D}$ be the set of duals of the edges in D. Then the edges of $\tilde{D}$ all disappear in* ContractBoth($\tilde{G}$).

Proof. Let $\tilde{G}_1$ = ContractPositive($\tilde{G}$). Let $\tilde{G}_2$ = ContractNegative($\tilde{G}_1$). Let U_o and U_i be the sets of outward and inward singular vertices in G. Let D_o and D_i be the sets of edges in G incident with U_o and U_i. Let $\tilde{D}_o$ and $\tilde{D}_i$ be the sets of duals of the edges in D_o and D_i. Note that $\tilde{G}_2$ = ContractBoth($\tilde{G}$) and $\tilde{D} = \tilde{D}_o \cup \tilde{D}_i$. Because $\tilde{G}_2$ is contracted from $\tilde{G}_1$, it suffices to show that the edges of $\tilde{D}_o$ disappear in $\tilde{G}_1$ and that the edges of $\tilde{D}_i$ disappear in $\tilde{G}_2$. Because these two claims are symmetric, only the former claim is proved, as follows.

Because U_o as an induced subgraph of G is an acyclic directed graph, it can be regarded as a partial order. By induction on this partial order, D_o consists of the incoming edges to U_o in G. To prove by contradiction, assume that for some vertex $u \in U_o$ and for some incoming edge d of u in G, the dual edge $\tilde{d}$ of d remains in $\tilde{G}_1$. Without loss of generality, further assume that u is a minimal element in the partial order U_o with such a property.

By the minimality of u, $\tilde{G}_1$ contains no duals of the incoming edges of the descendants of u in U_o. Because the outgoing edges of u are incoming edges of its descendants in U_o, the duals of outgoing edges of u all disappear in $\tilde{G}_1$. In other words, only incoming edges of u may have duals remaining in $\tilde{G}_1$.

Let D' be the set of incoming edges of u in G whose duals remain in $\tilde{G}_1$. Let $\tilde{D}'$ be the set of duals of the edges in D'. Recall that the dual $\tilde{u}$ of the vertex u is a face in $\tilde{G}$. Because the edges in D' are incoming edges of u, the edges in $\tilde{D}'$ are positive boundary edges of $\tilde{u}$. Also, the edges in $\tilde{D}'$ are the only remaining boundary edges of $\tilde{u}$ in $\tilde{G}_1$. Therefore, by Lemma 6.2 $\tilde{D}'$ forms positive subfaces in $\tilde{G}_1$, contradicting the fact that $\tilde{G}_1$ = ContractPositive($\tilde{G}$). □

6.4.3. Effects of contraction on one-hole components. In the next lemma let G be an embedded canonical graph. Let G_1 = ContractPositive(G), and then let G_2 = ContractNegative(G_1). Let S be a strongly connected component in G with exactly one nonempty internal hole. Let S_1 and S_2 be the versions of S in G_1 and G_2.

LEMMA 6.11. *If S_2 is not compact in G_2, then the following statements hold:*

1. *S_1 and S_2 each have exactly one nonempty internal hole.*
2. *At least one of the nonempty internal holes of S_1 and S_2 is a cycle hole.*

Proof. Because S_2 is not compact in G_2, by Lemma 6.4 S_1 is not compact in G_1. Because S has exactly one nonempty internal hole, by Lemma 6.4 S_1 and S_2 each have exactly one nonempty internal hole. This proves the first statement.

To prove the second statement, let X_1 and X_2 be the external holes of S_1 and S_2. Let Y_1 and Y_2 be the nonempty internal holes of S_1 and S_2. The goal is to show that $\mathcal{B}(Y_1)$ or $\mathcal{B}(Y_2)$ forms a directed cycle. To prove by contradiction, assume that neither $\mathcal{B}(Y_1)$ nor $\mathcal{B}(Y_2)$ forms a directed cycle.

S_1 can be regarded both as a subgraph of G_1 and as a strongly connected component. The boundary of X_1 is that of the external face h of the subgraph S_1 with the same orientation in both contexts. The boundary Y_1 is that of an internal face k of the subgraph S_1 with the same orientation in both contexts. Because $\mathcal{B}(Y_1)$ does not form a directed cycle, k is not a positive face of the subgraph S_1. If a face f of the subgraph S_1 is neither h nor k, then f is also a face of G_1 with the same orientation in both contexts. Moreover, because G_1 has no positive subfaces, f is not a positive face of the subgraph S_1.

Because the subgraph S_1 is strongly connected with more than one vertex, by Corollary 3.3 it has at least one positive face. Thus h is a positive face of the subgraph S_1, i.e.,

X_1 is a positive hole. Symmetrically, X_2 is a negative hole because G_2 has no negative subfaces. Because $\mathcal{B}(X_1)$ and $\mathcal{B}(X_2)$ have the opposite orientations, by Lemma 6.5(2) $\mathcal{B}(X_2)$ contains no edges from $\mathcal{B}(X_1)$. By Lemma 6.5(1) $\mathcal{B}(X_2)$ forms negative subfaces of G_2, contradicting the fact that G_2 = ContractNegative(G_1). □

7. Flattening the nesting of strongly connected components.

As highlighted in §1, a major difficulty in computing planar strongly connected components is that these components may be nested within one another. This section details a procedure called FlattenNesting that breaks the nesting of strongly connected components by contracting and separating them. The procedure is detailed in Algorithm 7, and its overview and analysis are given below.

ALGORITHM 7. *Procedure for breaking the nesting of strongly connected components.*

```
Procedure FlattenNesting
Input: an embedded canonical graph $G_{\text{in}}$.
Output: an embedded planar directed graph $G_{\text{out}}$ with the following properties:
    1. $G_{\text{out}}$ is constructed from $G_{\text{in}}$ by edge cutting and vertex contraction and has the
       same strongly connected components as $G_{\text{in}}$ does.
    2. Each connected component of $G_{\text{out}}$ is an embedded canonical graph.
    3. If the strongly connected components of $G_{\text{in}}$ are not all compact, then the total
       number of noncompact strongly connected components in the connected com-
       ponents of $G_{\text{out}}$ is fewer than half that of $G_{\text{in}}$.
    4. Every singular compact strongly connected component of $G_{\text{in}}$ becomes an iso-
       lated vertex in $G_{\text{out}}$.
begin
    Stage 1: contracting compact strongly connected components.
        1-1. Let $G_1$ be ContractBoth($G_{\text{in}}$).
    Stage 2: cutting off singular vertices.
        2-1. Let $\tilde{G}_1$ be the dual graph of $G_1$.
        2-2. Let $\tilde{G}'_1$ be ContractBoth($\tilde{G}_1$).
        2-3. Let $D_2$ be the set of edges in $G_1$ whose duals disappear in $\tilde{G}'_1$.
        2-4. Let $G'_1$ be $G_1$ without the edges in $D_2$.
        2-5. Let $G_2$ be $G'_1$ without its bridges.
    Stage 3: creating chambers and cutting off chamber edges.
        3-1. Let $G'_2$ be the graph constructed by applying ContractPositive to every con-
             nected component of $G_2$.
        3-2. Let $G''_2$ be the graph constructed by applying ContractNegative to every con-
             nected component of $G'_2$.
        3-3. Let $D_3$ be the set of chamber edges in $G'_2$ and $G''_2$.
        3-4. Let $G'''_2$ be $G''_2$ without the edges in $D_3$.
        3-5. Let $G_{\text{out}}$ be $G'''_2$ without its bridges.
    return $G_{\text{out}}$.
end.
```

7.1. An overview of FlattenNesting.

In the planar strongly connected component algorithm FlattenNesting is iteratively applied to each connected component of its output graph.

The first output property of FlattenNesting ensures that the strongly connected components of the input graph remain the same throughout iterations of FlattenNesting. The second output property permits such iterations by ensuring that each connected component of an output graph is canonical and therefore may be an input to FlattenNesting. The third output property measures the progress of FlattenNesting in breaking the nesting of strongly connected components. The fourth output property measures the progress of FlattenNesting in contracting and separating strongly connected components.

Based on Theorem 4.2, FlattenNesting focuses on compact, index-0, and index-1 strongly connected components of G_{in}. These components correspond to the leaves, and the internal vertices of index 0 or 1 in the enclosure forest $\mathcal{F}(G_{\text{in}})$. They are processed in three stages as outlined below.

• Stage 1 contracts all compact strongly connected components of G_{in} into single vertices. Let G_1 be the resulting graph. Intuitively, this stage preprocesses the leaves of $\mathcal{F}(G_{\text{in}})$. It has one major effect:

– All singular compact strongly connected components of G_{in} become singular vertices in G_1. These components include all those enclosed by index-0 components in G_{in} and almost all those enclosed by index-1 components.

• Stage 2 cuts off the singular vertices in G_1. Let G_2 be the resulting graph. Intuitively, this stage cuts off the edges in $\mathcal{F}(G_{\text{in}})$ between the internal vertices with index 0 or 1 and their leaf children. This stage has three major effects:

– Every singular compact strongly connected component of G_{in} becomes an isolated vertex in G_2.

– Every index-0 strongly connected component of G_{in} becomes compact in a connected component of G_2.

– All remaining nonempty internal holes of index-1 strongly connected components of G_{in} become very similar to chambers in G_2.

• Stage 3 converts into chambers all remaining nonempty internal holes of index-1 components of G_{in} and then cuts off their chamber edges. Let G_{out} be the resulting graph. Intuitively, this stage cuts the edges in $\mathcal{F}(G_{\text{in}})$ between the index-1 internal vertices and their nonleaf children. This stage has one major effect:

– Every index-1 strongly connected component of G_{in} becomes compact in a connected component of G_{out}.

The three stages of FlattenNesting are analyzed in §§7.2, 7.3, and 7.4, respectively. These analyses are summarized in §7.5.

7.2. Analysis of Stage 1 of FlattenNesting.

LEMMA 7.1. *Let n be the size of G_{in}. The following statements are true:*

1. *Stage* 1 *of* FlattenNesting *runs in $O(\log^2 n)$ time with $n/\log n$ processors.*
2. *G_1 has the same strongly connected components as G_{in} does.*
3. *G_1 is an embedded canonical graph.*

Proof. This lemma follows directly from Theorem 6.7 and a symmetric theorem for ContractNegative. □

LEMMA 7.2. *The following statements are true:*

1. *Every compact strongly connected component of G_{in} becomes a single vertex in G_1.*
2. *Every singular compact strongly connected component of G_{in} becomes a singular vertex in G_1.*
3. *For each index-*0 *strongly connected component S of G_{in} every strongly connected component in the internal holes of S becomes a singular vertex in G_1.*
4. *Let T be an index-*1 *strongly connected component of G_{in}. Let X be the internal hole of T that contains a noncompact strongly connected component. Then the strongly connected components in internal holes of T except possibly X all become singular vertices in G_1.*

Proof. The first statement follows from Theorem 6.8, the second statement follows from Theorem 6.9, the third statement follows from Lemma 4.5 and Theorem 6.9, and the fourth statement follows from Theorem 6.9 and Lemma 4.6(1). □

7.3. Analysis of Stage 2 of FlattenNesting.

LEMMA 7.3. *Let n be the size of G_{in}. The following statements are true:*

1. *Stage* 2 *of* FlattenNesting *runs in $O(\log^2 n)$ time with $n/\log n$ processors.*

2. *G_2 has the same strongly connected components as G_1 does.*

3. *Every connected component of G_2 is an embedded canonical graph.*

Proof. The third statement is straightforward. The proofs of the other statements are detailed below.

Statement 1. Step 2-1 uses list ranking and prefix computation to process the doubly linked circular lists of the combinatorial embedding of G_1. This takes $O(\log n)$ time with $n/\log n$ processors. Step 2-2 is performed in $O(\log^2 n)$ time with $n/\log n$ processors by means of Lemma 7.1(3), Theorem 6.7, and a symmetric theorem for ContractNegative. Steps 2-3 and 2-4 are straightforward and take $O(\log n)$ time with $n/\log n$ processors. Step 2-5 is performed in $O(\log n)$ time with $n/\log n$ processors and an optimal parallel algorithm for planar biconnectivity [14]. Thus the total complexity is as stated.

Statement 2. By the second specification of vertex contraction, the dual of each edge in D_2 is in a strongly connected component of $\tilde{G}_1$. Then by Lemma 3.1 each edge in D_2 is between different strongly connected components of G_1. Therefore, G_1' and G_1 have the same strongly connected components. Next, because removing bridges does not change the strongly connected components of a directed graph, G_1' and G_2 have the same strongly connected components. Thus G_1 and G_2 have the same strongly connected components. □

LEMMA 7.4. *The following statements are true:*

1. *Every singular vertex of G_1 is isolated in G_2.*

2. *Every index-*0 *strongly connected component of G_{in} becomes compact in a connected component of G_2.*

3. *Every index-*1 *strongly connected component of G_{in} either becomes compact or has exactly one nonempty internal hole in a connected component of G_2.*

4. *Let S be an index-*1 *strongly connected component in G_{in}. Let S_2 be the version of S in G_2. Then the edges in $\mathcal{E}_{\text{in}}(S_2)$ either all point from S_2 or all point to S_2.*

Proof. The statements are shown as follows.

Statement 1. By Theorem 6.10 D_2 includes all edges in G_1 that are incident with singular vertices. Thus all singular vertices of G_1 become isolated in G_1'. Because G_2 is G_1' without its bridges, the singular vertices of G_1 remain isolated in G_2.

Statement 2. The proof readily follows from the first statement of this lemma and Lemmas 7.2(3) and 6.4.

Statement 3. The proof readily follows from the first statement of this lemma and Lemmas 7.2(4) and 6.4.

Statement 4. Because G_2 is obtained from G by edge cutting and vertex contraction, by Lemma 6.4 $\mathcal{E}_{\text{in}}(S_2) \subseteq \mathcal{E}_{\text{in}}(S)$. Note that $\mathcal{E}_{\text{in}}(S) - \mathcal{E}_{\text{ns}}(S)$ consists of the edges between S and the singular compact strongly connected components enclosed in S. By Lemma 7.2(2) and the first statement of this lemma these edges are cut in Stage 2. Thus $\mathcal{E}_{\text{in}}(S_2) \subseteq \mathcal{E}_{\text{ns}}(S)$. By Lemma 4.6(2) this statement is true. □

7.4. Analysis of Stage 3 of FlattenNesting.

LEMMA 7.5. *Let n be the size of G_{in}. The following statements are true:*

1. *Stage* 3 *of* FlattenNesting *runs in $O(\log^2 n)$ time with $n/\log n$ processors.*

2. *G_{out} has the same strongly connected components as G_2 does.*

3. *Every connected component of G_{out} is an embedded canonical graph.*

Proof. The third statement is straightforward. The proofs of the other statements are detailed below.

Statement 1. Because the contraction procedures are applied to disjoint parts of G, by Lemma 7.3(3) and Theorem 6.7 and by symmetry Steps 3-1 and 3-2 take $O(\log^2 n)$ time and $n/\log n$ processors. By Theorem 5.12 and by symmetry Step 3-3 takes $O(\log n)$ time and $n/\log n$ processors. Step 3-4 can obviously be performed in $O(\log n)$ time and with $n/\log n$ processors. Step 3-5 is performed in $O(\log n)$ time with $n/\log n$ processors by using an optimal parallel algorithm for planar biconnectivity [14]. Thus the complexity of Stage 3 is as stated.

Statement 2. The proof follows from the fact that a chamber edge in D_3 is between different strongly connected components of G_2 and that a bridge in G_2''' is between different strongly connected components of G_2. □

LEMMA 7.6. *Every index-1 strongly connected component of G_{in} becomes compact in a connected component of G_{out}.*

Proof. Let S be an index-1 strongly connected component in G_{in}. Let S_2 be the version of S in G_2. Let H_2 be the connected component of G_2 that contains S_2. Let $H_2' = \text{ContractPositive}(H_2)$. Let $H_2'' = \text{ContractNegative}(H_2')$. Let S_2' and S_2'' be the versions of S_2 in H_2' and H_2''.

To prove the lemma, by Steps 3-3 and 3-4 of FlattenNesting it suffices to show that at least one of the following statements is true:

1. S_2'' is compact in H_2''.
2. S_2' has exactly one nonempty internal hole, and this hole is a chamber in H_2'.
3. S_2'' has exactly one nonempty internal hole, and this hole is a chamber in H_2''.

For proof of this claim it suffices to show that if S_2'' is not compact in H_2'', then either the second statement or the third statement is true. Because S_2'' is not compact in H_2'' and because S is index-1, by Lemmas 7.4(3) and 6.4 S_2' and S_2'' have exactly one nonempty internal hole each. Let X' and X'' be the nonempty internal holes of S_2' and S_2''. Then by Lemma 6.11 either $\mathcal{B}(X')$ is a directed cycle or $\mathcal{B}(X'')$ is a directed cycle. Futhermore, because $\mathcal{E}_{X'}(S_2') \subseteq \mathcal{E}_{\text{in}}(S_2)$, by Lemma 7.4(4) $\mathcal{E}_{X'}(S_2')$ is unidirectional. Similarly, $\mathcal{E}_{X''}(S_2'')$ is unidirectional. Thus either X' is a chamber in H_2' or X'' is a chamber in H_2''. □

7.5. Summary analysis of FlattenNesting.

THEOREM 7.7. FlattenNesting *correctly computes an output graph as specified. It runs in $O(\log^2 n)$ time with $n/\log n$ processors for an input graph of size n.*

Proof. The complexity of FlattenNesting follows from Lemmas 7.1(1), 7.3(1), and 7.5(1). The correctness of FlattenNesting is shown as follows. Property 1 of the output follows from Lemmas 7.1(2), 7.3(2), and 7.5(2). Property 2 of the output follows from Lemma 7.5(3). Property 3 of the output follows from Theorem 4.2 and Lemmas 6.4, 7.4(2), and 7.6. Property 4 of the output follows from Lemmas 7.2(2) and 7.4(1). □

8. Computing strongly connected components.

The main results of this paper are stated in the next two theorems. One is for embedded planar graphs, and the other is for planar graphs without given embeddings.

8.1. Strongly connected components of graphs with embeddings.

THEOREM 8.1. *Let G be an embedded canonical graph. Let n be the size of G. Let α be the number of noncompact strongly connected components in G. Then Algorithm 8 correctly computes the strongly connected components of G in $O(\lceil \log_2(\alpha + 2)\rceil \cdot \log^2 n)$*

*time with $n/\log n$ processors on a deterministic arbitrary-*CRCW PRAM. *Note that because $\alpha < n$, the time complexity is $O(\log^3 n)$.*

ALGORITHM 8. *Procedure for computing the strongly connected components of an embedded planar graph.*

```
Procedure ComputeSCC
Input: an embedded canonical graph $G$.
Output: the strongly connected components of $G$.
begin
  1. repeat
         Apply FlattenNesting to each connected component of $G$.
     until every vertex in $G$ is isolated.
  2. Expand every vertex in the current $G$ into a strongly connected component of the
     initial $G$.
  3. return the strongly connected components computed above.
end.
```

Proof. The correctness of ComputeSCC is proved as follows. Because G is bridgeless, it can be input to FlattenNesting at the beginning of Step 1. Then by the second output property of FlattenNesting Step 1 can iteratively apply FlattenNesting to each connected component of its output graphs. By the first output property of FlattenNesting the strongly connected components of G remain the same throughout the iterative applications of FlattenNesting. Therefore, at the end of Step 1 every isolated vertex is indeed contracted from an original strongly connected component of G. Consequently, Step 2 can expand each isolated vertex into an original strongly connected component of G.

The complexity of ComputeSCC is analyzed as follows. Step 2 of the algorithm can be performed by tree contraction in $O(\log n)$ time with $n/\log n$ processors. Thus it suffices to show that Step 1 takes $O(\lceil\log_2(\alpha+2)\rceil\cdot\log^2 n)$ time with $n/\log n$ processors.

By the third output property of FlattenNesting, within $\lceil\log_2(\alpha/2+1)\rceil$ iterations of FlattenNesting at Step 1 the strongly connected components of G all become compact in their respective connected components of the current G. The absence of noncompact strongly connected components ensures that all strongly connected components of G are singular in their respective connected components. Thus by the fourth output property of FlattenNesting, with one more application of FlattenNesting the strongly connected components of G all become isolated vertices. Therefore, the repeat loop of Step 1 iterates at most $\lceil\log_2(\alpha+2)\rceil$ times.

Because at each iteration of the repeat loop at Step 1 FlattenNesting is applied to disjoint parts of G, the connected components of G at each iteration of the repeat loop can be computed in $O(\log n)$ with $n/\log n$ processors [14]. Similarly, by Theorem 7.7 the body of the repeat loop takes $O(\log^2 n)$ time and $n/\log n$ processors. Checking the termination condition of the repeat loop takes only $O(\log n)$ time and $n/\log n$ processors. Thus each iteration of the repeat loop takes $O(\log^2 n)$ time and $n/\log n$ processors, and the complexity of Step 1 is as desired. □

8.2. Strongly connected components of graphs without embeddings.

THEOREM 8.2. *Let G be a planar directed graph of size n. Then Algorithm 9 correctly computes the strongly connected components of G in $O(\log^3 n)$ time with $n/\log n$ processors on a deterministic arbitrary-*CRCW PRAM.

ALGORITHM 9. *Procedure for computing the strongly connected components of a planar directed graph.*

```
Procedure ComputeStronglyConnectedComponents
Input: a planar directed graph $G$.
Output: the strongly connected components of $G$.
begin
    1. Delete all bridges from $G$.
    2. Compute a planar embedding for each connected component of $G$.
    3. Compute the strongly connected components of $G$ by applying the procedure in
       Algorithm 8 to each connected component of $G$.
    4. return the strongly connected components computed above.
end.
```

Proof. The correctness of Algorithm 9 follows from Theorem 8.1 and the fact that a strongly connected component contains no bridges. The complexity of the algorithm is analyzed as follows. Step 1 takes $O(\log n)$ time and $n/\log n$ processors when an optimal parallel algorithm for planar biconnectivity is used [14]. Step 2 takes $O(\log n \log\log n)$ time and $n/\log n$ processors [24]. Because ComputeSCC is applied to disjoint parts of G, by Theorem 8.1 Step 3 takes $O(\log^3 n)$ time and $n/\log n$ processors. Thus the total complexity is as stated. □

9. Open problems. This paper has shown that for a planar directed graph of size n the strongly connected components can be computed in $O(\log^3 n)$ time with $n/\log n$ processors. A subsequent paper will show that given a strongly connected planar directed graph of size n, a directed spanning tree rooted at a specified vertex can be built in $O(\log^2 n)$ time with $n/\log n$ processors. There are several fundamental problems left open in this paper. Perhaps the most important is to efficiently compute planar breadth-first search. Currently, the best algorithm for this problem is given by Pan and Reif [23]. Their algorithm computes the shortest paths in $O(\log^2 n)$ time with $n^{1.5}/\log n$ processors for undirected planar graphs. The algorithm is based on matrix operations and uses a randomized planar separator algorithm given by Gazit and Miller [10]. It would be significant to reduce to linear the processor complexity of planar breadth-first search.

Acknowledgments. The author wishes to thank Philip Klein, Gary Miller, Vijaya Ramachandran, and Greg Shannon for many helpful discussions and suggestions and to thank Fang Wan for helping to prepare some of the figures.

LINEAR-PROCESSOR NC ALGORITHMS FOR PLANAR DIRECTED GRAPHS II: DIRECTED SPANNING TREES*

MING-YANG KAO† AND GREGORY E. SHANNON‡

Abstract. It is a fundamental open problem whether polylogarithmic time and a *linear* number of processors are sufficient for computing the strongly connected components of a directed graph and constructing directed spanning trees for these components. This paper provides the first nontrivial partial solution to the tree problem: for a strongly connected planar directed graph of size n a directed spanning tree rooted at a specified vertex can be computed in $O(\log^2 n)$ time with $n/\log n$ processors. This result complements an algorithm by Kao that computes the strongly connected components of a planar directed graph in $O(\log^3 n)$ time with $n/\log n$ processors. Both algorithms run on a deterministic parallel random-access machine that permits concurrent reads and concurrent writes in its shared memory and, in case of a write conflict, allows an arbitrary processor to succeed.

Key words. linear-processor NC algorithms, directed spanning trees, strong connectivity, planar directed graphs, planar orientation, vertex expansion, vertex contraction, edge cutting, tree rerooting, duplicate removal

1. Introduction.

The problems of finding directed spanning trees and strongly connected components frequently appear in more complex problems involving directed graphs. In sequential computation both problems have optimal linear-time algorithms [2], [10]. In parallel computation on a parallel random-access machine (PRAM), the best algorithms for these two problems are based on matrix multiplication and require $O(\log^2 n)$ time and $n^{2.376}$ processors for an n-vertex directed graph [8], [12], [17].

The work of an algorithm can be estimated by the product of its time and processor complexities. Thus there is a substantial gap between the work done by the above sequential and parallel algorithms. In light of the gap it is a fundamental problem whether the strongly connected components and their directed spanning trees can be computed in polylogarithmic time with a *linear* number of processors.

This paper offers the first nontrivial partial solution to the spanning-tree problem: for a strongly connected planar directed graph of size n, a directed spanning tree rooted at a given vertex can be computed in $O(\log^2 n)$ time with $n/\log n$ processors. This result complements an algorithm by Kao that computes the strongly connected components of a planar directed graph in $O(\log^3 n)$ time with $n/\log n$ processors [18]. Both algorithms run on a deterministic PRAM that allows concurrent reads and concurrent writes (CRCW) in its shared memory and, in case of a write conflict, permits an arbitrary processor to succeed.

An insight used in the tree algorithm is as follows. A *cycle* face of the input graph is one whose boundary forms a directed cycle. A *positive* face is a cycle face whose boundary cycle runs clockwise. If the graph has only one positive face and its maximum degree is at most three, then a directed spanning tree is obtained by deleting a boundary

*Received by the editors April 4, 1990; accepted for publication (in revised form) February 26, 1992. An extended abstract of this work appeared as one of the two parts of *Local Reorientation, Global Order, and Planar Topology*, in Proc. 21st Annual Association for Computing Machinery Symposium on Theory of Computing, Seattle, Washington, May 15–17, 1989, pp. 286–296.

edge of the positive face and the *first* edge of each *positive segment* (a maximal clockwise-directed boundary path of a noncycle face); see Fig. 1.

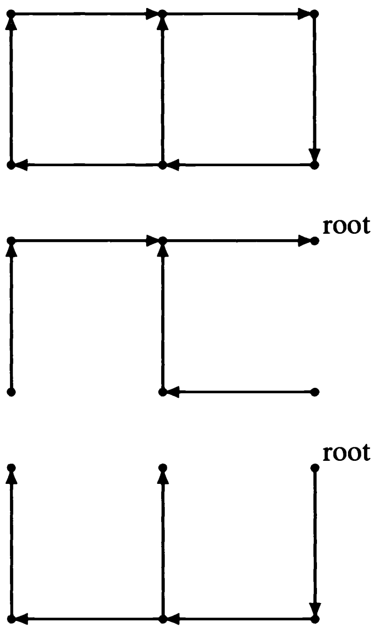

FIG. 1. *CD-pair of spanning trees obtained by edge cutting.*

The correctness of the technique derives from a fundamental orientation property: if an embedded planar directed graph is strongly connected, then its dual directed graph is acyclic. This acyclicity induces a partial order on the faces of the primal graph. This order, in turn, induces an ear decomposition for the primal graph with the boundary of the positive face being the first ear and the positive segments being the remaining ears. Then, for computation of a directed spanning tree for the primal graph, it suffices to remove an edge of the first ear and the first edge of each remaining ear.

A directed tree is *convergent* (respectively, *divergent*) if each edge points from a vertex to its parent (respectively, child). A *CD-pair* of spanning trees is a convergent spanning tree and a divergent spanning tree with the same root. The spanning tree constructed above is convergent. A divergent spanning tree can be computed by deleting a boundary edge of the positive face and the *last* edge of each positive segment. These two spanning trees form a CD-pair of spanning trees if the two boundary edges deleted from the positive face are chosen appropriately (see Fig. 1).

It is efficient to *reroot* this CD-pair, i.e., to compute another CD-pair of spanning trees rooted at a specified vertex. Therefore, the edge-cutting technique in effect computes a spanning tree with a specified direction and a specified root.

The edge-cutting technique fails in two cases. If the maximum degree of the input graph is four or greater, then the edge-cutting technique may produce a subgraph containing directed cycles (see Fig. 2). If the graph has two or more positive faces, then the edge-cutting technique may produce a CD-pair of spanning *forests* by deleting an appropriate pair of boundary edges of each positive face and the first and the last edge of each positive segment. (A CD-pair of spanning forests is a convergent spanning forest and a divergent spanning forest with the same roots.) (See Fig. 3.)

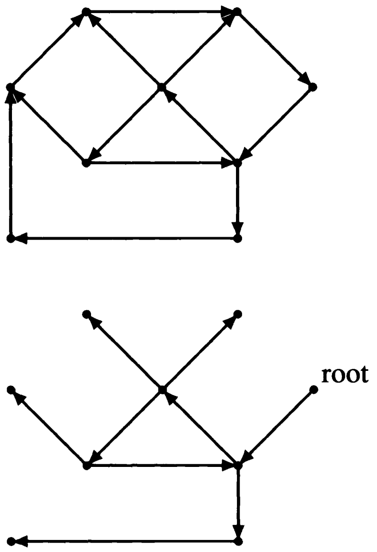

FIG. 2. *Effect of large-degree vertices on edge cutting.*

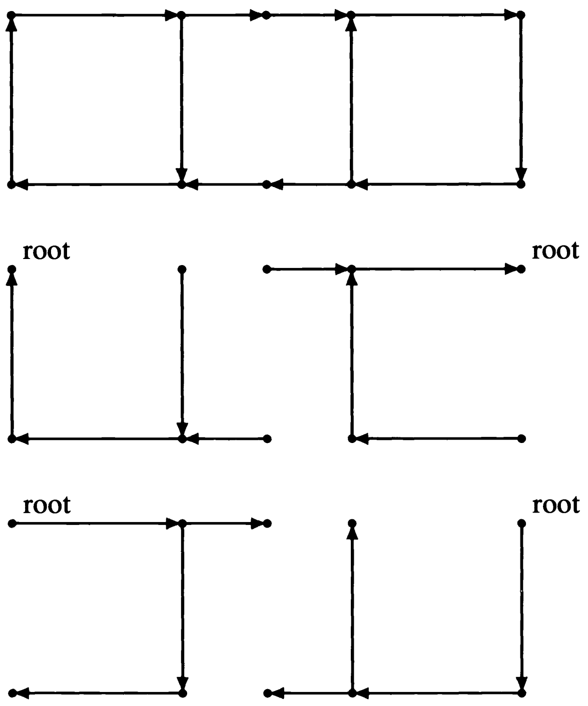

FIG. 3. *Effect of multiple positive faces on edge cutting.*

The tree algorithm resolves these two difficult cases by reducing the input graph to one with exactly one positive face and a maximum degree at most three.

Reducing the number of positive faces is coupled with merging the CD-pair of spanning forests produced by the edge-cutting technique. Let T_1 and T_2 be two disjoint divergent trees. Let $d = u_1 \rightarrow u_2$ be a directed edge from T_1 to T_2. Merging T_2 and T_1

through d involves two cases. If u_2 is the root of T_2, then a larger divergent tree is readily formed by d, T_1, and T_2. Otherwise, merging T_2 to T_1 through d requires changing the root of T_2 to u_2.

A key property of the CD-pair of spanning forests produced by the edge-cutting technique is that the boundary of each positive face is covered by a unique convergent tree and a unique divergent tree. These trees cover different vertices but share a well-structured neighborhood of that positive face. Their common root and opposite orientations may be used to reroot them efficiently at any vertex in the shared neighborhood. Moreover, this neighborhood can be contracted to reduce by half the number of positive faces. Of course, vertex contraction may produce large-degree vertices, and the two difficult cases of the edge-cutting technique must be resolved in concert.

To remove large-degree vertices, the spanning-tree algorithm expands them each into a cycle face (see Fig. 4). Let G be the input graph. Let G' be obtained from G by expanding the large-degree vertices into cycle faces. The tree algorithm first computes a spanning tree T' for G'. Then the problem is that T' contains several duplicates for each large-degree vertex of G. The tree algorithm uses a duplicate-removal technique to convert T' into a spanning tree of G.

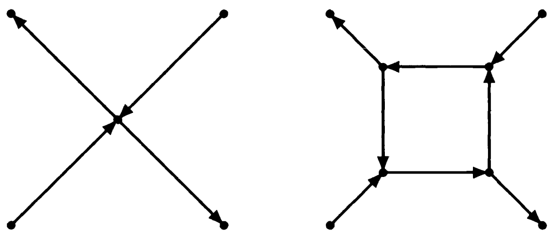

FIG. 4. *Example of expanding a large-degree vertex into a negative face.*

This paper is organized as follows. Section 2 gives basics of planar directed graphs and CD-pairs of trees, and §3 describes the orientation structure of primal and dual planar directed graphs. Section 4 presents the vertex expansion technique, §5 discusses the vertex-contraction technique, §6 analyzes the edge-cutting technique, and §7 elaborates on the techniques of tree rerooting and duplicate removal. Section 8 uses the preceding techniques to design the directed spanning tree algorithm, and §9 concludes with open problems.

2. Basics of planar directed graphs and CD-pairs of trees.

The following definitions and facts are useful.

2.1. CD-pairs of trees and forests.

A *divergent* (respectively, *convergent*) tree is a directed tree in which every edge points from a vertex to its child (respectively, parent). A *divergent* (respectively, *convergent*) forest is a directed forest in which every tree is divergent (respectively, convergent).

A CD-pair of trees is a convergent tree and a divergent tree with the same root. A CD-pair of spanning trees for a directed graph G is a CD-pair of trees that are also spanning trees of G.

A *covering* tree of a vertex subset U is a tree of G that contains at least the vertices in U. A CD-pair of covering trees for U is a CD-pair of trees that are also covering trees of U.

A CD-pair of forests is a convergent forest and a divergent forest with the same roots. A CD-pair of spanning forests for G is a CD-pair of forests that are also spanning forests of G.

2.2. Normal graphs. A *planar* directed graph is one that can be embedded on a sphere such that in the embedding the edges intersect only at common endpoints [5], [6], [15], [24]. An *embedded* planar directed graph is one with a given spherical embedding.

A *normal* graph is a planar directed graph that is strongly connected, has at least two vertices and may have multiple edges but has no loop edges.

Note that both multiple edges and loop edges can be deleted to simplify a strongly connected directed graph without affecting the existence of directed spanning trees. In this paper, however, the multiple edges created by vertex contraction must be kept in order to manage contraction invariants. For this reason most discussions in this paper focus on normal graphs.

2.3. Combinatorial embeddings and data structures. Let G be a normal graph. Algorithmically, a spherical embedding of G is encoded by the clockwise cyclic order of the edges incident with each vertex. Such an encoding is called a *combinatorial* spherical embedding of G. Topologically, a spherical embedding is uniquely specified by its corresponding combinatorial embedding.

The cyclic edge incidence in a combinatorial embedding is further encoded by the following data structure: for each vertex there is a doubly linked circular list consisting of the edges incident with that vertex in the clockwise order.

Given a normal graph of size n, a combinatorial spherical embedding can be computed in $O(\log n)$ time with $n \log\log n/\log n$ processors on a deterministic arbitrary-CRCW PRAM [26].

2.4. Faces, boundaries, orientations, cycle faces, subfaces, and clusters. Let G be an embedded normal graph. If the vertices and edges of G are deleted from its embedding sphere, then the sphere is divided into disconnected regions. Each region is called a *face* of G.

Let f be a face of G. The *boundary* of f, denoted by $\mathcal{B}(f)$, is the set of edges and vertices surrounding f. $\mathcal{B}(f)$ can be arranged into a unique edge-simple undirected cycle by having an observer stay inside f and walk around $\mathcal{B}(f)$ once. This cycle is called the *boundary* cycle of f. A *boundary* path of f is a subpath of its boundary cycle.

Let d be a boundary edge of f. The *orientation* of d with respect to f is defined as follows: the edge d is *positive* (respectively, *negative*) with respect to f if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of f with respect to an observer standing inside f.

A face is called a *cycle* face if its boundary cycle is a directed cycle. A cycle face f is called a *positive* (respectively, *negative*) face if every boundary edge of f is positive (respectively, negative) with respect to f.

A *subface* of a face f is a vertex-simple undirected subcycle of the boundary cycle of f. The boundary cycle of f can be partition into subfaces. Furthermore, if f is a cycle face, then its subfaces are all directed cycles.

Two positive (respectively, negative) faces g_1 and g_2 of G are *linked* if there is a sequence of positive (respectively, negative) faces $f_1, \ldots, f_s$ such that $g_1 = f_1$, $g_2 = f_s$, and for $1 \leq i \leq s-1$, f_i and f_{i+1} share at least one boundary vertex.

A *positive* (respectively, *negative*) *cluster* of G is the set of boundary cycles of a maximal family of linked positive (respectively, negative) faces.

The planar directed spanning tree algorithm is described mainly in terms of positive faces and clusters. By symmetry the algorithm can also be described by using mainly the negative orientation.

LEMMA 2.1. *Let G be an embedded normal graph of size n. The following can be computed in $O(\log n)$ time with $n/\log n$ processors:*

1. *the boundary cycles of the faces,*
2. *the boundary cycles of the positive faces,*
3. *the positive clusters, and*
4. *the subfaces of the positive faces.*

Proof. The boundary cycles of the faces can be computed by tracing the doubly linked circular lists of the combinatorial embedding of G. This is done by list ranking [3], [8], [16] in $O(\log n)$ time with $n/\log n$ processors. Next it is straightforward to determine the boundary cycles of the positive faces in $O(\log n)$ time with $n/\log n$ processors. Then the positive clusters can be computed in $O(\log n)$ time with $n/\log n$ processors by using an optimal parallel algorithm for planar connectivity [15].

To compute the subfaces of the positive faces, observe that the subfaces of a face f are just the biconnected components of $\mathcal{B}(f)$. Similarly, the subfaces of G are the face boundaries of the subgraphs that are induced by the biconnected components of G. On the basis of these observations the subfaces of G can be computed in a straightforward manner in $O(\log n)$ time with $n/\log n$ processors. This computation uses optimal algorithms for planar connectivity [15], planar biconnectivity [15], list ranking [3], [8], [16], and prefix computation [21], [22]. $\square$

2.5. Holes, boundaries, and orientations. Let G be an embedded normal graph. Let B be a connected subgraph of G with at least two vertices. If the vertices and edges of B are removed from the embedding sphere of G, then the sphere is divided into disconnected regions. Each region is called a *hole* of B.

Let X be a hole of B. The *boundary* of X, denoted by $\mathcal{B}(X)$, is the set of vertices and edges surrounding X. $\mathcal{B}(X)$ can be arranged into a unique undirected cycle by having an observer stay inside X and walk around $\mathcal{B}(X)$ exactly once. This cycle is called the *boundary* cycle of X. It may not be edge-simple.

Let d be a boundary edge of X. The *orientation* of d with respect to X is defined as follows: the edge d is *positive* (respectively, *negative*) with respect to X if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of X with respect to an observer standing inside X.

3. Planar orientation. This section describes orientation structures of primal and dual planar directed graphs.

3.1. Dual planar directed graphs. Let G be an embedded normal graph. The *dual* of G, denoted by $\tilde{G}$, is the embedded normal graph constructed below:

• For each face f in G there is a vertex, denoted by $\tilde{f}$, in $\tilde{G}$ that corresponds to f. The vertex $\tilde{f}$ is called the *dual* of f.

• For each edge d in G there is an edge, denoted by $\tilde{d}$, in $\tilde{G}$ that corresponds to d. The edge $\tilde{d}$ is called the *dual* of d and is determined as follows. Let f_1 and f_2 be the two faces in G that share d as a boundary edge. If d is positive (respectively, negative) with respect to f_1, then $\tilde{d}$ is a directed edge from $\tilde{f}_1$ to $\tilde{f}_2$ (respectively, from $\tilde{f}_2$ to $\tilde{f}_1$).

• The spherical embedding of $\tilde{G}$ is derived from that of G as follows. For each face f of G the vertex $\tilde{f}$ is placed inside f. For each edge d of G the edge $\tilde{d}$ is obtained by turning d counterclockwise 90°.

Note that the dual of the dual of G is the same as G with all edge directions reversed. Consequently, each vertex in G also corresponds to a face in $\tilde{G}$. In particular, a source (respectively, sink) in $\tilde{G}$ corresponds to a positive (respectively, negative) cycle face in G.

3.2. Primal-dual orientations. The following theorem is crucial to the planar directed spanning-tree algorithm.

THEOREM 3.1. *Let G be an embedded normal graph. Then $\tilde{G}$ is acyclic. Consequently, G has at least one positive face and one negative face.*

Proof. For a detailed proof, see the companion paper on computing planar strongly connected components [18]. □

4. Vertex expansion. The planar directed spanning-tree algorithm is sensitive to vertices of degree greater than three. For this reason such vertices are called the *large-degree* vertices.

A useful operation for eliminating large-degree vertices is to replace them each by a positive face or a negative face, as shown in Fig. 4. This operation is called *vertex expansion*.

In another important application vertex expansion is used to destroy cycle faces and may apply to vertices of degree two. Moreover, for technical uniformity, if the graph in question consists of a single vertex, then this vertex is expanded into a cycle face with two boundary edges.

The procedure in Algorithm 1 details how to expand vertices of degree two or more into negative faces.

ALGORITHM 1. *Procedure for expanding vertices into negative faces.*

```
Procedure ExpandVertex
Input: an embedded normal graph $G$ and a set $U$ of vertices.
Output: $G$ with each vertex in $U$ expanded into a negative face.
begin
    for each vertex $v \in U$ do
        begin
            1. Let $d_1, \dots, d_s$ be the edges incident with $v$ in the counterclockwise order.
            2. Create $s$ copies of $v$, namely, $v_1, \dots, v_s$.
            3. Replace the $v$-end of each $d_i$ by $v_i$.
            4. Link the vertices $v_i$ into a counterclockwise directed cycle, i.e., $v_1 \rightarrow v_2 \rightarrow \cdots \rightarrow v_{s-1} \rightarrow v_s \rightarrow v_1$.
        end.
    return $G$ with the above changes.
end.
```

The procedure for expanding vertices into positive faces can be obtained by symmetry.

THEOREM 4.1. *The following statements are true:*

1. *The output graph of* ExpandVertex *is an embedded normal graph.*

2. ExpandVertex *runs in $O(\log n)$ time with $n/\log n$ processors for an input graph of size n.*

Proof. The first statement is straightforward. As for the second statement, ExpandVertex can be done in a straightforward manner with fundamental techniques, including prefix computation [21], [22] and list ranking [3], [8], [16]. □

5. Vertex contraction. Throughout this paper vertex contraction always satisfies the following specifications:

• Vertex contraction keeps all multiple edges and deletes all loop edges that it creates.

• Vertex contraction contracts only connected vertex subsets of an embedded normal graph.

Contracting only connected vertex subsets preserves planarity. Deleting all loop edges simplifies a contracted graph. Keeping all multiple edges maintains crucial contraction invariants. In particular, each uncontracted edge keeps a unique identity because its link remains unchanged although its endpoints may be altered by contraction.

5.1. Spherical embeddings induced by vertex contraction. Let G be an embedded normal graph. Let B be the subgraph induced by a connected vertex subset of G. Let G' be the graph constructed from G by contracting B into a vertex B'. If B consists of at most one vertex, then G' and G are the same. If B consists of all the vertices of G, then G' is a single vertex. Otherwise, a spherical embedding for G' is specified as follows:

• For every vertex $v \notin B$ the clockwise cyclic order of the edges incident with v is the same in G and G'.

• The edges around each nonempty hole X of B stay together around B', and their clockwise cyclic order around B' is the same as their cyclic order around the boundary cycle of X in the negative direction of X.

In general, such a spherical embedding is not unique. For the purposes of this paper any spherical embedding that fits this construction is suitable.

THEOREM 5.1. *Given an embedded normal graph of size n, a spherical embedding induced by contracting a disjoint family of connected vertex subsets can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The edges around a new vertex of G' are collected by processing the doubly linked circular lists of the combinatorial embedding of G. The computation takes $O(\log n)$ time and $n/\log n$ processors, using optimal parallel algorithms for list ranking [3], [8], [16], prefix computation [21], [22], tree contraction [1], [10], [13], [18], [21], and planar connectivity [15]. □

5.2. Contraction invariants. Let G be an embedded normal graph. Let G' be a contracted version of G. Let f' be a face in G'. Let P' be a boundary path of f' whose internal vertices are original vertices in G.

LEMMA 5.2. *P' originally is a boundary path of a face f in G, and each edge of P' has the same orientation with respect to f and f'.*

Note. This lemma is false if multiple edges created by contractions are not kept.

Proof. Vertex contraction can be done by performing a sequence of contracting a nonloop edge and deleting a loop edge. The proof of the lemma is by straightforward induction and is based on direct observations about the effects of deleting a loop edge and contracting a nonloop edge. □

6. Edge cutting. Section 6.1 describes a procedure, called CutSegment, for the edge-cutting technique. Section 6.2 uses CutSegment to find a CD-pair of spanning trees for a positive cluster.

Section 6.3 uses CutSegment to compute a CD-pair of spanning forests for an embedded normal graph with no large-degree vertices. Section 6.4 uses these forests to find key neighborhoods of positive faces called *biconnected territories*. These neighborhoods are contracted in the planar directed spanning tree algorithms.

6.1. CutSegment. The procedure CutSegment is detailed in Algorithm 2, which is based on a generalization of the standard ear decomposition [23].

ALGORITHM 2. *Procedure for edge cutting.*

```
Procedure CutSegment
Input:
    1. a directed graph $G$,
    2. a symbolic parameter $x$ = "first" or "last,"
    3. the set $\Pi$ of ears in a multihead ear decomposition of $G$. Remark: The partial
       order of the decomposition is not part of the input.
Output: $G$ without the $x$ edge of each path in $\Pi$.
begin
    1. Delete from $G$ the $x$ edge of each path in $\Pi$.
    2. return the resulting $G$.
end.
```

Let G be a directed graph. An *ear* of G is an internally vertex-simple directed path, i.e., the internal vertices appear only once in the path. A *decomposition* of G is a partition of its edges into ears. An *ordered* decomposition is one whose ears are arranged into a partial order. A *head* is an ear that is a minimal element in the partial order. A *multihead ear decomposition* of G is an ordered decomposition with the following properties:

• The endpoints of each head are the same. Two distinct heads may not intersect at all.

• The endpoints of each nonhead ear must be in some smaller ears, but its internal vertices may not be in any smaller or incomparable ears.

Remark. A standard ear decomposition is a multihead ear decomposition with a total order [23].

THEOREM 6.1. *Let n be the size of G. Let G_c =* CutSegment(G, first, Π). *Also, let G_d =* CutSegment(G, last, Π). *Then the following statements are true:*

1. CutSegment *runs in $O(\log n)$ time with $n/\log n$ processors.*
2. *G_c and G_d form a* CD*-pair of spanning forests for G with the properties below:*
(a) *The vertices of each head are in exactly one tree in each forest.*
(b) *In each forest each tree contains the vertices of exactly one head.*
(c) *Each tree is rooted at the endpoint of its corresponding head.*

Proof. The first statement is straightforward. The second statement is proved by induction on the partial order of the ears. The idea is to add to an initially empty graph the ears one by one, starting with the heads. □

6.2. Computing spanning trees for positive clusters. Algorithm 3 is a procedure ComputeClusterSegments that computes the ears in a one-head ear decomposition for a positive cluster Φ.

ALGORITHM 3. *Procedure for computing an ear decomposition with one head for each positive cluster.*

```
Procedure ComputeClusterSegments
Input: a positive cluster $\Phi$ of an embedded normal graph $G$ that may have large-degree
vertices. Remark: $G$ is not part of the input.
Output: the set $\Pi$ of ears in a multihead ear decomposition of $\Phi$ with only one head.
begin
    1. Compute an auxiliary graph $\Phi'$ for $\Phi$ as follows:
        1-1. Let $\Gamma$ be the set of subfaces of the faces in $\Phi$.
        1-2. Let $U$ be the set of vertices shared by cycles in $\Gamma$.
        1-3. $\Phi'$ is the connected planar undirected graph defined below:
            • The vertex set of $\Phi'$ consists of the vertices in $U$ and the cycles in $\Gamma$ with
              each cycle treated as a single vertex.
            • For $C \in \Gamma$ and $u \in U$ there is an undirected edge in $\Phi'$ between $C$ and
              $u$ if and only if $u$ is a vertex in $C$.
    2. Impose a total order on the cycles in $\Gamma$ as follows:
      2-1. Compute an arbitrary undirected spanning tree $T$ of $\Phi'$.
      2-2. Compute a preorder numbering of $T$. Remark: This preorder numbering
           naturally induces a total order on the cycles in $\Gamma$.
    3. Use the above total order to construct $\Pi$:
      3-1. Compute the *breakpoints* of each cycle in $\Gamma$ defined as follows:
            • For the cycle with the smallest preorder number the *breakpoint* of that
              cycle is an arbitrary vertex in it.
            • For each other cycle the *breakpoints* are the vertices shared by that cycle
              and those with smaller preorder numbers.
           Remark: A breakpoint is defined with respect to a cycle. A vertex may be a
           breakpoint for a cycle but not for another.
      3-2. Compute the *segments* of each cycle $C$ in $\Gamma$ defined as follows:
            • If $C$ has only one breakpoint, then the *segment* of $C$ is the directed sub-
              path of $C$ from that breakpoint to itself.
            • If $C$ has two or more breakpoints, then a *segment* of $C$ is the directed
              subpath of $C$ between two consecutive breakpoints.
      3-3. Let $\Pi$ be the set of segments computed above.
    4. **return** $\Pi$.
**end**.
```

Based on Theorem 6.1, this procedure and CutSegment together can compute a CD-pair of spanning trees for Φ.

THEOREM 6.2. *Let n be the size of Φ. Then the procedure in Algorithm* 3 *correctly computes an output as specified in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The correctness of the procedure is shown as follows. Because the cycles in Γ are vertex-simple, the segments are internally vertex-simple. By the construction of Φ' and by the preorder of T, every cycle in Γ except the smallest-numbered one shares a vertex with a smaller-numbered cycle. Thus every cycle in Γ has at least one breakpoint and is partioned into segments, i.e., Π is a decomposition of Φ.

Π is an ordered decomposition with respect to the following partial order $\prec$: for $L_1, L_2 \in \Pi$ that are, respectively, segments of $C_1, C_2 \in \Gamma$, $L_1 \prec L_2$ if and only if the preorder number of C_1 is smaller than that of C_2.

The segment of the smallest-numbered cycle in Γ is the only head. Thus the first property for a multihead ear decomposition is satisfied. Because the preorder on Γ is a total order, by the choice of the breakpoints the second property for a multihead ear decomposition is also satisfied.

As for the complexity of the procedure, it suffices to show that Steps 1-1 through 3-3 each take $O(\log n)$ time with $n/\log n$ processors. By Lemma 2.1, Step 1-1 runs within the desired complexity. Step 1-2 is obvious. Step 1-3 is also straightforward; it need not compute a combinatorial embedding of Φ'. By the planarity of Φ', Step 2-1 uses an optimal algorithm for planar connectivity [15]. Because the size of Φ' is $O(n)$, Step 2-1 runs within the desired complexity. Step 2-2 uses the Euler tour [4]. Steps 3-1 through 3-3 are straightforward. $\square$

THEOREM 6.3. *For an embedded normal graph of size n, a CD-pair of spanning trees for each positive cluster can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The procedure in Algorithm 4 computes a CD-pair of spanning trees for each positive cluster within the desired complexity.

ALGORITHM 4. *Procedure for computing a* CD-*pair of spanning trees for each positive cluster.*

```
Procedure ComputeClusterCDTrees
Input: an embedded normal graph $G$.
Output: a CD-pair of spanning trees for each positive cluster of $G$.
begin
    1. Compute the positive clusters of $G$.
    2. for each positive cluster $\Phi$ do
          begin
             2-1. Let $\Pi$ = ComputeClusterSegments($\Phi$).
             2-2. Let $\Phi_c$ = CutSegment($\Phi$, first, $\Pi$).
             2-3. Let $\Phi_d$ = CutSegment($\Phi$, last, $\Pi$).
          end.
    3. return $\Phi_c$ and $\Phi_d$ for each $\Phi$.
end.
```

The correctness and the complexity of the procedure follow from Lemma 2.1 and Theorems 6.1 and 6.2. □

6.3. Computing spanning forests for embedded normal graphs. The procedure ComputePositiveSegments in Algorithm 5 computes a useful set of ears for an embedded normal graph without large degree vertices.

ALGORITHM 5. *Procedure for computing the ears in an ear decomposition for an embedded normal graph.*

```
Procedure ComputePositiveSegments
Input: an embedded normal graph $G$ with no large-degree vertices.
Output: the set $\Pi$ of ears in a multihead ear decomposition of $G$. Remark: The partial
order of the decomposition is not part of the output.
begin
    1. Compute the boundary cycles of the faces of $G$ and those of the positive faces.
       Remark: Because $G$ has no large-degree vertices, these cycles are vertex-simple.
    2. Compute the *breakpoints* of each face of $G$ defined as follows:
          • For a positive face the *breakpoint* of that face is an arbitrary boundary vertex
            of that face. A negative face has no breakpoint.
          • For a noncycle face the *breakpoints* of that face are the local sources and
            sinks on its boundary cycle.
       Remark: A breakpoint is defined with respect to a face. A vertex may be a break-
       point for a face but not for another.
    3. Compute the *positive segments* of each face $f$ of $G$ defined as follows:
          • If $f$ has only one breakpoint, then the *segment* of $f$ is the directed boundary
            path of $f$ from that breakpoint to itself.
          • If $f$ has two or more breakpoints, then a *segment* is the directed boundary
            path of $f$ between two consecutive breakpoints.
          • A *positive* segment of $f$ is one whose edges are all positive with respect to $f$.
    4. Let $\Pi$ be the set of positive segments computed above.
    5. return $\Pi$.
end.
```

Based on Theorem 6.1, this procedure and CutSegment together compute a useful CD-pair of spanning forests.

THEOREM 6.4. *The following statements are true:*

1. *For an input graph of size n the procedure in Algorithm 5 runs in $O(\log n)$ time with $n/\log n$ processors.*

2. *The output of the procedure consists of the ears in a multihead ear decomposition whose heads are exactly the segments of the positive faces of G.*

Proof. The two statements are proved as follows.

Statement 1. By Lemma 2.1, Step 1 takes $O(\log n)$ time with $n/\log n$ processors. Then Steps 2–4 can be done in a straightforward manner in $O(\log n)$ time on $n/\log n$ processors. Thus the total complexity is as stated.

Statement 2. Because the boundary cycles of the faces of G are vertex-simple, the positive segments are internally vertex-simple. Because an edge is positive on exactly one face, the positive segments partition the edges of G. Thus Π is a decomposition of G.

As for a suitable partial order on Π, by Theorem 3.1 $\tilde{G}$ is acyclic and can be regarded as a partial order $\prec_f$ on the faces of G with the positive faces being the minimal elements. The order $\prec_f$ induces the following partial order $\prec_s$ on Π: let f_1 and f_2 be two faces. Let L_1 and L_2 be two positive segments of f_1 and f_2, respectively. Then $L_1 \prec_s L_2$ if and only if $f_1 \prec_f f_2$.

Because the positive faces are the minima in $\prec_f$, their segments are the heads. Because a positive face has only one breakpoint, the two endpoints of a head are the same. Because G has no large-degree vertex, no two positive faces share a boundary vertex. Thus, the heads are disjoint, satisfying the first property for a multihead ear decomposition.

As for the second property of a multihead ear decomposition, let L_1 be a nonhead ear. Let L_2 be a distinct segment intersecting L_1 at a vertex v. There are two cases: (1) v is an endpoint of L_1 or (2) v is an internal vertex of L_1. These two cases are symmetric. Case (1) leads to the first half of the second property. Case (2) leads to the second half of that property. Only Case (1) is discussed below.

Let f_1 be the face of which L_1 is a positive segment. By definition v is a source or a sink of $\mathcal{B}(f_1)$; by symmetry assume that v is a source. By the strong connectivity and the degree condition of G the degree of v is three. Let w_1, w_2, w_3 be the vertices incident with v in the clockwise order. Assume that $w_1, w_2 \in \mathcal{B}(f_1)$ but $w_3 \notin \mathcal{B}(f_1)$. Then the edges incident with v are $d_1 = v \rightarrow w_1$, $d_2 = v \rightarrow w_2$, $d_3 = w_3 \leftarrow v$. Because $d_1, d_2 \in \mathcal{B}(f_1)$, L_1 is the positive segment of f_1 that contains d_1. Let f_2 be the face whose boundary contains d_2 and d_3. Then L_2 is the positive segment of f_2 that contains d_2 and d_3. Notice that $f_2 \prec_f f_1$. Thus $L_2 \prec_s L_1$. □

THEOREM 6.5. *The following statements are true:*

1. *For an input graph of size n the procedure in Algorithm 6 runs in $O(\log n)$ time with $n/\log n$ processors.*

2. *The output G_c and G_d of the procedure form a* CD*-pair of spanning forests for G with the following properties:*

(a) *For each positive face the boundary vertices of that face are contained in exactly one tree in each forest.*

(b) *In each forest each tree contains the boundary vertices of exactly one positive face.*

(c) *Each tree is rooted at the breakpoint of its corresponding positive face.*

ALGORITHM 6. *Procedure for computing a* CD*-pair of spanning forests for an embedded normal graph.*

```
Procedure ComputeCDForests
Input: an embedded normal graph $G$ with no large-degree vertices.
Output: a CD-pair of spanning forests $G_c$ and $G_d$ for $G$.
begin
    1. Let $\Pi$ = ComputePositiveSegments($G$).
    2. Let $G_c$ = CutSegment($G$, first, $\Pi$).
    3. Let $G_d$ = CutSegment($G$, last, $\Pi$).
    4. return $G_c$ and $G_d$.
end.
```

Proof. The theorem follows from Theorems 6.1 and 6.4. Note that the partial orders $\prec_f$ and $\prec_s$ are implicit and require no computation at all. □

THEOREM 6.6. *Given an embedded normal graph of size n with exactly one positive face and no large-degree vertices, a CD-pair of spanning trees can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. This a corollary of Theorem 6.5. Because the given graph has exactly one positive face, there is only one tree in each of G_c and G_d. □

6.4. Biconnected territories. Let G be an embedded normal graph with no large-degree vertices. A *biconnected territory* of a positive face of G is a vertex subset as defined by the procedure in Algorithm 7.

ALGORITHM 7. *Procedure for computing the biconnected territories.*

```
Procedure ComputeBiconnectedTerritories
Input: an embedded normal graph $G$ with no large-degree vertices.
Output: the biconnected territories of $G$.
begin
    1. Let $\Pi$ = ComputePositiveSegments($G$).
    2. Let $G_c$ = CutSegment($G$, first, $\Pi$).
    3. Let $G_d$ = CutSegment($G$, last, $\Pi$).
    4. for each positive face $f$ of $G$ do
        begin
            4-1. Let $\mathcal{C}_c(f)$ be the connected component in $G_c$ that contains the boundary vertices of $f$.
            4-2. Let $\mathcal{C}_d(f)$ be the connected component in $G_d$ that contains the boundary vertices of $f$.
            4-3. Let $\mathcal{S}(f)$ be the subgraph of $G$ induced from the vertices shared by $\mathcal{C}_c(f)$ and $\mathcal{C}_d(f)$.
            4-4. Let $\mathcal{BT}(f)$, the biconnected territory of $f$, be the biconnected component in $\mathcal{S}(f)$ that contains $\mathcal{B}(f)$.
        end.
    5. return all $\mathcal{BT}(f)$ computed above.
end.
```

6.4.1. Computing biconnected territories. The next theorem analyzes the procedure in Algorithm 7.

THEOREM 6.7. *The following statements are true:*

1. *$\mathcal{C}_c(f)$, $\mathcal{C}_d(f)$, and $\mathcal{BT}(f)$ exist.*

2. *The subgraphs $\mathcal{C}_c(f)$, $\mathcal{C}_d(f)$, and $\mathcal{BT}(f)$ for distinct positive faces are respectively disjoint.*

3. *Let n be the size of G. The biconnected territories of G can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The statements are proved as follows.

Statement 1. The existence of $\mathcal{C}_c(f)$ and $\mathcal{C}_d(f)$ follows from Theorem 6.5(2a). The existence of $\mathcal{BT}(f)$ derives from that of $\mathcal{C}_c(f)$ and $\mathcal{C}_d(f)$ and the fact that $\mathcal{B}(f)$ is biconnected because G has no large-degree vertices.

Statement 2. The disjointness of $\mathcal{C}_c(f)$'s and the $\mathcal{C}_d(f)$'s follows from Theorem 6.5(2b). The disjointness of $\mathcal{BT}(f)$'s follows from that of $\mathcal{C}_c(f)$'s and $\mathcal{C}_d(f)$'s.

Statement 3. The complexity of the procedure in Algorithm 7 is analyzed as follows. Steps 1 through 3 are performed by means of Theorem 6.5(1). Step 4 is started by computing the positive faces of G via Lemma 2.1. Steps 4-1 through 4-4 can be computed in $O(\log n)$ time with $n/\log n$ processors by using the second statement of this theorem and optimal parallel algorithms for planar connectivity and biconnectivity [15]. Thus the biconnected territories can be computed with the stated complexity. □

6.4.2. Contracting biconnected territories. Contracting biconnected territories is a key step in reducing the number of positive faces.

Let G be an embedded normal graph with no large-degree vertices. Let G' be the graph constructed from G by contracting each biconnected territory into a vertex.

Because G has no large-degree vertices, its positive faces have disjoint boundaries. The contraction of the biconnected territories may create large-degree vertices in G'. Thus positive faces in G' may cluster together. The next two propositions relate the number of positive clusters in G' to that of positive faces in G.

LEMMA 6.8. *Let f be a noncycle face in G. Let P be a directed boundary path of f that has at least two edges and consists of positive edges of f. If the endpoints of P are in biconnected territories of G but its internal vertices are not, then the endpoints of P are in different biconnected territories.*

Proof. Let $P = p_1, \ldots, p_s$. To prove by contradiction, assume that p_1 and p_s are in the same biconnected territory $\mathcal{BT}(f)$. It suffices to show that $P \subseteq \mathcal{BT}(f)$, contradicting the condition that the internal vertices of P are not in any biconnected territory.

Note that P is a subpath of a positive segment Q of f. Let $Q = q_1, \ldots, q_t$. After the first edge of Q is cut, the subpath $Q' = q_2, \ldots, q_t$ remains in G_c. Because the path $P_c = p_2, \ldots, p_s$ is a subpath of Q', the path P_c is connected to p_s in G_c. Because $p_s \in \mathcal{BT}(f) \subseteq \mathcal{C}_c(f)$, the path P_c is in $\mathcal{C}_c(f)$. On the other hand, because $p_1 \in \mathcal{BT}(f) \subseteq \mathcal{C}_c(f)$, p_1 is also in $\mathcal{C}_c(f)$. Thus P is in $\mathcal{C}_c(f)$. By symmetry P is also in $\mathcal{C}_d(f)$. Thus P is in $\mathcal{S}(f)$. By the proof assumption P is connected to $\mathcal{BT}(f)$ at both p_1 and p_s. Because G has no large-degree vertex, the union of P and $\mathcal{BT}(f)$ is biconnected in $\mathcal{S}(f)$. Consequently, P lies in $\mathcal{BT}(f)$. □

THEOREM 6.9. *The number of positive clusters in G' is at most half the number of positive faces in G.*

Proof. It suffices to show that the boundary of each positive face in G' contains at least two contracted biconnected territories of G. To prove by contradiction, assume that there is a positive face f' in G' whose boundary contains at most one contracted biconnected territory of G. If $\mathcal{B}(f')$ contains no contracted biconnected territory of G, then f' is a positive face in G, contradicting the fact that every positive face of G is contracted in G'. Thus, without loss of generality, assume that $\mathcal{B}(f')$ contains exactly one vertex v' that is a contracted biconnected territory of G. Let P' be a vertex-simple directed boundary path of f' from v' to v' with at least one edge. By Lemma 5.2 P' is originally a positive boundary path P of a noncycle face in G such that the two endpoints of P are in biconnected territories of G but its internal vertices are not. Because G' has no loop edges, P has at least two edges. By Lemma 6.8 the endpoints of P are in different biconnected territories of G, contradicting the proof assumption that $\mathcal{B}(f')$ contains only one contracted biconnected territory of G. □

7. Tree rerooting and duplicate removal.

7. Tree rerooting and duplicate removal. Tree rerooting and duplicate removal are useful techniques for computing directed spanning trees. When they are used together, duplicate removal provides crucial flexibility to tree rerooting so that forests can be merged efficiently. These two techniques are detailed in §§7.1 and 7.2. Their combination and applications are described in §§7.3 and 7.4.

7.1. Tree rerooting. The procedure in Algorithm 8 describes the technique of changing the roots of trees and the next theorem analyzes the procedure.

ALGORITHM 8. *Procedure for changing the root of a* CD*-pair of trees.*

```
Procedure RerootCDTrees
Input:
    1. a CD-pair of trees $T_c$ and $T_d$ of a directed graph $G$ (remark: $G$ is not part of the
       input),
    2. the common root $r$ of the two trees,
    3. a vertex $r'$ shared by the two trees.
Output: a CD-pair of trees $T'_c$ and $T'_d$ of $G$ with the following properties:
    1. $T'_c$ and $T'_d$ are both rooted at $r'$.
    2. $T'_c$ and $T'_d$ share at least the vertices originally shared by $T_c$ and $T_d$.
    3. $T'_c$ and $T'_d$ together contain at most the vertices originally contained in $T_c$ and $T_d$
       together.
begin
    1. Compute $T'_c$ as follows:
        1-1. Let $P_d$ be the tree path in $T_d$ from $r$ to $r'$.
        1-2. Let $T'_c$ be $T_c$ with $P_d$ added.
        1-3. For every vertex $v \in T'_c$, if $v$ has two outgoing edges, delete the one not in
             $P_d$. Also, delete from $T'_c$ the outgoing edge of $r'$.
    2. Compute $T'_d$ symmetrically.
    3. return $T'_c$ and $T'_d$.
end.
```

THEOREM 7.1. *Let n_c and n_d be the numbers of vertices in T_c and T_d. The procedure in Algorithm* 8 *correctly computes an output as specified in $O(\log(n_c+n_d))$ time with $(n_c+n_d)/\log(n_c+n_d)$ processors.*

Proof. The correctness of the procedure is straightforward. As for the complexity, the key fact is that P_d can be computed in the desired complexity by using tree contraction [1], [10], [13], [18], [21]. □

7.2. Duplicate removal. The procedure in Algorithm 9 describes the technique for removing duplicates from a tree and the next theorem analyzes the procedure.

ALGORITHM 9. *Procedure for removing the duplicates from a tree.*

```
Procedure RemoveDuplicates
Input:
    1. a directed graph $G$,
    2. a directed spanning tree $T$ of $G$,
    3. disjoint vertex subsets $U_1, \dots, U_s$ of $G$,
    4. the directed graph $G'$ constructed from $G$ by contracting each $U_i$ into a vertex.
```

```
Output: a directed spanning tree $T'$ of $G'$ with the same orientation and root as those of $T$.
begin
  1. For all $i$ let $u_i$ be the highest vertex of $U_i$ in $T$; if there are two vertices or more
     at the same smallest depth, choose one of them arbitrarily.
  2. For all $i$ delete from $T$ all edges between the vertices in $U_i - \{u_i\}$ and their parents.
  3. Construct $T'$ from the above $T$ by contracting $U_i$ into $u_i$.
  4. return $T'$.
end.
```

THEOREM 7.2. *The procedure in Algorithm 9 correctly computes an output as specified in $O(\log n)$ time with $n/\log n$ processors for an input graph of size n.*

Proof. The correctness of the procedure is straightforward. As for the complexity, the key fact is that the representatives u_i can be found in $O(\log n)$ time with $n/\log n$ processors by using tree contraction [1], [10], [13], [18], [21]. □

7.3. Combining tree rerooting and duplicate removal. The procedure in Algorithm 10 combines the techniques of tree rerooting and duplicate removal and the next theorem analyzes the procedure.

ALGORITHM 10. *Procedure for combining the techniques of tree rerooting and duplicate removal.*

```
Procedure RerootAndRemoveDuplicates
Input:
  1. a strongly connected directed graph $G$,
  2. disjoint vertex subsets $U_1, \dots, U_s$ of $G$,
  3. a CD-pair of forests for $G$ that consists of a CD-pair of covering trees $S_{i,c}$ and
     $S_{i,d}$ for each $U_i$,
  4. the directed graph $G'$ constructed from $G$ by contracting each $U_i$ into a supervertex $u'_i$,
  5. a CD-pair of spanning trees $T'_c$ and $T'_d$ for $G'$.
Output: a CD-pair of spanning trees $T_c$ and $T_d$ for $G$.
begin
  1. Compute $T_c$ as follows:
    1-1. Find a local root $r_i$ for each $U_i$:
           • For each supervertex $u'_i$, if $u'_i$ is the root of $T'_c$, then let $r_i$ be an arbitrary
             vertex in $U_i$.
           • Otherwise, let $d'$ be the outgoing edge of $u'_i$ in $T'_c$. Let $d$ be the original
             of $d'$ in $G$. Let $r_i \in U_i$ be the start vertex of $d$.
    1-2. For each $u'_i$ apply the procedure in Algorithm 8 to $S_{i,c}$ and $S_{i,d}$ to find a
         convergent tree $R_i$ of $G$ covering $U_i$ and rooted at $r_i$.
    1-3. Create duplicates to prepare for expanding $u'_i$ in $T'_c$ into $R_i$:
         For each vertex $v$ in $G$ replace each occurrence of $v$ in the trees $R_i$ with a
         distinct duplicate of $v$. Also collect the duplicates for $v$.
    1-4. Undo the contractions in $T'_c$ by expanding each $u'_i$ into $R_i$:
           • For each edge $d' \in T'_c$ let $d = v \to w$ be its original in $G$. If $v$ is in some
             $U_i$, then replace the $v$-end of $d$ by the duplicate of $v$ for $R_i$. Perform the
             same replacement to the $w$-end. Let $T''_c$ be the resulting $T'_c$.
           • Let $T_c$ be the tree formed by $T''_c$ and all trees $R_i$. Remark: The dupli-
             cates prevent cycles from being created in $T_c$; in fact, $T_c$ is a convergent
             spanning tree of $G$ with duplicates.
    1-5. Use the procedure in Algorithm 9 to remove duplicates from $T_c$.
  2. Compute $T_d$ symmetrically. To maintain the same root for $T_c$ and $T_d$, if the root
     of $T'_c$ and $T'_d$ is a supervertex $u'_i$, then choose the same $r_i$ for $U_i$ at Step 1-1 for
     both $T_c$ and $T_d$.
  3. return $T_c$ and $T_d$.
end.
```

THEOREM 7.3. *Let n be the size of G. Then the procedure in Algorithm* 10 *correctly computes an output as specified in $O(\log n)$ time with $n/\log n$ processors.*

Proof. The correctness of the procedure is analyzed as follows. First, the procedure in Algorithm 8 can be used at Step 1-2 because $r_i \in U_i \subseteq S_{i,c} \cap S_{i,d}$. Next, at Step 1-4, T_c is a convergent spanning tree of G with duplicates. This tree property follows from the creation of duplicates, the choice of r_i, and the fact that R_i covers U_i and is rooted at r_i. After the duplicates are removed at Step 1-5, the resulting T_c is a convergent spanning tree of G. By symmetry T_d found by Step 2 is a divergent spanning tree of G. If the root of T'_c and T'_d is a supervertex u'_i, then by the choice of r_i at Step 2, T_c and T_d have the same root. If the root of T'_c and T'_d is not a supervertex u'_i, then T_c, T_d, T'_c, and T'_d all have the same root.

As for the complexity, by symmetry it suffices to show that Steps 1-1–1-5 each take $O(\log n)$ time with $n/\log n$ processors. Step 1-1 is straightforward. By Theorem 7.1, Step 1-2 takes $O(\log n)$ time with $n/\log n$ processors. Because the trees $S_{i,c}$'s and the trees $S_{i,d}$'s are respectively disjoint, by the third output property in Algorithm 8 each vertex of G has at most three copies in T'_c and the trees R_i. Thus Steps 1-3 and 1-4 each take $O(\log n)$ time with $n/\log n$ processors. Then by Theorem 7.2, Step 1-5 takes $O(\log n)$ time with $n/\log n$ processors. □

7.4. Applications of tree rerooting and duplicate removal. Four applications are given below.

7.4.1. Changing the root of a CD-pair of spanning trees. Let G be a strongly connected directed graph of size n.

COROLLARY 7.4. *Given a* CD*-pair of spanning trees for G, a* CD*-pair of spanning trees for G rooted at a specified vertex can be computed in $O(\log n)$ time with $n/\log n$ processors.*

Proof. This is a straightforward corollary of Theorem 7.1. □

7.4.2. Undoing vertex expansion. Let G be an embedded normal graph of size n. Let G' be constructed from G by replacing some vertices each with a positive face or a negative face.

COROLLARY 7.5. *A* CD*-pair of spanning trees for G can be computed in $O(\log n)$ time with $n/\log n$ processors given G, G', and a* CD*-pair of spanning trees for G'.*

Proof. This is a corollary of Theorem 7.2 with G and G' in reversed roles. The key observation is that for each expanded vertex of G there is a U_i consisting of the vertices of the corresponding cycle face in G'. As for the complexity, note that the size of G' is at most $5n$. □

7.4.3. Undoing the contraction of biconnected territories. Let G be an embedded normal graph without large-degree vertices. Let n be the size of G. Let G' be the graph constructed by contracting each biconnected territory of G into a vertex. Let G_c and G_d be the graphs constructed by removing, respectively, the first edge and the last edge of each positive segment of G.

COROLLARY 7.6. *A* CD*-pair of spanning trees for G can be computed in $O(\log n)$ time with $n/\log n$ processors given G, its biconnected territories, G_c, G_d, G', and a* CD*-pair of spanning trees for G'.*

Proof. This is a corollary of Theorem 7.3 with each U_i being a biconnected territory. By the definition of a biconnected territory and by Theorem 6.5, G_c and G_c consist of a CD-pair of covering trees for each U_i. □

7.4.4. Undoing the contraction of positive clusters. Let G be an embedded normal graph of size n. Let G' be the graph constructed by contracting each positive cluster of G into a vertex.

COROLLARY 7.7. *A* CD*-pair of spanning trees for G can be computed in $O(\log n)$ time with $n/\log n$ processors given G, its positive clusters, a* CD*-pair of spanning trees for each positive cluster of G, the graph G', and a* CD*-pair of spanning trees for G'.*

Proof. This is a corollary of Theorem 7.3 with each U_i consisting of the boundary vertices of a positive cluster. □

8. Computing directed spanning trees. Section 8.1 gives a directed spanning tree algorithm for normal graphs without large-degree vertices, and §8.2 generalizes this algorithm for normal graphs that may have large-degree vertices.

8.1. Spanning trees for graphs without large-degree vertices. Algorithm 11 describes a directed spanning-tree algorithm for embedded normal graphs without large-degree vertices, and the algorithm is analyzed below.

ALGORITHM 11. *Procedure for computing* CD*-pairs of spanning trees for graphs with no large-degree vertex.*

```
Procedure ComputeCDT
Input: an embedded normal graph $G$ without large-degree vertices.
Output: a CD-pair of spanning trees for $G$.
begin
  if $G$ has exactly one positive face
    then $\Upsilon \leftarrow$ CutSegment($G$)
    else
      begin
        Stage 1:
          1-1. Let $G_c$ be the graph constructed by deleting the first edge of each
               positive segment of $G$.
          1-2. Let $G_d$ be the graph constructed by deleting the last edge of each
               positive segment of $G$.
          1-3. Find the biconnected territories of $G$ from $G_c$ and $G_d$.
          1-4. Construct $G_1$ from $G$ by contracting each biconnected territory
               into a single vertex.
        Stage 2:
          2-1. Compute the positive clusters of $G_1$.
          2-2. Compute a CD-pair of spanning trees for each positive cluster of
               $G_1$.
          2-3. Construct $G_2$ from $G_1$ by contracting each positive cluster into a
               single vertex.
        Stage 3:
          3-1. Construct $G_3$ from $G_2$ by expanding into a positive face each con-
               tracted positive cluster of $G_1$. Remark: As stated in §4, for techni-
               cal uniformity, if $G_2$ is a single vertex, it is expanded into a positive
```

```
            face with two boundary edges. Also, if a contracted positive clus-
            ter of $G_1$ is of degree two in $G_2$, it is also expanded into a positive
            face with two boundary edges.
        3-2. Construct $G_4$ from $G_3$ by expanding each large-degree vertex into
            a negative face.
      Stage 4:
        4-1. $\Upsilon_4 \leftarrow$ ComputeCDT($G_4$).
        4-2. Compute from $\Upsilon_4$ a CD-pair $\Upsilon_3$ of spanning trees for $G_3$ via Corol-
            lary 7.5.
        4-3. Compute from $\Upsilon_3$ a CD-pair $\Upsilon_2$ of spanning trees for $G_2$ via Corol-
            lary 7.5.
        4-4. Compute a CD-pair $\Upsilon_1$ of spanning trees for $G_1$ via Corollary 7.7
            from $\Upsilon_2$, the positive clusters of $G_1$, and the CD-pairs of spanning
            trees computed at Step 2-2.
        4-5. Compute a CD-pair $\Upsilon$ of spanning trees for $G$ via Corollary 7.6
            from $\Upsilon_1$, $G_c$, $G_d$, and the biconnected territories of $G$.
    end.
  return $\Upsilon$.
end.
```

LEMMA 8.1. *Let n be the size of G. Let n_i be the size of G_i for $i \in \{1,2,3,4\}$. Let β and β_4 be the numbers of positive faces in G and G_4. Then the following statements are true:*

1. *G_4 is an embedded normal graph without large-degree vertices.*
2. *$\beta_4 \leq \beta/2$.*
3. *$n_i \leq n$ for $i \in \{1,2,3,4\}$.*

Proof. The statements are shown below.

Statement 1. Step 3-1 ensures that G_4 contains at least two vertices. Next, because G_4 is obtained from G by vertex expansion and vertex contraction, G_4 remains an embedded normal graph. Step 3-2 ensures that G_4 has no large-degree vertices.

Statement 2. Let β_1 (respectively, β_3) be the number of positive clusters (respectively, faces) in G_1 (respectively, G_3). By Theorem 6.9, $\beta_1 \leq \beta/2$. Step 2-3 destroys the positive faces of G_1 but may create new positive faces in G_2. Next, because the boundary of each positive face in G_2 must contain at least one contracted positive cluster of G, Step 3-1 destroys all positive faces of G_2. Thus $\beta_3 = \beta_1$. Step 3-2 cannot destroy or create positive faces, and so $\beta_4 = \beta_3$. In sum, the statement is true.

Statement 3. Because vertex contraction does not increase the size of a graph, $n_2 \leq n_1 \leq n$. Also, $n_2 \leq n_3 \leq n_4$ because vertex expansion does not decrease the size of a graph. It remains to show $n_4 \leq n$.

Note that G_4 is in effect expanded from G_2. Also, G_2 is in effect contracted from G. Let u be a vertex of G_2 that is expanded in G_4. Let U be the connected vertex subset of G that is contracted into u.

U is shown to be biconnected in G as follows. A vertex in G_2 can be expanded at most once either at Step 3-1 or Step 3-2. Thus there are two cases based on which step expands u.

- Case (1): u is expanded at Step 3-1. Then u is contracted from a positive cluster of G_1 that contains contracted biconnected territories of G. Thus by the small degree of G the set U is biconnected in G.
- Case (2): u is expanded at Step 3-2. Then u is a contracted biconnected territory of G. Thus U is biconnected.

The biconnectivity of U is used to estimate the change from n to n_4 as follows. For an edge (respectively, vertex) set X let $|X|$ be the number of edges (respectively, vertices) in X. Let D_b (respectively, D_o) be the set of edges in G with both endpoints (respectively, only one endpoint) in U. By the small degree of G and the biconnectivity of U, $|D_o| \leq |D_b|$ and $|D_o| \leq |U|$. The contraction of U loses U and D_b, gains u, and keeps D_o. The expansion of u keeps D_o, loses u, and gains $|D_o|$ new edges and $|D_o|$ new vertices. Thus in the conversion from G to G_4 the net gain concerning U is $2|D_o| - |U| - |D_b|$, which is at most zero by the above two inequalities. Therefore, $n_4 \leq n$. □

THEOREM 8.2. *Let G be an embedded normal graph without large-degree vertices. Let n be the size of G. Let β be the number of positive faces in G. Then Algorithm* 11 *computes a* CD*-pair of spanning trees for G in $O(\lceil\log(\beta+1)\rceil \log n)$ time using $n/\log n$ processors on a deterministic arbitrary*-CRCW PRAM.

Proof. By Lemma 8.1(1), Step 4-1 can recurse on G_4. Then the correctness of the algorithm follows from Theorem 6.6 and Corollaries 7.5, 7.6, and 7.7.

As for the complexity, by Lemma 8.1(2) the recursion depth is $\lceil\log(\beta+1)\rceil$. Thus it suffices to show that each stage runs in $O(\log n)$ time with $n/\log n$ processors. By Lemma 8.1(3) the size of the graph processed by each step at each level of recursion is at most n. Based on this bound, the desired complexity for the stages follows from the implementation below.

The if-condition is tested by means of Lemma 2.1(1). The then-statement is performed by means of Theorem 6.1(1). Stage 1 is done by means of Theorems 6.1(1), 6.7(3), and 5.1. Stage 2 is done by means of Lemma 2.1(3) and Theorems 6.3 and 5.1. Stage 3 is performed by means of Theorem 4.1(2). Stage 4 is performed by means of Corollaries 7.5, 7.6, and 7.7. □

8.2. Spanning trees for graphs with large-degree vertices. Algorithm 12 describes a directed spanning-tree algorithm for embedded normal graphs that may have large-degree vertices, and the algorithm is analyzed below.

ALGORITHM 12. *Procedure for computing a* CD*-pair of spanning trees.*

```
Procedure ComputeCDTrees
Input: an embedded normal graph $G$.
Output: a CD-pair of spanning trees for $G$.
begin
    Stage 1:
      1-1. Compute the positive clusters of $G$.
      1-2. Compute a CD-pair of spanning trees for each positive cluster of $G$.
      1-3. Construct $G_1$ from $G$ by contracting each positive cluster into a single
           vertex.
      1-4. Construct $G_2$ from $G_1$ by expanding into a positive face each contracted
           positive cluster of $G$. Remark: As stated in §4, for technical uniformity, if
           $G_1$ is a single vertex, it is expanded into a positive face with two boundary
           edges. Also, if a contracted positive cluster of $G$ is of degree two in $G_1$,
           it is also expanded into a positive face with two boundary edges.
      1-5. Construct $G'$ from $G_2$ by expanding each large-degree vertex into a neg-
           ative face.
    Stage 2:
      2-1. $\Upsilon' \leftarrow$ ComputeCDT($G'$).
      2-2. Compute a CD-pair $\Upsilon_2$ of spanning trees for $G_2$ via Corollary 7.5 from
           $\Upsilon'$.
```

```
        2-3. Compute a CD-pair $\Upsilon_1$ of spanning trees for $G_1$ via Corollary 7.5 from
             $\Upsilon_2$.
        2-4. Compute a CD-pair $\Upsilon$ of spanning trees for $G$ via Corollary 7.7 from $\Upsilon_1$,
             the positive clusters of $G$, and the CD-pairs of spanning trees computed
             at Step 1-2.
    return $\Upsilon$.
end.
```

LEMMA 8.3. *Let n, n_1, n_2, and n' be the sizes of G, G_1, G_2, and G'. The following statements are true:*

1. *G' is an embedded normal graph without large-degree vertices.*
2. *The number of positive faces in G' equals that of positive clusters in G.*
3. $n'/5 \le n_2 \le n_1 \le n$.

Proof. The third statement is straightforward. As for the other two statements, note that Stage 1 of Algorithm 12 combines Stages 2 and 3 of Algorithm 11. Thus the proof for the first statement is similar to that for Lemma 8.1(1). The proof for the second statement is similar to that for Lemma 8.1(2). □

THEOREM 8.4. *Let G be an embedded normal graph. Let n be the size of G. Let β be the number of positive clusters in G. Then Algorithm 12 computes a* CD*-pair of spanning trees for G in $O(\lceil \log(\beta+1) \rceil \log n)$ time with $n/\log n$ processors on a deterministic arbitrary-*CRCW PRAM. *Consequently, by Corollary* 7.4 *a* CD*-pair of spanning trees rooted a specified vertex can be computed with the same complexity.*

Proof. The proof is similar to that of Theorem 8.2. The key points are as follows. By Lemma 8.3(1), Step 2-1 may apply ComputeCDT to G'. The cost of this step dominates the complexity of the algorithm. By Lemmas 8.3(2) and 8.3(3) this step takes $O(\lceil \log(\beta+1) \rceil \log n)$ time with $n/\log n$ processors. □

THEOREM 8.5. *For a normal graph of size n without a given embedding, a* CD*-pair of spanning trees rooted at a specified vertex can be computed in $O(\log^2 n)$ time with $n/\log n$ processors on a deterministic arbitrary-*CRCW PRAM.

Proof. To use Theorem 8.2, a spherical embedding for the input graph is first computed in $O(\log n \log\log n)$ time with $n/\log n$ processors [26]. The complexity follows from the fact that there are at most n positive clusters in the input graph with any embedding. □

9. Open problems. This paper has shown that for a strongly connected planar directed graph of size n, a directed spanning tree rooted at a specified vertex can be computed in $O(\log^2 n)$ time with $n/\log n$ processors. This result complements the linear-processor NC algorithm by Kao for computing the strongly connected components of a planar directed graph [18]. There are several fundamental problems left open in this paper. Perhaps the most important one is to compute planar breadth-first search trees efficiently. Currently, the best algorithm for this problem is by Pan and Reif [25]. Their algorithm computes the shortest paths in undirected planar graphs in $O(\log^2 n)$ time with $n^{1.5}/\log n$ processors. The algorithm is based on matrix operations and uses an almost optimal randomized algorithm for planar separators of Gazit and Miller [11]. Reducing to linear the processor complexity of planar breadth-first search would be of significant impact.

Acknowledgments. The authors thank Fang Wan for helping to prepare some of the figures. M.-Y. Kao gratefully acknowledges Philip Klein, Gary Miller, and Vijaya Ramachandran for many helpful discussions and suggestions.

BLOCKING SMALL CUTS IN A NETWORK, AND RELATED PROBLEMS*

DANIEL BIENSTOCK† AND NICOLE DIAZ†

Abstract. Let G be a graph with weights on the edges, S a subset of vertices, and k an integer. The problem of computing a minimum-weight subset of edges that meets all the cuts of cardinality $\leq k$ that separate pairs of vertices in S is considered. This problem is motivated by issues in network survivability. Assuming $|S| = 2$, it is shown that although this problem is NP-hard, it can be solved in linear time for each fixed value of k. Furthermore, if $|S| > 2$, the problem is NP-hard even for small values of k but can be solved in linear time for each fixed k and $|S|$.

Introduction. An increasingly important issue in communications networks design in the problem of building "survivability" into networks. Typically one wants to meet connectivity requirements between various pair of nodes. Such requirements are usually fairly small, as we are trying to guard against the unlikely (but not impossible) event of connection failures due to external factors. From a mathematical point of view, the problem can be stated as follows: Given a graph G, we want to add edges to G so that in the resulting graph, the edge connectivity between each pair i, j of vertices is at least a given number $r(i, j)$ (usually $r(i, j) \leq 3$, and possibly $r(i, j) = 0$). Moreover, each candidate edge has a certain cost associated with it, and we want to add to G a minimum-cost set of edges that is feasible in the above sense. This model has been considered by many authors, see [MMP], [BBM] for the cases $r(i, j) = 2$, and $r(i, j) = k$, respectively. Grötschel and Monma [GM] consider a cutting-plane algorithm for the case where $r(i, j)$ is of the form $\min\{r_i, r_j\}$. If in addition we have constant edge-costs, the problem is polynomially solvable (see [F]).

In order for the addition of an edge to be meaningful from a faulty-tolerance point of view, the geometrical layout of this edge must be physically diverse from the rest of the network. In some practical settings this requirement may make the addition of edges prohibitively expensive. On the other hand, the following may be possible: By paying a certain cost, we may be able to "reinforce" an existing edge, so as to make it immune to the type of damage under consideration. (See [C] for a different approach.)

In this new model (reinforcing existing edges instead of adding edges), the survivability problem can be stated as follows. We are given a graph G, a subset $S \subseteq V(G)$, and a weight function w on $E(G)$. We wish to find a minimum-weight subset of $E(G)$, whose contraction yields a graph with desired connectivity levels between vertices of S. Equivalently, we seek a minimum-weight subset $Z \subseteq E(G)$ such that $Z \cap C \neq \emptyset$ for every "small" cut C separating members of S. In the case where the $r(i, j)$ are equal to a constant k (for pairs i, j in S), we denote the problem by $P_w(S, G)$, and its value by $\tau_w(S, G)$. This paper begins the study of such problems, and we will primarily concentrate on the case $|S| = 2$. The case $|S| > 2$, which is substantially more intractable, will be considered in a future paper [BD]. However, the case $|S| = 2$ is already quite difficult and interesting from a theoretical point of view. Moreover, we expect that studying this special case will give insights useful for the general case.

Hence, given vertices s and t and a positive integer k, we want to block all s–t cuts of cardinality $\leq k$. We abbreviate, e.g., $P_w(\{s,t\},G)$ as $P_w(s,t,G)$. Not surprisingly, this class of problems is NP-hard (shown in §1) even when $w(e) = 1$ for all e. However, the proof produces values of k that grow with $|V(G)|$, and as stated above, we are mainly concerned in those cases where k is small. The main result of this paper, given in §2, is that for each fixed value of k there is a linear-time algorithm for the problem. The proportionality constant grows rapidly with k, of course, but for $k \leq 5$ the algorithm should be useful.

Sections 3 and 4 consider some related aspects of the problem. Viewed as an integer program, $P_w(s,t,G)$ is a set-covering problem. We expect that a cutting-plane algorithm will yield good computational results, especially when generalized for the case $|S| > 2$, and some initial computational experience suggests that this is the case [BD]. However, as shown in §3, there is a serious technical difficulty here in that solving the linear-programming relaxation of this set-covering problem turns out to be NP-hard. In §4 we return to the general case $|S| > 2$ and show that $P_w(S,G)$, is NP-hard already for $k = 8$ (although it is linear-time solvable for fixed k and fixed $|S|$).

The graphs we consider in this paper have no loops but may have parallel edges (all results are easily extended to simple graphs). If A is a set and f is a function from A to the reals, then for $X \subseteq A$, we write $f(X)$ or $\sum\{f(i) : i \in X\}$ to indicate the sum of values of f over X. We use the following notation, corresponding to a graph G. If $X, Y \subseteq V(G)$, then $\delta_G(X,Y)$ denotes the set of edges with one end in X the other in Y. We denote $\delta_G(X, V(G)\backslash X)$ by $\delta_G(X)$, and $d_G(X) = |\delta_G(X)|$ (if $X = \{u\}$ we write $\delta_G\{u\}$, etc.). For $X, Y \subseteq V(G)$, $\lambda_G(X,Y)$ denotes the maximum number of edge-disjoint paths from X to Y. A cut is a set of the form $\delta_G(X)$. A cut $\delta_G(X)$ *separates* vertex subsets A and B or is an A–B cut if (say) $A \subseteq X$ and (say) $B \subseteq V(G)\backslash X$. A *small* cut is one with at most k edges. If D is a digraph and $X \subseteq V(D)$, we write $\delta_D^+(X)$ for the set of edges with tail in X and head in $V(D)\backslash X$, and $d_D^+(X) = |\delta_D^+(X)|(\delta_D^-(X)$ and $d_D^-(X)$ are defined in a similar way). We say a set Z of edges is a *dicut* if for some $X, Z = \delta_D^+(X)$, and $\delta_D^-(X) = \emptyset$.

1. Blocking small cuts separating two vertices is NP-hard.

In this section we show that the problem $P_w(s,t,G)$ is NP-hard, even if $w(e) = 1$ for every edge e. More precisely, we show that the recognition problem: Given G, s, t, k, and $r \geq 0$, is $\tau_1(s,t,G) \leq r$?, is NP-complete.

The reduction is from the Steiner tree problem on graphs, defined as follows. Let H be a graph and $Z \subseteq V(H)$. A tree in H that spans Z (possibly together with other vertices) is called a *Steiner tree for* Z. Let n be an integer. Does H contain a Steiner tree for Z with at most n edges? This problem is NP-hard [GJ1]. We denote such an instance of the Steiner tree problem by (H, Z, n).

LEMMA 1.1. *The recognition version of the small cut blocking problem in* NP-*complete, even if all weights are polynomially bounded.*

Proof. Consider an instance (H, Z, n) of the Steiner tree problem. We next construct a problem $P_w(s,t,G)$. The graph G is defined by $V(G) = V(H) \cup \{t\}$, where t is a new vertex and $E(G)$ consists of $E(H)$, together with $u*$ copies of the edge $\{t, z\}$ (for each $z \in Z$), where $u* = |E(H)| + 1$.

Define w by

$$w(e) = 1 \text{ if } e \in E(H), \qquad w(e) = n + 1 \text{ otherwise.}$$

Set

$$k = u * |Z| - 1.$$

Finally, choose $s \in Z$ arbitrarily. Now consider the following three facts:

(i) $u * |Z| > k$. Consequently, if $\delta_G(X)$ is a cut separating s and t, with $d_G(X) \le k$, it must be the case that $(V(G) \backslash X) \cap Z \neq \emptyset$.

(ii) Suppose $Y \subseteq V(H)$ is such that $Y \cap Z \neq \emptyset$ and $(V(G) \backslash Y) \cap Z \neq \emptyset$. Without loss of generality, assume $s \in Y$. Then $\delta_G(Y)$ separates s from t and $d_G(Y) \le |E(H)| + |Y|u* \le |E(H)| + (|Z| - 1)u* = k$.

(iii) If $S \subseteq E(G)$ is such that $w(S) \le n$, then $S \subseteq E(H)$.

From (i) to (iii) we deduce that $\tau_w(s, t, G) \le n$ if and only if H contains a Steiner tree for Z with at most n edges. This concludes the proof. □

LEMMA 1.2. *The small cut blocking problem is* NP*-complete even with unit costs.*

Proof. Consider an instance $P_w(s, t, G)$, where $w(e) > 0$ for every $e \in E(G)$. Construct a new graph G' as follows. Every edge $e = \{x, y\} \in E(G)$ is replaced by a path $p(e)$ with ends x and y of length $w(e)$, with internal vertices not in $V(G)$. Further, for each pair $e \neq e'$, the set of internal vertices of $p(e)$ is disjoint from the corresponding set for $p(e')$. It is seen that $\tau_w(s, t, G) = \tau_1(s, t, G')$, which concludes the proof. □

We remark that the case $k = \lambda_G(s, t)$ can be solved in polynomial time. The algorithm makes use of a min–max relation and is sketched in §3.

2. The case of fixed k.

In this section we study the problems $P_w(s, t, G)$ in the case when k is fixed and show that there is a linear-time algorithm for such problems, i.e., an algorithm with complexity $O(|E(G)|)$. The constant in this $O(\,)$ is, in the worst case, a doubly exponential function of k. Hence, for $k \ge 10$ this algorithm may not be useful from a practical point of view. But, as stated before, in practice one would not be interested in such relatively high values of k. For $k \le 5$, we expect the algorithm to be computationally practicable.

2.1. Preliminaries.

We use the following terminology. If G is a graph, a *separation in* G is a triple $\{A, B, X\}$, where A and B are subgraphs of G such that $V(A) \cup V(B) = V(G), X = V(A) \cap V(B), E(A) \cap E(B) = \emptyset$, and $E(A) \cup E(B) = E(G)$. We say the separation is *at* X. If $|X| \le k$, we say the separation is *small.*

DEFINITION. Let G be a graph, and $\{A, B, X\}$ a separation in G. Let $Z \subseteq V(B)$ with $|Z| \le 2$, and let $R \subseteq E(G)$. The *B-consolidation of* G, *with respect to* R *and* Z, is the graph $G*$ obtained in the steps (i) and (ii) given next.

(i) For every $\emptyset \neq Y \subseteq X$ and each $z \in Z$, define a set $F(Y, z) \subseteq E(B) \backslash R$ as follows. If possible, choose W such that (1) $Y \subseteq W \subseteq V(B) \backslash ((X \backslash Y) \cup z)$, (2) $\delta_B(W) \cap R = \emptyset$, (3) $d_B(W)$ minimum subject to (1) and (2), and (4) W minimal subject to (1)–(3). If such a W exists *and* $d_B(W) \le k$, we set $F(Y, z) = \delta_B(W)$. Otherwise, we set $F(Y, z) = \emptyset$.

(ii) Let $F = \cup F(Y, z)$ (over all Y, z as in (i)). Obtain G^* by *contracting* (in G) all edges in $E(B) \backslash F$.

See Fig. 1 for an example.

Remark 2.1.1. Notice that G^* has a separation of the form $\{A^*, B^*, X^*\}$, where A^* is obtained from A by identifying elements of X (which maps X into X^*) and B^* is obtained from B by the edge contractions in the definition. For convenience, we regard $E(A^*)(E(B^*))$ as a subset of $E(A)$ (respectively, $E(B)$). Also notice that the number of edges in B^* is at most $k2^{|X|}$.

DEFINITION. A *type 1 small graph* is a connected graph H with a distinguished subset $X \subseteq V(H)$ and a distinguished vertex p, such that

(1) $|X| \le k$ and $|E(H)| \le k2^k$.

(2) $\lambda_H(p, X) > k$.

We say that X and p are the *boundary* and the *pole* of H, respectively.

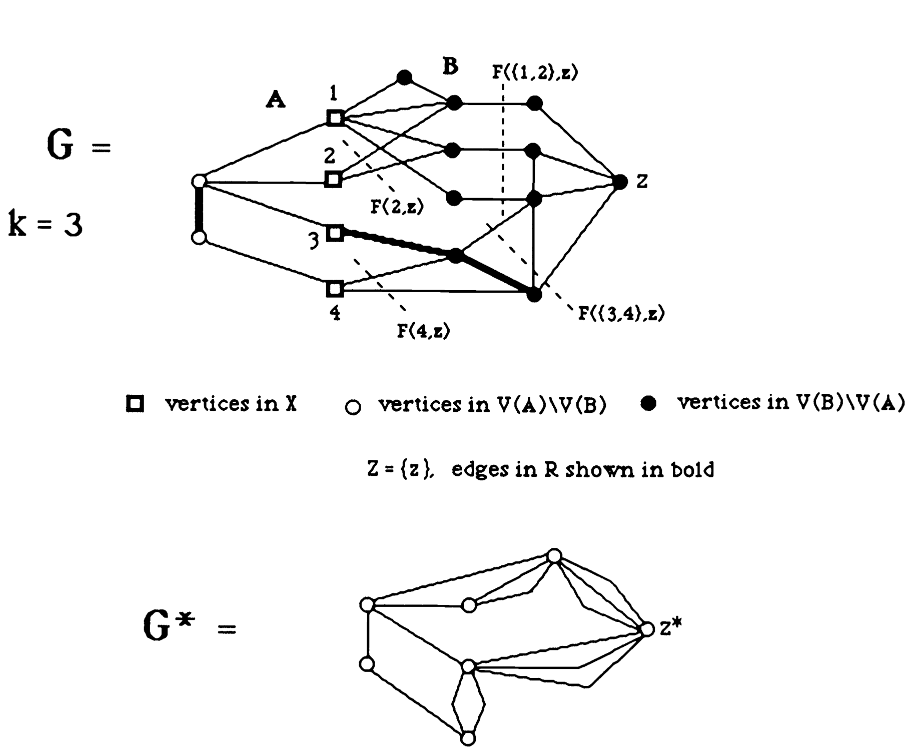

FIG. 1

Remark 2.1.2. Let $\{A, B, X\}$ be a small separation in a graph G, $R \subseteq E(G), p \in V(B)$. Let G^* be the B-consolidation of G (with respect to R and p) and consider the separation $\{A^*, B^*, X^*\}$ in G^*. Let $p^* \in V(B)$ be the image of p in G^*. If $\lambda_{B^*}(p^*, X^*) > k$, then B^* is a type 1 small graph.

In what follows, given a problem $P_w(s, t, G)$, a set $S \subseteq E(G)$ is called *feasible* if it intersects every small cut separating s and t.

PROPOSITION 2.1.1. *Let $\{A, B, X\}$ be a small separation in G such that A and B are connected, w is a weight function, $s \in V(A)$, and $t \in V(B)$. Let $S \subseteq E(G)$ be an optimal solution to the problem $P_w(s, t, G)$. Consider the problem $P_w(s^*, t^*, G^*)$, where G^* is the B-consolidation of G (with respect to S and t), t^* (respectively, s^*) is the image of t (respectively, s) in G^* and the weight function is extended by setting $w(e) = +\infty$ if $e \notin E(A)$. Finally, let $L^* \subseteq E(A)$ be an optimal solution to $P_w(s^*, t^*, G^*)$. Then*

(i) $\tau_w(s^*, t^*, G^*) = \sum\{w(e) : e \in S \cap E(A)\}$.

(ii) *$L^* \cup (S \cap E(B))$ is an optimal solution to $P_w(s, t, G)$.*

(iii) *B^* is a type 1 small graph, with boundary X^* and pole t^*.*

Proof. First we show (i) and (ii). We claim that

(a) $\tau_w(s^*, t^*, G^*) \leq \sum\{w(e) : e \in S \cap E(A)\}$.

Consider a small cut C^* separating s^* and t^* in G^*. Now in G, the edges of C^* form a small cut separating s and t. Consequently, since S is feasible for $P_w(s, t, G)$, $S \cap C^* \neq \emptyset$. Further, since $(S \cap E(B)) \cap C^* = \emptyset$ (or else at least one member of C would have been contracted in the construction of G^*) we must therefore have $(S \cap E(A)) \cap C^* \neq \emptyset$. Thus $S \cap E(A)$ is feasible for $P_w(s^*, t^*, G^*)$ and (a) follows.

Next we claim

(b) $\tau_w(s^*, t^*, G^*) \geq \sum\{w(e) : e \in S \cap E(A)\}$.

Write $R = S \cap E(B)$. To show (b) we prove that $L^* \cup R$ is a feasible solution to $P_w(s, t, G)$. Consider a small cut $C = \delta_G(D)$ separating s and t in G, with $s \in D$. If $C \subseteq E(A)$, then also $C \subseteq E(A^*)$ and it separates s^* and t^*; consequently $L^* \cap C \neq \emptyset$. Assume that $C \cap E(B) \neq \emptyset$. Write $D^X = D \cap X$ and $D^B = D \cap V(B)$. Then $\delta_B(D^B) = C \cap E(B)$ separates D^X from t in B. Suppose that $\emptyset = R \cap \delta_B(D^B) (= R \cap C)$. Since C is small, $d_B(D^B) \leq k$ and in the construction of G^*, we must have defined $F(D^X, t) = \delta_B(W)$, for some $W \subseteq V(B)$ with $d_B(W) \leq d_B(D^B)$ and $D^X \subseteq W$. Consequently, $(C \cap E(A)) \cup \delta_B(W)$ is the set of edges in a small cut in G^* separating s^* and t^*. By definition of L^* we then have that $L^* \cap (C \cap E(A)) \neq \emptyset$. We conclude, for any small cut C in G separating s and t, $(L^* \cup R) \cap C \neq \emptyset$. This settles (b). Hence (i) holds, and $L^* \cup R$ is an optimal solution to $P_w(s, t, G)$, i.e., (ii) holds as well.

In order to prove (iii) we have to show that $\lambda_{B^*}(t^*, X^*) > k$ (see Remark 2.1.2). If this does not hold, then there is a small cut $C^* \subseteq E(B^*)$ separating t^* and X^*. But then, in $G, C^* \subseteq E(B)$ separates t and X, and therefore it separates s and t, whereas $R \cap C^* = \emptyset$. This is impossible, since C^* is small. This concludes the proof. □

Remark 2.1.3. We stress that in Proposition 2.1.1 $\{B, A, X\}$ is also a small separation, and so a corresponding result holds with A and B interchanged.

Remark 2.1.4. Proposition 2.1.1 forms the basis of an algorithm for computing $\tau_w(s, t, G)$. Namely, construct a small separation $\{A, B, X\}$ of G as in the statement (and it is easy to see that such a separation exists if $\lambda_G(s, t) \leq k$). Then, recursively, solve the small cut blocking problem for all possible graphs obtained by "glueing" to A a type 1 small graph "at" X. Since $|X| \leq k$ the total number of such problems is bounded by a function of k. We keep track of an optimal solution to each such problem (call it an A-solution). Next, (recursively) we solve the small cut blocking problem for all possible graphs obtained by glueing to B a type 1 small graph, at X, and keep track of all such B-solutions. Finally, try all possible combinations of an A-solution and a B-solution, and from among all those combinations that are feasible for $P_w(s, t, G)$, select a minimum-weight one. Proposition 2.1.1 guarantees that this algorithm yields the correct answer. But in order to turn this into a polynomial-time algorithm, further tools are needed and will be given below. Nevertheless, Proposition 2.1.1 contains the main ideas in the algorithm we describe.

DEFINITION. A *type* 2 *small graph* is a graph H with a distinguished subset $Y \subseteq V(H)$ and a pair of distinguished vertices p_1, p_2, such that

(1) $|Y| \leq 2k$ and $|E(H)| \leq 2k2^{2k}$.

(2) If $i \neq j$, $\lambda_H(p_i, Y \cup p_j) > k$.

(3) Every vertex of H is in the same component as p_1 or p_2 (and hence H has at most two components).

We say that Y is the *boundary* and $\{p_1, p_2\}$ are the *poles* of H. Now we have the following analogue of Proposition 2.1.1.

PROPOSITION 2.1.2. *Consider a problem $P_w(s, t, G)$, where G has a separation $\{H, J, X\}$ with $s, t \in V(H)$ and $|X| \leq 2k$. Suppose J is connected and that every vertex of H is in the same component as s or t. Let S be an optimal solution to the problem $P_w(s, t, G)$. Let G^* be the H-consolidation of G with respect to S and $\{s, t\}$. Consider the problem $P_w(s^*, t^*, G^*)$, where s^* (respectively, t^*) is the image of s (respectively, t) in G^**

and the weight function w is as before extended by setting $w(e) = +\infty$ if $e \in E(H)$. Finally, let $R^* \subseteq E(J)$ be an optimal solution to $P_w(s^*, t^*, G^*)$. Then

(i) $\tau_w(s^*, t^*, G^*) = \sum\{w(e) : e \in S \cap E(J)\}$.

(ii) $(S \cap E(H)) \cup R^*$ *is an optimal solution to* $P_w(s, t, G)$.

(iii) H^* *is a type* 2 *small graph, with boundary* X^* *and poles* $\{s^*, t^*\}$.

Proof. The proof is similar to that of Proposition 2.1.1. □

2.2. The digraph of minimum cuts. Write $q = \lambda_G(s,t)$. Consider the graph Γ_q obtained from G by contracting every edge that is not in any s–t cut of size q (i.e., we contract the edges that do not appear in any min-cut). The following properties of Γ_q are well known. Suppose $\{u, v\} \in E(\Gamma_q)$. We orient $\{u, v\}$ as (u, v) if there is a minimum s–t cut $\delta_G(X)$ with $u \in X$ and $v \notin X$. This orientation is well defined (i.e., every minimum s–t cut containing $\{u, v\}$ yields the same orientation). The resulting digraph Δ has the properties (i)–(v) (where s' and t' are the images of s and t, respectively):

(i) Δ is acyclic.

(ii) Every dicut $\delta^+_\Delta(X)$ satisfies $|\delta^+_\Delta(X)| = q, s^* \in X$ and $t^* \notin X$.

(iii) The edges in every dicut $\delta^+_\Delta(X)$ form a minimum s–t cut in G and vice versa.

(iv) Every edge of Δ is contained in a directed path from s to t.

(v) $d^+_\Delta(x') = d^-_\Delta(t') = q, d^-_\Delta(s') = d^+_\Delta(t') = 0$.

We use the *topological ordering* of $V(\Delta)$. Here we number the vertices of Δ by $1, 2, \ldots, N$ (say), so that $s' = 1, t' = N$, and for $1 \leq i \leq N-1$, there are no edges (u, v) with $v \in \{1, \ldots, i\}$ and $u \in \{i+1, \ldots, N\}$. Although every acyclic digraph has such an ordering, notice that in our case it also implies that for $1 \leq i \leq N-1$, $d^+_\Delta(\{1, \ldots, i\}) = q$. In the algorithm given below, we use this numbering of the vertices, but apply it instead to the graph Γ_q.

2.3. Linear-time algorithm for computing $\tau_w(s, t, G)$. Given a subgraph A of G, we denote by $\nu_G(A)$ those vertices of A that are incident with edges not in A. For the case $k = q$, the problem $P_w(s, t, G)$ is easy. Here we want a minimum-weight set that blocks all dicuts in Δ, and the properties of this digraph imply that the elements of the blocker of the hypergraph of all s–t dicuts is $\{X$: there is an s–t path p where X = set of forward edges in $p\}$. The minimum-weight element of this blocker can be easily found as a shortest path problem in an auxiliary digraph.

In what follows, we assume $k > q$. Notice that each vertex i of Γ_q corresponds to a subset $V(i)$ of vertices of G (possibly a single vertex) contracted in the construction of Γ_q. We use the following notation (see Fig. 2 for an example).

For $1 \leq i \leq N$, $A(i)$ is the subgraph of G induced by $\cup\{V(j) : 1 \leq j \leq i\}$. For $1 \leq i \leq N$, $J(i)$ is the subgraph induced by $V(i)$. For $1 \leq i \leq N-1$, $B(i)$ is the union of the subgraph of G induced by $\cup\{V(j) : i < j \leq N\}$, together with all edges with only one end in $V(A(i))$.

Remark 2.3.1. For $1 \leq i \leq N-1$, G has a separation $\{A(i), B(i), X(i)\}$ (where $X(i) = \nu_G(A(i)) = \nu_G(B(i))$). This separation is small, since the number of edges of G with only one end in $V(A(i))$ equals $q \leq k$.

For $1 \leq i \leq N-1, D(i)$ is the union of $A(i)$, and all the edges with one end in $V(A(i))$ and the other in $V(i+1)$. For $2 \leq i \leq N-1$, $H(i)$ is $D(i-1) \cup B(i)$.

Remark 2.3.2. For $2 \leq i \leq N-1$, G has a separation $\{H(i), J(i), Y(i)\}$ (with $Y(i) = \nu_G(H(i)) = \nu_G(J(i))$). Further, $|Y(i)| \leq 2k$.

Remark 2.3.3. For $1 \leq i \leq N$, $J(i)$ is connected (as we obtained it by contracting edges of G into a single node of Γ_q). For $1 \leq i \leq N, A(i)$ is connected, and for $1 \leq i \leq N-1, B(i)$ and $D(i)$ are connected (this follows by property (v) of the topological

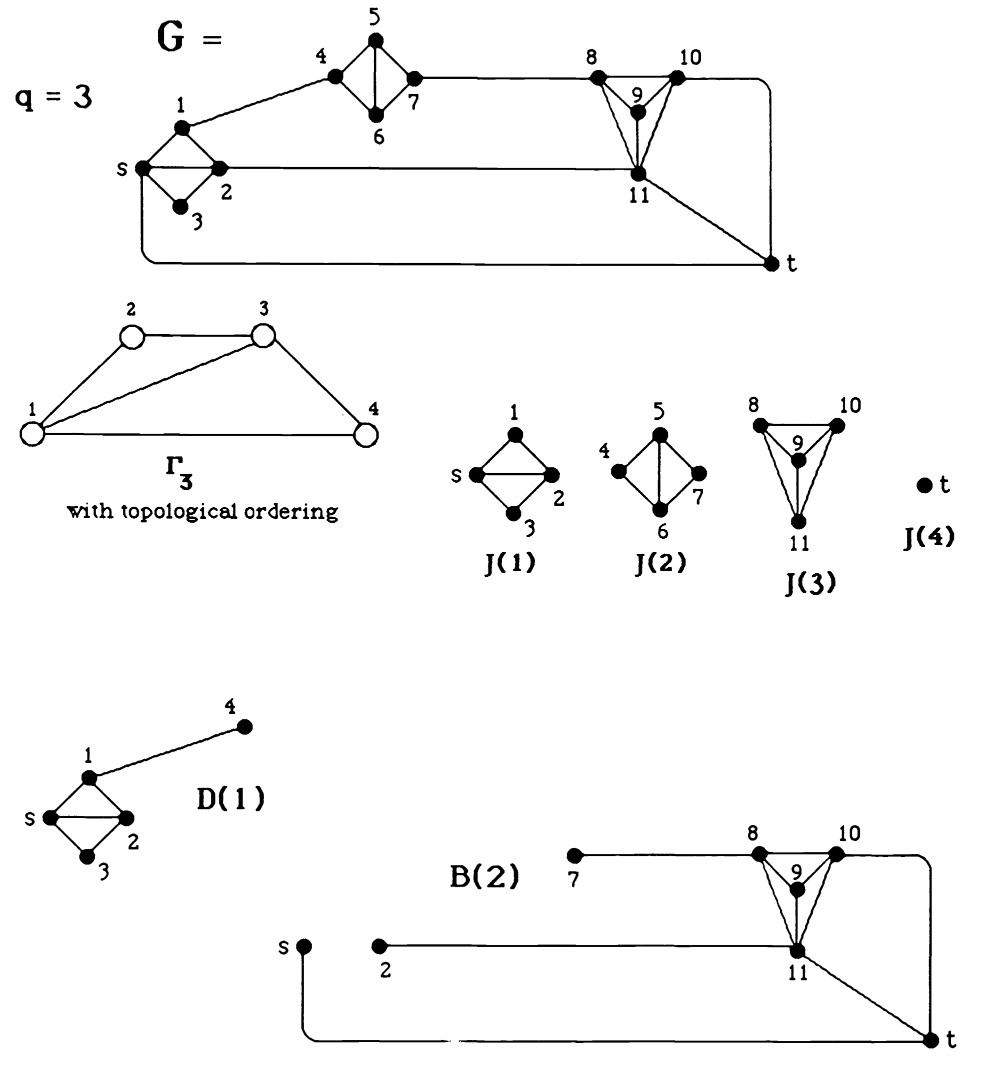

FIG. 2

ordering of $V(\Delta)$; see §2.2). Similarly, for $2 \leq i \leq N-1$, every vertex of $H(i)$ is in the same component of $H(i)$ as s or t.

Suppose S is a feasible solution to $P_w(s,t,G)$. For $1 \leq i \leq N-1$, consider the $B(i)$-consolidation of G with respect to S and t. Then by Proposition 2.1.1, its subgraph $B^*(i)$ is a type 1 small graph. Similarly, for $2 \leq i \leq N-1$, consider the $H(i)$-consolidation of G with respect to S and $\{s,t\}$. Then its subgraph $H^*(i)$ is a type 2 small graph. In fact, we can say more.

PROPOSITION 2.3.1. *Let S be a feasible solution to $P_w(s,t,G)$. Then*

(i) *Let I^* be the $B(1)$-consolidation of G with respect to S and t.*
Then $\lambda_{I^*}(s^*,t^*) \geq q+1$.

(ii) *For $2 \leq i \leq N-1$, let $M^*(i)$ be the $H(i)$-consolidation of G with respect to S and $\{s,t\}$. Then $\lambda_{M^*(i)}(s^*,t^*) \geq q+1$.*

Proof.

(i) Recall that I^* has a separation of the form $\{A^*(1), B^*(1), X^*(1)\}$. Consider any cut C separating s^* and t^* in I^*. If $C \subseteq E(B^*(1))$, then C separates t^* from $X^*(i)$ and thus $|C| \geq k+1 \geq q+1$ since $B^*(1)$ is a type 1 small graph. Suppose C intersects $E(A^*(1))$. Then C, now regarded as a cut in G separating s and t, intersects $E(A(1))$. But all edges in $A(1)$ were *contracted* in generating the graph Γ_q that contains all min-cuts. Thus again $|C| \geq q+1$.

(ii) This proof follows in a similar manner. □

Description of the algorithm. Consider the algorithm sketched in Remark 2.1.4. This algorithm works correctly, but is not necessarily polynomially bounded because the amount of recursive work may grow too fast. This obstacle is overcome by using the structure of Γ_q. Essentially, we solve all problems obtained by glueing to $A(i)$ each possible type 1 small graph at $X(i)$. Below we show that there is an easy inductive way to solve these problems for increasing i, so that the only recursive work we carry out involves graphs that are at least $q+1$ edge-connected between s and t. Since k is bounded, the total depth of recursions is bounded.

Our first step is to make formal the process of "glueing" two graphs. Let A be a graph and B be a type 1 small graph with boundary X. Let $Z \subseteq V(A)$, with $|Z| \geq |X| = r$, say. A *glueing of A and B, at Z*, is specified by a partition π of Z into r classes $\{C(1), \dots, C(r)\}$ and a labeling σ of B as $\{b(1), \dots, b(r)\}$. The glueing is the graph obtained by identifying (for $1 \leq j \leq r$) all vertices of $C(j)$ into a single vertex and then identifying this vertex with $b(j)$. We denote this graph by $A \otimes B$ (π and σ will be clear from the context). Suppose $s \in V(A)$, that t is the pole of B, and w is a weight function on $E(A)$. Let s^* (respectively, t^*) be the image of s (respectively, t) in the glueing $A \otimes B$. Then the *canonical problem* $P_w(s^*, t^*, A \otimes B)$ is that in which we extend w by setting $w(e) = +\infty$ if $e \in E(B)$. Similar definitions apply with regards to glueing a type 2 small graph and another graph.

Now we can describe our algorithm. The reader may already guess this algorithm, but we can formally describe it as follows.

```
Algorithm Block($s, t, G, w$)
Step 1  Test whether $q = \lambda_G(s,t) > k$. If so, set $\tau_w(s,t,G) = 0$ and stop.
Step 2  Construct the graph $\Gamma_q$.
Step 3  Execute algorithm Ext given below, which returns
        (a) an optimal solution to the canonical problem $P_w(s^*, u^*, D(N-1) \otimes B)$
        for every possible glueing of $D(N-1)$ and a type 1 small graph $B$ with pole
        $u$, at $\nu_G(D(N-1))$, such that $\lambda_{D(N-1)\otimes B}(s^*, u^*) \geq q+1$, and
        (b) an optimal solution to the canonical problem $P_w(t^*, v^*, J(N) \otimes A)$ for
        every possible glueing of $J(N)$ and a type 1 small graph $A$ with pole $v$, at
        $\nu_G(J(N))$, such that $\lambda_{J(N)\otimes A}(t^*, v^*) \geq q+1$.
Step 4  Set $\tau_w(s,t,G) =$
                $\min\{w(S_{N-1}) + w(R_N)$:
                $S_{N-1}$ is an optimal solution to one of the problems in (a),
                $R_N$ is an optimal solution to one of the problems in (b), and
                $S_{N-1} \cup R_N$ is feasible for $p_w(s,t,G)\}$
End
```

In the description of algorithm Ext, a *level i problem* $(1 \leq i \leq N-1)$ will be a canonical problem of the form $P_w(s^*, u^*, A(i) \otimes B)$, where B is a type 1 small graph with pole u.

```
Algorithm Ext
1 Recursively (i.e., using Block), solve every possible level 1 problem
  $P_w(s^*, u^*, A(1) \otimes B)$ such that $\lambda_{A(1)\otimes B}(s^*, u^*) \geq q+1$.
2 For $i = 1, 2, \ldots, N-1$, Do
  (a) Solve every problem $P_w(s^*, u^*, D(i) \otimes B)$, where $B$ is a type 1 small graph
  with pole $u$, and the glueing is at $\nu_G(D(i))$, as follows:
  $\tau_w(s^*, u^*, D(i) \otimes B) = \min\{w(L_i) + w(Z_i)$ :
        $L_i$ is an optimal solution to one of the level $i$ problems,
        $Z_i$ is a subset of the edges $\delta_G(V(A(i)), V(i+1))$, and
        $L_i \cup Z_i$ is feasible for $P_w(s^*, u^*, D(i) \otimes B)\}$.
[COMMENT: For $i = N-1$, (a) computes some the data required in step 3(a) of Block.]
  (b) If $i < N-1$, recursively solve every problem $P_w(u^*, v^*, J(i+1) \otimes H)$
  where $H$ is a type 2 small graph with poles $\{u, v\}$, such that $\lambda_{J(i+1)\otimes H}(u^*, v^*) \geq$
  $q+1$ and the glueing is at $\nu_G(J(i+1))$.
  (c) If $i < N-1$, solve each level $(i+1)$ problem $P_w(s^*, u^*, A(i+1) \otimes B)$ as
  follows:
  $\tau_w(s^*, u^*, A(i+1) \otimes B) = \min w(S_i) + w(J_{i+1})$
  such that
        $S_i$ is an optimal solution to one of the problems in (a),
        $J_{i+1}$ is an optimal solution to one of the problems in (b), and
        $S_i \cup J_{i+1}$ is feasible for $P_w(s^*, u^*, A(i+1) \otimes B)$.
  End For
3 Recursively, solve the problem $P_w(t^*, v^*, J(N) \otimes A)$ for every possible type 1
  small graph $A$ with pole $v$, such that $\lambda_{J(N)\otimes A}(t^*, v^*) \geq q+1$.
End
```

The correctness of algorithm Block follows from Proposition 2.1.1 (also recall Remarks 2.1.3 and 2.1.4, 2.1.2, and 2.3.1). Next we study its run time and show that it is linear in $|E(G)|$ for every fixed value of k. To this effect, we set $T(m, q)$ to be the maximum amount of work required by Block to solve a problem $P_w(s, t, G)$ when $\lambda_G(s, t) = q$. We will show (by induction on $k - q$) that

$$(*) \qquad T(m, q) \leq f(k-q)m + g(k-q),$$

for certain functions f and g. We have

(i) Step 1 of Block requires $O(km)$ time. This follows because it is not necessary to compute $\lambda_G(s, t)$; rather, we want to see if G has at least $k+1$ edge-disjoint paths from s to t, and any "augmenting path" algorithm does so in $O(km)$ time (see [T]). Consequently, $T(m, q) = O(km)$ for any m and $q > k$.

(ii) To construct Γ_q we must identify those edges of G that are contained in minimum s–t cuts, contract all others, and obtain the topological ordering. It is not difficult to see how to implement the last two tasks in $O(m)$ time. Further, the identification can be implemented in $O(qm^2)$ time; but as we show in Appendix A, with some care this step can be carried out in $O(q^3m)$ time.

(iii) In Step 4 of Block, each feasibility test requires $O(km)$ work, and if we write $n(k)$ = number of type 1 or type 2 small graphs, then the total number of tests is at most $(n(k))^2$.

(iv) Next we analyze the complexity of one call to Ext.

Consider first the recursive work. The recursive work appears in step 1 of Ext (involving graph $A(1) = J(1)$), in step 2(b) (involving $J(i)$, where $2 \leq i \leq N-1$) and in step 3, involving $J(N)$. Now any (type 1 or 2) small graph has at most $2k2^{2k}$ edges. So if $J(i)$ has $m(i)$ edges, then any recursive call to Block involving $J(i)$ is on a graph with at most $2k2^{2k}m(i)$ edges. Further, the different graphs $J(i)$ are edge-disjoint. Finally, the recursive calls are on graphs with edge-connectivity at least $q+1$ between the two relevant vertices. Hence, the total recursive work in one call to Ext is at most

$$\sum \left\{n(k)T(2k2^{2k}m(i), q+1) : 1 \le i \le N\right\},$$

which by induction (using (*)) is at most

$$n(k)2k2^{2k}f(k-q-1)m + n(k)2k2^{2k}g(k-q-1).$$

Now for the nonrecursive work in Ext. The major part of it is made up of the feasibility tests in steps 2(a) and 2(c). It is not difficult to see that *each* test can be carried out in $O(km)$ time, but this would lead to a bound $O(m^2)$ bound for all the tests. As we show in Appendix B, with some care we can attain an overall $O(n^2(k)m)$ bound for the feasibility tests.

(v) In summary, we obtain the following bound for $q \le k$:

$$\begin{aligned} T(m,q) \le O(q^3m) + O(n^2(k)m) + n(k)2k2^{2k}f(k-q-1)m + n(k)2k2^{2k}g(k-q-1) \\ + O(n^2(k)m) \le f(k-q)m + g(k-q), \end{aligned}$$

for appropriately defined f and g, as desired. This completes the proof of (*).

Remark 2.3.4. The function $n(k)$ is doubly exponential in k. From the analysis above, we conclude that the overall algorithm for $P_w(s,t,G)$ has complexity $O(h(k)m)$, where h is doubly exponential in k.

3. The linear programming relaxation. The small cut blocking problem $P_w(s,t,G)$ can be equivalently restated as the following set covering problem:

$$\tau_w(s,t,G) = \min \sum \{w(e)x(e) : e \in E(G)\}$$

such that

$$Ax \ge 1,$$

$$x \ge 0 \quad \text{integral},$$

where A is the incidence matrix of small s–t cuts versus edges of G, and 1 is the column of 1's. Even for k moderately small it may be convenient to view the problem $P_w(s,t,G)$ in this manner, since we may be able, for example, to obtain good approximations faster than the run time of the (theoretically efficient) exact algorithm described in §2. Indeed, cutting plane algorithms have been successfully used to effectively solve many types of combinatorial optimization problems, and one hopes that that would be the case here as well. Moreover, an understanding of the polyhedral structure of this set covering problem would probably be useful with regards to the general version $P_w(S,G)$ of the small cut blocking problem (which is NP-hard even for small k, as shown in the next section).

An important element in developing a cutting-plane algorithm for solving the integer program above would be the efficient solution of its linear-programming relaxation, which we denote $P_w(s,t,G)^*$, with value $\tau_w(s,t,G)^*$. The fact that the matrix A is potentially very large presents a difficulty: Even for k small, A could have many rows, and the practical computation of $\tau_w(s,t,G)^*$ could be costly (although theoretically efficient). For general k, it is not even clear how to solve the linear program in polynomial time. One wonders in that case if there is a *compact* reformulation of the linear program (one where the constraint matrix has polynomially many rows and columns). The main result in this section is negative: for general k, it is NP-hard just to compute the quantity $\tau_w(s,t,G)^*$ (and therefore, unless $P = \text{NP}$, there is no compact reformulation, even allowing for different variables).

We denote by $B(s,t,G)$ the polyhedron (where $d = |E(G)|)\{x \in \mathbb{R}^d : Ax \geq 1, x \geq 0\}$. Given a polyhedron $Q \subseteq \mathbb{R}^n$, the *separation problem* for Q is the following: Suppose $x \in \mathbb{R}^n$. Then either decide $x \in Q$ or provide a hyperplane that separates x and Q.

In the proof below, we make use of the *max-cut* problem. In this problem (whose recognition version is NP-complete [GJ1]), we are given a simple graph H and asked to produce a subset $x \subseteq V(H)$ such that $d_H(X)$ is maximum.

LEMMA 3.1. *The separation problem for polyhedra $B(s,t,G)$ is NP-hard.*

Proof. Consider an instance of the recognition version of the max-cut problem with graph H, where we seek cut of size $\geq L$. We assume $|E(H)| > L$ and H nonbipartite (otherwise the max-cut problem is trivial). We construct a graph G as follows. First, let $\bar{H}$ denote the complement graph of H, and set $m = |E(\bar{H})|$. Then $V(G) = V(H) \cup \{s,t\}$. $E(G)$ contains $E(\bar{H})$, as well as $m+2$ copies of the edge $\{s,v\}$ and one copy of the edge $\{t,v\}$, for every $v \in V(H)$.

We next define a vector $\mathbf{x}$. Write $n = |V(H)|$. Choose a *fixed* $u \in V(H)$. For $e \in E(G)$, set

$$x(e) = (n(n-1)/2 - L + 1)^{-1} \quad \text{if } e \in E(\bar{H}), \text{and}$$

$$x(e) = 0 \quad \text{if } e \text{ is incident with } s \text{ or } t, \text{ with one exception: } x(\{u,t\}) = 1.$$

Finally, set $k = (m+2)n - 1$.

Suppose $\delta_G(Y)$ is a cut separating s and t with $s \in Y$. Then $k < (m+2)n$ implies that if this cut is small, we must have $V(H) \cap Y \neq \emptyset$. Moreover, if $x(\delta_G(Y)) < 1$, then also $V(H) \cap V(G)\backslash Y \neq \emptyset$, and moreover, the number of edges of $\bar{H}$ with one end in $V(H) \cap Y$ and the other in $V(H) \cap (V(G)\backslash Y)$ must be at most $n(n-1)/2 - L$. In summary, if $\delta_G(Y)$ is a small cut with $x(\delta_G(Y)) < 1$, then $d_H(V(H) \cap Y) \geq L$, and the converse to this follows in a similar way. Hence, $x \notin B(s,t,G)$ if and only if there is a $W \subseteq V(H)$ with $d_H(W) \leq L$. This concludes the proof. □

Now consider a problem $P_w(s,t,G)$ with $d = |E(G)| \geq 1$. Let $\mathbf{e} \in \mathbb{R}^d$ be the vector of 1's. Clearly $\mathbf{e} \in B(s,t,G)$. Let $Q \subseteq \mathbb{R}^d$ be the polyhedron defined by $Q = \{z \in \mathbb{R}^d : z(x - \mathbf{e}) \leq 1 \text{ for all } x \in B(s,t,G)\}$. Q is called the *polar* of $B(s,t,G)$. It is not difficult to see that Q is well behaved: It contains a full-dimensional sphere with center $(-1/d)\mathbf{e}$ and polynomially bounded inverse radius. Using well-known results concerning the ellipsoid method [GLS], Lemma 3.1 implies that it is NP-hard to compute the value $\tau_w(s,t,G)^*$.

COROLLARY. *Unless $P = \text{NP}$, there is no compact reformulation of $P_w(s,t,G)^*$.*

How well does $\tau_w(s,t,G)^*$ approximate $P_w(s,t,G)$? We conjecture that on the average the approximation will be fairly good. However, in the worst case it is quite poor, as we show next.

LEMMA 3.2. *There exist examples with $\tau_1(s,t,G)/\tau_1(s,t,G)^*$ arbitrarily large.*

Proof. Let m be a positive integer. Consider the hypergraph of $(m+1)$ subsets of $\{1,2,\ldots,2m\}$ and let $S(m)$ denote the set covering problem whose corresponding matrix is the edge-vertex incidence matrix of this hypergraph. It is not difficult to see that the value of $S(m)$ is m, but that the value of the LP-relaxation is (only) $2m/(m+1)$ (*Remark*: This example is similar to one mentioned in [S].) Next we construct a graph G. We begin with vertices s, t and $\{1, 2, \dots, 2m\}$ and for $1 \leq i \leq 2m$, the edge $\{i, t\}$ and two copies of $\{s, i\}$. Next, we subdivide each edge incident with s, $2m-1$ times (i.e., each such edge is replaced by a path of length $2m$). The resulting graph is G. Color all edges of G incident with t blue, and all other edges, red. Set $k = 3m-1$, and consider $P_1(s, t, G)$.

We observe: (1) Suppose $\delta_G(Z)$ is a minimal s–t cut with $s \in Z$. Write $z = |Z \cap \{1, 2, \dots, 2m\}|$. Then $d_G(Z) = 4m - z$, and consequently, $\delta_G(Z)$ is small if and only if $z \geq m+1$. Moreover, (2) Suppose x is an optimal solution to either $P_1(s, t, G)$ or $P_1(s, t, G)^*$, chosen so that in addition $x(R)$ is minimized, where R is the set of red edges. It is not difficult to see that in this case $x(e) = 0$ for every red edge e (x must be constant on each "subdivided edge" between s and some i). (1) and (2) imply that $P_1(s, t, G)$ and $P_1(s, t, G^*)$ are isomorphic to $S(m)$ and its LP-relaxation, respectively. Thus $\tau_1(s, t, G)/\tau_1(s, t, G)^* = (m+1)/2$, as desired. □

We note that the lower bound achieved in Lemma 3.2 grows linearly in k. This is best possible since the rows of the matrix A have at most k 1's (see [HH]).

In spite of the negative results given in this section, one hopes that an effective cutting plane algorithm can be developed for problems $P_w(s, t, G)$, and this is an interesting topic which we plan to study shortly. We remark that there is a different formulation of the problem $P_w(s, t, G)$, as a mixed-integer program. Here we have, besides the 0–1 variables $x(e)$, additional *flow* variables for the edges. Then we want to select a minimum-weight subset of edges, each of which will be assigned *capacity* $k+1$ (and all other edges are assigned capacity 1), so that in the resulting network there is a flow of $k+1$ units from s to t. This program is compact, but its LP-relaxation can be far weaker than the one we considered above (and it is never better).

There is one special case where the linear program described above has integer solutions and can be solved in polynomial time. This is the case where $k = \lambda_G(s, t)$. Recall the digraph of minimum cuts Δ described in §2.2. This digraph has the property that every dicut $\delta +_\Delta (X)$ satisfies $|\delta +_\Delta (X)| = k, s^* \in X$ and $t^* \notin X$ and conversely. We use this fact as follows: For a given undirected $s-t$ path p in Δ, define $F(p) = \{e : e \text{ is a forward edge in } p\}$. Then, as stated in §2.3, it can be verified that the blocker of the clutter of dicuts in Δ (in this case) is the set of all sets $F(p)$. Using this fact, one can reduce the problem $P_w(s, t, G)$ to a shortest path problem in a related digraph. Further, this fact yields a min–max relation: $\tau_w(s, t, G)$ is equal to the maximum number of s–t cuts of size k (in G), such that no edge e is contained in more than $w(e)$ of the cuts.

4. Blocking small cuts between many vertices.

In this section we consider the small cut blocking problem, in the more general case $P_w(S, G)$ where we are interested in the cuts or cardinality $\leq k$ separating pairs of vertices in some set $S \subseteq V(G)$. One might expect that for k fixed this problem would be polynomially solvable. Indeed, at first glance it may appear that the algorithm in §2 could be generalized, so that instead of using a linear ordering of the graph (that decomposes the graph into small separations) one would use a tree-decomposition of small width (see [BLW] for an early reference) and then proceed with dynamic programming as in §2.

However, the problem is intractable even for small values of k. In fact, we show that it is NP-hard for $k = 8$ (and, thus, for any $k \geq 8$). On the other hand, using arguments very similar to those in §2, one obtains a linear-time algorithm for the case ≤ 2. We remark that this particular algorithm may be practical and also useful (since with $k = 2$

we effectively achieve 3-edge connectivity between vertices of S). Similarly, there is a linear-time algorithm for every fixed k *and* fixed $|S|$ (the complexity is singly exponential in $|S|$). We omit the description of this algorithm, which is essentially a more complicated version of that given in §2 (we use small graphs with many poles).

In the rest of this section we show that the class of instances $P_1(S, G)$ is NP-hard for $k = 8$. We show that the general weighted version is NP-hard; the rest of the proof (unit weights) proceeds as in §1.

The reduction is from the vertex cover problem in cubic graphs. Given a cubic graph H (i.e., H 3-regular) we seek a subset $X \subseteq V(H)$, with $|X|$ minimum, such that $X \cap e \neq \emptyset$ for every edge e. The fact that this problem is NP-hard can be deduced from the results in [GJ2].

Thus, consider an instance of the vertex cover problem in a cubic graph H on at least three vertices, where we seek a cover with at most N vertices. We next construct a problem $P_w(S, G)$. The graph G is obtained as follows.

First, for every vertex x of H (incident, say, with edges a, b, and c), G has three vertices $x(a)$, $x(b)$, and $x(C)$, which induce a triangle. We write $T(x) = \{x(a), x(b), x(c)\}$.

Next, for every edge $a = \{x, y\}$ of H, G has a vertex s_a, and the edges $\{s_a, x(a)\}$ and $\{s_a, y(a)\}$.

All edges f described so far have $w(f) = 1$.

Finally, there is a vertex s^* and two copies of $\{s^*, x(a)\}$ for every $x \in V(H)$ and $a \in E(H)$ such that x and a are incident. We also have six copies of the edge $\{s^*, s_a\}$ for every $a \in E(H)$. All edges incident with s^* have weight $2|V(H)| + N + 1$. We set $S = V(G)$, and as we said above, $k = 8$.

The following is easily obtained by counting:

CLAIM 4.1. *Consider an inclusion minimal cut $\delta_G(Z)$ with $d_G(Z) \leq 8$, where $s^* \notin Z$. Then either* (i) $Z = \{s_a\}$, *for some* $a = \{x, y\} \in E(H)$, *or* (ii) *for some* $x \in V(H)$, $Z \subseteq T(x)$ *and* $|Z| \leq 2$. *Conversely, all Z as in* (i) *or* (ii) *have* $d_G(Z) \leq 8$.

Let us color all edges of G contained in triangles $T(x), x \in V(H)$, red; the edges incident with s^*, blue; and all other edges, green.

CLAIM 4.2. *Suppose we can choose an optimal solution to $P_w(S, G)$ with no blue edges. Let B be such an optimal solution, such that in addition B has a minimum number of red edges. Then*

(i) *Let $x \in V(H)$, and suppose that B includes at least one green edge with one end in $T(x)$. Then B includes all green edges with one end in $T(x)$, and $B \cap E(T(x)) = \emptyset$. Conversely, if $B \cap E(T(x)) = \emptyset$, then B includes all green edges with one end in $T(x)$.*

(ii) *If $B \cap E(T(x)) \neq \emptyset$, then B includes at least two edges with both ends in $T(x)$.*

(iii) *The set $\{x \in V(H) : B$ includes all green edges with one end in $T(x)\}$ is a vertex cover in H.*

Proof. (i) Let a, b, and c be the three edges incident with x in H. Suppose first that (say) B includes $\{s_a, x(a)\}$ but not $\{s_b, x(b)\}$. Consider the cuts $\delta_G(X)$, where $X = \{x(b)\}$ or $X = \{x(b), x(c)\}$. In order for B to meet these two cuts, it must be the case that either B includes $\{s_c, x(c)\}$ and at least one edge from $T(x)$ or that B includes at least two edges from $T(x)$. In either case, $B' = (B \backslash E(T(x))) \cup \{\{s_b, x(b)\}, \{s_c, s(c)\}\}$, then B' is an optimal solution to $P_w(S, G)$ with no blue edges and fewer red edges than B, a contradiction. Consequently B includes $\{s_b, x(b)\}$ and $\{s_c, x(c)\}$, and the fact that $B \cap E(T(x)) = \emptyset$ now follows immediately. The converse statement follows from the first. (ii) (respectively, (iii)) follows from (i), and the fact that for all $x(a), d_G(x(a)) \leq 8$ (respectively, for all $s_a, d_G(s_a) \leq 8$). □

CLAIM 4.3. *Suppose S is a vertex cover for H. Define $B \subseteq E(G)$ as follows: For each $x \in V(H)$, if $x \in S$, then B includes all green edges with one end in $T(x)$, otherwise B includes two edges with both ends in T_x (arbitrarily chosen). Then B is a feasible solution to $P_w(S, G)$, and $w(B) = 2|V(H)| + |S|$.*

Proof. The proof follows from Claim 4.1. □

Putting together the above claims, we obtain the following theorem:

THEOREM 4.4. *H has a vertex cover of cardinality at most N, if and only if $\tau_w(S, G) \leq 2|V(H)| + N$.*

Proof. The only observation needed is that the bound on $\tau_w(S, G)$ excludes the edges incident with s^* from being used. □

5. Conclusion and related problems. One important future task is to better understand the problem $P_w(S, G)$ for small values of k. We conjecture that it is NP-hard already for $k = 3$. On the other hand, does there exist a polynomial-time algorithm for this problem, with fixed performance bound? Because of the similarity with the set covering problem, we again conjecture that the answer is negative. However, there is hope that a cutting-plane algorithm could be effective here from a practical point of view, as discussed in §3. Some early computational experience is promising [BD]. A polyhedral study of the problem would be the first step in this direction, and this will be our next area of work.

A problem that is seemingly related to blocking small cuts is that of blocking *short paths* between two vertices s and t in a graph. Here an adversary has to pay a price for removing any edge from the graph, and the adversary wants to remove edges (at minimum cost) so as to make the distance from s to t larger than some given amount h. For $h \leq 3$, this problem can be solved in polynomial time by reducing it to a matching problem. However, for $h \geq 5$, it is NP-hard (the proof of this fact uses essentially the same paradigm as the proof in §4). Here, again, one expects a cutting-plane algorithm to be effective.

Appendix A. In this appendix we provide a linear-time algorithm for finding those edges that are contained in min-cuts. More precisely, given G, selected vertices s and t, $q = \lambda_G(s, t)$ and $m = |E(G)|$, in time $O(q^3 m)$ the algorithm below finds which edges of G are contained in s–t cuts of size q (for short we will refer to these cuts as min-cuts). We call such edges *critical.*

In what follows, we use the following convention: Any time that we speak of a cut $\delta_A(X)$ separating s and t (in some graph A), we assume that $s \in X$. First, we make some observations.

If $\delta_G(X)$ and $\delta_G(Y)$ are min-cuts, then so are $\delta_G(X \cap Y)$ and $\delta_G(X \cup Y)$ (this follows using the submodular inequality). Hence, if $Z \subseteq V(G)\backslash t$ is such that $\lambda_G(Z \cup \{s\}, t) = q$, then there is a *unique minimal* subset $W \subseteq V(G)$, with $\{s\} \cup Z \subseteq W$, such that $\delta_G(W)$ is a min-cut. We call this cut the *Z-minimal min-cut* (and a similar definition is possible with maximal instead of minimal cuts). It is also seen that

(A.1) if $\delta_G(X)$ and $\delta_G(X')$ are, respectively, the Z- and Z'-minimal min-cuts, then $\delta_G(X \cup X')$ is the $(Z \cup Z')$-minimal min-cut.

Consequently, let $\delta_G(S)$ be an s-minimal min-cut (in other words, a min-cut closest to s), and $\delta_G(V(G)\backslash T)$ an s-maximal min-cut. By contracting S and T, respectively, into single vertices s' and t', we have that in the resulting graph s' and t' have degree q. For convenience, we retain the G, s, t notation for the new graph. Hence, we have the following:

(A.2) Without loss of generality, $\delta_G(s)$ and $\delta_G(X(G)\backslash t)$ are min-cuts.

Next, consider a family $\{p_1, p_2, \ldots, p_q\}$ of q pairwise edge-disjoint s–t paths in G. Clearly every critical edge is contained in one of these paths, and each min-cut C and each path p_i intersect at precisely one edge. Now suppose that for some vertex $w \neq s, t, r > 1$ of these paths are incident with w. For simplicity assume these are paths p_i, $1 \leq i \leq r$, and that the edges of p_i incident with w are $\{u(i), w\}$ and $\{w, v(i)\}$. We modify our graph as follows. First, we remove w, and then we add r new vertices $w(i), 1 \leq i \leq r$, which induce a tree (say, a star). Next, for each i we add the edges $\{u(i), w(i)\}$ and $\{w(i), v(i)\}$. It is clear that in the new graph there is a system of q edge-disjoint paths each of which is incident with a different vertex $w(i)$ and that the s–t edge connectivity has not changed. Furthermore, the set of critical edges in the new graph is isomorphic to the set of critical edges in the old graph (this follows because the $w(i)$ induce a connected graph). Hence, we have the following:

(A.3) We may assume that the paths $p_i, 1 \leq i \leq q$, are pairwise internally vertex disjoint.

We point out that the transformation above increases the number of edges by at most a factor of 2. Denote by $|p_i|$ the number of edges in $p_i, 1 \leq i \leq q$. Let us color the edges in the paths p_i green and all other edges, red. Next, we label each vertex in p_i by $p_i[j]$, where $0 \leq j \leq |p_i|$ is the distance from s to the vertex along p_i.

Our approach is as follows: For each i and j, we compute the $p_i[j]$-minimal min-cut $C_j[j]$. This is useful since the green edge $\{p_ij, p_i[j+1]\}$ is critical if and only if it belongs to $C_i[j]$. Recall that any min-cut intersects any path p_i on at least one edge and therefore on precisely one edge. Hence, we can describe any min-cut by specifying on which edge it intersects each path p_i. Thus we can describe each min-cut with $O(q)$ data.

We use the following notation. Let $1 \leq a, b \leq q$ (possibly $a = b$). For each vertex $p_a[j]$, we define a number $f(p_a[j], b)$. First, let

$$R(p_a[j], b) = \{g : \text{ there is a } \textit{red} \text{ edge } \{p_a[h], p_b[g]\} \text{ with } h \leq j\}.$$

Next, set

$$g(p_a[j], b) = \max\{g \in R(p_a[j], b)\}, \quad \text{if } R(p_a[j], b) \neq \emptyset \quad \text{ and } g(p_a[j], b) = 0 \text{ otherwise.}$$

Finally,

$$f(p_a[j], b) = g(p_a[j], b) \quad \text{if } a \neq b, \qquad \text{and } f(p_a[j], a) = \max\{j, g(p_a[j], a)\}.$$

Later we shall show how to compute all numbers $f(p_a[j], b)$ in $O(q^2m)$ time.

The algorithm we use to compute the cuts $C_i[j]$ is inductive. For $1 \leq h \leq q$, let $G[h]$ denote the subgraph of G induced by vertices in the paths $p_i, 1 \leq i \leq h$. It is seen that $\lambda_{G[h]}(s, t) = h$. For each vertex v in $G[h]$, let $A_h(v)$ denote the v-minimal min-cut in $G[h]$. Inductively (that is, in increasing values of h), our algorithm computes all the cuts $A_h(p_i[j])$, where $1 \leq i \leq h$ and $0 \leq j \leq |p_i|$. For $h = q$, this yields the cuts we desire $(A_q(p_i[j]) = C_i[j])$.

An algorithm for computing the cuts $A_h(p_i[j])$. Consider first the case $h = 1$. Then $\lambda_{G[1]}(s, t) = 1$, and it is seen that for each j, the cut $A_1(p_1[j])$ consists of the edge $\{p_1[z], p_q[z+1]\}$, where $z = f(p_1[j], 1)$.

Now for the general inductive step. Suppose we have computed all the cuts $A_{h-1}(p_i[j])$. Next we compute all cuts $A_h(p_i[j])$, beginning with the cuts $A_h(p_h[j])$. Fix j. For $1 \le i \le h-1$, write $\Phi(j,i) = f(p_h[j], i)$ and let $B(i,j) \subseteq V(G(h-1))$ be such that $\delta_{G[h-1]}(B(i,j))$ is the $p_i[\Phi(j,i)]$-minimal min-cut in $G[h-1]$. Define $B_j = \cup\{B(i,j) : 1 \le i \le h-1\}$. Then (refer to A.1) we have the following:

$$\text{(A.4)}\qquad \begin{aligned}&\delta_{G[h-1]}(B_j) \text{ is the } \{p_1[\Phi(j,1)],\\ &p_2[\Phi(j,2)], \dots, p_{h-1}[\Phi(j,h-1)]\} - \text{minimal min-cut in } G[h-1].\end{aligned}$$

We compute the cuts $A_h(p_h[j])$ in *decreasing* order of j. Thus, let j^* be such that $p_h[j^*+1] = t$. We have the following claims:

CLAIM 1. $A_h(p_h[j^*]) = \delta_{G[h-1]}(B_{j^*}) \cup \{p_h[j^*], p_h[j^*+1]\}$.

Proof. It is clear that $\delta_{G[h-1]}(B_{j^*}) \cup \{p_h[j^*], p_h[j^*+1]\}$ is a min-cut in $G[h]$ (recall (A.2)). Now let $X \subseteq V(G[h])$ be such that $\delta_{G[h]}(X) = A_h(p_h[j^*])$, and let $X' = X \cap V(G[h-1])$. Now $\delta_{G[h-1]}(X') = A_h(p_h[j^*]) \cap E(G[h-1])$ is a min-cut in $G[h-1]$. Further, $p_i[\Phi(j^*, i)] \in X$ for $1 \le i \le h-1$. Therefore $B_{j^*} \subseteq X'$, and then the minimality of $A_h(p_h[j^*])$ and (A.4) imply that $B_{j^*} = X'$, which proves the claim. □

Next, assume we have computed all the cuts $A_h(p_h[j'])$ for each $j' > j$. Define $F_j = \max\{f(p_i[\Phi(j,i)], h) : 1 \le i \le h-1\}$. We have the following claim:

CLAIM 2. $A_h(p_h[j]) = A_h(p_h[F_j])$ *if* $F_j > j$, $A_h(p_h[j]) = \delta_{G[h-1]}(B_j) \cup \{p_h[j], p_h[j+1]\}$ *otherwise.*

Proof. The proof follows by an argument similar to that in the proof of Claim 1. □

Finally, we compute all cuts $A_h(p_i[j]), 1 \le i < h$, as follows. Fix $i < h$, and consider any vertex $p_i[j], 0 \le j \le |p_i|$. Let $D \subseteq V(G[h-1])$ be such that $\delta_{G[h-1]}(D) = A_{h-1}(p_i[j])$. Set $H = \max\{f(v,h) : v \in D\}$ and let $X \subseteq V(G[h])$ be such that $\delta_{G[h]}(X) = A_h(p_h[H])$. Then we have the following claim:

CLAIM 3. $A_h(p_i[j]) + \delta_{G[h]}(D \cup X)$.

Proof. First, $\delta_{G[h]}(D \cup X)$ is a min-cut in $G[h]$. This follows because this cut contains no *red* edges. Moreover, if X' is such that $\delta_{G[h]}(X') = A_h(p_i[j])$. Then clearly $D \subseteq X' \cap V(G[h-1])$. Thus $D \cup X \subseteq X'$, which proves the claim. □

Complexity of the algorithm for computing the cuts $A_h(p_i[j])$. We next show that the total workload in computing all the cuts $A_h(p_i[j]), 1 \le h \le q$, is $O(q^3 m)$. First we show how to compute all numbers $g(p_a[j], b)$ in $O(q^2 m)$ time (from which we immediately have the numbers $f(p_a[j], b)$). For fixed a and b, this is easily done for *increasing* values of j. Suppose we know $g(p_a[j], b)$. Then

$$g(p_a[j+1], b) = \max\{g(p_a[j], b), \max\{d : \{p_a[j], p_b[d]\} \text{ is a red edge}\}\},$$

and a similar formula yields $g(p_1[0], b)$. Notice that for given a and b, the total amount of work involved in computing all numbers $g(p_a[j], b)$ is (at most) proportional to the number of edges with one end in p_a. Hence the computation of all the $g(p_a[j], b)$ (over all a, b, and $0 \le j \le |p_a|$) takes time $O(q^2 m)$ (with more care it can be done in $O(m)$, but that is not crucial here).

Next, recall that if a min-cut $\delta_{G[h]}(X)$ in $G[h]$ contains an edge $\{p_i[j], p_i[j+1]\}$, then X contains all vertices $p_i[r], 1 \le r \le j$, and consequently, we can compactly describe any min-cut by specifying just what edge of each path p_i it contains (i.e., using $O(h)$ data in $G[h]$). As a result, suppose, for example, that $\delta_{G[h]}(X)$ and $\delta_{G[h]}(Y)$ are min-cuts in $G[h]$, described as just stated. Then we can compute the min-cut $\delta_{G[h]}(X \cup Y)$ in $O(h^2)$ time (by computing the maxima of h sets of h numbers). Using this fact, it is not difficult to see that the operations leading to Claims 1–3 can be implemented in time $O(h^2m)$, assuming we already have the $A_{h-1}(p_i[j])$ data.

Consequently, in $O(q^3m)$ time we can compute all cuts $A_q(p_i[j])$, i.e., the $p_i[j]$-minimal min-cuts in G, as desired.

Appendix B. In this appendix we sketch how to efficiently carry out the "feasibility" tests in algorithm Ext.

The main thrust is as follows. Consider the level i problems. Let us write $S(i, B)$ for the optimal solution to $P_w(s^*, u^*, A(i) \otimes B)$ that is computed by Ext. Then, besides storing the solutions $S(i, B)$, we also compute their *compatibility*: For every pair B, B' of small graphs that we consider, we record where $S(i, B)$ is *feasible* for $P_w(s^*, u^*, A(i) \otimes B')$. We also compute similar compatibility data for problems of the form $P_w(s^*, u^*, D(i) \otimes B)$.

Suppose we have computed these data for the level i problems. Consider now one of the problems in step (a) of Ext, i.e., a problem $P_w(s^*, u^*, D(i) \otimes B)$. Here we have to test for each subset Z_i of the edges $\delta_G(V(A(i)), V(i+1))$ and each optimal solution $S(i, B')$ whether $S(i, B') \cup Z_i$ is feasible for $P_w(s^*, u^*, D(i) \otimes B)$. We do this as follows: Let $K(i)$ be the graph made up by the union of B and $\delta_G(V(A(i)), V(i+1))$. Then we compute the $K(i)$-consolidation of $D(i) \otimes B$ (with respect to Z_i and u^*, with a slight abuse of notation here: We really mean the *image* of $K(i)$ in $D(i) \otimes B$). Clearly, this graph is of the form $A(i) \otimes F$, for some small graph F, and therefore, using the compatibility data, we can look up the answer to the feasibility test. Moreover, this consolidation operation can be carried out in $O(2k2^{4k})$ time (a bounded number of tests for small min-cuts in a graph with a bounded number of edges). We also compute compatibility data for the optimal solutions to problems involving $D(i)$ in a similar way.

Finally, consider a level $(i + 1)$ problem, i.e., a problem $P_w(s^*, u^*, A(i + 1) \otimes B)$. In the feasibility tests here we consider pairs of the form S_i, J_i, where S_i is an optimal solution to a problem of the form $P_w(s^*, u^*, D(i) \otimes B')$, and J_i is an optimal solution to a problem of the form $P_w(u^*, v^*, J(i + 1) \otimes H)$ considered in step (b) of Ext. Here, as in the previous paragraph, we proceed with the feasibility test by first computing the B-feasibility of $A(i + 1) \otimes B$ with respect to $S_i \cup J_i$ and u^*. Having done so, once more the answer to the feasibility test is available from the compatibility data for the problems involving $D(i)$. Moreover, it is not hard to see that the consolidation operation can be carried out in time $O(2k2^{2k}m(i + 1) + k2^{4k})$, where $m(i + 1)$ denotes the number of edges in $J(i + 1)$: We perform, at most, 2^{2k} tests for small min-cuts in a graph with at most $m(i + 1) + k2^{4k}$ edges. The compatibility data for the level $(i + 1)$ problems is computed in a similar way.

Since the $J(i + 1)$ are pairwise edge-disjoint subgraphs of G, the overall complexity of the feasibility tests is thus $O(2k2^{2k}m)$, as desired.

FLOOR-PLANNING BY GRAPH DUALIZATION: 2-CONCAVE RECTILINEAR MODULES*

KOK-HOO YEAP† AND MAJID SARRAFZADEH†

Abstract. Given a planar triangulated graph (PTG) G, the problem of constructing a floor-plan F such that G is the dual of F and the boundary of F is rectangular is studied. It is shown that if only zero-concave rectilinear modules (CRM) (or rectangular modules) and 1-CRM (i.e., L-shaped) are allowed, there are PTGs that do not admit any floor-plan. However, if 2-bend modules (e.g., T-shaped and Z-shaped) are also allowed, then every biconnected PTG admits a floor-plan. Thus, the employment of 2-bend modules is necessary and sufficient for graph dualization floor-planning. A linear-time algorithm for constructing a 2-CRM floor-plan of an arbitrary PTG is proposed.

Key words. floor-planning, planar graphs, graph dualization, CRM

1. Introduction.

Floor-planning is an early step in VLSI chip design where one decides the relative location of functional entities in a chip. The most immediate representation of a floor-plan is the partition of a rectangular chip area into modules (usually rectilinear polygons) where each module represents a functional entity. Such a partition can be represented by a partition graph where faces of the graph correspond to modules, edges represent the sides of modules, and vertices are junctions. Figure 1(a) shows a floor-plan represented in partition graph.

The dual graph of a partition is a graph where each vertex represents a module and each edge (i, j) represents adjacency of module i and module j. Given a partition, its dual graph is easily and uniquely determined. However, given a dual graph specifying adjacency requirements, it is not readily converted into a partition. In this formulation of floor-planning problem, we are given a graph specifying the connection requirements of circuit modules and wish to find a rectilinear partition on a rectangular chip area.

For simplicity, most floor-planning systems are restricted to 0-concave rectilinear modules (0-CRM), i.e., rectangles. The dual graph of a rectangular floor-plan is a planar triangulated graph (PTG). However, there exist planar triangulated graphs that do not have any dual floor-plans. Kozminski and Kinnen developed the necessary and sufficient conditions for the existence of a 0-CRM floor-plan [2]. They also showed a technique to transform one floor-plan to another where the adjacency requirements were preserved [3]. A linear time algorithm for constructing a rectangular floor-plan, if one exists, was reported in [1]. An algorithm to enumerate all rectangular floor-plans was reported in [13]. An algorithm for sliceable floor-planning was proposed in [14].

The construction of a floor-plan is complicated by the existence of complex triangles (CTs) (a cycle of three edges that is not a face) because the dual of a rectangular floor-plan does not contain any CT. One approach eliminates all CTs to obtain a rectangular floor-plan [12]. This technique introduces new vertices and edges in the original PTG, producing empty spaces in the floor-plan. If the empty spaces are considered as part of some adjacent modules, this approach produces general rectilinear-shaped modules. The weighted CT elimination problem has been shown to be NP-complete [11].

Adjacency requirements of CTs can be achieved by introducing more complicated shapes instead of rectangular modules. A 1-concave rectilinear module (1-CRM) with 1-bend is required to satisfy the adjacency requirements of a CT. Similarly a 2-concave rectilinear module (2-CRM) can satisfy adjacency requirements of two CTs simultaneously. In some sense, the introduction of more complicated shapes is analogous to eliminating CTs. However, this approach maintains the adjacency requirements without arbitrarily adding new vertices and edges to the input PTG.

In this paper we examine 0-CRM (rectangle), 1-CRM, and 2-CRM. A 1-CRM refers to a rectilinear polygon that consists of six sides, five convex and one concave corners. Similarly, a 2-CRM refers to a rectilinear polygon with eight sides, six convex and two concave corners. A 2-CRM can be viewed as two adjacent 1-CRMs. In actual implementation, a 1- or 2-CRM can be represented by a set of adjacent rectangles.

The necessary and sufficient conditions for the existence of a 1-CRM floor-plan are given in [10]. However, there exist PTGs, as we will show, where 1-CRM floor-plan is not sufficient. Obviously, an arbitrary PTG admits a floor-plan if we allow general rectilinear-shaped modules, i.e., k-CRM for arbitrary large k. It was an open problem to find the least k in which some floor-plans exist for any PTG. We show that any biconnected PTG admits a 2-CRM floor-plan. A linear-time algorithm for constructing one is presented. The biconnected requirement is not a restrictive condition. By adding edges, a 1-connected planar graph can be transformed into a biconnected graph without loosing planarity and adjacency. We thus establish that employment of 2-bend modules is both necessary and sufficient.

The restriction of the dual graphs to PTG is a natural constraint. The dual of a floor-plan is planar since a floor-plan is planar by definition. Also, PTG represents the most dense planar graph. Any planar graph can be triangulated by adding edges. In the floor-planning process, an adjacency graph is first planarized and triangulated to yield a PTG. The PTG then serves as the input to the floor-planning problem.

This paper is organized as follows: Section 2 discusses the major issues arising in the floor-plan construction of a PTG, especially the local adjacency requirements. Section 3 presents a key theorem for the establishment of the sufficient conditions for dualization. An algorithm for floor-plan construction is proposed in §4.

2. Graph dualization. In this section, we discuss major issues arising in graph dualization of a PTG. We examine the local adjacency requirements of a PTG and show that a 1-CRM floor-plan is not sufficient. The notion of sharing, which is crucial to dual construction, is also discussed.

2.1. Floor-plan and its dual. A *floor-plan* F is a plane graph where

1. Each edge is either a horizontal or vertical line segment.
2. The boundary of F is rectangular.
3. Each vertex has either degree 2 or 3.

A degree 4 vertex can be represented by two vertices of degree 3 and an edge e_0 of zero length, as shown in Fig. 1(b). Thus we can assume that each vertex of F has degree 2 or 3 without loss of generality. Also we assume that there is no degree 2 vertex as shown in Fig. 1(c), because it can be represented by a single edge.

A face of a floor-plan is also called a *module*. An angle formed by two neighboring edges e_1 and e_2 incident to a common vertex v is called a *corner*. A corner is denoted by an ordered pair of edges (e_1, e_2) with e_1 preceding e_2 in a clockwise manner centered at v. There are three types of corners in F: *convex* ($90°$), *aligned* ($180°$), and *concave* ($270°$). Because modules are confined by horizontal an vertical line segments, the num-

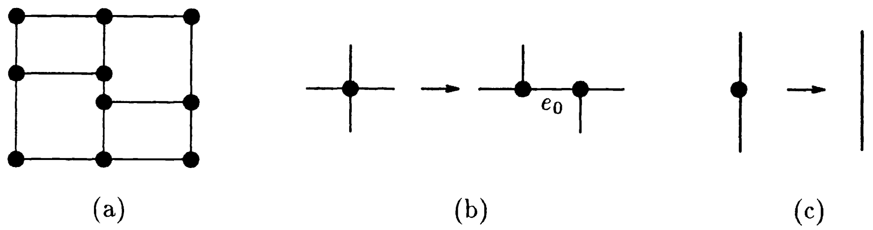

FIG. 1. *A floor-plan and its restrictions.*

ber of convex corners minus that of concave corners is always four. For the purpose of discussion, we always assume that F is confined by four infinite regions r, u, l, and b as shown in Fig. 2.

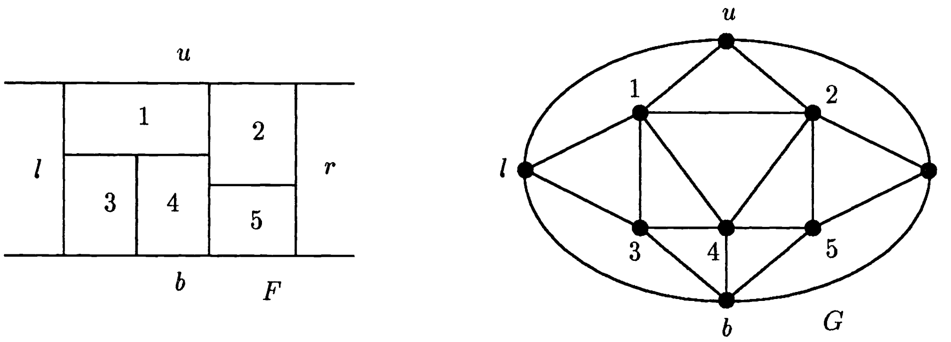

FIG. 2. *A floor-plan F and its dual G.*

The *dual* of a floor-plan F is a plane graph $G = (V, E)$, where each vertex in V corresponds to a face in F and each edge of G corresponds to an edge of F. A face bounded by three edges is also called a *triangle*. A face bounded by two parallel edges is called a *biface*. There is a one to one correspondence between the edges of F and that of G. Given F, the dual G is easily and uniquely determined. Figure 2 shows a floor-plan F and its dual G. If the vertices r, u, l, b (and incident edges) are deleted from G, the remaining subgraph G_c is called the *core* of G and G is called an *extended graph* of G_c. The vertices of G_c are called *core vertices*. Because corners are defined by two edges, there is also a one to one correspondence between corners of F and that of G. The bounded faces of F correspond to the core vertices of G.

In the graph dualization approach to floor-planning, we are given a core G_c and wish to find a floor-plan F where the dual G has core G_c. The very first step in the dualization process is to append the vertices r, u, l, b (and edges) to G_c to obtain G that matches the configuration shown in Fig. 3. This is not a trivial process. An excellent discussion on the details is contained in [2] and we shall not address this problem here. From now on, we will assume that G is given and conforms to the configuration as shown in Fig. 3. If F is restricted to 0-CRM modules, the dual G is a PTG. For a 1-CRM or 2-CRM floor-plan, the dual is also a PTG if we eliminate one parallel edge of each biface. Thus, it is reasonable to restrict our input G to PTGs. A PTG is also the most dense planar graph. Given a core G_c that specifies adjacency requirements of modules, we assume that some preprocessing has been performed to planarize and triangulate G_c to obtain G.

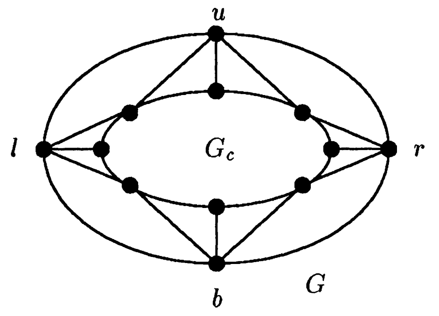

FIG. 3. *Configuration of a dual G.*

2.2. Alternate representation of a floor-plan with its dual. Let G be the dual of a floor-plan F. An *F-labeling* [3] of G is a labeling of edges and corners of G where

1. Dual edges of horizontal line segments are labeled H.
2. Dual edges of vertical line segments are labeled V.
3. Dual corners of G are labeled **convex, aligned,** or **concave.**

An edge label is also called *orientation*. The corners of the infinite face of G (e.g., $((l,u),(u,r))$) are not labeled because they are not interesting in our discussion. Figure 4 shows an example of F-labeling. Vertical edges are denoted by thick lines, whereas horizontal edges are shown with thin lines. A corner formed by two edges of identical orientations is an **aligned** corner. A corner formed by two edges of different orientations is **concave** if there is an arrow pointing to the vertex, otherwise it is **convex.**

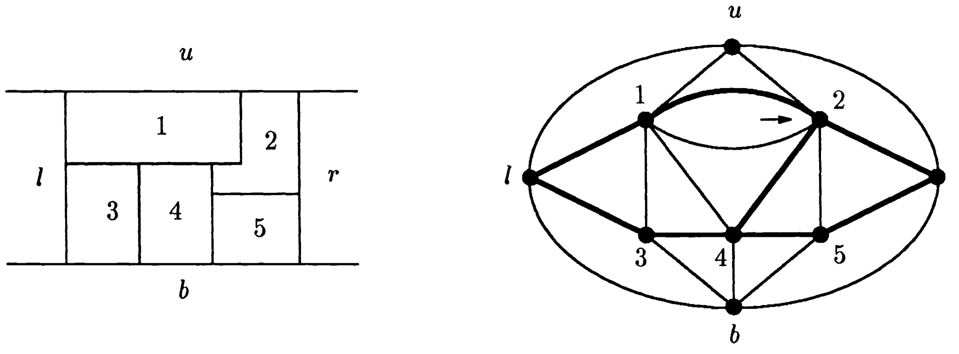

FIG. 4. *An example of F-labeling.*

An arbitrary F-labeling of G may not correspond to a floor-plan. We call an F-labeling *legal* if a corresponding floor-plan exists. There is a one-to-one correspondence between a legal F-labeling of G and a floor-plan F. Given G, the task of finding F can be viewed as finding a legal F-labeling in G.

Consider a legal F-labeling in G. By the definition of floor-plan, a legal F-labeling exhibits the following properties:

P1. All incident edges of u and b have horizontal orientation.

P2. All incident edges of l and r have vertical orientation except $(u,l),(u,r),(b,l)$, and (b,r).

P3. Let the convex, aligned, and concave corners be assigned cost 1, 0, and -1, respectively. The sum of all corner costs incident to a core vertex is exactly 4. The sum costs of u, b is 0, and l, r is 2. Also, the total corner cost of a triangle of G is 2, and the total cost of a biface is 0. This property is a consequence of rectilinear faces in F.

P4. Each triangle of G has at least one horizontal edge and at least one vertical edge. Each biface has exactly one horizontal and one vertical edge.

P5. No biface is incident to vertices r, u, l, b. All incident corners of r, u, l, b are not concave.

It is also evident that if an F-labeling of G satisfies the above conditions, it is a legal F-labeling. We can reconstruct the horizontal and vertical line segments of floor-plan F with the proper corners specified by the F-labeling. Thus a dualization process from G to F corresponds to finding an F-labeling satisfying the above conditions.

2.3. Complex triangles. A *complex triangle* (CT) is a nonface cycle containing exactly three edges. For our discussion, CTs are only defined on dual G. Figure 5 shows two examples of complex triangles.

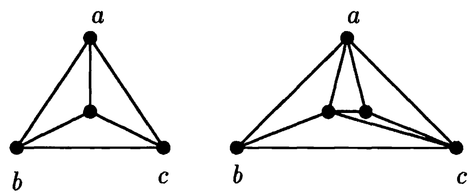

FIG. 5. *CTs.*

Consider the dualization of a CT $\triangle_{abc}$. If only 0-CRM is allowed in the floor-plan, it is impossible to satisfy the adjacency requirements of the edges (a, b), (b, c), and (a, c) simultaneously. However, if 1-CRM is allowed, a floor-plan exists as shown in Fig. 6. A 0-CRM floor-plan does not exist if and only if G contains a CT [2]. Note that the concave corner of module 3 contributes to the existence of a floor-plan. A biface is formed in the dual due to the concave corner of vertex 3. For clarity, some edges of the floor-plans are not shown in the duals.

As far as the CT is concerned, any of the vertices $1, 2, 3$ may be chosen to bear a concave corner so that the adjacency requirements are satisfied. We call such choice the *assignment* of a CT to a vertex. Vertices 1 and 2 are also suitable for assignment.

Intuitively, the assignment of a CT to a vertex v can be seen as adding a concave corner to module v, thus bending it to satisfy the adjacency of the CT. To construct a floor-plan, all CTs in G must be assigned. The number of assignments on a vertex is related to the number of concave corners in the final floor-plan. Since we only allow 2-CRM, the number of assignments on any vertex shall not exceed 2.

A *perfect assignment* of a dual G is a set of assignments of all CTs of G where

1. Every CT is assigned to a core vertex.
2. No vertex carries more than two assignments.
3. Noncore vertices of G (i.e., r, u, l, and b) are not assigned.

In a perfect assignment, a core vertex may be assigned zero, one, or two times.

In our algorithm, if a vertex is not assigned, its corresponding module in F is a rectangle. If a vertex is assigned once, it is a 1-CRM. There is only one type of 1-CRM if we disregard module orientations. A 1-CRM is also called an L-shaped module. If a vertex is assigned twice, a 2-CRM is formed. There are four classes of 2-CRM as shown in Fig. 7.

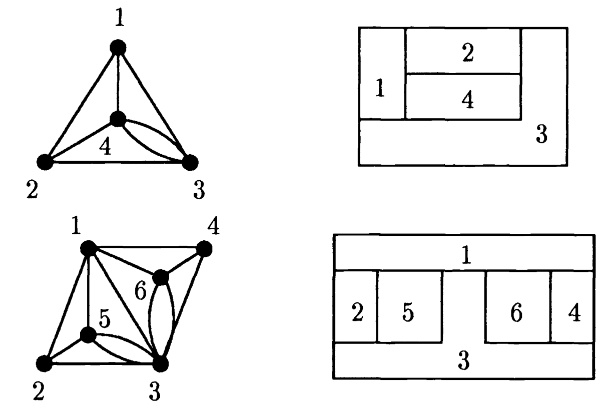

FIG. 6. *Floor-plans of CTs.*

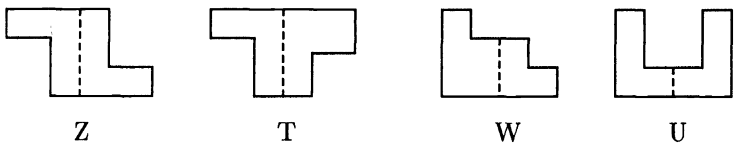

FIG. 7. *Four classes of 2-CRM: Z, T, W, and U.*

2.4. Insufficiency of 1-CRM duals. Given a PTG G, some vertices of a CT must be at least 1-CRM to satisfy the local adjacency requirements. Kozminski and Kinnen proved the necessary and sufficient conditions for a graph to admit a 0-CRM (rectangular) floor-plan [2]. It was further generalized by [10] to prove the necessary and sufficient conditions for the existence of a 1-CRM floor-plan. The primary condition for the existence of a 1-CRM floor-plan is that all nonoverlapping (i.e., one is not contained in the other) CTs can be assigned to some vertices and each vertex is not assigned more than once. If a vertex is assigned, it becomes a 1-CRM in the corresponding floor-plan; otherwise it is a rectangle. However, there exist PTGs that do not admit 1-CRM floor-plans. In particular, consider the graph shown in Fig. 8: The graph contains seven nonoverlapping CTs and only six vertices are available for assignment. There is no assignment that can satisfy the necessary conditions for the existence of a 1-CRM floor-plan. This suggests that the dualization of a PTG requires more complicated shapes. In this paper, we prove that generalization to 2-CRM is necessary and sufficient for the existence of a floor-plan for any biconnected PTG.

2.5. Complex triangle graph and containment tree. A *complex triangle graph* (CTG) of $G = (V, E)$ is $CTG(G) = (V_c, E_c)$, $V_c \subseteq V$ and $E_c \subseteq E$ where

$$V_c = \{\, v \mid v \text{ belongs to some CTs of } G \,\},$$
$$E_c = \{\, e \mid e \text{ belongs to some CTs of } G \,\}.$$

Given G, it is easy to construct the CTG thereof. A CT is always assigned to a vertex in V_c. Therefore, it suffices to consider $CTG(G)$ in search of a perfect assignment. In general, $CTG(G)$ may not be connected. However, it is easy for our assignment algorithm to be

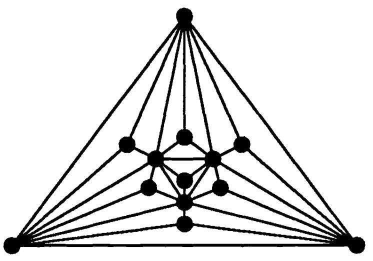

FIG. 8. *A PTG that does not admit any 1-CRM floor-plan.*

repeated for each connected component of $CTG(G)$. Therefore, we will assume that $CTG(G)$ is connected.

There is a natural hierarchy among the CTs of G. Formally, we say that CT $\triangle_{abc}$ *contains* CT $\triangle_{def}$ if the vertices d, e, and f lie in the region bounded by the edges (a,b), (a,c), and (b,c). The area of $\triangle_{def}$ must be strictly less than that of $\triangle_{abc}$. We say that $\triangle_{abc}$ *immediately contains* $\triangle_{def}$ if there exist no triangles contained in $\triangle_{abc}$, which contain $\triangle_{def}$. If two complex triangles have no containment relation, we say that they are *independent*. Figure 9 illustrates the containment relationship.

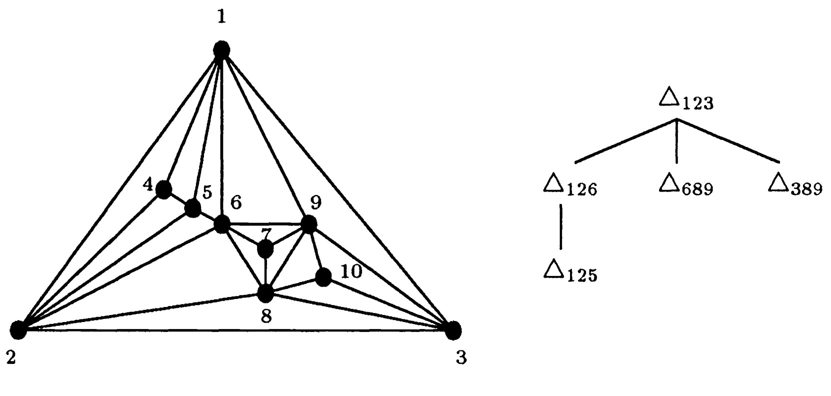

FIG. 9. *A PTG and its corresponding containment tree.*

Given G, we can construct the *containment tree* representing the hierarchy of the CTs. Each tree node represents a CT, and a parent node immediately contains its child nodes. A parent and a child can share at most two vertices. A pseudo-root node is added as the parent of top-level CTs, if needed. Traversing the tree top-down allows us to process all CTs hierarchically.

2.6. Sharing assignments. Consider two CTs $\triangle_{abc}$ and $\triangle_{ade}$ where $\triangle_{abc}$ immediately contains $\triangle_{ade}$. Suppose $\triangle_{abc}$ is assigned to vertex a. To satisfy the adjacency requirements of $\triangle_{ade}$, we can naturally assign it to vertex a to reduce the number of assigned vertices (see Fig. 10(b), where $\triangle_{abc} = \triangle_{123}$, $\triangle_{ade} = \triangle_{124}$, $a = 1$). Such assignment of the child $\triangle_{ade}$ is called *sharing assignment* because $\triangle_{ade}$ shares the same concave corner of a to satisfy its adjacency requirements. Certainly, $\triangle_{ade}$ has the freedom of being assigned to d or e, but the final floor-plan will have more nonrectangular modules, an undesirable feature (see Fig. 10(c), modules 1 and 4).

FIG. 10. *Sharing assignment:* (a) *adjacency graph,* (b) $\triangle_{123}$ *and* $\triangle_{124}$ *share vertex* 1; *and* (c) $\triangle_{123}$ *and* $\triangle_{124}$ *have independent assignments.*

When the child triangle $\triangle_{ade}$ shares an assignment with its parent, it does not add more bend to module a. Therefore, we do not increase the assignment count on vertex a when sharing occurs. All descendants of a CT can share its assignment as long as they have a common vertex. We will later see that sharing is necessary for the existence of 2-CRM floor-plans.

3. 2-CRM floor-plans. In this section, we first develop the properties of dual decomposition under a cut (to be defined). We then show that given a graph G with perfect assignment, we can construct a floor-plan where modules are 0-CRM, 1-CRM, or 2-CRM. The floor-plan construction is based on top-down recursive decomposition of G and a case analysis. The problem of floor-planning is thus reduced to finding a perfect assignment on G.

A *path* is an ordered set of vertices $(v_1, \dots, v_n)$ in $G = (V, E)$, where $v_i \in V$, $i = 1, \dots, n$, and $(v_i, v_{i+1}) \in E$, $i = 1, \dots, n-1$. $v_1, \dots, v_n$ are distinct. We consider the decomposition of G into two subgraphs G_1 and G_2. Let $P = (v_1 = u, \dots, v_n = b)$ be a path in G that begins on vertex u and ends on vertex b. The path P *decomposes* G into left and right subgraphs G_l and G_r as shown in Fig. 11(a). Note that the vertices of P are duplicated in both subgraphs and vertices r' and l' are appended to G_l and G_r, respectively. G_l and G_r both conform to the configuration of Fig. 3. For a nontrivial decomposition, the path should be chosen such that G_l and G_r each contains at least one core vertex (of G) not in P. An edge (v_i, v_j) where $\mid i - j \mid \geq 2$ is called a *chord* (with respect to P). The existence of a chord will create a new CT in a subgraph when G is decomposed along P. If P does not contain chords and generates nontrivial decomposition of G to left and right subgraphs, we call P a *vertical cut*. A *horizontal cut* is defined similarly where upper and lower subgraphs are decomposed. A *cut* is either a vertical or horizontal cut.

In our algorithm, a floor-plan is constructed by recursive subdivision based on cuts that decompose G into G_1 and G_2. Such a decomposition has the properties stated in Lemma 1.

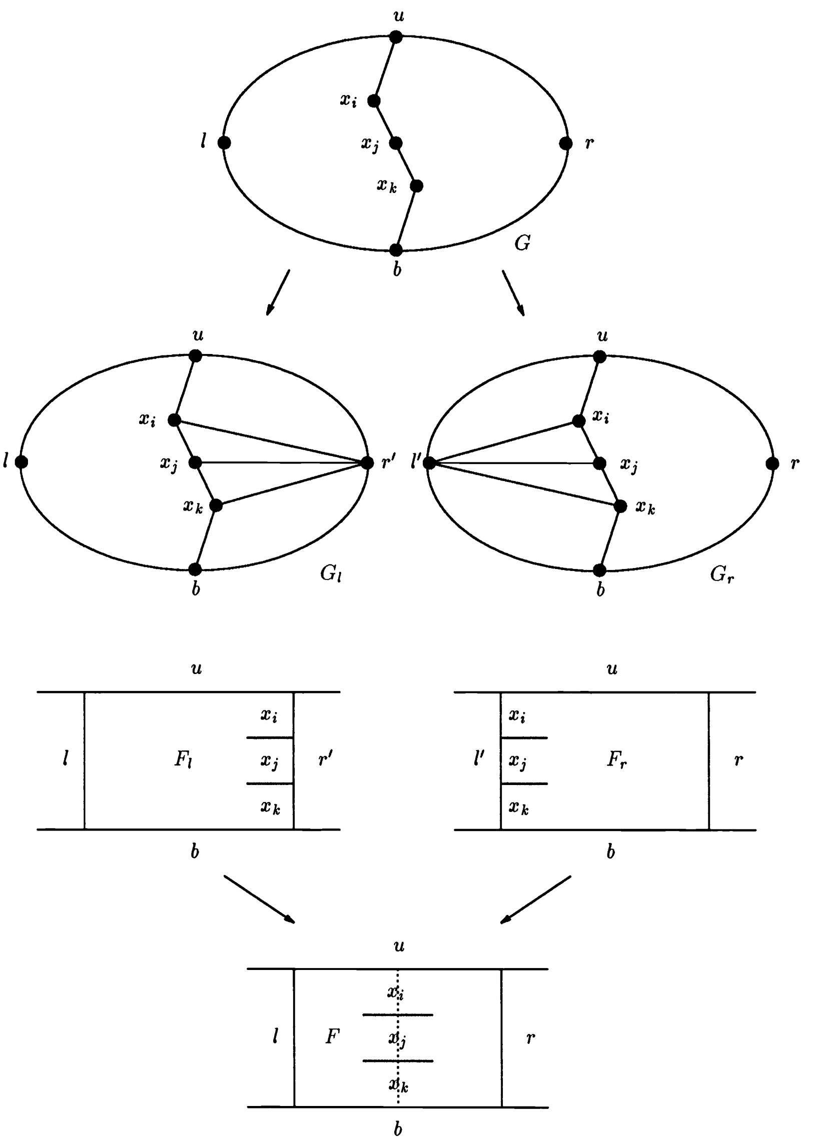

FIG. 11. *Decomposition by a cut:* (a) *decomposition of G to G_l and G_r*; *and* (b) *merging floor-plans of G_l and G_r to obtain the floor-plan of G.*

LEMMA 1. *Let $P^* = (u = v_1, \ldots, v_n = b)$ be a vertical cut in G where no edges (chords) (v_i, v_j), $| i - j | \geq 2$ exist. Let G_l and G_r be two subgraphs decomposed by P^*, then*

1. $CT(G) = CT(G_l) \cup CT(G_r)$ *and*
2. $CT(G_l) \cap CT(G_r) = \phi$,

where $CT(G)$ denotes the set of CTs of G.

Proof. There is no chord among vertices of P^*. Thus the introduction of vertices r' and l' will not create new CTs since r' and l' are only adjacent to vertices of P^*.

1. Since $G_l - r'$ and $G_r - l'$ are subgraphs of G, $CT(G) \supseteq CT(G_l) \cup CT(G_l)$ trivially holds. To show that $CT(G) \subseteq CT(G_l) \cup CT(G_r)$, we consider the converse: If it is true, there must be some CT $\triangle_{abc} \notin CT(G_l) \cup CT(G_l)$ but $\triangle_{abc} \in CT(G)$. The edges (a, b), (b, c), and (c, a) cannot appear simultaneously in G_l or G_r. Assume, without loss of generality, that (a, b) is in G_l and (b, c), (c, a) are in G_r. Since a, b appears in both subgraphs, $a, b \in P^*$. Let $a = v_i$ and $b = v_j$ for some integer i, j. If $\mid i - j \mid = 1$, $\triangle_{abc}$ will be in G_r, a contradiction. Thus $\mid i - j \mid \geq 2$ since a and b are distinct. But this would imply that (a, b) is a chord, another contradiction.

2. If $CT(G_l) \cap CT(G_r)$ is not empty, let $\triangle_{abc}$ be a CT of $CT(G_l) \cap CT(G_r)$. Since the common vertices of G_l and G_r are only the vertices of P^*, a, b, and c must be in P^*. Because P^* contains no chords, edges (a, b), (b, c), and (c, a) cannot form a CT. We reach a contradiction. □

A similar lemma applies to horizontal cuts. Intuitively, Lemma 1 says that the set of CTs in G can be decomposed into two disjoint sets by a cut. Such a decomposition preserves the "identity" of each CT in G, i.e., a complex triangle must be found in either G_1 or G_2, exclusively. Furthermore, no new CT is introduced by the decomposition nor does it destroy existing CTs. If (a, b) is an edge of some CT and $a = v_i$, $b = v_j$ are vertices of the cut, $\mid i - j \mid = 1$ must hold true. The lemma also suggests a method for recursive construction of floor-plans, which leads to our main result.

THEOREM 1. *If G has a perfect assignment, a 2-CRM floor-plan F exists with dual G_a and G is obtained from G_a by eliminating one edge from each biface of G_a.*

Proof. We prove the theorem by constructing an *augmented graph* G_a from the perfect assignment of G. By induction on the number of vertices of G_a, we generate a legal F-labeling on G_a. A 2-CRM floor-plan can thus be constructed.

For each assignment of CT $\triangle_{abc}$ to a, we chose an edge (a, x), $x \notin \{b, c\}$ in the CT and duplicate (a, x) to create a biface with an arrow pointing to vertex a. The resulting graph is G_a. The procedure is demonstrated in Fig. 12. There is a one-to-one correspondence between an assignment and a biface.

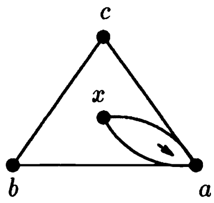

FIG. 12. *Transforming G to augmented graph G_a.*

We now show that there exists a legal F-labeling of G_a, thus implying the existence of a 2-CRM floor-plan.

Induction Basis: This is trivially true for G_a with five vertices.

Induction Hypothesis: There exists a legal F-labeling of G_a with no more than n vertices.

Induction Step: The initial labeling procedure is as follows:

1. All incident edges of u and b are labeled H.
2. All other unlabeled edges incident to l and r are labeled V.
3. If (x, y) is an edge where (u, x, y) or (b, x, y) is a face, label (x, y) as V.
4. If (x, y) is an edge where (l, x, y) or (r, x, y) is a face, label (x, y) as H.

In the labeling process, we only label the edges. The corners are implicitly labeled when their edges are labeled. The implicit rules for corner labeling are as follows:

1. If the two edges of a corner have identical labels, the corner is labeled **aligned** (180°).

2. If the two edges of a corner have distinct labels and there is an arrow pointing to the corner, the corner is labeled **concave** (270°); otherwise the corner is labeled **convex** (90°).

We first try to find a vertical cut P in G. The procedure is rather straightforward:

1. Path search. Find a path $P = (u = v_1, \dots, v_n = b)$ where there is at least one core vertex on the left and right of P.

2. Chord elimination. If a chord (v_i, v_j), $(i < j)$ exists in P, remove vertices v_k from P, where $i < k < j$. Repeat this procedure until all chords in P are eliminated.

If the resulting path P^* meets the criteria of a vertical cut, we decompose the graph as shown in Fig. 11. Vertices of P^* are duplicated and the vertices r', l' and corresponding edges are added. When the vertices of P^* are duplicated, the assignments are carried along with corresponding CTs that contributed to the assignments. Thus if $\triangle$ was assigned to v and $\triangle$ appears on the left subgraph after decomposition, vertex v on the left subgraph will carry the assignment of $\triangle$. The duplicated vertex v on the right subgraph will not carry the assignment of $\triangle$. However, the vertex v on the right subgraph may carry assignment of other CTs. It can be easily seen that if G has a perfect assignment, the subgraphs also have perfect assignments. Thus the induction hypothesis applies since each subgraph contains one less vertex. A similar procedure is applied to a horizontal cut.

By Lemma 1, CTs are not decomposed by a cut. Thus an edge of a cut cannot be an edge of a biface because a biface only exists in a CT. The decomposition process is depicted in Fig. 11. The resulting floor-plan F is constructed by merging the left and right floor-plans F_l and F_r as shown. Modules (of F_l and F_r) corresponding to vertices in the vertical cut P^* are coalesced when F_l and F_r are merged.

If vertical or horizontal cuts do not exist, we proceed with the following case analysis on G_a:

Case A. At least one of the noncore vertices has degree 3.

Case B. All noncore vertices have degree at least 4.

CASE A. *At least one of the noncore vertices has degree* 3.

Without loss of generality, we assume r has degree 3. The configuration of G_a with its initial labeling is shown in Fig. 13. Consider the distinguished vertex v adjacent to r. Vertex v has at least three edges (v, r), (v, u), (v, b). There are three possibilities for v:

A.1. v is not assigned.

A.2. v is assigned once.

A.3. v is assigned twice.

CASE A.1. *v is not assigned.*

We delete vertex r and its associated edges. We then relabel vertex v as r'. There is no biface incident to v since v is not assigned. All unlabeled incident edges of r' are labeled V except (u, r') and (b, r'), which have been labeled H. The resulting graph has one less vertex and thus the induction hypothesis applies. The F-labeling and corresponding floor-plans are demonstrated in Fig. 14. As before, thick edges have vertical orientation and thin edges have horizontal orientation. The orientations of dotted edges are not determined yet. One can easily verify that the F-labeling of vertex v does not violate the properties stated in §2.2.

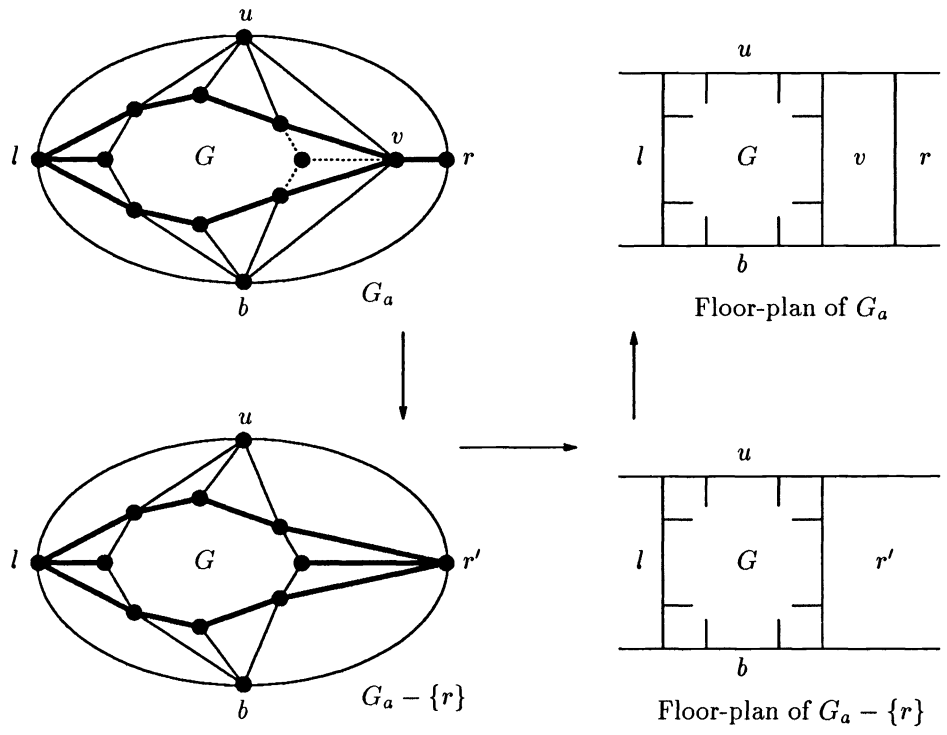

FIG. 14. *Floor-plans and duals in Case* A.1.

CASE A.2. *v is assigned once.*

Let (x_s, v) be the biface of the assignment of v. Refer to the configuration of G_a in Fig. 13. Let $P = \{u = x_1, \ldots, x_s, \ldots, x_p = b\}$ be the path from u to b in counterclockwise order where all vertices of P are adjacent to v. The general configuration of the graph is shown in Fig. 15.

The biface represents a concave corner of module v. Let $\{e_1 = (u, v), \ldots, e_s = (x_s, v), e_{s+1} = (x_s, v), \ldots, e_{p+1} = (b, v)\}$ be the set of edges in counterclockwise order with (e_s, e_{s+1}) as the biface. We claim that the other edges cannot form bifaces. Suppose

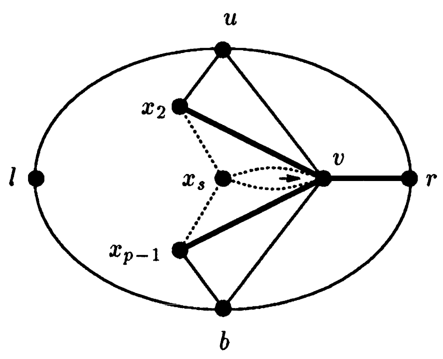

FIG. 15. *Graph of Case* A.2.

for contradiction that e_m, e_{m+1} is also a biface. If the convex corner of the biface is incident to v, v will have an assignment count of more than one. If the convex corner is incident to some other vertex, v must lie strictly inside some CT. From the configuration of Fig. 15, it is impossible for v to lie in any CT.

We perform a local transformation to the graph G_a so that the resulting graph has one less vertex. The transformation procedure is illustrated in Fig. 16. The initial labeling of G_a is shown on Fig. 16(a). We delete vertices r, b and their incident edges. We then split vertex v into two vertices and label them r' and b'. (See Fig. 16(c).) Edges $\{e_1, \ldots, e_s\}$ are now incident to r' and $\{e_{s+1}, \ldots, e_p\}$ are incident to b'. Edges (l, b') and (r', b') are also added. The unlabeled edges $\{e_2, \ldots, e_s\}$ are labeled V, and $\{e_{s+1}, \ldots, e_p\}$ are labeled H, as shown in Fig. 16(d).

Let G'_a be the resulting graph after the transformation. All CTs assigned to v, along with their bifaces, are disintegrated by the transformation process. From the floor-plan of Fig. 16(e), we see that the concave corner (biface) is eliminated by the introduction of edge (r', b'). The merging of the floor-plan of G' with 1-CRM module of v, is illustrated in Fig. 16(b). A degenerate case where $x_{p-1} = l$ is illustrated in Fig. 17. We can verify that the labeling of vertex v and P conforms to the properties stated in §2.2.

CASE A.3. *v is assigned twice.*

Refer to the general configuration of Fig. 13 again. Since v is assigned twice, there must be two bifaces incident to v. Let (x_{s1}, v) and (x_{s2}, v) be the bifaces. As before, we consider the vertices adjacent to v. Let $P = \{u = x_1, \ldots, x_{s1}, \ldots, x_{s2}, \ldots, x_p = b\}$ be the path from u to b in counterclockwise order where all vertices of P are adjacent to v. Also let $\{e_1, \ldots, e_{s1}, e_{s1+1}, \ldots, e_{s2+1}, e_{s2+2}, \ldots, e_{p+2}\}$ be the incident edges with bifaces (e_{s1}, e_{s1+1}) and (e_{s2+1}, e_{s2+2}). Since x_{s1} and x_{s2} are located in two independent CTs, $s2 \geq s1 + 2$ must hold true. Thus there is a vertex $x_s (s1 < s < s2)$ not located in any of the two CTs.

We claim that there are no vertices to the left of P. Otherwise, we can apply the chord elimination procedure to P to obtain the vertical cut P^* since vertices of P are adjacent to v. Because of the absence of such vertices, vertex x_{p-1} must be adjacent to l (by triangulation) or $x_{p-1} = l$. (If not, we would have a vertex z with edge (z, b) on the left of (x_{p-1}, b), where z is on the left of P.) We consider the general case where $x_{p-1} \neq l$ (Fig. 18) and treat the case where $x_{p-1} = l$ as a degenerate case (Fig. 19).

Consider the path $Q = (r, v, x_s, x_{s+1}, \ldots, x_{s2}, \ldots, x_{p-1}, l)$. Applying the chord elimination procedure (as described in the beginning of this proof) to the subpath Q'

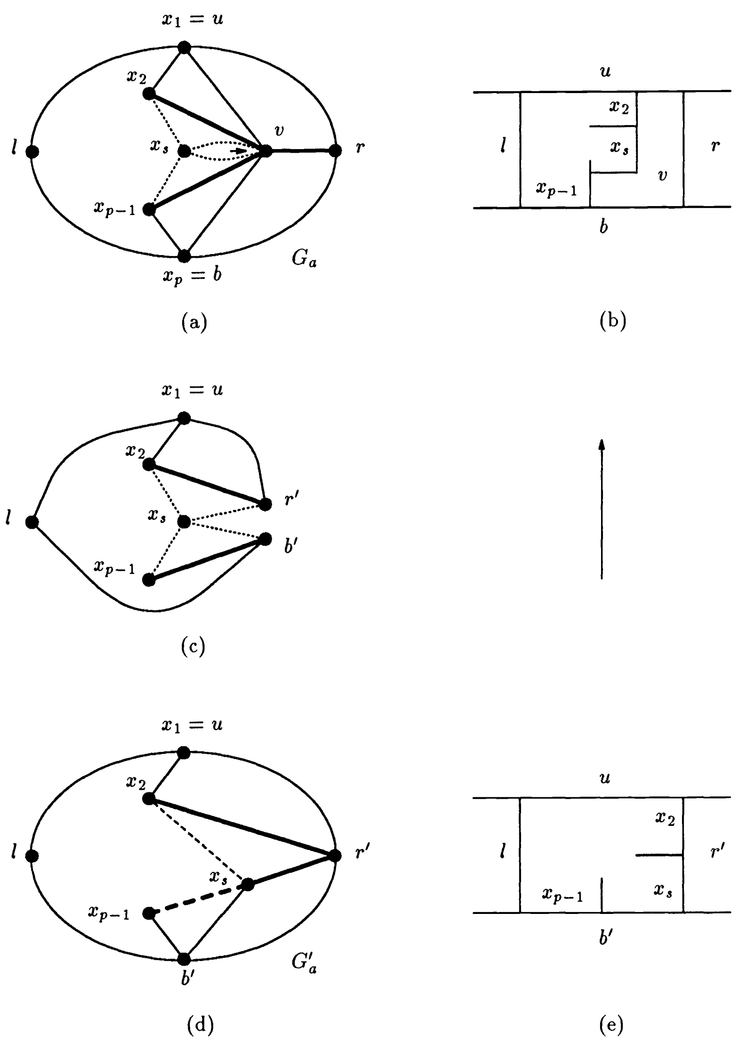

FIG. 16. *Transformation of G_a in Case* A.2.1.

$= (x_s, x_{s+1}, \ldots, x_{s2}, \ldots, x_{p-1}, l)$, we obtain a path $Q^* = (y_1 = r, y_2 = v, y_3 = x_s, \ldots, y_{q-1} = x_t, y_q = l)$. We have assumed that no horizontal cut existed in our case analysis implying Q^* is not a cut. However, all chords of Q^* must be incident to vertex v; otherwise they would have been eliminated by the chord elimination of Q' when constructing Q^*. Thus, the only condition that disqualify Q^* as a cut are the chords (y_j, v) for some j.

Despite the fact that Q^* is not a cut, we will decompose G_a along the horizontal path Q^* and give special treatment to the chords (y_j, v). Let the upper and lower subgraphs be G_u and G_b. The decomposition process is depicted in Fig. 18. Edges (y_i, b') are appended to G_u and edges (y_i, u') are appended to G_b, for $i = 1, \ldots, q$. Because of the chords (y_j, v), the addition of edges (y_j, u') in G_b results in new CTs $\triangle_{y_j v u'}$, which may not exist in G_a. However, from the figures, we can assign the concave corner of these

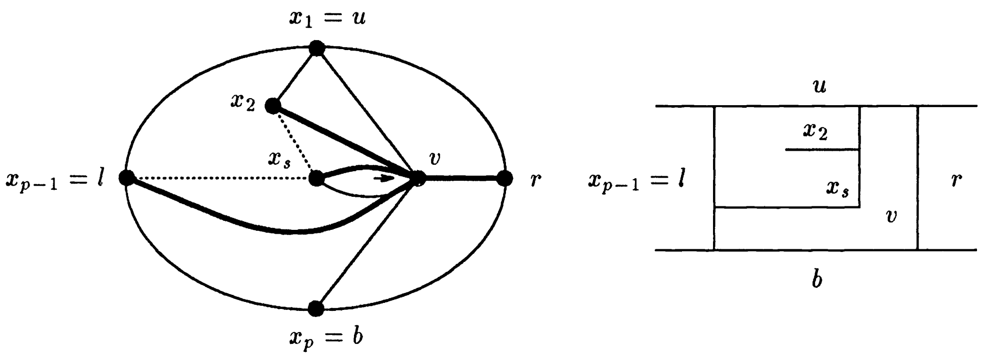

FIG. 17. *A degenerate graph of Case* A.2.

CTs to v. The assignment is a sharing assignment (see §2.6) using the concave corner of the biface (x_{s2}, v). Other CTs of G_a are handled as if Q^* is a cut. We can verify that the vertices along Q^* do not violate the properties given in §2.2.

Note that in some cases we may have $x_t = x_{p-1}$ or $x_t = x_s$ (see Fig. 18 for x_t), however, x_s and x_{p-1} are distinct by our construction. A degenerate example where $x_{p-1} = l$ is illustrated in Fig. 19.

CASE B. *All noncore vertices have degree at least* 4.

This is impossible as we shall show that we can construct a cut on G_a. The general configuration of the graph is shown in Fig. 20. Note that, there are at least four more distinct vertices v_1, v_2, v_3, v_4 in G_a as shown in the figure. We consider two possibilities:

B.1. Some of the edges (v_3, u), (v_3, r), and (v_1, b) exist.

B.2. None of the edges (v_3, u), (v_3, r), and (v_1, b) exist.

CASE B.1. *Some of the edges* (v_3, u), (v_3, r), *and* (v_1, b) *exist.*

Since the edges are topologically identical, we assume that (v_3, r) exists. The path (l, v_3, r) is a horizontal cut. Thus we have a contradiction.

CASE B.2. *None of the edges* (v_3, u), (v_3, r), *and* (v_1, b) *exists.*

We scan adjacent vertices of v_3 clockwise to obtain the path $(l, x_1, \ldots, x_m, b)$. Similarly, we scan adjacent vertices of b clockwise to obtain the path $(v_3, y_1, \ldots, y_n, r)$. Note that $x_m = y_1$ and $y_n = v_2$. We construct the path $P = (l, x_1, \ldots, x_m = y_1, \ldots, y_n, r)$ (see Fig. 21). Vertex u cannot appear in P due to the nonexistence of (v_3, u). Also, v_1 cannot appear in P, otherwise we have a horizontal cut (l, v_3, v_1, r). We apply the chord elimination procedure to P and obtain a horizontal cut P^*. This is another contradiction. □

From Theorem 1, the problem of the existence of a 2-CRM floor-plan is reduced to finding a perfect assignment in G. For a given G, there may be more than one perfect assignment. Different assignments correspond to different floor-plans. In the next section, we present an algorithm to obtain a perfect assignment in G.

4. An algorithm for perfect assignment.

In this section, we first demonstrate that assignment sharing is necessary for the existence of a 2-CRM floor-plan. We then propose a hierarchical assignment algorithm to obtain a perfect assignment in a PTG. The algorithm can be easily adapted to the extended dual G, as described in §4.3. Finally, we present an example.

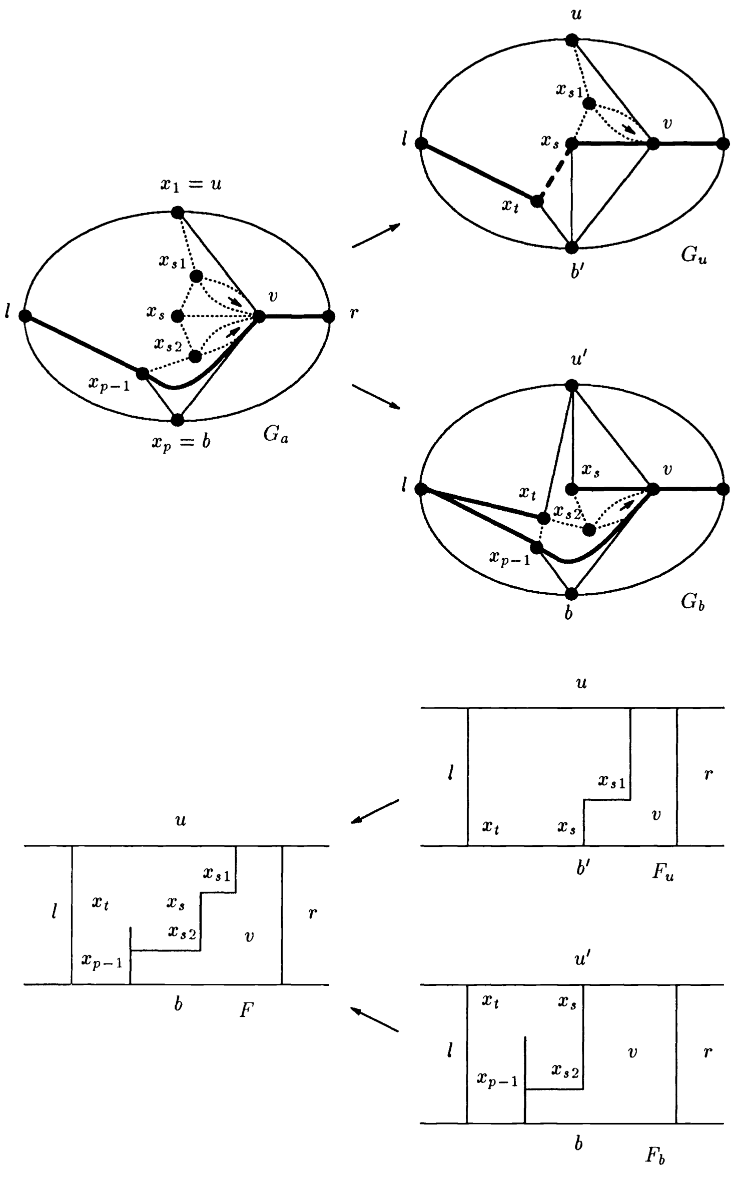

FIG. 18. *Dual decomposition of Case* A.3.

4.1. Necessity of sharing assignments. Sharing assignment refers to the assignment of a child CT that uses the concave corner of its parent CT to satisfy its adjacency requirements. The notion of sharing has been discussed in §2.6, and Fig. 10 illustrates an example of a sharing assignment. An assignment can be shared by more than one generation of CTs. Sharing reduces the number of nonrectangular modules in a floor-plan. In some graphs, sharing is even necessary to achieve perfect assignments.

Consider a series of PTGs G_i as shown in Fig. 22. G_n is obtained by adding a vertex and three edges to each bounded face of G_{n-1}. The containment tree of G_n is a full

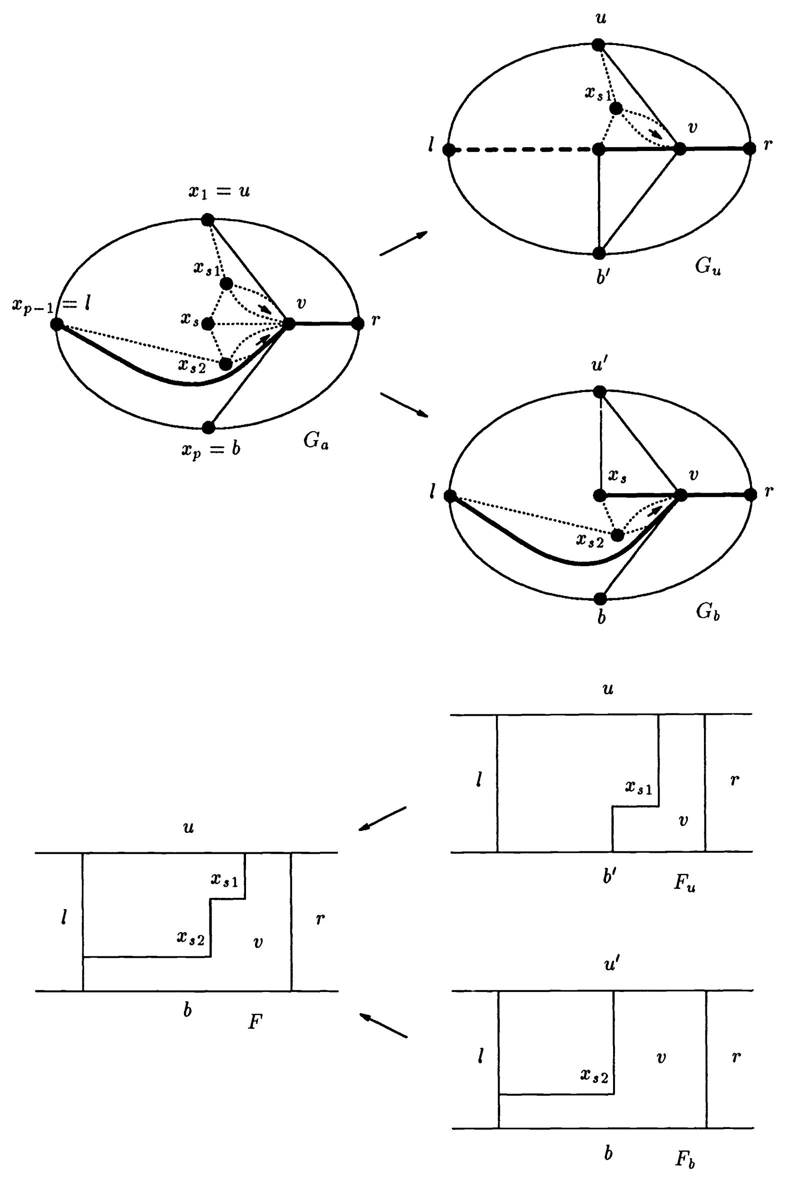

FIG. 19. *A degenerate example of Case* A.3.

ternary tree. Let $f(n)$ denote the number of bounded faces in G_n and $CT(G_n)$ denote the number of CTs in G_n. From G_n to G_{n+1}, each bounded face of G_n becomes a CT of G_{n+1}. Because $f(n) = 3^n$, we have

$$CT(G_{n+1}) = CT(G_n) + 3^n, \qquad n \geq 0,$$
$$CT(G_0) = 0.$$

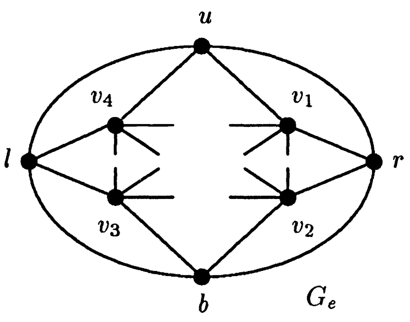

FIG. 20. *Graph of Case* B.

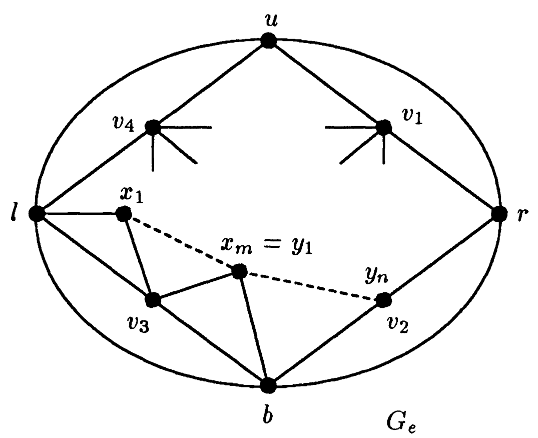

FIG. 21. *Graph of Case* B.2.

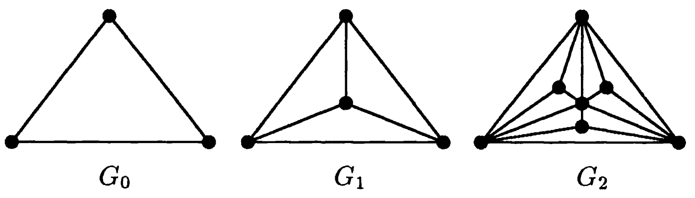

FIG. 22. *Family of graphs to show the necessity of sharing assignment.*

Solving the recurrence equations gives

$$CT(G_n) = (3^n - 1)/2,$$

which is also the number of nodes in the containment tree of G_n. Let $V(G_n)$ denote the number of vertices available for assignment in G_n (this number is not equal to the number of vertices in G_n). For $n \geq 1$, we have

$$V(G_{n+1}) = V(G_n) + 3^{n-1}, \qquad n \geq 1,$$
$$V(G_1) = 3.$$

Solving the recurrence equations gives

$$V(G_n) = (3^{n-1} + 5)/2.$$

Since each vertex can carry at most two assignments, the maximum number of assignments $A(G_n)$ in G_n is

$$A(G_n) = 2V(G_n) = 3^{n-1} + 5.$$

For $n \geq 4$, $CT(G_n) > A(G_n)$. If each assignment of a CT is counted once, it is impossible to obtain a perfect assignment since the number of CTs outnumber that of available assignments. This is also intuitively evident from the fact that each new vertex introduces three CTs but only two new assignments.

We thus see that sharing is necessary to achieve a perfect assignment. When a CT shares its assignment with its parent, we do not increase the assignment count on the vertex because sharing does not result in more complicated shapes. The assignment of a vertex is counted twice only if it is assigned by two independent CTs (i.e., one does not contain the other and vice versa). From the practical point of view, sharing should be encouraged whenever possible since we prefer simpler shaped modules.

4.2. Hierarchical assignment algorithm for PTG. The hierarchy of CTs suggests a recursive assignment procedure. We proceed in breadth-first manner in the containment tree. At each step of the recursion, we only consider the CTs that have identical parent. Let G_i be the graph induced by the CTs in step i, i.e., the CTG of siblings having identical parent $\triangle$. We also call $\triangle$ the parent of G_i. We assume that G_i is connected. If not, our algorithm will be applied to each connected component of G_i. After G_i is assigned, the algorithm is recursively applied to the children of each CT of G_i in the containment tree.

We define the following terms on G_i: An edge (a, b) is called a *boundary edge* if it is an edge of the infinite face of G_i; otherwise it is called an *internal edge*. A vertex is called a *boundary vertex* if there are some boundary edges incident to it; otherwise, it is called an *internal vertex*. From the definition, the following properties hold on graph G_i:

P1. A boundary edge has exactly one triangle on one side.

P2. A boundary vertex has at least two boundary edges incident to it.

P3. A boundary vertex is adjacent to at least two other boundary vertices.

We call a vertex *saturated* if it has already been assigned twice. Consider vertices of G_i. Let $\triangle_{abc}$ be the the parent of G_i. Vertices a, b, c may appear in G_i. In the worst case, all of them may be saturated due to previous recursive assignment steps. Suppose $\triangle_{abc}$ is assigned to vertex a in the previous recursive step. Because of the sharing scheme, vertex a is allowed to carry one more assignment in G_i. Therefore, even if the vertex is already saturated from its previous assignments, we can *force* (artificially set the assignment count) it to take one more assignment in G_i. Thus at most two vertices (b and c) are saturated in G_i, and both of them are boundary vertices. In fact, the vertex a is also allowed to carry assignments of any descendant of $\triangle_{abc}$ as long as the assignments are shared.

As the algorithm proceeds, we delete edges and vertices of G_i that do not have unassigned triangles incident to them. We always maintain the following invariant properties:

Q1. At most two boundary vertices are saturated. The other boundary vertices may have zero or one assignment.

Q2. Internal vertices have zero assignment.

We choose an unsaturated vertex v from the set of boundary vertices. Such a vertex always exists since a nontrivial G_i has at least three boundary vertices, of which at most two are saturated. We scan the vertices adjacent to v counterclockwise. Let $v_0, \dots, v_n$, $n \geq 1$ be the vertices, where (v, v_0) and (v, v_n) are boundary edges. (Note that v_0 and v_n are boundary vertices.) There are at most n triangles $\triangle_1, \dots, \triangle_n$ incident to v, where $\triangle_i$ is $\triangle_{v_{i-1}\, v_i\, v}$. There are two possible cases:

Case 1. $v_1, \dots, v_{n-1}$ are all internal vertices.

Case 2. Some of $v_1, \dots, v_{n-1}$ are boundary vertices.

CASE 1. $v_1, \dots, v_{n-1}$ *are all internal vertices.*

If $v_1, \dots, v_{n-1}$ are all internal vertices, we will assign $\triangle_i$ to v_i for $i = 1, \dots, n-1$ and assign $\triangle_n$ to v. If a $\triangle_i$ does not exist, we simply ignore its assignment. We delete vertex v and edges $(v, v_0), \dots, (v, v_n)$ since all incident triangles have been assigned. Each of the edges (v_i, v_{i+1}), $i = 0, \dots, n-1$ and vertices v_i, $i = 0, \dots, n$ is deleted if it has no more incident triangles. The remaining vertices in $\{v_1, \dots, v_{n-1}\}$ are added to the set of boundary vertices. The resulting graph is smaller and the invariant properties Q1, Q2 are maintained. If G_i is not connected, the assignment algorithm is applied to each connected component. The vertex v, which has been deleted, is assigned at most twice. The procedure is shown in Fig. 23.

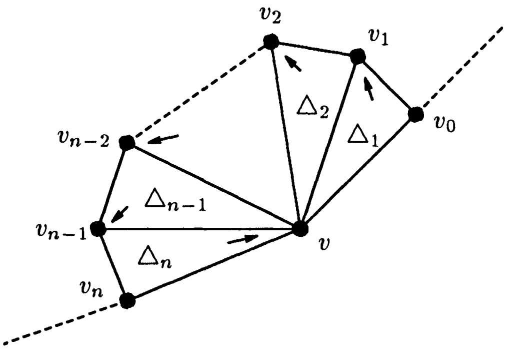

FIG. 23. *Assignment when* $v_1, \dots, v_{n-1}$ *are internal vertices.*

CASE 2. *Some of* $v_1, \dots, v_{n-1}$ *are boundary vertices.*

In this case, we will not make any assignment. Instead we will decompose G_i into two smaller subgraphs where the invariant properties Q1, Q2 are maintained in both subgraphs. Let v_m $(1 \leq m \leq n-1)$ be the boundary vertex with the smallest index m. Consider the edge (v, v_m) where v and v_m are boundary vertices. The edge (v, v_m) decomposes G_i into two subgraphs G_{ir} and G_{il} with (v, v_m) appearing in both subgraphs. There are two cases:

Case 2.1. v_m is saturated.

Case 2.2. v_m is not saturated.

CASE 2.1. v_m *is saturated.*

There are only two saturated vertices in G_i and by our selection, v is not saturated. Without loss of generality, we can assume that the other saturated vertex v_s is in G_{il}. We *force* vertex v in G_{ir} to be saturated, thus not allowing triangles in G_{ir} to be assigned to v. G_{ir} has exactly two saturated vertices: v_m and v (forced saturation), so does G_{il}: v_m and v_s. Vertex v in G_{il} will keep whatever assignment it carries in G_i but it will not be assigned by triangles in G_{ir}. Thus vertex v in G_i will not be oversaturated due to the forced saturation of v in G_{ir}. The decomposition is depicted in Fig. 24.

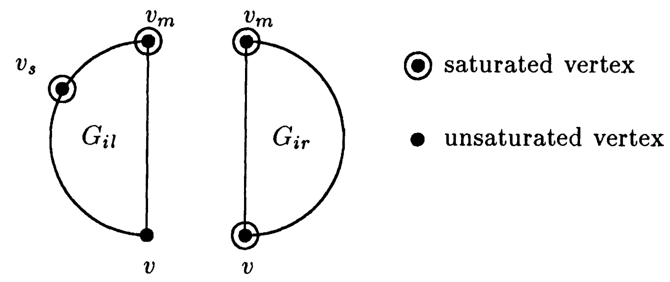

FIG. 24. *Decomposition when v_m is saturated.*

CASE 2.2. *v_m is not saturated.*

Let the two saturated vertices be v_{s1} and v_{s2}. v_{s1} (v_{s2}) appears in exactly one of the subgraphs after decomposition. If $v_{s1} \in G_{ir}$ and $v_{s2} \in G_{ir}$, we force v and v_m of G_{il} to be saturated. If $v_{s1} \in G_{ir}$ and $v_{s2} \in G_{il}$, we force v of G_{il} and v_m of G_{ir} to be saturated. If $v_{s1} \notin G_{ir}$ and $v_{s2} \notin G_{ir}$, we force v and v_m of G_{ir} to be saturated. In any case, G_{ir} and G_{il} have exactly two saturated vertices. v (v_m) of G_{il} is saturated if and only if v (v_m) of G_{ir} is not saturated. Thus v and v_m will not be oversaturated in G_i. The decomposition is shown in Fig. 25.

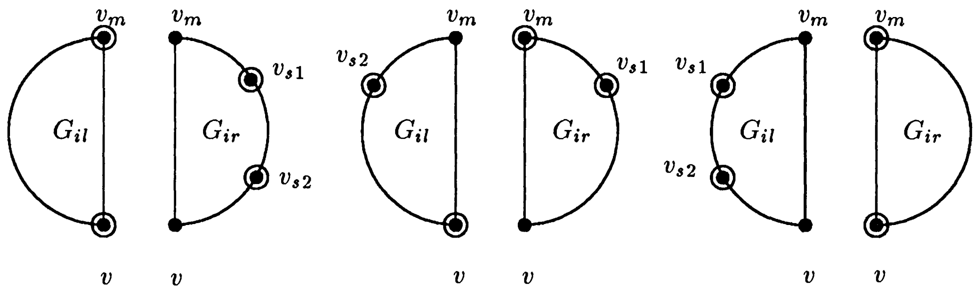

FIG. 25. *Decomposition when v_m is not saturated.* (a) $v_{s1}, v_{s2} \in G_{ir}$, (b) $v_{s1} \in G_{ir}$, $v_{s2} \in G_{il}$, (c) $v_{s1}, v_{s2} \notin G_{ir}$.

From the above discussion, we either eliminate some triangles or decompose G_i into smaller subgraphs. Thus, we have an assignment algorithm on G_i with the invariant properties as induction hypothesis. If G_i has only one triangle, the assignment problem is trivial.

A formal description of the algorithm is as follows:

```
ALGORITHM ASSIGN($CTG, TREE, root$)
INPUT: $CTG$ is a complex triangle graph of a planar triangulated graph and $TREE$
       is the corresponding containment tree. $root$ is the parent node of the set of
       complex triangles to be assigned in the current recursive step.
OUTPUT: A perfect assignment $ASSIGN = \{(\triangle_1, v_1), \ldots, (\triangle_n, v_n)\}$, where $\triangle_i =$
       $\triangle_{a_i b_i c_i}$ is a descendant complex triangle of $root$ and $v_i \in \{a_i, b_i, c_i\}$.

BEGIN
    Let $root$ be $\triangle_{abc}$ and assume it was assigned to $a$.
    Find the subgraph $G_i = (V_i, E_i)$ induced by the children of $root$.
    Force $v_{s1} = b$ and $v_{s2} = c$ to be saturated.
    If $a$ is saturated, force $a$ to have an assignment count of 1.
    $ASSIGN = \phi$.
    For each connected component $G_{ic}$ of $G_i$ do
        Let $G_{ic} = (V_{ic}, E_{ic})$.
        $B$ = CONNECTED_ASSIGN($G_{ic}, \{b, c\} \cap V_{ic}$).
        $ASSIGN = ASSIGN \cup B$.
    End For.
    For each $\triangle_{xyz} \in G_i$ do
        Let $G_{is}$ be the subgraphs induced by children of $\triangle_{xyz}$.
        $C$ = ASSIGN($G_{is}, TREE, \triangle_{xyz}$).
        $ASSIGN = ASSIGN \cup C$.
    End For.
    Return ($ASSIGN$).
END algorithm.
```

```
PROCEDURE CONNECTED_ASSIGN($G$, $SATURATED$)
INPUT: $G = (V, E)$ is a connected planar graph induced by children of a node in the
       containment tree. $SATURATED \subset V$ is the set of saturated boundary vertices
       of $G$, $|SATURATED| \leq 2$.
OUTPUT: A perfect assignment $A = \{(\triangle_1, v_1), \ldots, (\triangle_n, v_n)\}$, where $\triangle_i = \triangle_{a_i b_i c_i}$
       is a complex triangle of $G$ and $v_i \in \{a_i, b_i, c_i\}$.

BEGIN
    Find the set of boundary edges $E_b \subseteq E$.
    Find the set of boundary vertices $V_b \subseteq V$.
    $A = \phi$.
    Find a vertex $v \in (V_b - SATURATED)$.
    Let $v_0, \ldots, v_n$, $n \geq 1$ be the vertices where $(v, v_0), (v, v_n) \in E_b$ and $v_0, v_n \in V_b$.
    If $\{v_1, \ldots, v_{n-1}\}$ are all internal vertices then
        /* CASE 1, assign $\triangle_i$ to $v_i$ and $\triangle_n$ to $v$ */
        Let $\triangle_i = \triangle_{v_{i-1}\, v_i\, v}$, $i = 1, \ldots, n$.
        For $i = 1$ to $n - 1$ do
            $A = A \cup \{(\triangle_i, v_i)\}$ if $\triangle_i$ exists.
        $A = A \cup \{(\triangle_n, v)\}$ if $\triangle_n$ exists. /* last triangle */
        Delete vertex $v$ and incident edges.
        Delete vertex $v_i$, $i = 0, \ldots, n$ from $G$ if it has no more incident triangle.
        Delete edge $(v_i, v_{i+1})$, $i = 0, \ldots, n - 1$ from $G$ if it has no more incident triangle.
        For each connected component $G_c = (V_c, E_c)$ of the remaining graph do
```

```
            $A = A \cup$ CONNECTED_ASSIGN($G_c$, $SATURATED \cap V_c$).
    Else
        /* CASE 2, decompose $G$ into $G_l$ and $G_r$ */
        Let $v_{s1}$ and $v_{s2}$ be two vertices of $SATURATED$.
        Let $v_m \in \{v_1, \ldots, v_{n-1}\} \cap V_b$ where $v_1, \ldots, v_{m-1} \notin V_b$.
        $SATURATED\_L = \phi$.
        $SATURATED\_R = \phi$.
        Decompose $G$ into $G_l$ and $G_r$ with $(v, v_m) = G_l \cap G_r$.
        If $v_m \in SATURATED$ then
            /* CASE 2.1 */
            Let $v_{s1} = v_m$, without loss of generality.
            If $v_{s2}$ in $G_l$ then
                $SATURATED\_L = \{v_{s2}, v_m\}$.
                $SATURATED\_R = \{v, v_m\}$.
            Else
                $SATURATED\_L = \{v, v_m\}$.
                $SATURATED\_R = \{v_{s2}, v_m\}$.
            End If.
        Else /* $v_m \notin SATURATED$ */
            /* CASE 2.2 */
            If $v_{s1} \in G_r$ then
                $SATURATED\_R = SATURATED\_R \cup \{v_{s1}\}$.
                $SATURATED\_L = SATURATED\_L \cup \{v\}$.
            Else
                $SATURATED\_R = SATURATED\_R \cup \{v\}$.
                $SATURATED\_L = SATURATED\_L \cup \{v_{s1}\}$.
            End If.
            If $v_{s2} \in G_l$ then
                $SATURATED\_R = SATURATED\_R \cup \{v_m\}$.
                $SATURATED\_L = SATURATED\_L \cup \{v_{s2}\}$.
            Else
                $SATURATED\_R = SATURATED\_R \cup \{v_m\}$.
                $SATURATED\_L = SATURATED\_L \cup \{v_{s2}\}$.
            End If.
        End If.
        $B$ = CONNECTED_ASSIGN($G_l$, $SATURATED\_L$).
        $C$ = CONNECTED_ASSIGN($G_r$, $SATURATED\_R$).
        $A = A \cup B \cup C$.
    End if.
    Return ($A$).
END procedure.
```

Notice that the sharing assignment scheme is implicitly incorporated by forcing vertex a of $\triangle_{abc}$ in **ASSIGN()** to reduce its assignment count. Data structures that support **ASSIGN()** and **CONNECTED_ASSIGN()** are relatively simple. A doubly connected edge list [8] can be used to find CTs incident to a vertex. The algorithm visits each CT without backtracking. Thus the complexity of the assignment algorithm is $O(c)$, where c is the number of CTs. c is $O(|V|)$ in a planar graph. Therefore the overall time complexity is $O(|V|)$ and we have the following theorem:

THEOREM 2. *Given a PTG, a perfect assignment can be constructed in $O(|V|)$ time, where $|V|$ is the number of vertices of the PTG.*

4.3. Perfect assignment for extended graph. In general the algorithm will make an assignment to any nonsaturated vertex of G_i. We have pointed out that in a perfect assignment of G, the four noncore vertices r, u, l, b are not allowed to carry assignment. This may violate the invariant properties because in the worst case, we may have four saturated vertices to begin with. However, we know that all core vertices have an assignment count of zero initially. We can exploit this fact to decompose G into two subgraphs satisfying the invariant properties.

Given a biconnected PTG G_c, we construct an extended graph G by adding the vertices r, u, l, b. We force the vertices r, u, l, b to be saturated. Consider the graph $G' = G - \{(r,u),(u,l),(l,b),(b,r)\}$. Since G_c is biconnected, the edges (r,u), (u,l), (l,b), and (b,r) do not appear in any CT of G. Therefore the CTG of G' and that of G are identical, and we will only consider decomposition of G'.

If each connected component of CTG $CTG(G')$ contains no more than two saturated vertices, we are done. Suppose a connected component of $CTG(G')$ contains three or more saturated vertices. We identify the first boundary vertex v_r of G', which is clockwise adjacent to r. Similarly we find v_l. (See Fig. 26.) Since G_c is biconnected, v_r and v_l must be distinct. We find a path $P = (v_r, \ldots, v_l)$ in G' and construct a path P^* by applying the chord elimination procedure. By our selection, v_l and v_r are located at the infinite face of G'. We cut G' into G'_1 and G'_2 along the path P^*, as shown in Fig. 26. $CTG(G'_1)$ ($CTG(G'_2)$) has at most two saturated vertices since G'_1 (G'_2) has at most two saturated vertices. Vertices of P^* in $CTG(G'_1)$ and $CTG(G'_2)$ are forced to have assignment count of one. Therefore vertices of P^* in $CTG(G')$ will not be oversaturated after we apply the assignment algorithm to $CTG(G'_1)$ and $CTG(G'_2)$.

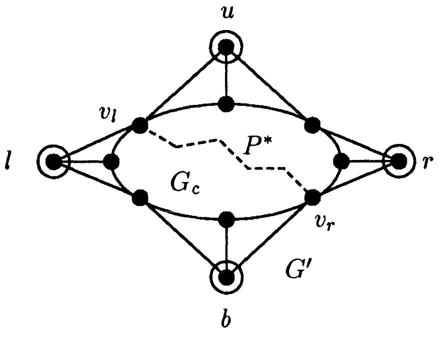

FIG. 26. *Initial decomposition of G.*

THEOREM 3. *Given any extended graph G constructed from a biconnected PTG G_c, a perfect assignment can be constructed in $O(|V|)$ time, where $|V|$ is the number of vertices of G_c.*

Note that the biconnected condition of G is needed only for the initial decomposition of G'. The assignment algorithm is still valid for some classes of weakly connected core graphs as long as the initial decomposition exists. However, not all extended graphs of planar graphs can be decomposed in this manner. Figure 27 is an example of such a graph.

As a direct result of Theorems 1 and 3, we have the follwing theorem:

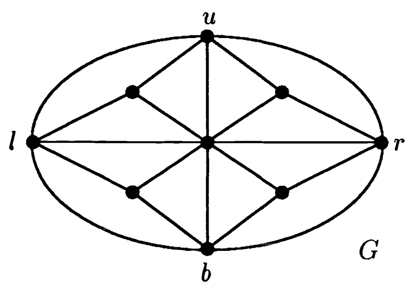

FIG. 27. *An example of G that does not have a perfect assignment.*

THEOREM 4. *Given any biconnected PTG G_c with $|V|$ vertices, a 2-CRM floor-plan F can be constructed in $O(|V|)$ time, where the dual of F has core G_c when parallel edges are eliminated.*

Example. We demonstrate an example of the construction process using the graph of Fig. 8, which does not admit any 1-CRM floor-plan. The results are shown in Fig. 28: (a) is the core graph and (b) shows an extended graph. (c) is a perfect assignment and (d) gives the 2-CRM dual floor-plan constructed with the perfect assignment in (c).

5. Conclusion. We have presented a linear time algorithm for floor-plan construction using a graph dualization technique. By allowing more general shapes, 1-CRM and 2-CRM, we have shown that all adjacency requirements of a PTG can be satisfied on a rectangular chip. The construction ensures that no unnecessary adjacency is added in the final floor-plan, thus paves the way for a more compact layout. If the input graph is planar but not triangulated, a floor-plan is still possible by introducing trivial adjacency. The most complicated shape created is 2-CRM but most modules are rectangular. The 1-CRM and 2-CRM can be easily incorporated in the widely used rectilinear systems. The expected number of CTs for a randomly generated PTG is approximately 16% of the number of vertices [14].

The algorithm presented serves as a theoretical basis for floor-planning based on the graph dualization approach. For practical applications, other requirements such as area, aspect ratio, and perimeter constraints should be considered. We are currently looking at the applications of the results obtained from this study. Sizing and aspect ratio is one of our major focuses. Only when such issues are resolved could one propose dualization-based floor-planning as a practical alternative. The floor-plan sizing problem has been shown to be NP-complete for general rectangular floor-plans [9]. Future research is focused on approximate solutions or restriction to special classes of floor-plans, for example, sliceable floor-plans, which are more promising in practice. More information can be found in [7] and in Chapter 7 of [5].

One interesting problem is to enumerate all floor-plans with identical duals. For rectangular floor-plans, the problem have been studied [3], [13]. For 1- and 2-CRM floor-plans, the problem has yet to be studied. Planarization of the circuit is especially not well understood. Current solutions are based on heuristic approaches [6]. Many problems related to graph dualization need to be investigated even for rectangular floor-plans.

A QUADRATIC TIME ALGORITHM FOR THE MINMAX LENGTH TRIANGULATION*

HERBERT EDELSBRUNNER† AND TIOW SENG TAN‡

Abstract. It is shown that a triangulation of a set of n points in the plane that minimizes the maximum edge length can be computed in time $O(n^2)$. The algorithm is reasonably easy to implement and is based on the theorem that there is a triangulation with minmax edge length that contains the relative neighborhood graph of the points as a subgraph. With minor modifications the algorithm works for arbitrary normed metrics.

Key words. computational geometry, point sets, triangulations, two dimensions, minmax edge length, normed metrics

AMS(MOS) subject classifications. 68Q25, 68U05, 65D05

1. Introduction.

A *triangulation* of a (finite) point set S in $\Re^2$ is a maximal connected straight-line plane graph whose vertices are the points of S. Maximality implies that, with the exception of the unbounded face, each face of the graph is a triangle. The number of different triangulations of S depends on $n = |S|$ and on the relative location of the points. As implied by a result in [ACNS82], 10^{13n} is an upper bound on the number of triangulations of any set of n points in $\Re^2$. Furthermore, if S is in convex position, then it admits $\frac{1}{n-1}\binom{2n-4}{n-2} \geq 2^{n-3}$ different triangulations. In order to choose an optimal triangulation, under some criterion, it is thus not feasible to exhaustively search the set of all triangulations.

Indeed, except for a handful of particular optimality criteria, the problem of finding an optimal triangulation for a given point set is hard, that is, no polynomial-time algorithms are known. Among these exceptions are the maxmin angle criterion [Sibs78], the minmax angle criterion [ETW92], the minmax smallest enclosing circle criterion [Raja91], and the minmax circumscribed circle criterion. The optimum under the first, third, and fourth criteria is achieved by the Delaunay triangulation which can be constructed in time $O(n \log n)$ [Del34], [PrSh85], [Edel87].

In this paper we study the complexity of minimizing the maximum edge length. A triangulation that minimizes the length of its longest edge is called a *minmax length triangulation*. It is related to the so-called *minimum length* (or *minimum weight*) *triangulation* that minimizes the sum of the edge lengths. The latter problem has been studied by Plaisted and Hong [PlHo87], Lingas [Ling87], and others. In spite of the lack of a proof that the problem is NP-hard, no polynomial time algorithm for constructing a minimum length triangulation is currently known. Even more annoying is the lack of a constant approximation scheme, that is, an algorithm that in polynomial time constructs a triangulation guaranteed to have total edge length of at most some constant times the optimum. The current best approximation scheme, described in [PlHo87], guarantees a factor of $O(\log n)$.

In view of the apparent difficulty of computing minimum length triangulations, it is somewhat surprising that we are able to provide a polynomial, in fact, a quadratic time algorithm, for constructing a minmax length triangulation. To our knowledge it is

the first polynomial-time algorithm for this problem. Although there is evidence for the potential usefulness of such a triangulation (see [BrZl70], [WGS90]), we consider the additional insight into optimum triangulations under edge length criteria to be the main contribution of this paper.

The reader might find it instructive to rule out seemingly promising approaches to computing minmax length triangulations before diving into the occasionally involved developments of the forthcoming sections. Note first that the Delaunay triangulation does not minimize the maximum edge length (see also §2). Second, the incremental greedy method, which repeatedly adds the shortest edge that does not intersect any previously added edge, also fails to minimize the maximum edge length. Third, let us take a brief look at the decremental greedy method that throws away edges in the order of decreasing length. It stops the deletion process if another deletion would render the set of edges so that it does not contain any triangulating subset (see Wismath [Wism80, p. 81]). The trouble with this approach is that it is not clear how to efficiently decide whether the evolving edge set is still sufficient to triangulate the point set. Indeed, Lloyd [Lloy77] proves that the general version of this problem (to decide whether a given edge set contains a triangulation) is NP-complete. Finally, the iterative methods that use the edge-flip [Laws77] or the more general edge-insertion operation [ETW92] can get caught in local optima. The approach taken in this paper is entirely different from the above paradigms.

The organization of this paper is as follows. Section 2 reviews a few results on relative neighborhood graphs and other subgraphs of the Delaunay triangulation. Section 3 formulates the global algorithm; its straightforward implementation using dynamic programming takes time $O(n^3)$. The only intricate part of this algorithm is the proof of correctness provided in §4. Sections 5 and 6 present a specialized polygon triangulation algorithm that can be used to speed up the general algorithm to time $O(n^2)$. Whereas §§2–6 assume that the Euclidean metric is used to measure length, §7 demonstrates that all results extend to general normed metrics. Indeed, the arguments in §§2–6 are axiomatically derived from a few basic lemmas in order to minimize the number of changes necessary to generalize the results. Finally, §8 briefly discusses the contributions of this paper and states some related open problems.

2. Subgraphs of the Delaunay triangulation. Our approach to constructing a minmax length triangulation first adds enough edges to decompose the plane into simple polygonal regions and then (optimally) triangulates these regions. Both Plaisted and Hong [PlHo87] and Lingas [Ling87] used this approach to compute approximations of the minimum length triangulation. In our case the initial set of edges is provided by the (boundary of the) convex hull and the relative neighborhood graph of the point set S. The remainder of this section formally introduces these graphs, along with the Delaunay triangulation and the minimum spanning tree of S, and reviews some basic facts about their relationships. If x, y, z are three points in $\Re^2$, then xy denotes the relatively open line segment with endpoints x and y, $|xy|$ denotes its length, and xyz denotes the open triangle with vertices x, y, z.

The *Delaunay triangulation* of S, denoted by $dt(S)$, contains an edge ab, $a, b \in S$, if there is a circle through a and b so that all other points lie outside the circle. If the points are in general position, then $dt(S)$ is indeed a triangulation.

As mentioned in §1, the Delaunay triangulation does not minimize the length of the longest edge. Take, for example, the points $a = (-2, 0)$, $b = (1, \sqrt{3})$, $c = (1, -\sqrt{3})$, $d = (2 - \epsilon, 0)$, with $0 < \epsilon < 1$. They form a convex quadrilateral $abdc$, and the Delaunay triangulation uses ad as the fifth edge. As ϵ approaches 0 the length of ad approaches

$2/\sqrt{3}$ times the length of the longest edge in the alternative triangulation. Indeed, $2/\sqrt{3}$ is the worst possible ratio, as can be shown by using the result of [Raja91] that the Delaunay triangulation minimizes the radius of the maximum smallest enclosing circle, where the maximum is taken over all triangles. If the radius of this circle is 1, then the longest edge of the Delaunay triangulation has length of at most 2. By the optimality result every minmax length triangulation has a smallest enclosing circle of radius at least 1 and therefore an edge of length at least $\sqrt{3}$ (see also [WGS90]).

The *convex hull* of S is the smallest convex polygon that contains S. We define $ch(S)$ as the graph defined by the edges of this polygon. In the (degenerate) case in which three or more collinear points lie on the boundary of this polygon we think of each such point as a vertex of the polygon. Thus edges are taken only between adjacent collinear points. Each convex hull edge is an edge of *every* triangulation of S and therefore also of every minmax length triangulation.

An edge ab belongs to the *relative neighborhood graph* of S, denoted by $rng(S)$, if

$$|ab| \leq \min_{x \in S - \{a,b\}} \max\{|xa|, |xb|\}.$$

This definition goes back to Toussaint [Tous80], who modified a similar definition by Lankford [Lank69] for use in pattern recognition. Alternatively, we can define the *lune* of ab as the set $\{x \in \Re^2 : \max\{|xa|, |xb|\} < |ab|\}$, and then define $rng(S)$ as the set of edges ab whose lunes have empty intersection with S.

A *minimum spanning tree* of S, denoted by $mst(S)$, is a spanning tree of S that minimizes the total edge length; it also minimizes the maximum edge length.

All four graphs, $dt(S), ch(S), rng(S), mst(S)$, are plane and connected, and, with the exception of $ch(S)$, they span S. Where convenient we will interpret these graphs as edge sets. Plainly, $ch(S) \subseteq dt(S)$, and, as observed by Toussaint [Tous80], we also have $mst(S) \subseteq rng(S) \subseteq dt(S)$. Obviously, $ch(S) \subseteq mlt(S)$ for every minmax length triangulation $mlt(S)$, and we will show in §4 that there exists an $mlt(S)$ so that $rng(S) \subseteq mlt(S)$.

3. The global algorithm. As mentioned above, there exists a minmax length triangulation $mlt(S)$ that contains all edges of $ch(S)$ and $rng(S)$. Because $ch(S) \cup rng(S)$ is a connected graph, it decomposes the convex hull of S into simple *polygonal regions*, which we define as open sets, that contain no points of S. It is thus natural to construct $mlt(S)$ by computing $ch(S) \cup rng(S)$ and then (optimally) triangulating each polygonal region.

Strictly speaking, however, the polygonal regions are not necessarily simple polygons in the usual sense of the term, although their interiors *are* simply connected. The difference is that the interior of the closure of a polygonal region is not necessarily the same as the region itself; it may contain edges of the region, and it may be nonsimply connected. The most effective way to deal computationally with this minor difficulty is to represent each edge by a pair of oppositely directed edges and to represent the boundary of each region by the collection of directed edges for which the region lies on their left-hand side. In effect, this means that we interpret each polygonal region as a genuine simple polygon simply by pretending that its zero-width cracks are opened up a tiny amount. In most cases this is a convenient interpretation, and the notation will be adjusted accordingly. Only occasionally will the difference between a simple polygonal region and a simple polygon be uncovered.

Let us now formally specify the algorithm and give a preliminary analysis.

Input. A set S of n points in $\Re^2$.

Output. A minmax length triangulation of S.

Algorithm.
1. Construct $ch(S)$ and $rng(S)$.
2. Determine the polygonal regions defined by $ch(S) \cup rng(S)$.
3. Find a minmax length triangulation for each such polygonal region.

Step 1 can be carried out in time $O(n \log n)$ by using results documented in [PrSh85] and [Supo83] (see also [JKY90]). By using the standard quad-edge data structure of [GuSt85] for storing the plane graph $ch(S) \cup rng(S)$, step 2 can be accomplished in time $O(n)$. Finally, we can use dynamic programming to compute an optimal triangulation for each polygon in time cubic and storage quadratic in the number of its vertices (see [Klin80], [Gilb79]). This adds up to time $O(n^3)$ and storage $O(n^2)$. The correctness of the algorithm will be established in §4. Sections 5 and 6 will show how to speed up the algorithm to time $O(n^2)$ by using a specialized polygon triangulation algorithm.

4. The Subgraph Theorem. The main result of this section is what we call the Subgraph Theorem, which was announced earlier. We begin with two elementary geometry lemmas about distances between four points in convex and in nonconvex position.

□-LEMMA. *For a convex quadrilateral abcd we have* $|ab| + |cd| < |ac| + |bd|$.

Proof. Let x be the intersection point of the two diagonals ac and bd. Clearly, $|ab| + |cd| < (|ax| + |xb|) + (|cx| + |xd|) = |ac| + |bd|$. □

In words, the total length of the two diagonals of a convex quadrilateral always exceeds the total length of two opposite sides. This is true even if three of the four vertices are collinear. It implies that if one diagonal is no longer than one of the edges, then the other diagonal is longer than the opposite edge.

Δ-LEMMA. *Let a, b, c, d be four distinct points so that the closure of the triangle abc contains d. Then* $|ad| < \max\{|ab|, |ac|\}$.

Proof. If a, b, c, d are collinear, the result is obvious. Otherwise, let d' be the intersection of the edge bc with the line passing through a and d, and note that $|ad| \leq |ad'|$. Of all points on bc only the endpoints can possibly maximize the distance to a. The assertion follows because if d' is an endpoint of bc, then $d \neq d'$ and therefore ad is strictly shorter than ad'. □

Note that the length of the longest edge of any minimum spanning tree is no longer than the longest edge of any triangulation of S. This follows trivially from the fact that every triangulation contains a spanning tree. It is not very difficult to prove that the same is true for the relative neighborhood graph of S. First we need some notation. The circle with center x and radius ρ is denoted by (x, ρ), and the *bisector* of two points p and q is the set of points equidistant to both.

LENGTH LEMMA. *Every triangulation of S contains an edge that is at least as long as the longest edge of $rng(S)$.*

Proof. Let pq be the longest edge of $rng(S)$, and let $t(S)$ be an arbitrary triangulation of S. If $pq \in t(S)$, there is nothing to prove. Otherwise, pq intersects edges $r_1s_1, r_2s_2, \ldots, r_ks_k$ of $t(S)$, sorted from p to q, with all r_i on one side of the line through p and q and all s_i on the other. If pq is longer than all edges in $t(S)$, then r_1 and s_1 are both inside the circle $C_p = (p, |pq|)$ because pr_1 and ps_1 are both edges of $t(S)$. By the definition of $rng(S)$, r_1 and s_1 are thus outside or on the circle $C_q = (q, |pq|)$. Therefore, r_1 and s_1 lie in the half-plane of points closer to p than to q. Symmetrically, r_k and s_k lie inside C_q and outside or on C_p and therefore in the half-plane of points closer to q than to p. For each $1 \leq i \leq k-1$ we have either $r_i = r_{i+1}$ or $s_i = s_{i+1}$, which implies that there is an index j so that r_j and s_j do not lie on the same side of the bisector of pq. But then the □-Lemma implies that $|r_j s_j| > |pq|$ because $|pq|$ is no longer than each of two opposite edges of the convex quadrilateral $pr_j qs_j$, a contradiction. □

The proof of the Subgraph Theorem is similar to that of the Length Lemma, although it is considerably more involved. The basic idea is to assume an extremal counterexample and to contradict its existence by retriangulating parts of it by using no long edges. In the following we first develop three facts that show the possibilities of retriangulations, and then we prove the theorem.

Let $t(S)$ be a minmax length triangulation of S that does not contain some edge pq of $rng(S)$. Suppose pq intersects the triangles $t_1, t_2, \ldots, t_k$ of $t(S)$ sorted from p to q (see Fig. 1 left).

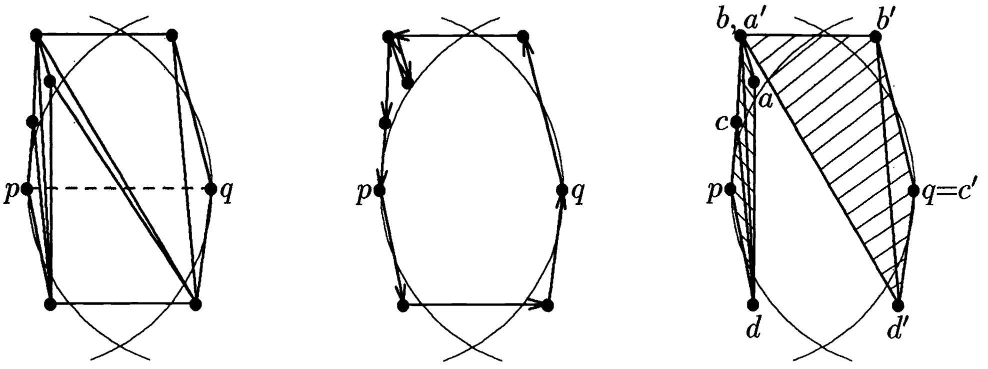

FIG. 1. *To the left are the triangles of $t(S)$ that intersect pq. If we remove the edges that intersect pq we get a polygon whose boundary is oriented in a counterclockwise order. The prefix P and the suffix Q defined for this configuration are illustrated to the right. Although b and a' are the same point, they refer to different angles of this point.*

The deletion of the edges that intersect pq would result in a simply connected region, which can be interpreted (as in §3) as a polygonal region—we treat each edge in its boundary as a pair of edges with opposite direction, and we trace the boundary of the region by traversing all directed edges that have the region on their left side. Any two consecutive (directed) edges define an *angle* (see Fig. 1 middle). Note that a vertex can correspond to many angles, although the common situation is that it corresponds only to one. We will therefore sometimes ignore the difference between vertices and corresponding angles. Points p and q correspond to only one angle each. An angle is *convex* if the two defining edges form a left turn. Call the sequence of edges from p to q the *lower chain*, and the sequence from q to p the *upper chain*. Each chain contains at least one convex angle different from p and q.

A *prefix* is an initial subsequence of $t_1, t_2, \ldots, t_k$, and a *suffix* is a terminal subsequence of $t_1, t_2, \ldots, t_k$. We say that a prefix (suffix) *covers* an angle of the polygon if it contains all triangles incident to this angle. Let i be minimal so that the prefix $P = t_1, t_2, \ldots, t_i$ covers a convex angle other than p, and let j be maximal so that the suffix $Q = t_j, t_{j+1}, \ldots, t_k$ covers a convex angle other than q. P and Q consist of at least two triangles each. We let b be the convex angle (vertex) covered by P—it is incident to both t_i and t_{i-1}—and we let d be the other vertex common to t_i and t_{i-1}. Furthermore, c is the third vertex of t_{i-1} and a is the third vertex of t_i (see Fig. 1 right). Symmetrically, define vertices b', d', c', a' of Q. We say that P (respectively, Q) is *type* 1 if the last (respectively, first) two triangles of P (respectively, Q) are the only ones incident to b

(respectively, b'), and we say that it is *type* 2 otherwise (see Fig. 2). If P is type 1, then a, b, c belong to the same chain and d belongs to the other chain (this includes the case that $c = p$), and if P is type 2, then a, b belong to one chain and c, d belong to the other.

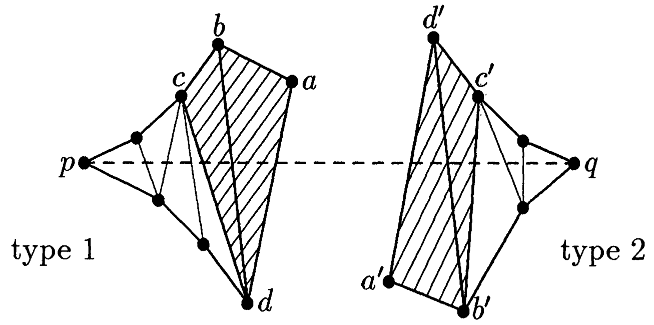

FIG. 2. *The definitions prefix P with vertices a, b, c, d and the suffix Q with vertices a', b', c', d' depend on pq. P is type 1, and Q is type 2. For illustration purposes the constraint that all vertices must lie outside the lune of pq has been ignored.*

FACT 1. *$P = t_1, t_2, \ldots, t_i$ and $Q = t_j, t_{j+1}, \ldots, t_k$ share at most two triangles, that is, $i - 1 \leq j$.*

Proof. We show that since the suffix $R = t_{i-1}, t_i, \ldots, t_k$ covers at least one convex angle other than q, Q cannot be bigger than R. If P is type 1, then R covers b, which is convex. Otherwise, R covers all angles between d and q, d included. Since all angles between p and d, p and d excluded, are nonconvex, at least one angle between d and q must be convex, and this angle is covered by R. □

It should be clear that $abcd$ and $a'b'c'd'$ are both convex quadrilaterals by the choice of their vertices. The next two facts imply that either $abcd$ or $a'b'c'd'$ or both have alternate triangulations that use ac or $a'c'$ while the maximum edge length of $t(S)$ is maintained. In other words, bd, or $b'd'$, or both can be switched. Formally, we call bd (respectively, $b'd'$) *switchable* if ac (respectively, $a'c'$) is no longer than the longest edge of $t(S)$. Fact 2 shows strong locality constraints for a and d (respectively, a' and d') if bd (respectively, $b'd'$) is not switchable. Define

$$A = \{x \in \Re^2 : |xp| > |pq| \text{ and } |xp| > |xq|\} \text{ and}$$

$$D = \{x \in \Re^2 : |xp| \geq |pq| \text{ and } |xq| < |pq|\},$$

with the understanding that A and a belong to one half-plane defined by the line passing through p and q and that D and d belong to the other (see Fig. 3).

FACT 2. *If bd is not switchable then $a \in A$ and $d \in D$.*

Proof. Since bd is not switchable, ac must be longer than the other five edges defined by a, b, c, d, and by the Length Lemma it must be longer than pq. We first show that $|ac| \leq |ap|$ and then derive the four inequalities needed to establish the claim.

(1) $|ac| \leq |ap|$. We can assume that $c \neq p$. Note that c is contained in the closure of triangle bdp. Since the line passing through b and d separates a from p, the closures of the two triangles abp and adp cover bdp completely, and therefore one of them contains

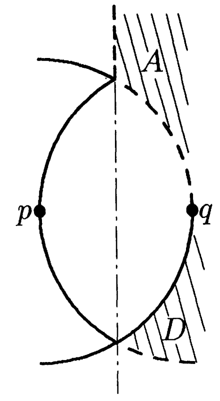

FIG. 3. *Regions A and D as defined for the case in which a is on the upper chain.*

c. If c lies in the closure of abp, the claim follows from $|ab| < |ac|$ and the Δ-Lemma for abp, and if c lies in adp, it follows from $|ad| < |ac|$ and the Δ-Lemma for adp.

(2) $|ap| > |pq|$. From the Length Lemma we get $|pq| < |ac|$, and from (1) we get $|ac| \leq |ap|$.

(3) $|dq| < |pq|$. Assume $|dq| \geq |pq|$. The $\Box$-Lemma for $paqd$ implies $|ad| > |ap|$ and thus $|ad| > |ac|$ because of (1), a contradiction.

(4) $|dp| \geq |pq|$. This is immediate from (3) because pq is an edge of $rng(S)$.

(5) $|ap| > |aq|$. Assume $|ap| \leq |aq|$, and recall $|dp| \geq |pq|$ from (4). By the $\Box$-Lemma for $paqd$ we get $|ad| > |aq|$, which implies $|ad| > |ap|$ by assumption and $|ad| > |ac|$ by (1), a contradiction.

The proof of Fact 2 is now complete because (2) and (5) are equivalent to $a \in A$ and because (3) and (4) are equivalent to $d \in D$. $\Box$

Symmetrically, we define regions A' and D', which are where a' and d' must lie if $b'd'$ is not switchable. Using Facts 1 and 2, we can now show that there is always an edge that can be switched.

FACT 3. *It is not possible that both bd and b'd' are nonswitchable.*

Proof. If bd and $b'd'$ are both nonswitchable, then ad lies on q's side of the bisector of pq and $a'd'$ lies on p's side by Fact 2. Because of Fact 1 and because ad is the last edge of P and $a'd'$ is the first edge of Q, we have $\{a, d, a', d'\} = \{a, b, c, d\} = \{a', b', c', d'\}$. Furthermore, the fact that bd and $b'd'$ are both edges of $t(S)$ implies that they are the same and thus that $b = d'$, $d = b'$, $a = c'$, $c = a'$ (see Fig. 4). It follows that the polygonal region has the shape of a diamond, with p, b, q, d as the only convex angles. This contradicts the locality constraints for a, b, c, d stated in Fact 2. In particular, the chain from p to $d \in D$ (as indicated by the dotted chain in Fig. 4) is concave or straight and therefore enclosed by the circle $(q, |pq|)$. It follows that this chain is disjoint from A', which is where $c = a'$, the predecessor of d in this chain, is supposed to lie. $\Box$

With the above results and notations we now choose an extremal counterexample to prove the main result of this section.

SUBGRAPH THEOREM. *Every finite point set S in $\Re^2$ has a minmax length triangulation $mlt(S)$ so that $rng(S) \subseteq mlt(S)$.*

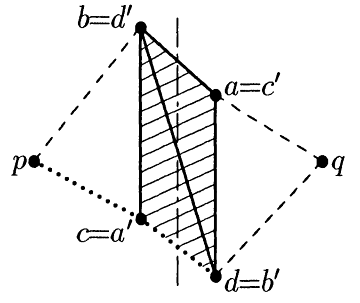

FIG. 4. *If bd and b′d′ are both nonswitchable, then b and d are the only convex angles besides p and q.*

Proof. We assume there is a set S so that no minmax length triangulation contains $rng(S)$. Let $t(S)$ be a minmax length triangulation of S that satisfies the following extremal properties, where later properties are contingent on earlier ones.

(i) $t(S)$ minimizes the number of edges that intersect pq.

(ii) $t(S)$ minimizes the number of edges incident to b that intersect pq.

(iii) $t(S)$ minimizes the number of edges incident to b' that intersect pq.

It is conceivable that $t(S)$ is not unique, but it will be sufficient to assume that $t(S)$ is any one of the remaining triangulations.

By Fact 3 either bd or $b'd'$, or both are switchable. If bd is switchable and P is type 1, then the number of edges that intersect pq decreases when bd is switched. This contradicts property (i). Thus P must be type 2 if bd is switchable, and, similarly, Q must be type 2 if $b'd'$ is switchable. When we switch bd, the degree of b decreases, which contradicts property (ii). Thus it must be that bd is not switchable and that $b'd'$ is. But switching $b'd'$ decreases the degree of b', which would contradict property (iii) unless the degree of b increases at the same time. Remember that because (iii) is contingent on (ii), so if (ii) is not satisfied any more, then we cannot draw any conclusion. Thus the configuration left for analysis is as shown in Fig. 5.

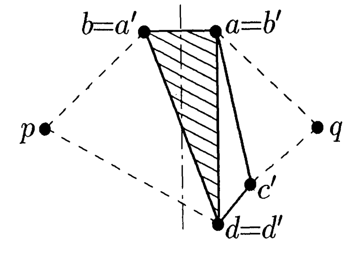

FIG. 5. *In the final configuration, because bd is nonswitchable,* $a \in A$ *and* $d \in D$, *and because b′d′ is switchable, so Q is type 2. Furthermore, because switching b′d′ to a′c′ increases the degree of b, so* $a' = b$, *and therefore P and Q overlap in exactly one triangle. The figure ignores the fact that by rights all points should lie outside the lune of pq.*

To reach the final contradiction we switch $b'd'$ and redefine Q on the basis of the new configuration. Since all angles from (the old) d' to q are nonconvex, the new points b' and a' are the same as before and the new d' is the old c'. Thus we can again switch

$b'd'$, and so on, until Q is type 1 or $c' = q$, at which point the next switch decreases the number of edges intersecting pq. This finally contradicts property (i). □

Remark. A natural extension of minimizing the length of the longest edge in a triangulation is to also minimize the length of the second-longest edge, and so on. Let $mvt(S)$ be a triangulation that minimizes the entire vector of edge lengths in this fashion. If the points of S are in general position, then $mvt(S)$ is unique. Curiously, it is not always true that (there is an) $mvt(S)$ (that) contains $rng(S)$ as a subgraph. The smallest example that illustrates this observation consists of four points a, b, c, d so that c and d lie fairly close to b, ab and cd intersect, and c and d both lie outside the circle $(a, |ab|)$.

5. Triangulating rng-polygons. The goal of this section and §6 is to improve the cubic-time algorithm of §3 to quadratic time. This is done by using a specialized polygon triangulation algorithm. The main part of the algorithm and the structural properties of minmax length triangulations that guarantee its correctness are developed in this section.

Recall that the first two steps of the algorithm in §3 decompose the convex hull of S into polygonal regions by drawing all edges of $ch(S)$ and $rng(S)$; these steps remain unaltered. Each region is represented by a cyclic chain of directed edges that trace its boundary in a counterclockwise order around the region. Because $rng(S)$ is a connected graph that spans S, any polygonal region is bounded by at most one edge not in $rng(S)$; this edge is in $ch(S) - rng(S)$. We call a polygonal region a *complete rng-polygon* if all its edges belong to $rng(S)$, and we call it an *incomplete rng-polygon* otherwise.

Obviously, rng-polygons are not as general as arbitrary polygonal regions because for each edge ab, except possibly for one, the lune of ab, $\lambda_{ab} = \{x \in \Re^2 : \max\{|ax|, |bx|\} < |ab|\}$, is free of points of S. We call pq a *diagonal* of a polygonal region if it lies entirely in the region. For each diagonal pq of an rng-polygon it must be that λ_{pq} contains at least one point of S. We further distinguish between the cases for which λ_{pq} contains points of S on both sides of pq and those for which it does not.

For a directed edge $\vec{pq}$ let $h_{\vec{pq}}$ be the set of points to the left of or on the directed line that passes through p and q in this order. Define the *half-lune* of $\vec{pq}$ as

$$\eta_{\vec{pq}} = \lambda_{pq} \cap h_{\vec{pq}}.$$

By definition, $\lambda_{pq} = \eta_{\vec{pq}} \cup \eta_{\vec{qp}}$, and we have $pq \in rng(S)$ if and only if $\eta_{\vec{pq}} \cap S = \eta_{\vec{qp}} \cap S = \emptyset$. We call pq a *2-edge* if both half-lunes contain points of S, and we call it a *1-edge* if only one half-lune contains points of S. For a 1-edge pq we say that the side where the half-lune contains points of S is *beyond* pq and that the other side is *beneath* pq. Note, for example, that if pq is a 1-edge bounding an incomplete rng-polygon R, then $pq \in ch(S)$ and therefore R is beyond pq. We will see later that 1-edges are useful in triangulating rng-polygons.

The first lemma of this section shows that when we triangulate an rng-polygon R, whether complete or incomplete, we can ignore all points outside R. More specifically, it shows that the type of any diagonal or edge of R remains unchanged when we remove all points of S that are not vertices of R.

REDUCTION LEMMA. *Let pq be a diagonal or edge of an rng-polygon R. If $\eta_{\vec{pq}}$ contains points of S, then it also contains vertices of R.*

Proof. If we assume $\eta_{\vec{pq}}$ contains points of S but no vertices of R, then it must intersect edges of R without containing their endpoints. Let yy' be the edge closest to p and q, and let x be a point in $\eta_{\vec{pq}} \cap S$. Since x is not a vertex of R, it must lie on the other side of yy' as seen from p and q. So $yy' \in rng(S) - ch(S)$, and therefore $\max\{|xy|, |xy'|\} \geq |yy'|$. Assume without loss of generality that $|xy| \geq |yy'|$. If y' lies outside or on the circle $(p, |pq|)$, we consider the convex quadrilateral $pyxy'$. Otherwise, y' lies outside or on $(q, |pq|)$, in which case we consider the convex quadrilateral $qyxy'$. But now we have $|xy| \geq |yy'|$ and either $|py'| > |px|$ or $|qy'| > |qx|$, a contradiction to the $\square$-Lemma in both cases. $\square$

Using the Reduction Lemma, we now address vertices visible from both endpoints of an edge. We need some notation. Two points x, y inside or on the boundary of a polygonal region are *visible* from each other if xy is contained in the region. The *distance* of a point x to an edge pq is defined as the infimum, over all points $z \in pq$, of $|xz|$. If $|pq| > \max\{|px|, |qx|\}$, then this distance is referred to as the *height* of the triangle pqx.

VISIBILITY LEMMA. *Let pq be a diagonal or edge of an rng-polygon R, and let x be a vertex of R that lies in $\eta_{\vec{pq}}$ and minimizes the distance from pq. Then x is visible from p and also from q.*

Proof. Consider the triangle pqx, let $x' \in pq$ be the point with minimum distance from x, and assume without loss of generality that x is not visible from q. Let yy' be an edge of R that intersects qx. The proof of the Reduction Lemma implies that at least one endpoint of yy' lies in $\eta_{\vec{pq}}$, say, $y \in \eta_{\vec{pq}}$. In addition, y and y' lie outside the triangle pqx because x is closest to pq (see Fig. 6). Hence yy' intersects xp, xq, and all edges

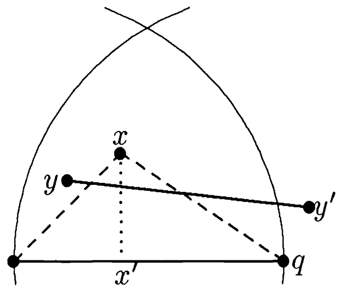

FIG. 6. *Quadrilateral $xyx'y'$ is convex because $x' \in pq$ and $y, y' \notin pqx$.*

xz with $z \in pq$. Thus $xyx'y'$ is a convex quadrilateral, and because of $|yx'| \geq |xx'|$ by the choice of x, we have $|yy'| > |y'x|$ from the $\square$-Lemma. By symmetry, if y' lies in $\eta_{\vec{pq}}$, we have $|yy'| > |xy|$, which implies $yy' \notin rng(S)$. This is a contradiction because $yy' \notin ch(S)$. Thus y' must lie outside $\eta_{\vec{pq}}$. If y' lies outside or on the circle $(p, |pq|)$, then $|py'| > |px|$ and therefore $|xy| < |yy'|$ by the $\square$-Lemma for $py'xy$. Symmetrically, we get $|xy| < |yy'|$ from the $\square$-Lemma for $qy'xy$ if y' lies outside or on the circle $(q, |pq|)$. Together with $|xy'| < |yy'|$ this contradicts $yy' \in rng(S)$. $\square$

We need one more elementary lemma.

CONTAINMENT LEMMA. *If $x \in \eta_{\vec{pq}}$, then $\eta_{\vec{xp}} \subseteq \lambda_{pq}$.*

Proof. Take a point $z \in \eta_{\vec{xp}}$ and consider the four points p, q, x, z. If $z \in pq$, there is nothing to prove. Otherwise, $pzqx$ or $pqzx$ is a convex quadrilateral (possibly with three of the four vertices collinear) or $z \in pqx$. In each case $|qz| < |pq|$ can be shown by using the $\square$-Lemma or the Δ-Lemma. This implies that $z \in \lambda_{pq}$. $\square$

The following lemma is of fundamental importance to the quadratic-time triangulation algorithm.

1-EDGE LEMMA. *Let pq be a 1-edge of an rng-polygon R, and let x be a vertex of R that lies in $\eta_{\vec{pq}}$ and minimizes the distance from pq. Then px is either an edge of R or a 1-edge with pqx beneath px, and the same is true for qx.*

Proof. We have $\eta_{x\vec{p}} \subseteq \lambda_{pq}$ by the Containment Lemma. The part of $\eta_{x\vec{p}}$ in $\eta_{q\vec{p}}$ contains no point of S because $\eta_{q\vec{p}} \cap S = \emptyset$ by assumption. Also, the part of $\eta_{x\vec{p}}$ in $\eta_{p\vec{q}}$ contains no point of S because a point $y \in \eta_{x\vec{p}} \cap \eta_{p\vec{q}}$ would be closer to pq than x is, as can be shown using the $\square$-Lemma for $px'yx$ (see Fig. 7). So px is an edge of R if $\eta_{p\vec{x}}$ contains no point of S either, and it is a 1-edge with triangle pqx on its beneath side otherwise. The argument for qx is symmetric. $\square$

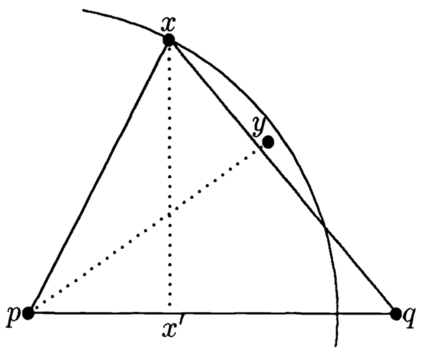

FIG. 7. *Vertex x is visible from p and from q, so pqx is empty. It follows that if $y \in \eta_{x\vec{p}} \cap \eta_{p\vec{q}}$ then $pqyx$ is a convex quadrilateral.*

5.1. Incomplete rng-polygons. The above lemmas are sufficient for efficiently triangulating an incomplete rng-polygon. As defined earlier, all edges of an incomplete rng-polygon R are rng-edges, except for one 1-edge, $pq \in ch(S) - rng(S)$, which has R on its beyond side. The algorithm below can triangulate more general incomplete rng-polygons, that is, it is not necessary that $pq \in ch(S)$, but it must be that pq is a 1-edge and R lies beyond pq.

Input. An incomplete rng-polygon R that lies beyond its 1-edge pq.

Output. A minmax length triangulation of R.

Algorithm.
1. Find a vertex x in λ_{pq} that minimizes the distance from pq.
2. Draw edges px and qx. This decomposes R into the triangle pqx and two possibly empty incomplete rng-polygons R_1 and R_2.
3. Recursively triangulate R_1 and R_2.

The correctness of this algorithm follows from the 1-Edge Lemma. Indeed, it implies that if R_1 is nonempty, then it lies beyond px, which is the only 1-edge of R_1. Similarly, R_2 lies beyond its 1-edge qx, provided that R_2 is nonempty. Thus the input invariant is maintained all the way through the recursion. This implies that the algorithm successfully triangulates. By the choice of point x, the edges px and qx are both shorter than pq. It follows that the diagonals are monotonically decreasing in length down a single branch of the recursion, and therefore all diagonals constructed by the algorithm are shorter than pq. A straightforward implementation of the algorithm takes time that is quadratic in the number of vertices of R.

Remark. Instead of choosing a vertex x that minimizes the distance to pq, step 1 of the algorithm could also choose other vertices as long as they are visible from p and

q and lie in their lune. An interesting choice among these vertices is the vertex y that minimizes $\max\{|yp|, |yq|\}$. As long as y is unique, which is the nondegenerate case, this choice leads to a triangulation of the polygon R that lexicographically minimizes the sorted vector of edge lengths. Another possible choice is the vertex z that minimizes $|zp| + |zq|$. This vertex is automatically visible from p and from q and might be useful in actual implementations because it is often considerably less expensive to compute the distance between two points than between a point and a line segment.

5.2. Lemma on polygon retriangulation. This subsection presents a technical lemma on retriangulating a polygonal region. It will find application in §§5.3 and 6 and is also of independent interest. In order to conveniently distinguish between boundary and nonboundary edges of a triangulation, we call a nonboundary edge a *diagonal*. Let X be a polygonal region, let $t(X)$ be a triangulation of X, and let xx' be a diagonal of X that is not in $t(X)$. We say that xx' *generates* $t(X)$ if it intersects every diagonal of $t(X)$. We give an algorithmic description of a particular triangulation of X, called the *fan-out triangulation* $f_x(X)$ with (*fan-out*) *center* x. The triangulation is illustrated in Fig. 8.

1. Connect x to all vertices of X that are visible from x. Call these vertices and also the two vertices connected to x by edges of X *neighbors* of x.

2. Two neighbors of x are said to be *adjacent* if they are consecutive in the angular order around x. Connect any two adjacent neighbors u, v of x unless uv is an edge of X.

3. Every edge uv created in step 2 decomposes X into two parts, and the part that does not contain x is called the *pocket* X_{uv} of uv. Assume that u is the endpoint of uv so that the other incident edge of the pocket uw is partially visible from x. Recursively construct the fan-out triangulation of X_{uv} with center v.

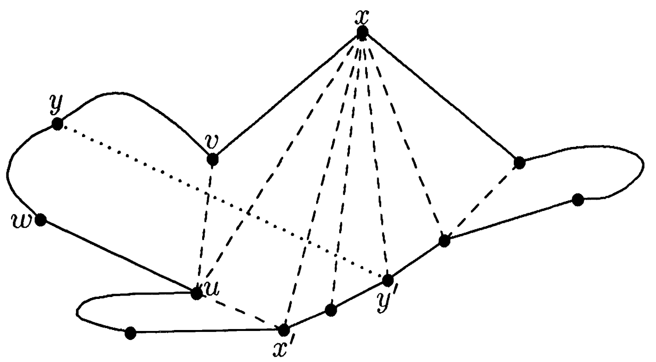

FIG. 8. *Polygonal region X is triangulated by fanning out from x, connecting adjacent neighbors of x, and recursing in the thus created pockets. The illustration of this process is schematic and ignores some of the inherent shape constraints for X.*

We introduce some terminology. Among the diagonals of $f_x(X)$ we distinguish between *fan-out* edges constructed in step 1 and *cut-off* edges constructed in step 2 of the above algorithm. Each call of the algorithm triangulates part of a pocket and recurses in each component (pocket) of the remainder. We call a pocket V a *child* of another pocket Z if $V \subset Z$ and V is maximal. The original polygonal region X is also called a pocket and forms the root of the tree defined by the child relation. This tree is exactly the recursion tree of the algorithm. Each pocket Z is associated with a fan-out center z. The maximum distance between z and any other vertex of Z is called the *width* of Z.

The lengths of the diagonals of $f_x(X)$ are constrained by the length of the longest edge of X, the length of the longest diagonal of $t(X)$, and the width of X. More specifically, we prove the following result.

FAN-OUT LEMMA. *Let X be a polygonal region, with δ_1 the length of its longest edge, let $t(X)$ be a triangulation of X, with δ_2 the length of its longest diagonal, let xx' be a generator of $t(X)$, and let δ_3 exceed the maximum distance of x from any vertex of X. Then $|ab| < \max\{\delta_1, \delta_2, \delta_3\}$ for every diagonal ab of $f_x(X)$.*

Proof. Note that the assertion follows if we prove that $\max\{\delta_1, \delta_2, \delta_3\}$ exceeds the width of every pocket Z created during the algorithm. To see this notice that the width of Z is an upper bound on the length of any fan-out edge emanating from the center of Z. Each cut-off edge uv that creates a child pocket V of Z is incident to the fan-out center of V, which implies that the width of V is an upper bound on its length.

The proof of the upper bound on the widths of all pockets proceeds inductively from the top to the bottom of the tree. The width of X is less than δ_3 by assumption, and it is therefore also less than $\max\{\delta_1, \delta_2, \delta_3\}$. For the inductive step consider a pocket Z and a child V of Z. We show that the bound on the width of Z is inherited by V, with some environmental influence from X and $t(X)$. Let z be the fan-out center of Z, let δ be the width of Z, let v be the fan-out center of V, let uv be the cut-off edge that creates V, and let w be the other vertex of V adjacent to u.

First, we prove $|uv| < \max\{\delta_1, \delta\}$. By the definition of a fan-out center, v lies inside the triangle uwz. The Δ-Lemma thus implies that $|uv| < \max\{|uw|, |uz|\}$, and we obtain the claimed inequality because $|uw| \le \delta_1$ and $|uz| \le \delta$. Second, we show that $\max\{\delta_2, \delta\}$ exceeds the maximum distance between v and any vertex of V other than u. Let $y \ne v, u$ be such a vertex, and let yy' be a diagonal of $t(X)$ that intersects xx'. Such a diagonal exists because xx' generates $t(X)$. It follows that yy' intersects uv and that therefore v lies inside the triangle $yy'z$. Using the Δ-Lemma we get $|yv| < \max\{|yy'|, |yz|\} \le \max\{\delta_2, \delta\}$ because $|yy'| \le \delta_2$ and $|yz| \le \delta$. The two bounds together imply that the width of V is less than $\max\{\delta_1, \delta_2, \delta\}$, and induction shows that it is less than $\max\{\delta_1, \delta_2, \delta_3\}$. □

In §6 we will need a result as given in the Fan-Out Lemma but restricted to the fan-out triangulation on one side of the generator. More specifically, we will need the following corollary whose proof is almost the same as the one of the Fan-Out Lemma.

FAN-OUT COROLLARY. *Suppose that W is a polygonal region, $t(W)$ is a triangulation of W, xx' is a generator of $t(W)$, and X is the part of W on one side of xx'. Let δ_1 be the length of the longest edge of X, let δ_2 be the length of the longest diagonal of $t(W)$, and let δ_3 exceed the maximum distance of x from any vertex of X. Then $|ab| < \max\{\delta_1, \delta_2, \delta_3\}$ for every diagonal ab of $f_x(X)$.*

Remark. The Fan-Out Lemma can also be formulated without the assumption of an initial triangulation. The condition on the diagonal xx' is now that each vertex of X must be visible from some point of xx'. The parameter δ_2 needs to be redefined as the maximum, over all vertices y of X, of the infimum, over all points a of xx' visible from y, of the distance between y and a.

5.3. Complete rng-polygons. It will be convenient to assume that no two diagonals and edges of the rng-polygon R are equally long. With this assumption we can show that every triangulation of R, and therefore also every minmax length triangulation, contains a 2-edge. To see this take the longest edge pq of a triangulation. It is not an edge of R because the third vertex of the incident triangle lies in its lune λ_{pq}. It is therefore a diagonal with incident triangles pqr and pqs, and we have $r, s \in \lambda_{pq}$ by maximality of pq. Since r and s lie on different sides of pq it follows that pq is a 2-edge.

We prove below that there is a minmax length triangulation $mlt(R)$ of R that contains only one 2-edge pq. By the argument above pq is the longest edge of $mlt(R)$. We call pq *expandable* if there are vertices r and s in λ_{pq}, on different sides of pq and both visible from p and q, so that $E = \{pr, qr, ps, qs\}$ is a set of rng- and 1-edges and the quadrilateral $prqs$ lies beneath the 1-edges in E. It should be clear that once we draw an expandable 2-edge, we can complete the triangulation by using the algorithm for incomplete rng-polygons (§5.1). The resulting triangulation uses no 2-edge other than pq, which is thus the longest edge of the triangulation.

We first present the algorithm, and then we prove its correctness by showing that every complete rng-polygon R has a minmax length triangulation that contains an expandable 2-edge. This, however, assumes that no two diagonals or edges of R have equal length. If this nondegeneracy constraint is not satisfied it is necessary to run the algorithm with a simulation of nondegeneracy; see [EdMü90]. The side effects of this simulation and how they can be undone will be discussed in §5.4.

Input. A complete rng-polygon R.

Output. A minmax length triangulation of R.

Algorithm.
1. Find the shortest expandable 2-edge pq, together with corresponding rng- and 1-edges pr, qr, ps, qs.
2. Triangulate the incomplete rng-polygons defined by pr, qr, ps, qs.

As mentioned in §5.1, step 2 takes time that is only quadratic in the number of vertices of R. In §6 we will see how step 1 can be implemented so that it runs in quadratic time too. We now formulate and prove the lemma that implies the correctness of the algorithm.

2-EDGE LEMMA. *Let R be a complete rng-polygon with no two diagonals or edges of the same length. Then there exists a minmax length triangulation $mlt(R)$ of R that contains an expandable 2-edge.*

Proof. We assume that there is no minmax length triangulation of R that contains an expandable 2-edge. A contradiction to this assumption will be derived by using a minmax length triangulation $t(R)$ that is defined as follows. Let pq be the longest edge of $t(R)$, and let pqr and pqs be the incident triangles. By the nondegeneracy assumption pq is the longest edge of *every* minmax length triangulation of R. Choose $t(R)$ so that the sum of heights of pqr and pqs (that is, the distance of r from pq plus the distance of s from pq) is a minimum. We will prove below that pq is expandable and that r and s are witnesses thereof, that is, that the quadrilateral $prqs$ lies beneath every 1-edge in $E = \{pr, qr, ps, qs\}$.

Case 1. Assume that $prqs$ lies beyond at least one 1-edge in E, say, beyond pr. Then we can retriangulate R on this side of pr by using the algorithm for incomplete rng-polygons. This algorithm removes edge pq, among others, and all new edges are shorter than pr, which itself is shorter than pq. This contradicts the assumption that $t(R)$ is a minmax length triangulation.

Case 2. Assume that one of the edges of E, say, pr, is a 2-edge, and assume without loss of generality that $r \in \eta_{\vec{pq}}$. Thus there is a nonempty set of vertices z of R contained in the half-lune $\eta_{\vec{rp}}$. By the Containment Lemma these vertices z lie in λ_{pq}, and by the Visibility Lemma a nonempty subset S' of the z are visible from both p and r.

If a vertex z is in S', then either $pz \cap rq \neq \emptyset$ or $rz \cap pq \neq \emptyset$; see Fig. 9. Let S'_p be the subset of vertices z of the first kind, and let S'_r be the subset of vertices of the second kind. If $S'_p \neq \emptyset$, choose $x \in S'_p$ so that the number of edges of $t(R)$ that intersect px, is a minimum. Next, remove all edges from $t(R)$ that intersect px, and denote by X the polygonal region thus generated. If, on the other hand, $S'_p = \emptyset$, then choose $x \in S'_r \neq \emptyset$ so that the number of edges in $t(R)$ that intersect rx is a minimum, again remove all edges from $t(R)$ that intersect rx, and denote the resulting polygonal region by X. For convenient reference we set $x' = p$ in the first case and $x' = r$ in the second. In either case we construct a retriangulation $f_x(X)$ of X by fanning out from x, as described in §5.2.

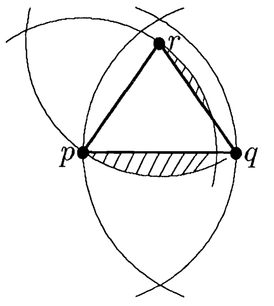

FIG. 9. *Points z lie in the interior of $\eta_{r\vec{p}} - pqr$, which consists of one or two connected components, depending on whether or not the angle at r in triangle pqr is nonacute.*

We will show below that the new triangulation of R has properties that contradict the assumptions of case 2. Most important, the Fan-Out Lemma of §5.2, together with a few claims that we are about to prove, imply that the edges of $f_x(X)$ do not exceed pq in length.

CLAIM 1. *Except for x, all vertices of X lie outside the half-lune $\eta_{r\vec{p}}$.*

Proof of Claim 1. Let $y_1y_2, y_3y_4, \ldots, y_{m-1}y_m$ be the edges, sorted from x' to x, that are removed from $t(R)$ when X is constructed. Suppose that the claim is not true. Then there is a smallest index $j, 3 \leq j \leq m-1$, so that one endpoint of y_jy_{j+1}, say, y_{j+1}, is in $\eta_{r\vec{p}}$. Consider the polygonal region X_j of $t(R)$ that is created by removing the edges $y_1y_2, y_3y_4, \ldots, y_{j-2}y_{j-1}$ from $t(R)$. Since y_{j+1} is the only vertex of X_j that lies in $\eta_{r\vec{p}}$, it is visible from p *and* from r, inside X_j. But this means that $y_{j+1}x'$ intersects fewer edges of $t(R)$ than does xx'. This contradicts the choice of x and completes the proof of Claim 1.

CLAIM 2. *For each vertex y of X we have $|xy| < |pq|$.*

Proof of Claim 2. Clearly, both px and rx are shorter than pq. So let y be any vertex different from p, r, x, and let yy' be an edge of $t(R)$ that intersects $x'x$. Because of Claim 1, x is visible within X from p and also from r, so $pyxy'$ and $ryxy'$ are convex quadrilaterals. Since y' lies outside $\eta_{r\vec{p}}$ it cannot lie inside both of the circles $(p, |pr|)$ and $(r, |pr|)$. If y' lies inside $(r, |pr|)$, then $|py'| > |px|$ which implies $|yy'| > |xy|$ by the $\square$-Lemma for $pyxy'$. Otherwise, we have $|ry'| > |rx|$ which implies $|yy'| > |xy|$ by the $\square$-Lemma for $ryxy'$. This concludes the proof of Claim 2 because yy' is an edge of $t(R)$ and is therefore no longer than pq.

Claim 2 and the Fan-Out Lemma imply that all diagonals of $f_x(X)$ are shorter than pq. In the case for which $pq \cap rx \neq \emptyset$ we now have a contradiction because the retriangulating process of X eliminates pq and all edges of the resulting new triangulation of R are shorter than pq. In the case for which $rq \cap px \neq \emptyset$ the new triangulation still includes pq. We will show below that the height of the new triangle incident to pq is smaller than the height of pqr and thus arrive at a contradiction.

So assume $rq \cap px \neq \emptyset$; in this case pq is an edge of the boundary of X and p is visible from x. If q is also visible from x, then the new triangle incident to pq is pqx with height $|xx'|$, where $x' \in pq$ minimizes the distance to x. Analogously, define $r' \in pq$ that minimizes the distance to r. Since $|pr| > |px|$, we have $|rr'| > |xr'|$ by the $\square$-Lemma for $prxr'$. Together with $|xr'| \geq |xx'|$, this implies $|rr'| > |xx'|$. If q is not visible from x, then pq belongs to the pocket X_{uv} defined by a cut-off edge uv. We have $u = p$, $w = q$, and the center v of X_{uv} lies inside pqx. So again, either pqv is a triangle, and its height is less than that of pqx and therefore that of pqr, or q is not visible from v, in which case the argument can be repeated. Eventually, we arrive at a triangle incident to pq whose height is less than that of pqr. $\square$

Remark. Recall that the assertion of the 2-Edge Lemma is made under the condition that no two diagonals or edges of the complete rng-polygon R are equally long. Indeed, the assertion is false without this condition. Take, for example, two equilateral triangles abc and abd and move d slightly towards the common edge ab. For $S = \{a, b, c, d\}$ we have that $rng(S) = \{ac, cb, bd, da\}$, ab is a 1-edge, and cd is a 2-edge. So $acbd$ is a complete rng-polygon. There is only one minmax length triangulation of $acbd$, namely, the one obtained by drawing the diagonal ab. But ab is not a 2-edge.

5.4. Undoing the simulated perturbation. For every finite point set S in $\Re^2$ there is an arbitrarily small perturbation S' so that S' satisfies convenient nondegeneracy assumptions (see [EdMü90]). For a point $p \in S$ we denote its perturbed version by p'. In the case of relative neighborhood graphs and minmax length triangulations this means that no two pairs of points in S' define the same distance. Because the perturbation is arbitrarily small, the nondegenerate properties of S are maintained, that is, for four not necessarily distinct points $p, q, r, s \in S$ with $|pq| < |rs|$ we have $|p'q'| < |r's'|$.

Let us consider the effect of the perturbation on the computation of a minmax length triangulation. Clearly, if $p'q' \in rng(S')$, then $pq \in rng(S)$, but not vice versa. The fact that in the perturbed setting the relative neighborhood graph has potentially fewer edges than in the unperturbed setting does not adversely influence the triangulation algorithm since $rng(S')$ is still connected and spans S'. When the edges of $ch(S')$ are added and the polygonal regions defined by $ch(S') \cup rng(S')$ are triangulated, it can happen that triangles $a'b'c'$ are constructed whose unperturbed counterparts abc are flat, that is, a, b, c are collinear. Although this is not a problem for the algorithm, it is somewhat distressing when this triangulation is interpreted as a triangulation of S. The remainder of this section shows how to remedy this deficiency.

Let $t(S')$ be a minmax length triangulation of S', and consider its unperturbed version $t(S)$, that is, $pq \in t(S)$ if and only if $p'q' \in t(S')$. A longest edge of $t(S)$ is no longer than a longest edge of any minmax length triangulation $mlt(S)$ of S since $mlt(S')$, the perturbed version of $mlt(S)$, is a valid triangulation of S' and would otherwise contradict that $t(S')$ is a minmax length triangulation of S'. The reverse is also true, namely, that a longest edge of $t(S)$ is no shorter than a longest edge of $mlt(S)$. We show this by converting $t(S)$ into a minmax length triangulation of S.

Consider the dual graph $t^*(S')$ of $t(S')$, and call a node $a'b'c'$ *flat* if a, b, c, are collinear. Determine the connected components of the subgraph of $t^*(S')$ induced by the set of all flat nodes. Each component corresponds to a collection of collinear points in S interconnected by flat triangles; see Fig. 10. Carry out the following steps for one component at a time. Remove all edges of the flat triangles of the component, sort the corresponding points along the supporting line, and add edges connecting points that are adjacent in the sorted order. This produces regions bounded by more than three edges, as shown in Fig. 10. All vertices x of such a region are collinear, except for one vertex y that is connected to the first and last of the vertices x. Triangulate this region by connecting y to all other vertices x. By the Δ-Lemma the newly introduced edges are no longer than the longer of the two original edges incident to y.

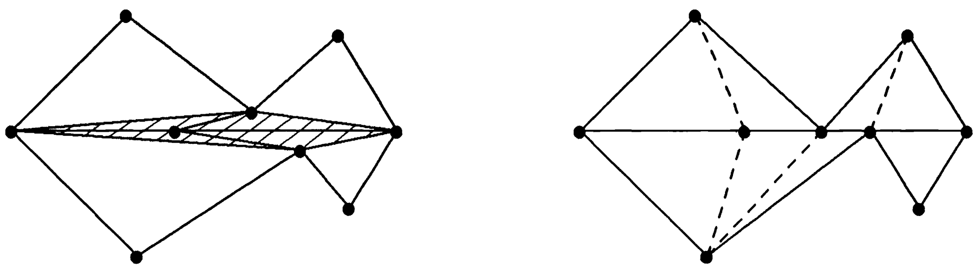

FIG. 10. *The five points in the middle of the left triangulation are the perturbed versions of five collinear points in the right triangulation.*

6. Finding the shortest expandable 2-edge. This section shows how the first step of the algorithm for triangulating a complete rng-polygon R can be made to run in time $O(n^2)$, where n is the number of vertices of R. As in §5.3, we assume that no two diagonals or edges of R are equally long; so the shortest expandable 2-edge is unique. For convenience we also assume that no three vertices of R are collinear.

Input. A complete rng-polygon R.

Output. The shortest expandable 2-edge of R.

Algorithm.
1. Determine the type of each diagonal pq of R.
2. For each 2-edge pq find vertices p', p'', q', q'' that minimize the counterclockwise angles $\angle p'pq, \angle qpp'', \angle q'qp, \angle pqq''$ contingent on pp', pp'', qq', qq'' being rng-edges or 1-edges with pq on their beneath sides (see Fig. 11).
3. Return the shortest 2-edge pq for which pp', qq', pp'', qq'' are such that $p' = q''$ or $pp' \cap qq'' \neq \emptyset$ and that $p'' = q'$ or $pp'' \cap qq' \neq \emptyset$.

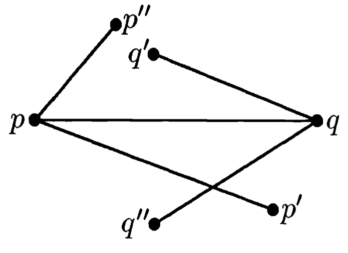

FIG. 11. *By the choice of p' the counterclockwise angle $\angle p'pq$ contains no 1-edge with pq on its beneath side. Symmetric statements hold for p'', q', and q''.*

Below we give the algorithmic details of the above steps.

Step 1. *Classifying diagonals*. For each vertex p of R we compute all incident diagonals pq and their angular order around p. Furthermore, we determine whether or not the half-lune $\eta_{p\bar{q}}$ contains any vertex of R. Recall that by the Visibility Lemma $\eta_{p\bar{q}}$ contains a vertex visible from p if it contains a vertex of R at all. We can thus base the decision of whether or not $\eta_{p\bar{q}}$ is empty of vertices solely on the vertices visible from p. As defined earlier, pq is a 2-edge if both half-lunes of pq contain vertices of R. Otherwise, pq is a 1-edge and its beyond side is where the half-lune contains vertices of R. We now show that the computation for p can be done in time $O(n)$. It follows that $O(n^2)$ time suffices for Step 1.

Computing the sorted sequence of diagonals $pp_1, pp_2, \dots, pp_m$ incident to p is a standard operation for simple polygons and can be done in time $O(n)$; see, e.g., [ElAv81], [JoSi87], [Lee83]. Let pp_0 and pp_{m+1} be the two edges of R incident to p, and assume that $p_0, p_1, p_2, \dots, p_m, p_{m+1}$ is in a counterclockwise order around p. To determine whether there is a vertex of R in the half-lune $\eta_{p\bar{p}_i}$ for $1 \leq i \leq m$, we scan the list $p_0, p_1, \dots, p_{m+1}$ once, from smallest index to largest. During the scan we maintain a stack of diagonals pp_l whose half-lunes $\eta_{p\bar{p}_l}$ are not yet found to contain any vertex of R. Before pushing pp_i onto the stack, we remove all diagonals pp_l whose half-lunes contain p_i. Using a straightforward extension of the Containment Lemma, we can show that the order of processing implies that the edges whose half-lunes contain p_i lie on top of the ones whose half-lunes do not contain p_i. Thus the former can be removed by simply repeatedly popping the topmost diagonal. When the scan is complete, the stack contains exactly all diagonals pp_l whose half-lunes contain no vertex of R. Since a diagonal can be pushed and popped only once each, the entire process takes constant time per diagonal.

Step 2. *Finding rng- and 1-edges*. For each vertex p we scan $pp_1, pp_2, \dots, pp_m$ in this order. In the process we keep track of the most recent rng-edge or 1-edge $p\bar{p}$ whose beneath side is in the direction of the scan. Initially, $p\bar{p} = pp_0$. When a 2-edge pq is encountered, then $p\bar{p}$ is the edge pp' that belongs to pq. A symmetric scan is carried out to find the edge pp'' that belongs to pq. The total time for all vertices p of R is clearly $O(n^2)$.

Step 3. *Returning the solution*. Step 3 is computationally trivial. It takes time $O(n^2)$ since constant time suffices to test whether or not pp', pp'', qq', qq'' satisfy the conditions of Step 3. However, it is not trivial to see that the edge pq returned in Step 3 is also the shortest expandable 2-edge. First, note that the shortest expandable 2-edge is no shorter than pq. This is because all 2-edges shorter than pq fail the test of Step 3. The following straightforward topological lemma implies that these 2-edges are not expandable.

CROSSING LEMMA. *Let $v_1, v_2, \dots, v_n$ be the sequence of vertices of a simple polygon, and let v_1v_i and v_jv_n be two diagonals. Then $v_1v_i \cap v_jv_n \neq \emptyset$ if and only if $j < i$.*

Proof. The edge v_jv_n decomposes the polygon into two disjoint polygons with vertex sequences $v_1, v_2, \dots, v_j, v_n$ and $v_j, v_{j+1}, \dots, v_n$. If $j < i$, then neither of the two polygons has v_1 *and* v_i on its boundary. It follows that v_1v_i crosses from one polygon into the other, and because v_1v_i is a diagonal, this is only possible by crossing v_jv_n. To prove the other direction we assume $v_1v_i \cap v_jv_n \neq \emptyset$ and observe that v_1 and v_i belong to different polygons because there is no way that v_1v_i can enter the second polygon and leave it again. Thus $j < i$. □

So it remains to show that the edge pq computed in Step 3 is indeed expandable.

EXPANDABILITY LEMMA. *The shortest 2-edge pq of R that satisfies the conditions of Step 3 is also expandable.*

Proof. We show below that R can be triangulated on both sides of pq by using only edges shorter than pq. If we now assume that pq is not expandable, we get a contradiction to the 2-Edge Lemma because pq is the longest edge of the triangulation and all expandable 2-edges are longer than pq.

We describe how to triangulate the part of R to the right of $\vec{pq}$; the other part is symmetric.

Case 1. $p' = q''$. Assume that $|qq''| > |pp'|$. Then $|qq''| < |pq|$, for otherwise $p \in \eta_{q\vec{q''}q}$ and qq'' would be neither an rng-edge nor a 1-edge with pq on its beneath side. If we apply the triangulation algorithm for incomplete rng-polygons (§5.1), once for pp' and once for qq'', we obtain a triangulation with the desired properties.

Case 2. $pp' \cap qq'' \neq \emptyset$. In this case pp' and qq'' are 1-edges. Because pp' and qq'' intersect, it must be that p' is closer to q than to p or that q'' is closer to p than to q. Assume without loss of generality that $|q''p| < |q''q|$. As in Case 1, we also have $|q''q| < |pq|$, but note that we do not necessarily have $|pp'| < |pq|$.

We now describe the triangulation process. It takes three steps, illustrated in Figs. 12 and 13.

1. Construct the triangulation $t_{qq''}$ of R beyond qq'' by using the algorithm for incomplete rng-polygons (see Fig. 12).

2. Find the subset V of vertices of R that lie inside the triangle pqq'', and compute the convex hull C of $V \cup \{p, q''\}$. Add the edges of C that are diagonals of R to the triangulation, and connect q to all vertices of C (see Fig. 12).

3. Step 2 creates untriangulated pockets Y_{uv}, one for each edge uv of C that is a diagonal of R. Assume that u precedes v on the clockwise path from p to q'' on the boundary of C. The pocket Y_{uv} is triangulated as follows.

 3.1 Set $u_L := v$ if uv is a 1-edge and pq lies on the beneath side of uv. Otherwise, find a vertex u_L so that $|uu_L| < |pq|$, uu_L is a 1-edge, pq lies beneath uu_L, and uu_L does not intersect C. (The existence of such a vertex u_L will be established shortly.)

 3.2 Construct the triangulation t_{uu_L} of R beyond uu_L, again using the algorithm for incomplete rng-polygons, but retain only the triangles that lie completely inside the pocket Y_{uv}. Let X_{uv} denote the untriangulated part of Y_{uv}.

 3.3 Construct the fan-out triangulation $f_v(X_{uv})$.

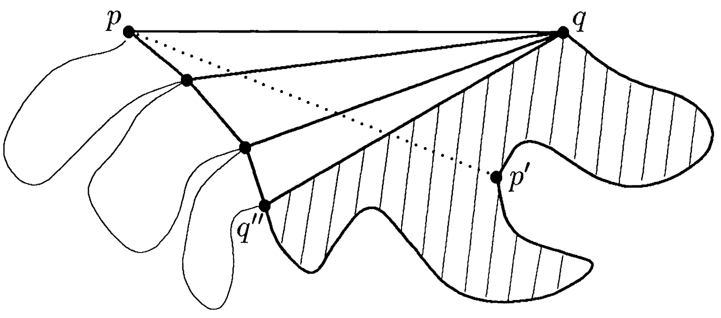

FIG. 12. *The shaded portion represents the triangulation beyond qq''; it forms part of the final triangulation.*

The remainder of the proof establishes that all diagonals of the thus constructed triangulation are shorter than pq. This is indeed obvious for $t_{qq''}$ as constructed in step 1. We now prove an easy extension of the Δ-Lemma that implies that all edges created in step 2 are shorter than pq.

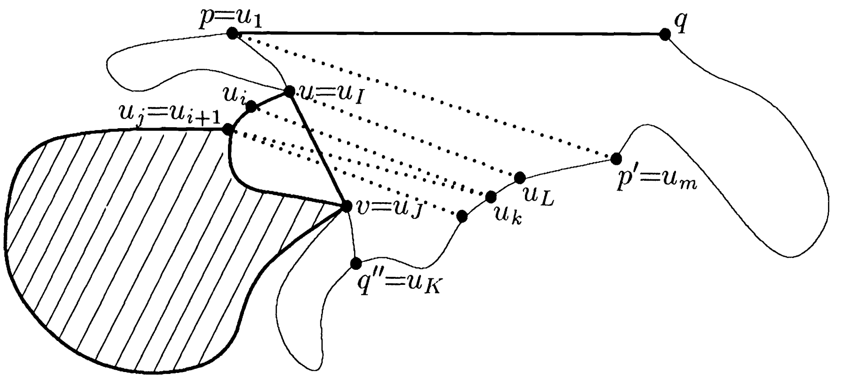

FIG. 13. *The shaded portion of the pocket Y_{uv} represents the part of the triangulation t_{uu_L} beyond uu_L that is retained for the final triangulation. The remaining portion is triangulated by fanning out from v.*

CLAIM 1. *Let abc be a triangle, and let d, e be two points inside abc. Then* $|de| < \max\{|ab|, |ac|, |bc|\}$.

Proof of Claim 1. Assume without loss of generality that e lies inside abd. The Δ-Lemma for abd implies that $|de| < \max\{|ad|, |bd|\}$, and the same lemma for abc implies that $\max\{|ad|, |bd|\} < \max\{|ab|, |ac|, |bc|\}$. This completes the proof of Claim 1.

If $uu_L = uv$, then $|uu_L| < |pq|$ which implies that all edges of t_{uu_L}, as constructed in step 3.2, are shorter than pq. In this case the proof is complete since $X_{uv} = \emptyset$ and no edges are added to Y_{uv} in step 3.3. For the remainder of the proof we thus assume that $u_L \neq v$, which is the case only if $\eta_{\vec{u}\vec{v}}$ contains at least one vertex of R. We show that a vertex u_L satisfying the conditions of step 3.1 indeed exists, and that all edges of the fan-out triangulation $f_v(X_{uv})$ are shorter than pq. Assume that the sequence of vertices of the part of R beyond pp' is $p = u_1, u_2, \dots, q'' = u_K, \dots, u_m = p'$ (see Fig. 13).

CLAIM 2. *There exists a* 1*-edge uu_L that satisfies the conditions of step* 3.1.

Proof of Claim 2. Construct a triangulation $t_{pp'}$ of R beyond pp' by using the algorithm for incomplete rng-polygons. This triangulation contains at least one edge uu_l disjoint from C. The main invariant of the algorithm (described in §5.1) implies that uu_l is a 1-edge and that pq lies on its beneath side. If $|uu_l| < |pq|$, then u_l satisfies the conditions for u_L and we are done.

So assume that $|uu_l| > |pq|$. As we showed for the Containment Lemma, we can show that the part of $\eta_{\vec{u}\vec{v}}$ to the left of $\vec{u}\vec{u}_l$ is contained in $\eta_{u\vec{u}_l}$ and thus contains no vertex of R. It follows that the vertices in $\eta_{\vec{u}\vec{v}}$ must be among $u_{K+1}, u_{K+2}, \dots, u_{l-1}$. By the Visibility Lemma at least one of these vertices is visible from u. Let U be the subset of vertices that are visible from u (including the ones outside $\eta_{\vec{u}\vec{v}}$), and let $u_L \in U$ minimize the distance to u. We have $|uu_L| < |uv| < |uu_l|$ and, as above, the part of $\eta_{u\vec{u}_L}$ to the left of $\vec{u}\vec{u}_l$ is contained in $\eta_{u\vec{u}_l}$. Therefore, this part contains no vertex of R. The part of $\eta_{u\vec{u}_L}$ to the right of $\vec{u}\vec{u}_l$ contains no vertex of R by the choice of u_L. It follows that uu_L is a diagonal that satisfies the conditions of step 3.1, which completes the proof of Claim 2.

We now show two easy facts about t_{uu_L} before examining the edges constructed by step 3.3.

CLAIM 3. *If $u_iu_ju_k$, with $i < j < k$, is a triangle of t_{uu_L}, then u_iu_k is its longest edge.*

Proof of Claim 3. The first triangle constructed is $u_Iu_lu_L$, for some $I < l < L$, and its longest edge is u_Iu_L because $u_l \in \lambda_{u_Iu_L}$. The general assertion follows by induction, which completes the proof of Claim 3.

CLAIM 4. *The edges of t_{uu_L} that intersect uv, sorted from u to v, are monotonically decreasing in length.*

Proof of Claim 4. If $u_iu_ju_k$, with $i < j < k$, intersects uv, $u = u_I$ and $v = u_J$, then either $I \leq i < j = i+1 \leq J < k$ or $I < i < J \leq j < k$ (see Fig. 13). In both cases u_iu_k intersects uv closer to u than the other intersecting edge, u_ju_k or u_iu_j. By Claim 3, u_iu_k is longer than both, which implies the assertion.

Note that if we delete edges from t_{uu_L} that intersect uv, then we get a polygonal region, say, W_{uv}, of which X_{uv} is the part on one side of uv. We can thus interpret uv as a generator of t_{uu_L} restricted to W_{uv}. Since the edges of X_{uv} and t_{uu_L} are shorter than $|pq|$, we need to show only that all vertices of X_{uv} are closer to v than $|pq|$, and the rest follows from the Fan-Out Corollary. Indeed, we prove a stronger bound on the maximum distance from v to a vertex of X_{uv}.

CLAIM 5. *For each vertex x of X_{uv} we have that $|vx| \leq |vu|$.*

Proof of Claim 5. Consider the vertices of X_{uv} in turn from $u = u_I$ to $v = u_J$, and assume inductively that $|vu_i| \leq |vu|$ for all $I \leq i < j$. Consider u_j and the triangle $u_{j-1}u_ju_k$ in t_{uu_L}. By Claim 4, we have that $|u_{j-1}u_k| > |u_ju_k|$. If $u_{j-1}u_jvu_k$ is a convex quadrilateral, then the $\square$-Lemma implies that $|vu_{j-1}| > |vu_j|$, as desired. Otherwise, u_j is contained in vu_ku_{j-1} and therefore also in vuu_{j-1}. The Δ-Lemma implies $|vu_j| < \max\{|vu|, |vu_{j-1}|\}$, which completes the proof of Claim 5.

This also completes the proof of the lemma. $\square$

The following theorem summarizes the algorithmic implications of all of this.

MINMAX LENGTH THEOREM. *A minmax length triangulation of a set of n points in $\Re^2$ can be constructed in time $O(n^2)$.*

The algorithm that constructs a minmax length triangulation in the claimed amount of time is a combination of the algorithms given in §§3, 5.1, 5.3, and 6. Its correctness has been demonstrated in §§4, 5.3, and 6.

7. Arbitrary normed metrics.

An open convex region $D \subseteq \Re^2$ that is symmetric with respect to the origin can be used to impose a *norm* on $\Re^2$: for a point $x \in \Re^2$ define $\|x\| = \|x\|_D = \alpha$ if x lies on the boundary of $\alpha D = \{\alpha y \in \Re^2 : y \in D\}$. The norm can then be used to impose a (*normed*) *metric* on $\Re^2$: for two points $x, y \in \Re^2$ define $|xy| = |xy|_D = \|y - x\|_D$. D is the *unit disk* of the metric and the boundary of D is its *unit circle*. Notice that the three requirements for a metric are indeed satisfied. First, $|ab| = 0$ if and only if $a = b$ because $\|x\| = 0$ if and only if x is the origin. Second, $|ab| = |ba|$ because D is centrally symmetric and therefore $\|x\| = \|-x\|$. Third, the triangle inequality $|ac| \leq |ab| + |bc|$ follows from the convexity of D. Examples of normed metrics are the l_p-metrics, for $1 \leq p \leq \infty$, and the so-called A-metric discussed in [WWW85] for its applications to VLSI.

In this section we assume that the triangle inequality is strict unless a, b, c lie on a line in this order. This is the case if and only if the defining convex region D is strictly convex, that is, no line intersects the boundary of D in more than two points. This assumption is convenient and, in fact, without loss of generality since every convex but not strictly convex region D' can be approximated arbitrarily closely by a strictly convex region D. Computationally, this approximation can be simulated by defining

$$\|x\|_D = \|x\|_{D'} + \epsilon\|x\|_2,$$

where $\|x\|_2$ is the Euclidean or l_2-norm and ϵ is an arbitrarily small but positive real number. Clearly, if ϵ is sufficiently small then a minmax length triangulation under D is also a minmax length triangulation under D'.

In the remainder of this section we point out where the developments in §§2–6 need to be adjusted when the Euclidean metric is replaced by an arbitrary normed metric. Most important, the graphs defined in §2 can be extended in a natural way. More specifically, the definition of $ch(S)$ remains unchanged since it makes no reference to any distance notion. If we now stipulate that "circle" means a homothetic copy of the unit circle as defined above and "$|ab|$" means the distance under the normed metric defined by D, then the definitions of $mlt(S)$, $dt(S)$, $rng(S)$, and $mst(S)$ can be taken verbatim. The minimum spanning tree $mst(S)$ is connected and spans S, and the Delaunay triangulation $dt(S)$ is plane because any two circles intersect in at most two points. Since we still have $mst(S) \subseteq rng(S) \subseteq dt(S)$, we conclude that all three graphs are connected and plane and that they span S. We remark that these three graphs are not necessarily plane if D is not strictly convex.

As mentioned in §1, the developments in §2–6 are all based on a small number of basic facts, namely, the distance relations expressed by the $\Box$-Lemma and the $\triangle$-Lemma, the convexity of the lune of an edge, and the straightness of the bisector of two points. The $\Box$-Lemma and the $\triangle$-Lemma are direct consequences of the triangle inequality and hold in the stated form (with strict inequality) for arbitrary normed metrics as long as D is strictly convex. The lune of two points is clearly convex since it is the intersection of two homothetic copies of D. Unfortunately, the bisector of two points $p \neq q$, $\ell_{pq} = \{x : |xp| = |xq|\}$, is not necessarily straight. Nevertheless, ℓ_{pq} is still a simple curve that divides $\Re^2$ into two unbounded regions, called *half-planes*, one containing p and the other containing q. The two half-planes are star-shaped with respect to p and q, that is, any line through p or q intersects ℓ_{pq} in at most one point. In addition, ℓ_{pq} is symmetric with respect to $\frac{p+q}{2}$ because D is centrally symmetric.

There is only one place where the straightness of the bisector is used in a substantial way, and that is in the proof of Fact 3 in §4. We restate this fact and show how to prove it without using the straightness of the bisector. We suggest that the reader go back to §4 and review Facts 1 and 2. Recall, in particular, that bd (respectively, $b'd'$) is said to be *switchable* if ac (respectively, $a'c'$) is no longer than the longest edge of the triangulation $t(S)$.

FACT 3. *It is not possible that both* bd *and* $b'd'$ *are nonswitchable.*

Proof. As established in Fact 2, if bd is nonswitchable, then a and d are contained in the open half-plane defined by ℓ_{pq} that contains q. Symmetrically, if $b'd'$ is nonswitchable, then, a' and d' are contained in the other open half-plane. Unlike in the Euclidean case, it is possible that ad and $a'd'$ intersect ℓ_{pq}. It is thus also possible that ad precedes $a'd'$ in the order of edges sorted from p to q by their intersections with pq (see Fig. 14). Below we will argue that if this is the case, then ad (and symmetrically $a'd'$) is switchable. In particular, we show that $|ad| > |ap|$, which, together with $|ap| \geq |ac|$ from Fact 2, implies that ad is switchable.

One characteristic of the described situation is that ad intersects ℓ_{pq} in at least one point inside the lune of pq. Let x be such an intersection point closest to a. If $pq \cap dx \neq \emptyset$ then $pdqx$ is a convex quadrilateral with $|pd| \geq |pq|$ by construction. The $\Box$-Lemma thus implies that $|dx| > |qx| = |px|$. It follows that $|ad| = |ax| + |dx| > |ax| + |px| > |ap|$. On the other hand, if $pq \cap dx = \emptyset$ then consider the point $y = ad \cap pq$ and note that $|py| \leq |qy|$. We derive $|dy| > |py|$ from $|py| + |dy| > |pd| \geq |pq| \geq 2|py|$. Therefore, $|ad| = |ay| + |dy| > |ay| + |py| > |ap|$, as desired. $\Box$

All other steps of the proof of the Subgraph Theorem go through unchanged for arbitrary normed metrics. We thus obtain the following generalization.

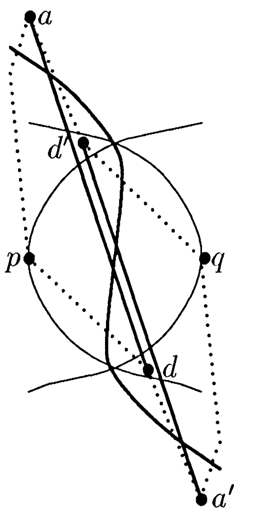

FIG. 14. *Although a and d lie on q's side of the bisector and a' and d' lie on p's side, ad intersects pq closer to p than a'd' does. This is not possible if the bisector is a line, as for the Euclidean metric, see Fig. 4.*

GENERAL SUBGRAPH THEOREM. *Let S be a finite point set in $\Re^2$ equipped with a normed metric with strictly convex unit disk. Then S has a minmax length triangulation $mlt(S)$ so that $rng(S) \subseteq mlt(S)$.*

So the algorithm for computing a minmax length triangulation is clear—it is the same as for the Euclidean metric, only the length of edges is now measured in terms of a normed metric that is possibly different from the Euclidean metric. We assume that the length of an edge in this metric can be computed in constant time. A careful reexamination of §§5 and 6 shows that the specialized polygon triangulation algorithm works also in the context of arbitrary normed metrics. We remark, however, that it includes the distance computation between a point and a line segment. Although it is certainly reasonable to assume that this can also be done in constant time, the observation in the remark at the end of §5.1 can be used to avoid this computation. We thus have the following algorithmic result, which generalizes the MinMax Length Theorem of §6.

GENERAL MINMAX LENGTH THEOREM. *Let S be a set of n points in $\Re^2$ equipped with a normed metric with strictly convex unit disk. Given the relative neighborhood graph, a minmax length triangulation of S can be constructed in time $O(n^2)$.*

The algorithmic result extends to arbitrary normed metrics. As mentioned above, a norm with nonstrictly convex unit disk can be simulated by one with strictly convex unit disk. It follows that the quadratic-time bound also holds for arbitrary normed metrics. The result stated in the General MinMax Length Theorem raises the question of how fast $rng(S)$ can be constructed. The trivial algorithm tests all $\binom{n}{2}$ edges, each in time $O(n)$, and therefore takes time $O(n^3)$. Faster algorithms are known for the l_p-metrics for which $O(n \log n)$ time suffices (see [JKY90] and [Lee85]).

8. Discussion. The main contribution of this paper is the first polynomial-time algorithm for computing a minmax length triangulation of a set S of n points in $\Re^2$. Given the relative neighborhood graph of S, the algorithm takes time $O(n^2)$. The algorithm works for arbitrary normed metrics. The polynomial time bound follows because the relative neighborhood graph of S can be found in polynomial time. The question of whether or not a minmax length triangulation can be computed in less than quadratic time remains.

The results of this paper are an outgrowth of our general efforts to understand triangulations that optimize length criteria. There are, however, still many related problems whose complexities remain open. These include the problem of minimizing the entire vector of edge lengths, the minimum length triangulation problem, and the maxmin length triangulation problem.

Acknowledgment. The authors thank an anonymous referee for suggestions on the organization of this paper.

INVERTING POLYNOMIALS AND FORMAL POWER SERIES*

K. KALORKOTI†

Abstract. The problem of inverting a general polynomial of degree $d > 0$, the inverse being a formal power series with coefficients $z_0, z_1, z_2, \ldots$ is considered. It is shown that computing $z_0, \ldots, z_n$ can be carried out in $n + (2d-1)\lceil \log_2 n \rceil + 2$ nonscalar operations over any infinite field. A lower bound of $n+1$ for all fields follows from standard linear-independence arguments. (The model of computation consists of straight-line algorithms.)

For fields of characteristic 0, it is also shown that computing $z_{n+1}, \ldots, z_{n+s}$ for $n \geq 0$, $s \geq 1$, requires at least $s + \min(n+1, d)/2 - 1$ nonscalar operations. For the case of inverting a general formal power series a corresponding lower bound of $s + (n+1)/2 - 1$ exists. In particular, computing the nth coefficient of the inverse of a general formal power series requires at least $n/2$ nonscalar operations (the coefficients are numbered from zero).

Key words. algebraic complexity, polynomials, formal power series, inverse

1. Introduction.

Let k be any infinite field, and let $t, x_0, x_1, x_2, \ldots$ be indeterminates over k. Define $y_0, y_1, y_2, \ldots$ by

$$\sum_{i=0}^{\infty} y_i t^i = \left(\sum_{i=0}^{\infty} x_i t^i \right)^{-1}.$$

Let L_n be the nonscalar complexity of computing $y_0, \ldots, y_n$, i.e.,

$$L_n = L(y_0, \ldots, y_n).$$

(See Borodin and Munro [2] for background.) It is easy to see that

$$y_i = \begin{cases} x_0^{-1} & \text{for } i = 0, \\ -x_0^{-1} \sum_{j=1}^{i} x_j y_{i-j} & \text{otherwise.} \end{cases} \tag{1}$$

The naïve algorithm implied by these equations clearly requires $\Omega(n^2)$ nonscalar operations. However, Sieveking [8] showed that $L_n \leq 5n - 2$. Kung [5] improved this to $L_n \leq 4n - \log_2 n$. Kung also showed that $L_n \geq n + 1$ and conjectured that $L_n \geq 4n -$ (lower-order terms). That the conjecture is false was observed by Schönhage [9], who noted that the second algorithm given in [5] requires at most $3.75n$ nonscalar operations. The improvement is obtained from the identity

$$\left(\sum_{i=0}^{n} a_i t^i \right)^2 \equiv \sum_{i=0}^{(n+1)/2-1} a_i t^i \left(\sum_{i=0}^{(n+1)/2-1} a_i t^i + 2 \sum_{i=(n+1)/2}^{n} a_i t^i \right) \qquad (\text{mod } t^{n+1}),$$

so that the first $n+1$ coefficients of the square can be computed in $3(n+1)/2$ nonscalar multiplications (this follows from the fact that the coefficients of the product of two polynomials of degree m and n, respectively, can be computed in $m + n + 1$ nonscalar multiplications—e.g., see Winograd [13]). Note that for fields of characteristic 2 we have

*Received by the editors May 8, 1991; accepted for publication (in revised form) February 27, 1992.

†Department of Computer Science, University of Edinburgh, Edinburgh EH9 3JZ, Scotland, United Kingdom.

the equality $(a_0+a_1+\cdots+a_m)^2 = a_0^2+a_1^2+\cdots+a_m^2$, which means that the coefficients can be computed in just $n/2+1$ nonscalar multiplications and that this leads to an upper bound of $3.25n$.

In this paper we examine the problem of inverting a general polynomial of degree $d > 0$. Set

$$\sum_{i=0}^{\infty} z_i t^i = \left(\sum_{i=0}^{d} x_i t^i\right)^{-1}$$

We show that

$$L(z_{n+1},\ldots,z_{n+s}) \geq s + \min(n+1,d)/2 - 1, \qquad n \geq 0, s \geq 1,$$

for all fields of characteristic 0. For arbitrary fields we have

$$L(z_0,\ldots,z_n) \geq n+1, \qquad n \geq 0.$$

For an upper bound we have, when $s \leq n+1$,

$$L(z_{n+1},\ldots,z_{n+s}) \leq L(z_0,\ldots,z_n) + s + 2d - 1$$

for all infinite fields. This yields

$$L(z_0,\ldots,z_n) \leq n + (2d-1)\lceil \log_2 n \rceil + 2$$

for all $n \geq 1$.

Taking $n = d-1$, $s = d$, we have

$$L(z_d,\ldots,z_{2d-1}) \geq 1.5d - 1$$

for all fields of characteristic 0. For an upper bound we have

$$\begin{aligned} L(z_d,\ldots,z_{2d-1}) &\leq L(z_0,\ldots,z_{d-1}) + 3d - 1 \\ &\leq L(y_0,\ldots,y_{d-1}) + 3d - 1 \\ &\leq 6.75d - 4.75. \end{aligned}$$

We also have that for all fields of characteristic 0

$$L(y_{n+1},\ldots,y_{n+s}) \geq s + (n+1)/2 - 1, \qquad n \geq 0, s \geq 1.$$

Consequently

$$L(y_n) \geq \frac{n}{2}$$

for all n.

It is worthwhile to remark that Kung's lower bound is, in fact, shown for computing the first $n+1$ coefficients of the inverse of $x_0 + t$. The argument is, therefore, not valid as a proof of a lower bound on L_n for the usual (symbolic) model of straight-line algorithms. However, the lower bound, which holds for all characteristics, is an immediate consequence of straightforward arguments based on linear independence, such as those given by Fiduccia [3].

An alternative and more fruitful approach to obtaining a lower bound for L_n, due to Stoss [10], is as follows. Suppose that $\mathcal{A}$ is an algorithm that computes $y_0, \ldots, y_n$. It is clear from equations (1) that each y_i is a polynomial in x_0^{-1} and $x_1, \ldots, x_i$. Regard $\mathcal{A}$ as having scalars $k(x_0)$, and transform it to an algorithm $\mathcal{B}$, which computes only terms of degree 2 (Strassen [11]). The nonscalar complexity of $\mathcal{B}$ is no higher than that of $\mathcal{A}$, and its results are the coefficients of

$$x_0^{-3}\left(\sum_{i=1}^{n-2} x_i t^{i-1}\right)^2 \qquad (\text{mod } t^{n-1}).$$

For fields of characteristic other than 2 it can be seen that computing the coefficients of $(a_0 + a_1 t + \cdots + a_r t^r)$ mod t^{r+1} (where the a_i are indeterminates over k) requires at least $r + \lceil (r+1)/2 \rceil - 1$ nonscalar operations. This yields the lower bound

$$L_n \geq (n-2) + \lceil (n-1)/2 \rceil - 1 \geq 1.5n - 4,$$

which seems to be the best that is currently known.

We now give a sketch proof of the lower bound result on squaring polynomials (the author has not been able to find a proof in the literature and does not have a copy of [9] so the approach given here might be different). The proof uses the simple observation that any algorithm which computes l linearly independent quadratic forms must use at least l non-scalar steps. Let

$$b_0 + b_1 t + \cdots + b_r t^r \equiv (a_0 + a_1 t + \cdots + a_r t^r)^2 \quad (\text{mod } t^{r+1}).$$

The b_i are quadratic forms and so, by [11], they can be computed as

$$(2) \qquad (b_0, b_1, \ldots, b_r)^T = M(u_1 \times v_1, \ldots, u_m \times v_m)^T,$$

where M is an $(r+1) \times m$ matrix of scalars and each u_i, v_i is a k-linear combination of $a_0, \ldots, a_r$. It is easily shown that the b_i are linearly independent (over k), and so $m \geq r+1$. Now a_r must be present in some step $u_j \times v_j$, and this can be killed by substituting for a_r a k-linear combination of $a_0, \ldots, a_{r-1}$. A similar observation applies in turn to $a_{r-1}, \ldots, a_{s+1}$ where $s = \lceil (r+1)/2 \rceil$. Thus after killing $r - s$ nonscalar steps in (2) we obtain an algorithm that computes $b_0, \ldots, b_s, \bar{b}_{s+1}, \ldots, \bar{b}_r$, where

$$b_0 + \cdots + b_s t^s + \bar{b}_{s+1} t^{s+1} + \cdots + \bar{b}_r t^r \equiv (a_0 + \cdots + a_s t^s + l_1 t^{s+1} + \cdots + l_{r-s} t^r)^2 \quad (\text{mod } t^{r+1}),$$

where each l_i is a k-linear combination of $a_0, \ldots, a_s$. It is now easy to see that the b_i, $\bar{b}_j$ are linearly independent (consider the term $a_s a_j$ that occurs in $\bar{b}_{s+j}$ but not in $\bar{b}_{s+i}$ for $i < j$). Thus the computation of $b_0, \ldots, b_s, \bar{b}_{s+1}, \ldots, \bar{b}_r$ requires at least $r+1$ nonscalar steps and so in (2) we have $m \geq r + 1 + r - s \geq r + \lceil (r+1)/2 \rceil - 1$.

2. The upper bound. We describe a recursive algorithm for computing $z_{n+1}, \ldots$, z_{n+s}, where $s \leq n+1$, from $z_0, \ldots, z_n$. (This is the same as the algorithm given in §2 of [5] but with the power series replaced by a polynomial.)

The *order* of a formal power series $\sum_{i=0}^{\infty} c_i t^i$ is the least i such that $c_i \neq 0$ if this exists and is undefined otherwise. Trivially,

$$\sum_{i=n+1}^{\infty} z_i t^i = \left(1 - \sum_{i=0}^{n} z_i t^i \sum_{i=0}^{d} x_i t^i\right) \sum_{i=0}^{\infty} z_i t^i.$$

Noting that the parenthesized expression has order at least $n+1$, we immediately have

$$\sum_{i=n+1}^{n+s} z_i t^i = \left(1 - \sum_{i=0}^{n} z_i t^i \sum_{i=0}^{d} x_i t^i\right) \sum_{i=0}^{s-1} z_i t^i \qquad (\text{mod } t^{n+s+1}).$$

Define $a_{n+1}, \ldots, a_{n+d}$ by

$$\sum_{i=0}^{n} z_i t^i \sum_{i=0}^{d} x_i t^i = 1 + \sum_{n+1}^{n+d} a_i t^i,$$

and note that the a_i can be computed in d non-scalar multiplications. Thus

$$\sum_{i=n+1}^{n+s} z_i t^i = -\sum_{n+1}^{n+d} a_i t^i \sum_{i=0}^{s-1} z_i t^i \qquad (\text{mod } t^{n+s+1}),$$

and the product can be computed in $s+d-1$ nonscalar multiplications. Thus

$$L(z_{n+1}, \ldots, z_{n+s}) \leq L(z_0, \ldots, z_n) + d + s + d - 1.$$

From this it follows that

$$L(z_0, \ldots, z_n) \leq n + (2d-1)\lceil \log_2 n \rceil + 2.$$

The lower order terms in this bound could be improved by observing that for $n \leq d$

$$L(z_0, \ldots, z_n) = L(y_0, \ldots, y_n) \leq 3.75n.$$

The identities

$$\left(\sum_{i=0}^{\infty} x_i t^i\right)^{p-1} \left(\sum_{i=0}^{\infty} y_i t^i - \sum_{i=0}^{n} y_i t^i\right)^{p} \equiv 0 \qquad (\text{mod } t^{pn+p}),$$
$$\left(\sum_{i=0}^{d} x_i t^i\right)^{p-1} \left(\sum_{i=0}^{\infty} z_i t^i - \sum_{i=0}^{n} z_i t^i\right)^{p} \equiv 0 \qquad (\text{mod } t^{pn+p}),$$

can be used to obtain many different recursive algorithms for computing the y_i and z_i. For example, the algorithm given above corresponds to $p=2$ (and $s=n+1$), and the second algorithm of [5] corresponds to $p=3$.

An alternative way of computing the z_i for $i \geq d$ is to view them as the solutions of a dth-order linear recurrence. Fiduccia [4] shows how to compute z_n in $O(\mu(d,k)\log n)$ operations, where $\mu(d,k)$ is the cost of multiplying two degree $d-1$ polynomials in $k[t]$ and $z_0, \ldots, z_{d-1}$ are assumed to be given. Interpreting Fiduccia's results with the nonscalar complexity measure, we have that z_n can be computed in $O((2d-1)\log n)$ nonscalar operations since $z_0, \ldots, z_{d-1}$ can be computed in $3.75(d-1)$ nonscalar operations.

3. The lower bounds.

3.1. Preliminaries. This subsection provides a couple of variants of well known results and various technicalities. Let X_1, X_0 be disjoint finite sets of indeterminates over k. A step $a \circ b$ in an algorithm with scalars k and input indeterminates $X_1 \cup X_0$ is X_0*-inactive* if $\circ \in \{\times, /\}$ and one of the following holds

1. $b \in k$,
2. $a \in k$ and $\circ = \times$,
3. $a, b \in k(X_0)$

(see Pan [7] or Borodin and Munro [2]). We define X_0*–active* operations in the obvious manner. (When X_0 is a singleton set $\{x_0\}$ we abuse notation slightly and write x_0-active, etc.) If $X_0 = \emptyset$, then the X_0-active steps are just the nonscalar ones.

Let $f_1, \ldots, f_m \in k(X_1, X_0)$ and set

$$A_k(X_1, X_0) = \sum_{x \in X_1} kx + k(X_0).$$

We say that $f_{i_1}, \ldots, f_{i_s}$ are linearly independent mod $A_k(X_1, X_0)$ if whenever

$$\alpha_1 f_{i_1} + \cdots + \alpha_s f_{i_s} \in A_k(X_1, X_0)$$

for $\alpha_1, \ldots, \alpha_s \in k$, then

$$\alpha_1 = \cdots = \alpha_s = 0.$$

It is easy to show that if $f_1, \ldots, f_m$ has at least r such members, then any algorithm that computes $f_1, \ldots, f_m$ requires at least r X_0-active operations [3] (see also [2]).

Let $X = \{x_1, \ldots, x_d\}$, and suppose that $f \in k(X, x_0)$. Let the formal Laurent series of f with respect to x_0 be

$$f = \sum_{i=-e}^{\infty} f_i(X) x_0^i,$$

where $f_i(X) \in k(X)$, and set

$$\text{coeff}(f, x_0) = \{ f_i(X) \mid i \geq -e \}.$$

We define $\text{td}(f, x_0)$ to be the maximum number of elements of $\text{coeff}(f, x_0) - \{f_0(X)\}$ that are algebraically independent over k. (See Zariski and Samuel [12] for material on algebraic independence.) The next lemma gives us a lower bound on the number of x_0-active operations required to compute f in terms of $\text{td}(f, x_0)$ (see Motzkin [6]).

LEMMA 3.1. *Let f be as above. Then any algorithm that computes f has at least $\text{td}(f, x_0)/2$ x_0–active operations.*

Proof. Let $\mathcal{A}$ be an algorithm that computes f and whose results at x_0-active steps are $g_1, \ldots, g_r$ and set

$$C_r = \text{coeff}(g_1, x_0) \cup \cdots \cup \text{coeff}(g_r, x_0).$$

We show by induction on r that C_r has at most $2r$ elements that are algebraically independent over k.

The result is trivial for $r = 0$. For the induction step we have

$$g_r = a_1 \circ a_2,$$

where

$$a_i = l_i(X) + u_i(x_0) + \sum_{j=1}^{r-1} \alpha_{ij} g_j,$$

with $l_i(X) \in \sum_{x\in X} kx$, $u_i(x_0) \in k(x_0)$, and $\alpha_{ij} \in k$ for $1 \le i \le 2$ and $1 \le j \le r-1$. Thus C_r depends algebraically on $\{l_1(X), l_2(X)\} \cup C_{r-1}$, and so it has at most $2+2(r-1)$ algebraically independent elements. This completes the induction.

Now

$$f = l(X) + u(x_0) + \sum_{i=1}^{r} \beta_i g_i,$$

where $l(X) \in \sum_{x\in X} kx$, $u(x_0) \in k(x_0)$, and $\beta_i \in k$ for $1 \le i \le r$. Thus coeff$(f, x_0) - \{f_0(X)\}$ is algebraically dependent on C_r, and so it has at most $2r$ algebraically independent elements. □

The next lemma is an analogue to Fiduccia's method for combining row and column ranks in lower bounds [3] (see also Aho, Hopcroft, and Ullman [1]). A proof is included for the sake of completeness.

LEMMA 3.2. *Suppose that the sequence $f_1, \ldots, f_m \in k(X, x_0)$ has r members that are linearly independent* mod $A_k(X, x_0)$. *Let*

$$s = \min\{\, \mathrm{td}(\alpha_1 f_1 + \cdots + \alpha_m f_m, x_0) \mid \alpha_1, \ldots, \alpha_m \in k, \alpha_i \ne 0, \textit{ for some } i\,\}.$$

Then any algorithm that computes $f_1, \ldots, f_m$ requires at least $r + s/2 - 1$ nonscalar operations.

Proof. We may assume that $r > 0$; otherwise, the result is trivial. Let $e_1, \ldots, e_l$ be the sequence of nonscalar steps of an algorithm that computes $f_1, \ldots, f_m$. Thus there is an $m \times l$ matrix M of elements of k and a column vector $\mathbf{a}$ of m elements of $k + \sum_{x \in X\cup\{x_0\}} kx$ such that

$$\begin{pmatrix} f_1 \\ \vdots \\ f_m \end{pmatrix} = M \begin{pmatrix} e_1 \\ \vdots \\ e_l \end{pmatrix} + \mathbf{a}.$$

From the remarks preceding the lemma we know that $l \ge r$, and so we can partition M into an $m \times (l - r + 1)$ matrix M_1 and an $m \times (r-1)$ matrix M_2. We also set $\mathbf{e}_1 = (e_1, \ldots, e_{l-r+1})^T$ and $\mathbf{e}_2 = (e_{l-r+2}, \ldots, e_m)^T$. Thus

$$\begin{pmatrix} f_1 \\ \vdots \\ f_m \end{pmatrix} = M_1\mathbf{e}_1 + M_2\mathbf{e}_2 + \mathbf{a}.$$

Since M_2 has more rows than columns, it follows that there are $\alpha_1, \ldots, \alpha_m \in k$, not all 0, such that $(\alpha_1, \ldots, \alpha_m)M_2 = 0$. Thus

$$\alpha_1 f_1 + \cdots + \alpha_m f_m = (\alpha_1, \ldots, \alpha_m)M_1\mathbf{e}_1 + (\alpha_1, \ldots, \alpha_m)\mathbf{a}.$$

Lemma 3.1 now implies that $l - r + 1 \ge s/2$. □

LEMMA 3.3. *Suppose that $f_1, \ldots, f_i \in k(x_1, \ldots, x_i) - k(x_1, \ldots, x_{i-1})$ for $1 \le i \le m$. Then $f_1, \ldots, f_m$ are algebraically independent over k.*

Proof. We claim that x_i depends algebraically on $f_i, x_1, \ldots, x_{i-1}$ for $1 \le i \le m$. To see this, set

$$f_i = \frac{p_i(x_1, \ldots, x_{i-1}, x_i)}{q_i(x_1, \ldots, x_{i-1}, x_i)},$$

where $p_i, q_i \in k[x_1, \dots, x_i]$ are coprime and at least one of them is not in $k[x_1, \dots, x_{i-1}]$. Let ξ be a new indeterminate, and set

$$P(\xi) = q_i(x_1, \dots, x_{i-1}, \xi) f_i - p_i(x_1, \dots, x_{i-1}, \xi).$$

It is clear from the conditions on f_i, p_i, and q_i that $P(\xi) \neq 0$. Since $P(x_i) = 0$, the claim is established.

The lemma now follows by induction on m. For $m = 1$ we have that x_1 depends algebraically on f_1, and so f_1, must be transcendental over k. For the induction step suppose that $f_1, \dots, f_{m-1}$ are algebraically independent but that f_m depends algebraically on $f_1, \dots, f_{m-1}$. Since $f_1, \dots, f_{m-1}$ depend on $x_1, \dots, x_{m-1}$, it follows that f_m depends on $x_1, \dots, x_{m-1}$. Now x_m depends on $f_m, x_1, \dots, x_{m-1}$ and hence on $x_1, \dots, x_{m-1}$, which is a contradiction. □

LEMMA 3.4. *For arbitrary fields, z_m is a polynomial in x_0^{-1} of degree $m+1$ for all $m \geq 0$. Moreover, for fields of characteristic* 0 *and $m > 0$*

$$z_m = p_{m1} x_0^{-m-1} + p_{m2} x_0^{-m} + \cdots,$$

where $p_{mi} \in k[x_1, \dots, x_i] - k[x_1, \dots, x_{i-1}]$ for $1 \leq i \leq \min(m, d)$.

Proof. We have that

$$z_m = \begin{cases} x_0^{-1} & \text{for } m = 0, \\ -x_0^{-1} \sum_{i=1}^{\min(m,d)} x_i z_{m-i} & \text{otherwise.} \end{cases}$$

The result now follows from an easy induction on m. □

3.2. Lower bound results.

THEOREM 3.5.

1. *Let k be any field. Then*

$$L(z_0, \dots, z_n) \geq n + 1$$

for all $n \geq 0$.

2. *Let k be a field of characteristic* 0. *Then*

$$L(z_{n+1}, \dots, z_{n+s}) \geq s + \min(n+1, d)/2 - 1$$

for $n \geq 0$ and $s \geq 1$.

Proof. 1. Without loss of generality, we may assume that k is infinite. By Lemma 3.4 z_i is a polynomial in x_0^{-1} of degree $i + 1$ and so the z_i are all linearly independent mod $A_k(\{x_0, \dots, x_d\}, \emptyset)$.

2. Suppose that $\alpha_{n+1}, \dots, \alpha_{n+s} \in k$ are not all 0, and let α_{n+r} be the last nonzero member of the sequence. From Lemma 3.4 we have

$$\alpha_{n+1} z_{n+1} + \cdots + \alpha_{n+r} z_{n+r} = q_1 x_0^{-(n+r)-1} + q_2 x_0^{-(n+r)} + \cdots,$$

where for $1 \leq i \leq \min(n+r, d)$

$$q_i = \sum_{j=0}^{\min(i,d)-1} \alpha_{n+r-j} p_{n+r-j, i-j}.$$

Now $p_{n+r-j,i} \in k[x_1, \dots, x_i] - k[x_1, \dots, x_{i-1}]$ and $p_{n+r-j,i-j} \in k[x_1, \dots, x_{i-j}] - k[x_1, \dots, x_{i-j-1}]$. Since $\alpha_{n+r} \neq 0$, it follows that $q_i \in k[x_1, \dots, x_i] - k[x_1, \dots, x_{i-1}]$ for $1 \leq i \leq \min(n+r, d)$. Lemma 3.3 now implies that

$$\mathrm{td}(\alpha_{n+1} z_{n+1} + \cdots + \alpha_{n+s} z_{n+s}, x_0) \geq \min(n+r, d) \geq \min(n+1, d).$$

An application of Lemma 3.2 completes the proof. □

COROLLARY 3.6. *Let k be a field of characteristic* 0. *Then*

$$L(y_{n+1}, \dots, y_{n+s}) \geq s + (n+1)/2 - 1$$

for $n \geq 0$ and $s \geq 1$.

Proof. This is an immediate consequence of Theorem 3.5, for if we take $d \geq n+s$, then $z_i = y_i$ for $0 \leq i \leq n+s$. □

Acknowledgment. I should like to thank an anonymous referee whose helpful comments led to improvements in the paper.

NONDETERMINISM WITHIN P*

JONATHAN F. BUSS† AND JUDY GOLDSMITH‡

Abstract. Classes of machines using very limited amounts of nondeterminism are studied. The $P =? NP$ question is related to questions about classes lying within P. Complete sets for these classes are given.

Key words. nondeterminism, quasilinear time, computational complexity

AMS(MOS) subject classifications. 68Q15, 68Q05

1. Introduction. Traditional complexity theory gives a distinguished role to the class P of languages that are computable in polynomial time. Languages not in P are considered to be computationally intractable. However, the converse assertion, that languages in P have efficient solutions, is untenable. Historically, one reason for the choice of polynomial time bounds was that no smaller class appears to be as robust against change of model. We consider here subclasses of P, defined (roughly) according to the exponent of the polynomial bounding the running time and also according to the small amount of nondeterminism allowed. Of particular interest is the class of languages computable in deterministic "quasilinear" time, which is less robust than P with respect to change of model, but is much closer to being a practical notion of feasible computation. We develop a complexity theory based on quasilinear-time many-one reducibility that is analogous to the theory of polynomial-time reducibility.

We primarily consider the trade-off between time and nondeterminism. To replace nondeterminism by time in Turing machine computations is easy: one binary nondeterministic choice may be eliminated by doubling the time. Two fundamental questions are whether nondeterminism can be eliminated at a lower cost in time, and whether computation time can be decreased by adding nondeterminism. We define subclasses of P by limiting the time bound to fixed-degree polynomials and allowing nondeterminism over a fixed polynomial-size search space. The inclusion relationships among the classes are particular cases of the two fundamental questions. We show that sufficient separation among these classes lying inside P implies that $P \neq NP$.

Let f and g be integer functions. We will write "$f \in Q(g)$" and say "f is of quasi-order g" if there is a positive constant k such that[1] $f \in O(g \log^k g)$. For any positive constant l, we denote by P_l the class of languages that can be accepted by a multitape Turing machine whose running time on inputs of length n is of quasi-order n^l. For integers $l \geq 1$ and $m \geq 0$, we denote by N^mP_l the class of languages accepted by nondeterministic machines in time of quasi-order n^l making at most $m \log n$ binary nondeterministic choices. For any m and l, N^mP_l is contained in P_{m+l}. We will also consider the classes NP_l having no bound on the amount of nondeterminism. The classes P_1 and NP_1 have been previously studied by Schnorr [16] under the names QL and NQL.

[1]We will write "$\log n$" to mean $\lfloor \log_2(n+1) \rfloor$ throughout the paper.

The $\log^k n$ factors in the allowed time bounds have a number of important consequences. First, the classes are independent of the number of tapes of a multitape Turing machine. Second, quasilinear-time reducibility is transitive and preserves membership in N^mP_l, for any m and l. Third, quasilinear time is large enough to admit basic algorithmic techniques such as sorting and multiplication. For computation of practical importance, the input size is generally less than, say, 10^{12}; hence $\log n$ is bounded by 40, and ignoring arbitrary logarithmic factors is no worse than ignoring arbitrary constant factors.

The notion of classifying problems according to the amount of nondeterminism required has appeared previously; see, e.g., Kintala and Fischer [13] and Wolf [17]. Àlvarez, Díaz, and Torán , [4], [8] consider a hierarchy, similar to the present one, of classes lying between P and NP. Their hierarchy differs from the present one in two ways. First, any polynomial is allowed in the running times, and second, the bound on the number of nondeterministic choices that defines each class is a power of $\log n$ rather than a multiple of $\log n$. Thus each class contains all of P, and the hierarchy does not provide a classification among computations feasible in practice.

More similar in method to the present paper is the work of Geske [9], who considers relations among classes $TIME(n^l)$ and $NTIME(n^l)$, which are similar to P_l and NP_l, but more restrictive. Weaker variants of our Theorems 5.1 and 5.4 are obtained.

In a related work, Kaye [12] gives two logical characterizations of a family of classes $L^{(\alpha)}$, $\alpha \geq 0$, lying between linear time and P. Kaye's class L^2 is precisely quasilinear time.

Gurevich and Shelah [10] consider quasilinear-time reductions among various models of random-access machines. They define *nearly linear time*, or NLT, and show that the models they consider, including Kolmogorov machines, Schönhage machines, and random-access Turing machines, all compute the same NLT functions in quasilinear time. They also show that the languages accepted nondeterministically by any of these machines in quasilinear time are precisely those languages accepted nondeterministically in quasilinear time by a multitape Turing machine (denoted NQL in [16], herein NP_1). They conjecture that the deterministic classes NLT and QL (herein P_1) are different. We offer some candidate languages for this separation.

Quasilinear-time reductions have been studied in other contexts as well. Hunt and Stearns [11] define the notion of Turing-SAT-hard (n polylog n, n) in order to make precise the notion that sets in NP have deterministic time and space complexity no less than that of SAT. Their definition restricts the reductions considered to quasilinear time *and* linear space complexity. Because the sets they consider are in $NP - P$ unless $P = NP$, their results do not provide much insight into the classes considered here.

Abrahamson et al. [1], [2] study the complexity of families of languages parameterized by the size of an associated search space. The present paper concerns the complexity of individual problems, which may or may not be part of a larger family. The relationship between the two approaches is investigated in §4 below.

This paper is organized as follows. Section 2 gives some basic properties of the classes N^mP_l and P_l. Section 3 shows that the classes have complete sets, and some natural problems are considered as candidate complete sets. Section 4 contains a discussion of the relationship of the present work to that of Abrahamson et al. Section 5 investigates relationships among the various classes N^mP_l. Section 6 concludes with some open problems and directions for future work.

2. Preliminaries. The classes N^mP_l can be characterized in terms of witnesses, analogously to NP.

THEOREM 2.1. *For all m and l, a set A is in N^mP_l if and only if there is an R in P_l such that for all strings x, $x \in A \Leftrightarrow \exists y\,[|y| \leq m \log |x| \wedge R(x,y)]$.*

The proof is left to the reader.

Like most hierarchies of complexity classes, the limited-nondeterminism classes exhibit downward separation (upward collapse).

THEOREM 2.2. *For all m and l,*

1. *if $N^1P_l \subseteq P_l$, then $N^1P_k \subseteq P_k$ for all $k \geq l$, and*
2. *if $N^{m+1}P_l \subseteq N^mP_l$, then $N^kP_l \subseteq N^mP_l$ for all $k \geq m$.*

Proof (sketch). Suppose that $N^1P_l \subseteq P_l$, and fix $k > l$ and $A \in N^1P_k$. Let R be as guaranteed in the previous result. Let $A' = \{\, x0^{\lfloor |x|^{k/l} \rfloor - |x|} \mid x \in A \,\}$. Then $x0^j \in A'$ if and only if $j = \lfloor |x|^{k/l} \rfloor - |x| \wedge \exists y\, |y| \leq \log |x| \wedge R(x,y)$ if and only if $\exists y\, |y| \leq \log |x0^j| \wedge R'(x0^j, y)$, where $R' = \{\, \langle x0^j, y \rangle \mid j = \lfloor |x|^{k/l} \rfloor - |x| \wedge y \leq \log |x| \wedge R(x,y) \,\}$. Hence $A' \in N^1P_l \subseteq P_l$, and thus $A \in P_k$.

Now suppose that $N^{m+1}P_l \subseteq N^mP_l$, and fix $k > m+1$ and $B \in N^kP_l$. There exists S such that $x \in B \Leftrightarrow \exists y\, |y| \leq k \log |x| \wedge \langle x, y \rangle \in S$. The latter condition is equivalent to $\exists y\, |y| \leq (k - m - 1) \log |x| \wedge S'(x,y)$, where $S' = \{\, \langle x, y \rangle \mid \exists z\, z \leq (m+1) \log |x| \wedge \langle x, yz \rangle \in S \,\}$ is in $N^{m+1}P_l$ and hence in N^mP_l by assumption. Thus $B \in N^{k-1}P_l$, which is contained in N^mP_l by induction. □

The hierarchy also exhibits a kind of upward separation.

THEOREM 2.3. *Suppose that for all l, there is an m such that N^mP_1 is not contained in P_l. Then $P \neq NP$.*

The result follows immediately from Theorem 2.4.

THEOREM 2.4. *If $P = NP$, then there is an l such that $NP_k \subseteq P_{kl}$ for all k.*

Proof. Let L be a complete set for NP_1 with respect to quasilinear-time reductions. (Schnorr has shown that SAT, the set of satisfiable Boolean formulas, is such a set [16].) Suppose $P = NP$; i.e., L is in P_l for some l. Let $A \in NP_k$. Membership questions of length n about A are reducible in time $Q(n^k)$ to membership questions of length $Q(n^k)$ about L (using a padding argument and Schnorr's result), which are answerable in time $Q(n^{kl})$ by assumption. Hence $NP_k \subseteq P_{kl}$. □

3. Complete sets.

The sets N^mP_l all have complete sets under quasilinear-time reducibility. We consider first a problem concerning acceptance by Turing machines. Let $\langle \cdot \rangle$ be a coding function for Turing machines such that given $\langle M \rangle$, a single step of M can be simulated by a multitape Turing machine in time proportional to $\log |\langle M \rangle|$. A unary code will have the required property.

Define $G_l^m = \{\, \langle M \rangle \# x \# 1^j \mid M$ accepts input x within $j|x|^{l-1}$ steps using at most $m \log |x|$ nondeterministic choices $\}$.

THEOREM 3.1. *For all m and l, G_l^m is complete for N^mP_l with respect to quasilinear-time reductions.*

Proof (sketch). The coding convention ensures that $G_l^m \in N^mP_l$. For $A \in N^mP_l$, fix a machine M and constants r and s such that M halts in at most $rn^l \log^s n$ steps, uses $m \log n$ nondeterministic choices on inputs of length n, and accepts A. Let $f(x) = \langle M \rangle \# x \# 1^{r|x| \log^s |x|}$. Then $x \in A$ if and only if $f(x) \in G_l^m$, and f is computable in time in $Q(n)$. Hence f is the desired reduction from A to G_l^m. □

In some cases, complete sets for N^mP_l can be obtained from NP-complete problems by bounding the size of allowable witnesses for membership. We first consider topologically ordered Boolean circuits.[2] A circuit is *satisfiable* if some setting of the inputs results

[2]A circuit is topologically ordered if each gate is numbered, and the inputs to a gate all have lower numbers than the gate itself.

in an output of 1. Let CSAT(k) be the set of satisfiable, topologically ordered circuits that have fewer than $k \log n$ inputs, where n is the number of gates in the circuit. (Constants 0 and 1 are not counted as inputs.)

THEOREM 3.2. *For all k,* CSAT(k) *is complete for N^kP_1 with respect to quasilinear-time reductions.*[3]

Proof (sketch). The standard methods for proving the formula-satisfiability problem to be NP-complete can easily be modified to produce a circuit rather than a formula. Schnorr [16] and Cook [7] have shown that the circuit (or formula) corresponding to a given input for a fixed Turing machine may be constructed in quasilinear time. In particular, the circuit has quasilinear size. Also, it is topologically ordered.

Let $A \in N^kP_1$, and let $R \in P_1$ be such that $x \in A \Leftrightarrow \exists y\, |y| \leq k \log |x| \wedge \langle x, y \rangle \in R$, for all strings x. Let M accept R in quasilinear time. The circuit $C_M(x)$ corresponding to M with input $\langle x, y \rangle$, for fixed x and undetermined y, has size quasilinear in $|x|$ and only $k \log |x|$ inputs. Hence $x \in A$ if and only if $C_M(x) \in$ CSAT(k), and CSAT(k) is hard for N^kP_1.

Evaluation of a circuit at given inputs can be accomplished in quasilinear time on a Turing machine by using an algorithm of Pippenger [14]. Hence CSAT(k) is in N^kP_1. □

The satisfiability problem for formulas with a limited number of variables, SAT(k), is perhaps easier than CSAT(k). The above proof of hardness of CSAT(k) does not apply to SAT(k), because too many auxiliary variables are required in a formula to simulate a Turing machine.[4] In the absence of a hardness proof for the restricted formula-satisfiability problem, hardness proofs for restrictions of other standard NP-complete problems are problematic. In some cases, the natural restriction is essentially as hard as the general case. For example, graph k-colorability remains NP-complete when k is fixed at 3.

The restricted vertex-cover problem exhibits different behaviour. Let VC(k) be the language of undirected graphs that have a vertex cover of size k. It is easy to show that VC(k) is in $N^{k-1}P_1$: the first $k-1$ vertices of a cover can be chosen nondeterministically, and the last vertex found by a quasilinear-time search. In fact, the language VC(k) can be accepted in linear time by the following algorithm due to S. Buss [6]. Given a graph $G = (V, E)$,

1. Let U be the set of vertices of degree more than k. If $|U| > k$, then reject; there is no cover of size k or less.
2. Let G' be the subgraph of G induced by $V - U$. Every k-cover of G consists of U together with a $(k - |U|)$-cover of G'. If G' has more than $k(k - |U|)$ edges, then reject; G' has no $(k - |U|)$-cover.
3. If G' has a cover of size $k - |U|$, then accept; otherwise reject.

Steps 1 and 2 can easily be implemented in quasilinear time. If step 3 is reached, then G' has a bounded number of edges; hence step 3 requires $Q(1)$ time. Therefore, VC(k) is in P_1, and a completeness proof for VC(k) would have strong consequences.

THEOREM 3.3. *If* VC(k) *is hard for N^jP_1 for some $j \geq 1$, then $N^mP_1 \subseteq P_1$ for all m.*

The result follows immediately from Theorem 2.2.

The k-clique problem, although often regarded as a trivial variation on the k-vertex cover problem, cannot be substituted for VC(k) in the above proof, because the condition on the degrees does not hold. Thus k-clique remains as a candidate hard problem for $N^{k-1}P_1$.

[3] Díaz and Torán [8] have shown that a variant of CSAT(k) is complete under logspace reductions for their class β_k, for each k.

[4] We return to the formula-satisfiability problem in §4.

Next, we consider the following problem concerning context-free grammars. Given a grammar $G = (N, \Sigma, P, S)$, does G generate any string comprising repetitions of a single terminal; i.e., is $\mathcal{L}(G) \cap \bigcup_{\sigma \in \Sigma} \sigma^* \neq \emptyset$? Let UNARYGEN be the set of grammars for which the answer is yes.

THEOREM 3.4. CSAT(1) $\leq_{ql}$ UNARYGEN.

Proof. Let C be a circuit with n gates $g_1, \ldots, g_n$. Assume without loss of generality that gates g_i with $i \leq \log n$ are the inputs and g_n is the output. Each gate g_j is represented by two nonterminal symbols A_j and A'_j. There are also n terminal symbols $b_0, \ldots, b_{n-1}$, each corresponding to one setting of the values of the input variables. The start symbol is A_n.

The productions are determined as follows.

• If g_i is an and-gate with predecessors g_j and g_k, use productions $A_i \longmapsto A_j A_k$ and $A'_i \longmapsto A'_j \mid A'_k$.

• If g_i is an or-gate with predecessors g_j and g_k, use productions $A_i \longmapsto A_j \mid A_k$ and $A'_i \longmapsto A'_j A'_k$.

• If g_i is a not-gate with predecessor g_j, use productions $A_i \longmapsto A'_j$ and $A'_i \longmapsto A_j$.

• For $1 \leq i \leq \log n$, for all j such that bit i of the binary expansion of j is 1, use $A_i \longmapsto b_j$.

• For $1 \leq i \leq \log n$, for all j such that bit i of the binary expansion of j is 0, use $A'_i \longmapsto b_j$.

The variable A_j derives a unary word if and only if g_j evaluates to 1, and A'_j derives a unary word if and only if g_j evaluates to 0.

LEMMA 3.5. *For all* $1 \leq i \leq n$ *and* $0 \leq j \leq n-1$, $A_i \longmapsto^* b_j^k$ *for some* k *if and only if* g_i *evaluates to* 1 *when the input vector is the binary expansion of* j. *Similarly*, $A'_i \longmapsto^* b_j^k$ *for some* k *if and only if* g_i *evaluates to* 0 *when the input vector is the binary expansion of* j.

Proof. Fix j. Define the *level* of a gate to be the length of the longest directed path from the gate to any input. We use induction on the level of gate g_i.

The base case is that g_i is an input. Then g_i evaluates to 1 if and only if bit i of j is 1 if and only if $A_i \longmapsto b_j$ if and only if $A_i \longmapsto^* b_j$. Also g_i evaluates to 0 if and only if bit i of j is 0 if and only if $A'_i \longmapsto b_j$ if and only if $A'_i \longmapsto^* b_j$.

Suppose that the lemma holds for all gates with level at most $l-1$, and let g_i have level l. If g_i is an and-gate with predecessors g_{i_1} and g_{i_2}, then g_i evaluates to 1 if and only if both g_{i_1} and g_{i_2} evaluate to 1 if and only if $A_{i_1} \longmapsto^* b_j^{k_1}$ and $A_{i_2} \longmapsto^* b_j^{k_2}$ for some k_1 and k_2 if and only if $A_i \longmapsto^* b_j^{k_1+k_2}$. Likewise, g_i evaluates to 0 if and only if either g_{i_1} or g_{i_2} evaluates to 0 if and only if $A'_{i_1} \longmapsto^* b_j^k$ or $A'_{i_2} \longmapsto^* b_j^k$ for some k if and only if $A'_i \longmapsto^* b_j^k$. The cases where g_i is a negation gate or an or-gate are similar. □

The theorem follows immediately from the lemma. □

The reduction given in the proof holds even if the circuit is not topologically ordered. If the circuit is ordered, then in the resulting grammar, every appearance of each nonterminal in the left-hand side of a production occurs after every appearance of the nonterminal on the right-hand side of a production. Call a grammar satisfying this condition an ordered grammar. Let UNARYGEN$_{\text{ord}}$ be the set of ordered grammars in UNARYGEN.

THEOREM 3.6. UNARYGEN$_{\text{ord}}$ *is complete for* N^1P_1.

Proof. Because the reduction of the previous theorem produces an ordered grammar from an ordered circuit, UNARYGEN$_{\text{ord}}$ is hard for N^1P_1. □

To show that UNARYGEN$_{\text{ord}}$ is in N^1P_1, we use the following lemma.

LEMMA 3.7. *The emptiness problem for ordered context-free grammars is in deterministic quasilinear time.*

Proof. Call a nonterminal "true" if some terminal string can be derived from it and "false" otherwise. The grammar is then a network in the sense of Pippenger [14] and thus can be evaluated in time $Q(n)$. □

Let $G = (N, \Sigma, P, S)$ be an ordered grammar. Nondeterministically guess a terminal $\sigma \in \Sigma$, using $\log |\Sigma| \leq \log |G|$ bits. Then eliminate all productions involving terminals other than σ. Accept if and only if the resulting grammar generates a nonempty language.

The above algorithm places UNARYGEN$_{\text{ord}}$ in N^1P_1, and hence it is complete. □

4. Families of constrained-search problems. Many NP-complete problems involve a parameter that defines a constraint on the associated search problem. Restriction of this parameter produces a problem whose complexity falls into one of at least three classes: (1) The restricted problem may be NP-complete; e.g., graph k-coloring, for any $k \geq 3$. (2) Every fixed value of the parameter may give the same polynomial complexity; e.g., vertex k-cover. (3) Every fixed value of the parameter may give polynomial-time complexity, but the exponent of the polynomial may depend on k. No instances of the third case are proven, but CSAT(k), k-clique and many other problems are candidates. The distinction between the second and third case has been recently investigated by Abrahamson et al. [1], [2], who considered families of associated search problems. We show here that limited nondeterminism provides an alternative to their methods.

Consider the case of CSAT(k), for $k \geq 1$. These languages form an infinite collection of complete sets, one for each class N^kP_1. It is not an arbitrary collection, however, since the complete set for N^kP_1 can easily be determined given k. We describe this situation using the concept of *language family*. A language family is a subset of $\Sigma^* \times \mathbf{N}$. The kth slice of a family B, denoted B_k, is the language $\{ x \mid (x, k) \in B \}$.

The class N^*P_j (for all $j \geq 1$) consists of all families B with the following properties.

• The kth slice of B is a language in N^kP_j.

• There is a quasilinear-time-computable function f such that for all k, the value of $f(k)$ is the code of a Turing machine witnessing that the kth slice of B is in N^kP_j. (An object x *witnesses* an existential property $\exists y\, p(y)$ if and only if $p(x)$ is true. The computability requirement on f may be relaxed without changing the essential character of the definition.)

A language family C in N^*P_j is *$\leq_{ql}$-complete for N^*P_j* if the following hold.

• For all k, the slice C_k is complete for N^kP_j.

• There is a quasilinear-time-computable function f such that for all k, the value of $f(k)$ is the code of a Turing machine witnessing that C_k is complete for N^kP_j (i.e., the Turing machine performs a quasilinear-time reduction from G_j^k to C_k).

For example, the family CSAT($*$) $= \{ (x, k) \mid x \in$ CSAT(k) $\}$ is complete for N^*P_1.

We draw a second example from Abrahamson et al. [2]. Consider a Boolean formula. A partial assignment of truth values to variables in the formula may induce values on other variables if the formula is to be true. Consider a formula in conjunctive normal form with three or fewer variables per clause (3CNF). If $(a_1 \vee a_2 \vee a_3)$ is a clause, and all but one of the a_i's are false, then the remaining variable is induced to assume the value true; if one variable a_i is true, then the clause is true, and no additional assignment is induced. If this procedure can be applied iteratively until all clauses evaluate to true, then we say the original partial assignment caused the formula to *unravel*. Let SHORTSAT(k) be the set of 3CNF formulas B such that some assignment to the first $k \log |B|$ variables causes B to unravel.[5]

[5]The definition in [2] allowed arbitrary CNF formulas instead of 3CNF. The difference appears to be necessary for Theorem 4.1. It does not affect the results of [1].

A formula $B = \bigwedge_{i=1}^{k} C_i$ in conjunctive normal form *unravels in order* if each initial subformula $\bigwedge_{i=1}^{j} C_i$ unravels. Let $\text{SHORTSAT}_{\text{ord}}(k)$ be the set of formulas B such that some assignment to the first $k \log |B|$ variables causes B to unravel in order.

THEOREM 4.1. *$\text{SHORTSAT}_{\text{ord}}(k)$ is $\leq_{ql}$-complete for N^kP_1, and $\text{SHORTSAT}(k)$ is $\leq_{ql}$-hard for N^kP_1, for all k.*

Proof (sketch). We first show that $\text{CSAT}(k) \leq_{ql} \text{SHORTSAT}_{\text{ord}}(k)$. Let Γ be an instance of $\text{CSAT}(k)$. The corresponding formula φ has one variable for each gate of the circuit, and two additional variables denoted z_1 and z_2. The first $k \log n$ clauses of φ represent the input. The connections of a gate g in Γ are represented in φ by a conjunction B of clauses. The conjunction B always unravels in φ, and the only unravelling induces the variable representing g to take on the value of g. The final clause of φ unravels if and only if the circuit evaluates to 1.

The clauses are as follows.

• For each input variable x_i of Γ, the corresponding clause is $(x_i \vee \neg x_i)$.

• If g is an and-gate with predecessors a and b, then the corresponding conjunction is $(\neg a \vee \neg b \vee g) \wedge (a \vee \neg g) \wedge (b \vee \neg g)$.

• If g is an or-gate with predecessors a and b, then the corresponding conjunction is $(a \vee b \vee \neg g) \wedge (\neg a \vee g) \wedge (\neg b \vee g)$.

• If g is a not-gate with predecessor a, then the corresponding conjunction is $(a \vee \neg g) \wedge (\neg a \vee g)$.

• If the output gate is g_{out}, the final clause is $(g_{\text{out}} \vee z_1 \vee z_2)$.

The reader can easily check that the formula has the required properties.

To show that $\text{SHORTSAT}_{\text{ord}}(k) \leq_{ql} \text{CSAT}(k)$, let φ be a formula in 3CNF, with clauses $\{\varphi_i\}_{i=1}^{c}$. Each clause φ_i will be represented by a circuit C_i, whose inputs will be outputs of the circuits representing earlier clauses. We assume without loss of generality that no variable appears twice in any one clause.

Consider $\varphi_i = v_{i1} \vee v_{i2} \vee v_{i3}$. The corresponding circuit C_i will have six inputs and six outputs. The circuit C_i will compute the status of each literal v_{ij} (either a variable or a negated variable) and produce two corresponding output values. Output $v_{ij}(1)$ is given value 1 if and only if the unravelling procedure assigns a value to v_{ij} at or before clause φ_i. If $v_{ij}(1) = 1$, then output $v_{ij}(2)$ is given the value assigned to v_{ij}.

The inputs to C_i are determined by the last occurrences of the variables of φ_i previous to φ_i itself. Denote by v'_{ij} the last literal containing the variable of v_{ij} appearing in φ before φ_i. The first input corresponding to v_{ij} is $v'_{ij}(1)$. The second input corresponding to v_{ij} is $v'_{ij}(2)$ if v_{ij} and v'_{ij} are both positive or both negative literals, and is $\neg v'_{ij}(2)$ otherwise. The construction of C_i is straightforward except for the identification of the input literals v'_{ij}.

If each v'_{ij} is found individually, the construction of the entire circuit may take quadratic time. Hence the successive occurrences of each variable must all be determined at once, as follows. For each v_{ij}, form a triple (x, i, j), where x is the index of the variable occurring in v_{ij}. Sort the triples, using the order $(x, i, j) < (y, k, l)$ if and only if $x < y$ or $x = y$ and $i < k$. If (x, i, j) and (x, k, l) are adjacent in the sorted list, then $v'_{kl} = v_{ij}$; form a quadruple (i, j, k, l). Sorting these quadruples gives the required adjacency information in the order needed to construct the circuit in topological order.

The final circuit comprises all subcircuits C_i and an additional output subcircuit. The output subcircuit computes $\bigwedge_{i=1}^{c} \bigvee_{j=1}^{3} \Big(v_{ij}(1) \wedge v_{ij}(2)\Big)$, which has value 1 if and only if the original formula φ unravels in order. □

The family $\text{SHORTSAT}_{\text{ord}}(*) = \{ (x, k) \mid x \in \text{SHORTSAT}_{\text{ord}}(k) \}$ is thus complete for N^*P_1.

THEOREM 4.2. *For all k,* SHORTSAT$(k) \in N^kP_2$.

Proof (sketch). To determine whether a formula φ is in SHORTSAT(k), it suffices to nondeterministically guess the values of the initial $k \log |\varphi|$ variables, and then make at most $|\varphi|$ passes through φ, inducing variables and propagating their values. □

A language family C is *$\leq_{ql}$-hard for N^*P_j* if the following hold.

• For all k, there is a $k' \geq k$ such that $C_{k'}$ is $\leq_{ql}$-hard for N^kP_j.

• There is a quasilinear-time-computable function f such that for all k, the value of $f(k)$ is the code of a Turing machine witnessing that $C_{k'}$ is $\leq_{ql}$-hard for N^kP_j.

For example, SHORTSAT(*)= $\{(x,k) \mid x \in \text{SHORTSAT}(k)\}$ is $\leq_{ql}$-hard for N^*P_1. The family $G_* = \{(G_k^0, k) \mid k \geq 1\}$ is $\leq_{ql}$-hard for N^*P_l, for every l.

Finally, a language family C is *weakly $\leq_{ql}$-complete for N^*P_j* if it is both in N^*P_j and $\leq_{ql}$-hard for N^*P_j. One example of a weakly complete set for N^*P_1 is $\{(x, 2k) \mid x \in \text{CSAT}(k)\}$.

The definition of N^*P_j is motivated by the work of Abrahamson et al. [1], [2] on their class PGT. Their work focused on families of problems in P, usually generated by parameterized problems in NP, such as SHORTSAT() and CSAT(). The class PGT is roughly equivalent to the notion "in some N^*P_j and hard for some N^*P_k." The major differences are that PGT includes nonuniform families and that reductions may be nonuniform; in the terms of this paper, the functions f above are not required to be computable. All of the complete families considered by Abrahamson et al., however, are uniform and are examples of families in some N^*P_j and hard for some N^*P_k. Thus, their work provided examples of sets in the classes N^iP_k, some of which were also hard for classes N^iP_1. Further work on limited nondeterminism is likely to yield additional complete sets for PGT.

5. Relationships among the classes.

The classes N^mP_l bear a strong analogy to NP; however, the analogy should not be taken too far. For example, one might conclude from Theorem 2.3 that NP_l behaves as a limiting case of N^mP_l as m goes to infinity. This conclusion, however, can be false in the presence of an oracle. Denote by C^X the class C relative to oracle X. The results of §2 hold relative to any oracle X.

THEOREM 5.1. *There is an oracle A such that $N^mP_k^A = P_k^A$ for all m and k, and yet $NP^A \not\subseteq P^A$.*

Proof. By Theorem 2.2, we need only show that $N^1P_1^A = P_1^A$ and $P^A \neq NP^A$.

Fix an enumeration $\{M_i\}_{i=1}^{\infty}$ of nondeterministic machines such that M_i runs in quasilinear time and makes at most $\log n$ nondeterministic choices on inputs of length n. Fix an enumeration $\{T_i\}_{i=1}^{\infty}$ of deterministic machines such that T_i runs for at most $p_i(n) = n^i + i$ steps on inputs of length n.

We construct A to have the following two properties for all i:

C$_i$: The coding condition: For all strings x and all positive integers s, the string $0^{2s}\#i\#x$ is in A if and only if $M_i^A(x)$ accepts within s steps. (Note that $M_i^A(x)$ cannot query whether $0^{2s}\#i\#x$ is in A within s steps.)

D$_i$: The diagonalization condition: The language

$$L_A = \{ 1^n \mid \exists y\, |y| = n \wedge 1^n y \in A \}$$

is not accepted by T_i.

The construction proceeds in stages. During stage k, all strings of length k are fixed to be in or out of A, in such a way that conditions C$_i$ hold up to length k. In addition, some strings of length longer than k may be fixed to satisfy some condition D_i. Because each string is fixed exactly once during the construction, the oracle A is well defined. In fact, A is computable in space $n^{O(\log n)}$.

Initially, all strings are unfixed. Set $k = d = l = 1$; k is the stage number, d is the current diagonalization condition, and l is a lower bound on the input at which condition D_d can be satisfied.

Stage k: For all strings z of length k of the form $z = 0^{2s}\#i\#x$ for some i, x, and s, fix z in A if M_i accepts x with oracle A in $\leq s$ steps; otherwise fix z out of A. (Note that this condition is determined by the preceding stages of the construction.) Fix all strings of length k not of the above form out of A. If $k < l$ or $2^k \leq p_d(k)^{1+\log p_d(k)}$, then stage k is complete—continue to stage $k+1$.

If $k \geq l$ and $2^k > p_d(k)^{1+\log p_d(k)}$, then a diagonalization condition can be satisfied. Simulate T_d on input 1^k. When T_d queries a string z not yet fixed, there are two cases.

1. If $z = 0^{2s}\#i\#x$ for some i, x, and s, then simulate M_i on input x for s steps, and fix z accordingly. Fix strings queried during the simulation by applying these cases recursively.

2. Otherwise, fix z out of A.

If T_d accepts 1^k, then fix all remaining strings of the form $1^k y$ with $|y| = k$ out of A. If T_d rejects 1^k, then fix all remaining strings of the form $1^k y$ with $|y| = k$ to be in A. In either case, set $l = p_d(k)$, increase d by one, and continue to stage $k+1$.

End of stage k.

We first show that the construction can be carried out.

LEMMA 5.2. *If the construction simulates T_d on input 1^k, then some string $1^k y$ with $|y| = k$ remains unfixed at the end of the simulation.*

Proof. The parameter l is an upper bound on the length of strings that have been fixed due to any diagonalization attempt prior to stage k. Because $k \geq l$ at the start of the simulation of T_d, all of the 2^k strings $1^k y$ are unfixed at that time.

Let $S(n)$ be the maximum number of strings fixed during the simulation of some $M_i^A(x)$ for s steps, where $|0^{2s}\#i\#x| = n$. In s steps, $M_i^A(x)$ queries fewer than $s2^{\log|x|} < n^2$ strings over all of its nondeterministic computations, and each queried string has length less than $n/2$. Hence $S(n) < n^2 S(n/2)$, and $S(1) = 1$. Therefore, $S(n) \leq n^{\log n}$.

T_d runs for at most $p_d(k)$ steps; therefore, the total number of strings queried during the simulation is at most $p_d(k) \cdot S(p_d(k)) \leq p_d(k)^{1+\log p_d(k)} < 2^k$. Hence some string of the form $1^k y$ with $|y| = k$ remains unfixed. $\square$

LEMMA 5.3. *The set A constructed as above satisfies conditions C_i and D_i for all i.*

Proof. Each string of the form $0^{2s}\#i\#x$ is eventually fixed in or out of A. Such a string is fixed only after the acceptance or rejection of $M_i^A(x)$ within s steps is determined, and is fixed according to that acceptance or rejection. Hence condition C_i holds for all i.

Because $p_d(n)^{1+\log p_d(n)} = o(2^n)$, each value of d is eventually considered at some stage k. The previous lemma ensures that condition D_d is established following the completion of stage k. $\square$

Conditions C_i together imply that $N^1P_1^A = P_1^A$, and hence $N^mP_k^A = P_k^A$ for all k and m by Theorem 2.2. Conditions D_i together imply that $L^A \in NP^A - P^A$. $\square$

Informally, Theorem 5.1 shows that large amounts of nondeterminism can be useful even if small amounts are not. The reverse is also possible—a large amount of nondeterminism may be no more advantageous than a small amount.

THEOREM 5.4. *There is an oracle B such that $P_m^B \neq N^1P_m^B$ and $N^1P_m^B = NP_m^B$ for all m.*

Proof. The proof depends in a small way on the definition of an oracle machine. There are two possibilities to be considered. If the query tape is erased following a query, define $\delta = 0$. If the query tape is not erased following a query, define $\delta = 1$. Although the relativized classes depend on the model used (see [5]), the necessary properties for the present proof are captured by the value of δ.

Let $\{M_{l,i}\}_{l,i=1}^{\infty}$ be an enumeration of nondeterministic oracle machines, and let $\{T_{l,i}\}_{l,i=1}^{\infty}$ be an enumeration of deterministic oracle machines, such that both $M_{l,i}$ and $T_{l,i}$ are clocked to run for $p_{l,i}(n) = n^l \log^i n + i$ steps. We construct B to meet the following conditions:

1. *Coding conditions.* For all l and i, for all sufficiently large x, $M_{l,i}^B(x)$ accepts if and only if there is a string y of length $(1+\delta l)\log|x|$ such that $0^{p_{l,i}(|x|)}\#l\#i\#x\#y$ is in B.

2. *Diagonalization conditions.* For all l, the language

$$L_l = \{\, x \mid \exists y\, |y| = (1+\delta l)\log|x| \wedge 1^{|x|^l} xy \in B \,\}$$

is not accepted by $T_{l,i}^B$ for any i.

Condition 1 implies that $NP_l^B \subseteq N^1P_l^B$ for all l, because $\log|x|$ bits of y can be guessed nondeterministically, and if $\delta = 1$, the remaining $l \log|x|$ bits found by exhaustive search in time $O(n^l)$. (If a string is erased upon being queried, each query of a coding string requires $Q(n^l)$ steps, and the search cannot be carried out deterministically.) Condition 2 implies that $L_l \in N^1P_l^B - P_l^B$.

Let $\langle \cdot, \cdot \rangle$ be a pairing function from positive integers to positive integers; e.g., let $\langle l, i \rangle = (l^2 + i^2 + 2li - 3l - i + 2)/2$. To start the construction, set $k = d = b = 1$; k is the stage number, d the current diagonalization condition, and b the barrier so that diagonalizations do not overlap. Throughout, l and i will be determined by $d = \langle l, i \rangle$. Once again, at stage k, all strings of length k will be fixed in or out of B.

Stage k: If possible, pick an integer $\hat{k}$ such that $b < \hat{k} < k^{1/l}$, $p_{l,i}(\hat{k}) < \hat{k}^{l+(1/d)}$, and $\hat{k}^l + \hat{k} + (1+\delta l)\log\hat{k} \geq k$. If $\hat{k}$ exists, then a diagonalization condition can be satisfied. Otherwise, continue immediately to the coding part of the stage.

To satisfy the diagonalization condition, simulate T_d on input $1^{\hat{k}}$. If T_d queries a string not yet fixed, fix that string to be out of B. (This may fix a coding string. See below.) At the end of the simulation, if $T_d^B(1^{\hat{k}})$ accepts, fix all strings of the form $1^{\hat{k}^l+\hat{k}}y$ with $|y| = (1+\delta l)\log k$ to be out of B. If $T_d^B(1^{\hat{k}})$ rejects, fix all remaining strings $1^{\hat{k}^l+\hat{k}}y$ with $|y| = (1+\delta l)\log k$ to be in B. Set $b = p_{l,i}(\hat{k}) + 1$, and increase d by one.

After the diagonalization condition is considered, satisfy the possible coding conditions up to length k, as follows. For all unfixed strings z of length k having the form $0^{p_{m,j}(|x|)}\#m\#j\#x\#y$ for some m, j, x, and y with $|y| = (1+\delta m)\log|x|$, fix z in B if $M_{m,j}^B(x)$ accepts and fix z out of B if $M_{m,j}^B(x)$ rejects.

End of stage k.

For each fixed l, i, and d, the conditions on $\hat{k}$ are satisfied for infinitely many values of k. Therefore, each diagonalization condition will eventually be satisfied, and $L_l \in N^1P_l^B - P_l^B$ for all l.

Coding strings may be fixed during diagonalization stages. However, for each fixed m and j, there is a bound on the size of x such that a coding string for $M_{m,j}(x)$ may be fixed during a diagonalization. A given coding string for $M_{m,j}$ may be fixed out of B during the diagonalization against at most one $T_{l,i}$, at some stage k. Since all strings of length less than k are fixed before stage k, the stage number satisfies $k \leq |0^{p_{m,j}(|x|)}\#m\#j\#x\#y| = Q(|x|^m)$. Note that $k < c|x|^{m+1/3}$ for some c and all sufficiently long strings x. At most $p_{l,i}(\hat{k})/k^{1-\delta}$ strings of length k are fixed during the diagonalization. The conditions on $\hat{k}$ imply that $p_{l,i}(\hat{k})/k^{1-\delta}$ is bounded by $\hat{k}^{l+(1/d)}k^{\delta-1} < k^{\delta+(1/dl)}$, which is less than $|x|^{1+\delta m}$ when $d > 3m$ and x is sufficiently long. Since d is nondecreasing and unbounded, each $M_{m,j}$ will be correctly coded for all but finitely many x, and condition 1 will be satisfied.

Therefore, the oracle B meets the required conditions. □

We expect that neither oracle A nor B represents the unrelativized case. The following result seems more likely.

THEOREM 5.5. *There is an oracle C such that $N^iP_j^C \neq N^kP_l^C$ for all distinct pairs (i,j) and (k,l). Also $P^C \neq NP^C$.*

Proof. Each class N^iP_j satisfies the following conditions.

1. Let X be any oracle, and let $A \in N^iP_j^X$. For each string x, to test if $x \in A$ requires only finite knowledge of X.

2. For all oracles X and Y that differ on only finitely many strings, $N^iP_j^X = N^iP_j^Y$.

3. For all oracles X, and for all sets A and B that differ on only finitely many strings, $A \in N^iP_j^X$ if and only if $B \in N^iP_j^X$.

4. Let X be any oracle, and let machine M accept A in $N^iP_j^X$. Then there are an oracle X^* and machine M^* running in N^iP_j such that
   - $N^iP_j^X = N^iP_j^{X^*}$,
   - M^* with oracle X^* accepts the language A, and
   - for all oracles Y and Z that differ on only finitely many strings, the language accepted by M^* with oracle Y differs from the language accepted by M with oracle Z on at most finitely many strings.

Conditions 1, 2, and 3 are immediate. The oracle X^* of condition 4 is simply $X \times \mathbf{N}$. Machine M^* acts as M except that a query s is replaced by $\langle s, n\rangle$, where n is the length of the input.

These properties permit the use of a result of Poizat [15].

LEMMA 5.6 (Poizat). *Let $\mathcal{S}$ and $\mathcal{T}$ be two classes that satisfy conditions* 1–4 *above, with the same mapping $X \mapsto X^*$. Suppose that there is an oracle X such that $\mathcal{S}^X \neq \mathcal{T}^X$. Then $\mathcal{S}^G \neq \mathcal{T}^G$ for all generic sets G.*

Hence one may reverse the order of quantifiers in the statement of the theorem.

LEMMA 5.7. *For all distinct pairs (i,j) and (k,l), there is an oracle C such that $N^iP_j^C \neq N^kP_l^C$.*

Proof (sketch). If $j \neq l$, the desired oracle is the set A of Theorem 5.1, because $P_j^A \neq P_l^A$. (An alternative proof may be obtained via a diagonalization using queries of length $n^{\max\{j,l\}}$ on inputs of length n.)

Suppose $j = l$ and $i < k$. For an oracle C, define $L_C = \{x \mid \exists y\, |y| = k \log x \wedge xy \in C\}$. A standard diagonalization constructs a C such that $L_C \notin P_{i+j}^C$. Because $L_C \in N^kP_l^C$, the desired result follows. □

The previous lemmas imply that $N^iP_j^C \neq N^kP_l^C$ for all generic oracles C. □

Theorems 5.1 and 5.4 indicate that mere equality or inequality among the classes N^mP_l is insufficient to determine whether $P = NP$. It is consistent either that small amounts of nondeterminism ($m \log n$ bits) are useful, but large amounts (polynomially many bits) are no more useful, or that small amounts of nondeterminism are useless, but large amounts are quite powerful. However, additional information about the complexity of these classes, such as in the hypothesis of Theorem 2.3, can suffice to decide $P =?\ NP$.

6. Conclusions and open problems. We have shown several problems to be complete for quasilinear time with restricted nondeterminism. Satisfiability of topologically ordered circuits with $k \log n$ inputs and ordered unravelling of Boolean formulas are each complete for N^kP_1, and a problem concerning context-free grammars is complete for N^1P_1. All of these complete problems require that the input be ordered appropriately. The corresponding unordered problems remain hard for N^kP_1 but do not appear to be in any class below N^kP_2. If random-access machines were used as the underlying model of computation instead of Turing machines, then the unordered problems would be in quasilinear time, but the hardness proofs would fail, due to our inability to simulate random access.

One motivation for this work, as yet unrealized, was to provide general lower bounds for problems of "nearly feasible" complexity. Existing lower bounds usually apply to restricted models of computation, such as one-tape Turing machines or constant-depth circuits, or prove only very large lower bounds, as in the proofs of hardness for exponential time. A proof that some problem S is hard for a particular P_k or N^jP_k ($k > 1$) is a general lower bound on the time complexity of problem S. Although S may already be known to be in P, and thus be considered "feasible," such a hardness proof would give concrete information about the practical complexity of S. The only results of this kind known to the authors are for certain pebble games [3].

This paper leaves many questions unanswered. Although the most dramatic question is whether the hypothesis of Theorem 2.3 holds, there are other, more approachable questions. There are several problems that are easily shown to be in Gurevich and Shelah's class NLT but are not known to be in QL. These include topological sorting, and the problem of generalized Boolean formulas (shown to be NLT-complete in [10]). Providing QL algorithms for these problems, or showing that none exist (i.e., that $NLT \neq QL$), would give us important information about the power of random access.

The fundamental question remains whether there are problems in P that can be computed more quickly with limited nondeterminism than without it. For instance, can one show a $Q(n^k)$ deterministic lower bound for $(k+1)$-clique, or for CSAT(k)?

Acknowledgments. The authors thank A. Klapper, N. Immerman, M. Groszek, A. Peterson, W. L. Ruzzo, and A. Selman for useful discussions of this material.

PARALLEL COMPLEXITY OF THE CONNECTED SUBGRAPH PROBLEM*

LEFTERIS M. KIROUSIS[†‡], MARIA SERNA[§], AND PAUL SPIRAKIS[†‡¶]

Abstract. This paper shows that the problem of testing whether a graph G contains an induced subgraph of vertex (edge) connectivity at least k is P-complete for any fixed $k \geq 3$. Moreover, if $k_{\max}$ is the largest vertex (edge) connectivity of any subgraph of G, it is shown that unless P = NC there is no NC algorithm that approximates $k_{\max}$ within any approximation factor $\frac{1}{2} < c < 1$ (such an algorithm is by definition one that outputs a number in the interval $[ck_{\max}, k_{\max}]$). In contrast, it is known that the problem of finding the Tutte (triconnected) components of G (i.e., the maximal subgraphs of G such that for any four vertices in any of them, any two of these vertices can be connected by a path in G that avoids the other two) is in NC. On the positive side, it is shown, by proving extremal graph results, that the maximum k for which there is a k-edge-connected induced subgraph of G can be approximated in NC for any approximation factor strictly less than $\frac{1}{2}$ and that the same is true for vertex connectivity for any approximation factor strictly less than $\frac{1}{4}$.

1. Introduction.

The *vertex* (respectively, *edge*) *connectivity* of a graph is defined to be the least number of vertices (respectively, edges) that must be removed from the graph in order to obtain a disconnected or trivial (i.e., with one vertex) graph. A graph G is said to be *k-vertex-connected* (respectively, *k-edge-connected*) if its vertex (respectively, edge) connectivity is at least k. We are interested here in the parallel complexity of testing whether a graph has an induced subgraph of vertex (or edge) connectivity at least k. We show these problems to be P-complete under logspace reductions for any fixed $k \geq 3$. Our results imply that to test whether a *k-block* (a maximal, under inclusion, induced subgraph that is k-vertex-connected) exists in a graph is P-complete. Matula [1978] characterizes the k-blocks of a graph and argues that they are an interesting alternative to cliques for graph-theory-based cluster analysis. Harary [1972] uses the term *n-connected components* for n-blocks.

A graph-theoretic notion similar to that of the 3-blocks is the notion of the *Tutte components*. The Tutte components of a graph G are usually defined to be the subgraphs of G obtained by a process of repetitively splitting the graph by using separation pairs of vertices. However, they can also be defined to be the maximal induced subgraphs of G that cannot be split apart by a pair of vertices, i.e., for any four vertices of the subgraph, any two of them must be connected by a path in G that avoids the other two. Notice that since the connecting path need not lie entirely in the subgraph, a Tutte component may not be a 3-vertex-connected graph on its own, and therefore it may not be a 3-block. For details see, e.g., Tutte [1966] or Hopcroft and Tarjan [1973]. The Tutte components are also called *triconnected components*, but we avoid this terminology to avert confusion

*Received by the editors August 8, 1990; accepted for publication (in revised form) March 19, 1992. This research was done during the visit of the second author to Patras University, and it was partially supported by a Spanish Research Scholarship, by the Ministry of Industry, Energy and Technology of Greece, and by the ESPRIT II Basic Research Actions Program of the European Community under contract 3075 (project ALCOM). A preliminary version of this paper was presented at the 30th Annual Symposium on Foundations of Computer Science, held October 30–November 1, 1989, in Research Triangle Park, North Carolina. The symposium was sponsored by the IEEE Technical Committee on Mathematical Foundations of Computing.

with the term "3-connected components" of Harary. In a possibly unexpected contrast to 3-blocks, the global characterization of Tutte components permits the construction of algorithms in NC for locating them or for testing whether at least one nontrivial such component exists (see, e.g., Miller and Ramachandran [1987] and the earlier works by Miller and Reif [1985] and JaJa and Simon [1982]). Although the definition of k-blocks (and 3-blocks especially) as maximal k-vertex-connected subgraphs is traditional, the Tutte components helped in characterizing planar graphs (see Bruno, Steiglitz, and Weinberg [1970]); thus they received more attention in the computer science literature.

Since the testing of whether a graph G contains a k-block (or a k-edge-connected maximal induced subgraph) is P-complete for $k \geq 3$, we lowered our sights and asked for efficient approximations (in NC) of the optimization versions of these problems. The optimization version is to find the maximum k for which there is a k-vertex-connected (or k-edge-connected) subgraph of G. Approximating this maximum k within a factor of $c(c \in (0,1))$ is defined to mean computing a k' such that $ck \leq k' \leq k$. We prove that unless P = NC no such approximations exist in NC within a factor c for any $c > \frac{1}{2}$, whereas we provide approximations in NC within a factor c for any $c < \frac{1}{2}$ for edge connectivity and for any $c < \frac{1}{4}$ for vertex connectivity. Our results increase the set of combinatorial P-complete problems whose approximations exhibit a *threshold behavior*. The first such problem, that of the high-degree subgraph, was posed by Anderson and Mayr [1984]. The high-degree subgraph problem consists of finding the largest d for which there is an induced subgraph S of G such that all nodes in S have degree $\geq d$ (with respect to S). Anderson and Mayr showed that approximating this maximum d within a factor $c < \frac{1}{2}$ is in NC, whereas it is not in NC for any factor $c > \frac{1}{2}$ unless P = NC. To obtain the analogous results for connectivity, we prove an extremal graph result that states that any graph with m edges and n vertices has an induced subgraph of vertex (respectively, edge) connectivity at least equal to $\lceil (m+n)/2n \rceil$ (respectively, $\lfloor m/(n-1) \rfloor$).

2. Parallel complexity of the vertex-connected subgraph problem.

2.1. Preliminaries. Let $\kappa(G)$ denote the vertex connectivity of a graph $G = (V, E)$. A *separating set* S of G is a vertex set $S \subseteq V$ such that $G - S$ is disconnected or trivial. A *minimum separating* set of G is a subset $S \subseteq V$ such that $|S| = \kappa(G)$. It is easy to see (see also, Matula [1978]) the following.

LEMMA 1. *Let $S \subseteq V$ be a minimum separating set of a noncomplete graph G, and let $\{A, B\}$ be a partition of the vertices of $G - S$ into two nonempty sets so that any path from a vertex in A to a vertex in B contains a vertex in S. Then for any $k > |S|$ the vertices of any k-block of G are contained in exactly one of the sets $A \cup S$ or $B \cup S$.*

Proof. Notice that if a k-block K intersects both A and B, then $K-S$ is disconnected. Now since $K - S = K - (K \cap S)$, we have that the connectivity of K is at most equal to the cardinality of S, a contradiction, because K is k-connected. □

The k-vertex-connected subgraph (k-VCS) problem is the following: given a graph $G = (V, E)$ and an integer k, does G contain an induced subgraph of vertex connectivity at least k?

2.2. P-completeness of the k-vertex-connected subgraph problem.

THEOREM 1. *The k-VCS problem has time complexity that is a polynomial function of $|G|$ and k.*

Proof. By Lemma 1 the procedure Test (G, k) given below answers the k-VCS problem.

```
**Procedure** Test($G, k$)
begin
if $G$ is $k$-connected return "true"
else if $G$ has $\leq k$ vertices return "false"
else do
    begin
    find a minimum separating set $S$ of $G$
    let $\{A, B\}$ be a partition of the vertices of $G - S$ such that
                any path from a vertex in $A$ to a vertex in $B$ contains a vertex in $S$
    return ((Test($A \cup S, k$)) $\vee$ (Test($B \cup S, k$)))
    end
end
```

Now let $T(n, k)$ be the complexity of the above procedure (n is the number of vertices of G). It is known (see, e.g., Even [1979]) that finding a minimum separating set of a graph G is polynomial in n. Therefore for some polynomial $p(n, k), T(n, k) = p(n, k) + T(|A| + k, k) + T(|B| + k, k)$ if $n > k$, whereas $T(n, k) = O(1)$ if $n \leq k$. Since $|A| + |B| + k = n$, it follows that $T(n, k)$ is polynomial. □

THEOREM 2. *For each $k \geq 3$ the k-VCS problem is P-complete under logspace reductions.*

Proof. We first prove the theorem for $k = 3$. The P-complete problem that we use for the reduction is the problem of computing the value of a Boolean circuit C with the following properties:

- C is monotone, i.e., the only gates in C are either OR or AND gates with in-degree 2.
- The out-degree of all gates and the input nodes is at most 2 (fan-out-2).
- There is a single output node of degree 1.
- There is at least one input with value 1.

The P-completeness of the above problem, known also as the monotone circuit value problem, was originally proved by Goldschlager [1977] (in the original proof it is not assumed that the fan-out is at most 2). For a proof of the P-completeness of the monotone, fan-out-2 circuit value problem see, e.g., Gibbons and Rytter [1988]. Assume now that C is as described above. For the reduction we generate a graph G_C as follows:

- Each input node of the circuit C as well as its output node are replaced by a $K_{2,2}$ graph, such as the one depicted in Fig. 1. We call the upper nodes of this gadget *in-nodes* and the lower ones *out-nodes*.
- Each OR gate of C is replaced by a copy of the graph depicted in Fig. 2. The four upper nodes of this gadget are called in-nodes, whereas, the lower ones are called out-nodes. The in-nodes are grouped in two pairs, each pair corresponding to an incoming edge of this gate.
- Each AND gate of C is replaced by a copy of the graph depicted in Fig. 3. Again, the upper nodes are the in-nodes, whereas the lower ones are the out-nodes, and the in-nodes are grouped in two pairs, each pair corresponding to the two incoming edges of the gate.
- An edge of the circuit connecting a gate (or input node) a to another gate (or output node) b is replaced by two parallel edges connecting the pair of out-nodes of the gadget that replaced a to one of the pairs of in-nodes of the gadget that replaced b (see Fig. 4). Different incoming edges to the same gate use different pairs of in-nodes, whereas different outgoing edges from the same gate use the same pair of out-nodes.

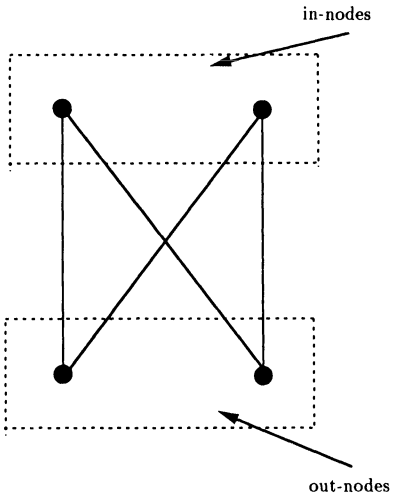

FIG. 1

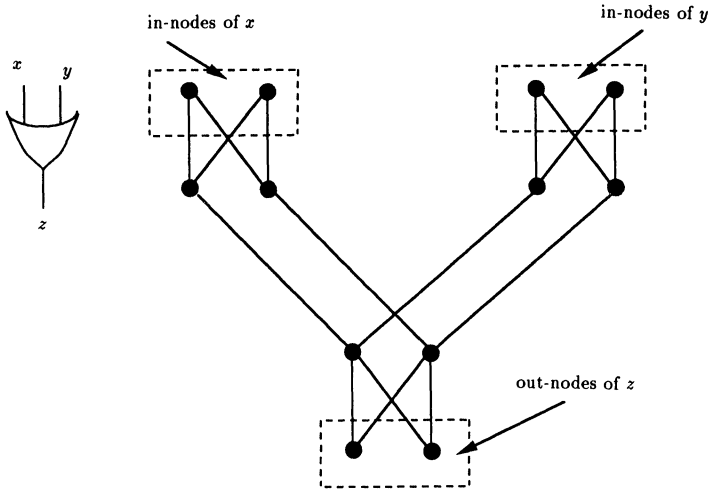

FIG. 2

• Besides the above modifications, a new node v_{new} is added as part of G_C, and this node is connected to the out-nodes of the gadget that replaced the output node of C and to all in-nodes of the gadgets that replaced those inputs of C that had value 1.

Notice that by the above construction an in-node in G_C has only one incoming edge, whereas an out-node, since the fan-out is at most 2, may have at most two outgoing edges (see Fig. 5). See Fig. 6 for an example of such a construction. It is not difficult to prove that the transformation of C described above can be carried out in logspace in the number of nodes of the graph. Indeed, it suffices to note that the transformation is a local one, i.e., at worst only the present node need be kept in the memory.

To prove now that the output of C is 1 if and only if G_C has a subgraph of vertex connectivity 3, we define an *elimination process*: Given a graph G, erase all nodes of

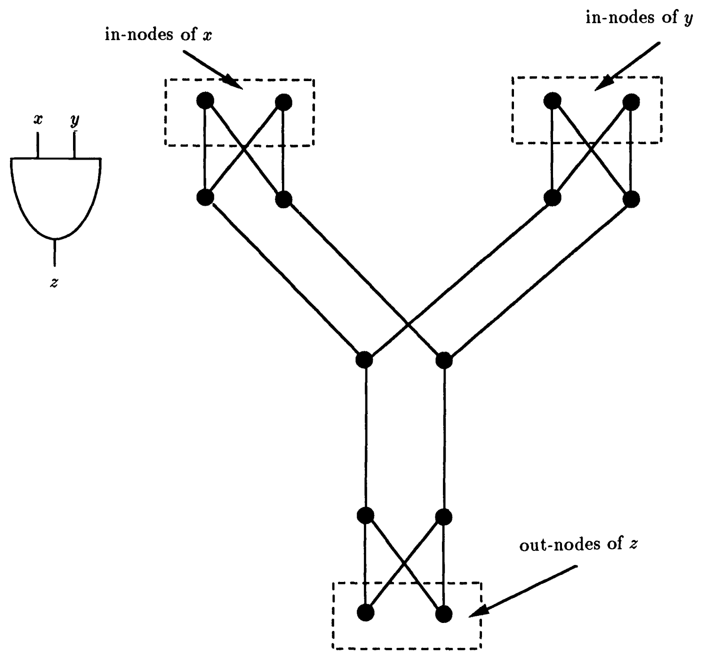

FIG. 3

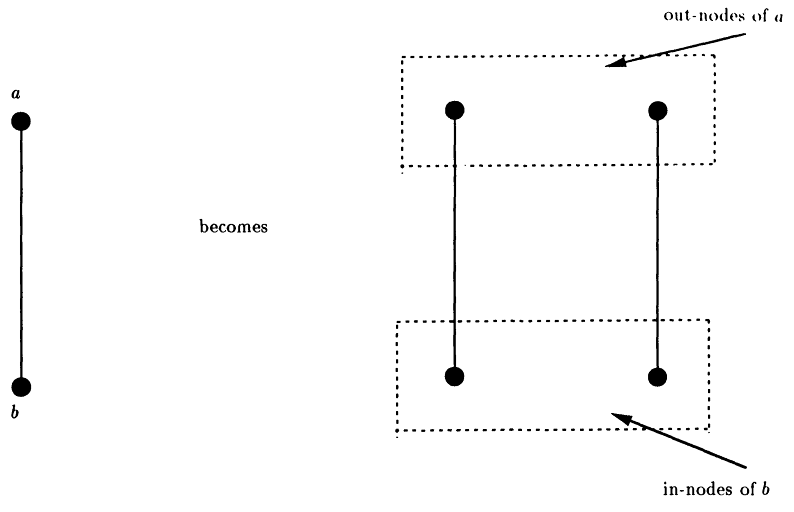

FIG. 4

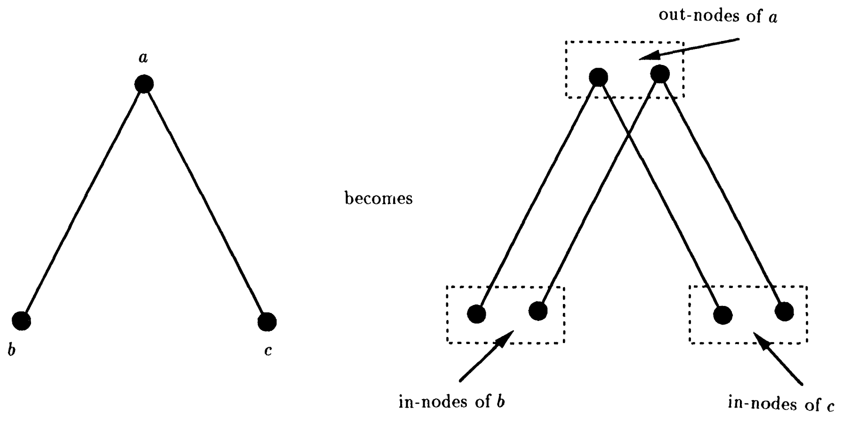
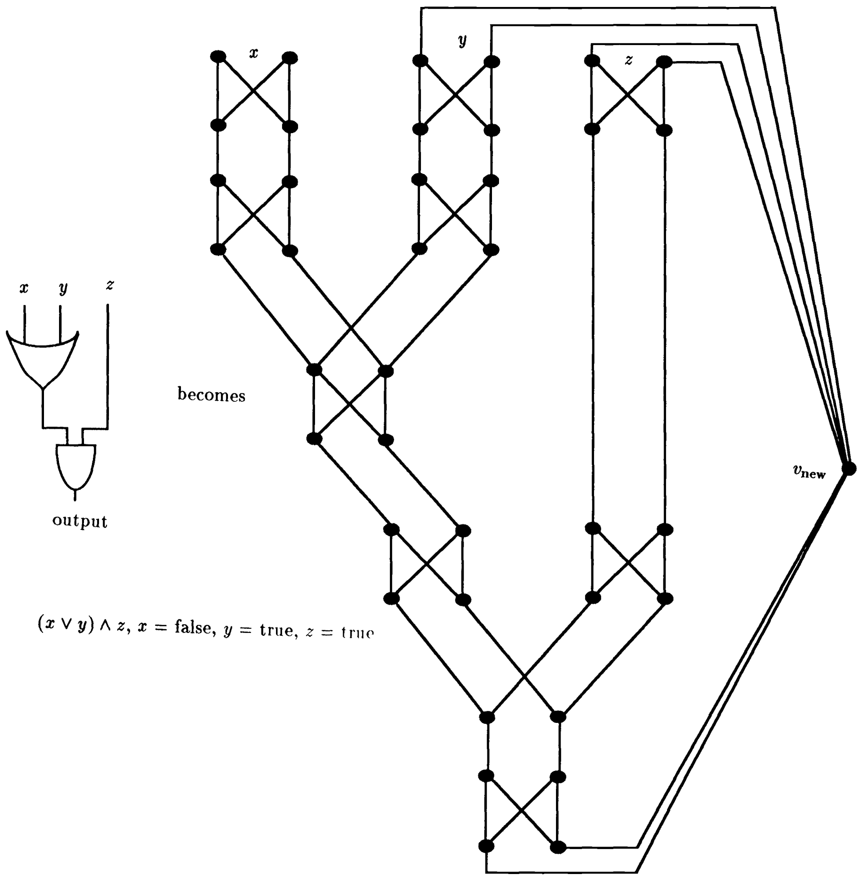
degree <3 and their incident edges, and repeat this procedure for the new graph thus obtained until the graph contains either only nodes of degree ≥ 3 or no nodes at all. Then the following claims are true.

CLAIM 1. *Given a graph G, if by application of the elimination process the whole graph disappears, then G does not contain a 3-connected induced subgraph.*



a
b
c
becomes
out-nodes of a
in-nodes of b
in-nodes of c

FIG. 5



x
y
z
x y z
output
becomes
v_{new}
$(x \vee y) \wedge z$, x = false, y = true, z = true

FIG. 6

The claim immediately follows from the fact that no 3-connected subgraph contains a node with degree <3.

CLAIM 2. *If the output of the monotone fan-out-2 circuit C is 0, then the whole graph G_C is eliminated by the elimination process; hence in this case G_C does not contain a 3-vertex-connected subgraph.*

Proof of Claim 2. Because v_{new} is connected only with the in-nodes of gadgets replacing input nodes with value 1, the in-nodes of gadgets replacing inputs of value 0 are eliminated by the elimination process. As a consequence, and since the fan-out is at most 2, the out-nodes of these gadgets are eliminated as well. Now, because of the way the AND and OR gadgets were constructed and by an easy induction on the longest distance of a gate from an input node, it follows that also all nodes of gadgets corresponding to value-0 gates are eliminated. Hence the output gadget is eliminated. To show now that nodes of gadgets corresponding to a value-1 gate a are eliminated, we use induction on he longest path that starts from a and ends at an immediate predecessor either of a value-0 gate or of the output and contains exclusively value-1 gates. Similarly, we show that nodes corresponding to gadgets of inputs with value 1 are eliminated. Therefore, v_{new} and hence the whole graph is eliminated. This proves Claim 2.

CLAIM 3. *If the output of C is 1, then G_C contains a 3-connected subgraph.*

Proof of Claim 3. Let G'_C be the subgraph of G_C induced by the set of nodes containing

- The node v_{new};
- All nodes in paths that start from an in-node of a gadget corresponding to an input with value 1 and end at an out-node of the output gadget and pass through nodes of gadgets of 1-result gates only.

The graph G'_C is 3-connected. Indeed, if any two nodes different from v_{new} are subtracted from G'_C, any two remaining nodes can be connected through v_{new}. If, on the other hand, v_{new} together with one more node are subtracted from G'_C, any two remaining nodes can still be connected by establishing a path through the gadgets that avoids the single subtracted node. This completes the proof of Claim 3 and the proof of Theorem 2 for the case $k = 3$.

For the case $k > 3$ the same proof works except that we have to modify the gadgets so that all copies of $K_{2,2}$ (even those that appear as parts of the gadgets of AND and OR gates) are replaced by copies of $K_{k-1,k-1}$ and all pairs of parallel edges (either appearing inside the gadgets or replacing edges of the circuit C) are replaced by a set of $k-1$ parallel edges. □

2.3. Approximations to the vertex-connected subgraph problem. The optimization version of k-VCS asks, What is the maximum k such that there is an induced subgraph of vertex connectivity k? Let max-VCS(G) denote this largest k. An approximate solution to this problem is to find a k' such that

$$\text{max-VCS}(G) \geq k' \geq c(\text{max-VCS}(G))$$

for some fixed $c < 1$. It will be shown that this approximation problem cannot be solved in NC for $c > \frac{1}{2}$ unless P = NC. However, max-VCS(G) can be approximated in NC for $c < \frac{1}{4}$. To show this we first prove an extremal graph result (Theorem 3 below). Of course, since by Theorem 1 the k-VCS(G) problem can be answered in time polynomial with respect to $|G|$ and k, computing max-VCS(G) is polynomial in $|G|$.

THEOREM 3. *If a graph has n vertices and m edges $(m \neq 0)$, then it has an induced subgraph that is $\lceil (m+n)/2n \rceil$-vertex-connected.*

It suffices to apply the following lemma for $p = \lfloor m/n \rfloor$ and to observe that

$$\lceil (\lfloor m/n \rfloor + 1)/2 \rceil = \lceil ((m/n) + 1)/2 \rceil .$$

LEMMA 2. *Let G be a graph with n vertices and m edges, where $n \geq 2$. For any integer p, if*

$$p(n - (p+1)/2) \leq m \quad \text{and} \quad 0 < p < n,$$

then G has an induced subgraph that is $\lceil (p+1)/2 \rceil$-vertex connected.

Proof. The proof is by induction on the number of vertices. The induction basis ($n = 2$) is trivial to check. As the inductive hypothesis now, suppose that the lemma is true for graphs with $<n$ vertices, where $n > 2$. We will now prove the result for a graph G with n vertices. Observe first that if $p = n - 1$, then by the first inequality in the hypothesis the graph is complete; therefore, the required follows immediately. So we may assume that $p < n - 1$. Suppose first that G has minimum degree at most p. In this case let G' be the graph obtained from G by deleting a vertex with minimum degree. Because $p < n-1$, the second inequality in the statement of the lemma is satisfied for G'. To show that the first inequality is also satisfied, observe that for G' the right-hand side of the inequality is equal to m decreased by the degree of the deleted vertex, whereas its left-hand side is reduced by p. The required follows because we have assumed that the minimum degree of G is at most p.

Suppose now that the minimum degree of G is $>p$. Let S be a minimum separating set of G, and let $\{A_1, A_2\}$ be a partition of the vertices of $G - S$ in two sets so that no vertex in A_1 is connected to a vertex in A_2 by a path that avoids the vertices in S. Let n_i (respectively, m_i) be the number of vertices (respectively, edges) of the graph induced by the vertices in $A_i \cup S$. Also, let n_S (respectively, m_S) be the number of vertices (respectively, edges) of the graph induced by S. Since G has minimum degree $>p$, it follows that $p < n_i$ for $i = 1, 2$. Therefore, by the induction hypothesis and by the first inequality in the statement of the lemma it follows that for $i = 1, 2$ either $A_i \cup S$ has a $\lceil (p+1)/2 \rceil$-vertex-connected subgraph or $p(n_i - (p+1)/2) > m_i$. Since a $\lceil (p+1)/2 \rceil$-vertex-connected subgraph of $A_i \cup S$ is also a $\lceil (p+1)/2 \rceil$-vertex-connected subgraph of G, we may assume that

$$(1) \qquad p(n_i - (p+1)/2) > m_i \quad \text{for } i = 1, 2.$$

Now taking into account that

$$n_1 + n_2 = n + n_S$$

and that

$$m_1 + m_2 = m + m_S,$$

and summing up the inequalities (1), we obtain

$$p(n + n_S - (p+1)) > m + m_S.$$

Subtracting from this last inequality the inequality $p(n - (p+1)/2) \leq m$ given by the hypothesis, we obtain

$$n_S \geq \frac{m_S}{p} + \frac{p+1}{2},$$

from which it follows that the minimum separating set of G has cardinality $\geq(p+1)/2$ and hence that G itself is at least $\lceil(p+1)/2\rceil$-vertex-connected. □

THEOREM 4. *For any $c < \frac{1}{4}$ an approximation of* max-VCS(G) *can be found in* NC *with approximation factor c.*

Proof. We first define a routine Test(k) that returns an answer that is either "the graph has no subgraph of vertex connectivity $\geq k$" or "the graph has a subgraph of vertex connectivity $\lceil ck\rceil$." The routine Test(k) discards all vertices of degree $<k$ from the graph until either the graph is empty of fewer than $(1-4c)n'$ vertices have degree $<k$, where n' is the number of vertices currently in the graph. It is easy to check that this routine can be implemented on an Exclusive Read Exclusive Write (EREW) parallel random-access machine (PRAM) with n processors in $O(\log^2 n)$ time (n is the number of nodes originally in the graph). Indeed, since a constant fraction of the existing vertices is deleted at each phase, there are $O(\log n)$ deletion phases. Each such phase requires $O(\log n)$ time to compute the fraction of the vertices with degree $<k$. Observe, however, that the $O(\log^2 n)$ complexity function depends on c.

Now if the routine stops with an empty graph, then G cannot have a subgraph of vertex connectivity at least k. If, on the other hand, Test(k) stops with n' vertices, where $n' \neq 0$, then at least $4cn'$ of these vertices have degree $\geq k$, and therefore the remaining graph will have at least $2ckn'$ edges. Therefore, by Theorem 3, G will have a subgraph of vertex connectivity at least $\lceil ck+\frac{1}{2}\rceil \geq \lceil ck\rceil$.

By now applying Test(k) in parallel for all $k = 1, \ldots, n$, a k_0 will be found such that G has no subgraph of connectivity $\geq k_0$ but has a subgraph of connectivity at least $\lceil ck_0\rceil$. Therefore,

$$k_0 \geq \text{max-VCS}(G) \quad \text{and} \quad \lceil ck_0\rceil \leq \text{max-VCS}(G).$$

It suffices now to choose as an approximation to max-VCS(G) the number $\lceil ck_0\rceil$. The approximation factor then is c, and the complexity of the algorithm depends on it. □

THEOREM 5. *If* P $\neq$ NC, *then* max-VCS(G) *cannot be approximated in* NC *by any factor $c > \frac{1}{2}$.*

Proof. Suppose, towards a contradiction, that such an approximation exists for a $c > \frac{1}{2}$. Given any $k \geq 2$, we will provide a logspace transformation that transforms a monotone Boolean circuit C satisfying the restrictions described in the proof of Theorem 2 to a graph G_C such that max-VCS$(G_C) = 2k$ if the output of C is 1 and max-VCS$(G_C) = k+1$ if the output of C is 0. Then it is easy to see that if we choose k so that $k+1 < 2ck$, we could decide in NC the output of C, a contradiction. To make the figures simpler, we give the transformation only for the case $k = 3$. To generalize the result to arbitrary $k \geq 2$, we substitute into Figs. 7–10 each group of three vertices with a group of k vertices and, moreover, we add the necessary edges so as to have the same type of connection between two groups of vertices. Also, in Fig. 9 not only do we change the cardinality of each group of vertices but we also make the number of groups equal to k.

The graph G_C is generated according to the following rules:

- Each input node of C and the output node of C are replaced by 3 (k in the general case) nodes totally disconnected from one another (Fig. 7).

FIG. 7

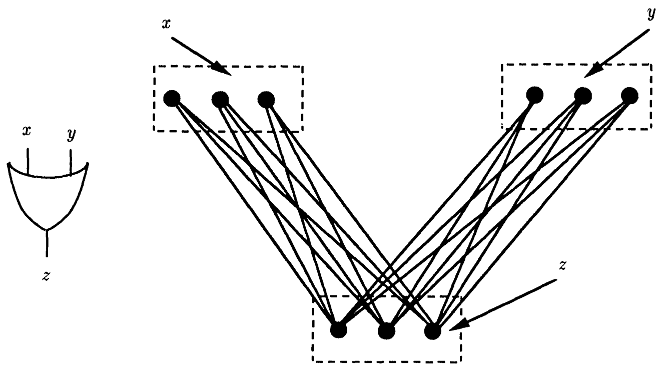


FIG. 8

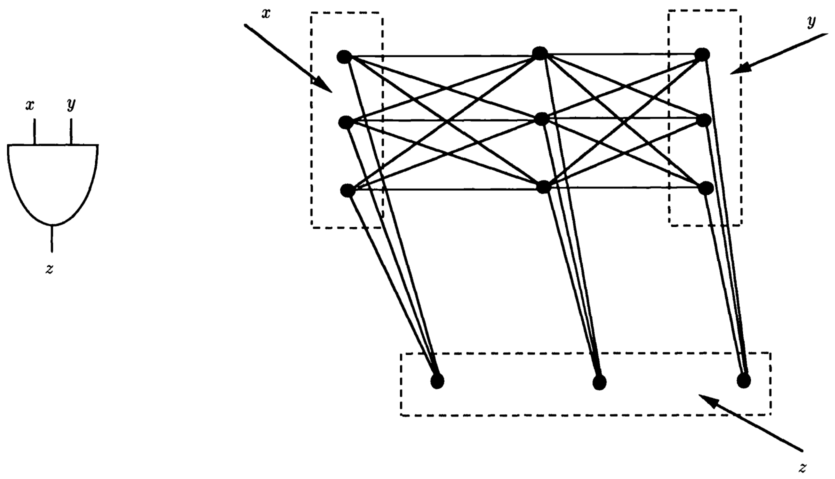

FIG. 9

• Each OR gate of C is replaced by a copy of the graph depicted in Fig. 8. The upper nodes of this gadget are called in-nodes and are divided into two groups, each corresponding to an incoming edge. The lower nodes are called out-nodes.

• Each AND gate is replaced by a copy of the graph depicted in Fig. 9. Adding more (or fewer) layers to this graph, we can generalize to an arbitrary k.

• The fanning out of the value of a gate (or an input node) to (at most 2) other gates (or the output node) is accomplished by using the fan-out gadget depicted in Fig. 10. The nodes a_1, a_2, a_3 of this gadget are the out-nodes of the gadget corresponding to gate a, whose value must be fanned out to gates b and c, respectively. On the other hand, nodes b_1, b_2, b_3 and c_1, c_2, c_3 are the in-nodes of the gadgets of b and c, respectively. Notice that by using more (or fewer) layers in this fan-out gadget, we could have implemented fan-out greater than 2 (less than 2, respectively). See also Anderson and Mayr [1984].

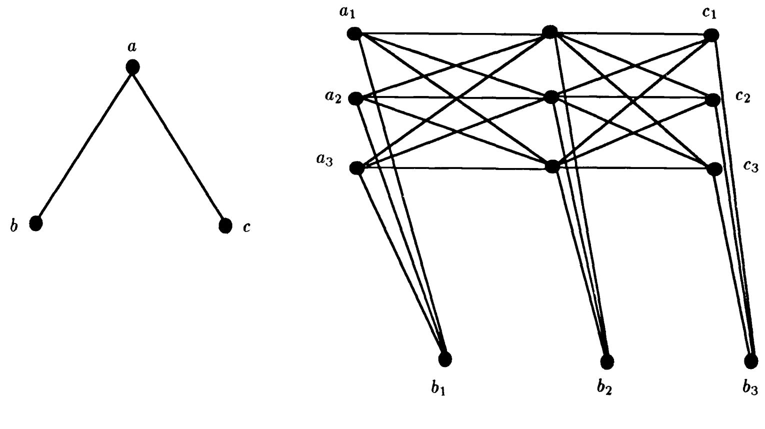

FIG. 10

• Finally, the nodes of the gadget corresponding to the output node of C are connected to the nodes of all value-1 input nodes of C by means of a multilayered fan-out gadget as described above.

Notice that thus every vertex in a group of out-nodes is connected by 4 ($k+1$ in the general case) edges to the nodes of the gadget leading to the corresponding in-nodes. Also, every vertex in a group of in-nodes is connected to the gadget leading to corresponding out-nodes with 3 or 4 (k or $k+1$ in the general case) edges.

Now it is not difficult to see that if all nodes of degree <6 ($<2k$ in the general case) are removed by an elimination process as described in the proof of Theorem 2, then all nodes of gadgets corresponding to nodes of C with value 0 will be removed. This is so because by construction the out-nodes of an OR gate are removed if and only if the vertices of both its groups of in-nodes are removed. Similarly, the vertices of a group of out-nodes of an AND gate are removed if and only if the vertices of at least one group of in-nodes are removed. Finally, the nodes of an input are removed if and only if either the input has value 0 or it has the value 1 and the output nodes are removed (this is so because only value-1 input nodes are connected to the output nodes).

Also, from the above we conclude that in case the output of C is 1, the nodes corresponding to gadgets of value 1 will remain. Actually, in this case the remaining graph will have vertex connectivity 6. Moreover, if all nodes of degree ≤ 6 are removed, everything is removed. This shows that if the output of C is 1, then max-VCS$(G_C) = 6$.

In case the output of C is 0, the removal of all gates of degree ≤ 4 ($\leq (k+1)$ in the general case) leaves nothing on the graph, whereas, since we have assumed that there is at least one input with value 1, there is a subgraph of G_C with vertex connectivity 4. This shows that if the output of C is 0, then max-VCS$(G_C) = 4$. $\square$

3. Parallel complexity of the edge-connected subgraph problem.

3.1. Preliminaries. Let $\lambda(G)$ denote the edge connectivity of a graph $G = (V, E)$. An *edge separating set* F of G is an edge-set $F \subseteq E$ such that $G - F$ is disconnected or trivial. An *l-edge-block* of G is a maximal, under inclusion, subgraph of G that is l-edge-connected. A *minimum edge separating set* of G is an edge separating subset $F \subseteq E$ such that $|F| = \lambda(G)$. By a proof completely analogous to that of Lemma 1 we can show the following.

LEMMA 3. *Let $F \subseteq E$ be an edge separating set of a graph G, and let $\{A, B\}$ be a partition of the vertices of G into two sets so that any path from a vertex in A to a vertex in B contains an edge in F. Then for any $l > |F|$ the vertices of any l-edge-block of G are contained in exactly one of the sets A or B.*

The l-edge-connected subgraph (l-ECS) problem is the following: given a graph $G = (V, E)$ and an integer l, does G contain an induced subgraph of edge connectivity at least l?

3.2. P-completeness of l-edge-connected subgraph problem.

THEOREM 6. *The l-ECS problem has time complexity that is a polynomial function of $|G|$ and l.*

Proof. By Lemma 3 the procedure Test(G, l) given below answers the l-ECS problem.

```
**Procedure** Test$(G, l)$
**begin**
**if** $G$ is $l$-edge-connected **return** "true"
**else if** $G$ has $<l$ edges **return** "false"
**else do**
    **begin**
    find a minimum edge separating set $F$ of $G$
    let $\{A, B\}$ be a partition of the vertices of $G$ such that
                any path from a vertex in $A$ to a vertex in $B$ contains an edge in $F$,
                and let $G_A(G_B)$ be the graphs induced by $A$ (respectively, $B$)
    **return** ((Test$(G_A, l)$) $\vee$ (Test$(G_B, l)$))
    **end**
**end**
```

Now let $T(n, l)$ be the complexity of the above procedure (n in the number of vertices of G). It is known (see, e.g., Even [1979]) that finding a minimum edge separating set of a graph G is polynomial in n. Therefore, for some polynomial $p(n, l)$

$$T(n, l) = p(n, l) + T(|A|, l) + T(|B|, l).$$

Since $|A| + |B| = n$, it follows that $T(n, l)$ is polynomial. □

THEOREM 7. *For each $l \geq 3$ the l-ECS problem is P-complete under logspace reductions.*

Proof. A proof completely analogous to the proof of Theorem 2 is sufficient for the following two reasons: (i) A graph containing a node with degree $<l$ cannot be l-edge-connected, and (ii) any l-vertex-connected subgraph is also l-edge-connected. □

3.3. Approximations to the edge-connected subgraph problem. The optimization version of l-ECS asks, What is the maximum l such that there is an induced subgraph of edge connectivity l? Let max-ECS(G) denote this largest l. As in the case of vertex connectivity, an approximate solution to this problem is to find an l' such that

$$\text{max-ECS}(G) \geq l' \geq c(\text{max-ECS}(G))$$

for some fixed $c < 1$. It will be shown that this approximation problem cannot be solved in NC for $c > \frac{1}{2}$ unless P = NC. However, max-ECS(G) can be approximated in NC for $c < \frac{1}{2}$. To show this we first prove an extremal graph result (Theorem 8 below). Of course, since by Theorem 6 the l-ECS(G) problem can be answered in time polynomial with respect to $|G|$ and l, computing max-ECS(G) is polynomial in $|G|$.

THEOREM 8. *If a graph has n vertices and m edges $(n > 1)$, then it has an induced subgraph that is $\lfloor m/(n-1) \rfloor$-edge-connected.*

The above theorem follows from the following lemma.

LEMMA 4. *Let G be a graph with n vertices and m edges $(n \geq 2)$. For any integer p if $pn \leq m + p$, then G has an induced p-edge-connected subgraph.*

Proof. The proof is by induction on the number of edges. Assume without loss of generality that $\lambda(G) < p$, and let F be a minimum edge separating set ($|F| = \lambda(G)$). Also let $\{A_1, A_2\}$ be a partition of the set of vertices of G in two sets so that no vertex in A_1 is connected to a vertex in A_2 by a path that avoids the edges in F, and let n_i (respectively, m_i) be the number of vertices (respectively, edges) of the subgraphs induced by A_i. Then $n_1 + n_2 = n$ and $m_1 + m_2 + \lambda(G) \geq m$. Now if $pn_1 \leq m_1 + \lambda(G)$, then $pn_1 \leq m_1 + p$ and the result follows from the induction hypothesis. So assume that $pn_1 > m_1 + \lambda(G)$. Then $m_2 \geq m - (m_1 + \lambda(G)) > m - pn_1$; therefore, $m_2 > m - p(n - n_2)$, and so

$$pn_2 < m_2 + pn - m \leq m_2 + p.$$

From the last inequality the required follows by the induction hypothesis. □

THEOREM 9. *For any $c < \frac{1}{2}$ an approximation of* max-ECS(G) *can be found in* NC *with approximation factor c.*

Proof. As in the case of vertex connectivity, we define a routine Test(l) that returns an answer that is either "the graph has no subgraph of edge connectivity $\geq l$" or "the graph has a subgraph of edge connectivity $\lfloor cl \rfloor$." The routine Test(l) discards all vertices of degree $<l$ from the graph until either the graph is empty of fewer than $(1-2c)n'$ vertices have degree $<l$, where n' is the number of vertices currently in the graph. Analogously to the case of vertex connectivity, it is easy to check that this routine can be implemented on an EREW PRAM with n processors in $O(\log^2 n)$ time (n is the number of nodes originally in the graph). If the routine stops with an empty graph, then G cannot have a subgraph of edge connectivity at least l. If, on the other hand, Test(l) stops with n' vertices, where $n' \neq 0$, then at least $2cn'$ of these vertices have degree $\geq l$ and therefore the remaining graph will have at least cln' edges. Therefore, by Theorem 8, G will have a subgraph of edge connectivity at least $\lfloor cln'/(n'-1) \rfloor \geq \lfloor cl \rfloor$.

Now by applying Test(l) in parallel for all $l = 1, \ldots, m$, an l_0 will be found such that G has no subgraph of edge connectivity $<l_0$ but has a subgraph of edge connectivity at least $\lfloor cl_0 \rfloor$. Therefore,

$$l_0 \geq \text{max-ECS}(G) \quad \text{and} \quad \lfloor cl_0 \rfloor \leq \text{max-ECS}(G).$$

It suffices now to choose as an approximation to max-ECS(G) the number $\lfloor cl_0 \rfloor$. The approximation factor is then c, and the complexity of the algorithm depends on it. □

THEOREM 10. *If* P $\neq$ NC, *then* max-ECS(G) *cannot be approximated in* NC *by any factor $c > \frac{1}{2}$.*

Proof. For reasons that were outlined in the proof of Theorem 7, it turns out that a proof completely analogous to the proof of Theorem 5 works for this case as well. □

4. Discussion.

We showed that the problem of approximating the largest l for which there is an l-edge-connected subgraph of a given graph is a problem that exhibits a threshold: for approximation factors strictly less than $\frac{1}{2}$ the problem is in NC, whereas for approximation factors strictly greater than $\frac{1}{2}$ it is P-complete. The case where the approximation factor is equal to $\frac{1}{2}$ is an open problem.

The situation is as follows for the corresponding problem for vertex connectivity: we have shown that the problem is P-complete for approximation factors strictly greater than $\frac{1}{2}$, whereas we have given an NC algorithm only for factors strictly less than $\frac{1}{4}$. We conjecture that for factors as great as (but not including) $\frac{1}{2}$, the approximation is in NC. This is so because we believe that Lemma 2 could be improved to cover these factors as well.

However, we believe it is improbable that the same techniques would yield an NC algorithm for the case in which the approximation factor is equal to $\frac{1}{2}$. This is so because then by continuity arguments we could find an NC algorithm for factors infinitesimally greater than $\frac{1}{2}$, thus contradicting the P-completeness result.

Acknowledgments. We wish to thank H. Jung, C. Papadimitriou, V. Ramachandran, J. Reif, and M. Yannakakis for their prompt feedback on preliminary work on the parallel complexity of the vertex-connected subgraph problem. Also, we thank the referees, whose remarks helped considerably in improving the paper.

FINDING TRICONNECTED COMPONENTS BY LOCAL REPLACEMENT*

DONALD FUSSELL†, VIJAYA RAMACHANDRAN‡, AND RAMAKRISHNA THURIMELLA§

Abstract. A parallel algorithm for finding triconnected components on a CRCW PRAM is presented. The time complexity of the algorithm is $O(\log n)$, and the processor-time product is $O((m+n)\log\log n)$, where n is the number of vertices and m is the number of edges of the input graph. The algorithm, like other parallel algorithms for this problem, is based on open ear decomposition, but it uses a new technique, local replacement, to improve the complexity. Only the need to use the subroutines for connected components and integer sorting, for which no optimal parallel algorithm that runs in $O(\log n)$ time is known, prevents the algorithm from achieving optimality.

Key words. parallel algorithm, triconnectivity, PRAM, graph, vertex connectivity

1. Introduction. A connected graph $G = (V, E)$ is k-vertex connected if it has at least $(k+1)$ vertices and removal of any $(k-1)$ vertices leaves the graph connected. Designing efficient algorithms for determining the connectivity of graphs has been a subject of great interest in the last two decades. Applications of graph connectivity to problems in computer science are numerous. Network reliability is one application: algorithms for edge and vertex connectivity can be used to check the robustness of a network against link and node failures, respectively. In spite of all the attention this subject has received, $O(m+n)$-time sequential algorithms for testing k-edge and k-vertex connectivity of an n-node, m-vertex graph are known only for $k \leq 3$ [5], [11]. Recently, Gabow has devised a very nice algorithm for edge connectivity. His algorithm, unlike previous algorithms for connectivity, does not appeal to Menger's theorem. It runs in $O(km\log(n^2/m))$ time [9]. The algorithms for vertex connectivity for $3 < k \leq \sqrt{n}$ currently require $O(k^2n^2)$ time [2], [13], [19].

The subject of this paper is the parallel complexity of 3-vertex connectivity. The importance of 3-vertex connectivity stems from the face that if a planar graph is 3-vertex connected (triconnected), then it has a unique embedding on a sphere. Hence an efficient algorithm that divides a graph into triconnected components is sometimes useful as a subroutine in problems such as planarity testing and planar graph isomorphism.

We present in this paper an algorithm, based on open ear decomposition, for dividing a biconnected graph into triconnected components. The model of computation used in this paper is a concurrent-read-concurrent-write (CRCW) parallel random-access machine (PRAM) in which write conflicts are resolved arbitrarily (the arbitrary-CRCW PRAM model). See [14] for a discussion on the PRAM model. Our algorithm runs

in $O(\log n)$ time performing at most $O((m+n)\log\log n)$ work, where m and n are the number of edges and the number of vertices of the input graph, respectively.

The first optimal sequential triconnected component algorithm (based on depth-first search (DFS)) was given by Hopcroft and Tarjan in 1973 [11]. Several parallel algorithms (e.g., [12], [16]) have been developed since then for addressing the triconnected component problem by using techniques other than DFS since the question of finding a DFS spanning tree efficiently in parallel remains one of the major open problems in the area of parallel algorithm design. The algorithms in [12] and [16] use parallel matrix multiplication as a subroutine; hence their processor complexity is far from optimal. Significant progress has been made in recent years: first, Miller and Ramachandran [18] derived an $O(\log^2 n)$ parallel algorithm; later, Ramachandran and Vishkin [21] derived an algorithm with $O(\log n)$ parallel time for the more restricted problem of finding separating pairs. A drawback with both of these algorithms is that the work performed by them in the worst case is a $O(\log^2 n)$ factor off the optimal. Independent of [18] and [21], Fussell and Thurimella [7] came up with a parallel algorithm for finding separating pairs whose time complexity is $O(\log n)$ while the work performed is only a $O(\log n)$ factor off the optimal; detecting separating pairs forms the central part of any triconnected component algorithm.

The chief method used by [18] and [21] can be broadly classified as divide-and-conquer. Additional complexity improvements are unlikely with this approach because of the end-node sharing problem: the difficulty arising from two or more ears sharing an end vertex. A novel technique known as *local replacement* was introduced in [7] as a method for obtaining efficient parallel reductions.

Using the local replacement technique and building on the algorithm in [7], we obtain an algorithm for triconnected components. A new linear-time sequential algorithm, an alternative to the algorithm of Hopcroft and Tarjan, for finding triconnected components can be easily extracted from our paper. We remark that a different presentation of the results of this paper is available in [20].

2. Preliminaries. Let $V(G)$ and $E(G)$ stand, respectively, for the vertex set and the edge set of a graph G. Assume that $|V(G)| = n$ and $|E(G)| = m$. We denote an edge between x and y as (x, y) or simply xy. A connected graph G is *k-vertex connected* if $|V(G)| > k$ and at least k vertices must be removed to disconnect the graph. A *biconnected graph* (or a *block*) is a 2-vertex connected graph. A pair of vertices $\{x, y\}$ of a biconnected graph is a *separating pair* if the number of components of the subgraph induced by $V(G) - \{x, y\}$ is more than one. An *ear decomposition starting with a vertex* P_0 of an undirected graph G is a partition of $E(G)$ into an ordered collection of edge disjoint simple paths $P_0, P_1, \ldots, P_k$ such that P_1 is a simple cycle starting and ending at P_0, and for P_i, $1 \le i \le k$, each end vertex is contained in some P_j for some $j < i$ and no internal vertex of P_i is contained in any P_j, $j < i$. Each of these paths P_i is an *ear.* P_0 is called the *root* of the decomposition and is referred to as r. If the two end vertices of a path P_i do not coincide, then P_i is an *open ear.* In an *open ear decomposition* every ear P_i, $1 < i \le k$, is open.

THEOREM 2.1 (Whitney [26]). *A graph has an open ear decomposition if and only if it is biconnected.*

From the above theorem we can conclude that the subgraph induced by the vertices of the ears of $P_0, P_1, \ldots, P_i$ for all i, $1 \le i \le k$, is biconnected.

An ear is a *nontrivial ear* if it consists of more than one edge; otherwise, it is a *trivial ear.* For an ear P and two vertices x and y of P, $P[x, y]$ (respectively, $P(x, y)$) denotes the segment of P that is between x and y, inclusive (respectively, exclusive) of x and y.

The segments $P(x, y]$ and $P[x, y)$ of P are defined similarly. A vertex is *internal* to an ear if it is not one of the end vertices of that ear. For two vertices v and w on P, $P - P[v, w]$ refers to the segment(s) of P formed by $V(P) - V(P[v, w])$.

Because an ear decomposition is a partition on the edge set of a graph, each edge (v, w) belongs to a unique ear (denoted by $ear(vw)$). Notice that, except for the root, each v is internal to exactly one ear; call it $ear(v)$. Refer to Fig. 1 for an example of a biconnected graph and an open ear decomposition for it. The following definition labels each vertex v depending on the *position* of v on $ear(v)$.

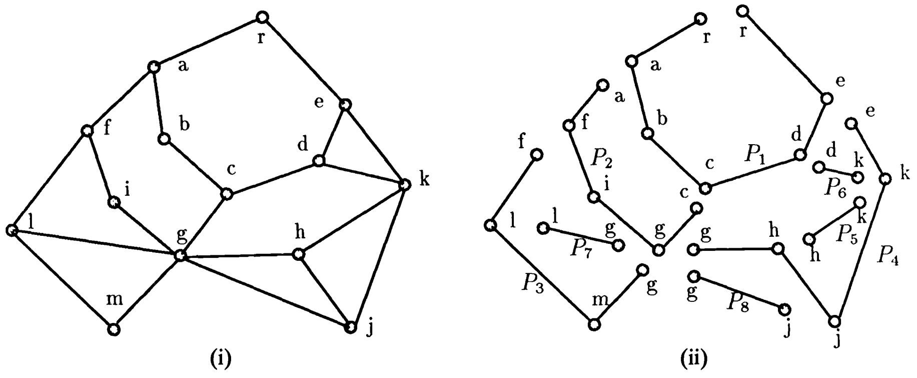

FIG. 1. (i) *A biconnected graph G with* 14 *vertices and* 21 *edges.* (ii) *Its open ear decomposition, where* $P_0 = \langle r\rangle$, $P_1 = \langle r, a, b, c, d, e, r\rangle$, $P_2 = \langle a, f, i, g, c\rangle$, $P_3 = \langle f, l, m, g\rangle$, $P_4 = \langle g, h, j, k, e\rangle$, $P_5 = \langle h, k\rangle$, $P_6 = \langle d, k\rangle$, $P_7 = \langle l, g\rangle$, *and* $P_8 = \langle g, j\rangle$.

Starting with an arbitrary end vertex p of P, define the position of p on P, $pos(p, P)$, to be zero. For every vertex v of P, $v \neq r$, the position of v on P, $pos(v, P)$ is equal to the number of edges between p and v on P. When a vertex v is an internal vertex of P, we omit the second argument and simply write $pos(v)$. The value of $pos(x, P)$ for $x \notin V(P)$ is undefined. Some example pos values for the graph of Fig. 1 are $pos(g) = pos(g, 2) = 3$, $pos(d, 6) = 0$, $pos(r, 1) = 0$, $pos(4, e) = 4$, and $pos(1, j)$ is undefined. For a pair of vertices u, v of P, u is to the *left* (respectively, *right*) of v if $pos(u, P) < pos(v, P)$ (respectively, $pos(u, P) > pos(v, P)$). The vertex of P that has no vertices of P to its left (respectively, right) is called the *left end vertex of P* (respectively, *right end vertex of P*).

For the sake of completeness we include the definition of bridges. Let $G = (V, E)$ be a biconnected graph, and let Q be a subgraph of G. We define the *bridges of Q in G* as follows (see, e.g., [5, p. 148]): Let V' be the vertices in $G - Q$, and consider the partition of V' into classes such that two vertices are in the same class if and only if there is a path connecting them that does not use any vertex of Q. Each such class K defines a *nontrivial bridge* $B = (V_B, P_B)$ of Q, where B is the subgraph of G with $V_B = K \cup \{$vertices of Q that are connected by an edge to a vertex in $K\}$ and P_B contains the edges of G incident on a vertex in K. The vertices of Q that are connected by an edge to a vertex in K are called the *attachments* of B, and these edges are called the *attachment edges* of B. An edge (u, v) in $G - Q$ with both u and v in Q is a *trivial bridge* of Q with attachments u and v. The trivial and nontrivial bridges together constitute the bridges of Q.

Remark. Throughout the paper we will address only how to detect pairs where r, the root of an ear decomposition, does not belong to $\{x, y\}$. The pairs in which one of the vertices is r can be detected as a special case by finding the articulation vertices of the graph induced by $V(G) - \{r\}$ within the claimed resource bounds.

LEMMA 2.2. *If $\{x, y\}$ is a separating pair of a graph G, then there exists a nontrivial ear P in any open ear decomposition of G such that $\{x, y\}$ is a pair of nonadjacent vertices on P.*

Proof. Let C be a connected component induced by $V(G) - \{x, y\}$ such that $r \notin V(C)$. Then P is the minimum$\{ear(v) | v \in V(C)\}$ since $\{x, y\}$ separates r from $v \in P - P(x, y)$. □

DEFINITION 1. An ear P *is separated by* $\{x, y\}$ if x and y are nonadjacent vertices of P and $P(x, y)$ is separated from the lower-numbered ears in $G - \{x, y\}$.

Notice that the number of ears separated by a pair of vertices $\{x, y\}$ is one fewer than the number of connected components of $G - \{x, y\}$. The location of separating pairs on an ear P can be stated precisely in terms of the attachments of the bridges of P.

THEOREM 2.3. *$\{x, y\}$ is a separating pair that separates ear P if and only if* (i) *there exists a nontrivial ear P containing x and y as nonadjacent vertices,* (ii) *the bridge B_r of P in G that contains r has no attachments on $P(x, y)$, and* (iii) *for all other bridges B of P in G, if B has an attachment on $P(x, y)$, then all attachments of B are on $P[x, y]$.*

Proof. ($\Longrightarrow$) Let P be an ear separated by $\{x, y\}$. Assume, for contradiction, that the forward implication is not true. From Definition 1 we know that x and y are not adjacent on P. For P either B_r has an attachment $P(x, y)$ or there is a B with one attachment on $P(x, y)$ and one on $P - P[x, y]$. In either case there is a path from one of the vertices of $P(x, y)$ to r in $G - \{x, y\}$, which contradicts the assumption that P is separated by $\{x, y\}$.

($\Longleftarrow$) There must be at least one vertex v of P between x and y since they are not adjacent on P. For all such v there cannot be a path in $G - \{x, y\}$ from v to r since that would imply a bridge of P in G with at least two attachments—one on $P(x, y)$ and the other on $P - P[x, y]$. Therefore, the segment $P(x, y)$ is disconnected from the components containing lower-numbered ears when x and y are deleted from G. □

Theorem 2.3 ensures that each ear P together with the bridges of P are sufficient for extracting separating pairs and that each ear with its bridges can be considered in isolation. But if we were to consider bridges of all ears in their entirety, the number of edges involved could be far more than $O(m)$. However, notice that for an ear P the information about its bridges that is of relevance in finding separating pairs is contained only in those edges of the bridges that are incident on P. We can succinctly encode the information about separating pairs by building a collection of simple graphs as shown in the following.

DEFINITION 2. The collection $\mathcal{H}$ consists of simple graphs, one for each nontrivial ear of G. The graph $H_P \in \mathcal{H}$ for the ear P is as follows. Suppose that x and y are the end vertices of P and that $pos(x) < pos(y)$. Each H_P is such that $V(H_P) = V(P) \cup \{r_P\}$ and $E(H_P)$ is as follows. (i) For each vertex $v \in V(P)$, an edge (v, r_P) is added if the bridge of P that contains the root r has an attachment at v. Otherwise, (ii) at most two edges are added to $E(H_P)$ by considering the bridges (possibly trivial) of P that have an attachment at v. Let a be the leftmost attachment of one such bridge where a is further to the left than the leftmost attachment for any other bridge that has an attachment at v. The edge (v, a) is added if a belongs to $P[x, v)$. Similarly, an edge (v, b) is added where b is the rightmost vertex that can be reached from v through a bridge of P.

An example of an ear P with its bridges and its corresponding H_P is illustrated in Fig. 2. Suppose that v and w are on P with $pos(v) < pos(w)$. From the definition of H_P it follows that there is a bridge of P in G with one attachment on $P(v, w)$ and another on $P - P[v, w]$ if and only if there is a bridge of P in H_P with one attachment on $P(v, w)$ and another on $P - P[v, w]$. Hence by Theorem 2.3 we have the following corollary.

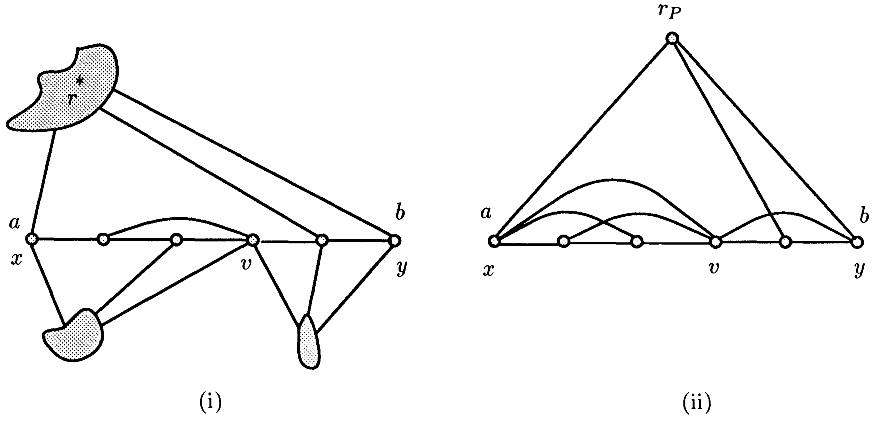

FIG. 2. (i) *An ear P and the bridges of P in G.* (ii) *The graph H_P.*

COROLLARY 2.4. *$\{v, w\}$ is a separating pair that separates P if and only if $\{v, w\}$ is a separating pair in H_P.*

3. Algorithm for separating pairs. Lemma 2.2 tells us that in our search for separating pairs we do not have to consider those vertex pairs for which there is no single ear containing them. If we further assured somehow that *every* separating pair belongs to the *internal* vertices of *some* ear, then we can efficiently reduce the problem of finding separating pairs to that of finding biconnected components. The idea is to build a multigraph by collapsing the internal vertices of every nontrivial ear to a single vertex. We elaborate more on this reduction in §3.2. But before we proceed to this reduction, we need to address a more serious difficulty: for a separating pair $\{x, y\}$ there *need not* be any ear in an open ear decomposition, for which x and y are internal. Section 3.1 shows how to circumvent this problem. In §3.2 we show how to find a collection of graphs similar to $\mathcal{H}$ that succinctly encode separating pairs. Finally, in §3.3 we address the extraction and the output representation of separating pairs.

3.1. Making separating pairs internal to an ear. In this subsection we show how to build a graph G', the *local replacement graph.* This graph is such that for every separating pair $\{x, y\}$ that separates P in G there is a corresponding separating pair $\{x_P, y_P\}$ and an ear P' in G' such that x_P and y_P are internal vertices of P'. Furthermore, for every separating pair $\{x_P, y_Q\}$ of G', $\{x, y\}$ is a separating pair in G. Roughly, the strategy is to divide the graph G into a set of paths by splitting the end vertices of the nontrivial ears of an open ear decomposition. This would result in making several copies of a vertex, i.e., one copy for each nontrivial ear that contains it. Next we add new edges to connect up the different copies of a vertex. The main difficulty is in figuring out an efficient way of connecting the split vertices without jeopardizing the primary goal of preserving the overall structure of separating pairs.

DEFINITION 3. (i) Define $\vec{G}$ to be a directed acyclic version of G that is obtained by the following construction. Suppose (a, b) is one of the end edges of P_1 and that (b, c) is next to (a, b) on P_1. Then give a direction to (a, b). Orient the rest of P_1 in the opposite direction. Now $\vec{G}$ is obtained by giving directions to the remaining ears of G so that the resulting digraph is acyclic.

(ii) Define $\overrightarrow{T}$ to be the directed spanning tree rooted at a obtained by removing the last edge in each directed ear P_i, $i > 1$, in $\overrightarrow{G}$ and deleting (b, c) in the case of P_1.

(iii) Define $\overleftarrow{T}$ to be the directed spanning tree rooted at b obtained as shown below. Let $\overleftarrow{G}$ be the graph resulting from reversing the directions of the edges of $\overrightarrow{G}$. Then $\overleftarrow{T}$ is obtained by deleting the last edge of each ear P_i, $i > 1$, in $\overleftarrow{G}$ and deleting the end edge of P_1 other than (a, b), in the case of P_1.

Figure 3 illustrates the above definitions. One efficient way of obtaining $\overrightarrow{G}$ for a given G, is by st-numbering the vertices of G. (Recall that for a biconnected graph $G(V, E)$ and an edge (s, t) of G, a 1–1 function $g : V \to \{1, 2, \ldots, |V|\}$ is called an *st-numbering* if (i) $g(s) = 1$, (ii) $g(t) = |V|$, and (iii) for every $v \in V - \{s, t\}$ there are adjacent vertices u and w such that $g(u) < g(v) < g(w)$.) For example, $\overrightarrow{G}$ can be obtained by assuming that (s, t) is an edge of P_1 with $s = r$ and directing each edge of an ear from the lower-numbered vertex to the higher-numbered one. Since each end vertex of every nontrivial ear belongs to a lower-numbered ear, we have the following proposition.

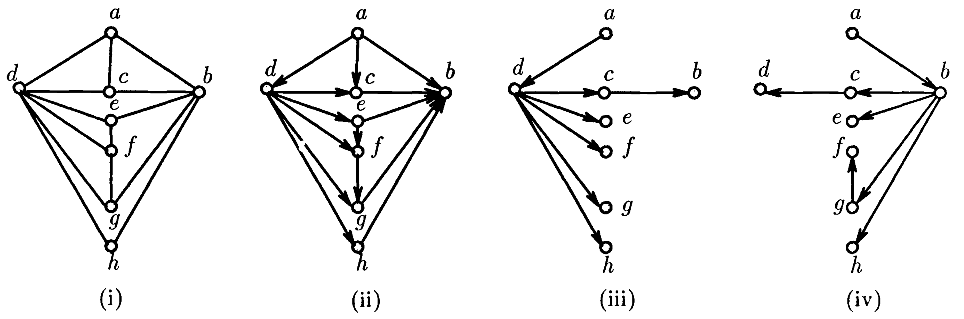

FIG. 3. (i) *A biconnected graph* G *with* $P_1 = \langle a, b, c, d, a\rangle$, $P_2 = \langle b, e, d\rangle$, $P_3 = \langle b, g, d\rangle$, P_4 $\langle b, h, d\rangle$, $P_5 = \langle d, f, g\rangle$, $P_6 = \langle e, f\rangle$, *and* $P_7\langle a, c\rangle$. (ii) $\overrightarrow{G}$. (iii) *An out-tree* $\overrightarrow{T}$ *with* a *as the root.* (iv) *An out-tree* $\overleftarrow{T}$ *with* b *as the root.*

PROPOSITION 3.1. *The ear numbers of the edges of the tree path from any vertex* v *to the root* r *in* $\overrightarrow{T}$ *decrease monotonically.*

DEFINITION 4. P_{xy} refers to an ear P with $\{x, y\}$ as the end vertices. If P is directed from x to y in $\overrightarrow{G}$, then we denote it as $P_{\overrightarrow{xy}}$.

The following useful lemma relates the attachments of a bridge and $\overrightarrow{G}$.

LEMMA 3.2. *Let* B *be a bridge of* $P_{\overrightarrow{xy}}$ *that contains no edge with an ear number less than* P. *Then if* B *has an attachment edge* (z, y) (*respectively,* (x, z)) *at* y (*respectively,* x), *then* zy (*respectively,* xz) *is directed from* z *to* y (*respectively,* x *to* z) *in* $\overrightarrow{G}$, *i.e.,* $xz \notin E(\overrightarrow{T})$.

Proof. We will prove only the case for which B has an attachment at y. A similar proof can be derived if B has an attachment at x. Figure 4 illustrates the statement of the lemma. Let $ear(z) = Q$, where the edges of Q belong to $E(B)$. Suppose that the lemma does not hold, i.e., that Q is directed such that the edge zy is directed from y to z. Trace a path $\overrightarrow{G}$ as shown in the following. Start from y, and traverse until the last vertex of Q, say, w is encountered. Suppose $ear(w) = S$ for some S that belongs to B. Since an end vertex of each ear belongs to a lower-numbered ear in an ear decomposition, we have $S < Q$. Now trace the edges of the ear S along the direction given to S until the last vertex of S is reached. This process, when continued in this fashion, uses edges of B with monotonically decreasing ear labels. Therefore, we must eventually encounter a vertex of P. From that vertex of P we can reach y by going along the direction given to P. In other words, if the lemma does not hold, we can trace a cycle starting and ending at y in $\vec{G}$, which contradicts the fact that $\vec{G}$ is acyclic. □

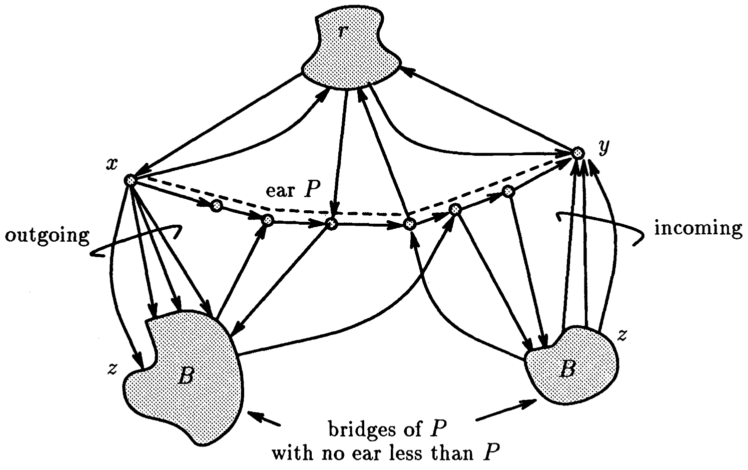

FIG. 4. *Illustration of Lemma* 3.2.

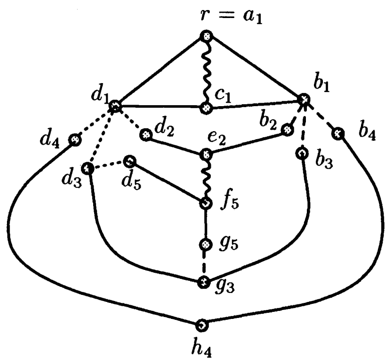
Using these directed graphs, we show how to build the local replacement graph in the following.

ALGORITHM. *Build* G'.
Input: A graph G, an open ear decomposition of G, and the directed graph $\vec{G}$ and its associated spanning trees $\vec{T}, \overleftarrow{T}$.
Output: A graph G' (local replacement graph) in which each separating pair of G is internal to some ear of G'.

1. *Construction of* $V(G')$
   $V(G') = \{v_P | v \in V(P)$ for some nontrivial ear $P\}$. Refer to v_P as a copy of v.
2. *Construction of* $E(G')$
   (a) Initialize $E(G')$ to $\{(u_P, v_P) | (u, v) \in E(P)\}$.
   (b) For every nontrivial ear $P_{\vec{vw}}$ add an edge as follows. If the least common ancestor of v and w (henceforth denoted as $lca(v, w)$) in $\vec{T}$ is v, then let Q be the ear number of the first tree edge in the path from v to w in $\vec{T}$. Then add (v_P, v_Q) to $E(G')$. If $lca(u, w) \neq v$ in $\vec{T}$, then add (v_P, v_Q) to $E(G')$, where Q is such that v is internal to Q.
   (c) Repeat Step 2(b) with $\vec{T}$ and $\vec{G}$ replaced by $\overleftarrow{T}$ and $\overleftarrow{G}$, respectively.
   (d) For all trivial ears uv, if u and v are internal to ears P and Q, respectively, then add (u_P, v_Q) to $E(G')$.

Figure 5 shows various stages of Step 2 on an example graph. The above algorithm does not quite suffice for our purposes, i.e., it need not be the case that there is a separating pair $\{x, y\}$ in G that separates an ear P if and only if $\{x_P, y_P\}$ is a separating pair in G'. This happens if the input graph G contains two or more ears with the same end vertices. Consider an example. Refer to the graph G of Fig. 3(i), and consider the subgraph $G - \{h\}$ obtained by deleting h and edges incident on h. In $G - \{h\}$ the separating pair $\{b, d\}$ separates the ear 2 but does not separate 1. In the local replacement graph corresponding to $G - \{h\}$, i.e., in $G' - \{h_4, b_4, d_4\}$ of Fig. 5, the pair $\{b_2, d_2\}$ is not a separating pair. Before we give the final step of *Build* G', we need the following definitions.



edge type	caused by
—	Step 2(a)
......	Step 2(b)
- - -	Step 2(c)
∿	Step 2(d)

FIG. 5. *Stages in the execution of Step* 2 *of Build G′ when the input graph is G of Fig.* 3.

DEFINITION 5. (i) An ear is a *parallel* ear if there is another ear with the same end vertices.

(ii) Consider the following partition on a set of parallel ears with $\{x, y\}$ as the end vertices. Denote the connected component of $G - \{x, y\}$ that contains the root by C_r. For each connected component C of $G - \{x, y\}$, $C \neq C_r$, denote the minimum of $\{ear(v) \mid v \in V(C)\}$ by P. Each such P is in a different partition. (Notice that every P has end vertices at $\{x, y\}$.) Additionally, for each P the partition that contains P contains exactly (no more than or no fewer than) those ears parallel to P whose internal vertices belong to C. Finally, the ears with $\{x, y\}$ as the end vertices that belong to C_r can be put in any (or additional) partition arbitrarily. Each partition is called a *bundle* of parallel ears.

(iii) The ear with the smallest label of a bundle is called the *representative* for that bundle.

In the example graph of Fig. 3, ears 2 and 3 are in one bundle and ear 4 is in a bundle by itself. Now we describe a method to handle parallel ears.

Algorithmically, partitioning a collection of ears into sets of parallel ears is easy because it is just grouping ears according to the end vertices. However, further classifying them into bundles is nontrivial. In the following we give an alternative definition for a bundle of parallel ears that is equivalent to Definition 5(ii).

DEFINITION 6. Define, recursively, when an ear Q *depends* on an ear P as follows. (a) P *depends* on P. (b) An ear Q depends on P if Q is not parallel to P and if for each of the end vertices v of Q there exists an ear R that depends on P such that $v \in V(R)$.

DEFINITION 7. Define, recursively, a *bundle* of parallel ears as follows. Two parallel ears P and Q are in the same bundle if one of the following holds. (a) There is a path from an internal vertex of P to an internal vertex of Q such that for every edge uv of that path, if $ear(uv) = R_{ab}$, then there exist ears that depend on either P or Q and that contain $ear(a)$ and $ear(b)$. (b) There is another parallel ear R such that P, R and R, Q are in the same bundle.

Suppose that $\{x, y\}$ separates a parallel ear P and that the component C of $G - \{x, y\}$ containing $P(x, y)$ also contains the internal vertices of Q_{xy}. Then notice that for all $v \in V(C)$, $ear(v)$ depends on either P or an ear parallel to P (such as Q) whose internal vertices belong to C. Therefore, it follows that the bundles resulting from this definition conform to the rules stated in Definition 5(ii).

In the following the first step shows how to partition parallel ears into bundles efficiently. Informally, it is as follows. First, we build an auxiliary graph G_p based on the parallel ears of G. G_p is such that P and Q belong to the same bundle if and only if the corresponding pair of vertices p and q are in the same connected component in G_p. The graph G_p is built by making use of the local replacement graph that is available after Step 2(b). Observe that after Step 2(b) each ear is hooked at only one of its ends.

Therefore, the partial G' after Step 2(b) is a tree. Denote it by $\vec{T_l}$. Now we describe the method.

ALGORITHM. *Build* G' (continued)

3. *Adjust* $E(G')$ *for parallel ears*
   (a) *Identify bundles.*
   Let G_p be an auxiliary graph whose vertices p correspond to the parallel ears P of G. The edges of G_p are added by making use of the tree $\vec{T_l}$. Consider two parallel ears $P_{\vec{xy}}$ and $Q_{\vec{xy}}$. An edge $(p,q) \in E(G_p)$ if and only if there exists an ear $R_{\vec{ab}}$ in G (possibly, a trivial ear) that satisfies the following two properties. (i) $\{a,b\} \cap \{x,y\} = \emptyset$. (ii) Let a and b are internal to the ears U and W in G, respectively. Then the tree paths in $\vec{T_l}$ from the $lca(a_U, b_W)$ to a_U and b_W start with the edges added by Step 2(b) for P and Q.
   (b) *Adjust* $E(G')$ *for parallel ears.*
   For each connected component C of G_p do the following. Find a spanning tree T and root it at the vertex with the smallest label (say, p). Let P be the ear in G that corresponds to p. For each ear $Q_{\vec{vw}}$ in G, $Q \neq P$, such that q belongs to T; (i) delete the end edges of Q added to $E(G')$ in Steps 2(b) and 2(c), and (ii) add (v_S, v_Q) and (w_S, w_Q) to $E(G')$, where s is the parent of q in T.

At the end of Step 3 of *Build* G' we still have a partition of the edge set into disjoint paths. However, because of the rearrangement of edges in Step 3(b), the end vertices of an ear may not lie on a lower-numbered ear if we continue to use the old ear labels for G'. But this deficiency is inconsequential to the rest of our algorithm, and hence we continue to use old ear labels. Notationally, if P is an ear of G, the path in G' consisting of P together with two new end edges created by local modifications will be referred to as P'. The following two propositions can be proved by induction and Definitions 6 and 7.

PROPOSITION 3.3. *If an ear* Q *depends on* $P_{\vec{xy}}$, *then both end vertices of* Q' *belong to the subtree of* $\vec{T_l}$ *rooted at* x_P.

PROPOSITION 3.4. *If an ear* Q *depends on* P, *then there is a path from any (internal or end) vertex of* Q *to an internal vertex of* P *such that if* uv *belongs to this path, then* $ear(uv)$ *depends on* P.

THEOREM 3.5. *Two parallel ears* $P_{\vec{xy}}$ *and* Q *are in the same bundle if and only if* p *and* q *are in the same connected component in* G_p.

Proof. In what follows we use the notation of Step 3. Since P and Q are parallel, Q is directed from x to y in $\vec{G}$. Furthermore, from the construction in Step 2 it follows that they have the same parent in $\vec{T_l}$; call it x_S. Denote the subtrees of $\vec{T_l}$ rooted at x_P and at x_Q by T_p and T_q, respectively. Recall that a is an end vertex of R that is internal to U. Assume without loss of generality that a_U is in T_p.

($\Rightarrow$) Assume $(p, q) \in E(G_p)$. If an ear R satisfies the condition (ii) of Step 3(a), then by Proposition 3.3 R depends neither on P nor on Q. Conversely, if R is the ear with smallest label that depends on neither P nor Q, then by Definition 6 R cannot have both its end vertices in one of T_p, T_q. This follows from the fact that if an ear has both its endpoints in T_p (respectively, T_q), then it depends on P (respectively, Q). Hence R satisfies the conditions of Step 3(a). Assume without loss of generality that R is the ear with the smallest label that satisfies the conditions of Step 3(a). Because U and W contain the end vertices of R, $U < R$ and $V < R$. Since R is the ear with smallest label that satisfies the conditions of Step 3(a), U depends on P and W depends on Q. Then by condition (i) of Step 3(a) and Proposition 3.4 there is a path from an internal vertex of P to an internal vertex of Q that satisfies the condition (a) of Definition 7.

($\Rightarrow$) Assume that there are no ears parallel to P except Q in the bundle containing P. Because the condition (b) of Definition 7 is transitive, it suffices to prove just this case. Suppose that $P < Q$. We are required to show that there exists an ear R that satisfies the conditions of Step 3. Consider the subgraph D of G formed by P, Q, and all those ears of G that depend on either P or Q. In this subgraph P and Q are clearly two different bridges of $\{x, y\}$. Now an inductive proof in which the induction step consists of adding an ear that depends on either P or Q shows that in the new subgraph D, P and Q are in different bridges of $\{x, y\}$. That is, there is no path from an internal vertex of P to that of Q in D. Denote the bridge of $\{x, y\}$ in D containing P and Q by D_p and D_q, respectively. If P and Q are in the same bundle, then by Definition 6 and the fact that there are no other parallel ears in D there must exist an ear R that connects a nonattachment vertex of D_p, say, a, to a nonattachment vertex of D_q, say, b. Because a and b are nonattachment vertices of D_p and D_q, neither of them is from $\{x, y\}$. Therefore, R satisfies condition (i) of Step 3(a). Since a and b are internal to ears that depend on P and Q, respectively, the end vertices of R' belong to T_p and T_q by Proposition 3.3. That is, R satisfies condition (ii) of Step 3(a). □

The reverse direction of the above theorem can be stated equivalently as follows.

COROLLARY 3.6. *If $(p, q) \in G_p$, then there is a path from an internal vertex of P to an internal vertex of Q such that this path does not use any vertices of P or of ears parallel to P.*

Next we prove the correctness of *Build G'*. The following simple facts are useful in the proofs. Observe that the number of copies of a vertex v in G' is one more than the number of nontrivial ears for which v is an end vertex, i.e., it is $1 + (\text{degree}(v) - 2)$. The algorithm *Build G'* adds an edge only between two copies of the same vertex, and it adds one edge for every end vertex of every nontrivial ear (see Fig. 6). Therefore, we have the following proposition.

PROPOSITION 3.7. (i) *The edges that connect different copies of a single vertex v form a tree in G'. Therefore, there is a path between any two copies of v in G' that uses only other copies v. As a consequence, for a vertex $v \notin V(P)$ all copies of v belong to a single bridge of P' in G'.* (ii) *The graph G can be obtained from G' by collapsing, for each v, all copies of v into one.*

DEFINITION 8. For an ear P we say a bridge of P is a *relevant* bridge if for each ear Q that belongs to it (a) $Q > P$ and (b) if Q is parallel to P, then Q is in the same bundle as P. If a bridge is not relevant, then it is said to be *irrelevant.*

Observe that for a set of parallel ears with x and y as the end vertices, if one of the ears in $\vec{G}$ is directed from x to y, then all of them are directed from x and y. After Step 2

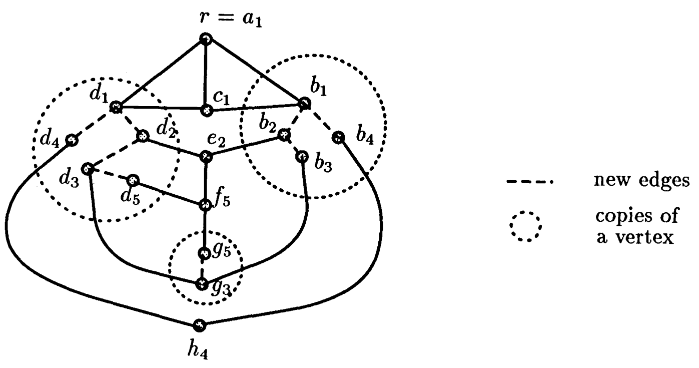


FIG. 6. *Final G' after Step* 3.

(but before Step 3), if P and Q are parallel in G, then P' and Q' are parallel in G' by the construction of Step 2. Because Step 3 does not change the end edges created in Step 2 for the representatives, we have the following proposition.

PROPOSITION 3.8. *If P and Q are parallel ears such that each is a representative of its bundle, then P' and Q' have the same end vertices in G'.*

For a subgraph D of G let $\mathcal{E}(D) = \{ear(uv) | uv \in E(D)\}$. The following can be derived from Definition 8 and the definition of open ear decomposition.

PROPOSITION 3.9. *Suppose that B is a relevant bridge of P. If B contains an edge of an ear Q, then B contains all edges of Q, i.e., if $Q \in \mathcal{E}(B)$, then all edges of Q belong to B.*

Another useful fact can be derived from the definition of open ear decomposition by using the minimum of $\mathcal{E}(B)$.

PROPOSITION 3.10. *If B is a bridge of an ear P that contains an edge whose ear label is less than P, then B has attachments at the end vertices of P.*

LEMMA 3.11. *Consider a relevant bridge B of $P_{\overrightarrow{xy}}$ (respectively, $P_{\overleftarrow{xy}}$) in G. Suppose it contains an ear Q with one end vertex at x (respectively, y) and the other at $v \notin V(P)$. Then the $lca(x, v)$ (respectively, $lca(y, v)$) in $\overrightarrow{T}$ (respectively, $\overleftarrow{T}$) is x (respectively, y).*

Proof. We will prove the lemma when Q has an attachment at x. A similar proof works when Q has an attachment at y. We will show that x is an ancestor of v in $\overrightarrow{T}$. Observe that all paths from v to r in G must go through a vertex of P because v belongs to a bridge of P and this bridge does not contain r. Specifically, the tree path from v to r must have a vertex, say, w, of P. This vertex w of P cannot be y because, by Lemma 3.2, y is not reachable in $\overrightarrow{T}$ from v. Hence the tree path from v to r must encounter a vertex w from $P[x, y)$. Now the last vertex of P on this tree path is x because of the direction given to P. Therefore, the tree path from v to r in $\overrightarrow{T}$ contains x. In other words, x is an ancestor of v in $\overrightarrow{T}$. □

LEMMA 3.12. *Consider a relevant bridge B of $P_{\overrightarrow{xy}}$ in G. Suppose it contains an ear Q with one end vertex at $u \in V(P)$ and the other at $v \notin V(P)$. If $lca(u, v) = u$, then the edges on the tree path from v to u in $\overrightarrow{T}$ belong either to P or to those ears of B whose label is less than Q.*

Proof. Assume $ear(v)$ is U for some $U \in \mathcal{E}(B)$. By the definition of a relevant bridge, $U > P$. We traverse the tree path from v to u. As argued in the proof for Lemma 3.11, we must encounter a vertex z of P from $P[x, y)$ in this traversal. Now u is an ancestor of v because $lca(u, v) = u$. Therefore, z is a descendant of u. Finish the traversal of the tree path from z to u by taking the edges of P from z to u. In this traversal U initially belongs to a relevant bridge, namely, B. Also, whenever the ear labels change from, say, P_1 to P_2 for $P_1, P_2 \neq P$, the switch occurs at the end vertex of P_1. This end vertex is a nonattachment vertex of B because otherwise we would have moved from P_1 to P instead of to P_2. Hence P_1 and P_2 are in the same bridge of P. Since U belongs to P, P_1 and hence P_2 belong to B. In summary, we showed that the traversal of the tree path from v to u uses the edges of the ears of B and possibly some of P. □

THEOREM 3.13. *Let B_q be the bridge of $P_{\overrightarrow{xy}}$ in G containing the ear Q. Let BL_q be the bridge of P' in G' containing the ear Q'. Then* (i) *for every ear S if $S \in \mathcal{E}(B_q)$, then $S' \in \mathcal{E}(BL_q)$. Additionally,* (ii) *if B_q is relevant bridge, then for every S' if $S' \in \mathcal{E}(BL_q)$, then $S \in \mathcal{E}(B_q)$.*

Proof. If two ears Q and S are in the same bridge B of P in G, then there must be a path between a vertex of Q and a vertex of S consisting of only the nonattachment vertices of B. Then by Proposition 3.7 it follows that there is a single bridge of P' in G' containing Q' and S'. That proves part (i).

Next we will prove by induction that if two ears belong to two different bridges B_1 and B_2 in G, then they belong to two different bridges of P' in G' provided that at least one of B_1, B_2 is a relevant bridge. For the base of the induction we start with the subgraph D_1 of G' formed by P' plus $\{Q' \mid$ where $Q < P$, or Q is the minimum labeled ear of a bridge of P, or Q is parallel to P and Q is the representative of its bundle$\}$. The ith induction step consists of building D_i from D_{i-1} by adding the smallest ear from $\mathcal{E}(G) - \mathcal{E}(D_{i-1})$. This ear is added in a manner that conforms with the construction rules of Steps 2 and 3, and thus we maintain the invariant that D_i is a subgraph of G' at all times.

To show that D_1 satisfies the base case, we claim that each ear of a relevant bridge of P in G is in a bridge (of P') by itself in D_1. First, observe these ears have their end vertices on P in G. In *Build G'* the end edges for the minimum labeled ears of a relevant bridge of P are decided in Step 2, and these are not changed later in Step 3. To prove the claim, it suffices to show that each of these ears is attached in Step 2 to some vertices of P'. All parallel ears are attached to the end vertices of P' by Proposition 3.8. For any other ear $Q_{\overrightarrow{vw}}$, $v, w \in V(P)$, if $w = y$, then $v \neq x$ because we assumed that Q is not parallel to P. In that case $lca(v, w) \neq v$ in $\overrightarrow{T}$ (because the end edge of P incident on y is not present in $\overrightarrow{T}$) and v_Q is attached to v_P. The other end vertex w is attached to w_P because $lca(w, v) = w = y$ in $\overleftarrow{T}$ and the tree path from w to v starts with an edge of P. The cases arising from the other positions for v and w on P can be analyzed similarly, and we conclude that v_Q and w_Q are attached to v_P and w_P, respectively.

Now we prove the induction step. Assume, inductively, that the theorem holds when the smallest $(i-1)$ ears from $\mathcal{E}(G) - \mathcal{E}(D_1)$ are added. Consider the ith smallest ear $Q_{\overrightarrow{uv}}$.

Suppose there is an ear (possibly P) parallel to $Q_{\overrightarrow{uv}}$. Then from the construction of Step 3(b) we notice that Q is attached to the copies of u and v, say, u_S and v_S, where s is (in the notation of Step 3(b)) the parent of q in T. The case in which $S = P$ results in creating a new bridge when Q' is added to D_{i-1}, and the induction step is trivially true. But if $s \neq p$ and $(s, q) \in E(G_p)$, then by Corollary 3.6 there is a path between an internal vertex of Q to an internal vertex of S that does not use any vertices of ears parallel to Q. Specifically, this path does not use any vertices of P. Hence S and Q are in the same bridge of P in G.

Next, assume that $Q_{\overrightarrow{uv}}$ has no parallel ears. Let $ear(u)$ and $ear(v)$ be S and U, respectively. We will analyze the cases resulting from assuming different positions for u and v.

Assume that neither u nor v belongs to P. Then by Proposition 3.7 Q' is connected to a nonattachment vertex of the bridge of P' (in D_{i-1}) containing S' (call it BL_s) to a nonattachment vertex of the bridge containing U' (call it BL_u). Clearly, S and U (and hence the ears of G corresponding to the ears of BL_s and BL_u) are in one bridge of P in G because of the path (namely, Q) between them that uses no vertices of P.

Now consider the case in which both u and v belong to P, i.e., $P = S = U$. Then it cannot be that $u = x$ and $v = y$ since that would make Q have an ear (namely, P) parallel to it. Hence one of the end vertices of Q must be internal to P. In this case, by a proof similar to the one used for the base case, Q' is attached to two of the vertices of P'. In other words, if both u and v belong to $V(P)$, then a new bridge is created and the induction step holds.

Next, assume that one of u, v belongs to P and the other does not. Assume without loss of generality that u belongs to P. Clearly, U and Q are in a single bridge of P in G because they are connected at v. Therefore, if Q' attaches itself to the bridge of P' in D_{i-1} that contains U' (denote this bridge by BL_u), then the induction step holds because U (and all the ears corresponding to the ears of BL_u) and Q are in a single bridge of P in G. We will show that this is indeed the case, i.e., that Q' attaches itself to BL_u. Notice that by Proposition 3.7 since $v \notin V(P)$, there exists a bridge of P' in D_{i-1} that contains all copies of v. Therefore, v_Q is connected to a copy of v that belongs to BL_u. It remains to be shown that v_Q is not connected to a nonattachment vertex of a bridge other than BL_u. Consider the $lca(u, v)$ in $\overrightarrow{T}$. If $lca(u, v) \neq u$, then u_Q is connected to u_P by Step 2. Otherwise, by Lemma 3.12 the tree path in $\overrightarrow{T}$ from v to u consists of edges of either P or the ears from $\mathcal{E}(BL_u)$. Therefore, u_Q is connected to u_P or u_W, where $W \in \mathcal{E}(BL_u)$. □

3.2. Reduction to biconnected components. We briefly alluded to reducing triconnectivity to biconnectivity at the beginning of §3. We elaborate more on this reduction here. In this subsection we show how to find a collection similar to $\mathcal{H}$ that encodes separating pairs. There are two reasons for finding a collection that is only similar to $\mathcal{H}$ and that is not $\mathcal{H}$ itself as defined before. The first reason is that the new collection suffices for our purposes, and the second reason is that it can be computed by an easy reduction to any biconnected component algorithm.

Recall the definition of $\mathcal{H}$ from Definition 2; it consists of a graph H_P for each nontrivial ear P. We slightly change the definition of H_P because it is difficult to efficiently check for $v \in V(P)$ if the bridge of P containing the root r is adjacent to v.

DEFINITION 9. The graph H_P is defined as in Definition 2 with the following modification to part (i) of that definition. We say that (v, r_P) is added to $E(H_P)$ if v is adjacent to w and w belongs to an irrelevant bridge of P.

Even though the resulting collection is slightly different, we will continue to denote it by $\mathcal{H}$. Let us see whether this new definition of graph H_P also encodes the set of separating pairs of G. If the bridge containing w also contains the root r, then the new rule results in the same H_P. Otherwise, the bridge containing w must necessarily have attachments at x and y by Proposition 3.10. Therefore, we would have added (v, x) and (v, y) to $E(H_P)$ instead of (v, r_P). A pair of vertices of P that is not a separating pair before would not be a separating pair now. The converse also holds except for the pair $\{x, y\}$. In this case notice that we would detect $\{x, y\}$ as a separating pair on H_Q, where

$\{x, y\}$ separates Q. This is true because by Definition 1 all vertices of $Q(x, y)$ are adjacent to vertices of bridges of Q relevant to Q. Therefore, the edges added to $E(H_Q)$ for the vertices of $Q(x, y)$ are identical irrespective of whether the old or new rule is used.

Next we show how to build $\mathcal{H}$ by a reduction to biconnected components. The biconnected component algorithm is run on a multigraph G_e (the subscript e to indicate that G_e is built from the ears of G') constructed from G' and its ears.

DEFINITION 10. Let P' be a nontrivial ear $\langle v_0, v_1, \ldots, v_k\rangle$ of length greater than two, i.e., $k \geq 3$. The graph G_e is obtained from G' by contracting all such ears P' by merging the internal vertices $v_1, v_2, \ldots, v_{k-1}$ into a single vertex p.

Figure 7 shows the multigraph G_e for the local replacement graph and its ear decomposition shown in Fig. 6. Recall that the representative (say, P) of a bundle of parallel ears is the ear of that bundle with the smallest label. Observe that the end vertices P belong to a lower-numbered ear that is not parallel to P. This observation together with the definition of open ear decomposition imply the following simple fact.

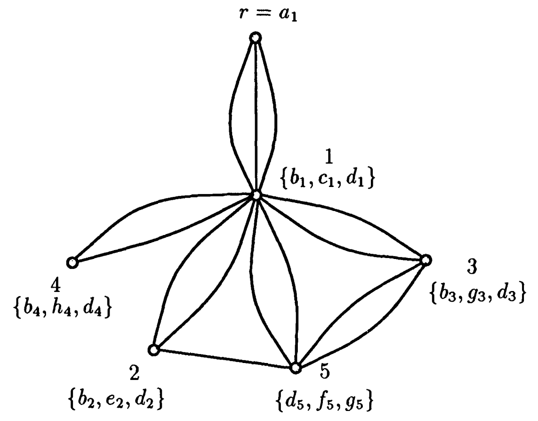

FIG. 7. *The multigraph G_e based on G' of Fig. 6.*

PROPOSITION 3.14. *If D is a biconnected component of G_e, then the vertex of D with the minimum label is either r or an articulation vertex of G_e.*

There is a correspondence between the relevant bridges of P_{xy} in G, the bridges of $P'[x_P, y_P]$ in G', and the connected components resulting from deleting p from G_e. The relation between the latter two is simple: from the definition of G_e it follows that the ears Q and R are in the same bridge of $P'[x_P, y_P]$ in G' if and only if q and r are in the same component in $G_e - \{p\}$. The relation between the attachments of the bridges of P in G and those of the bridges of $P'[x_P, y_P]$ in G' is stated below.

THEOREM 3.15. *Let B_q denote the bridge of $P_{\vec{xy}}$ in G that contains Q. Similarly, denote the bridge of P' in G' that contains Q' by BL_q.*

(i) *B_q is relevant to P if and only if BL_q has no attachments at the end vertices of P' in G'.*

(ii) *Assume that B_q is relevant to P. Then B_q has an attachment at v if and only if BL_q has an attachment at v_P.*

Proof. (i) Assume that B_q is a relevant bridge for P. Then by an inductive proof similar to the one used to show part (ii) of Theorem 3.13 the attachments of BL_q are from $P'[x_P, y_P]$. The invariant that should be maintained at all times is that if Q belongs to a relevant bridge, then the bridge of P' containing Q' in D_i has all its attachments on $P'[x_P, y_P]$.

Assume that B_q is not a relevant bridge. We will show that BL_q has attachments at the end vertices of P' in G'. There are two kinds of irrelevant bridges: the ones that have an ear whose number is less than P and the ones that have an ear parallel to P from a different bundle in G.

Case 1. Assume that B_q has an ear whose number is less than P. Then BL_q contains an ear whose number is less than P' by Theorem 3.13(i).

Case 1a. Assume, in addition, that BL_q contains an ear parallel to P from the same bundle as P. Then from the construction of Step 3(b) it follows that BL_q has attachments at the end vertices of P'.

Case 1b. Assume that ears of BL_q parallel to P are not from the same bundle as P. Consider the subgraph of G' consisting of P', the ears of BL_q that have no other ears parallel to them, plus the representative from each bundle of parallel ears that belongs to BL_q. Clearly, this subgraph is biconnected and the labels on the ears define an open ear decomposition. Therefore, by Proposition 3.10 BL_q has attachments at the end vertices of P'.

Case 2. Assume that B_q is an irrelevant bridge because it contains an ear S parallel to P such that P and S are in different bundles. Assume without loss of generality that S is the representative of its bundle. By Proposition 3.8 the end vertices of S' and the end vertices of the representative of the bundle of P' are the same. Therefore, BL_q has attachments at the end vertices of P'.

(ii) Assume that BL_q has an attachment at v_P and that this attachment belongs to an ear S' of BL_q. Since B_q is a relevant bridge, by part (ii) of Theorem 3.13, $S \in \mathcal{E}(B_q)$. By Proposition 3.7, $v \in V(S)$. Therefore, B_q has an attachment at v.

Consider the "only if" direction of the theorem. Let $S_{\overrightarrow{vw}}$ denote the ear from the bridge B_q with the least label that has an attachment at v. Then if $lca(v,w) \neq v$ in $\vec{T}$, then by Lemma 3.11 v is an internal vertex of P. Therefore, by Step 2(c), v_S is attached to v_P. Otherwise, i.e., if $lca(v,w) = v$, then by Lemma 3.12 the tree path from u to v consists of the edges from either P or the ears of B_q with a label less than S. Because there are no ears of B_q less than S incident on v, the tree path must end with the edges of P. Hence, by Step 2 v_S is attached to the vertex v_P. □

Part (ii) of Theorem 3.15 implies the following.

COROLLARY 3.16. *$\{x,y\}$ is a separating pair that separates P in G if and only if $\{x_P, y_P\}$ separates P' in G'.*

Proof. Consider the bridges BL_q of $P'[x_P, y_P]$ in G'. If $\{x_P, y_P\}$ separates P' in G', then the corresponding bridges B_q in G are relevant to P by the reverse direction of (i). Therefore, the reverse direction of the corollary follows from part (ii) of Theorem 3.15 and from Theorem 2.3. The argument for the forward direction is similar. □

We exploit this correspondence in building $\mathcal{H}$. The nontrivial part in building H_P is in identifying which edges, if any, to add for a vertex v of $P[x,y]$. This involves knowing the extreme attachments of the relevant bridges of P adjacent to v. If there are any bridges of P that are relevant, then p would be an articulation vertex in G_e; each block D of G_e attached to p that does not contain r' corresponds to a relevant bridge of P. Therefore, we give a common label, called α label, to all vertices (except p) of each such block D of G_e. This α label is a 3-tuple $\langle P, a, b\rangle$: a and b are the *pos* labels of the extreme attachments of the bridge of P that correspond to D, and the first tuple reflects the fact that these attachments are on P. We will denote the first, second, and the third tuples of $\alpha(q)$ by $\alpha(q).1$, $\alpha(q).2$, and $\alpha(q).3$, respectively.

It turns out that the α labeling can be computed efficiently by a slight modification of any biconnected component algorithm as shown below. Given α labeling, the edges that need to be added to build H_P can be figured out quite easily.

ALGORITHM. *Build $\mathcal{H}$.*
Input: A graph G, an open ear decomposition of G, *pos* labeling for each ear, and the local replacement graph G' for that decomposition.
Output: A collection of graphs $\mathcal{H}$ (built on the top of each nontrivial ear of G) that encode separating pairs succinctly.

1. Build a multigraph G_e from G' by merging the internal vertices of each nontrivial ear P' into a single vertex p. Discard the self loops from G_e.
2. Find the biconnected components $D_1, D_2, \ldots, D_k$ of G_e.
3. Label the vertices of G_e with 3-tuples:
   For each D_i do the following. Let p be the vertex of D_i with the smallest label. For each $q \in V(D_i) - \{p\}$ set the first component of $\alpha(q)$ to P. Of all edges ps of D_i incident on p, consider those that have an image, say, cd, in G. Assume $c \in V(P)$ (see Fig. 8). Let a and b the minimum and the maximum, respectively, of the *pos* labels of all such c. Then a and b are the second and third components of $\alpha(q)$.

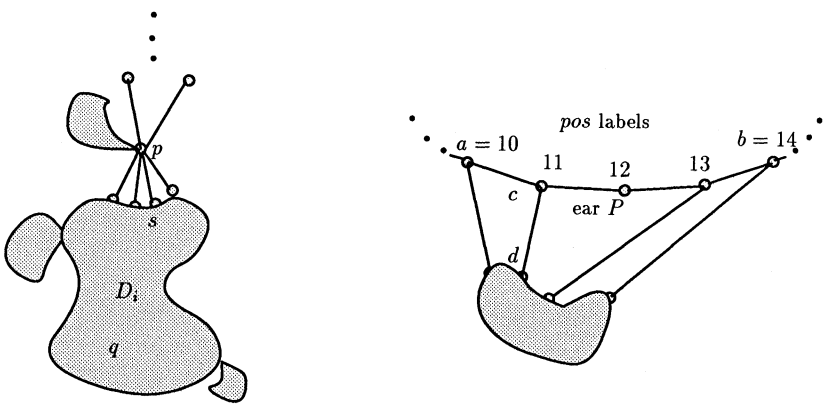

FIG. 8. *Illustration of Step* 3 *of Build $\mathcal{H}$.*

4. Build H_P for each nontrivial ear P by using the α labels:
   (a) Assign $V(H_P) = V(P) \cup \{r_P\}$.
   (b) Initialize $E(H_P) = E(P)$. For every vertex $v \in V(P)$ add the following edges. For an edge $vw \in E(G)$, $w \notin V(P)$, denote $ear(w)$ by Q.
      (i) If $\alpha(q).1$ is less than P, then add (v, r_P) to $E(H_P)$. Otherwise, add two edges as shown in the next step.
      (ii) Let a be such that $pos(a) = \min\{\{\alpha(q).2 | ear(w) = q \text{ and } vw \in E(G), w \notin V(P)\} \cup \{pos(w) | vw \in E(G) \text{ and } v, w \in V(P)\}\}$. Add (v, a) to $E(H_P)$. Also, add (v, b), where b is obtained similarly by using max and $\alpha(q).3$.

LEMMA 3.17. *Consider an ear P and an edge $vw \in E(G)$, $w \notin V(P)$, where v is an internal vertex of P. Let $ear(w)$ be Q. Then if the bridge B_q of P containing Q contains no ear number less than P, then $\alpha(q).1 = P$.*

Proof. If B_q contained ears parallel to P, then they would have to be in the same bundle with P because of the edge vw. Therefore, B_q is a relevant bridge of P. Now it follows from part (i) of Theorem 3.15 that the bridge containing Q' would have all its attachments on the internal vertices of P'. Then p would be an articulation vertex that is on every path between q and the root vertex r in G_e. Therefore, $\alpha(q).1 \geq P$. But p and q are in the same block because the edge vw of G causes an edge between p and q in G_e. Hence, $\alpha(q).1 = P$. □

THEOREM 3.18. *Algorithm Build $\mathcal{H}$ computes $\mathcal{H}$ as defined in Definition* 9.

Proof. Consider an ear $P_{\overrightarrow{xy}}$ and an internal vertex v of P. We need to argue that the construction carried out in Step 4 is correct. Suppose there is an edge $vw \in E(G)$, $w \notin V(P)$. Denote $ear(w)$ by Q. Denote the bridge of P containing Q by B_q and the $\min\{\mathcal{E}(B_q)\}$ by N. Note that regardless of whether vw is a trivial ear or one of the end edges of Q, it causes an edge to be added between p and q in G_e. Therefore, there is a block that contains both p and q.

According to Definition 9 the edge (v, r_P) is added to $E(H_P)$ if and only if N is less than P. Consider the construction in Step 4. We claim that $N < P$ if and only if $\alpha(q).1$ is less than P. To prove the forward direction of the claim, we need to prove that the block D of G_e containing p and q contains an articulation vertex m such that $M < P$. By Proposition 3.14 it is sufficient to show that p is not the articulation vertex in D with the smallest label. Because $N < P$, the bridge B_q is irrelevant to P. Now if p is an articulation vertex that appears on every path from q to the root r', then BL_q of P' containing Q' in G' has all its attachments on $P[x_P, y_P]$. This contradicts part (i) of Theorem 3.15. Hence p cannot be the articulation vertex with the smallest label in D. Consider the reverse direction. Assume for contradiction that $\alpha(q).1$ less than P but that $N \geq P$. Clearly, $N \neq P$ because N belongs to a bridge of P. But if $N > P$, then, from Lemma 3.17, $\alpha(q).1$ is exactly P and is not less than P.

Next consider the case in which there is an edge $vw \in E(G)$, $w \notin V(P)$, but for all such edges $\alpha(q).1$ is not less than P. By the claim of the previous paragraph if $\alpha(q).1$ is not less than P, then $N > P$. Therefore, by Lemma 3.17, $\alpha(q).1 = P$. That is, every bridge of P' with an attachment at v has all its attachments on $P'[x_P, y_P]$. Because of the edge vw, each such bridge B_q is a relevant bridge of P. Therefore, by part (ii) of Theorem 3.15 the attachments of BL_q on P' are identical to the attachments of B_q on P. From the definition of G_e the attachments of B_q become the edges of G_e incident on p where these edges belong to the block containing q. The attachments of B_q that are closest to x and y are reflected in the second and third tuples of $\alpha(q)$, as computed in Step 3. Therefore, Step 4(b)(ii) computes the $E(H_P)$ as defined in part (ii) of Definition 2. □

3.3. Extraction and output representation of separating pairs. Observe that in $O(m+n)$ time we cannot possibly list all separating pairs of a graph because there could be $O(n^2)$ of them. For example, in a simple cycle every pair of nonadjacent vertices is a separating pair. That is, a cycle of n vertices has $n(n-3)/2$ separating pairs. Our output representation is a set of paths referred to as candidate lists such that a pair of vertices $\{u, v\}$ separates P if and only if u and v are nonadjacent on P and there is a candidate list generated from H_P that contains u and v. Such a representation of separating pairs is sufficient to divide a graph into triconnected components.

Let us reexamine the graph H_P of $\mathcal{H}$ from §3.2. Assume that H_P happens to be planar and that it is drawn in the plane as shown in Fig. 9, i.e., P appears as a horizontal line and all its bridges in H_P are drawn on the top. (This embedding will henceforth be referred to as a *canonical* embedding.) Then an important, but easy to see, observation that follows from Theorem 2.3 is that a pair of vertices x and y separates P if and only if a bounded region in the canonical embedding of H_P contains x and y. This fact can be used quite effectively in producing candidate lists as demonstrated below.

ALGORITHM. *Find Candidate Lists.*
Input: A collection of planar graphs encoding separating pairs.
Output: A set of paths, called candidate lists, encoding separating pairs. The output representation is a linked list.

```
1. For every bridge $B$ of $P$ in $H_P$ that does not contain $r_P$ let $u$ and $v$, respectively,
   be the attachments of $B$ with the minimum and maximum $pos$ value and do the
   following:
   (i) Output the edge $(u, v)$.
   (ii) If $v$ is not adjacent to $r_P$ in $H_P$ and if the furthest vertex to the left that is
        reachable from $v$ through a bridge is $u$, then perform this step. Let $w$ be
        the furthest vertex to the right that is reachable through a bridge adjacent
        to $v$. Add a pointer from the output location of $(u, v)$ to that of $(v, x)$,
        where $x = w$ if $w \neq v$; otherwise, $x$ is the successor of $v$ on $P$ (see Fig. 9).
2. For every edge $(a, b)$ of $P, pos(a) < pos(b)$, that is not part of a triangular region
   do the following:
   (i) Output the edge $(a, b)$.
   (ii) If the furthest vertex to the left that is reachable from $b$ through a bridge
        is $b$, then perform this step. Let $c$ be the furthest vertex to the right that is
        reachable through a bridge adjacent to $b$. Add a pointer from the output
        location of $(a, b)$ to that of $(b, d)$, where $d = c$ if $c \neq b$; otherwise, $d$ is the
        successor of $b$ on $P$ (see Fig. 9).
```

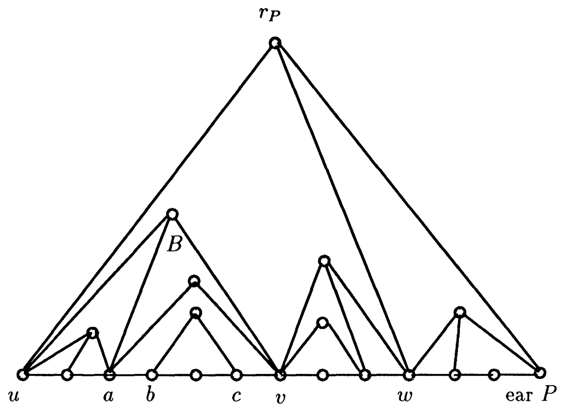

FIG. 9. *Generating candidate sets from a planar I_P.*

In the rest of this subsection we show how to take a nonplanar H_P and produce a planar graph I_P on the same set of vertices such that the set of separating pairs of H_P and that of I_P are identical. We will denote the resulting planar collection by $\mathcal{I}$. The process of planarizing H_P involves coalescing interlacing bridges. Call a pair of bridges B_1 and B_2 of P interlacing bridges if two of the attachments of B_1 and B_2 are at x, y and u, v, respectively, such that $pos(x) < pos(u) < pos(y) < pos(v)$. The operation of coalescing is to discard the bridges B_1 and B_2 and to put in a new, single bridge whose attachments are a union of the attachments of B_1 and B_2. A nice property of the operation of coalescing that follows from Theorem 2.3 is that it preserves the set of separating pairs. Now if bridges of H_P are coalesced until no more bridges are interlacing, then the resulting graph is planar; this fact can easily be proved by constructing a canonical embedding of the resulting graph. Denote the resulting planar graph by I_P.

In the following we give a fast parallel algorithm for finding $\mathcal{I}$. At a high level the algorithm reduces the problem of planarizing H_P to that of finding connected components of a graph G_b. The vertices of G_b correspond to bridges of P. Two vertices b_1 and b_2 of G_b are in the same connected components if and only if the bridges corresponding to the two vertices B_1 and B_2 are interlacing. In constructing G_b if we add edges between b_1 and all vertices whose corresponding bridges in H_P interlace with B_1, then there could be far too many edges in G_b (as many as $O(n^2)$). The trick is to add at most two edges per vertex. Add (b_1, b_2) (respectively, (b_1, b_3)) where B_2 (respectively, B_3) interlaces B_1 and furthermore, is the bridge with an attachment that is furthest to the left (respectively, right) with respect to the leftmost (respectively, rightmost) attachment of B_1. The following argument shows that this trick does not alter the connected components of G_b. Consider a proof by contradiction. Let $B_1 = (s, t)$ be the rightmost bridge (i.e., highest $pos(t)$ value) with an interlacing bridge $B_2 = (u, v), pos(u) < pos(s) < pos(v) < pos(t)$, such that $(b_1, b_2) \notin E(G_b)$. Then by our construction there must exist (b_2, r_1) and (b_1, l_1) in G_b where the bridges $R = (a, b)$ and $L = (c, d)$ interlace with B_2 and B_1, respectively. Furthermore, R and L are such that $pos(d) < pos(u)$ and $pos(b) > pos(t)$. Now since R interlaces with B_2, $a \in P(u, v)$. If $a \in P(s, v)$, then R and B_1 interlace. Because we assumed that B_1 is the rightmost bridge that belongs to a "bad" interlacement pair, we can conclude that $(r, b_1) \in E(G_b)$. On the other hand, if $a \in P(u, s)$, R and L interlace and $(r, l) \in E(G_b)$. In either case b_1 and b_2 belong to the same connected component in G_b, a contradiction.

We summarize the ideas below.

ALGORITHM. *Planarize $\mathcal{H}$.*
Input: The collection $\mathcal{H}$ of graphs encoding separating pairs of G.
Output: A collection $\mathcal{I}$ of planar graphs encoding separating pairs of G succinctly.

```
1. For each $H_P$ build a graph $G_b$ based on the bridges of $P_{xy}$ in $H_P$ that do not
   contain $r_P$. These bridges are all single edges $(u, v)$.
   (i) For each such $(u, v)$ create a vertex in $G_b$ denoted by the 2-tuple $\langle u, v\rangle$.
   (ii) Find the bridge $(a, b)$ (respectively, $(c, d)$) with one attachment on $P(u, v)$
        and the other furthest to the left (respectively, right) from $u$ (respectively,
        $v$) on $P[x, u)$ (respectively, $P(v, y]$).
   (iii) Add an edge between $\langle u, v\rangle$ and $\langle a, b\rangle$, and between $\langle u, v\rangle$ and $\langle c, d\rangle$ in $G_b$.
2. Find the connected components $C_1, C_2, \ldots, C_k$ of $G_b$.
3. Build $I_P$ by using the connected components of $G_b$.
   (i) $V(I_P) = V(H_P) \cup \{c_i | C_i \text{ is a component of } G_b\}$.
   (ii) $E(I_P) = E(P)$. Add the edges incident on $r_P$ to $E(I_P)$. In addition,
        include the following edges. Add $(c_i, u)$ if there a vertex in $C_i$ with $u$ as
        one of the 2-tuples in its label.
```

3.4. Complexity on a CRCW PRAM. The results of the previous subsections show that the following algorithm generates all separating pairs (as candidate lists) of a given biconnected graph G.

ALGORITHM. *Separating Pairs.*

```
1. Find an open ear decomposition of $G$.
2. Construct the local replacement graph $G'$ by executing *Build $G'$*.
```

3. Succinctly encode separating pairs by using *Build* $\mathcal{H}$.
4. Use *Planarize* $\mathcal{H}$ and obtain the collection $\mathcal{I}$.
5. Generate separating pairs as candidate lists by invoking *Find Candidate Lists* with $\mathcal{I}$ as its input.

The most expensive step of the above algorithm from the deterministic complexity point of view is providing the required input representations to some of the subroutines we use and building the adjacency lists of the auxiliary graphs. First, we show how to construct the needed representation of graphs by assuming that the input is a list of edges. This construction runs in $O(\log n)$ time with $((m+n)\log\log n)$ work. The needed representation is a special kind of adjacency list. In this representation every edge (u, v) appears as two directed edges $\langle u, v\rangle$ and $\langle v, u\rangle$, i.e., the vertices u and v appear in each other's adjacency lists. Given a list of edges, we can accomplish this by (1) sorting the edges to make sure that no edge appears twice initially, (2) creating $\langle v, u\rangle$ for every $\langle u, v\rangle$, (3) evaluating the degree of each vertex v by using the difference in the addresses in the sorted array of the first occurrence and last occurrence of v, (4) allocating in memory one array of size degree(v) for each v, and (5) making the processor allocated to (u, v) responsible for creating the entry in the list of u. We use the parallel bucket-sort algorithm of Hagerup [10], which runs in $O(\log n)$ time with $(n\log\log n)$ operations to sort n numbers to achieve the desired complexity.

In the remainder of this subsection we argue that the complexity of the rest of the algorithm is identical to that of the best-known parallel connected component algorithm.

Let G have n vertices and m edges. We say an algorithm has an "almost-optimal" processor–time bound if it runs in $O(\log n)$ parallel time with $O((m+n)\alpha(m,n)/\log n)$ processors on a CRCW PRAM, where α is the inverse Ackermann function. We first note the following results on optimal and almost-optimal parallel algorithms.

(A) List ranking on n elements can be performed optimally in $O(\log n)$ time on an Exclusive Read Exclusive Write (EREW) PRAM [3].

(B) Connected components and the spanning tree of an n-node, m-edge graph can be found in $O(\log n)$ time with $O((m+n)\alpha(m,n)/\log n)$ processors on an arbitrary-CRCW PRAM [3] provided that the input is presented as an adjacency list.

(C) Least common ancestors of k pairs of vertices in an n-node tree can be found in $O(1)$ time with k processors after $O(\log n)$ time preprocessing with $O(n/\log n)$ processors on an EREW PRAM by using the algorithm in [23].

(D) The Euler-tour technique on trees of [24] can be implemented optimally in $O(\log n)$ time with $O(n/\log n)$ processors on an EREW PRAM by using (A).

(E) Using the above-mentioned results as subroutines, we obtain an almost-optimal parallel algorithm for finding an open ear decomposition from the algorithm in [15], [17], for finding biconnected components from the algorithm of [24], and for finding an st-numbering in a biconnected graph from the algorithm of [15].

We will refer to the above five results while describing the processor-time complexity of the *Separating Pairs* algorithm.

Step 1 can be performed by using (E).

Consider Step 2. The digraphs $\overrightarrow{G}$, $\overrightarrow{T}$, $\overleftarrow{G}$, and $\overleftarrow{T}$ can be constructed in $O(\log n)$ time with an almost-optimal processor–time bound by using the st-numbering algorithm of (E). Splitting and renaming can be achieved by making the vertex labels a 2-tuple: the first component representing the vertex label and the second representing the ear label of the edge that is incident on that vertex. We can implement this in constant time per split node. The processors assigned to the end edges of each ear can be made responsible for adding the edge to attach that ear. The lca values of nontree edges can be computed optimally by (C). Step 3(a) of *Build G'* identifies the bundles of parallel ears. Let us analyze its complexity. For building G_p the processor assigned to the last edge (a, b) of each ear examines the ear labels of the two edges incident on the $lca(a, b)$ in the fundamental cycle created by including (a, b) in $\overrightarrow{T_l}$. Let the ear labels be P and Q. Next, it checks to see if P and Q have identical pair of end vertices. If so, an edge is added in G_p between p and q. Now using the connected component algorithm of (B) we can implement Step 3(b) of *Build G'*. This leads to an algorithm for implementing *Build G'* that runs in $O(\log n)$ time and has an almost-optimal processor–time bound.

Let us examine the complexity of *Build $\mathcal{H}$*. The *pos* labeling can be computed optimally in $O(\log n)$ time with the Euler-tour technique by using (D). The auxiliary multigraph G_e can be constructed as follows. The vertex set is easy to create. The processor assigned to the first edge of an ear R does the following. (i) It finds the end vertices u and v of that ear. (ii) It also finds the ears P and Q, where $p = ear(u)$ and $Q = ear(v)$, and the values $pos(u, P)$ and $pos(v, Q)$. Assume that the vertices corresponding to P, Q, and R in G_e are p, q, and r, respectively. Finally, (iii) it creates edges (p, r) and (r, q) and labels these edge with a 2-tuple $\langle pos(u, P), pos(v, Q)\rangle$.

The α labeling of the vertices of G_e consists of the following steps. Find the blocks of G_e by using (E). Treat each block D separately, and construct a spanning tree T_b in each block by using (B). The articulation vertex q with the smallest label in a block D can be found optimally by using the Euler-tour technique. That gives us the first component of α, i.e., Q. The values a and b can be found by examining the 2-tuple labels of the edges of D incident on q. These values are broadcast to all the vertices in the block D by again using the Euler-tour technique. Finally, building H_P involves computing the minimum and maximum of the labels of edges incident on a vertex. This can be done optimally in $O(\log n)$ time by using (A).

In *Planarize $\mathcal{H}$* the only nontrivial step is the construction of the G_b. It involves the identification of the arcs (a, b) and (c, d) for each arc (x, y). An optimal algorithm for this problem is given in [1] (this problem is also known as the range-minima problem). I_P can be built by an easy reduction to the connected components.

Finally, *Find Candidate Lists* requires computing the minimum and the maximum of the labels of edges incident on a vertex. This can be done optimally in $O(\log n)$ time by using (A).

4. Algorithm for finding triconnected components.

We start with some definitions.

Let $G = (V, E)$ be a biconnected graph, and let Q be a subgraph of G. We define the *bridge graph of* $Q, S = (V_S, P_S)$ as follows (this is a little modified from the usual definition in [5], [18], and [21]). Let the bridges of Q in G be B_i, $i = 1, \dots, k$. Then $V_S = V(Q) \cup \{B_1, \dots, B_k\}$ and $P_S = E(Q) \cup \{\text{edge } (v, B_i) \text{ for each edge } (v, w) \in B_i \text{ with } w \in V(Q), 1 \le i \le k\}$. Note that S is a *multigraph*, i.e., a graph in which there can be several edges between the same pair of vertices. Each $B_i \in V_S$ together with the edges incident on B_i is a bridge of Q in S.

A *star* is a connected graph with a vertex v such that every edge in the graph is incident on v. A *star graph* $G(P)$ is a graph G consisting of a simple path P, each of whose bridges is a star. Thus if Q is a simple path in G, then S, the bridge graph of Q, is a star graph. Let B be a star in a star graph $G(P)$, where for convenience let $P = \langle 0, \dots, k-1\rangle$. Let the attachments of B on P be $v_0, \dots, v_j$, with $v_0 < v_1 < \cdots < v_j$. Then the vertices v_0 and v_j are the *end attachments* of B, and the remaining attachments are its *internal attachments.* We will also refer to v_0 as the *left attachment* of B and to v_j as its *right attachment.* The closed interval $[v_0, v_j]$ is the *span* of B, and it contains all of the vertices on P between v_0 and v_j (both vertices inclusive).

We now review some material from [11], [18], and [25] relating to triconnected components. This material deals with multigraphs. An edge e in a multigraph is denoted by (a, b, i) to indicate that it is an edge between a and b; here i is the label that distinguishes e from the other edges between a and b. The third entry in the triplet may be omitted for one of the edges between a and b.

A pair of vertices a, b in a multigraph $G = (V, E)$ is a separating pair if and only if there are either two nontrivial bridges or at least three bridges, one of which is nontrivial, of $\{a, b\}$ in G. If G has no separating pair, then G is triconnected. The pair a, b is a *nontrivial* separating pair if there are two nontrivial bridges of $\{a, b\}$ in G.

Let $\{a, b\}$ be a separating pair for a biconnected multigraph $G = (V, E)$. For any bridge X of $\{a, b\}$ let $\bar{X}$ be the induced subgraph on $(V - V(X)) \cup \{a, b\}$. Let B be a bridge of G such that $|E(B)| \geq 2$, $|E(\bar{B})| \geq 2$, and either B or $\bar{B}$ is biconnected. We can apply a *Tutte split* [11], [25] $s(a, b, i)$ to G by forming G_1 and G_2 from G, where G_1 is $B \cup \{(a, b, i)\}$ and G_2 is $\bar{B} \cup \{(a, b, i)\}$. Here i is an index that distinguishes this split from other splits that may be performed at the separating pair $\{a, b\}$. Note that we consider G_1 and G_2 to be two separate graphs. Thus it should cause no confusion that there are two edges (a, b, i) since one of these edges is in G_1 and the other is in G_2. The graphs G_1 and G_2 are called the *split graphs of G with respect to* $\{a, b\}$. The *Tutte components* of G are obtained by successively applying a Tutte split to split graphs until no Tutte split is possible. Every Tutte component is one of three types: (i) a triconnected simple graph, (ii) a simple cycle (a *polygon*), or (iii) a pair of vertices with at least three edges between them (a *bond*); the Tutte components of a biconnected multigraph G are the unique *triconnected components* of G. In this section we give an $O(\log n)$-time parallel algorithm whose processor-time bound is almost optimal to find the triconnected components of G corresponding to triconnected simple graphs and polygons. The bonds can be inferred, if necessary, by counting the number of triconnected components with respect to each separating pair.

Let $G = (V, E)$ be a biconnected graph with an open ear decomposition $D = [P_0, \ldots, P_{r-1}]$. When referring to vertices on a specified ear P_i or on a path P, we assume for convenience that they are numbered in sequence from one end vertex of the path (its *left-end vertex*) to the other (its *right-end vertex*). Let $\{a, b\}$ be a pair separating P_i. Let $B_1, \ldots, B_k$ be the bridges of P_i with no attachments outside the interval $[a, b]$ on P_i, and let $T_i(a, b) = (\cup_{j=1}^{k} B_j) \cup P_i(a, b)$, where $P_i(a, b)$ is the segment of P_i between and including vertices a and b. Then the *ear split* $e(a, b, i)$ consists of forming the *upper split graph* $G_1 = T_i(a, b) \cup \{(a, b, i)\}$ and the *lower split graph* $G_2 = \bar{T}_i(a, b) \cup \{(a, b, i)\}$. An ear split $e(a, b, i)$ is a Tutte split if either $G_1 - \{(a, b, i)\}$ or $G_2 - \{(a, b, i)\}$ is biconnected.

Let S be a nontrivial candidate list for ear P_i. Two vertices u, v in S are an *adjacent separating pair for P_i* if u and v are not adjacent to each other on P_i and S contains no vertex in the interval (u, v) on P_i. Two vertices a, b in S are an *extremal separating pair for P_i* if $|S| \geq 3$ and S contains no vertex in the interval outside $[a, b]$. An ear split on an adjacent or extremal separating pair is a Tutte split, and the Tutte components of G are obtained by performing an ear split on each adjacent and extremal separating pair [18].

With each ear split $e(a, b, i)$ corresponding to an adjacent or extremal pair separating P_i, we can associate a unique Tutte component of G as follows. Let $e(a, b, i)$ be such a split. Then by definition $T_i(a, b) \cup \{(a, b, i)\}$ is the upper split graph associated with the ear split $e(a, b, i)$. The *triconnected component of the ear split* $e(a, b, i)$, denoted by $TC(a, b, i)$, is $T_i(a, b) \cup \{(a, b, i)\}$ with the following modifications: call a pair $\{c, d\}$ separating an ear P_j in $T_i(a, b)$ a *maximal pair for* $T_i(a, b)$ if there is no e, f in $T_i(a, b)$ such that $\{e, f\}$ separates some ear P_k in $T_i(a, b)$ and c and d are in $T_k(e, f)$. In $T_i(a, b) \cup \{(a, b, i)\}$

replace $T_j(c,d)$ together with all two-attachment bridges with attachments at c and d, for each maximal pair $\{c,d\}$ of $T_i(a,b)$, by the edge (c,d,j) to obtain $TC(a,b,i)$. We denote by $TC(0,0,0)$ the unique triconnected component that contains a specified edge on P_0.

We note that $TC(a,b,i)$ as defined above is a triconnected component of G since each split of $T_i(a,b)$ in the above definition is a valid Tutte split, and the final resulting graph contains no unprocessed separating pair. Furthermore, we also note that every triconnected component of G appears as $TC(a,b,i)$ for some adjacent or extremal separating pair. This is seen as follows. Let T be a triconnected component of G. By the results in [18] we know that T can be obtained by a sequence of ear splits at adjacent and extremal pairs separating ears in the open ear decomposition D of G. Since the order of processing these ear splits is arbitrary, let us consider a sequence in which these splits are performed in nonincreasing order of ear number. In this case every upper split graph formed at the end of processing ear P_i must be a triconnected component since it will contain no unprocessed separating pairs. Let P_i be the lowest-numbered ear that contains a separating pair whose copies are present in T, and let $e(a,b,i)$ be the last ear split performed in the generation of T. Then clearly $T = TC(a,b,i)$.

In our parallel algorithm we will make the collection of splits S_1 corresponding to adjacent separating pairs simultaneously, followed by the collection of splits S_2 for extremal separating pairs. We will call each component present after completion of splits in S_1 an *adjacent triconnected component* and will denote it by $TC_A(a,b,i)$. Since the virtual edges corresponding to the splits will be inserted by concurrent writes, we will have only one copy of each such edge between a given pair of vertices. Hence we will not generate the triconnected components corresponding to bonds. These can be inferred, if necessary, by counting the number of triconnected components of the other two types that are present at each separating pair.

The rest of this section is devoted to describing an algorithm for performing these operations. We first review some further material from [18] and [21].

Let G be a biconnected graph with an open ear decomposition $D = [P_0, \dots, P_{r-1}]$. Let $B_1, \dots, B_l$ be the bridges of P_i that contain a nonattachment vertex on an ear numbered lower than i; we call these the *anchor bridges of* P_i. The *ear graph of* P_i, denoted by $G_i(P_i)$, is the graph obtained from the bridge graph of P_i by the following operations:

(a) Replace all of the anchor bridges by a new star whose attachment edges are the union of the internal attachment edges of all anchor bridges, delete the attachments of anchor bridges to the end vertices of P_i, and replace them by one new edge to each end vertex. We will call this new star the *anchoring star* of $G_i(P_i)$.

(b) Remove any multiple two-attachment bridges with the same two attachments, and also remove any two-attachment bridge with the end vertices of P_i as attachments.

Note that $G_i(P_i)$ is a multigraph. (This definition of ear graph is slightly modified from that in [18] and [21] to reflect the change made in the definition of a bridge graph.) $G_i(P_i)$ is also a star graph.

Two stars S_j and S_k in a star graph $G(P)$ *interlace* (see also [5, p. 149]) if one of the following holds:

1. There exist four distinct vertices a, b, c, d in increasing order in P such that a and c belong to $S_j(S_k)$ and b and d belong to $S_k(S_j)$.

2. There are three distinct vertices on P that belong to both S_j and S_k.

The operation of *coalescing* two stars S_j and S_k is the process of forming a single new star S_l from S_j and S_k by combining the attachments of S_j and S_k and deleting S_j and S_k. Given a star graph $G(P)$, the *coalesced graph* $G_c(P)$ of $G(P)$ is the graph obtained from G by coalescing all pairs of stars that interlace. Note that $G_c(P)$ is a star graph with respect to P and that $G_c(P)$ has a planar embedding with P on the outer face since no pair of stars interlace on P.

Let $G(P)$ be a star graph in which no pair of stars interlace. If $G(P)$ contains no star that has attachments to the end vertices x and y of P, then add a virtual star X to $G(P)$ with attachments to x and y. The *star embedding* $G^*(P)$ of $G(P)$ is the planar embedding of (the possibly augmented) $G(P)$ with P on the outer face. A star B is the *parent-star* of star B' and B' a *child-star* of B if there is a face in the star embedding $G^*(P)$ that contains the left and right attachments x and y of B' as well as an attachment edge of B in each of the intervals $[l,x]$ and $[y,r]$, where l and r are the left and right end vertices of P.

The following lemma is shown in [18].

LEMMA 4.1. *A pair $\{a,b\}$ separates P_i in the coalesced graph $G_{i_c}(P_i)$ if and only if $\{a,b\}$ separates P_i in G.*

We will use the following corollary to Lemma 4.1.

COROLLARY 4.2. *An edge (x,y) incident on P_i is in $TC(a,b,i)$ if and only if (x,y) is in the triconnected component associated with pair $\{a,b\}$ separating P_i in $G_{i_c}(P_i)$.*

Proof. Let $C_i(P_i)$ be the bridge graph of P_i, and let $C_{i_c}(P_i)$ be its coalesced graph. A straightforward extension of the proof of Lemma 4.1 given in [18] shows that an edge incident on P_i is in $TC(a,b,i)$ if and only if it is in the triconnected component associated with the pair $\{a,b\}$ separating P_i in $C_{i_c}(P_i)$. We then observe that the edges of $C_i(P_i)$ that are deleted in the ear graph $G_i(P_i)$ cannot appear in $TC(x,y,i)$ for any pair x,y separating P_i. □

For convenience of notation we denote $G_{i_c}(P_i)$ by $G_c(P_i)$. Reference [21] includes an algorithm for forming the coalesced graph of a star graph $G(P)$ that runs in logarithmic time on a CRCW PRAM with an almost-optimal processor-time bound. This algorithm has the same processor-time complexity as that of finding connected components.

LEMMA 4.3. *In the coalesced graph $G_c(P_i)$, for each adjacent pair $\{a,b\}$ separating P_i there is at most one bridge of P_i with attachments on a,b and a vertex in (a,b), the portion of P_i between a and b.*

Proof. Suppose not, and let B_1 and B_2 be two bridges of P_i in $G_c(P_i)$ that have attachments on a,b and a vertex in (a,b). Then B_1 and B_2 must interlace, which contradicts the fact that $G_c(P_i)$ is the coalesced graph of the ear graph $G_i(P_i)$. □

LEMMA 4.4. *Let B be a two-attachment bridge of P_i in $G_c(P_i)$ with attachments a and b. Then*

(a) *If the span $[a,b]$ is degenerate (i.e., (a,b) is an edge in P_i) or if there is a bridge B' of P_i with attachments on a and b and at least one other vertex, then $G_c(P_i)-\{B\}$ defines the same set of polygons and simple triconnected components $TC(x,y,i)$, for i fixed, as $G_c(P_i)$.*

(b) *If part (a) does not hold, then $\{a,b\}$ is an extremal pair separating P_i as well as an adjacent pair separating P_i.*

Proof. Let P_j be the lowest-numbered ear in B. Then $j>i$, and a and b are the end vertices of P_j. Hence the ear split $e(a,b,j)$ separates B from P_i, and thus B is not part of $TC(x,y,i)$ for any pair $\{x,y\}$ separating P_i. So a 2-attachment bridge on P_i is never a part of a triconnected component associated with a pair separating P_i, although it may define some adjacent and extremal separating pairs as in case (b) of the lemma.

We now prove parts (a) and (b) of the lemma.

(a) Suppose span $[a,b]$ is degenerate. Then the triconnected component associated with split $e(a,b,i)$ is the single edge (a,b), which is a bond. Otherwise, if there is a bridge B' with attachments on a,b and at least one other vertex v, then the triconnected component associated with split $e(a,b,i)$ contains a portion of P_i between a and b together with B' if v is in the interval (a,b) and is a polygon if v is not in $[a,b]$. Both of these situations can be inferred without the presence of B. Note that it is not possible for B' to have an attachment v in the interval (a,b) and another attachment w that is not in $[a,b]$ since the bridge B would interlace with B' in such a case.

(b) Let the span $[a,b]$ be nondegenerate, and let the portion of P_i between a and b be $\langle a=a_1,a_2,\ldots,a_k=b\rangle$. Since there is no k-attachment bridge, $k>2$, with span $[a,b]$, there must exist an a_i, $1<i<k$, such that a, a_i, and b are in the same candidate list C and no vertex outside $[a,b]$ is in C. Hence $\{a,b\}$ is an extremal separating pair. Also, since there is no bridge with attachments on a,b and some other vertex c outside $[a,b]$, there must be some vertex c on P_i such that either $c<a<b$ or $a<b<c$ and a, b, and c are in the same candidate list C'. Furthermore, no vertex in the interval (a,b) can belong to C'. Hence $\{a,b\}$ is an adjacent pair in the candidate list C'. □

Let $\{a,b\}$ be an adjacent separating pair for ear P_i. The pair a,b is a *nonvacuous adjacent separating pair for* P_i if there is a bridge of P_i in $G_c(P_i)$ with attachments on a,b and one other vertex in the interval (a,b) on P_i; otherwise, the pair $\{a,b\}$ is a *vacuous adjacent separating pair.* We leave it as an exercise to verify that if $\{a,b\}$ if a nonvacuous adjacent separating pair, then $TC(a,b,i)$ is a simple triconnected graph and if $\{a,b\}$ is a vacuous adjacent separating pair, then $TC(a,b,i)$ is a bond; if $\{a,b\}$ is an extremal separating pair, then $TC(a,b,i)$ is a polygon.

Lemmas 4.3 and 4.4, in conjunction with Corollary 4.2, tell us that we can compute the triconnected components of G by the following method. Make the splits corresponding to the adjacent separating pairs by performing, for each star B in $G_c(P_i)$, an ear split $e(a,b,i)$, where $[a,b]$ is the span of B. Then break off chains of degree-2 vertices on the paths in the resulting star graphs to perform the splits corresponding to the extremal separating pairs.

There are two problems with using the above approach in an efficient logarithmic-time algorithm for forming the triconnected components of a graph. One is that we are working with the ear graphs of the ears and the total size of these graphs need not be linear in the size of G. The second is that this approach will not work if a vertex a appears in an ear split for two different ears. In particular, two-attachment bridges corresponding to adjacent separating pairs would be separated on two different ears, and this would cause processor conflicts.

We now turn to G', the local replacement graph of G that we defined in §3.1, in order to develop an efficient method of identifying the associated triconnected components.

Let G' be the local replacement graph of G, and let $D'=[P'_0,\ldots,P'_{r-1}]$ be the corresponding open ear decomposition. By Corollary 3.16 a pair $\{a,b\}$ separates P_i in G if and only if the pair $\{a_P,b_{P_i}\}$ separates P'_i in G'. Furthermore, neither a_{P_i} nor b_{P_i} is an end vertex of P'_i. The following lemma shows that in G' we can efficiently identify any bridge B of an ear P'_i that has no attachment to an end vertex of P'_i.

LEMMA 4.5. *Let G_e be the graph obtained from G' by collapsing all internal vertices of each ear into a single vertex. Let vertex v_i represent ear P'_i in G_e. Then the edges incident on v_i in each block of G_e whose lowest-numbered vertex is v_i correspond to the attachment edges of a bridge of P'_i in G', and, conversely, each bridge of P'_i in G' that has no attachments to the end vertices of P'_i corresponds to a block of G_e.*

Proof. Let e_1 and e_2 be any pair of edges incident on v_i that lie in the same block B of G_e whose lowest-numbered vertex is v_i. Then there is a path between e_1 and e_2 in B that avoids v_i, and hence in G' there is a path between e_1 and e_2 that avoids internal vertices of P'_i. But since the lowest-numbered vertex in B is v_i, the path between e_1 and

e_2 in B does not contain any vertex on an ear numbered lower than i, and hence e_1 and e_2 must lie in a connected component in $G' - \{P_i'\}$.

Conversely, let B be a bridge of P_i' in G' that has no attachments to the end vertices of P_i'. Then when the internal vertices of P_i' are collapsed into v_i, all of the attachments of B on P_i' become incident on v_i. Thus B becomes a block in G_e with articulation vertex v_i. Furthermore, since B has no attachments to the end vertices of P_i', B is not an anchor bridge of P_i' and hence v_i is the minimum-numbered vertex in B in G_e. □

Recall that (Proposition 3.7) the copies of a vertex v in G' are connected in the form of a tree. For the following lemma assume this local tree that replaces v is rooted at v_S, where $ear(v) = S$.
