Abstract. This paper defines and studies a computational model (a random access machine with powerful input/output instructions), and shows that the classes DLINEAR and NLINEAR of problems computable in deterministic (respectively, nondeterministic) linear time in this model of computation are robust and powerful. In particular, DLINEAR includes most of the concrete problems commonly regarded as computable in linear time (such as graph problems, topological sorting, strong connectivity, etc.). Most combinatorial NP-complete problems are in NLINEAR. The interest of NLINEAR class is enhanced by the fact that some natural NP-complete problems, for example, "reduction of incompletely specified automata" (RISA), are NLINEAR-complete (consequently, NLINEAR $\neq$ DLINEAR if and only if RISA $\notin$ DLINEAR). This notion strengthens NP-completeness, as this paper argues that propositional satisfiability is not NLINEAR complete.

Key words. linear time, model of computation, random access machine, input/output process, uniform cost measure, Turing machine, simulation, algorithms on graphs, sorting, reduction, NP-completeness, determinism, nondeterminism

1. Introduction and discussion.

It is usually admitted that the most efficient algorithms run in linear time. However, as far as we know, there is no robust and canonical definition of linear time in literature. (On the contrary, polynomial time is a very robust notion: it is sensitive neither to machine model nor to presentation of the input, provided they are "reasonable.") Papers and books (e.g., [AHU1], [AHU2], [FGS], [Kn], [Me], [Se]) concerning algorithms explicitly or, more often, implicitly use a variant of random access machine (RAM of Cook and Reckhow [CoRe]) but do not precisely explain or do not justify what "the good model" should be: what kind of elementary instructions must be taken (addition, subtraction, multiplication)?, what is the input/output device? (A notable exception is paper [AnVa] that describes and justifies the random access computer (RAC) model; however, their study is partial.) One generally adopts the uniform time criterion: each instruction requires one time unit, but it is not clear what an elementary instruction should be.

An algorithm runs in linear time if it performs $O(n)$ instructions on each input of "length" (or "size") n. Because the notion of instruction depends on the chosen machine, the notion of input length depends on the nature of the input. The length of a word $w \in \sum^n$ in a finite alphabet $\sum$ is n. The size of a graph (represented by its list of edges or by the successor lists of its vertices) is $m + p$, where m (respectively, p) is the number of vertices (respectively, edges). For example, [Ta] and [AHU1] compute the strongly connected components of a directed graph in "linear time" $O(m + p)$. The length of a propositional formula is often (but not always) the number n of its symbols: occurrences of connectives, parentheses, and variables (e.g., the length of formula $(p_0 \bigvee \lrcorner p_1) \bigwedge p_{10}$ is 8). [DoGa], [ItMa1], [ItMa2], and [Mi] describe some decision algorithms for satisfiability of Horn propositional formulas whose runtime is linear $O(n)$.

Gurevich and Shelah [GuSh] and Graedel [Gl] gave two "robust closures" of linear time. Previously, Schnorr [Sr] had similarly defined "quasi-linear time"(i.e., time $O(n(\log n)^{O(1)})$ for some Turing machine) and proved that many NP-complete problems belong to nondeterministic quasi-linear time class and are complete for this class. Those authors define extensions of linear time because, as [GuSh] explains, "It is possible that there is no universal notion of linear time and different versions of linear time are appropriate to different applications."

The present paper adopts the opposite point of view. We define and justify a unified, robust, and powerful notion of linear time both in deterministic and nondeterministic cases. In a former paper [Gr3], we define a complexity class, named LINEAR, by using a variant of classical RAM of [CoRe] under logarithmic cost criterion (time of each instruction is the total number of bits it manipulates, i.e., the sum of lengths of the integers it involves). Our RAM extends the classical model in some points and restricts it in some other ones. (Our purpose is to get a more realistic and more robust machine.) Let us describe informally the differences.

The input process of classical RAM is very restrictive: it can only read one bit at a time. (The output instruction of [CoRe] is more powerful: the RAM writes the whole contents of a register onto the output tape.) Schoenhage [Sc2] has proved that this RAM cannot compute the very simple function $w \mapsto ww$ (repetition of the input word w!) in linear time under logarithmic cost. We allow our RAM to *read its input in blocks* by an instruction, denoted $\text{READ}_v(u)$, which stores in register u a subword of the input as long as the contents of register v. Note that our input and output instructions are symmetrical to each other (in some manner).

In the classical model, the RAM memory can be used in a very *scattered* way because addresses and register contents are unbounded. Our RAM is similar to the RAC of Angluin and Valiant [AnVa], [GuSh]: a computation is allowed to use only integers *polynomially bounded* in the input length n (i.e., their length is $O(\log n)$).

The only available operations of the RAM of [CoRe] are addition (+) and subtraction (−); our RAM can perform any operation computable in linear time on a Turing machine (i.e., intuitively, "easy" operation): +, −, and concatenation but neither multiplication nor division. (Invariance properties of RAMs with compact memory and linear time Turing computable operations have been stated in [GrRo].)

Let LINEAR be the class of functions computable in linear time on the RAM described above. More precisely, a function $f : \sum^* \to \sum^*$ is in LINEAR if and only if there is such a RAM that computes (for each input $w \in \sum^*$) the value $f(w)$ in time $O(\text{length}(w))$ under logarithmic cost. In [Gr3] we have shown that LINEAR is a robust complexity class. However, we are unable to prove that it is closed under composition (i.e., if $f, g \in$ LINEAR, then $fog \in$ LINEAR) unless RAMs can use files (to contain intermediate results).

In this paper we still study the RAM as defined above but which uses the *uniform cost criterion*. This does not change the invariance properties of the machine model but we prove that the class, denoted DLINEAR, of functions computable by RAMs *without files* within time $O(n/\log n)$ (under uniform cost: n is the length of the input) is closed under composition. Note that DLINEAR $\subseteq$ LINEAR. The $O(n/\log n)$ time bound of DLINEAR seems to be very restrictive but is justified by the following facts:

(i) Katajainen et al. [KvLP] have proved that any function f computable in linear time $O(n)$ on a Turing machine can be computed in time $O(n \log\log n)$ on the classical RAM of [CoRe] (under logarithmic cost), and they have mentioned that "with better input/output pattern the simulation could perhaps be sped up further." We can prove (cf. §3 below) that function f is in DLINEAR (i.e., is computable by our RAM in time $O(n/\log n)$ under uniform cost).

(ii) Many (most?) concrete problems commonly regarded as computable in linear time belong to DLINEAR; that contrasts with the (abovementioned) lower bound result of Schönhage and shows the power of our input pattern.

The rest of the present paper is dedicated to the nondeterministic version of linear time. As mentioned above, Schnorr [Sr] has proved that many NP-complete problems are complete in nondeterministic quasi-linear time class (via deterministic quasi-linear time reduction). His computational model was Turing machine. We improve his results as follows. Let NLINEAR denote the nondeterministic version of the DLINEAR class; the RAM has a nondeterministic instruction because it can "guess" an integer. Note the inclusions NTIME $(n) \subseteq$ NLINEAR $\subseteq$ NTIME$(n \log n)$.

We show that many combinatorial NP-complete problems (20 among the 21 problems listed by Karp [Ka]) belong to NLINEAR. Moreover, we prove that *some* NP-complete problems (e.g., reduction of incompletely specified automata or RISA) are complete in NLINEAR via DLINEAR reductions (more strongly, reductions are computable in linear time on Turing machines). That improves the results of [Gr1], [Gr2], [Ra1], [Ra2], which state that each problem in NTIME(n) is reducible to RISA (and to some other NP-complete problems) in deterministic linear time. The proof of the strengthened result is similar to the original proof. That entails the following equivalence

$$\text{RISA} \notin \text{DLINEAR iff DLINEAR} \neq \text{NLINEAR},$$

which can be compared with the well-known equivalence

$$\text{SAT} \notin \text{P iff P} \neq \text{NP}.$$

Let us mention some related results. To our knowledge, Dewdney [De] was the first author who defined and exhibited linear time reductions. In particular, he proved that several NP-complete problems, including 3-SAT (i.e., satisfiability for clauses with three literals) and 3-COLORABILITY are mutually reducible via linear time reductions (on Turing machines). He assumes that inputs are previously normalized, for example, the set of variables that occur in a propositional formula must be exactly $\{p_1, p_2, \ldots, p_m\}$. More recently, Hunt and Stearns [HuSt] proved that a number of problems, including SAT, are mutually reducible via some comparable but weaker reduction (linear length bounded and computable in quasi-linear time). Note that if two problems are reducible to each other in linear time (e.g., two NLINEAR-complete problems), then they have the same time complexity.

After our machine model is defined in §2, the deterministic and nondeterministic linear time classes defined (DLINEAR and NLINEAR) are shown to be very robust (§3). In §4 we exhibit many problems in DLINEAR that are useful in the proof that most concrete problems usually regarded as computable in linear time belong to DLINEAR. Section 5 states properties of linear time reductions. In §6 we show that most combinatorial NP problems belong to NLINEAR. In §7 we prove that several NP-complete problems (e.g., RISA) are NLINEAR-complete, but we argue that propositional satisfiability must not be NLINEAR-complete. We also state other characterizations of the NLINEAR class. Section 8 gives conclusions and open problems.

2. Preliminaries: definitions of our machine model and of linear time complexity. Let $\log n$ denote the logarithm of n in base 2.

Let $\Gamma = \{1, 2, \ldots, d\}$ be a fixed alphabet, with $d \geq 2$. For convenience we identify a word $w = w_0 w_1 \ldots w_{n-1} \in \Gamma^n$ with the integer it represents in d-adic notation, that is,

$$w = \sum_{i<n} w_i d^i.$$

(In particular, the empty word is identified with zero.) Let length$(w) = n$; in particular, length$(0) = 0$.

Let c, d be some integers and let $\Gamma, \sum$ be alphabets such that $\Gamma = \{1, 2, \ldots, d\}$ and $\sum \subseteq \Gamma$. ($\sum$ will be called the input/output alphabet. Sometimes we will use more usual alphabets, including, for example, parentheses.) Our machine model, named DRAM, is the deterministic random access machine of [CoRe] (its sequence of registers are denoted $R(0)$, $R(1)$, $R(2)$, ...) with the following changes.

(i) An input (respectively, output) is a word $w \in \sum^n$ (respectively, $v \in \sum^m$) that is contained (respectively, that will be written) in a special one-way read-only (respectively, write-only) tape called the input (respectively, output) tape.

(ii) The contents of each register $R(i)$ is a nonnegative integer (which is initially 0) whose length, in d-adic notation, is at most $c \log n$ (similar to the memory condition of the RAC in [AnVa]); consequently, the total number of registers used by a DRAM is polynomially bounded in n.

(iii) A DRAM uses a fixed set of operations. All of them have to be computable in linear time on a deterministic Turing machine (e.g., $+$, $-$, concatenation, shift, length), denoted "linear time Turing computable" (LTTC).

(iv) The input/output instructions of a DRAM are the following: WRITE$(R(i))$ writes the contents of register $R(i)$ onto the output tape. READ$_{R(i)}(R(j))$ stores in register $R(j)$ a portion of the input of length L, where L is the length of the integer that register $R(i)$ contains at this moment (a special case occurs: if the nonread part of the input has length less than L, then the whole remainder is stored in $R(j)$).

An NRAM is the nondeterministic version of the previous DRAM. It works similarly but has the additional ability of guessing an integer by the nondeterministic instruction GUESS$(R(i))$ that stores any integer of length at most $c \log n$ in register $R(i)$.

We are now ready to define our time complexity classes.

DEFINITION. *Let $T(n) \geq n/\log n$ be any time function. A function $f : \sum^* \to \sum^*$ (respectively, a language $A \subseteq \sum^*$) belongs to class* DRAM $(T(n))$ *is f is computable (respectively, A is recognizable) by a* DRAM *that executes $O(T(n))$ instructions (uniform time criterion), where n denotes the length of the input w ($w \in \sum^n$). The class of languages* NRAM $(T(n))$ *is defined similarly.*

Convention. In this paper, when we write that a word w of length n is *accepted* by a nondeterministic machine *within some resource* (time $O(T(n))$, space $O(S(n)), \ldots$), we mean that there is an accepting computation of the machine (on that input w) that respects that resource (time $O(T(n)), \ldots$).

Notation. DLINEAR = DRAM$(n/\log n)$; NLINEAR = NRAM$(n/\log n)$.

Remark. These notations are justified by the fact that the time required by a DRAM$(n/\log n)$ (respectively, NRAM$(n/\log n)$) computation is linear (i.e., $O(n)$) under logarithmic cost.

Comments. The definition of the DLINEAR class has two features that at first seem counterintuitive.

(1) The seeming combination of Turing machine features (LTTC operations) with random access. Proposition 3.1(vi) below shows that such a machine can be simulated in linear time by a classical RAM (of [CoRe]) using addition and subtraction (and no other LTTC operation) and shows the robustness of our computational model. Notice that allowing LTTC operations is useful to prove that concrete problems (e.g., NORMALIZE and HORN-SAT; see §4) are in DLINEAR.

(2) The use of the strange time bound $O(n/\log n)$ rather than $O(n)$. This is justified by the following arguments.

(a) It is reasonable to require the available memory to be polynomial, implying that the maximal available address is of the form $N = \Theta(n^d)$, for a fixed d.

(b) In a real computer, addressing a big address register seems to require the same time as addressing a low address one; that explains why the uniform cost criterion is chosen.

(c) For an input of length n in a *fixed finite* alphabet, it is not reasonable to define a linear time computation as a sequence of $O(n)$ instructions because one instruction *does not* involve a *fixed number* of bits. We believe that linear time must be at most $O(n)$ under logarithmic cost measure. As argued above, any instruction is charged $\Theta(\log N) = \Theta(\log n)$ for that measure; that entails choosing the uniform time bound $O(n/\log n)$.

Conventions. In the sequel, in each case when the time cost criterion is not mentioned, we shall implicitly assume that the RAM uses *uniform cost criterion.* Letter n will always denote the *length* of the input.

3. Classes DLINEAR and NLINEAR are robust. On one hand, Katajainen et al. [KvLP] have shown that any function computable in linear time $O(n)$ on a Turing machine can be computed in time $O(n \log\log n)$ on an ordinary RAM (of [CoRe]) under logarithmic cost. (Recall that in one instruction, such a RAM can read at most one bit of the input.) On the other hand, Schoenhage [Sc2] has proved that time bound $O(n \log\log n)$ cannot be replaced by $O(n)$. In this section we show that the impossibility comes from the weakness of the input/output process of usual RAM and we state several robustness properties of the DRAM (respectively, NRAM).

For technical reasons, it is useful to define a variant of DRAM *without* input/output instructions. Instead, the input is divided and stored in a standard way at the beginning of a computation. (That can be compared with the start condition of RACs in [AnVa]; however, that paper does not state precisely how the input is stored in memory.)

Notation. Let $k \geq 1$ be a fixed integer. Let $b_k(n) = \ulcorner 1/k \log(n+1) \urcorner$.

DEFINITION. *Let $k \geq 1$ be a fixed integer. A* DRAM$_k$ *is like a* DRAM *except for input/output.*

(i) *Each input word $w \in \sum^n$ of length n is divided into nonempty words $w_1, w_2, \ldots, w_q$ initially stored in respective registers $R(1), R(2), \ldots, R(q)$:*

$$w = w_1 \,\hat{}\, w_2 \ldots \hat{}\, w_q (\text{concatenation}),$$

where length $(w_i) = b_k(n)$ for $i < q$ and $0 <$ length $(w_q) \leq b_k(n)$ (the other registers $R(q+1), \ldots$ initially contain zero). $w_1, w_2, \ldots, w_q$ are called the $b_k(n)$-blocks of w.

(ii) *An output word v (if any) is similarly divided into nonempty $b_k(n)$-blocks $v_1, v_2, \ldots, v_s$ (the last block v_s may be shorter), respectively, stored in registers $R(1), R(2), \ldots, R(s)$ at the end of a computation (with $R(s+1) = 0$). Note that n is not the length of the output but is still the length of the input. We define an* NRAM$_k$ *in the same manner.*

DEFINITION. *A function (respectively, a language) belongs to* DRAM$_k(n/\log n)$ *(respectively,* NRAM$_k(n/\log n)$*) if it is computed (respectively, recognized) by a* DRAM$_k$ *(respectively,* NRAM$_k$*) in time $O(n/\log n)$ under uniform cost.*

Remark. The important things about the block length $b_k(n)$ is the fact that it is easy to compute and that $b_k(n) = \Theta(\log n)$ for $n \geq 1$ and then the number q (respectively, s) of blocks of the input (respectively, output) is $O(n/\log n)$. We shall also use the fact that $\lim_{k \to +\infty} b_k(n) = 0$. The following proposition shows how robust the classes DLINEAR = DRAM$(n/\log n)$ and NLINEAR = NRAM$(n/\log n)$ are.

PROPOSITION 3.1. *Let $f : \sum^* \to \sum^*$ be a function.*

(i) *For all integers k, k', $f \in$* DRAM$_k(n/\log n)$ *if and only if $f \in$* DRAM$_{k'}(n/\log n)$.

(ii) *$f \in$* DRAM$(n/\log n)$ *if and only if $f \in$* DRAM$_k(n/\log n)$ *for some k.*

(iii) *If f is computable in linear time $O(n)$ by a deterministic Turing machine, then $f \in$* DRAM$(n/\log n)$.

(iv) *Assertions* (i)–(iii) *hold for languages (instead of functions) and the nondeterministic classes* NRAM$(n/\log n)$ *and* NRAM$_k(n/\log n)$.

(v) *Let $f, g : \sum^* \to \sum^*$ be two functions such that $f, g \in$* DRAM$(n/\log n)$; *then $g \circ f \in$* DRAM$(n/\log n)$.

(vi) *Let $f \in$* DRAM$(n/\log n)$ *and $\epsilon > 0$ any real number, then there is an integer K such that for each $k \geq K$, there are a* DRAM$_k$ *and a* DRAM *that compute f in time $O(n/\log n)$ and use exclusively the operation $+$ (respectively, concatentation) and integers $O(n^{1+\epsilon})$.*

(vii) *Let* $A \in \mathrm{NRAM}(n/\log n)$, *then there is an integer* K *such that for each* $k \geq K$, *there are an* NRAM_k *and an* NRAM *that recognize* A *in time* $O(n/\log n)$ *and use exclusively the successor operation* (*i.e., function* $x \mapsto x+1$) *or concatentation and integers* $O(n/\log n)$.

Sketch of proof. (i) and (ii) are roughly proved as follows: the simulating machine reorganizes blocks of the input (respectively, output) by using new LTTC operations (e.g., the length function).

To prove (i), it is sufficient to demonstrate

$$\text{(i}')\qquad f \in \mathrm{DRAM}_k(n/\log n) \text{ iff } f \in \mathrm{DRAM}_{k+1}(n/\log n).$$

To prove (i′) note that $b_{k+1}(n) \leq b_k(n) \leq 2b_{k+1}(n)$ (since $1/(k+1) \leq \frac{1}{k} \leq 2/(k+1)$, and thus an input organized in $b_{k+1}(n)$-blocks is reorganized into $b_k(n)$-blocks by concatenating fragments of two consecutive $b_{k+1}(n)$-blocks to obtain each $b_k(n)$-block. Note that values n, $b_k(n)$, and $b_{k+1}(n)$ have to be initially computed.

To prove (ii), use the fact that (by definition) a DRAM performs only $O(n/\log n)$ read (respectively, write) instructions on integers of length $O(\log n)$; for example, a read instruction is simulated on a DRAM_k by the concatenation of $O(1)$ (fragments of) $b_k(n)$-blocks. This proves the implication $f \in \mathrm{DRAM}(n/\log n)$ implies $f \in \mathrm{DRAM}_k(n/\log n)$. Let us prove the converse. The simulating DRAM first reads the input by blocks by the following subroutine (it stores into registers $R(1), R(2), \ldots, R(m)$ the respective subwords $w_1, w_2, \ldots, w_m$ of the input word w in such a way that $w = w_1 \,\hat{}\, w_2 \,\hat{}\, \ldots w_m$, where $\mathrm{length}(w_i) = \mathrm{length}(i)$ for $i < m$ and $0 < \mathrm{length}(w_m) \leq \mathrm{length}(m)$):

```
begin
    $R(0) \leftarrow 1$
    while the input is not entirely stored do
        begin
            $\mathrm{READ}_{R(0)}(R(R(0)))$
            $R(0) \leftarrow R(0) + 1$
        end
end;
```

We easily check that $m = \Theta(n/\log n)$. Then the simulating machine reorganizes the stored input into $b_k(n)$-blocks as above. This proves (ii).

(iii) easily follows from (ii) and the classical techniques of blocks (see for example [HPV] and [KvLP]) represent each block of $b_k(n)$ consecutive cells of a tape (of the Turing machine) by one register of a DRAM_k.

(iv) is proved exactly as (i)–(iii).

To prove (v), use (ii) and distinguish two cases according to the length, denoted L, of the intermediate value $f(w)$.

(1) $n^{1/2} \leq L = O(n)$, where $n = \mathrm{length}(w)$). It is easy to convert the $b_k(n)$-blocks of $f(w)$ into $b_k(L)$-blocks and to convert the $b_k(L)$-blocks of $g\ o\ f(w)$ into $b_k(n)$-blocks (because $\log L = \Theta(\log n)$).

(2) $L < n^{1/2}$. Block conversion of words $f(w)$ and $g\ o\ f(w)$ is easy because they have only $O(n^{1/2})$ blocks of length $O(\log n)$.

If we use (ii), assertion (vi) is essentially the same as Corollary 3.3 in [Gr3] with uniform time cost instead of logarithmic time cost; moreover, the proof can be simplified (because we no longer need to distinguish "little addresses"). It essentially combines two techniques: division of registers into "small registers" of length $b_k(n)$, and hashing techniques (and pairing functions) to encode big addresses with "small addresses" $O(n^{1+\epsilon})$. More precisely, a big address u is first divided into b-blocks (i.e., blocks of length $b = b_k(n)$): $u = u_m \ldots u_1 u_0$

(concatenation). Then we successively construct the numbers $p_1 = \text{PAIR}(u_0, u_1)$, $p_2 = \text{PAIR}(p_1, u_2), \ldots, p_m = \text{PAIR}(p_{m-1}, u_m)$. The big address u is roughly "simulated" by p_m, which is $O(n)$. (PAIR is a dynamical pairing function whose values are $O(n)$. It can be stored in a two-dimensional array whose first index is $O(n)$ and whose second index is a b-block, and then is $O(2^b) = O(n^{\epsilon/2})$. It can be simulated by a one-dimensional array of indices $O(n^{1+\epsilon})$. For more details, see [Gr3] or see below the proof of Proposition 4.1 where these techniques are reused.) Note that several LTTC operations on small operands are used. These operations can be initially precomputed (for all possible small operands) and stored in several arrays by only using addition (respectively, concatenation). This proves (vi) for a DRAM_k. The same result (vi) is obtained for a DRAM by using the following trick: for a fixed (sufficiently large) k, compute successively all the k-tuples $u_1, u_2, \ldots, u_k$ of integers such that $u_i \leq u_k = j$ for all $i < k$, for successive integers $j = 1, 2, 3, \ldots$, and for each produced k-tuple, read a part of the input of length equal to $\text{length}(u_k)$. (Note: this process generalizes the one presented above to prove (ii).) It is easy but tedious to show that length (u_k) is always less than about $1/k$ length(n) and that the input is entirely read in time $O(n/\log n)$.

(vii) is proved by variants of the above techniques (simplified): registers are divided into "little registers" of length $b_k(n)$ and addressing is simulated by an essential use of nondeterminism as described below. Let $a_1 < a_2 \ldots < a_m$ denote the list of distinct addresses (in increasing order) used by the simulated NRAM_k denoted M. First, the simulating NRAM_k M' guesses that list. Note that $\sum_{i \leq m}$ length $(a_i) \leq n$ and then $m = O(n/\log n)$. The main idea of the simulation is to represent the address a_i register (of M) by a register (of M') of address i. M' has two one-dimensional arrays, denoted $\text{ADDRESS}(1, \ldots, m)$ and $\text{CONTENTS}(1, \ldots, m)$, such that at each moment of the simulation $\text{ADDRESS}(i) = a_i$ $(1 \leq i \leq m)$ and $\text{CONTENTS}(i) =$ contents of register with address a_i (in M). (M' is a "multimemory" NRAM_k.) An access (by M) to some register of address α is simulated by M' as follows: guess an integer $i \in \{1, 2, \ldots, m\}$; check if $\text{ADDRESS}(i)$ (that is a_i) is equal to α (otherwise reject); and use $\text{CONTENTS}(i)$. Note that our multimemory NRAM_k M' can be simulated in linear time by an ordinary NRAM_k (interleave the arrays; see [CoRe] for details) and that we exclusively use addresses $O(m) = O(n/\log n)$. Notice that a NRAM using only the successor operation can simulate this NRAM_k: it initially guesses n and computes $b = b_k(n)$ and a block of length b. □

Remark. The exact function $b_k(n)$ we choose (for block length) is not essential. Proposition 3.1 and its proof still hold for other "easily computable" functions $\Theta(\log n)$; for example, $\llcorner 1/k \log n \lrcorner$ (with $n \geq 2^k$) or $\ulcorner 1/k \text{ length}(n) \urcorner$.

Equality $\text{DLINEAR} = \text{DRAM}_k(n/\log n)$ is essential in our proof that DLINEAR class is closed under composition. That characterization (respectively, the similar one for NLINEAR) will be useful in proofs that concrete problems belong to DLINEAR (respectively, NLINEAR).

4. Many problems computable in linear time. In this section we prove that most problems usually regarded as computable in linear time belong to DLINEAR. In the proofs we need several standard DLINEAR subroutines, for example, a normalization algorithm.

Remark. For convenience, our DRAMs (or DRAM_k) will sometimes use *multidimensional arrays.* It is not an essential extension of our machine model because a DRAM using a multidimensional array, for example, $A(i, j)$, can be simulated (in linear time) by a usual DRAM. Register $A(i, j)$ is represented by register $R(p)$, where $p = \text{Pair}(i, j)$ and Pair is an LTTC pairing function. That is (for example), $p = \text{Pair}(i, j) = i \mathbin{\hat{}} 12 \mathbin{\hat{}} \text{rep}(j)$ (concatenation), where $\text{rep}(j)$ is obtained by repeating twice each digit of j (see [Gr3] or [GrRo], [Ro1] for more details).

4.1. A normalization algorithm. In most of "linear time-bounded algorithms" on concrete data structures, such as graphs, formulas, and so on (cf. [AHU1], [AHU2], [FGS], [Kn],

[Me], [Se]), one implicitly assumes that input structures are initially normalized; for example, the set of vertices of a graph is the interval of integers $\{1, 2, \ldots, m\}$ and Dowling and Gallier [DoGa] and Minoux [Mi] assume that their satisfiability algorithm works on propositional Horn formulas whose variables are exactly $p_1, p_2, \ldots, p_m$.

However, it is not obvious how to transform an input, for example, a propositional formula into such a normalized one. Of course, we can list all the occurrences of variables p_i and then renumber them by sorting, but no linear time algorithm is known for the sorting problem. (Note that Itai and Makowsky [ItMa1] also mentioned the necessity of replacing large indices by small ones.)

We formalize the normalization problem as follows (assume we have fixed a finite alphabet $\sum = \{1, 2, \ldots, d\}$ that does not include symbols $\square$ and :).

PROBLEM NORMALIZE.

Input. A string S of the form $\square A_1 \square A_2 \ldots \square A_m$, where each $A_i \in \sum^*$. Let n denote the length of S ($n = m + \sum_{i \leq m}$ length (A_i)).

Output. A string S' of the form $\square A_1 : a_1 \square A_2 : a_2 \ldots \square A_m : a_m$, where

(i) for all i, j, $a_i = a_j$ if and only if $A_i = A_j$;

(ii) The a_i are integers such that $\{a_1, a_2, \ldots, a_m\} = \{1, 2, \ldots, M\}$

(a consequence of (i)–(ii) is $a_i = O(n/\log n)$ for each i);

(iii) length $(S') = O(n)$.

Remark. For each fixed alphabet $\sum$, the problem NORMALIZE is not unique. Our purpose is only to construct a DLINEAR algorithm that computes a string S' that satisfies (i–iii).

PROPOSITION 4.1. *Problem NORMALIZE belongs to DLINEAR.*

Proof. It is sufficient to prove that NORMALIZE belongs to $\mathrm{DRAM}_k(n/\log n)$ for sufficiently large k (we shall take $k \geq 2\log(d+1)$). Input S is initially divided into $b_k(n)$-blocks (in short, b-blocks with $b = b_k(n)$). Our DLINEAR algorithm will consist of two parts: first, lexical analysis of S and second, computation of the a_i (by hashing techniques).

Lexical analysis of S. In the sequel, a subword $\square A_i$ of S that includes at least the first symbol of a b-block in S will be called a "milestone." Lexical analysis consists in determining the milestones in S and dividing S as follows:

$$S = \square A_{h(1)} B_1 \square A_{h(2)} B_2 \ldots \square A_{h(q)} B_q,$$

where $\square A_{h(1)}, \square A_{h(2)}, \ldots, \square A_{h(q)}$ are the successive milestones (notice that $h(1) = 1$) and subwords $B_i \in (\sum \cup \{\square\})^*$ are the "remainders." For example, B_1 is the string of symbols (maybe empty) that lie between the first and second milestones A_1 and $A_{h(2)}$. We easily see that length$(B_i) < b$ (otherwise, B_i would contain the first symbol of a b-block and then it would include a milestone) and $q \leq$ (number of b-blocks) $= \ulcorner n/b \urcorner = O(n/\log n)$. It is easy to compute and store the list of milestones $\square A_{h(1)}, \ldots, \square A_{h(q)}$ (respectively, the list $B_1, B_2, \ldots, B_q$) in a two-dimensional (respectively, one-dimensional) array where each element has length $\leq b = \Theta(\log n)$. Notice that the total number of b-blocks in all the $A_{h(i)}$ is $O(n/b) = O(n/\log n)$.

Clearly a DRAM_k can perform the above computation in time $O(n/\log n)$. The lexical analysis of S is not complete because it does not separate the A_i contained in the B_j.

Computation of the a_i. We now use some techniques of [Gr3, paragraph III.3] (cf. [Wi2] for some comparable techniques). That requires some definitions: a subword A_i in S is "big" if length $(A_i) \geq b$; otherwise, it is "small." Note that each subword A_i of some B_j is small and that a word $A_{h(j)}$ (in a milestone $\square A_{h(j)}$) may be big or small. We do not separately encode each occurrence of a small A_i (it would require too many steps in case too many small A_i occur in S) but precompute them as follows.

In a first phase, recapitulate the small A_i that occur in S (use a boolean array, called PRESENT, indexed by words of $\sum^*$ of length less than b) and then encode them with an array denoted CODE (we take $a_i = \text{CODE}(A_i)$). The subroutine of this first phase is the following:

```
begin
        for each $w \in \sum^*$ such that length($w$) $< b$ do
                PRESENT($w$) := false {initialization}
        for $i := 1$ to $q$ do
                if length($A_{h(i)}$) $< b$, then PRESENT($A_{h(i)}$) := true
        for $i := 1$ to $q$ do
                if $B_i$ is "new" (i.e., $B_i \neq B_j$ for each $j < i$)
                then for each $A_j$ that occurs in $B_i$
                        do PRESENT($A_j$) := true
        {note: we check if $B_i$ is "new" by means of another boolean array indexed by
        words of length less than $b$}
        {we now encode "small" $A_i$ (that occur in $S$) with consecutive integers}
        $a := 1$
        for each $w \in \sum^*$ such that length($w$) $< b$ do
        if PRESENT($w$) then
                begin
                        CODE($w$) := $a${meaning: if $w = A_i$, then $a = \text{CODE}(A_i) = a_i$}
                        $a := a + 1$
                end
end;
```

Note that at each moment the global variable a represents the least integer that is not an encoding (it will be used in the third phase below).

In a second phase, encode all $B_i \in (\sum \cup \{\square\})^*$ in S as follows. If$B_i = \square\alpha_1\square\alpha_2 \ldots \square\alpha_s$, where each $\alpha_j \in \sum^*$, then take $\text{CODE}(B_i) := \square\alpha_1 : \text{CODE}(\alpha_1) \ldots \square\alpha_s : \text{CODE}(\alpha_s)$ (these encodings can be stored in the above CODE arrays, indexed by words of $(\sum \cup \{\square\})^*$ of length $< b$).

The reader should be convinced that first and second phases above require only $O(n/\log n)$ steps for sufficiently small $b = b_k(n)$, i.e., for sufficiently large k. In particular, the analysis of the A_j included in the "new" B_i requires time $O(b.(d+1)^b) = O((\log n)n^u)$, where $u = (1/k)\log(d+1)$ that is $O(n^{1/2}.\log n)$ if $k \geq 2\log(d+1)$. We can now compute the parts of the output S' that concern the subwords B_i and the milestones $\square A_{h(i)}$ for small $A_{h(i)}$. The third phase consists in encoding big milestones $\square A_j$ (i.e., for which length $(A_j) \geq b$) by techniques of [Gr3, paragraph III.3]. Let us describe it to have a self-contained proof.

Examine and encode successively the big words A_j by using two global variables denoted Nextp and Nexta and two "dynamic pairing functions" denoted PAIR and ENCODE (here we define a "pairing function" as an injective partial function $\mathbb{N} \times \mathbb{N} \to \mathbb{N} - \{0\}$). These functions are stored in two-dimensional arrays, also denoted PAIR and ENCODE, and each one is completed if necessary, i.e., when it is undefined on some useful arguments. At each moment, values of function PAIR (respectively, ENCODE) have to form an initial segment [1, Nextp - 1] (respectively, a segment [a, Nexta - 1], where a is the least positive integer that does not encode a little A_i; see first phase) and value Nextp (respectively, Nexta) is kept in a special register.

Let us explain how functions PAIR and ENCODE are computed and used. Let $u_1, u_2, \ldots, u_r$

denote the successive b-blocks of a big word A_j (length $(A_j) \geq b$) we want to encode. More precisely, $u = u_1 \hat{} \ u_2 \dots \hat{} \ u_r$ with $r \geq 1$, length$(u_i) = b$ for each $i < r$ and $0 <$ length$(u_r) \leq b$. Compute successively $p_2 = \text{PAIR}(p_1, u_2)$ where $p_1 = u_1$, $p_3 = \text{PAIR}(p_2, u_3), \dots, p_r = \text{PAIR}(p_{r-1}, u_r)$ and $e = \text{ENCODE}(p_r, r)$ in respecting the following rule: each time we need to use a pair of arguments (x, y) for which function PAIR is undefined (i.e., register PAIR(x, y) has never been visited and contains zero for that reason), execute the following assignments (and similarly for ENCODE):

$$\text{PAIR}(x, y) := \text{Nextp} \ ; \text{Nextp} := \text{Nextp} + 1.$$

At the beginning of the third phase, initialize variables by

$$\text{Nextp} := 1; \ \ \text{Nexta} := a.$$

Obviously, a nonzero integer is never contained in two distinct locations of the array PAIR (respectively, ENCODE); hence, PAIR and ENCODE are pairing functions. Let us define function PAIR^i : $\mathbb{N}^i \to \mathbb{N}$ by recurrence. PAIR$^i(x_1, x_2, \dots, x_i)$ is equal (if it is defined) to

$$\begin{aligned} &x_1 \quad \text{if } i = 1, \\ &\text{PAIR}(\text{PAIR}^{i-1}(x_1, \dots, x_{i-1}), x_i) \quad \text{if } i \geq 2. \end{aligned}$$

PAIR^i : $\mathbb{N}^i \to \mathbb{N}$ is clearly an injective partial function. In particular, we have considered (above) the following values associated with some big word $A_j = u_1 \hat{} \ u_2 \dots \hat{} \ u_r$; $p_2 = \text{PAIR}^2(u_1, u_2)$, $p_3 = \text{PAIR}^3(u_1, u_2, u_3), \dots p_r = \text{PAIR}^r(u_1, u_2, \dots, u_r)$ and $e =$ ENCODE (PAIR$^r(u_1, \dots, u_r), r)$.

We take $a_j := e$. Condition (i) of problem NORMALIZE is clearly respected. Notice that the last value of variable Nexta is $M + 1$, where M is the integer involved in Condition (ii).

We have now achieved the construction of output S'. One easily can be convinced that the third phase is performed within $O(n/\log n)$ steps (each b-block is manipulated $O(1)$ times) and only involves words of length $O(\log n)$. □

4.2. Other problems computable in linear time. In proofs that concrete problems belong to DLINEAR or NLINEAR we will often need the above NORMALIZE algorithm but also algorithms for the following problems.

PROBLEM LIST-COMPRESS.
Input. A string $S = \square A_1 \square A_2 \dots \square A_m$, where each $A_i \in \sum^*$ and $\square \notin \sum$.
Output. The string $S' = \square A'_1 \square A'_2 \dots \square A'_p$ such that:
(i) $\{A_1, A_2, \dots, A_m\} = \{A'_1, A'_2, \dots, A'_p\}$;
(ii) there is no repetition in S', i.e., $A'_i \neq A'_j$ if $i \neq j$;
(iii)A'_i occurs before A'_j in S' (i.e., $i < j$) iff the first occurrence of A'_i in S precedes the first occurrence of A'_j.

PROBLEM MULTISET-COMPRESS.
Input. A string $S = \square A_1 \square A_2 \dots \square A_m$, where each $A_i \in \sum^*$ and symbols □ and : do not belong to $\sum$.
Output. A string S' of the form $\square A'_1 : n_1 \square A'_2 : n_2 \dots \square A'_p : n_p$ such that
(i) $\{A_1, A_2, \dots, A_m\} = \{A'_1, A'_2, \dots, A'_p\}$;
(ii) $A'_1 \neq A'_j$ if $i \neq j$;
(iii) for each $i \leq p$, n_i is the number of indices j such that $A_j = A'_i$

PROBLEM ELEMENT-DISTINCTNESS.

Input. A string $\Box A_1 \Box A_2 \ldots \Box A_m$ where each $A_i \in \sum^*$ and $\Box \notin \sum$.

Question. Are the elements A_i all distinct?

Remark. The computational complexity of ELEMENT-DISTINCTNESS has been studied in some recent papers; for example, Yao [Ya] proves a near optimal time-space tradeoff for it.

PROBLEM PERMUTATION.

Input. A string $\Box A_1 \Box A_2 \ldots \Box A_m \Delta A'_1 \Box A'_2 \ldots \Box A'_m$, where A_i, A'_i are words of $\sum^*$ ($\Box$, $\Delta \notin \sum$).

Question. Is there a permutation π of $\{1, 2, \ldots, m\}$ such that $A'_i = A_{\pi(i)}$ for each $i \leq m$?

PROBLEM SET-INCLUSION (respectively, SET-EQUALITY).

Input. Two lists of words $A_1, A_2, \ldots, A_m$ and $A'_1, A'_2, \ldots, A'_p$.

Question. Does the inclusion $\{A_1, \ldots, A_m\} \subseteq \{A'_1, \ldots, A'_p\}$ (respectively, equality $\{A_1, \ldots, A_m\} = \{A'_1, \ldots, A'_p\}$) hold?

Remark. The input is presented above in a natural structured manner but formally the input of a DRAM is a string; the exact input of SET-INCLUSION has to be, for example, of the form $A_1 \Box A_2 \ldots \Box A_m \Delta A'_1 \Box A'_2 \ldots \Box A'_p$ (with new symbols $\Box$ and Δ). For convenience, in the sequel our problems will be presented in a structured manner.

PROBLEM CHECK-SORT.

Input. Two lists of integers (or words) $A_1, A_2, \ldots, A_m$ and $A'_1, A'_2, \ldots, A'_m$ such that $A'_1 \leq A'_2 \leq \cdots \leq A'_m$.

Question. Is the second list the sorted version of the first list, i.e., is there a permutation π of $\{1, 2, \ldots, m\}$ such that $A'_i = A_{\pi(i)}$ for each $i \leq m$?

PROBLEM PARTITION.

Input. A list P of "sets" $S_1, S_2, \ldots, S_m$, where each S_i is of the form: $S_i = \{e_1, e_2, \ldots, e_p\}$.

Question. Is P a "set partition," i.e., are the sets S_i mutually disjoint?

PROBLEM SET-INTERSECT (respectively, SET-DIFFERENCE).

Input. A set S and a list L of sets $S_1, S_2, \ldots, S_m$.

Output. The list L' of intersection sets $S_1 \cap S, \ldots, S_m \cap S$ (respectively, difference sets $S_1 - S, \ldots, S_m - S$).

PROBLEM ADDITION.

Input. A list of integers $A_1, A_2, \ldots, A_m$.

Output. The integer $A_1 + A_2 + \cdots + A_m$.

PROBLEM FUNCTION-DEF.

Input. A list of arrows $x_1 \rightarrow y_1, x_2 \rightarrow y_2, \ldots, x_m \rightarrow y_m$, where the x_i, y_i are words.

Question. Does that list define a function, i.e., does the implication $x_i = x_j \Rightarrow y_i = y_j$ hold for all i, j?

PROBLEM FUNCTION-APPLY (Assume that c is a fixed integer).

Input. A "finite" partial function F on integers, i.e., a list of arrows $x_1 \rightarrow y_1, x_2 \rightarrow y_2, \ldots, x_m \rightarrow y_m$, where words x_i are all distinct and length$(y_i) \leq c$ length(x_i) and a string of the form $\Box z_1 \Box z_2 \ldots \Box z_p$.

Output. The string $\Box z'_1 \Box z'_2 \ldots \Box z'_p$, where $z'_i = F(z_i)$ if $F(z_i)$ is defined (i.e., z_i is some x_j and $F(z_i) = y_j$) and $z'_i = z_i$ otherwise.

PROPOSITION 4.2. *Problems LIST-COMPRESS, MULTISET-COMPRESS, ELEMENT-DISTINCTNESS, PERMUTATION, SET-INCLUSION, and set-equality all belong to*

DLINEAR.

Proof. We only mention the differences with the proof of Proposition 4.1. After the lexical analysis of string S that produces (for instances of LIST-COMPRESS, MULTISET-COMPRESS, and ELEMENT-DISTINCTNESS) the decomposition

$$S = \Box A_{h(1)} B_1 \ldots \Box A_{h(q)} B_q$$

(as above), the output of LIST-COMPRESS is computed by the following loop:

```
For $i := 1$ to $q$ do
begin
    if $A_{h(i)}$is "new" {i.e., that is the first occurrence of $A_{h(i)}$ in $S$}
        then write $\Box A_{h(i)}$
    if $B_i$ is "new" {i.e., $B_i \neq B_j$ for each $j < i$}
        then for each $A_j$ that occurs in $B_i$ do
            if $A_j$ is "new" then write $\Box A_j$
end;
```

Note that we check if a small A_j is new with the boolean array PRESENT (of the proof of Proposition 4.1) indexed by words w, such that length$(w) < b$, and that a big A_j is new iff register ENCODE(PAIR$^r(u_1, \ldots, u_r), r)$ contains zero at that moment.

For MULTISET-COMPRESS, we compute the part of output S' concerning the big A_i by acceding to its encoding a_i (computed as usual) and to a counter COUNT(a_i) indexed by a_i. To produce the part of S' concerning the small A_i, we first compute for each word $w \in (\sum \cup \{\Box\})^*$ of length less than b, the number, denoted NUMBER(w), of indexes i such that $B_i = w$. Then for each word w of length less than b and of the form $\Box\alpha_1\Box\alpha_2 \ldots \Box\alpha_s$ with $\alpha_j \in \sum^*$, its contribution to the numbers of small A_i is counted by the loop

$$\text{for } j := 1 \text{ to } s \quad \text{do COUNTER}(\alpha_j) := \text{ COUNTER}(\alpha_j) + \text{ NUMBER}(w).$$

Finally, count the small $A_{h(i)}$ by the loop

```
for $i$ : = 1 to $q$ do
    if length $(A_{h(i)}) < b$  then COUNTER$(A_{h(i)})$ := COUNTER$(A_{h(i)}) + 1$.
```

This proves the proposition for MULTISET-COMPRESS.

Problem ELEMENT-DISTINCTNESS is obviously decided by MULTISET-COMPRESS algorithm. The PERMUTATION algorithm is similar to the previous one. The main difference is that the A_i and the A'_j are counted separately. At the end we check if the corresponding counters are equal. Problems SET-INCLUSION and SET-EQUALITY have similar algorithms. □

PROPOSITION 4.3. *Problem ADDITION belongs to DLINEAR.*

Proof. Without loss of generality, assume that the input is $\Box A_1\Box A_2 \ldots \Box A_m$. First, that input is transformed (as follows) in such a way that the number m of summands A_i becomes $O(n/\log n)$. After the lexical analysis that gives $\Box A_{h(1)}B_1\Box A_{h(2)}B_2 \ldots \Box A_{h(q)}B_q$ (cf. proof of Proposition 4.1), each string B_i is replaced by the sum of the integers that it contains; that is, more precisely, if $B_i = \Box\alpha_1\Box\alpha_2 \ldots \Box\alpha_s$, then B_i is replaced by string $\Box\ A'_i$, where A'_i is the result of the sum $\alpha_1 + \alpha_2 + \cdots + \alpha_s$. That can be done efficiently by computing previously for each w of the form $w = \Box\alpha_1\Box\alpha_2 \ldots \Box\alpha_s$ (where the α_i are integers), such that length$(w) < b$, the integer $\alpha_1 + \alpha_2 + \cdots + \alpha_s$, and storing it in a table SUM(w).

Second, add the $m = O(n/\log n)$ integers A_i by the usual classroom algorithm on b-blocks, that is, with integers in base d^b (recall that integers are originally written in d-adic notation). The reader should be easily convinced that it requires only $O(n/\log n)$ steps and involves integers of length $O(\log n)$ (because $b = \Theta(\log n)$). □

PROPOSITION 4.4. *Problems PARTITION, SET-INTERSECT, and SET-DIFFERENCE belong to DLINEAR.*

Proof. Let us consider PARTITION. Without loss of generality, assume that $m = O(n/\log n)$. (For that purpose, apply ELEMENT-DISTINCTNESS algorithm to the list P, where each S_i is regarded as a string, i.e., an ordered list. Reject if two lists S_i, S_j are equal.) A sufficiently large k is chosen to get a sufficiently small block length $b = b_k(n)$ (that will be precisely stated below).

Then use a deterministic Turing machine that separates the list P into two lists, P' and P'', such that $P' = (S'_1, S'_2, \ldots, S'_m)$, $P'' = (S''_1, S''_2, \ldots, S''_m)$, and each $S'_i = \{e \in S_i : \text{length}(e) \geq b\}$ and each $S''_i = \{e \in S_i : \text{length}(e) < b\}$.

Clearly, P is a partition if and only if both P' and P'' are partitions. The Turing machine runs in linear time $O(n)$ and can be simulated by a DRAM within time $O(n/\log n)$ (by Proposition 3.1 (iii)).

It is easy to check if P' is a partition by the above hashing techniques. Therefore, without loss of generality, assume that in $P = (S_1, S_2, \ldots, S_m)$, each S_i is a list of elements e such that length$(e) < b$. Then divide each string S_i into b-blocks, that is, into substrings $S_i = B_i^1 B_i^2 \ldots B_i^{p_i}$ (concatenation) where each block B_i^j is a sublist of S_i of the form $e_1, e_2, \ldots, e_s$ (each e_u is an "elementary element") such that length $(B_i^j) \leq b$. This can be done in such a way that the total number of blocks B_i^j (for all $i \leq m$ and $j \leq p_i$) is $O(n/\log n)$ (because $m = O(n/\log n)$).

Then for each block B_i^j, store (in an array denoted SET) the index $i = \text{SET}(B_i^j)$ of the set S_i where B_i^j is included; reject in case there is a collision, that is, $B_i^j = B_{i'}^{j'}$, for $i \neq i'$ (that means that S_i and $S_{i'}$ have common elements). Finally, for each possible pair of blocks B, B' that contain at least one common element e and such that $\text{SET}(B) \neq 0$ and $\text{SET}(B') \neq 0$ (i.e., both B and B' occur in P), check if $\text{SET}(B) = \text{SET}(B')$. That can be done in time $o(n/\log n)$ for sufficiently small block length b.

This proves that PARTITION belongs to DLINEAR. The algorithms and proofs for SET-INTERSECT and SET-DIFFERENCE are similar and then are left to the reader. □

PROPOSITION 4.5. *Problems CHECK-SORT, FUNCTION-DEF, and FUNCTION-APPLY are in DLINEAR.*

Proof. Problem CHECK-SORT is a restriction of the DLINEAR problem PERMUTATION.

Let us consider FUNCTION-DEF. Apply successively to its input the LIST-COMPRESS algorithm (to avoid repetitions of arrows) and the NORMALIZE algorithm. This gives a string of the form $a_1 \to b_1, a_2 \to b_2, \ldots, a_p \to b_p$, where $p = O(n/\log n)$ and each a_i, b_i is $O(n/\log n)$. Now by storing the arrows in an array F by assignments $F(a_i) := b_i$, check if there is no collision.

The construction of an algorithm for FUNCTION-APPLY is left to the reader. □

From the NORMALIZE algorithm, we deduce the following "thesis."

ASSERTION 4.6 (Linear Time Thesis). *"Concrete algorithms" usually regarded as "computable in linear time" and concerning (weighted, directed, nondirected) graphs given by their lists of edges or propositional formulas in clausal form are in DLINEAR.*

Remark. This statement is called an assertion or thesis because it seems to be vague. It can be *proved* only for specific problems, for example:

PROBLEM HORN-SAT [DoGa], [ItMa1], [ItMa2], [Mi].

Input. A set S of propositional Horn clauses $\{C_1, C_2, \ldots, C_m\}$.

Question. Is S satisfiable?

PROBLEM SCC ("strongly connected components" [Ta], [AHU1]).

Input. A directed graph $G = (V, E)$ given by its list of vertices $v_1, \dots, v_m$ and its list of arcs $e_1, \dots, e_p$ $(e_i \in V^2)$.

Output. The set of strongly connected components of graph G.

Proof of Assertion 4.6 *for SCC.* First normalize the input. Apply LIST-COMPRESS algorithm to remove repetitions in the list of vertices and the list of arcs; so, we can assume that $m + p = O(n/\log n)$. Apply NORMALIZE algorithm to these lists so that the set of vertices becomes $V = \{1, 2, \dots, m\}$. Then implement the usual algorithm of [Ta] (see also [AHU1], [AHU2]) on the DRAM model; it runs in time $O(m + p) = O(n/\log n)$. □

Proof of Assertion 4.6 *for HORN-SAT.* The algorithms of [DoGa], [ItMa1], [ItMa2], [Mi] can be trivially implemented on a DRAM in time $O(n/\log n)$ if in the list of clauses S

(i) each propositional variable has length $O(\log n)$, and

(ii) the total number of occurrences of variables is $O(n/\log n)$.

For that reason it is sufficient to exhibit a DRAM$(n/\log n)$ algorithm that computes from each input S a new set of Horn clauses S' for which (i)–(ii) hold and which is satisfiable if and only if S is satisfiable.

We can assume that each clause of S has one of the two following forms:

$$(v_1, \dots v_s \rightarrow v_0) : \text{ pure Horn clause;}$$
$$(v_1, \dots, v_s \rightarrow \text{ FALSE}) : \text{ negative clause,}$$

where each v_i is any propositional variable. The list of variables $v_1, \dots, v_s$ is called the *hypothesis list* of the clause. Let $C_1, C_2, \dots, C_m$ denote the list of clauses of S. By the LIST-COMPRESS algorithm, we can assume that there is no repeated clause so that $m = O(n/\log n)$.

Let us fix a sufficiently large integer k. We now separate in each hypothesis list the "big hypotheses," that is, variables v_i such that length$(v_i) \geq b = b_k(n)$, and the "small hypotheses," that is, the v_i such that length$(v_i) < b$. A linear time-bounded Turing machine can transform each clause into the form $(v_1, \dots, v_r, v_{r+1}, \dots, v_s \rightarrow u)$, where u is either a variable or the FALSE value and for $i \leq r$ (respectively, $i > r$), v_i is a big (respectively, small) hypothesis.

Then for each clause C_i $(i \leq m)$, divide its list of small hypotheses $L_i = v_{r+1}, \dots, v_s$ into "blocks": $L_i = B_i^1 B_i^2 \dots B_i^{q_i}$ (concatenation), where each "block" B_i^j is a sublist of L_i such that length$(B_i^j) \leq b$. This can be performed in such a way that the total number of sublists B_i^j (for $i \leq m$ and $j \leq q_i$) is $O(n/\log n)$ (because $m = O(n/\log n)$).

The next idea is to replace each B_i^j (in each clause C_i) by a new propositional variable, denoted v_i^j that will be interpreted as the conjunction of the variables of B_i^j. We store the new variable v_i^j in an array VARIABLE(B_i^j) so that if $B_i^j = B_{i'}^{j'}$, then v_i^j and $v_{i'}^{j'}$ denote the same variable. Let C_i' denote the clause C_i so transformed, that is,

$$C_i' = (v_1, \dots, v_r, v_i^1, v_i^2, \dots, v_i^{q_i} \rightarrow u).$$

Let S' be the set of clauses

$$S' = \{C_1', \dots, C_m'\} \cup \{B_i^j \rightarrow v_i^j\}_{i \leq m, j \leq q_i},$$

where repetitions among the clauses are removed. Note that there are as many distinct clauses $B_i^j \rightarrow v_i^j$ as distinct blocks B_i^j, that is, less then d^b (where d is the cardinality of the alphabet of clauses), which is $O(n^{1/2})$ for sufficiently small $b = b_k(n)$.

It remains to prove the two following claims.

Claim 1. The number of occurrences of propositional variables in S' is $O(n/\log n)$.

Claim 2. S is satisfiable if and only if S' is satisfiable.

Claim 1 follows from the following three facts:

- $m = O(n/\log n)$;
- there are $O(n/b)$ occurrences of hypotheses in $C'_1, \dots, C'_m$;
- there are $O(d^b) \cdot O(b) = O(n^{1/2} \cdot \log n)$ occurrences of variables in all the clauses of the form $B_i^j \rightarrow v_i^j$.

Claim 2 follows from the following two facts:

- S' implies S by transitivity of implication;
- conversely, if an interpretation satisfies S, then S' is trivially satisfied by the extended interpretation where each v_i^j is interpreted by the conjunction of the variables of B_i^j (i.e., v_i^j is true if and only if each variable of B_i^j is true). □

5. Linear time bounded reductions. In §§6 and 7, we will state that many NP-complete problems belong to NLINEAR or are complete in this class. In the proofs we use the following notions.

DEFINITIONS AND NOTATIONS. *Let $T(n) \geq n$ be a time function. A function on words (or a language) is in* DTIME($T(n)$) *(respectively,* NTIME($T(n)$)) *if it is computable (respectively, recognizable) by a deterministic (respectively, nondeterministic) Turing machine in time $O(T(n))$, where n is the length of the input word.*

Let A, $B \subseteq \sum^*$ be two languages. We write $B \in$ NTIME$^A(n)$ (respectively, $B \in$ NRAM$^A(n/\log n)$) or $B \leq_{\text{NTM}} A$ (respectively, $B \leq_{\text{NRAM}} A$) if there is a nondeterministic Turing machine (respectively, a NRAM*) M such that for each word $w \in \sum^n$: each computation of M on input w runs within time $O(n)$ (respectively, time $O(n/\log n)$) and w belongs to B iff some computation of M on w computes a word of A.*

In the special case when machine M is deterministic, we write $B \in$ DTIME$^A(n)$ (respectively, $B \in$ DRAM$^A(n/\log n)$) or $B \leq_{\text{DTM}} A$ (respectively, $B \leq_{\text{DRAM}} A$) and the function computed by M is called a reduction of B to A.

PROPOSITION 5.1. (i) DTIME(n) $\subseteq$ DRAM($n/\log n$); *in consequence, if $A \leq_{\text{DTM}} B$, then $A \leq_{\text{DRAM}} B$.*

(ii) *For each language A,* NTIME$^A(n) \subseteq$ NRAM$^A(n/\log n)$.

(iii) *If A, B are languages such that $A \in$ NTIME(n) (respectively, $A \in$ NRAM($n/\log n$)) and $B \in$ NTIME$^A(n)$ (respectively, $B \in$ NRAM$^A(n/\log n)$), then $B \in$ NTIME(n) (respectively, $B \in$ NRAM($n/\log n$)).*

(iv) *Relations $\leq_{\text{DTM}}$, $\leq_{\text{DRAM}}$, $\leq_{\text{NTM}}$, and $\leq_{\text{NRAM}}$ are transitive.*

(v) *Let $X \in \{D, N\}$ be a letter for "determinism" or "nondeterminism" and $T(n) \geq n$ (respectively, $T(n) \geq n/\log n$) be a nondecreasing function. If $A \leq_{\text{XTM}} B$ and $B \in$ XTIME($T(n)$) (respectively, $A \leq_{\text{XRAM}} B$ and $B \in$ XRAM($T(n)$)), then there is a constant c such that $A \in$ XTIME($T(cn)$) (respectively, $A \in$ XRAM($T(cn)$)).*

Proof. Assertions (i)–(v) either are classical results concerning Turing machines (see for example [HoUl], [Mo]) or are restatements or easy generalizations of assertions of Proposition 3.1. The proofs are similar. □

6. Most combinatorial NP problems belong to NLINEAR. We believe that the 21 NP-complete problems listed by Karp [Ka] are "combinatorial problems" (a possible exception is problem 19, called "job sequencing" in [Ka] and "sequencing to minimize tardy task weight" in [GaJo]; it seems to be more algebraic). The notion of combinatorial problem is as intuitive and at least as difficult to formulate as the notions of "computability" (captured by Turing computability) or "feasible computability" (captured by class P of polynomial time Turing computable problems). In the present section, we prove that many NP problems and, in particular, the 20 NP-complete problems 1–18 and 20 and 21 of [Ka] belong to NLINEAR. This justifies our conviction that combinatorial NP problems *are* NLINEAR problems. We choose to give explicit proofs for the following six significant problems.

SUBSET-SUM (Problem 18 in [Ka]).
Input. Integer B and list of integers $A_1, A_2, \ldots, A_m$.
Question. Is there a subset I of $\{1, 2, \ldots, m\}$ such that $\sum_{i \in I} A_i = B$?

EXACT-COVER (Problem 14 in [Ka]).
Input. List of sets $S_1, S_2, \ldots, S_m$ and set S.
Question. Is there a subset I of $\{1, 2, \ldots, m\}$ such that the family $(S_i)_{i \in I}$ is a partition of S?

HITTING-SET (Problem 15 in [Ka]; a variant numbered [SP8] appears in [GaJo]).
Input. List of sets $S_1, S_2, \ldots, S_m$.
Question. Is there a set S such that for each $i \leq m$, $S \cap S_i$ has exactly one element?

FEEDBACK-ARC-SET (Problem 8 in [Ka]).
Input. Integer K and directed graph $G = (V, A)$.
Question. Is there a subset $A' \subseteq A$ of cardinality at most K such that A' contains at least one arc from every directed cycle in G?

TRAVELING-SALESMAN (Problem [ND22] in [GaJo]).
Input. Integer K and weighted nondirected graph $G = (V, E)$ given by its list of weighted edges $e_1, e_1, \ldots, e_p$, where $e_i = (a_i, b_i, w_i)$, $a_i, b_i \in V$, and w_i is a positive integer.
Question. Has G a Hamilton circuit of weight not greater than K?

Pfleeger [Pf] has proved the NP completeness of the following problem.

PROBLEM RISA ([AL7] in [GaJo]).
Input. An integer K and an incompletely specified deterministic finite state automaton $\mathcal{A} = (Q, \sum, \delta, q_0, F)$, where Q is the set of states, $\sum$ is the input alphabet, $q_0 \in Q$ is the initial state, $F \subseteq Q$ is the set of final states, and δ is a partial function: $Q \times \sum \rightarrow Q$.
Question. Can δ be extended to a total function $Q \times \sum \rightarrow Q$ in such a way that the minimal automaton of the resulting completely specified automaton has no more than K states?

Remark (RISA characterization). It is easy to see that the question above is equivalent to the following one (where Q' denotes the set of states reachable from q_0). Is there a map $h : Q' \rightarrow \{1, 2, \ldots, K\}$ that respects the following conditions?

(i) For all $q, q' \in Q'$ such that $h(q) = h(q')$, we have $q \in F$ if and only if $q' \in F$ (i.e., h respects the distinction "final/nonfinal states").

(ii) For all $q, q' \in Q', \sigma \in \sum$ such that $h(q)$ and $h(q')$ are equal and $\delta(q, \sigma)$ and $\delta(q', \sigma)$ are both defined, we have $h(\delta(q, \sigma)) = h(\delta(q', \sigma))$ (i.e., h respects the deterministic nature of the automaton).

THEOREM 6.1. *Twenty among the* 21 *NP-complete problems given by* [*Ka*] *that are problems* 1–18 *and* 20 *and* 21 *and problems TRAVELING-SALESMAN and RISA belong to NLINEAR.*

Remark. When an input involves a (weighted, directed, nondirected) graph, we assume that it is represented by its list of arcs.

Proof of Theorem 6.1. We prove the theorem for the six problems explicitly given above. The reader is invited to adapt the proofs to the other ones.

- TRAVELING-SALESMAN. Apply the FUNCTION-DEF algorithm (to check if no edge has two distinct weights) and the LIST-COMPRESS one (to suppress edge repetitions). By the NORMALIZE algorithm, we can assume that the set of vertices is $V = \{1, 2, \dots, m\}$ with $m = O(n/\log n)$. Then guess a cycle $e'_1, e'_2, \dots, e'_m$, where e'_i is a weighted edge: check if the cycle is included in the list of edges of G and includes each vertex (by two applications of SET-INCLUSION algorithm); check that no vertex is repeated in the cycle (by ELEMENT-DISTINCTNESS algorithm); and check if the weight of the cycle does not exceed K (by ADDITION algorithm).
- RISA. By successive applications of FUNCTION-DEF, LIST-COMPRESS, and NORMALIZE algorithms, normalize the input as above. In particular, we can assume that $\sum = \{1, 2, \dots, r\}$ and $Q = \{1, 2, \dots, s\}$ with $r + s = O(n/\log n)$ and that the number t of transitions of δ is $O(n/\log n)$. By a classical algorithm, a DRAM can compute the set Q' of reachable states within time $O(t) = O(n/\log n)$ and suppress the nonreachable states and the transitions that involve them. We now use the RISA characterization given in the remark above.

Guess for each reachable state $q \leq s$ a value $h(q) \leq K < s$ with which q is identified (function h can be stored in an array). Transform each transition $\delta(q, \sigma) = q'$ into transition $\delta'(h(q), \sigma) = h(q')$ and check if the resulting automaton (with set of states included in $\{1, 2, \dots, K\}$ and transition function δ') is deterministic (with FUNCTION-DEF algorithm) and has a well-defined set F' of final states: $h(q) \in F'$ if and only if $q \in F$.

- SUBSET-SUM. A linear time-bounded nondeterministic Turing machine (simulated by a NRAM in time $O(n/\log n)$) can guess a sublist $(A_i)_{i \in I}$. Then check if $\sum_{i \in I} A_i = B$ (by ADDITION algorithm).
- EXACT-COVER. Guess the sublist $(S_i)_{i \in I}$ as above and then check if it is a partition (by PARTITION algorithm) and if S is equal to the union set $\cup_{i \in I} S_i$ (by SET-EQUALITY algorithm).
- HITTING-SET. Guess a set S (of course, length$(S) \leq n$) and then check if for each $i \leq m$, set $S_i \cap S$ has exactly one element (by SET-INTERSECT algorithm).
- FEEDBACK-ARC-SET. The question is equivalent to the following one. Is there a subset $A' \subseteq A$ of cardinality at most K such that the directed graph $G' = (V, A - A')$ is acyclic? The recognizability of acyclicity of directed graphs belongs to DLINEAR (use some classical algorithm). □

The reader is invited to prove similarly that many other combinatorial NP problems (subgraph isomorphism, graph isomorphism, partition into cliques, and so on) are in NLINEAR.

7. Some NP-complete problems are NLINEAR complete. As seen in §6, the class NLINEAR = NRAM$(n/\log n)$ that refines the NP class includes many natural NP-complete problems. The following notion is comparable with NP completeness.

DEFINITION. *A problem A is NLINEAR complete if*

(i) *$A \in$ NLINEAR and*

(ii) *A is NLINEAR hard, that is, for each problem B in NLINEAR, $B \leq_{\mathrm{DTM}} A$.*

Remark. It is obvious that a NLINEAR-complete problem is also NP complete. Recall that $B \leq_{\mathrm{DTM}} A$ implies $B \leq_{\mathrm{DRAM}} A$. The following proposition is an immediate consequence of the definition above.

PROPOSITION 7.1. *Let A be a NLINEAR-complete problem. The following assertions are equivalent:*

(i) *NLINEAR = DLINEAR;*

(ii) *$A \in$ DLINEAR.*

Remark. We do not know whether NLINEAR $\neq$ DLINEAR. However, Paul et al. [PPST] have proved a similar assertion for Turing machines, that is, NTIME$(n) \neq$ DTIME(n). It implies that no DTIME(n) algorithm exists for any NLINEAR-hard problem.

The following proposition means that any efficient algorithm for a NLINEAR-complete problem can be used to solve any other NLINEAR problem *without loss of efficiency.*

PROPOSITION 7.2. *Let* $T(n) \geq n$ (*respectively,* $T(n) \geq n/\log n$) *be any nondecreasing function. If any NLINEAR-complete* (*or NLINEAR-hard*) *problem belongs to* DTIME($T(n)$) (*respectively,* DRAM($T(n)$)), *then NLINEAR* $\subseteq \cup_c$ DTIME($T(cn)$) (*respectively, NLINEAR* $\subseteq \cup_c$ DRAM($T(cn)$)).

Proof. Immediate. □

COROLLARY 7.3. *Let* A, B *be two NLINEAR-complete problems and* $T(n) \geq n$ *and* $T'(n) \geq n/\log n$ *be two nondecreasing functions. Then*

(i) $A \in \cup_c$ DTIME($T(cn)$) *if and only if* $B \in \cup_c$ DTIME($T(cn)$);

(ii) $A \in \cup_c$ DRAM($T'(cn)$) *if and only if* $B \in \cup_c$ DRAM($T'(cn)$).

It is well known that the problem SAT of Cook ("satisfiability of propositional formulas in clausal form") is a "generic" NP-complete problem [Co1], [Co2], [HoUl]. Similarly, we are going to use the following problem, denoted CONTRACT ("contraction of partial functional structures"), as a tool to prove NLINEAR completeness of other problems.

PROBLEM CONTRACT [Ra1], [Ra2].

Input. Set C of "constants," set X of "variables," set $\mathcal{F}$ of unary function symbols (elements of sets C, X, $\mathcal{F}$ are assumed to be presented in *lexicographical order*) and conjunction Γ of equalities of the form $f(u) = v$, where $f \in \mathcal{F}$, $u, v \in C \cup X$ and such that terms $f(u)$ are all distinct in Γ and occur in lexicographical order.

Question. Is conjunction Γ satisfiable on set C, that is, is there a function $VAL\colon C \cup X \to C$ that is the identity on C and, for each $f \in \mathcal{F}$, an interpretation f', that is, a partial function $f' : C \to C$ such that if $f(u) = v$ is an equality in Γ, then $f'(VAL(u)) = VAL(v)$ holds?

The following logical notion (a variant of a concept introduced by Scholz [Sz] and generalized by Fagin [Fa]) will be an essential tool in our proof that CONTRACT is a NLINEAR-complete problem.

DEFINITION. *Let* φ *be a first-order sentence* (*with equality*) *with type* $\mathcal{T} = \{f_1, f_2, \ldots, f_p, g_1, g_2, \ldots, g_q\}$ *where the* f_i, g_j *are unary function symbols, respectively, called specified and unspecified function symbols. The generalized spectrum of* φ, *denoted* GenSPECTRUM(φ), *is the set of structures* $(m, f_1, f_2, \ldots, f_p)$ (*where m is a positive integer identified with set* $\{0, 1, \ldots, m-1\}$) *that have an expanded structure* $(m, f_1, f_2, \ldots, f_p, g_1, g_2, \ldots, g_q)$ *that satisfies* φ.

Remark. It is convenient that an interpretation of a function symbol f_i, g_j will be denoted f_i, g_j (i.e., without any change).

Fagin, in his well-known seminal paper [Fa], proved that the class of generalized first-order spectra (in other words, the existential second-order logic) exactly captures the class NP. The following proposition refines Fagin's result in some manner: it shows that the subclass NLINEAR can be similarly captured by the existential second-order logic with only one (first-order) variable.

PROPOSITION 7.4. *If* $A \in$ *NLINEAR, then there is a first-order sentence* φ *of unary type* $\mathcal{T}$ *as above, such that*

(i) $A \leq_{\mathrm{DTM}}$ GenSPECTRUM(φ);

(ii) φ *is of the form* $\forall x \Psi(x)$, *where* $\Psi(x)$ *has only one variable and is a conjunction* $\bigwedge_i \sigma_i(x) = \tau_i(x)$ *of equalities of the form*

$$G_r \ldots G_2 G_1(x) = H_s \ldots H_2 H_1(x),$$

where $r \geq 1$, $s \geq 0$ *and each* G_i, $H_j \in \mathcal{T}$, *and such that* (ii.1) *no term or subterm of the form* $f_i(x)$ (*where* f_i *is a specified function symbol*) *occurs in* Ψ; *and*

(ii.2) *no first member* $\sigma_i(x)$ *is a subterm of another first member* $\sigma_j(x)$ (*for* $i \neq j$) *or of a second member* $\tau_j(x)$ (*here "subterm" means "proper subterm or equal term"*).

Sketch of proof. The proof is rather long and technical. It is essentially given in [Gr2], [Ra1], [Ra2] where the result is stated in a slightly weaker form. In those papers Language A is assumed to be in NTIME(n) (because the authors focus on Turing machines), but as a matter of fact, they prove the stronger result $A \leq_{\text{DTM}}$ GenSPECTRUM(φ) for all $A \in \text{NRAM}_k(n/\log n)$ (for sufficiently large k) and use the inclusion NTIME(n) $\subseteq \text{NRAM}_k(n/\log n)$. Let us roughly recall the stages of the proof (for details, the reader is invited to read the complete proof in [Gr2], [Ra1], [Ra2]).

First, construct a prenex first-order sentence φ that describes the computation of the NRAM$_k$ (which recognizes A in time $O(n/\log n)$). φ has to be interpreted on domain $m = \{0, 1, \dots, m-1\}$ where $0, 1, \dots, m-1$ intuitively represent the m successive instants of the computation (in particular, $m = O(n/\log n)$). Moreover, the prenex sentence φ has only one universally quantified variable and its only nonlogical symbols are $=$, $<$ (equality and natural order on m) and unary function symbols.

Second, transform formula φ in such a way that it satisfies condition (ii) above. In particular, natural order $<$, negations, and disjunctions are removed by some techniques comparable with Skolemization. New specified or unspecified function symbols are introduced for that purpose. □

Remark. We can assume that an output of the reduction $A \leq_{\text{DTM}}$ GenSPECTRUM (in Proposition 7.4), which is a structure $\mathcal{S} = (m, f_1, f_2, \dots, f_p)$ with length($\mathcal{S}$) $= O(n)$, is presented in the following manner: each function f_j is given in increasing order of its arguments, that is, by a list of the form $0 \to f_j(0)$, $1 \to f_j(1), \dots, m-1 \to f_j(m-1)$ (recall that $m = O(n/\log n)$ and the number p of functions does not depend on input w).

LEMMA 7.5. *Let* φ *be the sentence* $\forall x \Psi(x)$ *of Proposition* 7.4. *We have*

$$\text{GenSPECTRUM}(\varphi) \leq_{\text{DTM}} \textit{CONTRACT},$$

where each input structure $\mathcal{S} = (m, f_1, \dots, f_p)$ *is assumed to be presented in increasing order* (*cf. remark above*).

Proof. The main idea of the DTIME(n) reduction is the following one: unroll the sentence $\varphi = \forall x \Psi(x)$ on its domain m; that is, replace φ by conjunction $\bigwedge_{e<m} \Psi(e)$ where $\Psi(e)$ is obtained by substituting constant e for each occurrence of x in Ψ. From the definition of generalized spectrum, it is obvious that a structure $\mathcal{S}$ (on domain m) belongs to GenSPECTRUM(φ) if and only if the following conjunction of equalities, denoted γ, is satisfiable on domain m:

$$\bigwedge_{e<m} \Psi(e) \wedge \bigwedge_{j \leq p} \text{Diagram } (f_j)$$

where Diagram(f_j) denotes the conjunction of equalities $\bigwedge_{e<m} f_j(e) = e_j$ (sorted by increasing order of argument e) and e_j denotes the value of the term $f_j(e)$ in $\mathcal{S}$.

The conjunction γ is almost an instance of problem CONTRACT (with constants $0, 1, \dots, m-1$).We now have to "cut" the compositions of functions in each conjunct $\Psi(e)$ ($\Psi(e)$ is of the form $\bigwedge_i \sigma_i(e) = \tau_i(e)$). For that purpose introduce for each (sub)term $\mathcal{O}(e)$ in γ (except for constants $e < m$) a "variable" denoted $\underline{\mathcal{O}(e)}$ (underlined). The instance of problem CONTRACT corresponding to $\mathcal{S}$ will be the following one:

- $C = m = \{0, 1, \dots, m-1\}$;
- $X = \{\underline{\mathcal{O}(e)} : \mathcal{O}(e)$ is a (sub)term in γ, distinct from $e\}$;
- $\mathcal{F} = \{f_1, \dots, f_p, g_1, \dots, g_q\}$;

• conjunction Γ is obtained by unrolling each (sub)term in γ; for example, if γ contains the equality $f_1 g_3(2) = g_1(2)$, we replace that equality by the following conjunction: $g_1(2) = \underline{g_1(2)} \bigwedge g_3(2) = \underline{g_3(2)} \bigwedge f_1(\underline{g_3(2)}) = \underline{g_1(2)}$.

We easily see that conjunction γ is satisfiable on m iff Γ is satisfiable on m. Hence, the correspondence $\mathcal{S} \mapsto (C, X, \mathcal{F}, \Gamma)$ is a reduction of GenSPECTRUM(φ) to problem CONTRACT. That reduction is computable in linear time by a deterministic Turing machine. □

COROLLARY 7.6. *Problem CONTRACT is NLINEAR hard.*

PROPOSITION 7.7. *CONTRACT* $\leq_{\mathrm{DTM}}$*RISA.*

Proof. An instance $\mathbb{C} = (C, X, \mathcal{F}, \Gamma)$ of problem CONTRACT (without loss of generality, we assume $C = \{0, 1, \ldots, m-1\}$) is reduced to the following instance $(\mathcal{A}, K)$ of problem RISA:

$$\mathcal{A} = (Q, \textstyle\sum, \delta, q_0, F)$$

where

• $Q = C \cup \{m\} \cup X$;

• $\sum = \mathcal{F} \cup \{\mathrm{Succ}\}$ (intuitively, Succ is the successor function on integers);

• partial transition function $\delta : Q \times \sum \to Q$ is defined by $\delta(u, f) = v$ for each conjunct $f(u) = v$ in Γ (note that $\delta(u, f)$ is not defined twice because term $f(u)$ occurs at most once in Γ) and $\delta(u, \mathrm{Succ}) = u + 1$ for each $u \in C = \{0, 1, \ldots, m-1\}$ ($\delta(m, \mathrm{Succ})$ is undefined); $q_0 = 0$; $F = \{m\}$; and $K = m + 1$ (K is the cardinality of set $C \cup \{m\}$).

It is easy to see that each state $q \in Q$ is reachable from $q_0 = 0$ and that a deterministic Turing machine can compute the instance $(\mathcal{A}, K)$ in linear time $O(n)$. It remains to prove the following equivalence: $\mathbb{C} \in$ CONTRACT if and only if $(\mathcal{A}, K) \in$ RISA. From a solution h, for instance, $\mathbb{C}$ (i.e., a "contraction" of $\mathbb{C}$), we easily deduce a K-reduction of the incomplete automaton $\mathcal{A}$; that is, the contraction h of $\mathbb{C}$ on C that is extended by setting $h(m) = m$. The backward direction of the proposition, that is, $(\mathcal{A}, K) \in$ RISA implies $\mathbb{C} \in$ CONTRACT, is an easy consequence of the following lemma. This concludes the proof of Proposition 7.7. □

LEMMA 7.8. *Let $\mathcal{A}' = (Q, \sum, \delta', q_0, F)$ be a completely specified finite automaton that completes the above $\mathcal{A}$, that is, whose transition function δ' extends δ. In $\mathcal{A}'$*

(i) *all the states are reachable (from q_0);*

(ii) *the equivalence class of state m is $\{m\}$;*

(iii) *if $\mathcal{A}'$ is K-reducible (recall $K = m + 1$), then its K equivalence classes are exactly the class of* 0, *the class of* $1, \ldots,$ *the class of* $m - 1$, *and* $\{m\}$.

Proof. (i) holds for $\mathcal{A}$ and then for $\mathcal{A}'$. (ii) follows from the fact that m is the only final state. Let us prove (iii): we have $\delta(j, \mathrm{Succ}^{m-j}) = m \in F$ and $\delta(i, \mathrm{Succ}^{m-j}) = m - j + i \notin F$ for all $i < j \leq m$; hence, states i, j are not equivalent. □

COROLLARY 7.9. *Problems CONTRACT and RISA are NLINEAR complete.*

Proof. It follows from the fact that for each A in NLINEAR, $A \leq_{\mathrm{DTM}}$ CONTRACT $\leq_{\mathrm{DTM}}$ RISA and RISA $\in$ NLINEAR. □

Remark. Ranaivoson [Ra1], [Ra2] has strengthened Corollary 7.9. Problem RISA (respectively, CONTRACT) remains NLINEAR complete when it is restricted to a binary alphabet $\sum = \{0, 1\}$ (respectively, to type $\mathcal{T} = \{f_0, f_1\}$ with only two function symbols). He also shows that RISA is in P when $\sum = \{1\}$. Moreover, he exhibits several NLINEAR-complete problems concerning acyclic directed graphs. Note that [Ra1], [Ra2] shows the NLINEAR completeness of each above problem A by proving CONTRACT $\leq_{\mathrm{DTM}}$ A, but the reduction itself and the proof of its correctness are much longer and more technical than ours for

$A =$ RISA. Our student, Creignou [Cr], has recently proved the NLINEAR completeness of problems of directed or nondirected graphs by a simpler method.

Proposition 7.4 will be useful in the proof of the following characterization of class NLINEAR.

PROPOSITION 7.10. *NLINEAR = NTIME$^A(n)$ for all $A \in$ {FUNCTION-DEF, CHECK-SORT, PERMUTATION, SET-EQUALITY, SET-INCLUSION}.*

Proof. We have seen that each problem A above belongs to DLINEAR. Hence, NTIME$^A(n) \subseteq$ NLINEAR. To get the converse inclusion for $A =$ FUNCTION-DEF, it suffices to prove that for each first-order sentence $\varphi = \forall x \Psi(x)$ described in Proposition 7.4, we have GenSPECTRUM(φ) $\leq_{\mathrm{NTM}}$ FUNCTION-DEF. We show it by a variant of the proof of Lemma 7.5 (that states GenSPECTRUM(φ) $\leq_{\mathrm{DTM}}$ CONTRACT). Let us describe only the differences with that proof. Instead of unrolling the conjunction γ (associated with structure $\mathcal{S}$) by the introduction of "variables" for terms and subterms in γ, we now guess the intermediate values (less than m), that is, values of concerned (sub)terms. For example, if $m = 5$ and if γ contains the equality $f_1 g_3(2) = g_1(2)$, this equality may be replaced by the following conjunction

$$g_1(2) = \underline{4} \bigwedge g_3(2) = \underline{0} \bigwedge f_1(0) = 4$$

(convention: underlined $\underline{4}$ and $\underline{0}$ are "guessed"; the other occurrences 2, 0, and 4 are only "copied"). Let Γ denote the conjunction γ so transformed (there are as many possible Γ as possible guessed assignments). γ is satisfiable on m iff some associated Γ is satisfiable. Γ is almost an instance of FUNCTION-DEF, but it concerns not one but *several* functions $f_1, \ldots, f_p, g_1, \ldots, g_q$. For that reason, each equality $f_i(u) = v$ (respectively, $g_j(u) = v$) in Γ is replaced by arrow $u' \rightarrow v$, where u' is the integer $(p+q)u+i$ (respectively, $(p+q)u+p+j$) and u' encodes the term $f_i(u)$ (respectively, $g_j(u)$). Let Γ' denote the resulting instance of FUNCTION-DEF. Clearly, Γ is satisfiable if and only if $\Gamma' \in$ FUNCTION-DEF.

A nondeterministic Turing machine with input $\mathcal{S}$ can be constructed such that γ, Γ, and Γ' are successively computed within linear time. That proves GenSPECTRUM(φ) $\leq_{\mathrm{NTM}}$ FUNCTION-DEF.

To obtain the same results for any of the other four problems A, it suffices to show FUNCTION-DEF $\leq_{\mathrm{NTM}} A$. For any instance $L = (x_1 \rightarrow y_1, x_2 \rightarrow y_2, \ldots, x_s \rightarrow y_s)$ of FUNCTION-DEF, guess some list $L = (x'_1 \rightarrow y'_1, \ldots, x'_s \rightarrow y'_s)$, where for each $i < s$: either $x'_i < x'_{i+1}$ or $x'_i = x'_{i+1}$ and $y'_i = y'_{i+1}$ (intuitively, L' defines a function and is sorted). Clearly, $L \in$ FUNCTION-DEF if there is some list L' such that $(L, L') \in$ CHECK-SORT (L' is the sorted version of list L). Moreover, a nondeterministic Turing machine can guess L' in linear time. Hence, FUNCTION-DEF $\leq_{\mathrm{NTM}}$ CHECK-SORT.

The same result is easily proved for problems PERMUTATION, SET-EQUALITY, and SET-INCLUSION with the same reduction. □

Remark. Proposition 7.10 holds for many other problems A. The abovementioned problems are the simplest ones we have found. In our opinion FUNCTION-DEF is the most significant. It indicates what computational power a nondeterministic linear time-bounded Turing machine lacks to capture NLINEAR.

COROLLARY 7.11. *NTIME(n) $\subseteq$ NLINEAR $\subseteq$ NTIME($n \log n$).*

Proof. The first inclusion has been proved above. The second one results from the following facts: NLINEAR $\leq_{\mathrm{NTM}}$ CHECK-SORT and CHECK-SORT $\in$ DTIME($n \log n$) (by the usual merge-sort algorithm). □

We have seen that several NP-complete problems (RISA, CONTRACT) are NLINEAR complete. The reader may ask whether most of natural NP-complete problems in NLINEAR are NLINEAR complete. We suggest a partial answer by studying problem SAT (i.e., satisfiability of propositional formulas in clausal form). We need the following mixed complexity class.

DEFINITION. *Let A be a language and $T(n)$, $T'(n)$ be time functions. We write*

$$A \in \mathrm{NDRAM}(T(n), T'(n))$$

if A is recognized by an NRAM *in such a way that for any input $w \in A$ of length n there is an accepting computation of the* NRAM *with only $O(T(n))$ GUESS instructions (i.e., nondeterministic steps) and $O(T'(n))$ other instructions (i.e., deterministic steps).*

PROPOSITION 7.12. *Problem SAT is in* $\mathrm{NDRAM}(n/(\log n)^2, n/\log n)$.

Proof. By running the NORMALIZE algorithm, we can assume that the set of propositional variables is $\{p_1, p_2, \ldots, p_r\}$, where $r = O(n/\log n)$. Guess a truth assignment $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_r) \in \{1, 2\}^r$ for the r variables (convention: $1 = \mathrm{TRUE}$, $2 = \mathrm{FALSE}$) by blocks of length $b = \ulcorner c \log(n+1) \urcorner$ (for a constant integer c). More precisely, a string $\alpha = B_1 B_2 \ldots B_s$, where each $B_i \in \{1, 2\}^*$, $\mathrm{length}(B_i) = b$ for $i < s$, and $0 < \mathrm{length}(B_s) \leq b$ ($s = \ulcorner r/b \urcorner$) is guessed and stored by s instructions $\mathrm{GUESS}(R(i))$ (B_i is stored in register $R(i)$).

The stored assignment α is analyzed by $O(r) = O(n/\log n)$ deterministic instructions that compute the list of pairs $(p_1, \alpha_1), (p_2, \alpha_2), \ldots, (p_r, \alpha_r)$.

Then run FUNCTION-APPLY algorithm to substitute for each variable p_i in each clause its truth value α_i. Finally, a finite automaton can evaluate all the clauses. Note that the number of nondeterministic instructions is $s = \ulcorner r/b \urcorner = O(n/(\log n)^2)$. □

COROLLARY 7.13. *The NLINEAR completeness of problem SAT would imply the following inclusion*: $\mathrm{NRAM}(n/\log n) \subseteq \mathrm{NDRAM}(n/(\log n)^2, n/\log n)$.

That inclusion is very unlikely: it would mean that any nondeterministic algorithm could be simulated by performing fewer nondeterministic steps and the same number (up to a multiplicative constant) of deterministic steps. We conjecture that that inclusion implies $P = NP$. (Indeed it seems stronger than $P = NP$.) Notice that Theorem 5 in [BuGo] presents a result (relative to an oracle) that, informally, shows that large amounts of nondeterminism can be useful even if small amounts are not.

Remark. Proposition 7.12 holds not only for SAT but also for many other NP-complete problems; in particular, it can be proved for five among the six problems studied in Theorem 6.1: TRAVELING-SALESMAN, SUBSET-SUM, EXACT-COVER, HITTING-SET, and FEEDBACK-ARC-SET (the proof is not trivial for TRAVELING-SALESMAN and SUBSET-SUM). The reader is encouraged to prove that and to discover other such problems.

Notice that Schnorr [Sr] and Cook [Co2] (respectively, Robson [Ro2]) have proved that any problem in $\mathrm{NTIME}(n)$ (respectively, computable by some nondeterministic RAM in linear time under logarithmic cost) is reducible to problem SAT in time $O(n(\log n)^2)$ on a deterministic Turing machine.

8. Conclusions and open problems. We have defined and studied two robust complexity classes: DLINEAR and NLINEAR. We believe that these classes satisfyingly capture the intuitive notions of deterministic and nondeterministic linear time.

- Each DLINEAR algorithm runs within linear time under logarithmic cost (hence, DLINEAR is included in the complexity class LINEAR defined in [Gr3]) and, similarly, for NLINEAR.
- DLINEAR contains most (all?) classical linear time-bounded algorithms (problems of graphs represented by their list of arcs, propositional Horn satisfiability, etc.) and several other ones (CHECK-SORT, LIST-COMPRESS, and so on).
- NLINEAR includes most of (all?) combinatorial NP-complete problems.

- The concepts we have introduced are natural and fruitful because there are *natural* NLINEAR-complete problems (the notion of NLINEAR completeness strengthens that of NP completeness) and then most combinatorial NP-complete problems are reducible to these problems in deterministic linear time.

The fact that many concrete algorithms run in linear time can be formalized in a uniform manner (i.e., independently of the nature of the inputs: graphs, lists, words, formulas) by using the DLINEAR concept. Similarly, we are convinced that our study of the class NLINEAR contributes to a better understanding of the theory of NP completeness of natural problems. In particular, it is interesting to notice that most of combinatorial NP-complete problems are in NLINEAR, which is a low (nondeterministic) complexity class.

We conclude this paper by describing some open problems and conjectures.

- Problem CHECK-SORT is in DLINEAR, but we have not been able to prove the same result for the sorting problem (our hashing techniques do not respect the natural order of integers).
- We strongly conjecture that DLINEAR includes the classical linear time-bounded algorithms when each graph is represented by its list of successors (respectively, predecessors), that is, by $(v_1, L_1), \ldots, (v_m, L_m)$ where L_i denotes the list of successors of vertex v_i. The difficult point is the fact that if such a representation has length n, then the number of distinct arcs of the graph is not necessarily $O(n/\log n)$ but may be $\Omega(n/\log\log n)$. We get over that difficulty by using the following remarks: it seems that each natural linear time algorithm on graphs is controlled either by depth-first search, by breadth-first search, or by topological sorting and it is very likely that the techniques of grouping "little vertices" into blocks can be naturally applied to these three searches in such a way that they work in time $O(n/\log n)$ on a DRAM.
- JOB-SEQUENCING is the only problem among the 21 NP-complete problems presented by Karp [Ka] for which we have not succeeded in proving that it belongs to NLINEAR. However, we strongly conjecture that it does (it seems to be more complicated and more algebraic than the 20 other ones. For example, partial sums occur in its statement).
- Class DLINEAR (respectively, NLINEAR) is contained in the class of problems computable in deterministic (respectively, nondeterministic) linear time under logarithmic cost. We conjecture that these classes are equal. Wiedermann [Wi2] has proved the following weaker result: a RAM that runs in time $T(n)$ under logarithmic cost can be simulated by a RAM that runs within time $O(T(n)/\log\log T(n))$ under uniform cost.
- We have proved that it can be required that NLINEAR (respectively, DLINEAR) computations involve only integers $O(n/\log n)$ (respectively, $O(n^{1+\epsilon})$); therefore, in the deterministic case, the DRAM may use somewhat "scattered" addresses $O(n^{1+\epsilon})$. It would be of great interest to show that the memory of a DRAM can be used in the most "compact" manner, that is, to require a DLINEAR computation to only involve addresses $O(n/\log n)$ like in the nondeterministic case.
- We have exhibited natural NLINEAR-complete problems. Similarly, the discovery of a natural *DLINEAR-complete* problem (i.e., a problem A such that DLINEAR $=$ DTIME$^A(n)$) would be a nice breakthrough; it would mean that *one* algorithm (the DLINEAR algorithm of A) would be the "pattern" of all the other DLINEAR algorithms (and they are numerous). We believe that such a result would follow from a logical characterization of class DLINEAR exactly as the NLINEAR completeness of problems CONTRACT and RISA has been deduced from our characterization of class NLINEAR by generalized spectra of first-order sentences.
- All the NLINEAR-complete problems we know concern contractions of structures (can a given structure be transformed by identification of some elements in such a way that the resulting structure respects some given constraint?) or satisfiability of formulas (cf. [Gr1]).

In fact, contraction problems can be regarded as satisfiability problems, and vice versa. Are there some NLINEAR-complete problems of some very different nature (e.g., subgraph isomorphism)?

- We conjecture that a careful analysis of the $\leq_{\mathrm{DTM}}$ reductions presented in §7 (to show that CONTRACT, RISA, and so on are NLINEAR hard) would prove that they are reset-loglin. This very strong reduction has been introduced by Compton and Henson [CoHe]. It strengthens the notion of logarithmic space linear time-bounded reduction. Moreover, the class of reset-loglin reductions is closed under composition.
- Does the NLINEAR completeness of problem SAT imply $P = NP$?

Acknowledgments. Thanks to Yuri Gurevich for stimulating discussions. Many thanks to Sylvie Hunout-Déroff for her help with the manuscript.

Note added in proof. Two abovementioned conjectures have been recently positively solved.

1. Grandjean (*Sorting, linear time, and the satisfiability problem*, to appear in a special issue of Annals of Math. and Artificial Intelligence) proved that the classical problem of SORTING *is* in DLINEAR and even belongs to the smaller class DLIN (DLIN is defined like DLINEAR but each RAM must only use integers $O(n/\log n)$ for any input of length n).

2. We recently noticed that JOB-SEQUENCING problem belongs to NLINEAR. This shows that *all* the NP-complete problems presented by Karp [Ka] *are* in NLINEAR.

DIGITAL SEARCH TREES AGAIN REVISITED: THE INTERNAL PATH LENGTH PERSPECTIVE*

PETER KIRSCHENHOFER[†], HELMUT PRODINGER,[†] AND WOJCIECH SZPANKOWSKI[‡]

Abstract. This paper studies the asymptotics of the variance for the internal path length in a symmetric digital search tree under the Bernoulli model. This problem has been open until now. It is proved that the variance is asymptotically equal to $N \cdot 0.26600 + N \cdot \delta(\log_2 N)$, where N is the number of stored records and $\delta(x)$ is a periodic function of mean zero and a very small amplitude. This result completes a series of studies devoted to the asymptotic analysis of the variances of digital tree parameters in the symmetric case. In order to prove the previous result a number of nontrivial problems concerning analytic continuations and some others of a numerical nature had to be solved. In fact, some of these techniques are motivated by the methodology introduced in an influential paper by Flajolet and Sedgewick.

Key words. digital search trees, algorithm analysis

AMS subject classifications. 68Q25, 05C80

1. Introduction. Digital trees [2], [9], [17] are experiencing a new wave of interest due to a number of novel applications in computer science and telecommunications. For example, recent developments in the context of large external files and ideas derived from the dynamic hashing (virtual hashing, dynamic hashing, extendible hashing) led to the analysis of digital trees [8], [10], [12], [14], [15], [25], [29], [30], [31]. In telecommunications, recent developments in conflict resolution algorithms [22] and data compression [19] have also brought a new interest in digital trees. Some other applications are radix exchange sort, polynomial factorizations, simulation, Huffman's algorithm, and so on [2], [9], [17].

The three primary digital tree search methods are *digital search trees* (*DST*), *radix search tries* (shortly, tries), and *Patricia tries* [2], [7], [9], [17], [28], [31]. In the context of search costs one is led to investigate the *depth* of a node (search time) and the (external or internal) *path length* in digital trees. The average depth of a node for digital trees has been studied in [8], [17], [29], [30], [31], the variance in [12], [29], [30], [31], and limiting distributions in [10], [24], [25], [20]. The average value of the (external or internal) path length is closely related to the average depth of a node but *not* the variance. In [14], [15] the authors obtained the asymptotics of the variance for symmetric regular tries and Patricia tries, respectively (for asymmetric extensions of these results see [10]).

In this paper, we propose to evaluate the variance for the digital search trees, which has been an open problem until now. It has to be stressed that the variance of the internal path length in a digital search tree is the most difficult to estimate. This was already seen in the paper by Flajolet and Sedgewick [8], who establish an analytical methodology to analyze digital search trees (e.g., the average depth of a node). In this paper in the process of establishing the asymptotics of the internal path length we had to obtain some new analytic continuations of functions, which are mainly based on the famous Euler product identities. As in [12] and [13],

to derive the final results, namely, to show the cancellation of the higher order asymptotics, we had to appeal to the theory of modular functions (cf. §3). In addition, this problem possesses nontrivial numerical challenge. A very preliminary version of our results was presented at the 1989 IFIP Congress [16].

This paper is organized as follows. In the next section, we define our model, establish the general methodology to attack the problem, and present our main results. In particular, we show that the variance of the internal path length for the *binary symmetric* digital search tree under the Bernoulli model is asymptotic to $N \cdot 0.26600 + N \cdot \delta(\log_2 N)$, where N is the number of records and $\delta(x)$ is a periodic function with a very small amplitude. Section 3 contains proofs of our main results, followed by a few concluding remarks in §4.

2. Main results. Let $\mathcal{D}_N$ be the family of digital search trees built from N records with keys from a random stream of bits. Under the Bernoulli model, a key consists of 0's and 1's with independent and equal probability of appearance. Let L_N denote the random variable "internal path length"of trees in $\mathcal{D}_N$ and $F_N(z)$ the corresponding probability generating functions, i.e., the coefficient $[z^k]F_N(z)$ of z^k in $F_N(z)$ is the probability that a tree in $\mathcal{D}_N$ has internal path length equal to k. Then the following recursion, which is a direct consequence of the definition, holds:

$$F_{N+1} = z^N \sum_{k=0}^{N} 2^{-N} \binom{N}{k} F_k(z) F_{N-k}(z), \qquad F_0(z) = 1. \tag{2.1}$$

The *expectation* l_N is given by $l_N = F'_N(1)$ and fulfills for $N \geq 0$

$$l_{N+1} = N + 2^{1-N} \sum_{k=0}^{N} \binom{N}{k} l_k, \qquad l_0 = 0. \tag{2.2}$$

This recursion may be solved explicitly by using *exponential generating functions.* With $L(z) = \sum_{N \geq 0} l_N z^N / N!$, (2.2) translates into the functional differential equation

$$L'(z) = ze^z + 2e^{z/2} L(z/2).$$

By the substitution $\hat{L}(z) = e^z L(-z)$ we have the easier equation

$$\hat{L}(z) - \hat{L}'(z) = -z + 2\hat{L}(z/2).$$

With $\hat{L}(z) = \sum_{N \geq 0} \hat{l}_N z^N / N!$ we find for $N \geq 2$

$$\hat{l}_N = Q_{N-2}, \qquad \hat{l}_0 = \hat{l}_1 = 0$$

with the finite product

$$Q_N = \left(1 - \frac{1}{2}\right)\left(1 - \frac{1}{4}\right) \cdots \left(1 - \frac{1}{2^N}\right) \tag{2.3}$$

so that finally

$$l_N = \sum_{k=2}^{N} \binom{N}{k} (-1)^k Q_{k-2}. \tag{2.4}$$

The reader should note that an asymptotic evaluation of (2.4) is nonelementary due to the fact that terms of almost-equal magnitude occur with alternating signs. For this reason sophisticated methods from complex analysis are needed to find the correct order of growth. An essential step is the application of the following lemma from the calculus of finite differences.

LEMMA 1 (cf. [17, p. 38], [23]). *Let $\mathcal{C}$ be a path surrounding the points $j, j+1, \dots, N$ and $f(z)$ be analytic inside $\mathcal{C}$ and continuous on $\mathcal{C}$. Then*

$$\sum_{k\geq j}\binom{N}{k}(-1)^k f(k) = -\frac{1}{2\pi i}\int_{\mathcal{C}}[N;z]f(z)\,dz \tag{2.5}$$

with

$$[N;z] = \frac{(-1)^{N-1}N!}{z(z-1)\cdots(z-N)}.$$

In our application $f(z)$ is a meromorphic function that continues a sequence $f(k)$, e.g., $j=2$ and $f(k)=Q_{k-2}$ in (2.4). Moving the contour of integration, one can obtain the asymptotic expansion of the alternating sum by Cauchy's residue theorem, that is, for any real c (2.5) becomes $\sum_{k\geq j}\binom{N}{k}(-1)^k f(k) = \sum_{z_i\in\mathcal{P}_c}\operatorname{Res}\bigl([N;z_i]f(z_i)\bigr) + \mathcal{O}(N^c)$, where the sum is taken over the set of poles $\mathcal{P}_c$ different from $j, j+1, \dots, N$ with real part larger than c.

We note that the function $f(k) = Q_{k-2}$ possesses the analytic continuation $Q_z = Q_\infty/Q(2^{-z})$ where $Q(t) = \prod_{i\geq 1}(1-t/2^i)$ [8]. Then, applying a refinement of the technique of Flajolet and Sedgewick, we can easily prove the following theorem (cf. §3).

THEOREM 2. *The expectation l_N of the internal path length of digital search trees built from N records fulfills*

$$\begin{aligned} l_N &= N\log_2 N + N\left[\frac{\gamma-1}{\log 2} + \frac{1}{2} - \alpha + \delta_1(\log_2 N)\right] + \log_2 N \\ &\quad + \frac{2\gamma-1}{2\log 2} + \frac{5}{2} - \alpha + \delta_2(\log_2 N) + \mathcal{O}(\log N/N) \end{aligned} \tag{2.6}$$

with $\gamma = 0.57721\ldots$ (Euler's constant) and $\alpha = \sum_{n\geq 1} 1/(2^n-1) = 1.60669\ldots$, where $\delta_1(x)$ and $\delta_2(x)$ are continuous periodic functions of period 1, mean 0, and very small amplitude ($< 10^{-6}$). For later use we mention the Fourier expansion of $\delta_1(x)$

$$\delta_1(x) = \frac{1}{\log 2}\sum_{k\neq 0}\Gamma\left(-1-\frac{2k\pi i}{\log 2}\right)e^{2k\pi i x}, \tag{2.7}$$

where $\Gamma(x)$ is the gamma function [1].

We mention in passing that the $\mathcal{O}(1)$-term in (2.6) is slightly incorrect in [17].

Now we turn to the *analysis of the variance*, which is given by $\operatorname{Var} L_N = s_N + l_N - l_N^2$ with $s_N = F_N''(1)$. From (2.1) we get the recurrence relation (for $N\geq 0$; $s_0 = 0$)

$$\begin{aligned} s_{N+1} &= N2^{2-N}\sum_{k=0}^{N}\binom{N}{k}l_k + N(N-1) \\ &\quad + 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}l_k l_{N-k} + 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}s_k. \end{aligned} \tag{2.8}$$

In order to find an explicit solution to this recurrence, we split it into three parts: $s_N = u_N + v_N + w_N$, where

$$u_{N+1} = 2N(l_{N+1}-N) + 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}u_k, \quad N\geq 0,\ u_0 = 0, \tag{2.9a}$$

$$v_{N+1} = N(N-1) + 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}v_k, \quad N \geq 0,\ v_0 = 0, \tag{2.9b}$$

$$w_{N+1} = 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}l_k l_{N-k} + 2^{1-N}\sum_{k=0}^{N}\binom{N}{k}w_k, \quad N \geq 0,\ w_0 = 0. \tag{2.9c}$$

All of the above recurrences, as well as that for the average internal path length (2.2), fall into the following general recurrence studied in [30]. Let (x_n) be a sequence of numbers satisfying

$$x_{n+1} = a_{n+1} + 2^{1-n}\sum_{k=0}^{n}\binom{n}{k}x_k, \qquad n \geq 2, \tag{2.10}$$

where (a_n) is any sequence of numbers. The solution of (2.10) depends on the so-called *binomial inverse relations* that are defined as

$$\hat{a}_n = \sum_{k=0}^{n}(-1)^k\binom{n}{k}a_k \quad \text{and} \quad a_n = \sum_{k=0}^{n}(-1)^k\binom{n}{k}\hat{a}_k.$$

The second equation justifies the name binomial inverse relations. For more details, see Riordan [26]. A similar treatment as in the case of (2.2) leads to the following explicit solution (for details see [30]).

LEMMA 3. *Let* $x_0 = x_1 = 0$. *Then the recurrence* (2.10) *possesses the solution*

$$x_n = x_0 + n(x_1 - x_0) - \sum_{k=2}^{n}(-1)^k\binom{n}{k}\hat{x}_{k-2} \tag{2.11a}$$

where

$$\hat{x}_n = Q_n\sum_{i=1}^{n+1}\left[\hat{a}_i - \hat{a}_{i+1} - a_1\right]/Q_{i-1} \tag{2.11b}$$

and Q_n *is defined in* (2.3).

Using Lemma 3 we immediately solve our recurrences (2.9a)—(2.9c). In particular, one proves

$$\hat{u}_k = 2Q_{k-2}\left\{4 + \sum_{j=1}^{k-2}\frac{1}{2^j - 1} - \sum_{j=1}^{k-2}\frac{j}{2^j - 1} - \frac{2k}{2^{k-2} - 1}\right\}$$

$$\text{for } k \geq 3,\ \hat{u}_0 = \hat{u}_1 = \hat{u}_2 = 0; \tag{2.12a}$$

$$\hat{v}_k = -4Q_{k-2} \quad \text{for } k \geq 3,\ \hat{v}_0 = \hat{v}_1 = \hat{v}_2 = 0; \tag{2.12b}$$

and

$$\hat{w}_k = -Q_{k-2}\sum_{j=4}^{k-1}\frac{2^{1-j}}{Q_{j-1}}\sum_{i=2}^{j-2}\binom{j}{i}Q_{i-2}Q_{j-i-2}$$

$$\text{(2.12c)} \qquad \text{for } k \geq 5, \ \hat{w}_0 = \cdots = \hat{w}_4 = 0.$$

Of course, the "unhatted" solutions u_N, v_N, and w_N follow from the binomial relations, as shown in (2.11a). It is also worth mentioning that the recurrence for v_N is easy, and after simple algebra one proves

$$\text{(2.12d)} \qquad v_N = 4\binom{N}{2} - 4l_N,$$

so the treatment of u_N and w_N remains to be done.

In principle, u_N and w_N may be analyzed by making use of Lemmas 1 and 3. However, it turns out to be a highly nontrivial problem to find an analytical continuation of $\hat{w}_k$. After lengthy and difficult computations the residue calculus leads us to the following main result of this paper, which is proved in the next section.

THEOREM 4. *The variance of the internal path length of digital search trees built from N records becomes*

$$\operatorname{Var} L_N = N \cdot \{C + \delta(\log_2 N)\} + \mathcal{O}(\log^2 N/N)$$

where C is a constant that can be expressed as

$$\begin{aligned} C = {} & -\frac{28}{3L} - \frac{39}{4} - 2\beta_1 + \frac{2\alpha}{L} + \frac{\pi^2}{2L^2} + \frac{2}{L^2} - \frac{2}{L}\sum_{k\geq 3} \frac{(-1)^{k+1}(k-5)}{(k+1)k(k-1)(2^k-1)} \\ \text{(2.13)} \qquad & + \frac{2}{L}\sum_{r\geq 1} b_{r+1}\left(\frac{L(1-2^{-r+1})/2-1}{1-2^{-r}} - \sum_{k\geq 2}\frac{(-1)^{k+1}}{k(k-1)(2^{r+k}-1)}\right) \\ & + \frac{2}{L}\hat{w}'(3) - 2[\delta_1\delta_2]_0 - [\delta_1^2]_0 \end{aligned}$$

with $L = \log 2$, $\alpha = \sum_{n\geq 1} 1/(2^n - 1)$, $\beta_1 = \sum_{n\geq 1} n2^n/(2^n-1)^2$, *and* $b_{r+1} = (-1)^r 2^{-\binom{r+1}{2}}$. *The fluctuating function* $\delta(x)$ *is continuous with period* 1, *mean zero, and* $|\delta(x)| \leq 10^{-6}$, *and* $|[\delta_1^2]_0| \leq 10^{-10}$, *and* $|[\delta_1\delta_2]_0| \leq 10^{-10}$. *Finally,* $\hat{w}(z)$ *is a function defined as*

$$\text{(2.14)} \quad \frac{\hat{w}(z+1)}{Q_{z-1}} = -2Q_\infty z + \frac{\xi(z+2)}{2^z Q_z} + \frac{\xi(z+3)}{2^{z+1}Q_{z+1}} + \sum_{j\geq 2}\left(\frac{\xi(z+j+2)}{2^{z+j}Q_{z+j}} - \frac{\xi(j+2)}{2^j Q_j}\right)$$

with $Q_z = Q_\infty/Q(2^{-z})$, *where* $Q(t) = \prod_{i\geq 1}(1 - t/2^i)$, $Q_\infty = Q(1)$, *and*

$$\begin{aligned} & \xi(z+1) = \sum_{r\geq 0}\frac{b_{r+1}}{Q_r}\cdot\frac{Q_\infty}{Q(2^{3-z-r})} \\ \text{(2.15)} \qquad & \cdot\left\{2^z - \frac{2}{1-2^{1-z-r}} - \frac{2z}{1-2^{2-z-r}} + 2\sum_{k\geq 2}\binom{z}{k}\frac{1}{2^{r+k-1}-1}\right\}. \end{aligned}$$

Numerical evaluation of the constant C reveals that $C = 0.26600\ldots$ *and all five digits after the decimal point are significant.*

We should point out that in order to achieve the same accuracy in C one needs to run the recurrence equations (2.9a)–(2.9c) for $N \sim 10^6$.

In the following lemma we present an explicit formula for $\hat{w}'(3)$ that is convenient for numerical evaluations.

LEMMA 5. *The following identity holds*:

$$\begin{aligned}\frac{2\hat{w}'(3)}{L} = &-\frac{2Q_\infty}{L} + \sum_{j\ge2}\frac{1}{2^jQ_j}\sum_{r\ge0}a_{r+1}Q_{r+j-2}\\ &\cdot\Bigg\{-\sum_{n\ge1}\frac{1}{2^{n+r+j+2}-1}\cdot\left(2^{j+1}-2j-4+2\sum_{k=2}^{j-1}\binom{j+1}{k}\frac{1}{2^{r+k-1}-1}\right)\\ &+\frac{2}{(1-2^{-j-r})^2}+\frac{2j+2}{(1-2^{1-j-r})^2}-\frac{2}{L}\frac{1}{1-2^{1-j-r}}\\ &-2\sum_{k=2}^{j+1}\binom{j+1}{k}\frac{1}{2^{r+k-1}-1}+\frac{2}{L}\sum_{k=1}^{j+1}\binom{j+1}{k}\frac{1}{2^{r+k}-1}\\ &+\frac{2}{L}\sum_{k=0}^{j+1}\binom{j+1}{k}\sum_{i\ge1}\frac{(-1)^i}{(i+1)(2^{r+k+i}-1)}\Bigg\}\\ &+\sum_{j\ge3}\frac{\xi(j+2)}{2^jQ_j}\sum_{k\ge j+1}\frac{1}{2^k-1}\end{aligned} \tag{2.16}$$

where

$$a_{r+1} = \frac{b_{r+1}}{Q_r} = (-1)^r 2^{-\binom{r+1}{2}}/Q_r \tag{2.17}$$

and

$$\xi(j+2) = \sum_{k=2}^{j-1}\binom{j+1}{k}Q_{k-2}Q_{j-k-1} \tag{2.18}$$

with Q_k defined in Theorem 4.

Before we proceed to the proof of our results, we first offer some remarks and extensions.

Theorem 4 and our previous results in [12] and [30] provide asymptotics for the average covariance between two different nodes in a digital search tree (DST). Let $D_N^{(i)}$ be the length of the path from the root to the ith node, i.e., the node corresponding to the ith key of the N keys. Observe that the distribution of the random variable defined by $D_N^{(i)}$ depends on i for DST, since, in contrast to tries and Patricia tries, the order of insertion of the keys is relevant in this instance. Note that the internal path length L_N is expressed in terms of $D_N^{(i)}$ as

$$L_N = \sum_{i=1}^{N} D_N^{(i)}. \tag{2.19}$$

In [12] it has been shown that, besides a small fluctuation,

$$A_N = \frac{1}{N}\sum_{i=1}^{N}E\left(D_N^{(i)2}\right) - \left(\frac{1}{N}\sum_{i=1}^{N}ED_N^{(i)}\right)^2 \sim 2.844\dots\,. \tag{2.20}$$

(The quantity NA_N was erroneously identified with the variance of the path length.) It is easily checked that

$$\sum_{i=1}^{N}\text{Var }D_N^{(i)} - NA_N = \frac{1}{N}\left(\sum_{i=1}^{N}ED_N^{(i)}\right)^2 - \sum_{i=1}^{N}\left(ED_N^{(i)}\right)^2. \tag{2.21}$$

The expectations $ED_N^{(i)} = ED_i^{(i)}$ (for $N \geq i$) may now be computed in a straightforward manner. Indeed,

$$ED_N^{(N)} = E\left(L_N - L_{N-1}\right) = -\sum_{k=1}^{N-1}\binom{N-1}{k}(-1)^k Q_{k-1}, \tag{2.22}$$

and we find

$$ED_N^{(N)} = \log_2 N + \frac{\gamma}{L} + \frac{1}{2} - \alpha + \tau(\log_2 N) + O\left(\frac{1}{N}\right) \tag{2.23}$$

with a small fluctuation $\tau(x)$. Altogether we get, besides the fluctuating term,

$$\sum_{i=1}^{N} \operatorname{Var} D_N^{(i)} - NA_N \sim -\frac{N}{L^2}, \tag{2.24}$$

and therefore, the average variance of the depth becomes

$$\frac{1}{N}\sum_{i=1}^{N} \operatorname{Var} D_N^{(i)} \sim 0.763\dots . \tag{2.25}$$

(Compare also [27].) Now

$$\operatorname{Var} L_N = \sum_{i=1}^{N} \operatorname{Var} D_N^{(i)} + 2\sum_{i \neq j} \operatorname{Cov}\left\{D_N^{(i)}, D_N^{(j)}\right\}.$$

Using Theorem 4 and the above we find that the average value of

$$\operatorname{Cov}\{D_N^{(i)}, D_N^{(j)}\} \text{ is } \sim -0.50\dots/N.$$

The last statement says that, on the average, $D_N^{(i)}$ and $D_N^{(j)}$ are negatively correlated. Note that the equivalent quantity for regular tries is approximately equal to $+0.84\dots/N$ [14] and for Patricia $= -0.63\dots/N$ [15].

In order to select the best digital tree one needs to compare different characteristics of digital trees, namely regular tries, Patricia tries, and Digital Search Trees (DST). Table 1 contains four important parameters that are often used to predict a random shape of these trees (cf. [8], [12], [14], [15], [17], [18], [29], [30], [31]).

TABLE 1

	$\mathrm{E}L_n$	$\mathrm{Var}L_N$	"average" $\mathrm{Var}D_N^{(i)}$	"average" $\mathrm{Cov}(D_N^{(i)}, D_N^{(j)})$
DST	$N(\log_2 N - 1.71)$	$N \cdot 0.26$	0.763	$-0.50/N$
TRIES	$N(\log_2 N + 1.33)$	$N \cdot 4.35$	3.507	$+0.84/N$
PATRICIA	$N(\log_2 N + 0.33)$	$N \cdot 0.37$	1.000	$-0.63/N$

It can be seen from the table that the average external (internal) path length is approximately the same for all three digital trees. However, the variance of the depths and internal (external) path lengths differ significantly. We also notice that the variance of the internal path length for DST as well as the variance of the depth are smaller than the respective quantities for Patricia.

We point out that from Theorem 4 it follows that L_N/EL_N tends to one *almost surely* (i.e., with probability one) as $N \to \infty$. This immediately follows from Theorem 4 and the Borel-Cantelli lemma. (Compare, e.g., [21] for this standard argument.)

Finally, Theorem 4 provides the missing coefficient in the variance of the numbers of phrases in the Lempel-Ziv parsing algorithm [3], [19] (cf. also [11]). More precisely, the Lempel-Ziv parsing algorithm partitions a single string into variable phrases (blocks) such that a new block is the shortest substring not seen in the past as a phrase. For example, the string 11001010001000100 0 is parsed into (1)(10)(0)(101)(00)(01)(000)(100). Let M_N be the number of phrases produced by the algorithm for a string of length N. Aldous and Shields [3] proved that for the symmetric alphabet $(M_N - EM_N)/\text{Var}\, M_N$ converges weakly to the standard normal distribution, where $EM_N \sim N/\log_2 N$ and $\text{Var}\, M_N = O(N/\log_2^3 N)$, however, the authors of [3] were not able to provide the coefficient at $N/\log_2^3 N$. It turns out that this coefficient is the same as the coefficient at N in the variance of the internal path length L_N, that is, $\text{Var}\, M_N \sim (C + \delta(\log_2 N))N/\log_2^3 N$. The details of the proof can be found in [11]. The main idea is that the number of phrases M_N can be expressed as

$$M_N = \max\left\{ M : \ L_M = \sum_{k=1}^{M} D_M^{(k)} \le N \right\}.$$

But this equation is known in the literature as the *renewal equation*. Billingsley (compare [6], Chapter 17, Theorem 17.3) proved that (for any dependent positive random variables) if $(L - EL_N)/\sqrt{\text{Var}\, L_N}$ converges weakly to the standard normal distribution $\mathcal{N}(0, 1)$, then

$$\frac{M_N - N/(EL_N/N)}{\sqrt{\text{Var}\, L_N}(EL_N/N)^{-3/2}} \to \mathcal{N}(0, 1).$$

Hence, by the standard uniform integrability arguments and by Theorem 4, we conclude that the variance of M_N becomes

$$\text{Var}\, M_N = \ \text{Var}\, L_N/\log_2^3 N \sim (C + \delta(\log_2 N))N/\log_2^3 N.$$

3. Analysis. As we already pointed out in §2, it is a nontrivial problem to find appropriate analytic continuations for the sequences of values $f(k)$ that occur in alternating sums (2.5). In order to illustrate our approach, we start with the easiest case, namely, the evaluation of the expectation l_N. From (2.4) we know

$$l_N = \sum_{k=2}^{N} \binom{N}{k} (-1)^k Q_{k-2}.$$

As in [8] we may rewrite $f(k) = Q_{k-2}$ as

$$Q_{k-2} = \frac{Q_\infty}{Q(2^{2-k})},$$

where

$$Q(x) = \prod_{i \ge 1} \left(1 - \frac{x}{2^i}\right) \quad \text{and} \quad Q_\infty = Q(1). \tag{3.1}$$

Therefore, we have the analytic continuation

$$f(z) = \frac{Q_\infty}{Q(2^{2-z})}. \tag{3.2}$$

The main contribution to l_N is given by $\operatorname{Res}([N;z]f(z); z=1)$. We have with $u=z-1\to 0$

$$[N;z]\sim\frac{N}{u}\bigl(1+u(H_{N-1}-1)\bigr)$$

and

$$\frac{Q_\infty}{Q(2^{2-z})}\sim\frac{1}{Lu}\left(1+Lu\left(\frac{1}{2}-\alpha\right)\right)$$

(remember $L=\log 2$), since

$$\alpha=\left(\frac{Q_\infty}{Q(x)}\right)'\bigg|_{x=1}. \tag{3.3}$$

Therefore,

$$\operatorname{Res}([N;z]f(z);z=1)=\frac{N}{L}\left(H_{N-1}-1+L\left(\frac{1}{2}-\alpha\right)\right).$$

Using the well-known asymptotics for the *harmonic numbers* H_{N-1} we get the contribution (from $z=1$)

$$N\log_2 N+N\left(\frac{\gamma}{L}-\frac{1}{L}+\frac{1}{2}-\alpha\right)-\frac{1}{2L}+\mathcal{O}\left(\frac{1}{N}\right). \tag{3.4}$$

Besides $z=1$ we have with the same real part 1 the simple poles $z_k=1+\frac{2k\pi i}{L}$, $k\in\mathbf{Z}$, $k\neq 0$, with

$$\operatorname{Res}\bigl([N;z]f(z);z=z_k\bigr)=[N;z_k]\cdot\frac{1}{L},$$

so we get the contribution

$$\frac{N^{z_k}}{L}\Gamma(-z_k)-\frac{(z_k-1)z_kN^{z_k-1}\Gamma(-z_k)}{2L}+\mathcal{O}(N^{z_k-2}). \tag{3.5}$$

The reader should take notice of the fact that the first term in (3.5) gives the Fourier coefficients of $\delta_1(x)$ in Theorem 1.

The next relevant pole is $z=0$ and yields a contribution of

$$\log_2 N+\frac{\gamma}{L}+\frac{5}{2}-\alpha. \tag{3.6}$$

The poles $z=z_k-1$ yield a periodic contribution of order N^0 and so on.

Collecting all contributions gives the expansion (2.6) in Theorem 2.

Next we focus our attention on the *asymptotics of* u_N. In order to find an appropriate analytic continuation of $\hat{u}_k$ we rewrite the sums appearing in (2.12a) as follows:

$$\sum_{j=1}^{k-2}\frac{1}{2^j-1}=\alpha-\sum_{j\geq 1}\frac{1}{2^{k-2+j}-1},$$

$$\sum_{j=1}^{k-2}\frac{j}{2^j-1}=\sum_{j\geq 1}\frac{j}{2^j-1}-\sum_{j\geq 1}\frac{k-2+j}{2^{k-2+j}-1}.$$

Thus we may continue $\hat{u}_k$ via the function

$$\begin{aligned}\hat{u}(z) = \frac{2Q_\infty}{Q(2^{2-z})}\Bigg[& 4+\alpha-\sum_{j\geq 1}\frac{1}{2^{z-2+j}-1} \\ & -\sum_{j\geq 1}\frac{j}{2^j-1}+\sum_{j\geq 1}\frac{z-2+j}{2^{z-2+j}-1}-\frac{2z}{2^{z-2}-1}\Bigg].\end{aligned} \tag{3.7}$$

Now the main contribution to u_N in Lemma 1 originates from a second-order pole of $[N;\, z]\hat{u}(z)$ in $z=2$. Further contributions that are necessary for the evaluation of the variance come from first-order poles in $z = 2+\frac{2k\pi i}{L}$, $k\neq 0$, a third-order pole in $z=1$, as well as second-order poles in $z=1+\frac{2k\pi i}{L}$, $k\neq 0$. Collecting all the above-mentioned contributions we get the following expansion of u_N (in all the following formulas $\delta_i(x)$ stands for a continuous periodic function of period 1 and mean zero).

LEMMA 6.

$$\begin{aligned} u_N \sim{} & 4N^2\log_2 N + N^2\left(\frac{4(\gamma-1)}{L}-6-4\alpha+\delta_3(\log_2 N)\right) \\ & -N\log_2^2 N + 2N\log_2 N\cdot\left(\frac{2-\gamma}{L}+8+\alpha+\delta_4(\log_2 N)\right) \\ & +N\Bigg(-\frac{\gamma^2}{L^2}+\frac{4\gamma}{L^2}+\frac{12\gamma}{L}+\frac{2\alpha\gamma}{L}-\frac{\pi^2}{6L^2}-\frac{4}{L^2}-\frac{10}{L}-\frac{2\alpha}{L} \\ & -\alpha^2+\beta-11\alpha-2\beta_1+\frac{133}{6}+\delta_5(\log_2 N)\Bigg)+\mathcal{O}(\log^2 N)\end{aligned}$$

with $\beta=\sum_{k\geq 1}1/(2^k-1)^2$, L, α, and β_1 *as in Theorem* 4.

As already mentioned in §2,

$$v_N = 4\binom{N}{2}-4l_N,$$

so the *asymptotics of* v_N are given by

$$\begin{aligned} v_N \sim{} & 2N^2-4N\log_2 N \\ & +4N\left(-1+\alpha-\frac{\gamma}{L}+\frac{1}{L}-\delta_1(\log_2 N)\right)+\mathcal{O}(\log N).\end{aligned} \tag{3.8}$$

The most challenging task is to find an appropriate *analytic continuation of* $\hat{w}(z)$.

From (2.12c) we have

$$\hat{w}_{k+1} = -Q_{k-1}\sum_{j=4}^{k}\frac{\xi(j+1)}{2^{j-1}Q_{j-1}} \tag{3.9}$$

with

$$\xi(j+1) = \sum_{i=2}^{j-2}\binom{j}{i}Q_{i-2}Q_{j-2-i}. \tag{3.10}$$

For the following the reader should note that $\xi(j+1)\sim Q_\infty^2 2^j$. We start by rewriting (3.9) in the following manner:

With $\eta(j+1) = \xi(j+1) - Q_\infty^2 2^j$ we have

$$\begin{aligned}
-\frac{\hat{w}_{k+1}}{Q_{k-1}} &= \sum_{j=4}^{k} \frac{\eta(j+1) + Q_\infty^2 2^j}{2^{j-1} Q_{j-1}} \\
&= \sum_{j\ge 4} \frac{\eta(j+1)}{2^{j-1}Q_{j-1}} - \sum_{j\ge k+1} \frac{\eta(j+1)}{2^{j-1}Q_{j-1}} + 2Q_\infty(k-3) \qquad (3.11)\\
&\quad +2Q_\infty^2\left(\sum_{j\ge 4}\left(\frac{1}{Q_{j-1}} - \frac{1}{Q_\infty}\right) - \sum_{j\ge k+1}\left(\frac{1}{Q_{j-1}} - \frac{1}{Q_\infty}\right)\right).
\end{aligned}$$

Therefore,

$$\begin{aligned}
\hat{w}_{k+1} = Q_{k-1}\Bigg[&-2Q_\infty(k-3) + \sum_{j\ge 0} \frac{\eta(j+k+2)}{2^{j+k}Q_{j+k}} - \sum_{j\ge 3}\frac{\eta(j+2)}{2^j Q_j} \\
&+2Q_\infty^2\left(\sum_{j\ge 0}\left(\frac{1}{Q_{j+k}} - \frac{1}{Q_\infty}\right) - \sum_{j\ge 3}\left(\frac{1}{Q_j} - \frac{1}{Q_\infty}\right)\right)\Bigg].
\end{aligned}$$

Since all involved series are now absolutely convergent, we may add them term-by-term and get

$$\hat{w}_{k+1} = Q_{k-1}\left[-2Q_\infty k + \frac{\xi(k+2)}{2^k Q_k} + \frac{\xi(k+3)}{2^{k+1}Q_{k+1}} + \sum_{j\ge 2}\left(\frac{\xi(k+j+2)}{2^{k+j}Q_{k+j}} - \frac{\xi(j+2)}{2^j Q_j}\right)\right].$$

From this, the representation for $\hat{w}(z+1)$ as in (2.14) is immediate, provided we have an appropriate interpretation for $\xi(z+1)$. This will be our next goal. The following well-known partition identities of Euler are our basic tool:

$$\frac{1}{Q(t)} = \prod_{n\ge 1}\frac{1}{(1-t2^{-n})} = \sum_{n\ge 0}\frac{t^n}{2^n Q_n} \qquad (3.12)$$

and

$$Q(t) = \prod_{n\ge 1}\left(1 - \frac{t}{2^n}\right) = \sum_{n\ge 0} a_{n+1} t^n \qquad (3.13)$$

with

$$a_{n+1} = (-1)^n 2^{-\binom{n+1}{2}}/Q_n.$$

Using (3.2) and (3.12) we have

$$\begin{aligned}
\xi(N+1) &= \sum_{k=2}^{N}\binom{N}{k}\frac{Q_\infty}{Q(2^{2-k})}\frac{Q_\infty}{Q(2^{2+k-N})} \\
&= Q_\infty^2 \sum_{i,j\ge 0}\frac{2^{i+j}}{Q_i Q_j}\sum_{k=2}^{N-2}\binom{N}{k}(2^{-i})^k(2^{-j})^{N-k},
\end{aligned}$$

where the innermost sum is now

$$(2^{-i} + 2^{-j})^N - 2^{-iN} - 2^{-jN} - N2^{-i(N-1)-j} - N2^{-i-j(N-1)}.$$

The last expression for $\xi(N+1)$ is symmetric in i and j. However, it turns out that for the purpose of finding an analytic continuation $\sum_{i,j\geq 0}$ should be rewritten as $-\sum_{j=i}+2\sum_{j\geq i\geq 0}$. Writing $j=i+h$ in the second sum we get

$$\begin{aligned}\xi(N+1)&=-(2^N-2-2N)\sum_{i\geq 0}\frac{Q_\infty^2}{Q_i^2}2^{i(2-N)}\\&+2\sum_{i,h\geq 0}\frac{Q_\infty^2}{Q_iQ_{i+h}}2^{i(2-N)}2^h\Big[(1+2^{-h})^N-1-N2^{-h}\Big]\\&-2\sum_{i,h\geq 0}\frac{Q_\infty^2}{Q_iQ_{i+h}}2^{i(2-N)}2^{h(1-N)}\\&-2N\sum_{i,h\geq 0}\frac{Q_\infty^2}{Q_iQ_{i+h}}2^{i(2-N)}2^{h(2-N)}.\end{aligned}\tag{3.14}$$

In expression (3.14) N can be replaced by z, yielding a meromorphic function, since all series converge uniformly. However, we are able to simplify $\xi(z+1)$ in the following way. Consider, for example, the last term in (3.14):

$$2z\sum_{i,h\geq 0}\frac{Q_\infty^2}{Q_iQ_{i+h}}2^{(i+h)(2-z)}=2z\sum_{i,h\geq 0}\frac{Q_\infty Q(2^{-i-h})}{Q_i}2^{(i+h)(2-z)},$$

which is by Euler's identity (3.13)

$$=2z\sum_{r\geq 0}a_{r+1}\sum_{i\geq 0}\frac{Q_\infty}{Q_i}(2^{-r+2-z})^i\sum_{h\geq 0}(2^{-r+2-z})^h$$

and by Euler's identity (3.12)

$$=2z\sum_{r\geq 0}a_{r+1}\frac{Q_\infty}{Q(2^{3-z-r})}\cdot\frac{1}{1-2^{2-z-r}}.$$

Rewriting the other terms from (3.14) in a similar way, especially using

$$(1+2^{-h})^z-1-z2^{-h}=\sum_{k\geq 2}\binom{z}{k}2^{-hk}$$

for the second term, we finally get (2.15).

Our next task is to investigate the poles of $[N;z]\hat{w}(z)$ different from $z=5,6,\ldots,N$.

From (3.11) we see that $\hat{w}(4)=\hat{w}(3)=0$ (observe that $\xi(4)=0$), so that the first poles occur with real part 2. In order to determine the residues of $[N;z]\hat{w}(z)$ in $z=2$ (respectively, $z=1$) we need the local behavior of $\hat{w}(z)$. Because of (2.14) this behavior will depend on the behavior of $\sigma(z):=\xi(z)/2^{z-2}Q_{z-2}$ near $z=2,3,\ldots$. From (2.15) we see that $\xi(z)$ has second-order poles for $z=2$ and $z=3$ and is analytic for $z=4,5,\ldots$. Since $[N;z]Q_{z-2}$ has already a second-order pole for $z=1$, it will be necessary to expand $\sigma(z)$ near $z=2,3,\ldots$ up to the linear terms. In particular, the reader should note that *all* the derivatives $\sigma'(z)$ for $z=4,5,\ldots$ will occur in $\operatorname{Res}\big([N;z]\hat{w}(z);z=1\big)$. This is the main reason that the constant C in the final result is rather a complicated one.

We start with the expansion of $\sigma(z)$ about $z = 3$. Let $u = z - 3$; then we find from (2.15) after laborious computations:

$$\begin{aligned}\sigma(3+u) \sim & -\frac{4}{L^2u^2} + \frac{1}{u}\left(\frac{6}{L} - \frac{2}{L^2}\right)\\ & +u^0\left(\frac{16}{3} + \frac{5}{L} + \frac{2\beta_2}{L} + 2\sum_{r\geq 2}\frac{b_{r+1}}{1-2^{-r}}\left(1 - \frac{2}{1-2^{-r}}\right)\right)\\ & +u^1\left(-\frac{223}{18}L - \frac{23}{6} - 3C_1 + \frac{C_2}{L} - 2C_3 + 2\sum_{r\geq 2}\frac{b_{r+1}}{1-2^{-r}}\right.\\ & \cdot\left\{1 - 3L + L\sum_{i=2}^{r-1}\frac{1}{2^i-1} + \frac{2^{-1-r}L}{(1-2^{-1-r})^2} + \frac{2L-1}{1-2^{-r}}\right.\\ & \left.\left. -\frac{2L}{1-2^{-r}}\sum_{i=2}^{r-1}\frac{1}{2^i-1} + \frac{2^{1-r}L}{(1-2^{-r})^2} + D_{r,1}\right\}\right)\end{aligned} \tag{3.15}$$

where

$$\begin{aligned}\beta_2 &= 2\sum_{k\geq 2}\frac{(-1)^k}{(k+1)k(k-1)(2^k-1)},\\ C_1 &= \sum_{h\geq 0}2^h\Big[(1+2^{-h})^2\log(1+2^{-h}) - 2^{-h}\Big],\\ C_2 &= \sum_{h\geq 0}2^h(1+2^{-h})^2\log^2(1+2^{-h}),\\ C_3 &= \sum_{h\geq 0}\Big[(1+2^{-h})^2\log(1+2^{-h}) - 2^{-h}\Big],\\ D_{r,1} &= \sum_{h\geq 0}2^{h(1-r)}\Big[(1+2^{-h})^2\log(1+2^{-h}) - 2^{-h}\Big].\end{aligned}$$

The constant in the u^0-term can be simplified according to the remarkable identity

$$\sum_{r\geq 1}\frac{b_{r+1}}{1-2^{-r}}\left(1 - \frac{2}{1-2^{-r}}\right) = \sum_{j\geq 1}\frac{2^j}{(2^j-1)^2} = \alpha + \beta. \tag{3.16}$$

For the proof of (3.16) we observe that the left-hand side equals

$$\sum_{r\geq 1}a_{r+1}Q_{r-1} - 2\sum_{r\geq 1}a_{r+1}\frac{Q_{r-1}}{1-2^{-r}}.$$

Using (3.12) and (3.13) this expression becomes

$$\begin{aligned}&\sum_{i\geq 0}Q(2^{-i})\left(Q(2^{-i}) - 1\right) - 2\sum_{i,k\geq 0}Q(2^{-i})\left(Q(2^{-i-k}) - 1\right)\\ &= -\left(\sum_{i\geq 0}\left(Q(2^{-i}) - 1\right)\right)^2 - \sum_{j\geq 0}(2j+1)\left(Q(2^{-j}) - 1\right)\\ &= -E_1^2 - 2E_2 - E_1,\end{aligned}$$

where

$$E_1 = \sum_{r\geq 1} \frac{a_{r+1}}{1-2^{-r}} \quad \text{and} \quad E_2 = \sum_{r\geq 1} a_{r+1} \frac{2^{-r}}{(1-2^{-r})^2}.$$

Now we observe

$$E_1 = \lim_{t\to 2} \left[\frac{Q_\infty}{Q(t)} - \frac{1}{1-t/2} \right] = - \left(\frac{Q_\infty}{Q(t)} \right)' \Bigg|_{t=1} = -\alpha$$

and

$$E_2 = 2 \lim_{t\to 2} \left[\left(\frac{Q_\infty}{Q(t)} \right)' - \frac{1/2}{(1-t/2)^2} \right] = -\frac{1}{2} \left(\frac{Q_\infty}{Q(t)} \right)'' \Bigg|_{t=1} = -\frac{\alpha^2+\beta}{2}$$

and get the right-hand side of (3.16).

The expansion of $\sigma(z)$ about $z=2$ reads with $u = z-2$:

$$\begin{aligned} \sigma(2+u) \sim {} & \frac{4}{L^2u^2} + \frac{1}{u}\left(\frac{2}{L} + \frac{2}{L^2}\right) \\ & + u^0\left(-\frac{16}{3} - \frac{6}{L} - \frac{2}{L}(C_4+C_6) + 2E_3\right) \\ & + u^1\Bigg(\frac{L}{6} - \frac{55}{6} - 3C_4 - \frac{C_5}{L} + C_6 - \frac{C_7}{L} \\ & + 2\sum_{r\geq 2} \frac{b_{r+1}}{(1-2^{1-r})(1-2^{-r})} \\ & \cdot\Bigg\{ D_{r,2} + 1 - 2L + L\sum_{i=1}^{r-2}\frac{1}{2^i-1} + \frac{L-1}{1-2^{1-r}} \\ & + L\Bigg(\frac{1}{(1-2^{-r})^2} - \frac{1}{1-2^{-r}}\sum_{i=1}^{r-2}\frac{1}{2^i-1} + \frac{2^{1-r}}{(1-2^{1-r})^2} \\ & - \frac{1}{1-2^{1-r}}\sum_{i=1}^{r-2}\frac{1}{2^i-1}\Bigg)\Bigg\}\Bigg) \end{aligned} \tag{3.17}$$

where

$$\begin{aligned} C_4 &= \sum_{h\geq 0} 2^h \left[(1+2^{-h})\log(1+2^{-h}) - 2^{-h}\right], \\ C_5 &= \sum_{h\geq 0} 2^h (1+2^{-h})\log^2(1+2^{-h}), \\ C_6 &= \sum_{h\geq 0} \left[(1+2^{-h})\log(1+2^{-h}) - 2^{-h}\right], \\ C_7 &= \sum_{h\geq 0} (1+2^{-h})\log^2(1+2^{-h}), \\ D_{r,2} &= \sum_{h\geq 0} 2^{h(1-r)} \left[(1+2^{-h})\log(1+2^{-h}) - 2^{-h}\right], \\ E_3 &= \sum_{r\geq 2} \frac{b_{r+1}}{(1-2^{1-r})(1-2^{-r})}\left(1 - \frac{1}{1-2^{-r}} - \frac{1}{1-2^{1-r}}\right). \end{aligned}$$

For later simplifications we note that

$$-\frac{2}{L}(C_4+C_6) = -8 + \frac{3}{L} - \frac{2\beta_2}{L} \tag{3.18}$$

and

$$E_3 = 2 - \alpha - \beta, \tag{3.19}$$

where (3.18) follows from the expansion of the logarithm and (3.19) by partial fraction decomposition and rearrangements of the sums.

We finally note that

$$C_5 + C_7 = C_2. \tag{3.20}$$

Next we discuss $\sigma(z)$ for z close to $j = 4, 5, \dots$.

$$\sigma(j+u) \sim \sigma(j) + \frac{u}{2^{j-2}Q_{j-2}}\left(\xi'(j) - L\xi(j) + L\xi(j)\sum_{k\geq 1}\frac{1}{2^{k+j-2}-1}\right). \tag{3.21}$$

From (3.21)

$$\begin{aligned}&\sum_{j\geq 4}\Bigl(\sigma(j+u)-\sigma(j)\Bigr)\\ &\quad\sim u\left(\sum_{j\geq 4}\frac{\xi'(j)-L\xi(j)}{2^{j-2}Q_{j-2}} + L\sum_{j\geq 4}\frac{\xi(j)}{2^{j-2}Q_{j-2}}\sum_{k\geq 1}\frac{1}{2^{k+j-2}-1}\right).\end{aligned} \tag{3.22a}$$

From (2.14) we find that the last expression equals

$$u\bigl(2\hat{w}'(3) + 2Q_\infty\bigr), \tag{3.22b}$$

where $\hat{w}'(3)$ may be computed from (2.15) to get the constant from Lemma 5.

Regarding (3.15), (3.17), and (3.22a) we find that $[N; z]\hat{w}(z)$ has third-order poles in $z = 2$ and $z = 1$ and second-order poles in $z_k = 2 + \frac{2k\pi i}{L}$, $k \in \mathbb{Z}$, $z \neq 0$, as well as in $z_k - 1$.

Our local expansions allow (after some lengthy but straightforward computations) to find the following asymptotic behavior of w_N:

LEMMA 7.

$$\begin{aligned}w_N = {}& N^2\log_2^2 N + N^2\log_2 N\cdot\left(-3 - \frac{2}{L} + \frac{2\gamma}{L} - 2\alpha + \delta_6(\log_2 N)\right)\\ &+N^2\biggl(\frac{1}{3} + \alpha^2 + 3\alpha + \frac{2\alpha}{L} - \frac{3\gamma}{L} - \frac{2\alpha\gamma}{L} - \frac{\beta_2}{L}\\ &+\frac{2}{L} + \frac{2}{L^2} + \frac{\gamma^2}{L^2} + \frac{\pi^2}{6L^2} - \frac{2\gamma}{L^2} + \delta_7(\log_2 N)\biggr)\end{aligned}$$

$$+3N\log_2^2 N + N\log_2 N\cdot\left(-\frac{7}{L}-3-6\alpha-\frac{10\gamma}{L}+\delta_8(\log_2 N)\right)$$
$$+N\left(-22-\frac{41}{6L}+\frac{\beta_2}{L}-\frac{3\gamma}{L}-\frac{7\gamma}{L^2}+2\alpha-\beta+\frac{7\alpha}{L}+3\alpha^2-\frac{6\alpha\gamma}{L}+\frac{3\gamma^2}{L^2}\right.$$
$$+\frac{\pi^2}{2L^2}+\frac{6}{L^2}-\frac{2}{L}\sum_{k\geq 3}\frac{(-1)^{k+1}(k-5)}{(k+1)k(k-1)(2^k-1)}+\frac{2}{L}\sum_{r\geq 1}b_{r+1}$$
$$\cdot\left(\frac{L(1-2^{-r+1})/2-1}{1-2^{-r}}-\sum_{k\geq 2}\frac{(-1)^{k+1}}{k(k-1)(2^{r+k}-1)}\right)$$
$$\left.+\frac{2}{L}\hat{w}'(3)+\delta_9(\log_2 N)\right)+\mathcal{O}\left(\frac{\log^2 N}{N}\right)$$

with $L, \alpha, \beta, b_{r+1}$ *as in Theorem* 4 (*respectively, Lemma* 6) *and* β_2 *from* (3.15).

It remains to combine the previous results to get an asymptotic expansion for

$$\operatorname{Var} L_N = u_N + v_N + w_N + l_N - l_N^2. \tag{3.23}$$

We start with an important observation concerning leading terms formed by periodic fluctuations of mean zero.

Let us assume that, at any stage, we are able to prove

$$\operatorname{Var} L_N = \delta_{10}(\log_2 N)\cdot N^\mu \log^\nu N + R_N, \tag{3.24}$$

where $\delta_{10}(x)$ is continuous and periodic with period 1 and mean zero and $R_N = o(N^\mu \log^\nu N)$. We claim that $\delta_{10}(x)$ must vanish identically under these conditions:

Let us assume $\delta_{10}(x) \not\equiv 0$. Then, since $\delta_{10}(x)$ is continuous with mean 0, there esists an $\epsilon > 0$ and an interval, say $[a, b] \subseteq [0, 1]$, such that $\delta_{10}(x) < -\epsilon$ for $x \in [a, b]$. Since $\log_2 N$ is dense modulo 1, $\operatorname{Var} L_N$ would be negative for an infinity of values, an obvious contradiction.

In other words: From (3.24) we may deduce that

$$\operatorname{Var} L_N \sim R_N, \qquad N \to \infty, \tag{3.25}$$

so, in order to prove that $\operatorname{Var} L_N = \mathcal{O}(N)$ we need not collect explicitly the fluctuating contributions of mean zero.

Observing these comments we easily find that all terms of order $N^2\log^2 N$, $N^2\log N$, $N\log^2 N$, and $N\log N$ in $\operatorname{Var} L_N$ cancel. The coefficient of N^2 is of a more delicate nature. The reader should note that the coefficient of N^2 in l_N^2 will contain the square δ_1^2 of the periodic fluctuation δ_1 from Theorem 2 and that the mean $[\delta_1^2]_0$ of δ_1^2 will *not* be zero. Therefore, we have to extract this term to end up with a fluctuation of mean zero and get for the coefficient of N^2 in $\operatorname{Var} L_N$ the expression

$$\frac{1}{L^2}+\frac{\pi^2}{6L^2}-\frac{1}{L}-\frac{\beta_2}{L}-\frac{47}{12}-[\delta_1^2]_0+\delta_{11}(\log_2 N). \tag{3.26}$$

The following lemma is crucial now.

LEMMA 8.

$$[\delta_1^2]_0 = \frac{1}{L^2}\sum_{k\neq 0}\left|\Gamma\left(-1-\frac{2k\pi i}{\log 2}\right)\right|^2 = \frac{1}{L^2}+\frac{\pi^2}{6L^2}-\frac{1}{L}-\frac{\beta_2}{L}-\frac{47}{12}.$$

Sketch of Proof[1]. The proof heavily relies on the following two series transformation results due to Ramanujan (compare [5]). The first is

$$\begin{aligned}(3.27)\qquad &\alpha^{-N}\left(\frac{1}{2}\zeta(2N+1)+\sum_{k\geq 1}\frac{k^{-2N-1}}{e^{2\alpha k}-1}\right)\\ &=(-\beta)^{-N}\left(\frac{1}{2}\zeta(2N+1)+\sum_{k\geq 1}\frac{k^{-2N-1}}{e^{2\beta k}-1}\right)\\ &-2^{2N}\sum_{k=0}^{N+1}(-1)^k\frac{B_{2k}}{(2k)!}\frac{B_{2N+2-2k}}{(2N+2-2k)!}\alpha^{N+1-k}\beta^k.\end{aligned}$$

Here and in the next identity, α and β have to be positive numbers with $\alpha\beta=\pi^2$, $\zeta(s)$ is the Riemann ζ-function; N has to be a positive integer, and B_n indicates the nth Bernoulli number defined by

$$\frac{z}{e^z-1}=\sum_{n\geq 0}B_n\frac{z^n}{n!}.$$

The second identity used in the proof is

$$(3.28)\qquad \sum_{k\geq 1}\frac{1}{k(e^{2\alpha k}-1)}-\frac{1}{4}\log\alpha+\frac{\alpha}{12}=\sum_{k\geq 1}\frac{1}{k(e^{2\beta k}-1)}-\frac{1}{4}\log\beta+\frac{\beta}{12}.$$

In fact, (3.28) is equivalent to a transformation result on Dedekind's η-function (compare [4])

$$(3.29)\qquad \eta(\tau)=e^{\pi i\tau/12}\prod_{n\geq 1}\left(1-e^{2\pi in\tau}\right),\qquad \Im(\tau)>0,$$

namely,

$$(3.30)\qquad \eta\left(-\frac{1}{\tau}\right)=(-i\tau)^{1/2}\cdot\eta(\tau),\qquad \Im(\tau)>0.$$

(This is a special instance of Dedekind's famous result on the behavior of η under a transformation of the modular group.) □

The consequences of Lemma 8 are twofold. On the one hand, we find from (3.26) that the N^2-term in Var L_N cancels, so that Var $L_N=\mathcal{O}(N)$. On the other hand we may use the identity to express β_2 by the other terms occurring in Lemma 8, including $[\delta_1^2]_0$, which yields the final form of the constant C in Theorem 2. $[\delta_1\delta_2]_0$ is the mean of $\delta_1(x)\delta_2(x)$, originating from l_N^2, which has to be extracted to get a fluctuation $\delta(x)$ of mean zero.

4. Concluding remarks. We would like to point out some final remarks concerning our analysis.

(i) The occurrence of the finite products Q_k gives rise to use results from the *theory of partitions*, especially the Euler product identities (3.12) and (3.13).

[1] A full proof of Lemma 8 is long and difficult and included in [13].

(ii) A periodic fluctuation $\delta_1(x)$ that has mean zero and very small amplitude may be safely neglected for practical purposes as long as we are only interested in the *expectation.* In order to establish the correct order of the *variance* it is of vital importance to study the behavior of $\delta_1(x)$, especially the mean of $\delta_1^2(x)$.

(iii) The predicted value $0.26600\ldots \cdot N$ matches perfectly with the values obtained by *computer simulations.*

(iv) As we mentioned in the introduction, with this paper we achieved our goal of obtaining second-order properties for the three digital tree search structures, namely, *Tries, Patricia Tries*, and *Digital Search Trees* in the symmetric case. In particular, we are now able to compare the variances of the path lengths in such trees. Furthermore, we note that the analysis of the variances is a key step toward getting the respective limiting distributions (compare [3] or [10]).

(v) Our methodology does not easily extend to the asymmetric Bernoulli model. The difficulty lies in the analytical continutation of w_N. We conjecture that in the asymmetric case the variance is of order $n \log n$, but it might be difficult to obtain the coefficient at $n \log n$.

Acknowledgment. The authors would like to thank R. F. Tichy for some helpful remarks.

IMPROVED APPROXIMATION ALGORITHMS FOR SHOP SCHEDULING PROBLEMS*

DAVID B. SHMOYS†, CLIFFORD STEIN‡, AND JOEL WEIN§

Abstract. In *the job shop scheduling* problem, there are m machines and n jobs. A job consists of a sequence of operations, each of which must be processed on a specified machine, and the aim is to complete all jobs as quickly as possible. This problem is strongly $\mathcal{NP}$-hard even for very restrictive special cases. The authors give the first randomized and deterministic polynomial-time algorithms that yield polylogarithmic approximations to the optimal length schedule. These algorithms also extend to the more general case where a job is given not by a linear ordering of the machines on which it must be processed but by an arbitrary partial order. Comparable bounds can also be obtained when there are m' types of machines, a specified number of machines of each type, and each operation must be processed on one of the machines of a specified type, as well as for the problem of scheduling unrelated parallel machines subject to chain precedence constraints.

1. Introduction.

In the *job shop scheduling* problem we are given m machines and n jobs. A job consists of a sequence of operations, each of which must be processed on a specified machine; a job may have more than one operation on a given machine. The operations of a job must be processed in the order specified by the sequence, subject to the constraint that on each machine at most one job is scheduled at any point in time. We wish to produce a schedule of jobs on machines that minimizes $C_{\max}$, the time when all jobs have completed processing. This problem is strongly $\mathcal{NP}$-hard; furthermore, except for the cases when there are two jobs or when there are two machines *and* each job has at most two operations, essentially all special cases of this problem are $\mathcal{NP}$-hard, and typically strongly $\mathcal{NP}$-hard [6], [7]. For example, it is $\mathcal{NP}$-hard even if there are three machines, three jobs, and each operation is of unit length; note that in this case we can think of the input length as μ, the maximum number of operations in a job. In addition to these theoretical results, the job shop problem is also one of the most notoriously difficult $\mathcal{NP}$-hard optimization problems in terms of practical computation, with even very small instances being difficult to solve exactly. A classic single instance of this problem involving only 10 jobs, 10 machines, and 100 operations, which was published in 1963, remained unsolved for 23 years despite repeated attempts to find an optimal solution [7]. Furthermore, several benchmark instances with 15 jobs, 15 machines, and 225 operations are too hard to be solved by known methods and were posed as open problems by Applegate and Cook [1].

In this paper we will focus on obtaining approximation algorithms for the job shop problem, and will evaluate these algorithms in terms of their performance guarantee, or in other words, their worst-case relative error. Let $C^*_{\max}$ be the maximum completion time of a job in

the optimal solution. If a polynomial-time algorithm always delivers a solution of maximum completion time of at most $\rho C^*_{\max}$, then we shall call it a ρ-approximation algorithm. The main result of this paper is the first randomized polynomial-time polylogarithmic approximation algorithm for the job shop scheduling problem.

THEOREM 1.1. *There exists a polynomial-time randomized algorithm for the job shop scheduling problem, that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2(m\mu)}{\log\log(m\mu)}C^*_{\max}\right).$$

We formally define the job shop problem as follows. We are given a set $\mathcal{M} = \{M_1, M_2, \ldots, M_m\}$ of machines, a set $\mathcal{J} = \{J_1, \ldots, J_n\}$ of jobs, and a set $\mathcal{O} = \{O_{ij} | i = 1, \ldots, \mu_j, j = 1, \ldots, n\}$ of operations, where κ_{ij} indexes the machine which must process operation O_{ij}. Thus m is the number of machines, n is the number of jobs, μ_j is the number of operations of job J_j, and $\mu = \max_j \mu_j$. Operation O_{ij} is the ith operation of J_j; it requires processing time on a given machine $M_k \in \mathcal{M}$, where $k = \kappa_{ij}$, for an uninterrupted period of a given length p_{ij}. (In other words, this is a *nonpreemptive* model; a model in which operations may be interrupted and resumed at a later time is called a *preemptive* model.) Each machine can process at most one operation at a time, and each job may be processed by at most one machine at a time. If the completion time of operation O_{ij} is denoted by C_{ij}, then the objective is to produce a schedule that minimizes the maximum completion time, $C_{\max} = \max_{i,j} C_{ij}$; the optimal value is denoted by $C^*_{\max}$.

Note that there are two very easy lower bounds on the length of an optimum schedule. Since each job must be processed, $C^*_{\max}$ must be at least the maximum total length of any job, $\max_{J_j} \sum_i p_{ij}$, which we shall call the *maximum job length* of the instance, and denote by $P_{\max}$. Furthermore, each machine must process all of its operations, and so $C^*_{\max}$ must be at least $\max_{M_k} \sum_{\kappa_{ij}=k} p_{ij}$, which we shall call the *maximum machine load* of the instance, and denote by $\Pi_{\max}$.

Our work is based on two very different approaches to the job shop problem. One approach is a geometric approach to shop scheduling, while the other is a randomized approach that finds its genesis in problems of packet routing. We briefly review both approaches here.

The best approximation algorithms to date for job shop scheduling have primarily appeared in the Soviet literature and are based on a beautiful connection to geometric arguments. This approach was independently discovered by Belov and Stolin [3] and Sevast'yanov [18], as well as by Fiala [4]. This approach typically produces schedules for which the length can be bounded by $\Pi_{\max} + q(m, \mu)p_{\max}$, where $q(\cdot, \cdot)$ is a polynomial, and $p_{\max} = \max_{ij} p_{ij}$ is the maximum operation length. For the job shop problem, Sevast'yanov [16], [17] gave a polynomial-time algorithm that delivered a schedule of length at most $\Pi_{\max} + O(m\mu^3)p_{\max}$. The bounds obtained in this way do not give good worst-case relative error bounds. Even for the special case of the *flow shop problem*, where each job has a single operation on each machine and for each job the operations must be processed in the same order, the best known algorithms delivered solutions of length $\Omega(mC^*_{\max})$.

In a different vein, Leighton, Maggs, and Rao [8] have proposed the following model for the routing of packets in a network: Find paths for the packets and then schedule the transmission of the packets along these paths so that no two packets traverse the same edge simultaneously. The primary objective is to minimize the time by which all packets have been delivered to their destination.

It is easy to see that the problem considered by Leighton, Maggs, and Rao is simply the job shop scheduling problem with each processing time $p_{ij} = 1$. They also added the restriction that each path does not traverse any edge more than once, or in scheduling terminology, each job has at most one operation on each machine. This restriction of the job shop problem remains (strongly) $\mathcal{NP}$-hard. The main result of Leighton, Maggs, and Rao was to show that for their special case of the job shop problem, there always exists a schedule of length $O(\Pi_{\max} + P_{\max})$. Unfortunately, this is not an algorithmic result, as it relies on a nonconstructive probabilistic argument based on the Lovász Local Lemma. They also obtained a randomized algorithm that delivers a schedule of length $O(\Pi_{\max} + P_{\max} \log n)$, with high probability. In this paper, we will show how their techniques can be generalized to handle the general job shop problem, as well as several related scheduling problems.

We also give a deterministic version of the job shop scheduling algorithm.

THEOREM 1.2. *There exists a deterministic polynomial-time algorithm for job shop scheduling that finds a schedule of length* $O(\log^2(m\mu)C^*_{\max})$.

This is the first polylogarithmic performance guarantee for a deterministic polynomial time approximation algorithm for job shop scheduling; no such algorithm was known even for the special case of flow shop scheduling. Note that if each job must be processed on each machine at most once, the factor of μ can be deleted for this, and all other performance guarantees in this paper. As a corollary, we also obtain a deterministic version of the randomized algorithm of Leighton, Maggs, and Rao. Our results rely on results of Raghavan and Thompson [14] and Raghavan [12] to approximate certain integer packing problems.

In contrast to this, the only "negative" result previously known for any shop scheduling problem is that the existence of a fully polynomial approximation scheme would imply that $\mathcal{P} = \mathcal{NP}$, due to the fact that these problems are strongly $\mathcal{NP}$-hard. Subsequent to our work, Williamson et al. [20] showed that the existence of a ρ-approximation algorithm for any shop scheduling problem with $\rho < 5/4$ would imply that $\mathcal{P} = \mathcal{NP}$.

Our techniques can also be made to apply to three important generalizations of the job shop problem. The first is *dag shop scheduling*, where each job consists of a set of operations on different machines that must be processed in an order consistent with a given partial order. (For job shop scheduling, this partial order is always a chain, while for flow shop the partial order is the same chain for all jobs.) Note that we still require that no two operations of the same job can be processed simultaneously. One can further generalize the problem to the situation where, rather than having m different machines, there are m' types of machines, and for each type, there are a specified number of identical machines; each operation, rather than being assigned to one machine, may be processed on any machine of the appropriate type. These problems have significant practical importance, since in real-world shops we would expect that a job need not follow a strict total order and that the shop would have more than one copy of many of their machines. Finally, a further generalization of this problem is the problem of scheduling on unrelated parallel machines subject to chain precedence constraints. In this problem, each job now consists of a single operation which may be scheduled on any machine, but its processing time depends on the machine on which it is scheduled. There is a set of disjoint chain precedence constraints that further restricts the order in which the jobs may be scheduled.

We also give some extensions of these results, including an $\mathcal{RNC}$ approximation algorithm for each scheduling model mentioned above, and a $(2 + \epsilon)$-approximation algorithm for the job shop scheduling problem with a fixed number of machines.

While all of the algorithms that we give are polynomial-time, they are all rather inefficient. Most rely on the algorithms of Sevast'yanov; for example, his algorithm for the job shop scheduling problem takes $O((\mu mn)^2)$ time. Furthermore, the deterministic versions rely on linear programming algorithms. As a result, we will not refer explicitly to running times throughout the remainder of this paper.

2. The basic algorithm.

In this section we extend the technique introduced by Leighton, Maggs, and Rao [8] of assigning random delays to jobs to the general case of non-preemptive job shop scheduling.

A valid schedule assigns at most one job to a particular machine at any time, and schedules each job on at most one machine at any time. Our approach will be to first create a schedule that obeys only the second constraint, and then build from this a schedule that satisfies both constraints and is not much longer. The outline of the strategy follows.

(1) Define the *oblivious* schedule, where each job starts running at time 0 and runs continuously until all of its operations have been completed. This schedule is of length $P_{\max}$, but there may be times when more than one job is assigned to a particular machine.

(2) Perturb this schedule by delaying the start of the first operation of each job by a random integral amount chosen uniformly in $[0, \Pi_{\max}]$. The resulting schedule, with high probability, has

$$O\left(\frac{\log(n\mu)}{\log\log(n\mu)}\right)$$

jobs assigned to any machine at any time.

(3) "Spread" this schedule so that at each point in time all operations currently being processed have the same size, and then "flatten" this into a schedule that has at most one job per machine at any time.

This strategy is very similar to the one used by Leighton, Maggs, and Rao for the special case of unit-length operations. Whereas Step 2 differs in only a few technical details, the essential difficulty in obtaining the generalization is in Step 3. For the analysis of Step 2, we assume that $p_{\max}$ is bounded above by a polynomial in n and μ; in the next section we will show how to remove this assumption. For simplicity, we shall assume that $n \geq m$; analogous bounds can be obtained when this is not true.

LEMMA 2.1. *Given a job shop instance in which $p_{\max}$ is bounded above by a polynomial in n and μ, the strategy of delaying each job an initial integral amount chosen randomly and uniformly from $[0, \Pi_{\max}]$ and then continuously processing its operations in sequence will yield an (invalid) schedule that is of length at most $\Pi_{\max} + P_{\max}$ and, with high probability, has*

$$O\left(\frac{\log(n\mu)}{\log\log(n\mu)}\right)$$

jobs scheduled on any machine during any unit of time.

Proof. Fix a time t and a machine M_i; let $p =$ Prob[at least τ units of processing are scheduled on machine M_i at time t]. There are at most $\binom{\Pi_{\max}}{\tau}$ ways to choose τ units of processing from those required on M_i. If we focus on a particular one of these τ units and a specific time t, then the probability that it is scheduled at time t is at most $1/\Pi_{\max}$, since we selected a delay uniformly at random from among $\Pi_{\max}$ possibilities. If ail τ units are from different jobs then the probability that they are all scheduled at time t is at most $(1/\Pi_{\max})^{\tau}$ since the delays are chosen independently. Otherwise, the probability that all τ are scheduled at time t is 0, since two units from the same job can never be assigned to the same time. Therefore

$$\begin{aligned} p &\leq \binom{\Pi_{\max}}{\tau}\left(\frac{1}{\Pi_{\max}}\right)^{\tau} \\ &\leq \left(\frac{e\Pi_{\max}}{\tau}\right)^{\tau}\left(\frac{1}{\Pi_{\max}}\right)^{\tau} \leq \left(\frac{e}{\tau}\right)^{\tau}. \end{aligned}$$

If

$$\tau = k\frac{\log(n\mu)}{\log\log(n\mu)}$$

then $p < (n\mu)^{-(k-1)}$. We can bound the probability that *any* machine at *any* time is assigned more than

$$k\frac{\log(n\mu)}{\log\log(n\mu)}$$

jobs by $m(P_{\max} + \Pi_{\max})p < n(P_{\max} + \Pi_{\max})(n\mu)^{-(k-1)}$. Since we have assumed that $p_{\max}$ is bounded by a polynomial in n and μ, $P_{\max} + \Pi_{\max}$ is as well. If we choose k sufficiently large, then with high probability, no more than

$$k\frac{\log(n\mu)}{\log\log(n\mu)}$$

jobs are scheduled on any machine during any unit of time. □

In the special case of unit-length operations treated by Leighton, Maggs, and Rao, a schedule $\mathcal{S}$ of length L that has at most c jobs scheduled on any machine at any unit of time can trivially be "flattened" into a valid schedule of length cL by replacing one unit of $\mathcal{S}$'s time with c units of time in which we run each of the jobs that was scheduled for that time unit (see Fig. 1).

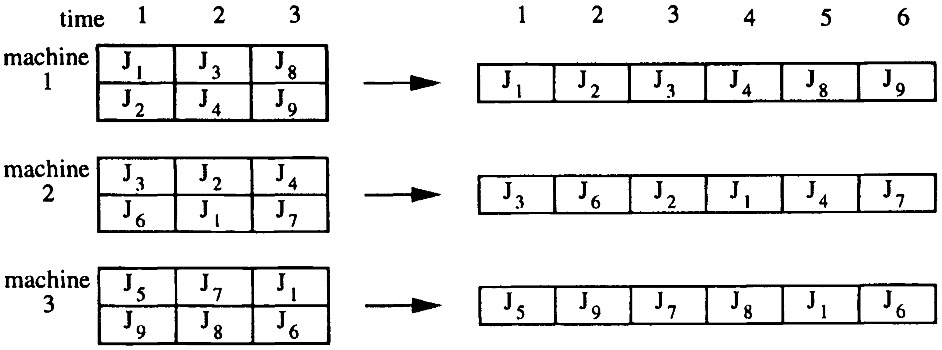

FIG. 1. *Flattening a schedule in the case with unit length operations.*

For *preemptive* job shop scheduling, where the processing of an operation may be interrupted, each unit of an operation can be treated as a unit-length operation and a schedule that has multiple operations scheduled simultaneously on a machine can easily be flattened into a valid schedule. This is not possible for *nonpreemptive* job shop scheduling, and in fact it seems to be more difficult to flatten the schedule in this case. We give an algorithm that takes a schedule of length L with at most c operations scheduled on each machine at any time and produces a schedule of length $O(cL\log p_{\max})$.

LEMMA 2.2. *Given a schedule $\mathcal{S}_0$ of length L that has at most c jobs scheduled on each machine during any unit of time, there exists a polynomial-time algorithm that produces a valid schedule of length $O(cL\log p_{\max})$.*

Proof. To begin, we round up each processing time p_{ij} to the next power of 2 and denote the corresponding rounded time by p'_{ij}; that is, $p'_{ij} = 2^{\lceil \log_2 p_{ij} \rceil}$. Let $p'_{\max} = \max_{ij} p'_{ij}$. From

$\mathcal{S}_0$, it is easy to obtain a schedule $\mathcal{S}$ that uses the modified p'_{ij} and is at most twice as long as $\mathcal{S}_0$; furthermore, an optimal schedule for the new problem is no more than twice as long as an optimal schedule for the original problem.

A *block* is an interval of a schedule with the property that each operation that begins during this interval is of length no more than that of the entire interval. (Note that this does not mean that the operation finishes within the interval.) We can divide $\mathcal{S}$ into $\lceil \frac{L}{p'_{\max}} \rceil$ consecutive blocks of size $p'_{\max}$. We will give a recursive algorithm that reschedules ("spreads") each block of size p (where p is a power of 2) into a sequence of schedule *fragments* of total length $p \log p$; the operations scheduled in a fragment of length T are all of length T, and start at the beginning of the fragment. This algorithm takes advantage of the fact that if an operation of length p is scheduled to begin in a block of size p, then that job is not scheduled on any other machine until after this block. Therefore, that operation can be scheduled to start after all of the smaller operations in the block finish.

To reschedule a block B of size $p'_{\max}$, we first construct the final fragment (which is of length $p'_{\max}$), and then construct the preceding fragments by recursive calls of the algorithm. For each operation of length $p'_{\max}$ that begins in B, reschedule that operation to start at the beginning of the final fragment, and delete it from B. Now each operation that still starts in B is of length at most $p'_{\max}/2$, so B can be subdivided into two blocks, B_1 and B_2, each of size $p'_{\max}/2$, and we can recurse on each. See Fig. 2 for an illustration of this rescheduling.

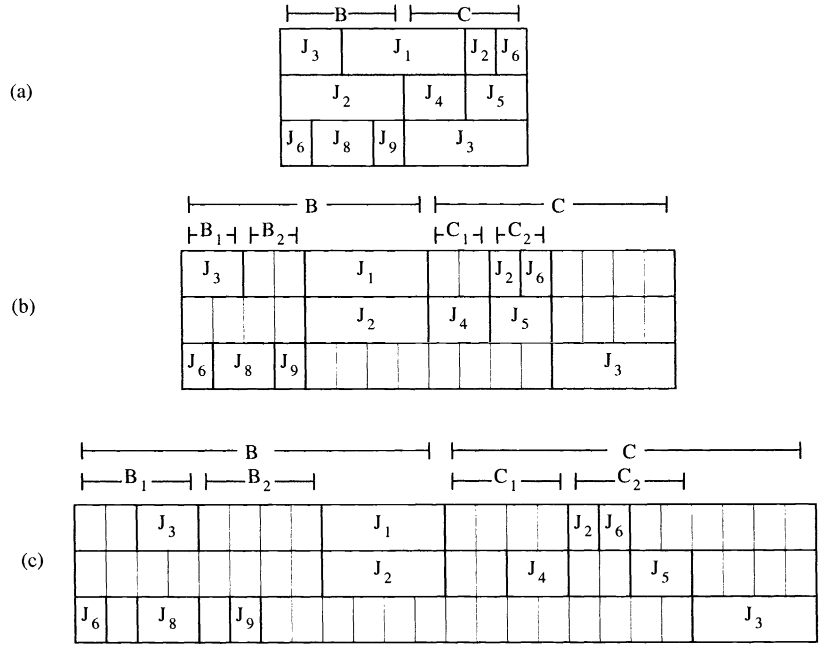

FIG. 2. (a) *The initial greedy schedule of length* 8. $p'_{\max} = 4$. (b) *The first level of spreading. All jobs of length* 4 *have been put in the final fragments. We must now recurse on* B_1 *and* B_2 *with* $p'_{\max} = 2$. (c) *The final schedule of length* $8 \log_2 8 = 24$.

The recurrence equation that describes the total length of the fragments produced from a block of size T is $f(T) = 2f(\frac{T}{2}) + T$; $f(1) = 1$. Thus $f(T) = \Theta(T \log T)$, and each block B in $\mathcal{S}$ of size $p'_{\max}$ is spread into a schedule of length $p'_{\max} \log p'_{\max}$. By spreading the schedule $\mathcal{S}$, we produce a new schedule $\mathcal{S}'$ that satisfies the following conditions:

(1) At any time in $\mathcal{S}'$, all operations scheduled are of the same length; furthermore, any two operations either start at the same time or do not overlap.

(2) If $\mathcal{S}$ has at most c jobs scheduled on one machine at any time, then this must hold for $\mathcal{S}'$ as well.

(3) $\mathcal{S}'$ schedules a job on at most one machine at any time.

(4) $\mathcal{S}'$ does not schedule the ith operation of job J_j until the first $i - 1$ are completed.

Condition 1 is satisfied by each pair of operations on the same machine by the definition of spreading, and by each pair of operations on different machines because the division of time into fragments is the same on all machines. To prove condition 2, note that operations of length T that are scheduled at the same time on the same machine in the expanded schedule started in the same block of size T on that machine. Since they all must have been scheduled during the last unit of time of that block, there can be at most c of them.

To prove condition 3, note that if a job is scheduled by $\mathcal{S}'$ on two machines simultaneously that means that it must have been scheduled by $\mathcal{S}$ to start two operations of length T in the same block of length T on two different machines. This means it was scheduled by $\mathcal{S}$ on two machines during the last unit of time of that block, which violates the properties of $\mathcal{S}$.

Finally we verify condition 4 by first noting that if two operations of a job are in different blocks of size $p'_{\max}$ in $\mathcal{S}$ then they are certainly rescheduled in the correct order. Therefore it suffices to focus on the schedule produced from one block. Within a block, if an operation is rescheduled to the final fragment then it is the last operation for that job in that block. Therefore $\mathcal{S}'$ does not schedule the ith operation of job J_j until the first $i - 1$ are completed.

The schedule $\mathcal{S}'$ can easily be flattened to a schedule that obeys the constraint of one job per machine at any time, since c operations of length T that start at the same time can just be executed one after the other in total time cT. Note that since what we are doing is effectively synchronizing the entire schedule block by block, it is important when flattening the schedule to make each machine wait enough time for all machines to process all operations of that fragment length, even if some machines have no operations of that length in that fragment.

The schedule $\mathcal{S}'$ was of length $L \log p'_{\max}$; therefore the flattened schedule is of length $Lc \log p'_{\max}$. □

3. Reducing the problem. In the previous section we showed how to produce, with high probability, a schedule of length

$$O\left((\Pi_{\max} + P_{\max}) \frac{\log(n\mu)}{\log\log(n\mu)} \log p_{\max}\right),$$

under the assumption that $p_{\max}$ was bounded above by a polynomial in n and μ. Since

$$\Pi_{\max} + P_{\max} = O(\max\{\Pi_{\max}, P_{\max}\}),$$

this schedule is within a factor of

$$O\left(\frac{\log(n\mu)}{\log\log(n\mu)} \log p_{\max}\right)$$

of optimality. In this section, we will first remove the assumption that $p_{\max}$ is bounded above by a polynomial in n and μ by showing that we can reduce the general problem to that special case while sacrificing only a constant factor in the approximation. This yields an

$$O\left(\frac{\log^2(n\mu)}{\log\log(n\mu)}\right) - \text{approximation algorithm.}$$

Then we will prove a similar result that reduces this case to one in which n is bounded by a polynomial in m and μ. Combining these two results, we conclude that we can reduce the job shop scheduling problem to its special case where n and $p_{\max}$ are polynomially bounded in m and μ, while changing the performance guarantee by only a constant.

3.1. Reducing $p_{\max}$. First we will show that we can reduce the problem to one where $p_{\max}$ is bounded by a polynomial in n and μ. Let $\omega = |\mathcal{O}|$ be the total number of required operations. Note that $\omega \leq n\mu$. Round down each p_{ij} to the nearest multiple of $p_{\max}/\omega$, and denote this value by p'_{ij}. This ensures that the value p'_{ij} takes at most ω distinct values, which are all multiples of $p_{\max}/\omega$. Therefore we can treat the p'_{ij} as integers in $\{0, \dots, \omega\}$; a schedule for this problem can be trivially rescaled to a schedule $\mathcal{S}'$ for the processing times p'_{ij}. (Note that assigning $p'_{ij} = 0$ does not mean that this operation does not exist; instead, it should be viewed as an operation that takes an arbitrarily small amount of time.) Let L denote the rescaled length of $\mathcal{S}'$.

We claim that $\mathcal{S}'$ for this rounded instance can be interpreted as a schedule for the original operations of length at most $L + p_{\max}$. If we increase the processing time of O_{ij} from p'_{ij} to its original time p_{ij}, we add an amount that is at most $p_{\max}/\omega$. Since the length of a schedule is determined by a critical path through the operations and there are ω operations, we add a total amount of at most $p_{\max}$ to the length of any path; thus the new schedule is of length at most $L + p_{\max} \leq L + C^*_{\max}$. Therefore we have rounded a general instance $\mathcal{I}$ of the job shop problem to an instance $\mathcal{I}'$ for which $p_{\max} = O(n\mu)$; furthermore, a schedule for $\mathcal{I}'$ yields a schedule for $\mathcal{I}$ that is no more than $C^*_{\max}$ longer. Thus we have shown the following lemma:

LEMMA 3.1. *There exists a polynomial-time algorithm that transforms any instance of the job shop scheduling problem into one with $p_{\max} = O(n\mu)$ with the property that a schedule for the modified instance of length $kC^*_{\max}$ can be converted in polynomial time to a schedule for the original instance of length $(k+1)C^*_{\max}$.*

3.2. Reducing the number of jobs. To reduce an arbitrary instance of job shop scheduling to one with a number of jobs that is polynomial in m and μ, we divide the jobs into big and small jobs. We say that job J_j is *big* if it has an operation of length more than $\Pi_{\max}/(2m\mu^3)$; otherwise we call the job *small*. For the instance consisting of just the short jobs, let $\Pi'_{\max}$ and $p'_{\max}$ denote the maximum machine load and operation length, respectively. Using the algorithm of [17] described in the introduction, we can, in time polynomial in the input size, produce a schedule of length $\Pi'_{\max} + 2m\mu^3 p'_{\max}$ for this instance. Since $p'_{\max}$ is at most $\Pi_{\max}/(2m\mu^3)$ and $\Pi'_{\max} \leq \Pi_{\max}$, we get a schedule that is of length no more than $2\Pi_{\max}$. Thus an algorithm that produces a schedule for the long jobs that is within a factor of k of optimal will yield a $(k+2)$-approximation algorithm. Note that there can be at most $2m^2\mu^3$ long jobs, since otherwise there would be more than $m\Pi_{\max}$ units of processing to be divided among m machines, which contradicts the definition of $\Pi_{\max}$. Thus we have shown the following lemma:

LEMMA 3.2. *There exists a polynomial-time algorithm that transforms any instance of the job shop scheduling problem into one with $O(m^2\mu^3)$ jobs with the property that a schedule for the modified instance of length $kC^*_{\max}$ can be converted in polynomial time to a schedule for the original instance of length $(k+2)C^*_{\max}$.*

From the results of the previous two sections we obtain the following theorem:

THEOREM 3.3. *There exists a polynomial-time randomized algorithm for job shop scheduling that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2(m\mu)}{\log\log(m\mu)} C^*_{\max}\right).$$

Proof. In §2 we showed how to produce a schedule of length

$$O\left((\Pi_{\max} + P_{\max})\frac{\log(n\mu)}{\log\log(n\mu)}\log p_{\max}\right)$$

under the assumption that $p_{\max}$ was bounded above by a polynomial in n and μ. From Lemmas 3.1 and 3.2 we know that we can reduce the problem to one where n and $p_{\max}$ are polynomial in m and μ, while adding only a constant to the factor of approximation. Since now $\log p_{\max} = O(\log(m\mu))$ and $\log n = O(\log(m\mu))$ our algorithm produces a schedule of length

$$O\left(\frac{\log^2(m\mu)}{\log\log(m\mu)}C^*_{\max}\right). \qquad \square$$

Note that when μ is bounded by a polynomial in m the bound only depends on m. In particular, this implies the following corollary.

COROLLARY 3.4. *There exists a polynomial-time randomized algorithm for flow shop scheduling that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2 m}{\log\log m}C^*_{\max}\right).$$

Except for the use of Sevast'yanov's algorithm, all of these techniques can be carried out in $\mathcal{RNC}$. We assign one processor to each operation. The rounding in the proof of Lemma 2.2 can be done in $\mathcal{NC}$. We set the random delays and inform each processor about the delay of its job. By summing the values of p_{ij} for all of its job's operations, each processor can calculate where its operation is scheduled with the delays and then where it is scheduled in the recursively spread out schedule. These sums can be calculated via parallel prefix operations. With simple $\mathcal{NC}$ techniques we can assign to each operation a rank among all those operations that are scheduled to start at the same time on its machine, and thus flatten the spread out schedule to a valid schedule.

COROLLARY 3.5. *There exists a $\mathcal{RNC}$ algorithm for job shop scheduling that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2(n\mu)}{\log\log(n\mu)}C^*_{\max}\right).$$

4. Applying the techniques to related problems.

4.1. A fixed number of machines. In this subsection we will show that the technique of partitioning the set of jobs by size can be applied to give a much better performance guarantee in the special case in which the number of machines and the maximum number of operations per machine are assumed to be constants. It is interesting to note that Sevast'yanov's algorithm for the job shop problem can be viewed as a $(1+m\mu^3)$-approximation algorithm, so that when m and μ are constant, this is a $O(1)$-approximation algorithm. We will give a ρ-approximation algorithm for ρ arbitrarily close to two.

To apply the idea of partitioning the jobs in this setting, call a job J_j *big* if there is an operation O_{ij} with $p_{ij} > \epsilon\Pi_{\max}/(m\mu^3)$, where ϵ is an arbitrary positive constant. Note that there are at most $m^2\mu^3/\epsilon$ big jobs, and since m, μ and ϵ are fixed, this is a constant.

Now use Sevast'yanov's algorithm to schedule all of the small jobs. The resulting schedule will be of length at most $(1+\epsilon)C^*_{\max}$. There are only a constant (albeit a huge constant) number of ways to schedule the big jobs. Therefore the best one can be selected in polynomial time and executed after the schedule of the short jobs. The additional length of this part is no more than $C^*_{\max}$.

Thus we have proven the following theorem:

THEOREM 4.1. *For any fixed value of $\epsilon > 0$, there is a polynomial-time algorithm for the special case of the job shop scheduling problem where both m and μ are fixed that produces a schedule of length $\leq (2+\epsilon)C^*_{\max}$.*

4.2. Dag shop scheduling with identical copies of machines. The fact that the quality of our approximations is based solely on the lower bounds $\Pi_{\max}$ and $P_{\max}$ makes it quite easy to extend our techniques to the more general problem of *dag shop scheduling*, in which each job is given by a specified partial order of operations. We define $\Pi_{\max}$ and $P_{\max}$ exactly the same way, and $\max\{\Pi_{\max}, P_{\max}\}$ remains a lower bound for the length of any schedule. We can reduce this dag shop scheduling problem to a job shop problem by selecting for each job an arbitrary total order that is consistent with its partial order. The maximum job length and maximum machine load for the job shop instance constructed are equal to the analogous values for the original dag shop instance. Therefore, a schedule of length $\rho \cdot (\Pi_{\max} + P_{\max})$ for this job shop instance is a schedule for the original dag shop scheduling instance of length $O(\rho C^*_{\max})$.

A further generalization to which our techniques apply is when, rather than m different machines, we have m' types of machines, and for each type we have a specified number of identical machines of that type. Instead of requiring an operation to run on a particular machine, an operation now has to run on only one of these identical copies. $P_{\max}$ remains a lower bound on the length of any schedule for this problem. $\Pi_{\max}$, which was a lower bound for the job shop problem, must be replaced, since we do not have a specific assignment of operations to machines and the sum of the processing times of all operations assigned to a type is *not* a lower bound. Let S_i, $i = 1, \ldots, m'$, denote the sets of identical machines, and let $\Pi(S_i)$ be the sum of the lengths of the operations that run on S_i. Our strategy is to reduce this to a job shop problem by assigning operations to specific machines in such a way that the maximum machine load is within a constant factor of the fundamental lower bounds for this problem. For each set of machines S_i, $i = 1, \ldots, m'$, the average load on that set of machines is clearly a lower bound on the maximum machine load of machines within that set; thus

$$\Pi_{\text{avg}} = \max_{S_i} \frac{\Pi(S_i)}{|S_i|}$$

is a lower bound on the maximum machine load. Furthermore, we cannot split operations, so $p_{\max}$ is also a lower bound. We will now describe how to assign operations to machines so that the maximum machine load of the resulting job shop scheduling problem is at most $2\Pi_{\text{avg}} + p_{\max}$. A schedule for the resulting job shop problem of length $\rho \cdot (\Pi_{\max} + P_{\max})$ yields a solution for the more general problem of length $O(\rho \cdot (\Pi_{\text{avg}} + P_{\max}))$. Sevast'yanov [17] used a somewhat more complicated reduction to handle a slightly more general setting.

For each operation O_{ij} to be processed by a machine in S_k, if $p_{ij} \geq \Pi(S_k)/|S_k|$, assign O_{ij} to one machine in S_k. There are certainly enough machines in S_k to assign these operations so that each machine is assigned at most one of them; this contributes at most $p_{\max}$ to the maximum machine load. Those operations not yet assigned are each of length at most $\Pi(S_k)/|S_k|$ and have total length $\leq \Pi(S_k)$. Therefore, these can be assigned easily to the remaining machines so that less than $2\Pi(S_k)/S_k$ processing units are assigned to each machine. Combining these two bounds, we get an upper bound on the maximum machine load of $2\Pi_{\text{avg}} + p_{\max}$, which is within a constant factor of the lower bound of $\max\{\Pi_{\text{avg}}, p_{\max}\}$.

THEOREM 4.2. *There exists a polynomial-time randomized algorithm for dag shop scheduling with identical copies of machines that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2(m\mu)}{\log\log(m\mu)}C^*_{\max}\right).$$

COROLLARY 4.3. *There exists an $\mathcal{RNC}$ algorithm for dag shop scheduling with identical copies of machines that, with high probability, yields a schedule that is of length*

$$O\left(\frac{\log^2(n\mu)}{\log\log(n\mu)}C^*_{\max}\right).$$

4.3. Unrelated parallel machines with chain precedence constraints. A further generalization of the job shop problem is the problem of scheduling jobs on unrelated parallel machines subject to chain precedence constraints, which is denoted $R|chain|C_{\max}$ in the notation of [7]. In this problem, we are given a set of jobs $\mathcal{J} = \{J_1, \dots, J_n\}$, each of which is to be processed by exactly one of a set of machines $\mathcal{M} = \{M_1, \dots, M_m\}$; if J_j is processed by M_i, it takes p_{ij} time units. We are also given a partial order $\prec$ that specifies job precedence constraints: if $J_j \prec J_k$ then J_k may not start processing until J_j has completed processing. The precedence constraints are restricted to be a disjoint union of chains; that is, we are given a set $\mathcal{C} = \{C_1, \dots, C_k\}$, where each chain $C_l \in \mathcal{C}$ consists of some μ_l jobs, given with a linear ordering on these jobs; each job is in exactly one chain (where unconstrained jobs are viewed as chains of length one). The objective is to construct a schedule consistent with the precedence constraints so as to minimize the maximum job completion time $C_{\max}$.

We will view the problem of finding a feasible solution for this problem as having two phases: finding an assignment of jobs to machines, and then constructing a schedule consistent with that assignment. It is easy to see that the second phase is a job shop scheduling problem: each operation of the job shop problem corresponds to a job of the parallel machines problem, and each job of the job shop problem corresponds to a chain of the parallel machines problem. We will construct an assignment such that the resulting job shop instance has $\Pi_{\max} \leq 4L$ and $P_{\max} \leq 2L$, where L is a lower bound for the original instance of $R|chain|C_{\max}$. By applying our approximation algorithms for the job shop problem to this instance, we obtain approximation algorithms for $R|chain|C_{\max}$ with an identical performance guarantee (up to a constant factor).

To find a suitable assignment, we give an algorithm that takes a given threshold value d, and either proves that any feasible schedule for the instance of $R|chain|C_{\max}$ has $C_{\max} > d$, or else constructs an assignment such that the resulting job shop instance has $\Pi_{\max} \leq 4d$ and $P_{\max} \leq 2d$. By performing a bisection search with initial lower bound 0 and upper bound $\sum_j \max_i p_{ij}$, we obtain a polynomial-time algorithm that finds a value L such that no schedule of length $L - 1$ exists (and hence L is a valid lower bound), and we have an assignment such that the resulting job shop instance has $\Pi_{\max} \leq 4L$ and $P_{\max} \leq 2L$.

The algorithm that tests a given threshold is based on results of Lenstra, Shmoys, and Tardos [9] and Lin and Vitter [10]. It works by first constructing an integer program which must be feasible if there is a schedule of length d, and then checks if its linear relaxation is feasible. If the linear program is infeasible, then no schedule of length d exists, and if the linear program is feasible, then the fractional solution can be rounded to yield an integer assignment with the claimed properties.

Observe that if there is a schedule with $C_{\max} \leq d$, then the following linear program has a feasible solution:

$$\begin{aligned}
\sum_{j=1}^{n} p_{ij}x_{ij} &\leq d, & i &= 1, \ldots, m, \\
\sum_{i=1}^{m} \sum_{j \in C_l} p_{ij}x_{ij} &\leq d, & l &= 1, \ldots, k, \\
\sum_{i=1}^{m} x_{ij} &= 1, & i &= 1, \ldots, m, \\
x_{ij} &\geq 0, & i &= 1, \ldots, m, \qquad j = 1, \ldots, n.
\end{aligned}$$

Let x_{ij} denote such a feasible solution; we can view this solution as a fractional assignment where an x_{ij} fraction of job J_j is assigned to M_i. Let p_j denote the total time spent processing J_j in this fractional assignment; that is,

$$p_j = \sum_{i=1}^{m} p_{ij}x_{ij}, \qquad j = 1, \ldots, n.$$

In this fractional assignment, it is possible for J_j to have a small fraction assigned to a machine M_i for which its p_{ij} value is substantially more than p_j. To make sure that this does not occur, we first apply the filtering technique of Lin and Vitter [10], and round x_{ij} to $\bar{x}_{ij}$ by setting

$$\bar{x}_{ij} = \begin{cases} x_{ij}, & \text{if } p_{ij} \leq 2p_j, \\ 0, & \text{otherwise.} \end{cases} \tag{1}$$

Of course, for each job J_j, only a fraction $t_j = \sum_{i=1}^{m} \bar{x}_{ij}$ of it is now assigned. We renormalize this fractional assignment by forming $\tilde{x}_{ij} = \bar{x}_{ij}/t_j$. Observe that $t_j \geq 1/2$, $j = 1, \ldots, n$, since less than half of each job J_j can be assigned to any machine M_i for which $p_{ij} > 2p_j$. Therefore $\tilde{x}$ satisfies

$$\begin{aligned}
&\sum_{j=1}^{n} p_{ij}\tilde{x}_{ij} \leq 2d, && i = 1, \ldots, m, \\
&\sum_{i=1}^{m} \tilde{x}_{ij} = 1, && i = 1, \ldots, m, \\
&\tilde{x}_{ij} = 0, \quad \text{if } p_{ij} > 2p_j, && i = 1, \ldots, m, \qquad j = 1, \ldots, n, \\
&\tilde{x}_{ij} \geq 0, && i = 1, \ldots, m, \qquad j = 1, \ldots, n.
\end{aligned}$$

A result of Lenstra, Shmoys, and Tardos [9] states that, in polynomial-time, any extreme point of such a linear program can be rounded to an integer solution x^* such that

$$\begin{aligned}
&\sum_{j=1}^{n} p_{ij}x^*_{ij} \leq 2d + 2\max_j\{p_j\}, && i = 1, \ldots, m, \\
&\sum_{i=1}^{m} x^*_{ij} = 1, && i = 1, \ldots, m, \\
&x^*_{ij} = 0, \quad \text{if } p_{ij} > 2p_j, && i = 1, \ldots, m, \qquad j = 1, \ldots, n, \\
&x^*_{ij} \geq 0, && i = 1, \ldots, m, \qquad j = 1, \ldots, n.
\end{aligned}$$

Furthermore, since $\sum_{j \in C_l} p_j \leq d, l = 1, \ldots, k$, we have that

$$\sum_{j \in C_l} \sum_{i=1}^{m} p_{ij} x_{ij}^* \leq \sum_{j \in C_l} 2p_j \leq 2d.$$

Consequently, if for each job J_j we assign the corresponding operation to the machine M_i for which $x_{ij}^* = 1$, then we obtain a job shop instance for which $P_{\max} \leq 2d$, and $\Pi_{\max} \leq 2d + 2 \max_j \{p_j\} \leq 4d$, as claimed.

THEOREM 4.4. *There exists a polynomial-time randomized algorithm for $R|chain|C_{\max}^*$ that, with high probability, yields a schedule that is of length at most*

$$O\left(\frac{\log^2 n}{\log \log n} C_{\max}^*\right).$$

5. A deterministic approximation algorithm. In this section, we "derandomize" the results of the previous sections: we give a deterministic polynomial-time algorithm that finds a schedule of length $O(\log^2(m\mu)C_{\max}^*)$. Of all the components of the algorithm of Theorem 3.3, the only step that is not already deterministic is the step that uniformly chooses a random initial delay for each job with the resulting property that, with high probability, no machine is assigned too many jobs at any time. In particular, the reduction to the special case in which n and $p_{\max}$ are bounded by a polynomial in m and μ is entirely deterministic, and so we can focus on that case alone.

We will give an algorithm that deterministically assigns delays to each job so as to produce a schedule in which each machine has $O(\log(m\mu))$ jobs running at any one time. We then apply Lemma 2.2 to produce a schedule of length $O(\log^2(m\mu)C_{\max}^*)$. Note that the $O(\log(m\mu))$ jobs per machine is not as good as the probabilistic bound of

$$O\left(\frac{\log(m\mu)}{\log \log(m\mu)}\right).$$

Recently, Schmidt, Siegel, and Srinivasan [15] have given a different derandomizing strategy for this problem that yields delays that match the performance of the randomized algorithm.

Our approach to the problem of selecting good delays is to frame it as a *vector selection* problem and then apply techniques developed by Raghavan and Thompson [13], [14] and Raghavan [12] that find constant factor approximations to certain "packing" integer programs. The approach is to formulate the problem as a {0, 1}–integer program, solve the linear programming relaxation, and then randomly round the solution to an integer solution. For certain types of problems this yields provably good approximations with high probability [13], [14]. Furthermore, for many of the problems for which there are approximations with high probability, the algorithm can be derandomized. Raghavan [12] has shown how to do this by essentially setting the random bits one at a time.

We now state the problem formally:

PROBLEM 5.1. *Deterministically assign a delay to each job in the range* $[0, \Pi_{\max}/\log(m\mu)]$ *so as to produce a schedule with* $O(\log(m\mu))$ *jobs on any machine at any time.*

LEMMA 5.2. *Problem* 5.1 *can be solved in deterministic polynomial time.*

Proof. Since we introduce delays in the range $[0, \Pi_{\max}/\log(m\mu)]$, the resulting schedule has length $\ell = P_{\max} + \Pi_{\max}/\log(m\mu)$. We can represent the processing of a job J_j with a given initial delay d by $\{0, 1\}$–vector of length $\ell \cdot m$, where each component corresponds to a particular machine at a particular time. The position corresponding to machine M_i and time

t is 1 if M_i is processing job J_j at time t, and 0 otherwise. For each job J_j and each possible delay d, there is a vector $V_{j,d}$ that corresponds to assigning delay d to J_j.

Let λ_j be the set of vectors $\{V_{j,1}, \dots, V_{j,d_{\max}}\}$, where $d_{\max} = \Pi_{\max}/\log(m\mu)$, and let $V_{j,k}(i)$ be the ith component of $V_{j,k}$. Given the set $\Lambda = \{\lambda_1, \dots, \lambda_n\}$ of sets of vectors, our problem can be stated as the problem of choosing one vector V_j^* from each λ_j such that

$$\left\| \sum_{j=1}^{n} V_j^* \right\|_\infty = O(\log(m\mu));$$

that is, at any time on any machine, the number of jobs using that machine is $O(\log(m\mu))$.

As in [12], we can reformulate this as a $\{0, 1\}$–integer program. Let $x_{j,k}$ be the indicator variable used to indicate whether $V_{j,k}$ is selected from λ_j. Consider the integer program (IP) that assigns $\{0, 1\}$ values to the variables $x_{j,k}$ to minimize W subject to the constraints

$$\sum_{k=1}^{d_{\max}} x_{j,k} = 1, \qquad j = 1, \dots, n,$$

$$\sum_{j=1}^{n} \sum_{k=1}^{d_{\max}} x_{j,k} V_{j,k}(i) \le W, \qquad i = 1, \dots, \ell \cdot m.$$

Let W_{OPT} be the optimum value of W, which is the maximum number of jobs that ever use a machine at any time. We already know, by Lemma 2.1, that $W_{\mathrm{OPT}} = O(\log(m\mu))$, and so an optimal solution to this integer program would solve Problem 5.1. However, the problem is $\mathcal{NP}$-hard. Instead, we rely on the following theorem, which is immediate from the results in [12] and [14].

THEOREM 5.3 [12], [14]. *A feasible solution to (IP) with $W = O(W_{\mathrm{OPT}} + \log(m\mu))$ can be found in polynomial time.*

We then apply Lemma 2.2 to obtain the following result:

THEOREM 5.4. *There exists a deterministic polynomial-time algorithm that finds a schedule of length $O(\log^2(m\mu)\, C^*_{\max})$.* □

6. Conclusions and open problems. We have given the first polynomial-time polylog-approximation algorithms for minimizing the maximum completion time for the problems of job shop scheduling, flow shop scheduling, dag shop scheduling, and several other generalizations.

One particularly simple special case of dag shop scheduling can be obtained if the partial order for each job is empty; in other words, each job consists of a number of operations that may be performed in any order. This is called the *open shop* problem, and it is traditional in the scheduling literature to focus on the case when each job is processed on each machine at most once (since operations on the same machine can be coalesced).

A consequence of our results is the following observation about the structure of shop scheduling problems. Assume we have a set of jobs that need to run on a set of machines. We know that any schedule for the associated open shop problem must be of length $\Omega(\Pi_{\max} + P_{\max})$. Furthermore, we know that no matter what type of partial ordering we impose on the operations of each job we can produce a schedule of length

$$O\left((\Pi_{\max} + P_{\max}) \frac{\log^2 m}{\log \log m} \right).$$

Hence for any instance of the open shop problem, we can impose an arbitrary partial order on the operations of each job and increase the length of the optimal schedule by a factor of

$$O\left(\frac{\log^2 m}{\log\log m}\right).$$

On the other hand, there does exist a schedule of length $O(P_{\max}+\Pi_{\max})$ for the open shop problem. Consider the simple greedy algorithm that, whenever a machine is idle, assigns to it any job that has not yet been processed on that machine and is not currently being processed on another machine. Anná Racsmány [2] has observed that the greedy algorithm delivers a schedule of length at most $\Pi_{\max} + (m - 1)p_{\max}$. We can adapt her proof to show that, in fact, the greedy algorithm delivers a schedule that is of length less than $\Pi_{\max} + P_{\max} \le 2C^*_{\max}$. Consider the machine M_k that finishes last in the greedy schedule; this machine is active sometimes, idle sometimes, and finishes by completing some job J_j. Since the schedule is greedy, whenever M_k is idle, J_j is being processed by some other machine, and so the idle time is at most $\sum_{M_i \ne M_k} p_{ij} < P_{\max}$. Thus machine M_k is processing for at most $\Pi_{\max}$ units of time and is idle for less than $P_{\max}$ units of time; hence $C_{\max} < \Pi_{\max} + P_{\max}$. Fiala [5] has also shown that if $\Pi_{\max} \ge (16m\log m + 21m)p_{\max}$, then $C^*_{\max}$ is just $\Pi_{\max}$, and there is a polynomial-time algorithm to find an optimal schedule.

We have seen that in two interesting special cases, job shop scheduling with unit-length operations and open shop scheduling, there is a schedule of length $O(\Pi_{\max} + P_{\max})$, and so the major open question left unresolved by this paper is:

- Does there exist an $O(\Pi_{\max}+P_{\max})$ schedule for the general job or flow shop scheduling problem? If so, when can it be found in polynomial time?

Beyond this, there are a number of interesting questions raised by this work, including

- Do there exist parallel algorithms that achieve the approximations of our sequential algorithms? For the general job shop problem this seems hard, since we rely heavily on the algorithm of Sevast'yanov. For open shop scheduling, however, a simple sequential algorithm achieves a factor of two, whereas the best $\mathcal{NC}$ algorithm that we have achieves only an $O(\log n)$-approximation. As a consequence of the results above, all one would need to do is to produce any greedy schedule.
- Are there simple variants of the greedy algorithm for open shop scheduling that achieve better performance guarantees? For instance, how good is the algorithm that always selects the job with the maximum total (remaining) processing time? Williamson et al. [20] have shown that the existence of a ρ-approximation algorithm with $\rho < 5/4$ would imply that $\mathcal{P} = \mathcal{NP}$. It remains an interesting open problem to close this gap.
- Our algorithms, while polynomial-time algorithms, are inefficient. Are there significantly more efficient algorithms which have the same performance guarantees? Stein [19] has given an algorithm that directly finds a good approximate solution to the integer program (IP) by using the framework of Plotkin, Shmoys, and Tardos [11]. This yields an implementation of our algorithm that runs in $O(n^2m^2\mu^2 + n^3\mu^2\log(m\mu)(\mu+\log(m\mu)))$ time. Although this represents a dramatic improvement over the previously known bound, it remains an interesting question to give substantially more efficient algorithms.

Acknowledgments. We are grateful to David Williamson for working with us in the early stages of this research, and to Imre Bárány, Tom Leighton, Bruce Maggs, and Yishay Mansour for many helpful discussions. We thank Jim Orlin for the observation about the gap between open shop and dag shop scheduling.

RANDOMIZED ALGORITHMS FOR BINARY SEARCH AND LOAD BALANCING ON FIXED CONNECTION NETWORKS WITH GEOMETRIC APPLICATIONS*

JOHN H. REIF† AND SANDEEP SEN‡

Abstract. There are now a number of fundamental problems in computational geometry that have optimal algorithms on PRAM models. This paper presents randomized parallel algorithms that execute on an n-processor butterfly interconnection network in $O(\log n)$ time for the following problems of input size n: trapezoidal decomposition, visibility, triangulation, and two-dimensional convex hull. These algorithms involve tackling some of the very basic problems, like binary search and load balancing, that are taken for granted in PRAM models. Apart from a two-dimensional convex hull algorithm, these are the first nontrivial geometric algorithms that attain this performance on fixed connection networks. These techniques use a number of ideas from *Flashsort* that have to be modified to handle more difficult situations; it seems likely that they will have wider applications.

Key words. parallel algorithms, randomization, computational geometry, butterfly network

AMS subject classifications. 68E05, 68C05, 68C25

1. Introduction.

1.1. Motivation and overview.

In the past decade, we have witnessed a systematic growth in state-of-the-art parallelizing algorithms in the Parallel Random Access Machine (PRAM) environment. As a result, a number of basic problems have been recognized and many sophisticated techniques have been developed—these can be viewed as a "tool-kit" for tackling increasingly complex problems. There is a general consensus that PRAM models are appropriate for the algorithm designer but that these algorithms have to be implemented on fixed-connection networks to be of any practical significance. Using well-known general-purpose emulation schemes, all these algorithms can be implemented to run on a butterfly (or a hypercube) network with a $O(\log n)$ multiplicative factor degradation in time complexity. The crucial question is: Can PRAM algorithms be extended to fixed-connection networks without this logarithmic penalty in running time?

In a top–down approach to algorithm design, complicated algorithms are built on top of less complex procedures. The answer to the above question would depend on how far down in this hierarchy one can go without running into problems that cannot be mapped optimally on the fixed-connection network. Moreover, this would also depend on the nature of the algorithm itself. One of the most basic problems in this hierarchy is sorting. For example, Reischuk's [19] $O(\log n)$ time, n processor randomized PRAM sorting algorithm was successfully extended to networks by Reif and Valiant [18] to run in $O(\log n)$ time by using additional new sampling techniques for problem-size control. In contrast, Cole's deterministic $O(\log n)$ time parallel mergesort algorithm seems prohibitively difficult to implement (without a logarithmic slowdown) on the networks because of its liberal use of pointers. Consequently a number of algorithms that use this approach on PRAM models would be at least as difficult as being adapted to network models.

Although the eventual goal of this paper is to present efficient algorithms on interconnection networks, we would like the reader to view this in the more general context of mapping certain kinds of PRAM algorithms on fixed-connection networks and the difficulties associated therewith. We encountered several problems that appear to be very basic for this line of research, and we believe that these will have much wider applications.

Remark. In this paper, the term fixed-connection network has been used to allude to networks that have $O(\log n)$ diameter for n-node networks. There already exists a large body of literature for geometric algorithms on grid-like networks where the diameter is a bottleneck for achieving the kind of time complexity for which we are aiming.

One of the underlying problems is doing binary search optimally in a model that does not allow concurrent reads. A common scenario is the following: we are given a tree whose leaves represent intervals and n keys for which we have to determine the interval in which each key lies. If the depth of this tree is d, then it is trivial to do this sequentially in $O(nd)$ time. In case of PRAM models that allow concurrent reads, the problem is again quite simple. With n processors, we can simultaneously search for all keys in $O(d)$ parallel time, thus resulting in an optimal speed-up. The main difficulty associated with this problem stems from the possibility that the keys may be unevenly distributed among the intervals. In this paper we have described a randomized algorithm to do this in an $EREW$ PRAM in $O(\log n)$ time and refined it further to run in the same asymptotic time on an n-node butterfly network.

An additional problem is that of allocation of subproblems to subnetworks for recursive calls. Unlike $PRAM$ models, the network topology imposes severe constraints on processor allocation — not only should the number of processors match with the subproblem sizes but they should also be interconnected in a certain manner. Our solution to this problem could be applied to a more general situation than the applications described in this paper. Some of the ideas are similar to *Flashsort* where one does *splitter-directed routing* to route the keys to the appropriate subnetworks. However, unlike *Flashsort*, we may be confronted with situations where we have to allocate resources dynamically, as the subproblems could have varying sizes. One of our results is that we have near-optimal solutions to the above problems that should have applications to a wide class of algorithms. These basic procedures serve as a crucial link between the PRAM algorithms and interconnection networks.

1.2. Geometry on fixed-connection networks and main results. Designing efficient parallel algorithms for various fundamental problems in computational geometry has received much attention in the last few years. There have been two fundamentally distinct approaches to this area of research, namely, the deterministic methods and algorithms that use random sampling. Some of the earliest work in this area was by Chow [4], who developed algorithms for a number of fundamental problems that were deterministic and executed in interconnection networks with polylogarithmic running time. A more general approach for deterministic PRAM algorithms was pioneered by Aggarwal et al. [1], who developed some new techniques for designing efficient parallel algorithms for fundamental geometric problems. However, a majority of the algorithms were not optimal in $P \cdot T$ bounds. A number of the most efficient deterministic PRAM algorithms are from Atallah, Cole, and Goodrich [2], who extended the techniques used by Cole [8] for his parallel mergesort algorithm. Their technique is called *Cascaded merging* and has been subsequently used (independently by Chandran [3]) for a number of other problems. Note that most of the geometric problems in the context of research in parallel algorithms have sequential time complexity of $\Omega(n \log n)$ and a typical performance that one aims for is $O(\log n)$ parallel time using an optimal number of processors.

In an independent development, Reif and Sen [17] were also able to derive $O(\log n)$ time-optimal algorithms for point-location and trapezoidal decomposition, which were randomized. Later they extended their methods to give optimal algorithms for three-dimensional convex hulls (and hence two-dimensional Voronoi diagrams) on the *CREW* PRAM model. At the core of their algorithms were random sampling techniques that had also been introduced by Clarkson [5], [6], [7] and Haussler and Welzl [10]. In addition, a new resampling technique called *Polling* was used successfully to derive the parallel algorithms. In essence, it is an efficient resampling procedure that enables us to choose a sample that satisfies certain properties with high probability from a set of samples for which only expected behavior is known. While no deterministic algorithms have been developed for some of the above problems that attain optimal bounds, we feel that the real impact of randomized techniques will be in the domain of parallel algorithms on fixed-connection networks.

In spite of interesting developments in the PRAM world, the state-of-art of geometric algorithms in the case of small-diameter fixed-connection networks is lagging far behind. Presently, the only known $O(\log n)$ time algorithm for the network model is a two-dimensional convex hull algorithm due to Miller and Stout [13]. Consequently, the *Cascaded-merge technique* of Atallah, Cole, and Goodrich [2], in spite of its elegance on the PRAM models, appear to be of little use in a fixed-connection model. The only obvious way to implement pointer updates takes $O(\log n)$ time per step of the PRAM algorithm, which results, in an $\tilde{O}(\log^2 n)$ time algorithm.

The randomized algorithms seem to be more amenable to mapping on fixed-connection networks, although they are far from straightforward. We derive an optimal $O(\log n)$ time randomized algorithm for constructing the trapezoidal decomposition. Using this, we can triangulate a simple polygon in $O(\log n)$ time.

1.3. Model of computation and notation. Throughout this paper we will be using the butterfly interconnection model where the processors operate in a synchronous fashion and have bounded buffer size. These assumptions are consistent with some of the existing machines such as the BBN Butterfly and Connection Machine. During every step, each processor is allowed to perform a real-arithmetic operation consistent with standard models used for sequential geometric algorithms. Moreover, each processor has access to a random-number generator that returns in unit time a truly random number of $O(\log n)$ bits. One of the primary reasons for choosing the butterfly network is because of its "recursive" nature. A butterfly network of order k (which will be referred to as BF_k) has k levels of 2^k nodes each, i.e., it has $k2^k$ nodes. Each node has an address (w, t) where $w \in \{0, 1\}^k$ and $0 \leq t < k$ (see Fig. 1). The first component of this address will be referred to as *row* and the second component as *rank*. The significance of this network is that there are numerous "copies" of BF_l in BF_k for $l < k$. We shall make crucial use of the following fact.

Fact 1. For any w_1, w_2 such that $|w_1| + |w_2| = k - l$, the subgraph of BF_k spanned by the nodes $\{(w_1 w w_2, i) | w \in \{0, 1\}^l\}$ and $|w_1| \leq i \leq |w_1| + l$ is isomorphic to BF_l.

Here $|w|$ is used to denote the length of the (binary) string w. Moreover, we may need to emulate a larger butterfly in a work-preserving fashion. The following simple result can be used.

Fact 2. A BF_k can emulate a BF_{k+c} within $O(3^c)$ slowdown where c is a positive integer.

This is similar to Brent's slowdown lemma except that we must construct a mapping of the processors of BF_{k+c} to BF_k respecting the interconnection topology. In this case it is very straightforward. Assume that $c = 1$ and map the processors with addresses (xw, i) where $x \in \{0, 1\}$ and $|w| = k$ and $i \leq k$ to (w, i). One can verify that the processors of BF_{k+1} that were neighbors are neighbors in the smaller network. Each processor in the smaller network has to do at most twice the amount of work and requires twice the amount of local memory. Only the processors of rank k must do the extra work of emulating the processors of rank

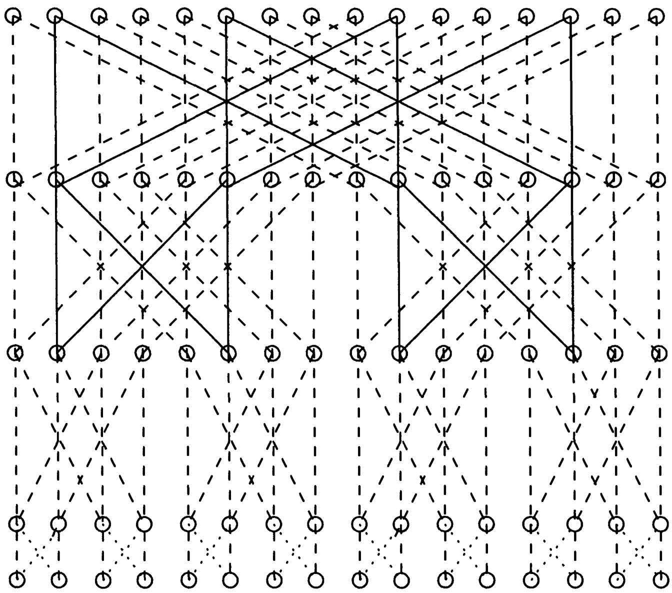

FIG. 1. *A butterfly network of order* 4. *The solid lines illustrate a subnetwork isomorphic to* BF_2.

$k+1$. This scheme can be extended directly to yield the claimed bound. For a fixed c, this implies that there is a constant factor slow-down. In this paper this scheme will often be used with the value of c being 1 or 2.

The term *very high likelihood* (*probability*) is used in this paper to denote probability $> 1 - n^{-\alpha}$ for some $\alpha > 1$ where n is the input size. Just like the big-O function serves to represent the complexity bounds of deterministic algorithms, we shall use $\tilde{O}$ to represent complexity bounds of the randomized algorithms. We say that a randomized algorithm has resource bound $\tilde{O}(f(n))$ if there is a constant c such that the resource used by the algorithm is no more than $c\alpha f(n)$ with probability $\geq 1 - 1/n^{\alpha}$ for any $\alpha > 1$ for an input of size n. (An equivalent definition will bound the resource by $\alpha \cdot f(n)$ with probability greater than 1 - $n^{-c\alpha}$, and in the rest of the paper they will be used in an interchangeable manner.)

The rest of the paper is organized as follows. In §2, we briefly review two important subroutines in a fixed-connection network, namely, sorting and routing. In §3, we describe an algorithm for conducting a binary search. This is used in §4 to develop fast methods for searching in arrangements. We give a brief description of the algorithm for trapezoidal decomposition. We focus mainly on those portions for which we need different methods from the PRAM algorithms — the reader is referred to a previous paper (Reif and Sen [17]) for a more detailed description of the algorithms that were developed for the $CREW$ PRAM model.

2. Overview of sorting and routing on fixed-connection networks. Our algorithms use sorting and routing extensively at various stages, and a brief review of these routines will help us in understanding the latter algorithms that use them as building blocks. The problem of *packet routing* involves routing a message from processor i to $\Pi(i)$ for all i where Π is a permutation function. There has been a long and rich history of routing algorithms for fixed connection networks (see [22], [21], [15], [11]), and these can be summarized as follows.

LEMMA 2.1. *There exists an algorithm for permutation routing on an n-node butterfly network that executes in* $\tilde{O}(\log n)$ *steps and uses only constant size queues to achieve this running time.*

A more general result has been proved by Maggs et al. [21] for *layered* networks. A *layered* network is one whose nodes can be assigned layer numbers and in which each edge connects a layer i node to a layer $i+1$ node (butterfly is an example of such a network). Let d denote the maximum distance traveled by any packet and c the largest number of packets that must traverse a single edge (this parameter c is also called the congestion). These parameters are fixed for a given selection of paths by all the packets to be routed. Then there exists a scheme for scheduling the movements of the packets such that with high probability the routing can be completed in $O(c + d + \log n)$ steps where n is the size of the network and $O(n)$ packets are being routed.

Remark. Given the above result and the fact that d is $O(\log n)$ for most path selection strategies, especially in a butterfly network, it remains to bound the value of c to get a bound on the routing time. For packets being routed to a random location, c can be bounded by $O(\log n)$ with high probability.

The first optimal $\tilde{O}(\log n)$ time-sorting algorithm, called *Flashsort*, for the butterfly network was by Reif and Valiant [18]. It was based on a PRAM sorting algorithm by Reischuk [19] but required several additional techniques because of the constraints imposed by the network connectivity. A slightly simplified version can be presented as follows.

1. Select n^{ϵ_0}-($\epsilon_0 < 1/2$) sized random subset from the given set of n keys.

2. Sort these, using a simple method, like doing all the pairwise comparisons and ranking them.

3. Use these keys to set up a binary tree such that the leaves of the tree correspond to the intervals defined by a pair of consecutive splitter keys. Over-sampling techniques are used to ensure that these intervals partition the remaining keys into roughly equal-sized subsets. This eliminates the need for dynamic load balancing in the special case of sorting. The keys are assumed to be in random locations initially. For each subset a subnetwork of appropriate size is set aside and the keys that belong to this subset are routed to this part of the network. This is done using a procedure called *Splitter Directed Routing*, which will be referred to as SDR in future references. Since this is a crucial component of our algorithm, we describe it in more detail in the appendix.

4. These steps are applied recursively until the size of the subproblems is no more than $\log^2 n$.

Although the original analysis showed that a $\tilde{O}(\log n)$ buffer size may be required, the more recent results on routing enables one to make do with a constant amount of storage in each buffer [21]. The overall running time of the sorting algorithm was analyzed using the property that the problem size at the ith stage of recursion is no more than $n^{\epsilon_0^i}$, $\epsilon_0 < 1$, and there are at most a polynomial number of problems at any stage of recursion. This recursive algorithm can be modelled as a process-tree where the root of this tree corresponds to the original problem and the leaf nodes correspond to procedures that are solved directly. The following result (Reif and Sen [16]) will be used to bound the running time of such algorithms.

LEMMA 2.2. *Given a process-tree that models the recursive algorithm, which has the property that a procedure at depth i from the root takes time T_i such that*

$$P[T_i \ \geq \ k(\epsilon_0)^i c\alpha \log n] \leq \ 2^{-(\epsilon_0)^i c\alpha \log n},$$

all the leaf-level procedures are completed in $\tilde{O}(\log n)$ time.

We shall also use a straightforward generalization of the above result where the process tree is modified in the following manner. Instead of all the subroutines from a node proceeding independently, all the subroutines for a fixed (constant) depth subtree are required to finish

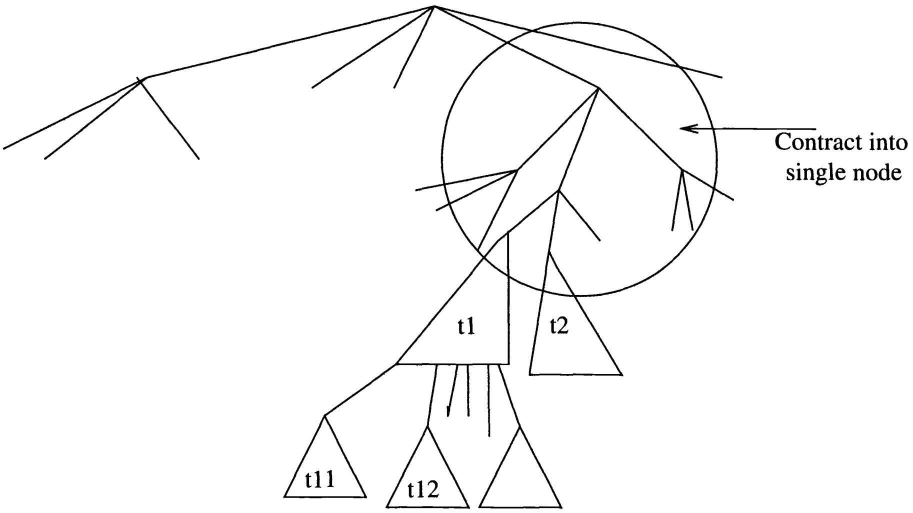

FIG. 2. *By contracting subtrees of a fixed depth, we get another tree satisfying the preconditions of Lemma* 2.2.

before proceeding to the next level of subtrees. This can be reduced to the previous case if we contract a subtree of fixed depth (see Fig. 2) into a single node of the tree. The time taken at any node of this new (contracted) tree also satisfies the property required by Lemma 2.2 with appropriate adjustments in the constants. This follows from the observation that at any level of the process-tree all the procedures terminate in $\tilde{O}(\log n)$ time, and if the process-tree is of constant depth, then clearly the total time is also $\tilde{O}(\log n)$. Thus any contracted node that is actually a subtree of constant depth satisfies the precondition of Lemma 2.2. Consequently, we can prove the following result on similar lines as the previous lemma.

COROLLARY 2.3. *All the leaf-level procedures of this modified tree will terminate in* $\tilde{O}(\log n)$ *steps.*

The above two results will be used repeatedly in the rest of the paper.

3. Binary search without concurrent reads. One of the frequently encountered problems in the case of sequential and parallel algorithms is that of doing a binary search on a tree structure. In particular, given a binary tree of depth $O(\log n)$ whose leaves represent certain intervals and $O(n)$ keys with one processor per key, we would like to locate the interval containing the key in $O(\log n)$ parallel time for each key simultaneously. This problem is trivial in a model allowing concurrent reads. However, the problem becomes more complicated when concurrent reads are not permitted in the model, which is the case with interconnection networks. The simple algorithm uses concurrent reads in an inherent fashion, and for situations where the distribution of the keys is not known, this problem appears even more formidable. To make the exposition simpler we shall first describe a scheme for the *EREW* PRAM and then modify it for the butterfly network. We also note that in certain cases where the intervals and the keys are chosen from the same total ordering the problem reduces to that of merging, which can be done efficiently. However, we are concerned about cases where the intervals may induce an ordering different from the ordering among the keys (see Fig. 3).

We shall look at a special case where the number of leaves is n^{ϵ} for $0 < \epsilon < 1$ and the search tree is roughly balanced, so it has depth $O(\log n)$. The basic strategy is the following. We first try to get a reasonably accurate estimate of the number of keys associated with each of the leaf nodes. Following this, we simulate an interconnection network like the butterfly and allocate an appropriate number of subnetworks based on the estimate. Next we route the keys to their destination subnetworks using a scheme similar to the *SDR* used in *Flashsort.*

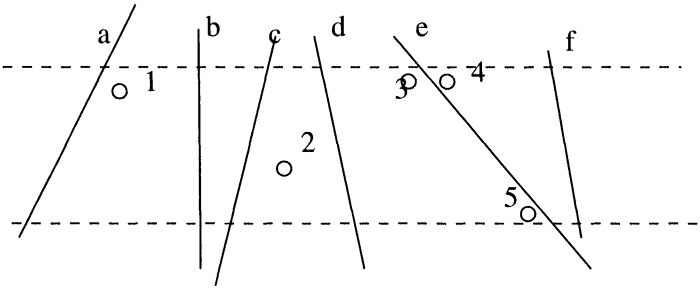

FIG. 3. *Points* 4 *and* 5 *are in different relative orderings with respect to each other and the segments.*

The analysis for *SDR* carries through in this case, although some of the nodes of the splitter tree may be artificial, i.e., both edges departing from a node may lead to the same interval (which is a large subnetwork in our case). We show that each of these steps succeeds with high probability.

To obtain an estimate of the number of keys in each range, we make use of a technique used earlier in Reif and Sen [16] and Rajasekaran and Reif [14]. The result can be summarized in the following manner. Unless otherwise mentioned, we shall use the notation $|S|$ to denote the cardinality of set S.

LEMMA 3.1. *Let S_j, $1 \leq j \leq m \leq n$, be disjoint subsets such that $\sum_{i=1}^{m} |S_i| = n$. If we sample elements independently and uniformly from the union of the subsets with probability p and n_j is the number of elements in the sample from S_j, then for all j such that $p|S_j| \geq d \log n$, n_j is within a constant factor of $p|S_j|$ with high probability. Here d is a constant and the ratio of n_j to $|S_j|$ depends on d.*

In the context of our problem each subset S_i is an interval and $|S_i| = N_i$, the number of keys in the ith interval. As a consequence of this lemma, we set aside $\max\{d \log n \cdot 1/p, E_j\}$ space for each interval. E_j is an estimate for N_j computed from n_j and is $O(1/p \cdot n_j)$. Note that for most applications we choose a value of p such that $md \log n/p \leq n$. We start by selecting each key with probability $1/n^{1-\beta}$; the exact value of β will be determined later. From Chernoff bounds, it follows that the number of keys in the sample is $O(n^{\beta})$ with high probability. For each of these keys, we can determine to which interval they belong by using a brute-force method; for example, simply checking each key against every interval. This can be done in $O(\log n)$ time if we choose $\epsilon + \beta < 1$. From the previous lemma, it follows that if N_i exceeds $cn^{1-\beta} \log n$, where c is a constant independent of n, we can get estimates E_i (of N_i) within a constant factor. So we can set aside $\max(cn^{1-\beta} \log n, E_i)$ space for each interval. For $n^{1-\beta} \cdot n^{\epsilon} \log n < n$, the total space can be bounded by kn for some constant k. From the previous two inequalities involving ϵ it can be seen that $\epsilon < 0.5$. A possible choice for the parameters ϵ and β can be 0.49 and 0.5, respectively. After routing (i.e., by simulating a bounded queue butterfly network), we have the keys in the appropriate interval. We can now sort them in $\tilde{O}(\log n)$ time and determine exactly how many keys there are in each interval.

3.1. Binary search and splitter-directed routing. From the scheme described in the previous paragraph, we set aside $\max(cn^{1-\beta} \log n, E_i)$-sized subnetwork for keys in interval i. The number of rows allocated to a particular interval j is E_j/L. The total number of packets that arrive at any fixed row (that is over all the L ranks) is $\tilde{O}(L)$. This follows from Chernoff bounds as the expected number of packets arriving at any fixed row is $L = \Theta(\log n)$).

Remark. Note that the "subnetworks" are not isomorphic to "butterfly" networks of that size — they have to be routed to "sub-butterflies" after the termination of the splitter directed routing when we map this algorithm to the butterfly network.

We can assume $cn^{1-\beta} \log n$ divides E_i, so we can refer to this size as a "unit" of a subnetwork. We can also assume for simplicity that this is a power of two. Therefore, we can allocate a number of "units" of subnetworks from our estimates. As seen from Fig. 4 the number of these subnetworks may not be aligned with the binary search data structure. Henceforth, any reference to the *search data structure* will imply the splitter tree (of relevant keys) for conducting SDR. More specifically, at a particular node, there could be subnetworks allocated for a particular interval on both the left and right subtrees. We can handle this problem as follows. Each packet i that could go either left or right goes left with probability $L_{k(i)}/(L_{k(i)} + R_{k(i)})$ where $L_{k(i)}$ ($R_{k(i)}$) is the number of "units" on the left (right) subtree for the interval $k(i)$. The packet goes right with the complementary probability. It must be clear that any node of the splitter tree can partition at most one interval and will be labeled accordingly. A packet arriving at the node will check if it belongs to the labeled interval; if it does, then it will branch with the probabilities mentioned previously. The probabilities for this branching can be assigned when the data structure is set up. Setting up the data structure involves constructing the splitter tree as in [18]. The label of each internal node can be determined easily from the number of "units" of each interval. The number of packets going left (right) is a binomial random variable with mean at least $n^{1-\beta} \log n$. Thus the probability that it deviates from the mean by a small factor like $1/\log n$ is less than $1/n^{\alpha}$ for any fixed $\alpha > 0$ from Chernoff bounds. This imbalance factor can accumulate over the $O(\log n)$ branches through which a packet passes during the SDR. However, since $(1 + 1/\log n)^{\log n} = O(1)$, we can conclude that in the modified SDR, the deviation in the number of packets arriving in a subnetwork from the usual SDR is negligible with high probability.

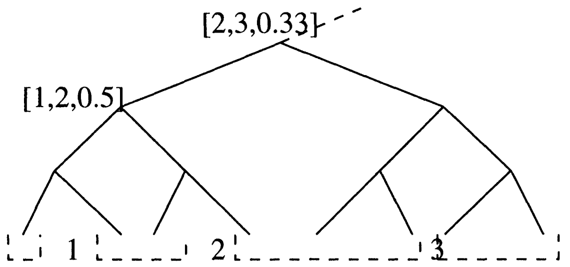

FIG. 4. *Intervals* 1–2 *and* 2–3 *are not aligned with the binary tree. The labels at the nodes indicate the range and the probability that a key in the range taking the left branch. Keys outside this range take the conventional routes.*

We can now use arguments similar to Maggs [12] to bound the congestion. The number of packets that enter any sub-butterfly is within a constant factor of the size of the sub-butterfly. For a switch at rank l, at most $O(L \cdot 2^{L-l})$ rows of the butterfly can be reached for a BF_L. Moreover, a switch at rank l can be reached from 2^l different inputs. If a packet begins at a random node, the probability of reaching a particular switch is 2^{l-L}. The number of packets that pass through a given switch is a binomial random variable. Using Chernoff bounds it follows that the probability of this number (i.e., the congestion) exceeds $O(L)$ and ($\geq O(\log n)$) is less than $n^{-\alpha}$ for any fixed α. We can therefore conclude from the remark after Lemma 2.1 that this *Modified Splitter Directed Routing* (to be referred as $MSDR$) terminates in $\tilde{O}(\log n)$ steps.

We now apply this procedure recursively in the following manner: For each interval with N_i keys we make $\lfloor N_i/n^{1-\epsilon}\rfloor$ "copies" of the subtree whose root will be denoted by L_i. This subtree is present in the (global) shared memory and can be accessed directly. L_i is the internal node of the tree corresponding to interval i. The "copying" can be done easily in $O(\log n)$ phases by the usual doubling strategy — each phase requiring constant time. The number of processors allocated to each of these problems is $n^{1-\epsilon}$. For the remaining keys, say r_i, we round it to the nearest power of 2 and "copy" a subtree with that many nodes and apply this strategy recursively. Clearly, the problem size is decreasing as $n^{1-\epsilon}$, and it follows from Lemma 2.2 that the entire procedure terminates in $\tilde{O}(\log n)$ time. Notice that when the problem size becomes $O(\log n)$, we can solve the problem in $O(\log n)$ time by pipelining a sequential search algorithm. The number of processors required at any stage of the algorithm is no more than twice the number of keys. Thus we may conclude:

THEOREM 3.2. *Given a binary search tree with $O(n)$ leaves and a set of n keys, we can locate the interval (leaf) containing each of the n keys in $\tilde{O}(\log n)$ time using n processors in an EREW* PRAM.

Mapping this algorithm on the interconnection network is not straightforward since we do not have the luxury of allocating the required space as in the case of PRAMS. Instead, we have to simulate a larger sized butterfly network (larger by a constant factor). Moreover, between successive recursive stages we have to do a careful routing to set up the search tree. Unlike the PRAM model where the search tree could be accessed directly by all processors, here we may be forced to conduct global routing to access the relevant parts of the search data structure. So, each recursive call could take $\tilde{O}(\log n)$ time. Note that the sorting algorithm is randomized. Consequently, the expected running time increases by an $O(\log\log n)$ multiplicative factor.

To circumvent the above difficulty we take a different approach. Once the problem size becomes $[O(\log^p n),\ O(\log^p n)]$ (the number of keys and the size of data structure, respectively), we can solve the problem by emulating PRAM algorithms in an additional $O(\log\log^2 n)$[1] deterministic time per step. Here p is some fixed integer. This has the following consequence: we can look at a pruned search tree of size $O(n/\log^p n)$ since if we can determine the subtree where each key belongs to, in an additional $O(\log\log^3 n)$ time, we can complete the entire search procedure. We need some more observations.

Given a search tree T of size $|T|$, we prune off the tree at a certain depth and perform a search on this truncated tree for a set of N keys. We allocate space to the subtrees that are not empty (i.e., there are keys that lie in the corresponding interval) in the following manner. If the keys exceed the subtree size, then we make copies of the subtree and assign a matching number of keys to each copy of the subtree. For the remaining keys we simply make one copy of the subtree. Note that a subtree refers to a part of the original search data structure. Then

LEMMA 3.3. *The total size of the subproblems is no more than $|T| + N$. Size refers to the quantity maximum {size of data structure, number of keys}.*

Proof. For the subtrees that are full, we can charge the space to the keys in it. For the partially full subtrees, there can be at most one for each subtree, and the lemma follows. □

This lemma implies that after completing the search on the $O(n/\log^p n)$-sized tree, $p > 1$, the total space required is less than $2n$, which can be simulated on the network with only a constant factor increase in running time. Moreover, the lemma also says that if we use the above processor allocation strategy, the size of the network required at stage i of the recursion can be bounded as follows:

LEMMA 3.4. *The total size of the subnetworks at stage i is no more than $i(N + |T|)$, where N is the number of keys and T is the data structure.*

[1] We shall use $\log\log^k n$ to denote $(\log\log n)^k$.

Proof. We prove it using induction on the depth (stage) of recursion i. Clearly this holds after the first stage ($i = 1$) from Lemma 3.3. Assume that this is true for stage k, i.e., the total space required is no more than $k(N + |T|)$. In the next recursive call, we use the strategy described previously for making "copies" and use the following charging scheme. For the "completely full" subtrees of stage k, the space required for the completely full subtrees of stage $k + 1$ is charged to the keys. For the partially full subtrees of stage $k + 1$ resulting from "completely full" subtrees of stage k, the extra space can again be charged to the keys since the size of the data structure in stage k was matched with the number of keys. For the partially full subtrees from stage k, the completely full subtrees can be charged to the keys by the previous argument. For the partially full subtrees of stage $k + 1$ resulting from partially full subtrees of stage k, they are charged to the data structure of stage k.

Hence the total amount of extra space required at stage $k + 1$ is $N + |T|$. □

From the above observations, we proceed as follows. We consider first a reduced problem where the number of keys $N = n/\log n$ and the size of the tree is $n/\log^3 n$. The $O(n/\log n)$ keys are chosen uniformly at random, and the tree is pruned to this size. The processor-allocation strategy at recursive stage j is to allocate subnetworks proportional to size $(\log\log n - j)(|T_i| + n_i)$ for a subproblem with subtree size $|T_i|$ and n_i keys. We postpone the discussion of processor allocation to the next section; however, we make note of the following fact.

Since the $|T_i|$'s are identical and $n_i \leq |T_i|$, the network can be partitioned into equal-sized subnetworks proportional to $|T_i|$. The motivation for this is that such a partitioning can be done relatively easily (cf. Lemma 3.5). The drawback is that the space requirement could grow by a factor of two at each recursive level (Lemma 3.3), so we set aside space proportional to $2^{\log\log n - j}|T_i|$ at stage j. Since $\sum_i |T_i|$ can be bounded by the total number of keys, i.e., $n/\log n$, the space requirement is $O(n)$. Even if the number of recursive levels is greater than $\log\log n$ (but still $O(\log\log n)$), we can conduct a global routing after every $\log\log n$ stages so that the size is no more than $2n$ after each of those processor-allocation procedures.

From the previous lemmas, we have sufficient processors to carry out the reduced search problem. If the keys are chosen uniformly at random with probability $1/\log n$, then for all the subtrees of size $\log^3 n$ that have more than $\log^2 n$ keys we have very accurate estimates (Lemma 3.1). So we can set aside $\max\{c\log^2 n, E_l\}$-sized subnetworks for subtree l where E_l is an estimate. Note that $cn/\log n + \sum_l E_l$ is $O(n)$ so we can perform the SDR on all the n keys this time. Subsequently we count explicitly the number of keys in each subtree and allocate subnetworks with the maximum problem size of $O(\log^3 n)$. We can then emulate any PRAM algorithm adding $O(\log\log^3 n)$ to time complexity.

3.2. Load balancing and processor reallocation. The previous strategy for processor allocation would work if the size of the subproblems always matches the sub-butterfly size; however, it may not always be the case. So we have to design a more general processor-allocation procedure that can be done dynamically and also evenly distribute the work load among the sub-butterflies. If all the subproblems are of the same size, then such a load distribution can be achieved easily.

LEMMA 3.5. *Given problems p_i of identical sizes, such that $\sum |p_i| \leq N$, where N is the size of the butterfly network, the problems can be allocated to sub-butterfly networks $\mathcal{N}_i$ satisfying $c|\mathcal{N}_i| \geq |p_i|$. Here c is a constant less than* 6.

Proof. Let p be the largest number less than or equal to p_i that is of the form $k \cdot 2^k$ where k is an integer. For $p_i > 2 \cdot 2^2$, the ratio p_i/p is less than 3. Let $N = h \cdot 2^h$ and $p = l \cdot 2^l$. Then from Fact 1, the butterfly network can be rank-partitioned into $\lfloor h/l \rfloor$ parts, each consisting of 2^{h-l} sub-butterflies of size p. Assuming that $h/l > 1$, the "unused" part of the butterfly is less than 1/2, where by "unused" part we are referring to the $h - (\lfloor h/l \rfloor) \cdot l$ ranks. To each sub-butterfly of size p in each partition we allocate 2 problems of size $|p_i|$. This achieves the required ratio as stated in the lemma. □

The previous lemma in conjunction with Fact 2 guarantees that if all problems are of the same size, then the processor allocation achieves roughly the same work-load distribution as in PRAM (as is the case with binary search). However, it is not clear as to how to do the same when the problems may be of varied sizes. Instead, we aim for a weaker result than Lemma 3.5.

Let us denote the subproblem j by $\mathcal{P}_j$ and a subnetwork (which may not be topologically equivalent to a butterfly network) to which the subproblem is allocated by $\mathcal{N}_j$.

LEMMA 3.6. *Given that $\sum |\mathcal{P}_j| \leq c_1 N$, where N is the total size of the network and c_1 constant, there is a processor-allocation scheme such that for all j, $|\mathcal{P}_j| \leq c_2 |\mathcal{N}_j|$ where c_2 is another constant. Moreover, if some algorithm $\mathcal{A}$ takes time $O(\log^\alpha |\mathcal{P}_j|)$, $\alpha > 1$, for problem $\mathcal{P}_j$ on a butterfly network, then the allocation scheme ensures that the algorithm running in parallel for all the subproblems terminate in $O(\log^\alpha N)$ time.*

Note that the running time for algorithm $\mathcal{A}$ depends on N and not simply on $|\mathcal{P}_j|$ as in the case of PRAM.

Proof. Assume that the network is of size $M \geq k \sum |\mathcal{P}_j|$ since we can always simulate a network larger by a factor of k. This constant k will compensate for the constant c_1 and simplify the proof while slowing down the network only by a constant factor. Let $N = \hat{h} 2^{\hat{h}}$ and $M = h \cdot 2^h$. Let $S_i, i \geq 0$, denote the set of subproblems whose sizes are in the range $\lfloor h/2^i \rfloor 2^{\lfloor h/2^i \rfloor}$ and $\lfloor h/2^{i+1} \rfloor 2^{\lfloor h/2^{i+1} \rfloor}$. For notational simplicity we shall denote $\lfloor h/2^i \rfloor$ by h_i. Note that $h_i / h_{i+1} < 4$ for $h > 4$. Form groups by sorting the sizes of the problems.

The idea is to allocate contiguous rows of the network to each S_i. For problems in S_i, we make $m_i = \lfloor h/h_i \rfloor$ horizontal partition in the network, each of h_i ranks. In S_i let $k_{i,j}$ denote the set of problems of sizes between $(h_i - j) \cdot 2^{h_i - j}$ and $(h_i - j - 1) \cdot 2^{h_i - j - 1}$. Let $r_{i,j} = |k_{i,j}| \cdot 2^{h_i - j} / m_i$ rounded to the nearest integer, which is the number of rows allocated to problems of $k_{i,j}$. Allocate two problems to each $h_i \times 2^{h_i - j}$ "rectangular partition."

At most 1/2 the number of ranks is unused when m_i horizontal partitions are created. At most 3/4 of the space within each rectangular region is unused since $h_i / h_{i+1} < 4$. Moreover, for each $i = 1, 2, \ldots, \hat{h}$, at most 2^i rows are unused viz., $h \cdot 2^{\hat{h}+1}$ processors. In addition, we may have to double the number of rows so that $\sum_i k_{i,j}$ add up to a power of two for the butterfly network. From the previous bounds on the amount of "unused" space, one can verify that by choosing $k > 64$, the above scheme succeeds.

Note that for each problem size within S_i only the bottom-most h_i ranks form a sub-butterfly. So for problems in S_i, we require m_i times the time required to execute an algorithm $\mathcal{A}$. For logarithmic time complexity of $\mathcal{A}$ the total time in each S_i is clearly $O(\log N)$. A similar observation applies to the case $\alpha > 1$. □

The above two lemmas do not directly imply a general processor-allocation strategy. Even in the simple case where all problems are of the same size, if we were to continue with this scheme recursively, a network could be loaded by a factor of approximately c^2 in the next recursive call. By "loading" we mean the ratio of the subproblem to the subnetwork size (which is unity in the beginning), and this is also a lower bound on the slow down of the algorithm. This is undesirable if the depth of recursion is $O(\log \log n)$. However, we can use the previous lemmas in the following useful manner. We can apply them for a constant number of stages of recursive calls without increasing the run time by more than a constant factor (in every call the load on a processor increases by a constant factor). We shall show that this suffices for our processor-allocation strategy, where we redistribute the load "evenly" after a fixed number of stages of recursive call. The network topology, where the subnetworks are of sizes $h2^h$ (h is an integer) necessitates this kind of rebalancing strategy.

We shall start with a special case where the network size is $h2^h$ where $h = 2^l$ for some integer l. In two stages of recursive call we can reduce the subproblem sizes to $2^{h/2}$. One call is not sufficient since the subproblem sizes could be larger than $n^{1/2}$, which is $2^{h/2+\log h}$ in this case. Now we can pack $h/2$ subproblems into a subnetwork of size $(h/2) \cdot 2^{h/2}$. Moreover, there are $2 \cdot 2^{h/2}$ subnetworks of this size (Fact 1), which implies that the entire network is being used instead of a fraction of it. Now we are in subnetworks of size $(h/2) \cdot 2^{h/2}$, and hence the procedure can be applied inductively. Notice however that we have $h/2$ subproblems in the network (instead of one) and we have to use Lemma 3.6 to allocate subnetworks, thereby loading the subnetwork by a constant factor in the next recursive call. But this is only for a fixed (at most 2) stages of recursive call, and hence we can maintain the same asymptotic run time. Moreover, we also observe the following.

LEMMA 3.7. *If a set of processors is initially loaded by a factor λ, then this load factor does not increase during the course of the processor-allocation strategy.*

To generalize this scheme to an arbitrary value of network-size, we reduce the problem sizes to 2^{2^k} for some k. This can be done in a constant number of recursive calls since $2^{2^{k+1}} = (2^{2^k})^2$. Using Lemma 3.6, we can allocate subproblems such that only a constant fraction of the network is unused. This happens if 2^k does not divide h evenly, and consequently some processors may be loaded by a factor of 2. But from this stage we can use the scheme described in the previous paragraph without increasing the load factor any further (Lemma 3.7).

We summarize our result as follows.

THEOREM 3.8. *Given a binary search tree with $O(k)$ leaves, we can perform binary search for $O(k)$ keys in $\tilde{O}(\log k)$ time in a butterfly network using k processors.*

In a more general scenario, as will be required for the applications in the next section, the subproblems could be of different sizes. However, a key fact is that we can bound the size of the maximum-sized subproblem by $n^{1-\epsilon}$ where n^{ϵ} is a sample size (similar to the previous case). Let $[i]$ denote the largest number less than i that is a power of 2, i.e., if $[i] = 2^j$, then $2^j \leq i \leq 2^{j+1}$. By choosing the sample sizes appropriately (n^{ϵ} for some $\epsilon > 0$), we can reduce the maximum subproblem size to $2^{[h]}$. This may require more than one recursive call, each of which is handled using the processor-allocation scheme of Lemma 3.6.

We then greedily pack as many subproblems as we can in a subnetwork of size $[h] \cdot 2^{[h]}$. This is done by sorting the subproblem sizes and an application of parallel prefix followed by actually routing the subproblems to the assigned subnetworks. We pack in subproblems as long as there is space, so that we do not "load" a subnetwork by more than a factor of $(1 + 1/\log n^{1-\epsilon})$ (specifically, $1 + 1/h$ since we are packing at most $h + 1$ subproblems in a network that can accommodate h subproblems).

We apply this procedure recursively such that the extra loading factor at stage i of recursion is no more than $1 + 1/\log n^{(1-\epsilon)^i}$. Note that in the first stage of recursion, we could misuse a constant fraction of the network (because of problem size mismatch), but thereafter the degree of misuse can be bound by the above quantity by our processor-reallocation strategy. If the subproblems are never smaller than $\log n$, then the load factor can be bound by $\prod_{i=1}^{O(\log\log n)}(1 + 1/\log n \cdot (1 - \epsilon)^i)$. If the smallest term is larger than $\log\log n$, then the above product is bounded by e^{α}, where α is a constant. Note that the "load factor" is maintained inductively in the subnetworks, by redistribution of work load. The slowdown at any stage is at least 2 and no more than e^{α}.

4. Applications to computational geometry. In this section we apply the techniques developed in the previous sections to map some geometric algorithms efficiently on the butterfly network. The description relies partly on the work of the authors on randomized PRAM algorithms. For a better understanding of the original algorithms, the reader is encouraged to refer to the papers [17], [16].

4.1. Searching in arrangements. We focus our attention on the following problem. Given an arrangement of n^{γ} lines, $\gamma < 1/3$, we want to find out for n given points the region to which it belongs. In particular, we would like to do this in $O(\log n)$ time on a butterfly network. Dobkin and Lipton had described a very simple method for solving this problem using the following data structure. Find out all the pairwise intersections (there are $n^{2\gamma}$ in this case) and project them on the X-axis. Within each interval, the lines can be totally ordered and one can set up a binary tree corresponding to this ordering. Thus, there are $n^{2\gamma}$ binary trees each of size n^{γ}. To find the region (which is a trapezoid by the above partitioning scheme) to which a point belongs, we do two binary searches — one along each direction.

To implement this algorithm in parallel, the data structure can be set up very easily in parallel by sorting. To search n points, we first sort the n points by their x coordinates and merge them with the endpoints of the intervals. This saves the binary search in the x-direction. If I_i is the set of points in the ith interval, we allocate a subcube of size $|I_i| + n^{\gamma}$ nodes. This is done using the network partitioning scheme of Lemma 3.6. Since $n + n^{3\gamma} < 2n$, for appropriate choice of γ and moderately large n, this can be done by simulating a network twice the size. The binary search can then be done within each subnetwork in $\tilde{O}(\log n)$ time using the procedure outlined in the previous section. Thus the overall algorithm runs in $\tilde{O}(\log n)$ time.

THEOREM 4.1. *Given n points on the plane and an arrangement of m lines, $m < n^{1/3}$, for each of the n points, the (unique) region of the arrangement containing the point can be identified in $\tilde{O}(\log n)$ in an n-node butterfly network.*

We shall see in the next section that these trapezoidal regions define a finer partition of equivalence classes, which are the regions in the original partition.

4.2. A framework for randomized divide-and-conquer. Given a set of nonintersecting line segments and points, we wish to determine for each point, the line segment(s) that lay directly below and above each of these points. There may be 0, 1, or 2 such edges, which are called the trapezoidal edges.

We shall recapitulate the main steps of the algorithm for trapezoidal decomposition described in [20] in a more general context of a divide-and-conquer algorithm.

1. Select $O(\log n)$ subsets of random objects (in case of two-dimensional hulls these were half-planes) each of size $\lfloor n^{\epsilon} \rfloor$ for some $0 < \epsilon < 1$. Each such subset is used to partition the original problem into smaller subproblems. A sample is "good" if the maximum subproblem size is less than $O(n^{1-\epsilon} \log n)$ and the sum of the subproblem sizes is less than $\bar{c}n$ for some constant $\bar{c}$. From the probabilistic bounds proved in Reif and Sen [17] (for problems considered in the paper) and Clarkson [7] (for very general situations that are applicable to our problems), it is known that the first condition for a "good" sample holds with high probability. However, the second condition is satisfied with probability at least 1/2.

2. Select a sample that is "good" with high probability using *Polling*. At least one of the $\log n$ samples in the previous case is "good" with high probability. *Polling* [16] is a sampling technique that allows us to choose a "good" sample efficiently.

3. Divide the original problem into smaller subproblems using the "good" sample. The maximum size can be bound by $O(n^{1-\epsilon} \log n)$.

4. Use a *Filtering* procedure to bound the sum of the subproblem sizes by some fixed measure like the output size or input size. The reason for this being that the probabilistic bounds in step 1 bounds the sum of the subproblems by $\bar{c}n$. If this increase by a multiplicative constant continues over each recursive stage, after $O(\log \log n)$ depth, the input size will have

increased by a polylogarithmic factor. This *filtering* procedure is problem dependent and uses the specific geometry properties of a problem. The purpose is to bound the number of processors.

5. If the size of a subproblem is more than a threshold (usually it is chosen to be $O(\log^k n)$ for some constant k), then call the algorithm recursively, else solve the problem using some direct method.

The algorithms presented in this paper are based on this approach. However, the implementation of some of these steps depend heavily on the specific problem. The procedure used for dividing the subproblems depends on the problem at hand, and this is also closely linked with *Polling*. *Polling* involves selecting $n/\log^2 n$ input objects and partitioning them using a random subset chosen in step 1 instead of the entire input set. Since there are $O(\log n)$ subsets, this saves the extra work we would have had to do if we tested the "goodness" of the sample on the entire input. The *Polling lemma* [16] guarantees that with high probability we can choose a good sample using this method. Since the test for "goodness" is carried out independently for each of the samples, this part of the algorithm is inherently parallelizable even on the networks. Perhaps the step that is most specific to a problem is the *Filtering* step where we have to use some geometric properties of the problem.

In the context of mapping algorithms to interconnection networks, step 3 turns out to be the most difficult. Steps 1 and 2 are inherently parallel, and step 4 for the problems that we are interested in, is not very involved. We shall show that step 3 reduces to searching in an arrangements of lines in two dimensions.

4.3. Trapezoidal decomposition. For trapezoidal decomposition, we sample line segments and build its convex map (see Fig. 5). We can build this using the following brute-force approach. For every segment endpoint, we order the line segments by their y coordinates. For every segment, we order the projection of the endpoints those are visible from below and above. From this information, we can construct the trapezoids by simulating "pointer-jumping" a fixed (at most 6) number of times.

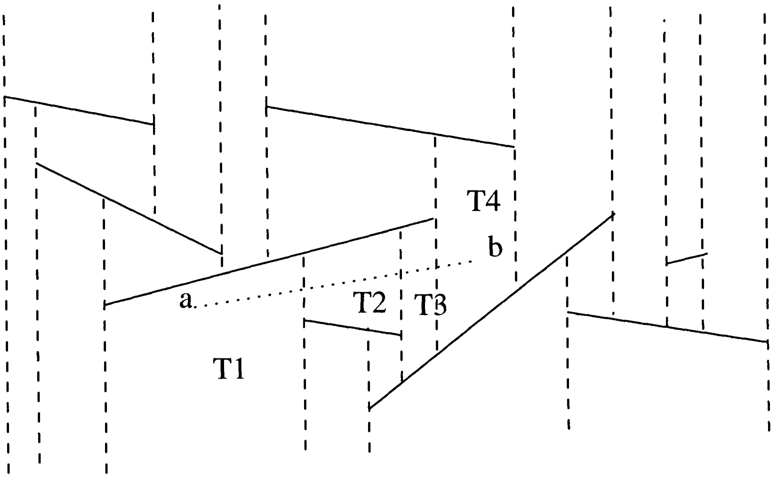

FIG. 5. *Convex map of nonintersecting line segments. Line segment ab intersects the trapezoids T1, T2, T3, T4.*

LEMMA 4.2. *The trapezoidal map of n^ϵ segments can be constructed in $\tilde{O}(\log n)$ time in an $n^{3\epsilon}$ processor butterfly network.*

The remaining segments (not part of the sample) are partitioned into subproblems defined by the trapezoidal map. The partitioning step in trapezoidal decomposition can also be reduced to the problem of searching in arrangements of linear constraints in two dimensions (see Reif and Sen [17]). This is also known as the *locus* method where the problem reduces to finding the region of the arrangement in which a query point lies. These regions are preprocessed so that after the point location one has to perform a table look-up to determine the answer. In this case it is a set of trapezoids that a segment intersects. Since this can be of various lengths, it has to be done with a little care. First the number of trapezoids is determined, which is an integer, and then an appropriate number of processors is delegated the responsibility of determining the actual trapezoids. This allocation is done with the help of a prefix computation. Subsequently, each of these processors do a table look up. The table look-up is done by emulating a single step of the CREW PRAM in $\tilde{O}(\log n)$ steps.

For the filtering step, we need to keep track of parts of segments that completely span a trapezoid. Such segments within a trapezoid have to be processed for binary search such that for endpoints lying within the trapezoid we can quickly determine its closest visible (upper and lower) segments. This can be done in $\tilde{O}(\log n)$ time using the binary search algorithm described in § 3. Moreover, only the segments that partially or completely lie within a trapezoid are needed for further recursive calls.

At each stage we keep track for each endpoint, which are its closest (upper and lower) segments, and hence at the end we have its trapezoidal edge(s). From this information, we can decompose a simple polygon into one-sided monotone polygons (see Fig. 7). This can be accomplished by an application of sorting and prefix computation (Goodrich [9]). Using Yap's [23] technique, further calls to trapezoidal decomposition within these one-sided monotone polygons enable us to determine all the triangulation edges. The procedure is as follows.

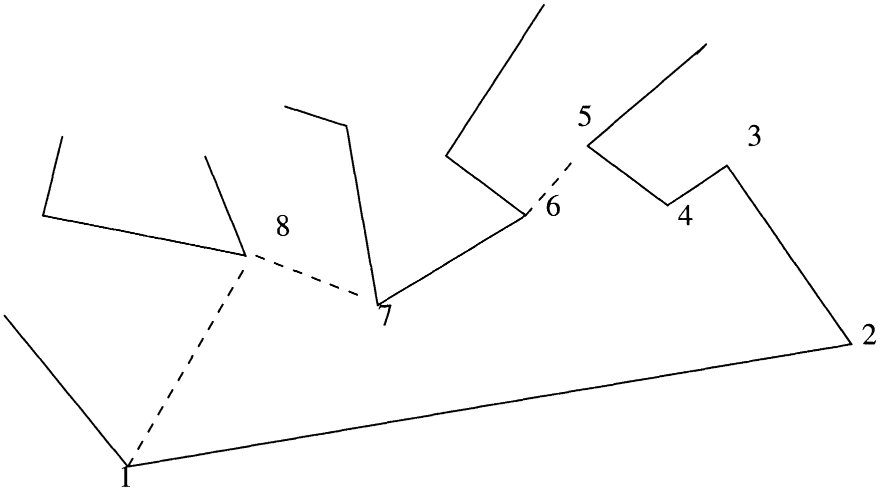

FIG. 6. *Decomposition into one-sided monotone polygons. The dotted lines indicate some of the triangulation edges. The distinguished edge is* 1, 2.

Step 1. Construct the horizontal trapezoidal decomposition of the one-sided monotone polygon, i.e., for every vertex v determine the edges of the polygon through which a horizontal line passes v while the line is contained within the polygon. Assume that the distinguished edge, i.e., the one with which the polygon is monotone, is horizontal.

Step 2. Denote the left visible edge by $l(v)$ and right visible edge by $r(v)$, and let $\lambda(v)$ and $\rho(v)$ denote vertices of $l(v)$ and $r(v)$, respectively, which have the lower altitude.

Step 3. The set of edges $E = \{v\lambda(v)\} \cup \{v\rho(v)\}$ form a triangulation of the polygon.

Trapezoidal decomposition also enables us to solve the problem of determining visibility of a set of nonintersecting line segments when they are projected orthogonally. Sort the endpoints of the line segments projected on the x-direction and choose a point (say the midpoint) in every interval. For each of these points, determine its trapezoidal edge using the trapezoidal decomposition algorithm described above.

We can state the main result of this section as the following.

THEOREM 4.3. *We can construct the trapezoidal decomposition of n segments in time $\tilde{O}(\log n)$ on an n-processor, bounded-buffer butterfly network, where n is the input size of the problem. Using this as a subroutine, a simple polygon of n vertices can be triangulated in the same bounds.*

To the best of our knowledge, for the above problems, no matching algorithms are known even on the *EREW* PRAM model.

4.4. Two-dimensional convex hulls. We need the following preliminary results:

LEMMA 4.4. *The convex hull of n^α, $\alpha < 1/2$, half-planes can be constructed in $O(\log n)$ time in an n-node butterfly network.*

Assume that the intersection is nonempty and bounded, and then a brute-force algorithm suffices.

Given this hull and a point that lies in the final hull, we divide this hull into triangular sectors and find out for the remaining half-planes which of the sectors they intersect. For this we go to the dual plane and search in the arrangements of the (duals of) vertices of the convex hull of the sampled half-spaces. This can be done using the procedure described in the previous section — the details are straightforward and are omitted for brevity.

The filtering scheme for two-dimensional convex hulls involves an application of two-dimensional maxima. A large number of redundant half-planes like a can be identified by an application of the two-dimensional maxima algorithm where the coordinates are the ranks of the ordering of intersections of the half-planes on the two sides of a sector (starting from the apex). For example, in Fig. 7 the coordinate corresponding to b dominates that of a.

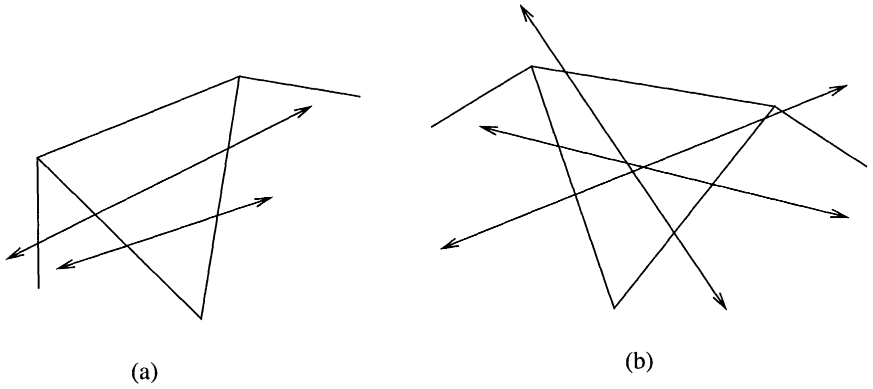

FIG. 7. *In case (a), line a is completely occluded by b. In case (b), line c is occluded by d and e but not by any one of them competely. However, in the other sectors, line c is eliminated by case (a).*

LEMMA 4.5. *The maximal points of n points in a plane can be computed in $\tilde{O}(\log n)$ time in an n-node butterfly network.*

Proof. We use a variation of the sequential algorithm in the following manner. We sort the points based on their x-coordinates and perform a prefix computation on the operation maximum on this sorted set. If $p_1, p_2, \ldots, p_n$ are the points sorted on the x-coordinates, then we compute an array MAX such that MAX_i has the maximum y coordinate for all points p_j such that $j > i$. If the y-coordinate of p_i is smaller than MAX_i, then it is not a maximal element. □

Finally we can state the result of this section as

THEOREM 4.6. *The convex hull of n points in a plane can be constructed in $\tilde{O}(\log n)$ in an n-node butterfly network with bounded buffer size.*

5. Concluding remarks. In this paper, we have described a strategy for implementing PRAM algorithms for geometric problems on fixed-connection networks. These methods involve tackling some of the very basic problems, like binary search and dynamic load balancing that we take for granted in PRAM models. Our techniques use a number of ideas from *Flashsort*, but they have to be modified to handle more difficult situations, namely, searching in partial orders and dynamically allocating subnetworks to recursive calls.

An important goal of our research is to build a hierarchy of fundamental geometric algorithms for fixed-connection networks similar to that of PRAM algorithms. Two important problems in this list include those of constructing two-dimensional Voronoi diagrams and three-dimensional convex hulls in optimal (or near-optimal) time.

6. Appendix.

6.1. Splitter-directed routing. Let X be the set of cN keys that are totally ordered by the relation $<$. V is the set of nodes in the network. Suppose that for some l $(1 \leq l \leq n)$ we are given a set of *splitters* $\Sigma \subseteq X$ of size $|\Sigma| = 2^l - 1$. We index each splitter $\sigma[w] \in \Sigma$ by a distinct binary string $w \in \{0, 1\}^L$ of length less than L. Let $\prec$ denote the ordering defined as follows: For $u, v, w \in \{0, 1\}^L$, $w0u \prec w \prec w1v$. We require that for all $w_1, w_2 \in \{0, 1\}^L, \sigma[w_1] < \sigma[w_2]$ if and only if $w_1 \prec w_2$. We assume that a copy of each splitter $\sigma[w]$ is available in each node $V[w]$. $V[w]$ is the set of nodes with rank $|w|$ with row addresses prefixed by w (same as in Reif and Valiant [18]).

Let $X[\lambda] = X$ where λ is the empty string. Initially we assume that the keys of $X[\lambda]$ are located in $V[\lambda]$, that is, the nodes of V having stage 0. The splitter-directed routing tree is executed in l temporarily overlapping stages $i = 0, 1, \ldots, l-1$. For each $w \in \{0, 1\}^i$ the set of keys $X[w]$ that are eventually routed through $V[w]$ is defined recursively. The splitter $\sigma[w]$ partitions $X[w] - \sigma[w]$ into disjoint subsets

$$X[w0] = \{x \in X[w] | x < \sigma[w]\}$$

and

$$X[w0] = \{x \in X[w] | x > \sigma[w]\},$$

which are subsequently routed through $V[w0]$ and $V[w1]$, respectively.

In our case, we assume that after each recursive call, the subnetworks (of varying sizes corresponding to different subroutine calls) are relabeled as if they were isolated networks. The $V[w]$'s are then defined accordingly. The time analysis for this procedure is carried out using a *delay-sequence* argument, and it was shown [15] that the running time is $\tilde{O}(\log n)$ time in a BF_n.

6.2. Probabilistic inequalities. We say a random variable X upper bounds another random variable Y (equivalently Y lower bounds X) if for all x such that $0 \leq x \leq 1$, Prob$(X \leq x)$ $\leq$ Prob$(Y \leq x)$.

A Bernoulli trial is an experiment with two possible outcomes, namely, success and failure. The probability of success is p.

A binomial variable X with parameters (n, p) is the number of successes in n independent Bernoulli trials, the probability of success in each trial being p. The *probability mass function* of X can easily be seen to be

$$\text{Prob}(X \leq x) = \sum_{k=0}^{x} \binom{n}{k} p^k (1-p)^{n-k}.$$

The tail end of the Binomial distribution can be bounded by *Chernoff* bounds. In particular, the following approximations due to Angluin and Valiant are frequently used:

$$\text{Prob}(X \geq m) \leq \left(\tfrac{np}{m}\right)^m e^{m-np}, \tag{1}$$

$$\text{Prob}(X \leq m) \leq \left(\tfrac{np}{m}\right)^m e^{-np+m}, \tag{2}$$

$$\text{Prob}(X \leq (1-\epsilon)pn) \leq exp(-\epsilon^2 np/2), \tag{3}$$

$$\text{Prob}(X \geq (1+\epsilon)np) \leq exp(-\epsilon^2 np/3) \tag{4}$$

for all $0 < \epsilon < 1$.

COMMUNICATION-SPACE TRADEOFFS FOR UNRESTRICTED PROTOCOLS*

PAUL BEAME†, MARTIN TOMPA†, AND PEIYUAN YAN‡

Abstract. This paper introduces communicating branching programs and develops a general technique for demonstrating communication-space tradeoffs for pairs of communicating branching programs. This technique is then used to prove communication-space tradeoffs for any pair of communicating branching programs that hashes according to a universal family of hash functions. Other tradeoffs follow from this result. As an example, any pair of communicating Boolean branching programs that computes matrix-vector products over GF(2) requires communication-space product $\Omega(n^2)$, provided the space used is $o(n/\log n)$. These are the first examples of communication-space tradeoffs on a completely general model of communicating processes.

Key words. communication complexity, lower bound, tradeoff, branching program, universal family of hash functions

AMS subject classifications. 68Q05, 68Q10, 68Q22, 68Q25

1. Communication and space.

The amount of communication required among processors cooperatively performing a computation is often the dominant factor in determining the efficiency of parallel or distributed systems, in both practical and theoretical terms. In addition, communication complexity has found surprising applications in the complexity of Boolean circuits (Karchmer and Wigderson [14], Raz and Wigderson [19]), Boolean decision trees (Hajnal, Maass, and Turán [13]), combinatorial optimization (Yannakakis [23]), VLSI (Aho, Ullman, and Yannakakis [3], Lipton and Sedgewick [16], Mehlhorn and Schmidt [18], Yao [25]), and pseudorandom number generators (Babai, Nisan, and Szegedy [5]).

Nearly all the previous work on the communication complexity of various problems has focused on their communication requirements alone, in the absence of any limitations on the individual processors. Lam, Tiwari, and Tompa [15] initiated the study of communication complexity when the processors have limited work space. As is customary, the systems studied consist of two communicating processors that are given private inputs x and y, respectively, and are to output some function $f(x, y)$. With no restriction on the workspace it is impossible to prove superlinear lower bounds on the amount of communication, since one processor can send its entire input to the other, which then computes and outputs $f(x, y)$. In contrast, Lam, Tiwari, and Tompa proved several nonlinear lower bounds on communication in the straight-line model, when space is limited. For example, one of their results of particular relevance to what follows is that multiplication of an $n \times n$ matrix by an n-vector in the Boolean straight-line model with one-way communication requires communication $C = \Theta(n^2/S)$ when the processors' workspace is restricted to S.

In this paper we remove the restrictions of straight-line computation and one-way communication, proving for the first time communication-space tradeoffs on a completely general model of communicating processes. This result is analogous to Borodin and Cook's time-space tradeoff for sorting on a general sequential model [7].

More specifically, we introduce the notion of communicating branching programs. We use these to demonstrate that if one of the branching programs is given a member h of a universal family of hash functions (Carter and Wegman [9], [10]) and the other is given x

and their goal is to compute $h(x)$ cooperatively, then their communication C and space S must satisfy the tradeoff $CS = \Omega(nm)$, where h maps n-bit inputs to m-bit outputs, provided $S = o(n/\log m)$. As an example, any pair of communicating Boolean branching programs that multiplies an $n \times n$ matrix by an n-vector over GF(2) satisfies $CS = \Omega(n^2)$, provided $S = o(n/\log n)$. Similar applications hold over more general finite fields and for other hash functions such as arithmetic over large finite fields, convolution, and matrix multiplication.

If a single processor can compute $f(x, y)$ in time C and space S, then a system of two processors can compute $f(x, y)$ in communication $O(C)$ and space $O(S)$, simply by communicating the result of every instruction executed by either. Thus, the lower bounds outlined above imply the corresponding time-space tradeoffs of Grigoriev [12] for straight-line programs and Abrahamson [2] for branching programs. The converse, however, is false. Whereas the time T and space S must satisfy $TS = \Omega(n^2)$ when computing the discrete Fourier transform [2], [21], [27] or sorting [6], [8], [21], Lam, Tiwari, and Tompa [15] demonstrated that both of these functions can be computed in linear communication steps and $O(\log n)$ space simultaneously. Thus, these results strictly generalize previous time-space tradeoffs.

2. Communicating branching programs. The general framework for dealing with problems of two party communication requires an accurate notion of both the computational power of the two parties involved and their method of communicating with each other. A restricted model in which each party executes a straight-line program was defined by Lam, Tiwari, and Tompa [15]. In their model each straight-line program is augmented with *send* and *receive* instructions. They leave open the question of defining an appropriate nonoblivious model.

Since branching programs have proved to be useful sequential models for the simultaneous measure of time and space [1], [2], [6], [7], [8], [27] it is natural to use them to model the communicating parties. Making the analogous changes to branching programs that Lam, Tiwari, and Tompa made to straight-line programs leads to the following model.

A *communicating pair of* (*Boolean*) *branching programs* consists of two branching programs, known as the X-program and the Y-program, that have input vectors $x \in X = \{0, 1\}^{n_X}$ and $y \in Y = \{0, 1\}^{n_Y}$, respectively. The X-program is a labeled directed acyclic graph with a designated start node, and each of whose nodes has outdegree 0 or 2. Each node of outdegree 2 is labeled either by an index in $\{1, \dots, n_X\}$ or by **receive**, and its two emanating edges are labeled 0 and 1, respectively. In addition to its 0 or 1 label, an edge may be labeled either by an output statement of the form $z_j = 0$ or $z_j = 1$ or a communication statement of the form **send**(0) or **send**(1). The Y-program is defined analogously.

The pair of branching programs computes a function $f : X \times Y \to Z \subseteq \{0, 1\}^{\leq n_Z}$ in the following natural way. Each program accesses its portion of the input and, starting at its start node, operates like a conventional branching program by following the edge labeled x_i (respectively, y_i) when encountering a node labeled i. Outputs are produced according to the output label on this edge, if any. When a program encounters a **receive** node it waits until the other program traverses an edge labeled **send**(b), and then the receiving program follows the edge labeled b. Similarly a program executing a **send** is blocked until the other program reaches a **receive** node. When a program reaches a node of outdegree 0, it halts. We require that each output bit may only be produced once on any given input pair. The function f is computed correctly on inputs x and y if the union of the outputs produced by the two programs comprises the bits of $f(x, y)$.

The *space* of each branching program is the base 2 logarithm of the number of its nodes. (This is the standard definition for branching programs [8], motivated by the fact that each node represents a different configuration of the program.) The *space* of the pair of programs is the maximum of the space of the two branching programs, and the *communication* is the length of the longest sequence of **send-receive** pairs executed on any input (x, y). The definitions can be generalized to communicating R-way branching programs for any R [7].

This model is a very natural one and a very general one as well. It can simulate, for example, two communicating space-bounded random access machines with a common write-only area for their output values.

One aspect of communicating branching programs that is somewhat subtle is the way in which output values are produced. Since all branchings of one of the programs that do not affect its communication with the other program are hidden from that other program, output values may be produced by one branching program without the explicit knowledge of the other branching program. In fact, all the bits communicated by the pair of branching programs may not be sufficient to determine the value of the function. However, the model in which all output values are communicated explicitly is a useful special case. We say that a pair of communicating branching programs is *open* if and only if the natural encoding of each output statement produced by either processor is communicated bit by bit to the other processor.

3. The general lower bound. The technique we develop here is an extension of the technique of Borodin et al. [7], [8] for time-space tradeoffs on sequential branching programs. Being purposely vague for the moment, their technique requires the following:

(1) a probability distribution on the set of inputs such that, with high probability, a large number of output bits are produced on any given input, and

(2) a proof that, given the distribution in (1), for any way of fixing a limited number of input variables, the probability that an input whose variables are so fixed produces a given set of k output bits whose values are fixed in any given way is exponentially small in k.

We develop a similar pair of conditions that allow proofs of communication-space tradeoffs. We first state our general technique for open pairs of communicating branching programs since this is the most natural argument. Then we outline how it can be extended to arbitrary pairs of communicating branching programs.

In order to motivate the properties that are appropriate for showing lower bounds for pairs of communicating branching programs, we first develop some facts about their operation.

Fix some $c > 0$ and any pair (u, v) of nodes in the pair of communicating branching programs, u in the X-program and v in the Y-program, and consider the action of the branching programs on input pair (x, y) starting at (u, v). For each input pair (x, y) we can follow the paths that the computation would take starting at (u, v) and stop when either a total of c bits of communication have been sent in both directions or the programs halt. (A third possibility is that there is no consistent computation on input (x, y) starting at (u, v), but any input (x, y) that reaches (u, v) will have a consistent computation. In the following definitions, we consider such an input pair (x, y) for which there is a consistent computation.) This produces a string of up to c communication bits, with fewer than c bits only if the programs halt before c bits of communication have been sent. Let $\gamma^c_{(u,v)}(x, y)$ be the following representation of this sequence of up to c bits communicated on input (x, y) starting at (u, v): represent each communicated bit b by two bits, using the extra bit to indicate which program sent b. For each string $\alpha \in \{0, 1\}^{\le 2c}$ we can define a set

$$R^\alpha_{(u,v)} = \{(x, y) \in X \times Y \mid \gamma^c_{(u,v)}(x, y) = \alpha\}.$$

A set $R \subseteq X \times Y$ is a *rectangle* if and only if there are sets $A \subseteq X$ and $B \subseteq Y$ such that $R = A \times B$.

LEMMA 3.1. *Let (u, v) be a pair of nodes in a pair of communicating branching programs, u in the X-program and v in the Y-program. The elements of $\{R^\alpha_{(u,v)} \mid \alpha \in \{0, 1\}^{\le 2c}\}$ are disjoint rectangles in $X \times Y$ whose union contains all input pairs (x, y) that reach (u, v).*

Proof. The fact that the sets $R^\alpha_{(u,v)}$ are disjoint is immediate from their definition. It is also clear that if (x, y) reaches (u, v), then $\gamma^c_{(u,v)}(x, y) = \alpha$ is defined and so $(x, y) \in R^\alpha_{(u,v)}$. The fact that each $R^{\alpha}_{(u,v)}$ is a rectangle follows by standard arguments in communication complexity (Yao [24]). It is proved inductively on the prefixes of α. □

We are now ready to state properties of a function that make it possible to prove communication-space tradeoffs. These properties will depend on certain parameters p, m, β, q, a, and K that will be set in later applications.

If $f(x, y) = z$, we will call the bits of x and y *input values* and the bits of z *output values*. For a function $f : X \times Y \to Z$ and a distribution $\mathcal{D}$ on $X \times Y$, the two properties are as follows:

Property A. There are $0 < p \leq 1$ and a positive integer m such that

$$\Pr_{\mathcal{D}}[f(x, y) \text{ has at least } m \text{ output values }] \geq p.$$

(Recall that, as (x, y) varies, $f(x, y)$ may have varying lengths.)

Property B. There are $0 < \beta < 1$, $0 < q < 1$, $a \geq 2$, and a positive integer K such that, for all positive integers $k \leq K$, the following holds: Let $R \subseteq X \times Y$ be any rectangle such that $\Pr_{\mathcal{D}}[(x, y) \in R] \geq q$. Then, for any set $V = \{z_{i_1} = b_1, \dots, z_{i_k} = b_k\}$ of k output values,

$$\Pr_{\mathcal{D}}[f(x, y) \text{ is consistent with } V \mid (x, y) \in R] \leq a\beta^k.$$

THEOREM 3.2. *Suppose that for* $f : X \times Y \to Z$ *there is a distribution* $\mathcal{D}$ *on* $X \times Y$ *such that Properties* A *and* B *hold with* $p > \max(a2^{-S+1}, 2a\beta^m)$. *Then any open pair* $\mathcal{P}$ *of communicating branching programs computing* f *using space* S *and communication* C *must satisfy*

$$C \cdot S = \Omega(m \log_a(1/\beta) \min(K, \log(p/q))).$$

(Note that, although the hypothesis $p > a2^{-S+1}$ refers to the space bound, it is even weaker than the relatively innocuous assumption $p > 2a/n$, where n is the number of input bits, since reading this many bits requires $S \geq \log_2 n$. Note also that, since there are 2^k choices for k output values and Property B must hold for all choices of output values, $2^k a\beta^k \geq 1$. Thus, $\log_a(1/\beta) \leq \log_a 2 + 1/k \leq 2$, so $\log_a(1/\beta)$ contributes at most a constant factor to the lower bound. However, β may be close to 1, so the $\log_a(1/\beta)$ factor in the lower bound may be close to 0.)

Proof. Let $\mathcal{P}$ be an open pair of communicating branching programs computing f, and let C and S be the communication and space, respectively, used by $\mathcal{P}$.

Case 1 ($S + 2 \geq \log_2(p/q)/4$). As explained above, $\log_a(1/\beta) \leq 2$. By Property A and the fact that $\mathcal{P}$ is open, $C \geq m$. Thus,

$$6CS \geq 2C(S+2) \geq m \log_a(1/\beta) \log_2(p/q)/4.$$

Case 2 ($S + 2 < \log_2(p/q)/4$). Let $c = \min(C, \lfloor \frac{1}{2} \log_2(p/q) - S - 1 \rfloor) \geq \min(C, \lfloor 2S + 4 - S - 1 \rfloor) > 0$. Fix any pair (u, v) of nodes, u in the X-program and v in the Y-program of $\mathcal{P}$. Fix $\alpha \in \{0, 1\}^{\leq 2c}$ such that α determines $k \leq K$ output values, that is, α contains the encoding of k output values. Let (x, y) be chosen at random according to $\mathcal{D}$. Suppose that $\Pr_{\mathcal{D}}[(x, y) \in R^{\alpha}_{(u,v)}] \geq q$. By Property B, Lemma 3.1, and the fact that $\mathcal{P}$ correctly computes f,

$$\Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \mid (x, y) \in R^{\alpha}_{(u,v)}] \leq a\beta^k. \tag{1}$$

Call $R^{\alpha}_{(u,v)}$ *tiny* if and only if $\Pr_{\mathcal{D}}[(x, y) \in R^{\alpha}_{(u,v)}] < q$. Let $T_{(u,v)}$ be the set of α such that $R^{\alpha}_{(u,v)}$ is tiny. For fixed (u, v) and varying α, Lemma 3.1 says that the sets $R^{\alpha}_{(u,v)}$ are disjoint and their union contains all pairs (x, y) that reach (u, v). Let

$$W = \{\alpha \in \{0, 1\}^{\leq 2c} \mid \alpha \text{ determines } k \text{ output values}\}.$$

For all (u, v) and all $k \leq K$,

$$\begin{aligned}
&\Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \ \wedge\ \gamma^{c}_{(u,v)}(x, y) \text{ determines } k \text{ output values}]\\
&\quad = \sum_{\alpha\in W} \Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \ \wedge\ (x, y) \in R^{\alpha}_{(u,v)}]\\
&\quad = \sum_{\alpha\in W\setminus T_{(u,v)}} \Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \ \wedge\ (x, y) \in R^{\alpha}_{(u,v)}]\\
&\qquad + \sum_{\alpha\in T_{(u,v)}} \Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \ \wedge\ (x, y) \in R^{\alpha}_{(u,v)}]\\
&\quad < \sum_{\alpha\in W\setminus T_{(u,v)}} \Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \ \wedge\ (x, y) \in R^{\alpha}_{(u,v)}] + |T_{(u,v)}|q\\
&\quad \leq 2^{2c+1}q + \sum_{\alpha\in W\setminus T_{(u,v)}} \Pr_{\mathcal{D}}[(x, y) \text{ reaches } (u, v) \mid (x, y) \in R^{\alpha}_{(u,v)}]\\
&\qquad\qquad \times \Pr_{\mathcal{D}}[(x, y) \in R^{\alpha}_{(u,v)}]\\
&\quad \leq 2^{2c+1}q + a\beta^{k} \sum_{\alpha\in W\setminus T_{(u,v)}} \Pr_{\mathcal{D}}[(x, y) \in R^{\alpha}_{(u,v)}]\\
&\quad \leq a\beta^{k} + 2^{2c+1}q,
\end{aligned} \tag{2}$$

the last two lines following from inequality (1) and the fact that the sets $R^{\alpha}_{(u,v)}$ are disjoint, respectively.

Inequality (2) is used in two different ways. For the first, by applying it to the start nodes u and v of their respective branching programs, we have

$$C > \min\left(K, \left\lfloor \frac{1}{2}\log_2(p/q) - S - 1\right\rfloor\right). \tag{3}$$

For assume to the contrary that $C \leq K$ and $C \leq \left\lfloor \frac{1}{2}\log_2(p/q) - S - 1\right\rfloor$. Then by the definition of c, $c = C$. Now choose $k = m$. By Property A and the fact that $\mathcal{P}$ is open, $k = m \leq C \leq K$, so inequality (2) holds. By the definition of c, $2^{2c+1}q \leq 2^{\log_2(p/q)-2+1}q = p/2$, so inequality (2) and Property A together yield $p \leq a\beta^{m} + 2^{2c+1}q \leq a\beta^{m} + p/2$. That is, $p/2 \leq a\beta^{m}$, which contradicts the hypothesis $p > 2a\beta^{m}$.

Now let $k = \min(K, m/\lceil C/c\rceil - 1)$ in inequality (2). Suppose $\mathcal{P}$ uses exactly C' bits of communication on input (x, y). Divide this sequence of C' bits into $\lceil C'/c\rceil$ segments, each consisting of c consecutive bits of communication (except possibly the last segment). If $f(x, y)$ has at least m output values, then (x, y) reaches some pair (u, v) of nodes such that $\gamma^{c}_{(u,v)}(x, y)$ determines at least $m/\lceil C'/c\rceil - 1 \geq m/\lceil C/c\rceil - 1 \geq k$ output values, for otherwise fewer than m output values are produced by $\mathcal{P}$ on input (x, y). (The -1 term accounts for the possibility that an output crosses a segment boundary.) Therefore, since $k \leq K$ and there are at most 2^{2S} node pairs (u, v),

$$\begin{aligned}
p &\leq \Pr_{\mathcal{D}}[(\exists u, v)((x, y) \text{ reaches } (u, v) \ \wedge\\
&\qquad\qquad \gamma^{c}_{(u,v)}(x, y) \text{ determines } k \text{ output values})]\\
&\leq 2^{2S}(a\beta^{k} + 2^{2c+1}q) = 2^{2S}a\beta^{k} + 2^{2S}2^{2c+1}q \leq 2^{2S}a\beta^{k} + p/2,
\end{aligned}$$

by the definition of c. Solving this yields $2S + \log_2(2a/p) \geq k\log_2(1/\beta)$. Since $p \geq a2^{-S+1}$, it follows that $3S \geq k\log_2(1/\beta)$.

Case 2.1 ($K < m/\lceil C/c\rceil - 1$). Then $k = K$. By Property A and the fact that $\mathcal{P}$ is open, $C \geq m$, so $3CS \geq mK\log_2(1/\beta) \geq mK\log_a(1/\beta)$.

Case 2.2 ($K \geq m/\lceil C/c\rceil - 1$). Then $k + 1 = m/\lceil C/c\rceil \geq mc/(C + c)$, so

$$
\begin{aligned}
12CS &\geq 6(C+c)S \\
&\geq 2(C+c)k\log_2(1/\beta) \\
&\geq (C+c)(k+1)\log_2(1/\beta) \\
&\geq mc\log_2(1/\beta) \\
&\geq m\log_2(1/\beta)\min\left(C, \left\lfloor \frac{1}{2}\log_2(p/q) - S - 1\right\rfloor\right) \\
&\geq m\log_2(1/\beta)\min\left(K, \left\lfloor \frac{1}{2}\log_2(p/q) - S - 1\right\rfloor\right) \qquad (4)\\
&\geq m\log_2(1/\beta)\min(K, \log_2(p/q)/4) \qquad (5)\\
&\geq m\log_a(1/\beta)\min(K, \log_2(p/q)/4).
\end{aligned}
$$

Inequality (4) follows from inequality (3), and inequality (5) from the condition of Case 2. □

Theorem 3.3 extends Theorem 3.2 to the case when the pair of communicating branching programs is not necessarily open.

THEOREM 3.3. *Suppose that for $f : X \times Y \to Z$ there is a distribution $\mathcal{D}$ on $X \times Y$ such that Properties* A *and* B *hold with $p > \max(a2^{-S+1}, 2a\beta^m)$. Then any pair $\mathcal{P}$ of communicating branching programs computing f using space S and communication C must satisfy*

$$(C + m\log m)\cdot S = \Omega(m\log_a(1/\beta)\min(K, \log(p/q))).$$

Proof. For any pair $\mathcal{P}$ of communicating branching programs, let the *observable behavior* of $\mathcal{P}$ on input (x, y) be the sequence of communicated bits and up to the first m output values produced on (x, y) by $\mathcal{P}$. Because of the structure of branching program pairs, there is no ambiguity about the order in which communication steps occur. However, the interleaving of the two programs' output values between communication steps is not determined, so for definiteness we assume that, between communication steps, outputs in the observable behavior produced by the X-program precede those produced by the Y-program. Since each output value is produced only once by the pair of branching programs, it is easy to see that, for any input pair, the observable behavior may be encoded using $O(C + m\log m)$ bits, where each output value is encoded using $O(\log m)$ bits that specify (1) that it is an output rather than a communication, (2) which output bit is being produced, (3) its value, and (4) which program produced it. Let $2C^*$ be the maximum, over all (x, y), of the length of the observable behavior on input (x, y). (We use $2C^*$ as the analogue of the $2C$ bits used in Theorem 3.2 to encode the communication in the strings $\gamma^c_{(u,v)}(x, y)$.)

The proof of Theorem 3.3 is analogous to that of Theorem 3.2, except that the communication C is replaced by the number of bits needed to describe the observable behavior, C^*. The main technical difference is in the definition of $\gamma^c_{(u,v)}(x, y)$, which, instead of being the string of length $2c$ describing the next c bits of communication on (x, y) starting at (u, v), is now the string of the next $2c$ bits of the observable behavior of $\mathcal{P}$ on (x, y) starting at (u, v). Since outputs are included in the observable behavior, the string $\gamma^c_{(u,v)}(x, y)$ determines output values just as the communication did in the case of an open pair of branching programs. The crucial fact, which is easily verified, is that the new $R^\alpha_{(u,v)}$ based on this definition of $\gamma^c_{(u,v)}(x, y)$ still are disjoint rectangles that cover the set of input pairs that arrive at (u, v).

The remainder of the proof is identical to that of Theorem 3.2 except for a couple of points. The part of the proof of Theorem 3.2 where the communication is divided into segments of length c is slightly different. When c bits of communication are replaced by $2c$ bits of observable behavior, it is no longer obvious that every boundary between segments of the computation on (x, y) can be chosen to be at a pair of nodes (u, v) since an output value may be produced along an edge and this is $O(\log m)$ bits of observable behavior as opposed to the single bit of communication that may occur on an edge. However, because the argument ignores any output whose production overlaps the boundary, if a boundary would naturally fall in the middle of an edge, then the boundary may be shifted past the edge to the subsequent node with no loss in the argument. The remaining difference is that, in the places where Property A and openness were used to show that $m \leq C$, in the modified proof $m \leq C^*$ follows directly from Property A and the definition of C^*. The conclusion of the argument is exactly the same with C^* replacing C as required. □

It is not too hard to see how the argument and Properties A and B can be modified to deal with R-way branching programs (Borodin and Cook [7]) or when the output values described in Properties A and B are of a restricted type (as in, for example, Abrahamson [1]).

4. Hash functions. We now apply the lower bound technique of the previous section to universal families of hash functions (Carter and Wegman [9], [10]). This will allow us to obtain lower bounds for a variety of interesting computational problems. We make use of a beautiful analog due to Mansour, Nisan, and Tiwari [17] of a lemma of Lindsey [4], [11] concerning Hadamard matrices.

Our results (and those in [17]) use the more restrictive definition of a universal family of hash functions given by Carter and Wegman in [10] (which they called "strongly universal" in [10]) rather than the somewhat broader definition given in [9]. To emphasize the nature of this stronger requirement we will call such families *pairwise universal.*

A pairwise universal family H of hash functions from a set X to a set Z satisfies the following two properties for h chosen uniformly at random from H:

1. For any $x \in X$, $h(x)$ is uniformly distributed in Z.
2. For any $x, x' \in X$ with $x \neq x'$ and for any $z, z' \in Z$, the events $h(x) = z$ and $h(x') = z'$ are independent.

We say that a pair of communicating branching programs computes the universal family of hash functions H if and only if it computes the function $f : X \times H \to Z$ given by $f(x, h) = h(x)$.

Of the two properties of a function required to apply our lower bound technique, Property B is the more difficult to prove. The following lemma on pairwise universal hash functions is critical in proving Property B for families of hash functions.

LEMMA 4.1 (Mansour, Nisan, and Tiwari [17]). *Let H be a pairwise universal family of hash functions from X to Z. Let $A \subseteq X$, $B \subseteq H$, and $E \subseteq Z$. Then*

$$\left| \Pr_{x\in A, h\in B}[h(x) \in E] - \frac{|E|}{|Z|} \right| \leq \sqrt{\frac{|H| \cdot |E|}{|A| \cdot |B| \cdot |Z|}}.$$

This lemma is used by Mansour, Nisan, and Tiwari [17] to prove time-space tradeoffs for computing hash functions. A somewhat weaker form of this lemma was proved independently by Yan [22] for the special case when the family of hash functions is given by matrix-vector product over GF(2).

THEOREM 4.2. *Let $\mathcal{P}$ be an open pair of communicating branching programs computing a pairwise universal family of hash functions from X to Z using communication C and space S. Let $n = \lfloor \log_2 |X| \rfloor$, $m = \lfloor \log_2 |Z| \rfloor - 1$, and $Z \subseteq \{0, 1\}^{\leq m+l}$, where $l < \min(\log_2 n, m) - 3$ is included to allow some slack in the output encoding. Then $C \cdot S = \Omega(nm/l)$.*

Proof. Let $\mathcal{D}$ be the uniform distribution on pairs (x, h). Since $h(x)$ is uniformly distributed in Z, Property A is satisfied with $p = 1/2$. Let $R = A \times B$ satisfy $|R| \geq 2^{K-n}|X \times H|$, where $K = n/2$. For any set $V = \{z_{i_1} = b_1, \ldots, z_{i_k} = b_k\}$ of $k \leq K$ output values, let

$E \subseteq Z$ be the set of vectors consistent with V. At most $2^{m+l-k+1}$ vectors are in E so that $|E|/|Z| \leq 2^{-(k-l)}$. Then Lemma 4.1 states that

$$\begin{aligned} \Pr_{\mathcal{D}}[h(x) \text{ is consistent with } V \mid (x,h) \in R] &\leq \frac{|E|}{|Z|} + \sqrt{\frac{|H|}{|R|} \cdot \frac{|E|}{|Z|}} \\ &\leq 2^{-(k-l)} + 1/\sqrt{2^{K-n}|X|2^{k-l}} \\ &\leq 2^{l+1} \cdot 2^{-k}. \end{aligned}$$

Thus Property B is satisfied with $q = 2^{-n/2}$, $\beta = 1/2$, $a = 2^{l+1}$, and $K = n/2$. Since $l < \min(\log_2 n, m) - 3$, $p = 1/2 > 2a/n$ and $p > 2a\beta^m$, so Theorem 3.2 implies that $C \cdot S = \Omega(nm/l)$. □

Theorem 4.3 extends Theorem 4.2 to the case in which the pair of communicating branching programs is not necessarily open.

THEOREM 4.3. *Any pair of communicating branching programs computing a pairwise universal family of hash functions from X to Z with communication C and space $S = o(n/(l \log m))$ satisfies $C \cdot S = \Omega(nm/l)$, where $n = \lfloor \log_2 |X| \rfloor$, $m = \lfloor \log_2 |Z| \rfloor - 1$, and $Z \subseteq \{0,1\}^{\leq m+l}$ for $l < \min(\log_2 n, m) - 3$.*

Proof. Using Theorem 3.3 in place of Theorem 3.2 in the proof of Theorem 4.2,

$$(C + m \log m)S = \Omega(nm/l).$$

Since, by hypothesis, $Sm \log m = o(nm/l)$, the conclusion $CS = \Omega(nm/l)$ follows. □

Similar statements to Theorem 4.3 can be made for each of the following corollaries. We simply state our results for open pairs of branching programs for convenience.

In the following corollaries, we can always choose l to be a constant.

COROLLARY 4.4. *Any open pair of communicating branching programs computing the product of an $n \times n$ matrix and an n-vector over* GF(2) *requires communication C and space S such that $C \cdot S = \Omega(n^2)$.*

COROLLARY 4.5. *If $r \geq 2^n$, then any open pair of communicating branching programs computing f :* $\mathrm{GF}(r) \times \mathrm{GF}(r)^2 \to \mathrm{GF}(r)$ *given by $f(x,(a,b)) = a \cdot x + b$ (in* GF(r)) *requires communication C and space S such that $C \cdot S = \Omega(n^2)$.*

The next two corollaries follow from Theorem 4.2 exactly as shown by Mansour, Nisan, and Tiwari [17] for time-space tradeoffs.

COROLLARY 4.6. *Any open pair of communicating branching programs computing the m-bit convolution of an n-bit string with an $(n + m - 1)$-bit string requires communication C and space S such that $C \cdot S = \Omega(nm)$.*

COROLLARY 4.7. *Any open pair of communicating branching programs computing the product of two $n \times n$ matrices over* GF(2) *requires communication C and space S such that $C \cdot S = \Omega(n^3)$.*

Corollaries 4.5, 4.6, and 4.7 are interesting in their own right and because they demonstrate tradeoffs in cases where the lower bound is greater than the total number of inputs that the two programs receive.

Using the natural generalization of communicating branching programs to pairs of r-way branching programs that are allowed to send and receive values in GF(r) one can prove, either by direct simulation or an analog of Theorem 3.2, the following analog of Theorem 4.2 for hash functions whose domain and range are vectors over GF(r).

THEOREM 4.8. *Any open pair of communicating r-way branching programs computing a pairwise universal family of hash functions from X to Z requires communication C and space S such that $C \cdot S = \Omega(nm(\log r)/l)$, where $n = \lfloor \log_r |X| \rfloor$, $m = \lfloor \log_r |Z| \rfloor - 1$, and $Z \subseteq (\mathrm{GF}(r))^{\leq m+l}$, for $l < \min(\log_r n, m) - 3$.*

This theorem has corollaries analogous to those of Theorem 4.2, such as the following.

COROLLARY 4.9. *Any open pair of communicating r-way branching programs computing the product of an $n \times n$ matrix and an n-vector over* GF(r) *requires communication C and space S such that $C \cdot S = \Omega(n^2 \log r)$.*

5. Open questions.

It is an interesting question whether or not similar bounds hold for $\wedge$-$\vee$ matrix-vector product. The results of Lam, Tiwari, and Tompa [15] show that such results do hold in a more restricted model in which the programs are restricted to being oblivious, i.e., straight-line, and the communication is one-way.

A natural approach to proving such a bound would be to try to prove Properties A and B for this problem using the distribution $\mathcal{D}$ employed by Babai, Frankl, and Simon [4] for proving a distributional communication complexity lower bound of $\Omega(\sqrt{n})$ for $\wedge$-$\vee$ dot product (i.e., set disjointness) and by Abrahamson [1] for proving a time-space tradeoff of $TS = \Omega(n^{1.5})$ on matrix-vector product. However, this approach cannot yield any interesting communication-space tradeoff since under this distribution, which chooses each input bit independently to be 1 with probability $1/\sqrt{n}$ and 0 with probability $(1 - 1/\sqrt{n})$, the program with the vector can simply communicate its value in expected $O(\sqrt{n} \log n)$ bits to the matrix program, which can store this value and perform the rest of the computation on its own.

An alternative approach would be to try to generalize the distribution on inputs that Razborov [20] used to prove that the distributional communication complexity of the set disjointness problem is $\Omega(n)$. Unfortunately, the fact that this distribution does not set the values of the inputs to the two programs independently creates serious problems when trying to generalize from a problem whose input consists of two vectors to a problem with a matrix and a vector as input. It seems unlikely that one can maintain sufficient independence between the inputs to the two programs while maintaining sufficient information content in the two inputs. It may be that the oblivious one-way result is leading us astray, but it seems more likely that we are unable to generalize it because our technique is fundamentally distributional in nature.

The question of the communication-space tradeoff for $\wedge$-$\vee$ matrix product and GF(2) matrix-vector product raises another interesting question. Suppose that function f on $X \times Y$ has ϵ-error distributional communication complexity (Yao [24], [26]) at least D_ϵ. Under what circumstances does the function F on $X^n \times Y$ given by $F((x_1, \ldots, x_n), y) = (f(x_1, y), \ldots, f(x_n, y))$ have communication-space tradeoff $\Omega(nD_\epsilon)$? As shown by Yao [24], [26] and extended by Babai, Frankl, and Simon [4], a lower bound $D_\epsilon \geq k$ can be obtained by showing that, for an appropriate distribution on $X \times Y$ under which f takes on each value at least a constant fraction of the time, any rectangle R, in which the probability of $f(x, y)$ taking on a particular value is less than ϵ, must have total probability at most $1/2^k$. This condition is very similar to our Property B, the important difference being that we require that this be true for ϵ much smaller than a constant, that is, for $\epsilon = \beta^k$ for $\beta < 1$. If the only rectangles $A \times B$ in $X^n \times Y$ had A of the form $A_1 \times \cdots \times A_n$, then there would be a direct translation of distributional communication complexity lower bounds for f to those for F. It is not clear what conditions on f will allow the handling of general A as well. The technique of Mansour, Nisan, and Tiwari [17] and Yan [22] implies that it is sufficient to have not only a small probability of a value in such a rectangle R but also a small variance in the probability of the value occurring in the rows (or columns) of R.

A NEW INSIGHT INTO THE COFFMAN–GRAHAM ALGORITHM*

BERTRAND BRASCHI† AND DENIS TRYSTRAM†

Abstract. The approximate solution of the m-machine problem is addressed. The Lam–Sethi worst-case analysis of the Coffman–Graham algorithm is set up to be partly incorrect. A slightly different context is set up to correct and complete this analysis. It is shown that the makespan of a schedule computed by an extended Coffman–Graham algorithm is lower than or at worst equal to $(2 - 2/m)\omega_{\text{opt}} - (m - 3)/m$, where ω_{opt} is the minimal makespan of a schedule.

Key words. scheduling theory, worst-case analysis, list scheduling

AMS subject classification. 90B35

1. Introduction. The m-machine problem is to schedule a set of tasks on a given number of identical machines, m, with a minimum makespan. The tasks are subject to precedence constraints and have the same unit execution time. Preemption is not allowed. The Coffman–Graham algorithm (CG-algorithm) is the only polynomial algorithm which solves exactly the two-machine problem [1], [3], [4] and whose worst-case behavior has been analyzed for more than two machines.

We present the m-machine problem in §2 and we give the elements of the Coffman–Graham analysis in §3. We show in §4 that a part of the worst-case analysis of the CG-algorithm published by Lam and Sethi [6], for two machines or more, is not correct. In §5, an extension of the CG-algorithm is considered. We correct the contentious point of the Lam–Sethi analysis and refine their worst-case bound for this extended algorithm in §6.

2. Definitions. The set of tasks and the precedence relation among the tasks are represented by an acyclic directed graph $(\mathcal{C}, \ll)$ (see Fig. 1). Let T and T' be two tasks of $\mathcal{C}$; we note $T \ll T'$ if and only if (iff) (T, T') belongs to $\ll$. T is a *predecessor* of T', and T' a *successor* of T iff $T \ll T'$. The precedence relation between T and T' is *immediate* iff there exists no task T'' such that $T \ll T''$ and $T'' \ll T'$. The set of immediate successors of T is noted $\mathcal{S}(T)$. A set of tasks C is a *chain* iff the restriction of the transitive closure of $(\mathcal{C}, \ll)$ to C is a total order on C. Let $\mathcal{S}$ and $\mathcal{S}'$ be two sets of tasks. We say that $\mathcal{S}$ precedes $\mathcal{S}'$ and note $\mathcal{S} \ll \mathcal{S}'$ iff each task of $\mathcal{S}$ precedes all the tasks of $\mathcal{S}'$. The concept of chain applies also to a collection of sets of tasks. A schedule of $(\mathcal{C}, \ll)$ on a set of m machines $[M_1, \dots, M_m]$ is defined by assigning to every task T a machine $\mu(T)$ and a *slot* of execution $\lambda(T)$, a positive integer, such that the following conditions are verified:

- if $T \ll T'$, then $\lambda(T) < \lambda(T')$—a task is executed before its possible successors,
- if $\mu(T) = \mu(T')$, then $\lambda(T) \neq \lambda(T')$—a machine executes only one task during a slot.

The definition of λ is extended to the sets of tasks: $\lambda(\mathcal{S}) = \{\lambda(T)/T \in \mathcal{S}\}$. We note $\omega(\mathcal{S})$ the makespan of $\mathcal{S}$: $\omega(\mathcal{S}) = |\lambda(\mathcal{S})|$, and we define Idle$(\mathcal{S})$ as $m\omega(\mathcal{S}) - |\mathcal{S}|$. The schedule of $(\mathcal{C}, \ll)$ is said to be *optimal* iff $\omega(\mathcal{C})$ is minimal. The minimal makespan is noted $\omega_{\text{opt}}(\mathcal{C})$. We define the optimal makespan of a subset $\mathcal{S}$ of $\mathcal{C}$, $\omega_{\text{opt}}(\mathcal{S})$, as the makespan of the optimal schedule for the restriction of the transitive closure of $(\mathcal{C}, \ll)$ to $\mathcal{S}$: We note: $\text{Idle}_{\text{opt}}(\mathcal{S}) = m\omega_{\text{opt}}(\mathcal{S}) - |\mathcal{S}|$.

3. The Coffman–Graham analysis [2]. The CG-algorithm begins to assign to each task T a positive integer $\alpha(T)$, its *priority*. These priorities follow a rule, which we translate into

FIG. 1. *A precedence graph* $(\mathcal{C}, \ll)$ *and one of its possible schedules on two machines. The tasks of* $\mathcal{S} = \{A_2, A_1\}$ *are executed during the slots of* $\lambda(\mathcal{S}) = \{4, 5\}$: $\omega(\mathcal{S}) = 2$ *and* $\text{Idle}(\mathcal{S}) = 2$. *There is no precedence relation between* A_1 *and* A_2 : A_1 *and* A_2 *could be executed during the same slot. Thus the optimal makespan of* $\mathcal{S}$ *is* $\omega_{\text{opt}}(\mathcal{S}) = 1$ *and* $\text{Idle}_{\text{opt}}(\mathcal{S}) = 0$.

the *CG-rule* below, where $\alpha(\mathcal{S})$ denotes the set of priorities for the tasks set $\mathcal{S}$ and $\alpha(\emptyset)$ is equal to $\{0\}$.

CG-RULE. *If* $T \neq T'$, *then* $\alpha(T) \neq \alpha(T')$, *and if* $\alpha(T) \geq \alpha(T')$, *then* $\max(\alpha(\mathcal{S}(T)\backslash\mathcal{S}(T'))) \geq \max(\alpha(\mathcal{S}(T')\backslash\mathcal{S}(T)))$.

Then the CG-algorithm computes a schedule such that if there exists a task T and a slot L lower than $\lambda(T)$ during which a machine is idle or executes a task whose priority is lower than $\alpha(T)$, then T has a predecessor executed during L. Such a schedule is said to be a *list schedule* [5].

We consider a schedule computed by the CG-algorithm and assume that the tasks are executed on $M_1, M_2, \ldots$, in decreasing order of priority during a given slot. We note $\text{Next}(T)$ the task executed on M_1 during the slot $\lambda(T) + 1$, if such a task exists.

A series of *critical tasks* is defined by a right to left scanning of the schedule (see Fig. 2). Let us assume that the critical task U_i, $i \geq 0$, is defined. If there exists at least one slot lower than $\lambda(U_i)$, during which the task executed by M_2 has a priority lower than $\alpha(U_i)$, then the critical task U_{i+1} is defined to be the task executed by M_1 during the rightmost of these slots. A *block* $\mathcal{X}_i$ is then defined so that U_{i+1} precedes each task of $\mathcal{X}_i$:

$$\mathcal{X}_i = \{T/\alpha(T) \geq \alpha(U_i) \quad \text{and} \quad \lambda(T) > \lambda(U_{i+1})\}.$$

If U_{i+1} cannot be defined then $\mathcal{X}_i$ is defined as:

$$\mathcal{X}_i = \{T/\alpha(T) \geq \alpha(U_i)\}.$$

The first critical task, U_0, is the task executed by M_1 during the rightmost slot of $\lambda(\mathcal{C})$. The following lemma is derived from the block definition:

BLOCK COMPOSITION LEMMA. *At least two tasks of a block* $\mathcal{X}_i$ *are executed during each slot of* $\lambda(\mathcal{X}_i)$ *except the last slot* $\lambda(U_i)$.

4. The Lam–Sethi analysis [6]. Lam and Sethi define a second layer of tasks sets upon the blocks layer, the *segments*. The segments can be characterized by the *segment composition lemma*:

SEGMENT COMPOSITION LEMMA. *A segment* $\mathcal{W}$ *is the disjoint union of* k *consecutive blocks,* $k \geq 1$, *and of a set of at least* $k - 1$ *additional tasks. Each additional task is preceded by a task of* $\mathcal{W}$.

Lam and Sethi bound $\omega(\mathcal{W})$ with respect to $\omega_{\text{opt}}(\mathcal{W})$ by means of a chain of tasks of $\mathcal{W}$. We show that each task of this chain does not necessarily belong to $\mathcal{W}$, as Lam and Sethi presume.

An inductive argument employing the CG-rule makes it clear that the priorities are compatible with the precedence relation: if $T \ll T'$, then $\alpha(T) > \alpha(T')$. The following property is a consequence of this compatibility (Lemma 2.1 of [6]):

MONOTONY PROPERTY. *If* T *is executed on* M_1 *and* $\lambda(T) \leq \lambda(T')$, *then* $\alpha(T) \geq \alpha(T')$.

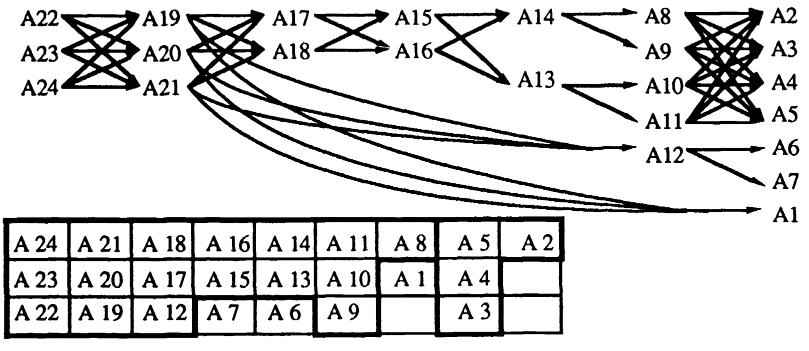
According to Lam and Sethi, a task executed during a slot of $\lambda(\mathcal{W})$ that does not belong to a block, is called an *extra task* and a slot of $\lambda(\mathcal{W})$ during which an extra task is executed is called a *partial slot*. The p partial slots of $\lambda(\mathcal{W})$ are noted $\lambda_1, \ldots, \lambda_p$ from left to right. The task executed by M_1 during λ_i is noted T_i. The following lemma relates the partial slots to the precedence constraints.

LAM–SETHI LEMMA. *Let λ_i be a partial slot of $\lambda(\mathcal{W})$ such that* $\mathrm{Next}(T_i)$ *exists. Every task R_i such that $\alpha(R_i) \geq \alpha(T_i)$ has an immediate successor R_{i+1} such that $\alpha(R_{i+1}) \geq \alpha(\mathrm{Next}(T_i))$.*

Proof. It can be induced from the monotony property and the block definition that any extra task E either is executed during the last slot of $\lambda(\mathcal{W})$ or has a priority lower than $\alpha(\mathrm{Next}(E))$.

Let E be an extra task executed during λ_i such that $\mathrm{Next}(T_i)$ exists. Obviously we have $\alpha(E) < \alpha(\mathrm{Next}(E))$, and because $\mathrm{Next}(T_i) = \mathrm{Next}(E)$, there exists an immediate predecessor T^* of $\mathrm{Next}(T_i)$, executed during λ_i. The task T_i is executed on M_1, and thus the inequality $\alpha(T_i) \geq \alpha(T^*)$ holds and therefore by transitivity, $\alpha(R_i) \geq \alpha(T^*)$. According to the CG-rule, an immediate successor R_{i+1} of R_i, such that $\alpha(R_{i+1}) \geq \alpha(\mathrm{Next}(T_i))$, must exist. □

If the slot λ_i is not the last partial slot of $\lambda(\mathcal{W})$, the monotony property makes it possible to state that $\alpha(\mathrm{Next}(T_i)) \geq \alpha(T_{i+1})$, thus, by transitivity, $\alpha(R_{i+1}) \geq \alpha(T_{i+1})$. This enables Lam and Sethi to conclude, by induction, that every task T such that $\alpha(T) \geq \alpha(T_i)$ precedes a chain of at least $p - i$ tasks. The point is that these tasks do not necessarily belong to $\mathcal{W}$. It is actually possible that $\alpha(R_i) < \alpha(U_j)$ even if $\alpha(R_i) \geq \alpha(\mathrm{Next}(T_i))$, where $\alpha(U_j)$ determines if R_i belongs to a block or not. Then, we cannot decide whether R_i belongs to $\mathcal{W}$ or not. Hence, the number of tasks in such a chain cannot be used as a lower bound for $\omega_{\mathrm{opt}}(\mathcal{W})$, as Lam and Sethi do. The definition of a segment given by Lam and Sethi is too narrow: in Fig. 2, the tasks A_6 and A_7 are similar but A_7 belongs to the segment, which is not the case for A_6. We modify the segment definition in §6 to add to the blocks of a segment as many tasks as possible.



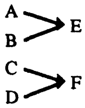
A 24	A 21	A 18	A 16	A 14	A 11	A 8	A 5	A 2
A 23	A 20	A 17	A 15	A 13	A 10	A 1	A 4	
A 22	A 19	A 12	A 7	A 6	A 9		A 3	

FIG. 2. *Analysis of the structure of a schedule on three machines. The tasks are given priorities according to the CG-rule. The priority of the task A_i is its index: $\alpha(A_i) = i$. The task U_0 is A_2. The first task executed on M_2 before $\lambda(U_0)$ with a priority lower than $\alpha(U_0)$ is A_1: the task U_1 is A_8 and $\mathcal{X}_0 = \{A_2, A_3, A_4, A_5\}$. There is no task executed on M_2 before $\lambda(U_1)$ with a priority lower than $\alpha(U_1)$: $\mathcal{X}_1 = \{A_8, A_9, A_{10}, A_{11}, A_{13}, A_{14}, A_{15}, A_{16}, A_{12}, A_{17}, A_{18}, \ldots, A_{24}\}$. The task A_{12} belongs to $\mathcal{X}_1$, has no successor in $\mathcal{X}_1$ and does not precede all the tasks of $\mathcal{X}_0$: A_{12} has at least one successor of priority greater than or equal to $\alpha(U_0)$ executed during a slot of $\lambda(\mathcal{X}_1)$. The task A_6, or A_7, is such a successor. A segment $\mathcal{W}$ can be set as the disjoint union of $\mathcal{X}_1$, $\{A_7\}$, and $\mathcal{X}_0$. There are four partial slots: T_1 is A_{16}, T_2 is A_{14}, T_3 is A_8, and T_4 is A_2. Since $\alpha(A_{24}) \geq \alpha(T_1)$, there exists a successor of A_{24}, say A_{21}, such that $\alpha(A_{21}) \geq \alpha(T_2)$. Recursively, $A_{21} \ll A_{12}(\alpha(A_{12}) \geq \alpha(T_3))$, and $A_{12} \ll A_6(\alpha(A_6) \geq \alpha(T_4))$. In conclusion, A_{24} precedes the chain $\{A_{21}, A_{12}, A_6\}$ but A_6 does not belong to $\mathcal{W}$.*

5. An extended algorithm. The CG-algorithm makes an arbitrary choice to assign different priorities to two different tasks T and T' such that $\max(\alpha(\mathcal{S}(T)\backslash\mathcal{S}(T')))$ is equal to $\max(\alpha(\mathcal{S}(T')\backslash\mathcal{S}(T)))$. This choice restricts the set of priorities the predecessors of T and T' can have, and thus, the set of schedules the CG-algorithm can compute. Let us consider a straightforward extension of the CG-algorithm, the *ECG-algorithm*, which assigns to each task T a priority $\alpha(T)$ according to the following *relaxed rule* and then computes a list schedule according to these priorities:

RELAXED RULE. *If* $\alpha(T) \geq \alpha(T')$, *then* $\max(\alpha(\mathcal{S}(T)\backslash\mathcal{S}(T'))) \geq \max(\alpha(\mathcal{S}(T')\backslash\mathcal{S}(T)))$.

Any schedule computed by the CG-algorithm can be computed by the ECG-algorithm but the converse is not true, as depicted in Fig. 3. We show in §6 that the main ideas of Lam and Sethi still hold for the ECG-algorithm.



Tasks	A	B	C	D	E	F
An instance of CG-priorities	6	5	4	3	2	1
An instance of relaxed priorities	2	2	2	2	1	1

A list schedule according to the instance of relaxed priorities	A	B	E
	C	D	F

FIG. 3. *Contribution of the ECG-algorithm. According to the CG-rule, either α (A) and $\alpha(B)$ are greater than $\alpha(C)$ and $\alpha(D)$ or the inverse is true. Thus, in any schedule computed by the CG-algorithm on two machines, A and B are executed during the same slot. On the other hand, we show a list schedule on two machines, based on priorities which follow the relaxed rule, where A and B are not executed during the same slot.*

6. An extended analysis. Now we consider a schedule computed by the ECG-algorithm. Let the critical tasks and the blocks be defined as in §3. Any critical task still precedes each task of the block to its right, if it exists. The block composition lemma and the monotony property remain valid. We give a new definition of the segments.

6.1. The segment definition. A series of *critical blocks* is defined by a left-to-right scanning of the schedule (see Fig. 4). Let us assume that the critical block $\mathcal{Y}_j$, $j \geq 0$, is defined. The set of tasks $\mathcal{W}_j(\mathcal{X}_i)$ is defined for each block $\mathcal{X}_i$ as follows:

$$\mathcal{W}_j(\mathcal{X}_i) = \{T/T \in \mathcal{Y}_j \text{ or } T \text{ is preceded by a task of } \mathcal{Y}_j \text{ and } \alpha(T) \geq \alpha(U_{i+1})\}.$$

If there exists at least one block $\mathcal{X}_i$ to the right of $\mathcal{Y}_j$ such that $\mathcal{W}_j(\mathcal{X}_i) \ll \mathcal{X}_i$, then $\mathcal{Y}_{j+1}$ is defined to be the leftmost of these blocks. The *segment* $\mathcal{W}_j$ is defined as $\mathcal{W}_j(\mathcal{Y}_{j+1})$. If there is no block $\mathcal{X}_i$ to the right of $\mathcal{Y}_j$ such that $\mathcal{W}_j(\mathcal{X}_i) \ll \mathcal{X}_i$, then $\mathcal{W}_j$ is defined as follows:

$$\mathcal{W}_j = \{T/T \in \mathcal{Y}_j \text{ or } T \text{ is preceded by a task of } \mathcal{Y}_i \text{ and } \alpha(T) \geq \alpha(U_0)\}.$$

The first critical block, $\mathcal{Y}_0$, is the leftmost block. We note ${}^jU$ and U^j, the leftmost and the rightmost critical tasks of $\mathcal{W}_j$, respectively.

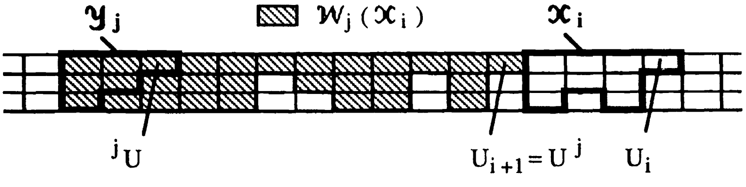


FIG. 4. *The segment definition. $\mathcal{W}_j$ is equal to $\mathcal{W}_j(\mathcal{X}_i)$, ${}^jU$ is equal to the critical task of $\mathcal{Y}_j$ and U^j is U_{i+1}.*

6.2. The segment composition lemma. We use the arguments of Lemmas 2.3 and 2.2 in [6] and show that the segment composition lemma holds in this context. Let us consider a critical block $\mathcal{Y}_j$ and a block $\mathcal{X}_i$ to the right of $\mathcal{Y}_j$.

If $\mathcal{W}_j(\mathcal{X}_i)$ does not precede $\mathcal{X}_i$, then there exists a task T of $\mathcal{W}_j(\mathcal{X}_i)$ and a task T' of $\mathcal{X}_i$ such that T does not precede T'. The tasks T and T' can be respectively considered without successor in $\mathcal{W}_j(\mathcal{X}_i)$ and without predecessor in $\mathcal{X}_i$. The critical task U_{i+1} precedes T' and thus T' belongs to $\mathcal{S}(U_{i+1})$. Furthermore, the priorities follow the relaxed rule and the fact that T belongs to $\mathcal{W}_j(\mathcal{X}_i)$ implies that $\alpha(T) \geq \alpha(U_{i+1})$. Hence, there exists a task B such that B belongs to $\mathcal{S}(T)\backslash\mathcal{S}(U_{i+1})$ and

$$(1) \qquad \alpha(B) \geq \max(\alpha(\mathcal{S}(U_{i+1})\backslash\mathcal{S}(T))).$$

Because B is not an immediate successor of U_{i+1}, if B were a successor of U_{i+1}, an immediate successor A of U_{i+1} preceding B should exist. As the priorities are compatible with the precedence relation, A should verify $\alpha(A) > \alpha(B)$ and thus, according to (1), A should be an immediate successor of T. This would contradict the fact that B is an immediate successor of T. Therefore, B is not a successor of U_{i+1}.

For T' belongs to $\mathcal{S}(U_{i+1})$, the inequality (1) induces that $\alpha(B) \geq \alpha(T')$, and for T' belongs to $\mathcal{X}_i$, $\alpha(B) \geq \alpha(U_i)$. Hence, B cannot be executed after $\lambda(U_{i+1})$ because otherwise it would belong to $\mathcal{X}_i$ and therefore be preceded by U_{i+1}. This means that B neither belongs to $\mathcal{W}_j(\mathcal{X}_i)$ nor to $\mathcal{X}_i$. In conclusion, the task B is a successor of T and thus is preceded by a task of $\mathcal{Y}_j$ and $\alpha(B) \geq \alpha(U_i)$. The disjoint union of $\mathcal{W}_j(\mathcal{X}_i)$, $\mathcal{X}_i$, and $\{B\}$ is included in $W_j(\mathcal{X}_{i-1})$, if $\mathcal{X}_{i-1}$ exists, or in $\mathcal{W}_j$, if $\mathcal{X}_{i-1}$ does not exist. This leads by induction to the segment composition lemma.

We point out that we have modified the scope of the set of *additional tasks*. No task T such that $\alpha(T) \geq \alpha(U^j)$ executed during $\lambda(\mathcal{W}_j)$ is excluded from $\mathcal{W}_j$, as it actually appears to be the problem on Fig. 2.

6.3. The partial-slot lemma. We continue the reasoning that has led to the Lam–Sethi lemma to build a chain and ensure that each task of the chain belongs to a given segment $\mathcal{W}_j$. We consider λ_i a partial slot of $\mathcal{W}_j$ that is not the rightmost, if such a slot exists.

If the task T_i is a critical task, then it is clear that $T_i \ll \text{Next}(T_i)$. If T_i is not a critical task, then because of the monotony property and the block definition, every extra task E executed during λ_i is such that $\alpha(E) < \alpha(\text{Next}(E))$. Thus, following the proof of the Lam–Sethi lemma, T_i has an immediate successor of priority greater than or equal to $\alpha(\text{Next}(T_i))$.

Therefore, if R_i is a task of $\mathcal{W}_j$ such that $\alpha(R_i) \geq \alpha(T_i)$, then R_i has an immediate successor R_{i+1} such that $\alpha(R_{i+1}) \geq \alpha(\text{Next}(T_i))$. Because of the monotony property, we can state that $\alpha(R_{i+1}) \geq \alpha(T_{i+1}) \geq \alpha(U^j)$. These inequalities mean that R_{i+1} belongs to $\mathcal{W}_j$ and provide the material for the straightforward recursive proof leading to the partial-slot lemma.

PARTIAL-SLOT LEMMA. *Let $\mathcal{W}$ be a segment and $\lambda_1, \ldots, \lambda_p$ be the p partial slots of $\lambda(\mathcal{W})$. Every task of $\mathcal{W}$ with a priority greater than or equal to $\alpha(T_i)$ precedes a chain of at least $p - i$ tasks of $\mathcal{W}$.*

6.4. The local-bound lemma. We consider a segment $\mathcal{W}_j$ and we bound the worst makespan $\omega(\mathcal{W}_j)$ the ECG-algorithm can compute. Let k be the number of blocks included in $\mathcal{W}_j$, $\mathcal{X}$ be the union of these blocks, $\mathcal{A}$ be the set $\mathcal{W}_j\backslash\mathcal{X}$ of additional tasks, ${}^jU$ and $\mathcal{Y}_j$ be the leftmost critical task and the leftmost critical block of $\mathcal{W}_j$, and $\lambda_1, \ldots, \lambda_p$ be the p partial slots of $\lambda(\mathcal{W}_j)$. We note $\mathcal{F}$ the set of the tasks of $\mathcal{X}$ executed during λ_1.

- We bound $\text{Idle}(\mathcal{W}_j)$ with respect to p and $\mathcal{F}$. It is easy to verify that $\lambda(\mathcal{W}_j)$ and $\lambda(\mathcal{X})$ are equal and that $\text{Idle}(\mathcal{W}_j)$ is equal to $\text{Idle}(\mathcal{X}) - |\mathcal{A}|$. The set $\lambda(\mathcal{W}_j)$ is divided into three disjoint subsets by checking the type of each slot:

$\mathcal{L}_1 = \{L \in \lambda(\mathcal{W}_j)/L$ is a partial slot during which only one task of $\mathcal{X}$ is executed$\}$,
$\mathcal{L}_{1,m} = \{L \in \lambda(\mathcal{W}_j)/L$ is a partial slot during which at least two tasks of $\mathcal{X}$ are executed$\}$,
$\mathcal{L}_m = \{L \in \lambda(\mathcal{W}_j)/L$ is not a partial slot$\}$.

The block composition lemma entails that

$$(2) \qquad |\mathcal{L}_1| \leq k \qquad (k \text{ is the number of blocks included in } \mathcal{W}_j),$$

and the partial-slot definition leads to

$$(3) \qquad |\mathcal{L}_1| + |\mathcal{L}_{1,m}| = p \qquad (p \text{ is the number of partial slots of } \lambda(\mathcal{W}_j)).$$

The definition of $\mathcal{L}_1$, $\mathcal{L}_{1,m}$, and $\mathcal{L}_m$ and the equality between Idle(W_j) and Idle($\mathcal{X}$) $- |\mathcal{A}|$ lead to

$$(4) \qquad \text{Idle}(\mathcal{W}_j) \leq (m-1)|\mathcal{L}_1| + (m-2)|\mathcal{L}_{1,m}| - |\mathcal{A}|.$$

We substitute $|\mathcal{L}_1|$ and $|\mathcal{L}_{1,m}|$ using (2) and (3) and substitute $|\mathcal{A}|$ by $k-1$, according to the segment composition lemma:

$$(5) \qquad \text{Idle}(\mathcal{W}_j) \leq (p+1)(m-2) - (m-3).$$

Furthermore, if the first slot of $\lambda(\mathcal{W}_j)$ is partial, we derive the inequality (4′), if λ_1 belongs to $\mathcal{L}_1$ or (4″), if λ_1 belongs to $\mathcal{L}_{1,m}$, instead of (4):

$$(4') \qquad \text{Idle}(\mathcal{W}_j) \leq \text{Idle}(\mathcal{F}) + (m-1)(|\mathcal{L}_1| - 1) + (m-2)|\mathcal{L}_{1,m}| - |\mathcal{A}|,$$

$$(4'') \qquad \text{Idle}(\mathcal{W}_j) \leq (m-1)|\mathcal{L}_1| + \text{Idle}(\mathcal{F}) + (m-2)(|\mathcal{L}_{1,m}| - 1) - |\mathcal{A}|.$$

In either case, we can derive

$$(5') \qquad \text{Idle}(\mathcal{W}_j) \leq \text{Idle}(\mathcal{F}) + p(m-2) - (m-3).$$

- We now establish lower bounds for $\omega_{\text{opt}}(\mathcal{W}_j)$ and $\text{Idle}_{\text{opt}}(\mathcal{W}_j)$ with respect to p and $\mathcal{F}$. It can be induced from the partial-slot lemma that each task T such that $\alpha(T) \geq \alpha(T_1)$ precedes a chain of at least $p-1$ tasks of $\mathcal{W}_j$.

Let us assume that the first slot of $\lambda(\mathcal{W}_j)$ is not partial. If a task T of $\mathcal{W}_j$ is such that $\lambda(T) < \lambda(T_1)$ and $\alpha(T) < \alpha(T_1)$, then, because the ECG-algorithm computes a list schedule, at least one task of $\mathcal{W}_j$ precedes T_1. This proves the existence of a chain of at least $p+1$ tasks of $\mathcal{W}_j$ and thus

$$(6) \qquad p + 1 \leq \omega_{\text{opt}}(\mathcal{W}_j).$$

On the other hand, if each task T of $\mathcal{W}_j$ executed before T_1 is such that $\alpha(T) \geq \alpha(T_1)$, then there exists at least $m+1$ tasks of $\mathcal{W}_j$ preceding a chain of at least $p-1$ tasks of $\mathcal{W}_j$ and the inequality (6) still holds.

Now we consider that the first slot of $\lambda(\mathcal{W}_j)$ is partial and establish a lower bound of $\text{Idle}_{\text{opt}}(\mathcal{W}_j)$. The existence of a chain including p tasks of $\mathcal{W}_j$ leads to

$$(6') \qquad p \leq \omega_{\text{opt}}(\mathcal{W}_j).$$

Let us assume that ${}^jU$ is not executed during λ_1. Then, each task of $\mathcal{Y}_j \backslash \mathcal{F}$ is preceded by at least one task of $\mathcal{F}$ for the ECG-algorithm computes a list schedule. Furthermore, every task of $\mathcal{A}$ is preceded by a task of $\mathcal{Y}_j$ and it is easy to verify that ${}^jU$ precedes all the tasks of $\mathcal{X}\backslash\mathcal{Y}_j$. Hence, each task of $\mathcal{W}_j\backslash\mathcal{F}$ is preceded by a task of $\mathcal{F}$ and thus

$$\text{(7)} \qquad \text{Idle}(\mathcal{F}) \leq \text{Idle}_{\text{opt}}(\mathcal{W}_j).$$

If ${}^jU$ is executed during λ_1 then $\mathcal{W}_j$ is equal to $({}^jU)$ and the inequality (7) still holds.

- The inequality (8) is derived from the usual expressions $\omega(\mathcal{W}_j) = (|\mathcal{W}_j|+\text{Idle}(\mathcal{W}_j))/m$ and $(|\mathcal{W}_j| + \text{Idle}_{\text{opt}}(\mathcal{W}_j))/m = \omega_{\text{opt}}(\mathcal{W}_j)$ and from the inequality (5) and (6), or from the inequality (5′), (6′), and (7) depending on whether the first slot of $\lambda(\mathcal{W}_j)$ is partial or not:

$$\text{(8)} \qquad \omega(\mathcal{W}_j) \leq (2-2/m)\omega_{\text{opt}}(\mathcal{W}_j) - (m-3)/m.$$

The inequality (8) is refined by factorizing its righthand member, which becomes equal to

$$\text{(8)} \qquad 2\omega_{\text{opt}}(\mathcal{W}_j) - 1 - \frac{2\omega_{\text{opt}}(\mathcal{W}) - 3}{m}.$$

When m is even, the term $(2\omega_{\text{opt}}(\mathcal{W}) - 3)/m$ cannot be integer, and hence (8) can be changed into (8′):

$$\text{(8}'\text{)} \qquad \omega(\mathcal{W}_j) \leq (2-2/m)\omega_{\text{opt}}(\mathcal{W}_j) - (m-2)/m.$$

Figure 5 presents the worst case leading to (8) or (8′). The local-bound lemma ensues from these facts (*odd* (m) is equal to 1 if m is odd and is equal to 0 otherwise).

LOCAL-BOUND LEMMA. *Let a schedule of* $(\mathcal{C}, \ll)$ *be computed on m machines by the* ECG-*algorithm and* $\mathcal{W}$ *be a segment with respect to this schedule. If* $m \geq 2$, *then*

$$\omega(\mathcal{W}) \leq \left(2 - \frac{2}{m}\right) w_{\text{opt}}(\mathcal{W}) - \frac{m - 2 - \text{odd}(m)}{m}$$

and the equality is achieved in the worst case.

6.5. The worst-case bound. We remain in the context of the subsection 6.4. If the critical block $\mathcal{Y}_{j+1}$ exists, the segment $\mathcal{W}_j$ precedes $\mathcal{Y}_{j+1}$ by definition. Furthermore, the critical task of $\mathcal{Y}_{j+1}$ precedes each task of the blocks to its right and each additional task of $\mathcal{W}_{j+1}$ is preceded by a task of $\mathcal{Y}_{j+1}$. Thus $\mathcal{W}_j \ll \mathcal{W}_{j+1}$ and the segments make up a chain. The local-bound lemma can hence be extended to the entire set of tasks:

THEOREM. *Let a schedule of* $(\mathcal{C}, \ll)$ *be computed on m machines by the* ECG-*algorithm. If* $m \geq 2$, *then*

$$\omega(\mathcal{C}) \leq \left(2 - \frac{2}{m}\right) \omega_{\text{opt}}(\mathcal{C}) - \frac{m - 2 - \text{odd}(m)}{m}$$

and the equality is possible.

The analysis we have presented still holds if the set $\mathcal{S}(T)$ includes all the successors of T rather than its immediate successors only. The only point that is different if $\mathcal{S}(T)$ includes all the successors of T is the proof of the segment properties that is based on the segment definition. It becomes simpler. Therefore, if the transitive closure of the graph to be scheduled is available, it is not necessary to compute the transitive reduction of the graph.

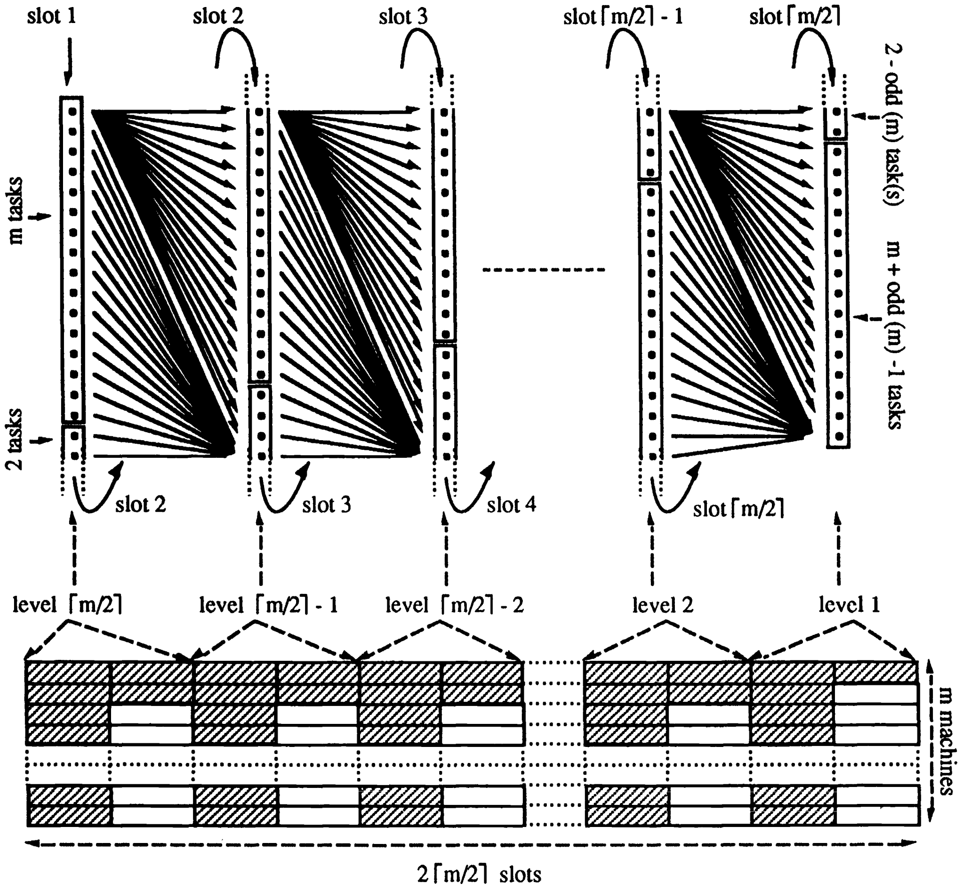

FIG. 5. *Worst-case instance of the local-bound lemma. The graph is made up of* $\lceil m/2 \rceil$ *levels, following a basic critical-path analysis. The first level is composed of* $m + 1$ *tasks and all other levels include* $m + 2$ *tasks. The task at the top of the figure on level* $i, i > 1$ *precedes all the tasks on level* $i - 1$ *except the task at the bottom. On the one hand, the optimal schedule on m machines is sketched directly on the graph: the boxes show the tasks executed during a particular slot. The length of the optimal schedule is* $\lceil m/2 \rceil + 1$*. On the other hand, we give priorities to the task according to the CG-rule and we break the ties between two tasks by giving the lowest priority to the topmost task. In each level, the priorities are decreasing from the bottom to the top. The induced schedule length is* $2\lceil m/2 \rceil$.

A NEW APPROACH TO STABLE MATCHING PROBLEMS*

ASHOK SUBRAMANIAN†

Abstract. It is shown that Stable Matching problems are the same as problems about stable configurations of X-networks. Consequences include easy proofs of old theorems, a new simple algorithm for finding a stable matching, an understanding of the difference between Stable Marriage and Stable Roommates, NP-completeness of Three-party Stable Marriage, CC-completeness of several Stable Matching problems, and a fast parallel reduction from the Stable Marriage problem to the Assignment problem.

Key words. stable matching, stable marriage, stable roommates, stable configuration, circuit value, network stability, parallel complexity, comparator, CC, scatter, assignment problem, weighted matching

1. Introduction.

In a Stable Matching problem, the task is to match a number of persons in pairs, subject to certain preference information. Briefly, each person regards some of the others as acceptable mates and ranks them in order of preference. A matching is unstable if there are two persons, not matched to each other, who would rather be together. The task is to find a stable matching, i.e., one that is not unstable.

This problem was first studied by Gale and Shapley [7]. They showed that a stable matching always exists if the problem is a Marriage problem, i.e., if the participants can be divided into two sexes, the men and the women, in such a way that the acceptable mates of each person are all of the opposite sex; in fact, they gave a linear-time algorithm to find such a matching. Irving, in [14], gave a linear-time algorithm for the general problem. An introductory treatment of Stable Matching appears in [23]; a comprehensive treatment may be found in [12].

This paper explores the relationship between Stable Matching and Network Stability. For our purposes, a network is a boolean circuit with feedback. The task in Network Stability is, given a network and its inputs, to find an assignment of boolean values to the edges of the network that respects the input constraints and the gate equations. The Network Stability problem is NP-complete in general [21], but when every gate in the network is a special gate called the X-gate, the problem becomes equivalent to Stable Matching. The X-gate has a certain nice property—it is *scatter-free*. We exploit this property to solve X-Network Stability efficiently.

The appropriateness of the new framework is illustrated by new easy proofs of old theorems and simple algorithms. We give simple linear-time algorithms for finding a stable matching and for finding a "minimum-regret" stable matching. For both of these problems, optimal algorithms were already known [14], [15]. We give an easy proof of the theorem of Gale and Sotomayor [8] that every stable matching of a given instance matches the same set of persons. We also prove a structural theorem that might help us understand why certain instances of Stable Matching have no solutions. We give a new simple proof of the #P-completeness of counting the number of solutions to an instance of Stable Matching; this result, in a stronger form, was first proven in [16]. It turns out that just as Stable Matching is equivalent to Network Stability for X-networks, a certain "three-party" version of Stable Matching is equivalent to Network Stability for Y-networks. We use properties of the Y-gate to

conclude that Three-party Stable Marriage is NP-complete, thus partly answering a question posed by Knuth [20].

It has been observed repeatedly that the Stable Marriage problem seems easier and has more structure than Stable Matching. We explain this difference by observing that the networks corresponding to Stable Marriage are comparator networks. The comparator gate is a simpler gate than the X-gate. The monotonicity of the comparator is responsible for the fact that Stable Marriage instances always have solutions. Also, Conway's lattice theorem for Stable Marriage can be viewed as a direct consequence of the lattice theorem for comparator networks.

We also study the parallel complexity of Stable Matching. While we do not give any fast parallel algorithms for the problem, we do point out that several problems related to Stable Matching are complete for the class CC of problems defined in [21]. We use these ideas to give a fast parallel reduction from the Stable Marriage problem to the Assignment problem, thus partially solving a problem of Knuth [20].

Our approach does not seem to apply when the instances of Stable Matching have ties or when issues of deceit are involved. It does not explore the structure of all stable matchings of an instance, as does the work of Gusfield [10], [11], Irving [15], [17], or Feder [5].

2. Preliminaries.

2.1. Stable Matching.

An instance of Stable Matching (also called Stable Roommates) consists of a set of persons, each of whom regards some of the others as acceptable mates, and ranks them in decreasing order of preference. For our purposes we may assume that acceptability is mutual—x is acceptable to y if and only if y is acceptable to x. A matching is a pairing of some or all of the persons. A matching may be *unstable* in three ways—two unmatched persons may find each other acceptable; a matched person may prefer an unmatched person to his current mate; or two matched persons may prefer each other to their current mates. A matching that is not unstable is said to be *stable*.

An instance of Stable Matching is an instance of Stable Marriage if the persons can be divided into two sets, the men and the women, so that the acceptable mates of each person are all of the opposite sex. An instance of Stable Matching is an instance of Complete Stable Matching if there are an even number of persons and each person is acceptable to everyone else. Similarly, an instance of Stable Marriage is an instance of Complete Stable Marriage if there are an equal number of men and women and each person is acceptable to every person of the opposite sex.

The size of an instance of Stable Matching is the sum, over all persons x, of the number of persons acceptable to x. The most common tasks associated with an instance of Stable Matching are to determine whether a stable matching exists and to construct one if possible. Other tasks might include counting and enumerating all stable matchings of a given instance.

Remark. Historically, most of the interest in the literature has been in Complete Stable Marriage and Complete Stable Matching; these problems are commonly called the Stable Marriage and Stable Roommates problems, respectively. Also, it has been traditional to measure the running time of algorithms in terms of the number of participants and not in terms of the "length of the input." Our departure from this tradition might lead to one cause of confusion: algorithms that we describe as linear time (in terms of the size of the instance) might be described in the literature as taking quadratic time (in terms of the number of participants).

2.2. Gates, circuits, and networks.

The definitions in this section and in §2.3 are taken almost entirely from [21].

A λ-input, μ-output *gate* is a function $g : \{0, 1\}^\lambda \rightarrow \{0, 1\}^\mu$ from λ-bit input words to μ-bit output words. In this paper, all gates have a fixed number of inputs and outputs. Further, a gate does not have useless inputs or outputs—each input bit affects some output bit, and each output bit depends nontrivially on some input bit. A *basis* is a set of gates. The gates that appear in this paper are listed in Table 1.

TABLE 1
The gates that appear in this paper.

Gate	Inputs	Outputs
ID	i_1	$o_1 = i_1$
COPY	i_1	$o_1 = i_1,\ o_2 = i_1$
NOT	i_1	$o_1 = \overline{i_1}$
AND	i_1, i_2	$o_1 = i_1\, i_2$
OR	i_1, i_2	$o_1 = i_1 + i_2$
NAND	i_1, i_2	$o_1 = \overline{i_1} + \overline{i_2}$
C	i_1, i_2	$o_1 = i_1\, i_2,\ o_2 = i_1 + i_2$
X	i_1, i_2	$o_1 = i_1\, \overline{i_2},\ o_2 = \overline{i_1}\, i_2$
Y	i_1, i_2, i_3	$o_1 = i_1\, (\overline{i_2} + \overline{i_3}),\ o_2 = i_2\, (\overline{i_1} + \overline{i_3}),\ o_3 = i_3\, (\overline{i_1} + \overline{i_2})$

A *network* is a finite labeled directed graph. Source (in-degree zero) nodes of the directed graph have out-degree one and are called input nodes; sink (out-degree zero) nodes have in-degree one and are called output nodes. Each internal node is labeled with a gate and an ordering of its predecessors and successors. If an internal node has in-degree λ and out-degree μ, its gate has λ inputs and μ outputs. If the underlying directed graph of a network is acyclic, the network is called a *circuit*. A circuit computes a set of functions in the standard manner. A network (circuit) is said to be *over* a basis Ω if every gate in it is from Ω. The *size* of a network is the number of edges in it.

Our definition of circuit differs from the standard definition in two respects—all fanout is explicit and must occur within a gate, and multiple-output gates are allowed. Our definition of "network" is nonstandard. A network is essentially a combinational circuit with feedback; it is not intended to compute anything.

A gate g_1 is a *restriction* of gate g_2 if it can be obtained as follows. Fix a subset (possibly empty) of the inputs of g_2 to constant values. This operation fixes a (possibly empty) set of outputs of g_2 to constant values. Now discard all the inputs and outputs of g_2 that are fixed and perhaps some outputs that are not fixed. For example, the *NOT*-gate is a restriction of the X-gate, obtained by fixing any one input of the X-gate to 1. Also, the *closure* of any basis Ω is the basis Ω^* consisting of all restrictions of gates in Ω.

Gate g can be *simulated* by basis Ω if g is a restriction of the function computed by some circuit over Ω. We say, for convenience, that gate g_1 can be simulated by gate g_2 when we mean g_1 can be simulated by the basis $\{g_2\}$; similarly, we say a basis can be simulated (by another basis) if every gate in it can be simulated. For instance, a gate (or basis) is monotone if it cannot simulate $\{$*NOT*$\}$.

A gate has *scatter* if it has a restriction that has more outputs than inputs; otherwise, it is *scatter-free*. A basis is said to be scatter-free if every gate in it is scatter-free. All the gates in Table 1, except the *COPY*-gate and the Y-gate, are scatter-free.

The X-gate and the C-gate (comparator) play crucial roles in this paper. These gates are scatter-free; in addition, the comparator is monotone. Many of the results of this paper rely on these elementary facts.

The following easy lemma is crucial.

LEMMA 2.1. *Let N be any network over a scatter-free basis Ω. Then N has at most as many outputs as inputs. In particular, if N has no inputs, it has no outputs.*

Proof. Sum the quantity (#(inputs of g) $-$ #(outputs of g)) over all gates g of N. Each input edge of N is an input edge of exactly one gate of N and thus contributes one to the sum;

similarly, each output edge of N contributes minus one. Each internal edge of N is an input edge of exactly one gate of N and an output edge of exactly one gate of N and so contributes zero. Thus the sum equals the difference between the number of inputs of N and the number of outputs of N. Notice, however, that the sum is nonnegative, because each (scatter-free) gate of N contributes a nonnegative quantity to the sum; hence N has at most as many outputs as inputs. □

2.2.1. X-networks and snakes in X-networks. An X-network is a network over $\{X\}$. We introduce some terminology to describe X-networks. Recall that the X-gate has inputs i_1, i_2 and outputs $o_1 = i_1 \overline{i_2}$, $o_2 = \overline{i_1} i_2$. We *associate* input i_j and output o_j. This association allows us to describe an X-network in terms of *snakes*. A snake is a sequence of edges; the sequence may be cyclic or acyclic. If an input edge of an X-gate is in snake q, the associated output edge is the next element of q; if an output edge of an X-gate is in q, the associated input edge is the previous element of q. The first element of an acyclic snake is thus an input edge of the network; the last element of an acyclic snake is an output edge of the network. The snakes of a network constitute a partition of its edges.

We often describe an X-network by naming its snakes and telling how they meet each other; in such a description, the gates are implicit—there is a gate wherever two snakes meet. We say that a snake enters a gate with value v if the edge of the snake that is an input to the gate has the value v. (Some care is needed, because a snake could enter the same gate twice, once through each input.)

2.3. The Circuit Value and Network Stability problems. The Circuit Value problem (CV) is the task of computing the value assigned to a specified output of a circuit, when the circuit is evaluated on a given input assignment. More formally, given a circuit with λ inputs and an input assignment $s_{\text{in}} \in \{0, 1\}^\lambda$ to the circuit, determine whether the specified output takes the value 1.

The Network Stability problem is a question about the existence of *configurations* of a network consistent with a given input assignment. Let N be a network with $\lambda \geq 0$ inputs. Let $s_{\text{in}} \in \{0, 1\}^\lambda$ be an input assignment to N. A *configuration* Q of N is an assignment of boolean values (0s and 1s) to the edges of N. It is a *stable configuration* of $[N, s_{\text{in}}]$ if it satisfies the gate equations at each internal node and is consistent with the input assignment s_{in}. The *Network Stability problem* (NS) is this: given a network N and an input assignment s_{in}, determine whether $[N, s_{\text{in}}]$ has a stable configuration. Often we leave the input assignment implicit, and say "N has a stable configuration" when we mean "$[N, s_{\text{in}}]$ has a stable configuration."

Given a basis Ω, we define Ω-CV and Ω-NS to be the special cases of CV and NS, respectively, in which the network is required to be over Ω. For instance, C-CV is the circuit value problem for comparator circuits, and X-NS is the stability problem for X-networks.

The input assignment that assigns every input of a network the value 1 is called **1**; the empty input assignment is called **e**.

3. The Stable Matching problem is an X-Network Stability problem. We show how to transform an instance I of Stable Matching into an X-network N in such a way that the stable matchings of I are in one-to-one correspondence with the stable configurations of $[N, \mathbf{1}]$. Here is the transformation. Network N has one acyclic snake q_x for each person x of instance I; there are no other snakes. Snakes q_x and q_y meet if and only if x and y find each other acceptable; snake q_x meets the snakes of other persons in the order that these persons appear on the preference list of person x, i.e., in decreasing order of their popularity with x. Any two snakes meet at most once; no snake meets itself. This description completely specifies N. We present a method to construct N given the description. For each pair x, y of persons who find each other acceptable, introduce an X-gate labeled with the pair $\{x, y\}$. For each person, introduce a snake that visits all the gates whose labels contain his name, in the order determined by his preference list. This completes the construction. An example is shown in Fig. 1. (In this figure, the snake of each person is labeled with his name for clarity.)

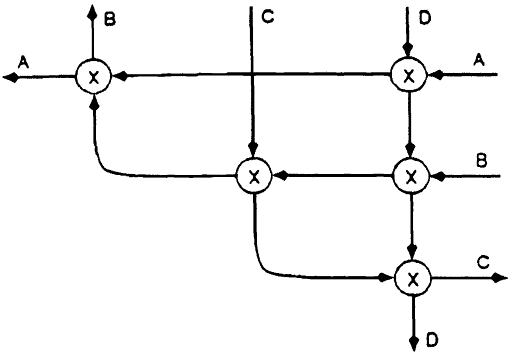

FIG. 1. *Reducing Stable Matching to X-Network Stability.*

In §3.1, we prove a lemma about stable configurations of X-networks. We then prove the correspondence between stable matchings and stable configurations in §3.2.

3.1. A preliminary lemma about stable configurations of X-networks. Let N be any X-network without cyclic snakes. Let Q be a stable configuration of $[N, \mathbf{1}]$. The stability of Q places two conditions upon it—it must satisfy the input assignment, and it must satisfy all the gate equations. Let us investigate what these conditions really mean. Let $q = \langle e_1, e_2, \ldots \rangle$ be any snake of N; for each j, let v_j be the value on edge e_j. Every input edge has the value 1, so $v_1 = 1$. The behaviour of the X-gate requires that $v_j = 0 \Rightarrow v_{j+1} = 0$. Thus, the sequence $\langle v_1, v_2, \ldots \rangle$ is a sequence of 1s, followed perhaps by a sequence of 0s. Define the *1-segment* of snake q in configuration Q to be the subsequence of edges that have value 1.

We say that snake q *drops* at gate g if the 1-segment of q ends at gate g; we say that g is the endpoint of the 1-segment of q. (A snake that has the value 1 along its entire length is identical with its 1-segment and has no endpoint.) It is clear that each snake drops at most once.

A snake that enters a gate with value 1 will drop if and only if the other snake entering the gate also enters with value 1. Thus, snakes must drop in pairs. Also, the 1-segments of different snakes cannot share vertices, except possibly a common endpoint. We describe this situation informally by saying that 1-segments avoid one another.

It turns out that the conditions listed above are necessary and sufficient for Q to be a stable configuration. In other words,

LEMMA 3.1. *Let N be an X-network without cyclic snakes; let Q be a configuration of* $[N, \mathbf{1}]$. *Then Q is stable if and only if:*

(i) *the values on any given snake of N form a nonempty sequence of* 1*s, followed by a possibly empty sequence of* 0*s,*

(ii) *snakes drop in pairs, and*

(iii) *the* 1*-segments of different snakes avoid one another.*

Proof. We have already seen that the above three conditions will be met if Q is stable. Suppose now that Q is a configuration that meets the three conditions; we show that Q must be stable. The first value on each snake is a 1, so the input conditions are satisfied. Let g be an arbitrary gate of N; we must show that the gate equations are satisfied at g. If both snakes entering g do so with value 0, condition (i) requires that both outputs of g be 0 as well. If one snake is 0 and the other is 1 while entering g, conditions (i) and (ii) demand that both snakes leave g with the same values with which they entered it. If both snakes are 1 while entering g, condition (iii) demands that both drop. In all three cases, the gate equations are satisfied. □

3.2. The correspondence between stable matchings and stable configurations.

THEOREM 3.2. *Let I be an instance of Stable Matching; let N be the corresponding X-network. Then there is a one-to-one correspondence between the stable matchings of I and the stable configurations of* $[N, \mathbf{1}]$.

Proof. The rule to read off a matching of I from a stable configuration of $[N, \mathbf{1}]$ is this: two persons are matched to each other if their snakes drop together; a person is unmatched if his snake does not drop. To produce the configuration of $[N, \mathbf{1}]$ corresponding to a given matching of I, we invert the above rule: if person x is matched to person y, snake q_x takes the value 1 until it meets snake q_y and the value 0 thereafter; if x is unmatched, snake q_x is 1 along its entire length. We now show that stable configurations yield stable matchings and vice-versa.

Suppose that stable configuration Q yields matching M. Assume that M is unstable. Hence there must be two persons x and y, each of whom prefers the other to his mate in M or to the state of being unmatched. Since x and y are acceptable to each other, snakes q_x and q_y meet. We claim that q_x is 1 after meeting q_y. To prove the claim, we consider two cases. If x is unmatched, then q_x must be 1 along its entire length, and we are done. In the other case, let z be the mate of x. Then q_x and q_z must meet with value 1; hence q_x must be 1 all the way until it meets q_z. Since x prefers y to z (by hypothesis), q_x meets q_y *before* it meets q_z. It follows that q_x is 1 after meeting q_y; this proves the claim. By an entirely analogous argument, q_y is 1 after meeting q_x. This means that the 1-segments of q_x and q_y do not avoid one another. Lemma 3.1 tells us that Q must be unstable, which is a contradiction. Hence M must be stable.

Now suppose that stable matching M yields configuration Q. It is clear that Q meets conditions (i) and (ii) of Lemma 3.1. To prove that Q is stable, it suffices to show that condition (iii) is met as well. Assume, for the sake of contradiction, that there are two persons whose snakes violate condition (iii). Then it follows that each of these persons prefers the other to his mate (if any) in M, contradicting the stability of M. □

Remark. We reiterate the meaning of the value assigned to an edge by a stable configuration of $[N, \mathbf{1}]$. Let e be the edge of snake q_x just after q_x meets q_y. Then e is assigned the value 0 in a stable configuration of $[N, \mathbf{1}]$ if and only if x has a mate no worse than y in the corresponding stable matching of I.

4. Solving Network Stability for scatter-free networks.

4.1. The algorithm. In this section, we show how to construct a stable configuration of a network over any scatter-free basis. This algorithm was presented in [21]. The X-gate is scatter-free, so the results of this section apply to Stable Matching. In particular, we get a simple linear-time algorithm for constructing a Stable Matching. A different linear-time algorithm for this problem was already known [14].

Let N be any network over a scatter-free basis Ω; let s_{in} be an input assignment to N. We show how to find a stable configuration of $[N, s_{\text{in}}]$. The interesting case is when N has no inputs, i.e., when s_{in} is the null assignment $\mathbf{e}$. Otherwise, we could use the input assignment to simplify the network. After all, if we know the value of an input to a gate g, we can replace g by a restriction with fewer inputs and perhaps deduce the value of some of the outputs of g. Iterating this process of "input elimination" yields a partial assignment P

of values to edges and an input-free network N' on the remaining edges, with the property that the stable configurations of $[N, s_{\text{in}}]$ are obtained by augmenting the stable configurations of $[N', \mathbf{e}]$ with P. In particular, $[N, s_{\text{in}}]$ has a stable configuration if and only if $[N', \mathbf{e}]$ does. Notice that the time taken to perform input elimination is linear in the amount of simplification performed, i.e., in the number of edges that are assigned values by the partial assignment P. The order in which the inputs are eliminated is immaterial; in fact, the process is properly regarded as a concurrent process, although we do not use this fact here. Lemma 2.1 assures us that N' will have no outputs. Henceforth we will simply assume that N has no inputs or outputs.

Consider what happens if we break an edge e of N, thus creating an input $e(\text{in})$ and an output $e(\text{out})$, and then place the value $v \in \{0, 1\}$ on $e(\text{in})$. We get a network with one input and one output; we may apply input elimination to this network. We call this the process of *propagating* the pair $[e, v]$. The following observation is crucial: the elimination of the sole input of the network must assign a value, say $v(\text{out})$, to the output edge $e(\text{out})$. To see this, apply Lemma 2.1 to the network that remains after the propagation. If $v(\text{out}) = v$, we say that the propagation is *successful* and that $[e, v]$ is *viable* in N. The result of a successful propagation is a partial assignment P and an input-free network N' on the remaining edges, with the property that the stable configurations of $[N, \mathbf{e}]$ that assign edge e the value v are obtained by augmenting the stable configurations of $[N', \mathbf{e}]$ with P. If, on the other hand, $v(\text{out}) \neq v$, no stable configuration of $[N, \mathbf{e}]$ may assign edge e the value v; in this case, we say the propagation is *unsuccessful*. Again, the time taken by a successful propagation is linearly related to the amount of simplification achieved.

The *type* of an edge in an input-free network is the set of viable values for it, i.e., $\text{type}_N(e) = \{v \mid [e, v] \text{ is viable in } N\}$. If $\text{type}_N(e) = \emptyset$, we say that e is a *contradicting* edge. Clearly, if the edge we select is contradicting, there can be no stable configurations. Also, if its type is $\{0\}$ or $\{1\}$, there is only one possible value that this edge could take in any stable configuration; thus we can assign this edge its value and simplify the network accordingly. The difficulty arises when both values seem possible, i.e., when $\text{type}_N(e) = \{0, 1\}$.

Our strategy in such a situation is to pick *either* value and proceed. Clearly, if we are lucky, we will make all the right choices and find a stable configuration. But what if we are unlucky? Might not a set of bad choices early on in the algorithm lead us to a situation where we can no longer complete the partial assignment we have to a stable configuration? Lemma 4.1 comes to our rescue, because it says that the type of an edge is preserved by successful propagations. This means that if we find a contradicting edge after performing a sequence of successful propagations, then the same edge must have been contradicting in the original network as well, meaning that there were no stable configurations from the start. In other words, there are no bad choices.

LEMMA 4.1. *Let N be an input-free network over a scatter-free basis Ω. Suppose that $[e_1, v_1]$ is viable in N. Let N' be the network left after propagating $[e_1, v_1]$ in N; let e_2 be an edge of N'. Then* $\text{type}_{N'}(e_2) = \text{type}_N(e_2)$.

Proof. This proof is due to Feder [6]; our original proof was much more complicated. We make the following definition. A *trace* of the propagation of $[e_0, v_0]$ in N is a sequence of statements that records all the assignments that are made during this propagation, along with the dependencies between the assignments. Each statement is of the form $e \leftarrow v$, meaning "edge e gets value v." The first statement is $e_0 \leftarrow v_0$ and constitutes the *preamble* of the trace; the rest of the trace is called its *body*. A statement in the body of the trace is said to be *terminal* if it mentions edge e_0. All other statements of the trace are *nonterminal*. Every statement in the body is derived from a subset of the nonterminal statements preceding it in the trace by invoking the equation of a single gate. The trace is complete, in the sense that all statements that are derivable in the above manner are included. A statement may occur at most once in the body of the trace; any subsequent occurrences would be redundant.

Each statement of a trace may be regarded as a step in the propagation process. A propagation succeeds if the statement $e_0 \leftarrow v_0$ appears in the body of the trace; it fails if the statement $e_0 \leftarrow \overline{v_0}$ appears in the body. Clearly both statements cannot appear simultaneously in the body of any trace; on the other hand, we know that at least one of these statements will appear in the body, because the network is input-free and scatter-free.

Let T_1 be a trace of $[e_1, v_1]$ in N; let T_2 be a trace of $[e_2, v_2]$ in N. The effect of propagating $[e_1, v_1]$ is to assign values to some edges of N. We would like to claim that, even after these assignments are made, each statement in the body of T_2 can still be inferred from the preamble of T_2. This would mean that propagating $[e_2, v_2]$ in N' will establish every assignment that would have been made by the propagation of $[e_2, v_2]$ in N that has not already been made by the propagation of $[e_1, v_1]$ in N. It would then follow that $[e_2, v_2]$ is viable in N if and only if it is viable in N', completing the proof of Lemma 4.1.

To prove the claim, it suffices to show that there is no conflict between the two traces. A conflict is a situation where the statement $e \leftarrow v$ appears in one trace while the statement $e \leftarrow \overline{v}$ appears in the other. We assume a conflict exists and derive a contradiction. Let S_2 be the earliest statement in T_2 that is involved in a conflict; assume that it says $e_c \leftarrow v_c$ and that it conflicts with statement S_1 of T_1. Statement S_2 cannot be in the preamble of T_2, because, by hypothesis, edge e_2 does not appear in T_1. Hence, edge e_c is the output of some gate; let this gate be g_c. The gate equations used to derive S_1 and S_2 assert that g_c has two partial input assignments P_1 and P_2, such that on one of these assignments, output e_c takes the value v_c, whereas on the other assignment, output e_c takes the value $\overline{v_c}$. Now, by the choice of S_2, the partial input assignments P_1 and P_2 do not conflict. Let P be the partial input assignment that is the union of P_1 and P_2. Consider the behaviour of gate g_c on P. Clearly, output e_c must be both 0 and 1 in this situation, which is a contradiction. □

An immediate consequence of Lemma 4.1 is the correctness of the following simple polynomial-time algorithm for constructing a stable configuration of a network over any scatter-free basis.

ALGORITHM 1.

1. Eliminate all inputs.
2. Pick any edge e. (If there are no edges, there is nothing to do.)
3. Determine that e is contradicting (in which case there are no stable configurations), or find a value v such that $[e, v]$ is viable.
4. Suppose $[e, v]$ is viable. Propagate $[e, v]$, obtaining a partial assignment P and a simplified network N'.
5. Find a stable configuration of N' and augment it with P to yield the desired stable configuration. If N' has no stable configuration, neither does N.

THEOREM 4.2. *Let N be a network over a scatter-free basis Ω; let s_{in} be any input assignment to N. There is a linear-time algorithm that will construct a stable configuration of $[N, s_{\text{in}}]$ if there is one, or conclude that none exists.*

Proof. Algorithm 1 can be implemented to run in time that is linear in the size (number of edges) of the network N. Notice that steps 1 and 4 take time linear in the amount of simplification they perform and that step 2 takes constant time. Also, if step 3 determines that e is contradicting, the time needed to do so is linear in the size of the network. The only obstacle to a linear run-time is that step 3 may take a long time to return a viable value v. To avoid this, we use the following standard trick. Implement step 3 as follows: propagate $[e, 0]$ and $[e, 1]$ "in parallel"; whichever propagation succeeds first determines the value v to be used in step 4. This guarantees that step 3 runs in time linear in the amount of simplification performed in step 4. The linear time bound for the algorithm follows from the observation that the size of N' in step 5 is less than the size of N by the amount of simplification achieved in step 4. □

The following corollary is useful in the context of parallel computation:

THEOREM 4.3. *Let N be an input-free network over a scatter-free basis Ω. Then N has a stable configuration if and only if it has no contradicting edge.*

Proof. If N has a contradicting edge, this edge can take neither the value 0 nor the value 1 in any stable configuration. Hence there cannot be any stable configurations. If, on the other hand, there are no contradicting edges, Algorithm 1 will find a stable configuration. □

The type of an edge has a nice interpretation:

THEOREM 4.4. *Let N be an input-free network over a scatter-free basis Ω; suppose that N has no contradicting edges. Let e be an edge of N. Then the* type *of e in N equals the set of values assigned to e in the (various) stable configurations of N.*

Proof. Clearly, if $[e, v]$ is not viable in N, then no stable configuration of N may assign e the value v. If $[e, v]$ is viable, on the other hand, we can construct a stable configuration that assigns e the value v, by letting $[e, v]$ be the first edge-value pair picked by Algorithm 1. □

The following theorem is proven for Stable Marriage in [8]; a proof for the Stable Matching case can be found in [12]. We give an easy alternative proof.

THEOREM 4.5. *The set of unmatched persons in any instance of Stable Matching is the same in every stable matching.*

Proof. Let I be an instance of Stable Matching; let N be the corresponding X-network. The process of eliminating the inputs of N assigns a value to every output edge of N. Hence every stable configuration of $[N, \mathbf{1}]$ has the same output assignment. The theorem follows by observing that a person is unmatched in a stable matching of instance I if and only if the output edge of his snake takes the value 1 in the corresponding stable configuration of $[N, \mathbf{1}]$. □

It is an interesting exercise to interpret Irving's original algorithm for Stable Matching [14] in the network framework. Phase 1 of Irving's algorithm achieves essentially the same effect as input elimination on the appropriate X-network. Each phase 2 reduction of Irving's algorithm either finds a contradicting edge (and concludes that there are no stable configurations) or finds a viable edge-value pair, propagates it, and simplifies the network accordingly. The specific method used by Irving to find the viable edge-value pair (the seek-cycle procedure) is sophisticated and uses specific properties of X-gates that are not shared by all scatter-free gates. The amount of simplification achieved is proportional to the length of the all-or-nothing cycle found, whereas the amount of time spent in a phase 2 reduction is proportional to the length of the all-or-nothing cycle plus the length of the "tail"; hence Irving uses the device of remembering the tail in order to achieve a linear-time algorithm.

4.2. Application to Minimum-regret Stable Matching. Algorithm 1 has two kinds of flexibility: edge e may be chosen to be any edge of the network, and there is some flexibility in the choice of value v. We have already demonstrated how to use the second kind of flexibility to make the algorithm run in linear time. Here we explore a different possibility.

Let I be any instance of Stable Matching. The *regret* of a participant in a stable matching of I is the position of his mate on his preference list. Thus, a participant who gets his first choice of mate has regret 1. Clearly, each participant would like to minimize his regret. In the Minimum-regret Stable Matching problem, we seek a stable matching that minimizes the largest regret among all the participants. A linear-time algorithm is given in [10]. However, this algorithm relies on nontrivial properties of the structure of all stable matchings of an instance of Stable Marriage; moreover, it works only for instances of Stable Marriage. Irving [15] gives a linear-time algorithm that works for all instances of Stable Matching; see [12] for an exposition. We give a different linear-time solution based on the network formulation.

We assume that I has a stable matching and that no person is unmatched in the stable matchings of I. The second assumption is legal because, by Theorem 4.5, the unmatched persons are the same in every stable matching; hence we can find these unmatched persons by input elimination in linear time, delete them, and find a minimum-regret matching of the remaining participants.

Define regret(I) to be the value of the largest regret in a minimum-regret stable matching of I. The crux of the problem is the computation of regret(I). We first show how to proceed if regret(I) is known and then show how to compute regret(I).

Suppose regret$(I) = r$. Delete from each person's list all but the first r persons, and then make the acceptability relation symmetric: if person x does not appear on the list of person y, delete y from the list of person x. Let us call the resulting instance I_r. It is easily checked that the stable matchings of I_r are precisely the minimum-regret stable matchings of I. A stable matching of I_r may be found in linear time by using the strategy outlined in the proof of Theorem 4.2.

We show how a modified version of Algorithm 1 can compute regret(I) in linear time. Let N be the X-network for I. Number each edge of N by its position on its snake: input edges get the number 1; output edges get big numbers. The value of the largest regret in any stable matching is given by the largest number of an edge, among all the edges with value 1 in the corresponding stable configuration. This means that the way to get a small regret is to assign the value 0 to the edges with big numbers.

Run Algorithm 1 with the following modifications. Whenever we have to pick an edge-value pair to propagate, we choose an edge e that has the largest number and assign it the value 0. Suppose edge e is the edge numbered k on the snake of person x. Then assigning e the value 0 amounts to guaranteeing that person x gets one of his first $(k-1)$ choices. If the propagation of $[e, 0]$ fails, there is no stable matching, consistent with the choices already made, that assigns x one of his first $(k-1)$ choices; hence regret(I) must be k. (The reason it cannot be larger than k is because at the time we assign edge e the value 0, we have already succeeded in assigning every edge with number larger than k the value 0.) Also, if the propagation assigns the value 1 to another edge with number k, then again the value of the minimum regret is k. We continue assigning the value 0 to more and more edges with large numbers, until ultimately one of the two exit conditions applies. Thus this algorithm will compute regret(I). To see that it takes linear time, observe that the time taken by all the successful propagations taken together is linear in the number of edges of N; also, there is at most one unsuccessful propagation, which can take at most linear time.

5. The structure of the network of contradicting edges. Theorem 4.3 says that if an instance of X-network stability has no stable configurations, the associated input-free network contains at least one contradicting edge. In this section, we prove that the contradicting edges form disjoint cycles, each containing an odd number of *NOT*-gates. We believe this is a step toward understanding why certain instances of Stable Matching do not have stable matchings.

LEMMA 5.1. *Let N be any input-free network over X^*. Suppose that $[e_1, v_1]$ is viable in N and that edge e_2 is assigned the value v_2 during the propagation of $[e_1, v_1]$. Then $[e_2, v_2]$ is viable in N.*

Proof. As in the proof of Lemma 4.1, let T_1 be a trace of $[e_1, v_1]$ in N and T_2 be a trace of $[e_2, v_2]$ in N. If $e_1 = e_2$, then $v_1 = v_2$ and there is nothing to prove; so assume that $e_1 \neq e_2$. Notice that the preamble of T_2 occurs in T_1, and every statement of T_1 occurs as a nonterminal statement in T_1. Hence we may show inductively that each statement of T_2 occurs in T_1. It follows that the value assigned to edge e_2 by the propagation of $[e_2, v_2]$ is v_2. □

Lemma 5.1 says that successful propagations do not assign values to contradicting edges. By repeatedly performing successful propagations, we can assign values to all noncontradicting edges. What is left is an input-free network $N_\emptyset$ over X^* consisting of exactly the contradicting edges.

LEMMA 5.2. *The network $N_\emptyset$ of contradicting edges does not contain any X-gates.*

Proof. Assume the opposite, that $N_\emptyset$ contains an X-gate g, with input edges i_1, i_2 and output edges o_1, o_2. We derive a contradiction.

Let T_1 be a trace of $[o_1, 0]$ in $N_\emptyset$. Since o_1 is contradicting, the statement $o_1 \leftarrow 1$ must appear in the body of T_1. In order for this to happen, statements $i_1 \leftarrow 1$ and $i_2 \leftarrow 0$ must also appear in T_1; hence so must $o_2 \leftarrow 0$.

Now let T_2 be a trace of $[o_2, 0]$ in $N_\emptyset$. Edge o_2 must be assigned a value by the propagation of $[o_2, 0]$; hence at least one of the edges i_1 or i_2 must be assigned a value during this propagation. Let S be the first statement in the body of T_2 that assigns a value to any of the edges incident upon gate g. Clearly, statement S assigns a value to either i_1 or i_2. We claim that S appears in T_1. To prove the claim, observe that the preamble of T_2 occurs in T_1 and that the derivation of S in T_2 does not involve edge o_1 in any intermediate step. Hence we may prove inductively that every statement involved in the derivation of S in T_2 occurs as a nonterminal statement in T_1, and the claim follows. Thus S must be either $i_1 \leftarrow 1$ or $i_2 \leftarrow 0$. In either case, the statement $o_2 \leftarrow 0$ will appear in the body of T_2. This indicates that $[o_2, 0]$ is viable, which is a contradiction. □

THEOREM 5.3. *Each connected component of $N_\emptyset$ is a directed cycle over the basis $\{ID, NOT\}$ with an odd number of NOT-gates.*

Proof. Follows from the fact that $N_\emptyset$ is input-free and contains no X-gates. Each cycle must have an odd number of NOT-gates in order for the edges on it to be contradicting. □

Remark. The results of this section extend naturally to the case where N is over any scatter-free basis, but the proof of Theorem 5.3 is more involved. (See [27] for details.)

6. The case of Stable Marriage.

In this section, we examine the X-networks arising from instances of Stable Marriage. We show that these networks of X-gates may be replaced by comparator networks. This observation, together with the monotonicity of the comparator, yield easy algorithms for certain problems associated with Stable Marriage.

6.1. Bipartitionable X-networks and comparator networks.

A network of X-gates is *bipartitionable* if its snakes can be two-colored so that snakes of the same color never meet; such a coloring is called a bipartition. In any bipartition, the color of an edge is defined to be the color of the snake to which it belongs. In this paper, whenever we say that a network is bipartitionable, we shall implicitly mean that a bipartition is given. The X-networks corresponding to instances of Stable Marriage are bipartitionable: color the snakes of the men red and the snakes of the women blue. This shows that instances of Stable Marriage may be solved by solving X-Network Stability for bipartitionable X-networks. The converse is also true; see §7.3.

We adopt the following conventions: in all diagrams containing X-gates, an input and its associated output appear opposite each other; in diagrams of bipartitionable X-networks, the red edges are drawn vertically and the blue edges are drawn horizontally; in all bipartitionable networks derived from instances of Stable Marriage, the red snakes belong to men and the blue snakes belong to women.

Given a bipartitionable X-network N and an input assignment s_{in}, we show how to transform them into a comparator network N' and an input assignment s'_{in} to N' in such a way that the stable configurations of $[N, s_{\text{in}}]$ and $[N', s'_{\text{in}}]$ are isomorphic. Bipartition the snakes of N into red and blue snakes. Replace every blue edge of the network by two *NOT*-gates in series. Regard every X-gate g to be part of a triplet of gates: g, the *NOT*-gate on the blue input of g, and the *NOT*-gate on the blue output of g. Each triplet is functionally equivalent to, and hence may be replaced by, a comparator; see Fig. 2(a). After these replacements, the only noncomparator gates in the network are the *NOT*-gates on the blue inputs and outputs. These *NOT*-gates just mean that the input and output assignments of the two networks do not match exactly: the blue bits have to be complemented. Delete the *NOT*-gates to get N'. To get s'_{in}, complement the blue input bits of s_{in}.

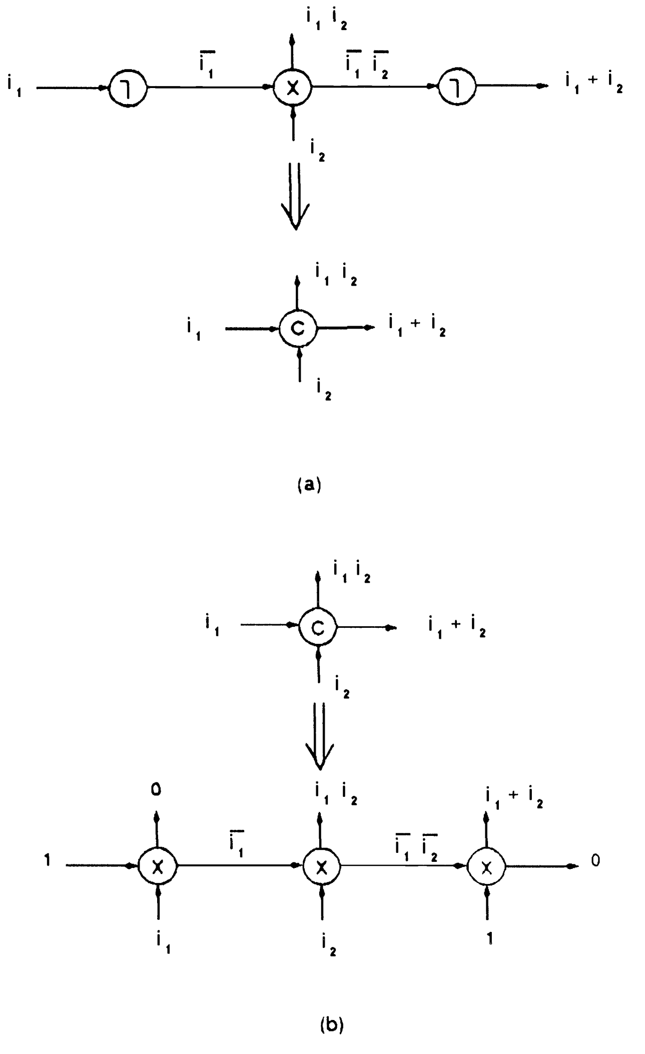

FIG. 2. *Interchanging comparators and X-gates.*

Essentially the same transformation may be used to replace a comparator network by a bipartitionable X-network on a different input assignment. Proceed as follows. Replace each comparator by three X-gates as shown in Fig. 2(b). A bipartition of the resulting X-network is obtained by coloring all the "horizontal" snakes blue and all the "vertical" snakes red.

These transformations show that finding stable configurations in bipartitionable X-networks is just the same as finding stable configurations in comparator networks. Thus, we may find stable matchings for instances of Stable Marriage by finding stable configurations of comparator networks.

6.2. Applications. In this section, we give linear-time algorithms for some problems related to Stable Marriage. For convenience of presentation, we phrase the following discussion partly in terms of bipartitionable X-networks and partly in terms of comparators.

6.2.1. Existence of stable matchings. The standard way to show that every instance of Stable Marriage has a stable matching is to give an algorithm, the proposal algorithm of [7], that finds the *man-optimal* stable matching in linear time. It is nice to be able to give a proof of the existence of stable matchings that does not involve an algorithm. Here is such a proof. An instance of Stable Marriage has a stable matching if and only if the associated comparator network has a stable configuration (on the appropriate input assignment). Comparator gates are monotone; monotone networks always have stable configurations.

6.2.2. Finding a stable matching. Finding a stable configuration of a monotone network is easy: eliminate the inputs, and then assign all remaining edges the value 0. This stable configuration is the "most-0" stable configuration Q^0 of the network (on the given input assignment), because every edge that is assigned the value 1 in this stable configuration must have the value 1 in every stable configuration. We show that this strategy yields the man-optimal stable matching found by the proposal algorithm of [7].

THEOREM 6.1. *Let I be an instance of Stable Marriage; let $[N, s_{\text{in}}]$ be the associated instance of Comparator Network Stability. Then the "most-0" stable configuration Q^0 of $[N, s_{\text{in}}]$ yields the man-optimal stable matching of I.*

Proof. Let $\tilde{N}$ be the X-network corresponding to I. (Thus, N is obtained from $\tilde{N}$ by applying the first transformation of §6.1.) The configuration of $[\tilde{N}, \mathbf{1}]$ that corresponds to Q^0 has the following property: it assigns each edge on a red snake the value 1 only if it must be 1 in every stable configuration of $[\tilde{N}, \mathbf{1}]$; likewise, each edge on a blue snake is 0 only if it must be 0 in every stable configuration of $[\tilde{N}, \mathbf{1}]$. The implication for the Stable Marriage instance is that the stable matching found by the above procedure assigns every man the best possible mate he could get in any stable matching; similarly, every woman gets the worst possible mate she could get in any stable matching. □

We may obtain the woman-optimal stable matching by an analogous procedure: eliminate the inputs of N, and then assign the remaining edges the value 1. Thus input elimination gives us both extremal matchings. The first phase of Irving's algorithm [14] also simultaneously finds both extremal matchings in instances of Stable Marriage.

6.2.3. Stable matchings are fixpoints. Any network stability problem may be viewed as a fixpoint problem: find a configuration that is a fixpoint of the network. The discussion in §6.2.2 tells us that the man-optimal and woman-optimal stable matchings of an instance of Stable Marriage are given by the least (maximally false) and greatest (maximally true) fixpoints respectively of the following system of equations: for every edge e of the comparator network, introduce a boolean variable $one(e)$ (intended to evaluate to true exactly if edge e is assigned the value 1); for each red input edge e of the network, introduce the ground condition $one(e)$; for each blue input edge e of the network, introduce the ground condition $\overline{one(e)}$; for each comparator gate with input edges i_1 and i_2 and output edges o_1 and o_2, introduce the gate equations $one(i_1) \wedge one(i_2) \Rightarrow one(o_1)$, $one(i_1) \Rightarrow one(o_2)$, and $one(i_2) \Rightarrow one(o_2)$. The system of equations is monotone because the gate equations are monotone; hence the least and greatest fixpoints are unique. Eliminating the inputs of the network corresponds to determining all those variables whose values are forced by the ground conditions. Our algorithm then computes the two extremal fixpoints by assigning all remaining variables the same value (false for the least fixpoint, true for the greatest fixpoint).

By interpreting it in the network framework, it can be seen that the proposal algorithm of [7] is a clever strategy to compute the least fixpoint of the same system of equations. It has been observed that several different serializations of the proposal algorithm yield the same final result; this is because the various serializations merely represent different routes to the unique least fixpoint.

6.2.4. Finding other stable matchings. The following lemma is useful in giving another algorithm to find a stable matching.

LEMMA 6.2. *Let N be an input-free network over a monotone scatter-free basis; let e be an edge of N. Then* $\mathrm{type}_N(e) = \{0, 1\}$.

Proof. The "all-0" and "all-1" configurations of $[N, \mathbf{e}]$ are stable; this means that e takes both values in stable configurations of $[N, \mathbf{e}]$. The result follows from Theorem 4.4. □

Let N be the comparator network corresponding to an instance of Stable Marriage; let N' be the network left after input elimination. By Lemma 6.2, each edge of N' has type $\{0, 1\}$; thus, every edge-value pair leads to a successful propagation. This means that we may, in steps 2 and 3 of Algorithm 1, pick the next edge-value pair arbitrarily and still retain the guarantee of a successful propagation; moreover, the algorithm still runs in linear time. This appears to be an interesting way to pick an arbitrary stable matching out of all the different possible stable matchings.

6.3. The lattice theorem for stable configurations of comparator networks. We show that the stable configurations of comparator networks form a distributive lattice. Conway's lattice theorem for Stable Marriage follows directly. For an introduction to the theory of lattices, see [1].

Let N be any network. The set of all configurations of N has the structure of the boolean lattice $\mathbf{2}^m$ under the natural ordering. (Here, m is the number of edges of N.) It is an easy exercise in lattice theory to show that any subset of $\mathbf{2}^m$ that is closed under the operations of bitwise *AND* and bitwise *OR* forms a distributive sublattice of $\mathbf{2}^m$ under the following definition of *meet* and *join*: the meet of two elements is their bitwise *AND* and the join of two elements is their bitwise *OR*. We show that the set of stable configurations of a comparator network is closed under bitwise *AND* and *OR*; it follows that they form a distributive sublattice of the boolean lattice of all configurations.

We need the following lemma.

LEMMA 6.3. *Let s_{in} be an input assignment to a comparator network N. Let e_1 and e_2 be two edges that are inputs to the same gate g of N. Then there cannot be two stable configurations Q_α and Q_β of $[N, s_{\mathrm{in}}]$, such that $e_1 \leftarrow 0$ and $e_2 \leftarrow 1$ in Q_α and $e_1 \leftarrow 1$ and $e_2 \leftarrow 0$ in Q_β.*

Proof. Assume the contrary, i.e., suppose $e_1 \leftarrow 0$ and $e_2 \leftarrow 1$ in Q_α and $e_1 \leftarrow 1$ and $e_2 \leftarrow 0$ in Q_β. Eliminate the inputs of N. This process will not assign a value to either e_1 or e_2, because, by hypothesis, these edges take on both possible values in the stable configurations of $[N, s_{\mathrm{in}}]$. Hence the network left after input elimination will also have two stable configurations Q'_α and Q'_β such that $e_1 \leftarrow 0$ and $e_2 \leftarrow 1$ in Q'_α and $e_1 \leftarrow 1$ and $e_2 \leftarrow 0$ in Q'_β. Hence it suffices to prove Lemma 6.3 for input-free networks. From now on, we assume $s_{\mathrm{in}} = \mathbf{e}$.

Let e_3 be the "min" output edge of g. Since $e_3 \leftarrow 0$ in Q_α and Q_β, $[e_3, 0]$ is viable in N. Hence the propagation of $[e_3, 0]$ must assign the value 0 to at least one of e_1 and e_2. Assume that e_1 is assigned the value 0. This means that e_1 is assigned the value 0 in every stable configuration of $[N, s_{\text{in}}]$ in which e_3 is assigned the value 0. This contradicts the stability of Q_β. Similarly, if e_2 is assigned the value 0, the stability of Q_α is contradicted. □

THEOREM 6.4. *Let N be a comparator network, and let s_{in} be an input assignment to N. Then the stable configurations of $[N, s_{\text{in}}]$ form a distributive sublattice of the lattice of all configurations, under the following definition of* meet *and* join: *the* meet *of two configurations is their bitwise* ***AND***; *the* join *of two configurations is their bitwise* ***OR***.

Proof. By previous remarks, it suffices to prove that the set of stable configurations is closed under bitwise ***AND*** and bitwise ***OR***.

Let Q_α and Q_β be two stable configurations of $[N, s_{\text{in}}]$. Let Q be the bitwise ***AND*** of Q_α and Q_β. The values assigned by Q_α, Q_β, and Q to any particular input edge of N are the same, so Q trivially satisfies the input conditions. Hence it suffices to show that Q satisfies the gate equations at every gate of N. Let g be an arbitrary gate of N; let e_1 and e_2 be its two input edges. The following simple case analysis shows that the gate equations are satisfied at gate g.

The first case is where one of Q_α and Q_β assigns both input edges the value 0. If this happens, the input and output edges of g are all assigned the value 0 in Q, so the gate equations are satisfied. The second case is where one of Q_α and Q_β, say Q_α, assigns both input edges the value 1. In this case, the input and output edges of g are assigned the same values in Q and in Q_β, so the gate equations are satisfied. In the third case, Q_α and Q_β both assign the same values to the two input edges. In this case, the input and output edges of g are assigned the same values in Q, in Q_α, and in Q_β, so again the gate equations are satisfied. The only remaining case is when one of Q_α and Q_β assigns the input edges the values $e_1 \leftarrow 0, e_2 \leftarrow 1$ and the other assigns the input edges the values $e_1 \leftarrow 1, e_2 \leftarrow 0$. But Lemma 6.3 assures us that this is not possible.

The case of the bitwise ***OR*** of Q_α and Q_β is analogous. □

Remarks. Tarski's theorem [28] says that the set of fixpoints of any monotone function from a complete lattice to itself forms a complete lattice. This theorem, together with Lemma 2.1, is sufficient to prove that the stable configurations (on a given input assignment) of any monotone scatter-free network form a lattice. However, this approach does not seem to yield the sublattice property. Nevertheless, and even though our proof is specific to the comparator, Theorem 6.4 does extend to any monotone scatter-free network. An easy application of the ideas in [5] yields the desired proof.

Interpreting Lemma 6.3 in the context of Stable Marriage yields the following theorem proven in [16].

LEMMA 6.5. *Let I be an instance of Stable Marriage. Suppose man m is matched to woman w in some stable matching M of I. Then there is no stable matching of I in which both m and w get better mates than in M.*

Proof. Consider the comparator network corresponding to instance I, and apply Lemma 6.3. □

An easy corollary of Theorem 6.4 is the Lattice Theorem for Stable Marriage, proven and attributed to Conway in [20].

THEOREM 6.6. *The stable matchings of a given instance of Stable Marriage form a distributive lattice, under the following definition of* meet *and* join: *The* meet *of two matchings M_1 and M_2 is a matching in which every man is married to the better of his two mates in M_1 and M_2*; *the* join *of M_1 and M_2 is a matching in which every man is married to the worse of his two mates in M_1 and M_2. (A man who is unmatched in M_1 and M_2 stays unmatched in* meet(M_1, M_2) *and* join(M_1, M_2)*).*

Remark. By Theorem 4.5, it is not possible for a man to be matched in exactly one of the two matchings.

7. Implications for parallel complexity.

7.1. Complexity theory background. For an introduction to complexity theory, see [13],[26]; for an introduction to parallel computation, see [3], [19].

The reductions in this paper are the many-one logspace reductions of [18]. We believe our reductions are simple enough that they will continue to hold under reasonable alternative definitions of reducibility. A problem is complete for a class if it is in the class and every problem in the class reduces to it. The class CC is the class of decision problems that are equivalent to Comparator Circuit Value (C-CV); see [21].

7.2. Overview of reductions. In the following sections, we show that several problems related to Stable Matching are CC-complete. Section 7.3 shows that Stable Matching and Network Stability for X-networks are essentially the same problem and that Stable Marriage and Network Stability for comparator networks are essentially the same problem. Thus, determining whether an X-network has a stable configuration is just as hard as determining whether an instance of Stable Roommates has a stable assignment; constructing a stable configuration of an X-network is just as hard as constructing a stable roommate assignment for an instance of Stable Roommates. Similar remarks apply to Stable Marriage and Network Stability for comparator networks. Of course, in this case the existence questions are trivial, because the answer is always "Yes."

Section 7.5 shows that the existence of stable configurations in X-networks is equivalent to Comparator Circuit Value. In §7.6, it is shown that constructing a stable matching for an instance of Stable Marriage is equivalent to Comparator Circuit Value: given an oracle for C-CV, we can compute the man-optimal stable matching; in the other direction, C-CV reduces to the problem of telling whether man m is married to woman w in an instance of Stable Marriage that has exactly one stable matching. This leaves the problem of constructing a stable configuration of an X-network in the nonbipartitionable case; our methods do not tell us whether this problem reduces to C-CV.

Section 7.6 also shows the following problems to be equivalent to C-CV: the Fixed Pair and Stable Pair problems, and the decision version of the Minimum-regret problem. For these problems, it does not matter whether the instance is one of Stable Matching or Stable Marriage. For the Minimum-regret problem, there is a difference between three and two: determining whether the largest regret is at most three is equivalent to C-CV, but telling whether the largest regret is two seems easier—at least it is no harder than a 2-SAT computation. (Of course, at this point, we have no proof that C-CV is harder than 2-SAT.)

Section 7.6 also shows that constructing a minimum-regret stable matching for an instance of Stable Marriage is just as hard as C-CV. The proof indicates that constructing a minimum-regret stable matching for instances of Stable Matching reduces to C-CV if and only if constructing a stable configuration of an X-network reduces to C-CV. However, we do not know how to reduce directly the construction of a minimum-regret stable matching to the construction of a stable configuration of an X-network.

Feder [5] has recently shown that (the decision problem corresponding to) constructing a stable configuration of an X-network is no harder (for parallel computation) than determining its existence. Given this theorem, it follows that all the problems considered above (except Regret-2 Stable Matching and 2-SAT) are equivalent to Comparator Circuit Value or, in other words, are CC-complete.

Finally, in §7.7, we give a reduction from C-CV to the Assignment problem (also called Bipartite Weighted Matching). This implies a fast parallel transformation of instances of Stable Marriage into instances of the Assignment problem in such a way that the solution of the Assignment problem yields the man-optimal stable matching of the Stable Marriage instance; this partially answers a question posed in [20]. However, our reduction is not entirely satisfactory, because it loses all the stable matchings except the man-optimal one. It is an open problem to give a fast parallel transformation from Stable Marriage to the Assignment problem in a manner that preserves the structure of all solutions.

7.3. Stable Matching is the same as X-Network Stability. In this section, we show that Stable Matching and X-Network Stability are essentially the same problem. There are easy reductions between the two problems that map instances of one problem to instances of the other in a manner that preserves the structure of solutions. These reductions take Stable Marriage instances into instances of Network Stability for bipartitionable X-networks. We have already seen that bipartitionable X-networks and comparator networks are interchangeable. It follows that Stable Marriage and Network Stability for comparator networks are essentially the same problem.

THEOREM 7.1. *Stable Matching is equivalent to X-Network Stability.*

Proof. The reduction from Stable Matching to X-Network Stability follows immediately from the reduction of §3. We show how to reduce X-Network Stability to Stable Matching. Given an X-network N and its input assignment s_{in}, we construct an auxiliary X-network $\tilde{N}$ in such a way that the stable configurations of $[N, s_{\text{in}}]$ are in one-to-one correspondence with the stable configurations of $[\tilde{N}, \mathbf{1}]$. The new network $\tilde{N}$ has the following properties: every snake is acyclic; no two snakes meet more than once; no snake meets itself.

The first step is to delete snakes whose input edges are assigned the value 0 by s_{in}. Observe that if an input edge of a snake is 0, every edge on this snake will take the value 0 in every stable configuration; furthermore, every snake that intersects this snake will have the same value after the intersection as it did before it. Hence, such 0-snakes may be identified and removed without altering the set of stable configurations.

The next step is to insert two *NOT*-gates in series on every noninput edge of N. We then replace each *NOT*-gate by an X-gate with one input fixed at the value 1. The resulting network is the desired network $\tilde{N}$. It is easy to check that it has the properties claimed above.

Finally, we can read off the desired instance I of Stable Matching from the network $\tilde{N}$ by inverting the reduction of §3 in the following manner. Introduce a person for each snake of $\tilde{N}$. Two persons find each other acceptable if and only if their snakes meet. Finally, the order in which a person's snake meets the other snakes gives his preference ordering. It follows from Theorem 3.2 that the stable configurations of $[N, s_{\text{in}}]$ are in one-to-one correspondence with the stable matchings of instance I. □

Remarks. The above proof actually proves a little more. First, if N is bipartitionable, so is $\tilde{N}$, and then instance I will be an instance of Stable Marriage. Second, the sizes of $\tilde{N}$ and I are linear in the size of N. Finally, note that in $\tilde{N}$, each snake meets at most three other snakes, and furthermore, if a snake meets more than one other snake, the value on its output edge is 0. This means that in instance I, each person has at most three persons on his preference list. Also, in every stable matching of I, the persons who list more than one other person are guaranteed to be matched to one of their first three choices. We shall use this later, to prove Theorem 7.15.

We give an easy proof, based on the network formulation of Stable Matching, of the following well-known lemma.

LEMMA 7.2. *Complete Stable Matching is no easier than Stable Matching. Complete Stable Marriage is no easier than Stable Marriage.*

Proof. Given an instance of Stable Matching, we convert it to an instance of Complete Stable Matching, without affecting the set of stable matchings. The first step is to introduce the appropriate number of extra persons and decree that they have no acceptable mates. This does not affect the set of stable matchings. In terms of X-networks, introducing these extra persons amounts to adding new snakes with input 1 as separate connected components.

It is instructive to do the rest of the proof with networks instead of preference lists. Let N_1 be the X-network corresponding to the Stable Matching instance we have so far. Network N_1 has one deficiency: each snake of N_1 might not meet every other snake that it should meet. We remedy this by a "cascade" construction, i.e., by appending a new network N_2 at the "back" of N_1. The outputs of N_1 become the inputs of N_2. Our final network N will be the composition of these two networks.

Let us examine what properties N_2 should have. First, each snake of N_2 must meet a prescribed set of the other snakes, each exactly once. Second, the sets of stable configurations of $[N, \mathbf{1}]$ and $[N_1, \mathbf{1}]$ should be isomorphic. The second condition will be met if the following condition is met: whenever s is the output word of some stable configuration of $[N_1, \mathbf{1}]$, $[N_2, s]$ has exactly one stable configuration. A simple solution is to make N_2 a circuit. This works because every circuit has exactly one stable configuration on any given input assignment.

We construct N_2 as follows. Pick any fixed total order O of the snakes, and let each snake meet all the snakes it ought to meet in the order induced by O. This defines N_2 and hence N. The desired instance of Stable Matching can be read off from N. This completes the reduction. The proof for Marriage instances is similar.

Notice that the cascade construction actually does something very simple with the preference lists: it enlarges the preference list of each person x, by appending to it all the mates originally unacceptable to x, in the order given by O. □

7.4. On reducing problems to Comparator Circuit Value. Following [18], we say that a problem Z is *many-one* reducible to C-CV if we can exhibit a reduction from Z to C-CV that takes each instance of Z to a comparator circuit plus an input assignment to it, so that the instance has a "Yes" answer if and only if the circuit has output 1 when evaluated on the given input assignment. In proofs, it is more convenient to think in terms of Turing reductions to C-CV. The following lemma helps convert Turing reductions to many-one reductions.

LEMMA 7.3. *If* Z_1 *and* Z_2 *are many-one reducible to* C-CV, *so are* $\mathsf{OR}(Z_1,Z_2)$, $\mathsf{AND}(Z_1,Z_2)$, *and* $\mathsf{NOT}(Z_1)$.

Proof. The many-one reducibility of $\mathsf{OR}(Z_1,Z_2)$ and $\mathsf{AND}(Z_1,Z_2)$ to C-CV follows from the fact that the comparator can simulate the OR-gate and the AND-gate. The many-one reducibility of $\mathsf{NOT}(Z_1)$ to C-CV follows because the X-gate can simulate $\{\mathrm{C}, \mathsf{NOT}\}$ and because X-CV reduces to C-CV by Lemma 7.4. □

LEMMA 7.4. X-CV *is equivalent to* C-CV.

Proof. The basis $\{X\}$ can simulate $\{C\}$; hence C-CV reduces to X-CV. The reduction in the other direction utilizes Goldschlager's idea of using "double-rail" logic [9]. In other words, encode the values 0 and 1 by the pairs $(1, 0)$ and $(0, 1)$ respectively. Replace every edge e in the original circuit by a pair of edges (e^-, e^+); the rest of the construction will guarantee that the two edges in a pair will always have complementary values. If e is an input edge that is assigned the value v, edges e^- and e^+ are assigned the values $\overline{v}$ and v respectively. Finally, we must replace every X-gate by an appropriate gate. The X-gate has two inputs i_1, i_2 and two outputs $o_1 = i_1 \overline{i_2}$, $o_2 = \overline{i_1} i_2$. The new gate will have four inputs $i_1^-, i_1^+, i_2^-, i_2^+$ and four outputs $o_1^-, o_1^+, o_2^-, o_2^+$. The new gate must simulate the behaviour of the X-gate in the following sense: when presented with an input word that is a valid encoding of the input word to an X-gate, it must produce an output word that is the valid encoding of the corresponding output word of the X-gate. The action of the gate on input words like 0010 may be arbitrarily chosen. One solution is to use the gate defined by the equations $o_1^- = i_1^- + i_2^+$, $o_1^+ = i_1^+ i_2^-$, $o_2^- = i_1^+ + i_2^-$, $o_2^+ = i_1^- i_2^+$. It is easily seen that this gate can be simulated by the comparator.

An easy inductive proof shows that if edge e in the original circuit has value v, then the pair of edges (e^-, e^+) in the new circuit will be assigned the value-pair $(\overline{v}, v)$. Hence, in particular, if e_0 is the output edge of the original circuit, the edge e_0^+ will serve as the output edge of the new circuit. Finally, since the new gate can be simulated by the comparator, the new circuit can be converted into a comparator circuit. □

7.5. X-Network Stability is equivalent to Comparator Circuit Value. Let Ω be a scatter-free basis that can simulate $\{NAND\}$. The objective of this section is to show that Ω-NS and Ω-CV are equivalent. (This result was presented in [21]; here we give a complete proof.) In particular, X-NS is equivalent to X-CV; hence, using Lemma 7.4, X-NS is equivalent to C-CV.

7.5.1. Reducing Ω-CV to Ω-NS. The proof uses the idea of a *forcer*. A v-forcer is a one-input, zero-output network that has a stable configuration if and only if the input takes the value v. A 0-forcer may be built by tying the output of a $NAND$-gate to one of its inputs, and a 1-forcer may be obtained by adding a NOT-gate at the input of a 0-forcer.

LEMMA 7.5. *Let Ω be any basis that can simulate $\{NAND\}$. Then Ω-*CV *reduces to Ω-NS.*

Proof. To determine the output of a circuit over Ω, feed its output into a 1-forcer. The resulting network has a stable configuration if and only if the circuit has output 1. Since basis Ω can simulate $\{NAND\}$, we can build forcers over Ω. □

7.5.2. Reducing Ω-NS to Ω-CV. Given a network N over a scatter-free basis Ω and an input assignment s_{in} to N, we wish to construct a circuit over Ω so that the output of the circuit is 1 if and only if $[N, s_{\text{in}}]$ has a stable configuration.

Let N' be the network left after the inputs of N are eliminated. We say that an edge of N is *bad* if it is a contradicting edge of N'. By Theorem 4.3, network N has no stable configuration if and only if it has a bad edge. Thus the key step is to construct a circuit that will tell us if a given edge is bad. Once this is done (independently) for every edge of N, we may combine the results and answer the stability question by using some simple additional circuitry. The rest of the discussion is divided into three stages. In the first stage, we show how to tell if an edge is bad; in the second stage, we define a network process that will compute whether or not an edge is bad; in the final stage, we convert the network process into a circuit computation.

Stage 1. How do we tell if edge e is bad? Break edge e, thus creating an extra input e(in) and an extra output e(out). Call the resulting network N_e. Let s_e be the input assignment to N_e obtained by augmenting s_{in} with the assignment $e(\text{in}) \leftarrow v$. Consider the following experiment Expt(e, v): Assign each input of N_e the value it gets under the input assignment s_e, and perform input elimination. Since the gates are scatter-free, each output of N_e will be assigned a value. We say that experiment Expt(e, v) succeeds if the value assigned to edge e(out) is v; otherwise it fails.

LEMMA 7.6. *Edge e is bad if and only if both the experiments* Expt(e, 0) *and* Expt(e, 1) *fail.*

Proof. The key observation is that the result of input elimination does not depend on the order in which the inputs are eliminated. Hence we may pretend that experiment Expt(e, v) is conducted in two phases: in the first phase, all the inputs except e(in) are eliminated; in the second phase, input e(in) is eliminated. There are two cases, depending on whether or not edge e(out) is assigned a value in the first phase.

Case 1. Suppose edge e(out) is assigned a value v' in the first phase. This means that edge e would be assigned the value v' when the inputs of N are eliminated. It follows that e is not an edge of N'; hence e is not a bad edge of N. Notice also that Expt(e, v') will succeed. Thus Lemma 7.6 is true in this case.

Case 2. Suppose edge e(out) is not assigned a value in the first phase. This means two things: first, the effect of the first phase is identical to that obtained by eliminating the inputs of N; second, edge e is an edge of N'. Notice that the second phase of Expt(e, v) will assign value v to edge e(out) if and only if $[e, v]$ is viable in N'. It follows that both Expt$(e, 0)$ and Expt$(e, 1)$ fail if and only if edge e is contradicting in N'. Hence Lemma 7.6 is true in this case as well. □

Stage 2. We now define a network process that will compute the value assigned to edge e(out) by experiment Expt(e, v). Consider the following network process: Initialize network N_e to any configuration consistent with the input assignment s_e. Then let the network "run." In other words, perform the following primitive operation at each gate of the network, in parallel: apply the gate function to the values on the input edges, and use the result to update the values on the output edges of the gate. The crucial observation is that the values on certain edges of the network will stabilize, i.e., will not change after a certain number of parallel steps. In particular, the value on edge e(out) will stabilize at the value it is assigned in experiment Expt(e, v).

LEMMA 7.7. *Each edge that is assigned a value in experiment* Expt(e, v) *will stabilize at the same value in the network process.*

Proof. Notice that the value on each input edge of network N_e is held constant. Hence Lemma 7.7 is true for these edges. The process of eliminating the inputs of N_e in experiment Expt(e, v) gradually assigns values to some edges of N_e. An assignment to an output edge of gate g follows from an assignment to a subset of the inputs of g by invoking the equation of g. This process is faithfully mimicked in the network process: first each edge in the relevant subset of the inputs stabilizes to the correct value; then the output edge stabilizes. □

The proof of Lemma 7.7 may be extended to bound the number of parallel steps needed for edge e(out) to stabilize. Let m be the number of edges in network N. Then the longest chain of influence in the input elimination process of experiment Expt(e, v) involves at most $m + 1$ edges. Hence edge e(out) will reach its correct value after at most m parallel steps.

Stage 3. The final step is to use the regularity of the network process to "unravel" it into a circuit computation. In other words, we construct a circuit over Ω that will simulate the network process. The idea is to make m copies of network N_e (we call each copy a layer) and connect these layers up into a circuit C in such a way that the values that leave the tth layer are the values that appear in network N_e after parallel step t. As a result, the correct value of edge e(out) may be read off from the top layer of the circuit.

More accurately, we make m copies of network N_e and change the output edges of all the gates so that they enter the next layer, instead of the same layer. The gates of C are $\{(g, t) \mid g$ is a gate of N_e; $1 \le t \le m\}$; the edges are $\{(\tilde{e}, t) \mid \tilde{e}$ is an edge of N_e; $0 \le t \le m\}$. (Not quite! The edges of the form $(\tilde{e}, 0)$ for $\tilde{e}$ an output edge of N_e or of the form $(\tilde{e}, m)$ for $\tilde{e}$ an input edge of N_e are not actually present.) The gates $\{(g, t) \mid 1 \le t \le m\}$ all have the same gate type as g. If g has inputs $i_1, \ldots, i_\lambda$ and outputs $o_1, \ldots, o_\mu$, then (g, t) has inputs $(i_1, t-1), \ldots, (i_\lambda, t-1)$ and outputs $(o_1, t), \ldots, (o_\mu, t)$.

If $\tilde{e}$ is an input edge of N_e with value $\tilde{v}$, all the input edges $\{(\tilde{e}, t) \mid 0 \le t < m\}$ get the value $\tilde{v}$ in C; this has the effect of presenting the real inputs of N_e to each layer of the circuit. The edges $(\tilde{e}, 0)$, for $\tilde{e}$ an internal edge of N_e, are assigned arbitrary values; this reflects the arbitrariness in the initial configuration of N_e. Finally, if $\tilde{e}$ is a noninput edge of N_e, edge $(\tilde{e}, m)$ is an output edge of C. This completes the description of C.

The following lemma may be proven by an easy induction on t.

LEMMA 7.8. *The value on edge $(\tilde{e}, t)$ of C equals the value on edge $\tilde{e}$ of N_e after parallel step t.*

In particular, the value assigned to edge e(out) in experiment Expt(e, v) is given by the value assigned to edge $(e(\text{out}), m)$ in C. Once we have the values assigned to edge e(out) in experiments Expt$(e, 0)$ and Expt$(e, 1)$, we may determine whether or not edge e is bad by adding an *AND*-gate and a *NOT*-gate. We may then combine the results for each edge and answer the stability question by adding *OR*-gates and a *NOT*-gate. Thus we get a circuit over $\Omega\cup\{NAND\}$ that computes the answer to the question "Does $[N, s_{\text{in}}]$ have a stable configuration?" This circuit has $O(m^3)$ gates.

THEOREM 7.9. *Let Ω be any scatter-free basis that can simulate $\{NAND\}$. Then Ω-NS is equivalent to Ω-CV.*

Proof. The reduction from Ω-NS to Ω-CV follows from the construction above; the reduction from Ω-CV to Ω-NS follows from Lemma 7.5. □

7.6. More Stable Matching problems equivalent to Comparator Circuit Value. In this section, we prove that several Stable Matching problems are CC-complete. We begin by showing (Lemma 7.10) that X-network stability problems remain just as hard even if we place certain constraints on the values that certain edges can take.

LEMMA 7.10. *The following problems are equivalent (and hence equivalent to* C-CV):

1. *Given an X-network N, an input assignment s_{in}, and a partial assignment P to the noninput edges of N, can P be completed to a stable configuration of the network?*
2. *Given an X-network N and an assignment s_{in} to the input edges of N, is there a stable configuration of $[N, s_{\text{in}}]$?*

Proof. Problem 2 is clearly a special case of problem 1, so it suffices to reduce problem 1 to problem 2. This can be done by using forcers. Suppose P requires that edge e get the value v. Break edge e, creating input e(in) and output e(out). Assign edge e(in) the value v, and feed e(out) into a v-forcer. □

THEOREM 7.11. *The following problems reduce to* C-CV.

1. *Fixed Pair. Is the given pair of persons a fixed pair of the given instance of Stable Matching, i.e., is it true that these two persons are matched to each other in every stable matching?*
2. *Stable Pair. Is the given pair of persons a stable pair, i.e., is it true that there is a stable matching that matches these two people to each other?*
3. *Minimum-regret. Is it true that there is a stable matching of the given instance in which every person has regret at most k?*

Proof. To check that two persons form a fixed pair, it suffices to check that the snakes corresponding to these two persons always meet each other with the value 1 in the corresponding instance of X-Network Stability. Let g be the gate where the two snakes meet; we have to check that there is no stable configuration that assigns either edge entering g the value 0. This reduces to C-CV by Lemma 7.10 and Lemma 7.3.

To check that two persons form a stable pair, it suffices to check that there is a stable configuration that matches these two persons to each other, i.e., a stable configuration in which the snakes corresponding to these two people meet each other with the value 1. This reduces to C-CV by Lemma 7.10.

To check that there is a stable matching in which every person has regret at most k, just check whether there is a stable configuration that assigns each snake the value 0 after it has traversed k gates. (If snake q has fewer than k gates on it, the desired stable configuration must assign the output edge of q the value 0.) Again, we invoke Lemma 7.10 to reduce this problem to C-CV. □

THEOREM 7.12. *The Man-optimal Stable Marriage problem, "Given an instance I of Stable Marriage, a man m, and a woman w, determine whether m is matched to w in the man-optimal stable matching M^0 of I," reduces to* C-CV.

Proof. Let $[N, s_{\text{in}}]$ be the instance of Comparator Network Stability corresponding to instance I; let Q^0 be the stable configuration of $[N, s_{\text{in}}]$ corresponding to the man-optimal stable matching of I. We show how to construct a comparator circuit to compute Q^0. The proof of Theorem 7.12 then follows by applying Lemma 7.3.

Theorem 6.1 tells us that Q^0 is the "most-0" stable configuration of $[N, s_{\text{in}}]$. We claim the following network process finds Q^0. Initialize N to the "all-0" stable configuration. Then make all the red inputs 1. These changes create disturbances that propagate through the network. But the network will eventually enter the stable configuration Q^0.

We justify the claim. Notice that all the input disturbances "increase" the value assigned to an input edge. The comparator is a monotone gate—increasing the values assigned to the inputs can never cause an output to decrease. Hence, the effect of the disturbances as they move through the network will be to increase the value of some edges of N, but no edge will ever move from 1 to 0. It follows that the disturbances will die out in at most m steps. Now observe that an edge is assigned the value 1 during the network process only if it must have the value 1 in every stable configuration of $[N, s_{\text{in}}]$. It follows that the stable configuration the network reaches is Q^0.

The network computation on N may be unravelled into a circuit computation over the same basis in the standard fashion. (See, for example, the discussion in §7.5.) □

We can also reduce the problem of constructing a minimum-regret stable matching for an instance of Stable Marriage to C-CV. Let I be any instance of Stable Marriage; let regret(I) be the value of the largest regret in a minimum-regret stable matching of I. The discussion in §4.2 tells us that there is a single instance $I_{\text{regret}(I)}$ of Stable Marriage whose stable matchings are all the minimum-regret stable matchings of I. Define the man-optimal minimum-regret stable matching of I to be the man-optimal stable matching of $I_{\text{regret}(I)}$. The following theorem shows that the construction of this special stable matching reduces to C-CV.

THEOREM 7.13. *The Man-optimal Minimum-regret Stable Marriage problem, "Given an instance I of Stable Marriage, a man m and a woman w, determine whether m is matched to w in the man-optimal minimum-regret stable matching of I," reduces to* C-CV.

Proof. Assume without loss of generality that there are at least as many men as women in instance I; let n be the number of men. Then regret(I) is one of the integers between 1 and $(n + 1)$. If regret$(I) = (n + 1)$, this is taken to mean that there is some person who is unmatched in every stable matching of I. The idea is to compute the man-optimal stable matching separately in each of the $(n + 1)$ cases and then select the correct stable matching using the value of regret(I).

Suppose we wish to compute whether m is matched to w in the matching that is best for the men from among all the stable matchings in which each person has regret at most k. First compute the appropriate instance I_k of Stable Marriage as in §4.2. The proof of Theorem 7.12 can be made to yield a comparator circuit C_k whose output is 1 if and only if man m is matched to woman w in the man-optimal stable matching of instance I_k.

The reduction from the Minimum-regret problem to C-CV (see Theorem 7.11 above) can be made to yield, for each $k \in [1, (n + 1)]$, a comparator circuit Atmost$_k$ whose output is 1 if and only if regret$(I) \leq k$. (The circuit Atmost$_{n+1}$ is trivial; its output is always 1.) Now build a comparator circuit Exact$_k$, where the output of Exact$_k$ is 1 if and only if regret$(I) = k$. For $k > 1$, regret$(I) = k$ if and only if Atmost$_k$ has output 1 but Atmost$_{k-1}$ has output 0; Lemma 7.3 then yields the comparator circuit Exact$_k$. Also, Exact$_1$ is just Atmost$_1$. (Of course, for these constructions, we need two copies of the circuits Atmost$_k$.)

The circuit $\underset{k}{\mathit{OR}}(\mathit{AND}(\text{Exact}_k, C_k))$ has output 1 if and only if man m is matched to woman w in the man-optimal minimum-regret stable matching of I. This circuit can be built with comparators—just simulate the AND-gate and the OR-gate with comparators. □

The problems reduced to C-CV in the previous three theorems are in fact equivalent to C-CV.

THEOREM 7.14. C-CV *reduces to the Fixed Pair problem, the Stable Pair problem, the Man-optimal Stable Marriage problem, and the Man-optimal Minimum-regret Stable Marriage problem.*

Proof. Let C be the given comparator circuit. Use the transformation of Fig. 2(b) to replace it by a bipartitionable X-circuit. Delete snakes whose input edges have the value 0, as in the proof of Theorem 7.1. Circuit C has output 1 (on a given input assignment s_{in}) if and only if the output edge of a certain vertical snake q of the X-circuit is assigned the value 1. Add a new horizontal snake q' with input 1 to the X-circuit. Let q' meet q and no other snake. Let q meet q' last. Then C has output 1 on s_{in} if and only if q and q' meet each other with value 1 in the new X-circuit. The method used in the proof of Lemma 7.2 can be used to ensure that the number of horizontal and vertical snakes are equal and that every horizontal snake meets every vertical snake exactly once. Now, read off an instance of Complete Stable Marriage from the X-gate circuit. This instance will have exactly one stable matching. Also, the output of C is 1 on s_{in} if and only if the persons corresponding to snakes q and q' are married to each other in the unique stable matching. The theorem follows. □

THEOREM 7.15. C-CV *reduces to the question "Does the given instance of Complete Stable Marriage have a stable matching in which every person has regret at most* 3?"

Proof. Given an instance of C-CV, we produce an instance of Complete Stable Marriage with the following properties: there is exactly one stable matching; the regret of every person except woman w in this stable matching is at most 3; woman w has regret 3 if and only if the instance of C-CV has output 1, otherwise she has regret 4.

As in the proof of Theorem 7.14, replace the given comparator circuit C by a bipartitionable X-circuit without 0-snakes, so that C has output 1 on input assignment s_{in} if and only if the output edge of a certain vertical snake q_1 of the X-circuit is assigned the value 1.

The next step is to prepare the snake of woman w appropriately. Introduce the following new snakes: $q_0, q_2, q_3, q_4, q_5, q_7$. The input edge of each of these snakes is assigned the value 1. The snakes with odd subscripts will be vertical snakes, and the snakes with even subscripts will be horizontal snakes. Snake q_0 will ultimately become the snake of woman w. Snake q_0 meets q_3, q_5, q_1, q_7 in that order; snake q_2 meets q_3 only; snake q_3 meets q_2 and q_0 in that order; snake q_4 meets q_5 only; snake q_5 meets q_4 and q_0 in that order; snake q_7 meets q_0 only. Snake q_1 meets q_0 last. The effect of this construction is to guarantee that woman w gets either her third choice or her fourth choice; she gets her third choice if and only if circuit C on input s_{in} has value 1.

The rest of the proof contains a general construction that can be used to simultaneously reduce the regret of some or all of the participants to three and make the instance "complete," without changing the structure of the set of all stable matchings. It introduces new persons, but each of them has regret at most three. The same construction works, with the appropriate changes, for the nonbipartitionable case. The size of the output instance produced by the construction is $O(n^4)$, where n is the size of the comparator circuit; it is possible to produce an instance of size $O(n^2)$ if the output instance is not required to be bipartitionable, but such considerations are largely irrelevant from the viewpoint of parallel reductions.

The method used in the proof of Lemma 7.2 converts our bipartitionable X-network into the X-network corresponding to an instance of Complete Stable Marriage. There is one difficulty, however: some of the participants other than w might have regret more than 3, or in other words, some snakes other than q_0 might have the value 1 even after meeting three other snakes. This can be rectified by performing some minor surgery on the network. The trick, much as in the proof of Theorem 7.1, is to insert two *NOT*-gates in series into every noninput edge of the network except the edges on snake q_0 and then to replace each *NOT*-gate by an X-gate with input 1. The result is a bipartitionable X-circuit with the following properties: each snake except q_0 meets at most three other snakes; the value on the input edge of every snake is 1; the value on the output edge of every snake is 0; there are an equal number of man-snakes and woman-snakes. Now convert this to an instance of Complete Stable Marriage by completing each person's list in any manner. The resulting instance will have all the desired properties. □

It follows from the following theorem and Theorem 4.5 that the question "Does the given instance of Stable Matching have a stable matching in which every person has regret at most 2?" is in NC. This suggests that the number 3 in Theorem 7.15 cannot be reduced.

THEOREM 7.16. *Stable Matching is in* NC *if each person lists at most two other participants as acceptable mates.*

Proof. Introduce for each person x two boolean variables $\text{gets}(x, 1)$ and $\text{gets}(x, 2)$. The intended meaning is that $\text{gets}(x, j)$ is made true by a stable matching if and only if x is matched to his jth choice. Then the stable matchings are precisely the solutions of the following equations.

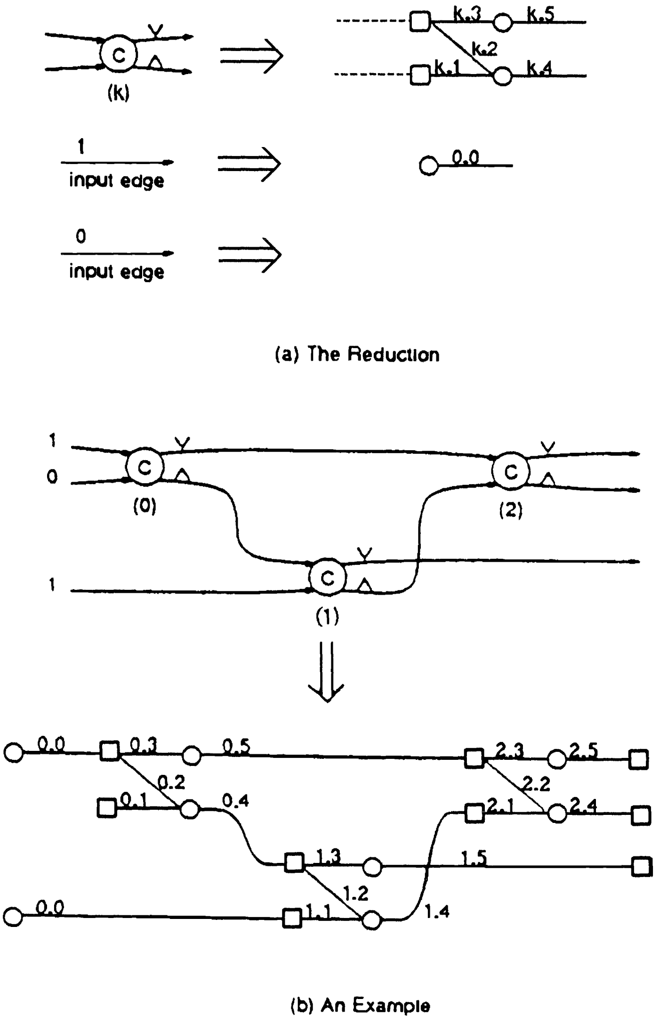
1. $\overline{\text{gets}(x, 1) \wedge \text{gets}(x, 2)}$.
2. If x is the jth choice of y and y is the kth choice of x, then $\text{gets}(y, j) \equiv \text{gets}(x, k)$.
3. If x is the first choice of y and y is the first choice of x, then $\text{gets}(x, 1)$.
4. If x is the first choice of y and y is the second choice of x, then $\text{gets}(x, 1) \vee \text{gets}(x, 2)$.
5. If x is the second choice of y and y is the second choice of x, then $\text{gets}(x, 1) \vee \text{gets}(y, 1) \vee \text{gets}(x, 2)$.

Notice that if x and y are second choices of each other, then all the equations involving $\text{gets}(x, 2)$ and $\text{gets}(y, 2)$ may be replaced by the single defining equation $\text{gets}(x, 2) \equiv \text{gets}(y, 2) \equiv \overline{\text{gets}(x, 1) \vee \text{gets}(y, 1)}$. We say that such variables $\text{gets}(x, 2)$ and $\text{gets}(y, 2)$ are *inessential.* Solve the original system of equations as follows: delete all the equations involving inessential variables; solve the resulting system of equations; and then solve for the inessential variables by using their defining equations. The key observation is that eliminating the inessential variables renders the system of equations simpler—each equation in the new system mentions at most two variables. Hence the new system may be converted into an instance of 2-SAT and can be solved in NC [4]. □

Remark. The difference between preference lists of lengths two and three has also been observed by Soroker [25]. He considers a special case of Stable Marriage, called Priority Marriage. He shows that Priority Marriage is just as hard even if each preference list is at most three long; however, if each list has at most two persons on it, the problem is in NC.

7.7. A reduction from Comparator Circuit Value to the Assignment problem. In this section, we exhibit a fast parallel reduction from C-CV to Bipartite Weighted Matching. Cook [2] initially showed that X-CV is equivalent to a problem called Lex-first Maximal Matching; also, there are easy reductions from C-CV to X-CV and from Lex-first Maximal Matching to Weighted Matching. The actual reduction used in this section incorporates these ideas; the specific gadgets used are due to Soroker [25].

Let C be the given comparator circuit, with n gates; let s_{in} be the given input assignment to C. We shall assume that C is topologically sorted, that is, we are given a function *num* that maps the gates of C into distinct integers in $[0, \ldots, (n - 1)]$, in such a way that if an output edge of g_1 is an input edge of g_2, then $\text{num}(g_1) < \text{num}(g_2)$. This assumption is justified (see [24]) because there is a fast parallel transformation that takes as input any circuit C and an input assignment s_{in} and returns a (larger) circuit C' over the same basis, a topological-sorting function num for C', and an input assignment s'_{in}, so that $[C', s'_{\text{in}}]$ has output 1 if and only if $[C, s_{\text{in}}]$ has output 1. We shall also assume, without loss of generality, that the output whose value we wish to compute is the *OR* output of gate $(n - 1)$. We shall construct a bipartite graph G and a function *weight* from the edges of G into the positive integers, so that the maximum-weight matching of G is unique; furthermore, this matching has odd weight if and only if the output of C on the input assignment s_{in} is 1.



(a) The Reduction

(b) An Example

FIG. 3. *Reducing Comparator Circuit Value to Bipartite Weighted Matching.*

The construction is illustrated in Fig. 3(a). Each comparator gate g is locally transformed into a graph gadget with four vertices and five edges. If $\text{num}(g) = k$, the edges of the gadget are labeled from $k.1$ to $k.5$ as shown. The weight of an edge labeled $k.l$ will be $2^{5n-(5k+l)}$. Think of the gadget as taking in two input edges (shown dotted) and producing two output edges, the edges labeled $k.4$ and $k.5$. The gadgets for different gates are connected to one another in exactly the same way as the gates are connected in C.

Input edges of C are treated as follows. Suppose e is an input edge of C. If e is assigned the value 1 by s_{in}, it becomes an edge with label 0.0 (and weight 2^{5n}) in G. On the other hand, if e is assigned the value 0, it does not appear in G. An example of the transformation is shown in Fig. 3(b).

It is easy to prove that G is bipartite—the shape of the vertices (square or round) in Fig. 3 gives a bipartition.

THEOREM 7.17. *The maximum-weight matching of G is unique, and it has odd weight if and only if the value assigned to the output edge of C on input assignment s_{in} is* 1.

Proof. Say an edge is *heavy* if its weight is 2^{5n}; it is *light* otherwise. Every heavy edge will appear in every maximum-weight matching of G, because these edges do not share vertices, and the combined weight of all the light edges is $2^{5n} - 1$, which is less than 2^{5n}. The weights of the light edges are decreasing powers of 2, and no two light edges have the same weight. This means that the heaviest light edge weighs more than all the other light edges combined, and hence it is always advantageous to add the heaviest light edge to the current matching. Reasoning in this fashion, we conclude that the maximum-weight matching is unique and can be found by the following greedy algorithm. Start with a matching consisting of the heavy edges, and then inspect each light edge in decreasing order of weight, adding it to the current matching if at all possible.

We prove the following inductive assertion.

($*$) Edge e of C is assigned the value 1 in the unique stable configuration of $[C, s_{\text{in}}]$ if and only if the corresponding edge in G is matched in the unique maximum weight matching M of G.

We first prove ($*$) when e is an input edge. Then we consider each gate of G, in increasing order of $\text{num}(g)$, and prove that if ($*$) is true for the edges that are inputs to g, it must also be true for the edges that are outputs of g. This will complete the proof of ($*$).

The base case is when e is an input edge of C. If e is assigned the value 0 by s_{in}, ($*$) is vacuously true. If e is assigned the value 1 by s_{in}, the corresponding edge in G is heavy and will be included in M.

Now assume that ($*$) is true for the edges that are inputs to the gate g with $\text{num}(g) = k$. We wish to prove ($*$) for the outputs of g. To do this, examine the graph gadget corresponding to gate g. See Fig. 3(a). Define the boolean variables a_1 and a_2 as follows: a_1 is true if and only if the top input to g is 1; a_2 is true if and only if the bottom input to g is 1. By assumption, these variables also capture whether or not the input edges to the graph gadget are matched in M. Now notice that in the vicinity of the graph gadget, the weights decrease in the following order: the input edges (in some order); then the edges labeled $k.1$, $k.2$, $k.3$, $k.4$, $k.5$, in this order; then the other edges, if any, that are incident to the right endpoints of the edges labeled $k.4$ and $k.5$. This allows us to infer when (under what conditions on the variables a_1 and a_2) the greedy algorithm will match the edges labeled $k.l$. The computations in Table 2 verify that ($*$) holds for the output edges of g.

TABLE 2
When the edges of the graph gadget are matched.

Edge	When Matched
Top input edge	a_1
Bottom input edge	a_2
Edge labeled $k.1$	$\overline{a_2}$
Edge labeled $k.2$	$\overline{a_1}\, a_2$
Edge labeled $k.3$	$\overline{a_1}\, \overline{a_2}$
Edge labeled $k.4$	$a_1\, a_2$
Edge labeled $k.5$	$a_1 + a_2$

Given ($*$), we complete the proof of Theorem 7.17. All the edges of G have even weights except the edge labeled $(n - 1).5$, which has weight 1. Hence M has odd weight if and only if this edge is in M, which happens if and only if the output edge of C is assigned the value 1 when C is evaluated on input assignment s_{in}. □

Remark. By combining the reduction of this section with the reduction in the proof of Theorem 7.12, we get a reduction from the Man-optimal Stable Marriage problem to Bipartite

Weighted Matching. This reduction takes an instance of Stable Marriage with n men and n women to an instance of Bipartite Weighted Matching that has $(2+o(1))n^4$ vertices on either side of the graph and edge weights that have $(5+o(1))n^4$ bits each. Given the optimal matching M of the Weighted Matching instance, we can read off the man-optimal stable matching of the Stable Marriage instance.

8. Other reductions.

8.1. Counting the number of stable matchings is #P-complete. We show how to use the network formulation to give a simple proof that the problem of counting the number of stable matchings in an instance of Stable Matching is #P-complete. A stronger result is known [16], namely, that the theorem holds even if the instance is one of Stable Marriage, but the proof of the stronger result uses a nontrivial theorem about the structure of all stable matchings of an instance of Stable Marriage.

THEOREM 8.1. *The problem of counting the number of stable configurations in an instance of X-Network Stability is #P-complete.*

Proof. Testing whether a configuration of an X-network is stable is clearly in P; this puts the counting problem in #P. To show completeness for #P, we give a parsimonious reduction from Monotone 2-SAT. Monotone 2-SAT is shown to be #P-complete in [29].

Let I be the instance of Monotone 2-SAT. Construct X-network N as follows: it has a cyclic snake q_a for each variable a of I; snakes q_a and q_b intersect if and only if the clause $a \vee b$ appears in I. The instance of X-Network Stability is $[N, \mathbf{e}]$.

Notice that all the edges of any snake q_a are assigned the same value in any stable configuration of $[N, \mathbf{e}]$. If this value is 0, this is taken to mean that the variable a is "true." It is easy to check that this gives a one-to-one correspondence between the stable configurations of $[N, \mathbf{e}]$ and the satisfying assignments of I. □

8.2. Three-party Stable Marriage is NP-complete. Knuth [20] asks about the complexity of Stable Marriage if the participants are of three kinds: men, women, and dogs. We show that one possible formulation of this problem is NP-complete. It has been independently shown in [22] that this problem is NP-complete.

We consider the following formulation. An instance of Three-party Stable Marriage has equal numbers of three kinds of participants, say men, women, and dogs. A matching M is a set of triplets: each triplet contains exactly one participant of each kind, and each participant is in exactly one triplet of M. The participants have preference lists. Each participant lists all the triplets containing his name in order of preference. Matching M is unstable if there is a man m, a woman w, and a dog d, each of whom prefers the triplet (m, w, d) to the triplet he is assigned to in M. The problem is: given an instance of Three-party Stable Marriage, determine whether there is a stable matching.

LEMMA 8.2. *Three-party Stable Marriage is equivalent to Y-Network Stability.*

Proof. Section 3 shows that every instance of Stable Matching is an instance of X-Network Stability. In an analogous fashion, it can be shown that every instance I of Three-party Stable Marriage is an instance $[N, \mathbf{1}]$ of Y-Network Stability. The Y-gate is a natural generalization of the X-gate. It has three inputs i_1, i_2, i_3 and three outputs o_1, o_2, o_3. The function $Y : i_1, i_2, i_3 \rightarrow o_1, o_2, o_3$ is defined as follows: $Y(1,1,1) = (0,0,0)$; on all other input words, $Y(i_1, i_2, i_3) = (i_1, i_2, i_3)$. Input i_j and output o_j are associated. This association allows us to describe Y-networks in terms of snakes, just as we did for X-networks.

Network N contains one acyclic snake per participant. Snakes meet in triples at Y-gates. The sequence of Y-gates on the snake of a participant corresponds exactly to the sequence of triples that appear on his preference list. Proceeding in much the same way as in §3, it can be shown that snakes drop in triples in any stable configuration of $[N, \mathbf{1}]$, and that the stable matchings of I are in one-to-one correspondence with the stable configurations of $[N, \mathbf{1}]$—three persons are matched in I if and only if their snakes drop together in $[N, \mathbf{1}]$. This completes the reduction from Three-party Stable Marriage to Y-Network Stability.

The reduction from Y-Network Stability to Three-party Stable Marriage is similar to the reductions in §7.3. Given a Y-network N and its input assignment s_{in}, we construct an auxiliary Y-network $\tilde{N}$ in such a way that the stable configurations of $[N, s_{\text{in}}]$ are in one-to-one correspondence with the stable configurations of $[\tilde{N}, \mathbf{1}]$; furthermore, network $\tilde{N}$ has the following properties: every snake is acyclic; no two snakes meet more than once; no snake meets itself; each snake is assigned a *color* $\in \{1, 2, 3\}$; if an edge of snake q is input i_j or output o_j of some gate g of $\tilde{N}$, the color of snake q is j.

A snake whose input edge is assigned the value 0 by s_{in} may be deleted from the network, just as we did for X-networks. Next, assign each edge a color $\in \{1, 2, 3\}$ as follows: if edge e is output o_j of some gate, set color(e) equal to j; if e is an input edge of the network and is input o_j to some gate, set color(e) equal to j. (Edges that are both input and output edges of the network may be assigned an arbitrary color.) There are two difficulties to resolve—the network may have cyclic snakes, and there may be color conflicts, i.e., an edge with color j may be input i_k to a gate, with $j \neq k$.

Notice that $Y(1, 1, a) = (\bar{a}, \bar{a}, 0)$ and $Y(1, \bar{a}, 1) = (a, 0, a)$. Connect these two gates together by making the second output of the first gate be the second input of the second gate. Color the resulting circuit in the obvious fashion. The resulting circuit serves to "change the color" of an edge from 3 to 1. (Just ignore all outputs except output o_1 of the second gate.) Simple variants of this circuit can be used to change from any color j to any color k. Inserting such circuits in every noninput edge of the Y-network resolves all color conflicts and makes each snake acyclic. Let the color of a snake be the common color of its edges. The resulting network is $\tilde{N}$; it is easy to verify that it has all the desired properties.

We can read off an instance of Three-party Stable Marriage from network $\tilde{N}$, as follows. Introduce a participant for each snake of $\tilde{N}$, and read off the preference ordering of a participant from the order in which his snake participates in triples. A participant is a man, woman, or dog if and only if his snake is colored 1, 2, or 3 respectively. There are two difficulties: in the resulting instance, the numbers of the three different kinds of participants may not be equal, and each participant may not list all the triples he is supposed to. These difficulties may be resolved as in the proof of Lemma 7.2 by introducing extra snakes and appending a circuit. □

THEOREM 8.3. *Three-party Stable Marriage is NP-complete.*

Proof. By Lemma 8.2, it suffices to show that Y-NS is NP-complete. The Y-gate can simulate and be simulated by $\{NAND, COPY\}$, so Y-NS is equivalent to $\{NAND, COPY\}$-NS, which is known to be NP-complete [21]. □

Remark. Knuth [20] also proposes another formulation of Three-party Stable Marriage. In this "circular" version, men list women in order of preference, women list dogs, and dogs list men. A matching M of men, women, and dogs is stable if there is no destabilizing triple (m, w, d) such that man m prefers woman w to the woman he has been assigned to in M, woman w prefers dog d to the dog she has been assigned to in M, and dog d prefers man m to the man it has been assigned to in M. It is not known whether this problem has a polynomial-time solution.

9. Open problems. We seek new applications of the network approach to Stable Matching. We would like to find a fast parallel algorithm for Stable Matching. We would also like to find a fast parallel reduction from the Stable Marriage problem to the Assignment problem that preserves the structure of solutions.

Acknowledgments. This research has benefited from the ideas and suggestions of many. Ernst Mayr introduced me to the X-gate, and Danny Soroker introduced me to Stable Marriage. Discussions with Richard Anderson, Richard Cleve, Shaibal Roy, and Danny Soroker were very helpful in the early stages of this research. Marianne Baudinet helped me read portions of [20] and pointed me to Tarski's theorem; David Wolfe suggested that I look at Three-party Stable Marriage; and Alan Hoffman pointed out the importance of the nonalgorithmic proof of §6.2.1. Tomás Feder deserves very special thanks for simplifying the proof of Lemma 4.1, for many absorbing discussions, and for extending the network approach in wonderful ways in [5].

I would especially like to thank Ernst Mayr and Christos Papadimitriou for many useful discussions and for steadfast guidance and encouragement throughout the tenure of this research. I would also like to thank Andrew Goldberg, Dan Gusfield, Don Knuth, and Jeff Ullman for their comments at various stages of this research. This research has also been enriched by many intangible contributions from my fellow students and friends. Finally, thanks to the referees for their careful reading and constructive criticism.

WAIT-FREE CONSENSUS USING ASYNCHRONOUS HARDWARE*

BENNY CHOR[†], AMOS ISRAELI[‡], AND MING LI[§]

Abstract. This paper studies the wait-free consensus problem in the asynchronous shared memory model. In this model, processors communicate by shared registers that allow atomic read and write operations (but do not support atomic test-and-set). It is known that the wait-free consensus problem cannot be solved by *deterministic* protocols. A *randomized* solution is presented. This protocol is simple, constructive, tolerates up to $n - 1$ processors crashes (where n is the number of processors), and its *expected* run-time is $O(n^2)$.

Key words. asynchronous distributed systems, wait-free protocols, fault tolerance, randomized algorithms, consensus

AMS subject classifications. 68Q22, 90D10

1. Introduction. The problem of reaching consensus among different processors in a distributed environment [20] is one of the most fundamental problems whenever any type of cooperation is to be achieved. The nature of solutions to this problem depends on the properties of communication media, on the reliability of participating processors, and on their relative speeds. In this paper we investigate the consensus problem in a totally asynchronous system, where communication is carried out by shared registers that are atomic with respect to *read* and *write* operations, and up to $n - 1$ out of n processors may fail-stop (i.e., crash).

The consensus problem we study is the following multivalued problem: Every processor starts the protocol with an arbitrary input value (for example, an externally supplied variable or an internally computed constant). Upon termination, each processor decides on an output value. We have two requirements from the output. The first is that all processors that have terminated hold the same output value. The second is that the output value must be one of the input values of the processors. The consensus problem has been extensively studied in the asynchronous message passing model (e.g., [6], [24], [10]). The original version of this work [9] is the first one that studies and solves consensus in this asynchronous shared memory model.

It is convenient to think about all the *read* and *write* operations in terms of a global time model. In this model each such I/O operation takes place in a closed interval on the global-time axis. Atomicity of a register means that every set of *read*s and *write*s from/to this register is equivalent to a sequence in which each interval is shrunk to a distinct point, hence all these operations are totally ordered. We refer the reader to the works of Lamport [19], Herlihy and Wing [16], and Ben-David [5] for precise definitions of atomicity and linearizability. In particular, the techniques of [5] imply that when analyzing protocols that use atomic shared registers, the global time model can be used with no loss of generality.

We look for solutions to the consensus problem that satisfy the *wait-free termination* requirement. Wait-free termination means that every processor that is activated a sufficient number of times will decide and terminate. We would like to have a solution that guarantees that every schedule in which a processor is activated at least $k(n)$ times (for some $k(n)$ which is a function of n, the number of processors, but does not depend on the scheduler) leads to termination of that processor. This implies, in particular, that no processor needs to wait for other processors to take steps—it should terminate regardless of whether or not other processors were active in between its own steps (the output value could, however, depend on other processors' activity). Such a requirement is in accordance with the complete asynchrony of the system: It does not make sense to force the very fast processors to wait until a very slow processor makes a move. Furthermore, wait-free termination implies *resilience* to any number of processor crashes.

It is known that wait-free consensus cannot be achieved by *deterministic* protocols, even for systems with $n = 2$ processors. This impossibility result has been proven in the original version of this paper [9] and independently by Loui and Abu Amara [22]. It is also implicit in the work of Dolev, Dwork, and Stockmeyer [13]. All those proofs follow the ideas in the impossibility proof for the message passing model of Fischer, Lynch, and Paterson [17]. The gist of the proof is as follows: First, one shows that there are *bivalent* initial configurations of the system, namely, configurations that can lead to more than one decision value (under different schedulers). After establishing this fact, it is shown that starting from any bivalent configuration, there is an *infinite* scheduler that keeps the deterministic system in a bivalent state.

It is by now a well-known fact in the area of distributed computing that certain problems that cannot be solved by deterministic protocols do admit randomized solutions [24], [21], [6]. It is then only natural that in order to overcome the above-mentioned impossibility result, we employ a randomized protocol, allowing processors to toss coins. We present an efficient randomized protocol, that achieves consensus for systems of size n, using atomic single-writer multireader registers. The protocol is fairly simple and constructive, and its *expected* run-time is $O(n^2)$. This means that for any adversary scheduler, the system reaches a decision after $O(n^2)$ expected number of steps by *all* processors. The protocol uses unbounded size registers (though large values are actually written only with very low probability). The main usage of the unboundedness is to maintain a global order among processors. Processors who maintain larger values get preference over processors holding lower values. Coin flips are used to break possible ties among processors holding equal values.

We briefly discuss other approaches and developments. Loui and Abu-Amara [22] overcome the impossibility of deterministic consensus by using a much stronger communication primitive, namely, atomic test-and-set. Following the publication of the original version of our work [9], various improvements were made: One was designing protocols that operate in the presence of a stronger adversary model than the one used here. Another direction was the development of the so-called "bounded time stamps" [18], [14], and using them in consensus protocols with registers of bounded size. See §§2 and 4 for further details.

The remainder of this paper is organized as follows: In §2 we formally define the model, the class of admissible schedules, and the consensus problem. In §3 we present the protocol, and §4 contains some concluding remarks.

2. Model and definitions. In this section we define our model of asynchronous concurrent computation, the consensus problem, and the class of schedulers in which we are interested.

An asynchronous concurrent system is a collection of n processors. Every processor P is a (not necessarily finite) state automaton with an internal input register i_P and an internal output register o_P. The input register contains any value v taken from a set V, while the output register has initially the value $\perp$ ($\perp \notin V$) and could be changed once to a value in V. The set of all states of processor P will be denoted by S_P. The set S_P contains a set of states I_P that are the *initial states* of the processor P. States in S_P where o_P contains a value $\neq \perp$ are called the *decision states* of processor P. The set S_P might be infinite. In particular, this enables every internal state to include a description of the whole history of the computation of the processor P.

Processors communicate via *shared registers.* We use atomic single-writer multireader registers: Every shared register can be written by one processor and read by all other processors. Processors execute their programs by taking steps. A step consists of an internal operation, possibly involving coin tosses, and an input/output operation. In the model we consider, these two parts are executed as a single atomic step whenever the processor is scheduled.[1] Formally, every processor P takes steps according to its *transition function* T_P. Each step consists of a single input/output operation, followed by a state transition. The input/output operation could either be "read register r" or "write the value v to register r." In case the communication action is a read, the new state of P depends not only on the old state but also on the value read by this action. The transition function T_P could be either deterministic or randomized. In the latter case, for every state $s \in S_P$, there is a probability measure assigned to the next step. The choice of the actual step is done, according to these probabilities, only when the processor makes its next step. Given an asynchronous system as specified above, a *protocol* is a collection of n transition functions $T_1, \ldots, T_n$, one per processor.

A *configuration* C of the system consists of the state of each processor together with the contents of the shared registers. In an *initial configuration*, every processor is in an initial state, and all shared registers and output registers contain the default value $\perp$. The set of all configurations will be denoted by $\mathcal{C}$. A *step* takes one configuration to another by activating a single processor P. A *run* of length ℓ is a sequence of ℓ steps. Each run has an associated *schedule* that is a sequence of ℓ processors, numbered according to the order of processors that take steps in that run. We denote schedules, finite or infinite, by a list of processor numbers, e.g., $(2, 3, 3, 2, 1)$. If S is a finite schedule, then we denote by $S \circ i$, where i is any processor number, the schedule obtained from the schedule S by concatenating the number i to the end of S. We say that processor P is activated k times in a run if P appears k times in its schedule. The *history* $\mathcal{H}$ of a run is the sequence obtained by interleaving the sequence of configurations with the steps in the run, starting with the initial configuration. For a finite run, we refer to the last configuration in its history as the *current* configuration.

When arguing about randomized protocols, the power of the scheduler crucially depends on its adaptivity (see [8] for a discussion of this issue). *Adaptive schedulers* can use information derived from the state of the system and its history in making scheduling decisions. Formally, an admissible *scheduler* $\mathcal{S}$ in our system is a mapping from $\mathcal{H}$ into the set of n processors. Given the configuration of the system, the scheduler picks the next processor that is to take a step. The scheduler could either be a deterministic mapping or a randomized one. The scheduler is best viewed as an adversary that tries to prevent us from reaching our goal. Under the definition, this adversary scheduler is adaptive, and it has complete knowledge on the state of every processor and on the contents of the shared registers during the entire history.[2] In case the processors are randomized, the scheduler could also base its choices on the outcome

[1] An alternative approach separates the atomic operations to internal operations, input operations, and output operations.

[2] In the more refined level of atomicity, where internal operations, input operations, and output operations are separate, the adversary is even stronger. For example, it knows what a processor is about to write before scheduling that processor. For more details, see §4.

of past coin flips. We do not allow it, though, to be able to predict *future* randomized moves of the processors. This is a necessary requirement if randomization is to be helpful at all, and it is used in all algorithms where randomization is employed, e.g., [24], [21], [6]. In particular, in randomized protocols, a processor might be in a state in which the adversary does not know which input/output operation will be taken by that processor, before the action takes place. Given a history $\mathcal{H}$ and a scheduler $\mathcal{S}$, the runs that can be produced by $\mathcal{S}$, extending $\mathcal{H}$, on some possible randomized choices are called the runs *compatible* with $\mathcal{H}$ and $\mathcal{S}$. Notice that if both processors and scheduler are deterministic, then there is a single compatible run extending $\mathcal{H}$.

We say that a configuration C is reachable from history $\mathcal{H}$ with schedule $\mathcal{S}$ if there is a run compatible with $\mathcal{H}$ and $\mathcal{S}$ that leads to configuration C. We say that a configuration has a decision value v if some processor P is in a decision state with its output register o_P containing $v \neq \perp$.

A *randomized consensus protocol* is designed for an asynchronous system of n processors ($n \geq 2$). The protocol specifies a set V of possible inputs whose cardinality is at least two (otherwise the problem is trivial). It is required to satisfy the following properties:

(1) **Consistency:** for every schedule, no configuration reachable from an initial configuration has more than one decision value.

(2) **Nontriviality:** if processor P has decided on value v in a run, then v is an input value for at least one processor.

(3) **Randomized wait-free termination:** each processor must decide after taking a finite expected number of steps. Formally, there is a probability function f from the natural numbers into the interval [0, 1] $\left(\sum_{k=1}^{\infty} f(k) = 1\right)$, satisfying $\sum_{k=1}^{\infty} kf(k) < \infty$, such that for every initial configuration C_0 and for every admissible scheduler, if a processor P was activated k times by the scheduler, then the conditional probability that P is in a decision state, conditioned on P not being in a decision state after its previous activation, is at least $f(k)$.

We required that randomized consensus protocols will never err. The randomization effects only the running time of the protocol and not its correctness. There could be a positive probability for arbitrary long nonterminating runs, but this probability should be very small (converging to 0 with the length of the run), so that the expected running time is bounded.

3. Wait-free consensus protocol. The high-level structure of the protocol is as follows: In every point of an execution, each processor holds a preferred value (which is a potential decision value) and a confidence level (which is a nonnegative integer). Initially, the confidence level is 0, and the preferred value of the processor is its input value. Both the preferred value and the confidence level are written by each processor into a shared register, which can be read by all others. Processors compare their confidence levels, and if a large enough gap forms, the leading processor decides on its preferred value. In case of ties, processors increment their confidence level. In order to prevent live locks, where competing processors concurrently increment their confidence ad infinitum, coin flips are used. Confidence levels can possibly reach any nonnegative integer, which means that registers of unbounded size are used by the protocol. There is a positive (though very small) probability for very large numbers to be written into the shared registers. This probability decreases to 0 when the numbers increase to infinity.

To simplify the description of the protocol, we will say that a processor is on node i if its confidence level is i. The initial node is node 0. Before deciding and terminating, the processor moves to a special node, denoted by ∞ (this move facilitates the design and analysis of the protocol). Each processor starts execution by writing its input value in its register while staying on the start node. The steps of each processor in any given history H of the protocol are divided into *phases*. In each *phase* a processor reads the registers of all other processors, computes a new value, and writes it in its own register. A processor decides if it is at least two nodes ahead of all other processors with contending values. Thus, by the time of decision, processors with contending values are at least one step behind and will change their preferred value to that of the leading processor. There could be a situation with ties. The protocol resolves ties by having the option of advancing (to the next node) or not advancing, according to the outcome of coin tossing. This is where the use of randomization overcomes the deterministic impossibility result. In a bivalent configuration, only some of the choices made by some processors lead to another bivalent configuration. Other choices could lead to a univalent configuration. The adversary does not know which choices the processor will make *before* scheduling it, because the choice is made by flipping a coin.

If the coin used by every processor (in choosing whether to advance or not) would be unbiased, then with high probability, about half the contenders would advance. Those lagging behind would then join them, and again we would be in a tied situation. While such protocol, using unbiased coins, would satisfy the requirements of randomized consensus, it would lead to exponential (in n) expected running time (for an appropriate adversary strategy). To be more efficient, our protocol tries to have, with high probability, only one successful advancement out of n attempts. Leading processors in a tied situation flip a *biased* coin and advance only with small probability. Intuitively, this probability should be $\theta\left(\frac{1}{n}\right)$. The specific value we use, $\frac{1}{2n}$, is based on calculations done to minimize the expected running time.

It is dangerous to let a lagging processor decide, even if all leading processors have the same preferred value. The reason is that another processor might advance substantially after its value was last read by the lagging processor. The lagging processor, who thinks all leading processors have the same value, would in fact be wrong. Therefore, in our protocol, processors lagging behind never decide, and they always advance. A lagging processor who sees all leading processors with the same preferred value changes its own value. If the lagging processor sees conflicts at the top, it retains its old preferred value. In both cases, the lagging processor advances. If it is no more than two nodes behind the maximum, it advances by one. If it more than two nodes behind the maximum, it "jumps" to a point that is the maximum minus two. This shortcut allows the protocol to converge quickly to a decision, even if it starts from a configuration where one processor is way behind other active processors (e.g., if it just woke up). Thus, our upper bound on the expected running time will be valid starting from *every* reachable configurations, and not just the initial one.

To continue the description of the protocol, some definitions are introduced. Assume that processor P_i has just finished all the read steps in its jth phase, a phase we denote by ϕ_j^i. Let maxnode_j^i be the maximum node on which P_i sees a processor during ϕ_j^i (including itself). Using the data collected on ϕ_j^i, P_i computes two sets of processors, L and AL. The set L (the leaders) contains the processors whose node, as read by P_i , is maxnode_j^i. The set AL (the almost leaders) is the set of processors whose node, as read by P_i , is $\text{maxnode}_j^i - 1$. Denote by L_j^i (AL_j^i) the set L (AL) computed by P_i in phase ϕ_j^i.

A processor P_i terminates after the write step of phase ϕ_j^i in one of two cases:

T_1 If another processor has already terminated. The decision value is the value of the terminating processor.

T_2 If P_i itself is in the set L_j^i and all processors in the set $L_j^i \cup AL_j^i$ have the same *pref*. The decision value is the common *pref*.

We say that a processor P_i is *committed to terminate* in phase ϕ_j^i if it completed all the read steps of the phase and one of the termination conditions T_1 or T_2 holds (so its next step is a write, after which P_i decides and terminates). If none of the termination conditions holds, then P_i either moves to a new node or it stays put. The motivation behind the protocol design is to create a single leader. If P_i is a leader (that is, $P_i \in L_j^i$), then the new node to which

```
        $newreg := (input, 0)$
        $reg_1$ :=write($newreg$)
        repeat
              $v_1 := newreg$
              for $i := 2$ through $n$ do $v_i$ :=read ($reg_i$) od
              $maxnode := \max_{1 \le i \le n}\{v_i.node\}$
              $L := \{P_i : v_i.node = maxnode\}$
              $AL := \{P_i : v_i.node = maxnode - 1\}$
($T_1$)       if $\exists i \; v_i.node = \infty$
                then $reg_1$ := write($v_i.pref$, $\infty$), decide $v_i.pref$ and halt.
($T_2$)       elseif $P_1 \in L$ and $pref$ of all processors in $L \cup AL = v_1.pref$
                    then $reg_1$ :=write($v_1.pref$, $\infty$), decide $v_1.pref$ and halt.
              elseif $P_1 \in L$
                    then

FIG. 1. *The n processor protocol (for P_1).*

it can move is the successor of its node. However, it moves to its successor node only with probability[3] $1/2n$. With probability $1 - 1/2n$, P_i stays on its current node. In both cases, the leader P_i retains its old preferred value.

If P_i is not a leader, then it always moves to a new node. Let k denote P_i's node during ϕ^i_j. If $\text{maxnode}^i_j - k \le 2$, then P_i moves to the successor of its node, $k + 1$. In this case, P_i's new preferred value is determined as follows: If all processors in L^i_j have the same *pref*, this value is the new *pref* of P_i. If this is not the case, then P_i keeps its own *pref*.

If P_i is not a leader and $\text{maxnode}^i_j - k \ge 3$, then P_i moves to node $\text{maxnode}^i_j - 2$. In such case, we say that P_i *jumps*. In case of a jump, the new *pref* of P_i is the *pref* of the processor in L^i_j with the minimal index.

LEMMA 3.1. *Let H_0 be an initial segment of a history H of an arbitrary execution of the protocol. If in H_0 no processor reaches node i with preferred value v, then for any node $j > i$, no processor reaches j, in H_0, with preferred value v.*

Proof. Assume, toward a contradiction, that H is the history of an execution not satisfying the lemma. Let H_0 be an initial segment of H of minimal length that violates the lemma. This

[3] This specific probability $1/2n$ was chosen in order to optimize the expected running time.

means that there is a node i such that in H_0 no processor reaches i with preferred value v and there is a processor P_k that reaches a node $j > i$ with preferred value v.

Let ϕ_ℓ^k be the phase in which P_k moves to node j. If P_k jumps to j, then, by the protocol, at least one processor $P_m \in L_\ell^k$ has been on node $j + 2$ with preferred value v before this jump. Since $j+2 > i$, this contradicts the minimality of H_0. We can therefore assume that P_k moves to node j from node $j - 1$ without jumping. First, we show that the preferred value of P_k at $j - 1$ is $v' \neq v$. If $j - 1 = i$ then, this is true by our assumption that in H_0 no processor prefers the value v on node i. If $j - 1 > i$, then this is true because of the minimality of H_0. Having established this claim, we observe that by the protocol, in order for P_k to change its preferred value from v' to v while moving from $j-1$ to j it has to see all processors in L_ℓ^k with preferred value v. We now show that for any possible value of maxnode_ℓ^k this is impossible. In ϕ_ℓ^k P_k is on $j - 1 \geq i$. Therefore $\text{maxnode}_\ell^k \geq j - 1 \geq i$. If $\text{maxnode}_\ell^k = i$, then by our assumption no processor has preferred value v on i. If $\text{maxnode}_\ell^k > i$, then as we have shown above, no processor in L_ℓ^k has preferred value v. □

LEMMA 3.2. *Let P_k be the first processor reaching node i with preferred value v. Then P_k does not jump to i, and its preferred value on node $i - 1$ is also v.*

Proof. Let ϕ_ℓ^k denote the phase in which P_k moves to node i, and let H_0 be the initial segment of the history of the execution that ends with the last read step of P_k in ϕ_ℓ^k. In H_0 no processor has reached node i with preferred value v. Thus, by Lemma 3.1, no processor has reached any node $j \geq i$ in H_0 with preferred value v. Therefore P_k sees no leader on any node $j \geq i$ with preferred value v during ϕ_ℓ^k. According to the protocol, P_k does not jump to node i with preferred value v in ϕ_ℓ^k. Since P_k reaches node i with preferred value v, this argument implies that P_k does not jump to node i.

Assume, by way of contradiction, that P_k changes its preferred value from v' to v while moving from $i - 1$ to i at the end of ϕ_ℓ^k. This happens only if *pref* of all processors in $L_{k,\ell}$ is v. Consider the following cases:

Case 1: $\text{maxnode}_\ell^k = i - 1$. In this case $P_k \in L_\ell^k$. By the protocol P_k keeps its preferred value while moving to i. Contradiction.

Case 2: $\text{maxnode}_\ell^k = i$. In this case the preferred value of all processors in L_ℓ^k does not equal v, since we assumed that P_k is the first processor reaching i with preferred value v. Contradiction.

Case 3: $\text{maxnode}_\ell^k > i$. In H_0 no processor has been on node i with preferred value v, and by Lemma 3.1, in this execution no processor has preferred value v on maxnode_ℓ^k before the completion of ϕ_ℓ^k. Contradiction.

We conclude that P_k prefers the value v during ϕ_ℓ^k, its last phase on node $i - 1$. By the protocol, processors retain their preferred values when staying on the same node. This means that P_k prefers the value v during all phases it executes while residing on node $i - 1$. □

LEMMA 3.3. *Let H be the history of an arbitrary execution of the protocol. Let P_j be a processor committed to terminate, in H, by T_2. If P_j is committed to terminate on i with decision value v, then in H, no processor reaches i with a preferred value $v' \neq v$.*

Proof. Assume, by way of contradiction, that P_ℓ is the first processor reaching i with preferred value $v' \neq v$. By Lemma 3.2, P_ℓ moves to node i without jumping, and the preferred value of P_ℓ on $i - 1$ is also v'. Let ϕ_k^j be the phase in which P_j is committed to terminate with v. At the beginning of ϕ_k^j, P_ℓ is on node $m < i - 1$. (Otherwise P_j sees P_ℓ as either a leader or an almost leader during phase ϕ_k^j, and condition T_2 does not hold.) After P_ℓ advances to $i - 1$ it starts a new phase ϕ_r^ℓ. In ϕ_r^ℓ, P_ℓ reads the values of all processors. The leaders in L_r^ℓ are on a node $\geq i$. The value preferred by all these leaders before P_ℓ moves there is v, as the only value preferred at i is v. By the protocol P_ℓ takes v as its new preferred value and advances to i. Contradiction. □

LEMMA 3.4. *Let H be the history of an arbitrary execution of the protocol. Assume that in H a single processor P_i moves from node.m to node $m + 1$ as a result of a successful coin toss. (That is, all other processors that tried to move from m to $m + 1$ as a result of a coin toss fail to do so.) If P_i's preferred value on node m is v, then all processors reaching node $m + 1$ in H have v as their preferred value on node $m + 1$.*

Proof. Assume, by way of contradiction, that the lemma does not hold. Let P_j $(i \neq j)$ be the first processor reaching node $m + 1$ with preferred value v' $(v' \neq v)$ in H. By Lemma 3.2, P_j does not jump to node $m + 1$. By the supposition, P_j does not flip a coin when moving from node m to node $m + 1$. This implies, by the protocol, that P_j is not one of the leaders during the phase ϕ_ℓ^j in which it moves to node $m + 1$ (i.e., $P_j \notin L_\ell^j$). Since all processors who move to node $m + 1$ in H *before* P_j's move prefer the value v on node $m + 1$, it follows from Lemma 3.1 that all leading processors (those in L_ℓ^j) prefer the value v. All these leaders are on a node $\geq m + 1$ and according to the protocol P_j moves to $m + 1$ with preferred value v in phase ϕ_ℓ^j—contradiction. □

LEMMA 3.5. *Let H be the history of an arbitrary execution of the protocol. Assume that in H, processor P_i is the first processor who moves from node m to node $m + 1$ as a result of a successful coin toss. Then after this write step of P_i, any other processor P_j makes at most one attempt to move from node m to node $m + 1$ as a result of a coin toss.*

Proof. Consider the execution after P_i's move. If P_j succeeds in its first attempt to move from node m to node $m + 1$ as a result of a coin toss, then we are done. If P_j fails, then it stays on node m. In the phase following the failed attempt, P_j is not a leader (as it sees P_i at least one node ahead). By the protocol, P_j does not flip a coin in its next phase on node m and moves to a new node in this phase. □

THEOREM 3.6. *The n processor protocol is consistent.*

Proof. Let H be an arbitrary history of the protocol. It is easy to see that a processor terminates by T_1 with value v only if some other processor terminated earlier with v by T_2. Therefore, it suffices to show that in H all processors that terminate by T_2 have the same decision value. Let i be a minimal node on which some processor is committed to terminate by T_2. Without loss of generality assume that P_j terminates on i with value v. In order to prove that the protocol is consistent we will show that no other processor is committed to terminate on any node with a value $v' \neq v$. By the protocol, the first processor committed to terminate with value v' is committed by T_2. Since i is a minimal node on which any processor is committed to terminates by T_2, no processor is committed to terminate by T_2 on any node $k < i$. By Lemma 3.3 no processor reaches i with any preferred value $v' \neq v$. By the protocol, this implies that no processor is committed to terminate by T_2 on node i with decision value v'. This also implies, by Lemma 3.1, that no processor reaches any node $k > i$ with preferred value $v' \neq v$. Therefore, by the protocol, no processor is committed to terminate by T_2 with decision value $v' \neq v$. □

We now proceed to analyze the expected running time of the multiprocessor protocol.

THEOREM 3.7. *Let C be any reachable configuration of the n processor system and $\mathcal{A}$ an arbitrary adversary scheduler. If $\mathcal{A}$ schedules the processors such that at least $15n$ entire phases are executed following C, then with probability ≥ 0.4534, at least one processor decides and terminates.*

Proof. Let m $(m \geq 0)$ be the maximal node on which any processor resides at C. By the protocol, any processor P_i that executes an entire phase following C finds that some processor resides on a node $\geq m$ and will subsequently move to a node $j \geq m - 2$ in the write step of this phase. After completing two additional phases, P_i reaches node $j \geq m$. (Recall that if a processor is not among the leaders in some phase, then it does not flip a coin and traverses at least one edge in the **write** step of that phase.)

Thus, of the $15n$ entire phases that are executed following C, at most $3n$ are executed by processors residing on nodes smaller than m. Therefore, at least $12n$ entire phases are executed, following C, by processors residing on nodes greater than or equal to m.

Consider the first processor P_i that is scheduled to make a **write** step while residing on node m following C. If some other processor has already decided before this write step of P_i, then we are done. If no other processor has yet decided, then since m is the maximal node in C, the value maxnode that P_i maintains at the time of this write equals m. If P_i decides and moves to ∞, then we are done. Otherwise, according to the protocol, P_i flips a coin when making its write step, and if it succeeds (this happens with probability $1/2n$), it moves to node $m + 1$.

We base our analysis on the following two events:

- E_1: Of the first $4n$ attempts to move from node m to node $m + 1$ as a result of a coin toss following C, *exactly* one succeeds. Subsequent to the successful move, all attempts to move from node m to node $m + 1$ as a result of a coin toss fail.
- E_2: Of the first $4n$ (or fewer) attempts to move from node $m + 1$ to node $m + 2$ as a result of a coin toss following C, *at least* one succeeds.

Using Lemma 3.5, the number of subsequent attempts to toss a coin on node m, after the first successful toss on node m, is less than or equal to $n - 1$. Since the adversary is unable to predict the outcome of a write that uses coin tossing before the action takes place, we have

$$Pr(E_1) \geq \left(\overbrace{\frac{1}{2n}}^{\text{success in 1st}} + \overbrace{\left(1 - \frac{1}{2n}\right)\frac{1}{2n}}^{\text{success in 2nd}} + \dots + \overbrace{\left(1 - \frac{1}{2n}\right)^{4n-1}\frac{1}{2n}}^{\text{success in }4n\text{th}} \right)$$
$$\cdot \overbrace{\left(1 - \frac{1}{2n}\right)^{n-1}}^{\text{no subsequent success}}$$
$$= \left(1 - \left(1 - \frac{1}{2n}\right)^{4n}\right)\left(1 - \frac{1}{2n}\right)^{n-1}.$$

If E_1 occurs, then at most $4n + n - 1 = 5n - 1$ of the entire phases that are executed on nodes $\geq m$ following C involve an attempt to move from node m to $m + 1$ by tossing a coin. At most $n - 1$ additional phases can involve moving from node m to $m + 1$ without tossing a coin. Thus overall, if E_1 occurs, then at most $6n - 2$ of the entire phases that are executed on nodes $\geq m$ following C are executed by processors residing on node m. This implies that at least $(12 - 6)n + 2 = 6n + 2$ entire phases are executed, following C, by processors residing on nodes greater than or equal to $m + 1$.

Consider the first processor P_i that is scheduled to make a **write** step while residing on node $m + 1$ following C. If some other processor has already decided before this write step of P_i, then we are done. If no other processor has yet decided, then since m is the maximal node in C, the value maxnode that P_i maintains at the time of this write must equal $m + 1$. If P_i decides and moves to ∞, then we are done. Otherwise, according to the protocol, P_i flips a coin when making its write step, and if it succeeds (this happens with probability $1/2n$), it moves to node $m + 2$. If P_i does not succeed, then by the same reasoning the next processor that resides on node $m + 1$ flips a coin when it is scheduled to write , and so on. Thus, until at least one processor succeeds, all processors that reside on node $m + 1$ try to move to node $m + 2$ by flipping a coin. The probability that out of the first $4n$ attempts at least one is successful satisfies

$$Pr(E_2 \mid E_1) \geq 1 - \left(1 - \frac{1}{2n}\right)^{4n} .$$

The sequence $\{(1 - \frac{1}{2n})^{n-1}\}_{n=2}^{\infty}$ is monotonically decreasing to the limit $\frac{1}{\sqrt{e}}$. The sequence $\{1 - (1 - \frac{1}{2n})^{4n}\}_{n=2}^{\infty}$ is monotonically decreasing to the limit $1 - \frac{1}{e^2}$ (the limits can easily be verified, using the fact that $\{(1 - \frac{1}{k})^k\}_{k=2}^{\infty}$ monotonically increases to $\frac{1}{e}$). Combining these properties with the two inequalities above, we have (for $n \geq 2$)

$$\begin{aligned} Pr(E_2 \cap E_1) &\geq \left(1 - \left(1 - \frac{1}{2n}\right)^{4n}\right)^2 \left(1 - \frac{1}{2n}\right)^{n-1} \\ &\geq \left(1 - \frac{1}{e^2}\right)^2 \cdot \frac{1}{\sqrt{e}} \\ &> 0.4534 . \end{aligned}$$

If E_2 occurs, then at least one of the first $4n$ (or fewer) attempts succeeds. Using Lemma 3.5, the number of subsequent attempts to toss a coin on node $m + 1$ after the first successful toss is less than or equal to $n - 1$. At most $n - 1$ additional phases can involve moving from node $m + 1$ to $m + 2$ without tossing a coin. Thus overall, at most $6n - 2$ of the entire phases that are executed on nodes $\geq m + 1$ following C are executed by processors residing on node $m + 1$. This implies that at least $(6n + 2) - (6n - 2) = 4$ entire phases are executed, following C, by processors residing on nodes greater than or equal to $m + 2$.

In particular, it follows that at least one processor P_i completes a phase, including a write step, while residing on node $m + 2$. By Lemma 3.4, if E_1 occurs, all processors reaching node $m + 1$ have the same preferred value v on node $m + 1$. But since on node $m + 1$ all processors prefer the same value v, Lemma 3.1 implies that on $m + 2$ all processors prefer v as well. Thus the first processor P_i that completes a phase while residing on node $m + 2$ finds out during that phase that all leaders (processors on $m + 2$) and almost leaders (processors on $m + 1$) prefer v. P_i thus moves to the decision node ∞ by T_2, and terminates.

Therefore, with probability at least 0.4534, at least one processor terminates after $15n$ phases are completed following C. □

Using Theorem 3.7, we can easily give an upper bound on the expected time until some processor decides, starting from any reachable configuration C. Dividing the execution into blocks such that in each block exactly $15n$ phases are completed, we know that the probability of termination in each block is at least 0.4534. The expected number of entire phases is thus $15n/0.4534 < 33.1n$ operations. In terms of *elementary* operations (atomic read, atomic write), each entire phase involves exactly n elementary operations. At most $n(n - 1)$ initial elementary operations can belong to phases whose execution have already begun. Thus, the expected number of elementary operations until at least one processor decides is at most $33.1n^2 + n(n - 1) < 35n^2$. This implies the following.

THEOREM 3.8. *The n processor protocol is a randomized wait-free consensus protocol. Starting from any reachable configuration, the expected number of elementary steps until at least one processor decides is less than $35n^2$.*

4. Concluding remarks.

The analysis of the expected running time of our n processors protocols relied on the inability of the adversary to predict the outcome of a write that uses coin tossing, before the action takes place. Following the publication of the original version of our paper [9], Abrahmson [1] considered a stronger adversary model, where the outcome of the coin toss that is used in the next write step is known to the adversary before the step takes place. In this adversary model, the scheduling choices can be based on the outcome of the coin. Abrahmson modified our protocol and produced one that works in the presence of the strong adversary but has exponential ($2^{O(n^2)}$) expected running time. Subsequently, this was dramatically improved by Aspnes and Herlihy [3], who designed an efficient wait-free consensus protocol for this strong adversary model, with $n^{O(1)}$ expected running time. The protocol of Aspnes and Herlihy employs the same basic structure of our protocol, namely an incremental walk on the line of nonnegative integers. It introduces novel ideas from the theory of random walks in the implementation of the coin flips. Improved algorithms that use *bounded* shared registers and work in the presence of the strong adversary were later designed by Attiya, Dolev, and Shavit [4], Aspnes [2], and Saks, Shavit, and Wohl [25]. (Most of these algorithm solve the somewhat simpler problem of *binary* consensus, where the input set is $\{0, 1\}$.) The expected running time of the later protocol is $\Theta(n^3)$ elementary steps. This has subsequently been improved by Bracha and Rachman [7] to an $O(n^2 \log n)$ consensus protocol. Despite these improvements, our protocol remains the most efficient of which we know for the model considered in this paper and is a strong candidate for practical consensus protocols. By bounding the size of the shared registers in our protocol to, say, 128 bits per processor, we get a protocol that still never errs and has probability less than 2^{-56} of nontermination.

We view the possibility of achieving wait-free consensus as a fundamental tool in shared memory systems and believe it is only the first step in a promising direction. The subsequent results of Herlihy [15] and Plotkin [23] on wait-free implementation of sequential objects and of Chor, Moscovici, and Nelson [11], [12] on solvability of distributed decision tasks and distributed interactive tasks seem to support this belief.

Acknowledgments. We thank Maurice Herlihy for pointing out an error in the original version of the protocol. Discussions with Nissim Francez and Lenny Pitt that helped initiating this work are also acknowledged.

INFERRING EVOLUTIONARY HISTORY FROM DNA SEQUENCES*

SAMPATH K. KANNAN† AND TANDY J. WARNOW‡

Abstract. One of the longstanding problems in computational molecular biology is the *Character Compatibility Problem*, which is concerned with the construction of phylogenetic trees for species sets, where the species are defined by characters. The character compatibility problem is NP-Complete in general. In this paper an $O(n^2k)$ time algorithm is described for the case where the species are described by quaternary characters. This algorithm can be used to construct phylogenetic trees from DNA sequences.

Key words. algorithms, graphs, evolutionary trees, evolution

1. Introduction. Given a set S of n species, a *phylogenetic tree*, or, more simply, a *phylogeny* or *evolutionary tree*, is a rooted tree with n leaves that describes the evolution of the species in S from a common ancestor. The internal nodes represent ancestral species, and the leaves represent the species in S.

One standard way to describe species is through the use of characters. A *character* is an equivalence relation on the set S of species, partitioning the species set into the distinct equivalence classes, which we will call the *character states*. Since the number of possible states of any character is finite over any finite species set, we can number the states of each character. If there are n species and k characters, we can represent our data by an $n \times k$ integer matrix M, where the entry M_{ij} is the state of species s_i for the jth character. The ith row in this matrix is a vector over Z^k (where Z denotes the integers) that is identified with the species s_i.

In any phylogeny T for the species set S each leaf has a vector of character states in Z^k associated with it. We also assign to each internal node of the tree T a vector in Z^k thereby hypothesizing the character states of the ancestral species in our phylogeny. The desired property for this phylogeny (and assignment of vectors to internal nodes) is that, for each state of each character, the set of nodes in the phylogeny having that state should form a subtree. That is, the subgraph induced by those nodes should be a connected graph. Such a phylogeny is called a *perfect phylogeny*. This is also expressed by saying the phylogeny is convex for each character, or simply that it has the *convexity* property.

Given a phylogeny T, Fitch [17] has shown that one can efficiently determine whether there is an assignment of character vectors to the internal nodes so as to make T perfect. Thus the crux of the problem is the choice of phylogeny.

When a perfect phylogeny exists for a set C of characters defining a species set S, we say the character set is *perfectly compatible*, or, simply, *compatible*, on the species set S. In the literature it is common to drop the reference to the species set S and simply say the character set C is *compatible*. When there is no possibility of confusion about the species set, we shall use this convention.

We can now state the following.

Perfect phylogeny problem. Given a set of species defined by a set of characters, determine whether a perfect phylogeny exists.

This problem is also referred to in the literature as the *Character Compatibility Problem.*

What we will describe is an $O(n^2k)$ divide-and-conquer algorithm that will determine whether a set of n species defined by k quaternary characters has a perfect phylogeny; when a perfect phylogeny exists, the algorithm will construct one. If each species in S is defined by a DNA sequence and the DNA sequences are all perfectly aligned (so that there are no gaps), then each position in the sequences represents a character. Thus we have the quaternary character compatibility problem, since each position must take on one of only four possible values (A, C, T, or G). We can apply the algorithm to this case and determine whether a perfect phylogeny exists for species defined by perfectly aligned DNA sequences.

Unfortunately, in practice the set of characters is seldom perfectly compatible. We can still use our algorithm to find *maximal* sets of compatible characters. This can be done by iteratively adding a compatible character to a set of mutually compatible characters until no further characters can be added. This procedure takes time $O(n^2k^2)$. By contrast, the problem of finding a *maximum* set of compatible quaternary characters is *NP-Hard* [7].

The structure of the remainder of the paper is as follows. We discuss the history of the character compatibility problem in §2. Essential concepts that are used in the algorithm for quaternary character compatibility are defined in §3. We show how we reduce to subproblems for the trinary character compatibility problem in §4. The reduction to subproblems for quaternary characters is described in §5. We conclude with a discussion of further problems in §6.

2. History of the character compatibility problem. The character compatibility approach to phylogenetic tree construction is related to parsimony and compatibility criteria. Parsimony criteria seek to find a tree of minimum size, where the size of the tree is the number of character state changes indicated by the edges. Compatibility criteria seek instead to keep as many characters as possible while eliminating others, so that with respect to the characters that are kept, it is possible to construct a perfect phylogeny. Each approach has its proponents, but essentially they agree in their philosophy, which is that *the tree of minimum evolution is the right tree.*

This approach to phylogenetic tree construction originated in the 1960s. (Edwards and Cavalli-Sforza are usually credited with introducing parsimony in their papers from the early 1960s [9], [10]); variations on the basic parsimony criterion were also proposed ([22],[23], [24], [4] and others).

The concept of characters being perfectly compatible with a given tree arose naturally from these approaches, in that it represents the best *possible* tree (i.e., having minimum possible evolution on the tree). This objective was championed by LeQuesne in a series of papers [23], [24], [25], [26], and later given its firm mathematical foundation in the literature by two papers of Estabrook and McMorris [11], [12].

Since construction of phylogenies using compatibility criteria was shown to be an *NP-hard* problem by Day and Sankoff in [7] and many variations of parsimony were also shown to result in *NP-hard* problems [5], [6], [18], the character compatibility problem was assumed to be *NP-Complete* as well. This was finally proved independently in 1991 by Steel [29] and Bodlaender, Fellows, and Warnow [1].

Until 1990, the only progress on algorithms for the character compatibility problem was to show that binary character compatibility [27] and compatibility of two characters at a time [13], [17] could be solved in polynomial time. An important theoretical breakthrough came in 1974, when Buneman proved a beautiful result [3] showing that the problem reduced in polynomial time to the graph-theoretic *Triangulating Colored Graphs Problem.* These problems were shown polynomially equivalent by Kannan and Warnow in [21] in 1990. This equivalence was used in [1] to show that the character compatibility problem was *NP-Complete*, so that no polynomial time algorithm for the character compatibility problem will exist unless $P = NP$.

In the biological literature, the first algorithms presented to determine compatibility of two characters were given in 1975 [13], [17] and only proved correct two years later by Estabrook and McMorris in [14]. Algorithms for three characters at a time were discovered first by Kannan and Warnow [21] and later by Bodlaender and Kloks [2] and Idury and Schaffer [20]. Each of these algorithm used linear time, but [21] required quadratic space, while the others find linear space implementations. The only algorithm for the character compatibility problem that runs in polynomial time when the number of characters is bounded by a constant is the algorithm of McMorris, Warnow, and Wimer [28] that achieves a running time of $O(r^{k+1}k^{k+1} + nk^2)$. Since this grows exponentially in the number of characters, it is primarily of theoretical interest.

Characters derived from molecular data (such as DNA sequences) are associated with the columns of a multiple alignment and thus have the restriction that the number of states achieved by any particular character is limited to a small constant. In the case of DNA or RNA sequences, this number is four, while for amino-acid sequences, the number is 20. As we will see, by restricting the number of states, we are able to obtain efficient algorithms for constructing perfect phylogenies. (If they exist, of course!)

The first case of this type that was handled was for binary characters. Polynomial time algorithms for binary character compatibility were found by several authors with the best being the $O(nk)$ algorithm of Gusfield [19], for testing compatibility of k characters on n species. This is optimal, since the input requires $O(nk)$ space, and each entry must be checked. Finally, an $O(nk^2)$ algorithm for compatibility of three-state characters was found by Dress and Steel [8].

In this paper we present two new results: an $O(\min(nk^2, n^2k))$ algorithm for the trinary character compatibility problem, and an $O(n^2k)$ algorithm for the quaternary character compatibility problem.

3. Basic concepts. We describe in this section the basic concepts which are used in our techniques for determining character compatibility for four-state characters. These concepts form the basis of our divide-and-conquer algorithms.

3.1. Canonical labeling of phylogenies. Let P be a proposed phylogeny for S in which only the leaves are assigned labels. To determine whether we can label the internal nodes in P so that the phylogeny is *perfect*, we apply a modification of Fitch's algorithm [16] for finding the minimum size assignment of labels to internal nodes. The difference is that we will permit an internal node to take on a *dummy* state, if its state for a character is not constrained by values at the leaves. The technique we will describe will simultaneously set the labels at the internal nodes and determine whether a labeling that is convex for every character is possible.

Let v be an internal node of P that is not yet labeled. We can define $\alpha(v)$ for every character $\alpha \in C$ by using the following rule: $\alpha(v) = \alpha(x)$ if there exist leaves x and y in different components of $P - \{v\}$ such that $\alpha(x) = \alpha(y)$. If for some internal node v we do not have such a pair of leaves, and thus for all leaves x and y in different components of $P - \{v\}$ we have $\alpha(x) \neq \alpha(y)$, we let $\alpha(v)$ remain "unset," i.e., it takes on the dummy state, α^*. The labeling we have described thus is determined entirely by the topology and the leaf labels. We call this the *canonical* labeling.

To determine if P with the canonical labeling at the nodes (as described above) is perfect, it suffices, clearly, that for every node v, we do not have a conflict in how to set $\alpha(v)$ for any character α. That is, if $P - \{v\}$ has components $P_1, P_2, \ldots, P_r$, we do not have $s_1 \in P_i$, $s_2 \in P_j$, $t_1 \in P_l$, and $t_2 \in P_m$ such that $i \neq j$ and $l \neq m$ and $\alpha(s_1) = \alpha(s_2) \neq \alpha(t_1) = \alpha(t_2)$. Thus, we can determine whether a phylogeny is perfect by knowing the topology and examining the labels at the leaves.

We can assume that every perfect phylogeny P is given the canonical labeling.

Two adjacent nodes v, w in P can be identified if, under the canonical labeling, for each $\alpha \in C$, whenever $\alpha(v) \neq \alpha(w)$, " $*$ " $\in \{\alpha(v), \alpha(w)\}$. In other words, if two nodes disagree for a character only when one is given the dummy state, then we can identify the two nodes. We will sometimes use this flexibility in a phylogeny and thus change the topology of a perfect phylogeny.

We make the following definitions.

DEFINITION 1. *Let P be a perfect phylogeny such that, using the canonical labeling, every two adjacent nodes v and w* cannot *be identified. Then P is said to be* rigid.

3.2. Tree-structures. Let P be a (possibly perfect) phylogeny for S, and consider a specific character, α. The α-tree-structure for P is formed by repeatedly contracting edges connecting nodes that have the same (nondummy) state for α. This tree does not depend on the sequence of edge-contractions and is thus well defined. We are interested in the set of tree-structures that can arise from perfect phylogenies and hence make the following definition.

DEFINITION 2. *A tree-structure for α that can be obtained from some perfect phylogeny will be called a* realizable tree-structure *for α.*

Note that when a phylogeny is perfect, the resultant tree-structure for α has exactly one node for each state of α.

For quaternary characters, the set of possible tree-structures is shown in Fig. 1.

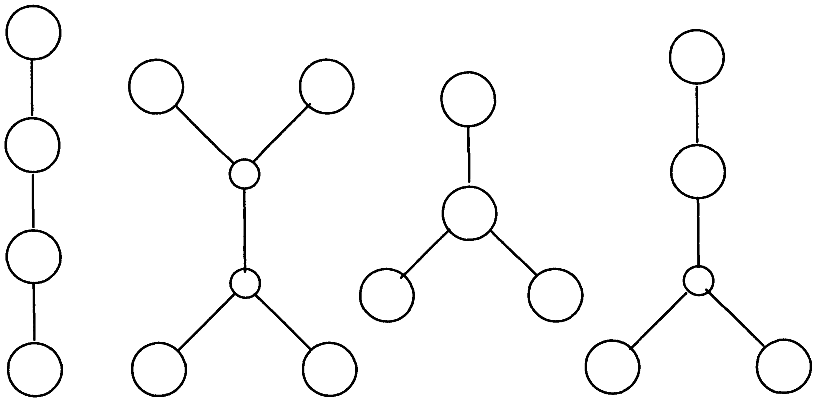

FIG. 1. *Tree structures for a quaternary character.*

We first make the following definition.

DEFINITION 3. *We will say that a perfect phylogeny P is in* reduced form *if it satisfies the following conditions*:

(i) *every internal node of P has degree at least three, and*

(ii) *P has $|S|$ leaves, each labeled by a distinct element of S.*

Clearly, every perfect phylogeny can be put in reduced form and then labeled using the canonical labeling. Thus, in searching for a realizable tree-structure, it will suffice to look for a tree-structure arising from such a perfect phylogeny. We make the following definition:

DEFINITION 4. *A tree-structure that arises from a perfect phylogeny in reduced form and canonically labeled is called a* realizable elementary *tree-structure.*

It is not hard to prove that a phylogeny in reduced form is defined by its set of tree-structures (one for each character in C). It can also be noted that when a tree-structure is derived from a canonically labeled phylogeny in reduced form, then a node with a dummy state has degree at least three in the tree structure.

The tree-structure of a perfect phylogeny for a character α is thus node labeled by α states. We will define some notation that will be used in representing tree-structures as well as in the algorithm statement.

DEFINITION 5. *The denote by α_i the set $\{s \in S : \alpha(s) = i\}$.*

We will use a slightly nonstandard definition of "adjacency" in a tree-structure.

DEFINITION 6. *We will say that two states α_i and α_j are adjacent in a tree-structure T if α_i and α_j are connected by an edge or the path from α_i to α_j in T goes only through dummy nodes.*

This definition suits the usage made of the concept of adjacency in this paper. However, when we say that α_i is *between* α_j and α_k, we will mean that the path from α_j to α_k goes through α_i.

We call a set *big* if it contains at least two elements. Thus α_i is big if $|\alpha_i| \geq 2$. We then make the following definition:

DEFINITION 7. *A character is* informative *if it has at least two* big *states.*

Using this definition, we can state the following:

LEMMA 3.1. *Let C be a set of characters for a set S of species, and suppose that the character α is not informative. Then C is compatible on S if and only if $C - \{\alpha\}$ is compatible on S.*

Proof. One direction is obvious. Now suppose that α is a noninformative character (i.e., it has only one state, α_1, which is big), and suppose that $C - \alpha$ is compatible on S. Let P be a perfect phylogeny for S with respect to the characters in $C - \alpha$. The species in S each occupy a leaf and are labeled by a vector of character states of length $|C| - 1$ (one position per character in $C - \{\alpha\}$).

We can now set the α-state for each node in P, both internal and external, in such a way that the resulting node-labeled tree will be a perfect phylogeny for S with respect to the character set C. The internal nodes will all have state α_1, while the external nodes (leaves) will have their α states set according to the "true" character state information. It is easy to see that this is a perfect phylogeny for the enlarged character set. □

We will show that if we can find a realizable tree structure in some manner (for example by consulting an oracle) for an *informative* character, then we can construct subproblems of strictly smaller size so that the two subproblems have perfect phylogenies if and only if the original instance had a perfect phylogeny. More precisely, given a realizable tree-structure for an informative character, we can construct what we call a *legal partition* of the set S, and from this partition, we can define subproblems. We now define these partitions.

3.3. Legal partitions.

Let S be the set of species and C the set of characters.

DEFINITION 8. *Given a phylogeny P, we will let $\mathcal{L}(P)$ indicate the leaf set of P.*

DEFINITION 9. *A partition of S into S_1 and S_2, with $n - 2 \geq |S_1|, |S_2| \geq 2$, is called a* legal partition *if whenever C is compatible on S there is a perfect phylogeny P with the following property: P contains an edge e whose removal breaks up P into subtrees P_1 and P_2 with $\mathcal{L}(P_i) = S_i$, $i = 1, 2$.*

When the character set is incompatible, *any* partition of S into two big parts is a legal partition. The reason we require the cardinalities of each side of the partition to be between 2 and $n - 2$ is that by doing so we ensure that the subproblems on which we will recurse are small enough.

3.4. Splitting vectors. We begin by making the following definition.

DEFINITION 10. *Given a partition $S = S_1 \cup S_2$, we define the* splitting vector x *(sometimes also called the splitting species), as follows. Let $\alpha \in C$ be a character. If there exist $s_1 \in S_1$ and $s_2 \in S_2$ such that $\alpha(s_1) = \alpha(s_2)$, then we set $\alpha(x) = \alpha(s_1)$; otherwise we set $\alpha(x) =$ "$*$".*

Thus, we define the vector x using exactly the technique we used for labeling the internal nodes of a perfect phylogeny. We will refer to x as the *splitting vector* defined by the partition $S = S_1 \cup S_2$.

Note that the method used in setting x depends *only* on the partition $S = S_1 \cup S_2$ and *not* on the actual perfect phylogeny P yielding that partition. If the method of setting x fails (so that for some character α, there are species $s_1, t_1 \in S_1$ and $s_2, t_2 \in S_2$ with $\alpha(s_1) = \alpha(s_2) \neq \alpha(t_1) = \alpha(t_2)$), then we know immediately that either the character set is not compatible or the partition we have is not a legal partition.

LEMMA 3.2. *Let C be a set of characters on the species set S, and let $S = S_1 \cup S_2$ be a legal partition of S. Let x be the splitting vector defined by the partition $S = S_1 \cup S_2$. Then C is perfectly compatible on S if and only if there exists a perfect phylogeny T for S, C and an edge $e \in E(T)$ such that*

1. *$\mathcal{L}(T_i) = S_i$ for $i = 1, 2$, where $T - \{e\}$ has components T_1 and T_2;*

2. *the labeled phylogeny T' formed by inserting x into the edge e is also a perfect phylogeny for S, C.*

Proof. If C is perfectly compatible on S and if $S = S_1 \cup S_2$ is a legal partition, then the perfect phylogeny T and edge e in T must exist producing the partition. Let x be the splitting vector for $S = S_1 \cup S_2$. If we insert x into e (i.e., *subdivide the edge*), it is easy to see that the convexity property still holds for the new tree. Thus, if C is perfectly compatible with S and $S = S_1 \cup S_2$ is a legal partition, then C is perfectly compatible on $S \cup \{x\}$, where x is the splitting vector defined by the legal partition.

The other direction is trivial to prove. □

3.5. Deriving subproblems. We now state the lemma that permits us to use a legal partition of the species.

LEMMA 3.3. *Let C be a set of characters defined on the species set S, and let $S = S_1 \cup S_2$ be a legal partition. Let x be the splitting vector defined by the previous lemma. Then C is compatible on $S_1 \cup \{x\}$ and $S_2 \cup \{x\}$ if and only if C is compatible on S.*

Proof. Suppose C is compatible on each of $S_1 \cup \{x\}$ and $S_2 \cup \{x\}$ and that T_1 and T_2 are perfect phylogenies for $S_1 \cup \{x\}$ and $S_2 \cup \{x\}$, respectively. Define the phylogeny T by identifying the leaf for x in T_1 with the leaf for x in T_2. We will show that this phylogeny is also perfect. Suppose that u and v are nodes in T with $\alpha(u) = \alpha(v)$ for some character α, and let w be a node on the path from u to v. We will show that $\alpha(w) = \alpha(u)$.

Since T_1 and T_2 are perfect phylogenies, if u and v are both within the same T_i, then $\alpha(w) = \alpha(u)$. If u is in T_1 and v is in T_2, then by our definition of the splitting vector x, $\alpha(x) = \alpha(u)$. Without loss of generality, assume that w is in T_1. Then w is on the path from u to x, and therefore $\alpha(w) = \alpha(u)$. Thus, T is a perfect phylogeny.

Now suppose that C is compatible on S but not on, say, $S_1 \cup \{x\}$. Since $S = S_1 \cup S_2$ is a legal partition, the fact that C is compatible on S implies that there exists a perfect phylogeny T and an edge e in T such that $T - \{e\}$ is the union of two subtrees T_1 and T_2, where the leaves of T_i are the species in S_i. Furthermore, the way we set the character states for the splitting vector x (to be inserted into the edge e) allows us to enlarge T_1 into a perfect phylogeny for $S_1 \cup \{x\}$: we simply make x a leaf and attach it to T_1 at the point where the edge e was attached to T_1.

Thus, C is also compatible on $S_1 \cup \{x\}$. □

The subproblems will have one more species each than the sizes of the parts of the partition, and this is why we constrained each set S_i to have at most $n - 2$ species. Note that the way we have defined $\alpha(x)$ may result in α having $r + 1$ states on $S \cup \{x\}$, where α had r states on S. When we reduce to subproblems, however, we will only have r states for α in each subproblem. We now show this.

LEMMA 3.4. *Let $S = S_1 \cup S_2$ be a legal partition, and let x be the splitting vector defined by the previous theorem. Then in each subproblem $S_i \cup \{x\}$, the number of states for a character α is bounded by r, where α had r states on S.*

Proof. If $\alpha(x) \neq$ " $*$ ", then it is trivially true. Otherwise, if $\alpha(x) =$ " $*$ ", then the states of α are partitioned by $S_1 \cup S_2$ (i.e., no state is on both sides of the partition). The only way that $S_1 \cup \{x\}$ can have $r + 1$ states is for all r original states of α to be in the S_1 side. But in this case, S_2 is empty, and hence $S = S_1 \cup S_2$ is not a legal partition. □

At this point, all we need to do is show how to find a legal partition for S, given a realizable tree-structure.

LEMMA 3.5. *Given a realizable tree-structure T for an informative character α, we can find a legal partition of S.*

Proof. The removal of any edge from T defines a partition that is legal, provided that the parts of the partition have at least two and no more than $n - 2$ species each. We will show that T has at least one edge e whose parts satisfy this constraint.

Since α is informative, α must have at least two big states. Let e be an edge in T such that each subtree of $T - \{e\}$ has at least one big state. Then each component of $T - \{e\}$ has at most $n - 2$ species, and thus we have a legal partition. □

We will call this kind of legal partition of S a *legal partition of α* since members of the same α-state belong to the same part of the partition. Note that this implies a constructive algorithm for reducing to subproblems, given a realizable tree-structure.

3.6. The top-down structure of the algorithm. A top-down description of the algorithm is then as follows:

```
Algorithm Findtree(S)
begin
    if $|S| < 7$ then do exhaustive search
    else
        find a legal partition of $S = S_1 \cup S_2$
        define the splitting vector $s$ (as defined in Section 3.4)
        if both Findtree($S_1 \cup \{s\}$) and Findtree($S_2 \cup \{s\}$) produce trees
          $T_1$ and $T_2$ respectively then
          define $T$ to be the tree formed by identifying the leaves for $s$
          in each tree $T_i$ and return T
          else return No
end of algorithm
```

Note that the splitting vector s can be determined in $O(nk)$ time. The algorithm may determine that no legal partition exists, in which case it does not recurse on subproblems but returns "No."

It is clear that the only difficult part of this algorithm is to find a legal partition of S. We will now describe the techniques we use for finding a legal partition when all the characters have at most three states. The techniques we use for four-state characters involve the same basic ideas but require a much more complicated case analysis.

4. Finding a legal partition from trinary characters. For trinary characters, there are only four possible tree-structures: the three paths, $\alpha_i - \alpha_j - \alpha_k$, for $\{i, j, k\} = \{1, 2, 3\}$, and the star with the dummy node in the center. We will describe a rule-based technique for finding a legal partition of S where all characters have three states. The rules we will present will use character state intersection information to determine which of the four tree-structures could arise from canonically labeled perfect phylogenies in reduced form (i.e., be *elementary realizable tree-structures*). These rules will also be applied for deriving a legal partition for quaternary characters and are thus stated and proved in general terms. We may abuse notation and sometimes indicate the *value* of a species s for the character α by α_i instead of i.

4.1. Rules for deriving tree-structures. We now define two rules for reducing the original set of four possible tree-structures (three paths and one star) to a smaller set of tree-structures, when the characters are trinary.

RULE 1. *Suppose for two characters, α and β, we know that $\alpha_1 \subset \beta_1$, $\alpha_2 \cap \beta_2 \neq \emptyset$, and $\alpha_3 \cap \beta_2 \neq \emptyset$. If the character set is compatible and T is a realizable elementary tree structure for α, then α_1 is not on the path between α_2 and α_3.*

Proof. Suppose that the character set is compatible, and yet the only realizable elementary tree-structures have α_1 on the path between α_2 and α_3. Let T be one perfect phylogeny for the species set, and consider the path P in T from α_2 to α_3. On this path there is at least one, and possibly several, nodes labeled α_1. Attached to each of these nodes are one or more subtrees with species in S having state α_1. Each node v in the path must have β-state β_2, since the α_2 species and α_3 species are in different components of $T - \{v\}$.

Now consider the number of possible subtrees containing species labeled α_1 hanging off nodes labeled α_1 in P. There can be at most one such subtree, since if there were two, the node(s) in P between the two subtrees would have to have state β_1, since all species having state α_1 also have state β_1. Thus, we see that the number of subtrees (containing species in S) must be exactly one. Since P is in reduced form and canonically labeled, the tree-structure arising from P is elementary and α_1 does not lie in the path between α_2 and α_3. □

RULE 2. *Let β and α be characters such that $\alpha_1 \cap \beta_1 \neq \emptyset$, $\alpha_1 \cap \beta_2 \neq \emptyset$, $\alpha_2 \cap \beta_2 \neq \emptyset$, and $\alpha_2 \cap \beta_3 \neq \emptyset$. If T is a realizable elementary tree-structure for α, then α_2 falls between α_1 and α_3 in T.*

The proof of this rule is easy, and is omitted.

4.2. Intersection patterns. To describe the intersection patterns between characters we introduce the following notation. If α is an r-state character then for any character β, its intersection with α is represented by an r-tuple, the ith component of which lists all the β-states that have nonempty intersection with α_i.

As an example, consider two trinary characters α and β on $S = \{1, 2, ..., 8\}$, defined by the following partitions: α partitions S into $\{1, 2\}, \{3, 4, 5\}, \{6, 7, 8\}$, and β partitions S into $\{2, 3, 4, 5\}, \{1, 6, 7\}, \{8\}$. Using the representation above, we determine that α_1 intersects β_1 and β_2, α_2 intersects only β_1, and α_3 intersects β_2 and β_3. Thus, the three-tuple used to describe the intersection pattern is $(\beta_1\beta_2, \beta_1, \beta_2\beta_3)$.

The different intersection patterns are then classified by *type*. Since often we only care about β-states that intersect more than one α-state, we will use symbols x, y, and z to represent possibly empty subsets of β-states that are contained in one α-state. Subsets represented by these letters are mutually disjoint and do not include any explicitly mentioned β-states. Whenever we use the above notation we will bear in mind the symmetries due to relabeling of the α- and β-states.

For trinary characters only a few kinds of intersection patterns are possible. Here we list the types up to symmetry. When the symmetry is broken and we have to distinguish between two characters of the same type, we will refer to *subtypes* of a type. A subtype is defined by a particular rearrangement of the α-states.

Type 1: $(\beta_1 x, \beta_1 y, \beta_1 z)$.

Type 2: (β_1, β_1, x).

Type 3: $(\beta_1 x, \beta_1 y, \beta_3)$.

Type 4: $(\beta_1 x, \beta_1 \beta_2 y, \beta_2 z)$.

Type 5: Any other intersection pattern where α and β are both trinary characters.

Some of these types of intersection immediately allow us to reduce the set of four possible tree-structures (the three paths and one star) to a smaller set. We will therefore define the set Q, which will be used in the algorithm for quaternary character compatibility as well as in the algorithm for trinary character compatibility.

4.3. The set Q of candidates.

DEFINITION 11. *Let $\mathcal{R}_i$ be the set of rules used to remove α tree-structures for i-state character information. Q is the set of tree-structures that are not eliminated by applications of these rules.*

The analysis that we will now make of the implications of the different intersection types will be used to reduce the original set of tree-structures to the (possibly smaller) set Q.

A type-5 intersection can only mean that α and β are themselves incompatible, so that the entire set C is incompatible. A type-4 intersection immediately implies (by an application of Rule 2) that the only possible realizable tree-structure is $\alpha_1 - \alpha_2 - \alpha_3$. If β has a type-3 intersection, then by an application of Rule 1, we know that we can remove the $\alpha_1 - \alpha_3 - \alpha_2$ tree-structure from Q. Type-1 and -2 intersections do not allow us to reduce Q.

Now suppose $Q = \emptyset$. In this case, we know that no tree structure is realizable, so that the character set is incompatible. If Q contains a single tree-structure, then that is the tree-structure we use to reduce to subproblems. Otherwise, Q contains at least two tree-structures, and so we have processed only characters of types 1–3. We will show now that we can handle each of these cases. Before we introduce our technique, we need to make some definitions.

DEFINITION 12. *Let T be an α-tree-structure, e be an edge in T, and $T - \{e\}$ have components T_1 and T_2 with underlying species sets S_1 and S_2, respectively. Then we say that the vector $x \in (Z \cup \{\text{“}*\text{”}\})^k$ is* compatible *with the pair (T, e) if the following is true*:

(i) *If there exists $s_1 \in S_1$ and $s_2 \in S_2$ with $\alpha(s_1) = \alpha(s_2)$ then $\alpha(x) = \alpha(s_1)$.*

(ii) *Else, $\alpha(x)$ is either set to the dummy state “ $*$ ” or is set to i, where either S_1 or S_2 is contained in α_i.*

Thus, a vector is compatible with an edge in a tree if we can insert the vector into that edge without changing the convexity property of the tree.

DEFINITION 13. *Let T be a tree-structure for α, and let $e \in E(T)$. We define $f(T, e) = \{x \in (Z \cup \{\text{“}*\text{”}\})^k : x$ is compatible with (T, e) $\}$.*

That is, $f(T, e)$ consists of all the possible vectors, with dummy states permitted, that can be inserted compatibly into the edge $e \in E(T)$.

DEFINITION 14. *For a tree-structure T for α, we define a* disconnector *to be a minimal set of edges of T whose removal puts each of the α-states into a separate component. If $e_1, \ldots, e_t$ is a disconnector of a tree structure T, a set of species $\mathcal{D} = \{s_1, s_2, \ldots, s_t : s_i \in f(T, e_i), i = 1, \ldots, t\}$ will be termed a* disconnecting species set.

We extend these concepts to the case where we have a collection of tree-structures, Q and state the following theorem.

THEOREM 4.1. *Let C be a set of characters defining a species set S, and assume that C is compatible on S. Let $\alpha \in C$ be a character, and let $\mathcal{T}$ be any set of tree-structures that contains at least one realizable tree-structure. If there exists a set D that is a disconnecting species set for every $T \in \mathcal{T}$, then every tree in $\mathcal{T}$ is realizable.*

Proof. Assume that such a set D exists and that $\mathcal{T}$ contains at least one realizable tree-structure, T^*. Let P^* be a perfect phylogeny for S with tree-structure T^*. Since D is a disconnecting species set for T^*, we can insert the elements of D compatibly into their associated edges of T^*, and hence C is compatible on $S \cup D$.

Now let $T \in \mathcal{T}$ be arbitrarily chosen. If we remove the edges associated with the nodes in D from T, we separate T into r components, each containing one state of α. We can then reattach the deleted edges to each of these components and insert into each such edge the associated element of D. Call these subgraphs $T_1, T_2, \dots, T_r$. Each T_i consists of one α-state and at least one element from D. Every two such subgraphs share at most one element of D. Since C is perfectly compatible on $S \cup D$, there is a perfect phylogeny P_i for each subgraph T_i. We can then combine these perfect phylogenies P_i into a perfect phylogeny for $S \cup D$, in the following way. Each $d \in D$ is a leaf in at least two of these perfect phylogenies P_i. Identify the leaves corresponding to each d. The resultant graph P is acyclic, has the convexity property, and contains S and is therefore a perfect phylogeny for S. Furthermore, it is easy to verify that T is the tree-structure for P, so that T is realizable. □

THEOREM 4.2. *Let C be a set of trinary characters defining a species set S, and let us assume that every character in C is informative. Let α be any character in C, and let Q be the set of candidate tree-structures not eliminated by Rules* 1 *and* 2. *Either some big α-state is a leaf in every $T \in Q$, so that we have a legal partition, or either every tree-structure in Q is realizable or none is.*

Proof. If C is not compatible on S, the theorem trivially follows. Otherwise, assume that C is a set of informative characters that is compatible on S and let $\alpha \in C$ be any character. We will either determine that some big α-state is a leaf in every tree-structure in Q or we will define a disconnecting species set D for Q. Since C is compatible, it must contain at least one realizable tree-structure. The existence of D will then ensure that every tree-structure in Q is realizable, by Theorem 4.1.

The proof continues using a case analysis.

Handling only Type-1 and -2 characters. Consider the case where there have only been characters of Types 1 and 2, so that Q consists of all four possible tree-structures. In this case, we will define a vector A as follows. Each character β has exactly one state, β_1, which intersects more than one α-state; let $\beta(A) = 1$. To set the α-state of A, we use a new dummy state. Note that if P is a perfect phylogeny for S, C and e is an edge in P between two α-states, then A can be inserted into that edge without changing the convexity of P. Thus, $\{A\}$ is a disconnecting species set for Q.

When there are Type-3 characters. The definition of the set D depends on the exact constitution of Q, which can vary when there are Type-3 characters. Each Type-3 character removes one path tree-structure from Q. If there is at least one Type-3 character present and $|Q| > 1$, then we either have removed one or two path tree-structures from Q.

If we have removed two path tree-structures, then we have reduced Q to consisting of one path and the star. Without loss of generality, assume that the only path tree-structure in Q is $\alpha_1 - \alpha_2 - \alpha_3$. Then α_1 and α_3 are *leaf-states* in every tree-structure in Q. Since α has at least two big states, without loss of generality, we can assume α_1 is big. Thus, α_1 is a big state that is a leaf in every tree-structure in Q.

If Q contains two paths, say $\alpha_1 - \alpha_2 - \alpha_3$ and $\alpha_3 - \alpha_1 - \alpha_2$, then all Type-3 characters have had the same intersection subtype (that is, exactly as indicated above). Note that for every tree-structure in Q, α_1 and α_2 are adjacent and α_3 is a leaf. If α_3 is a big state, then we are done. Otherwise, if $|\alpha_3| = 1$, we will need to define two vectors A and B so that $D = \{A, B\}$ is a disconnecting species set.

The node A will be inserted between α_3 and $\alpha_1 \cup \alpha_2$ and the node B will be inserted between α_1 and α_2 in each tree-structure. Note that setting $A = x$, where $\alpha_3 = \{x\}$ will always work. To set $\beta(B)$, note that since every character has type 1, 2, or 3, β has exactly one state in common between α_1 and α_2. Let $\beta(B)$ be that common state. It can then be checked that the nodes A and B can be inserted into each candidate tree-structure in Q so as to preserve convexity. Thus, D is a disconnecting species set, so that every tree-structure in Q is realizable. □

We thus have the following.

THEOREM 4.3. *Given a set of three-state characters, we can in $O(nk)$ time either find a legal partition of S or determine that the set of characters is incompatible.*

Proof. We can compute the pairwise intersections of α with every other character β in $O(nk)$ time and apply Rules 1 and 2, thus reducing the set of four possible tree-structures to a (possibly smaller) set Q. If this set Q is empty, then the characters are incompatible. Otherwise, let T be any tree-structure in Q. By Theorem 4.2, T is realizable, and by Lemma 3.5, we can find a legal partition of S given T. □

Using the same top-down structure as described for the quaternary character compatibility problem in §3.6, we now have an algorithm for trinary character compatibility. We now analyze the complexity of this algorithm.

THEOREM 4.4. *We can determine compatibility of k trinary characters on n species in $O(nk \min\{n, 2k\})$ time.*

Proof. It suffices to show that we recurse at most $\min\{n, k\}$ times, since each recursion costs us only $O(nk)$ time. Having computed a legal partition of $S = S_1 \cup S_2$, we note that the number of species always goes down by at least one in each part, so that the number of iterations is at most n. Now consider what happens to a character as we reduce to solving subproblems. If it becomes uninformative on one side, it is eliminated from the subproblem. Furthermore, if the character only has two states on a subproblem, the reduction to subproblems takes $O(n)$ time instead of $O(nk)$ time. Thus, a character continues to contribute to the cost of its subproblem only by being informative and having at least three states. If a character remains informative and has at least three states in one subproblem, then in the other subproblem it is uninformative. Thus, the total number of characters present between the two subproblems goes down by one at each iteration. Therefore, the number of iterations is $\min\{n, 2k\}$, and the algorithm has running time $O(nk \min\{n, 2k\})$. □

4.4. Application to quaternary character compatibility. The algorithm given above for the compatibility of trinary characters has an important extension to quaternary character compatibility. Suppose we are given a set C of quaternary characters (i.e., characters with number of states bounded by four), and suppose that $\alpha \in C$ is actually a trinary character. Then for any quaternary character β (which is compatible with α), its intersection pattern with α either belongs to one of the four types described or is of the form $(\beta_1\beta_2, \beta_1, \beta_3\beta_4)$, which we will denote as Type 6. Thus, any other pattern will indicate pairwise incompatibility of α and β.

If all characters β intersect α with a pattern that belongs to one of the first four types, then we can obtain a legal partition of α using the trinary character algorithm. Suppose, however, that there is a β of Type 6. Then looking at α's intersection with respect to β we note that α has the pattern $(\alpha_1\alpha_2, \alpha_1, \alpha_3, \alpha_3)$. When the intersection pattern of α with β is of the above form (where one state of α is shared by two states of β and another state of α is shared by the other two states of β and no other α states are shared), α is said to induce a *matching* on β. In §5.4 we describe how a legal partition may be found in the presence of matchings. It will be seen that matchings can be handled even in the presence of some characters with fewer than four states. Thus, we will assume (without loss of generality) that all characters are quaternary, since the presence of even one informative character with at most three states can be handled using simpler techniques.

5. The quaternary character compatibility algorithm. We have described in detail in the previous section how we solved the trinary character compatibility problem in polynomial time. We will describe in this section a more complicated case analysis that permits us to solve the quaternary character compatibility problem in polynomial time as well. The algorithm we give for quaternary characters has much the same structure as the algorithm for trinary character compatibility, in that it operates by finding a realizable tree-structure for a character. In §5.1 we state the third rule for reducing the set of tree-structures to a smaller set of *candidate* tree-structures, which presumes an intersection pattern called a *matching*. In §5.2 we describe a new technique (similar to the technique given in Theorem 1) for finding a legal partition from the set Q of candidates. In §5.3 we define the character intersection types and show how applications of Rules 1–3 permit us to derive information about Q from quaternary characters. In §5.4 we show how to derive a legal partition in the presence of a matching pair. In §5.5 we show how to derive a legal partition when no character β induces a matching on the base character. The analysis of the running time is presented in §5.6.

5.1. The third rule. For the trinary character compatibility problem, we defined two rules that allowed us to reduce the set of possible tree-structures to a smaller set, Q, and from Q we either were able to find a big α-state that was a leaf in every tree-structure in Q or to use any tree-structure in Q as the basis of a legal partition. The case for quaternary characters is a bit more difficult. In addition to the two rules described earlier we need one extra rule, which concerns a different type of intersection pattern. However, in addition, the determination of a legal partition from the set Q of tree-structures that are not eliminated by any of these *three* rules is much more complicated. This complication is due in part to the fact that the intersection patterns can be much more involved, due to the larger number of states. Thus, we will use a great deal of case analysis to determine a legal partition from Q. Still, the general approach is similar, in that we derive a legal partition of S by fixing a base character α and then looking at intersections of α's states with the states of other characters.

We begin by describing the third rule we need.

RULE 3. *Let β and α be characters such that $\beta_1 \cap \alpha_1 \neq \emptyset$, $\beta_1 \cap \alpha_2 \neq \emptyset$, $\beta_2 \cap \alpha_3 \neq \emptyset$, and $\beta_2 \cap \alpha_4 \neq \emptyset$. If T is a realizable elementary tree-structure other than a star, then T contains an edge e such that $T - \{e\}$ has components T_1 and T_2 with $V(T_1) = \{\alpha_1, \alpha_2\}$ and $V(T_2) = \{\alpha_3, \alpha_4\}$.*

Proof. If T is a realizable tree-structure that is not a star, then it contains an edge e that is not incident to any leaf. Let P be a perfect phylogeny that has the T tree-structure for α, and let $e' = (u, v)$ be the edge in P corresponding to e. Clearly, $P - \{e'\}$ partitions the α-states. If $P - \{e'\}$ has $\alpha_1 \cup \alpha_2$ on one side and $\alpha_3 \cup \alpha_4$ on the other, then our rule is valid. Otherwise, without loss of generality, let $\alpha_1 \cup \alpha_3$ be on one side and $\alpha_2 \cup \alpha_4$ be on the other. How do we label $\beta(u)$? Since α_1 is on one side and α_2 is on the other, $\beta(u) = 1$. On the other hand, α_3 is on one side and α_4 is on the other, so that $\beta(u) = 2$. This yields a contradiction, so that e' must separate $\alpha_1 \cup \alpha_2$ from $\alpha_3 \cup \alpha_4$. Therefore, $T - \{e\}$ must have components $\alpha_1 \cup \alpha_2$ and $\alpha_3 \cup \alpha_4$. □

DEFINITION 15. *A character β having the above intersection pattern with α is said to induce a* matching *on α. The pair (α, β) is referred to as a matching pair.*

We can now make some observations.

LEMMA 5.1. *Let C be a set of quaternary characters, S a set of species defined in terms of C, and α a character in C. Suppose that Q is the set of candidate tree-structures for α derived* *from C by applications of Rules* 1, 2, *and* 3. *If the set C is compatible, then Q contains a realizable tree-structure.*

Proof. If C is a compatible set of characters on S, then there is a perfect phylogeny P for S. Without loss of generality, P can be assumed to be canonically labeled and in reduced form. Let $\alpha \in C$ be a character, and let T be the tree-structure for P with respect to α. Then T is an elementary realizable tree-structure and hence will not be eliminated by any of the rules above. Thus $T \in Q$. □

5.2. Finding a legal partition from Q. Our algorithm starts by picking a *base character*, α, arbitrarily and finding the set Q of candidate tree structures for α by applications of Rules 1–3. If $|Q| = 0$, by Lemma 5.1, the character set C is incompatible on S. Again, if $|Q| = 1$, we know, by Lemma 5.1, that if the characters are compatible, then there is only one possible tree structure for α, and it is the unique element of Q. We can then split the problem into subproblems using that tree-structure. The difficulty is when $|Q| > 1$. In what follows we describe some general techniques for dealing with the case that Q contains more than one candidate tree-structure. Although these techniques cover most situations, we will, in some cases, find it necessary to change the base character and find a legal partition on the basis of some other character.

We now generalize the techniques we used for trinary characters, in which we derived a legal partition from the set Q. Recall that for trinary characters, we were able to state that any tree-structure that is not eliminated by Rules 1 and 2 is realizable, provided that the set of characters is compatible. We proved this by proving the existence of a disconnecting species set D, which allowed us to transform any given tree-structure from Q into any other. By contrast, when working with quaternary characters, the existence of a disconnecting species set D cannot be assumed, although we may be able to define such a set of vectors under certain circumstances.

Another technique we use for quaternary characters is described in the following theorem.

THEOREM 5.2. *Suppose s is a vector and $\{e_T \in E(T) : T \in Q\}$ is a collection of edges such that s is compatible with every pair (T, e_T). Suppose there exists $T \in Q$ such that $T - \{e_T\}$ has components T_1 and T_2 whose underlying species sets S_1 and S_2 are both big. Then $S = S_1 \cup S_2$ is a legal partition of the original species set.*

The proof of the above theorem follows along the same lines as the proof of Theorem 4.1.

The above two techniques try to find similarities among the tree-structures in Q and exploit this similarity to find a legal partition. In the case where we have a character β inducing a matching on our base character α, such similarities are hard to find. For example, if the intersection of β with α is given by $(\beta_1\beta_2, \beta_1, \beta_3\beta_4, \beta_4)$, then the possible tree structures for α include stars centered at α_1 and α_3 and the four paths with α_1 and α_2 on one side and α_3 and α_4 on the other. It is hard to find splitting vectors that work for both of these types of realizable tree-structures. To handle matchings we introduce a new technique.

The technique we use involves a concept we call a *rigid tree-structure*. Certain phylogenies are flexible in the sense that the labeling at some adjacent internal nodes are compatible and the nodes can therefore be identified, so that the topology changes, and hence also the tree-structure(s). Thus, it is possible to move from one tree-structure to another, and under the proper conditions, we may be able to know that certain tree-structures may be removed from Q by the above process. We discuss the details of this technique in the subsection on handling matchings.

5.3. Analysis of the character intersection information. Our divide-and-conquer algorithm solves the perfect phylogeny problem by exhaustive search when there are at most six species. In practice, this can be done more efficiently by considering a partition of S into two sets containing 2 and $k-2$ species (assuming $|S| = k \leq 6$), defining the splitting vector for this partition, and checking that the two subproblems created both have solutions.

We first preprocess the data so as to remove all noninformative characters. We then assume that the (reduced) character set contains at least one quaternary character, since if it consists of entirely three-state characters, we will use the simpler algorithm described in §4.

We pick a character α arbitrarily from C and call it the *base* character. We then compute the intersections of the α-states with every state of every remaining character.

We list (up to symmetry) the types of intersections that other characters can have with α assuming that they are compatible with α. Thus, we have eliminated all intersection patterns of α with β that indicate that α and β are pairwise incompatible, so that the entire set C is incompatible. Any β whose intersection does not fit any of the following eight types will thus imply incompatibility of the character set. As before we will sometimes refer to subtypes of a type.

As explained before, we will represent the intersection of a character β with a character α by a four-tuple, the ith component of which lists all the β-states that have nonempty intersection with α_i, for $i = 1, \ldots, 4$. We indicate pairwise disjoint (possibly empty) subsets of β-states by lower-case letters (w, x, y, and z), and we use a "." in a component of the four-tuple to indicate that we do not care about the β-states in that component even if they cross α-state boundaries.

Intersection Types of Characters.

1. $(\beta_1 x, \beta_1\beta_2 y, \beta_2\beta_3, \beta_3)$ or $(\beta_1\beta_2\beta_3 x, \beta_1 y, \beta_2 z, \beta_3 w)$.
2. $(\beta_1 w, \beta_1 x, \beta_2 y, \beta_2 z)$, $(\beta_1\beta_2, \beta_1, \beta_1, \beta_3\beta_4)$, or $(\beta_1, \beta_1\beta_2, \beta_2, \beta_3\beta_4)$.
3. $(\beta_1 x, \beta_1\beta_2 y, \beta_2, \beta_4)$.
4. $(\beta_1 w, \beta_1 x, \beta_3, \beta_4)$.
5. $(\beta_1 w, \beta_1\beta_2 x, \beta_2 y, \beta_2 z)$.
6. $(\beta_1 x, \beta_1 y, \beta_1 z, \beta_4)$.
7. $(\beta_1, \beta_1, \beta_2\beta_3, \beta_4)$.
8. $(\beta_1 x, \beta_1 y, \beta_1 z, \beta_1)$ or $(\beta_1, \beta_1, \beta_1, z)$.

There are conclusions which can be drawn from each of these types of intersections, by applying Rules 1–3. These are as follows:

Type 1: When we have an intersection of this type, the tree-structure of α is entirely determined. To make the problem interesting, we will assume that no character β has this type of intersection pattern with α.

Type 2: The first case has β inducing a matching on α, and the last two cases have α inducing a matching on β. In the last two cases, we switch the roles of α and β, since we have special techniques for handling matchings.

Type 3: In this case, we can assume that α_4 is a leaf-state and that α_2 is between α_1 and α_3.

Type 4: We can assume that α_1 and α_2 are adjacent.

Type 5: (α_1, α_2) is an edge in every tree-structure for α, and α_1 is a leaf-state occurring between α_1 and α_2.

Type 6: We can assume that α_4 is a leaf-state.

Type 7: We can assume that α_4 does not fall between α_1 and α_2.

Type 8: This intersection pattern does not permit us to eliminate any tree-structures from the thirty-two possible candidates but does permit us to set the splitting vectors (which will make up our *disconnecting species set*) easily.

The above enumeration also expresses the order in which we will process other characters with respect to α. We first bucket sort all other characters by the type of intersection they have with α and process them starting with Type-1 characters, if any.

Some comments are in order with regard to the algorithmic implementation. If it is determined that α_i is a leaf-state, then we immediately check the cardinality of α_i. If $|\alpha_i| > 1$, then $S = \alpha_i \cup (S - \alpha_i)$ is a legal partition, and we are done.

5.4. Handling matchings. When we have a character β that induces a matching on α we can find a legal partition based either on α or on β. Note that if β induces a matching on α, then α must perforce be a character with four states.

In order to discuss matchings, we will need to analyze the phylogenies that give rise to tree-structures that are stars.

5.4.1. Star tree-structures and their phylogenies. Assume that the only realizable tree-structures for α are stars and that one such tree-structure is an α_1-star, i.e., a star with α_1 as the node at the center. Consider the phylogenetic tree T that yielded this tree-structure. In T the points of attachments P, Q, and R of the α_2, α_3, and α_4 subtrees to the α_1 subtree must be distinct. If two of these points, say P and Q, are not distinct, we can modify T to create a tree T' that yields a path structure for α (Fig. 2).

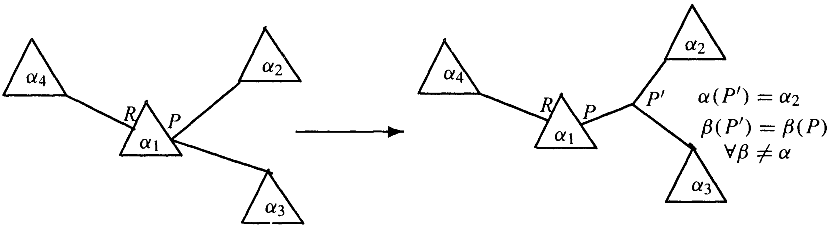

FIG. 2. *Converting a star to a path.*

Furthermore, we may be able to change the character states for these vertices P, Q, and R and still have a perfect phylogeny. If this can be done so that two of these vertices become indistinguishable, then we can transform the star into a path, as before. This can always be done unless we are forbidden from making these changes by the existence of certain characters. For example, we could relabel P and Q unless they differed for some character γ, and we could not change their character state for γ. Thus, $\gamma(P) = \gamma_1 \neq \gamma(Q) = \gamma_2$.

We make the following definition:

DEFINITION. *A star tree-structure for α that cannot be transformed into a path* (*using the techniques described above*) *is called a* rigid star.

If none of the realizable tree-structures for α is a rigid star, then it is clear that α has a realizable tree-structure that is a path (unless, of course, the character set is incompatible). This allows us to reduce to small subproblems, as we showed earlier.

Types of rigid stars and matchings. Let us suppose that we have a matching for α and that we have a rigid star for α, in which α_1 is the center. There are basically two types of perfect phylogenies that yield star tree-structures for α. Figure 3 shows the two different types.

The first star has the points of attachment of α_2, α_3, and α_4 to α_1 all falling on a path. The second star has these points not falling on a single path. We will call the first type a *linear star*, and the second a *nonlinear star.*

We suppose now that β induces a matching on α.

There are, up to symmetry, the following types of matchings:

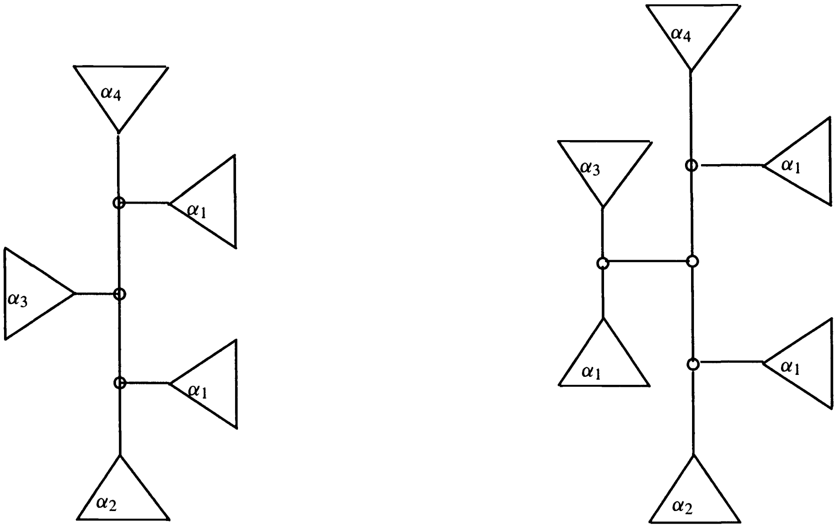

FIG. 3. *Types of stars.*

1. $(\beta_1, \beta_1\beta_2, \beta_3, \beta_3\beta_4)$,
2. $(\beta_1\beta_3, \beta_1\beta_2, \beta_4, \beta_4)$, and
3. $(\beta_1, \beta_1\beta_2\beta_3, \beta_4, \beta_4)$,

We refer to the first two kinds of matchings as *weak* matchings since there are two possible star tree-structures for α in these cases. We will refer to the third kind of matching as a strong matching since in this case the only possible star tree-structure for α is the star with center α_2. (If β has less than four states, the matching is of the form $(\beta_1 x, \beta_1, \beta_2, \beta_2)$.) We can treat this as a special case of a matching of the first kind.

Both linear and nonlinear stars are possible as tree-structures for α if the matching induced on α is strong while only the linear star is possible if the matching is weak. This is because an α-state that is the central state of a nonlinear star must intersect three β-states.

Again this enumeration expresses the order in which the algorithm will process characters that induce matchings.

5.4.2. Matchings of the first kind. Assume that the character β has intersection given by $(\beta_1, \beta_1\beta_2, \beta_3, \beta_3\beta_4)$. If a rigid star exists, by Rule 1, it must be a linear star and have one of α_2 and α_4 for the center. Without loss of generality, let us suppose that a rigid star exists with α_2 as center and the picture looks like Fig. 4. (There could be a potentially different situation if the positions of α_3 and α_4 were interchanged. However, in our argument, these two cases will be completely symmetric. Thus, we can without loss of generality claim that the figure shown is valid.)

Here A is the point of attachment of the α_1 subtree to the α_2 tree, B the point of attachment of the α_3-subtree to the α_2 subtree, and C the point of attachment of the α_4 subtree to the α_2 subtree. The distinctness of B and C and the rigidity of the star implies the existence of a character γ for which C has state γ_1 and B has state γ_2. Further the γ-states of B and C cannot simply be relabeled to be identical, and this implies that γ_1 intersects α_2 and α_4 (and no other α-state) and γ_2 intersects α_3 and one of α_1 and α_2, a fact that we will in the future indicate by the notation

$\gamma_1 : (\alpha_2, \alpha_4)$ and $\gamma_2 : (\alpha_3, \alpha_1 \cup \alpha_2)$.

Note that if $\gamma_2 \cap \alpha_2 \neq \emptyset$, then by Rule 2, the intersection pattern for γ implies that α_2 is between α_3 and α_4. The combined information of β and γ thus rules out all path tree-

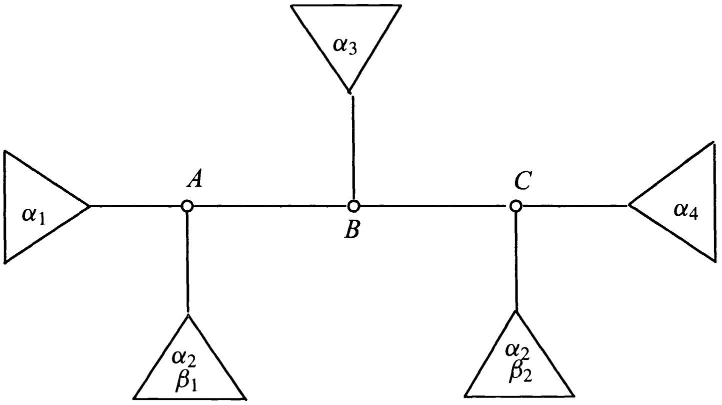

FIG. 4. *A rigid linear α_2 star.*

structures paths as well as the α_4-star, so that Q will contain only the α_2-star. The remaining case, $\gamma_2 : (\alpha_3, \alpha_1)$, requires more careful analysis.

First we note that the intersections of γ and β with α indicate that the only realizable tree-structure for α is a star. If β were a trinary character, then β_2 or β_4 would be empty, so that at most one of the α-states would not be contained inside a single β-state. Thus, Q would be reduced to a single tree-structure. Thus, if β were trinary, we would be able to obtain a legal partition and recurse. If β is truly quaternary, then we have reduced Q to two tree-structures, the α_2-star and the α_4-star.

Consider the intersections of γ with β. If we examine the previous figure, we can see that $\gamma_1 : (\beta_2, (\beta_3 \cup \beta_4))$ and $\gamma_2 : (\beta_1, \beta_3)$. If $\gamma_1 \cap \beta_3 \neq \emptyset$, then the tree-structure for β is forced to be a star with β_3 as the center. Thus, we can assume that $\gamma_1 : (\beta_2, \beta_4)$.

We know at this point that any realizable tree-structure for β must be a star with either β_1 or β_3 as center. If either β_1 or β_3 has a single γ-state, we can immediately determine which of the two stars is realizable. Similarly if either α_2 or α_4 has a single γ-state, we can determine which of the two α-stars is realizable. Thus, the only case left to handle is the following:

Intersections with respect to α:

$$(\beta_1, \beta_1\beta_2, \beta_3, \beta_3\beta_4),$$

$$(\gamma_2, \gamma_1\gamma_3, \gamma_2, \gamma_1\gamma_4).$$

Intersection with respect to β:

$$(\gamma_2\gamma_3, \gamma_1, \gamma_2\gamma_4, \gamma_1).$$

It can be seen that each of $\alpha_1, \alpha_3, \beta_2, \beta_4, \gamma_3, \gamma_4$ forms a leaf in their corresponding tree-structures. Thus if any one of these states is big, we can obtain a legal partition. On the other hand, if each is occupied by a single species, then, in fact, the entire set of species is limited to six species, since every species in S is in one of these states. However, we stated at the beginning that the case of six or fewer species would be handled by exhaustive search. Thus, we can always find a legal partition of a character in this case.

To sum up, whenever β induces a matching of the first kind on α, either the tree structure of α or β is identified as a star with a particular center or a third character γ is found such that there is a legal partition based on a leaf state of one of α, β, or γ. Otherwise, there is no rigid star tree structure for α, and we can assume the legal partition, $(\alpha_1\alpha_2)$, $(\alpha_3\alpha_4)$.

5.4.3. Matchings of the second kind. We assume that there is a character β whose intersection with α is given by $(\beta_1\beta_3, \beta_1\beta_2, \beta_4, \beta_4)$. Suppose there is a realizable rigid star tree-structure for α. Without loss of generality assume that this is an α_2-star. The configuration is the same as Fig. 4. The distinctness of B and C implies the existence of a character γ such that $\gamma_1 : (\alpha_2, \alpha_4)$ and $\gamma_2 : (\alpha_3, \alpha_1 \cup \alpha_2)$. If γ_2 has a nonempty intersection with α_2, the α_2-star is forced as the tree-structure for α. Otherwise, it is clear that α is forced to have a star tree-structure although the center of the star could be either α_1 or α_2. In order for us not to be able to decide which star is the correct one, γ must have at least two of its states intersecting each of α_1 and α_2. This forces the intersection of γ with α to look like : $(\gamma_2\gamma_3, \gamma_1\gamma_4, \gamma_2, \gamma_1)$, a matching of the first kind. Since we look for matchings of the first kind before we look for matchings of the second kind, this case will not occur and thus the tree-structure for α will always be determined.

5.4.4. Strong matchings or matchings of the third kind. Now, suppose we have a matching on α induced by β and that the intersection of α and β is $(\beta_1, \beta_1\beta_2\beta_3, \beta_4, \beta_4)$. Suppose we have a phylogenetic tree T for which the tree-structure on α is a rigid star with α_2 as the center. We have two cases, depending on whether the star is linear or nonlinear.

Case 1: *The rigid star is non-linear.* The tree T must have the structure shown in Fig. 5.

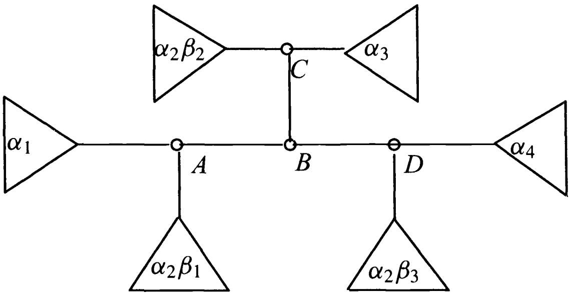

FIG. 5. *Rigid non-linear star.*

The rigidity of T implies that B and C differ for some character γ, since otherwise, we could transform T into a linear star. Thus, we assume that $\gamma(C) = \gamma_1$ and $\gamma(B) = \gamma_2$. It follows that $\gamma_1 : (\beta_4, \beta_2)$ and $\gamma_2 : (\beta_1, \beta_3 \cup \beta_4)$. The distinctness of B and D in turn implies the existence of a character δ such that $\delta_1 : (\beta_3, \beta_4)$ and $\delta_2 : (\beta_1, \beta_2 \cup \beta_4)$. We thus have three possibilities for each of γ_2 and δ_2 and nine possibilities for combinations. In all but two cases, the information gathered from γ and δ allows us to determine the tree-structure for β as a star centered at β_4. The two problem cases are:

(1) $\gamma_1 : (\beta_2, \beta_4), \gamma_2 : (\beta_1, \beta_3), \delta_1 : (\beta_3, \beta_4), \delta_2 : (\beta_1, \beta_2)$.

In this case, it is clear that the tree-structure for β must be a star and the center must be either β_1 or β_4. In order for us not to be able to decide which star is the correct one, neither β_1 nor β_4 can be contained in a single δ-state, and hence we have the following intersection of δ with respect to $\beta : (\delta_2\delta_3, \delta_2, \delta_1, \delta_1\delta_4)$. In this case, however, δ induces a matching of the first kind on β and we switch to β as the base character and process this weak matching.

(2) $\gamma_1 : (\beta_2, \beta_4), \gamma_2 : (\beta_1, \beta_4), \delta_1 : (\beta_3, \beta_4), \delta_2 : (\beta_1, \beta_4)$. It is clear that β_1 must be a leaf-state, and since β_1 is not a singleton, we have a legal partition of β.

Thus, in each of these cases, we were either able to determine a legal partition of β or we reduced to handling a matching of the first kind. Note that without such characters γ and δ, the star would not be rigid, and thus we would have been able to assume that a path was a realizable tree-structure for α, yielding a nontrivial partition of the character α.

Case 2: *The rigid star is linear.* Let us now consider the case of strong matchings, where the rigid star is linear. In this case, we have the same $\alpha - \beta$ intersection as before, and the phylogenetic tree yielding the rigid star must essentially look like Fig. 4 although α_2 now has three β-states instead of two.

As before, we note that the rigidity of the star and the distinctness of B and C imply the existence of a character γ such that $\gamma_1 : (\alpha_2, \alpha_4), \gamma_2 : (\alpha_3, (\alpha_1 \cup \alpha_2))$. Each of the possible cases indicates that a path is not a realizable tree-structure for α, and hence it must be that the tree-structure for α is a star (unless, of course, the character set is incompatible). As we mentioned earlier, since we have a strong matching, only α_2 can be a center of a star. Thus, we know that the tree structure is the star with α_2 as center. This gives us a legal partition of α.

Thus, given any strong matching of β on α, we are either able to find a legal partition of either α or β or we reduce to solving a weak matching.

5.5. When no character induces a matching on α. We assume now that Q is nonempty and contains at least two tree-structures and that we had no matching pairs involving α. This indicates that the only characters we may have seen are of Types 3–8. In the light of our discussion in §4.4, we will also assume that all characters are truly four-state characters (i.e., each character partitions the species set into four nonempty subsets).

We will attempt to define three vectors A, B, and C that form a disconnecting species set for every $T \in Q$. If we succeed, we can divide into subproblems on the basis of any tree-structure in Q, by applying Theorem 4.1 and Lemma 3.5. In what follows we show that in cases where Theorem 4.1 does not apply, we either find a legal partition of α or find a matching pair (β, γ), or discover that the characters are not compatible. Thus in all cases, our algorithm either succeeds in dividing into subproblems or discovers that the character set is incompatible.

Type 3: Suppose that we process a character β of Type 3, with the vector $(\beta_1 x, \beta_1\beta_2 y, \beta_2, \beta_4)$ describing the intersection between α and β. Such a character informs us that α_2 is between α_1 and α_3. Furthermore, we know that α_4 is a leaf-state and that α_2 is never a leaf-state. If α_4 contains more than one species, we have found a legal partition. Otherwise let s be the only species in α_4. After processing all other characters if Q consists of a single tree-structure, we will have found a legal partition. Hence assume that Q has more than one tree-structure. We can name our splitting vectors in this case, with A inserted between α_1 and α_2, B inserted between α_2 and α_3, and C inserted in the edge from α_4. Having identified these splitting vectors, we then set $\beta(A) = \beta_1$, $\beta(B) = \beta_2$, and $\beta(C) = \beta_4$.

For any subsequent character γ, we set the γ-values of A, B, and C as follows: $\gamma(C) = \gamma(s)$. For A if either α_1 or α_2 is covered by a single γ-state, γ_1, we set $\gamma(A) = \gamma_1$. Otherwise, if a γ-state, γ_1, intersects both α_1 and α_2, we set $\gamma(A) = \gamma_1$. Any other intersection pattern for γ that is consistent with the partial α tree-structure implies that α induces a matching on γ and hence this situation would have been handled earlier. Splitting vector B is handled symmetrically to A.

We show why the splitting vectors correctly define a disconnecting species set. Since α_4 is a singleton and a leaf-state in all tree-structures, C is certainly correct.

Now consider vector A. Clearly, if α_1 and α_2 are truly adjacent in a tree-structure (without dummy nodes in between), then A can be inserted compatibly into the edge between α_1 and α_2. There is only one tree-structure T^* not of this form. T^* has a dummy node d, with α_1, α_2, and α_4 connected by edges to d and α_3 a leaf hanging off α_2. We will show that if $|Q| > 1$, then we can identify one of the two edges in the path from α_1 to α_2 in T^* in which we can place A compatibly. This will show that we can place A compatibly into every tree-structure in Q.

If we place A on the edge (α_1, d) in this tree structure, then the only potential problem is a character γ such that γ_1 is shared by α_1 and α_4 and γ_2 covers α_2. Such a character might cause $\gamma(A)$ to be set to γ_2, which would be incorrect. However, if such a character γ exists and $|Q| > 1$, we will show we can place A in the edge (α_2, d). This placement of A will always work unless there is a character δ such that δ_1 is shared by α_2 and α_4 and δ_2 covers α_1. In this case we could set $\delta(A) = \delta_2$, and this would be incorrect. However, note that γ implies that α_2 is not between α_1 and α_4 and that δ implies that α_1 is not between α_2 and α_4. But the combined character information from β, γ, and δ reduces Q to a single possible tree-structure, T^*. Since we have presumed $|Q| > 1$, we can always insert A compatibly into T^* and, hence, into every tree-structure in Q.

Using a symmetric analysis, we show that we can define the vector B and insert it compatibly into every tree-structure in Q, unless $|Q| = 1$.

Having set the splitting vectors A, B, and C, we then apply Theorem 4.1 and Lemma 3.5 to derive a legal partition of S.

Type 4: If the first character β is of type four, then without loss of generality it is of the form $(\beta_1, \beta_1\beta_2, \beta_3, \beta_4)$ and says that α_1 and α_2 are adjacent in every realizable tree-structure for α. If after processing all characters there is a big leaf-state in all tree-structures in Q or if $|Q| = 1$, we can derive a legal partition. We assume that this is not the case. Note that since we presume β to be truly quaternary, the α_2-state is *big*; thus, if the intersection patterns permit us to deduce that α_2 is a leaf in every tree-structure, then we have a legal partition. We will think of A as being inserted on the edge incident to α_1 along the path to α_2. We set $\beta(A) = 1$. We need to define $\gamma(A)$ for every subsequent character γ.

We begin our analysis by noting that in the presence of certain Type-4 characters γ, we will switch to processing β as our base character. If there is a second Type-4 character γ that says that α_3 and α_4 are adjacent, then γ has intersection pattern either $(\gamma_1, \gamma_2, \gamma_3\gamma_4, \gamma_4)$ or $(\gamma_1, \gamma_2, \gamma_4, \gamma_3\gamma_4)$ with α. It is then easy to see that γ induces a matching on β with γ_2 shared by β_1 and β_2 and γ_4 shared by β_3 and β_4. We then switch to β as the base character and process it as in Type 2. Similarly, if γ is a subsequent Type-4 character implying that either α_1 and α_3 or α_1 and α_4 are adjacent, then γ is of Type 3 with respect to β, and we switch to β as the base character and process it as in Type 3. Thus, we only need to concern ourselves with processing Type-4 characters that imply adjacencies between α_1 and α_2, α_2 and α_3, or α_2 and α_4.

We need to show how to set $\gamma(A)$ for characters γ of Type 4 that indicate adjacency of α_1 and α_2, α_2 and α_3, or α_2 and α_4. If γ is a subsequent Type-4 character indicating that α_1 and α_2 are adjacent (by $\gamma_1 \cap \alpha_i \neq \emptyset$, for $i = 1, 2$), we set $\gamma(A) = 1$. If γ is a subsequent Type-4 character and says that α_2 and α_3 or α_2 and α_4 are adjacent, α_1 must be covered by a single γ-state γ_1 and we will set $\gamma(A) = 1$. Thus for every subsequent Type-4 character γ, we can set $\gamma(A)$.

If γ is of Type 5, then there must be a γ-state, γ_1, shared by α_1 and α_2 and we set $\gamma(A) = 1$ (otherwise α_1 and α_2 are *not* adjacent, as implied by β). If γ is of Type 8, we set $\gamma(A) = 1$ where γ_1 is the state of γ that crosses α state boundaries. If γ is of Type 6 and there is a γ-state, γ_1, shared by α_1 and α_2, we set $\gamma(A) = 1$. If not, α_1 must be covered by a single γ-state, γ_2, and we set $\gamma(A) = 2$.

If γ is a Type-7 character, then there is exactly one γ-state, γ_1, that crosses α-state boundaries. If γ_1 has a nonempty intersection with α_1 or α_2, then we set $\gamma(A) = \gamma_1$. Otherwise, one of α_1 or α_2 must be covered by one γ-state, γ_3, and we set $\gamma(A) = \gamma_3$. Clearly, if $\alpha_1 \subset \gamma_1$, this setting will permit us to insert A compatibly into every tree-structure in Q. The only problem arises when intersection of γ with α is given by $(\gamma_1\gamma_2, \gamma_3, \gamma_4, \gamma_4)$. However, in this case γ's intersection with β is given by $(\gamma_1\gamma_2\gamma_3, \gamma_3, \gamma_4, \gamma_4)$ and hence γ induces a matching on β and thus we can process β instead.

Thus we have shown that either we can switch to processing a different character as the base character or that we can set A compatibly with every tree-structure in Q. At this point we check to see if the split produced by A is a legal partition in at least one of the tree-structures in Q. If so, we can apply Theorem 5.2 and use that legal partition. Otherwise α_1 must be a leaf in all of the tree-structures and so presumably a singleton state (otherwise we have a legal partition). Since α must have at least two big states, without loss of generality, let α_3 be a big state. We assume that α_3 is not a leaf in all the tree-structures in Q (since otherwise we can derive a legal partition).

We will now set the splitting vector B. The placement of the vector B into each tree-structure T in Q depends on the topology of T. If T contains an edge e whose removal separates $\{\alpha_1, \alpha_2\}$ from $\{\alpha_3, \alpha_4\}$, then we will insert B into edge e. Otherwise, α_3 is a leaf, and we insert B into the edge incident to α_3. We set $\beta(B) =$ " $*$ " where β^* is a new state of β. We now show how to define $\gamma(B)$ for every subsequent character γ.

Of the Type-4 characters, by a previous analysis we only need to concern ourselves with characters γ that indicate adjacency between α_1 and α_2, α_2 and α_3, or α_2 and α_4, because the other subtypes have intersections with β of Types 2 or 3, permitting us to switch to processing β. On the other hand, since α_3 is presumed to be a big state, we can presume that we do not have characters of Type 4 indicating that α_2 and α_4 are adjacent, since then α_3 is a leaf in every tree-structure and we can derive a legal partition. Handling Type-4 characters γ indicating adjacency between α_2 and α_3 is easy, since then there is a common γ-state γ_1 intersecting both α_2 and α_3, and we can set $\gamma(B) = 1$. The remaining Type-4 character to consider indicates that α_1 and α_2 are adjacent. In this case, α_3 is contained in a single γ-state, γ_1, and we can set $\gamma(B) = 1$.

If γ is of Type 5 or 6 and a γ-state is shared between α_2 and α_3, we can set $\gamma(B)$ to be that γ-state. If not, one of α_2 and α_3 must have been proven to be a leaf and since these are both big states, we will have a legal partition. If γ is of Type 8 and the shared γ-state is γ_1, we simply set $\gamma(B) = \gamma_1$.

Finally if γ is of Type 7 and the γ-state crossing α-state boundaries is γ_1, we will set $\gamma(B) = 1$. It is easy to see that this setting is compatible for tree-structures containing two dummy nodes (so that all α-states are leaves) and any tree-structure containing an edge separating $\{\alpha_1, \alpha_2\}$ from $\{\alpha_3, \alpha_4\}$. The remaining case is where Q contains the α_2-star tree-structure. Again, however, if either α_2 or α_3 is covered by γ_1, then the setting of B is correct. The problem arises if the shared γ-state is between α_1 and α_4. Since in the α_2-star α_2 comes between α_1 and α_4, by Rule 1, we must have α_2 covered by two γ-states, γ_2 and γ_3. In this case α_3 is covered by the single γ-state, γ_4. If such a γ exists, then it says that α_3 is not between α_1 and α_4. The character β says that α_3 is not between α_1 and α_2. Together, these two characters imply that α_3 is a leaf in all the tree-structures in Q. Since α_3 was presumed to be a big state, we can derive a legal partition.

Types 5–8: Suppose all the characters have intersection types between 5 and 8. We will show that we can define a single splitting vector, A, such that one of the following will be true.

(1) A will be compatible with every tree structure in Q other than nonrigid stars, and A will produce a legal partition in at least one of these tree-structures, OR

(2) some big α-state will be a leaf in every tree-structure in Q.

If the first case holds, then Theorem 5.2 tells us that we can use A to derive a legal partition. In the second case, we can derive a legal partition using the big α-state. Thus, in either case, we can derive a legal partition.

The vector we choose will have its states set as follows: If β is a Type-5 character intersecting α, $\beta(A)$ will be the unique β-state that intersects three α-states. For any other character β, $\beta(A)$ will be the only β-state that crosses α-state boundaries.

We will now assume that there is no α-state that is a leaf in every tree-structure in Q and that is also a big state. Using this, we will show that A is compatible with every tree-structure in Q (other than the nonrigid stars). We will look at each type of tree structure in turn.

It is clear that tree-structures with two dummy nodes will not be in Q if there is a Type-5 character. When such tree-structures are in Q (so that all characters have Types 6, 7, or 8), then for every character β, one of the dummy nodes must have the β-state that crosses α-state boundaries. We can assume then that both of the dummy nodes have this β-state since the dummy nodes are adjacent and there is no constraint on the β-state of the other dummy node. Clearly the vector consisting of the common states is a splitting vector whenever the tree-structure has two dummy nodes.

When the tree structure has one dummy node, we will again show that our vector is a valid setting for the position represented by the dummy node. For a Type-5, -6, or -8 character, this is obvious. For a Type-7 character, if the common β-state is shared by the two α-states on one side of the dummy node, we can still set the β-state of the dummy node to be that β-state since it is the only one that crosses α-state boundaries and it is present at a neighboring node to the dummy node.

When the tree structure is a path, we will show that the splitting vector in the middle edge can be set in the way we described. Again for Type-5, Type-6, and Type-8 characters this is obvious. If the character is Type-7 also, it is pretty evident since if the shared β-state does not cross the middle edge, we can still set it to be the β-state of the middle edge because it is the only state on a node incident with the middle edge.

Now consider the case where Q contains a rigid star, T. For the sake of our discussion, we will assume T is an α_1-star. It is clear from our earlier analysis that α_1 will not be a singleton state. Thus, at least one edge in this tree-structure will be between two big states, α_1 and some other α-state. We will prove that either we can insert A compatibly into *every* such edge or we will be able to deduce that either the α_1-star is nonrigid or that some big α-state is a leaf in every tree-structure in Q.

Consider the case where β is a Type-5 character, in which β_1 intersects α_1 and α_2 and β_2 intersects α_1, α_3, and α_4. The intersection pattern then implies that α_2 is a leaf in every tree-structure in Q, so that we can presume α_2 is a singleton state. The β setting for A is then seen to be compatible with the edges (α_1, α_3) and (α_1, α_4), which go between two big states.

If β is a Type-6 character, then without loss of generality β has intersection pattern $(\beta_1 x, \beta_1 y, \beta_1 z, \beta_4)$. This implies that α_4 is always a leaf in every tree-structure in Q. It follows that α_4 is a singleton state (since otherwise we can derive a legal partition). By our construction, then, we will have placed A into an edge between α_1 and one of the remaining two α-states, and for each of these two edges the β-state of A is compatible.

There are two subtypes for Type-8 characters γ; one has a γ-state γ_1 intersecting all the α-states, and the other has one γ-state intersecting three α-states, while the fourth α-state is contained in a single γ-state. In the first case, γ_1 is always compatible with every edge of any tree-structure. In the second case, the fourth α-state is a leaf in every tree-structure in Q and so is small (otherwise we have a legal partition). Thus, in each edge between two big states, the γ setting for A is compatible, when γ has Type 8.

Hence, in each of the cases where β is a Type-5, -6, or -8 character, A can be inserted compatibly into any edge in the α_1-star tree-structure between two big states.

Now, let β be a Type-7 character with β_1 the sole β-state crossing α-states. If α_1 is covered by β_1, then we can insert A into every edge of the α_1-star tree-structure. If α_1 is covered by a single β-state that is not β_1, then we would not have the α_1-star in Q. The only other possibility is that α_1 is covered by two β-states. Without loss of generality, we will assume that β is given by the intersection $(\beta_2\beta_3, \beta_4, \beta_1, \beta_1)$, indicating that α_2 does not fall between α_3 and α_4. We will now show that this star is either nonrigid or that the character that makes this star rigid would rule out enough tree-structures for us to deduce a big leaf-state.

So let us assume that this α_1-star is rigid. Recall that to ensure rigidity of a star we need characters with two states that cross α-state boundaries. Since all the characters are of Types 5–8, the only characters that can ensure rigidity of this star must be Type-5 characters. If there is a perfect phylogeny P realizing the rigid α_1-star, let X, Y, and Z be the points of attachment to the α_1 subtree of the α_2, α_3, and α_4 subtrees, respectively. Since α_1 has only two β-states, X, Y, and Z must lie on a path and one of Y and Z must be an extreme point on the path. Without loss of generality assume that Y is an extreme point. Since the entire path from Y to Z must be labeled by β_1, there can be only two α_1 subtrees hanging off this path, one with β-state β_2 and the other with β-state β_3. Thus Y is adjacent to one of X and Z, and to make sure that Y cannot be identified with this neighbor, we must have a Type-5 character γ that indicates (α_1, α_3) is a true tree edge and α_3 is a leaf. Since β implies α_2 is not between α_3 and α_4, this forces α_2 to be a leaf as well. Thus by assumption α_2 and α_3 are singleton states and α_4 is a big state. We will prove that we can insert A compatibly into the edge (α_4, α_1).

From our previous analysis, we will not have any problem with any character δ having intersection type other than the following: $(\delta_1\delta_2, \delta_3, \delta_3, \delta_4)$. This character, however, implies that α_4 is not between α_2 and α_3. The combined information between β, γ, and δ would then imply that α_4 was also a leaf-state. Since we presume α_4 to be a big state, this would contradict our assumption that no big α-state be a leaf in every tree structure in Q.

Note that each edge we indicated for the insertion of A separated S into two big sets, so that we can apply Theorem 5.2 if A can be inserted compatibly in order to obtain a legal partition. The only tree-structure into which we fail to be able to insert A is the nonrigid α_1-star. If the α_1-star is in Q and is rigid, then we are able to obtain a legal partition of S via other means. Thus, we are able to derive a legal partition of S in this case as well.

We summarize with the following:

THEOREM 5.3. *If α is a character that is not involved in a matching pair, we can find a legal partition of S by analyzing the intersection of other characters with α.*

Putting the above theorem together with our results when α is part of a matching pair, we can state our major theorem.

THEOREM 5.4. *The algorithm either determines that the character set is incompatible or produces a perfect phylogeny.*

To summarize, the algorithm uses a divide-and-conquer strategy to reduce to subproblems, by finding a *legal partition* of the species set S. The legal partition that it finds is based on the kinds of intersections the characters have with a fixed base character α. In the event of a *matching pair*, it uses the techniques described in §5.4. When α is not a member of a matching pair, then the algorithm is able to find a legal partition of α by using the techniques of §5.5.

5.6. Analysis of running time. We assume that the input to the problem is a matrix whose (ij)th entry gives the state of species i for character j. We can construct the sets of species corresponding to each of the character states of each of the characters in $O(nk)$ time. The sets are constructed using a sequence of unions as we examine each species in turn. Since we always union singleton sets to existing sets, the elements of the sets are always at depth one, and hence subsequent FIND operations can be performed in $O(1)$ time. Thus, we can now find the pairwise intersections of the character sets in $O(nk)$ time. The algorithm then picks a character α, makes a linear pass through the characters, and bucket sorts them according to type. This is $O(k)$ time. The separation into subproblems takes $O(n)$ time, and defining the splitting vector takes $O(nk)$ time. We then recurse on the subproblems.

Since each of these subproblems involves less than n species, we have an $O(n^2k)$ algorithm.

The overall running time of the trinary character compatibility algorithm is seen to be $O(n^2k)$, the same as for quaternary character compatibility. This has lead us to conjecture that the techniques we use for determining compatibility of four-state characters can be extended to the general case and will yield an $O(r^{r-2}n^2k)$ algorithm for the case of k characters, n species, and with the restriction to at most r states per character.

6. Comments. Recently [15], Richa Agarwala and David Fernandez-Baca have developed an $O(2^{3r}(nk^3 + k^4))$ algorithm for solving the perfect phylogeny problem when the number of states is bounded by r.

7. Acknowledgments. The authors wish to thank Gene Lawler and Manuel Blum for financial help and encouragement and Chris Meacham, who first introduced us to the character compatibility problem. Special thanks are due to Dan Gusfield, who recommended this special case to us and who went over intermediate drafts of this paper with great care.

DYNAMIC PERFECT HASHING: UPPER AND LOWER BOUNDS*

MARTIN DIETZFELBINGER†, ANNA KARLIN‡, KURT MEHLHORN§, FRIEDHELM MEYER AUF DER HEIDE¶, HANS ROHNERT‖, AND ROBERT E. TARJAN**

Abstract. The dynamic dictionary problem is considered: provide an algorithm for storing a dynamic set, allowing the operations insert, delete, and lookup. A dynamic perfect hashing strategy is given: a *randomized* algorithm for the dynamic dictionary problem that takes $O(1)$ worst-case time for lookups and $O(1)$ amortized expected time for insertions and deletions; it uses space proportional to the size of the set stored. Furthermore, lower bounds for the time complexity of a class of *deterministic* algorithms for the dictionary problem are proved. This class encompasses realistic hashing-based schemes that use linear space. Such algorithms have amortized worst-case time complexity $\Omega(\log n)$ for a sequence of n insertions and lookups; if the worst-case lookup time is restricted to k, then the lower bound becomes $\Omega(k \cdot n^{1/k})$.

Key words. data structures, dictionary problem, hashing, universal hashing, randomized algorithm, lower bound

1. Introduction. A *dictionary* over a *universe* $U = \{0, 1, \dots, N-1\}$ is a partial function S from U to some set I. The operations *Lookup*(x), *Insert*(x, i), and *Delete*(x) are available on a dictionary S; *Lookup*(x) returns $S(x)$, *Insert*(x, i) adds x to the domain of S and sets $S(x)$ to i, and *Delete*(x) removes x from the domain of S. In the following, the "information field" $S(x)$ associated with the "key" x in the dictionary will be ignored; thus, S is identified with its domain and regarded as a (dynamic) set. There are two major techniques for implementing dictionaries: trees and hashing.

For a static set S (no updates), Fredman, Komlós, and Szemerédi [9] described a hashing technique that achieves linear storage (in n) and constant query time for all N and n, where n is the size of S.

In this paper (§2), we present an extension of their scheme to the dynamic situation, wherein membership queries are processed in constant worst-case time; insertions and deletions are processed in constant expected amortized time; and the storage used at any time is proportional to the number of elements currently stored in the dictionary. The algorithm is randomized; the averaging involved in the analysis is over choices made by the algorithm and not over the sequence of operations.

Besides solutions that use (balanced) search trees, several other approaches to the dynamic dictionary problem have been proposed, some of which lead to expected or average constant time per instruction. Aho and Lee [1] presented a scheme achieving the same time and storage

bounds as our algorithm. However, in order to prove these bounds, they require that the items being inserted be chosen uniformly at random from the universe of possible elements.

Carter and Wegman [4] proposed *universal hashing* as a way of avoiding assumptions on the distribution of input values. This approach works particularly well in combination with the idea of "continuous rehashing" introduced by Brassard and Kannan [3]. In this way an algorithm is obtained that needs linear space and expected constant time for each single instruction. However, for n keys being stored in the dictionary in a scheme of this kind the best upper bound known on the expected *worst-case time* for an instruction (i.e., the length of the longest chain in the resulting hash table with chaining) is $O(\log n/\log\log n)$ (cf. [7], [16]), and it can be argued that it is $\Omega(\log n/\log\log n)$ no matter what universal class is used. In fact, this lower bound even holds in the case of uniform hashing, where one assumes that the hash values for different keys are chosen uniformly at random [11], [15].

In contrast, our algorithm guarantees constant time for each membership query.

When we say that no assumption is made about the sequence of operations, we mean that the sequence is arbitrary but fixed before the algorithm starts running. In essence, all that is needed for the analysis is that the sequence of operations be independent of the random choices made by the algorithm. Thus, we require that the party that chooses the sequence of operations not use any knowledge on these random choices to determine which items to insert in the table.

In the second part of the paper (§§4 and 5), we consider the case that we have to deal with an adversary that knows the random choices made by the algorithm or, equivalently, that the algorithm is deterministic. We prove an $\Omega(\log n)$ lower bound on the amortized worst-case time complexity for any deterministic solution to the dictionary problem which is solely based on hashing and uses only linear space. Furthermore, if we assume the worst-case lookup time to be bounded by k, the amortized worst-case complexity is $\Omega(k\cdot n^{1/k})$.

Remark 1.1. Some of the lower bounds that hold for the model considered in §§4 and 5 are bigger than the $O(\log n)$ worst-case bound guaranteed by balanced search trees. This results from the fact that our model is defined so as to cover only pure hashing strategies. In [14], which was motivated by the first version of the present paper, a lower bound of $\Omega(n\log\log n)$ for n insertions is shown in a stronger lower bound model that encompasses both hashing strategies and search trees. In [17], this lower bound was extended, by different methods, to an even wider class of models.

In §3, some general facts concerning the performance of universal classes of hash functions consisting of polynomials of constant degree or variants thereof are established. These results have proved useful for variations of the scheme presented in this paper, which yield constructions of dynamic dictionaries for parallel and distributed machine models as well as further improvements of the sequential scheme [2], [6], [7], [10].

2. Dynamic perfect hashing. We begin by reviewing the Fredman–Komlós–Szemerédi (FKS) scheme for statically storing a set S of size n. Assume p is prime and $p\geq N$. For $1\leq s\leq p$, let

$$\mathcal{H}_s=\{h:U\rightarrow\{0,\dots,s-1\}\mid\exists a\in\{1,\dots,p-1\}\forall x\in U:h(x)=(ax \bmod p)\bmod s\}.$$

The scheme has two levels. At the top level, a hash function partitions the elements being stored into s sets. The second level consists of a perfect hash function for each of these sets. Specifically, a function h chosen uniformly at random from $\mathcal{H}_s$ is used to partition the set S into s blocks. Let $W_j^h=\{x\in S\mid h(x)=j\}$; the superscript h is omitted when h is understood. Fredman, Komlós, and Szemerédi show that if a function h is chosen from $\mathcal{H}_s$

uniformly at random, then

$$E\left(\sum_{0\le j<s}\binom{|W_j|}{2}\right) \le \frac{n(n-1)}{s} \tag{2.1}$$

(where $E(X)$ denotes the expectation of the random variable X) and consequently that

$$\Pr\left(\sum_{0\le j<s}\binom{|W_j|}{2} < \frac{2n(n-1)}{s}\right) \ge \frac{1}{2}. \tag{2.2}$$

Choosing $s = 2(n-1)$, relation (2.2) implies that for at least half of the functions $h \in \mathcal{H}_s$ one has

$$\sum_{0\le j<s}\binom{|W_j|}{2} < n.$$

Such a function is used to partition S into blocks W_j, $0 \le j < s$. For each block W_j one uses relation (2.2) with $s_j = \max\{1, 2|W_j|(|W_j|-1)\}$. It follows that for at least half of the functions $h \in \mathcal{H}_{s_j}$ one has

$$\sum_{0\le l<s_j}\binom{|W_{j,l}|}{2} < 1,$$

where $W_{j,l} = \{x \in W_j \mid h(x) = l\}$, i.e. , $|W_{j,l}| \le 1$ for all l. For each j, therefore, at least half of the functions in $\mathcal{H}_{s_j}$ are injective on W_j. One uses one such function for each W_j. The total space requirement is linear since

$$\sum_{0\le j<s} s_j \le s + 4\cdot\sum_{0\le j<s}\binom{|W_j|}{2} = O(n),$$

by the choice of the hash functions.

For the dynamic case, we use the standard doubling method to deal with the fact that we do not know in advance how big the top-level table or any of the subtables will get.

Suppose that n is the current number of elements stored in the table. The FKS scheme in use will accommodate up to M elements. The value of M will initially be set to $(1+c)\cdot n$, for some c with $0 < c < 1$, and as n changes will never be more than $\frac{1+c}{1-c}\cdot n$. Let $s(M)$, to be specified, be the number of sets into which the top-level hash function is to partition the elements of S. The function h will be a random element of $\mathcal{H}_{s(M)}$. Thus, the set S is partitioned by h into the subsets $W_j = \{x \in S \mid h(x) = j\}, 0 \le j < s(M)$.

Let T_j be the block of memory used for storing W_j. The amount of space allocated to T_j is s_j, where $s_j = 2m_j(m_j-1)$ and m_j is the maximal size of W_j the current table T_j is meant to manage. The quantity m_j is always at least as big as $|W_j|$ and is at most twice the number of all elements ever mapped to j by the current top-level function h. The subset W_j is resolved within T_j by using a perfect hash function h_j from $\mathcal{H}_{s_j}$. If the value a_j specifies which hash function h_j is being used, then $x \in W_j$ is stored in location $(a_j x \bmod p) \bmod s_j$ of subtable T_j. It will be arranged that the following condition is always satisfied:

$$\sum_{0\le j<s(M)} s_j \le \frac{32M^2}{s(M)} + 4M\ . \tag{2.3}$$

The parameter $s(M)$ will be chosen to be $\Theta(n)$ so that the right-hand side of this equation is $O(n)$. We will see that this guarantees that the total space used is linear in the number of elements currently stored in the table.

The algorithm can be specified more precisely as described in the program given in Figs. 1 and 2. The variable *count* keeps track of the number of updates performed in the hash table of the present size M. From time to time it becomes necessary to restructure the whole table. This is the case when *count* reaches M or when condition (2.3) becomes wrong. In both cases, we start a *new phase*, resetting M to the new value $(1+c)\cdot n$, where n is the number of elements currently stored in the dictionary; the variable *count* is set to n, so that the system is able to perform up to $c \cdot n$ updates before the beginning of the next phase. Deletions are performed by attaching a tag "deleted" to the table entry to be erased; only when a new level-one hash function h or a new hash function h_j for the subtable T_j is chosen, do we drop the elements with a tag "deleted" from T_j. Note that all variables occurring in the procedures (in particular M, $s(M)$, *count*, h, h_j, for $0 \leq j < s(M)$) are global; an exception are the lists L and L_j, for $0 \leq j < s(M)$, which are local to the procedures that use them.

Let us first analyze the space needed by the scheme. By a *phase* we mean the time period during which one level-one hash function h is "in use": a phase starts when some h is chosen and ends when the next level-one function is chosen, either in the same or the subsequent call to *RehashAll*. Phases that only consist of choosing an h to find out that h does not satisfy condition (2.3) are called *degenerate*. During any phase that starts with n keys being stored in the dictionary the number of keys will never drop below $(1-c)\cdot n$, since at most $c \cdot n$ updates are made. Thus, the following lemma is sufficient to prove the claimed space bound.

LEMMA 2.1. *The memory space used during a phase that starts with n keys being stored in the dictionary is $O(n)$.*

Proof. The lemma is obviously true for degenerate phases, since $s(M) = \Theta(n)$. Thus, we assume that a function h is chosen that satisfies condition (2.3) and determine how big the table T has to be to accommodate all versions of all subtables. For $0 \leq j < s(M)$, let $\bar{m}_j$ denote the final capacity of T_j, that is, the value of m_j at the end of the phase, and let $\bar{s}_j = 2\bar{m}_j(\bar{m}_j - 1)$ be the final size of T_j. The previous versions of T_j (if there were any) had capacity $\frac{1}{2}\bar{m}_j, \frac{1}{4}\bar{m}_j, \ldots$. Since, for $l \geq 0$,

$$2 \cdot (2^{-l} \cdot \bar{m}_j)(2^{-l} \cdot \bar{m}_j - 1) \leq 4^{-l} \cdot 2\bar{m}_j(\bar{m}_j - 1) = 4^{-l} \cdot \bar{s}_j,$$

the total number of cells occupied by all versions of all subtables T_j is bounded by

$$\sum_{0 \leq j < s(M)} \sum_{l \geq 0} 4^{-l} \cdot \bar{s}_j = \frac{4}{3} \cdot \sum_{0 \leq j < s(M)} \bar{s}_j \leq \frac{4}{3} \cdot \left(\frac{32M^2}{s(M)} + 4M\right).$$

The last inequality holds since the algorithm makes sure that condition (2.3) remains valid throughout the phase.

The space required by the header table is at most $5s(M)$, since the jth entry of the header table need only contain a pointer to T_j, the variables s_j, b_j, and m_j, and the number a_j that describes the hash function h_j. If we let $s(M) = \frac{8}{15}\sqrt{30} \cdot M$, the space needed by the subtables and the header table taken together is bounded by $\frac{4}{3} \cdot ((32M^2 \cdot 15)/(8\sqrt{30} \cdot M) + 4M) + 5 \cdot \frac{8}{15}\sqrt{30} \cdot M = \frac{16}{3}(\sqrt{30} + 1) \cdot M < 35 \cdot (1+c) \cdot n$, which proves the lemma. □

Now we turn to the time bounds. Note first that membership queries do not interfere with the time analysis, since they are executed in constant time in the worst case. Thus, there is no harm in assuming that there are no membership queries at all. Note further that instructions that are executed in constant time (i.e., deletions in any case and insertions if they do not cause a subtable T_j to be rearranged) can be safely ignored, since they will not invalidate an overall linear time bound. Thus, we only need to worry about the time spent for installing

```
procedure $Insert(x)$;
  $count \leftarrow count + 1$;
  if $count > M$
  then
    $RehashAll(x)$;
  else
    $j \leftarrow h(x)$;

FIG. 2. *Setup, deletion, lookup, and rehashing.*

new level-one functions at the beginning of a phase (in *RehashAll*) and for constructing new versions of the subtables T_j (in *RehashAll* or in *Insert*).

LEMMA 2.2. *The expected time for a phase that starts with n keys being stored in the dictionary is $O(n)$.*

Proof. Consider the call to *RehashAll* in which the phase starts. Clearing the old table (header table and the subtables) and building up the list L takes time $O(n)$, since by Lemma 2.1 the old table occupies only space $O(n)$. Time linear in n suffices to construct the sublists L_j, to compute the values b_j, m_j, and s_j, $0 \le j < s(M)$, and to compute $\sum_{0\le j<s(M)} s_j$. Thus, if the phase is degenerate, it takes $O(n)$ time in the worst case. In a nondegenerate phase h initially satisfies condition (2.3). By the remarks immediately preceding Lemma 2.2, we only have to estimate the time spent for installing new hash functions h_j for the subtables. Fix some j, and split the phase, as far as T_j is concerned, into subphases, one subphase being defined as a maximal time period in which the capacity m_j and hence the size s_j of T_j have a fixed value. We need the following observation:

Claim. Assume a hash function h_j is chosen for T_j at the beginning or in the course of a subphase. Then the probability that h_j stays in use until the end of the subphase exceeds $\frac{1}{2}$.

Proof of Claim. Let the capacity of T_j during the phase be m_j. Let W_j be the set of keys x contained in the list L_j when h_j is chosen. Let V_j be the set of the first $m_j - |W_j|$ *different* keys x in the sequence of the *Insert* instructions to be executed next that satisfy $h(x) = j$ and do not occur in W_j. Then, by relation (2.2), table size $s_j = 2m_j(m_j - 1)$ (for $m_j \neq 0$) implies that with probability exceeding $\frac{1}{2}$ the elements of $W_j \cup V_j$ will be mapped by h_j to different locations in T_j. If this happens, the way b_j is changed and repeated keys are treated in *Insert* and *Delete* implies that h_j stays in use until b_j grows beyond m_j, that is, until the end of the subphase. This proves the claim.

By the claim, the probability that u or more hash functions h_j are used in a single subphase is at most $2^{-(u-1)}$, and hence the expected number of functions h_j chosen during the subphase is bounded by 2. Thus, the expected cost for installing new hash functions h_j during a subphase in which T_j has size s_j is $O(s_j)$. Exactly as in the proof of Lemma 2.1 we get an overall bound of $O(M) = O(n)$ for the expected time for installing new hash functions h_j, $0 \le j < s(M)$, by summing over all subtable sizes and all j, and using condition (2.3). □

In order to finish the time analysis, we will show in the following two lemmas that there will not be too many phases. Fix some phase (no assumptions are made as to whether the phase will turn out to be degenerate or nondegenerate), and let S be the set of elements stored in the table at the beginning of the phase (whose number is n) together with those that occur in the next $c \cdot n$ update instructions to be executed. (Even though elements may occur repeatedly in these instructions, they appear only once in the set S.) Let $M = (1 + c) \cdot n$; clearly, $|S| \le M$. For $h \in \mathcal{H}_{s(M)}$ chosen at random, define $W_j = \{x \in S \mid h(x) = j\}$, $0 \le j < s(M)$.

LEMMA 2.3. (a) *With probability exceeding $\frac{1}{2}$ we have*

$$\sum_{0\le j<s(M)} 4|W_j|(2|W_j| - 1) < \frac{32M^2}{s(M)} + 4M.$$

(b) *If the inequality in* (a) *is satisfied for the level-one function h chosen at the beginning of the phase, then the phase ends with the variable count reaching M; i.e., the phase comprises $c \cdot n$ updates.*

Proof. (a) In the situation just described, relation (2.2) reads

$$\Pr\left(\sum_{0\le j<s(M)} \binom{|W_j|}{2} \le \frac{2M(M-1)}{s(M)}\right) \ge \frac{1}{2}.$$

The claim then follows by a simple transformation, using the obvious inequality $\sum_{0\le j<s(M)} |W_j| = |S| \le M$.

(b) It is immediate from the way the variables b_j and m_j are initialized in *RehashAll* and updated in *Insert* and from the fact that only keys from S can occur in the phase that $b_j \le |W_j|$, and hence $m_j \le 2|W_j|$, throughout the phase. Since the equality $s_j = 2m_j(m_j-1)$ is preserved by the algorithm, we see that the inequality in (a) entails that relation (2.3) stays valid throughout the phase. □

LEMMA 2.4. *Suppose that RehashAll is called at a time when $n \ge 1$ keys are stored in the dictionary. Then the (expected) time needed until the first call to RehashAll after $c \cdot n$ updates have been performed is $O(n)$.*

Proof. Consider an arbitrary phase (degenerate or nondegenerate) that starts before the next $c \cdot n$ updates have been processed. The number of keys in the table at the beginning of this phase is n', where $(1-c)\cdot n < n' < (1+c)\cdot n$. By Lemma 2.3(a),(b), the probability that during this phase $c \cdot n'$ updates are performed exceeds $\frac{1}{2}$. Since $c \cdot n - |n' - n| \le c \cdot n'$ no matter if $n' < n$ or $n' \ge n$, this means that the probability that this phase extends further than the $c \cdot n$ updates we are considering is at least $\frac{1}{2}$. Thus, the expected number of phases (degenerate or nondegenerate) needed to perform these $c \cdot n$ updates is not more than 2. Each phase occurring starts with n' keys, $(1-c)\cdot n < n' < (1+c)\cdot n$, and takes $O(n')$ steps (expected) by Lemma 2.2. This finishes the proof of Lemma 2.4 and the time analysis. □

Lemmas 2.1–2.4 taken together yield the following result.

THEOREM 2.5. *Dynamic perfect hashing, as described by the algorithm in this section, uses linear space, needs constant time for membership queries, and has $O(1)$ expected amortized insertion and deletion cost.*

Remark 2.6. Obviously, the space bound $35(1+c)n$ proved in 2.1 is not satisfactory from a practical point of view. There are many conceivable ways of reducing the space bound: by varying the parameters fixed in the algorithm, by using slightly different hash functions, or by adapting more involved schemes, e. g., that described in [9], which achieves an $n + o(n)$ space bound in the static case. Most of these variations will increase the bounds on the expected computation time, but this does not necessarily mean that the time requirements observed in practice will grow significantly. Wenzel [20] has implemented a variant of the scheme described above. In his implementation the universe U is $\{0, 1, \ldots, 2^{31}-1\}$; the space requirements are kept small by avoiding the use of subtables if $|W_j|$ is small. He reports that the space requirements of his implementation are comparable to those of balanced trees and that the running time is superior to search trees provided n is moderately large ($n \ge 1000$). We refer the reader to [20] for details.

Remark 2.7. It is intuitively clear, and it can be seen in practice, that the evaluation time for the hash functions is critical for the performance of every implementation of the algorithm. In many installations, the functions from the following alternative class will be faster to evaluate than those from the class $\mathcal{H}_s$ above, since division by powers of 2 can be effected by shifts of binary representations of integers. The class corresponds to the classic multiplicative hashing scheme (see [12, p. 509]) with a randomly chosen multiplier. Assume $U = \{0, \ldots, N-1\}$, where $N = 2^\nu$ is a power of 2, and that $s = 2^\lambda$, for $1 \le \lambda \le \nu$. Let

$$\mathcal{H}'_s = \{h \mid \exists a \in \{1, \ldots, 2^\nu - 1\}, a \text{ odd}, \forall x \in U : h(x) = (ax \bmod 2^\nu) \operatorname{div} 2^{(\nu-\lambda)}\}.$$

In [8] it is shown that the class $\mathcal{H}'_s$ also satisfies inequality (2.1), thus it can be used in the algorithm described above without impairing the performance guarantees given by Theorem 2.5.

3. Higher-order hash functions. In this section we generalize inequality (2.1) from §2 (which originated in [9]) to polynomials of degree larger than 1 and note some consequences of this generalization. These extensions have proved useful since the first version of this paper appeared as [5]; see, e. g., [2], [6], [7], [10]. In order to formulate the result in a slightly more general way than just for polynomials, we recall a definition given originally in [19] and studied further (with varying notation) for example in [15], [16].

DEFINITION 3.1 [19]. *Let $\mathcal{H}$ be a collection of functions h with domain D and range R. Let $c > 0$, and let $k \geq 1$ be an integer. The class $\mathcal{H}$ is called* (c, k)-universal *if for all sequences $x_1, \ldots, x_k$ of different elements of D, all sequences $y_1, \ldots, y_k$ of elements of R, and randomly chosen $h \in \mathcal{H}$*

$$\Pr(h(x_i) = y_i \text{ for } 1 \leq i \leq k) \leq \frac{c}{|R|^k}.$$

(Alternatively, such classes have been called c strongly k universal or $(k)_c$-independent.)

Examples. (a) [19] If F is a finite field, we may let $D = R = F$; then

$$\mathcal{H} = \left\{ h \,\middle|\, \exists a_0, \ldots, a_{k-1} \in F : h(x) = \sum_{0 \leq i < k} a_i x^i \text{ for all } x \in F \right\}$$

is $(1, k)$-universal. This holds since for each sequence of k different arguments in F and k prescribed values there is exactly one polynomial of degree at most $k - 1$ that interpolates through these argument-value pairs.

(b) [15], [19] If $\mathcal{H}$ is (c, k)-universal and $r : R \to R'$ is such that $|r^{-1}(j)| \leq d$ for all j, then the (multi)set $\mathcal{H}' = \{r \circ h \mid h \in \mathcal{H}\}$ is $(\hat{c}, k)$-universal, for $\hat{c} = c \cdot (d|R'|/|R|)^k$.

(c) A direct consequence of (a) and (b): If p is prime and $1 \leq s \leq p$, then for $D = \{0, \ldots, p - 1\}$ and $R = \{0, \ldots, s - 1\}$ the set

$$\mathcal{H}_s^k = \left\{ h_{a_0, \ldots, a_{k-1}} \mid 0 \leq a_0, \ldots, a_{k-1} < p \right\},$$

where

$$h_{a_0, \ldots, a_{k-1}}(x) = \left(\sum_{0 \leq i < k} a_i x^i \bmod p \right) \bmod s, \quad \text{for } x \in D \text{ and } 0 \leq a_0, \ldots, a_{k-1} < p,$$

is (c, k)-universal, for $c = \left(\lceil p/s \rceil \cdot s/p\right)^k \leq (1 + s/p)^k$.

(d) For the finite field $D = R = GF(p^l)$, p prime, $l \geq 1$, we obtain $(1, k)$-universal classes with $|R'| = p^{l'}$, $1 \leq l' \leq l$, by combining (a) with a suitable function $r : R \to R'$. (See [15] for further examples.)

In the following, we assume that D and $R = \{0, \ldots, s - 1\}$ are fixed and that $\mathcal{H}$ is a class of functions from D to R. Let a set $S \subseteq D$ be fixed, $|S| = n$, and let x_0 be an element of $D - S$. For $h \in \mathcal{H}$ and $0 \leq j < s$ we define $B_j^h = \{x \in S \mid h(x) = j\}$ and $b_j^h = |B_j^h|$; further, we define $B_{x_0}^h = \{x \in S \mid h(x) = h(x_0)\}$ and $b_{x_0}^h = |B_{x_0}^h|$. Assume that h is chosen uniformly at random from $\mathcal{H}$. (In the notation, we drop the superscript h.) For arbitrary $z \in \mathbb{R}$, $k \geq 0$, we let $(z)_k$ denote the "falling factorial" $z(z - 1) \cdots (z - k + 1)$.

LEMMA 3.2. *If $\mathcal{H}$ is (c, k)-universal for D and R, then*

(a) $E\big((b_j)_k\big) \leq c \cdot (n)_k / s^k \leq c \cdot (n/s)^k$ *for* $0 \leq j < s$;

(b) $E\big((b_{x_0})_{k-1}\big) \leq c \cdot (n)_{k-1}/s^{k-1} \leq c \cdot (\frac{n}{s})^{k-1}$.

Proof. For $l \geq 1$, let $(S)_l$ denote the set $\{(x_1, \ldots, x_l) \in S^l \mid x_1, \ldots, x_l \text{ different}\}$.

(a) Fix j, and define random variables $X_{x_1, \ldots, x_k}$, *for* $(x_1, \ldots, x_k) \in (S)_k$, by

$$X_{x_1, \ldots, x_k} = \begin{cases} 1 & \text{if } h(x_1) = \cdots = h(x_k) = j, \\ 0 & \text{otherwise.} \end{cases}$$

Then $E(X_{x_1,\dots,x_k}) = \Pr(X_{x_1,\dots,x_k} = 1) \le c/s^k$, since $\mathcal{H}$ is (c,k)-universal. On the other hand, it is clear that

$$(b_j)_k = \sum_{(x_1,\dots,x_k)\in(S)_k} X_{x_1,\dots,x_k}.$$

Consequently,

$$E\big((b_j)_k\big) = \sum_{(x_1,\dots,x_k)\in(S)_k} E(X_{x_1,\dots,x_k}) \le |(S)_k| \cdot \frac{c}{s^k} = (n)_k \cdot \frac{c}{s^k}.$$

(b) The proof is similar to the one given in (a). Define random variables $Y^j_{x_1,\dots,x_{k-1}}$, $(x_1,\dots,x_{k-1}) \in (S)_{k-1}, 0 \le j < s$, by

$$Y^j_{x_1,\dots,x_{k-1}} = \begin{cases} 1 & \text{if } h(x_1) = \cdots = h(x_{k-1}) = h(x_0) = j, \\ 0 & \text{otherwise.} \end{cases}$$

Then $E(Y^j_{x_1,\dots,x_{k-1}}) \le c/s^k$, since $\mathcal{H}$ is (c,k)-universal. Further,

$$(b_{x_0})_{k-1} = \sum_{(x_1,\dots,x_{k-1})\in(S)_{k-1}} \sum_{0\le j<s} Y^j_{x_1,\dots,x_{k-1}}.$$

Taking expected values, we get

$$E\big((b_{x_0})_{k-1}\big) \le |(S)_{k-1}| \cdot s \cdot \frac{c}{s^k} = (n)_{k-1} \cdot \frac{c}{s^{k-1}},$$

as claimed. □

A hash function h is called *l-perfect* for S if $b^h_j \le l$ for all j, $0 \le j < s$, i.e., if no block B^h_j has size exceeding l.

COROLLARY 3.3. *In the situation of Lemma* 3.2, *if we further assume that $s \ge n$, we have*:

(a) $\Pr(h \text{ is } (k-1)\text{-perfect}) \ge 1 - (c/k!) \cdot n \cdot (n/s)^{k-1}$. *In case $s = n^{1+1/(k-1)}$ this probability exceeds* $1 - c/k!$.

(b) $E\left(\sum_{0\le j<s} (b_j)^k\right) \le c_k \cdot n$, *for some constant c_k.* (*Here $(b_j)^k$ is the kth power of b_j.*)

(c) $\Pr\left(\sum_{0\le j<s} (b_j)^k \le 2c_k \cdot n\right) \ge \frac{1}{2}$, *for c_k as in* (b).

Proof. (a) We estimate the probability that h is not $(k-1)$-perfect.

Clearly,

$$\Pr(\exists j : b_j \ge k) = \Pr(\exists j : (b_j)_k \ge k!) \le \sum_{0\le j<s} \Pr((b_j)_k \ge k!).$$

By 3.2(a) and the Markov inequality the last term is bounded above by $s \cdot (c/k!) \cdot (n/s)^k = (c/k!) \cdot n \cdot (n/s)^{k-1}$.

(b) Let $J = \{\, j \mid b_j \le k-1\}$. Since $\sum_{j\in J} b_j \le |S| = n$, it follows from elementary considerations that $\sum_{j\in J} (b_j)^k \le \lfloor \frac{n}{k-1} \rfloor \cdot (k-1)^k + (n - \lfloor \frac{n}{k-1} \rfloor \cdot (k-1))^k \le n \cdot (k-1)^{k-1}$.

We need the following simple fact:

Claim. If $z \ge k$, then $z^k/(z)_k < e^{k-1}$.

Proof of Claim.

$$\frac{z^k}{(z)_k} = \prod_{j=1}^{k-1} \frac{z}{z-j} \le \prod_{j=1}^{k-1} \frac{k}{k-j} = \frac{k^{k-1}}{(k-1)!}$$

$$= \sum_{l=0}^{k-1} \binom{k-1}{l} \cdot \frac{(k-1)^l}{(k-1)!} < \sum_{l=0}^{k-1} \frac{(k-1)^l}{l!} < e^{k-1}.$$

Thus, we may write:

$$E\Big(\sum_{0\le j<s}(b_j)^k\Big) \le E\Big(\sum_{j\in J}(b_j)^k + \sum_{j\notin J}(b_j)^k\Big) \le n\cdot(k-1)^{k-1} + e^{k-1}\cdot E\Big(\sum_{0\le j<s}(b_j)_k\Big).$$

By Lemma 3.2, we obtain for $c_k = (k-1)^{k-1} + ce^{k-1}$ that $E(\sum_{0\le j<s}(b_j)^k) \le c_k\cdot n$, as claimed.

(c) is immediate from (b). □

COROLLARY 3.4. *In the situation of Lemma* 3.2 *we have*

(a) *For* $0 \le j < s$ *arbitrary*

$$\Pr(b_j \ge u) \le \begin{cases} c\cdot(e^{u-1}/u^u)\cdot(n/s)^u & \text{for } 1 \le u < k;\\ c\cdot(e^{k-1}/u^k)\cdot(n/s)^k & \text{for } k \le u.\end{cases}$$

In particular, for $s \ge n$ *and* $u \ge k$, *we have* $\Pr(b_j \ge u) = O(u^{-k})$.

(b)

$$\Pr(b_{x_0} \ge u) \le \begin{cases} c\cdot(e^{u-1}/u^u)\cdot(n/s)^u & \text{for } 1 \le u < k-1;\\ c\cdot(e^{k-2}/u^{k-1})\cdot(n/s)^{k-1} & \text{for } k-1 \le u.\end{cases}$$

In particular, for $s \ge n$ *and* $u \ge k-1$, *we have* $\Pr(b_{x_0} \ge u) = O(u^{-(k-1)})$.

(*Note.* The special case $k = u$ in Corollary 3.4(a) has already been analyzed in [15].)

Proof. (a) Assume first that $u \ge k$. Then, by Lemma 3.2(a),

$$\Pr(b_j \ge u)\cdot(u)_k = \Pr\big((b_j)_k \ge (u)_k\big)\cdot(u)_k \le E\big((b_j)_k\big) \le c\cdot\left(\frac{n}{s}\right)^k,$$

whence we get

$$\Pr(b_j \ge u) \le \frac{c}{(u)_k}\cdot\left(\frac{n}{s}\right)^k.$$

By the claim in the proof of Corollary 3.3(b), this implies

$$\Pr(b_j \ge u) \le \frac{c\cdot e^{k-1}}{u^k}\cdot\left(\frac{n}{s}\right)^k.$$

In case $1 \le u \le k-1$ it is easily seen that $\mathcal{H}$ is also (c, u)-universal. Applying the above result yields the desired estimate $\Pr(b_j \ge u) \le c\cdot e^{u-1}\cdot(n/s)^u/u^u$.

(b) The argument is exactly the same as in (a); just use Lemma 3.2(b) instead of Lemma 3.2(a). □

4. Optimal lower bounds for the deterministic case. In this and the following section we consider *deterministic* algorithms for the dictionary problem that are based on hashing and lower bounds on their performance. It will turn out that such deterministic algorithms must be much slower than the randomized algorithms described in the preceding sections.

As a basis for our lower bound proofs we introduce a simplified, abstract type of algorithm. Such algorithms maintain the following data structure D. If $S \subseteq U$ is the set of elements in the dictionary, then D consists of a rooted tree whose leaves are labeled with the elements of S. The inner nodes are labeled with hash functions whose values correspond to the edges leaving the node. In order to access a key $x \in S$, one starts at the root and repeatedly evaluates the hash function at the current node (with x as argument) to determine the edge to be followed out of the node until a leaf is reached. This leaf has label x. This data structure generalizes the one used in §2, where two hash functions had to be evaluated to access a key. We count one step for the evaluation of a hash function.

In more detail, the data structure can be described as follows. D is a rooted tree in which each inner node v is labeled with a hash function $h_v : U \to \{0, 1, \ldots, m_v - 1\}$, with $m_v \geq 2$, and has m_v children, one for each value of h_v. Each $x \in U$ determines a path from the root to a leaf. This path is given by $w_0, w_1, \ldots, w_r$, where w_0 is the root, w_{t+1} is the $h_{w_t}(x)$th child of w_t, for $0 < t < r$, and w_r is a leaf. We say that D is a dictionary for $S = \{x_0, \ldots, x_n\} \subseteq U$ if each leaf contains exactly one of the x_i. To each node v of D we associate the set $A(v) \subseteq U$ of keys that are "sent to" v by the hash functions on the path from the root to v. We define inductively: $A(v) = U$ for v the root and $A(v_q) = \{x \in A(v) \mid h_v(x) = q\}$ for $0 \leq q < m_v$ where v_q, for $0 \leq q < m_v$, are the children of v.

For our lower bound arguments, we will consider only insertions. To insert a key $x_{n+1} = x \in U$ into a dictionary D for S, we follow the path $w_0, w_1, \ldots, w_r$ determined by x, and for some node v on this path (determined by the algorithm) perform a *rehashing* at v, which means that we choose a new perfect hash function h_v for $A(v) \cap (S \cup \{x\})$. Thus, all $|A(v) \cap (S \cup \{x\})|$ children of v become leaves, and to each of them corresponds exactly one element of $A(v) \cap (S \cup \{x\})$. Such a rehashing *must* be performed for exactly one node v on the path. The cost of such an insertion is depth(v) + $|A(v) \cap (S \cup \{x\})|$. The cost of inserting $x_1, x_2, \ldots, x_n \in U$ into a dictionary D is the sum of the costs of the single insertions. Note that we assume that D initially contains one element x_0 in a leaf, with no root.

Remark 4.1. When a rehashing at v is performed, a perfect hash function for $A(v) \cap (S \cup \{x\})$ is given at linear cost; in addition, setting up the hash table, i.e, the subtree of depth 1, for this set has linear cost as well. This assumption excludes search trees that use an order on the universe U to define the way keys are distributed at nodes, as well as other schemes involving cleverly chosen hash functions that can be extended to additional keys at low cost while keeping the function injective.

Remark 4.2. (a) We require that collisions are resolved immediately by rehashing. In particular, we do not allow forming chains, i.e., linked lists, at the leaves of the tree as is done in many hashing schemes. But the absence of this restriction would not change the lower bounds by much. If we were to allow chaining, inserting n elements would cost n steps, because we could insert each element at the head of the chain, which would mean constant time per insertion. To justify our model, we have to consider tasks with insertions *and* lookups. If after inserting x we include a lookup for the element at the end of the chain into which x was inserted, then this lookup costs essentially as much as rehashing at the leaf to which the chain belongs. Thus algorithms for insertions and lookups, with chaining allowed, are at least as costly as algorithms without chaining for insertions only.

(b) One could ask if it would be advantageous to allow also rehashings at nodes v that do not lie on the path determined by the x just being inserted. But it is easily checked that the algorithm does not become slower if such rehashings are performed at the time when the last element of $S \cap A(v)$ is inserted into D. Thus it is justified not to admit such "spontaneous" rehashings.

Remark 4.3. *The role of space limitations.* In the description of the data structure D, we did not introduce the concept of the space used by D. On the other hand, some space restriction is necessary, since using the identity function as the hash function at the root would make all rehashing superfluous.

If we assume that storing a hash function h_v together with the corresponding table takes space $O(m_v) = O(|\text{range}(h_v)|)$, then $\sum_{v \text{ node in } D} m_v$ is a reasonable measure for the space used by D. In our description of the data structure D we assumed that every leaf of D contained an element of S, so for every h_v and every $j \in \{0, \dots, m_v - 1\}$ there is some $x \in S$ with $h_v(x) = j$. Since in every rooted tree with $n+1$ leaves and outdegree at least 2 the number of edges is bounded by $2n$, our data structure D satisfies $\sum_v m_v \le 2n$, which means that it needs linear space.

If the algorithm were allowed to use hash functions h_v with range larger than $|A(v) \cap S|$ when rehashing at node v, then the lower bounds given in the theorems below would still hold, with constants smaller by a factor of $\frac{1}{4}$ than those in the theorems. We only have to assume that the space used by D is not too large in relation to the size of the universe U (namely, $|U| \ge (S(n) 2 \log n)^{2 \log n} \cdot (n+1)$ in Theorem 4.4 and $|U| \ge (S(n)/k)^k$ in Theorem 4.6 for $S(n) = \sum_v m_v$). We shall comment on this in more detail below when the adversary strategies for the lower bound proofs are discussed.

We want to study the following quantities.

$T(n)$ = worst-case (amortized) cost incurred by an optimal algorithm to insert n elements.

$T_{\max}(n)$ = worst-case cost needed for a single insertion or membership query in a sequence of n instructions.

$T_k(n)$ = worst-case amortized cost needed by an optimal algorithm to insert n elements, if the depth of the tree is not allowed to exceed k, i.e., if the worst case lookup time is k.

The following three theorems sum up the results (upper and lower bounds) concerning these three quantities. Theorem 4.4 shows that amortized time $O(n)$ for n insertions cannot be achieved in the deterministic case but rather that a slowdown by a factor $\log n$ is unavoidable. Theorem 4.5 shows that in any case there will be single instructions that are very costly. If we demand constant lookup time to be guaranteed, Theorem 4.6 shows that this can only be achieved by many costly rehashings.

THEOREM 4.4. (a) $T(n) \ge (n+1) \cdot \log(n+1)$, *if* $|U| \ge (n/\log n)^{2 \log n} \cdot (n+1)$.

(b) $T(n) \le 3(n+1)\log(n+1)$.

THEOREM 4.5. (a) $T_{\max}(n) = \sqrt{n}$, *if* $|U| \ge 2(\sqrt{n})^{\sqrt{n}}$.

(b) *If only algorithms with a total cost smaller than* $f(n) \cdot n$ *for* n *insertions are considered and* $|U| \ge (n/f(n))^{2f(n)} \cdot (n+1)$, *then* $T_{\max}(n) = \Omega(n/f(n))$.

THEOREM 4.6. (a) $T_k(n) \ge (k/e) \cdot n^{1+1/k}$ *for* $n \ge e^k$, *if* $|U| > (2n/k)^k$.

(b) $T_k(n) \le d_k \cdot n^{1+1/k}$ *for all sufficiently large* n, *where the constants* d_k *can be chosen to satisfy* $d_k \sim k/e$. (*Here* $e = 2.71828 \cdots =$ *the base of the natural logarithm.*)

The *proofs* of the theorems will be given in the next section.

Remark 4.7. If we reconsider the randomized algorithm presented in §2, we see that randomization is only used for constructing perfect hash functions at expected linear cost. Thus, if we give such hash functions at guaranteed linear cost, we should obtain a deterministic algorithm that is at least not slower than the randomized one. This seems to contradict our lower bounds! To resolve this paradox, consider adversary strategies for the randomized computation model. Here the adversary has to determine the moves of the strategy without knowledge of the outcomes of the coin flips of the algorithm to be executed. This means that the data structure produced by the algorithm cannot be taken into consideration by the adversary. But this is what happens in the deterministic case and what makes the adversary as strong as indicated in the lower bounds for the deterministic model.

Remark 4.8. Theorem 4.5 gives a lower bound for our model that is bigger than the $O(\log n)$ worst-case bound for single instructions guaranteed by implementations of dictionaries as balanced search trees. This is an effect of the quite severe restriction that rehashing at a node v has cost linear in the size of the subtree rooted at v. (Cf. Remark 1.1.)

5. Proofs of the lower bounds. This section contains the proofs of the theorems stated in §4.

5.1. The adversary strategy. For proving the lower bounds, we apply an adversary argument in each case. Let us first give a general description of the adversary strategy. Initially, the tree D contains one element x_0. The adversary chooses, step by step, the element x_i to be inserted next. Basically, x_i is always chosen in such a way that it has to follow a longest path in D.

In order to be always able to find such an element x_i, we must make sure that the set of elements of U that belongs to such a longest path is not empty. The aim of the adversary is to build up long paths $w_0, w_1, w_2, \ldots$ in the tree and to make sure that the sets $A(w_0)$, $A(w_1)$, $A(w_2), \ldots$ are as large as possible. Thus, if a decision is to be made which path to choose, the adversary will, at each node v, choose that child q of v that maximizes $|h_v^{-1}[q] \cap A(v)|$, $0 \le q < m_v$. (If there is a tie, the smallest such q is chosen.) For the sake of simplicity of notation, we will assume that $q = 0$ always has this property. (If this is not the case, renumber the children of v.)

ASSUMPTION 5.1. *For all trees D ever built by the algorithms and for all nodes v of D, the set $A(v) \cap h_v^{-1}[0]$ is maximal (with respect to cardinality) among $A(v) \cap h_v^{-1}[q]$, $0 \le q < m_v$.*

We will regard the child number 0 of v as the leftmost child of v and define the leftmost path and the leftmost leaf in D accordingly (always follow the edge to child 0).

Simple adversary strategy: Choose $x_1 \neq x_0$ arbitrarily. For $i > 1$, assume that $x_1, \ldots, x_{i-1}$ have been inserted and that a tree D has been set up by the algorithm. Then let x_i be an arbitrary element of $A(v) - \{x_0, x_1, \ldots, x_{i-1}\}$, where v is the leftmost leaf of D.

Note that all elements inserted follow the leftmost path in D. This path grows as the result of inserting x_i if the algorithm chooses to perform a rehashing only at the leftmost leaf, or it is cut off at v if the algorithm performs a rehashing at an inner node v of the leftmost path.

Remark 5.2. We have made the assumption that in all nodes v of D all values of h_v are used by members of S. This has the effect that each insertion causes a collision at some node on the path to the leaf reached by the newly inserted element and, hence, causes a rehashing. Here, we wish to justify the statement made in Remark 4.3 that the lower bounds essentially also hold in the more general model where it is permitted that some values of h_v are not used by elements of S. We apply the same adversary strategy. But now it may happen that when x_i is inserted, it reaches a leaf that is not already occupied by a key from $\{x_0, \ldots, x_{i-1}\}$, hence no rehashing is necessary. However, observe that out of two subsequent insertions performed according to the adversary strategy at least one must cause a rehashing somewhere along the leftmost path. It is then seen that all lower bounds proved below hold under the assumption that not n but $2n$ keys are inserted, because they cause at least n rehashings.

The following lemma makes precise how big U has to be in order to guarantee that some suitable x_i is available in each step of the adversary strategy.

LEMMA 5.3. *Let v be a node on the leftmost path in D, and let the depth of v in D be r. Then*

(a) $|A(v)| \ge |U|/(2n/r)^r$.

(b) *If we drop the assumption (cf. Remark 4.3) that for all nodes v in the tree $A(v) \cap S \neq \emptyset$ and regard $s(D) = \sum_{v \text{ node in } D} m_v$ as a measure for the space needed by D, then for v as in* (a) *we have $|A(v)| \ge |U|/(s(D)/r)^r$.*

Proof. Let $w_0, w_1, \ldots, w_r = v$ be the path from the root w_0 to v. By definition, $|A(w_0)| = |U|$; further, $|A(w_{t+1})| \ge |A(w_t)|/m_{m_t}$, by Assumption 5.1. Thus, $|A(v)| \ge |U|/(\prod_{t=0}^{r-1} m_{w_t})$. Obviously, $\sum_{t=0}^{r-1} m_{w_t} \le s(D)$. From this it is easily seen that the denominator $\prod_{t=0}^{r-1} m_{w_t}$ cannot be larger than $(s(D)/r)^r$. This proves (b). As noted already in Remark 4.3, if $A(v) \cap S \neq \emptyset$ for all nodes v in D, then $s(D) \le 2n$. This proves (a). □

LEMMA 5.4. *Let $\bar{T}(n)$ denote the minimal number of steps needed by any algorithm for inserting n elements, if these elements are chosen according to the simple adversary strategy. (In particular, the algorithm has to admit the simple adversary strategy, which means that for each $i < n$ we have that after inserting x_i the set $A(v) - \{x_0, x_1, \ldots, x_i\}$ is nonempty, for v the leftmost leaf in D.) Then*

$$\bar{T}(n) \geq (n+1)\log(n+1).$$

Proof. (Induction on n.) Fix such an algorithm for n elements. Clearly, $\bar{T}(0) = 0$, $\bar{T}(1) = 2$ (rehashing at the root is forced). Let $n > 1$. Let $1 \leq i \leq n$ where i is maximal such that x_i is inserted by rehashing at the root. (Such an i exists, since this applies to $i = 1$.) Inserting $x_1, \ldots, x_{i-1}$ costs at least $\bar{T}(i-1)$, by the definition of $\bar{T}$; inserting x_i costs $i+1$; inserting $x_{i+1}, \ldots, x_n$ costs at least $n - i + \bar{T}(n-i)$, since the hash function at the root has to be evaluated for $x_{i+1}, \ldots, x_n$, and all these elements are sent into the leftmost subtree and have to be inserted there and are chosen according to the simple adversary strategy with respect to this subtree. (Note that this subtree already has an element.) Thus

$$\bar{T}(n) \geq \bar{T}(i-1) + (i+1) + (n-i) + \bar{T}(n-i).$$

By the induction hypothesis, this entails

$$\bar{T}(n) \geq i\log i + (n+1-i)\log(n+1-i) + n + 1,$$

and the right-hand side of the last inequality is at least $(n+1)\log(n+1)$, since the function $y\log y + (n+1-y)\log(n+1-y)$ attains its minimum in the range $1 \leq y \leq n$ in $y = (n+1)/2$. □

5.2. Proof of Theorem 4.4. We first consider the lower bound (part (a)). We would like to use the adversary strategy described above. However, to provide for the case that the leftmost path in D becomes very long and U is not as big as demanded in Lemma 5.3, we must slightly change the adversary strategy: We choose x_i so that it aims at the $\lfloor 2\log n \rfloor$th node on the leftmost path in D.

Modified adversary strategy: Choose $x_1 \neq x_0$ arbitrarily. For $i > 1$, assume that $x_1, \ldots, x_{i-1}$ have been inserted and that a tree D has been set up by the algorithm. Let $w_0, w_1, \ldots, w_r$ be the path from the root to the leftmost leaf in D. Choose x_i to be an arbitrary element of $A(w_{r'}) - \{x_0, \ldots, x_{i-1}\}$, where $r' = \min(r, \lfloor 2\log n \rfloor)$.

By Lemma 5.3, this strategy will work as long as $|U|/((2n)/(2\log n))^{2\log n} \geq n+1$, i.e., $|U| \geq (n/\log n)^{2\log n} \cdot (n+1)$.

Define

$$L = \{x_i \mid 1 \leq i \leq n, \text{depth}(v) \geq 2\log n \text{ for the vertex } v \text{ in } D \text{ at which rehashing is performed when } x_i \text{ is inserted}\}.$$

Clearly, for each $x_i \in L$ the cost of evaluating the hash functions on the way down to v alone is at least $2\log n$. We determine a lower bound for inserting the elements in $\{x_{i_1}, x_{i_2}, \ldots, x_{i_{n'}}\} = \{x_1, \ldots, x_n\} - L$ into the tree as follows. (Here, $n' = n - |L|$.) Observe that if we disregard all elements $x_i \in L$ and all inner nodes at depth $\geq 2\log n$ in the computation for $x_1, \ldots, x_n$, then we obtain a computation in which $x_{i_1}, \ldots, x_{i_{n'}}$ are inserted into a dictionary that always has depth smaller than $2\log n$ and $x_{i_1}, \ldots, x_{i_{n'}}$ are chosen according to the simple adversary strategy considered in Lemma 5.4. Thus we may conclude from Lemma 5.4 that inserting $x_{i_1}, \ldots, x_{i_{n'}}$ has cost at least $(n'+1)\log(n'+1)$. Altogether we get

$$\begin{aligned} T(n) &\geq |L| \cdot 2\log n + (n - |L| + 1) \cdot \log(n - |L| + 1) \\ &\geq \min_{0 \leq y \leq n-1} (y \cdot 2\log n + (n - y + 1) \cdot \log(n - y + 1)). \end{aligned}$$

For $n \geq 4$, the minimum is attained for $y = 0$; hence $T(n) \geq (n+1)\log(n+1)$. For $n = 1, 2, 3$, the lower bound in Theorem 4.4 is obvious. This finishes the proof of Theorem 4.4(a).

To prove the upper bound in Theorem 4.4 (part (b)), we use the following algorithm for arbitrary n: Perform a global rehashing (i. e., a rehashing at the root) for x_i if i is a power of 2. Choose the hash functions h_v, for v the root, in such a way that $|h_v^{-1}[q]| = 1$ for all $q > 0$; then all insertions that do not cause a rehashing at the root go into the leftmost subtree, to which the same algorithm is applied recursively. Let $\tilde{T}(n) =$ cost of this algorithm when applied to n elements. By inspection, $\tilde{T}(1) = 2$, $\tilde{T}(2) = 5$, $\tilde{T}(3) = 8$. We claim that $\tilde{T}(n) \leq 3(n+1)\log(n+1)$ for all n. Fix $n \geq 4$, and let $t = \lfloor \log n \rfloor$. We split $x_1, \dots, x_n$ into three groups and two single elements:

- inserting $x_1, \dots, x_{2^{t-1}-1}$ costs $\tilde{T}(2^{t-1} - 1)$;
- inserting $x_{2^{t-1}}$ costs $2^{t-1} + 1$;
- inserting $x_{2^{t-1}+1}, \dots, x_{2^t-1}$ costs $\tilde{T}(2^{t-1} - 1) + (2^{t-1} - 1)$;
- inserting x_{2^t} costs $2^t + 1$;
- inserting $x_{2^t+1}, \dots, x_n$ costs $\tilde{T}(n - 2^t) + (n - 2^t)$.

Thus, by the induction hypothesis,

$$\tilde{T}(n) \leq 2 + 2^{t-1} + n + 2 \cdot 3 \cdot 2^{t-1} \log(2^{t-1}) + 3 \cdot (n - 2^t + 1) \log(n - 2^t + 1).$$

With $2 + 2^{t-1} + n \leq 3 \cdot 2^t$ it follows that

$$\tilde{T}(n) \leq 3 \cdot 2^t \log(2^t) + 3 \cdot (n - 2^t + 1) \log(n - 2^t + 1);$$

hence, by the convexity of the function $y \log y$, we get $\tilde{T}(n) \leq 3(n+1)\log(n+1)$, as desired. This finishes the proof of Theorem 4.4(b).

5.3. Proof of Theorem 4.5. (a) Apply the simple adversary strategy from §5.1. If at some time the leftmost path in the tree becomes longer than $\sqrt{n}$, then at least one insertion had cost $\sqrt{n}$. Otherwise, the assumption $|U| \geq 2(\sqrt{n})^{\sqrt{n}}$ guarantees, by Lemma 5.3, that the adversary strategy can be carried out. Only nodes on the leftmost path have children; hence, there must be one node on the leftmost path that has at least $\sqrt{n}$ children. Thus, the cost of the last rehashing at this node was at least $\sqrt{n}$.

(b) Apply the modified adversary strategy from the proof of Theorem 4.4, for $r' = \min\{r, 2f(n)\}$. At most $n/2$ keys can be inserted below level $2f(n)$, by the overall time bound; hence, at least $n/2$ will be above that level. In levels smaller than $2f(n)$, only nodes on the leftmost path can have children; as in (a) it follows that one insertion must have had cost at least $n/2f(n)$.

5.4. Proof of Theorem 4.6.

5.4.1. The lower bound. Recall that in Theorem 4.6 only algorithms that produce trees whose depth is bounded by some constant k are considered. Let such an algorithm for inserting $x_1, \dots, x_n$ (into a table that initially contains one element x_0) be given. We use the simple adversary strategy from §5.1. From Lemma 5.3 we know that the assumption $|U| \geq (2n/k)^k$ is sufficient to ensure that $|A(v)| \geq 2$ for v the leftmost leaf of D and hence that the strategy is always applicable under this assumption.

For $k \geq 1$, $n \geq 1$ define $\hat{T}_k(n) =$ the minimal number of steps needed by any algorithm that produces only trees of depth at most k to insert $x_1, \dots, x_n$ chosen according to the adversary strategy. Clearly, $T_k(n) \geq \hat{T}_k(n)$. Trivially, $\hat{T}_k(0) = 0$ for all $k \geq 1$.

LEMMA 5.5. *$\hat{T}_k(n)$ satisfies the following inequalities.*

(a) $\hat{T}_1(n) = (n+1)(n+2)/2 - 1$, *for* $n \geq 0$.

(b) $\hat{T}_k(n) \geq \min\{l + \sum_{j=1}^{l}(ja_j + \hat{T}_{k-1}(a_j - 1)) \mid l \geq 1, a_1, \ldots, a_l \in \mathbb{N}, \sum_{j=1}^{l} a_j = n\}$, *for* $n \geq 1$, $k \geq 2$.

Proof. (a) If $k = 1$, then every element x_i is inserted by rehashing at the root, which has cost $i + 1$. Thus $\hat{T}_1(n) = \sum_{i=1}^{n}(i+1) = (n+1)(n+2)/2 - 1$.

(b) Let $x_1, \ldots, x_n$ be inserted, chosen according to the simple adversary strategy. Consider an algorithm that for inserting these elements needs $\hat{T}_k(n)$ steps. Let $x_{i_0}, x_{i_1}, \ldots, x_{i_{l-1}}$ be those elements that are inserted by global rehashing, i.e., by constructing a new perfect hash function at the root. (For x_1 this is forced, hence $i_0 = 1$.) Also, let $i_l = n + 1$. Note that between global rehashings the elements $x_{i_{j-1}+1}, \ldots, x_{i_j - 1}$ are chosen so that they are all sent to the subtree rooted at the leftmost child of the root of D and that insertions into this subtree are performed according to some strategy for $i_j - i_{j-1} - 1$ elements and depth $k - 1$; further, after the insertion of $x_{i_{j-1}}$ this subtree already has one element. By the definition of $\hat{T}_k(n)$, inserting these elements into the subtree has cost at least $\hat{T}_{k-1}(i_j - i_{j-1} - 1)$. In addition, for these elements the hash function at the root has to be evaluated, which has cost $i_j - i_{j-1} - 1$. Inserting x_{i_j}, $j = 0, 1, \ldots, l-1$, has cost $i_j + 1$. Thus the total cost is

$$\begin{aligned}\hat{T}_k(n) &\geq \sum_{j=1}^{l}\bigl((i_j - i_{j-1} - 1) + \hat{T}_{k-1}(i_j - i_{j-1} - 1)\bigr) + \sum_{j=0}^{l-1}(i_j + 1)\\ &= \sum_{j=1}^{l}\hat{T}_{k-1}(i_j - i_{j-1} - 1) + \sum_{j=1}^{l} i_j.\end{aligned}$$

Let $a_{l+1-j} = i_j - i_{j-1}$ for $1 \leq j \leq l$. Then $\sum_{j=1}^{l} a_j = i_l - i_0 = n$ and $\sum_{j=1}^{l} i_j = l \cdot i_0 + \sum_{j=1}^{l}(l + 1 - j) \cdot a_{l+1-j}$; hence,

$$\hat{T}_k(n) \geq \sum_{j=1}^{l}\bigl(j \cdot a_j + \hat{T}_{k-1}(a_j - 1)\bigr) + l.$$

This proves part (b). □

The proof of Theorem 4.6 is completed by the following lemma.

LEMMA 5.6.

$$\hat{T}_k(n) \geq g_k(n+1)$$

for all $k \geq 1$, $n \geq 0$, *where*

$$g_k(y) = \begin{cases} 0 & \textit{for} \quad y = 0;\\ y \ln y & \textit{for} \quad 0 < y \leq e^k;\\ \dfrac{k}{e} \cdot y^{1+1/k} & \textit{for} \quad e^k < y.\end{cases}$$

For the *proof* of this lemma see the appendix. It is a technical argument based solely on the inequalities of Lemma 5.5.

5.4.2. The upper bound. We will describe an algorithm for inserting n elements $x_1, \ldots, x_n \in U$ into a table (which initially contains one element x_0) so that the depth of the resulting tree never becomes larger than k. As in the proof of Theorem 4.4(b), the hash function h_v chosen for a vertex v always satisfies $|h_v^{-1}[q] \cap A(v)| = 1$ for all $q > 0$. This means that subsequent elements that are inserted in the subtree rooted at v are always sent to the leftmost subtree of v. Let

$$d_1 = 1, \qquad d_k = k \cdot \frac{k+1}{k+2} \cdot \left(\frac{d_{k-1}}{k-1}\right)^{(k-1)/k} \qquad \text{for } k > 1.$$

Then $d_k = k \cdot \left(\prod_{q=2}^{k}\big((q+1)/(q+2)\big)^q\right)^{1/k}$. As an abbreviation, let $b_k = d_k/k$.

Algorithm for a table of depth at most k (inductive description):
$k = 1$: Insert each element by global rehashing.
$k > 1$: Let $i_t = \left\lceil \sum_{s=1}^{t}\big(s/(k \cdot b_{k-1})\big)^{k-1} \right\rceil$, for $t = 0, 1, 2, 3, \dots$. Insert the elements $x_1 = x_{i_1}, x_{i_2}, x_{i_3}, \dots$ by global rehashing; that is, by establishing a new hash function h_v at the root v. Between these global rehashings the elements $x_{i_{t-1}+1}, \dots, x_{i_t-1}$ all go into the leftmost subtree of the root. Apply the algorithm for depth at most $k-1$ to this subtree, for these $i_t - i_{t-1} - 1$ elements.

It is obvious that this algorithm always maintains a tree of depth at most k; hence, a lookup time of k is guaranteed. We only have to analyze the time required for insertions. For $k \geq 1$, $n \geq 0$, let

$$\tilde{T}_k(n) = \text{cost of inserting } x_1, \dots, x_n \text{ into a table, which initially has one element, using the algorithm just described.}$$

(Note that for the cost of the algorithm it is irrelevant which particular elements $x_1, \dots, x_n$ are inserted.) To finish the proof of Theorem 4.6(b), we just have to show the following.

LEMMA 5.7. (a) $\tilde{T}_k(n) \leq d_k \cdot n^{1+1/k}$ *for all* $n \geq n_k$, *for* n_k *large enough (for all* $k \geq 1$).
(b) $\lim_{k\to\infty} d_k/(k/e) = 1$.

Proof. (a) (Induction on k.)
Initial step ($k = 1$): Obviously, $\tilde{T}_1(n) = (n+1)(n+2)/2 - 1 \leq n^2$ for $n \geq 3$.

Induction step ($k > 1$): Assume $\tilde{T}_{k-1} \leq d_{k-1} \cdot n^{k/(k-1)}$ for all $n \geq n_{k-1}$. Now let n be fixed, n large enough. Define $t_0 = \min\{t \geq 1 \mid i_t > n\}$, for the sequence i_t, $t \geq 1$, defined in the strategy. We first estimate t_0. Clearly, by the definition of i_t and t_0 we have

$$\sum_{s=1}^{t_0-1} s^{k-1} \leq (k \cdot b_{k-1})^{k-1} \cdot n < \sum_{s=1}^{t_0} s^{k-1},$$

hence (by estimating the sums by integrals and taking kth roots),

$$t_0 - 1 \leq k \cdot b_{k-1}^{(k-1)/k} \cdot n^{1/k} < t_0 + 1\,. \tag{5.1}$$

In the following, we estimate $\tilde{T}_k(i_{t_0} - 1)$, which certainly is an upper bound for $\tilde{T}_k(n)$. We let $i_0 = 0$. Then inserting the element x_{i_t} (by global rehashing) has cost i_t+1, for $t = 1, 2, \dots, t_0 - 1$; inserting the elements $x_{i_{t-1}+1}, \dots, x_{i_t-1}$ has cost $(i_t - i_{t-1} - 1) + \tilde{T}_{k-1}(i_t - i_{t-1} - 1)$, for $t = 1, 2, \dots, t_0$. Thus,

$$\tilde{T}_k(n) \leq \sum_{t=1}^{t_0}\big((i_t - i_{t-1} - 1) + \tilde{T}_{k-1}(i_t - i_{t-1} - 1)\big) + \sum_{t=1}^{t_0-1}(i_t + 1),$$

or, after a trivial transformation,

$$\tilde{T}_k(n) \leq \sum_{t=1}^{t_0}\big((t_0 + 1 - t)(i_t - i_{t-1}) + \tilde{T}_{k-1}(i_t - i_{t-1} - 1)\big).$$

Substituting the induction hypothesis $\tilde{T}_{k-1}(n') \leq d_{k-1} \cdot (n')^{k/(k-1)}$, for $n' \geq n_{k-1}$, into this inequality yields

$$\tilde{T}_k(n) \leq \sum_{t=1}^{t_0}\big((t_0 + 1 - t)(i_t - i_{t-1} - 1) + d_{k-1}(i_t - i_{t-1} - 1)^{k/(k-1)}\big) + \tfrac{1}{2}t_0(t_0 + 1) + E_k,$$

for some constant E_k (needed to make up for the error caused by replacing $\tilde{T}_{k-1}(i_t - i_{t-1} - 1)$ by $d_{k-1}(i_t - i_{t-1} - 1)^{k/(k-1)}$ for t so small that $i_t - i_{t-1} - 1 < n_{k-1}$). By the definition of i_t we clearly have $i_t - i_{t-1} - 1 \le \big(t/(kb_{k-1})\big)^{k-1}$; furthermore, from the bounds on t_0 in (5.1) it follows that $t_0^2 = O\big((n^{1/k})^2\big) = O(n)$. Thus,

$$\begin{aligned}\tilde{T}_k(n) &\le \sum_{t=1}^{t_0}\left[\left(\frac{t}{kb_{k-1}}\right)^{k-1} \cdot (t_0 + 1 - t) + d_{k-1} \cdot \left(\frac{t}{kb_{k-1}}\right)^{k}\right] + O(n)\\ &= (kb_{k-1})^{1-k} \cdot \left(\sum_{t=1}^{t_0}(t_0+1)t^{k-1} - \sum_{t=1}^{t_0} t^k/k\right) + O(n).\end{aligned}$$

We substitute the two inequalities $\sum_{t=1}^{t_0} t^{k-1} \le (t_0 + 1)^k/k$ and $\sum_{t=1}^{t_0} t^k \ge t_0^{k+1}/(k+1)$ (obtained by replacing the sums by integrals) and simplify, noting that $(t_0 + 1)^{k+1} = t_0^{k+1} + O(t_0^k)$. In this way we get

$$\tilde{T}_k(n) \le \frac{1}{k+1} \cdot (kb_{k-1})^{1-k} \cdot t_0^{k+1} + O(t_0^k) + O(n).$$

By (5.1), we have $t_0^k = O\big((n^{1/k})^k\big) = O(n)$ and furthermore that $t_0^{k+1} = k^{k+1} \cdot b_{k-1}^{k-1/k} \cdot n^{1+1/k} + O(t_0^k)$. Hence

$$\begin{aligned}\tilde{T}_k(n) &\le \frac{1}{k+1} \cdot (kb_{k-1})^{1-k} \cdot k^{k+1} \cdot b_{k-1}^{k-1/k} \cdot n^{1+1/k} + O(n)\\ &= \frac{k^2}{k+1} \cdot b_{k-1}^{(k-1)/k} \cdot n^{1+1/k} + O(n).\end{aligned}$$

For n large enough, this implies

$$\tilde{T}_k(n) \le k \cdot \frac{k+1}{k+2} \cdot b_{k-1}^{(k-1)/k} \cdot n^{1+1/k} = d_k \cdot n^{1+1/k},$$

and this is what we wanted to show.

(b) By definition, $d_k/k = \left(\prod_{q=2}^{k}((q+1)/(q+2))^q\right)^{1/k}$. Recall that

$$\left(\frac{q+1}{q+2}\right)^{q+2} \le \frac{1}{e} \le \left(\frac{q+1}{q+2}\right)^{q+1}$$

for all q, and hence

$$\frac{d_k}{k} \cdot \left(\prod_{q=2}^{k}\left(\frac{q+1}{q+2}\right)^2\right)^{1/k} \le \left(\frac{1}{e}\right)^{(k-1)/k} \le \frac{d_k}{k} \cdot \left(\prod_{q=2}^{k}\left(\frac{q+1}{q+2}\right)\right)^{1/k}.$$

Clearly,

$$\lim_{k\to\infty}\left(\prod_{q=2}^{k}\frac{q+1}{q+2}\right)^{1/k} = \lim_{k\to\infty}\left(\frac{3}{k+1}\right)^{1/k} = 1,$$

and thus $\lim_{k\to\infty} d_k/k = 1/e$, as claimed. □

A. Appendix.

A.1. Proof of Lemma 5.6. We show the following: If the functions $T_k, k \geq 1$, satisfy slightly weaker inequalities than those stated in Lemma 5.5, namely, $T_k(0) = 0$ for all $k \geq 1$, and

(a) $T_1(n) \geq (n+1)(n+2)/2 - 1$ for all $n \geq 1$,

(b) $T_k(n) \geq \min\{\, 1 + \sum_{j=1}^{l}(ja_j + T_{k-1}(a_j - 1)) \mid l \geq 1, a_1, \ldots, a_l \in \mathbb{N}, \sum_{j=1}^{l} a_j = n\,\}$, for all $n \geq 1, k \geq 2$, then the functions T_k satisfy the assertion of Lemma 5.6, that is,

$$T_k(n) \geq g_k(n+1)$$

for all $k \geq 1, n \geq 0$, where, for $k \geq 1$,

$$g_k(y) = \begin{cases} 0 & \text{if } y = 0; \\ y \ln y & \text{if } 0 < y \leq e^k; \\ (k/e) \cdot y^{1+1/k} & \text{if } e^k < y. \end{cases}$$

We proceed by induction on k. For $k = 1$, it is easily checked that $g_1(n+1) \leq (n+1)(n+2)/2 - 1$ for all $n \geq 0$. Thus, let $k > 1$, and assume the claim to be true for $k-1$; that is, $T_{k-1}(n) \geq g_{k-1}(n+1) = g(n+1)$, for all $n \geq 0$. (From here on, we will write g for g_{k-1}.) For $n = 0$, the claim is trivially satisfied. Let $n \geq 1$ be fixed. By assumption (b) above and the induction hypothesis, we may fix some $l \geq 1$ and a sequence $a = (a_1, \ldots, a_l)$ of natural numbers with $\sum_{j=1}^{l} a_j = n$ and

$$T_k(n) - 1 \geq \sum_{j=1}^{l}(ja_j + T_{k-1}(a_j - 1)) \geq \sum_{j=1}^{l}(ja_j + g(a_j)). \tag{A.1}$$

We want to find a lower bound on the last sum in (A.1). The first step we take is to transform sums to integrals and sequences of natural numbers to real functions. The sequence a may be regarded as equivalent to the piecewise constant function $f_a \colon \mathbb{R}_0^+ \to \mathbb{R}_0^+$ defined by

$$f_a(x) = \begin{cases} a_j & \text{if } j - 1 \leq x < j,\ j = 1, \ldots, l; \\ 0 & \text{if } l \leq x < \infty. \end{cases}$$

The condition $\sum_{j=1}^{l} a_j = n$ translates to $\int_0^\infty f_a(x)\,dx = n$, and the sum in (A.1) can be expressed as

$$\sum_{j=1}^{l}(ja_j + g(a_j)) = \int_0^\infty \Big(xf_a(x) + g(f_a(x))\Big)\,dx + \frac{n}{2}. \tag{A.2}$$

Our aim is now to find a lower bound on the integral in (A.2). To this end, we transform the minimization problem a little further: instead of piecewise constant functions such as f_a we will consider continuous functions.

DEFINITION A.1. (a) *Let $\mathcal{D}$ be the class of all continuous functions $f \colon \mathbb{R}_0^+ \to \mathbb{R}^+$ (strictly positive) so that $\int_0^\infty f(x)\,dx = n$ and so that* $\lim_{x\to\infty} e^x f(x)$ *exists and is positive.*

(b) *Let $G \colon \mathbb{R}_0^+ \times \mathbb{R}_0^+ \to \mathbb{R}$ be defined by $G(x, y) = xy + g(y) = xy + g_{k-1}(y)$.*

(c) *For $f \in \mathcal{D}$ let $I(f) = \int_0^\infty G(x, f(x))\,dx$. (Note that the condition* $\lim_{x\to\infty} e^x f(x) > 0$ *ensures that the integral exists.)*

It is easy to see that for any given $\varepsilon > 0$ the piecewise constant function f_a can be approximated by some $f_{a,\varepsilon} \in \mathcal{D}$ in such a way that

$$I(f_{a,\varepsilon}) < \varepsilon + \int_0^\infty xf_a(x) + g(f_a(x))\,dx. \tag{A.3}$$

Now it follows from (A.1), (A.2), (A.3), and the fact that $f_{a,\varepsilon} \in \mathcal{D}$ for all $\varepsilon > 0$ that

$$T_k(n) - \left(\frac{n}{2} + 1\right) \geq \inf\{ I(f) \mid f \in \mathcal{D}\}. \tag{A.4}$$

The following proposition establishes the existence of a function $f_0 \in \mathcal{D}$ that realizes this infimum; moreover, it provides an equation for f_0 that will enable us to calculate f_0 explicitly. Then we may evaluate $I(f_0)$ to obtain the desired lower bound on $T_k(n)$. The proposition is proved by reducing the problem of minimizing $I(f)$ over $\mathcal{D}$ to a standard situation treated in the Calculus of Variations. (The details of this proof, which will be given in the second part of the appendix, are irrelevant for the rest of the argument.)

PROPOSITION A.2. *There is a unique function $f_0 \in \mathcal{D}$ such that*

$$I(f_0) = \min\{ I(f) \mid f \in \mathcal{D}\}. \tag{A.5}$$

Moreover, there is some constant $A \in \mathbb{R}$ such that f_0 satisfies

$$\left.\frac{\partial}{\partial y} G(x, y)\right|_{y=f_0(x)} = A \quad \textit{for all } x \in \mathbb{R}_0^+. \tag{A.6}$$

Our next goal is to use (A.6) in order to obtain an expression for f_0. First, we calculate A. By the definition of G, we have that $(\partial/\partial y)G(x, y) = x + g'(y)$, and hence (A.6) becomes

$$x + g'(f_0(x)) = A \quad \text{for } x \geq 0. \tag{A.7}$$

It follows easily from the definition of $g = g_{k-1}$ that

$$g'(y) = \begin{cases} 1 + \ln y & \text{if } 0 < y \leq e^{k-1}; \\ (k/e) \cdot y^{1/(k-1)} & \text{if } e^{k-1} \leq y < \infty. \end{cases}$$

Obviously, $g'(y)$ is a strictly increasing function of y with range $\mathbb{R}$, and the inverse of g' is given by

$$(g')^{-1}(z) = \begin{cases} e^{z-1} & \text{if } -\infty < z \leq k; \\ (ez/k)^{k-1} & \text{if } k \leq z < \infty. \end{cases} \tag{A.8}$$

Thus (A.7) can be transformed to

$$f_0(x) = (g')^{-1}(A - x) \quad \text{for } x \geq 0. \tag{A.9}$$

Since $f_0 \in \mathcal{D}$, we have (using the explicit formula (A.8) for $(g')^{-1}$):

$$n = \int_0^\infty (g')^{-1}(A - x)\, dx = \begin{cases} e^{A-1} & \text{if } A \leq k; \\ (e^{k-1}/k^k) \cdot A^k & \text{if } A \geq k. \end{cases} \tag{A.10}$$

We may now solve (A.10) for A to obtain

$$A = \begin{cases} 1 + \ln n & \text{if } n \leq e^{k-1}; \\ (n/e^{k-1})^{1/k} \cdot k & \text{if } n \geq e^{k-1}. \end{cases} \tag{A.11}$$

Now, finally, we are in a position to evaluate $I(f_0)$. First, we substitute (A.9) into the definition of $I(f_0)$ (see Definition A.1(b),(c)) to obtain

$$I(f_0) = \int_0^\infty x \cdot (g')^{-1}(A - x) + g((g')^{-1}(A - x))\, dx. \tag{A.12}$$

Case 1: $n \geq e^{k-1}$. Then $A - k \geq 0$, and we get from (A.12), by substituting (A.8) and the definition of $g = g_{k-1}$, that

$$I(f_0) = \int_0^{A-k} x \cdot (e(A-x)/k)^{k-1} + \frac{k-1}{e} \cdot (e(A-x)/k)^k \, dx$$

$$+ \int_{A-k}^{\infty} x \cdot e^{A-x-1} + e^{A-x-1} \cdot \ln(e^{A-x-1}) \, dx.$$

The second integral evaluates to $(A-1)e^{k-1}$; the first one equals

$$A \cdot \left(\frac{e}{k}\right)^{k-1} \cdot \int_0^{A-k} (A-x)^{k-1} \, dx - \frac{e^{k-1}}{k^k} \cdot \int_0^{A-k} (A-x)^k \, dx$$

$$= A \cdot e^{k-1} \cdot \frac{1}{k^k} \cdot (A^k - k^k) - \frac{e^{k-1}}{k^k} \cdot \frac{1}{k+1}(A^{k+1} - k^{k+1})$$

$$= A^{k+1} \cdot e^{k-1} \cdot \frac{1}{k^k} \cdot \frac{k}{k+1} - A \cdot e^{k-1} + e^{k-1} \cdot \frac{k}{k+1}.$$

Altogether,

$$I(f_0) = A^{k+1} e^{k-1} \cdot \frac{1}{k^k} \cdot \frac{k}{k+1} - \frac{1}{k+1} \cdot e^{k-1}.$$

Substituting the value $A = (n/e^{k-1})^{1/k} \cdot k$ given by (A.11) into the last equation and using the fact that $k/(k+1) \geq e^{-1/k}$ results in

$$I(f_0) = \frac{k}{k+1} \cdot e^{-1+1/k} \cdot k \cdot n^{1+1/k} - \frac{e^{k-1}}{k+1} \geq \frac{k}{e} \cdot n^{1+1/k} - \frac{e^{k-1}}{k+1}.$$

In combination with (A.4) and (A.5) this yields

$$T_k(n) \geq \frac{k}{e} \cdot n^{1+1/k} - \frac{e^{k-1}}{k+1} + \frac{n}{2} + 1. \tag{A.13}$$

Elementary estimates (which use the assumption that $n \geq e^{k-1}$) show that the right-hand side of (A.13) is bounded from below by $(n+1)\ln(n+1)$ if $n+1 \leq e^k$ and by $(k/e) \cdot (n+1)^{1+1/k}$ if $n+1 \geq e^k$. This proves the inequality $T_k(n) \geq g_k(n+1)$ in Case 1.

Case 2: $n \leq e^{k-1}$. Then $A - k \leq 0$, and we get from (A.12) and (A.8) that

$$I(f_0) = \int_0^{\infty} x \cdot e^{A-x-1} + e^{A-x-1} \cdot \ln(e^{A-x-1}) \, dx = (A-1) \cdot e^{A-1}.$$

We now substitute the value $A = 1 + \ln n$ from (A.11) to obtain that $I(f_0) = n \ln n$. In combination with (A.5) and (A.4) this entails that

$$T_k(n) \geq n \ln n + \frac{n}{2} + 1.$$

Elementary estimates show that the right-hand side of this inequality is bounded from below by $(n+1)\ln(n+1) = g_k(n+1)$. This finishes the proof of Lemma 5.6.

A.2. Proof of Proposition A.2. We sketch a proof of Proposition A.2 stated in the first part of this appendix. We reduce the proposition to a standard theorem from the Calculus of Variations. First, instead of dealing with conditions defined by the *integrals* of the functions in class $\mathcal{D}$ (see Definition A.1(a)) we need conditions on the *values* of the functions considered at the boundaries of the interval. For this, we consider the integral functions $x \mapsto \int_0^x f(\xi)\,d\xi$, for $f \in \mathcal{D}$, $x \in \mathbb{R}_0^+$. Second, we transform the unbounded interval $\mathbb{R}_0^+$ to the bounded interval $[0, 1]$ by means of the transformation $x = x(t) = -\ln(1-t)$, for $0 \le t < 1$, with inverse transformation $t = t(x) = 1 - e^{-x}$, for $0 \le x < \infty$.

DEFINITION A.3. (a) *Let $\mathcal{E}$ be the class of all functions $\varphi\colon [0,1] \to \mathbb{R}_0^+$ that have a continuous derivative $(d/dt)\varphi(t) = \varphi'(t) > 0$ in $[0,1]$ and satisfy $\varphi(0) = 0$ and $\varphi(1) = n$.*

(b) *Let $H\colon [0,1] \times \mathbb{R}_0^+ \to \mathbb{R}$ be defined by*

$$H(t,z) = \begin{cases} \frac{1}{1-t} \cdot G(-\ln(1-t), (1-t)z) & \text{if } z > 0 \text{ and } 0 \le t < 1, \\ z \ln z & \text{if } z > 0 \text{ and } t = 1, \end{cases}$$

where $G(x,y) = xy + g(y)$ is as in Definition A.1(b).

(c) *For $\varphi \in \mathcal{E}$ let $J(\varphi) = \int_0^1 H(t, \varphi'(t))\,dt$. (The following lemma implies that the integral is well defined.)*

LEMMA A.4. *The function H from the previous definition is continuous, and for each fixed $t \in [0,1]$ the function $z \mapsto (\partial^2/\partial z^2)H(t,z)$, $z \in \mathbb{R}$, is continuous and strictly positive, excepting for $t \neq 1$ and $y = e^{k-1}/(1-t)$.*

Proof. Straightforward verification. □

LEMMA A.5. *There is a bijection between $\mathcal{D}$ and $\mathcal{E}$ given by the mappings $f \mapsto \varphi_f$ and $\varphi \mapsto f_\varphi$, where*

$$\varphi_f(t) = \begin{cases} \displaystyle\int_0^{-\ln(1-t)} f(\xi)\,d\xi & \text{if } 0 \le t < 1, \\ n & \text{if } t = 1, \end{cases}$$

and

$$f_\varphi(x) = \tfrac{d}{dx}\varphi(1 - e^{-x}) = \varphi'(1 - e^{-x}) \cdot e^{-x} \quad \text{if } \; 0 \le x \le \infty.$$

Moreover, we have $I(f) = J(\varphi_f)$, for all $f \in \mathcal{D}$.

Proof. Straightforward verification. □

We now need the following theorem, which is obtained by combining Proposition (3.10) and Theorem (3.7) from [18].

THEOREM A.6. *If $H = H(t,z)$ is continuous on $[0,1] \times \mathbb{R}_0^+$ and if, for each $t \in [0,1]$, the function $z \mapsto (\partial^2/\partial z^2)H(t,z)$ is continuous and positive (except possibly at a finite set of z-values), then there is exactly one function $\varphi_0 \in \mathcal{E}$ that minimizes $\int_0^1 H(t, \varphi'(t))\,dt$ on $\mathcal{E}$. Moreover, this function φ_0 satisfies $(\partial/\partial z)H(t,z)|_{z=\varphi_0'(t)} = \text{const}$, for $t \in [0,1]$.*

By Lemma A.4, the function H from Definition A.3 satisfies the hypothesis of this theorem, and hence there is a unique function $\varphi_0 \in \mathcal{E}$ that minimizes $J(\varphi)$ over $\mathcal{E}$; moreover, there is some $A \in \mathbb{R}$ with $(\partial/\partial z)H(t,z)|_{z=\varphi_0'(t)} = A$ for all $t \in [0,1]$. By Lemma A.5, the function $f_0 = f_{\varphi_0}$ minimizes $I(f)$ over $\mathcal{D}$. It remains to establish equation (A.6).

By Definition A.3(b) we have $(\partial/\partial z)H(t,z) = (\partial/\partial y)G(-\ln(1-t), y)|_{y=(1-t)z}$, and hence

$$\text{(A.14)} \qquad A = \frac{\partial}{\partial z}H(t,z)\bigg|_{z=\varphi_0'(t)} = \frac{\partial}{\partial y}G(-\ln(1-t), y)\bigg|_{y=(1-t)\varphi_0'(t)} \qquad \text{for } 0 \le t \le 1.$$

By Lemma A.5, we have $f_0(x) = (d/dx)\varphi_0(1 - e^{-x}) = \varphi_0'(1 - e^{-x}) \cdot e^{-x} = \varphi_0'(t) \cdot (1 - t)$, under the bijection $t \mapsto x(t) = -\ln(1 - t)$. Hence, equation (A.14) entails that $(\partial/\partial y)G(x, y)|_{y=f_0(x)} = A$ for all $x \in \mathbb{R}_0^+$, as claimed. This finishes the proof of Proposition A.2.

MEASURE, STOCHASTICITY, AND THE DENSITY OF HARD LANGUAGES*

JACK H. LUTZ[†] AND ELVIRA MAYORDOMO[‡]

Abstract. The main theorem of this paper is that, for every real number $\alpha < 1$ (e.g., $\alpha = 0.99$), only a measure 0 subset of the languages decidable in exponential time are $\leq^{\mathrm{P}}_{n^\alpha-tt}$-reducible to languages that are not exponentially dense. *Thus every* $\leq^{\mathrm{P}}_{n^\alpha-tt}$*-hard language for* E *is exponentially dense.* This strengthens Watanabe's 1987 result, that every $\leq^{\mathrm{P}}_{O(\log n)-tt}$-hard language for E is exponentially dense. The combinatorial technique used here, the *sequentially most frequent query selection*, also gives a new, simpler proof of Watanabe's result.

The main theorem also has implications for the structure of NP under strong hypotheses. Ogiwara and Watanabe (1991) have shown that the hypothesis $\mathrm{P} \neq \mathrm{NP}$ implies that every $\leq^{\mathrm{P}}_{btt}$-hard language for NP is nonsparse (i.e., not polynomially sparse). Their technique does not appear to allow significant relaxation of either the query bound or the sparseness criterion. It is shown here that a stronger hypothesis—namely, that NP does not have measure 0 in exponential time—implies the stronger conclusion that, for every real $\alpha < 1$, every $\leq^{\mathrm{P}}_{n^\alpha-tt}$-hard language for NP is exponentially dense. Evidence is presented that this stronger hypothesis is reasonable.

The proof of the main theorem uses a new, very general *weak stochasticity theorem*, ensuring that almost every language in E is statistically unpredictable by feasible deterministic algorithms, even with linear nonuniform advice.

Key words. complexity classes, computational complexity, dense languages, polynomial reductions, resource-bounded measure, sparse languages, weak stochasticity

AMS subject classification. 68Q15

1. Introduction.

How dense must a language $A \subseteq \{0, 1\}^*$ be in order to be hard for a complexity class $\mathcal{C}$? The ongoing investigation of this question, especially important when $\mathcal{C} = \mathrm{NP}$, has yielded several significant results [3], [12], [20], [22], [23], [30], [31] over the past fifteen years.

Any formalization of this question must specify the class $\mathcal{C}$ and give precise meanings to "hard" and "how dense." The results of this paper concern the classes $\mathrm{E} = \mathrm{DTIME}(2^{\mathrm{linear}})$, $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{polynomial}})$, and all subclasses $\mathcal{C}$ of these classes, though we are particularly interested in the case $\mathcal{C} = \mathrm{NP}$.

We will consider the polynomial-time reducibilities $\leq^{\mathrm{P}}_m$ (*many-one* reducibility), $\leq^{\mathrm{P}}_{\mathrm{T}}$ (*Turing* reducibility), $\leq^{\mathrm{P}}_{btt}$ (*bounded truth-table* reducibility), and $\leq^{\mathrm{P}}_{q(n)-tt}$ (truth-table reducibility with $q(n)$ queries on inputs of length n, where $q : \mathbf{N} \to \mathbf{Z}^+$). If $\leq^{\mathrm{P}}_r$ is any of these reducibilities, we say that a language A is $\leq^{\mathrm{P}}_r$*-hard* for a class $\mathcal{C}$ of languages if $\mathcal{C} \subseteq \mathrm{P}_r(A)$, where $\mathrm{P}_r(A) = \{\, B \subseteq \{0, 1\}^* \mid B \leq^{\mathrm{P}}_r A\}$.

Two criteria for "how dense" a language A is have been widely used. A language A is (*polynomially*) *sparse*, and we write $A \in \mathrm{SPARSE}$, if there is a polynomial p such that $|A_{\leq n}| \leq p(n)$ for all $n \in \mathbf{N}$, where $A_{\leq n} = A \cap \{0, 1\}^{\leq n}$. A language A is (*exponentially*) *dense*, and we write $A \in \mathrm{DENSE}$, if there is a real number $\epsilon > 0$ such that $|A_{\leq n}| \geq 2^{n^\epsilon}$ for all sufficiently large $n \in \mathbf{N}$. It is clear that no sparse language is dense.

For any of the above choices of the reducibility $\leq^{\mathrm{P}}_r$, *all known* $\leq^{\mathrm{P}}_r$*-hard languages for* NP *are dense*. Efforts to explain this observation (and similar observations for other classes and reducibilities) have yielded many results. (See [9] for a thorough survey.) We mention four such results that are particularly relevant to the work presented here.

*Received by the editors September 24, 1992; accepted for publication (in revised form) April 23, 1993.

Let DENSE^c denote the complement of DENSE, i.e., the set of all languages A such that, for all $\epsilon > 0$, there exist infinitely many n such that $|A_{\leq n}| < 2^{n^\epsilon}$. For each reducibility $\leq_r^{\mathrm{P}}$ and set $\mathcal{S}$ of languages, we write

$$\mathrm{P}_r(\mathcal{S}) = \bigcup_{A \in \mathcal{S}} \mathrm{P}_r(A).$$

The first result on the density of hard languages was the following.

THEOREM 1 (Meyer [22]). *Every $\leq_m^{\mathrm{P}}$-hard language for* E (*or any larger class*) *is dense. That is,*

$$\mathrm{E} \not\subseteq \mathrm{P}_m(\mathrm{DENSE}^c).$$

Theorem 1 was subsequently improved to truth-table reducibility with $O(\log n)$ queries in the next theorem.

THEOREM 2 (Watanabe [31], [30]). *Every $\leq_{O(\log n)-tt}^{\mathrm{P}}$-hard language for* E *is dense. That is,*

$$\mathrm{E} \not\subseteq \mathrm{P}_{O(\log n)-tt}(\mathrm{DENSE}^c).$$

Regarding NP, Berman and Hartmanis [3] conjectured that no sparse language is $\leq_m^{\mathrm{P}}$-hard for NP, unless P = NP. This conjecture was subsequently proven correct as seen in the following.

THEOREM 3 (Mahaney [20]). *If* P $\neq$ NP, *then no sparse language is $\leq_m^{\mathrm{P}}$-hard for* NP. *That is,*

$$\mathrm{P} \neq \mathrm{NP} \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_m(\mathrm{SPARSE}).$$

Theorem 3 has recently been extended to truth-table reducibility with a bounded number of queries.

THEOREM 4 (Ogiwara and Watanabe [23]). *If* P $\neq$ NP, *then no sparse language is $\leq_{btt}^{\mathrm{P}}$-hard for* NP. *That is,*

$$\mathrm{P} \neq \mathrm{NP} \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{btt}(\mathrm{SPARSE}).$$

The Main Theorem of this paper, Theorem 14, extends Theorems 1 and 2 by showing that, for every real $\alpha < 1$ (e.g., $\alpha = 0.99$), only a measure 0 subset of the languages in E are $\leq_{n^\alpha-tt}^{\mathrm{P}}$-reducible to nondense languages. "Measure 0 subset" here refers to the resource-bounded measure theory of Lutz [18], [15] (also explained in §3 below). In the notation of this theory, our Main Theorem says that, for every real $\alpha < 1$,

$$\mu(\mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^c) \mid \mathrm{E}) = 0. \tag{1.1}$$

This means that $\mathrm{P}_{n^\alpha-\mathrm{tt}}(\mathrm{DENSE}^c) \cap \mathrm{E}$ is a *negligibly small* subset of E [18], [15].

In particular, our Main Theorem implies that

$$\mathrm{E} \not\subseteq \mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^c), \tag{1.2}$$

i.e., every $\leq_{n^\alpha-tt}^{\mathrm{P}}$-hard language for E is dense. This strengthens Theorem 2 by extending the truth-table reducibility from $O(\log n)$ queries to n^α queries ($\alpha < 1$). It is also worth noting that the combinatorial technique used to prove (1.1) and (1.2)—the *sequentially most frequent query selection*—is simpler than Watanabe's direct proof of Theorem 2. This is not surprising, once one considers that our proof of (1.2) via (1.1) is a resource-bounded instance of the *probabilistic method* [5], [25], [26], [6], [27], [1], which exploits the fact that it is often easier to prove the *abundance* of objects of a given type than to construct a *specific* object of that type.

Our proof of (1.1) also shows that, for every real $\alpha < 1$,

$$\mu(\mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^c) \mid \mathrm{E}_2) = 0. \tag{1.3}$$

Much of our interest in the Main Theorem concerns the class NP and Theorems 3 and 4. As already noted, for all reducibilities $\leq_r^{\mathrm{P}}$ discussed in this paper, all known $\leq_r^{\mathrm{P}}$-hard languages for NP are dense. One is thus led to ask whether there is a reasonable hypothesis θ such that we can prove results of the form

$$\theta \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_r(\mathrm{DENSE}^c), \tag{1.4}$$

for various choices of the reducibility $\leq_r^{\mathrm{P}}$. (Such a result is much stronger than the corresponding result

$$\theta \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_r(\mathrm{SPARSE}),$$

because there is an enormous gap between polynomial and 2^{n^ϵ} growth rates.)

Ogiwara and Watanabe's proof of Theorem 4 does not appear to allow significant relaxation of either the query bound or the sparseness criterion. In fact, it appears to be beyond current understanding to prove results of the form (1.4) if θ is "P $\neq$ NP." Karp and Lipton [12] have proven that

$$\Sigma_2^p \neq \Pi_2^p \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_T(\mathrm{SPARSE}).$$

That is, the stronger hypothesis $\Sigma_2^p \neq \Pi_2^p$ gives a stronger conclusion than those of Theorems 3 and 4. However, Karp and Lipton's proof does not appear to allow relaxation of the sparseness criterion, and results of the form (1.4) do not appear to be achievable at this time if θ is taken to be "$\Sigma_2^p \neq \Pi_2^p$."

To make progress on matters of this type, Lutz has proposed investigation of the measure-theoretic hypotheses $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$. These expressions say that NP does not have measure 0 in E_2 ("NP is not a negligible subset of E_2") and that NP does not have measure 0 in E ("NP $\cap$ E is not a negligible subset of E"), respectively. We now explain the meaning of these hypotheses. Both are best understood in terms of their negations.

The condition $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$ means that there exist a *fixed* polynomial q, a *fixed* positive quantity c_0 of capital (money), and a *fixed* betting strategy (algorithm) σ with the following properties. Given any language A, the strategy σ *bets* on the membership or nonmembership of the successive strings $\lambda, 0, 1, 00, 01, 10, \ldots$ in A. Before the betting begins, σ has capital (money) c_0. When betting on a string $w \in \{0,1\}^*$, the strategy σ is given as input the string consisting of the successive bits $[\![v \in A]\!]$ for all strings v that precede w in the standard ordering of $\{0,1\}^*$. On this input, the strategy σ computes, in $\leq 2^{q(|w|)}$ steps, a fraction $r \in [-1, 1]$ of its current capital to bet that $w \in A$. If σ's capital prior to this bet is c, then σ's capital after the bet is $c(1+r)$ if $w \in A$ and $c(1-r)$ if $w \notin A$. (That is, the betting is fair.) Finally, the strategy σ is *successful*, in the sense that, for all $A \in \mathrm{NP}$, σ's capital diverges to $+\infty$ as the betting progresses through the successive strings $w \in \{0,1\}^*$.

Thus, *the condition* $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$ *asserts the existence of a fixed* $2^{q(n)}$*-time-bounded algorithm* for betting successfully on membership of strings in all languages in NP. If NP $\subseteq$

DTIME($2^{r(n)}$) for some fixed polynomial r, it is easy to devise such a strategy, so $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$. (In fact, $\mu(\mathrm{DTIME}(2^{r(n)}) \mid \mathrm{E}_2) = 0$ [18].) Conversely, if $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$, then NP is "nearly contained in some fixed DTIME($2^{q(n)}$)," in the sense that there is a fixed $2^{q(n)}$-time-bounded algorithm σ for successfully betting on all languages in NP.

There does not appear to be any a priori reason for believing that such a strategy σ exists, i.e., there does not appear to be any a priori reason for believing that $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$. Similarly, there does not appear to be any a priori reason for believing that $\mu(\mathrm{NP} \mid \mathrm{E}) = 0$. The hypotheses $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$ are thus *reasonable relative to our current knowledge.* (The hypothesis that the polynomial-time hierarchy separates into infinitely many levels enjoys a similar status. It *may* be false, but if it *is* false, then a very remarkable algorithm exists.) Lutz has conjectured that the conditions $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$ may be true.

It should be noted here that the conditions $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$ are merely the negations of $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) = 0$, respectively. For example, a resource-bounded extension of the classical Kolmogorov zero-one law [15] implies that exactly one of the following three conditions must hold:

(i) $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$.

(ii) $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 1$, i.e., $\mu(\mathrm{NP}^c \mid \mathrm{E}_2) = 0$.

(iii) NP is not measurable in E_2, i.e., the expression $\mu(\mathrm{NP} \mid \mathrm{E}_2)$ has no value.

The condition $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ thus means that (ii) or (iii) is true. It does not mean that $\mu(\mathrm{NP} \mid E_2)$ has some positive value. The analogous remark applies to the condition $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$.

At this time, we are unable to prove or disprove the widely believed conjectures $\mathrm{P} \neq \mathrm{NP}$, $\mathrm{NP} \neq \mathrm{E}_2$, and $\mathrm{E} \not\subseteq \mathrm{NP}$. This, together with the known implications [18]

$$\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0 \Longrightarrow \mathrm{P} \neq \mathrm{NP},$$

$$\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0 \Longrightarrow \mathrm{P} \neq \mathrm{NP},$$

$$\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0 \Longrightarrow \mathrm{NP} \neq \mathrm{E}_2,$$

$$\mu(\mathrm{NP} \mid \mathrm{E}) = 0 \Longrightarrow \mathrm{E} \not\subseteq \mathrm{NP},$$

means that we are currently unable to prove or disprove the statements $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$.

Thus, at present, we are interested in the conditions $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$, not as conjectures, but rather as *scientific hypotheses*, which may have more *explanatory power* than traditional complexity-theoretic hypotheses such as $\mathrm{P} \neq \mathrm{NP}$ or the separation of the polynomial-time hierarchy. Until such time as mathematical proof or refutation is available, the reasonableness (or unreasonableness) of such hypotheses can be illuminated only by investigation of their *consequences*. Such investigation may indicate, for example, that the consequences of $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ form, en masse, a credible state of affairs, thereby increasing the reasonableness of this hypothesis. On the other hand, such investigation may uncover implausible consequences of $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$, or even a proof that $\mu(\mathrm{NP} \mid \mathrm{E}_2) = 0$. Either outcome would contribute to our understanding of NP.

Our Main Theorem implies that, for all $\alpha < 1$,

$$\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0 \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^c) \tag{1.5}$$

and

$$\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0 \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^c). \tag{1.6}$$

(This is Theorem 16.) That is, each of the hypotheses $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$ implies that every $\leq^{\mathrm{P}}_{n^\alpha-tt}$-hard language for NP is dense. This conclusion, which is credible and consistent with all observations to date, is not known to follow from $\mathrm{P} \neq \mathrm{NP}$ or other traditional complexity-theoretic hypotheses.

Recent investigation has also shown that the hypotheses $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$ and $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$ imply that NP contains P-bi-immune languages [21] and that every $\leq^{\mathrm{P}}_{m}$-hard language for NP has an exponentially dense, exponentially hard complexity core [10]. Taken together, such results appear to indicate that these are reasonable hypotheses that may have considerable explanatory power.

The proof of our Main Theorem is based on a very general result, the Weak Stochasticity Theorem proven in §3. In very brief terms, this result says that almost every language in E, and almost every language in E_2, is "weakly stochastic," in the sense that it is statistically unpredictable by feasible deterministic algorithms, even with linear nonuniform advice. (See §3 for precise definitions.) This result enables us to prove our Main Theorem, that

$$\mu(\mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^{\mathrm{c}}) \mid \mathrm{E}) = \mu(\mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^{\mathrm{c}}) \mid \mathrm{E}_2) = 0$$

for all $\alpha < 1$, by a simple combinatorial technique, without reference to measure-theoretic notions. Specifically, in §4, this combinatorial technique—the *sequentially most frequent query selection*—is introduced and used to prove that *no* language in $\mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^{\mathrm{c}})$ is weakly stochastic. The Main Theorem follows immediately from this by the Weak Stochasticity Theorem.

This use of weak stochasticity in E and E_2 is analogous to earlier uses of space-bounded Kolmogorov complexity in the complexity class ESPACE $= \mathrm{DSPACE}(2^{\mathrm{linear}})$. It is known [18], [11] that almost every language in ESPACE has very high space-bounded Kolmogorov complexity. Using this fact, a variety of sets X have been shown to have measure 0 in ESPACE, simply by proving that every element of X has low space-bounded Kolmogorov complexity [18], [17], [19], [11]. Informally, we say that high space-bounded Kolmogorov complexity is a "general-purpose randomness property of languages in ESPACE." This expression, which is heuristic, means the following two things.

(a) Almost every language in ESPACE has the property (high space-bounded Kolmogorov complexity).

(b) It is often the case that, when one wants to prove a result of the form $\mu(X \mid \mathrm{ESPACE}) = 0$, it is convenient to prove that no language in X has the property and then appeal to (a).

It is natural to hope that high time-bounded Kolmogorov complexity would be, in the analogous sense, a general-purpose randomness property of language in E and E_2. Unfortunately, however, the strongest known lower bounds on time-bounded Kolmogorov complexity in these classes [18] are far too weak to provide a useful time-bounded analogue of condition (a) above. Moreover, improving these bounds appears to require a major breakthrough in complexity theory.

Our results suggest that, even without such a breakthrough, weak stochasticity may be a "general-purpose randomness property of languages in E and E_2." This would entail the following two heuristic conditions.

(a′) Almost every language in E (respectively, in E_2) is weakly stochastic.

(b′) It is often the case that, when one wants to prove a result of the form $\mu(X \mid \mathrm{E}) = 0$ (respectively, $\mu(X \mid \mathrm{E}_2) = 0$), it is convenient to prove that no language in X is weakly stochastic and then appeal to (a′).

The Weak Stochasticity Theorem gives us condition (a′) immediately. The proof of our Main Theorem gives us the *instance* $X = \mathrm{P}_{n^\alpha-tt}(\mathrm{DENSE}^{\mathrm{c}})$ of condition (b′). It appears likely that more such instances will arise, i.e., that weak stochasticity is a general-purpose randomness property of languages in E and E_2 that will be useful in future investigations.

2. Preliminaries. In this paper, $[\![\psi]\!]$ denotes the *Boolean value* of the condition ψ, i.e.,

$$[\![\psi]\!] = \begin{cases} 1 & \text{if } \psi, \\ 0 & \text{if not } \psi. \end{cases}$$

All *languages* here are sets of binary strings, i.e., sets $A \subseteq \{0,1\}^*$. We identify each language A with its *characteristic sequence* $\chi_A \in \{0,1\}^\infty$ defined by

$$\chi_A = [\![s_0 \in A]\!][\![s_1 \in A]\!][\![s_2 \in A]\!]\ldots,$$

where $s_0 = \lambda$, $s_1 = 0$, $s_2 = 1$, $s_3 = 00, \ldots$ is the standard enumeration of $\{0,1\}^*$. Relying on this identification, the set $\{0,1\}^\infty$, consisting of all infinite binary sequences, will be regarded as the set of all languages.

For $w \in \{0,1\}^*$ and $x \in \{0,1\}^* \cup \{0,1\}^\infty$, we say that w is a *prefix* of x and write $w \sqsubseteq x$, if $x = wy$ for some $y \in \{0,1\}^* \cup \{0,1\}^\infty$. The *cylinder generated by* a string $w \in \{0,1\}^*$ is

$$\mathbf{C}_w = \{x \in \{0,1\}^\infty \mid w \sqsubseteq x\}.$$

Note that $\mathbf{C}_w$ is a set of languages. Note also that $\mathbf{C}_\lambda = \{0,1\}^\infty$, where λ denotes the empty string.

As noted in §1, we work with the exponential time complexity classes E = DTIME(2^{linear}) and E_2 = DTIME($2^{\text{polynomial}}$). It is well known that $P \subsetneqq E \subsetneqq E_2$, that $P \subseteq NP \subseteq E_2$, and that $NP \neq E$.

We let $\mathbf{D} = \{m2^{-n} \mid m \in \mathbf{Z}, n \in \mathbf{N}\}$ be the set of *dyadic rationals*. (These are rational numbers whose standard binary representations have finite length.) We also fix a one-to-one pairing function $\langle\, , \rangle$ from $\{0,1\}^* \times \{0,1\}^*$ onto $\{0,1\}^*$ such that the pairing function and its associated projections, $\langle x, y\rangle \mapsto x$ and $\langle x, y\rangle \mapsto y$, are computable in polynomial time.

Several functions in this paper are of the form $d : \mathbf{N}^k \times \{0,1\}^* \to Y$, where Y is $\mathbf{D}$ or $[0, \infty)$, the set of nonnegative real numbers. Formally, in order to have uniform criteria for their computational complexities, we regard all such functions as having domain $\{0,1\}^*$ and having codomain $\{0,1\}^*$ if $Y = \mathbf{D}$. For example, a function $d : \mathbf{N}^2 \times \{0,1\}^* \to \mathbf{D}$ is formally interpreted as a function $\tilde{d} : \{0,1\}^* \to \{0,1\}^*$. Under this interpretation, $d(i, j, w) = r$ means that $\tilde{d}(\langle 0^i, \langle 0^j, w\rangle\rangle) = u$, where u is a suitable binary encoding of the dyadic rational r.

For a function $d : \mathbf{N} \times X \to Y$ and $k \in \mathbf{N}$, we define the function $d_k : X \to Y$ by $d_k(x) = d(k, x) = d(\langle 0^k, x\rangle)$. We then regard d as a "uniform enumeration" of the functions $d_0, d_1, d_2, \ldots$. For a function $d : \mathbf{N}^n \times X \to Y$ ($n \geq 2$), we write $d_{k,l} = (d_k)_l$, and so on.

For a function $\delta : \{0,1\}^* \to \{0,1\}^*$ and $n \in \mathbf{N}$, we write δ^n for the n-fold composition of δ with itself.

Our proof of the Weak Stochasticity Theorem uses the following form of the Chernoff bound.

LEMMA 5 [4], [8]. *If $X_1, \ldots, X_N$ are independent 0-1-valued random variables with the uniform distribution, $S = X_1 + \cdots + X_N$, and $\epsilon > 0$, then*

$$\Pr\left[\left|S - \frac{N}{2}\right| \geq \frac{\epsilon N}{2}\right] \leq 2e^{-\epsilon^2 N/6}.$$

In particular, taking $\epsilon = 2/(j+1)$, where $j \in \mathbf{N}$,

$$\Pr\left[\left|S - \frac{N}{2}\right| \geq \frac{N}{j+1}\right] \leq 2e^{-N/2(j+1)^2}.$$

Proof. See [8]. □

3. Measure and weak stochasticity. In this section, after reviewing some fundamentals of measure in exponential-time complexity classes, we prove the Weak Stochasticity Theorem. This theorem will be useful in the proof of our main result in §4. We also expect it to be useful in future investigations of the measure structure of E and E_2.

Resource-bounded measure [18], [15] is a very general theory whose special cases include classical Lebesgue measure, the measure structure of the class REC of all recursive languages, and measure in various complexity classes. In this paper we are interested only in measure in E and E_2, so our discussion of measure is specific to these classes. The interested reader may consult §3 of [18] for more discussion and examples.

Throughout this section, we identify every language $A \subseteq \{0, 1\}^*$ with its characteristic sequence $\chi_A \in \{0, 1\}^\infty$, defined as in §2.

A *constructor* is a function $\delta : \{0, 1\}^* \to \{0, 1\}^*$ such that $x \underset{\neq}{\sqsubseteq} \delta(x)$ for all $x \in \{0, 1\}^*$. The *result* of a constructor δ (i.e., the *language constructed by* δ) is the unique language $R(\delta)$ such that $\delta^n(\lambda) \sqsubseteq R(\delta)$ for all $n \in \mathbf{N}$. (Recall that this means that each string $\delta^n(\lambda)$ is a prefix of the characteristic sequence of $R(\delta)$.) Intuitively, δ constructs $R(\delta)$ by starting with λ and then iteratively generating successively longer prefixes of $R(\delta)$. Given a set Δ of functions from $\{0, 1\}^*$ into $\{0, 1\}^*$, we write $R(\Delta)$ for the set of all languages $R(\delta)$ such that $\delta \in \Delta$ and δ is a constructor.

We first note that the exponential-time complexity classes E and E_2 can be characterized in terms of constructors.

Notation. The classes $p_1 = p$ and p_2, both consisting of functions $f : \{0, 1\}^* \to \{0, 1\}^*$, are defined as follows.

$$p_1 = p = \{f \mid f \text{ is computable in polynomial time}\},$$

$$p_2 = \{f \mid f \text{ is computable in } n^{(\log n)^{O(1)}} \text{ time}\}.$$

LEMMA 6 [16]. (1) $R(p) = E$. (2) $R(p_2) = E_2$.

Using Lemma 6, the measure structures of E and E_2 are now developed in terms of the classes p_i, for $i = 1, 2$.

DEFINITION. *A* density function *is a function $d : \{0, 1\}^* \to [0, \infty)$ satisfying*

$$d(w) \geq \frac{d(w0) + d(w1)}{2} \tag{3.1}$$

for all $w \in \{0, 1\}^*$. The global value *of a density function d is $d(\lambda)$. The* set covered by *a density function d is*

$$S[d] = \bigcup_{\substack{w \in \{0,1\}^* \\ d(w) \geq 1}} \mathbf{C}_w. \tag{3.2}$$

(*Recall that $\mathbf{C}_w = \{x \in \{0, 1\}^\infty \mid w \sqsubseteq x\}$ is the cylinder generated by w.*) *A density function d* covers *a set $X \subseteq \{0, 1\}^\infty$ if $X \subseteq S[d]$.*

Consider the random experiment in which a sequence $x \in \{0, 1\}^\infty$ is chosen by using an independent toss of a fair coin to decide each bit of x. Taken together, parts (3.1) and (3.2) of the above definition imply that $\Pr[x \in S[d]] \leq d(\lambda)$ in this experiment. Intuitively, given a set $X \subseteq S[d]$, a density function d simply "asserts" that $d(\lambda)$ is an upper bound for $\Pr[x \in X]$ and then "verifies" this assertion by providing additional details in the form of values $d(w)$ satisfying conditions (3.1) and (3.2).

More generally, we will be interested in "uniform systems" of density functions that are computable within some resource bound.

DEFINITION. *An n-dimensional* density system *(n-DS) is a function*

$$d : \mathbf{N}^n \times \{0, 1\}^* \to [0, \infty)$$

such that $d_{\vec{k}}$ is a density function for every $\vec{k} \in \mathbf{N}^n$. It is sometimes convenient to regard a density function as a 0-DS.

DEFINITION. *A* computation *of an n-DS d is a function $\widehat{d} : \mathbf{N}^{n+1} \times \{0, 1\}^* \to \mathbf{D}$ such that*

$$\left|\widehat{d}_{\vec{k},r}(w) - d_{\vec{k}}(w)\right| \leq 2^{-r}$$

for all $\vec{k} \in \mathbf{N}^n$, $r \in \mathbf{N}$, and $w \in \{0, 1\}^*$. For $i = 1, 2$, a p_i-computation *of an n-DS d is a computation $\widehat{d}$ of d such that $\widehat{d} \in \mathrm{p}_i$. An n-DS d is* p_i-computable *if there exists a p_i-computation $\widehat{d}$ of d.*

If d is an n-DS such that $d : \mathbf{N}^n \times \{0, 1\}^* \to \mathbf{D}$ and $d \in \mathrm{p}_i$, then d is trivially p_i-computable. This fortunate circumstance, in which there is no need to compute approximations, occurs frequently in practice. (Such applications typically do involve approximations, but these are "hidden" by invoking fundamental theorems whose proofs involve approximations.)

We now come to the key idea of resource-bounded measure theory.

DEFINITION. *A* null cover *of a set $X \subseteq \{0, 1\}^\infty$ is a 1-DS d such that, for all $k \in \mathbf{N}$, d_k covers X with global value $d_k(\lambda) \leq 2^{-k}$. For $i = 1, 2$, a* p_i-null cover *of X is a null cover of X that is p_i-computable.*

In other words, a null cover of X is a uniform system of density functions that cover X with rapidly vanishing global value. It is easy to show [15] that a set $X \subseteq \{0, 1\}^\infty$ has classical Lebesgue measure 0 (i.e., probability 0 in the above coin-tossing experiment) if and only if there exists a null cover of X.

DEFINITION. *A set X has* p_i-measure 0, *and we write $\mu_{\mathrm{p}_i}(X) = 0$, if there exists a p_i-null cover of X. A set X has* p_i-measure 1, *and we write $\mu_{\mathrm{p}_i}(X) = 1$, if $\mu_{\mathrm{p}_i}(X^c) = 0$.*

Thus a set X has p_i-measure 0 if p_i provides sufficient computational resources to compute uniformly good approximations to a system of density functions that cover X with rapidly vanishing global value.

We now turn to the internal measure structures of $\mathrm{E} = R(\mathrm{p})$ and $\mathrm{E}_2 = R(\mathrm{p}_2)$.

DEFINITION. *A set X has* measure 0 in $R(\mathrm{p}_i)$, *and we write $\mu(X \mid R(\mathrm{p}_i)) = 0$, if $\mu_{\mathrm{p}_i}(X \cap R(\mathrm{p}_i)) = 0$. A set X has* measure 1 in $R(\mathrm{p}_i)$, *and we write $\mu(X \mid R(\mathrm{p}_i)) = 1$, if $\mu(X^c \mid R(\mathrm{p}_i)) = 0$. If $\mu(X \mid R(\mathrm{p}_i)) = 1$, we say that* almost every *language in $R(\mathrm{p}_i)$ is in X.*

The following lemma is obvious but useful.

LEMMA 7. *For every set $X \subseteq \{0, 1\}^\infty$,*

$$\begin{tikzcd}
\mu_p(X) = 0 \arrow[r, Rightarrow] \arrow[d, Rightarrow] & \mu_{p_2}(X) = 0 \arrow[r, Rightarrow] \arrow[d, Rightarrow] & \Pr[x \in X] = 0 \\
\mu(X|\mathrm{E}) = 0 & \mu(X|\mathrm{E}_2) = 0,
\end{tikzcd}$$

where the probability $\Pr[x \in X]$ is computed according to the random experiment in which a sequence $x \in \{0, 1\}^\infty$ is chosen probabilistically, using an independent toss of a fair coin to decide each bit of x.

Thus a proof that a set X has p-measure 0 gives information about the size of X in E, in E_2, and in $\{0, 1\}^\infty$.

It was noted in Lemma 7 that $\mu_{\mathrm{p}}(X) = 0$ implies $\mu_{\mathrm{p}_2}(X) = 0$. In fact, more is true.

LEMMA 8 [14]. *Let Z be the union of all sets X such that $\mu_p(X) = 0$. Then $\mu_{p_2}(Z) = \mu(Z \mid \mathrm{E}_2) = 0$.*

Lemma 8 is also called the Abundance Theorem, because it implies that almost every language $A \in \mathrm{E}_2$ is p-*random*, i.e., has the property that the singleton set $\{A\}$ does *not* have p-measure 0. The proof of Lemma 8 makes essential use of the fact that p_2 contains a universal function for p. It is *not* the case that $\mu_{\mathrm{p}}(Z) = 0$.

It is shown in [18] that these definitions endow E and E_2 with internal measure structure. Specifically, for $i = 1, 2$, if $\mathcal{I}$ is either the collection $\mathcal{I}_{\mathrm{p}_i}$ of all p_i-measure 0 sets or the collection $\mathcal{I}_{R(\mathrm{p}_i)}$ of all sets of measure 0 in $R(\mathrm{p}_i)$, then $\mathcal{I}$ is a "p_i-ideal," i.e., is closed under subsets, finite unions, and "p_i-unions" (countable unions that can be generated with the resources of p_i). More importantly, the Measure Conservation Theorem of [18] says that the ideal $\mathcal{I}_{R(\mathrm{p}_i)}$ is a *proper* ideal, i.e., that E does *not* have measure 0 in E and E_2 does *not* have measure 0 in E_2. Taken together, these facts justify the intuition that, if $\mu(X|\mathrm{E}) = 0$, then $X \cap \mathrm{E}$ is a *negligibly small* subset of E (and similarly for E_2).

Our proof of the Weak Stochasticity Theorem does not directly use the above definitions. Instead we use a sufficient condition, proved in [18], for a set to have measure 0. To state this condition we need a polynomial notion of convergence for infinite series. All our series here consist of nonnegative terms. A *modulus* for a series $\sum_{n=0}^{\infty} a_n$ is a function $m : \mathbf{N} \to \mathbf{N}$ such that

$$\sum_{n=m(j)}^{\infty} a_n \leq 2^{-j}$$

for all $j \in \mathbf{N}$. A series is p-*convergent* if it has a modulus that is a polynomial. A sequence

$$\sum_{k=0}^{\infty} a_{j,k} \qquad (j = 0, 1, 2, \ldots)$$

of series is *uniformly* p-*convergent* if there exists a polynomial $m : \mathbf{N}^2 \to \mathbf{N}$ such that, for each $j \in \mathbf{N}$, m_j is a modulus for the series $\sum_{k=0}^{\infty} a_{j,k}$. We will use the following sufficient condition for uniform p-convergence. (This well-known lemma is easily verified by routine calculus.)

LEMMA 9. *Let $a_{j,k} \in [0, \infty)$ for all $j, k \in \mathbf{N}$. If there exist a real $\epsilon > 0$ and a polynomial $g : \mathbf{N} \to \mathbf{N}$ such that $a_{j,k} \leq e^{-k^{\epsilon}}$ for all $j, k \in \mathbf{N}$ with $k \geq g(j)$, then the series*

$$\sum_{k=0}^{\infty} a_{j,k} \qquad (j = 0, 1, 2, \ldots)$$

are uniformly p-convergent.

The proof of the Weak Stochasticity Theorem is greatly simplified by using the following special case (for p) of a uniform, resource-bounded generalization of the classical first Borel-Cantelli lemma.

LEMMA 10 [18]. *If d is a p-computable 2-DS such that the series*

$$\sum_{k=0}^{\infty} d_{j,k}(\lambda) \qquad (j = 0, 1, 2, \ldots)$$

are uniformly p-convergent, then

$$\mu_p\left(\bigcup_{j=0}^{\infty} \bigcap_{t=0}^{\infty} \bigcup_{k=t}^{\infty} S[d_{j,k}]\right) = 0.$$

If we write $S_j = \bigcap_{t=0}^{\infty} \bigcup_{k=t}^{\infty} S[d_{j,k}]$ and $S = \bigcup_{j=0}^{\infty} S_j$, then Lemma 10 gives a sufficient condition for concluding that S has p-measure 0. Note that each S_j consists of those languages A that are in infinitely many of the sets $S[d_{j,k}]$.

We now formulate our notion of weak stochasticity. For this we need a few definitions. Our notion of advice classes is standard [12]. An *advice function* is a function $h : \mathbf{N} \to \{0, 1\}^*$. Given a function $q : \mathbf{N} \to \mathbf{N}$, we write ADV$(q)$ for the set of all advice functions h such that $|h(n)| \leq q(n)$ for all $n \in \mathbf{N}$. Given a language $A \subseteq \{0, 1\}^*$ and an advice function h, we define the language A/h ("A with advice h") by

$$A/h = \{x \in \{0, 1\}^* \mid \langle x, h(|x|)\rangle \in A\}.$$

Given functions $t, q : \mathbf{N} \to \mathbf{N}$, we define the *advice class*

$$\mathrm{DTIME}(t)/\mathrm{ADV}(q) = \{A/h \mid A \in \mathrm{DTIME}(t), h \in \mathrm{ADV}(q)\}.$$

DEFINITION. *Let $t, q, \nu : \mathbf{N} \to \mathbf{N}$ and let $A \subseteq \{0, 1\}^*$. Then A is* weakly (t, q, ν)-stochastic *if, for all $B \in \mathrm{DTIME}(t)/\mathrm{ADV}(q)$ and all $C \in \mathrm{DTIME}(t)$ such that $|C_{=n}| \geq \nu(n)$ for all sufficiently large n,*

$$\lim_{n\to\infty} \frac{|(A \triangle B) \cap C_{=n}|}{|C_{=n}|} = \frac{1}{2}.$$

Intuitively, B and C together form a "prediction scheme" in which B tries to guess the behavior of A on the set C. A is weakly (t, q, ν)-stochastic if no such scheme is better in the limit than guessing by random tosses of a fair coin.

Our use of the term "stochastic" follows Kolmogorov's terminology [13], [29] for properties defined in terms of limiting frequencies of failure of prediction schemes. The adverb "weakly" distinguishes our notion from a stronger stochasticity property considered in [14], but weak stochasticity is a powerful and convenient tool.

The following lemma is central to this section because it captures the main technical content of the Weak Stochasticity Theorem.

LEMMA 11. *Fix $c \in \mathbf{N}$ and $0 < \gamma \in \mathbf{R}$, and let*

$$WS_{c,\gamma} = \{A \subseteq \{0, 1\}^* | A \textit{ is weakly } (2^{cn}, cn, 2^{\gamma n})\textit{-stochastic}\}.$$

Then $\mu_{\mathrm{p}}(WS_{c,\gamma}) = 1$.

Proof. Assume the hypothesis. Let $U \in \mathrm{DTIME}(2^{(c+1)n})$ be a language that is universal for $\mathrm{DTIME}(2^{cn}) \times \mathrm{DTIME}(2^{cn})$ in the following sense. For each $i \in \mathbf{N}$, let

$$C_i = \{x \in \{0, 1\}^* | \langle 0^i, 0x\rangle \in U\},$$

$$D_i = \{x \in \{0, 1\}^* | \langle 0^i, 1x\rangle \in U\}.$$

Then $\mathrm{DTIME}(2^{cn}) \times \mathrm{DTIME}(2^{cn}) = \{(C_i, D_i) | i \in \mathbf{N}\}$.

Our objective is to use Lemma 10 to prove that $WS^{c}_{c,\gamma}$, the complement of $WS_{c,\gamma}$, has p-measure 0. In order to do this, for all $i, j, k \in \mathbf{N}$, we define the set $Y_{i,j,k}$ of languages as follows. If k is not a power of 2, then $Y_{i,j,k} = \emptyset$. Otherwise, if $k = 2^n$, where $n \in \mathbf{N}$, then

$$Y_{i,j,k} = \bigcup_{z \in \{0,1\}^{\leq cn}} Y_{i,j,k,z},$$

where each

$$Y_{i,j,k,z} = \left\{ A \subseteq \{0,1\}^* \;\middle|\; |(C_i)_{=n}| \geq 2^{\gamma n} \right.$$
$$\left. \text{and} \left| \frac{|(A \bigtriangleup (D_i/z)) \cap (C_i)_{=n}|}{|(C_i)_{=n}|} - \frac{1}{2} \right| \geq \frac{1}{j+1} \right\}.$$

(The notation D_i/z here denotes D_i/h, where $h : \mathbf{N} \to \{0,1\}^*$ is the constant function $h(n) = z$.) The point of this definition is that, if a language $A \subseteq \{0,1\}^*$ is *not* an element of $WS_{c,\gamma}$, then the definition of weak stochasticity says that there exist $i, j \in \mathbf{N}$ such that $A \in Y_{i,j,k}$ for infinitely many k. That is,

$$WS^c_{c,\gamma} \subseteq \bigcup_{i=0}^{\infty} \bigcup_{j=0}^{\infty} \bigcap_{m=0}^{\infty} \bigcup_{k=m}^{\infty} Y_{i,j,k}.$$

It follows by Lemma 10 that it suffices to exhibit a p-computable 3-*DS* d with the following two properties.

(I) The series $\sum_{k=0}^{\infty} d_{i,j,k}(\lambda)$, for $i, j \in \mathbf{N}$, are uniformly p-convergent.

(II) For all $i, j, k \in \mathbf{N}$, $Y_{i,j,k} \subseteq S[d_{i,j,k}]$.

Define the function $d : \mathbf{N}^3 \times \{0,1\}^* \to [0,\infty)$ as follows. If k is not a power of 2, then $d_{i,j,k}(w) = 0$. Otherwise, if $k = 2^n$, where $n \in \mathbf{N}$, then

$$d_{i,j,k}(w) = \sum_{z \in \{0,1\}^{\leq cn}} \Pr(Y_{i,j,k,z} | \mathbf{C}_w),$$

where the conditional probabilities $\Pr(Y_{i,j,k,z}|\mathbf{C}_w) = \Pr[A \in Y_{i,j,k,z} | A \in \mathbf{C}_w]$ are computed according to the random experiment in which the language $A \subseteq \{0,1\}^*$ is chosen probabilistically, using an independent toss of a fair coin to decide membership of each string in A.

It follows immediately from the definition of conditional probability that d is a 3-*DS*. Since $U \in \mathrm{DTIME}(2^{(c+1)n})$ and c is fixed, we can use binomial coefficients to compute (exactly) $d_{i,j,k}(w)$ in time polynomial in $i + j + k + |w|$. Thus d is p-computable.

To see that d has property (I), note first that the Chernoff bound, Lemma 5, tells us that, for all $i, j, k \in \mathbf{N}$ and $z \in \{0,1\}^{\leq cn}$ (writing $k = 2^n$ and $N = k^\gamma = 2^{\gamma n}$),

$$\Pr(Y_{i,j,k,z}) \leq 2e^{-N/2(j+1)^2},$$

whence

$$\begin{aligned} d_{i,j,k}(\lambda) &= \sum_{z \in \{0,1\}^{\leq cn}} \Pr(Y_{i,j,k,z}) \\ &\leq 2^{cn+1} \cdot 2e^{-N/2(j+1)^2} \\ &< e^{cn+2-N/2(j+1)^2}. \end{aligned}$$

Let $a = \lceil \frac{1}{\gamma} \rceil$, let $\delta = \frac{\gamma}{4}$, and fix $k_0 \in \mathbf{N}$ such that

$$k^{2\delta} \geq k^{\delta} + c \log k + 2$$

for all $k \geq k_0$. Define $g : \mathbf{N} \to \mathbf{N}$ by

$$g(j) = 4^a (j+1)^{4a} + k_0.$$

Then g is a polynomial and, for all $i, j, n \in \mathbf{N}$ (writing $k = 2^n$ and $N = k^\gamma = k^{4\delta}$),

$$k \geq g(j) \implies \left\{ \begin{array}{rcl} N & = & k^{2\delta}k^{2\delta} \\ & \geq & [4^\alpha(j+1)^{4\alpha}]^{2\delta}(k^\delta + c\log k + 2) \\ & \geq & 2(j+1)^2(k^\delta + cn + 2) \end{array} \right.$$
$$\implies d_{i,j,k}(\lambda) < e^{-k^\delta}.$$

Thus $d_{i,j,k}(\lambda) < e^{-k^\delta}$ for all $i, j, k \in \mathbf{N}$ such that $k \geq g(j)$. Since $\delta > 0$, it follows by Lemma 9 that (I) holds.

Finally, to see that (II) holds, fix $i, j, k \in \mathbf{N}$. If k is not a power of 2, then (II) is trivially affirmed, so assume that $k = 2^n$, where $n \in \mathbf{N}$. Let $A \in Y_{i,j,k}$. Fix $z \in \{0, 1\}^{\leq cn}$ such that $A \in Y_{i,j,k,z}$ and let w be the $(2^{n+1} - 1)$-bit characteristic string of $A_{\leq n}$. Then

$$d_{i,j,k}(w) \geq \Pr(Y_{i,j,k,z}|\mathbf{C}_w) = 1,$$

so $A \in \mathbf{C}_w \subseteq S[d_{i,j,k}]$. This completes the proof of Lemma 11. □

We now have the main result of this section.

THEOREM 12 (Weak Stochasticity Theorem). (1) *For all* $c \in \mathbf{N}$ *and* $\gamma > 0$, *almost every language* $A \in \mathrm{E}$ *is weakly* $(2^{cn}, cn, 2^{\gamma n})$*-stochastic.* (2) *Almost every language* $A \in \mathrm{E}_2$ *is, for all* $c \in \mathbf{N}$ *and* $\gamma > 0$, *weakly* $(2^{cn}, cn, 2^{\gamma n})$*-stochastic.*

Proof. Part (1) follows immediately from Lemma 11 via Lemma 7. Part (2) follows from Lemma 11 via Lemmas 8 and 7. □

4. The density of hard languages. In this section we prove our main result, that for every real $\alpha < 1$, the set $\mathrm{P}_{n^\alpha-\mathrm{tt}}(\mathrm{DENSE}^c)$ has measure 0 in E and in E_2. We then derive some consequences of this result. Some terminology and notation will be useful.

Given a query-counting function $q : \mathbf{N} \to \mathbf{Z}^+$, a $q(n)$*-query function* is a function f with domain $\{0, 1\}^*$ such that, for all $x \in \{0, 1\}^*$,

$$f(x) = (f_1(x), \ldots, f_{q(|x|)}(x)) \in (\{0, 1\}^*)^{q(|x|)}.$$

Each $f_i(x)$ is called a *query* of f on input x. A $q(n)$*-truth-table function* is a function g with domain $\{0, 1\}^*$ such that, for each $x \in \{0, 1\}^*$, $g(x)$ is the encoding of a $q(|x|)$-input, 1-output Boolean circuit. We write $g(x)(w)$ for the output of this circuit on input $w \in \{0, 1\}^{q(|x|)}$. A $\leq^{\mathrm{P}}_{q(n)-tt}$*-reduction* is an ordered pair (f, g) such that f is a $q(n)$-query function, g is a $q(n)$-truth-table function, and f and g are computable in polynomial time.

Let $A, B \subseteq \{0, 1\}^*$. A $\leq^{\mathrm{P}}_{q(n)-tt}$*-reduction of* A *to* B is a $\leq^{\mathrm{P}}_{q(n)-tt}$-reduction (f, g) such that, for all $x \in \{0, 1\}^*$,

$$[\![x \in A]\!] = g(x)([\![f_1(x) \in B]\!] \cdots [\![f_{q(|x|)}(x) \in B]\!]).$$

(Recall that $[\![\psi]\!]$ denotes the Boolean value of the condition ψ.) In this case we say that $A \leq^{\mathrm{P}}_{q(n)-tt} B$ via (f, g). We say that A is $\leq^{\mathrm{P}}_{q(n)-tt}$*-reducible to* B and write $A \leq^{\mathrm{P}}_{q(n)-tt} B$, if there exists (f, g) such that $A \leq^{\mathrm{P}}_{q(n)-tt} B$ via (f, g).

The proof of our main result makes essential use of the following construction.

Given an n^α-query function f and $n \in \mathbf{N}$, the *sequentially most frequent query selection* (*smfq selection*) for f on inputs of length n is the sequence

$$(S_0, Q_0, y_0), (S_1, Q_1, y_1), \ldots, (S_{n^\alpha}, Q_{n^\alpha}, y_{n^\alpha})$$

defined as follows. Each $S_k \subseteq \{0, 1\}^n$. Each Q_k is an $|S_k| \times n^\alpha$ matrix of strings, with each string in Q_k colored either green or red. The rows of Q_k are indexed lexicographically by the elements of S_k. For $x \in S_k$, row x of Q_k is the sequence $f_1(x), \ldots, f_{n^\alpha}(x)$ of queries of f on input x. If Q_k contains at least one green string, then y_k is the green string occurring in the greatest number of rows of Q_k. (Ties are broken lexicographically.) If Q_k is entirely red, then $y_k = \top$ ("top," i.e., undefined). The sets S_k and the coloring are specified recursively. We set $S_0 = \{0, 1\}^n$ and color all strings in Q_0 green. Assume that S_k, Q_k, and y_k have been defined, where $0 \leq k < n^\alpha$. If $y_k = \top$, then $(S_{k+1}, Q_{k+1}, y_{k+1}) = (S_k, Q_k, y_k)$. If $y_k \neq \top$, then S_{k+1} is the set of all $x \in S_k$ such that y_k appears in row x of Q_k. The strings in Q_{k+1} are then colored exactly as they were in Q_k, except that all y_k's are now colored red. This completes the definition of the smfq selection.

For $0 \leq k \leq n^\alpha$, it is clear that every row of Q_k contains at least k red strings. In particular, the matrix Q_{n^α} is entirely red.

Our main results follow from the following lemma. Recall that $WS_{c,\gamma}$ is the set of all weakly $(2^{cn}, cn, 2^{\gamma n})$-stochastic languages.

LEMMA 13. *For every real* $\alpha < 1$, $\mathrm{P}_{n^\alpha\text{-tt}}(\mathrm{DENSE}^c) \cap WS_{3,1/2} = \emptyset$.

Proof. Let $\alpha < 1$, and assume that $A \leq^{\mathrm{P}}_{n^\alpha-tt} L$ via (f, g), where $L \notin$ DENSE. It suffices to show that $A \notin WS_{3,1/2}$. Fix a polynomial p such that $|f_i(x)| \leq p(|x|)$ for all $x \in \{0, 1\}^*$ and $1 \leq i \leq |x|^\alpha$. Let $\epsilon = (1 - \alpha)/4$, and fix $n_0 \in \mathbf{N}$ such that the following conditions hold for all $n \geq n_0$:

(i) $n \geq 2 \cdot n^{1-2\epsilon}$,

(ii) $n^{2\epsilon} - n^\epsilon \geq 2$.

Let

$$K = \{n \in \mathbf{N} \mid n \geq n_0 \text{ and } |L_{\leq p(n)}| < 2^{n^\epsilon}\}.$$

Note that K is infinite because L is not dense.

Define languages B, C, D and an advice function $h : \mathbf{N} \to \{0, 1\}^*$ as follows. For all $n < n_0$, we let $C_{=n} = \{0, 1\}^n$, $h(n) = \lambda$, and $D_n = \{\langle x, \lambda\rangle \mid x \in \{0, 1\}^n\}$. For all $n \geq n_0$, $C_{=n}$, $h(n)$, and D_n are defined from the smfq selection for f on inputs of length n as follows: Let $k = k(n)$ be the greatest integer such that $0 \leq k \leq n^\alpha$ and $|S_k| \geq 2^{n-kn^{2\epsilon}}$. (Note that k exists because $|S_0| = 2^n$.) We then define

$$C_{=n} = S_k,$$

$$h(n) = [\![y_0 \in L]\!] \cdots [\![y_{k-1} \in L]\!],$$

and we let D_n be the set of all coded pairs $\langle x, z\rangle$ such that $x \in S_k$, $z \in \{0, 1\}^k$, and $g(x)(b_1 \ldots b_{n^\alpha}) = 1$, where each

$$b_i = \begin{cases} z[j] & \text{if } f_i(x) = y_j, 0 \leq j < k, \\ 0 & \text{if } f_i(x) \notin \{y_0, \ldots, y_{k-1}\}. \end{cases}$$

Finally, we let $D = \bigcup_{n=0}^{\infty} D_n$ and $B = D/h$. Intuitively here, B tries to predict A on C. Specifically, for each $n \geq n_0$ and each $x \in C_{=n} = S_k$, the bit $[\![x \in B]\!]$ is a "guessed value" of the bit $[\![x \in A]\!]$. The actual value, given by the reduction (f, g) to L, is

$$[\![x \in A]\!] = g(x)([\![w_1 \in L]\!] \cdots [\![w_{n^\alpha} \in L]\!]),$$

where $w_1, \ldots, w_{n^\alpha}$ are the entries in row x of the matrix Q_k. The guessed value $[\![x \in B]\!] = g(x)(b_1 \ldots b_{n^\alpha})$ uses the advice function h to get the *correct* bit $b_i = [\![w_i \in L]\!]$ when the string w_i is red in Q_k, and *guesses* that $w_i \notin L$ when the string w_i is green in Q_k.

It is easy to see that $C, D \in \mathrm{DTIME}(2^{3n})$ and $B \in \mathrm{DTIME}(2^{3n})/\mathrm{ADV}(3n)$. (The bound $3n$ is generous here.) Also, by condition (i) in our choice of n_0,

$$|C_{=n}| \geq 2^{n-n^{\alpha}n^{2\epsilon}} \geq 2^{n/2}$$

for all $n \geq n_0$, whence $|C_{=n}| \geq 2^{\frac{n}{2}}$ for all $n \in \mathbf{N}$.

We now show that B does a good job of predicting A on $C_{=n}$, for all $n \in K$. Let $n \in K$. We have two cases.

(I) If $k = k(n) = n^{\alpha}$, then all strings in Q_k are red, so *all* the guesses made by B are correct, so

$$|(A \triangle B) \cap C_{=n}| = 0.$$

(II) If $k = k(n) < n^{\alpha}$, let r be the number of rows in Q_k, i.e., $r = |S_k| = |C_{=n}|$. By our choice of k, we have

$$|S_{k+1}| \leq 2^{n-(k+1)n^{2\epsilon}} \leq 2^{-n^{2\epsilon}}r.$$

That is, no green string appears in more than $2^{-n^{2\epsilon}}r$ of the rows of Q_k. Moreover, since $|L_{\leq p(n)}| \leq 2^{n^{\epsilon}}$, there are at most $2^{n^{\epsilon}}$ green strings w in Q_k such that $w \in L$. Thus there are at most $2^{n^{\epsilon}} \cdot 2^{-n^{2\epsilon}}r = 2^{n^{\epsilon}-n^{2\epsilon}}r$ rows of Q_k in which B makes an incorrect guess that a green string is not in L; the guesses made by B are correct in all other rows! By condition (ii) in our choice of n_0, then, B is incorrect in at most $\frac{1}{4}r$ rows of Q_k. That is,

$$|(A \triangle B) \cap C_{=n}| \leq \tfrac{1}{4}r.$$

In either case, (I) or (II), we have

$$|(A \triangle B) \cap C_{=n}| \leq \tfrac{1}{4}|C_{=n}|.$$

Since this holds for all $n \in K$, and since K is infinite,

$$\frac{|(A \triangle B) \cap C_{=n}|}{|C_{=n}|} \not\to \frac{1}{2}.$$

Thus B and C testify that A is not weakly $(2^{3n}, 3n, 2^{n/2})$-stochastic, i.e., that $A \notin WS_{3,1/2}$. □

Our main results are now easily derived. We start with the fact that most languages decidable in exponential time are not $\leq^{\mathrm{P}}_{n^{\alpha}-tt}$-reducible to nondense languages.

THEOREM 14 (Main Theorem). *For every real number* $\alpha < 1$,

$$\mu(\mathrm{P}_{n^{\alpha}-tt}(\mathrm{DENSE}^{\mathrm{c}}) \mid \mathrm{E}) = \mu(\mathrm{P}_{n^{\alpha}-tt}(\mathrm{DENSE}^{\mathrm{c}}) \mid \mathrm{E}_2) = 0.$$

Proof. This follows immediately from Theorem 12 and Lemma 13. □

The Main Theorem yields the following separation result.

THEOREM 15. *For every real* $\alpha < 1$,

$$\mathrm{E} \not\subseteq \mathrm{P}_{n^{\alpha}-tt}(\mathrm{DENSE}^{\mathrm{c}}).$$

That is, every $\leq^{\mathrm{P}}_{n^{\alpha}-tt}$*-hard language for* E *is dense.*

Proof. By the Measure Conservation Theorem [18], $\mu(\mathrm{E} \mid \mathrm{E}) \neq 0$, so this follows immediately from Theorem 14. □

Note that Theorem 15 strengthens Theorem 2 by extending the number of queries from $O(\log n)$ to n^{α}, where $\alpha < 1$ (e.g., $\alpha = 0.99$).

It is worthwhile to examine the roles played by various methods. Theorem 14, a measure-theoretic result concerning the *quantitative* structure of E and E_2, yields the *qualitative* separation result Theorem 15. From a technical standpoint, this proof of Theorem 15 has the following three components.

(i) The sequentially most frequent query selection (Lemma 13). This is used to prove that every language in $P_{n^{\alpha}-tt}(\mathrm{DENSE}^c)$ is predictable, i.e., fails to be weakly stochastic (with suitable parameters).

(ii) The Weak Stochasticity Theorem (Theorem 12). This shows that only a measure 0 subset of the languages in E are predictable.

(iii) The Measure Conservation Theorem [18]. This shows that E is not a measure 0 subset of itself.

Of these three components, (ii) and (iii) are general theorems concerning measure in E. Only component (i) is specific to the issue of the densities of $P_{n^{\alpha}-tt}$-hard languages. That is, *given the general principles* (ii) and (iii), the proof of Theorem 15 is just the sequentially most frequent query selection, i.e., the proof of Lemma 13. The latter proof is combinatorially much simpler than Watanabe's direct proof of Theorem 2. This is not surprising, once it is noted that our proof of Theorem 15 is an application of (a resource-bounded generalization of) the *probabilistic method* [5], [25], [26], [6], [27], [1], which exploits the fact that it is often easier to establish the *abundance* of objects of a given type than to construct a *specific* object of that type. Much of our proof of Theorem 15 is "hidden" in the power of this method (i.e., in the proofs of the Measure Conservation and Weak Stochasticity Theorems), freeing us to apply the sequentially most frequent query selection to the problem at hand.

An important feature of this general method is that it is *uniformly constructive* in the following sense. Taken together, the proofs of the Measure Conservation and Weak Stochasticity Theorems give a straightforward, "automatic" construction of a language $A \in \mathrm{E} \cap \mathrm{WS}_{3,1/2}$. By Lemma 13, it follows immediately that $A \in \mathrm{E} \backslash P_{n^{\alpha}-tt}(\mathrm{DENSE}^c)$. Thus one can apply this complexity-theoretic version of the probabilistic method with complete assurance that the resulting existence proof will automatically translate into a construction.

The primary objective of resource-bounded measure theory is to give a detailed account of the *quantitative structure* of E, E_2, and other complexity classes. The derivation of *qualitative* separation results, such as Theorems 15 and 2, is only a by-product of this quantitative objective. (By analogy, the value of classical Lebesgue measure and probability far surpasses their role as tools for existence proofs.) In the case of E, for example, the quantitative content of Theorem 14 is that the set $P_{n^{\alpha}-tt}(\mathrm{DENSE}^c) \cap \mathrm{E}$ is a *negligibly small* subset of E.

As noted in the introduction to this paper, we are interested in the consequences of the hypothesis that NP is *not* a negligibly small subset of exponential time. In this regard, our main theorem yields the following result.

THEOREM 16. *If* $\mu(\mathrm{NP}|\mathrm{E}) \neq 0$ *or* $\mu(\mathrm{NP}|\mathrm{E}_2) \neq 0$, *then for all* $\alpha < 1$, *every* $\leq^{\mathrm{P}}_{n^{\alpha}-tt}$*-hard language for* NP *is dense, i.e.,* $\mathrm{NP} \not\subseteq P_{n^{\alpha}-\mathrm{tt}}(\mathrm{DENSE}^c)$.

Proof. If NP has a $\leq^{\mathrm{P}}_{n^{\alpha}-tt}$-hard language H that is not dense then Theorem 14 tells us that $\mu(\mathrm{NP}|\mathrm{E}) = \mu(P_{n^{\alpha}-\mathrm{tt}}(H)|\mathrm{E}) = 0$ and $\mu(\mathrm{NP}|\mathrm{E}_2) = \mu(P_{n^{\alpha}-\mathrm{tt}}(H)|\mathrm{E}_2) = 0$. □

Note that the hypothesis and conclusion of Theorem 16 are both stronger than their counterparts in Ogiwara and Watanabe's result that

$$\mathrm{P} \neq \mathrm{NP} \Rightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{btt}}(\mathrm{SPARSE}).$$

Note also that our proof of Theorem 16 actually shows that

$$\mathrm{NP} \cap \mathrm{WS}_{3,1/2} \neq \emptyset \Longrightarrow \mathrm{NP} \not\subseteq P_{n^{\alpha}-tt}(\mathrm{DENSE}^c).$$

In fact, this implication and Theorem 16 both hold with NP replaced by PH, PP, PSPACE, or any other class.

5. Conclusion. The density criterion in Theorem 14 cannot be improved, since for every $\epsilon > 0$ there is a language $A \in \mathrm{E}$ that is $\leq^{\mathrm{P}}_{m}$-hard for E_2 and satisfies $|A_{\leq n}| < 2^{n^{\epsilon}}$ for all n. It is an open question whether the query bound n^{α} can be significantly relaxed. A construction of Wilson [32] shows that there is an oracle B such that $\mathrm{E}^B \subseteq \mathrm{P}^B_{O(n)-\mathrm{tt}}(\mathrm{SPARSE})$, so progress in this direction will require nonrelativizable techniques. (The proof of Theorem 14 relativizes in a straightforward manner.)

There are several open questions involving special reducibilities. We mention just one example. Very recently, Arvind, Köbler, and Mundhenk [2] proved that

$$\mathrm{P} \neq \mathrm{NP} \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{btt}(\mathrm{P}_{ctt}(\mathrm{SPARSE})),$$

where P_{ctt} refers to polynomial-time *conjunctive* reducibility. (This strengthens Theorem 4.) Does the class $\mathrm{P}_{btt}(\mathrm{P}_{ctt}(\mathrm{DENSE}^{\mathrm{c}}))$ have measure 0 in E?

As noted in the introduction, all known $\leq^{\mathrm{P}}_{\mathrm{T}}$-hard languages for NP are dense, i.e., our experience suggests that $\mathrm{NP} \not\subseteq \mathrm{P}_T(\mathrm{DENSE}^{\mathrm{c}})$. This suggests two open questions. (See Fig. 1.) Karp and Lipton [12] show that

$$\begin{tikzcd}
 & \Sigma^{\mathrm{p}}_2 \neq \Pi^{\mathrm{p}}_2 \arrow[dl] \arrow[dd, "\text{Karp and Lipton}"] & & \mu(\Sigma^{\mathrm{p}}_2 \setminus \Pi^{\mathrm{p}}_2 \mid \mathrm{E}_2) \neq 0 \arrow[lll] \arrow[dl, dashed, "\text{open}"] \arrow[dd, dashed, "\text{open}"] \\
\mathrm{P} \neq \mathrm{NP} \arrow[dd, "\text{Ogiwara and Watanabe}"] & & \mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0 \arrow[ll] \arrow[dd, "\text{this paper}"] & \\
 & \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{T}}(\mathrm{SPARSE}) \arrow[dl] & & \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{T}}(\mathrm{DENSE}^{\mathrm{c}}) \arrow[ll] \arrow[dl] \\
\mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{btt}}(\mathrm{SPARSE}) & & \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{n}^{\alpha}\text{-}\mathrm{tt}}(\mathrm{DENSE}^{\mathrm{c}}) \arrow[ll] &
\end{tikzcd}$$

Fig. 1. *Two open problems.*

$$\Sigma^p_2 \neq \Pi^p_2 \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_T(\mathrm{SPARSE}).$$

Theorem 16 of the present paper shows that

$$\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0 \Longrightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{n^{\alpha}-tt}(\mathrm{DENSE}^{\mathrm{c}})$$

for $\alpha < 1$. The first question, posed by Selman [24], is whether the strong hypothesis $\mu(\Sigma^p_2 \backslash \Pi^p_2 \mid \mathrm{E}_2) \neq 0$ can be used to combine these ideas to get a conclusion that $\mathrm{NP} \not\subseteq \mathrm{P}_T(\mathrm{DENSE}^{\mathrm{c}})$. The second, more fundamental, question is suggested by the first. A well-known downward separation principle [28] says that, if the polynomial time hierarchy separates at some level, then it separates at all lower levels. Thus, for example, $\Sigma^p_2 \neq \Pi^p_2$ implies that

P $\neq$ NP. Is there a "downward measure separation principle," stating that $\mu(\Sigma_{k+1}^p \backslash \Pi_{k+1}^p \mid \mathrm{E}_2) \neq 0 \Longrightarrow \mu(\Sigma_k^p \backslash \Pi_k^p \mid \mathrm{E}_2) \neq 0$? In particular, does $\mu(\Sigma_2^p \backslash \Pi_2^p \mid \mathrm{E}_2) \neq 0$ imply that $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$?

The hypothesis that $\mu(\mathrm{NP}|\mathrm{E}_2) \neq 0$, i.e., that NP is not a negligibly small subset of E_2, was recently shown to have a number of credible consequences: If $\mu(\mathrm{NP}|\mathrm{E}_2) \neq 0$, then NP contains p-random languages [14]; NP contains E-bi-immune languages [21]; every $\leq_m^{\mathrm{P}}$-hard language for NP has an exponentially dense, exponentially hard complexity core [10]; and now, by Theorem 15, every $\leq_{n^\alpha-tt}^{\mathrm{P}}$-hard language for NP ($\alpha < 1$) is exponentially dense. Further investigation of the consequences and reasonableness of $\mu(\mathrm{NP}|\mathrm{E}_2) \neq 0$ and related strong, measure-theoretic hypotheses is clearly indicated.

Acknowledgments. The first author thanks Bill Gasarch and Alan Selman for helpful discussions. Both authors thank two anonymous referees for several suggestions that improved the exposition.

Note added in proof. Very recently, and independently, Fu [7] used resource-bounded Kolmogorov complexity to prove results similar to Theorem 15 but for Turing reducibilities instead of truth-table reducibilities.

FINDING k DISJOINT PATHS IN A DIRECTED PLANAR GRAPH*

ALEXANDER SCHRIJVER†

Abstract. It is shown that, for each fixed k, the problem of finding k pairwise vertex-disjoint directed paths between given pairs of terminals in a directed planar graph is solvable in polynomial time.

Key words. disjoint, path, directed, planar, graph, polynomial-time, algorithm, free group, homologous, cohomologous

1. Introduction and statement of result. In this paper we show that the following problem, the *k disjoint paths problem for directed planar graphs*, is solvable in polynomial time, for any fixed k:

$$\text{(1)}\quad \begin{array}{rl} \text{given :} & \text{a directed planar graph } D = (V, A) \text{ and } k \text{ pairs } (r_1, s_1), \ldots, (r_k, s_k) \text{ of} \\ & \text{vertices of } D; \\ \text{find :} & k \text{ pairwise vertex-disjoint directed paths } P_1, \ldots, P_k \text{ in } D, \text{ where } P_i \text{ runs} \\ & \text{from } r_i \text{ to } s_i (i = 1, \ldots, k). \end{array}$$

The problem is NP-complete if we do not fix k (even in the undirected case; Lynch [2]). Moreover, it is NP-complete for $k = 2$ if we delete the planarity condition (Fortune, Hopcroft, and Wyllie [1]). This is in contrast to the undirected case (for those believing NP≠P), where Robertson and Seymour [4] showed that, for any fixed k, the k disjoint paths problem is polynomial-time solvable for any graph (not necessarily planar).

In this paper we do not aim at obtaining the best possible running time bound, as we presume that there are much faster (but possibly more complicated) methods for (1) than the one we describe in this paper. In fact, recently Reed, Robertson, Schrijver, and Seymour [3] showed that for undirected planar graphs the k disjoint paths problem can be solved in *linear* time, for any fixed k. This algorithm makes use of methods from Robertson and Seymour's theory of graph minors. A similar algorithm for directed planar graphs might exist but probably would require extending parts of graph minors theory to the directed case.

Our method is based on cohomology over free (nonabelian) groups. For the k disjoint paths problem we use free groups with k generators. It extends methods given in [5] for undirected graphs on surfaces based on homotopy. Cohomology is in a sense dual to homology and can be defined in any directed graph, even if it is not embedded on a surface. We apply cohomology to an *extension* of the planar graph dual of D—just applying homology to D itself seems not powerful enough.

We remark that in our approach free groups and (co)homology are used mainly as a framework to formulate certain ideas smoothly; they give us a convenient tool for recording shifts of curves over the plane. No deep group theory or topology is used. We could avoid free groups and cohomology by adopting a more complex notation and terminology; that would, however, implicitly mimic free groups and cohomology. The present approach also readily allows application of the algorithm where the embedding of the graph in the plane is given combinatorially, that is, by a list of the cycles that bound the faces of the graph.

2. The cohomology feasibility problem.

2.1. Free groups. The *free group* G_k, generated by the *generators* $g_1, g_2, \ldots, g_k$, consists of all words $b_1 b_2 \cdots b_t$ where $t \geq 0$ and $b_1, \ldots, b_t \in \{g_1, g_1^{-1}, \ldots, g_k, g_k^{-1}\}$ such that $b_i b_{i+1} \neq g_j g_j^{-1}$ and $b_i b_{i+1} \neq g_j^{-1} g_j$ for $i = 1, \ldots, t-1$ and $j = 1, \ldots, k$. The product $x \cdot y$ of two such words is obtained from the concatenation xy by deleting iteratively all occurrences of any $g_j g_j^{-1}$ and $g_j^{-1} g_j$. (So in our notation $x \cdot y \neq xy$ in general.) This defines a group, with unit element 1 equal to the empty word $\emptyset$. We call $g_1, g_1^{-1}, \ldots, g_k, g_k^{-1}$ the *symbols*. The *size* $|x|$ of a word x is the number of symbols occurring in it, counting multiplicities.

A word y is called a *segment* of a word w if $w = xyz$ for certain words x, z. It is called a *beginning segment* if $x = 1$ and an *end segment* if $z = 1$. A subset Γ of a free group is called *hereditary* if for each word $y \in \Gamma$, each segment of y belongs to Γ.

We define a partial order $\leq$ on G_k by

$$x \leq y \Leftrightarrow x \text{ is a beginning segment of } y. \tag{2}$$

This gives a lattice if we extend G_k with an element ∞ at infinity. We denote the meet and join by $\wedge$ and $\vee$. So $x \wedge y$ is equal to the longest common beginning segment of x and y. Moreover, $x \vee y = \infty$ except if $x \leq y$ or $y \leq x$.

We make two easy observations.

LEMMA 2.1. *Let α be a symbol, and let $x, z \in G_k$. If $x \leq \alpha \cdot z$ and $z \leq \alpha^{-1} \cdot x$, then $x^{-1} \cdot \alpha \cdot z = 1$ or $x = z = 1$.*

Proof. Let $y := x^{-1} \cdot \alpha \cdot z$, and suppose that $y \neq 1$. Since $x \leq \alpha \cdot z$, it follows that $\alpha \cdot z = xy'$ for some y', and hence $y = x^{-1} \cdot \alpha \cdot z = x^{-1} \cdot (xy') = y'$. Consequently $xy \in G_k$; and since $z \leq \alpha^{-1} \cdot x$, it follows similarly that $zy^{-1} \in G_k$, that is, $yz^{-1} \in G_k$. Since $y \neq 1$, this implies that $xyz^{-1} \in G_k$, and so $\alpha = x \cdot y \cdot z^{-1} = xyz^{-1}$. In particular, $1 = |\alpha| = |x| + |y| + |z| \geq |x| + 1 + |z|$. Therefore, $x = z = 1$. □

LEMMA 2.2. *Let $x, y \in G_k$. If $x \not\leq y$, then the last symbol of x is equal to the last symbol of $y^{-1} \cdot x$.*

Proof. Let $z := x \wedge y$. Write $x = zx'$ and $y = zy'$, where $x' \neq 1$. Let α be the first symbol of x'. Since $z = x \wedge y$, we know $\alpha \not\leq y'$. Hence $(y')^{-1} \cdot x' = (y')^{-1} x'$ (i.e., no cancellation). Consequently,

$$y^{-1} \cdot x = ((y')^{-1} z^{-1}) \cdot (zx') = (y')^{-1} \cdot x' = (y')^{-1} x'. \tag{3}$$

Hence, as $x' \neq 1$, the last symbol of x is equal to the last symbol of $y^{-1} \cdot x$. □

2.2. The cohomology feasibility problem for free groups. Let $D = (V, A)$ be a weakly connected directed graph, let $r \in V$, and let $(G, \cdot)$ be a group. (We allow directed graphs to have parallel arcs.) Two functions $\phi, \psi : A \longrightarrow G$ are called *r-cohomologous* if there exists a function $f : V \longrightarrow G$ such that

$$\begin{aligned} &\text{(i) } f(r) = 1; \\ &\text{(ii) } \psi(a) = f(u)^{-1} \cdot \phi(a) \cdot f(w) \text{ for each arc } a = (u, w). \end{aligned} \tag{4}$$

One easily checks that this gives an equivalence relation.

Consider the following *cohomology feasibility problem for free groups*:

$$\begin{aligned} &\text{given : a weakly connected directed graph } D = (V, A), \text{ a vertex } r, \text{ a function} \\ &\qquad \phi : A \longrightarrow G_k, \text{ and for each } a \in A \text{ a hereditary subset } \Gamma(a) of G_k; \\ &\text{find : a function } \psi : A \longrightarrow G_k \text{ such that } \psi \text{ is } r\text{-cohomologous to } \phi \text{ and such that} \\ &\qquad \psi(a) \in \Gamma(a) \text{ for each arc } a. \end{aligned} \tag{5}$$

We show the following.

THEOREM 2.3. *The cohomology feasibility problem for free groups is solvable in time bounded by a polynomial in* $|A| + \sigma + k$.

Here σ is the maximum size of the words $\phi(a)$ and the words in the $\Gamma(a)$. (In fact we can drop k and assume that G_k is the free group generated by the generators occurring in the $\phi(a)$ and the words in the $\Gamma(a)$.)

Note that, by the definition of r-cohomologous, equivalent to finding a ψ as in (5) is finding a function $f : V \longrightarrow G_k$ satisfying

$$(6) \quad \begin{array}{l} \text{(i) } f(r) = 1; \\ \text{(ii) } f(u)^{-1} \cdot \phi(a) \cdot f(w) \in \Gamma(a) \text{ for each arc } a = (u, w). \end{array}$$

We call such a function *f feasible.*

In solving the cohomology feasibility problem for free groups we may assume

$$(7) \quad \begin{array}{l} \text{(i) } \Gamma(a) \neq \emptyset \text{ for each arc } a; \\ \text{(ii) } |\phi(a)| \leq 1 \text{ for each arc } a; \\ \text{(iii) with each arc } a = (u, w) \text{ also } a^{-1} = (w, u) \text{ is an arc, with } \phi(a^{-1}) = \phi(a)^{-1} \\ \qquad \text{and } \Gamma(a^{-1}) = \Gamma(a)^{-1}. \end{array}$$

Here $\Gamma(a)^{-1} := \{x^{-1} | x \in \Gamma(a)\}$. Condition (7)(ii) can be attained by replacing any arc $a = (u, w)$ such that $\phi(a) = \beta_1 \cdots \beta_t$ and $t \geq 2$ by a $u - w$ path $a_1 \cdots a_t$ with $\phi(a_i) := \beta_i$ $(i = 1, \dots, t)$ and $\Gamma(a_1) := \Gamma(a)$ and $\Gamma(a_i) := \{1\}$ $(i = 2, \dots, t)$. (Here and below we indicate a path P by the string of arcs traversed by P (in the order traversed by P). If P traverses an arc a in the backward direction, then we denote this in the string by a^{-1}. For instance, $P = a_1 a_2^{-1} a_3$ means that P traverses first a_1 in the forward direction, next a_2 in the backward direction, and finally a_3 in the forward direction. The arcs need not be distinct.)

2.3. Pre-feasible functions. Let input $D = (V, A), r, \phi, \Gamma$ for the cohomology feasibility problem for free groups (5) be given, assuming (7). We call a function $f : V \longrightarrow G_k$ *pre-feasible* if

$$(8) \quad \begin{array}{l} \text{(i) } f(r) = 1; \\ \text{(ii) for each arc } a = (u, w) \text{ with } f(u)^{-1} \cdot \phi(a) \cdot f(w) \notin \Gamma(a) \text{ one has } f(u) = \\ \qquad f(w) = 1. \end{array}$$

Define a partial order $\leq$ on the set G_k^V of all functions $f : V \longrightarrow G_k$ by

$$(9) \qquad f \leq g \Leftrightarrow f(v) \leq g(v) \quad \text{for each } v \in V. \qquad \Box$$

It is easy to see that G_k^V forms a lattice if we add an element ∞ at infinity. Let $\wedge$ and $\vee$ denote the meet and join, respectively.

Pre-feasibility behaves nicely with respect to the lattice:

PROPOSITION 1. *If f_1 and f_2 are pre-feasible, then so is $f := f_1 \wedge f_2$.*

Proof. Clearly $f(r) = 1$. Let $a = (u, w)$ be an arc such that $y := f(u)^{-1} \cdot \phi(a) \cdot f(w) \notin \Gamma(a)$ while not $f(u) = f(w) = 1$. By Lemma 2.1 and by symmetry we may assume that $f(u) \not\leq \phi(a) \cdot f(w)$. Let x and x' be such that $f_1(u) = f(u)x$ and $f_2(u) = f(u)x'$, and let z and z' be such that $f_1(w) = f(w)z$ and $f_2(w) = f(w)z'$. Let α and β be the first and last symbol, respectively, of y. Since $z_1 \wedge z_2 = 1$, we know $\beta^{-1} \not\leq z$ or $\beta^{-1} \not\leq z'$. Without loss of generality, $\beta^{-1} \not\leq z$.

Since $f(u) \not\leq \phi(a) \cdot f(w)$, by Lemma 2.2 the first symbol of $f(u)^{-1}$ is equal to α. So $\alpha \not\leq x$, and hence

$$f_1(u)^{-1} \cdot \phi(a) \cdot f_1(w) = x^{-1} \cdot y \cdot z = x^{-1}yz. \tag{10}$$

So y is a segment of $f_1(u)^{-1} \cdot \phi(a) \cdot f_1(w)$. By the heredity of $\Gamma(a)$ this implies that $f_1(u)^{-1} \cdot \phi(a) \cdot f_1(w) \not\in \Gamma(a)$. So, as f_1 is pre-feasible, $f_1(u) = f_1(w) = 1$. Therefore $f(u) = f(w) = 1$. □

So for any function $f : V \longrightarrow G_k$ there exists a smallest pre-feasible function $\bar{f} \geq f$, provided there exists at least one pre-feasible function $g \geq f$. If no such g exists, we set $\bar{f} := \infty$. We observe the following proposition.

PROPOSITION 2. *If $\bar{f}$ is finite, then*

(i) $f(r) = 1$ *and* $|f(v)| < 2\sigma|V|$ *for each vertex* v;

(ii) *for each arc* $a = (u, w)$: *if* $f(u)^{-1} \cdot \phi(a) \cdot f(w) \not\in \Gamma(a)$, *then* $f(u) \leq \phi(a) \cdot f(w)$ *or* $f(w) \leq \phi(a^{-1}) \cdot f(u)$.

(11)

Proof. Clearly, $f(r) \leq \bar{f}(r) = 1$. Moreover, by induction on the minimum number t of arcs in any $r - v$ path one shows $|\bar{f}(v)| \leq 2\sigma t$. Indeed, if $a = (u, v)$ is the last arc in the path, then $y := \bar{f}(u)^{-1} \cdot \phi(a) \cdot \bar{f}(v)$ belongs to $\Gamma(a)$ or is equal to $\phi(a)$ and, hence, has size at most σ. So

$$|\bar{f}(v)| = |\bar{f}(u) \cdot \phi(a)^{-1} \cdot y| \leq |\bar{f}(u)| + |\phi(a)| + \sigma \leq 2\sigma(t-1) + 1 + \sigma \leq 2\sigma t. \tag{12}$$

This implies $|f(v)| \leq |\bar{f}(v)| < 2\sigma|V|$.

To see (ii), suppose $f(u) \not\leq \phi(a) \cdot f(w)$ and $f(w) \not\leq \phi(a^{-1}) \cdot f(u)$. The first implies (by Lemma 2.2) that the first symbol of $f(u)^{-1} \cdot \phi(a) \cdot f(w)$ is equal to the first symbol of $f(u)^{-1}$. The second implies (again by Lemma 2.2) that the last symbol of $f(u)^{-1} \cdot \phi(a) \cdot f(w)$ is equal to the last symbol of $f(w)$. Since $f \leq \bar{f}$, it follows that $f(u)^{-1} \cdot \phi(a) \cdot f(w)$ is a segment of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot \bar{f}(w)$. So $\bar{f}(u)^{-1} \cdot \phi(a) \cdot \bar{f}(w) \not\in \Gamma(a)$. Hence, as $\bar{f}$ is pre-feasible, $\bar{f}(u) = \bar{f}(w) = 1$, and therefore $f(u) = 1$. This contradicts the fact that $f(u) \not\leq \phi(a) \cdot f(w)$.
□

2.4. A subroutine finding $\bar{f}$. Let input $D = (V, A), r, \phi, \Gamma$ for the cohomology feasibility problem for free groups (5) be given, again assuming (7). We describe a polynomial-time subroutine that outputs $\bar{f}$ for any given $f : V \longrightarrow G_k$.

If f is pre-feasible, output $\bar{f} := f$. If f violates (11), output $\bar{f} := \infty$. Otherwise choose an arc $a = (u, w)$ satisfying $f(u)^{-1} \cdot \phi(a) \cdot f(w) \not\in \Gamma(a)$ and $f(w) \not\leq \phi(a^{-1}) \cdot f(u)$ (as f is not pre-feasible and satisfies (11), such an arc exists by Lemma 2.1). Perform the following:

Iteration: Write $\phi(a) \cdot f(w) = xy$, with $y \in \Gamma(a)$ and $|y|$ as large as possible, reset $f(u) := x$, and start anew.

PROPOSITION 3. *In the iteration, resetting f increases $|f(u)|$ and does not change $\bar{f}$.*

Proof. Consider the iteration. Denote by f' the reset f. As (11)(ii) holds, $f(u) \leq \phi(a) \cdot f(w)$. Since $f(u)^{-1} \cdot \phi(a) \cdot f(w) \not\in \Gamma(a)$, $f(u)$ is a segment of x with $f(u) \neq x$. So $|f'(u)| > |f(u)|$.

To see $\bar{f'} = \bar{f}$, we must show $f' \leq \bar{f}$, that is, $f'(u) \leq \bar{f}(u)$ if $\bar{f}$ is finite. Suppose that $\bar{f}$ is finite and that $f'(u) \not\leq \bar{f}(u)$. Let β be the last symbol of $x = f'(u)$. As $x \not\leq \bar{f}(u)$ and as $\phi(a) \cdot f(w) = xy$, βy is an end segment of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot f(w)$.

Since $\phi(a) \cdot f(w) \not\leq \bar{f}(u)$ (as $x \leq \phi(a) \cdot f(w)$), by Lemma 2.2 the last symbol of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot f(w)$ is equal to the last symbol of $\phi(a) \cdot f(w)$. Since $\phi(a) \cdot f(w) \not\leq f(u)$ (as $x \leq \phi(a) \cdot f(w)$ and $f(u) \leq \bar{f}(u)$), by Lemma 2.2 the last symbol of $\phi(a) \cdot f(w)$ is equal to the last symbol of $f(u)^{-1} \cdot \phi(a) \cdot f(w)$. Since $f(w) \not\leq \phi(a^{-1}) \cdot f(u)$, by Lemma 2.2 the last symbol of $f(u)^{-1} \cdot \phi(a) \cdot f(w)$ is equal to the last symbol of $f(w)$. Concluding, the last symbol of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot f(w)$ is equal to the last symbol of $f(w)$. Hence $\bar{f}(u)^{-1} \cdot \phi(a) \cdot f(w)$ is a beginning segment of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot \bar{f}(w)$. So βy is a segment of $\bar{f}(u)^{-1} \cdot \phi(a) \cdot \bar{f}(w)$, and hence βy belongs to $\Gamma(a)$. This contradicts the maximality of y. □

Since at each iteration $|f(u)|$ increases for some vertex u, after at most $2\sigma|V|^2$ iterations either we get a prefeasible function f or (11) is violated. Thus the subroutine is polynomial time.

2.5. Algorithm for the cohomology feasibility problem for free groups. Let input $D = (V, A), r, \phi, \Gamma$ for the cohomology feasibility problem for free groups (5) be given. We find a feasible function f as follows.

Again we may assume (7). For every $a = (u, w) \in A$ let f_a be the function defined by $f_a(u) := \phi(a)$ and $f_a(v) := 1$ for each $v \neq u$. Let E be the set of pairs $\{a, a'\}$ from A for which $\bar{f}_a \vee \bar{f}_{a'}$ is finite and pre-feasible. Let E' be the set of pairs $\{a, a^{-1}\}$ with $a \in A$ and $\phi(a) \notin \Gamma(a)$.

We search for a subset X of A such that each pair in X belongs to E and such that X intersects each pair in E'. This is a special case of the two-satisfiability problem and, hence, can be solved in polynomial time.

PROPOSITION 4. *If X exists, then the function $f := \bigvee_{a \in X} \bar{f}_a$ is feasible. If X does not exist, then there is no feasible function.*

Proof. First assume that X exists. Let f be as given. Since $\bar{f}_a \vee \bar{f}_{a'}$ is finite and pre-feasible for each two a, a' in X, f is finite and $f(r) = 1$. Moreover, suppose $f(u)^{-1} \cdot \phi(a) \cdot f(w) \notin \Gamma(a)$ for some arc $a = (u, w)$. Let $f(u) = \bar{f}_{a'}(u)$ and $f(w) = \bar{f}_{a''}(w)$ for $a', a'' \in X$. As $\bar{f}_{a'} \vee \bar{f}_{a''}$ is pre-feasible, $\bar{f}_{a'}(u) = \bar{f}_{a''}(w) = 1$. So $\phi(a) \notin \Gamma(a)$, and hence a or a^{-1} belongs to X. By symmetry we may assume $a \in X$. Then

$$\phi(a) = f_a(u) \leq \bar{f}_a(u) \leq f(u) = \bar{f}_{a'}(u) = 1, \tag{13}$$

a contradiction.

Assume conversely that there exists a feasible function f. Let X be the set of arcs $a = (u, w)$ with the property that $\phi(a) \leq f(u)$. Then X intersects each pair in E'. For let $a = (u, w)$ be an arc satisfying $a \notin X$ and $a^{-1} \notin X$, that is, $\phi(a) \not\leq f(u)$ and $\phi(a^{-1}) \not\leq f(w)$. Hence $f(u)^{-1} \cdot \phi(a) \cdot f(w) = f(u)^{-1}\phi(a)f(w)$. So $f(u)^{-1} \cdot \phi(a) \cdot f(w)$ contains $\phi(a)$ as a segment (as $|\phi(a)| \leq 1$). So $\phi(a) \in \Gamma(a)$ and hence $\{a, a^{-1}\} \notin E'$.

Moreover, each pair in X belongs to E. For let $\{a', a''\}$ be a pair in X. We show that $\{a', a''\} \in E$, that is, $f' := \bar{f}_{a'} \vee \bar{f}_{a''}$ is finite and pre-feasible. As $a' \in X$, we have $\phi(a') \leq f(u)$ and hence $f_{a'} \leq f$, implying $\bar{f}_{a'} \leq f$. Similarly, $\bar{f}_{a''} \leq f$. So f' is finite and $f'(r) = 1$. Consider an arc $a = (u, w)$ with $y := f'(u)^{-1} \cdot \phi(a) \cdot f'(w) \notin \Gamma(a)$. We may assume $f'(u) = \bar{f}_{a'}(u)$ and $f'(w) = \bar{f}_{a''}(w)$ (since $\bar{f}_{a'}$ and $\bar{f}_{a''}$ are pre-feasible). To show $f'(u) = f'(w) = 1$, by Lemma 2.1 we may assume $f'(w) \not\leq \phi(a^{-1}) \cdot f'(u)$.

First assume $f'(u) \not\leq \phi(a) \cdot f'(w)$. Then by Lemma 2.2 the first and the last symbols of y are equal to the first symbol of $f'(u)^{-1}$ and the last symbol of $f'(w)$, respectively. Since $f' \leq f$, this implies that y is a segment of $f(u)^{-1} \cdot \phi(a) \cdot f(w) \in \Gamma(a)$. This contradicts the heredity of $\Gamma(a)$ as $y \notin \Gamma(a)$.

Second assume $f'(u) \leq \phi(a) \cdot f'(w)$. So $\phi(a) \cdot f'(w) = f'(u)y$ for some y. Since $\bar{f}_{a''}(u) \leq f'(u)$, it follows that y is an end segment of

$$(14) \qquad \bar{f}_{a''}(u)^{-1} \cdot (f'(u)y) = \bar{f}_{a''}(u)^{-1} \cdot \phi(a) \cdot f'(w) = \bar{f}_{a''}(u)^{-1} \cdot \phi(a) \cdot \bar{f}_{a''}(w).$$

So $\bar{f}_{a''}(u)^{-1} \cdot \phi(a) \cdot \bar{f}_{a''}(w) \notin \Gamma(a)$, since $y \notin \Gamma(a)$. As $\bar{f}_{a''}$ is pre-feasible, this implies $\bar{f}_{a''}(u) = \bar{f}_{a''}(w) = 1$; so $f'(w) = 1$. Hence $f'(u) \leq \phi(a)$ and therefore, since $y \notin \Gamma(a)$ and $|\phi(a)| \lesssim 1$, $f'(u) = 1$. □

Thus we have proved Theorem 2.3.

3. The k disjoint paths problem for directed planar graphs.

3.1. Directed planar graphs, R-homology, and flows. Let input $D = (V, A)$, $r_1, s_1, \ldots, r_k, s_k$ for problem (1) be given. In solving (1) we may assume that D is weakly connected and that for each $i = 1, \ldots, k$, r_i is incident with exactly one arc, which is leaving r_i, and s_i is incident with exactly one arc, which is entering s_i. We fix an embedding of D. Let $\mathcal{F}$ denote the collection of faces of D and let R be the unbounded face of D.

Call two functions $\phi, \psi : A \longrightarrow G_k$ *R-homologous* if there exists a function $f : \mathcal{F} \longrightarrow G_k$ such that

(i) $f(R) = 1$;

(15) (ii) $f(F)^{-1} \cdot \phi(a) \cdot f(F') = \psi(a)$ for each arc a, where F and F' are the faces at the left-hand side and right-hand side of a, respectively.

The relation to cohomologous is direct by duality. The *dual* graph $D^* = (\mathcal{F}, A^*)$ of D has as vertex set the collection $\mathcal{F}$ of faces of D, while for any arc a of D there is an arc a^* of D^* from the face of D at the left-hand side of a to the face at the right-hand side. Define for any function ϕ on A the function ϕ^* on A^* by $\phi^*(a^*) := \phi(a)$ for each $a \in A$. Then ϕ and ψ are R-homologous (in D) if and only if ϕ^* and ψ^* are R-cohomologous (in D^*).

For any solution $\Pi = (P_1, \ldots, P_k)$ of (1) let $\psi_\Pi : A \longrightarrow G_k$ be defined by $\psi_\Pi(a) := g_i$ if path P_i traverses a ($i = 1, \ldots, k$), and $\psi_\Pi(a) := 1$ if a is not traversed by any of the P_i.

Call a function $\phi : A \longrightarrow G_k$ a *flow* if for each vertex $v \in V$ with $v \notin \{r_1, s_1, \ldots, r_k, s_k\}$ one has

$$(16) \qquad \phi(a_1)^{\varepsilon_1} \cdot \phi(a_2)^{\varepsilon_2} \cdot \cdots \cdot \phi(a_n)^{\varepsilon_n} = 1,$$

where $a_1, \ldots, a_n$ are the arcs incident with v, in clockwise order, where $\varepsilon_i = +1$ if a_i has its tail at v and $\varepsilon_i = -1$ if a_i has its head at v (if a_i happens to be a loop we take $\varepsilon_i = +1$ and $\varepsilon_i = -1$ at the corresponding positions in (16)), and if moreover for any arc a incident with r_i or s_i one has $\phi(a) = g_i$ ($i = 1, \ldots, k$).

Clearly, if Π is a solution of (1), then ψ_Π is a flow. Moreover, if ϕ is a flow and ϕ' is R-homologous to ϕ, then also ϕ' is a flow.

3.2. Deriving a solution from a flow. We first show the next proposition.

PROPOSITION 5. *There exists a polynomial-time algorithm that, for any flow ϕ, either finds a solution Π of (1) or concludes that there does not exist a solution Π of (1) such that ψ_Π is R-homologous to ϕ.*

[Here *polynomial-time* means: polynomial-time in the size of D and the maximum size of the $\phi(a)$. Note that it is not required that if we find a solution Π of (1), then ψ_Π is R-homologous to ϕ.]

Proof. Let ϕ be a flow. Consider the dual graph $D^* = (\mathcal{F}, A^*)$ of D. We construct the 'extended' dual graph $D^+ = (\mathcal{F}, A^+)$ by adding in each face of D^* all chords. (So D^+ need not be planar.) More precisely, for any two vertices F, F' of D^* and any (undirected) $F - F'$

path π on the boundary of any face of D^*, extend the graph with an arc, denoted by a_π, from F to F'. Define $\phi^+ : A^+ \longrightarrow G_k$ by

(17)
(i) $\phi^+(a^*) := \phi(a)$ for each arc a of D;
(ii) $\phi^+(a_\pi) := \phi(a_1)^{\varepsilon_1} \cdot \dots \cdot \phi(a_t)^{\varepsilon_t}$ for any path $\pi = (a_1^*)^{\varepsilon_1} \cdots (a_t^*)^{\varepsilon_t}$ with $\varepsilon_1, \dots, \varepsilon_t \in \{+1, -1\}$.

(As before, $(a_i^*)^{-1}$ means that π traverses a_i^* in the backward direction.) Moreover, let $\Gamma(a^*) := \{1, g_1, \dots, g_k\}$ and $\Gamma(a_\pi) := \{1, g_1, g_1^{-1}, \dots, g_k, g_k^{-1}\}$.

By Theorem 2.3 we can find in polynomial time a function ψ that is R-cohomologous to ϕ^+ in D^+, with $\psi(b) \in \Gamma(b)$ for each arc b of D^+, provided that such a ψ exists. If we find such a ψ, let P_i be any directed $r_i - s_i$ path traversing only arcs a satisfying $\psi(a^*) = g_i$ (for $i = 1, \dots, k$). (Such paths exist since ϕ is a flow.) Then $P_1, \dots, P_k$ form a solution to (1). Indeed, $P_1, \dots, P_k$ are vertex-disjoint, for suppose that there exist arcs a and b of D that are both incident with a vertex v and $\psi(a^*) = g_i^{\pm 1}$, $\psi(b^*) = g_j^{\pm 1}$, and $i \neq j$. Consider a shortest path π along the face of D^* corresponding to v such that π contains arcs a^* and b^*. We may assume that we have chosen a and b such that π is as short as possible. Then $|\psi(a_\pi)| \geq 2$, as $\psi(a_\pi)$ contains both $g_i^{\pm 1}$ and $g_j^{\pm 1}$ (neither of them can be cancelled, since a and b are chosen so that π is shortest). This contradicts the fact that $\psi(a_\pi) \in \Gamma(a_\pi)$.

If we do not find such a function ψ, we may conclude that there does not exist a solution Π of (1) such that ψ_Π is R-homologous to ϕ, since otherwise the cohomology feasibility problem has a solution, viz. $\psi := (\psi_\Pi)^+$. □

3.3. Enumerating homology types. In this section we show the following.

PROPOSITION 6. *For each fixed k, we can find in polynomial time flows $\phi_1, \dots, \phi_N$ with the property that for each solution Π of* (1), *ψ_Π is R-homologous to at least one of $\phi_1, \dots, \phi_N$.*

Proof. Consider systems $\Pi = (P_1, \dots, P_k)$ satisfying:

(18)
(i) P_i is an undirected path from r_i to s_i, not traversing the same edge more than once, and not having any self-crossing ($i = 1, \dots, k$);
(ii) P_i and P_j are edge-disjoint and do not have any crossing ($i, j = 1, \dots, k$; $i \neq j$).

(An *undirected* path is a path that may traverse arcs in the backward direction.)

For any such system Π, define $\psi_\Pi : A \longrightarrow G_k$ by $\psi_\Pi(a) := g_i$ if P_i traverses a in the forward direction, $\psi_\Pi(a) := g_i^{-1}$ if P_i traverses a in the backward direction ($i = 1, \dots, k$), and $\psi_\Pi(a) := 1$ if a is not traversed by any P_i.

We will show that for each fixed k, we can find in polynomial time flows $\phi_1, \dots, \phi_N$ with the property that

(19) for each Π satisfying (18), ψ_Π is R-homologous to at least one of $\phi_1, \dots, \phi_N$.

This is stronger than what we need to show.

Consider a nonloop arc a' not incident with any r_i or s_i. Contract a', yielding graph D'. Let $\phi_1', \dots, \phi_N'$ be flows in D' satisfying (19) with respect to D'. Then for each j there is a unique flow ϕ_j in D such that $\phi_j(a) = \phi_j'(a)$ for each arc $a \neq a'$. Moreover, if Π satisfies (18) in D, then contracting a' gives a system Π' satisfying (18) in D'. Hence there exists a j such that ϕ_j' is R-homologous to $\psi_{\Pi'}$ (in D'), implying that ϕ_j is R-homologous to ψ_Π (in D).

Concluding, we can obtain from a system of flows satisfying (19) for D' a system of flows satisfying (19) for D. Repeating this we obtain that we may assume that there is only one vertex v in $V \setminus \{r_1, s_1, \dots, r_k, s_k\}$ and that each arc not incident with $r_1, s_1, \dots, r_k, s_k$ is a loop at v. We may assume that each loop is oriented clockwise (since presently we are interested in undirected paths). For each loop l let X_l be the set of vertices in $r_1, s_1, \dots, r_k, s_k$ enclosed by l. Call loops l, l' *parallel* if $X_l = X_{l'}$. Trivially, there are at most 2^{2k} parallel classes. (By Euler's theorem, there are at most $4k$ parallel classes, but we do not need this stronger bound, since k is fixed.)

If Π satisfies (18), then there is a system Π' satisfying (18) such that $\psi_{\Pi'}$ is R-homologous to ψ_Π and such that the paths in Π do not contain any loop l with $X_l = \emptyset$ and do not contain $l'l^{-1}$ or $l^{-1}l'$ for any two parallel loops l, l'. So we can restrict the systems Π to systems having this additional property.

For any such system Π and any two subsets $B, C \subseteq \{a, a^{-1} | a \in A\}$, let $x_\Pi(B, C)$ denote the number of occurrences of bc in the paths in Π such that $b \in B, c \in C$. Then Π is up to R-homology fully determined by the system of numbers $x_\Pi(B, C)$, where B and C range over all sets

$$(20) \qquad \begin{array}{ll} L, L^{-1} & (L \text{ a parallel class of loops}), \\ \{(r_i, v)\}, \{v, s_i\} & (i = 1, \dots, k), \end{array}$$

with $L^{-1} := \{l^{-1} | l \in L\}$. Since each such number $x_\Pi(B, C)$ is at most $|A|$ and since there are at most $2(k+2^{2k})$ sets among (20), for fixed k we can enumerate all possibilities in polynomial time. □

3.4. The disjoint paths problem.

THEOREM 3.1. *For each fixed k, the k disjoint paths problem for directed planar graphs* (1) *is solvable in polynomial time.*

Proof. By Proposition 3.3 we can find in polynomial time (fixing k) a list of flows $\phi_1, \dots, \phi_N$ such that for each solution Π of (1), ψ_Π is R-homologous to at least one of the ϕ_j.

Now for each $j = 1, \dots, N$ we apply the algorithm of Proposition 3.2 to input ϕ_j. If for some j we find a solution Π of problem (1), we are done. If for each of $j = 1, \dots, N$ it concludes that there is no solution Π of (1) such that ψ_Π is R-homologous to ϕ_j, we may conclude that (1) has no solution at all. □

Quite directly one can extend the method to the following problem:

(21)
given : a directed planar graph $D = (V, A)$, k pairs $(r_1, s_1), \dots, (r_k, s_k)$ of vertices
of D, and subsets $A_1, \dots, A_k$ of A;
find : k pairwise vertex-disjoint directed paths $P_1, \dots, P_k$ in D, where P_i runs
from r_i to s_i and uses only arcs in $A_i (i = 1, \dots, k)$.

The polynomial-time solvability of this problem (for fixed k) follows by restricting in the proof of Proposition 3.2 each $\Gamma(a^*)$ to those g_i for which A_i contains a.

Acknowledgments. I am grateful to Coelho de Pina, Paul Seymour, and an anonymous referee for carefully reading the manuscript, for pointing out some inaccuracies, and for giving several helpful suggestions improving the presentation.

FINITE AUTOMATA COMPUTING REAL FUNCTIONS*

KAREL CULIK II† AND JUHANI KARHUMÄKI‡

Abstract. A new application of finite automata as computers of real functions is introduced. It is shown that even automata with a restricted structure compute all polynomials, many fractal-like and other functions. Among the results shown, the authors give necessary and sufficient conditions for continuity, show that continuity and equivalence are decidable properties, and show how to compute integrals of functions in the automata representation.

Key words. weighted finite automata, fractals, image generation, data compression

AMS subject classifications. 68Q45, 68Q99, 68U05, 68Q10

1. Introduction. We study weighted finite automata that are finite automata with transitions (edges in a diagram) labeled by real numbers. Such automata have already been extensively studied with various motivations; see, for example, [10] for a general definition and theoretical properties.

Historically, such devices were originally studied as probabilistic automata [12], first mainly as language acceptors like ordinary automata and later as devices defining a probability distribution on Σ^* with various application, for example, in learning theory [14]. As a quite different approach, attempts to generalize and at the same time to unify results of classical automata theory lead to the study of formal power series [13] that was based on weighted finite automata.

Recently, a new and different application of weighted finite automata was introduced in [3], where they were called probabilistic finite generators. They were used as a formal specification of grey-scale images as an alternative to the more analytical approach of [1]. Our theoretical work is motivated by these practical applications. The usefulness of this approach is demonstrated in [3], [5], [4]. Recent work [6] indicates that weighted finite automata are an excellent tool for data compression, especially in combination with wavelets.

We will concentrate mainly on weighted automata with special structures called level automata and line automata. However, even this special subset of weighted automata is powerful enough to generate all polynomials and many other interesting functions including many fractal-type functions.

We give the basic definitions and properties in §2. Our basic results, including the necessary and sufficient condition for a function $\hat{f}_A$ defined by level automaton A to be continuous, are shown in §3. This result is then used to show that it is decidable whether a given level automaton defines a continuous function. Further, we show that the problem whether two level automata define the same real function is decidable.

In §4 we study in detail the line automata of degree one that are weighted automata with two states that are interconnected in one direction only. Our main observation here is that the only smooth functions defined by the line automata of degree one are the constant and the linear functions but that such automata also define continuous fractal-type functions, that is, functions with self-similar graphs, including for example a function with a dense (or even uncountable) set of points where it does not have a derivative, and also functions that are not continuous.

Our main and surprising result in §5 is that all polynomials of one variable and degree up to n are defined by line automata with the same structure and weights (only the initial distribution determines a particular polynomial). For polynomials of more variables an analogous result holds for level automata that are weighted automata having only loops of length one.

In §6 we consider average preserving weighted automata that are such automata that for each node the sum of all weights at all transitions is equal to 2^d where d is the dimension, i.e., the space $[0, 1]^d$ is considered. We use the fact, shown in §3, that every weighted level automaton can be converted into an average preserving level automaton defining the same real function. Then we show a rather surprising result that for every level automaton A in one dimension we can easily construct a level automaton B such that $\hat{f}_B(x) = \int_0^x \hat{f}_A(t)\,dt$ for each $x \in [0, 1]$. For automata defining smooth functions we cannot only integrate but also mechanically compute derivatives.

2. Preliminaries. Let Σ be a finite alphabet and $\Sigma^\star$ the monoid generated by Σ. Elements of $\Sigma^\star$ are called words; in particular, the unit of $\Sigma^\star$ is called the empty word and denoted by ϵ. For a word u we denote its length by $|u|$, its prefix of length k by $\mathrm{pref}_k(u)$, and the number of letters a in u by $|u|_a$.

In this paper we are mainly concerned with (one-way) infinite words or ω-words over Σ. Formally, they can be viewed as mappings $\mathbb{N} \to \Sigma$ or, equivalently, as sequences $a_1a_2\ldots$ with $a_i \in \Sigma$. The set of all infinite words over Σ is denoted by Σ^ω. Clearly, the operator pref_k extends to Σ^ω as well. If there is no danger of confusion, we call infinite words simply words.

As is well known, each infinite word can be interpreted as a real number in the interval $[0, 1]$. We make use of this interpretation. When doing so we assume throughout this paper, if not stated otherwise, that Σ is binary, say $\Sigma = \{0, 1\}$. Hence, the infinite word

$$w = a_1a_2\ldots \quad \text{with } a_i \in \{0, 1\} \tag{1}$$

is interpreted as the number

$$\hat{w} = \sum_{i=1}^{\infty} a_i 2^{-i}. \tag{2}$$

Clearly, the only real numbers in $[0, 1]$ that have two representations (1) are those that have a finite representation (2), i.e., the numbers that have a finite binary representation. For such words the two representations are $v10^\omega$ and $v01^\omega$ for some finite v. We refer to the first one as the *standard* representation of the considered number and may write instead of $v10^\omega$ simply $v1$. It follows that the mapping $\wedge$:

$$\wedge : \Sigma^\omega \to [0, 1],\ \wedge(w) = \hat{w}$$

is one-to-one if and only if we restrict it to $\Sigma^\omega - \Sigma^\star 1^\omega$.

We also want to use infinite words to represent d-dimensional vectors in $[0, 1]^d$. Then we proceed as follows. First we present the ith component of the vector $x = (x_1, \ldots, x_d)$ as the binary ω-word $w_i \in \Sigma^\omega$. Then we make use of the inclusion

$$(\Sigma^d)^\omega \subseteq (\Sigma^\omega)^d$$

and say that x is represented by the ω-word

$$b_1b_2\ldots \quad \text{with } b_j = (a_{1j}, \ldots, a_{dj}),$$

where a_{ij} is the jth symbol of w_i. Consequently, the real vectors in $[0, 1]^d$ are represented by ω-words over the alphabet of size 2^d and not by d tuples of binary ω-words. From the point of view of automata theory this is a clear advantage. The notion of the standard representation obviously extends from numbers to vectors.

We now introduce our basic tool to define real functions, namely, that of a weighted finite automaton. A *weightedfinite automaton*, (WFA, for short) is a five-tuple $A = (Q, \Sigma, W, I, T)$, where

- Q is a finite set of *states* of the cardinality t,
- Σ is a finite *alphabet*,
- $W : Q \times \Sigma \times Q \to \mathbb{R}$ is a *weight function*,
- $I : Q \to \mathbb{R}$ is the *initial distribution*,
- $T : Q \to \mathbb{R}$ is the *final distribution*.

Clearly, the weight function W decomposes in a natural way to functions W_a for $a \in \Sigma$ and each W_a can be viewed as a $t \times t$ matrix over reals. We use the same notation W_a for these matrices. Consequently, if $W(p, a, q) = \alpha$, then the matrix W_a contains α at the entry of the row corresponding to the state p and of the column corresponding to the state q. As we shall see it is natural to view I as a row vector and T as a column vector. Note that weighted finite automata are called $(\mathbb{R} - \Sigma)$-automata in [10]. By the *underlying automaton* of a WFA A we mean the nondeterministic automaton whose transitions consist of those triples (p, a, q) for which $W(p, a, q) \neq 0$, and initial and final states are those that get nonzero value under I and T, respectively. Hence, we can talk about initial and final states of a WFA as well. This notion is used in the definition of our central notion of a level automaton.

As is well known, weighted finite automata can be used to compute functions $\Sigma^\star \to \mathbb{R}$, so-called $\mathbb{R}$-*rational* functions, as follows; cf. [10], [2], [13]. First, the *distribution* defined by $u \in \Sigma^\star$ on A, in symbols $P_A(u)$, is defined recursively:

$$\begin{aligned} P_A(\varepsilon) &= I, \\ P_A(va) &= P_A(v) \cdot W_a, \quad \text{for } v \in \Sigma^\star. \end{aligned}$$

Then the rational function determined by A, in symbols F_A, is defined by

$$F_A(u) = P_A(u) \cdot T.$$

Of course, the product here is the matrix product.

We want to use WFA to compute real functions on the interval $[0, 1]$ (or on the cube $[0, 1]^d$). This is achieved by extending the above word functions to infinite words corresponding to reals or to real vectors. Consequently, we now assume that $\Sigma = \{0, 1\}$ (or $\{0, 1\}^d$, possibly renamed). Then we say that A defines the *ω-word function*

$$(3) \qquad f_A : \Sigma^\omega \to \mathbb{R}, \qquad f_A(w) = \left(\lim_{n\to\infty} P_A(\mathrm{pref}_n(w))\right) \cdot T$$

and the *real function*

$$(4) \qquad \hat{f}_A : [0, 1] \to \mathbb{R}, \qquad \hat{f}_A(x) = f_A(w),$$

where w is the standard representation of x.

The definitions of f_A and $\hat{f}_A$ tacitly assume the existence of the limit in (3). We do not analyze this in detail here but instead study several special types of automata, which make these definitions mathematically sound (cf. §3) and at the same time are suitable for our results.

We call a WFA A a *level automaton* if and only if the following conditions are satisfied:

(i) The only loops in the underlying automata of A are transitions of the form $p \xrightarrow{a} p$.

(ii) $W(p, a, q) \geq 0$ for all $p, q \in Q, a \in \Sigma$.

(iii) For every $p \in Q$ the following holds. If there are $q \in Q,\ a \in \Sigma,\ q \neq p$ such that $W(p, a, q) \neq 0$ for some a, then $W(p, a, q) < 1$ for every $a \in \Sigma$ and $q \in Q$. If there are no such q and a, then $W(p, a, p) = 1$ for every $a \in \Sigma$.

(iv) $I \in \mathbb{R}_+^t$ and $T = \mathbb{R}_+^t$.

(v) The underlying automaton of A is reduced that is does not have useless states.

By condition (i) we can associate with each state of a WFA A a number called its *degree*, as follows:

- A state that leads in the underlying automaton only to itself is of degree 0.
- A state that is not of a degree smaller than i and leads in the underlying automaton only to states of degrees at most $i - 1$ or itself is of degree i.

Finally, a level automaton A is a *line* automaton if and only if for each number $0, \dots, \mathrm{card}(Q) - 1$ there exists exactly one state of this degree.

Several comments concerning the choice of conditions (i)–(v) are in order. Condition (i) strongly restricts the family of considered WFA. This, however, is needed in order to be able to handle WFA and, as we shall see, still gives a class large enough to yield interesting and surprising results. Conditions (ii) and (iv) mean that the functions F_A are $\mathbb{R}_+$-rational and not only $\mathbb{R}$-rational. The latter are more general than the former; cf. [2], [10], [13]. After (ii) and (iv) condition (iii) is natural: it guarantees that $\hat{f}_A$ is bounded, cf. Lemma 6. Finally, condition (v) is a standard one in automata theory. Concerning the choice of I and T we make the following conventions: *If not otherwise stated, we assume that* $I = (1, 0, \dots, 0)$ *and* $T = (1, 1, \dots, 1)$; however, as we shall see in the proof of Lemma 6 in a level automaton the final distribution $(1, 1, \dots, 1)$ can always be replaced by $(0, \dots, 0, 1)$ without affecting the function the automaton computes. In §5 we allow negative values of I in order to synthesize polynomials with negative coefficients easily.

To conclude we define two particular classes of WFA. We say that WFA A over $\{0, 1\}$ is 0-*faithful* (respectively 1-*faithful*) if and only if

$$\sum_{q \in Q} W(p, 0, q) = 1 \quad \text{for all } p \text{ in } Q$$

$$\left(\text{respectively} \quad \sum_{q \in Q} W(p, 1, q) = 1 \quad \text{for all } p \text{ in } Q\right).$$

Further, a WFA A over Σ^d, with $\Sigma = \{0, 1\}$, is *average preserving* if and only if

$$\sum_{q \in Q, a \in \Sigma} W(p, a, q) = 2^d \quad \text{for all } p \text{ in } Q.$$

These special classes of WFA have nice properties assuming that we have our standard choice $T = (1, 1, \dots, 1)$.

LEMMA 1. *If a* WFA A *is* 0-*faithful, then*

$$F_A(v) = f_A(v0^\omega) \quad \text{for all } v \text{ in } \Sigma^\star.$$

In other words, if $x \in [0, 1)$ *has a finite binary representation* v, *then* $F_A(v) = \hat{f}_A(x)$.

Proof. Straightforward by definitions. □

A similar result holds for 1-faithful WFA as well.

LEMMA 2. *If a* WFA A *is average preserving, then*

$$F_A(v) = \frac{1}{2^d} \sum_{a \in \Sigma^d} F_A(va) \quad \text{for all } v \in \Sigma^\star. \tag{5}$$

Proof. Again straightforward by definitions. □

Functions satisfying the condition of Lemma 2 are called *average preserving* functions (ap-functions, for short). The name is self-explanatory: its value at any point v (read: any pixel) is the average of its values on points va (read: its subpixels).

Average preserving functions $\Sigma^\star \to \mathbb{R}_+$ are closely related to *measures*, (cf. [1]), defined on Borel subsets of the complete metric space $(\Sigma^d)^\omega$ or $[0, 1]^d$, which are additive functions mapping the whole space X to 1, i.e., $\mu : (\Sigma^d)^\omega \to \mathbb{R}_+$ is a measure (called a normalized measure in [1]) if for each countable I and pairwise disjoint collection $\{A_i\}_{i\in I}$ of Borel subsets of $(\Sigma^d)^\omega$

$$\mu\left(\bigcup_{i\in I} A_i\right) = \sum_{i\in I} \mu(A_i) \tag{6}$$

and

$$\mu((\Sigma^d)^\omega) = 1.$$

Consequently, a measure function gives a weight (or greyness) for each (Borel) subset of X.

A WFA A satisfying

$$\sum_{p,q\in Q, a\in\Sigma} W(p,a,q) = 1,$$

defines a measure function μ_A on (Borel) subsets of $(\Sigma^d)^\omega$. Indeed, the automaton starting with the distribution $(1, 0, \ldots, 0)$ redistributes in an additive way the total amount of ink (equal to 1) to different pixels; the pixel addressed by the word v gets $F_A(v)$ amount of ink.

The connection between average preserving WFA and the measure defining WFA is straightforward due to (5) and (6). If A is an average preserving WFA, then by dividing each of its weights by 2^d we obtain a WFA that defines a measure function. The converse transformation is equally easy: weights must be multiplied by 2^d. However, this transformation does not necessarily preserve level automata; therefore, the limit in (3) might not exist and $\hat{f}(x)$ might be undefined.

3. Basic results. In this section we prove several basic results on WFA, in particular, on real functions defined by them. We state all the results for level automata only, although some of them are valid in general as well.

We start with closure properties.

LEMMA 3. *The family of real functions defined by level automata is closed under the operation of sum, product, and multiplication by a constant.*

Proof. For the first two operations the ordinary constructions of automata to recognize the union and the intersection work here as well. The closure under the last operation is due to the fact that we can multiply the initial distribution by a constant (so that here also a negative initial distribution must be allowed if the constant is negative). □

Our next representation is a straightforward consequence of the definitions.

LEMMA 4. *For each level automaton A there exists a finite number of line automata $A_1, \ldots, A_n$ such that $f_A = \sum_{i=1}^n f_{A_1}$.*

Our next lemma provides a normal form for level automata that turns out to be very important in § 6.

LEMMA 5. *For each level automaton A there exists an average preserving level automaton A_{ap} such that f_A and $f_{A_{\mathrm{ap}}}$ coincide.*

Proof. We prove the lemma only in case $\Sigma = \{0, 1\}$; the general proof is similar. Since each level automaton can be decomposed into a finite number of line automata, we may assume that A is a line automaton. Let its degree be t. Consequently, for $i = 0, \ldots, t$, there exists exactly one state of degree i, say q_i. Let us fix i and set

$$k = \frac{2 - W(q_i, 0, q_i) - W(q_i, 1, q_i)}{\sum_{p \neq q_i} W(q_i, 0, p) + \sum_{p \neq q_i} (q_i, 1, p)}. \tag{7}$$

Now, we will modify A to obtain the automaton A' as follows:

(i) The weight of each nonloop transition starting from q_i is multiplied by k.

(ii) If $i < t$, then the weight of each nonloop transition ending at q_i is multiplied by k^{-1}, otherwise $I(q_i)$ is multiplied by k^{-1}.

By (7), k is positive and chosen in such a way that the condition for q_i to be average preserving is satisfied.

We have to analyze the effects of the above modification to the computations of A. Let w be an arbitrary ω-word and w_n its prefix of length n. Assuming as above that the states of A and A' are ordered from q_t to q_0, we define

$$a_n(j) = P_A(w_n) \cdot \eta_j \quad \text{for } j = 0, \ldots, t$$

and

$$a'_n(j) = P_{A'}(w_n) \cdot \eta_j \quad \text{for } j = 0, \ldots, t,$$

where η_j is the vector having 1 as the jth component and 0 elsewhere.

Then it follows from the facts that A and A' are level automata and from the modifications (i) and (ii) that

$$\begin{aligned} a_n(j) &= a'_n(j) \quad \text{for } j > i, \\ a_n(i) &= \frac{1}{k} a'_n(i), \\ a_n(j) &= a'_n(j) \quad \text{for } j < i. \end{aligned}$$

Consequently (for details cf. (i)–(iii) in the proof of Lemma 6) we have

$$f_A(w) = f_{A'}(w)\,. \tag{8}$$

Note, however, that $F_A(w_n) \neq F_A(w_n)$ unless $k = 1$.

Now, the result follows easily. Since the state of degree 0 satisfies, by the definition of a level automaton, the average preserving condition, we first do the above modification to the state of degree 1. Then we repeat the process in the new automaton for the state of degree 2 and so on. Observe that in the last stage when doing (ii) we change the initial distribution from $(1, 0, \ldots, 0)$ to $(k^{-1}, 0, \ldots, 0)$. The automaton A_{ap} thus obtained is clearly average preserving, and moreover by (8), $f_{A_p} = f_A$. □

Lemma 5 deserves a few comments. On one hand, we have a normal form for functions on Σ^ω, or equivalently on $[0, 1]^d$, defined by level automata. On the other hand, Lemma 2 shows that average preserving automata define only the average preserving functions on $\Sigma^\star$, hence clearly not all the functions on $\Sigma^\star$ defined by level automata.

The proof of Lemma 5 was based on the idea of multiplying certain weights by suitable numbers in order to make a particular state to fulfill the average preserving condition. Another technique would be to increase the weights of some transitions by adding a constant to these weights. This addition can be compensated by changing the initial distribution at the state considered. In fact, it may get a negative value. We leave the details to the reader. We only note that by this method we can for any level automaton A find an average preserving level automaton A_{ap} defining the same real function as A. Similarly, we can show that any level automaton can be replaced by a 0- or 1-faithful automaton defining the same real function.

The next three lemmas deal with the continuity of the functions $\hat{f}_A$, where A is a given level automaton.

LEMMA 6. *The value $f_A(w)$ is defined* (*and finite*) *for each $w \in \{0, 1\}^\omega$. Consequently, $\hat{f}_A$ is continuous at any point x having only an infinite binary representation.*

Proof. Let A be a level automaton of degree t. Since A can be decomposed into a finite number of line automata of degree at most t, we can actually assume that A is a line automaton. Further, we can assume that its initial distribution is $(1, 0, 0, \ldots, 0)$ and that the ith component of this vector corresponds to the state of degree $t + 1 - i$ for $i = 1, \ldots, t + 1$. Let η_i be the $(t + 1)$-dimensional column vector such that its ith component equals to 1 and others to 0.

We define a new line automaton $A_{\max}$ of degree t as follows. Let α equal the maximum of the weights of the loops of the states having positive degree in A and β equal the total maximum of weights of A. Then in $A_{\max}$ all the loops at the states of a positive degree have the weight α, the loops at the state of degree 0 have the weights 1, and all the other weights equal β, in particular different from 0. Clearly, $A_{\max}$ is a well-defined line automaton and

$$0 \le P_A(u) \cdot \eta_i \le P_{A_{\max}}(u) \cdot \eta_i, \quad \text{for } i = 1, \ldots, t+1 \text{ and } u \in \Sigma^\star. \tag{9}$$

We prove that for any given $w \in \{0, 1\}^\omega$

$$\lim_{n\to\infty} P_A(\mathrm{pref}_n(w)) \cdot \eta_i = 0 \quad \text{for } i = 1, \ldots, t \tag{10}$$

and

$$\lim_{n\to\infty} P_A(\mathrm{pref}_n(w)) \cdot \eta_{t+1} \text{ exists.} \tag{11}$$

This clearly implies the first sentence of the lemma (and shows also that we can instead of the final distribution of the form $(1, \ldots, 1)$ use the distribution η_{t+1}).

To conclude (10) it is, by (9), enough to prove this for the automaton $A_{\max}$. This, in turn, is seen as follows. Define, for $i = 1, \ldots, t + 1$

$$a_n(i) = P_{A_{\max}}(\mathrm{pref}_n(w)) \cdot \eta_i \quad \text{for } n \ge 0.$$

Clearly, for all $n \ge 0$, we have

$$\begin{aligned} a_{n+1}(0) &= \alpha a_n(0), \\ a_{n+1}(j) &= \alpha a_n(j) + \beta(a_n(j-1) + \cdots + a_n(0)), \quad \text{for } j \le t, \\ a_{n+1}(t+1) &= a_n(t+1) + \beta(a_n(t) + \cdots + a_n(0)). \end{aligned}$$

It follows that

(i) $\lim_{n\to\infty} a_n(0) = 0$,
(ii) $\lim_{n\to\infty} a_n(j) = 0$ for $j \le t$, and
(iii) the sequence $(a_n(t+1))_{n\ge 0}$ is bounded.

Now, (10) follows from (i), (ii), and (9). To conclude (11) we first note that the sequence $(P_A(\mathrm{pref}_n(w)) \cdot \eta_{t+1})_{n\ge 0}$ is monotonous, and hence the limit exists by (9) and (iii).

The second sentence is a straightforward consequence of the first and its above proof. In particular, the fact implied by (9) and (iii) that f_A is a bounded function is needed. We leave the details to the reader. □

COROLLARY 1. *Let A be a level automaton. Then $\hat{f}_A$ is continuous if and only if it is continuous at the points that have a finite binary representation.*

Our next example shows that $\hat{f}_A$ can be noncontinuous at all points having a finite binary representation; cf. also Example 4 in §4.

Example 1. Consider the automaton A shown in Fig. 1. Observe that it slightly violates condition (ii) in the definition of the level automaton.

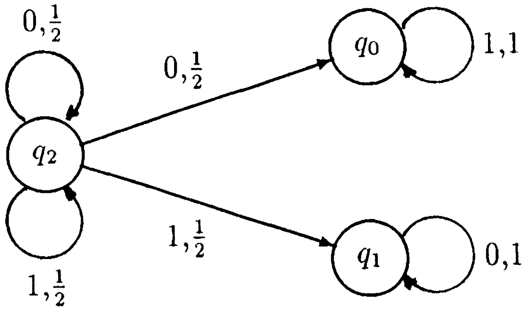

FIG. 1. *Automaton A of Example* 1.

Assume that the state q_2 is initial and q_0 and q_1 are final. Then

$$f_A(v01^\omega) = 2^{-|v|-1} = f_A(v10^\omega) \quad \text{for each } v \text{ in } \Sigma^\star$$

and

$$f_A(w) = 0 \quad \text{for each } w \text{ in } \Sigma^\omega.$$

Consequently, $\hat{f}_A$ is continuous exactly at those points that have only infinite binary representations. The graph of $\hat{f}_A$ is shown in Fig. 2.

Our next lemma shows that the obvious necessary condition for $\hat{f}_A$ to be continuous at the point 1/2 is also sufficient.

LEMMA 7. *The function $\hat{f}_A$ is continuous at the point* 1/2 *if and only if*

$$f_A(01^\omega) = f_A(10^\omega).$$

Proof. The necessity is obvious. The sufficiency follows from the proof of Lemma 6, in particular, that of the second sentence. □

LEMMA 8. *Let $x \in (0,1)$ have a finite binary representation, say, x is represented by the ω-words $v10^\omega$ and $v01^\omega$. Then $\hat{f}_A$ is continuous at x if and only if $\hat{f}_{A_v}$ is continuous at* 1/2 *where A_v is the WFA A with the initial distribution $P_A(v)$.*

Proof. Obvious by Lemma 7 and the identity

$$P_A(vu) = P_{A_v}(u) \quad \text{for all } u \text{ in } \Sigma^\star. \qquad □$$

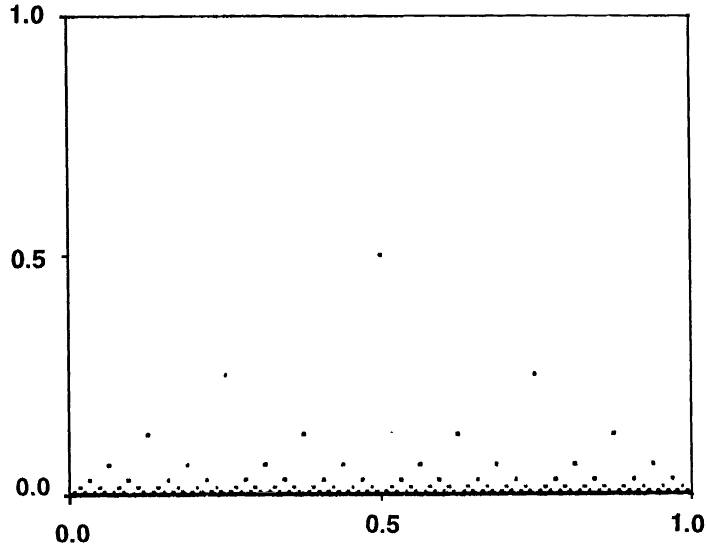

FIG. 2. *The graph of* $\hat{f}_A$ *of Example* 1.

By Lemma 8 we reduced the question of the continuity of a given $\hat{f}_A$ at a point with a finite binary representation to the same question at the point 1/2 of another function that is defined by the *same* automaton but different initial distribution. Typically, functions defined by level automata are continuous at 1/2 if and only if they are continuous at points having finite binary representations. However, this is not true in general as shown by the following example.

Example 2. Consider any level automaton A with initial state q_t and final state q_0 defining a noncontinuous function. Extend A to A' by adding to A a new state q_{t+1} and transitions

$$q_{t+1} \xrightarrow{0,1} q_t \quad \text{and} \quad q_{t+1} \xrightarrow{1,\hat{f}_A(1)} q_0.$$

Then clearly A' with the initial and final states q_{t+1} and q_0, respectively, defines the function that is continuous at 1/2 but not everywhere.

Our next example shows that even the very same level automata can define continuous and discontinuous functions depending on the initial distribution.

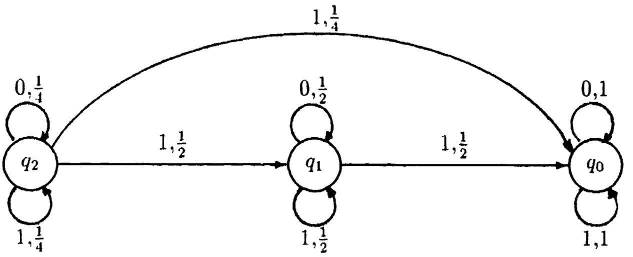

FIG. 3. *Line automaton A of Example* 3.

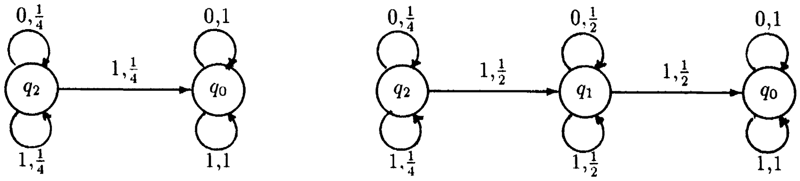
Example 3. Consider the line automaton A with the initial distribution $(1, 0, 0)$ shown in Fig. 3. As we shall see in §5, $\hat{f}_A(x) = x^2$ and thus $\hat{f}_A$ is continuous. However, A decomposes into two level automata, A_1 and A_2, shown in Fig. 4 in such a way that they



Automaton A_1

Automaton A_2

FIG. 4.

define noncontinuous functions at points having finite representations; cf. §4. Consequently, the level automaton A_3 shown in Fig. 5 is an example of such an automaton that with the initial distribution $(1, 0, 0, 0, 0)$ defines a continuous function and with the initial distribution $(0, 1, 0, 0, 0,)$ defines a noncontinuous function.

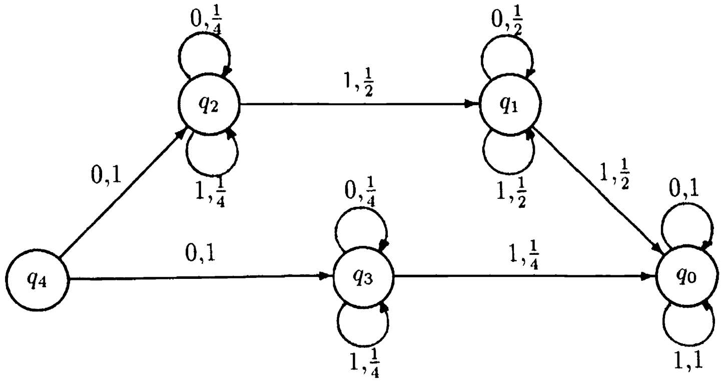


FIG. 5. *Automaton A_3.*

The above lemmas and examples show that although we can characterize the continuity of $\hat{f}_A$ at the point having a finite binary representation (or, in fact, at any point) in terms of the continuity of the very related function at the point $1/2$, it is not possible to characterize the continuity of $\hat{f}_A$ in terms of its continuity at the point $1/2$. However, our results allow us to prove the following important result.

THEOREM 1. *For a given level automaton A with rational weights it can be decided whether or not $\hat{f}_A$ is continuous.*

Proof. Assume that A has t states. Consider the set

$$X = \{P_A(v) \mid v \in \Sigma^\star\} \subseteq \mathbb{R}_+^t.$$

Let B be a base of the vector space over $\mathbb{R}$ generated by X. Clearly, its dimension is at most t, and such a base can be found effectively as follows. Consider a lexicographic order of $\Sigma^\star : u_0 = \varepsilon, u_1, u_2, \ldots$. Check systematically whether $P_A(u_i)$ is linearly independent of the vectors $P_A(u_j)$, $j < i$, as long as for some $k \geq 0$ no $u_i, i > k$, is linearly independent. Let the maximal set of linearly independent words thus obtained be $v_1, \ldots, v_s$. Then we can choose $B = \{P_A(v_i) | i = 1, \ldots, s\}$. For $i = 1, \ldots, s$ let A_i be the automaton A with the initial distribution $P_A(v_i)$.

CLAIM. *$\hat{f}_A$ is continuous if and only if each of the functions $\hat{f}_{A_i}$ for $i = 1, \ldots, s$ is continuous at the point $1/2$.*

Proof of the claim. If $\hat{f}_A$ is continuous, then in particular it is continuous at points represented by the words $v_i 10^\omega$ for $i = 1, \dots, s$. Now, the continuity of $\hat{f}_{A_i}$ at the point 1/2 follows since $f_A(v_i w) = f_{A_i}(w)$ for all $i = 1, \dots, s$ and $w \in \{0, 1\}^\omega$.

Conversely, assume that each of the functions $\hat{f}_{A_i}$ is continuous at the point 1/2. By Lemma 6, it is enough to show that $\hat{f}_A$ is continuous at an arbitrary point x having a finite binary representation, say, x is represented by $v10^\omega$. Now, by the choice of B there exist numbers α_i, for $i = 1, \dots, s$, such that

$$P_A(v) = \sum_{i=1}^{s} \alpha_i P_A(v_i),$$

implying that

$$f_A(vw) = \sum_{i=1}^{s} \alpha_i f_{A_i}(w).$$

This, however, by our assumption and Lemmas 7 and 8, proves that f_A is continuous at the point x. This completes the proof of the claim.

In order to finish the proof of Theorem 1, we have to show how to decide, for a given level automaton A, whether $\hat{f}_A$ is continuous at the point 1/2 or, equivalently, to decide whether the following identity holds true:

$$f_A(10^\omega) = f_A(01^\omega).$$

This can be equivalently stated as the question whether

$$\lim_{n\to\infty} (F_A(10^n) - F_A(01^n) \doteq 0$$

or whether

$$\lim_{n\to\infty} \pi \begin{pmatrix} W_0 & \Theta \\ \Theta & -W_1 \end{pmatrix}^n \eta = 0, \tag{12}$$

where W_0 and W_1 are the matrices of A associated to letter 0 and 1, Θ is the zero matrix of the appropriate size, π is the vector whose first half is equal to the distribution $\pi_1 W_1$ and the second half to $\pi_1 W_0$, and η is the vector whose both halves are equal to the final distribution of A.

The validity of (12) is easy to test. Indeed, since the matrices involved are upper triangular, their eigenvalues are directly visible and hence a formula for the number $F_A(01^n) - F_A(10^n)$ can be computed. It is of the form

$$\Sigma_i P_i(n)\rho_i^n,$$

where P_i's are polynomials and ρ_i's are the weights of the loops of A. This completes the proof of Theorem 1. □

Observe that the claim in the proof of Theorem 1 provides a characterization of the continuity of $\hat{f}_A$.

As the second important result we prove the following.

THEOREM 2. *It can be decided whether two given level automata with rational weights define the same real function.*

Proof. For 0-faithful level automata this follows straightforwardly from the Equality Theorem of Eilenberg [10]. Indeed, for such two automata A_1 and A_2 we have

$$(13) \qquad F_{A_i}(u) = f_{A_i}(u0^\omega) \quad \text{for } i = 1, 2,$$

and hence the problem to decide the equivalence of the functions $\hat{f}_{A_i}$ and $\hat{f}_{A_2}$ on numbers having a finite binary representation reduces, by the Equality Theorem, to the question of testing whether

$$(14) \qquad F_{A_1}(u) = F_{A_2}(u),$$

for words u of length at most the sum of the numbers of the states of A_1 and A_2. Of course, this can be done. Finally, the same test reveals, by Lemma 6, whether the identity

$$f_{A_1}(w) = f_{A_2}(w)$$

holds true for all ω-words w as well.

If A_1 and A_2 are not 0-faithful, then the above proof has to be modified as follows. Now, we first decide whether

$$(15) \qquad f_{A_1}(u0^\omega) = f_{A_2}(u0^\omega) \quad \text{for all } u \in \{0, 1\}^\star.$$

This is reduced, as in the Equality Theorem, using the very same idea as in the proof of Theorem 1, to test (15) on a finite number of words u only. Hence, the considerations at the end of Theorem 1 guarantee that we can decide whether (15) holds true, that is whether

$$(16) \qquad \hat{f}_{A_1}(x) = \hat{f}_{A_2}(x) \quad \text{for all } x \text{ having a finite representation.}$$

But then as above, by Lemma 6, we can also test whether (16) holds true for all x in $[0, 1]$. □

4. Line automata of degree one. In this section we investigate functions defined by WFA of the form shown in Fig. 6, where all the weights are positive and the initial and final distributions are $(1, 0)$ and $(1, 1)$, respectively. We want A to define a bounded function $\hat{f}_A : [0, 1] \to \mathbb{R}$. Consequently, the weights α, β, ζ and δ are at most 1. On the other hand, if all of them are smaller than 1, then A defines the zero-function. Therefore, we assume that $0 \leq \alpha, \beta, \zeta, \delta \leq 1$ and some of them equal to 1. The most natural case is that $\varepsilon = \delta = 1$, which corresponds to the case of line automata of degree 1. We shall analyze this case in detail.

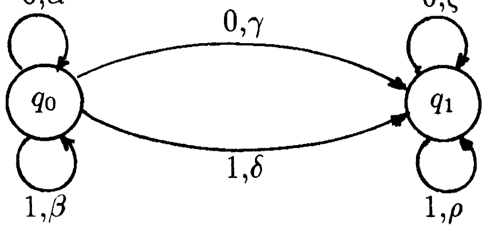

FIG. 6. *A general* WFA *A of* §4.

We propose two questions:

(I) Under which conditions is $\hat{f}_A$ continuous?

(II) Under which conditions is $\hat{f}_A$ *smooth*, that is, have all derivatives?

In order to answer (I) we start to consider the continuity at point 1/2. Since 1/2 has the representations 01^ω and 10^ω, we must have

$$f_A(01^\omega) = f_A(10^\omega). \tag{17}$$

Now, $P_A(01^n) = (\alpha\beta^n, \alpha\delta \sum_{i=0}^{n-1} \beta^i + \gamma)$ so that if $\beta < 1$, we obtain

$$\begin{aligned} f_A(01^\omega) &= \lim_{n\to\infty} \left(\alpha\beta^n + \alpha\delta \sum_{i=0}^{n-1} \beta^i + \gamma\right) \\ &= \alpha\delta\frac{1}{1-\beta} + \gamma. \end{aligned} \tag{18}$$

Similarly assuming that $\alpha < 1$ we have

$$f_A(10^\omega) = \beta\gamma\frac{1}{1-\alpha} + \delta.$$

Hence, (17) yields the condition

$$\alpha\delta\frac{1}{1-\beta} + \gamma = \beta\gamma\frac{1}{1-\alpha} + \delta \tag{19}$$

or, equivalently,

$$(\alpha+\beta-1)(\delta(1-\alpha)-\gamma(1-\beta)) = 0.$$

It follows that under the assumption $\alpha, \beta < 1$ the continuity of $\hat{f}_A$ at 1/2 requires that one of the following two conditions is satisfied:

(i) $\alpha + \beta = 1$,

(ii) $\delta(1-\alpha) = \gamma(1-\beta)$.

These considerations can be reversed by Lemma 7 or straightforward calculations based on the implication: If $P_A(v) = (A, B)$, then $P_A(v0) = (\alpha A, \gamma A + \zeta B)$ and $P_A(v1) = (\beta A, \delta A + \rho B)$. Consequently, conditions (i) and (ii) (under the assumption $\alpha, \beta < 1$) characterize the continuity of $\hat{f}_A$ at the point 1/2.

The continuity of $\hat{f}_A$ at the point x that has a finite binary representation $v1$ can be analyzed by considering instead of (17) the condition

$$f_A(v01^\omega) = f_A(v10^\omega). \tag{20}$$

Now, if $P_A(v) = (A, B)$, then (19) can be written as

$$A(\alpha\delta\,\frac{1}{1-\beta} + \gamma) + B = A(\beta\gamma\,\frac{1}{1-\beta} + \gamma) + B, \tag{21}$$

which is equivalent to (18), since clearly $A > 0$. Consequently, the continuity of $\hat{f}_A$ at x is characterized by exactly the same conditions as that at 1/2, namely, (i) and (ii).

The continuity of $\hat{f}_A$ at the point x that does not have a finite binary representation follows from Lemma 6.

All in all, we have established the following.

THEOREM 3. *The automaton A with $0 \leq \alpha, \beta < 1$, $0 \leq \gamma, \delta$, and $\zeta = \rho = 1$ defines a continuous function $\hat{f}_A$ if and only if either* (i) *or* (ii) *holds true.*

Observe that conditions (i) and (ii) are not exclusive and that the first condition does not give any restriction for γ and δ, while the second one fixes their ratio. We shall see in a moment that (ii) gives only constant functions. Condition (i), in turn, gives both linear functions and something that can be called fractal-type functions.

In order to complete the analysis of the continuity of $\hat{f}_A$ we have to consider the excluded cases $\alpha = 1$ or $\beta = 1$. If $\beta = 1$, then in order to keep $\hat{f}_A$ bounded, necessarily $\alpha = 0$ or $\delta = 0$. In the first case (19) can be rewritten as $\gamma = \gamma + \delta$ so that $\delta = 0$, and hence $\hat{f}_A(1) = 1$ and $\hat{f}_A(x) = \gamma$ for $x < 1$. In the second case (19) can be rewritten as $\gamma = \gamma(1-\alpha)^{-1}$, so that $\alpha = 0$, and we are back in the first case. Finally, if both $\beta = 1$ and $\alpha = 1$, then, as above, we have $\gamma = \delta = 0$, and hence $\hat{f}_A$ is the constant function $\hat{f}_A = 1$.

In the above we completely answered question (I) (in the case $\zeta = \rho = 1$). Now, we turn to consider question (II), and we can restrict our considerations to the case when $\alpha, \beta < 1$.

Let us assume that $\hat{f}_A$ is smooth, in particular, that it has a derivative at the point $1/2$. This means that the limits

$$\lim_{n\to\infty} \frac{f_A(10^\omega) - f_A(01^n0^\omega)}{2^{-(n+1)}}$$

and

$$\lim_{n\to\infty} \frac{f_A(10^n1^\omega) - f_A(01^\omega)}{2^{-(n+1)}}$$

exist and are equal.

We already computed that

$$f_A(01^\omega) = \alpha\delta\frac{1}{1-\beta} + \gamma.$$

Further, we obtain (cf. (18) and (21)).

$$f_A(01^n0^\omega) = \alpha\beta^{n-1}\left(\alpha\delta\frac{1}{1-\beta} + \gamma\right) + \alpha\delta\sum_{i=0}^{n-2}\beta^i + \gamma.$$

Therefore, recalling that we are working under the assumption that $\hat{f}_A$ is continuous, we obtain

$$(22) \qquad \lim_{n\to\infty} \frac{f_A(10^\omega) - f_A(01^n0^\omega)}{2^{-(n+1)}}$$

$$= \lim_{n\to\infty} 2^{n+1}\left(\alpha\delta\frac{\beta^{n-1}}{1-\beta} - \alpha^2\delta\frac{\beta^{n-1}}{1-\beta} - \alpha\gamma\beta^{n-1}\right)$$

$$= \begin{cases} 0 & \text{if (i) is satisfied and } \beta < 1/2, \\ 4\alpha((2-2\alpha)\delta - \gamma) & \text{if (i) is satisfied and } \beta = 1/2, \\ 0 & \text{if (ii) is satisfied,} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Similarly,

$$(23)\qquad \lim_{n\to\infty} \frac{f_A(10^n1^\omega) - f_A(01^\omega)}{2^{-(n+1)}}$$

$$= \begin{cases} 0 & \text{if (i) is satisfied and} \, \alpha < 1/2 \, , \\ 4\beta(\delta - (2-2\beta)\gamma) & \text{if (i) is satisfied and} \, \alpha = 1/2 \, , \\ 0 & \text{if (ii) is satisfied ,} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

As in the case of continuity, the above considerations can be extended from point 1/2 to any point having a finite binary representation. Then in formulas (4) and (23) the right-hand sides are replaced by constant multiples of those in (4) and (23); cf. considerations in obtaining (21). Whether $\hat{f}_A$ has derivatives at the points that do not have a finite binary representation is discussed later.

Now, we determine the existence of the derivative of $\hat{f}_A$ at the point 1/2 (or equivalently at any point with a finite binary representation). We have two main cases depending on which of the continuity conditions (i) and (ii) is satisfied.

Case I. Condition (i) holds true. There are three subcases.

(a) $\beta < 1/2$. Now, either (ii) is satisfied as well or $\alpha > 1/2$ and the fourth alternative of (23) takes place. The first possibility is treated in Case II. In the second possibility the derivative (in fact, also the right derivative) of $\hat{f}_A$ at 1/2 is undefined.

(b) $\beta = 1/2$, and hence also $\alpha = 1/2$. Now, the left and right derivatives of $\hat{f}_A$ at 1/2 equal $2(\delta - \gamma)$ and hence

$$(24)\qquad \hat{f}'_A(1/2) = 2(\delta - \gamma).$$

Observe that this is consistent with the possibility that (ii) also holds true. Namely, then $\gamma = \delta$ and so (8) yields $\hat{f}'_A(1/2) = 0$ as it should by the third lines of (4) and (23). Now, the automaton is of the form shown in Fig. 7.

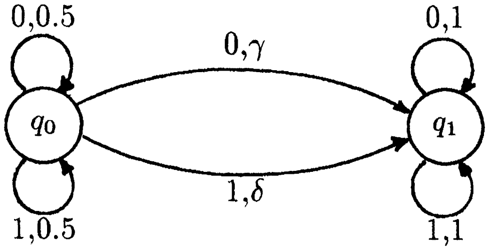

FIG. 7. *Automaton* A_1.

Since (24) holds true not only at 1/2 but also at any point having a finite binary representation, it strongly supports that $\hat{f}_A$ is a linear function. This can be confirmed easily from the form of the WFA, which at the same time proves that (24) holds true for all x in (0, 1). Indeed, we claim that

$$\hat{f}_A(x) = 2(\delta - \gamma)x + 2\gamma \quad \text{for}\, x \in [0, 1].$$

Let $w = a_1a_2\ldots$ be the standard binary representation of the number x in [0, 1], i.e.,

$$x = \sum_{i=1}^{\infty} a_i 2^{-i} \quad \text{with}\, a_i \in \{0, 1\}.$$

Then clearly,

$$\begin{aligned} f_A(w) &= \delta \sum_{a_i=1} 2^{-i+1} + \gamma \sum_{a_i=0} 2^{-i+1} \\ &= \delta \sum_{a_i=1} 2^{-i+1} - \gamma \sum_{a_i=1} 2^{-i+1} + \gamma \sum_{i=1}^{\infty} 2^{-i+1} \\ &= 2\delta x - 2\gamma x + 2\gamma, \end{aligned}$$

which proves the claim.

(c) $\beta > 1/2$ and (ii) is satisfied. This is symmetric to the second possibility of Case I(a).

Case II. Condition (ii) holds true. Now, the automaton, say A_2, is of the form shown in Fig. 8, where the case of $\alpha = 0$ is allowed. Using the method of Case I(b) one easily concludes that

$$\hat{f}_{A_2}(x) = 2\delta \quad \text{for all } x \text{ in } [0, 1].$$

Observe that this again is consistent with our computed value of the derivative of $\hat{f}_A$ at $1/2$. As a conclusion of the above we have proved:

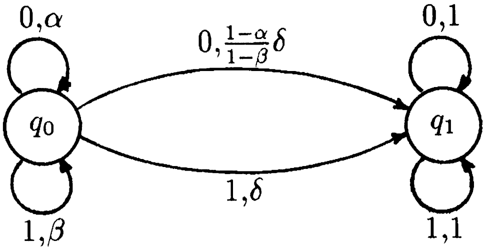

FIG. 8. *Automaton* A_2.

THEOREM 4. *The function* $\hat{f}_A$ *defined by the* WFA A *of Fig.* 6 *is smooth if and only if it is linear. Moreover, such a function is not a constant if and only if* $\alpha = \beta = 1/2$ *and* $\gamma \neq \delta$.

Actually, we proved a stronger result, as seen in the following theorem.

THEOREM 5. *The function* $\hat{f}_A$ *defined by the* WFA A *of Fig.* 6 *has the derivative at the point* $1/2$ *if and only if it is a linear on the interval* $(0, 1)$.

We have completely characterized both continuous and smooth functions defined by automaton A. Most typically, such functions are not continuous like the one given in Example 4, and they are smooth only in very exceptional cases as shown by Theorem 4. What is most interesting is that there exist such functions that are continuous but not smooth. As we saw such functions do not possess a derivative at any point having a finite binary representation. We analyze such functions in more details in Example 5.

Example 4. The choice $\alpha = 1/2$, $\beta = 1/4$, $\gamma = 1$, and $\delta = 0$ in the automaton of Fig. 6 gives an example of a noncontinuous function, in fact, of the function that is not continuous at any point having a finite binary representation. Its graph is illustrated in Fig. 9.

Example 5. Let us analyze the function defined by the automaton B shown in Fig. 10.

Let the initial and final distributions of B be the standard ones, $(1, 0)$ and $(1, 1)$. Then for any finite word u

$$P_B(u) = (a(u), b(u)), \tag{25}$$

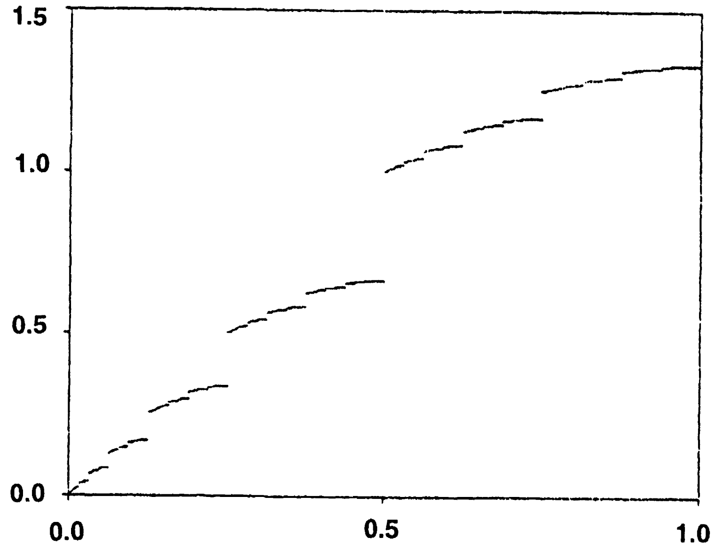

FIG. 9. *The graph of the* WFA *of Example* 4.

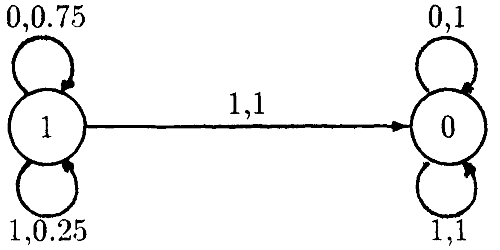

FIG. 10. *Automaton B of Example* 5.

where

$$a(u) = \frac{3^{|u|_0}}{4^{|u|}} \tag{26}$$

and $b(u)$ is defined recursively on prefixes v of u as follows:

$$\begin{aligned} b(\varepsilon) &= 0 \\ b(vt) &= \begin{cases} b(v) & \text{if } t = 0, \\ b(v) + a(v) & \text{if } t = 1. \end{cases} \end{aligned} \tag{27}$$

By our general considerations $\hat{f}_B$ is continuous; cf. Fig. 14 showing its graph. Moreover, the above formulas show that it is monotonous and for any $w \in \{0, 1\}^\omega$

$$\hat{f}_B(w) = \lim_{n \to \infty} b(w_n), \tag{28}$$

where w_n denotes the prefix of w of the length n.

We consider the derivability of $\hat{f}_B$ in two particular points:

$$\begin{aligned} w_1 &= (01)^\omega, \quad \text{and} \\ w_2 & \quad \text{satisfying for each prefix u of } w_2, |u|_0 \geq 2|u|_1. \end{aligned}$$

The existence of the derivative at $\hat{w}_1$ is concluded as follows. First we calculate that

$$\begin{aligned} f_B(w_1) &= \tfrac{3}{4} \textstyle\sum_{i=0}^{\infty} (\tfrac{1}{4} \cdot \tfrac{3}{4})^i = \tfrac{3}{4} \cdot \tfrac{16}{13} = \tfrac{12}{13}, \\ f_B((01)^{n-1}0^\omega) &= \tfrac{12}{13}(1 - (\tfrac{3}{16})^{n-1}) = \tfrac{12}{13} - \tfrac{12}{13}(\tfrac{3}{16})^{n-1}, \\ f_B((01)^{n-1}1^\omega) &= \tfrac{12}{13}(1 - (\tfrac{3}{16})^{n-1}) + \tfrac{4}{3} \cdot (\tfrac{3}{16})^{n-1} = \tfrac{12}{13} + \tfrac{16}{39}(\tfrac{3}{16})^{n-1}. \end{aligned}$$

Therefore, by the monotonicity of $\hat{f}_B$, for any $w = (01)^{n-1}w'$ we have

$$|f_B(w_1) - f_B(w)| \leq \tfrac{16}{39}(\tfrac{3}{16})^{n-1}.$$

But these w's are exactly those that satisfy $|\hat{w} - \hat{w}_1| \leq 4 \cdot 4^{-n}$ and hence $\hat{f}'_B(\hat{w}_1) = 0$.

The nonexistence of the derivative at the point $\hat{w}_2$ is seen as follows. If w_2 contains ultimately only 1's, our earlier general considerations apply. Otherwise we consider the word $w_2(n)$ that is obtained from w_2 by changing the nth symbol from 0 to 1 assuming that it is originally 0. Then

$$|\widehat{w_2(n)} - \hat{w}_2| = 2^{-n}.$$

Moreover, by formulas (25), (27), and (28), we conclude that

$$f_B(w_2(n)) - f_B(w_2) \geq a(\text{pref}_{n-1}(w_2)),$$

and hence, by (26) and the special form of w_2, we have

$$f_B(w_2(n) - f_B(w_2) \geq \frac{3^{2/3n}}{4^n}.$$

Consequently,

$$\frac{f_B(w_2(n)) - f_B(w_2)}{\widehat{w_2(n)} - \hat{w}_2} \geq 2^n(\frac{\sqrt[3]{2}}{4})^n > (1,03)^n,$$

which proves our claim.

As a conclusion we note that $\hat{f}_B$ is an example of a continuous function that is not at all smooth. Indeed, the set of points where it does not have a derivative is not only dense but also uncountable. Observe also that our choice for the decomposition $\alpha + \beta = 1$ is not essential.

5. Generation of polynomials. In the previous section we analyzed what it means for a function defined by a WFA to have certain regularity properties. As a byproduct we concluded that all linear functions (in the interval [0, 1]) are definable by very simple two-state WFA, which is by the line automata of degree one. Here we take a synthesizing approach and show that all polynomials in one or several variables can be defined as functions of WFA.

THEOREM 6. *For each polynomial $P(x)$ with nonnegative coefficients and of degree n there exists a line automaton A_n of degree n such that $f_{A_n}(x) = P(x)$ for all x in* [0, 1].

The restriction of coefficients can be dropped if negative values in the initial distribution are allowed.

Proof. We first prove the result for powers of x, that is, for polynomials of the form x^n. For these we prove an even stronger result:

CLAIM. The polynomial x^n, for $n \geq 0$, can be defined by a line automaton A_n of degree n of the following form: The initial and final distributions of A_n are $(1, 0, \ldots, 0)$ and $(1, 1, \ldots, 1)$, and denoting by $\{q_n, \ldots, q_0\}$ the state set of A_n the transitions are

(i) $q_i \xrightarrow{j,2^{-i}} q_i$, for $j = 0, 1$ and $i = 0, \ldots, n$,

(ii) $q_i \xrightarrow{1,q^{-i}\binom{i}{t}} q_{i-t}$ for $i = 1, \ldots, n$ and $t = 1, \ldots, i$.

Proof of the claim. For $n = 0$ the claim is trivial, and for $n = 1$ it was established in the previous section. Indeed, function x is defined by the automaton shown in Fig. 11 with standard initial and final distributions. Assume now inductively that the claim has been proved for a fixed n. For $n + 1$ the automaton A_{n+1} is of the form shown in Fig. 12.

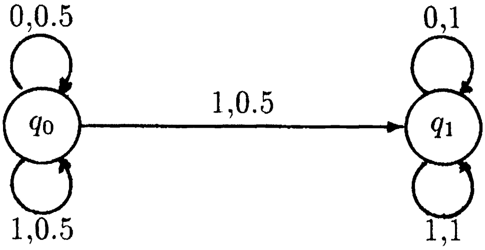

FIG. 11. *Line automaton A_1.*

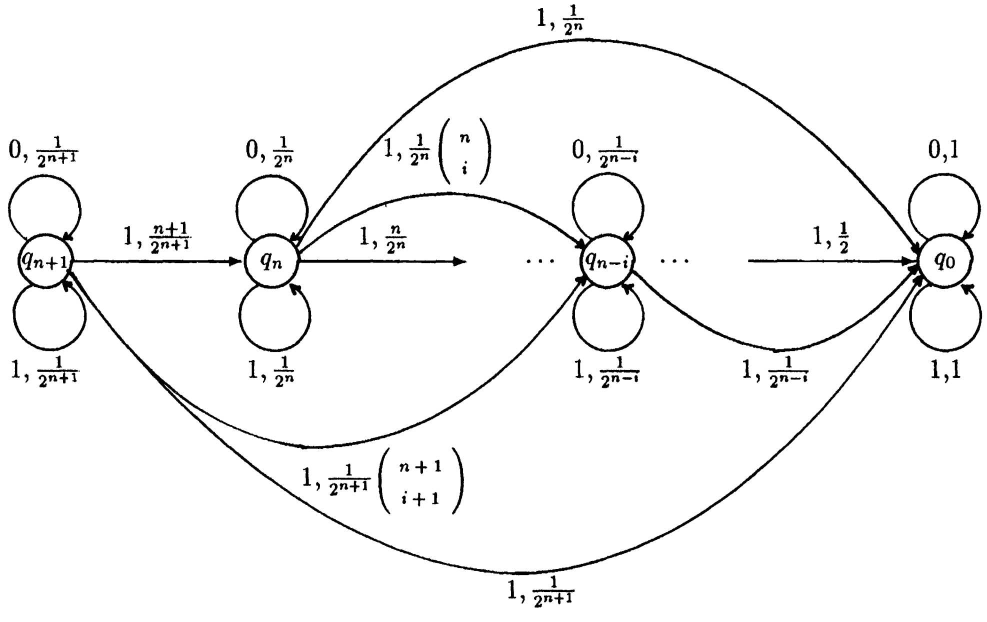

FIG. 12. *Line automaton A_n.*

By construction the automaton A_{n+1} has the following nice properties.

(i) For each $i = 0, \dots, n+1$, the sum of weights of transitions starting from q_i and labeled by 1 equals 1 by the binomial formula. Therefore, f_{A_i} is 1-faithful.

(ii) A_i for $i \leq n$ is obtained from A_{n+1} by deleting states $q_{n+1}, \dots, q_{i+1}$ and transitions connected to these.

Let x be an arbitrary number in [0, 1] and w its standard binary representation so that $x = \hat{w}$. By construction of A_{n+1}

$$f_{A_{n+1}}(0w) = \frac{1}{2^{n+1}} f_{A_{n+1}}(w)$$

and

$$f_{A_{n+1}}(1w) = \frac{1}{2^{n+1}} f_{A_{n+1}}(w) + \sum_{i=0}^{n} \frac{1}{2^{n+1}} \binom{n+1}{i+1} f_{A_{n-1}}(w).$$

Since $\widehat{0w} = \frac{1}{2}x$ and $\widehat{1w} = \frac{1}{2}x + \frac{1}{2}$, these equations can be rewritten, by induction assumption, as

$$\hat{f}_{A_{n+1}}\left(\frac{1}{2}x\right) = \frac{1}{2^{n+1}} \hat{f}_{A_{n+1}}(x) \tag{29}$$

and

$$\hat{f}_{A_{n+1}}\left(\frac{1}{2}x + \frac{1}{2}\right) = \frac{1}{2^{n+1}} \hat{f}_{A_{n+1}}(x) + \sum_{i=0}^{n} \frac{1}{2^{n+1}} \binom{n+1}{i+1} x^n. \tag{30}$$

Moreover, by (i),

$$\hat{f}_{A_{n+1}}(1) = 1. \tag{31}$$

Formulas (29) and (30) hold true for all x in [0, 1]. So together with (31) they imply that

$$\hat{f}_{A_{n+1}}(z) = z^{n+1}$$

for all z having a finite binary representation. Consequently, since the set of such points is dense in [0, 1], the claim follows if we show that $\hat{f}_{A_{n+1}}$ is continuous. This is seen as follows. By induction hypothesis and the claim in the proof of Theorem 1, $\hat{f}_{A_{n+1}}$ is continuous at points having finite binary representations if and only if it is continuous at the point 1/2. Therefore, the continuity of $\hat{f}_A$ follows from Lemmas 6 and 7 together with the equations

$$f_{A_{n+1}}(10^\omega) = \frac{1}{2^{n+1}} = f_A(01^\omega),$$

the first of which is obvious and the second one is due to (i). This completes the proof of the claim. □

After establishing the claim, Theorem 6 follows easily. Polynomial $a_{n+1}x^{n+1} + \cdots + a_0$, with $a_i \in \mathbb{R}_+$, is obtained by using the automaton A_{n+1} with the initial distribution $(a_{n+1}, \dots, a_0)$. Obviously, the second sentence of the theorem follows as well.

In the above proof we constructed directly a WFA for a given polynomial. In this construction there are several interesting phenomena. First, for any polynomial of degree n, or in fact of degree at most n, we can use the *same* line automaton A_n, only with different initial distributions. A related observation is that our WFA for x^n can be extended by introducing a new state and transitions for it to a WFA for the function x^{n+1}.

Second, the structure of A_{n+1} is very interesting. For each state there are equally weighted loops for both letters, the weights being inverses of powers of 2 : $2^{-(n+1)}, 2^{-n}, \dots, 2^{-1}, 1$. All states connected by transitions are connected by transitions labeled by 1, and all states are acyclically connected in this way. Moreover, for each state the sum of weights starting from this state and labeled by 1 equal 1, as already noted in (i). Consequently, our WFA is 1-faithful. Of course, it would be possible to change the roles of the input letters and make it 0-faithful. Now, with the initial distribution $(1, 0, \dots, 0)$, we obtain functions that at 0 assume value 0 and at 1 value 1; by the change we would get functions that at 0 get value 1 and at 1 value 0.

There is another way to find a WFA defining a given polynomial function P of degree n. This is based on the closure properties of WFA. We can start from a WFA defining the linear function x, such as A_1. Then for x^n we get a WFA as an n-fold product of A_1, and finally as a sum we obtain a WFA automaton for P. Now, the resulting automaton is not a line automaton but a level automaton of degree n (possibly with negative values in the initial distribution). However, it also has several important properties of A_n. Indeed, for each state there are equally weighted loops for both letters, and the weights are as in A_n powers of inverses of two. Moreover, all the other transitions are labeled only by 1's with possibly different weights. Finally, the automaton is 1-faithful, if the starting automaton is so, and no states except the sink states are merged when summing the automata together.

Now, we turn to consider the generation of polynomials over several variables by WFA. In addition to Theorem 6 we need one operation on automata that is quite natural but not widely used, namely, their *Cartesian product* [11]. We formulate it here for WFA. For $i = 1, 2$ let

$$A_i = (Q_i, \Sigma_i, W_i, I_i, T_i)$$

be a WFA. We define Cartesian product of A_1 and A_2 as a WFA

$$A = A_1 \times A_2 = (Q_1 \times Q_2, \Sigma_1 \times \Sigma_2, W, I, T)$$

where

$$I : Q_1 \times Q_2 \to \mathbb{R}, \qquad I(q_1, q_2) = (I_1(q_1), I_2(q_2));$$

$$T : Q_1 \times Q_2 \to \mathbb{R}, \qquad T(q_1, q_2) = (T_1(q_1), T_2(q_2));$$

and

$$W(p_1, p_2, a_1, a_2, q_1, q_2) = W_1(p_1, a_1, q_1) W_2(p_2, a_2, q_2).$$

Consequently, A defines a function $F_A : (\Sigma_1 \times \Sigma_2)^\star \to \mathbb{R}$, which is a rational function over the alphabet of the Cartesian product of the original alphabets. For example, if $\Sigma_1 = \Sigma_2 = \{0, 1\}$, this is exactly what we need in order to compute two-dimensional functions $\mathbb{R}^2 \to \mathbb{R}$, since a vector (u, v), with $u, v \in \{0, 1\}^\star$ and $|u| = |v|$, addresses a point in the square $[0, 1] \times [0, 1]$. Such a vector can be viewed, as we do, in a natural way as a word over the four-letter alphabet. Of course, if we want to compute functions $\mathbb{R}^d \to \mathbb{R}$ we take the n-fold Cartesian product of two WFA over $\{0, 1\}$, so that the alphabet Σ^d of the WFA has 2^d letters.

THEOREM 7. *For each polynomial $P(x_1, \dots, x_d)$ with nonnegative coefficients and defined in $[0, 1]^d$ there exists a WFA A defining it. Moreover, A can be chosen to have the level structure of depth equal to the maximum of the powers of variables in $P(x_1, \dots, x_d)$. The restriction on coefficients can be dropped out if negative values in the initial distributions are allowed.*

Proof. We consider first the case when P is of the form $P(x, y) = x^n y^m$. By Theorem 6, we can find line automata A_n and A_m such that

$$\hat{f}_{A_n}(x) = x^n \quad \text{and} \quad \hat{f}_{A_m}(y) = y^m .$$

We claim that the Cartesian product $A = A_n \times A_m$ computes P, that is,

$$\hat{f}_A(x, y) = x^n y^m , \tag{32}$$

or, equivalently, denoting by $\pi_i(w)$ the ith projection of $w \in (\{0, 1\} \times \{0, 1\})^\omega$, that is,

$$f_A(w) = f_{A_1}(\pi_1(w)) \cdot f_{A_2}(\pi_2(w))$$

with $\pi_1(w)$ and $\pi_2(w)$ representing x and y, respectively.

The proof of (32) is straightforward. Let $\gamma \in (\{0, 1\} \times \{0, 1\})^*$, and denote $u = \pi_1(\gamma)$ and $v = \pi_2(\gamma)$. As it is easy to see by induction, it follows from the construction of A that the weight caused by w to the state (p, q) of A equals

$$w_p(u)\, w_q(v) ,$$

where $w_p(u)$ and $w_q(v)$ define the weights of the states p of A_n and q of A_m caused by the words u and v, respectively. Consequently, for $w \in (\{0, 1\} \times \{0, 1\})^\omega$ we can write

$$f_A(w) = \lim_{n\to\infty} \sum_{p\in Q_1, q\in Q_2} w_p(u_n) \cdot w_q(v_n), \tag{33}$$

where u_n and v_n are the prefixes of length n of $\pi_1(w)$ and $\pi_2(w)$, respectively. Since Q_1 and Q_2 are finite, we conclude that

$$\begin{aligned} f_A(w) &= \sum_{p\in Q_1} \lim_{n\to\infty} w_p(u_n) \left(\sum_{q\in Q_2} \lim_{n\to\infty} w_q(v_n) \right) \\ &= \sum_{p\in Q_1} \lim_{n\to\infty} w_p(u_n) \cdot f_{A_2}(\pi_2(w)) \\ &= f_{A_1}(\pi_1(w)) \cdot f_{A_2}(\pi_2(w)) , \end{aligned}$$

as claimed.

Now, the proof of the general case is easy. Each monomial of P is definable by a certain product of line automata of depths equal to the power of the corresponding variable in the monomial. Such a product is, as is obvious, a level automaton of degree of the highest power of the variables. Hence, for any monomial of P we obtain a level automaton of an appropriate depth and having a suitable initial distribution (determined by the coefficient of the monomial). Moreover, it is a consequence of Theorem 6 that this level automata can be chosen the *same* for each monomial. Hence, the polynomial is definable, with a suitable initial (not necessarily positive) distribution, by a level automaton of degree the maximum of the powers of the variables in $P(x_1, \ldots, x_d)$. □

The above proof deserves two comments. Part of the proof of Theorem 7 was to show a closure property of WFA automata. It was formulated for particular level automata (to guarantee the existence of the limits) but actually holds in a much more general form. The other point worth noticing is that, as in Theorem 6, also here we get all polynomials up to certain degree from the same WFA having only different initial distributions. Moreover, this WFA possesses the level (but not necessarily line) structure of the depth of the maximal degree of variables in P. This property might have practical importance as well.

6. Integration. This section is devoted to prove the following result, where the integral means ordinary Riemann integral.

THEOREM 8. *For each level automaton A of degree n there exists a level automaton A_I of degree $n+1$ such that*

$$\hat{f}_{A_I}(x) = \int_0^x f_A(t)\,dt. \tag{34}$$

Moreover, given the automaton A the automaton A_I can be constructed by uniform rules.

Proof. Assume that A defining the function $\hat{f}_A : [0,1] \to \mathbb{R}$ is given. We first apply Lemma 5 in order to find an average preserving level automaton A_{ap} (of the same degree) defining $\hat{f}_A$. Next, we define a level automaton A_I of degree $n+1$ as follows:

(i) Its states are those of A_{ap} together with one new state called t.

(ii) Its transitions contain transitions of A_{ap} with weights divided by 2.

(iii) From each original state q of A_{ap} there is a transition in A_I to the state t labeled by 1 and with the weight $\frac{1}{2}\sum_{p\in Q} W(q,0,p)$, where W is the weight function of A_{ap} and Q is its set of states.

(iv) The weight 1.

It remains to prove that (34) holds true. We do that in two stages.

CLAIM 1. $f_{A_I}(w) = \sum_{i=1}^{\infty} \mathrm{Bin}(i)\cdot 2^{-i} F_{A_{\mathrm{ap}}}(\mathrm{pref}_{i-1}(w)\cdot 0)$, where $w = a_1a_2\ldots$ with $a_i \in \{0,1\}$ and $\mathrm{Bin}(i)$ in the ith bit of w.

Proof of Claim 1. Let η_{n+1} denote the $(n+1)$-dimensional vector such that its last component equals 1 and the others equal 0. Then by the construction of A_I we have

$$P_{A_I}(\varepsilon)\cdot\eta_{n+1} = 0$$

and for all $u \in \{0,1\}^*$ we have

$$P_{A_I}(u0)\cdot\eta_{n+1} = P_{A_I}(u)\cdot\eta_{n+1},$$

$$P_{A_I}(u1)\cdot\eta_{n+1} = P_{A_I}(u)\cdot\eta_{n+1} + 2^{-|u|-1}F_{A_{\mathrm{ap}}}(u0).$$

Since A_I is a level automaton, the value of f_{A_I} is obtained in the last state t only (although the values of $F_{A_{\mathrm{ap}}}$ are obtained by summing up the values of all states). Therefore Claim 1 follows from the above equalities.

CLAIM 2. $\int_0^x f_{A_{\mathrm{ap}}}(t)\,dt = \sum_{i=1}^{\infty} \mathrm{Bin}(i)\, 2^{-i} F_{A_{\mathrm{ap}}}(\mathrm{pref}_{i-1}(w)\cdot 0)$, where $w = a_1a_2\ldots$ is the standard representation of $x \in [0,1]$ and $\mathrm{Bin}(i)$ is the ith bit of w.

Proof of Claim 2. We write w in the form

$$w = u10^k1w' = v1w' \quad \text{for some } k \geq 0, \tag{35}$$

and denote by x_1 and x_2 the numbers having the representations $u1$ (or 0 if the shown k 0's are at the beginning of w) and $u10^k1$, respectively. We show that

$$I = \int_{x_1}^{x_2} f_{A_{\mathrm{ap}}}(t)dt = \frac{1}{2^{|v0|}}F_{A_{\mathrm{ap}}}(v0). \tag{36}$$

By the definition of the integration

$$I = \lim_{n\to\infty}\sum_{i=0}^{2^n-1}\frac{f_{A_{\mathrm{ap}}}(v0w_i0^{\omega})}{2^{|v0w_i|}}, \tag{37}$$

where w_i is the ith word in the lexicographic order of the words of length n. Now, by arguments of the proof of Lemma 6 we conclude the existence of the function $\varepsilon : \mathbb{N} \to \mathbb{R}_+$ such that

$$(38)\qquad | f_{A_{\mathrm{ap}}}(z0^{\omega}) - F_{A_{\mathrm{ap}}}(z) | \le \varepsilon(|z|), \quad \forall z \in \{0,1\}^*$$

and

$$(39)\qquad \lim_{n\to\infty} \varepsilon(n) = 0.$$

Finally, since $F_{A_{\mathrm{ap}}}$ is average preserving, we have

$$(40)\qquad \sum_{i=0}^{2^n-1} \frac{F_{A_{\mathrm{ap}}}(v0w_i)}{2^{|v0w_i|}} = \frac{F_{A_{\mathrm{ap}}}(v0)}{2^{|v0|}}.$$

Now, (36) follows straightforwardly from (37)–(40). □

Observe that the rules (i)–(iv) to construct A_I from A_{ap} are extremely simple. Note also that Theorem 8 provides an alternate way to show that all polynomials can be defined by level automata. Finally, we illustrate Theorem 8 by the following example.

Example 6. Consider the automaton B of Example 5. As we saw $\hat{f}_A$ is continuous but does not possess derivatives at any point having a finite binary representation, nor at many other points as well. Since B is already average preserving, we can apply directly the rules (i)–(iv) and hence obtain the WFA B_I shown in Fig. 13. Of course, $\hat{f}_{B_I}$ is continuous, and $\hat{f}'_{B_I}(x) = \hat{f}_B(x)$. However, $\hat{f}_{B_I}$ does not have the second derivative at many points. Observe also that, as illustrated in Fig. 14,

$$\hat{f}_{B_I}\left(\frac{11}{32}\right) = \frac{1}{4}F_B(00) + \frac{1}{16}F_B(0100) + \frac{1}{32}F_B(01010).$$

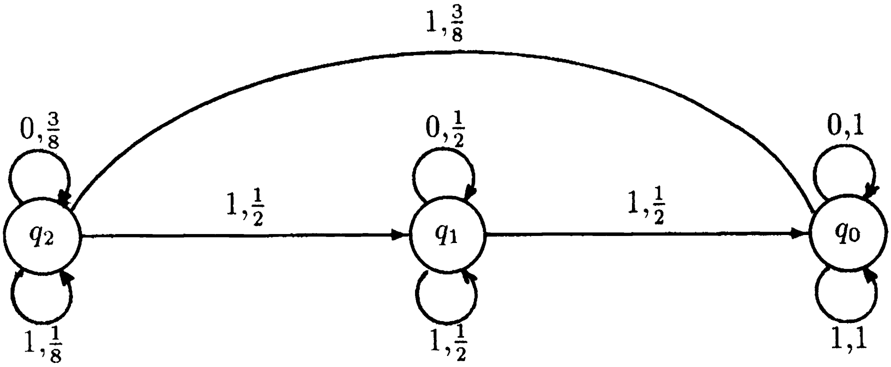

FIG. 13. *Automaton* B_I.

Note that by the integration (rules (i)–(iv)) starting from a noncontinuous function defined by a level automaton we obtain an automaton specifying a continuous function that, however, is not smooth.

7. Recent work. Since the first draft of this paper, the investigations of WFA continued intensively. We mention some recent results. In [4] it is shown that for each $n \ge 1$ the Daubechies wavelet W_{2n} [7] can be implemented by a WFA with $2n - 1 + \lceil \log(2n-1) \rceil$ states. These WFA are the first natural examples of WFA that are not level WFA. It is important that all the discrete W_{2n} transforms of size 2^k can be computed by a WFA with $2^k + 0(k)$ nodes,

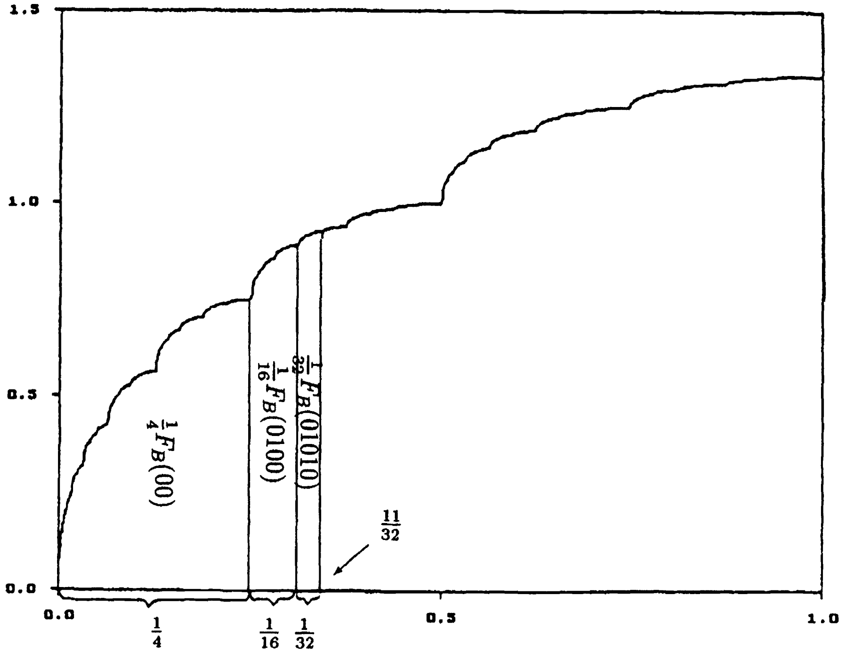

FIG. 14. *The graph of* $\hat{f}_B$.

a fixed structure and weights, and only the initial distribution depending on the given vector (function). This situation is similar to that of the polynomials of degree n considered in §5.

In [5] the first inference algorithm for WFA is given. Theoretically, for an infinitely precisely given function (i.e., function on [0, 1]), this algorithm produces a WFA with a minimal number of states that generates the given function if such a WFA exists. For a function f given by a finite table (finite resolution image), it produces a WFA that approximates f and has a relatively small number of states but possibly many edges (not very sparse weight matrices).

The second inference algorithm for the discrete case is described in [6]. It produces a WFA with highly sparse weight matrices, that is, a WFA with a relatively large number of states but a relatively small number of edges. This algorithm gives an excellent tool for data compression. For gray-scale images, it performs better than Daubechies W_6 wavelets and in combination with wavelets gives even higher compression rates with the same quality of the regenerated images. In this case the WFA can be viewed as a sophisticated method for the quantization of the wavelet coefficients [6].

Further theoretical results on WFA are shown in [8] and [9]. In [8] it is shown that the only smooth functions (functions that have everywhere all the derivatives) defined by WFA are the polynomials. In [9] a WFA is given that generates a function that is everywhere continuous but does not have the derivative anywhere.

ON THE COMPLEXITY OF BILINEAR FORMS OVER ASSOCIATIVE ALGEBRAS*

NADER H. BSHOUTY†

Abstract. Let F be a field, and let $q(\alpha) = q_1^{d_1}(\alpha)\cdots q_k^{d_k}(\alpha) \in F[\alpha]$ be a polynomial of degree n, where $q_1(\alpha), \ldots, q_k(\alpha)$ are distinct irreducible polynomials. Let $y(\alpha), y_1(\alpha), \ldots, y_r(\alpha), x_1(\alpha), \ldots, x_s(\alpha)$ be $(n-1)$-degree polynomials with distinct nonscalar coefficients. The authors show the following: the number of nonscalar multiplications/divisions required to compute the coefficients of $x_i(\alpha)y(\alpha) \bmod q(\alpha)$ for $i = 1, \ldots, s$ by straight line algorithms is $s(2n-k)$. If H is a $s \times r$- matrix with entries from F, then the number of nonscalar multiplications/ divisions required to compute the coefficients of $(x_1(\alpha), \ldots, x_s(\alpha))\, H(y_1(\alpha), \ldots, y_r(\alpha))^T \bmod q(\alpha)$ by straight line algorithms is equal to $(2n-k)\mathrm{rank}(H)$. All the above systems satisfy the direct sum conjecture strongly. The above results also hold for some other algebras that are direct sums of local algebras, such as commutative algebras and division algebras.

Key words. associative algebras, bilinear forms, multiplicative complexity, direct sum

AMS subject classifications. 68C20, 68C25, 68Q05, 68Q25, 68Q40

1. Introduction.

Is it always true that the *multiplicative complexity* (i.e., the number of nonscalar multiplications) of multiplying one element x with many elements $y_1, \ldots, y_n$ in an algebra is equal to n times the multiplicative complexity of multiplying two elements in the algebra? The answer is "no." One simple example is $\mathcal{M}_{2\times 2}$, the algebra of 2×2 matrices: to multiply two 2×2 matrices we need seven nonscalar multiplications, and multiplying a 2×2 matrix X with n 2×2 matrices $Y_1, \ldots, Y_n$ requires $6n + 2$ nonscalar multiplications.

In [5] and [13], it is proved that the answer to the above question is "yes" when the algebra is a field. In this paper we study this property for other algebras and prove that it holds for commutative algebras of minimal rank. In particular, it holds for simply generated algebras (i.e., multiplication of two polynomials modulo a fixed polynomial). The technique used in this paper can also be used to prove this property for clean algebras of minimal rank. A clean algebra is an algebra $\mathcal{A}$ where $\mathcal{A}/\mathrm{rad}\,\mathcal{A}$ is a direct product of local algebras.

Let F be a field, and let $\mathbf{x} = (x_1, \ldots, x_n)^T$ be a vector of indeterminates . Let $Q_{\mathbf{x}} = \{\mathbf{x}^T Q_1 \mathbf{x}, \ldots, \mathbf{x}^T Q_m \mathbf{x}\}$ be a set of quadratic forms on $x_1, \ldots, x_n$ over F, where the Q_i are $n \times n$ matrices with entries from F. A *straight line algorithm* that computes $Q_{\mathbf{x}}$ is a sequence of rational functions $\sigma_1, \ldots, \sigma_L$, where:
(1) for every $1 \le j \le L$ we have $\sigma_j = w_{j,1} \circ w_{j,2}$, where $\circ \in \{\times, \div\}$ and

$$w_{j,1}, w_{j,2} \in \left(F + \sum_{i=1}^{n} Fx_i + \sum_{i=1}^{j-1} F\sigma_i\right) \backslash F$$

or $\circ = \div$, $w_{j,1} \in F\backslash\{0\}$, and $w_{j,2} \in \left(F + \sum_{i=1}^{n} Fx_i + \sum_{i=1}^{j-1} F\sigma_i\right) \backslash F$;
and
(2)

$$Q_{\mathbf{x}} \subseteq F + \sum_{i=1}^{n} Fx_i + \sum_{i=1}^{L} F\sigma_i.$$

We call the operation $\circ$ in (1) a *nonscalar* $\circ$. In this model we only count nonscalar multiplications/divisions. The minimal L in (1) is denoted by $L(Q_{\mathbf{x}})$ or $L_F(Q_{\mathbf{x}})$ and is called the *multiplicative complexity* of $Q_{\mathbf{x}}$.

When $Q_{\mathbf{x}}$ is computed by an algorithm $\sigma_1, \dots, \sigma_\mu$, where $\sigma_j = w_{j,1} \times w_{j,2}$ and $w_{j,1}, w_{j,2} \in \sum_{i=1}^{n} Fx_i \backslash F$, then we call the algorithm a *quadratic algorithm*. The minimal μ is denoted by $\mu(Q_{\mathbf{x}})$ or $\mu_F(Q_{\mathbf{x}})$ and is called the *quadratic complexity* of $Q_{\mathbf{x}}$. Strassen [17] proved that for infinite fields F,

$$L_F(Q_{\mathbf{x}}) = \mu_F(Q_{\mathbf{x}}). \tag{1}$$

Let $\mathbf{u} = (u_1, \dots, u_n)^T$ be a vector of new indeterminates, and let

$$Q_{\mathbf{x}}^{(1)} = \{\mathbf{x}^T Q_1 \mathbf{x}, \dots, \mathbf{x}^T Q_{m_1} \mathbf{x}\} \quad \text{and} \quad Q_{\mathbf{u}}^{(2)} = \{\mathbf{u}^T Q_{m_1+1} \mathbf{u}, \dots, \mathbf{u}^T Q_{m_2} \mathbf{u}\}$$

be two sets of quadratic forms. When the vectors of indeterminates $\mathbf{x}$ and $\mathbf{u}$ are distinct, $Q_{\mathbf{x}}^{(1)} \cup Q_{\mathbf{u}}^{(2)}$ is called the *direct sum* of $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$. It is also denoted by $Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)}$. It is obvious that

$$\mu(Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)}) \le \mu(Q_{\mathbf{x}}^{(1)}) + \mu(Q_{\mathbf{u}}^{(2)}). \tag{2}$$

Fiduccia and Zalcstein [9] Strassen [17], and Winograd [18] conjectured that for every two sets of quadratic forms $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$, we have

$$\mu(Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)}) = \mu(Q_{\mathbf{x}}^{(1)}) + \mu(Q_{\mathbf{u}}^{(2)}). \tag{3}$$

Furthermore, they conjectured that every minimal quadratic algorithm $\sigma_1, \dots, \sigma_\mu$ for $(Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)})$ can be split into two minimal algorithms

$$s_1 = (\sigma_i)_{i \in I} \quad \text{and} \quad s_2 = (\sigma_i)_{i \in J}, \tag{4}$$

where $I \cup J = \{1, \dots, \mu\}$, $I \cap J = \emptyset$, and s_1 and s_2 are minimal quadratic algorithms for $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$, respectively.

When (3) is satisfied, then we say that $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$ satisfy the *direct sum conjecture* in the model of quadratic algorithms. We define DSC_{QA} and $DSC_{QA}(F)$ to be the set of all pairs $(Q_{\mathbf{x}}^{(1)}, Q_{\mathbf{u}}^{(2)})$, such that $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$ satisfy the direct sum conjecture in the quadratic algorithms model. When (4) is satisfied for $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$, then, we say that $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$ satisfy the *direct sum conjecture strongly* in the model of quadratic algorithms. We define $DSCS_{QA}$ or $DSCS_{QA}(F)$ to be the set of all pairs $(Q_{\mathbf{x}}^{(1)}, Q_{\mathbf{u}}^{(2)})$ such that $Q_{\mathbf{x}}^{(1)}$ and $Q_{\mathbf{u}}^{(2)}$ satisfy the direct sum conjecture strongly in the quadratic algorithms model. If for any set of quadratic form $Q_{\mathbf{u}}^{(2)}$ we have that $(Q_{\mathbf{x}}^{(1)}, Q_{\mathbf{u}}^{(2)}) \in DSCS_{QA}$, then we simply write $Q_{\mathbf{x}}^{(1)} \in DSCS_{QA}$.

Similarly, we define the classes DSC_{SLA} and $DSCS_{SLA}$ for the straight line model. It is obvious that

$$DSCS_M \subseteq DSC_M$$

for any model of computation, M. By the results of Strassen in [17] and Bshouty in [8], for infinite fields F, we also have

$$DSC_{SLA}(F) = DSC_{QA}(F) \quad \text{and} \quad DSCS_{SLA}(F) = DSCS_{QA}(F). \tag{5}$$

Let $\mathbf{x} = (x_1, \dots, x_n)^T$ and $\mathbf{y} = (y_1, \dots, y_m)^T$ be vectors of indeterminates. Let $B_{\mathbf{x},\mathbf{y}}$ be a set of bilinear forms $\{\mathbf{x}^T B_1 \mathbf{y}, \dots, \mathbf{x}^T B_k \mathbf{y}\}$, where the B_i are $n \times m$ matrices. A *bilinear* *algorithm* that computes $B_{\mathbf{x},\mathbf{y}}$ is a quadratic algorithm $\sigma_1, \ldots, \sigma_\delta$, where $\sigma_j = w_{j,1} \times w_{j,2}$, $w_{j,1} \in \sum_{i=1}^{n} Fx_i \backslash F$ and $w_{j,2} \in \sum_{i=1}^{m} Fy_i \backslash F$. In a similar manner we define $\delta(B_{\mathbf{x},\mathbf{y}})$ to be the *bilinear complexity* of $B_{\mathbf{x},\mathbf{y}}$. Obviously, $\mu(B_{\mathbf{x},\mathbf{y}}) \leq \delta(B_{\mathbf{x},\mathbf{y}})$. We also define DSC_{BA} and $DSCS_{BA}$ in a similar manner.

Let $\mathbf{A}$ be an associative algebra of dimension k with an identity element 1, and let $\{a_1, \ldots, a_k\}$ be a basis of $\mathbf{A}$. Let $\mathbf{x} = (x_1, \ldots, x_n)^T$ and $\mathbf{y} = (y_1, \ldots, y_n)^T$ be vectors of indeterminates, and let $x = \sum_{i=1}^{k} x_i a_i$ and $y = \sum_{i=1}^{k} y_i a_i$. We denote by $[xy]_{\mathbf{A}} = \{\mathbf{x}^T B_1 \mathbf{y}, \ldots, \mathbf{x}^T B_k \mathbf{y}\}$, the set of bilinear forms defined by the product of two elements in the algebra $\mathbf{A}$. That is,

$$\sum_{i=1}^{k} (\mathbf{x}^T B_i \mathbf{y}) a_i = \left(\sum_{i=1}^{k} x_i a_i \right) \left(\sum_{i=1}^{k} y_i a_i \right).$$

In a similar manner we also define $[x_1 y, x_2 y, \ldots, x_n y]_{\mathbf{A}}$ and $[x_1 y_1 + \ldots + x_n y_n]_{\mathbf{A}}$, or more generally, $[x^T C_1 y, \ldots, x^T C_h y]_{\mathbf{A}}$, where $x = (x_1, \ldots, x_n)^T \in \mathbf{A}^n$, $y = (y_1, \ldots, y_m)^T \in \mathbf{A}^m$, and where $C_1, \ldots, C_h$ are $n \times m$ matrices. Formally, let $x_i = \sum_{j=1}^{k} x_{i,j} a_j$ and $y_l = \sum_{j=1}^{k} y_{l,j} a_j$ for $j = 1, \ldots, n$ and $l = 1, \ldots, m$, where $x_{i,j}$ and $y_{l,j}$ are distinct indeterminates. Let $x = (x_1, \ldots, x_n)^T$ and $y = (y_1, \ldots, y_m)^T$. Then $[x^T C_1 y, \ldots, x^T C_h y]_{\mathbf{A}}$ is the set of bilinear forms that is the set of the coefficients of $x^T C_i y$, $i = 1, \ldots, h$.

Obviously, $[x^T C_1 y, \ldots, x^T C_h y]_{\mathbf{A}}$ depends on the chosen basis $\{a_1, \ldots, a_k\}$. Feduccia and Zalcstein [9] proved that the complexity of $[x^T C_1 y, \ldots, x^T C_h y]_{\mathbf{A}}$ does not depend on the chosen basis.

In [4], Alder and Strassen proved that for any set of quadratic forms $Q_{\mathbf{u}}$ we have

$$\mu([xy]_{\mathbf{A}} \oplus Q_{\mathbf{u}}) \geq 2 \dim \mathbf{A} - I(\mathbf{A}) + \mu(Q_{\mathbf{u}}),$$

where $I(\mathbf{A})$ is the number of the maximal two sided ideals of $\mathbf{A}$. This result was generalized by Auslander and Winograd [5] and Hartman [13]. They proved that if $\mathbf{A}$ is a direct product of division algebras, then

$$\mu([x_1 y, x_2 y, \ldots, x_n y]_{\mathbf{A}}) \geq (2 \dim \mathbf{A} - I(\mathbf{A}))n.$$

If $\mu([x_1 y, x_2 y, \ldots, x_n y]_{\mathbf{A}}) \leq (2 \dim \mathbf{A} - I(\mathbf{A}))n$, then we call $\mathbf{A}$ an algebra of *n-minimal complexity*, and if $\delta([x_1 y, x_2 y, \ldots, x_n y]_{\mathbf{A}}) \leq (2 \dim \mathbf{A} - I(\mathbf{A}))n$, then we call $\mathbf{A}$ an algebra of *n-minimal rank*. Obviously, if $\mathbf{A}$ is an algebra of 1-minimal complexity (rank), then it is an algebra of n-minimal complexity (rank) for every n. In [10], De Groote proved that a division algebra $\mathbf{A}$ over a field F is an algebra of 1-minimal complexity if and only if $\mathbf{A}$ is a field with $|F| \geq 2 \dim \mathbf{A}$. Other characterizations of 1-minimal rank algebras over closed fields can be found in [12] and [15].

In this paper, we generalize all of the results in [4], [5], [6], [13], and [18]. We prove the following:

THEOREM I. *Let $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ be an algebra, where the $\mathbf{A}_i$ are local algebras and there exists some $d_i \in \mathbf{A}_i$ such that the left annihilator of the radical $l(\text{rad } \mathbf{A}_i) = \{a | a \text{ rad } \mathbf{A}_i = 0\} = d_i \mathbf{A}_i$. Then for any set of quadratic forms C, we have*

$$\mu([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus C) \geq (2 \dim \mathbf{A} - k)n + \mu(C).$$

If $\mathbf{A}$ is an algebra of n-minimal complexity, then

$$[x_1 y, \ldots, x_n y]_{\mathbf{A}} \in DSCS_{SLA}.$$

THEOREM II. *Let* $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ *be an algebra, where the* $\mathbf{A}_i$ *are local algebras. Then for any set of bilinear forms* B, *we have*

$$\delta([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus B) \geq (2 \dim \mathbf{A} - k)n + \delta(B).$$

If $\mathbf{A}$ *is an algebra of* n*-minimal rank, then*

$$[x_1 y, \ldots, x_n y]_{\mathbf{A}} \in DSCS_{BA}.$$

Notice that in Theorems I and II, $I(\mathbf{A}) = k$.

THEOREM III. *Let* $\mathbf{A}$ *be a commutative algebra, and let* H *be an* $n \times m$ *matrix. Then*

$$\mu([x^T H y]_{\mathbf{A}}) \geq (2 \dim \mathbf{A} - I(\mathbf{A}))\mathrm{rank}(H).$$

If $\mathbf{A}_1$ *and* $\mathbf{A}_2$ *are commutative algebras of* $\mathrm{rank}(H_1)$*-minimal rank and* $\mathrm{rank}(H_2)$*-minimal rank, respectively, then*

$$([x^T H_1 y]_{\mathbf{A}_1}, [x^T H_2 y]_{\mathbf{A}_2}) \in DSCS_{SLA}.$$

THEOREM IV. *Let* $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ *be an algebra, where the* $\mathbf{A}_i$ *are local algebras, and let* H *be an* $n \times m$ *matrix. Then for any set of bilinear forms* B, *we have*

$$\delta([x^T H y]_{\mathbf{A}} \oplus B) \geq (2 \dim \mathbf{A} - k)\mathrm{rank}(H) + \delta(B).$$

If $\mathbf{A}$ *is an algebra of* $\mathrm{rank}(H)$*-minimal rank, then*

$$[x^T H y]_{\mathbf{A}} \in DSCS_{BA}.$$

Since, by the Artinian theorem, every commutative algebra is a direct product of local commutative algebras, Theorems II and IV are true for commutative algebras. In this case we have $k = I(\mathbf{A})$.

Theorems I, II, III, and IV imply the following results:

Let $\mathbf{A} = F[\alpha]/(p(\alpha))$, where $p(\alpha) = p_1^{d_1}(\alpha) \ldots p_k^{d_k}(\alpha) \in F[\alpha]$ is a polynomial of degree n and $p_1, \ldots, p_k$ are distinct irreducible polynomials. Then $[xy]_{\mathbf{A}}$ is the problem of computing the product of two $(n-1)$-degree polynomials modulo $p(\alpha)$. By Theorems I and II, we have:

COROLLARY I. *Let* $\mathbf{A} = F[\alpha]/(p(\alpha))$, *where* $p = p_1^{d_1} \ldots p_k^{d_k}$, $p_1, \ldots, p_k$ *are distinct irreducible polynomials and* $|F| \geq 2 \max_{1 \leq i \leq k} \deg\ p_i^{d_i} - 2$. *Then for any set of quadratic forms* C *and any set of bilinear forms* B, *we have*

$$\mu([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus C) = (2 \deg\ p - k)n + \mu(C),$$

$$\delta([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus B) = (2 \deg\ p - k)n + \delta(B),$$

and

$$[x_1 y, \ldots, x_n y]_{\mathbf{A}} \in DSCS_{SLA}, DSCS_{BA}.$$

For a set of quadratic forms $Q_{\mathbf{x}}^{(1)}$ (respectively, bilinear forms $B_{\mathbf{x},\mathbf{y}}$), let $\mathrm{Alg}_{SLA}(Q_{\mathbf{x}}^{(1)})$ (respectively, $\mathrm{Alg}_{BA}(B_{\mathbf{x},\mathbf{y}})$) denote the set of all minimal straight line algorithms that compute $Q_{\mathbf{x}}^{(1)}$ (respectively, bilinear algorithms that compute $B_{\mathbf{x},\mathbf{y}}$). We denote by $\mathrm{Alg}_{SLA}(Q_{\mathbf{x}}^{(1)}) \oplus \mathrm{Alg}_{SLA}(Q_{\mathbf{u}}^{(2)})$, the set of all straight line algorithms $\sigma_1, \dots, \sigma_t$ such that there exist sets I, $J \subset \{1, \dots, t\}$, $I \cup J = \{1, \dots, t\}$ and $I \cap J = \emptyset$; where $(\sigma_i)_{i \in I} \in \mathrm{Alg}_{SLA}(Q_{\mathbf{x}}^{(1)})$ and $(\sigma_i)_{i \in J} \in \mathrm{Alg}_{SLA}(Q_{\mathbf{u}}^{(2)})$. Obviously, $(Q_{\mathbf{x}}^{(1)}, Q_{\mathbf{u}}^{(2)}) \in DSCS_{SLA}$ if and only if $\mathrm{Alg}_{SLA}(Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)}) = \mathrm{Alg}_{SLA}(Q_{\mathbf{x}}^{(1)}) \oplus \mathrm{Alg}_{SLA}(Q_{\mathbf{u}}^{(2)})$. By Corollary I, we have:

COROLLARY II. *Let* $\mathbf{A} = F[\alpha]/(p(\alpha))$, *where* $p = p_1^{d_1} \dots p_k^{d_k}$, $p_1, \dots, p_k$ *are distinct irreducible polynomials and* $|F| \geq 2\max_{1 \leq i \leq k} \deg\ p_i^{d_i} - 2$. *Then for the basis* $\{a_1, \dots, a_n\}$ *that represents* $\mathbf{A}$ *as* $F[\alpha]/(p_1^{d_1}(\alpha)) \times \cdots \times F[\alpha]/(p_k^{d_k}(\alpha))$, *we have*

$$\begin{aligned}\mathrm{Alg}_{SLA}([x_1 y, \dots, x_n y]_{\mathbf{A}}) = {} & \mathrm{Alg}_{SLA}([x_1 y, \dots, x_n y]_{F[\alpha]/(p_1^{d_1}(\alpha))}) \oplus \cdots \\ & \oplus \mathrm{Alg}_{SLA}([x_1 y, \dots, x_n y]_{F[\alpha]/(p_k^{d_k}(\alpha))})\end{aligned}$$

and

$$\begin{aligned}\mathrm{Alg}_{BA}([x_1 y, \dots, x_n y]_{\mathbf{A}}) = {} & \mathrm{Alg}_{BA}([x_1 y, \dots, x_n y]_{F[\alpha]/(p_1^{d_1}(\alpha))}) \oplus \cdots \\ & \oplus \mathrm{Alg}_{BA}([x_1 y, \dots, x_n y]_{F[\alpha]/(p_k^{d_k}(\alpha))}).\end{aligned}$$

This corollary shows that a classification of all the minimal straight line algorithms (respectively, bilinear algorithms) for $[x_1 y, \dots, x_n y]_{\mathbf{A}}$, where $\mathbf{A} = F[\alpha]/(p_i^{d_i}(\alpha))$ in which $p_i(\alpha)$ is irreducible, gives a classification for all the minimal straight line algorithms (respectively, bilinear algorithms) for $[x_1 y, \dots, x_n y]_{\mathbf{A}}$, where $\mathbf{A} = F[\alpha]/(p(\alpha))$, for *any* polynomial $p(\alpha)$. A classification of all minimal bilinear algorithms for the case of $n = 1$ is completely studied in [2] and [3].

Theorems III and IV imply:

COROLLARY III. *Let* $\mathbf{A} = F[\alpha]/(p(\alpha))$, *where* $p = p_1^{d_1} \dots p_k^{d_k}$, $p_1, \dots, p_k$ *are distinct irreducible polynomials and* $|F| \geq 2\max_{1 \leq i \leq k} \deg\ p_i^{d_i} - 2$. *Then*

$$\mu([x^T H y]_{\mathbf{A}}) = (2 \deg\ p(\alpha) - k)\mathrm{rank}(H),$$

and for any set of bilinear forms B,

$$\delta([x^T H y]_{\mathbf{A}} \oplus B) = (2 \deg\ p(\alpha) - k)\mathrm{rank}(H) + \delta(B)$$

and

$$[x^T H y]_{\mathbf{A}} \in DSCS_{BA}.$$

As in Corollary II, we have

COROLLARY IV. *Let* $\mathbf{A} = F[\alpha]/(p(\alpha))$, *where* $p = p_1^{d_1} \dots p_k^{d_k}$, $p_1, \dots, p_k$ *are distinct irreducible polynomials and* $|F| \geq 2\max_{1 \leq i \leq k} \deg\ p_i^{d_i} - 2$. *Then for the basis* $\{a_1, \dots, a_n\}$ *that represents* $\mathbf{A}$ *as* $F[\alpha]/(p_1^{d_1}(\alpha)) \times \cdots \times F[\alpha]/(p_k^{d_k}(\alpha))$, *we have*

$$\mathrm{Alg}_{SLA}([x^T H y]_{\mathbf{A}}) = \mathrm{Alg}_{SLA}([x^T H y]_{F[\alpha]/(p_1^{d_1}(\alpha))}) \oplus \cdots \oplus \mathrm{Alg}_{SLA}([x^T H y]_{F[\alpha]/(p_k^{d_k}(\alpha))})$$

and

$$\mathrm{Alg}_{BA}([x^T H y]_{\mathbf{A}}) = \mathrm{Alg}_{BA}([x^T H y]_{F[\alpha]/(p_1^{d_1}(\alpha))}) \oplus \cdots \oplus \mathrm{Alg}_{BA}([x^T H y]_{F[\alpha]/(p_k^{d_k}(\alpha))}).$$

The technique we shall use in this paper can also be used to prove lower bounds for many other bilinear systems over associative algebras.

This paper is organized as follows: In §2 we give some preliminary results from bilinear and quadratic complexity theory and the theory of associative algebras. In §§3 and 4 we study the complexity of $[x_1 y, \ldots, x_n y]_{\mathbf{A}}$ and $[x^T H y]_{\mathbf{A}}$, respectively.

2. Preliminary results. In this section we give some preliminary results.

2.1. Dual sets and equivalent sets.

DEFINITION 1. *Let $B = \{B_1, \ldots, B_k\}$ be a set of $n \times m$ matrices. We define the T-dual and D-dual sets of B to be*

$$B^T = \{B_1^T, \ldots, B_k^T\} \quad \text{and} \quad B^D = \{C_1, \ldots, C_m\},$$

respectively. Here B_i^T is the transpose of B_i and B^D denotes the set of $n \times k$ matrices that satisfy

$$C_i^{(j)} = B_j^{(i)}, \qquad i = 1, \ldots, m\ ;\ j = 1, \ldots, k,$$

where $B_i^{(j)}$ is the jth column of B_i. That is,

$$C_i = [B_1 e_{m,i} | \ldots | B_k e_{m,i}],$$

where $e_{m,i}$ is the ith column unit vector of order m.

We also define $B^E = B^{T\,DT}$, i.e., $B^E = \{D_1, \ldots, D_n\}$, where each

$$D_i = \begin{bmatrix} e_{n,i}^T B_1 \\ \vdots \\ e_{n,i}^T B_k \end{bmatrix}.$$

DEFINITION 2. *Let $B = \{B_1, \ldots, B_k\}$ be a set of $n \times m$ matrices. Let M, N, and $K = (K_{i,j})$ be $m \times m'$, $n' \times n$, and $k' \times k$ matrices, respectively. We define*

$$NBM = \{NB_1M, \ldots, NB_kM\} \quad \text{and} \quad B[K] = \left\{ \sum_{j=1}^{k} K_{1,j} B_j, \ldots, \sum_{j=1}^{k} K_{k',j} B_j \right\}.$$

DEFINITION 3. *Let $B = \{B_1, \ldots, B_k\}$ and $C = \{C_1, \ldots, C_{k'}\}$ be sets of $n \times m$ and $n' \times m'$ matrices, respectively. We define*

$$B \oplus C = \{\tilde{B}_1, \ldots, \tilde{B}_k, \tilde{C}_1, \ldots, \tilde{C}_{k'}\},$$

where

$$\tilde{B}_i = \begin{pmatrix} B_i & 0_{n \times m'} \\ 0_{n' \times m} & 0_{n' \times m'} \end{pmatrix}, \qquad \tilde{C}_j = \begin{pmatrix} 0_{n \times m} & 0_{n \times m'} \\ 0_{n' \times m} & C_j \end{pmatrix},$$

in which $0_{s \times r}$ denotes the zero $s \times r$ matrix.

Define

$$B \otimes C = \left\{ B_i \otimes C_j \middle|\ i = 1, \ldots, k\ ;\ j = 1, \ldots, k' \right\},$$

where $\otimes$ is the Kronecker product of matrices. If $k = k'$, then

$$\operatorname{diag}(B, C) = \{\operatorname{diag}(B_1, C_1), \ldots, \operatorname{diag}(B_k, C_k)\},$$

where

$$\operatorname{diag}(B_i, C_i) = \begin{pmatrix} B_i & 0_{n\times m'} \\ 0_{n'\times m} & C_i \end{pmatrix}.$$

The following properties, which were shown in [7], hold for these definitions:

LEMMA 1 ([7]). *Let A_1, A_2, and A be sets of k_1, k_2, and k matrices of size $n_1 \times m_1$, $n_2 \times m_2$, and $n \times m$, respectively. Let N, M, and K be matrices of appropriate size and I_r be the identity matrix of order r. Then:*

(1) $A^{TT} = A$, $A^{DD} = A$, $A^{EE} = A$, $A^E = A^{TDT} = A^{DTD}$.

(2) $A[K][J] = A[JK]$, $(NAM)[K] = N(A[K])M$.

(3) $(NAM)^T = M^T A^T N^T$, $(A[K])^T = A^T[K]$.

(4) $(NA)^D = NA^D$, $(AM)^D = A^D[M^T]$, $(A[K])^D = A^D K^T$.

(5) $(A_1 \oplus A_2)^T = A_1^T \oplus A_2^T$, $(A_1 \oplus A_2)^D = A_1^D \oplus A_2^D$.

(6) $(A_1 \otimes A_2)^T = A_1^T \otimes A_2^T$, $(A_1 \otimes A_2)^D = A_1^D \otimes A_2^D$.

(7) $A_1[K] \oplus A_2 = (A_1 \oplus A_2)[\operatorname{diag}(K, I_{k_2})]$, $NA_1M \oplus A_2 = \operatorname{diag}(N, I_{n_2})(A_1 \oplus A_2)\operatorname{diag}(M, I_{m_2})$.

(8) $A_1[K] \otimes A_2 = (A_1 \otimes A_2)[K \otimes I_{k_2}]$, $NA_1M \otimes A_2 = (N \otimes I_{n_2})(A_1 \otimes A_2)(M \otimes I_{m_2})$.

(9) $A \otimes (A_1 \oplus A_2) = (A \otimes A_1) \oplus (A \otimes A_2)$.

If we add $A^I = A$, then the set $\{I, T, D, TD, DT, E\}$ is a group that is isomorphic to the symmetric group $S_3 = \{(\,), (1, 2), (2, 3), (1, 3, 2), (1, 2, 3), (1, 3)\}$.

DEFINITION 4. *For two k-sets of $n \times m$ matrices B and C we say that B is equivalent to C and write $B \equiv C$, if there exist nonsingular matrices N, M, and K such that*

$$B = N(C[K])M.$$

Obviously, this relation is an equivalence relation.

The following lemma gives some properties of the equivalece relation.

LEMMA 2 ([7]). *Let $A_1, \ldots, A_j$; $B_1, \ldots, B_j$ be sets of matrices. Then:*

(1) *If $A_1 \equiv B_1$, then $A_1^D \equiv B_1^D$ and $A_1^T \equiv B_1^T$.*

(2) *$B_1 \oplus \cdots \oplus B_j \equiv B_{\phi(1)} \oplus \cdots \oplus B_{\phi(j)}$ and $B_1 \otimes \cdots \otimes B_j \equiv B_{\phi(1)} \otimes \cdots \otimes B_{\phi(j)}$ for any permutation ϕ on $\{1, \ldots, j\}$.*

(3) *If $A_i \equiv B_i$, $i = 1, \ldots, j$, then $A_1 \oplus \cdots \oplus A_j \equiv B_1 \oplus \cdots \oplus B_j$ and $A_1 \otimes \cdots \otimes A_j \equiv B_1 \otimes \cdots \otimes B_j$.*

2.2. Quadratic and bilinear complexity.

DEFINITION 5. *Let $A = \{A_1, \ldots, A_k\}$ be a set of matrices. We define*

$$\operatorname{rowrank}(A) = \operatorname{rank}[A_1 | \ldots | A_k], \qquad \operatorname{colrank}(A) = \operatorname{rank}[A_1^T | \ldots | A_k^T],$$

and

$$\dim(A) = \dim \operatorname{Span}(A),$$

where Span(A) *is the linear space spanned by the elements of A.*

The following can be easily proved

LEMMA 3. *Let A be a set of matrices. Then*

(1) rowrank$(A) = \dim(A^E)$, colrank$(A) = \dim(A^D)$.

(2) *If* $A \equiv B$, *then*

$$\text{rowrank}(B) = \text{rowrank}(A), \qquad \text{colrank}(B) = \text{colrank}(A).$$

Let $\mathbf{x} = (x_1, \dots, x_n)$ and $\mathbf{y} = (y_1, \dots, y_n)$ be vectors of indeterminates. For a set of $n \times m$ matrices $A = \{A_1, \dots, A_k\}$, we denote by $\mu(A)$ (respectively, by $\delta(A)$) the quadratic complexity (respectively, bilinear complexity) of the bilinear forms $\{\mathbf{x}^T A_1 \mathbf{y}, \dots, \mathbf{x}^T A_k \mathbf{y}\}$. We will call $\{\mathbf{x}^T A_1 \mathbf{y}, \dots, \mathbf{x}^T A_k \mathbf{y}\}$ the set of bilinear forms *defined by* $A = \{A_1, \dots, A_k\}$.

From [8], [14], and [16] we have:

LEMMA 4. *Let A and B be sets of matrices. We have:*

(1) $\mu(A) \le \delta(A) < 2\mu(A)$.

(2) $\delta(A) = \delta(A^T) = \delta(A^D) = \delta(A^E)$, $\mu(A) = \mu(A^T)$.

(3) *If* $A \equiv B$, *then* $\mu(A) = \mu(B)$.

(4) $\mu(A \oplus B) \le \mu(A) + \mu(B)$ *and* $\mu(I_t \otimes A) \le \mu(\bigoplus_{i=1}^t A) \le t\mu(A)$.

(5) $\mu(A \otimes B) \le \mu(A)\mu(B)$.

(6) $\mu(A) \ge \frac{1}{2}\delta(\text{diag}(A, A^T))$.

(7) $DSC_{SLA} = DSC_{QA}$ *and* $DSCS_{SLA} = DSCS_{QA}$.

(8) *If* $A, B \in DSCS_{SLA}$, *then* $A \oplus B \in DSCS_{SLA}$.

(3), (4), (5), *and* (8) *are also true for the bilinear complexity*, δ.

From [6] we have:

LEMMA 5 ([6]). *Let A be a set of matrices. If for every nonsingular matrix N there exist* $A_1, \dots, A_s \in A[N]$ *such that*

$$\text{rowrank}\{A_1, \dots, A_s\} \ge t \qquad \text{or} \qquad \text{colrank}\{A_1, \cdots, A_s\} \ge t,$$

then

$$\mu(A) \ge \dim\ A + t - s.$$

2.3. Complexity of a direct sum of sets.

DEFINITION 6. *We denote by $DS^*(r)$ the collection of sets of matrices A, such that there exists a linear subspace A_1 of* Span(A) *and integers s and t, where:*

(1) *For any nonsingular matrix N and for any* $B_1 \in (\text{Span}(A)\backslash A_1) \cap A[N]$ *there exist* $s - 1$ *matrices* $B_2, \dots, B_s \in (\text{Span}(A)\backslash A_1) \cap A[N]$ *such that*

$$\text{rowrank}\{B_1, \dots, B_s\} \ge t \qquad \textit{or} \qquad \text{colrank}\{B_1, \dots, B_s\} \ge t,$$

and

(2) $\mu(A) = \dim(A) + t - s + r$.

In [6], we proved the following two lemmas.

LEMMA 6. (1) *If* $A \in DS^*(0)$, *then* $A \in DSCS_{SLA}$.

(2) *If* $A \in DS^*(1)$, *then* $A \in DSC_{SLA}$.

(3) *If* $A \in DS^*(r), r > 1$, *then for every set of matrices B we have*

$$\mu(A \oplus B) \ge \mu(A) + \mu(B) - (r - 1).$$

Notice that all the results in Lemmas 5 and 6 are also true for the bilinear complexity.

LEMMA 7 ([6]). $A \in DSCS_{BA}$ *if and only if* $A^D \in DSCS_{BA}$ *if and only if* $A^E \in DSCS_{BA}$.

Using the results in [16] we prove another lemma that will be used in this paper. For the proof, we need the following

PROPOSITION 1 ([6]). *Let* $\mathbf{x}$ *and* $\mathbf{u}$ *be distinct vectors of indeterminates and let* $Q_{\mathbf{x}}^{(1)}$ *and* $Q_{\mathbf{u}}^{(2)}$ *be two sets of quadratic forms. Then* $(Q_{\mathbf{x}}^{(1)}, Q_{\mathbf{u}}^{(2)}) \in DSCS_{SLA}$ *if and only if for any minimal quadratic algorithm* $\sigma_1, \dots, \sigma_t$ *for* $Q_{\mathbf{x}}^{(1)} \oplus Q_{\mathbf{u}}^{(2)}$ *we have* $\sigma_i \in F[\mathbf{x}] \cup F[\mathbf{u}]$ *for all* $1 \le i \le t$.

The proposition is also true for the bilinear complexity.

LEMMA 8. *Let* $A = \{A_1, \dots, A_k\}$ *and* $B = \{B_1, \dots, B_{k'}\}$ *be sets of matrices. If*

(1) $(\mathrm{diag}(A, A^T), \mathrm{diag}(B, B^T)) \in DSCS_{BA}$

and

(2) $\delta(\mathrm{diag}(A, A^T)) = 2\delta(A)$ *and* $\delta(\mathrm{diag}(B, B^T)) = 2\delta(B)$,

then $(A, B) \in DSCS_{SLA}$.

Proof. If $(A, B) \notin DSCS_{SLA}$, then by Proposition 1, there exists a minimal quadratic algorithm $\sigma_1, \dots, \sigma_t$ for $\{\mathbf{x}^T A_1 \mathbf{y}, \dots, \mathbf{x}^T A_k \mathbf{y}, \mathbf{u}^T B_1 \mathbf{v}, \dots, \mathbf{u}^T B_{k'} \mathbf{v}\}$, where $\sigma_{i_0} \in F[\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{v}] \setminus (F[\mathbf{x}, \mathbf{y}] \cup F[\mathbf{u}, \mathbf{v}])$ for some $1 \le i_0 \le t$.

Let

$$\sigma_i = (a_{i,1}(\mathbf{x}) + a_{i,2}(\mathbf{y}) + a_{i,3}(\mathbf{u}) + a_{i,4}(\mathbf{v}))(b_{i,1}(\mathbf{x}) + b_{i,2}(\mathbf{y}) + b_{i,3}(\mathbf{u}) + b_{i,4}(\mathbf{v})).$$

It is known from [16] that the algorithm $(\tilde{\sigma}_{i,j})_{i=1,\dots,t,\ j=1,2}$, where

$$\tilde{\sigma}_{i,1} = (a_{i,1}(\mathbf{x}) + a_{i,2}(\mathbf{x}') + a_{i,3}(\mathbf{u}) + a_{i,4}(\mathbf{u}'))(b_{i,1}(\mathbf{y}') + b_{i,2}(\mathbf{y}) + b_{i,3}(\mathbf{v}') + b_{i,4}(\mathbf{v}))$$

and

$$\tilde{\sigma}_{i,2} = (b_{i,1}(\mathbf{x}) + b_{i,2}(\mathbf{x}') + b_{i,3}(\mathbf{u}) + b_{i,4}(\mathbf{u}'))(a_{i,1}(\mathbf{y}') + a_{i,2}(\mathbf{y}) + a_{i,3}(\mathbf{v}') + a_{i,4}(\mathbf{v})),$$

is a bilinear algorithm that computes the bilinear forms defined by $D = \mathrm{diag}(A, A^T) \oplus \mathrm{diag}(B, B^T)$. Since

$$\delta(\mathrm{diag}(A, A^T) \oplus \mathrm{diag}(B, B^T)) = \delta(\mathrm{diag}(A, A^T)) + \delta(\mathrm{diag}(B, B^T)) = 2\delta(A) + 2\delta(B),$$

we have that $\{\tilde{\sigma}_{i,j}\}_{i=1,\dots,t,\ j=1,2}$ is a minimal bilinear algorithm for D. Since

$$(\mathrm{diag}(A, A^T), \mathrm{diag}(B, B^T)) \in DSCS_{BA}$$

and since

$$\tilde{\sigma}_{i_0,1} \in F[\mathbf{x}, \mathbf{x}', \mathbf{y}, \mathbf{y}', \mathbf{u}, \mathbf{u}', \mathbf{v}, \mathbf{v}'] \setminus (F[\mathbf{x}, \mathbf{x}', \mathbf{y}, \mathbf{y}'] \cup F[\mathbf{u}, \mathbf{u}', \mathbf{v}, \mathbf{v}']),$$

we have a contradiction to Proposition 1, which implies the result. □

2.4. Regular representation of algebras. In this subsection we will give the results of [7] that will be used in the following sections.

Let **A** be an associative algebra with identity element 1, and let $\{a_1, \dots, a_n\}$ be a basis of the algebra **A**. Let

$$a_i a_j = \sum_{k=1}^{n} \gamma_{i,j,k} a_k,$$

with $\gamma_{i,j,k} \in F$, $i, j, k = 1, \dots, n$. Then for $x = \sum_{i=1}^n x_i a_i$ and $y = \sum_{j=1}^n y_j a_j$ we have

$$xy = \left(\sum_{i=1}^{n} x_i a_i\right)\left(\sum_{j=1}^{n} y_j a_j\right) = \sum_{k=1}^{n}\left(\sum_{i=1}^{n}\sum_{j=1}^{n} \gamma_{i,j,k} x_i y_j\right) a_k.$$

Let $a_i a = \sum_{k=1}^{n} \sigma_{i,k} a_k$, and define $A_a = (\sigma_{i,k})$ to be a square $n \times n$ matrix. Then it is known that $\mathbf{RR}(\mathbf{A}) = \{A_a | a \in \mathbf{A}\}$ forms an algebra over F that is isomorphic to $\mathbf{A}$ under the correspondence $a \to A_a$ and that $\{A_{a_1}, \ldots, A_{a_n}\}$ is a basis for the algebra $\mathbf{RR}(\mathbf{A})$. Therefore, we have: $A_\lambda = \lambda I_n$; $A_a A_b = A_{ab}$; $A_a + A_b = A_{a+b}$; $\lambda A_a = A_{\lambda a}$ for $\lambda \in F$; and if $ab = 1$, then $A_a^{-1} = A_b$. The algebra $\mathbf{RR}(\mathbf{A})$ is called the *right regular representation* of $\mathbf{A}$.

We define

$$\mathbf{B}(\mathbf{A}) = \{B_1, \ldots, B_n\},$$

where

$$\mathbf{x}^T B_i \mathbf{y} = \sum_{i=1}^{n} \sum_{j=1}^{n} \gamma_{i,j,k} x_i y_j,$$

for $\mathbf{x} = (x_1, \ldots, x_n)^T$, $\mathbf{y} = (y_1, \ldots, y_n)^T$. That is, $\mathbf{x}^T B_i \mathbf{y}$ is the ith coefficient of the product

$$xy = \left(\sum_{i=1}^{k} x_i a_i\right)\left(\sum_{i=1}^{k} y_i a_i\right).$$

Let $\mathbf{C}(\mathbf{A}) = \{A_{a_1}, \ldots, A_{a_n}\}$. In [7] we gave the following connection between $\mathbf{B}(\mathbf{A})$ and $\mathbf{C}(\mathbf{A})$.

LEMMA 9. *We have*

$$\mathbf{C}(\mathbf{A})^D = \mathbf{B}(\mathbf{A}).$$

Obviously, $\mathbf{C}(\mathbf{A})$ and $\mathbf{B}(\mathbf{A})$ depend on the chosen basis $B = \{a_1, \ldots, a_n\}$. When we want to emphasize this dependency, we write $\mathbf{C}(\mathbf{A}, B)$ and $\mathbf{B}(\mathbf{A}, B)$.

The following two lemmas are also well known.

LEMMA 10. *Let* $\mathbf{A}_1$ *and* $\mathbf{A}_2$ *be algebras. Let* $\mathbf{A}_1 \otimes \mathbf{A}_2$ *be the tensor product of the algebras* $\mathbf{A}_1$ *and* $\mathbf{A}_2$, *and let* $\mathbf{A}_1 \times \mathbf{A}_2$ *be the direct product of* $\mathbf{A}_1$ *and* $\mathbf{A}_2$. *Then*

$$\mathbf{C}(\mathbf{A}_1 \times \mathbf{A}_2) \equiv \mathbf{C}(\mathbf{A}_1) \oplus \mathbf{C}(\mathbf{A}_2), \quad \mathbf{B}(\mathbf{A}_1 \times \mathbf{A}_2) \equiv \mathbf{B}(\mathbf{A}_1) \oplus \mathbf{B}(\mathbf{A}_2),$$

$$\mathbf{C}(\mathbf{A}_1 \otimes \mathbf{A}_2) \equiv \mathbf{C}(\mathbf{A}_1) \otimes \mathbf{C}(\mathbf{A}_2), \quad \mathbf{B}(\mathbf{A}_1 \otimes \mathbf{A}_2) \equiv \mathbf{B}(\mathbf{A}_1) \otimes \mathbf{B}(\mathbf{A}_2).$$

For the next lemma we need the following

DEFINITION 7. *An algebra* $\mathbf{A}$ *is called a Frobenuis algebra if there exists a linear function* $\lambda \in \mathbf{A}^*$ *whose kernel contain no left or right ideals different from zero. For other definitions of Frobenuis algebras see* [19]. *The following lemma can also be a definition for Frobenuis algebras*

LEMMA 11. *Let* $\mathbf{A}$ *be an algebra, and let* $\mathbf{A}^-$ *be the reciprocal algebra. Then* $\mathbf{A}$ *is a Frobenuis algebra if and only if*

$$\mathbf{C}(\mathbf{A}^-) \equiv \mathbf{B}(\mathbf{A}).$$

In [7] it is proved that

LEMMA 12. *A local algebra* $\mathbf{A}$ *is a Frobenuis algebra if and only if there exists an element* $d \in \mathbf{A}$ *such that*

$$l(\text{rad}\mathbf{A}) = \{a | a \ \text{rad}\mathbf{A} = 0\} = d\mathbf{A}.$$

Let $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_n$ *where each* $\mathbf{A}_i$ *is a local algebra. Then* $\mathbf{A}$ *is a Frobenuis algebra if and only if each* $\mathbf{A}_i$ *is a Frobenuis algebra.*

Before we leave this subsection we shall prove the following.

LEMMA 13. *Let* $\mathbf{A}$ *be a local algebra. There exists a basis* $\{a_1, \ldots, a_k, a_{k+1}, \ldots, a_{rk}\}$ *for* $\mathbf{A}$*, such that* $a_1, \ldots, a_k \notin \text{rad } \mathbf{A}$, $a_{k+1}, \ldots, a_{rk} \in \text{rad } \mathbf{A}$,

$$(6) \qquad A_{a_i} = \begin{pmatrix} \tilde{A}_i & & * \\ & \ddots & \\ 0 & & \tilde{A}_i \end{pmatrix}, \qquad i = 1, \ldots, k,$$

where $\mathbf{C}(\mathbf{A}/\text{rad } \mathbf{A}) = \{\tilde{A}_i\}_{i=1,\ldots,k}$, *and*

$$(7) \qquad A_{a_i} = \begin{pmatrix} 0_{k\times k} & & * \\ & \ddots & \\ 0 & & 0_{k\times k} \end{pmatrix}, \qquad i = k+1, \ldots, rk.$$

Proof. Let $\mathbf{A} = L \oplus_F \text{rad } \mathbf{A}$, where L is a complementary subspace of rad $\mathbf{A}$ and $\oplus_F$ is the direct sum of subspaces. Let $\{a_1, \ldots, a_k\}$ be a basis for L. Since $\mathbf{A}$ is local, all the elements in L are invertible. Let i_0 be the least integer such that $(\text{rad } \mathbf{A})^{i_0} \neq 0$ and $(\text{rad } \mathbf{A})^{i_0+1} = 0$. We now prove that there exist $b_1, b_2, \ldots, b_{k_0} \in (\text{rad } \mathbf{A})^{i_0}$, such that $b_1 L \oplus_F \cdots \oplus_F b_{k_0} L = (\text{rad } \mathbf{A})^{i_0}$. We first choose an element $b_1 \in (\text{rad } \mathbf{A})^{i_0}$. Since L contains invertible elements, we have that $b_1 L \subseteq (\text{rad } \mathbf{A})^{i_0}$. Suppose $b_1 L \oplus_F \cdots \oplus_F b_k L \subseteq (\text{rad } \mathbf{A})^{i_0}$ for some $b_1, \ldots, b_k \in (\text{rad } \mathbf{A})^{i_0}$. Let $b_{k+1} \in (\text{rad } \mathbf{A})^{i_0} \backslash (b_1 L \oplus_F \cdots \oplus_F b_k L)$. Then $b_{k+1} L \subseteq (\text{rad } \mathbf{A})^{i_0}$. If $b_{k+1} L \cap (b_1 L \oplus_F \cdots \oplus b_k L) \neq 0$, then there exist $a_1, \ldots, a_{k+1} \in L$ such that $b_{k+1} a_{k+1} = b_1 a_1 + \cdots + b_k a_k$, which implies that $b_{k+1} = b_1 a_1 a_{k+1}^{-1} + \cdots + b_k a_k a_{k+1}^{-1} \in b_1 \mathbf{A} + \cdots + b_k \mathbf{A} = b_1 (L \oplus_F \text{rad } \mathbf{A}) + \cdots + b_k (L \oplus_F \text{rad } \mathbf{A}) = b_1 L + \cdots + b_k L$. This is a contradiction. Therefore $b_1 L \oplus_F \cdots \oplus_F b_{k+1} L \subseteq (\text{rad } \mathbf{A})^{i_0}$.

This proves that there exist $b_1, \ldots, b_{k_0} \in (\text{rad } \mathbf{A})^{i_0}$ such that $\{b_i a_j\}_{\substack{i=1,\ldots,k_0 \\ j=1,\ldots,k}}$ is a basis for $(\text{rad } \mathbf{A})^{i_0}$ and

$$L_{i_0} = b_1 L \oplus_F \cdots \oplus_F b_{k_0} L = (\text{rad } \mathbf{A})^{i_0}.$$

We now handle the set $(\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}$. Let $b_{k_0+1} \in (\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}$. Then $b_{k_0+1} L \subseteq (\text{rad } \mathbf{A})^{i_0-1} \backslash\ (\text{rad } \mathbf{A})^{i_0}$ and therefore $b_{k_0+1} L \cap L_{i_0} = 0$. Suppose $b_{k_0+1} L \oplus_F \cdots \oplus_F b_k L \subseteq (\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}$. Let $b_{k_0+k+1} \in ((\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}) \backslash\ (b_{k_0+1} L \oplus_F \cdots \oplus_F b_k L)$, where $b_{k_0+1}, \ldots, b_k \in (\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}$. If $b_{k_0+k+1} L \cap (b_{k_0+1} L \oplus_F \cdots \oplus_F b_k L \oplus_F L_{i_0}) \neq \{0\}$, then there exist $a_1, \ldots, a_{k+1} \in L$ and $c \in L_{i_0}$, such that $b_{k_0+k+1} a_{k+1} = b_{k_0+1} a_1 + \cdots + b_{k_0+k} a_k + c$. Then $b_{k_0+k+1} = b_{k_0+1} a_1 a_{k+1}^{-1} + \cdots + b_{k_0+k} a_k a_{k+1}^{-1} + c a_{k+1}^{-1}$. Since the $a_i a_{k+1}^{-1}$ are invertible, we have $a_i a_{k+1}^{-1} = c_i + w_i$, where $0 \neq c_i \in L$ and $w_i \in \text{rad } \mathbf{A}$. As a result, $b_{k_0+k+1} = \sum_{i=1}^{k} b_{k_0+i} c_i + \sum_{i=1}^{k} b_{k_0+i} w_i + c a_{k+1}^{-1}$. Now, $\sum_{i=1}^{k} b_{k_0+1} w_i + c a_{k+1}^{-1} \in (\text{rad } \mathbf{A})^{i_0}$ and $c_i \in L$. Therefore $b_{k_0+k+1} \in b_{k_0+1} L + \cdots + b_{k_0+k-1} L + L_{i_0}$, which is a contradiction. In this way we can find $b_{k_0+1}, \ldots, b_{k_1}$ such that

$$L_{i_0-1} = b_{k_0+1} L \oplus_F \cdots \oplus_F b_{k_1} L = (\text{rad } \mathbf{A})^{i_0-1} \backslash (\text{rad } \mathbf{A})^{i_0}.$$

Therefore (by induction) there exist elements $b_1, \ldots, b_r$ such that

$$\mathbf{A} = L \oplus_F b_1 L \oplus_F \cdots \oplus_F b_r L$$

and such that if $b_{i_1} \in (\text{rad } \mathbf{A})^{j_1} \backslash (\text{rad } \mathbf{A})^{j_1-1}$, $b_{i_2} \in (\text{rad } \mathbf{A})^{j_2} \backslash (\text{rad } \mathbf{A})^{j_2-1}$ and $i_2 > i_1$, then $j_2 \leq j_1$.

We now find the regular representation $\mathbf{C}(\mathbf{A}, B)$, where $B = \{b_{r-i+1}a_j\}_{\substack{i=0,\ldots,r\\ j=1,\ldots,k}}$ and $b_0 = 1$.

Let $\phi : \mathbf{A} \to \mathbf{A}/\text{rad } \mathbf{A}$ be a canonical projection. Then $c_i = \phi(a_i)$, $i = 1, \ldots, k$, is a basis of $\mathbf{A}/\text{rad } \mathbf{A}$. If

$$c_i c_j = \sum_{l=1}^{k} \gamma_{i,j,l} c_l, \tag{8}$$

then since $\phi(a_i a_j) = c_i c_j = \sum_{l=1}^{k} \gamma_{i,j,l} c_l = \phi\left(\sum_{l=1}^{k} \gamma_{i,j,l} a_l\right)$, we have

$$a_i a_j = \sum_{l=1}^{k} \gamma_{i,j,l} a_l + w_{i,j}, \quad \text{for some } w_{i,j} \in \text{rad } \mathbf{A}.$$

Suppose

$$b_i \in (\text{rad } \mathbf{A})^{n_{b_i}} \backslash (\text{rad } \mathbf{A})^{n_{b_i}+1}, \qquad n_{b_i} \geq 1 \text{ and } b_0 = 1 \notin \text{rad } \mathbf{A}.$$

Now since

$$(b_t a_i) a_j = \sum_{l=1}^{k} \gamma_{i,j,l} b_t a_l + b_t w_{i,j}$$

and since $b_t w_{i,j} \in (\text{rad } \mathbf{A})^{n'} \backslash (\text{rad } \mathbf{A})^{n'+1}$ for $n' > n_{b_t}$, by (8) we have that A_{a_j} is a matrix with the shape in (6), where $\tilde{A}_j = A_{c_j}$ in $\mathbf{C}(\mathbf{A}/\text{rad } \mathbf{A}, \{c_1, \ldots, c_k\})$.

Since we have $(b_r a_i)(b_s a_j) \in b_{e-1}L \oplus_F \cdots \oplus_F b_1 L$ for $r, s > 0$, $e = \min(r, s)$, we also have that $A_{b_s a_j}$ is a matrix with the shape in (7). □

2.5. Complexity of algebras. Let $C = \{C_1, \ldots, C_k\}$ be a set of $n \times m$ matrices and let $\mathbf{A}$ be an algebra. The *quadratic complexity of C over the algebra* $\mathbf{A}$ is $\mu(C \otimes \mathbf{B}(\mathbf{A}))$, i.e., the complexity of $\{\mathbf{x}^T C_1 \mathbf{y}, \ldots, \mathbf{x}^T C_k \mathbf{y}\}$, where $\mathbf{x} = (x_1, \ldots, x_n)^T$, $\mathbf{y} = (y_1, \ldots, y_m)^T$ and x_i, y_j are elements in the algebra $\mathbf{A}$. In the same manner, we can define the bilinear complexity of C over the algebra $\mathbf{A}$ as $\delta(C \otimes \mathbf{B}(\mathbf{A}))$.

The following is proved in [7].

LEMMA 14. (1) $\delta(C \otimes \mathbf{B}(\mathbf{A})) = \delta(C^D \otimes \mathbf{C}(\mathbf{A}))$.

(2) $\mu(C \otimes \mathbf{B}(\mathbf{A})) = \mu(C^T \otimes \mathbf{B}(\mathbf{A}^-))$.

(3) *If* $\mathbf{A}$ *is a Frobenuis algebra, then* $\mu(C \otimes \mathbf{B}(\mathbf{A})) = \mu(C \otimes \mathbf{C}(\mathbf{A}))$.

3. Complexity of $x_1 y, \ldots, x_n y$ in algebras. In this section we investigate the complexity of computing $\{x_1 y, \ldots, x_n y\}$ in algebras that are direct product of local algebras. This problem is equivalent to the complexity of $\mathbf{I}_n^D = \{e_{n,1}, \ldots, e_{n,n}\}$ over the algebra $\mathbf{A}$, where $e_{n,i}$ is the ith column unit vector of order n and $\mathbf{I}_n = \{I_n\}$ in which I_n is the identity $n \times n$ matrix. Therefore,

$$\mu([x_1 y, \ldots, x_n y]) = \mu(\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A})).$$

Since $(\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}))^D = \mathbf{I}_n \otimes \mathbf{C}(\mathbf{A}) = \left\{I_n \otimes A_{a_i} \middle| \{a_i\}_{i=1,\ldots,k} \text{ is a basis for } A\right\}$, we have

$$\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) = \left\{[(I_n \otimes A_{a_1})e_{nk,i} \mid \ldots |(I_n \otimes A_{a_n})e_{nk,i}]\middle| i = 1, \ldots, nk\right\},$$

where $k = \dim\ \mathbf{A}$.

For $v \in F^{nk}$, we denote by $B(v)$ the matrix

$$B(v) = \left[(I_n \otimes A_{a_1})v\middle| \ldots \middle|(I_n \otimes A_{a_k})v\right].$$

Since $\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) = \{B(e_{nk,1}), \ldots, B(e_{nk,nk})\}$ and

$$\lambda_1 B(v_1) + \lambda_2 B(v_2) = B(\lambda_1 v_1 + \lambda_2 v_2), \tag{9}$$

we have that

$$\operatorname{Span}(\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A})) = \{B(v) | v \in F^{nk}\}.$$

We will first investigate the complexity of division algebras.

LEMMA 15. *Let* $\mathbf{A}$ *be a division algebra of dimension* k, *and let* $\{a_1, \ldots, a_k\}$ *be a basis for* $\mathbf{A}$. *Let* $v_1, \ldots, v_l \in F^{nk} \backslash \{0\}$ *and*

$$s = \dim \operatorname{Span}\left\{(I_n \otimes A_{a_i})v_j \middle| i = 1, \ldots, k;\ j = 1, \ldots, l\right\}.$$

Then for any nonsingular $l \times l$ *matrix* N, *there exist* $\frac{s}{k} - 1$ *matrices* $B(w_{i_2}), \ldots, B(w_{i_{(s/k)}})$ *in* $\{B(w_1), \ldots, B(w_l)\} = \{B(v_1), \ldots, B(v_l)\}[N]$, *such that*

$$\operatorname{rowrank}(\{B(w_1), B(w_{i_2}), \ldots, B(w_{i_{s/k}})\}) = s.$$

Proof. By (9) we have that $\{w_1, \ldots, w_l\} = \{v_1, \ldots, v_l\}[N] \subset F^{nk}$. Since N is nonsingular,

$$\operatorname{Span}(w_1, \ldots, w_l) = \operatorname{Span}(v_1, \ldots, v_l),$$

and therefore

$$\dim \operatorname{Span}\left\{(I_n \otimes A_{a_i})w_j \middle| i = 1, \ldots, k;\ j = 1, \ldots, l\right\} = s. \tag{10}$$

If $l = s/k$, then

$$\operatorname{rowrank}(\{B(w_1), B(w_2) \ldots, B(w_l)\}) = \operatorname{rank}[B(w_1)|B(w_2)| \ldots |B(w_l)]$$

$$= \dim \operatorname{Span}\left\{(I_n \otimes A_{a_i})w_j \middle| i = 1, \ldots, k,\ j = 1, \ldots, l\right\} = s, \tag{11}$$

and the proof is completed.

If $l > s/k$, then the set $\{(I_n \otimes A_{a_i})w_j | i = 1, \ldots, k\ ;\ j = 1, \ldots, l\}$ contains $lk > s$ vectors, and therefore there exists one vector that is dependent on the other. Assume that

$$\sum_{i=1}^{k} \lambda_i (I_n \otimes A_{a_i}) w_{j_0} = \sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq j_0}}^{l} \delta_{i,j} (I_n \otimes A_{a_i}) w_j \tag{12}$$

for some $1 \leq j_0 \leq l$, where not all the λ_i are zero. If all the $\delta_{i,j}$ are zero, then $\sum_{i=1}^{k} \lambda_i (I_n \otimes A_{a_i}) w_{j_0} = 0$, and therefore

$$\sum_{i=1}^{k} \lambda_i (I_n \otimes A_{a_i}) w_{j_0} = \left(I_n \otimes \left(\sum_{i=1}^{k} \lambda_i A_{a_i}\right)\right) w_{j_0} = (I_n \otimes A_a) w_{j_0} = 0, \tag{13}$$

for $a = \sum_{i=1}^{k} \lambda_i a_i \neq 0$. Since $\mathbf{A}$ is a division algebra, $I_n \otimes A_a$ is a nonsingular matrix and (13) implies that $w_{j_0} = 0$. This is a contradiction. Therefore, not all of the $\delta_{i,j}$ are zero. This implies that we can choose $j_0 \neq 1$, such that (12) is satisfied. Then for $a = \sum_{i=1}^{k} \lambda_i a_i$, we obtain

$$(I_n \otimes A_a)w_{j_0} = \sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq j_0}}^{l} \delta_{i,j}(I_n \otimes A_{a_i})w_j,$$

which implies

$$w_{j_0} = \sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq j_0}}^{l} \delta_{i,j}(I_n \otimes A_{a^{-1}a_i})w_j = \sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq 0}}^{l} \delta'_{i,j}(I_n \otimes A_{a_i})w_j.$$

Now for every $d = 1, \ldots, k$ we have

$$(I_n \otimes A_{a_d})w_{j_0} = \sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq 0}}^{l} \delta_{i,j,d}(I_n \otimes A_{a_i})w_j,$$

which implies that

$$\dim\ \mathrm{Span}\left\{(I_n \otimes A_{a_i})w_j \middle| i = 1, \ldots, k;\ j = 1, \ldots, l;\ j \neq j_0 \neq 1\right\} = s.$$

Now, by induction it can be proved that there exist $i_1 = 1, i_2, \ldots, i_{(s/k)}$ such that

$$\dim\ \mathrm{Span}\left\{(I_n \otimes A_i)w_{i_q} \middle| i = 1, \ldots, k; q = 1, \ldots, s/k\right\} = s.$$

Then, as in (11), we have

$$\mathrm{rowrank}(\{B(w_1), B(w_{i_2}), \ldots, B(w_{i_{(s/k)}})\}) = s. \qquad \square$$

Let $\mathbf{A}$ be an algebra, and let $\{a_1, \ldots, a_k\}$ be a basis for $\mathbf{A}$. For $v_1, \ldots, v_l \in F^{nk}$ we define

$$L_{\mathbf{A}}(\{v_1, \ldots, v_l\}) = \mathrm{Span}\left(\left\{(I_n \otimes A_{a_i})v_j \middle| i = 1, \ldots, k\ ;\ j = 1, \ldots, l\right\}\right).$$

The following theorem gives a lower bound for the complexity of a subset $B \subseteq \mathrm{Span}(\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}))$.

THEOREM 1. *Let* $\mathbf{A}$ *be a division algebra,* $V = \{v_1, \ldots, v_l\} \subseteq F^{n \dim \mathbf{A}}$ *and* $B = \{B(v_1), \ldots, B(v_l)\}$. *Then*

$$\mu(B) \geq \mu_0 = \dim\ \mathrm{Span}(V) + \left(1 - \frac{1}{\dim \mathbf{A}}\right) \dim\ L_{\mathbf{A}}(V).$$

(1) *If* $\mu(B) = \mu_0$, *then* $B \in DSCS_{SLA}$.
(2) *If* $\mu(B) = \mu_0 + 1$, *then* $B \in DSC_{SLA}$.
(3) *If* $\mu(B) > \mu_0 + 1$, *then for any set of matrices* C *we have*

$$\mu(B \oplus C) \geq \mu_0 + 1 + \mu(C).$$

Proof. We shall prove that $B \in DS^*$. By Lemma 15, for any nonsingular $l \times l$ matrix N and any $B(w_1) \in B[N]$, there exist $r - 1 = (\dim\ L_{\mathbf{A}}(\{v_1, \ldots, v_l\}) / \dim \mathbf{A}) - 1$ matrices $B(w_2), \ldots, B(w_r) \in B[N]$ such that

$$\mathrm{rowrank}(\{B(w_1), \ldots, B(w_r)\}) \geq \dim\ L_{\mathbf{A}}(\{v_1, \ldots, v_l\}).$$

Then by Lemma 5,

$$\mu(B) \geq \dim(B) + \left(1 - \frac{1}{\dim \mathbf{A}}\right) \dim L_{\mathbf{A}}(V)$$
$$= \dim \operatorname{Span}(V) + \left(1 - \frac{1}{\dim \mathbf{A}}\right) \dim L_{\mathbf{A}}(V).$$

By Lemma 6, the results (1) through (3) follow. □

THEOREM 2. *Let* $\mathbf{A}$ *be a direct sum of division algebras* $\mathbf{D}_1 \times \cdots \times \mathbf{D}_k$. *Then for any set of matrices* C,

$$\mu((\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A})) \oplus C) \geq (2 \dim \mathbf{A} - k)n + \mu(C).$$

If the bound is tight, then $\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) \in DSCS_{SLA}$.

Proof. By Theorem 1, we have for $B = \mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}_i)$ that $\dim B = n \dim \mathbf{D}_i$ and $\dim L_{\mathbf{D}_i}(V) = n \dim \mathbf{D}_i$, and therefore

$$\mu((\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{D}_i)) \oplus C) \geq (2 \dim(\mathbf{D}_i) - 1)n + \mu(C).$$

Since by Lemma 1 and (10), we have $\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) = \bigoplus_{i=1}^{w} (\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{D}_i))$, the result follows. □

For a matrix S we denote the linear space spanned by the columns and the rows of S by $L_{\text{col}}(S)$ and $L_{\text{row}}(S)$, respectively. We have:

LEMMA 16. *Let* $\mathbf{A}$ *be a division algebra of dimension* k. *Then for any nonsingular* $(nk \times nk)$ *matrix* N *and for any* $C_1 \in (\mathbf{I}_n^D \otimes \mathbf{C}(\mathbf{A}))[N]$, *there exist* $n-1$ *matrices* $C_2, \ldots, C_n \in (\mathbf{I}_n^D \otimes \mathbf{C}(\mathbf{A}))[N]$ *such that*

$$L_{\text{col}}[C_1 | \ldots | C_n] = F^{nk}.$$

And for any nonsingular $(nk \times nk)$ *matrix* N *and for any* $C_1 \in (\mathbf{I}_n^E \otimes \mathbf{C}(\mathbf{A}))[N]$, *there exist* $n-1$ *matrices* $C_2, \ldots, C_n \in (\mathbf{I}_n^E \otimes \mathbf{C}(\mathbf{A}))[N]$ *such that*

$$L_{\text{row}}[C_1 | \ldots | C_n] = F^{nk}.$$

Proof. Since $\mathbf{A}$ is a division algebra, $\mathbf{A}$ is a Frobenuis algebra, by Lemma 12. Therefore, by Lemmas 11 and 2 and since $\mathbf{B}(\mathbf{A}^-) = \mathbf{B}(\mathbf{A})^T$,

$$\mathbf{I}_n^D \otimes \mathbf{C}(\mathbf{A}) \equiv \mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}^-) \quad \text{and} \quad \mathbf{I}_n^E \otimes \mathbf{C}(\mathbf{A}) \equiv \mathbf{I}_n^E \otimes \mathbf{B}(\mathbf{A}^-) = (\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}))^T.$$

Therefore, by Lemma 15, the result follows. □

LEMMA 17. *Let* $\mathbf{A}$ *be a local algebra of dimension* k *and* $S = \mathbf{I}_n^D \otimes \mathbf{C}(\mathbf{A})$. *There exists a linear space* $S_1 \subseteq \operatorname{Span}(S)$ *such that for any nonsingular* $(nk \times nk)$ *matrix* N *and any* $C_1 \in S[N] \cap (\operatorname{Span}(S) \backslash S_1)$ *there exist* $C_2, \ldots, C_n \in S[N] \cap (\operatorname{Span}(S) \backslash S_1)$, *where*

$$\operatorname{colrank}\{C_1, \ldots, C_n\} = n \dim \mathbf{A}.$$

This lemma is also true for $S' = \mathbf{I}_n^E \otimes \mathbf{C}(\mathbf{A})$ with rowrank.

Proof. We shall use the basis in Lemma 13. Let $\mathbf{C}(\mathbf{A}) = \{A_{a_1}, \ldots, A_{a_k}, A_{a_{k+1}}, \ldots, A_{a_{rk}}\}$, $S_1 = \mathbf{I}_n^D \otimes \operatorname{Span}\{A_{a_{k+1}}, \ldots, A_{a_{rk}}\}$ and $S_2 = (\operatorname{Span}(S) \backslash S_1)$. By Lemma 13, taking the first k columns in A_{a_i}, $i = 1, \ldots, k$, we get $[\tilde{A}_i^T | 0_{k \times k} | \ldots | 0_{k \times k}]^T$, where $\mathbf{C}(\mathbf{A}/\text{rad } \mathbf{A}) = \{\tilde{A}_i\}$.

Taking the first k columns of A_{a_i}, $i > k$, we get $[0_{k\times k}|\ldots|0_{k\times k}]^T$. Since $\mathbf{A}$ is local, $\mathbf{A}/\text{rad}\,\mathbf{A}$ is a division algebra, and therefore we can apply Lemma 16 to it.

Let N be any nonsingular $(nk\times nk)$ matrix. Observing the first k columns of the matrices in $(\mathbf{I}_n^D\otimes\mathbf{C}(\mathbf{A}))[N]$, we conclude by Lemma 16 that for any $C_1\in(\mathbf{I}_n^D\otimes\mathbf{C}(\mathbf{A}))[N]\cap S_2$ there exist $C_2,\ldots,C_n\in(\mathbf{I}_n^D\otimes\mathbf{C}(\mathbf{A}))[N]\cap S_2$, such that $\dim\ L_{\text{col}}(\text{first } k \text{ columns in } C_1,\ldots,C_n)=nk$. In fact, it can be easy to verify that

$$\begin{aligned}&L_{\text{col}}(\text{first } k \text{ columns in } C_1,\ldots,C_n)\\&\quad=\left\{(v_1,0_{\dim\mathbf{A}-k},v_2,0_{\dim\mathbf{A}-k},\ldots,v_n,0_{\dim\mathbf{A}-k})^T|(v_1,v_2,\ldots,v_n)\in F^{nk}\right\},\end{aligned}$$

where $0_j=(0,\overset{j\text{times}}{\ldots},0)$. Since $[C_1|\ldots|C_n]$ is of the form

$$\begin{pmatrix}
C_{1,1} & & & * & & C_{1,n} & & & *\\
& C_{1,1} & & & \cdots & & C_{1,n} & & \\
& & \ddots & & \cdots & & & \ddots & \\
0 & & & C_{1,1} & & 0 & & & C_{1,n}\\
C_{2,1} & & & * & & C_{2,n} & & & *\\
& C_{2,1} & & & \cdots & & C_{2,n} & & \\
& & \ddots & & \cdots & & & \ddots & \\
0 & & & C_{2,1} & & 0 & & & C_{2,n}\\
& \vdots & & & \vdots & & \vdots & & \\
& \vdots & & & \vdots & & \vdots & & \\
& \vdots & & & \vdots & & \vdots & & \\
& \vdots & & & \vdots & & \vdots & & \\
C_{n,1} & & & * & & C_{n,n} & & & *\\
& C_{n,1} & & & \cdots & & C_{n,n} & & \\
& & \ddots & & \cdots & & & \ddots & \\
0 & & & C_{n,1} & & 0 & & & C_{n,n}
\end{pmatrix},$$

it follows that

$$L_{\text{col}}\begin{pmatrix}C_{1,1} & \cdots & C_{1,n}\\ \vdots & \vdots & \vdots\\ C_{n,1} & \cdots & C_{n,n}\end{pmatrix}=F^{nk}.$$

Therefore,

$$\begin{aligned}&L_{\text{col}}(i\text{th set of } k \text{ columns of } C_1,\ldots,C_n)\\&\quad=\{(*_{(i-1)k},v_1,0_{i(\dim\mathbf{A}-k)},*_{(i-1)k},v_2,0_{i(\dim\mathbf{A}-k)},\ldots,*_{(i-1)k},v_n,0_{i(\dim\mathbf{A}-k)})^T|\\&\qquad\qquad(v_1,v_2,\ldots,v_n)\in F^{nk}\},\end{aligned}$$

where $*_{(i-1)k}$ represents $(i-1)k$ entries with some possible nonzero elements from the field. Then obviously,

$$\begin{aligned}L_{\text{col}}(C_1,\ldots,C_n)&=L_{\text{col}}(\text{first set of } k \text{ columns of } C_1,\ldots,C_n)\oplus_F\\&\ L_{\text{col}}(\text{second set of } k \text{ columns of } C_1,\ldots,C_n)\oplus_F\\&\ \vdots\\&\ L_{\text{col}}(\text{last set of } k \text{ columns of } C_1,\ldots,C_n)=F^{n\,\dim\mathbf{A}}.\end{aligned}$$

This implies that $\text{colrank}\{C_1,\ldots,C_n\}=n\ \dim\ \mathbf{A}$. □

Lemma 17 implies the following theorem.

THEOREM 3. *Let* $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ *be an algebra where each* $\mathbf{A}_i$ *is local algebra. If* $\mathbf{A}$ *is a Frobenuis algebra, then for any set of matrices* C *we have*

$$\mu([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus C) \geq (2\dim\ \mathbf{A} - k)n + \mu(C). \tag{14}$$

If $\mathbf{A}$ *is an algebra of* n*-minimal complexity, then* (14) *holds for equality and*

$$[x_1 y, \ldots, x_n y]_{\mathbf{A}} \in DSCS_{SLA}. \tag{15}$$

Proof. We have, by Lemmas 1 and 10, that

$$[x_1 y, \ldots, x_n y] = \mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) = \bigoplus_{i=1}^{k} (\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}_i)).$$

Then by Lemmas 4 and 12 it is sufficient to prove the theorem for each of the local Frobenuis algebra $\mathbf{A}_i$.

Now since $\mathbf{A}_i$ is a Frobenuis algebra, by Lemma 14, $\mu(\mathbf{I}_n \otimes \mathbf{B}(\mathbf{A}_i)) = \mu(\mathbf{I}_n \otimes \mathbf{C}(\mathbf{A}_i))$. By Lemmas 5, 6, and 17 the result follows. □

THEOREM 4. *Let* $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ *be an algebra where each* $\mathbf{A}_i$ *is a local algebra. Then for any set of matrices* C *we have*

$$\delta([x_1 y, \ldots, x_n y]_{\mathbf{A}} \oplus C) \geq (2\dim\ \mathbf{A} - k)n + \delta(C). \tag{16}$$

If $\mathbf{A}$ *is an algebra of* n*-minimal rank, then* (16) *hold for equality and*

$$[x_1 y, \ldots, x_n y]_{\mathbf{A}} \in DSCS_{BA}.$$

Proof. As in the proof of Theorem 3, $[x_1 y, \ldots, x_n y] = \mathbf{I}_n^E \otimes \mathbf{B}(\mathbf{A})$ and

$$\delta((\mathbf{I}_n^E \otimes \mathbf{C}(\mathbf{A}^-)) \oplus C^{TD}) \geq (2\dim\ \mathbf{A} - k) + \delta(C^{TD}).$$

Then, by Lemma 4, and since $\mathbf{I}_n^{ED} = \mathbf{I}_n^E$, we have

$$\delta((\mathbf{I}_n^E \otimes \mathbf{B}(\mathbf{A}^-)) \oplus C^T) \geq (2\dim\ \mathbf{A} - k) + \delta(C^T).$$

And by Lemma 14 and since $\mathbf{I}_n^{ET} = \mathbf{I}_n^D$ and $\mathbf{B}(\mathbf{A}^-)^T = \mathbf{B}(\mathbf{A})$, we have

$$\delta((\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A})) \oplus C) \geq (2\dim\ \mathbf{A} - k) + \delta(C).$$

If $\mathbf{A}$ is of n-minimal rank, then $\mathbf{I}_n^D \otimes \mathbf{C}(\mathbf{A}) \in DSCS_{BA}$, and therefore, by Lemma 7, $\mathbf{I}_n^D \otimes \mathbf{B}(\mathbf{A}) \in DSCS_{BA}$. □

4. Complexity of one bilinear form over algebras. In this section we shall study the complexity of one bilinear form over algebras.

Let H be an $n \times m$ matrix, and let $\mathbf{A}$ be an algebra. Then:

LEMMA 18. $\mu(\{H\} \otimes \mathbf{B}(\mathbf{A})) = \mu(\mathbf{I}_r \otimes \mathbf{B}(\mathbf{A}))$, *where* $r = \mathrm{rank}(H)$.

Proof. Let N and M be nonsingular matrices such that $NHM = \mathrm{diag}(I_r, 0)$. Then

$$(N \otimes I_k)(\{H\} \otimes \mathbf{B}(\mathbf{A}))(M \otimes I_k) = \mathrm{diag}(\mathbf{I}_r, \{0\}) \otimes \mathbf{B}(\mathbf{A}),$$

which implies the result. □

The main results of this section are:

COROLLARY 1. *Let $\mathbf{A} = \mathbf{A}_1 \times \cdots \times \mathbf{A}_k$ be an algebra where each $\mathbf{A}_i$ is a local algebra. Let H be an $n \times m$ matrix. Then for every set of matrices C we have*

$$\delta([x^T Hy]_{\mathbf{A}} \oplus C) \geq (2 \dim\ \mathbf{A} - k)\mathrm{rank}(H) + \delta(C).$$

If $\mathbf{A}$ is an algebra of rank(H)*-minimal rank, then*

$$[x^T Hy]_{\mathbf{A}} \in DSCS_{BA}.$$

Proof. Let $r = \mathrm{rank}(H)$. In Lemma 17 we proved this theorem for $\mathbf{I}_r^D \otimes \mathbf{C}(\mathbf{A})$. Then by Lemmas 1 and 4 it is also true for

$$(\mathbf{I}_r^D \otimes \mathbf{C}(\mathbf{A}))^D = \mathbf{I}_r \otimes \mathbf{B}(\mathbf{A}) = [x_1 y_1 + \cdots + x_n y_n]_{\mathbf{A}} \equiv [x^T Hy]_{\mathbf{A}}. \qquad \square$$

THEOREM 5. *Let $\mathbf{A}$ be a commutative algebra. Let H be $n \times m$ matrix. Then*

$$\mu([x^T Hy]_{\mathbf{A}}) \geq (2 \dim\ \mathbf{A} - I(\mathbf{A}))\mathrm{rank}(H).$$

If $\mathbf{A}_1$ and $\mathbf{A}_2$ are commutative algebras of minimal rank, then

$$([x^T H_1 y]_{\mathbf{A}_1}, [x^T H_2 y]_{\mathbf{A}_2}) \in DSCS_{SLA}.$$

Proof. Let $r = \mathrm{rank}(H)$. By Lemmas 4 and 18, we have

$$\mu([x^T Hy]_{\mathbf{A}}) = \mu(\mathbf{I}_r \otimes \mathbf{B}(\mathbf{A})) \geq \frac{1}{2}\delta(\mathrm{diag}((\mathbf{I}_r \otimes \mathbf{B}(\mathbf{A})), (\mathbf{I}_r \otimes \mathbf{B}(\mathbf{A}))^T)).$$

Since $\mathbf{A}$ is commutative, we have $\mathbf{B}(\mathbf{A})^T = \mathbf{B}(\mathbf{A})$, and by Theorem 5, we have

$$\mu([x^T Hy]_{\mathbf{A}}) \geq \frac{1}{2}\delta(\mathbf{I}_{2r} \otimes \mathbf{B}(\mathbf{A})) = (2 \dim\ \mathbf{A} - k)\mathrm{rank}(H).$$

Now by Lemma 8, $([x^T H_1 y]_{\mathbf{A}_1}, [x^T H_2 y]_{\mathbf{A}_2}) \in DSCS_{SLA}$. $\square$

A NEW LOWER BOUND TECHNIQUE AND ITS APPLICATION: TIGHT LOWER BOUND FOR A POLYGON TRIANGULATION PROBLEM*

PRAKASH RAMANAN†

Abstract. A new technique for obtaining lower bounds on the worst-case time-complexity of optimization problems in the linear decision tree model of computation is presented. This technique is then used to obtain a tight $\Omega(n \log n)$ lower bound for a problem of finding a minimum cost triangulation of a convex polygon with weighted vertices. This problem is similar to the problem of finding an optimal order of computing a matrix chain product. If the lower bound technique could be extended to bounded degree algebraic decision trees, a tight $\Omega(n \log n)$ lower bound for this latter problem would be obtained.

Key words. optimization problem, time-complexity, algebraic decision tree model, lower bound, polygon triangulation, matrix chain product

1. Introduction.

Let P be an optimization problem whose input instances are points $\vec{x} = (x_1, x_2, \ldots, x_n)$ in (the positive orthant of) the n-dimensional real space R^n, for some $n \geq 1$. Let $S(P)$ be the finite set of solutions of P. Associated with each $s \in S(P)$ is a polynomial cost function $c_s(\vec{x})$. P can be stated as follows:

Given $\vec{x} \in R^n$, find $s \in S(P)$ such that $c_s(\vec{x})$ is as small as possible.

Suppose that each $s \in S(P)$ is the unique optimal solution for some instance $\vec{x} \in R^n$. Then $|S(P)|$ is a lower bound on the number of leaves of any decision tree that solves P. The following is well known.

THEOREM 1. *Any decision tree that solves P has $\Omega(\log |S(P)|)$ height.*

For many problems, the lower bound obtained using the above theorem is unsatisfactory. In §2, we present a new technique for obtaining a lower bound on the worst-case time-complexity of P, in the linear decision tree model of computation. In §3, we use this technique to obtain a tight $\Omega(n \log n)$ lower bound for a problem of finding a minimum cost triangulation of a convex polygon with weighted vertices. This problem is similar to the problem of finding an optimal order of computing a matrix chain product. If we could extend our lower-bound technique to bounded degree algebraic decision trees, we would have a tight $\Omega(n \log n)$ lower bound for this latter problem. In §4, we present our conclusions.

2. The lower-bound technique.

The model of computation we refer to is the *algebraic decision tree model* (see [1], [2]). An input instance is a sequence $\vec{x} = (x_1, x_2, \ldots, x_n) \in R^n$. An algebraic decision tree is a ternary tree. Each internal node v of the decision tree contains a comparison of the form $f_v(\vec{x}) : 0$, for some nonzero polynomial function f_v of n arguments; the three branches emanating from v are labeled with $<$, $=$, and $>$, corresponding to the three possible outcomes of the comparison. Each leaf l of the decision tree contains a solution sol(l). For any input $\vec{x}$, the computation moves from the root down the decision tree, at each internal node v testing and branching according to whether $f_v(\vec{x})$ is < 0, $= 0$, or > 0, until a leaf l is reached; then sol(l) is the output of the decision tree. The worst-case time-complexity of the decision tree is its height. An algebraic decision tree is said to be of *degree d* if the degrees of the polynomials f_v are all at most d. An algebraic decision tree is said to be of

bounded degree if it is of degree d for some constant d independent of n. The *linear decision tree model* is a special case, where each of the polynomials is restricted to be of degree one.

Let P be an optimization problem. For an instance $\vec{x} \in R^n$, let $\mathrm{sol}(\vec{x}) \subseteq S(P)$ be the set of all optimal solutions for $\vec{x}$. For $s \in S(P)$, let $\mathrm{set}(s)$ be the set of all instances $\vec{x}$ such that $s \in \mathrm{sol}(\vec{x})$. Let D be a decision tree that solves P. When presented with an instance $\vec{x}$, D needs to output some $s \in \mathrm{sol}(\vec{x})$.

Suppose that for each $s \in S(P)$, the cost function $c_s(\vec{x})$ is a linear function of $\vec{x}$; then P can be solved by a linear decision tree. There exists a partition of R^n defined by hyperplanes, into convex polyhedral regions, such that each $s \in S(P)$ is associated with a unique polyhedron; so $\mathrm{set}(s)$ is a closed convex polyhedron. The solution associated with a polyhedron is uniquely optimal for each instance in the interior of that polyhedron. For an instance $\vec{x}$ on the boundary of two or more polyhedra, $\mathrm{sol}(\vec{x})$ consists of the solutions associated with each of the polyhedra which share that boundary. Consider the following problem of testing the optimality:

Given $s \in S(P)$ and $\vec{x} \in R^n$, determine if s is optimal for instance $\vec{x}$.

This is the problem of testing if $\vec{x}$ is inside (or on the boundary of) the polyhedron $\mathrm{set}(s)$.

Let $K = \{1, 2, \ldots, k\}$ for some positive integer k, and let $C \subseteq R^n$ be the convex polyhedron defined by the set of linear inequalities $\{p_i(\vec{x}) \leq 0 | i \in K\}$. For $F \subseteq K$, let $C_F = \{\vec{x} \in R^n | p_i(\vec{x}) = 0 \text{ for } i \in F \text{ and } p_i(\vec{x}) < 0 \text{ for } i \in K - F\}$. If C_F is nonempty, then it is called a *face* of C (the face defined by F). The *dimension* of a face is the dimension of the smallest affine space that contains the face (see [6]); note that if the dimension is at least one, then the face is an open subset of this affine space. A zero-dimensional face is a vertex, a one-dimensional face is an edge, and an $(n-1)$-dimensional face is called a *facet*. According to our definition, a face cannot be contained in another (higher dimensional) face. Yao and Rivest [7] proved the following.

THEOREM 2 [7]. *Let C be a fixed convex polyhedron in R^n. Any linear decision tree that gives $\vec{x} \in R^n$, determines if $\vec{x} \in C$ has $\Omega(\log f)$ height, where f is the total number of faces (of all dimensions) of C.*

We say that $S' \subseteq S(P)$ is a *realizable optimal solution set* (ross), if there exists an instance $\vec{x}$ such that $S' = \mathrm{sol}(\vec{x})$; that is, if there exists an instance of P for which each $s \in S'$ is an optimal solution and no $s \in (S(P) - S')$ is optimal. Each ross corresponds to a face in the polyhedral subdivision of R^n corresponding to P. Let ROSS(P) be the set of all ross's of P. We have the following.

THEOREM 3. *Any linear decision tree that solves P has $\Omega(\log |\mathrm{ROSS}(P)|)$ height.*

We can prove this theorem using Theorem 2; we give a direct proof. We need the following definitions and notations. Let D be a linear decision tree that solves P. For a leaf l in D, let ξ_l be the path from the root to l, and let $\mathrm{set}(l)$ be the set of all instances that follow this path. For any $s \in S(P)$, let $L(s)$ be the set of all leaves l in D such that $\mathrm{sol}(l) = s$. Let

$$L'(s) = \{l \in L(s) | \xi_l \text{ does not contain any branch labeled } =\}.$$

Let $L(D)$ be the set of all leaves in D, and let

$$L'(D) = \{l \in L(D) | \xi_l \text{ does not contain any branch labeled } =\}.$$

For a set $X \subseteq R^n$, let *closure*(X) denote the smallest closed set in R^n containing X; that is, *closure*$(X) = X \cup$ *boundary*(X).

Proof of Theorem 3. There is a natural one-to-one correspondence between $\mathrm{ROSS}(P)$ and the set of faces in the polyhedral subdivision of R^n corresponding to P; so, $|\mathrm{ROSS}(P)|$ is the total number of faces in the subdivision. Let D be a linear decision tree of height h that solves P. We will prove that

$$(0)\qquad |\mathrm{ROSS}(P)| \leq \sum_{l\in L'(D)} \text{number of faces of } closure(set(l)) \leq 2^{2h}.$$

This will imply the desired result.

Consider a leaf $l \in L'(s)$ for some $s \in S(P)$. Clearly, set(l) and set(s) are open and closed convex polyhedra, respectively, and set(l) $\subseteq$ set(s); so, no face of set(s) can intersect with a higher dimensional face of *closure*(set(l)). Because set(s) $= \cup_{l\in L'(s)}$ *closure*(set(l)), each face of set(s) must contain a face (of the same dimension) of *closure*(set(l)) for some $l \in L'(s)$. So number of faces of set(s) $\leq \sum_{l\in L'(s)}$ number of faces of *closure*(set(l)). Hence, $\sum_{s\in S(P)}$ number of faces of set(s) $\leq \sum_{l\in L'(D)}$ number of faces of *closure*(set(l)). Also, $|\mathrm{ROSS}(P)| \leq \sum_{s\in S(P)}$ number of faces of set(s). The latter two inequalities, together, imply the first of the two inequalities in (0).

At each node v on the path ξ_l, let the comparison performed be of the form $f_v(\vec{x}) : 0$. A face of *closure*(set(l)) corresponds to some of these comparisons resulting in equality, and the others resulting in strict inequality. Hence, *closure*(set(l)) has at most 2^h faces. This, together with $|L'(D)| \leq 2^h$, implies the second inequality in (0). □

Note that, with slight modifications, the above lower bound proof also holds for problem P restricted to instances $\vec{x} \in R^n - A$, where A is any set of measure zero. In particular, it holds for problem P restricted to instances $\vec{x}$ such that $|\mathrm{sol}(\vec{x})| = 1$. With slight modifications, it even holds for the following problem of testing if the optimal solution is unique: Given $\vec{x} \in R^n$, determine if $|\mathrm{sol}(\vec{x})| = 1$.

When $c_s(\vec{x})$ is nonlinear in $\vec{x}$ for some s, the subdivision of R^n corresponding to P need not be a polyhedral subdivision. In this case, P cannot be solved by any linear decision tree, and any lower bound based on Theorem 3 would be useless. It would be nice if the result of Theorem 3 could be extended to bounded degree algebraic decision trees.

Now, we will extend the result of Theorem 3 (as well as any similar future results for algebraic decision trees) to the case when the input is restricted to contain only integers. $\vec{x} \in R^n$ is said to be *rational* if each component of $\vec{x}$ is rational. $\vec{x}$ is said to be *integral* if each component of $\vec{x}$ is integral. Let P_I be the integer version of problem P, that is, problem P restricted to integral instances $\vec{x} \in I^n$, where I^n is the set of all n tuples of (positive) integers. An algebraic decision tree that solves P_I could output a wrong solution when given an input $\vec{x} \in R^n - I^n$. We now prove that for many problems P, the lower bound result of Theorem 3 also holds for P_I.

Let sign(u) be 1, 0, or -1 depending on whether the real number u is positive, zero, or negative, respectively. A polynomial $f(\vec{x})$ is said to be *scale invariant* if $\mathrm{sign}(f(\vec{x})) = \mathrm{sign}(f(\alpha\vec{x}))$ for all $\vec{x} \in R^n$ and real $\alpha > 0$; if all the monomials in $f(\vec{x})$ have the same degree, then clearly $f(\vec{x})$ is scale invariant. A set $X \subseteq R^n$ is said to be *scale invariant* if $\vec{x} \in X \rightarrow \alpha\vec{x} \in X$, for all real $\alpha > 0$. An optimization problem P is said to be *scale invariant* if set(s) is scale invariant for all $s \in S(P)$; if $c_s(\vec{x}) - c_{s'}(\vec{x})$ is scale invariant for all $s, s' \in S(P)$, then clearly P is scale invariant.

We need the following definitions from Yao [8]. For a polynomial $f(\vec{x})$, let $\phi f(\vec{x}) = \lim_{\lambda\to 0} \lambda^d f(\vec{x}/\lambda)$, where d is the degree of f; $\phi f(\vec{x})$ is the sum of the degree d monomials in $f(\vec{x})$, and so it is scale invariant. For an algebraic decision tree D, let $\phi(D)$ be the decision tree obtained from D by replacing at each internal node v, the comparison $f_v(\vec{x}) : 0$ by the comparison $\phi f_v(\vec{x}) : 0$. The node in $\phi(D)$ corresponding to $v \in D$ will be referred to as $\phi(v)$. Using arguments similar to those of Yao [8, Lemma 3], we prove the following.

LEMMA 1. *Let P be an optimization problem that is scale invariant. Let D be an algebraic decision tree that solves P_I. For $\vec{x} \in R^n$, if $\vec{x} \in$ set($\phi(l)$) for some $l \in L'(D)$, then* sol($\phi(l)$) $\in$ sol($\vec{x}$); *so there exists a set $A \subseteq R^n$ of measure zero, such that $\phi(D)$ correctly solves P for any $\vec{x} \in R^n - A$.*

Proof. Let $\vec{x} \in \text{set}(\phi(l))$ for some $l \in L'(D)$. Each connected component of $\text{set}(\phi(l))$ is an open set of dimension n. So, we can pick an $\varepsilon > 0$ such that

$$B_\varepsilon = \{\vec{y} \in R^n \mid \|\vec{y} - \vec{x}\| < \varepsilon\} \subseteq \text{set}(\phi(l)).$$

Let $\vec{z} \in B_\varepsilon$; then $\vec{z} \in \text{set}(\phi(l))$. Because $\phi(l) \in L'(\phi(D))$, we have

$$\text{sign}(\phi f_v(\vec{z})) = \text{sign}(\phi f_v(\vec{x})) \neq 0$$

for all $v \in \xi_l$. We pick $\vec{z}$ to be rational. Let N be a positive integer such that $N\vec{z}$ is integral. Because $\phi f(\vec{x})$ is scale invariant, we have

$$\text{sign}(\phi f_v(N\vec{z})) = \text{sign}(\phi f_v(\vec{z})) \neq 0$$

for all $v \in \xi_l$. We will pick N large enough such that

$$\text{sign}(\phi f_v(N\vec{z})) = \text{sign}(f_v(N\vec{z}))$$

for all $v \in \xi_l$. Putting together all the preceding equalities, we have that

$$\text{sign}(f_v(N\vec{z})) = \text{sign}(\phi f_v(\vec{x}))$$

for all $v \in \xi_l$; so $N\vec{z} \in \text{set}(l)$. Because D correctly solves P_I, $\text{sol}(l) \in \text{sol}(N\vec{z})$. Because P is scale invariant, $\text{sol}(l) \in \text{sol}(\vec{z})$; this is true for any rational $\vec{z} \in B_\varepsilon$.

An optimization problem corresponds to a subdivision of R^n into regions such that each solution is optimal over some region; the boundaries between the regions are defined by polynomial equations. Because $\text{sol}(\phi(l)) = \text{sol}(l) \in \text{sol}(\vec{z})$ for any rational $\vec{z} \in B_\varepsilon$, this implies that $\text{sol}(\phi(l)) \in \text{sol}(\vec{x})$.

Finally, let $A = \cup_{l \in L(D)-L'(D)} \text{set}(\phi(l))$; $A \subseteq \{\vec{y} \in R^n \mid \phi f_v(\vec{y}) = 0 \text{ for some } v \in D\}$, and so A is of measure zero. $\phi(D)$ correctly solves P for any $\vec{x} \in R^n - A$. □

As a corollary, we have the following.

THEOREM 4. *Let P be an optimization problem that is scale invariant. Any linear decision tree that solves P_I has $\Omega(\log|\text{ROSS}(P)|)$ height.*

Proof. The proof follows from Lemma 1, Theorem 3, and the comment immediately following the proof of Theorem 3. □

Previously, there has been no natural problem for which a nontrivial lower bound has been obtained using Theorems 2–4. In this paper, we present such a lower bound. As a simple application of Theorems 3 and 4, consider the following problem:

(MIN) Given $\vec{x} = (x_1, x_2, \ldots, x_n) \in R^n$, find i, $1 \le i \le n$, such that $x_i = \min\limits_{1 \le j \le n} x_j$.

We have $S(\text{MIN}) = \{1, 2, \ldots, n\}$. It is well known that $n - 1$ comparisons are necessary and sufficient to solve (MIN), but the lower bound is based on ad hoc arguments. Theorem 1 yields only an $\Omega(\log n)$ lower bound. Note that any nonempty subset $S' \subseteq S(\text{MIN})$ is a ross. Hence, an $\Omega(n)$ lower bound follows from Theorem 3. A similar lower bound can be obtained using Theorem 2, but it is more tedious. Also, MIN is scale invariant. Hence, by Theorem 4, MIN_I also has an $\Omega(n)$ lower bound.

3. Tight lower bound for a polygon triangulation problem.

A convex polygon is specified by a list (i.e., a sequence) of vertices, in cyclic order, around the boundary of the polygon. Let $SP = (v_1, v_2, \ldots, v_n)$ be a convex polygon. An *edge* $v_i v_{i \bmod n+1}$, $1 \le i \le n$, is a straight line segment that connects the two adjacent vertices v_i and $v_{i \bmod n+1}$ of the polygon.

An arc $v_i v_j$ is a straight line segment that connects the two nonadjacent vertices v_i and v_j of the polygon. Each vertex v_i, $1 \leq i \leq n$, has a *weight* $w_i > 0$ associated with it. A *triangulation* T (of the interior) of SP consists of $n-2$ triangles formed by the n edges and $n-3$ nonintersecting arcs. The *cost* of a triangle $v_i v_j v_k$ is $c(w_i, w_j, w_k)$. The *cost of* T, denoted by $c_T(\vec{w})$, is the sum of costs of all the triangles in T. The triangulation problem we are interested in is as follows.

(TP)
Given $\vec{w} = (w_1, w_2, \ldots, w_n)$, find a triangulation T such that $c_T(\vec{w})$ is as small as possible.

There are C_{n-2} triangulations of SP, where C_k is the kth Catalan number, $C_k = 2^{\theta(k)}$ (see [3]). Hence, Theorem 1 yields only a trivial lower bound.

We consider two different cost functions. In the sum case, $c(w_i, w_j, w_k) = w_i + w_j + w_k$; in the *product case*, $c(w_i, w_j, w_k) = w_i w_j w_k$. These two versions of *TP* will be referred to as *TPS* and *TPP*, respectively. Note that for *TPS*, for any two triangulations T_1 and T_2, $c_{T_1}(\vec{w}) - c_{T_2}(\vec{w})$ remain unchanged if the cost function is redefined as follows: The *cost* of an arc $v_i v_j$ is $w_i + w_j$; $c_T(\vec{w})$ is the sum of costs of all the arcs in T. Also note that *TPS* can be solved by a linear decision tree. *TPP* cannot be solved by any degree two decision tree; this can be shown as follows: Let $n = 4$ and $w_1 < w_2 < w_4 < w_3$; to find an optimal triangulation of SP, we need to determine which of the two costs $w_1 w_3 (w_2 + w_4)$ and $w_2 w_4 (w_1 + w_3)$ is smaller. This cannot be determined by any degree two decision tree.

Hu and Shing [4], [5] considered the following matrix chain product problem.

(MCPP) Given integers $(w_1, w_2, \ldots, w_n)$, find an optimal order of computing the matrix chain product $M_1 \times M_2 \times \cdots \times M_{n-1}$, where M_i is of dimensions $w_i \times w_{i+1}$ and the cost of computing the product of a $w_i \times w_j$ matrix with a $w_j \times w_k$ matrix is $w_i w_j w_k$.

They showed that this problem is equivalent to TPP_I, and they presented an $O(n \log n)$ algorithm for *TPP*. This algorithm can be easily modified to solve *TPS*. In §3.1, we present a simpler exposition of their algorithm for *TPS* and *TPP*. In §3.2, based on this algorithm, we identify $n^{\theta(n)}$ ross's for *TPS* and *TPP*. Note that *TPS* and *TPP* are scale invariant. So an $\Omega(n \log n)$ lower bound for *TPS* and TPS_I in the linear decision tree model follows from Theorems 3 and 4, respectively. Note that any lower bound for *TPP* based on Theorem 3 would be useless, because *TPP* cannot be solved by any linear decision tree. If we could extend the result of Theorem 3 to bounded-degree algebraic decision trees, we would have a tight $\Omega(n \log n)$ lower bound for *TPP* and for $TPP_I \equiv MCPP$. In §3.3, we discuss the similarity and the relationship between *TPS* and *TPP*.

3.1. The algorithm. Let $SP = (v_1, v_2, \ldots, v_n)$ be a convex polygon. Without loss of generality, let v_1 be a vertex of smallest weight in SP; that is, $w_1 = \min_{1 \leq i \leq n} w_i$; such a vertex is said to be a *global minimum*. A *global maximum* vertex is defined analogously. A vertex v_i is said to be a *local minimum* if $w_i \leq \min(w_{i-1}, w_{i+1})$. A *local maximum* vertex is defined analogously. For the sake of simplicity, we make the following assumptions concerning SP:

(A1) v_1 is the unique vertex of smallest weight.

(A2) For $i < j$ such that $w_i = w_j$, there exists k, $i < k < j$, such that $w_k < w_i$.

Then the number of local minimum vertices and local maximum vertices are the same. SP is said to be *m-modal* if it has m local minimum vertices.

We let $w(v)$ denote the weight of a vertex v. An arc $r = v_i v_j$, $1 < i < j \leq n$, is called a *primary horizontal arc* (*ph-arc*) if $w_k \geq \max(w_i, w_j)$ for all k, $i < k < j$ (Hu and Shing [4] called it a *potential horizontal arc*). If r is a ph-arc, $SP(r) = (v_i, v_{i+1}, \ldots, v_j)$ is called the *upper subpolygon* of SP that is *bounded below* by r.

An arc $r = v_1v_j, 2 < j < n$, is called a *secondary horizontal arc* (*sh-arc*) if either of the following two conditions hold:

(a) $w_k \geq w_j$ for all k, $1 < k < j$. In this case, $SP(r) = (v_1, v_2, \ldots, v_j)$ is called the *upper subpolygon* of SP that is *bounded below* by r.

(b) $w_k \geq w_j$ for all $k > j$. In this case, $SP(r) = (v_1, v_j, v_{j+1}, \ldots, v_n)$ is called the *upper subpolygon* of SP that is *bounded below* by r.

An arc is called a *horizontal arc* (*h-arc*) if it is either a ph-arc or a sh-arc. Hu and Shing [4] showed that, under assumptions (A1) and (A2), there are exactly $n - 3$ h-arcs of SP, and no two of them intersect; so they constitute a triangulation of SP. Hu and Shing also presented a linear-time *One-Sweep algorithm* for finding all the h-arcs.

For two h-arcs r and r' of SP, r is said to be *below* r', denoted by $r < r'$ (equivalently, r' is *above* r, denoted by $r' > r$), if all the vertices of $SP(r')$ are also vertices of $SP(r)$. Two h-arcs are said to be *comparable* if one of them is below the other; otherwise they are said to be *incomparable*.

A *subpolygon* of SP is a polygon each of whose edges is either an edge or an h-arc of SP. Note that the h-arcs of a subpolygon of SP are those h-arcs of SP that are in the subpolygon.

If r_i, $1 \leq i \leq k$, are pairwise incomparable h-arcs, we let $SP(; r_1, r_2, \ldots, r_k)$ denote the subpolygon obtained from SP as follows. For each i, $1 \leq i \leq k$, remove from SP all the vertices of $SP(r_i)$ except the endpoints of r_i. This subpolygon is said to be *bounded above* by r_i, $1 \leq i \leq k$. If r is another h-arc such that $r < r_i$, $1 \leq i \leq k$, we let $SP(r; r_1, r_2, \ldots, r_k)$ denote the subpolygon obtained from $SP(r)$ in a similar manner, that is, $SP(r; r_1, r_2, \ldots, r_k) = (SP(r))(; r_1, r_2, \ldots, r_k)$. This subpolygon is said to be *bounded below* by r and *bounded above* by r_i, $1 \leq i \leq k$.

A *fan* of a (sub)polygon is a triangulation of the (sub)polygon in which a vertex v of smallest weight is connected to all the other vertices; v is called the *center* of the fan. The following lemma and its corollary are from Hu and Shing [5, Lemma 1]. For the sake of completeness, we present their proof here.

LEMMA 2 [5]. *If an optimal triangulation of a polygon contains none of the ph-arcs, then it must be a fan of the polygon.*

Proof. The proof is by induction on the number of vertices in the polygon. For a polygon with three vertices, a triangulation contains no arcs, and so the statement of the lemma is vacuously true. For the basis step, consider the polygon (v_1, v_2, v_3, v_4) with four vertices, where v_1 is a global minimum. There are only two different triangulations, each containing one arc. The triangulation containing the arc v_1v_3 is a fan. So, let the triangulation containing the arc v_2v_4 be optimal; we will prove that v_2v_4 is a ph-arc. For *TPS*, we have $w_2 + w_4 \leq w_1 + w_3$. For *TPP*, we have $w_2w_4(w_1 + w_3) \leq w_1w_3(w_2 + w_4)$; dividing both sides of this inequality by $w_1w_2w_3w_4$, we get $1/w_1 + 1/w_3 \leq 1/w_2 + 1/w_4$. For both *TPS* and *TPP*, because v_1 is a global minimum, the corresponding inequality implies that v_3 is a global maximum. So v_2v_4 is a ph-arc.

For the induction hypothesis, let the statement of the lemma be true for all polygons with fewer that n vertices. Let $SP = (v_1, v_2, \ldots, v_n)$ be a polygon with n vertices, where v_1 is a global minimum. Let T be an optimal triangulation of SP that contains no ph-arcs. If T contains an arc v_1v_j for some $j, 2 < j < n$, then consider the polygons $SP_1 = (v_1, v_2, \ldots, v_j)$ and $SP_2 = (v_1, v_j, v_{j+1}, \ldots, v_n)$; let T_1 and T_2 be their respective optimal triangulations induced by T. Because v_1 is a global minimum in SP, any ph-arc of SP_1 or SP_2 is also a ph-arc of SP. Then, because T contains no ph-arcs of SP, T_1 and T_2 contain no ph-arcs. Hence, by induction hypothesis, T_1 and T_2 must be fans of SP_1 and SP_2, respectively, with center v_1. So, T must be a fan of SP with center v_1.

So, assume that T does not contain the arc v_1v_j for any j, $2 < j < n$; we will show that this leads to a contradiction. T must contain the arc v_2v_n; without loss of generality, let

$w_2 \leq w_n$. Let $SP' = (v_2, v_3, \ldots, v_n)$, and let T' be the optimal triangulation of SP' induced by T. We will consider two cases.

Case 1. v_2 is a global minimum vertex in SP'. Then, any ph-arc of SP' is also a ph-arc of SP. Because T contains no ph-arcs of SP, by induction hypothesis, T' must be a fan of SP' with center v_2. Among the vertices v_i, $3 \leq i < n$, let v_a be a vertex of smallest weight (see Fig. 1a). Because v_2v_n is not a ph-arc of SP, we have $w_a < w_n$. Let $SP'' = (v_1, v_2, v_a, v_{a+1}, \ldots, v_n)$, and let T'' be the optimal triangulation of SP'' induced by T; T'' consists of the triangle $v_1v_2v_n$ and the fan of $(v_2, v_a, v_{a+1}, \ldots, v_n)$ centered at v_2. Because $w_1 \leq w_2 \leq w_a < w_n$, the fan of SP'' with center v_1 has lesser cost compared to T'', contradicting our assumption that T is optimal.

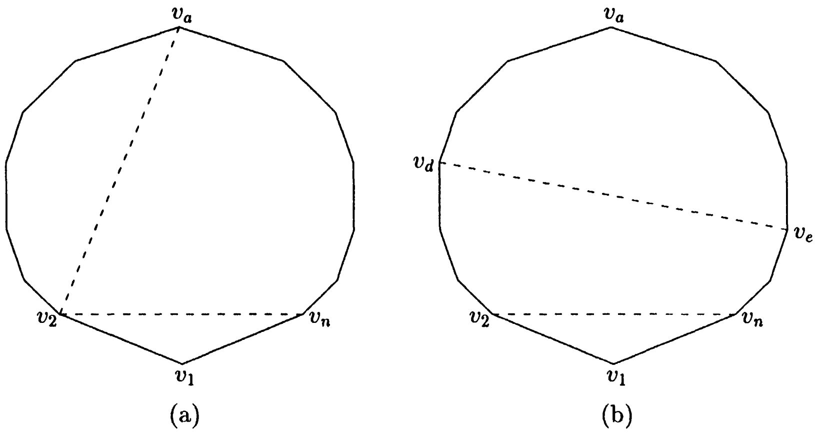

FIG. 1.

Case 2. v_2 is not a global minimum vertex in SP'. Let v_a, $3 \leq a < n$ be a global minimum vertex in SP'; we have $w_a < w_2 \leq w_n$. We consider two subcases.

Subcase 2.1. T' contains no ph-arcs of $SP' = (v_a, v_{a+1}, \ldots, v_n, v_2, v_3, \ldots, v_{a-1})$ (see Fig. 1a). By induction hypothesis, T' must be a fan of SP' with center v_a. Then, in T, the quadrilateral $v_1v_2v_av_n$ is triangulated by the arc v_2v_n. If we replace this arc by the arc v_1v_a, the resulting triangulation has lesser cost compared to T (because $w_1 \leq w_a < w_2 \leq w_n$), contradicting our assumption that T is optimal.

Subcase 2.2. T' contains some ph-arcs of $SP' = (v_a, v_{a+1}, \ldots, v_n, v_2, v_3, \ldots, v_{a-1})$ (see Fig. 1b). Let r be any such ph-arc. Because T contains no ph-arcs of SP, the upper subpolygon $SP'(r)$ of SP' must contain v_2 and v_n. Because this is true for any ph-arc r of SP' in T', these ph-arcs must be one above the other in SP'. Among these ph-arcs, let $r' = v_dv_e, d < e$, be the topmost one (i.e., the one closest to v_2v_n). Let SP'' denote $SP'(r') = (v_d, v_e, v_{e+1}, \ldots, v_n, v_2, v_3, \ldots, v_{d-1})$, and let T'' be the optimal triangulation of SP'' induced by T. Because r' is a ph-arc of SP', v_d, or v_e (whichever is of smaller weight) is a global minimum vertex in SP''. By our choice of r', T'' contains no ph-arcs of SP''. So, by induction hypothesis, T'' must be a fan of SP'' with center v_d or v_e. We will consider three subcases.

Subcase 2.2.1. $\{d, e\} \cap \{2, n\} = \phi$. Without loss of generality, let T'' be the fan of SP'' with center v_d. Then, in T, the quadrilateral $v_1v_2v_dv_n$ is triangulated by the arc v_2v_n. If we replace this arc by the arc v_1v_d, the resulting triangulation has lesser cost compared to T (because $w_1 \leq w_d \leq w_2 \leq w_n$, and $w_1 \leq w_a < w_2$), contradicting our assumption that T is optimal.

Subcase 2.2.2. $e = n$. Because $r' = v_d v_e$ is a ph-arc of SP', we have $w_d \le w_2 \le w_n$. Then, the proof is similar to that of Subcase 2.2.1.

Subcase 2.2.3. $d = 2$. If $w_e \le w_2$, then the proof is similar to that of Subcase 2.2.1, with v_e playing the role of v_d. If $w_e > w_2$, then we have $w_1 \le w_a < w_2 < w_e \le w_n$; then the proof is similar to that of Case 1. □

COROLLARY 2.1. *Let H be the set of h-arcs in an optimal triangulation of SP. If a subpolygon of SP that is bounded by some of the h-arcs in H contains none of these h-arcs in its interior, then a fan is an optimal triangulation of the subpolygon.*

Proof. Let $r = v_i v_j$ be an h-arc of SP. Then v_i or v_j (whichever is smaller weight) is a global minimum vertex in any subpolygon of SP that is bounded below by r. So, any ph-arc of the subpolygon is also a ph-arc of SP. Then the proof follows from Lemma 2. □

By Corollary 2.1, we only need to determine which of the h-arcs appear in an optimal triangulation of SP. For this, we need to be able to efficiently compute the cost of a fan of a subpolygon. For an h-arc $r = v_i v_j$, the *weight* of $SP(r)$, denoted by $W(r)$, is defined as follows. For *TPS*, $W(r) = (\mathit{weight}(r), \mathit{count}(r))$ where $\mathit{weight}(r)$ is the sum of weights of all the vertices in $SP(r)$ except v_i and v_j, and $\mathit{count}(r)$ is the number of vertices in $SP(r)$ excluding v_i and v_j; for *TPP*, $W(r) = \sum w_a w_b$ where the summation is taken over all the edges $v_a v_b$ of $SP(r)$ except r. The modality and the local minima of a polygon can be easily found in linear time. If we first find the local minima, then the One-Sweep Algorithm of Hu and Shing [4] can be easily modified so that it also computes $W(r)$ for each h-arc r. Note that the cost of a fan of a subpolygon can be easily computed using the $W(r)$s of the h-arcs r that bound the subpolygon.

The next concept we introduce is the *cutoff value* of an h-arc. For an h-arc $r = v_i v_j$, $i < j$, let $SP'(r)$ be the polygon obtained from $SP(r)$ by inserting a new vertex v between v_i and v_j, that is, $SP'(r) = (v, v_i, v_{i+1}, \dots, v_j)$ (see Fig. 2). The cutoff value of r, denoted by $co(r)$, is defined to be *the* value of $w(v)$ for which the following holds: the minimum cost of a triangulation of $SP'(r)$ that contains r equals the minimum cost of a triangulation of $SP'(r)$ that does not contain r; that is, there exists an optimal triangulation of $SP'(r)$ that contains r, and there exists another optimal triangulation of $SP'(r)$ that does not contain r (for *TPS*, such a value of $w(v)$ could be negative; for *TPP*, it is always nonnegative). Now, we prove that if such a value of $w(v)$ exists, then it is unique and is at most $\min(w_i, w_j)$. In §§3.1.1 and 3.1.2, we will show how to determine $co(r)$ (thereby also proving that is exists).

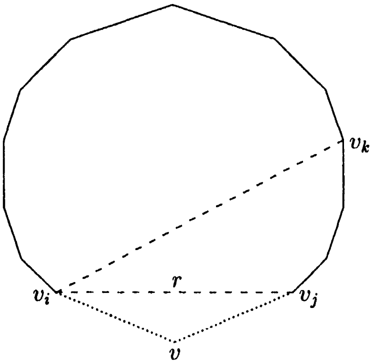

FIG. 2.

The motivation behind the definition of cutoff values is as follows. Let T be an optimal triangulation of SP; let r be an h-arc that is not in T. We say that an arc r' (*not* an h-arc of SP) in T *cuts* r if r' has one endpoint in $SP(; r)$ and another endpoint in $SP(r)$, with neither endpoint being an endpoint of r. By Corollary 2.1, all the arcs in T that cut r must have the same endpoint, say v, in $SP(;r)$. Also, by the definition of $co(r)$, we must have $w(v) \leq co(r)$.

LEMMA 3. *Let $SP'(r)$ be as defined above. If $w(v) > \min(w_i, w_j)$, then every optimal triangulation of $SP'(r)$ will contain r. So, if a value of $w(v)$ satisfies the definition of $co(r)$, then it is at most $\min(w_i, w_j)$.*

Proof. Without loss of generality, let $w_i \leq w_j$. Let $w(v) > w_i$, and let T' be any triangulation of $SP'(r)$ that does not contain r; we will prove that T' is not optimal. T' must contain a triangle vv_iv_k, for some k, $i < k < j$, and a triangulation of the polygon $(v, v_k, v_{k+1}, \ldots, v_j)$ (see Fig. 2). Consider replacing these two items by the triangle vv_iv_j and an optimal triangulation of the polygon $(v_i, v_k, v_{k+1}, \ldots, v_j)$. Because r is an h-arc, $w_k \geq w_j$; so, $c(w(v), w_i, w_k) \geq c(w(v), w_i, w_j)$. Also, because $w(v) > w_i$, the cost of an optimal triangulation of the polygon $(v, v_k, v_{k+1}, \ldots, v_j)$ is more that the cost of an optimal triangulation of the polygon $(v_i, v_k, v_{k+1}, \ldots, v_j)$. The last two statements together imply that T' is not optimal. □

LEMMA 4. *Let $SP'(r)$ be as defined above. For $w(v)$ equal to some fixed $w \leq \min(w_i, w_j)$, let T_1' be a triangulation that is of minimum cost among all triangulations of $SP'(r)$ that contain r (note that T_1' is independent of w). Let T_2' be a triangulation that is of minimum cost among all triangulations of $SP'(r)$ that do not contain r. Let $C_1'(x)$ and $C_2'(x)$ be the costs of (the* fixed *triangulations) T_1' and T_2', respectively, as a function of $w(v) = x$. Then $C_1'(x) - C_2'(x)$ increases strictly as x decreases. So, if $C_1'(w) \geq C_2'(w)$, then $C_1'(w') > C_2'(w')$ for all $w' < w$.*

Proof. For an h-arc r_p, let $T(r_p)$ be an optimal triangulation of $SP(r_p)$, and let $C(r_p)$ be its cost. T_1' consists of the triangle vv_iv_j and an optimal triangulation $T(r)$ of $SP(r)$. So

$$C_1'(x) = c(x, w_i, w_j) + C(r).$$

For $w(v)$ equal to (fixed) $w \leq \min(w_i, w_j)$, v is a global minimum vertex in $SP'(r)$. By Corollary 2.1, there exist h-arcs r_q, $1 \leq q \leq k$, no two of which are comparable, such that T_2' consists of r_q and $T(r_q)$, $1 \leq q \leq k$, and the fan of $(SP'(r))(; r_1, r_2, \ldots, r_k)$ centered at v (see Fig. 3) (if T_2' is the fan of $SP'(r)$ centered at v, we have $k = 0$). Let $F'(x)$ be the cost of this fan as a function of $x = w(v)$. Then

$$C_2'(x) = F'(x) + \sum_{q=1}^{k} C(r_q).$$

So, we have

$$C_1'(x) - C_2'(x) = C(r) - \sum_{q=1}^{k} C(r_q) - (F'(x) - c(x, w_i, w_j)).$$

Because r is an h-arc, the weight of each vertex in $SP(r)$ is at least $\max(w_i, w_j)$. It can be easily verified that, for both *TPS* and *TPP*, $F'(x) - c(x, w_i, w_j)$ is a strictly increasing function of x. So, the result follows. □

COROLLARY 4.1. *Let $SP'(r)$ be as defined above. There is at most one value of $w(v)$ that satisfies the definition of $co(r)$. Suppose that such a value exists; then it is at most* $\min(w_i, w_j)$. *Moreover, if $w(v) < co(r)$, then no optimal triangulation of $SP'(r)$ can contain r. If $w(v) > co(r)$, then every optimal triangulation of $SP'(r)$ will contain r. If $w(v) = co(r)$, then there exists an optimal triangulation of $SP'(r)$ that contains r, and there exists another optimal triangulation of $SP'(r)$ that does not contain r.*

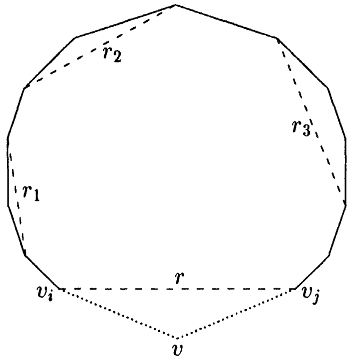

FIG. 3.

Proof. Follows from Lemmas 3 and 4. □

Hu and Shing [5] presented an $O(n \log n)$ algorithm for finding an optimal triangulation. In §3.1.1, we will describe their linear-time algorithm for unimodal polygons. In §3.1.2, we will describe its extension to an $O(n \log n)$ algorithm for general multimodal polygons. Our description of the algorithm is substantially simpler than the one given in [5]. The simplification is essentially due to the concept of cutoff values introduced above.

3.1.1. Algorithm for unimodal polygons. Let $SP = (v_1, v_2, \dots, v_n)$ be a unimodal polygon, where v_1 is the global minimum and v_a is the global maximum (see Fig. 4). From now onward, in our figures, we let the relative order of the y-coordinates of the vertices of a unimodal (sub)polygon be the same as the relative order of their weights. Each ph-arc of SP is of the form $v_i v_j$, where $1 < i < a < j$. In our figures, broken lines are used to represent h-arcs. Any two h-arcs of SP are comparable; so, the $n-3$ h-arcs are one above the other. Let the h-arcs be labeled $r_1, r_2, \dots, r_{n-3}$ from bottom to top. Let $r_i{}^1$ and $r_i{}^2$ be the two endpoints of r_i such that $w(r_i{}^1) \le w(r_i{}^2)$; $r_i{}^1$ and $r_i{}^2$ will be referred to as the *lower* and *upper* endpoints of r_i. Let $l \in \{2, n\}$ be such that $w_l = \min(w_2, w_n)$; $r_0 = v_1 v_l$ and $r_{n-2} = r^2_{n-3} v_a$ are considered to be *degenerate* h-arcs. For $1 \le i \le n-2$, r_i and r_{i-1} share the endpoint $r_i{}^1$; that is, $r_i{}^1$ is either r^1_{i-1} or r^2_{i-1}.

We now describe a linear-time algorithm for finding an optimal triangulation of SP. The algorithm performs a scan from top to bottom and processes the h-arcs one by one in the order $r_{n-2}, r_{n-3}, \dots, r_1, r_0$. When it processes r_i, it constructs an optimal triangulation $T(r_i)$ of $SP(r_i)$ and computes its cost $C(r_i)$ and $co(r_i)$. By Corollary 2.1, $T(r_i)$ can be represented by a list $L1(r_i)$ of the h-arcs that are in $T(r_i)$; $L1(r_i)$ contains these h-arcs in bottom to top order, and its first element is r_i. Note that the cutoff values of these arcs need not be in decreasing order. After processing r_i, the algorithm has two lists $L1(r_i)$ and $L2(r_i)$. $L2(r_i)$ is defined as follows. It is a sublist (i.e., a subsequence) of $L1(r_i)$. Its first element is r_i; an element of $L1(r_i)$ is in $L2(r_i)$ if and only if its cutoff value is less than that of all the preceding elements in $L1(r_i)$.

Now, we will show how to update $L1$ and $L2$ when the algorithm processes r_{i-1}. Let v' be the vertex in $\{r_{i-1}{}^1, r_{i-1}{}^2\} - \{r_i{}^1\}$. $L1(r_{i-1})$ is obtained from $L1(r_i)$ as follows. Remove the longest prefix of elements (i.e., h-arcs) all of which have cutoff values greater than or equal to $w(v')$, and then insert r_{i-1} at the front. Let r_j be the second element of $L1(r_{i-1})$. Then the triangulation $T(r_{i-1})$ consists of $T(r_j)$ and a fan of $SP(r_{i-1}; r_j)$ centered at $r_{i-1}{}^1$; its cost $C(r_{i-1})$ can be computed in constant time, using $C(r_j)$, $W(r_j)$ and $W(r_{i-1})$.

Before we can get $L2(r_{i-1})$, we need to compute $co(r_{i-1})$. We take $co(r_{n-2})$ to be $-\infty$ for *TPS*, and 0 for *TPP*. For *TPS*,

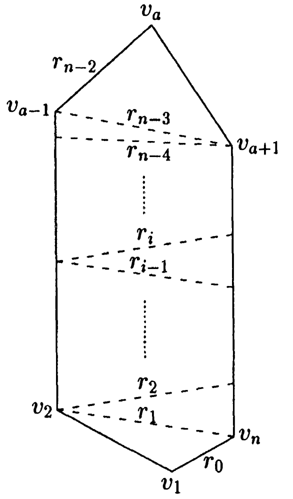

FIG. 4.

$$co(r_{n-3}) = w({r_{n-3}}^1) + w({r_{n-3}}^2) - w_a = w_{a-1} + w_{a+1} - w_a.$$

For *TPP*,

$$co(r_{n-3}) = w({r_{n-3}}^1)w({r_{n-3}}^2)w_a/[w_a(w({r_{n-3}}^1) + w({r_{n-3}}^2)) - w({r_{n-3}}^1)w({r_{n-3}}^2)]$$

$$= w_{a-1}w_aw_{a+1}/[w_a(w_{a-1} + w_{a+1}) - w_{a-1}w_{a+1}].$$

Before we can compute $co(r_{n-4})$, we need to know whether or not r_{n-3} will get "cutoff" at $co(r_{n-4})$, that is, whether $co(r_{n-4}) \leq co(r_{n-3})$ or $co(r_{n-4}) > co(r_{n-3})$.

For $i - 1 \leq n - 4$, $co(r_{i-1})$ is computed as follows. Recall, from Corollary 4.1, that $co(r_{i-1}) \leq w({r_{i-1}}^1)$. Let $L2'(r_{i-1})$ be the list obtained from $L2(r_i)$ by removing the longest prefix of elements all of which have cutoff values greater than to equal to $w({r_{i-1}}^1)$. We will first locate $co(r_{i-1})$ to be either equal to the cutoff value of a particular element in $L2'(r_{i-1})$, to be greater than the cutoff value of the first element in $L2'(r_{i-1})$, or to be strictly between the cutoff values of a particular pair of adjacent elements in $L2'(r_{i-1})$. In the latter two cases, $co(r_{i-1})$ is obtained by solving an equation.

Let $SP'(r_{i-1})$ be the polygon obtained from $SP(r_{i-1})$ by inserting a new vertex v between ${r_{i-1}}^1$ and ${r_{i-1}}^2$. Let $T'_1(r_{i-1})$ be the triangulation of $SP'(r_{i-1})$ that consists of $T(r_{i-1})$ and the triangle $v{r_{i-1}}^1{r_{i-1}}^2$. For any value of $w(v)$, $T'_1(r_{i-1})$ is of minimum cost among all triangulations of $SP'(r_{i-1})$ that contain r_{i-1}. Note that $T'_1(r_{i-1})$ is independent of $w(v)$. Its cost is

$$C'_1(r_{i-1}) = C(r_{i-1}) + c(w(v), w({r_{i-1}}^1), w({r_{i-1}}^2)).$$

Let $T'_2(r_{i-1})$ denote a triangulation that is of minimum cost among all triangulations of $SP'(r_{i-1})$ that do not contain r_{i-1}. Clearly, $T'_2(r_{i-1})$ depends on $w(v)$.

We will let $w(v)$ successively take the cutoff value of each of the h-arcs in $L2'(r_{i-1})$. Suppose that we are currently considering $co(r_p)$ as the value of $w(v)$, for some $r_p \in L2'(r_{i-1})$; let r_q be the h-arc following r_p in $L2'(r_{i-1})$. Let $T'_{2,p}(r_{i-1})$ be the triangulation of $SP'(r_{i-1})$ that consists of r_q, $T(r_q)$ and the fan of $(SP'(r_{i-1}))(; r_q)$ centered at v. By Corollary 4.1, when $co(r_q) < w(v) \leq co(r_p)$, $T'_{2,p}(r_{i-1})$ is of minimum cost among all triangulations of $SP'(r_{i-1})$

that do not contain r_{i-1}; its cost $C'_{2,p}(r_{i-1})$ can be computed (as a function of $w(v)$) in constant time, using $C(r_q)$, $W(r_q)$ and $W(r_{i-1})$. For $co(r_q) < w(v) \leq co(r_p)$, we take $T'_2(r_{i-1})$ to be $T'_{2,p}(r_{i-1})$; its cost $C'_2(r_{i-1})$ equals $C'_{2,p}(r_{i-1})$. We compare $C'_2(r_{i-1})$ with $C'_1(r_{i-1})$, at $w(v) = co(r_p)$.

This process is repeated for each $r_p \in L2'(r_{i-1})$ sequentially from the front until, for the first time, $C'_2(r_{i-1}) \leq C'_1(r_{i-1})$ at $w(v) = co(r_p)$. If the two costs are equal, then $co(r_{i-1}) = co(r_p)$; else, $co(r_{i-1})$ is greater than $co(r_p)$, but less than the cutoff values of all the arcs that preceed r_p in $L2'(r_{i-1})$. In the latter case, by Corollary 4.1, r_p would be the first (i.e., bottom most) h-arc in $T'_2(r_{i-1})$, when $w(v)$ is arbitrarily close to $co(r_{i-1})$. Then $co(r_{i-1})$ can be computed in constant time, as the value of $w(v)$ that satisfies the equation $C'_2(r_{i-1}) = C'_1(r_{i-1})$ (for *TPS*, this equation is linear in $w(v)$ and $\vec{w}$; for *TPP*, it is linear in $w(v)$ but cubic in $\vec{w}$).

LEMMA 5. *The algorithm outlined above correctly computes* $co(r_{i-1})$.

Proof. Because $T'_1(r_{i-1})$ is a fixed triangulation, $C'_1(r_{i-1})$ is a continuous function of $w(v)$. For a fixed $r_p \in L2'(r_{i-1})$, $T'_{2,p}(r_{i-1})$ is a fixed triangulation; so, $C'_{2,p}(r_{i-1})$ is a continuous function of $w(v)$. By the definition of $co(r_p)$, $C'_2(r_{i-1})$ is continuous at $w(v) = co(r_p)$, for each $r_p \in L2'(r_{i-1})$. So, $C'_2(r_{i-1})$ is a continuous function of $w(v)$. Hence, $C'_2(r_{i-1}) - C'_1(r_{i-1})$ is a continuous function of $w(v)$. At $w(v) = w({r_{i-1}}^1)$, by Lemma 3, $C'_2(r_{i-1}) - C'_1(r_{i-1})$ is nonnegative. As $w(v)$ decreases and approaches its limiting value of $co(r_{n-2})$ (i.e., $-\infty$ for *TPS*, 0 for *TPP*), $C'_2(r_{i-1}) - C'_1(r_{i-1})$ becomes negative. So, there must be a value of $w(v)$ for which $C'_2(r_{i-1}) = C'_1(r_{i-1})$; by definition, this value is $co(r_{i-1})$. It is clear that the above algorithm correctly determines this value. □

Finally, $L2(r_{i-1})$ is obtained from $L2'(r_{i-1})$ as follows. Remove the longest prefix of elements all of which have cutoff values greater than or equal to $co(r_{i-1})$ and then insert r_{i-1} at the front.

$L1(r_0)$ contains the h-arcs in an optimal triangulation $T(r_0)$ of $SP(r_0) = SP$, and $C(r_0)$ is the cost of $T(r_0)$. Obtaining $L1(r_{i-1})$ and $L2(r_{i-1})$ takes time proportional to the number of elements removed from $L1(r_i)$ and $L2(r_i)$. Hence the above algorithm runs in linear time. Note that the algorithm can compute $C(r_{i-1})$, $co(r_{i-1})$, and $L2(r_{i-1})$ from $L2(r_i)$, without using $L1(r_i)$. So we can compute $co(r_i)$ and $L2(r_i)$ for i varying from $n-3$ down to 0, in linear time, without keeping track of $L1$. After the cutoff values of all the h-arcs have been found, we can determine $L1(r_0)$ in linear time by performing a bottom to top scan of SP. Also note that before terminating, the algorithm computes $co(r_0)$. Both these observations will be of use in the next subsection.

3.1.2. Algorithm for multimodal polygons. In this subsection, we describe the $O(n \log n)$ algorithm for general multimodal polygons. First, we describe the algorithm for bimodal polygons. Let $SP = (v_1, v_2, \ldots, v_n)$ be a bimodal polygon, where v_1 is the global minimum, v_b is a local minimum, and v_{a1} and v_{a2} are the local maxima, $1 < a1 < b < a2 < n$, and $w_n < w_b$ (see Fig. 5). Then there exists a vertex v_d, $1 \leq d < a1$, such that $w_d < w_b \leq w_{d+1}$; also there exists a vertex v_e, $a2 < e \leq n$, such that $w_e < w_b \leq w_{e-1}$. $r_{1,0} = v_d v_b$, $r_{2,0} = v_b v_e$, and $r_0 = v_d v_e$ are h-arcs of SP (if $d = 1$ and $e = n$, then $r_0 = v_1 v_n$ is a degenerate h-arc). $SP(r_{1,0})$, $SP(r_{2,0})$, and $SP(; r_0)$ are unimodal polygons. The h-arcs of $SP(; r_0)$ will be labeled as $r_1, r_2, \cdots$ from top to bottom. Without loss of generality, let $w_d \leq w_e$.

The definitions of r^1 and r^2 (the lower and upper endpoints of r), $T(r)$, and $C(r)$ for an h-arc r of a multimodal polygon are the same as those in §3.1.1 for unimodal polygons. Note that once the cutoff values of all the h-arcs have been found, we can determine the h-arcs in an optimal triangulation of SP by performing a bottom to top scan in linear time.

The algorithm for finding the cutoff values for the above bimodal polygon SP works as follows. First compute the lists $L12(r_{1,0})$ and $L22(r_{2,0})$ (analogous to the list $L2$ in §3.1.1) for

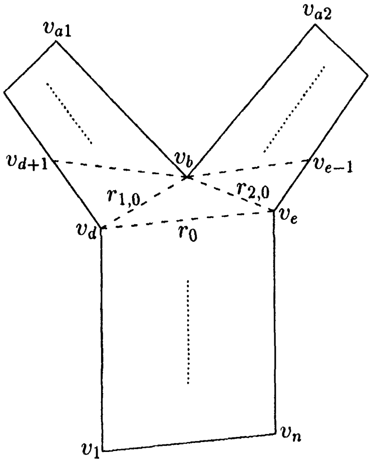

FIG. 5.

unimodal subpolygons $SP(r_{1,0})$ and $SP(r_{2,0})$, respectively, using the algorithm in §3.1.1. Because $w_d \leq w_e$, let $L22'(r_0)$ be the list obtained from $L22(r_{2,0})$ by removing the longest prefix of elements all of which have cutoff values greater than or equal to w_d. If $r_{2,i}$ is the first element of $L22'(r_0)$, then $T(r_0)$ consists of $T(r_{1,0})$, $T(r_{2,i})$, and a fan of $SP(r_0; r_{1,0}, r_{2,i})$ centered at v_d; its cost $C(r_o)$ can be computed in constant time, using $C(r_{1,0})$, $C(r_{2,i})$, $W(r_0)$, $W(r_{1,0})$, and $W(r_{2,i})$. Let $L2'(r_0)$ be the list obtained by *merging* $L12(r_{1,0})$ and $L22'(r_0)$ into a single list such that the cutoff values of the elements in $L2'(r_0)$ are in decreasing order from left to right. Using $L2'(r_0)$, we can compute $co(r_0)$ as explained in §3.1.1. Then $L2(r_0)$ is obtained from $L2'(r_0)$ as follows. Remove the longest prefix of elements all of which have cutoff values greater than or equal to $co(r_0)$ and then insert r_0 at the front. Then, we can perform a top to bottom scan of $SP(; r_0)$; for $i \geq 1$, $co(r_i)$, and $L2(r_i)$ can be computed from $L2(r_{i-1})$ as explained in §3.1.1. This completes our description of the algorithm for bimodal polygons.

In the above bimodal polygon, if $r_{1,i}$ and $r_{2,j}$ are h-arcs of $SP(r_{1,0})$ and $SP(r_{2,0})$, respectively, then they are incomparable, but they are above r_0. The h-arc r_0 will be called a *bridge*. In general, a *bridge* is an h-arc r whose endpoints are the lower endpoints of two other h-arcs r' and r''; r' and r'' will have the same upper endpoint. The preceding paragraph describes a general procedure for obtaining $L2(r)$ from $L2(r')$ and $L2(r'')$. In general, an m-modal polygon will have $m - 1$ bridges. It is easily seen how the above top-down algorithm for bimodal polygons can be extended to general m-modal polygons. Unfortunately, we have no control over the positions of the bridges or the relative order of the sizes of the two lists to be merged. If we actually form the sorted list $L2(r)$ for each bridge r, we cannot guarantee $O(n \log n)$ time complexity. Note that the only operations we need to perform on the $L2$ lists are the following:

INSERT: Insert an element into the list

DELETE: Delete an element from the list

MAX: Find the largest element in the list

UNION: Take the union of two lists

In fact, we only need to INSERT an element that is larger than all the other elements in the list and to DELETE the largest element from the list. When we process an h-arc r, we will maintain the unordered set of elements in $L2(r)$ as a *Mergeable Heap* (see [1]). This data structure allows each INSERT, DELETE, MAX, or UNION operation to be performed in $O(\log n)$ time. Because we only need to perform $O(n)$ such operations, the overall algorithm runs in $O(n \log n)$ time. Note that apart from the heap operations mentioned above, all the other operations performed by the algorithm require only linear time.

3.2. The lower bound. The algorithm in §3.1 finds an optimal triangulation of $SP(r)$ for each h-arc r. This seems wasteful, because we are only interested in an optimal triangulation of SP. The natural question is whether it is possible to reduce the heap operations and find an optimal triangulation of SP in $o(n \log n)$ time. We will prove that this is not possible for *TPS*. We will show that there are $n^{\Omega(n)}$ ross's for *TPS* and *TPP*. Then a tight $\Omega(n \log n)$ lower bound for *TPS* will follow from Theorem 3. If we could extend our lower bound technique to bounded degree algebraic decision trees, we would have a tight $\Omega(n \log n)$ lower bound for *TPP*.

Consider the following worst-case instance of the algorithm described in §3.1. Let m be even, and let $SP = (p_m, p_{m-2}, \ldots, p_2, p_0, q_{1,1}, q_{1,2}, q_{2,1}, q_{2,2}, \ldots, q_{m,1}, q_{m,2}, p_1, p_3, \ldots, p_{m-1})$ (see Fig. 6 for $m = 4$). SP has $n = 3m + 1$ vertices. Let $q_{0,2} = p_0$, $p_{-1} = q_{m,2}$ and $p_{-2} = q_{1,2}$. Let $w(p_i) > w(p_{i+1})$, $-2 \le i < m$, $w(q_{1,1}) > w(q_{1,2})$, and $w(q_{j,1}) > w(q_{j-1,2}) > w(q_{j,2})$, $1 < j \le m$. Then SP is m-modal, p_m is the global minimum, $q_{j,2}$, $1 \le j < m$ are the local minima, and $q_{j,1}$, $1 \le j \le m$, are the local maxima.

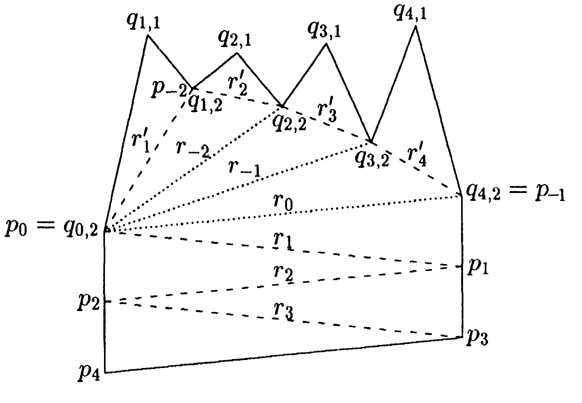

FIG. 6.

$r_i = p_i p_{i-1}$, $1 \le i < m$; $r_i = p_0 q_{m+i,2}$, $-(m-2) \le i \le 0$; $r'_j = q_{j-1,2} q_{j,2}$, $1 \le j \le m$; these are the h-arcs. $r_i = p_0 q_{m+i,2}$, $-(m-2) \le i \le 0$, are the bridges. $r_m = p_m p_{m-1}$ is a degenerate h-arc.

Let $L = (\alpha_1, \alpha_2, \ldots, \alpha_m)$ be the list of r'_j, $1 \le j \le m$, in decreasing order of cutoff values. $\alpha_j = r'_{\pi(j)}$, $1 \le j \le m$, for some permutation π of $(1, 2, \ldots, m)$; we let L be denoted by L_π. We will show that, for both *TPS* and *TPP*, all the $m! = [(n-1)/3]!$ permutations π are possible. We will also show that each π corresponds to a ross, and that no two π's correspond to the same ross. This will imply that there are at least $m!$ ross's for *TPS* and *TPP*. We have the following.

LEMMA 6. *Let π be any fixed permutation of $(1, 2, \ldots, m)$. Suppose that the weights $\vec{w} = (w_1, w_2, \ldots, w_n)$ of the vertices of SP are such that*

(i) *$w(q_{1,2}) - w(q_{m-1,2})$ is arbitrarily small,*

(ii) *$L_\pi = (\alpha_1, \alpha_2, \ldots, \alpha_m)$ is the list of r'_js in decreasing order of cutoff values,*

(iii) *$w(p_i) < co(\alpha_i) < w(p_{i-1})$ for $1 \le i \le m$, and*

(iv) *$co(r_{i-1}) = w(p_i)$ for $1 \le i \le m$.*

Let $\hat{T}$ *be the triangulation of* SP *consisting only of h-arcs (see Fig. 6). For* $0 \le k \le m$, *let* T_k *be the triangulation obtained from* $\hat{T}$ *as follows. Remove* α_j, $1 \le j \le k$, *and* r_i, $-(m-2) \le i < k$; *the resulting figure will have only one nontriangular face* F_k, *and* p_k *will be the smallest weight vertex in that face; triangulate that face as a fan. Note that* $T_0 \equiv \hat{T}$. *Let* $S_\pi = \{T_k | 0 \le k \le m\}$. *The set* $sol(\vec{w})$ *of all optimal triangulations of* SP *is* S_π; *so* S_π *is a* ross.

Proof. Let π and $\vec{w}$ be such that conditions (i)–(iv) hold. By (i), for both *TPS* and *TPP*, the cutoff values of the top $m-2$ bridges $r_i = p_o q_{m+i,2}$, $-(m-2) \le i < 0$, which are all less than $w(p_0)$, are very close to $w(p_0)$. Because by (iv), $co(r_0) = w(p_1) < w(p_0)$, if an optimal triangulation does not contain the bridge r_0, then it cannot contain any of the other bridges. Also by (iv), if an optimal triangulation does not contain r_k for some k, $1 \le k < m$, then it cannot contain any of the h-arcs r_i, $0 \le i < k$.

For an optimal triangulation T of SP, let k be the smallest integer, $0 \le k \le m$, such that T contains r_k. Then, by the arguments in the preceding paragraph and by (iii), T must be T_k. Also, it is easily seen that each of the triangulations T_k, $0 \le k \le m$, is optimal. Hence $S_\pi = \text{sol}(\vec{w})$ is a ross. □

Note that π serves as a "signature" for S_π. Hence two different π's cannot correspond to the same S_π. In §3.2.1, we will show that, for *TPS*, for each permutation π of $(1, 2, \dots, m)$, we can find a $\vec{w}$ that satisfies the conditions of Lemma 6. In §3.2.2, we will prove the analogous result for *TPP*.

3.2.1. Tight lower bound for TPS. Let π be a fixed permutation of $(1, 2, \dots, m)$. We will find a $\vec{w}$ that satisfies the conditions of Lemma 6. Let ${\alpha_i}^1$ and ${\alpha_i}^2$ denote the lower and upper endpoints of α_i, respectively; let u_i denote the unique vertex of SP that lies between ${\alpha_i}^1$ and ${\alpha_i}^2$. Condition (iii) of Lemma 6 translates to the following: for $1 \le i \le m$,

$$(1) \qquad w(p_i) + w(u_i) < w({\alpha_i}^1) + w({\alpha_i}^2) < w(p_{i-1}) + w(u_i).$$

Condition (iv) of the lemma essentially equates the costs of T_{i-1} and T_i, for $1 \le i \le m$. T_{i-1} and T_i differ only in the triangulation of the face F_i. In T_i, the triangulation of F_i is a fan centered at p_i. In T_{i-1}, the triangulation of F_i consists of a fan of F_{i-1} centered at p_{i-1}, and the triangles ${\alpha_i}^1{\alpha_i}^2 u_i$ and $p_i p_{i-1} p_{i-2}$. So, condition (iv) translates to the following: for $1 \le i \le m$,

$$(2) \; (m+2i-3)w(p_{i-1}) + w(p_{i-2}) + w({\alpha_i}^1) + w({\alpha_i}^2) = (m+2i-2)w(p_i) + w(p_{i-3}) + w(u_i).$$

Solving (2) for $w(u_i)$, we get

(2′)

$$w(u_i) = w({\alpha_i}^1) + w({\alpha_i}^2) + (m+2i-3)w(p_{i-1}) - (m+2i-2)w(p_i) + w(p_{i-2}) - w(p_{i-3}).$$

Substituting (2′) in (1), we get

$$(1') \; (m+2i-3)(w(p_{i-1}) - w(p_i)) < w(p_{i-3}) - w(p_{i-2}) < (m+2i-2)(w(p_{i-1}) - w(p_i)).$$

We can first choose $w(p_i)$, for i varying from m down to -2, obeying (1′). Note that (1′) and (2′) do not restrict $w(q_{j,2})$, $1 < j < m$; so, we can choose them such that condition (i) of Lemma 6 is satisfied, and $w(q_{j-1,2}) > w(q_{j,2})$ for $1 < j \le m$. Finally, we can compute the $w(u_i)$'s (i.e., $w(q_{j,1})$'s) from (2′). Then, from (1′) and (2′), we are guaranteed that

$$w({\alpha_i}^1) + w({\alpha_i}^2) - w(p_{i-1}) < w(u_i) < w({\alpha_i}^1) + w({\alpha_i}^2) - w(p_i)$$

or in particular that $w(u_i) > w({\alpha_i}^2)$. So we are guaranteed that $w(q_{1,1}) > w(q_{1,2})$ and $w(q_{j,1}) > w(q_{j-1,2})$ for $1 < j \le m$. Hence we have shown that for each π, we can find a $\vec{w}$ that satisfies the conditions of Lemma 6. By Theorem 4, this leads to the following.

THEOREM 5. *Any linear decision tree that solves TPS_I has $\Omega(n \log n)$ height.*

Note that by (1′), $[w(p_{-2}) - w(p_{-1})]/[w(p_{m-1}) - w(p_m)]$ is of the order $m^{\theta(m)}$. So our lower bound proof requires that the input consist of a large number of bits.

3.2.2. Ross count for TPP. Let π be a fixed permutation of $(1, 2, \dots, m)$. Let ${\alpha_i}^1$, ${\alpha_i}^2$, and u_i be as defined in the preceding subsection. To simplify the arithmetic, we change condition (iii) of Lemma 6 to

$$w(p_i) = co(\alpha_i) < w(p_{i-1}) \quad \text{for} \quad 1 \le i \le m.$$

Since $w(p_i) < w(p_{i-1})$, this is equivalent to replacing (iii) by

$$\text{(iii}'\text{)} \qquad w(p_i) = co(\alpha_i) \quad \text{for} \quad 1 \le i \le m.$$

For $1 \le k \le m$, let T'_k be the triangulation of SP obtained from T_k by replacing the arc $p_k u_k$ by the h-arc α_k. Let $S'_\pi = S_\pi \cup \{T'_k | 1 \le k \le m\}$. Let Lemma 6′ be the statement that results from Lemma 6 when condition (iii) is replaced by (iii'), and S_π is replaced by S'_π. Proof of Lemma 6′ is similar to that of Lemma 6.

We will find a $\vec{w}$ that satisfies the conditions of Lemma 6′. Condition (iii′) of Lemma 6′ translates to the following: for $1 \le i \le m$,

$$(3) \qquad w(p_i)w(u_i)(w({\alpha_i}^1) + w({\alpha_i}^2)) = w({\alpha_i}^1)w({\alpha_i}^2)(w(p_i) + w(u_i)).$$

Solving (3) for $w(u_i)$, we get

$$(3') \qquad 1/w(u_i) = 1/w({\alpha_i}^2) + [1/w({\alpha_i}^1) - 1/w(p_i)].$$

Because $w({\alpha_i}^1) > w(p_i)$, the term in the square bracket is negative. So, as long as the right-hand side is positive, $w(u_i) > w({\alpha_i}^2)$; that is, $w(q_{1,1}) > w(q_{1,2})$ and $w(q_{j,1}) > w(q_{j-1,2})$ for $1 < j \le m$.

For $0 \le i \le m$, let $W'(F_i)$ denote $\sum w(v)w(v')$ where the summation is taken over all the edges vv' around the face F_i (see Lemma 6 for the definition of F_k), except the edges $p_i p_{i-1}$ and $p_i p_{i-2}$. Condition (iv) of the lemma essentially equates the costs of T_{i-1} and T_i, for $1 \le i \le m$. T_{i-1} and T_i differ only in the triangulation of the face F_i. In T_i, the triangulation of F_i is a fan centered at p_i. In T_{i-1}, the triangulation of F_i consists of a fan of F_{i-1} centered at p_{i-1} and the triangles ${\alpha_i}^1{\alpha_i}^2 u_i$ and $p_i p_{i-1} p_{i-2}$. Because of condition (iii′), condition (iv) translates to the following: for $1 \le i \le m$,

$$(4) \quad w(p_i)w(p_{i-1})w(p_{i-2}) + w(p_{i-1})W'(F_{i-1}) = w(p_i)w(p_{i-1})w(p_{i-3}) + w(p_i)W'(F_{i-1}).$$

Solving (4) for $w(p_i)$, we get

$$(4') \qquad 1/w(p_i) = 1/w(p_{i-1}) + [w(p_{i-3}) - w(p_{i-2})]/W'(F_{i-1}).$$

This guarantees that $w(p_i) < w(p_{i-1})$. We can first choose $w(p_{-2}) = w(q_{1,2})$, $w(q_{j,2})$, $1 < j < m$, $w(q_{m,2}) = w(p_{-1})$, and $w(p_0)$. Then we can compute the pair $(w(p_i), w(u_i))$ from (4′) and (3′), for i varying from 1 to m.

Because $W'(F_{i-1}) \ge w(p_{i-2})w(p_{i-3})$, (4′) implies that

$$(5) \qquad 1/w(p_i) - 1/w(p_{i-1}) \le 1/w(p_{i-2}) - 1/w(p_{i-3}).$$

By taking $w(p_{-2}) - w(p_0)$ to be small, say $1/w(p_0) - 1/w(p_{-2}) = 1/(2mw(p_0))$, we can guarantee, using (5) and a simple induction, that

$$1/w(p_m) \le (3/2)(1/w(p_0)) \le 2/w(p_{-2}).$$

Then it follows that the right-hand side of (3′) is positive for all i, $1 \leq i \leq m$. Note that (3′) and (4′) do not restrict $w(q_{j,2})$, $1 < j < m$; so, we can choose them such that condition (i) of Lemma 6′ is satisfied, and $w(q_{j-1,2}) > w(q_{j,2})$ for $1 < j \leq m$. Hence, we have shown that for each π, we can find a $\vec{w}$ that satisfies the conditions of Lemma 6′. This leads to the following.

LEMMA 7. $|\mathrm{ROSS}(TPP)| \geq [(n-1)/3]!$.

3.3. The relationship between TPS and TPP. The definitions of *TPS* and *TPP* are very similar. In §3.1, we saw that the two problems can be solved by very similar algorithms. In §3.2, we saw that we can obtain a good lower bound on the number of ross's for the two problems using very similar ideas. In this subsection, we will discuss an even deeper relationship between the two problems. For an instance $\vec{w} = (w_1, w_2, \ldots, w_n)$ and a triangulation T of SP, let $c_T{}^{TPS}(\vec{w})$ and $c_T{}^{TPP}(\vec{w})$ be the costs of T in *TPS* and *TPP*, respectively. Let $\mathrm{sol}^{TPS}(\vec{w})$ and $\mathrm{sol}^{TPP}(\vec{w})$ denote the sets of all optimal solutions for $\vec{w}$ in *TPS* and *TPP*, respectively. For any real number N, let $\vec{N}$ denote $(N, N, \ldots, N) \in R^n$.

LEMMA 8. *For any $\vec{w}$, there exists a positive real number $N_{\vec{w}}$ such that* $\mathrm{sol}^{TPS}(\vec{w}) \supseteq \mathrm{sol}^{TPP}(\vec{w} + \vec{N})$, *for all $N \geq N_{\vec{w}}$.*

Proof. For a triangulation T of SP and fixed $\vec{w}$,

$$c_T{}^{TPP}(\vec{w} + \vec{N}) = (n-2)N^3 + N^2 c_T{}^{TPS}(\vec{w}) + O(N).$$

(Note that the hidden constant in the $O(N)$ term is a function of $\vec{w}$.) Hence, for any two triangulations T and T' of SP, and for all sufficiently large N, if $c_T{}^{TPP}(\vec{w}+\vec{N}) \leq c_{T'}{}^{TPP}(\vec{w}+\vec{N})$ then $c_T{}^{TPS}(\vec{w}) \leq c_{T'}{}^{TPS}(\vec{w})$. Hence the result follows. □

For a polynomial $f(\vec{w})$, let $\psi f(\vec{w})$ be the coefficient of the highest power of N in $f(\vec{w} + \vec{N})$; note that $\psi f(\vec{w})$ is a polynomial in $\vec{w}$, and its degree is no more than that of $f(\vec{w})$. For an algebraic decision tree D, let $\psi(D)$ be the decision tree obtained from D by replacing at each internal node v, the comparison $f_v(\vec{w}) : 0$ by the comparison $\psi f_v(\vec{w}) : 0$. The node in $\psi(D)$ corresponding to $v \in D$ will be referred to as $\psi(v)$. We have the following.

LEMMA 9. *Let D be an algebraic decision tree that solves TPP. For $\vec{w} \in R^n$, if $\vec{w} \in$* $\mathrm{set}(\psi(l))$ *for some $l \in L'(D)$, then* $\mathrm{sol}(\psi(l)) \in \mathrm{sol}^{TPS}(\vec{w})$; *so there exists a set $A \subseteq R^n$ of measure zero, such that $\psi(D)$ correctly solves TPS for any $\vec{w} \in R^n - A$.*

Proof. Let $\vec{w} \in \mathrm{set}(\psi(l))$ for some $l \in L'(D)$. Then, for all sufficiently large N, we have

$$\mathrm{sign}(f_v(\vec{w} + \vec{N})) = \mathrm{sign}(\psi f_v(\vec{w})) \neq 0$$

for all $v \in \xi_l$; so $\vec{w} + \vec{N} \in \mathrm{set}(l)$. Because D correctly solves *TPP*, $\mathrm{sol}(l) \in \mathrm{sol}^{TPP}(\vec{w} + \vec{N})$. By Lemma 8 we have that $\mathrm{sol}(\psi(l)) = \mathrm{sol}(l) \in \mathrm{sol}^{TPS}(\vec{w})$.

Finally, let $A = \cup_{l \in L(D)-L'(D)} \mathrm{set}(\psi(l))$; $A \subseteq \{\vec{w} \in R^n | \psi f_v(\vec{w}) = 0 \text{ for some } v \in D\}$, and so A is of measure zero. $\psi(D)$ correctly solves *TPS* for any $\vec{w} \in R^n - A$. □

This leads to the following.

LEMMA 10. *Let H_{TPS} be a lower bound on the height of any degree d algebraic decision tree that solves TPS for all but a measure zero set of inputs. Then H_{TPS} is also a lower bound on the height of any degree d algebraic decision tree that solves TPP.*

4. Conclusion. We first presented a new technique for obtaining lower bounds on the worst-case time-complexity of optimization problems, in the linear decision tree model of computation. Then, we used this technique to obtain a tight $\Omega(n \log n)$ lower bound for a problem of finding a minimum cost triangulation of a convex polygon with weighted vertices. This problem is very similar to the problem of finding an optimal order of computing a matrix chain product. If we could extend our lower bound technique to bounded degree algebraic decision trees, we would have a tight $\Omega(n \log n)$ lower bound for this latter problem.

Acknowledgment. The author is very grateful to the referee, Prof. George Lueker, for many valuable suggestions. In particular, the results in §3.3 were suggested by him.

ON "AXIOMATISING FINITE CONCURRENT PROCESSES"*

LUCA ACETO[†]

Abstract. In his pioneering paper [*Axiomatising finite concurrent processes*, SIAM J. Comput., 17 (1988), pp. 997–1017], Hennessy gave complete axiomatizations of Milner's observational congruence and of t-observational congruence which made use of an auxiliary operation to axiomatize parallel composition. Unfortunately, those axiomatizations turn out to be flawed due to the subtle interplay between Hennessy's auxiliary parallel operator and synchronization. The aim of this paper is to present correct versions of the equational characterizations given in Hennessy's paper. Some of the problems which arise in giving operational semantics to the auxiliary operators used by Bergstra and Klop and Hennessy in the theory of congruences like Milner's observational congruence are also discussed.

Key words. concurrent processes, observational congruence, t-observational congruence, equational logic

AMS subject classification. 68Q55

1. Introduction.

In his seminal paper [14], Matthew Hennessy gave complete axiomatizations of two behavioural congruences, namely, those associated with Milner's *weak bisimulation equivalence* [19] and *t-observational equivalence* [14] (also known as *split*-2 *equivalence* [10] and *timed equivalence* [1]), over a simple language for concurrent processes. Hennessy's paper [14] evolved from an early preprint, entitled *On the relationship between time and interleaving*, which dated back to 1981 and, in my opinion at least, did not receive the attention it deserved at the time of its first circulation.

Hennessy's *On the relationship between time and interleaving* and its published version [14] have historically played an important role in the development of the theory of process algebras for at least two reasons. First, the equational characterization of observational congruence presented in these papers was, to the best of my knowledge, the first one to use auxiliary operators in the axiomatization of CCS parallel composition [19]. At more or less the same time, J. A. Bergstra and J. W. Klop were working on a finite axiomatization of strong bisimulation equivalence over ACP which used two auxiliary operators [4], but extensions of their ideas to a setting involving internal actions were first presented in [6]. Secondly, Hennessy's papers presented the first axiomatization known to the author of a noninterleaving behavioural equivalence and its laws have helped shape the form of many axiomatizations which followed. (See, e.g., [7], [8], [18], [15].)

Unfortunately, however, there are subtle problems with the axiomatizations published in [14]. In particular, two of the axioms given by Hennessy for his auxiliary parallel operation are *unsound* due to the problems introduced by synchronization. In fact, the whole issue of giving semantics to the auxiliary operations used in [4], [6], [14] to axiomatize various parallel composition operators turns out to be rather subtle in the theory of behavioural congruences associated with weak bisimulation-like equivalences, such as observational congruence and t-observational congruence. The aim of this paper is to present correct versions of the axiomatizations given in [14]. In passing, I shall also comment on some of the issues involved in giving suitable operational semantics for the auxiliary operations of ACP in the setting of observational congruence and related congruences. I hope that this will make this paper a useful reference for researchers interested in complete axiomatizations of behavioural congruences.

The paper is organized as follows: §2 is devoted to a discussion of Hennessy's axiomatization of t-observational congruence [14] and an example showing that it is unsound is

*Received by the editors Janaury 12, 1993; accepted for publication (in revised form) May 18, 1993.

given. I then present a sound and complete axiomatization for this congruence which uses the auxiliary operations of ACP. In §2.1, I present an example showing that the axiomatization of observational congruence in [14] is also unsound and give a correct sound and complete axiomatization for this congruence. Finally, in §3, I discuss the operational semantics of the auxiliary operations of ACP in the setting of observational congruence.

2. An axiomatization of Hennessy's t-observational congruence. I assume that the reader is familiar with [14] and the basic notions on process algebras and bisimulation equivalence. The uninitiated reader is referred to the textbooks [19], [3] for extensive motivations and background. As this is not an introductory paper, I shall feel free to refer the reader to the motivations, definitions, and results given in [14]. Precise pointers to material in [14] will be given whenever necessary.

The language **P** used by Hennessy in [14] is a simple extension of finite, restriction- and relabelling-free CCS. It is given by the grammar

$$p ::= \mathbf{0} \mid \mu.p \mid p + p \mid p \| p \mid p \lfloor p$$

where μ ranges over the set of *actions* **Act**. The set **Act** is assumed to have the form $\{\tau\} \cup \Lambda \cup \bar{\Lambda}$, where Λ is a given countable set of names, $\bar{\Lambda} = \{\bar{a} \mid a \in \Lambda\}$ is the set of complement names, and τ is a distinguished action. As usual, we assume that complementation is symmetric, i.e., $\bar{\bar{a}} = a$. We use **VAct** to denote $\Lambda \cup \bar{\Lambda}$, the set of *visible actions*, and a, b to range over it.

The operational semantics for the language **P** given by Hennessy in §2.1 of [14] is based on the idea that visible actions have a beginning and an ending. Moreover, these distinct events may be observed and are denoted by $S(a)$ and $F(a)$, respectively. Let $\mathbf{E} = \{S(a), F(a) \mid a \in \mathbf{VAct}\} \cup \mathbf{Act}$; in the terminology of [14], this is the set of *events* and I shall use e to range over it. The operational semantics is given in terms of a set of next-state relations $\overset{e}{\Rightarrow}$, one for each $e \in \mathbf{E}$. As explained at length in [14], the relations $\overset{e}{\Rightarrow}$ are defined over the set of states **S**, a superlanguage of **P** obtained by adding new prefixing operators a_S to the formation rules for **P**. I shall use s, s', s_1, s_2 to range over the set of states **S**. The relations $\overset{e}{\Rightarrow}$ are defined to be the least ones over **S** that satisfy the rules in Fig. 1. Comments on these rules may be found in §2.1 of [14].

The relation of *t-observational equivalence* $\approx_T$ is now defined as the largest symmetric relation on states which satisfies

$s_1 \approx_T s_2$ if and only if for every $e \in \mathbf{E}$, $s_1 \overset{e}{\Rightarrow} s_1'$ implies
(i) $e = \tau$ and $s_1' \approx_T s_2$, or
(ii) $s_2 \overset{e}{\Rightarrow} s_2'$ for some s_2' such that $s_1' \approx_T s_2'$.

Following Hennessy, I shall only be interested in $\approx_T$ as it applies to the language of processes **P**. The interested reader is referred to §2.1 of [14] for examples of equivalent and inequivalent processes with respect to $\approx_T$. Here, I shall only remark that t-observational equivalence is a noninterleaving equivalence, in whose theory the concurrent execution of actions is discriminated from their arbitrary interleaving by means of information about the structure of actions. For example, the processes $a.\mathbf{0} \parallel b.\mathbf{0}$ and $a.b.\mathbf{0} + b.a.\mathbf{0}$ are inequivalent with respect to $\approx_T$ because the former can start an a action and subsequently start a b action, whilst the latter cannot.

The equivalence $\approx_T$ is not a congruence over **P** for the usual reasons associated with the operators $+$ and $\lfloor$. For example, it is easy to see that $\mathbf{0} \approx_T \tau.\mathbf{0}$, but

$$\mathbf{0} \lfloor a.\mathbf{0} \approx_T \mathbf{0} \not\approx_T \tau.a.\mathbf{0} \approx_T \tau.\mathbf{0} \lfloor a.\mathbf{0}.$$

$$\frac{}{a.p \overset{S(a)}{\Rightarrow} a_S.p} \qquad \frac{}{a_S.p \overset{F(a)}{\Rightarrow} p} \qquad \frac{}{\mu.p \overset{\mu}{\Rightarrow} p}$$

$$\frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_1 + s_2 \overset{e}{\Rightarrow} s_1'} \qquad \frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_2 + s_1 \overset{e}{\Rightarrow} s_1'}$$

$$\frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_1 \| s_2 \overset{e}{\Rightarrow} s_1' \| s_2} \qquad \frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_2 \| s_1 \overset{e}{\Rightarrow} s_2 \| s_1'} \qquad \frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_1 \lceil s_2 \overset{e}{\Rightarrow} s_1' \| s_2}$$

$$\frac{s_1 \overset{a}{\Rightarrow} s_1',\ s_2 \overset{\bar{a}}{\Rightarrow} s_2'}{s_1 \| s_2 \overset{\tau}{\Rightarrow} s_1' \| s_2'} \qquad \frac{s_1 \overset{a}{\Rightarrow} s_1',\ s_2 \overset{\bar{a}}{\Rightarrow} s_2'}{s_1 \lceil s_2 \overset{\tau}{\Rightarrow} s_1' \| s_2'}$$

$$\frac{s_1 \overset{\tau}{\Rightarrow} s_1',\ s_1' \overset{e}{\Rightarrow} s_2}{s_1 \overset{e}{\Rightarrow} s_2} \qquad \frac{s_1 \overset{e}{\Rightarrow} s_1',\ s_1' \overset{\tau}{\Rightarrow} s_2}{s_1 \overset{e}{\Rightarrow} s_2}$$

FIG. 1. *Operational rules for* $\overset{e}{\Rightarrow}$.

One of the main results in [14] is a complete equational characterization of the largest congruence $\approx_T^C$ contained in $\approx_T$ over the set of processes. (See Theorem 2.1.2 in [14].) For ease of reference, Hennessy's equations for $\approx_T^C$ are collected in Fig. 2.

Unfortunately, however, the axiomatization presented in Fig. 2 is incorrect. This is due to the fact that axiom (B2), which plays a vital role in the reduction of terms to *simple forms* (see the proof of Proposition 2.2.3 in [14]), is unsound as the following example shows. (A similar example may be found on page 142 of [7].)

Example. Consider the terms $p \equiv (a.c.\mathbf{0} \lceil b.\mathbf{0}) \lceil \bar{b}.\bar{a}.\mathbf{0}$ and $q \equiv a.c.\mathbf{0} \lceil (b.\mathbf{0} \| \bar{b}.\bar{a}.\mathbf{0})$. I claim that $p \not\approx_T^C q$. In fact, using the rules in Fig. 1, it is easy to see that $b.\mathbf{0} \| \bar{b}.\bar{a}.\mathbf{0} \overset{\bar{a}}{\Rightarrow} \mathbf{0} \| \mathbf{0}$. This allows one to derive that $q \overset{c}{\Rightarrow} \mathbf{0} \| (\mathbf{0} \| \mathbf{0})$. On the other hand, p cannot initially perform a c action.

The problem in the equational characterization of Hennessy's auxiliary operator $\lceil$ derives from the fact that, although simpler than $\|$, $\lceil$ still captures two conceptually distinct features of parallel composition. One of them is the asynchronous behaviour due to one of the parallel components; the other is synchronization between processes. In their work on ACP, Bergstra and Klop have used two auxiliary operators, namely, *left-merge* $\lfloor\!\lfloor$ and *communication merge* $|$, to give a finite equational axiomatization of the parallel composition operation. Intuitively, the left-merge operation is used to capture the behaviour of parallel composition due to one of the parallel components and the communication merge is used to capture the behaviour deriving from synchronization. In the remainder of this section, I shall present an equational characterization of $\approx_T^C$ over $\mathbf{P}$ which will make a fundamental use of a noninterleaving variation on Bergstra and Klop's auxiliary operations[1]. All my attempts to find a sound and complete axiom system for $\mathbf{P}$ without the introduction of Bergstra and Klop's auxiliary operators have been to no avail.

[1] Bergstra and Klop's left-merge operation satisfies axiom (NLM2) in Fig. 4, whilst the left-merge operation I shall use in this section does not.

\text{NX3} & x\lceil \tau.y & = & x\lceil y \\
\\
\text{C} & a.x_1\lceil ((\bar{a}.x_2\lceil y)+z) & = & a.x_1\lceil ((\bar{a}.x_2\lceil y)+z)+\tau.(x_1\|x_2\|y)
\end{array}
$$

FIG. 2. *Hennessy's equations for* $\approx_T^C$.

Let $\mathbf{P}_{\text{ext}}$ denote the language obtained by extending the grammar for $\mathbf{P}$ with the following formation rule:

if $p, q \in \mathbf{P}_{\text{ext}}$, then $p \mathbin{|\!\!\lfloor} q \in \mathbf{P}_{\text{ext}}$ and $p|q \in \mathbf{P}_{\text{ext}}$.

The set of states $\mathbf{S}_{\text{ext}}$ associated with the extended language $\mathbf{P}_{\text{ext}}$ is defined in exactly the same way as $\mathbf{S}$. The operational semantics for the language of extended states $\mathbf{S}_{\text{ext}}$ is obtained by adding the following rules for the new operators to those in Fig. 1:

$$\frac{s_1 \overset{e}{\Rightarrow} s_1'}{s_1 \mathbin{|\!\!\lfloor} s_2 \overset{e}{\Rightarrow} s_1'\|s_2} \qquad \frac{s_1 \overset{a}{\Rightarrow} s_1',\ s_2 \overset{\bar{a}}{\Rightarrow} s_2'}{s_1|s_2 \overset{\tau}{\Rightarrow} s_1'\|s_2'}.$$

The notions of t-observational equivalence and t-observational congruence can now be conservatively extended to the language $\mathbf{P}_{\text{ext}}$ and, as in Lemmas 2.1.1 and 2.2.1 in [14], the following results hold.

LEMMA 2.1. *For all* $p, q \in \mathbf{P}_{\text{ext}}$,

(1) $p \approx_T^C q$ *if and only if* $p + a.\mathbf{0} \approx_T q + a.\mathbf{0}$ *for some* $a \in \mathbf{VAct}$ *not occurring in* p *and* q;

(2) $p \approx_T q$ *if and only if* $p \approx_T^C q$ *or* $\tau.p \approx_T^C q$ *or* $p \approx_T^C \tau.q$.

A standard, useful corollary of the characterization given in statement (1) of the above lemma is that if $p \approx_T^C q$, then p and q must have matching τ-transitions. (See, e.g., [14, p. 1010].)

I shall now address the problem of giving a sound and complete axiomatization of t-observational congruence over the language $\mathbf{P}_{\text{ext}}$ and, hence, over its sublanguage $\mathbf{P}$. First of all, note that sound versions of equations (B1)–(B4) may be given by replacing Hennessy's $\lceil$ with the left-merge operator. In particular, the following variation on equation (B2) holds in the quotient algebra $\mathbf{P}_{\text{ext}}/\approx_T^C$:

$$(x \mathbin{|\!\!\lfloor} y) \mathbin{|\!\!\lfloor} z = x \mathbin{|\!\!\lfloor} (y\|z).$$

The key to the soundness of the above equation is the fact that the left-merge operation does not allow for synchronization between its operands. For example, the reader can easily adapt the aforementioned example showing the unsoundness of axiom (B2) to prove that a version of the above equation in terms of the communication merge is not valid in $\mathbf{P}_{\mathbf{ext}}/\approx_T^C$, i.e., that there are processes $p, q, r \in \mathbf{P}_{\mathbf{ext}}$ such that

$$(p \mid q) \mid r \not\approx_T^C p \mid (q \| r).$$

Synchronization between processes is described by the communication merge operator. In fact, left-merge and communication merge together allow one to describe equationally the behaviour of parallel composition and of Hennessy's $\upharpoonright$ operator. The relevant equations are

$$(x \upharpoonright y) = x \mathbin{\|\!\!\lfloor} y + x \mid y, \tag{1}$$

$$x \| y = x \mathbin{\|\!\!\lfloor} y + y \mathbin{\|\!\!\lfloor} x + x \mid y. \tag{2}$$

Equation (1) was given in [5] in a setting without internal actions, while equation (2) is the key to the finite axiomatizations of bisimulation congruences presented in many papers in the literature on ACP. (See, e.g., [6].) Note that, in the presence of left-merge and communication merge, Hennessy's merge operator is no longer necessary to axiomatize CCS parallel composition.

The communication merge operator satisfies, among other laws, the following version of axiom (C):

$$(a.x \mathbin{\|\!\!\lfloor} y) \mid (b.w \mathbin{\|\!\!\lfloor} z) = \begin{cases} \tau.(x \| y \| w \| z) & \text{if } a = \bar{b}, \\ \mathbf{0} & \text{otherwise,} \end{cases}$$

where I have taken the liberty of omitting a cumbersome use of parentheses because parallel composition is commutative and associative modulo $\approx_T^C$. An equation expressing a fundamental property of the communication merge operator in the theory of t-observational congruence is the following:

$$\tau.x \mid y = x \mid y.$$

This law was first presented in [6], where it was shown to be sound with respect to a graph model for Milner's observational congruence (or rooted τ-bisimulation equivalence, in Bergstra and Klop's terminology). It expresses the subtle interplay between internal τ-actions and synchronization in the theory of observational congruence-like relations.

The set $\mathcal{E}$ of equations which make up the axiomatization of t-observational congruence over $\mathbf{P}_{\mathbf{ext}}$ is given in Fig. 3. The main result of this paper may now be stated.

THEOREM 2.2. *For all* $p, q \in \mathbf{P}_{\mathbf{ext}}$, $p \approx_T^C q$ *if and only if* $\mathcal{E} \vdash p = q$.

I shall now sketch the steps involved in the proof of Theorem 2.2. The presentation will closely follow §2.2 in [14] and the interested reader is referred to that reference for many details.

The first step in the proof of Theorem 2.2 is to show that all the equations in $\mathcal{E}$ are indeed satisfied by $\approx_T^C$. This is the import of the following result, whose proof is straightforward but rather tedious.

PROPOSITION 2.3 (Soundness). *For all* $p, q \in \mathbf{P}_{\mathbf{ext}}$, $\mathcal{E} \vdash p = q$ *implies* $p \approx_T^C q$.

The proof of the completeness of the equations in $\mathcal{E}$ with respect to t-observational congruence follows the general outline of that of Theorem 2.1.2 in [14]. As usual, I shall rely on the existence of normal forms for processes. These are very similar to Hennessy's simple

$$

\end{array}
$$

FIG. 3. *Complete equations for* $\approx_T^C$ *over* $\mathbf{P}_{\text{ext}}$.

forms. (See Definition 2.2.2 in [14].) As usual in the literature on process algebras, the notation $\sum\{p_i \mid i \in I\}$ is used as a shorthand for $p_{i_1}+\cdots+p_{i_n}$ where $I=\{i_1,\ldots,i_n\}$. If $I=\emptyset$, then $\sum\{p_i \mid i \in \emptyset\} \equiv \mathbf{0}$.

DEFINITION 2.4. *The set of* normal forms **NF** *is the least subset of* $\mathbf{P}_{\text{ext}}$ *such that*

$\sum\{a_i.p_i\lfloor\!\lfloor p_i' \mid i \in I\}+\sum\{\tau.q_j \mid j \in J\} \in \mathbf{NF}$ *if* I, J *are finite index sets and each* $p_i, p_i', q_j \in \mathbf{NF}$.

PROPOSITION 2.5 (Normalization). *For every process* $p \in \mathbf{P}_{\text{ext}}$, *there exists a normal form* $\hat{p} \in \mathbf{NF}$ *such that* $\mathcal{E} \vdash p = \hat{p}$.

Proof. The proof of this result is standard and many similar ones may be found in the literature. Detailed proofs for closely related languages may be found in, e.g., [7], [18]. Equations (A3), (I1), (I2), (ILM1), and (ILM3) are not needed in the proof. □

Following Hennessy, the proof of completeness of the set of equations $\mathcal{E}$ relies on establishing so-called "derivation lemmas." As in [14], I shall only be interested in derivations with respect to τ-actions and $S(a)$-actions.

LEMMA 2.6 (Derivation lemma). *Let* $p \in \mathbf{P}_{\text{ext}}$. *Then*

(1) $p \overset{\tau}{\Rightarrow} q$ *implies* $\mathcal{E} \vdash p = p+\tau.q$;

(2) $p \overset{S(a)}{\Rightarrow} a_S.p_1\|p_2$ *implies* $\mathcal{E} \vdash p = p+a.p_1\lfloor\!\lfloor p_2$.

Proof. By Proposition 2.5, it is sufficient to prove the above statements for normal forms. Assume then that p is of the form $\sum\{a_i.p_i\lfloor\!\lfloor p_i' \mid i \in I\}+\sum\{\tau.q_j \mid j \in J\}$.

(1) Then by induction on the length of the derivation $p \equiv \sum\{a_i.p_i \mathbin{|\!\lfloor} p'_i \mid i \in I\} + \sum\{\tau.q_j \mid j \in J\} \overset{\tau}{\Rightarrow} q$.

Base case: $q \equiv q_j$ for some $j \in J$. Then $\mathcal{E} \vdash p = p + \tau.q$ follows immediately by using equations (A1)–(A4).

Inductive step: $q_j \overset{\tau}{\Rightarrow} q$ for some $j \in J$. By the inductive hypothesis, it follows that $\mathcal{E} \vdash q_j = q_j + \tau.q$. By equations (I1) and (A1)–(A4), it is easy to derive that $\mathcal{E} \vdash \tau.q_j = \tau.q_j + \tau.q$, from which $\mathcal{E} \vdash p = p + \tau.q$ follows immediately.

(2) This statement is proven exactly as Corollary 2.2.5 in [14]. □

The key to the proof of the completeness theorem is an important decomposition result proven by Hennessy in [14] for the language **P**. The extension of Hennessy's result to the language $\mathbf{P_{ext}}$ is immediate, and, in fact, his proof carries over unchanged to this language.

PROPOSITION 2.7 (Hennessy). *For all $p, p', q, q' \in \mathbf{P_{ext}}$, $a_S.p \| p' \approx_T a_S.q \| q'$ implies $p \approx_T q$ and $p' \approx_T q'$.*

Proof. See the proof of Proposition 2.2.8 in [14] and those of the lemmas leading up to it. □

The above results are all that is needed in the proof of the completeness result to follow.

THEOREM 2.8 (Completeness). *For all $p, q \in \mathbf{P_{ext}}$, $p \approx_T^C q$ implies $\mathcal{E} \vdash p = q$.*

Proof. This is just a reworking of Hennessy's proof of Theorem 2.2.9 in [14] using the results given above. The interested reader will have no difficulty in filling in the details following Hennessy's proof. □

2.1. An axiomatization of observational congruence. As mentioned in the introduction, Hennessy's axiomatization of Milner's observational congruence in [14] was the first to use an auxiliary operator to give an equational characterization of parallel composition. For the sake of clarity and in order to support the discussion to follow, I shall now recapitulate the definitions of weak bisimulation equivalence and its associated congruence.

The relation of *weak bisimulation equivalence* $\approx$ is defined as the largest symmetric relation over **P** which satisfies

$p \approx q$ if and only if for every $\mu \in \mathbf{Act}$, $p \overset{\mu}{\Rightarrow} p'$ implies
(i) $\mu = \tau$ and $p' \approx_T q$, or
(ii) $q \overset{\mu}{\Rightarrow} q'$ for some q' such that $p' \approx_T q'$.

As usual, $\approx$ is not a congruence over **P**. The largest congruence relation contained in $\approx$ will be denoted by $\approx^C$ and will be referred to as *observational congruence*.

The key to the axiomatization of observational congruence presented in Theorem 1.3.4 of [14] is a version of Milner's *interleaving law* in terms of Hennessy's $\lceil$. This is the following conditional equation schema:

$$\text{(X2)}\ \frac{y = \sum\{\lambda_j.y_j \mid j \in J\}\ (J \text{ a finite index set})}{\mu.x \lceil y = \mu.(x \| y) + \sum\left\{\tau.(x \| y_j) \mid \mu = \bar{\lambda}_j\right\}}.$$

This equation schema plays a vital role in the reduction of process terms to the sumforms used by Hennessy and Milner in [16] and Hennessy in [14]. Unfortunately, however, it is *not* sound with respect to observational congruence as the following example shows.

Example. Consider the instance of the above equation obtained by taking $\mu \equiv a$, $x \equiv \mathbf{0}$, and $y \equiv \tau.\bar{a}.\mathbf{0}$. Then (X2) allows us to derive that $a.\mathbf{0} \lceil \tau.\bar{a}.\mathbf{0} = a.(\mathbf{0} \| \tau.\bar{a}.\mathbf{0})$. However, this equality does not hold in the quotient algebra $\mathbf{P}/{\approx^C}$ as $a.\mathbf{0} \lceil \tau.\bar{a}.\mathbf{0} \overset{\tau}{\Rightarrow} \mathbf{0} \| \mathbf{0}$, whilst obviously $a.(\mathbf{0} \| \tau.\bar{a}.\mathbf{0})$ has no comparable transition.

The reader will have noticed that, once again, the unsoundness of axiom (X2) derives from the fact that Hennessy's $\lceil$ allows for communication between its arguments. The above problem with the axiomatization presented in [14] can be solved by resorting to Bergstra and Klop's auxiliary operators. In fact, it is possible to extend conservatively observational congruence to the language $\mathbf{P}_{\mathrm{ext}}$ and give a sound and complete equational axiomatization of equality in the quotient algebra $\mathbf{P}_{\mathrm{ext}}/\approx^C$. In fact, all that is needed for this purpose is to add the following equations to those presented in Fig. 3:

$$a.x \mathbin{\lfloor\!\lfloor} y = a.(x \,\|\, y), \tag{3}$$

$$a.(x + \tau.y) = a.(x + \tau.y) + a.y. \tag{4}$$

Equation (3) is the one that essentially expresses the fact that observational congruence induces an interleaving semantics on processes. Together with the other equations for left-merge and communication merge it allows for the derivation of Milner's expansion theorem. (See, e.g., [6] for a detailed proof of this fact.) Equation (4) is Milner's "third τ-law." As it is well known (see, e.g., [14], p. 1010), this equation does not hold for $\approx^C_T$ because it strongly depends on the assumption of atomicity of action occurrences.

In the presence of (3), several of the equations in Fig. 3 are not necessary to give a complete equational characterization of observational congruence over the language $\mathbf{P}_{\mathrm{ext}}$. (Note, however, that those equations lead to more powerful axiomatic systems for what concerns provability of equivalences between *open terms* over sublanguages of $\mathbf{P}_{\mathrm{ext}}$. The interested reader is referred to [20], [13] for more on this issue.) Moreover, axiom (CM4) may be simplified to

$$a.x \mid b.y = \begin{cases} \tau.(x \,\|\, y) & \text{if } a = \bar{b}, \\ \mathbf{0} & \text{otherwise.} \end{cases}$$

A complete set of axioms for $\approx^C$ is given in Fig. 4. Let $\mathcal{E}'$ denote the set of equations in Fig. 4.

THEOREM 2.9. *For all $p, q \in \mathbf{P}_{\mathrm{ext}}$, $p \approx^C q$ if and only if $\mathcal{E}' \vdash p = q$.*

Proof. This is just a reworking of many similar results in the literature (see, e.g., [16], [6], [19]), following the outline of the proof of Theorem 1.3.4 in [14, p. 1008]. □

3. Remarks on the operational semantics of Bergstra and Klop's auxiliary operators. The reader familiar with the literature on bisimulation semantics for CCS will have already noted that the operational semantics for the language $\mathbf{P}_{\mathrm{ext}}$ given in the previous section is slightly nonstandard. The rules in Fig. 1 and those for Bergstra and Klop's auxiliary operators define the so-called *weak transition relations* over the language $\mathbf{P}_{\mathrm{ext}}$ in one step, so to speak. This is in contrast to the developments in, e.g., [19], where the operational semantics of CCS is defined first in terms of single-step transition relations. These concrete transition relations are then used in the definition of the weak transition relations, which capture the intuition that τ-labeled transitions correspond to invisible events. For easy reference, the defining rules of the one-step transition relations, $\xrightarrow{e}$, for the language $\mathbf{P}_{\mathrm{ext}}$ are collected in Fig. 5. The associated transition relations that abstract from internal τ-transitions are then usually defined by

$$s \overset{e}{\Rightarrow} s' \Leftrightarrow \exists s_1, s_2 : s \xrightarrow{\tau}{}^{\star} s_1 \xrightarrow{e} s_2 \xrightarrow{\tau}{}^{\star} s',$$

where $\xrightarrow{\tau}{}^{\star}$ denotes the reflexive and transitive closure of the relation $\xrightarrow{\tau}$.

The process of abstraction from τ-labeled transitions is instead built in the definition of the transition relations $\overset{e}{\Rightarrow}$ by means of the rules

$$\frac{s_1 \overset{\tau}{\Rightarrow} s_1',\ s_1' \overset{e}{\Rightarrow} s_2}{s_1 \overset{e}{\Rightarrow} s_2} \qquad \frac{s_1 \overset{e}{\Rightarrow} s_1',\ s_1' \overset{\tau}{\Rightarrow} s_2}{s_1 \overset{e}{\Rightarrow} s_2}.$$

$$

\end{array}
$$

FIG. 4. *Complete equations for* $\approx^C$ *over* $\mathbf{P}_{\mathrm{ext}}$.

It is easy to see that, for processes in $\mathbf{P}_{\mathrm{ext}}$ not containing occurrences of the communication merge and of Hennessy's $\lceil$, the weak transition relations $\overset{e}{\Rightarrow}$ and $\overset{e}{\Rrightarrow}$ are in complete agreement, i.e., for all such s,

$$s \overset{e}{\Rightarrow} s' \Leftrightarrow s \overset{e}{\Rrightarrow} s'.$$

In particular, this implies that observational congruence and t-observational congruence over the sublanguage of $\mathbf{P}_{\mathrm{ext}}$ consisting of these terms can be defined using either of these two transition relations.

This agreement does, however, break down for terms having the communication merge operator or Hennessy's $\lceil$ as head operator. Consider, for example, the term $p \equiv \tau.a \mid \bar{a}.b.\mathbf{0}$. Then, using the defining rules for $\dot{\Rightarrow}$, it is easy to derive that $p \overset{b}{\Rightarrow} \mathbf{0}\|\mathbf{0}$. However, p has no outgoing transition according to $\dot{\Rrightarrow}$, as rule

$$\frac{s_1 \xrightarrow{a} s_1',\, s_2 \xrightarrow{\bar{a}} s_2'}{s_1 \mid s_2 \xrightarrow{\tau} s_1'\|s_2'}$$

is not applicable to it. This fact has disastrous consequences in the theory of congruences that, like observational congruence and t-observational congruence, satisfy axiom

$$(\mathrm{I1}) \quad x+\tau.x \;=\; \tau.x.$$

In fact, the communication merge operation and Hennessy's $\lceil$ would not preserve any such congruence, if their operational semantics were given in terms of $\Rrightarrow$.

$$\frac{}{a.p \xrightarrow{S(a)} a_S.p} \qquad \frac{}{a_S.p \xrightarrow{F(a)} p} \qquad \frac{}{\mu.p \xrightarrow{\mu} p}$$

$$\frac{s_1 \xrightarrow{e} s_1'}{s_1 + s_2 \xrightarrow{e} s_1'} \qquad \frac{s_1 \xrightarrow{e} s_1'}{s_2 + s_1 \xrightarrow{e} s_1'}$$

$$\frac{s_1 \xrightarrow{e} s_1'}{s_1 \| s_2 \xrightarrow{e} s_1' \| s_2} \qquad \frac{s_1 \xrightarrow{e} s_1'}{s_2 \| s_1 \xrightarrow{e} s_2 \| s_1'} \qquad \frac{s_1 \xrightarrow{e} s_1'}{s_1 \mathbin{\lfloor\!\lfloor} s_2 \xrightarrow{e} s_1' \| s_2} \qquad \frac{s_1 \xrightarrow{e} s_1'}{s_1 \lceil s_2 \xrightarrow{e} s_1' \| s_2}$$

$$\frac{s_1 \xrightarrow{a} s_1',\ s_2 \xrightarrow{\bar{a}} s_2'}{s_1 \| s_2 \xrightarrow{\tau} s_1' \| s_2'} \qquad \frac{s_1 \xrightarrow{a} s_1',\ s_2 \xrightarrow{\bar{a}} s_2'}{s_1 \mid s_2 \xrightarrow{\tau} s_1' \| s_2'} \qquad \frac{s_1 \xrightarrow{a} s_1',\ s_2 \xrightarrow{\bar{a}} s_2'}{s_1 \lceil s_2 \xrightarrow{\tau} s_1' \| s_2'}$$

FIG. 5. *Operational rules for* $\xrightarrow{e}$.

Example (in terms of observational congruence). Consider the terms $\tau.a.\mathbf{0}$ and $a.\mathbf{0}+\tau.a.\mathbf{0}$. As $\approx^C$ satisfies axiom (I1), one has that $\tau.a.\mathbf{0} \approx^C a.\mathbf{0} + \tau.a.\mathbf{0}$. However, if the semantics of the communication merge operator were given in terms of the rules in Fig. 5, it would be the case that

$$p \equiv \tau.a.\mathbf{0} \mid \bar{a}.b.\mathbf{0} \not\approx^C (a.\mathbf{0} + \tau.a.\mathbf{0}) \mid \bar{a}.b.\mathbf{0} \equiv q.$$

In fact, $q \overset{b}{\Rrightarrow} \mathbf{0}\|\mathbf{0}$, whilst, as remarked above, p has no outgoing transitions with respect to $\Rrightarrow$.

The outcome of this discussion is that a suitable operational semantics for the communication merge operator and Hennessy's $\lceil$ in the theory of congruences that, like those axiomatized in this paper, satisfy axiom (I1) can only be given by defining the weak transition relations in one step[2], as in Fig. 1. I believe that this observation was already implicit in the denotational semantics for ACP in terms of process graphs presented by Bergstra and Klop in their seminal paper [6], but, probably because of the denotational nature of the semantics presented in that reference, it seems to have gone unnoticed in several papers in the literature. (A notable exception is [9], where an interesting operational semantics for ACP along the lines of that in Fig. 1 has been presented.)

Indeed, contrary to what happens for the basic CCS combinators, the operational semantics of the auxiliary operators used in the axiomatization of parallel composition is highly sensitive to the kind of behavioural congruence one wants to impose on terms. A full discussion of this point would lead me too far from the main aim of this paper. Thus, I shall just end by giving a short "recipe book" for giving semantics to the auxiliary operators discussed in this paper in the setting of some of the best-known semantic theories for processes, with pointers to references where they are discussed in detail. These may be found in Fig. 6. I hope that they

[2] The point here is that one is really interested in the identifications induced by the chosen congruence over the basic language, e.g., CCS, used to write specifications of concurrent systems. Auxiliary operators are only added for axiomatization purposes and as an aid in algebraic manipulations of terms. Hence, one should like to add these operations *conservatively*, that is to say that their presence should not influence the equalities over the basic language. This, of course, requires that these new operations preserve the chosen behavioural congruence.

Behavioural Congruences	Suitable Transition Relations
Observational congruences satisfying (I1)	Define the semantics of the auxiliary operators by giving rules that give the weak transition relations in one step, as in Fig. 1.
Branching bisimulation congruence [12]	Define the semantics of the auxiliary operators by giving rules that give the one-step transition relation, as in Fig. 5. See, e.g., [3].
Testing and failures congruences	As remarked in [11], for these congruences the left-merge operator causes just as many problems as the other auxiliary operators. A possible solution, based on the use of the nondeterministic operators from CSP [17] in lieu of the CCS/ACP combination of sum and τ and on the possibility of giving a suitable one step transition relation for the modified language, may be found in [2].

FIG. 6. *A menagerie of suitable semantics for the auxiliary operators.*

will be a useful reference for researchers interested in complete axiomatizations of behavioural congruences.

Acknowledgments. I thank Matthew Hennessy for his encouragement to write this paper.

THE COMPLEXITY OF MULTITERMINAL CUTS*

E. DAHLHAUS†, D. S. JOHNSON‡, C. H. PAPADIMITRIOU§, P. D. SEYMOUR¶, AND M. YANNAKAKIS‡

Abstract. In the multiterminal cut problem one is given an edge-weighted graph and a subset of the vertices called terminals, and is asked for a minimum weight set of edges that separates each terminal from all the others. When the number k of terminals is two, this is simply the mincut, max-flow problem, and can be solved in polynomial time. It is shown that the problem becomes NP-hard as soon as $k = 3$, but can be solved in polynomial time for planar graphs for any fixed k. The planar problem is NP-hard, however, if k is not fixed. A simple approximation algorithm for arbitrary graphs that is guaranteed to come within a factor of $2 - 2/k$ of the optimal cut weight is also described.

Key words. NP-completeness, network flow, partitioning, planar graphs

AMS subject classifications. 68Q25, 90B10

1. Introduction. The *multiterminal cut* problem can be defined as follows. Given a graph $G = (V, E)$, a set $S = \{s_1, s_2, \dots, s_k\}$ of k specified vertices or *terminals*, and a positive weight $w(e)$ for each edge $e \in E$, find a minimum weight set of edges $E' \subseteq E$ such that the removal of E' from E disconnects each terminal from all the others.

When $k = 2$ this problem reduces to the famous "min-cut/max-flow" problem, a problem of central significance in the field of combinatorial optimization because of its many applications and the fact that it can be solved in polynomial time (e.g., see [7], [17], [18], [20]). The "k-terminal cut" problem for $k > 2$ has been a subject of discussion in the combinatorics community for years (closely-related variants were proposed as early as 1969 by Hu [17, p. 150]). A variety of applications have been suggested, most having to do with the minimization of communication costs in parallel computing systems. In [23], Stone points out how the problem of assigning program modules to processors can be formulated in this framework. Other applications involve partitioning files among the nodes of a network, assigning users to base computers in a multicomputer environment and partitioning the elements of a circuit into the subcircuits that will go on different chips. It is known that such problems can become NP-hard even for $k = 2$ if there is a constraint imposed on the *size* of the components into which the graph is cut [9], [10]. In this paper we ask whether the problem might be tractable without such a constraint (as it is for $k = 2$).

Our first results concern the planar case. The restriction to planar graphs, besides its basic graph-theoretic significance, has potential relevance in the circuit partitioning application.

THEOREM 1.

(a) *For $k = 3$, the planar multiterminal cut problem can be solved in time $O(n^3 \log n)$.*

(b) *For any fixed $k \geq 3$, the planar multiterminal cut problem is solvable in polynomial time.*

The algorithms of Part (b) are, unfortunately, exponential in k. (Specifically, they are $O((4k)^k n^{2k-1} \log n)$.) That such exponential behavior is likely to be unavoidable follows from the next result.

THEOREM 2. *If k is not fixed, the multiterminal cut problem for planar graphs is* NP*-hard even if all edge weights are equal to* 1.

For the multiterminal cut problem in arbitrary graphs, NP-hardness sets in much earlier.

THEOREM 3. *The multiterminal cut problem for arbitrary graphs is* NP*-hard for all fixed $k \geq 3$ even if all edge weights are equal to* 1.

This theorem is proved using a "gadget" that has interesting properties on its own (as a counterexample to a conjecture about the possible submodularity of 3-terminal cut). The theorem's negative consequences are partially mitigated by technical lemmas that may yield substantial reductions in the sizes of instances encountered in practice.

Finally, we have the following two approximation results, one positive and one negative.

THEOREM 4. *There is an $O(knm \log(n^2/m))$ approximation algorithm for the multiterminal cut problem that for arbitrary graphs and arbitrary k is guaranteed to find cuts that are within $2(k-1)/k$ of optimal.*

THEOREM 5. *For any fixed $k \geq 3$, the k-terminal cut problem is* MAX SNP*-hard (and hence cannot have a polynomial time approximation scheme unless P =*NP [1], [21]).

The results presented here can be contrasted to those of [13], [16], [22], which concern what might be called the *k-Cut* problem. In this problem we are given G, k, and w as above (but not S) and are asked merely for a minimum weight set of edges E' whose removal separates the graph into at least k nonempty connected components. Although this problem is NP-hard for arbitrary k, it is solvable in polynomial time for each fixed $k > 2$, even for arbitrary graphs [13]. The running time is $O(n^{k^2/2-k+11/2})$. Thus the k-cut problem is significantly easier than the problem we study here. Note, however, that this may not hold true in the case of planar graphs. At present there is no known general method for exploiting planarity in the k-cut problem, in contrast to our results for planar multiterminal cut. Thus for fixed $k \geq 6$, our planar multiterminal cut algorithm currently provides the best method for solving the planar k-cut problem: Simply run our algorithm for all possible sets S of k terminals and take the least-weight solution found. A factor proportional to n^k is added to our running time, but the resulting time bound is still $O(n^{3k-1} \log n)$, which beats $O(n^{k^2/2-k+11/2})$ when $k \geq 6$. (For $k = 3$ and *unweighted* planar graphs, the $O(n^7)$ of the general k-cut result has been beaten more directly, first by an $O(n^2)$ algorithm in [16], and subsequently by an $O(n \log n)$ algorithm in [15]). Reference [22] concerns approximation results for the k-cut problem, showing that the bounds we obtain in Theorem 4 for multiterminal cut can be obtained for k-cut directly, without having to apply our multiterminal result to all possible sets of k terminals.

To avoid bibliographic confusion, we should mention that, with the exception of Theorem 5, the results in the current paper were first announced in 1983 in an unpublished but widely circulated extended abstract [4]. The abstract has since been widely cited, both in the above-mentioned work on k-Cut and in follow-up work on the multiterminal cut problem itself. In [2], Chopra and Rao observe, as we failed to do in our original abstract, that for trees and 2-trees, the general k-Terminal Cut problem can be solved in linear time by a straightforward dynamic programming algorithm. (This can be generalized to graphs of bounded tree-width for any fixed bound, by standard techniques.) The facets of the multiterminal cut polyhedron are studied in [2], [3]. An interesting generalization of the multiterminal cut problem, about which we shall have more to say in our concluding section, is studied in [5], [6]. The 1983 abstract did not contain our proofs; these are presented here for the first time. (The 1983 abstract also used the less-descriptive term *multiway* cut for what we now call a multiterminal cut. The new terminology was introduced in [3] and we adopt it here for added clarity.)

The paper is organized as follows. In §2 we cover the positive results for the planar case (Theorem 1a and 1b). The corresponding negative result for the planar case (Theorem 2) is covered in §3. §4 covers our results for general graphs (Theorems 3, 4 and 5 and associated technical lemmas). A concluding §5 discusses additional variants and generalizations of multiterminal cut to which our techniques can apply and points out some of the remaining open problems in the area.

2. Algorithms for the planar case. Our main result for planar graphs (Theorem 1) says that for all fixed k, the multiterminal cut problem is solvable in polynomial time. This is in contrast to Theorem 3 that says that for arbitrary graphs the problem is NP-hard for any fixed $k \geq 3$. The key advantage we gain from planarity lies in the existence of a planar dual to our given graph G. We will assume without loss of generality that our graph $G = (V, E)$ is connected and that we have fixed an embedding of it on the plane. We will use a superscript D to denote a dual object. Thus G^D is the dual graph of G. If F is a subset of the edges of G, F^D is the corresponding set of edges of G^D. (Note: F^D is *not* the dual of the subgraph (V, F) of G.)

We start with Theorem 1a and the case of $k = 3$ and then show how our proof techniques can be generalized to cover the case of general fixed k (Theorem 1b).

2.1. Planar 3-terminal cuts. A key concept in all that follows is the idea of an *isolating cut.*

DEFINITION. *For a given terminal s_i, an* isolating cut *for s_i is any set of edges that cuts all paths between s_i and all the other terminals.*

Note that a minimum weight isolating cut for s_i can be constructed by merging all the terminals other than s_i into a special vertex s_0, and then finding a minimum $s_i - s_0$ cut in the resulting graph by a standard 2-terminal minimum cut algorithm. Note also that any k-terminal cut induces isolating cuts for each of the k terminals. An optimal k-terminal cut need not induce optimal isolating cuts however, because of the savings that can be obtained when the induced isolating cuts share edges. As we shall see, when G is planar, the sharing of edges has a convenient interpretation in terms of paths in the dual graph G^D.

For the purpose of introducing some terminology, let us for simplicity first look at the dual in the case when there is no sharing of edges. From now on in this section, we shall assume $k = 3$. Figure 1 shows a graph G with a 3-terminal cut C, together with the duals G^D and C^D of each. The thicker edges in the figure are those of C and C^D, respectively. Note that the edges of C^D partition the geometric embedding of G^D into three regions. (In the case of Fig. 1, two of these regions are single faces of G^D, but the other is the union of several faces.) Let us say that a vertex of G is *in* a given region if the face of G^D to which the vertex corresponds is part of that region. Then observe that in the figure, each of the terminals of G is in a separate region of C^D. This is clearly a general property: C is a 3-terminal cut of a graph G if and only if the terminals s_1, s_2, s_3 are in different regions of C^D. (The boundary of the region containing x_i is the dual of an isolating cut for x_i.) If C is an *optimal* 3-terminal cut, C^D has exactly three regions, each one containing a distinct terminal. Furthermore, removing any edge from C^D must merge two regions, as otherwise the corresponding edge of C is not needed in the cut.

For a general instance of the 3-terminal cut problem, there are two topologically distinct possibilities for an optimal cut C^D. See Fig. 2, where $\{i, j, k\} = \{1, 2, 3\}$.

Cut type I. C^D consists of two edge-disjoint cycles. (See Fig. 2a,b.) Note that the cycles may have one vertex in common and/or one cycle may lie inside the other, as in Fig. 2b. They cannot have more than one vertex in common, however, as this would imply that C^D had more than three regions.

Cut type II. Each pair of regions of C^D shares an edge. (See Fig. 2c.)

We shall now describe how to find an optimal 3-terminal cut. We provide procedures that

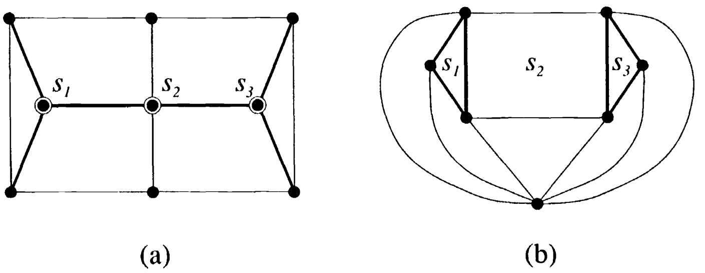

FIG. 1. *A planar 3-terminal cut* (a) *and its dual* (b).

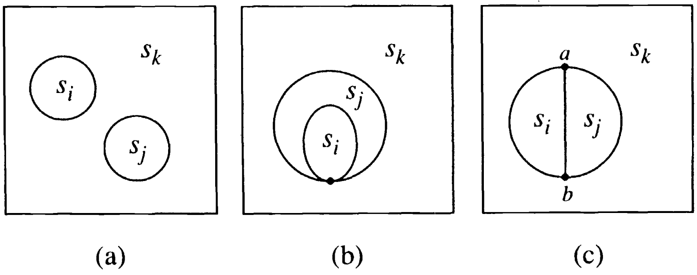

FIG. 2. *Types of 3-terminal cuts: type I* (a) *and* (b), *type II* (c).

work for each type of cut. Each procedure either returns the best cut of the corresponding type or else reports (correctly) that any optimal cut is of the other type.

Our procedure for Type I cuts is straightforward. We simply compute the three minimum weight isolating cuts for s_1, s_2, and s_3, respectively. Note that a minimum weight Type I cut must have weight at least as large as the sum of the weights of the two smallest of these three isolating cuts. If the two smallest are edge-disjoint, then their union is optimal among all 3-terminal cuts of Type I. If the two smallest are not edge-disjoint, then their union is a 3-terminal cut that has strictly smaller weight (because all edge weights are by assumption positive). Consequently, the best 3-terminal cut is not of Type I.

Our procedure for Type II cuts is significantly more complicated. Suppose we have an optimal 3-terminal cut that is of Type II. Look again at Fig. 2c. The cycle that bounds each region corresponds to an isolating cut for the terminal contained in that region, but these isolating cuts are not necessarily optimal, as they overlap. Consider the two vertices that are of degree 3 in C^D and are labeled a and b in the figure. The following lemma allows us to fix one of the three paths connecting a and b in G^D.

LEMMA 2.1. *Suppose that the dual of an optimal* 3*-terminal cut C is of Type II and a and b are the two vertices of degree* 3 *in C^D. Let P be any shortest path from a to b in G^D. Then there is an optimal* 3*-terminal cut C_0 that is of Type II, has a and b as its two vertices of degree* 3 *in C_0^D, and such that P is one of the three paths that join a to b in C_0^D.*

Proof. Consider all optimal 3-terminal cuts C_t such that C_t^D is of Type II with a and b as specified. Among these cuts, pick C_0 to be the cut C_t for which C_t^D contains the longest possible initial segment of P starting at a. We will show that C_0^D contains all of P.

Assume that P is *not* one of the three paths connecting a to b in C_0^D. As we traverse P from a to b, let x be the first vertex of P such that the edge leaving x in P is not in C_0^D. Let y be the first vertex of P after x that is in C_0^D. Note that it is possible that $x = a$ and/or $y = b$, or that x and y are consecutive vertices of P but the edge $\{x, y\}$ is not in C_0^D. Let Q_1, Q_2, Q_3

be the three $a-b$ paths in C_0^D. The path P initially follows one of these paths, say Q_1 without loss of generality, leaves it at vertex x, and then hits a path again at vertex y. We distinguish two cases depending on whether y is on the same path Q_1 as x (Fig. 3a) or on a different path, say without loss of generality Q_2 (Fig. 3b). In both cases the portion of P between x and y lies entirely in one region of C_0^D (by planarity), and partitions that region into two subregions. One of these two subregions contains the terminal that was contained in the original region, and the other contains no terminals at all.

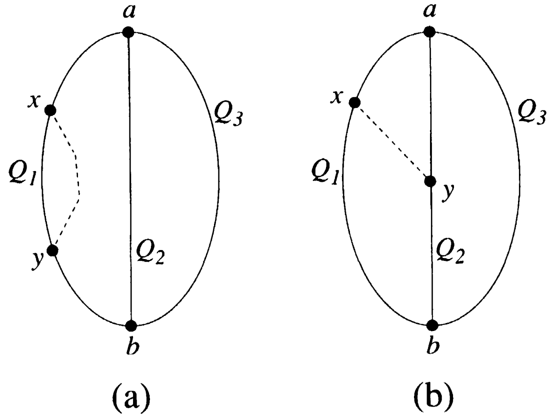

FIG. 3. *Possibilities for the* $P[x, y]$ *in the proof of Lemma* 2.1.

Case 1. Vertices x and y are both on Q_1. (This includes the cases when $x = a$ or $y = b$.) Let us denote the portion of a path Q between two of its vertices u and v as $Q[u, v]$. Let us assume without loss of generality that $P[x, y]$ lies in the region of C_0^D bounded by Q_1 and Q_2, as illustrated in Fig. 3a.

Subcase 1.1. The subregion bounded by $Q_1[x, y]$ and $P[x, y]$ contains no terminal.

Consider the path from a to b that follows P (and Q_1) from a to x, follows Q_1 from x to y, and then follows P from y to b. It must be at least as long as P because P is a shortest path from a to b. Therefore $w(Q_1[x, y]) \geq w(P[x, y])$, where if F is a set of edges, we take $w(F)$ to be $\Sigma_{e\in F} w(e)$. If we modify C_0^D so that $Q_1[x, y]$ is replaced by $P[x, y]$, we will obtain a path Q' that is no longer than Q_1, agrees with a longer initial segment of P and remains disjoint from Q_2 and Q_3 (except at their endpoints). Because the subregion bounded by $Q_1[x, y]$ and $P[x, y]$ contained no terminals, the union of Q' with Q_2 and Q_3 will still constitute the dual of a 3-terminal cut. This thus contradicts our definition of C_0, and so the subcase cannot apply.

Subcase 1.2. The subregion bounded by $Q_1[x, y]$ and $P[x, y]$ contains the terminal that lies in the region of C_0^D bounded by Q_1 and Q_2 (and hence the region bounded by Q_2 and the path consisting of $Q_1[a, x]$, $P[x, y]$, and $Q_1[y, b]$ contains no terminal).

In this case, we propose to modify C_0^D by deleting the path Q_2 and adding the path $P[x, y]$. Given the location of the terminal that was in the region of C_0^D bounded by Q_1 and Q_2, this will still be the dual of a 3-terminal cut. Thus all we must do now is argue that such a cut would violate the definition of C_0. First, observe that because P is a shortest path between its endpoints, all subpaths of P must themselves be shortest paths between their endpoints. In particular, we must have $w(P[x, y]) \leq w(Q_1[y, b]) + w(Q_2) + w(Q_1[a, x])$. If either $x \neq a$ or $y \neq b$, we would then have $w(P[x, y]) < w(Q_2)$, because all edge weights are positive by definition. Thus our modified 3-terminal cut would be strictly lighter than C_0, contradicting its definition. Therefore we must have $x = a$, $y = b$, and the current 3-terminal cut contains no edges from P. Note, however, that by our choice of P we have $w(P) \leq w(Q_2)$, and so we can replace Q_2 by P and obtain a new 3-terminal cut whose weight is at least as small. The new cut is hence also optimal and contradicts our assumption that no optimal cut could contain a longer subpath of P (starting from a) than does the cut containing Q_2. Thus this subcase cannot hold either, and Case 1 is ruled out.

Case 2. Vertex x is on $Q_1, x \neq a$, and vertex y is on Q_2, $y \neq b$.

Subcase 2.1. The region bounded by $Q_1[a, x]$, $P[x, y]$, and $Q_2[a, y]$ contains no terminal.

In this case, replacing $Q_2[a, y]$ by $P[x, y]$ in C_0^D will yield the dual of a 3-terminal cut. We argue that this new 3-terminal cut must have strictly smaller weight than C_0, contradicting the definition of C_0. Consider the path from a to b consisting of $Q_2[a, y]$ and $P[y, b]$. It must be at least as long as P, so we must have $w(Q_2[a, y]) \geq w(P[a, y])$. Consequently, because $a \neq x$, we must have $w(Q_2[a, y]) > w(P[x, y])$, and the new cut indeed has smaller weight.

Subcase 2.2. The region bounded by $Q_1[x, b]$, $P[x, y]$, and $Q_2[y, b]$ contains no terminal.

In this case we replace $Q_2[y, b]$ by $P[x, y]$ and obtain a contradiction analogous to the one of Subcase 2.1.

Thus Case 2 as well as Case 1 is ruled out. Consequently, P is contained in C_0, and the optimal 3-terminal cut called for by Lemma 2.1 exists. □

In light of Lemma 2.1, our procedure for Type II cuts can work by repeatedly calling a subroutine, once for each potential pair a, b of degree-3 vertices in C^D. The subroutine either constructs a minimum weight 3-terminal cut C that is of Type II and has a and b as the two degree-3 vertices in C^D, or reports (correctly) that no minimum weight 3-terminal cut has that form. The subroutine proceeds as follows.

First, construct a shortest path P between a and b in G^D. By Lemma 2.1 we may assume that P is contained in C^D. Delete the edges in G corresponding to the edges of P, obtaining a new graph H. In the embedding of this new graph induced by our original embedding of G, all the regions of G corresponding to vertices on P in G^D are merged into a single region. This corresponds in H^D to coalescing all the vertices along the path P from a to b into a single vertex v_P. This coalescence turns C^D from a Type II cut into a Type I cut like the one in Fig. 2b in which the two edge-disjoint cycles share a common vertex, in this case v_P. (The two cycles need not however be nested as they are in the figure; they can have disjoint interiors.)

We can now apply our previously described procedure for Type I cuts to H, obtaining a Type I cut C_H, or a report that the best 3-terminal cut for H is *not* of Type I. In the latter case, an optimal 3- terminal cut for G could not have been of Type II with the pair a, b as its degree-3 vertices, and we report this fact. In the former case, the cut C_H will, when augmented with the edges of G corresponding to the edges of P in G^D, be a 3-terminal cut for G. It cannot be an optimal cut, however, unless C_H^D has the desired form of two edge-disjoint cycles with v_P as a single common vertex. Otherwise the edges corresponding to P can be deleted and a valid (and lighter) 3-terminal cut for G will remain. Thus if C_H^D does not have the desired form, we once again report that no optimal 3-terminal cut for G is of Type II with a, b as its two degree-3 vertices.

Our overall algorithm for finding an optimal 3-terminal cut can thus proceed as follows.

Procedure 3-terminal.

1. Perform the Type I procedure on G.
   If a valid Type I cut is found, put it on the list of potential optima.
2. Construct the dual graph G^D and perform an all-pairs shortest path computation for G^D. For each pair a, b of vertices in G^D, do the following:

2.1. Let P be the shortest path in G^D between a and b as constructed in step 2 and let H be the graph obtained from G by deleting the edges corresponding to edges of P.
2.2. Perform the Type I procedure on H.
2.3. Let v_P be the coalesced vertex in H^D corresponding to the path P. If a valid Type I cut C_H for H is found and has a dual consisting of two edge-disjoint cycles having v_P as their unique common vertex, do the following:
 2.3.1 Let C_G be the 3-terminal cut for G consisting of C_H together with the edges of G corresponding to the edges of P in G^D.
 2.3.2 Add C_G to the list of potential optima.
3. Output the lightest 3-terminal cut on the list of potential optima.

THEOREM 1a. *Given a planar graph G with specified terminals s_1, s_2, and s_3, Procedure* 3-*terminal outputs an optimal* 3-*terminal cut and can be implemented to run in time $O(n^3 \log n)$, where n is the number of vertices in G.*

Proof. The fact that Procedure 3-terminal outputs an optimal cut follows from the above discussion. To analyze the running time, note that the bulk of the time is spent in the all-pairs shortest path computation of Step 2 and the isolating cut computations needed for each of the $\binom{n}{2}$ invocations of the Type I procedure in Step 2.2. The all-pairs shortest path computations takes place in a planar graph and so can be implemented to run in time $O(n^2)$ using the techniques of [8]. The isolating cut computations reduce as noted to 2-terminal minimum cut computations and so can be performed using standard 2-terminal cut algorithms.

For planar graphs, such algorithms run in time $O(n \log n)$, again using techniques from [8]. Unfortunately, if we use the techniques we originally described for computing isolating cuts, the graphs to which the 2-terminal cut algorithm is applied will not necessarily be planar. (Recall that our original proposal was to apply the 2-terminal cut algorithm to graphs constructed from G by coalescing pairs of terminals and note that those pairs need not be adjacent in G.) Thus without a further idea, we might be forced to use a general algorithm, and the running time would grow to $O(n^2 \log n)$. (This can be obtained for instance by using the $O(nm \log(n^2/m))$ 2-terminal cut algorithm of [12] and taking advantage of the fact that although our graphs need not remain planar, they do remain sparse.) This would force our overall running time up to $O(n^4 \log n)$. Fortunately, we can get around this obstacle as follows.

Recall that our goal in the Type I procedure is to find the two lightest among the isolating cuts for s_1, s_2, and s_3. For $i \neq j \in \{1, 2, 3\}$, let $c(i)$ denote the weight of a minimum isolating cut for s_i and $c(i, j)$ denote the weight of a minimum (2-terminal) cut separating s_i from s_j. Clearly, both $c(i), c(j) \geq c(i, j)$. Now note that in any cut separating s_i from s_j, the third terminal will be disconnected from at least one of s_i, s_j, and therefore the cut must isolate either s_i or s_j. Thus either $c(i) \leq c(i, j)$ or $c(j) \leq c(i, j)$. Combining this with the previous inequality, it follows that $c(i, j) = \min\{c(i), c(j)\}$. We compute the best two isolating cuts as follows.

Compute a minimum 2-terminal cut $C_{1,2}$ separating s_1 from s_2 in G. This will be an isolating cut for one of the two terminals, say s_1 without loss of generality. At this point we have $c(1, 2) = c(1) \leq c(2)$. Now compute a minimum 2-terminal cut $C_{2,3}$ separating s_2 (the nonisolated terminal) from s_3 in G. If this second cut isolates s_2 we have $c(2, 3) = c(2) \leq c(3)$; if it isolates s_3 we have $c(2, 3) = c(3) \leq c(2)$. In either case $C_{1,2}$ and $C_{2,3}$ are the two lightest isolating cuts as desired, and both were computed in the original planar graph G.

Step 2.2 thus involves $2\binom{n}{2} \approx n^2$ planar 2-terminal cut computations, for an overall time of $O(n^3 \log n)$. Because this is the dominant component of the running time, it also provides a bound on the overall running time of Procedure 3-terminal, which thus obeys the claimed running time bound. □

2.2. Planar multiterminal cuts. In this section we turn to the case of k-terminal cuts where $k > 3$. The algorithm we present will work for all $k \geq 3$ and will have a running time that, although exponential in k, is polynomial whenever k is fixed. It can be viewed as a (major) generalization of the algorithm of the previous section for the $k = 3$ case. For our discussion here, it will be convenient to assume that no two subsets of edges have the same total weight. (We can make sure that the assumption is satisfied in various ways. For instance, if Δ is the weight of the lightest edge and the edges are ordered $e_1, e_2, \ldots, e_m$, we could use the revised edge weights $w'(e_i) = w(e_i) + \Delta/2^i$.) The key consequence of the assumption is that optimal cuts, shortest paths, etc. are unique, so that we can refer to *the* optimal cut, etc. A less desirable consequence is that the cost of doing additions and comparisons of edge weights may go up by a factor of n, given the large number of bits needed to represent them, but given that our main goal here is to show that running times are $O(n^{ck})$ for some c, a factor of n will not make a significant difference.

In the $k = 3$ case, we observed that the dual C^D of the optimal cut was a subgraph of G^D that partitioned the embedding of G^D into three regions, each containing a distinct terminal. We then reduced the problem to the computation of 2-terminal cuts and shortest paths by first guessing (i.e., trying all possibilities for) some information about C^D. In particular, we guessed the *topology* (whether the cut consisted of two edge-disjoint cycles or not) and (in the latter case) the identity of the two degree-3 nodes a and b in C^D.

For general $k \geq 3$, we follow the same approach. Assume as before that we have previously decided on some fixed embedding of G. Suppose C is the optimal k-terminal cut, and once again let C^D be the dual of C viewed as a subgraph of a predetermined planar embedding of G^D. Then C^D must partition the embedding of G^D into precisely k regions, each containing a distinct terminal. Our notion of a *topology* for C^D is derived as follows. Consider the connected components of C^D and call such a component *complex* if it contains more than one vertex that has degree three or more in C^D. Let $C_1^D, C_2^D, \ldots, C_q^D$ be an enumeration of the complex components of C^D, and for each i, $1 \leq i \leq q$, let N_i be the set of vertices with degree three or more in C_i^D. (Note that we must have $q \leq k - 1$, because every connected component of C^D must enclose at least one terminal, and the infinite region of C^D contains one terminal.) Let $N = \cup_{i=1}^q N_i$. The *topology* of C^D is simply the (unordered) partition of N given by the sets $N_1, N_2, \ldots, N_q$. See Fig. 4 for an example of a C^D and its topology, consisting of two sets N_1 and N_2. In the figure the vertices in N are highlighted. Note that the degree-6 vertex v_{16} does not participate in the topology because its connected component contains only one vertex of degree three or greater.

FIG. 4. *The dual C^D of an optimal cut C and its topology* $\{N_1, N_2\}$.

LEMMA 2.2. *If G is a connected planar graph with n vertices, let C be an optimal k-terminal cut for G, and let C^D be the planar dual of C, viewed as a subgraph of G^D. Then the number of distinct possibilities for the topology of C^D is $O((2n)^{2k-4})$.*

Proof. Let an *arc* of C^D be any maximal path, all of whose interior vertices have degree two in C^D. Note that a cycle of C^D may be an arc, so long as the cycle contains at most one vertex of degree three or greater. Consider the graph whose vertex set is N and whose edge set is the arcs of C^D with both endpoints in N. This graph is planar, and has q connected components. Let m be the number of arcs it contains and $k' \leq k$, the number of regions. By Euler's formula, we have $|N| - m + k \geq q + 1$. Because all vertices of this graph have degree three or more by definition, we have $m \geq 3|N|/2$. Thus $|N| \leq 2(k - q - 1)$.

Now let V^D denote the set of vertices of G^D and consider the set of sequences $x_1, x_2, \ldots, x_{2k-4}$, with each x_i being either a member of V^D or the special symbol $|$. Such a sequence corresponds to a collection of subsets $S_1, S_2, \ldots$ of V^D in a natural way. Let us pretend our sequence is augmented by placing one copy of the special symbol $|$ at the beginning and one at the end. Then S_i is simply the set of vertices that occur in between the ith and $i+$ 1st occurrences of $|$ in the sequence. Note that every topology can be represented in this way, because all we need is $|N| + q - 1$ symbols, where N and q are as above, and $|N| + q - 1 \leq 2k - q - 3 \leq 2k - 4$ by the remark at the end of the preceding paragraph. Thus the total number of topologies is bounded by the total number of such sequences, which is $(|V^D| + 1)^{2k-4}$. (Note that this is a gross overcount on the topologies, because a given topology will be represented many times, and most sequences will not represent topologies at all. It probably represents the correct order of magnitude, however; for $k = 3$ it is $O(|V^D|^2)$, and we did have to consider $\Theta(|V^D|^2)$ topologies in the $k = 3$ case.)

To complete the proof of the lemma, we must bound $|V^D|$ in terms of n, the number of vertices in the original graph G. But note that each vertex in V^D corresponds to a region in the embedding of G, and (again by Euler's formula) the number of such regions is at most $2n - 4$. Thus the total number of topologies is $O((2n)^{2k-4})$ as claimed. □

Our algorithm for the general k-terminal cut problem will work by considering in turn each of the possibilities for the topology of the optimal cut. For each we will invoke a subroutine analogous to those used in our 3-terminal cut algorithm. The subroutine will either output the shortest cut that has the given topology, or else report (correctly) that the optimal cut cannot have the given topology. To specify the subroutine, we will need to know some structural results relating the optimum cut and its topology.

So suppose we are given a topology $N_1, N_2, \ldots, N_q$. If this is the optimal topology, then C^D contains connected components $C_1^D, C_2^D, \ldots, C_{q'}^D, q' \geq q$, where for $1 \leq i \leq q$, N_i is the set of vertices with degree three or more in C_i^D, and for $q < i \leq q'$, C_i^D contains at most one vertex with degree three or more. The analogue of Lemma 2.1 for this general k case is that for each C_i^D, $i \leq q$, we can efficiently identify a subtree T_i^D of C_i^D that spans all the vertices of N_i. This was the case in Lemma 2.1, where for $N_1 = \{a, b\}$ (Fig. 2c), we identified a path between the two degree-3 vertices a and b by doing a shortest path computation. For the general case, we shall need both shortest paths and minimum spanning trees.

For a given topology, the trees T_i^D, $i \leq q$, are constructed as follows. We treat the sets N_i, $i \leq q$, in turn. (Order is not important.) Given N_i, we construct an auxiliary weighted complete graph H_i with N_i as its vertex set and with the weight of the edge linking u and v being the length of the shortest path in G^D between u and v. Compute the minimum spanning tree $T[H_i]$ of H_i, and let T_i^D be the subgraph of G^D formed by replacing each edge in $T[H_i]$ by the corresponding shortest path in G^D. We shall call T_i^D the *minimum spanning tree* of N_i (although note that it may not even be a tree if C^D does not have the given topology). Figure 5 portrays the C^D of Fig. 4 with the trees T_i^D (chosen according to the correct topology) highlighted. (For future reference, the figure also indicates which terminal is contained in which region of C^D.) The next lemma establishes the key properties satisfied by T_i^D when C^D has the given topology.

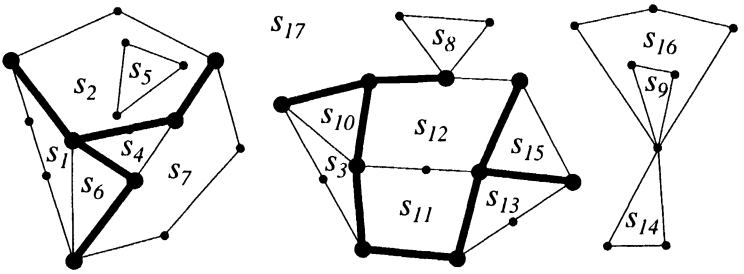

FIG. 5. *The dual C^D with the trees T_i^D highlighted and the locations of terminals indicated.*

LEMMA 2.3. *Let C be the optimal k-terminal cut and C^D be its planar dual, viewed as a subgraph of G^D. Let C_i^D, $1 \le i \le q$, be the complex connected components of C^D, and let N_i be the set of vertices with degree three or greater in C_i^D, $1 \le i \le q$. Then* (a) *each C_i^D, $1 \le i \le q$, contains the minimum spanning tree T_i^D for N_i, and* (b) *no two of the paths in T_i^D corresponding to edges of $T[H_i]$ intersect except at a common endpoint (and hence T_i^D is indeed a tree).*

Proof. Let us assume that the edges of $T[H_i]$ are labeled $F_1, F_2, \ldots, F_{|N_i|-1}$ in order of increasing weight. Thus if we let $T^j[H_i]$, $0 \le j < m$, be the graph consisting of the first j edges of $T[H_i]$, then for $0 \le j < m$, F_{j+1} is the shortest edge joining two different connected components (subtrees) of $T^j[H_i]$. Suppose $1 \le j \le m$, let $F_j = \{u, v\}$ and let S and T be the subtrees of $T^{j-1}[H_i]$ containing u and v, respectively. Let P be the shortest path in G^D between u and v. Because of our assumption that no two sets of edges have the same aggregate weight, we can prove the desired properties of P directly, without the induction that was needed in the proof of Lemma 2.1. We shall prove three claims, from which the current lemma follows. Claims 2 and 3 correspond to parts (a) and (b) of the lemma, respectively. Claim 1 is used in the proof of each of the latter two.

Claim 1. P contains no vertex of N_i other than u and v.

Note that if P contained such a vertex w, then either w is not in S or w is not in T. If w is not in S, then the edge $\{u, w\}$ in H_i connects two different subtrees and has length at most $P[u, w]$, which is strictly less than the length of P. This contradicts our assumption about the ordering of edges in $T[H_i]$. A similar argument applies to the path $P[w, v]$, if w is not in T. This gets us part of the way toward proving that no two paths of T_i^D intersect and will also be useful in Case 3 below.

Claim 2. P is entirely contained in C_i^D.

Suppose P is not entirely contained in C_i^D. As we traverse P from u to v, let x be the first vertex such that the edge leaving x is not included in C_i^D. Let y be the first vertex after x that is again included in C_i^D. As in the 3-terminal case, it is possible that $x = u$ and/or $y = v$, or that x and y are consecutive in P but $\{x, y\}$ is not in C_i^D. It is also possible that some portions of $P[x, y]$ hit components of C^D other than C_i^D. In any case, from planarity, $P[x, y]$ must be contained in one region of C_i^D, which it divides into two regions. Let B denote the boundary of that region, and let B_1 and B_2 be the two (closed) parts into which B is divided by $P[x, y]$. Call the region itself R_B. Then let R be the region of C^D (as opposed to just C_i^D) that is bounded by B together possibly with edges from connected components of C^D other than C_i^D, if such are contained in R_B. The region R is divided by $P[x, y]$ into (at least) two subregions R_1 and R_2. The boundary of $R_i, i \in \{1, 2\}$ consists of B_i, $P[x, y]$, and possibly edges from other components. At least one of these two subregions of C^D contains no terminal; without loss of generality we may assume R_1 contains no terminal.

If we add $P[x, y]$ to C^D and remove a subpath of B_1 that contains no vertex of N_i as an interior point, the region R_1 will be merged with a single adjacent region. Because R_1 contains no terminal, the new subset of edges of G^D will still be the dual of a k-terminal cut. We will show that we can always find such a subpath of B_1 having higher weight than $P[x, y]$. This will mean that the replacement yields a k-terminal cut of lesser weight, contradicting the optimality of C. In the three cases below, we use "contains" as a shorthand for "contains as an interior vertex."

Case 1. B_1 contains no vertex of N_i.

This corresponds to Subcase 1.1 of Lemma 2.1 (see Fig. 3a). Because P is a shortest path in G^D, $P[x, y]$ must be the shortest path between x and y in G^D. Thus it is shorter than B_1. Because the latter contains no vertex of N_i, we can replace all of B_1 by $P[x, y]$, thereby obtaining a shorter cut, in contradiction of the assumed optimality of C.

Case 2. B_1 contains vertices of N_i that are in different subtrees of $T^{j-1}[H_i]$.

This corresponds to Subcase 1.2 of Lemma 2.1 (see Fig. 3a). Because B_1 contains vertices from N_i from different subtrees, it has two consecutive such vertices, say a and b. By our ordering of the edges F_h of $T[H_i]$, $w(P[x, y]) \leq w(P) < w(B_1[a, b])$. Thus we can replace $B_1[a, b]$ by $P[x, y]$, obtaining a shorter cut and hence another contradiction.

Case 3. B_1 contains at least one vertex of N_i, and all such vertices are in the same subtree of $T^{j-1}[H_i]$.

This corresponds to Case 2 of Lemma 2.1 (Fig. 3b). Suppose first that none of the vertices from N_i contained in B_1 are in the subtree S of $T_{j-1}[H_i]$ that contains u. Let z be the first vertex of N_i encountered as we traverse B_1 from x to y. Note that z cannot be x by Claim 1. Consider the path from u to z that follows P from u to x and then B_1 from x to z. It connects vertices of N_i in different subtrees, and so $w(P[u, x]) + w(B_1[x, z]) > w(P) > w(P[u, x]) + w(P[x, y])$. Consequently, we must have $w(B_1[x, z]) > w(P[x, y])$, and we can replace $B_1[x, z]$ by $P[x, y]$ for a shorter cut and a contradiction. An analogous argument holds for the case when none of the vertices from N_i contained in B_1 are in the subtree T containing v.

This exhausts the possibilities, so the path corresponding to F_j must be included in C_i^D.

Claim 3. P does not intersect any of the other paths in T_i^D corresponding to edges of $T[H_i]$ except at common endpoints.

Suppose P intersects another path P' of T_i^D at a vertex other than a common endpoint. We shall derive a contradiction, using the fact that Claims 1 and 2 hold for P' as well as for P. Of all the nonendpoint vertices the two paths share, let w be the closest one to u in P. Because all the edges of both P and P' are included in C_i^D by Claim 2, w must have degree three or greater in C_i^D, and hence by definition of *topology*, w must be included in N_i. This, however, contradicts Claim 1, which says that no interior vertices of P are in N_i. Thus Claim 3 holds, and the Lemma is proved. □

Lemma 2.3 treats the connected components C_i^D of C^D in isolation. Let us now look at how they interact. First note that the trees T_i^D are all vertex disjoint, because each is a subgraph of a different connected component of C^D. Thus they constitute a subforest of C^D. Let T^D represent this subforest, the union of all the edges in the T_i^D, and let T be the subset of edges in G whose planar dual is T^D. By Lemma 2.3, the optimal cut C for G will consist of T plus some additional edges, assuming we chose the correct topology for C. To find those additional edges, we delete T from G to obtain a new graph that we shall call $G[0]$. Assuming we have the correct topology, the optimal cut for $G[0]$ will be $C[0] = C - T$.

Let $G[0]^D$ be the embedded dual of $G[0]$ obtained by coalescing all the edges of each T_i^D in G^D to a single point. Note that $G[0]^D$ remains connected and has lost none of the regions from G^D because only trees were coalesced. Assuming that we have the optimal topology, $C[0]^D$ will be a collection of $k-1$ simple cycles in $G[0]^D$, each of which is a biconnected component of $C[0]^D$. That is, a connected component of $C[0]^D$ may consist of more than one cycle, but all such cycles must share a single common vertex. (In particular, the coalesced vertices corresponding to the T_i^D will be such common vertices, although there may be others that were already present in C^D.) See Fig. 6.

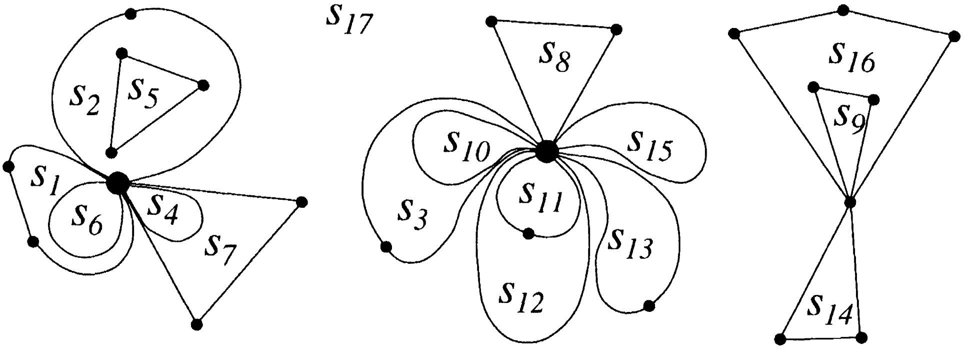

FIG. 6. *The graph $C[0]^D$ obtained by coalescing the spanning trees T_i^D in C^D.*

Note that in the embedding of $G[0]^D$, some of the cycles of $C[0]^D$ will contain others. An innermost cycle will constitute the complete boundary of a region in $C[0]^D$, whereas other regions may have boundaries made up of the edges of several cycles. We shall show that if one treats the cycles in an appropriate "inside out" order, each of these cycles can be viewed as a minimum isolating cut in an appropriately constructed graph. Let us identify each region with the terminal s_i it contains and construct a partial order $\leq$ on the terminals as follows. $s_i \leq s_j$ if and only if the outermost cycle bounding s_i's region is contained in the outermost cycle bounding s_j's region. (By convention, we assume that "the outermost bounding cycle" for the infinite region contains all other cycles, so that the terminal contained in the infinite region is $>$ all other terminals.) Note that by this definition, the outermost bounding cycle for s_i must separate s_i from all terminals $s_j > s_i$.

Let π be an ordering of the terminals that is consistent with this partial order, that is, if $s_i \leq s_j$, then $\pi(i) \leq \pi(j)$. For instance, for the $C[0]^D$ depicted in Fig. 6, such an ordering would be $s_6, s_1, s_4, s_7, s_5, s_2, s_{10}, s_3, s_{11}, s_{12}, s_8, s_{15}, s_{13}, s_9, s_{16}, s_{14}, s_{17}$. We define a sequence of graphs and isolating cuts as follows. For $1 \leq i \leq k-1$, let A_i^D be the set of edges in $G[0]^D$ making up the outer boundary cycle for the region containing terminal $s_{\pi(i)}$. Let A_i be the corresponding set of edges in $G[0]$. Note that $C[0] = \cup_{i=1}^{k-1} A_i$. Now let $G[i]$ be the graph obtained from $G[0]$ by deleting the edges of $\cup_{j=1}^{i} A_j$.

LEMMA 2.4. *For $1 \leq i \leq k-1$, A_i is a minimum isolating cut for terminal $s_{\pi(i)}$ in graph $G[i-1]$.*

Proof. Suppose not, and assume j is the lowest index for which the Lemma is violated. Let B_j be the minimum isolating cut for $s_{\pi(j)}$ in $G[j-1]$. Note that A_j is also an isolating cut for $s_{\pi(j)}$ in $G[j-1]$: by the minimality of j, all terminals $s_{\pi(i)}, i < j$, are already isolated in $G[j-1]$, and by our ordering of the terminals, all terminals of higher index are separated from $s_{\pi(j)}$ by the outermost bounding cycle for $s_{\pi(j)}$, that is, A_j^D. Because the minimum weight isolating cut B_j is unique (by our assumption about edge weights) A_j does not equal it, $w(B_j) < w(A_j)$. But then the set $(C[0] - A_j) \cup B_j$ will have lower weight than $C[0]$. The set will also be a k-terminal cut for $G[0]$. Removing the edges of A_j^D from $C[0]$ will merge $s_{\pi(j)}$'s region with exactly one other, and the terminal for the region must have higher index, by our ordering of the terminals. But B_j separates $s_{\pi(j)}$ from all higher-indexed terminals. Thus $C[0]$ was *not* the optimum cut for $G[0]$, a contradiction. □

Given Lemmas 2.3 and 2.4, the following procedure will handle any given topology $N_1, N_2, \ldots, N_q$ appropriately, either outputting the minimum weight cut with that topology or reporting correctly that the optimal cut cannot have that topology. Assume that as a preprocessing step we have constructed our standard embedding of the dual graph G^D and computed all shortest paths between vertices of G^D.

Procedure check topology $(N_1, N_2, \ldots, N_q)$.

```
1. For $1 \leq i \leq q$, do the following.
   1.1. Construct the auxiliary graph $H_i$, the minimum spanning tree $T[H_i]$, and the
        subtree $T_i^D$.
   1.2. If any two paths in $T_i^D$ corresponding to edges of $T[H_i]$ share a vertex other than
        a common endpoint, reject the topology.
2. If any two subtrees $T_i^D$ share a common vertex, reject the topology.
   Otherwise, let $T^D$ be the union of the edge sets $T_i^D$, let $G[0]$ be the graph obtained
   from $G$ by deleting all edges in the dual set $T$.
3. Let $W^* = \infty$ (our initial estimate of the optimal cut weight).
   For all possible permutations $s_{\pi(1)}, s_{\pi(2)}, \ldots, s_{\pi(k)}$ of the terminals, do the following.
   3.1. Set $C = T$.
   3.2. For $1 \leq i \leq k - 1$ do the following:
        3.2.1. Find a minimum isolating cut $A_i$ for $s_{\pi(i)}$ in $G[i-1]$.
        3.2.2. Set $C = C \cup A_i$, and let $G[i]$ be the graph obtained by deleting the edges
               of $A_i$ from $G[i-1]$.
   3.3. If $w(C) < W^*$, set $W^* = w(C)$ and $C^* = C$ (the current best cut with this
        topology).
4. Output $C^*$.
```

It should be clear from the above discussion that this subroutine has the desired properties. Its running time is dominated by that for the minimum isolating cut computations occurring at Step 3.2.1. As discussed, each such computation can be performed using a standard 2-terminal minimum cut algorithm in time $O(n^2 \log n)$, assuming a machine model in which additions, subtractions, and comparisons take constant time. Given our proposed method for imposing the restriction that all sets of edges have unique weights, however, such a model is inappropriate. Even given the standard assumption that the original instance has edge weights that fit into a single computer word, our method for insuring the subset weight uniqueness restriction gives rise to weights whose binary representations involve $\Theta(n)$ bits. With such large numbers, the time bound for the isolating cut computations grows to $O(n^3 \log n)$. We perform $k - 1$ such computations for each of the $k!$ permutations of the terminals, yielding a total of $O(k^k)$ for each topology.

The overall algorithm then consists of performing Procedure Check Topology for each possible topology, of which there are $O((2n)^{2k-4})$ by Lemma 2.2, and outputting the best cut found for any nonrejected topology. Thus we have our claimed result for general fixed k, stated here in slightly more precise form than given in the introduction.

THEOREM 1b. *Given a planar graph G with n vertices and k specified terminals, a minimum k-terminal cut can be constructed in time $O((4k)^k n^{2k-1} \log n)$.*

Note that if we specialize this result to the previously considered case of $k = 3$, the time bound is $O(n^5 \log n)$, substantially larger than the $O(n^3 \log n)$ of Theorem 1a. This is a result of two factors: (1) A factor of n because we can't in general find the needed isolating cuts using planar 2-terminal cut algorithms, as we could when $k = 3$, and so have to use general 2-terminal cut algorithms. (2) A factor of n because we needed to operate with $\Theta(n)$-bit weights to insure that every subset of edges had a unique weight.

It may well be that more efficient algorithms can be derived by careful algorithmic design and analysis, but the bounds we have presented adequately fulfill our goal of showing that the k-terminal cut problem can be solved in polynomial time for fixed k and planar graphs. Moreover, as the NP-completeness result of the next section implies, it is likely that any algorithms for the general problem will have exponential (or at least super-polynomial) running times.

3. Complexity of planar multiterminal cut for arbitrary *k*. We saw in the previous section that the Multiterminal Cut problem is solvable in polynomial time for planar graphs and fixed k. In this and the next section we shall show that the problem becomes NP-hard if we allow either general graphs or general k. In this section we consider the case of planar graphs and general k. As is traditional for complexity results, we concentrate on a decision problem version of our problem. By proving it NP-complete for planar graphs, we imply that the corresponding optimization is NP-hard.

MULTITERMINAL CUT

INSTANCE: Graph $G = (V, E)$, subset $\{s_1, s_2, \ldots, s_k\} \subseteq V$ of terminals, for each edge e a positive integer weight $w(e)$, and a bound B.

QUESTION: Is there a subset $E' \subseteq E$ such that $w(E') \leq B$ and $G' = (V, E - E')$ contains no path linking two distinct terminals?

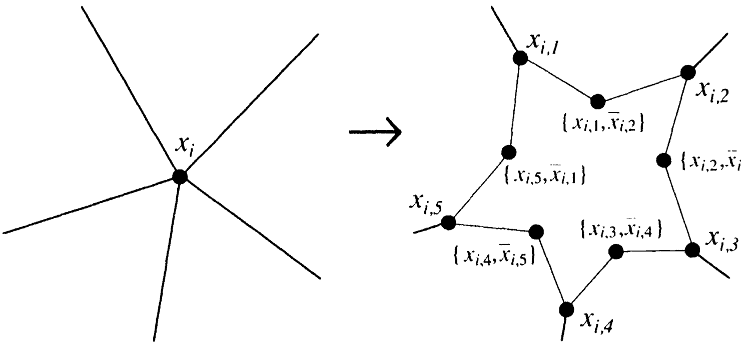
We shall prove that MULTITERMINAL CUT is NP-complete, even if restricted to bounded-degree planar graphs with all edge weights equal to 1. Note that this is a stronger result than that quoted in the introduction, where for simplicity the question of degree bounds was not raised. We actually prove two separate results. The first allows weights to differ, but restricts vertex degrees to be 3 or less. (Note that the problem becomes trivial if vertex degrees must all be 2 or less.) The second result covers the equal-weight case and follows by a slight modification of the proof of the first.

THEOREM 2a. *MULTITERMINAL CUT is NP-complete for planar graphs, even if edge weights are bounded and the maximum vertex degree is* 3.

Proof. That planar MULTITERMINAL CUT is in NP is immediate. To complete the proof, we need to provide a polynomial transformation to it from some known NP-complete problem. The source problem we choose is PLANAR 3-SATISFIABILITY [9], [19] (PLANAR 3-SAT for short). In the 3-SATISFIABILITY problem we are given a set $X = \{x_1, x_2, \ldots, x_n\}$ of variables and a collection $C = \{c_1, c_2, \ldots, c_m\}$ of 3-element *clauses*, that is, subsets of the set of *literals* for X, where if x_i is a variable, the corresponding literals are x_i and $\overline{x}_i$. The question is whether there exists a satisfying truth assignment for X and C, where a *truth assignment* for X is a subset T of the literals for X that contains precisely one of $x_i, \overline{x}_i$ for each i, $1 \leq i \leq n$, and T satisfies C if for all clauses $c_j \in C$, $c_j \cap T \neq \phi$. (If $x_i \in T$, we say x_i is *true*; if $\overline{x}_i \in T$, we say x_i is *false*.) A natural graph to associate with this problem is the bipartite graph $G_{X,C}$ that has $X \cup C$ as its vertex set and has an edge between the vertices x_i and c_j if c_j contains either of the literals x_i or $\overline{x}_i$. PLANAR 3-SAT is 3-SATISFIABILITY restricted to those instances (X, C) for which $G_{X,C}$ is planar.

For our transformation to planar MULTITERMINAL CUT we shall actually use a restricted variant of PLANAR 3-SAT, one in which we allow clauses of size two as well as three, but require that each variable have degree exactly three in $G_{X,C}$, with one of its literals occurring in two clauses and the other in one. We can prove this variant NP-complete by a simple local-replacement transformation from ordinary PLANAR 3-SAT. Let X, C denote an instance of ordinary PLANAR 3-SAT, as specified above. First note that we may assume without loss of generality that both x_i and $\overline{x}_i$ are contained in $\cup_{j=1}^{m} c_j$ for every variable x_i. If $\overline{x}_i$ does not occur in any clause, we may assume without loss of generality that x_i goes in our truth assignment, and hence all the clauses containing x_i are always satisfied. Thus, we might as well delete those clauses (and the variable x_i) from our instance. Similarly if x_i is not contained in any clause, we might as well delete the variable x_i and all clauses containing $\overline{x}_i$. We may also assume that no clause contains both x_i and $\overline{x}_i$, as such a clause is always satisfied and so could also be deleted. Thus every variable occurs in at least two clauses, and all variable vertices in $G_{X,C}$ have degree at least two.

Our method for converting such an instance X, C to an instance X', C' of our restricted PLANAR 3-SAT variant involves replacing the old variables, adding some new clauses, and modifying the old clauses. First, we replace each variable x_i by a set of $degree(x_i)$ new variables $x_{i,1}, x_{i,2}, \ldots, x_{i,degree(x_i)}$ along with $degree(x_i)$ new clauses. Together, these form a length-$(2degree(x_i))$ cycle in $G_{X',C'}$, as illustrated in Fig. 7 for the case where $degree(x_i) = 5$. The added clauses insure that all the new variables must have the same truth value in any satisfying truth assignment. Note that we make this replacement even for variables with degrees two and three in $G_{X,C}$. These replacements together determine the structure of our new graph $G_{X',C'}$. The construction of X', C' is completed by modifying the old clauses so as to make the new instance consistent with the new graph. For each literal occurrence $x_i(\overline{x}_i)$ in a clause c_j, there must be an edge in $G_{X',C'}$ between c_j and a new variable $x_{i,k}$. We replace the literal $x_i(\overline{x}_i)$ by the new literal $x_{i,k}(\overline{x}_{i,k})$. It is not difficult to verify that the new instance has the desired format and is satisfiable if and only if the original instance was.



x_i
→
$x_{i,1}$
$x_{i,2}$
$\{x_{i,1},\overline{x}_{i,2}\}$
$\{x_{i,5},\overline{x}_{i,1}\}$
$\{x_{i,2},\overline{x}_{i,3}\}$
$x_{i,5}$
$\{x_{i,3},\overline{x}_{i,4}\}$
$x_{i,3}$
$\{x_{i,4},\overline{x}_{i,5}\}$
$x_{i,4}$

FIG. 7. *Reducing the number of occurrences per variable in PLANAR 3-SAT.*

To complete our proof of Theorem 2a, we now show how to transform an instance X, C of restricted PLANAR 3-SAT into an instance of planar MULTITERMINAL CUT in which all weights are five or less and all vertices have degree three or less. We use the "component design" approach of [9]. Figure 8 shows the components we shall use to represent variables and clauses, with each edge labeled by its weight.

A variable x_i is represented by one of the two structures at the top of the figure, the first if the literal x_i occurs in two clauses, the second if $\overline{x}_i$ occurs in two clauses. (By our definition of restricted PLANAR 3-SAT one of these two possibilities must hold, and the other literal must occur exactly once.) The terminals in these structures are the vertices labeled x_i and $\overline{x}_i$. The *connector triangles* of these structures are the three triangles whose edge weights are 1,1,2 or 1,1,4. The *connector bases* are the weight-2 and weight-4 edges in these triangles, the *connector edges* are the weight-1 edges, and the *connector vertices* are the degree-2 vertices of the triangles. Each connector triangle, base, edge, and vertex will be thought of as representing the literal labeling the terminal nearest to it in the structure. Note that each literal is represented by precisely the same number of connector triangles as it has occurrences in clauses.

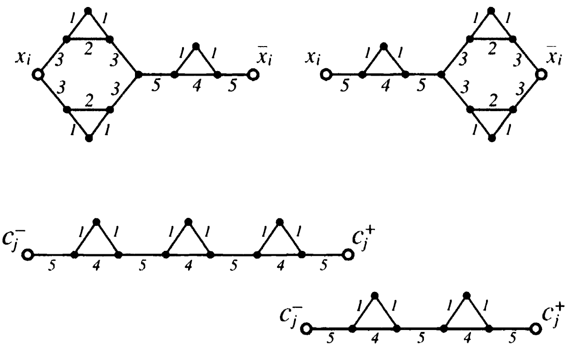


FIG. 8. *Variable and clause components in the proof of Theorem* 2.

A clause c_j is represented by one of the two structures at the bottom of the figure, the first if $|c_j| = 3$, the second if $|c_j| = 2$. Here the terminals are the vertices labeled c_j^- and c_j^+. The *connector triangles* are the triangles whose edge weights are 1,1,4, and the *connector bases, connector edges*, and *connector vertices* are again the weight-4 edges, weight-1 edges, and degree-2 vertices of these triangles. Note that there are precisely as many connector triangles as there are literals in the clause. We shall assume that each connector is assigned to represent a distinct one of those literals.

Note that all the structures of Fig. 8 have maximum degree three. To complete our construction of the MULTITERMINAL CUT instance graph $G[X, C]$, we have only to hook together the clause and variable structures so as to maintain this property and yield a planar graph. This is done by adding *link* edges of weight 2 between variable connector vertices and clause connector vertices as indicated in Fig. 9. (Each clause connector vertex is linked to a variable connector vertex that represents the same literal.) By the definition of restricted PLANAR 3-SAT, there will be precisely the right number of connector vertices for this to be done in a one-one fashion, with all connectors incident on precisely one weight-2 linking edge, implying that the maximum vertex degree in the resulting graph $G[X, C]$ is three. Moreover, it is not difficult to convince oneself that $G[X, C]$ is indeed planar, given that $G_{X,C}$ was.

The only thing remaining to be specified is the upper bound B on the weight of the desired multiterminal cut. This is given by $B = 10n + 4m$, where n and m are the numbers of variables and clauses, respectively, in our restricted PLANAR 3-SAT instance.

The construction just described can clearly be accomplished in polynomial time. To complete the proof that it is a polynomial transformation, we need to show that the following two statements are equivalent.

(1) The PLANAR 3-SAT instance X, C has a satisfying truth assignment.

(2) There is a set E' of edges in $G[X, C]$ whose total weight is B or less and whose deletion would disconnect all $2n + 2m$ terminals from each other.

First suppose that the desired truth assignment T exists. Then the desired multiterminal cut is easy to construct. For each clause c_j pick a literal in $c_j \cap T$ (one must exist because T is a satisfying truth assignment) and delete all three edges of the corresponding connector triangle from the structure representing c_j in $G[X, C]$. For each variable, delete all three edges from each connector triangle representing the literal *not* in T. Finally delete each linking edge that is not adjacent to an already deleted connector triangle. Let E' be the set of deleted edges.

First, we note that E' has the desired cut properties. By our choice of when to delete link edges, we know that at least one endpoint of each remaining link edge must have degree one in the graph after E' is deleted. Thus no path between terminals can pass through a link edge.

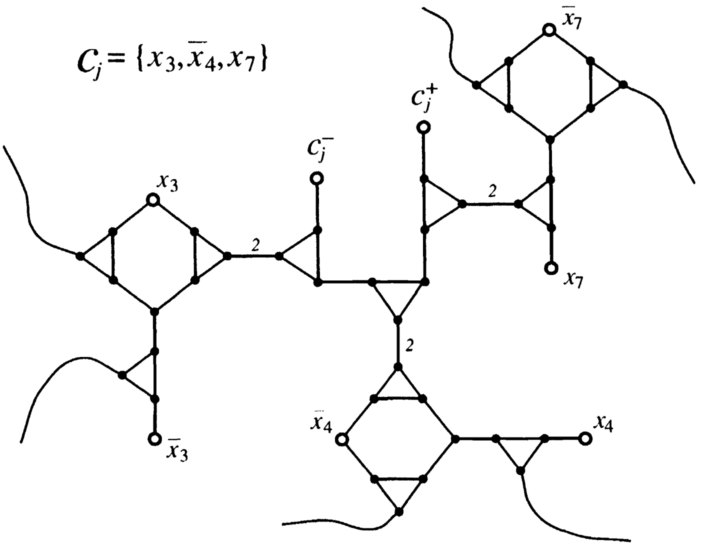

FIG. 9. *Hooking up the components in the proof of Theorem* 2.

Consequently, if there is any path linking terminals, it must either link a pair of terminals x_i, $\bar{x}_i$ in the same variable structure, or a pair c_j^+, c_j^- in the same clause structure. In the former case, all such paths must pass through connector triangles representing both literals, and so must be broken, given that we deleted all connector triangles representing one of the literals. In the latter case, any such path must go through all the connector triangles of the c_j structure, and so must be broken because we deleted one of them.

We now claim that $w(E') = 10n + 4m = B$, and so E' obeys the weight bound and is the desired cut. To see this, let us for accounting purposes divide up the edges of $G[X, C]$ in a slightly different fashion. In particular, let us group each weight-2 link edge with the four weight-1 edges from connector triangles to which it is incident, and call the 5-edge ensemble a *link structure*. See Fig. 10, where edges $\{a, c\}$, $\{b, c\}$, $\{c, d\}$, $\{d, e\}$, and $\{d, f\}$ constitute a link structure joining the structures for clause c_j and variable x_i. (Note that the base edges of the connector triangles, $\{a, b\}$ and $\{e, f\}$, are still viewed as being part of the corresponding clause and variable structures.)

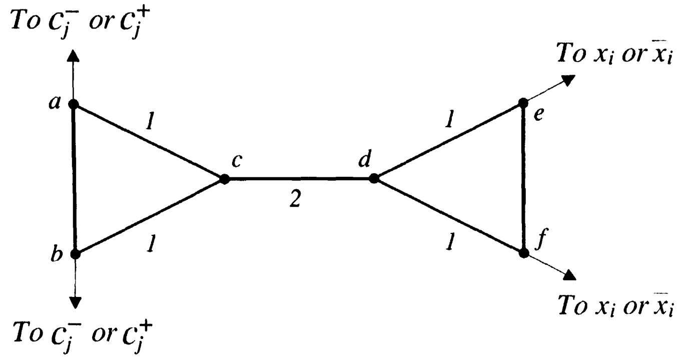

FIG. 10. *A typical connection between a clause and a variable component.*

We claim that for any link structure, the total weight of deleted edges is exactly 2. This is clear if the weight-2 link edge is deleted, because that happens if and only if none of the weight-1 edges were deleted. Suppose one of the pairs of weight-1 edges was deleted. If it is the pair from the clause connector triangle, this means that the corresponding literal must be true. If it is from the variable connector triangle, this means that the corresponding literal must be false. Because both cannot happen simultaneously, only two of the weight-1 edges can be in E'. Thus the total weight of edges deleted from the link structure is two, and the total overall weight of edges deleted from link structures is twice the number of such structures, i.e., $6n$.

Now consider the clause and variable structures. We deleted one edge of weight 4 from each of the former, for a total weight of $4m$. From the latter, we deleted either one edge of weight 4 or two of weight 2, for a total weight of $4n$. This exhausts the possibilities, so we conclude that $w(E') = 6n + 4m + 4n = B$, as desired.

Conversely, suppose a set E' exists with the specified properties. We shall show that X, C has a satisfying truth assignment. We begin with a sequence of "normal form" lemmas. In what follows, we assume E' is a minimum weight set satisfying the specified properties.

LEMMA 3.1. *Suppose e is an edge incident on a degree-3 vertex v. If e has weight greater than or equal to the sum of the weights of the other two edges incident on v, we may assume that e is not in E'.*

Proof. Suppose $e \in E'$, and consider the result of removing e from E' and replacing it by all the other edges incident on v and not already in E'. This will clearly not increase the weight of E'. It also cannot cause any two terminals to become linked by a path in the residual graph. If it did, that path would have to contain e. Because v now has degree one in the residual graph, v would consequently have to be one end of the path, and so would have to be a terminal. This is impossible since, as can be seen from Figs. 7 and 8, no degree-3 vertex in our construction is a terminal. □

As a consequence of Lemma 3.1, we shall assume in what follows that none of the weight-5 edges in any clause structure are in E', and none of the weight-5 and weight-3 edges in any variable structure.

LEMMA 3.2. *If any edge in a cycle of $G[X, C]$ is in E', then at least two are.*

Proof. If e is the only edge from a given cycle in E', then removing e from E' will decrease $w(E')$ without adding any new connections, contradicting our assumption that E' was a minimum weight cut. □

LEMMA 3.3. *At most one connector base (weight-4 edge) in any clause structure is in E'.*

Proof. Suppose the structure for c_j had two weight-4 edges in E'. Let us consider the total clause structure, including all the connector edges, as in Fig. 8. By Lemma 3.2, we may assume that E' contains at least one connector edge adjacent to each connector base it contains, and hence the total weight of edges from the clause structure that are in E' is at least 10. Consider the following modification to E'. Remove one of the two connector bases and add in all the remaining connector edges (there can be at most four). This modification obviously does not increase the weight of E'. Nor can it create any new interterminal paths in the residual graph. Because all the connector edges are now deleted, such a created path could only link c_j^- and c_j^+, but those terminals remain separated since one of the weight-4 edges remains in E'. □

LEMMA 3.4. *For each variable x_i, E' either contains the connector base(s) representing the literal x_i or the base(s) representing the literal $\overline{x}_i$, but not both.*

Proof. Let us consider the total variable structure, including all connector edges, as depicted in Fig. 8. Because no weight-3 and weight-5 edges are in E' by Lemma 3.1, we must either delete the weight-4 base or both weight 2 bases if we are to disconnect terminal x_i from terminal $\overline{x}_i$. By Lemma 3.2, if we delete one of the weight-2 bases, we must delete both. So the only possibility we need to rule out is the situation in which we delete all three base connectors. Should we do this, we will also have to delete at least one connector edge from each connector triangle by Lemma 3.2. Thus the total weight of edges from the structure that would be in E' would be at least 11. Consider the following modification of E': remove the two weight-2 bases and add in all the remaining connector edges (there can be at most three). This modification cannot create any new paths in the residual graph, because x_i remains separated from $\overline{x}_i$ and no path involving a terminal other than these two can traverse the structure. Moreover, it decreases the weight of E' (the total weight of edges from the x_i-structure that are in E' is now 10). Again we have a contradiction of the minimality of E'. □

LEMMA 3.5. *For each link structure, E' contains edges of weight totaling exactly two.*

Proof. We first show that the total must be at least two. This will imply that it is exactly two, because by Lemmas 3.3 and 3.4, E' contains connector bases of total weight at least $4m + 4n$. This leaves at most $6n$ weight for the edges of link structures, and there are $3n$ such structures. So look again at the generic link structure pictured in Fig. 10. By Lemmas 3.1, 3.3, and 3.4, the vertices a and b remain connected to clause terminals in the residual graph, and the vertices e and f remain connected to variable terminals. But this means that there will be a path in the residual graph from a variable terminal to a clause terminal unless we either delete the weight-2 link edge or two weight-1 edges from the same connector triangle. In either case the weight of the two deleted edges is at least two. □

We can now prove our claim that a satisfying truth assignment T must exist. For each variable x_i, put the literal whose connector base is *not* in E' into T. By Lemma 3.4, this is a valid truth assignment. We claim that it satisfies all the clauses. Consider a clause c_j, and let z be the literal corresponding to its broken connector base. By Lemma 3.3, a unique such z exists. Now consider the link structure joining the structure for c_j to the variable structure for z. Note that by our choice of z, the edge (a, b) is in E'. If z were nct in T, then the edge (e, f) would also be in E'. Thus by Lemma 3.2, at least one connector edge from each connector triangle must be in E'. But note that if no other edges from the link structure are in E', there will still be a path from one of a, b to one of e, f within the structure. By Lemmas 3.1, 3.3, and 3.4, this would mean there is a path from a variable terminal to a clause terminal, a contradiction. Thus T is the desired truth assignment, and we have indeed constructed a polynomial transformation, and Theorem 2a is proved. □

THEOREM 2b. MULTITERMINAL CUT *is* NP-*complete for bounded degree planar graphs even if all weights are equal.*

Proof. This is a fairly immediate corollary of the previous proof. Note that our construction would still have worked if we had replaced each edge of weight w by w parallel paths, each consisting of two weight-1 edges. Because no vertex in our construction had incident edges of total weight exceeding 11, this would yield a graph with maximum degree 11, and all edges with weight equal to 1. (The degree bound of 11 is not the best possibility. Using a slight variant on the construction and considerably more complicated arguments, we believe it can be reduced at least to 6.) □

4. Complexity of multiterminal cut for fixed $k \geq 3$ and arbitrary graphs. In this section we prove Theorem 4, which says that MULTITERMINAL CUT is NP-complete for all fixed $k \geq 3$ when arbitrary graphs are allowed. Note that it suffices to prove the problem NP- complete for $k = 3$, because the problem for higher values of k can trivially be derived from that for $k = 3$: simply add $k - 3$ additional terminals with no edges incident on them. Thus we shall concentrate on the $k = 3$ case. In addition to proving this case NP-complete, we shall also present results that may be of assistance in coping with the NP- completeness. We present efficient algorithms that should allow us to reduce significantly the number of vertices and edges in 3-terminal (and multiterminal) cut instances that arise in practice, and we show how to get within a factor of 4/3 of the optimal 3-terminal cut (and $2 - 2/k$ of the optimal k-terminal cut) with a relatively simple heuristic.

First, however, a brief digression into what at first seemed like a promising algorithmic approach to the 3-terminal cut problem, on the basis of results on submodular set functions by Grötschel, Lovász, and Schrijver [14]. The key "gadget" in the NP-completeness proof we shall be presenting also serves as a counterexample to the applicability of this approach. (Indeed, before we discovered the gadget, we already had a proof that either 3-terminal cut was solvable in polynomial time by the submodular set function approach or it was NP-complete by a construction like the one given here.)

4.1. Submodular set functions: algorithms and counterexamples. To understand the results of [14], we first need some definitions. Let U be a finite set. A function f defined on the subsets of U is *submodular* if for any two subsets X and Y of U, $f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y)$. Grötschel, Lovász, and Schrijver [14] show that if a submodular set function f can be computed in polynomial time, then f can also be *minimized*, that is, a set Y with $f(Y) = \min\{f(X) : X \subseteq U\}$ can be found, in polynomial time. (The algorithm involves an appropriate application of the ellipsoid method.)

A paradigmatic example of a submodular set function involves the usual (2-terminal) minimum cut problem. In this case, U is the set of nonterminal vertices $V - \{s_1, s_2\}$, and $f(X)$ is the total cost of the edges that have precisely one endpoint in the set $X \cup \{s_1\}$. The submodularity of this function is easy to verify, as is the fact that $\min\{f(X) : X \subseteq U\}$ is the weight of a minimum 2- terminal cut. We of course already know how to minimize this function f in polynomial time without resorting to the ellipsoid method, but the formulation is suggestive. Could it be possible that 3-terminal cuts might also be computable as minima of a submodular set function?

It is easy to define a set function for 3-terminal cuts that is analogous to the one above for the 2-terminal case. Let $U = V - \{s_1, s_2, s_3\}$ be the set of nonterminal vertices, and for any subset X of U, let $f(X)$ be the minimum cost of a 3-terminal cut that leaves no vertex in X connected to s_2 or s_3 (and no vertex in $U - X$ is connected to s_1 or a vertex in X). It is easy to see that the minimum value for this function equals the minimum weight for *any* 3-terminal cut. Moreover, we can use a polynomial-time algorithm for the 2-terminal cut problem to evaluate f in polynomial time. Given a subset X of U, find a minimum weight cut separating s_2 from s_3 in the graph obtained by deleting s_1 and all the vertices in X from G. Add to the weight of this cut the weight of all edges with precisely one endpoint in $X \cup \{s_1\}$. Therefore, if f were submodular (for all graphs), we could solve the 3-terminal cut problem in polynomial time.

Unfortunately, this is not the case. Consider the 9-vertex graph C depicted in Fig. 11. Note that in addition to the three terminals s_1, s_2, s_3, the graph contains two specified vertices x and y. The 12 edges incident on the terminals have weight 4, as indicated in the figure. The other 6 edges, unlabeled in the figure, have weight 1. Let c^* be the cost of an optimal 3-terminal cut for C. For each i, j, $1 \leq i, j \leq 3$, let an *i, j-cut* be a 3-terminal cut that leaves vertex x connected to s_i and vertex y connected to s_j, and let $c(i, j)$ be the cost of a minimum *i, j-cut*. The sets X and Y that cause f to violate submodularity are defined as follows:

Let X be the set of vertices connected to s_1 in an optimal 1,2 cut. (Note that by definition of *i, j-cut*, x is in X and y is not.) Let Y be the set of vertices connected to s_1 in an optimal 2, 1 cut. (Note that y is in Y and x is not.) By definition, we have $f(X) = c(1, 2)$ and $f(Y) = c(2, 1)$. We also must have $f(X \cup Y) \geq c(1, 1)$ and $f(X \cap Y) \geq \min\{c(2, 3), c(3, 2), c(2, 2), c(3, 3)\}$.

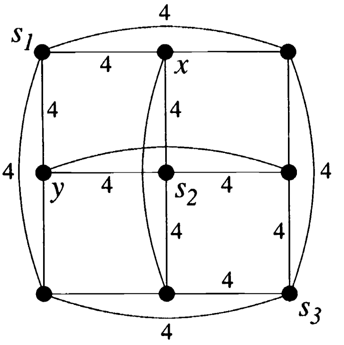

FIG. 11. *Graph C: submodularity counterexample and* NP- *completeness gadget.*

Thus if f were to be submodular, we would need to have $c(1, 2) + c(2, 1) \geq c(1, 1) + \min\{c(2, 3), c(3, 2), c(2, 2), c(3, 3)\}$. In light of the following lemma, however, this claim is false.

LEMMA 4.1. *For the graph C of Fig.* 11, *the following properties hold:*

(a) $c(1, 2) = c(2, 1) = c^*$,

(b) $c(i, j) \geq c^* + 1$ *for all other pairs* i, j, *and*

(c) $c(1, 1) = c(2, 2) = c^* + 1$.

Proof. As depicted in Fig. 11, graph C has its vertices located at the nodes of a 3 × 3 grid. As an alternative naming convention for the vertices, let v_{ij} denote the vertex in the row i, column j, $1 \leq i, j \leq 3$. Thus the terminals are $s_1 = v_{11}, s_2 = v_{22}$, and $s_3 = v_{33}$, and the distinguished vertices x and y are v_{12} and v_{21}, respectively.

We first claim that $c(1, 2) = c(2, 1) = c^* = 27$. Note that the set consisting of the nine vertical edges in C is a weight-27 1,2 cut in which every vertex v_{ij} is left connected with the terminal s_i in its row, $1 \leq i \leq 3$. Similarly, the set consisting of the nine horizontal edges is a weight-27 2,1-cut in which every vertex v_{ij} is connected to the terminal s_j in its column. Could there be a 3-terminal cut of less weight? Note that each of the six nonterminal vertices v_{ij} is connected by weight-4 edges to both s_i and s_j. Thus in any 3-terminal cut at least six weight-4 edges must be deleted, one for each nonterminal v_{ij}. If the weight of the cut is to be 27 or less, no further weight-4 edges can be deleted, and so each nonterminal must remain connected to one terminal by a weight-4 edge. In particular, v_{ij} must remain connected either to s_i or s_j. Let us say that v_{ij} *belongs* to the terminal to which it remains connected.

Now consider the weight-1 edges. These all join nonterminal vertices, and together they form a cycle of length six with alternating vertical and horizontal edges: $v_{21}(y)$-v_{31}-v_{32}-$v_{12}(x)$-v_{13}-v_{23}-v_{21}. Suppose two consecutive edges of this cycle remain undeleted, say without loss of generality $\{v_{ij}, v_{ik}\}$ and $\{v_{ik}, v_{lk}\}$. Note that we must have $i \neq j, i \neq k, j \neq k, i \neq l$, and $l \neq k$. In order to rule out any interterminal paths, v_{ij}, v_{ik}, and v_{lk} must then all belong to the same terminal. That terminal must be either s_i or s_j, because those are the only two to which v_{ij} can belong. Similarly, it must be either s_i or s_k, because those are the only two to which v_{ik} can belong. Thus, because $j \neq k$, it must be i. But this is impossible, because v_{lk} can only belong to s_l or s_k, and neither of these can equal i, as already observed. Thus the cut must contain one of every two consecutive edges in the cycle of weight-1 edges, or at least three such edges, for a total weight of at least 27. The only way that precisely three can be chosen is if we take every other edge in the cycle, that is, either the three vertical edges or the three horizontal ones, as was done in the horizontal and vertical cuts mentioned in the previous paragraph. We now can conclude that those cuts were optimal, and hence $c^* = c(1, 2) = c(2, 1) = 27$. Thus part (a) of the lemma holds.

For part (b), we shall show that any cut other than the horizontal and vertical cuts mentioned above must have weight 28 or more. Assume there were such a cut of weight 27. As argued above, its intersection with the cycle of weight-1 edges is either the set of three vertical edges of the cycle or the set of three horizontal ones. By the symmetry of C, we may assume that it contains the three vertical edges. Because it is not the vertical cut, it must thus fail to contain at least one vertical weight-4 edge. For specificity (and again without loss of generality because of the symmetry of C), we may assume that the missing vertical weight-4 edge is $\{s_1, v_{21}\}$. But then, since the horizontal weight-1 edge $\{v_{21}, v_{23}\}$ is also not in the cut, the vertex v_{23} is connected to the terminal s_1 in the residual graph. This means that the cut must contain both the edge joining v_{23} to s_2 and the edge joining it to s_3. Because, as remarked earlier, the cut must contain at least one weight-4 edge incident on each of the six nonterminals, this yields a total of at least seven weight-4 edges, and so the cut will have weight at least 28, a contradiction. Thus part (b) is proven.

To prove part (c), we need to show that there exist 1,1- and 2,2-cuts of weight 28. It suffices (again by symmetry) to consider the 1,1 case. A weight-28 1,1-cut is obtained by modifying the weight-27 cut consisting of all vertical edges. Instead of deleting the vertical weight-4 edge $\{y, s_1\}$, we delete the two horizontal edges incident on y: the weight-4 edge $\{y, s_2\}$ and the weight-1 edge $\{y, v_{23}\}$. It is easy to see that the result continues to be a 3-terminal cut, although it now has weight 28, and y as well as x is connected to s_1. Thus the cut is a 1,1-cut of the desired weight, and part (c) holds. □

4.2. The NP-completeness of 3-terminal cut. We are now ready to prove Theorem 3, which we restate in terms of the $k = 3$ special case to which it reduces.

THEOREM 3. *If arbitrary graphs are allowed, MULTITERMINAL CUT for $k = 3$ (i.e., 3-TERMINAL CUT) is NP-complete even if all weights are equal to* 1.

Proof. It is immediate that 3-TERMINAL CUT is in NP. We shall show that 3-TERMINAL CUT is NP-complete if weights 1 and 4 are allowed. This will suffice to prove the theorem, because a weight-4 edge could always be replaced by four parallel length-2 paths of weight-1 edges.

Our proof is by a polynomial transformation from the SIMPLE MAX CUT problem [9], [10]. In SIMPLE MAX CUT, we are given a graph $G = (V, E)$ (without weights) and a number K, and are asked whether there is a partition of the vertices of G into two sets V_1 and V_2 such that there are at least K edges between V_1 and V_2. Given (G, K), we construct a corresponding instance (F, B) of 3-TERMINAL CUT as follows.

The graph F has three terminals s_1, s_2, s_3 and contains the vertices of G, but not the edges. For each edge $\{u, v\}$ of G, the graph F instead contains a copy of our "gadget graph" C, with the vertices s_1, s_2, s_3 of C identified with their named counterparts in F, and with x and y identified with u and v. The other vertices of different copies of C (i.e., the four nonterminals other than x and y) are distinct. Thus the total number of vertices in F is $3 + |V| + 4|E|$. We claim that G has a cut of size K or greater if and only if F has a 3-terminal cut of weight $B = 28|E| - K$ or less. Given that F and B can clearly be constructed in polynomial time, Theorem 3 will follow from this claim.

So suppose there is a cut V_1, V_2 for G of size $K' \geq K$. Consider the 3-terminal cut induced by the following assignment of the vertices of F to the terminals: First, vertices in V_1 are assigned to s_1, and vertices in V_2 are assigned to s_2. At this point, each copy of C has its x and y vertices assigned to one of s_1 or s_2, say s_i for x and s_j for y. Assign the remaining nonterminals of this copy of C to terminals according to a minimum weight i, j-cut for C. Note that the contribution to our 3-terminal cut from edges in this copy of C will thus be $c(i, j)$. In particular, if x and y were in the same set the contribution will by Lemma 4.1 be 28; if they were in different sets it will be 27. The overall weight thus becomes $28|E| - K' \leq 28|E| - K$, as desired.

Conversely, suppose a 3-terminal cut of size $B' \leq 28|E| - K$ exists. Let V_i be the set of vertices in V that are left connected to s_i, $i = 1, 2, 3$. For each edge $\{u, v\}$ of G with $u \in V_i$, $v \in V_j$, the cut removes edges of total weight at least $c(i, j)$ from the corresponding copy of C. By Lemma 4.1, $c(i, j) \geq 28$ unless $\{i, j\} = \{1, 2\}$, and so there must be at least K edges between V_1 and V_2. Thus we can assign the vertices of V_3 to the two sets V_1 and V_2 arbitrarily and still obtain the desired cut for G. □

Note that the graph constructed in our proof of Theorem 3 does not have bounded vertex degrees. This is unavoidable, so long as we assume all edge weights are equal. If k is fixed, all edge weights are equal, and there is a bound d on vertex degree, then multiterminal cut can be solved in polynomial time! Observe that in this case the weight of a cut is simply the number of edges it contains, and an optimal cut can contain no more than kd edges (because the cut that simply breaks all the edges incident on each terminal is no bigger than this). But because k and d are fixed, kd is a constant independent of n. Consequently, we can use exhaustive search and still take time that is polynomially bounded in n.

If we remove the restriction to equal-weight edges, however, the fixed-k problem becomes NP-complete even if all vertex degrees are three or less. Simply replace each vertex v in our construction that has $degree(v) > 3$ by a cycle of $degree(v)$ vertices, each of which is adjacent to one of the former neighbors of v, and let the weights of the cycle edges be sufficiently high that they can't be chosen for an optimal cut.

4.3. Reducing the instance size. The results of §§4.1 and 4.2 effectively dash any hope of finding optimal k-terminal cuts, $k \geq 3$, efficiently by means of 2-terminal cut (i.e., max flow) algorithms. Such algorithms may still be useful, however, as we shall see in this and the next section. Recall that an *isolating cut* for a terminal s_i is a set of edges that separates s_i from the other terminals, and that minimum weight isolating cuts can be found in $O(nm \log(n^2/m))$ time by performing max flow computations in a modified graph. The following lemma implies that the computation of minimum weight isolating cuts can be used to reduce the number of vertices in an instance. Suppose $G = (V, E)$ is a connected graph with specified terminals $s_1, s_2, \ldots, s_k$.

LEMMA 4.2. *Suppose $i \in \{1, 2, \ldots, k\}$, $k \geq 3$. Let E_i be a minimum weight isolating cut for terminal s_i, and let V_i be the set of vertices that remain connected to s_i when the edges of E_i are removed from G. Then there exists an optimal k-terminal cut for G that leaves all the vertices of V_i connected to s_i.*

Proof. Without loss of generality, we may assume that $i = 1$. Suppose the lemma were false for some $k \geq 3$, and let G be a minimal counterexample, that is, a counterexample having the fewest vertices, and, among those counterexamples with that number of vertices, the fewest edges. Let E^* be a minimum weight k-terminal cut for G, and let c_1 and c^* be the weights of E_1 and E^*, respectively. Label every vertex u of G with a pair (j, l) where $j = 1$ or 2 depending on whether u is in V_1 or not, and l is the index of the terminal to which u is left connected under E^*. (This index is defined, because u must be left connected to some terminal if E^* is to have minimum weight.)

The above labelling partitions the vertices into $2k$ groups. We first claim that, by the minimality of G, each group can consist of at most one vertex. Suppose u and v have the same label, and consider the graph G' in which we merge u and v. The cuts induced on G' by E_1 and E^* will have the same weights as did the original cuts, and clearly no better cuts of the corresponding types can exist. Thus G' would be a counterexample with fewer vertices, a contradiction of our minimality assumption.

Next we claim that if $\{u, v\}$ is an edge of G and the labels of u and v are (j_u, l_u) and (j_v, l_v) respectively, then it cannot be the case that both $j_u \neq j_v$ and $l_u \neq l_v$. Suppose such an edge e were in G, and note that e must be in both E_1 and E^*. Thus, consider the graph G'

obtained by removing e from G. The sets $E_1 - \{e\}$ and $E^* - \{e\}$ will continue to be isolating and k-terminal cuts respectively for G' and the weight of each will drop by $w(e)$. Furthermore, there cannot be a k-terminal cut E' of weight less than $c^* - w(e)$ (isolating cut E_1' of weight less than $c_1 - w(e)$) in G', as otherwise we could get a k-terminal cut in G of weight less than c^* (isolating cut of weight less than c_1) by simply adding e to E' (to E_1'). Thus $E_1 - \{e\}$ and $E^* - \{e\}$ continue to be optimal in G', so that G' would be a counterexample with fewer edges and the same number of vertices, again a contradiction of our minimality assumption.

Thus for $k = 3$ our minimal counterexample is a subgraph of the 6-vertex graph depicted in Fig. 12, where the vertices of G are placed on a 2×3 grid, with the vertex in row i and column $j(v_{ij})$ being the one with label (i, j). For $k > 3$, we would have a $2 \times k$ grid, with all k vertices in the top row connected in a clique, as are all k vertices in the bottom row. Note that for G to be a counterexample, at least one of the nonterminal vertices in the graph must be present in G. The set V_1 of vertices connected to s_1 under E_1 is simply the set of all vertices in the top row that are present in G.

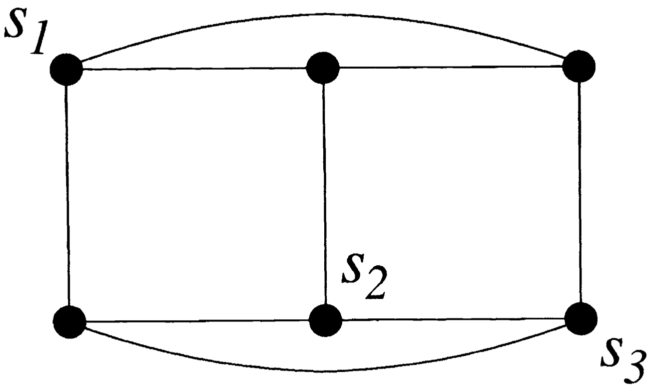

FIG. 12. *Schematic of the assumed minimal counterexample in Lemma* 4.2 (*if* $k = 3$).

Now observe that because E_1 consists of the vertical edges in this figure, these edges have total weight c_1. Similarly, E^* consists of the horizontal edges, and these edges consequently have total weight C^*. Thus the total weight of all the edges in G is $c_1 + c^*$. Consider the set $\hat{E}_1$ of edges incident on s_1 in G. This is clearly an isolating cut, and so $w(\hat{E}_1) \geq c_1$. But then consider the k-terminal cut $\hat{E}^*$ consisting of all edges incident on s_2 through s_k. This is disjoint from $\hat{E}_1$, and so can have weight at most $c^* + c_1 - w(\hat{E}_1) \leq c^*$. Hence it has weight precisely c^* and is itself an optimal k-terminal cut. But note that it leaves s_1 connected to all the vertices in V_1. Thus G actually satisfies the lemma statement, and there can be no counterexample. □

Using Lemma 4.2, we can reduce the number of vertices in our instance by $|V_i - 1|$. Simply construct a new graph in which all the vertices of V_i are merged into the terminal s_i. An optimal k-terminal cut for this shrunken graph will induce an optimal cut for the original one.

To get the maximum effect from applying Lemma 4.2 in this way, we should start with the minimum isolating cut for s_i such that V_i is as big as possible. Let us say that a set V_i is an *isolation set* for a terminal s_i if it is the set of vertices left connected to s_i by some minimum weight isolating cut. Let us call it an *optimum isolation set* for s_i if it has maximum cardinality over all isolation sets for s_i. From observations made in [7, pp. 10–13], it can be seen that the optimum isolation set for a given terminal is unique and contains all other isolation sets for that terminal. It can be found by performing one maximum-flow computation followed by some linear-time post-processing. A corollary of the following Lemma is that k optimum isolating set computations suffice to shrink G as far as it can go.

LEMMA 4.3. *Let V_i be the optimum isolation set for s_i, $1 \leq i \leq k$, and let $\overline{G}$ be the graph obtained from G by merging all the vertices of V_1 into s_1. Then in $\overline{G}$ the optimum isolation set for s_1 is $\{s_1\}$, and the optimum isolation set for s_i is $V_i - V_1$, $2 \leq i \leq k$.*

Proof. For $i = 1, 2, \ldots, k$, let w_i and $\overline{w}_i$ denote the weights of a minimum weight isolating cut for s_i in G and $\overline{G}$, respectively. Let $\overline{V}_i$ be the optimum isolation set for s_i in $\overline{G}$.

We begin with $\overline{V}_1$. Note that the isolating cut for s_1 that separates s_1 from all other vertices in $\overline{G}$ has weight w_1 by hypothesis, and we must have $\overline{w}_1 \leq w_1$. On the other hand, $\overline{V}_1 \cup V_1$ induces an isolating cut for s_1 in G that has weight $\overline{w}_1$, so we must have $\overline{w}_1 \geq w_1$. Thus equality holds and $\overline{V}_1 \cup V_1$ is an isolation set for s_1 in G. But this means that $\overline{V}_1 \cup V_1$ is contained in V_1, by the properties of maximum isolation sets mentioned above, and hence $\overline{V}_1 \subseteq V_1$. Because the only member of V_1 that exists in $\overline{G}$ is s_1, this implies that $\overline{V}_1 = \{s_1\}$, as claimed.

Now consider $\overline{V}_2$. (The arguments for $\overline{V}_i, k > 2$ are analogous and hence omitted.) Let $\hat{V}_2 = V_2 - V_1$. We first show that $\hat{V}_2$ induces a minimum weight isolating cut for s_2 in G (although $\hat{V}_2$ will not be an optimum isolation set for s_2 in G unless $V_1 \cap V_2 = \phi$). Partition the vertices of V into the four sets $A = V_1 - V_2$, $B = V_2 - V_1$, $C = V_1 \cap V_2$, and $D = V - (V_1 \cup V_2)$. If X and Y are two disjoint subsets of the vertices of G, let $E(X; Y)$ denote the set of edges that link vertices in X with vertices in Y, and let $w(X; Y)$ denote their weight.

By hypothesis $w_1 = w(A; B) + w(A; D) + w(B; C) + w(C; D)$ and $w_2 = w(A; B) + w(B; D) + w(A; C) + w(C; D)$. Thus $w_1 + w_2 = W + w(A; B) + w(C; D)$, where W is the total weight of the edges that link vertices in different sets of our partition. Now consider the isolating cuts for s_1 and s_2 induced by $V_1 - V_2$ and $V_2 - V_1$, respectively, and let $\hat{w}_1$ and $\hat{w}_2$ be their weights. Then $\hat{w}_1 = w(A; B) + w(A; C) + w(A; D)$ and $\hat{w}_2 = w(A; B) + w(B; C) + w(B; D)$, so that $\hat{w}_1 + \hat{w}_2 = W + w(A; B) - w(C; D) \leq w_1 + w_2$. Because by hypothesis we must have $w_i \leq \hat{w}_i$, $i \in \{1, 2\}$, this implies that equality must hold in both cases, and so $\hat{V}_2 = V_2 - V_1$ must induce a minimum weight isolating cut for s_2 in G. Because none of the vertices of $\hat{V}_2$ were merged with s_1 in the construction of $\overline{G}$, $\hat{V}_2$ must consequently also induce a minimum weight isolating cut for s_2 in $\overline{G}$, and so $\hat{w}_2 = \overline{w}_2 = w_2$. Thus $\hat{V}_2$ is an isolation set for s_2 in $\overline{G}$, and by the properties of optimal isolation sets, we must have $\hat{V}_2 = V_2 - V_1 \subseteq \overline{V}_2$.

On the other hand, because $\overline{V}_2$ induces an isolating cut of weight $\overline{w}_2 = w_2$ for s_2 in $\overline{G}$, it induces an isolating cut of the same weight in G, and so $\overline{V}_2$ is an isolation set for s_2 in G. Thus we must have $\overline{V}_2 \subseteq V_2$. Because the only vertices of V_2 that remain in $\overline{G}$ are those in $V_2 - V_1$, this implies that $\overline{V}_2 = V_2 - V_1$, as claimed. This completes the proof of the lemma. □

Lemma 4.3 indicates both the efficiency with which we can apply Lemma 4.2 to reduce the instance size, and the bounds on how much shrinkage can be obtained. In particular, k optimum separation set computations suffice to yield all the shrinkage one can expect. Note that the proof of Lemma 4.3 would apply just as well if we renamed the terminals in any order. So let $G_0 = G$, and inductively obtain G_i from G_{i-1} by performing an optimum isolation set computation for s_i and merging all the vertices in the set obtained into the terminal s_i. Lemma 4.2 says that an optimal k-terminal cut in G_i induces one in G_{i-1} (and, by induction, in G), and Lemma 4.3 says that the optimum isolation set for s_i in G_i is $\{s_i\}$ (and by induction, the optimum isolation set for s_h, $1 \leq h \leq i$, is $\{s_h\}$). Thus in G_k, the optimum isolation set for each terminal consists of the terminal itself, but a minimum weight k-terminal cut still induces one in the original graph G. Thus G_k is a maximally shrunken graph that can still induce an optimal k-terminal cut.

4.4. Near-optimal multiterminal cuts. If one is willing to settle for cuts that are only *near*-optimal, one can exploit a bit further our ability to construct optimum isolating cuts. Consider the following straightforward heuristic.

Isolation heuristic.

1. For $1 \leq i \leq k$ construct a minimum weight isolating cut $\hat{E}_i$ for terminal s_i.
2. Determine h such that $\hat{E}_h$ has maximum weight among all the $\hat{E}_i$'s.
3. Let $\hat{E}$ be the union of all cuts $\hat{E}_i$ except $\hat{E}_h$.
4. Return $\hat{E}$.

Note that the Isolation Heuristic clearly outputs a k-terminal cut. Moreover, it can be implemented to run in $O(knm \log(n^2/m))$ time by using the max flow algorithm of [12] to compute each of the k required isolating cuts. This is the heuristic to which we referred in Theorem 4 of the Introduction. A more precise statement of that theorem can now be given.

THEOREM 4. *The Isolation Heuristic constructs a k-terminal cut whose weight is guaranteed to be no more than* $2(k-1)/k$ *times the optimal weight.*

Proof. Let $\overline{E}$ be an optimal k-terminal cut, and let $\overline{w} = w(\overline{E})$. For $1 \leq i \leq k$, let $\overline{V}_i$ be the set of vertices left connected to s_i by $\overline{E}$, and let $\overline{E}_i$ be the set of edges in $\overline{E}$ with one endpoint in $\overline{V}_i$. Note first that for each i, the set $\overline{E}_i$ is an isolating cut for s_i. Hence $w(\overline{E}_i) \geq w(\hat{E}_i)$. On the other hand, each edge in $\overline{E}$ is in exactly two different sets $\overline{E}_i$, and so $\Sigma_{i=1}^{k} w(\overline{E}_i) = 2\overline{w}$. Thus

$$w(\hat{E}) \leq \frac{k-1}{k}\sum_{i=1}^{k} w(\hat{E}_i) \leq \frac{k-1}{k}\sum_{i=1}^{k} w(\overline{E}_i) = 2\frac{k-1}{k}\overline{w}$$

as claimed. □

The bound given by Theorem 4 is tight. More precisely, for each $k \geq 3$ and any $\varepsilon > 0$, there exist instances for which the cut constructed by the Isolation Heuristic has weight $(2-\varepsilon)(k-1)/k$ times the optimal. The generic construction contains $2k$ edges and vertices, with the nonterminal vertices $v_1, v_2, \ldots, v_k$ linked in a simple k-cycle of weight-1 edges, and terminal s_i linked by a weight-$(2-\varepsilon)$ edge to vertex v_i, $1 \leq i \leq k$. See Fig. 13 for an illustration of the case for $k = 4$.

Note that for each terminal s_i, the minimum weight isolating cut is unique and consists of the edge of weight $2-\varepsilon$ connecting it to v_i. Thus the weight of the cut constructed by the heuristic is $(k-1)(2-\varepsilon)$. An optimal cut, on the other hand, would consist simply of all the k weight-1 edges in the cycle linking the nonterminals, for a total weight of k. The ratio thus has the claimed value. (Note that if we are willing to assume that our heuristic always breaks ties in the worst possible way, we can take $\varepsilon = 0$ in the above example and obtain a ratio that precisely matches the upper bound of Theorem 4.)

For $k = 3$, the ratio guaranteed by Theorem 4 is 4/3 and fairly close to 1. An interesting question is whether there are any polynomial time heuristics that provide better guarantees. In particular, is it conceivable that we could guarantee ratios arbitrarily close to 1? Formally, is there a *polynomial time approximation scheme* for 3-terminal cut i.e., a sequence of polynomial time algorithms A_t, where A_t is guaranteed to find a 3-terminal cut of weight at most $1 + 1/t$ times the optimal weight? (The algorithms need not be polynomial in t, only in the instance size.)

There is significant evidence that the answer to this question is no. In particular, our proof of Theorem 3 implies that the 3-terminal cut problem is what is known as *MAX SNP-hard* [21], and this implies that 3-terminal cut cannot have a polynomial time approximation scheme unless P = NP. Let us explain.

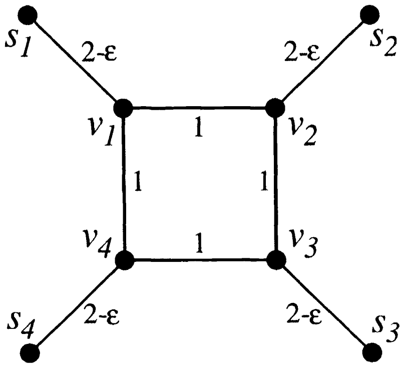

FIG. 13. *Worst-case graph for the Isolation Heuristic when* $k = 4$.

An optimization problem is in MAX SNP if the optimal value sought can be described as $\max_S |\{\bar{x} : \phi(\bar{x}, I, S)\}|$, where I is an instance, S is a relational structure such as a truth assignment in the case of 3-SAT, x is the object being counted, such as satisfied clauses, and ϕ is a first order logical expression. A second relevant example of a problem in the class MAX SNP is *Max Cut*, the optimization version of the problem SIMPLE MAX CUT that we used to prove that 3-TERMINAL CUT is NP-complete in §4.2. In the Max Cut problem, the instance I is a graph, the structure S is a partition of the vertices into two sets, and the objects $\bar{x}$ are edges, where $\phi(\bar{x}, I, S)$ is true if and only if $\bar{x}$ does not have both its endpoints in the same set of the partition S.

MAX SNP was introduced in [21], where it was observed that although each problem in MAX SNP could be approximated to within *some* constant ratio in polynomial time, no problem in the class was known to have a polynomial time approximation scheme. The concept of MAX SNP-hardness was also introduced in [21] and defined in such a way that it could be applied both to problems, such as MAX 3-SAT and Max Cut, that are in MAX SNP and to problems, such as 3-Terminal Cut, that are minimization problems and hence by definition not in MAX SNP. The key observation about MAX SNP-hardness in [21] was that no MAX SNP-hard problem could have a polynomial time approximation scheme unless all problems in MAX SNP had them. Arora et al. [1] have now shown that the latter event cannot occur unless $P = NP$. Consequently no MAX-SNP-hard problem can have a polynomial time approximation scheme unless $P = NP$.

Proofs of MAX SNP-hardness involve *linear reductions*, a generalization of the familiar polynomial transformations used in NP-hardness proofs. Let A and B be two optimization problems (either maximization or minimization). We say that A linearly reduces to B if there are two polynomial time algorithms f and g and constants $\alpha, \beta > 0$ such that

1. Given an instance a of A, algorithm f produces an instance $b = f(a)$ of B such that the cost of an optimal solution for b, $opt(b)$, is at most $\alpha \cdot opt(a)$, and

2. Given a, $b = f(a)$, and any solution y of b, algorithm g produces a solution x of a such that $|cost(x) - opt(a)| \le \beta |cost(y) - opt(b)|$.

It can be shown [21] that linear reductions are transitive, that is, are closed under composition, and that if A linearly reduces to B and B has a polynomial-time approximation algorithm guaranteed to produce solutions y with $|cost(y) - opt(b)|/opt(b) \le \varepsilon$, then A has a polynomial-time approximation algorithm that guarantees to keep the analogous ratio bounded by $\alpha\beta\varepsilon$. Thus if B had a polynomial time approximation scheme, so would A. A problem is MAX SNP-hard if every problem in MAX SNP linearly reduces it to, or equivalently, given the transitivity of linear transformations, if some single previously identified MAX SNP-hard problem linearly reduces to it.

THEOREM 5. *For any fixed $k \geq 3$, k-terminal cut is MAX SNP-hard.*

Proof. We prove the result for $k = 3$. The extension to $k > 3$ follows immediately. Our proof is by a linear reduction from the Max Cut problem described above, previously proved MAX SNP-hard in [21]. For the reduction, we need only reinterpret the transformation from SIMPLE MAX CUT to 3-TERMINAL CUT used in the proof of Theorem 3. Note that for that construction we showed that if k is the size of the maximum cut in the original instance, then the size of the optimal 3-terminal cut is $28|E| - K$. Now note that the maximum cut must have size at least $|E|/2$, because a simple greedy heuristic will construct a cut that large. (Start with two adjacent vertices as the nuclei of V_1 and V_2, and then assign the rest of the vertices one at a time, choosing for each the set that maximizes the number of edges added to the cut.) Thus if we let $f(G)$ denote the instance of 3-Terminal Cut derived from an instance G of Max Cut, we have $OPT_{\text{3-TerminalCut}}(f(G)) \leq 56\, OPT_{\text{MAXCUT}}(G)$, and our transformation satisfies Property (a) of the definition of linear reduction with $\alpha = 56$.

For property (b), note that our proof of Theorem 3 implies that any solution y for $f(G)$ of weight $28|E| - K$ can be easily converted to a solution $x = g(y)$ of size K for G. Thus for any solution y of $f(G)$ we have $|cost(x) - opt(a)| \leq |cost(y) - opt(b)|$, and so property (b) holds with $\beta = 1$.

We conclude that the transformation used in the proof of Theorem 3 was a linear reduction, and so 3-terminal cut is MAX SNP-hard. □

5. Related results and open problems. Our NP-completeness results in §3 and §4 can be adapted to several related problems of interest. In 1969, Hu [17] raised the question of the complexity of the following problem that we might call the *multipair cut* problem. Suppose we are given a list of vertex pairs (u_i, v_i), $1 \leq i \leq k$, and are asked to find a minimum $C(u_1, u_2, \ldots, u_k, v_1, v_2, \ldots, v_k)$ cut, that is, a minimum weight set of edges separating each pair of vertices u_i, v_i, $1 \leq i \leq k$. This is just 2-terminal cut when $k = 1$. The problem is also polynomial time solvable when $k = 2$, by using two applications of a 2-terminal cut algorithm [24]. Our result for 3-terminal cut implies that it is NP-hard for arbitrary graphs when $k = 3$, even if all edge weights are equal: merely let the three pairs be (s_1, s_2), (s_2, s_3), and (s_3, s_1). (If one wants all the u_i and v_i to be distinct, the problem remains NP-hard, as can be proved via a simple modification to the input graph.)

Note that for any fixed k the Isolation Heuristic of §4.4 can be used in the design of a polynomial-time approximation algorithm for multipair cut. Consider partitions P of the vertices $u_1, u_2, \ldots, u_k, v_1, v_2, \ldots, v_k$ into sets $S_1, \ldots, S_{|P|}$ such that no pair (u_i, v_i) is in the same set, and such that for every pair of sets S_h and S_j there is some i such that u_i is in one set and v_i is in the other. Note that the latter constraint implies that $|P| \leq \sqrt{2k}+1$, and so there are at most $(\sqrt{2k}+1)^{2k}/(\sqrt{2k}+1)!$ such partitions. For any such partition P, let G_P be the graph obtained by merging all the vertices in the set S_j into a single terminal vertex s_j, $1 \leq j \leq |P|$. Run the Isolation Heuristic on each such graph G_P, at a cost of $O((\sqrt{2k}+1)nm \log(n^2/m))$ per graph, and output the best cut found. Because the optimal $C(u_1, u_2, \ldots, u_k, v_1, v_2, \ldots, v_k)$ cut must induce one of the partitions P, and because no partition contains more than $\sqrt{2k} + 1$ sets, the weight of the cut we output is at most $2\sqrt{2k}/(\sqrt{2k}+1) < 2$ times optimal by Theorem 4. The running time is

$$O\left(\frac{(\sqrt{2k})^{2k}(1 + 1/\sqrt{2k})^{2k}}{(\sqrt{2k} + 1)!}(\sqrt{2k} + 1)nm \log(n^2/m)\right) = O\left((2k)^k nm \log(n^2/m)\right)$$

which is polynomial for fixed k. The question remains open as to whether there is a polynomial-time approximation algorithm that works for arbitrary k and provides a constant guarantee, although Garg et al. [11] have devised a polynomial-time algorithm that works for arbitrary k and has worst-case ratio $O(\log k)$.

More recently, Erdös and Székely in [5], [6] proposed the following generalization of multiterminal cut. Suppose you are given a graph $G = (V, E)$ with weighted edges, and a partial k-coloring of the vertices, that is, a subset $V' \subseteq V$ and a function $f : V' \rightarrow \{1, 2, \ldots, k\}$. Can f be extended to a total function such that the total weight of edges that have different colored endpoints is minimized? The k-terminal cut problem is the special case where $|V'| = k$ and f is 1-1, that is, each color is initially assigned to precisely one vertex. It is easy to see that for general graphs, this problem is in fact equivalent to multiterminal cut. Simply merge all the vertices with the same color, call the resulting merged vertices "terminals," and find the minimum weight k-terminal cut for the resulting graph. For special classes of graphs, however, the "Colored Multiterminal Cut" problem can be more general. (The above merging trick need not for instance preserve planarity or acyclicity.) Nevertheless, in the case of trees, the dynamic programming algorithm for multiterminal cut mentioned in the Introduction extends in a natural way to the colored multiterminal cut problem, yielding an $O(nk)$ algorithm, as Erdös and Székely observe. This, is turn, implies that if G is such that deleting all the terminals renders it acyclic, then multiterminal cut can itself still be solved in $O(nk)$ time. (Simply split each terminal s_i into *degree*(s_i) separate vertices, one for each edge incident on s_i, assign color i to all the derived vertices, and apply the abovementioned algorithm for colored multiterminal cut on trees to the resulting graph [6]).

An obvious question is whether our algorithms for planar graphs also extend to Colored Multiterminal Cut problem. The answer is no. Colored multiterminal cut is clearly polynomial-time solvable if $k = 2$, even for general graphs. For any fixed $k \geq 3$, however, if remains NP-complete even for planar graphs and all weights equal to 1. The $k = 4$ case follows directly from our proof of Theorem 2. Simply use the four colors $x, \overline{x}, c^+$, and c^-, and assign x to each terminal x_i, $\overline{x}$ to each terminal $\overline{x}_i$, c to each terminal c_j^+, and c^- to each terminal c_j^-. It is straightforward to verify that the proof still goes through. For $k = 3$, the result can be proved by a transformation from PLANAR 3-COLORABILITY [9], [10], using a local replacement argument in which each edge is replaced by a partially colored structure designed to make it expensive for the endpoints of the original edge to get the same color. We leave the details to the enterprising reader. (Note that this last result provides us with an alternate proof of the NP-completeness of 3-TERMINAL CUT for general graphs: once again simply merge all vertices with the same color. The fact that such an operation may destroy planarity is in this case irrelevant.)

Returning to the original multiterminal cut problem, in our opinion the most interesting open problem is whether one can improve upon the approximation results of Theorem 4. Although polynomial-time algorithms with worst-case ratios arbitrarily close to 1 are unlikely in light of Theorem 5, can we do better than the $2(k-1)/k$ guarantee we proved for the Isolation Heuristic? Noga Alon (private communication, 1991) has observed that for the special cases of $k = 4$ and $k = 8$ improvements can be obtained using a variant of our approach. For $k = 4$, the Isolation Heuristic provides a guarantee of 3/2. An improved guarantee of 4/3 can be obtained as follows. For each partition of the terminals into sets S_1, S_2 of size two, use max flow techniques to compute the minimum cut that separates the terminals in S_1 from those in S_2. Output the union of the two best such cuts. The reader can readily verify that this union is a 4-terminal cut whose weight is at most 4/3 optimal. Note that this approach requires only three max flow computations versus the four needed by the Isolation Heuristic, so it is faster as well. (Cunningham reports in [3] that Zhang has independently obtained this $k = 4$ improvement.)

For $k = 8$, the guarantee of our theorem can be improved from 7/4 to 12/7. Here one computes minimum 2-terminal cuts on the basis of partitions of the set of terminals into sets of size four. It can be shown that the average weight of these cuts is at most 4/7 times the weight of an optimal 8-terminal cut, and that there exists a set of three of these cuts whose union is an 8-terminal cut and whose total weight is no more than average. This yields the claimed bound. Moreover, the running time is once again an improvement on the Isolation Heuristic, which in this case would require eight max flow computations. This is because we can show that it suffices to restrict attention to just seven of the 35 possible partitions of the eight terminals into sets of size four (the seven being derived from the rows of a Hadamard matrix).

Unfortunately, the above approach does not yield improvements over the Isolation Heuristic for any values of k other than 4 and 8. Is there some general technique that will improve on the Isolation Heuristic for arbitrarily large values of k? What about simply beating our bound for the case of $k = 3$?

Turning to our optimization algorithms for the planar case, the obvious question is whether the running times can be improved, although for the case of general k the improvement would have to be substantial to be interesting. For instance, although we would expect any algorithm to be exponential in k, the exponent containing k might not have to be attached to n. Could there be an algorithm whose running time was $c^k n^\alpha$, where α was independent of k?

Acknowledgment. The authors thank the anonymous referees for suggestions that improved the performance of our approximation algorithm for the multipair cut problem and more generally helped us clarify our presentation.

DIAGNOSIS OF $t/(t+1)$-DIAGNOSABLE SYSTEMS*

A. DAS[†], K. THULASIRAMAN[‡], AND V. K. AGARWAL[§]

Abstract. A classic PMC (Preparata, Metze, and Chien) multiprocessor system [F. P. Preparata, G. Metze, and R. T. Chien, IEEE Trans. Electr. Comput., EC-16 (1967), pp. 848–854] composed of n units is said to be $t/(t+1)$ diagnosable [A. D. Friedman, *A new measure of digital system diagnosis*, in Dig. 1975 Int. Symp. Fault-Tolerant Comput., 1975, pp. 167–170] if, given a syndrome (complete collection of test results), the set of faulty units can be isolated to within a set of at most $t+1$ units, assuming that at most t units in the system are faulty. This paper presents a methodology for determining when a unit v can belong to an allowable fault set of cardinality at most t. Based on this methodology, for a given syndrome in a $t/(t+1)$-diagnosable system, the authors establish a necessary and sufficient condition for a vertex v to belong to an allowable fault set of cardinality at most t and certain properties of $t/(t+1)$-diagnosable systems. This condition leads to an $O(n^{3.5})t/(t+1)$-diagnosis algorithm. This $t/(t+1)$-diagnosis algorithm complements the $t/(t+1)$-diagnosability algorithm of Sullivan [*The complexity of system-level fault diagnosis and diagnosability*, Ph.D. thesis, Yale University, New Haven, CT, 1986].

1. Introduction.

Several models have been proposed in the literature for diagnosable system design. Of these, the now well-known PMC model introduced by Preparata, Metze, and Chien [1] has been extensively studied. In this model, each processor tests some of the other processors and produces test results, which are unreliable if the testing processor is itself faulty. The collection of all test results over the entire system is referred to as a *syndrome*. The classic constraint used in the study of diagnosable systems is to assume that the number of faulty processors in the entire system is upper-bounded by an integer t. A system is then said to be *t diagnosable* if given a syndrome, all processors can be correctly identified as faulty or fault free, provided that the number of faulty processors present in the system does not exceed t. Three problems of interest in this context are the *t-characterization problem* to determine the necessary and sufficient conditions for the system test assignment to be t diagnosable, the t-diagnosability problem to determine the largest value of t for which a given system is t diagnosable, and finally the t-diagnosis problem to locate the faulty units present in a t-diagnosable system, using a given syndrome.

Hakimi and Amin [2] gave a solution to the t-characterization problem. An $O(|E|n^{3/2})$ algorithm for the t-diagnosability problem was presented by Sullivan [3]. Subsequently, Raghavan [4] improved on this result by presenting an algorithm that runs in $O(nt^{2.5})$ time. Dahbura and Masson [5] published an $O(n^{2.5})$ algorithm for the t-diagnosis problem; a t-diagnosis algorithm with complexity $O(|E|+t^3)$ was presented by Sullivan [6].

The requirement that all the faulty processors in a multiprocessor system be identified exactly is rather restrictive. Friedman [7] introduced the concept of t/s-diagnosability. A multiprocessor system S is said to be t/s diagnosable if, given a syndrome, the set of faulty processors can be isolated to within a set of at most s processors provided that the number of faulty processors does not exceed t. Allowing some fault-free processors to be possibly identified as faulty permits the system to have far fewer tests. It has been shown that t/t-diagnosable systems with $n^*\lceil(t+1)/2\rceil$ tests can be constructed [8]. t/t-diagnosable systems have been studied extensively in the literature. Chwa and Hakimi [9] gave a characterization of t/t-diagnosable systems, Sullivan [10] presented a polynomial time algorithm

for the t/t-diagnosability problem, and Yang, Masson, and Leonetti [11] presented an $O(n^{2.5})$ algorithm for the t/t-diagnosis problem. Sullivan also presented in [10] a polynomial time $t/(t+1)$-diagnosability algorithm based on a characterization of $t/(t+1)$-diagnosable systems also developed in [10].

The objective of this work is to develop an efficient diagnosis algorithm for $t/(t+1)$-diagnosable systems. The paper is organised as follows. In §2, we present certain basic definitions, notations, and results. With the objective of determining an effecient test for a vertex v to be in an allowable fault set of cardinality at most t, we then establish in §3 several properties of allowable fault sets and present a methodology for determining when a unit v belongs to an allowable fault set of cardinality at most t. Using these properties and certain properties of $t/(t+1)$-diagnosable systems, we develop in §4 a necessary and sufficient condition for a vertex v to belong to an allowable fault set of cardinality at most t. This leads to an $O(n^{3.5})$ algorithm for diagnosis of a $t/(t+1)$-diagnosable system. The work presented here is a revised version of our earlier paper [12].

2. Preliminaries. A multiprocessor system S consists of n units or processors, denoted by the set $U = \{u_1, u_2, \ldots, u_n\}$. Each unit is assigned a subset of other units for testing. Thus the test interconnection can be modeled as a directed graph $G = (U, E)$. The test outcome a_{ij}, which results when unit u_i tests unit u_j, has value 1 (respectively, 0) if u_i evaluates unit u_j to be faulty (respectively, fault free). Since all faults considered are permanent, the test outcome a_{ij} is reliable if and only if unit u_i is fault free. The collection of all test results over the entire system is referred to as a *syndrome*. If $a_{ij} = 0$ (respectively, 1) then u_i is said to have a 0-link (respectively, 1-link) to u_j and u_j is said to have a 0-link (respectively, 1-link) from u_i.

Given a syndrome, the *disagreement set* $\Delta_1(u_i)$ of $u_i \in U$ is defined as

$$\Delta_1(u_i) = \{u_j | a_{ij} = 1 \text{ or } a_{ji} = 1\}.$$

For a subset $W \subseteq U$,

$$\Delta_1(W) = \bigcup_{u_j \in W} \Delta_1(u_j).$$

Given a syndrome, the set of 0-*descendents* of u_i is represented by the set

$$D_0(u_i) = \{u_j : \text{ there is a directed path of 0-links from } u_i \text{ to } u_j\}$$

and for a set $W \subseteq U$, the 0-*ancestors* of W denote the set

$$A_0(W) = \{u_i : \exists u_j \in W \text{ such that } u_j \in D_0(u_i)\}.$$

For $u_i \in U$, $H_0(u_i)$ corresponds to the set $A_0(u_i) \cup \{u_i\}$.

DEFINITION 1 [5]. *Given a system* S *and a syndrome, a subset $F \subseteq U$ is an* allowable fault set (AFS) *if and only if*

1. *$u_i \in (U - F)$ and $a_{ij} = 0$ imply $u_j \in (U - F)$, and*
2. *$u_i \in (U - F)$ and $a_{ij} = 1$ imply $u_j \in F$.*

In other words, F is an AFS for a given syndrome if and only if the assumption that the units in F are faulty and the units in $U - F$ are fault free is consistent with the given syndrome. A *minimum allowable fault set* (MAFS) is an allowable fault set of minimum cardinality.

DEFINITION 2 [5]. *Given a system* S *and a syndrome, the* implied-fault set $L(u_i)$ *of $u_i \in U$ is the set of all units of* S *that may be deduced to be faulty under the assumption that u_i is fault free.*

It follows that

$$L(u_i) = \Delta_1(D_0(u_i)) \bigcup A_0(\Delta_1(D_0(u_i))).$$

Note that if $u_j \in L(u_i)$ then there exists a 1-link (u_k, u_l) or (u_l, u_k) such that there is a directed path of 0-links from u_i to u_k and a directed path of 0-links from u_j to u_l. This observation motivates the definition of an *implied-fault path* between u_i and u_j.

DEFINITION 3. *Given a system* S *and a syndrome, a path* P *between* u_i *and* u_j *is an* implied-fault path *if there exist units* u_k *and* u_l *on* P *such that the following are satisfied.*

(i) *All the links of* P *that lie between* u_i *and* u_k *constitute a directed path of* 0*-links from* u_i *to* u_k.

(ii) *All the links of* P *that lie between* u_j *and* u_l *constitute a directed path of* 0*-links from* u_j *to* u_l.

(iii) *Either* (u_k, u_l) *or* (u_l, u_k) *is a* 1*-link on* P.

Given two sets X_i and X_j, $X_i \oplus X_j$ denotes the *symmetric difference* of X_i and X_j. That is,

$$X_i \oplus X_j = (X_i - X_j) \bigcup (X_j - X_i).$$

If $u_i \in L(u_i)$ then clearly the unit u_i is faulty. Such a unit will be in every AFS. Without loss of generality, we assume in this paper that $u_i \notin L(u_i)$ for any $u_i \in U$.

The following lemmas determine a few properties of AFSs and implied faulty sets.

LEMMA 1 [5]. *Given a system* S *and a syndrome, each of the following statements holds.*

(1) *For* $u_i, u_j \in U$, $u_i \in L(u_j)$ *if and only if* $u_j \in L(u_i)$.

(2) *For* $u_i, u_j \in U$, *if* $a_{ij} = 0$ *then* $L(u_j) \subseteq L(u_i)$.

(3) *If* $F \subseteq U$ *is an* AFS, *then* $\bigcup_{u_i \in U-F} L(u_i) \subseteq F$.

LEMMA 2 [10]. *Given a system* S *and a syndrome, if* F_1 *and* F_2 *are* AFSs *then so is* $(F_1 \bigcup F_2)$.

LEMMA 3. *Given a system* S *and a syndrome, let* $F \subseteq U$ *be an* AFS *containing* $u_i \in U$. *Then* $H_0(u_i) \subseteq F$.

Proof. Suppose that $u_j \in H_0(u_i)$ is not a member of F. Since $u_j \in H_0(u_i)$ there exists a directed path of 0-links from u_j to u_i. Since $u_j \in U - F$ and $u_i \in F$, there exists an 0-link from $U - F$ to F on this path, contradicting the assumption that F is an AFS. □

For what follows, let $G' = (U', E')$ denote a general, undirected graph.

DEFINITION 4. *A subset* $K \subseteq U'$ *is called a* vertex cover set (VCS) [13] *of* G' *if every edge in* G' *is incident on at least one vertex in* K. *A* minimum vertex cover set (MVCS) *is a* VCS *of minimum cardinality in* G'.

DEFINITION 5. *A subset* $M \subseteq E'$ *is called a* matching [13] *if no vertex in* U' *is incident on more than one edge in* M. *A* maximum matching *is a matching of maximum cardinality in* G'.

A *bipartite graph*, with bipartition (X, Y), is one whose vertex set can be partitioned into two subsets X and Y such that every edge is incident to a vertex in X and a vertex in Y. Finally, for $u_i \in U'$, $N(u_i)$ denotes the set of all vertices that are adjacent to u_i.

3. Basic properties of allowable fault sets.

In this section we establish certain properties of allowable fault sets with respect to a given syndrome. Our study is directed toward investigating conditions for a vertex v to be in an allowable fault set of cardinality at most t. For this purpose we use the notion of implied-fault set and the implied-fault graph used by Dahbura and Masson [5] in their study.

Given a syndrome for a system S, define the implied-fault graph $G^* = (U^*, E^*)$ to be an undirected graph such that $U^* = U$ and $E^* = \{(u_i, u_j) : u_i \in L(u_j)\}$. For $u \in U$, let G_u^*

denote the subgraph of G^* obtained after all units in $H_0(u)$ and all edges incident on these units have been removed from G^*. Let K_u represent an MVCS of G_u^* and let $G - H_0(u)$ denote the subgraph of G where all vertices in $H_0(u)$ along with all edges incident on these vertices have been removed from G. Finally, we define $G^*(F)$ to be the subgraph of G^* such that all edges that connect vertices entirely inside F have been deleted.

Recall that we have assumed that $u_i \notin L(u_i)$ for any $u_i \in U$. This means that G^* has no self-loops.

The results of the following lemma can be found in [5]. We present this lemma for the sake of completeness.

LEMMA 4. *Given a syndrome for a system* S, *we have the following.*

(i) *Every* AFS *of G is a* VCS *of G^*.*

(ii) *If $F \subseteq U$ is a minimal* VCS *of G^*, then F is an* AFS *of G.*

(iii) *$F \subseteq U$ is an* MAFS *of G if and only if F is an* MVCS *of G^*.*

Proof. (i) Let F be an AFS of G for the given syndrome. Assume F is not a VCS of G^*. Then there exist $u_i, u_j \in U - F$ such that (u_i, u_j) is an edge in G^*. Since all edges from $U - F$ into F in G are 1-links (F is an AFS of G) and an implied-fault path between u_i and u_j can contain only one 1-link, all vertices that lie on an implied-fault path between u_i and u_j must belong to $U - F$. But this implies that there is a 1-link between two vertices in $U - F$, contradicting the assumption that F is an AFS of G. This shows that (i) holds.

(ii) Let F be a minimal VCS of G^*. Assume (ii) does not hold. Then at least one of the following conditions is satisfied.

(a) There exist $u_i, u_j \in U - F$ with $a_{ij} = 1$.

(b) There exist $u_j \in F, u_i \in U - F$ with $a_{ij} = 0$.

Assume (a) holds. Then the edge (u_i, u_j) is in G^*. But this contradicts the fact that F is a VCS of G^* since neither u_i nor u_j is a member of F.

Now assume (b) holds and (a) does not hold. Since F is a minimal VCS of G^* there exists a unit u_k in $U - F$ such that (u_j, u_k) is an edge in G^*; otherwise $F - \{u_j\}$ will be a VCS, contradicting the minimality of F. Hence $u_j \in L(u_k)$. Since $a_{ij} = 0$, it follows that $u_i \in L(u_k)$ and so (u_i, u_k) is an edge in G^*. Since neither u_i nor u_k is a member of F, this contradicts the fact that F is a VCS of G^*.

(iii) Statement (iii) follows from (i) and (ii). □

LEMMA 5. *F is an* AFS *in G of minimum cardinality containing unit v if and only if $H = F - H_0(v)$ is an* MAFS *of $G - H_0(v)$.*

Proof. We first prove necessity. We first show that H is an AFS of $G - H_0(v)$. Since $U - F = (U - H_0(v)) - H$ and F is an AFS of G, all edges within $(U - H_0(v)) - H$ are 0-links and all edges from $(U - H_0(v)) - H$ into H are 1-links. Hence H is an AFS of $G - H_0(v)$. To show that H is an MAFS of $G - H_0(v)$, assume H_1 is an AFS of $G - H_0(v)$. Clearly all edges with both vertices incident on vertices in $(U - H_0(v)) - H_1$ are 0-links and all edges from $U - H_0(v) - H_1$ into H_1 are 1-links. Now consider edges from $(U - H_0(v)) - H_l$ into $H_0(v)$. These edges must all be 1-links, otherwise the vertices incident on these edges would all belong to $H_0(v)$. This shows that the set $H_1 \bigcup H_0(v)$ is an AFS of G. Hence if $|H_1| < |H|$ then $H_1 \bigcup H_0(v)$ is an AFS of smaller cardinality than F, contradicting the fact that F is an AFS of minimum cardinality containing v. Hence $|H_1| \geq |H|$ and H is an MAFS of $G - H_0(v)$.

We will now prove sufficiency. If $F - H_0(v)$ is an MAFS of $G - H_0(v)$ then, as we have shown in the proof of necessity, F is an AFS of G. If F is not an AFS in G of minimum cardinality containing v, then let F_1 be an AFS of G containing v with $|F_1| < |F|$. But then $F_1 - H_0(v)$, from the necessity part, would be an AFS of $G - H_0(v)$ of smaller cardinality than $F - H_0(v)$, which is a contradiction. □

LEMMA 6. *For $v \in U$, $(G - H_0(v))^* = G_v^*$.*

Proof. Since the vertex sets of both graphs are the same, we need only show that the edge sets are identical. Clearly every edge in $(G - H_0(v))^*$ is in G_v^*. Now assume that there is an edge (u_i, u_j) in G_v^* that is not in $(G - H_0(v))^*$. Then every implied-fault path in G between u_i and u_j must contain at least one vertex from $H_0(v)$. But this implies that either u_i or u_j is a member of $H_0(v)$, contradicting the assumption that both vertices are members of $G - H_0(v)$. Hence the two edge sets are also identical. □

LEMMA 7. *Given a syndrome for a system* S, *let* $F \subseteq U$ *be an* AFS *containing* $v \in U$. *Then* $F - H_0(v)$ *is a* VCS *of* G_v^*.

Proof. Let $F_1 = F - H_0(v)$. From Lemma 3 and the proof of Lemma 5, it follows that F_1 is an AFS of $G - H_0(v)$. Then from Lemma 4, F_1 is a VCS of $(G - H_0(v))^*$. Thus, by Lemma 6, F_1 is a FCS of G_v^*. □

THEOREM 1. *Given a syndrome for a system* S, F *is an* AFS *of minimum cardinality among all allowable fault sets that contain unit* $v \in U$ *if and only if* $F - H_0(v)$ *is a* MVCS *of* G_v^*.

Proof. The proof follows from Lemmas 4, 5 and 6. □

The condition given in the above theorem can be used to test whether a unit belongs to an AFS of cardinality at most t for a given syndrome. However, this condition requires determining an MVCS for a general undirected graph, a problem known to be NP complete. Therefore we would like to develop a test that requires determining an MVCS of a bipartite graph. With this objective in mind, we first define a bipartite graph for each vertex v. This bipartite graph is derived from G_v^*. We then relate an MVCS of this graph to an AFS containing vertex v and establish certain properties of this AFS that will be used in the following section to develop the appropriate diagnosis algorithm.

Given a system S and a syndrome, define $B = (U_B, E_B)$ to be the undirected bipartite graph with bipartition (X, Y) where

$$X = \{x_1, \dots, x_n\}, \qquad Y = \{y_1, \dots, y_n\}$$

and

$$E_B = \{(x_i, y_j) : u_i \in L(u_j) \text{ in S}\}.$$

For $v \in U$, define the undirected bipartite graph $B_v = (U_v, E_v)$ with bipartition (X_v, Y_v) to be the vertex-induced subgraph of B such that

$$X_v = \{x_i : u_i \in U - H_0(v)\}, \qquad Y_v = \{y_i : u_i \in U - H_0(v)\}.$$

For each vertex v in G, let

$$t_v = t - |H_0(v)|$$

and

$$U_v = U - H_0(v).$$

THEOREM 2. *Given a syndrome for a system* S, *a unit* $v \in U$ *does not belong to any* AFS *of cardinality at most* t *if* B_v *has an* MVCS *of cardinality greater than* $2t_v$.

Proof. Let the cardinality of an MVCS of B_v be greater than $2t_v$. Assume $v \in U$ belongs to an AFS F such that $|F| \leq t$. Let $H = F - H_0(v)$. Since, by Lemma 3, $H_0(v) \subseteq F$, it follows that $|H| = |F| - |H_0(v)| \leq t - |H_0(v)| = t_v$. Define $B_X(H) = (U_X, E_X)$ to be the vertex-induced subgraph of B_v, where

$$U_X = \{x_i : u_i \in H\} \cup \{y_i : u_i \in U - H\}.$$

$B_Y(H) = (U_Y, E_Y)$ is defined to be the vertex-induced subgraph of B_v, where

$$U_Y = \{x_i : u_i \in U - H\} \cup \{y_i : u_i \in H\}.$$

Clearly $F_X = \{x_i : u_i \in H\}$ and $F_Y = \{y_i : u_i \in H\}$ are VCSs of $B_X(H)$ and $B_Y(H)$, respectively. It follows that $F_B = F_X \cup F_Y$ is a VCS of $B_X(H) \cup B_Y(H)$. Since F is an AFS, in G^* there are no edges connecting vertices of $U - F$. From this it follows that every edge in $B_v - B_X(H) - B_Y(H)$ connects vertices in F_B. Therefore F_B is a VCS of B_v, contradicting our assumption that the cardinality of an MVCS of B_v is greater than t_v. Hence v is not contained in any AFS of cardinality at most t. □

In the following we use $F_B(v)$ to denote an MVCS of B_v. For a given $F_B(v)$ let

$$F_I = \{u_i | x_i \in F_B(v) \text{ and } y_i \in F_B(v)\}$$

and

$$F_v = \{u_i | x_i \in F_B(v) \text{ or } y_i \in F_B(v)\}.$$

We now proceed to establish certain properties of F_v.

LEMMA 8. *$F_v \cup H_0(v)$ is an* AFS *of G.*

Proof. Assume the contrary. Then at least one of the following conditions is satisfied.

(a) There exist $u_i, u_j \in U - F_v - H_0(v)$ with $a_{ij} = 1$.

(b) There exist $u_j \in F_v \cup H_0(v)$ and $u_i \in U - (F_v \cup H_0(v))$ with $a_{ij} = 0$.

Assume (a) holds. Then the edge (u_i, u_j) is in G_v^*. Hence (x_i, y_j) is an edge in B_v. But this contradicts the fact that $F_B(v)$ is a VCS of B_v since neither x_i nor y_j is a member of $F_B(v)$.

Now assume (b) holds and (a) does not hold. Clearly $u_j \notin H_0(v)$; otherwise u_i would also belong to $H_0(v)$. Thus $u_j \in F_v$. Hence either x_j or y_j is a member of $F_B(v)$. Without loss of generality, let $x_j \in F_B(v)$. Since $F_B(v)$ is an MVCS of B_v, there exists y_k in B_v with $y_k \notin F_B(v)$ such that (x_j, y_k) is an edge in B_v. Hence $u_j \in L(u_k)$. Since $a_{ij} = 0$, $u_i \in L(u_k)$. Hence (x_i, y_k) is an edge in B_v. Since neither x_i nor y_k is a member of $F_B(v)$, this contradicts the fact that $F_B(v)$ is a VCS of B_v. □

LEMMA 9. *Given a syndrome for a system* S, *a unit $v \in U$, and an* MVCS *$F_B(v)$ of B_v, we have the following.*

(i) *In G^*, there is no edge (u_i, u_j) with $u_i \in U - (F_v \cup H_0(v))$ and $u_j \in F_v - F_I$.*

(ii) *In G, there is no edge (u_i, u_j) with $u_i \in U - (F_v \cup H_0(v))$ and $u_j \in F_v - F_I$.*

Proof. (i) Assume the contrary. Let (u_i, u_j) be an edge from $U - (F_v \cup H_0(v))$ into $F_v - F_I$ in G^*. Then either x_j or y_j is not a member of $F_B(v)$. Thus in B_v either the edge (x_i, y_j) or the edge (x_j, y_i) is not incident on any vertex in $F_B(v)$, contradicting the fact that $F_B(v)$ is a VCS of B_v.

(ii) By Lemma 8, the set $F_v \cup H_0(v)$ is an AFS of G. Thus every edge from $U - (F_v \cup H_0(v))$ into $F_v - F_I$ in G must be a 1-link. So if such an edge (u_i, u_j) exists in G, then (u_i, u_j) is an edge in G^*. Thus from (i) it follows that there is no edge (u_i, u_j) in G with $u_i \in U - (F_v \cup H_0(v))$ and $u_j \in F_v - F_I$. □

LEMMA 10. *Every* AFS *of G contained in $F_v \cup H_0(v)$ contains the subset F_I.*

Proof. To show that every AFS of G contained in $F_v \cup H_0(v)$ contains the subset F_I it suffices to show that every VCS of G^* contained in $F_v \cup H_0(v)$ contains F_I. The above assertion holds if every vertex in F_I is incident on some vertex of $U - (F_v \cup H_0(v))$ in G^*. Assume the contrary. Let u_k be a vertex in F_I that is not incident on any vertex of the set $U - (F_v \cup H_0(v))$. Then let $W_B(v) = \{x_i | u_i \in F_v\} \cup \{y_i | u_i \in F_I - \{u_k\}\}$. From Lemma 9(i) and the construction of B_v it follows that in B_v, there is no edge (x_i, y_j) with $u_i \in U - (F_v \cup H_0(v))$ and $u_j \in F_v - F_I$. So $W_B(v)$ is a VCS of B_v. But $|W_B(v)| = |F_B(v)| - 1$. This contradicts the assumption that $F_B(v)$ is an MVCS of B_v. Thus every vertex in F_I is incident on some vertex of $U - (F_v \cup H_0(v))$ in G^*. This implies that every VCS of G^* contained in $F_v \cup H_0(v)$ contains the subset F_I. By Lemma 4, it follows that every AFS of G contained in $F_v \cup H_0(v)$ contains the subset F_I. □

4. $O(n^{3.5})$ algorithm for diagnosis of a $t/(t+1)$-diagnosable system. In this section we present a necessary condition for a system S to be $t/(t+1)$ diagnosable. We then establish that in the case of a $t/(t+1)$-diagnosable system, the condition of Theorem 2 is both necessary and sufficient for a vertex v to be in an AFS of cardinality at most t. This will lead to an $O(n^{3.5})$ diagnosis algorithm to isolate all faulty units to within at most $t+1$ units in a $t/(t+1)$-diagnosable system.

Recall (§1) that a system S is said to be $t/(t+1)$ diagnosable if, given a syndrome, the set of faulty processors can be isolated to within a set of at most $t+1$ processors provided that the number of faulty processors does not exceed t.

It should be observed that a system is trivially $t/(t+1)$ diagnosable if $n = t+1$. Thus it is required that $0 \le t < n-1$. It should be noted [1] that under these conditions $n \ge 2t+1$ for $t/(t+1)$-diagnosable systems.

THEOREM 3. *If* S, *a multiprocessor system with test interconnection* $G = (U, E)$, *is* $t/(t+1)$ *diagnosable then for all* $X_i, X_j \subseteq U$ *with* $|X_i| > t$, $X_j \not\subseteq X_i$, *and* $|X_i| + |X_j| \le 2t$, *there exists a test from* $U - X_i - X_j$ *into* $X_i \oplus X_j$.

Proof. Assume S is $t/(t+1)$ diagnosable but the condition does not hold. Then there exist $X_i, X_j \subseteq U$ with $|X_i| > t$, $X_j \not\subseteq X_i$, $|X_i| + |X_j| \le 2t$ such that there is no test from $U - X_i - X_j$ into $X_i \oplus X_j$.

Since $|X_i| > t$ and $X_j \not\subseteq X_i$, $|X_i \cup X_j| > t+1$, we construct two sets F_1 and F_2 from X_i and X_j by moving elements from $X_i - X_j$ into $X_j - X_i$ until F_1 and F_2 have cardinality at most t. Thus we obtain two sets F_1 and F_2 with $|F_1| \le t$, $|F_2| \le t$ such that there is no test from $U - F_1 - F_2$ into $F_1 \oplus F_2$. Now consider the following syndrome (see Fig. 1) where for each edge $(u_k, u_l) \in E$ the outcome is defined as follows.

Case 1. $u_l \in U - (F_1 \cup F_2)$; then set $a_{kl} = 0$.
Case 2. $u_l \in F_1 \cup F_2$.
2.1. $u_l \in F_1 \cap F_2$; then set $a_{kl} = 1$.
2.2. $u_k, u_l \in F_1 - F_2$; then set $a_{kl} = 0$.
2.3. $u_k, u_l \in F_2 - F_1$; then set $a_{kl} = 0$.
2.4. $u_k \in F_1 \cap F_2$; then set $a_{kl} = 1$.
2.5. $u_k \in F_1 - F_2$ and $u_l \in F_2 - F_1$; then set $a_{kl} = 1$.
2.6. $u_k \in F_2 - F_1$ and $u_l \in F_1 - F_2$; then set $a_{kl} = 1$.

Both F_1 and F_2 are allowable fault sets of cardinality at most t for the given syndrome and $|F_1 \cup F_2| > t+1$. This contradicts the assumption that S is $t/(t+1)$ diagnosable. □

Recall from the previous section that $F_B(v)$ is an MVCS of B_v and F_v and F_I are sets derived from $F_B(v)$.

THEOREM 4. *Given a syndrome for a* $t/(t+1)$*-diagnosable system* S, *a unit* $v \in U$ *belongs to an* AFS *of cardinality at most t if and only if* $|F_B(v)| \le 2t_v$.

Proof. If $|F_B(v)| > 2t_v$ then, by Theorem 2, G does not contain an AFS of cardinality at most t containing the unit v.

Now assume $|F_B(v)| \le 2t_v$. If $F_v \cup H_0(v)$ contains an AFS of G of cardinality at most t containing the unit v then we are through. So assume $|F_B(v)| \le 2t_v$ and $F_v \cup H_0(v)$ does not contain any AFS of G of cardinality at most t containing the unit v. From Lemma 8, $F_v \cup H_0(v)$ is an AFS of G containing the unit v. If $F_v = F_I$ then $|F_v \cup H_0(v)| \le t$ since $|F_B(v)| \le 2t_v$. So we further assume that $F_v \ne F_I$. Since G^* does not contain any units with

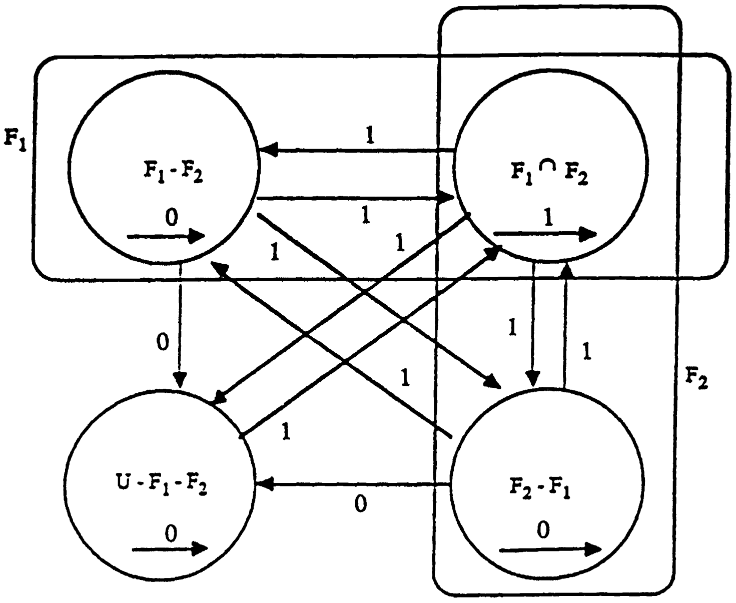

FIG. 1. *Two allowable fault sets generating a common syndrome.*

self-loops and $F_v \neq F_I$, the subset $|F_v - F_I| \geq 2$. Let F_α be an AFS of smallest cardinality containing unit v such that $F_\alpha \subseteq F_v \cup H_0(v)$. Clearly $|F_\alpha| > t$.

By Lemma 10 every AFS of G contained in $F_v \cup H_0(v)$ contains the subset F_I, and since $v \in F_\alpha$, it follows that $F_I \cup H_0(v) \subseteq F_\alpha$.

We next show that $F_\alpha \neq F_v \cup H_0(v)$. Let $u_i \in F_v - F_I$. Then $W = F_v - \{u_i\}$ is a VCS of G_v^* because, by Lemma 9(i), in G_v^* there is no edge (u_i, u_j) with $u_i \in U - (F_v \cup H_0(v))$ and $u_j \in F_v - F_I$. Hence by Lemma 6, W is a VCS of $(G - H_0(v))^*$. This means that, by Lemma 4(ii), W contains an AFS of $G - H_0(v)$. Thus $W \cup H_0(v)$ has an AFS of G containing unit v and of cardinality less than that of $F_v \cup H_0(v)$. Now let $F_a = F_\alpha - (H_0(v) \cup F_I)$, $F_b = (F_v \cup H_0(v)) - F_\alpha)$, and $F_\beta = F_b \cup H_0(v) \cup F_I$. Since F_α is an AFS of smallest cardinality containing v such that $F_\alpha \subseteq F_v \cup H_0(v)$, it follows that $|F_b| = |(F_v \cup H_0(v)) - F_\alpha| > 0$ and $F_\beta \not\subseteq F_\alpha$ (see Fig. 2).

Now

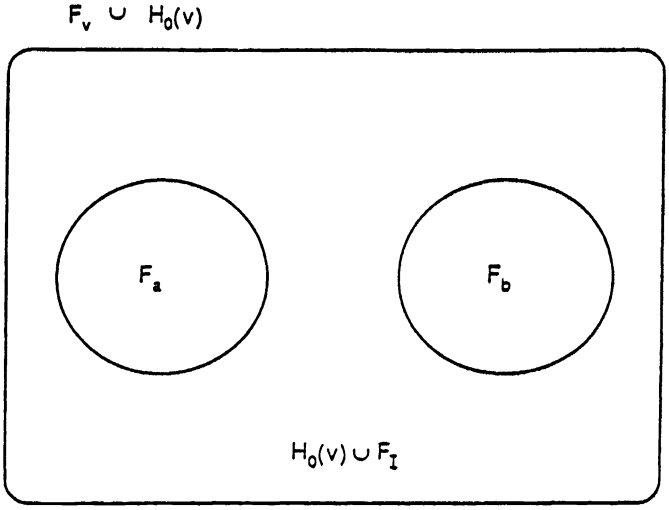
$$\begin{aligned} |F_\alpha| + |F_\beta| &= 2|F_I| + 2|H_0(v)| + |F_a| + F_b| \\ &= |F_B(v)| + 2|H_0(v)| \\ &\leq 2t_v + 2|H_0(v)| \leq 2t \end{aligned}$$

(see also Fig. 2).

Since $U - F_\alpha - F_\beta = U - (F_v \cup H_0(v))$ and $F_\beta \oplus F_\alpha = F_v - F_I$, it follows from Lemma 9(ii) that in G there is no edge (u_i, u_j) with $u_i \in U - (F_v \cup H_o(v)$ and $u_j \in F_v - F_I$.

Thus we have $|F_\alpha| > t$, $F_\beta \not\subseteq F_\alpha$, $|F_\alpha| + |F_\beta| \leq 2t$, and there is no test from $U - F_\alpha - F_\beta$ into $F_\alpha \oplus F_\beta$. This, by Theorem 3, contradicts our assumption that the system S is $t/(t+1)$ diagnosable. □

Given a valid syndrome for a $t/(t+1)$-diagnosable system S and a unit v in S, we have shown that the bipartite graph B_v has an MVCS of cardinality at most $2t_v$ if and only if G has an AFS of cardinality at most t containing the unit v. Since an MVCS of a bipartite graph has



$$F_\alpha = F_a \cup H_0(v) \cup F_I$$

$$F_\beta = F_b \cup H_0(v) \cup F_I$$

$$F_v = F_a \cup F_b \cup F_I$$

$$|F_{B(v)}| = 2|F_I| + |F_a| + |F_b|$$

$$F_\alpha \cap F_\beta = H_0(v) \cup F_I$$

$$F_\alpha \ominus F_\beta = F_a \cup F_b$$

FIG. 2. *Illustration for proof of Theorem* 4.

the same cardinality as a maximum matching of the bipartite graph [13], it follows that B_v has a maximum matching of cardinality at most $2t_v$ if and only if G has an AFS of cardinality at most t containing the unit v. Thus Theorem 4 can be stated in an equivalent manner as follows.

THEOREM 5. *Given a syndrome for a $t/(t+1)$-diagnosable system* S, *a unit $v \in U$ belongs to an* AFS *of cardinality at most t if and only if B_v has a maximum matching of cardinality at most* $2t_v$.

The above theorem suggests the following $t/(t+1)$-diagnosis algorithm.

```
ALGORITHM. Diagnosis of a $t/(t+1)$-diagnosable system
Step 1. Given a $t/(t+1)$-diagnosable system S and a valid syndrome, construct the
        bipartite graph $B = (U_B, E_B)$ with bipartition $(X, Y)$.
Step 2. Set $F = \phi$; for all $v \in U$, label $v$ unmarked.
Step 3. While there exists an unmarked $v \in U$
          begin
            3.1. Label $v$ marked.
            3.2. Set $t_v = t - |H_0(v)|$.
            3.3. Construct $B_v$ from $B$.
            3.4. Compute a maximum matching $K_v$ of $B_v$ using the Hopcroft/Karp al-
                 gorithm [14].
            3.5. If $|K_v| \leq 2t_v$ then add $v$ to $F$.
          end
Step 4. $F$ is the required set.
```

The proof of correctness of the above algorithm is as follows.

Essentially the algorithm proceeds as follows. Given a syndrome, for each unit $v \in U$ the algorithm tests if the cardinality of a maximum matching of B_v is at most $2t_v$. If unit v satisfies this requirement, then v is added to the set F. When the algorithm terminates we have

$$F = \{v : v \in U \text{ and } B_v \text{ has a maximum matching of cardinality at most } 2t_v\}.$$

Given a valid syndrome, in $t/(t+1)$-diagnosis we are required to isolate all faulty units to within a set of cardinality at most $t+1$. In other words, we need to determine the set of all units that are likely to be faulty under the given syndrome. By the definition of a $t/(t+1)$-diagnosable system, a unit v is likely to be faulty if and only if it belongs to an AFS of cardinality at most t. It then follows from Theorem 5 that a unit v is likely to be faulty if and only if B_v has a maximum matching of cardinality at most $2t_v$. The set F determined by the algorithm is therefore the required set consisting of all units that are likely to be faulty. By the definition of a $t/(t+1)$-diagnosable system, this set has cardinality at most $t+1$. Thus F is the required set isolating all the faulty units to within a set of cardinality at most $t+1$. This completes the proof of correctness of our $t/(t+1)$-diagnosis algorithm.

The bipartite graph in step 1 can be constructed in $O(n^{2.5})$ operations [5]. Step 2 requires $O(n)$ operations. The computation within step 3 is dominated by the computation of a maximum matching that requires $O(n^{2.5})$ operations [14]. Since step 3 is performed for each unit in U, the complexity of the entire algorithm is $O(n^{3.5})$.

5. Conclusions. In this paper we have studied the problem of diagnosing $t/(t+1)$-diagnosable systems. We presented a diagnosis for $t/(t+1)$-diagnosable systems that runs in $O(n^{3.5})$ time. This algorithm is based on the structure of allowable fault sets (§3) and on certain properties of $t/(t+1)$-diagnosable systems (§4).

IMPROVED ALGORITHMS FOR BIPARTITE NETWORK FLOW*

RAVINDRA K. AHUJA†, JAMES B. ORLIN‡, CLIFFORD STEIN§, AND ROBERT E. TARJAN¶

Abstract. In this paper, network flow algorithms for bipartite networks are studied. A network $G = (V, E)$ is called *bipartite* if its vertex set V can be partitioned into two subsets V_1 and V_2 such that all edges have one endpoint in V_1 and the other in V_2. Let $n = |V|$, $n_1 = |V_1|$, $n_2 = |V_2|$, $m = |E|$ and assume without loss of generality that $n_1 \leq n_2$. A bipartite network is called *unbalanced* if $n_1 \ll n_2$ and *balanced* otherwise. (This notion is necessarily imprecise.) It is shown that several maximum flow algorithms can be substantially sped up when applied to unbalanced networks. The basic idea in these improvements is a *two-edge push rule* that allows one to "charge" most computation to vertices in V_1, and hence develop algorithms whose running times depend on n_1 rather than n. For example, it is shown that the two-edge push version of Goldberg and Tarjan's FIFO preflow-push algorithm runs in $O(n_1 m + n_1^3)$ time and that the analogous version of Ahuja and Orlin's excess scaling algorithm runs in $O(n_1 m + n_1^2 \log U)$ time, where U is the largest edge capacity. These ideas are also extended to dynamic tree implementations, parametric maximum flows, and minimum-cost flows.

Key words. network flow, bipartite graphs, maximum flow, minimum-cost flow, parametric maximum flow, parallel algorithms

1. Introduction.

In this paper, we study network flow algorithms for bipartite networks. A network $G = (V, E)$ is called *bipartite* if its vertex set V can be partitioned into two subsets V_1 and V_2 such that all edges have one endpoint in V_1 and the other in V_2. Let $n = |V|$, $n_1 = |V_1|$, $n_2 = |V_2|$, $m = |E|$, and assume without loss of generality that $n_1 \leq n_2$. We call a bipartite network *unbalanced* if $n_1 \ll n_2$ and *balanced* otherwise. We show that several maximum flow algorithms can be substantially sped up when applied to *unbalanced networks*. At first glance, it may appear that unbalanced networks are of limited practical utility. This is not true, however. Gusfield, Martel, and Fernandez-Baca [21] have compiled a list of many practical applications of unbalanced networks. Further applications of unbalanced networks appear in [14].

Specialized bipartite flow algorithms for unbalanced networks were first studied by Gusfield, Martel, and Fernandez-Baca [21]. They developed modifications of the algorithms of Karzanov [25] and Malhotra, Pramodh Kumar, and Maheshwari (MPM)[27] for the maximum flow problem that improved their running times from $O(n^3)$ to $O(n_1^2 n_2)$. For the bounded degree case, i.e., when the degree of each vertex in V_2 is bounded by a fixed constant, they

developed a further modification of the MPM algorithm that runs in $O(n_1 m + n_1^3)$ time. We suggest several algorithms for the maximum flow problem on unbalanced networks that improve the running times of Gusfield et al. for all classes of unbalanced networks.

Gusfield [20] has shown that on a particular bipartite network in which each vertex in V_2 has constant degree, an algorithm similar to the FIFO preflow-push maximum flow algorithm of Goldberg and Tarjan [15],[16] runs in $O(n_1 m + n_1^3)$ time. Further, he observes that this result extends to parametric maximum flow; he solves a series of n_1 maximum flow problems in $O(n_1 m + n_1^3)$ time. We have similar results, which were obtained independently and apply to a more general class of networks.

We begin with the observation of Gusfield, Martel, and Fernandez-Baca [21] that the time bounds for several maximum flow algorithms automatically improve when the algorithms are applied *without modification* to unbalanced networks. A careful analysis of the running times of these algorithms reveals that the worst-case bounds depend on the number of edges in the longest vertex-simple path in the network. We call this the *path length* of the network and denote it by L. For a general network, L may be as large as $n - 1$; but, for a bipartite network, L is at most $2n_1 + 1$. Hence for unbalanced networks the path length is much less than n, and we get an automatic improvement in running times. As an example, consider Dinic's algorithm [10] for the maximum flow problem. This algorithm constructs $O(L)$ layered networks and finds a blocking flow in each one. Each blocking flow computation performs $O(m)$ augmentations and each augmentation takes $O(L)$ time. Consequently, the running time of Dinic's algorithm is $O(L^2 m)$. Thus, when applied to unbalanced networks, the running time of Dinic's algorithm improves from $O(n^2 m)$ to $O(n_1^2 m)$. Column 3 of Table 1.1 summarizes these improvements for several network flow algorithms.

We obtain further running-time improvements by modifying the algorithms. This modification applies only to preflow-push algorithms [2], [3], [14]–[17]; we call it the *two-edge push rule*. According to this rule, we always push flow from a vertex in V_1 and push flow on two edges at a time, in a step called a *bipush*, so that no excess accumulates at vertices in V_2. This rule allows us to charge all computations to examinations of vertices in V_1, though without this rule they might be charged to vertices in V_2. As an outcome of this rule, we develop algorithms whose running times depend on n_1 rather than n. We incorporate the two-edge push rule in several maximum flow algorithms, dynamic tree implementations, a parametric maximum flow algorithm, and algorithms for the minimum-cost flow problem. Column 4 of Table 1.1 summarizes the improvements obtained using this approach.

In the presentation to follow, we assume some familiarity with preflow-push algorithms and we omit many details, since they are straightforward modifications of known results. The reader interested in further details is urged to consult the appropriate paper or papers discussing the corresponding result for general networks or the book [1] or the survey paper [18].

2. Preliminaries.

2.1. Network definitions. Let $G = (V, E)$ be a directed bipartite network. We associate with each edge (v, w) in E a finite real-valued *capacity* $u(v, w)$. Let $U = \max\{u(v, w) : (v, w) \in E\}$. Let source s and sink t be the two distinguished vertices in the network. We make the assumption that $s \in V_2$ and $t \in V_1$. We further assume, without loss of generality, that if (v, w) is in E then so is (w, v), and that the network contains no parallel edges. We define the *edge incidence list* $I(v)$ of a vertex $v \in V$ to be the set of edges directed out of vertex v, i.e., $I(v) = \{(v, w) : (v, w) \in E\}$.

2.2. Flow. A *flow* is a function $f : E \to \mathbf{R}$ satisfying

$$f(v, w) \leq u(v, w) \quad \forall (v, w) \in E, \tag{2.1}$$

TABLE 1.1

A summary of the results discussed in this paper. Column 2 contains previously known results for general graphs. Column 3 gives bounds on bipartite networks based on the improved bound on L. Column 4 gives our new results based on the two-edge push rule.

Algorithm	Running time, general network	Running time, bipartite network	Running time, modified version
Maximum Flows			
Dinic [10]	n^2m	n_1^2m	does not apply
Karzanov [25]	n^3	n_1^2n[21]	$n_1m + n_1^3$
MPM [27]	n^3	n_1^2n[21]	does not apply
FIFO preflow-push [15], [16]	n^3	n_1^2n	$n_1m + n_1^3$
Highest label preflow-push [7]	$n^2\sqrt{m}$	$n_1n\sqrt{m}$	n_1m $+ \min\{n_1^3, n_1^2\sqrt{m}\}$
Excess scaling [2]	$nm + n^2 \log U$	$n_1m + n_1n \log U$	$n_1m + n_1^2 \log U$
Wave scaling [3]	$nm + n^2\sqrt{\log U}$	$n_1m + n_1n\sqrt{\log U}$	$n_1m + n_1^2\sqrt{\log U}$
FIFO w/ dynamic trees [15], [16]	$nm \log(\frac{n^2}{m})$	$n_1m \log(\frac{n^2}{m})$	$n_1m \log(\frac{n_1^2}{m} + 2)$
Parallel excess scaling [2]	$n^2 \log U \log(\frac{m}{n})$, $\lceil m/n \rceil$ processors	$n_1n \log U \log(\frac{m}{n})$, $\lceil m/n \rceil$ processors	$n_1^2 \log U \log(\frac{m}{n_1})$, $\lceil m/n_1 \rceil$ processors
Parametric Flows			
GGT [14]	n^3	n_1n^2	n_1^2n
GGT w/ dynamic trees [14]	$nm \log(\frac{n^2}{m})$	$n_1m \log(\frac{n^2}{m})$	$n_1m \log(\frac{n_1^2}{m} + 2)$
Min-Cost Flows			
Cost scaling [17]	$n^3 \log(nC)$	$n_1^2n \log(n_1C)$	$n_1m + n_1^3 \log(n_1C)$
Cost scaling w/ dynamic trees [17]	$nm \log(\frac{n^2}{m})$ $\cdot \log(nC)$	$n_1m \log(\frac{n^2}{m})$ $\cdot \log(n_1C)$	$n_1m \log(\frac{n_1^2}{m} + 2)$ $\cdot \log(n_1C)$

$$f(v, w) = -f(w, v) \quad \forall (v, w) \in E, \tag{2.2}$$

$$\sum_{v \in V} f(v, w) = 0 \quad \forall w \in V - \{s, t\}. \tag{2.3}$$

The *value* of a flow is the net flow into the sink, i.e.,

$$|f| = \sum_{v \in V} f(v, t).$$

The *maximum flow problem* is to determine a flow f for which $|f|$ is maximum.

2.3. Preflow. A *preflow* is a function $f : E \to \mathbf{R}$ that satisfies conditions (2.1), (2.2), and the following relaxation of condition (2.3):

$$\sum_{v \in V} f(v, w) \geq 0 \quad \forall w \in V - \{s\}. \tag{2.4}$$

The maximum flow algorithms described in this paper maintain a preflow during the computation. For a given preflow f, we define, for each vertex $w \in V$, the *excess* $e(w) = \sum_{v \in V} f(v, w)$. A vertex other than t with strictly positive excess is called *active*.

2.4. Residual capacity. With respect to a preflow f, we define the *residual capacity* $u_f(v, w)$ of an edge (v, w) to be $u_f(v, w) = u(v, w) - f(v, w)$. The *residual network* is the network consisting only of edges that have positive residual capacity.

2.5. Distance labels. A distance function $d : V \to \mathbf{Z}^+ \cup \{\infty\}$ with respect to the residual capacities $u_f(v, w)$ is a function mapping the vertices to the nonnegative integers. We say that a distance function is *valid* if $d(s) = 2n_1$, $d(t) = 0$, and $d(v) \leq d(w) + 1$ for every edge (v, w) in the residual network. We call a residual edge with $d(v) = d(w) + 1$ *eligible*. The eligible edges are exactly the edges on which we push flow.

We refer to $d(v)$ as the *distance label* of vertex v. It can be shown that if the distance labels are valid, then each $d(v)$ is a lower bound on the length of the shortest path from v to t in the residual network. If there is no directed path from v to t, however, then $d(v)$ is a lower bound on $2n_1$ plus the length of the shortest path from v to s. If, for each vertex v, the distance label $d(v)$ equals the minimum of the length of the shortest path from v to t and $2n_1$ plus the length of the shortest path from v to s, then we call the distance labels *exact*.

3. The generic preflow-push algorithm on bipartite networks. All maximum flow algorithms described in this paper are *preflow-push algorithms*, i.e., algorithms that maintain a preflow at every stage. They work by examining active vertices and pushing excess from these vertices to vertices estimated to be closer to t. If t is not reachable, however, an attempt is made to push the excess back to s. Eventually, there will be no excess on any vertex other than t. At this point the preflow is a flow, and moreover it is a maximum flow [15], [16]. The algorithms use distance labels to measure the closeness of a vertex to the sink or the source.

The generic preflow-push algorithm consists of a preprocessing stage followed by repeated application of a procedure called *push/relabel*. These two procedures appear in Fig. 3.1.

```
procedure preprocess
begin
    f = 0;
    push $u(s, v)$ units of flow on each edge $(s, v) \in I(s)$;
    compute the exact distance label function $d$ by
        backward breadth-first searches from $t$ and from $s$
        in the residual network;
end
procedure push/relabel($v$)
begin
    if there is an eligible edge $(v, w)$
    then
        begin select an eligible edge $(v, w)$;
            push $\delta = \min\{e(v), u_f(v, w)\}$ units of flow from $v$ to $w$
        end
    else replace $d(v)$ by $\min\{d(w) + 1 : (v, w) \in I(v)$ and $u_f(v, w) > 0\}$
end
```

FIG. 3.1. *Two procedures for the generic preflow-push algorithm.*

Increasing the flow on an edge is called a *push* through the edge. We say a push of δ units of flow on edge (v, w) is *saturating* if $\delta = u_f(v, w)$ and *nonsaturating* otherwise. A nonsaturating push at vertex v reduces $e(v)$ to zero. We refer to the process of increasing the distance label of a vertex as a *relabel* operation. The purpose of the relabel operation is to create at least one eligible edge on which the algorithm can perform further pushes.

Not specified in Fig. 3.1 is an efficient way to choose edges for pushing steps. We assume the same mechanism as that proposed by Goldberg and Tarjan [15], [16]. The algorithm maintains the incidence list $I(v)$ for each vertex v, and a pointer into each such list indicating a *current edge*. Initially the current edge of each incidence list is the first edge on the list. To perform *push/relabel*(v), the current edge pointer for v is moved through the list $I(v)$ until it indicates an eligible edge or it reaches the end of the list. In the former case, a push is done on the current edge. In the latter case, a relabel of v is done and the pointer is reset to indicate the first edge on $I(v)$. Figure 3.2 contains the algorithm *preflow-push*, which combines the two subroutines of Fig. 3.1. At the termination of the algorithm, each vertex in $V - \{s, t\}$ has zero excess; thus the final preflow is a flow. It is easy to establish that this flow is maximum. We shall briefly discuss the worst-case time complexity of the algorithm. (We refer the reader to the paper of Goldberg and Tarjan [16] for a complete discussion of the algorithm.)

```
algorithm preflow-push
begin
        preprocess;
        while the network contains an active vertex do
        begin
            select an active vertex $v$;
            push/relabel($v$)
        end
end
```

FIG. 3.2. *Algorithm* preflow-push.

We begin by stating two lemmas from [15] and [16].

LEMMA 3.1 [15], [16]. *The generic preflow-push algorithm maintains valid distance labels at each step. Moreover, each relabeling of a vertex v strictly increases $d(v)$.*

LEMMA 3.2 [15], [16]. *At any time during the preflow-push algorithm, for each vertex v with positive excess, there is a directed path from vertex v to vertex s in the residual network.*

Now we can derive the necessary results specific to bipartite networks.

COROLLARY 3.3. *For each active vertex v, $d(v) \leq 4n_1$.*

Proof. When a vertex v is relabeled, it has positive excess, and hence the residual network contains a path P from v to s. Since the vertices on this path are alternately in V_1 and V_2, the maximum possible length of the path is $2n_1$. Since $d(s) = 2n_1$ and, for every edge (w, x) on P, $d(w) \leq d(x) + 1$, it must be the case that $d(v) \leq d(s) + 2n_1 = 4n_1$. □

COROLLARY 3.4. *The number of relabel steps is $O(n_1 n)$. Further, the time spent performing relabels is $O(n_1 m)$. The time spent scanning edges while finding eligible edges on which to push flow is also $O(n_1 m)$.*

Proof. The first statement follows directly from Lemma 3.1 and Corollary 3.3. The second statement follows from the fact that in order to relabel a vertex v, we must look at all of the edges in $I(v)$. Hence, we can bound the total relabeling time by $O((\sum_{v \in V} |I(v)|)(4n_1)) = O(n_1 m)$. The same bound holds for the time spent finding edges on which to push flow. □

COROLLARY 3.5. *The preflow-push algorithm performs $O(n_1 m)$ saturating pushes.*

Proof. Between two consecutive saturating pushes on an edge (v, w), both $d(v)$ and $d(w)$ must increase by 2. By Lemma 3.1 and Corollary 3.3, only $O(n_1)$ saturating pushes can be done on (v, w). Summing over all edges gives the bound. □

LEMMA 3.6. *The preflow-push algorithm performs $O(n_1^2 m)$ nonsaturating pushes.*

Proof. Omitted. (Analogous to the proof of Lemma 3.10 in [16].) □

```
procedure bipush/relabel($v$)
begin
    if there is an eligible edge $(v, w)$
    then
        begin select an eligible edge $(v, w)$;
            if there is an eligible edge $(w, x)$
            then
                begin select an eligible edge $(w, x)$;
                    push $\delta = \min\{e(v), u_f(v, w), u_f(w, x)\}$ units of flow
                        along the path $v - w - x$
                end
            else replace $d(w)$ by $\min\{d(x) + 1 : (w, x) \in I(w)$ and $u_f(w, x) > 0\}$
        end
    else replace $d(v)$ by $\min\{d(w) + 1 : (v, w) \in I(v)$ and $u_f(v, w) > 0\}$
end
```

FIG. 3.3. *The procedure* bipush/relabel.

The results in column 3 of Table 1.1 for preflow-push algorithms all follow from the known results by using Corollaries 3.4 and 3.5 to replace certain $O(n)$ bounds in the general case with $O(n_1)$ bounds in the bipartite case. Since all these results are straightforward to obtain and are dominated by those in column 4, we omit their derivations and move on to the more interesting results in column 4.

4. The bipartite preflow-push algorithm. The basic idea behind the bipartite preflow-push algorithm is to perform bipushes from vertices in V_1. A *bipush* is a push over two consecutive eligible edges; it moves excess from a vertex in V_1 to another vertex in V_1. This approach has all the advantages of the usual approach, and the additional advantage that it leads to improved running times. This approach ensures that no vertex in V_2 ever has any excess. Since all the excess resides at vertices in V_1, it suffices to account for the nonsaturating bipushes emanating from vertices in V_1. Since $|V_1| \leq |V_2|$, the number of nonsaturating bipushes is reduced.

The bipartite preflow-push algorithm is a simple generalization of the generic preflow-push algorithm. The bipartite algorithm is the same as the generic algorithm given in §3 except that the procedure *bipush/relabel* appearing in Fig. 3.3 replaces the procedure *push/relabel* in the original algorithm. The algorithm identifies eligible edges emanating from a vertex using the current edge data structure described earlier.

We call a push of δ units on the path $v - w - x$ a *bipush*. The bipush is *saturating* if $\delta = \min\{u_f(v, w), u_f(w, x)\}$ and *nonsaturating* otherwise. Observe that a nonsaturating bipush reduces the excess at vertex v to zero. The following lemma is an easy consequence of the two-edge push rule implemented in *bipush/relabel*.

LEMMA 4.1. *During the execution of the bipartite preflow-push algorithm, all excess remains on the vertices in* V_1.

Proof. The first thing the algorithm does is to saturate all edges leaving s. Since $s \in V_2$, the claim is true immediately after this step. All the other pushes in the algorithm are done using the procedure *bipush/relabel*, which pushes from a vertex in V_1 through a vertex in V_2 to another vertex in V_1, never leaving any excess on a vertex in V_2. No other operations create excess at any vertex. □

As in the original preflow-push algorithm, the bipartite preflow-push algorithm always pushes flow on eligible edges and relabels a vertex only when there are no eligible edges emanating from it. Hence Lemma 3.1 holds for this algorithm too. Lemma 3.2 also holds. Corollary 3.3 holds for vertices in V_1, but a modified version holds for vertices in V_2: if $v \in V_2$, then either $d(v) \leq 4n_1 + 1$ or $d(v) = \infty$. Corollary 3.4 holds as stated. Corollary 3.5

translates into a bound of $O(n_1 m)$ saturating bipushes. The Lemma 3.6 bound of $O(n_1^2 m)$ on nonsaturating pushes becomes a bound of $O(n_1^2 m)$ on nonsaturating bipushes. Thus we get the following result.

THEOREM 4.2. *The bipartite preflow-push algorithm runs in $O(n_1^2 m)$ time.*

We now define the concept of a *vertex examination*. In an iteration, the generic bipartite preflow-push algorithm selects an active vertex v and performs a saturating bipush or a nonsaturating bipush or relabels a vertex. In order to develop more efficient algorithms, we incorporate the rule that whenever the algorithm selects an active vertex $v \in V_1$, it keeps pushing flow from that vertex until either its excess becomes zero or it is relabeled. Consequently, there may be several saturating bipushes followed either by a nonsaturating bipush or a relabel operation; there will in general also be relabelings of vertices in V_2. We associate this sequence of operations with a vertex examination. We shall henceforth assume that the bipartite preflow-push algorithm follows this rule.

5. Specific implementations of the bipartite preflow-push algorithm. The bottleneck in the bipartite preflow-push algorithm is the time spent doing nonsaturating bipushes. There are two orthogonal approaches to reducing this time. One approach is to reduce the number of nonsaturating bipushes by selecting the vertices for *bipush/relabel* operations cleverly. We shall consider several such selection rules in §§5.1–5.4. The second approach is to reduce the time spent per nonsaturating bipush. The idea is to use a sophisticated data structure in order to push flow along a whole path in one step, rather than pushing flow along a single pair of edges. We shall study this approach in §5.5. Finally, in §5.6 we study a parallel implementation of one version of the bipartite preflow-push algorithm.

5.1. The first-in first-out (FIFO) algorithm. The FIFO preflow-push algorithm examines active vertices in first-in, first-out (FIFO) order. The algorithm maintains a queue Q of active vertices. It selects a vertex v from the front of Q and performs pushes from v while adding newly active vertices to the rear of Q. The algorithm examines v until either it becomes inactive or it is relabeled. In the latter case, v is added to the rear of Q. The algorithm terminates when Q is empty. Goldberg and Tarjan [17] showed that the FIFO algorithm performs $O(n^3)$ nonsaturating pushes. We show, using a similar analysis, that the number of nonsaturating bipushes in the bipartite case is $O(n_1^3)$.

For the purpose of the analysis, we partition the sequence of vertex examinations into several *passes*. The first pass consists of examining the vertices that become active during the *preprocess* step. For $k \geq 2$, the kth pass consists of examining all vertices that were added to the queue during the $k - 1$st pass.

LEMMA 5.1. *The number of passes over Q is $O(n_1^2)$.*

Proof. Let $\Phi = \max\{d(v) | v \text{ is active}\}$. The initial value of Φ is at most $4n_1$. Consider the effect that a pass over Q can have on Φ. If, during the pass, no vertex in V_1 is relabeled, then the excess at every vertex is pushed to a vertex with a distance label smaller by at least two, and consequently Φ decreases by at least two. If some vertex in V_1 is relabeled during the pass, however, then Φ can increase or remain the same. In such a case the increase in Φ is bounded by the largest increase in any distance label. Hence, by Corollary 3.3, the total increase in Φ over all passes is at most $4n_1^2$. Consequently, the total number of passes is $O(n_1^2)$. □

Now observe that any pass examines each vertex in V_1 at most once and each vertex examination performs at most one nonsaturating bipush. Consequently, the algorithm performs $O(n_1^3)$ nonsaturating bipushes. We noted in the previous section that all other operations take $O(n_1 m)$ time. Thus we obtain the following result.

THEOREM 5.2. *The bipartite* FIFO *preflow-push algorithm runs in $O(n_1m + n_1^3)$ time.*

We note that this bound is also achieved by Karzanov's algorithm [25] if it is implemented using the two-edge push rule. A modification of Karzanov's algorithm by Tarjan [36], which he calls the *wave algorithm*, also has the same time bound. The analysis of both of these algorithms is straightforward and hence omitted.

5.2. The highest-label preflow-push algorithm. The highest-label preflow-push algorithm always pushes from an active vertex with highest distance label. This rule can be implemented using a simple bucketing approach so that the overhead for vertex selection is $O(n_1^2)$. The nonsaturating bipushes performed by the algorithm can be divided into passes. A *pass* consists of all bipushes that occur between two consecutive relabel steps of vertices in V_1. Within a pass, vertices in V_2 can possibly be relabeled several times. Notice that in this algorithm, excesses that are most distant from the sink are pushed down two levels at a time. Consequently, if the algorithm does not relabel any vertex during n_1 consecutive vertex examinations, all excess reaches the sink and the algorithm terminates. Since the algorithm performs $O(n_1^2)$ relabel operations on vertices in V_1, we immediately obtain a bound of $O(n_1^3)$ on the number of vertex examinations. As each vertex examination entails at most one nonsaturating bipush, this gives a bound of $O(n_1^3)$ on the number of nonsaturating bipushes and a bound of $O(n_1m + n_1^3)$ on the running time of the algorithm.

Cheriyan and Maheshwari [7] showed by a clever argument that the highest label preflow-push algorithm performs $O(n^2\sqrt{m})$ nonsaturating pushes for general networks. Modifying their argument to fit the bipartite case, we obtain a running time of $O(n_1m + \min\{n_1^3, n_1^2\sqrt{m}\})$. This improves the above bound of $O(n_1m + n_1^3)$ if $\sqrt{m} < n_1$. We shall give a potential-based argument that is slightly different from the analysis of Cheriyan and Maheshwari.

We focus on the set of edges that are both current and eligible; we call these edges *live*. Recall that an edge (v, w) is eligible if it has positive residual capacity and $d(v) = d(w) + 1$; (v, w) is current if the current edge pointer for vertex v indicates (v, w). Each vertex has at most one outgoing live edge, and the live edges form no cycles since $d(v) > d(w)$ if (v, w) is a live edge. Thus the set of live edges defines a forest, which we call the *live forest*. We call an active vertex *maximal* if it has no active proper descendant in the live forest. For a vertex v, let $desc(v)$ be the number of descendants of v in the live forest, including v itself, that are in V_1. Let p be a positive integer parameter whose value we shall choose later. For a maximal active vertex v, we define the *uncounted cost* $c(v)$ of v to be $\min\{0, desc(v) - p\}$. For any vertex v that is not maximal active, we define $c(v) = 0$. We use the sum $\sum_{v \in V_1} c(v)$ to help bound the number of nonsaturating bipushes.

We wish to count nonsaturating bipushes. Our strategy is to charge nonsaturating bipushes against changes in current edges, relabelings, increases in the total uncounted cost, and certain other events. We shall obtain an overall bound of $O(n_1mp + n_1^3/p)$ on the number of nonsaturating bipushes. Choosing $p = \max\{1, \lceil n_1/\sqrt{m}\rceil\}$ then gives a bound of $O(\min\{n_1m + n_1^3, n_1^2\sqrt{m}\})$ on the number of nonsaturating bipushes.

Define a *pass* of the algorithm to be a maximal interval of time during which all vertices selected for *bipush/relabel* steps have the same distance label. A pass terminates either when a relabeling occurs or when all excess at vertices with maximum distance label is moved to vertices of distance label lower by two.

LEMMA 5.3. *The total number of nonsaturating bipushes is $O(n_1mp + n_1^3/p)$.*

Proof. An argument like that in Lemma 5.1 shows that the total number of passes is $O(n_1^2)$. Consider the nonsaturating bipushes that occur during a pass. Every vertex from which a bipush occurs is maximal active. For a vertex v, call a nonsaturating bipush from v *large* if $c(v) = 0$ before the bipush and *small* otherwise. Two vertices v and w from which

```
algorithm bipartite excess scaling
begin
    preprocess;
    $\Delta = 2^{\lceil \log U \rceil}$;
    while $\Delta \geq 1$ do
    begin
        while the network contains a vertex $v \in V_1$
            with excess greater than $\Delta/2$ do
        begin
            among vertices with excess exceeding $\Delta/2$,
                select a vertex $v$ with smallest distance label;
            perform bipush/relabel($v$)
                (modified to ensure that no excess exceeds $\Delta$)
        end;
        $\Delta = \Delta/2$
    end
end
```

FIG. 5.1. Bipartite excess scaling *algorithm.*

nonsaturating bipushes occur during the pass have disjoint sets of descendants in the live forest. If a large bipush occurs from a vertex v, v has at least p V_1-descendants before the bipush. Since the total number of vertices in V_1 is n_1, there can be at most n_1/p large bipushes during the pass.

The following argument shows that every small nonsaturating bipush causes an increase of at least one in the total uncounted cost. Consider such a bipush from a vertex v to a vertex x. The bipush causes vertex v to become inactive and may cause vertex x to become maximal active; no other vertex can become maximal active. If x becomes maximal active, the total uncounted cost increases by at least one, because $desc(x) > desc(v)$ and $desc(v) < p$. If x does not become maximal active, then the total uncounted cost still increases by at least one, since the negative term $desc(v) - p$ is removed from the total uncounted cost.

We conclude that there are $O(n_1^3/p)$ nonsaturating bipushes (the large ones) plus those accounted for by increases in the total uncounted cost. It remains to bound the sum of all increases in the total uncounted cost. The total uncounted cost remains between $-pn_1$ and zero. A nonsaturating bipush cannot decrease the total uncounted cost. A saturating bipush or a relabeling or a change in a current edge can reduce the total uncounted cost by at most $O(p)$, since any such operation affects only $O(1)$ maximal active vertices. We conclude that the sum of all decreases in the total uncounted cost is $O(n_1 mp)$, and so is the sum of all increases in the total uncounted cost. The lemma follows. □

THEOREM 5.4. *The highest label preflow-push algorithm runs in* $O(n_1 m + \min\{n_1^3, n_1^2\sqrt{m}\})$ *time.*

Proof. Immediate from Lemma 5.3 by choosing $p = \max\{1, \lceil n_1/\sqrt{m}\rceil\}$. □

5.3. The excess scaling algorithm. The *excess scaling* algorithm, due to Ahuja and Orlin [2], incorporates scaling of the excesses into the generic preflow-push algorithm, thereby reducing the number of nonsaturating pushes from $O(n^2 m)$ to $O(n^2 \log U)$. The basic idea is to push flow from active vertices with sufficiently large excess to vertices with sufficiently small excess while never letting the excesses become too large. We shall develop an adaptation of the excess scaling algorithm for bipartite networks, which we call the *bipartite excess scaling algorithm.* This algorithm, in contrast to the algorithms in §§5.1 and 5.2, requires that the edge capacities be integral.

Fig. 5.1 describes the bipartite excess scaling algorithm. The algorithm uses the same *bipush/relabel* step as the generic bipartite preflow-push algorithm but with one slight difference. If $x \neq t$, instead of pushing $\delta = \min\{e(v), u_f(v, w), u_f(w, x)\}$ units of flow, it pushes $\delta = \min\{e(v), u_f(v, w), u_f(w, x), \Delta - e(x)\}$ units, where Δ is a positive *excess bound* maintained by the algorithm. This change ensures that the algorithm permits no excess on an active vertex to exceed Δ units. Since Δ is integral until the algorithm terminates, all excesses remain integral, which implies that on termination only s and t can have nonzero excess. This implies that the algorithm is correct.

LEMMA 5.5. *The bipartite excess scaling algorithm maintains the following three invariants:*

1. *No vertex in V_2 ever has positive excess.*
2. *Any bipush that does not saturate an edge moves at least $\Delta/2$ units of flow.*
3. *No vertex ever has excess greater than Δ.*

Proof. Invariant 1 is satisfied because the bipartite excess scaling algorithm is a special case of the generic algorithm and the generic algorithm satisfies it. For invariants 2 and 3, see [2] and [3]. □

We can use these invariants to establish a bound on the number of nonsaturating bipushes. We define a *scaling phase* to be a maximal period of time during which Δ does not change.

LEMMA 5.6. *The bipartite excess scaling algorithm performs $O(n_1^2 \log U)$ nonsaturating pushes and runs $O(n_1 m + n_1^2 \log U)$ time.*

Proof. As in [3], we consider the potential function $\Phi = \sum_{v \in V} \frac{e(v)d(v)}{\Delta}$, which by invariant 1 is the same as $\sum_{v \in V_1} \frac{e(v)d(v)}{\Delta}$. By invariant 3, at the beginning of a scaling phase, $\Phi \leq 4n_1^2$. The actions of the algorithm consist of bipushes and relabels. We consider the two cases separately.

Case 1. A relabel occurs. If a vertex in V_2 was relabeled, Φ remains unchanged. If a vertex in V_1 was relabeled, Φ increases by at least one. By Corollary 3.3, such increases sum to $O(n_1^2)$. (This bound actually applies to the whole algorithm, not just one scaling phase.)

Case 2. A bipush occurs. This must decrease Φ. If the bipush is nonsaturating, then by invariant 2, it moves at least $\frac{\Delta}{2}$ units of flow to a vertex with distance label two units lower, so Φ decreases by at least 1. As the initial value plus the total increase to Φ are $O(n_1^2)$, Φ can decrease by $O(n_1^2)$ per scaling phase, which means there are $O(n_1^2)$ nonsaturating pushes per scaling phase.

Observe that originally $\Delta < 2U$, where U is the maximum capacity in the network, and that when Δ decreases below 1, the algorithm terminates. In each scaling phase, Δ decreases by a factor of 2, so there are $O(\log U)$ scaling phases. Thus the total number of nonsaturating pushes is $O(n_1^2 \log U)$.

The running time of the algorithm is $O(n_1 m + n_1^2 \log U)$ plus the time required to select the smallest distance vertices for *push/relabel* steps. The bucket-based data structure described in [3] makes the total time for vertex selection $O(n_1 m + n_1^2 \log U)$. □

5.4. Variants of excess scaling. Ahuja, Orlin, and Tarjan [3] have developed two variants of the excess scaling algorithm that achieve improved time bounds. The faster of these, called the *wave scaling algorithm*, runs in $O(nm + n^2\sqrt{\log U})$ time. The idea of bipushes can easily be incorporated into both of their algorithms, thereby improving the running times for bipartite networks. The following theorem states the running time of the bipartite wave scaling algorithm.

THEOREM 5.7. *The bipartite wave scaling algorithm runs in $O(n_1 m + n_1^2\sqrt{\log U})$ time.*

The derivation of this time bound is similar to that of the excess scaling algorithm. The analysis of the original algorithm uses arguments based on potential functions defined over the vertex set V. For bipartite networks, we define the potential functions over the set V_1 and are able to replace n by n_1 in the running time. The detailed proof of this theorem is quite lengthy but contains no new ideas; therefore we omit it. A similar improvement can be obtained in Ahuja, Orlin, and Tarjan's less efficient algorithm, called the *stack scaling algorithm*.

5.5. Dynamic trees. In the previous four sections, we reduced the time needed to compute a maximum flow by reducing the number of nonsaturating pushes. In this section, we consider a different approach: we reduce the time spent per nonsaturating push. The idea is to use a sophisticated data structure in order to push flow along a whole path in one step, rather than pushing flow along a single edge. The *dynamic tree* data structure of Sleator and Tarjan [34], [33], [37] is ideally suited for this purpose.

The dynamic tree data structure allows the maintenance of a collection of vertex-disjoint rooted trees, each edge of which has an associated real value. We adopt the convention that tree edges are directed towards the root. We denote the parent of v by $p(v)$ and regard each vertex as an ancestor and descendent of itself. We call a dynamic tree *trivial* if it contains only one V_2-vertex and *nontrivial* otherwise. The data structure supports the operations in Fig. 5.2. It is shown in [34] that if the maximum number of vertices in any tree is k, we can perform an arbitrary sequence of l tree operations in $O(l \log k)$ time.

make-tree(v)	Make vertex v into a one-vertex dynamic tree.
find-root(v)	Return the root of v's tree.
find-size(v)	Return the number of vertices in v's tree.
find-value(v)	Return the value of the tree edge from v to its parent. Return ∞ if v is a root.
find-min(v)	Return the ancestor w of v with minimum *find-value*(w). In case of a tie, choose the w closest to the root. Choose v if v is the root.
change-value(v, z)	Add z to the value of every edge from v to *find-root*(v).
link(v, w, x)	Combine the trees containing v and w by making w the parent of v and giving edge (v, w) the value x. Do nothing if v and w are in the same tree or if v is not a root.
cut(v)	Break v's tree into two trees, by deleting the edge joining v and v's parent. Do nothing if v is a root.

FIG. 5.2. *Dynamic tree operations.*

In maximum flow algorithms, the dynamic tree edges are a subset of the *current edges*. The value of a tree edge is its residual capacity. We maintain the invariant that every active vertex is a dynamic tree root. For this section, we relax the invariant that all excess is on vertices in V_1 and allow excess to accumulate on vertices in V_2.

The key to the dynamic tree implementation is the *tree-push/relabel* operation in Fig. 5.3. The operation is applied to an active vertex v. If there is an eligible edge (v, w) then the operation adds (v, w) to the forest of dynamic trees, pushes as much flow as possible from v to the root of the tree containing w, and then deletes from the forest all edges which are saturated by this push. Otherwise, v is relabeled and its children are cut off. We refer to the operation of pushing flow from a node of a dynamic tree to the root as a *tree-push*.

The first dynamic tree algorithm we consider is just the generic *preflow-push* algorithm with the *push/relabel* operation replaced by the *tree-push/relabel* operation of Fig. 5.3. We modify the initialization so that each vertex is in its own one-vertex dynamic tree and we add a post-processing step which extracts the correct flow on each edge that remains in a dynamic tree. We call this algorithm the *generic bipartite dynamic tree* algorithm.

The correctness of this algorithm is straightforward to verify (see [15] and [16]). We show that this implementation yields an efficient algorithm.

```
      procedure tree-push/relabel($v$)
      begin
          if there is an eligible edge $(v, w)$
          then
              begin $link(v, w, u_f(v, w))$
                  $p(v) \leftarrow w$
                  $\delta \leftarrow \min\{e(v), find\text{-}value(find\text{-}min(v))\}$
                  $change\text{-}value(v, -\delta)$
(*)               while $v \neq find\text{-}root(v)$ and $find\text{-}value(find\text{-}min(v)) = 0$ do
                      begin $z \leftarrow find\text{-}min(v)$
(**)                      $cut(z)$
                      end
              end
          else begin replace $d(v)$ by $\min\{d(w) + 1 : (v, w) \in I(v)$ and $u_f(v, w) > 0\}$
(†)               for all children $y$ of $v$ do
(‡)                   $cut(y)$
              end
      end
```

FIG. 5.3. *The tree-push/relabel operation.*

LEMMA 5.8. *The number of* tree-push/relabel *operations done by the generic bipartite dynamic tree algorithm is $O(n_1 m)$.*

Proof. Each *tree-push/relabel* operation either relabels a vertex or pushes flow along a tree path. If it pushes flow then it must either saturate an edge or decrease the number of tree roots by one. By Corollaries 3.4 and 3.5 a relabeling or an edge saturation can occur at most $O(n_1 m)$ times. Furthermore the total increase in the number of tree roots caused by such operations is $O(n_1 m)$. Thus a push which decreases the number of tree roots by one can occur at most $O(n_1 m + n)$ times, which is the sum of the number of times the number of tree roots can increase by one plus the number of initial tree roots. □

Recalling the assumption about vertex examinations that bounds the time spent deciding which vertex and edge to process, we get the following theorem.

THEOREM 5.9. *The generic bipartite dynamic tree algorithm runs in $O(n_1 m \log n)$ time.*

Proof. Each call to *tree push/relabel* does $O(1)$ dynamic tree operations and then executes the *while* loop in line (*) or the *for* loop in line (†) a number of times. Each execution of the *while* loop takes $O(1)$ dynamic tree operations, and the *while* loop is executed at most $O(n_1 m)$ times over the course of the whole algorithm, since each *cut* in line (**) corresponds to a saturating push. Similarly the *cuts* in line (‡) correspond to edges looked at while relabeling and by Corollary 3.4 there are only $O(n_1 m)$ of these. Thus the algorithm performs $O(n_1 m)$ dynamic tree operations. Since the maximum tree size is n, the algorithm takes $O(n_1 m \log n)$ time. □

Note that we have used the fact that the number of links, the number of cuts, the number of saturating pushes, and the relabeling time are all $O(n_1 m)$.

5.5.1. Further improvements. While for many values of n, n_1, m, and U, the bound given by Theorem 5.9 is an improvement over those of the algorithms in the previous four sections, it is possible to use dynamic trees in a more sophisticated manner to achieve a running time of $O(n_1 m \log((n_1^2/m) + 2))$. In order to realize this bound, we must overcome a few obstacles. First, as in [3], [15], and [16], we need to limit the tree size. Moreover, we need to make the tree size bound solely a function of n_1 rather than n. Finally, we must deal with the fact that a *cut* can make a V_2-vertex a tree root. This leaves open the possibility that a V_2-vertex will become active, thus violating one of the invariants we have previously maintained. We see no way to avoid this—instead we control how this happens and use a fairly complicated analysis to show that we can achieve the desired time bounds.

To ensure that the tree size is a function of n_1 and not n, we use the following.

LEMMA 5.10. *If all the leaves in a nontrivial dynamic tree are V_1-vertices, then the number of vertices in the tree is at most twice the total number of V_1-vertices in the tree.*

Proof. Since no V_2-vertex is a leaf, all V_2-vertices have at least one child. The graph is bipartite, which means that all these children must be V_1-vertices. Therefore, the total number of V_1 vertices in the tree must be at least as large as the total number of V_2-vertices. □

We will use two rules to enforce this invariant. First, if a *link* operation could make a V_2-vertex a leaf, we do not perform that *link*. This rule will be respected in all the procedures that follow. Second, if a *cut* causes a V_2-vertex to become a leaf, we immediately cut that vertex from the tree. This idea is implemented in procedure *bi-cut*, which appears in Fig. 5.4. Procedure *bi-cut* will be used in place of *cut*. Observe that procedure *bi-cut* performs at most two dynamic tree operations.

```
procedure bi-cut($v$)
begin
    if $v \in V_1$
    then cut($p(v)$)
    cut($v$)
end
```

FIG. 5.4. *The bi-cut operation.*

We also want to maintain the invariant that no tree have more than k vertices (k will be chosen later). As in [15] and [16] we achieve this by preceding each *link* operation by a calculation of whether or not the result of the link will be a tree of greater than k vertices. If so, we do not perform the link. Since trees only grow as the result of *link* operations, it is clear that this maintains the desired invariant.

The main problem left to address is the complexity added by allowing excess to remain on V_2-vertices. In general, this yields slower running times. We maintain the following invariant, however.

INVARIANT 5.11. *Whenever a V_2-vertex is relabeled, it does not have any excess on it.*

As we shall see, this will allow us to get a good bound on the number of tree operations.

To maintain this invariant we need to ensure that we always have the flexibility to send all the excess from a V_2-vertex out over the current edge. The following lemma gives a condition sufficient to guarantee this flexibility.

LEMMA 5.12. *Let out-cap(v) be the residual capacity of the current edge of v. If for all V_2-vertices v that are dynamic tree roots, we maintain that*

$$e(v) \leq \textit{out-cap}(v) \tag{5.1}$$

and that the current edge of v is eligible, then Invariant 5.11 *can be satisfied with* $O(1)$ *additional work per tree-push or relabeling operation.*

Proof. The left side of (5.1) can change when we do a push that involves v, and the right side can change when the current edge of v changes. We deal with these two cases separately. When doing a tree-push that terminates at a root r that is a V_2-vertex we must ensure that the new excess does not exceed *out-cap*(r). To do this we simply push less flow. This idea is captured in a new procedure called *bi-send*, which appears in Fig. 5.5. This procedure will be used whenever we want to push flow along a path from a tree vertex to the root.

```
procedure bi-send(v)
begin
        $f \leftarrow$ find-root(v)
        if $r \in V_1$
        then
                $\delta \leftarrow \min\{e(v), \textit{find-value}(\textit{find-min}(v))\}$
        else
(*)             $\delta \leftarrow \min\{e(v), \textit{find-value}(\textit{find-min}(v)), \textit{out-cap}(r) - e(r)\}$
        change-value(v, $-\delta$)
        while $v \neq$ find-root(v) and find-value(find-min(v)) $= 0$ do
                begin $z \leftarrow$ find-min(v)
                        bi-cut(z)
                end
end
```

FIG. 5.5. *The bi-send operation.*

Next we have to deal with the case when *out-cap*(v) changes. Let (v, w) be the current edge of v. The value of *out-cap*(v) may change in two different ways. One way is that (v, w) may become saturated. When this happens, invariant (5.1) implies that the push saturating (v, w) rids v of all its excess. After the push, we advance the current edge pointer of v to the next eligible edge, doing a relabeling if necessary. The second case is that w may be relabeled, thus making (v, w) ineligible. The current edge pointer of v is advanced to the next eligible edge; for this new edge, (5.1) may be violated, however. To handle this case, we always push flow over edge (v, w) before relabeling w. This change is summarized in procedure *bi-relabel*(w), which appears in Fig. 5.6. Observe that since all edges incident to w must be inspected in order to relabel w, procedure *bi-relabel* runs in the same asymptotic time as procedure *relabel*.

```
procedure bi-relabel(w)
begin
        if $w \in V_1$
        then for all $v$ s.t. the current edge of $v$ is $(v, w)$ do
                        push $e(v)$ units of flow over edge $(v, w)$
        replace $d(v)$ by $\min\{d(w) + 1 : (v, w) \in I(v)$ and $u_f(v, w) > 0\}$
        for all children $y$ of $v$ do
                bi-cut(y)
end
```

FIG. 5.6. *The bi-relabel operation.*

What we have shown is that whenever the current edge pointer of $w \in V_2$ advances, there is no excess at w. Since this pointer advances to the end of the list before a relabel, it must be true that at the time of a relabel there is no excess on w. Further, the only algorithmic changes are the change in line (*) of *bi-send*, which adds $O(1)$ work per tree push, the change in *bi-relabel*, which adds $O(1)$ work per relabel, and a change in the current edge advancement procedure, to make sure that current edges from V_2-vertices are always eligible. □

Given these building blocks we can give the procedure *bi-tree push/relabel*, which incorporates all of these ideas. The procedure appears in Fig. 5.7. The basic idea is similar to that used in [3], [15], and [16], in that we do a tree-push, but only perform a *link* if the size of the resulting tree is not too large. We also have the additional constraint of not performing a *link* that will cause a V_2-vertex to become a leaf. This leads to lines (T1) through (T2) of *bi-tree push/relabel* which handle the case when we are pushing from a trivial dynamic tree. In this case we first push flow over v's eligible edge (v, w). Then we do a *bi-send*(w) and proceed as if we had started at the root of w's dynamic tree. We also make one technical change and use a procedure called *bi-send** instead of *bi-send* in line (TB). Procedure *bi-send** differs from *bi-send* in that it defers doing its *cuts* until line (**) of procedure *bi-tree push/relabel.* This is done in order to avoid the case that the *link* performed in line (†) is linking a trivial dynamic tree, as this would make a V_2-vertex a leaf. (This is done purely for ease of presentation and is not necessary.)

```
procedure bi-tree-push/relabel($v$)
begin
        if there is an eligible edge ($(v, w)$)
(T1)    then begin if $v$ is a trivial $V_2$ tree
                   then begin push flow on edge $(v, w)$
                              $r \leftarrow$ find-root($w$)
(TB)                          bi-send*($w$)
                              if there is an eligible edge $(r, q)$
                              then begin $v \leftarrow r$
                                         $w \leftarrow q$
                                   end
                              else bi-relabel($r$)
(T2)                    end

                   if find-size($v$) + find-size($w$) $\leq k$
(†)                then begin link($v$, $w$, $u_f(v, w)$)
                              $p(v) \leftarrow w$
                        end
(*)                else begin push flow on edge $(v, w)$
                              bi-send($w$)
(**)                          Perform the cuts from line (TB) (there may be none)
                        end
             end
        else
             bi-relabel($v$)
end
```

FIG. 5.7. *The bi-tree-push/relabel procedure.*

We now use procedure *bi-tree-push/relabel* in a FIFO algorithm. We call this the *FIFO bipartite dynamic tree algorithm.*

Since, by Invariant 5.11, whenever a V_2-vertex is relabeled it has no excess, we can derive a bound of $O(n_1^2)$ passes over the queue, by a proof similar to that of Lemma 5.1. Define a *vertex activation* to be the event that either a vertex with zero excess receives positive excess, or a vertex with positive excess is relabeled. This corresponds to a vertex being placed on the queue. We will need to bound the number of times this occurs.

First, we give a lemma, the proof of which is simliar to that of Lemma 5.8 and Theorem 5.9, with the additional observation that the time spent in an iteration of *bi-tree-push/relabel* is within a constant factor of the amount of work done by *tree-push/relabel.*

LEMMA 5.13. *The FIFO bipartite dynamic tree algorithm runs in* $O(n_1 m \log k)$ *time plus* $O(\log k)$ *time per vertex activation.*

All that remains is to bound the number of vertex activations. First we introduce some terminology. We denote the tree containing vertex v by T_v. We call a tree *large* if the number of nodes in the tree is at least $k/2$. As a consequence of Lemma 5.10, there are only $2n_1$ vertices in all the nontrivial dynamic trees, hence there are no more than $4n_1/k$ large trees at any time. In particular we will use the fact that there are $O(n_1/k)$ large trees at the beginning of a pass over the queue.

LEMMA 5.14. *The number of vertex activations is* $O(n_1 m + n_1^3/k)$.

Proof. By Invariant 5.11, all V_2-vertices have zero excess when relabeled, thus the only vertex activations due to relabelings are from V_1-vertices. There are at most $O(n_1^2)$ of these.

There can be only $O(n_1 m)$ vertex activations for which the corresponding *bi-tree-push/relabel* executions perform a *cut* or *link* or a saturating push in line (*).

It remains to count the vertex activations for which the corresponding invocation of *bi-tree-push/relabel* does neither a cut nor a link nor a saturating push. If this occurs then it must be that *find-size*(v) +*find-size*$(w) \geq k$, i.e., either T_v or T_w is large. We consider the two cases separately.

Suppose T_v is large. Vertex v is the root of T_v. Since the push is nonsaturating, it must rid v of all its excess. If T_v has changed since the beginning of the current pass, we charge the activation to the *link* or *cut* that most recently changed T_v. This occurs at most once per *cut* and twice per *link* for a total of $O(n_1 m)$ time overall. If T_v has not changed since the beginning of the pass, we charge the activation to T_v. There are at most $O(n_1/k)$ large trees at the start of a pass, hence this case counts for $O(n_1^3/k)$ charges overall.

Suppose T_w is large. In this case the root r of T_w may be added to the queue. As before, if T_w changed during the pass we charge the activation to the *link* or *cut* which caused it, otherwise we charge it to the large tree.

We have ignored so far the possible activations in lines (T1) through (T2). It is easy to verify that these only add a constant factor to the bounds mentioned above. The reason for adding this case is to ensure that in every iteration either a *link*, *cut*, or saturation is performed, or a large tree is involved. This additional case allows us to ensure this with no asymptotic loss in the running time of the procedure.

Combining all these cases we get $O(n_1 m + n_1^3/k)$ vertex activations. □

THEOREM 5.15. *The* FIFO *bipartite dynamic tree algorithm runs in* $O(n_1 m \log((n_1^2/m) + 2))$ *time.*

Proof. Apply Lemmas 5.13 and 5.14 and choose $k = (n_1^2/m) + 2$. □

5.6. A parallel implementation. In this section, we give a parallel implementation of the bipartite excess scaling algorithm. Our model of computation is an exclusive-read exclusive-write parallel random access machine (EREW PRAM) [13]. Our algorithm runs in $O((n_1 m)/d + n_1^2 \log U) \log d)$ time using $d = \lceil \frac{m}{n_1} \rceil$ processors, thus achieving near-optimal speedup for the given number of processors. We assume familiarity with parallel prefix operations [22] and refer the reader to [2], [16], [26], and [32] for examples of the use of parallel prefix operations in network flow algorithms. Specifically, we use the fact that using d processors and $O(\log d)$ time, we can execute the following parallel prefix operation:

> *Parallel Prefix Operation*: Given $l \leq d$ numbers $f(v_1), \ldots, f(v_l)$, compute the partial sums $f(v_1), f(v_1) + f(v_2), \ldots, f(v_1) + \ldots + f(v_l)$.

Our algorithm will be the same as the excess-scaling algorithm of §5.3 with a parallel implementation of *bipush/relabel* and a few additional data structures. The same approach was taken by Ahuja and Orlin [2] in developing a parallel version of their original excess scaling algorithm.

The first step in our algorithm is to transform the input graph so that each vertex has out-degree no greater than d. This transformation yields a graph with $O(n_1)$ V_1-vertices, $O(n_2)$ V_2-vertices and $O(m)$ edges. We achieve this by repeating the following step until it is no longer applicable:

> *splitting step*: Pick a vertex v with out-degree $k > d$. Create two new vertices v' and v'' and replace edges $(v, v_{k-d+1}) \ldots (v, v_k)$ with edges (v, v'), (v', v''), and $(v'', v_{k-d+1}) \ldots (v'', v_k)$. Edges (v, v') and (v', v'') have infinite capacity, while each edge (v'', v_k) has its capacity set equal to $u(v, v_k)$.

The splitting step creates one new V_1-vertex, one new V_2-vertex, and 2 more edges. Let $\Phi = \sum_v \max\{0, \lceil(\text{out-degree}(v) - d)/(d-1)\rceil\}$. Each splitting step reduces Φ by one. Initially $\Phi = O(n_1)$ and $\Phi \geq 0$ when the algorithm terminates. Thus, we only need to perform the splitting step $O(n_1)$ times overall, adding $O(n_1)$ vertices and $O(n_1)$ edges. Similarly, we can repeat the same step to reduce the in-degree of each vertex.

Further, we can perform this step in $O(n_1 \log m)$ time on d processors. We explain how to reduce the in-degree; the out-degree can be reduced in a similar manner. First, we lexicographically sort the list of edges by their tails. This can be done on d processors in $O(n_1 \log m)$ time using Cole's sorting algorithm [8] and Brent's theorem [6]. Next, we assign one processor to each of the last d edges on the list. In $O(\log d)$ time, we can determine if all these edges have the same tail. If so, we perform the splitting step, which can be done in $O(1)$ time on d processors. We then delete these edges from the list and continue on the remainder of the list. If they do not all have the same tail, then the last vertex on the list must have degree $\leq d$. In this case we delete all edges which have the same tail as the last edge and continue on the remainder of the list. In each iteration we either delete all the edges incident to a vertex or we process d edges. Hence there are $O(n_1 + \frac{m}{d}) = O(n_1)$ iterations, each of which can be performed in $O(\log m)$ time on d processors.

For the rest of this section, we will assume, without loss of generality, that every vertex in our graph has both in-degree and out-degree $\leq d$.

We first address the problem of implementing a bipush in parallel. In the bipush operation for the maximum flow problem, it is necessary to scan the edge list for vertex v starting with the current edge for vertex v until either an eligible edge is determined or until the edge list is exhausted. In the parallel algorithm, we will scan these edges in parallel.

We begin by introducing some terminology. Let $I(v)$ denote the set of vertices w such that (v, w) is an edge, and let $\hat{I}(v)$ denote the set of vertices w such that (v, w) is an eligible edge. Let us assume that the vertices in $I(v)$ are denoted $v_1, v_2, \ldots, v_k$, where $k = |I(v)|$. Thus the jth edge emanating from vertex v is edge (v, v_j).

For each vertex $v \in V_2$, we let $\hat{r}(v) = \sum_{w \in \hat{I}(v)} r(v, w)$, and refer to $\hat{r}(v)$ as the effective residual capacity of vertex v. Note that we can always push all of the excess out of a vertex v in V_2 prior to a relabeling of v so long as the excess does not exceed the effective residual capacity.

We define the *effective residual capacity* $\hat{r}(v, w)$ of edge (v, w) as

$$\hat{r}(v,w) = \begin{cases} 0 & \text{if } (v,w) \text{ is not eligible,} \\ r(v,w) & \text{if } (v,w) \text{ is eligible and } v \in V_2, w \in V_1, \\ \min\{r(v,w), \hat{r}(w)\} & \text{if } (v,w) \text{ is eligible and } v \in V_1, w \in V_2. \end{cases}$$

In the algorithm, we will be performing pushes from one vertex in V_1 at a time, and we will subsequently push from several vertices in V_2 in parallel. By defining the effective residual capacity for edges (v, w) as we do, we will ensure that we never push more flow into any vertex $v \in V_2$ than the effective residual capacity of v. Subsequently, all of the flow can be pushed out prior to a relabel of v.

In order to achieve the speedup desired, we cannot assign one processor to each edge of $I(v)$ in a push from vertex v. Thus, we will have to more efficiently allocate processors to edges on which we wish to push flow. In order to do so, we introduce the following four procedures. In all these procedures v is a vertex from which we wish to push δ units of flow.

We use Current(v) to denote v's current edge and store the edge lists in arrays.

1. *NextCurrent*(v, δ): if pushing δ units of flow would saturate all of v's admissible edges, then output $|I(v)| + 1$. Otherwise, output the index of the edge that will be current after pushing δ units of flow from v.

2. *NewRelabel*(v, δ): output true if NextCurrent $(v, \delta) = |I(v)| + 1$ and false otherwise.

3. *NextIncrement*(v, δ): output the amount of flow that will be sent in edge NextCurrent(v, δ) when pushing flow from v.

4. *Requirement*(v, δ): output the number of edges scanned in order to send δ units of flow from v without a relabel. It is equal to $NextCurrent(v, \delta) - Current(v) + 1$.

LEMMA 5.16. *There exists a data structure that allows us to implement each of these operations in $O(\log d)$ time on one processor.*

We defer the proof until later. Assume for now that such an implementation exists.

Using these procedures, we can implement the main operation, which we call *parallel-push*(v, δ, S). This operation tries to push up to δ units of flow from vertex v using the set S of parallel processors, and so that no relabel occurs. The implementation is straightforward, and appears in Fig. 5.8.

```
procedure Parallel-push($v, \delta, S$)
begin
      $c = Current(v)$. $k = NextCurrent(v, \delta)$. $s = |S|$
(*)   For each $i$ from $c$ to $\min(k-1, c+s-1)$ do in parallel
          send $\hat{r}(v, v_i)$ units of flow in edge $(v, v_i)$, and update $\hat{r}$.
      if $s \geq k - c + 1$ and $k \leq |I(v)|$
          then send $NextIncrement(v, \delta)$ units of flow in edge $(v, v_k)$.
      $Current(v) = NextCurrent(v, \delta)$.
      end
```

FIG. 5.8. *The procedure parallel push.*

LEMMA 5.17. *Parallel-push can be implemented in $O(\log d)$ time on d processors.*

Proof. Step (*) can be implemented by a parallel prefix operation on d processors. By Lemma 5.16 all the other steps can be implemented on 1 processor in $O(\log d)$ time. □

Part of the input to parallel-push is a set of processors. We use a procedure Allocate(v, D) to implement this.

Allocate(v, D)

input: vertex v, and D, a d-dimensional vector of demands for processors from the vertices in $I(v)$. $D(j)$ is the number of processors requested by vertex v_j.

output: The vector Processors( ), where Processors(j) is the set of processors allocated to vertex v_j.

It is straightforward to implement *Allocate* with a parallel prefix operation.

Now, we are ready to put all the pieces together to get an implementation of *parallel bipush/relabel*. This simply consists of a parallel push from v, followed by a set of parallel pushes from vertices $w \in V_2$ with excess, each of which is preceded by processor allocation. The procedure concludes by relabeling the necessary vertices. The details appear in Fig. 5.9. One detail deserves explanation. We always try to push exactly $\Delta/2$ units of flow from a vertex in V_1. This is necessary to maintain the invariant that no vertex ever accumulates more than Δ units of excess.

To begin the analysis, we bound the number of iterations of this procedure.

LEMMA 5.18. *There are $O(n_1^2 \log U)$ calls to* parallel bipush/relabel *over the course of the whole algorithm.*

Proof. Each parallel bipush/relabel in the first line either moves $\Delta/2$ units of flow or results in a relabeling. By a proof similar to that of Lemma 5.6, there are at most $O(n_1^2 \log U)$ such pushes over the whole algorithm. □

LEMMA 5.19. *Each call to* parallel bipush/relabel *takes O(# of iterations of the while loop $\times \log d +$ time spent relabeling) time on d processors.*

```
procedure parallel bipush/relabel($v$)
begin
    Parallel push($v$, $\Delta/2$, $d$)
    while $e(v_j) \neq 0$ for some $v_j \in I(v)$ do
    begin
        for each j = 1 to d do in parallel
            $D(v_j) = Requirement(v_j, e(v_j))$.
        $Allocate(v, D, d)$.
        for $i = 1$ to $d$ do in parallel
        begin
(*)         $push(v_i, e(v_i), processors(i))$.
            update data structures.
        end
    end
    create a list $L$ of indices $j$ s.t. $j \in V_2$ and $NewRelabel(v_j)$ = true.
    for each $i \in L$ do $Relabel(v_i)$.
    if $NewRelabel(v) = true$ then $relabel(v)$.
end
```

FIG. 5.9. *Procedure parallel bipush/relabel.*

Proof. By Lemma 5.16 and the fact that Allocate takes $O(\log d)$ time, each step except for the parallel push in line (*) takes $O(\log d)$ time. We know from Lemma 5.17 that a push takes $O(\log d)$ time. It is easy to see that a set of pushes which use a total of d edges can also be completed in $O(\log d)$ time; thus each iteration of the while loop takes $O(\log d)$ time. The lemma follows. □

It remains to bound the number of iterations of the while loop.

LEMMA 5.20. *The while loop is executed $O((n_1 m/d) + n_1^2 \log U)$ times over the whole algorithm.*

Proof. First we observe that each vertex in $I(v)$ may have at most one nonsaturating push from it per execution of the while loop. Lemma 5.18 implies that the number of nonsaturating pushes is at most $O(n_1^2 d \log U)$ overall. Let nsp be the number of nonsaturating pushes that have occurred since the beginning of the algorithm. Consider the potential function $F = \sum_v current(v) + nsp$. Initially $F = 0$ and at termination $F =$ (# of nonsaturating pushes) $= O(n_1^2 d \log U)$. The only way for F to decrease is by a relabel. Each relabel decreases F by at most $|I(v)|$; the total decrease is $O(n_1 m)$. So, the total increase in F over the algorithm is $O((n_1^2 d \log U + n_1 m))$. A parallel push with k processors increases F by k or results in a relabeling. Each iteration in a while loop except for the last one allocates d processors; hence it increases F by d or results in a relabeling. Ignoring the last iteration of the while loop in each call to parallel bipush/relabel, we find that there are at most $O((n_1^2 d \log U + n_1 m)/d)$ iterations of the while loop. To count the last iterations, we observe that there is one last iteration per call for a total of $O(n_1^2 \log U)$. Thus, overall there are $O(\frac{n_1 m}{d} + n_1^2 \log U)$ iterations. □

LEMMA 5.21. *The total time spent relabeling is $O(((n_1 m/d) + n_1^2 \log U) \log d)$.*

Proof. We spend a total of $O(n_1 m)$ work relabeling. However, at each relabeling step we look at d edges at a time, except for the last relabel step in a call to parallel bipush/relabel. Hence the total time is $O(\frac{n_1 m}{d} + n_1^2 \log U)$ □

Now we turn to the proof of Lemma 5.16.

Proof (of Lemma 5.16). Assume for now that $k = |I(v)|$ is a power of 2 for each vertex. We create a complete binary tree whose leaves are the indices of the vertices in I(v). The key of each leaf j in the binary tree is $\hat{r}(v, v_j)$. The key of each internal vertex of the binary tree is the sum of the keys of its descendent leaves.

Whenever a vertex v is relabeled, each vertex v_j of $I(v)$ is assigned a processor, and its binary tree is updated. The assignment of processors takes $O(\log d)$ steps per relabel. Moreover, each processor updates its binary tree in $O(\log d)$ steps.

When a push from vertex v is performed, the binary tree for vertex v must be updated. If k processors are assigned then Current(v) is increased by $\leq k$, and the updating can be accomplished with k processors in $O(\log \text{d})$ time.

In order to compute $NextCurrent(v, \delta)$, we start at the root of the binary tree for v, and we select the right child or the left child depending on whether δ is less than or greater than the key of the right child. We then recur on the selected child. We also can compute $NextIncrement$ in this manner. □

Combining all the above results, we have the following theorem.

THEOREM 5.22. *Algorithm* Bipartite Excess Scaling *with* bipush/relabel *replaced by* parallel bipush/relabel *runs in* $O(((n_1 m/d) + n_1^2 \log U) \log d)$ *time on d processors on an EREW PRAM.*

Plugging in $d = \lceil \frac{m}{n_1} \rceil$, we can restate the theorem as the following corollary.

COROLLARY 5.23. *Algorithm* Bipartite Excess Scaling *with* bipush/relabel *replaced by* parallel bipush/relabel *runs in* $O(n_1^2 \log U \log \frac{m}{n_1})$ *time on* $\lceil \frac{m}{n_1} \rceil$ *processors on an EREW PRAM.*

The work done by this algorithm is within a logarithmic factor of the running time of the sequential bipartite excess scaling algorithm.

6. Parametric maximum flow. A natural generalization of the maximum flow problem is obtained by making the edge capacities functions of a single parameter λ. This problem is known as the *parametric maximum flow problem.* We consider parametric maximum flow problems in which the capacities of the edges out of the sink are nondecreasing functions of λ, the capacities of the edges into the sink are nonincreasing functions of λ, and the capacities of the remaining edges are constant. Although this type of parameterization appears to be quite specialized, Gallo, Grigoriadis, and Tarjan [14] have pointed out that this parametric problem has many applications, in computing subgraph density and network vulnerability and in solving other problems, some of which are mentioned at the end of this section.

Let $u_\lambda(v, w)$ denote the capacity of edge (v, w) as a function of λ and suppose that we wish to solve the maximum flow problem for parameter values $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_l$. Clearly, for l different values of λ, a solution can be found using l invocations of a maximum flow algorithm. This approach takes no advantage of the similarity of the successive problems to be solved, however. Gallo, Grigoriadis, and Tarjan [14] gave an algorithm for finding the maximum flow for $O(n)$ increasing values of λ in the same asymptotic time that it takes to run the Goldberg–Tarjan maximum flow algorithm *once*. If the capacities are linear functions of λ, it is easy to show that the value of the maximum flow, when viewed as a function of λ, is a piecewise linear function with no more than $n - 2$ breakpoints. In this case, they give an algorithm for finding all of the breakpoints of this function in the same asymptotic time as it takes to run the Goldberg–Tarjan maximum flow algorithm once.

In this section we give an algorithm which for l increasing values of λ finds all l maximum flows in $O(ln + ln_1^2 + n_1^3 + n_1 m)$ time. Using the dynamic tree data structure, this algorithm runs in $O(ln + n_1 m \log((ln_1 + n_1^2)/m + 2))$ time.

We begin by giving one iteration of the algorithm, i.e., determining the maximum flow for parameter value λ_i, if the maximum flow for parameter value λ_{i-1} is given. The algorithm appears in Fig. 6.1. First, we update the capacities. The capacity of an edge leaving the source may have increased. If so, we saturate the edge, by setting its flow equal to its new capacity. The capacity of an edge leaving the sink may have decreased. If it has decreased below the flow on the edge, we decrease the flow so that it is equal to the capacity. Since $t \in V_1$ by assumption, this may create excess on vertices in V_2. Therefore, we immediately push any such excess to vertices in V_1, thus re-establishing the invariant that no excess is on vertices in V_2. The second step consists of running the bipartite FIFO algorithm in the network beginning with the current f and d. This gives us a maximum flow for the parameter value λ_i.

```
Step 1 (Update preflow)
Let $i = i + 1$
$\forall(s, v) \in E$ with $d(v) < 2n_1$, let $f(s, v) = \max\{u_{\lambda_i}(s, v), f(s, v)\}$.
$\forall(v, t) \in E$, let $f(v, t) = \min\{u_{\lambda_i}(v, t), f(v, t)\}$.
$\forall v \in V_2$ while $e(v) > 0$, do push/relabel$(v)$.
Step 2 (Find maximum flow) Run the bipartite FIFO algorithm on the network with capacities $u_{\lambda_i}$, beginning with flow $f$ and distance labels $d$.
```

FIG. 6.1. *Algorithm* parametric bipartite flow.

Remark. In applications of the parametric maximum flow problem, it may happen that $s \in V_1$ or $t \in V_2$, contrary to our assumption. Such a possibility can be handled by making minor changes to the algorithm, without affecting its running time.

Now we must prove that the algorithm is correct and efficient. We do this by means of the following lemmas.

LEMMA 6.1. *At the end of each step in the algorithm, there is no excess on any vertex in V_2.*

Proof. It suffices to restrict our attention to Step 1, since Step 2 always maintains this condition. Since by assumption $s \in V_2$, increasing the flow on edges out of s can increase the excess only on vertices in V_1. Since $t \in V_2$, decreasing the flow on edges into t may create excesses on vertices in V_2. This excess is immediately removed from vertices in V_2 by the procedure *push/relabel*, however. □

LEMMA 6.2. *Throughout all iterations of the* parametric bipartite flow algorithm, *distance labels are nondecreasing.*

Proof. We first show that updating the residual capacities and the preflow between iterations maintains the validity of the distance labels. Increasing the flow on an edge (s, v) may create a new residual edge (v, s), but since $d(v) < 2n_1$, the labeling is still valid. Decreasing the flow on edges into t does not create any new residual edges, so the distance labels are still valid. We noted earlier that procedures *push/relabel* and *bipush/relabel* maintain a valid labeling. The lemma follows. □

A consequence of Lemma 6.2 is that, over all iterations of the algorithm, each vertex is relabeled $O(n_1)$ times, and the total relabeling time is $O(n_1 m)$. Furthermore, the total number of saturating pushes over the whole algorithm is $O(n_1 m)$. We bound the number of nonsaturating bipushes in the next lemma.

LEMMA 6.3. *The algorithm performs a total of $O(ln_1^2 + n_1^3)$ nonsaturating bipushes over all l iterations.*

Proof. As in the bipartite FIFO algorithm, consider the following potential function: $\Phi = \max\{d(v) | v \text{ is active}\}$. The potential function increases due to relabelings, and this increase has already been shown to be at most $4n_1^2$. The potential function may also increase in Step 1 when the preflow is updated. But this increase is at most $O(n_1)$ per iteration, and $O(n_1 l)$ over all iterations. Thus the total number of passes over the queue is $O(ln_1 + n_1^2)$ and the total number of nonsaturating bipushes is $O(ln_1^2 + n_1^3)$. □

THEOREM 6.4. *A total of l iterations of the* parametric bipartite flow algorithm *take $O(ln + n_1 m + ln_1^2 + n_1^3)$ time.*

Proof. Each execution of Step 1 takes $O(n)$ time to update the residual capacities and flows. Getting rid of the excesses at vertices in V_2 by performing *push/relabel* steps takes

$O(n)$ time per iteration plus the time to perform saturating pushes, which is $O(n_1 m)$ time overall. Hence l executions of Step 1 take $O(ln + n_1 m)$ time. The l executions of Step 2 take a total of $O(n_1 m + ln_1^2 + n_1^3)$ time, as was shown previously. The theorem follows. □

The dynamic tree data structure can be incorporated into the parametric maximum flow algorithm to improve its computational complexity. Using the ideas described in §5.5, it can be shown that the dynamic tree implementation of the parametric maximum flow problem runs in $O(ln + n_1 m \log((ln_1 + n_1^2)/m + 2))$ time.

Often applications of the parametric maximum flow problem require that the minimum cut be determined for each of the parameter values $\lambda_1, \lambda_2, \ldots, \lambda_l$. Obviously each such minimum cut can be determined by a breadth-first search of the network, requiring $O(m)$ effort per cut. Overall this time would be $O(ml)$ and for larger values of l would be a bottleneck. In order to achieve a faster time bound we maintain exact distance labels of vertices as explained in [16]. Maintaining exact distance labels requires some additional effort but no more than $O(n_1 m)$ time over all iterations. While using this method, the *minimum cut* $(X_i, \overline{X_i})$, at the end of iteration i is defined as $X_i = \{v \in V : d(v) \geq 2n_1\}$ and $\overline{X_i} = \{v \in V : d(v) < 2n_1\}$. It may also be pointed out the minimum cuts in the parametric maximum flow problem are nested, i.e., for $\lambda_1 \leq \lambda_2 \leq \lambda_3$, with corresponding cuts $(X_1, \overline{X_1})$, $(X_2, \overline{X_2})$, $(X_3, \overline{X_3})$, we have that $X_1 \subseteq X_2 \subseteq X_3$ [12]. This property allows us to store all l cuts in $O(n + l)$ space, and recreate any one cut in $O(n)$ time.

While we have only given an algorithm for the case where the λ's are given in increasing order, actually we can solve a more general problem. Let $\kappa(\lambda)$, the *min-cut capacity function*, be the capacity of the minimum cut as a function of λ. If the edge capacities are linear functions of λ, then $\kappa(\lambda)$ is a piecewise-linear concave function with at most $n - 2$ breakpoints. We can actually compute all of these breakpoints in $O(n^2 + n_1 m \log((nn_1/m) + 2))$ time, and can do even better if we know a priori that $l = o(n)$. This result directly follows from the results of [14] and the details appear in [35].

We conclude by noting that the bipartite parametric flow problem has many applications including multiprocessor scheduling with release times and deadlines [21], [24], 0-1 integer programming problems [29], [30], maximum subgraph density [21], finding a maximum-size set of edge-disjoint spanning trees in an undirected graph [28], [29], [30], network vulnerability [9], [19], partitioning a data base between fast and slow memory [11], and the sportswriter's end-of-season problem [23], [31]. For all these problems we improve on or match the best known bounds.

7. Minimum-cost circulation. In this section we examine the *minimum-cost flow problem* on bipartite networks. We consider the recent cost-scaling minimum-cost flow algorithm of Goldberg and Tarjan [17], and describe the improvement in its running time that can be obtained when it is adapted for bipartite networks. We shall be very sketchy in our description, since all the results are analogous to the results in §5.

The minimum cost flow problem is a generalization of the maximum flow problem. In this problem, each edge (v, w) has a cost $c(v, w)$. We formulate the problem as a circulation problem, since it is equivalent to other formulations. (See [1] and [18].) We assume that the costs are *antisymmetric*, i.e., $c(v, w) = -c(w, v)$ for each edge (v, w). Let $C = \max\{c(v, w) : (v, w) \in E\}$. The minimum-cost circulation problem can be formulated as follows:

$$\text{Minimize} \sum_{(v,w)\in E} c(v, w) f(v, w)$$

subject to

$$f(v,w) \leq u(v,w) \quad \forall (v,w) \in E, \tag{7.1}$$

$$f(v,w) = -f(w,v) \quad \forall (v,w) \in E, \tag{7.2}$$

$$\sum_{w \in V} f(v,w) = 0 \quad \forall v \in V. \tag{7.3}$$

A *circulation* is a function of satisfying constraints (7.1), (7.2), and (7.3). A *pseudoflow* is a function f satisfying only constraints (7.1) and (7.2). For any pseudoflow f, we define the *excess* of vertex w to be

$$e(w) = \sum_{v:(v,w) \in E} f(v,w). \tag{7.4}$$

The excess at a vertex may be positive or negative. A vertex v is called *active* if $e(v) > 0$. The residual network is defined as for the maximum flow problem. We associate with each vertex v a real-valued *price* $p(v)$. The prices correspond to linear programming dual variables. In the analysis, the prices play a role similar to that played by the distance labels in the maximum flow algorithm. The *reduced cost* of an edge (v, w) with respect to the price function p is denoted by $c_p(v, w)$ and is defined by $c_p(v, w) = c(v, w) + p(v) - p(w)$.

7.1. The cost-scaling algorithm. The cost-scaling algorithm of Goldberg and Tarjan [17], relies on the concept of *approximate optimality*. A circulation f is said to be *ϵ-optimal* for some $\epsilon > 0$ if f together with some price function p satisfies the following condition:

$$u_f(v,w) > 0 \Rightarrow c_p(v,w) \geq -\epsilon \Longrightarrow (\epsilon\text{-optimality}). \tag{7.5}$$

We refer to this condition as the *ϵ-optimality condition.* Let l be the number of edges on the longest simple cycle in the network. It can be shown that any feasible flow is ϵ-optimal for $\epsilon \geq C$ and any ϵ-optimal feasible flow for $\epsilon < 1/l$ is an optimum flow [4]. Since in a bipartite network every other vertex on a cycle must be a vertex in V_1, any ϵ-optimal feasible flow for $\epsilon < 1/(2n_1)$ is an optimum flow.

The cost-scaling algorithm treats ϵ as a parameter and iteratively obtains ϵ-optimal flows for successively smaller values of ϵ. Initially, $\epsilon = C$; on termination, $\epsilon < 1/(2n_1)$. The algorithm performs repeated cost-scaling phases, each of which consists of applying an *improve-approximation* procedure that transforms a 2ϵ-optimal circulation into an ϵ-optimal circulation. After $1 + \lceil \log(2n_1C) \rceil$ cost scaling phases, $\epsilon < 1/(2n_1)$, and the algorithm terminates with an optimal circulation. To get the algorithm started, an initial circulation can be found by using any maximum flow algorithm, such as one of those discussed in §5. A more formal description of this algorithm appears in Fig. 7.1.

Recall that in the maximum flow algorithm, we maintained the invariant that all excess was on V_1-vertices. This will be our goal in the minimum cost circulation algorithm also. The procedure *improve-approximation* given in Fig. 7.2 first converts the 2ϵ-optimal circulation it receives as input into a 0-optimal pseudoflow (lines (*) through (**)). This may leave positive excess on V_2-vertices. So we execute the while loop at line (†), which applies *push/update* operations to these vertices until they are rid of all their excess. Now we have established the invariant that the only vertices with positive excess are V_1-vertices. We will maintain this invariant for the rest of procedure *improve-approximation.* The remainder of the procedure moves flow from vertices with positive excess to vertices with negative excess. As vertices

FIG. 7.2. *The procedure* improve-approximation.

in V_2 may have negative excess, this will sometimes involve a one-edge push and sometimes involve a two-edge push.

We call an edge (v, w) in the residual network *admissible* if $c_p(v, w) < 0$. We define the subnetwork of G consisting solely of admissible edges to be the *admissible network*. The basic operations in the procedure are selecting active vertices, pushing flows on admissible edges, and updating vertex prices. The details of *improve-approximation*, adapted to the bipartite case, appear in Figs. 7.2 and 7.3.

```
procedure bipush/update($v$)
begin
        if there exists an admissible edge $(v, w)$
        then if $e(w) < 0$
                then push $\min\{e(w), e(v), u_f(v, w)\}$ units of flow on $(v, w)$
                else if there exists an admissible edge $(w, x)$
                        then push $\delta = \min\{e(v), u_f(v, w), u_f(w, x)\}$ units of flow
                                along the path $v - w - x$
                        else replace $p(w)$ by $\max_{(w,x) \in E_f}\{p(x) - c(w, x) - \epsilon\}$
        else replace $p(v)$ by $\max_{(v,w) \in E_f}\{p(w) - c(v, w) - \epsilon\}$
end
procedure push/update($v$)
begin
        if there exists an admissible edge $(v, w)$
        then push $\min\{e(w), e(v), u_f(v, w)\}$ flow on $(v, w)$
        else replace $p(v)$ by $\max_{(v,w) \in E_f}\{p(w) - c(v, w) - \epsilon\}$
end
```

FIG. 7.3. *The procedures* push/update *and* bi-push/update.

To identify admissible edges emanating from a vertex, the algorithm uses the same *current edge* data structure used in the preflow-push algorithm for the maximum flow problem.

A movement of flow along a path $v-w-x$ in *bipush/update* is called a *bipush*. The bipush is *saturating* if $\delta = \min\{u_f(v, w), u_f(w, x)\}$ and *nonsaturating* otherwise. The correctness and efficiency of the algorithm rest on the following results.

LEMMA 7.1. 1. *The* improve-approximation *procedure always maintains ϵ-optimality of the pseudoflow, and at termination yields an ϵ-optimal circulation.*

2. *Each vertex price never increases, and it decreases $O(n_1)$ times during an execution of the procedure.*

3. *There are $O(n_1 m)$ saturating pushes and bipushes during an execution of the procedure.*

4. *Immediately before, during, and immediately after the while loop in line (‡) of* improve-approximation, *all excess is on V_1-vertices.*

Proof. These results follow directly from the proofs of Goldberg and Tarjan [17] adapted for bipartite networks. □

As in the preflow-push algorithm, it can easily be shown that the time spent updating prices in an execution of *improve-approximation* is $O(n_1 m)$. The bottleneck in the procedure is the number of nonsaturating pushes and bipushes. Observe that there are three different types of pushes and bipushes to bound:

1. pushes in the while loop at line (†),
2. bipushes in the while loop at line (‡),
3. pushes in the while loop at line (‡).

We bound the first type by observing the all the pushes are saturating except for at most one per V_2-vertex. Therefore, there are at most n nonsaturating pushes.

To bound the second type of bipushes, we need the following lemma from [17].

LEMMA 7.2 [17]. *The admissible network remains acyclic throughout the execution of the* improve-approximation *procedure.*

The number of nonsaturating bipushes performed by the procedure depends upon the order in which active vertices are examined. Goldberg and Tarjan [17] show that the generic version of the procedure, in which active vertices are examined in an arbitrary order, performs $O(n^2 m)$ pushes for general networks. They show that a specific implementation of the generic implementation, called the *first-active method* algorithm, performs $O(n^3)$ nonsaturating pushes, as does a related method, the *wave method.* (The wave method was developed independently by Bertsekas and Eckstein [5].) We shall show that an adaptation of the first-active method for bipartite networks performs $O(n_1^3)$ nonsaturating bipushes.

The first-active method uses the acyclicity of the admissible network. As is well known, the vertices of an acyclic network can be ordered so that for each edge (v, w), v precedes w in the ordering. Such an ordering of vertices is called a *topological ordering* and can be found in $O(m)$ time. The first-active method maintains a list L of all vertices in V_1 in topological order. The algorithm examines each vertex $v \in L$ in order. If v is active, it performs *bipush/update* operations on vertex v until either it becomes inactive or $p(v)$ is updated. In the former case, the algorithm examines the next vertex on L. In the latter case, the algorithm moves v from its current position on L to the front of L, and restarts the scan of L at the front. Moving v to the front of L preserves the invariant that L is a topological order of the vertices, because immediately after v is assigned a new prices, it has no incoming admissible edges. The algorithm terminates when L is scanned in its entirety. Note that updating the price of a vertex in V_2 does not affect the topological order of vertices in V_1. On termination, no vertex can be active.

Observe that if within n_1 consecutive vertex examinations the algorithm performs no price updates then all active vertices have discharged their excesses and the algorithm obtains a flow. This follows from the fact that when vertices are examined in the topological order, active vertices push flow to vertices after them in the topological order. As there are $O(n_1^2)$ price updates of vertices in V_1, we immediately obtain an $O(n_1^3)$ bound on the number of vertex examinations. Each vertex examination entails at most one nonsaturating bipush. Consequently, the wave algorithm performs $O(n_1^3)$ nonsaturating bipushes per execution of *improve-approximation*.

Now we bound the third type of push. A push in this case is performed over an edge (v, w) such that $e(w) < 0$. There are three cases. Either the value of the push is $u_f(v, w)$ (saturating), $e(v)$ (nonfilling), or $e(w)$ (filling). For the first case we have already bounded the number of saturating pushes. In the second case, we can bound the number of nonfilling pushes by $O(n_1^3)$ by arguments similar to those for non-saturating pushes above. For filling pushes, observe that each vertex is filled at most once per iteration of *improve-approximation*; thus there are a total of n such pushes overall.

Combining the three cases, we find that the number of nonsaturating pushes and bipushes is $O(n_1^3+n)$. As all other steps take $O(n_1 m)$ time per execution of the *improve-approximation* procedure and the procedure is called $O(\log(n_1 C))$ times, we get the following result.

THEOREM 7.3. *The wave algorithm solves the minimum cost flow problem on a bipartite network is $O((n_1 m + n_1^3)\log(n_1 C))$ time.*

8. Summary and conclusions. We have considered a number of maximum flow algorithms and algorithms for other network flow problems for bipartite networks in which one side is much smaller than the other. Our work is motivated by and improves upon the work of Gusfield, Martel, and Fernandez-Baca [21]. In that paper, the authors demonstrated the importance of bipartite maximum flow problems in which one side is much smaller than the other. In addition, they showed that existing algorithms run much faster on these "unbalanced" networks.

We have extended the results of Gusfield et al. in several ways. First of all, we showed that their analysis applies to other maximum flow algorithms. In addition, we developed the concept of the *bipush* for preflow-push algorithms and showed that bipushes lead to further improvements in several algorithms for the maximum flow problem. We further generalized the results to algorithms for the parametric maximum flow problem, as well as the minimum cost flow problem. We also showed that the results apply as well to dynamic tree implementations if the dynamic tree algorithms are modified appropriately.

Although the theory in this paper has been concerned with bipartite networks, it would be just as valid for networks in which we allow edges joining two vertices in V_1. More generally, it is valid for networks in which have a small *vertex cover*. A vertex cover of a network $G = (V, E)$ is a set S of vertices such that each edge in E is incident to at least one vertex in S. A minimum vertex cover is one with the smallest number of vertices. Although it is NP-hard to determine a minimum vertex cover of a graph, it is possible to find a vertex cover in $O(n + m)$ time whose cardinality is within a factor of 2 of the cardinality of a minimum vertex cover. (Just find any maximal matching and include each of the matched vertices).

If the size of the minimum vertex cover of a graph is n_1, then all of the time bounds presented in the previous sections apply. It is easy to show that the length of the longest path in such a network is at most $2n_1$. As for bipushes they would have to be replaced as follows. Suppose G is a network, not necessarily bipartite, in which V_1 is a vertex cover. As before we maintain the invariant that each active vertex is in V_1. Suppose that v is active, and that (v, w) is eligible. If w is in V_1 then we perform a normal push. If w is not in V_1, then each edge incident to w is in V_1 and we perform a bipush. All of the results in this paper are thus easily generalized to networks with small vertex covers, and the time bounds stated in Table 1.1 apply to such networks.

It is likely that improvements could be obtained in the running times of other algorithms for network flow problems on unbalanced bipartite networks, or on networks in which the cardinality of a minimum vertex cover is small. For example, one can obtain improved running times for dynamic programming algorithms for the shortest path problem, and one can improve the running time for all pairs shortest path algorithms. We conjecture that one can also obtain improved time bounds for the b-matching problem on networks with small vertex covers. We also conjecture that one can obtain improved results for polymatroidal network flows.

Acknowledgments. We are grateful to David Shmoys for many helpful conversations and suggestions, and for a careful reading of an earlier draft of this paper.

NEW RESULTANT INEQUALITIES AND COMPLEX POLYNOMIAL FACTORIZATION *

V.Y. PAN[†]

Abstract. The author deduces some new probabilistic estimates on the distances between the zeros of a polynomial $p(x)$ by using some properties of the discriminant of $p(x)$ and applies these estimates to improve the fastest deterministic algorithm for approximating polynomial factorization over the complex field. Namely, given a natural n, positive ϵ, such that $\log(1/\epsilon) = O(n \log n)$, and the complex coefficients of a polynomial $p(x) = \sum_{i=0}^{n} p_i x^i$, such that $p_n \neq 0$, $\sum_i |p_i| \leq 1$, a factorization of $p(x)$ (within the error norm ϵ) is computed as a product of factors of degrees at most $n/2$, by using $O(\log^2 n)$ time and n^3 processors under the PRAM arithmetic model of parallel computing or by using $O(n^2 \log^2 n)$ arithmetic operations. The algorithm is randomized, of Las Vegas type, allowing a failure with a probability at most δ, for any positive $\delta < 1$ such that $\log(1/\delta) = O(\log n)$. Except for a narrow class of polynomials $p(x)$, these results can be also obtained for ϵ such that $\log(1/\epsilon) = O(n^2 \log n)$.

1. Introduction.

Randomization is a powerful tool for designing effective numerical and algebraic algorithms over finite fields (see, for instance, [23]), but over infinite fields, the application of randomization is usually limited to verification of polynomial identities and to avoiding singularities (see [18] and [26]). We are going to demonstrate the power of randomization in a new area, for approximate factorization (over the complex field) of a monic univariate polynomial of degree n,

$$p(x) = \sum_{i=0}^{n} p_i x^i = p_n \prod_{j=1}^{n} (x - x_j), \qquad \|p(x)\| = \sum_i |p_i|, \tag{1}$$

that is, given a set of complex coefficients $p_0, p_1, \ldots, p_n$ and a positive ϵ, we seek approximations $x_1^*, \ldots, x_n^*$ to the zeros $x_1, \ldots, x_n$ of $p(x)$ such that

$$\|p(x) - p_n \prod_{j=1}^{n} (x - x_j^*)\| \leq \epsilon. \tag{2}$$

The requirement (2) can be motivated by the observation that in practice of numerical computation, the coefficients of $p(x)$ are most frequently available only within certain truncation errors. For the worst case input polynomial $p(x)$, where $p_n = 1$, $|x_j| \leq 1$, for all j (we may satisfy this assumption by scaling x by a power of 2, thus preserving the binary length of the coefficients), (2) implies the more classical requirement that

$$|x_j - x_j^*| < \tilde{\epsilon} \quad \text{for all} \quad j, \tag{3}$$

as long as $\tilde{\epsilon} \geq 4.4(2\epsilon)^{1/n}$; $2\epsilon < 40^{-n}$ (see Proposition 11 in the appendix). Moreover, we may represent the perturbed polynomial as $p_\epsilon(x) = p(x) + \epsilon\, q(x)$ and let $x_j(\epsilon)$ denote its zeros, so that

$$x_j(0) = x_j, \quad p_\epsilon(x_j(\epsilon)) = 0, \quad j = 1, \ldots, n.$$

We may differentiate the latter expression, ignore the term $O(\epsilon)$, and obtain that

$$x_j'(\epsilon) = -q(x_j(\epsilon))\,/\,p'(x_j(\epsilon)),$$

provided that $p'(x_j(\epsilon)) \neq 0$. If x_j is a simple zero of $p(x)$, that is, if

$$p(x_j) = 0, \qquad p'(x_j) \neq 0,$$

then we have

$$x_j(\epsilon) = x_j + \epsilon\, x_j'(v\epsilon) = x_j - \epsilon\, q(x_j(v\epsilon))\,/\,p'(x_j(v\epsilon))$$

for some v, $0 \leq v \leq 1$.

Therefore, (2) implies (3) for simple zeros of $p(x)$ and for $\epsilon/\tilde{\epsilon}$ of the order of $|p'(x_j)|$, that is, (2) implies (3) for small ϵ and for $\tilde{\epsilon}$ roughly proportional to ϵ, unless $p(x)$ has some other zeros near x_j, so that $p'(x_j)$ is close to 0.

For polynomials $p(x)$ with multiple or clustered zeros, (2) implies (3), with $\tilde{\epsilon}$ tending to be substantially larger than ϵ as $\epsilon \to 0$.

Example 1. $p(x) = x^n$ has the only zero $x_1 = x_2 = \cdots = x_n = 0$, whose multiplicity is n. $p(x) - \epsilon = x^n - \epsilon$ has the zeros $x_j^* = \epsilon^{1/n}\omega^j$, $j = 1, \ldots, n$; $\omega = \exp(2\pi\sqrt{-1}/n)$, so that $\tilde{\epsilon} = \epsilon^{1/n}$.

Example 1 suggests that, for polynomials with multiple or clustered zeros, computing the factorization under (2) is numerically better conditioned than the zero finding problem under (3).

More important for us, the same example also suggests that after a small random perturbation of the coefficients of $p(x)$, the zeros of the resulting polynomial $p(x) + \Delta(x)$, with $\|\Delta(x)\| = \epsilon$, tend to stay apart from each other at the distance at least of the order of $(1/n)\epsilon^{1/n}$ (even if they correspond to the multiple or clustered zeros of $p(x)$), so that such a perturbation promises to eliminate a major obstacle to a rapid convergence of many known algorithms for polynomial factorization, namely, those which converge slowly on the input polynomials whose zeros form clusters.

Substantiation of this intuitive argument is not straightforward, however.

In this paper we achieved some progress towards such a substantiation, by exploiting some properties of the resultant of $p(x)$ and of its derivative (or of the discriminant of $p(x)$). Based on these properties, we estimated the *mth diameter* $d_m = d_m(x_1, \ldots, x_n)$ of the set $\{x_1, \ldots, x_n\}$,

$$d_m = \min_{|T|=m} \max_{i,j \in T} |x_i - x_j|\,, \qquad m = 2, 3, \ldots, n\,, \tag{4}$$

where the minimum is was over all the cardinality m subsets of the set $\{1, 2, \ldots, n\}$ (that is, d_m denotes the minimum diameter of a subset of m elements of the set $\{x_1, \ldots, x_n\}$, so that, in particular, $d_n = \max_{1 \leq i,j \leq n} |x_i - x_j|$). More precisely, we estimated the mth diameter of the set of the zeros of the polynomials

$$p(x) + x^h \Delta \quad \text{for} \quad h = 0, 1, \ldots, n,$$

for a random complex Δ, uniformly distributed on the circle $|\Delta| = \rho$, and for a fixed small positive ρ. We have set $m = n/2$ (assuming n even) and proved that, with a probability at least $1/(2n+1)$, the reciprocal of the mth diameter of the set of the zeros of $p(x) + x^h\Delta$ was bounded by $O(1/\rho^{4/(n-2)})$ (as $\rho \to 0$) if $h = 0$, and moreover, for a large class of the input polynomials $p(x)$, the maximum of such a reciprocal over all integers h, $0 \leq h \leq n$, was bounded by $O(1/\rho^{4/(n-2)n})$ (see (18), (53), and Proposition 4, for more specific estimates).

We also examined the resulting effect of the perturbation of $p(x)$ on the computation of the factorization of $p(x)$ by means of an effective factorization algorithm based on a combination of the techniques of [25] and [19]. The resulting hybrid algorithm recursively computes a *complete numerical factorization* (2) of $p(x)$ and supports the record running time bounds for this computation, both in terms of arithmetic and Boolean (bit) operations involved. The intermediate steps compute *incomplete numerical factorizations* of $p(x)$. If the degrees of the output factors are less than, say, 1/2 of the input degree in every recursive step, then in at most $\lfloor \log_2 n \rfloor$ recursive steps, a complete numerical factorization (2) is computed, and the worst case bounds on *both* sequential and parallel running times of the entire algorithm decrease roughly by the factors of n and $n/\lfloor \log_2 n \rfloor$, respectively. This is because in the worst case for each i, recursive step i splits its input polynomial of degree $n+1-i$ into two factors of degrees 1 and $n-i$, respectively, so that $n-1$ recursive steps are required to compute a complete recursive factorization (2).

Actually, such a balanced splitting was a cornerstone of several recent successful algorithms for polynomial factorization and/or rootfinding [4]–[7], [20]. The algorithms of [4]–[6] and [20], however, only apply to the polynomials all of whose zeros are real, whereas the parallel algorithm of [17] reaches decisive parallel acceleration in the general (complex) case, but at the expense of a great increase of its processor and sequential time bounds.

Unlike the cited papers, our approach is not fully recursive, and it works for a more limited range of the output error bounds ϵ, but it does not restrict itself to the real case, and leads to parallel acceleration without blowing up the processor bound. More specifically, by using the cited lower bounds on the distances among the zeros of the slightly perturbed polynomial, $p(x) + x^h \Delta$, we prove that, with a probability bounded away from 0, for a random choice of Δ, practically the *same algorithm* splits such a perturbed polynomial into factors of degrees less than $n/2$. Thus, the randomization alone *strictly improves* the performance of the original algorithms.

The same randomization techniques can be recursively applied to split the computed factors of $p(x)$. In each new recursive step the randomization may give us less and less advantages (see §8 on the details), and we may end up with shifting to the original deterministic factorization algorithm at some recursive step at which using randomization gives us no advantage anymore. Some techniques may counter such a deficiency (see §9), and in any case, our acceleration (due to randomization) applies to the hardest recursive steps, in which we split into factors the polynomials of higher degrees.

We will formally state our main results in the form of Theorem 1, which presents our estimates for the error and for the parallel and sequential computational complexity of a single step of splitting $p(x) + \Delta$ (for a random Δ, $|\Delta| = \rho$) into factors of degrees less than $n/2$. We note that our randomization is of Las Vegas type, where no undetected errors may occur (the algorithm may output FAILURE but with a low and controlled probability).

For simplicity, we will use the arithmetic (rather than Boolean) complexity estimates, which is adequate since our deviation from the original algorithms of [25] and [19] does not affect the required precision of the computation. We will assume the customary RAM and PRAM models of sequential and parallel arithmetic computations, respectively (see [1] and [14]), and will adopt the customary notation $O_A(t, p)$, which means that $O(t)$ parallel arithmetic steps and p processors suffice in the parallel implementation of the solution algorithm. (From now on, we use the "O" notation assuming that $n \to \infty$ and $\epsilon, \rho \to 0$.) $O_A(t, p)$ also implies $O_A(ts, p/s)$, for any integer $p/s > 0$, which gives us the sequential time bound $O_A(tp, 1)$, for $s = p$ (Brent's principle [10]).

We will assume hereafter that

$$\|p(x)\| = 1, \tag{5}$$

$$(6) \qquad 1/4 \le r(C, p(x)) = \max_j |x_j - C| \le 1 \,, C = (1/n) \sum_j x_j = -p_{n-1}/(np_n).$$

We may closely approximate $r(C, p(x))$ at the cost $O_A(\log n, n)$ (see Proposition 5), and if $r(C, p(x)) > 1$ or if $0 < r(C, p(x)) < 1/4$, we may shift, also at the cost $O_A(\log n, n)$ (see [2]), to a polynomial

$$q(y) = ap(by + c) = q_n \prod_{j=1}^{n} (y - y_j),$$

for fixed complex a, b and c such that $ab \neq 0$,

$$\|q(y)\| = 1, \quad 1/4 < r(\widetilde{C}, q(y)) = \max_j |y_j| \le 1, \quad nb\widetilde{C} = \sum_j (x_j - c).$$

Here, several choices of the values of a, b and c are possible. For instance, we may set $b = 4r(C, p(x))$, $c = C + 0.5$ and define a from the equation $\|q(y)\| = 1$. (Actually, in a more careful implementation, we may somewhat relax some constraints of (5) and (6) in order to be able to choose lower precision values for a, b, and c, thus decreasing the Boolean cost of the computations. For instance, we may require that $\frac{1}{2} \le \|q(x)\| \le 1$ (rather than $\|q(x)\| = 1$) and choose a to be a power of 2.)

We are now ready to state our main result, which we will prove in §§6 and 7 (also compare Remark 8).

THEOREM 1. *Suppose that we are given complex coefficients $p_0, \ldots, p_n$ of the polynomial $p(x)$ of* (1), *satisfying* (5), (6), *and four positive α, β, δ and ϵ such that*

$$(7) \qquad 1 > \delta > 0, \quad n|p_n|20^{-n} > \epsilon.$$

Then there exists a randomized algorithm (*of Las Vegas type*) *that either reports a failure with a probability at most δ or, otherwise, computes an incomplete numerical factorization of $p(x)$* (*within error norm ϵ*) *into a product of polynomials, each of degree less than $n/2$. The algorithm supports the following parallel and sequential complexity estimates for this computation*:

$$(8) \qquad c_A = O_A\left(\phi(n, \epsilon) \log n, n^3 \log(1/\delta)/\phi(n, \epsilon)\right),$$

$$(9) \qquad (sc)_A = O_A(\phi(n, \epsilon) n^2 \log n + n(\log n)^2 \log(1/\delta), 1),$$

where $\phi(n, \epsilon) = \log(\log(1/\epsilon) + (n/\epsilon^{1/n}))$.

Remark 1. If

$$(10) \qquad \log(1/\delta) = O(\log n), \qquad \log(1/\epsilon) = O(n^\alpha (\log n)^\beta),$$

then $\log\log(1/\epsilon) = O(\log n)$, $\log(1/\epsilon^{1/n}) = O(n^{\alpha-1}(\log n)^\beta)$, and the estimates (8) and (9) are specified as follows:

$$(11) \qquad c_A = O_A\big(n^{\alpha-1}(\log n)^{\beta+1}, n^3(\log n)^{1-\beta}\big),$$

$$(12) \qquad (sc)_A = O_A(n^{1+\alpha}(\log n)^{\beta+1}, 1).$$

(In the summary, we cited (11) and (12) for $\alpha = \beta = 1$.)

Remark 2. We also show (in §9) how the complexity bounds (8) and (9) can be ensured, except for a narrow class of input polynomials $p(x)$, with $\phi(n, \epsilon)$ replaced by the substantially smaller quantity $\psi(n, \epsilon) = \log(\log(1/\epsilon) + (n/\epsilon^{1/n^2}))$, which (for all but a narrow class of input polynomials $p(x)$) implies the bounds (11) and (12), even provided that the upper bound of (10) on $\log(1/\epsilon)$ is increased by the factor of n, to

$$\log(1/\epsilon) = O(n^{\alpha+1}(\log n)^{\beta}).$$

In particular, for $\alpha = 1$, which implies the time bound $(\log n)^{\beta+1}$ in (11), we have the bound $\log(1/\epsilon) = O(n^2(\log)^{\beta})$ versus $O(n(\log n)^{\beta})$ of (10) for $\alpha = 1$. According to the estimates of [4] (p. 1084, the last paragraph of §2) or [17], (Lemma 4.1 and the paragraph following equation (2.8)) (or alternatively, this can be deduced by analyzing the implications of our Proposition 8), this improvement gives us a basis for separating and isolating the zeros of $p(x)$ from each other and, therefore, for their rapid subsequent refinement via Newton's iteration.

We organize the remaining part of the paper as follows: In §2 we estimate some correlations between the absolute value of the discriminant of $p(x)$ (or of the resultant $R(p, p')$ of $p(x)$ and $p'(x)$) and the mth diameter of the set of zeros of $p(x)$. In §3 we estimate $|R(p + \Delta, p')|$ as a function in Δ. In §4 we show our hybrid deterministic algorithm. In §5 we combine the results of §§2–4 into our basis lemma (Proposition 9). In §6 we summarize our study in the form of a parallel algorithm. In §7 we modify this algorithm for the sequential computation and will deduce the complexity estimates of Theorem 1. In §8 we comment on the recursive application of our algorithms. In §9 we improve our complexity estimates over a large class of the input polynomials $p(x)$. Finally, in the appendix we recall some auxiliary results on perturbation of polynomial zeros.

Hereafter, all logarithms are to the base 2, and each polynomial zero of multiplicity μ is counted as μ zeros.

2. The magnitude of the resultant and the distances between polynomial zeros. In this section we will relate the distances between some zeros of a polynomial $p(x)$ of (1) to the absolute value of R, the resultant of this polynomial and its derivative $p'(x)$. We will make use of the two following expressions for R:

$$(13) \qquad R = R(p_0, \ldots, p_n) = (-1)^{n(n-1)/2} p_n^{2n-1} \prod_{1 \le i < j \le n} (x_i - x_j)^2;$$

R equals the determinant of the $(2n - 1) \times (2n - 1)$ Sylvester (resultant) matrix,

$$(14) \qquad R = \det S\,, \quad S = \begin{bmatrix} p_n & & O & (np_n) & & O \\ \vdots & \ddots & & \vdots & \ddots & \\ p_2 & \cdots & p_n & (2p_2) & & \\ p_1 & \cdots & p_{n-1} & p_1 & \cdots & (np_n) \\ p_0 & \cdots & p_{n-2} & & & \\ & \ddots & \vdots & & \ddots & \vdots \\ O & & p_0 & O & & p_1 \end{bmatrix}.$$

Equation (14) implies, in particular, the following proposition.

PROPOSITION 2. *The resultant R is a polynomial in* $p_0, p_1, \ldots, p_n$ *with integer coefficients, having the total degree* $2n - 1$.

We will recall (4), ignore the case of multiple zeros, assume for a moment that $R \neq 0$, and will immediately deduce from (13) the following proposition.

PROPOSITION 3. *Let us denote that*

$$D = D(p_0, \dots, p_n) = |R(p_0, \dots, p_n)/p_n^{2n-1}|. \tag{15}$$

Then for any integer m, $2 \leq m \leq n$, *we have that*

$$D \leq d_n^{n(n-1)}(d_m/d_n)^{m(m-1)}, \qquad m = 1, 2, \dots, n. \tag{16}$$

Hereafter, we will assume that n is even, $n = 2m$, so that $m(m-1) = n(n-2)/4$. Then we will deduce from (16) that

$$D/d_n^{n(3n-2)/4} \leq d_m^{n(n-2)/4}, \tag{17}$$

$$D^{4/n(n-2)}/d_n^{(3n-2)/(n-2)} \leq d_m. \tag{18}$$

3. Probabilistic lower bound on the magnitude of the resultant. Let Δ denote a random complex parameter under the uniform probability distribution on the circle

$$|\Delta| = \rho, \tag{19}$$

where the value ρ will be fixed later on. We are going to deduce some probabilistic lower bound on $|R_h(\Delta)| = |R(p_0, \dots, p_{h-1}, p_h + \Delta, p_{h+1}, \dots, p_n)|$, $0 \leq h \leq n$ (compare (13)). Recall Proposition 2 and rewrite $R_h(\Delta)$ as a polynomial in Δ,

$$R_h(\Delta) = \sum_{i=0}^{n} r_{h,i}\Delta^i = r_{h,k}\prod_{j=1}^{k}(x - x_{j,h}(\Delta)), \qquad k = k(h) \leq n, \tag{20}$$

where $r_{h,i}$ are polynomials in $p_0, \dots, p_n$ with integer coefficients and have total degrees at most $2n - 1 - i$, $i = 0, 1, \dots, n$. Furthermore,

$$r_{h,1} = \partial R/\partial p_h, \qquad h = 0, 1, \dots, n, \tag{21}$$

$$r_{0,n} = 0, \qquad r_{0,n-1} = (-1)^{n(n-1)/2}(np_n)^n. \tag{22}$$

The next simple result is the basis for our algorithms.

PROPOSITION 4. *For a random* $\Delta = |\rho|$, *under the uniform probability distribution on the circle* (19), *for any pair of nonnegative integers* $h \leq n$, $u \leq n$, *and for any fixed positive* ρ, *we have*

$$|R_h(\Delta)| > 0.5|r_{h,u}|\rho^u \tag{23}$$

with a probability at least $1/(2k(h) + 1) \geq 1/(2n + 1)$, *where* $k(h)$ *is defined by* (20).

Proof. Let j be an integer such that

$$|r_{h,u}|\rho^u \leq |r_{h,j}|\rho^j = \max_{0 \leq i \leq n}(|r_{h,i}|\rho^i), \qquad 0 \leq j \leq n. \tag{24}$$

It is well known from analytic function theory that

$$\int_{|\Delta|=\rho}(R_h(\Delta)/\Delta^{j+1})\,d\Delta = 2\pi\sqrt{-1}\,r_{h,j}.$$

Representing Δ as $\rho \exp(2\pi\sqrt{-1}\,\phi)$, we obtain that

$$(1/\rho^j)\int_0^{2\pi} |R_h(\Delta)|\,d\phi = \int_0^{2\pi} |R_h(\Delta)/\Delta^{j+1}|\,\rho\, d\phi \geq 2\pi |r_{h,j}|,$$

$$\frac{1}{2\pi}\int_0^{2\pi} |R_h(\Delta)|\,d\phi \geq |r_{h,j}|\,\rho^j,$$

so that $|r_{h,j}|\rho^j$ is a lower bound on the average value of $|R_h(\Delta)|$ on the circle (19). To complete the proof, we compare this bound with the following upper bound: $|R_h(\Delta)| \leq \sum_{i=0}^{k(h)} |r_{h,i}|\rho^i \leq (k(h)+1)|r_{h,j}|\rho^j$, then recall (24). □

Hereafter, denote that

$$\tilde{p}_{h,n} = p_n + \Delta \text{ if } h = n; \qquad \tilde{p}_{h,n} = p_n \text{ otherwise.}$$

Assume that $\tilde{p}_{h,n} \neq 0$ for all h. Recall (20) and, similarly to the definitions (15) and (4), denote that

$$D_h(\Delta) = |R_h(\Delta)/\tilde{p}_{h,n}^{2n-1}|,$$

$$d_{h,k}(\Delta) = \min_{|J|=k}\max_{i,j\in J} |x_{h,i}(\Delta) - x_{h,j}(\Delta)|, \qquad k = 2, 3, \ldots, n, \quad h = 0, 1, \ldots, n,$$

and rewrite (18) as

$$(25) \qquad (D_h(\Delta))^{4/n(n-2)} / (d_{h,n}(\Delta))^{(3n-2)/(n-2)} \leq d_{h,m}(\Delta), \qquad m = n/2.$$

Rewrite $(3n-2)/(n-2)$ as $3 + 4/(n-2)$, combine (23) and (25), and obtain that

$$(26) \qquad d_{h,m}(\Delta) > (0.5\,|\,r_{h,u}\tilde{p}_{h,n}^{1-2n}|\rho^u)^{4/n(n-2)} / (d_{h,n}(\Delta))^{3+4/(n-2)},$$

$u, h = 0, 1, \ldots, n$, with a probability at least $1/(2n+1)$.

In particular, substitute (22) into (26), for $h = 0$, $u = n-1$, and arrive at the inequality

$$(27) \qquad d_{0,m}(\Delta) > (0.5n^n)^{4/n(n-2)} |\rho/p_n|^{4(n-1)/n(n-2)} / \left(d_{0,n}(\Delta)\right)^{3+4/(n-2)},$$

where $\lim_{n\to\infty}(0.5n^n)^{4/n(n-2)} = 1$.

Also, substitute (21) into (26), for $u = 1$ and $h = 0, 1, \ldots, n$, to obtain that

$$(28) \qquad d_{h,m}(\Delta) > \left(0.5|\tilde{p}_{h,n}^{1-2n}\frac{\partial R}{\partial p_h}|\rho\right)^{4/n(n-2)} / (d_{h,n}(\Delta))^{3+4/(n-2)}.$$

4. A deterministic algorithm for polynomial factorization. Hereafter, $S(C, r)$ will denote the square on the complex plane, with the center C and with the sides parallel to the real and imaginary axes and having length $2r$. $D(C, r)$ will denote the disc on the complex plane, with the center C and radius r. We assume that $S(C, r)$ and $D(C, r)$ denote closed complex domains.

$\tilde{R}/r$ is called the *isolation ratio* of the square $S(C, r)$ or of the disc $D(C, r)$ if $\tilde{R}$ is the minimum value such that the domains $S(C, \tilde{R}) - S(C, r)$ or, respectively, $D(C, \tilde{R}) - D(C, r)$ contain a zero of $p(x)$.

We next recall some known results.

PROPOSITION 5. *Given the coefficients $p_0, \dots, p_n$, a complex C and a constant θ, $0 < \theta < 1$, it is possible, at the cost $O_A(\log n, n)$, to evaluate r such that*

$$\theta r \le r(C, p(x)) = \max_{1 \le j \le n} |C - x_j| \le r. \tag{29}$$

Remark 3. $d_n \le 2r(C, p(x)) \le 2r$, under the notation of (29).

Proposition 5 relies on an old algorithm of Turan (see [27] and [28]) complemented with more recent estimates for the complexity of its blocks.

PROPOSITION 6 [19]. *Let a complex C and a positive r be two given values that satisfy* (6) *and* (29). *Then there exists a natural $H = H(n, r, \theta) = O(\log n)$ such that, for every $K > H$, it is possible, at the cost $O_A(K \log n, n^2)$, to compute complex C_i, real r_i, and natural $g \ge 2$ and $k_i \ge 1$, $i = 1, \dots, g$, such that for all i*

$$r_i \le rn/2^K, \tag{30}$$

and $S(C_i, r_i)$ has an isolation ratio of at least 3 *and contains exactly k_i zeros of $p(x)$; furthermore, $\sum_{i=1}^{g} k_i = n$, and $S(C_j, r_j) \cap S(C_h, r_h)$ is empty for any pair of j and h such that $1 \le j < h \le g$.*

The proof of Proposition 6 in [19] exploits and improves the search-and-exclusion construction of Weyl for approximating polynomial zeros (compare [12], [22], and [24] on other applications of Weyl's construction).

PROPOSITION 7. *Let $S(C_i, r_i)$, the squares defined in Proposition* 6, *for $i = 1, \dots, g$, be given to us, together with the associated integers k_i and with a positive ϵ^*. Let us denote*

$$b = b(\epsilon^*) = (1/n)\log(1/\epsilon^*). \tag{31}$$

Then, at the cost $O_A(\log n \log(bn), gn \log b/\log(bn))$, the coefficients of $g \le n$ monic polynomials $p_1(x), \dots, p_g(x)$ can be computed such that the polynomial $p_i(x)$ has exactly k_i zeros, all lying in $S(C_i, r_i)$, $i = 1, \dots, g$, and

$$\|p(x) - p_1(x) \cdots p_g(x)\| \le \epsilon^*. \tag{32}$$

Proposition 7 follows from the results of [25] (Corollary 4.3 and §12) applied to the discs $D(C_i, r_i\sqrt{2})$, $i = 1, \dots, g$; such a disc $D(C_i, r_i\sqrt{2})$ contains exactly k_i zeros of $p(x)$ (lying in the square $S(C_i, r_i)$) and has an isolation ratio at least $3/\sqrt{2} > 2$ (compare Remark 4).

Combining Propositions 5–7, we devise the following algorithm.

Algorithm 1. Input: the complex coefficients $p_0, \dots, p_{n-1}$ of a polynomial $p(x)$ of (1) and a positive ϵ^*.

Output: positive integers $g > 1$, $k_1, \dots, k_g$ (such that $k_1 + \cdots + k_g = n$) and the coefficients of monic polynomials $p_i(x)$ of degrees k_i, $i = 1, \dots, g$, satisfying (32).

Stage 1. Compute C and r satisfying (6) and (29).

Stage 2. Compute the squares $S(C_i, r_i)$ defined in Proposition 6.

Stage 3. Compute a factorization (32), by following Proposition 7.

We immediately deduce the bounds

$$C_A^* = O_A((K + \log(bn))\log n, n^2) \tag{33}$$

on the parallel cost of the computation by Algorithm 1, where b has been defined in Proposition 7 and where we may choose any K exceeding $H = O(\log n)$. (Later on, we will see some advantages of choosing a larger value of K.)

We may recursively apply Algorithm 1 in whose input set we replace $p(x)$ by the polynomials $p_1(x), \dots, p_g(x)$, as long as they have degrees exceeding 1 (these g applications can be performed concurrently, and similarly in the further recursive steps). The maximum degree of the output polynomials of Algorithm 1 is $n - g + 1$ or less, so that in at most $n - 1$ its applications and at the overall cost bounded by $O_A((K + \log(bn))n \log n, n^2)$, we will arrive at the factorization (2) of $p(x)$ into linear factors. Here, we impose the same error bound ϵ^* for the numerical factorization of all the auxiliary polynomials that we factorize in this recursive process. We choose this bound ϵ^* sufficiently small, so as to ensure the error bound ϵ for the complete numerical factorization (2). Specifically, we are guided by the next proposition from §5 of [25], which relates ϵ^* to ϵ:

PROPOSITION 8. *Let*

$$\|p(x) - p_1(x) \cdots p_h(x)\| \le \epsilon h/n, \quad \|p_1(x) - f(x)g(x)\| \le \epsilon^*,$$

$$\epsilon^* = \frac{\epsilon \|p_1(x)\|}{n2^n \|p(x)\|}.$$

Then

$$\|p(x) - f(x)g(x)p_2(x) \cdots p_h(x)\| \le (h + 1)\epsilon/n.$$

Due to Proposition 8, it is sufficient to choose

$$\epsilon^* = \frac{\epsilon \|w(x)\|}{n2^n \|p(x)\|} \ge \frac{\epsilon}{n2^n \|p(x)\|} \tag{34}$$

whenever Algorithm 1 is applied to a monic polynomial $w(x)$ in the recursive process described above.

Next suppose that, by modifying the first step of this recursive process, we may ensure a more rapid decrease of the degrees of the factors, such that

$$\max_{1 \le i \le g} \deg p_i(x) < 0.5 \deg p(x) = n/2,$$

and similarly at all the next recursive steps. Then it would have sufficed to use $\lfloor \log n \rfloor$ (rather than $n - 1$) concurrent recursive steps of application of Algorithm 1 (as before, we ensure the desired output error bound ϵ by imposing the error bound ϵ^* of (34) at all the recursive steps).

We easily estimate that in this case the complexity of recursive step i is $O_A((K + \log(bn)) \log n, n^2/2^i)$, for $i = 1, 2, \dots, \lfloor \log n \rfloor$, which implies that the overall complexity of the complete numerical factorization of $p(x)$ into linear factors is $O_A((K + \log(bn)) \log^2 n, n^2/\log n)$. (To arrive at this bound, we apply Brent's principle of [10] by slowing down those recursive steps that otherwise would have used more than $n^2/\log n$ processors.)

In comparison to our previous bound of $O_A((K + \log(bn))n \log n, n^2)$ in the case of unbalanced recursive splitting of $p(x)$, we now note the decrease of both the sequential time bound (by the factor of n) and the parallel time bound (by the factor of $n/\log n$), so that Algorithm 1 performs much more effectively in the cases where the factors computed at its recursive steps have smaller degrees. In the next sections we will apply a randomization technique to split $p(x)$ into factors of degrees less than $n/2$.

Remark 4. Algorithm 1 is a modification (based on the results of [19]) of the algorithm of [25]. The recursive step of [25] splits $p(x)$ into two factors, whose zeros lie inside and, respectively, outside a fixed disc that has an isolation ratio of the order of $1 + 1/n$. Since we deal with the squares $S(C_i, r_i)$ of Propositions 6 and 7, having isolation ratios at least 3, the computation of the splitting by using Algorithm 1 is substantially simpler than the similar computation in [25].

5. How to ensure a balanced partition of the set of zeros. In the next result, we use D and r defined by (15) and (29).

PROPOSITION 9. *Let the integer K of Proposition 6 be chosen such that*

$$2^{K-0.5} > n(2r)^{4(n-1)/(n-2)} \,/\, D^{4/(n(n-2))}. \tag{35}$$

Then $2\sqrt{2}r_i < d_m$ for $i = 1, \dots, g$, that is, every square $S(C_i, r_i)$, $i = 1, \dots, g$, of Proposition 6 contains less than $m = n/2$ zeros of $p(x)$.

Proof. Proposition 9 immediately follows from the comparison of the upper bound (30) on r_i with the lower bound (18) on d_m. (Compare also Remark 3 and observe that the diameter of the square $S(C_i, r_i)$ equals $2\sqrt{2}\,r_i$.) □

Remark 5. The reader may extend (18) and Proposition 9, as well as our subsequent study, by choosing a smaller m, say, $m = \sqrt{n}$.

Proposition 9 can be immediately extended to the case where $p(x)$ is replaced by $p(x)+\Delta$, for Δ of (19), D by $D_0(\Delta)$ (see §3) and similarly r of (29) by $r_0(\Delta)$; in particular, we may rewrite the assumption (35) as follows:

$$D_0(\Delta) > (2r_0(\Delta))^{(n-1)n}\, n^{(n-2)n/4}\, 2^{-(K-0.5)(n-2)n/4}, \tag{36}$$

where the quantity K will be estimated later on.

Now let d, K, Δ and $\rho = |\Delta|$ be such that $d \geq 2r_0(\Delta)$,

$$0.5|r_{0,n-1}\, p_n^{1-2n}|\rho^{n-1} \geq d^{(n-1)n}\, n^{n(n-2)/4} \,/\, 2^{(K-0.5)n(n-2)/4}. \tag{37}$$

Apply Proposition 4 for $h = 0$, $u = n - 1$ and deduce that (with a probability at least $1/(2n + 1)$) we have:

$$\begin{aligned} D_0(\Delta) = |R_0(\Delta) \,/\, p_n^{2n-1}| &> 0.5|r_{0,n-1} \,/\, p_n^{2n-1}|\rho^{n-1} \\ &\geq d^{(n-1)n}\, n^{n(n-2)/4}\, 2^{-(K-0.5)n(n-2)/4}. \end{aligned}$$

Since $d \geq 2r_0(\Delta)$, the latter inequality implies (36), and, consequently, implies the extension of Proposition 9 to the case where the polynomial $p(x) + \Delta$ replaces $p(x)$.

6. The factorization algorithm. Now we are ready to summarize our previous study, by devising the following randomized (of Las Vegas type) algorithm.

Algorithm 2. Input: the complex coefficients $p_0, \dots, p_{n-1}$ of a polynomial $p(x)$ of (1), a positive ρ such that

$$r(C, p(x)) \leq 2r(C, p(x) + \Delta) \leq 3r(C, p(x)) \text{ if } |\Delta| = \rho, \quad C = -p_{n-1}/(np_n) \tag{38}$$

(compare Remark 6), and a tolerance δ to the probability of a failure, $0 < \delta < 1$ (compare (7)).

Output: FAILURE with a probability at most δ or, otherwise, an integer g, $g > 2$, a complex value Δ, $|\Delta| = \rho$, and the coefficients of g polynomials $p_i^*(x, \Delta)$ having degrees less than $n/2$ and satisfying the inequality (40) below.

Stage 1. Successively compute the values

$$\nu = \lceil (2n + 1)\log(1/\delta) \,/\, \log 3 \rceil, \tag{39}$$

then C and r satisfying (6) and (29), setting throughout $\Theta = 0.99$ (compare (29) and Remark 6), then $d = 3.1\,r$, and finally, the minimum positive integer K exceeding H of Proposition 6 and satisfying (37). Choose ν independent random values Δ on the circle $|\Delta| = \rho$, under the uniform probability distribution.

Stage 2. For all such values Δ and for $\Delta = 0$, concurrently compute $D_0(\Delta)$. If (36) has been satisfied for none of the values Δ, end this computation and output FAILURE. Otherwise, fix some Δ for which (36) holds, apply Algorithm 1 to the polynomial $p(x) + \Delta$ in order to compute and to output a natural $g > 2$ and the coefficients of the polynomials $p_i^*(x, \Delta)$ that approximate g distinct nonconstant factors $p_i(x, \Delta)$ of $p(x) + \Delta$, for $i = 1, \ldots, g$, such that

$$(40) \qquad \begin{gathered} p(x) + \Delta = \textstyle\prod_{i=1}^{g} p_i(x, \Delta); \quad \|p(x) + \Delta - \prod_{i=1}^{g} p_i^*(x, \Delta)\| \leq \rho; \\ \|p(x) - \textstyle\prod_{i=1}^{g} p_i^*(x, \Delta)\| \leq 2\rho, \end{gathered}$$

and end the computations. (Note that 2ρ plays the role of ϵ^* of (32), (34), and Algorithm 1.)

Let us next show the correctness of the algorithm. First observe that $d = 3.1\,r \geq 3.1\,r\big(C, p(x)\big)$ (due to (29)). Recall (38) and obtain that $d \geq 2.05\,r(C, p(x) + \Delta)$. Extend (29) by replacing $p(x)$ by $p(x) + \Delta$ and r by $r_0(\Delta)$, and obtain that $d \geq 2.05\,\Theta\, r_0(\Delta)$. Substitute $\Theta = 0.99$ and obtain that

$$(41) \qquad d > 2r_0(\Delta).$$

Now apply Proposition 4, for $h = 0$, $u = n - 1$, and deduce that, with a probability at least $1/(2n + 1)$,

$$|R_0(\Delta)| > 0.5 r_{0,n-1}\rho^{n-1},$$

which implies that

$$D_0(\Delta) = |R_0(\Delta) \,/\, p_n^{2n-1}| > 0.5\, r_{0,n-1}|p_n^{1-2n}|\rho^{n-1}.$$

The latter inequality implies (36) since we have chosen the value of K satisfying (37). Therefore, we may apply Proposition 9 extended to the case of the input polynomial $p(x) + \Delta$. Then, application of Algorithm 1 at stage 2 of Algorithm 2 gives us a numerical factorization of $p(x) + \Delta$ satisfying (40), and we observe that the probability of a failure in an application of stage 2 to $p(x) + \Delta$ for all the ν values $\Delta \neq 0$ is at most $(1 - 1/(2n+1))^{\nu} < 1/3^{\log(1/\delta)/\log 3} = \delta$ (see (39)).

Remark 6. The assumption (38) surely holds for any sufficiently small positive ρ. In particular, we may deduce from Proposition 11 of Appendix A that it is sufficient if

$$(42) \qquad 2\rho < 40^{-n}|p_n|\,.$$

Of course, the reader may replace the "magic" numbers 2 and 3 in (38) and the value $\Theta = 0.99$ by various other candidate values, so as to preserve the correctness of Algorithm 2, respectively modifying (42).

Remark 7. In a heuristic attempt of derandomization, we may further modify stage 2 of Algorithm 2 by first computing the values of $R_0(\Delta)$ for $\Delta = \rho \exp(2\pi\sqrt{-1}\,k/n)$, $k = 0, \ldots, n - 1$, then the coefficients $r_{0,0}, \ldots, r_{0,n-1}$ of $R_0(\Delta)$ (by first performing FFT (which gives us $r_{0,i}\rho^i$, for $i = 0, 1, \ldots, n - 1$) and then scaling) and, finally, a complex Δ, $|\Delta| = \rho$, for which $|R_0(\Delta)|$ reaches its maximum on the circle $|\Delta| = \rho$. We may approximate (within the factor $\sqrt{2}$) this maximum by the maximum of the absolute value of its real and imaginary parts. If the coefficients $p_0, \ldots, p_n$ and, therefore, $r_{0,0}, \ldots, r_{0,n-1}$ are real, then these real and imaginary parts are represented as the trigonometric polynomials $\sum_{k=0}^{n-1} \rho^k r_{0,k} \cos(kt)$ and $\sqrt{-1}\sum_{k=0}^{n-1} \rho^k r_{0,k} \sin(kt)$, respectively, where $\Delta = \rho \exp(t\sqrt{-1})$ and t ranges from 0 to 2π. For a large class of input polynomials $p(x)$, such a reduction to approximating the maximum absolute value of the above trigonometric polynomials simplifies the original task of the factorization of a polynomial.

7. Computational complexity estimates. Next, we will assume that $p(x)$ and x have been scaled so that

$$d \leq 1 \tag{43}$$

and will estimate the parallel complexity c_A of performing Algorithm 2. Clearly, c_A is dominated by the complexity of computing $D_0(\Delta)$ for all the ν values Δ (bounded by $O_A(\log^2 n, \nu n^2 / \log n)$, due to [21]) and of applying Algorithm 1 (see (33)), so

$$c_A = O_A\big[(K + \log(bn)) \log n, n^2(1 + \nu/(K + \log(bn)))\big], \tag{44}$$

where K denotes the minimum integer exceeding H (defined in Proposition 6) and satisfying (37), $bn = -1 + \log(1/\rho)$ (compare (31)) and ν is defined by (39).

Now observe that (40) implies (32), for any $\rho \leq \epsilon^*/2$ and for $p_i(x) = p_i^*(x, \Delta)$, $i = 1, \dots, g$. Suppose that α, β, δ and ϵ are given as in Theorem 1, such that (7) holds. Then (38) holds for $\rho = \epsilon^*/2$ (see (5), (34), and Remark 6). Set $\rho = \epsilon^*/2$ and apply Algorithm 2.

Next, recall the definition of K given at stage 1 of this algorithm and choose the minimum K satisfying this definition, that is, the minimum $K \geq H + 1$ satisfying (37). Formally, let

$$K = \max\{H + 1, \lceil K^* \rceil\}, \tag{45}$$

where K^* is such that setting $K = K^*$ turns (37) into an equation, that is,

$$2^{(K^*-0.5)n(n-2)/4} = 2d^{(n-1)n}\, n^{(n-2)n/4}\, |p_n^{2n-1} / r_{0,n-1}\rho^{n-1}|.$$

Substitute (22), take logarithms on both sides, divide the resulting equation by $n(n-2)/4$ and obtain that

$$\begin{aligned} K^* &= 0.5 + 4/(n-2)n \\ &\quad + (1 - 4/(n-2)) \log n + ((4n-4) / (n-2)n) \log |p_n d^n / \rho|. \end{aligned} \tag{46}$$

Replace ρ by $\epsilon^*/2$, recall (5), (34), (43) and Proposition 9, and deduce from (43), (46) and the equation $H = O(\log n)$ (see Proposition 6) that

$$K = O(\log n + (1/n) \log(1/\epsilon)) = O(\log(n/\epsilon^{1/n})). \tag{47}$$

We also have that

$$bn = O(\log(1/\epsilon^*)), \tag{48}$$

$$\nu = O(n \log(1/\delta)) \tag{49}$$

(compare (31), (39)). Combining (34), (44)–(49), we obtain that $K + \log(bn) = \phi(n, \epsilon) = O(\log(\log(1/\epsilon) + (n/\epsilon^{1/n})))$, and arrive at (8):

$$c_A = O_A(\phi(n, \epsilon) \log n, n^3 \log(1/\delta) / \phi(n, \epsilon)).$$

To deduce the bound (9), we modify Algorithm 2 as follows.

Algorithm 3.

(a) Compute $R_0(\Delta)$ for n values Δ equal to all the nth roots of 1; for each value of Δ, such an evaluation amounts to computing the determinant of a Sylvester matrix, at the sequential cost $O_A(n(\log n)^2, 1)$ [7], [8], [16]; this means $O_A((n \log n)^2, 1)$ for all the values Δ;

(b) compute the coefficients of $R_0(\Delta)$ as a polynomial in Δ (see (14) and (20)) by means of the inverse FFT, at the cost $O_A(\log n, n)$ or $O_A(n \log n, 1)$ [1];

(c) define ν by (39) and compute $D_0(\Delta)$, for ν random and independent values Δ on the circle $|\Delta| = \rho$, at the overall cost $O_A((\nu + n)\log^2 n, 1)$ [1], [7], [9];

(d) among these ν values, choose the value Δ that maximizes $|D_0(\Delta)|$ and output FAILURE if (36) does not hold, for this value of Δ;

(e) otherwise, if (36) holds, apply Algorithm 1 to the polynomial $p(x) + \Delta$, at the cost $C_A^* = O_A((K + \log(bn))\log n, n^2)$, bounded according to (33), (45)–(48); by Brent's principle of [10], this implies the sequential cost bound $(sC)_A^* = O_A(n^2(K + \log(bn))\log n, 1)$.

Summarizing all these estimates for the complexity of performing Algorithm 3 and assuming (7), (38), and (39), we arrive at the bound (9) on the sequential complexity of computing the approximate factorization (2), thus proving Theorem 1. □

Remark 8. We may perform stage (a) of Algorithm 3 at the cost $O_A(\log^2 n, n^3/\log n)$ by concurrently applying the parallel algorithm of [21] for all the n values of Δ. Stage (c) can be performed at the parallel cost $O_A(\log^2 n, (\nu + n)\log\log(\nu + n))$ [7], which turns into $O_A(\log^2 n, n\log(1/\delta)\log\log(n\log(1/\delta)))$ under (39) and which is dominated by the above bound on the cost at stage (a) under the mild condition that $\log(1/\delta) = o(n^2/\log n)$. Assuming this condition and recalling the bound $O_A(\phi(n,\epsilon)\log n, n^2)$, $\phi(n,\epsilon) = O(\log(\log(1/\epsilon) + (n/\epsilon^{1/n})))$, on the cost at stage (e), we obtain the overall cost bound

$$O_A(\phi(n,\epsilon)\log n\,,\; n^2 + n^3/\phi(n,\epsilon)), \tag{50}$$

which slightly improves (8).

8. Extension to recursive factorization. Unless FAILURE has been output, stages 1 and 2 of Algorithms 2 or 3 can be repeated with each of the polynomials $p_i(x, \Delta)$ of degree $k_i > 1$ replacing $p(x)$, with k_i replacing n in (37), and with

$$\nu_i = \lceil (2k_i - 1)\log(1/\delta)\,/\,\log 3 \rceil$$

replacing ν of (39). Then the failure probability is at most δ at this factorization stage for all the $p_i^*(x, \Delta)$. The difficulty with this extension of Algorithms 2 and 3 is that in order to compute the factorization of $p_i^*(x, \Delta)$, we need to replace n by k_i in both (37) and (46), so that at this step, our estimate gives us $K = O((1/k_i)\log(1/\rho))$, rather than $K = O((1/n)\log(1/\rho))$. At the subsequent recursive steps, we need to replace k_i, in this expression for K, by smaller and smaller values. This means that we need to choose larger and larger values of K to ensure the desired bound on the approximation error of the factorization. This would increase the running time of the algorithm. Thus, at some recursive step, the estimated time of our randomized computation may exceed the estimated time bound for the recursive step of the deterministic algorithm (based on Algorithm 1), to which we shall shift at this point. It is desired, of course, to decrease the error of the factorization, so as to take advantage of the randomization as long as possible, reaching the factors of $p(x)$ that have smaller degrees. To achieve this, we will next slightly modify our randomization approach. (An alternative is to rely on Remark 5 instead of recursion.)

9. Decreasing upper bounds on the factorization error. Algorithms 2 and 3 and their analysis in §7 relied on (22) and (27). For a very large class of input polynomials $p(x)$, we may substantially improve the asymptotic complexity bounds (8) and (9). In particular, we may insure the complexity estimates (11) and (12) under the assumption on ϵ that is weaker than (10), namely, if we only assume that, roughly,

$$\log(1/\epsilon) = O(n^{1+\alpha}(\log n)^{\beta}), \tag{51}$$

that is, for a large class of inputs, we may arrive at a superior approximation to the factorization of $p(x)$ by using roughly the same amount of computational resources. (We refer to (55) and (56) below, for a more precise statement of the assumption (51).) The improvement is important in the recursive application of the factorization algorithms (see the previous section).

Let us supply some details. Denote

$$w_h = 0.5|\tilde{p}_{h,n}^{1-2n}\,\partial R/\partial p_h|, \qquad h = 0, 1, \dots, n, \tag{52}$$

substitute this expression on the right side of (28), also replacing $d_{h,n}(\Delta)$ by d of (41), $d \geq d_{h,n}(\Delta)$, and obtain that

$$d_{h,m}(\Delta) > (w_h\rho)^{4/n(n-2)} \,/\, d^{3+4/(n-2)}. \tag{53}$$

We need to choose K such that $dn\sqrt{2}/2^K < d_{h,m}(\Delta)$, due to Proposition 6. Assume that $w_h \neq 0$ and extend Proposition 9 replacing (45) and (46) by the following expression:

$$K = \max\left\{H+1, \left\lceil 0.5 - \frac{4}{n(n-2)}\log(w_h\rho) + \log n + \frac{4n-4}{n-2}\log d\right\rceil\right\}. \tag{54}$$

Assume that $\rho = \epsilon^*/2$ and $d \leq 1$ (compare (34) and (43)), and deduce that

$$K = O(\log n + (1/n^2)\log(1/(w_h\epsilon))) = O(\log n \,/\, (w_h\epsilon)^{1/n^2}), \text{ unless } w_h = 0.$$

This is a considerable improvement of (47) unless w_h is small. Clearly, w_h does not decrease as $\epsilon \to 0$, and (52) and Proposition 2 imply that

$$w_h \geq 0.5\, z\, |z\tilde{p}_{h,n}|^{1-2n}$$

if $z \neq 0$, zp_i are integers for all i and $\partial R/\partial p_h \neq 0$. Furthermore, we may evaluate $\partial R/\partial p_h$, for $h = 0, 1, \dots, n$, at the same asymptotic computational cost (bounded by $O_A(\log^2 n, n^2 \,/\, \log n)$ or alternatively by $O_A(n\log^2 n, 1)$) that we need for the evaluation of R. We achieve this just by applying to R the parallel algorithm of [13], which extends the sequential algorithm of [3] and [15]. (The algorithm of [13] computes all the first order partial derivatives of any polynomial $p(y_1, \dots, y_s)$ at the cost $O_A(t, p)$, provided that an algorithm is available that computes $p(y_1, \dots, y_s)$ at the cost $O_A(t, p)$, by using only arithmetic operations, with no branchings.)

Thus, initially, we may compute $\partial R/\partial p_h$ and $w_h\rho$, for $h = 0, 1, \dots, n$, then choose h for which w_h is maximum, and finally compare $w_h\rho$ with $0.5\,n^n\,|\rho \,/\, p_n|^{n-1}$ (see (22), (23)). If the latter value is greater, we shall go to Algorithms 2 or 3 with no changes. Otherwise, we shall apply one of these algorithms, replacing $D_0(\Delta)$ by $D_h(\Delta)$ and K of (45) and (46) by K of (54).

In the latter case, we shall replace $\phi(n, \epsilon)$ in (8), (9), and (50) by $\psi(n, \epsilon) = \log(\log(1/\epsilon) + n/(\epsilon w_h)^{1/n^2})$, and thus shall arrive at the improved overall complexity estimates. In particular, we may deduce (11) and (12) relaxing our previous assumption that $\log(1/\epsilon) = O(n^\alpha(\log n)^\beta)$ and only assuming that

$$\log\log(1/\epsilon) = O((\log n)^\beta), \tag{55}$$

$$\log(1/(\epsilon w_h)) = O(n^{\alpha+1}(\log n)^\beta), \quad \text{for fixed} \quad \alpha \geq 1,\ \beta \geq 1. \tag{56}$$

(Equations (55) and (56) turn into (51) if, say, $1/w_h = O(1)$.)

Remark 9. Instead of computing all the partial derivatives, we may just try to factorize the polynomial $\sum_{i=0}^{n}(p_i + c_i\Delta)x^i$ where c_i have been chosen at random, say, in the real interval from 1 to 2 and Δ has been chosen as before, at random on the circle (19) for an appropriate ρ. This approach (for appropriate ρ) shall work as long as $\partial^h(\det S)/(\partial p_i)^h \neq 0$ for some $h = O(1)$ and for some $i \geq 1$ (not necessarily for $i = 1$).

Appendix A. Perturbation of polynomial zeros. Approximation to polynomial zeros and numerical polynomial factorization involve some nontrivial estimates of how much the zeros are perturbed by the perturbation of the coefficients (compare (2), (3), and Proposition 8). This problem is closely related to our study, and next, for the reader's convenience, we will recall and adjust to our purpose some known results on this topic.

We will first recall a simple corollary (see [12] and [17]) from a perturbation theorem by Ostrowski. This theorem bounds the magnitude of the perturbation of the coefficients so that the magnitude of the resulting perturbation of the zeros of $p(x)$ never exceeds $2^{-\mu}$.

Let us denote that

$$\|u_i x^i\|_\infty = \max_i |u_i|.$$

PROPOSITION 10. *For two monic polynomials $p(x)$ and $p^*(x)$ of degree n, where $\|p(x)\|_\infty < 2^m$, $\|p(x) - p^*(x)\|_\infty \leq 2^{-h}$, the zeros $x_1, \dots, x_n$ of $p(x)$ and $x_1^*, \dots, x_n^*$ of $p^*(x)$ can be enumerated so that* $\max_j |x_j - x_j^*| < 2^{m+\log n+2-h/n}$.

We may improve the latter estimates for a large class of polynomials whose zeros inside and outside the unit circle $|x| \leq 1$ are isolated from each other (see [25]). Alternatively, without imposing the latter restriction, we may just scale x so as to place all the zeros inside this circle (as we have assumed in (6)), then argue somewhat similarly to [25], and arrive at the next improved estimates.

PROPOSITION 11. *Given a natural N, a positive $\epsilon < 0.5/40^N$, and the complex coefficients of two monic polynomials of degree N, $P(x)$ and $P^*(x)$, such that $P(x) = \prod_{j=1}^N (x - x_j)$,*

$$\|P(x) - P^*(x)\| < \epsilon, \tag{57}$$

$$\max_j |x_j| \leq 1, \tag{58}$$

we may enumerate the zeros of $P^*(x)$ so that $P^*(x) = \prod_{j=1}^N (x - x_j^*)$ and

$$|x_j - x_j^*| < 4.4(2\epsilon)^{1/N}, \qquad j = 1, \dots, N. \tag{59}$$

Proof. First observe that $P^*(x) = 0$ implies that

$$|P(x)| = |P(x) - P^*(x)| \leq \|P(x) - P^*(x)\| \max(1, |x|^N). \tag{60}$$

Therefore, the open set

$$T = \{z\colon\ |P(z)| < \epsilon \max\{1, |z|^N\}\}$$

contains all the zeros of $P(x)$ and $P^*(x)$. Furthermore, the homotopy argument shows that in a fixed component T_k of T, the polynomial $P(t, x) = P(x) + t(P^*(x) - P(x))$ has the same number of zeros for all t from 0 to 1; in particular, the two polynomials $P(x) = P(0, x)$ and $P^*(x) = P(1, x)$ have the same number of zeros in T_k.

Now, let $P(x) = 0$, for some $x \in T_k$, so that $|x| \leq 1$ (see (58)). Let

$$\operatorname{arc}(x, y) = \{x(u) = x + u\,z(u)\,,\ |z(u)| = 1,\ 0 \leq u \leq d\} \tag{61}$$

be an arc in T_k with the endpoints $x = x(0)$, $y = x(d)$. Then $|P(x + u\,z(u))| = \prod_j |x - x_j + u\,z(u)|$. On the other hand, by applying first (60) and then (57) and (61), we deduce that $|P(x + u\,z(u))| < \epsilon \max\{1, |x + u\,z(u)|^N\} \leq \epsilon(1 + u)^N \leq \epsilon(1 + d)^N$. Therefore,

$$|s(u)| = \left|\prod_{j=1}^N (u - |x - x_j|)\right| \leq \prod_{J=1}^N |x - x_j + u\,z(u)| < \epsilon(1 + d)^N \quad \text{for} \quad 0 \leq u \leq d.$$

The monic polynomial $s(u)$ has degree N, so that $2\max_{0\leq u\leq d}|s(u)| \geq (d/4)^N$ [11, p. 241]. Consequently, $(d/4)^N < 2\epsilon(1+d)^N, d < 4(1+d)(2\epsilon)^{1/N}$. It follows that

$$d \leq 0.1(1+d),\ d \leq 1/9 \quad \text{for} \quad 2\epsilon \leq 1/40^N,$$

and therefore

$$d < 4.4(2\epsilon)^{1/N},$$

which implies (59). □

Let us now apply Proposition 11 under (42), to ensure (38). Equations (42) and (59) together imply that

$$|r(C, p(x)+\Delta) - r(C, p(x))| < 4.4(2\rho/|p_n|)^{1/n} < 0.11,$$

which together with (6) implies (38). (Note that the alternative application of Proposition 10 (instead of Proposition 11) would require that one replace (42) by a stronger bound, of the order of $\rho = (1/n)O(n)$, in order to deduce (38).)

Acknowledgments. I wish to thank Joseph Lewittes and John Reif for their stimulating discussions, the referees for their helpful comments, also C. Engle for her assistance in typing the manuscript.

Note added in proof. RANDOMIZED ALGORITHMS FOR MULTIPROCESSOR PAGE MIGRATION*

JEFFERY WESTBROOK†

Abstract. The *page migration* problem is to manage a globally addressed shared memory in a multiprocessor system. Each physical page of memory is located at a given processor, and memory references to that page by other processors incur a cost proportional to the network distance. At times the page may migrate between processors at cost proportional to the distance times D, a page size factor. The problem is to schedule movements on-line so that the total cost of memory references is within a constant factor c of the best off-line schedule. An algorithm that does so is called c-competitive. Black and Sleator gave 3-competitive deterministic on-line algorithms for uniform networks (complete graphs with unit edge lengths) and for trees with arbitrary edge lengths. No good deterministic algorithm is known for general networks with arbitrary edge lengths.

Randomized algorithms are presented for the migration problem that are both simple and better than 3-competitive against an oblivious adversary. An algorithm for uniform graphs is given. It is approximately 2.28-competitive as D grows large. A second, more powerful algorithm that works on graphs with arbitrary edge distances is also given. This algorithm is approximately 2.62-competitive (or, 1 plus the golden ratio) for large D. Both these algorithms use random bits only during an initialization phase, and from then on run deterministically. The competitiveness of a very simple coin-flipping algorithm is also examined.

1. Introduction.

A common design for a shared memory multiprocessor system is a network of processors, each of which has its own local memory [9], [14], [19]. In such a design, a programming abstraction of a single global memory address space is supported by a virtual memory system that distributes one or more copies of each physical page of memory among the processors' local memories. When processor p wishes to read or write to memory address a, located in page b, it first looks to see if page b is contained in its own local memory. If so, then the memory access is done immediately. If not, p determines some processor q that does hold page b, and transmits a memory request to q over the network. The communication cost is dependent on the interconnection distance between p and q. Processor q services the request, and transmits back to p the (updated) value at address a.

Having a given virtual page stored at multiple processors reduces communication overhead during memory reads, but introduces the problem of maintaining consistency among the multiple copies during writes. Most multiprocessors do not provide mechanisms for maintaining consistency [5]. Therefore, various network designers have studied the *page migration* problem [4], [5], [17], which arises when each writeable page is restricted to a single copy. Suppose the single copy of page b is initially located at processor q. If the page is going to be accessed frequently by processor p, then migrating the page from p to q will reduce the communication overhead. On the other hand, moving a full page of memory incurs a large amount of communication overhead, proportional to the size of the page. In addition, moving the page to p may increase the cost of satisfying future memory requests should the pattern of accesses change. The problem, then, is to design an on-line algorithm to schedule page migrations in response to dynamically changing access patterns.

Formally, an instance of the migration problem consists of an edge-weighted undirected graph G, and a real-valued constant, D, no smaller than 1. The graph G describes the

† Department of Computer Science, Yale University, New Haven, Connecticut 06520-8285 (westbrook@cs.yale.edu).

interconnection network; each node contains a processor. We assume the nodes are numbered from 1 to n. One node of G, denoted p, contains the page. Initially the page resides at node 1. The constant D corresponds to the size of the page. A *request at node r* is a reference by processor r to some memory address on the page. A sequence of requests is generated at the nodes of G. Each new request r is satisfied immediately at cost $\delta_{p,r}$, the shortest distance in G between p and r. After satisfying a request, the page can be moved from p to a new node p' at cost $d \cdot \delta_{p,p'}$. By definition, the distance function δ satisfies the triangle inequality: $\delta_{x,y} \leq \delta_{x,z} + \delta_{z,y}$. Since G is undirected, δ is symmetric.

For any sequence of requests, there is an optimum schedule of page movements that minimizes the total cost of requests and migrations. In general, an on-line algorithm cannot compute the optimum schedule, since it lacks knowledge of the future requests. An on-line algorithm is called *c-competitive* if, for any request sequence, its cost is no more than c times the cost of the optimum off-line cost for that sequence, for some constant c. Recently much attention has been given to *competitive analysis* of on-line algorithms [6], [13], [15], [18].

Black and Sleator [5] formalized and studied the page migration problem in the context of competitive analysis. They considered two classes of networks: uniform networks, i.e., complete graphs with each edge having length 1; and trees with arbitrary edge lengths. They developed 3-competitive deterministic algorithms for these two classes for any D. In addition, they showed that for all D, no deterministic algorithm could be better than 3-competitive, even if the graph consists of only a single edge. Little is known about deterministic algorithms for a complete graph with arbitrary edge weights. This problem seems quite hard. The best previous deterministic bound for the general case was either the $2n - 1$ bound for metrical task systems [6][1] or a $2D + 2$ bound given by a simple algorithm that moves the page to the requesting node after each request.

In this paper we use randomization to beat the deterministic lower bound and to give a fast algorithm for the general case. No randomized algorithms were known prior to this work. A randomized on-line algorithm is *c-competitive* (against an oblivious adversary) if, for any request sequence, its expected cost is no more than c times the cost of the optimum off-line cost for that sequence, for some constant c. There are also definitions of randomized competitiveness against stronger adaptive adversaries which are given in §2.

For uniform networks, we give a simple algorithm, UNIFORM, that is 2.38-competitive for large values of D. This algorithm is "barely random," in the sense that it only uses a small number of random bits during an initialization phase, and from then on runs deterministically. Such a barely random algorithm has practical value since random bits can be an expensive resource.

For the general problem (which includes trees) we develop a basic algorithm from which variants can be constructed by choosing different probability distributions. We consider two such choices. The first uses random coin flips after each request and gives an algorithm that is $(1 + \phi)$-competitive for large D, where ϕ is the golden ratio, approximately 1.62. We then show that a deterministic resetting strategy gives a barely random algorithm with a competitive ratio that also tends to $1 + \phi$, although it is always slightly larger than the competitive ratio of the first algorithm. Lastly we examine the competitiveness of a very simple coin-flipping algorithm. We show that on any network and for any D it is 3-competitive against an adaptive on-line adversary. The coin flipping algorithm is memoryless, and hence has no storage or network overhead, but needs to generate a random number every request. Applying a result of Ben-David et al. [2] to the coin-flipping algorithm and the $(1 + \phi)$-competitive algorithm mentioned above, we prove the existence of a $(3 + 3\phi)$-competitive deterministic algorithm for general networks.

[1] Technically, the metrical task bound hold for a slightly different model. See below.

Page migration is one of several problems that arise in managing data in a distributed environment. Black and Sleator [5] have studied the related problem of page replication, in which one may make multiple copies of a read-only page, and Karlin et al. [11] studied snoopy caching, which is memory management given a bus-based interconnection network. Other memory management problems have been studied in references [1], [12], [15]. Migration is related to the 1-*server with excursions* problem defined by Manasse et al. [13]. Migration and 1-server with excursion are also related to the k-*server* problems [3], [7], [13]. Practical issues and applications of page migration are discussed more fully in [4], [5], and [17]. Subsequent to the work presented here, Chrobak et al. found a $2 + 1/2D$-competitive algorithm for a single edge and for the tree topology [8], and showed that this bound is tight.

2. Competitive analysis and lower bounds. Let σ be a sequence of requests. The cost of an algorithm A on σ is denoted $\mathrm{A}(\sigma)$. We denote by OPT the off-line algorithm that achieves the optimum cost on σ. Following [6], [13] we say a deterministic algorithm A is c-*competitive* if there is a constant b such that for all request sequences σ,

$$\mathrm{A}(\sigma) \le c \cdot \mathrm{OPT}(\sigma) + b.$$

For randomized algorithms the competitiveness of an algorithm is defined with respect to an *adversary*. Following [2] and [15] we consider three kinds of adversaries.

A randomized on-line algorithm, A, is c-competitive against an *oblivious* or *weak* adversary if there is a constant b such that for all graphs and for all finite request sequences σ,

$$\mathrm{E}[\mathrm{A}(\sigma)] \le c \cdot \mathrm{OPT}(\sigma) + b.$$

The expectation is over the random choices made by the on-line algorithm. This is the natural extension of deterministic competitiveness, and models a situation in which the random choices of the algorithm do not affect the choice of requests. We will typically use "c-competitive" as an abbreviation for "c-competitive against an oblivious adversary." When an adaptive adversary is intended we will state so explicitly.

An *adaptive* adversary generates the request sequence on-line, choosing requests based on the actual moves made by the on-line algorithm. That is, an adaptive adversary $\hat{\mathrm{A}}$ is a function that takes as input a sequence of $k - 1$ requests and corresponding actions by the on-line algorithm, and outputs the kth request, up to a maximum number of requests, m. (Each adversary has its own value of m.) Since the output of $\hat{\mathrm{A}}$ depends on the random choices of the on-line algorithm, a randomized on-line algorithm and an adaptive adversary together generate a probability distribution over request sequences σ.

There are two ways to charge the adversary for the request sequence. If $\hat{\mathrm{A}}$ is an *adaptive off-line* adversary, then $\hat{\mathrm{A}}(\sigma)$ is simply $\mathrm{OPT}(\sigma)$, the optimum off-line cost for σ. If $\hat{\mathrm{A}}$ is an *adaptive on-line* adversary, then $\hat{\mathrm{A}}(\sigma)$ is the cost incurred on σ by an auxiliary on-line algorithm $M_{\hat{\mathrm{A}}}$. An on-line algorithm A is c-competitive against an adaptive adversary $\hat{\mathrm{A}}$ if there exists a constant b such that

$$\mathrm{E}\left[\mathrm{A}(\sigma) - c \cdot \hat{\mathrm{A}}(\sigma)\right] \le b.$$

The adaptive adversaries model a situation in which the random choices of the algorithm may affect the future request sequence. The adaptive on-line adversary is not entirely intuitive, in that the cost measure seems somewhat unnatural, but this adversary is useful in proving theorems about deterministic algorithms.

Black and Sleator showed that in the simple case of two processors linked by a single edge of length 1, no deterministic algorithm can be better than 3-competitive for any D.

In addition, Chrobak et al. [8] give an example of a 4-processor network on which every deterministic algorithm has a competitive ratio slightly larger than 3 when $D = 1$. By a theorem of [2], these deterministic lower bounds also apply to randomized algorithms facing an adaptive off-line adversary.

The results in this paper demonstrate that against an oblivious adversary, randomized algorithms can beat the deterministic lower bound. By considering the case of a single edge, one can show that for a given page factor D no randomized algorithm can be better than $2 + \frac{1}{2D}$-competitive against an oblivious adversary [8]. We suspect, however, that the lower bound is higher for more complicated graphs.

In §5 we show a randomized algorithm that is 3-competitive against adaptive on-line adversaries for all D. One can apply a technique from [10], [16] to show that no algorithm can do better. This lower bound follows from considering the simple case of two processors linked by a single edge of length 1. The adaptive adversary's strategy is to watch the on-line algorithm and always generate requests at the processor that does not contain the on-line algorithm's page. Thus the on-line algorithm pays 1 per request. Prior to generating the first request, the adaptive on-line adversary simulates the on-line algorithm over all possible random choices, using the above strategy to generate a probability distribution over request sequences σ of length m. From the simulation, the adversary computes the expected number of requests at processors p_1 and p_2, and expected total cost of page migrations, B, paid by the on-line algorithm. If $B > m/2$, the adversary initially places its page at the processor most often requested, and never moves it again. The expected cost to the adversary is at most $D + m/2$, while the expected cost to the on-line algorithm is at least $3m/2$. If $B \leq m/2$, the adversary always moves so as to keep its page at the processor that does *not* contain the on-line algorithm's page. In this case, the adversary pays B, while the on-line algorithm pays $B + m \geq 3B$. Thus in either case, the on-line algorithm cannot guarantee to be better than 3-competitive.

The above discussion shows that in the migration problem the oblivious, adaptive on-line, and adaptive off-line adversaries are strictly differentiated from each other in their power. This is the first natural on-line problems for which this is known to be true.

3. Uniform graphs. In this section we describe and analyze a randomized algorithm, UNIFORM, designed for uniform graphs. The uniform graph is a common and important network topology [5]. In this model, $\delta_{v,v} = 0$ for all processor nodes v, $\delta_{u,v} = 1$ for all pairs $u \neq v$, and the cost of moving the page from node u to node v is $D \geq 1$.

Before describing the algorithm, we remark that when the graph is a single edge between two nodes, this problem is identical to the two-item list update problem. Reingold et al. [10], [16] gave a simple randomized algorithm for the list-update problem, which UNIFORM parallels.

Each processor node v of the graph is given an associated counter, C_v, that takes on values between 0 and $k - 1$. The optimum value of k depends on D; we will see later how to choose k. Let $\underline{C} = (C_1, C_2, \ldots, C_n)$ be a vector of the counter values at each of the n nodes of the graph. There are k^n such vectors. Let $\underline{C}_i$ be the ith such vector.

Let U^i denote a deterministic algorithm that begins with initial counter vector $\underline{C}_i$ and processes a request at node r as follows:

1. The page request is satisfied at cost at most 1.
2. The counter at r, C_r, is incremented.
3. If C_r has value k, the page is moved to node r, if it is not already there, and C_r is reset to 0.

Prior to processing any requests, the UNIFORM algorithm chooses a deterministic algorithm U^i uniformly at random, and then runs it. The random choice is made by initializing each node counter uniformly at random, using $\Theta(n \log k)$ random bits.

THEOREM 3.1. UNIFORM *is c_k-competitive against an oblivious adversary, where k is the maximum counter value and c_k is the maximum of* $1+(k+1)/2D$ *and* $1+\frac{1}{k}(2D+(k+1)/2)$.

Proof. We show that E [UNIFORM(σ)] $\leq c_k \cdot \mathrm{OPT}(\sigma)$ for any finite request sequence σ.

To analyze the expected cost of UNIFORM we imagine that the ensemble of $m = k^n$ different deterministic algorithms U^i is being run simultaneously on the request sequence. The expected cost of UNIFORM is the total cost of the ensemble divided by m. We use the following observation: At any time, each algorithm in the ensemble has a distinct counter vector. This follows by an easy induction on the number of requests. The observation implies that at any time the number of algorithms in the ensemble with the same value of C_v is exactly m/k. Equivalently, at any time during the running of algorithm UNIFORM, $\Pr[C_v = j] = 1/k$ for $0 \leq j \leq k-1$.

Our proof uses the technique of comparing simultaneous runs of U^i and OPT on the request sequence σ. The actions of U^i and OPT are partitioned into two kinds of events, which together account for all costs to the algorithms. The first kind of event is the servicing of a request by both U^i and OPT. This event may involve U^i moving its page. The second kind of event is OPT moving its page. After the tth event, let p^i denote the node where U^i has the page and opt denote the node where OPT has the page. We define a *potential function* Φ:

$$\Phi_t = \begin{cases} 0 & \text{if } p^i = \text{opt}, \\ D+k-C_{\text{opt}} & \text{if } p^i \neq \text{opt}. \end{cases}$$

Each event has an actual cost to OPT, and an *amortized cost* to U^i, defined to be the actual cost of the event to U^i plus the change in the potential function, $\Delta\Phi = \Phi_t - \Phi_{t-1}$. The potential Φ is always nonnegative, and $\Phi_0 = 0$, since OPT and U^i begin with the page at the same node. This implies, by standard amortized analysis arguments, that the total actual cost to U^i is bounded by the sum of the amortized costs for all events. To prove the theorem, we show that for each event the sum of the amortized costs to the algorithms in the ensemble is less than mc_k times the actual cost to OPT.

1. The event is a request. There are two subcases.

(i) The request is at node opt. In this case OPT pays 0, so we must show that the amortized cost to each algorithm U^i is also zero. If $p^i =$ opt then the actual and amortized cost to U^i is also 0. Otherwise, U^i pays 1, but since C_{opt} is incremented, the potential decreases by 1. If the counter reaches k, then the page moves to opt. This costs D, but decreases the potential by a further D. Thus the amortized cost is always 0.

(ii) The request is at node $r \neq$ opt. The cost to OPT is 1. Each algorithm U^i pays at most 1 for the request. For m/k of the algorithms in the ensemble, C_r reaches k and the page is moved to r at cost D. If $p^i \neq$ opt prior to moving, then there is no change in the potential. In the worst case, $p^i =$ opt prior to the move and the potential increases by $D+k-C_{\text{opt}}$. No more than m/k^2 algorithms, however, can move from opt with $C_{\text{opt}} = i$, for $0 \leq i \leq k-1$. Therefore, the total cost of the event to the ensemble is bounded by

$$m + D\frac{m}{k} + \sum_{0 \leq i \leq k-1} \frac{m}{k^2}(D+k-i).$$

Summing and dividing by m gives the expected amortized cost to UNIFORM,

$$1 + \frac{1}{k}\left(2D + \frac{k+1}{2}\right),$$

which is bounded by c_k times the cost to OPT.

2. The event is that OPT moves its page to a new node r. The actual cost to OPT is D, and the actual cost to each algorithm U^i is 0. Now we consider the cost due to changes in potential. If $r = p^i$, the potential decreases by at least D. If $r \neq p^i$ and opt $\neq p^i$, then $\Delta\Phi = C_{\text{opt}} - C_r$, which is bounded by $k - C_r$. In the worst case, $r \neq p^i$ and initially opt $= p^i$. Then $\Delta\Phi = D + k - C_r$. Exactly m/k algorithms have $C_r = i$, so the total cost to the ensemble of this event is at most

$$\sum_{0 \le i \le k-1} \frac{m}{k}(D + k - i).$$

Summing and dividing by m gives the expected cost to UNIFORM, $D + (k+1)/2$, which is at most c_k times the cost to OPT. □

This completes the proof of Theorem 3.1. Given a value of D, we can choose k to minimize the maximum of $1 + (k+1)/2D$ and $1 + \frac{1}{k}(2D + (k+1)/2)$.

Table 1 shows the best competitive ratio for UNIFORM for values of D up to 10. These values are found by setting

$$1 + \frac{k+1}{2D} = 1 + \frac{1}{k}\left(2D + \frac{k+1}{2}\right)$$

and solving for k in terms of D. Then the best integer approximation to this value is taken. As D tends to infinity, the best competitive ratio decreases and tends to $(5 + \sqrt{17})/4 \approx 2.28$. Note that all these values are better than the deterministic lower bound of 3. It is possible to slightly improve upon the values for small D by using the random reset techniques employed in [16].

TABLE 1
Best competitive ratios for UNIFORM.

The next theorem shows that our analysis is tight.

THEOREM 3.2. *The UNIFORM algorithm is no better than c_k-competitive, where c_k is defined as in Theorem* 3.1.

Proof. Consider two processors, labelled "1" and "2," connected by a single edge of length 1. Initially the page is located at processor 1. There are two kinds of bad request sequences: $\sigma_a = 2^k$ and $\sigma_b = 21^k$, where 1 and 2 denote page requests at processors 1 and 2 respectively, and i^k denotes k consecutive requests at processor i. Sequence σ_a can be satisfied at cost D, and σ_b can be satisfied at cost 1.

The expected cost to UNIFORM on σ_a is simply the expected time until the page migrates to 2, which is determined by the expected value of the counter at 2, plus the cost of migration. (UNIFORM is guaranteed to move the page eventually, since there are k requests.) Therefore

$$\mathrm{E}\left[\mathrm{UNIFORM}(\sigma_a)\right] = D + \frac{k+1}{2},$$

or $(1 + (k + 1)/2D) \cdot \mathrm{OPT}(\sigma_a)$.

On σ_b, UNIFORM moves its page to 2 after the first request with probability $1/k$, in which case the remainder of the sequence looks identical to σ_a. Hence

$$\mathrm{E}\left[\mathrm{UNIFORM}(\sigma_a)\right] = \left(1 + \frac{1}{k}(2D + \frac{k+1}{2})\right) \cdot \mathrm{OPT}(\sigma_b).$$

The adversary can generate arbitrarily long request sequences by repeating σ_a or σ_b, so the UNIFORM algorithm cannot be better than c_k-competitive. □

4. General graphs. In this section we consider the migration problem on undirected graphs with arbitrary edge distances. Recall that even with arbitrary edge lengths the shortest distance function δ remains symmetric and still satisfies the triangle inequality.

One reason the general case seems harder than the uniform case is that a general graph may contain clusters of processors that are very close to each other but relatively far from other clusters. Such a situation models a collection of local-area networks tied together in a wide-area network. Even though no single processor in a cluster is accessing the page especially often, the cluster as a whole may generate many requests for the page, and it may be advantageous to move the page to some node in the cluster. On the other hand, in the uniform case a cluster of processors that access the page equally often is an easy situation for the on-line algorithm to handle, since both it and OPT must pay about 1 per request.

The previous best known deterministic competitive ratio for general graphs is $2n - 1$, given by the general metrical task system algorithm [6]. Technically, that result holds for a different model, the "lookahead-1" model, in which the algorithm is allowed to move the page after seeing the next request but before actually servicing it. In our "lookahead-0" model, the request must be serviced immediately it is seen. It is easily checked that an algorithm for the lookahead-1 model can be used to derive an algorithm for the lookahead-0 model that has a competitive ratio no more than 2 times worse than that of the original algorithm. Furthermore, the bounds converge as D grows large. One can also show that the strategy of moving the page to the last requesting node yields a competitive ratio of $2D + 2$. Thus even when the graph is a single triangle, the best known deterministic algorithm for large D is only 5-competitive. Our randomized algorithms for the general case are simple enough to be practical, and beat the deterministic lower bound.

The general algorithm G maintains a *single* counter with value $C \geq 1$. After each request to the page, we perform the following.

1. The counter is decremented by one, regardless of where the request is.

2. If the counter reaches 0, the page is moved to the location of the current request. After the move, the counter is reset according to a *resetting distribution* $\mathcal{D} = (\alpha_1, \alpha_2, \alpha_3, \ldots)$, where α_i is the probability of resetting the counter to value i.

The distribution $\mathcal{D}$ is fixed in advance and is independent of the request sequence. Let $k = \max\{i \mid \alpha_i > 0\}$. We are only interested in distributions for which k exists (i.e., is not infinite).

The counter value forms a Markov chain in which state i corresponds to the counter having value i, for $1 \leq i \leq k$. Being in state i means that the page will be moved after i accesses. A state transition occurs with every access. The transition matrix for the corresponding Markov chain is shown in Fig. 1. Note that the probability of being in a given state depends only on the number of requests that have been processed, not on the nature of the requests.

Let ρ_i denote the steady state probability of being in state i. Given a resetting distribution $\mathcal{D}$, let $\bar{C}_R(\mathcal{D})$ denote the expected value of the counter immediately following a reset and let $\bar{C}_S(\mathcal{D})$ denote the expected value of the counter in steady state. By definition,

$$\begin{pmatrix} \alpha_1 & 1 & 0 & 0 & \dots & 0 \\ \alpha_2 & 0 & 1 & 0 & & 0 \\ \alpha_3 & 0 & 0 & \ddots & & 0 \\ \vdots & & & & & \\ \alpha_{k-1} & & & & & 1 \\ \alpha_k & & & & & 0 \end{pmatrix}$$

FIG. 1. *Markov chain transition matrix. Entry* (i, j) *contains the probability of a transition to counter value* i *from counter value* j *following a request,* $1 \le i, j \le k$.

$\bar{C}_R(\mathcal{D}) = \sum_{i=1}^{k} i\alpha_i$ and $\bar{C}_S(\mathcal{D}) = \sum_{i=1}^{k} i\rho_i$. We will abbreviate the notation to $\bar{C}_R$ and $\bar{C}_S$ when the distribution $\mathcal{D}$ is clear.

The steady state probabilities ρ_i are given by the eigenvector of the transition matrix corresponding to eigenvalue 1. One may verify that in steady state,

$$\rho_i = \frac{1}{\bar{C}_R} \sum_{j=i}^{k} \alpha_j .$$

This implies

$$\begin{aligned} \bar{C}_S &= \frac{1}{\bar{C}_R} \left(\sum_{i=1}^{k} i \sum_{j=1}^{k} \alpha_j \right) \\ &= \frac{1}{\bar{C}_R} \left(\sum_{i=1}^{k} \alpha_i \sum_{j=1}^{i} j \right) \\ &= \frac{1}{\bar{C}_R} \left(\sum_{i=1}^{k} i(i+1)\alpha_i \right). \end{aligned}$$

Prior to starting a run of the algorithm, the counter is initialized according to the steady state distribution, i.e., the counter is initialized to i with probability ρ_i, for $1 \le i \le k$.

LEMMA 4.1. *Let* $\mathrm{G}(\mathcal{D})$ *be the general algorithm with resetting distribution* $\mathcal{D}$. $\mathrm{G}(\mathcal{D})$ *is* $c_{\mathcal{D}}$*-competitive, where* $c_{\mathcal{D}}$ *is the maximum of* $2 + (2D/\bar{C}_R(\mathcal{D}))$ *and* $1 + (\bar{C}_S(\mathcal{D})/D)$.

Proof. As before, we partition the actions and costs into two events: a request that both $\mathrm{G}(\mathcal{D})$ and OPT satisfy, and a page movement by OPT. A given σ fixes a sequence of events and determines an ensemble of deterministic on-line algorithms that correspond to all possible random choices that can be made throughout the processing of σ. At any time, the fraction of algorithms in this ensemble that have counter value i is given by the steady state probability, ρ_i. The average cost of the algorithms in this ensemble gives the expected cost of one run of G on σ. We will calculate the expected amortized cost per operation of G directly. Let random variable X_t be the amortized cost of the tth event. The total amortized cost is $\sum_t X_t$, and by linearity of expectations the expected total amortized cost is $\sum_t \mathrm{E}[X_t]$. To prove the theorem we bound $\mathrm{E}[X_t]$ in terms of the cost to OPT.

At the time of event t, let opt be the node where OPT has its page and g be the node where G has its page. Let C be the value of the counter. Both g and C depend upon previous random choices, but opt is fixed by σ.

We use the potential function

$$\Phi_t = (D + C) \cdot \delta_{g,\mathrm{opt}}.$$

Note that $\Phi = 0$ when OPT and G have their pages at the same node.

Now we analyze the expected amortized cost of each event.

1. The event is a request at node r. Let $\ell_0 = \delta_{r,\mathrm{opt}}$, $\ell_1 = \delta_{g,\mathrm{opt}}$ and $\ell_2 = \delta_{g,r}$. (See Fig. 2.) The cost to OPT is ℓ_0. The actual cost to G is ℓ_2. The counter is decremented, so $\Delta\Phi = -\ell_1$, and hence the amortized cost to G is $\ell_2 - \ell_1$. By the triangle inequality, $\ell_2 \leq \ell_0 + \ell_1$. Therefore, the amortized cost to G to satisfy the request is at most ℓ_0.

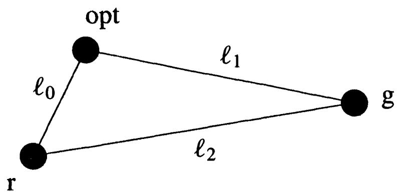

FIG. 2. *Diagram for proof of Lemma* 4.1.

With probability ρ_1, the counter value is 1 just prior to the request and becomes 0 after the request is satisfied. Then G moves the page to node r at cost $D\ell_2$ and resets the counter according to $\mathcal{D}$. The potential change is

$$\ell_0(D + C') - D\ell_1,$$

where C' is the value to which the counter is reset. The *expected* change in potential is determined by the expected value of the counter after the reset, $\bar{C}_R$. Hence the expected amortized cost of a move is

$$D\ell_2 + \ell_0(D + \bar{C}_R) - D\ell_1.$$

Again applying the triangle inequality, this is bounded by

$$\ell_0(2D + \bar{C}_R).$$

Combining the cost to satisfy the request with the expected move cost in the case that $C = 1$, the total expected amortized cost to G is bounded by

$$\ell_0 \left(1 + \rho_1(2D + \bar{C}_R)\right).$$

Since $\rho_1 = (1/\bar{C}_R)$, this is at most $c_{\mathcal{D}}$ times the cost to OPT.

2. The event is OPT moving its page from node opt to a new node opt$'$. Let $\ell_0 = \delta_{\mathrm{opt},\mathrm{opt}'}$. The actual cost to OPT is $D\ell_0$ and the actual cost to G is 0. Now we consider the cost due to changes in potential. Let ℓ_1 be $\delta_{g,\mathrm{opt}}$ and ℓ_2 be $\delta_{g,\mathrm{opt}'}$. The actual potential change is

$$(\ell_2 - \ell_1) \cdot (D + C),$$

where C is the actual counter value. The *expected* potential change is determined by the steady state expected value of the counter, $\bar{C}_S$. Since $\ell_2 \leq \ell_0 + \ell_1$, the expected potential change is bounded by $\ell_0 \cdot (D + \bar{C}_S)$, which is at most $c_{\mathcal{D}}$ times the cost to OPT. □

LEMMA 4.2. *The general algorithm,* $G(\mathcal{D})$*, is no better than* $c_{\mathcal{D}}$*-competitive, where* $c_{\mathcal{D}}$ *is defined as in Lemma* 4.1.

Proof. As in Theorem 3.2 we consider two processors, connected by an edge of length 1, and two request sequences: $\sigma_a = 2^k$ and $\sigma_b = 21^k$.

The expected cost to $G(\mathcal{D})$ on σ_a is $\bar{C}_S$, the initial expected time until the page migrates to 2, plus the cost of the migration. Therefore

$$E[G(\sigma_a)] = D + \bar{C}_S,$$

or $(1 + (\bar{C}_S)/D) \cdot \mathrm{OPT}(\sigma_a)$.

On σ_b, $G(\mathcal{D})$ moves its page to 2 after the first request with probability ρ_1. In this case the cost on the remainder of σ_b is determined by the expected time to return the page to 1, given that it has moved initially. This expected time is $\bar{C}_R$. Hence

$$E[G(\sigma_a)] = (1 + \rho_1(2D + \bar{C}_R)) \cdot \mathrm{OPT}(\sigma_b) = \left(2 + \frac{2D}{\bar{C}_R}\right)\mathrm{OPT}(\sigma_b).$$

The adversary can generate arbitrarily long request sequences by repeating σ_a or σ_b. □

In the next two subsections we analyze two choices for the resetting distribution $\mathcal{D}$. First we give a randomized resetting strategy with a competitive ratio that tends to $1 + \phi$, where ϕ is the golden ratio, approximately 1.618. Then we discuss the deterministic strategy of resetting the counter to a single value k after a move. We show that the competitive ratio of the deterministic strategy approaches that of the random resetting distribution as D grows large. Deterministic resetting gives a simple, practical, near-optimal barely random algorithm.

4.1. Random resetting. We restrict our attention to distributions $\mathcal{D}$ that satisfy

$$2 + \frac{2D}{\bar{C}_R} = 1 + \frac{\bar{C}_S}{D}. \tag{1}$$

Then the competitive ratio is given by the choice of resetting probabilities that minimizes $2 + 2D/\bar{C}_R$. This is minimized when $\bar{C}_R$ is maximized. For a fixed value of k, the following linear program computes an optimum resetting distribution subject to constraint 1:

$$\text{maximize } \sum_{i=1}^{k} i\alpha_i,$$

subject to the constraints

$$\sum_{i=1}^{k} \alpha_i = 1,$$

$$\sum_{i=1}^{k} (i^2 - (2D-1)i)\alpha_i = 4D^2,$$

$$\alpha_i \geq 0, \qquad 1 \leq i \leq k.$$

Let x be the positive solution to $x^2 - (2D-1)x = 4D^2$. Hence $x = D + \frac{1}{2}((20D^2 - 4D + 1)^{1/2} - 1)$. Then $k_0 = \lceil x \rceil$ is the least integer such that constant on the k_0th term in the second constraint of the linear program is greater than $4D^2$.

LEMMA 4.3. *There is a feasible solution to the linear program with only* α_{k_0-1} *and* α_{k_0} *nonzero.*

Proof. Let $\alpha = \alpha_{k_0-1}$. By the first constraint of the linear program, $\alpha = 1 - \alpha_{k_0}$. Setting $\alpha_i = 0$ for all other i, the second constraint becomes

$$0 = k_0^2 - (2D - 1)k_0 - 4D^2 + \alpha(2D - 2k_0).$$

Replacing k_0 by $x + \epsilon$, where $0 \leq \epsilon < 1$, and using the fact that $x^2 - (2D - 1)x = 4D^2$, this constraint further reduces to

$$0 = (2x - 2D + 1 + \epsilon)\epsilon - (2x - 2D + 2\epsilon)\alpha,$$

implying

$$\alpha = \epsilon + \epsilon(1 - \epsilon)/(2x - 2D + 2\epsilon).$$

Observing that $2x - 2D \geq 0$ for all $D \geq 0$, it is easily verified that $0 \leq \alpha \leq 1$. Hence constraint three is satisfied. □

THEOREM 4.4. *The competitive ratio of the algorithm given by choosing k_0 and α as above is* $2 + 2D/(k_0 - \alpha)$

Proof. This theorem follows from straightforward substition into the formula for $\bar{C}_R$. □

Table 2 shows several competitive ratios given by Theorem 4.4. As D gets large, the best competitive ratio decreases and tends to $1 + (1 + \sqrt{5})/2$, which is one plus the golden ratio, or approximately 2.62.

TABLE 2
Best general competitive ratios, resetting randomly with α_{k_0-1} and α_{k_0}.

512	1657	2.618

4.2. Deterministic resetting. We can turn the randomized resetting strategy of the previous section into a deterministic resetting strategy by setting either α_{k_0-1} or α_{k_0} to 1, depending on which gives the lowest maximum competitive ratio. Let $s = k_0 - 1$ or k_0 depending on whether we choose $\alpha_{k_0-1} = 1$ or $\alpha_{k_0} = 1$, respectively.

THEOREM 4.5. *The general algorithm with deterministic resetting is c_s-competitive against an oblivious adversary, where c_s is the maximum of* $1 + (s+1)/2D$ *and* $2 + (2D/s)$.

Proof. The counter is initialized by setting it to value i with probability $1/s$ for $1 \leq i \leq s$. At any time thereafter, the counter values are uniformly distributed from 1 to s. Calculating $\bar{C}_R$ and $\bar{C}_S$ from the formulas given above and applying Lemma 4.1 completes the proof. □

Table 3 shows the best competitive ratios achieved by this deterministic resetting strategy for various values of D. As D and hence k_0 grows, the deterministic and random resetting algorithms tend to the same competitiveness. Deterministic resetting has the advantage of greater simplicity, since it requires random bits only during initialization.

5. The coin-flipping algorithm. A very simple randomized strategy is to flip a weighted coin at each request, and move to the requested node if the coin comes up heads. That is, at each request, the page is moved to the requesting node with probability $p > 0$. This strategy can be used on a general graph with arbitrary edge weights. It has the advantage of being *memoryless*; no state information is remembered other than that given by the location of the page. Furthermore, it achieves exactly a competitive ratio of 3 against both adaptive on-line adversaries and oblivious adversaries. On the other hand, it has a poorer competitiveness against an oblivious adversary than the algorithms for the uniform and general problems presented in §§3 and 4, respectively, and it requires a random number call every access.

In this section we analyze the competitiveness of the coin-flipping algorithm. First we give a lower bound.

THEOREM 5.1. *The coin-flipping algorithm is no better than* 3*-competitive against an oblivious adversary.*

Proof. We use our standard scenario of two processors and two request sequences: $\sigma_a = 2^j$ and $\sigma_b = 21^j$. We require that $j > D$. For σ_a the optimum cost is D, and for σ_b the optimum cost is 1.

Let $q = 1-p$. The expected cost of the coin-flipping algorithm on σ_a is $(D+1/p)(1-q^j)$. For any $p \leq 1/2D$, this is at least $3(1-q^j)$ times the optimal cost. The expected cost of the coin-flipping algorithm on σ_b is $1 + p(D+(D+1/p)(1-q^j)) \geq 2pD+2(1-q^j)$. For any $p \geq 1/2D$, this is at least $3-2q^j$ times the optimal cost. Hence for any choice of p, there is a sequence and a choice of j such that the competitive ratio of the coin-flipping algorithm is arbitrarily close to 3. □

Now we show that the coin-flipping algorithm is 3-competitive against an adaptive on-line adversary.

To perform the analysis, we use the request-answer game framework of [2]. The adversary initially commits to a request sequence length m. The game proceeds as a sequence of m rounds. In each round, the adversary first moves its page, if it so chooses. Then the adversary generates a request, and immediately services it. Then the on-line algorithm services the request and possibly moves its page. At the end of each round, the adversary is told the location of the page of the on-line algorithm.

THEOREM 5.2. *The coin-flipping algorithm with $p = 1/2D$ is* 3*-competitive against any adaptive on-line adversary $\hat{A}$.*

Proof. We use the following crucial observation. In each round, the probability that the coin-flipping algorithm moves its page is independent both of the request and of the location of the adversary's page when the request is generated. This observation is not true for the algorithms of §§3 and 4, which make moves based on counter values that the adaptive adversary knows and can use in generating its requests. This observation is also not true for the coin-flipping algorithm against an adaptive off-line adversary. In the off-line case, the location of the adversary's page depends deterministically upon future requests, which in turn depend upon the outcomes of future coin-flips by the algorithm.

Using the observation, we show that the expected amortized cost of each event is no more than 3 times the cost to the adversary of that event. Let f denote the processor containing the page of the coin flipping algorithm, a denote the processor containing the page of $\hat{A}$, and ℓ denote the distance from f to a. We use the following potential function:

$$\Phi = 3D\ell.$$

There are two events to consider in each round:

1. A request occurs at node r. Let f and a denote the nodes containing the pages of the coin-flipping algorithm and the adversary, respectively, just prior to the request. There are three distances of interest: ℓ_0, the distance from f to a; ℓ_1, the distance from a to r; and ℓ_2, the distance from f to r. The cost to $\hat{A}$ is ℓ_1. The expected cost to the coin-flipping algorithm is

$$\ell_2 + \frac{1}{2D}(D\ell_2 + 3D\ell_1 - 3D\ell_0).$$

By the triangle inequality, $\ell_2 \leq \ell_1 + \ell_0$. This implies that the expected cost to the coin flipping algorithm is at most $3\ell_1$.

2. $\hat{A}$ moves its page from a to a'. Let ℓ_0 and ℓ_1 denote the distance from f to a and f to a', respectively. Let ℓ_2 be the distance from a to a'. The cost to $\hat{A}$ of the move is $D\ell_2$. The cost to the coin flipping algorithm is $3D\ell_1 - 3D\ell_0$, which is at most $3D\ell_2$, by the triangle inequality. □

COROLLARY 5.3. *The coin-flipping algorithm is* 3*-competitive against an oblivious adversary.*

Proof. This follows trivially from the fact that an oblivious adversary is simply an adaptive on-line adversary that generates the same requests regardless of the random choices made by the on-line algorithm and services these requests optimally. □

COROLLARY 5.4. *On any graph the competitiveness of the coin-flipping algorithm against an adaptive off-line adversary tends to* $3 + 3\phi \approx 7.86$ *as D grows large.*

Proof. Theorem 2.2 of [2] states that if algorithm B is β-competitive against an adaptive on-line algorithm and there exists an algorithm A that is α-competitive against an oblivious adversary, then B is $\alpha\beta$-competitive against an adaptive off-line algorithm. We take A to be the general algorithm with deterministic resetting from §4.2 and B to be the coin-flipping algorithm. For various values of D, the competitive factor of the coin-flipping algorithm against an adaptive off-line adversary can be found by multiplying by 3 the appropriate entries in Table 3. □

COROLLARY 5.5. *There exists a deterministic algorithm for the migration problem with competitive ratio that tends to* $3 + 3\phi \approx 7.86$ *as D grows large.*

Proof. Theorem 2.1 of [2] states that if there is a randomized algorithm that is α-competitive against any adaptive off-line algorithm, then there is also a α-competitive deterministic algorithm. The theorem gives a method of constructing the deterministic algorithm, but we have not attempted to do so here. □

6. Remarks. This paper presented randomized algorithms for page migration. We have shown the following.

(i) An algorithm for uniform graphs that tends toward being 2.38-competitive as D gets large.

(ii) An algorithm for general graphs that is parameterized by a resetting distribution. Deterministic resetting gives a variant that tends toward being $1 + \phi$-competitive as D gets large.

(iii) A very simple coin-flipping algorithm that is 3-competitive against adaptive on-line adversaries.

We have also shown that the analysis is tight for each algorithm and that coin-flipping is optimal against an adaptive on-line adversary.

There are several interesting open problems. One is to improve upon our randomized algorithms, and to improve or generalize the lower bounds. A second one is to find a good deterministic algorithm for migration on general graphs. Another open problem is to extend any of these results to the more general problem of 1-server with excursions.

In recent work, Bartal et al. [1] studied file allocation in distributed systems. In this situation multiple physical copies of writeable pages or data files are sometimes allowed. In this problem, the competitive ratio rises to $\Theta(\log n)$, where n is the number of processors.

Acknowledgments. The author thanks Daniel D. Sleator for suggesting the migration problem and Nick Reingold for helpful conversations.

NEAR-OPTIMAL TIME-SPACE TRADEOFF FOR ELEMENT DISTINCTNESS*

ANDREW CHI-CHIH YAO†

Abstract. It was conjectured in Borodin et al. [J. Comput. System Sci., 22 (1981), pp. 351–364] that to solve the element distinctness problem requires $TS = \Omega(n^2)$ on a comparison-based branching program using space S and time T, which, if true, would be close to optimal since $TS = O((n \log n)^2)$ is achievable. Recently, Borodin et al. [SIAM J. Comput., 16 (1987), pp. 97–99] showed that $TS = \Omega(n^{3/2}(\log n)^{1/2})$. This paper presents a near-optimal tradeoff $TS = \Omega(n^{2-\epsilon(n)})$, where $\epsilon(n) = O(1/(\log n)^{1/2})$.

Key words. branching programs, comparisons, element distinctness, linear ordering, lower bounds, time-space tradeoff

AMS subject classifications. 68P10, 68Q25

1. Introduction. In Cobham's classic paper [C], time-space tradeoffs were established for one-tape Turing machines. In recent years, a number of time-space tradeoff results have been obtained for various computational models, such as Boolean and arithmetic circuits [To], a general sequential computing model [BC], [B], multihead Turing machines [DG], [K], comparison-based branching programs [BFKLT], [Y], [BFMUW], [K], and very large scale integration (VLSI) models [Th] (see [U] for a review of results). In this paper, we establish a tradeoff result in the comparison-based branching program model, proving in weaker form an interesting conjecture of Borodin et al. [BFKLT].

Borodin et al. [BFKLT] proved a tradeoff $TS = \Omega(n^2)$ for sorting n numbers on a comparison-based branching program, but were not able to establish a similar tradeoff for any decision problem in their model. They conjecture, however, that the tradeoff $TS = \Omega(n^2)$ is also true for the element distinctness problem. This, if proved, would be close to the best possible, since an upper bound $TS = O((n \log n)^2)$ is achievable for sorting [MP], and hence for the element distinctness problem. Recently, Borodin et al. [BFMUW] gave a partial resolution to the above conjecture, showing in the same model that $TS = \Omega(n^{3/2}(\log n)^{1/2})$. In this paper, we will prove that $TS = \Omega(n^{2-\epsilon(n)})$, where $\epsilon(n) = O(1/(\log n)^{1/2})$. As mentioned earlier, such a tradeoff is nearly the best possible.

Let $x_1, x_2, \dots, x_n$ be n elements chosen from a linearly ordered set $(D, \leq)$. The element distinctness problem (with parameter n) is to decide whether all x_i are distinct. As discussed in [BFMUW], a *comparison branching program A* is a labeled directed acyclic graph with a distinguished nonsink node, called *source*. Each nonsink node is labeled by a comparison $x_i : x_j$ with $i \neq j$, and has three outgoing edges labeled by $<, =, >$, respectively. The sinks are labeled by either "accept" or "reject." An input $\tilde{x} = (x_i, x_2, \dots, x_n) \in D^n$ starts at the source and traverses A, making comparisons and branching according to the outcomes, until a sink is reached. The input is accepted if and only if it reaches a sink with an "accept" label. The *capacity* of A is the base-2 logarithm of the number of nodes. The *length* of A, or the *time T* used by A, is the length of the longest path starting with source. We say that A is an *algorithm* for *the element distinctness problem* if $\tilde{x}$ is accepted when and only when all x_i are distinct. Let $\mathcal{A}_n$ denote the set of all algorithms for the element distinctness problem. We now state our main result.

THEOREM 1. *Any* $A \in A_n$ *with capacity S and time T must satisfy* $TS = \Omega(n^{2-\epsilon(n)})$ *for large n, where* $\epsilon(n) = 5/(\ln n)^{1/2}$.

2. Preliminaries.

2.1. Overview. As discussed in [BFKLT], using a result of Nick Pippenger, we can assume without loss of generality that A is *leveled*, i.e., each node is assigned a level number and each edge goes from a node in level i to a node in level $i+1$. The source node has level 0, and all sinks are at level T. From now on, all branching programs will mean leveled comparison branching programs.

We review the ideas involved in the proof of $TS = \Omega(n^{3/2}(\log n)^{1/2})$ in [BFMUW]. (Some of these ideas originated in [BFKLT].) Let $A \in \mathcal{A}_n$. For any input $\tilde{x} = (x_1, x_2, \ldots, x_n)$ with distinct x_i, the sequence of comparisons made by A must include all the "adjacent" ones, i.e., comparisons of the form $x_{i_j} : x_{i_{j+1}}$ if the input satisfies $x_{i_1} < x_{i_2} < \cdots < x_{i_n}$; otherwise we could have two identical x_r. The idea is to show that any branching program of length less than or equal to n_0, where $n_0 = (nS/(16e))^{1/2}$, can make more than S adjacent comparisons only for a very small fraction of the $n!$ possible linear orderings in the input. Thus, A must have $(n-1)/S$ consecutive blocks of levels, each block of length n_0, to perform the needed $n-1$ adjacent comparisons for all linear orderings.

To prove Theorem 1, we will adopt the same general approach. We will show that any branching program of length less than or equal to $n_1 = n^{1-\epsilon(n)}$, can make more than $O(S \cdot n^{\epsilon(n)})$ adjacent comparisons only for a very small fraction of the possible linear orderings. The asserted tradeoff then follows the same line of reasoning as before.

We first give some intuitive ideas behind the proof. In [BFMUW], the main technical lemma can be roughly described as follows. Given T inequalities of the form $x_i < x_j$, if we take a random linear ordering of the x_k's, the expected number of these inequalities being adjacent comparisons is $O(T^2/n)$. The bound $O(T^2/n)$ is tight in some cases, such as when the sequence of inequalities are $x_1 < x_2 < \cdots < x_{T+1}$. However, in many other cases, this bound is too large an overestimate. For example, if the inequalities are $x_1 < x_2, x_3 < x_4, \ldots, x_{2T-1} < x_{2T}$, then the expected number of these inequalities being adjacent comparisons is $O(T/n)$. We have an opportunity to derive an improved bound, if a branching program of length T can only infrequently produce T inequalities with the $O(T^2/n)$ behavior.

To see how such a plan might work, consider any branching program of length $o(n^{5/3})$ and $O(\log n)$ capacity. For simplicity, we will ignore logarithm factors in the rest of this overview. Divide the program into blocks of length $n^{2/3}$. Assume that associated with each block b there is a subset D_b of $O(n^{2/3})$ variables x_i such that, within the block b, all comparisons made are between variables in D_b. We will argue informally that this branching program cannot solve the element distinctness problem. For each block b, we can regard b as a branching program working on the input numbers in D_b. Using the original argument in [BFMUW], one can easily show that typically the sequence of inequalities produced by the block b will have an expected $O(n^{1/3})$ comparisons that are *adjacent within* D_b (for a random linear ordering among the elements in D_b). Now, when we throw in the $n - O(n^{2/3}) x_i$ outside of D_b, a simple calculation shows that the expected number of adjacent comparisons globally is $O(1)$. This suggests that one needs $\Omega(n)$ blocks b to get all the $n-1$ adjacent comparisons, and hence a branching program of length $o(n^{5/3})$ would not be able to solve the element distinctness problem.

To carry out a proof along the above line, one needs to develop the arguments without the assumption that within each block b only variables among a small subset D_b can be used. Also, it seems that we might apply the argument recursively to the blocks b in the hope of getting lower bounds on TS better than $\Omega(n^{5/3})$. Theorem 1 is the result of the development of such a recursive proof.

Before presenting the proof, we introduce a concept important for all the ensuing technical discussions. Given any T inequalities $x_{i_1} < x_{j_1}, x_{i_2} < x_{j_2}, \ldots, x_{i_T} < x_{j_T}$ where $T \leq \frac{n}{2}$, let support (C) denote the set of all x_k involved in the inequalities, and let V be the set of the $2T - |\text{support}(C)|$ variables x_r with the smallest indices r that do not appear in support (C). Write support$'(C) = \text{support}(C) \cup V$. Let P_C denote the partial order generated by the T inequalities $x_{i_s} < x_{j_s}$ on support$'(C)$. The following proposition is obviously true.

Fact 1. Let C, D be two sequences of inequalities. If $C \subseteq D$, then support$'(C) \subseteq$ support$'(D)$.

We will use a measure of progress of the computation more refined than the one used in [BFMUW]. Roughly speaking, instead of using the number of adjacent comparisons among all x_i, we look at only the x_i we have seen so far and use the number of adjacent comparisons among them. We give an informal description here and will define it formally at the end of §2.2.

Let A be a branching program trying to solve the distinctness problem. How well is it doing, for example, after τ steps? Take a random linear ordering of n x_i as input, and let C be the sequence of comparisons encountered in the first τ steps. We concentrate on the subset support$'(C)$, and record the number of comparisons (call it κ) that are adjacent within support$'(C)$. We use the probability of $\kappa \geq m(\tau)$ (where $m(\tau)$ is some suitably chosen benchmark) as a measure of how well is A doing. If this probability is small, then A is not making good progress.

In the rest of this section, we introduce some additional needed notation and prove an auxiliary lemma. The proof of Theorem 1 will be given in §3.

2.2. Terminology. Let $W = \{w_1, w_2, \ldots, w_n\}$ be any nonempty finite set. A *linear ordering on* W is a sequence $\sigma = \langle w_{i_1} < w_{i_2} < \cdots < w_{i_n}\rangle$, in which each element of W appears exactly once. Let $\Gamma(W)$ denote the set of all linear orderings on W.

Let $P = (<_P, W)$ be a partial order on W. A linear ordering $\rho \in \Gamma(W)$ is said to be *consistent with* P, if $w <_P w'$ implies $w < w'$ in ρ. Let $\Delta(P)$ denote the set of all linear orderings on W consistent with P.

We will use the symbol X to denote exclusively the set $\{x_1, x_2, \ldots, x_n\}$ of the n input elements. Let $X' \subseteq X$. For any $\sigma \in \Gamma(X')$, let $L(\sigma)$ denote the set of all $\rho \in \Gamma(X)$ consistent with σ.

Suppose $\sigma = \langle x_{r_1} < x_{r_2} < \cdots < x_{r_l}\rangle$. A comparison $x_i < x_j$ is *adjacent in* σ if x_i, x_j are adjacent in the linear ordering σ, i.e., there exists an m such that $i = r_m$ and $j = r_{m+1}$. For any $\rho \in \Gamma(X)$, let $\rho|_{X'}$ denote the $\sigma \in \Gamma(X')$ obtained from the restriction of ρ to X'. For example, if $\rho = \langle x_3 < x_2 < x_5 < x_1 < x_4\rangle$ and $X' = \{x_2, x_4, x_5\}$, then $\rho|_{X'} = \langle x_2 < x_5 < x_4\rangle$.

Let C be a sequence of inequalities $(x_{i_1} < x_{j_1}, x_{i_2} < x_{j_2}, \ldots, x_{i_T} < x_{j_T})$. We say that C is *nontrivial* if there is a linear ordering $x_{r_1} < x_{r_2} < \cdots < x_{r_n}$ such that all inequalities in C are true. Let C be nontrivial and let $0 \leq a_1 < a_2 \leq T$ be two integers. For any $\sigma \in \Delta(P_C)$, let $Z(C, a_1, a_2, \sigma)$ be the number of pairs (i_s, j_s), $a_1 < s \leq a_2$, such that the comparisons $x_{i_s} < x_{j_s}$ are adjacent in σ.

Let A be any branching program of variables $x_1, x_2, \ldots, x_n$. For any node u and positive integer s, let $A[u, s]$ denote the subbranching program of A of length s and rooted at node u. A *path* δ in A is a sequence $u_0, e_1, u_1, e_2, \ldots, u_{s-1}, e_s, u_s$, where each e_r is an edge from node u_{r-1} to u_r; s is the *length* of δ. We will restrict ourselves to paths for which no edge is labeled by "=." Let C_δ denote the sequence of comparison inequalities of the form $x_i < x_j$ obtained along the path δ. For any linear ordering $\rho \in \Gamma(X)$, let $\tilde{x}_\rho$ denote an input $(x_1, x_2, \ldots, x_n)$ that satisfies all the inequalities in ρ. Let $\xi_{A,\rho}$ be the (entire) path traversed by input $\tilde{x}_\rho$ in A.

Let A be a branching program of length T. Let m be any integer. Take a random ρ uniformly chosen from $\Gamma(X)$. Let $g_A(m)$ denote the probability of the event $Z(C_\delta, 0, T, \rho|_{X'}) \geq m$, where $\delta = \xi_{A,\rho}$ and $X' = \text{support}'(C_\delta)$. We regard $g_A(m)$, with a suitably chosen m, as a measure of how effective A is in solving the distinctness problem. The plan for proving

Theorem 1 is to show that $g_A(m)$ is small unless T is sufficiently large; m is chosen in a way that accommodates an inductive proof.

2.3. An auxiliary lemma. We begin with an informal description of the problem to be addressed by the lemma. Let a subset $W \subseteq X$ of elements obeying a linear ordering σ on W be given, say, $x_{r_1} < x_{r_2} < \cdots < x_{r_{|W|}}$. Among the $|W|-1$ adjacent pairs $(x_{r_j}, x_{r_{j+1}})$, l of them are *marked*. Assume that it is known that all possible linear orderings $\rho \in \Gamma(X)$ consistent with σ are equally likely. We would like to find, by no more than T adaptive comparisons, a set of $2T$ elements outside W with the objective of maximizing the probability p of success, where *success* means that at least m of the marked adjacent pairs remain adjacent within the larger "output" set $W'(W'$ being the union of W plus the $2T$ elements found). The lemma provides an upper bound on the achievable p.

To specify the problem precisely, let $W \subseteq X$ be a nonempty set, and $\sigma \in \Gamma(W)$. Let C be a nontrivial sequence of comparisons $x_i < x_j$ with $x_i, x_j \in W$, with exactly l of them being adjacent in σ, where $0 \leq l < |W|$. Let A be a branching program of length T with $n \geq 2T + |W|$. For any possibly traversed path δ of length T, let W_δ be any subset of X such that $|W_\delta| = 2T + |W|$ and $W_\delta \supseteq W \cup \text{support}(C_\delta)$. Denote by $\mathcal{V}$ the collection $\{W_\delta |$ all paths $\delta\}$.

Now, take a random $\rho \in L(\sigma)$. Let $f_{n,A,W,\mathcal{V}}(\sigma, C, m)$ be the probability that the number of comparisons of C adjacent in $\rho|_{W_\delta}$ is greater or equal to m, where $\delta = \xi_{A,\rho}$.

LEMMA 1. $f_{n,A,W,\mathcal{V}}(\sigma, C, m) \leq \binom{l}{m} \cdot (|W|/2T)^m$.

Proof. Without loss of generality, assume that $W = \{x_1, x_2, \ldots, x_w\}$ where $w = |W|$, and σ is the linear ordering $x_1 < x_2 < \cdots < x_w$. Let C' be the set of the comparisons of C that are adjacent in σ, for example, $C' = \{x_{i_1} < x_{i_1+1}, x_{i_2} < x_{i_2+1}, \ldots, x_{i_l} < x_{i_l+1}\}$. Let $s = 2T + w$.

We express $f_{n,A,W,\mathcal{V}}$ in terms of a stochastic process. Take a random $\rho \in L(\sigma)$ and traverse the path $\xi_{A,\rho}$. Let us keep a sorted list W'; initially, W' is the sorted version of W. When we encounter a new node u with a comparison $x_r : x_{r'}$, we insert the elements in $\{x_r, x_{r'}\} - W'$, if any, one at a time into the ordered list W'. Note that each new element, when added to an ordered list of c elements, will be equally likely in any of the $c+1$ ranks. When we reach the leaf, we add $s - |W'|$ new elements of W_δ, one at a time, into W'. Again, each new element is equally likely to occupy any of the ranks currently possible in W'. The quantity $f_{n,A,W,\mathcal{V}}(\sigma, C, m)$ can thus be calculated as follows. We start with an ordered list of w items with l of the intervals (between the i_j and the $i_j + 1$st items for $1 \leq j \leq l$) marked; then we sequentially insert new items into the list. Each time the new item is equally likely to be inserted into any of the existing intervals; $f_{n,A,W,\mathcal{V}}(\sigma, C, m)$ is the probability that, after $2T$ insertions, at least m of the original l marked intervals remain intact (no item has been inserted into these intervals).

We will obtain an upper bound on $f_{n,A,W,\mathcal{V}}(\sigma, C, m)$. (Essentially, this is now reduced to a calculation that was done in [BFMUW].) Let us describe the process using a sequence of $2T$ integers $j_1, j_2, \ldots, j_{2T}$, where $1 \leq j_r \leq w + r$ is the rank of the rth inserted item when it is being inserted. Thus, there are in all $\prod_{1 \leq r \leq 2T}(w+r)$ configurations. To specify a configuration for which at least m marked intervals remain intact, we first specify m such intervals, and then specify the ranks of the inserted items by integers $j_1, j_2, \ldots, j_{2T}$, where $1 \leq j_r \leq w + r - m$. The total number of such configurations is thus at most $\binom{l}{m} \prod_{1 \leq r \leq 2T}(w + r - m)$. It follows that

$$f_{n,A,W,\mathcal{V}}(\sigma, C, m) \leq \binom{l}{m} \frac{\prod_{1 \leq r \leq 2T}(w + r - m)}{\prod_{1 \leq r \leq 2T}(w + r)},$$

$$= \binom{l}{m} \frac{w!\ (s-m)!}{s!\ (w-m)!},$$
$$= \binom{l}{m} \frac{w(w-1)\dots(w-m+1)}{s(s-1)\dots(s-m+1)},$$
$$\le \binom{l}{m} \cdot \left(\frac{w}{2T}\right)^m. \quad \square$$

Remarks. The bounds derived and the formulas involved in the above proof do not have any explicit dependency on the choice of W_δ. This is not a surprise, since it is not hard to see that $f_{n,A,W,\mathcal{V}}(\sigma, C, m)$ is in fact independent of $\mathcal{V}$. For any input consistent with σ, when we have carried out the comparisons according to A (traversing a path δ), the x_i's outside $W \cup$ support(C_δ) are isolated elements in the partial order generated by σ and the comparisons. The choice of W_δ only affects which of these isolated elements are to be included in the final *output* W' (in the sense described in the first paragraph of this subsection). By symmetry, this choice does not affect the probability of "success" (in the sense defined in the first paragraph of this subsection).

3. Proof of Theorem 1. The heart of the proof is the next lemma. Let $N_0 = 10^{14}, n \ge N_0, S > 0, t = \lceil e^{(\ln n)^{1/2}} \rceil$, and $k_0 = \lfloor \log_t(n/4) \rfloor$. Then $t > e^5, k_0 > 3$. For any integer $k > 0$, let $m_k = 2^{k_0+4k+16} t S$, and $q_k = 4^{(k-k_0)S}(4t)^{k-k_0} 2^{-10S}$.

MAIN LEMMA. *Let* $1 \le k \le k_0$. *Then* $g_A(m_k) \le q_k$, *for any branching program* A *of length* t^k *and capacity* S.

COROLLARY. *Let* A *be a branching program of length* $\le t^{k_0}$ *and capacity* S. *Take a random* ρ, *uniformly chosen from* $\Gamma(X)$ *and input* $\tilde{x}_\rho$ *to* A. *Then the probability that* A *makes at least* m_k *comparisons adjacent in* ρ *is* $\le q_k$.

The corollary follows from the Main Lemma, since the introduction of additional elements x_i into support$'(C_\delta)$ will not increase the number of adjacent comparisons.

We first restate the Main Lemma. Take a random ρ, uniformly chosen from $\Gamma(X)$, and input $\tilde{x}_\rho$ to A. Let $\delta = \xi_{A,_\rho}$. The Main Lemma asserts that

$$\Pr\{Z(C_\delta, 0, t^k, \rho|_{X'}) \ge m_k\} \le q_k,$$

where $X' = \text{support}'(C_\delta)$.

We will prove the above inequality by induction on $k \ge 1$. For $k = 1$, we have $m_k > t^k$. Since A can make only t^k comparisons, the inequality is true (the left-hand side being 0).

We now assume that $1 < k \le k_0$, and that the Main Lemma has been proved for all values less than k.

Let $\rho \in \Gamma(X)$. Write $\delta = \xi_{A,_\rho}$ and $X' = \text{support}'(C_\delta)$. If $Z(C_\delta, 0, t^k, \rho|_{X'}) \ge m_k$, then there is a $1 \le d_\rho \le t$, such that $Z(C_\delta, (d_\rho - 1)t^{k-1}, d_\rho t^{k-1}, \rho|_{X'}) \ge m_k/t$. Thus, for a random ρ uniformly chosen from $\Gamma(X)$,

$$(1) \quad \Pr\{Z(C_\delta, 0, t^k, \rho|_{X'}) \ge m_k\} \le \sum_{1 \le d \le t} \Pr\{Z(C_\delta, (d-1)t^{k-1}, dt^{k-1}, \rho|_{X'}) \ge m_k/t\}.$$

We will show that, for each $1 \le d \le t$,

$$(2) \qquad \Pr\{Z(C_\delta, (d-1)t^{k-1}, dt^{k-1}, \rho|_{X'}) \ge m_k/t\} \le (2^s + 1)q_{k-1}.$$

This will complete the inductive proof of the Main Lemma, since it follows from (1) and (2) that

$$\Pr\{Z(C_\delta, 0, t^k, \rho|_{X'}) \ge m_k\} \le (2^S + 1)tq_{k-1}$$
$$\le q_k.$$

Fix $1 \leq d \leq t$. Let $v_1, v_2, \ldots, v_r$ be the nodes of A at level $(d-1)t^{k-1}$. For each i, let B_i be the set of paths β of length t^{k-1} starting at node v_i. Let

$$\Psi_i = \cup_{\beta \in B_i} \Delta(P_{C_\beta}).$$

Note that Ψ_i consists of all linear orderings σ of the comparisons along β restricted to the subset support$'(C_\beta)$ (not just support(C_β)) for all paths $\beta \in B_i$. The following two facts are obviously true. Let $1 \leq i \leq r$.

Fact 2. Let $\beta, \beta' \in B_i$. If $\sigma \in \Delta(P_{C_\beta}) \cap \Delta(P_{C_{\beta'}})$, then $\beta = \beta'$. We can thus write $\beta(i, \sigma)$ for the unique $\beta \in B_i$ for which $\sigma \in \Delta(P_{C_\beta})$.

Fact 3. The family $L(\sigma)$, $\sigma \in \Psi_i$, forms a partition of the set $\Gamma(X)$.

To prove (2), we divide the set of inputs according to which node v_i an input reaches. For $1 \leq i \leq r$, let R_i be the set of $\rho \in \Gamma(X)$ such that input $\tilde{x}_\rho$ will reach v_i A. We further subdivide each R_i into three parts. Let $\Psi_i^{(1)}$ be the set of $\sigma \in \Psi_i$ such that $C_{\beta(i,\sigma)}$ contains at least m_{k-1} comparisons adjacent in σ. Let $\Psi_i^{(2)}$ be the set of $\sigma \in \Psi_i$ such that $|L(\sigma) \cap R_i| \leq |L(\sigma)| q_{k-1}/(10 \cdot 2^S)$. Let $\Psi_i^{(0)} = \Psi_i - \Psi_i^{(1)} - \Psi_i^{(2)}$. We will estimate the contribution to $\Pr\{Z(C_\delta, (d-1)t^{k-1}, dt^{k-1}, \rho|_{X'}) \geq m_k/t\}$ from

$$\rho \in R_i \cap (\cup_{\sigma \in \Psi_i^{(j)}} L(\sigma))$$

for each $j \in \{0, 1, 2\}$. The overwhelming majority of the ρ's belong to the part $j = 0$; the part $j = 2$ groups some infrequently visited nodes and paths; the part $j = 1$ gathers paths making many local adjacent comparisons, and hence cannot include too many ρ's by the induction hypothesis. Facts 4–6 give estimates of the contributions from the various parts to the right-hand side of (2).

Generate a random ρ uniformly chosen from $\Gamma(X)$. Let δ be $\xi_{A,\rho}$, the path traversed by $\tilde{x}_p$ in A. We consider the probabilities for two events. First, let $p_{i,\sigma}$ be the probability that $\rho \in L(\sigma)$ and the path δ contains v_i. Clearly, $p_{i,\sigma} = |R_i \cap L(\sigma)|/n!$. Second, let $\alpha_{i,\sigma}$ be the conditional probability that, for such an input $\tilde{x}_\rho$, the branching program $A[v_i, t^{k-1}]$ will make m_k/t comparisons adjacent in $\rho|_{X'}(X' = \text{support}'(C_\delta))$. Clearly,

$$\begin{aligned}(3)\qquad &\Pr\{Z(C_\delta, (d-1)t^{k-1}, dt^{k-1}, \rho|_{X'}) \geq m_k/t\} \\ &\qquad = \sum_{1 \leq i \leq r} \sum_{\sigma \in \Psi_i} p_{i,\sigma}\alpha_{i,\sigma}.\end{aligned}$$

We need three facts. Let $1 \leq i \leq r$.

Fact 4.

$$\sum_{\sigma \in \Psi_i^{(1)}} p_{i,\sigma} \leq q_{k-1}.$$

Fact 5.

$$\sum_{\sigma \in \Psi_i^{(2)}} p_{i,\sigma} \leq q_{k-1}/(10 \cdot 2^S).$$

Fact 6. For each $\sigma \in \Psi_i^{(0)}$, $\alpha_{i,\sigma} \leq q_{k-1}/10$.

Applying the induction hypothesis to $A[v_i, t^{k-1}]$, we obtain

$$\frac{1}{n!}\left|\cup_{\sigma \in \Psi_i^{(1)}} L(\sigma)\right| \leq q_{k-1},$$

from which Fact 4 follows immediately. We obtain Fact 5 from the following derivation, using Fact 3 in the last step,

$$\begin{aligned}\sum_{\sigma\in\Psi_i^{(2)}} p_{i,\sigma} &= \sum_{\sigma\in\Psi_i^{(2)}} \frac{|L(\sigma)\cap R_i|}{n!}\\ &= \frac{1}{n!}\sum_{\sigma\in\Psi_i^{(2)}} |L(\sigma)|\frac{|L(\sigma)\cap R_i|}{|L(\sigma)|}\\ &\le \frac{1}{n!}\frac{1}{10\cdot 2^S}q_{k-1}\sum_{\sigma\in\Psi_i^{(2)}}|L(\sigma)|\\ &\le \frac{1}{10\cdot 2^S}q_{k-1}.\end{aligned}$$

We now prove Fact 6. Let $\sigma\in\Psi_i^{(0)}$. Let u denote the node at the end of the path $\beta(i,\sigma)$. Thus u is at a distance dt^{k-1} from the source of the branching program A.

We first construct a new branching program $A_{i,\sigma}$. Take the branching program $A[\text{root}, (d-1)t^{k-1}]$, and attach to the end node v_i a copy of $A[u, t^k - dt^{k-1}]$ by identifying u with v_i. This is now a (nonleveled) branching program that may also be obtained by deleting from A all outgoing edges from all nodes v_j at level $(d-1)t^{k-1}$ except the one edge (out of v_i) on the path $\beta(i,\sigma)$, contracting the path $\beta(i,\sigma)$ to a point, and pruning away nodes and edges unreachable by inputs. Call this the *main portion* of $A_{i,\sigma}$. We finish the construction by adding arbitrary pieces to the other end nodes $v_j (j\neq i)$ to make it a leveled branching program (to conform to our convention of the definition of a branching program); for example, for each $v_j\neq v_i$, we can sequentially make the comparisons $x_a : x_{a+1}$ for $a = 1, 2, \ldots, t^k - dt^{k-1}$ and go to new nodes $u_{j,a}$ irrespective of the results of the comparisons. Clearly, $A_{i,\sigma}$ is of length $t^k - t^{k-1}$. Note that the capacity of $A_{i,\sigma}$ depends on how we choose the pieces outside the main portion and may be different from the capacity of A. We will use $A_{i,\sigma}$ only for the purpose of analyzing $\alpha_{i,\sigma}$.

For any path δ of length t^k in A starting at the source and containing $\beta(i,\sigma)$ there is an obvious corresponding path $\hat{\delta}$ of length $t^k - t^{k-1}$ in $A_{i,\sigma}$ that lies completely in the main portion. The converse is also true. Any such $\hat{\delta}$ in $A_{i,\sigma}$ will be called a *central path*.

For any central path $\hat{\delta}$ in $A_{i,\sigma}$, define $W_{\hat{\delta}} = \text{support}'(C_\delta)$. For any noncentral path δ' of length $t^k - t^{k-1}$ in $A_{i,\sigma}$, choose $W_{\delta'}$ arbitrarily but subject to the conditions $|W_{\delta'}| = 2t^k$ and $\text{support}'(C_{\delta'})\cup \text{support}'(C_{\beta(i,\sigma)}) \subseteq W_{\delta'}$. This is always feasible since $|\text{support}'(C_{\delta'})| = 2(t^k - t^{k-1})$ and $|\text{support}'(C_{\beta(i,\sigma)})| = 2t^{k-1}$. (We use the notation δ' for paths in $A_{i,\sigma}$ to avoid confusion with the paths in A.) Let $\mathcal{V}$ be the collection of $W_{\delta'}$ for all paths δ' (of length $t^k - t^{k-1}$) in $A_{i,\sigma}$.

Note that, for any central path $\hat{\delta}$ in $A_{i,\sigma}$, we have $W_{\hat{\delta}} = \text{support}'(C_\delta)$ by definition. Also from Fact 1 (§2.1) $\text{support}'(C_\delta)$ contains both $\text{support}'(C_{\beta(i,\sigma)})$ and $\text{support}'(C_{\hat{\delta}})$; this implies $\text{support}'(C_{\beta(i,\sigma)})\cup \text{support}'(C_{\hat{\delta}}) \subseteq W_{\hat{\delta}}$. Thus, for all paths δ' (of length $t^k - t^{k-1}$) in $A_{i,\sigma}$,

$$\text{support}'(C_{\beta(i,\sigma)}) \cup \text{support}'(C_{\delta'}) \subseteq W_{\delta'}. \tag{4}$$

Let b denote the probability that, for a random $\tilde{x}_\rho$, with ρ uniformly chosen from $R_i\cap L(\sigma)$, the path δ' traversed by $\tilde{x}_\rho$ in the branching program $A_{i,\sigma}$ possesses the property that $C_{\beta(i,\sigma)}$ contains at least m_k/t comparisons adjacent in $W_{\delta'}$. (Note that $\beta(i,\sigma)$ is *not* a subpath of δ' but the path in A between nodes v_i and u.) Define c in the same fashion as b was defined, except that ρ is uniformly chosen from $L(\sigma)$. (These are well defined, since support $(C_{\beta(i,\sigma)}) \subseteq W_{\delta'}$ by (4).) Because any ρ satisfying the defining constraints for b must satisfy the defining constraints for c, we have

$$b\cdot|R_i\cap L(\sigma)| \le c\cdot|L(\sigma)|. \tag{5}$$

Let $\rho \in R_i \cap L(\sigma)$. If $\tilde{x}_\rho$ is input to A and traverses a path δ, then the same $\tilde{x}_\rho$ when input to $A_{i,\sigma}$ will trace the central path $\hat{\delta}$; furthermore, by definition we have $W_{\hat{\delta}} = \mathrm{support}'(C_\delta)$. Recall that $\alpha_{i,\sigma}$ is the probability that, for a random $\tilde{x}_\rho$, with ρ uniformly chosen from $R_i \cap L(\sigma)$, $C_{\beta(i,\sigma)}$ contains at least m_k/t comparisons adjacent in $\rho|'_X(X' = \mathrm{support}'(C_\delta)$ with $\delta = \xi_{A,\rho})$. Comparing this with the definition of b, we have

$$\alpha_{i,\sigma} = b. \tag{6}$$

Now, let $W = \mathrm{support}'(C_{\beta(i,\sigma)})$ and $T = t^k - t^{k-1}$; then $|W| = 2t^{k-1}$ and $2T + |W| = 2t^k$. Note that $n \geq 4t^k \geq 2T + |W|$. From (4), we have $W_{\delta'} \supseteq W \cup \mathrm{support}(C_{\delta'})$ for all paths δ' (of length T) in $A_{i,\sigma}$. From the definition of $f_{n,A,W,\mathcal{V}}$ stated at the beginning of §2.3, we see that c is exactly equal to $f_{n,A_{i,\sigma},W,\mathcal{V}}(\sigma, C_{\beta(i,\sigma)}, \lceil m_k/t \rceil)$. We have thus from (5) and (6) and the fact that $\sigma \in \Psi_i^{(0)}$

$$\begin{aligned} \alpha_{i,\sigma} &\leq \frac{|L(\sigma)|}{|R_i \cap L(\sigma)|} \cdot c \\ &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot f_{n,A_{i,\sigma},W,\mathcal{V}}(\sigma, C_{\beta(i,\sigma)}, \lceil m_k/t \rceil). \end{aligned} \tag{7}$$

Let l_σ denote the number of comparisons of $C_{\beta(i,\sigma)}$ adjacent in σ. Then by definition $l_\sigma \leq m_{k-1}$ for any $\sigma \in \Psi_i^{(0)}$. By applying Lemma 1 to the branching program $A_{i,\sigma}$ to get an upper bound on $f_{n,A_{i,\sigma},W,\mathcal{V}}(\sigma, C_{\beta(i,\sigma)}, \lceil m_k/t \rceil)$, and then substituting it into (7), we obtain

$$\begin{aligned} \alpha_{i,\sigma} &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot \binom{l_\sigma}{\lceil m_k/t \rceil} \left(\frac{2t^{k-1}}{2(t^k - t^{k-1})} \right)^{\lceil m_k/t \rceil} \\ &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot \binom{m_{k-1}}{\lceil m_k/t \rceil} (t-1)^{-\lceil m_k/t \rceil} \\ &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot \left(\frac{e m_{k-1}}{(t-1)\lceil m_k/t \rceil} \right)^{\lceil m_k/t \rceil} \\ &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot \left(\frac{et}{16(t-1)} \right)^{m_k/t} \\ &\leq \frac{10 \cdot 2^S}{q_{k-1}} \cdot \left(\frac{1}{2} \right)^{2^{16+k_0}S} \\ &\leq \frac{1}{10} q_{k-1}. \end{aligned}$$

This proves Fact 6.

We will now complete the proof of (2). From (3) and Facts 4–6, we obtain $Pr\{Z(C_\delta, (d-1)t^{k-1}, dt^{k-1}, \rho|_{X'}) \geq m_k/t\}$

$$\begin{aligned} &= \sum_{1 \leq i \leq r} \sum_{\sigma \in \Psi_i} p_{i,\sigma} \alpha_{i,\sigma} \\ &\leq \sum_i \sum_{\sigma \in \Psi_i^{(1)}} p_{i,\sigma} + \sum_i \sum_{\sigma \in \Psi_i^{(2)}} p_{i,\sigma} \\ &\quad + \sum_i \sum_{\sigma \in \Psi_i^{(0)}} p_{i,\sigma} \alpha_{i,\sigma} \end{aligned}$$

$$
\begin{aligned}
&\le q_{k-1}\sum_i 1 + \sum_i \frac{1}{10\cdot 2^S} q_{k-1} + \sum_i \sum_{\sigma\in\Psi_i^{(0)}} p_{i,\sigma}\frac{1}{10} q_{k-1}\\
&\le 2^S q_{k-1} + \frac{1}{10} q_{k-1} + \frac{1}{10} q_{k-1}\\
&\le (2^S+1) q_{k-1}.
\end{aligned}
$$

We have proved (2). This completes the inductive step in the proof of the Main Lemma.

We will now use the Main Lemma to complete the proof of Theorem 1. Let $n \ge N_0$, where $N_0 = 10^{14}$. Because $k_0 \le \ln n/\ln t \le (\ln n)^{1/2}$, we have

$$
\begin{aligned}
t\cdot 2^{5k_0} &\le 2\cdot \exp((\ln n)^{1/2} + k_0 5\ln 2)\\
&= O\left(n^{\epsilon(n)}\right).
\end{aligned} \tag{8}
$$

Let $A \in \mathcal{A}_n$. If $S \ge \frac{1}{10}\frac{n}{t}2^{-5k_0-16}$, then since $T \ge n-1$, we have by (8) $TS = \Omega(n^2/t2^{5k_0}) = \Omega(n^{2-\epsilon(n)})$. We now consider the case $S < \frac{1}{10}\frac{n}{t}2^{-5k_0-16}$. In this case

$$
0 < m_{k_0} < n/10. \tag{9}
$$

Since A has to have at least $n-1$ nodes, we have $S \ge \log_2(n-1) > 0$. Suppose that A has length $T < t^{k_0}n/2m_{k_0}$. We will derive a contradiction.

Let $\rho \in \Gamma(X)$. For each node v, let A_v denote the branching program $A[v, \min\{t^{k_0}, T - l_v\}]$, where l_v is the level number of v. Let K_v be the set of $\rho \in \Gamma(X)$ such that $C_{\delta(v,\rho)}$ contains at least m_{k_0} comparisons adjacent in ρ, where $\delta(v,\rho) = \xi_{A_v,\rho}$. By the corollary to the Main Lemma, $|K_v| \le q_{k_0}\cdot n!$.

Thus,

$$
\begin{aligned}
|\cup_v K_v| &\le 2^S q_{k_0}\cdot n!\\
&< n!.
\end{aligned}
$$

It follows that there exists a $\rho \notin \cup_v K_v$. Let us input $\tilde{x}_\rho$ to A. The traversed path δ can be decomposed into $\delta(v_1,\rho)\delta(v_2,\rho)\ldots\delta(v_d,\rho)$, where $d = \lceil T/t^{k_0}\rceil$, v_1 is the source, and $v_1, v_2, \ldots, v_d$ are nodes in δ with distance t^{k_0} between v_i and v_{i+1}; for each i, the subpath $\delta(v_i,\rho)$ is a path in the subbranching program A_{v_i}. For each i, as $\rho \notin K_{v_i}$, the number of comparisons made along $\delta(v_i,\rho)$ contains less than m_{k_0} comparisons adjacent in ρ. It follows that the total number of comparisons made by A that are adjacent in ρ is less than $dm_{k_0} \le \lceil n/2m_{k_0}\rceil\cdot m_{k_0} \le m_{k_0} + \frac{n}{2}$, which by (9) is less than $n-1$. This is a contradiction.

Thus, using (8) we obtain

$$
\begin{aligned}
T &\ge t^{k_0}\frac{n}{2m_{k_0}}\\
&= \Omega\left(\frac{t^{k_0-1}}{2^{5k_0}}\frac{n}{S}\right)\\
&= \Omega\left(\frac{n^2}{S}\frac{1}{t2^{5k_0}}\right)\\
&= \Omega\left(\frac{1}{S}n^{2-\epsilon(n)}\right).
\end{aligned}
$$

This completes the proof of Theorem 1.

4. Concluding remarks. In this paper we have shown a $TS = \Omega(n^{2-\epsilon(n)})$ time-space tradeoff for the element distinctness problem for comparison branching programs. It remains an interesting open question whether $TS = \Omega(n^2)$. Another direction of research is to investigate whether the time-space tradeoff presented here can be obtained for linear-test or arithmetic branching programs.

Acknowledgments. The author thanks Paul Beame for pointing out an error in the statement of Fact 4 in the original draft of this paper. The author also wishes to thank an anonymous referee for valuable suggestions to correct an inaccuracy and improve the presentations.

EXISTENCE AND CONSTRUCTION OF EDGE-DISJOINT PATHS ON EXPANDER GRAPHS*

ANDREI Z. BRODER†, ALAN M. FRIEZE‡ AND ELI UPFAL§

Abstract. Given an expander graph $G = (V, E)$ and a set of q disjoint pairs of vertices in V, the authors are interested in finding for each pair (a_i, b_i) a path connecting a_i to b_i such that the set of q paths so found is edge disjoint. (For general graphs the related decision problem is NP complete.)

The authors prove sufficient conditions for the existence of edge-disjoint paths connecting any set of $q \leq n/(\log n)^\kappa$ disjoint pairs of vertices on any n vertex bounded degree expander, where κ depends only on the expansion properties of the input graph, and not on n. Furthermore, a randomized $o(n^3)$ time algorithm, and a random $\mathcal{NC}$ algorithm for constructing these paths is presented. (Previous existence proofs and construction algorithms allowed only up to n^ϵ pairs, for some $\epsilon \ll \frac{1}{3}$, and strong expanders [D. Peleg and E. Upfal, Combinatorica, 9 (1989), pp. 289–313.].)

In passing, an algorithm is developed for splitting a sufficiently strong expander into two edge-disjoint spanning expanders.

Key words. edge-disjoint paths, expanders

1. Introduction. Given an expander graph $G = (V, E)$ and a set of q disjoint pairs of vertices in V, we are interested in finding for each pair (a_i, b_i), a path connecting a_i to b_i, such that the set of q paths so found is edge disjoint.

For arbitrary graphs, the related decision problem is in $\mathcal{P}$ for fixed q [21], but is $\mathcal{NP}$ complete if q is part of the input. However, this negative result can be circumvented for certain classes of graphs. For certain bounded degree expander graphs, Peleg and Upfal [19] have presented a polynomial time algorithm and a random $\mathcal{NC}$ algorithm for constructing up to n^ϵ disjoint paths, where $0 < \epsilon \ll \frac{1}{3}$ is a constant that depends on the expansion properties of the input graph.

In this paper we describe a new algorithm for constructing edge-disjoint paths. Using it we can construct up to $n/(\ln n)^\kappa$ disjoint paths on bounded degree graphs with a sufficiently strong expansion property, where κ is a constant that depends only on the expansion property of the input graph. Our algorithm is based on two probabilistic tools: the rapid mixing properties of random walks on expanders and the Lovász Local Lemma [10].

As in [19], the disjoint paths are constructed in two stages. In the first stage we choose a random set Q of $2q$ vertices that are at least $\kappa_1 \ln \ln n$ apart from each other. (The constant κ_1 will be defined later.) We connect the original endpoints to the vertices of Q in an arbitrary fashion via edge-disjoint paths, such that each Q-vertex is the endpoint of exactly one path. A simple flow argument proves constructively the existence of such edge-disjoint paths on any graph with edge expansion larger than one.

Let $\tilde{a}_i$ (respectively, $\tilde{b}_i$) denote the vertex in Q that was connected to the original endpoint a_i (respectively, b_i) in the first stage. The core of the algorithm consists of constructing edge-disjoint paths connecting $\tilde{a}_i$ to $\tilde{b}_i$, for $i = 1, \ldots, q$.

In the second stage of the algorithm we choose for each pair $(\tilde{a}_i, \tilde{b}_i)$ a bundle of $(\ln n)^2$ random paths connecting them. The goal is to show via the Lovász Local Lemma that there

§IBM Almaden Research Center, San Jose, California 95120, and Department of Applied Mathematics, Weizmann Institute of Science, Rehovot, Israel.

is one choice out of each bundle of paths such that the set of chosen paths is edge disjoint. However, the Local Lemma cannot be applied to sets of paths chosen uniformly at random, since the dependency graph that corresponds to such choices is too dense. The crux of the proof is that for any expander graph there is a simple pruning mechanism that reduces the dependency so that the Lemma can be applied.

To convert the existence proof to an explicit algorithm, we observe that the dependency graph constructed in this process is almost surely composed of sufficiently small components, such that the paths can be selected in polynomial time by exhaustive search.

Each of the two stages of the algorithm requires an expander graph. If we apply both stages to the same expander we prove the following theorem.

THEOREM 1.1. *Given any n vertex, bounded degree, regular graph G with edge expansion greater than one, and given any set of $q \leq n/(\log n)^{\kappa}$ disjoint pairs of vertices in G, with high probability our algorithm finds in $o(n^3)$ steps a set of paths in G connecting the q pairs, such that each edge in G participates in no more than two paths.* (*The constant κ is exposed in the proof.*)

While the above result is sufficient for most applications, it is still of theoretical interest to find edge-disjoint paths. To achieve this goal we develop a new algorithm for splitting a sufficiently strong expander into two edge-disjoint spanning expanders. We believe that this algorithm is of independent interest. The splitting algorithm requires a stronger but still bounded degree expander. Splitting it and applying each stage of our algorithm to a different set of edges we prove the following theorem.

THEOREM 1.2. *Given an n vertex graph with sufficiently strong edge expansion, and given any set of $q \leq n/(\log n)^{\kappa}$ disjoint pairs of vertices in G, with high probability our algorithm finds in $o(n^3)$ steps a set of edge-disjoint paths in G connecting the q pairs.* (*The constant κ and the required edge expansion are defined later.*)

The disjoint paths problem has numerous algorithmic applications. One that has received increased attention in recent years is in the context of communication networks for parallel and distributed computing. While packet routing is the communication protocol of choice for bounded size messages, it cannot always be used efficiently for high volume communication such as in multimedia applications and two-way communication. A more efficient way to transmit such information is through disjoint paths (virtual circuits) that are dedicated to one pair of processors for the duration of the communication. Our result gives yet more evidence of the usefulness of a communication network with strong expansion properties [24], [16], [20].

A preliminary version of this paper has appeared in [8].

2. Preliminaries.

There are various ways to define expander graphs; here we define them in terms of edge expansion (a weaker property than vertex expansion).

Let $G = (V, E)$ be a graph. For a set of vertices $S \subset V$ let out(S) be the set of edges with one endpoint in S and one endpoint in $V \setminus S$, that is

$$\text{out}(S) = \Big\{\{u, v\} \mid \{u, v\} \in E, u \in S, v \notin S\Big\}.$$

Similarly

$$\text{in}(S) = \Big\{\{u, v\} \mid \{u, v\} \in E, u \in S, v \in S\Big\}.$$

DEFINITION 1. A graph $G = (V, E)$ is a β-expander if for every set $S \subset V$, $|S| \leq |V|/2$ we have $|\text{out}(S)| \geq \beta|S|$.

DEFINITION 2. An r-regular graph $G = (V, E)$ is an (α, β, γ)-expander if for every set $S \subset V$

$$\text{out}(S) \geq \begin{cases} (3r/4 + \alpha)|S| & \text{if } |S| \leq \gamma|V|, \\ \beta|S| & \text{if } \gamma|V| < |S| \leq |V|/2. \end{cases}$$

DEFINITION 3. The t-neighborhood of a vertex u in G is the set of all vertices that are at distance t or less from u in G.

The notation $\text{dist}(u, v)$ refers to the distance from vertex v to vertex u. If U is a set of vertices, then $\text{dist}(U, v) = \min_{u \in U} \text{dist}(u, v)$. If P is a path (which we view as a set of edges), then $\text{dist}(P, v)$ is the minimum over all vertices u on P of $\text{dist}(u, v)$. These definitions generalize in the obvious manner when both arguments are paths, sets, and so on.

A *random walk* on the undirected graph $G = (V, E)$ is a Markov chain $\{X_t\} \subseteq V$ associated with a particle that moves from vertex to vertex according to the following rule: the probability of a transition from vertex i, of degree d_i, to vertex j is $1/d_i$ if $\{i, j\} \in E$, and 0 otherwise. (In case of a bipartite graph we need to assume that we do nothing with probability $\frac{1}{2}$ and move off with probability $\frac{1}{2}$ only. This technicality is ignored for the remainder of the paper.) Its stationary distribution, denoted π, (or $\pi(G)$) is given by $\pi_v = d_v/(2|E|)$. A trajectory W of length τ is a sequence of vertices $[w_0, w_1, \ldots, w_\tau]$ such that $\{w_t, w_{t+1}\} \in E$. The Markov chain $\{X_t\}$ induces a probability distribution on trajectories, namely the product of the probabilities of the transitions that define the trajectory.

The notation $B(m, p)$ stands for the binomial random variable with parameters m = number of trials, and p = probability of success.

The notation $[m]$ stands for the set $\{1, 2, \ldots, m\}$ for any positive integer m.

3. The sequential algorithm. Below we present the algorithm for finding disjoint paths. If we relax the requirements so that edges can be used twice, then the input can be any β-expander, $\beta > 1$, and phase 1 is omitted entirely. The algorithm involves certain constants $\kappa, \kappa_1, \kappa_2, \kappa_3$, and κ_4. The required relations between these constants are explicitly given in equations (13)–(15). At various points of the algorithm we stop if certain conditions fail to hold. The subsequent analysis shows that premature termination is unlikely.

Algorithm DisjPaths
Input: An r-regular graph $G = (V, E)$ with sufficiently strong expansion. A collection of q disjoint pairs of vertices $\{(a_1, b_1), \ldots, (a_q, b_q)\}$. (The term "sufficiently strong" will be fully explained below.)

Output: A set of q edge-disjoint paths $\{P_1, \ldots, P_q\}$ such that P_i connects a_i to b_i.

Phase 1. Split G into two spanning expanders $G_R = (V, E_R)$ and $G_B = (V, E_B)$ such that $E = E_R \cup E_B$ and $E_R \cap E_B = \emptyset$. We require G_R to be a 1-expander and G_B to be a β'-expander for some $\beta' > 0$. (The details of this procedure are presented in §4.1.)

The steady state distribution of the random walk on G_B is easily seen to be given by

$$\pi(v) = \frac{d_B(v)}{2|E_B|}, \quad v \in V,$$

where $d_B(v)$ denotes the degree of the vertex v in G_B. Our construction guarantees that

$$\frac{1}{2n} \leq \pi(v) \leq \frac{3}{2n} \quad \forall v \in V. \tag{1}$$

Phase 2. Choose independently (with replacement) according to the distribution $\pi(G_B)$, a multiset of $4q$ vertices in V. Let $R = \{r_1, \ldots, r_{4q}\}$ be the multiset of vertices so chosen.

Phase 3. Select a set $Q \subset R$ of $2q$ vertices, such that every pair of vertices in Q are $\kappa_1 \ln\ln n$ apart from each other, as follows.

```
$Q \leftarrow \emptyset$
for $i = 1, \ldots, 4q$ while $|Q| < 2q$ do
    if dist$(Q, r_i) \geq \kappa_1 \ln\ln n$ then $Q \leftarrow Q \cup \{r_i\}$ fi
od
```

If at the end of this procedure $|Q| < 2q$ then **stop**. The algorithm has failed.

Phase 4. Let $S = \{a_1, \ldots, a_q, b_1 \ldots, b_q\}$. Using a flow algorithm in G_R, connect in an arbitrary manner the vertices of S to the vertices of Q by $2q$ edge-disjoint paths. (Except for the edges on these paths, no other edges of G_R are used for the final construction.) If such a flow cannot be constructed then **stop**. The algorithm has failed. (This can happen only if G_R did not have sufficient edge expansion.)

Phase 5. Let $\tilde{a}_i$ (respectively, $\tilde{b}_i$) be the vertex in Q that was connected to a_i (respectively, b_i). For each pair $(\tilde{a}_i, \tilde{b}_i)$ construct $m = (\ln n)^2$ paths, $P_{i,1}, \ldots, P_{i,m}$ connecting $\tilde{a}_i$ to $\tilde{b}_i$, as follows.

```
for $j = 1, 2, \ldots, m$ do
    Pick a vertex $x_{i,j}$ according to the distribution $\pi(G_B)$.
    Choose a trajectory $W'_{i,j}$ (respectively, $W''_{i,j}$) of length
      $\tau = \kappa_2 \ln n$ that goes from $\tilde{a}_i$ to $x_{i,j}$ (respectively, $\tilde{b}_i$ to $x_{i,j}$)
      in $G_B$, according to the distribution on trajectories,
      conditioned on $w_{i,j,0} = \tilde{a}_i$ and $w_{i,j,\tau} = x_{i,j}$. (The
      distribution for $W''_{i,j}$ is analogous.)
    Let $W_{i,j}$ be the walk formed by $W'_{i,j}$ followed by $W''_{i,j}$ reversed.
    Reduce $W_{i,j}$ to a path $P_{i,j}$ by removing cycles.
od
```

(The purpose of the remainder of the algorithm is to find among the set of $q \cdot m$ paths constructed in this phase a *solution set*, that is, a subset of q edge-disjoint paths, one for each pair $(\tilde{a}_i, \tilde{b}_i)$.)

Phase 6. We refer to the set of paths $B_i = \{P_{i,1}, P_{i,2}, \ldots, P_{i,m}\}$ as *bundle i*. The purpose of this phase is to prune from each bundle those paths that go "too close" to the endpoints of other bundles or to each other.

Let $w'_{i,j,t}$ and $w''_{i,j,t}$ denote the tth vertices of $W'_{i,j}$ and $W''_{i,j}$, respectively. Let $M_{i,j} = \{w'_{i,j,t}, w''_{i,j,t} : t \geq (\kappa_1 - \kappa_3) \ln\ln n\}$.

```
for $i = 1, 2, \ldots, q$ do
    for $j = 1, 2, \ldots, m$ do
        (a) if dist$(M_{i,j}, \bigcup_{k<j} M_{i,k}) \leq 2\kappa_3 \ln\ln n$ then
            $B_i \leftarrow B_i \setminus \{P_{i,j}\}$ fi
        (b) if dist$(W_{i,j}, Q \setminus \{\tilde{a}_i, \tilde{b}_i\}) < \kappa_3 \ln\ln n$ then
            $B_i \leftarrow B_i \setminus \{P_{i,j}\}$ fi
    od
od
```

(Condition (a) ensures that outside the $(\kappa_1 - \kappa_3) \ln\ln n$ neighborhood of the common endpoints, all paths remaining in B_i are at least $2\kappa_3 \ln\ln n$ apart. Condition (b) ensures that all paths in B_i are at least $\kappa_3 \ln\ln n$ from the endpoints of other bundles.)

Let m_i denote the number of paths left in bundle i for $i = 1, 2, \dots, q$, and rename the paths such that $B_i = \{P_{i,1}, \dots, P_{i,m_i}\}$.

Check that for all $i \in [q]$, the number of paths in B_i satisfies $m_i \geq (\ln n)^2/2$. If this does not hold then **stop**. The algorithm has failed.

Phase 7. Let $H = (V_H, E_H)$ be the graph defined by

$$V_H = \left\{(i, j) \mid i = 1, \dots, q; j = 1, \dots, m_i\right\}$$

and

$$E_H = \left\{\{(i, j), (i', j')\} \mid i \neq i' \text{ and } P_{i,j} \cap P_{i',j'} \neq \emptyset\right\}.$$

The ith *row* of H is the set of vertices $\{(i, j) \mid 1 \leq j \leq m_i\}$. A row represents the bundle of paths associated to a certain pair of endpoints, and a solution set corresponds to an independent set of size q that spans all the q rows of H.

Let Δ_H denote the maximum degree of a vertex in H. If there is an i such that $m_i \leq 8\Delta_H$ then **stop**, the algorithm has failed. (As shown in the analysis of this phase, the Local Lemma implies that the condition $m_i > 8\Delta_H$ is sufficient for the existence of at least one solution set.)

Optionally, for efficiency reasons, we can arbitrarily delete paths from each bundle until for every i we have $m_i = 8\Delta_H + 1$.

Phase 8. Let $H' = ([q], E_{H'})$ be the graph on q vertices defined by

$$E_{H'} = \left\{\{i, i'\} \mid \exists j, j' \text{ s.t. } P_{i,j} \cap P_{i',j'} \neq \emptyset\right\}.$$

(In other words H' contains an edge from i to i' if and only if any of the paths from $\tilde{a}_i$ to $\tilde{b}_i$ intersects any of the paths from $\tilde{a}_{i'}$ to $\tilde{b}_{i'}$. Clearly H' can be obtained from H by contracting each row of H to a single vertex.)

If any connected component of H' has size greater than $3 \ln n/(2 \ln \ln n)$ then **stop**. The algorithm has failed.

Phase 9. For each connected component J of H', find by exhaustive search an independent set in H of size $|J|$ that spans the rows of H corresponding to the vertices of J. (We checked in phases 6 and 7 that such a set exists, and we checked in phase 8 that the components of H' are sufficiently small to ensure that the exhaustive search takes only polynomial time.)

The union of independent sets thus found is independent and spans all the rows of H, and hence corresponds to a solution set.

The final path from a_i to b_i is the union of the paths from a_i to $\tilde{a}_i$, and from b_i to $\tilde{b}_i$ found in phase 4, and the path from $\tilde{a}_i$ to $\tilde{b}_i$ selected here.

End DisjPaths

Observation: Phases 6 and 7 are essential only for the proof and can be omitted while running the algorithm. In this case, the exhaustive search in phase 9 would still take only polynomial time, but with small probability (corresponding to failure in phase 6 or 7) it might not find a solution set. Nevertheless, the running time is likely to be shortened if phases 6 and 7 are run, since the search space is reduced.

4. Analysis of the algorithm.

4.1. Splitting expanders. In this subsection we present an algorithm that partitions the edge set of the input graph into two spanning expanders.

Algorithm Split

Input: An r-regular (α, β, γ)-expander graph $G = (V, E)$. For simplicity we assume that $r = 4s$, for an integer s.

Output: Two spanning β'-expanders $G_R = (V, E_R)$ and $G_B = (V, E_B)$ such that $E = E_R \cup E_B$ and $E_R \cap E_B = \emptyset$. (The constant β' is greater than 1 and will be exposed in the proof.)

1. Using an arbitrary Euler tour, orient the edges of G in such a way that each vertex has indegree and outdegree $2s$.

2. For each vertex v, randomly divide the edges from v into a red set and a blue set, each of size s. Set E_R (respectively, E_B) to be the set of red (respectively, blue) edges, un-oriented.

End Split

Clearly, our construction guarantees that (1) holds, since in each subgraph every vertex has degree at least s and at most $3s$, and each subgraph has exactly ns edges.

We now analyze the probability that **Split** will produce useful results. We start by defining two functions, H and ψ, on [0,1]:

$$H(\gamma) = ((1-\gamma)^{1-\gamma}\gamma^{\gamma})^{-1},$$

$$\psi(\epsilon) = (1-\epsilon)\ln(1-\epsilon) + \epsilon.$$

(Observe that $\psi(\epsilon) \geq \epsilon^2/2$.)

Let $\text{in}_R(S)$, $\text{out}_R(S)$ refer to $\text{in}(S)$ and $\text{out}(S)$ as applied to the graph G_R.

THEOREM 4.1. *Suppose that G is an (α, β, γ)-expander and let $0 < \epsilon < 1$ be such that*

$$\beta > \frac{2}{\psi(\epsilon)}\gamma^{-1}\ln H(\gamma). \tag{2}$$

For every set $S \subset V$, $|S| \leq |V|/2$, we have

$$\min\{\text{out}_R(S), \text{out}_B(S)\} \geq \min\{\alpha, (1-\epsilon)\beta/2\}\,|S|\,, \tag{3}$$

with probability $1 - o(1)$ as $n \to \infty$.

Proof. We obtain a lower bound for out_R. We consider two cases.

Case 1. $|S| \leq \gamma n$. By construction every vertex has degree at least s in G_R. Hence

$$\begin{aligned} s|S| &\leq 2\,\text{in}_R(S) + \text{out}_R(S) \\ &\leq 2\,\text{in}(S) + \text{out}_R(S). \end{aligned} \tag{4}$$

On the other hand, by the definition of G,

$$\begin{aligned} 4s|S| &= 2\,\text{in}(S) + \text{out}(S) \\ &\geq 2\,\text{in}(S) + (3s+\alpha)|S|. \end{aligned} \tag{5}$$

Inequalities (4) and (5) imply

$$\mathrm{out}_R(S) \geq \alpha|S|. \tag{6}$$

Case 2. $\gamma n \leq |S| \leq \frac{n}{2}$. Partition out($S$) so that two edges are in the same subset if in the Euler orientation they have the same start vertex.

Let there be m such sets, $A_1, \dots, A_m$, with $|A_i| = k_i \leq 2s$, and $\sum_{i=1}^m k_i = k$, where $k \geq \beta|S|$ by the definition of G. Let Z_i be the number of edges of A_i that are colored red. Clearly the Z_i's are independent. For any $t > 0$ and $\frac{k}{2} > u > 0$ we have

$$\begin{aligned}
&\mathbf{Pr}(Z_1 + \cdots + Z_m \leq k/2 - u)\\
&= \mathbf{Pr}\Big(\exp\big(-t(Z_1 + \cdots + Z_m - k/2 + u)\big) \geq 1\Big)\\
&\leq \mathbf{E}\Big(\exp\big(-t(Z_1 + \cdots + Z_m) - k/2 + u\big)\Big)\\
&= e^{t(k/2-u)} \prod_{i=1}^{m} \mathbf{E}(e^{-tZ_i}).
\end{aligned}$$

But

$$\begin{aligned}
\mathbf{E}(e^{-tZ_i}) &= \binom{2s}{s}^{-1} \sum_{j=0}^{k_i} \binom{k_i}{j}\binom{2s-k_i}{s-j} e^{-tj}\\
&\leq \left(1 + (e^{-t} - 1)\frac{k_i}{2s}\right)^s\\
&\leq \exp\big((e^{-t} - 1)k_i/2\big).
\end{aligned}$$

For a proof of the first inequality above see either Hoeffding [14, §6] or Chvátal [9]. (Note that although $Z_1, Z_2, \dots, Z_m$ are independent, a simple application of Theorem 2 of [14] will not suffice. This is because the Z_i have too large a range. The interested reader can check that one obtains a factor s^{-2} in the exponent of the probability bound.)

Hence

$$\begin{aligned}
&\mathbf{Pr}\big(Z_1 + \cdots + Z_m \leq k/2 - u\big)\\
&\quad\leq \exp\big(t(k/2 - u) + (k/2)(e^{-t} - 1)\big).
\end{aligned} \tag{7}$$

Putting $t = -\ln(1 - 2u/k)$ minimizes the right-hand side (RHS) of (7), which then becomes $\exp\big(-(k/2 - u)(\ln(1 - 2u/k)) - u\big)$. Hence if $u = \epsilon k/2$, then

$$\mathbf{Pr}\big(Z_1 + \ldots + Z_m \leq (1 - \epsilon)k/2\big) \leq e^{-k\psi(\epsilon)/2}$$

and consequently

$$\mathbf{Pr}\big(\mathrm{out}_R(S) \leq (1 - \epsilon)\beta|S|/2\big) \leq e^{-\beta|S|\psi(\epsilon)/2}.$$

Thus

$$\mathbf{Pr}\big(\exists|S| \geq \gamma n \text{ such that } \mathrm{out}_R(S) \leq (1 - \epsilon)\beta|S|/2\big) \leq \sum_{i \geq \gamma n} \binom{n}{i} e^{-\beta k\psi(\epsilon)/2}. \tag{8}$$

Now if $i = \theta n$, for $\theta \geq \gamma$ then $\binom{n}{i} = e^{o(n)}H(\theta)^n$, and the summand, u_i say, on the RHS of (8) is then

$$\exp\bigl(n(o(1) + \ln H(\theta) - \beta\theta\psi(\epsilon))/2\bigr).$$

Now

$$\theta^{-1}\ln H(\theta) = -\ln\theta + 1 - \frac{\theta}{2} - \frac{\theta^2}{6} - \frac{\theta^3}{12} - \cdots$$

clearly decreases with θ and so if β satisfies (2) then u_i is exponentially small. The result follows. □

COROLLARY 4.2. *Suppose that G is an* (α, β, γ)*-expander. Let* $0 < \epsilon_0 < 1$ *be the unique solution to*

$$(9)\qquad \frac{1-\epsilon}{\psi(\epsilon)} = \frac{\gamma}{\ln H(\gamma)}$$

and let

$$\beta_0 = \frac{2}{\psi(\epsilon_0)}\gamma^{-1}\ln H(\gamma).$$

If $\alpha > 1$ *and* $\beta > \beta_0$ *then both* G_R *and* G_B *are* β'*-expanders for some* $\beta' > 1$, *with probability* $1 - o(1)$.

Proof. The existence of ϵ_0 follows from the fact that the left-hand side of (9) decreases from ∞ to 0 as ϵ increases from 0 to 1. Plugging $\beta > \beta_0$ in (3), we get that $\beta' > 1$. □

It is fairly easy to apply this to the Ramanujan graphs of Lubotsky, Phillips, and Sarnak [17] and to random regular graphs. It follows from Lemma 2.3 of Alon and Chung [4] that

$$(10)\qquad |X| = \delta n \quad \text{implies } \operatorname{out}(X) \geq r(1-\lambda)(1-\delta)|X|,$$

where λ is the second largest eigenvalue of the transition probability matrix associated with the random walk on G. If G is one of the Ramanujan graphs then $\lambda = 2\sqrt{r-1}/r$ and if G is a large random r-regular graph then $\lambda \approx 2/\sqrt{r}$ (see Friedman, Kahn, and Szemerédi [13]). One can then show that in these cases $\min\{\operatorname{out}_R(S), \operatorname{out}_G(S)\} \geq (r/4 - o(1))\,|S|$ for $|S| \leq |V|/2$, as r grows. (For simplicity take $\gamma = \epsilon = r^{-1/3}$.)

The above ideas can be extended to arbitrary graphs. We need to be able to assert that (i) small sets of vertices, $|S| \leq \gamma n$, contain *few* edges; and that (ii) one can orient the edges so that every vertex has *large* outdegree. Given (ii) we can then randomly split the edges into two sets. It is known [11], [12] that the edge set of a graph can be oriented so that the out-degree of each vertex is at least k if and only if $|\mu(S)| \geq k|S|$ for all $S \subseteq V$ where $\mu(S) = \{e \in E : e \cap S \neq \emptyset\}$, and that this can be checked in polynomial time. We do not consider this generalization in this paper, however.

4.2. Analysis of the main algorithm. Let P denote the transition probability matrix of the random walk on G_B, and let $P^{(t)}_{v,w}$ denote the probability that the walk is at w at step t given that it started at v. Let λ be the second largest eigenvalue of P. (All eigenvalues of P are real.) It is known that

$$(11)\qquad P^{(t)}_{v,w} = \pi(w) + O(\lambda^t\sqrt{\pi(w)/\pi(v)}).$$

To ensure rapid convergence we need $\lambda \leq 1 - \epsilon$ for some *constant* $\epsilon > 0$. This holds for all expanders [1]. In particular if

$$\text{out}_B(S) \geq \beta'|S| \qquad \forall S \subseteq V, |S| \leq |V|/2, \tag{12}$$

for some *constant* $\beta' > 0$, Sinclair and Jerrum [22] show that (12) implies

$$\lambda \leq 1 - \frac{1}{2}\left(\frac{\beta'}{r}\right)^2.$$

We will now explicitly state our claims about the performance of our algorithm. As input, G is an n-vertex, bounded degree, r-regular (α, β, γ)-expander graph where $\alpha > 1$ and $\beta > \beta_0$, with β_0 as in Corollary 4.2.

Suppose that

$$\kappa > \max\{7, \kappa_1 \ln r, 2 + \kappa_3 \ln r\}, \tag{13}$$

$$\kappa_1 > \frac{4 + 2\kappa_3 \ln r}{\ln \lambda^{-1}} + \kappa_3, \tag{14}$$

$$\kappa_2, \kappa_3 > \frac{3}{\ln \lambda^{-1}}. \tag{15}$$

THEOREM 4.3. *Under the above assumptions with n sufficiently large, given any set of $q = n/(\log n)^{\kappa}$ disjoint pairs of vertices in G such that $\alpha > 1$ and $\beta > \beta_0$, with high probability our algorithm finds in $o(n^3)$ time, edge-disjoint paths connecting these q pairs.*

In §3 we pointed out for each phase the conditions under which it might fail. We now proceed to bound the associated failure probabilities.

Phase 1. The failure probability of this phase is $o(1)$ by Corollary 4.2. Also the time to carry out the construction is $O(n)$.

Phase 3. The $\kappa_1 \ln\ln n$ neighborhood of any vertex contains at most $\nu = r^{\kappa_1 \ln\ln n} = (\ln n)^{\kappa_1 \ln r}$ vertices. Using (1), the probability that r_i is rejected is thus never more than $3q\nu/2n$. Thus the probability that this phase fails is at most

$$\mathbf{Pr}(B(4q, 3q\nu/2n) \geq 2q)$$

and this is $o(1)$ if

$$\kappa_1 \ln r < \kappa, \tag{16}$$

since $q \leq n/(\ln n)^{\kappa}$. It is of course straightforward to carry out this selection in $o(n^2)$ time.

Phase 4. A straightforward application of the Max-Flow Min-Cut Theorem shows that success is certain provided that G_R is a β'-expander for some $\beta' > 1$. By Corollary 4.2 this happens with probability $1 - o(1)$. Furthermore it only takes $o(n^3)$ time to find the required flow since arc capacities are 1 for the arcs of the network.

Phase 5. The remainder of the proof relies heavily on the fact that the trajectories $W'_{i,j}$ constructed by our algorithm, have the same distribution (up to negligible factors) as m independent random trajectories of length $\tau = \kappa_2 \ln n$ from $\tilde{a}_i$, the difference being that we pick the endpoint of the trajectory using π instead of $P^{(\tau)}_{\tilde{a}_i,\cdot}$. Using (11), since

$$\kappa_2 > \frac{3}{\ln \lambda^{-1}} \tag{17}$$

we see that

$$|P^{(\tau)}_{v,w} - \pi(w)| = O(n^{-3})$$

for all v, w.

To allow us to view the trajectories $W'_{i,j}$, $W''_{i,j}$ as having *exactly* the same distribution as random trajectories we can imagine generating $W'_{i,j}$ as follows.

(a) Choose $x = x_{i,j}$ according to the distribution $P^{(\tau)}_{\tilde{a}_i,\cdot}$.
(b) Choose a random trajectory $W'_{i,j}$ from $\tilde{a}_i$ to x.
(c) If $\theta(x) = P^{(\tau)}_{\tilde{a}_i,x} - \pi(x) > 0$ then with probability $\theta(x)/P^{(\tau)}_{\tilde{a}_i,x}$ do
  1. discard $W'_{i,j}$;
  2. choose $y \in \Omega^- = \{v : \theta(v) < 0\}$ with probability $\theta(y)/\theta(\Omega^-)$;
  3. choose a new random trajectory $W'_{i,j}$ from $\tilde{a}_i$ to y.

It is not hard to see that the endpoint of $W'_{i,j}$ other than $\tilde{a}_i$ is now chosen according to the distribution π. Furthermore, as long as (1)–(3) above are not executed, we can view $W'_{i,j}$ as a random walk of length τ from $\tilde{a}_i$. But

$$\begin{aligned}&\mathbf{Pr}((1) - (3) \text{ occur during the algorithm})\\ &= O(qm \max \theta(x)) = O((\ln n)^{2-\kappa}/n) = o(1).\end{aligned}$$

This justifies viewing the $W'_{i,j}$, $W''_{i,j}$ as unbiased random walks.

The next question is how, given $x_{i,j}$, do we compute a random trajectory of length τ from $\tilde{a}_i$ to $x_{i,j}$? This is not difficult.

To simplify notation, suppose we want to compute a random trajectory $W = [u_0 = u, u_1, \ldots, u_t = v]$ of length t from a vertex u to a vertex v. If w is a neighbor of v then

$$\mathbf{Pr}(u_{t-1} = w | u_t = v) = \frac{P^{(t-1)}_{u,w} P_{w,v}}{P^{(t)}_{u,v}}. \tag{18}$$

Thus our algorithm to generate W is to choose w according to (18) and then choose a random trajectory of length $t - 1$ from u to w. To compute $P^{(t)}$ we need only compute powers of P. Because G has bounded degree we can compute P^k from P^{k-1} in $O(n^2)$ time. Thus the total time to compute all the trajectories is $O(\tau n^2) = o(n^3)$, for $\kappa > 7$.

Phase 6. We prove several intermediate propositions. Our aim is to show that relatively few paths get deleted.

PROPOSITION 4.4. *Assume that*

$$\kappa_1 \geq \frac{4 + 2\kappa_3 \ln r}{\ln \lambda^{-1} + \kappa_3}. \tag{19}$$

Then with probability $1 - o(1)$ *the number of paths deleted due to condition* (a) *is* $O(\ln n)$ *simultaneously for each* $i \in [q]$.

Proof. Recall that $M_{i,j} = \{w'_{i,j,t}, w''_{i,j,t} : t \geq (\kappa_1 - \kappa_3) \ln \ln n\}$, and a path $P_{i,j}$ is deleted due to condition (a) if $\operatorname{dist}(M_{i,j}, \bigcup_{k<j} M_{i,k}) \leq 2\kappa_3 \ln \ln n$.

For $t \geq (\kappa_1 - \kappa_3) \ln \ln n$ the probability that $w'_{i,j,t} = v$ is (by (11)) $O(\lambda^t + 1/n) = O((\ln n)^{-(\kappa_1-\kappa_3)\ln \lambda^{-1}})$ for any vertex v. Also the $2\kappa_3 \ln \ln n$ neighborhood of $\bigcup_{k<j} M_{i,k}$ is of size $O((\ln n)^{3+2\kappa_3 \ln r})$ and so the probability that $W'_{i,j}$ or $W''_{i,j}$ wanders into this neighborhood after $(\kappa_1 - \kappa_3) \ln \ln n$ steps, is only

$$O((\ln n)^{3+2\kappa_3 \ln r-(\kappa_1-\kappa_3)\ln \lambda^{-1}}) = O(1/\ln n),$$

given (19). Thus the number of paths deleted from bundle i is dominated by a binomial random variable $B(N, p)$ with $Np = O(\ln n)$.

The inequality (see, e.g., [7, Thm. I.7])

$$\mathbf{Pr}(B(N, p) \geq aNp) \leq \left(\frac{e}{a}\right)^{aNp} \tag{20}$$

is, for sufficiently large a, enough to verify the proposition. (Take $a = c \ln n/(Np)$ for a sufficiently large c.) □

PROPOSITION 4.5. *Assume that*

$$\kappa \geq 2 + \kappa_3 \ln r. \tag{21}$$

Let

$$N_i = \{v \in R - \{\tilde{a}_i, \tilde{b}_i\} : \text{dist}(v, B_i) \leq \kappa_3 \ln \ln n\}.$$

Then $|N_i| = O(\ln n)$ *simultaneously for each* $i \in [q]$, *with probability* $1 - o(1)$.

Proof. The size of the $\kappa_3 \ln \ln n$ neighborhood of all the bundles B_i together is $O((\ln n)^{3+\kappa_3 \ln r})$. The number of vertices in R chosen in this neighborhood is a binomial with mean $O(\ln n)$, given (21). The result follows again by using (20). □

We can now bound the number of paths deleted from each bundle in phase 6 due to condition (b). Recall that the vertices of $Q \setminus \{\tilde{a}_i\}$ are at least $\kappa_1 \ln \ln n$ away from $\tilde{a}_i$. Hence, if two paths in a bundle are simultaneously closer than $\kappa_3 \ln \ln n$ to the endpoint of another bundle, then one of them is deleted by condition (a). Thus any $v \in N_i \cap Q$ can lead to the deletion of a single path via condition (b), so almost surely only a total $O(\ln n)$ paths are deleted from each bundle.

Phase 7. We start by proving the following proposition.

PROPOSITION 4.6. *The maximum degree in the graph* H (*the incidence graph of the paths*) *satisfies* $\Delta_H = O((\ln n)^2/\ln \ln n)$, *almost surely.*

Proof. We will show below in the analysis of phase 8 that with probability $1 - o(1)$ the graph H' has maximum component size $O(\ln n/\ln \ln n)$ and so it suffices to prove that with probability $1 - o(1)$ for every i, j, k, the trajectory $W'_{i,j}$ meets only $O(\ln n)$ trajectories in the bundle B_k.

Now fix i, j, k. The pruning done in phase 6 allows us to assume now that $\text{dist}(W'_{i,j}, \{\tilde{a}_k, \tilde{b}_k\})$ is at least $\kappa_3 \ln \ln n$. Consider a trajectory $W'_{k,l}$. The probability that $W'_{k,l}$ meets $W'_{i,j}$ is by (11) of order $O((\ln n)^{2-\kappa_3 \ln \lambda^{-1}}) = O(1/(\ln n))$ provided that

$$\kappa_3 \geq \frac{3}{\ln \lambda^{-1}}. \tag{22}$$

Treating the construction of each $W'_{k,l}$ as an independent trial we see that the expected number of trials in which $W'_{i,j} \cap W'_{k,l} \neq \emptyset$ is $O(\ln n)$. We can now use (20). □

We now show that if we reach the start of phase 7 and $m_i > 8\Delta_H$ for each i then we can be sure that there is a set of disjoint paths contained in our bundles. We use the following lemma [10], [23].

LOVÁSZ LOCAL LEMMA. *Let* $A_1, \ldots, A_N$ *be events with dependency graph* G_A. *Let* $\deg(i)$ *be the degree of* A_i *in* G_A. *If*

$$\begin{aligned} \mathbf{Pr}(A_i) &\leq p \quad \forall \text{i}, \\ \deg(i) &\leq d \quad \forall \text{i}, \\ 4pd &< 1, \end{aligned}$$

then

$$\mathbf{Pr}(\wedge \bar{A_i}) > 0.$$

Consider the experiment in which a random vertex is chosen from each row of H. The events A_i (the "bad" events) are defined by the choice of two vertices joined by an edge. The maximum degree in the dependency graph for the Lovász Local Lemma is $2m\Delta_H$ and each bad event has probability at most $4/m^2$. The Local Lemma now proves easily that our independent set exists, since $m = (\ln n)^2$ and $\Delta_H = O((\ln n)^2/\ln\ln n)$.

(Alon has shown in [2] the existence of such spanning independent sets in a similar setting using the same technique. Later he proved in [3] that for m sufficiently large relative to the dependency degree there is a proper m-coloring of the graph so that each row uses m colors. Furthermore, Beck has shown that this coloring can be found in polynomial time [6]. However, for our purposes it is necessary to show that the component size does not exceed $O(\log n/\log\log n)$ (see below), hence these more sophisticated algorithms seem unnecessary.)

Phase 8. Pair the vertices in $R \setminus Q$ arbitrarily. Connect each of the q new pairs by m random walks as is phase 5. Define a supergraph $H'' \supset H'$ obtained from H' by adding q additional vertices corresponding to bundles of paths connecting vertices of $R \setminus Q$, and by adding extra edges in an obvious way (we ignore the pruning of phase 6).

Let $\pi(r)$ be the other end of a bundle that has endpoint r. Let $\tilde{W}_r$ be the set of m random walks of length τ starting at vertex $r \in R$. We claim that if r is fixed and r' is chosen uniformly at random from $R \setminus \{r, \pi(r)\}$, then there exists a constant κ_4 such that the probability that $\tilde{W}_r$ and $\tilde{W}_{r'}$ intersect is bounded by

$$\mathbf{Pr}(\tilde{W}_r \cap \tilde{W}_{r'} \neq \emptyset) \leq \frac{\kappa_4(\ln n)^6}{4n}. \tag{23}$$

To see this, consider a random walk from r' of length τ and assume for the moment that r' is chosen uniformly at random in R. Since r' is thus chosen from the steady state of the random walk, the expected number of vertices of $\tilde{W}_r$ visited by this random walk is $O(m\tau^2/n)$. Summing over all walks in $\tilde{W}_{r'}$ we obtain $O(m^2\tau^2/n)$ as the expected number of visits to $\tilde{W}_r$. The probability of at least one visit is bounded by this expectation. Now if r' is chosen uniformly at random only within $R \setminus \{r, \pi(r)\}$, the probability of intersection increases at most by a factor of $(1 - 2/|R|)^{-1} = 1 + o(1)$. Thus we have (23).

Each bundle B_i is composed of two sets of m random walks. Hence, for i fixed, and i' chosen uniformly at random in $\{1, \ldots, 2q\} \setminus \{i\}$ we have

$$\mathbf{Pr}(\{B_i, B_{i'}\} \text{ is an edge of } H'') \leq \kappa_4 \frac{(\ln n)^6}{n}. \tag{24}$$

Furthermore, if σ is a random permutation of $[2q]$,

$$\mathbf{Pr}(H'' \text{ contains a component of size } \geq k)$$

$$\leq \sum_{\substack{S\subseteq[2q]\\ |S|=k}} \sum_{T\in\Omega_{\sigma(S)}} \mathbf{Pr}(\mathcal{E}_T) = \binom{2q}{k} \sum_{T\in\Omega_{\sigma([k])}} \mathbf{Pr}(\mathcal{E}_T),$$

where Ω_A denotes the set of trees with vertex set A, and $\mathcal{E}_T$ denotes the event that H'' contains a tree isomorphic to T, under the isomorphism $i \leftrightarrow B_i$. The inequality is immediate because any component of size $\geq k$ must contain a tree of size k, and the equality follows from symmetry.

We can restrict our attention to the range where $k/q < \frac{1}{2}$. We claim that $\mathbf{Pr}(\mathcal{E}_T) \leq (2\kappa_4(\ln n)^6/n)^{k-1}$. Indeed consider the edges of T in a breadth-first search order from some arbitrary root; assume that we have already explored $l-1$ edges, and thus l vertices numbered without loss of generality $1, \ldots, l$. The probability that the lth edge exists is given by the probability that for a certain fixed $i \in \{1, \ldots, l\}$ the bundle B_i intersects $B'_{i'}$ where i' is chosen uniformly at random (via σ) in $\{l+1, \ldots, 2q\}$. This probability can be proven via essentially the same argument used to derive (23) and (24) to be less than $(1-(2l)/(2q))^{-1}\kappa_4(\ln n)^6/n$, independently of the existence of previous edges.

Now, since $|\Omega_{\sigma([k])}| = k^{k-2}$ we obtain that

$$\begin{aligned}
&\mathbf{Pr}(H'' \text{ contains a component of size } \geq k)\\
&= O\left(\left(\frac{2qe}{k}\right)^k \left(\frac{2\kappa_4(\ln n)^6}{n}\right)^{k-1} k^{k-2}\right)\\
&= O\left(\left(\frac{n}{(\ln n)^6}\left(\frac{4e\kappa_4 q(\ln n)^6}{n}\right)^k\right)\right)\\
&= O\left(\frac{n}{(\ln n)^6}\left(\frac{4e\kappa_4}{(\ln n)^{\kappa-6}}\right)^k\right) = o(1)
\end{aligned}$$

for $\kappa > 7$ and $k \geq k_0 = \ln n/(\ln\ln n)$.

Phase 9. The execution time of Phase 9, given that there are no large components in H'', is bounded by

$$\frac{n}{(\ln n)^\kappa}((\ln n)^2)^{\ln n/\ln\ln n} = o(n^3).$$

5. Random $\mathcal{NC}$ algorithms.

In this section we show that our construction can be done in random $\mathcal{NC}$. To convert **DisjPaths** to a random $\mathcal{NC}$ algorithm we need to modify phases 2 and 3 of the algorithm. We replace them by the following two phases:

Phase 2*. Each vertex $v \in V$ is included in R with probability $8q\pi_v$ independent of the other vertices.

Phase 3*. A vertex $u \in R$ is in Q if no vertex in its $\kappa_1 \ln\ln n$ neighborhood is in R.

We now consider each phase in turn.

Phase 1. The algorithm **Split** is in $\mathcal{NC}$ since computing an Euler Path is in $\mathcal{NC}$ [5].

Phases 2* and 3*. With probability $1-o(1)$, R has at least $4q$ vertices. The probability that a vertex in R has another vertex in R in its $\kappa_1 \ln\ln n$ neighborhood is smaller than $\frac{1}{2}$, thus with probability $1-o(1)$, Q has at least $2q$ vertices. The fact that Q might have more than $2q$ vertices does not matter since the flow algorithm gives an integer solution, and only $2q$ vertices in Q will participate in the flow.

Phase 4. Flow with unit capacities is in Random $\mathcal{NC}$ [15], [18].

Phases 5, 6, and 7. By attaching one processor to each of the $q(\ln n)^2$ paths used in the algorithm, all these phases can be computed in $O(\ln n)$ time.

Phase 8. Computing connected components is in $\mathcal{NC}$.

Phase 9. Observe that there are no more than $n/(\ln n)^{\kappa}$ components, and with high probability there are no more than

$$((\ln n)^2)^{\ln n/\ln\ln n} = n^2$$

choices of paths for each component. Given a possible choice, it can be checked by one processor in $O(\ln^2 n)$ steps. Thus, phase 9 can be computed by $o(n^3)$ processors in $O(\ln^2 n)$ parallel steps.

SEPARATING DISTRIBUTION-FREE AND MISTAKE-BOUND LEARNING MODELS OVER THE BOOLEAN DOMAIN*

AVRIM L. BLUM†

Abstract. Two of the most commonly used models in computational learning theory are the distribution-free model in which examples are chosen from a fixed but arbitrary distribution, and the absolute mistake-bound model in which examples are presented in an arbitrary order. Over the Boolean domain $\{0, 1\}^n$, it is known that if the learner is allowed unlimited computational resources then any concept class learnable in one model is also learnable in the other. In addition, any polynomial-time learning algorithm for a concept class in the mistake-bound model can be transformed into one that learns the class in the distribution-free model.

This paper shows that if one-way functions exist, then the mistake-bound model is strictly harder than the distribution-free model for polynomial-time learning. Specifically, given a one-way function, it is shown how to create a concept class over $\{0, 1\}^n$ that is learnable in polynomial time in the distribution-free model, but not in the absolute mistake-bound model. In addition, the concept class remains hard to learn in the mistake-bound model even if the learner is allowed a polynomial number of membership queries.

The concepts considered are based upon the Goldreich, Goldwasser, and Micali random function construction [Goldreich, Goldwasser, and Micali, *Journal ACM*, 33 (1986), pp. 792–807] and involve creating the following new cryptographic object: an exponentially long sequence of strings $\sigma_1, \sigma_2, \dots, \sigma_r$ over $\{0, 1\}^n$ that is hard to compute in one direction (given σ_i one cannot compute σ_j for $j < i$) but is easy to compute *and even make random-access jumps* in the other direction (given σ_i and $j > i$ one *can* compute σ_j, even if j is exponentially larger than i). Similar sequences considered previously [Blum, Blum, and Shub, *SIAM J. Comput.*, 15 (1986), pp. 364–383], [Blum and Micali, *SIAM J. Comput.*, 13 (1984), pp. 850–863] did not allow random-access jumps forward without knowledge of a seed allowing one to compute backwards as well.

Key words. machine learning theory, learning models, one-way functions

AMS subject classifications. 68Q25, 68T05, 94A60

1. Introduction.

Two of the most popular theoretical models for learning from examples are the distribution-free model, also known as the *probably-approximately-correct* (PAC) or "Valiant-style" learning model [17], [25], and the absolute mistake-bound model [21]. In both models, the goal of a learner is to approximately infer some unknown target concept from positive and negative examples of that concept. In the distribution-free model, an adversary chooses a distribution over the labeled examples from which the learner may sample. The learner, from a polynomial (in relevant parameters discussed in §2) number of samples, must produce a hypothesis that agrees with the target concept over most of the distribution. In the mistake-bound model, the adversary instead actually chooses the order in which examples appear. Here the learner sees unlabeled examples, and after each one must predict whether it is positive or negative before being told its true classification. The job of the learner in the mistake-bound model is to make a polynomially bounded number of mistakes.

In this paper, we will consider the "representation-independent" versions of the distribution-free and mistake-bound models, also known as the "prediction" model [12], [13], in which the learner's hypotheses need not be the same form as the target concept. The mistake-bound model is equivalent to Angluin's equivalence query model [3], [21] when query hypotheses are similarly not restricted.

It is known that any algorithm for learning a concept class in the mistake-bound model can be converted to one that will learn the class in the distribution-free model [3], [18]. If computational considerations are ignored, then over the Boolean domain $\{0, 1\}^n$ the converse holds as well. Any concept class over $\{0, 1\}^n$ learnable with polynomial sample size (and

†School of Computer Science, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3891 (avrim@cs.cmu.edu). This work was done while the author was at the MIT Lab for Computer Science and supported by an NSF Graduate Fellowship, NSF grant CCR-8914428 and the Siemens Corporation.

not necessarily polynomial time) in the distribution-free model can also be learned with a polynomial mistake bound (in not necessarily polynomial time) in the mistake-bound model [3], [21]. At the heart of the proof for this last direction is the use in the mistake-bound model of the "halving algorithm." This algorithm enumerates all concepts in the class, predicts according to majority vote, and when a mistake is made throws out the concepts that predicted incorrectly. The equivalence of learnability in the *non*computational setting has led researchers to wonder (e.g., [16]) whether the models remain equivalent when computation *is* limited—especially in light of recent work showing that the distribution-free model is equivalent to a seemingly much easier form of learning known as "weak-learning" [24].

In this paper we show that if we consider only algorithms that run in polynomial time, then if one-way functions exist, the distribution-free and mistake-bound models over $\{0, 1\}^n$ are *not* equivalent. Specifically, we create a concept class starting from a pseudorandom bit generator [6], [7], [26], which is learnable in polynomial time in the distribution-free model but not in the mistake-bound model. The existence of pseudorandom bit generators has been proven equivalent to the existence of one-way functions [20], [15], [11]. The concept class we create remains hard to learn in the mistake-bound model even if the learning algorithm is allowed membership queries—the ability to ask whether examples of its own choosing belong to the target concept. So, for instance, the position of this concept class contrasts with that of deterministic finite automata (DFAs) which *are* learnable in a mistake-bound model with membership queries [2] but not in the distribution-free model [19].

The concept class created is based upon the Goldreich, Goldwasser, and Micali random function construction [9] and involves creating the following new cryptographic object: an exponentially long sequence of strings $\sigma_1, \sigma_2, \ldots, \sigma_r$ over $\{0, 1\}^n$ that is hard to compute in one direction (given σ_i one cannot compute σ_j for $j < i$) but is easy to compute *and even make random-access jumps* in the other direction (given σ_i and $j > i$ one *can* compute σ_j, even if j is exponentially larger than i). This sequence is "stronger" than those considered previously [6], [7] in the sense that for those sequences, the only known way to compute in the forward direction (without knowing the seed that allows one to compute in the other direction as well) is to compute the strings sequentially in order.

The sequence of strings is useful for separating the learning models for roughly the following reason. Attached to each σ_i is a classification that can only be computed given σ_j for $j < i$. So, an adversary can present the strings in the reverse order $\sigma_r, \sigma_{r-1}, \ldots$ and cause the learner to make a mistake nearly half the time. However, for any distribution over the strings, if a learner collects m samples, we expect that about $m/(m + 1)$ of the distribution falls on the "easy side" (the set of σ_j for $j > i$) of the string σ_i of least index seen. The "random-access forward" property of the sequence then allows the distribution-free learner to use σ_i as a predictor for any σ_j for $j > i$. Notice that without the random-access property, then even on a uniform distribution the learner might still fail because the examples seen would likely all be exponentially far away from each other.

An earlier version of this paper appears in [5].

2. Notation, definitions, and background. An *example* x is an element of $\{0, 1\}^n$ and a concept is a set of examples (subset of $\{0, 1\}^n$). We will also identify concepts with their indicator functions, defining $c(x) = 1$ if $x \in c$ and $c(x) = 0$ otherwise. For a given target concept c, a *labeled example* of c is a pair $\langle x, c(x) \rangle$ where x is an example and $c(x)$ is its *classification*. An example x is a *positive example* if $c(x) = 1$; otherwise it is a negative example. A *concept class* is a collection of concepts, together with a (sometimes implicit) representation for each concept.[1] For instance, the class of DNF formulas consists of concepts

[1] To be rigorous, we should define a concept class C to be a family $\{C_n\}$ (one for each n) where C_n is defined over $\{0, 1\}^n$. In order to avoid overly cumbersome notation, we shall assume this type of indexing is done implicitly.

given in a disjunctive normal-form representation. If c is a concept in a given concept class C, we use $|c|$ to denote the size of the (smallest) representation of c under C. In both the distribution-free and mistake-bound models, the object of a learning algorithm for a concept class C is to approximately infer an unknown target concept $c \in C$ from examples. The models differ in how examples are chosen and how successful learning is defined.

In the distribution-free model, there is some distribution $\mathcal{D}$ over the set of labeled examples of the target concept. The learning algorithm is allowed to sample from $\mathcal{D}$ and based on this information and knowledge of the class C to which the target concept belongs, must produce a hypothesis h that approximates the target concept. In particular, if c is the target concept, we say a hypothesis h has *error* ε if on pair $\langle x, c(x)\rangle$ chosen from $\mathcal{D}$, the probability that $h(x)$ does not equal $c(x)$ is ε. We will allow the hypothesis produced by the algorithm to not necessarily belong to concept class C (this version is sometimes termed "polynomial predictability" [12], [13]). More formally, an Algorithm A *learns in the distribution-free model* a concept class C over $\{0, 1\}^n$ if for some polynomial P, for all target concepts $c \in C$, distributions $\mathcal{D}$, and error parameters ε and δ: in time at most $P(n, \frac{1}{\varepsilon}, \frac{1}{\delta}, |c|)$ the algorithm with probability at least $1 - \delta$ finds a polynomial-time evaluatable hypothesis h (not necessarily from C) with error at most ε. See Haussler, Kearns, Littlestone, and Warmuth [12] for various equivalent formulations of the distribution-free model.

In the mistake-bound model, instead of a distribution, we imagine there is some adversary presenting the examples in any order it wishes. Learning is done on-line in a sequence of *stages*. In each stage the adversary presents an unlabeled example to the learner, the learner suggests a labeling, and then the learner is told whether or not that labeling was correct. The object of the learning algorithm is to make at most a polynomial number of mistakes. Algorithm A *learns* a concept class C *in the mistake-bound model* if for some polynomial P, for all target concepts $c \in C$ and all orderings of the examples, the algorithm makes at most $P(n, |c|)$ mistakes using polynomial time in each stage [21].

A *membership query* is a query in which the learner selects an unlabeled example of its own choosing and asks for (and is told) that example's classification. We may incorporate membership queries into the mistake-bound model by allowing the learner at each stage to choose either to make a membership query or else to receive an example from the adversary. We will say that Algorithm A *learns* a concept class C *in the mistake-bound model with membership queries* if for some polynomial P, for all target concepts $c \in C$, the algorithm makes at most $P(n, |c|)$ mistakes and membership queries using polynomial time in each stage.

Note that in all models we require a learning algorithm to run in polynomial time. In some of the literature, this is called "polynomial learnability."

We now review some useful notation and definitions from the cryptographic literature. If S is a set we will use the notation $s \in_R S$ to mean that s is chosen uniformly at random from S. For convenience, if A is a probabilistic polynomial time (PPT) algorithm and g is some function, we will use $\mathcal{P}_d(A, g(s))$ to mean $\mathbf{Pr}\left[A(g(s)) = 1 \mid s \in_R \{0, 1\}^d\right]$. If $g(s) = s$ we will just write $\mathcal{P}_d(A, s)$. In order to simplify the statements of some of the theorems, in this paper we will use the term "algorithm" to include circuit families (nonuniform algorithms).

Informally, a cryptographically strong pseudorandom bit generator, or CSB generator to use the notation of GGM, is a deterministic polynomial-time algorithm that given a randomly chosen input produces a longer pseudorandom output. More formally we have the following.

DEFINITION 1. *A deterministic polynomial-time program G is a* CSB generator with stretch *t if on input $s \in \{0, 1\}^k$ it produces a tk-bit output, and for all probabilistic polynomial-time algorithms A, for all polynomials Q, for all sufficiently large k:*

$$|\mathcal{P}_k(A, G(s)) - \mathcal{P}_{tk}(A, s)| < \frac{1}{Q(k)}.$$

That is, no polynomial-time algorithm can distinguish with a $1/\text{poly}(k)$ probability between a string chosen randomly from $\{0, 1\}^{tk}$ and the output of G on a string chosen randomly from $\{0, 1\}^k$. For this paper, we will just need a CSB generator G with stretch 2.

For a CSB generator G that on input $s \in \{0, 1\}^k$ produces a $2k$-bit output $G(s) = b_1, \ldots, b_{2k}$, let us define the following notation.

(i) Let $G_0(s)$ be the leftmost k bits $b_1, \ldots, b_k$ of $G(s)$, and let $G_1(s)$ be the rightmost k bits $b_{k+1}, \ldots, b_{2k}$.

(ii) For a d-bit string $i = i_1 \ldots i_d \in \{0, 1\}^d$, let

$$G_{i_1 \cdots i_d}(s) = G_{i_d}(G_{i_{d-1}}(\ldots G_{i_2}(G_{i_1}(s)) \ldots)).$$

Note that this is well defined because $G_0(s)$ and $G_1(s)$ are both k-bit strings.

(iii) Let $G'_0(s) = G_1(s)$ and let $G'_1(s) = \lambda$ (i.e., the empty string). Think of G' as a rightward-shift of G.

If x and y are strings, we will use $x \circ y$ to denote the concatenation xy. Also, if an example created by a concatenation of strings has length less than n, then we will implicitly pad with zeros, say, on the right. Finally, let $\text{LSB}[x]$ denote the rightmost bit of string x.

We now review the GGM random function construction. Let G be a CSB generator that on input $s \in \{0, 1\}^k$ produces a $2k$-bit output. Goldreich, Goldwasser, and Micali define the function $f_s : \{0, 1\}^k \to \{0, 1\}^k$ on input $i = i_1 \ldots i_k$ to be

$$f_s(i) = G_{i_1 \cdots i_k}(s) = G_{i_k}(G_{i_{k-1}}(\ldots G_{i_1}(s) \ldots)).$$

The function f_s can be viewed as a complete binary tree of depth k. The root is the seed s, and on input i, the output $f_s(i)$ is the ith leaf in the tree if i is viewed as a binary number between 0 and 2^k. Though this fact will not be needed for our purposes, it is proved that the collection $F_k = \{f_s\}_{s \in \{0,1\}^k}$ is a "polyrandom" collection of functions over $\{0, 1\}^k$. Essentially, this means that no polynomial-time algorithm can distinguish between a function chosen randomly from F_k and a function chosen randomly from the class of all functions from $\{0, 1\}^k$ to $\{0, 1\}^k$.

We will use the basic form of the GGM construction as a starting point to create a concept class that separates the distribution-free and mistake-bound learning models.

3. A concept class to separate the learning models. We now create a concept class over $\{0, 1\}^n$ that is learnable in the distribution-free model but not in the mistake-bound model if one-way functions exist. We first give the formal definition of the class, and follow this by a more informal explanation and example. Given a CSB generator G, we will fix k, the size of seed s, to equal $\lfloor \sqrt{n} \rfloor$.

DEFINITION 2. *Let $\mathcal{C}_G = \{c_s\}_{s \in \{0,1\}^k}$ where the concepts c_s are defined as follows*:

$$c_s = \{x_s^i : i \in \{0, 1\}^k \text{ and } \text{LSB}[G_{i_1 \cdots i_k}(s)] = 1\},$$

where for each $i = i_1 \cdots i_k$,

$$x_s^i = i \circ G'_{i_1}(s) \circ G'_{i_2}(G_{i_1}(s)) \circ G'_{i_3}(G_{i_1 i_2}(s)) \circ \ldots \circ G'_{i_k}(G_{i_1 \cdots i_{k-1}}(s)).$$

Now the informal description. There is one concept c_s for each $s \in \{0, 1\}^k$. For each i such that $\text{LSB}[f_s(i)] = 1$, there is an associated positive example x_s^i for c_s, so there are about $2^{\lfloor \sqrt{n} \rfloor - 1}$ positive examples for c_s. We can think of the labeled example $\langle x_s^i, c_s(x_s^i) \rangle$ as the pair $(i, \text{LSB}[f_s(i)])$ together with the following extra information: for each bit i_j equal to zero (running left to right along i), we include the right half of $G(G_{i_1 \cdots i_{j-1}}(s))$. For example, if $k = 4$ and $i = 0101$, then we would have (see Fig. 1)

$$\begin{aligned} x_s^i &= 0101 \circ G_1(s) \circ \lambda \circ G_1(G_1(G_0(s))) \circ \lambda, \\ &= 0101 \circ G_1(s) \circ G_{011}(s), \\ c_s(x_s^i) &= \mathrm{LSB}[G_{0101}(s)]. \end{aligned}$$

We will think of the index i as both a bit string and a binary number between 0 and 2^k.

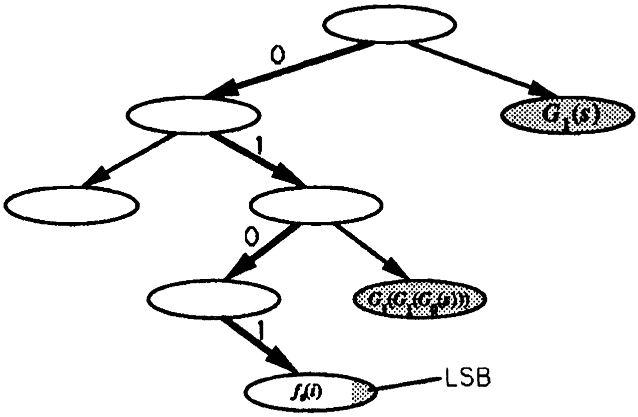

FIG. 1. *Darkened regions are information given with* $\langle x_s^i, c_s(x_s^i)\rangle$ *for* $i = 0101$.

Notice that negative examples of c_s come in two forms: some are examples x_s^i for which $\mathrm{LSB}[f_s(i)] = 0$ and some are just bit strings from $\{0, 1\}^n$ that are not of the form x_s^i for any i. We will call the examples x_s^i the "good examples" of c_s; so the positive examples of c_s are the good examples x_s^i such that $\mathrm{LSB}[f_s(i)] = 1$. The examples x_s^i will be shown to have the property of the strings σ_i mentioned in the introduction.

For convenience, let us define the following additional notation.

(i) Let z_s^i be the (correctly) labeled good example $\langle x_s^i, c_s(x_s^i)\rangle$.

(ii) Let $\bar{z}_s^i$ be the incorrectly labeled good example $\langle x_s^i, 1 - c_s(x_s^i)\rangle$.

(iii) For $i_1 \ldots i_d \in \{0, 1\}^d$, let:

$$G^{i_1 \cdots i_d}(s) = G'_{i_1}(s) \circ G'_{i_2}(G_{i_1}(s)) \circ \ldots \circ G'_{i_d}(G_{i_1 \cdots i_{d-1}}(s)).$$

So example x_s^i is equal to $i \circ G^{i_1 \cdots i_k}(s)$.

We now demonstrate an algorithm that on input x_s^i and $j > i$ computes z_s^j in time $O(nT_k)$ where T_k is the time to compute G on a k-bit input. The essential idea of the algorithm is that contained in example x_s^i are ancestors in the full binary tree of each piece of information contained in z_s^j. The reason we want to compute the entire z_s^j and not just the classification $c_s(x_s^j)$ is that the learning algorithm, given an example x that purports to be some x_s^j (because its first k bits are j), first will compute x_s^j to verify that x really is the "good example," and then predict positive exactly when both $x = x_s^j$ and the classification of x_s^j is 1.

ALGORITHM COMPUTE-FORWARD

Given: x_s^i and $j > i$.

1. Write $i = i_1 \cdots i_k$ and $j = j_1 \cdots j_k$. Let r be the least index such that $i_r \neq j_r$. Since $j > i$, we have $i_r = 0$ and $j_r = 1$.

2. Extract from x_s^i the portions:

$$u = G'_{i_1}(s) \circ G'_{i_2}(G_{i_1}(s)) \circ \ldots \circ G'_{i_{r-1}}(G_{i_1 \cdots i_{r-2}}(s)) \;=\; G^{i_1 \cdots i_{r-1}}(s).$$

$$v = G'_{i_r}(G_{i_1 \cdots i_{r-1}}(s)) \;=\; G_{j_1 \cdots j_r}(s).$$

(Notice that $G'_{j_r}(G_{j_1 \cdots j_{r-1}}(s)) = \lambda$.)

3. If $r = k$, output: $\langle j \circ u \circ \lambda, \mathrm{LSB}[v] \rangle$.
Otherwise, output: $\langle j \circ u \circ \lambda \circ G^{j_{r+1} \cdots j_k}(v), \mathrm{LSB}[G_{j_{r+1} \cdots j_k}(v)] \rangle$.

Algorithm Compute-Forward produces z_s^j as output for the following reason. By the definition of r, we know $G^{i_1 \cdots i_{r-1}}(s) = G^{j_1 \cdots j_{r-1}}(s)$, so $u \circ \lambda = G^{j_1 \cdots j_{r-1}}(s) \circ G'_{j_r}(G_{j_1 \cdots j_{r-1}}(s)) = G^{j_1 \cdots j_r}(s)$. Since $v = G_{j_1 \cdots j_r}(s)$, we have

$$u \circ \lambda \circ G^{j_{r+1} \cdots j_k}(v) \;=\; G^{j_1 \cdots j_r}(s) \circ G^{j_{r+1} \cdots j_k}(G_{j_1 \cdots j_r}(s)) \;=\; G^{j_1 \cdots j_k}(s),$$

and $\mathrm{LSB}[G_{j_{r+1} \cdots j_k}(v)] = \mathrm{LSB}[G_{j_1 \cdots j_k}(s)] = c_s(x_s^j)$. In addition, Algorithm Compute-Forward uses at worst $O(k^2)$ computations of G.

THEOREM 3.1. *Concept class $\mathcal{C}_G$ is learnable in the distribution-free model.*

Proof. Algorithm Learn-$\mathcal{C}_G$ works as follows. Collect $m \geq \frac{1}{\varepsilon} \ln \frac{1}{\delta}$ labeled examples. If all examples are negative, hypothesize the empty concept. Otherwise, we know each positive example is a "good example," so let i be the index (first k bits) of the positive example x_s^i of least index seen so far. Produce the following hypothesis: "On example x, let j be the first k bits of x. If $j < i$ predict 0. If $j > i$, use algorithm Compute-Forward to produce labeled example $\langle x_s^j, c_s(x_s^j) \rangle$. If $x = x_s^j$ then predict $c_s(x_s^j)$; otherwise predict 0."

One simple way to see that Learn-$\mathcal{C}_G$ learns in the distribution-free model is just to notice that it is an "Occam Algorithm" in the sense of Blumer, Ehrenfeucht, Haussler, and Warmuth [8] since for any size sample, the hypothesis produced has size $O(n)$ and is consistent with all the data seen. Alternatively, one can use a direct argument of the type used for learning a subinterval $[0, a]$ of the interval $[0, 1]$. Let l be the least index such that the set of examples $S_l = \{z_s^j : j \leq l \text{ and } c_s(x_s^j) = 1\}$ has probability at least ε. Algorithm Learn-$\mathcal{C}_G$ fails to learn with error less than ε exactly when it sees no example from S_l. So, the probability Learn-$\mathcal{C}_G$ fails is at most $(1 - \varepsilon)^m$ which is less than δ for $m \geq \frac{1}{\varepsilon} \ln \frac{1}{\delta}$. □

THEOREM 3.2. *Concept class $\mathcal{C}_G$ cannot be learned in the mistake-bound model if G is a CSB generator.*

In order to prove Theorem 3.2, we show that the sequence of examples x_s^i is difficult to compute in the reverse direction, as described in the following lemma and corollary.

LEMMA 3.3. *For any PPT Algorithm A and polynomial Q, for sufficiently large k, for all $i \in \{0, 1\}^k$,*

$$|\mathcal{P}_k(A, z_s^i) - \mathcal{P}_k(A, \bar{z}_s^i)| < \frac{1}{Q(k)}.$$

That is, for any Algorithm A and index i, for random seeds s, Algorithm A cannot distinguish between a correctly labeled x_s^i and an incorrectly labeled one. Using Algorithm Compute-Forward, on input x_s^i one can easily compute any other labeled example z_s^j for $j > i$. So, Lemma 3.3 could equivalently be written as the following.

COROLLARY 3.4. *For any PPT algorithm A and polynomial Q, for sufficiently large k, for all $i \in \{0, 1\}^k$,*

$$|\mathcal{P}_k(A^{\mathcal{O}}, z_s^i) - \mathcal{P}_k(A^{\mathcal{O}}, \bar{z}_s^i)| < \frac{1}{Q(k)},$$

where $\mathcal{O}$ is an oracle that on any input $j > i$ outputs labeled example z_s^j.

Lemma 3.3 implies, as shown below, that any learning algorithm will be fooled in the mistake-bound model by an adversary that presents the examples x_s^i in reverse order. In fact, Lemma 3.3 is stronger than we need because it implies that any algorithm will fail not just on *some* $c_s \in \mathcal{C}_G$ but on almost all of the concepts c_s.

Proof of Theorem 3.2 (assuming Lemma 3.3). Suppose there exists a learning algorithm L and polynomial P such that for all $c_s \in \mathcal{C}_G$ over $\{0, 1\}^n$, Algorithm L makes at most $P(n)$ mistakes. Consider an adversary that presents the good examples in reverse order: $x_s^{2^k}, x_s^{2^k-1}, \dots$. Algorithm L makes a mistake on at most $\frac{1}{4}$ of the first $4P(n)$ examples presented. If L is deterministic, this implies there exists some index t ($2^k - 4P(n) \leq t \leq 2^k$) such that over all $c_s \in \mathcal{C}_G$, Algorithm L makes an error an at most $\frac{1}{4}$ of the examples x_s^t. If L is randomized, we still have that for some t the probability over the choice of s and the coin tosses of L that L makes a mistake on x_s^t is at most $\frac{1}{4}$. So, we can use L in an Algorithm A that contradicts Corollary 3.4: On input $\langle x_s^t, b\rangle$ we use the oracle (or Algorithm Compute-Forward) to simulate the adversary presenting examples to L and then output 1 if L's prediction of $c_s(x_s^t)$ equals b. If b was the correct classification, there is at least a $\frac{3}{4}$ probability that L will output 1, but there is only a $\frac{1}{4}$ probability if b was incorrect. □

We now prove Lemma 3.3, showing that given only example x_s^i it is difficult to calculate the classification $c_s(x_s^i)$. The basic idea of the proof is a version of a standard cryptographic technique described by Yao [26]. Roughly, if an algorithm can distinguish strings z_s^i from strings $\overline{z}_s^i$, then we will slowly substitute bits in those strings with random bits and watch the performance of the algorithm degrade. At some point before the strings have become completely random the performance must degrade significantly, and we will focus on that location to break the generator.

Proof of Lemma 3.3. Suppose to the contrary there is a PPT Algorithm A and polynomial Q such that for infinitely many k, for some $t(k) \in \{0, 1\}^k$, we have $|\mathcal{P}_k(A, z_s^{t(k)}) - \mathcal{P}_k(A, \overline{z}_s^{t(k)})| \geq \frac{1}{Q(k)}$. Without loss of generality, let us assume that A has $\{0, 1\}$ output. We will use A to create an Algorithm B that breaks generator G. In particular, for infinitely many k, we will have $|\mathcal{P}_k(B, G(s)) - \mathcal{P}_{2k}(B, s)| \geq 1/2kQ(k)$.[2] Let $S_0' = \{0, 1\}^k$ and $S_1' = \{\lambda\}$ (to correspond to the notation for G_0' and G_1') and let $t = t(k) = t_1 \dots t_k$. Let $p_{1,k} = \mathcal{P}_k(A, z_s^t)$ and $\overline{p}_{1,k} = \mathcal{P}_k(A, \overline{z}_s^t)$, and for $1 < d \leq k$, define:

$$p_{d,k} = \mathbf{Pr}[A\langle t \circ r_1 \circ \dots \circ r_{d-1} \circ G^{t_d \cdots t_k}(s), b\rangle = 1 \mid r_1 \in_R S_{t_1}', \dots, r_{d-1} \in_R S_{t_{d-1}}',$$
$$s \in_R \{0, 1\}^k]$$

$$\overline{p}_{d,k} = \mathbf{Pr}[A\langle t \circ r_1 \circ \dots \circ r_{d-1} \circ G^{t_d \cdots t_k}(s), \overline{b}\rangle = 1 \mid r_1 \in_R S_{t_1}', \dots, r_{d-1} \in_R S_{t_{d-1}}',$$
$$s \in_R \{0, 1\}^k]$$

where $b = \mathrm{LSB}[G_{t_d \cdots t_k}(s)]$ and $\overline{b} = 1 - \mathrm{LSB}[G_{t_d \cdots t_k}(s)]$.

So, for $d > 1$, $p_{d,k}$ is the probability that A outputs 1 on input z_s^t where the first $d - 1$ "pieces" of x_s^t have been replaced by random strings of the appropriate length and the application of generator G begins at depth d in the full binary tree.

We have by assumption that $|p_{1,k} - \overline{p}_{1,k}| \geq 1/Q(k)$ for infinitely many k. We now consider two cases. The first is that $|p_{k,k} - \overline{p}_{k,k}| \geq 1/(kQ(k))$ for infinitely many k. The second is that

[2] Algorithm B will be nonuniform, in part because we have no guarantee that the index $t(k)$ is easy to compute given k (to contradict Lemma 3.3 just requires there exist *some* $t(k)$). One could modify (and make less "clean") the statement of Lemma 3.3 so that this problem no longer occurs and still separate the learning models, since our adversary chooses the examples in an easy to compute ordering.

for infinitely many k we have both $|p_{1,k} - \overline{p}_{1,k}| \geq 1/Q(k)$ and $|p_{k,k} - \overline{p}_{k,k}| < 1/(kQ(k))$. In the first case, the following Algorithm B will break generator G (the analysis follows the description of the algorithm).

ALGORITHM B

```
1. On input $y \in \{0,1\}^{2k}$, let $y_0$ be the left half of $y$ and $y_1$ be the right half of $y$. Let
   $y'_0 = y_1$ and $y'_1 = \lambda$.
2. For $i \in \{1, \ldots, k-1\}$ choose $r_i \in_R S'_{t_i}$.
3. Flip a coin:
      (i) If heads, output: $A\langle t \circ r_1 \circ \ldots \circ r_{k-1} \circ y'_{t_k}, \mathrm{LSB}[y_{t_k}]\rangle$.
      (ii) If tails, output: $1 - A\langle t \circ r_1 \circ \ldots \circ r_{k-1} \circ y'_{t_k}, 1 - \mathrm{LSB}[y_{t_k}]\rangle$.
```

If the input y to B equals $G(s)$ for random s, then the probability B outputs 1 is: $\frac{1}{2}p_{k,k} + \frac{1}{2}(1-\overline{p}_{k,k}) = \frac{1}{2}+\frac{1}{2}(p_{k,k}-\overline{p}_{k,k})$. If the input y to B is randomly chosen from $\{0,1\}^{2k}$, however, then we claim the probability B outputs 1 is just $\frac{1}{2}$. The reason is that since y_{t_k} and y'_{t_k} are disjoint pieces of y, B outputs with equal probability either $A\langle t \circ r, b\rangle$ or $1 - A\langle t \circ r, b\rangle$ for independent, random r and b. So, for infinitely many k we have $|\mathcal{P}_k(B, G(s)) - \mathcal{P}_{2k}(B, s)| \geq |\frac{1}{2}(p_{k,k} - \overline{p}_{k,k})| \geq 1/(2kQ(k))$; breaking G.

The second case, recall, is that for infinitely many k we have $|p_{1,k} - \overline{p}_{1,k}| \geq \frac{1}{Q(k)}$ and $|p_{k,k} - \overline{p}_{k,k}| < \frac{1}{kQ(k)}$. If k is such that these two inequalities hold, then either $|p_{d,k} - p_{d+1,k}| \geq 1/((2k-1)Q(k))$ or $|\overline{p}_{d,k} - \overline{p}_{d+1,k}| \geq 1/((2k-1)Q(k))$ for some $d \in \{1, 2, \ldots, k-1\}$; this just follows from the fact that $|p_{1,k} - \overline{p}_{1,k}| \leq |p_{1,k} - p_{2,k}| + \cdots + |p_{k-1,k} - p_{k,k}| + |p_{k,k} - \overline{p}_{k,k}| + |\overline{p}_{k,k} - \overline{p}_{k-1,k}| + \cdots + |\overline{p}_{2,k} - \overline{p}_{1,k}|$. So, this second case implies that either

(i) for infinitely many k there exists $d = d(k) \in \{1, \ldots, k-1\}$ such that $|p_{d,k} - p_{d+1,k}| > 1/(2kQ(k))$, or

(ii) for infinitely many k there exists $d = d(k) \in \{1, \ldots, k-1\}$ such that $|\overline{p}_{d,k} - \overline{p}_{d+1,k}| > 1/(2kQ(k))$.

Let us assume that the first situation occurs; the second situation is completely analogous. Algorithm B' to break generator G is then as follows.

ALGORITHM B′

```
1. On input $y \in \{0,1\}^{2k}$, let $y_0$ be the left half of $y$ and $y_1$ be the right half of $y$. Let
   $y'_0 = y_1$ and $y'_1 = \lambda$. Let $d = d(k)$ as above.
2. For $i \in \{1, \ldots, d-1\}$ choose $r_i \in_R S'_{t_i}$.
3. Output:
      $A\langle t \circ r_1 \circ r_2 \circ \ldots \circ r_{d-1} \circ y'_{t_d} \circ G^{t_{d+1} \cdots t_k}(y_{t_d}), \mathrm{LSB}[G_{t_{d+1} \cdots t_k}(y_{t_d})]\rangle$.
```

If the input y to B' equals $G(s)$ for random s, then $y'_{t_d} \circ G^{t_{d+1} \cdots t_k}(y_{t_d}) = G^{t_d \cdots t_k}(s)$ and $G_{t_{d+1} \cdots t_k}(y_{t_d}) = G_{t_d \cdots t_k}(s)$. So the probability B' outputs 1 is $p_{d,k}$. On the other hand, if $y \in_R \{0,1\}^{2k}$, then y_{t_d} and y'_{t_d} are completely independently chosen strings, so the probability B' outputs 1 is $p_{d+1,k}$. By the choice of d, Algorithm B' breaks the generator G on infinitely many k, a contradiction. □

So by Theorems 3.1 and 3.2, concept class C_G is learnable in the distribution-free model but not in the absolute mistake-bound model if G is a CSB generator, and such G exist if one-way functions exist.

4. Allowing membership queries. It turns out that a mistake-bound model learning algorithm can do no better on this concept class even if it is allowed to make membership queries. The reason is that in order for membership queries to help, the algorithm at some point must produce an entire good example x_s^i it has not yet seen to query. (Otherwise the membership query oracle could be replaced by a machine that always answers "negative" to any query of an example not yet seen.) As we show below, this would allow one to break G.

THEOREM 4.1. *Concept class $\mathcal{C}_G$ cannot be learned in the mistake-bound model with membership queries if G is a CSB generator.*

Proof. Suppose for contradiction there is a learning algorithm L and polynomial P such that for all $c_s \in \mathcal{C}_G$ over $\{0, 1\}^n$, Algorithm L makes at most $P(n)$ mistakes plus queries. The adversary will present the good examples in the order: $x_s^{2^k}, x_s^{2^k-1}, \ldots$, and let us consider the behavior of L on the first $5P(n)$ examples. Clearly, L makes a mistake on at most $\frac{1}{5}$ of the examples and makes at most $P(n)$ membership queries.

Let us say that a membership query is a "good query" if it is a query of a good example L has not yet seen. Also, let us define the algorithm *dequery*(L) to be the algorithm for the mistake-bound model (no queries) that runs L, and each time L attempts to make a membership query on an example it has not yet seen, returns to L the answer "no."

Suppose first that the probability that L makes no good queries during the first $5P(n)$ examples is at least $\frac{4}{5}$ (probability taken over the random choice of $c_s \in \mathcal{C}_G$ and the coin tosses of L). This would imply that for some index t, over random s, the algorithm *dequery*(L) has a probability at least $\frac{4}{5} - \frac{1}{5} = \frac{3}{5}$ of producing the correct classification of example x_s^t. This contradicts Corollary 3.4.

We may now assume that L makes a good query at some point in the first $5P(n)$ examples with probability at least $\frac{1}{5}$ (over random s). Thus, for some $t \geq 2^k - 5P(n)$, the probability algorithm L makes its *first* good query after seeing x_s^t but before seeing x_s^{t-1} is at least $1/(25P(n))$. Let $t = t_1 \ldots t_k$ and let $Q(n) = 25[P(n)]^2$.

Note that $G_{t_1 \cdots t_k}(s)$ is efficiently computable from any good example x_s^i for $i < t$. So, we can use L in an Algorithm A that on input x_s^t has a probability at least $\frac{1}{Q(n)}$ of producing $G_{t_1 \cdots t_k}(s)$ as output, as follows. Algorithm A uses x_s^t and Algorithm Compute-Forward to run L on inputs $x_s^{2^k}, x_s^{2^k-1}, \ldots, x_s^t$, returning "no" as an answer to each membership query made. It then guesses which membership query made after x_s^t is the good query (in case L makes several queries after x_s^t; the number of such queries is at most $P(n)$). A then uses that query to produce a hypothesis for $G_{t_1 \cdots t_k}(s)$.

In analogy to definitions in the proof of Lemma 3.3, let $q_{d,k}$ be the probability that A outputs $G_{t_d \cdots t_k}(s)$ on input $t \circ r_1 \circ \cdots \circ r_{d-1} \circ G^{t_d \cdots t_k}(s)$, where r_i is a randomly chosen string of length k if $t_i = 0$ and $r_i = \lambda$ if $t_i = 1$. We are given that $q_{1,k} \geq \frac{1}{Q(k)}$. However, we know that $q_{k,k}$ must be small for the following reason. Quantity $q_{k,k}$ is the probability that A outputs $G_{t_k}(s)$ on input $t \circ r \circ G'_{t_k}(s)$, where r is a random string of the appropriate length. If A does so with probability greater than $1/kQ(k)$, then Algorithm B to break G is as follows: on input y (let y_0 be the left half and y_1 be the right half), pick a random r and feed to A input $t \circ r \circ y_1$ if $t_k = 0$ or $t \circ r \circ \lambda$ if $t_k = 1$, and output 1 if A outputs y_{t_k}. If $y = G(s)$ for random s, then B outputs 1 with probability at least $1/kQ(k)$, but if y is a random string then B outputs 1 with probability at most $(1/2)^k$ since y_{t_k} is a random string of length k and independent of the input to A. Hence B breaks G.

Thus, there must exist some value d such that $|q_{d,k} - q_{d+1,k}| > 1/kQ(k)$. We can now break G with a variant of Algorithm B' of the proof of Lemma 3.3. On input $y \in \{0, 1\}^{2k}$ the algorithm outputs 1 if $A(t \circ r_1 \circ \cdots \circ r_{d-1} \circ y'_{t_d} \circ G^{t_{d+1} \cdots t_k}(y_{t_d})) = G_{t_{d+1} \cdots t_k}(y_{t_d})$. So if $y = G(s)$ for random s, it outputs 1 with probability $q_{d,k}$, and if $y \in_R \{0, 1\}^{2k}$, then it outputs 1 with probability $q_{d+1,k}$, and thus breaks G. □

5. Conclusion. We have shown how to construct a concept class over $\{0, 1\}^n$ that is learnable in the distribution-free model but not in the mistake-bound model if cryptographically secure bit generators (or equivalently one-way functions) exist. In fact, the assumption of one-way functions gives us something stronger. Not only is the concept class $\mathcal{C}_G$ hard to learn in the mistake-bound model in the sense that for any learning algorithm there is *some* $c \in \mathcal{C}_G$ hard to learn, but in fact we have that for any learning algorithm, nearly all $c \in \mathcal{C}_G$ are hard to learn. The fraction of concepts which an algorithm *can* learn is less than any polynomial fraction $\frac{1}{Q(n)}$ (for sufficiently large n). This fact leads one to ask the question: is it possible to separate the two models using a weaker assumption? Some assumption is apparently necessary since if computational considerations are ignored, any concept class learnable in one model is learnable in the other.

The concept class $\mathcal{C}_G$ remains difficult to learn in the mistake-bound model even if the learner is allowed membership queries. This lies in contrast to the class of DFAs which *are* learnable in the mistake-bound (equivalence query) model with membership queries [2] but not in the distribution-free model [19]. Thus, neither model is strictly easier than the other. Recently, membership queries have been shown not to help in learning (for a reason similar to that described here) for the important class of DNF formulas [4].

The concept class constructed here is very nonnatural. To date, every "natural" concept class known to be polynomial-time learnable in the distribution-free model is also known to be polynomial-time learnable in the mistake-bound model. However, for some of these classes the known mistake-bound algorithm is qualitatively more difficult and sometimes followed quite a bit later than the distribution-free algorithm. One such case is the class of decision lists (distribution-free algorithm by Rivest [23], mistake-bound algorithm by Littlestone (personal communication) and Helmbold, Sloan, and Warmuth [14]). With the addition of membership queries to both models, another case is that of read-twice DNF (distribution-free with queries algorithm by Hancock [10], and a more complicated mistake-bound with queries algorithm by Aizenstein and Pitt [1]). An interesting open problem is whether there is any natural class that would be a good candidate for being learnable in the distribution-free model but not the mistake-bound model.

Acknowledgments. I would like to thank Shafi Goldwasser, Silvio Micali, Ron Rivest, and Phil Rogaway for helpful discussions, and Rob Schapire for suggesting the simple "Occamness" argument for the proof of Theorem 3.1.

COMPUTING WITH NOISY INFORMATION*

URIEL FEIGE†, PRABHAKAR RAGHAVAN‡, DAVID PELEG§ AND ELI UPFAL¶

Abstract. This paper studies the depth of *noisy* decision trees in which each node gives the wrong answer with some constant probability. In the *noisy Boolean decision tree* model, tight bounds are given on the number of queries to input variables required to compute threshold functions, the parity function and symmetric functions. In the *noisy comparison tree* model, tight bounds are given on the number of noisy comparisons for searching, sorting, selection and merging. The paper also studies parallel selection and sorting with noisy comparisons, giving tight bounds for several problems.

Key words. fault-tolerance, reliability, noisy computation, sorting and searching, error-correction

AMS subject classifications. 68M15, 68P10, 68R05

1. Introduction.

Fault-tolerance is an important consideration in large systems. Broadly, there are two approaches to coping with faults. The first is the "reconfiguration" approach [7], [13], in which faults are identified and isolated in real time. This is done concurrently with computation, and often has a significant overhead. A second, different approach is to devise robust algorithms that work despite unreliable information operations, without singling out the faulty components. This latter approach has been the focus of much recent work [11], [23], [16]–[19] [26], [22], [14], [15]. These papers differ in their general setting and in the mechanisms they use to model the faulty behavior of components. This paper concerns the probabilistic setting to this latter paradigm, as in [22], [14], and [15].

1.1. Model.

Our general model will be a (possibly randomized) computation tree, in which each node gives the correct answer with some probability, which is at least p, where p is a fixed constant in $(1/2, 1)$, bounded away from $1/2$ and 1. The node faults are independent. We study the depth of the computation tree in terms of a tolerance parameter $Q \in (0, 1/2)$: on any instance, the computation tree must lead to a leaf giving the correct answer on that instance with probability at least $1 - Q$. The success probability of the algorithm is computed over the combined probability space of the outcome of individual operations and the results of coin flips (in case our algorithm is randomized).

There are several possible types of computation trees that could be studied in this noisy tree model; this paper focuses on two. The first is the *noisy Boolean decision tree*, in which the tree computes a Boolean function of N Boolean variables $x_1, \dots, x_N$. Each node in the tree corresponds to querying one of the input variables; with some probability, we are given the wrong value of that variable. Each leaf is labeled 0 or 1, and corresponds to an evaluation of the function.

The second type studied is *noisy comparison trees* for problems such as sorting, selection, and searching. Here the input is a set $\{x_1, x_2, \dots, x_N\}$ of N numbers. (For searching, the input contains also x_{-1}, the searched element.) Each node in the tree specifies two indices i and j of the elements to be compared. (In our searching algorithms, for instance, one of these indices is always the searched element.) The node responds with either "$x_i \geq x_j$" or

"$x_i \leq x_j$," and gives the wrong answer with some probability. Each leaf is labeled with a permutation representing the sorted order for the input (for sorting and merging) or an index in $[1, N]$ (for selection and searching).

A simple example is in order here. In the absence of errors, the maximum of N numbers can be found by a comparison tree of depth $N - 1$. In the face of a constant probability of error, it is possible to repeat each comparison of the fault-free decision tree $O(\log(N/Q))$ times and obtain, by majority voting, a guess for the true result of the comparison that is wrong with probability at most Q/N. (Note that this does not require a special majority operation, but only "blowing up" each node of the tree into a subtree of the appropriate depth.) Doing this for every comparison immediately gives us a noisy comparison tree of depth $O(N \log(N/Q))$ for finding the maximum (we can afford to sum the failure probability of Q/N over the $N - 1$ events). In a similar fashion, any decision tree that has depth d in the absence of noise can be used to devise a noisy one of depth $O(d \log(d/Q))$.

The crux of our work is to show that while this logarithmic blowup is unavoidable for certain problems, it is (perhaps surprisingly) unnecessary for certain others. In fact, we are able to show such a separation between problems that have the same decision tree complexity in the absence of errors, such as the threshold function with various parameters (Theorems 2.2 and 2.7). A major obstacle to proving the lower bounds is that *errors cancel*—multiple errors could compound on an input to lead to a leaf giving the correct answer to that input, for the "wrong reason."

Another distinction we make is between a *static adversary*, where the probability of correctness of every node of the tree is fixed at p, and a *dynamic adversary* who can set the probability of correctness of each tree node to any value in $[p, 1)$.

It turns out that there is a difference between these two cases. In the dynamic case, the noisy decision tree complexity is bounded below by the deterministic (noise free) decision tree complexity, since the adversary may always opt for a correct execution (with all individual operations giving the correct value). In contrast, in the static case, the noisy decision tree complexity is bounded above by $\log(n/Q)$ times the *randomized* noise free decision tree complexity. This follows from the fact that the availability of basic operations with fixed success probability provides us with a fixed-bias coin, which in turn can be used to generate a fair coin. Since there are problems for which the randomized decision tree complexity is significantly smaller than the deterministic decision tree complexity (cf. [24]), it follows that the presence of fixed probability faults may actually *help* the algorithm. This points out another source of difficulty in proving lower bounds in the noisy decision tree model.

1.2. Related previous work. Noisy comparison trees for binary search and related problems were studied by Renyi [22] and by Pelc [14], [15]. Pippenger [16] and others have studied networks of noisy gates, in which every gate could give the wrong answer with some probability. Kenyon-Mathieu and Yao [11] study a Boolean decision tree in which an adversary is allowed to corrupt at most k nodes (read operations) along any root-leaf path. Rivest et al. [23] consider the problem of binary search on N elements using a comparison tree when an adversary can choose k comparisons to be incorrect ("lies") on any root-leaf path. This model was further studied by Ravikumar et al. [18], [19]. Yao and Yao [26] study sorting networks with at most k faulty comparators.

Our work differs from [11], [23], [18], [19] in that we allow every node of the decision tree to be independently faulty with some probability. Thus in our model the number of faults is not prescribed in advance—knowledge of this number could well be exploited by a "fault-tolerant" algorithm. The probabilistic model allows us to tolerate a relatively large number of faults compared to [11], [23], [18], [19].

1.3. Results. Let $D^{\text{Prob}}_{N,Q}(\Pi)$ (respectively, $D^{\text{Det}}_{N,Q}(\Pi)$) denote the minimum depth of any noisy probabilistic (respectively, deterministic) decision tree for instances of size N of problem Π, with tolerance Q. For notational simplicity, we shall write $D_{N,Q}(\Pi) = \Theta(f)$ to denote both $D^{\text{Prob}}_{N,Q}(\Pi) = \Omega(f)$ and $D^{\text{Det}}_{N,Q}(\Pi) = O(f)$.

All our lower bounds are for probabilistic trees, and all the upper bounds (with the exception of parallel sorting) are for deterministic trees. Furthermore, all our lower bounds apply against the weaker static adversary (and hence also against a dynamic adversary), and all the upper bounds apply against a dynamic adversary (and hence also against a static adversary). Since all of our bounds are tight (up to constant factors), we conclude that randomization does not significantly help for the problems studied (with the possible exception of parallel sorting).

For any problem Π, the depth of its optimal decision tree is at most polynomial in the length of the input. However, the size of the decision tree is often exponential. An important feature of our upper bounds is that the corresponding decisions trees have descriptions which are polynomial in the length of the input. At any time step, the next query (or comparison) to be made is a simple function (i.e., computable in polynomial time) of the outcomes of the previous queries.

Let TH^N_K denote the K-of-N threshold function: given N Boolean inputs, the output is 1 if and only if K or more of the inputs are 1. The PARITY function on N Boolean inputs outputs 1 if and only if the number of 1's in the input is even. For noisy Boolean decision trees we have the following results (in §2).

(1) $D_{N,Q}(\text{TH}^N_K) = \Theta(N\log(m/Q))$, where $m = \min\{K, N-K\}$. In particular, $D^{\text{Det}}_{N,Q}(\text{OR})$ and $D^{\text{Det}}_{N,Q}(\text{AND})$ are both $O(N\log(1/Q))$.

(2) $D_{N,Q}(\text{PARITY}) = \Theta(N\log(N/Q))$.

Notice the wide range of noisy tree depths in these results, whereas in the absence of noise, decision trees for all these problems have depth N. Problems such as parity have a blowup in tree depth that grows with N, rather than p or Q alone (unlike the OR function). In §2 we extend these results to all symmetric functions.

Let K-SEL be the problem of selecting the Kth largest of N elements. In the noisy comparison tree model we have the following tight results (in §3).

(1) $D_{N,Q}(\text{BINARY SEARCH}) = \Theta(\log(N/Q))$.

(2) $D_{N,Q}(\text{SORTING}) = \Theta(N\log(N/Q))$.

(3) $D_{N,Q}(\text{MERGING}) = \Theta(N\log(N/Q))$.

(4) $D_{N,Q}(K\text{-SEL}) = \Theta(N\log(m/Q))$, where $m = \min\{K, N-K\}$.

In particular, the maximum or the minimum element can be found by a noisy tree of depth $O(N\log(1/Q))$.

A well-known sports commentator has observed [9] that the problem of finding the maximum by a noisy comparison tree has a sporting interpretation: we wish to find the best of N teams by a tournament. In each game, the better team wins with some probability, which is at least p; how many games must be played in order that the best team wins with probability at least $1-Q$? One algorithm we give for finding the maximum by a noisy comparison tree bears a remarkable resemblance to the NBA championship: teams pair up and play a game at the first round, the winners pair up and play three games at the next, five in the third round and so on. It can be shown that the best team fails to win such a tournament with probability at most $c'(1-p)$ for some c', and that the total number of games is $O(N)$. This failure probability can be reduced to Q by multiplying the number of games in each round by $c\log(1/Q)$.

This brings up the following natural question: how many days must such a tournament last, assuming a team plays at most one game a day? Similarly, what is the depth of a noisy "EREW" parallel comparison tree with up to $N/2$ parallel comparisons at each node? The "NBA" algorithm described above requires $\Theta(\log N\log(N/Q))$ rounds.

In §4 we show that $O(\log(N/Q))$ rounds suffice for this problem, while keeping the total number of games down to $O(N\log(1/Q))$. More precisely, we show that there is an N-processor EREW-PRAM algorithm that computes the maximum of N elements with noisy comparisons, using $O(\log(N/Q))$ rounds and a total of $O(N\log(1/Q))$ comparisons, with failure probability at most Q. The algorithm applies even when each element is allowed to participate in at most one comparison per round (i.e., no element duplication is allowed).

In §5 we give a randomized parallel algorithm for sorting. The algorithm is based on a randomized, noisy, parallel comparison tree (with N comparisons per node) of depth $O(\log N)$. For sorting N numbers, the failure probability of the algorithm can be made as small as $1-N^{-c}$ for any constant $c > 0$.

2. Boolean decision trees. The main result of this section is a lower bound on the depth of any noisy Boolean decision tree computing the K-of-N threshold function TH_K^N. As a first step, we prove a lower bound for the case $K = 1$, which is the OR function.

THEOREM 2.1. $D_{N,Q}^{\mathrm{Prob}}(\mathrm{OR}) = \Omega((N\log\frac{1-Q}{Q})/(\log\frac{p}{1-p}))$.

Proof. Let $\bar{X} = (X_1, \ldots, X_N)$ be the input vector, let $\bar{0} = (0, \ldots, 0)$ and let $\bar{1}_j$ denote an input vector $X_j = 1$ and the remaining inputs zero. The proof is based on showing that distinguishing between $\bar{0}$ and the adjacent vectors $\bar{1}_j$ requires the stated depth. For a leaf ℓ of a Boolean decision tree of depth d and an input vector $\bar{X}$, let $Pr\{\ell|\bar{X}\}$ denote the probability of reaching ℓ (in a probabilistic decision tree it combines the probabilities of the random choices of the algorithm with the probabilities of the random answers to the queries) on an input $\bar{X}$.

Assume that X_j appears $r(j, \ell)$ times on the path from the root to ℓ. Then

$$Pr\{\ell|\bar{1}_j\} \geq \left(\frac{1-p}{p}\right)^{r(j,\ell)} Pr\{\ell|\bar{0}\}.$$

For any ℓ, $\sum_{j=1}^N r(j,\ell) = d$. Therefore $\sum_{j=1}^N((1-p)/p)^{r(j,\ell)}$ achieves its minimum (over all choices of $r(j,\ell)$) at $N((1-p)/p)^{d/N}$.

For a set L of leaves, define

$$Pr\{L|\bar{X}\} = \sum_{\ell\in L} Pr\{\ell|\bar{X}\}.$$

Thus, letting S denote the set of leaves labeled 0, we get

$$\begin{aligned}\sum_{j=1}^N Pr\{S|\bar{1}_j\} &= \sum_{j=1}^N\sum_{\ell\in S} Pr\{\ell|\bar{1}_j\}\\ &\geq \sum_{\ell\in S}\sum_{j=1}^N\left(\frac{1-p}{p}\right)^{r(j,\ell)} Pr\{\ell|\bar{0}\}\\ &\geq Pr\{S|\bar{0}\}N\left(\frac{1-p}{p}\right)^{d/N}.\end{aligned}$$

Clearly $Pr\{S|\bar{0}\} \geq (1-Q)$, and for every j, $Pr\{S|\bar{1}_j\} \leq Q$, and hence

$$QN \geq (1-Q)N\left(\frac{1-p}{p}\right)^{d/N}.$$

The bound on d follows.

Note that the proof works with a static adversary. A somewhat simpler proof can be given if the adversary is dynamic (Theorem 4.1). □

Let us now turn to the general threshold function TH_K^N. For a vector $\bar{X} = (X_1, \ldots, X_N)$ of N bits, let $\omega(\bar{X})$ denote the *weight* of $\bar{X}$, i.e., $\omega(\bar{X}) = \sum_{i=1}^N X_i$. Thus

$$\mathrm{TH}_K^N = \begin{cases} 1, & \omega(\bar{X}) \geq K, \\ 0, & \text{otherwise.} \end{cases}$$

THEOREM 2.2. *For every* $K < N/2$,

$$D_{N,Q}^{\mathrm{Prob}}(\mathrm{TH}_K^N) = \Omega\left(\theta N \log K + \frac{N \log \frac{1-Q}{Q}}{\log \frac{p}{1-p}}\right),$$

for $\theta = (1 - \frac{Q}{1-Q})/(\log 1/(1-p))$.

We first give a high level overview of the main ideas of the proof.

The main difficulty in proving lower bounds in our model stems from the fact that algorithms may be adaptive. For our lower bound, it suffices to use a static adversary: each query has a fixed probability p of giving the right answer.

Let T be a noisy decision tree (algorithm) of depth γN that computes TH_K^N, where γ may be a function of N. Now we strengthen the algorithm, but make its adaptive behavior easier to analyze, by transforming it to a two-phase algorithm T_1 in a "more powerful" model. The transformation is based on the observation that in any execution of T, at most $N/3$ input variables are each queried more than $\alpha = 3\gamma$ times. (The choice of $1/3$ is somewhat arbitrary, and is replaced by the parameter μ later.)

(A) Nonadaptive phase: Query each variable exactly α times. Each query returns the correct value with probability p.

(B) Adaptive phase: Request the values of $N/3$ of the input variables. These requests are answered correctly. At each point, T_1's choice of which variable to read next may depend upon all the answers up to that point.

Since we are considering static adversaries and randomized algorithms, T_1 can simulate the execution of T. The algorithm T_1 first runs the nonadaptive phase (A), querying each input variable α times. In phase (B) it starts simulating the execution of T. As long as T queries a variable fewer than α times, T_1 supplies the answers from the answers it got in phase (A) on queries to that variable. Once T queries a variable more than α times (note that this may happen for at most $N/3$ of the variables), T_1 requests the (correct) value of this variable in the adaptive phase (B). It then uses this value to answer T's subsequent queries after corrupting it randomly with probability p. Clearly, on any input, the probability distribution on T_1's outputs is identical to that on T's outputs. Noting that the depth of T_1 is at most a constant times the depth of T plus N, any lower bound on the depth of T_1 implies a corresponding lower bound for T.

We now outline the approach to proving that TH_K^N cannot be computed reliably by a T_1 type algorithm if γ is $o(\log K)$. For the lower bound, we only supply inputs to the algorithm with weights either $K - 1$ (for which the algorithm should output 0) or K (for which the algorithm should output 1). We show that if T_1 has insufficient depth, it is unlikely to distinguish between inputs from these different weights (and thus output values).

Since phase (A) of T_1 is nonadaptive, it is relatively easy to analyze its outcome. We view this phase as a game of randomly placing N balls, $K - 1$ or K of which are black and the rest white, into $\alpha + 1$ bins, numbered 0 to α. A white (respectively, black) ball i corresponds to an input variable X_i that is set to 0 (respectively, 1). Ball i is placed in bin j if exactly j of the α queries to X_i were answered 1. (By symmetry, it suffices to count the number of 1 answers and ignore the ordering between them and the 0 answers.) The vector $(s_0, \ldots, s_\alpha)$, where s_j

is the number of balls in bin j, is called the *execution profile* of the nonadaptive phase (A). If $K > 1/(1-p)^{\alpha}$, each bin can be expected to have at least one ball of each color.

At the end of phase (A), T_1 gets to see its profile, but not the actual colors of the balls in the bins. Its must determine the number of black balls using noiseless queries to $N/3$ of the balls in phase (B), together with the execution profile from phase (A).

We employ one final device to simplify the analysis of phase (B). Before phase (B) begins, we "help" the algorithm T_1 by revealing the values "for free" of $K-1$ of the black balls (creating a new profile). In particular, if the input contained K black balls, then the single black ball to be left hidden, is chosen randomly with the probability distribution of the *white* balls. Now, if there were just $K-1$ black balls, then phase (B) will reveal only white balls, and if there were K black balls, then the probability that phase (B) reveals the remaining ball is only constant (bounded from above by $N/3(N-K+1) < 2/3$). Thus with constant probability, phase (B) gives T_1 no additional information about the number of black balls. In this case, T_1 must base its decision upon only two profiles seen, both of which were seen before phase (B) of the algorithm has begun. Thus we reduce our problem to the analysis of simple random allocation games. Now standard probability theory can be used to show that the distribution of profiles that result from inputs having $K-1$ black balls is statistically similar to the one that results from inputs having K black balls, making it impossible for T_1 to achieve a success probability better than some fixed constant bounded away from 1.

We turn to a detailed proof of the theorem.

Proof of Theorem 2.2. If $K \leq \max\{(1-Q)/Q, C\}$, for some constant C, then the adversary can announce the values of input variables $X_1, X_2, \ldots X_{K-1}$ in advance to be 1. Computing TH_K^N is then reduced to the problem of computing the OR function of the remaining $N-K+1$ bits. By Theorem 2.1, this requires a tree of depth

$$\Omega\left(\frac{N\log((1-Q)/Q)}{\log(p/(1-p))}\right).$$

Thus for the rest of the proof assume that $K > \max\{(1-Q)/Q, C\}$, for a sufficiently large constant C. Fix constants μ, θ such that

$$0 < \mu < \frac{1}{2}\left(1-\frac{Q}{1-Q}\right)$$

and

$$0 < \theta \leq -\frac{\mu}{3\log(1-p)}.$$

Given a noisy decision tree for TH_K^N of depth $\gamma \leq \theta N \log K$, we show that its failure probability exceeds Q, and this will yield the lower bound of $\theta N \log K$ on the depth.

Let

$$\alpha = -\frac{\log K}{3\log(1-p)}.$$

Since $\gamma \leq \theta N \log K$, the number of input variables that are queried more than α times in any particular computation path is at most

$$\frac{\gamma}{\alpha}.$$

By the previous discussion we may, without loss of generality, grant the decision tree some additional information as outlined, and prove the lower bound for trees of the following two-phase form, which are more powerful than any decision tree of depth $\gamma \leq \theta N \log K$.

Phase (A). Query every variable exactly α times. Each query returns the correct value with probability p.

Phase (B). Request the values of μN of the input variables $X_1, \ldots X_N$; these queries are answered correctly.

The proof is by means of the probabilistic method. We present the tree with randomly chosen inputs having $K-1$ or K ones. We show that certain leaves of the tree will be reached with almost the same probability regardless of whether the input has $K-1$ or K ones. We first analyze the outcome of Phase (A). Let S_i denote the set of variables, of whose α queries, i were answered 1 in Phase (A). The outcome of Phase (A) is fully characterized by the vector $\bar{S} = (S_0, \ldots, S_\alpha)$. Let $s_i = |S_i|$, and $\bar{s} = (s_0, \ldots, s_\alpha)$ (the execution profile of Phase (A)). Let z_i (respectively, y_i) denote the number of input variables in S_i whose actual values are 0 (respectively, 1). Let $\bar{z} = (z_0, \ldots, z_\alpha)$ and $\bar{y} = (y_0, \ldots, y_\alpha)$.

For a variable X, let

$$P_i^0 = Pr\{X \in S_i | X = 0\} = \binom{\alpha}{i} p^{\alpha-i}(1-p)^i.$$

Note that the expected value of z_i over the inputs of interest is either $(N-K)P_i^0$ or $(N-K+1)P_i^0$.

LEMMA 2.3. *$Pr\{\exists i, y_i = 0\} \leq 1/N$.*

Proof.

$$Pr\{\exists i, y_i = 0\} \leq \sum_{i=1}^{\alpha}(1-P_i^0)^{N-K}.$$

Since the minimum value of P_i^0 is obtained when $i = \alpha$,

$$Pr\{\exists i, y_i = 0\} \leq (\alpha+1)(1-P_\alpha^0)^{N-K} \leq (\alpha+1)(1-(1-p)^{\frac{-\log K}{3\log(1-p)}})^{N-K} \leq 1/N,$$

for sufficiently large N. □

We now argue that the probability of getting a vector $\bar{S}$ given $\omega(\bar{X}) = K$ and given $\omega(\bar{X}) = K-1$ are very close to each other. In order to prove that, we shall restrict our attention to the case when none of the z_i variables diverges from its expected value by much more than the standard deviation. Formally, let $\mathcal{E}$ be the event that for all $1 \leq i \leq \alpha$,

$$(N-K)P_i^0(1-\Delta_i) \leq z_i \leq (N-K)P_i^0(1+\Delta_i),$$

where

$$\Delta_i = 6\sqrt{\frac{\log N}{(N-K)P_i^0}}.$$

By the Chernoff bound [4], it follows that the case we focus on is the dominant one.

LEMMA 2.4. *$Pr\{\bar{\mathcal{E}}\} \leq 1/N$, where $\bar{\mathcal{E}}$ is the complement of $\mathcal{E}$.* □

We now derive the following lemma.

LEMMA 2.5.

$$1 - \frac{1}{N^{1/5}} \leq \frac{Pr\{\bar{S}|(\omega(\bar{X}) = K) \wedge \mathcal{E}\}}{Pr\{\bar{S}|(\omega(\bar{X}) = K-1) \wedge \mathcal{E}\}} \leq 1 + \frac{1}{N^{1/5}}.$$

Proof. Let $\bar{s}(\ell) = (s_0, \ldots, s_\ell - 1, \ldots, s_\alpha)$ denote a distribution of $N-1$ variables ($K-1$ ones and $N-K$ zeros) among the sets $S_0, \ldots, S_\alpha$. Similarly, denote by $\bar{z}(\ell) = (z_0, \ldots, z_\ell - 1, \ldots, z_\alpha)$ a distribution of the $N-K$ 0-variables among $S_0, \ldots, S_\alpha$.

For any ℓ_1, ℓ_2,

$$\frac{Pr\{\bar{z}(\ell_1)|\mathcal{E}\}}{Pr\{\bar{z}(\ell_2)|\mathcal{E}\}} = \frac{\binom{N-K}{z_1,\ldots,z_{\ell_1}-1,\ldots,z_\alpha}\prod_{i=1}^{\alpha}(P_i^0)^{z_i}\cdot\frac{1}{P_{\ell_1}^0}}{\binom{N-K}{z_1,\ldots,z_{\ell_2}-1,\ldots,z_\alpha}\prod_{i=1}^{\alpha}(P_i^0)^{z_i}\cdot\frac{1}{P_{\ell_2}^0}} = \frac{z_{\ell_1}P_{\ell_2}^0}{z_{\ell_2}P_{\ell_1}^0}.$$

By condition $\mathcal{E}$,

$$\frac{1-\Delta_{\ell_1}}{1+\Delta_{\ell_2}} \le \frac{z_{\ell_1}P_{\ell_2}^0}{z_{\ell_2}P_{\ell_1}^0} \le \frac{1+\Delta_{\ell_1}}{1-\Delta_{\ell_2}}.$$

Since for any i, $K^{-1/3} \le P_i^0 \le 1$,

$$\Delta_m = 6\sqrt{\frac{\log N}{N}} \le \Delta_i \le 6\sqrt{\frac{2\log N}{N^{2/3}}} = \Delta_M.$$

Thus,

$$1 - \frac{1}{N^{1/5}} \le 1 - \frac{2\Delta_m}{1+\Delta_m} \le \frac{z_{\ell_1}P_{\ell_2}^0}{z_{\ell_2}P_{\ell_1}^0} \le 1 + \frac{2\Delta_M}{1-\Delta_M} \le 1 + \frac{1}{N^{1/5}}.$$

By summing over all possible pairs $(\bar{z}(\ell), \bar{y})$ such that $\bar{z}(\ell) + \bar{y} = \bar{s}(\ell)$ we get

$$\frac{Pr\{\bar{s}(\ell_1)|\mathcal{E}\}}{Pr\{\bar{s}(\ell_2))|\mathcal{E}\}} = \frac{\sum_{\bar{z}(\ell_1)+\bar{y}=\bar{s}(\ell_1)} Pr\{\bar{z}(\ell_1)|\mathcal{E}\}Pr\{\bar{y}|\mathcal{E}\}}{\sum_{\bar{z}(\ell_2)+\bar{y}=\bar{s}(\ell_2)} Pr\{\bar{z}(\ell_2)|\mathcal{E}\}Pr\{\bar{y}|\mathcal{E}\}}.$$

Thus,

$$1 - \frac{1}{N^{1/5}} \le \frac{Pr\{\bar{s}(\ell_1)|\mathcal{E}\}}{Pr\{\bar{s}(\ell_2))|\mathcal{E}\}} \le 1 + \frac{1}{N^{1/5}}.$$

We now add the last variable X, with value either one or zero, and get

$$\frac{Pr\{\bar{s}|(\omega(\bar{X}) = K) \wedge \mathcal{E}\}}{Pr\{\bar{s}|(\omega(\bar{X}) = K-1) \wedge \mathcal{E}\}} = \frac{\sum_{\ell=1}^{\alpha} Pr\{\bar{s}(\ell)|\mathcal{E}\}Pr\{X \in S_\ell | X = 1\}}{\sum_{\ell=1}^{\alpha} Pr\{\bar{s}(\ell)|\mathcal{E}\}Pr\{X \in S_\ell | X = 0\}}.$$

Using the fact that $Pr\{X \in S_\ell | X = 0\} = Pr\{X \in S_{\alpha-\ell} | X = 1\}$ we have

$$1 - \frac{1}{N^{1/5}} \le \frac{Pr\{\bar{s}|(\omega(\bar{X}) = K) \wedge \mathcal{E}\}}{Pr\{\bar{s}|(\omega(\bar{X}) = K-1) \wedge \mathcal{E}\}} \le 1 + \frac{1}{N^{1/5}}.$$

Since all assignments of K or $K-1$ ones to the variables have equal probability, by symmetry, all partitions of the variables into sets of sizes $s_1, \ldots, s_\alpha$ have equal probability and the claim is proven. □

To simplify the analysis of Phase (B) we assume without loss of generality that at the end of Phase (A) the adversary reveals the locations of $K-1$ input variables with value 1. If

$\omega(\bar{X})$ is K, and for all i, $y_i > 0$, the remaining (unexposed) variable is chosen to be from set S_i with probability $z_i/(\sum_{j=1}^{\alpha} z_j) = z_i/(N-K)$.

Denote by $\tilde{S_1}, \ldots, \tilde{S_\alpha}$ the input to Phase (B), where $\tilde{S_i}$ contains the variables in S_i that were not revealed by the adversary. Note that $z_i/|\tilde{S_i}| \leq 1$ for all i (more specifically, $|\tilde{S_i}| = z_i$ for all sets S_i except at most one, which might have $z_i + 1$ variables).

The tree cannot distinguish between variables in $\tilde{S_i}$. Suppose that the tree queries r_i variables in $\tilde{S_i}$ ($\sum_i r_i = \mu N$). If $\tilde{S_i}$ contains the unexposed 1-variable, the probability that the tree hits the unexposed 1-variable is $r_i/|\tilde{S_i}|$. The probability that the 1-variable is in $\tilde{S_i}$ is proportional to $|\tilde{S_i}|$. Thus the probability P_{hit} of hitting the 1-variable in Phase (B) when for all i, $y_i > 0$ is bounded above by

$$(*) \qquad P_{hit} \cdot \frac{r_i}{|\tilde{S_i}|}.$$

Let $\mathcal{S}$ denote the event that the output of Phase (A) is a vector $\bar{S}$ with the property that if Phase (B) does not find a 1-variable, the algorithm outputs 0.

LEMMA 2.6.

$$Pr\{\mathcal{S}|\omega(\bar{X}) = K\} \geq \left(1 - \frac{1}{N^{1/5}}\right)(1-Q) - \frac{1}{N}.$$

Proof. Clearly $Pr\{\mathcal{S}|\omega(\bar{X}) = K-1\} \geq 1-Q$, or else the tree does not perform as claimed. Now

$$Pr\{\mathcal{S}|\omega(\bar{X}) = K-1\} \leq Pr\{\bar{\mathcal{E}}\} + Pr\{\mathcal{S}|(\omega(\bar{X}) = K-1) \wedge \mathcal{E}\}.$$

By Lemma 2.5,

$$\begin{aligned} Pr\{\mathcal{S}|\omega(\bar{X}) = K-1\} &\leq Pr\{\bar{\mathcal{E}}\} + Pr\{\mathcal{S}|(\omega(\bar{X}) = K) \wedge \mathcal{E}\}\left(1 + \frac{1}{N^{1/5}}\right) \\ &\leq Pr\{\bar{\mathcal{E}}\} + \frac{Pr\{\mathcal{S}|\omega(\bar{X}) = K\}}{Pr\{\mathcal{E}\}}\left(1 + \frac{1}{N^{1/5}}\right). \end{aligned}$$

Thus, for an input $\bar{X}$ with $\omega(\bar{X}) = K$, by Lemma 2.4,

$$\begin{aligned} Pr\{\mathcal{S}|\omega(\bar{X}) = K\} &\geq \frac{(1-\frac{1}{N})}{(1+\frac{1}{N^{1/5}})}\left(Pr\{\mathcal{S}|\omega(\bar{X}) = K-1\} - \frac{1}{N}\right) \\ &\geq \left(1 - \frac{1}{N^{1/5}}\right)\left(1 - Q - \frac{1}{N}\right), \end{aligned}$$

implying the lemma. □

We are now ready to complete the proof of Theorem 2.2. By $(*)$, when the output of Phase (A) satisfies event $\mathcal{S}$, $\omega(\bar{X}) = K$, and for all i, $y_i > 0$, the probability that Phase (B) finds the unexposed 1 is at most 2μ. Otherwise the algorithm outputs 0. Since $Q < 1/2$, when $\omega(\bar{X}) = K$, by Lemma 2.3,

$$Pr\{\exists i : y_i = 0|\mathcal{S}\} \leq \frac{Pr\{\exists i : y_i = 0\}}{Pr\{\mathcal{S}\}} \leq \frac{2}{N}.$$

Thus, the probability that the algorithm fails and outputs 0 when $\omega(\bar{X}) = K$ is at least

$$Pr\{\mathcal{S}|\omega(\bar{X}) = K\}(1 - Pr\{\exists i : y_i = 0|\mathcal{S}\})(1 - 2\mu) > Q$$

for sufficiently large N. □

A matching upper bound for TH_K^N follows from a variant of the algorithm for K-SEL in §3. We defer the details of the algorithm to §3. Thus we have a deterministic upper bound matching the lower bound for randomized algorithms.

THEOREM 2.7. *$D_{N,Q}^{\mathrm{Det}}(\mathrm{TH}_K^N) = O(N \log(m/Q))$, where $m = \min\{K, N-K\}$. In particular, $D_{N,Q}^{\mathrm{Det}}(\mathrm{OR})$ and $D_{N,Q}^{\mathrm{Det}}(\mathrm{AND})$ are both $O(N \log(1/Q))$.*

In fact, the algorithm for K-SEL implies a more general result. A Boolean function f on N Boolean variables is *symmetric* if $f(X_1, \ldots, X_N) = f(X_{\pi(1)}, \ldots, X_{\pi(N)})$ for every permutation π on $\{1, \ldots, N\}$. For the function f, let k_1 be the largest $i < N/2$ such that there exist $\bar{x}$ with $\omega(\bar{X}) = i - 1$, and $\bar{X}'$ with $\omega(\bar{X}') = i$, and $f(\bar{X}) \neq f(\bar{X}')$. Similarly, let k_2 be the smallest $i \geq N/2$ such that there exist $\bar{x}$ with $\omega(\bar{X}) = i$, and $\bar{X}'$ with $\omega(\bar{X}') = i + 1$, and $f(\bar{X}) \neq f(\bar{X}')$. Let $\hat{k} = \max\{k_1, N - k_2\}$.

THEOREM 2.8. *For any symmetric function f, $D_{N,Q}(f) = \Theta(N \log(\hat{k}/Q))$. In particular, $D_{N,Q}(\mathrm{PARITY}) = \Theta(N \log(N/Q))$.*

For the proof of this theorem see the end of §3.

3. Comparison trees. This section concerns noisy comparison trees. Our first claim is that binary searching and insertion in a balanced search tree does not require a blowup in noisy tree depth that grows with N. This result can be derived by modifying the algorithms of [23] or [25] and adapting them to our model, or from [14]. We present a different algorithm, which has the advantage that the ideas it is based on can also be used for other problems, where the techniques of [23] or [25] do not seem to apply (see Theorem 4.2). The algorithm is obtained by thinking of a noisy binary search as a *random walk* on the (exact) binary search tree.

In discussing upper bounds for searching among a set of elements $x_1 \leq x_2 \leq \cdots \leq x_N$ in a binary search tree, we will refer to our noisy comparison tree as an "algorithm" (rather than tree) to avoid confusion with the binary search tree. For simplifying the description we shall assume that the key being searched for is not in the tree (so that its insertion location has to be determined).

Each node of the tree represents a subinterval of $(-\infty, \infty]$, and is labeled by a pair representing the endpoints of this interval. In particular, each leaf of the search tree represents an interval between two consecutive input values. There are $N + 1$ leaves, with the ith $(1 \leq i \leq N + 1)$ representing $(x_{i-1}, x_i]$ (assume $x_0 = -\infty$ and $x_{N+1} = \infty$). For an internal node u of the tree, let T_u denote the subtree rooted at u. Then the intervals associated with the leaves of T_u are contiguous, and u represents the interval obtained by merging them. That is, u is labeled with the interval $(x_\ell, x_h]$, for $0 \leq \ell \leq h \leq N + 1$, where x_ℓ is the smallest endpoint of an interval associated with a leaf in T_u, and x_h is the largest such endpoint. The tree is nearly balanced, in the sense that for a vertex u labeled by $(x_\ell, x_h]$, the left child of u is labeled $(x_\ell, x_z]$ and the right child is labeled $(x_z, x_h]$, where $z = \lceil \frac{\ell+h}{2} \rceil$. The tree has depth $\lceil \log N \rceil$.

To search with unreliable comparisons we extend the tree in the following way: each leaf x_ℓ is a parent of a chain of length $m' = O(\log(N/Q))$. The nodes of the chain are labeled with the same interval as the leaf. (In practice, these chains can be implemented by counters representing the "depth" from the leaf.) Fig. 1 depicts the resulting tree for three values, $(x_1, x_2, x_3) = (2, 5, 7)$.

Let X (given, say, as x_{-1} in the input set) be the key being searched for in the tree. The search begins at the root of the tree, and advances or backtracks according to the results of the

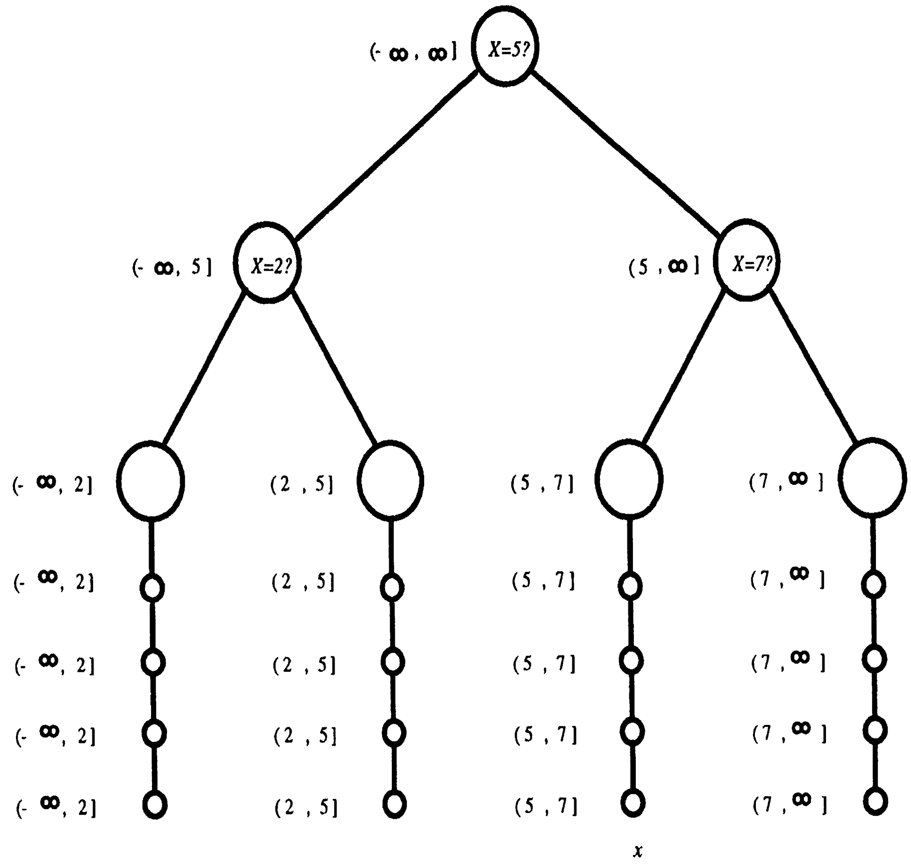

FIG. 1. *The extended comparison tree corresponding to the input list* (2, 5, 7).

comparisons. Whenever reaching a node u, the algorithm first checks that X really belongs to the interval $(x_\ell, x_h]$ associated with u, by comparing it to the endpoints of the interval. This test may either succeed, i.e., respond in $X > x_\ell$ and $X < x_h$, or fail, i.e., respond in $X < x_\ell$ or $X > x_h$ (or both). Such failure of the test may be due to noisy comparisons. However, the search algorithm always interprets a failure as revealing an inconsistency due to an earlier mistake, and consequently, the computation backtracks to the parent of u in the tree. If the test succeeds, on the other hand, then the computation proceeds to the appropriate child of u. That is, if u has two children, the algorithm compares X to x_z, the "central element" in u's interval (i.e., such that $z = \lceil \frac{\ell+h}{2} \rceil$), and continues accordingly.

The search is continued for $m = O(\log(N/Q))$ steps, $m < m'$ (hence it never reaches the endpoint of any chain). The outcome of the algorithm is the left endpoint of the interval labeling the node at which the search ends. For example, in the search tree depicted in Fig. 1, the search for the value $X = 6$ should terminate at the leaf marked x.

LEMMA 3.1. *For every $Q < 1/2$, the algorithm computes the correct location of X with probability at least $1 - Q$ in $O(\log(N/Q))$ steps.*

Proof. We model the search as a Markov process. Consider a leaf w of the extended tree T, and suppose that X belongs to the interval labeling this leaf. Orient all the edges of T towards w. Note that for every node v, exactly one adjacent edge is directed away from v and the other adjacent edges are directed towards v. Without loss of generality we can assume that the transition probability along the outgoing edge is at least $2/3$, and the probability of transitions along all other (incoming) edges is at most $1/3$. Otherwise, we can bootstrap the probability to $2/3$ by repeating each comparison $O(1)$ times and taking the majority.

Let m_f be a random variable counting the number of forward transitions (i.e., transitions in the direction of the edges) and let m_b denote the number of backward transitions ($m_f + m_b = m$). We need to show that $m_f - m_b > \log N$ with probability at least $1 - Q$, implying that the appropriate chain is reached. This follows from Chernoff's bound [4] for $m = c \log(N/Q)$, for a suitably chosen constant c. □

Using N insertions of the above algorithm, each with failure probability Q/N, yields a noisy comparison tree of depth $O(N \log(N/Q))$ for sorting.

THEOREM 3.2. (1) $D^{\text{Det}}_{N,Q}(\text{BINARY SEARCH}) = O(\log(N/Q))$.

(2) $D^{\text{Det}}_{N,Q}(\text{SORTING}) = O(N \log(N/Q))$.

(3) $D^{\text{Det}}_{N,Q}(\text{MERGING}) = O(N \log(N/Q))$.

We now present a noisy comparison tree of depth $O(N \log(m/Q)), m = \min\{K, N - K\}$ for selecting the Kth largest of N elements (in fact, the tree described can find *all* K largest elements, or all $N - K$ smallest elements for $K < N/2$). By symmetry, we need only consider the case $K < N/2$. Furthermore, the case $\sqrt{N} \leq K \leq N/2$ can be handled using our $O(N \log(N/Q))$ sorting algorithm. Thus we assume that $K < \sqrt{N}$. The idea in finding the Kth largest element when K is "small" is to use "tree selection" or "heapsort" (see Knuth, pp. 142–145 [12]). In essence, the algorithm operates as follows. Once a heap is created, the largest element can be extracted from the top of the heap, and "reheapifying" the rest of the elements requires at most $\log N$ noiseless comparisons. Thus, extracting the K largest elements can be done in $K \log N$ noiseless comparisons. By repeating each of these $K \log N$ comparisons $O(\log((K \log N)/Q))$ times in the face of noise we can extract each of the K largest elements from the heap with error probability at most $Q/2K$. Thus with $O(K \log N \log((K \log N)/Q))$ noisy comparisons we can extract the K largest elements with probability at most $Q/2$. For $K < \sqrt{N}$, this number of comparisons is $O(N \log(K/Q))$.

The only remaining problem is that of constructing the initial heap. In order to do this, run a "tournament" algorithm similar to the "NBA" algorithm in the introduction for finding the maximum with failure probability $Q/2K$. The algorithm takes $O(N \log(K/Q))$ steps, and each of the K largest elements has probability at most $Q/2K$ of being eliminated by a smaller element. Thus, with probability $1 - Q/2$, the initial heap is consistent with respect to the K largest elements, and this suffices for our purposes. Therefore we have the following theorem.

THEOREM 3.3. $D^{\text{Det}}_{N,Q}(K\text{-SEL}) = O(N \log(m/Q))$, *where* $m = \min\{K, N - K\}$.

In §2 we proved lower bounds on the threshold function in the noisy Boolean decision tree model, whereas in this section we prove upper bounds on selection in the noisy comparison tree model. We can use a reduction between the two problems to show that both bounds are tight (up to constant factors). But first, since the results are proven in different computational models, we need to show a reduction from the Boolean decision tree model to the comparison model.

LEMMA 3.4. *A noisy comparison between two Boolean variables can be implemented by a constant number of noisy queries.*

Proof. Query each of the two variables a constant number of times, obtain an estimate for each of the variables by taking the majority of the corresponding responses, and compare the estimates. □

For Boolean inputs, selecting the Kth largest element and testing (by $O(\log N)$ queries) if its value is 1, is equivalent to computing TH^N_K. The upper bound in Theorem 2.7 follows trivially. The upper bound for computing any symmetric function (Theorem 2.8) follows from the fact that the comparison tree for K-SEL actually finds *all* K largest (or $N-K$ smallest, if $K > N/2$) elements. By repeating K-SEL once with $K = k_1$ and once with $K = k_2$ (see the prologue to Theorem 2.8 for the interpretation of these parameters), and then querying each of the k_1 largest and each of the $N - k_2$ smallest elements $O(\log N)$ times, the value of any symmetric function can be established.

We now turn to lower bounds for the problems discussed above.

THEOREM 3.5. (1) $D^{\text{Prob}}_{N,Q}(\text{BINARY SEARCH}) = \Omega(\log(N/Q))$.

(2) $D^{\text{Prob}}_{N,Q}(\text{SORTING}) = \Omega(N \log(N/Q))$.

(3) $D^{\text{Prob}}_{N,Q}(K\text{-SEL}) = \Omega(N \log(m/Q))$, *where* $m = \min\{K, N-K\}$.

(4) $D^{\text{Prob}}_{N,Q}(\text{MERGING}) = \Omega(N \log(N/Q))$.

Proof. It is immediate that our searching and sorting algorithms are asymptotically optimal in the comparison model, hence claims (1) and (2).

Next, the fact that a comparison tree for K-SEL implies a comparison tree for TH^N_K enables us to derive claim (3) from Theorem 2.2.

Finally, a lower bound for MERGING (claim (4)) can be derived by a reduction from PARITY. We first show how a merging algorithm can be used to establish parity. Consider a vector $\bar{X} = (x_1, \dots, x_N)$ of Boolean inputs whose parity is to be established. Transform it to a vector of increasing integers $\bar{I} = (I_1, \dots, I_N)$, where for each j, $I_j = 2x_j + 3j$. Consider the merge operation of $\bar{I}$ with the vector $\bar{Y} = (Y_1, \dots, Y_N)$, where $Y_j = 3j + 1$. The result establishes the value of each of the x_j, since $I_j < Y_j$ iff $x_j = 0$. So in order to compute the parity of $\bar{X}$, it is sufficient to simulate the merging of $\bar{I}$ and $\bar{Y}$. Claim (4) now follows from Theorem 2.8 and the argument of Lemma 3.4. □

4. Parallel tournaments.

4. Parallel tournaments. In this section and the next we consider two problems on noisy N-processor PRAMs in which each comparison operation between two elements independently gives the correct result with probability at least p. In this section we discuss the problem of finding the maximum of N elements. Our solution can be implemented on an EREW parallel decision tree with at most $N/2$ comparisons per round in $O(\log(N/Q))$ rounds. Furthermore, each input element is involved in at most one comparison per round, and no element is ever copied to create a replica of the element. Because of its sporting interpretation, we will describe the algorithm in the tournament setting introduced in the introduction. Let us now describe this setting in more detail.

A parallel algorithm for computing the maximum is called a *tournament* if in each parallel step of the algorithm, each input element is involved in at most one comparison. A tournament is *deterministic* if the comparisons made at each step are uniquely determined by the results of comparisons in previous steps (no randomization is allowed). The *depth* of a tournament is the total number of parallel steps it takes. The *size* of a tournament is the total number of comparisons it involves. A tournament is *noisy* if comparisons might output the wrong answer. We consider noisy tournaments with a dynamic adversary. A noisy tournament is *Q-tolerant* if it outputs the maximal element with probability at least $1 - Q$.

THEOREM 4.1. *Any deterministic Q-tolerant tournament has depth* $\Omega(\log(N/Q))$ *and size* $\Omega(N \log(1/Q))$.

Proof. Let T be any Q-tolerant tournament. Let d denote its depth and s its size. Any Q-tolerant tournament is also a deterministic noise-free tournament for finding the maximum, hence its depth is at least $\log N$. Thus for $Q \geq N^{-1}$ we immediately derive that $d \geq \frac{\log(N/Q)}{2}$.

Assume now that $Q < N^{-1}$. For simplicity, we describe the argument as if a dynamic adversary were controlling the probability of error for each comparison. Fix an arbitrary input with a unique largest element. The adversary decides to introduce no noise in the comparisons. The tournament must output the correct maximal element. Now switch the indices of the largest and second largest elements in the input. Now the adversary introduces noise only in comparisons between the two largest elements, and T proceeds exactly as in the case that the inputs are not switched. Since there are at most d comparisons between the two largest elements, the probability that the algorithm returns the same index as that of the maximum element on both runs is $(1-p)^d$, implying that $d \geq (\log(1/Q))/(\log \frac{1}{1-p})$.

The bound on the size follows from Theorem 2.1, together with the equivalence of the models from Lemma 3.4. □

We remark that a stronger version of the above theorem, in which the algorithm is probabilistic and the adversary is static, can be proved along similar lines as those of Theorem 2.1.

We state an inequality, due to Hoeffding [8], to be used in the proof of the next theorem. Let X_i, for $1 \leq i \leq n$, be n independent random variables with identical probability distributions, each ranging over the interval $[a, b]$. Let $\bar{X}$ be a random variable denoting the average of the X_i's. Then

$$\text{Prob}(|\bar{X} - E(\bar{X})| \geq \delta) \leq 2e^{-\frac{2n\delta^2}{b-a}}.$$

THEOREM 4.2. *For every* $0 < Q < 1/2$ *there is a* Q*-tolerant deterministic tournament for finding the maximum with depth* $O(\log(N/Q))$ *and size* $O(N\log(1/Q))$ *simultaneously.*

The tournament we construct is similar in spirit to the noisy binary search procedure of §3. For simplicity (and without loss of generality) we assume that $N = 2^m - 1$ for some m. Create a balanced binary tree of depth m, and arbitrarily place one input element in each node (including leaves, root and internal nodes). The algorithm proceeds in rounds. In each round, many mini-tournaments are performed in parallel. Each mini-tournament involves three players, and the largest of the three wins with probability at least q, for some constant q to be computed later. The mini-tournaments are organized by partitioning the nodes of the tree into triplets in a way to be described shortly, and forming a mini-tournament between the three elements stored in each triplet. The partition into triplets depends on the round. In even rounds, each triplet consists of a node at an even level of the tree and its two children. Analogously, in odd rounds, each triplet consists of a node at an odd level and its two children. At the end of the round, the winner of each mini-tournament is stored at the parent node, and the two other elements are placed arbitrarily at the children. The whole procedure is repeated for $O(\log(N/Q))$ rounds.

We give some intuition on why our construction computes the maximum. The tournament is best described as a random walk taken by the maximal element, M, over the balanced binary tree. A win at a single mini-tournament may or may not advance M towards the root, depending on whether M is already placed at the parent node before the mini-tournament begins. But wins in two successive mini-tournaments advance M by at least one step. Likewise, if it loses one of two successive mini-tournaments, it may move away from the root by one step, and if it loses two successive mini-tournaments, it may move away from the root by two steps. Summing up the probabilities of these events, it follows that on the average, in two successive rounds, M is expected to decrease its distance to the root by at least $q^2 + 2q - 2$ steps. For $q > 15/16$, this value is greater than $3/4$, and so any ℓ rounds are expected to advance M by $3\ell/8$, and in less than $8m/3$ steps M is expected to reach the root. (Note that guaranteeing that M wins each mini-tournament with probability $q > 15/16$ can be achieved in a constant number of comparisons, since a mini-tournament involves only three players.)

Two parts are still missing from the construction. One is a method of preventing M from leaving the root once it reaches it. The other is a method of decreasing the total number of comparisons from $O(N\log(N/Q))$ to $O(N\log(1/Q))$. This is significant if $Q > N^{-c}$ asymptotically for any constant c.

In order to secure M at the root with high probability we adopt the following policy: an element stays at the root as long as it has won the majority of mini-tournaments since it last reached the root. We employ a root counter which is initialized to 0. In mini-tournaments which involve the root, if the element placed at the root wins the mini-tournament, the root counter is incremented by 1. If a different element wins, and the root counter is at 0, this element exchanges places with the root element. If the root element does not win and the root counter has value greater than 0, then the root counter is decremented by 1, and no exchange takes place.

LEMMA 4.3. *The probability that M is at the root after $d = 256\log(N/Q)$ rounds is at least* $1 - Q/2$.

Proof. Assume that some other element W wins the tournament, i.e., occupies the root by the end of the process. We do not decrease the probability of W ending up at the root if we let it begin the tournament placed at the root, and let it win without competition any mini-tournament in which M is not involved. This implies that during the whole tournament, only two elements, M and W, could have occupied the root. Furthermore, W played exactly $d/2$ mini-tournaments involving the root, losing at most $d/4$.

Now consider M's performance in the tournament. Envision a *scoring system*, where M starts with 0 *points*. Partition the rounds of the tournament into successive pairs of mini-tournaments. For each such pair, M's score is decremented by 1 point for each mini-tournament that it loses, and if M did not lose in any mini-tournaments, then its score is incremented by 1 point. In d rounds, M's score is expected to be at least $3d/8$. Applying the Hoeffding inequality with $d/2$ (for the d selected above), we get that with probability $1 - Q/N$, M's scores are at least $5d/16$ points. At most $\log n$ of these points can be accounted for as steps taking M from a leaf to just below the root. The other $5d/16 - \log n$ points must have been "wasted" on decrementing W's root counter. For d as in the lemma, this value is greater than $d/4$, contradicting our assumption that W ends the tournament at the root. □

Though the depth of the above tournament is $O(\log(N/Q))$ as desired, its size is $O(N\log(N/Q))$, which is too large (for $1/Q = o(N)$). In order to diminish the total number of comparisons when $1/Q < N$, we execute the following truncation procedure during the first $(\log N)/3$ rounds. After $O(i\log(1/Q))$ rounds, we delete the ith level from the bottom of the competition tree. This has the effect of reducing the number of parallel mini-tournaments by a constant factor every $O(\log(1/Q))$ rounds, and thus reducing the size of the first $(\log N)/3$ rounds of the competition to $O(N\log(1/Q))$. Since for $1/Q < N$ the total number of rounds is $O(\log N)$, it follows that the size of the whole competition remains $O(N\log(1/Q))$.

LEMMA 4.4. *The probability that M is at a leaf of the truncated tree after* $16i(\log(1/Q)+2)$ *rounds is less than* $Q/2^{i+1}$.

Proof. We may assume that M starts at a leaf of the tree. Observe that $(\log N)/3$ rounds are insufficient for M to reach the root, and thus we can ignore the effect of the root counter. In $\ell = 16i(\log(1/Q)+2)$ rounds, M is expected to advance by at least $3\ell/8 = 6i(\log(1/Q)+2)$ steps. The probability it advanced less than i steps is as specified in the lemma, by the Hoeffding inequality. □

We now have all the ingredients to complete the proof of Theorem 4.2.

Proof of Theorem 4.2. From Lemma 4.4 it follows that the probability that the maximal element M is lost in the truncation process is less than $Q/2$. Thus the total probability that M does not win the tournament is at most Q, completing the proof of the theorem. □

5. Parallel sorting. The main result of this section is an N processors randomized $O(\log N)$ time noisy sorting algorithm. We first present the algorithm in an N-parallel decision tree model, and then modify it to an N-processor PRAM algorithm.

Our proof uses the following results of Assaf and Upfal [2].

THEOREM 5.1 [2]. *There is a constant α, such that for every constant $c > 1$ there is an $N\log N$ processor deterministic* EREW-PRAM *algorithm that sorts N elements in the noisy comparison model in $O(c\alpha\log N)$ parallel time with failure probability $Q \leq N^{-c}$.*

(The result in [2] is stronger, the sorting algorithm is nonadaptive and can be implemented as a network of comparators; however the PRAM version is sufficient for the proofs in this section.)

THEOREM 5.2. *There is a constant β, such that for any constant $c > 1$ there is a randomized, noisy, parallel comparison tree (N comparisons per node) of depth $c\beta \log N$ that sorts N numbers with error probability $Q \le N^{-c}$.*

Proof. The algorithm has three phases. In the first phase it chooses a random sample of $N/\log N$ elements and sorts them by running the algorithm of Theorem 5.1 $(c+2)\beta \log N$ steps. Since $(N/\log N)^{-(c+2)} \le N^{-(c+1)}$ for sufficiently large N, the probability that the first phase fails to sort the sample correctly is bounded by $1/N^{c+1}$.

The second phase of the algorithm partitions the N elements into $\ell = N/\log N$ sets, $S_1, \ldots, S_\ell$, such that with probability $1 - 1/N^{c+1}$ all elements in each set S_i are not smaller than the $(i-1)$st sample element and are not larger than the ith sample element (in the correct sorted order). To achieve this, we assign one processor to each element. The processor runs the noisy binary search algorithm of Theorem 3.2 for $O((c+3)\log N)$ steps. The probability that one search fails is at most $1/N^{c+2}$, so that the probability that any element is misplaced is at most $1/N^{c+1}$.

The third phase sorts the $O(N/\log N)$ sets. The probability that any set has more than $(c+2)\log^2 N$ elements is bounded by

$$N\left(1 - \frac{(c+2)\log^2 N}{N}\right)^{N/\log N} \le N^{-(c+1)}.$$

In what follows we assume that all sets have no more than $(c+2)\log^2 N$ elements. We sort the sets in parallel in $O(\log N)$ parallel steps, using any logarithmic parallel algorithm such as the AKS network [1] or [5], repeating each comparison $\log N/\log\log N$ times and taking the majority value.

The probability that the majority of $\log N/\log\log N$ comparisons does not give the correct answer is bounded (using Chernoff bound) by

$$\exp\left(-\frac{1}{3}p\frac{\log N}{\log\log N}\left(1 - \frac{1}{2p}\right)^2\right).$$

Since the sorting algorithm of each set uses $O(\log^2 N \log\log N)$ comparisons, the probability that a given set is not correctly sorted is bounded by $\exp(-\theta \frac{\log N}{\log\log N})$ for some constant $\theta > 0$. Thus, the probability that more than $N/\log^3 N$ sets are not correctly sorted is bounded by

$$\binom{N/\log N}{N/\log^3 N}\exp\left(-\theta\frac{\log N}{\log\log N}\frac{N}{\log^3 N}\right) \le N^{-(c+1)}.$$

By comparing each element $O(\log N)$ times (sequentially) to its two neighbors in the computed order we can identify, with probability $1 - N^{-(c+1)}$, all the sets that are not correctly sorted. Since with high probability the total number of elements in these $O(N/\log^3 N)$ sets is bounded by $O(N/\log N)$ we can assign $\log N$ processors to each element and sort all the sets correctly, with probability $1 - 1/N^{c+1}$, in $O(\log N)$ additional parallel steps, using again the algorithm of Theorem 5.1 Summing the run-time and the failure probabilities of the three phases we get that the correct sorted order is computed in $O(c \log N)$ time with probability $1 - 1/N^c$. □

THEOREM 5.3. *There is a constant γ, such that for any constant $c > 1$ there is an N processor randomized* CRCW-PRAM *algorithm that sorts N elements in the noisy comparison model in $c\gamma \log N$ parallel time with failure probability $Q \le N^{-c}$.*

Proof. The three phases of the previous algorithm are implemented on an N processor randomized CRCW-PRAM as follows.

Phase one: Each element chooses to participate in the sample with probability $2N/\log N$. With probability $1 - 1/N^{c+1}$ the sample has at least $N/\log N$ elements and no more than $3N/\log N$ elements. Using an $O(\log N)$-time prefix sum algorithm we copy the sample to a second array. The fault tolerant sorting network can be directly modified to a PRAM algorithm.

Phase two: The binary search can be done in parallel by the N processors on a CREW-PRAM. The main complication in implementing this phase is in placing the elements in the sets. We use the counting method of Reischuk [20] to count the number of elements in each set, and allocate them in $N/\log N$ arrays.

Phase three: The only complication in implementing this phase is in assigning $\log N$ processors to each of the elements in sets that need to be sorted again. When these sets are identified, the allocation can be done by a $O(\log N)$-time prefix-sum procedure. □

6. Extensions and open problems. Using reductions from the bounds given above, it is possible to derive tight bounds on the depths of noisy tree for the following problems: finding the leftmost 1, UNARY-BINARY, COMPARISON, ADDITION and MATCHING (see [3] for definitions).

The results of §2 can also be extended to show that there is a noisy Boolean decision tree of depth $O(N \log(1/Q))$ for any function that can be computed by a constant-depth formula of size N.

In Theorem 2.8 we characterized the noisy decision tree complexity of all symmetric functions. Obtaining such a characterization for general functions is a major open question. Some progress was achieved by Kenyon and King [10], who showed that $O(N \log(k/Q))$ queries suffice to compute any function f that can be represented either in k-DNF form or in k-CNF form. As for lower bounds, Reischuk and Schmeltz [21] showed that almost all functions require $\Theta(N \log(N/Q))$ queries. A simpler proof of this result is presented in [6].

An interesting open question is to give a deterministic noisy PRAM algorithm for sorting. We conjecture that there is no noisy sorting *network* of size $O(N \log N)$ that sorts N elements with polynomially small error probability.

Acknowledgments. We thank Noga Alon and Yossi Azar for helpful discussions, and for directing us to some of the references. Thanks are also due to Oded Goldreich and two anonymous referees for their illuminating comments on previous drafts of the paper.

ON COMPETITIVE GROUP TESTING*

DING-ZHU DU† AND HAESUN PARK†

Abstract. In many fault detection problems, the goal is to identify defective items from a set of items with a minimum number of tests. Each test is on a subset of items, which tells whether the subset contains a defective item or not. The concept of *competitive* algorithm has been developed to relate the properties of the group testing algorithms that assume that the number of defective items d is known, to those without any a priori knowledge on d. A new concept of *strongly competitive* algorithm is defined that relates different characteristics of these two classes of algorithms and present an interesting relationship between the two concepts *competitive* and *strongly competitive*. A strongly competitive algorithm is also presented.

Key words. competitive algorithm, group testing, fault detection, strongly competitive algorithm

AMS subject classifications. 68P10, 68Q25, 68R05

1. Introduction.

Consider a set of n items in which some items are *defective* and others are *good*. The problem is to identify them by a sequence of tests. Each test is on a subset of items, which tells us whether the subset contains a defective item or not. In the former case, the subset is said to be *contaminated* and in the latter case, the subset is said to be *pure*. The problem has applications in high speed computer networks [4], medical examination [1], [2], quantity searching [3], and statistics [1], etc. In the literature, the problem has been named *group testing*.

A classic model for group testing is to assume that the number of defective items is known. This assumption is restrictive since in practice this number is usually unknown a priori and it can be discovered only after testing. If the number of defective items is unknown at the beginning, how do we design and analyze algorithms? Motivated from the study of on-line problems [16], [17], Du and Hwang [9] proposed the concept of competitive algorithm for the group testing problem as follows.

For an algorithm α, let $N_\alpha(s \mid d, n)$ ($N_\alpha(s \mid n)$) be the number of tests that algorithm α spends on a sample s of n items under the condition that d, the number of defective items, is known (unknown). Denote

$$M_\alpha(d, n) = \max_{s \in \mathcal{A}(d,n)} N_\alpha(s \mid d, n),$$

$$M(d, n) = \min_{\alpha} M_\alpha(d, n),$$

$$M_\alpha(d \mid n) = \max_{s \in \mathcal{A}(d,n)} N_\alpha(s \mid n),$$

where $\mathcal{A}(d, n)$ is the set of samples of n items containing d defective items. An algorithm α is called a *c-competitive* algorithm if there exists a constant a such that for $0 < d < n$, $M_\alpha(d \mid n) \leq c \cdot M(d, n) + a$. Note that in the definition we exclude the case $d = n$ because $M(n, n) = 0$ and $M_\alpha(d \mid n)$ may depend on n. The exclusion of the case $d = 0$ is not necessary, but is convenient. We will remark on this in §4. A c-competitive algorithm for a constant c is simply called a competitive algorithm while c is called the *competitive ratio* of the algorithm.

*Received by the editors March 22, 1993; accepted for publication (in revised form) June 28, 1993.

†Computer Science Department, University of Minnesota, Minneapolis, Minnesota 55455. The work of the first author was supported in part by the National Science Foundation under grant CCR-9208913 and by the Institute of Applied Mathematics, Chinese Academy of Sciences, Beijing, China.

Du and Hwang [9] presented two competitive algorithms, a bisecting algorithm with competitive ratio 2.75 and a hybrid algorithm α that has the following property:

$$(*) \qquad \lim_{n\to\infty} \frac{M_\alpha(d \mid n)}{M(d,n)} = 1.$$

They conjectured that there exists a bisecting algorithm A such that

$$(1) \qquad M_A(d \mid n) \leq 2M(d,n) + 1 \quad \text{for } 0 \leq d \leq n-1.$$

Bar-Noy, Hwang, Kessler and Kutten [4] discovered a 2.15-competitive algorithm with a new technique, called a *doubling algorithm*. Du, Xue, Sun, and Cheng [12] introduced a new method to analyze the competitive algorithms. They proved that the bisecting algorithm appeared in an earlier version of Du and Hwang's paper [10] actually satisfies (1). Du and Hwang [11] pointed out that with a similar method, the doubling algorithm can be proved to have competitive ratio 2, too. Du, Xue, Sun, and Cheng [12] also obtained a competitive algorithm with ratio 1.65 by modifying the doubling algorithm. Neither the doubling algorithm nor its modified version has the property $(*)$.

In this paper, we propose a new competitiveness for group testing and prove that a competitive algorithm in the new sense must both satisfy property $(*)$ and be competitive in the original sense. We also present an algorithm which is competitive in the new sense.

2. Strong competitiveness. A number of papers [5]–[7], [14]–[15] have appeared on group testing algorithms for $1 \leq d \leq 3$. In those papers, the following number was studied:

$$n(d,k) = \max\{n \mid M(d,n) \leq k\}.$$

Motivated from previous work on this number, we defined the second competitiveness as follows.

Consider an algorithm α. Define $n_\alpha(d \mid k) = \max\{n \mid M_\alpha(d \mid n) \leq k\}$. An algorithm α is called a *strongly c-competitive* algorithm if there exists a constant a such that for every $d \geq 1$ and $k \geq 1$, $n(d,k) \leq c \cdot n_\alpha(d \mid k) + a$. Note that we have to exclude the case $d = 0$ because $n(0,k) = \infty$ for $k \geq 1$. A strongly c-competitive algorithm for a constant c is called a strongly competitive algorithm. An interesting property of strong competitiveness is as follows.

THEOREM 2.1. *Every strongly competitive algorithm α is a competitive algorithm satisfying the following condition*:

$$\lim_{n\to\infty} \frac{M_\alpha(d \mid n)}{M(d,n)} = 1.$$

Before proving this theorem, let us first state a lemma.

LEMMA 2.2. *For* $1 \leq d \leq n$,

$$d \log_2 \frac{n}{d} \leq M(d,n) \leq d \log_2 \frac{n}{d} + 4d.$$

Proof. There are $\binom{n}{d}$ samples. Each test divides these samples into two sets. So, the information lower bound for $M(d,n)$ is $\lceil \log_2 \binom{n}{d} \rceil$. (A better bound can be found in [8] and [13].) The first inequality follows immediately from $\binom{n}{d} \geq \left(\frac{n}{d}\right)^d$. The second inequality will be proved in the next section. □

Now we prove Theorem 2.1.

Proof of Theorem 2.1. Let $n(d, k) \le c \cdot n_\alpha(d \mid k) + a$. Without loss of generality, assume that c and a are positive integers; otherwise, we may use two positive integers bigger than c and a instead of c and a. From the above inequality, we obtain

$$\begin{aligned} M_\alpha(d \mid n) &= \min\{k \mid n_\alpha(d \mid k) \ge n\} \\ &\le \min\{k \mid (n(d,k) - a)/c \ge n\} = M(d, cn + a). \end{aligned}$$

Thus, for $d \ge 1$,

$$1 \le \frac{M_\alpha(d \mid n)}{M(d,n)} \le \frac{M(d, cn+a)}{M(d,n)} \le \frac{d \log_2 \frac{cn+a}{d} + 4d}{d \log_2 \frac{n}{d}}.$$

Clearly, the right side is bounded by a constant for $d < n$. Thus, α is a competitive algorithm. Moreover, the right side approaches one as n goes to infinity and d is fixed. Therefore $\lim_{n \to \infty} M_\alpha(d \mid n)/M(d,n) = 1$ for $d \ge 1$. □

The inverse of the above theorem is not true. Next, we give a sufficient condition for strong competitivity.

THEOREM 2.3. *If for algorithm α there exists a constant c such that for $1 \le d \le n - 1$,*

$$M_\alpha(d \mid n) \le d \log_2 \frac{n}{d} + cd,$$

then α is strongly competitive.

Proof. Note that

$$\begin{aligned} n_\alpha(d \mid k) &= \max\{n \mid M_\alpha(d \mid n) \le k\} \\ &\ge \max\left\{n \mid d \log_2 \frac{n}{d} + cd \le k\right\} \\ &\ge d2^{\frac{k}{d} - c} - 1 \end{aligned}$$

and

$$\begin{aligned} n(d, k) &= \max\{n \mid M(d,n) \le k\} \\ &\le \max\left\{n \mid d \log_2 \frac{n}{d} \le k\right\} \\ &\le d2^{\frac{k}{d}}. \end{aligned}$$

Thus,

$$n(d,k) \le 2^c(n_\alpha(d \mid k) + 1). \qquad \square$$

3. Strongly competitive algorithm. A bisecting algorithm for group testing can be simply described as follows: Starting from the input set of items, the algorithm tests a set and bisects it when the set is found to be contaminated. Continue to do this until every item is either in a pure set or in a contaminated singleton. A lot of tests are wasted in the bisecting algorithm in the following situation: When X and X' both are contaminated sets with $X' \subset X$, then the test on X' would render the test on X useless. From this observation, we make the following improvement: Once a contaminated set is found, a defective item is eliminated from the set. This idea may decrease the frequency of the occurrence of the above situation, which results in a strongly competitive algorithm.

First, we introduce a procedure ELIMINATE which eliminates a defective item from a contaminated set X with $\lceil \log_2 |X| \rceil$ tests. Note that performing a test on set X will be written as TEST(X). Let G and D be containers for good items and defective items, respectively.

```
Procedure ELIMINATE($X$);
    $Y := X$;
    while $|Y| \geq 2$ do begin
        $Y' := \lceil |Y|/2 \rceil$ items from $Y$;
        TEST($Y'$);
        if $Y'$ is contaminated then $Y := Y'$
            else $Y := Y \setminus Y'$;
                 $G := G \cup Y'$;
                 $X := X \setminus Y'$;
    end-while;
    $X := X \setminus Y$;
    $D := D \cup Y$;
end-procedure.
```

Now we give an algorithm as follows.

```
ALGORITHM A:
input $S$;
$G := \emptyset$;
$D := \emptyset$;
$Q := \{S\}$;
repeat
    pop $X$ from queue $Q$;
    TEST($X$);
    if $X$ is pure
    then $G := G \cup X$
    else ELIMINATE($X$);
        if $|X| = 1$ then push $X$ into queue $Q$;
        if $|X| \geq 2$ then bisect $X$ into $X'$ and $X''$ such that $|X'| = 2^{\lceil \log_2 |X| \rceil - 1}$ and
            $X'' = X \setminus X'$ and push $X'$ and $X''$ into queue $Q$;
until $Q = \emptyset$.
end-algorithm.
```

Next, we analyze Algorithm A. We first consider n which is a power of 2 since the analysis is easier in this case.

LEMMA 3.1. *Let n be a power of 2. Then for $0 \leq d \leq n$.*

$$M_A(d \mid n) \leq d \log_2 \frac{n}{d+1} + 4d - \log_2(d+1) + 1.$$

Proof. Let $n = 2^u$, $v = \lfloor \log_2(d+1) \rfloor$ and $v' = \log_2(d+1) - v$. Note that detecting a defective item from a set of size s by procedure ELIMINATE needs $\lceil \log_2 s \rceil$ TESTs. In Algorithm A, once a contaminated set is discovered, a defective item is eliminated from the set and then the remainder is divided into two sets if the remainder contains at least two items. It is not hard to see that procedure ELIMINATE is applied to at most one set of size n, at most two sets of sizes between $1 + n/4$ and $n/2, \ldots$, and in general, at most 2^i sets of sizes between $1 + n/2^{i+1}$ and $n/2^i$ for $i < v$. Thus, the number of TESTs required by procedure ELIMINATE is at most

$$\sum_{i=0}^{v-1} 2^i(u-i) + \left(d - \sum_{i=0}^{v-1} 2^i\right)(u-v)$$

$$= u(2^v - 1) - (v2^v - 2^{v+1} + 2) + (d - 2^v + 1)(u - v)$$

$$
\begin{aligned}
&= ud - v(d+1) + 2^{v+1} - 2\\
&= d(u-v-v') + v'd - v + 2^{v+1} - 2\\
&= d(u-v-v') + (v' + 2^{1-v'})(d+1) - 2 - \log_2(d+1)\\
&\le d\log_2 \frac{n}{d+1} + 2d - \log_2(d+1).
\end{aligned}
$$

The last inequality holds because $v' + 2^{1-v'} \le 2$ for $0 \le v' < 1$. In fact, $v' + 2^{1-v'}$ is a convex function with value 2 at $v' = 0$ and $v' = 1$.

Now, consider the tree T^* which is built up by the bisecting process as follows: The node set of T^* consists of S and all sets X' and X'' appearing in the computation. A node X is the father of two sons X' and X'' if and only if X' and X'' are obtained by bisecting X after eliminating a defective item. Clearly, every internal node is a contaminated set from which a defective item is eliminated. Thus, T^* has at most d internal nodes. It follows that the total number of nodes of T^* is at most $2d+1$. Therefore,

$$M_A(d \mid n) \le d\log_2 \frac{n}{d+1} + 4d - \log_2(d+1) + 1. \qquad \square$$

For convenience, we assume that the value of function $d\log_2 \frac{n}{d}$ at $d = 0$ is 0 because $\lim_{d\to 0} d\log_2 \frac{n}{d} = 0$. The following lemma is an important tool for our analysis.

LEMMA 3.2. *Let $d = d_1 + d_2$ and $n = n_1 + n_2$, where $d_1 \ge 0, d_2 \ge 0, n_1 > 0$ and $n_2 > 0$. Then*

$$d_1 \log_2 \frac{n_1}{d_1} + d_2 \log_2 \frac{n_2}{d_2} \le d \log_2 \frac{n}{d}.$$

Proof. Note that $d^2/dx^2(x\log_2 \frac{1}{x}) = -1/(x\ln 2) < 0$ for $x > 0$, so $-x\log_2 x$ is a concave function. Thus,

$$
\begin{aligned}
&d_1 \log_2 \frac{n_1}{d_1} + d_2 \log_2 \frac{n_2}{d_2}\\
&= n\left(\frac{n_1}{n}\frac{d_1}{n_1}\log_2 \frac{n_1}{d_1} + \frac{n_2}{n}\frac{d_2}{n_2}\log_2 \frac{n_2}{d_2}\right)\\
&\le n\left(\frac{d}{n}\log_2 \frac{n}{d}\right)\\
&= d\log_2 \frac{n}{d}. \qquad \square
\end{aligned}
$$

LEMMA 3.3. *For $1 \le d \le n$,*

$$M_A(d \mid n) \le d\left(\log_2 \frac{n}{d} + 4\right).$$

Proof. We prove it by induction on d. For $d = 1$, the algorithm finds the only defective item with $\lceil \log_2 n \rceil + 1$ TESTs which is clearly bounded by $\log_2 n + 4$. For $d > 1$, the algorithm eliminates the first defective item with $\lceil \log_2 n \rceil + 1$ TESTs, and bisects the remaining $n-1$ items into two sets S' and S'' of size n_1 and n_2, respectively, where $n_1 = 2^{u-1}$ with $u = \lceil \log_2(n-1) \rceil$. Suppose that S' and S'' contain d_1 and d_2 defective items, respectively. So, $d_1 + d_2 + 1 = d$ and $n_1 + n_2 + 1 = n$. Then by Lemma 3.1, the number of TESTs for identifying items in S' is at most

$$d_1\left(\log_2 \frac{n_1}{d_1+1} + 4\right) - \log_2(d_1+1) + 1.$$

Next, we consider two cases.

Case 1. $d_2 > 0$. By the induction hypothesis, all defective items in S'' can be identified in at most $d_2(\log_2(n_2/d_2) + 4)$ tests. Thus, the total number of TESTs is at most

$$\begin{aligned}
&(\lceil \log_2 n \rceil + 1) + \left(d_1 \log_2 \frac{n_1}{d_1+1} + 4d_1 - \log_1(d_1+1) + 1\right) + \left(d_2 \log_2 \frac{n_2}{d_2} + 4d_2\right)\\
&\leq u + 3 + d_1\left(\log_2 \frac{n_1}{d_1+1} + 4\right) - \log_2(d_1+1) + d_2\left(\log_2 \frac{n_2}{d_2} + 4\right)\\
&= (d_1+1)\left(\log_2 \frac{n_1}{d_1+1} + 4\right) + d_2\left(\log_2 \frac{n_2}{d_2} + 4\right) \qquad \text{(since } u = 1 + \log_2 n_1\text{)}\\
&\leq d\left(\log_2 \frac{n-1}{d} + 4\right) \qquad \text{(by Lemma 3.2)}\\
&< d\left(\log_2 \frac{n}{d} + 4\right).
\end{aligned}$$

Case 2. $n \neq 2^u + 1$ and $d_2 = 0$. In this case, $u = \lceil \log_2(n-1) \rceil = \lceil \log_2 n \rceil$ and the algorithm uses one TEST to detect S''. Thus, the total number of TESTs is at most

$$\begin{aligned}
&(\lceil \log_2 n \rceil + 1) + \left(d_1 \log_2 \frac{n_1}{d_1+1} + 4d_1 - \log_1(d_1+1) + 1\right) + 1\\
&\leq u + 3 + d_1\left(\log_2 \frac{n_1}{d_1+1} + 4\right) - \log_2(d_1+1)\\
&= (d_1+1)\left(\log_2 \frac{n_1}{d_1+1} + 4\right) \qquad \text{(since } u = 1 + \log_2 n_1\text{)}\\
&< d\left(\log_2 \frac{n}{d} + 3\right).
\end{aligned}$$

Case 3. $n = 2^u + 1$ and $d_2 = 0$. In this case, $u + 1 = \lceil \log_2 n \rceil$ and $n_1 = n_2 = 2^{u-1}$ and the total number of TESTs is at most

$$\begin{aligned}
&u + 4 + d_1\left(\log_2 \frac{n_1}{d_1+1} + 4\right) - \log_2(d_1+1)\\
&\leq 1 + d\left(\log_2 \frac{n_1}{d} + 4\right)\\
&\leq d\left(\log_2 \frac{n}{d} + 4\right). \qquad \square
\end{aligned}$$

It is an immediate consequence that $M(d, n) \leq d \log_2 \frac{n}{d} + 4d$ for $1 \leq d \leq n$.

THEOREM 3.4. *Algorithm* A *is strongly competitive.*

Proof. It follows immediately from Lemma 3.3 and Theorem 2.3. □

4. Discussions.

In the definition of competitive algorithm, the exclusion of the case $d = 0$ is not necessary because all current existing competitive algorithms spend a constant number of tests in this case. However, this case makes some unnecessary noise. In fact, if we include this case in the definition, all results in this paper still hold provided we add "$M_\alpha(0, n)$ is a constant" in the definition of strongly competitive and in the assumption of Theorem 2.3 and note that $M_A(0, n) = 1$ for Algorithm A in §3.

The strongly competitive algorithms are near optimal when $d << n$. This happens often in practice.

The hybrid algorithm in [9] is also a strongly competitive algorithm. However, the competitive ratio $2^{5.28}$ is bigger than that of the algorithm which we presented in the last section. We can design other strongly competitive algorithms with the same upper bound as that in Lemma 3.3. The coefficient 4 for the term d in the upper bound seems to be a barrier.

The lower bound for $M(d, n)$ has been established by [8], [13]. Whether the ratio $(M(d \mid n) - M(d, n))/d$ is close to 4 or close to 1 is an open question.

A UNIFORM CIRCUIT LOWER BOUND FOR THE PERMANENT*

ERIC ALLENDER† AND VIVEK GORE‡

Abstract. The authors show that uniform families of ACC circuits of subexponential size cannot compute the permanent function. This also implies similar lower bounds for certain sets in PP. This is one of the very few examples of a lower bound in circuit complexity whose proof hinges on the uniformity condition; it is still unknown if there is any set in Ntime ($2^{n^{O(1)}}$) that does not have nonuniform ACC circuits.

Key words. circuit complexity, uniformity, permanent, lower bounds, complexity classes

AMS subject classifications. 68Q05, 68Q15, 03D15

1. Introduction.

Circuit complexity classes consisting of circuits of constant depth and polynomial size have been intensely studied in the last decade. The first such class to be studied was AC^0, the class of languages accepted by polynomial size, constant depth circuits consisting of NOT gates and unbounded fan-in AND and OR gates. Machinery for proving lower bounds for AC^0 has been developed in a series of papers, culminating in the powerful and elegant techniques of [18], [29], [3]. These papers provide exponential size lower bounds for constant depth circuits computing the PARITY function. These lower bounds prompted people to look at constant depth, polynomial size circuits with PARITY gates along with AND, OR, and NOT gates, but Razborov [22] proved that these circuits could not compute the MAJORITY function. Smolensky [25] extended Razborov's method to show that an AC^0 circuit with MOD_p gates cannot compute the MOD_q function if p and q are distinct primes. This implies that no AC^0 circuit containing MOD gates for a single prime can compute the MAJORITY function. Therefore, the next natural extension of the above class was to allow MOD_m gates for composite moduli m. This extension is known as the class ACC, and it was introduced (implicitly) by Barrington in [4]. Although there has been a fair amount of research on ACC, we still do not know much about this class except the trivial fact that $AC^0 \subsetneq ACC \subseteq NC^1$ where NC^1 is the class of languages accepted by polynomial size, $O(\log n)$ depth circuits with NOT gates, and bounded fan-in AND and OR gates. Barrington [4] has conjectured that $ACC \subsetneq NC^1$.

Yao [30] proved the first nontrivial upper bounds on the power of ACC circuits, showing that each set in ACC is accepted by a family of depth three threshold circuits of size $2^{(\log n)^{O(1)}}$; these bounds were slightly improved by Beigel and Tarui [10]. These results have been proved for nonuniform ACC. We are, however, interested in the uniform version of ACC.

A circuit family consists of a sequence of circuits $C_1, C_2, \ldots,$ where circuit C_n takes n Boolean inputs. The circuit family is *uniform* if a description of C_n can be computed efficiently from n; otherwise the circuit family is said to be *nonuniform*. The original motivation for studying uniform circuit families came from a desire to relate time and space complexity classes to circuit complexity (see, e.g., [11]). Some sort of uniformity condition is essential for this endeavor to succeed, since it is an easy observation that there are sets with trivial circuit complexity that are not even recursive. The question of exactly which uniformity condition one should use has proved to be somewhat controversial, and largely it has been a matter of taste.

When providing upper bounds, or when defining complexity classes, as a practical matter it usually makes no difference which uniformity condition one uses. For example, Ruzzo [23] considers a number of related uniformity conditions, and shows that, for all $k \geq 2$, NC^k consists of languages defined by uniform circuits of polynomial size and $O((\log n)^k)$ depth, no matter which of those uniformity conditions is considered. For very small complexity classes, however, the uniformity condition is sometimes crucial. For example, P-uniform NC^1 circuits are known for division [8], but it remains an open question whether one can improve this result using a more restrictive uniformity condition. Similarly, [6] presents a number of beautiful characterizations of subclasses of NC^1 using Dlogtime uniformity, but these characterizations are not believed to hold if less restrictive uniformity conditions are used. In this paper, we consider uniform circuits out of necessity. The lower bounds that we present are not known to hold in the nonuniform setting.

Before we can state our results, we need a few technical definitions. We are interested in two classes of subexponential functions that we call subexp and subsubexp. Let us call a function f *constructible* if $f(n) = 2^{g(n)}$, where $g(n)$ can be computed from n (in binary) in time polynomial in $g(n)$. Let subexp denote the class of all monotonic functions that are bounded above by some constructible function f such that $\forall \epsilon > 0$, $f(n) = o(2^{n^\epsilon})$. Let subsubexp denote any class of monotonic functions closed under composition with polynomials, such that for any two functions f and g in this class, the composition of f and g is in subexp.

A typical example of a function in subexp is $2^{n^{1/\log^* n}}$, and typical choices for subsubexp are $n^{\log^{o(1)} n}$ or $2^{(\log n)^{O(\log\log n)}}$. It is not hard to prove that if s is in subexp, then so is $s^{(\log s)^k}$, for any constant k.

In this paper, we provide lower bounds for the classes of languages accepted by uniform circuit families of ACC circuits of subsubexponential and subexponential size. Let those classes be denoted by ACC(subexp), and ACC(subsubexp). Formal definitions can be found in §2 (Definition 2.10). For the rest of this section, we assume that ACC, ACC(subexp), and ACC(subsubexp), denote the uniform versions of these classes for the notion of uniformity defined in §2 (Definition 2.9). Any other notions of uniformity that we use will be mentioned explicitly. We show that PERM (the permanent of a matrix) is not in ACC(subexp), and that PP $\not\subseteq$ ACC(subsubexp). We are also able to show that ACC $\subsetneq$ $\mathrm{C_=P}$ and that $\mathrm{C_=P}$ $\not\subseteq$ ACC(subsubexp). Our main tool in proving these results is the following theorem.

THEOREM 1.1. *There is a set Y in* PP *such that* ACC(subexp), $\subseteq \mathrm{Dtime}(n^2)^Y$.

Theorem 1.1 trivially gives us an important corollary (which also follows from a more general lower bound proved in Theorem 3.5 later in the paper).

COROLLARY 1.2. ACC $\subsetneq$ PP.

Proof. Theorem 1.1 implies that ACC $\subseteq \mathrm{Dtime}(n^2)^Y$ for some $Y \in$ PP. Since ACC $\subseteq$ PP, suppose for the sake of contradiction that ACC = PP. Then ACC = P = PP. Therefore, $\mathrm{Dtime}(n^3)^Y \subseteq \mathrm{P}^Y \subseteq \mathrm{P} = \mathrm{ACC} \subseteq \mathrm{Dtime}(n^2)^Y$. But this contradicts the time hierarchy theorem of [17]. □

This seems to be one of the very few instances where lower bounds are known for the uniform circuit complexity of certain languages or functions, but where nothing is known about the nonuniform circuit complexity. In fact, the only other instance that we are aware of is that it is not known if EXPTIME contains sets that are not in P/poly (the class of languages accepted by nonuniform circuit families of polynomial size), whereas it does contain sets that are not in P (which is the class of languages accepted by uniform circuit families of polynomial size). In contrast with our results, the combinatorial and algebraic techniques developed in [18], [22], [25] make no use of uniformity, and thus they provide lower bounds on nonuniform circuit size. The uniformity condition is critical in the proof of Theorem 1.1; it is still unknown if PP = Dlogspace-uniform ACC. Although Dlogspace-uniform ACC is trivially seen to be properly contained in PSPACE, it is not known if P-uniform ACC = PSPACE. In fact, it is even unknown if there is any set in Ntime $(2^{n^{O(1)}})$ that is not accepted by a nonuniform ACC circuit family.

To prove Theorem 1.1, we will first use the results of Toda [26], Yao [30], and Beigel and Tarui [10] to convert a circuit family in ACC(subexp) into an equivalent circuit family of depth-two circuits with a symmetric gate at level two, AND gates of small fan-in at level one, and the input gates at level zero. However, since we need the resulting circuit family to be uniform as well, we need to show that the above conversion process can be done uniformly. We then show that the language recognized by the new circuit family can be quickly recognized by a deterministic Turing machine that has access to a particular oracle set in PP. Results about PERM then follow from Valiant's [27] results about the class #P.

Section 2 presents some basic definitions. Section 3 states Theorem 3.1, which is a uniform version of the main result of [10]. Theorem 3.1 is then used to prove the main results of the paper. The final section of the paper presents conclusions and open problems.

The proof of Theorem 3.1, which is the longest and most technically involved part of the paper, is presented in the Appendix. Even though the basic machinery of the proof was developed in [30], [10], there are many obstacles to overcome to ensure that one maintains uniformity.

2. Preliminaries. We will assume that the reader is familiar with circuits and standard complexity classes such as NP, PP, PH, etc., and the various notions of reducibility.

DEFINITION 2.1. *Let m be a positive integer. A* MOD$_m$ gate *outputs* 1 *if the sum of its* (*binary*) *inputs is* 0 *modulo m*; 0, *otherwise. That is,*

$$\mathrm{MOD}_m(x_1,\ldots,x_n)=\begin{cases}1 & \mathit{if} \sum_i x_i \equiv 0 \pmod{m},\\ 0 & \mathit{otherwise.}\end{cases}$$

DEFINITION 2.2. *A* MAJORITY gate *with n inputs outputs* 1 *if $\frac{n}{2}$ or more of its inputs are* 1; 0, *otherwise. That is,*

$$\mathrm{MAJORITY}(x_1,\ldots,x_n)=\begin{cases}1 & \mathit{if} \sum_i x_i \ge \frac{n}{2},\\ 0 & \mathit{otherwise.}\end{cases}$$

DEFINITION 2.3 [21], [4], [7]. *A language L is in* ACC *if there exists a positive integer m such that L is recognized by a family of constant depth polynomial size circuits containing* NOT *gates and unbounded fan-in* AND, OR, *and* MOD$_m$ *gates.*

ACC was first defined and studied in [21], [4], [7] under the name ACC^0. Barrington and Thèrien showed that ACC is equal to the class of languages recognized by polynomial length programs over solvable monoids [7]. Razborov [22] and Smolensky [25] also studied bounded depth circuits containing AND, OR, and MOD gates. Yao's definition of ACC is slightly different from the one given by Barrington et al.; it allows a fixed finite set S of moduli instead of a single modulus m. It is easy to see that a MOD$_m$ gate can simulate a MOD$_k$ gate for any k that divides m. Letting m be the least common multiple of the elements in S makes the two definitions equivalent. Yao [30] showed that every language in ACC is recognized by a family of depth-two probabilistic circuits with a symmetric gate at level two and $2^{(\log n)^{O(1)}}$ AND gates having fan-in $(\log n)^{O(1)}$ at level one. Beigel and Tarui [10] improved this to show the existence of deterministic circuit families of this sort.

DEFINITION 2.4. *For an* NP *machine M, let $\#M$ be the function $\#M : \Sigma^* \to \mathbf{N}$ defined by $\#M(x)$ = number of accepting paths of M on input x. Then $\#P = \{\#M : M$ is an* NP *machine$\}$.*

It is well known from [27] that PERM is complete for #P under polynomial time many-one reductions ($\leq_m^p$). (See also [31], [9].)

DEFINITION 2.5. *A language L is said to be in* PrTime($t(n)$) *if there exists a nondeterministic machine M that runs in time $t(n)$ such that for all $x \in \Sigma^*$, $x \in L \iff$ more than half of the computation paths of M on input x are accepting.*

DEFINITION 2.6. *A language L is said to be in* $\mathrm{C_{=}Time}(t(n))$ *if there exists a nondeterministic machine M that runs in time $t(n)$ such that for all $x \in \Sigma^*$, $x \in L \iff$ exactly half of the computation paths of M on input x are accepting.*

In particular, for polynomial running times we get the well-known classes $\mathrm{PP} = \mathrm{PrTime}(n^{O(1)})$ and $\mathrm{C_{=}P} = \mathrm{C_{=}Time}(n^{O(1)})$.

DEFINITION 2.7. *Let $\{C_n\}$ be a family of circuits. Following* [23], *we define the direct connection language L of $\{C_n\}$ as $L = \{\langle n, g_1, g_2\rangle : g_1 = g_2$ and g_1 is a gate in C_n or $g_1 \neq g_2$ and g_2 is an input to g_1 in $C_n\}$.* Here g_1 and g_2 are names of gates and n is in binary notation.

DEFINITION 2.8. *A circuit family $\{C_n\}$ is* dlogtime-uniform *if its direct connection language can be recognized in* linear *time by a* deterministic *Turing machine. The Turing machine that recognizes the direct connection language of $\{C_n\}$ will be referred to as the* uniformity machine *for $\{C_n\}$.*

The above notion of uniformity is the one that is generally used for small complexity classes (see [6], [12], [23]). However, we are going to use a slightly less restrictive notion of uniformity for our results. Our notion of uniformity can be informally referred to as polylogtime-uniformity. The reason that we use this notion is that we are dealing with circuits of possibly superpolynomial size and the proofs are much simpler with this uniformity condition. It should be noted that a set has uniform ACC(subexp) circuits with respect to our notion of uniformity if and only if it has Dlogtime-uniform ACC(subexp) circuits. This can be established by "padding" a circuit with many dummy gates.

DEFINITION 2.9. *A circuit family $\{C_n\}$ is* uniform *if its direct connection language can be recognized in* polynomial *time by a* deterministic *Turing machine. Note that the time is polynomial with respect to the length of the strings in the language ($|\langle n, g_1, g_2\rangle|$) and not merely polynomial in n.*

DEFINITION 2.10. *Let* ACC($s(n)$) *denote the class of languages accepted by circuit families of constant depth circuits with* NOT *gates and unbounded fan-in* AND, OR, *and* MOD_m *gates (for some integer $m \geq 2$) of size $s(n)$. Then*

$$\mathrm{ACC(subexp)} = \bigcup_{s \in \mathrm{subexp}} \mathrm{ACC}(s(n)),$$

$$\mathrm{ACC(subsubexp)} = \bigcup_{s \in \mathrm{subsubexp}} \mathrm{ACC}(s(n)).$$

Throughout the rest of the paper, classes ACC, ACC(subexp), and ACC(subsubexp) denote *uniform* circuit classes according to the notion of uniformity in Definition 2.9 unless the uniformity condition is mentioned explicitly.

3. The main results. For the proof of Theorem 1.1, we will first show the following.

THEOREM 3.1. *Suppose L is accepted by an ACC(subexp) circuit family. Then L is accepted by a uniform, depth-two circuit family*[1] *of $s(n)$ sized circuits that have the following properties:*

[1] This circuit family is not an ACC(subexp) circuit family because the circuits have arbitrary symmetric gates at their roots. When we say that it is uniform, we are using a slightly different notion of uniformity which is explained in Definition A.22.

1. *Level one consists of a subexponential number of* AND *gates having fan-in* $(\log s(n))^{O(1)}$. *Furthermore, given the name of one of these* AND *gates, the exact fan-in of this AND gate can be computed deterministically in time* $(\log s(n))^{O(1)}$.

2. *There is a symmetric gate at level two. Furthermore, given the number m of* AND *gates that evaluate to one, it can be determined deterministically in time* $(\log s(n))^{O(1)}$ *if the symmetric gate will evaluate to one.*

The above theorem is the most important part of the argument. It is equivalent to saying that the main theorem of [10] holds also in the setting of uniform circuit complexity. Unfortunately, transformations that are obvious in the nonuniform setting require considerable care when undertaken in the uniform setting; we present a complete proof of Theorem 3.1 in the Appendix. The rest of this section assumes that Theorem 3.1 is true and uses it to prove our main results.

Proof of Theorem 1.1. Let $\{C_n\}$ be a circuit family in ACC(subexp) that accepts L. Using the result in Theorem 3.1, we can get a uniform family of circuits $\{D_n\}$ such that for every n, D_n is a deterministic depth-two circuit with the properties mentioned in the statement of Theorem 3.1.

Let M_L be a nondeterministic Turing machine that, on input x, guesses the name of one of the AND gates of D_n ($n = |x|$) and the names of all the inputs of D_n that are connected to this gate. It verifies that the guesses are correct (using the uniformity machine for $\{D_n\}$). It then accepts if and only if the AND gate evaluates to 1 when x is the input to D_n. Since $\{D_n\}$ is uniform and the AND gates have fan-in $o(n^\epsilon)$ (for every ϵ), M_L can do this computation in linear time. Note that $\#M_L(x)$ is the number of AND gates of D_n that evaluate to 1 on input x.

Let $M_1, M_2, \ldots,$ be an enumeration of nondeterministic machines running in linear time. Define the set Y to be $\{\langle i, x, l\rangle : x \in \{0,1\}^* \text{ and } \#M_i(x) > l\}$. Note that Y is in PP[2]. With oracle Y, a deterministic machine (say M) can compute $\#M_L(x)$ in time n^2 using the binary search technique. Then, since this is the number of AND gates of D_n that evaluate to 1 on input x, it can then in linear time determine if D_n accepts x, using the properties guaranteed by Theorem 3.1. Thus membership of x in L can be determined in time n^2 relative to oracle Y. (Note that the running time can actually be brought down to $o(n)$ by modifying the oracle Turing machine model, but we choose not to do so for the sake of clarity.) □

COROLLARY 3.2. *The following statements are true*:

1. ACC(subexp) $\subseteq$ Dtime$(n^9)^{\text{PERM}[1]}$ *where* PERM[1] *refers to the case when only one call is made to* PERM.

2. *There is a set Z in* $C_=P$ *such that* ACC(subexp) $\subseteq$ Ntime$(n^2)^Z$.

Proof. 1. Let M_L and M be the machines from the proof of Theorem 1.1. Note that if M has access to PERM, it can compute $\#M_L(x)$ in time n^9 with just one call to PERM because PERM gives the exact number of accepting paths. The bound n^9 comes from a naïve analysis of Valiant's reduction [27] applied to nondeterministic Turing machines running in linear time.

2. As before, let $M_1, M_2, \ldots,$ be an enumeration of nondeterministic Turing machines running in linear time. Let Z be the set $\{\langle i, x, l\rangle : x \in \{0,1\}^* \text{ and } \#M_i(x) = l\}$. It is not hard to see that Z is in $C_=$P (much like $Y \in$ PP in Theorem 1.1). Let M_L be as above. A nondeterministic machine can compute $\#M_L(x)$ in time n^2 using Z as an oracle. It guesses a value l for $\#M_L(x)$ and asks the appropriate query $\langle i, x, l\rangle$ to Z. □

THEOREM 3.3. ACC $\subsetneq$ $C_=$P.

[2] Let M be a nondeterministic machine that is given input $\langle i, x, l\rangle$. Suppose $t(|x|)$ is the total number of paths of M_i on input x. The computation of M will have $2t(|x|)$ paths; the first $t(|x|)$ of those consist of $t(|x|) - l$ trivially accepting and l trivially rejecting paths, and the other $t(|x|)$ paths will simulate the computation of M_i on x. It is easy to see that $\langle i, x, l\rangle \in Y$ if and only if $\#M_i(x) > l$ if and only if more than half of the paths of M are accepting.

Proof. Corollary 3.2 implies that ACC $\subseteq$ Ntime$(n^2)^Z$ for a set $Z \in$ C$_=$P. Since ACC $\subseteq$ C$_=$P, for the sake of contradiction assume that ACC = C$_=$P. Since co-NP $\subseteq$ C$_=$P and ACC is closed under complement, it follows that ACC = P = NP = C$_=$P. Therefore, Ntime$(n^3)^Z \subseteq$ NP$^Z \subseteq$ NP$^{\text{ACC}}$ = NP$^{\text{P}}$ = NP = ACC $\subseteq$ Ntime$(n^2)^Z$, which contradicts the hierarchy theorem of [15] for nondeterministic time classes. □

THEOREM 3.4. *The permanent function* (PERM) *does not have* ACC(subexp) *circuits.*

Proof. Corollary 3.2 states that ACC(subexp)$\subseteq$ Dtime$(n^9)^{\text{PERM}[1]}$. By the hierarchy theorem of [17], we know that Dtime$(n^9)^{\text{PERM}[1]} \subsetneq$ Dtime$(n^{10})^{\text{PERM}[1]}$. Suppose PERM has ACC(subexp) circuits. Let $L \in$ Dtime$(n^{10})^{\text{PERM}[1]}$ and let M be the oracle machine that accepts L making at most one call to PERM. Let $L' = \{\langle x, z\rangle : M$ accepts x if z is used as the answer to the query made by M to PERM on input x }. Clearly, $L' \in$ P. Similarly, let $L'' = \{\langle x, i\rangle :$ the ith bit of the query by M on input x is 1}. Clearly, $L'' \in$ P as well. A careful reading of Valiant's proof [27] reveals that the membership question for any set in P can be reduced to PERM via uniform AC^0 circuits. (In brief, Valiant's reduction takes an input y to a #P function f, builds a CNF formula ϕ such that $f(y)$ is equal to the number of satisfying assignments to ϕ, and then builds a weighted graph whose permanent is equal to $f(y)$. It has been noted before (e.g., in [19]) that ϕ can be built in uniform AC^0. An inspection of Valiant's graph construction shows that the presence or absence of each edge depends only on the presence of a literal in a given clause, and thus can be computed in uniform AC^0.) Therefore, by the hypothesis, P has ACC(subexp) circuits. Now we can describe an ACC(subexp) circuit family for L. On any input, the query made to PERM is constructed using the circuits for L''; the circuits for PERM are then used to get the answer to the query, and finally, we use the circuits for L' to determine whether $x \in L$. Since L', L'', and PERM all have ACC(subexp) circuit families, the resulting family for L is also in ACC(subexp). Therefore, using the result in Theorem 1.1, $L \in$ Dtime$(n^9)^{\text{PERM}[1]}$, which contradicts the hierarchy theorem of [17] since we started with an arbitrary L in Dtime$(n^{10})^{\text{PERM}[1]}$. □

THEOREM 3.5. PP $\not\subseteq$ ACC(subsubexp).

Proof. We claim that if PP $\subseteq$ ACC(subsubexp), then PrTime(subsubexp) $\subseteq$ ACC(subexp). To see this, note that if $L \in$ PrTime$(t(n))$ for some $t \in$ subsubexp, then $L' \in$ PP, where $L' = \{x10^{t(|x|)} : x \in L\}$. Since by assumption $L' \in$ ACC(subsubexp), one can build subexponential size circuits for L because the composition of two functions in subsubexp is in subexp. This implies that PrTime(subsubexp) $\subseteq$ ACC(subexp).

Note that using the result in Theorem 1.1 and the hierarchy theorem of [17], we know that there are sets in P$^{\text{PP}}$ that are not in ACC(subexp). However, if PP is contained in ACC(subsubexp), then

$$\begin{aligned} \text{P}^{\text{PP}} &\subseteq \text{P}^{\text{ACC(subsubexp)}} \\ &\subseteq \text{P}^{\text{Dtime(subsubexp)}} \\ &\subseteq \text{Dtime(subsubexp)} \\ &\subseteq \text{PrTime(subsubexp)} \\ &\subseteq \text{ACC(subexp)}. \end{aligned}$$

The last step follows from the claim above. Hence, P$^{\text{PP}} \subseteq$ ACC(subexp), which is a contradiction, and the theorem follows. □

Theorem 3.6 is stronger than Theorem 3.5; we include both results to demonstrate the proof technique.

THEOREM 3.6. C$_=$P $\not\subseteq$ ACC(subsubexp).

Proof. We note, as above, that if $\mathrm{C_=P} \subseteq$ ACC(subsubexp), then ACC(subexp) contains $\mathrm{C_=}$Time(subsubexp). We also have that co-$\mathrm{C_=}$Time(subsubexp) $\subseteq$ ACC(subexp) since ACC(subexp) is closed under complement.

Using the result in Corollary 3.2 and the hierarchy theorem of [15] for nondeterministic time, we know that there are sets in $\mathrm{NP^{C_=P}}$ that are not in ACC(subexp). If $\mathrm{C_=P} \subseteq$ ACC(subsubexp), then

$$\begin{aligned}\mathrm{NP^{C_=P}} &\subseteq \mathrm{NP^{ACC(subsubexp)}}\\ &\subseteq \mathrm{NP^{Dtime(subsubexp)}}\\ &\subseteq \mathrm{Ntime(subsubexp)}\\ &\subseteq \mathrm{co\text{-}C_=Time(subsubexp)}\\ &\subseteq \mathrm{ACC(subexp)},\end{aligned}$$

which is a contradiction. □

4. Conclusion. We have shown that uniform ACC circuits of subexponential size cannot compute the permanent function. We have also proved a somewhat weaker bound for some sets in PP. The proofs are based on a simulation of ACC given by Beigel and Tarui in [10]. We have shown how to carry out this simulation in the uniform setting. Some of the obvious open problems are the following.

1. Is uniformity really necessary? Our lower bound proofs work only in the uniform setting. Can we prove a lower bound for the permanent with respect to nonuniform ACC circuits?

2. How powerful are nonuniform ACC circuits? It is still unknown if Ntime $(2^{n^{O(1)}})$ contains sets that are not accepted by nonuniform ACC circuit families.

3. The lower bound that we have for PP is not as strong as the one for permanent. Can it be improved? Even though the permanent function seems to provide more information about the number of accepting paths of NP machines (the permanent gives us all the bits whereas PP only gives us the most significant bit) we still think that a subexponential lower bound can be proved for PP as well.

The work presented here originally started off as the study of sets that are immune to small complexity classes such as $\mathrm{AC^0}$ and ACC. An infinite set L is immune to a complexity class $\mathcal{C}$ if no infinite subset of L is in $\mathcal{C}$. In [1], we show that $\mathrm{P^{PP}}$ contains sets that are immune to ACC, and that nonrelativizing proof techniques suitable for attacking the Dtime vs. Ntime question about exponential time would result from a proof of existence as well as a proof of nonexistence of sets in NP that are immune to $\mathrm{AC^0}$.

It should be emphasized that our results about the complexity of PERM do not rely on any unproven complexity-theoretic assumptions. This is in contrast to other results, such as [14], which proves stronger intractability results about PERM under the hypothesis that the polynomial hierarchy is infinite.

We conclude with a few remarks about some related work that has been done recently. In [16], Green et al. have studied the class of languages that can be recognized in polynomial time with the information about just one bit from the value of a #P function. They define the class MidBitP and show that the classes $\mathrm{MOD}_k\mathrm{P}$, for every k, and the class PH are all low for MidBitP. They have also improved the existing upper bounds for ACC by introducing the idea of MidBit gates. A MidBit gate over w inputs $x_1, x_2, \ldots, x_w$ is a gate that outputs the value of the middle bit in the binary representation of the number $\sum_{i=1}^{w} x_i$. They show that every language in ACC can be accepted by a family of depth-two deterministic circuits of size $2^{(\log n)^c}$ with a MidBit gate at the root and AND gates of fan-in $(\log n)^c$ at the second level.

It would be interesting to see if our techniques can be used in this setting to obtain stronger lower bounds.

Barrington has written an article [5] about the power of circuits of constant depth and $2^{(\log n)^{O(1)}}$ (quasipolynomial) size. The article surveys many results that deal with these kinds of circuits and provides an overview of the new complexity classes that have been introduced. The paper also shows that the notion of uniformity introduced for constant depth circuit families of polynomial size in [6] can be extended to quasipolynomial size as well. It should be noted that this extended notion of uniformity coincides with the one that we have used. Independently of our work, Barrington's paper outlines a proof that shows that the simulation of Beigel and Tarui [10] is uniform according to this new notion of uniformity; thus [5] may be consulted for an alternative approach to proving Theorem 3.1. (The proof in [5] leaves many details to the reader.) In addition, it also shows that the simulation of Green et al. [16] is uniform under this notion as well.

A. Appendix. The appendix is devoted to the proof of Theorem 3.1, which can be regarded as a uniform version of the main theorem of [10]. The definitions, lemmas, and theorems presented in this section all lead up to the proof. Since the proof of Theorem 3.1 is fairly involved, we first start with a very high level outline.

Outline. Since our goal in this section is to prove that the construction of [10] can be done uniformly, it is necessary to prove some preliminary results about uniform constant depth circuits. To that end, we define the notions of "clean" and "nice" circuits, which are circuits that have certain properties that we find essential in presenting our uniformity results. The proof of Theorem 3.1 consists of a number of transformations of a circuit. Without loss of generality, we start out with a "nice" circuit family. After each transformation, we will have a circuit that may not obviously satisfy the "niceness" condition, but at least satisfies the weaker notion of being "clean." We show that this clean circuit can then be transformed into a nice circuit of the same depth, and the process repeats.

The main steps in the transformation are as follows.

1. All the AND and OR gates in the circuits are replaced by constant depth probabilistic subcircuits. This step removes all the OR gates from the circuits and the only remaining AND gates have small fan-in. The circuits are probabilistic but the number of probabilistic bits used in each case is small and is in fact a simple function of the size of C_n.

2. All the MOD gates in the circuit with composite moduli are replaced with equivalent subcircuits so that the resultant circuits consist only of MOD gates with prime moduli.

3. The circuits are now made deterministic by taking separate copies of those for each setting of the probabilistic bits and connecting all outputs to a MAJORITY gate.

4. A general technique is used, showing how nice circuits with small fan-in AND gates can be replaced by equivalent circuits with the same depth, whose outputs are MOD gates.

5. An induction is begun where each step reduces the depth of the circuit. At the beginning of the inductive step, the circuit consists of a symmetric gate on the output level, where the inputs to the symmetric gate are "nice" ACC circuits with MOD$_p$ gates feeding into the symmetric gate. Then, using techniques developed by Toda [26], Yao [30], and Beigel and Tarui [10], we create an equivalent circuit with a new symmetric gate that "absorbs" the level of MOD$_p$ gates; thus the new circuit has smaller depth.

A.1. Nice circuits. In this section, we present a series of "niceness" conditions, and prove that it is no loss of generality to deal only with "nice" circuits.

DEFINITION A.1. *A circuit family $\{C_n\}$ is* well named *if for every n, the name of the output gate of C_n can be computed from n (in binary) in polynomial time (i.e., in $(\log n)^{O(1)}$ time).*

DEFINITION A.2. *A circuit family $\{C_n\}$ is said to have the* strong connection *property if for all n, for every connection $g \rightarrow h$ in C_n, where i is the number such that g is the* ith *input to h*

(assuming lexicographic ordering), it is the case that h can be computed in polynomial time from $\langle n, g, i\rangle$, and additionally, given $\langle n, h, g\rangle$, the number i can be computed in polynomial time. Under the weaker assumption that this condition holds whenever h is an AND *gate then* $\{C_n\}$ *is said to have the* strong connection property for ANDs.

DEFINITION A.3. *A circuit family* $\{C_n\}$ *is said to have* small fan-in AND gates *if for every n, the fan-in of each* AND *gate in C_n is polylogarithmic in the size of C_n.*

DEFINITION A.4. *Let C be a circuit and let P be a path in C from the output gate to an input gate (say t). Let $G_1, G_2, \ldots, G_k$ be the sequence of the types of gates occurring on P so that G_1 is the type of the output gate of C and G_k is the type of the gate that t is connected to. Then the sequence $(G_1, G_2, \ldots, G_k)$ is defined as the* signature *of the path P.*

DEFINITION A.5. *The* compression *of a signature s is the sequence s' that results from applying the following operation as many times as possible to s: replace* "AND, AND" *by* "AND" *and replace* "OR, OR" *by* "OR". *That is, the compression of s contains no two adjacent* ANDs *or* ORs.

DEFINITION A.6. *A circuit family* $\{C_n\}$ *is* clean *if*

1. *It is well named.*
2. *It has the strong connection property for* ANDs.
3. *Every path from an output gate to an input gate in C_n (for every n) has the same signature. (Note that only constant depth circuit families can be clean, since the signature does not depend on n.)*

DEFINITION A.7. *A circuit family* $\{C_n\}$ *of size $s(n)$ is* nice *if it has the following properties.*

1. *It is clean.*
2. *For every n, the fan-in of every gate g in C_n can be computed from g in time* $(\log s(n))^{O(1)}$.
3. *For every n, the depth of a gate g in C_n can be computed from g in time* $(\log s(n))^{O(1)}$.
4. *Each circuit C_n is in tree form (excluding the inputs and negated inputs, which may fan out to many gates at level* 1*).*
5. *It has the strong connection property.*
6. *For all input lengths n, all the* MOD *gates in C_n have the same fan-in.*

Our main lemma in this section is Lemma A.8, which states that any uniform ACC(subexp) circuit family can be transformed into an equivalent nice family.

LEMMA A.8. *Suppose* $\{C_n\}$ *is an ACC*(subexp) *circuit family. Then there exists an equivalent nice family* $\{D_n\}$ *of subexponential size. Furthermore,*

1. *If* $\{C_n\}$ *is clean, then the signature of* $\{D_n\}$ *is the compression of the signature of* $\{C_n\}$.
2. *If* $\{C_n\}$ *is clean and has small fan-in* AND *gates, then* $\{D_n\}$ *has small fan-in* AND *gates.*

The proof of the above lemma follows from a sequence of lemmas that are presented below. The proofs of these lemmas make use of a version of the Alternating Turing Machine (ATM) model of computation. For background on alternation, see [13]. It should be noted that the model that we use here is somewhat different from the one defined in [13]. Some of the lemmas that follow are similar in flavor to the results in [23], in which correspondences between ATMs and uniform circuits were first established; the reader may wish to consult [23].

The following "road map" is intended to explain how the following lemmas combine to prove Lemma A.8.

(i) Lemma A.15: circuit $\mapsto$ ATM.

(ii) Lemma A.16: ATM $\mapsto$ clean ATM.

(iii) Lemma A.17: clean ATM $\mapsto$ nice ATM.
(iv) Lemma A.18: nice ATM $\mapsto$ nice circuits.

The transformations in Lemmas A.15, A.17, and A.18 preserve various properties, such as the property of having small fan-in AND gates.

The existential and universal states in our ATMs behave as usual. Each configuration of an ATM has either zero, one, or two successor configurations (i.e., the fan-out of any node in the computation tree is at most two). We follow the convention that the ATM is always provided the length of the input (in binary) on the work tape as part of its initial configuration on a particular input. This convention has been introduced to simplify the proof.[3] We consider ATMs that access their input only at the leaves. (That is, the only configurations that depend on the input are halting configurations. These are of two types: those that accept if and only if bit i of the input is 1, and those that accept if and only if the complement of bit i is 1 (for some i that is recorded on the address tape). The results in [24] show that this convention can be introduced without loss of generality.)

The MOD states and other aspects of our ATM model are described in the following definitions.

DEFINITION A.9. *For a modulus m, a* MOD$_m$ *configuration* (*say* σ) *is the root of a subtree of associated configurations. This tree is called the* subtree associated with σ *and is represented as T_σ. We say that σ is* accepting *if and only if the number of leaves of T_σ that are accepting is congruent to 0 modulo m. We also use the term* MOD-tree *at times to refer to a subtree associated with a* MOD *configuration.*

DEFINITION A.10. *There is said to be an* alternation *between two configurations σ_1 and σ_2 of an* ATM *if and only if σ_2 follows from σ_1 via one step of the* ATM *and one of the following conditions hold.*

1. *σ_1 is the leaf of a* MOD*-tree, and σ_2 is of type* $\exists$, $\forall$ *or* MOD.
2. *σ_1 is of type $\exists$ and σ_2 is of type $\forall$ or* MOD.
3. *σ_1 is of type $\forall$ and σ_2 is of type $\exists$ or* MOD.

Let T denote the computation tree of an ATM *M on a particular input. The root of the tree is said to have* alternation depth 1. *A node in the tree labeled by configuration σ_2 with parent labeled by configuration σ_1 is defined to have alternation depth one greater than the alternation depth of σ_1 if there is an alternation between σ_1 and σ_2; the alternation depth of σ_2 is equal to that of σ_1 otherwise. The alternation depth of a tree is the maximum alternation depth of all nodes in the tree. The alternation depth of an* ATM *is the maximum alternation depth of all its alternation trees.*

It is necessary for us to define a notion of "clean" ATMs corresponding to our notion of "clean" circuit families. This is accomplished using the following definitions.

DEFINITION A.11. *Let σ and τ be two different configurations of an* ATM. *If τ is reached from σ via a path that contains an alternation only in the step at which τ is reached, then τ is called a* primary descendent *of σ.*

DEFINITION A.12. *For a computation path of an* ATM *on an input, let $C_1, C_2, \dots, C_k$ be the sequence of configurations such that C_1 is the initial configuration, and C_{i+1} is a primary descendent of C_i. The* signature *of the path is the sequence $t_1, t_2, \dots, t_k$ such that if configuration C_i is existential* (*universal,* MOD$_m$), *then $t_i =$* OR (AND, MOD$_m$).

DEFINITION A.13. *An* ATM *is* clean *if every path in every alternation tree of the* ATM *on every input has the same signature.* (*Note that only* ATMs *making $O(1)$ alternations can be clean.*)

[3] It is worthwhile to note that the input length can be computed deterministically in logarithmic time (see [12]) but this requires multiple accesses to the input along a given computation path.

DEFINITION A.14. *An* ATM *running in time $t(n)$ has* well-behaved universal configurations *if each universal configuration has $t(n)^{O(1)}$ primary descendents, and given a universal configuration σ and a number i, the* ith *primary descendent of σ can be computed in time $t(n)^{O(1)}$.*

LEMMA A.15. *Let $L \subseteq \{0, 1\}^*$, let s be a function in subexp, and let L be accepted by a uniform family $\{C_n\}$ of depth d circuits ($d = O(1)$) of type* ACC$(s(n))$. *Then L is accepted by an* ATM *M that has existential* ($\exists$), *universal* ($\forall$), *and* MOD *states (for the same set of moduli) that runs in time* $(\log s(n))^{O(1)}$ *and has alternation depth $a = O(1)$. Moreover,*

1. *If $\{C_n\}$ is clean, then the signature of M is the compression of the signature of $\{C_n\}$.*
2. *If $\{C_n\}$ is clean and has small fan-in* AND *gates, then M has well-behaved universal configurations.*

Proof. Suppose L is accepted by a uniform circuit family $\{C_n\}$. Let U be the uniformity machine for $\{C_n\}$. M behaves as follows.

```
On input $x$, (with $n = |x|$ on the work tape)
    ($\exists$) guess the name of the output gate (say $g$) of $C_n$ of length $(\log s(n))^{O(1)}$.
    Use $U$ to verify that $g$ is indeed a gate in $C_n$ (i.e., check that $U$
    accepts $\langle n, g, g\rangle$).
    ($\forall$) gates $h$ of length $(\log s(n))^{O(1)}$ check that $U$ rejects $\langle n, h, g\rangle$
    (so that $g$ is indeed the output gate).
    Call Eval($g$).

Eval($g$)
    If $g$ is an OR gate then
        ($\exists$) guess $h$ (an input to $g$) of length $(\log s(n))^{O(1)}$.
        If $U$ rejects $\langle n, g, h\rangle$ then reject
        else call Eval($h$).
    If $g$ is an AND gate then
        ($\forall$) guess $h$ (an input to $g$) of length $(\log s(n))^{O(1)}$.
        If $U$ rejects $\langle n, g, h\rangle$ then accept
        else call Eval($h$).
    If $g$ is a MOD$_m$ gate then
        Switch to a MOD$_m$ configuration.
        ($\exists$) guess $h$ (an input to $g$) of length $(\log s(n))^{O(1)}$.
            (This is the subtree associated with the MOD$_m$ configuration.)
        If $U$ rejects $\langle n, g, h\rangle$ then reject
        else call Eval($h$).
    If $g$ is a constant gate then
        Accept iff $g$ is the constant 1 gate.
    If $g$ is an input gate then
        Accept iff the corresponding input is 1.
end (Eval).
```

It is fairly obvious that M accepts x if and only if $C_{|x|}$ evaluates to 1 on input x. Note that M consults its input only at the leaves. It is clear that M makes a constant number of alternations and runs in time $(\log s(n))^{O(1)}$. Indeed, the most time-consuming part of the simulation involves running the uniformity machine U. The constructibility conditions on s are also essential here.

If $\{C_n\}$ is clean, then it is well named, and thus the name of the output gate g can be computed deterministically. Also, since all circuits in $\{C_n\}$ have the same signature, each output gate is of the same type. If the type of the output gate is MOD$_m$, for instance, we can avoid the extra two levels of alternation caused by the processing outside the routine Eval by starting out in a MOD_m configuration, deterministically computing g, existentially guessing h, rejecting if U rejects $\langle n, g, h\rangle$, and otherwise proceeding to Eval(h). The case when the output gate is an AND or OR gate is handled similarly. Thus if $\{C_n\}$ is clean, the signature of M can easily be seen to be the compression of the signature of $\{C_n\}$.

If $\{C_n\}$ has the strong connection property for ANDs and all AND gates have fan-in $(\log s(n))^c$, then instead of universally guessing an input h to an AND gate g, universally guess a number $i \leq (\log s(n))^c$ and deterministically compute the name of the gate h. If M is simulating r consecutive levels of AND gates of C_n, it is not hard to see that each universal configuration of M will have at most $(\log s(n))^{rc}$ primary descendents, and M thus has well-behaved universal configurations.

The other claims of the lemma are easily seen to hold. □

Lemma A.15 does not guarantee the existence of a clean ATM accepting a language when the given circuit family is not already clean. This is remedied by the following lemma.

LEMMA A.16. *If L is accepted by an* ATM *M that makes a constant number of alternations between* $\mathrm{MOD}_{m_1}, \mathrm{MOD}_{m_2}, \ldots, \mathrm{MOD}_{m_k}, \exists$, *and* $\forall$ *states and runs in time $t(n)$ then L is accepted by a* clean ATM *N running in $O(t(n))$ time with a constant number of alternations between* $\mathrm{MOD}_{m_1}, \mathrm{MOD}_{m_2}, \ldots, \mathrm{MOD}_{m_k}, \exists$, *and* $\forall$ *states.*

Proof. Suppose M makes at most λ alternations on any input. Then N has the sequence $\mathrm{MOD}_{m_1}, \mathrm{MOD}_{m_2}, \ldots, \mathrm{MOD}_{m_k}, \exists, \forall$ (repeated λ times) hardwired into its finite control. N simply simulates M but follows the signature in its finite control. If N is trying to simulate a move that does not involve an alternation or that involves moving into a state that has the same type as the next type in its signature, it simply proceeds with the simulation and behaves exactly as M does. In the case of a type mismatch, N behaves as follows.

1. If the next state in the sequence is universal (existential), then it executes a one-ary universal (existential) branch and continues the simulation. (Note that amounts to adding a "dummy" node in the alternating tree.)

2. If the next state in the sequence is a MOD_m state for some m, then it executes a m-way MOD_m branch. It trivially accepts along $m-1$ of these branches (following the signature) and continues the simulation on the remaining one.

It is fairly obvious that N is clean and for every x, N accepts x if and only if M accepts x. □

Our main reason for introducing the ATM model is the following lemma, which enables us to construct "nice" circuits.

LEMMA A.17. *Let $2^{t(n)}$ be constructible, and suppose L is accepted by a clean* ATM *M running in time $t(n)$. Then L is accepted by a clean* ATM *N with the same signature (and hence with the same alternation depth) that runs in time $t(n)^{O(1)}$ and also has the following properties.*

1. *Given a configuration σ on an input of length n, the number of primary descendents of σ is computable from σ in time $t(n)^{O(1)}$.*

2. *Given a configuration σ on an input of length n, the alternation depth of σ is computable from σ in time $t(n)^{O(1)}$.*

3. *Given a configuration σ and number $i \leq$ the number of primary descendents of σ, the* ith *primary descendent of σ (under the usual lexicographic ordering) can be computed in time $t(n)^{O(1)}$ from the encoding of σ.*

4. *All the* MOD *configurations in the computation tree have the same number of primary descendents.*

5. *If M has well-behaved universal configurations, then N also has this property.*

Proof. The proof is very similar to the proof of Lemma A.15. We will need to settle on some convention of encoding paths in an alternation tree, with the property that for every path of length $i \leq t(n)$ in an alternation tree, there is exactly one string of length $2 \cdot t(n)$ that denotes that path. This can easily be accomplished by encoding sequences in {left, right, stop}* in the obvious way; note that there will be many strings that do not correspond to any path in the tree. Similarly, pick some encoding of configurations of M so that any configuration σ of M on inputs of length n has a unique encoding using $c \cdot t(n)$ bits (for some constant c). Again, many strings of length $c \cdot t(n)$ will not correspond to any configuration of M.

N will begin its computation on x by first computing (deterministically) $t(n)$. (Note that this can be done regardless of whether the initial configuration of N is existential, universal, or MOD_m.) If M has well-behaved universal configurations, then let $I(n) = b \log t(n)$ for some constant b; otherwise let $I(n) = t(n)$. (Note that the decision of which value to use for $I(n)$ can be encoded in the finite control of N.) Then N will set σ to be equal to the initial configuration of M, and run the routine Eval(σ).

```
Eval($\sigma$)
    If $\sigma$ is an existential or $\mathrm{MOD}_m$ nonhalting configuration then
        existentially guess strings $w$ of length $2 \cdot t(n)$ and $\tau$ of length $c \cdot t(n)$.
        If $w$ encodes a path from $\sigma$ to configuration $\tau$, where the last step
        in the path involves an alternation (so $\tau$ is a primary descendent of $\sigma$)
            then enter a configuration of the same type as $\tau$ and call Eval($\tau$)
            else call Trivial(reject)
    If $\sigma$ is a universal nonhalting configuration then there are two cases:
        (1) We are simulating a machine $M$ with well-behaved universal
        configurations.
            Universally guess $i \leq b \log t(n)$. Let $\tau$ be the $i$th primary descendent
            of $\sigma$. Call Eval($\tau$).
            (If there is no such $\tau$, then call Trivial(accept).)
        (2) Otherwise.
            Universally guess strings $w$ of length $2 \cdot t(n)$ and $\tau$ of length $c \cdot t(n)$.
            If $w$ encodes a path from $\sigma$ to configuration $\tau$, where the last step in
            the path involves an alternation (so $\tau$ is a primary descendent of $\sigma$)
                then enter a configuration of the same type as $\tau$ and call Eval($\tau$)
                else call Trivial(accept)
    If $\sigma$ is a halting configuration, then
        Accept iff $\sigma$ is accepting. (Note that this may involve accessing the input,
        if $\sigma$ depends on input bit $i$ for some $i$.)
end (Eval).
```

The routine Trivial(d) (for $d \in$ {*accept, reject*}) used in the routine Eval is a simple routine that depends on the number of alternations executed thus far by N in its simulation of M. If the next step in the signature calls for computation of type $\exists$ ($\forall$), then N executes a $2^{(c+2)t(n)}$-way existential (universal) branch, all of which in turn call Trivial(d). If the next step in the signature calls for computation of type MOD_m, and $d =$ *accept* (respectively, $d =$ *reject*), then N enters a MOD_m state, executes a $2^{(c+2)t(n)}$-way existential branch all of which call Trivial(*reject*) (respectively, the first of which calls Trivial(*accept*) and the rest of which call Trivial(*reject*)).

Machine N uses its worktape to record the path in the alternation tree leading to the current configuration. Thus no configuration of N will label two distinct nodes in the alternation tree.

Let us now verify the various properties claimed in the statement of the lemma.

Given σ a configuration of N, one can trace through the path in the alternation tree leading to σ (since this information is recorded in σ). This allows one to compute the alternation depth of σ, as well as to find the configuration τ reached after the last alternation on this path, and compute the number j of moves with fan-out 2 that have occurred along this path between τ and σ. If σ is an $\exists$ or MOD configuration, the number of primary descendents of σ is $2^{(c+2)t(n)-j}$. If σ is a $\forall$ configuration, then this number is $2^{(c+2)I(n)-j}$. In the particular case that σ is a MOD configuration, note that $j = 0$; thus all the MOD configurations have the same number of primary descendents. Furthermore, if σ' is the ith primary descendent of σ, then the number i is encoded in $(c+2)t(n) - j$ consecutive positions in the bit string encoding the path leading to σ', thus enabling us to compute σ' given $\langle n, \sigma, i\rangle$. The other claims of the lemma are easy to verify. □

LEMMA A.18. *Let L be accepted by an* ATM *M satisfying the conditions of Lemma* A.17, *running in time $t(n)$. Then there is a nice* ACC($2^{O(t(n))}$) *circuit family $\{C_n\}$ accepting L, such that the signature of $\{C_n\}$ is the same as the signature of M. Furthermore, if M has well-behaved universal configurations, then $\{C_n\}$ has small fan-in* AND *gates.*

Proof. The proof of this lemma is by a standard simulation of the sort introduced by [23]. The output gate of C_n will be labeled by the initial configuration of N on an input of length n (i.e., with n recorded on the worktape, as per the conventions of our ATM model). The inputs to any gate labeled with configuration σ will be all of the primary descendents of σ. Universal configurations are represented by AND gates, existential configurations by OR gates, and MOD$_m$ configurations by MOD$_m$ gates. Halting configurations are either constant 1 or 0 gates (if they do not depend on the input) or are input gates connected to (negated) input i (if they access input bit i).

It is easily verified that $\{C_n\}$ satisfies the requirements of the lemma. □

Proof of Lemma A.8. This follows immediately from Lemmas A.15, A.16, A.17, and A.18. □

A.2. Transformations on circuits. In this section we prove a general lemma, enabling us to replace gates by equivalent subcircuits. (This, of course, is completely obvious in the nonuniform setting. However, in the uniform setting, where we need the additional property that the fan-in of a circuit be easy to compute, we need all of the "niceness" conditions guaranteed by the preceding section.) Then we apply this lemma to remove OR gates, large fan-in AND gates, and composite MOD gates from ACC circuits.

DEFINITION A.19. *Suppose G is a particular type of gate. Let $\{G_r\}$ denote a family of gates such that the gate G_r is of type G and takes r inputs. Let $\{E_r\}$ be a family of subcircuits so that for every r, E_r takes r inputs and has a single output. We will assume an ordering on the inputs of G_r and E_r and let $x_1, x_2, \ldots, x_r$ denote the inputs to G_r and $y_1, y_2, \ldots, y_r$ denote the inputs to E_r. We say that E_r* replaces *G_r in a circuit C if we remove G_r from C and put E_r in its place in such a way that the output gate of E_r is connected to exactly the gates that G_r is connected to in C, and the inputs to G_r now become inputs to E_r so that for all i, $1 \leq i \leq r$, $x_i = y_i$. In general, when we talk about replacing a gate type G in a circuit, we will mean that all occurrences of G in the circuit are replaced simultaneously.*

LEMMA A.20. *Suppose $\{C_n\}$ and $\{E_r\}$ are nice circuit families. Let G denote a particular type of gate used in the circuits of $\{C_n\}$. For every n, let $\{D_n\}$ denote the circuit family obtained by replacing* all *occurrences of G (of the form G_r for various r) by a subcircuit E_r. Then the circuit family $\{D_n\}$ is clean.*

Proof. It is clear that $\{D_n\}$ is well named and that every path from output to input has the same signature. Thus we need only show that $\{D_n\}$ is uniform and has the strong connection property.

Consider the transformation from C_n to D_n for a particular value of n. Let g (with fan-in r) be an instance of G in C_n and let E_r be the subcircuit that replaces g. Suppose E_r consists of the gates $h_0, h_1, \ldots, h_s$ where h_0 is the output gate of E_r. The names of these gates in the new circuit D_n will be $g\#h_i$, for $0 \leq i \leq s$. Let L_0 be the direct connection language for $\{C_n\}$, L_1 for $\{E_r\}$, and L for $\{D_n\}$. Similarly, let f_0, f_1, and f be the functions that, given $\langle n, g, h\rangle$, compute the number i such that h is the ith input to g in C_n, E_n, and D_n, respectively, and let f_0', f_1', and f' be the related functions that compute h given $\langle n, g, i\rangle$. To accept L, and to compute f, one has to consider the following cases.

1. Strings of the form $\langle n, g, h\rangle$ where neither g nor h are of type G. In this case $\langle n, g, h\rangle \in L \iff \langle n, g, h\rangle \in L_0$. Also, $f(n, g, h) = f_0(n, g, h)$.
2. Strings of the form $\langle n, g\#h, g\#h\rangle$. This is done as follows.
   a. Check that $\langle n, g, g\rangle \in L_0$ and that g has type G.
   b. Compute the fan-in r of g from the description of g.
   c. Check that $\langle r, h, h\rangle \in L_1$.
3. Strings of the form $\langle n, g\#h, g\#h'\rangle$ with $h \neq h'$. This is done as follows.
   a. Check that $\langle n, g, g\rangle \in L_0$ and that g has type G.
   b. Compute the fan-in r of g from the description of g.
   c. Check that $\langle r, h, h'\rangle \in L_1$.
   d. Note that $f(n, g\#h, g\#h') = f_1(n, g\#h, g\#h')$.
4. Strings of the form $\langle n, g', g\#h_0\rangle$ where G is not the type of g'. This is done as follows.
   a. Check that $\langle n, g', g'\rangle$ and $\langle n, g, g\rangle \in L_0$, and that g has type G.
   b. Compute the fan-in r of g from the description of g.
   c. Check that $\langle r, h_0, h_0\rangle \in L_1$ (h_0 is the output gate of E_r).
   d. Check that $\langle n, g', g\rangle \in L_0$.
   e. Note that $f(n, g', g\#h_0) = f_0(n, g', g)$.
5. Strings of the form $\langle n, g\#h, g'\rangle$, where G is not the type of g'. This is done as follows.
   a. Check that $\langle n, g, g\rangle$ and $\langle n, g', g'\rangle$ are in L_0, where g has type G.
   b. Check that $\langle n, g, g'\rangle \in L_0$.
   c. Compute the fan-in r of g from its description.
   d. Check that $\langle r, h, h\rangle \in L_1$.
   e. Compute the number j such that g' is the jth input to g (using the strong connection property).
   f. Let $x_1, x_2, \ldots, x_r$ denote the inputs to E_r. Check that $\langle r, h, x_j\rangle \in L_1$.
   g. Note that $f(n, g\#h, g') = j$.
6. Strings of the form $\langle n, g'\#h, g\#h_0\rangle$ where both g and g' are of type G. This is done as follows.
   a. Check that $\langle n, g, g\rangle$ and $\langle n, g', g'\rangle$ are in L_0.
   b. Compute the fan-in r of g and check that h_0 is the output gate of E_r.
   c. Compute the fan-in r' of g' and check that $\langle r', h, h\rangle \in L_1$.
   d. As in the previous case, check that g is the jth input to g' and that h is connected to input j of $E_{r'}$.

It is not hard to see that all the above cases can be checked within the required time bounds and hence the new circuit family $\{D_n\}$ is uniform as well.

A similar analysis shows that f' can also be computed in time polynomial in the length of its input, and thus $\{D_n\}$ has the strong connection property. □

LEMMA A.21. *Suppose L is accepted by an* ACC(subexp) *family* $\{C_n\}$. *Then L is accepted by a nice probabilistic* ACC(subexp) *circuit family* $\{D_n\}$[4] *such that*

1. $\{D_n\}$ *has no* OR *gates and no* MOD$_m$ *gates for composite modulus m.*
2. $\{D_n\}$ *has small fan-in* AND *gates.*
3. *For every n, the number of probabilistic inputs in D_n is polylogarithmic in the size of D_n.*

[4] Note that the circuits in $\{D_n\}$ are probabilistic and hence also have probabilistic inputs, but when we say D_n we mean the circuit that has n nonprobabilistic inputs. We follow this convention because the proof shows how to convert C_n into D_n for every n.

Proof. By Lemma A.8, we may assume that $\{C_n\}$ is nice.

Let n be fixed. The transformation $C_n \rightarrow D_n$ is carried out by performing the following sequence of steps.

1. By a construction in the proof of Lemma 13 in [2], one can replace the AND and OR gates in the circuit by nice depth-six probabilistic circuits with MOD_2 gates and small fan-in AND gates. (This construction is based on an idea of Valiant and Vazirani in [28]; similar constructions may be found in work by Toda [26] and Kannan, et al. [20].) The size of the new circuit is only polynomially more than that of the old one. If the AND or OR gate being replaced has r inputs, then the probabilistic circuit that replaces it uses $O((\log r)^3)$ random bits. The probabilistic circuits have the property that the probability of error for the whole circuit is less than $\frac{1}{4}$ after all the AND and OR gates have been replaced by these probabilistic circuits, even when the same $O((\log s(n))^3)$ probabilistic bits are fed into the probabilistic inputs of each of these subcircuits. (Even though Allender and Hertrampf discuss space uniformity, it is clear from their proof that the probabilistic circuits are uniform even in our sense of uniformity.) We can now apply Lemma A.20 to prove that the new circuit family (now probabilistic) is clean, and thus by Lemma A.8 there is an equivalent nice circuit family $\{C_n^1\}$. Note that $\{C_n^1\}$ has small fan-in AND gates and has no OR gates.

2. Suppose the circuit C_n^1 contains a MOD_m gate (call it G) where m is composite. Let

$$m = \prod_{i=1}^{t} a_i^{e_i},$$

where $a_i < a_{i+1}$ for all i such that $1 \le i \le t-1$ and for all i, $1 \le i \le t$, a_i is prime and $e_i > 0$. We use the elementary fact that $x \equiv 0 \pmod{m} \Longleftrightarrow x \equiv 0 \pmod{a_i^{e_i}}$ for all i, $1 \le i \le t$ to change G into an AND of $\mathrm{MOD}_{a_i^{e_i}}$'s. Suppose G has r inputs. For each m, the subcircuit family $\{E_r\}$ that replaces the MOD_m gates is easily seen to be nice. The subcircuit E_r has depth two, with an AND gate at the top level and $\mathrm{MOD}_{a_i^{e_i}}$ gates at the bottom level for all i, $1 \le i \le t$. The top level AND gate has fan-in t and is connected to each of the MOD gates at the second level. All the MOD gates at the second level have fan-in r and are all connected to each of the inputs of the gate G. We can now use the result of Lemma A.20 to conclude that the new circuit family is clean. Moreover, the family contains MOD gates with only prime power moduli. The subcircuit E_r, other than its input gates, contains only a constant number of gates that depend on m. Since the original circuit family $\{C_n\}$ only has MOD gates for a fixed set of moduli, the size of the circuit after this step goes up by at most a constant factor. We again use Lemma A.8 to get a nice family of probabilistic circuits $\{C_n^2\}$ that has no composite MOD gates, no OR gates, and small fan-in AND gates.

3. This step eliminates all the MOD gates that have moduli of the form p^e where p is prime and $e > 1$ from C_n^2 and replaces them with subcircuits consisting of AND and MOD_p gates. Suppose C_n^2 contains a MOD_{p^e} gate G for some prime p and $e > 1$. This step uses the following result (for references, see, e.g., [10]): x is congruent to 0 (mod p^e) if and only if each of x, $\binom{x}{p}$, $\binom{x}{p^2}$, $\ldots$, $\binom{x}{p^{e-1}}$ are congruent to 0 (mod p). If $x = \sum_{i=1}^{r} x_i$, then for $1 \le j \le e-1$

$$\binom{x}{p^j} = \binom{x_1+x_2+\cdots+x_r}{p^j} = \sum_{S \subseteq \{1,2,\ldots,r\}, |S|=p^j} \bigwedge_{k \in S} x_k.$$

The subcircuit that replaces G is a three level subcircuit that is described as follows.

(a) The top level consists of an AND gate that has fan-in e.

(b) The middle level consists of e MOD_p gates and each of those is connected to the top level AND gate. For all j, $0 \le j \le e-1$, the jth MOD_p gate outputs 1 if and only if

$\binom{x}{p^j} \equiv 0 \pmod{p}$. If G has fan-in r, then the jth MOD_p gate at this level has fan-in $\binom{r}{p^j}$, one corresponding to each subset of the inputs of size p^j.

(c) The bottom level consists of $\sum_{j=1}^{e-1} \binom{r}{p^j}$ AND gates divided into $e - 1$ groups. For all j, $1 \leq j \leq e - 1$, the jth group consists of $\binom{r}{p^j}$ AND gates, one corresponding to each subset of the inputs of size p^j. The inputs to a particular gate in the jth group are the p^j inputs in the subset to which it corresponds and it fans out to the jth MOD_p gate at the middle level. Note that all the AND gates introduced here have constant fan-in.

It is not hard to see that the subcircuit family described above is nice for every prime power p^e. (The only point that is not completely obvious is checking that the strong connection property holds, but this is straightforward to verify.) Using Lemma A.20 we can now replace every MOD gate with a prime power modulus with a subcircuit that consists only of MOD gates with prime moduli and we now get a clean circuit family that only has AND gates and MOD gates with prime moduli. The size of the subcircuit that replaces a MOD_{p^e} gate is $O(\sum_{j=1}^{e-1} \binom{r}{p^j})$ which is a polynomial in the size of the circuit C_n^2, and thus the new circuit family also has subexponential size. The proof is completed by appeal to Lemma A.8. □

A.3. Circuits with symmetric gates. In order to prove Theorem 3.1 we need to show how to convert an ACC(subexp) circuit family into a uniform deterministic depth two-circuit family that has a symmetric gate at the root and AND gates of small fan-in at the bottom level. So far we have only dealt with ACC type circuits. To proceed, we need to deal with circuits that have arbitrary symmetric gates (but only at the root). However, since most of the results proved so far only deal with uniform ACC type circuits, we need to expand the notion of uniformity a little so that the results can also be used with circuits that have arbitrary symmetric gates at the root. The new notion of uniformity is explained in the following definition.

DEFINITION A.22. *Let $f : \mathbf{N} \to \mathbf{N}$ be a function. Then $\{C_{n,t} : n \in \mathbf{N}, 1 \leq t \leq f(n)\}$ is a* uniform family of ACC sequences *if there is a constant d and a finite set S such that for all n and for all t, $C_{n,t}$ is a circuit of depth d taking inputs from the set $\{x_1, x_2, \ldots, x_n\}$ and having* AND, OR, *and* MOD_m *gates (for $m \in S$) and the direct connection language defined as $\{\langle n, t, g_1, g_2\rangle : g_1 = g_2$ and g_1 is a gate in $C_{n,t}$ or $g_1 \neq g_2$ and g_2 is an input to g_1 in $C_{n,t}\}$ can be recognized in polynomial time. A uniform family of* ACC *sequences $\{C_{n,t} : n \in \mathbf{N}, 1 \leq t \leq f(n)\}$ together with a function* SYM : $\mathbf{N} \times \mathbf{N} \to \{0, 1\}$, *defines a uniform* SYMACC *circuit family $\{D_n\}$ such that for every n,*

1. D_n is a circuit with a symmetric gate at the output level that computes SYM(n, i) *where i is the number of its inputs that evaluate to* 1.

2. The symmetric gate has fan-in $f(n)$ and the output gates of $C_{n,t}$, $1 \leq t \leq f(n)$, are connected to it.

3. Given n and i, $f(n)$ and SYM(n, i) *can be computed in time polylogarithmic in the size of D_n.*

Note that the results proved so far also hold with this new notion of uniformity. In particular, letting $f(n) = 1$ for all n and letting SYM be the identity function reduces this to the old notion of uniformity. Also, we will use the fact that Lemma A.8 also holds in this new setting. That is, given a uniform *clean* family of ACC sequences, there is an equivalent *nice* family of ACC sequences with the same signature and of approximately the same size. (In proving the analog of Lemma A.8 in this new setting, the index t of circuit $C_{n,t}$ would be provided to the ATM as an additional parameter on the worktape, along with n.)

LEMMA A.23. *Let L be accepted by an* ACC(subexp) *circuit family $\{C_n\}$. Then there is a constructible subexponential function s and there is a constant c such that L is accepted by a deterministic circuit family $\{D_n\}$ where for every n, D_n has a* MAJORITY *gate at the root, connected to the output gates of $C_{n,t}$, $1 \leq t \leq 2^{(\log s(n))^c}$ where $\{C_{n,t} : n \in \mathbf{N},$

$1 \le t \le 2^{(\log s(n))^c}\}$ *is a uniform family of* ACC *sequences with small fan-in* AND *gates, no* OR *gates, and no* MOD_m *gates for composite* m.

Proof. By Lemma A.21, if L is accepted by an ACC(subexp) circuit family, then L is accepted by a nice ACC(subexp) family of *probabilistic* circuits with small fan-in AND gates, no OR gates, and no MOD_m gates for composite m, using at most $(\log s(n))^c$ probabilistic bits (for some constant c), where $s(n)$ bounds the size of C_n.

Now construct the sequence of circuits $\{C_{n,t}\}$ where t is a bit string of length $(\log s(n))^c$. The gates in $\{C_{n,t}\}$ will have names of the form $\langle t, g\rangle$ where g is a gate in C_n, and the connections among all gates are the same, except that if gate g in C_n is connected to probabilistic bit number j, then gate $\langle t, g\rangle$ will be connected to the jth bit of t. (i.e., the new circuit sequence consists of identical copies of C_n, with particular choices of probabilistic bits hardwired in.)

Let D_n consist of a MAJORITY gate with inputs from the various $C_{n,t}$. It is clear that the new circuit accepts the same language as $\{C_n\}$. The size of D_n is $O(s(n)2^{(\log s(n))^c})$, which is subexponential. It is immediate that the other required properties also hold. □

The following lemma shows how one can in effect "push" an AND gate below a level of MOD gates (much as multiplication distributes over addition).

LEMMA A.24. *Let* $\{C_{n,t}\}$ *be a nice family of* ACC *sequences of subexponential size, having small fan-in* AND *gates, no* OR *gates, and no* MOD_m *gates where m is composite, where the output gate of each circuit is an* AND *gate, and the inputs to that* AND *gate are* MOD_p *gates. Then there is an equivalent nice sequence* $\{D_{n,t}\}$ *with the same depth, also of subexponential size with small fan-in* AND *gates, no* OR *gates, and no* MOD_m *gates where m is composite, where the output gate of each circuit is a* MOD_p *gate, and the inputs to that* MOD_p *gate are* AND *gates.*

Proof. Our proof again follows the outline given in [10] (see also [2], [20]), where we must be careful to see that the transformation can be done uniformly.

Suppose G is an AND gate (the output gate of some $C_{n,t}$ that has r MOD_p gates $G_1, G_2, \dots, G_r$ as inputs). Note that r is polylogarithmic in $s(n)$, where $s(n)$ bounds the size of $C_{n,t}$. Since the sequence $C_{n,t}$ is nice, all the MOD_p gates $G_1, G_2, \dots, G_r$ have the same fan-in. Let this fan-in be denoted by n_0 and let $\{x_{ij}\}$, $1 \le j \le n_0$ denote the set of inputs to G_i. Finally, let $x_i = \sum_{1\le j\le n_0} x_{ij}$. Consider the AND of $G_1, G_2, \dots, G_r$. By Fermat's Little Theorem, for $1 \le i \le r$,

$$1 - x_i{}^{p-1} \equiv \begin{cases} 0 \pmod p & \text{if } x_i \not\equiv 0 \pmod p, \\ 1 \pmod p & \text{otherwise.} \end{cases}$$

Therefore,

$$\bigwedge_{i=1}^{r}[x_i \equiv 0 \pmod p] \Longleftrightarrow 1 - \prod_{i=1}^{r}(1 - x_i{}^{p-1}) \equiv 0 \pmod p.$$

Note that $1 - \prod_{i=1}^{r}(1 - x_i{}^{p-1})$ is a polynomial of degree $r(p-1)$ in the variables x_{ij}, $1 \le i \le r$, $1 \le j \le n_0$. Let $[r]$ denote the set $\{1, 2, \dots, r\}$.

$$\begin{aligned} 1 - \prod_{i=1}^{r}(1 - x_i{}^{p-1}) &= 1 - \left(\prod_{i=1}^{r}\left(1 - \left(\sum_{j=1}^{n_0} x_{ij}\right)^{p-1}\right)\right) \\ &= \sum_{k=1}^{r} \sum_{I\subseteq[r],|I|=k} (-1)^{k-1} \prod_{i\in I}\left(\sum_{j=1}^{n_0} x_{ij}\right)^{p-1} \end{aligned}$$

$$= \sum_{k=1}^{r}(-1)^{k-1} \sum_{I\subseteq[r],|I|=k} \prod_{i\in I} \left(\sum_{j=1}^{n_0} x_{ij}\right)^{p-1}$$

$$= \sum_{k=1}^{r}(-1)^{k-1} \sum_{I\subseteq[r],|I|=k} \prod_{i\in I} \sum_{J_i=\langle j_{i,1},j_{i,2},\ldots,j_{i,p-1}\rangle\in[n_0]^{p-1}} \prod_{l=1}^{p-1} x_{i j_{i,l}}$$

$$= \sum_{k=1}^{r}(-1)^{k-1} \sum_{I\subseteq[r],I=\{i_1,i_2,\ldots,i_k\}} \sum_{J_{i_1},J_{i_2},\ldots,J_{i_{k}k}} \prod_{s=1}^{k}\prod_{l=1}^{p-1} x_{i_s j_{i_s,l}} \quad (*).$$

This expression can be realized by a MOD_p gate (call it g) with AND gates of fan-in at most $r(p-1)$ as inputs. Since r is $(\log s(n))^{O(1)}$, the fan-in of these AND gates is also polylogarithmic in $s(n)$. The only things we need to take care of are the negative coefficients in the above expression. That is done by multiplying[5] the negative coefficients by $(1-p)$. The expression is changed slightly and the term $(-1)^{k-1}$ is replaced by c_k where $c_k = 1$ if k is even and $c_k = p-1$ if k is odd. Now we interpret scalar multiplication as repeated addition and the multiplication of variables is realized by AND gates. From the expression $(*)$, it is not hard to see that the number of AND gates that are input to the new MOD_p gate g is $\sum_{k=1}^{r} c_k\binom{r}{k}(n_0^{p-1})^k$. Note that since r is polylogarithmic in $s(n)$, this expression (i.e., the fan-in of the new MOD gate) can be computed in time $(\log s(n))^{O(1)}$ from $\langle G, G_1, \ldots, G_r\rangle$.

To show that this step can be done uniformly, we must show how the new gates created in this step should be named so that the direct connection language of the new circuit family can be recognized within the required time bound. The name of the new MOD_p gate is $g = \langle G\#\langle G_1, G_2, \ldots, G_r\rangle, \mathrm{MOD}_p\rangle$. Looking at the expression $(*)$, it is clear that a typical AND gate has $k(p-1)$ inputs where $1 \le k \le r$. The $k(p-1)$ inputs can be divided up into k groups of size $(p-1)$ each. Every group represents a distinct gate in the set $\{G_1, G_2, \ldots, G_r\}$. The $(p-1)$ inputs in a particular group (representing say G_i) are simply some of the input gates to G_i (with repetitions allowed) in $C_{n,t}$. Depending on the value of c_k, such an AND gate either appears once or $(p-1)$ times. The name of such an AND gate is $\langle G\#\langle\langle H_1\#L_1\rangle, \langle H_2\#L_2\rangle, \ldots, \langle H_k\#L_k\rangle\rangle\#m, \mathrm{AND}\rangle$ where $H_1, H_2, \ldots, H_k$ are distinct gates from the set $\{G_1, G_2, \ldots, G_r\}$ and each L_i, $1 \le i \le k$ is a list of $(p-1)$ of the gates that are input to H_i in the original circuit. Note that L_i is allowed to have repetitions. The number m is either 0 (indicating only one copy of the gate; this will be the case if k is even) or between 1 and $(p-1)$ and is used for indexing the $(p-1)$ different copies.

We now show how to recognize the direct connection language for the new circuit family that we get after applying this transformation. Let L_0 be the direct connection language before the step and L the one after the step. Note that the strings in L conform to the naming scheme discussed above. The following cases must be considered.

1. Let g be a new[6] gate. To check if $\langle n, t, g, g\rangle \in L$, we have the following two subcases.
   (a) g is a new MOD_p gate of the form $\langle G\#\langle G_1, G_2, \ldots, G_r\rangle, \mathrm{MOD}_p\rangle$. We do the following:
      i. Check that G is the output gate of $C_{n,t}$. (This can be done because the circuits are well-named.)
      ii. Check that $\langle n, t, G, G_i\rangle \in L_0$ for all i, $1 \le i \le r$, where r is the fan-in of G. (Recall that r can be computed from G, by one of the niceness properties.)

[5] Note that this does not change the value of the expression mod p.

[6] The word "new" will hereafter be used to refer to gates that were created in the current step.

(b) g is a new AND gate of the form

$$\langle G\#\langle\langle H_1\#L_1\rangle, \langle H_2\#L_2\rangle, \ldots, \langle H_k\#L_k\rangle\rangle\#m, \text{AND}\rangle.$$

We do the following:

i. Check that G is the output gate of $C_{n,t}$.
ii. Verify that $H_1, H_2, \ldots, H_k$ are all distinct.
iii. Check that for all i, $1 \leq i \leq k$, $\langle n, t, G, H_i\rangle \in L_0$.
iv. Check that m has the right value based on the parity of k.
v. For all i, $1 \leq i \leq k$, verify that L_i is indeed a list of $(p-1)$ gates that are all input to H_i.

2. Let g_1 be an old gate and g_2 a new gate. Then $\langle n, t, g_1, g_2\rangle \notin L$.

3. Let g_1 be a new gate and g_2 an old gate. The only way for $\langle n, t, g_1, g_2\rangle \in L$ to hold is that g_1 is a new AND gate created in this step. Hence g_1 has the form $\langle G\#\langle\langle H_1\#L_1\rangle, \langle H_2\#L_2\rangle, \ldots, \langle H_k\#L_k\rangle\rangle\#m$, AND$\rangle$. We do the following to check if $\langle n, t, g_1, g_2\rangle \in L$.

a. Check that $\langle n, t, g_1, g_1\rangle \in L$.
b. Check that $\langle n, t, g_2, g_2\rangle \in L_0$.
c. Verify that $\exists\, i$, $1 \leq i \leq k$, such that g_2 belongs to the list of gates L_i.

4. Let g_1 and g_2 both be new gates. The only way for g_2 to be an input to g_1 is if $g_1 = \langle G\#\langle G_1, G_2, \ldots, G_r\rangle, \text{MOD}_p\rangle$ and $g_2 = \langle G\#\langle\langle H_1\#L_1\rangle, \langle H_2\#L_2\rangle, \ldots, \langle H_k\#L_k\rangle\rangle\#m, \text{AND}\rangle$ where $\{H_1, \ldots, H_k\} \subseteq \{G_1, \ldots, G_r\}$. This is obviously easy to check.

The only remaining property that needs to be checked is the strong connection property for ANDs. However, this is immediate using the naming system that we use, since the name of each new AND gate explicitly lists the names of each of its inputs.

Let us now consider the size of the new circuit after a single level of AND gates has been pushed below a level of MOD gates. The increase in size comes mainly because of all the new AND gates that get created. For a circuit of size s, the number of new AND gates created to change an AND of r MOD$_p$ gates is $\leq \sum_{k=1}^{r} c_k\binom{r}{k}s^{(p-1)k} \leq (p-1)2^r s^{(p-1)r}$. Therefore, the overall size of the new circuit is at most $O(2^r s^{(p-1)r+1})$. Since s is subexponential and r is polylogarithmic in s, the size of the new circuits is still subexponential.

Note that this step does not preserve the tree structure of the circuit so we use Lemma A.8 to produce an equivalent nice circuit sequence. □

LEMMA A.25. *Let L be accepted by a uniform nice* SYMACC *circuit family $\{C_n\}$ of subexponential size, with small fan-in* AND *gates, no* OR *gates, and no* MOD$_m$ *gates for composite m, such that each path from the output gate to an input passes through $k \geq 1$* MOD *gates. Then there is an equivalent* SYMACC *circuit family $\{D_n\}$ satisfying the same conditions, such that each path from the output gate to an input gate passes through $k-1$* MOD *gates.*

Proof. Our proof follows the outline in [10], using techniques developed in [30], [26].

Let L and $\{C_n\}$ be as in the statement of the lemma, where the output gate of C_n computes the function $A(n, \eta)$, where η is the number of elements of $\{C_{n,i} : 1 \leq i \leq f(n)\}$ that evaluate to 1. By Lemma A.24, we may assume without loss of generality that the output of each circuit $C_{n,i}$ is a MOD$_p$ gate. Since $\{C_n\}$ is nice, for each n there is some n_0 so that each MOD$_p$ gate in $C_{n,t}$ has fan-in n_0 (where n_0 can be computed in $(\log s(n))^{O(1)}$ time from n). For each $i \leq f(n)$, let the inputs to the ith of these MOD$_p$ gates be denoted by $x_{i,j}$, $1 \leq j \leq n_0$. Then the value of $\{C_n\}$ can be expressed as $A(n, \sum_{1\leq i\leq f(n)} \text{MOD}_p(x_{i,1}, x_{i,2}, \ldots, x_{i,n_0}))$.

Let $k(n) = 1 + \lfloor \log_p f(n) \rfloor$ so that $p^{k(n)} > f(n)$. Note that $k(n)$ is computable in time $(\log s(n))^{O(1)}$. For the rest of this discussion, fix n, and let k denote $k(n)$.

It is shown in [10] that the polynomial P_k defined by

$$P_k(y) = (-1)^{k+1}(y-1)^k \left(\sum_{j=0}^{k-1} \binom{k+j-1}{j} y^j \right) + 1$$

satisfies the property that for every $m \geq 1$ and $y \geq 0$,

$$y \equiv 0 \pmod{m} \Longrightarrow P_k(y) \equiv 0 \pmod{m^k}$$

and

$$y \equiv 1 \pmod{m} \Longrightarrow P_k(y) \equiv 1 \pmod{m^k}.$$

Let $Q_k(y) = 1 - P_k(y^{p-1})$. Then

$$Q_k(y) \equiv \begin{cases} 1 \pmod{p^k} & \text{if } y \equiv 0 \pmod{p}, \\ 0 \pmod{p^k} & \text{otherwise.} \end{cases}$$

If $y = \sum_{i=1}^r y_i$ then

$$Q_k\left(\sum_{i=1}^r y_i\right) \equiv \mathrm{MOD}_p(y_1, y_2, \ldots, y_r) \pmod{p^k}.$$

Thus, recalling that the value of the circuit C_n is

$$A\left(n, \sum_{1 \leq i \leq f(n)} \mathrm{MOD}_p(x_{i,1}, x_{i,2}, \ldots, x_{i,n_0})\right),$$

we see that this can also be expressed as

$$A\left(n, \sum_{1 \leq i \leq f(n)} \left(Q_k\left(\sum_{1 \leq j \leq n_0} x_{i,j}\right) \pmod{p^k}\right)\right).$$

Since $f(n) < p^k$ and Q_k is always 0 or 1 $\pmod{p^k}$, we can bring the outer sum inside the modulus to obtain the equivalent expression

$$A\left(n, \left(\sum_{1 \leq i \leq f(n)} Q_k\left(\sum_{1 \leq j \leq n_0} x_{i,j}\right)\right) \pmod{p^k}\right).$$

Let $B(n, i)$ be defined to be $A(n, (i \bmod p^k))$. Thus the value of $\{C_n\}$ is equal to

$$B\left(n, \sum_{1 \leq i \leq f(n)} Q_k\left(\sum_{1 \leq j \leq n_0} x_{i,j}\right)\right).$$

Note that B is computable in time polylogarithmic in $s(n)$.

Note that $(\sum_{1 \leq i \leq f(n)} Q_k(\sum_{1 \leq j \leq n_0} x_{i,j}))$ is a low degree polynomial in the variables $\{x_{i,j}\}$. As in the proof of Lemma A.24, our strategy will be to implement scalar multiplication with AND gates, and multiply the negative coefficients by $(1 - p^k)$ to make them positive[7], to obtain a realization of this polynomial in terms of circuits.

[7] This does not change the value of the expression mod p^k.

Our first task is to compute the coefficients in the polynomial

$$\left(\sum_{1\le i\le f(n)} Q_k\left(\sum_{1\le j\le n_0} x_{i,j}\right)\right).$$

Since this is just a sum of $f(n)$ similar polynomials, we can consider each of them separately.

Recall that $Q_k(y) = 1 - P_k(y^{p-1})$. Let $z = y^{p-1}$. After a little simplification we get $1 - P_k(z) = (1-z)^k(\sum_{j=0}^{k-1}\binom{k+j-1}{j}z^j)$. This is a polynomial of degree $2k-1$. For $i \ge 0$, let $b_i = 1$ if i is even, and $b_i = p^k - 1$ if i is odd. The coefficients of z^m, say c_m, are given by

$$c_m = \begin{cases} 1 & \text{if } m = 0, \\ 0 & \text{if } 1 \le m \le k-1, \\ \displaystyle\sum_{0\le i\le k, 0\le j\le k-1, i+j=m} b_i\binom{k}{i}\binom{k+j-1}{j} & \text{if } k \le m \le 2k-1. \end{cases}$$

These coefficients c_m can be computed in $(\log s(n))^{O(1)}$ time, because we only need to compute $O(k)$ binomial coefficients, each involving numbers that are $O(k\log k)$ bits long. It can be verified that $O(k^4\log k)$ time suffices, which is polylogarithmic in the size of the circuit since k is logarithmic in the size.

Now observe that the value of circuit $\{C_n\}$ is given by

$$\begin{aligned} B\left(n, \sum_{i=1}^{f(n)} Q_k\left(\sum_{j=1}^{n_0} x_{i,j}\right)\right) &= B\left(n, \sum_{i=1}^{f(n)} 1 - P_k\left(\left(\sum_{j=1}^{n_0} x_{i,j}\right)^{p-1}\right)\right) \\ &= B\left(n, \sum_{i=1}^{f(n)}\sum_{m=0}^{2k-1} c_m\left(\sum_{j=1}^{n_0} x_{i,j}\right)^{(p-1)m}\right) \\ &= B\left(n, \sum_{i=1}^{f(n)}\sum_{m=0}^{2k-1}\sum_{c=1}^{c_m}\sum_{\langle j_1, j_2, \ldots, j_{p-1}\rangle\in[n_0]^{(p-1)m}} \bigwedge_{l=1}^{(p-1)m} x_{i,j_l}\right). \end{aligned}$$

In place of each circuit $C_{n,t}$ in the original sequence of circuits, there will be several new circuits, each of the form $D_{n,\langle i,m,c,j_1,\ldots,j_{(p-1)m}\rangle}$ where $0 \le m \le 2k-1$, $1 \le c \le c_m$, and each j_l is in $[n_0]$. (Of course, by our conventions, there will also be circuits $D_{n,t}$ where t is not of this form; each such circuit $D_{n,t}$ will be a trivial rejecting circuit that will therefore have no effect on the output of the symmetric gate.)

The output gate of each circuit $D_{n,\langle i,m,c,j_1,\ldots,j_{(p-1)m}\rangle}$ will be an AND gate with the name $g = \langle n, i, m, c, j_1, \ldots, j_{(p-1)m}, \text{AND}\rangle$. The inputs to g will be the $(p-1)m$ gates that are the j_lth inputs to the MOD$_p$ gate G_i in the original circuit $C_{n,i}$. Note that since $C_{n,i}$ has the strong connection property, one can show that $D_{n,\langle i,m,c,j_1,\ldots,j_{(p-1)m}\rangle}$ does, too.

Note that the number of bits needed to express $\langle i, m, c, j_1, \ldots, j_{(p-1)m}\rangle$ is bounded by $(\log s(n))^b$ for some constant b, and thus if we define $f'(n)$ to be equal to $2^{(\log s(n))^b}$, it follows that the symmetric gate computing B in circuit D_n has fan-in $f'(n)$, where $f'(n)$ is computable in time polylogarithmic in $s(n)$.

Since the new circuit consists of a subexponential number of circuits, each of which is of subexponential size, the new circuit is also of subexponential size.

The depth of the new circuit family is the same as $\{C_n\}$ but the top layer of MOD$_p$ gates has been "absorbed" into the symmetric gate computing B and been replaced by a layer of

AND gates of small fan-in. Now, by an appeal to Lemma A.8, the circuit can be converted into nice form, which completes the proof. □

Proof of Theorem 3.1. By Lemma A.23, every language in ACC(subexp) is accepted by a deterministic SYMACC circuit family of subexponential size, with small fan-in AND gates, no OR gates, and no MOD_m gates for composite m. Successive applications of Lemma A.24 and Lemma A.25 remove all MOD gates from the circuit, while maintaining the property that all AND gates have small fan-in. This suffices to prove the theorem. □

Acknowledgments. We thank the anonymous referees for suggestions that improved the presentation of these results. We also thank Richard Beigel for suggesting that our results concerning PP could be extended to $C_=P$.

THE JOINT DISTRIBUTION OF ELASTIC BUCKETS IN MULTIWAY SEARCH TREES*

WILLIAM LEW† AND HOSAM M. MAHMOUD‡

Abstract. Random search trees are studied when they grow under a general computer memory management scheme. In a general scheme, the space is released in buckets of certain predesignated sizes. For a search tree with branch factor m, the nodes may hold up to $m-1$ keys. Suppose the buckets of the memory management scheme that can hold less than m keys have key capacities $c_1, \dots, c_p$. The search tree must then be implemented with multitype nodes of these capacities. After n insertions, let $X_n^{(i)}$ be the number of buckets of type i (i.e., of capacity c_i, $1 \le i \le p$). The multivariate structure of the tree is investigated. For the vector $\mathbf{X}_n = (X_n^{(1)}, \dots, X_n^{(p)})^T$, the asymptotic mean and covariance matrix are determined. Under practical memory management schemes, all variances and covariances experience a phase transition: For $3 \le m \le 26$, all variances and covariances are asymptotically linear in n; for higher branch factors the variances and covariances become a superlinear (but subquadratic) function of n. The joint distribution of $\mathbf{X}_n$ is shown to be multivariate normal in a range of m. While the tree is growing, conversions between types are necessary. A multivariate problem concerning these conversions with an asymptotic multivariate normal distribution is also studied. The fixed bucket, exact fit, and buddy system allocation schemes will serve as illustrating examples.

1. Introduction.

The *m-ary search tree* is a data structure that grows by the progressive insertion of keys into a tree with branch factor m. The subtrees are numbered 1 to m, from left to right. The tree is constructed by placing up to $m-1$ keys in its root, sorted from left to right, and then guiding a subsequent key to the jth subtree, $1 \le j \le m$, if that key is greater than exactly $j-1$ of the root keys. In the jth subtree, the newcomer is subjected recursively to the same procedure until a unique insertion position is found.

The usual data probability model is the *random permutation model* where all permutations of $\{1, \dots, n\}$ are considered equally likely input sequences (see [12]). The random permutation model covers a wide variety of situations, since clearly the only data aspect relevant to the structure of the tree is the order statistics; the ranks of data taken from any continuous distribution follows the random permutation model (see [17] for a detailed discussion). For the rest of this paper the term *random tree* will refer to a tree constructed from a random permutation.

In practice, a random tree grows under a computer memory management scheme. Memory management schemes allocate space in blocks of storage called buckets or pages. Sometimes the buckets come in fixed allowed sizes. For example, the buddy system releases blocks of sizes 2^k words of memory, $k = 1, 2, \dots$. We shall assume a general scheme under which the buckets are measured in terms of key capacity. It is clear from the insertion algorithm that the largest buckets that may be used as a tree node must be capable of holding $m-1$ keys and m pointers. Thus the design parameter m must be chosen in an application so that the space for $m-1$ keys, m pointers, and any space needed for system use coincide with the capacity of a system's bucket. It should also be clear that a node with less than $m-1$ keys has no descendants and thus may be implemented without pointers as it is a terminal node. Also some terminal nodes may be holding $m-1$ keys, but they do not need pointers as well. Nonterminal nodes must have pointers.

Let $c_1, c_2, \ldots, c_p$ be all the bucket sizes (in terms of keys) that are less than or equal to $m-1$, with

$$c_1 < c_2 < \cdots < c_{p-1} \le c_p = m - 1. \tag{1.1}$$

We shall call a bucket (a tree node) of capacity c_i, a bucket of type i, $1 \le i \le p$. It is also helpful to think of **NIL** pointers as buckets of type 0 with capacity $c_0 = 0$. The tree thus grows by allocating a bucket of type 1 when insertion falls in an empty subtree. Subsequent insertions that fall in the same bucket will increase the number of keys in the bucket until it is filled with c_1 keys. A later insertion attempting to fall in the same bucket will force it to be stretched into a bucket of the next size c_2, and so on. We call the stretching of a bucket to become a larger bucket a *conversion*, and because of this stretching, some authors call such stretchable buckets "*elastic*." Thus types $1, \ldots, p-1$ are pointerless, but type p must contain m pointers. Notice that the inequalities (1.1) are all strict except possibly the last. For it is conceivable that $c_{p-1} < c_p$, in which case an insertion in a node of type $p-1$ converts it into a partially filled node of type p that will continue to accept some more keys until it is filled before the keys are sent to the subtrees. On the other hand, it is conceivable that in some memory management schemes $c_{p-1} = c_p = m - 1$, in which case an insertion in the pointerless type $p-1$ will convert it into a type p bucket with the same number of keys $c_p = m - 1$ but with an extra m pointers; the new key will then appear by itself in a new node (of type 1, of course) that will be linked as a subtree. Figure 1 illustrates the growth of a tree with branch factor 8 from eight keys under a scheme that allows buckets of capacities $c_1 = 3$, $c_2 = 5$, $c_3 = 7$ (and type 3 has eight pointers).

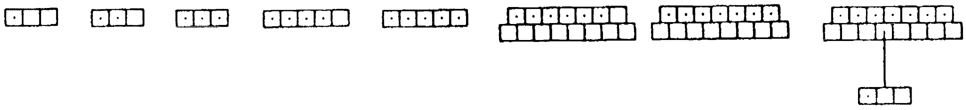

FIG. 1. *The step-by-step growth of an 8-way tree with node capacities* 3, 5, *and* 7.

The advantage of random search trees is that they are almost complete (i.e., shortest possible) with very high probability (see [20], [4], [17], [18], [22]). Thus time-performance is almost the best possible. Under a *fixed allocation scheme* (a scheme with only one type node, i.e., $p = 1$), search trees are known to be wasteful of space (see [12], [1], [21], and [17]; [12, Exercise 6.3.20, p. 501] presents the first known analysis of trees with buckets). We investigate in this paper the possibility of rectifying the situation via elastic buckets so as to get good space performance too. The notion of increasing sizes for different type nodes of a linked data structure was introduced before in the class of balanced trees. Frederickson [8] and Lomet [15] used elastic buckets to implement increasing size nodes when they overflow instead of the usual splitting of nodes in B-trees and their derivatives. Baeza-Yates and Larson [2] analyzed mathematically the storage utilization of B^+-trees with elastic buckets. The possibility of using elastic buckets was also made implicit by Hoshi and Flajolet [10], who computed the average number of nodes of each type in a paged quadtree. Baeza-Yates [1] found the optimal second size in the case where two page sizes are allowed for a multiway search tree.

In practice, an algorithm on the m-ary tree may require knowledge of the sizes of the nodes and most memory management systems reserve some bytes in each block for system use. These hidden bytes may hold information like the size of the bucket. We shall call these hidden bytes the *hidden tag*. In most memory allocation schemes, the hidden tag has a uniform length in all buckets regardless of their size. Practical multitype memory management systems include the following:

(a) The *exact fit scheme* where type i buckets contain the exact space for i keys and the hidden tag, $i = 1, \dots, p-1$, and type p contains the exact space for $m-1$ keys, m pointers, and the hidden tag.

(b) The *buddy system scheme*, which allocates space in blocks that are proper powers of two words. One word is reserved in each bucket for a hidden tag. Thus in an application with real or integer data (where each datum needs one word of memory), a bucket of size 2^k words can accommodate $2^k - 1$ data items (even if the data are not numeric, uniform pointers occupying one word each may be used for indirect addressing). Thus the bucket capacities (in terms of keys) are $1, 3, 7, 15, \dots, 2^p - 1$ (with the branching factor $m = 2^p$, a proper power of 2). This is the choice method of accessing the free space in some popular systems such as the simulation programming language SIMSCRIPT and the MALLOC memory allocation function in the programming language C (on the UNIX 4.3 BSD operating system).

Let $X_n^{(i)}$ be the number of nodes of type i after n insertions. We shall investigate the multivariate structure of the tree by examining the vector $\mathbf{X}_n = (X_n^{(1)}, \dots, X_n^{(p)})^T$. We shall compute the asymptotic average of this vector. We shall further find the covariance matrix and (for a range of m) the joint asymptotic distribution of the components of $\mathbf{X}_n$. It will turn out that in practical systems all variances and covariances are linear in n for $3 \le m \le 26$, and then they suffer from a phase transition: For $m > 26$, the variances and covariances become a superlinear (but subquadratic) function of n. The asymptotic distribution for the linear range of the variances and covariances ($3 \le m \le 26$) is multivariate normal (multinormal).

An associated multivariate problem is a study of the number of conversions between types. The total number of conversions may not be an accurate measure of the cost of conversions since different conversions involve movements of different block sizes of data. A more accurate measure is obtained by studying the number of conversions of each type. More precisely, let $C_n^{(i)}$ be the number of times a node of type $i-1$ is converted into a node of type i (a conversion of type i), $i = 1, \dots, p$, and $C_n^{(1)}$ be interpreted as the number of times a node is created for the first time, i.e., the number of times a **NIL** pointer (a node of type 0) is converted into a node of type 1. We are interested in the behavior of the vector

$$\mathbf{C}_n = (C_n^{(1)}, \dots, C_n^{(p)})^T.$$

The same questions about average, covariance matrix, and any phase transitions that may appear therein, and limiting joint distribution may be addressed again. Results about $\mathbf{C}_n$ may be found from the behavior of $\mathbf{X}_n$ since their components are related as follows. When a bucket of capacity c_i first appears, it increases $C_n^{(i)}$ by one. But this node may grow into a bigger bucket later on. In other words, in the final tree, every node of capacity c_i or larger has passed at some point in its history through one conversion of the ith type or

$$C_n^{(i)} = X_n^{(i)} + X_n^{(i+1)} + \cdots + X_n^{(p)},$$

or $\mathbf{C}_n = \mathbf{J}_p \mathbf{X}_n$, in matrix form, where $\mathbf{J}_p$ is the $p \times p$ upper diagonal matrix whose upper diagonal elements are all 1. To avoid duplicating the effort to find results about each bucket type, we shall instead study the linear combination

$$\mathcal{X}_n = a_1 X_n^{(1)} + \cdots + a_p X_n^{(p)}$$

for any arbitrary real numbers $a_1, \dots, a_p$. This adds flexibility to our calculations: results concerning the mean and variance of an individual type, type i, say, are obtained by setting $a_j = 0$, $j \ne i$, and $a_i = 1$. For the covariance between types i and j we set $a_i = a_j = 1$ and $a_s = 0$, $s \notin \{i, j\}$, to obtain

$$\begin{aligned}\mathbf{Var}[\mathcal{X}_n] &= \mathbf{Var}[X_n^{(i)} + X_n^{(j)}] \\ &= \mathbf{Var}[X_n^{(i)}] + \mathbf{Var}[X_n^{(j)}] + 2\mathbf{Cov}[X_n^{(i)}, X_n^{(j)}].\end{aligned}$$

Results about the total number of nodes allocated are obtained by setting $a_1 = a_2 = \cdots = a_p = 1$, and results about the actual number of words allocated may be obtained by setting a_i to the actual number of words taken by a bucket of type i (e.g., $a_i = k_1 i + k_2$ for the exact fit scheme with constants k_1 and k_2, and $a_i = 2^i$ under the buddy system scheme). The added advantage of studying the linear combination $\mathcal{X}_n$ is that it prepares for use of the Cramér-Wold device to prove the joint asymptotic normality of the components of the vector $\big(X_n^{(1)}, \dots, X_n^{(p)}\big)^T$ in a range of m.

We shall use the following notation for the falling and rising factorials:

$$(z)_j \overset{\text{def}}{=} z(z-1)\cdots(z-j+1), \qquad (z)_0 \overset{\text{def}}{=} 1,$$

$$\langle z\rangle_j \overset{\text{def}}{=} z(z+1)\cdots(z+j-1), \qquad \langle z\rangle_0 \overset{\text{def}}{=} 1.$$

We shall also denote by $[z^n]f(z)$ the coefficient of z^n in $f(z)$. The kth harmonic number $1 + 1/2 + 1/3 + \cdots + 1/k$ will be denoted by H_k. The rest of the paper will be organized into sections as follows: In §2, we set up a partial differential equation for a supergenerating function that generates the moment generating functions of the linear combination $\mathcal{X}_n$ for all values of n. Although this partial differential equation is not tractable, we can develop from it tractable ordinary differential equations for the moments. In §3, we solve the ordinary differential equation for the first moment and obtain an asymptotic estimate for the components of $\mathcal{X}_n$, and in §4, we solve for the second moment and obtain the asymptotic covariance matrix between the types. The main result of this paper, the asymptotic joint normality of the components of $\mathcal{X}_n$ in a range of m, is presented in §5. In §6, we use the fixed bucket, exact fit, and the buddy system schemes as illustrating examples and provide comparisons between these practical methods. Section 7 is a conclusion.

2. A differential equation for a super moment generating function of $\mathcal{X}_n$. Given that the number of keys that end up in the jth subtree is n_j ($n_1 + \cdots + n_m = n - m + 1$), the ith type bucket satisfies the recurrence

$$X_n^{(i)} = \begin{cases} X_{n_1}^{(i)} + X_{n_2}^{(i)} + \cdots + X_{n_m}^{(i)}, & i = 1, 2, \dots, p-1, \\ X_{n_1}^{(i)} + X_{n_2}^{(i)} + \cdots + X_{n_m}^{(i)} + 1, & i = p, \end{cases}$$

valid for $n \ge c_p + 1 = m$. Thus, given $n_1, \dots, n_m, n \ge m$,

(2.1)

$$\begin{aligned}\mathcal{X}_n &= a_1[X_{n_1}^{(1)} + \cdots + X_{n_m}^{(1)}] + a_2[X_{n_1}^{(2)} + \cdots + X_{n_m}^{(2)}] + \cdots + a_p[X_{n_1}^{(p)} + \cdots + X_{n_m}^{(p)} + 1] \\ &= a_p + \sum_{j=1}^{m}\big(a_1 X_{n_j}^{(1)} + a_2 X_{n_j}^{(2)} + \cdots + a_p X_{n_j}^{(p)}\big) \\ &= \mathcal{X}_{n_1} + \mathcal{X}_{n_2} + \cdots + \mathcal{X}_{n_m} + a_p.\end{aligned}$$

Let $\phi_n(t)$ be the moment generating function of $\mathcal{X}_n$, and denote the number of keys in the jth subtree by τ_j, $j = 1, \dots, m$. We can write a recurrence for $\phi_n(t)$ by conditioning as follows

$$\begin{aligned}\phi_n(t) &= \mathbf{E}\big[\exp(\mathcal{X}_n t)\big]\\ &= \sum_{n_1+\cdots+n_m=n-m+1} \mathbf{E}\big[\exp(\mathcal{X}_n t) \mid \tau_1 = n_1, \dots, \tau_m = n_m\big]\\ &\qquad\qquad \times \Pr\big(\tau_1 = n_1, \dots, \tau_m = n_m\big).\end{aligned}$$

The condition is known to occur with probability $\binom{n}{m-1}^{-1}$ under the random permutation model (see [19] for a probabilistic proof or [16] for a combinatorial proof). So from the recurrence (2.1),

$$\phi_n(t) = \frac{1}{\binom{n}{m-1}} \sum_{n_1+\cdots+n_m=n-m+1} \mathbf{E}\big[\exp\{(\mathcal{X}_{n_1} + \cdots + \mathcal{X}_{n_m} + a_p)t\}\big]$$

or

$$(2.2)\qquad (n)_{m-1}\phi_n(t) = (m-1)!\, \exp\big(a_p t\big) \sum_{n_1+\cdots+n_m=n-m+1} \mathbf{E}\big[\exp(\mathcal{X}_{n_1} t)\big] \cdots \mathbf{E}\big[\exp(\mathcal{X}_{n_m} t)\big]$$

(valid only for $n \geq m$), where the last relation follows from the independence of the structures of the subtrees (after checking the root, the insertion algorithm goes into a subtree and does not look at any of the other subtrees after that point). Define the supergenerating function

$$\Phi(x, t) = \sum_{n=0}^{\infty} \phi_n(t) x^n.$$

Multiply both sides of (2.2) by x^{n-m+1} and sum over $n \geq m$ to get

$$(2.3)\qquad \frac{\partial^{m-1}\Phi(x,t)}{\partial x^{m-1}} = (m-1)!\, \exp\big(a_p t\big)\Phi^m(x,t) + (m-1)!\,\big[\phi_{m-1}(t) - \exp\big(a_p t\big)\big].$$

The last term on the right appears owing to the necessary corrections for $n = 0, 1, \dots, m-1$ as the general recurrence (2.1) is not valid for these values of n.

The partial differential equation (2.3) seems to be intractable; however, tractable ordinary differential equations for the moments may be obtained from it as in several instances discussed in a few papers and reported in [17]. Derivatives of $\Phi(x, t)$ with respect to t at $t = 0$ are generating functions for the moments of $\mathcal{X}_n$. Calling the kth derivative $G_k(x)$, we can easily see that

$$G_k(x) = \frac{\partial^k \Phi(x, 0)}{\partial t^k} = \sum_{n=0}^{\infty} \mathbf{E}[\mathcal{X}_n^k] x^n$$

is the ordinary generating function for the kth moment of $\mathcal{X}_n$.

3. The first moment. In particular, $G_1(x)$ generates the sequence of averages $\mathbf{E}\big[\mathcal{X}_n\big]$, $n \geq 0$. Differentiating both sides of (2.3) once with respect to t and evaluating it at $t = 0$ we obtain

(3.1)

$$\frac{d^{m-1}}{dx^{m-1}} G_1(x) = m!\, G_1(x)\Phi^{m-1}(x,0) + (m-1)!\, a_p \Phi^m(x,0) + (m-1)!\,\big[\phi'_{m-1}(0) - a_p\big].$$

But $\Phi(x,0) = \sum_{n=0}^{\infty} x^n = (1-x)^{-1}$ for $|x| < 1$ and

$$\begin{aligned}\phi'_{m-1}(0) &= \frac{d}{dt}\big(\mathbf{E}[\exp(t\mathcal{X}_{m-1})]\big)_{t=0}\\ &= \mathbf{E}\big[a_1 X_{m-1}^{(1)} + \cdots + a_{p-1}X_{m-1}^{(p-1)} + a_p X_{m-1}^{(p)}\big].\end{aligned}$$

From the behavior of the algorithm with multitype buckets

$$X_{m-1}^{(i)} \equiv 0, \qquad i = 1, \ldots, p-2,$$

and

$$X_{m-1}^{(p-1)} \equiv \delta_{c_p, c_{p-1}}, \qquad X_{m-1}^{(p)} \equiv 1 - \delta_{c_p, c_{p-1}},$$

where δ is the Kronecker delta function. Hence (3.1) can be written as

$$\frac{d^{m-1}}{dx^{m-1}} G_1(x) = \frac{m!\, G_1(x)}{(1-x)^{m-1}} + H_1(x), \tag{3.2}$$

where

$$H_1(x) = \frac{(m-1)!\, a_p}{(1-x)^m} + (m-1)!\,(a_{p-1} - a_p)\delta_{c_p, c_{p-1}}.$$

Equation (3.2) can be solved under the obvious initial conditions

$$\frac{d^i}{dx^i} G_1(0) = i!\, \mathbf{E}[\mathcal{X}_i] = i!\, a_r, \qquad i = 0, 1, \ldots, m-2, \tag{3.3}$$

where by definition: (i) $c_0 = 0$, (ii) $r = 0$ and $a_0 = 0$ for $i = 0$, and (iii) r is defined by $c_{r-1} < i \le c_r$ for $i = 1, \ldots, m-2$ (i.e., r is the index of the type that corresponds to the smallest capacity for i keys).

The homogeneous part of the differential equation (3.2) is of the Euler type and has solution $(1-x)^{-\lambda_j}$ for each λ_j that is a solution to the characteristic equation

$$\psi(\lambda) = 0,$$

where

$$\psi(\lambda) = \psi_m(\lambda) \overset{\text{def}}{=} \lambda(\lambda+1)\cdots(\lambda+m-2) - m!.$$

Mahmoud [17] discusses in detail the role of the roots of this characteristic function for a class of random variables called *additive* on m-ary trees and surveys the results of several papers solving other instances. Our linear combination $\mathcal{X}_n$ falls into this class.

We list here some of the properties of the roots of the characteristic function, $\psi(\lambda)$, for the sake of completeness:

(a) $\psi(2) = 0$; denote this root by λ_1; λ_1 is a simple root and $\Re\lambda_j < 2$, $j = 2, \ldots, m-1$. The number $-m$ is a simple root if and only if m is odd. All the other roots of $\psi(\lambda)$ are complex valued, each of multiplicity one.

(b) No two roots may have the same real part unless they are mutually conjugate.

(c) For $m \ge 4$ there is precisely one pair of complex conjugate roots $\lambda_2 = \alpha + i\beta$, $\lambda_3 = \alpha - i\beta$ ($\beta > 0$), with $\alpha < 2$ being the second largest among the real parts of the roots. Thus, $\Re\lambda_j < \alpha$ for $4 \le j \le m-1$.

(d) $\alpha = \alpha_m \to 2$ as $m \to \infty$. Moreover, $\alpha < 1$ for $3 \le m \le 13$ and $1 < \alpha < 3/2$ for $14 \le m \le 26$.

(e) $\psi'(\lambda_k) = m!\sum_{j=0}^{m-2}(\lambda_k + j)^{-1}$, $1 \le k \le m-1$. Another useful expression for $\psi'(\lambda_k)$ is

$$\prod_{\substack{1\le j\le m-1\\ j\ne k}} (\lambda_k - \lambda_j).$$

For more details on the properties of the roots of $\psi(\lambda)$, see [21].

It can be checked that the term $H_1(x)$ in (3.2) gives rise to the particular solution

$$h_1(x) = -\frac{a_p}{(m-1)(1-x)} - \frac{\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)}{m+(-1)^m}(1-x)^{m-1}.$$

Thus the complete solution to (3.2) is given by

$$G_1(x) = \sum_{j=1}^{m-1} A_j(1-x)^{-\lambda_j} + h_1(x), \tag{3.4}$$

where A_j are the constants of integration obtained from (3.3) by solving the linear system of equations

$$\sum_{j=1}^{m-1}\langle\lambda_j\rangle_i A_j = \frac{d^i}{dx^i}G_1(0) - \frac{d^i}{dx^i}h_1(0), \qquad i = 0, \dots, m-2,$$

which can be written in matrix form as

$$\mathbf{V}_{m-1}\mathbf{A} = \mathbf{b},$$

where

$$\begin{aligned}\mathbf{V}_{m-1} &= \mathbf{V}_{m-1}(\lambda_1, \dots, \lambda_{m-1})\\ &= \left[\langle\lambda_j\rangle_i\right], \qquad i = 0, \dots, m-2, \quad j = 1, \dots, m-1.\end{aligned}$$

After some elementary row operations the determinant of $\mathbf{V}_{m-1}$ reduces to the well-known Van Dermonde determinant of order $m-1$. In the vector $\mathbf{A}= \left(A_1, \dots, A_{m-1}\right)^T$, each of the constants A_j, $j = 1, \dots, m-1$ is of course a function of $a_1, \dots, a_p$. For each allocation scheme and each choice of the numbers $a_1, \dots, a_p$, the constants in the vector $\mathbf{b} = \left(b_0, \dots, b_{m-2}\right)^T$ are completely known from (3.3) to be

$$b_i = \begin{cases} -h_1(0), & i = 0,\\ i!\,a_r - \dfrac{d^i}{dx^i}h_1(0), & i = 1, \dots, m-2,\end{cases}$$

where r is defined by $c_{r-1} < i \le c_r$ for $i = 1, \dots, m-2$. Specific examples of bucket multityping will be used to illustrate the procedure of obtaining the constants A_j at the end of the paper. Thus for any given allocation scheme, we have a procedure for obtaining the constants A_j, $j = 1, \dots, m-1$. Extracting the coefficients of x^n from both sides of (3.4) we obtain

$$\mathbf{E}[\mathcal{X}_n] = \sum_{j=1}^{m-1}[x^n]A_j(1-x)^{-\lambda_j} - \frac{a_p}{m-1} - \frac{\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)}{m+(-1)^m}(-1)^n\binom{m-1}{n}.$$

According to the binomial theorem, for any complex number λ, the imaginary part of the coefficient of x^n will only provide oscillation with no growth in magnitude; the growth comes only from the real part, and $n^{\Re\lambda-1}$ is its exact order of magnitude as $n \to \infty$. Hence the root with the largest real part, $(\lambda = 2)$ of the characteristic equation gives a term that asymptotically dominates all other terms, and the average of $\mathcal{X}_n$ can be written in the form

$$\begin{aligned}\mathbf{E}[\mathcal{X}_n] &= A_1[x^n](1-x)^{-2} + [x^n]\left(\sum_{j=2}^{m-1}A_j(1-x)^{-\lambda_j}\right) - \frac{a_p}{m-1}\\ &\quad - \frac{\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)}{m+(-1)^m}(-1)^n\binom{m-1}{n}\\ &= A_1 n + \left(A_1 - \frac{a_p}{m-1}\right) + O\left(n^{\alpha-1}\right)\\ &= A_1 n + O\left(n^b\right),\end{aligned}$$

where $b = \max\{0, \alpha - 1\}$. From the list of properties of the roots of the characteristic equations for $m \leq 13$ and $\alpha \leq 1$ the lower-order term is $O\left(1\right)$ and for $m > 13$ it grows sublinearly with n.

4. The covariance between types. Differentiating (2.3) twice with respect to t at $t = 0$ gives

$$\frac{d^{m-1}}{dx^{m-1}}G_2(x) = \frac{m!\,G_2(x)}{(1-x)^{m-1}} + H_2(x),$$

where

$$\begin{aligned}H_2(x) &\overset{\text{def}}{=} \frac{m!\,(m-1)G_1^2(x)}{(1-x)^{m-2}} + \frac{(m-1)!\,a_p^2}{(1-x)^m} + \frac{2a_p(m!)G_1(x)}{(1-x)^{m-1}}\\ &\quad + (m-1)!\,(a_{p-1}^2 - a_p^2)\delta_{c_p,c_{p-1}},\end{aligned}$$

and $G_1(x)$ was completely determined in the previous section. Thus, in a manner similar to the integration steps used for $G_1(x)$, we obtain

$$G_2(x) = \sum_{j=1}^{m-1}K_j(1-x)^{-\lambda_j} + h_2(x),$$

where K_j are integration constants, λ_j are the roots of the characteristic equation for $j = 1, \ldots, m-1$, and $h_2(x)$ is the particular solution corresponding to the integration of $H_2(x)$. The initial conditions are

$$(4.1)\qquad \frac{d^i}{dx^i}G_2(0) = i!\,\mathbf{E}[\mathcal{X}_i^2] = i!\,a_r^2, \qquad i = 0, 1, \ldots, m-2,$$

where by definition: (i) $c_0 = 0$, (ii) $r = 0$ and $a_0 = 0$ for $i = 0$, and (iii) r is defined by $c_{r-1} < i \leq c_r$ for $i = 1, \ldots, m-2$ (i.e., r is the index of the type that corresponds to the smallest capacity for i keys). Thus the constants K_j are solutions of a linear system that may be written in the form

$$\mathbf{V}_{m-1}\mathbf{K} = \mathbf{f}.$$

Note that like A_j, the constants K_j are functions of $a_1, \ldots, a_p$. For each allocation scheme and each choice of the numbers $a_1, \ldots, a_p$, the constants in the vector $\mathbf{f} = \big(f_0, \ldots, f_{m-2}\big)^T$ are completely known from (4.1) to be

$$f_i = \begin{cases} -h_2(0), & i = 0, \\ i!\,a_r^2 - \dfrac{d^i}{dx^i}h_2(0), & i = 1, \ldots, m-2, \end{cases}$$

where r is defined by $c_{r-1} < i \le c_r$ for $i = 1, \ldots, m-2$. Specific examples of bucket multityping will be used to illustrate the procedure of obtaining the constants K_j at the end of the paper.

Observe that all the terms of $H_2(x)$ have the general form $c(1-x)^{-\lambda-m+1}$. As in [17], each term of $H_2(x)$ of the form $c(1-x)^{-\lambda-m+1}$ contributes to the particular solution $h_2(x)$ a term of the form

$$\frac{c}{\psi(\lambda)}(1-x)^{-\lambda},$$

provided that $\psi(\lambda) \ne 0$. If $\psi(\lambda) = 0$, then a term of the form

$$\frac{c}{\psi'(\lambda)}(1-x)^{-\lambda}\ln\Big(\frac{1}{1-x}\Big)$$

is contributed to the particular solution. Thus, $h_2(x)$ can be obtained by organizing the terms of $H_2(x)$ into cases according to the powers λ in the term $(1-x)^{-\lambda-m+1}$. The details of this calculation are given in the appendix. The final conclusion is the following:

THEOREM 1.

$$\mathbf{Var}\big[\mathcal{X}_n\big] = \gamma_m n + c_m(n)n^{2\alpha-2} + O\big(n^b\big)$$

for every $b > \max\{0, 2\alpha-2, \alpha-1\}$, *where* $\gamma_m = K_1 + A_1^2 + \frac{2a_pA_1}{m-1}$ *and* $c_m(n)$ *is the* $\frac{\pi}{\beta}$*-periodic function*

$$c_m(n) = \sum_{2\le j,k\le 3} A_jA_k\Big[\frac{m!\,(m-1)}{\psi(\lambda_{jk})\Gamma(\lambda_{jk})} - \frac{1}{\Gamma(\lambda_j)\Gamma(\lambda_k)}\Big]n^{i\Im\lambda_{jk}}. \tag{4.2}$$

The factors A_j, K_j, $j = 1, \ldots, m-1$, depend on the allocation scheme and on our choice of $a_1, \ldots, a_p$. In the computation of variances and covariances, we shall need the values of A_j and K_j corresponding to setting all a_i's to 0 except for a pair of indices, say, s and t (not necessarily distinct). We denote by $A_j^{(st)}$ and $K_j^{(st)}$ the values of A_j and K_j with $a_r = 0, r \notin \{s, t\}$, and $a_s = a_t = 1$. Similarly, $\gamma_m^{(ij)}$ and $c_m^{(ij)}(n)$ refer to γ_m and $c_m(n)$ when $a_i = a_j = 1$ and all the other a's are 0. For the variances of the individual types we compute

$$\begin{aligned}\mathbf{Var}\big[X_n^{(i)}\big] &= \mathbf{Var}\big[\mathcal{X}_n\big]_{\substack{a_i=1\\ a_k=0;\, k\ne i}} \\ &= \gamma_m^{(ii)}n + c_m^{(ii)}(n)\,n^{2\alpha-2} + O\big(n^b\big),\end{aligned}$$

for every $b > \max\{0, \alpha-1, 2\alpha-2\}$. Thus, the variance of each bucket type satisfies a formula that is essentially like that of $\mathbf{Var}\big[\mathcal{X}_n\big]$. For practical memory management systems, both $\gamma_m^{(ii)}(n)$ and $c_m^{(ii)}(n)$ are nonzero as illustrated by a few examples at the end of the paper. That is, for such memory management systems, the variance of each bucket type suffers from a phase transition at $m = 26$. The value 26 is an exact result based on an analysis of the roots of the characteristic equation $\psi(\lambda) = 0$ mentioned in §3 and is independent of the bucket sizes. Furthermore, the covariances between different types of buckets may be found from the relation

$$\begin{aligned}\mathbf{Var}[\mathcal{X}_n] \underset{\substack{a_i=a_j=1\\ a_s=0;\ s\notin\{i,j\}}}{} &= \mathbf{Var}\big[X_n^{(i)} + X_n^{(j)}\big]\\ &= \mathbf{Var}\big[X_n^{(i)}\big] + \mathbf{Var}\big[X_n^{(j)}\big] + 2\mathbf{Cov}\big[X_n^{(i)}, X_n^{(j)}\big]\end{aligned}$$

or

$$\begin{aligned}\mathbf{Cov}\big[X_n^{(i)}, X_n^{(j)}\big] &= \frac{1}{2}\big[\gamma_m^{(ij)} - \gamma_m^{(ii)} - \gamma_m^{(jj)}\big]n\\ &\quad + \frac{1}{2}\big[c_m^{(ij)}(n) - c_m^{(ii)}(n) - c_m^{(jj)}(n)\big]n^{2\alpha-2} + O\big(n^b\big)\end{aligned}$$

for every $b > \max\{0, \alpha - 1, 2\alpha - 2\}$. For practical memory management systems, the covariances also have phase transitions after branch factor 26, from a linear behavior to a superlinear (but subquadratic) behavior with oscillations. It appears that the phase transition persists in all practical memory management systems. This phase transition is known to be true for trees with a fixed bucket size implementation and the study of multitype buckets could be thought of as lumping nodes holding a certain number of keys into one type. It is therefore expected that properties such as phase transition in the variance for trees with a fixed bucket capacity will carry over to multitype search trees. Since the asymptotic variances and covariances between the components of $\mathbf{X}_n = \big(X_n^{(1)}, \dots, X_n^{(p)}\big)^T$ all have the same linear order of magnitude for $3 \le m \le 26$, the asymptotic variance-covariance matrix is of the form $\mathbf{\Lambda}_p n$, with $\mathbf{\Lambda}_p$ being a $p \times p$ matrix of coefficients for this range of m.

5. Asymptotic joint normality of the different types. Let $\hat{X}_n^{(i)}$ be the normalized random variable $\big(X_n^{(i)} - \mathbf{E}\big[X_n^{(i)}\big]\big)/\sqrt{n}$. The main result of this paper is the following:

THEOREM 2. *In the range of m for which $\alpha < 3/2$ (which happens if $3 \le m \le 26$), the components of the vector $(\hat{X}_n^{(1)}, \dots, \hat{X}_n^{(p)})^T$ are asymptotically jointly multinormal with a covariance structure $\mathbf{\Lambda}_p$ that follows from the procedure of the previous section.*

The idea of the proof is similar to that in the case of the fixed allocation scheme [21] but extends their previous result to cover the entire range of linearity of the variance, where they only showed asymptotic normality for $3 \le m \le 15$. For the univariate random variable $\mathcal{X}_n$, we give an outline of a streamlined proof by only listing the adjustments needed in the proof of the fixed allocation scheme by a few lemmas without proof except for Lemma 4 in the following text. A proof for Lemma 4 is given to show the extension to the entire range of linearity of variances and covariances. The idea in the proof of asymptotic normality is to compare the moment generating function $\phi_n(t)$ (for which the recursive nature of the data partitioning process provides a recurrence) with the moment generating function

$$\xi_n(t) = \exp\left\{\mathbf{E}[\mathcal{X}_n]t + \mathbf{Var}[\mathcal{X}_n]\frac{t^2}{2}\right\},$$

which is the moment generating function of a normally distributed random variable with mean and variance like $\mathcal{X}_n$. The proof works by conditioning on the number of keys in the subtrees: for any particular partitioning $(n_1, \dots, n_m)$ of keys into the subtrees (of course $n_1 + \cdots + n_m =$

$n-m+1$), $\phi_n(t)$ can be written as an expression involving the product $\phi_{n_1}(t)\ldots\phi_{n_m}(t)$ and $\xi_n(t)$ can be written as an expression involving the product $\xi_{n_1}(t)\ldots\xi_{n_m}(t)$. The similarity of the two forms is advantageously used in an inductive proof to give tight upper and lower bounds on $\phi_n(t)/\xi_n(t)$. In what follows, $\mathbf{n}$ denotes a row vector $(n_1,\ldots,n_m)$ whose components satisfy $n_1+\cdots+n_m=n-m+1$.

LEMMA 1.

$$\phi_n(t)=\frac{\exp(a_pt)}{\binom{n}{m-1}}\sum_{\mathbf{n}}\prod_{j=1}^{m}\phi_{n_j}(t).$$

LEMMA 2.

$$\frac{\exp(a_pt)}{\binom{n}{m-1}\xi_n(t)}\sum_{\mathbf{n}}\prod_{j=1}^{m}\xi_{n_j}(t)=1+\Theta\big(n^c\big)$$

with

$$c=\max\{3c_1,c_1+c_2,2c_2\},$$

$$c_1=\max\{-1/2,\alpha-3/2\},\quad \textit{and}\quad c_2=\max\{2\alpha-3,-1,\alpha-2\}.$$

LEMMA 3. *For large n and every* $0\le\nu\le n$:

$$\exp\Big(-\frac{d\nu n^c}{m-1}\Big)\le\frac{\phi_\nu(t)}{\xi_\nu(t)}\le\exp\Big(\frac{d\nu n^c}{m-1}\Big)$$

for some positive number d.

LEMMA 4.

$$\lim_{n\to\infty}\frac{\phi_n(t)}{\xi_n(t)}=1.$$

Proof. First, observe that if $m\le 26$, then $\alpha<3/2$, and the constant c can be computed from Lemma 2 yielding $c<-0.00255$. Choose $0<\delta<-c$. Let $\nu(n)=\lfloor n^\delta\rfloor$, and note that $\nu(n)$ ranges over the set of positive integers $I\!\!N$ (with repetitions) as n varies from 1 to ∞. Conversely, for each ν, we can define $n_1=n_1(\nu)=\max\big\{n\big|\lfloor n^\delta\rfloor=\nu\big\}$. Observe that $\nu<n_1$ and $n_1=O(\nu^{1/\delta})$, as $\nu\to\infty$ and we can apply Lemma 3 with large ν to get

$$\exp\Big(-\frac{d\nu n_1^c}{m-1}\Big)\le\frac{\phi_\nu(t)}{\xi_\nu(t)}\le\exp\Big(\frac{d\nu n_1^c}{m-1}\Big)$$

or

$$\exp\Big(-O\big(\nu^{(c+\delta)/\delta}\big)\Big)\le\frac{\phi_\nu(t)}{\xi_\nu(t)}\le\exp\Big(O\big(\nu^{(c+\delta)/\delta}\big)\Big).$$

According to our choices of δ, the right and left ends of the above inequality tend to 1 as $\nu\to\infty$, giving us the desired result. □

LEMMA 5. $(\mathcal{X}_n - \mathbf{E}[\mathcal{X}_n])/\sqrt{\mathbf{Var}[\mathcal{X}_n]}$ *converges in distribution to the standard normal distribution with mean* 0 *and variance* 1.

Since

$$\frac{\mathcal{X}_n - \mathbf{E}[\mathcal{X}_n]}{\sqrt{\mathbf{Var}[\mathcal{X}_n]}} \xrightarrow{\mathcal{D}} N(0, 1),$$

this implies that

$$\frac{\mathcal{X}_n - \mathbf{E}[\mathcal{X}_n]}{\sqrt{n}} \xrightarrow{\mathcal{D}} N\left(0, \lim_{n\to\infty} \frac{\mathbf{Var}[\mathcal{X}_n]}{n}\right),$$

which implies that

$$\frac{\mathcal{X}_n - \mathbf{E}[\mathcal{X}_n]}{\sqrt{n}} \xrightarrow{\mathcal{D}} N\left(0, \sum_{1\le i,j\le p} a_i a_j s_{ij}\right)$$

where s_{ij} is the (i, j)th entry of $\mathbf{\Lambda}_p$ or

$$\frac{\mathcal{X}_n - \mathbf{E}[\mathcal{X}_n]}{\sqrt{n}} \xrightarrow{\mathcal{D}} N(0, \mathbf{a}^T \mathbf{\Lambda}_p \mathbf{a}).$$

However, $N(0, \mathbf{a}^T\mathbf{\Lambda}_p\mathbf{a})$ is the distribution of $\mathbf{a}^T\mathbf{Y}$ where $\mathbf{Y}$ is a multinormal vector of p components and variance-covariance matrix $\mathbf{\Lambda}_p$. So, this can be summed up as

$$\mathbf{a}^T\left(\frac{\mathbf{X}_n - \mathbf{E}[\mathbf{X}_n]}{\sqrt{n}}\right) \xrightarrow{\mathcal{D}} \mathbf{a}^T\mathbf{Y}$$

for all p-component row vector $\mathbf{a}^T \in I\!R^p$ and Theorem 2 follows from the Cramér-Wold device (see [3]).

COROLLARY 1. *For* $3 \le m \le 26$, *the normalized number of buckets of type* i, *that is* $\hat{\mathcal{X}}_n^{(i)}$, *converges in distribution to the normal distribution with mean* 0 *and variance* $\gamma_m^{(ii)}$.

As discussed in the introduction, each $C_n^{(i)}$ (the number of conversions from type $i - 1$ bucket to type i bucket) is a linear combination of $\mathcal{X}_n^{(1)}, \ldots, \mathcal{X}_n^{(p)}$. In matrix form, we have

$$\mathbf{C}_n = \mathbf{J}_p\mathbf{X}_n.$$

Whence

$$\mathbf{Cov}[\mathbf{C}_n] = \mathbf{J}_p\mathbf{X}_n\mathbf{J}_p^T.$$

As is well known, linear combinations of normal variates are themselves normal, and we have

COROLLARY 2. *Let* $\hat{C}_n^{(i)} = (C_n^{(i)} - \mathbf{E}[C_n^{(i)}])/\sqrt{n}$. *For* $3 \le m \le 26$, *the random vector* $(\hat{C}_n^{(1)}, \ldots, \hat{C}_n^{(p)})^T$ *is asymptotically jointly normal (with mean* $\mathbf{0}$ *and covariance matrix* $\mathbf{J}_p\mathbf{\Lambda}_p\mathbf{J}_p^T$*) and each* $\hat{C}_n^{(i)}$ *converges in distribution to the normal distribution with mean* 0 *and variance equal to the* (i, i)th *entry of* $\mathbf{J}_p\mathbf{\Lambda}_p\mathbf{J}_p^T$.

6. Some illustrating examples. (a) *Fixed Bucket Scheme.* Under several operating systems, like IBM's OS/2 for personal computers and IBM's VM/CMS, virtual memory is used where external storage devices can be thought of as extensions to the primary computer memory. Communication with the external devices takes place in *fixed* units called pages (a typical page size is: 0.5 – 4K bytes where 1K = 1024 bytes). For these operating systems, a tree node with all its keys and pointers may be designed as one page giving rise to a branch factor in the range of hundreds. This special case corresponds to $p = 1$, as we have only one type of nodes with capacity $c_1 = m - 1$. Let S_n be the total actual space in words taken by the tree. If each bucket (page) size is θ words, then

$$\mathbf{E}[S_n] = \mathbf{E}[\theta \mathcal{X}_n]_{a_1=1} = \frac{\theta n}{2(H_m - 1)} + O(n^b)$$

with $b = \max\{0, \alpha - 1\} < 1$. This result was derived by different methods in [12], [1], and [21]. Moreover, the result about the variance and its phase transition and the asymptotic normality of S_n appears in [21]. These results are special cases of the results in this paper as $S_n = \mathcal{X}_n|_{a_1=1}$. As a consequence of a forthcoming discussion about the exact fit scheme, it can be shown that $Y_n^{(i)}$, the number of fixed buckets with i keys, $i = 1, \dots, m-1$, is asymptotically normal and its variance suffers from a phase transition after $m = 26$. Also, $Y_n^{(1)}, \dots, Y_n^{(m-1)}$ are asymptotically jointly normal with covariances suffering from phase transitions after $m = 26$. The space utilization of the fixed bucket will be discussed in the exact fit scheme method.

(b) *Exact Fit Scheme.* This is a multitype scheme with complete control over memory. A request for a certain number of bytes is honored exactly. This kind of control may be achieved by accessing a "heap" of free space. When a tree grows under this scheme, the type i bucket for $i = 1, \dots, p-1$ will have the exact space required for i keys and a hidden tag meaning $c_i = i$ for $i = 1, \dots, p-1$. The type p bucket will have the exact space for $m - 1$ keys, m pointers, and a hidden tag. Clearly, we have m types of buckets in this scheme ($p = m$) and $c_{p-1} = c_p$. The average of the linear combination $\mathcal{X}_n$ is given by

$$\mathbf{E}[\mathcal{X}_n] = \sum_{j=1}^{m-1} A_j [x^n](1-x)^{-\lambda_j} - \frac{a_p}{m-1} - \frac{(a_{p-1} - a_p)}{m + (-1)^m}(-1)^n \binom{m-1}{n}.$$

For large n

$$\mathbf{E}[\mathcal{X}_n] = A_1 n + \left(A_1 - \frac{a_p}{m-1}\right) + O(n^{\alpha-1}).$$

Hence

$$\begin{aligned}\mathbf{E}[X_n^{(i)}] &= \mathbf{E}[\mathcal{X}_n] \Big|_{\substack{a_i=1 \\ a_j=0;\ j\neq i}} \\ &\sim A_1^{(ii)} n.\end{aligned}$$

The factors $A_1^{(ii)}$ were obtained for $i = 1, \dots, m-2$ by Baeza-Yates [1] by a fringe analysis method (originated by Yao [25] in the context of B-trees and by Poblete and Munro [23] in the context of balancing heuristics for binary trees). For $i = 1, \dots, m-2$, Baeza-Yates found

$$A_1^{(ii)} = \frac{1}{(i+1)(i+2)(H_m - 1)}.$$

Thus we need only complete Baeza-Yates's calculations for the last two terms. We have

$$\begin{aligned}\sum_{j=1}^{m-1} \langle \lambda_j \rangle_k A_j^{(m-1,m-1)} &= k!\,\mathbf{E}[\mathcal{X}_k]\Big|_{\substack{a_{m-1}=1\\ a_j=0;\ j\neq m-1}} + \frac{(-1)^k}{m+(-1)^m}(m-1)_k \\ &= \frac{1}{m+(-1)^m}\langle -m+1\rangle_k, \qquad k=0,\dots,m-2,\end{aligned}$$

or, in matrix form,

$$\begin{aligned}&\begin{pmatrix} \langle\lambda_1\rangle_0 & \langle\lambda_2\rangle_0 & \cdots & \langle\lambda_{m-1}\rangle_0 \\ \langle\lambda_1\rangle_1 & \langle\lambda_2\rangle_1 & \cdots & \langle\lambda_{m-1}\rangle_1 \\ \vdots & \vdots & \ddots & \vdots \\ \langle\lambda_1\rangle_{m-2} & \langle\lambda_2\rangle_{m-2} & \cdots & \langle\lambda_{m-1}\rangle_{m-2} \end{pmatrix} \begin{pmatrix} A_1^{(m-1,m-1)} \\ A_2^{(m-1,m-1)} \\ \vdots \\ A_{m-1}^{(m-1,m-1)} \end{pmatrix} \\ &\quad = \frac{1}{m+(-1)^m} \begin{pmatrix} \langle -m+1\rangle_0 \\ \langle -m+1\rangle_1 \\ \vdots \\ \langle -m+1\rangle_{m-2} \end{pmatrix}.\end{aligned} \tag{6.1}$$

Similarly, $A_1^{(mm)}$ is obtained by solving the linear system

$$\begin{aligned}\sum_{j=1}^{m-1} \langle \lambda_j \rangle_k A_j^{(mm)} &= k!\,\mathbf{E}[\mathcal{X}_k]\Big|_{\substack{a_m=1\\ a_j=0;\ j\neq m}} + \frac{k!}{m-1} - \frac{(-1)^k}{m+(-1)^m}(m-1)_k \\ &= -\frac{1}{m+(-1)^m}\langle -m+1\rangle_k + \frac{k!}{m-1}, \qquad k=0,\dots,m-2,\end{aligned}$$

or, in matrix form,

$$\begin{aligned}&\begin{pmatrix} \langle\lambda_1\rangle_0 & \langle\lambda_2\rangle_0 & \cdots & \langle\lambda_{m-1}\rangle_0 \\ \langle\lambda_1\rangle_1 & \langle\lambda_2\rangle_1 & \cdots & \langle\lambda_{m-1}\rangle_1 \\ \vdots & \vdots & \ddots & \vdots \\ \langle\lambda_1\rangle_{m-2} & \langle\lambda_2\rangle_{m-2} & \cdots & \langle\lambda_{m-1}\rangle_{m-2} \end{pmatrix} \begin{pmatrix} A_1^{(mm)} \\ A_2^{(mm)} \\ \vdots \\ A_{m-1}^{(mm)} \end{pmatrix} \\ &\quad = -\frac{1}{m+(-1)^m} \begin{pmatrix} \langle -m+1\rangle_0 \\ \langle -m+1\rangle_1 \\ \vdots \\ \langle -m+1\rangle_{m-2} \end{pmatrix} + \frac{1}{m-1}\begin{pmatrix} \langle 1\rangle_0 \\ \langle 1\rangle_1 \\ \vdots \\ \langle 1\rangle_{m-2} \end{pmatrix}.\end{aligned} \tag{6.2}$$

Applying Cramer's rule to (6.1) yields

$$A_1^{(m-1,m-1)} = -\frac{1}{m+(-1)^m} \times \frac{\Delta_1}{\Delta},$$

where $\Delta = \det\left[\mathbf{V}_{m-1}(\lambda_1,\dots,\lambda_{m-1})\right]$ and Δ_1 is obtained from Δ by replacing its first column with the right-hand side vector in (6.1). After some elementary row operations, Δ_1 has the form of the Van Dermonde determinant $\det\left[\mathbf{V}_{m-1}(-m+1,\lambda_2,\dots,\lambda_{m-1})\right]$. Using the well-known expansion of the Van Dermonde determinant, one obtains

$$
\begin{aligned}
A_1^{(m-1,m-1)} &= \frac{\displaystyle\prod_{s=2}^{m-1}\big[\lambda_s-(-m+1)\big]}{\big[m+(-1)^m\big]\displaystyle\prod_{s=2}^{m-1}\big[(\lambda_s-\lambda_1)\big]}\\[2ex]
&= \frac{\displaystyle\prod_{s=2}^{m-1}\big[(-m+1)-\lambda_s\big]}{\big[m+(-1)^m\big]\displaystyle\prod_{s=2}^{m-1}\big[(2-\lambda_s)\big]}\\[2ex]
&= \frac{\psi(-m+1)}{[m+(-1)^m](-m-1)\psi'(2)}\\[2ex]
&= \frac{1}{m(m+1)(H_m-1)}.
\end{aligned}
$$

In a similar manner, one finds from (6.2)

$$
A_1^{(mm)} = \frac{\Delta_1}{\big[m+(-1)^m\big]\Delta} + \frac{\Delta_2}{(m-1)\Delta}
$$

where $\det \Delta_2 = \det\big[\mathbf{V}_{m-1}(1,\lambda_2,\dots,\lambda_{m-1})\big]$. After simplification, one obtains

$$
A_1^{(mm)} = \frac{1}{(m+1)(H_m-1)}.
$$

Assuming that we are dealing with an application where the keys are α bytes each on a computer whose memory addressing requires pointers of size β bytes each and the memory management system reserves ρ bytes for system usage, the actual average space S_n occupied by the random tree is

$$
\begin{aligned}
\mathbf{E}\big[S_n\big] &= \mathbf{E}\big[\big((m-1)\alpha+m\beta+\rho\big)X_n^{(m)}\big]+\sum_{i=1}^{m-1}\mathbf{E}\big[X_n^{(i)}(i\alpha+\rho)\big]\\
&\sim \big[(m-1)\alpha+m\beta+\rho\big]A_1^{(mm)}n+\sum_{i=1}^{m-1}(i\alpha+\rho)A_1^{(ii)}n\\
&= n\Bigg\{\big[(m-1)\alpha+m\beta+\rho\big]\frac{1}{(m+1)(H_m-1)} \qquad (6.3)\\
&\qquad+\alpha\sum_{i=1}^{m-1}\frac{i}{(i+1)(i+2)(H_m-1)}+\rho\sum_{i=1}^{m-1}\frac{1}{(i+1)(i+2)(H_m-1)}\Bigg\}\\
&= \left[\frac{\beta m}{m+1}+(H_m-1)\alpha+\frac{\rho}{2}\right]\frac{n}{H_m-1}.
\end{aligned}
$$

Under a fixed-bucket scheme for the same environment, each node is like a type m bucket of the exact fit scheme, i.e., the total actual space is asymptotic to

$$\frac{(m-1)\alpha + m\beta + \rho}{2(H_m - 1)} n.$$

Thus the asymptotic space of the exact fit scheme relative to the fixed-bucket scheme is

$$\frac{\text{average total space for exact fit}}{\text{average total space for fixed buckets}} = \frac{m\beta/(m+1) + \big(H_m - 1\big)\alpha + \rho/2}{\big[(m-1)\alpha + m\beta + \rho\big]/2}.$$

For large m, this is about

$$\frac{\beta + \rho/2 + \alpha \ln m}{(\alpha + \beta)m/2}.$$

As an example, in a personal computer environment, pointers are 4 bytes and each page of virtual memory under IBM's OS/2 operating system is 4K bytes. Under OS/2, $\rho = 1$ byte. Thus, a search tree implementation in this environment means a full node has 511 four-byte keys, a one-byte hidden tag, and 512 four-byte pointers. That is, $m = 512$, $\alpha = 4$, $\beta = 4$, and $\rho = 1$. In this instance, the relative efficiency between exact fit and fixed bucket is about $(9 + 36 \ln 2)/4096 \approx 8.4\%$. For small m ($m \le 26$), the reduction ratio is achieved with very high probability, in view of the small variance. In these cases, the asymptotic efficiency is obtained in probability since the space of each method is asymptotic to its average in probability.

(c) *Buddy System Scheme*. This memory management scheme allocates buckets with sizes that are proper powers of two. The smallest example that illustrates partial filling is the four-way branching with buckets of two, four, and eight words. We intend to present this instance in some detail to put all the procedures and distributions already discussed in perspective. This model may be suitable for internal memory use on a mainframe computer. In each bucket, one word of memory is reserved for system use. The largest bucket size must contain four pointers (four words on a mainframe computer). Thus the bucket with eight words can accommodate three keys. In terms of keys, the capacities of the three types of buckets involved are $c_1 = 1$, $c_2 = 3$, and $c_3 = 3$. The first two types are pointerless. The formula for the average of the linear combination $\mathcal{X}_n$ gives

$$\begin{aligned}\mathbf{E}\big[\mathcal{X}_n\big] &= \frac{A_1\langle\lambda_1\rangle_n}{n!} + \frac{A_2\langle\lambda_2\rangle_n}{n!} + \frac{A_3\langle\lambda_3\rangle_n}{n!} - \frac{1}{3}a_p - \frac{a_{p-1} - a_p}{5}(-1)^n\binom{3}{n} \\ &= A_1(n+1) + 2\Re\left\{\frac{A_2\langle\lambda_2\rangle_n}{n!}\right\} - \frac{1}{3}a_p - \frac{a_{p-1} - a_p}{5}(-1)^n\binom{3}{n}.\end{aligned}$$

The function $h_1(x)$ that appears in the linear system for the A's is given by

$$h_1(x) = -\frac{a_p}{3(1-x)} - \frac{(a_{p-1} - a_p)}{5}(1-x)^3.$$

The characteristic equation is $\lambda(\lambda+1)(\lambda+2) - 24 = 0$ and has the roots

$$\lambda_1 = 2, \qquad \lambda_2 = \frac{-5 + \sqrt{23}\,i}{2}, \qquad \lambda_3 = \frac{-5 - \sqrt{23}\,i}{2}.$$

Here, $G_1(0) = 0$, $G_1'(0) = \mathbf{E}\big[\mathcal{X}_1\big] = a_1$, $G_1''(0) = 2\mathbf{E}\big[\mathcal{X}_2\big] = 2a_2$. Thus the constants of integration A_1, A_2, and A_3 are determined by solving the linear system

$$\begin{pmatrix} 1 & 1 & 1 \\ \lambda_1 & \lambda_2 & \lambda_3 \\ \lambda_1(\lambda_1+1) & \lambda_2(\lambda_2+1) & \lambda_3(\lambda_3+1) \end{pmatrix} \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}$$

$$= \begin{pmatrix} 0 \\ a_1 \\ 2a_2 \end{pmatrix} - \begin{pmatrix} -\frac{1}{5}a_2 - \frac{2}{15}a_3 \\ \frac{3}{5}a_2 - \frac{14}{15}a_3 \\ -\frac{6}{5}a_2 + \frac{8}{15}a_3 \end{pmatrix}. \tag{6.4}$$

Solving this linear system with $a_1 = 1$, $a_2 = a_3 = 0$, one gets

$$A_1^{(11)} = \frac{2}{13}, \qquad A_2^{(11)} = -\frac{1}{13} - \frac{4\sqrt{23}}{299}i, \qquad A_3^{(11)} = -\frac{1}{13} + \frac{4\sqrt{23}}{299}i;$$

thus,

$$\mathbf{E}\big[X_n^{(1)}\big] = \frac{2}{13}(n+1) + \frac{2}{n!}\Re\left\{\left(-\frac{1}{13} - \frac{4\sqrt{23}}{299}i\right)\left\langle\frac{-5+\sqrt{23}\,i}{2}\right\rangle_n\right\} \sim \frac{2}{13}n.$$

Similar calculations with $a_1 = 0$, $a_2 = 1$, $a_3 = 0$, and $a_1 = a_2 = 0$, $a_3 = 1$, lead to

$$\mathbf{E}\big[X_n^{(2)}\big] \sim \frac{8}{65}n \quad \text{and} \quad \mathbf{E}\big[X_n^{(3)}\big] \sim \frac{12}{65}n,$$

respectively. Consequently, the asymptotic average number of conversions of different types are

$$\mathbf{E}\big[C_n^{(1)}\big] \sim \frac{6}{13}n, \qquad \mathbf{E}\big[C_n^{(2)}\big] \sim \frac{4}{13}n, \qquad \mathbf{E}\big[C_n^{(3)}\big] \sim \frac{12}{65}n.$$

The formula for the variances of the linear combination $\mathcal{X}_n$ follows from

$$\mathbf{Var}\big[\mathcal{X}_n\big] = \mathbf{E}\big[\mathcal{X}_n^2\big] - \mathbf{E}^2\big[\mathcal{X}_n\big],$$

where $\mathbf{E}\big[\mathcal{X}_n\big]$ has already been determined and $\mathbf{E}\big[\mathcal{X}_n^2\big]$ is given by

$$\begin{aligned}
\mathbf{E}\big[\mathcal{X}_n^2\big] = {} & K_1(n+1) + 2\Re\left\{\frac{K_2\langle\lambda_2\rangle_n}{n!}\right\} + \frac{a_p^2}{9} \\
& + (-1)^{n+1}\frac{(a_{p-1}^2 - a_p^2)}{5}\binom{3}{n} + \frac{4}{325}(-1)^{n+1}(a_{p-1} - a_p)^2\binom{7}{n} \\
& + \frac{6(a_{p-1} - a_p)A_1}{5} \times \frac{\langle -2\rangle_n}{n!} \\
& - \frac{288(a_{p-1} - a_p)}{5}\Re\left\{\frac{A_2}{\psi(\lambda_2 - 4)} \times \frac{\langle\lambda_2 - 4\rangle_n}{n!}\right\} \\
& + A_1^2 n^2 + 3A_1^2 n + 2A_1^2 + 4A_1\Re\left\{(\lambda_2 + n)A_2\frac{\langle\lambda_2\rangle_n}{n!}\right\} \\
& + 144\Re\left\{\frac{A_2^2}{\psi(\lambda_{22})} \times \frac{\langle\lambda_{22}\rangle_n}{n!}\right\} + \frac{144|A_2|^2}{\psi(2\Re\lambda_2 - 1)} \times \frac{\langle 2\Re\lambda_2 - 1\rangle_n}{n!}.
\end{aligned}$$

The function $h_2(x)$ that appears in the linear systems for second moments is

$$\begin{aligned} h_2(x) &= \frac{a_p^2}{9(1-x)} - \frac{a_{p-1}^2 - a_p^2}{5}(1-x)^3 - \frac{4}{325}(a_{p-1}-a_p)^2(1-x)^7 \\ &+ \frac{6(a_{p-1}-a_p)A_1}{5}(1-x)^2 - \sum_{j=2}^{3} \frac{144(a_{p-1}-a_p)A_j}{5\psi(\lambda_j-4)(1-x)^{\lambda_j-4}} + \frac{2A_1^2}{(1-x)^3} \\ &+ \frac{2\lambda_2 A_1 A_2}{(1-x)^{\lambda_2+1}} + \frac{2\lambda_3 A_1 A_3}{(1-x)^{\lambda_3+1}} + \sum_{2\le j,k\le 3} \frac{72 A_j A_k}{(1-x)^{\lambda_{jk}}\psi(\lambda_{jk})}. \end{aligned}$$

Here, $G_2(0) = 0$, $G_2'(0) = \mathbf{E}[\mathcal{X}_n^2] = a_1^2$, $G_2''(0) = 2\mathbf{E}[\mathcal{X}_n^2] = 2a_2^2$. Thus the constants of integration K_1, K_2, and K_3 are determined by solving the linear system

$$\begin{pmatrix} 1 & 1 & 1 \\ \lambda_1 & \lambda_2 & \lambda_3 \\ \lambda_1(\lambda_1+1) & \lambda_2(\lambda_2+1) & \lambda_3(\lambda_3+1) \end{pmatrix} \begin{pmatrix} K_1 \\ K_2 \\ K_3 \end{pmatrix} = \begin{pmatrix} 0 \\ a_1^2 \\ 2a_2^2 \end{pmatrix} - \begin{pmatrix} h_2(0) \\ h_2'(0) \\ h_2''(0) \end{pmatrix}. \tag{6.5}$$

Solving this linear system with $a_1 = 1$, $a_2 = a_3 = 0$, one gets

$$K_1^{(11)} = \frac{31}{377}, \qquad K_2^{(11)} = \frac{-35-\sqrt{23}\,i}{208}, \qquad K_3^{(11)} = \frac{-35+\sqrt{23}\,i}{208};$$

thus,

$$\begin{aligned} \mathbf{Var}\big[X_n^{(1)}\big] &= \frac{4}{169}n^2 + \frac{751}{4901}n + \frac{635}{4901} + (-1)^{n+1}\frac{3}{299}\binom{6}{n} \\ &+ \frac{2}{n!}\Re\left\{\left(\frac{-35-\sqrt{23}\,i}{208}\right)\left\langle\frac{-5+\sqrt{23}\,i}{2}\right\rangle_n\right\} \\ &+ \frac{8}{13(n!)}\Re\left\{\left(-\frac{1}{13} - \frac{4\sqrt{23}}{299}i\right)\left(\frac{-5+\sqrt{23}\,i}{2} + n\right)\right. \\ &\qquad\qquad \left.\left\langle\frac{-5+\sqrt{23}\,i}{2}\right\rangle_n\right\} \\ &+ \frac{144}{n!}\Re\left\{\left(\frac{1199+139\sqrt{23}\,i}{43285632}\right)\left\langle -6+\sqrt{23}\,i\right\rangle_n\right\} \\ &- \left[\frac{2}{13}(n+1) + \frac{2}{n!}\Re\left\{\left(-\frac{1}{13} - \frac{4\sqrt{23}}{299}i\right)\left\langle\frac{-5+\sqrt{23}\,i}{2}\right\rangle_n\right\}\right]^2 \\ &\sim \frac{519}{4901}n. \end{aligned}$$

Similar calculations with various settings for a_1, a_2, and a_3 lead to

$$\mathbf{Var}\big[X_n^{(2)}\big] \sim \frac{7586}{122525}n, \qquad \mathbf{Var}\big[X_n^{(3)}\big] \sim \frac{2276}{122525}n,$$

$$\mathbf{Var}\big[X_n^{(1)} + X_n^{(2)}\big] \sim \frac{5276}{122525}n,$$

$$\mathbf{Var}\big[X_n^{(2)} + X_n^{(3)}\big] \sim \frac{126}{4901}n,$$

$$\mathbf{Var}\big[X_n^{(3)} + X_n^{(1)}\big] \sim \frac{19061}{122525}n.$$

Hence, the asymptotic variance-covariance matrix for $\mathbf{X}_n$ is

$$\mathbf{\Lambda}_3 n = \begin{pmatrix} \frac{519}{4901} & -\frac{3057}{49010} & \frac{381}{24505} \\ -\frac{3057}{49010} & \frac{7586}{122525} & -\frac{3356}{122525} \\ \frac{381}{24505} & -\frac{3356}{122525} & \frac{2276}{122525} \end{pmatrix} n$$

and the corresponding asymptotic variance-covariance matrix for $\mathbf{C}_n$ is

$$\mathbf{J}_3\mathbf{\Lambda}_3\mathbf{J}_3^T n = \begin{pmatrix} \frac{186}{4901} & -\frac{207}{9802} & \frac{33}{4901} \\ -\frac{207}{9802} & \frac{126}{4901} & -\frac{216}{24505} \\ \frac{33}{4901} & -\frac{216}{24505} & \frac{2276}{122525} \end{pmatrix} n.$$

An exact computation of all variances and covariances for this example was carried out; for details of these computations, see [14]. The essential behavior in all averages, variances and covariances, is a linear component in n accompanied by very small periodic oscillations. In view of Theorem 2, the vector $(\hat{X}_n^{(1)}, \hat{X}_n^{(2)}, \hat{X}_n^{(3)})^T$ converges in distribution to a multinormal distribution with variance-covariance matrix $\mathbf{\Lambda}_3$ and the vector $(\hat{C}_n^{(1)}, \hat{C}_n^{(2)}, \hat{C}_n^{(3)})^T$ converges in distribution to a multinormal distribution with variance-covariance matrix $\mathbf{J}_3\mathbf{\Lambda}_3\mathbf{J}_3^T$. More generally, for higher branch factor m, the buckets are of size 2^k words, with one reserved in each bucket for system use. With numeric keys occupying one word each and one-word long pointers, the pointerless buckets have capacities $c_i = 2^i - 1$, $i = 1, \ldots, p-1$, and contain a hidden tag. Like type $p-1$, the last bucket type, type p, contains a hidden tag and has capacity $c_p = 2^{p-1} - 1$, but it also contains 2^{p-1} pointers. By lumping together nodes in the exact fit scheme that are collapsed into one bucket under the buddy system, we can obtain the relative space economy achieved by the buddy system allocation scheme. Nodes containing $2^{k-1}, 2^{k-1}+1, \ldots, 2^k - 1$ in the exact fit scheme are all implemented as buckets of type k with capacity $c_k = 2^k - 1$ under the buddy system. The space is not tight like the perfect packing of the exact fit scheme, but for small k (these are the majority of nodes, on average) only a small waste is still an improvement over the severe waste of the fixed-bucket scheme. If $\tilde{X}_n^{(j)}$ is the number of nodes holding exactly j keys under exact fit, then the average number of nodes under the buddy system, for type k, $k = 1, 2, \ldots, p-1$, is

$$\begin{aligned} \mathbf{E}\big[X_n^{(k)}\big] &= \sum_{j=2^{k-1}}^{2^k-1} \mathbf{E}\big[\tilde{X}_n^{(j)}\big], \qquad k = 1, 2, \ldots, p-1, \\ &\sim \sum_{j=2^{k-1}}^{2^k-1} \frac{n}{(j+1)(j+2)(H_m - 1)} \\ &\sim \Big(\frac{n}{H_{m-1} - 1}\Big)\Big(\frac{1}{2^{k-1}+1} - \frac{1}{2^k+1}\Big) \end{aligned}$$

and the average number of nodes of type p is

$$\mathbf{E}[X_n^{(p)}] \sim \frac{n}{(m+1)(H_m-1)}.$$

Thus, S_n, the total actual space, has an average

$$\begin{aligned}
\mathbf{E}[S_n] &= \sum_{k=1}^{p} 2^k \mathbf{E}[X_n^{(k)}] \\
&\sim \frac{n}{(H_m-1)}\left[\sum_{k=1}^{p-1} 2^k\left(\frac{1}{2^{k-1}+1} - \frac{1}{2^k+1}\right) + \frac{2^p}{m+1}\right] \\
&= \frac{n}{(H_{2^{p-1}}-1)}\left(p-1+\frac{2^{p-1}}{2^{p-1}+1} - \sum_{k=1}^{p-2}\frac{1}{2^k+1}\right) \\
&\approx \frac{n}{(H_{2^{p-1}}-1)}\left(p-0.7645\right), \quad \text{for large } p \\
&\approx \frac{n}{\ln 2} \\
&\approx 1.44n.
\end{aligned}$$

We compare this scheme to the previous two schemes under the same environment (i.e., same assumptions concerning the space for data, pointers, and hidden tag) and same branch factor. Compared with the fixed-bucket scheme, for which there is an average $\frac{n}{2}(H_{2^{p-1}}-1)^{-1}$ nodes, each requiring 2^p bytes, the efficiency of the buddy system is $p/2^{p-1}$, which tends to 0 fast as $p \to \infty$. Compared to the exact fit scheme, when we take $\alpha = 1$ word in formula (6.3) (i.e., when (6.3) is interpreted in units of words instead of bytes), the efficiency for large m is about

$$\begin{aligned}
\frac{\left(p/(H_m-1)\right)n}{\left(\alpha H_m/(H_m-1)\right)n} &\approx \frac{p}{\ln m} = \frac{p}{\ln 2^{p-1}} = \frac{p}{(p-1)\ln 2} \\
&\approx \frac{1}{\ln 2} \\
&\approx 1.44.
\end{aligned}$$

This method is only 44% worse than exact fit on average but may suit computer systems where exact fit is not available. The filling ratio $(\ln 2)^{-1} = 1.44$ has been observed in a number of data structures in comparison with the perfect packing and appears to be a universal constant underlying data retrieval methods. Instances may be found in digital search trees (see [7]), quadtrees (see [10]), B-trees (see [25] and [5]), hashing schemes (see [13] and [6]), and tries (see [11] and [24]). These results are surveyed in [9].

7. Conclusion. A random search tree with branch factor m and elastic buckets for keys was discussed, and the case of buckets with general capacities was examined. Formulas were derived for the expectations and variances of $X_n^{(i)}$, the number of buckets of type i, and for the covariances between different types. For $3 \le m \le 26$, all variances and covariances were found to be asymptotically linear in n, but for higher branch factors they experience a phase transition and become a superlinear (but subquadratic) function of n. This phase transition persists in all practical memory management schemes and seems to be independent of the bucket sizes. The joint distribution of $(\hat{X}_n^{(1)}, \dots, \hat{X}_n^{(p)})^T$, a vector of the normalized random variables for $X_n^{(i)}$, was found to be asymptotically jointly multinormal for $3 \le m \le 26$.

An illustrating example of the buddy system scheme, the four-way branching case with bucket sizes of two, four, and eight words for data, pointers, and a hidden tag for system use, is worked out in detail. For large branch factor, this method is shown to be only 44% worse than exact fit but may suit computer systems where exact fit is not available.

An associated problem, the study of the number of conversions between bucket types can also be found from the behavior of the random variables $\mathcal{X}_n^{(i)}$. In practical memory management schemes, knowledge of the number of conversions between bucket types may be of use in determining the associated cost in the storage and handling of data. The same properties exhibited by $\mathbf{X}_n$, a phase transition of all variances and covariances for $m > 26$ and asymptotic multinormality in the range $3 \le m \le 26$, are also inherent in the conversions problem.

Appendix. The purpose of this appendix is to compute the particular solution, $h_2(x)$, of the equation

$$\frac{d^{m-1}}{dx^{m-1}}G_2(x) = \frac{m!\,G_2(x)}{(1-x)^{m-1}} + H_2(x),$$

where

$$H_2(x) \overset{\text{def}}{=} \frac{m!\,(m-1)G_1^2(x)}{(1-x)^{m-2}} + \frac{(m-1)!\,a_p^2}{(1-x)^m} + \frac{2a_p(m!)G_1(x)}{(1-x)^{m-1}}$$
$$+ (m-1)!\,(a_{p-1}^2 - a_p^2)\delta_{c_p,c_{p-1}}.$$

Observe that all the terms of $H_2(x)$ have the general form $c(1-x)^{-\lambda-m+1}$. Each term of $H_2(x)$ of the form $c(1-x)^{-\lambda-m+1}$ contributes to the particular solution $h_2(x)$ a term of the form

$$\frac{c}{\psi(\lambda)}(1-x)^{-\lambda},$$

provided that $\psi(\lambda) \ne 0$. If $\psi(\lambda) = 0$, then a term of the form

$$\frac{c}{\psi'(\lambda)}(1-x)^{-\lambda}\ln\left(\frac{1}{1-x}\right)$$

is contributed to the particular solution. Thus, $h_2(x)$ and its contribution to $\mathbf{E}[\mathcal{X}_n^2]$ can be obtained by organizing the terms of $H_2(x)$ into the following cases:

(i) $(m-1)!\,a_p^2(1-x)^{-m}$. For this term $\lambda = 1$ with $\psi(1) = -(m-1)!\,(m-1) \ne 0$ for all $m \ge 2$. Thus this term contributes

$$-\frac{a_p^2}{(m-1)(1-x)}$$

to the particular solution and adds

$$-\frac{a_p^2}{m-1}$$

to $\mathbf{E}[\mathcal{X}_n^2]$.

(ii) $(m-1)!\,(a_{p-1}^2 - a_p{}^2)\delta_{c_p,c_{p-1}}$. For this term

$$\lambda = -m+1, \qquad \psi(\lambda) = -(m-1)!\,\big[m+(-1)^m\big] \neq 0,$$

for all $m \geq 2$. Thus this term contributes

$$-\frac{(a_{p-1}^2 - a_p{}^2)\delta_{c_p,c_{p-1}}}{\big[m+(-1)^m\big]}(1-x)^{m-1}$$

to the particular solution which adds

$$\frac{(-1)^{n+1}(a_{p-1}^2 - a_p{}^2)\delta_{c_p,c_{p-1}}}{\big[m+(-1)^m\big]}\binom{m-1}{n}$$

to $\mathbf{E}\big[\mathcal{X}_n^2\big]$, a term that disappears for $n \geq m$.

(iii) $2a_p(m!)G_1(x)(1-x)^{-m+1}$. Using the solution for $G_1(x)$ from §3, this term presents three subcases as follows:

(a) $2a_p(m!)(1-x)^{-m+1}\big[-a_p(m-1)^{-1}(1-x)^{-1}\big] = -2a_p^2(m!)(m–1)^{-1}(1-x)^{-m}$. For this term $\lambda = 1$ with $\psi(1) = -(m-1)!\,(m-1) \neq 0$, for all $m \geq 2$. Thus this term contributes

$$\frac{2a_p^2 m}{(m-1)^2(1-x)}$$

to the particular solution which adds

$$\frac{2a_p^2 m}{(m-1)^2}$$

to $\mathbf{E}\big[\mathcal{X}_n^2\big]$.

(b) $-2a_p(m!)\delta_{c_p,c_{p-1}}(a_{p-1} - a_p)\big[m+(-1)^m\big]^{-1}$. This term cancels out with a similar term that appears in $m!\,(m-1)G_1^2(x)(1-x)^{-m+2}$.

(c) $2a_p(m!)(1-x)^{-m+1}\big[A_j(1-x)^{-\lambda_j}\big]$. These terms cancel out with similar terms that appear in $m!\,(m-1)G_1^2(x)(1-x)^{-m+2}$.

(iv) $m!\,(m-1)G_1^2(x)(1-x)^{-m+2}$. Using the solution for $G_1(x)$ from §3, this term presents six subcases as follows:

(a) $m!\,a_p^2(m-1)^{-1}(1-x)^{-m}$. For this term $\lambda = 1$ with $\psi(1) = -(m-1)!\,(m-1) \neq 0$ for all $m \geq 2$. Thus this term contributes

$$-\frac{ma_p^2}{(m-1)^2(1-x)}$$

to the particular solution, which adds

$$-\frac{ma_p^2}{(m-1)^2}$$

to $\mathbf{E}\big[\mathcal{X}_n^2\big]$.

(b) $m!\,(m-1)\delta^2_{c_p,c_{p-1}}(a_{p-1}-a_p)^2\big[m+(-1)^m\big]^{-2}(1-x)^m$. For this term $\lambda = -2m+1$ but the smallest real part of any root of $\psi(\lambda)$ is no less than $-m$, so $-2m+1$ cannot be a root. Thus this term contributes

$$\frac{m!\,(m-1)\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)^2(1-x)^{2m-1}}{\big[m+(-1)^m\big]^2\psi(-2m+1)}$$

to the particular solution, which adds

$$(-1)^n\frac{m!\,(m-1)\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)^2}{\big[m+(-1)^m\big]^2\psi(-2m+1)}\binom{2m-1}{n}$$

to $\mathbf{E}\big[\mathcal{X}_n^2\big]$, a term that disappears for $n \geq 2m$.

(c) $-2a_p(m!)(1-x)^{-m+2}\big[A_j(1-x)^{-\lambda_j-1}\big]$. These terms cancel out with the terms in subcase iii(c).

(d) $2a_p(m!)\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)\big[m+(-1)^m\big]^{-1}$. This term cancels out with the term in subcase iii(b).

(e) $m!\,(m-1)\big[-2\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)A_j\big\{m+(-1)^m\big\}^{-1}(1-x)^{-\lambda_j+1}\big]$. For these terms $\lambda = \lambda_j - m$ and the contribution, $\mu_j(x)$, to the particular solution is of the form

$$\mu_j(x) = \begin{cases} \theta_j(1-x)^{-\lambda_j+m}\big\{\psi(\lambda_j-m)\big\}^{-1}, & \psi(\lambda_j-m)\neq 0,\\ \theta_j(1-x)^{-\lambda_j+m}\big\{\psi'(\lambda_j-m)\big\}^{-1}\ln\Big(\dfrac{1}{1-x}\Big), & \psi(\lambda_j-m)=0. \end{cases}$$

where $\theta_j = -2(m!)(m-1)\big[\delta_{c_p,c_{p-1}}(a_{p-1}-a_p)A_j\big\{m+(-1)^m\big\}^{-1}\big]$. The added contribution is $O\big(n^{\Re\lambda_j-m-1+\epsilon}\big)$ for every $\epsilon > 0$. But $\Re\lambda_j \leq 2$ for $j = 1, \dots, m-1$, i.e., this term is only $O\big(n^\epsilon/n^{m-1}\big)$. As $m \geq 2$, this contribution diminishes if $\epsilon > 0$ is small enough; for $\epsilon < m-2$ this term is $O\big(n^{-1}\big)$ as $n \to \infty$.

(f) $m!\,(m-1)A_jA_k(1-x)^{-\lambda_j-\lambda_k-m+2}$. Setting $\lambda_{jk} = \lambda_j + \lambda_k - 1$ puts these terms into the form $m!\,(m-1)A_jA_k(1-x)^{-\lambda_{jk}-m+1}$. For these terms $\lambda = \lambda_{jk}$ and the contribution, $\eta_{jk}(x)$, to the particular solution is of the form

$$\eta_{jk}(x) = \begin{cases} \beta_{jk}(1-x)^{-\lambda_{jk}}\big\{\psi(\lambda_{jk})\big\}^{-1}, & \psi(\lambda_{jk})\neq 0,\\ \beta_{jk}(1-x)^{-\lambda_{jk}}\big\{\psi'(\lambda_{jk})\big\}^{-1}\ln\Big(\dfrac{1}{1-x}\Big), & \psi(\lambda_{jk})=0, \end{cases}$$

where $\beta_{jk} = m!\,(m-1)A_jA_k$. The contribution of these terms into $\mathbf{E}\big[\mathcal{X}_n^2\big]$ can be classified into four categories:

(1) The case $j = 1, k = 1$. For this pair of indices $\lambda_{11} = 3$, $\psi(3) = m!\,(m-1)/2$, and the contribution, $\eta_{11}(x)$, to the particular solution is

$$\eta_{11}(x) = \frac{2A_1^2}{(1-x)^3},$$

which adds

$$A_1^2(n+1)(n+2) = A_1^2n^2 + 3A_1^2n + 2A_1^2$$

to $\mathbf{E}\big[\mathcal{X}_n^2\big]$.

(2) The case $j = 1, k > 1$ (symmetric with this case is $k = 1$ and $j > 1$). For this pair of indices

$$\lambda_{1k} = \lambda_k + 1, \qquad \psi(\lambda_k + 1) = m!\,(m-1)\lambda_k^{-1} \neq 0,$$

for any $m \geq 2$ and the contribution, $\eta_{1k}(x)$, to the particular solution is

$$\frac{\lambda_k A_1 A_k}{(1-x)^{\lambda_k+1}},$$

which adds

$$A_1 A_k (\lambda_k + n) \frac{\langle \lambda_k \rangle_n}{n!}$$

to $\mathbf{E}[\mathcal{X}_n^2]$. The collective contribution of all such terms to the expectation is

$$2A_1 \sum_{k=2}^{m-1} A_k (\lambda_k + n) \frac{\langle \lambda_k \rangle_n}{n!} = 2A_1 \sum_{k=2}^{m-1} \lambda_k \frac{A_k \langle \lambda_k \rangle_n}{n!} + 2A_1 n \sum_{k=2}^{m-1} \frac{A_k \langle \lambda_k \rangle_n}{n!}.$$

The first term on the right is $O(n^{\alpha-1})$, the second appears in $\mathbf{E}^2[\mathcal{X}_n]$, and thus this order of magnitude disappears in $\mathbf{Var}[\mathcal{X}_n] = \mathbf{E}[\mathcal{X}_n^2] - \mathbf{E}^2[\mathcal{X}_n]$.

(3) The case $2 \leq j, k \leq 3$. These terms are the causes of the aforementioned phase transitions in the variances and covariances since its behavior for $m \leq 26$ is different from that for $m > 26$ as discussed next. For each of these terms and whether $\ln\left(\frac{1}{1-x}\right)$ appears in it or not, if $\alpha < 3/2$, then $\Re\lambda_{jk} = 2\alpha - 1 < 2$ and for every $\epsilon > 0$.

$$\begin{aligned}[x^n]\eta_{jk}(x) &= O\left(n^{\Re\lambda_{jk}-1+\epsilon}\right) \\ &= o(n),\end{aligned}$$

where the last equality holds for small enough ϵ. But if $\alpha > 3/2$, we have $\Re\lambda_{jk} = 2\alpha - 1 > 2$ and so $\psi(\lambda_{jk}) \neq 0$ and the contributed solution is

$$m!\,(m-1) \sum_{2 \leq j,k \leq 3} \frac{A_j A_k}{\psi(\lambda_{jk})} (1-x)^{-\lambda_{jk}}.$$

By the Stirling approximation of the Gamma function, this adds to $\mathbf{E}[\mathcal{X}_n^2]$ the term

$$c_m(n) \stackrel{\text{def}}{=} n^{2\alpha-2} \sum_{2 \leq j,k \leq 3} A_j A_k \frac{m!\,(m-1)}{\psi(\lambda_{jk})\Gamma(\lambda_{jk})} n^{i\Im\lambda_{jk}},$$

where $i = \sqrt{-1}$. This growth is superlinear for $\alpha > 3/2$ (but subquadratic as $\alpha < 2$ for all m). The function $c_m(n)$ is $\frac{\pi}{\beta}$-periodic in $\ln n$.

(4) All the other indices: For these $\lambda_{jk} = \lambda_j + \lambda_k - 1$ and at least one index, j or k, has to be greater than 2, i.e., $\Re\lambda_{jk} < 2\alpha - 1$. The corresponding solution therefore (whether it has a logarithmic term or not) contributes $o\left(n^{2\alpha-2+\epsilon}\right)$, for every $\epsilon > 0$. Putting all of the above contributions to $\mathbf{E}[\mathcal{X}_n^2]$ together and then subtracting $\mathbf{E}^2[\mathcal{X}_n]$, we get the variance as in Theorem 1.

Acknowledgment. Our original proof of the asymptotic normality covered the range of $3 \leq m \leq 15$. The authors are indebted to Dr. Robert T. Smythe for suggesting an extension of the proof for Theorem 2 to work in the entire range of the linearity of variances and covariances ($3 \leq m \leq 26$). We also wish to thank Ricardo Baeza-Yates for updating some references and for several other helpful comments.

TIGHT BOUNDS ON THE COMPLEXITY OF THE BOYER-MOORE STRING MATCHING ALGORITHM*

RICHARD COLE†

Abstract. The problem of finding all occurrences of a pattern of length m in a text of length n is considered. It is shown that the Boyer–Moore string matching algorithm performs roughly $3n$ comparisons and that this bound is tight up to $O(n/m)$; more precisely, an upper bound of $3n - 3(n-m+1)/(m+2)$ comparisons is shown, as is a lower bound of $3n(1-o(1))$ comparisons, as $\frac{n}{m} \to \infty$ and $m \to \infty$. While the upper bound is somewhat involved, its main elements provide a simple proof of a $4n$ upper bound for the same algorithm.

Key words. string matching, character comparisons, Boyer–Moore algorithm, amortized analysis

AMS subject classifications. 68Q20, 68Q25, 68R15

1. Introduction.

String matching is the problem of finding a pattern of length m in a text of length n; often all occurrences of the pattern are sought. This problem is well studied and is a staple of textbooks on algorithms (for instance, [3], [5], [12]). It is an important subproblem in a number of domains including text editing, symbol manipulation, and data retrieval.

The best known algorithms for this problem are the Knuth–Morris–Pratt algorithm [19] and the Boyer-Moore algorithm [7] (we refer to these as the KMP and BM algorithms, respectively). Both these algorithms are linear time; the bound for the KMP algorithm is very straightforward, the bound for the BM algorithm is considerably less so. An interesting aspect of the BM algorithm is that on average (in probabilistic settings) it takes sublinear time; this effect is observed in practice too. A recent study of this behavior is given in [6].

Many other types of string matching algorithms have been studied; these include matching several strings simultaneously [1], real-time matching [15], matching in constant space [17], [13], randomized algorithms [20], parallel algorithms [26], [27], approximate matching [21], [16], [25], and two-dimensional matching [4].

Both the KMP and BM algorithms begin by computing a shift function. (We review the shift function for the BM algorithm later.) Following the precomputation of the shift function, the actual match is carried out. The complexity of the algorithm is usually stated in terms of the number of comparisons required for the matching stage (excluding the precomputation stage). The KMP algorithm requires $2n - m$ comparisons in the worst case and this is a tight bound for $m \geq 2$. For the BM algorithm, the first linear bound was given by Knuth in [19] as a bound of $7n$ comparisons (often misquoted as $6n$ comparisons); this proof is difficult. In 1980, Guibas and Odlyzko gave another proof [18], obtaining a bound of $4n$ comparisons; their proof is also nontrivial. Guibas and Odlyzko also conjectured that $2n$ comparisons might be the correct bound. Our contribution is twofold.

- We give a bound, tight up to lower-order terms, of roughly $3n$ comparisons, thereby disproving the just-mentioned conjecture.
- In addition, the basic elements of this proof provide a direct and straightforward demonstration of an upper bound of $4n$ comparisons.

The above bounds for the BM algorithm assume that the pattern is not *periodic*, i.e., of the form wv^k, where w is a proper suffix of v and $k \geq 2$. Galil [14] showed how to modify the BM algorithm so that a linear bound applies in this case too; in fact, using essentially Galil's modification, our bounds apply unchanged to such patterns.

A preliminary version of this paper appeared in the Proceedings of the 1991 ACM-SIAM Symposium on Discrete Algorithms.

†Courant Institute, New York University, 251 Mercer Street, New York, New York 10012 (cole@cs.nyu.edu).

Another approach to improving the bound on the number of comparisons for the BM algorithm is to modify the algorithm so that it no longer necessarily compares characters of the pattern in consecutive right-to-left order. Such a modification was given in [2]; they thereby obtained a bound of $2n - m + 1$ character comparisons, at the cost of a more complex control structure. Crochemore et al. [8] showed that remembering just the most recently matched portion of the text reduces the upper bound of BM from $3n$ to $2n$ comparisons.

Recently algorithms that combine the left-to-right sweep of the KMP algorithm with the right-to-left sweep of the BM algorithm have been studied. In particular, Galil and Giancarlo analyzed and modified a string matching algorithm designed by Colussi [11]; they showed it makes at most $\frac{4}{3}n$ comparisons. In fact, [11] give this bound in a sharper form as a function of the period z of the pattern; the bound becomes $n + (n - m)\min\{\frac{1}{3}, (\min\{z, m - z\} + 2)/2m\}$. Very recently, almost tight bounds on the comparison complexity of string matching algorithms have been given by Cole et al. [9], [10]; they give an upper bound of $n(1 + 8/(3(m + 1)))$ character comparisons and a lower bound of $n + 2(n - m)/(m + 3)$ character comparisons for infinitely many m.

However, their lower bound does not appear to cover algorithms of the BM type, which can take advantage of a finite alphabet and perform a bad character shift (see §2). The bad character shift can contribute substantially to the expected sublinear behavior of the BM algorithm. Likewise, the algorithms of Colussi et al. and Cole and Hariharan do not incorporate a shift of this type, nor is it clear whether these algorithms can be modified to incorporate shifts of this type. So while the worst-case bound of these algorithms is better than that for the BM algorithm, it is still of interest to understand the behavior of the BM algorithm.

The remainder of the paper is organized as follows. In §2, we briefly review the BM algorithm. In §3 we show the lower bound of roughly $3n$ comparisons. In §4 we prove a number of lemmas needed for both upper bound results. In §5 we complete the proof of the $4n$ upper bound for nonperiodic patterns; in §6 we extend this upper bound to an upper bound of roughly $3n$ comparisons. In §7 we extend the results to periodic patterns.

2. The BM algorithm: A review. We first describe BM-type algorithms and then specify the BM algorithm itself. To find occurrences of the pattern in the text, a BM-type algorithm tests whether given substrings, t', of the text of length m match the pattern; each such test is called an *attempted match*. An attempted match is performed as follows. The characters of the pattern are compared one by one, in right-to-left order, with the corresponding characters of substring t' until either a mismatch is found or the match is complete. When an attempted match completes (either by a mismatch or by finding a match) the pattern is shifted to the right, ideally by the maximum distance consistent with not missing any potential matches; the actual shift may be smaller than this maximum. The shift is determined by a shift function associated with the algorithm. Following the shift, another attempted match is performed. This procedure is continued until the pattern is shifted beyond the right end of the text. The initial attempted match is with the leftmost m characters of the text.

The BM algorithm uses as its shift function the maximum of the following two shift functions. If there is a mismatch, the first shift function, the *bad character shift*, implicitly provides the location of the rightmost character, c, in the pattern, if any, that matches the mismatched character in the text. If c is present the shift specified by the bad character shift would cause c to become aligned with the mismatched text character. If c is not present the shift aligns the leftmost character of the pattern with the text character immediately to the right of the mismatched text character. The second shift function, the *good suffix shift*, is illustrated in Fig. 1; it specifies the smallest shift such that the shifted pattern matches the unshifted pattern on all the characters that were successfully matched, and fails to match the unshifted pattern on the mismatched character. If there is no such shift then the smallest shift that causes a prefix of the shifted pattern to match a suffix of the matched characters is specified. If there is no shift of this type either, then a shift of length m is specified.

Variants of the BM algorithm use the bad character shift only for a mismatch at the first character, or indeed omit its use altogether. Whichever is done, our upper and lower bounds apply. The presence of the bad character shift is desirable, however, since it helps ensure a sublinear behavior in practice. The only difficulty is that the proof of the upper bound becomes more involved, although the essentials are unchanged.

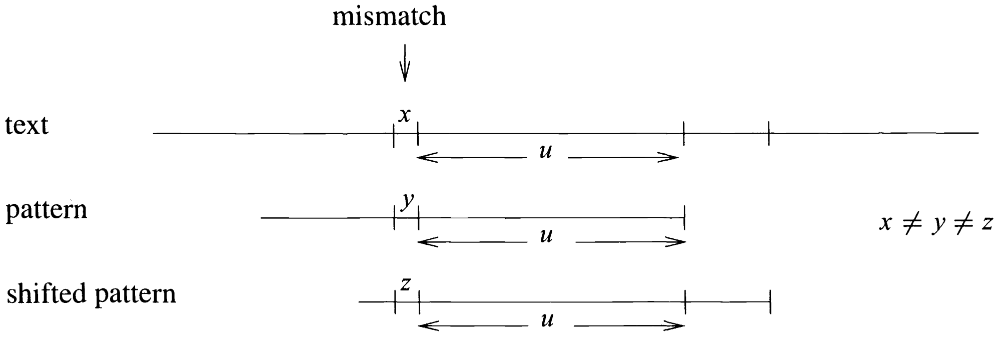

FIG. 1. *The good suffix shift.*

Remark. The terms bad character shift and good suffix shift are due to [12].

3. The lower bound. We give example patterns p, of length $m = 2k - 1$, and texts t, which demonstrate the lower bound of $3n(1 - o(1))$ comparisons (as $\frac{n}{m} \to \infty$ and $m \to \infty$).

The basic idea is to have frequent shifts by k on attempted matches comprising $2k - 1$ comparisons. In addition, to have roughly three comparisons per text character, we also seek to have short shifts on attempted matches of roughly k comparisons.

In particular, we choose $p = a^{k-1}ba^{k-1}$ and $t = a^{k-1}(aba^{k-1})^{\lambda}$. Let $v' = aba^{k-1}$.

Consider a situation in which the b in the pattern is aligned with the left end of a v' in the text, denoted $\bar{v}'$. (See Fig. 2.) The attempted match will be of length $k - 1$ and it will cause a shift of length 1. The next attempted match will have right(p) aligned with right($\bar{v}'$). The attempted match will be of length $2k - 1$ and it will result in a shift of length k. We return to the first situation. We note that t has been chosen so that the initial situation is the first situation. Thus we have shown the results given in Fig. 2.

text	···	a	b	a	a	a	b	a	a	a	b	a	a	···	
pattern				a	a	b	*a*	a							mismatch at *a*
first shift					a	a	b	a	a						match
second shift								a	a	b	a	a			iterate

FIG. 2. *The lower bound for* $k = 3$.

THEOREM 3.1. *There exist patterns of length* $m = 2k - 1$ *and texts of length* $n = \lambda(k + 1) + (k - 1)$, *for any integers* $k \geq 2$ *and* $\lambda \geq 1$, *for which the* BM *string matching algorithm performs*

$$\frac{3k-2}{k+1}(n-k+1) = (n - \frac{m-1}{2})(3 - \frac{10}{m+3})$$

comparisons. This is $3n(1-o(1))$ *comparisons as* $\frac{n}{m} \to \infty$ *and* $m \to \infty$.

For even length patterns, with $p = a^{k-2}ba^{k-1}$, for $k \geq 2$, and t one character shorter at the left end, we obtain a similar bound of

$$\frac{3k-3}{k+1}(n-k+2) = (n - \frac{m-2}{2})(3 - \frac{12}{m+4})$$

comparisons.

4. Preliminary lemmas.

DEFINITION 4.1. *A string u is* periodic *if $u = wv^k$, where w is a proper suffix of v and $k \geq 2$. u is 3-periodic if $k \geq 3$. If $w = \epsilon$, u is said to be* cyclic. *Also, u is said to be, respectively,* periodic, cyclic *in v. It is convenient to extend this terminology to allow the wording u is periodic (respectively, cyclic) in v to include the case $k = 1$; no ambiguity will result. u is* primitive *if it is not cyclic. If $u = v^k$, with v primitive, $k > 1$, v is called the* generator *of u. If $u = wv^k$, with v primitive, w a proper suffix of v, $k \geq 2$, v is called the* core *of u.*

The following lemma and corollary are well known (see [22], for example).

LEMMA 4.2. *Let x and y be two nonempty strings. If $xy = yx$ then there is a string z such that both x and y are cyclic in z.*

Proof. The proof is by induction on $|x| + |y|$. If $|x| = |y|$, then take $z = x$ $(= y)$; the result follows. Otherwise, without loss of generality, suppose that $|x| < |y|$. Then x is a prefix of y, so $y = xy_1$. Note that $y_1 \neq \epsilon$. Substituting gives $xxy_1 = xy_1x$, i.e., $xy_1 = y_1x$. The result now follows by induction. □

COROLLARY 4.3. *Suppose that v is a proper cyclic shift of w. If $v = w$, v is cyclic.*

Proof. Since v is a proper cyclic shift of w, we can write $w = xy$ and $v = yx$, where $x, y \neq \epsilon$. By Lemma 4.2, there is a string z with $x = z^i$ and $y = z^j$ for some $i, j \geq 1$. So $v = z^k$, for some $k \geq 2$, i.e., v is cyclic. □

LEMMA 4.4. *Let w be a string and let $s \leq |w|$ be an integer. Suppose that the prefix of w of length $|w| - s$ matches the suffix of $|w|$ of length $|w| - s$. Then w is periodic in u, the length s suffix of w.*

Proof. Consider two instances of w, overlapping in $|w| - s$ characters, as shown in Fig. 3. Denote the leftmost instance by w_L and the rightmost by w_R. Then $w_L = z_Lu$, $w_R = z_Ru$, for some identical strings z_L, z_R. If $|z_R| < |u|$, z_R is a suffix of u and the result is immediate. Otherwise, as w_L and w_R match on their aligned portions, w_R has u as its length s suffix; the result then follows by an inductive argument applied to z_L and z_R. □

The analysis will focus on one attempted match at a time; the attempted match AM being analyzed is called the *current attempted match*. We introduce the following notation and definitions.

DEFINITION 4.5. *t denotes the portion of text matched by AM. s denotes the length of the good suffix shift for AM. u denotes the suffix of the pattern of length s. Suppose that $u = v^k$, $k \geq 1$, where v is primitive. An attempted match AM', which precedes AM and begins by comparing a character of t, is called an* early attempted match *(with respect to AM). Throughout the paper, t and v are defined with respect to the current attempted match. w_r denotes the rightmost character of w.* right(w, z) *denotes the rightmost substring of w equal to z. w_l and* left(w, z) *are defined analogously. Let w and z be two overlapping strings; character c in string w is said to be* aligned *with z if it is aligned with some character in z.*

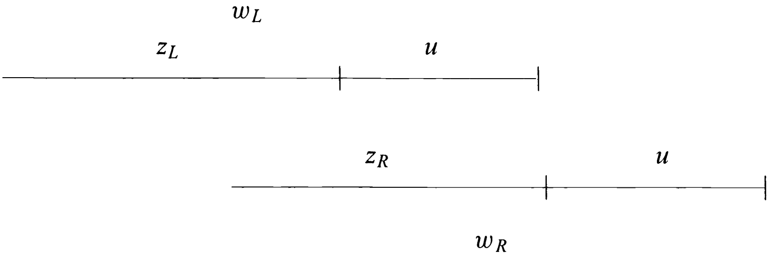

FIG. 3. *Overlapping instances of u.*

LEMMA 4.6. (i) *t and the suffix w of p of length* $\min\{|t| + |u|, |p|\}$ *are both periodic in u and v.*

(ii) *Suppose $|t| + |u| < |p|$. Then $p[m - |t| - |u|] \neq p[m - |t| - |u| + |v|]$ (i.e., the character immediately to the left of the length $|t| + |u|$ suffix of p is not equal to the character in p distance $|v|$ to its right. In addition, the character immediately to the left of t differs from $t[v]$.*

Proof. See Fig. 4. Because the good suffix shift has length $|u|$, w obeys the conditions of Lemma 4.4; thus w is periodic in u. Because u is periodic in v, result (i) for w follows. And because t is a suffix of w, result (i) for t follows also.

Result (ii) is immediate from the definition of the good suffix shift. □

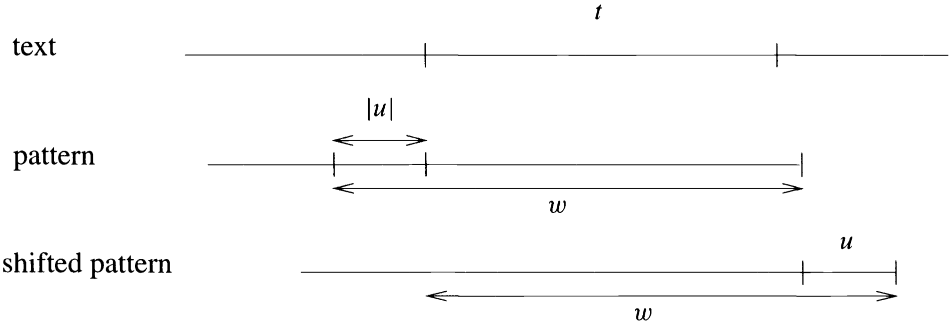

FIG. 4. *t is periodic.*

LEMMA 4.7. *Let AM_1 be an early attempted match. Suppose that $|p| > |t|$. Then p_r is not aligned with v_r for any substring v in t.*

Proof. See Fig. 5. Suppose that the pattern were so aligned. Let t_a be the text character immediately to the left of t_l. By Lemma 4.6(i), the suffix of p of length $\min\{|t| + |u|, |p|\}$ is periodic in u; thus the character in p aligned with t_a during AM_1 is identical to the character aligned with t_a during the current attempted match. Consequently, the good suffix shift would shift p_r to distance s to the right of t_r, contradicting the fact that AM_1 is an early attempted match. (Any shorter shift by a multiple of $|v|$ would place the same character in the mismatch location; this is not a good suffix shift. Any other shorter shift causes a proper cyclic shift of v (in p) to be aligned with an instance of v in t, and this cannot be a good suffix shift by Corollary 4.3, since v is primitive.) □

LEMMA 4.8. *Let AM_1 be an early attempted match. Suppose that either*

(i) $|p| > |t|$, *or*

(ii) $|p| = |t|$ *and p_r is not aligned with $\bar{v}_r$ for any instance $\bar{v}$ of v in t.*

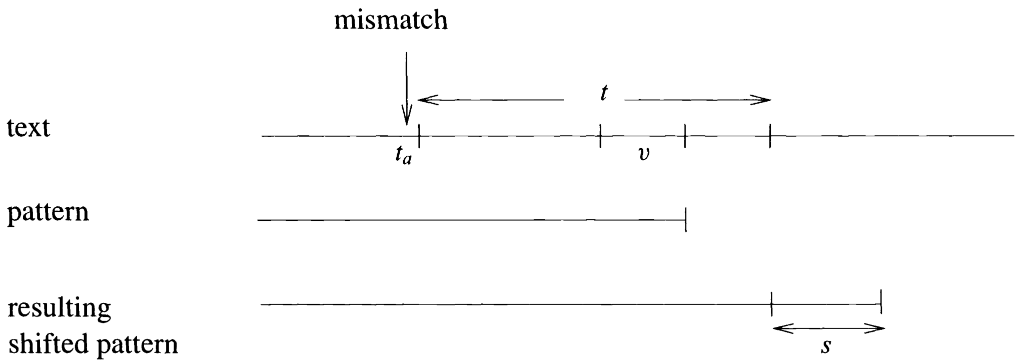

FIG. 5. *Alignment of p.*

Then AM_1 performs at most $|v|$ comparisons with characters of t. Further, if there are $|v|$ such comparisons, the last comparison is a mismatch.

Proof. p_r is not aligned with v_r for any substring v in t (by Lemma 4.7 for $|p| > |t|$ and by assumption for $|p| = |t|$). Thus if $|v|$ characters of t were matched, by Corollary 4.3, v would be cyclic, contrary to its definition. □

LEMMA 4.9. *Let AM_1 be an early attempted match. If $|p| > |t|$, p_r is either aligned with a character in* right(v, t) *or with one of the leftmost $|v| - 1$ characters in t. This remains true for $|p| = |t|$, on the condition that p_r is never aligned with $\bar{v}_r$ for any instance $\bar{v}$ of v in t apart from the rightmost instance.*

Proof. See Fig. 6. If p_r is elsewhere, the first $|v|$ comparisons, if there were that many, would be with characters in t. Then by Lemma 4.8, there must be a mismatch on or before the $|v|$th comparison, i.e., there are at most $|v|$ comparisons. Let $\bar{v}$ denote the substring v of t with which p_r is aligned. But then the shift at most moves p_r to $\bar{v}_r$. (This shift would produce a match with all the text characters compared in the attempted match and so is at least as long as the actual match.) In fact, if p_r is shifted less far, eventually, following a sequence of such attempted matches, p_r is aligned with $\bar{v}_r$. But this contradicts Lemma 4.7. □

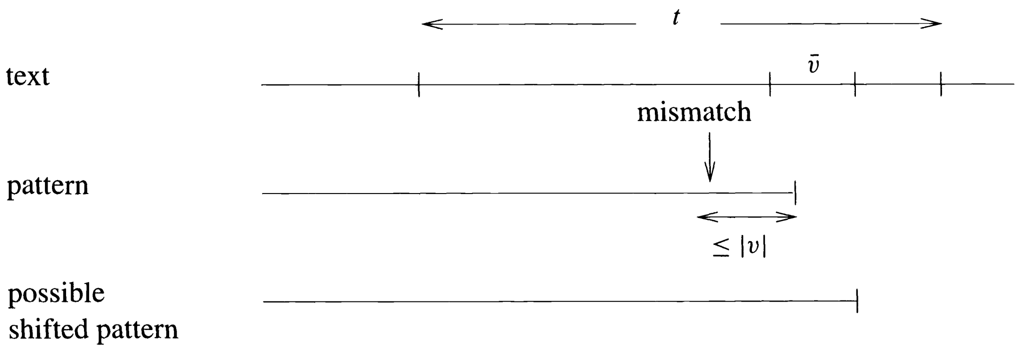

FIG. 6. *Location of p_r.*

5. A simple upper bound: 4n comparisons.

LEMMA 5.1. *If $|p| > |t|$, prior to the current attempted match at most $3|v| - 3$ characters of t have been compared.*

Proof. See Fig. 7. By Lemma 4.9, in the early attempted matches, p_r is either aligned with one of the rightmost $|v|$ characters of t or with one of the leftmost $|v| - 1$ characters of t.

By Lemma 4.8, each of the early attempted matches performs at most $|v|$ comparisons. Since t_r is not compared prior to the current attempted match, the lemma follows. □

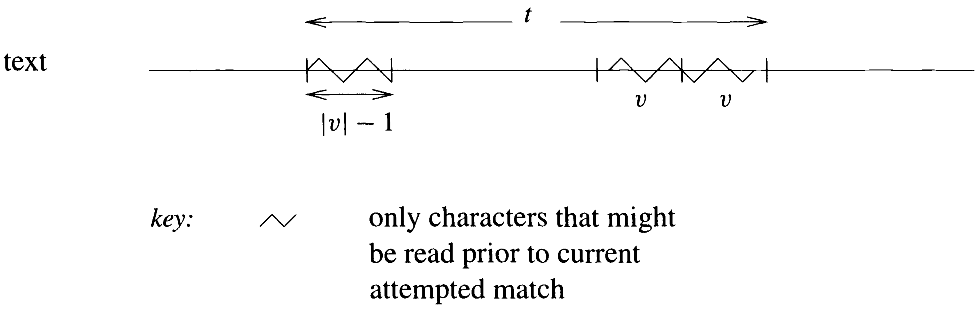

FIG. 7. *Characters already read.*

THEOREM 5.2. *The* BM *pattern string algorithm performs at most* $4n$ *comparisons when matching a non-*3*-periodic pattern of length m against a text of length n.*

Proof. We will show that the number of comparisons performed in each attempted match AM is bounded as follows.

Attempted match bound. The attempted match bound equals the number of text characters compared for the first time during AM plus three times the length of the ensuing shift.

It then follows that the total number of character comparisons is at most $4n$.

Consider AM, the current attempted match. If $|t| \leq 3s$, because the number of characters compared is $|t|$ or $|t|+1$, the attempted match bound holds for AM (since t_r was compared for the first time during the current attempted match).

So suppose that $|t| > 3s$. Since p is not 3-periodic, $|p| > |t|$. By Lemma 5.1, the number of previously uncompared characters compared by the current attempted match is at least $|t| - (3|v| - 3) \geq (|t| + 3) - 3s$; because the number of characters compared by AM is $|t| + 1$, the attempted match bound holds in this case too. □

6. An upper bound of roughly $3n$ comparisons. The $3n$ upper bound is proved using an amortized analysis, an approach for analyzing algorithms due to Sleator and Tarjan [24]. The method is as follows. Following the ith shift performed by the algorithm a potential ϕ_i is associated with the current state of the algorithm. ϕ_0 denotes the initial potential, before any shifts. Let t_i be the number of comparisons performed by the ith attempted match (i.e., between the $(i-1)$th and the ith shifts). Then the amortized cost of the ith attempted match, in comparisons, is defined to be $t_i + \phi_{i+1} - \phi_i$. The reason for using amortized costs is that with a well-chosen potential function, they can be easier to bound than the actual costs.

The total number of comparisons performed by the algorithm is given by

$$\sum_{i\geq 1} t_i = \sum_{i\geq 1} (a_i - \phi_{i+1} + \phi_i) = \sum_{i\geq 1} a_i - \phi_f + \phi_0,$$

where ϕ_f is the final potential, the potential at the end of the algorithm.

The $3n$ bound is proved using the following potential function.

$\phi = 2 \times$ the number of still-readable characters $+$ the number of unmarked characters.

A character is readable if it is not yet to the left of the left end of the pattern. For the purposes of analysis characters may be marked and then unmarked, possibly repeatedly. Initially every character is unmarked.

Clearly $\phi_0 = 3n$ and $\phi_f \geq 0$. We will show that the amortized cost (in comparisons) of each attempted match is at most -1. Thus the total number of comparisons performed is bounded by $3n$. In fact, the negative bound on the cost of each attempted match leads to a slightly tighter bound, as we will see.

Now we turn to the analysis of the BM algorithm. As in §5, we are assuming that the pattern is non-3-periodic.

As in §5, we consider a current attempted match that matches a substring t of the text and either has $|p| = |t|$ or mismatches at character t_a immediately to the left of t_l. We also consider earlier attempted matches in which p_r is aligned with t. Let s be the distance shifted in the current attempted match. There are a number of cases to consider; in all the cases we show an amortized cost of -1 or better for the current attempted match.

Before proceeding with the analysis, we specify the rules for unmarking text characters. When an unmarked character is read it becomes marked. However, a marked character can be unmarked again as follows. Whenever an attempted match would have an amortized cost less than -2, if the shift made is due to the good suffix shift, then the leftmost characters compared in the current attempted match are unmarked so as to increase the amortized cost to -2 (or until all the characters read in the current attempted match are unmarked, whichever occurs sooner). Actually, as we see below in Case 1, there is a special case for shifts of length 1. If the shift of length s is due to the bad character shift and the good suffix shift had length $s' < s$, then the same characters are unmarked as for a good suffix shift of length s'. In addition, the rightmost $\min\{2(s - s'), |t| + 1\}$ characters compared are unmarked.

Case 1. $s = 1$. Let t' be the text read by the current attempted match. Then $t' = ba^j$ for some $j \geq 0$, where $a \neq b$. We claim that the characters of t' had not been read previously. This would give an overall amortized cost of -2 for the attempted match, except that we unmark t'_r, giving an amortized cost of -1. It remains to demonstrate the claim. If there had been an earlier attempted match with p_r aligned with t', then the mismatch would have been at character b of t' and the resulting shift would have moved p_r beyond t'_r; therefore there was no such earlier attempted match, i.e., all of t' was unmarked immediately prior to the current attempted match.

Remark 6.1. Henceforth we can assume that at each attempted match the rightmost two characters compared (if at least two are compared) are unmarked.

Case 2. $|t| < 2s$. The decrease in potential is at least $2s + 2$. The cost of the current attempted match is $|t| + 1$. So the amortized cost of the current attempted match is at most -2.

Case 3. $|t| \geq 2s$ and $s > 1$. Then by Lemma 4.6(i), $t = wv^k$, for some $k \geq 2$, where w is a proper suffix of v, v is primitive, and s is an integer multiple of $|v|$. A little more notation is helpful. Let w_L, v_L, v_{R1}, v_{R2} denote, respectively, left(w, t), left(v, t), right(v, t), and the second rightmost v in t. It may be that $v_L = v_{R2}$. (See Fig. 8.) There are five subcases to consider.

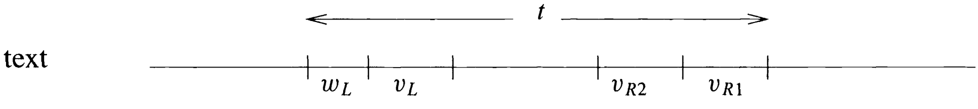

FIG. 8. *Further notation.*

Case 3.0. There is no early attempted match.

Case 3.1. AM_1, the first early attempted match, has p_r aligned with a character of v_{R1} other than $(v_{R1})_r$.

Case 3.2. AM_1 is an early attempted match which results in a shift by distance greater than $|p| - |v|$.

Case 3.3. AM_1 is an early attempted match in which p_r is aligned with w_L and following which p_r becomes aligned with v_{R1}. In addition, the resulting shift has length at most $|p| - |v|$.

Case 3.4. AM_1 is an early attempted match in which p_r is aligned with v_L but not with $(v_L)_r$, and following which p_r becomes aligned with v_{R1}. In addition, the resulting shift has length at most $|p| - |v|$.

Case 3.5. AM_1, an early attempted match, had p_r aligned with $(v_L)_r$.

By Lemma 4.9, if $|p| > |t|$, either case 3.0 applies or there is an early attempted match falling into one of cases 3.1–3.4. If $|p| = |t|$, $p = wvv$, since p is not 3-periodic. If none of cases 3.0–3.4 apply, the only remaining possibility is given by case 3.5. We analyze each of the cases in turn.

Case 3.0. There is no early attempted match. Then the current attempted match has an amortized cost of at most $-2s + 1 \leq -3 \leq -2$.

Case 3.1. AM, the first early attempted match, has p_r aligned with a character of v_{R1} other than $(v_{R1})_r$. Then at most $2|v| - 3$ characters of t will have been read and remain marked prior to the current attempted match (because among the characters of v_{R1} the rightmost two are unmarked, and by Lemma 4.8, besides characters of v_{R1}, only the $|v| - 1$ rightmost characters of v_{R2} can have been read). Thus the amortized cost of the current attempted match is at most -2.

In the remaining subcases, the analysis will focus on the early attempted match that causes p_r to become aligned with v_{R1}.

Before considering the next case, we prove several lemmas.

LEMMA 6.1. *Let AM_1 be an early attempted match for which the good suffix shift has length $s_1 \leq |p| - |v|$.*

(i) *If AM_1 matches at least $|v|$ characters, then s_1 is an integer multiple of $|v|$.*

(ii) *If AM_1 matches fewer than $|v|$ characters, then $s_1 < |v|$.*

Proof. First note that the suffix of p of length $s_1 + |v|$ is periodic in v. This follows by Lemma 4.6(i), since $s_1 < |t|$ and thus $s_1 + |v| \leq \min\{|p|, |t| + |u|\}$.

Now we prove (i). Let $\bar{v}$ be the string in the text which matches right(v, p) during attempted match AM_1. Following the shift, the substring $\bar{\bar{v}}$ of p aligned with $\bar{v}$ must be identical to the pattern v (since $s_1 \leq |p| - |v|$, $\bar{\bar{v}}$ exists). Furthermore, $\bar{\bar{v}}$ is part of the suffix of p of length $s_1 + |v|$, and this suffix is periodic in v. Thus $\bar{\bar{v}}$ is a cyclic shift of v. By Corollary 4.3, because v is primitive this cyclic shift must be the trivial shift; hence s_1 is an integer multiple of $|v|$.

We turn to (ii). Suppose that $s_1 > |v|$. Further suppose that c characters are compared by AM_1. (See Fig. 9.) Then a shift by $s_1 - |v|$ would also be a legal shift, in that the characters of the pattern aligned with the c text characters compared by AM_1 are identical in a shift by s_1 and a shift by $s_1 - |v|$ (because the portion of p periodic in v has length at least $s_1 + |v|$). Thus $s_1 \leq |v|$. But a shift by $|v|$ is not possible because this would replace the mismatched character of the pattern by the same character, which is not a good suffix shift. Thus $s_1 < |v|$. □

LEMMA 6.2. *Let AM_1 be an early attempted match that shifts p so that p_r is aligned with a character of v_{R1} other than $(v_{R1})_r$. Suppose AM_1 uses the bad character shift. If at least $|v|$ characters are matched by AM_1, then the good suffix shift for AM_1 also aligns p_r with v_{R1}.*

Proof. By Lemma 6.1, the shift due to the good suffix shift has length at least $|v|$. If $|p| > |t|$, by Lemma 4.9, p_r becomes aligned with a character of v_{R1}. If $|p| = |t|$, p is periodic in v and the bad character shift moves p so that p_l is to the immediate right of the mismatched text character. (If not the shift would have length less than $|v|$.) Similarly,

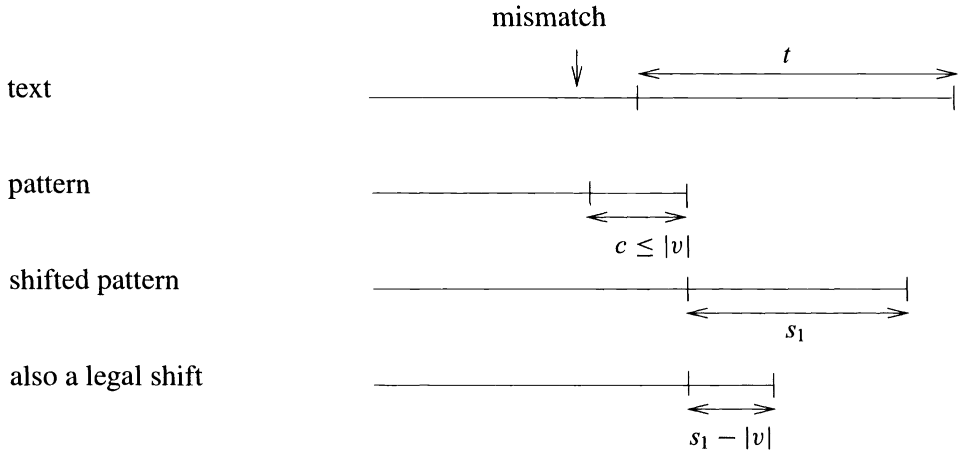

FIG. 9. *Case* (ii): *what if* $s_1 > |v|$.

the good suffix shift would shift p so that the mismatched text character was to the left of p_l. (If not p would overlap the matched characters after the shift, and its length would therefore be a multiple of $|v|$; but then identical characters would be aligned with the mismatched text character before and after the shift, which would not be a good suffix shift.) But then the good suffix shift would be at least as long as the bad character shift, contrary to assumption. □

LEMMA 6.3. *Let AM_1 be an early attempted match that uses the bad character shift and compares at most $|v|$ characters. Then its shift has length either greater than $|p| - |v|$ or less than $|v|$.*

Proof. Suppose that the shift has length at most $|p| - |v|$. Then after the shift a pattern character p_a is aligned with the mismatched text character; consequently, p_a must be among the rightmost $|t| + |v|$ characters of p. But because the suffix of p of length $\min\{|t| + |v|, |p|\}$ is periodic in v, by the definition of the bad character shift p_a is among the rightmost $|v|$ characters in p. Thus in this case the shift has length less than $|v|$. □

Case 3.2. AM_1 is an early attempted match which results in a shift by distance more than $|p| - |v|$. Then all but the rightmost $|v| - 1$ characters shifted over remain unmarked until the current attempted match, by Lemma 4.8. Let w' be the suffix of p overlapping t at the start of AM_1. $|w'| + |p| - |v| + 1 \leq |t| \leq |p|$; hence $|w'| \leq |v| - 1$. If $|w'| = |v| - 1$ then $|w'|$ characters of t are marked at the time of the current attempted match; thus is has amortized cost at most -2. If $|w'| = |v| - 2$ then after AM_1 p_r is aligned with one of the two rightmost characters in v_{R1}; the next and last early attempted match, if any, compares at most $|v|$ characters. Thus for the current attempted match there are at most $|w'| + |v| - 1$ marked characters in t; hence it has amortized cost at most $(2|v| - 3 + 1) - 2s \leq -2$. If $|w'| \leq |v| - 3$ there are at most $[(|v| - |w'| - 1) - 2] + |v| + |w'| \leq 2|v| - 3$ marked characters for the current attempted match. (The first term is the number of characters in t to the right of p_r after the shift due to AM_1; -2 is due to the fact that the rightmost two characters in t are unmarked at the start of the current attempted match; $|v|$ is the bound due to Lemma 4.8 on the number of characters that become marked that are aligned with or to the left of p_r after the shift due to AM_1; and $|w'|$ is for the characters marked by or before AM_1.) This yields an amortized cost of at most -2 for the current attempted match.

Case 3.3. AM_1 is an early attempted match in which p_r is aligned with w_L and following which p_r becomes aligned with v_{R1}. In addition, the resulting shift has length at most $|p| - |v|$.

We show that at most $2|v| - 3$ characters of t are read in early attempted matches; it follows that the current attempted match has amortized cost at most -2.

First we show that AM_1 matches at least $|v|$ characters. Clearly the shift has length greater than $|v|$ as p_r shifts over the whole of v_L. If the shift is due to the good suffix shift, then the claim is immediate from Lemma 6.1(ii). Likewise, if the shift is due to the bad character shift, then the claim is immediate from Lemma 6.3.

Suppose that at the start of AM_1 p_r is aligned with the rth rightmost character of w_L. We show that following AM_1, p_r is aligned with or to the right of the rth rightmost character of v_{R1}. Let s_1 be the length of the good suffix shift due to AM_1. By Lemma 6.2, a shift by distance s_1 following attempted match AM_1 would align p_r with v_{R1}. By Lemma 6.1(i), s_1 is an integer multiple of v.

By Lemma 4.8, at most $|v| - 1$ characters of the text immediately to the left of the rth rightmost character of v_{R1} can be read prior to the current attempted match, and then only if $r > 1$. Thus the number of characters of t that can be marked prior to the current attempted match is bounded as follows: at most $|w| - r + 1$ characters of w_L, plus at most $\max\{(r-2) + (|v| - 1), 0\} = (r-2) + (|v| - 1)$ characters at the right end of t (recall that the two rightmost characters of v_{R1} are unmarked). This is a total of $|w| + |v| - 2 \leq 2|v| - 3$ characters. Hence the current attempted match has amortized cost at most -2.

Case 3.4. AM_1 is an early attempted match in which p_r is aligned with v_L but not $(v_L)_r$, and following which p_r becomes aligned with v_{R1}. In addition, the resulting shift has length $s_1 \leq |p| - |v|$. The characters matched by AM_1 include at least all the characters up to t_l. (If not a shift that aligns p_r and $(v_L)_r$ would leave all the compared characters matched and hence would be as long as the actual shift.) There are two subcases depending on the number of characters matched by AM_1.

Case 3.4.1. At least $|v|$ characters are matched.

The following two lemmas will be useful.

LEMMA 6.4. *Suppose that an early attempted match AM_2 starts with suffix x of p overlapping v_{R1}. Suppose further that the maximum length suffix of v periodic in x is $\tilde{w}x$. Finally, suppose that x is also a prefix of v. Then*

(i) $|\tilde{w}x| < |v|$.

(ii) *AM_2 mismatches at the $(|\tilde{w}x| + 1)$th character compared.*

(iii) *Suppose AM_2 produces a good suffix shift of length s_2. Let $\bar{x}$ be the generator of x. Then $s_2 > |\tilde{w}x| - |\bar{x}| \geq |\tilde{w}|$.*

Proof. See Fig. 10. By Lemma 4.8, AM_2 compares at most $|v|$ characters. Since v and p both have suffix $\tilde{w}x$ and v_{R1} has prefix x, it is clear that AM_2 matches the first $(|\tilde{w}x|)$ characters compared; hence, $|\tilde{w}x| < |v|$. Since $\tilde{w}x$ is the longest suffix of v, and hence of p, periodic in x it follows that AM_2 mismatches at the $(|\tilde{w}x| + 1)$th character compared.

Let z be the suffix of p of length s_2. Suppose, for a contradiction, that $|z| \leq |\tilde{w}x| - |\bar{x}|$. By Lemma 4.4, the suffix of p of length $|z\tilde{w}x|$ is periodic in z as the good suffix shift due to AM_2 causes a match on the characters matched by AM_2. Consider the suffix of length $|\bar{x}|$ of the second rightmost instance of z in p; it lies within the suffix $\tilde{w}x$ of p, which is periodic in $\bar{x}$. By Corollary 4.3, any matching cyclic shift of this suffix of z is a trivial cyclic shift; consequently, the length $|z|$ suffix of $\tilde{w}x$, and hence z itself, are cyclic in $\bar{x}$. Since v is also a suffix of p and $|\tilde{w}| + 1 \leq |v|$, the rightmost $|\tilde{w}| + 1$ characters of v are periodic in $\bar{x}$, thus there is no mismatch by AM_2 at the location assumed (the $(|\tilde{w}x| + 1)$th character compared by AM_2). This is a contradiction. Consequently $s_2 = |z| > |\tilde{w}x| - |\bar{x}|$. □

Case 3.4.1.A. AM_1 uses the good suffix shift. Let x be the suffix of p overlapping v_L before attempted match AM_1, let y be the suffix of p overlapping v_{R1} after attempted match AM_1, and let $\tilde{w}x$ be the longest suffix of v periodic in x. In turn, we show:

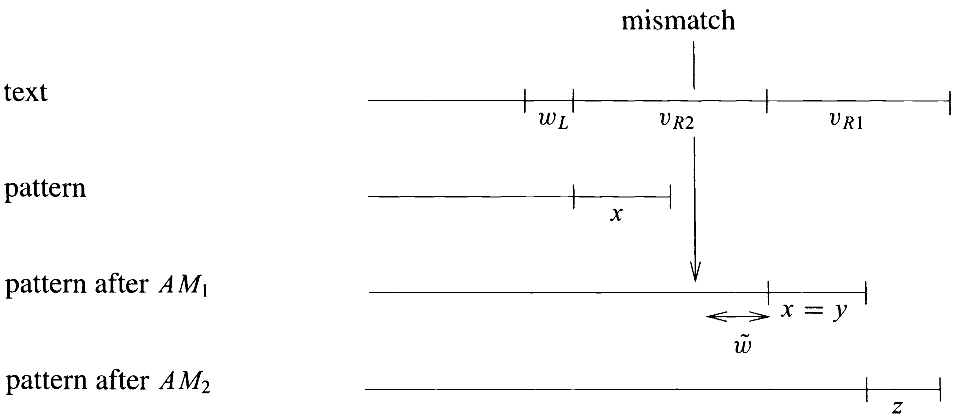

FIG. 10. *Attempted match AM_2.*

(i) $|x| = |y|$.

(ii) The attempted match AM_2, immediately following AM_1, mismatches at the $(|\tilde{w}x|+1)$th character compared.

(iii) Let the good suffix shift due to AM_2 have length s_2. Then $s_2 > |\tilde{w}| \geq |w|$.

(iv) The amortized cost of the current attempted match is at most -2.

By Lemma 6.1(i), s_1 is an integer multiple of $|v|$. Thus $x = y$. This shows (i). (ii) and the first part of (iii) are immediate from Lemma 6.4. To see the remainder of (iii), consider the characters matched by AM_1. It follows that v has suffix wx; in addition, by Lemma 4.4, wx is periodic in x. Thus $|\tilde{w}| \geq |w|$.

Prior to unmarking read nodes, the amortized cost of AM_2 would be at most $-2s_2$, since all the characters compared by AM_2 were previously unread (for $|\tilde{w}x| < |v|$ by Lemma 6.4(i)). Hence $\min\{2s_2 - 2, |\tilde{w}x| + 1\} \geq |\tilde{w}|$ characters are unmarked. Following this unmarking, the $|\tilde{w}| \geq |w|$ characters immediately to the right of left(x, v_{R2}) are unmarked; by Lemma 4.8, these characters are not read again prior to the current attempted match. So the number of marked characters in t at the time of the current attempted match is bounded by the sum of:

(i) $(|v| - 2)$ characters in v_{R1},

(ii) If $v_{R2} = v_L$, $(|v| - |w|)$ characters in v_{R2}, and otherwise $|x|$ characters in v_L and $(|v| - |w| - |x|)$ characters in v_{R2},

(iii) $|w|$ characters in w_L.

This is a total of at most $2|v| - 2$ marked characters. Hence the amortized cost of the current attempted match is at most -1. (This can be improved to -2 by a more elaborate argument.)

Case 3.4.1B. AM_1 uses the bad character shift. Let x denote the overlap of p and v_L prior to attempted match AM_1. Let AM_2 be the first subsequent early attempted match that compares a character of v_{R2}, if any.

We observe that the bad character shift overlaps v_{R1} by more than $|x|$ characters. By Lemma 6.2, the good suffix shift of AM_1 aligns p_r with v_{R1}. Since the length of the good suffix shift, in this case, is a multiple of $|v|$ (by Lemma 6.1(i)), following the good suffix shift p would overlap v_{R1} by $|x|$ characters. Since the bad character shift is used, it results in a larger overlap.

There are three subcases.

Subcase (i). AM_2 does not exist, or in AM_2, p_r is to the right of the leftmost $|wx|$ characters of v_{R1}. Then the number of marked characters in t at the time of the current attempted match is at most $(|v| - 1 - |wx|) + (|v| - 2) + |w| + |x| \leq 2|v| - 3$ ($|v| - 2$ bounds the number of marked characters in v_{R1}, $|v| - 1 - |wx|$ bounds the number in v_{R2} marked after the shift by AM_1, and $|w| + |x|$ bounds the number marked before the shift by AM_1). Thus the amortized cost of the current attempted match is at most -2.

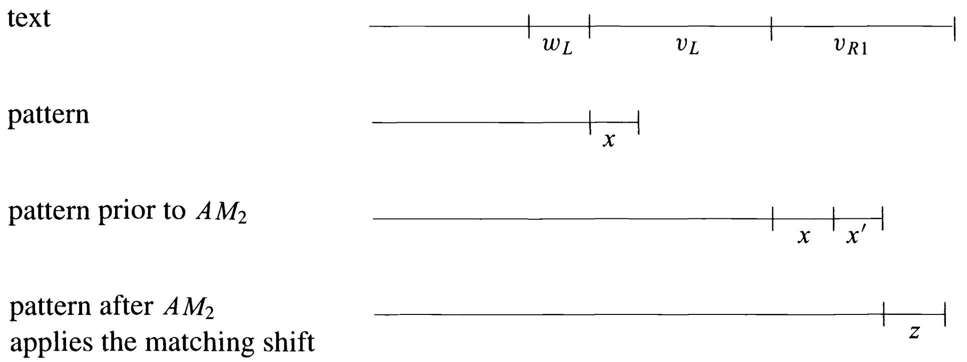

FIG. 11. Case 3.4.1B–*the bad character shift.*

Subcase (ii). p_r is aligned with one of the leftmost $|wx|$ characters in v_{R1} and $|x| \leq |v|/2$. (See Fig. 11.) Let s_2 be the length of the good suffix shift for AM_2 and let z be the suffix of p of length s_2. Let x' be the overlap of p beyond left(x, v_{R1}) at the start of attempted match AM_2; by assumption, $|x'| \leq |w|$. Let $\tilde{w}x$ be the longest suffix of v periodic in x. In turn, we show the following.

(i) Let $\bar{x}'$ be the generator for x'. x is cyclic in $\bar{x}'$.

(ii) AM_2 mismatches at the $(|\tilde{w}x| + 1)$th character compared.

(iii) $|\tilde{w}| < |z|$.

(iv) The amortized cost is at most -2.

(i) is shown as follows. Lemma 4.4 is applied to the prefix x of v_{R1} and to the suffix xx' of p, which match on their overlapping portion during AM_2; because p has suffix x also, it follows that xx' is periodic in x'. Let $\bar{x}'$ be the generator for x'. Next, by applying Lemma 4.4 to the suffix wx of p and the string w_L, which match on their overlapping portion during AM_1, it follows that wx is periodic in x. Since $|w_L| \geq |x'|$, x' is a suffix of w_L. Let $\bar{\bar{x}}'$ be the substring of p aligned with right($w_L, \bar{x}'$) during AM_1; by Corollary 4.3, $\bar{\bar{x}}'$ is the trivial cyclic shift of $\bar{x}'$. Thus x is cyclic in $\bar{x}'$. It follows that w is cyclic in $\bar{x}'$ and as p has suffix wx, $|\tilde{w}| \geq |w|$.

By Lemma 6.4, AM_2 mismatches at the $(|\tilde{w}x| + 1)$th character compared (to see this note that the longest suffix of v periodic in $\bar{x}'$ and hence xx' has length $|\tilde{w}x|$). (Note that $\tilde{w}$ has different meanings here and in the lemma.) Also by Lemma 6.4, $|z| > |\tilde{w}x| - |\bar{x}'| \geq |\tilde{w}|$.

To obtain the amortized bound we need at least $|w| + 1$ characters of v_{R2} to remain unmarked aside from left(x, v_{R2}); then at most $2|v| - 3$ characters of t will be marked at the time of the current attempted match, which yields the -2 bound on the amortized cost. Following the shift due to AM_2, the potential at hand for unmarking characters again is at least $2|z| - |x| - |x'|$; to obtain $|w| + 1$ unmarked characters in v_{R2} aside from left(x, v_{R2}), we need

$$(|v| - |x|) - (|\tilde{w}x| - |xx'| + 1) + (2|z| - |x| - |x'|) \geq |w| + 1.$$

(The first term is the number of characters in v_{R2} unmarked before AM_2; the second term is the number of characters in v_{R2} read by AM_2.) Thus it suffices that $|v| - 2|x| + 2|z| \geq 2|\tilde{w}| + 2$, which is true when $|x| \leq |v|/2$.

Subcase (iii). p_r is aligned with one of the leftmost $|wx|$ characters in v_{R1} and $|x| > |v|/2$. Let y be the generator of the suffix of p of length $|v| - |x|$. In turn, we show the following.

(i) x has core y.

(ii) AM_2 compares at most $|y|$ characters of v_{R2}.

(iii) AM_2 is the last early attempted match for the current attempted match.

(iv) The number of marked characters for the current attempted match is at most $2|v|-3$, and hence the amortized cost is at most -2.

By Lemma 4.4, v and hence x have core y. (since x, a suffix of v, matches a prefix of v). Any early attempted match AM_2, subsequent to AM_1, which matches a character of v_{R2} will have matched a suffix of p of length greater than $|x|$ ($> |y|$) and at least $|x|$ characters of v_{R1}. Also, AM_2 can compare at most $|y|$ characters of v_{R2} (this can be seen as follows: v is not cyclic in y, by assumption, and at least one character of v_{R1} is compared, thus the "y" substrings in p and v_{R2} cannot be aligned). The resulting good suffix shift will have a length of a multiple of $|y|$, since y is primitive and v is periodic in y. Furthermore, the resulting shift must align p_r and t_r (since this is the least shift by a multiple of $|y|$ that places a different character in the mismatch location).

Consequently, the number of marked characters for the current attempted match is at most $|v| + (|w| + |x|) - 2 \leq 2|v| - 3$ ($|v|$ is the number of characters compared in the attempted matches between AM_1 and the current attempted match, $|w| - |x|$ is the number of characters of t compared by AM_1, and 2 is the lower bound on the number of characters unmarked due to the bad character shift).

Case 3.4.2. Fewer than $|v|$ characters are matched. The shift is a good suffix shift. For by Lemma 6.3 a bad character shift has length less than $|v|$. Thus the bad character shift would align the rightmost instance in p of the mismatched text character with that text character, thereby leaving p_r aligned with one of the leftmost $|v|$ characters of t, contrary to the definition of Case 3.4.

Let r be the number of characters matched. Note that $r > |w|$. We show that $s_1 > r$ and then we upper bound the amortized cost by -2.

Suppose, for a contradiction, that $s_1 \leq r$. Since $s_1 < |v|$, $|y| < |x|$. (See Fig. 12.) Since a suffix of p, of length $|t|$, is periodic in v (by Lemma 4.6(i)) and the shifted pattern matches the text characters matched by AM_1, y must be a prefix of x.

Next, we show that there is a string z such that both x and y are cyclic in z. The portion $\bar{x}$ of the shifted pattern, aligned with the suffix x of p prior to the shift, must match the suffix x. Note that $\bar{x} = yv'$ where v' is a prefix of v. Prior to the shift, x_l is aligned with $(v_L)_l$, so v' is a prefix of x also. By Lemma 4.4, applied to x reversed, $x = y^i y'$ for some $i \geq 1$ where y' is a proper prefix of y. Because y is also a suffix of x (since they are both suffixes of p), using Corollary 4.3, we conclude that there is a primitive string z such that both x and y are cyclic in z.

In addition, the suffix of p of length r has core z. (Consider the portion of the pattern, following AM_1, that is aligned with the r text characters matched by AM_1; it comprises the prefix of v of length $|x| - |y|$, preceded on the left by the suffix of v of length $r - (|x| - |y|)$. Also, it matches the suffix of v of length r. By Lemma 4.4, the suffix of $|v|$ of length r is periodic in its suffix of length $|x| - |y|$; in turn, this suffix is periodic in z.) The assertion follows.

Finally, note that x is a prefix of v (consider the attempted match AM_1 and the portion of t with which x is matched).

To avoid v being cyclic in z, we need that in $\bar{v} = \text{right}(v, p)$, the suffix of length r overlaps with left$(x, \bar{v})$ by fewer than $|z|$ characters. Otherwise, by Corollary 4.3, the overlapping portion would comprise aligned instances of string z; it would follow that v was cyclic in z.

Thus we need $r+|x| < |v|+|z|$, which implies $r < |v|+|y|-|x| = s_1$; this is a contradiction. Thus the case $s_1 \leq r$ does not arise.

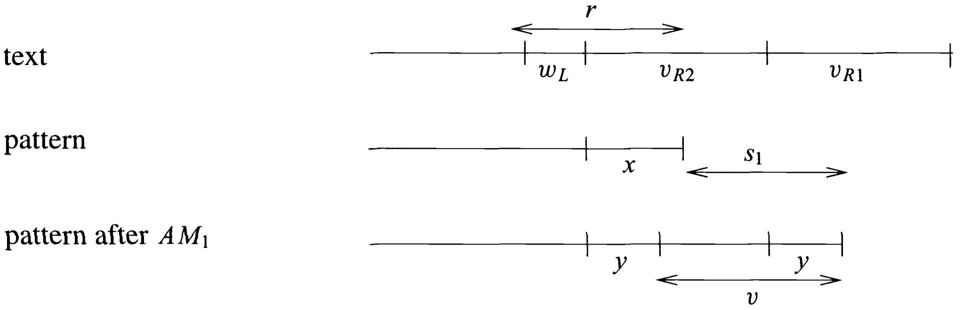

FIG. 12. *Case* 3.4.2.

Following the shift due to AM_1, up to s_1 characters can be unmarked; hence all the characters read by AM_1 are unmarked. These unmarked characters include w_L plus the character immediately to the right of w_L. By Lemma 4.8, these $|w|+1$ characters are not reread until the current attempted match. So there are at most $2|v|-3$ marked characters in t at the time of the current attempted match, and hence the amortized cost of the current attempted match is at most -2.

Case 3.5. AM_1, an early attempted match, had p_r aligned with $(v_L)_r$. Because p is not 3-periodic, $p = \tilde{w}vv$, $t = wvv$, where w is a suffix of $\tilde{w}$, which in turn is a proper suffix of v. The resulting shift has length $|v|$. Hence the number of unmarked characters for the current attempted match is at least $|v|$. Thus the amortized cost of the current attempted match is bounded by $|v|+|w|+1-2|v|$ if $|\tilde{w}| > |w|$, and by $|v|+|w|-2|v|$ otherwise; these are both at most -1.

In conclusion we have the following theorem.

THEOREM 6.5. *The* BM *string matching algorithm performs at most* $3n - 3(n-m+1)/(m+2)$ *comparisons when matching a nonperiodic pattern of length m against a text of length n.*

Proof. Clearly each pair of consecutive attempted matches, whose shifts have combined length at most $\lfloor\frac{m}{3}\rfloor + \lceil\frac{m}{3}\rceil + 1$, has amortized cost at most -2. We show that each pair of consecutive matches, whose shifts have combined length $\lfloor\frac{m}{3}\rfloor + \lceil\frac{m}{3}\rceil + 1 + s$, $s \geq 1$, has amortized cost at most $-2-s$. Let the initial attempted match result in a shift of length s'; then it has amortized cost $-2s'$ if $s' > 1$ and -1 if $s' = 1$. Thus the maximum total amortized cost is obtained if all the attempted matches form pairs with associated combined shifts of length $\lfloor\frac{m}{3}\rfloor+\lceil\frac{m}{3}\rceil+1$. This leads to a total amortized cost of at most $3n-2(n-m+1)/(\lfloor\frac{m}{3}\rfloor+\lceil\frac{m}{3}\rceil+1)$ which is bounded by $3n-3(n-m+1)/(m+2)$.

In right-to-left order, each unpaired (*long*) shift of length $\lfloor\frac{m}{3}\rfloor + 1 + r$, $r \geq 0$, is paired with the immediately preceding shift. This leaves at most one unpaired shift of length greater than $\lfloor\frac{m}{3}\rfloor + 1$, and if present it is the very first shift of the algorithm.

Consider such a pair of consecutive shifts. Let the first shift have length l. If $l+r \leq \lceil\frac{m}{3}\rceil$, then the pair of attempted matches producing these two shifts has amortized cost at most -2. If $l+r = \lceil\frac{m}{3}\rceil + s$, $s \geq 1$, the amortized cost of the second attempted match is at most $m - l - 2(\lfloor\frac{m}{3}\rfloor + 1 + r) = -1 - s - r \geq -1 - s$. Because the first attempted match has amortized cost at most -1, together the pair have amortized cost at most $-2-s$, as claimed. □

COMMENT. When matching the pattern $p = wvv$ against text $t = wv^k$, where w is the length $|v| - 1$ suffix of v and v is primitive, for $k \geq 2$, $3n - 3\frac{n+1}{m+1} - 2m + 3$ comparisons are performed, a slight improvement on the lower bound given in §3. We do not state this lower bound there, because variants of the BM algorithm avoid this case.

7. 3-periodic patterns. Suppose that the pattern, p, is of the form $p = wv^i$, where v is the core of p, w is a proper suffix of v, possibly empty, and $i \geq 3$.

One approach is to find instances of the pattern $p' = wv$. A sequence of i such instances, each separated by distance $|v|$, corresponds to an instance of pattern p. It is not hard to determine p' in $O(m)$ time. However, this is not a very attractive solution since p' can itself be periodic and thus a recursive use of this approach may be needed. Clearly this approach performs no additional comparisons with text characters over what is implied by the bound of Theorem 6.5, where the m in the theorem now denotes the length of the pattern that is actually being matched (i.e., the pattern obtained by the just-described recursive decomposition). However, additional work is needed to keep track of the sequence of patterns p' that have been found; it can be shown that over all recursive levels of such patterns, this is an additional $O(n)$ work.

Instead, we use the fact that the bound of Theorem 6.5 applies when matching pattern $p' = wvv$. Clearly there is no recursive decomposition in this case. To detect instances of pattern p, the following index j is recorded. Let $q_j = wv^j$. (See Fig. 13.) We record the largest j such that the text contains an instance $\bar{q_j}$ of the pattern q_j, where $(\bar{q_j})_r$ is aligned with p'_r.

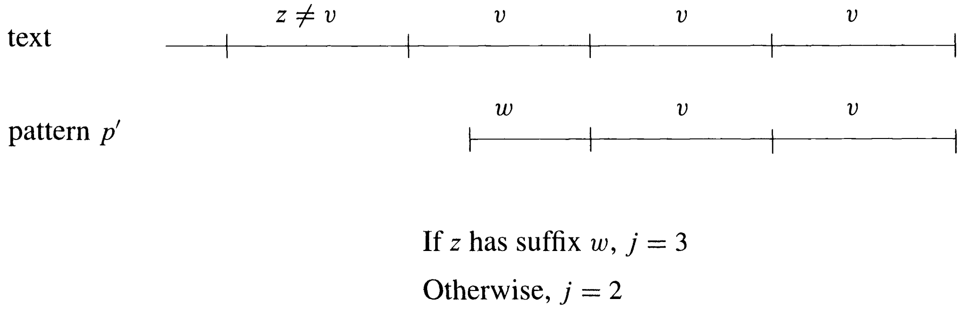

FIG. 13. *Periodic patterns.*

Following a successful match of p', j is modified as follows. If $j = i - 1$, then a match of p has been found; j is unchanged. If $j < i - 1$, then j is incremented. If the attempted match is not successful j is set to one.

In conclusion, we have the following theorem.

THEOREM 7.1. *Suppose the* BM *string matching algorithm is applied to a pattern p and a text of length n. Let $p = wv^i$, where v is the core of p. Then the* BM *algorithm performs at most* $3n - 3(n - m' + 1)/(m' + 2)$ *comparisons, where* $m' = |p|$ *if* $i \leq 2$, *and* $m' = |wv^2|$ *if* $i > 2$.

Comment. Some further slight improvements to the bound are possible. Specifically, note that $p = wv$, with v the core of p, does not have another core v', with $p = w'v'^k$, for some $k \geq 2$ if $|w| = |v| - 1$ or $|v| - 2$. Thus patterns $p = wv^k$, $k \geq 2$, with $|w| = |v| - 1$ or $|v| - 2$ can be matched by matching $p' = wv$, as in this section. This then allows the amortized bounds given earlier for cases 2 and 3 to be improved to -2 for each attempted match, giving an upper bound of roughly $3n - \frac{6n}{m}$. Further improvements are much more intricate.

Acknowledgments. I thank Rajamani Sundar for his comments. I also thank the referees for their suggestions concerning the presentation of the result.

A GRAMMAR-BASED APPROACH TOWARDS UNIFYING HIERARCHICAL DATA MODELS*

MARC GYSSENS†, JAN PAREDAENS‡, AND DIRK VAN GUCHT§

Abstract. A simple model for representing the hierarchical structure of information is proposed. This model, called the grammatical model, is based on trees that are generated by grammars; the grammars describe the hierarchy of the information represented by the trees. Two methods for querying in this data model are given. The first, called the grammatical algebra, is based on a set of primitive grammar-oriented operators, the second, called the grammatical calculus, on local transformations on the trees. The semantics of both is formally defined. Decidability issues regarding the grammatical calculus are investigated. Finally, the two querying methods are proved to be equally expressive.

Key words. information base, grammars, trees, transformations, algebra, calculus

AMS subject classification. 68P15

1. Introduction. Until the mid-1980s much attention was paid to the relational database model (see, e.g., [17], [18], and [21]). We were intrigued by its simplicity, both for modeling and manipulating data. Recently, however, we became aware of its drawbacks when trying to model data applications beyond the traditional business-oriented applications, such as CAD-CAM, office automation, and text-oriented and multimedia databases. Therefore, a great number of data models have been proposed as a possible successor of the relational model.

Semantic data models, such as ER [7], FDM [19], SDM [12], Format [13], and IFO [2], provide a rich set of design tools for representing the complex interrelationships of data. These tools are typically variants of familiar aggregation, generalization, and set-formation constructs. Although query languages have been defined for some semantic data models, their main purpose is to provide database design tools that are more powerful than the modeling tools of the relational model. The logic-based models, such as Datalog [21], LDM [16], and LDL [4], zero in on the limited expressiveness of data manipulation languages of the relational model, i.e., they generalize the relational calculus to express queries that can be specified recursively. Finally, there are the relational extensions of the standard relational model, such as RM/T [8] and the nested relational model [9], [14], [20]. These models try to strike a balance between the elegance of the relational model and the expressiveness of semantic data models. In other words, they are not as rich as the semantic models in their modeling power, but they provide simple yet powerful extensions of the relational model.

Although there exist significant differences between all these models, they share the property that they recognize as the most fundamental characteristic of data its hierarchical structure. On the other hand, however, it is not quite clear whether they can effectively model all data applications which exhibit a hierarchical nature. A good example are textbases [11], which in addition to having a hierarchical structure, are constructed out of rules that follow a grammatical structure. Grammatical structures are also implicitly present in, e.g., VERSO [1], [5], a variation of the nested relational model, where at some level data are structured as regular expressions.

It is the intention of this paper to use a simple and a well-known model as a unifying skeleton to describe the hierarchy in an information base as well as the grammatical structure

of texts. This model has been presented informally in [11]. It is called the grammatical model and is based on grammars introduced some 30 years ago to study the syntax of programming and formal languages (see, e.g., [10]). The grammatical model will benefit greatly from the clear understanding of the grammars and from their major importance for computer science.

It seems natural to formalize a hierarchical structure by a tree. Therefore, we represent information as a tree which can be generated by a grammar. Each leaf of the tree represents an object, and the internal nodes represent the relationship between the objects. The grammar specifies the scheme, i.e., the overall structure between these relationships. In this way, the information about two employees (one manager and one worker) will be represented by the tree in Fig. 1.

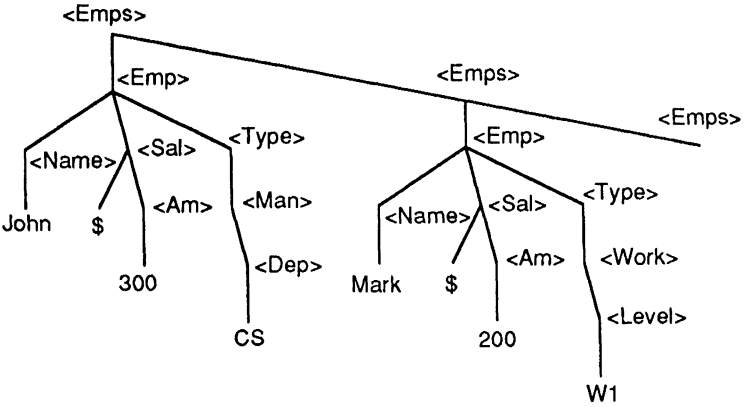

FIG. 1. *Tree representing information about employees.*

This tree is generated by a grammar with the following productions:

P1 : $\langle Emps\rangle \rightarrow \langle Emp\rangle\langle Emps\rangle$ P4 : $\langle Type\rangle \rightarrow \langle Work\rangle$ P6 : $\langle Work\rangle \rightarrow \langle Level\rangle$
P2 : $\langle Emp\rangle \rightarrow \langle Name\rangle\langle Sal\rangle\langle Type\rangle$ P5 : $\langle Man\rangle \rightarrow \langle Dep\rangle$ P7 : $\langle Sal\rangle \rightarrow \$\langle Am\rangle$
P3 : $\langle Type\rangle \rightarrow \langle Man\rangle$.

Notice that production P1 specifies information as a list, which is used here to model a set. Production P2 specifies an employee as the aggregation of his/her name, salary, and type. Productions P3 and P4 define the type of an employee as either manager or worker, which is an example of generalization, or, alternatively viewed, an example of specialization. This example illustrates that the grammatical model allows for the three basic constructs of most data models (set-formation, generalization, and aggregation) in a uniform way. Finally notice production P7. The grammatical model allows, in a convenient way, for additional syntactic features; e.g., the terminal symbol "$" indicates that the salary is expressed in dollar amounts.

For hierarchically organized data, the tree structure of the grammatical model also has some advantages with respect to implementation. Contrary to the relational and the nested relational models, for example, the straightforward implementation of the grammatical model is feasible, yielding a physical representation that is fairly close to the conceptual representation.

Turning to the dynamical aspects of the grammatical model, we see that there are two obvious ways to express queries by transforming the trees. A first method consists of defining operators that locally transform the trees and the grammars. A second way consists of describing this transformation in a less procedural way, indicating the relationship between the given trees and the result trees. For reasons that are evident these methods are called the algebra and the calculus, respectively. They are proved to be equivalent. Although the calculus is the more natural of both methods, its formal semantics need a detailed description to handle all possible problems of cyclicity and ambiguity.

The paper is organized as follows. In §2, we give the basic definitions of the grammatical model. In §3, we define an algebra to query and manipulate information bases defined over the grammatical model. Section 4 introduces an alternative query mechanism called the grammatical calculus. The grammatical calculus is based on pattern-matching. Section 5 briefly discusses some decidability issues regarding the grammatical calculus. In §6, we show that the grammatical algebra and calculus are equivalent with respect to expressive power. Finally, §7 proposes some directions for future research.

2. The grammatical model. Throughout this paper, we assume the reader is familiar with the basic terminology concerning trees (e.g., [3]) and formal languages (e.g., [10]). As stated in §1, we shall represent an information base as a tree, the structure of which is controlled by a formal grammar. We shall borrow the terms "scheme" and "instance" from the relational model and use the former to indicate the grammar and the latter to indicate the tree.

DEFINITION 2.1. An *information base scheme* is a grammar $\mathcal{G} = (V, T, S, P)$ with

- V being a finite set of attributes;
- T being a finite set of constants;
- S being a set of axioms, $S \subseteq V$;
- P being a finite set of productions of the form $A \rightarrow s$ where
  - –$A \in V$,
  - –$s \in (V \cup T)^*$,
  - –each attribute appears at most once in s.[1]

Actual data will be represented in a tree the internal nodes of which are labeled by attributes. Note that we do not require the leaves to be labeled by constants; if a leaf is labeled by an attribute, this simply means there are no data known for that attribute.

DEFINITION 2.2. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. A *data-tree* (D-*tree*) over $\mathcal{G}$ is a tree whose nodes are labeled with elements of $V \cup T$ in such a way that each internal node is labeled by an attribute. The set of all D-trees over $\mathcal{G}$ is denoted $\mathcal{D}(\mathcal{G})$. The empty D-tree is denoted **E**.

In the upcoming sections, we shall frequently use some operations on D-trees, which will be denoted as in Definition 2.3.

DEFINITION 2.3. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let **D** be a D-tree over $\mathcal{G}$. Then

- if **n** is a node of **D**, lbl(**n**) denotes its label;
- **rt(D)** denotes the root of **D** and rt(**D**) the label of the root of **D**;
- if **n** is a node of **D** with **n**$\neq$ **rt(D)**, **par(n)** denotes its parent and par(**n**) the label of its parent;
- if **n** is a node of **D**, **chln(n)** is the sequence of all its children, **chtrs(n)** is the sequence of the subtrees of **D** whose roots are the children of **n**, and chln(**n**) is the sequence of the labels of all the children of **n**.

Finally, a D-tree over an information base scheme that is also a derivation tree will be called an information base instance.

DEFINITION 2.4. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. A D-tree **D** over $\mathcal{G}$ is called an *information base instance* over $\mathcal{G}$ if

- rt(**D**) $\in S$;
- for each internal node **n** in **D**, the production lbl(**n**) $\rightarrow$ chln(**n**) is in P.

[1] The empty string is denoted ε.

Example 2.5. Consider the information base scheme $\mathcal{G} = (V, T, S, P)$ with

- $V = \{Fams, Fam, Father, Mother, Children, Child, String, Chr\}$;
- $T = \{A, \ldots, Z, a, \ldots, z\}$;
- $S = \{Families\}$;
- $$P = \{\begin{array}{ll} \langle Fams\rangle \longrightarrow \langle Fam\rangle\langle Fams\rangle & \langle Child\rangle \longrightarrow \langle String\rangle \\ \langle Fam\rangle \longrightarrow \langle Father\rangle\langle Mother\rangle\langle Children\rangle & \langle String\rangle \longrightarrow \langle Chr\rangle\langle String\rangle \\ \langle Children\rangle \longrightarrow \langle Child\rangle\langle Children\rangle & \langle Chr\rangle \longrightarrow A \\ \langle Father\rangle \longrightarrow \langle String\rangle & \quad\vdots \\ \langle Mother\rangle \longrightarrow \langle String\rangle & \langle Chr\rangle \longrightarrow z\} \end{array}$$

representing the structure on information base concerning families with their children. Note that this information base scheme also includes an "implementation" of strings. For example, the string *Ian* must be represented as the D-tree in Fig. 2.

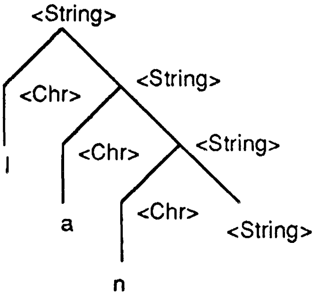

FIG. 2. *Representation of a string.*

However, we might have considered strings as elements of some set, sufficiently large for our purposes, rather than as a sequence of characters. In the upcoming sections we shall not bother with this low-level representation, since this is not our main concern. From now on, we shall no longer write productions for attributes such as $\langle String\rangle$. With this in mind, the D-tree in Fig. 3 represents an information base instance over $\mathcal{G}$ showing two families, the former composed of *Ian* and *Mary* with children *Brian* and *Wendy* and the latter composed of *Nick* and *Brenda* with no children.

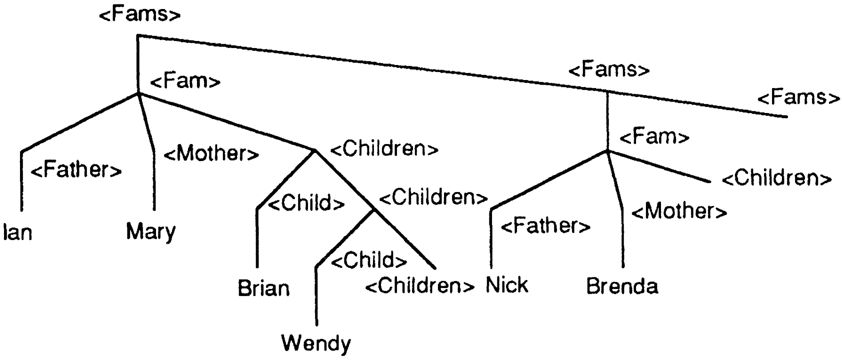

FIG. 3. *An instance of an information base about families.*

Grammar-based models turn out to be highly appropriate for representing text-dominated databases, as was observed by Gonnet and Tompa. The following example is inspired by [11].

Example 2.6. Consider an information base scheme with the following productions:

$\langle \mathit{Refs} \rangle \longrightarrow \langle \mathit{Ref} \rangle \langle \mathit{Refs} \rangle$ $\qquad \langle \mathit{Source} \rangle \longrightarrow \langle \mathit{Journ} \rangle \langle \mathit{Issue} \rangle$
$\langle \mathit{Ref} \rangle \longrightarrow \langle \mathit{Auths} \rangle \langle \mathit{Tit} \rangle \langle \mathit{Source} \rangle \langle \mathit{Year} \rangle$ $\qquad \langle \mathit{Source} \rangle \longrightarrow \langle \mathit{Book} \rangle$
$\langle \mathit{Auths} \rangle \longrightarrow \langle \mathit{Auth} \rangle \langle \mathit{Auths} \rangle$ $\qquad \langle \mathit{Issue} \rangle \longrightarrow \langle \mathit{Vol} \rangle : \langle \mathit{Nr} \rangle.$

The attributes not mentioned in the left-hand side of some production are supposed to take either a string or a number as a value. Part of some information base instance is represented in Fig. 4.

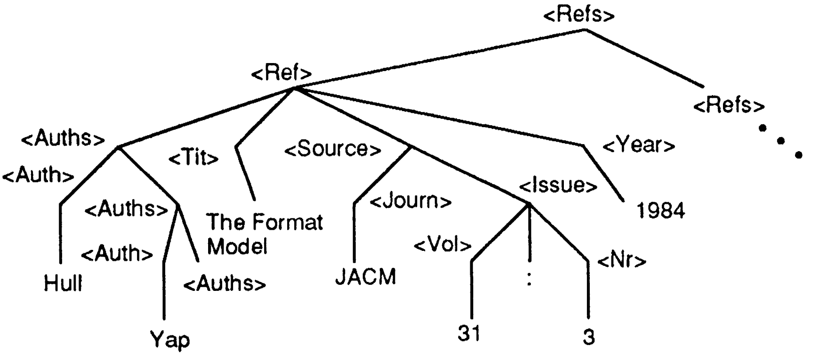

FIG. 4. *An instance of a bibliographic information base.*

We will also need the notion of isomorphic D-trees:

DEFINITION 2.7. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}_1$ and $\mathbf{D}_2$ be D-trees over $\mathcal{G}$. $\mathbf{D}_1$ and $\mathbf{D}_2$ are said to be *isomorphic*, denoted $\mathbf{D}_1 \cong \mathbf{D}_2$, if there exists a mapping between the nodes of $\mathbf{D}_1$ and $\mathbf{D}_2$ that is one to one and onto, preserving the labels and the tree structure. Isomorphism is extended to finite sequences of D-trees in the canonical way.

3. An algebra for transforming information bases. In this section, we propose an algebraic language for the manipulation of grammatically defined information bases that not only allows us to formulate queries, but also to apply more general transformations. Each operator is defined both on scheme and on instance level. Here we implicitly assume that only one information base instance is considered at a time.

The algebra we propose consists of eight basic operators, defined below. At the same time, we also define some derived operators, both as an illustration and because we need them further on.

First, we define three types of substitutions, which do not alter the structure of an information base instance, but only change (attribute) labels.

The parent substitution $\Sigma\pi[A \to s, B]$ substitutes by B all attributes A from which s is derived.

DEFINITION 3.1. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s \in P$, or $A \in V$ and $s = \varepsilon$. Let B be an attribute (B does not have to be in V), and suppose that A and B never occur simultaneously in the right-hand side of a production of P. The *parent substitution* is defined as follows:

- $\Sigma\pi[A \to s, B](\mathcal{G}) = \mathcal{G}' = (V', T, S', P')$ where
  - $V' = V \cup \{B\}$;
  - if $A \in S$, then $S' = S \cup \{B\}$, else $S' = S$;
  - Let $P'' = (P - \{A \to s\}) \cup \{B \to s\}$. Then

$$P' = P'' \cup \{C \to s_1 B s_2 \mid C \in V',\ s_1 s_2 \in (V \cup T)^*,\ \text{and}\ C \to s_1 A s_2 \in P''\}.$$

- $\Sigma\pi[A \to s, B](\mathbf{D})$ is obtained by simultaneously relabeling by B each node $\mathbf{n}$ in $\mathbf{D}$ with $\mathrm{lbl}(\mathbf{n}) = A$ and $\mathrm{chln}(\mathbf{n}) = s$.

Note that the condition of A and B not occurring simultaneously in the right-hand side of a production of $\mathcal{G}$ prevents B from appearing more than once in the right-hand side of a production of $\mathcal{G}'$.

The child substitution $\Sigma\chi[A \to s_1Bs_2, B, C]$ substitutes by C all attributes B in a string s_1Bs_2 that is derived from A.

DEFINITION 3.2. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $B \in V$, and let $A \to s_1Bs_2 \in P$. Let C be an attribute (C does not have to be in V), and suppose that C does not occur in s_1s_2. The *child substitution* is defined as follows:

- $\Sigma\chi[A \to s_1Bs_2, B, C](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{C\}$;
  - Let $P'' = (P - \{A \to s_1Bs_2\}) \cup \{A \to s_1Cs_2\}$. Then

$$P' = P'' \cup \{C \to s \mid s \in (V' \cup T)^* \text{ and } B \to s \in P''\}.$$

- $\Sigma\chi[A \to s_1Bs_2, B, C](\mathbf{D})$ is obtained by simultaneously relabeling by C each internal node $\mathbf{n}$ in $\mathbf{D}$ with $\mathrm{lbl}(\mathbf{n}) = B$, $\mathrm{par}(\mathbf{n}) = A$ and $\mathrm{chln}(\mathbf{par}(\mathbf{n})) = s_1Bs_2$.

As before, the condition on C prevents illegal substitutions.

Finally, we define child equality substitution. The child equality substitution $\Sigma\epsilon[A \to s_1Bs_2, B \to s_3, C, D]$ substitutes by D all attributes B in a string s_1Bs_2 that is derived from A and from which s_3 is derived, provided B has both a sibling and a child labeled C that define isomorphic subtrees.

DEFINITION 3.3. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1Bs_2, B \to s_3 \in P$. Let $C \in V$, and suppose that C occurs both in s_1s_2 and s_3. Let D be an attribute (D does not have to be in V), and suppose that D does not occur in s_1s_2. The *child equality substitution* is defined as follows:

- $\Sigma\epsilon[A \to s_1Bs_2, B \to s_3, C, D](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{D\}$;
  - if $A = B$, then $P' = P \cup \{A \to s_1Ds_2, D \to s_3, D \to s_1Ds_2\}$, else $P' = P \cup \{A \to s_1Ds_2, D \to s_3\}$.
- Let $\mathbf{n}$ be an internal node in $\mathbf{D}$ with $\mathrm{lbl}(\mathbf{n}) = B$, $\mathrm{par}(\mathbf{n}) = A$, $\mathrm{chln}(\mathbf{par}(\mathbf{n})) = s_1Bs_2$, and $\mathrm{chln}(\mathbf{n}) = s_3$. Let $\mathbf{m}_1$ be the sibling and $\mathbf{m}_2$ be the child of $\mathbf{n}$ with label C and let $\mathbf{D}_1$ and $\mathbf{D}_2$ be the subtrees of $\mathbf{D}$ with $\mathbf{rt}(\mathbf{D}_1) = \mathbf{m}_1$ and $\mathbf{rt}(\mathbf{D}_2) = \mathbf{m}_2$. Then $\Sigma\epsilon[A \to s_1Bs_2, B \to s_3, C, D](\mathbf{D})$ is obtained by simultaneously relabeling by D each such node $\mathbf{n}$ for which $\mathbf{D}_1 \cong \mathbf{D}_2$.

Example 3.4. Consider an information base scheme $\mathcal{G} = (V, T, S, P)$ with $V = \{A, B, C, D\}$, $T = \{a, b\}$, $S = \{A\}$, and

$$P = \{A \to BA, A \to B, B \to CD, C \to a, C \to b, D \to a, D \to b\},$$

and let $\mathbf{D}$ be the information base instance over $\mathcal{G}$ shown in Fig. 5.

Then the parent substitution $\Sigma\pi[A \to BA, E]$ yields the information base scheme $\mathcal{G}' = (V', T, S', P')$ with $V' = \{A, B, C, D, E\}$, $S' = \{A, E\}$, and

$$P' = \{E \to BA, A \to B, B \to CD, C \to a, C \to b, D \to a, D \to b, E \to BE\}$$

and the information base instance $\mathbf{D}'$ in Fig. 6.

The child substitution $\Sigma\chi[E \to BA, A, E]$ applied to the information base thus obtained yields the information base scheme $\mathcal{G}'' = (V', T, S', P'')$ with

$$P'' = \{A \to B, B \to CD, C \to a, C \to b, D \to a, D \to b, E \to BE, E \to B\}$$

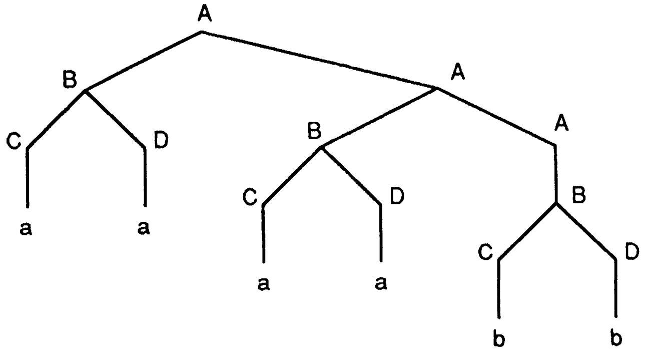

FIG. 5. *An information base instance* **D**.

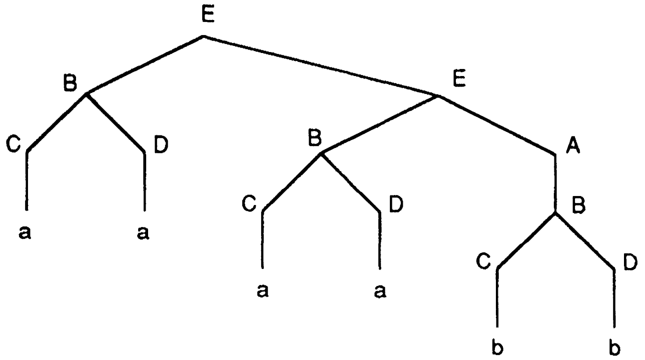

FIG. 6. *The information base instance* $\mathbf{D}' = \Sigma\pi[A \rightarrow BA, E](\mathbf{D})$.

and the information base instance $\mathbf{D}''$ in Fig. 7.

Finally, the child equality substitution $\Sigma\epsilon[E \rightarrow BE, E \rightarrow BE, B, D]$ applied to the last result yields the information base scheme $\mathcal{G}''' = (V', T, S', P''')$ with

$$P''' = \{A \rightarrow B, B \rightarrow CD, C \rightarrow a, C \rightarrow b, D \rightarrow a, D \rightarrow b,$$
$$E \rightarrow BE, E \rightarrow B, E \rightarrow BD, D \rightarrow BE, D \rightarrow BD\}$$

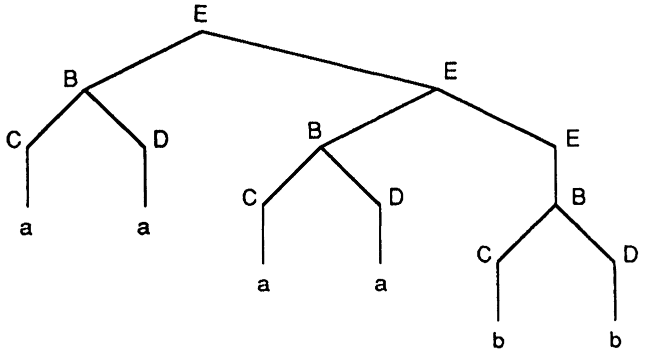

FIG. 7. *The information base instance* $\mathbf{D}'' = \Sigma\chi[E \rightarrow BA, A, E](\mathbf{D}')$.

and the information base instance $\mathbf{D}'''$ in Fig. 8.

Next, we define two operators that allow the introduction of new nodes and the removal of existing ones.

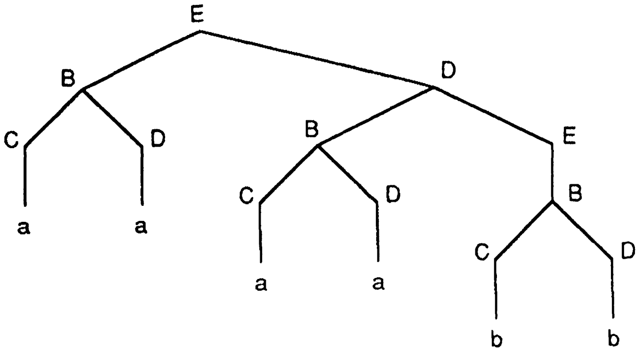

FIG. 8. *The information base instance* $\mathbf{D}''' = \Sigma\epsilon[E \rightarrow BE, E \rightarrow BE, B, D](\mathbf{D}'')$.

The node insertion $N\iota[A \rightarrow s_1s_2s_3, s_1Bs_3]$ inserts in each derivation of $s_1s_2s_3$ from A a node B as a child of A and the father of s_2.

DEFINITION 3.5. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \rightarrow s_1s_2s_3 \in P$, or $A \in V$ and $s_1s_2s_3 = \varepsilon$. Let B be an attribute not in V. The *node insertion* is defined as follows:

- $N\iota[A \rightarrow s_1s_2s_3, s_1Bs_3](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{B\}$;
  - $P' = (P - \{A \rightarrow s_1s_2s_3\}) \cup \{A \rightarrow s_1Bs_3, B \rightarrow s_2\}$.
- Let $\mathbf{n}$ be a node of $\mathbf{D}$ with $\text{lbl}(\mathbf{n}) = A$ and $\text{chln}(\mathbf{n}) = s_1s_2s_3$. Then $N\iota[A \rightarrow s_1s_2s_3, s_1Bs_3](\mathbf{D})$ is obtained by simultaneously inserting for each such node $\mathbf{n}$ a node $\mathbf{n}'$ for which $\text{lbl}(\mathbf{n}') = B$, $\mathbf{par}(\mathbf{n}') = \mathbf{n}$, and $\mathbf{chln}(\mathbf{n}')$ is the subinterval of $\mathbf{chln}(\mathbf{n})$ corresponding to s_2.

The node deletion $N\delta[A]$ deletes each subtree whose root is labeled by A.

DEFINITION 3.6. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \in V$. The *node deletion* is defined as follows:

- $N\delta[A](\mathcal{G}) = \mathcal{G}' = (V', T, S', P')$ where
  - $V' = V - \{A\}$;
  - $S' = S - \{A\}$;
  - Let $P'' = \{B \rightarrow s \mid B \in V',\ s \in (V' \cup T)^*, \text{ and } B \rightarrow s \in P\}$. Then

$$P' = P'' \cup \{B \rightarrow s_1s_2 \mid B \in V',\ s_1s_2 \in (V' \cup T)^*, \text{ and } B \rightarrow s_1As_2 \in P\}.$$

- $N\delta[A](\mathbf{D})$ is obtained by deleting each subtree $\mathbf{D}'$ from $\mathbf{D}$ with $\text{rt}(\mathbf{D}') = A$.

Example 3.7. Consider an information base scheme $\mathcal{G} = (V, T, S, P)$ with $V = \{A, B, C, D, E\}$, $T = \{a, b, c, d, e\}$, $S = \{A\}$, and

$$P = \{A \rightarrow BCD, B \rightarrow abEd, C \rightarrow c, D \rightarrow Bd, E \rightarrow e\},$$

and let $\mathbf{D}$ be the information base instance over $\mathcal{G}$ shown in Fig. 9.

Then the node insertion $N\iota[B \rightarrow abEd, aFd]$ yields the information base scheme $\mathcal{G}' = (V', T, S, P')$ with $V' = \{A, B, C, D, E, F\}$ and

$$P' = \{A \rightarrow BCD, B \rightarrow aFd, C \rightarrow c, D \rightarrow Bd, E \rightarrow e, F \rightarrow bE\}$$

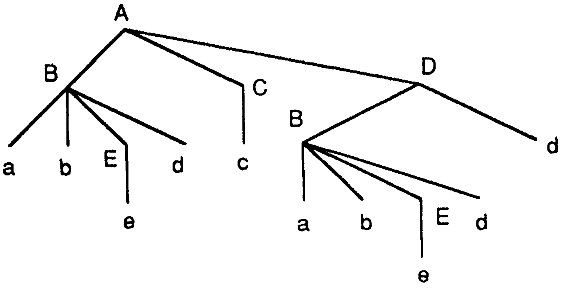

FIG. 9. *An information base instance* **D**.

and the information base instance **D**$'$ in Fig. 10.

The node deletion N$\delta[F]$ applied to the information base thus obtained yields the information base scheme $\mathcal{G}'' = (V'', T, S, P'')$ with $V'' = \{A, B, C, D, E\}$ and

$$P'' = \{A \rightarrow BCD, B \rightarrow ad, C \rightarrow c, D \rightarrow Bd, E \rightarrow e\}$$

and the information base instance **D**$''$ of Fig. 11.

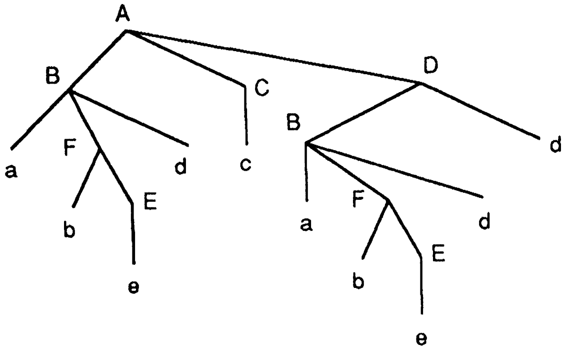

FIG. 10. *The information base instance* $\mathbf{D}' = \mathrm{N}\iota[B \rightarrow abEd, aFd](\mathbf{D})$.

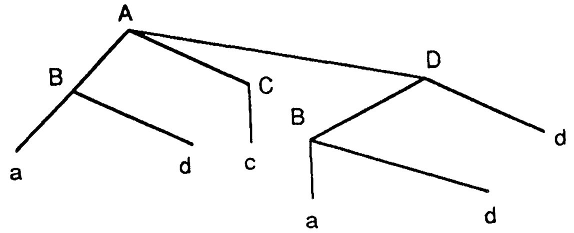

FIG. 11. *The information base instance* $\mathbf{D}'' = \mathrm{N}\delta[F](\mathbf{D})$.

Note that N$\delta[A]$ applied to any of the above information bases would yield the empty information base.

We also need two operators that copy information from one place in an information base to another. They are defined recursively.

Essentially, the downward duplication $\Delta\delta[A \rightarrow s_1Bs_2, B \rightarrow s_3, C, D]$ copies the subtree with root C in a string s_1Bs_2 derived from A as the rightmost sibling of a string s_3 which is derived from B, and renames the root of that copy to D. What makes the definition below somewhat involved is that, for reasons of uniformity, we have to require that this duplication is propagated into these subtrees as well.

DEFINITION 3.8. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1Bs_2 \in P$, and let either $B \to s_3 \in P$ or $s_3 = \varepsilon$. Let $C \in V$, and suppose that C occurs in s_1s_2. Let D be an attribute (D does not have to be in V), and suppose that D does not occur in s_3. The *downward duplication* is recursively defined as follows:

- $\Delta\delta[A \to s_1Bs_2, B \to s_3, C, D](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{D\}$;
  - $P' = P \cup \{B \to s_3D\} \cup \{D \to s \mid s \in (V \cup T)^* \text{ and } C \to s \in P\}$.
- Let $\mathbf{n}$ be a internal node in $\mathbf{D}$ with $\text{lbl}(\mathbf{n}) = B$, $\text{par}(\mathbf{n}) = A$, $\text{chln}(\mathbf{par}(\mathbf{n})) = s_1Bs_2$, and $\text{chln}(\mathbf{n}) = s_3$. Let $\mathbf{m}$ be the node in $\mathbf{chln}(\mathbf{par}(\mathbf{n}))$ with $\text{lbl}(\mathbf{m}) = C$. Let $\mathbf{D}''$ be the subtree of $\mathbf{D}$ defined by $\mathbf{rt}(\mathbf{D}'') = \mathbf{m}$, and let $\mathbf{D}''' = \Delta\delta[A \to s_1Bs_2, B \to s_3, C, D](\mathbf{D}'')$. Then $\Delta\delta[A \to s_1Bs_2, B \to s_3, C, D](\mathbf{D})$ is obtained by simultaneously adding to $\mathbf{chln}(\mathbf{n})$ for each such node $\mathbf{n}$ a rightmost sibling $\mathbf{n}'$ with $\text{lbl}(\mathbf{n}') = D$. The subtree $\mathbf{D}'$ of $\Delta\delta[A \to s_1Bs_2, B \to s_3, C, D](\mathbf{D})$ defined by $\mathbf{rt}(\mathbf{D}') = \mathbf{n}'$ is then determined by $\mathbf{chtrs}(\mathbf{n}') \cong \mathbf{chtrs}(\mathbf{rt}(\mathbf{D}'''))$.

Example 3.9. Consider an information base scheme $\mathcal{G} = (V, T, S, P)$ with $V = \{A, B, C\}$, $T = \{a, b, c, d\}$, $S = \{A\}$, and $P = \{A \to BaC, B \to bd, C \to cA, C \to c\}$, and let $\mathbf{D}$ be the information base instance over $\mathcal{G}$ in Fig. 12.

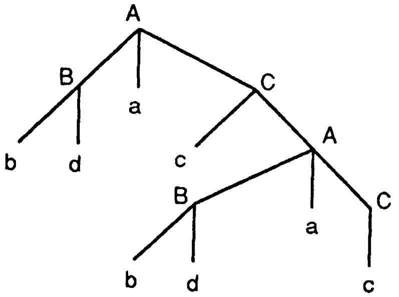

FIG. 12. *An information base instance* $\mathbf{D}$.

Then the downward duplication $\Delta\delta[A \to BaC, B \to bd, C, D]$ yields the information base scheme $\mathcal{G}' = (V', T, S, P')$ with $V' = \{A, B, C, D\}$ and

$$P' = \{A \to BaC, B \to bdD, C \to cA, C \to c, D \to cA, D \to c\}$$

and the information base instance $\mathbf{D}'$ of Fig. 13.

The downward duplication copies information downward into the tree; the upward duplication is its upward counterpart.

DEFINITION 3.10. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1Bs_2, B \to s_3 \in P$. Let $C \in V$, and suppose that C occurs in s_3. Let D be an attribute (D does not have to be in V), and suppose that D does not occur in s_1s_2. The *upward duplication* is recursively defined as follows:

- $\Delta\upsilon[A \to s_1Bs_2, B \to s_3, C, D](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{D\}$;
  - $P' = P \cup \{A \to s_1Bs_2D\} \cup \{D \to s \mid s \in (V \cup T)^* \text{ and } C \to s \in P\}$.
- Let $\mathbf{n}$ be a internal node in $\mathbf{D}$ with $\text{lbl}(\mathbf{n}) = B$, $\text{par}(\mathbf{n}) = A$, $\text{chln}(\mathbf{par}(\mathbf{n})) = s_1Bs_2$, and $\text{chln}(\mathbf{n}) = s_3$. Let $\mathbf{m}$ be the node in $\mathbf{chln}(\mathbf{n})$ with $\text{lbl}(\mathbf{m}) = C$. Let $\mathbf{D}''$ be the subtree of $\mathbf{D}$ defined by $\mathbf{rt}(\mathbf{D}'') = \mathbf{m}$, and let $\mathbf{D}''' = \Delta\upsilon[A \to s_1Bs_2, B \to s_3, C, D](\mathbf{D}'')$. Then $\Delta\upsilon[A \to$

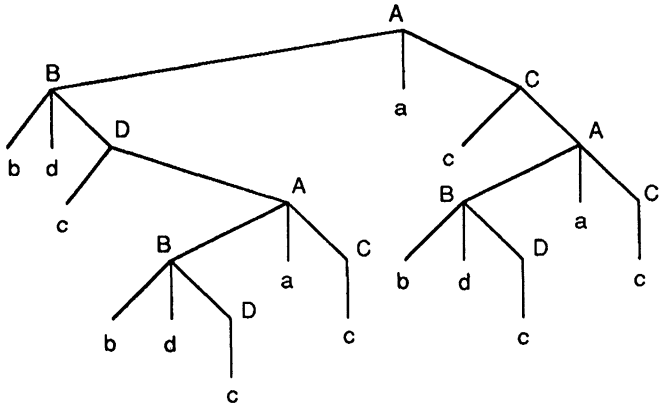

FIG. 13. *The information base instance* $\mathbf{D}' = \Delta\delta[A \rightarrow BaC, B \rightarrow bd, C, D](\mathbf{D})$.

$s_1Bs_2, B \rightarrow s_3, C, D](\mathbf{D})$ is obtained by simultaneously adding to **chln**(**par**(**n**)) for each such node **n** a rightmost sibling **n**′ with lbl(**n**′) $= D$. The subtree $\mathbf{D}'$ of $\Delta\upsilon[A \rightarrow s_1Bs_2, B \rightarrow s_3, C, D](\mathbf{D})$ defined by $\mathbf{rt}(\mathbf{D}') = \mathbf{n}'$ is then determined by **chtrs**(**n**′) $\cong$ **chtrs**(**rt**($\mathbf{D}'''$)).

Since upward duplication is very similar to downward duplication, we omit an example.

Using both downward and upward duplication, it is possible to simulate sidewise duplication, defined below.

DEFINITION 3.11. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let **D** be an information base instance over $\mathcal{G}$. Let $A \rightarrow s_1Cs_2 \in P$. Let D be an attribute (D does not have to be in V), and suppose that D does not occur in s_1s_2. The *sidewise duplication* is recursively defined as follows:

- $\Delta\sigma[A \rightarrow s_1Cs_2, C, D](\mathcal{G}) = \mathcal{G}' = (V', T, S, P')$ where
  - $V' = V \cup \{D\}$;
  - $P' = P \cup \{A \rightarrow s_1Cs_2D\} \cup \{D \rightarrow s \mid s \in (V \cup T)^*$ and $C \rightarrow s \in P\}$.

- Let **n** be a node in **D** with lbl(**n**) $= A$ and chln(**n**) $= s_1Cs_2$. Let **m** be the node in **chln**(**n**) with lbl(**m**) $= C$. Let $\mathbf{D}''$ be the subtree of **D** defined by $\mathbf{rt}(\mathbf{D}'') = \mathbf{m}$, and let $\mathbf{D}''' = \Delta\sigma[A \rightarrow s_1Cs_2, C, D](\mathbf{D}'')$. Then $\Delta\sigma[A \rightarrow s_1Cs_2, C, D](\mathbf{D})$ is obtained by simultaneously adding to **chln**(**n**) for each such node **n** a rightmost sibling **n**′ with lbl(**n**′) $= D$. The subtree $\mathbf{D}'$ of $\Delta\sigma[A \rightarrow s_1Cs_2, C, D](\mathbf{D})$ defined by $\mathbf{rt}(\mathbf{D}') = \mathbf{n}'$ is then determined by **chtrs**(**n**′) $\cong$ **chtrs**(**rt**($\mathbf{D}'''$)).

THEOREM 3.12. *Sidewise duplication can be expressed in terms of node insertion, downward duplication, upward duplication, and node deletion.*

Proof. Let $\mathcal{G} = (V, T, S, P)$ be the scheme of some information base, and consider the sidewise duplication $\Delta\sigma[A \rightarrow s_1Cs_2, C, D]$ in which A, C, D, s_1, and s_2 are as in Definition 3.11. Let E be an attribute not in V. Then $\Delta\sigma[A \rightarrow s_1Cs_2, C, D]$ can be performed by consecutively executing the following operations:

1. the node insertion $\mathrm{N}\iota[A \rightarrow s_1Cs_2, s_1Cs_2E]$;
2. the downward duplication $\Delta\delta[A \rightarrow s_1Cs_2E, E \rightarrow \varepsilon, C, C]$;
3. the upward duplication $\Delta\upsilon[A \rightarrow s_1Cs_2E, E \rightarrow C, C, D]$;
4. the node deletion $\mathrm{N}\Delta[E]$.

In step 1, the node E is actually created so that downward duplication can always be applied, even if $s_1s_2 = \varepsilon$. □

Note that the effects of downward duplication, upward duplication, and sidewise duplication can be easily undone by deleting D (using the notations used in the respective definitions). This observation yields a natural "embedding" of the nodes of the original information base instance into the resulting instance. From the definitions of the above operations, the result below follows in a straightforward manner.

THEOREM 3.13. *Let* $\mathbf{D}$ *be an information base instance over some appropriate scheme, and let* $\mathbf{D}'$ *be the resulting instance after a downward duplication, an upward duplication, or a sidewise duplication. Let* $\mathbf{n}_1$ *and* $\mathbf{n}_2$ *be two nodes in* $\mathbf{D}$, *and let* $\mathbf{n}'_1$ *and* $\mathbf{n}'_2$, *respectively, be the corresponding nodes in* $\mathbf{D}'$. *Let* $\mathbf{D}_1$ *and* $\mathbf{D}_2$ *be the subtrees of* $\mathbf{D}$ *defined by* $\mathbf{rt}(\mathbf{D}_1) = \mathbf{n}_1$ *and* $\mathbf{rt}(\mathbf{D}_2) = \mathbf{n}_2$ *and let* $\mathbf{D}'_1$ *and* $\mathbf{D}'_2$ *be the subtrees of* $\mathbf{D}'$ *defined by* $\mathbf{rt}(\mathbf{D}'_1) = \mathbf{n}'_1$ *and* $\mathbf{rt}(\mathbf{D}'_2) = \mathbf{n}'_2$. *Then* $\mathbf{D}'_1 \cong \mathbf{D}'_2$ *if and only if* $\mathbf{D}_1 \cong \mathbf{D}_2$. *Suppose furthermore that in* $\mathbf{D}'$ *the subtree* $\mathbf{D}'_3$ *is a 'duplicate" of* $\mathbf{D}_2$. *Let* $\mathbf{D}''_3$ *be any* D-*tree defined by* $\mathrm{rt}(\mathbf{D}''_3) = \mathrm{rt}(\mathbf{D}'_2)$ *and* $\mathbf{chtrs}(\mathbf{rt}(\mathbf{D}''_3)) = \mathbf{chtrs}(\mathbf{rt}(\mathbf{D}'_3))$. *Then* $\mathbf{D}'_2 \cong \mathbf{D}''_3$ *whence* $\mathbf{D}'_1 \cong \mathbf{D}''_3$ *if and only if* $\mathbf{D}_1 \cong \mathbf{D}_2$.

Theorem 3.13 will turn out to be essential in the proof of our main theorem, given in §6.

Finally, we introduce a permutation. Basically, a permutation recursively rearranges the children derived by some production $A \to s$.

DEFINITION 3.14. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1 \in P$, or $A \in V$ and $s_1 = \varepsilon$, and let $s_2 \in (V \cup T)^*$ contain the same attributes as s_1. The *permutation* is recursively defined as follows:

- $\Pi[A \to s_1, s_2](\mathcal{G}) = \mathcal{G}' = (V, T, S, P')$ where

$$P' = (P - \{A \to s_1\}) \cup \{A \to s_2\}.$$

- Let $\mathbf{n}$ be a node in $\mathbf{D}$ with $\mathrm{lbl}(\mathbf{n}) = A$ and $\mathrm{chln}(\mathbf{n}) = s_1$. $\Pi[A \to s_1, s_2](\mathbf{D})$ is obtained by first simultaneously substituting new nodes for $\mathbf{chln}(\mathbf{n})$ such that $\mathrm{chln}(\mathbf{n})$ becomes s_2. Now let B be an attribute in s_2, and let $\mathbf{m}$ be the node in $\Pi[A \to s_1, s_2](\mathbf{D})$ with $\mathrm{lbl}(\mathbf{m}) = B$ and $\mathbf{par}(\mathbf{m}) = \mathbf{n}$. Then the subtree $\mathbf{D}'$ of $\Pi[A \to s_1, s_2](\mathbf{D})$ defined by $\mathbf{rt}(\mathbf{D}') = \mathbf{m}$ is isomorphic to $\Pi[A \to s_1, s_2](\mathbf{D}'')$, where the D-tree $\mathbf{D}''$ is the subtree of $\mathbf{D}$ defined by $\mathrm{rt}(\mathbf{D}'') = B$ and $\mathbf{par}(\mathbf{rt}(\mathbf{D}'')) = \mathbf{n}$.

Our notion of permutation is somewhat wider than what is usually understood by this term. A permutation does indeed permute attributes, but can also insert, delete, and rearrange constants.

Example 3.15. Consider an information base scheme $\mathcal{G} = (V, T, S, P)$ with $V = \{A, B\}$, $T = \{a, b, c\}$, $S = \{A\}$, and $P = \{A \to aB, B \to bBc\}$, and consider the information base instance over $\mathcal{G}$ shown in Fig. 14 left.

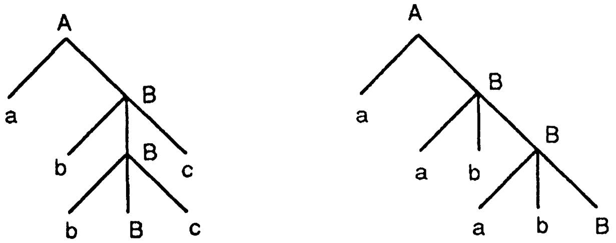

FIG. 14. *An example of a permutation.*

Then the permutation $\Pi[B \to bBc, abB]$ yields the information base scheme $\mathcal{G}' = (V, T, S, P')$ with $P' = \{A \to aB, B \to abB\}$ and the information base instance shown in Fig. 14 right.

Parent substitution, child substitution, child equality substitution, node insertion, node deletion, downward duplication, upward duplication, and permutation define the *grammatical algebra*. Many other conceivable operators can be expressed in terms of these eight, meaning there is a sequence of instance-independent grammatical algebra operations that returns the same result *at the instance level*. In general, however, it is unavoidable that the scheme returned by the algebra sequence defines a larger language than the scheme returned by the original operator (although in Theorem 3.12, they are equal).

We already saw that sidewise duplication can be expressed in the grammatical algebra. Below, we give two more examples of derived operations that are often needed in practical applications.

First, we introduce node merging. The node merging $\mathrm{N}\mu[A \to s_1Bs_2, B \to s_3]$ is obtained by pruning out each attribute B in a string s_1Bs_2 which is derived from A and from which s_3 is derived. In this way, $s_1s_3s_2$ will be derived from A instead.

DEFINITION 3.16. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1Bs_2 \in P$, and let $B \to s_3 \in P$, or $B \in V$ and $s_3 = \varepsilon$. Suppose that no attribute in s_3 appears in s_1s_2. The *node merging* is defined as follows:

- $\mathrm{N}\mu[A \to s_1Bs_2, B \to s_3](\mathcal{G}) = \mathcal{G}' = (V, T, S, P')$ where

$$P' = P \cup \{A \to s_1s_3s_2\}.$$

- Let $\mathbf{n}$ be a node of $\mathbf{D}$ with $\mathrm{lbl}(\mathbf{n}) = B$, $\mathrm{par}(\mathbf{n}) = A$, $\mathrm{chln}(\mathbf{par}(\mathbf{n})) = s_1Bs_2$, and $\mathrm{chln}(\mathbf{n}) = s_3$. Then $\mathrm{N}\mu[A \to s_1Bs_3, B \to s_3](\mathbf{D})$ is obtained by simultaneously substituting each such node $\mathbf{n}$ in $\mathbf{chln}(\mathbf{par}(\mathbf{n}))$ by $\mathbf{chln}(\mathbf{n})$.

Clearly, on instance level, a node insertion $\mathrm{N}\iota[A \to s_1s_2s_3, s_1Bs_3]$ can be undone by the node merging $\mathrm{N}\mu[A \to s_1Bs_3, B \to s_2]$. We now show the following.

THEOREM 3.17. *Node merging can be expressed in the grammatical algebra.*

Proof. Rather than giving a notationally cumbersome proof, we illustrate the general techniques that are needed on an example.

Consider an information base with scheme $\mathcal{G} = (V, T, S, P)$ where $V = \{A, B, C\}$, $T = \{a, b, c\}$, $S = \{A\}$, and $P = \{A \to aBc, B \to bC, C \to c\}$. The node merging $\mathrm{N}\mu[A \to aBc, B \to bC]$ can be expressed by consecutively performing the following operations:

1. the child substitution $\Sigma\chi[A \to aBc, B, B']$;
2. the upward duplication $\Delta\upsilon[A \to aB'c, B' \to bC, C, C]$;
3. the child substitution $\Sigma\chi[A \to aB'cC, B', B'']$;
4. the node deletion $\mathrm{N}\delta[B'']$;
5. the permutation $\Pi[A \to acC, abCc]$;
6. the child substitution $\Sigma\chi[A \to aB'c, B', B]$.

We invite the reader to check our claim on a concrete instance.

In general, step 2 must be carried out for each attribute in s_3. In step 5, all the copied attributes must be arranged in the right order and all the constants in s_3 inserted in the right place. □

Below, we give another example of a derived operator that will turn out to be very useful in the proof of our main result in §5.

DEFINITION 3.18. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $A \to s_1C_1s_2C_2s_3 \in P$ with $C_1 \neq A$ and $C_2 \neq A$. Let B be an attribute (B does not have to be in V), and suppose that A and B never occur simultaneously in the right-hand side of a production of P. The *parent equality substitution* is defined as follows:

- $\Sigma\sigma[A \to s_1C_1s_2C_2s_3, C_1, C_2, B](\mathcal{G}) = \mathcal{G}' = (V', T, S', P')$ where
  - $V' = V \cup \{B\}$;
  - if $A \in S$, then $S' = S \cup \{B\}$, else $S' = S$;

– Let $P'' = P \cup \{B \to s_1C_1s_2C_2s_3\}$. Then

$$P' = P'' \cup \{C \to s_4Bs_5 \mid C \in V',\ s_4s_5 \in (V \cup T)^*, \text{ and } C \to s_4As_5 \in P''\}.$$

• Let **n** be a node in **D** with lbl(**n**) $= A$ and **chln(n)** $= s_1C_1s_2C_2s_3$. Let $\mathbf{m}_1$ be the child of **n** with label C_1 and $\mathbf{m}_2$ be the child of **n** with label C_2 and let $\mathbf{D}_1$ and $\mathbf{D}_2$ be the subtrees of **D** with $\mathbf{rt}(\mathbf{D}_1) = \mathbf{m}_1$ and $\mathbf{rt}(\mathbf{D}_2) = \mathbf{m}_2$. Let $\mathbf{D}_3$ be the D-tree defined by $\mathbf{rt}(\mathbf{D}_3) = \mathbf{m}_1$ and $\mathbf{chtrs}(\mathbf{D}_3) = \mathbf{chtrs}(\mathbf{D}_2)$. Then $\Sigma\sigma[A \to s_1C_1s_2C_2s_3, C_1, C_2, B](\mathbf{D})$ is obtained by simultaneously relabeling by B each such node **n** for which $\mathbf{D}_1 \cong \mathbf{D}_3$.

The reader may wonder why we have imposed the restriction $C_1 \neq A$ and $C_2 \neq A$. Indeed, without this restriction, parent equality substitution would still be well defined. In the upcoming sections, however, we only need the restricted parent equality substitution, and, although Theorem 3.19 below still holds for the unrestricted parent equality substitution, the proof would become very involved.

THEOREM 3.19. *Parent equality substitution can be expressed in the grammatical algebra.*

Proof. Let $\mathcal{G} = (V, T, S, P)$ be the scheme of some information base, and consider the parent equality substitution $\Sigma\sigma[A \to s_1C_1s_2C_2s_3, C_1, C_2, B]$ (cf. Definition 3.18). Let D and E be attributes not in V. Then $\Sigma\sigma[A \to s_1C_1s_2C_2s_3, C_1, C_2, B]$ can be performed by consecutively performing the following operations:

1. the node insertion $\mathrm{N}\iota[A \to s_1C_1s_2C_2s_3, s_1C_1s_2Ds_3]$;
2. the child substitution $\Sigma\chi[A \to s_1C_1s_2Ds_3, C_1, C_2]$;
3. the child equality substitution $\Sigma\epsilon[A \to s_1C_2s_2Ds_3, D \to C_2, C_2, E]$;
4. the parent substitution $\Sigma\pi[A \to s_1C_2s_2Es_3, B]$;
5. the child substitution $\Sigma\chi[B \to s_1C_2s_2Es_3, C_2, C_1]$;
6. the child substitution $\Sigma\chi[A \to s_1C_2s_2Ds_3, C_2, C_1]$;
7. the node merging $\mathrm{M}\mu[B \to s_1C_1s_2Es_3, E \to C_2]$;
8. the node merging $\mathrm{M}\mu[A \to s_1C_1s_2Ds_3, D \to C_2]$. □

We now return to the bibliographical Example 2.6 to illustrate on a more realistic information base how the grammatical algebra can be used to solve queries or to perform transformations.

Example 3.20. Reconsider the information base of Example 2.6. Suppose we want to extract only the information on journal titles (between double quotes) with the name of the journal and the volume. The instance of Fig. 4 would then be transformed into the instance of Fig. 15.

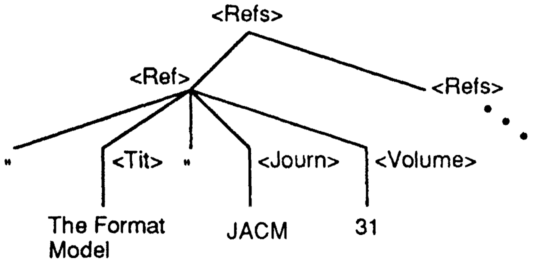

FIG. 15. *A transformation of the information base instance of Fig.* 4.

The transformation can be accomplished by consecutively performing the following operations:

1. $\mathrm{N}\delta[\langle Auths\rangle]$;
2. $\mathrm{N}\delta[\langle Year\rangle]$;
3. $\Delta\upsilon[\langle Source\rangle \to \langle Journ\rangle\langle Issue\rangle, \langle Issue\rangle \to \langle Vol\rangle : \langle Nr\rangle, \langle Vol\rangle, \langle Volume\rangle]$;

4. $\mathrm{N}\delta[\langle \mathit{Issue} \rangle]$;
5. $\mathrm{N}\mu[\langle \mathit{Ref} \rangle \rightarrow \langle \mathit{Tit} \rangle\langle \mathit{Source} \rangle, \langle \mathit{Source} \rangle \rightarrow \langle \mathit{Journ} \rangle\langle \mathit{Volume} \rangle]$;
6. $\Pi[\langle \mathit{Ref} \rangle \rightarrow \langle \mathit{Tit} \rangle\langle \mathit{Journ} \rangle\langle \mathit{Volume} \rangle,\text{''}\ \langle \mathit{Tit} \rangle\text{''}\langle \mathit{Journ} \rangle\langle \mathit{Volume} \rangle]$.

Observe that the instance obtained in the above example can be considered as a representation of a flat relational database model relation in the grammatical model. Below, we show how unary relational algebra operators can be performed. Note that, in order to simulate union, difference, and join, we need binary operators on information bases. This is beyond the scope of the present paper, however.

Example 3.21. Consider the following relational database relation R:

A	B	C
a_1	b_1	c_1
a_2	b_2	c_2
	$\vdots$	

This relation can be represented as an information base with scheme $\mathcal{G} = (V, T, S, P)$ where $V = \{U, R, A, B, C\}$, $T = \{a_1, \ldots, b_1, \ldots, c_1, \ldots\}$, $S = \{U\}$, and

$$P = \{U \rightarrow RU, R \rightarrow ABC, A \rightarrow a_1, \ldots, B \rightarrow b_1, \ldots, C \rightarrow c_1, \ldots\}$$

and with instance the tree shown in Fig. 16.

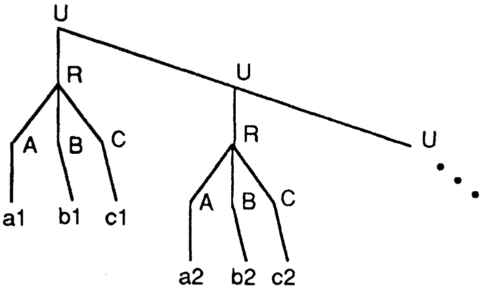

FIG. 16. *A representation of a flat relation instance in the grammatical model.*

We now consider three typical examples of unary relational algebra operators:

- The *renaming* of A to A' can be expressed as the child substitution $\Sigma\chi[R \rightarrow ABC, A, A']$.
- The *projection* of R onto AB can be expressed as the node deletion $\mathrm{N}\delta[C]$.
- The *selection* $A = C$ can be expressed by consecutively performing the following operations:
  1. the parent equality substitution $\Sigma\sigma[R \rightarrow ABC, A, C, R']$;
  2. the node deletion $\mathrm{N}\delta[R]$;
  3. the parent substitution $\Sigma\pi[R' \rightarrow ABC, R]$.

If desired, redundant U-nodes can be removed by repeatedly applying the node mergings $\mathrm{N}\mu[U \rightarrow U, U \rightarrow RU]$ and $\mathrm{N}\mu[U \rightarrow RU, U \rightarrow U]$.

Notice in the last example that the grammatical algebra does *not* have an iteration construct. The number of applications of the node mergings is therefore instance dependent (in this case, linear in the size of the instance).

4. A calculus for transforming information bases. Whereas in the previous section we defined a transformation language on information bases based on eight primitive operators which we claim to be sufficiently powerful to express a large class of queries, it is also possible to define a more declarative transformation language inspired by the relational calculus.

An expression in the grammatical calculus we propose consists of a set of conditions and a transformation clause, both built from variables. Informally, applying a calculus expression to an information base means performing the required transformations for each "occurrence" of the variables satisfying the set of conditions. Since the variables in a calculus expression represent so-called *rootless data trees*, we first explain this notion.

DEFINITION 4.1. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. A *rootless data tree* (R-tree) over $\mathcal{G}$ is a finite sequence of D-trees over $\mathcal{G}$. The set of all R-trees over $\mathcal{G}$ is denoted $\mathcal{R}(\mathcal{G})$.

We have to introduce the following notations concerning R-trees.

DEFINITION 4.2. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{R}$ be an R-tree over $\mathcal{G}$. Then

- $\mathbf{R}= (\mathbf{D}_1, \ldots, \mathbf{D}_n)$ denotes the sequence of D-trees of which $\mathbf{R}$ consists;
- $\mathbf{top}(\mathbf{R}) = (\mathbf{rt}(\mathbf{D}_1), \ldots, \mathbf{rt}(\mathbf{D}_n))$ denotes the sequence of the roots of the D-trees of which $\mathbf{R}$ consists;
- $\mathbf{F}$ denotes the empty R-tree.

Obviously, the isomorphism between D-trees defined in Definition 2.7 can be extended in a natural way to R-trees. The definition of R-trees also leads us to the following straightforward conclusions.

PROPOSITION 4.3. *Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme.*

- *Any interval*[2] *of an* R*-tree over $\mathcal{G}$ is also an* R*-tree over $\mathcal{G}$.*
- *Let* $\mathbf{D}$ *be a* D*-tree over $\mathcal{G}$. Then* $(\mathbf{D})$ *is an* R*-tree.*
- *Let* $\mathbf{D}$ *be a* D*-tree over $\mathcal{G}$. Then* $\mathbf{chltrs}(\mathbf{rt}(\mathbf{D}))$ *is an* R*-tree.*

It follows from Proposition 4.3 that R-trees can be contained in D-trees.

DEFINITION 4.4. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. Let $\mathbf{D}$ be a D-tree and $\mathbf{R}$ be an R-tree over $\mathcal{G}$. $\mathbf{R}$ is called a *rootless subtree* of $\mathbf{D}$ if $\mathbf{R}= (\mathbf{D}_1, \ldots, \mathbf{D}_n)$, $\mathbf{D}_1, \ldots, \mathbf{D}_n$ are subtrees of $\mathbf{D}$ and $\mathbf{top}(\mathbf{R})$ is a sequence of consecutive siblings of $\mathbf{D}$. The common parent of these siblings is denoted $\mathbf{par}(\mathbf{R})$. The set of all rootless subtrees of $\mathbf{D}$ is denoted $\mathbf{rst}(\mathbf{D})$. The R-tree $\mathbf{R}$ is called a *maximal rootless subtree* of $\mathbf{D}$ if, in addition, $\mathbf{top}(\mathbf{R})$ is a maximal sequence of consecutive siblings of $\mathbf{D}$, i.e., if $\mathbf{top}(\mathbf{R}) = \mathbf{chln}(\mathbf{par}(\mathbf{R}))$.

Finally, we need two simple operations on R-trees.

DEFINITION 4.5. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme.

- Let $\mathbf{R}_1 = (\mathbf{D}_1, \ldots, \mathbf{D}_m)$ and $\mathbf{R}_2 = (\mathbf{D}_{m+1}, \ldots, \mathbf{D}_n)$ be R-trees over $\mathcal{G}$. Then the *concatenation* $\mathbf{R}_1\mathbf{R}_2$ is the R-tree defined by $\mathbf{R}_1\mathbf{R}_2 = (\mathbf{D}_1, \ldots, \mathbf{D}_n)$.
- Let $\mathbf{R}$ be an R-tree over $\mathcal{G}$ and let $\mathbf{n}$ be an arbitrary node. If $\mathrm{lbl}(\mathbf{n})$ is an attribute or $\mathbf{R}$ is empty, then the *completion* $\mathbf{nR}$ is the D-tree defined by $\mathbf{rt}(\mathbf{nR}) = \mathbf{n}$ and $\mathbf{chltrs}(\mathbf{n}) = \mathbf{R}$.

As mentioned, variables in a calculus expression represent rootless subtrees of the information base instance under consideration. From these variables, terms are built using concatenation and completion. As a consequence of Proposition 4.3, these terms in turn represent R-trees. The set of conditions in a calculus expression consists of declarations of variables by terms and of equations between variables and terms; the substitution clause consists of a variable and the term by which that variable has to substituted. Of course, the variables in the substitution clause have to occur in the set of conditions. Before formalizing the syntax of a grammatical calculus expression, we clarify the concept by an example.

Example 4.6. Reconsider the information base of Example 2.6 and the query of Example 3.20, described in the grammatical algebra. This query can also be solved by the following

[2] By an interval of a sequence we mean a subsequence consisting of consecutive elements.

grammatical calculus expression:

$$\begin{aligned}[\rho_2 \leftarrow{}'' (\langle \mathit{Tit}\rangle \rho_4)''(\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Volume}\rangle \rho_9) \mid \\ \{\rho_1 &:= (\langle \mathit{Ref}\rangle \rho_2) \\ \rho_2 &:= (\langle \mathit{Auths}\rangle \rho_3)(\langle \mathit{Tit}\rangle \rho_4)(\langle \mathit{Source}\rangle \rho_5)(\langle \mathit{Year}\rangle \rho_6) \\ \rho_5 &:= (\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Issue}\rangle \rho_8) \\ \rho_8 &:= (\langle \mathit{Vol}\rangle \rho_9) : (\langle \mathit{Nr}\rangle \rho_{10})\}].\end{aligned}$$

Another similar grammatical calculus expression that has the same effect on information bases over the scheme of Example 2.6 is the following:

$$\begin{aligned}[\rho_2 \leftarrow{}'' (\langle \mathit{Tit}\rangle \rho_4)''(\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Volume}\rangle \rho_9) \mid \\ \{\rho_1 &:= (\langle \mathit{Ref}\rangle \rho_2) \\ \rho_2 &:= (\langle \mathit{Auths}\rangle \rho_3)(\langle \mathit{Tit}\rangle \rho_4)(\langle \mathit{Source}\rangle \rho_5)\rho_6 \\ \rho_5 &:= (\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Issue}\rangle \rho_8) \\ \rho_8 &:= (\langle \mathit{Vol}\rangle \rho_9) : (\langle \mathit{Nr}\rangle \rho_{10})\}].\end{aligned}$$

In both expressions, the four declarations in the right-hand side specify a "pattern" in the bibliographic information base; each time that pattern is found in the instance, it must be changed according to the substitution clause.

We now formally define the syntax of the grammatical calculus. Throughout this exposition, we assume that $\mathcal{V} = \{\rho_i \mid i \geq 1\}$ is an infinitely enumerable set of *variables*.

DEFINITION 4.7. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme.

- A *basic term* over $\mathcal{G}$ has one of the following three types:
  - –type 0: a $(a \in T)$;
  - –type 1: ρ_i $(\rho_i \in \mathcal{V})$;
  - –type 2: $(A\rho_i)$ $(A \in V, \rho_i \in \mathcal{V})$.
- A *term* over $\mathcal{G}$ is a finite sequence of basic terms over $\mathcal{G}$ that contains at most one basic term of type 1 and in which each variable and each attribute appears at most once. The empty term is denoted ε. The set of all variables occurring in a term t is denoted $\mathrm{var}(t)$.

DEFINITION 4.8. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme.

- A *declaration* over $\mathcal{G}$ has the form $\rho_i := t$ with $\rho_i \in \mathcal{V}$ and t a term over $\mathcal{G}$ in which ρ_i does not occur.
- An *equation* over $\mathcal{G}$ has the form $\rho_i = \rho_j$ with $\rho_i, \rho_j \in \mathcal{V}$.

DEFINITION 4.9. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. Let $\mathcal{D} = \{\rho_i := t_i \mid i \in I\}$, I a set of indices, be a finite set of declarations over $\mathcal{G}$ in which no variable appears in the left-hand side of more than one declaration and in the right-hand side of more than one declaration. Let $\mathrm{var}(\mathcal{D})$ denote the set of all variables occurring in $\mathcal{D}$. Consider the *associated directed graph* $\mathcal{G}(\mathcal{D})$ with set of nodes $\mathrm{var}(\mathcal{D})$ and set of edges $\{\rho_j \rightarrow \rho_k \mid j \in I \text{ and } \rho_k \in \mathrm{var}(t_j)\}$. $\mathcal{D}$ is called *hierarchical* if $\mathcal{G}(\mathcal{D})$ is a tree, and, furthermore, the root ρ_{root} has a declaration of the form $\rho_{\mathrm{root}} := (A\rho_l)$ for some $A \in V$ and $\rho_l \in \mathcal{V}$.

For a hierarchical set of declarations it makes sense to define the following.

DEFINITION 4.10. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathcal{D}$ be a hierarchical set of declarations over $\mathcal{G}$.

- Let $\rho_i \in \mathrm{var}(\mathcal{D})$ be a variable which is not the root of $\mathcal{G}(\mathcal{D})$. Then ρ_i is said to be *of type* 1 (*of type* 2) if the unique basic term containing ρ_i in the right-hand side of a declaration of $\mathcal{D}$ is of type 1 (of type 2).
- Let $\rho_i \in \mathrm{var}(\mathcal{D})$ be an arbitrary variable. The *depth* $\mathrm{d}(\rho_i)$ of ρ_i is recursively defined as follows, using the hierarchy in $\mathcal{G}(\mathcal{D})$:

1. If ρ_i is the root of $\mathcal{G}(\mathcal{D})$, then $\mathrm{d}(\rho_i) = 0$;
2. If ρ_i is of type 1 and ρ_j is the parent of ρ_i, then $\mathrm{d}(\rho_i) = \mathrm{d}(\rho_j)$;
3. If ρ_i is of type 2 and ρ_j is the parent of ρ_i, then $\mathrm{d}(\rho_i) = \mathrm{d}(\rho_j) + 1$.

Observe that, given a hierarchical set of declarations $\mathcal{D}$, the root of $\mathcal{G}(\mathcal{D})$ has no type.

Example 4.11. Consider the set of declarations in the right-hand side of the first expression in Example 4.6:

$$\begin{aligned}\{\rho_1 &:= (\langle \mathit{Ref}\rangle \rho_2)\\ \rho_2 &:= (\langle \mathit{Auths}\rangle \rho_3)(\langle \mathit{Tit}\rangle \rho_4)(\langle \mathit{Source}\rangle \rho_5)(\langle \mathit{Year}\rangle \rho_6)\\ \rho_5 &:= (\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Issue}\rangle \rho_8)\\ \rho_8 &:= (\langle \mathit{Vol}\rangle \rho_9) : (\langle \mathit{Nr}\rangle \rho_{10})\}.\end{aligned}$$

Obviously, this is a hierarchical set of declarations. Its associated tree is shown in Fig. 17.

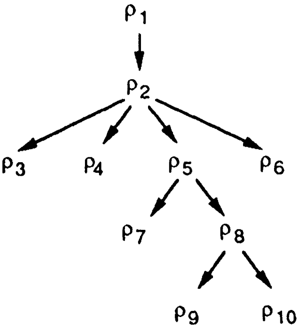

FIG. 17. *The tree associated with the hierarchical sets of declarations in Example* 4.11.

All variables (except of course for ρ_1) are of type 2. Furthermore, $\mathrm{d}(\rho_1) = 0$, $\mathrm{d}(\rho_2) = 1$, $\mathrm{d}(\rho_3) = \mathrm{d}(\rho_4) = \mathrm{d}(\rho_5) = \mathrm{d}(\rho_6) = 2$, $\mathrm{d}(\rho_7) = \mathrm{d}(\rho_8) = 3$, and $\mathrm{d}(\rho_9) = \mathrm{d}(\rho_{10}) = 4$. Now, consider the set of declarations in the right-hand side of the second expression in Example 4.6:

$$\begin{aligned}\{\rho_1 &:= (\langle \mathit{Ref}\rangle \rho_2)\\ \rho_2 &:= (\langle \mathit{Auths}\rangle \rho_3)(\langle \mathit{Tit}\rangle \rho_4)(\langle \mathit{Source}\rangle \rho_5)\rho_6\\ \rho_5 &:= (\langle \mathit{Journ}\rangle \rho_7)(\langle \mathit{Issue}\rangle \rho_8)\\ \rho_8 &:= (\langle \mathit{Vol}\rangle \rho_9) : (\langle \mathit{Nr}\rangle \rho_{10})\}.\end{aligned}$$

This is a hierarchical set of declarations with the same associated tree as the previous one. However, ρ_6 is now of type 1 with $\mathrm{d}(\rho_6) = 1$.

We now have all the ingredients to define an expression.

DEFINITION 4.12. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. An *expression* over $\mathcal{G}$ has the form $[\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ with $\rho_j \in \mathcal{V}$, u a term over $\mathcal{G}$ with $\rho_j \notin \mathrm{var}(u)$, $\mathcal{D}$ a hierarchical set of declarations over $\mathcal{G}$, and $\mathcal{E}$ a set of equations over $\mathcal{G}$, satisfying the following conditions:

1. All variables in the expression occur in $\mathcal{D}$;
2. No variable in u is an ancestor of ρ_j in $\mathcal{G}(\mathcal{D})$;
3. If, in addition, ρ_j is the root of $\mathcal{G}(\mathcal{D})$, then $u = (B\rho_k)$ for some $B \in V$ and $\rho_k \in \mathcal{V}$, or $u = \varepsilon$.

We invite the reader to check that the expression (without equations) in Example 4.6 satisfies Definition 4.12.

Before formally defining the semantics of a grammatical calculus expression, we show with examples how the grammatical algebra operators can be expressed in the calculus. As in the previous section, we are not concerned with the resulting information base schemes (about which we have not yet said anything with regard to the calculus).

Example 4.13. Reconsider Examples 3.4, 3.7, 3.9, and 3.15.

- The parent substitution $\Sigma\pi[A \to BA, E]$ can be expressed by

$$[\rho_1 \leftarrow (E\rho_2) \mid \{\rho_1 := (A\rho_2), \rho_2 := (B\rho_3)(A\rho_4)\}].$$

- The child substitution $\Sigma\epsilon[E \to BA, A, E]$ can be expressed by

$$[\rho_2 \leftarrow (B\rho_3)(E\rho_4) \mid \{\rho_1 := (E\rho_2), \rho_2 := (B\rho_3)(A\rho_4)\}].$$

- The child equality substitution $\Sigma\epsilon[E \to BE, E \to BE, B, D]$ can be expressed by

$$[\rho_2 \leftarrow (B\rho_3)(D\rho_4) \mid \{\rho_1 := (E\rho_2), \rho_2 := (B\rho_3)(E\rho_4), \rho_4 := (B\rho_5)(E\rho_6), \rho_3 = \rho_5\}].$$

- The node insertion $\text{N}\iota[B \to abEd, aFd]$ can be expressed by

$$[\rho_2 \leftarrow a(F\rho_3)d \mid \{\rho_1 := (B\rho_2), \rho_2 := a\rho_3 d, \rho_3 := b(E\rho_4)\}].$$

- The node deletion $\text{N}\delta[F]$ can be expressed by $[\rho_1 \leftarrow \varepsilon \mid \rho_1 := (F\rho_2)\}]$.
- The downward duplication $\Delta\delta[A \to BaC, B \to bd, C, D]$ can be expressed by

$$[\rho_3 \leftarrow bd(D\rho_4) \mid \{\rho_1 := (A\rho_2), \rho_2 := (B\rho_3)a(C\rho_4), \rho_3 := bd\}].$$

- The permutation $\Pi[B \to bBc, abB]$ can be expressed by

$$[\rho_2 \leftarrow ab(B\rho_3) \mid \{\rho_1 := (B\rho_2), \rho_2 := b(B\rho_3)c\}].$$

Describing the semantics of the grammatical calculus should consist of two parts: explaining what happens with schemes and explaining what happens with instances. Since, as observed earlier in this paper, it is unrealistic to compare information base operations at the scheme level with respect to expressiveness, we shall not elaborate on how calculus expressions work on information base schemes. The example below, however, should nevertheless convince the reader that calculus expressions can be applied to the schemes as well.

Example 4.14. Consider the calculus expression

$$[\rho_2 \leftarrow (D\rho_4) \mid \{\rho_1 := (A\rho_2), \rho_2 := (B\rho_3)(C\rho_4)\}]$$

and let $\mathcal{G} = (V, T, S, P)$ be an information base scheme to which this calculus expression is applied. Let $\mathcal{G}' = (V', T', S', P')$ denote the resulting scheme. Then $V' = V \cup \{D\}$ and $T' = T$ since there are no other attributes or constants in the substitution clause not occurring in one of the declarations. Furthermore, $S' = S$, since the attribute in the term defining the root variable is not altered. Finally, if $A \to BC \in P$, then $P' = P \cup \{A \to D\} \cup \{D \to s \mid C \to s \in P\}$, else $P' = P$.

Note that, for the sake of generality, the application of a calculus expression to an information base scheme can only result in *adding* new productions.

We now formally define the semantics of a grammatical calculus expression at the instance level. Although it is conceptually simple, as should be clear from the examples given thus far, the formalism itself is rather involved. This stems mainly from the fact that, when rearranging subtrees in applying a calculus expression, one must be able to describe how this rearrangement is "propagated" downward into these subtrees.

The evaluation of a calculus expression on a given information base instance can be described in two distinct stages.

1. First, the variables in an expression are "valuated" as rootless subtrees of the considered information base instance, satisfying the declarations and equations in that expression.

2. Then, the D-tree representing the information base instance is transformed according to these valuations and the transformation rule in the left-hand side of the expression.

The first stage is described in Definition 4.15, the second one in Definition 4.18.

DEFINITION 4.15. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $\mathcal{D}$ be a set of declarations and $\mathcal{E}$ a set of equations over $\mathcal{G}$ such that all variables in $\mathcal{E}$ occur in $\mathcal{D}$. Let $f\colon \text{var}(\mathcal{D}) \to \mathbf{rst}(\mathbf{D})$ be a total mapping from variables in $\mathcal{D}$ to rootless subtrees of $\mathbf{D}$. f is called a *valuation* of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$ if

1. for each declaration $\rho_i := \varepsilon$ in $\mathcal{D}$, $f(\rho_i) = \mathbf{F}$;

2. for each declaration $\rho_i := t$ in $\mathcal{D}$ with $t = t_1 \dots t_k$, $t_1, \dots, t_k$ being basic terms, $f(\rho_i) = \mathbf{R}_1 \dots \mathbf{R}_k$ with, for each $j = 1, \dots, k$,

    1. if $t_j = a$ for some $a \in T$, then $\mathbf{R}_j$ is a single-node rootless tree the node of which is labeled a,

    2. if $t_j = \rho_k$ for some $\rho_k \in \mathcal{V}$, then $\mathbf{R}_j = f(\rho_k)$,

    3. if $t_j = (A\rho_k)$ for some $A \in V$ and $\rho_k \in \mathcal{V}$, then there is a node $\mathbf{n}$ in $\mathbf{D}$ with $\text{lbl}(\mathbf{n}) = A$ such that $\mathbf{R}_j = (\mathbf{n} f(\rho_k))$,

3. for each equation $\rho_i = \rho_j$ in $\mathcal{E}$, $f(\rho_i) \cong f(\rho_j)$.

The set of all valuations of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$ is denoted $\mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$.

Example 4.16. Consider the information base instance $\mathbf{D}$ of Fig. 18 (over some appropriate scheme) and let E be the following calculus expression:

$$[\rho_5 \leftarrow (C\rho_7)\rho_8 \mid \{\rho_1 := (A\rho_2),\ \rho_2 := \rho_3 c(A\rho_4),\ \rho_3 := (B\rho_5)\rho_6,\ \rho_4 := \rho_7 c(A\rho_8),$$
$$\rho_5 := (C\rho_9)(D\rho_{10}),\ \rho_7 := (B\rho_{11})\rho_{12},\ \rho_{10} := \varepsilon,\ \rho_{11} := (C\rho_{13})\rho_{14},\ \rho_9 = \rho_{13}\}].$$

There are three valuations of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$. For each such valuation f, the node $\mathbf{n}$ satisfying $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$ has been marked by a square in Fig. 18. We leave it to the reader to check that these markings completely determine the corresponding valuations.

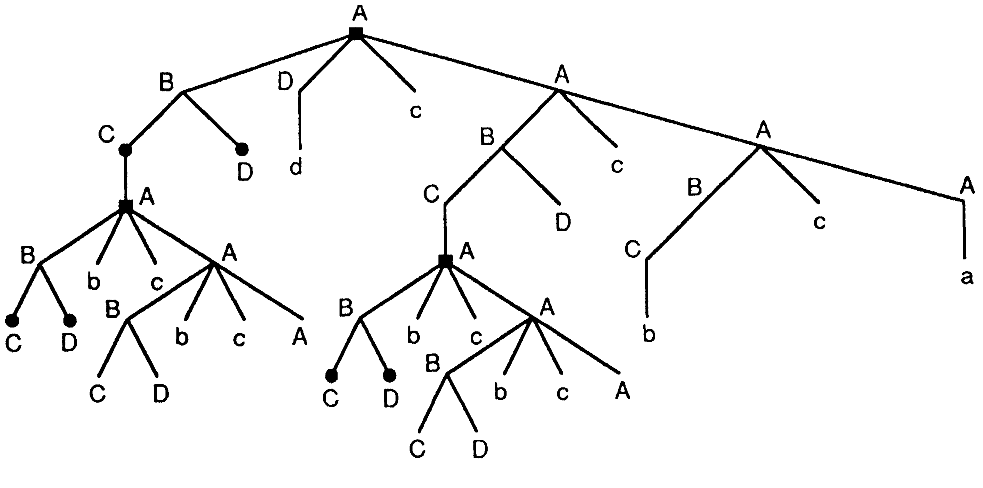

FIG. 18. *An information base instance* $\mathbf{D}$.

For later use, we used dots to mark all nodes in Fig. 18 that occur in $\mathbf{top}(f(\rho_5))$, for each valuation f of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$.

In Example 4.16, it turned out that the valuations under consideration can be completely characterized by indicating to which rootless subtree the root variable of the expression is mapped. Lemma 4.17 says even more: it suffices to specify a rootless subtree of which the valuation of one arbitrary variable is an interval. In particular, Lemma 4.17 ensures that the way in which $f(\rho_5)$ was indicated in Example 4.16 is unambiguous. More generally, it excludes that images of the same variables under different valuations "overlap." This will allow us to define the result of a calculus expression by performing a transformation on the information base instance under consideration for each valuation of its hierarchical set of declarations and set of equations.

LEMMA 4.17. *Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let $\mathcal{D}$ be a hierarchical set of declarations over $\mathcal{G}$, and let $\mathcal{E}$ be a set of equations over $\mathcal{G}$ such that all variables in $\mathcal{E}$ occur in $\mathcal{D}$. Let ρ_i be an arbitrary variable in $\mathcal{D}$, and let $\mathbf{R}$ be a rootless subtree of $\mathbf{D}$. There exists at most one valuation f of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$ such that $f(\rho_i)$ is an interval of $\mathbf{R}$.*

Proof. Suppose there exists a valuation f such that $f(\rho_i)$ is an interval of $\mathbf{R}$. We first show that for some variable $\rho_l \in \operatorname{var}(\mathcal{D})$, $f(\rho_l)$ is unambiguously determined by this condition. If ρ_i is the root of $\mathcal{G}(\mathcal{D})$, we know there exists a declaration in $\mathcal{D}$ of the form $\rho_i := (A\rho_j)$. Since $\mathbf{R}$ contains at most one subtree with a root labeled A, $f(\rho_i)$ is unambiguously determined. Now suppose ρ_i is *not* the root of $\mathcal{G}(\mathcal{D})$. Then there exists a sequence of variables in $\mathcal{D}$, say $\rho_{i_0}, \ldots, \rho_{i_k}$, $k \geq 1$, that satisfy the following conditions:

1. $\rho_{i_0} = \rho_i$;
2. For all $l = 1, \ldots, k-1$ there is a declaration in $\mathcal{D}$ of the form $\rho_{i_l} := \ldots \rho_{i_{l-1}} \ldots$;
3. There is a declaration in $\mathcal{D}$ of the form $\rho_{i_k} := \ldots (A\rho_{i_{k-1}}) \ldots$.

Note that the second condition is voidlessly satisfied if $k = 1$. The last condition can always be satisfied because a similar condition holds for the root of $\mathcal{G}(\mathcal{D})$. Now let $\mathbf{R}'$ be the unique maximal rootless subtree of $\mathbf{D}$ containing $\mathbf{R}$. Then, by condition 2 above, $f(\rho_i)$ being an interval of $\mathbf{R}$ implies that $f(\rho_{i_0}), \ldots, f(\rho_{i_{k-1}})$ are all intervals of $\mathbf{R}'$. Since a declaration of the form $\rho_{i_k} := (A\rho_{i_{k-1}})$ is in $\mathcal{D}$, it now follows that $f(\rho_{i_{k-1}})$ *equals* $\mathbf{R}'$.

Up to now, we have shown there exists some variable ρ_l in $\mathcal{D}$ for which $f(\rho_l)$ is a fully determined rootless subtree of $\mathbf{D}$. Since it is easily shown that whenever f is unambiguously determined for a certain variable it is also unambiguously determined for both the parent and all children of that variable, a straightforward induction shows that f is unambiguously determined for *all* variables in $\mathcal{D}$. □

We now define how an expression transforms D-trees. First, Definition 4.18 introduces so-called E-transformations. Theorem 4.19 then establishes the uniqueness of these E-transformations. Finally, Definition 4.20 points out how the unique E-transformation must be used to define the result of the calculus expression E.

We start with the notion of E-transformation. When rearranging rootless subtrees of a given D-tree in applying a calculus expression, we must be able to describe how the rearrangement is "propagated" downward into these subtrees. Intuitively, the resulting tree will therefore have to be constructed "bottom-up." Thus we cannot just define the effect of a calculus expression on D-trees alone; we need to define the effect on all rootless subtrees as well. The effect of a calculus expression on a rootless subtree is context-sensitive, however. Therefore, we introduce the notion of E-transformation, which defines the effect of a calculus expression E on an R-tree $\mathbf{R}$ in the context of a D-tree $\mathbf{D}$ of which $\mathbf{R}$ is a rootless subtree.

DEFINITION 4.18. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme and let $E \equiv [\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ be an expression over $\mathcal{G}$. A partial mapping $g\colon \mathcal{R}(\mathcal{G}) \times \mathcal{D}(\mathcal{G}) \rightarrow \mathcal{R}(\mathcal{G})/_{\cong}$ is an *E-transformation* of $\mathcal{G}$ if it satisfies the following conditions:[3]

[3] For reasons of convenience, the conditions are formulated as if $g(\mathbf{R}, \mathbf{D})$ were an arbitrary representation of the class under consideration.

1. $g(\mathbf{R}, \mathbf{D})$ is defined if and only if $\mathbf{R} \in \mathbf{rst}(\mathbf{D})$;
2. For all $\mathbf{D} \in \mathcal{D}(\mathcal{G})$, $g(\mathbf{F}, \mathbf{D}) \cong \mathbf{F}$;[4]
3. For some $\mathbf{D} \in \mathcal{D}(\mathcal{G})$, let $(\mathbf{nR}) \in \mathbf{rst}(\mathbf{D})$ be a rootless subtree such that for no valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$, $f(\rho_j) = (\mathbf{nR})$. Then $g((\mathbf{nR}), \mathbf{D}) \cong (\mathbf{n}g(\mathbf{R}, \mathbf{D}))$;
4. For some $\mathbf{D} \in \mathcal{D}(\mathcal{G})$, let $\mathbf{R} \in \mathbf{rst}(\mathbf{D})$ be a rootless subtree such that for no valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$, $f(\rho_j)$ is an interval of $\mathbf{R}$. Then if $\mathbf{R} = \mathbf{R}_1\mathbf{R}_2$, $g(\mathbf{R}, \mathbf{D}) \cong g(\mathbf{R}_1, \mathbf{D})g(\mathbf{R}_2, \mathbf{D})$;
5. For some $\mathbf{D} \in \mathcal{D}(\mathcal{G})$, let $\mathbf{R} \in \mathbf{rst}(\mathbf{D})$ be a rootless subtree such that for some valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$, $f(\rho_j) = \mathbf{R}$. Let $u = u_1 \ldots u_n$ with $u_1, \ldots, u_n$ basic terms. Then $g(\mathbf{R}, \mathbf{D}) \cong \mathbf{R}_1 \ldots \mathbf{R}_n$ with, for $k = 1, \ldots, n$,
    1. if $u_k = a$ for some $a \in T$, then $\mathbf{R}_k$ is a one-node rootless tree labeled a,
    2. if $u_k = \rho_l$ for some $\rho_l \in \mathcal{V}$, then we distinguish two cases:[5]
        1. if ρ_l is of type 1 in $\mathcal{D}$, and $f(\rho_l) = (\mathbf{D}_1, \ldots, \mathbf{D}_m)$, then
$$\mathbf{R}_k \cong g((\mathbf{D}_1), \mathbf{D}_1) \ldots g((\mathbf{D}_m), \mathbf{D}_m),$$
        2. if ρ_l is of type 2 in $\mathcal{D}$, and $\mathbf{n} = \mathbf{par}(f(\rho_l))$, then
$$\mathbf{R}_k \cong g(f(\rho_l), \mathbf{n}f(\rho_l));$$
    3. if $u_k = (A\rho_l)$ for some $A \in V$ and $\rho_l \in \mathcal{V}$, then we distinguish two cases:[6]
        1. if ρ_l is of type 1 in $\mathcal{D}$, and $f(\rho_l) = (\mathbf{D}_1, \ldots, \mathbf{D}_m)$, then $\mathbf{R}_k \cong (\mathbf{n}'\mathbf{R}')$ with $\mathrm{lbl}(\mathbf{n}') = A$ and $\mathbf{R}' \cong g((\mathbf{D}_1), \mathbf{D}_1) \ldots g((\mathbf{D}_m), \mathbf{D}_m)$,
        2. if ρ_l is of type 2 in $\mathcal{D}$, and $\mathbf{n} = \mathbf{par}(f(\rho_l))$, then $\mathbf{R}_k \cong (\mathbf{n}'\mathbf{R}')$ with $\mathrm{lbl}(\mathbf{n}') = A$ and $\mathbf{R}' \cong g(f(\rho_l), \mathbf{n}f(\rho_l))$;
6. For some $\mathbf{D} \in \mathcal{D}(\mathcal{G})$, let $\mathbf{R} = \mathbf{R}_1\mathbf{R}_2\mathbf{R}_3 \in \mathbf{rst}(\mathbf{D})$ be a rootless subtree such that for some valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$, $f(\rho_j) = \mathbf{R}_2$. Then $g(\mathbf{R}, \mathbf{D}) \cong g(\mathbf{R}_1, \mathbf{D})g(\mathbf{R}_2, \mathbf{D})g(\mathbf{R}_3, \mathbf{D})$.

We now establish the uniqueness of E-transformations.

THEOREM 4.19. *Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme and let $E \equiv [\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ be an expression over $\mathcal{G}$. Then there exists a unique E-transformation of $\mathcal{G}$.*

Proof. The proof goes by double induction. For the empty D-tree $\mathbf{E}$, we know that $g(\mathbf{F},\mathbf{E}) = \mathbf{F}$. We now assume that g is uniquely defined on all pairs $(\mathbf{R}, \mathbf{D})$ with $\mathbf{R}$ being a rootless subtree of $\mathbf{D}$ and the depth of $\mathbf{D}$ at most, say p (outer induction hypothesis). Now let $\mathbf{D}$ be a D-tree over $\mathcal{G}$ with depth $p + 1$. We know that $g(\mathbf{F}, \mathbf{D}) = \mathbf{F}$. We now also assume that g is uniquely defined on all pairs $(\mathbf{R}, \mathbf{D})$ with $\mathbf{R}$ being a rootless subtree of $\mathbf{D}$ and the depth[7] of $\mathbf{R}$ at most, say q (inner induction hypothesis). Now let $\mathbf{R}$ be a rootless subtree of $\mathbf{D}$ with depth $q + 1$. We distinguish two cases.

Case 1. *There is no valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$ for which $f(\rho_j)$ is an interval of* $\mathbf{R}$. Let $\mathbf{R} = (\mathbf{D}_1, \ldots, \mathbf{D}_n)$ with, for $i = 1, \ldots, n$, $\mathbf{D}_i = \mathbf{n}_i\mathbf{R}_i$ for some $\mathbf{R}_i \in \mathbf{rst}(\mathbf{D})$ with the depth of $\mathbf{R}_i$ at most q. Items 2, 3, and 4 of Definition 4.18 and the inner induction hypothesis guarantee that $g(\mathbf{R}, \mathbf{D})$ is uniquely defined.

Case 2. *For some valuation $f \in \mathcal{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{D})$, $f(\rho_j)$ is an interval of* $\mathbf{R}$. By Lemma 4.17, we know this f is unique. Let $\mathbf{R} = \mathbf{R}_1\mathbf{R}_2\mathbf{R}_3$ with $\mathbf{R}_2 = f(\rho_j)$. By item 6 of Definition 4.18, $g(\mathbf{R}, \mathbf{D}) \cong g(\mathbf{R}_1, \mathbf{D})g(\mathbf{R}_2, \mathbf{D})g(\mathbf{R}_3, \mathbf{D})$. By the first case of this proof, $g(\mathbf{R}_1, \mathbf{D})$ and $g(\mathbf{R}_3, \mathbf{D})$ are uniquely determined. Let $u = u_1 \ldots u_n$ with $u_1, \ldots, u_n$ basic terms. By item 5 of

[4] Recall from Definition 4.2 that $\mathbf{F}$ is the empty R-tree.

[5] The reason for this distinction is the following. If a variable is part of a basic term of type 2, then we are interested in the entire tree this basic term represents, as opposed to merely the R-tree the variable represents.

[6] See footnote 5.

[7] The depth of $\mathbf{F}$ is 0; the depth of another R-tree is defined as the maximum of the depths of the D-trees of which it is composed.

Definition 4.18, we know that $g(\mathbf{R}_2, \mathbf{D}) \cong \mathbf{R}_{21} \dots \mathbf{R}_{2n}$ for some R-trees $\mathbf{R}_{21}, \dots, \mathbf{R}_{2n}$. It remains to show that, for $k = 1, \dots, n$, $\mathbf{R}_{2k}$ is uniquely determined. To do this we distinguish five subcases.

Subcase 1. *$u_k = a$ with $a \in T$.* By item 5.1 of Definition 4.18, $\mathbf{R}_{2k}$ is unambiguously determined.

Subcase 2. *$u_k = \rho_l$ with ρ_l a type* 1 *variable in $\mathcal{D}$.* Let $f(\rho_l) = (\mathbf{D}_1, \dots, \mathbf{D}_m)$. By item 5.2.1 of Definition 4.18, we know that $\mathbf{R}_{2k} \cong g((\mathbf{D}_1), \mathbf{D}_1) \dots g((\mathbf{D}_m), \mathbf{D}_m)$. Since, by Definition 4.12, the depth of ρ_l in $\mathcal{G}(\mathcal{D})$ is at least 1, it follows that, for all $j = 1, \dots, m$, the depth of $\mathbf{D}_j$ is at most p. Hence the desired conclusion follows from the outer induction hypothesis.

Subcase 3. *$u_k = \rho_l$ with ρ_l a type* 2 *variable in $\mathcal{D}$.* Let $\mathbf{n} = \mathbf{par}(f(\rho_l))$. By item 5.2.2 of Definition 4.18, we know that $\mathbf{R}_{2k} \cong g(f(\rho_l), \mathbf{n}f(\rho_l))$. If $\mathbf{n}$ is *not* the root of $\mathbf{D}$, then the depth of $\mathbf{n}f(\rho_l)$ is at most p. Hence the desired conclusion follows from the outer induction hypothesis. However, if $\mathbf{n} = \mathbf{rt}(\mathbf{D})$, then $\mathbf{D} = \mathbf{n}f(\rho_l)$, whence the depth of $f(\rho_l)$ is at most p. Moreover, by Definition 4.12, it follows that $f(\rho_j) = (\mathbf{D}) = \mathbf{R}_2 = \mathbf{R}$, whence $n = k = 1$ and $p = q$. So, $f(\rho_l)$ has also depth at most q. The uniqueness of $\mathbf{R}_{2k} = \mathbf{R}_{21}$ now follows from the inner induction hypothesis.

Subcase 4. *$u_k = (A\rho_l)$ with $A \in V$ and ρ_l a type* 1 *variable in $\mathcal{D}$.* Let $f(\rho_l) = (\mathbf{D}_1, \dots, \mathbf{D}_m)$. By item 5.3.1 of Definition 4.18, we know that $\mathbf{R}_{2k} \cong (\mathbf{n}'\mathbf{R}')$ with $\mathrm{lbl}(\mathbf{n}') = A$ and $\mathbf{R}' \cong g((\mathbf{D}_1), \mathbf{D}_1) \dots g((\mathbf{D}_m), \mathbf{D}_m)$. The remainder of this case is now analogous to subcase 2.

Subcase 5. *$u_k = (A\rho_l)$ with $A \in V$ and ρ_l a type* 2 *variable in $\mathcal{D}$.* Let $\mathbf{n} = \mathbf{par}(f(\rho_l))$. By item 5.3.2 of Definition 4.18, we know that $\mathbf{R}_{2k} \cong (\mathbf{n}'\mathbf{R}')$ with $\mathrm{lbl}(\mathbf{n}') = A$ and $\mathbf{R}' \cong g(f(\rho_l), \mathbf{n}f(\rho_l))$. The remainder of this case is now analogous to subcase 3. □

Using the unique transformation defined above, we finally define the result of a calculus expression.

DEFINITION 4.20. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme and let $\mathbf{D}$ be an information base instance over $\mathcal{G}$. Let E be an expression over $\mathcal{G}$. Let g be the unique E-transformation of $\mathcal{G}$. Then $E(\mathbf{D})$ is (the class of) the D-tree $\mathbf{D}'$ for which $g((\mathbf{D}), \mathbf{D}) \cong (\mathbf{D}')$, if this D-tree is in turn an information base instance, and undefined otherwise.

We conclude this section with a final example.

Example 4.21. Reconsider the information base instance $\mathbf{D}$ and the calculus expression E of Example 4.16. Recall that in Fig. 18, for each valuation f, the (unique) node in $\mathbf{top}(f(\rho_1))$ is marked by a square and all nodes in $\mathbf{top}(f(\rho_5))$ are marked by dots (ρ_1 is the root of the expression and ρ_5 is the left-hand side of the substitution clause). The reader is invited to check that the result $E(\mathbf{D})$ of applying the calculus expression E to the information base instance $\mathbf{D}$ indeed equals the instance of Fig. 19.

5. Properties of the grammatical calculus. The definition of the grammatical calculus given in the previous section raises several decidability issues. Since a full treatment of these decidability issues would go beyond the scope of the present article, we shall deal with these here only briefly, in a fairly informal manner.

The key construct of this section is that of a *condition tree* of a calculus expression, or more precisely, of the set of hierarchical declarations and equations of a calculus expression. We first define this notion for the case in which no equations are present.

DEFINITION 5.1. Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $\mathcal{D}$ be a hierarchical set of declarations.

- The condition tree $\mathbf{C}(\mathcal{D})$ of $\mathcal{D}$ is constructed as follows. First, initialize $\mathbf{C}(\mathcal{D})$ to a tree consisting of one node labeled with the root of $\mathcal{G}(\mathcal{D})$. Then, as long as there is a node $\mathbf{n}$ in $\mathbf{C}(\mathcal{D})$ labeled with a variable ρ_i that is not a leaf in $\mathcal{G}(\mathcal{D})$, i.e., for which there exists some

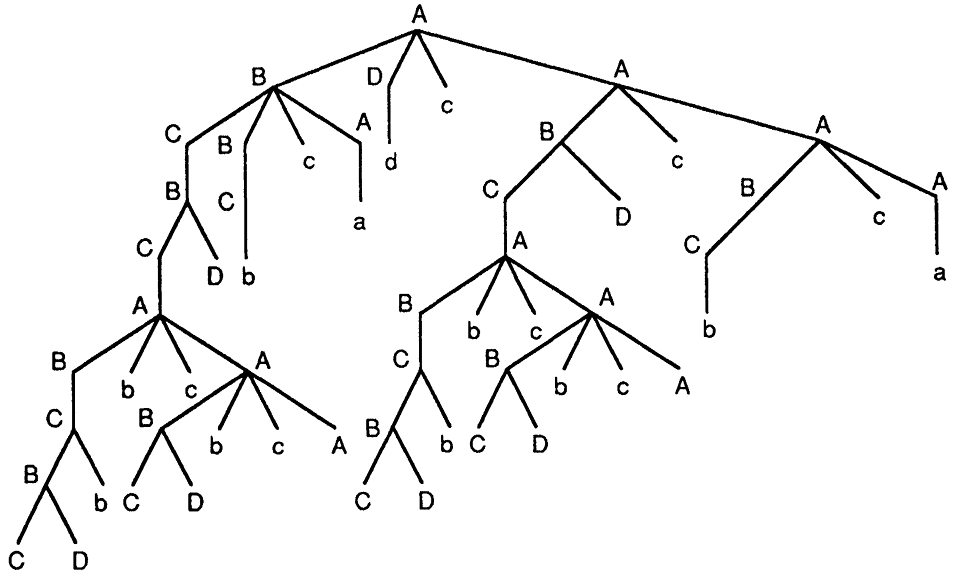

FIG. 19. *The information base instance $E(\mathbf{D})$.*

hierarchical declaration $\rho_i := t_1 \ldots t_m$ in $\mathcal{D}$, substitute $\mathbf{n}$ by the rootless subtree $(\mathbf{C}_1, \ldots, \mathbf{C}_m)$ where, for $k = 1, \ldots, m$,

1. if $t_k = a$ with $a \in T$, $\mathbf{C}_k$ consists of one node which is labeled a;

2. if $t_k = \rho_l$ with ρ_l a type 1 variable in $\mathcal{D}$, $\mathbf{C}_k$ consists of one node which is labeled ρ_l;

3. if $t_k = (A\rho_l)$ with $A \in V$ and ρ_l a type 2 variable in $\mathcal{D}$, $\mathbf{C}_k$ is a two-node tree the root of which is labeled A and the leaf of which is labeled ρ_l.

- Let $E \equiv [\rho_j \leftarrow u \mid \mathcal{D}]$ be an expression over $\mathcal{G}$ without equations. Then $\mathbf{C}(E) = \mathbf{C}(\mathcal{D})$.

Notice that $\mathbf{C}(\mathcal{D})$ in Definition 5.1 above is indeed a tree since the right-hand side of the declaration for the root in $\mathcal{D}$ consists of only one basic term, which is of type 2.

Example 5.2. Let $\mathcal{D}$ be the set of hierarchical declarations in Example 4.16. The condition tree $\mathbf{C}(\mathcal{D})$ of $\mathcal{D}$ is shown in Fig. 20.

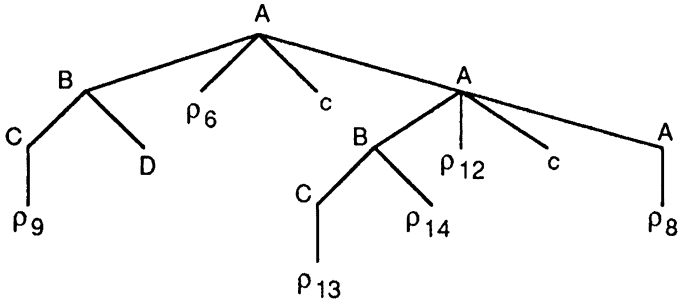

FIG. 20. *The condition tree $\mathbf{C}(\mathcal{D})$.*

Intuitively, the condition tree of an expression shows the pattern that must be present in an information base instance for the expression to have an action on that instance.

The notion of condition tree can be extended to the case in which both hierarchical declarations and equations are present. We shall informally explain how. Thereto, suppose that in addition to the assumptions of Definition 5.1 we have a set of equations $\mathcal{E}$ over $\mathcal{G}$.

If the equations only involve variables that are leaves in $\mathbf{C}(\mathcal{D})$ and hence also in $\mathcal{G}(\mathcal{D})$, then the condition tree $\mathbf{C}(\mathcal{D} \cup \mathcal{E})$ of $\mathcal{D}$ and $\mathcal{E}$ is straightforwardly constructed from $\mathbf{C}(\mathcal{D})$ by equating labels according to the equations in $\mathcal{E}$. For instance, if E is the expression in Example 4.16, then $\mathbf{C}(E)$[8] is obtained from the condition tree in Example 5.2, Fig. 20, by equating ρ_9 and ρ_{13}.

In the perhaps more pathological case in which variables are equated that are not necessarily leaves of $\mathbf{C}(\mathcal{D})$, the construction is somewhat more involved. To illustrate this, let $\mathcal{D}$ be the hierarchical set of declarations in the expression of Example 4.16 and consider the equation $\rho_5 = \rho_{11}$. The rootless subtrees corresponding to ρ_5 and ρ_{11} in $\mathbf{C}(\mathcal{D})$ in Example 4.16 are shown in Fig. 21 left and right, respectively.

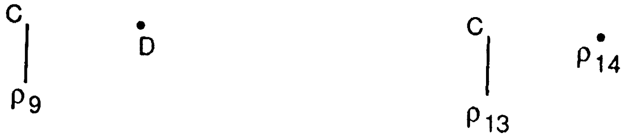

FIG. 21. *The rootless subtrees corresponding to ρ_5 and ρ_{11}.*

We can now try to expand in both rootless subtrees the nodes corresponding to variables in a minimal way such that the R-trees become isomorphic. In our example, this can be achieved by substituting ρ_{14} by D and equating ρ_9 and ρ_{13}. The R-tree thus obtained is actually the most general unifier of ρ_5 and ρ_{11}. Finally, the condition tree $\mathbf{C}(\mathcal{D} \cup \{\rho_5 = \rho_{11}\})$ of $\mathcal{D}$ and $\{\rho_5 = \rho_{11}\}$ is obtained by substituting ρ_5 and ρ_{11} by their most general unifier.

Of course this most general unifier need not exist, e.g., because the two rootless subtrees involved are incompatible. Also, the unification process might result in an infinite tree. The latter case would occur if we tried to compute $\mathbf{C}(\mathcal{D} \cup \{\rho_2 = \rho_4\})$. During the unification process we would find that ρ_8 must be equated to an R-tree strictly containing ρ_8 as a rootless subtree, whence the resulting tree would be infinite. Finally, it is possible that the resulting tree is not a *legal* D-*tree* in the sense that it contains sibling nodes labeled by the same attribute, whence the tree cannot be considered as an information base instance over some scheme.

Each time the construction of a condition tree requires an impossible unification process or a unification process resulting in an infinite tree, or does not result in a legal D-tree, we say that that the condition tree is *undefined.* Obviously, this property is decidable. The undefinedness of a condition tree corresponds to the fact that any associated expression is not applicable to any information base instance.

Several decidability results regarding the grammatical calculus can be proved by using condition trees. The techniques employed in these proofs in essence come down to applying expressions to their own condition tree and are therefore reminiscent of similar techniques used in the relational model for conjunctive queries [6], [21].

The first decidability result is concerned with checking whether or not a calculus expression represents the identity.

LEMMA 5.3. *Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, and let $E \equiv [\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ be an expression over $\mathcal{G}$. Then E represents the identity if and only if either the condition tree of E is undefined or $E(\mathbf{C}(E)) \cong \mathbf{C}(E)$.*

Proof. Obviously, if E represents the identity and the condition tree of E is defined, then $E(\mathbf{C}(E)) \cong \mathbf{C}(E)$, whence the "only if." To see the "if," we need to distinguish two cases. If

[8] If $E \equiv [\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ is an arbitrary expression over $\mathcal{G}$, then $\mathbf{C}(E) = \mathbf{C}(\mathcal{D} \cup \mathcal{E})$.

the condition tree of E is undefined, then E obviously represents the identity, since it is not applicable to any information base instance. Thus suppose the condition tree of E does exist and satisfies $E(\mathbf{C}(E)) \cong \mathbf{C}(E)$. Let f be the valuation[9] of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{C}(E)$. If f is extended to terms in the natural way, then $E(\mathbf{C}(E)) \cong \mathbf{C}(E)$ is equivalent to $f(\rho_j) \cong f(u)$. Using this latter condition, the proof can be completed by a straightforward double induction, as in the proof of Theorem 4.19. □

Using Lemma 5.3, we can prove the following necessary condition for two expressions to be equivalent.

THEOREM 5.4. *Let $\mathcal{G} = (V, T, S, P)$ be an information base scheme. Two expressions over $\mathcal{G}$ are equivalent only if either they both represent the identity or their condition trees are isomorphic upon renaming of variables.*

Proof. Let $E_1 \equiv [\rho_j^1 \leftarrow u_1 \mid \mathcal{D}_1 \cup \mathcal{E}_1]$ and $E_2 \equiv [\rho_j^2 \leftarrow u_2 \mid \mathcal{D}_2 \cup \mathcal{E}_2]$ be two equivalent expressions that do not represent the identity. By Lemma 5.3, the condition trees of E_1 and E_2 exist and satisfy $E_1(\mathbf{C}(E_2)) \not\cong \mathbf{C}(E_1)$ and $E_2(\mathbf{C}(E_2)) \not\cong \mathbf{C}(E_2)$. Hence, by the equivalence of E_1 and E_2, $E_2(\mathbf{C}(E_1)) \not\cong \mathbf{C}(E_1)$ and $E_1(\mathbf{C}(E_2)) \not\cong \mathbf{C}(E_2)$. In particular, this implies there must exist a valuation of $\mathcal{C}_1$ and $\mathcal{D}_1$ in $\mathbf{C}(E_2)$ as well as a valuation of $\mathcal{C}_2$ and $\mathcal{D}_2$ in $\mathbf{C}(E_1)$. Using this fact, the theorem is now easily shown. □

Given Theorem 5.4, it is now tempting to conjecture that two grammatical calculus expressions that do not represent the identity are equivalent if and only if they yield the same result when applied to their common condition tree. Unfortunately, this condition is not sufficient because of the special way in which type 2 variables in a substitution term are handled in the calculus. Example 5.5 gives a counterexample.

Example 5.5. Let $\mathcal{D} \cup \mathcal{E}$ be the following set of hierarchical declarations and equations (over some appropriate scheme):

$$\{\rho_1 := (A\rho_2),\ \rho_2 := (B\rho_3)(A\rho_4)(C\rho_5),\ \rho_3 := (A\rho_6),\ \rho_6 := \rho_7 b,\ \rho_4 = \rho_7\}.$$

The condition tree of $\mathcal{D}$ and $\mathcal{E}$ is shown in Fig. 22.

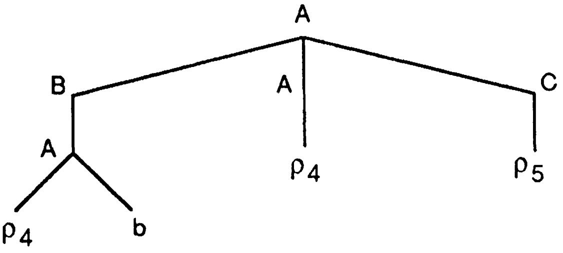

FIG. 22. *The condition tree* $\mathbf{C}(\mathcal{D} \cup \mathcal{E})$.

Now consider the expressions

$$E_1 \equiv [\rho_5 \leftarrow \rho_4 \mid \mathcal{D} \cup \mathcal{E}];$$
$$E_2 \equiv [\rho_5 \leftarrow \rho_7 \mid \mathcal{D} \cup \mathcal{E}].$$

Notice that ρ_4 is of type 2 while ρ_7 is of type 1.

Obviously, $E_1(\mathbf{C}(\mathcal{D}\cup\mathcal{E})) \cong E_2(\mathbf{C}(\mathcal{D}\cup\mathcal{E}))$, because these resulting trees are both obtained by substituting ρ_5 by ρ_4 in the tree of Fig. 22. Nevertheless, E_1 and E_2 are *not* equivalent. To see this, we replace the nodes in Fig. 22 that are labeled ρ_4 with the rootless subtree obtained

[9] By the definition of condition tree, there is a unique valuation $f \in \mathrm{F}(\mathcal{D} \cup \mathcal{E}, \mathbf{C}(E))$ determined by $f(\rho_{\mathrm{root}}) = (\mathbf{C}(E))$, ρ_{root} being the root of $\mathrm{G}(\mathcal{D})$.

by chopping off the root from a copy of the condition tree. The result of this modification is shown in Figure 23.

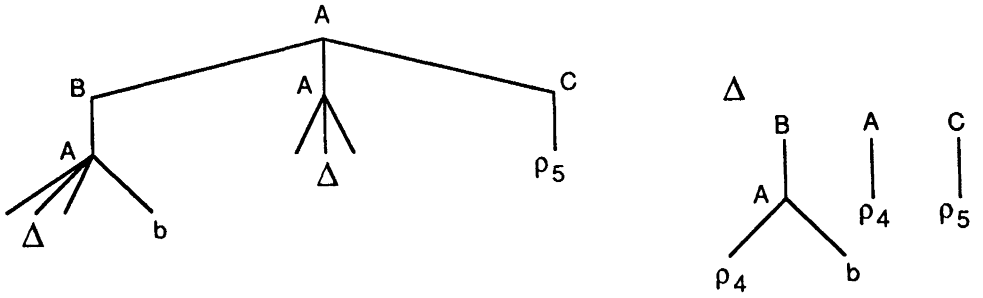

FIG. 23. *The modified condition tree.*

The purpose of this modification was substituting the tree rooted in the parent of ρ_4 by its most general unifier with a copy of the entire condition tree.

Applying expression E_2 to the tree in Fig. 23 results in the straightforward substitution of ρ_5 by the rootless subtree identified by Δ, as shown in Fig. 24 bottom.

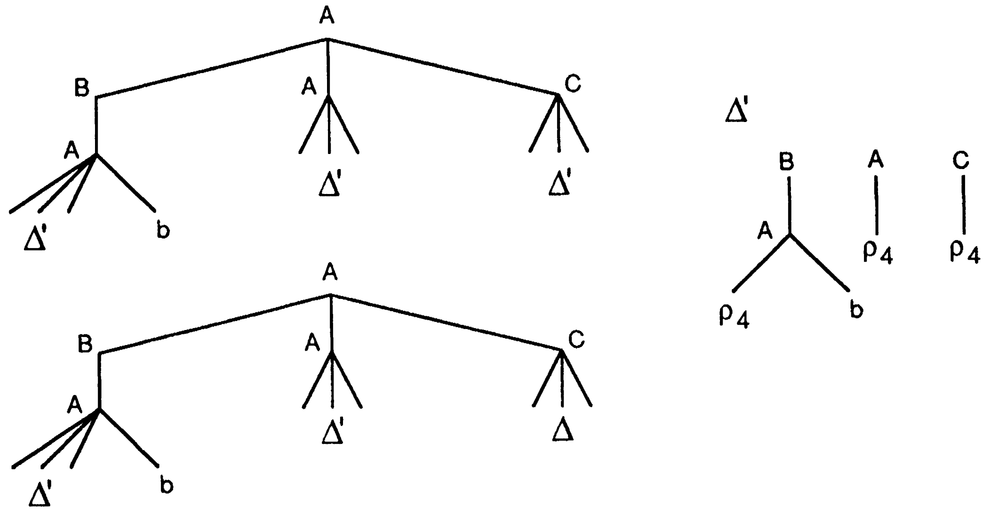

FIG. 24. *The results of applying* E_1 (top), *respectively,* E_2 (bottom), *to the tree of Fig.* 23.

In contrast, the application of E_1 results in the substitution of ρ_5 by Δ' where Δ' is obtained from Δ by applying E_1 to the tree rooted in the parent of ρ_4. This asymmetry is due to the fact that ρ_4 is of type 2, while ρ_7 is of type 1. The result of applying E_1 to the tree in Fig. 23 is shown in Fig. 24 top.

In general, given an expression and its condition tree, one has two choices for each type 2 variable in the substitution tree: one can either leave the corresponding node or rootless subtree in the condition tree unchanged, or one can transform it in the sense of Example 5.5. This procedure leads to a number of trees that is potentially exponential in the number of type 2 variables in the substitution term.[10] To facilitate our further discussion, we shall

[10] In most cases, however, the number of trees obtained will be significantly smaller because the transformation described in Example 5.5 requires a unification whose result may well be undefined.

call the set of legal D-trees thus obtained the *set of representative instances* of the given expression.

Intuitively, the set of representative instances of a calculus expression is constructed in such a way that for every possible valuation of the expression's set of declarations and equations in a concrete information base instance, there is a representative instance whose transformation by the expression "models" the way in which the information base instance is transformed locally.

Therefore, we conjecture that equivalence of nonidentity expressions can be decided by considering all trees in their sets of representative instances and verifying whether both expressions yield the same results for all those trees.

Finally, the set of representative instances can also be used to decide whether or not the result of a calculus expression is always defined, independent of the information base instance to which the expression is applied. Now, the result of a calculus expression applied to a concrete information base instance can only be undefined if the resulting tree is no longer an instance, i.e., if this tree contains sibling nodes labeled with the same attribute in V. By what has been said above, it suffices to apply the calculus expression to all representative instances to verify whether or not undefinedness can occur. Thereto, one has to check whether or not

1. one of the resulting trees contains sibling nodes labeled by the same attribute;
2. in one of the resulting trees it is possible to substitute a variable by a sibling attribute.

The latter case occurs precisely when a variable in a resulting instance has a sibling attribute that is not a sibling to that variable in the original representative instance. Hence we have the following theorem.

THEOREM 5.6. *It is decidable whether or not the result of a calculus expression over a given information base scheme is always defined.*

6. The equivalence between algebra and calculus. In §3, we presented the grammatical algebra as a query language for transforming information bases. In §§4 and 5, we introduced and discussed grammatical calculus expressions. We can now consider the grammatical calculus as the language consisting of all finite sequences of calculus expressions. Note that, in contrast to the relational calculus, we cannot hope such a sequence will always be equivalent to a single expression, since in general there is no way to combine the various condition trees of the expressions in the sequence into one single condition tree that could be used to describe the net effect of the transformation. Since each grammatical algebra operation can be expressed by a single calculus expression, the grammatical calculus will nevertheless allow a more succinct representation of queries than the algebra.

In this section, we compare the expressive power of the grammatical algebra and calculus. Inspired by the classical result in the relational model, we were able to prove their equivalence. In view of the technical complexity of this proof, we use Example 4.16 as running example throughout the proof in order to improve its readability.

THEOREM 6.1. *The grammatical algebra and grammatical calculus are equivalent with regard to expressive power.*

Proof. In Example 4.13, applications of all algebra operators (except for upward duplication, which is analogous to downward duplication) are expressed in the calculus. It is straightforward to generalize the techniques used in these examples. Hence the algebra can be simulated in the calculus. The more involved part of the proof consists of showing that a calculus expression can be simulated in the algebra. In order to show this, we shall simulate in the algebra the various steps needed to evaluate a calculus expression of which, without loss of generality, we assume it does not represent the identity. (This assumption is needed to guarantee, by Lemma 5.3, the existence of the expression's condition tree, which in turn is needed to validate some of the constructions made below.)

Therefore, let $\mathcal{G} = (V, T, S, P)$ be an information base scheme, let $\mathbf{D}$ be an instance over $\mathcal{G}$, and let $[\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$ be a calculus expression with $\mathrm{var}(\mathcal{D}) = \{\rho_1, \ldots, \rho_n\}$ and $\mathcal{D} = \{\rho_i := t_i \mid i \in I\}, I \subseteq \{1, \ldots, n\}$. Without loss of generality, we assume that ρ_k being an ancestor of ρ_l in $\mathcal{G}(\mathcal{D})$ implies $k < l$. (Observe that Example 4.16 satisfies this requirement.) We further assume that ρ_1 is the root of $\mathcal{G}(\mathcal{D})$ and that the unique declaration for ρ_1 in $\mathcal{D}$ has the form $\rho_1 = (A\rho_2)$.

We also number the equations starting from $n+1$: $\mathcal{E} = \{e_{n+1}, \ldots, e_{n+l}\}$. Since, obviously, a nontrivial equation involving ρ_1 can never be satisfied, we may assume, again without loss of generality, that ρ_1 is not contained in an equation of $\mathcal{E}$.

Let J be an arbitrary set of nonnegative integers. For each $B \in V$, we assume that B^J denotes an attribute; similarly, for each $a \in T$, we assume that a^J denotes a constant. We also assume that N_i, $i = 1, 2, 3, \ldots$, are attributes not in V. Finally, we also assume that N_i^J denotes an attribute. Informally speaking, the superscripts of the labels will be used to remember which variables can be valuated into which rootless subtrees. The N_i^J are auxiliary attributes which will be used for copying information in $\mathbf{D}$ from one place to another in the tree.

The proof is basically a construction that consists of the following steps:

Step 1. *Initialization.* We index all node labels in $\mathbf{D}$ with the empty set. This is done by using parent substitution (for the attribute nodes) and permutation (for the constant nodes).

Step 2. *Determination of all valuations of $\mathcal{D}$ in* $\mathbf{D}$. We shall relabel by $A^{\{1\}}$ all nodes $\mathbf{n}$ for which there exists a valuation[11] f of $\mathcal{D}$ in $\mathbf{D}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$. (Remember that A is the attribute in the declaration for the root ρ_1 of $\mathcal{G}(\mathcal{D})$.) Therefore, we do the following steps:

Substep 1. *Transforming $\mathcal{D}$.* From $\mathcal{D}$ we construct $\mathcal{D}'$ as follows. $\mathcal{D}'$ contains $\rho_1 := (A\rho_2)$ as well as one declaration for each type 2 variable. The right-hand side of this declaration contains only type 2 variables and type 1 variables that are leaves in $\mathcal{G}(\mathcal{D})$. These right-hand sides are obtained from the original right-hand sides in $\mathcal{D}$ by subsequent substitutions. For example, if $\mathcal{D}$ is the set of declarations in Example 4.16, then

$$\mathcal{D}' = \{\rho_1 := (A\rho_2),\ \rho_2 := (B\rho_5)\rho_6 c(A\rho_4),\ \rho_4 := (B\rho_{11})\rho_{12} c(A\rho_8),$$
$$\rho_5 := (C\rho_9)(D\rho_{10}),\ \rho_{10} := \varepsilon,\ \rho_{11} := (C\rho_{13})\rho_{14}\}.$$

Note that $\mathcal{D}'$ actually describes the structure of the condition tree $\mathbf{C}(\mathcal{D})$ (see Definition 5.1).[12] Obviously, the restriction to $\mathrm{var}(\mathcal{D}')$ of a valuation of $\mathcal{D}$ in $\mathbf{D}$ is a valuation of $\mathcal{D}'$ in $\mathbf{D}$; conversely, each valuation of $\mathcal{D}'$ in $\mathbf{D}$ can be extended to a valuation of $\mathcal{D}$ in $\mathbf{D}$.

Substep 2. *Indicating all rootless subtrees in* $\mathbf{D}$ *to which type* 2 *leaf nodes in $\mathcal{G}(\mathcal{D})$ can be mapped.* We shall indicate these rootless subtrees by adding to the superscripts of the labels of their parent nodes the indices of the corresponding variables. Thereto, we perform, in any order, the following operation for each type 2 leaf node ρ_i in $\mathcal{G}(\mathcal{D}')$, until no further action is possible. If there is no declaration $\rho_i := \varepsilon$ in $\mathcal{D}'$, we do $\Sigma\pi[B^J \to s, B^{J\cup\{i\}}]$ for each $B^J \to s$ with $i \notin J$ and either $B^J \to s$ a production in the current scheme or B^J an attribute in the current scheme and $s = \varepsilon$; if $\rho_i := \varepsilon$ is in $\mathcal{D}'$, we only do $\Sigma\pi[B^J \to \varepsilon, B^{J\cup\{i\}}]$.

In our example, ρ_{10} is the only type 2 leaf node in $\mathcal{G}(\mathcal{D})$ that has a declaration with an empty right-hand side. Consequently, an index 10 must be added to the D-labels of leaf nodes in the current instance: there are six such nodes. The other type 2 leaf nodes of $\mathcal{G}(\mathcal{D})$ are ρ_8, ρ_9 and ρ_{13}. Consequently, an index 8 must be added to all A-labels and indices 9 and 13 to all C-labels of nodes in the current instance. The result of these operations is shown in Fig. 25.

[11] For the time being, we ignore the equations in $\mathcal{E}$.

[12] Since by assumption the condition tree $\mathbf{C}(\mathcal{D})$ exists, it follows that the substitutions performed cannot yield illegal terms, i.e., terms containing two basic terms of type 2 with the same attribute.

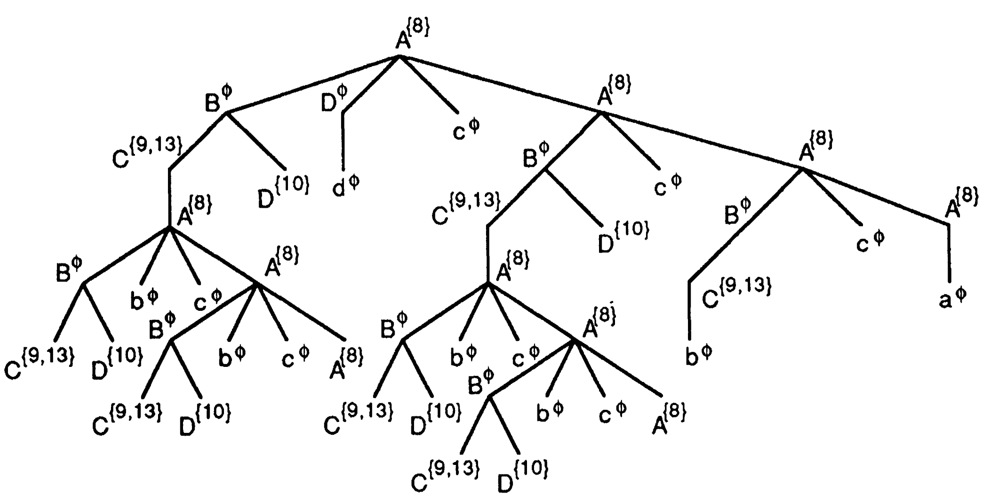

FIG. 25. *The result of marking all rootless subtrees in* **D** *to which type 2 leaf nodes in* $\mathcal{G}(\mathcal{D})$ *can be mapped.*

Substep 3. *Iteratively building up all valuations of* $\mathcal{D}$ *in* **D**. Let $\rho_{i_1}, \ldots, \rho_{i_m}$ be (in ascending order) all type 2 variables in $\mathcal{D}'$. Let, for $1 \le p \le m$, $\mathcal{D}'_p$ be the set of all declarations of $\mathcal{D}'$ involving only variables whose index is at least i_p. We will relabel the nodes in the current instance in such a way that, for each $p = 1, \ldots, m$,

the superscript of the label of a node **n** *contains the index* i_p *if and only if there exists a valuation* f *of* $\mathcal{D}'_p$ *in* **D** *with* $\mathbf{par}(f(\rho_{i_p})) = \mathbf{n}$ (condition (p)).

Note that, by the construction in the previous step, the current instance already satisfies all conditions (p) for which ρ_{i_p} is a leaf node in $\mathcal{G}(\mathcal{D}')$. By a downward iterative procedure, we now enforce the conditions (p) for which ρ_{i_p} is *not* a leaf node in $\mathcal{G}(\mathcal{D}')$. Thereto, we perform the following operation for those $p := m$ down to 1 for which ρ_{i_p} is an internal node of $\mathcal{G}(\mathcal{D}')$. Let $\rho_{i_p} := t_1 \ldots t_l$ be the declaration for ρ_{i_p} in $\mathcal{D}'$ with the t_q, $q = 1, \ldots, l$, basic terms. Let $\rho_k := \ldots (B\rho_{i_p}) \ldots$ be the declaration in $\mathcal{D}'$ containing ρ_{i_p} in its right-hand side. Then, in any order and until no further action is possible, we do $\Sigma\pi[B^J \to s_1 \ldots s_l,\ B^{J \cup \{i_p\}}]$ for each production $B^J \to s_1 \ldots s_l$ in the current scheme in which $i_p \notin J$ and, for $q = 1, \ldots, l$, the s_q have the following form:

$$s_q = \begin{cases} a^{\emptyset} & \text{if } t_q = a,\, a \in T; \\ C^K & \text{if } t_q = (C\rho_r),\, C \in V,\, \rho_r \in \operatorname{var}(\mathcal{D}'), \text{ and } r \in K \end{cases}$$

(s_q is arbitrary if t_q is of type 1).

The current instance for our example is now as shown in Fig. 26.

Observe that, by necessity, $i_1 = 2$. Hence the superscript of the label of a node **n** contains the index 2 if and only if there exists a valuation f of $\mathcal{D}' - \{\rho_1 \leftarrow (A\rho_2)\}$ in **D** with $\mathbf{par}(f(\rho_2)) = \mathbf{n}$.

Substep 4. *Indicating all rootless subtrees of* **D** *to which* ρ_1 *can be mapped by a valuation of* $\mathcal{D}$. We will add an index 1 to the superscript of the label of all nodes **n** for which there exists a valuation f of $\mathcal{D}$ in **D** with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$, or, equivalently, for which there exists a valuation f of $\mathcal{D}'$ in **D** with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$. Now, a valuation f of $\mathcal{D}' - \{\rho_1 \leftarrow (A\rho_2)\}$ can be extended to a valuation of $\mathcal{D}$ in **D** if and only if $\mathbf{par}(f(\rho_2))$ is labeled A. Therefore, in any order and until no further action is possible, we have to perform $\Sigma\pi[A^J \to s,\ A^{J \cup \{1\}}]$ for each $A^J \to s$ with $2 \in J$, $1 \notin J$, and either $A^J \to s$ a production in the current scheme or A^J an attribute in the current scheme and $s = \varepsilon$.

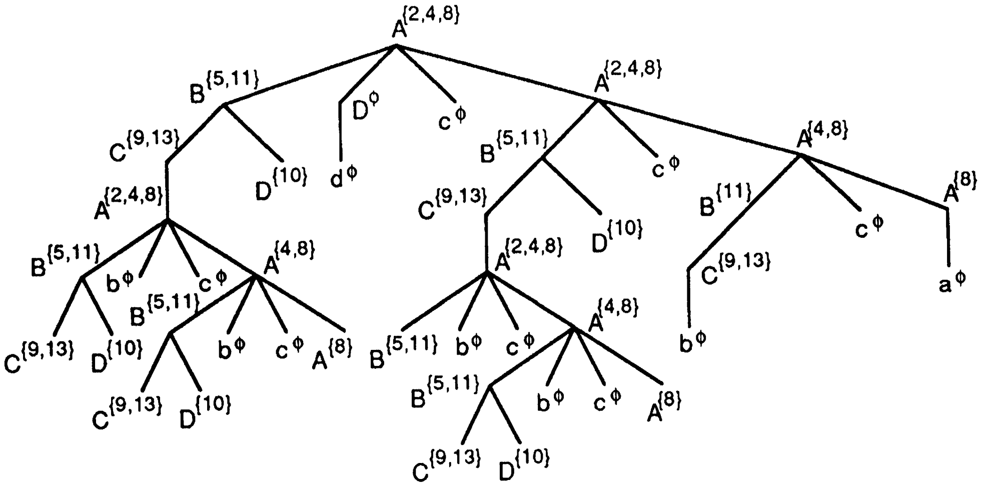

FIG. 26. *Recursively building up all valuations of $\mathcal{D}$ in* **D**.

Substep 5. *Cleaning up.* Using parent substitution, we rename all node labels A^J with $1 \in J$ to $A^{\{1\}}$ and all other node labels B^J with $B \in V$ and $1 \notin J$ to $B^{\emptyset}$.

All nodes **n** labeled A for which there exist a valuation f of $\mathcal{D}$ in **D** with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$ are now indexed by $\{1\}$; all other nodes are indexed by the empty set.

The current instance for our example is now as shown in Fig. 27. There are four valuations of $\mathcal{D}$ in **D**.

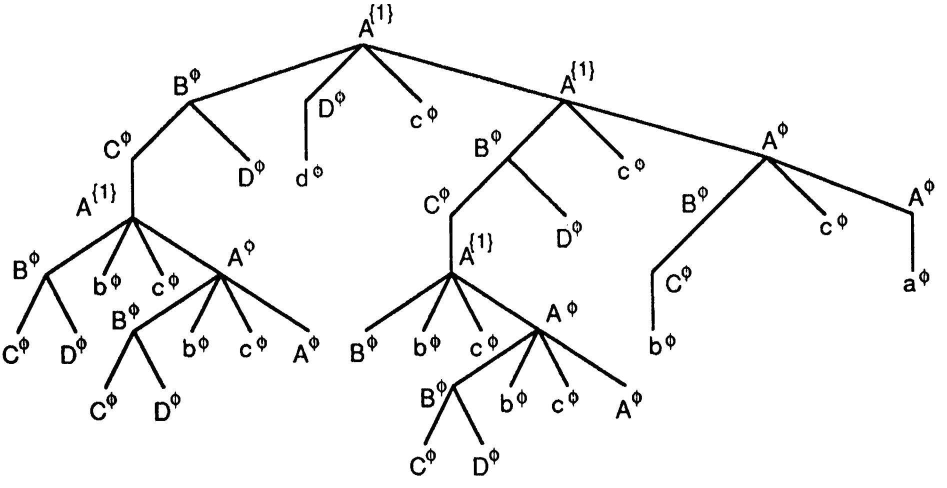

FIG. 27. *Determination of all valuations of $\mathcal{D}$ in* **D**.

Step 3. *Evaluation of all type* 2 *variables under the valuations of $\mathcal{D}$ in* **D**. Once again, let $\rho_{i_1}, \ldots, \rho_{i_m}$ be the type 2 variables in $\mathcal{D}'$ (or, equivalently, in $\mathcal{D}$). We will relabel the nodes in the current instance in such a way that, for each $p = 1, \ldots, m$,

the superscript of the label of a node **n** *contains the index i_p if and only if there exists a valuation f of $\mathcal{D}'$ in* **D** *with* $\mathbf{par}(f(\rho_{i_p})) = \mathbf{n}$ (condition (p')).

Since we will need approximately the same procedure on several other occasions in the following parts of this proof, we will describe it in slightly more general terms than needed right now. Recalling that $\rho_{i_1} = \rho_2$, we can easily satisfy condition (1′) by doing, in any order, until no further action is possible, the parent substitution $\Sigma\pi[B^{\{1\}} \to s, B^{\{1,2\}}]$ for each $B^{\{1\}} \to s$ with either $B^{\{1\}} \to s$ a production in the current scheme or $B^{\{1\}}$ an attribute in the current scheme and $s = \varepsilon$.[13] By an upward iterative procedure, we now enforce conditions (2′)–(m').

Thereto, we perform the following operation for $p := 2$ up to m. Let $\rho_k := \ldots (B\rho_{i_p}) \ldots$ be the declaration in $\mathcal{D}'$ containing ρ_{i_p} in its right-hand side. Then, in any order and until no further action is possible, we do $\Sigma\chi[C^K \to s_1 B^J s_2, B^J, B^{J \cup \{i_p\}}]$ for each production $C^K \to s_1 B^J s_2$ in the current scheme with $C \in V$, $k \in K$, and $i_p \notin J$.

The current instance of our example is now as shown in Fig. 28.

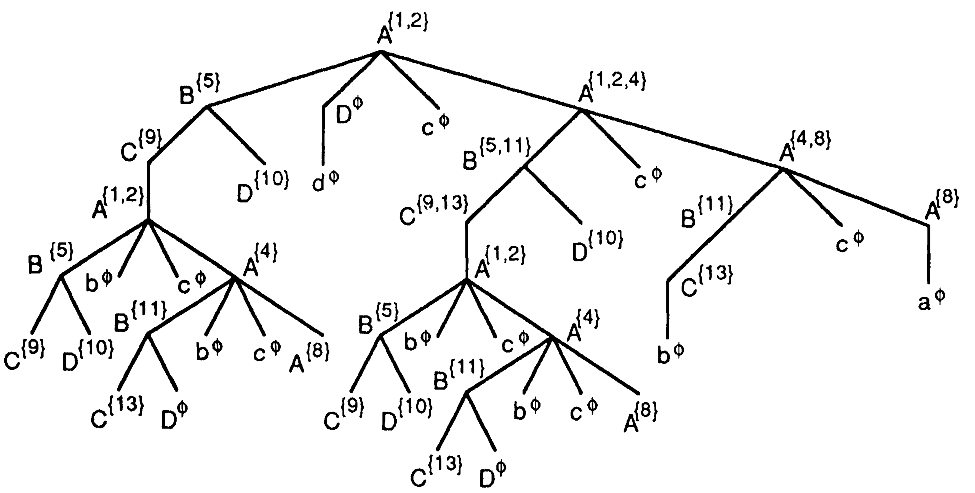

FIG. 28. *Evaluation of all type* 2 *variables under the valuations of* $\mathcal{D}$ *in* **D**.

Step 4. *Evaluation of all type* 1 *variables under the valuations of* $\mathcal{D}$ *in* **D**. We will relabel the nodes in the current instance in such a way that for each type 1 variable ρ_i, the superscript of the label of a node **n** contains the index i if and only if there exists a valuation f of $\mathcal{D}$ in **D** with **top**($f(\rho_i)$) containing **n**. Therefore, we do the following steps:

Substep 1. *Transforming* $\mathcal{D}$. From $\mathcal{D}$ we construct $\mathcal{D}''$ as follows. $\mathcal{D}''$ contains one declaration for each type 1 variable. This type 1 variable is contained in the right-hand side of the declaration. The left-hand side is a type 2 variable. As for $\mathcal{D}'$, the declarations of $\mathcal{D}''$ are obtained by subsequent substitutions.[14] For example, in our example,

$$\mathcal{D}'' = \{\rho_2 := \rho_3 c(A\rho_4),\ \rho_2 := (B\rho_5)\rho_6 c(A\rho_4),\ \rho_4 := \rho_7 c(A\rho_8),$$
$$\rho_4 := (B\rho_{11})\rho_{12} c(A\rho_8),\ \rho_{11} := (C\rho_{13})\rho_{14}\}.$$

Clearly, a valuation of $\mathcal{D}$ in **D** is also a valuation of $\mathcal{D}' \cup \mathcal{D}''$ in **D**; conversely, the extension of a valuation of $\mathcal{D}'$ in **D** to var($\mathcal{D}$) is a valuation of $\mathcal{D}$ in **D** if and only if it is a valuation of $\mathcal{D}' \cup \mathcal{D}''$ in **D**.

[13] Note that, at this stage of the proof, the attribute B will always equal A, the attribute in the declaration $\rho_1 := (A\rho_2)$ for the root of G($\mathcal{D}$).

[14] Again, these substitutions cannot yield illegal terms.

Substep 2. *Relabeling.* In order to enforce for each valuation of $\mathcal{D}$ in $\mathbf{D}$ and for each type 1 variable ρ_i that each node in $\mathbf{top}(f(\rho_i))$ contains the index i in the superscript of its label, we perform the following operations. For later use, they will be once again described in slightly more general terms than required right now. Let $\rho_k := t_1 \ldots t_l$ be the unique declaration in $\mathcal{D}''$ containing ρ_i in its right-hand side. Let in the above declaration t_q, $1 \le q \le l$, be the basic term with $t_q = \rho_i$. Let $\rho_r := \ldots (B\rho_k) \ldots$ be the unique declaration in $\mathcal{D}'$ containing ρ_k in its right-hand side. Then, by step 3 of the construction in this proof, each node $\mathbf{n}$ occurring in $f(\rho_i)$ for some valuation of $\mathcal{D}$ in $\mathbf{D}$ is the child of a node labeled B^J with $k \in J$.

We first relabel all nodes occurring in $f(\rho_i)$ for some valuation of $\mathcal{D}$ in $\mathbf{D}$ labeled by a constant. Thereto, we introduce the following notation. Let $s = \alpha_1 \ldots \alpha_w$ be an arbitrary word over the current attributes and constants. (For $v = 1, \ldots, w$, α_v is an attribute or a constant.) Then we denote by $\bar{s}$ the word $\bar{\alpha}_1 \ldots \bar{\alpha}_w$ with, for $v = 1, \ldots, w$,

$$\bar{\alpha}_v = \begin{cases} a^{K \cup \{i\}} & \text{if } \alpha_v = a^K, a \in T; \\ \alpha_v & \text{otherwise.} \end{cases}$$

The relabeling of the constant nodes is now achieved by performing, in any order and until no further action is possible, the permutation

$$\Pi[B^J \to s_1 \ldots s_{q-1} s_q s_{q+1} \ldots s_l s_{l+1}, s_1 \ldots s_{q-1} \bar{s}_q s_{q+1} \ldots s_l s_{l+1}]$$

for each production $B^J \to s_1 \ldots s_{q-1} s_q s_{q+1} \ldots s_l s_{l+1}$ in the current instance with $k \in J$, in which for $r = 1, \ldots, q-1, q+1, \ldots, l$,

$$s_r = \begin{cases} a^K & \text{if } t_r = a, a \in T; \\ C^K & \text{if } t_r = (C\rho_u), C \in V, \end{cases}$$

for some set K of nonnegative integers, s_{l+1} is a (possibly empty) string of symbols N_u^K,[15] and s_q is an arbitrary word in which the index i does not yet occur as a superscript. Finally, the attribute-labeled nodes occurring in $f(\rho_i)$ for some valuation of $\mathcal{D}$ in $\mathbf{D}$ are labeled by performing, in any order and until no further action is possible, the child substitution $\Sigma\chi[B^J \to s_1 \ldots s_{q-1} s_{q,1} C^L s_{q,2} \ldots s_l, C^L, C^{L \cup \{i\}}]$ for each production $B^J \to s_1 \ldots s_{q-1} s_{q,1} C^L s_{q,2} \ldots s_l$ with $k \in J$ and $i \notin L$ and in which, for $r = 1, \ldots, q-1, q+1, \ldots, l, l+1$, s_r is as above while $s_{q,1}$ and $s_{q,2}$ are arbitrary.

The current instance of our example is now as shown in Fig. 29.

Step 5. *Duplication of rootless subtrees corresponding to variables occurring in equations of* $\mathcal{E}$. We will now take into account the set of equations $\mathcal{E} = \{e_{n+1}, \ldots, e_{n+l}\}$. For each variable ρ_i occurring in an equation of $\mathcal{E}$ and each valuation f of $\mathcal{D}$ in $\mathbf{D}$, we will add to $\mathbf{chln}(\mathbf{n})$, $\mathbf{n}$ being the node with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$, a node $\mathbf{m}$ with $\mathbf{chtrs}(\mathbf{m})$ a "duplicate" of $f(\rho_i)$. Therefore, we do the following steps, keeping in mind that the root ρ_1 of $\mathcal{G}(\mathcal{D})$ does not occur in $\mathcal{E}$:

Substep 1. *Duplicating rootless subtrees corresponding to type* 1 *variables.* For each type 1 variable ρ_i occurring in $\mathcal{E}$, we perform the following procedure. Let $\rho_k := \ldots \rho_i \ldots$ be the unique declaration in $\mathcal{D}''$ containing ρ_i in its right-hand side and let $\rho_r := \ldots (B\rho_k) \ldots$ be the unique declaration in $\mathcal{D}'$ containing the type 2 variable ρ_k in its right-hand side.

In order to be able to apply sidewise duplication on rootless subtrees $f(\rho_i)$, f a valuation of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$, we first have to insert a node $\mathbf{p}$ satisfying $\mathbf{chln}(\mathbf{p}) = \mathbf{top}(f(\rho_i))$. So we do, in any order and until no further action is possible, the node insertion $\mathrm{N}\iota[B^J \to s_1 s_2 s_3, s_1 N_i^{\{0\}} s_3]$ for each $B^J \to s_1 s_2 s_3$ with (i) $k \in J$, (ii) either $B^J \to s_1 s_2 s_3$ a production in the current scheme or B^J an attribute in the current scheme and $s_1 s_2 s_3 = \varepsilon$, and (iii)

[15] Recall that $N_u \notin V$ are some of the auxiliary attributes introduced at the beginning of this proof. At this stage of the proof, however, the information base scheme does not yet contain auxiliary attributes, whence by necessity $s_{l+1} = \varepsilon$.

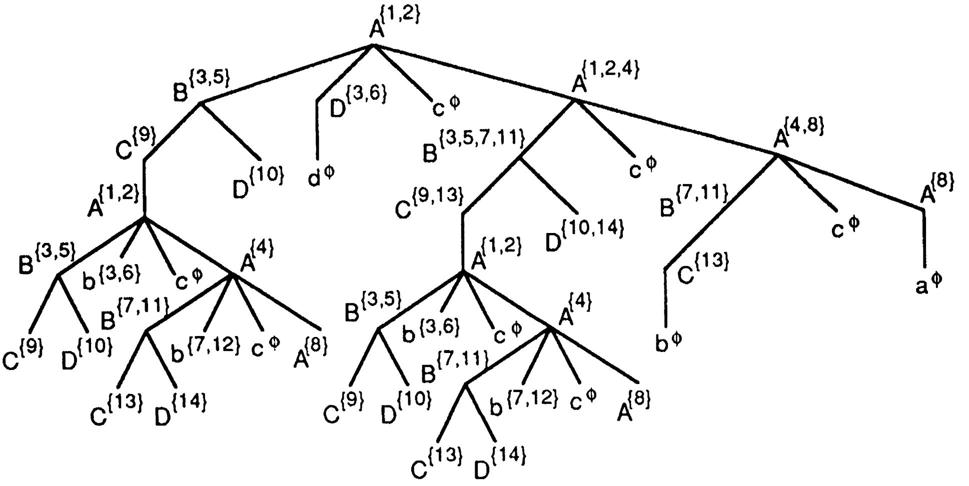

FIG. 29. *Evaluation of all type* 1 *variables under the valuations of* $\mathcal{D}$ *in* **D**.

- for each symbol α^K in s_2, $i \in K$,
- $N_i^{\emptyset}$ not in s_1s_3, and
- for each symbol α^K in s_1s_3,

immediately followed by the sidewise duplication $\Delta\sigma[B^J \rightarrow s_1N_i^{\{0\}}s_2, N_i^{\{0\}}, N_i^{\emptyset}]$ and the node merging $\mathrm{N}\mu[B^J \rightarrow s_1N_i^{\{0\}}s_2N_i^{\emptyset}, N_i^{\{0\}} \rightarrow s_3]$.[16]

Substep 2. *Duplicating rootless subtrees corresponding to type* 2 *variables.* For each type 2 variable ρ_i occurring in $\mathcal{E}$, we perform the following procedure. Let $\rho_k = \ldots(B\rho_i)\ldots$ be the unique declaration in $\mathcal{D}'$ containing ρ_i in its right-hand side.

First, we do, in any order and until no further action is possible, the node insertion $\mathrm{N}\iota[B^J \rightarrow s, N_i^{\{0\}}]$ for each $B^J \rightarrow s$ with $i \in J$, s not containing $N_i^{\emptyset}$, and either $B^J \rightarrow s$ a production in the current scheme or B^J an attribute in the current scheme and $s = \varepsilon$, immediately followed by the sidewise duplication $\Delta\sigma[B^J \rightarrow N_i^{\{0\}}, N_i^{\{0\}}, N_i^{\emptyset}]$ and the node merging $\mathrm{N}\mu[B^J \rightarrow N_i^{\{0\}}N_i^{\emptyset}, N_i^{\{0\}} \rightarrow s]$.

The current instance of our example is now as shown in Fig. 30.

Substep 3. *Eliminating the undesired side effects of the duplication.* For each variable ρ_i occurring in an equation of $\mathcal{E}$ and for each valuation of $\mathcal{D}$ in **D**, it is now our intention to propagate upward the "duplicate" of $f(\rho_i)$, the parent of which is labeled $N_i^{\emptyset}$, until that parent node becomes a child of the node **n** with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$. Unfortunately, we may run into trouble if the duplicate of $f(\rho_i)$ contains a "copy of the duplicate" of $g(\rho_k)$, g another valuation of $\mathcal{D}$ in **D** and ρ_k an arbitrary variable, *without containing a corresponding "copy" of* $g(\rho_1)$. Such copies of duplicates will be called *undesired copies of duplicates.*

For example, in our example, "copies of duplicates" occur. For instance, if f is the valuation of $\mathcal{D}$ in **D** for which $f(\rho_1) = (\mathbf{D})$ and g is the valuation of $\mathcal{D}$ in **D** for which $g(\rho_1)$ is the leftmost subtree of **D** of which the root is labeled A (see Fig. 29), then the rightmost occurrence of Δ_1 in Fig. 30 is the duplicate of $f(\rho_{13})$. Clearly, the leftmost occurrence of Δ_1 in Fig. 30 contains $g(\rho_9)$ (which is empty) as well as the duplicate of $g(\rho_9)$. Hence the

[16] Observe that if $f(\rho_i)$ is the empty rootless subtree, then, by the first operation, one $N_i^{\{0\}}$-labeled leaf node is inserted in an arbitrary place between the children of the corresponding B^J-node, not necessarily corresponding with the place of ρ_i in the right-hand side of the declaration $\rho_k := \ldots\rho_i\ldots$ in $\mathcal{D}''$. Fortunately, this nondeterminism gets immediately eliminated by the subsequent sidewise duplication and node merging.

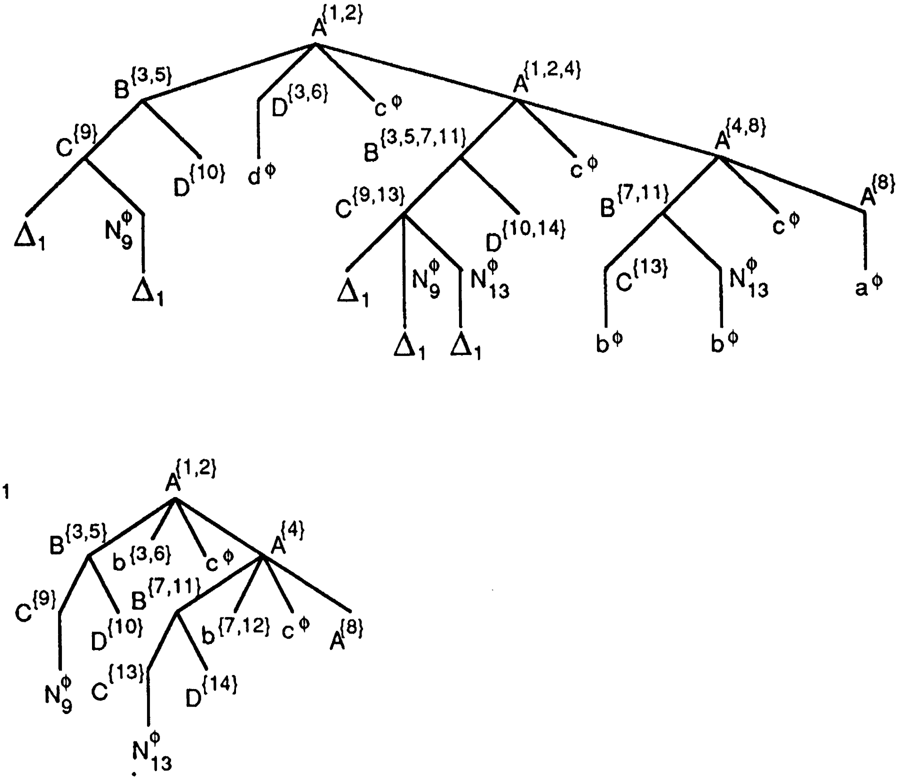

FIG. 30. *Duplication of rootless subtrees corresponding to type* 1 *and type* 2 *variables.*

duplicate of $f(\rho_{13})$ contains a copy of the duplicate of $g(\rho_9)$. However, the duplicate of $f(\rho_{13})$ also contains a copy of $g(\rho_1)$ (namely the duplicate of $f(\rho_{13})$ itself). Such copies of duplicates do not cause problems later; in fact, we will need them in order to generate the correct result. Undesired copies of duplicates do not occur in our example, and, as a consequence, the operations described below will not alter the instance in Fig. 30. An example in which undesired copies of duplicates do occur is given in the Appendix. There, it is also shown why these undesired copies of duplicates cause trouble.

We now remove undesired copies of duplicates as follows.[17] First, we remove all indices except the index 1 from the superscripts of the node labels using the cleaning-up procedure in step 2.5 of this construction. Then, we reintroduce the other indices by repeating steps 3 and 4. The way the auxiliary attributes N_u^K are treated there prevents the indexing to be propagated downward through the parent nodes of duplicates.

Next, we will add an index 0 to the N_u^K corresponding to undesired copies of duplicates.[18] They are recognized as follows. For each type 1 variable ρ_i occurring in $\mathcal{E}$, we do the child substitution $\Sigma\chi[B^J \to s_1 N_u^K s_2, N_u^K, N_u^{K\cup\{0\}}]$ for all productions $B^J \to s_1 N_u^K s_2$ in the current

[17] Of course, *desired* copies of duplicates can in turn contain *undesired* "copies of copies of duplicates," and so on, down to arbitrarily deep levels in the information base instance. While we choose not to complicate this already involved proof any further by explaining the problem only at the highest level where it can occur, the procedure described here is nevertheless general and removes undesired copies at any level in the information base instance.

[18] Note that, even if step 5.3 is initiated with an instance in which the superscripts of auxiliary attributes are arbitrary finite sets of nonnegative integers, we always have at this point that either $K = \{1\}$ or $K = \emptyset$, so K never contains 0.

scheme for which the superscript of no symbol in s_1 contains the index i. Similarly, for each type 2 variable ρ_i occurring in $\mathcal{E}$, we do the child substitution $\Sigma\chi[B^J \to s_1 N_u^K s_2,\ N_u^K,\ N_u^{K\cup\{0\}}]$ for all productions $B^J \to s_1 N_u^K s_2$ in the current scheme with $i \notin J$. Finally, undesired copies of duplicates are now removed by the node deletions $N\delta[N_u^K]$ with N_u^k in the current scheme, N_u an auxiliary attribute, and $0 \in K$.

If for some type 1 or type 2 variables ρ_i and ρ_k and for some valuation f of $\mathcal{D}$ in $\mathbf{D}$, $f(\rho_i)$ and $f(\rho_k)$ are isomorphic, then all their respective duplicates are also isomorphic, by Theorem 3.13. In general, some of these duplicates will have disappeared and some others will have been "trimmed" after step 5.3. However, the operations in step 5.3 preserve isomorphism.

Substep 4. *Propagating duplicates upward in the instance.* For each variable ρ_i occurring in an equation of $\mathcal{E}$ and for each valuation of $\mathcal{D}$ in $\mathbf{D}$, we will now move upward the "duplicate" of $f(\rho_i)$, the parent of which is labeled $N_i^{\emptyset}$, until that parent node becomes a child of the node $\mathbf{n}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$. This is achieved by performing, in any order and until no further action is possible, the upward duplication $\Delta\upsilon[C^K \to s_1 D^L s_2,\ D^L \to s_3 N_k^{\emptyset} s_4,\ N_k^{\emptyset},\ N_{k+n}^{\emptyset}]$, immediately followed by the node deletion $\mathrm{N}\delta[N_k^{\emptyset}]$, and this for all productions $C^K \to s_1 D^L s_2$ and $D^L \to s_3 N_k^{\emptyset} s_4$ in the current scheme with $k \operatorname{div} n + 2 \leq \mathrm{d}(\rho_{k \bmod n})$. As a consequence of this condition, duplicates of variables of depth 1 in $\mathcal{G}(\mathcal{D})$ are not moved upward; indeed, they already are in their right position.

Finally, in order to be able to immediately recognize the variable to which an $N_k^{\emptyset}$-labeled node corresponds, we perform, in any order and until no further action is possible, the child substitution $\Sigma\chi[A^J \to s_1 N_k^{\emptyset} s_2,\ N_k^{\emptyset},\ N_{k \bmod n}^{\emptyset}]$ for each production $A^J \to s_1 N_k^{\emptyset} s_2$ in the current scheme with $k > n$.

For each variable ρ_i occurring in an equation of $\mathcal{E}$ and for each valuation of $\mathcal{D}$ in $\mathbf{D}$ the A-labeled node $\mathbf{n}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$ has a child $\mathbf{m}$ labeled $N_i^{\emptyset}$ with $\mathbf{chtrs}(\mathbf{m})$ a "duplicate" of $f(\rho_i)$. Because of Theorem 3.13, it suffices to compare these "duplicates" in order to decide the isomorphism of the original $f(\rho_i)$'s.

The current instance of our example is now as shown in Fig. 31.

Observe that the $N_i^{\emptyset}$-labeled nodes always occur to the right of each of their siblings labeled by another symbol.

Step 6. *Determination of all valuations of $\mathcal{D}$ and $\mathcal{E}$ in* $\mathbf{D}$. We will relabel by $A^{\{1\}}$ all nodes $\mathbf{n}$ for which there exists a valuation f of $\mathcal{D}$ and $\mathcal{E}$ in $\mathbf{D}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$. (The superscript of the label of all other nodes will be replaced by the empty set.) Therefore, we do the following steps:

Substep 1. *Indicating the equations of $\mathcal{E}$ satisfied by the valuations of $\mathcal{D}$ in* $\mathbf{D}$. For each equation $e_k \equiv \rho_{k_1} = \rho_{k_2}$ in $\mathcal{E}$, $n+1 \leq k \leq n+l$ and for each valuation f of $\mathcal{D}$ in $\mathbf{D}$, we will add the index k to the superscript of the label of the node $\mathbf{n}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$ if and only if f satisfies e_k, i.e., if $f(\rho_{k_1})$ and $f(\rho_{k_2})$ are isomorphic. This is achieved by performing, in any order and until no further action is possible, the parent equality substitution $\Sigma\sigma[A^J \to s,\ N_{k_1}^{\emptyset},\ N_{k_2}^{\emptyset},\ A^{J\cup\{k\}}]$ for all productions $A^J \to s$ in the current scheme with $N_{k_1}^{\emptyset}$ and $N_{k_2}^{\emptyset}$ in s and $k \notin J$.

In our example, we only have one equation: $e_{15} \equiv \rho_9 = \rho_{13}$. Three of the four valuations of $\mathcal{D}$ in $\mathbf{D}$ satisfy this equation. Their corresponding A-nodes see an index 15 added to the superscript of their label. The current instance in our example is now shown in Fig. 32.

Substep 2. *Relabeling and cleaning up.* In any order and until no further action is possible, we perform $\Sigma\pi[A^J \to s,\ A^{\{1\}}]$ for each production $A^J \to s$ in the current scheme with $\{n+1, \ldots, n+l\} \subseteq J$.

Using parent substitution, we now rename all attribute node labels B^J with $B \in V$ and $1 \notin J$ to $B^{\emptyset}$; using permutation, we rename all constant node labels a^J with $a \in T$ by $a^{\emptyset}$. Finally, we remove all $N_i^{\emptyset}$, as well as the subtrees of which they are the root, using node deletion.

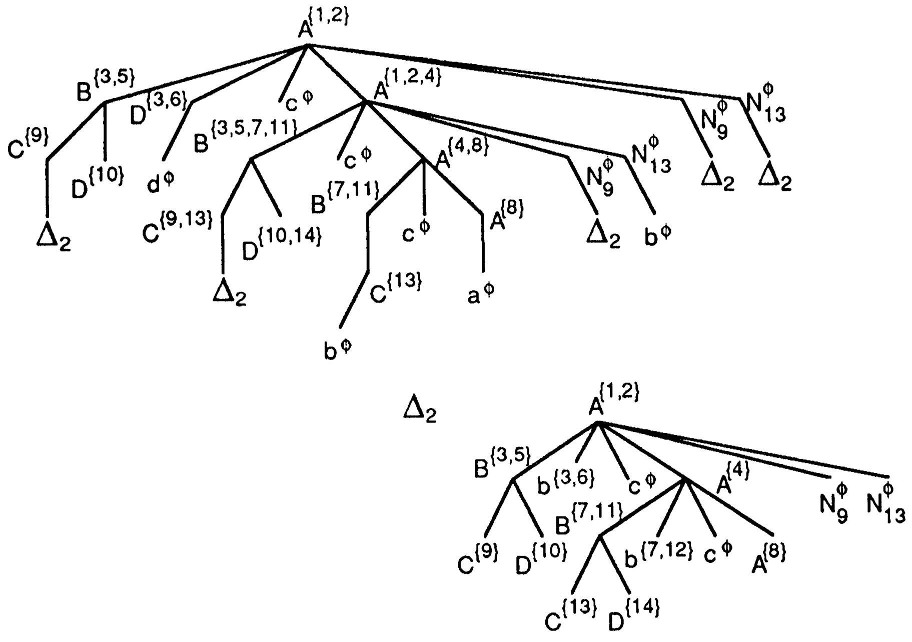

FIG. 31. *Duplication of rootless subtrees corresponding to variables occurring in equations of $\mathcal{E}$.*

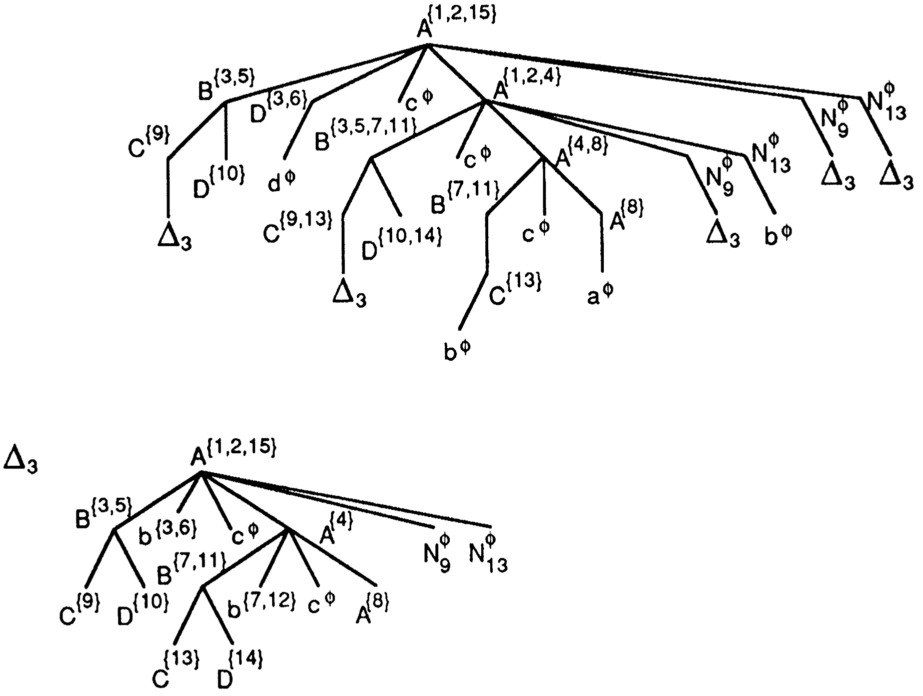

FIG. 32. *The result of marking the equations of $\mathcal{E}$ satisfied by the valuations of $\mathcal{D}$ in* **D**.

Now, all nodes **n** for which there exists a valuation f of $\mathcal{D} \cup \mathcal{E}$ in **D** with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$ are labeled $A^{\{1\}}$; all other nodes are labeled with an attribute or a constant indexed by the empty set.

Comparing the instances obtained at the end of step 2 and this step respectively, we have now eliminated all valuations of $\mathcal{D}$ in **D** that are not valuations of $\mathcal{D}$ and $\mathcal{E}$ in **D**. In our example, one of the valuations identified in Fig. 27, namely that for which the corresponding A-node did not receive an index 15 in Fig. 32, is eliminated.

Step 7. *Evaluation of all variables under the valuations of* $\mathcal{D}$ *and* $\mathcal{E}$ *in* **D**. We will relabel the nodes in the current instance in such a way that

- for each type 2 variable ρ_i, the superscript of the label of a node **n** contains the index i if and only if there exists a valuation f of $\mathcal{D}$ and $\mathcal{E}$ in **D** with $\mathbf{par}(f(\rho_i)) = \mathbf{n}$;
- for each type 1 variable ρ_i, the superscript of the label of a node **n** contains the index i if and only if there exists a valuation f of $\mathcal{D}$ and $\mathcal{E}$ in **D** with $\mathbf{top}(f(\rho_i))$ containing **n**.

Thereto, it suffices to repeat steps 3 and 4 of the construction of this proof, starting from the current instance. In our example, the resulting instance is then as shown in Fig. 33.

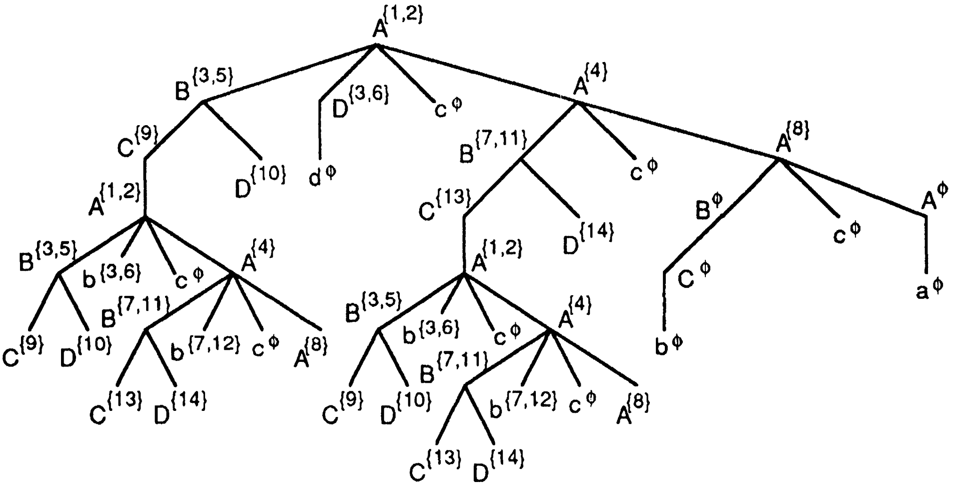

FIG. 33. *Evaluation of all variables under the valuations of* $\mathcal{D}$ *and* $\mathcal{E}$ *in* **D**.

Step 8. *Duplication of rootless subtrees corresponding to variables in u.* Now that all valuations of $\mathcal{D}$ and $\mathcal{E}$ in **D** have been fully specified, we can start with the simulation of the actual transformation. Thereto, for each variable ρ_i in the substitution term u and each valuation f of $\mathcal{D}$ and $\mathcal{E}$ in **D**, we will add to $\mathbf{chln}(\mathbf{n})$, **n** being the node with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$, a node **m** with $\mathbf{chtrs}(\mathbf{m})$ a "duplicate" of $f(\rho_i)$. Therefore, we do the following steps, keeping in mind that ρ_1 does not occur in u:

Substep 1. *Duplicating rootless subtrees corresponding to type* 1 *variables.* Thereto, we simply repeat step 5.1 of the construction in this proof.

Substep 2. *Duplicating rootless subtrees corresponding to type* 2 *variables.* In order to duplicate type 2 variables, we *cannot* simply repeat step 5.2. This is because of the different ways in which type 1 and type 2 variables are treated in Definition 4.18. Indeed, if ρ_i is a variable of type 1 in u, f is a valuation of $\mathcal{D}$ and $\mathcal{E}$ in **D** with $f(\rho_i) = (\mathbf{D}_1, \dots, \mathbf{D}_w)$, and g is an E-transformation, then we have to compute $g((\mathbf{D}_1), \mathbf{D}_1) \dots g((\mathbf{D}_m), \mathbf{D}_m)$. If, on the other hand, ρ_i is a type 2 variable, we have to compute $g(f(\rho_i), \mathbf{p}f(\rho_i))$, where $\mathbf{p} = \mathbf{par}(f(\rho_i))$.

Therefore, if ρ_i is a type 2 variable in u and f is a valuation of $\mathcal{D}$ and $\mathcal{E}$ in **D**, we will duplicate the *completion* of $f(\rho_i)$ with its parent node, rather than $f(\rho_i)$ itself. Thereto, we perform the following procedure for each type 2 variable ρ_i in u. Let $\rho_k = \ldots(B\rho_i)\ldots$ be the unique declaration in $\mathcal{D}'$ containing ρ_i in its right-hand side.

First, we do, in any order and until no further action is possible, the node insertion N$\iota[B^J \to s, N_i^{J\cup\{0\}}]$ for each $B^J \to s$ with $i \in J$, s not containing N_i^J, and either $B^J \to s$ a production in the current scheme or B^J an attribute in the current scheme and $s = \varepsilon$, immediately followed by the sidewise duplication $\Delta\sigma[B^J \to N_i^{J\cup\{0\}}, N_i^{J\cup\{0\}}, N_i^J]$ and the node merging N$\mu[B^J \to N_i^{J\cup\{0\}} N_i^J, N_i^{J\cup\{0\}} \to s]$.

In comparison with step 5.2, we now also duplicated the superscript of the label of the parent node of $f(\rho_i)$.

Substep 3. *Eliminating the undesired side effects of the duplication.* We repeat step 5.3 of the construction in this proof.

Substep 4. *Propagating duplicates upward in the instance.* We repeat step 5.4 of the construction in this proof.

For each variable ρ_i in the substitution term u and for each valuation of $\mathcal{D}$ in **D**, the A-labeled node **n** with **top**$(f(\rho_1)) = (\mathbf{n})$ has a child **m** labeled N_i^J for some $J \subseteq \{1, \ldots, n\}$ with **chtrs**(**m**) a "duplicate" of $f(\rho_i)$.

The current instance of our example is now as shown in Fig. 34.

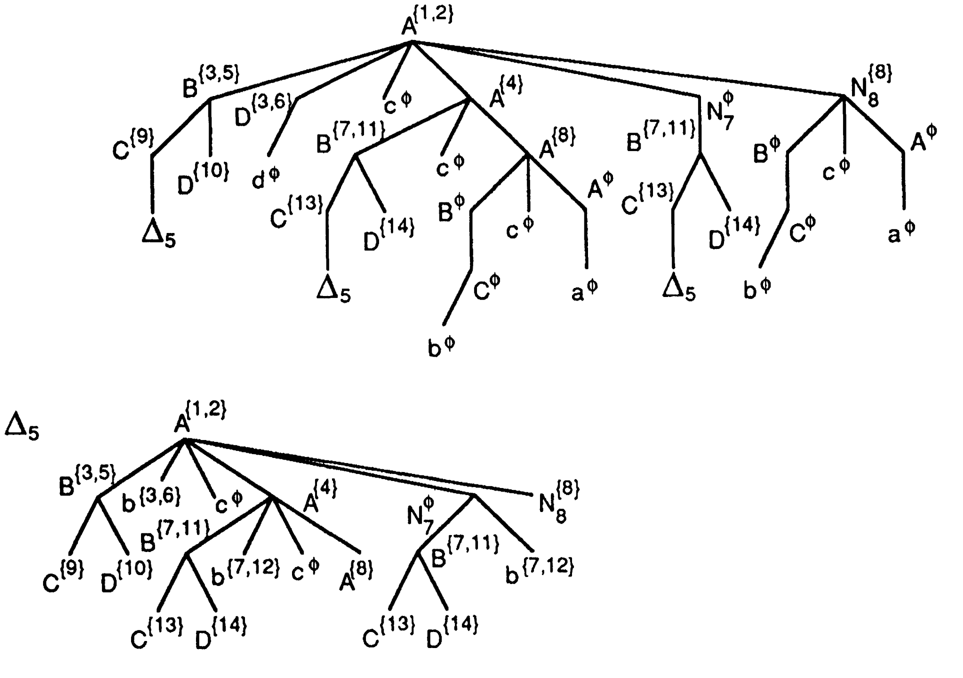

FIG. 34. *Duplication of rootless subtrees corresponding to variables in u.*

Observe that the N_i^J-labeled nodes always occur to the right of each of their siblings labeled by another symbol.

Step 9. *Downward propagation of duplicates to the place where they have to be inserted.* If ρ_j, the left-hand side of the substitution clause $\rho_j \leftarrow u$, equals ρ_1, the root of $\mathcal{G}(\mathcal{D})$, then no alterations are made.

Otherwise, for each variable ρ_i in u and for each valuation of $\mathcal{D}$ and $\mathcal{E}$ in **D**, we will move downward the "duplicate" of $f(\rho_i)$ until it becomes a "sibling" of $f(\rho_j)$. Therefore, we do the following steps:

Substep 1. *Identifying the paths for the downward propagation of duplicates.* We will identify these paths with the sequence of variables $\rho_{q_1}, \ldots, \rho_{q_{d(\rho j)}}$ where, for $1 \leq l \leq \mathrm{d}(\rho_j)$, ρ_{q_l} is the unique ancestor of ρ_j in $\mathcal{G}(\mathcal{D})$ that is of type 2 and has depth l.

Remembering that $\rho_1 := (A\rho_2)$ is the declaration of the root of $\mathcal{G}(\mathcal{D})$, we always have $\rho_{q_1} = \rho_2$. In our example, we have $\rho_j = \rho_5$, $\mathrm{d}(\rho_5) = 2$, and $\rho_{q_1} = \rho_2$, $\rho_{q_2} = \rho_5$.

Substep 2. *Propagating duplicates downward in the instance.* For each variable ρ_i in u and for each valuation of $\mathcal{D}$ and $\mathcal{E}$ in **D**, we will now move downward the "duplicate" of $f(\rho_i)$ along the path identified in the previous step, until it becomes a "sibling" of $f(\rho_j)$, i.e., until it has the same parent node as $f(\rho_j)$, or, equivalently, until it has the same parent node as $f(\rho_{q_{d(\rho_j)}})$.

This is achieved by performing, in any order and until no further action is possible, the downward duplication $\Delta\delta[B^K \to s_1 C^L s_2 N_k^J s_3, C^L \to s_4, N_k^J, N_{k+n}^J]$, immediately followed by the node deletion $\mathrm{N}\delta[N_k^J]$, for each production $B^K \to s_1 C^L s_2 N_k^J s_3$ in the current scheme with $C \in V$, $k \operatorname{div} n + 2 \leq \mathrm{d}(\rho_j)$, and $q_{k \operatorname{div} n+2} \in L$ (whence $q_{k \operatorname{div} n+1} \in K$), and for each $C^L \to s_4$ with either $C^L \to s_4$ a production in the current scheme or $s_4 = \varepsilon$.

Finally, in order to be able to immediately recognize the variable to which an $N_k^{\emptyset}$-labeled node corresponds, we perform, in any order and until no further action is possible, the child substitution $\Sigma\chi[B^K \to s_1 N_k^J s_2, N_{k \bmod n}^J]$ for each production $B^K \to s_1 N_k^J s_2]$ with $q_{d(\rho_j)} \in K$ and $k > n$.

The current instance of our example is now as shown in Fig. 35.

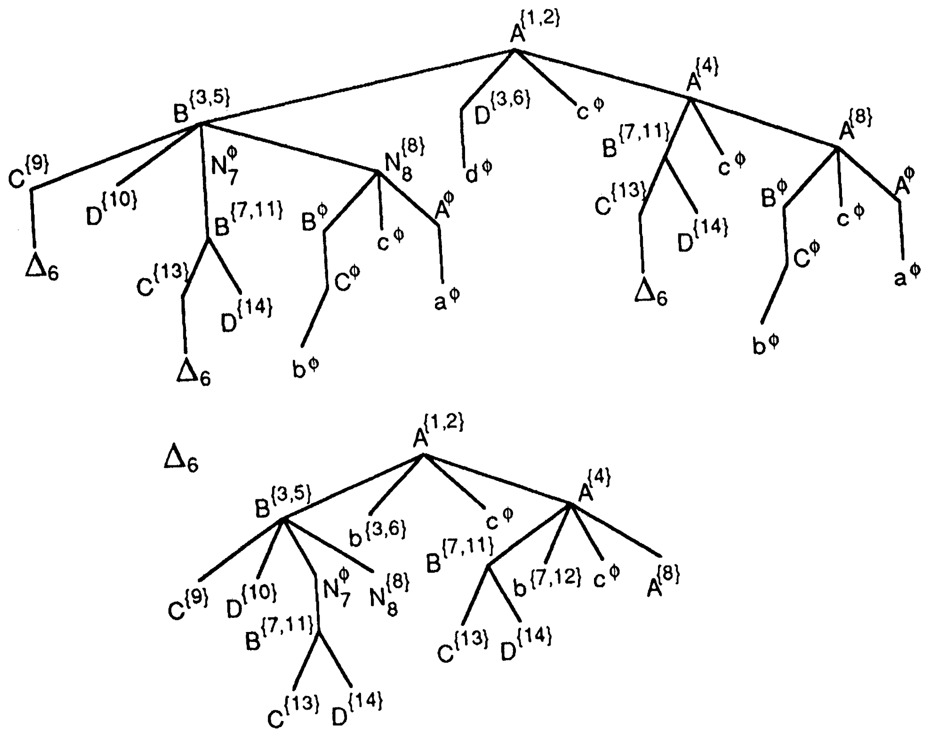

FIG. 35. *Downward propagation of duplicates to the place where they have to be inserted.*

Observe that step 9.2 does not produce alterations if $l = 1$, i.e., if $\rho_j \equiv \rho_2$. Indeed, in that case, all duplicates already have the same parent node as $f(\rho_j) \equiv f(\rho_2)$, namely the A-labeled node $\mathbf{n}$ with $\mathbf{top}(f(\rho_1)) = (\mathbf{n})$.

Step 10. *The actual transformation in the case when in the substitution clause $\rho_j \leftarrow u$, $\rho_j \equiv \rho_1$.* We distinguish two cases.

Case 1. *The substitution clause is $\rho_1 \leftarrow \varepsilon$.* Then, in any order and until no further action is possible, we do the node deletion $\mathrm{N}\delta[A^J]$ for each attribute in the current scheme with $1 \in J$. Finally, we remove the superscripts from all labels using parent substitution (for the attribute nodes) and permutation (for the constant nodes).

The resulting instance is $[\rho_1 \leftarrow \varepsilon \mid \mathcal{D} \cup \mathcal{E}](\mathbf{D})$.

Case 2. *The substitution clause has the form $\rho_1 \leftarrow (B\rho_i)$ with $B \in V$ and $\rho_i \in$* var$(\mathcal{D})$. First, we mark the subtrees to be deleted with the index $n+1$ by doing, in any order and until no further action is possible, the child substitution

$$\Sigma\chi[C^J \to s_1 D^K s_2, D^K, D^{K \cup \{n+1\}}]$$

for each production $C^J \to s_1 D^K s_2$ in the current scheme with $1 \in J$ (whence $C = A$ or $C = N_i$), $n+1 \notin K$, and $D \neq N_i$. Then, we actually remove these subtrees using the node deletions $\mathrm{N}\delta[D^K]$ for all attributes D in the current scheme with $n+1 \in K$. Next, we remove the auxiliary attributes by applying, in any order and until no further action is possible, the node merging $\mathrm{N}\mu[A^J \to N_i^K, N_i^K \to s]$ for all productions $A^J \to N_i^K$ and $N_i^K \to s$ in the current scheme with $1 \in J$. Finally, in any order and until no further action is possible, we perform the parent substitution $\Sigma\pi[A^J \to s, B]$ for each $A^J \to s$ with $1 \in J$ and either $A^J \to s$ a production in the current scheme or A^J an attribute in the current scheme and $s = \varepsilon$. Using parent substitution (for the attribute nodes) and permutation (for the constant nodes), we remove the index sets from all other labels.

The resulting instance is $[\rho_1 \leftarrow (B\rho_i) \mid \mathcal{D} \cup \mathcal{E}](\mathbf{D})$.

Step 11. *The actual transformation in the case when in $\rho_j \leftarrow u$, ρ_j is of type* 1 *in $\mathcal{D}$.* Let $k = q_{d(\rho_j)}$ and let $\rho_k := t_1 \ldots t_l$ be the unique declaration in $\mathcal{D}''$ containing ρ_i in its right-hand side. Let in the above declaration t_q, $1 \leq q \leq l$, be the basic term with $t_q = \rho_j$. Let $\rho_r := \ldots (B\rho_k) \ldots$ be the unique declaration in $\mathcal{D}'$ containing ρ_k in its right-hand side. Let $u = u_1 \ldots u_w$ with $u_1, \ldots, u_w$ basic terms. We then do the following steps:

Substep 1. *Identifying and removing subtrees to be deleted.* In any order and until no further action is possible, we do the node insertion $N\iota[C^J \to s_1 s_2 s_3, s_1 N_0^{\emptyset} s_3]$ for each production $C^J \to s_1 s_2 s_3$ in the current scheme with $k \in J$, s_2 the substring of $s_1 s_2 s_3$ of *all* symbols containing the index j in the superscript of their label, and $s_2 \neq \varepsilon$, immediately followed by the node deletion $N\delta[N_0^{\emptyset}]$.[19]

Substep 2. *Rearranging subtrees to be substituted.* In any order and until no further action is possible, we perform the permutation $\Pi[C^J \to s_1 s_2 s_3, s_1 s_4 s_2]$ for each $C^J \to s_1 s_2 s_3$ with (i) $k \in J$, (ii) either $C^J \to s_1 s_2 s_3$ a production in the current scheme, or C^J an attribute in the current scheme and $s_1 s_2 s_3 = \varepsilon$, and (iii)

- the superscript of no symbol in $s_1 s_2 s_3$ contains the index j;
- s_1 consists of $q-1$ symbols;
- s_2 consists of $l-q$ symbols;
- s_3 only consists of symbols N_i^K with N_i an auxiliary attribute; and
- $s_4 = \alpha_1 \ldots \alpha_l$ with, for $v = 1, \ldots, l$,

$$\alpha_v = \begin{cases} a & \text{if } u_v = a; \\ N_i^K & \text{if } u_v = \rho_i \text{ and } N_i^K \text{ is in } s_3; \\ N_i^K & \text{if } u_v = (D\rho_i) \text{ and } N_i^K \text{ is in } s_3. \end{cases}$$

(Observe that s_4 is uniquely defined by the above conditions.)

[19] Observe that, in the above production, either $C = B$ (B being the attribute in the declaration $\rho_r := \ldots (B\rho_k) \ldots$) or C is an auxiliary attribute.

Substep 3. *Cleaning up.* For each indexed attribute N_i^K in the current scheme with ρ_i a variable that occurs in u as a basic term of type 2, say $(D\rho_i)$, we do the parent substitution $\Sigma\pi[N_i^K \to s, D]$ for each production $N_i^K \to s$ in the current scheme. Then, for each indexed attribute N_i^K in the current scheme with ρ_i a variable that occurs in u as a basic term of type 1, we do the node merging $N\mu[B^J \to s_1 N_i^K s_2, N_i^K \to s_3]$ for all productions $B^J \to s_1 N_i^K s_2$ and $N_i^K \to s_3$ in the current scheme with $k \in J$ (B being the attribute in the declaration $\rho_r := \dots (B\rho_k) \dots$). Finally, we remove all remaining index sets from node labels using parent substitution (for the attribute nodes) and permutation (for the constant nodes).

The resulting instance is $[\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$.

Step 12. *The actual transformation in the case that in $\rho_j \leftarrow u$, ρ_j is of type* 2 *in $\mathcal{D}$.* If ρ_j is of type 2 in $\mathcal{D}$, then $q_{d_{(\rho_j)}} = j$. Let $\rho_r := \dots (B\rho_j) \dots$ be the unique declaration in $\mathcal{D}'$ containing ρ_j in its right-hand side. Let $u = u_1 \dots u_w$ with $u_1, \dots, u_w$ basic terms. We then do the following steps:

Substep 1. *Identifying and removing subtrees to be deleted.* In any order and until no further action is possible, we do the node insertion $N\iota[C^J \to s_1 s_2, N_0^{\emptyset} s_2]$ for each production $C^J \to s_1 s_2$ in the current scheme with $j \in J$, s_2 the substring of $s_1 s_2$ of *all* auxiliary attributes, and $s_1 \neq \varepsilon$, immediately followed by the node deletion $N\delta[N_0^{\emptyset}]$.[20]

Substep 2. *Rearranging subtrees to be substituted.* In any order and until no further action is possible, we perform the permutation $\Pi[C^J \to s_1, s_2]$ for each $C^J \to s_1$ with $j \in J$, either $C^J \to s_1$ a production in the current scheme, or C^J an attribute in the current scheme and $s_1 = \varepsilon$, and $s_2 = \alpha_1 \dots \alpha_l$ with, for $v = 1, \dots, l$,

$$\alpha_v = \begin{cases} a & \text{if } u_v = a; \\ N_i^K & \text{if } u_v = \rho_i \text{ and } N_i^K \text{ is in } s_1; \\ N_i^K & \text{if } u_v = (D\rho_i) \text{ and } N_i^K \text{ is in } s_1. \end{cases}$$

(Observe that s_1 only consists of auxiliary attributes and that s_2 is uniquely defined by the above conditions.)

Substep 3. *Cleaning up.* We repeat step 11.3 in the construction of this proof.

The resulting instance is $[\rho_j \leftarrow u \mid \mathcal{D} \cup \mathcal{E}]$. Particularly, in our example, the operations above finally yield the information base instance shown in Fig. 19.

Finally note that all constructions in this proof were done at scheme level, i.e., they do not depend on the instance under consideration. □

Hence the grammatical algebra and the grammatical calculus are equivalent. As Codd concluded for the relational model, this equivalence gives a naturalness to both languages. However, it still requires further investigation to find a precise language-independent characterization for the expressive power of the grammatical algebra and calculus.

7. Conclusions and future work. In this paper a simple model for representing the hierarchical structure in information is proposed. Two methods for querying in this data model are given and shown to be equivalent. The expressive power of these querying methods is not yet clear, however. In particular, it is not known how these methods are related to querying facilities in other data models, that can be simulated by the grammatical model. Furthermore, we are looking for a well-adapted interface that is integrated in a more general environment. It is remarkable that there seems to be no fundamental distinction between updating and querying in this model. Other aspects, such as transforming several given trees into one result tree, constraint checking, and implementation strategies, are under investigation.

Although it can be considered as an extension of the relational model, the grammatical model, because it is hierarchical in nature, is of course not suited for all database applications.

[20] Observe that, in the above production, either $C = B$ (B being the attribute in the declaration $\rho_r := \dots (B\rho_j) \dots$) or C is an auxiliary attribute.

In particular, the notion of "shared component" is difficult to express in a tree. It is therefore interesting to look for a characterization of the semantic expressiveness of the grammatical model. On the other hand, one could also look for "network-like" extensions of this model, using the theory of graph-grammars (e.g., [15]).

Appendix. As promised in step 5.3 of the construction in the proof of Theorem 6.1, we shall now exhibit an example in which duplication yields undesired side effects.

Example. Consider the information base instance **D** of Fig. 36 (over some appropriate scheme), let

$$\mathcal{D} = \{\rho_1 := (A\rho_2),\ \rho_2 := (A\rho_3)(B\rho_4)(C\rho_5),\ \rho_3 := (A\rho_6)(B\rho_7)(C\rho_8)\},$$

and let E be an arbitrary calculus expression involving $\mathcal{D}$ and the set of equations $\mathcal{E} = \{\rho_6 = \rho_8\}$.

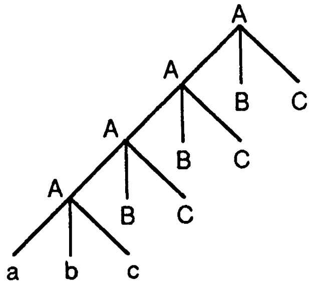

FIG. 36. *The information base instance* **D**.

If we apply the construction in the proof of Theorem 6.1 to the instance **D** up to step 4, i.e., until all valuations of $\mathcal{D}$ are determined and fully specified, we obtain the instance in Fig. 37.

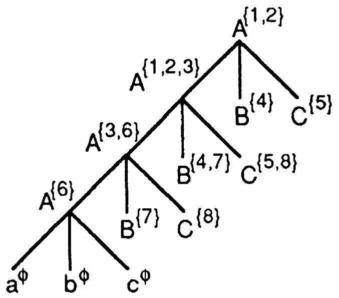

FIG. 37. *The instance* **D** *after determination and full specification of all valuations of* $\mathcal{D}$ *in* **D**.

Clearly, there are two valuations of $\mathcal{D}$ in **D**. One of this, say f, is determined by $f(\rho_1) = (\mathbf{D})$. For the other one, say g, $g(\rho_1)$ is the leftmost component of **chtrs(rt(D))**. Since ρ_6 and ρ_8 are the only variables occurring in an equation of $\mathcal{E}$, the only subtrees to be duplicated are $f(\rho_6)$, $f(\rho_8)$, $g(\rho_6)$, and $g(\rho_8)$. The result of applying steps 5.1 and 5.2 to the instance of Fig. 37 is shown in Fig. 38.

Now observe that the duplicate of $f(\rho_6)$ contains a "copy" of the duplicate of $g(\rho_6)$ as well as a "copy" of the duplicate of $g(\rho_8)$. Clearly, the duplicate of $f(\rho_6)$ does not contain a duplicate of $g(\rho_1)$.

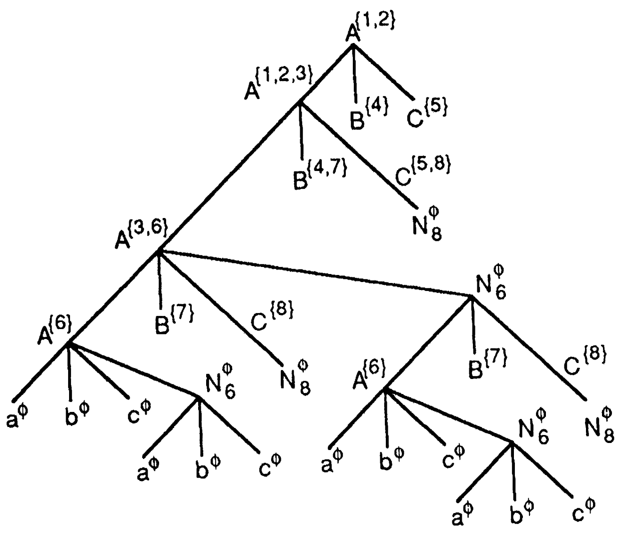

FIG. 38. *The instance of Fig. 37 after duplication of $f(\rho_6)$, $f(\rho_8)$, $g(\rho_6)$, and $g(\rho_8)$.*

If we now would try to apply step 5.4 of the construction in the proof of Theorem 6.1 straight away, we would have to move all duplicates (and hence also all copies of duplicates) two levels upward. We leave it to the reader to verify that, for ρ_6, this would result in two nodes at the same level (more concrete, as children of the root) with the same attribute label $N_{24}^{\emptyset}$, which would imply that the result is undefined, and this is obviously not what we want. Clearly, a duplicate of $g(\rho_6)$ does not belong at that level. Luckily, the relabeling procedure of step 5.3 reevaluates the valuations of $\mathcal{D}$ in **D** and prevents them from being propagated downward through nodes labeled by auxiliary attributes. The result of the relabeling is shown in Fig. 39.

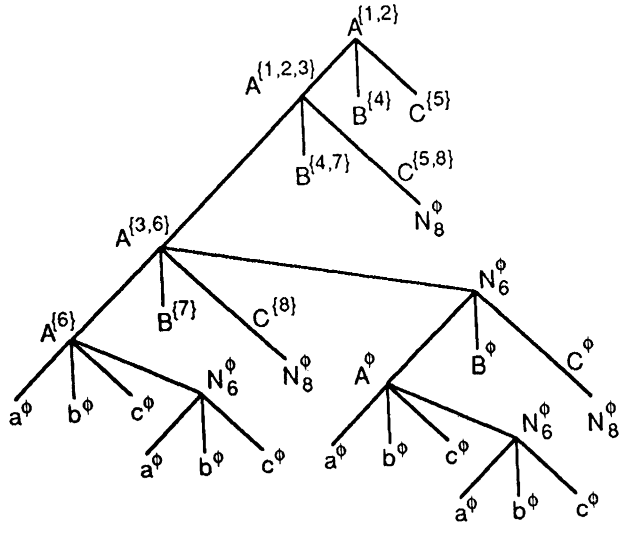

FIG. 39. *The instance of Fig. 38 after relabeling.*

The undesired node with label $N_6^{\emptyset}$ (as well as the undesired node with label $N_8^{\emptyset}$) is now easily recognized from the fact that the label of its parent node no longer contains the index 6, and hence, by step 5.3, the undesired copy of the duplicate of $g(\rho_6)$ (as well as the undesired copy of the duplicate of $g(\rho_8)$) will be deleted.

Acknowledgments. The authors are indebted to Peter Peelman who produced the figures in this article and to Jan Van den Bussche whose critical comments on a previous version of this paper were very helpful.

SELECTING HEAVILY COVERED POINTS*

BERNARD CHAZELLE†, HERBERT EDELSBRUNNER‡, LEONIDAS J. GUIBAS§, JOHN E. HERSHBERGER¶, RAIMUND SEIDEL‖, AND MICHA SHARIR**

Abstract. A collection of geometric *selection lemmas* is proved, such as the following: For any set P of n points in three-dimensional space and any set $\mathcal{S}$ of m spheres, where each sphere passes through a distinct point pair in P, there exists a point x, not necessarily in P, that is enclosed by $\Omega(m^2/(n^2 \log^6 \frac{n^2}{m}))$ of the spheres in $\mathcal{S}$. Similar results apply in arbitrary fixed dimensions, and for geometric bodies other than spheres. The results have applications in reducing the size of geometric structures, such as three-dimensional Delaunay triangulations and Gabriel graphs, by adding extra points to their defining sets.

Key words. discrete geometry, computational geometry, selecting points, covering, intervals, boxes, spheres, Delaunay triangulations, finite-element meshes, Gabriel graphs

1. Introduction.

The research that led to the results reported in this paper was originally focused on a problem about Delaunay triangulations for finite point sets in three-dimensional space. For such a set $P = \{p_1, p_2, \ldots, p_n\}$, the *Delaunay triangulation*, $\mathcal{D}(P)$, consists of all tetrahedra whose circumscribed spheres enclose no points of P [7], [10], [17]. Depending on how the points are distributed, the number of edges can vary between linear and quadratic in n. Euler's relation for three-dimensional cell complexes implies that the number of triangles and tetrahedra, and therefore the total combinatorial size of $\mathcal{D}(P)$, is proportional to the number of edges. We considered the question whether for every set of n points P there exists a point set Q so that $\mathcal{D}(P \cup Q)$ is guaranteed to have only a small number of edges. This question is motivated by the use of Delaunay triangulations in the discretization of three-dimensional objects [4], for finite-element analysis and related applications, where the size of the analysis has a strong effect on the efficiency of the analysis [18]. Of course, any set of n points in three dimensions admits a linear-size triangulation [10]; however, the Delaunay triangulation is preferred in these applications, because its tetrahedra are, in a certain sense, the most "round" possible, a property that affects the quality of the finite-element analysis.

A fairly intuitive approach to the problem is to identify a point that lies inside a large number of spheres circumscribing the tetrahedra of the current Delaunay triangulation. Adding this point will remove all corresponding tetrahedra and replace them by at most a linear number of new tetrahedra. Thus, the problem of slimming Delaunay triangulations can be attacked by showing that if there are many circumscribing spheres then there must be a point enclosed by many of them. It turns out that this is indeed true, for certain quantifications of "many," and

that similar results can be obtained in more general settings, involving various other geometric objects, in two, three, and beyond three dimensions. We now summarize the main results and present the outline of this paper.

TABLE 1
Summary of combinatorial results on multiply covered points.

objects	dimension	bound	§
intervals	1	$\Omega(m^2/n^2)$	2.1
rectangular boxes	d	$\Omega\left(m^2 \Big/ \left(n^2 \log^{2d-2} \frac{n^2}{m}\right)\right)$	2.2
diameter spheres	d	$\Omega\left(m^2 \Big/ \left(n^2 \log^{2d-2} \frac{n^2}{m}\right)\right)$	3.1
general spheres	d	$\Omega\left(m^2 \Big/ \left(n^2 \log^{2d} \frac{n^2}{m}\right)\right)$	3.2

Sections 2 and 3 present the main results of the paper. They are combinatorial in nature and show how to select multiply covered points in collections of rectangular boxes (§2) and spheres or more general convex bodies (§3). Table 1 lists these results. In each case, the problem is defined for a set of n points in d dimensions, and for a subset of m of the $\binom{n}{2}$ point pairs, where each of these pairs defines a geometric object of some kind. The bound given in the third column of the table is $\Omega(f(n, m))$ if there is always a point enclosed by at least that many of the m objects. In all cases, the bounds are nontrivial only if the number of objects is significantly larger than the number of points.

Sections 4 and 5 discuss the problem of reducing the combinatorial size of certain geometric structures by adding new points. The combinatorial result for general spheres is used in §4 to show, using a constructive proof, that for any set P of n points in three dimensions there is a set Q of $O(n^{1/2} \log^3 n)$ points so that the Delaunay triangulation of $P \cup Q$ has at most $O(n^{3/2} \log^3 n)$ edges. Section 5 studies the case of *Gabriel graphs*. The Gabriel graph of a set P of n points in $d \geq 1$ dimensions, denoted by $\mathcal{G}(P)$, has an edge between two points p and q in P if and only if the sphere whose diameter is pq encloses no point of P. We show that the size of $\mathcal{G}(P)$ in three dimensions can be $\Omega(n^2)$, and that it can be slimmed down by adding extra points, as in the case of Delaunay triangulations.

The idea of adding points to slim down the size of Delaunay triangulations has already been used in a paper of Chew [6], where he triangulates polygons without small angles, by finding sharp triangles in the constrained Delaunay triangulation of the polygon, and by adding new points at their circumcenters. After the original appearance of this paper [5], an improved and fairly complete solution to the slimming problem has been given by Bern, Eppstein, and Gilbert [3] (see also [2]), who showed that, in any fixed dimension, $O(n)$ points can always be added to any given set of n points, to reduce the size of the Delaunay triangulation of the combined set to linear in n. The technique of [3] is not really comparable to the approach taken here, and it does not supercede our main selection lemmas, which, as we believe, provide useful machinery for tackling other, unrelated geometric problems. Indeed, our selection results have been used in a companion paper [1] to derive an improved bound on the number of halving planes of a point set in three dimensions.

2. Selecting a point within rectangular boxes. The primary combinatorial tool used to prove the results of this paper is what we call the "selection lemma" (Lemma 2.1). This section formulates and proves this lemma and demonstrates its generalization to rectangular boxes in

$d \geq 2$ dimensions. Although we phrase the results in geometric terms, they are combinatorial in nature.

2.1. The selection lemma. To state the selection lemma we make the following definition. For two points $p < q$ on the real line we call $\beta_{pq} = \{x \mid p < x < q\}$ the *interval* of $\{p, q\}$. For any set V, we denote by $\binom{V}{2}$ the set of all unordered pairs $\{p, q\}$, for $p \neq q \in V$. The following lemma can also be found in [1], where generalizations different from the ones in this paper are studied.

LEMMA 2.1. *Let V be a set of n points on the real line and let $E \subseteq \binom{V}{2}$ be a set of m edges. For a point x not necessarily in V, let $E(x)$ denote any subset of the edges in E whose intervals contain x, define $m(E(x)) = |E(x)|$, and let $n(E(x))$ be the number of points incident to (i.e., endpoints of) edges in $E(x)$.*

(i) *There is a point x and a set $E(x)$ with $m(E(x)) \geq m^2/4n^2$.*

(ii) *There is a point y for which there is a set $E(y)$ with*

$$m(E(y))/n(E(y)) \geq m/\left(6n \log \frac{n^2}{m}\right).$$

Both bounds are tight up to multiplicative constants.[1]

Proof. We assume that $m \geq 2n$; otherwise both assertions hold trivially. In order to show (i) choose $k - 1$ points, none of which are in V, cutting the line into k intervals so that each contains no more than $\lceil \frac{n}{k} \rceil < \frac{n}{k} + 1$ points of V (k will be specified later). The number of edges whose intervals contain none of the $k - 1$ points is therefore at most $k\binom{\lceil \frac{n}{k} \rceil}{2} < (n^2 + nk)/2k$. Each of the remaining intervals contains at least one of the $k - 1$ points and there are at least $m - (n^2 + nk)/2k$ such intervals, which is at least $\frac{m}{2}$ if we choose $k = \lceil n^2/(m - n) \rceil$. By the pigeonhole principle one of the chosen points is contained in at least $m/2(k - 1) \geq (m^2 - mn)/2n^2 \geq m^2/4n^2$ intervals (it is only in the last inequality that we needed the assumption $m \geq 2n$).

It is easy to see that this bound is tight, up to the multiplicative constant. For given m and n let V consist of about $n^2/2m$ groups of about $\frac{2m}{n}$ consecutive points each, and let E contain only edges within but not across groups. Any point x can only be covered by the intervals within one group and there are at most about m^2/n^2 such intervals covering a common point.

To prove (ii), build an ordered minimum height binary tree whose nodes are the $k - 1$ chosen points (for the same k chosen in (i)), so that the tree inorder gives the points sorted from left to right. The height of the tree is $h = \lfloor \log(k - 1) \rfloor \leq 2 \log n^2/m$, as is easily verified. For a node y define $E(y)$ as the set of edges in E whose intervals contain y but no ancestors of y. In this way each edge whose interval contains at least one of the $k - 1$ points is counted exactly once. By what we said above we therefore have $\sum_y m(E(y)) \geq \frac{m}{2}$. Because each point can be incident to edges of at most one node per level we also have $\sum_y n(E(y)) < n(1 + h)$. Now suppose that $m(E(y))/n(E(y)) < m/(2n(1 + h))$ for each node y. But then

$$\sum_y m(E(y)) < \frac{m}{2n(1 + h)} \sum_y n(E(y)) < \frac{m}{2},$$

which is a contradiction. This implies that there is a point y with $m(E(y))/n(E(y)) \geq m/(2n(1 + h)) \geq m/\left(6n \log \frac{n^2}{m}\right)$.

The remainder of the proof shows that the lower bound in (ii) is tight, up to the multiplicative constant. The argument consists of two steps. For the first step consider the graph defined by the set of points $W = \{1, 2, \ldots, \ell\}$ and the set of edges $F = \{\{i, j\} \mid j - i \text{ is a power of } 2\}$.

[1] All logarithms in this paper are to the base 2.

Notice that $|F| = \Theta(\ell \log \ell)$. We show that the edges whose intervals contain some arbitrary point y form a forest by arguing that these edges cannot form a cycle. So assume there is a cycle of edges $\{i_0, i_1\}, \{i_1, i_2\}, \ldots, \{i_k, i_0\}$ whose intervals all contain y, and let i_0 be the point closest to y (we may assume that y is not an integer multiple of $\frac{1}{2}$ so i_0 is uniquely defined). By definition we have $|i_j y| < |i_{j+1} y|$ for $j = 0$ and we now argue that this is true in general. Assume it is true up to j. Because $|i_j y| < |i_{j+1} y|$ and the lengths of all intervals are powers of 2, $|i_{j+1} i_{j+2}| \geq 2 |i_j i_{j+1}|$ unless $i_{j+2} = i_j$, which is impossible because this would mean that an edge is reused. Consequently, the distances of the i_j from y strictly increase with increasing index, which contradicts the assumption of a cycle. Since every subgraph of a forest is again a forest and since every forest has more vertices than edges the above argument proves that the lower bound in (ii) is asymptotically tight for $m = \Theta(n \log n)$. Nothing has to be proved if m is even smaller than that.

The second step covers other ratios of m and n as follows. For each point $i \in W$ let V contain a group, G_i, of κ consecutive points, for κ some fixed positive integer. We also define $E = \{\{p, q\} \mid p \in G_i,\ q \in G_j,\ \{i, j\} \in F\}$. Now, $n = |V| = \kappa\ell$ and $m = |E| = \Theta(\kappa^2 \ell \log \ell)$ and therefore $\frac{m}{n} = \Theta(\kappa \log \ell)$. We show below that $m(E(y))/n(E(y)) \leq \kappa$ for every point y and every subset $E(y)$ of the set of edges in E whose intervals contain y. But this is equivalent to showing that (ii) is asymptotically tight because

$$\frac{m}{6n \log \frac{n^2}{m}} = \Theta\left(\frac{\kappa \log \ell}{\log \frac{\ell}{\log \ell}}\right) = \Theta(\kappa).$$

To show $m(E(y))/n(E(y)) \leq \kappa$ let $E(y)$ be a subset of the edges whose intervals contain y and let n_i be the number of points in G_i incident to at least one edge in $E(y)$. Define $F(y)$ as the set of pairs $\{i, j\} \in F$ so that $E(y)$ contains an edge $\{p, q\}$ with $p \in G_i$ and $q \in G_j$. Clearly, $m(E(y)) = |E(y)| \leq \sum_{\{i,j\} \in F(y)} n_i n_j$. By the argument of the previous paragraph, $F(y)$ defines a forest which implies the existence of a leaf i whose contribution to $\sum n_i n_j$ is therefore at most $n_i \kappa$. Since we can reduce a forest to the empty graph by repeatedly removing a leaf with its incident edge, we get $\sum n_i n_j \leq \kappa \sum n_i = \kappa n(E(y))$, thus proving that (ii) is asymptotically tight. □

Remarks. (1) Part (ii) of the selection lemma implies an inequality that is only slightly weaker than (i). To see this note that $m(E(y))/n(E(y))^2 \leq 1$, which implies $n(E(y)) \geq m/\left(6n \log \frac{n^2}{m}\right)$ using (ii). Using (ii) again gives $m(E(y)) \geq m^2/\left(36n^2 \log^2 \frac{n^2}{m}\right)$.

(2) The proofs of the lower bounds in the selection lemma are constructive. Assume the graph (V, E) is given with the points sorted from left to right. Point x can be found in time $O(m)$ by a single scan from left to right that keeps track of how many intervals cover the gap between the current two adjacent points. By a slightly more complicated algorithm we can also find a point y satisfying (ii) in time $O(m)$. The idea is to build explicitly the binary tree described in the proof above (see also [9]). We first build the tree in time $O(k)$ and then assign the endpoints of the edges to the gaps between the $k - 1$ points in time $O(m)$ during a left to right scan. From the gaps of its endpoints we get the leftmost and rightmost of the $k - 1$ points that lie in the interval of the edge and we get the lowest common ancestor of the corresponding two nodes, all in constant time (see [14]). It now remains to traverse all nodes of the tree and to select the best one. If the points in V are not presorted then points x and y can be computed in time $O(m + n \log n)$.

2.2. Rectangular boxes. For two points $p = (\pi_1, \pi_2, \ldots, \pi_d)$ and $q = (\phi_1, \phi_2, \ldots, \phi_d)$ in d dimensions we define

$$\beta_{pq} = \{x = (\xi_1, \xi_2, \ldots, \xi_d) \mid \pi_i < \xi_i < \phi_i \text{ or } \phi_i < \xi_i < \pi_i \text{ for } 1 \leq i \leq d\}$$

and call it the *box* of $\{p, q\}$. We now generalize Lemma 2.1 from intervals to boxes in d dimensions.

THEOREM 2.2. *Let V be a set of n points in $d \geq 1$ dimensions, so that no two coordinates of any two points in V are the same. Let $E \subseteq \binom{V}{2}$ be a set of $m \geq 2n$ edges. For a point x not necessarily in V, let $E(x)$ denote any subset of the edges in E whose boxes contain x, define $m(E(x)) = |E(x)|$, and let $n(E(x))$ be the number of points incident to edges in $E(x)$. Then there exists a constant $c_d > 0$ depending only on d such that the following holds.*

(i) *There is a point x and a set $E(x)$ with $m(E(x)) \geq m^2/\left(c_d n^2 \log^{2d-2} \frac{n^2}{m}\right)$.*

(ii) *There is a point y for which there is a set $E(y)$ with*

$$m(E(y))/n(E(y)) \geq m/\left(c_d n \log^d \frac{n^2}{m}\right).$$

Proof. We prove the theorem for $c_d = 6^{2^d-1}$ using induction over d; the base case, $d = 1$, is settled by the selection lemma. We remark that no effort is made to minimize c_d.

If $d \geq 2$ then project all points orthogonally onto the $(d-1)$-dimensional hyperplane $x_d = 0$. By the inductive assumption there is a point y' in this hyperplane and a subset $E(y')$ of the edges in E whose $(d-1)$-dimensional boxes (the projections of the boxes β) contain y' so that

$$\frac{m(E(y'))}{n(E(y'))} \geq \frac{m}{c_{d-1} n \log^{d-1} \frac{n^2}{m}}.$$

The edges whose $(d-1)$-dimensional boxes contain y' are such that their d-dimensional boxes intersect the line parallel to the dth coordinate axis that goes through y'. On this line we have a one-dimensional problem with $m(E(y'))$ intervals defined by $n(E(y'))$ endpoints. The selection lemma thus implies that there are points x and y with

$$m(E(x)) \geq \frac{m(E(y'))^2}{4n(E(y'))^2} \geq \frac{m^2}{c_d n^2 \log^{2d-2} \frac{n^2}{m}}$$

because $4c_{d-1}^2 \leq c_d$, and

$$\frac{m(E(y))}{n(E(y))} \geq \frac{m(E(y'))}{6n(E(y')) \log \frac{n(E(y'))^2}{m(E(y'))}} \geq \frac{m}{c_d n \log^d \frac{n^2}{m}}$$

because $6c_{d-1} \log(n(E(y'))^2/m(E(y'))) \leq 6c_{d-1} \log((n^2/m) \cdot c_{d-1} \log^{d-1}(n^2/m)) \leq c_d \log^d(n^2/m)$ if $d \geq 2$. □

Remarks. (1) Here is a purely combinatorial formulation of Theorem 2.2: Take a graph with vertex set $\{1, 2, \ldots, n\}$ and a set of m edges, and consider d permutations of the vertex set. Then it is possible to cut each permutation into a left and a right part so that there are "many" edges $\{i, j\}$ with i and j separated in each permutation. How many such edges there are is quantified as in Theorem 2.2.

(2) A noninductive proof of Theorem 2.2 can be given by choosing some k points in d dimensions and then using the pigeonhole principle directly. If the point set is based on the so-called d-fold rectangle or interval tree [9] then the same bounds as above can be derived.

(3) We have seen that the lower bounds of the (one-dimensional) selection lemma are tight up to the multiplicative constants. This is equivalent to saying that Theorem 2.2 is asymptotically tight for $d = 1$. Are the bounds of Theorem 2.2 asymptotically tight also for $d \geq 2$?

(4) Note that (ii) implies (i) up to a polylogarithmic factor. This is because $m(E(y))/(n(E(y))^2) \leq 1$ and therefore $n(E(y)) \geq m/\left(c_d n \log^d \frac{n^2}{m}\right)$ using (ii). Using (ii) again gives $m(E(y)) \geq m^2/\left(c_d^2 n^2 \log^{2d} \frac{n^2}{m}\right)$.

(5) Given a graph (V, E) with the points sorted along each axis, a point y satisfying Theorem 2.2 (ii) can be computed in time $\mathrm{O}(m)$. The algorithm that finds y within this time bound iterates the one-dimensional algorithm mentioned in remark (2) after the selection lemma, once for each dimension. A point x satisfying (i) can be constructed in the same amount of time. If no presorting is assumed then the time to find points x and y is $\mathrm{O}(m + n \log n)$.

3. Selecting a point within spheres. This section extends the selection lemma to circles, spheres, and other geometric objects. In §3.1 we consider spheres defined by antipodal point pairs. In §3.2 we generalize the result to the case where the sphere defined by two points is arbitrary as long as it passes through the two points. We say that a sphere *encloses* a point, or the point lies *inside* the sphere, if the point belongs to the open ball bounded by the sphere. Section 3.3 studies a sufficient but fairly general condition that allows a similar result as for spheres. Finally, §3.4 presents a curious application of our methods to a problem about points and angles.

3.1. Diameter spheres. Let V be a set of n points in $d \geq 2$ dimensions. The *diameter sphere* of a point pair $\{p, q\}$, δ_{pq}, for $p, q \in V$, is the smallest $(d-1)$-sphere that passes through both points. Thus, $z = (p+q)/2$, the midpoint between p and q, is its center and $\rho = \frac{|pq|}{2}$, half the distance between p and q, is its radius. Observe that for all points x in the box β_{pq} the distance to z is smaller than ρ. In other words, β_{pq} is enclosed in δ_{pq}. Moreover, if we rotate the coordinate axes, as necessary, we may assume that no two coordinates of any two distinct points in V are the same. The following result is therefore an immediate corollary of Theorem 2.2.

COROLLARY 3.1. *Let V be a set of n points in $d \geq 2$ dimensions and let $E \subseteq \binom{V}{2}$ denote any set of $m \geq 2n$ edges. For a point x not necessarily in V, let $E(x)$ be a subset of the edges whose diameter spheres enclose x, let $m(E(x)) = |E(x)|$, and let $n(E(x))$ be the number of points incident to edges in $E(x)$.*

(i) *There is a point x and a set $E(x)$ with $m(E(x)) \geq m^2/\left(c_d n^2 \log^{2d-2} \frac{n^2}{m}\right)$.*

(ii) *There is a point y for which there is a set $E(y)$ with*

$$m(E(y))/n(E(y)) \geq m/\left(c_d n \log^d \frac{n^2}{m}\right).$$

Remark. This result can also be interpreted in terms of angles $\angle pxq$, where p and q are points of V and x is an observation point. We consider all pairs $\{p, q\}$ and thus set $m = \binom{n}{2}$. Point x lies inside δ_{pq} if and only if $\angle pxq > \frac{\pi}{2}$. Thus, Corollary 3.1 implies that it is always possible to find a point x so that $\Omega(n^2)$ point pairs define an obtuse angle at x. Section 3.4 will elaborate on this interpretation and show a similar result for angles larger than $\frac{\pi}{2}$.

3.2. General spheres. Next we extend the result for diameter spheres to general spheres. For this extension we let V be a set of n points in $d \geq 2$ dimensions and E be a set of undirected edges between the points as usual. For each edge $\{p, q\} \in E$ we let σ_{pq} be an arbitrary but fixed $(d-1)$-sphere that passes through p and q. Unless $\sigma_{pq} = \delta_{pq}$, σ_{pq} intersects δ_{pq} in a great-$(d-2)$-sphere of δ_{pq}. Therefore, exactly half of δ_{pq} is enclosed by σ_{pq} and at least half of the ball bounded by δ_{pq} lies inside σ_{pq}. If we are lucky then point x (or y) of Corollary 3.1 lies in the halves enclosed by the spheres σ for a constant fraction of the diameter spheres.

In this case, the bounds of Corollary 3.1 are the same, up to a constant multiplicative factor, as for general spheres. Otherwise, almost all spheres do not contain x. We call σ_{pq} *anchored* if this is the case, that is, x does not lie inside σ_{pq} but it lies inside δ_{pq}. All anchored spheres must lie fairly close to x in the sense that the cone with apex x tangent to any such sphere has opening angle at least $\frac{\pi}{2}$. We will show how to select another point that is guaranteed to lie inside many of the anchored spheres. More precisely, we show the following theorem.

THEOREM 3.2. *Let V be a set of n points in $d \geq 2$ dimensions, and let $E \subseteq \binom{V}{2}$ be a set of $m \geq 2n$ edges. For a point x not necessarily in V let $m(E(x))$ be the number of edges whose spheres enclose x.*

(i) *There is a point x with $m(E(x)) \geq m^2/\left(c_d'' n^2 \log^{2d} \frac{n^2}{m}\right)$, where c_d'' is a positive constant that depends only on d.*

(ii) *There is a point y and a subset $E(y)$ of the edges in E whose spheres enclose y so that*

$$\frac{m(E(y))}{n(E(y))} \geq \frac{m}{c_d''' n \log^{d+1} \frac{n^2}{m}},$$

where $m(E(y))$ and $n(E(y))$ are defined as usual and c_d''' is some positive constant.

Proof. We prove only (i); claim (ii) can be proved in a similar manner, using Lemma 2.1 (ii) instead of (i). Let y be a point that lies inside many diameter spheres of the edges in E, where "many" is quantified as in Corollary 3.1 (ii). Thus, there is a subset $E(y)$ of the edges in E whose diameter spheres enclose y so that

$$\text{(1)} \qquad \frac{m(E(y))}{n(E(y))} \geq \frac{m}{c_d n \log^{d} \frac{n^2}{m}},$$

where $m(E(y)) = |E(y)|$ and $n(E(y))$ is the number of points incident to edges in $E(y)$. Let $\mathcal{S}$ be the set of spheres of edges in $E(y)$ that do not enclose y; so all spheres in $\mathcal{S}$ are anchored and we can assume that $|\mathcal{S}| \geq \frac{m(E(y))}{2}$.

To argue about y's view of the world we consider a sphere σ_y with center y and centrally project all centers of spheres in $\mathcal{S}$ onto σ_y. We can assume that no two centers project onto the same point on σ_y. Define a *cap* of σ_y as its intersection with a closed cone with apex y whose opening angle is $\frac{\pi}{6}$, that is, the cone consists of all points p so that the angle between the cone's axis and the half-line through p that starts at y is at most $\frac{\pi}{12}$. By a standard compactness argument, σ_y can be covered by a finite (i.e., constant) number, c_d', of caps [12]. Therefore, there exists a cap that contains a constant fraction of the projected centers. Let R be the half-line that is the axis of the corresponding cone C_R and let $\mathcal{S}_R$ be the set of spheres in $\mathcal{S}$ whose centers lie in C_R (that is, project to points in the cap). Since the opening angle of the cone with apex y tangent to any sphere σ in $\mathcal{S}_R$ is at least $\frac{\pi}{2}$, it easily follows that R intersects σ in two points which delimit an interval that is at least as long as the radius of σ. To see this it suffices to consider the two-dimensional cross section of σ with the plane spanned by R and by the center of σ. In this plane, the angle δ between R and the tangent from y to σ that is nearer to R (see Fig. 1) is at least $\frac{\pi}{4} - \frac{\pi}{12} = \frac{\pi}{6}$. However, $\delta = \frac{1}{2}s - \frac{1}{2}s'$, where s and s' are the two arcs of σ, measured in radians, delimited between R and the tangent line. In particular, this implies that the smaller arc cut off σ by R is $s + s' \geq \frac{\pi}{3}$, from which it follows trivially that R intersects σ in a chord whose length is at least the radius of σ.

At this point we face a one-dimensional problem on R. Intersect R with all open balls bounded by spheres in $\mathcal{S}_R$. This gives a set of at least $m(E(y))/(2c_d')$ intervals, and we want to show, using the selection lemma, that there is a point in many such intervals and therefore inside many spheres. The difficulty we have to cope with is that the intervals can have many

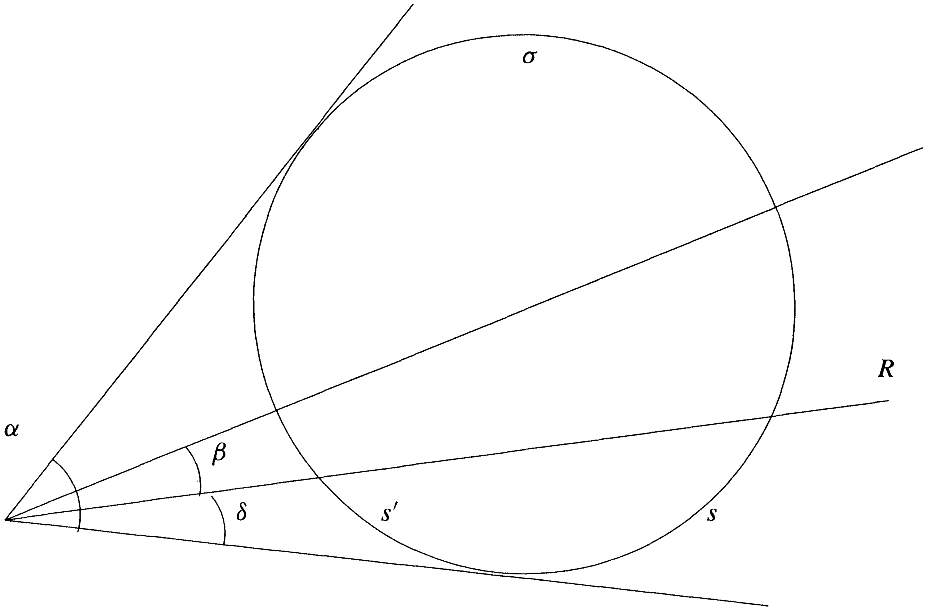

FIG. 1. *R intersects σ in a long chord.*

more than $n(E(y))$ endpoints. In fact, most likely there are twice as many endpoints as there are intervals. We show below that it is possible to replace each interval by an interval contained in it so that the total number of endpoints of the new intervals is at most $6n(E(y))$. Using Lemma 2.1 (i) it follows then that there is a point x contained in

$$m(E(x)) \geq \frac{m(E(y))^2}{4(2c'_d)^2(6n(E(y)))^2}$$

intervals. Together with (1) this implies

$$m(E(x)) \geq \frac{m^2}{c''_d n^2 \log^{2d} \frac{n^2}{m}},$$

where $c''_d = (24c_d c'_d)^2$.

We now show how to reduce the number of endpoints to $6n(E(y))$. Take all spheres in $\mathcal{S}_R$ that go through a common point $p \in V$ and intersect them with the (two-dimensional) plane h that contains R and p. Let $\sigma \in \mathcal{S}_R$ go through p and denote by $\bar{\sigma}$ the closed ball bounded by σ. Clearly, the radius of the circle $h \cap \sigma$ is smaller than or equal to the radius of σ. Furthermore, the interval $R \cap \bar{\sigma}$ is at least as long as the radius of σ because of the way R is chosen. Let a and b be the endpoints of this interval. Then the angle $\angle apb$ is at least $\frac{\pi}{6}$ (see Fig. 2). Hence, 12 half-lines starting at p suffice to stab all these angles, and at most six of them intersect R. These at most six half-lines stab all intervals of the form $R \cap \bar{\sigma}_{pq}$ with $\sigma_{pq} \in \mathcal{S}_R$, p fixed, and q arbitrary.

For the final argument we place at most six points for each one of the $n(E(y))$ points incident to edges in $E(y)$, which gives at most $6n(E(y))$ points on R. The interval $R \cap \bar{\sigma}_{pq}$ is guaranteed to contain at least one of the at most six points generated by p and at least one of the at most six points generated by q. We can thus replace $R \cap \bar{\sigma}_{pq}$ by one of the at most

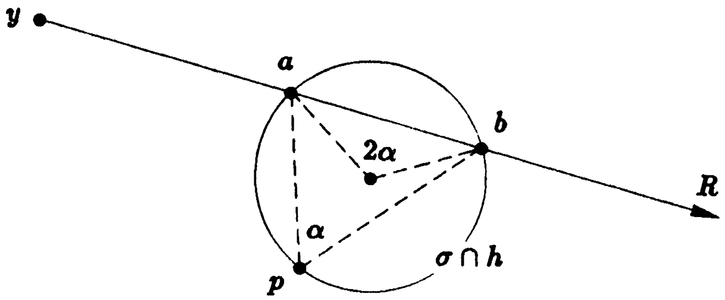

FIG. 2. *The angle formed by a, p, and b is equal to half the angle formed by a, the center of the circle, and b. Since the interval ab is at least as long as the radius of the circle, the latter angle is at least* $\frac{\pi}{3}$.

36 intervals defined by the 12 points generated by p and q and apply the selection lemma as described above. □

Remark. The proof of Theorem 3.2 is constructive and leads to an algorithm that computes a point x with the desired properties in time $O(m + n \log n)$. The first step of this algorithm finds a point y within the required number of diameter spheres (see remark (5) after Theorem 2.2). This takes time $O(m + n \log n)$. Second, a ray R that intersects many anchored spheres sufficiently close to their centers is determined by projecting centers of spheres onto the sphere σ_y around y, covering σ_y with a constant number of caps, and choosing the cap that contains the largest number of projected points. This takes time proportional to the number of projected centers, which is $O(m)$. Finally, the spheres whose centers project onto the chosen cap are intersected with R, thus the defined intervals are replaced by smaller intervals as described, and point x is selected in time $O(m + n \log n)$ in a single scan along R.

3.3. Round objects. A result similar to Theorem 3.2 can be established for a more general class of objects than just spheres. Let p and q be two points in $d \geq 2$ dimensions, let $|pq|$ denote their euclidean distance, and let c_0 and C_0 be two positive constants. A convex set τ_{pq} is said to be (c_0, C_0)-*round* (or simply *round*) for $\{p, q\}$ if

(i) p and q lie on the boundary of τ_{pq}, and

(ii) τ_{pq} contains a d-dimensional ball β_{pq} whose radius is at least $c_0|pq|$ and whose center is at a distance at most $C_0|pq|$ from p and from q.

For example, the ball bounded by the diameter sphere δ_{pq} of p and q is $(\frac{1}{2}, \frac{1}{2})$-round, and it is fairly easy to see that any ball with p and q on its boundary is $(\frac{1}{2}, \frac{\sqrt{2}}{2})$-round. With this definition we can show the following generalization of Theorem 3.2.

THEOREM 3.3. *Let V be a set of n points in $d \geq 2$ dimensions and let $E \subseteq \binom{V}{2}$ be a set of $m \geq 2n$ edges $\{p, q\}$, each associated with an round object τ_{pq}. For a point x not necessarily in V let $m(E(x))$ be the number of edges $\{p, q\}$ with $x \in \tau_{pq}$. Then there is a point x with $m(E(x)) \geq m^2 / \left(cn^2 \log^{2d} \frac{n^2}{m}\right)$, where c is a positive constant that depends on d, c_0, and C_0.*

Proof. To describe where this proof differs from the one of Theorem 3.2 we introduce two auxiliary objects: the ball β'_{pq} and the cone γ_{pq}. The ball β'_{pq} has the same center as β_{pq} and its radius is half of the radius of β_{pq}; the cone γ_{pq} is the convex hull of β_{pq} and p (see Fig. 3). Clearly, we have $\tau_{pq} \supseteq \gamma_{pq} \supseteq \beta_{pq} \supseteq \beta'_{pq}$.

When we construct the half-line R out of point y (defined as in the proof of Theorem 3.2), we make sure it intersects many of the balls β'_{pq} associated with edges in $E(y)$. Because of condition (ii), R can be found so that it intersects at least a constant fraction of the β'_{pq}.

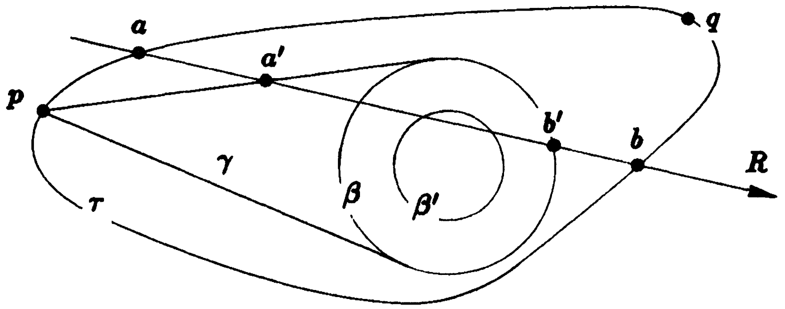

FIG. 3. *The edge $\{p, q\}$ defines an round object τ that contains γ, β, and β'. The half-line R intersects β'; its intersection with γ is $a'b'$ and with τ it is ab.*

Let us now fix our attention on a particular $\tau = \tau_{pq}$ and let a and b be the endpoints of the interval $R \cap \tau$. In order to complete the proof in the same way as the proof of Theorem 3.2 we need to show that the angle $\angle apb$ (and analogously $\angle aqb$) is at least some constant fraction of π.

Notice that the boundary of $\gamma = \gamma_{pq}$ consists of a fan of line segments that form the tangents from p to $\beta = \beta_{pq}$, as well as part of the boundary of β itself (see Fig. 3). Let a' and b' be the endpoints of $R \cap \gamma$; we will prove the stronger result that the angle $\angle a'pb'$ is at least some fixed fraction of π. If one of the points a' or b' lies on one of the line segments that form the tangents from p to β then the result is immediate: the angle subtended at p goes from the boundary of β at least as far as to some point of β'. By condition (ii) the balls β and β' look big from p, so this angle cannot be too small. On the other hand, if both a' and b' lie on the boundary of β then the result follows because $a'b'$ cannot be too short—in particular, it is longer than the radius of β.

We omit all further details, as they are the same as in the proof of Theorem 3.2. □

Remarks. (1) As follows from the above proof, it is not necessary to require that τ_{pq} be convex and that p and q lie on its boundary. All that is needed is condition (ii) and that τ_{pq} contains the cones γ_{pq} and γ_{qp} defined by β_{pq} and points p and q.

(2) It is also interesting to observe that condition (ii) is not sufficient to prove Theorem 3.3. Indeed a counterexample exists already in one dimension. Let $V = \{p_i = 2^i \mid 1 \leq i \leq n\}$ be the set of n points and for $i < j$ define $\tau_{ij} = \{x \mid (2p_i + p_j)/3 < x < (p_i + 2p_j)/3\}$. Thus, τ_{ij} has the same midpoint as the interval β_{ij} delimited by p_i and p_j and its length is one third of that of β_{ij}. However, for any $i < j < k$ we have $\tau_{ij} \cap \tau_{ik} = \emptyset$ because $(2^i + 2^{j+1})/3 < (2^{i+1} + 2^k)/3$. Thus, the set of $\binom{n}{2}$ intervals τ_{ij} can be partitioned into n subsets so that two intervals are disjoint if they belong to the same subset. It follows that there is no point x contained in more than n intervals τ_{ij}.

3.4. A problem about points and angles. For points p and q in d-dimensional space and for angle α, $\frac{\pi}{2} \leq \alpha \leq \pi$, define the *$\alpha$-football* of $\{p, q\}$ as the set

$$\phi_{pq}(\alpha) = \{x \mid \angle pxq \geq \alpha\}.$$

For example, $\phi_{pq}(\frac{\pi}{2})$ is the closed ball bounded by the diameter sphere δ_{pq}, and $\phi_{pq}(\pi)$ is the line segment pq. For general α, $\phi_{pq}(\alpha)$ is the intersection of all closed balls that contain p and q and have a fixed radius depending on $|pq|$ and α. If $\alpha < \pi$ is fixed, then $\phi_{pq}(\alpha)$ contains a ball centered at the midpoint between p and q whose radius is some fixed positive fraction of $|pq|$. Hence, $\phi_{pq}(\alpha)$ is round for $C_0 = \frac{1}{2}$ and $c_0 > 0$ (c_0 goes to zero if α approaches π) and Theorem 3.3 applies. We reformulate this result for the case where *every* pair of points defines an α-football and phrases it in terms of angles.

COROLLARY 3.4. *Let P be a set of n points in $d \geq 2$ dimensions and let $\alpha \geq \frac{\pi}{2}$ be a fixed angle strictly smaller than π. Then there exists a constant c depending on d and α and a point x so that $\angle pxq \geq \alpha$ for at least cn^2 pairs $\{p, q\} \in \binom{P}{2}$.*

Loosely speaking, point x is almost collinear with a constant fraction of the point pairs if α is insignificantly smaller than π, for example $\alpha = 179°$. In other words, x almost lies on each one of a constant fraction of the lines defined by the points.

4. Slimming down spatial Delaunay triangulations. This section deals with Delaunay triangulations for point sets in (three-dimensional) space. Let P be a set of n points in space and let $\mathcal{D}(P)$ be its Delaunay triangulation. For simplicity we assume that no five points are cospherical so that $\mathcal{D}(P)$ is uniquely defined. If this is not the case then it is always possible to enforce it by simulating an arbitrarily small perturbation of the points; see [11]. As mentioned in the introduction, $abcd$ is a tetrahedron of $\mathcal{D}(P)$ if and only if the sphere through points a, b, c, and d does not enclose any points of P.

For $0 \leq i \leq 3$, let f_i be the number of i-dimensional faces of $\mathcal{D}(P)$, that is, $f_0 = n$ is the number of vertices, f_1 is the number of edges, f_2 is the number of triangles, and f_3 is the number of tetrahedra of $\mathcal{D}(P)$. By Euler's relation we have $f_0 - f_1 + f_2 - f_3 = 1$ (see Hopf [15] for an elementary proof of this relation). Because every tetrahedron is bounded by four triangles and every triangle bounds at most two tetrahedra we also have $2f_3 \leq f_2$. This implies

$$f_3 \leq f_1 - n + 1 \quad \text{and} \quad f_2 \leq 2f_1 - 2n + 2. \tag{2}$$

We thus see that f_1, the number of edges of $\mathcal{D}(P)$, is a good measure of the combinatorial complexity of $\mathcal{D}(P)$. We call f_1 the *size* of $\mathcal{D}(P)$.

Depending on how the points are distributed, the size of $\mathcal{D}(P)$ can vary between linear in n and quadratic in n. An extreme example is when the points of P lie on the positive branch of the moment curve, $\mathcal{M} = \{(x, x^2, x^3) \mid x > 0\}$. Because a sphere intersects $\mathcal{M}$ in at most four points, which can be shown using Descartes' sign rule for the polynomial that arises, every point pair defines an edge of $\mathcal{D}(P)$. It follows that the size of $\mathcal{D}(P)$ is $\binom{n}{2}$ (see also [8]). The goal of this section is to show that no matter how badly P is distributed, there is always a small set Q of points in space so that $\mathcal{D}(P \cup Q)$ has size at most $O(n^{3/2} \log^3 n)$.

A sphere is called a *Delaunay sphere* of P if it is the circumscribed sphere of a tetrahedron $abcd$ of $\mathcal{D}(P)$. Using Theorem 3.2 we can show that if there are many Delaunay spheres, then there are many that enclose a common point.

LEMMA 4.1. *Let P be a set of n points in space defining t Delaunay spheres. There is a point x enclosed by $m(E(x)) \geq t^2 / \left(cn^2 \log^6 \frac{n^2}{t}\right)$ Delaunay spheres, for some positive constant c.*

Proof. Note that an edge ab is incident to as many Delaunay spheres as there are tetrahedra in $\mathcal{D}(P)$ that share ab; this number can be as large as $n - 2$. In order to apply Theorem 3.2 we match the edges of $\mathcal{D}(P)$ with the Delaunay spheres so that the Delaunay sphere matched with an edge passes through its endpoints and at least $\frac{t}{6}$ Delaunay spheres have a matching edge. We do this as follows. By definition, each Delaunay sphere is incident to six edges, and, by (2), there are at least t edges. Match an edge with an incident sphere arbitrarily and remove both from further consideration. Thus, there are at most five more edges that can no longer find a matching sphere. If we iterate this process we get at least $\frac{t}{6}$ matched pairs as required.

We thus arrive at a situation where we have n points and $m \geq \frac{t}{6}$ edges with a unique corresponding sphere each. Theorem 3.2 implies that there is a point x enclosed by at least

$$\frac{m^2}{c_3''n^2 \log^6 \frac{n^2}{m}} \geq \frac{t^2}{6^2 c_3'' n^2 \log^6 \frac{6n^2}{t}} \geq \frac{t^2}{cn^2 \log^6 \frac{n^2}{t}}$$

spheres, e.g., for $c = 6^8 c_3''$. □

If we add x to P then all tetrahedra whose circumscribed spheres enclose x disappear by definition. Lemma 4.1 thus implies that it is possible to destroy $\Omega\left(t^2/\left(n^2 \log \frac{n^2}{t}\right)\right)$ tetrahedra at once. However, x also gives rise to new tetrahedra. Because all new tetrahedra are incident to x we can bound their number from above as follows.

LEMMA 4.2. *Let P be a set of n points in space and x a point not in P. Then x is incident to at most $2n - 4$ tetrahedra in $\mathcal{D}(P \cup \{x\})$.*

Proof. Let σ be a sufficiently small sphere with center at x. If we intersect σ with the edges, triangles, and tetrahedra of $\mathcal{D}(P)$ we get a planar graph. Each vertex of this graph corresponds to an edge of $\mathcal{D}(P)$, and if σ is sufficiently small all such edges are incident to x. Because x is incident to at most n edges (at most one per point in P), the planar graph has at most n vertices and, by Euler's relation, at most $2n - 4$ regions. These regions correspond to the tetrahedra incident to x. □

What we said about Delaunay triangulations in space suggests the following algorithm for reducing the size of a Delaunay triangulation by adding points at well-chosen locations. Recall that $m(E(x))$ is the number of Delaunay spheres destroyed by adding point x.

Input. A set P of n points in space.
Output. A set Q of points in space so that $\mathcal{D}(P \cup Q)$ has at most $O(n^{3/2} \log^3 n)$ edges.
Algorithm.

```
Construct $\mathcal{D}(P)$ and set $Q := \emptyset$;
loop find a point $x$ that maximizes $m(E(x))$ in $\mathcal{D}(P \cup Q)$;
    if $m(E(x)) \geq 4n$ then $Q := Q \cup \{x\}$ and update $\mathcal{D}(P \cup Q)$ accordingly
                         else exit
    endif
forever.
```

Using Lemmas 4.1 and 4.2, one can establish the following result.

THEOREM 4.3. *For any set of n points P in three-dimensional space there is a set Q of at most $O(n^{1/2} \log^3 n)$ points so that the Delaunay triangulation of $P \cup Q$ has at most $O(n^{3/2} \log^3 n)$ edges. Such a set Q can be computed in time $O(n^2 \log^7 n)$.*

We omit here details of the analysis, because this result is less significant now, in view of the recent results of Bern et al. [3]. Interested readers are referred to an earlier and fuller version of this paper [5].

5. The size of Gabriel graphs. The Gabriel graph of a finite point set is a subgraph of the Delaunay triangulation that has applications in zoology and geography [13], [16]. Let P be a set of n points in $d \geq 1$ dimensions. The Gabriel graph of P, denoted by $\mathcal{G}(P)$, has an edge between two points p and q in P if and only if their diameter sphere, δ_{pq}, encloses no point of P. The definition implies that the edges of $\mathcal{G}(P)$ are a subset of the edges of the Delaunay triangulation. Thus, $\mathcal{G}(P)$ has only $O(n)$ edges when $d \leq 2$, and trivially at most $O(n^2)$ edges, otherwise. The bound is tight for $d \leq 2$, since each point is incident to at least one edge. The following lemma shows that the bound is also tight for $d > 2$.

LEMMA 5.1. *The maximum number of edges of the Gabriel graph of n points in $d \geq 3$ dimensions is $\Omega(n^2)$.*

Proof. We exhibit a set P of $2n$ points in three dimensions such that $\mathcal{G}(P)$ has at least n^2 edges. Embedding this example in higher-dimensional space proves the lemma for $d > 3$.

We place the points in two groups $\{a_i\}$ and $\{b_j\}$ on interlocking, orthogonal circles. Each circle passes through the center of the other, and the points on each circle are located near the center of the other circle. Each circle has radius 2. The points a_i lie near $(0, 1, 0)$ on a circle in the xy-plane centered on $(0, -1, 0)$. The b_j lie near $(0, -1, 0)$ on a circle in the yz-plane centered on $(0, 1, 0)$. To quantify "nearness" we use a small parameter ϵ:

$$a_i = (f(i), 1 - i\epsilon, 0) \quad \text{and} \quad b_j = (0, -1 + j\epsilon, f(j)),$$

where $1 \leq i, j \leq n$ and $f(k) = \sqrt{4k\epsilon - k^2\epsilon^2} < \sqrt{4k\epsilon}$. We show that for $\epsilon > 0$ sufficiently small, the diameter sphere determined by a pair $\{a_i, b_j\}$ contains no other points of P. The center of the sphere is

$$c_{ij} = \frac{a_i + b_j}{2} = \frac{1}{2}(f(i), \epsilon(j - i), f(j)).$$

We prove that the distance from c_{ij} to a point a_k (or b_k) is minimized when $k = i$ $(k = j)$. The square of the distance is

$$\begin{aligned}(a_k - c_{ij})^2 &= \frac{1}{4}((2f(k) - f(i))^2 + (2 - 2k\epsilon - j\epsilon + i\epsilon)^2 + f(j)^2)\\ &= \frac{1}{4}(16k\epsilon - 4f(k)f(i) + 4i\epsilon + 4 - 8k\epsilon - 4j\epsilon + 4i\epsilon + 4j\epsilon) + \mathrm{O}(\epsilon^2)\\ &= 1 + 2\epsilon(k + i) - f(k)f(i) + \mathrm{O}(\epsilon^2).\end{aligned}$$

Because $f(k)f(i) = 4\epsilon\sqrt{ki} + \mathrm{O}(\epsilon^2)$, we have

$$(a_k - c_{ij})^2 = 1 + 2\epsilon(k - 2\sqrt{ki} + i) + \mathrm{O}(\epsilon^2) = 1 + 2\epsilon(\sqrt{k} - \sqrt{i})^2 + \mathrm{O}(\epsilon^2).$$

For ϵ small enough, this quantity is minimized only when $k = i$. □

We can use Corollary 3.1 to reduce the size of Gabriel graphs. In three dimensions this gives a better bound than the one for Delaunay triangulations, which is based on Theorem 3.2.

THEOREM 5.2. *For any set of n points P in $d \geq 3$ dimensions there is a set Q of $O(n^{1/2} \log^{d-1} n)$ points so that the Gabriel graph of $P \cup Q$ has at most $O(n^{3/2} \log^{d-1} n)$ edges.*

Proof. Here is a sketch of the proof. By Corollary 3.1, if $m \geq 2n$, m the number of edges of $\mathcal{G}(P \cup Q)$, then there is a point x whose addition to Q deletes $m(E(x))$ edges from $\mathcal{G}(P \cup Q)$, where

$$m(E(x)) \geq \frac{m^2}{c_d n^2 \log^{2d-2} \frac{n^2}{m}}.$$

Adding a point to Q adds at most $|P \cup Q|$ edges to $\mathcal{G}(P \cup Q)$. Using an argument similar to that of §4, one can show that the number of edges of $\mathcal{G}(P \cup Q)$ can be reduced to $\mathrm{O}(n^{3/2} \log^{d-1} n)$ by adding points to Q. By reasoning similar to that used in the proof of Theorem 4.3, one can show that the algorithm of §4, modified for Gabriel graphs, produces a set Q of size $\mathrm{O}(n^{1/2} \log^{d-1} n)$. □

DISTRIBUTED ALGORITHMS FOR UNIDIRECTIONAL NETWORKS*

YEHUDA AFEK[†] AND ELI GAFNI[‡]

Abstract. This paper addresses the question of distributively computing over a strongly connected unidirectional data communication network. In unidirectional networks the existence of a communication link from one node to another does not imply the existence of a link in the opposite direction. The strong connectivity means that from every node there is a directed path to any other node. The authors assume an arbitrary topology network in which the strong connectivity is the only restriction. Four models are considered, synchronous and asynchronous, and for each node space availability, which grows as either $O(1)$ bits or $O(\log n)$ bits per incident link, where n is the total number of nodes in the network, is considered.

First algorithms for two basic problems in distributed computing in data communication networks, *traversal*, and *election*, are provided. Each of these basic protocols produces two directed spanning trees rooted at a distinguished node in the network, one called *in-tree*, leading to the root, and the other, *out-tree*, leading from the root. Given these trees, the authors efficiently transform bidirectional algorithms to run on unidirectional networks, and in particular solve other problems such as the broadcast and echo [E. J. CHANG, *Decentralized Algorithms in Distributed Systems*, Ph.D. thesis, University of Toronto, October 1979] in a way that is more efficient ($O(n^2)$ messages) than direct transformation (which yields $O(nm)$ messages algorithm). The communication cost of the traversal and election algorithms is $O(nm + n^2 \log n)$ bits ($O(nm)$ messages and time), where m is the total number of links in the network. The traversal algorithms for unidirectional networks of finite automata achieve the same cost ($O(nm + n^2 \log n)$ bits) in the asynchronous case, while in the synchronous case the communication cost of the algorithm is $O(mn)$ bits.

Key words. unidirectional, distributed algorithms, traversal, election

AMS subject classification. 68Q22

1. Introduction.

Distributed network protocols research has focused most of its efforts on bidirectional networks. However, unidirectional networks appear more often than expected. Unidirectional networks appear as a result of a failure of a link or a subset that disrupts communication in one direction but not in the other. For example, the modem circuit at one end could fail to receive (or send) data but still be operating correctly in the other direction. Networks with unidirectional links are also found in radio networks with asymmetric transmission matrices due to differences in transmission power of the stations, in fiber optics, and in very-large-scale integration (VLSI) [ELW90].

In this paper we consider both asynchronous and synchronous unidirectional networks. For election, a problem that we solve over these networks, each node needs at least $O(\log n)$ bits of memory, where n is the total number of nodes in the network. Our algorithms require as much. However, in solving the traversal problem we consider two possibilities of memory space availability. In one case a node has memory that grows logarithmically in n. In the other case the memory stays finite. More precisely, in the first model $O(\log\ n + d_v)$ bits of memory are available for the algorithm in node v, where d_v is the degree of node v. In the second model only $O(d_v)$ bits of memory are available at each node. Note that any distributed algorithm for a strongly connected unidirectional network is obviously also an algorithm for a bidirectional network.

1.1. Unidirectional network traversal—background.

In the traversal problem, one node, called the *root*, creates a token, which has to visit all the nodes in the network one at a time.

*Received by the editors May 29, 1992; accepted for publication (in revised form) June 21, 1993.

When the token arrives at a node the algorithm has to make two decisions: first, whether there are any more unvisited nodes in the network and second, in case there are, to which outgoing neighbor the token should be passed. This is similar to an on-line version of the "Chinese postman" problem: A postman is placed in a new city in which some or all the streets are one way. The postman has to traverse all the streets of the city but he has no map or any global information on the topology of the city. The question is to devise a strategy by which he will traverse the minimum number of streets, retracing streets as few times as possible.

There are two ways in which we can view the token. One view is that of a mail letter. It is going from place to place. The decisions about the route are made by a sequence of local post offices, while the letter may carry on it some "control information," e.g., an address. This view supports the traversal as handing over a token from node to node. The other is that of the postman above. It is the actual route decision-maker who passes from node to node, while being allowed to leave "marks" in various nodes. This view supports viewing traversal as a process (single thread of control program) that passes from node to node reading from and writing to the nodes. For convenience we will use these two views interchangeably.

Clearly, to be able to traverse a bidirectional network, the network has to be connected. Similarly, to traverse a unidirectional network, the network has to be strongly connected, i.e., there should be a directed path from every node to every other node. Message complexity of $\Omega(m)$ is obviously a lower bound to any traversal algorithm, where m is the total number of links in the network, since every link in the network has to be traversed. Otherwise an untraversed subnetwork could reside in the midst of any untraversed link.

The problem of distributively traversing a bidirectional network has been thoroughly investigated. One such obvious algorithm is based on the depth-first-search (DFS) algorithm [Tar72], [HT73]. In the resulting DFS traversal the process makes $2 \cdot m$ hops, and the number of memory bits it uses at each node is linear in the degree of the node.

In solving the unidirectional traversal problem we would like to adapt the bidirectional DFS traversal. However, DFS employs *backtracking*, i.e., a step in which the DFS process backtracks a link previously traversed in the forward direction. It is not obvious how to emulate backtracking in a unidirectional network. One of the contributions of this paper is such a backtracking scheme. It is facilitated by constructing, on the fly, a structure called an *in-directed forest*. With the help of the in-directed forest the process identifies a path that brings it from the head of the link which is to be backtracked to its tail. The construction of the in-directed forest is reminiscent of the strongly connected components algorithm of Hopcroft and Tarjan [HT73] (see also [Eve79]).

In §2, three traversal algorithms are presented. Traversal-1 is simple but inefficient. In many network instances the process of Traversal-1 makes an exponential number of link traversals before terminating. Traversal-2, which is based on the DFS algorithm, makes at most $O(n \cdot m)$ link traversals on any network (i.e., its time complexity is $O(n \cdot m)$). Furthermore, we show that $\Omega(n \cdot m)$ is, in general, a lower bound on the number of link traversals (time complexity). Both in Traversal-1 and Traversal-2 $O(\log n + d_v)$ bits of memory are required at each node v, and the traversing process carries along $O(\log n)$ bits. Both achieve the same complexity for synchronous and asynchronous networks.

In some applications, such as VLSI, memory size and message length are restricted and the question then arises, could a unidirectional traversal be implemented using only a constant number of bits in every node and with the traversing process carrying some finite amount of information (i.e., in a unidirectional network of finite automata).

Traversal-3 is the variant of Traversal-2 for finite automata network. In the asynchronous case it makes at most $O(n \cdot m + n^2 \cdot \log n)$ link traversals, which is optimal in the worst case (dense networks, in which $m = \Omega(n \log n)$). In the synchronous case it makes at most $O(n \cdot m)$ link traversals. Traversal-3 in the case of a unidirectional ring is an example of a problem whose complexity depends on whether the underlying system is synchronous or asynchronous [AFL83].

All the traversal algorithms yield a spanning infrastructure of the network consisting of two rooted spanning trees, one called an out-tree, in which paths are directed away from the root, and another called an in-tree, in which paths are directed to the root.

1.2. Unidirectional network election—background. In §3 we present a distributed algorithm for election in strongly connected unidirectional networks. The algorithm requires $O(\log n)$ bits of memory in each processor and its communication complexity is $O(n \cdot m + n^2 \log n)$ bits.

To design an election algorithm for strongly connected networks we employ Traversal-2. As a first attempt, consider the following straightforward approach: every initiator starts a traversal. Whenever a lower ID traversal learns about the existence of a higher ID one, it stops. The worst case communication complexity of this algorithm is $O((n \cdot m + n^2 \cdot \log n) \cdot n)$ bits, since $O(n)$ traversals could be initiated such that each spends $O(n \cdot m + n^2 \cdot \log n)$ bits. Clearly this approach is inefficient. As a second attempt, one can improve on it by using the modular technique of Korach, Kutten, and Moran [KKM85] to economically eliminate traversals. Using their technique, the communication complexity is reduced to $O((n \cdot m + n^2 \cdot \log n) \cdot \log n)$ bits, which is still a logarithmic factor away from our complexity. The election algorithm we design employs Traversal-2 as the underlying mechanism but uses it in a more sophisticated way to achieve a communication complexity of $O(nm + n^2 \log n)$ bits and $O(nm)$ time.

1.3. Related work. Although most of the results in this paper were derived in [GA84], before other works explicitly investigated unidirectional networks [ELW90], [GK84], [Kut88], [Kut84] (with the exception of [Kob78]), two bidirectional algorithms, the shortest path algorithm of Gallager [Gal76] and the connectivity checking algorithm of Segall [Seg83], both easily suggest unidirectional election algorithms. In [Seg83], Segall presents a connectivity checking algorithm in which at termination every node knows the IDs of all the other nodes in its connected component. The shortest path algorithm in [Gal76] exhibits the same property when it terminates. The communication complexity of the two algorithms is $O(n \cdot m \cdot \log n)$ bits, and each node is assumed to have $O(n \log n)$ bits of memory.

The suggested unidirectional variation of the two algorithms proceeds in two phases. In the first phase, every node acquires the IDs of its incoming neighbors; in the second, it acquires the IDs of all the other nodes in the network.

More specifically, let an *incoming* neighbor of node v be a node at the other end of an incoming link of v, and let *in-neighbors* of v be the set of all the incoming neighbors of v. Let the *record* of node v be a two-field data structure, of which the first contains the ID of v and the second the IDs of v's in-neighbors. In the first phase, every node transmits its ID on all its incident outgoing links and receives the IDs of its in-neighbors. In the second phase, every node broadcasts its record, via flooding, to all the other nodes in the network. For this purpose, each node v maintains two sets of IDs, the *received* set and the *known* set. The received set contains the IDs of the nodes whose records were already received by v. The known set contains IDs which appeared in a record of at least one node from the received set, i.e., IDs of nodes whose existence is known to v. Initially, at the beginning of the second phase, the received set of node v contains the ID of v, and the known set contains the IDs of v and of v's in-neighbors. Clearly, when the two sets in a node are identical, they contain the IDs of all the nodes in the network (which can easily be proved by induction).

The communication complexity of the algorithm thus described is $O(m^2 \cdot \log n)$ bits; however, assuming that messages sent over one link are received in the order transmitted, i.e., FIFO links, the communication complexity can be reduced to $O(n \cdot m \cdot \log n)$ bits by avoiding repeated transmission of the same ID over the same link. Note that for these algorithms each node is assumed to have $O(n \cdot \log n)$ bits of memory. Similar adaptation and analysis applies to [Gal76].

Our election algorithm is thus an improvement on the algorithms of Gallager and Segall in terms of both communication complexity and the number of memory bits required at each node. Furthermore, our algorithm produces the infrastructure of the in-tree and out-tree mentioned above, which neither Segall's FIFO link case nor Gallager's algorithms provide.

Following publication of this work Kutten [Kut84] independently developed a traversal algorithm for unidirectional networks. He considered only the logarithmic memory asynchronous model, for which he derived an $O(nm)$ messages algorithm [Kut88]. Gafni and Korfhage [GK84] designed an election algorithm for unidirectional Eulerian networks whose message complexity is $O(m \cdot \log n)$. A preliminary version of most of the results reported in this paper appear in [GA84].

More recently Even, Litman, and Winkler [ELW90] proposed a new approach to the problem of traversing a unidirectional synchronous network of finite automata. Assuming that the degree of each node in the network is constant (implying $M = O(n)$) they derive a traversal algorithm that runs in $O(n^2)$ time. They also study the firing squad problem in the synchronous network of finite automata, which is not addressed in this paper.

Interestingly, the results in this paper and in [ELW90] suggest that the unidirectional network of finite automata is inherently sequential. In the traversal algorithm of [ELW90] more than one message is sent in the network in a given time. However, it does not improve the time complexity or the communication complexity of our synchronous traversal algorithm for a network of finite automata, which sends at most one message in the network at any given time. Furthermore, notice that for increased space complexity at each node we were not able to improve the time complexity of the traversal algorithm. However, for the election problem and when the space at the nodes is increased to $O(n \log n)$ bits, the methods of Gallager and Segall can be used to improve the time complexity of our election algorithm but have worse communication complexity. It is interesting to consider whether there is a spectrum of time-space trade-off here.

Perhaps the first paper to consider the traversal problem in a unidirectional network of finite-automata was that of Kobayashi [Kob78], in which he presented an exponential complexity traversal algorithm that is based on the directed depth-first-search idea.

Organization of the paper. In the next section we present four traversal algorithms and, in §3, an election algorithm. In §4 we show how the traversal algorithms may be derived from the election algorithm and we discuss other applications of the various algorithms. Concluding remarks are given in §5.

2. Traversal of unidirectional networks.

2.1. Traversal-1: A simple traversal algorithm.

The first traversal algorithm presented is similar to the centralized algorithm of Fraenkel [Fra70] and is composed of two mechanisms: a termination detection mechanism, and a routing mechanism. The termination detection mechanism enables the traversing process to detect when it has traversed all the links in the network. The routing mechanism is used at each node to select the next link on which to send the process such that in a finite number of link traversals the process will detect termination.

The termination detection mechanism is implemented by a counter, called the *debt-counter*, which is carried by the process. The root starts the traversal by initializing the debt counter to zero and sending the process to itself. The counter is incremented by one as soon as the process arrives at a node for the first time (i.e., when the process is initially received by the root the counter is incremented to one). Then the counter value is tested; if its value is zero then the process is stopped at this node (see Fig. 1). Otherwise, the counter is decremented by one just before leaving a node through its last untraversed outgoing link. After leaving a node at least once through each of its outgoing links, the debt counter is never changed again at this node.

```
Response to receiving process($Debt\text{-}counter$) at node $v$
                    /* Also performed by the initiator with $Debt\text{-}counter = 0$ */
1.  If $v$ is unmarked
    then begin
2.      mark $v$
3.      $Debt\text{-}Counter := Debt\text{-}Counter + 1$ ;
    end
4.  else if $Debt\text{-}Counter = 0$ then stop;

5.  let $l$ be the next link in the cyclic order of $v$'s incident links.

6.  If $l$ is unmarked
    then begin
7.      mark $l$
8.      If $l$ is the last unmarked link of $v$
9.      then $Debt\text{-}Counter := Debt\text{-}Counter - 1$ ;
    end
10. Send the process($Debt\text{-}Counter$) over $l$
```

FIG. 1. *Traversal-1.*

LEMMA 2.1. *The debt-counter is equal to zero when it is tested* (*in line* 4 *in the code of Fig.* 1) *if and only if all links have been traversed.*

Proof. ($\leftarrow$) Clearly, for each newly visited node the process increments the counter by one. Similarly, for each visited node whose outgoing links have been all traversed, the process decrements the counter by one. Hence, when all links are traversed, the counter has been incremented and decremented the same number of times and is therefore back to its initial value.

($\rightarrow$) Assume that the counter is zero but not all the links in the network have been traversed. Since the network is strongly connected there is a directed path from a visited node to the tail node of any untraversed link. Let l be the first untraversed link on one of these paths. Thus, l is untraversed and its tail node v was visited. Hence, the counter was incremented at least once more (at v) than it was decremented, which leads to contradiction. □

The mechanism implied by Lemma 2.1 may serve as a termination detection mechanism. However, the process needs to employ a routing rule that will lead to termination. We present different routing rules, which lead to different traversal algorithms. These algorithms are presented in this and the next section.

The routing rule used by traversal-1 is as follows: every node orders its outgoing links cyclically, i.e., the first link in the order follows the last one. Each time that the process arrives at a node it is sent on the next outgoing link according to the cyclic order.

LEMMA 2.2. *Using the above routing rule the process eventually traverses all the links.*

Proof. Assume the contrary. Then, since the network is strongly connected and finite, there must exist a set S of nodes that have been visited infinitely many times. Thus by the routing rule each of the outgoing links of a node in S has been traversed infinitely many times.

Consequently, any node reachable from S has been visited infinitely many times. Since the network is strongly connected S is the whole set of nodes. Since each of the links outgoing from S has been traversed infinitely many times, and in particular each of the links has been traversed at least once, we have a contradiction. □

Lemmas 2.1 and 2.2 suggest the traversal algorithm of Fig. 1. Initially all nodes and links are assumed to be unmarked. To start the algorithm the root initiates a process with a debt-counter set to zero and sends the process to itself (i.e., it places the process in its input queue).

Figure 2 is an example of a network on which Traversal-1 requires 2^{n-1} link traversals. Let N_l be the number of traversals over link l in some execution of the algorithm. Clearly, $N_0 = 2 \cdot N_{1L} = 2 \cdot N_{1R}$ and $N_{iL} = 2 \cdot N_{(i+1)L} = 2 \cdot N_{(i+1)R}$ for $i = 1, \ldots, n-1$. Since N_{nL} and N_{nR} are both equal to 1 by the end of the traversal, $N_0 = 2^{n-1}$.

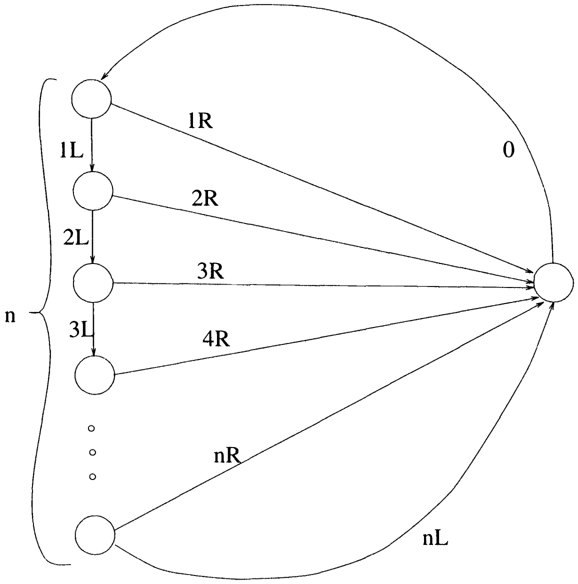

FIG. 2. *An example for the exponential complexity of Traversal-1.*

2.2. Traversal-2: Simulating directed depth first traversal. The source of Traversal-1's inefficiency is the routing procedure. A different routing rule is employed in this section to derive a traversal which requires $O(n \cdot m)$ link traversals.

We present the algorithm of Traversal-2 in three stages. First, a bidirectional depth first traversal algorithm is described. Second, a unidirectional implementation of the first algorithm is presented by assuming that a structure, called a *spanning in-directed tree*, is available. Finally, a mechanism to build the in-directed tree on the fly is given, thus providing a unidirectional traversal algorithm.

2.2.1. Bidirectional directed depth first traversal. Throughout the rest of the section we make a distinction between *unidirectional* and *directed* networks. A unidirectional network, as defined before, is a network in which some or all the links are unidirectional links. A directed network is a bidirectional network in which a unique direction is associated with each link. The link directions are given as part of the problem definition. Here we assume that the directed graph induced by the directions associated with the links is strongly connected.

In the bidirectional directed depth first search algorithm [HT73], the root spawns a process which visits all the nodes in the network. Upon arriving at node v for the first time, say through link l, the process marks v as *active*, l as the *parent link* of v, and iteratively traverses each of v's incident outgoing links. If the process arrives at an already marked node, it backtracks to the node from which it came. After backtracking on all of v's incident outgoing links, the process marks v as *fully backtracked* and backtracks from v on the parent incoming link, l. The traversal is completed when the root is marked fully backtracked.

A formal description of the algorithm is given in Fig. 3. Note that the process passed between the nodes is merely a token. It does not carry any information except its actual presence. Unlike this traversal, in the next sections we will use the process to carry control information between the nodes.

```
Initially all nodes and links are unmarked.
To start, the root $s$ performs:
    mark $s$ active ;
    select a link $l'$, outgoing from $s$ ;
    mark $l'$ active ;
    send the process over $l'$ ;

Response to receiving the process at node $v$ over incoming link $l$
If $v$ marked
then send the process back over $l$ ;
else
    mark $v$ active ;
    mark $l$ parent ;
    select a link, $l'$, outgoing from $v$ ;
    mark $l'$ active
    send the process over $l'$ ;
end

Response to receiving the process at node $v$ over outgoing link $l$
mark $l$ backtracked ;
If there is an unmarked outgoing link $l'$
then
    mark $l'$ active ;
    send the process over $l'$
else
    mark $v$ fully backtracked ;
    If there is no parent link
    then stop ;
    else send the process over the parent incoming link ;
end
```

FIG. 3. *The bidirectional directed depth-first traversal algorithm.*

The proof of the algorithm is a simple modification to the proof given in [Eve79]. The interested reader is referred to [Afe85] for the detailed proof. Here we state only the lemmas and corollaries.

LEMMA 2.3. *The bidirectional directed depth-first process traverses every link in the network at most once in each direction.*

COROLLARY 2.4. *The above traversal algorithm eventually terminates.*

LEMMA 2.5. *The bidirectional depth-first process traverses every link in the network once in each direction.*

COROLLARY 2.6. *The number of link traversals made by a traversing process in the bidirectional depth-first search is exactly* $2 \cdot m$.

2.2.2. Unidirectional depth first traversal, using a spanning in-directed tree.

The following two observations are used in this section to implement the bidirectional depth first traversal on a unidirectional network in which an in-directed spanning tree is defined. The resulting traversal makes $n \cdot m$ link traversals in the worst case.

Let the *parent node* of every node v, except the root, be the node from which the process arrived at v for the first time. At any given time, the link through which the traversing process left an active node most recently is called the *active link*.

Observation 1: The active nodes together with the active links form a directed path, called the *active path*. The first node on the active path is the root and the last link in the path either closes a cycle of active links (see Fig. 4), or leads to a node that is either fully backtracked or newly discovered. The most recently marked node among the active nodes is called the *focal point* of the traversal (e.g. see Fig. 4).

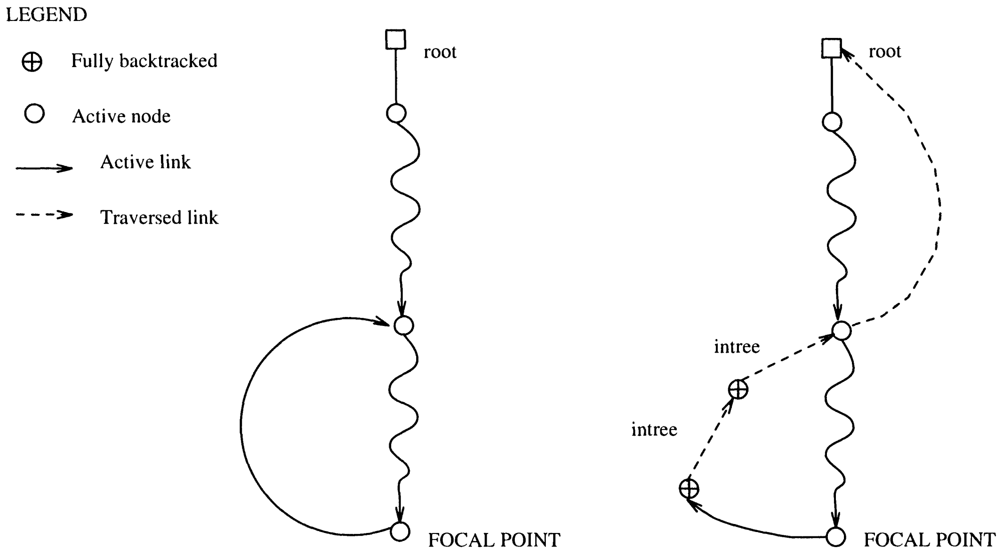

FIG. 4. *The active path.*

Observation 2: All backtracking is over the last link of the active path, i.e., either from an active node, or from a fully backtracked node to the last active node on the active path.

Observation 1 follows inductively from the fact that every node has at most one active outgoing link, and if it has one it must have an active incoming link (the parent link). Observation 2 follows immediately from Observation 1 and the algorithm.

An *in-directed tree* (or in-tree) is a subnetwork in which every node except one, called the *root*, has exactly one outgoing link, the underlying undirected graph is a tree, and all links are directed towards the root. An *in-directed spanning tree* is an in-tree which spans the network.

The difficulty in emulating the directed depth first traversal on a unidirectional network is that of emulating the backtrack, since links are unidirectional. In [Kob78], Kobayashi devised a solution to this problem with an exponential overhead, i.e., each backtracking incurred an exponential number of messages. To construct a linear overhead per backtracking, we note that whenever the process wants to backtrack over link l, a directed cycle, called the *backtracking cycle* is defined by concatenating l, the unique path in the in-tree from the head node of l to the root, and the active path. Thus, to backtrack over link l (from the head node of l to its tail node) the process goes along the backtracking cycle until it arrives at the tail node of l. To this end, the unique IDs of each node are used by the process to identify the tail node of l. Note that shortcuts are possible if the unique path of the in-tree intersects the active path before reaching the root (i.e., whenever the cycle is not simple). In particular, if the head node of l is active the process needs to follow only the active path in order to backtrack to l's tail node.

A formal description of the traversal algorithm is given in Fig. 5. The lines marked "I" are the code that the initiator has to execute in order to start the traversal.

To implement the backtracking mechanism, whenever the traversing process traverses link l from node v to node u it carries the ID of v. If u is unmarked (unvisited yet) then node u remembers that v is its parent. If node u is already marked, the process follows the cycle until it arrives back to v. When node u becomes fully backtracked the traversing process is sent along the backtracking cycle to u's parent.

LEMMA 2.7. *The number of link traversals made by a traversing process in the unidirectional depth-first traversal is a most $n \cdot m$.*

Proof. In Lemma 2.2 we saw that every link is backtracked exactly once. The lemma follows since in each such backtracking the process goes around a cycle of length at most n. □

In §2.5 it will be shown that $\Omega(n \cdot m)$ is also the lower bound on the number of link traversals.

2.2.3. On-the-fly in-tree construction. In this section we do away with the assumption that an in-tree is available by constructing the in-tree on the fly, while the process is traversing the network.

The essential use of the in-tree in the previous section was to backtrack from a fully backtracked node. Backtracking from an active node is accomplished simply by following the active path. While a node is active it computes its unique outgoing link in the in-tree, called *intree* as described below. While an active node may change its choice of the intree link, a fully backtracked may not. In this section we will maintain the following property throughout the algorithm execution.

Property 1: From any fully backtracked node, the unique path defined by following the intree marked links leads either to an active node, or if there are no active nodes, to the root.

The basic idea of the intree link selection is based on Property 1, above. We observe that the property is provided by maintaining a simpler property.

Property 2: From any fully backtracked node v the unique path defined by following the intree marked links leads to a node that was discovered before v (i.e., a node that would have a lower depth first number if such were assigned).

That is, at the time that v becomes fully backtracked (i.e., when its parent is still active) the intree links lead from v to some node u that is still active. The observation is that recursive applications of Property 2 ensure Property 1 (i.e., apply Property 2 to u, etc., as is formally stated and proved in Lemma 2.8).

Since the network is strongly connected, a path like the one required by Property 2 exists. Consider each backtracking cycle. Each such cycle consists of zero or more intree links and zero or more active links. If a backtracking cycle goes over an active link ($t \rightarrow h$), and it is the first time that a backtracking cycle goes over this active link, then from h's point of view, this cycle contains a path that leads from h to a node that was discovered before h was. Thus,

```
Response to receiving the traversal process, P, at node v:

If v is an unvisited node:
     v.parent := P.PreviousNode ;
I    v.activelink := any unused outgoing link ; {The "I" mark lines that are executed}
I    mark v active                                {by the root to start the algorithm}
I    P.PreviousNode := v.ID ;
I    send P over v.activelink ;

If v is an Active node and P is in the Forward mode:
     P.mode := backtrack ;
     P.FocalPoint := P.PreviousNode ;
     P.PreviousNode := v.ID ;
     send P over v.activelink ;

If v is an Active node and P is in the backtrack mode:
     if v.ID = P.FocalPoint
     then begin                          {v is the destination of the backtracking }
          if there are unused outgoing links
          then begin
               v.activelink := any unused outgoing link ;
               P.mode := Forward
          end
          else begin;                        {No more unused outgoing links : }
               mark v fully-backtracked ;
               if v has no parent then STOP;                    {v is the root }
               P.FocalPoint := v.parent ;
     end end
     P.PreviousNode := v.ID ;
     if v is still marked active
     then send P over v.activelink ;
     else send P over v.intree ;

If v is a Fully Backtracked node:
     if P.mode = Forward
     then begin
          P.mode := backtrack ;
          P.FocalPoint := P.PreviousNode ;
     end ;
     send P over the intree link ;
```

FIG. 5. *Traversal-2, the unidirectional depth-first traversal algorithm.*

the active links along the cycle, from h to the focal point, should be marked as intree links. Clearly such demarcation would not violate the property for descendants of h on the active path because this new intree path also provides them with Property 2.

To implement the above idea every node remembers whether or not its parent incoming link has already participated in a backtracking cycle. When the parent incoming link of node v participates in a backtracking cycle for the first time all the active nodes from v to the end of the active path select their present active link as their intree link. In the rest of this section a parent link which has never participated in a backtracking cycle is called a *bridge*.

Aside from the in-tree construction, the traversal is the same as the depth first traversal given in the previous subsection. It is assumed here that whenever a shortcut in the backtracking cycle is possible it is done, i.e., the backtracking cycle is a simple directed cycle.

The mechanism to construct the in-tree can be viewed as an approximation of the mechanism to determine the low-points of vertices in a directed graph, which was introduced by Hopcroft and Tarjan [HT73], [Eve79] in their algorithm for strongly connected components.

A formal description of the traversal algorithm, with the in-tree construction, is obtained by adding the code in Fig. 6 to the code in Fig. 5. The codes are combined in the following way. In case the traversal process arrives at an active node in the backtracking mode, then first the corresponding code in Fig. 6 is executed, and only then is the corresponding code of Fig. 5 executed. The lines that are marked by an "I" are the steps which the root executes in order to start the traversal.

```
Response to receiving the traversal process, P, at node ν:

If ν is an unvisited node:
        ν.BrdgHd := true;  {BrdgHd since ν's parent link have not yet been on a cycle }
        Continue with the code of Fig. 5 for the same case (unvisited ν)

If ν is an Active node and P is in the backtrack mode:
        if (ν.BrdgHd) and (P.PreviousNode =ν.parent)
        then begin              {1-st time that ν's parent link is on a backtracking cycle}
                P.XBrdg := true ;
                ν.BrdgHd := false ;
        end
        if P.XBrdg then ν.intree := ν.activelink ;
        if ν.ID = P.FocalPoint
        then P.XBrdg := false ;              {ν is the destination of the backtracking }
        Continue with the code of Fig. 5 for the same case (Active ν and
                                                         P in the backtrack mode)
```

FIG. 6. *Traversal-2, the additional code for the in-tree construction.*

In this algorithm node ν knows which of its incoming links is the parent link by recording the ID of the node on the other side of the parent link; this is the parent node of ν. The first time that a parent incoming link of node ν participates in a backtracking cycle is easily detected, because it is exactly the second time that the process arrives at ν through this link. To this end, a boolean variable, called BrdgHd (Bridge Head), is used at every node to indicate whether its parent incoming link is a bridge (i.e., if it has already participated in a backtracking cycle). Another boolean variable, called XBrdg (crossed bridge), is used on the traversing process to indicate whether the current backtracking cycle goes over a bridge. Whenever the process arrives at an active node ν in the backtracking mode, and the XBrdg indicator is on, ν selects its active link to be its intree link. Aside from BrdgHd, every node ν has the following fields: *ID*, which is the ID of ν; *parent*, which is the ID of the parent node of ν; *activelink*, which points to the activelink of ν; and *intree*, which points to the intree outgoing link of ν. Aside from XBrdg, the traversing process p, has the following fields: *mode*, which indicates whether the process is now backtracking or not; *PreviousNode*, which is the ID of the node that p visited last; and *FocalPoint*, which is used in the backtracking mode and is the ID of the backtracking destination node.

It remains to prove that the intree links selected by any fully backtracked node span all these nodes and always lead to an active node.

Let us define an *in-directed forest* as a collection of disjoint in-trees.

LEMMA 2.8. *The intree marked links of the fully backtracked nodes constitute an in-directed forest.*

Before proving the lemma we note the following two implications of its proposition. First, if there are still active nodes, then the roots of in-trees in the forest must be active nodes, which is exactly what we need for the backtracking process. This is because all the fully backtracked nodes have an intree outgoing link which obviously cannot lead to an unvisited node. Second, the proposition implies that when the algorithm terminates, the intree links constitute a spanning in-directed tree rooted at the traversal initiator, the root.

Proof of Lemma 2.8. The claim will be proved by induction. Clearly, the lemma holds when the algorithm starts at a time when no node is fully backtracked. It is also clear that the lemma holds when the first node to become fully backtracked, becomes fully backtracked, since one node with one outgoing link make up a legal tree. Assume that the claim holds just before node v becomes fully backtracked, and we will prove that it holds after v becomes fully backtracked.

If v is the root then the claim certainly holds, since v selects no in-tree link. Henceforth assume v is not the root, and when v becomes fully backtracked there is at least one active node in the network (the root).

Assume to the contrary that after v becomes fully backtracked the claim does not hold. Let B be the set of nodes which were already visited before v was visited for the first time. Let A be the set of nodes that includes v and all the nodes that were visited for the first time after v was, and before v became fully backtracked. Let L be the set of links which are directed from a node at A to a node at B. Clearly, $L \neq \emptyset$ since the network is strongly connected. By the definition of A and B there is no traversed link from B to A except the parent link of v, before v becomes fully backtracked. Thus, all the in-trees in B are rooted at active nodes in B and each backtracking cycle, C_l, which is associated with each $l \in L$ passes from B to A on the parent link of v. Clearly, at least one $C_{l,}$ $l \in L$, passed on a bridge (the parent link of v was a bridge when v was visited for the first time). Let link $l^* = (a \rightarrow b)$ be that link in L whose associated backtracking cycle, C_{l^*}, was the last cycle among the backtracking cycles associated with the links in L to pass over a bridge before v becomes fully backtracked.

Cycle C_{l^*} is used as a backtracking cycle for the first time when l^* is traversed for the first time, which is when a is still active. Since at this time C_{l^*} passes over a bridge, all the links from v to b on C_{l^*} must have been marked as intree links. Since no node in B becomes fully backtracked after v is visited and before v becomes fully backtracked, no intree mark of a node in B is changed at that period. Also, since C_{l^*} is the last backtracking cycle to pass over a bridge before v becomes fully backtracked, all the intree marks along C_{l^*} do not change before v becomes fully backtracked. Hence, the intree links that have been selected by v when v becomes fully backtracked cannot close a cycle of fully backtracked nodes and intree marked links, which is a contradiction. □

2.2.4. Reducing the communication complexity of Traversal-2 to O ($n \cdot m + n^2 \log n$) bits. In this section Traversal-2 is modified so in at most $2n - 2$ of its backtracking cycles the process will carry $O(\log\ n)$ bits around the backtracking cycle. In the rest of the backtrackings the process need not carry more than a constant number of bits. Thus the bit complexity is reduced from $O(n \cdot m \cdot \log\ n)$ to $O(n \cdot m + n^2 \cdot \log\ n)$. A variation of the traversal presented here is also presented in §4 in a much different setting.

The modification of the algorithm is as follows:

1. Every active node uses a boolean variable, called the *focal point*, to assert whether or not it is the focal point of the traversal. If the focal point variable of node v is false then v is not the focal point of the traversal. When v is visited for the first time it sets its focal point to true. When v becomes fully backtracked it sets its focal point to false.
2. Whenever the process arrives in the forward mode at an already marked node (i.e., an active node), v, a two-phase backtracking is started. In the first phase the process is sent around the backtracking cycle and back to v, counting whether there are one or more nodes on the backtracking cycle whose focal point is true. To this end only a constant number of bits has to be carried around by the process.
3. If only one node on the cycle has its focal point "on," then this node must be the node preceding v on the cycle (see Fig. 7, case 1), i.e., it is the backtracking destination. In this case, the process is sent around the backtracking cycle again with a constant number of bits, to the unique node which asserts itself as the focal point. Hence, a complete backtracking is performed with the process carrying only a constant number of bits.

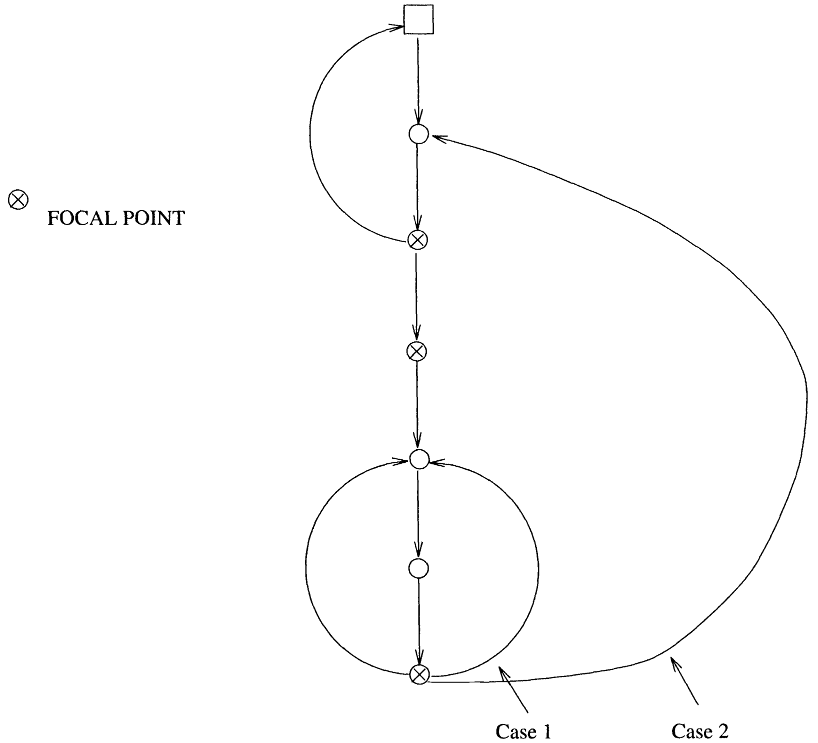

FIG. 7. *Backtracking in Traversal-3.*

4. If more than one node on the backtracking cycle has its focal point "on," then a bridge was included in the backtracking cycle (see Fig. 7, case 2) and a backtracking identical to the one used in Traversal-2 is initiated by v (with XBrdg set to true). In this phase of the backtracking all the nodes, aside from the last one on the active path, set their focal point to false. A bridge is included since the active link leaving any node whose focal point is true, aside from the last one, must have led to a new node

(i.e., it is the parent link of the next node on the active path) and has never been on a backtracking cycle before (otherwise the focal point would not have been true).

5. The backtracking from a fully backtracked node remains the same as in Traversal-2 except that the focal point of the destination is set to true.

The main claim of this subsection is given in the following lemma.

LEMMA 2.9. *By the above modification the process will have to carry $O(\log n)$ bits around a backtracking cycle only $2n - 2$ times.*

Proof. The process has to carry $O(\log\ n)$ bits around the backtracking cycle either when it backtracks from a fully backtracked node to its parent, or when the backtracking cycle goes over some bridge for the first time. Thus we can associate one such backtracking with each node that becomes fully backtracked, and one with each bridge. Clearly there are $n - 1$ nodes which become fully backtracked (except the root from which the process never backtracks). Similarly, there are $n - 1$ bridge links since each such link is the unique incoming parent link of some node (except the root which has no bridge link entering it). □

In the remaining $m - 2n + 2$ backtrackings the process carries only a constant number of bits. Since every backtracking requires at most n link traversals we get the following corollary.

COROLLARY 2.10. *The communication complexity of the modified Traversal-2 is $O(n \cdot m + n^2 \cdot \log n)$ bits.*

2.3. Traversal-3: An algorithm for a network of finite automata. In this section the assumption that every node has $O(\log\ n)$ bits of memory is relaxed. Instead, every node is assumed to be a finite automaton, i.e., to have constant size memory regardless of the network size, in which case the nodes do not have unique IDs. Since each node has a constant number of memory bits, the traversing process has to be of constant size too. We will show that with a constant size process the traversal requires at most $O(n \cdot m + n^2 \cdot \log\ n)$ link traversals, which is also the bit complexity of the algorithm. Note that the only nonconstant space used by Traversal-2 is the usage of $O(\log n)$ bits to carry the identity of the backtracking destination (this is also the only usage of the unique IDs) in each of the backtrackings considered in Lemma 2.9. Here we show how each of these backtrackings can be implemented by a constant size process which will go around the backtracking cycle $O(\log\ n)$ times.

To recognize the preceding node on the backtracking cycle using a constant size process, we use a solution to the following "last in the ring" puzzle: In a unidirectional ring of finite automata, design an algorithm by which a designated node, v, will distinguish the node preceding it, u, from all other nodes.

LEMMA 2.11. *The bit communication complexity of the "last in the ring" puzzle in an asynchronous ring is $\Theta(n \cdot \log\ n)$.*

Proof. A solution to the puzzle works in $\log n$ phases. Initially, all nodes except v are candidates for the position. In each phase we eliminate half of the remaining candidates by sending a token around the ring, alternately marking the candidate nodes even and odd. When the token arrives at v, it remembers the parity of the candidate preceding v. In the next phase, the token eliminates all candidates whose parity differs from the parity of the desired node. The last phase is detected by the token when it sees that only one node has not been eliminated. Thus, the token carries one more bit to indicate whether there are one or more nodes that have not yet been eliminated on the cycle. Hence, $O(n \log\ n)$ is an upper bound on the bit complexity of the puzzle.

To prove that this is also the lower bound we first claim that the sequence of bits transmitted over each link must be unique. Otherwise, there must be two distinct links, $u_0 \to u_1$ and $v_0 \to v_1$, such that both have seen the same sequence. Since the network is asynchronous, u_1 and v_1 are in the same state and both have generated the same sequences on their outgoing links, which implies that their down neighbors u_2 and v_2 are also in the same state. Continuing this argument inductively, we conclude that the node preceding the designated one has to be at an equal distance from both u_0 and v_0. This is a contradiction; hence, the sequence of bits transmitted over each link is unique. Since with $\lfloor \log(n) \rfloor - 1$ bits at most $n/2$ unique sequences can be written, over at least $n/2$ of the links $\Omega(\log n)$ bits were transmitted. Thus, $\Omega(n \log n)$ is also the lower bound. □

Thus, whenever node v becomes fully backtracked, or a backtracking cycle with more than one focal point is closed at v, v starts the algorithm described in the proof of Lemma 2.11 to send the process to the node preceding it. The total bit complexity of the traversal does not change with this modification; however, the number of link traversals made by the process is linear with the bit complexity of the traversal, i.e., $O(n \cdot m + n^2 \cdot \log n)$.

2.4. Traversal-4: An algorithm for a synchronous network of finite automata. Traversal-3 can be run on a synchronous network without any modification, in which case it will exhibit the same performances. The question arises whether any gains can be achieved in the synchronous model. To answer that question positively, we provide an $O(n \cdot m)$ time and bit complexities traversal algorithm for an arbitrary topology, unidirectional synchronous network, which matches our general case lower bound.

Following the proof of Lemma 2.9 and in the same spirit as §2.3, we show here how each backtracking from Lemma 2.9 can be implemented by a constant size process which goes around the backtracking cycle $O(1)$ times.

LEMMA 2.12. *The bit complexity of the "last in the ring" puzzle in a* synchronous *ring is* $\Theta(n)$.

Proof. $\Omega(n)$ is clearly a lower bound since a signal has to go around the ring from the designated node to the node preceding it.

An algorithm to match this lower bound uses two tokens that start moving around the ring from the designated node. The synchronous mode of communication is used to move one token at half the speed of the other token. The fast token makes one hop in each round of the computation, while the slow token makes one hop every two rounds. Both tokens are moving for $2n - 1$ rounds, after which the node preceding the designated node removes them from the ring. The fast token catches up with the slow token at the node preceding the designated node after going around two times. The node preceding the designated node is the first node to receive the fast token for the second time while holding the slow token (each node holds the slow token one extra round). To see this let f_t and s_t be the indices of the nodes holding the fast and the slow tokens, respectively, at round t. Clearly $f_t = t \bmod n$ and $s_t = \lceil \frac{t}{2} \rceil \bmod n$. The result follows since $n - 1$ is the lowest positive value of t at which $f_t = s_t$. □

2.5. Lower bounds. After arriving at the upper bounds of $O(n \cdot m + n^2 \cdot \log n)$ bits and $O(nm)$ bits on the communication complexity for traversal, we determine the lower bound. Much research is still needed on establishing tight lower bounds on the unidirectional traversal problem in general. In this section we present one step in this direction. We show that $\Omega(n \cdot m)$ is a lower bound on the number of link traversals required by a single token traversal, i.e., when the traversal is restricted to send at most one message at a time.

LEMMA 2.13. $\Omega(n \cdot m)$ *bits is the lower bound to a single token traversal of a unidirectional graph of arbitrary topology.*

Proof. The proof is by example; see Fig. 8. The result follows since each traversal of a link from A to B must be followed by a traversal of the path C. □

Lemma 2.13 proves that our traversal algorithm is optimal for dense networks (in which $m = \Omega(n \cdot \log n)$) and under the restriction that the traversal has at most one outstanding message at a time. Furthermore, it suggests that the algorithm is optimal in the general case.

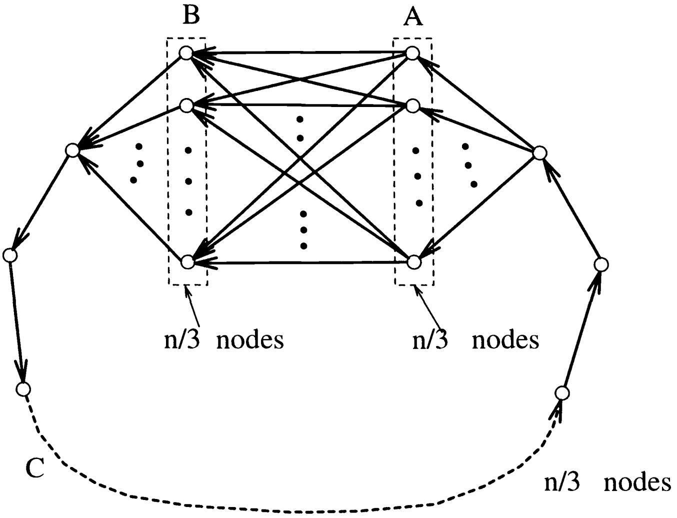

FIG. 8. *A network for the $\Omega(n \cdot m)$ lower bound.*

2.6. Producing a spanning out-tree. Traversals 2, 3, and 4, which are different implementations of the same algorithm, can be modified to produce a useful structure, called an *infrastructure*, on the network. The infrastructure is the combination of an in-directed spanning tree and an out-directed spanning tree. The in-tree construction was detailed in §2.2.3. Here we will describe how an out-tree may be produced by Traversal-2. Note that the defined infrastructure is a strongly connected subnetwork which spans the network and has $2n - 2$ links. The infrastructure proves to have several practical applications, outlined in §4.3.

An *out-directed tree* (or out-tree) is a subnetwork in which every node except one, called the *root*, has exactly one incoming link and the underlying undirected graph is a tree. Since every node in the out-tree has exactly one incoming link, there is a unique path from the root to every node in the out-tree. An *out-directed spanning tree* is an out-tree which spans the network. An example of an out-tree is given in Fig. 9.

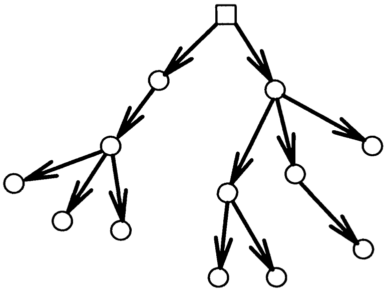

FIG. 9. *An example of an out-tree.*

We now explain how every node in the network marks some of its outgoing links *outtree* during the traversal algorithm such that, when the algorithm terminates, the collection of outtree marked links constitutes a spanning out-tree of the network rooted at the traversal initiating node.

To construct an out-tree we make the following observation: the collection of parent links constitutes an out-tree. To prove it note the following: (1) every node, except the root, has exactly one parent incoming link, and (2) going backward on the path defined by the parent links from any node v, we always arrive at the root. Note that (2) follows from the fact that the incoming parent link of any node v connects v to a node which was explored before v, thus we cannot close a cycle and we must arrive at the root.

To detect the parent outgoing links of node v we observe the following: the traversing process leaves node v twice or more through link l (in Traversal-2) while v is *active* if and only if l is a parent link. Thus, every *active* node counts whether or not each of its outgoing links has been on a backtracking cycle more than once. If a link participated in a backtracking cycle more than once while v is active then it is a parent link and is marked outtree.

3. Election in unidirectional networks.

In this section we present a recursive distributed algorithm for election in unidirectional strongly connected networks. One version of Traversal-2 (where an intree is assumed to exist in the network, see §2.2.2) is used as a tool in the construction of the election algorithm, while Traversals 2 and 3 with no a priori structures are a special case of the election algorithm, as shown in the next section.

3.1. Definitions and outline.

The election algorithm is based on the following recursive properties of strongly connected directed multigraphs:

1. The set of links, defined by selecting one outgoing link from every node, contains a nonempty set of disjoint directed cycles.
2. The subgraph, obtained from G by contracting any of the cycles defined above into one node, results in a strongly connected multigraph.
3. Repeated application of the operation in 1 and 2 contracts G into a single node.

The distributed algorithm proceeds in conceptual phases, which follow the above contraction process. When a cycle is detected, its nodes are grouped into a cluster. Similar phases are used in [Hum83]. Initially we consider each node to be a single node cluster. The phases of the algorithm are selection of an outgoing link from each cluster, called a *selected* link, detection of cycles among clusters, and contraction of cycles of clusters.

A cluster is recursively defined as follows:

1. A single node is a cluster.
2. A set of clusters that are joined in a ring by their selected outgoing links is a cluster.

Recursively we assume that every cluster satisfies the following four properties (see Fig. 10):

1. A unique node in the cluster is distinguished as the *cluster-head.*
2. All the nodes in the cluster know the ID of the cluster-head, which is also the *ID of the cluster.*
3. Each node in the cluster, except the cluster-head, has one outgoing link marked as *intree* link. The collection of intree links forms a directed incoming tree, spanning the cluster and rooted at the cluster-head.
4. A strongly connected subnetwork which spans the cluster, called the *infrastructure* of the cluster, is defined on the cluster.

The cluster head of the unique final cluster that contains the whole network is the elected leader. Clearly, a single node cluster satisfies the inductive assumptions. It is the cluster-head of itself, a single node in-tree, and a strongly connected subnetwork. To describe the algorithm we will describe the inductive step, i.e., we assume that a set of clusters which satisfy the assumptions already exists and explain how a bigger cluster which satisfies the inductive assumptions is composed out of this set.

To select a cluster outgoing link, each cluster head initiates a depth-first traversal (DFT) process (Traversal-2). The traversal process is used to search for a link which is potentially outgoing from the cluster. For the depth-first traversal algorithm we use the traversal algorithm developed in §2.2.2.

To detect a cycle, we use a simple algorithm for election on a unidirectional ring. Each cluster forwards the largest ID it has seen. When a cluster receives the same ID twice it has detected a cycle.

The contraction of a cycle is accomplished by first electing one of the cluster-heads on the cycle to be the cluster-head of the expanded cluster. Then, the newly elected cluster-head synchronizes the cluster by broadcasting the new cluster-ID to all the nodes and constructing all the inductive requirements on the new cluster.

The most expensive phase is the DFT in a search for a cluster outgoing link, because in the contraction phase we lose the DFT information accumulated by all the clusters around the cycle except one. When the cluster-head initiates a DFT in the next phase, the search will have to spend much effort regaining all the lost DFT information. However, by selecting the cluster-head of the largest cluster on the ring to be the new cluster-head, we minimize the amount of information lost. Thus, we limit the rate of information loss to the rate of cluster growth (i.e., if a large cluster were contracted with a small one, the amount of information lost is proportional to the size of the small one). In fact, we are able to show that the cost of all the DFTs conducted during the algorithm is within a constant factor of the cost of a single DFT. Since this point is critical to the complexity calculation, but rather minor to the description of the algorithm, we postpone a detailed discussion of it until the complexity section.

After a cluster is formed, its nodes are synchronized to search for an untraversed link outgoing from the cluster. To achieve this synchronization, the in-tree rooted at the cluster-head is used. When a cycle of clusters is contracted into a bigger cluster, all their in-trees are merged into one in-tree, spanning the new cluster. The operations of merging in-trees and searching clusters utilize each other alternately. The structures left by the DFTs are used to modify and merge the separate in-trees around the cycle into one in-tree. In turn, the in-tree in a cluster is used for routing purposes, by its DFT process (see §2.2.2.).

In the next three subsections we present the three phases of the algorithm, starting with the cluster outgoing link selection (see Fig. 10). During the algorithm, links are in one of three states: *new*, *elementary*, or *killed*. A *new* outgoing link is one which has not yet been traversed. An *elementary* link is a link which was a cluster selected outgoing link during one of the previous stages. The set of elementary links within one cluster forms the infrastructure of the cluster. A *killed* link is an already traversed link that has never been selected as the outgoing link of a cluster (i.e., an intra-cluster link that is not elementary).

3.2. Selection of a cluster—outgoing link. Once a cluster is formed, its head node initiates a DFT algorithm to search the cluster's infrastructure for a node with an untraversed outgoing link. The first such link to be found is selected as the cluster's outgoing link. If it turns out to be an intra-cluster link, the DFT continues where it was stopped in the search of another untraversed outgoing link. If no cluster outgoing link is found, the cluster contains all the nodes of the network and the algorithm terminates.

The cluster outgoing link selection phase begins after the synchronization of the cluster has terminated. The head node of the new cluster initiates a DFT token on the cluster's infrastructure. The token carries the ID of the cluster which created it and the maximum cluster-ID observed so far (maximum-ID). The cluster-ID is used to distinguish between inter- and intra-cluster links, and the maximum-ID is used to detect a cycle of clusters. The DFT token searches the cluster for a new link, i.e., a link that has never been used by the algorithm. In doing so, the DFT token leaves behind a trail of active links, which leads from the cluster-head to the token location (which is the traversal focal point).

Upon finding a new outgoing link, l, the token traverses link l to node v on the other end of l. If v belongs to the same cluster, the token returns to l's tail via the in-tree and the active path. Link l is then marked killed, and it will never again be traversed. If, on the other hand,

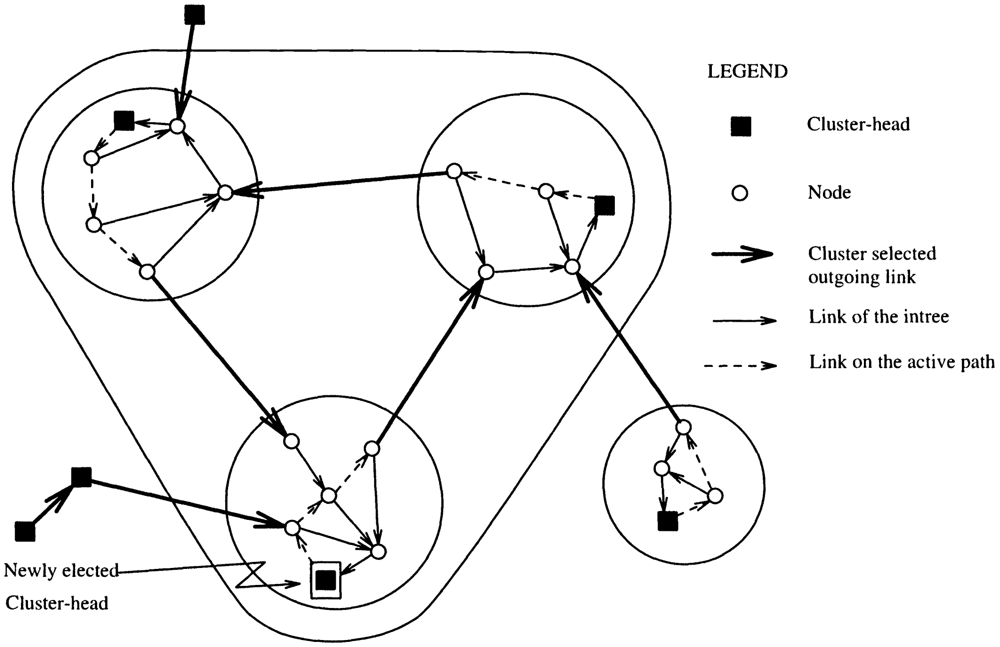

FIG. 10. *Clusters in the election algorithm.*

the token arrives at a different cluster, the information it carries and the newly selected link it has established enable the cycle detection to continue as described below.

3.3. Cycle detection. For the sake of simplicity, we have selected an inefficient algorithm for cycle detection. Since its complexity is, in general, not the bottleneck, we have avoided discussing an improved mechanism for cycle detection (the improvements are a generalization of [Pet82], [DKR82], with which our algorithm will perform optimally on rings).

After each cluster selects an outgoing link, the network contains at least one cycle which consists of two or more clusters (see Fig. 10). Let each cluster send its ID on the cluster outgoing link. A cluster forwards another cluster-ID only if it is larger than all the cluster-IDs it has received in the past. Eventually, one and only one cluster in each cycle will receive the same cluster-ID twice, thus detecting a cycle. The cluster-head that detected the cycle synchronizes the new cluster.

The operation of cycle detection is carried out by the cluster-heads. To implement it, each node receiving a message from a different cluster forwards it to its cluster-head through the cluster's in-tree. To forward a maximum-ID from a cluster-head to the next cluster, the cluster-head broadcasts the maximum-ID over the infrastructure of its cluster. All nodes (including the cluster-head) retain a maximum-ID variable, which is updated by the maximum-ID of the broadcast message. The DFT token updates its maximum-ID to the largest it encounters along its way. If a cluster outgoing link has been selected, the broadcast message is simply forwarded over the outgoing link to the next cluster.

When a cluster-head receives a maximum-ID which is equal to its own, it has detected a cycle and it is elected to start the synchronization phase.

3.4. Cycle contraction and cluster synchronization. In the cycle detection phase a new cluster with an elected cluster-head was found. In this phase the elected cluster-head establishes the remaining three inductive assumptions on the new cluster. The elected cluster-head thus (1) notifies all the nodes in the clusters around the cycle of their new cluster-ID,

(2) combines the in-trees of all the clusters into one in-tree which spans the new cluster and is rooted at the elected cluster-head, and (3) combines the infrastructures into one infrastructure spanning the new cluster. After receiving a positive acknowledgment that all the nodes have completed these constructions, the elected cluster-head starts the next phase of cluster outgoing link selection. The synchronization phase is carried out by a broadcast with echo mechanism on the cluster new infrastructure.

Upon receiving the first copy of the broadcast message, every node performs the following five operations in the following order: (1) It updates its own cluster-ID. (2) If one of its links is a selected cluster-outgoing link then it marks that link as elementary and sends a message to this effect over that link. Every node maintains a list of its incoming elementary links, which it updates on the reception of such messages (this list is necessary for the echo phase of the broadcast and echo described below). (3) It updates (if necessary) its intree mark. (4) It forwards copies of the broadcast message over its elementary outgoing links. (5) It acknowledges the reception of the message through the in-tree. Any duplicate copies of the message are discarded.

The second operation combines the infrastructures into one infrastructure which spans the new cluster.

Merging the in-trees. To merge all the in-trees around the cycle, we use the active paths in each cluster which lead from the cluster-heads to the head nodes of the selected outgoing links. The active paths are constructed during the DFT in the cluster's outgoing link selection phase (see §2.2.2).

We notice that if each node of a cluster that has an active outgoing link puts its intree mark on the active link, then the incoming spanning tree is rerooted to the *head* node of the cluster outgoing link (see Fig. 11). (Note that the head node of the cluster outgoing link belongs to the next cluster on the cycle of clusters.) To obtain a directed in-tree which spans all the clusters around the cycle, we perform this operation in all the clusters around the cycle except for the elected cluster. Thus, the in-tree formed is rooted at the elected cluster-head. This in-tree is used by the nodes to notify their new cluster-head of the contraction termination.

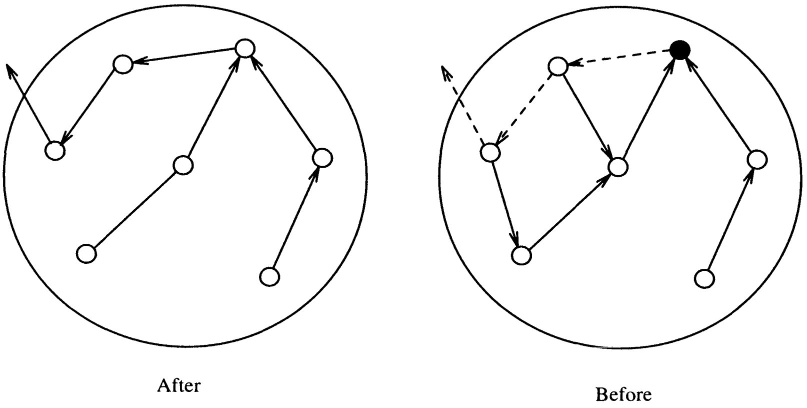

FIG. 11. *Rerooting an in-tree.*

Acknowledging the broadcast. To notify the cluster-head that all the nodes in the new cluster are aware of their new cluster-ID, every node sends an acknowledgment as follows. After receiving the first copy and making all the necessary updates, every node sends an acknowledgment over all the elementary outgoing links aside from the intree marked link. An acknowledgment is sent over the intree marked outgoing link only after an acknowledgment has been received on all the elementary incoming links.

When the elected cluster-head has received the acknowledgment message over all of its elementary incoming links, the contraction has terminated, and a new phase of cluster outgoing link selection is started.

To prevent messages with new and larger maximum-IDs from being lost during the contraction phase we specifically forward them as follows. First, every node that receives a new and larger ID forwards it to its cluster-head in a special message. Second, when a cluster-head broadcasts a new and larger maximum-ID it also does it in a specifically marked message. These messages are not destroyed by the contraction operations unless they encounter a node with a larger maximum-ID. Moreover, any new and larger maximum-ID which arrives at the cluster-head that has detected the cycle (in such a special message) during the synchronization phase is held back by this cluster-head. It is redelivered to the cluster-head upon termination of the synchronization broadcast and echo.

Termination. The algorithm terminates when a cluster fails to select a cluster-outgoing link. This cluster spans the whole network; its cluster-head is the elected node and its maximum-ID is the largest ID.

3.5. Complexity of the election algorithm. Communication complexity analysis involves counting the total number of bits transmitted over all the network links. The communication cost of the algorithm has three components: the cost of cluster synchronization, the cost of cycle detections, and the cost of cluster-outgoing link selection.

We observe the following two facts.

Fact 1: The number of cycle detections is at most $n - 1$.

Fact 2: In a cluster of size k, there are at most $2k - 1$ *elementary* links.

Fact 1 holds because the contraction of a cycle strictly reduces the network size. Fact 2 follows from Fact 1 and the observation that there exists a one-to-one correspondence between clusters and elementary links.

LEMMA 3.1. *The total cost of synchronizing the clusters is at most $O(n^2 \log n)$ bits.*

Proof. According to Fact 1 there are at most $n-1$ cluster synchronizations. The synchronization messages propagate on the infrastructure of a cluster which contains at most $2n - 1$ links. In each synchronization one broadcast message and one echo message are transmitted on each elementary link. Since each message is of size $O(\log n)$ bits the result follows. □

LEMMA 3.2. *The total cost of all cycle detections is at most $O(n^2 \log n)$ bits.*

Proof. Each time a new cluster-head is elected a new maximum-ID is sent around a cycle of clusters. Thus, by Fact 2, there are at most $2n - 2$ maximum-ID initiations. Each such initiation is sent over the infrastructure of some cluster. The same maximum-ID is forwarded at most three times on the same link in a particular cluster: once when it enters the cluster and the link is an in-tree link on which it was forwarded to the cluster-head; once when the cluster-head broadcasts the maximum-ID; and once on its return to that cluster-head (which then detects a cycle). Since a link forwards the same maximum-ID at most three times for each cluster it belongs to, the result follows. □

The cost involved in selecting outgoing links consists of the cost of killing inter-cluster links and the cost of the DFTs.

To kill link l, the algorithm transmits one message of $O(\log n)$ bits over l and a kill message of size $O(1)$ bits over a path from the head of l to its tail. The kill message goes down the in-tree to the cluster-head and then along the active path to the tail of l. This node is distinguished from other nodes on the active path since it is the focal point of the DFT. Thus, the killing of one link costs $O(n)$ bits. Since the algorithm kills, at most, m links, the killing of intercluster links adds up to, at most, $O(n \cdot m)$ bits.

As mentioned, the cost of one DFT on a network with n nodes and m links is $O(n \cdot m \cdot \log n)$ since there is one backtracking for each link of the network and each backtracking costs $O(n \log n)$. The DFT operation is employed in the election algorithm to search the infrastructures of different clusters. Since there are, at most, twice as many links as nodes in an infrastructure, the cost incurred by each DFT of a cluster with k nodes is $O(k^2 \log n)$. As the DFT could be used $n - 1$ times by the algorithm, the total cost of all DFTs might be $O(n^3 \log n)$.

To reduce the total cost of all DFTs from $O(n^3 \log n)$ bits, a special *cluster-head election* phase is added after the cycle detection and before the synchronization phases. In this phase the cluster-head which is elected in the cycle detection phase synchronizes the election of the cluster-head of the largest size cluster around the cycle. The new cluster-head then proceeds with the cluster synchronization phase as described before. After synchronizing the cluster, the cluster-head resumes its DFT process from the previous stage, i.e., from the head node of its former cluster outgoing link, thus avoiding re-searching nodes that were already searched. The head node of its former cluster outgoing link is now the last node on the active path.

Cluster-head election. To elect a cluster-head of a largest size cluster (ties are resolved by cluster-IDs), the cluster-head detecting the cycle sends an elect-message around the alternating sequence of active paths and in-trees which form a directed cycle (see Fig. 10). On its way, the elect-message finds out which cluster has the largest number of nodes and what the total number of nodes in all the clusters around the cycle is. This information is updated on the elect-message by the cluster-heads along the directed cycle.

Once the elect message returns to the originating cluster-head, the control of cluster synchronization is passed to the newly elected cluster-head. Any new and larger maximum-ID which arrives at the cluster-head detecting the cycle during the election and the synchronization phase is held back by this node. It is delivered to the new cluster-head upon the reception of the synchronization broadcast.

After being elected, the new cluster-head resumes its DFT of the previous cluster outgoing link selection phase. In doing so it uses the active path and the node marks which its DFT had left. The algorithm thus can be viewed as a process in which all the cluster-heads are candidates for leadership. When clusters owned by different candidates form a cycle, the candidate which owns the largest size cluster eliminates all the other candidates. In doing so the candidate merely has enlarged its cluster to include the clusters of the candidates it has eliminated. The DFT structures it had in its original cluster are now extended to search the enlarged cluster. Henceforth, we refer to the clusters which did not change their cluster-ID as one cluster which has consumed other clusters during the algorithm.

The above scheme is similar in principle to the capturing rule of [Gal77] and algorithm A in [AG91]. There we enabled the largest candidate, in terms of captured nodes, to kill and take nodes from a smaller candidate. To see that the above scheme does not add more than a constant factor to the complexity of a single DFT, we will use a lemma which was introduced in a similar context by Gallager [Gal77].

LEMMA 3.3. *For any given k, the number of clusters that own n/k nodes or more is, at most, k.*

Proof. Let C_1 and C_2 be any two clusters which had size n/k at some point of time. We shall show that each of C_1 and C_2 must have had n/k nodes disjointly. If they have never consumed each other, we are done, since the clusters were certainly disjoint. If, w.l.o.g., C_1 has consumed C_2, then C_1 must have already had n/k nodes at the time of eliminating C_2. □

COROLLARY 3.4. *The largest cluster to be consumed by another cluster owns at most $n/2$ nodes, the next largest at most $n/3$, etc.*

Thus, we arrive at the following lemma.

LEMMA 3.5. *The total cost of the* DFT *is* $O(n^2 \log n)$ *bits.*

Proof. The cost of traversing a cluster of size k is at most $k^2 \log n$ bits. Hence, the total cost is bounded by $\sum_{i=1}^{n}(\frac{n}{i})^2$ messages. But $\sum_{i=1}^{n}(\frac{n}{i})^2 \leq \sum_{i=0}^{\lfloor \log n \rfloor} 2^i \cdot (\frac{n}{2^i})^2 = \sum_{i=0}^{\lfloor \log n \rfloor}(\frac{n^2}{2^i}) \leq 2n^2$. Hence, the bit complexity of the depth-first traversals is $O(n^2 \cdot \log n)$ bits. □

Adding the bit costs of all three components, we arrive at a total communication complexity of $O(n^2 \log n + n \cdot m)$ bits for the whole algorithm. By the arguments presented in §2.5 we conjecture that this is also the lower bound on the communication complexity of the election problem on arbitrary topology, strongly connected unidirectional networks.

4. The traversal algorithm as a special case of the election algorithm. In this section we show how Traversals 2 and 3 can be derived as a special case of the election algorithm. Imagine the behavior of the election algorithm when it is started by a single node. In this case, the initiator initiates a process which visits all the nodes in the network and terminates. In the first subsection we show that the process can be modified to behave exactly like the process in Traversal-2. In §4.2 we show how Traversal-3 can be derived from the election algorithm.

The process of deriving the traversal algorithms from the election algorithm provides a constructive proof of Lemma 2.8.

4.1. Deriving Traversal-2 from the election algorithm. Assuming that only one node initiates the election algorithm, we make the following observations.

Observation 1: At any given time, at most one cluster is searched, i.e., no messages are exchanged in any of the other clusters.

Observation 2: All the clusters and their selected outgoing links form a simple directed path in which each cluster is a node and each link is a selected outgoing link. This path, called the *clusters active path*, occasionally closes on itself (see Fig. 12). When the path closes either a cycle of clusters is formed, or the last link on the path is an intra-cluster link (in the last cluster on the path, see Fig. 12, cases 2 and 1, respectively).

Observation 3: Consider the cluster's active path when it does not close on itself. Then, the nodes at which the cluster's active path enters other clusters are the first nodes to be explored in each cluster. Therefore, if these nodes were selected as the cluster-heads of their clusters, the active paths of all the clusters would form a single contiguous path at all times.

We now modify the election algorithm according to the above observations, that is, in each cluster the first node to be explored is elected as the cluster-head. Cycle detection (case 2 in Fig. 12) occurs when the token leaves one cluster C_1 (by traversing its selected outgoing link for the first time) and arrives at another, previously explored, cluster C_2. Recalling the third observation, the cluster-head of C_2 is the "oldest" node on the newly formed cycle of clusters. This cluster-head (h) synchronizes the cycle of clusters and is elected to be the cluster-head of the new cluster. Also (from the third observation), the active paths around the cycle form a single contiguous path. If the synchronization phase is modified to leave all the active paths intact, the distinct DFTs may be considered as one DFT. Thus, the newly elected cluster-head h resumes a DFT which already has an active path going through all the clusters around the cycle. As a result, no node in the network is searched more than once during the whole algorithm. The cluster-head resumes the DFT at the node in which the cycle was detected (the LOOP node in Fig. 12, case 2).

The above variation of the election algorithm can be viewed as a traversal process. One node spawns the process which terminates at the initiator after it visits all the nodes in the network one at a time. This traversal process can be further modified to work on a unidirectional network of finite automata, as we show in the next section.

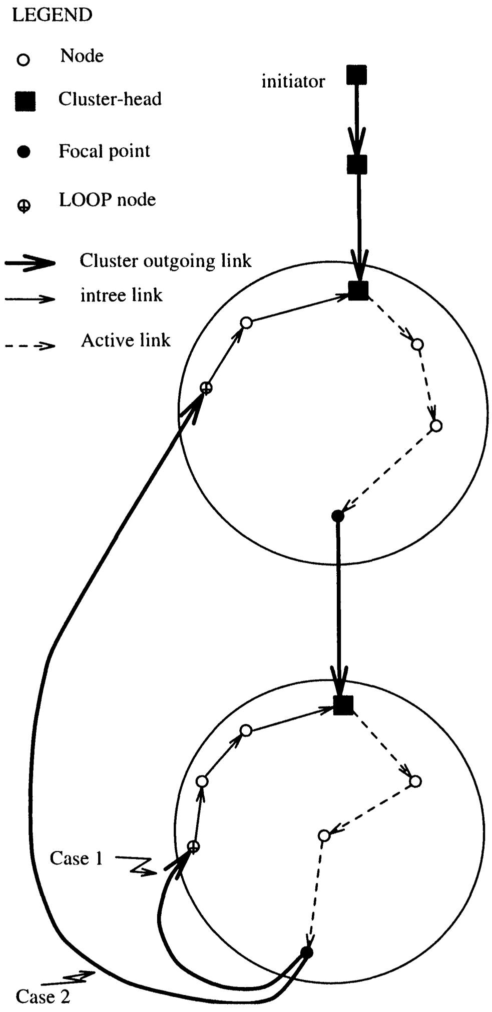

FIG. 12. *Clusters in the traversal algorithm.*

4.2. Deriving Traversal-3 from the election algorithm. Two operations in the preceding traversal algorithm require $O(\log n)$ bits memory in each node. The first is distinguishing an intra-cluster from an inter-cluster link. The second (which occurs during the DFT of the infrastructure) is backtracking from the last node on the active path.

In the first operation, the $O(\log n)$ bits are used to distinguish between the case where a newly traversed link, l, is an intra-cluster link and the case where l closed a cycle of clusters. This operation was accomplished in the preceding algorithm by comparing the ID carried by the token with the cluster-ID of the head node of l. To perform the operation without IDs, we note that, in both cases, l closed a directed cycle of nodes and links (composed of an active path followed by a path in an in-tree, see Fig. 12). In the first case, exactly one cluster-head resides on the cycle, while in the second case, at least two cluster-heads reside on the cycle (see Fig. 12).

We now explain how the token decides whether there is more than one cluster-head on the cycle. The last node on the active path in each cluster is marked as the focal point (it is the focal point of that cluster's DFT, see §2.2.2). The head node of a newly traversed link l is marked LOOP if it is an already explored node. Upon arriving at a LOOP node, the token is sent around the cycle to find out whether there is more than one cluster-head on it. Since there is exactly one LOOP node on such a cycle, the walk around it utilizes a finite number of bits on the token. The token then walks around to the focal point, kills l, and resumes the DFT. If, on the other hand, more than one cluster-head was found, a cycle of clusters was identified. The token then makes another trip around the cycle in order to synchronize its clusters. On the second round, the token first erases all the focal point marks. Second, it erases all the cluster-head marks, aside from the first. Third, the token modifies the in-trees of all clusters, aside from the first one, to be rerooted at the LOOP node (in the same way as was done in the election algorithm). Notice that the active path of the first cluster lies between the first and the second cluster-head. When it arrives at the LOOP node for the second time, the synchronization phase terminates. The LOOP mark is removed, the focal point mark is put on, and the DFT is resumed.

The backtracking in the DFT is performed without using node IDs by using the same solution suggested in §2.3.

The communication cost of the cycle detection and synchronization phases does not change in the modified algorithm. The cost of the cluster outgoing link selection phases is $O(n^2 \log n)$ bits since the DFT searching for outgoing links requires one backtracking for each link of the infrastructure. Thus, the communication complexity of the traversal algorithm is the same as that of the election algorithm.

4.3. Applications.

4.3.1. Applications of the traversal algorithm. In this section we show how the traversal algorithms and their resulting infrastructure can be used to solve other problems. In particular we apply the traversal algorithm to perform broadcasting, route messages, and systematically emulate any bidirectional algorithm on a unidirectional network. Each of the applications can be solved by a traversal; however, after executing the traversal, the application problems may be solved more efficiently using the infrastructure produced by the traversal.

4.3.2. Broadcast with echo. In the broadcast with echo problem one node, the root, has a piece of information which it sends to all the nodes in the network, and the root gets a positive acknowledgment that all the nodes have received the information.

A straightforward solution to the problem will use a traversing process to carry the information on it. The message complexity of this solution is the message complexity of the traversal algorithm, $O(n \cdot m)$.

After one traversal, the next broadcast with echo can be more efficiently performed by traversing only the infrastructure links. Since the infrastructure defines a strongly connected network, any node (not only the root) may start a traversal for this purpose. The complexity of this traversal is $O(n^2)$ since the number of links in the infrastructure is at most $2n - 2$.

After one traversal was performed, a further improvement can be achieved as follows. Every node that wants to start a broadcast with echo first sends the information of the broadcast to the root node along the out-tree marked links, and then the root node starts a broadcast with echo as described below. After receiving the echo, the root node will broadcast an echo on the out-tree links.

The infrastructure can be used for an efficient broadcast with echo from the root as follows. The root sends the broadcast message on all its outgoing links in the infrastructure. Upon receiving the broadcast message for the first time, every other node sends the message to all its outgoing neighbors in the infrastructure. Any other copy of the broadcast message is discarded. This implements the broadcast part of the algorithm. To notify the root that all the nodes in the network have received the broadcast message, every node ν sends an echo as follows. After sending the copy of the broadcast message, ν sends an echo over all of its infrastructure outgoing links except the link marked intree. Node ν sends an echo over the intree marked outgoing link only after an echo has been received on all of its infrastructure incoming links. When the root has received the echo over all of its infrastructure incoming links, the notification has been completed, and a message to this effect is sent on the outtree marked links.

The average message complexity of the resulting broadcast with echo algorithm is $6n$ (averaging out the first broadcast, which is a regular traversal). Sending the broadcast message from the initiating node to the root of the infrastructure costs at most $n - 1$ messages. The broadcast message is then transmitted once over each infrastructure link, which adds at most $2n - 2$ messages to the complexity. The echo message is also sent once over each infrastructure link, hence another $2n - 2$ messages. Then, to pass the echo to the initiating node, another $n - 1$ messages are transmitted on the outtree marked links.

4.3.3. Message sending. The in- and out-trees which result from the traversal algorithm enable us to efficiently send a message from every node to every other node. To pass a message from node ν to node u, node ν sends the message along the intree marked links to the root, which then broadcasts the message on the out-tree. Thus, at most $2n - 2$ messages are sent in the routing mechanism, in order to send a message from any node to any other node.

4.3.4. Transforming bidirectional distributed algorithms to unidirectional networks. The above routing mechanism can be used as a means to emulate any bidirectional distributed algorithm on a strongly connected unidirectional network. Whenever a node has to send a message on an incoming link, it will use the above message passing mechanism. Thus, if a problem has a bit complexity $O(P(n))$ on a bidirectional network, then its complexity on the unidirectional network is upper bounded by $O(n \cdot P(n) + n^2 \cdot \log\ n + n \cdot m)$ (the last two terms entail the construction of the infrastructure).

In case when the bidirectional algorithm is for a network of finite automata, i.e., if nodes are anonymous, then we can send a message backward from node v to its incoming neighbor u by adapting the solution to the "last in the ring" puzzle. However, the adaptation costs $O(m)$ messages (bits) in the synchronous network and $O(m + n \log n)$ messages in the asynchronous network for each message sent backward. The solution is adapted by performing the algorithm on the cycle defined by the unique path from v to the root in the in-tree concatenated with the unique path from the root to u and with the $u \rightarrow v$ link. The messages of the protocols in the proofs of Lemmas 2.11 and 2.12 are marked differently when they go from v to the root and when they travel from the root down to v via the out-tree. Messages going from v to the root behave exactly the same as in the original solutions. Each node participates in the algorithm for a message it receives in the "down" mode over its parent link in the out-tree, and sends the message it would have sent as a response on a ring on all its outgoing links. Any message received by a node other than v, not on the parent out-tree, is ignored, and v responds only to messages it receives from u. This guarantees that messages cycle only on the desired cycle. On all other potential cycles, starting at v the messages are eliminated when they reach a leaf of the out-tree.

5. Concluding remarks.

An interesting observation is that the amount of communication in the unidirectional election algorithm, $O(n \cdot m + n^2 \log\ n)$ bits, is n times the number of messages in the optimal bidirectional algorithm. We would obtain the same cost if we were to simulate the bidirectional algorithm [GHS83], with each acknowledgment charged as n bits, on a unidirectional network. Together with Lemma 2.13, this leads to the conjecture that our election algorithm is as efficient as possible in terms of communication cost.

Acknowledgments. We would like to thank Shimon Even and Peter Winkler for encouraging us to rewrite the results reported here. We would also like to thank an anonymous referee for many helpful corrections.

SIMPLE AND FAST ALGORITHMS FOR LINEAR AND INTEGER PROGRAMS WITH TWO VARIABLES PER INEQUALITY*

DORIT S. HOCHBAUM† AND JOSEPH (SEFFI) NAOR‡

Abstract. The authors present an $O(mn^2 \log m)$ algorithm for solving feasibility in linear programs with up to two variables per inequality which is derived directly from the Fourier–Motzkin elimination method. (The number of variables and inequalities are denoted by n and m, respectively.) The running time of the algorithm dominates that of the best known algorithm for the problem, and is far simpler. Integer programming on monotone inequalities, i.e., inequalities where the coefficients are of opposite sign, is then considered. This problem includes as a special case the simultaneous approximation of a rational vector with specified accuracy, which is known to be NP-complete. However, it is shown that both a feasible solution and an optimal solution with respect to an arbitrary objective function can be computed in pseudo-polynomial time.

Key words. linear programming, integer programming

1. Introduction.

In this paper we examine linear and integer programming problems with two variables per inequality. The problem of computing a feasible solution in the linear (or fractional) case has been investigated extensively. Shostak [18] suggested that a linear program with two variables per inequality can be represented as a graph: since each inequality contains two variables, one can represent the linear program by a graph which has a vertex for each variable, and an additional vertex x_0. Any inequality involving two variables is represented as an edge between the respective pair of vertices. As for inequalities involving only one variable (upper and lower bounds on variables), these are represented as edges to and from vertex x_0. We denote the number of variables by n, and the number of inequalities by m. (W.l.o.g. we can assume that $m \geq n$.) The graph consists therefore of $n + 1$ vertices and m edges, and there may be multiple edges between any pair of vertices.

Shostak [18] proved that feasibility can be tested by following paths and cycles in this graph, and thus laid the foundation for all subsequently considered algorithms for the problem. This feasibility test was refined to a polynomial algorithm by Aspvall and Shiloach [1], and later still to an $O(mn^3 \log m)$ strongly polynomial algorithm by Megiddo [14]. Recently, Cohen and Megiddo [4] obtained new algorithms for this problem: (i) they presented a new $O(mn^2(\log m + \log^2 n))$ time algorithm; (ii) they also gave a randomized algorithm for finding a feasible solution in the special case of monotone inequalities (to be defined later) with an expected running time of $O(n^3 \log n + mn \log^3 m \log n + mn \log^5 n)$. (This randomized algorithm was later generalized to hold for the non-monotone case as well in [2]; however, it follows from [5] that the non-monotone case can be reduced to the monotone case at no extra cost.) The main feature common to all of these algorithms is determining upper and lower bounds for each variable by following paths and cycles in the graph.

The first result we present is an $O(mn^2 \log m)$ algorithm for the feasibility problem. This algorithm is faster (although only for $m < n^{o(\log n)}$), and moreover it is *simpler* than all other known algorithms. The backbone of our algorithm is the Fourier–Motzkin elimination method

(Introduced by Fourier (1827), and discovered later by Dines (1918–1919) and Motzkin (1936); see [17] for details.) In general, this algorithm does not run in polynomial time because it may generate an exponential number of inequalities in the process of eliminating variables. However, we show how to implement this algorithm *efficiently* for linear programs where each inequality may contain at most two variables. First, at each elimination step, the number of inequalities on every edge adjacent to the variable currently to be eliminated is reduced to two. This serves to control the exponential growth of the number of inequalities. In addition, we maintain the inequalities corresponding to two variables as upper and lower envelopes, where the envelopes (which are piecewise linear functions) are characterized by their breakpoints. This representation allows us to dispose of redundant inequalities in each elimination step quickly by examining all breakpoints associated with the variable currently to be eliminated.

The analogue of the Fourier–Motzkin procedure in computational logic is *resolution.* Using resolution, one obtains a satisfying assignment to a set of clauses (in, say, propositional logic) by eliminating the variables one by one. It is known that resolution can be efficiently implemented for the case of 2-SAT clauses, i.e., the satisfiability problem, where each clause may contain at most two literals. This follows since every elimination step generates 2-SAT clauses, and the total number of 2-SAT clauses is always bounded by a polynomial. Our algorithm may be viewed as an efficient implementation of resolution for the case of linear constraints with two variables per inequality.

A linear program with two variables per inequality is called *monotone* if each inequality is of the form $ax_i - bx_j \leq c$, where both a and b are positive. We will consider integer programming problems on monotone inequalities. We note that the aforementioned reduction from the non-monotone case to the monotone case does not preserve integrality.

Lagarias [11] has shown that the problem of deciding whether a given rational vector α has a simultaneous approximation of specified accuracy with respect to the maximum norm, with denominator Q in a given interval $1 \leq Q \leq N$, is NP-complete. The problem of deciding the feasibility of a monotone system in integers is a generalized form of this question and hence NP-complete as well (it is obviously in NP).

The set of feasible solutions of a monotone system can be shown to form a *distributive lattice* where the *join* and *meet* operations are defined to be maximum component-wise and minimum component-wise, respectively. This has been observed before by Veinott [20]. We present an algorithm that computes the solution vectors corresponding to the top and bottom of the lattice. The lattice structure is crucial for the algorithm, and the manner in which the search for a feasible solution is conducted guarantees that if one exists, then we are going to find the solution which is at the top (or bottom). The running time of this algorithm is a polynomial which depends on the sum of the number of integer valued points in each one-dimensional projection of the feasible polytope in the fractional case. Hence, this algorithm is pseudo-polynomial in the case when the variables in the integer program are bounded. Also, in this case the problem is weakly NP-complete.

It is interesting to note that the strongly polynomial feasibility algorithm for linear inequalities with two variables per inequality does not extend to a strongly polynomial *optimization* algorithm over such inequalities. (It is only known that when the objective function consists of d variables, then there is a strongly polynomial algorithm when d is fixed, i.e., it is exponential in d.)

In contrast, for the integer case, we present a pseudo-polynomial algorithm for the optimization problem over a monotone system with an arbitrarily long objective function (that is, with up to n variables in the objective). We note that the optimization problem over a non-monotone system is NP-complete in the strong sense, since the vertex cover problem is a special case of it. The algorithm hinges on the following two observations:

- The elements of a distributive lattice can be represented as closed subsets of a directed graph (of pseudo-polynomial size) which is derived from the lattice.
- A linear objective function defines a modular function on the lattice which in turn implies that the lattice element of optimal cost corresponds to the closed subset of optimal cost (when costs are properly defined).

The complexity of computing the closed subset of optimal cost is bounded by a polynomial in the size of the graph, i.e., it can be computed in pseudo-polynomial time. Even though the directed graph that represents the lattice is of pseudo-polynomial size, it has a succinct description, i.e., it can be encoded in polynomial space. This provides a compact encoding of the complete feasible solution set of a monotone system of inequalities.

Finally, we present an application of our Fourier–Motzkin algorithm to identifying *fat* polytopes. Fat polytopes are those containing a sphere which circumscribes a unit hypercube, and hence must contain an integer point. For polytopes derived from inequalities with two variables per inequality, the procedure for identifying fat polytopes runs in strongly polynomial time, and thereby can be viewed as an efficient heuristic for finding a feasible integer solution. A strongly polynomial algorithm for a related problem of finding the largest sphere contained in a polytope is presented as well.

2. Efficient implementation of the Fourier–Motzkin algorithm. In this section we show how the Fourier–Motzkin elimination method for finding a feasible solution of a linear program can be implemented efficiently when the number of variables in each inequality is at most two. We begin by an informal description of the method for a general linear program. (The reader is referred to [17, pp. 155–156] for more details.)

Let the variables of the linear program be $x_1, \ldots, x_n$ and let the set of inequalities be denoted by E. The variables are eliminated one by one. At step i, the linear program will only contain variables $x_i, \ldots, x_n$; the set of inequalities at step i is denoted by E_i, where initially $E_1 = E$. To eliminate variable x_i, all the inequalities in which x_i participates are partitioned into two sets, L and H. The set L contains all the inequalities which are of the form $x_i \geq l$, and the set H contains all the inequalities which are of the form $x_i \leq h$, where l and h are linear functions. To obtain the set E_{i+1}, for all $l \in L$ and $h \in H$, a new inequality $l \leq h$ is added to E_i, and all the inequalities in L and H are eliminated from it. The number of new inequalities produced is $|H| \cdot |L|$. The next theorem is immediate.

THEOREM 2.1. *The linear program E_{i+1} has a feasible solution if and only if the linear program E_i has a feasible solution.*

Hence, a feasible solution can be computed recursively for E_{i+1} and then extended to E_i. The main drawback of this method is that the running time is not necessarily polynomial, i.e., in general the number of inequalities may grow exponentially.

The discussion henceforth is restricted to inequalities that contain at most two variables per inequality. It is interesting to note that Nelson [15] proved that when implementing the Fourier–Motzkin method in this case, the total number of inequalities is bounded by $m \cdot n^{\log n}$.

As mentioned in the introduction, an equivalent representation of the linear program is by the graph $G = (V, E)$. The vertex set V contains vertices $x_0, x_1, \ldots, x_n$; an edge between vertex x_i and x_j (for $1 \leq i, j \leq n$) represents the set of inequalities in which x_i and x_j participate. The vertex x_0 is needed to represent inequalities that contain precisely one variable, i.e., an edge from x_i to x_0 denotes an inequality of the form $x_i \leq a$ or $x_i \geq a$ for some constant a.

The main feature that allows for the efficient implementation of the Fourier–Motzkin algorithm is the following. The set of inequalities that correspond to an edge between x_i and x_j is represented in the (x_i, x_j) plane as two envelopes, an upper envelope and a lower envelope. The feasible region of x_i and x_j is in between the two envelopes and it is not hard to see that each envelope is a *piecewise linear* function that can be represented by its breakpoints (see Fig. 1(a)).

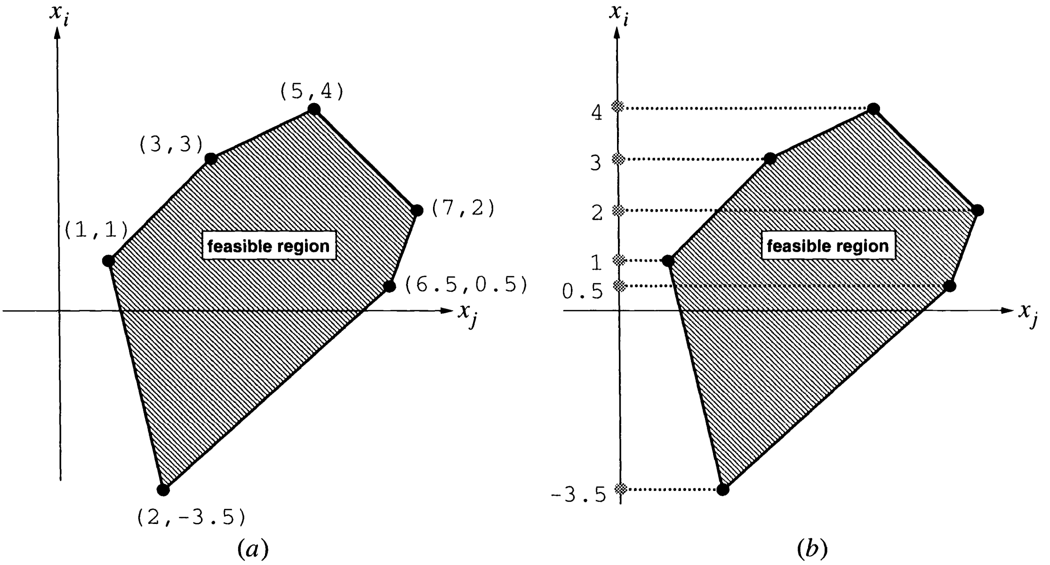

FIG. 1. (a) *The feasible region defined by the inequalities containing x_i and x_j is a piecewise linear function defined by its breakpoints.* (b) *The set $B_j = \{-3.5, 0.5, 1, 2, 3, 4\}$ is the set of breakpoints projected on the x_i axis.*

The following procedure of Aspvall and Shiloach [1] plays a crucial role in our algorithm. This procedure was used by [14] and [4] as well. Let $x_i^{\min}$ and $x_i^{\max}$ denote the respective minimum and maximum feasible values of x_i. That is, any value assigned to x_i from the range $[x_i^{\min}, x_i^{\max}]$ can be complemented to a feasible solution. If the feasible range of some of the variables is unbounded, then there exist numbers bounded by a polynomial in the binary representation of the data [17], such that if $x_i^{\min}$ and $x_i^{\max}$ are set to them, the existence of a feasible solution is assured.

PROCEDURE 2.1 [1]. *Given a variable x_i and a value λ, it can be decided in $O(mn)$ operations whether (i) $\lambda < x_i^{\min}$, (ii) $\lambda > x_i^{\max}$, or (iii) $x_i^{\min} \leq \lambda \leq x_i^{\max}$.*

The main idea underlying Procedure 2.1 is propagating the implications of the equality $x_i = \lambda$ in a manner very similar to the Bellman–Ford algorithm for computing all shortest paths from a single source. We remark that even if the linear program in hand is infeasible, the procedure may still provide one of the above three answers. In this case, infeasibility will be detected by our algorithm at a later stage. (Note for example the case in which the linear system consists of two independent subsystems, one feasible and one infeasible.)

We are now ready to provide a high-level view of the algorithm. The main idea is that the number of inequalities in which x_i (the variable to be eliminated) participates can be significantly reduced using Procedure 2.1. It should be mentioned that a similar idea was used by Megiddo [14] to obtain upper and lower bounds on the feasible values of variables. The following is performed at step i of the Fourier–Motzkin algorithm. Let G_i denote the graph corresponding to the linear program E_i.

1. Let the neighbors of x_i in the graph G_i be $x_{i_1}, \ldots, x_{i_d}$.
   Let B_j $(1 \leq j \leq d)$ denote the set of breakpoints of the edge (x_i, x_{i_j}) projected on the x_i coordinate (see Fig. 1(b)).

2. Merge the d sorted sequences B_i into a sorted sequence B. (Let the sorted sequence be $b_1, \ldots, b_k$.)
3. Perform a binary search on the sequence B. The aim of the search is to obtain either
   (a) a breakpoint $b_l \in B$ such that $x_i^{\min} \leq b_l \leq x_i^{\max}$, or
   (b) an interval $[b_l, b_{l+1}]$ $(1 \leq l < k)$ such that $b_l < x_i^{\min}$ and $x_i^{\max} < b_{l+1}$.
4. In step 3a, variable x_i is assigned the value b_l and "contracted" with vertex x_0 in graph G_i.
   In step 3b, the number of inequalities on each edge adjacent to x_i is reduced to at most two (see Fig. 2). Now, the generic Fourier–Motzkin elimination step is applied to variable x_i.

Let us further elaborate on how the algorithm is implemented and analyze its complexity. The following invariant is maintained throughout the algorithm; we defer its proof to the end of the discussion. It is obviously true initially.

INVARIANT 2.1. *The number of breakpoints on an edge is at most $O(m)$.*

By the invariant, the cardinality of the set B is at most $O(mn)$. The binary search at step 3 is performed by successive calls to Procedure 2.1. At each call, either a breakpoint which is feasible for x_i is discovered, or the number of breakpoints to be examined is reduced by half. Hence, the complexity of sorting the set B and performing the binary search is at most $O(mn \log m)$. We should remark that in the course of the elimination process, to bound the running time of Procedure 2.1 by $O(mn)$, we run it on the original graph G and not on the current graph G_i. However, G is updated as follows. For each eliminated variable (say x) that was assigned a value (say a) at step 3a, two inequalities are added to graph G: $x \leq a$ and $x \geq a$. If x is already connected to x_0, then the respective bounds are updated according to the most restrictive bound, or an inconsistency is detected and the algorithm terminates with a discovery that the system is infeasible.

In step 3a, the linear program E_{i+1} is obtained from E_i by assigning the value b_l to the variable x_i. Otherwise, in step 3b, the generic Fourier–Motzkin elimination step is applied. Notice that the number of inequalities on each edge adjacent to x_i is reduced to at most two (see Fig. 2). (We assume that the intersections of the upper and lower envelopes (up to two) are also counted among the original breakpoints.) In addition, two more inequalities, $b_l \leq x_i$ and $x_i \leq b_{l+1}$, are added to the linear program E_i.

Let x_{i_p} and x_{i_q} be any two variables that are adjacent to x_i. The edge (x_i, x_{i_q}) and the edge (x_i, x_{i_q}) may each contain at most two inequalities; hence, at step 4, the Fourier–Motzkin elimination step adds up to four new inequalities between the variables x_{i_p} and x_{i_q}. These four inequalities are added to the set of inequalities that already exist between them. The running time of adding a new inequality to an already existing envelope is $O(\log m)$ time. This follows since the existing set of inequalities includes at most $O(m)$ inequalities (Invariant 2.1), which is represented as an (upper and lower) envelope, i.e., as a sorted sequence of breakpoints. Adding a new inequality amounts to identifying where to insert the newly created breakpoint in the existing sequence, which can be done using a binary search. We note that it may be the case that, as a result of adding a new breakpoint, many other breakpoints can disappear. Since there are at most $\binom{n}{2}$ pairs of neighbors, the complexity of this step is at most $O(n^2 \log m)$.

To prove Invariant 2.1, notice that for each variable that is eliminated, the number of breakpoints added to an edge is a constant, and hence the invariant is maintained. In fact, the number of breakpoints on an edge will never exceed $m + 4n$ throughout the execution of the algorithm.

At the end of the elimination step, we are left with two variables, x_0 and x_n. We now backtrack and assign values to the inequalities as follows. Choose any feasible value in the feasible range for x_n. Now choose a feasible value for x_{n-1}, that satisfies the inequalities w.r.t.

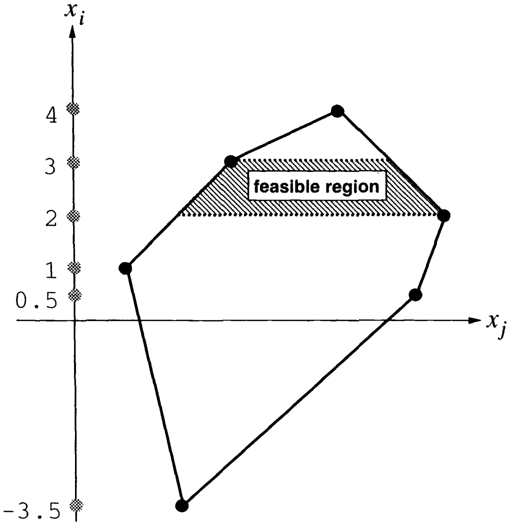

FIG. 2. *Step* 3b *of the algorithm: for example,* $b_l = 2$ *and* $b_{l+1} = 3$. *Consequently, the number of inequalities involving* x_i *and* x_j *is reduced to two. In addition, there are two more inequalities:* $2 \leq x_i$ *and* $x_i \leq 3$.

x_n and x_0. Continue inductively by determining a value for x_i, based on the inequalities of x_i and x_j for $j > i$, and the range determined by the upper and lower bound inequalities with x_0. Since there are now at most two inequalities on each edge, the running time for the entire backtracking process is $O(n^2)$.

The correctness of the next theorem follows from the above discussion.

THEOREM 2.2. *The complexity of eliminating a variable in the algorithm is* $O(mn \log m)$. *Hence, the complexity of the entire algorithm is* $O(mn^2 \log m)$.

3. Integer programming on monotone inequalities. A linear program with two variables per inequality is called *monotone* if for every inequality, the coefficients of the two variables have opposite signs. We begin by studying the properties of the set of feasible vectors in the case of monotone inequalities. This set can be looked upon as a partial order under the following definition of dominance. Given two feasible vectors, L_1 and L_2, we say that $L_1 \succeq L_2$ if for all components i, $L_1(i) \geq L_2(i)$. Let $\mathcal{L}$ denote the set of all feasible vectors of a monotone system. We prove that $\mathcal{L}$ has the nice property that it forms a *distributive lattice*. This property will turn out to be very useful for finding a feasible solution and optimizing with respect to an objective function. It was previously observed by Veinott [20]. A distributive lattice is a partial order in which

1. Each pair of elements has a greatest lower bound, or *meet*, denoted by $a \wedge b$, so that $a \wedge b \preceq a$, $a \wedge b \preceq b$, and there is no element c such that $c \preceq a$, $c \preceq b$ and $a \wedge b \prec c$.
2. Each pair of elements has a least upper bound, or *join*, denoted by $a \vee b$, so that $a \preceq a \vee b$, $b \preceq a \vee b$, and there is no element c such that $a \preceq c$, $b \preceq c$ and $c \prec a \vee b$.
3. The *distributive* laws hold, namely $a \vee (b \wedge c) = (a \vee b) \wedge (a \vee c)$ and $a \wedge (b \vee c) = (a \wedge b) \vee (a \wedge c)$.

To prove that $\mathcal{L}$ is, in fact, a distributive lattice, we define appropriately the *meet* and *join* operations. The meet of two vectors L_1 and L_2 is defined to be the vector where each component is the minimum of the two corresponding components in L_1 and L_2. The join of two vectors is defined similarly where minimum is replaced by maximum. (See Fig. 3 for an example.)

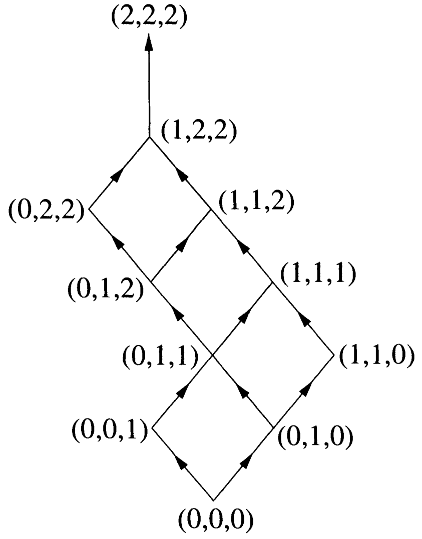
THEOREM 3.1 [20]. *The partial order* $(\mathcal{L}, \preceq)$ *of feasible vectors forms a distributive lattice under the above definitions of meet and join.*

Proof. We first establish that $(\mathcal{L}, \preceq)$ is a lattice. To do that, we prove one case, other cases follow similarly. Let $L_1 = (u_1, \dots, u_n)$, $L_2 = (v_1, \dots, v_n)$, and let $L = L_1 \vee L_2 = (w_1, \dots, w_n)$. We show that L is also a feasible solution vector. For a particular inequality $ax_i - bx_j \le c$, we know that

$$au_i - bu_j \le c; \quad av_i - bv_j \le c.$$

If, for example, $w_i = u_i$ and $w_j = v_j$, then since b is positive, $bu_j \le bv_j$, and the inequality holds for solution vector L as well.

Let a, b, and c be any integers. Then, $\min(a, \max(b, c)) = \max(\min(a, b), \min(a, c))$ and $\max(a, \min(b, c)) = \min(\max(a, b), \max(a, c))$. Hence, the distributive laws hold for the lattice $\mathcal{L}$. □



$$\begin{aligned} y - x &\le 2 \\ x - y &\le 0 \\ 2z - y &\le 3 \\ 2y - z &\le 2 \end{aligned}$$

$$0 \le x,\ y,\ z \le 2$$

FIG. 3. *The sublattice of integral solutions of a monotone system. Each solution vector is of the form* (x, y, z).

Notice that the lattice property holds in both the fractional and the integer case, and in fact the set of integer feasible solutions is a *sublattice* of the lattice of feasible solutions. From now on $\mathcal{L}$ will denote the lattice in the integer case and we restrict the discussion to this lattice. It is easy to see that the lattice properties imply that a lattice has a unique minimum and maximum, denoted by B (bottom) and T (top), respectively.

The problem of checking whether an integer monotone system has a feasible solution was shown to be NP-complete by Lagarias [11]. This was shown by proving that the following problem, *good simultaneous approximation*, is NP-complete. An instance of this problem consists of a vector of rationals, $\alpha = (a_1/b_1, \dots, a_n/b_n)$, and positive integers N, s_1, and s_2. The question is whether there exists an integer Q, $1 \le Q \le N$, such that

$$\max_{1 \le i \le n} \{Qa_i/b_i\} \le \frac{s_1}{s_2},$$

where $\{\beta\}$ denotes the distance of β to the closest integer. This problem can be expreseed as an instance of finding an integer feasible solution $(x_1, \dots, x_n, Q)$ for the following monotone system:

$$-s_1 \cdot B \leq s_2 \left(\frac{a_i \cdot B}{b_i} \cdot Q - B \cdot x_i \right) \leq s_1 \cdot B, \qquad 1 \leq i \leq n,$$

$$\text{where} \quad B = b_1 \cdot b_2 \cdots b_n \qquad \text{and} \qquad 1 \leq Q \leq N.$$

However, we will show in §§3.1 and 3.2 that for the case of bounded variables, both the feasibility problem and the optimality problem with respect to an arbitrary objective function can be solved in pseudo-polynomial time over a monotone system of inequalities. Consequently, integer programming over monotone inequalities with bounded variables is only weakly NP-complete.

3.1. Integer feasibility over monotone inequalities. In this section we show how a feasible integer solution can be found. More specifically, our aim is to compute the feasible solution which corresponds to the top of the lattice, i.e., the feasible vector whose components are maximal. The same procedure with a slight modification can be applied to find the solution corresponding to the bottom of the lattice.

During the course of this procedure a current solution vector $L = (x_1, \ldots, x_n)$ (which is infeasible) is maintained with the invariant that $L \succeq T$. The initial value of L is the top of the fractional lattice where each component is rounded downward to the nearest integer.

It should be noted that in the monotone case, the top (or bottom) of the lattice in the fractional case can be computed via a simple modification of the algorithm defined in §2. In step 3a of the algorithm, instead of assigning a value to the variable that is eliminated, two consecutive breakpoints are computed with the following property. One breakpoint belongs to the feasible region, and the other breakpoint (the larger one) does not belong to it. The algorithm continues similarly to step 3b. In the backtracking process, the highest feasible value is chosen for each variable.

The generic step in the algorithm is as follows. Traverse all the inequalities in the linear program in some arbitrary order. If an inequality $ax_i - bx_j \leq c$ is invalid, then it is *validated* by updating the value of x_i as follows:

$$x_i \leftarrow \left\lfloor \frac{c + bx_j}{a} \right\rfloor.$$

The algorithm terminates if either all inequalities traversed in a single step are valid, or $L \preceq B$.

THEOREM 3.2. *The algorithm tests in time $O(mn^2 \log m + m \cdot \sum_{i=1}^{n}(x_i^{\max} - x_i^{\min} + 1))$ whether a monotone system of inequalities has a feasible solution.*

Proof. Assume that the given system of inequalities has a feasible solution. We show that the invariant that $L \succeq T$ is maintained throughout the algorithm. Given an invalid inequality $ax_i - bx_j \leq c$, where $x_i = u_i$ and $x_j = u_j$, it is validated by decreasing x_i. Assume that the values of x_i and x_j in T are $\hat{x}_i$ and $\hat{x}_j$, respectively. By the invariant, $u_j \geq \hat{x}_j$. Hence,

$$\hat{x}_i \leq \left\lfloor \frac{c + b\hat{x}_j}{a} \right\rfloor \leq \left\lfloor \frac{c + bu_j}{a} \right\rfloor = u_i$$

and the invariant is maintained.

It follows from the invariant that we will never need to backtrack, and since the value of a variable is always decreased by at least one unit whenever an inequality is validated, the running time of the algorithm is bounded by $O(mn^2 \log m + m \cdot \sum_{i=1}^{n}(x_i^{\max} - x_i^{\min} + 1))$. This running time is pseudo-polynomial since the feasible range of the variables is bounded.

If the monotone system does not have an integer feasible solution, this will be detected when $L \preceq B$, since $T \succeq B$ must hold. □

Recently, T. Feder (private communication) observed that an integer feasible solution can be computed in pseudo-polynomial time in the non-monotone case when the variables are bounded.

3.2. Integer optimization over monotone inequalities. In this section we consider the following integer optimization problem:

$$\min \quad \sum_{i=1}^{n} w_i \cdot x_i$$

$$\text{subject to} \quad a_k x_i - b_k x_j \leq c_k, \quad k = 1, \ldots, m,$$

$$1 \leq i, j \leq n \quad \text{and} \quad a_k,\ b_k \geq 0.$$

We show that the optimal solution can be computed in pseudo-polynomial time where the polynomial depends on $\sum_{i=1}^{n}(x_i^{\max} - x_i^{\min})$. Recall that the optimization problem over a non-monotone system is NP-complete in the strong sense since vertex cover is a special case of it.

DEFINITION 3.3. *Let f be a function defined on a lattice $\mathcal{L}$, and let $a, b \in \mathcal{L}$. The function f is called modular if $f(a) + f(b) = f(a \vee b) + f(a \wedge b)$.*

It is straightforward to verify that any linear objective function defined on an integer monotone system is modular.

DEFINITION 3.4. *For a directed graph G, a subset S is said to be closed if for every $s \in S$, all its predecessors, i.e., all vertices s' for which there exists a directed path from s' to s, belong to the subset S.*

We first review our scheme for minimizing with respect to an objective function. The following theorem in lattice theory (see [6, p. 72, Thm. 9] and [7, Thm. 2.2.1]) is relevant to our result.

THEOREM 3.5. *Given a distributive lattice $\mathcal{L}$, a partial order can always be associated with it, such that a one-to-one correspondence can be established between its closed subsets and the elements of $\mathcal{L}$.*

The proof of this theorem is constructive and it implies an algorithm for constructing the partial order. In general, there may be more than one partial order that has the above property; we denote by $I(\mathcal{L})$ the partial order obtained by following the proof of Theorem 3.5 and call it the *generic partial order*.

Suppose now that a modular function f is defined on the lattice $\mathcal{L}$. It can be shown that in this case, the elements of the partial order can be assigned costs in such a way that the lattice element of optimal cost would correspond to the closed subset of $I(\mathcal{L})$ of optimal cost. Computing a closed subset of optimal cost in a partial order is a well-known problem and its complexity is bounded by a polynomial in the size of $I(\mathcal{L})$ [16]. (The size of $I(\mathcal{L})$ is pseudo-polynomial in the case of our lattice.)

The disadvantage of computing with the generic partial order $I(\mathcal{L})$ is that its structure is rather complicated, and it seems that it cannot be described compactly, i.e., in polynomial space (as opposed to pseudo-polynomial space). Instead, we present a directed graph, denoted by $G(\mathcal{L})$, that also has the property that a one-to-one correspondence exists between its closed subsets and the elements of $\mathcal{L}$. The advantage of this graph is that it can be encoded in polynomial space via an algorithm which has a short (polynomial) description.

The rest of the section is organized as follows. In §3.2.1 we define the directed graph $G(\mathcal{L})$ and prove that it has the desired properties. In §3.2.2 we show how to compute a closed subset of minimum cost in $G(\mathcal{L})$. For the sake of completeness, we discuss in §3.2.3 how to obtain the graph $G(\mathcal{L})$ from the generic partial order $I(\mathcal{L})$.

It should be noted that similar methods were used by Gusfield and Irving [7] to compute efficiently an *egalitarian* solution for the Stable Marriage problem. See also [9], [19] for an application of these methods.

3.2.1. Constructing the directed graph. In this section we define a directed graph $G(\mathcal{L})$ such that a one-to-one correspondence can be defined between its closed subsets and the elements of $\mathcal{L}$. (See Fig. 4 for an example.)

Let the set V_i be defined as the set of integers that are contained between the largest and smallest integer feasible values of variable x_i. The vertex set of $G(\mathcal{L})$ is $V_1 \cup \cdots \cup V_n$, i.e., a vertex is created for each $v \in V_i$, where $1 \leq i \leq n$. In addition, there is a special vertex denoted by s. The edge set of $G(\mathcal{L})$ is defined as follows.

- For each variable x_i, a directed chain is defined on the set V_i in sorted order. That is, for each pair of vertices representing two consecutive values, v and $v + 1$, there is an arc $(v, v + 1)$. Such a chain is called an x_i-chain.
- For each inequality $ax_j - bx_i \leq c$, the following "ladder" is defined between the x_i-chain and the x_j-chain. For all $v \in V_j$, there is an arc from the value corresponding to $\lceil \frac{av-c}{b} \rceil$ in the x_i-chain, to the vertex corresponding to v in the x_j-chain. Intuitively, the arcs can be thought of as constraints, i.e., if the value of variable x_j is v, then the value of variable x_i must be at least $\lceil \frac{av-c}{b} \rceil$ in any feasible solution
- For each x_i-chain, there is a bidirectional edge connecting the vertex corresponding to the smallest value in V_i to the vertex s. The purpose of these edges is to ensure that any closed set contains at least one vertex in each x_i-chain.

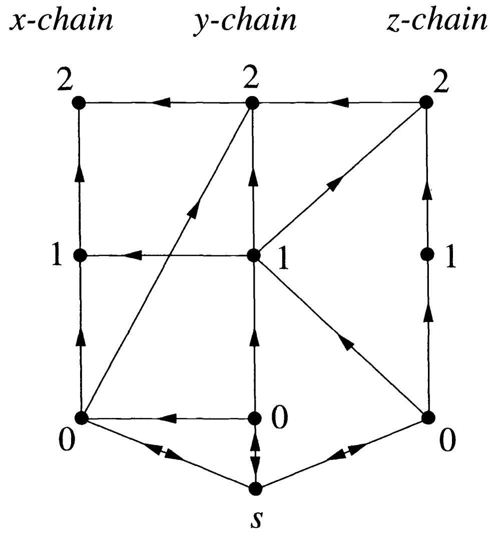


FIG. 4. *The directed graph $G(\mathcal{L})$ corresponding to the set of inequalities of Fig. 3. For example, the arc connecting the "0" value in the x-chain to the "2" value in the y-chain is implied by the inequality $y - x \leq 2$.*

The next theorem states that this construction is valid.

THEOREM 3.6. *There is a one-to-one correspondence between the closed subsets of $G(\mathcal{L})$ that contain vertex s and the elements of $\mathcal{L}$.*

Proof. We first prove that every feasible solution vector L defines a closed subset in $G(\mathcal{L})$. Let $L = (u_1, \ldots, u_n)$. The corresponding subset S_L in $G(\mathcal{L})$ is defined by taking for all i, all the vertices corresponding to integers that are smaller or equal than u_i in V_i, and $s \in S_L$. Assume now that S_L is not a closed subset. Then there exist two vertices, $v \in V_i$ and $w \in V_j$, such that

- $w \in S_L$ and $v \notin S_L$, and,
- there is an arc from v to w in $G(\mathcal{L})$.

This arc can only be generated by the inequality $ax_j - bx_i \leq c$. (We now abuse terminology by treating v and w as both vertices and integers.) Thus, by the construction of $G(\mathcal{L})$, $v = \lceil \frac{aw-c}{b} \rceil$; since $u_i \geq \lceil \frac{au_j-c}{b} \rceil$ and $w \leq u_j$, we get that $v \leq u_i$ and hence $v \in S_L$, contradicting our assumption.

We now prove the other direction. Let S_L be a closed subset in $G(\mathcal{L})$. The solution vector $L = (u_1, \ldots, u_n)$ corresponding to S_L is defined by taking u_i to be the largest integer belonging to S_L in V_i. Since $s \in S_L$, then every x_i-chain in the graph $G(\mathcal{L})$ has at least one representative in the closed subset S_L. Suppose L is infeasible, i.e., there exists an inequality $ax_j - bx_i \leq c$ such that $au_j - bu_i > c$. By the construction of $G(\mathcal{L})$, there is an arc from the vertex in V_i corresponding to $\lceil \frac{au_j-c}{b} \rceil$ to the vertex in V_j corresponding to u_j. Since S_L is a closed subset, the vertex corresponding to $\lceil \frac{au_j-c}{b} \rceil$ must belong to S_L, and hence, $u_i \geq \lceil \frac{au_j-c}{b} \rceil$, which contradicts the invalidity of the inequality. □

REMARK 3.1. *Notice that $G(\mathcal{L})$ has a succinct description and can be encoded in polynomial space. This implies that the complete set of solutions of a monotone system can be completely encoded in polynomial space.*

3.2.2. Minimizing with respect to a modular function. In this section we discuss how to compute a lattice element minimizing an objective function $\sum_{i=1}^{n} w_i x_i$. As mentioned earlier, this objective function also defines a modular function on the lattice. We first show how to assign costs to the vertices of $G(\mathcal{L})$ such that a closed subset of minimum cost corresponds to a lattice element of minimum cost. Then we briefly review Picard's algorithm [16] for finding a closed subset of minimum cost in a directed graph.

The cost of every vertex in $G(\mathcal{L})$ is determined as follows. Let the smallest value in V_i be b_i. The cost of the vertex corresponding to b_i is $w_i \cdot b_i$, and the cost of the other vertices in V_i is w_i. It is not hard to see that finding the optimal solution with respect to an objective function is equivalent to finding the closed subset of minimum cost in $G(\mathcal{L})$, where the cost of a closed set is defined to be the sum of the costs of its members. The problem of computing the minimum cost closed set can be reduced to computing the minimum cut in the following graph (of pseudo-polynomial size), denoted by G, which is derived from $G(\mathcal{L})$. (Computing the minimum cut in G can be done by finding the maximum flow from the source to the sink.)

- Connect all positive cost vertices to a source and all negative cost vertices to a sink.
- The capacity assigned to edges adjacent to the source or sink is equal to the absolute value of the cost of the vertices to which they are adjacent.
- All other edges in $G(\mathcal{L})$ have infinite capacity in G.

By our construction, the minimum cut must either contain edges adjacent to the source or to the sink. (Other edges have infinite capacity.) The *sink-set* of a cut is defined to be the set of vertices that can be reached from the source only via the cut. Picard [16] proved that the sink-set defined by the minimum cut in G corresponds to a closed subset of minimum cost in $G(\mathcal{L})$. To see that, let N be the sum of the capacities of the edges adjacent to the source in G. It is not hard to see that the cost of the vertices in the sink-set of any finite cut is equal to $-N$ plus the capacity of the cut. Hence, a minimum cut defines a closed subset of minimum cost.

Since a minimum cut can be identified in a graph $G = (V, E)$ in $O(|E||V| \log |V|)$, e.g., [8], and in our graph $|V| = O(\sum_{i=1}^{n} |V_i|)$ and $|E| \leq O(m \sum_{i=1}^{n} |V_i|)$, we have the following theorem.

THEOREM 3.7. *The integer optimal solution of a monotone system of inequalities with respect to an arbitrary linear objective function can be computed in pseudo-polynomial time, in $O(m(\sum_{i=1}^{n}|V_i|)^2 \log(\sum_{i=1}^{n}|V_i|))$ time.*

3.2.3. The generic construction. In order to motivate the construction of $G(\mathcal{L})$, we now present without proof how it can be obtained from the generic partial order $I(\mathcal{L})$.

Let $\mathcal{L}[x_i = a]$ denote the set of all feasible solution vectors for which $x_i = a$. Obviously, $\mathcal{L}[x_i = a]$ induces a sublattice of $\mathcal{L}$. We call a lattice element *irreducible* if for some variable x_i and integer a, it is the bottom element of the sublattice $\mathcal{L}[x_i = a]$. The partial order $(I(\mathcal{L}), \preceq)$ is defined as follows: the vertex set is the set of irreducible elements of the lattice $\mathcal{L}$; for elements $a, b \in I(\mathcal{L})$, there is an edge from a to b, if $a \preceq b$ in $\mathcal{L}$. The following theorem is proved in [6, p. 72, Thm. 9] and [7, Thm. 2.2.1].

THEOREM 3.8. *There is a one-to-one correspondence between the nonempty closed subsets of $I(\mathcal{L})$ and the elements of $\mathcal{L}$. Moreover, if closed subsets S and S' of $I(\mathcal{L})$ correspond to vectors L and L', respectively, then L' dominates L if and only if $S \subseteq S'$.*

However, the partial order $I(\mathcal{L})$ has a "complicated" structure which we now show how to simplify and make more regular. (This generalizes the construction in [10].)

The elements L_1 and L_2 are called *consecutive* elements in the lattice $\mathcal{L}$ if L_2 covers L_1, i.e., there is no element M such that $L_1 < M < L_2$. Suppose elements L_1 and L_2 are consecutive and $L_1 < L_2$. The *minimal difference* between L_1 and L_2 is defined to be the "set of changes" between L_1 and L_2. More formally, by a single *change* we mean the difference between the value of a variable in L_1 and L_2. We denote by $\mathcal{D}$ the set of all minimal differences in $\mathcal{P}$.

A *maximal chain* in a lattice is a chain of consecutive elements that starts at B and ends at T. An interesting property of distributive lattices is that each maximal chain contains *all* the minimal differences. The minimal differences appear on each maximal chain in some order and each minimal difference appears exactly once.

We can now define the partial order $(T(\mathcal{L}), \preceq)$. Let $D_1, D_2 \in \mathcal{D}$; then $D_1 < D_2$ if and only if D_1 precedes D_2 on every maximal chain in $\mathcal{P}$. We are now ready for the next theorem, whose proof follows from [7, Thm. 2.4.4] and which relates the partial orders $I(\mathcal{L})$ and $T(\mathcal{L})$.

THEOREM 3.9. *There is a one-to-one correspondence between the closed subsets of $I(\mathcal{L})$ and $T(\mathcal{L})$.*

In fact, the partial order $T(\mathcal{L})$ is very similar to $G(\mathcal{L})$. Let $\hat{V}_i$ denote the set of integer feasible values of variable x_i. Notice that the elements of $\hat{V}_i$ do not necessarily form a consecutive interval, in contrast to the fractional case, where all values λ such that $x_i^{\min} \leq \lambda \leq x_i^{\max}$ are feasible. Notice that $T(\mathcal{L})$ is the structure we obtain if we follow the definition of $G(\mathcal{L})$ except that the set V_i is replaced by $\hat{V}_i$. For example, if $\hat{V}_i = \{1, 5, 6\}$, then there is an arc from the vertex corresponding to "1" to the vertex corresponding to "5", and an arc from the vertex corresponding to "5" to the vertex corresponding to "6."

The difficulty in constructing the partial order $T(\mathcal{L})$ is that we need to generate the elements of the sets $\hat{V}_i$ one by one, since they are not necessarily sets of consecutive integers. This can be done in pseudo-polynomial time; however, $T(\mathcal{L})$ does not have a succinct description which motivates the construction of $G(\mathcal{L})$.

4. Identifying fat polytopes. This section presents an application of the Fourier–Motzkin algorithm for identifying *fat* polytopes.

Even though it is NP-hard to decide whether a set of inequalities has an integer feasible solution, one can use a fast preprocessing stage to compute an integer feasible solution in certain cases. This preprocessing stage runs in strongly polynomial time for the case of linear programs with two variables per inequality. It checks whether the polytope is *fat*, i.e., whether it contains a sphere circumscribing a unit hypercube. Since a unit hypercube must contain at least one integer lattice point, an integer feasible point is found by rounding the coordinates of the center of the sphere to the nearest integer. This procedure is a heuristic for finding a feasible integer point, since there may exist a feasible integer point in the polytope, yet the polytope does not contain a large enough sphere. Lenstra [12] uses a similar procedure that works in polynomial time and may identify a feasible integer point; however, in his procedure the running time depends on the ellipsoid method and is therefore not strongly polynomial.

The idea of the procedure is to shift all constraints by a distance of r. Any feasible point in the resulting set of inequalities is at a distance of r from all the faces of the polytope, and hence a sphere of radius r around any such feasible point is contained in the polytope. In order to obtain a sphere large enough to contain a unit hypercube, we need to set $r = \sqrt{n}/2$.

Shifting a constraint by a distance r is done as follows. Given an inequality $\sum_{i=1}^{n} a_i x_i \leq c$, the shifted inequality is $\sum_{i=1}^{n} a_i x_i \leq \bar{c}$, where

$$\bar{c} = c - \frac{r}{\sqrt{\sum_{i=1}^{n} a_i^2}} \sum_{i=1}^{n} a_i .$$

In the case of two variables per inequality, the sum includes at most two terms. The new set of inequalities, each with a constant c substituted by $\bar{c}$, is also a set of inequalities with two variables per inequality, and hence is solvable in the running time reported in §2. Consequently, we can test whether a polytope is *fat* and find an integer feasible point in $O(mn^2 \log m)$ time.

Although the running time is polynomial, the procedure involves the manipulation of square roots, which may be difficult in practice. Since this algorithm only finds a feasible integer point in a special case, it is satisfactory for this purpose to truncate $\bar{c}$ to a small number of accuracy bits, where the small number depends on the machine word length or on other implementation considerations.

An interesting related problem is to find the *largest* sphere contained in a polytope. For this we need to maximize the value of r such that the system still has a feasible solution. Although such a problem has three variables per inequality, it is still solvable in strongly polynomial time. This follows from the results of [3] and [13], where it is shown that a problem can be solved in strongly polynomial time if, by deleting a constant number of columns (in this case the constant is equal to one), it can be converted to a problem which is solvable in strongly polynomial time. Since treating r as a variable adds only one more variable to the problem, the problem of finding a largest sphere in the polytope defined by a set of inequalities with two variables per inequality is solvable in strongly polynomial time.

Acknowledgments. We thank the two anonymous referees for clarifying the presentation of the paper. We thank Arik Tamir for pointing out that the running time of the integer feasibility algorithm is pseudo-polynomial only in the case where the variables are bounded. We would also like to thank Edith Cohen for helpful remarks. Many thanks to Yossi Friedman for his help in making the figures.

COMPUTING THE ORDER OF A LOCALLY TESTABLE AUTOMATON*

SAM M. KIM[†] AND ROBERT MCNAUGHTON[‡]

Abstract. A locally testable language is a language with the property that, for some positive integer j, whether or not a string x is in the language depends on (1) the prefix and suffix of x of length $j-1$, and (2) the set of substrings of x of length j, without regard to the order in which these substrings occur or the number of times each substring occurs. For any j for which this is true, it is said that the language is *j-testable*. For a given locally testable language, the smallest such number j is called the *order* of the language. Locally testable languages are regular and therefore these concepts apply to the finite automata that recognize the languages. The authors show that computing the order of a given locally testable deterministic automaton is NP-hard and present a polynomial-time ϵ-approximation algorithm for computing it. In addition, an upper bound of $2n^2+1$ on the order of a locally testable automaton of n states is obtained, and the co-NP-completeness of the problem of whether, for a given j, a given deterministic automaton is j-testable is proven.

1. Introduction.

The concept of local testability is rooted in the study of pattern recognition. It is best understood in terms of a kind of computational procedure used to classify a two-dimensional image: a window of relatively small size is moved around on the image and a record is made of the various attributes of the image that are detected by what is observed through the window. No record is kept of the order in which the attributes are observed and the positions of the image, where each attribute occurs, or how many times it occurs. We say that a classification on the possible images is *locally testable* if a decision about how the image is classified can be made simply on the basis of the set of attributes that occur. Certainly, some patterns involve global constraints and therefore cannot be recognized by local testing. Nevertheless, for many patterns, local testing is sufficient. In [8], local testability is discussed in terms of diameter-limited perceptrons.

The one-dimensional analogy to this concept has been well studied and is the subject of this paper. If we think of such an image as a character string, then the classification becomes a language. Formally, a locally testable language is defined as follows [2], [9].

DEFINITION 1.1. *Let Σ be a finite alphabet. For an integer $k \geq 0$ and $x \in \Sigma^*$ such that $|x| \geq k+1$, define $f_k(x)$ as the prefix ("front end") of x of length k, $t_k(x)$ as the suffix ("tail") of x of length k, and $I_{k+1}(x)$ as the set of ("intermediate") substrings of x of length $k+1$, i.e., $\{v | v \in \Sigma^{k+1}$ and $x = uvw$, for some $u, w \in \Sigma^*\}$. For $|x| \leq k$, $f_k(x) = t_k(x) = x$ and $I_{k+1} = \emptyset$ (the empty set). Let $SV_{k+1}(x)$ denote the triple $(f_k(x), I_{k+1}(x), t_k(x))$, called the* substring vector *of x. For $L \subseteq \Sigma^*$,*

(a) *L is 0-testable if and only if it is Σ^* or $\emptyset$.*

(b) *For an integer $k \geq 0$, L is $(k+1)$-testable if and only if, for all $x, y \in \Sigma^*$, $SV_{k+1}(x) = SV_{k+1}(y)$ implies that either both x and y are in L or neither is in L.*

(c) *An automaton is j-testable if it accepts a j-testable language.*

(d) *A language or an automaton is locally testable, if it is j-testable for some $j \geq 0$.*

It is well known that all locally testable languages are regular. The only automata considered in this paper are DFAs (deterministic finite automata). Throughout this paper we let $M = (Q, \Sigma, \delta, q_{st}, F)$ be a DFA, with the understanding that Q is the set of states, Σ the input alphabet, δ the state-transition function, $q_{st} \in Q$ the initial state and $F \subseteq Q$ the set of final (or accepting) states. For any $q \in Q$ and $w \in \Sigma^*$, by $\delta(q, w)$ we mean the state that results when input w is applied to M in state q. For notation we follow [4].

Clearly, if a language or an automaton is j-testable, it is j'-testable for any $j' > j$. We say a locally testable language or automaton has *testability order* j (*order*, for brevity) if it is j-testable but not $(j-1)$-testable. In the early 1970s, these languages and their finite state automata were extensively investigated [2], [9], [10], [12]. However, there were several open problems concerning locally testable automata that did not yield to practical solutions. (1) Is a given deterministic finite automaton locally testable? (2) If it is locally testable, what is the order? (3) What is the largest order that a locally testable finite automaton with n states can have?

Brzozowski and Simon [2] introduced the following characterization theorem for locally testable automata. Much of the theoretical work in this paper is based on part (b) of this theorem.

THEOREM 1.2 [2]. *For any M*

(a) *M is locally testable if and only if, for all $q \in Q$, $x \in \Sigma^+$, $y, z \in \Sigma^*$, and $n \geq |Q|$,*
 (i) $\delta(q, x^n y x^n) = \delta(q, x^n y x^n y x^n)$, *and*
 (ii) $\delta(q, x^n y x^n z x^n) = \delta(q, x^n z x^n y x^n)$.

(b) *M is $(k+1)$-testable, if and only if, for all $q \in Q$, $y, z \in \Sigma^*$ and $x \in \Sigma^k$,*
 (i) $xy = zx$ *implies* $\delta(q, xy) = \delta(q, xyy)$, *and*
 (ii) $\delta(q, xyxzx) = \delta(q, xzxyx)$.

In Fig. 1, we illustrate situations in which part (b) of Theorem 1.2 is not true. The falsity of condition (i) is illustrated in parts (a) and (b) of that figure; the falsity of condition (ii) is illustrated in part (c). Thus, $\delta(p_0, xy) = q_m \neq r_m = \delta(p_0, xyy)$ in both (a) and (b), and $\delta(p_0, xyxzx) = r_m \neq r'_m = \delta(p_0, xzxyx)$ in (c).

In [2] and [10], another characterization of locally testable automata was introduced in terms of algebraic properties of the semigroups of locally testable automata. (The semigroup concept will not be used in this paper.) The papers suggested algorithms for problems (1) and (2), which simply check whether the semigroup of the given automaton satisfies the appropriate algebraic properties. However, both algorithms take exponential time in the worst case, since the size of the semigroup of a deterministic automaton can be exponential in the number of states of the automaton. The papers left open whether it was possible to find better algorithms for problems (1) and (2). There was an answer to problem (3) in [2], which was a bound equal to the size of the semigroup of the automaton, which is also exponential in the number of states in the worst case. The answer we give in the present paper (Theorem 2.8) is polynomial in the size of automaton. Recently, in [6] we gave a characterization of locally testable deterministic finite automata and introduced an O(n^2) time algorithm for problem (1), the local testability problem, where n is the number of states of the automaton. Using the abbreviation SCC to mean a maximal strongly connected component of a directed graph, i.e., a subgraph that is strongly connected and is not a proper subgraph of another strongly connected subgraph, we restate this characterization theorem.

THEOREM 1.3 [6]. *An automaton M is locally testable if and only if its state transition graph satisfies the following two properties:*

(a) *No* SCC *of the state transition graph of the automaton has a pair of distinct states p and q such that $\delta(p, x) = p$ and $\delta(q, x) = q$, for any $x \in \Sigma^+$.*

(b) *For every pair of* SCCs *m_1 and m_2 such that m_1 is an ancestor of m_2, either*

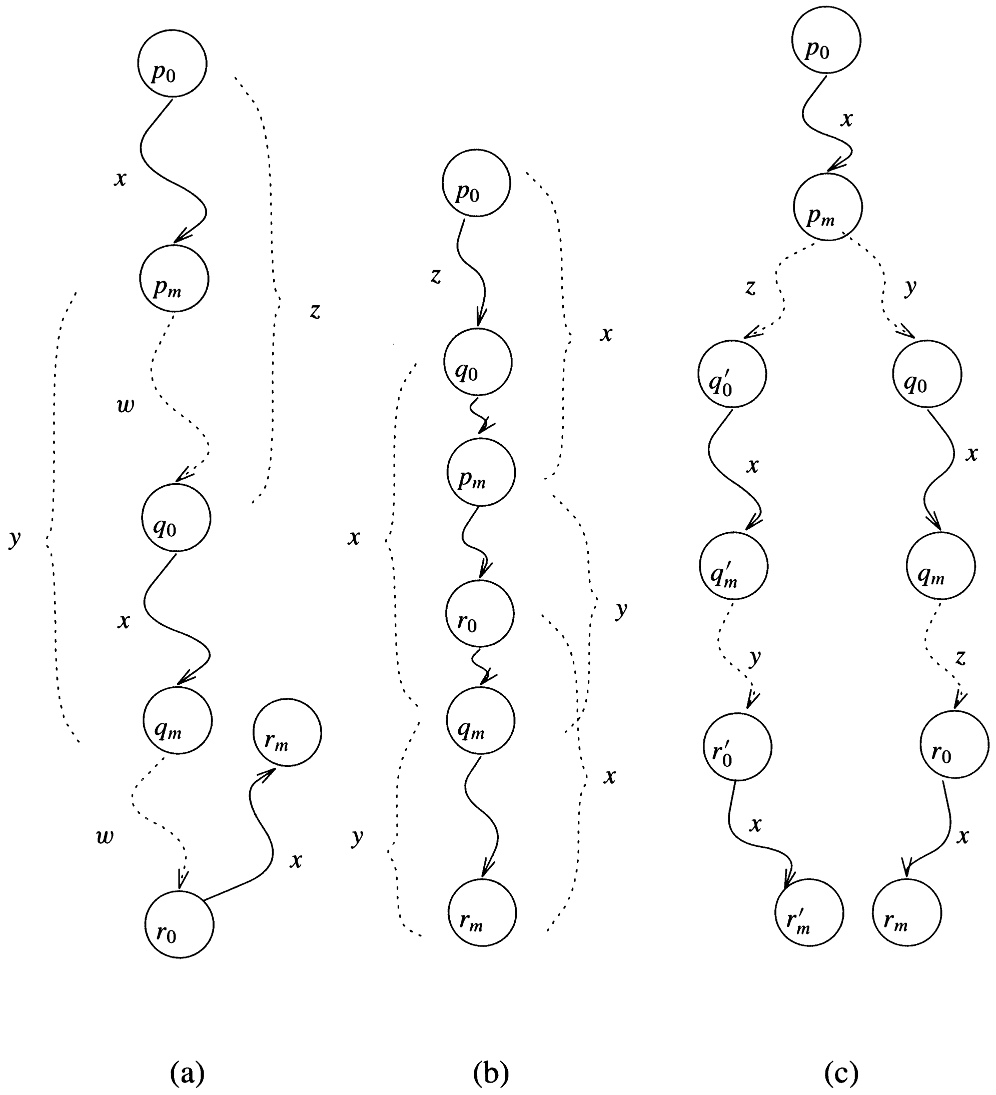

FIG. 1. *Typical transitions for part* (b) *of Theorem* 1.2.

(i) *no two states p in m_1 and q in m_2 exist such that $\delta(p, x) = p$ and $\delta(q, x) = q$, for any $x \in \Sigma^+$, or*

(ii) *for every such state pair p and q, there is a path from $\delta(p, w)$ to q if and only if $\delta(q, w)$ is in m_2, for every $w \in \Sigma^*$.*

This paper shows that problem (2), i.e., the problem of computing the order of a locally testable deterministic automaton, is NP-hard but has a polynomial-time ϵ-approximation algorithm. The algorithm, given a constant $\epsilon > 0$ and a locally testable deterministic automaton, computes an approximate order $\hat{k}$ of the automaton such that if k is the order then $\hat{k} \geq k$ and $(\hat{k} - k)/k \leq \epsilon$. For any constant ϵ the algorithm runs in polynomial time, the degree of the polynomial depending on ϵ. In order to deal with NP-hardness we define *the k-testability problem*: given a deterministic finite automaton M, and a nonnegative integer k, is M

k-testable? Following some preliminaries and a bound on the order in §2, §3 establishes that the k-testability problem is co-NP-complete. Sections 4 and 5 lay the theoretical groundwork for the approximation algorithm, §6 presents the algorithm itself and its analysis, and finally, §7 makes some concluding remarks.

2. Preliminaries and a bound on order. We assume throughout this paper that a problem instance is given in terms of the state transition graph of a reduced deterministic finite automaton M. This paper deals with edge-labeled directed graphs exclusively. The label on each edge is a letter of Σ. By *path* we mean a sequence of nodes $p_0 p_1 \dots p_n$ such that if p_{i+1} immediately follows p_i in the sequence then there is a directed edge from p_i to p_{i+1} in the graph. The length of the path is one less than the length of the sequence. The string $a_1 a_2 \dots a_n$ is a *span* of this path if and only if for each i, $1 \leq i \leq n$, a_i appears on the edge from p_{i-1} to p_i. For $p \in Q$, if $\delta(p, w) = p$, for some $w \in \Sigma^+$, then we say that p has a w loop.

We shall use q_e and q_d to denote, respectively, the accepting sink state and the nonaccepting sink state (or dead state) of the automaton; thus $\delta(q_e, a) = q_e$ and $\delta(q_d, a) = q_d$, for all $a \in \Sigma$.

It is trivial to identify 0-testable deterministic automata, i.e., those accepting Σ^* or $\emptyset$. Theorem 2.1 below shows a simple characterization of 1-testable deterministic automata, which can thereby be identified by a simple algorithm whose time complexity is on the order of the square of the size of the state transition graph.

Recalling Definition 1.1, note that $f_0(x) = t_0(x) = \epsilon$, for all strings x. Consequently, for all x and x', $SV_1(x) = SV_1(x')$ if and only if $I_1(x) = I_1(x')$. Thus a language L is 1-testable if and only if the following holds: for all x and x', if the set of letters occurring in x equals the set of letters occurring in x' then $x \in L$ if and only if $x' \in L$. In the proof of the following theorem, however, we do not use this characterization of 1-testability, but rather the characterization of part (b) of Theorem 1.2.

THEOREM 2.1. *A reduced automaton M is* 1*-testable if and only if, for all $q \in Q$ and $a, b \in \Sigma$,*

(1) *$\delta(q, a) = \delta(q, aa)$, and*

(2) *$\delta(q, ab) = \delta(q, ba)$.*

Proof. Assume first that M is 1-testable. We can show that in each case, since M is reduced, a violation of (1) or (2) would imply that the automaton is not 1-testable.

If $\delta(q, a) \neq \delta(q, aa)$, then we have $\delta(q, xax) \neq \delta(q, xaxax)$, for $x = \epsilon$. By letting $y = ax$ and $z = xa$, we have $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$. The automaton does not satisfy Condition (i) of Theorem 1.2(b) for x of length zero, and so it is not 1-testable.

If $\delta(q, ab) \neq \delta(q, ba)$ then, for $x = \epsilon$, we have $\delta(q, xaxbx) \neq \delta(q, xbxax)$. The automaton does not satisfy Condition (ii) of Theorem 1.2(b) for x of length zero, and so it is not 1-testable.

For the proof of sufficiency, suppose that M satisfies conditions (1) and (2) of our theorem. We note that, using mathematical induction on $|y|$, it can easily be proved that (2) implies

(a) for all $a \in \Sigma$, $y \in \Sigma^*$, $q \in Q$, $\delta(q, ay) = \delta(q, ya)$.

From (1) and (a), for any $u, v \in \Sigma^*$, we get $\delta(q, uav) = \delta(q, uaav) = \delta(q, uava)$. Hence, by taking y as uav, we get

(b) for all $y \in \Sigma^*$, $q \in Q$, if a is a letter in y then $\delta(q, y) = \delta(q, ya)$.

From (b) and (a), respectively, we get, for all $q \in Q$ and $y, z \in \Sigma^*$,

(c) $\delta(q, y) = \delta(q, yy)$ and

(d) $\delta(q, yz) = \delta(q, zy)$.

Finally, by part (b) of Theorem 1.2, (c) and (d) above imply that M is 1-testable. □

The test that Theorem 2.1 gives us is, as far as we know, the most efficient test to determine whether a given reduced deterministic finite automaton is 1-testable. We now proceed with the theoretical development needed to achieve our announced objectives for this section, which will not make use of Theorem 2.1.

We need the following well-known theorem (e.g., [3, p. 7]).

THEOREM 2.2. *For all strings x, y, z, $xy = zx$ if and only if there are strings u and v and integer $h \geq 0$ such that $z = uv$, $y = vu$ and $x = (uv)^h u$.*

DEFINITION 2.3 (periodic string). *Let $x = a_1 a_2 \ldots a_m$ be a string over a finite alphabet Σ. String x is* periodic *with period d, $1 \leq d \leq m - 1$, if $a_i = a_{i+d}$, for all i, $1 \leq i \leq m - d$.*

Notice that if a string x of length m is periodic with a period d, then $x = z^k u$, where z is the prefix of x of length d, $k = \lfloor m/d \rfloor$ and u is the prefix of z of length m mod d. The following lemma directly follows from Definition 2.3.

LEMMA 2.4. *If a string x is periodic with period d, then x has the following properties. Let z and y be, respectively, the prefix and suffix of length d of x.*

(a) *$x = zw = wy$, for some string w.*

(b) *$x = z^h u$, where $h = \lfloor |x|/d \rfloor$ and u is the prefix of length $|x|$* mod *d of z.*

(c) *every substring of length $> d$ of x is also periodic with the same period d.*

In order to establish that the k-testability problem is in co-NP we use the fact that a locally testable automaton M is k-testable for some $k \leq 2n^2 + 1$, where n is the number of states of M. This polynomial bound on k will be established in Theorem 2.8 below.

LEMMA 2.5. *Let M be reduced and locally testable. Let q_0 and q_1 be a pair of states such that $\delta(q_0, z) = q_0$ and $\delta(q_1, z) = q_1$ for some $z \in \Sigma^+$. If $\delta(q_0, w) = q_1$, then, for every $i \geq 0$ and any prefix u of w, all nodes in the path corresponding to $\delta(q_1, w^i u)$ are in the same* SCC *with q_1.*

Proof. Since q_0 has a loop and q_1 also has a loop, each must be in an SCC. If $q_0 = q_1$ the matter is trivial, so we assume $q_0 \neq q_1$. But then, since M is locally testable, q_0 and q_1 must be in distinct SCCs. Let m be the SCC which includes q_1, and for each $j \geq 1$, let $\delta(q_0, w^j) = q_j$.

Since $\delta(q_0, w) = q_1$ and there is a path from q_1 to q_1, by condition (ii) of Theorem 1.3(b), $\delta(q_1, w) = q_2$ is in m. Since $\delta(q_1, w) = \delta(q_0, w^2)$ is in m, by the same theorem, $\delta(q_1, w^2) = q_3$ is in m. Continuing in this way, we see that all the q_j's, for $j \geq 1$, are in m, as are all nodes in the path corresponding to $\delta(q_1, w^j)$. Thus, for any prefix u of w, all nodes in the path corresponding to $\delta(q_1, w^{j-1} u)$ are also in m. □

LEMMA 2.6. *Let M have n states (not necessarily reduced) and let $x \in \Sigma^*$, $|x| \geq n^2$. Then, for any states p and r, there exist x', w and x'' such that $x = x'wx''$, $|x'w| \leq n^2$, $|w| \geq 1$, $\delta(p, x'w) = \delta(p, x')$, and $\delta(r, x'w) = \delta(r, x')$ (viz., $\delta(p, x')$ and $\delta(r, x')$ both have a loop with the same span w).*

Proof. Let $|x| = k$, $p = p_0$ and $r = r_0$. For $0 \leq i \leq k$, let $\sigma_i = (\delta(p_0, t_i), \delta(r_0, t_i)) = (p_i, r_i)$, where t_i is the prefix of x of length i. Since $k \geq n^2$, by the pigeonhole principle there exist i_1, i_2, $0 \leq i_1 < i_2 \leq n^2 \leq k$, such that $\sigma_{i_1} = \sigma_{i_2}$, viz., $p_{i_1} = p_{i_2}$ and $r_{i_1} = r_{i_2}$. Set x', w and x'' so that $|x'| = i_1$, $|w| = i_2 - i_1$ and $x'wx'' = x$. Then the required equations are satisfied. □

LEMMA 2.7. *Let m be an* SCC *of a locally testable automaton, and let h be the number of states in m. For $u, v, x \in \Sigma^*$, $|x| \geq h^2$, and a pair of states s and t both in m, which are not necessarily distinct, if $\delta(s, ux)$ and $\delta(t, vx)$ are both in m, then $\delta(s, ux) = \delta(t, vx)$.*

Proof. Let M be the subautomaton of the given automaton whose state transition graph is m. Let $p = \delta(s, u)$ and $r = \delta(t, v)$. Since $|x| \geq h^2$, by Lemma 2.6 there exist x', w, and x'' such that $x = x'wx''$, $|x'w| \leq h^2$, $\delta(p, x') = \delta(p, x'w)$, and $\delta(r, x') = \delta(r, x'w)$. Thus, both $\delta(p, x')$ and $\delta(r, x')$ have a loop with span w. Since m is an SCC of a locally testable deterministic automaton, by condition (i) of Theorem 1.3(b), it must be $\delta(p, x') = \delta(r, x')$, which gives $\delta(p, x'wx'') = \delta(r, x'wx'')$, i.e., $\delta(p, x) = \delta(r, x)$. Thus $\delta(s, ux) = \delta(t, vx)$. □

THEOREM 2.8. *If M is a reduced locally testable finite automaton with n states, then M is $(2n^2+1)$-testable. In other words, the upper bound on the order of a locally testable automaton with n states is $2n^2+1$.*

Proof. For the proof by contradiction, suppose that M is not $(k+1)$-testable for some $k \geq 2n^2$. Then, by part (b) of Theorem 1.2, there exist $q \in Q$, $y, z \in \Sigma^*$ and $x \in \Sigma^k$, such that either $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$, or $\delta(q, xyxzx) \neq \delta(q, xzxyx)$.

Case I. $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$. By Theorem 2.2, there exist $u, v \in \Sigma^*$ such that $y = vu$, $z = uv$ and $x = (uv)^h u$, for some $h \geq 0$. Let $a = |y| = |z|$. Note that $a > 0$; consequently, $2n^2 < |xy| = k + a < |xyy| = k + 2a$.

Let $q_0 = q$ and, for each i, $1 \leq i \leq k+2a$, let $q_i = \delta(q_0, t_i)$, where t_i is the prefix of xyy of length i. Note that $xyy = zxy = zzx$, $\delta(q_0, z) = q_a$, $\delta(q_0, x) = q_k$, and $\delta(q_a, x) = q_{k+a}$. Applying Lemma 2.6 with x, q_0, and q_a, we find x', α, and x'' such that $x = x'\alpha x''$, $|x'\alpha| \leq n^2$, $|\alpha| \geq 1$, $\delta(q_0, x') = \delta(q_0, x'\alpha)$, and $\delta(q_a, x') = \delta(q_a, x'\alpha)$. Letting $i_1 = |x'|$, we have $\delta(q_{i_1}, \alpha) = q_{i_1}$ and $\delta(q_{a+i_1}, \alpha) = q_{a+i_1}$. We illustrate this in Fig. 2(a). Note the following, which we shall use later.

(a) $x''y = z'x''$, for some z' (i.e., x'' is a suffix of $x''y$), since $xy = x'\alpha x''y = zx'\alpha x''$.

(b) $|x''| \geq n^2$, since $|x| \geq 2n^2$ and $|x'\alpha| \leq n^2$.

(c) $\delta(q_0, zx'\alpha) = \delta(q_0, zx') = q_{i_1+a}$.

Since $x''yy$ is a substring of length $> |z|$ of the periodic string $x'\alpha x''yy$, by part (c) of Lemma 2.4 it is also a periodic with period a. Let β be the prefix of $x''yy$ of length a, so that $\delta(q_{i_1}, \beta) = q_{a+i_1}$. By part (b) of Lemma 2.4 we have $x''yy = \beta^{h'}u'$, for some $h' \geq 1$, where u' is a prefix of β.

We note that Lemma 2.5 can be applied as follows. Take α, β, q_{i_1}, and q_{i_1+a}, respectively, as the z, w, q_0, and q_1 of Lemma 2.5. We have $\delta(q_{i_1}, \alpha) = q_{i_1}$, $\delta(q_{i_1}, \beta) = q_{i_1+a}$, and $\delta(q_{i_1+a}, \alpha) = q_{i_1+a}$, which establishes the application. Let m be the SCC with q_{i_1+a}. From Lemma 2.5 we infer that all nodes on the path from q_{i_1+a} having the string $\beta^i u'$ (for any value of $i \geq 0$) as a span are in the same SCC m. But this set includes all the nodes on the path corresponding to the transition $\delta(q_{i_1+a}, x''y)$. Since $x''y = z'x''$ from (a) above, all the nodes in the transition $\delta(q_{i_1+a}, z'x'')$ are in SCC m.

Recalling that $|x''| \geq n^2$ from (b) above, we apply Lemma 2.7 with $s = q_{i_1+a}$, $t = q_{i_1+a}$, $u = \epsilon$, $v = z'$, and $x = x''$, and conclude that $\delta(q_{i_1+a}, x'') = \delta(q_{i_1+a}, z'x'')$. But from (c) above we get $\delta(q_{i_1+a}, x'') = \delta(q_0, zx'\alpha x'') = \delta(q_0, zx) = \delta(q_0, xy)$ and $\delta(q_{i_1+a}, z'x'') = \delta(q_{i_1+a}, x''y) = \delta(q_0, zx'\alpha x''y) = \delta(q_0, zxy) = \delta(q_0, xyy)$. It follows that $\delta(q_0, xy) = \delta(q_0, xyy)$, a contradiction.

Case II. $\delta(p_0, xyxzx) \neq \delta(p_0, xzxyx)$ (using p_0 in place of q). For $1 \leq i \leq k$, let $p_i = \delta(p_0, t_i)$ where t_i is the prefix of x of length i. Thus, $p_k = \delta(p_0, x)$. Let $\delta(p_k, y) = q_0$, $\delta(p_k, z) = q'_0$, $\delta(q_0, x) = q_k$, $\delta(q'_0, x) = q'_k$, $\delta(q_k, z) = r_0$, and $\delta(q'_k, y) = r'_0$. Finally, for $1 \leq i < k$, let q_i, q'_i, r_i, r'_i be, respectively, $\delta(q_0, t_i)$, $\delta(q'_0, t_i)$, $\delta(r_0, t_i)$, $\delta(r'_0, t_i)$, where t_i is the prefix of x of length i. Thus $r_k = \delta(p_0, xyxzx)$ and $r'_k = \delta(p_0, xzxyx)$. All this is summarized in Fig. 2(b).

Applying Lemma 2.6 with states p_0 and r_0 and string x, we find x', w, and x'' such that $x = x'wx''$, $|x'w| \leq n^2$, $|w| \geq 1$, $\delta(p_0, x') = \delta(p_0, x'w)$, and $\delta(r_0, x') = \delta(r_0, x'w)$. Letting $|x'| = i_1$, we have $\delta(p_{i_1}, w) = p_{i_1}$ and $\delta(r_{i_1}, w) = r_{i_1}$. Let C_p and C_r be the SCCs containing p_{i_1} and r_{i_1}, respectively.

By condition (ii) of Theorem 1.3(b), since there is a path from $\delta(p_{i_1}, x''yxzx'w^k) = r_{i_1}$ to r_{i_1}, the node $s = \delta(r_{i_1}, x''yxzx'w^k)$ is in C_r. Since $\delta(r_{i_1}, w^k) = r_{i_1}$ and $|w^k| > n^2$, we can apply Lemma 2.7, taking s and t of the lemma to be s and r_{i_1}, respectively; we infer $s = r_{i_1}$. Thus r_{i_1} has a $x''yxzx'w^k$ loop. Since $\delta(r_{i_1}, x'') = r_k$ is on this loop, it is in the SCC C_r.

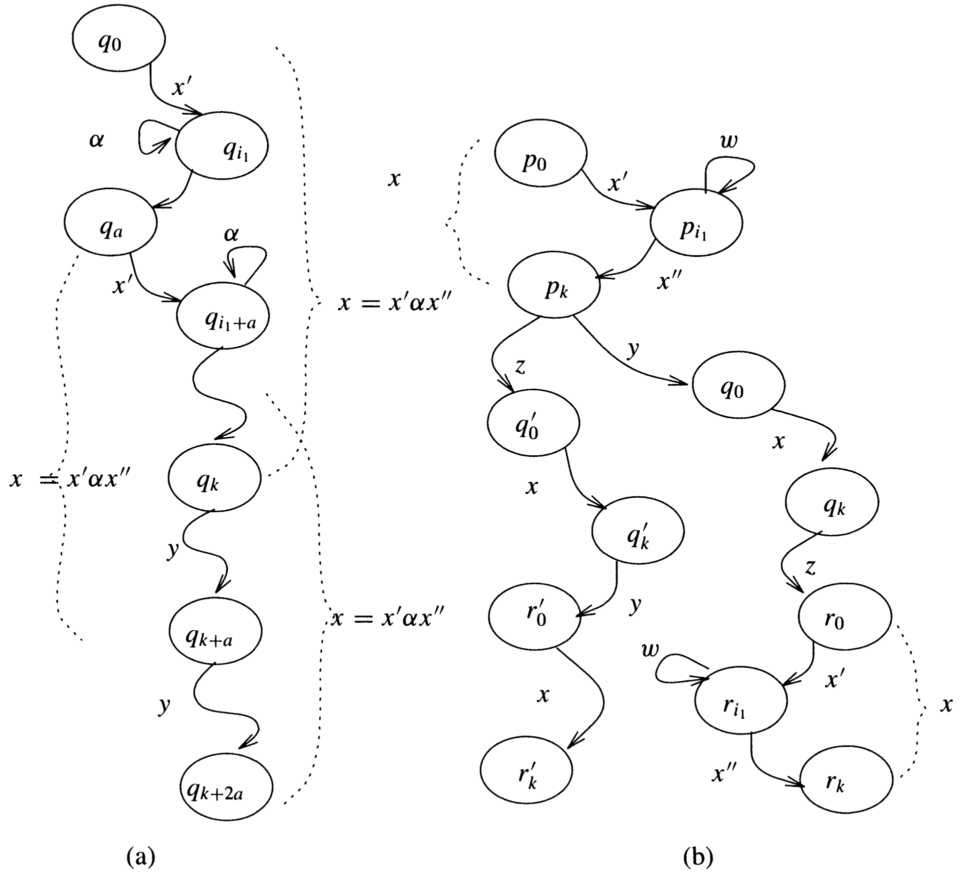

FIG. 2. *Proof of Theorem* 2.8. (a) *Case* I; (b) *Case* II.

Again, we apply condition (ii) of Theorem 1.3(b) with p_{i_1} and r_{i_1}. Since there is a path from $r_k = \delta(p_{i_1}, x''yxzx'wx'') = \delta(p_{i_1}, x''yxzx)$ to r_{i_1}, the node $s' = \delta(r_{i_1}, x''yxzx)$ is in C_r. Thus, we have $r_k = \delta(r_{i_1}, x'')$, $s' = \delta(r_{i_1}, x''yxzx)$, and $t = \delta(r_{i_1}, x''yx)$ all in SCC C_r. Since $x = x'wx''$ and $|x''| \geq n^2$, by Lemma 2.7, we have $r_k = s' = t$. It follows that $\delta(r_k, yx) = \delta(r_k, zx) = r_k$. Since $\delta(r_{i_1}, x''zxyx) = r_k$ is in SCC C_r, by condition (ii) of Theorem 1.3(b), there must be a path from $\delta(p_{i_1}, x''zxyx) = r'_k$ to r_k.

In summary, we have proved that (1) $\delta(r_k, yx) = r_k$, (2) $\delta(r_k, zx) = r_k$, and (3) there is a path from r'_k to r_k. By symmetry (interchanging y and z, q_i and q'_i, r_i and r'_i for each i) we can prove that (1) $\delta(r'_k, zx) = r'_k$, (2) $\delta(r'_k, yx) = r'_k$, and (3) there is a path from r_k to r'_k, which is in an SCC $C_{r'}$.

It follows that r_k and r'_k are in the same SCC, i.e., $C_r = C'_r$. Since $\delta(r_k, yx) = r_k$ and $\delta(r'_k, yx) = r'_k$, by Lemma 2.7 we get $r_k = r'_k$, a contradiction.

Both Case I and Case II having been proved contradictory; the proof of our theorem is complete. □

Since k-testability implies k'-testability for any $k' > k$, we have the following corrollary.

COROLLARY 2.9. *If M has n states and is reduced, then M is locally testable if and only if it is $(2n^2 + 1)$-testable.*

As far as we know $2n^2 + 1$ is the best upper bound on the order of a reduced locally testable DFA. We conjecture that the order is no greater than $O(n^{1.5})$ when the alphabet size is 2, and no less than $O(n^2)$ in the general case. Figure 3 shows an idea for constructing a locally testable automaton whose order approaches a bound that is $O(n^{1.5})$. The automaton has order 128 with 29 states, including the nonaccepting sink state q_d not shown in the figure. Let $x = a^{26}ba^{25}ba^{23}ba^{20}ba^{16}ba^{11}$, $y = bax$, and $z = xba$. Then $xy = zx$ and $\delta(p, xy) = t \neq \delta(p, xyy) = q_d$. It is not difficult to show that for any state q of the automaton and $x', y', z' \in \{a, b\}^+$ such that $x'y' = z'x'$ and $|x'| > |x|$, it satisfies $\delta(q, x'y') = \delta(q, x'y'y') = q_d$ and $\delta(q, x'y'x'z'x') = \delta(q, x'z'x'y'x') = q_d$. Since $|x| = 126$, by part (b) of Theorem 1.2 the automaton is not 127-testable, but we are satisfied that there is no similar situation with any x of length 127. Thus the order is 128. We think that this is the largest order achievable with 29 states and two input symbols. (In [6] we discussed this example, stating erroneously that the automaton had 28 states and had order 127.)

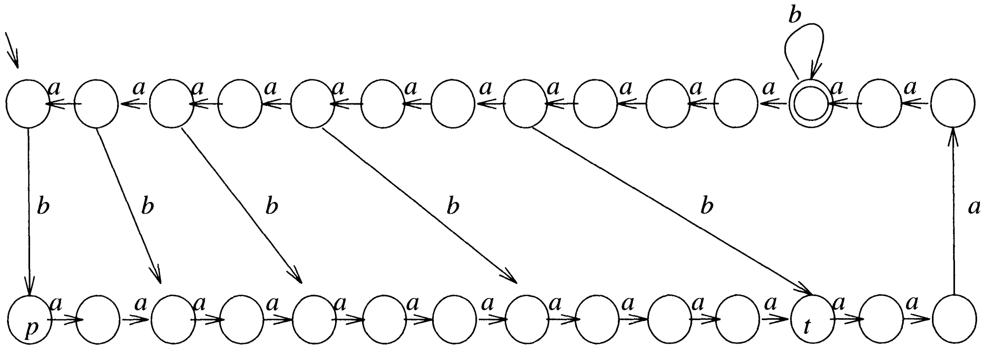

FIG. 3. *A* DFA *whose order is* 128 *with* 29 *states.*

3. Proof of co-NP-completeness.

With the groundwork established in §2, this section shows that the problem of computing the order of a locally testable deterministic automaton is NP-hard by proving that the k-testability problem is co-NP-complete. Before we show the main result, we need some working lemmas.

LEMMA 3.1. *If M has n states and y is a string such that $\delta(p_1, y) = q_1$ and $\delta(p_2, y) = q_2$, then there is a y_1 such that $|y_1| \leq n^2 - 1$, $\delta(p_1, y_1) = q_1$, and $\delta(p_2, y_1) = q_2$.*

Proof. We prove the lemma by proving instead that if y satisfies the hypothesis but does not satisfy $|y| \leq n^2 - 1$, then there is a shorter y_1 satisfying the hypothesis.

So, suppose $|y| \geq n^2$. Then, by Lemma 2.6, there exist y', w, and y'' such that $y = y'wy''$, $|y'w| \leq n^2$, and $|w| \geq 1$, and both $\delta(p_1, y')$ and $\delta(p_2, y')$ have w loops. It follows that $\delta(p_1, y'y'') = q_1$ and $\delta(p_2, y'y'') = q_2$. Then $y_1 = y'y''$ satisfies the hypothesis. □

LEMMA 3.2. *Let M have n states and let $k \geq 1$, $q \in Q$, $x \in \Sigma^{k-1}$, and $y, z \in \Sigma^*$. If $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$, then there exist y', z' such that $|y'|, |z'| \leq k + n^2 - 2$, $xy' = z'x$, and $\delta(q, xy') \neq \delta(q, xy'y')$.*

Proof. Clearly, $|y| = |z|$. Assume that $|y| > k + n^2 - 2$. Then $|y| > |x|$ and the equation $zx = xy$ implies the existence of y_1 such that $z = xy_1$ and $y = y_1x$. Hence, $xy = xy_1x$ and $xyy = xy_1xy_1x$. Let $\delta(q, x) = q_1$, $\delta(q_1, y_1) = q_2$, $\delta(q_2, x) = q_3$, $\delta(q_3, y_1) = q_4$, and $\delta(q_4, x) = q_5 \neq q_3$.

Applying Lemma 3.1 with states q_1 and q_3, and string y_1, we find y_1', $|y_1'| \leq n^2 - 1$, such that $\delta(q_1, y_1') = q_2$ and $\delta(q_3, y_1') = q_4$. Putting $y' = y_1'x$ and $z' = xy_1'$ we get $|y'| = |z'| \leq k + n^2 - 2$, $z'x = xy'$, and $\delta(q, xy') = q_3 \neq q_5 = \delta(q, xy'y')$. □

LEMMA 3.3. *Let M have n states, $q \in Q$, and $x, y, z \in \Sigma^*$. If $\delta(q, xyxzx) \neq \delta(q, xzxyx)$ then, for some y', z' where $|y'|, |z'| \leq n^2 - 1$, $\delta(q, xy'xz'x) \neq \delta(q, xz'xy'x)$.*

We omit the proof, which makes straightforward use of Lemma 3.1.

THEOREM 3.4. *The k-testability problem is in co-NP.*

Proof. For given deterministic automaton M and nonnegative integer k, the nondeterministic algorithm for the co-problem of the k-testability problem is shown in Fig. 4. This polynomial time procedure will terminate negative without reaching step 3 or will terminate negative for some allowable choice in step 3 if and only if M is not k-testable. We leave the proof to the reader, noting only that Theorem 1.2(b), Theorem 2.8, and Lemmas 3.2 and 3.3 are involved; in particular, the two lemmas justify restricting the choice of n_1 and n_2 to integers less than $k + n^2 - 2$. □

```
Procedure CO-NP ($M$, $k$);
(// $n$ is the number of states of $M$ //)

begin
1. if $k = 0$ then
      begin
         if $M$ is 0-testable
                  then output "$M$ is $k$-testable" and terminate
                  else output "$M$ is not $k$-testable" and terminate
      end;

2. Nondeterministically choose $x \in \Sigma^{k-1}$, $q \in Q$, nonnegative integers
      $n_1, n_2 \leq k + n^2 - 2$ and strings $y \in \Sigma^{n_1}$ and $z \in \Sigma^{n_2}$;
3. if $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$
      then output "$M$ is not $k$-testable"
      else if $\delta(q, xyxzx) \neq \delta(q, xzxyx)$ then output "$M$ is not $k$-testable"
end.
```

FIG. 4. *The nondeterministic algorithm for the co-k-testability problem.*

Our proof of co-NP-completeness involves reducing SAT (the satisfiability problem of a propositional formula in conjunctive normal form) to the complement of the k-testability problem in polynomial time.

Let $A = C_1C_2 \ldots C_m$, $m \geq 4$, be a propositional formula in conjunctive normal form (CNF) having $r \geq 4$ variables $v_1, v_2, \ldots, v_r$. We shall show how to construct a locally testable deterministic automaton M that is not $5rm$-testable if and only if A is satisfiable. The idea is best understood by an example; Fig. 5 depicts the automaton for $A = C_1C_2C_3C_4$, where

$$\begin{aligned} C_1 &= v_1 \vee \overline{v_2} \vee \overline{v_4} \vee v_5, \\ C_2 &= v_1 \vee \overline{v_2} \vee v_4 \vee \overline{v_5}, \\ C_3 &= \overline{v_3} \vee \overline{v_5}, \\ C_4 &= \overline{v_1} \vee \overline{v_2} \vee v_4. \end{aligned}$$

The figure does not show the rejecting sink state q_d or the transitions to it.

In general, we construct the automaton $M = (Q, \{a, b\}, \delta, q_{st}, F)$ from A as follows. The automaton has the nonaccepting sink state q_d and the accepting sink state q_e. For each clause C_i, the state transition graph has two parallel paths $p_{i,0}p_{i,1} \ldots p_{i,r-1}$ and $q_{i,1}q_{i,2} \ldots q_{i,r}$, each having r states. Among these states δ is defined as follows. For all j, $0 \leq j \leq r - 1$, if C_i has variable v_{j+1} then $\delta(p_{i,j}, b) = q_{i,j+1}$ and $\delta(p_{i,j}, a) = p_{i,j+1}$ or q_d if $j = r - 1$. If C_i has $\overline{v_{j+1}}$ then $\delta(p_{i,j}, a) = q_{i,j+1}$ and $\delta(p_{i,j}, b) = p_{i,j+1}$ or q_d if $j = r - 1$. But if C_i has neither v_{j+1} nor $\overline{v_{j+1}}$ then $\delta(p_{i,j}, a) = \delta(p_{i,j}, b) = p_{i,j+1}$ or q_d if $j = r - 1$. For all j, $1 \leq j \leq r - 1$, $\delta(q_{i,j}, a) = \delta(q_{i,j}, b) = q_{i,j+1}$. We call the resulting graph G_i the clause-graph (CG) for C_i.

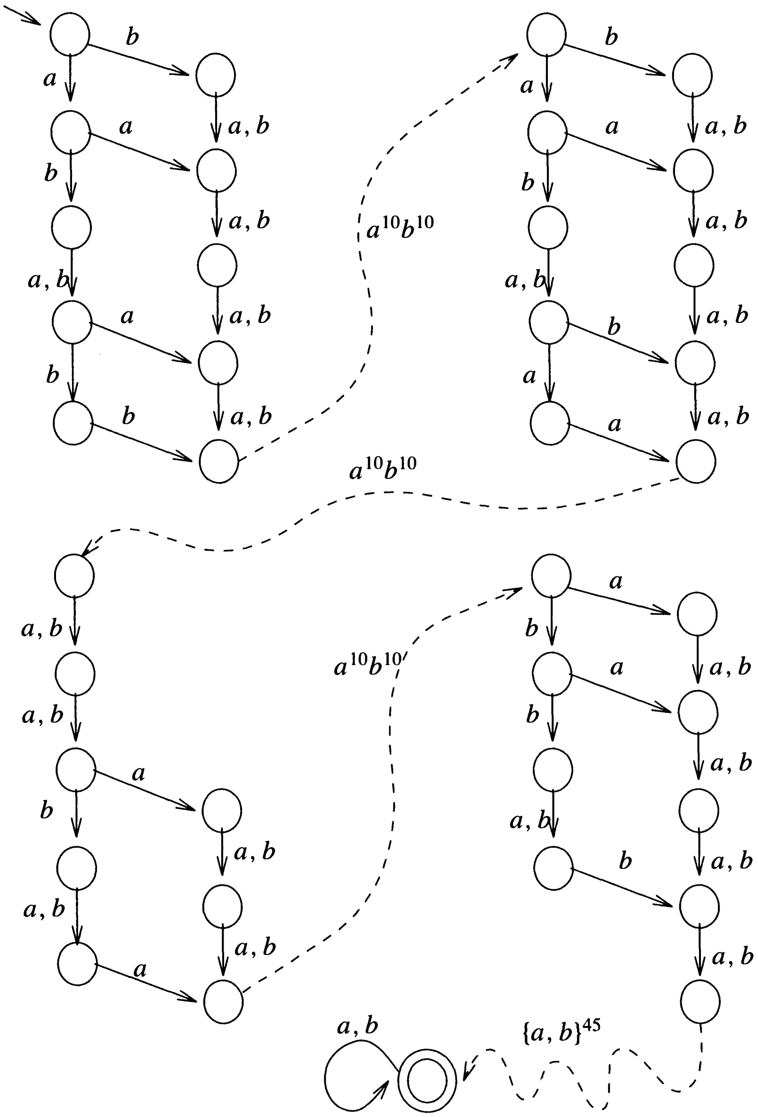

FIG. 5. *Constructing a locally testable* DFA *from a formula.*

Now, we link all CGs into a single chain by establishing a path with span $\alpha = a^{2r}b^{2r}$ from $q_{i,r}$ to $p_{i+1,0}$, $1 \leq i < m$, and we link $q_{m,r}$ of G_m to the accepting sink state q_e by a nonbranching path of length $2|\alpha| + r = 9r$. To say a path $P = q_1q_2 \ldots q_n$ is nonbranching is to say that for all i, $1 \leq i \leq n-1$, $\delta(q_i, a) = \delta(q_i, b) = q_{i+1}$. (The reason for the string α will be made clear in the following lemmas.) All transitions not so far defined go to the dead state q_d. Finally, we complete the construction by defining the start state q_{st} to be $p_{1,0}$ and reducing the automaton. Notice that in the reduced automaton q_e is the only accepting state, there is a path from the initial state to every other state, and there is a path from every state, except q_d, to q_e.

Let us make some observations about M and the language L that it accepts. Since every path from $p_{1,0}$ to q_e has length $5r(m+1)$ and q_e is the only accepting state, we have $L \subseteq \{a,b\}^{5r(m+1)}\{a,b\}^*$. There is only one path from $q_{m,r}$ to q_e, and all nodes on this path are nonbranching; this implies that, whenever $|z| = |z'|$, $\delta(q_{m,r}, z) = \delta(q_{m,r}, z')$. Finally, we note that the graph is acyclic except for q_e and q_d. Clearly, by Theorem 1.3, M is a locally testable automaton.

Now let $t_1, \ldots, t_r$ be truth value assignments, respectively, to variables $v_1, \ldots, v_r$, and let $w \in \Sigma^r$ be the string $\sigma_1\sigma_2 \ldots \sigma_r$, where, for each j, $\sigma_j = b$ if t_j is true, and $\sigma_j = a$ if t_j is false. Observe that there is a path in G_i from node $p_{i,0}$ to node $q_{i,r}$ with span w if and only if the clause C_i is true under this assignment. Therefore, the formula $C_1C_2 \ldots C_m$ is satisfiable if and only if there exists a string w such that $(w\alpha)^{m+1}$ is in the language of M. In Lemmas 3.5 through 3.8 below, M refers to the automaton that has just been constructed and $\alpha = a^{2r}b^{2r}$.

LEMMA 3.5. *Let $w_1, w_3 \in \Sigma^*$, $w_2 \in \Sigma^r$, and $x = w_1\alpha w_2\alpha w_3$. If x has period d, then $d \geq 5r$.*

Proof. Let $s = |w_1|$ and let $x[i]$, $1 \leq i \leq |x|$, denote the ith symbol in x. Then we have the following:

(a) $x[i] = a$ for all i, $s+1 \leq i \leq s+2r$, and for all i, $s+5r+1 \leq i \leq s+7r$.

(b) $x[i] = b$ for all i, $s+2r+1 \leq i \leq s+4r$, and for all i, $s+7r+1 \leq i \leq s+9r$.

If x has period d then $x[i] = x[i+d]$, for all i, $1 \leq i \leq |x| - d$. We prove our lemma by exhibiting a contradiction for each d, $1 \leq d \leq 5r-1$.

Case 1. $1 \leq d \leq 2r$. Then $x[s+2r] = a$ but $x[s+2r+d] = b$.

Case 2. $2r \leq d \leq 4r-1$. Then $x[s+1] = a$ but $x[s+1+d] = b$.

Case 3. $4r \leq d \leq 5r-1$. Then $x[s+2r+1] = b$ but $x[s+2r+1+d] = a$. □

LEMMA 3.6. *For $x \in \Sigma^*$, if $|x| \geq 5rm - 1$ then, for all $z, y \in \Sigma^*$ and $q \in Q$, $\delta(q, xyxzx) = \delta(q, xzxyx) \in M$.*

Proof. If $|x| \geq 5rm - 1$, by the construction of M, $\delta(q, x)$ is either q_d or a node on the nonbranching path from $q_{m,r}$ to q_e. (Indeed, this would be true even if $|x|$ were as small as $5rm - 4r$.) Thus, for all z_1 and z_2, $|z_1| = |z_2|$ implies $\delta(q, xz_1) = \delta(q, xz_2)$, which gives us the lemma. □

The following lemma is immediate from Theorem 1.2(b) and Lemma 3.6.

LEMMA 3.7. *If M is not $5rm$-testable, then there are q, x, y, z such that $|x| = 5rm - 1$, $xy = zx$, and $\delta(q, xy) \neq \delta(q, xyy)$.*

LEMMA 3.8. *The automaton M is not $5rm$-testable if and only if the formula $C_1 \ldots C_m$ is satisfiable.*

Proof. Assume M is not $5rm$-testable, and let q, x, y, z be the result of applying Lemma 3.7. The construction of M and the fact that $xy = zx$ and $\delta(q, xy) \neq \delta(q, xyy)$ imply that $q_d \neq \delta(q, xy) \neq q_e$ and $|xy| < 5r(m+1)$. Since $|x| = 5rm - 1$, we get $|y| \leq 5r$.

By construction of M, since $m \geq 4$ and $|x| = 5rm - 1$, xy must cover at least two α's, and therefore must be of the form $w_1\alpha w_2\alpha w_3$, where $|w_2| = r$. By Lemma 3.5, xy cannot have a period $< 5r$. By Theorem 2.2, $xy = zx$ implies that, for some u, v and $h \geq 0$, $y = vu$, $z = uv$ and $x = (uv)^h u$; hence, $xy = (uv)^{h+1}u$. Since $|x| \neq 0$, we cannot have both $|u| = 0$ and $h = 0$. Thus xy is periodic with period $|z|$. Thus $|y| = |z| \geq 5r$.

From the above conclusion, i.e., $|y| \leq 5r$, we get $|y| = 5r$, and hence

$$|xy| = 5r(m+1) - 1.$$

By the construction of M, the start state q_{st} is the only state from which there is a path of length $5r(m+1) - 1$ to a state other than q_e or q_d. Since $q_d \neq \delta(q, xy) \neq q_e$, we get $q = q_{st}$.

Since xy is a periodic span of a path of length $5r(m+1)-1$ with period $5r$ that starts from q_st, it must be that $xy = (w\alpha)^m wa^{2r}b^{2r-1}$ for some $w \in \Sigma^r$, where $\alpha = a^{2r}b^{2r}$. Thus w represents a set of truth values satisfying each of the clauses $C_1, C_2, \ldots, C_m$ and hence the formula is satisfiable.

It remains to prove that if the formula is satisfiable then M is not $5rm$-testable. But if it is satisfiable then there is a $w \in \Sigma^r$ that represents a satisfying set of truth values for every clause, implying that $\delta(q_{st}, (w\alpha)^{m+1}) = q_e$. Putting $x = (w\alpha)^{m-1}wa^{2r}b^{2r-1}$, $y = bwa^{2r}b^{2r-1}$, and $z = w\alpha$, we get $zx = xy$ and $\delta(q_{st}, xy) \neq q_e = \delta(q_{st}, xyy)$, showing that M is not $5rm$-testable. □

THEOREM 3.9. *The k-testability problem is co-NP-complete.*

Proof. Given a conjunctive normal formula with at least four clauses and at least four variables, we have shown how to construct an automaton M and an integer k such that M is not k-testable if and only if the formula is satisfiable. We leave it to the reader to verify that this construction can be completed in polynomial time. Thus SAT is polynomial-time reducible to the complement of the k-testability problem. From this and Theorem 3.4, the k-testability problem is co-NP-complete. □

COROLLARY 3.10. *The problem of computing the order of a locally testable automaton is NP-hard.*

4. Toward an approximation algorithm. Having shown that the problem of computing the order of a locally testable DFA is NP-hard, we seek to develop a polynomial-time algorithm for computing an approximate order. When we know a language L is locally testable, to make use of this fact we need to find a k such that L is k-testable, and we would like k to be as small as we can get it. The order k_{or} of L is the ideal value of k, since it is the smallest k such that L is k-testable. Since (probably) no tractable algorithm exists to find k_{or}, we must settle for some k that is larger and reasonably close. In §6 we shall present an ϵ-approximation algorithm that will serve this purpose: given ϵ and a locally testable automaton, it finds a value of $k \geq k_{or}$ such that

$$\frac{k - k_{or}}{k_{or}} \leq \epsilon.$$

(See [5] for other polynomial-time ϵ-approximation algorithms for NP-hard problems.) In this section and the next, we shall lay the theoretical foundation and a computational tool for our algorithm.

Let us reflect on part (b) of the Brzozowski–Simon theorem (Theorem 1.2). Note that if conditions (i) and (ii) are satisfied for all $x \in \Sigma^k$ then they are satisfied for any x of longer length. (In other words, if M is $(k+1)$-testable then it is $(k+i)$-testable for any $i > 1$.) Likewise if either (i) or (ii) fails for any $x \in \Sigma^{k-1}$ then it fails for some x of any shorter length. (If M is not k-testable then it is not $(k-i)$-testable for any $i > 0$.)

Thus a correct but inefficient algorithm to find the order of a given M, already known to be locally testable, is as follows: find the smallest k such that, for all $x \in \Sigma^k$, conditions (i) and (ii) are satisfied for all $q \in Q$, and $y, z \in \Sigma^*$, where $|y|, |z| \leq n^2 - 1$, n being the number of states of M. The order is then $k+1$. The limits on y and z are justified by Lemma 3.1. We know by Theorem 2.8 that we shall not have to search beyond $k = 2n^2 - 1$.

This algorithm takes exponential time, and our NP-hardness result inhibits any attempt to improve on it. However, we note that there is a polynomial-time algorithm to find the smallest k satisfying condition (ii). Since this algorithm is a part of our approximation algorithm, we shall present it (implicitly) in this section, deferring condition (i) to the next section.

DEFINITION 4.1 (n-tuple-graph, etc.). *For $n \geq 1$, the n-tuple-graph of M is the edge-labeled directed graph $G_n = G(V, E)$, where $V = Q^n$ and E is the set of labeled edges* *defined as follows. There is an edge from* $(p_1, p_2, \ldots, p_n)$ *to* $(q_1, q_2, \ldots, q_n)$ *labeled by* $a \in \Sigma$ *if* $\delta(p_i, a) = q_i$, *for all* i, $1 \leq i \leq n$. *Where* α *is a set of nodes of* G_n, *we obtain an abridgment* G_n^α *of* G_n *by deleting all the nodes of* α *and deleting all edges incident on nodes of* α. *Specifically, we define* $H_n = G_n^\alpha$, *where* α *is the set of all nodes* $(p_1, \ldots, p_{n-1}, p_n)$ *such that* $p_{n-1} = p_n$; $I_n = G_n^\beta$, *where* β *is the set of all nodes* $(p_1, \ldots, p_n)$ *such that, for some* i, j, $1 \leq i < j \leq n$, $p_i = p_j$; $H_n^{ac} = (H_n)^\gamma$, *where* γ *is the set of all nodes of* H_n *that have a loop; and* $I_n^{ac} = (I_n)^\eta$, *where* η *is the set of all nodes of* I_n *that have a loop.*

Note that a node $(p_1, \ldots, p_n)$ of G_n is in H_n if and only if $p_{n-1} \neq p_n$, and is in I_n if and only if $p_i \neq p_j$ for all i and j such that $i \neq j$. Note also that H_n^{ac} and I_n^{ac} are acyclic directed graphs (hence the designation "ac"). We shall use the graphs H_n, I_n, H_n^{ac}, and I_n^{ac} for various values of n in our algorithm. Obviously, $H_1 = I_1 = G_1$, which is the state transition graph of M itself; also $H_2 = I_2$. Figure 6 is an example of M, as given by its state transition graph, and the corresponding $H_2 = I_2$. Similarly, Fig. 7 is another M and its I_3 (which in this example happens to be the same as I_3^{ac}), showing only one sixth of the graph I_3; the other five portions of I_3 are each isomorphic to the part shown, with permuted node labeling (e.g., the permuted nodes corresponding to the visible node pqr are prq, qpr, qrp, rpq, and rqp). An example of a node in the H_3 of this M but not in I_3 is dds, to which there is a transition from the node dsr which is in I_3.

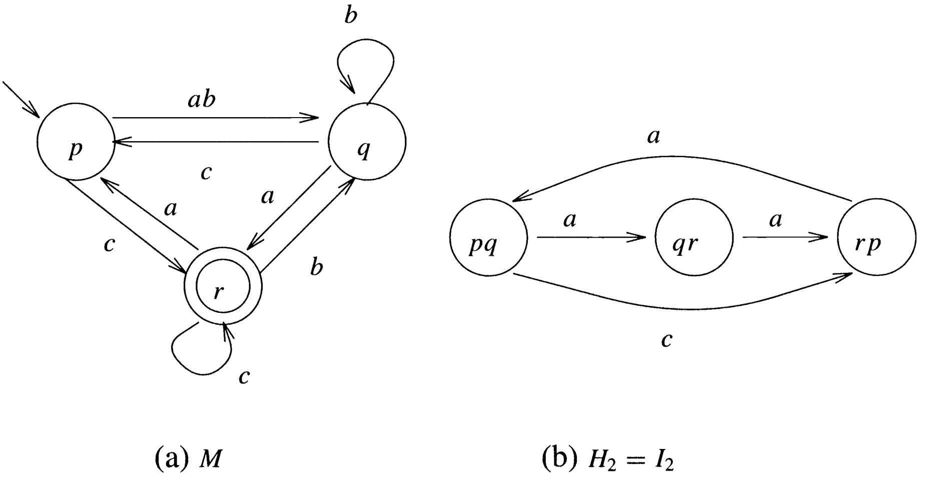

FIG. 6. *Constructing* H_2 *and* I_2 *for an automaton* M.

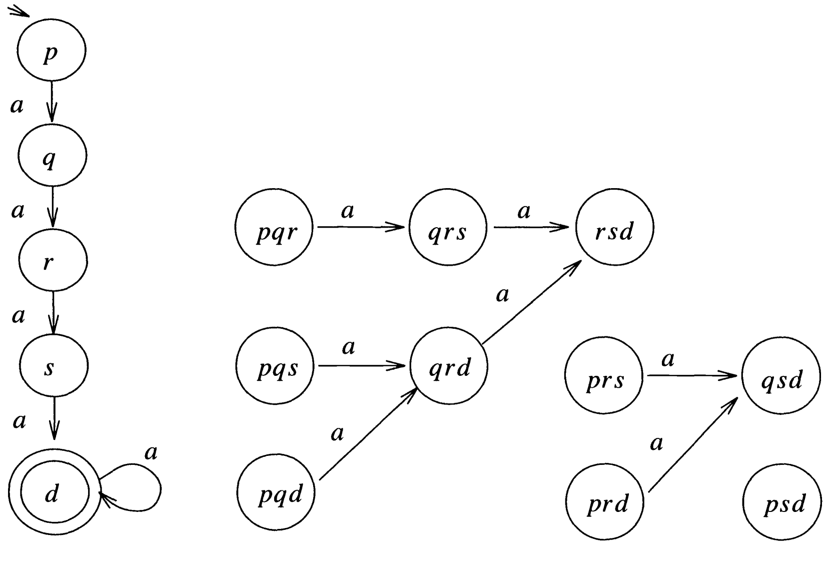
DEFINITION 4.2 (QCP). *Given* M, *let* $P = N_0 N_1 \ldots N_m$, $m \geq 0$, *be a path on* H_5, *where* $N_i = (p_i, q_i, q_i', r_i, r_i')$, $p_i, q_i, q_i', r_i, r_i' \in Q$, $1 \leq i \leq m$. *We say* P *is a* QCP (quintuple coherent-path) *if* G_2 *has a path from* (p_m, q_m) *to* (q_0', r_0) *and a path from* (p_m, q_m') *to* (q_0, r_0'). (*See Fig.* 1(c) *for a typical structure of transitions that give a* QCP *with span* x.)

For a graph G, we identify $|G|$ (the size of G) with the number of vertices plus the number of edges. For a finite automaton M, we identify $|M|$ with $i(j+1)$ where $i = |Q|$ and $j = |\Sigma|$. Thus the size of M is the size of the state transition graph G_1 of M, since i is the number of nodes and ij the number of edges of G_1.

LEMMA 4.3. *The graphs* G_n, H_n, *and* I_n *can be constructed from* M *and from* G_{n-1}, H_{n-1}, *and* I_{n-1}, *respectively, in time* $O(|M|^n)$.

Proof. Assume $|Q| = i$ and $|\Sigma| = j$. Since G_n has i^n nodes and each node has j outgoing edges, G_n can be constructed in time $O(ji^n)$, which is also a bound on the time for



(a) M (b) Part of I_3

FIG. 7. *Constructing I_3 for an automaton M.*

computing H_n and I_n. Since $|M|$ is of size $i(j+1)$, ji^n is $O(|M|^n)$. The same argument holds for the construction of H_n from H_{n-1} and the construction of I_n from I_{n-1}. □

LEMMA 4.4. *If M is locally a testable automaton and k is the largest integer such that H_5 has a* QCP *of length $k-1$ then k is the smallest integer satisfying condition* (ii) *of Theorem* 1.2(b), *i.e., for all $x \in \Sigma^k$, $q \in Q$, $y, z \in \Sigma^*$, $\delta(q, xyxzx) = \delta(q, xzxyx)$.*

Proof. Assume k is the largest integer such that H_5 has a QCP of length $k-1$; let this QCP be $P = N_0N_1 \ldots N_{k-1}$, $N_i = (p_i, q_i, q_i', r_i, r_i')$. Let $x \in \Sigma^{k-1}$ be a span of this path. By Definition 4.2 G_2 has paths from (p_{k-1}, q_{k-1}') to (q_0, r_0') and from (p_{k-1}, q_{k-1}) to (q_0', r_0). Let y be a span on the former path and z be a span on the latter.

Since N_{k-1} is a node of H_5, by Definition 4.1 we have $r_{k-1}' \neq r_{k-1}$. From the definition of QCP (see Fig. 1(c)) we conclude that $\delta(p_0, xyxzx) = r_{k-1} \neq r_{k-1}' = \delta(p_0, xzxyx)$. Thus $k-1$ does not satisfy condition (ii) of Theorem 1.2(b).

It remains to prove that k satisfies condition (ii). To this end, let $x \in \Sigma^k$, $y, z \in \Sigma^*$, and $p_0 \in Q$. Let $p_k = \delta(p_0, x)$, $q_0 = \delta(p_k, y)$, $q_0' = \delta(p_k, z)$, $q_k' = \delta(q_0', x)$, $q_k = \delta(q_0, x)$, $r_0 = \delta(q_k, z)$, $r_0' = \delta(q_k', y)$, $r_k = \delta(r_0, x)$, and $r_k' = \delta(r_0', x)$. For each i, $1 \leq i \leq k$, let x_i be the prefix of x of length i, $r_i = \delta(r_0, x_i)$, and $r_i' = \delta(r_0', x_i)$ as in Fig. 1(c).

We claim $r_k = r_k'$. To justify our claim we note that $r_k \neq r_k'$ implies $r_i \neq r_i'$, for each i. Thus $r_k \neq r_k'$ implies that the sequence $(p_0, q_0, q_0', r_0, r_0'), \ldots, (p_k, q_k, q_k', r_k, r_k')$ is a path in H_5 and is, therefore, a QCP of length k, whose connecting paths are as indicated in the paragraph above. This contradicts the hypothesis of our lemma.

Thus $r_k = r_k'$ and we are able to infer that $\delta(p_0, xyxzx) = \delta(p_0, xzxyx)$. The node p_0 and $x \in \Sigma^k$, $y, z \in \Sigma^*$ being arbitrary, we conclude that k satisfies condition (ii) of Theorem 1.2(b). □

LEMMA 4.5. *No* QCP *of a locally testable* DFA *contains a node that has a loop in H_5. Thus all* QCPs *are in H_5^{ac}.*

Proof. Suppose node N_i, $1 \leq i \leq m$, of a QCP $N_0 \ldots N_i \ldots N_m$ has a loop, i.e., there is a path $N_0' \ldots N_j'$, $j \geq 1$, such that $N_0' = N_j' = N_i$. Clearly, for any positive integer α, the path $N_0 \ldots (N_0' \ldots N_j')^\alpha \ldots N_m$, is also a QCP of length $m + (\alpha - 1)j$.

Since there are QCPs of arbitrary length, from Lemma 4.4 and Theorem 1.2(b), we infer that, for all k, the automaton is not $(k+1)$-testable, and hence that it is not locally testable, contrary to the hypothesis in our lemma. □

DEFINITION 4.6. *Where G is a directed graph, $EP(G)$ is the table telling, for each ordered pair of nodes (v, v') of G, whether or not there exists a path in G from v to v'. If in addition G is acyclic then we define $LP(G)$ as the table telling, for each (v, v'), whether there exists a path from v to v' and, if so, the length of the longest such path.*

LEMMA 4.7. *Given a directed graph G, $EP(G)$ can be constructed in time $O(|G|^2)$.*

Proof. For a fixed vertex v of G, the entries for (v, v') where v' ranges over all vertices of G can all be entered in time $O(|G|)$ by a depth-first search for all the descendants of v. The algorithm for our lemma simply repeats this step for each vertex of G. □

LEMMA 4.8. *Given a directed graph G, the graph G^{ac} can be constructed in time $O(|G|)$.*

Proof. Let α be the set of nodes v of G that have no loops. The procedure to construct G^{ac} begins by constructing the set α. It does this by first executing an algorithm due to Tarjan that lists all SCCs of G in time $O(|G|)$ [1], [11]. Now each node v is in α if and only if $\{v\}$ is a singleton SCC and, for all $a \in \Sigma$, $\delta(v, a) \neq v$. Thus α is constructed in time $O(|G|)$. Finally $G^{ac} = G^{V-\alpha}$ is constructed from G and α in time $O(|G|)$. □

LEMMA 4.9. *If G is an acyclic directed graph then the table $LP(G)$ can be constructed in time $O(|G|^2)$ from G.*

Proof. The first step is to construct for each node v of G a list of nodes to which there is an edge from v, and a list of nodes from which there is an edge to v (if such lists are not already available). The time for this step is $O(|G|)$.

Let m be the number of edges of G and n the number of nodes. The second step is to give the nodes of G the names $v_1, \ldots, v_n$ in such a way that $(v_i, v_j) \in E$ implies $i < j$. The technique to accomplish this is well known (e.g., [7, pp. 259–265]); the time is $O(m+n) = O(G)$.

The third step is to fill in the entries of our table $LP(G)$ in which v_1 is the origin vector. The entries for $(v_1, v_2), (v_1, v_3), \ldots$, are computed in order. Assuming that the entries for $(v_1, v_2), \ldots, (v_1, v_j)$ have all been filled in, we consider each of the nodes that are edge-connected to v_{j+1}. We find the maximum path length from v_1 to one of these vertices; the maximum path length from v_1 to v_{j+1} equals one plus that value. (If there is no path from v_1 to any of the vertices that are edge-connected to v_{j+1} then, of course, there is no path from v_1 to v_{j+1}.) The time to compute the table entries for $(v_1, v_2), (v_1, v_3), \ldots, (v_1, v_n)$ is $O(m+n)$, since each edge is involved only once during this entire step.

This step is repeated for all entries whose origin node is v_2, with the same time analysis, then for v_3, v_4, etc. Thus the time for the entire algorithm ($n+2$ steps) is $O((n+2)(m+n))$, and is therefore $O(|G|^2)$. □

LEMMA 4.10. *There is an algorithm that, given G_2 and H_5, computes in time $O(|M|^{10})$ the table telling, for all nodes N and N' of H_5, the length of the longest* QCP *(if any) from N to N'.*

Proof. The proof is by Lemmas 4.5, 4.7, 4.8, and 4.9 and Definition 4.2 (QCP). □

THEOREM 4.11. *There is an algorithm that, given a locally testable* DFA *M, computes the smallest k satisfying condition* (ii) *of Theorem* 1.2(b) *in time $O(|M|^{10})$.*

Proof. The graphs G_2 and H_5^{ac} can be constructed in time $O(|M|^5)$ by Lemmas 4.3 and 4.8. The table of Lemma 4.10 can be constructed in time $O(|M|^{10})$. By Lemma 4.4, this table enables us to determine the smallest k satisfying condition (ii). □

We have shown, in effect, how to deal with condition (ii) of Theorem 1.2(b) in our computation of the order of a locally testable automaton. In the next section we focus on condition (i), which is the bigger obstacle.

5. Accommodating condition (i). Theorems 3.9 and 4.11 imply that, given a locally testable M, computing the smallest k satisfying condition (i) of Theorem 1.2(b) is NP-hard, so we must resort to approximation techniques for this subproblem of finding the order.

Our idea for the approximation begins with Theorem 2.2, which permits us to revise condition (i) of the condition for $(k+1)$-testability to an alternative condition on k.

Condition (i′). For all $q \in Q$, $u, v \in \Sigma^*$ and $h \geq 0$, $h|uv| + |u| = k$ implies $\delta(q, (uv)^{h+1}u) = \delta(q, (uv)^{h+2}u)$.

Conditions (i) and (i′) are related by the equations $x = (uv)^h u$, $y = vu$ and $z = uv$, justified by Theorem 2.2. Theorem 1.2 is valid when condition (i) is replaced by condition (i′).

Ideally, we should search for the largest k not satisfying condition (i′), considering each triple (q, u, v) to find the largest h such that $\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+2}u)$. Lemma 5.2 below will assure us that h exists, and also that it is the unique value of h for which the following relations hold:

$$\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+2}u) = \delta(q, (uv)^{h+3}u).$$

Having found h, it is the length of $x = (uv)^h u$ that is significant. In fact, we should search for the length of the longest such x, over all triples (q, u, v). Our result in §3 indicates that this search cannot be done in polynomial time. However, if we choose a fixed positive $\overline{h}$ and restrict our investigation of u's, v's, and h's to cases where $h \leq \overline{h}$, we do get a polynomial-time algorithm, with the degree of the polynomial depending on $\overline{h}$. It will turn out that by so doing we can compute the smallest k satisfying condition (i′) approximately. The degree of approximation will depend only on $\overline{h}$ and will be valid for all locally testable finite automata M, however large.

Our algorithm will assume a specification of the desired accuracy of the approximation, represented in the familiar way by a positive real number ϵ. The value of $\overline{h}$ depends on ϵ, but for the moment we ignore ϵ and assume that $\overline{h}$ is given. It is the purpose of this section to present this procedure in detail and to justify it. We begin with two rudimentary lemmas and a corollary.

LEMMA 5.1. *For any M, let $p \in Q$, $u, v \in \Sigma^*$, $|uv| \geq 1$, $k \geq 1$, and $h \geq i \geq 0$. Then, for any $u_1, u_2, v_1, v_2 \in \Sigma^*$, such that $u = u_1u_2$ and $v = v_1v_2$,*

(a) *$\delta(p, (uv)^i u_1) = \delta(p, (uv)^{i+k}u_1)$ implies $\delta(p, (uv)^h u) = \delta(p, (uv)^{h+k}u)$, and*

(b) *$\delta(p, (uv)^i uv_1) = \delta(p, (uv)^{i+k}uv_1)$ implies $\delta(p, (uv)^{h+1}u) = \delta(p, (uv)^{h+1+k}u)$.*

Proof. (a) Note that $(uv)^i u_1 = u_1(u_2vu_1)^i$. We can therefore rewrite the hypothesis in (a) as $\delta(p, u_1(u_2vu_1)^i) = \delta(p, u_1(u_2vu_1)^{i+k})$. Where $q_1 = \delta(p, u_1(u_2vu_1)^i)$, we see that $\delta(q_1, (u_2vu_1)^k) = q_1$, i.e., q_1 has a $(u_2vu_1)^k$ loop of length $k|uv|$. Notice that

$$(uv)^h u = (uv)^i u(vu)^{h-i} = (uv)^i u_1u_2(vu)^{h-i} = u_1(u_2vu_1)^i(u_2vu_1)^{h-i}u_2.$$

Thus, the node $q_2 = \delta(p, (uv)^h u) = \delta(q_1, (u_2vu_1)^{h-i}u_2)$ is also on the loop corresponding to the transition $\delta(q_1, (u_2vu_1)^k) = q_1$. So we have $\delta(q_2, (vu)^k) = q_2$. In other terms, $\delta(p, (uv)^h u(vu)^k) = \delta(p, (uv)^{h+k}u) = \delta(p, (uv)^h u)$, proving part (a). The proof of part (b) is similar. □

LEMMA 5.2. *Given $u, v \in \Sigma^*$, and $p \in Q$, let h be the smallest nonnegative integer such that, for some $k \geq 1$, $\delta(p, (uv)^h u) = \delta(p, (uv)^{h+k}u)$. If the smallest such k is greater than* 1 *then M is not locally testable.*

Proof. Let $q_1 = \delta(p, (uv)^h u)$. Then we have

$$\delta(p, (uv)^h u) = q_1 = \delta(p, (uv)^{h+k}u) = \delta(p, (uv)^h u(vu)^k) = \delta(q_1, (vu)^k),$$

i.e., q_1 has a $(vu)^k$ loop. If the smallest such $k > 1$, then $q_2 = \delta(q_1, vu) \neq q_1$. Clearly, $q_2 = \delta(q_2, (vu)^k)$, i.e., q_2 has a $(vu)^k$ loop. There are two distinct states q_1 and q_2 in an SCC that have a $(vu)^k$ loop. By Theorem 1.3(a) M is not locally testable. □

COROLLARY 5.3. *If M is locally testable, then, for any $q \in Q$, $u, v \in \Sigma^*$, there exists a nonnegative integer h such that*

(a) $\delta(q, (uv)^h u) = \delta(q, (uv)^{h+\beta} u)$ *for all* $\beta \geq 1$, *and*

(b) *for all* γ *and* γ' *such that* $\gamma < h$ *and* $\gamma \neq \gamma'$, $\delta(q, (uv)^{\gamma} u) \neq \delta(q, (uv)^{\gamma'} u)$.

Before embarking on the theoretical justification of our procedure, we consider an example. Assume $\overline{h} = 20$, $x = (uv)^{50}u$, and $\delta(q, (uv)^{51}u) \neq \delta(q, (uv)^{52}u)$. Here $h = 50$, and we must show that there is an $h' < 20$, and strings u' and v' such that $x' = (u'v')^{h'}u'$ fails to satisfy condition (i) and the length of x' will be almost that of $x = (uv)^{50}u$. We accomplish this by taking $u'v' = (uv)^s$, for some appropriate s, $u' = (uv)^i u$, for some $i \leq s - 1$, and $v' = v(uv)^{s-i-1}$. Then if s has been well chosen we shall be able to select $h' < 20$ and $i \leq s - 1$ so that $x' = (u'v')^{h'}u'$ can play the desired rôle. For this example, we see that if we take $s = 3$, $h' = 15$, and $i = 1$ (so that $u' = uvu$ and $v' = vuv$), we get $x' = (u'v')^{15}u' = (uv)^{46}u$. Furthermore, Corollary 5.3 implies that $\delta(q, (u'v')^{16}u') = \delta(q, (uv)^{49}u) \neq \delta(q, (u'v')^{17}u') = \delta(q, (uv)^{52}u)$, since $\delta(q, (uv)^{51}u) \neq \delta(q, (uv)^{52}u)$. Thus $\delta(q, (u'v')^{h'+1}u') \neq \delta(q, (u'v')^{h'+2}u')$, showing that $k = h'|u'v'| + |v'|$ does not satisfy condition (i′), and hence this k (which is $|x'|$) does not satisfy condition (i), as required. Of interest are the comparative lengths of x and x' as given by the fraction

$$\frac{|x| - |x'|}{|x'|} \leq \frac{4}{46}.$$

In general, suppose we have M, q, and $x = (uv)^h u$ such that $\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+2}u)$ but $h > \overline{h}$. In order to justify our algorithm, we prove the existence of integers $s \geq 2$, $i \leq s - 1$, and $h' \leq \overline{h}$, such that, for u' and v' determined as above, $x' = (u'v')^{h'}u'$ also satisfies the desired property and $|x'|$ is appropriately close to $|x|$. We postpone the consideration of what s must be until after the next lemma, and we assume for the moment that s is given.

LEMMA 5.4. *Where M is locally testable, suppose that* $2 \leq s \leq h$, $x = (uv)^h u$, $|uv| > 0$, *and* $\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+2}u)$, *for some* $q \in Q$. *Then, if we take* $h' = \lfloor (h+1)/s \rfloor - 1$ *and* $i = (h+1) \bmod s$, *we get*

$$\text{(a) } \delta(q, (u'v')^{h'+1}u') \neq \delta(q, (u'v')^{h'+2}u')$$

and

$$\text{(b) } \frac{|x|}{|x'|} \leq \frac{h}{h - (s-1)}$$

where, as above, $x' = (u'v')^{h'}u'$, $u' = (uv)^i u$, $v' = v(uv)^{s-i-1}$ *and hence* $u'v' = (uv)^s$.

Intuitively, Lemma 5.4 says that, given x and s, we can find an $x' = (u'v')^{h'}u'$, related to x as described in the paragraphs above, where $|x|/|x'| < h/(h - (s-1))$. The significance of this is that, if s had been chosen appropriately, h' would be no greater than $\overline{h}$, and $|x'|$ would be a good approximation to $|x|$. The lemmas that follow will make this statement precise and will justify it.

Proof of Lemma 5.4. (a) Note that $h' + 1$ is the quotient and i the remainder when $h + 1$ is divided by s. Thus $h + 1 = s(h' + 1) + i$. We get

$$\delta(q, (u'v')^{h'+2}u') = \delta(q, (uv)^{s(h'+2)}(uv)^i u) = \delta(q, (uv)^{s(h'+1)+i+s}u) = \delta(q, (uv)^{h+1+s}u),$$

and

$$\delta(q, (u'v')^{h'+1}u') = \delta(q, (uv)^{s(h'+1)+i}u) = \delta(q, (uv)^{h+1}u).$$

But, by Corollary 3.5 and $\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+2}u)$, it follows that $\delta(q, (uv)^{h+1}u) \neq \delta(q, (uv)^{h+1+s}u)$, which gives us part (a) of our lemma.

For part (b) note that

$$|x'| = h'|u'v'| + |u'| = sh'|uv| + i|uv| + |u| = (sh' + i)|uv| + |u|,$$

and $|x| = h|uv| + |u|$. For convenience, take $\alpha = |u|/|uv|$. Then, from $sh' + i = s(h' + 1) + i - s = h + 1 - s = h - (s - 1)$, we get

$$\frac{|x|}{|x'|} = \frac{h + \alpha}{sh' + i + \alpha} = \frac{h + \alpha}{h - (s - 1) + \alpha} \leq \frac{h}{h - (s - 1)},$$

since $\alpha \geq 0$ and $h > h - (s - 1) > 0$. □

We now take on the task of chosing a value for s. One consideration is that s should be as small as possible to make the ratio $h/(h - (s - 1))$ of Lemma 5.4 as small as possible. However, there is a restraint: we must make sure that $h' \leq \bar{h}$. So we must take s as the smallest positive integer such that $h' = \lfloor (h + 1)/s \rfloor - 1 \leq \bar{h}$. We need a lemma from elementary number theory.

LEMMA 5.5. *If a and b are positive integers and $a > b$, then thê smallest positive integer c such that $\lfloor a/c \rfloor \leq b$ equals $\lfloor a/(b + 1) \rfloor + 1$.*

Proof. Consider the set

$$\{x \mid \lfloor a/x \rfloor \leq b\} = \{x \mid a/x < b + 1\} = \{x \mid x > a/(b + 1)\}.$$

The smallest integer in this set is $\lfloor a/(b + 1) \rfloor + 1$. □

Applying Lemma 5.5 to the discussion immediately preceding, we see that we should take $s = \lfloor (h + 1)/(\bar{h} + 2) \rfloor + 1$. Lemma 5.5 tells us that this value of s gives us the optimal approximation. The remaining lemmas, which are proved without reference to Lemma 5.5, tell us how good the approximation is.

LEMMA 5.6. *Suppose it is given that $h > \bar{h} \geq 1$ and $x = (uv)^h u$, for a given M. Taking $s = \lfloor (h + 1)/(\bar{h} + 2) \rfloor + 1$ and h', u', v', and x' as in Lemma 5.4, we get $h' \leq \bar{h}$ and $|x|/|x'| \leq (\bar{h} + 1)/\bar{h}$.*

Proof. First note that $2 \leq s \leq h$, which shows that Lemma 5.4 is applicable. We are assured by the informal discussion since Lemma 5.4 that $h' \leq \bar{h}$. By Lemma 5.4, $|x|/|x'| \leq h/(h - (s - 1))$. Since $s - 1 = \lfloor (h + 1)/(\bar{h} + 2) \rfloor \geq 1$, if we take $r = (h + 1) - (s - 1)(\bar{h} + 2)$ then we have $0 \leq r \leq \bar{h} + 1$ and $h = (s - 1)(\bar{h} + 2) + r - 1$. (Note that $s - 1$ and r are quotient and remainder when $h + 1$ is divided by $\bar{h} + 2$.) Thus

$$\frac{h}{h - (s - 1)} = \frac{(s - 1)(\bar{h} + 2) + r - 1}{(s - 1)(\bar{h} + 1) + r - 1} = \frac{\bar{h} + 2 + (r - 1)/(s - 1)}{\bar{h} + 1 + (r - 1)/(s - 1)} \leq \frac{\bar{h} + 1}{\bar{h}},$$

since $1 + (r - 1)/(s - 1) \geq 1 - 1/(s - 1) \geq 0$. □

The significance of Lemma 5.6 is that, having picked $\bar{h}$, we can be sure that, for any locally testable automaton M, however large, and for any $u, v \in \Sigma^*$ and h, however large, the following will hold: for $x = (uv)^h u$, there exist u', v', and $h' \leq \bar{h}$ such that we can use $x' = (u'v')^{h'} u'$ instead of x to compute the largest k not satisfying condition (i′), and our result will be off by a quantity that is a function of $\bar{h}$ only. This implies that if we compute for any M the largest k not satisfying condition (i′), ignoring strings of the form $(uv)^h u$ where $h > \bar{h}$, the result will be off by at most a quantify that is a function of $\bar{h}$ only. Furthermore, the value of this function can be made as small as we please provided we are willing to pay the penalty of a sufficiently large $\bar{h}$.

Under the assumption that $\overline{h}$ is fixed, we consider the problem of finding, for any given M, the largest k not satisfying the following condition.

Condition (i″). For all $q \in Q$, $u, v \in \Sigma^*$ and $h \leq \overline{h}$, $h|uv| + |u| = k$ implies $\delta(q, (uv)^{h+1}u) = \delta(q, (uv)^{h+2}u)$.

Note that condition (i″) is like condition (i′) except for the upper limit on h. Unlike condition (i′), condition (i″) is not equivalent to condition (i) of Theorem 1.2(b). Although it cannot be used to find the order of a locally testable automaton, it will be used to find an approximate order.

DEFINITION 5.7 (n-CP). *For $n \geq 2$, let $P = N_0N_1 \ldots N_m$, $m \geq 0$, be a path on I_n, where $N_j = (p_{1,j}, p_{2,j}, \ldots, p_{n,j})$, $p_{i,j} \in Q$ for $0 \leq j \leq m$, and $1 \leq i \leq n$. We say path P is an* n-CP (n-fold coherent path) *if and only if I_{n-1} has a path, called a* connecting path, *of length ≥ 0 from $(p_{1,m}, p_{2,m}, \ldots, p_{n-1,m})$ to $(p_{2,0}, p_{3,0}, \ldots, p_{n,0})$.*

Note that QCPs (Definition 4.2) and 5-CPs are different. Also note that the length m of an n-CP and the length of the connecting path cannot both be 0, since that would force $p_{1,0} = p_{1,m} = p_{2,0}$, and N_0 would not be a node of I_n. The significance of n-CPs will be demonstrated in Lemmas 5.8 and 5.9.

LEMMA 5.8. *Let M be a locally testable automaton. For $p_{1,0} \in Q$ and $h \geq 0$, if $\delta(p_{1,0}, (uv)^{h+1}u) \neq \delta(p_{1,0}, (uv)^{h+2}u)$ then there is an $(h+3)$-*CP *spanned by u whose connecting path is spanned by v.*

Proof. Let $m = |u|$. Take $N_0 = (p_{1,0}, p_{2,0}, \ldots, p_{h+3,0})$ and $N_j = (p_{1,j}, \ldots, p_{h+3,j})$, where, for each i and j, $p_{i,j} = \delta(p_{i,0}, u_j)$, where u_j is the prefix of u of length j, and $p_{i+1,0} = \delta(p_{i,m}, v)$. Also, take $L_0 = (p_{1,m}, \ldots, p_{h+2,m}) = (q_{1,0}, \ldots, q_{h+2,0})$ and, for each j such that $1 \leq j \leq |v|$, $L_j = (q_{1,j}, \ldots, q_{h+2,j})$, where, for $1 \leq i \leq h+2$, $q_{i,j} = \delta(q_{i,0}, v_j)$, v_j being the prefix of v of length j. Thus $L_{|v|} = (q_{1,|v|}, \ldots, q_{h+2,|v|}) = (p_{2,0}, \ldots, p_{h+3,0})$. We proceed to demonstrate that $N_0N_1 \ldots N_m$ is an $(h+3)$-CP spanned by u. Actually, it is quite clear that this is so if $N_0, \ldots, N_m$ are all nodes of I_{h+3} and $L_0, \ldots, L_{|v|}$ are all nodes of I_{h+2}, which we now prove by contradiction.

Accordingly, assume $N_j = (p_{1,j}, \ldots, p_{h+3,j})$ is not a node of I_{h+3}. Then $p_{i,j} = p_{i+k,j}$ for some $i \geq 1$ and $k \geq 1$, where $i+k \leq h+3$. Assume, without loss of generality, that k is the smallest integer satisfying this equation for any i and j. Note that $p_{i,j} = \delta(p_{1,0}, (uv)^{i-1}u_j)$, for all i and j.

Case I. $k = 1$. Then $\delta(p_{1,0}, (uv)^i u_j) = \delta(p_{1,0}, (uv)^{i+1}u_j)$. By Lemma 5.1, part (a), $\delta(p_{1,0}, (uv)^{h+1}u) = \delta(p_{1,0}, (uv)^{h+2}u)$, which contradicts the hypothesis of our lemma.

Case II. $k > 1$. Then $\delta(p_{1,0}, (uv)^{i-1}u_j) = p_{i,j} = p_{i+k,j} = \delta(p_{1,0}, (uv)^{i-1+k}u_j)$, but $p_{i,j} \neq p_{i+1,j} = \delta(p_{i,0}, (uv)^i u_j)$, which, by Lemma 5.2, implies that M is not locally testable, again contradicting the hypothesis of our lemma.

It remains to prove that the nodes $L_0, \ldots, L_{|v|}$ are in I_{h+2}. The proof is similar to the above proof for $N_0, \ldots, N_m$, using part (b) of Lemma 5.1 instead of part (a). □

The following lemma follows directly from the definition of n-CP.

LEMMA 5.9. *For $h \geq 0$, if there is an $(h+3)$-CP $N_0 \ldots N_m$ spanned by a string u and with a connecting span v then $\delta(p_{1,0}, (uv)^{h+2}u) \neq \delta(p_{1,0}, (uv)^{h+1}u)$, where $p_{1,0}$ is the first coordinate of N_0.*

LEMMA 5.10. *If M is locally testable then* (a) *all $(h+3)$-CPs are in I^{ac}_{h+3}, for all $h \geq 0$, and* (b) *the connecting paths of all $(h+3)$-CPs are in I^{ac}_{h+2} for all $h \geq 1$.*

Proof. Let $N_0 \ldots N_m$ be an $(h+3)$-CP, $N_i = (p_{1,i}, \ldots, p_{h+3,i})$, $0 \leq i \leq m$. For (a), assume that N_j $(0 \leq j \leq m)$ is not in I^{ac}_{h+3}. Then N_j has a loop and we would have arbitrarily long $(h+3)$-CPs from N_0 to N_m (cf. the proof of Lemma 4.5). Thus, by Lemma 5.9, for arbitrarily long u and for some fixed v, $\delta(p_{1,0}, (uv)^{h+2}u) \neq \delta(p_{1,0}, (uv)^{h+1}u)$, where $p_{1,0}$ is the first coordinate of N_0. But this would imply, by Theorems 1.2(b) (i) and 2.2 (cf. our discussion of condition (i′) above), that, for all $k \geq 1$, M is not k-testable. Thus M would not be locally testable. This establishes part (a).

For (b), assume $h \geq 1$ and assume that the connecting path from $(p_{1,m}, \ldots, p_{h+2,m})$ to $(p_{2,0}, \ldots, p_{h+3,0})$ has a node which has a loop. Where u is the span of the $(h+3)$-CP, we see that the $(h+3)$-CP has arbitrarily long connecting string v. For each v, $\delta(p_{1,0}, (uv)^{h+2}u) \neq \delta(p1, 0, (uv)^{h+1}u)$. Since the v's are arbitrarily long and $h \geq 1$, again by Theorems 1.2(b)(i) and 2.1, M is not locally testable. □

Note that part (b) of Lemma 5.10 does not apply to the case $h = 0$, viz., the connecting paths of 3-CP's need not be in I_2^{ac}. For in the case $h = 0$ we get $\delta(p_{1,0}, (uv)^1u) \neq \delta(p_{1,0}, (uv)^2u)$ from which we take $x = (uv)^0u = u$ and say that M is not $(|x|+1)$-testable. If there is a loop on a node in the connecting path then we do get arbitrarily long v's, but this does not give us arbitrarily long x's.

6. The approximation algorithm and its analysis. Our algorithm begins with a given M known to be locally testable. The largest k_2 not satisfying condition (ii) of Theorem 1.2(b) is determined without regard to ϵ, as discussed in §4. Then the algorithm computes $\bar{h}$ from ϵ (in a manner to be described), constructs I_2, and for each j, $3 \leq j \leq \bar{h}+3$, constructs the graph I_j^{ac} and the table $LP(I_j^{ac})$, using Lemmas 4.3, 4.8, and 4.9. (In some cases the algorithm will not need to go as far as $j = \bar{h}+3$, as we shall see.)

For each $h \leq \bar{h}$ and for each pair of nodes $N = (p_1, \ldots, p_{h+3})$ and $N' = (p'_1, \ldots, p'_{h+3})$ of I_{h+3}^{ac}, we define $\Delta_{h+3}(N, N')$ as follows. If there is no path from N to N' in I_{h+3}^{ac} or if there is no path in I_{h+2}^{ac} from $(p'_1, \ldots, p'_{h+2})$ to $(p_2, \ldots, p_{h+3})$ then $\Delta_{h+3}(N, N') = 0$. Otherwise, let $d_1 = d_1(N, N')$ be the maximum length of a path in I_{h+3}^{ac} from N to N' and $d_2 = d_2(N, N')$ be the maximum length of a path in I_{h+2}^{ac} from $(p'_1, \ldots, p'_{h+2})$ to $(p_2, \ldots, p_{h+3})$, and take $\Delta_{h+3}(N, N') = h(d_1 + d_2) + d_1$.

Note that for $h = 0$, d_2 has no material affect on $\Delta_{h+3}(N, N')$, as we discussed at the end of the preceding section. Hence in our algorithm we do not compute d_2 in the case $h = 0$. However, the algorithm must still verify that a connecting path in I_2 exists.

We take $\Delta(h+3)$ to be the maximum value of $\Delta_{h+3}(N, N')$ over all pairs of nodes (N, N') of I_{h+3}^{ac}. Finally, we take

$$k_1 = \mathrm{MAX}_{0 \leq h \leq \bar{h}}(\Delta(h+3)).$$

The proofs of the following two lemmas are straightforward from the definitions of $\Delta_{h+3}(N, N')$ and $(h+3)$-CP.

LEMMA 6.1. *For any nodes N and N' of I_{h+3}^{ac}, if $\Delta_{h+3}(N, N') = 0$, then there is no $(h+3)$-CP from N to N'. But if $\Delta_{h+3}(N, N') > 0$, then there exist an $(h+3)$-CP P from N to N', and strings $u, v \in \Sigma^*$ such that*

(a) *u is a span of P and, for $h > 0$, v is a span of a connecting path of P,*

(b) *$|u| = d_1(N, N')$, $|v| = d_2(N, N')$, and, hence, $|(uv)^h u| = \Delta_{h+3}(N, N')$, for some $h > 0$, and*

(c) *for any $(h+3)$-CP from N to N' with a span u' and a connecting path with a span v', it satisfies $|(u'v')^h u'| \leq |(uv)^h u|$.*

LEMMA 6.2. *For a given $\bar{h}$, the largest k not satisfying condition* (i″) *of* §5 *is the k_1 determined above.*

We now determine how to compute $\bar{h}$ from ϵ. Lemma 5.6 tells us that, if $x = (uv)^h u$ with $h > \bar{h}$, we can get $x' = (u'v')^{h'}u'$ with $h' \leq \bar{h}$ and $|x|/|x'| \leq (\bar{h}+1)/\bar{h}$. We want $(|x| - |x'|)/|x'|$ to be $\leq \epsilon$, and hence we want $|x|/|x'|$ to be $\leq 1+\epsilon$. We can accomplish this by taking $\bar{h}$ so that $(\bar{h}+1)/\bar{h} \leq 1+\epsilon$, or $\bar{h} \geq 1/\epsilon$. So we take $\bar{h} = \lceil 1/\epsilon \rceil$.

The value of k_2 that is computed is exact but (except for the circumstances noted below) the value of k_1 that is computed is only approximately the value needed to compute the order.

These values could be used to compute an approximation to the order k_{or} of M. But the approximation, if not exact, is less than k_{or}, since k_1 is generally less than the true value needed for condition (i) of Theorem 1.2(b). As we explained at the beginning of §4, we prefer to have the approximate order greater than k_{or} rather than less, so a modification must be made.

Recall that k_1 is the length of the longest $x' = (u'v')^{h'}u'$, for some u', v' and $h' \leq \bar{h}$, such that k_1 does not satisfy condition (i) of Theorem 1.2(b). Let $x = (uv)^h u$ be a longest x, with no limit on h, such that x does not satisfy that condition; let $c = |x|$. We know that $k_1 \leq c$ and $(c - k_1)/k_1 \leq \epsilon$. The next lemma enables us to find an integer k_1' such that $k_1' \geq c$ and $(k_1' - c)/c \leq \epsilon$.

LEMMA 6.3. *Let k_1 and c be as described above and $k_1' = k_1(1 + \epsilon)$; then $k_1' \geq c$ and $(k_1' - c)/c \leq \epsilon$.*

Proof. Where x and x' are as described above, Lemma 5.6 tells us that

$$\frac{c}{k_1} = \frac{|x|}{|x'|} \leq \frac{\bar{h}+1}{\bar{h}} = \frac{\lceil 1/\epsilon \rceil + 1}{\lceil 1/\epsilon \rceil} \leq \frac{1/\epsilon + 1}{1/\epsilon} = 1 + \epsilon.$$

Hence $k_1' = k_1(1 + \epsilon) \geq c$. Also, since $k_1 \leq c$, it follows that

$$\frac{k_1' - c}{c} \leq \frac{k_1' - k_1}{k_1} = \frac{k_1'}{k_1} - 1 = 1 + \epsilon - 1 = \epsilon. \qquad \square$$

There are two circumstances in which execution of the algorithm permits it to assert that the exact order has been computed. The first is the discovery of an $h \leq \bar{h} + 3$ such that there are no h-CPs, revealed in the result that $\Delta(h) = 0$. From this fact it follows that there are no h'-CPs for any $h' > h$. (From the definition of n-CP, it is easy to see that $h' > h$ implies that every h'-CP can be converted into an h-CP.) Thus execution in this circumstance reveals with certainty that all the n-CPs needed to compute the exact order have been examined.

The second such circumstance is that in which k_1, after being multiplied by $1 + \epsilon$, is no greater than k_2. Since k_2 has been computed with absolute precision, in this circumstance also it is known with certainty that the exact order has been computed.

The approximation algorithm is given in schematic form in Fig. 8. The correctness of the algorithm will follow from our work above once we prove the following lemma.

LEMMA 6.4. *The assertions $k_1 \geq c$ and $(k_1 - c)/c \leq \epsilon$ after line* 12 *of the algorithm are justified.*

Proof.

Case I. $i < \bar{h}+3$ at line 12. Then $k_1 = c$ is true upon leaving the loop under the condition that $\Delta(i + 1) = 0$, as explained above. Our lemma is therefore true in this case.

Case II. $i = \bar{h} + 3$ at line 12. Let k_{10} and k_{11}, respectively, be the values of k_1 before and after line 12 has been executed. Then $k_{11} = \lfloor k_{10}(1 + \epsilon) \rfloor$. We know $(c - k_{10})/k_{10} \leq \epsilon$ or, equivalently, $c \leq k_{10}(1 + \epsilon)$. From the fact that c is an integer it follows that $k_{11} \geq c$. Lemma 6.3 tell us that $(k_{11} - c)/c \leq \epsilon$. $\square$

In analyzing this algorithm, we note that it is dominated by the time it takes to construct the various graphs and their longest-path tables. Put $|M| = m$. The time to compute k_2 is $O(m^{10})$ by Theorem 4.11 (the k of Theorem 4.11 is one more than k_2).

To analyze the computation of k_1 we first note that each of the constructions in the while-loop of line 10, for a given value of i, is done in time

$$O(|G_{i+1}|^2) = O((m^{i+1})^2) = O(m^{2i+2})$$

by Lemmas 4.3, 4.8, and 4.9. We can ignore what is outside the loop; thus the time to compute k_1 is

$$O(\sum_{i=3}^{\bar{h}+2} m^{2i+2}) = O(m^{2\bar{h}+6}).$$

Thus the time for the execution of the algorithm is $O(|M|^{\mathrm{MAX}(10,6+2\bar{h})})$, where $\bar{h} = \lceil 1/\epsilon \rceil$. We see that the algorithm is less costly to operate the larger the value of ϵ, but increasing ϵ to values greater than $1/2$ is to no avail. Taking $\epsilon = 1/2$ allows the algorithm to operate in time $O(|M|^{10})$. In this case $\bar{h} = 2$ and n-tuple graphs are constructed only as far as G_5, which are precisely those used to compute k_2 in the algorithm, and which therefore would be needed even if ϵ were increased.

```
Procedure ApproxOrder($M$, $\epsilon$);

begin
    (// We first compute $k_2$. //)
1.  Construct $G_1$ from $M$; $G_2$ from $G_1$;
2.  Construct $EP(G_2)$; Construct $G_3$ from $G_2$ and $G_1$;
3.  Construct $G_5$ from $G_3$ and $G_2$; $H_5$ from $G_5$; $H_5^{ac}$ from $H_5$; Construct $LP(H_5^{ac})$;
4.  Find the length $k_2$ of the longest QCP from $LP(H_5^{ac})$ and $EP(G_2)$;

    (// We now compute $k_1$. //)
5.  $\bar{h} := \lceil 1/\epsilon \rceil$;
6.  Construct $I_2$ from $G_2$; Construct $EP(I_2)$;
7.  Construct $I_3$ from $G_3$; $I_3^{ac}$ from $I_3$; Construct $LP(I_3^{ac})$;
8.  Compute $\Delta(3)$ from $LP(I_3^{ac})$ and $EP(I_2)$;
9.  $i := 3$; exit := false;

10. While (($i \leq \bar{h} + 2$) and (not exit)) do
        begin
            Construct $I_{i+1}$ from $I_i$ and $G_1$; $I_{i+1}^{ac}$ from $I_{i+1}$; Construct $LP(I_{i+1}^{ac})$;
            Compute $\Delta(i + 1)$ from $LP(I_{i+1}^{ac})$ and $LP(I_i^{ac})$;
            if $\Delta(i + 1) = 0$ then exit := true else $i := i + 1$
        end;

11. $k_1 := MAX_{3 \leq j \leq i}(\Delta(j))$;
12. if $i = \bar{h} + 3$ then $k_1 := \lfloor k_1(1 + \epsilon) \rfloor$;
    (// At this point, $k_1 \geq c$ and $(k_1 - c)/c \leq \epsilon$, where $c$ is the largest integer
        not satisfying condition (i). //)

    (// Finally the order, precise or approximate, is computed. //)
13. $k := MAX(k_1, k_2) + 2$;
14. if ($i < \bar{h} + 3$ or $k_2 \geq k_1$)
        then return ('We found the exact order:' $k$)
        else return ('We found an approximate order:' $k$)
end.
```

FIG. 8. *The ϵ-approximation algorithm.*

There is a question as to whether the complexity bound $O(|M|)^{\mathrm{MAX}(10,6+2\bar{h})})$ for the algorithm can be decreased. If one could rewrite the algorithm so that the maximum lengths of the i-CPs and QCPs could be computed in time linear in the graph involved, then it might be possible to get the time complexity of the algorithm down to $O(|M|^{\mathrm{MAX}(5,3+\bar{h})})$. As it is, the construction of the tables $LP(H_5^{ac})$ and $LP(I_i^{ac})$ requires time on the order of the square of the size of the graphs involved.

7. Conclusions. We have showed that computing the order k of a locally testable deterministic automaton is NP-hard and have presented a polynomial-time algorithm for ϵ-approximation. These results answer the open questions raised in [2].

Our approximation algorithm is a polynomial-time approximation scheme since, for any constant $\epsilon > 0$, it computes an approximate order $\hat{k}$ such that $\hat{k} \geq k$ and $(\hat{k} - k)/k \leq \epsilon$ in time polynomial in the size of the automaton. However, since the time complexity is exponential in $1/\epsilon$, it is not a fully polynomial-time approximation scheme in the sense of Chapter 12 of [5].

We are interested in knowing whether there is a practical method of determining, for certain small values of k, if a given automaton is k-testable. For example, could the easy algorithm for the 1-testability problem established by Theorem 2.1 be extended to 2-testability, 3-testability, etc., without an excessive increase in complexity? This question is a challenge for future research.

Theorem 2.8 shows an upper bound $2n^2 + 1$ on the order of a locally testable deterministic automaton, where n is the number of states of the automaton. In [6] we conjectured that the bound is $O(n^2)$ and, for automata whose alphabet size is two, $O(n^{1.5})$. Thus Theorem 2.8 verfies part of our conjecture. As we discussed in §2, we still think that the other part of our conjecture is true.

A POLYNOMIAL-TIME ALGORITHM FOR THE PERFECT PHYLOGENY PROBLEM WHEN THE NUMBER OF CHARACTER STATES IS FIXED*

RICHA AGARWALA† AND DAVID FERNÁNDEZ-BACA‡

Abstract. This paper presents a polynomial-time algorithm for determining whether a set of species, described by the characters they exhibit, has a perfect phylogeny, assuming the maximum number of possible states for a character is fixed. This solves a longstanding open problem. This result should be contrasted with the proof by Steel [*J. Classification*, 9(1992), pp. 91–116] and Bodlaender, Fellows, and Warnow [*Proceedings of the* 19*th International Colloquium on Automata, Languages, and Programming*, Lecture Notes in Computer Science, 1992, pp. 273–283] that the perfect phylogeny problem is NP complete in general.

Key words. algorithms, character compatibility, evolution, perfect phylogeny

AMS subject classifications. 68Q25, 68R, 92A12, 92-08

1. Introduction. A fundamental problem in biology is that of inferring the evolutionary history of a set of species, each of which is specified by the set of *traits* or *characters* that it exhibits [9], [11], [17], [18]. Information about evolutionary history can be conveniently represented by an evolutionary or *phylogenetic* tree, often referred to simply as a *phylogeny*. In one of the standard models, the problem can be expressed mathematically as follows. Let $\mathcal{C} = \{1, \ldots, m\}$ be the *character set*, and for every $c \in \mathcal{C}$, let $\mathcal{A}_c = \{1, \ldots, r_c\}$ be the set of allowable *states* for character c. We write r to denote $\max_{c \in \mathcal{C}} r_c$. A *species* $\boldsymbol{s}$ is a vector $(s_1, \ldots, s_m)$ such that $\boldsymbol{s} \in \mathcal{A}_1 \times \cdots \times \mathcal{A}_m$; s_c is referred to as the *state of character c for* $\boldsymbol{s}$, or the *state of* $\boldsymbol{s}$ *on character c*. We assume that if $i \in \mathcal{A}_c$, then there exists a species $\boldsymbol{s} \in \mathcal{S}$ such that $s_c = i$. The *perfect phylogeny problem* is to determine whether a given set of n distinct species $\mathcal{S}$ has a tree T with the following properties:

(C1) $\mathcal{S} \subseteq V(T) \subseteq \mathcal{A}_1 \times \cdots \times \mathcal{A}_m$,
(C2) Every leaf in T is in $\mathcal{S}$,
(C3) For every $c \in \mathcal{C}$ and every $j \in \mathcal{A}_c$, the set of all $\boldsymbol{u} \in V(T)$ such that $u_c = j$ induce a subtree of T.

The tree T, if it exists, is called a *perfect phylogeny* for $\mathcal{S}$ and the set of characters $\mathcal{C}$ is said to be *compatible*. We should point out that in the biology literature, the perfect phylogeny problem is more commonly known as the *character compatibility problem* [6]. In this context, one is frequently interested in computing a maximal set of compatible characters since in practice character sets tend to be incompatible. Note also that instances of the phylogeny problem are often expressed in matrix form, by giving the set of species $\mathcal{S}$ as an $n \times m$ matrix M whose rows are the species in $\mathcal{S}$ [5], [14].

The perfect phylogeny problem was shown to be NP complete by Bodlaender, Fellows, and Warnow [2] and, independently, by Steel [20]. This fact suggests at least two lines of attack: one is to restrict m, the number of characters; the other is to restrict r. Pursuing the first approach, McMorris, Warnow, and Wimer have shown that the perfect phylogeny problem is solvable in $O(n^{m+1})$ time [19], which is polynomial for every fixed m; linear time algorithms have been found for $m = 3$ [3], [15]. In this paper, we pursue the second approach. Gusfield [14] gave an $O(nm)$ algorithm for $r = 2$, the *binary* character case; the procedure

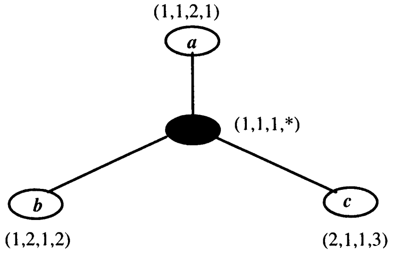

FIG. 1. *Forced and unforced states.*

is optimal if the input is given as a matrix of zeros and ones. In [1] it is shown that, under a suitable representation of the input, the run time can be reduced to $O(C)$ where C is the number of ones in the matrix. This reference also presents efficient algorithms for dynamic insertion and deletion of species and characters. All of the above results for the binary case are based on an elegant and well-known characterization of the set of "yes" instances [8]. Dress and Steel [7] devised an $O(nm^2)$ algorithm for $r \leq 3$. Kannan and Warnow [16] gave an $O(n^2m)$ algorithm for $r \leq 4$ (*quaternary* characters) and conjectured the existence of an $O(r^{r-2}n^2m)$ algorithm, which is polynomial for every fixed r. Here we prove the existence of a polynomial-time algorithm for any fixed r by giving an $O(2^{3r}(nm^3 + m^4))$ algorithm for the perfect phylogeny problem.

Instances of the perfect phylogeny problem where there is a known upper bound on the number of states per character are of interest to biologists. For instance, quaternary characters arise when using DNA to describe species; each possible state of a character corresponds to a nucleotide, A, G, C, or T. Other instances of interest are those where $r = 20$, which occur when species are described by protein sequences. These can be viewed as strings from a 20-letter alphabet, with each letter corresponding to one amino acid. While admittedly the running time of our algorithm grows quickly with r, it is a worst-case estimate which in practice may not pose too large a problem for current computational technology. Furthermore, the dependency on r can be reduced by a factor of 2^r using recent ideas due to Kannan and Warnow (see §6).

2. Preliminaries.

We now introduce some definitions and prove certain preliminary results.

DEFINITION 2.1. *Suppose T is a perfect phylogeny for $\mathcal{S}$ and let $\mathbf{p}$ be some vertex in T. We shall say that the state of $\mathbf{p}$ on character c is* forced *if $\mathbf{p}$ lies on the path between vertices $\mathbf{a}$ and $\mathbf{b}$ in $\mathcal{S}$ such that $a_c = b_c$. (Observe that if this is the case, in order to satisfy condition* (C3) *we must have $p_c = a_c = b_c$.)*

If the state of a character of a node is unforced, several assignments may be possible. In Fig. 1, for example, the state of the fourth character of the internal node is unforced and we could assign it a value of 1, 2, or 3.

LEMMA 2.2. *A set of species $\mathcal{S}$ has a perfect phylogeny if and only if every subset of $\mathcal{S}$ has one.*

Proof. The "if" part is trivial. For the "only if" part, let $\mathcal{S}'$ be any subset of $\mathcal{S}$ and let T be a perfect phylogeny of $\mathcal{S}$. Clearly, T satisfies (C1) and (C3) for $\mathcal{S}'$ but possibly not (C2). To obtain a perfect phylogeny for $\mathcal{S}'$, repeatedly delete from T any leaf that is not in $\mathcal{S}'$ until this operation is no longer possible. Since each deletion preserves properties (C1) and (C3) for $\mathcal{S}'$, the final tree will also satisfy (C2) for $\mathcal{S}'$. □

DEFINITION 2.3. *Suppose $G \subset \mathcal{S}$ and let $G' = \mathcal{S} - G$. $\mathcal{D}(G)$, the set of* distinguishing characters *of G, is the set of all $c \in \mathcal{C}$ such that for every $\mathbf{a} \in G$ and every $\mathbf{b} \in G'$, $a_c \neq b_c$. $\mathcal{M}(G)$, the set of* common characters, *is $\mathcal{C} - \mathcal{D}(G)$.*

Obviously, $\mathcal{D}(G) = \mathcal{D}(G')$ and $\mathcal{M}(G) = \mathcal{M}(G')$.

DEFINITION 2.4. *A pair (G, G') where $G \subset \mathcal{S}$ and $G' = \mathcal{S} - G$ is called a* split *if, for every character, the number of common character states between G and G' is at most one. A split (G, G') is a* c-split *if $\mathcal{D}(G) \neq \emptyset$. If (G, G') is a split (c-split), G and G' are called* clusters (c-clusters).

Although there can be up to $2^{n-1} - 1$ splits, the total number of c-splits is at most $(2^{r-1} - 1) \cdot m$. Observe that we can determine whether a partition (G, G') of $\mathcal{S}$ is a split in $O(nm)$ time. Note also that if G is a cluster but not a c-cluster, then $\mathcal{M}(G) = \mathcal{C}$.

DEFINITION 2.5. *Let (G, G') be a split. We say that (G, G') is of* type I *if there exists an $s \in G$ such that for all $c \in \mathcal{M}(G)$, s_c equals the unique common state between G and G' on character c and $|G - \{s\}|, |G'| \geq 1$. If (G, G') is of type* I, *we refer to s as a* connecting species. *If (G, G') is not of type* I, *we say that it is of type* II.

Checking whether a split (G_1, G_2) is of type I can be achieved in $O(nm)$ time as follows. First, compute $\mathcal{M}(G_1)$ and the common state between G_1 and G_2 on each $c \in \mathcal{M}(G_1)$. This can be done in $O(nm)$ time by considering characters one at a time. Now, it suffices to search for a species s such that for all $c \in \mathcal{M}(G_1)$, s_c equals the common state between G_1 and G_2. This takes $O(m)$ time per species, for a total of $O(nm)$ time.

If there is a type I c-split (G_1, G_2) where s is a connecting species, the problem can be divided into constructing perfect phylogenies T_1 and T_2 for $G_1 \cup \{s\}$ and $G_2 \cup \{s\}$. If one or both of the latter sets has no perfect phylogeny then, by Lemma 2.2, neither does $\mathcal{S}$. If both sets have perfect phylogenies, then a perfect phylogeny for $\mathcal{S}$ is obtained by identifying the nodes for s in T_1 and T_2. We now consider the case where all c-splits are of type II.

LEMMA 2.6. *If all c-splits are of type* II, *then, in every perfect phylogeny T of $\mathcal{S}$, every species $s \in \mathcal{S}$ is a leaf in T.*

Proof. Suppose there exists a species $s \in \mathcal{S}$ such that s is an internal node in some perfect phylogeny T of $\mathcal{S}$. Let T' be any connected component of $T - s$, let G' be the set of species in T', and let $G = \mathcal{S} - G'$. Clearly, (G, G') is a c-split with $|G'| \geq 1$ and $|\mathcal{S} - G'| \geq 2$. One can also readily verify that c-split (G, G') is of type I, with s as a connecting species. □

3. Subphylogenies.

In this section and the next we assume that $\mathcal{S}$ has no type I splits.

DEFINITION 3.1. *A* subphylogeny *T_G for a cluster G is a perfect phylogeny for G containing a node x such that for every $c \in \mathcal{M}(G)$, x_c equals the (unique) common state for character c between G and $\mathcal{S} - G$, and for every $c \in \mathcal{D}(G)$, x_c is the state of some species in G on character c. Node x is referred to as the* connection *of T_G.*

The next result implies that, in searching for a perfect phylogeny for $\mathcal{S}$, we can restrict our attention to perfect phylogenies constructed entirely from subphylogenies.

LEMMA 3.2. *$\mathcal{S}$ has a perfect phylogeny if and only if there exists a split (G_1, G_2) such that both G_1 and G_2 have subphylogenies.*

Proof. For the "if" part, let (G_1, G_2) be a split satisfying the requirements of the lemma and let T_1 and T_2 be subphylogenies for G_1 and G_2, respectively. Let x^1 and x^2 be the connections of T_1 and T_2. We can obtain a perfect phylogeny for $\mathcal{S}$ by taking T_1 and T_2 and connecting them as follows. If $\mathcal{D}(G_1) = \emptyset$, identify x^1 and x^2. Otherwise, add an edge (x^1, x^2). It is not hard to check that conditions (C1)–(C3) hold.

For the "only if" part, let T be a perfect phylogeny for $\mathcal{S}$ and let (u, v) be any edge in T. Without loss of generality, assume that every node in T that is not in $\mathcal{S}$ has a degree of at least three. Let T_1 and T_2 be the subtrees of $T - (u, v)$ containing u and v, respectively, and let $G_1 = \mathcal{S} \cap V(T_1)$ and $G_2 = \mathcal{S} - G_1$. T_1 and T_2 are obviously perfect phylogenies for G_1 and G_2. We can construct a subphylogeny for G_1 from T_1 as follows. For each $c \in \mathcal{D}(G_1)$ such that u_c is not the state of some species in G_1, let B_c be the set of all $b \in V(T_1)$ such that $b_c = u_c$. Let d be any node in $V(T_1) - B_c$ that is adjacent to a node in B_c. Such a d must exist, for otherwise we would have $a_c = u_c$ for every $\boldsymbol{a} \in G_1$, which contradicts the assumption that u_c is not the state of some species in G_1. We must have $d_c = a_c$ for some $\boldsymbol{a} \in G_1$, otherwise (C3) would be violated in T because we would have $a_c = b_c$ for some $\boldsymbol{b} \in T_2$, and the node $\boldsymbol{u}$ which is on the path between $\boldsymbol{a}$ and $\boldsymbol{b}$ in T is such that $u_c \neq a_c$. Now, set $b_c = d_c$ for all $\boldsymbol{b} \in B_c$. Since T satisfies (C3), for every $c \in \mathcal{M}(G_1)$, u_c equals the unique common state between G_1 and G_2. The resulting modification of T_1 is therefore a subphylogeny for G_1 with connection $\boldsymbol{u}$. An analogous construction can be used to obtain a subphylogeny for G_2. □

DEFINITION 3.3. *A cluster G is said to be* compatible *with a vector* $\boldsymbol{s}$ *if for every* $c \in \mathcal{M}(G)$, s_c *equals the unique common state for character c between G and* $\mathcal{S} - G$.

The following result demonstrates that a subphylogeny for a cluster can always be assembled from subphylogenies for c-clusters.

LEMMA 3.4. *Let G be a cluster. Then G has a subphylogeny if and only if there exist pairwise disjoint c-clusters* $G_1, \ldots, G_k$ *and a vector* $\boldsymbol{x}$ *such that* (i) *for every* $c \in \mathcal{M}(G)$, x_c *equals the* (*unique*) *common state for character c between G and* $\mathcal{S} - G$, (ii) $\cup_{i=1}^{k} G_i = G$, *and* (iii) *each* G_i *is compatible with* $\boldsymbol{x}$ *and has a subphylogeny.*

Proof. For the "if" part, let $T_1, \ldots, T_k$ be the subphylogenies for $G_1, \ldots, G_k$ with roots $\boldsymbol{x}^1, \ldots, \boldsymbol{x}^k$. Clearly, the tree T consisting of a node for $\boldsymbol{x}$ and the trees $T_1, \ldots, T_k$ connected to $\boldsymbol{x}$ by edges $(\boldsymbol{x}^1, \boldsymbol{x}), \ldots, (\boldsymbol{x}^k, \boldsymbol{x})$ is a subphylogeny for G.

For the "only if " part, let T be a subphylogeny for G with connection $\boldsymbol{x}$. Without loss of generality, assume that all nodes in T are distinct. Let $\boldsymbol{x}^1, \ldots, \boldsymbol{x}^k$ be the neighbors of $\boldsymbol{x}$ in T, and for $1 \leq i \leq k$ let T_k be the subtree of $T - \boldsymbol{x}$ containing $\boldsymbol{x}^i$ and let $G_i = V(T_i) \cap \mathcal{S}$. For each $c \in \mathcal{M}(G_i)$, x_c equals the unique common state between G_i and $\mathcal{S} - G_i$. This is because either this state is shared with some species in G_j, for some $j \neq i$, or it is shared with some species in $\mathcal{S} - G$. In either case, due to condition (C3), the value of x_c^i must equal the common state and, hence, G_i is compatible with $\boldsymbol{x}$. Also, as in the proof of Lemma 3.2, we can ensure that for every character c, the state of any $\boldsymbol{v} \in V(T_i)$ on character c will be that of some species in G_i on c, by altering unforced states if needed. Thus, T_i can be transformed into a subphylogeny for G_i. All that is left is to verify that each G_i is indeed a c-split; i.e., that $\mathcal{D}(G_i) \neq \emptyset$. Suppose $\mathcal{D}(G_i) = \emptyset$. Then we must have had $\boldsymbol{x}^i = \boldsymbol{x}$ in T, contradicting our earlier assumption that all nodes are distinct, since for every character c, there is one common character state between G and $\mathcal{S} - G$ and condition (C3) must be satisfied in T. □

To find a perfect phylogeny for $\mathcal{S}$, we shall rely on certain properties of subphylogenies which allow them to be combined into larger subphylogenies. These properties are discussed next.

LEMMA 3.5. *Let* G, G_1, G_2 *be clusters such that* $G = G_1 \cup G_2$ *and* $G_1 \cap G_2 = \emptyset$. *If* G_1 *and* G_2 *have subphylogenies, then there exists a subphylogeny T for G.*

Proof. Let T_1 and T_2 be subphylogenies for G_1 and G_2, respectively. Let $\boldsymbol{x}^1$ and $\boldsymbol{x}^2$ be the connections of T_1 and T_2. Let $\boldsymbol{x}$ be a node where for each $c \in \mathcal{M}(G)$, x_c equals the unique common state between G and $\mathcal{S} - G$ and for each $c \in \mathcal{D}(G)$, x_c equals x_c^1. Construct T by adding a node $\boldsymbol{x}$ and connecting the trees T_1 and T_2 to $\boldsymbol{x}$ by edges $(\boldsymbol{x}, \boldsymbol{x}^1)$ and $(\boldsymbol{x}, \boldsymbol{x}^2)$, respectively; $\boldsymbol{x}$ will be the connection of T. Since $\boldsymbol{x}$ has the necessary states to be a connection for a subphylogeny of G, it suffices to prove that T is a perfect phylogeny for G. For this, we need to verify that T satisfies conditions (C1)–(C3). Since T_1 and T_2 are subphylogenies, and for every character c, x_c is the state of some species in G_1 or G_2, it is clear that T satisfies (C1) and (C2) for G. To verify that T satisfies (C3), we must show that if $x_c^1 = x_c^2 = j$ for any character $c \in \mathcal{C}$, then $x_c = j$. This is trivially true when $c \in \mathcal{D}(G)$, since $x_c = x_c^1$. If $c \in \mathcal{M}(G)$, x_c equals the unique common state for character c between G and $\mathcal{S} - G$. We must have $x_c = x_c^1$ or $x_c = x_c^2$ because the species in G sharing the common character state with a species in $\mathcal{S} - G$ belongs to either G_1 or G_2. Hence, T satisfies (C3).

Note that if $\mathcal{D}(G_1) = \emptyset$, then, rather than adding an edge $(\boldsymbol{x}, \boldsymbol{x}^1)$, we can simply identify nodes $\boldsymbol{x}^1$ and $\boldsymbol{x}$. A similar situation arises when $\mathcal{D}(G_2) = \emptyset$. □

LEMMA 3.6. *Let G, G_1, G_2 be clusters such that $G = G_1 \cup G_2$ and $G_1 \cap G_2 = \emptyset$. Suppose that G_1 has a subphylogeny T_1 and that there exists a subphylogeny T for G with T_1 as a subtree at the connection $\boldsymbol{x}$ of T. Then if G_2 is not a c-cluster, the value of x_c on every $c \in \mathcal{D}(G)$ is forced.*

Proof. If G_2 is not a c-cluster, $\mathcal{M}(G_2) = \mathcal{C}$; i.e., for every $c \in \mathcal{C}$, there exists a common state between a species in G_2 and one in $\mathcal{S} - G_2$. Consider any character $c \in \mathcal{D}(G)$. We claim that G_1 and G_2 share a state on c. This implies that x_c is forced. To prove the claim, assume the contrary. Since $c \in \mathcal{M}(G_2)$, G_2 must share a state with $\mathcal{S} - G$ on character c. But this would imply that $c \in \mathcal{M}(G)$, a contradiction. □

4. Building a subphylogeny. The heart of our perfect phylogeny algorithm is a procedure SUBPHYLOGENY that determines whether a cluster G has a subphylogeny and, if so, constructs one. It assumes that for every c-cluster $G' \subset G$, a subphylogeny has been constructed, if one exists.

```
        Algorithm SUBPHYLOGENY($G$)
        begin
            if $|G| = 1$ then
(S1)            return the tree $T_G$ consisting of the single species $a \in G$
(S2)        for each c-cluster $G_1 \subset G$ such that $G_1$ has a subphylogeny $T_1$ do
                $G_2 = G - G_1$
                if $G_2$ is a c-cluster having a subphylogeny then
                    Use Lemma 3.5 to construct a subphylogeny $T_G$ for $G$
(S3)                return $T_G$
                else        /* $G_2$ is not a c-cluster */
                    Use Lemma 3.6 to compute the states of the connection $x$ of $T_G$
                    Initialize $T_G$ to consist of $x$ together with $T_1$ as its subtree
(S4)                for each c-cluster $H \subseteq G_2$ do
                        if $H$ has a subphylogeny $T_H$ and $H$ is compatible with $x$ then
                            $G_2 = G_2 - H$
                            Make $T_H$ a subtree of $x$ in $T_G$
(S5)                        if $G_2 = \emptyset$ then return $T_G$
                endif
            endfor
            return FAILURE
        end
```

LEMMA 4.1. *Let G be a cluster and suppose that for every c-cluster G' such that $G' \subset G$, we have determined whether G' has a subphylogeny and, if so, one has been constructed. Then, if G has a subphylogeny,* SUBPHYLOGENY(G) *constructs it. Otherwise, the procedure returns* FAILURE.

Proof. When $|G| = 1$, a node for the single species $s \in G$ is indeed a subphylogeny for G. Hence, the tree returned in (S1) is correct.

Suppose $|G| > 1$ and that G has a subphylogeny T_G with connection $\boldsymbol{x}$. Then there must exist a c-cluster $G_1 \subseteq G$ having a subphylogeny T_1 such that T_1 is a subtree in some subphylogeny T_G of G. At some point during the execution of **for** loop (S2), we will consider one such G_1. If $G_2 = G - G_1$ is a c-cluster having a subphylogeny, then, by Lemma 3.5, (S3) returns a subphylogeny for G.

If G_2 is not a c-cluster, then, by Lemma 3.6, the states of the connection $\boldsymbol{x}$ are completely determined and, by Lemma 3.4, there exists a collection of pairwise disjoint c-clusters having subphylogenies such that their union is G and each c-cluster in the collection is compatible with $\boldsymbol{x}$. In the **for** loop (S4), a subphylogeny for a c-cluster $H \subseteq G$ is added to the current T_G only if H is compatible with $\boldsymbol{x}$ and every species in H is not yet in T_G, and a tree is returned only when the union of all the c-clusters added is $G - G_1$; i.e., $G_2 = \emptyset$. Therefore, any tree T_G returned in (S5) is a subphylogeny for G. We now argue that if there exists a subphylogeny for G with T_1 as a subtree, then one such subphylogeny will be constructed by the loop (S4) and G_2 will become empty. We shall do this by showing that if there is such a subphylogeny for G, then at the beginning of each iteration of loop (S4) there is always at least one c-cluster $H' \subseteq G_2$ compatible with $\boldsymbol{x}$ that has not yet been considered.

By Lemma 2.2, if G has a subphylogeny, then for every $J \subseteq G$ the set of species $J \cup \{\boldsymbol{x}\}$ has a perfect phylogeny. We claim that there exists a c-cluster $J' \subseteq J$ such that J' has a subphylogeny. To prove this, suppose T_J is a perfect phylogeny for $J \cup \{\boldsymbol{x}\}$, let $\boldsymbol{y}$ be any neighbor of $\boldsymbol{x}$ in T_J, and let J' be the set of species in the subtree T_y of $T_J - \boldsymbol{x}$ containing $\boldsymbol{y}$. Clearly, J' is a cluster; moreover, J' is a c-cluster since we can assume that all the nodes in T_J are distinct. Furthermore, T_y can be modified to obtain a subphylogeny for J' as in the proof of Lemma 3.2.

In particular, if we take $J = G_2$ in the above argument, we have that in each iteration of (S4), there exists a c-cluster $J' \subseteq G_2$ such that J' has a subphylogeny. Since at the beginning of each iteration, for all c-clusters J'' considered up to this point $J'' \not\subseteq G_2$, either H itself is a subset of G_2 and has a subphylogeny, or some yet-to-be-considered c-cluster H' is a subset of G_2 and has a subphylogeny.

SUBPHYLOGENY returns FAILURE only if no choice of G_1 led to the construction of a subphylogeny for G. In this event, there was certainly no subphylogeny for G. □

Running time of SUBPHYLOGENY. SUBPHYLOGENY(G) considers each of the $O(2^r m)$ c-clusters G_1 such that $|G_1| < |G|$. For each such c-cluster, it verifies that $G_1 \subset G$, which can be done in $O(n)$ time. With a particular G_1, the algorithm goes through $O(2^r m)$ c-clusters, checking in $O(n + m)$ time whether they are subsets of G_2 that are compatible with $\boldsymbol{x}$. The total time taken by SUBPHYLOGENY is therefore $O(2^{2r}(nm^2 + m^3))$.

5. Building a perfect phylogeny.

We now describe the algorithm PHYLOGENY, which constructs a perfect phylogeny for $\mathcal{S}$, if it has one. The algorithm first tries to determine if one of the $O(2^{r-1} \cdot m)$ c-splits is of type I. If there is a type I c-split (G_1, G_2) where $\boldsymbol{s}$ is a connecting species, the algorithm recursively attempts to construct perfect phylogenies T_1 and T_2 for $G_1 \cup \{\boldsymbol{s}\}$ and $G_2 \cup \{\boldsymbol{s}\}$. As stated earlier, if one or both of the latter sets has no perfect phylogeny then, by Lemma 2.2, neither does $\mathcal{S}$. Otherwise, a perfect phylogeny for $\mathcal{S}$ is obtained by identifying the nodes for $\boldsymbol{s}$ in T_1 and T_2.

If there is no type I c-split then, by Lemma 2.6, none of the species appears as an internal node in any perfect phylogeny for $\mathcal{S}$. In this case, PHYLOGENY considers each possible c-cluster G such that $|G| \leq n - 1$ and attempts to build a subphylogeny for it using SUBPHYLOGENY. It then uses this information to build a perfect phylogeny for $\mathcal{S}$, if possible. The steps of PHYLOGENY are as follows.

```
 Algorithm PHYLOGENY($\mathcal{S}$)
begin
    if $|\mathcal{S}| = 1$ then
        return the tree $T$ consisting of the single species $a \in \mathcal{S}$
    if there exists a type I c-split $(G_1, G_2)$ then
        Let $s$ be the connecting species
```

```
            Call PHYLOGENY($G_1 \cup \{s\}$) and PHYLOGENY($G_2 \cup \{s\}$)
            if both calls succeed then
                Combine the resulting trees into a perfect phylogeny for $\mathcal{S}$
            else return FAILURE
        else                    /* All c-splits are of type II */
            $size = 1$
            while $size \leq n - 1$ do
(P1)            for each c-cluster $G$ such that $|G| = size$ do
                    Call SUBPHYLOGENY($G$)
                    if $G$ has a subphylogeny $T_G$, record $T_G$ and its connection
                endfor
                $size = size + 1$
            endwhile
            Pick any $s \in \mathcal{S}$
            if $G = \mathcal{S} - \{s\}$ has a subphylogeny $T_G$ then
                let $x$ be the connection of $T_G$
(P2)            return the tree obtained by adding a node $s$ and the edge $(s, x)$ to $T_G$
(P3)        else return FAILURE
        endif
    end
```

THEOREM 5.1. PHYLOGENY *correctly determines whether or not $\mathcal{S}$ has a perfect phylogeny and, if so, constructs one.*

Proof. The correctness of the algorithm hinges on how it deals with the case where no c-split is of type I. We first note that by the proof of Lemma 3.2, and because for any $s \in \mathcal{S}$ the tree consisting of node s is a subphylogeny for $\{s\}$, if a tree is returned by our algorithm in (P2), then the tree is a perfect phylogeny for $\mathcal{S}$. Thus, it suffices to argue that PHYLOGENY will never return FAILURE if $\mathcal{S}$ has a perfect phylogeny.

If $\mathcal{S}$ has a perfect phylogeny and all c-splits are of type II, then every $s \in \mathcal{S}$ will be a leaf in any perfect phylogeny of $\mathcal{S}$. Hence, both $\{s\}$ and $\mathcal{S} - \{s\}$ must be c-clusters. As we noted above, a subphylogeny for $\{s\}$ is s itself, while the subphylogeny of $\mathcal{S} - \{s\}$ must have been constructed in some iteration of (P1). Therefore, (P2) will not return FAILURE. □

Running time of PHYLOGENY. PHYLOGENY spends $O(2^r nm^2)$ time generating c-clusters and testing each of these to find out whether it is of type I. It is clear that, in the worst case, the running time of PHYLOGENY is dominated by the time required to deal with the case where all c-clusters are of type II. SUBPHYLOGENY is applied to each of the $O(2^r m)$ c-clusters, which requires $O(2^{3r}(nm^3 + m^4))$ total time. Hence, the running time of PHYLOGENY is $O(2^{3r}(nm^3 + m^4))$ as well.

6. Concluding remarks. Our algorithm uses dynamic programming to construct perfect phylogenies by working from the bottom up. One can use *memoization* (a technique described in some detail in pp. 312–314 of [4]) to obtain an equivalent top-down recursive algorithm with the same running time. Such a procedure has been proposed to us by E. L. Lawler (personal communication).

Algorithm PHYLOGENY can be modified to work correctly and within the same time bounds even if instances with type I c-splits are not treated separately. However, in practice, exploiting the presence of such splits may tend to reduce the running time of the algorithm.

Kannan and Warnow (personal communication) have discovered a clever way to reduce the running time of our algorithm by a factor of 2^r. Their technique speeds up step (S4) of SUBPHYLOGENY by providing a way to determine in $O(nm)$ time whether there exists a subphylogeny for G having a subphylogeny for a given c-cluster G_1 as a subtree. Even with this improvement, the algorithms presented in [16] and [7] are faster than ours for the cases where $r \leq 4$ and $r \leq 3$, respectively. It is an open problem whether our algorithm can be improved to match those bounds on those special cases.

Other methodologies for reconstructing phylogenies have been proposed in the past; these have been ably surveyed by Felsenstein [10]. We shall limit ourselves here to discussing one problem that is closely related to perfect phylogeny: the *Steiner tree problem in phylogeny* [12], [13]. A Steiner tree for a set of species $\mathcal{S}$ is a tree T satisfying (C1) and (C2). Obviously, a perfect phylogeny for $\mathcal{S}$ is also a Steiner tree for $\mathcal{S}$. The length of T is the sum of the lengths of its edges, where the length of an edge $(\boldsymbol{u}, \boldsymbol{v}) \in E(T)$ is the Hamming distance between $\boldsymbol{u}$ and $\boldsymbol{v}$ (i.e., the number of characters in which $\boldsymbol{u}$ and $\boldsymbol{v}$ differ). The Steiner tree problem in phylogeny is to compute a minimum length Steiner tree for a given set of species. Minimum length Steiner trees satisfy the *parsimony* criterion [10], because they give phylogenies in which species evolve with the least number of character changes. The following theorem establishes a relationship between the perfect phylogeny problem and the Steiner tree problem in phylogeny.

THEOREM 6.1. *$\mathcal{S}$ has a perfect phylogeny if and only if the minimum length of a Steiner tree for $\mathcal{S}$ is $\sum_{i=1}^{m}(r_i - 1)$.*

Proof. Suppose T is a Steiner tree. It follows from the definition that the length of T is the sum of contributions of the individual characters, where the contribution of character c to the length of T is the number of edges $(\boldsymbol{u}, \boldsymbol{v}) \in E(T)$ such that $u_c \neq v_c$. Since there are at least r_c species which differ from each other on any $c \in \mathcal{C}$, the contribution of character c to the length of T must be at least $r_c - 1$, implying that the length of any Steiner tree for $\mathcal{S}$ is at least $\sum_{i=1}^{m}(r_i - 1)$.

A Steiner tree T for $\mathcal{S}$ has length *exactly* $\sum_{i=1}^{m}(r_i - 1)$ if and only if for every $c \in \mathcal{C}$, T can be partitioned into exactly r_c subtrees $T_1, \ldots, T_{r_c}$ such that $u_c = i$ for every $\boldsymbol{u} \in T_i$. If such a partition is possible, T will satisfy (C3), in addition to (C1) and (C2), and must be a perfect phylogeny for $\mathcal{S}$. □

It does not seem possible to generalize our algorithm in any straightforward way to produce minimum length Steiner trees for sets of species. To illustrate the difficulty in doing so, note that whereas for binary characters, the perfect phylogeny problem can be solved in time linear in the size of the input, the Steiner tree problem in phylogeny remains NP complete [13].

Acknowledgments. We thank Martin Farach, Sampath Kannan, and Tandy Warnow for their encouragement; Mike Steel for bringing his results to our attention; and the referees for their useful suggestions. Special thanks are due to Eugene Lawler, who carefully read our manuscript and suggested numerous improvements in terminology and exposition.

PRIORITY QUEUES AND PERMUTATIONS*

M. D. ATKINSON† AND ROBERT BEALS‡

Abstract. A priority queue transforms an input permutation σ of some set of size n into an output permutation τ. The set R_n of such related pairs (σ, τ) is studied. Efficient algorithms for determining $s(\tau) = |\sigma : (\sigma, \tau) \in R_n|$ and $t(\sigma) = |\tau : (\sigma, \tau) \in R_n|$ are given, a new proof that $|R_n| = (n+1)^{n-1}$ is given, and the transitive closure of R_n is found.

Key words. priority queue, permutation, enumeration

1. Introduction. The topic studied in this paper was suggested by the beautiful and combinatorially rich theory of permutations that can be generated by a stack. In this theory an input sequence of n distinct elements, $x_1, x_2, \ldots, x_n$, is presented to a stack and is subjected to a series of *push* and *pop* operations; each push operation pushes the next input element on the stack and each pop operation removes the top element of the stack and places it in an output stream. When the entire input has been consumed and the stack is empty, the input sequence has been converted into an output sequence $x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}$ that is a permutation of the input sequence. The permutation π that arises in this way depends only on the series of push and pop operations and, in particular, is independent of the input sequence. It is well known that there are c_n such *stack permutations,* one for each push–pop sequence, where

$$c_n = \frac{\binom{2n}{n}}{n+1}$$

is the nth Catalan number. There are several interesting correspondences between stack permutations and other combinatorial objects (for example, binary trees, triangulations of a polygon, well-formed bracket sequences; see [3] and the references cited therein).

We shall investigate the analogous theory where a priority queue replaces a stack. In other words the pop operation "delete the most recently inserted" is replaced by "delete the smallest." We use the terms *Insert* and *Delete-Minimum* rather than push and pop and we shall call a series of n Inserts and n Delete-Minimums a *priority queue computation.* There are c_n different priority queue computations, each of which converts an input sequence (of n distinct elements) into an output sequence. But, unlike the case of stacks, it is no longer true that the permutational effect is independent of the input sequence nor that all inputs can be permuted in the same number of ways.

To handle this greater complexity we define a relation R_n called *allowability* on the set of sequences of length n by the rule $(\sigma, \tau) \in R_n$ if there exists a priority queue computation which transforms the input sequence σ into the output sequence τ. The elements of R_n will be called *allowable pairs.* It was shown in [1] that there are $(n+1)^{n-1}$ allowable pairs of permutations on a fixed set of size n and this result is a strong hint that an interesting combinatorial theory awaits investigation.

It is simple to recognize whether a pair of sequences (σ, τ) is allowable. One just constructs a suitable priority queue computation. If such a computation exists, it may not be unique, but it is easy to see that there is always a "natural" computation in which elements

*Received by the editors November 30, 1992; accepted for publication July 20, 1993.

‡Department of Computer and Information Science, University of Oregon, Eugene, Oregon 97403.

are output as soon as possible (that is, if x is the next element to output, and is present in the priority queue, then it should be output before further input elements are inserted). This observation results in the following algorithm:

```
$Q$ := empty priority queue
$i := 1$; $j := 1$
while $j \leq n$ do
        while $\tau_j \notin Q$ do
                insert($\sigma_i$)
                $i := i + 1$
        endwhile
        if min($Q$) $\neq \tau_j$ then return (false) else
                deleteMin; $j := j + 1$
        endif
endwhile
return(true).
```

The time complexity of this algorithm depends, of course, on the implementation of the priority queue operations. With a heap-based implementation it would be $O(n \log n)$, whereas if we regarded Insert and Delete-Minimum as atomic constant time operations it would be $O(n)$.

In the next section of the paper we take up rather more interesting algorithmic questions by giving efficient methods for the two complementary problems:

(1) Given an output τ, find the number of allowable pairs (σ, τ).

(2) Given an input σ, find the number of allowable pairs (σ, τ).

Then, in §3 we concentrate more on combinatorial questions. We give a one-to-one correspondence between allowable pairs and labeled trees from which we obtain another proof of the main result of [1]. Next we give a result about the average number of outputs for a random priority queue computation. Finally we characterize the transitive closure of the allowability relation and discuss the connection with serial networks of priority queues.

2. The number of inputs and outputs. In this section we consider the computation of the following two quantities: the number $s(\tau) = |\sigma : (\sigma, \tau) \in R_n|$ of allowable pairs having a fixed output τ, and the number $t(\sigma) = |\tau : (\sigma, \tau) \in R_n|$ of allowable pairs having a fixed input σ.

On the surface $t(\sigma)$ seems to be the more natural quantity to calculate since it enumerates the different ways that a priority queue can process a particular input, while $s(\tau)$ enumerates the different starting points that can give rise to some fixed result. Despite this, it turns out that the numbers $s(\tau)$ are rather easier to compute and have more obvious properties (for example, they are always divisors of $n!$). Indeed, in [1], an algorithm of average time complexity $O(n \log n)$ was given for computing $s(\tau)$. Here we shall give an algorithm for this problem whose worst case complexity is $O(n)$. We turn then to the problem of computing $t(\sigma)$. Although we have been unable to find a comparably efficient algorithm, we are at least able to place the problem in the complexity class $\mathcal{P}$ by giving a dynamic programming algorithm of time complexity $O(n^4)$.

For a given output sequence $\tau = [\tau_1, \ldots, \tau_n]$ we let τ_0 be any element greater than those occurring in the remainder of τ and define

$$b(i) = \max\{j : 1 \leq j < i, \tau_j > \tau_i\}.$$

The following lemma was proved in [1].

LEMMA 2.1.

$$s(\tau) = \prod_{i=1}^{n} (i - b(i)).$$

Thus, once $b(1), b(2), \ldots, b(n)$ have been calculated, $s(\tau)$ can be found in $O(n)$ steps. The obvious algorithm for computing $b(1), b(2), \ldots, b(n)$ is as follows.

```
$i := 0$
*repeat*
    $i := i + 1$; $j := i - 1$
    *while* $\tau_j < \tau_i$ *do* $j := j - 1$
    $b(i) := j$
*until* $i = n$.
```

It requires quadratic time in the worst case, since to compute $b(i)$ as many as i values of τ may need to be examined. A simple observation improves the computation time. Suppose that when computing $b(i)$, we tested the element τ_j (with $j < i$) and found that $\tau_j < \tau_i$. Then none of $\tau_{j-1}, \tau_{j-2}, \ldots, \tau_{b(j)+1}$ need be compared with τ_i and the next test can be whether $\tau_{b(j)} < \tau_i$. In other words the statement $j := j - 1$ may be replaced by $j := b(j)$.

The new algorithm runs in linear time: the statement $j := b(j)$ cannot be executed more than once with the same value of j. Consequently $s(\tau)$ can be found from τ in $O(n)$ steps.

We now consider the second computation: finding $t(\sigma)$. The following result was proved in [1].

LEMMA 2.2. *Let σ be some input sequence expressed in the form $\alpha m \beta$ where m is the maximal symbol. Suppose $\beta = b_1 b_2 \cdots b_r$ and $\alpha_i = \alpha b_1 \cdots b_i$, $\beta_i = b_{i+1} \cdots b_r$, then*

$$t(\sigma) = \sum_{i=0}^{r} t(\alpha_i) t(\beta_i).$$

We make this lemma the basis of a dynamic programming algorithm. For convenience assume that σ is a permutation of $\{1, 2, \ldots, n\}$. Let $\sigma^{(m)}$ denote the permutation obtained from σ by deleting all the symbols $m + 1, \ldots, n$ and let $\Sigma^{(m)}$ denote the set of substrings of $\sigma^{(m)}$.

We can compute $t(\theta)$ for all $\theta \in \Sigma^{(m)}$ for the values $m = 0, 1, 2, \ldots, n$ in turn. The empty string λ is the only member of $\Sigma^{(0)}$ and $t(\lambda) = 1$. Suppose that $m \geq 1$ and $t(\theta)$ is known for all $\theta \in \Sigma^{(m-1)}$. A string ϕ of $\Sigma^{(m)}$ is either in $\Sigma^{(m-1)}$ (in which case $t(\phi)$ will be known) or it has the form $\alpha m \beta$. In the latter case we may compute $t(\alpha m \beta)$ in linear time using the formula of the previous lemma since all the strings required in the calculation belong to $\Sigma^{(m-1)}$. The total time required for the whole computation is

$$O\left(n \times \sum_{m=1}^{n} |\Sigma^{(m)}|\right) = O(n^4).$$

3. Combinatorial results. The number of allowable pairs was proved in [1] to be $(n + 1)^{n-1}$ using partially ordered sets and one of Abel's summation formulae. Here we give another proof which depends on establishing a 1-1 correspondence between allowable pairs and labeled trees.

Let (σ, τ) be an allowable pair on n symbols and let m be the maximal symbol. Suppose $\tau = \alpha m \beta$. At the point that m is output, the priority queue is empty. Therefore m and all the symbols of α occur in σ earlier than all the symbols of β. Let γ,δ be the symbols of α,

β, respectively, in order of their occurrence within σ. Then σ has the form $\gamma_{(i,m)}\delta$ where $\gamma_{(i,m)}$ denotes the result of inserting m within γ after the symbol i (i is given the conventional name "root" if m is inserted at the beginning of γ). Clearly (γ, α) and (δ, β) are allowable pairs.

Thus (σ, τ) has given rise to allowable pairs (γ, α), (δ, β) and a symbol i (one of the symbols of α or "root"). Conversely, (γ, α), (δ, β), and i define a unique allowable pair (σ, τ) by reversal of this construction.

We can now associate, with any allowable pair (σ, τ), a tree on $n+1$ symbols ("root" and the n symbols being permuted). The construction is inductive. If $n = 0$ the tree is a single node called "root." If $n > 0$ we find (γ, α), (δ, β), and i as above. The trees for (γ, α), (δ, β) exist by induction and have roots "root1" and "root2." The tree for (σ, τ) is obtained by letting "root1" be the new "root," "root2" be labeled as m, and joining nodes i and m.

The construction is obviously reversible since the parent of the maximal node in a tree defines i and removal of the branch between i and m defines the trees for the allowable pairs (γ, α), (δ, β).

THEOREM 3.1 (Atkinson–Thiyagarajah [1]). *The number of allowable pairs on a set of size n is $(n+1)^{n-1}$.*

Proof. By Cayley's theorem the number of labeled unrooted trees on $n+1$ nodes is $(n+1)^{n-1}$. The trees defined above are rooted (which would increase their number by a factor $n+1$) but the root is labeled with a fixed symbol "root" (which decreases their number by a factor $n+1$). The result now follows from the correspondence above. □

We now consider the number of outputs that a fixed priority queue computation can produce as the input varies over all permutations of an n-element set. Clearly, there is considerable variation. If we let $\mathcal{I}$ and $\mathcal{D}$ denote the operations Insert and Delete-Minimum, respectively, then priority queue computations can be represented by "well-formed" words in these two symbols. For example, the computation $(\mathcal{ID})^n$ simply copies the input to the output so all $n!$ outputs are achievable. On the other hand, $\mathcal{I}^n\mathcal{D}^n$ only produces that output whose elements are in ascending order. For notational simplicity we shall assume that all inputs and outputs are permutations of $\{1, 2, \dots, n\}$. Let $k(w)$ denote the number of outputs that can be generated by the well-formed word w.

LEMMA 3.2.

(1) *If u, v are well formed of length $2a$, $2b$, then*

$$k(uv) = k(u)k(v)\binom{a+b}{a}.$$

(2) *If u is well formed, then $k(\mathcal{I}u\mathcal{D}) = k(u)$.*

Proof. First, consider $k(uv)$. The priority queue in the computation uv is empty just before the $(a+1)$th symbol of the input is read. So the first a symbols of the output are a permutation of the first a symbols of the input. The first a symbols may be chosen in $\binom{a+b}{a}$ ways and, once chosen, may be permuted by u in $k(u)$ ways, after which the remaining b symbols may be permuted in $k(v)$ ways. The first part now follows.

Now consider $k(\mathcal{I}u\mathcal{D})$. Note first that if τ is an output of the priority queue computation u (arising, say, from the input σ) then τn is an output from the computation $\mathcal{I}u\mathcal{D}$ (clearly, it is the result of processing the input $n\sigma$). On the other hand, any output from $\mathcal{I}u\mathcal{D}$ must have the form τn for some τ. This is because, for the computation $\mathcal{I}u\mathcal{D}$, the priority queue cannot become empty at any intermediate step and so n cannot be deleted from it as smallest element until the end of the computation. To complete the proof, it is only necessary to prove that τ is an output of the priority queue computation u. Let ρ be an input to the computation $\mathcal{I}u\mathcal{D}$ which gives the output τn. If n is not the first symbol of ρ then we can write $\rho = \alpha m \beta n \gamma$, where m is the maximum symbol that precedes n in ρ. When this input is processed by $\mathcal{I}u\mathcal{D}$, the symbol m will remain in the priority queue after it is inserted at least until n is inserted (otherwise the priority queue would become empty before the computation terminates). It therefore follows that the input $\alpha n\beta m\gamma$ will result in the same output as ρ. By repetition of this principle, we obtain an input of the form $n\sigma$ which generates the output τn. It is apparent that the priority queue computation u transforms σ into τ as required. □

COROLLARY 3.3. *For every priority queue computation u, $k(u)$ divides $n!$.*

We have already remarked that $k(u)$ varies considerably as u varies over the possible priority queue computations. Despite this, it is possible to compute its average value defined as

$$k_n = \sum_u k(u)/c_n,$$

where the summation is over all priority queue computations with n Inserts and n Delete-Minimums.

THEOREM 3.4. $k_n = (n+1)!/2^n$.

Proof. Let $l_n = \sum_u k(u)$ so that $k_n = l_n/c_n$. Every priority queue computation can be expressed in the form $u = \mathcal{I}v\mathcal{D}w$, where v, w are themselves priority queue computations and are uniquely determined by u. Since the length of v can be any even integer from 0 to $2n-2$ we have

$$l_n = \sum_u k(u) = \sum_{i=0}^{i=n-1} \sum_v \sum_w k(\mathcal{I}v\mathcal{D}w),$$

where the second and third summations are over all priority queue computations v, w which process inputs of length i, $n-i-1$, respectively. Thus, by the previous lemma,

$$l_n = \sum_{i=0}^{i=n-1} \sum_v \sum_w k(v)k(w)\binom{n}{i+1} = \sum_{i=0}^{i=n-1} l_i l_{n-i-1}\binom{n}{i+1}.$$

Put $h_n = l_n/n!$. Then $h_n = \sum_{i=0}^{i=n-1} h_i h_{n-i-1}/(i+1)$. This recurrence can be solved by introducing the generating function

$$H(x) = \sum_{r=0}^{r=\infty} h_r x^r$$

which is easily seen to satisfy the integral equation

$$H(x)\int H(x)dx = H(x) - 1,$$

from which it follows that $H(x) = 1/\sqrt{1-2x}$ and the result follows by expanding the generating function. □

Finally we consider the transitive closure of the allowability relation R_n. One motivation for this is Tarjan's paper [5] where the permutations obtainable from a series network of stacks are considered. In a related work, Pratt [4] considers permutations computable by double-ended queues, parallel stacks, and parallel queues. The corresponding scenario for us is a series network of priority queues $P_1, P_2, \ldots, P_k$ on which the following operations are allowed:

(1) Insert, which transfers the next element of the input sequence into P_1,

(2) Move(i) with $1 \le i < k$, which transfers the minimal element of P_i into P_{i+1},

(3) Delete-Minimum, which appends the minimal element of P_k onto the output sequence.

Let ${R_n}^k$ denote the k-fold composition of R_n with itself. Then it is easy to verify that ${R_n}^k$ is precisely the set of (input, output) pairs associated with a series network of k priority queues.

The *weak order* W_n on the set of all permutations on n symbols is defined by $(\sigma, \tau) \in W_n$ if and only if every pair of symbols of σ, which are in increasing order, are also in increasing order in τ. The weak order is an important tool for the study of geometric and combinatorial properties of the symmetric group; its properties are discussed at length in [2]. It is clear that $R_n \subseteq W_n$ and, since W_n is transitively closed, ${R_n}^k \subseteq W_n$ for all k.

THEOREM 3.5. ${R_n}^{n-2} \neq {R_n}^{n-1} = W_n$.

Proof. For $(\sigma, \tau) \in W_n$ let $\rho(\sigma, \tau)$ be the smallest integer k such that all but the leftmost k symbols of σ and τ agree (that is, the rightmost $n-k$ symbols agree). Observe that ρ is never equal to 1. In order to show that ${R_n}^{n-1} = W_n$ it suffices to show that for any $(\sigma, \tau) \in W_n$ with $\sigma \neq \tau$, there exists a σ' such that all of the following hold:

(1) $(\sigma, \sigma') \in R_n$,

(2) $(\sigma', \tau) \in W_n$,

(3) $\rho(\sigma', \tau) < \rho(\sigma, \tau)$.

To see this, write σ as $\alpha x \beta \gamma$ and τ as $\delta x \gamma$ such that $|\gamma| = n - \rho(\sigma, \delta)$. Since $(\sigma, \tau) \in W_n$, it follows that x must be larger than all symbols in β. Therefore, $\sigma' = \alpha\beta x \gamma$ satisfies condition (1) above (in fact a priority queue can input σ and output σ' by only placing two symbols, x and the current input symbol, in the queue at one time). Also, σ' satisfies condition (2) because any pair of symbols in σ' appear either in the same order as in σ, or the same order as in τ. Finally, since σ' and τ both end with $x\gamma$, condition (3) is satisfied. Since ρ cannot have the value 1, the sequence $\sigma', \sigma'', \dots$ must reach τ in at most $n-1$ steps, proving ${R_n}^{n-1} = W_n$.

To complete the proof, we prove that the pair

$$([n, n-1, \dots, 2, 1], [1, n, n-1, \dots, 3, 2]),$$

which plainly lies in W_n, does not belong to ${R_n}^{n-2}$. Suppose that it were possible to transform $[n, n-1, \dots, 2, 1]$ into $[1, n, n-1, \dots, 3, 2]$ by a series network of $n-2$ priority queues. When the final element of the input (symbol 1) has been placed in priority queue P_1 the other $n-1$ symbols must all be in the $n-2$ priority queues of the network since none can be output yet. One of the priority queues must therefore contain at least two of the symbols in $\{2, 3, \dots, n\}$. Clearly this is impossible, since these two symbols would then have to be output eventually in increasing order. □

Therefore, W_n describes the relation between input and output permutations for a series network of k priority queues for any $k \geq n-1$.

Acknowledgment. We thank Katherine Anderson and Murali Thiyagarajah for several useful conversations during the course of this work, and Gerald Ostheimer for the insight leading to the $O(n)$ algorithm for computing $s(\tau)$.

A MODEL FOR ASYNCHRONOUS SHARED MEMORY PARALLEL COMPUTATION*

NAOMI NISHIMURA†

Abstract. Traditional theoretical shared memory parallel models have been based on a number of assumptions which simultaneously simplify solutions to problems and distance the models from actual parallel machines. One such assumption is that processors work together in a synchronous fashion. Recent work has focused on finding a model that captures the essence of computation by processors communicating asynchronously through shared memory. In this paper, a general framework and set of criteria used to analyze these models, including the complexity analysis of several fundamental algorithmic paradigms, are considered. A general asynchronous model is introduced and how it satisfies these criteria is demonstrated. In this model, $O(\log p)$ algorithms are demonstrated for solving p-input versions of the problems of AND, OR, parity, maximum, minimum, and list ranking. To handle list ranking, a technique of analyzing algorithms is developed in which the set of tasks that are to be executed depends on the processor schedules.

1. Introduction.

As our understanding of the parallel random access machine (PRAM) [7], [10], [17] deepens, it becomes possible to extend the notion of a shared memory model to capture additional features of actual multiprocessor architectures. Implicit in the definition of a PRAM is the existence of a global clock, by means of which processors are able to synchronize actions and perform in lock-step. At each tick of the global clock, or *timestep* of a PRAM, each processor performs a local operation or accesses a shared memory cell. The synchronization of all processors with each other (the execution of a *synchronization barrier*) can be viewed as a PRAM primitive that requires time no greater than the time to execute a single processor step. In reality, however, synchronization of parallel processors itself can be a time-consuming task. Since synchronization is not necessarily built into the architecture, it is desirable to have algorithms that do not depend on the precise timing of steps taken by the various processors. The actual speeds of processors may vary according to operating system interference, contention for the network and memory, user requests, and disparities between the numbers of cycles required for different instructions. Similar arguments can be made with respect to asynchronous behavior of processes sharing processors; in the remainder of this paper we model processes by processors. Although the absence of asynchrony is only one of the impractical assumptions on which a PRAM is based, we initially remove only this assumption in order to isolate the contribution of synchronization and to keep problems tractable.

In order to implement a PRAM algorithm directly on an underlying asynchronous architecture, all processors must be synchronized after each PRAM step. Not only is this synchronization costly in terms of time, but it can also hide the true asynchronous complexity of the problem. To better understand the realities of asynchronous parallel computation, we begin, in §2, by outlining criteria for an asynchronous shared memory model. Of particular interest is the choice of the underlying synchronization primitive, viewed as a parameter of the model, and the choice of complexity measure. The measure is designed to reflect elapsed time, including effects of fluctuations in processor speeds and load balance; this is demonstrated with respect to three basic parallel algorithm paradigms.

*Received by the editors September 23, 1991; accepted for publication (in revised form) August 24, 1992. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

†Department of Computer Science, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1 (nishi@plg.uwaterloo.ca).

In §3, we introduce a new model and analyze it with respect to the criteria. The choice of complexity measure constitutes the major difference between the various asynchronous models proposed. In this model, the running time of an algorithm is defined to be the expected maximum number of steps taken by any processor, where the expectation is calculated given a distribution on all possible schedules and the number of steps can be normalized by a weighting function for relative processor speeds (as discussed in §7). Finally, in §§5 and 6 we analyze the paradigms of synchronization and pointer jumping, respectively. The results establish the complexities of various fundamental algorithms and the desirability of our complexity measure. The analyses themselves present general techniques for handling the dependencies that arise between processor actions.

2. Criteria for asynchronous models. Our first task is to provide a natural framework for considering algorithms performed by processors communicating asynchronously through shared memory cells. The removal of a global clock from a PRAM model leaves undefined several aspects of the resulting asynchronous model. On a PRAM, we can assume that a timestep is broken into separate read, local computation, and write phases, and that read and write conflicts are resolved by various rules. In an asynchronous environment, resolving read and write conflicts is less straightforward. In particular, a read and a write can occur simultaneously. From this possibility arises the question of which possible values may be returned by a read concurrent with a write. The choice of a *synchronization primitive*, discussed in §2.1, indicates which operations are atomic, and thus settles this concurrency question for our purposes. The choice of a synchronization primitive will induce a set of allowable schedules of processor steps, which may or may not be further restricted in the definition of the model. For the most general purposes, a model should make use of a weak synchronization primitive, and any algorithm on the model should perform correctly for any possible schedule of processor steps. Section 2.2 is concerned with the attributes of complexity measures. In §2.3, we identify three basic paradigms that serve as building blocks for many parallel algorithms. The quality of a complexity measure can be tested by applying it to these paradigms.

2.1. Synchronization primitives. The power of a particular model of computation depends heavily on the synchronization primitives that are assumed, as well as on assumptions about execution time. At one end of the spectrum is the synchronous PRAM model, which makes use of atomic synchronization barriers that cost unit time. The schedule of processor steps is constrained to allow each processor to take at most one step between each pair of barriers. It is the atomicity of the execution of barriers that makes the PRAM a synchronous model; by removing the assumption of a global clock, we are replacing this strong synchronization primitive with a weaker one. The choice of a primitive is a parameter of our model.

In this paper, we consider the atomic read/write cell [15], [16]. The reader is referred to Herlihy [11] for a discussion of several primitives and their relative strengths in an environment where processors are subject to arbitrary delays; under such a measure, the atomic read/write cell is the weakest of the primitives studied. Intuitively, reads and writes are the only atomic operations applied to such a cell; these operations are seen as covering intervals, not points, in time. An assignment of processor actions to time intervals is a *schedule*. Operations in a schedule are concurrent if and only if the associated time intervals overlap. The following property can be guaranteed of accesses to an atomic read/write cell: for any schedule, the values returned by the reads are consistent with some total ordering of processor steps formed by shrinking each time interval to a point within the interval. This property is also known as the correctness condition of *linearizability* [12]. When the accesses to each cell are linearizable, it can be shown that all actions taken together are linearizable. Herlihy and Wing [12] argue that linearizability is the basic correctness condition needed for reasoning about concurrent objects. In this sense, the atomic read/write cell is the weakest synchronization primitive.

2.2. Complexity measures. The absence of a global clock results in the absence of an obvious choice for a time complexity measure. Our complexity measure should reflect the actual elapsed time achieved on real machines, and therefore should appropriately capture the notions of processor speed and load balance. The relationship with processor speeds can be phrased in the following simple-minded fashion. Consider the time complexity, according to some measure, of executing an algorithm with processors operating at certain fixed speeds. If we then consider the complexity when several of the processors are replaced by faster (or slower) ones, the time measure should not increase (respectively, decrease). The issue of load balance can be illustrated by considering an execution in which all processors have the same speeds and the work is balanced among the processors. If we compare the complexity with that arising from a situation in which the work is unbalanced, it would be expected that the complexity should not be any higher in the balanced case. Intuitively, if the machine speeds are close and the parallelism is high, the time measure should be low; if imbalance in speeds results in the inefficient use of processors, the time measure could be high. Finally, we would like our measure to be a generalization of the measure used in the synchronous PRAM model, so that comparisons between synchronous and asynchronous complexities have some meaning.

It is important to note that the initial and final locations of information may be key factors in influencing an algorithm's complexity (or even whether or not a problem is tractable). In particular, it may be important to specify whether inputs are distributed in local memory or stored in shared memory. It may also be important to define at what point an algorithm has been completed, where completion conditions range from all processors knowing that the algorithm has been completed to having the correct answer somewhere in global memory. Unless otherwise stated, we will assume that initial values are held in global memory and that the algorithm has terminated when some processor writes into a special write-once answer cell. This implies that at least the writing processor is aware that the computation has been completed.

2.3. Paradigms. The behavior of various algorithms in an asynchronous setting depends on the degree of interaction between processors. In the following, we distinguish between *problems*, particular *algorithms* to solve problems, and *paradigms*, or classes of algorithms. The *independence* paradigm captures algorithms in which the processors work independently from one another. The synchronous cost of an algorithm in the independence paradigm is simply the maximum number of steps taken by any of the processors. Since in this case there is no interaction at all, it would seem that the synchronous and asynchronous time measures should be identical.

In contrast, the *synchronization* paradigm, encompassing such algorithms as the execution of a synchronization barrier and the computation of the OR of the inputs, involves strong interaction between processors. In essence, each processor must wait until all processors are ready to synchronize. Equivalently, an algorithm in this paradigm can be seen as delaying all processors until each processor has reached a particular step in its program. In a synchronous model, the execution of a synchronization barrier is assumed to be atomic; to compute the OR in an asynchronous model, the straightforward adaptation of the constant time synchronous algorithm does not yield a correct solution. In fact, it does not seem likely that a synchronization barrier can be executed in constant time in an asynchronous setting.

The third paradigm is *pointer jumping*, in which processors interact, but at the same time adapt to each others' speeds. In algorithms of this type, the inputs initially form a linked list in global memory and each processor holds in local memory the address of a unique node in this list. The particular algorithms will differ in the values held at each node and the functions used to update them. For example, in a list ranking algorithm, the value at a node at any time indicates the number of successors of the node detected thus far. The program executed by a particular processor consists of phases, where in each phase a processor chooses a node, reads its pointer, follows the pointer to read its successor's value and pointer, and then updates its node's value and pointer. As such an algorithm progresses, each node's pointer advances toward the tail of the list, coalescing information along the way, using its successor's pointer and value. When all pointers have reached the tail of the list, the algorithm has been completed. In a particular synchronous algorithm, each processor is assigned a particular node, which it repeatedly updates. This synchronous algorithm on n inputs consists of $\log n$ phases. After phase i each processor points to the cell that was 2^i links away in the original list or points to the tail of the list. Since each phase consists of $O(1)$ timesteps, the running time is in $O(\log n)$.

A single slow processor will not substantially alter the $O(\log n)$ running time of this algorithm. Each processor that reads the slow processor's cell has just one more pointer to read; when the slow processor gets around to taking a step, it benefits from the work done by the owner of the cell it reads. It seems that the difference between the synchronous and asynchronous complexity of pointer jumping should be greater than the difference between synchronous and asynchronous complexity of the independence paradigm and less than that of the synchronization paradigm.

3. A new model and measure.

3.1. Definition of the model. In this section, we introduce a new model which consists of p processors communicating asynchronously through m shared atomic read/write cells. As in the PRAM model, each processor is a random access machine executing a program made up of reads and writes to global memory and local operations [1]. The model is based on most PRAM assumptions: the existence of unique processor IDs, the lack of faults of any kind, and the equality of costs of all operations. However, in a departure from the PRAM, there is no assumption of synchrony and hence no implicit global clock. Consequently, although the steps of a particular processor's program are executed sequentially, global memory accesses by different processors can be interleaved or overlapped in arbitrary ways, resulting in arbitrary schedules of processor steps.

In the absence of a global clock, it is not immediately clear how time can be measured; it is this aspect that gives rise to the widest divergence among asynchronous models, as will be discussed in §3.4. A possible starting point is the synchronous complexity measure, which is usually stated in terms of the global clock. Removing the clock from discussion, the synchronous time complexity of an algorithm on a particular input can also be expressed as the maximum number of steps taken by any processor in the course of the execution. In the asynchronous setting, the actions performed in the execution of a particular algorithm on a particular input might depend on the particular schedule of processor steps that occurs. Consequently, the maximum number of steps taken by any processor might depend on which schedule occurs. A worst-case measure can be determined by maximizing over all schedules. If all possible schedules are allowable, then the worst-case measure can in essence be a determination of how well the algorithm degrades into a sequential algorithm. (Although this measure is of interest in its own right, it is based on an event that has very low probability, yielding a sequential measure.)

Instead, we consider time to be defined as the *expected* maximum number of steps taken by any processor, where the expectation is calculated given a distribution on all possible schedules. Instead of expressing this distribution in terms of schedules, we make use of the fact that the results of the accesses to all the memory cells in any schedule are as if the accesses occurred in a sequential order, as discussed in §2.1. We define a *linearization* for p processors to be a sequence of the processor IDs; a linearization represents a schedule for a particular computation if the result of the computation is as if steps were taken sequentially by the processors in the order specified in the linearization. Since there may be more than one total order of the actions consistent with a particular schedule, there may be more than one linearization that can represent a particular schedule. Each linearization represents at least one schedule, namely, a schedule in which no actions are concurrent. We can thus express a distribution on the set of all schedules by a distribution on the set of all linearizations, where if each schedule has a nonzero probability of occurring, each linearization has a nonzero probability of occurring.

In our formal definition of the time complexity of an algorithm, the numbers of steps taken by the various processors can be normalized by a weighting function for relative processor speeds, as discussed in §7. Here we define the time complexity of algorithm A when the weights of the p processors are all equal to one. For I an input of size n, δ a distribution on linearizations for p processors, and ℓ a linearization, the time complexity of A, $t_A(p, n)$, is

$$\max_I \sum_\ell Pr_\delta[\ell] \cdot \max_j \left\{ \begin{pmatrix} \text{number of steps taken by processor } j \text{ on input } I \\ \text{using algorithm } A \text{ with linearization } \ell \end{pmatrix} \right\}.$$

The time complexity of a problem can be defined, as in the synchronous setting, as the minimum over all algorithms solving the problem of the time complexity of the algorithm.

3.2. Intuition. To develop our intuition, we consider the pointer jumping paradigm, and determine the maximum number of steps taken by any processor for several specific linearizations. To begin, we focus on a simple situation in which processors progress at roughly the same rate. We will say that a linearization of p processors is a *round-robin ordering* if for all i, steps $pi + 1$ through $p(i + 1)$ of the linearization contain exactly one step by each processor. In the case of a round-robin ordering, the progress made is akin to that made in the synchronous environment, and the maximum number of steps taken by any processor is $O(\log p)$. Now suppose that we altered the above linearization by delaying one processor P. Any processor assigned to a cell closer to the tail of the list than P's cell would not be affected by P's actions. The progress by processors farther from the tail may be slowed by one doubling phase, or a constant number of steps, over their progress in the round-robin case. The processor P itself will take at most $O(\log p)$ steps, yielding an overall maximum of $O(\log p)$ steps. On the other hand, the degenerate sequential case (in which processor i takes all its steps before processor $i + 1$, where processors are numbered in increasing order from the head of the list) takes $O(p)$ time by our measure. This makes sense; it is very far from being synchronous and hence is not making good use of the parallelism.

3.3. Evaluation of the new model. Our model fulfills the criteria outlined in §2. The synchronization primitive assumed is a very weak one, the atomic read/write cell, the use of which can be simulated on models with stronger primitives. The model does not pose any restrictions on the class of allowable algorithms. Correct algorithms are correct for any possible schedule of processor steps. The complexity of an algorithm does not depend on restrictions on the set of schedules that may occur, only on the probability distribution on the schedules in the set. The use of a weighting function (§7) allows for the complexity measure to differentiate between replacing a subset of the processors by slower processors and by faster processors. Since the synchronous measure is in fact the expected maximum number of steps taken by any processor, the time complexity on our model, under the distribution in where there is a single possible interleaving, can be compared to the time complexity on synchronous PRAMs.

Finally, the complexities of the three basic paradigms for distributions in $\mathcal{C}$ and $\mathcal{S}$ (as defined in §4) conform to our intuition. Pointer jumping and synchronization both have complexity $O(\log n)$ for problems of size n using n processors; this will be discussed in §§4–6. In the independence paradigm, each processor exits the computation as soon as it has completed its individual steps. Thus, the number of steps taken by a processor is the same for all linearizations. The time required is exactly the maximum number of steps in any processor's program.

3.4. Related work. In the last few years, several different asynchronous models have been proposed; we restrict our attention to those which communicate through shared memory. These models differ from ours primarily in the definition of complexity measures. Each measure is defined to avoid the degenerate sequential case; some restrict the legal linearizations, some restrict the algorithms under consideration.

Gibbons [8], [9] observes that although any synchronous algorithm can be transformed into a synchronous one by inserting a synchronization barrier after each step, for certain algorithms fewer synchronization barriers are necessary. To keep analysis simple, Gibbons stipulates that if one processor reads a cell and another processor writes the same cell, there must be a synchronization barrier between these two actions. This results in the inclusion of barriers, and consequently the increase in running time, in algorithms for problems that have no inherent need for synchronization. Moreover, the set of allowable algorithms is constrained by this rule. The time complexity of a sequence of steps between synchronizations, a *phase*, is taken to be the maximum number of steps taken by any processor during the phase. The insertion of a synchronization barrier after each phase ensures that the algorithm is slowed to the speed of the slowest processor each phase. Although the complexity measure remains the same no matter what interleaving of processor steps occurs, the actual elapsed time is in fact very sensitive to changes in speeds of processors.

Valiant's [25], [26] message-passing Bulk-Synchronous Parallel model (BSP) shares with Gibbons' model the division of processing into phases between synchronization barriers. Relying on a sufficiently large number of virtual processors for which an algorithm is written in comparison to the number of processing units on the actual machine, a balance between computation and communication costs can be realized. Valiant argues that his model captures the true essence of parallel computation by bridging shared memory and message-processing models. As a consequence of that very generality, however, the BSP is not sufficiently fine-grained to allow for a full investigation of the power of asynchrony in a shared memory setting.

The model proposed by Kruskal, Rudolph, and Snir [14] and Cole and Zajicek [2] measures time as the maximum number of minimal rounds needed to complete the algorithm, where a *round* is a sequence of steps during which each processor takes at least one step (the notion of rounds was first introduced by Fischer and Lynch [6]). This has the effect of removing certain linearizations from consideration. In the case of pointer jumping, the maximum occurs in the synchronous case, when each processor takes only a single step each round.

Martel, Park, and Subramonian [18] consider an asynchronous model subject to fail-stop errors, where the schedule is chosen by an adversary. As ammunition to use against the adversary, the processors each have independent random number generators, used to perform probabilistic computations. Since all algorithms in this model are probabilistic, this model is best compared to a probabilistic PRAM model.

More recently, in independent work Cole and Zajicek [3] have defined a model based on distributions of interleavings. Their unbounded delay model consists of a class of distributions that is strictly contained in the classes of distributions considered in this work.

4. Probability distributions. It seems that our measure is only as good as the choice of a distribution over linearizations. Ideally, it is desirable to be able to analyze each algorithm with respect to all possible distributions. We begin by considering the behavior of asynchronous algorithms under certain distributions, chosen for their proximity to possible behavior of actual processors. These distributions are fairly close to the synchronous setting, which can be seen in this model as subject to a distribution on linearizations, all of which are round-robin orderings of processor IDs. In §§4.1 and 4.2, we define two general classes of distributions and state facts that apply to these classes. The proofs of the facts, which use only elementary probability theory, appear in [21]; Facts 4.5 and 4.9 are consequences of Raghavan's version of the Chernoff bound [22]. In §4.3, observations are made concerning the application of facts to algorithmic complexity and the relations of the distributions to those used in other work.

4.1. Simple delay distributions. A simple way of generating a distribution is by allotting steps in an approximate round-robin ordering, where a processor may miss a step from time to time. Such a distribution can be represented by a set of Markov chains, with one chain per processor. Transitions are made simultaneously on all Markov chains, and the resultant outputs are ordered to form a linearization. The only type of output symbol generated by the Markov chain for the ith processor is the ID i. The outputs are ordered according to a sequence of permutations of processor IDs, one permutation per transition; the outputs resulting from a particular transition are ordered in a manner consistent with the permutation for that transition. Recall that a linearization represents a schedule of possibly overlapping processor actions (§3.1); the simultaneous transitions of the Markov chains are used to create linearizations that approximate round-robin orderings and hence do not necessarily imply simultaneous processor actions. The simplest nontrivial distributions of this type are generated by Markov chains with two states, one corresponding to a step (an output state), the other to idle time (a nonoutput state); we call these the *simple delay* distributions. We define the time complexity of an algorithm A for a fixed set of two-state Markov chains. For I an input of size n, $\mathcal{O}$ a sequence of permutations of IDs of p processors, and ℓ a linearization for p processors, the complexity of A, $t_A(p, n)$, is

$$\max_I \max_{\mathcal{O}} \sum_{\ell} Pr_{\mathcal{O}}[\ell] \cdot \max_j \left\{ \begin{pmatrix} \text{number of steps taken by processor } j \text{ on input } I \\ \text{using algorithm } A \text{ with linearization } \ell \end{pmatrix} \right\}.$$

As before, the time complexity of a problem is defined analogously. Let ρ_i be the probability of transition from the step state to the step state in the Markov chain for processor i, and let $\bar{\rho}_i$ be the probability of transition from the idle state to the step state. In subsequent sections we will consider the set of distributions $\mathcal{S}$, defined as follows.

DEFINITION 1. *The set $\mathcal{S}$ is the set of simple delay distributions such that all ρ_i's and $\bar{\rho}_i$'s are within a constant factor of each other independent of p, and are in $\Omega(1/p^{O(1)})$.*

The Markov chain for one processor is illustrated in Fig. 1, for $\rho = 1/3$ and $\bar{\rho} = 1/4$.

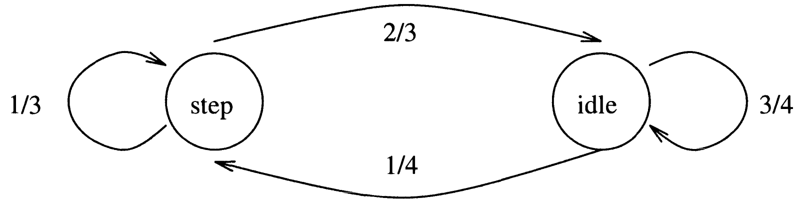

FIG. 1 *A simple delay distribution.*

Distributions of this type are intended to approximate slight deviations from a synchronous setting. In order to assess the accuracy of the approximation, we characterize the synchronous setting in terms of possible linearizations and their frequencies, and then compare this characterization with that of the simple delay distributions. Since in a synchronous PRAM a write never takes place at the same time as a read, each read or write phase can be seen as adhering to a round-robin ordering of the processor steps. If we slightly modify this model to allow writes to take place at the same time as reads, it is possible that in a round-robin ordering more progress could be made than if all actions occurred in lock-step. For example, whereas in the synchronous setting if one processor writes to a memory cell, another processor can read it only in the next read phase; here the write can precede the read in a round-robin ordering. We avoid this possibility by defining the complexity of A so that the steps within a transition occur in the least advantageous possible order. The simple delay distributions deviate further from the synchronous setting by allowing the possibility that in some phases not all processors take steps.

The next facts are of use when considering simple delay distributions. Here we relate the expected maximum number of steps taken by any processor to the number of transitions. Recall that for these distributions, the transitions for the processors are in lock-step, though the resulting set of processor steps may not be. Let $\sigma_* = \min_i\{\rho_i, \bar{\rho}_i\}$ and let $\sigma^* = \max_i\{\rho_i, \bar{\rho}_i\}$. By definition of $\mathcal{S}$, $\sigma_* \in \Theta(\sigma^*)$ and $\sigma_* \in \Omega(1/n^{O(1)})$.

FACT 4.1. *The expected maximum number of steps taken by any of n processors in an expected t transitions is in $O(t\sigma^*)$, for $t \in \Omega((\log n)/\sigma^*)$.*

FACT 4.2. *For any $g \leq n$, the expected number of transitions needed to allot at least one step to each of a fixed set of g out of n processors is in $\Omega((\log g)/\sigma^*)$, provided that $\sigma^* < k/\ln g$ for a constant $k < 1$.*

FACT 4.3. *The expected number of transitions needed for each of n processors to take at least $kt\sigma_*$ steps is in $\Theta(t)$ for any constant $k > 0$ and for $t \in \Omega((\log n)/\sigma^*)$.*

FACT 4.4. *Suppose that t transitions, $t \in \Omega((\log n)/\sigma_*)$, are taken by n processors. For $t = (c' \ln n)/\sigma_*$, there exists a constant $c > 0$ depending on c' such that the probability that there is a processor that takes fewer than $ct\sigma_*$ steps is at most $1/n^{O(1)}$.*

FACT 4.5. *If the expected number of steps taken by a processor is at least E, then the actual number of steps taken by that processor is at least $E/2$ with probability at least $1 - e^{-E/8}$.*

By using Fact 4.1 in upper bounds, we can determine the expected maximum number of steps per processor by simply finding the total number of transitions taken. If we do not know the total number of transitions, it in fact suffices to know the expected total number of transitions. Facts 4.2 and 4.3 have the following useful consequence. Suppose we take enough steps to ensure that each processor takes at least one step. By taking a constant factor more steps, we are ensured that each processor takes at least $\log n$ steps.

4.2. Constant speed distributions. We may instead wish to model a situation in which processor actions are not independent of each other, such as when one processor's use of the network slows down another processor's accesses. We can assign to each processor j a probability ρ_j of being allotted the next step in the linearization, where $\sum_{j=1}^{p} \rho_j = 1$. We call such a distribution a *fixed speed* distribution, since it corresponds to processors maintaining particular speeds throughout the course of the computation. A fixed speed distribution can be represented as the vector $(\rho_1, \ldots \rho_p)$. Each ρ_i is a function only of p, the total number number of processors. A *uniform distribution* is a special case of a fixed speed distribution, where $\rho_i = 1/p$ for all i. We consider the following set of distributions.

DEFINITION 2. *The set $\mathcal{C}$, or* constant speed *distributions, is the set of fixed speed distributions where for all i and j, ρ_i/ρ_j is bounded by a constant independent of p.*

In the simple delay distributions, each transition by the various Markov chains could be seen as generating a section of the linearization that approximated a round-robin ordering. In constant speed distributions, however, there is no local sense in which the linearizations produced approximate those associated with the synchronous setting. However, the deviations remain moderate in that in a long enough section of a linearation, with high probability each processor will take a number of steps roughly proportional to its speed.

The following facts allow us to determine the expected maximum number of steps taken by any processor by first determining the expected total number of steps taken by all processors. Throughout this section, it is assumed that all processors are active until the end of the computation. In Facts 4.6–4.9, we consider an arbitrary distribution δ on linearizations of n processors such that $\delta \in \mathcal{C}$. Let $\gamma^* = \max_i\{\rho_i\}$ and let $\gamma_* = \min_i\{\rho_i\}$. We know that γ^* and γ_* are within a constant factor of each other, by the definition of $\mathcal{C}$.

FACT 4.6. *The expected maximum number of steps taken by any of the processors in a linearization of expected length t is in $O(t/n)$, provided that $t \in \Omega(n \log n)$.*

FACT 4.7. *For any $g \leq n$, the expected number of steps needed to guarantee that each of a fixed set of g out of n processors take at least one step is in $\Theta(n \log g)$.*

FACT 4.8. *The expected number of steps needed to guarantee that each processor takes at least $kt\gamma_*$ steps is in $\Theta(kt)$, for any constant $k > 0$ and for $t \in \Omega((\log n)/\gamma_*)$.*

FACT 4.9. *If the expected number of steps taken by a processor is at least E, then the actual number of steps taken by that processor is at least $E/2$ with probability at least $1 - e^{-E/8}$.*

Facts 4.6–4.9 are analogous to Facts 4.1, 4.2, 4.3, and 4.5, respectively, and have the same uses as noted in §4.2. In particular, as a consequence of Facts 4.2 and 4.3, the number of transitions needed to obtain $O(\log n)$ steps per processor is within a constant factor of the number needed to ensure one step per processor. Note, in Fact 4.6, that the expected total number of steps divided by the number of processors will be equal to the time, as in the synchronous case.

4.3. Further observations about distributions.

4.3.1. Other useful theorems. In each algorithm considered in this paper, it is assumed for simplicity that all processors remain in the computation until its completion. Since allowing processors to exit early will only decrease the complexity of an algorithm, the results are not restricted by this assumption. However, in the case of lower bounds, the issue of early exiting processors cannot be ignored.

The proof of Theorem 4.10 follows from the facts in §§4.1 and 4.2; it can be found in [21].

THEOREM 4.10. *Let X be an algorithm such that no processor can exit the computation until all n processors have entered the computation. Then the algorithm X requires $\Omega(\log n)$ time using n processors for distribution δ on linearizations such that $\delta \in \mathcal{C} \cup \{s \in \mathcal{S} \mid \sigma^* < k/\ln n$ for a constant $k < 1\}$.*

THEOREM 4.11. *If an algorithm A can be decomposed into A' and A'' such that the preconditions for A'' are a subset of the postconditions for A', then the time needed to execute A is at most the sum of the times needed to execute A' and A''.*

4.3.2. Distributions and other models. Another way to view distributions on linearizations is by considering the distribution on times taken between steps by each processor. The uniform distribution corresponds to choosing this waiting time for each processor according to an exponential distribution, independent of all other processors.

Many other models can be characterized as special cases of the general model, with specific distributions and restrictions on algorithms imposed. A special case of a simple delay distribution, where $\rho_i = \bar{\rho}_i = \rho$ for all i and ρ is bounded below by a constant, yields Cole and Zajicek's [3] unbounded delay model. The synchronous PRAMs are generated by distributions in which only linearizations corresponding to round-robin orderings have nonzero probabilities; the only algorithms allowed are those where reads and writes occur in alternating rounds. In the case of the PRIORITY PRAM, steps $pi + 1$ to $p(i + 1)$ must be ordered from lowest priority to highest. The various types of global access result from further restrictions on allowable algorithms. Probabilistic models of fail-stop errors, such as those considered by Kedem, Palem, and Spirakis [13], are formed by simple delay distributions where $\rho_i = \rho$ and $\bar{\rho}_i = 1$ for all i, so that once a step is missed, the processor takes no further steps.

It is important to note that the constant speed distributions differ from any of the distributions considered by Cole and Zajicek [3]; to see this, consider in the uniform distribution the probability that a processor takes three consecutive steps without any steps by other processors intervening. In essence, the uniform distribution provides a more pessimistic view of the world, since greater deviations from a round-robin allocation of steps are more likely to occur. This pessimism results in more robust upper bounds.

5. Barrier synchronization.

In this section we establish the upper and lower bounds of $\Theta(\log n)$ on the complexity of executing a synchronization barrier by n processors. We then show how this result can be used to obtain complexities of various algorithms, including general classes of algorithms transformed in a uniform way from their synchronous counterparts.

5.1. Time complexity analysis.

A synchronization barrier can be seen as an algorithm that begins by each processor signaling that it is ready to synchronize and ends by each processor knowing that all the other processors have signaled. In particular, no processor can exit the computation until all processors have entered the computation. It is in fact possible to obtain a tight bound on the complexity of synchronization.

THEOREM 5.1. *Synchronization of n processors can be performed in $O(\log n)$ time for any distribution δ on linearizations such that $\delta \in \mathcal{C} \cup \mathcal{S}$. Synchronization of n processors requires $\Omega(\log n)$ time for any distribution δ' on linearizations such that $\delta' \in \mathcal{C} \cup \{s \in \mathcal{S} \mid \sigma^* < k/\ln n$ for a constant $k < 1\}$.*

Proof. We let $\sigma^* = \max_i\{\rho_i, \bar{\rho}_i\}$ in the simple delay distributions, and we note in square brackets the modifications needed to alter the proof for constant speed distributions to one for simple delay distributions.

The lower bound is a consequence of Theorem 4.10. For the upper bound, we consider an algorithm operating on a binary tree all of whose nodes initially contain the value 0 (it is not clear how the algorithm can work without some assumption on initialization). We will say that a node in the tree has been *filled* if some processor has written a 1 in it. Each processor begins by filling a leaf node to indicate that it is ready to synchronize. When the root node has been filled, all processors are ready to synchronize; a particular processor completes its computation of the synchronization as soon as it reads a 1 from the root node. The reading of the root can be accomplished in one more step by each processor, or in $O(\log n)$ time, by Facts 4.7 and 4.6 [by Facts 4.2 and 4.1] and by having processors alternate between steps taken to do work in the tree and steps taken to read the root node. It will suffice to analyze the filling of the nodes of the tree.

The nodes of the tree are filled from the bottom up, with each processor attempting to fill one node at each level. The nodes that a processor attempts to fill form a path from a leaf to the root. A node can be filled only after both its children have been filled. More formally, we make the following definitions. A distinct leaf node, ℓ_P, is assigned to each processor P. The nodes on the path from ℓ_P to the root of the tree form the set nodes(P). For a node u, let proc(u) be the set of processors P such that $u \in$ nodes(P). The set proc(u) is exactly the set of processors that attempt to fill u. Equivalently, proc(u) can be seen as the set of processors P such that ℓ_P is a leaf in the subtree rooted at u.

The processors will have completed the algorithm as soon as the root is filled. Suppose that each processor takes $\Theta(\log n)$ steps. By Fact 4.8 [Fact 4.3], the expected total number of steps will be in $\Theta(n \log n)$ [the expected number of transitions will be in $\Theta(\log n/\sigma^*)$]; by Fact 4.6 [Fact 4.1], the expected maximum number of steps per processor will be in $O(\log n)$.

To complete the proof of the theorem, it will suffice to show that if each processor takes $\Theta(\log n)$ steps, the root will be filled, regardless of the ordering of steps. The key notion is that of delay.

DEFINITION 5.2. *A processor P is* delayed at node u *if the child of u in* nodes(P) *has been filled, the other child of u has not been filled, and it is P's turn to take a step.*

DEFINITION 5.3. *A processor P is* delayed in the subtree rooted at u *if $P \in$* proc(u) *and P has been delayed at a node $v \in$* nodes(P), *where v is a descendant of u (note that v can be u itself). Let* delay(u) *be the set of processors delayed in the subtree rooted at u.*

The lemma below shows that at least one processor is never delayed in the tree; such a processor can fill the root in $\Theta(\log n)$ steps. This completes the proof of the theorem.

LEMMA 5.4. *There exists at least one processor $P \in$* proc(u) *such that P is not delayed in the subtree rooted at u; equivalently,*

$$|\text{delay}(u)| < |\text{proc}(u)|.$$

Proof. We prove our lemma by induction on the height of u. The base case is trivial: At a leaf, no processor is delayed. Now consider a node u, with children x and y. Note that $\text{proc}(u) = \text{proc}(x) \cup \text{proc}(y)$.

Without loss of generality, assume that x is filled before y. Consider a processor $P \in \text{proc}(y)$; it is clear that P cannot be delayed at u. However, for all $Q \in \text{proc}(x)$ it is possible for Q to be delayed at u, in particular if Q takes a step after x has been filled but before y is filled. We then determine that the number of processors delayed in the subtree rooted at u is

$$|\text{delay}(u)| \leq |\text{proc}(x)| + |\text{delay}(y)|.$$

By the induction hypothesis, $|\text{delay}(y)| < |\text{proc}(y)|$. Thus $|\text{delay}(u)| < |\text{proc}(u)|$, as needed. □

5.2. Consequences.

5.2.1. Processor-efficient solutions. With a bit of refinement to the algorithm presented above, the synchronization paradigm can be used to obtain processor-efficient algorithms for various problems. Although a synchronization problem of size n, by definition, requires n processors, other problems in the synchronization paradigm can be solved using $n/\log n$ processors. Note, furthermore, that the lower bound of Theorem 4.10 does not apply to algorithms in which certain processors may exit before each processor has taken a step. Whether or not there is an $\Omega(\log n)$ lower bound for OR in such a circumstance remains an open question.

THEOREM 5.5. *The n-input problems of* OR, AND, MAX, MIN, *and* PARITY *can be solved in $O(\log n)$ time using $n/\log n$ processors for any distribution δ on linearizations such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

Proof. The algorithms for the various problems are very similar; here we concentrate on the algorithm that computes the OR of n bits. We can think of the input as being partitioned into $n/\log n$ blocks of $\log n$ bits each. In the first stage, each processor reads a different block of bits and computes the OR of these $\log n$ bits sequentially, in time in $O(\log n)$.

In the second stage, the processors perform an algorithm similar to that described in Theorem 5.1. We make use of a binary tree with $n/\log n$ leaves. Each leaf is filled with the OR of $\log n$ bits (as calculated in the first stage); each interior node is filled with the OR of the values of its children. By Theorem 5.1, the time complexity of this algorithm is in $O(\log(n/\log n)) = O(\log n)$. Since the time required for each stage is in $O(\log n)$, the total running time is in $O(\log n)$, as claimed. □

5.2.2. Simulation of circuits and asynchronous PRAMs. Since a Boolean formula, and hence a Boolean circuit, can be viewed as a tree, it is not difficult to transform one into an asynchronous algorithm. For a sufficient number of processors, the depth of the circuit yields an immediate upper bound on the time of the algorithm, as in the following theorems.

THEOREM 5.6. *The problem of multiplying two $n \times n$ Boolean matrices can be solved in $O(\log n)$ time using $O(n^3/\log n)$ processors for any distribution δ on linearizations such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

Proof. Two n by n Boolean matrices can be multiplied by using a simple circuit of ANDs and ORs. There are $n/\log n$ processors assigned to each of the n^2 matrix positions. Each processor computes the AND of $\log n$ pairs of bits and then the OR of the $\log n$ results. The OR of the $n/\log n$ values for a particular position are then computed in time $O(\log n)$, yielding a total time complexity of $O(\log n)$. □

COROLLARY 5.7. *Transitive closure can be solved asynchronously in $O(\log^2 n)$ time using $O(n^3/\log n)$ processors for any distribution δ on linearizations such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

Proof. The transitive closure of a matrix, can be computed by taking the nth power of the matrix by $O(\log n)$ squarings, or a total running time of $O(\log^2 n)$. □

Further results can be obtained by simulating algorithms developed for Gibbons' ASYNCHRONOUS PRAM. Since the algorithms considered by Gibbons [8], [9] alternate between the independence paradigm and the synchronization paradigm, we can easily simulate these algorithms and analyze their running time on our model. The complexity results obtained on an ASYNCHRONOUS PRAM with a charge for latency can be obtained (or improved) on an ASYNCHRONOUS PRAM where there is no charge for latency. The following theorem is a direct consequence of the construction of the ASYNCHRONOUS PRAM algorithms and Theorem 4.11; the function $B(n)$ is the cost of executing a synchronization barrier on n items in Gibbons' model.

THEOREM 5.8. *Any problem that can be solved in $f(B(n))$ time on an n-processor* ASYNCHRONOUS PRAM *with no charge for latency can be solved on our model in $O(f(\log n))$ time using n processors for any distribution δ such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

COROLLARY 5.9. *The n-input problem of fast Fourier transform can be solved in time $O(\log^2 n/\log\log n)$ using $n\log\log n/\log n$ processors for any distribution δ such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

COROLLARY 5.10. *The problem of merging two bitonic lists can be solved in time $O(\log^2 n/\log\log n)$ using $n/\log n$ processors for any distribution δ such that $\delta \in \mathcal{C} \cup \mathcal{S}$.*

5.2.3. Simulation of synchronous PRAMs. As a consequence of Theorem 5.1, we obtain the following relation between synchronous and asynchronous complexity classes.

THEOREM 5.11. *Any problem that can be solved in t time on an* ARBITRARY CRCW PRAM *using p processors can be solved asynchronously in time $O(t(p/p' + \log p'))$ using p' processors for any distribution δ such that $\delta \in \mathcal{C} \cup \mathcal{S}$, and for $1 \le p' \le p$.*

Proof. It will suffice to show how a single write phase of ARBITRARY can be simulated by p' asynchronous processors in $O(p/p' + \log p')$ time. The read phase is analogous.

Each asynchronous processor is assigned $\lfloor p/p' \rfloor$ ARBITRARY CRCW PRAM processors. At a given PRAM step, each asynchronous processor executes the appropriate step taken by each of the $\lfloor p/p' \rfloor$ simulated processors. The p' processors then synchronize in $O(\log p')$ time using separate parts of memory. It is not difficult to see that the memory cell contents in simulating cells at the end of the synchronization will correspond to those obtained after a synchronous step. □

When $p' = 1$, the result corresponds to a single processor sequentially executing all $O(tp)$ work. The other extreme, when $p' = p$, corresponds to inserting a synchronization barrier after each PRAM step and the work decreases to $O(t\log p)$. When $p' \in O(p\log\log p/\log p)$, we obtain the result that any problem that can be solved in time t on an ARBITRARY CRCW PRAM using p processors can also be solved asynchronously in time $O(tp/p')$ using p' processors for any distribution δ such that $\delta \in \mathcal{C} \cup \mathcal{S}$, using within a constant factor the same total amount of work as in the synchronous case.

6. Pointer jumping. In the paradigm of pointer jumping, processors interact, but at the same time adapt to each other's speeds. This adaptation allows for an $O(\log n)$ time asynchronous pointer jumping algorithm, matching the synchronous time bound. Since pointer jumping forms the basis of many fundamental problems, it is no surprise that Theorems 6.3 and 6.13 yield identical complexity measures for other problems such as list ranking and suffix sum. By adding a preprocessing stage during which the list is made doubly-linked, we can compute for each node in an input tree such information as preorder number, post-order number, level, and number of descendants in $O(\log n)$ time using the Euler tour technique [24].

In the following treatment, we consider a particular pointer jumping algorithm that starts with n inputs forming a linked list in global memory. Each node is associated with a distinct processor which has its address stored in local memory. The program of each processor is identical to that in the standard synchronous algorithm; however, the set of tasks executed may vary with the linearization. As the algorithm progresses, each processor advances the pointer of its node toward the tail of the list. Repeatedly, it follows its node's pointer to read the successor's pointer, and then updates its node's pointer. The algorithm ends when all pointers point to the tail of the list. Alternatively, we could have all processors execute a synchronization barrier after updating their pointers to point to the end of the list. We show in Theorems 6.3 and 6.13 that the complexity of pointer jumping is in $O(\log n)$, and hence an extra $O(\log n)$ for synchronization does not change the overall complexity.

6.1. Time complexity analysis.

6.1.1. Simple delay distributions. We begin by analyzing the complexity of the pointer jumping algorithm when the linearization is chosen subject to a distribution in $\mathcal{S}$. The analysis for distributions in $\mathcal{C}$, which follows in §6.1.2, is more complicated.

The analysis of the algorithm is based on a very simple idea. We would like to divide the sequence of steps taken during an execution of the algorithm into $\log n$ phases, and show that after phase i, each processor's node is either pointing at least 2^i positions closer to the tail of the list than at the start of the computation, or pointing to the tail of the list. We will say that such a processor is *on-time at the end of phase i*, or more succinctly, *on-time at i*. If this were true, then after phase i any node would be at least as far along the list as the corresponding node after the ith step of a synchronous computation. After $\log n$ phases, each node would point to the tail of the list. Ensuring that each processor is on-time at the end of each phase, however, would require that a phase have a prohibitively large number of steps.

Instead, we look at phases of $\lceil 18/\sigma_* \rceil$ transitions and relax the requirement for progress (recall that σ_* is the minimum probability of any processor taking a step at any transition). Namely, we wish to show that with probability at least a constant, say $1/3$, an arbitrary processor P is on-time at the end of phase i. We divide the linearization into two stages, and show that in each stage the expected maximum number of steps taken by any processor is in $O(\log n)$. The first stage consists of $\log n$ phases; we show in Lemma 6.1 that at the end of this stage, each processor is pointing to the tail of the list with probability at least $1/3$. The second stage consists of the remainder of the algorithm. In Lemma 6.2, we show that this stage can also be completed in $O(\log n)$ time, yielding an overall time complexity of $O(\log n)$. We now consider the analysis of the stages one at a time.

LEMMA 6.1. *After the first* $\lceil 18 \log n/\sigma_* \rceil$ *transitions in a linearization chosen from a distribution in* $\mathcal{S}$, *for each processor* P, *the probability that* P *is pointing to the tail of the list is at least* $1/3$.

Proof. Since any processor P will point to the tail of the list if it is on-time at the end of the $(\log n)$th phase, it will suffice to prove by induction on phase numbers that for phase i, P is on-time at i with probability at least $1/3$.

A processor is on-time at the end of phase i if there were at least two times during phase i at which it updated its node's pointer to point to the node of a processor that was on-time at the end of phase $i-1$. For convenience, we will use the phrase "*P updated to a cell of a processor on-time at $i-1$*" to express the notion that P updated its node's pointer to point to a node of a processor that was on-time at the end of phase $i-1$. We have a lower bound on the probability that an arbitrary processor P is on-time at i, that is, the probability that P updated to cells of at least two processors that were on-time at $i-1$.

For any events A and B, we know that $Pr[A] \geq Pr[A|B] \cdot Pr[B]$. Here we let A be the event that P updated to cells of at least two processors that were on-time at $i-1$ and B be the event that P took at least 9 steps. It will now suffice to determine lower bounds on $Pr[A|B]$ and $Pr[B]$.

We first determine a lower bound on the probability that P took at least 9 steps in a particular phase. Since P takes a step with probability at least σ_*, it is clear that $E \geq 18$, and hence by Fact 4.5

$$Pr[B] \geq 1 - e^{-2.25} \geq .89.$$

In order to show that $Pr[A] \geq 1/3$, it will now suffice to show that $Pr[A|B] \geq .38$. Of the 9 or more steps taken by P during phase i, there will be at least four reads followed by writes, updates to nodes of four different processors. By the induction hypothesis, each of these processors was on-time at the end of phase $i-1$ with probability at least $1/3$. Relying on the fact that in this type of distribution the probability of each processor taking steps is independent of the steps taken by any other processor,

$$\begin{aligned} Pr[A|B] &\geq 1 - Pr[\text{none are on-time}] - Pr[\text{exactly one is on-time}] \\ &\geq 1 - (\tfrac{2}{3})^4 - 4 \cdot \tfrac{1}{3} \cdot (\tfrac{2}{3})^3 > 0.38, \end{aligned}$$

completing the proof of Lemma 6.1. □

We are now ready to determine the complexity of stage 2.

LEMMA 6.2. *Suppose that for each processor* P, *the probability that* P *is pointing to the tail of the list is at least* $1/3$. *Consider a linearization chosen according to a distribution in* $\mathcal{S}$. *Then the expected maximum number of steps taken by any processor in the second stage is in* $O(\log n)$.

Proof. Let a' be a constant defined later, and let an experiment consist of $a' \log n/\sigma_*$ transitions. For $t = a' \log n/\sigma_*$, we know from Fact 4.4 that there exists a constant a such that the probability that there is a processor that takes fewer than $a \log n$ steps is at most $1/n^{O(1)}$. We say an experiment is successful if each processor takes at least $a \log n$ steps and each processor reaches the end of the list. The expected number of experiments is at most $1/p$, where p is the probability of success. To obtain an upper bound of $O((\log n)/\sigma_*)$ on the expected number of transitions (to which we can apply Fact 4.1 to obtain our result), it will suffice to obtain as an upper bound on the probability of failure a constant less than 1.

Let $\mathcal{A}$ be the event that there exists a processor that takes fewer than $a \log n$ steps, and let $\mathcal{B}$ be the event that there exists a processor that does not reach the end of the list. Then

$$\begin{aligned} Pr[\text{Failure}] &= Pr[\mathcal{A} \vee \mathcal{B}] \\ &\leq Pr[\mathcal{A}] + Pr[\mathcal{B}|\neg\mathcal{A}]. \end{aligned} \tag{1}$$

The upper bound of $1/n^{O(1)}$ on $Pr[\mathcal{A}]$ is a consequence of Fact 4.4. To obtain a similar upper bound on $Pr[\mathcal{B}|\neg\mathcal{A}]$, we note that if a processor reads the node of a single processor whose node is pointing to the tail of the list, it too advances its pointer to point to the tail of the list. The probability of a successor pointing to the end of the list at any point in this stage is at least 1/3, and hence $Pr[\mathcal{B}|\neg\mathcal{A}] \leq (2/3)^{a \log n}$ which is bounded above by $1/n^{O(1)}$ for a suitable value of a. We can choose a' appropriately. □

We can now prove Theorem 6.3. By Fact 4.1, the expected maximum number of steps taken by any processor in stage 1 is in $O(\log n)$. By Lemmas 6.1 and 6.2, stage 2 can be completed in $O(\log n)$, yielding a total time of $O(\log n)$.

THEOREM 6.3. *Pointer jumping can be performed in time $O(\log n)$ using n processors for any distribution $\delta \in \mathcal{S}$.*

6.1.2. Constant speed distributions. The time complexity analysis for constant speed distributions is complicated by the fact that the probability of one processor taking a step is not independent of the steps taken by other processors. In this section we develop a general technique for handling such dependencies, which may prove of use in complexity analysis of other algorithms.

To determine the complexity of the algorithm given a linearization chosen according to a distribution in $\mathcal{C}$, we again divide the linearization into phases, this time of $(8w + 4)(c_*)^{-2}n$ steps, where c_* and c^* are constants such that $\gamma_* \geq c_*/n$, $\gamma^* \leq c^*/n$, and $w \geq 2$ is a value such that

$$\left(1 - \frac{2c^*}{c_*(2w+1)}\right)\left(1 - \left(\frac{2}{3}\right)^{w} - w \cdot \frac{1}{3} \cdot \left(\frac{2}{3}\right)^{w-1}\right) \geq 0.53.$$

(Note that each of the two factors increases as a function of w, so such a w exists for all values of c_* and c^*.) The complexity analysis for this type of distribution is complicated by the correlation between different processors being allocated steps. In a fixed total number of steps, if one processor takes a large number of steps, any other processor is less likely to take a large number of steps. In particular, suppose that processor P' reads the node of processor P during phase i. The fact that P' reads the node of P implies that a certain amount of progress, and hence a certain number of steps, were allocated to P' and the processors with nodes between the nodes of P' and P. Since these steps were allocated in this way, we know that they were not allocated to P and its successors. This decreases the probability that P and its successors were allocated steps, and hence the probability that P is on-time.

We consider the probability of P being on-time conditioned on progress made by its predecessors. We can represent the state of the algorithm at any time by a directed graph, as follows: each processor is represented as a vertex, and a pointer from the node of P' to the node of P in the list is represented as a solid edge from the vertex for P' to the vertex for P. Clearly each vertex will have a single solid outedge. In addition, a processor $\hat{P}$ may have read and calculated a new pointer value, for example to $\bar{P}$, but not yet written the new value from its local memory to update its pointer in global memory; the new pointer value is represented as a dashed directed edge from the vertex for $\hat{P}$ to the vertex for $\bar{P}$. The *configuration* of predecessors of P at a particular time is simply the induced subgraph on all vertices that can reach P by any combination of solid and dashed edges; the set of predecessors is defined not to include P. We let $Q^i{}_P$ be a configuration of the predecessors of P at the end of phase i. If we know the configurations Q_P^{i-1} and $Q^i{}_P$, we have partial information about the progress made during phase i by the predecessors of P at the end of phase i.

Consider a particular configuration at the end of phase $i - 1$. Fixing a configuration at the end of phase i induces a distribution on the number of steps that are allotted during phase i to the predecessors of P at phase $i-1$ and the number that are allotted to the nonpredecessors. Given an allotment of steps to the nonpredecessors, we would like to be able to argue that, with reasonable probability, P is allotted a certain number of steps. This requires that the set of nonpredecessors be fairly large. Notice that if a node is originally closer to the tail of the list than P's node, then its processor is never a predecessor of P.

DEFINITION 6.4. *A processor P is a* tail *processor if it is initially assigned one of the $\sqrt{n}-1$ nodes closest to the tail of the list; otherwise, P is a* head *processor.*

Let S_P be the set consisting of P along with the tail processors. Whenever P is a head processor, we can conclude that S_P contains no proper predecessors of P at any time.

Initially we concentrate only on the progress of the head processors; we modify the definition of on-time for such processors.

DEFINITION 6.5. *A head processor P is* on-time *at the end of phase i if it is pointing either to the node of a tail processor or to a node that was originally at least 2^i positions closer to the tail of the list.*

For convenience, let $C(P, i, Q)$ denote the condition that for a head processor P, and a configuration Q of the predecessors of P at i, $Pr[P$ is on-time at $i \mid Q] \geq 1/3$. Of particular interest is the condition $C(P, \log n, Q)$, since a processor that is on-time after the $(\log n)$th phase is pointing to a tail processor. We will say that a head processor pointing to a tail processor is *promoted.* Let $D(P)$ be the condition that after phase $\log n$, $Pr[P$ is promoted$] \geq 1/3$.

We divide the linearization into four stages, treating head and tail processors separately. We show that in each stage the expected maximum number of steps taken by any processor is in $O(\log n)$. As in §6.1.1, the division is part of the analysis, not part of the algorithm. In the first two stages, we consider the progress of the head processors. The first stage consists of $\log n$ phases; Lemma 6.11 below will show that with high probability, condition $D(P)$ will hold for each head processor at the end of stage 1. Stage 2 begins when the first $(8w+4)(c_*)^{-2}n \log n$ steps have been completed, and ends as soon as each head processor is promoted. The next stage ends when each tail processor has advanced its pointer to the tail of the list. Finally, in stage 4 each head processor takes at most one more step to point to the tail of the list and complete the pointer jumping problem. We now consider the analysis of the stages one at a time.

For stage 1, we would like to claim that $D(P)$ holds for each head processor P. Since any head processor will be promoted if it is on-time at the end of the $(\log n)$th phase, it would suffice to prove for each phase i and each configuration Q of predecessors of P at i that condition $C(P, i, Q)$ holds. However, for some pairs of configurations at phases $i-1$ and i, the probability of a processor being on-time may be much smaller than $1/3$. We instead show in Lemma 6.8 that with high probability $C(P, i, Q)$ holds. Consider a configuration ${Q^i}_P$ of the predecessors of P at i; associated with each linearization that leads to ${Q^i}_P$ is a particular configuration of the predecessors of P at $i-1$. We will say that a configuration Q_P^{i-1} is *good with respect to ${Q^i}_P$* if

$$Pr[S_P \text{ gets} > (4w+2)|S_P|/c_* \text{ steps during } i \mid Q_P^{i-1} \wedge {Q^i}_P] \geq 1 - e^{-\sqrt{n}}.$$

We will establish the fact that for a fixed configuration Q of predecessors of P at i, it is likely that the configuration at time $i-1$ was good with respect to Q. We first show in Lemma 6.6 that with very high probability, S_P will get more than $(4w+2)|S_P|/c_*$ steps during i. Then, we show that the configuration at time $i-1$ is good with respect to Q with very high probability, by a simple averaging argument in Lemma 6.7.

LEMMA 6.6. *For any configuration Q of the predecessors of P at i,*

$$Pr[S_P \textit{ gets} > (4w+2)|S_P|/c_* \textit{ steps during } i|Q] \geq 1 - e^{-2.5\sqrt{n}}.$$

Proof. Since the number of steps taken during a phase is fixed, there is a fixed number of possible sequences of steps taken during a phase and a probability associated with each one.

To determine the probability that S_P gets more than $(4w+2)|S_P|/c_*$ steps, we make use of the fact that the expected number of steps allotted to S_P in a phase of $(8w+4)(c_*)^{-2}n$ steps is at least $(8w+4)|S_P|/c_*$. From Fact 4.9 it follows that

$$Pr[S_P \text{ gets} > (4w+2)|S_P|/c_* \text{ steps}] \geq 1 - e^{-(8w+4)\cdot|S_P|/8c_*}.$$

By definition $w \geq 2$, $c_* \leq 1$, and $|S_P| = \sqrt{n}$, and hence

$$Pr[S_P \text{ gets} > (4w+2)|S_P|/c_* \text{ steps}] \geq 1 - e^{-2.5\sqrt{n}}. \qquad \square$$

We fix a configuration Q of predecessors of P at i and consider the possible previous configurations at $i-1$, which we call $Q_1, Q_2, \ldots$. Let $\mathcal{A}_j$ be the set of linearizations that result in Q at i given Q_j at $i-1$. Let $\mathcal{M}_j$ be the subset of $\mathcal{A}_j$ in which S_P gets at most $(4w+2)|S_P|/c_*$ steps during the phase i. It follows from the statement of Lemma 6.6 that

$$\sum |\mathcal{M}_j| \leq e^{-2.5\sqrt{n}} \sum |\mathcal{A}_j|.$$

LEMMA 6.7. *The configuration at $i-1$ is good with respect to Q with probability at least $1 - e^{-\sqrt{n}}$.*

Proof. Let $\mathcal{B} = \{j \mid |\mathcal{M}_j| \geq e^{-\sqrt{n}}|\mathcal{A}_j|\}$. Then the statement of Lemma 6.7 is

$$\sum_{j\in\mathcal{B}} |\mathcal{A}_j| \leq e^{-\sqrt{n}} \sum |\mathcal{A}_j|.$$

It follows from Lemma 6.6 and the definition of $\mathcal{B}$ that

$$\begin{aligned} e^{-2.5\sqrt{n}} \sum |\mathcal{A}_j| &\geq \sum |\mathcal{M}_j| \geq \sum_{j\in\mathcal{B}} |\mathcal{M}_j| \\ &\geq \sum_{j\in\mathcal{B}} e^{-\sqrt{n}}|\mathcal{A}_j| = e^{-\sqrt{n}} \sum_{j\in\mathcal{B}} |\mathcal{A}_j| \end{aligned} \tag{2}$$

which implies the desired result. $\square$

LEMMA 6.8. *For any phase i, head processor P, and configuration Q of predecessors of P at i, $C(P, i, Q)$ is true with probability at least $1 - (w+1)^i e^{-\sqrt{n}}$.*

Proof. We prove this lemma by induction on the phase number. A processor is on-time at the end of phase i if there were at least two times during phase i at which it updated its node's pointer to point to the node of a processor that was on-time at the end of phase $i-1$. Consequently, we have a lower bound on the probability that an arbitrary head processor P is on-time at i:

$$\begin{aligned} &Pr[P \text{ is on-time at } i \mid Q] \\ &\geq Pr[P \text{ updated to} \geq 2 \text{ processors on-time at } i-1 \mid Q]. \end{aligned}$$

For any events A and B, we know that $Pr[A|Q] \geq Pr[A|B \wedge Q] \cdot Pr[B|Q]$. Here we let A be the event that during phase i P updated to cells of at least two processors that were on-time at $i-1$, and B be the event that P took at least $2w+1$ steps during phase i. It will now suffice to determine lower bounds on $Pr[A|B \wedge Q]$ and $Pr[B|Q]$. Let C be the event that S_P is allotted more than $(4w+2)|S_P|/c_*$ steps. As before, since $Pr[B|Q] \geq Pr[B|C \wedge Q] \cdot Pr[C|Q]$, it will suffice to consider $Pr[B|C \wedge Q]$, $Pr[C|Q]$, and $Pr[A|B \wedge Q]$.

CLAIM 6.9. $Pr[B|C \wedge Q] > 1 - 2c^*/(c_*(2w+1))$.

Proof. We wish to determine a lower bound on the probability that P takes at least $2w+1$ steps, given the fact that S_P gets more than $(4w+2)|S_P|/c_*$ steps. Suppose that S_P gets more than $(4w+2)|S_P|/c_*$ steps; let X be a random variable equal to the number of steps taken by P.

We can consider the choice of the processor to take the next step as a two-part process. First, we decide whether the processor is in S_P. If the processor is not in S_P, we next choose a particular processor; we do not care about the outcome. Otherwise, the processor is in S_P, and we next choose a processor from S_P. We are interested in the number of steps that P receives during phase i. If we know the number of steps that S_P receives, then the specific configuration has no bearing on the number of steps that P receives. Since the probability of P taking a step is at least c_*/n and at most c^*/n when considered among all n processors, the probability among a set of $|S_P|$ processors is at least $c_*/|S_P|$ and at most $c^*/|S_P|$. Thus $E[X] \geq 4w+2$, and

$$\begin{aligned} Pr[X \geq 2w+1] &\geq Pr[|X - E[X]| < 2w+1] \\ &= 1 - Pr[|X - E[X]| \geq 2w+1]. \end{aligned}$$

Since X is binomially distributed,

$$\mathrm{Var}(X) \leq \frac{(4w+2)|S_P|}{c_*}\left(\frac{c^*}{|S_P|}\right)\left(1 - \frac{c_*}{|S_P|}\right).$$

Chebyshev's inequality states that $Pr[|X - E[X]| \geq t] \leq \frac{\mathrm{Var}(X)}{t^2}$. In our case, we let $t = 2w+1$ to get

$$\begin{aligned} Pr[X \geq 2w+1] &\geq 1 - \frac{(4w+2)}{(2w+1)^2}\left(\frac{c^*}{c_*}\right)\left(1 - \frac{c^*}{|S_P|}\right) \\ &\geq 1 - \frac{2c^*}{c_*(2w+1)} \end{aligned}$$

as claimed. □

CLAIM 6.10. *With probability at least* $1 - w((w+1)^{i-1}e^{-\sqrt{n}})$,

$$Pr[A|B \wedge Q] \geq 1 - (\tfrac{2}{3})^w - w \cdot \tfrac{1}{3} \cdot (\tfrac{2}{3}).^{w-1}$$

Proof. Suppose that P has taken $2w+1$ or more steps during phase i. Then there will be at least w reads followed by writes. If we consider the state of the algorithm at the end of phase $i-1$, the w nodes read by P during i are arranged along some path of solid and dashed edges from P to the tail of the list. For any such path, the least progress P could make would be by reading its w immediate successors. Although the particular path followed and the particular w nodes read depend on the ordering of steps within phase i, we can determine a lower bound on $Pr[A|B \wedge Q]$ independent of such an ordering. For any path, P will be on-time at i if it took at least $2w+1$ steps and if at least two of the processors associated with its w immediate successors were on-time at $i-1$. We now apply the induction hypothesis to the processors of each of the w nodes that were read. For a particular one of these processors P_j and any configuration Q_j of predecessors of P_j at $i-1$, with probability at least $1 - (w+1)^{i-1}e^{-\sqrt{n}}$, the condition $C(P_j, i-1, Q_j)$ held at the end of phase $i-1$, and hence $Pr[P_j$ is on-time at $i-1 \mid Q_j] \geq 1/3$. It is then simple to calculate that, with probability at least $1 - w((w+1)^{i-1}e^{-\sqrt{n}})$, for all w processors the conditions are true. When all the conditions are true,

$$\begin{aligned} Pr[A|B \wedge Q] &\geq 1 - Pr[\text{none are on-time}] - Pr[\text{exactly one is on-time}] \\ &\geq 1 - (\tfrac{2}{3})^w - w \cdot \tfrac{1}{3} \cdot (\tfrac{2}{3})^{w-1} \end{aligned}$$

as claimed. □

To complete the proof of Lemma 6.8, let $\mathcal{A}$ be the condition that $Pr[A \mid B \wedge Q] \geq 1 - (\frac{2}{3})^w - w \cdot \frac{1}{3} \cdot (\frac{2}{3})^{w-1}$, and let $\mathcal{B}$ be the condition that $Pr[C|Q] \geq 1 - e^{-\sqrt{n}}$. If $\mathcal{A}$ and $\mathcal{B}$ are true, then

$$\begin{aligned} &Pr[P \text{ is on-time at } i \mid Q] \\ &\quad \geq Pr[A \mid B \wedge Q] \cdot Pr[C \mid Q] \cdot Pr[B \mid C \wedge Q] \\ &\quad \geq \left(1 - \left(\frac{2}{3}\right)^w - w \cdot \frac{1}{3} \cdot \left(\frac{2}{3}\right)^{w-1}\right)(1 - e^{-\sqrt{n}})\left(1 - \frac{2c^*}{c_*(2w+1)}\right). \end{aligned}$$

By the definition of w and by the fact that $1 - e^{\sqrt{n}} \geq 0.63$ for $n \geq 1$, this quantity is at least $1/3$. The probability of failure $Pr[\neg\mathcal{A} \vee \neg\mathcal{B}] \leq Pr[\neg\mathcal{A}] + Pr[\neg\mathcal{B}]$. Recall that by definition, the configuration at $i - 1$ being good with respect to Q means that $Pr[C \mid Q] \geq 1 - e^{-\sqrt{n}}$. Then, by making use of Claim 6.10 and Lemma 6.7, we obtain

$$\begin{aligned} Pr[\neg\mathcal{A}] + Pr[\neg\mathcal{B}] &\leq w((w+1)^{i-1} e^{-\sqrt{n}}) + e^{-\sqrt{n}} \\ &\leq (w+1)^i e^{-\sqrt{n}} \end{aligned} \tag{3}$$

and hence the condition $C(P, i, Q)$ is true with probability at least $1 - (w+1)^i e^{-\sqrt{n}}$, as claimed. □

Lemma 6.11 is a simple corollary of the previous lemma.

LEMMA 6.11. *Suppose that ℓ is a linearization chosen according to a distribution in $\mathcal{C}$. Then after $(8w+4)(c_*)^{-2} n \log n$ steps of ℓ, for each head processor P, the condition $Pr[P$ is promoted$] \geq 1/3$ is true with probability at least $1 - (w+1)^{\log n} e^{-\sqrt{n}}$.*

Proof. From Lemma 6.8, we know that after $\log n$ phases for any head processor P and any configuration Q of predecessors of P at $\log n$, the condition $C(P, \log n, Q)$ is true with probability at least $1 - (w+1)^{\log n} e^{-\sqrt{n}}$. We then determine that

$$\begin{aligned} Pr[P \text{ is promoted}] &= \sum_Q Pr[P \text{ is promoted} \mid Q] \cdot Pr[Q] \\ &\geq \frac{1}{3} \sum_Q Pr[Q] \geq \frac{1}{3} \end{aligned} \tag{4}$$

as claimed. □

We proceed to the second stage.

LEMMA 6.12. *Suppose that at the end of the first stage for each head processor P, $D(P)$, defined as "$Pr[P$ is promoted$] \geq 1/3$," is true with probability at least $1 - (w+1)^{\log n} e^{-\sqrt{n}}$. Then for a linearization chosen according to a distribution in $\mathcal{C}$, consider the running of the algorithm until all head processors are promoted. The expected maximum number of steps taken by any processor in this stage is at most $a_0 \log n$, for a constant a_0 and sufficiently large n.*

Proof. We note that if a processor reads the node of a single processor that is promoted, when it advances its node's pointer, it too is promoted. Each head processor can advance its node's pointer at most $n - \sqrt{n} < n$ times before reaching a tail processor. When the condition $D(P)$ holds for each processor, we can use the arguments developed in Lemma 6.2 to show that the expected maximum number of steps taken by any processor in this stage is at most $a_0 \log n$ for a constant a_0. The overall expected maximum is thus at most

$$a_0 \log n \cdot Pr[\text{All } D(P) \text{ true}] + n \cdot Pr[\text{One } D(P) \text{ false}].$$

It will suffice to show that $Pr[\text{One } D(P) \text{ false}] < 1/n$. By Lemma 6.11, the probability that $D(P)$ is false for a particular P is at most $(w+1)^{\log n} e^{-\sqrt{n}}$, or

$$Pr[\text{One } D(P) \text{ false}] \leq n \cdot (w+1)^{\log n} e^{-\sqrt{n}} \leq 1/n$$

for sufficiently large n. This completes the proof of Lemma 6.12. □

THEOREM 6.13. *The n-input problem of pointer jumping can be completed in $k \log n$ time, using n processors, with the distribution on linearizations chosen from $\mathcal{C}$, for some constant k.*

Proof. We prove the theorem by induction on the size of the pointer jumping problem, analyzing one stage at a time. The expected maximum number of steps taken by any processor in stage 1 is at most $c' \log n$, where c' is a constant depending only on w. By Lemmas 6.11 and 6.12, the expected maximum for stage 2 is at most $a_0 \log n$. In stage 3, we consider the progress of the tail processors. By the induction hypothesis, this requires a maximum of $k \log \sqrt{n} = (k/2) \log n$ steps. Finally, stage 4 is completed in another $O(n \log n)$ steps (by Fact 4.7), yielding an expected maximum of $c'' \log n$, for c'' a constant depending only on Fact 4.6. The total expected maximum is at most $(c' + a_0 + k/2 + c'') \log n$, and since c', a_0, and c'' are independent of k, we can choose $k \geq 2(c' + a_0 + c'')$, to complete the proof of the theorem. □

6.2. More complex delays. In the previous analysis, we considered together the behavior of all processors. In fact, we can assume that a constant number of processors (not including the anchor, defined in §7) are arbitrarily slow with respect to the other processors. In particular, a constant number of failures can be tolerated. Recall that a processor exits the computation as soon as it has updated its pointer to point to the tail of the list; we consider separately the steps taken by the slow and fast processors. To analyze the slow-down caused to the fast processors, we assume the worst case from the perspective of these processors: no slow processor takes a step before the fast processors finish their work. We modify our earlier analysis by showing that with high probability each processor takes $w+s$ steps per phase, where s is the number of slow processors. Even if a processor has to bypass all s slow processors in one phase, it will still have sufficiently high probability of reading two on-time processors. Finally we consider the number of steps taken by each slow processor, divided into those steps taken while the fast processors are active and those taken after all fast processors have exited the computation. Since the slow processors are no more likely to be allotted steps than the fast processors, there will be at most $O(\log n)$ steps of the first type. After the fast processors have all reached the tail of the list, a slow processor needs to read only one fast processor to update its pointer to the tail of the list. In the worst case, a slow processor will have s steps of the second type, for a total of $O(\log n)$.

7. Extensions. In the distributions considered in this paper, the speeds of the processors are within a constant factor of each other. Since in results discussed in this paper constant factors are unimportant, we have not been concerned with the difference between replacing a subset of processors by slower processors and replacing a subset of processors by faster processors. In this section we consider how the model could be extended by introducing a weighting function to incorporate other situations.

The weighting function arises from our wish to have our complexity measure reflect differences in intrinsic processor speeds. In the absence of such a function, replacing slow processors with faster ones might cause our measurement of time to increase, since faster processors might be likely to take more steps and thereby increase the expected maximum. We wish for our measure to reflect elapsed time; for example, we would like to be able to distinguish between the effect of replacing half the processors with faster ones and that of replacing half the processors with slower ones.

The weighting function, W, provides a mechanism for normalizing the numbers of steps taken by the various processors. In its fullest generality, the weight of a particular processor may depend on the number of steps it has taken, or the number of processors remaining active during the computation. In this case, rather than simply determining the sum of the steps taken by a processor, we determine the weighted sum, where each step is multiplied by the weight of that processor for that step. In a simple scenario where the weights of the processors remain the same throughout the computation, we can express W as a vector $(w_1, \ldots, w_p)$. We may wish to express the complexity of an algorithm with respect to the speed of a particular *anchor* processor. In the replacement of processors by slower or faster ones, the speed of the anchor is assumed not to have changed.

8. Conclusions and open problems. We have considered a framework for the asynchronous communication of processors through shared memory cells. We introduce a general model, parameterized by the choice of the underlying synchronization primitive and the distribution on possible processor schedules. The model and measure are shown to satisfy various criteria essential to the asynchronous setting.

The criteria include the application of the measure to the independence, synchronization and pointer jumping paradigms. For any choice of parameters, the complexity of an algorithm in the independence paradigm is equal to its synchronous PRAM complexity. For the atomic read/write cell and several classes of distributions, we can show that the complexity of the synchronization paradigm on n processors is in $\Theta(\log n)$. This result can be used to obtain straight-forward simulations of synchronous PRAM and circuit models.

It is possible to improve on the bounds obtained by the simulation of a synchronous PRAM algorithm; the pointer jumping algorithm analyzed here constitutes one such improvement. Using a synchronization primitive as weak as the atomic read/write cell and one of a general class of distributions on processor schedules, we obtain a running time of $O(\log n)$ for a pointer jumping problem of size n. The result implies fast algorithms for problems such as list ranking; the techniques used may be applicable to a wider class of problems.

Although the paradigms considered here form the basis of most synchronous parallel algorithms, it is possible that there are other paradigms that are particularly suited to the asynchronous environment. The identification and analysis of such paradigms will form part of the foundational work in the area. The algorithms given in this paper are designed to work quickly when the distribution on schedules corresponds to processors working at similar speeds. Of possible interest is the development of algorithms geared to other, more skewed distributions, or algorithms in which processors adapt themselves to fit the currently perceived distribution. In addition, it would be helpful to determine whether or not there exist algorithms such that one is faster under one distribution and the other faster under another. Finally, there is a need for algorithms that are robust in the sense that they work fairly quickly for a large class of distributions, and algorithm design techniques that apply to large classes of problems.

TIGHT BOUNDS ON OBLIVIOUS CHAINING*

SHIVA CHAUDHURI†

Abstract. The *chaining* problem is defined as follows. Given values $a_1, \ldots, a_n$, $a_i = 0$ or 1, $1 \le i \le n$, compute $b_1, \ldots, b_n$ such that $b_i = \max\{j \mid a_j = 1, j < i\}$. (Define $\max\{\} = 0$.) The chaining problem appears as a subproblem in many contexts. There are known algorithms that solve the chaining problem on CRCW PRAMs in $O(\alpha(n))$ time, where $\alpha(n)$ is the inverse of Ackerman's function, and is a very slowly growing function. The author studies a class of algorithms (called oblivious algorithms) for this problem. A simple oblivious chaining algorithm running in $O(\alpha(n))$ time is presented. More importantly, the optimality of the algorithm is demonstrated by showing a matching lower bound for oblivious algorithms using n processors. The first steps toward a lower bound for all chaining algorithms are also provided by showing that any chaining algorithm that runs in two steps must use a superlinear number of processors. The proofs use *prefix graphs* and *weak superconcentrators*. An interesting connection between the two is demonstrated and this idea is used to obtain improved bounds on the size of prefix graphs.

Key words. parallel, chaining, superconcentrators, lower bound, prefix graphs, Ackerman's function

1. Introduction.

Consider the following problem called *chaining*. Given values $a_1, \ldots, a_n$, $a_i = 0$ or 1, $1 \le i \le n$, compute $b_1, \ldots, b_n$ such that $b_i = \max\{j \mid a_j = 1, j < i\}$. (Define $\max\{\} = 0$.) The output can be viewed as pointers that chain the 1s into a linked list. The chaining problem is a natural problem to consider in the context of database retrieval operations; all the records that satisfy a particular predicate correspond to the input bits that have value 1. Chaining the 1s then corresponds to making a linked list of these records for future processing. Apart from this it appears as a subproblem in many contexts and has been studied before in [16] and [17]. Parallel integer sorting [2], [14], parallel merging of integers drawn from a restricted domain [3], parallel subset compaction [18], [13], [16], and circuits for computing threshold functions [15] are examples. It is easy to solve the problem in $O(n)$ time using one processor. Using n processors, very fast parallel algorithms exist, with running times close to constant. For this reason, and because of its simplicity, it is an open question of theoretical interest [3], [16], [17] whether constant time parallel algorithms exist.

Berkman and Vishkin [4] and Ragde [16] have given parallel algorithms that solve the chaining problem in $O(\alpha(n))$ time using n processors, where $\alpha(n)$ is the inverse of Ackerman's function and is a very slowly growing function. Using algorithms similar to the chaining algorithm, Berkman and Vishkin [5] give algorithms achieving the same bounds for other problems: The lowest-common-ancestor problem and a parenthesis matching problem.

We study oblivious algorithms for the chaining problem. Informally, an oblivious algorithm is one in which the pattern of memory access depends only on n (the size of the problem), and not on the specific input. This class of algorithms is of interest because the algorithms of Berkman and Vishkin and Ragde can be modified to be oblivious. We present a simple oblivious algorithm for chaining running in $O(\alpha(n))$ time. While the performance bounds are the same as previously known algorithms, our algorithm is simple and makes use of previously known graph structures. More importantly, we show that for the class of oblivious algorithms this is optimal, by proving that an oblivious chaining algorithm using n processors requires $\Omega(\alpha(n))$ time. Since all known algorithms for chaining can be made oblivious, this gives evidence of a superconstant lower bound for all chaining algorithms.

Chandra, Fortune, and Lipton [7] showed that a circuit of bounded depth for the prefix-carry problem requires superlinear size, implying a superconstant lower bound on depth for circuits with linear size. Essentially they show that such a circuit must have the structure of a special type of graph called a prefix graph. They then prove the upper and lower bounds on the size of prefix graphs of bounded depth [6], [7]. We demonstrate a connection between prefix graphs and another family of graphs called *weak superconcentrators* [11]. Using this idea, we present a simple proof that improves the lower bound of [7], and shows that the construction in [6] is optimal.

Dolev, Dwork, Pippenger, and Wigderson [11] showed a lower bound on weak superconcentrators of bounded depth. Our lower bound for oblivious chaining algorithms is obtained by interpreting such algorithms as graphs and using the techniques of [11] to analyze their properties. It is worth noting that there are chaining algorithms whose graphs are not weak superconcentrators, hence the lower bound of [11] cannot be used directly.

We provide the first steps toward proving a lower bound for all algorithms by showing that any chaining algorithm that terminates in two steps requires a superlinear number of processors. At the time of submission of this paper, we conjectured that the techniques developed in this paper would be useful in proving a lower bound for all algorithms. This was indeed the case, as the techniques used here were recently extended to prove a lower bound for all chaining algorithms in [9].

The model of computation used in this paper is the Concurrent-Read Concurrent-Write Parallel Random Access Machine (CRCW PRAM). In the COMMON model of CRCW PRAM, all processors that simultaneously write to the same memory cell must write the same value. In the more powerful PRIORITY model, each processor has an associated priority and when several processors simultaneously write to the same memory cell, the highest priority processor succeeds. It has been shown that the PRIORITY model is strictly stronger than the COMMON model [1]. We show that when considering oblivious algorithms, both models are equivalent if the COMMON machine has some extra memory. Thus, throughout this paper, the algorithms described run on the COMMON model and the lower bound is proved on the PRIORITY model.

2. Oblivious computation on PRAMs. The input to an algorithm for chaining consists of a value n (the size of the problem), and n bits (called the input vector) representing the problem. At any step each processor computes, based on its actions so far, a memory address to access and the contents to write (if it is a write step). By an *oblivious* algorithm, we mean one where the address accessed is fixed over all input vectors, i.e., it depends only on the value n. However, whether or not the processor performs any action may depend on the input vector; for example, when $n = 100$, on the fifth write step, p_1 may or may not write depending on the input vector, but if it does write, it always writes to c_{15}. (Our definition of oblivious algorithms coincides with what is called *semi-oblivious* in [10].)

It will be convenient to model the computation of an oblivious algorithm on a graph. Given an algorithm A and an input size n, the directed graph $G_{A,n}$ is defined as follows. The vertices of $G_{A,n}$ are grouped into levels. Suppose the algorithm solves the chaining problem in k steps. Then the graph $G_{A,n}$ will consist of $2k + 1$ levels of vertices, numbered $0, \dots, 2k$.

At even levels we will have a vertex for each cell in the memory that is accessed by the algorithm. These vertices will have the form $(c, 2j)$, $0 \leq j \leq k$ and will be called cell vertices (or just cells). At odd levels we will have a vertex for each processor. These vertices will have the form $(p, 2j + 1)$, $0 \leq j \leq k - 1$, and will be called processor vertices (or just processors). Thus there are k levels of processor vertices and $k + 1$ levels of cell vertices.

Edges of $G_{A,n}$ are defined as follows.

$(c, 2j) \rightarrow (p, 2j + 1)$: if for some input vector, at step $j + 1$, processor p reads cell c.

$(p, 2j+1) \rightarrow (c, 2(j+1))$: if for some input vector, at step $j+1$, processor p writes to cell c.

$(p, 2j+1) \rightarrow (p, 2(j+1)+1)$.

$(c, 2j) \rightarrow c(2(j+1))$.

Initially, bit i of the input vector is assumed to be in cell i, $1 \leq i \leq n$, and finally the output value corresponding to bit i is assumed to be in cell i. We shall refer to vertices $(i, 0)$ as x_i and vertices $(i, 2k)$ as y_i.

Let P be the number of processors used by A. The number of cells accessed during the computation is at most $2kP$. There are two kinds of edges in the graph, those adjacent to a processor vertex and others. Since each processor vertex has at most degree 4, the former are at most $4kP$ in number. For each cell accessed during the computation, there are k cell vertices in the graph, one at each even level. Thus the total number of cell vertices in the graph is $2k^2P$. Since each cell vertex is adjacent to at most two of the latter type of edge, there are at most $2k^2P$ such edges. Hence the number of edges in the graph is certainly upperbounded by $6k^2P$.

Given an input vector D of length n, we shall associate with each cell vertex a content and with each processor vertex a state. The content associated with $(c, 2j)$ is the content of cell c at step j (just before the $(j+1)$st read-write step) in the computation of A on input D. The state associated with $(p, 2j+1)$ is the state of the processor p after the read step of the $(j+1)$th read-write step in the same computation. At any time in the computation, the action of a processor is dependent solely on its state. Each processor starts with a fixed initial state.

A *partial input* $B = b_1b_2 \ldots b_n$ is one in which each $b_i \in \{0, 1, *\}$. An input vector $D = d_1d_2 \ldots d_n$, each $d_i = 0$ or 1, is consistent with B if $\forall i$, $1 \leq i \leq n$, $b_i \neq * \Longrightarrow b_i = d_i$. X_B will denote the set of inputs consistent with B. For a partial input B and a cell vertex $(c, 2j)$ define

$$S_B((c, 2j)) = \{d \mid \text{ cell } (c, 2j) \text{ has content } d \text{ for some } x \in X_B\}.$$

Similarly, for a processor vertex $(p, 2j+1)$, define

$$S_B((p, 2j+1)) = \{e \mid (p, 2j+1) \text{ has state } e \text{ for some } x \in X_B\}.$$

We say a (cell or processor) vertex (x, j) is *fixed* for a partial input B if $|S_B((x, j))| = 1$.

2.1. Oblivious COMMON simulation of oblivious PRIORITY. Consider the following problem called the *leftmost-one* problem. Given input $B = b_1, \ldots, b_n, b \in \{0, 1\}$, compute $s = \min\{j \mid b_j = 1\}$. Fich, Ragde, and Wigderson [12] show that the leftmost-one problem can be solved in $O(1)$ time on COMMON using n processors and n memory cells. Their algorithm can be made oblivious. We shall use this fact to prove the following.

LEMMA 2.1. *Consider an oblivious algorithm that runs on a* PRIORITY PRAM *with p processors and M memory cells, in k steps. Then there is an oblivious algorithm solving the same problem on a* COMMON PRAM *with p processors and M + p memory cells in $O(k)$ steps.*

Proof. It suffices to show that one write step of an oblivious PRIORITY algorithm can be simulated on an oblivious COMMON machine in $O(1)$ steps. Suppose the PRIORITY machine writes to r cells $c_1, \ldots, c_r$. Let D_i denote the set of processors that may write to c_i. D_i is a fixed set. Note that some of the processors may choose not to write. It is sufficient for the COMMON machine to find, for each i, the highest priority processor in D_i that chooses to write. This is done by solving a leftmost-one problem of size $|D_i|$, using $|D_i|$ cells, processors from D_i, and $O(1)$ time. The space bound follows from the fact that $\sum_{i=1}^{r} |D_i| \leq p$. □

Henceforth we shall refer only to PRIORITY algorithms, and by the lemma, all the algorithms run on COMMON with the same time bounds. Note that in general it is not true that one step of a PRIORITY algorithm can be simulated by a COMMON algorithm in $O(1)$ steps. Boppana [1] gives an example of a problem that can be solved in $O(1)$ time on PRIORITY but requires $\Omega(\frac{\log n}{\log\log n})$ time on COMMON.

3. Upper bounds. Ackerman's function is defined as follows:

$$A(0,0) = 0;\; A(i,0) = 1 \quad \text{for } i > 0;\; A(0,j) = 2j \quad \text{for } j > 0,$$
$$A(i,j) = A(i-1, A(i,j-1)).$$

For a function f let $f^{(1)}(n) = f(n)$; $f^{(i)}(n) = f(f^{(i-1)}(n))$, $i > 1$. Define $I_0(n) = \lceil \frac{n}{2} \rceil$ and $I_k(n) = \min\{j \mid I_{k-1}^{(j)}(n) \leq 1\}$, $k > 1$. The functions I_k are the inverses of the kth level of Ackerman's function, i.e., $I_k(n) = \min\{j \mid A(k,j) \geq n\}$. I_1 behaves like $\log n$ and I_2 like $\log^* n$. Define $\alpha(n) = \min\{j \mid I_j(n) \leq j\}$.

Berkman and Vishkin et al. [4], [3], and Ragde [16] have given algorithms that solve the chaining problem on PRIORITY in ck steps using $nI_k(n)$ processors, where c is a constant ≥ 2. From these algorithms one can construct an algorithm using $O(n)$ processors that takes $O(\alpha(n))$ time. We give simple oblivious algorithms that solve the problem in $2k$ steps on PRIORITY using $nI_k(n)$ processors. Though the performance bounds are the same, we feel our algorithm is easier to understand.

A *prefix graph* of size n is a directed acyclic graph with n vertices $(x_1, \ldots, x_n)$ of indegree 0 called input vertices and n vertices $(y_1, \ldots, y_n)$ of outdegree 0 called output vertices. The depth of a prefix graph is the length of the longest path from an input to an output. Prefix graphs have the following property: $\forall i, j \in [n]$, there is a directed path from x_i to y_j iff $i < j$. Say a prefix graph is *levelled* if the vertices can be partitioned into levels numbered $0, 1, 2, \ldots$, such that every edge is from a level $i-1$ vertex to a level i vertex for some $i \geq 1$. Call such an edge a level i edge. A prefix graph is *contiguous* if for any vertex v the inputs from which v is reachable are of the form x_r, $r \in [i,j]$. It is possible to construct [6] levelled contiguous prefix graphs of size n and depth $2k$ such that $\forall i$, $1 \leq i \leq 2k$, the number of level i edges $\leq nI_k(n)$.

The *restricted-domain prefix-maxima* problem is defined as follows: Given an input $a_1, \ldots, a_n$; $a_i \geq 0$, $1 \leq i \leq n$, and $\forall i, j$, $1 \leq i < j \leq n, a_i, a_j \neq 0 \Longleftarrow a_i < a_j$, compute $b_1, \ldots, b_n$ where $b_i = \max\{a_j \mid j < i\}$. We show how to solve this problem using a prefix graph. Initially set the value at vertex $x_i = a_i$, $1 \leq i \leq n$. At step i, level i edges propagate the values at their tails to their heads and vertices at level i select the largest value propagated to them. It is easy to see that the value at a vertex $v = \max\{a_j | v \text{ is reachable from } x_j\}$ and thus the value at $y_i = b_i$, $1 \leq i \leq n$.

THEOREM 3.1. $\forall k \geq 1$, *there is an oblivious* PRIORITY PRAM *algorithm using* $nI_k(n)$ *processors that solves the chaining problem in* $2k$ *steps.*

Proof. We show how an oblivious PRIORITY PRAM algorithm can simulate the computation of a levelled, contiguous prefix graph G. Label the edges of G as follows. Let $\{x_r | r \in [i,j]\}$ be the set of input vertices that can reach the vertex at the tail of edge e. Label e with j. Designate a memory cell $m(v)$ to correspond to each vertex v of G. At step i, allocate a processor $p(e)$ to each level i edge of G so that for any two edges e, f such that label$(e) <$ label(f), $p(f)$ has a higher priority than $p(e)$. Such an allocation is easy to do. For e, an edge from v to w, $p(e)$ reads the value in $m(v)$. If the value is 0, then $p(e)$ does nothing, otherwise it writes the value to $m(w)$. It is easy to show that the value in $m(w)$ is $\max\{a_r | w \text{ is reachable from } x_r\}$, and so $m(y_i) = b_i$, $1 \leq i \leq n$. To solve the chaining problem with input $a_1, \ldots, a_n$, at first, $1 \leq i \leq n$, p_i writes i into $m(x_i)$ if $a_i = 1$. Then simply solve the restricted-domain prefix-maxima problem with the values in $m(x_i)$, $1 \leq i \leq n$ as input. The stated bounds follow from the bounds on prefix graphs. □

3.1. Weak superconcentrators and prefix graphs. In [7], it is proved that a prefix graph of depth $2k$ requires $\Omega(nI_{2k-1}(n))$ edges. We improve the lower bound, showing that the construction is optimal.

A *weak superconcentrator* is a directed acyclic graph with n vertices $x_1, \ldots, x_n$ of indegree 0 and n vertices $y_1, \ldots, y_n$ of outdegree 0, and the property that $\forall k$ and $i_1 < j_1 < i_2 < j_2 < \cdots < i_k < j_k$, there exist vertex disjoint paths between $\{x_{i_1}, \ldots, x_{i_k}\}$ and $\{y_{j_1}, \ldots, y_{j_k}\}$. The depth of a weak superconcentrator is the length of the longest directed path in it. It is proved in [11] that a weak superconcentrator of depth $2k$ requires $\Omega(nI_k(n))$ edges.

THEOREM 3.2. *A prefix graph of depth* $2k$ *requires* $\Omega(nI_k(n))$ *edges.*

Proof. We show that every prefix graph is a weak superconcentrator. Let $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$ be the input and output vertices of a prefix graph G. $\forall k$ and $i_1 < j_1 < i_2 < j_2 < \cdots < i_k < j_k$ there exist paths from x_{i_m} to y_{i_m}. If they are not all vertex disjoint, then $\exists p, q,\ 1 \leq p < q \leq k$ such that the paths from x_{i_p} to y_{j_p} and x_{i_q} to y_{j_q} have a common vertex. But then there is a path from x_{i_q} to y_{j_p}, $i_q > j_p$, a contradiction. □

4. Some useful functions and their properties. Following [11], we define the trees $T_k(l),\ l \geq 1$. $T_k(l)$ has all its leaves at depth k and each edge is labelled with a power of 2. The outdegree of the root is l and the outdegree of every other vertex is the label of the edge coming into the vertex from its parent. We describe how to construct $T_k(l)$, starting from the root. The edges and vertices of $T_k(l)$ will be created in a certain order. We think of the vertices at a given depth as being arranged from left to right in order of creation. The rule governing the labelling of edges is, at any depth, the label of the first edge created is 1 and the label of the jth edge created is twice the maximum of the product of labels on a path starting with the $(j-1)$th edge created and ending at a leaf.

Initially we are at the root. When we are at a vertex v at depth less than k, and the number of children of v created so far is less than the label of the edge to v from its parent (or less than l, if v is the root), then we create a new child of v, label the connecting edge as per the rule, and move to the new child. If the number of children created so far is equal to the label on the edge to v from its parent, we move to the parent of v. If v is the root and it already has l children, the construction is complete. When we are at a vertex at depth k, i.e., a leaf, we simply move back to the parent.

Recall the definition of Ackerman's function from the previous section. In the Appendix, it is shown that the maximum of the product of the labels on a path in $T_k(l)$, from the root to a leaf is at most $A(k, 2l)$. Set $l = \lfloor \frac{I_k(n)-1}{2} \rfloor \geq \frac{I_k(n)}{3}$ for n sufficiently large. Let H be the set of leaves. For $h \in H$, let $c_1(h), \ldots, c_k(h)$ be the labels on the edges of the path from the root to h, in that order. Then the following inequalities hold. (1a)–(1f) are similar to inequalities that were proved before in [11] and [8]. We include their proofs in the Appendix. We shall prove the others here.

$$\forall h \in H,\ c_1(h) \geq 1, \ldots, c_k(h) \geq 1, \tag{1a}$$

$$\forall h \in H, c_1(h) \ldots c_k(h) \leq n, \tag{1b}$$

$$\sum_{h \in H} c_k(h) \leq 2n, \tag{1c}$$

$$\sum_{h \in H} \frac{1}{c_1(h) \ldots c_k(h)} \leq 2, \tag{1d}$$

$$1 \le j \le k-1, \quad \sum_{h \in H, c_1(h) \dots c_k(h) < y} c_1(h) \dots c_{j-1}(h) c_k(h) \le 2y, \tag{1e}$$

$$\sum_{h \in H} \frac{1}{c_1(h) \dots c_{k-1}(h)} \ge \frac{I_k(n)}{3}, \tag{1f}$$

$$\exists y_0(k), \text{ s.t. } \forall y > y_0(k), \ 1 \le j \le k-1, \tag{1g}$$

$$\sum_{h \in H, \ c_j(h) < y \le c_1(h) \dots c_k(h)} \frac{1}{c_j(h) \dots c_{k-1}(h)} \le 2,$$

$$\forall y > 0, \ 1 \le j \le k-1, \quad \sum_{h \in H, \ c_j(h) < y \le c_1(h) \dots c_k(h)} \frac{1}{c_j(h) \dots c_{k-1}(h)} \le y. \tag{1h}$$

Fact. Let v be a nonleaf node in the tree $(T_k(l))$ and let w be the next node to its right at the same level. Let c and d be the labels of the edges to v and w from their parent(s), respectively, and let e be the label of the edge from v to the rightmost child of v. Then it is easily seen that $e \ge 2^c$ and $d > e \ge 2^c$.

LEMMA 4.1. *Let $c_1, \dots, c_k$ be the labels on some path from the root to a leaf. Then* $1 \le i \le k-1, \ c_i \le c_{i+1}^2$.

Proof. Let $h_1, \dots, h_{|H|}$ be the leaves of the tree, from left to right. The lemma clearly holds for the path to h_1 (all the labels are 1). Assuming the lemma holds for the path to h_m, we shall show that it holds for the path to h_{m+1}.

The paths to h_m and h_{m+1} diverge at some level; call this level r. Then $c_1, \dots, c_r$ are common to both levels. Let $c_{r+1}, \dots, c_k$ and $d_{r+1}, \dots, d_k$ be the remaining labels on the paths to h_m and h_{m+1}, respectively. Note that each of $c_{r+2}, \dots, c_k$ are labels to rightmost children, so by the fact mentioned previously, $c_{j+1} \ge 2^{c_j}$ for $r+1 \le j \le k-1$. By the inductive hypothesis, $\forall j, 1 \le j \le r-1, \ c_j \le c_{j+1}^2$. Since $d_{r+1} > c_{r+1}$ and $c_r \le c_{r+1}^2$, we have $c_r \le d_{r+1}^2$. Now $\forall j, \ r+1 \le j \le k-1, d_j = 2c_j \dots c_k \le 22^{c_j} c_{j+1} \dots c_k \le 2c_{j+1}^2 c_{j+2} \dots c_k \le 4(c_{j+1} \dots c_k)^2 = d_{j+1}^2$. This completes the proof. □

LEMMA 4.2. *There is a function $y_0(k)$ such that the following holds. Let l, y, j be positive integers. Let $1 \le j \le k-1$. Let $y > y_0(k)$. Consider the set of paths from the root to a leaf, which have the property that $c_j < y \le c_1 \dots c_k$. Let $S_j, \dots, S_k$ be the set of vertices they pass through at levels $j, \dots, k$, respectively. Then $|S_j| \le 2$.*

Proof. Let $v_1, \dots, v_{|s_j|}$ be the vertices in S_j, from left to right. Consider the path to the leftmost leaf, among the set of considered paths. This path passes through v_1. Let the labels on this path be $c_1, \dots, c_k$.

If $c_j \ge \log \ y$, then the label of the edge to the vertex to the right of v_1 is at least y, and we are done. So assume $c_j < \log \ y$. Then by Lemma 4.1, $1 \le i \le j-1, \ c_i \le (\log \ y)^{2^{j-i}}$, i.e., $c_1 \dots c_{j-1} \le (\log \ y)^{2^j} \le (\log \ y)^{2^k}$. Since $c_1 \dots c_k \ge y$, we have $c_j \dots c_k \ge y/((\log y)^{2^k})$. Let $2 \le i \le |S_j|$, d_i be the label of the edge to the $i-1$th vertex to the right of v_1. We have $d_2 = 2c_j \dots c_k \ge 2y/((\log y)^{2^k})$ and from the fact mentioned previously, $d_3 \ge 2^{2y/((\log y)^{2^k})}$. Define $y_0(k) = \min\{x \mid 2^{2x/((\log x)^{2^k})} > x\}$. For $y > y_0(k), d_3 > y$, hence $|S_j| \le 2$. □

COROLLARY 4.3 (Inequalities (1g), (1h)). *If $y > y_0(k)$,*

$$\sum_{h \in H, \ c_j(h) < y \le c_1(h) \dots c_k(h)} \frac{1}{c_j(h) \dots c_{k-1}(h)} \le 2.$$

If $y \le y_0(k)$,

$$\sum_{h\in H,\ c_j(h)<y\le c_1(h)\dots c_k(h)} \frac{1}{c_j(h)\dots c_{k-1}(h)} \le y.$$

Proof. For v a vertex at level j of $T_k(l)$, let $c_1(v), \dots, c_j(v)$ be the labels on the path from the root to v, in that order. Then we have

$$\sum_{h\in H,\ c_j(h)<y\le c_1(h)\dots c_k(h)} \frac{1}{c_j(h)\dots c_{k-1}(h)} = \sum_{s\in S_k} \frac{1}{c_j(h)\dots c_{k-1}(h)}$$

$$\le \sum_{s\in S_{k-1}} \frac{1}{c_j(h)\dots c_{k-2}(h)} \le \cdots \le \sum_{s\in S_j} 1 = |S_j|.$$

From Lemma 4.2 we have $|S_j| \le 2$ if $y > y_0(k)$. On the other hand, since the labels on successive edges at the same level increase by at least a factor of two, there can be at most $\log\ y \le y$ edges at level j before the label exceeds y. □

5. The lower bound. Consider the following facts. Theorem 3.1 shows how to obtain an oblivious chaining algorithm whose graph (as defined in §2) is a prefix graph. By Theorem 3.2, every prefix graph is a weak superconcentrator. A lower bound for weak superconcentrators is known from [11]. Given these facts, it is tempting to conjecture that the graph of every oblivious chaining algorithm is a prefix graph and thereby directly obtain a lower bound. However, there are chaining algorithms whose graphs are not weak superconcentrators. As an example, consider an algorithm in which, in the first two steps, processor P_1 reads $x_1$and x_2 without writing anywhere. In the next two steps, P_1 writes the values of x_1 and x_2 to cells z_1 and z_2, respectively. Now the chaining problem is solved for input $z_1, z_2, x_3, \dots, x_n$, without any processor ever reading cells x_1 and x_2 again. In the graph of this computation, all paths from x_1 and x_2 must pass through vertex $(P_1, 3)$ and hence are never vertex disjoint. Thus the graph is not a weak superconcentrator. This simple example generalizes. It is necessary, therefore, to carefully analyze the structure of the graph of a chaining algorithm.

We now prove that a PRIORITY algorithm that solves the chaining problem with n processors requires $\Omega(\alpha(n))$ time. It suffices to prove the following.

THEOREM 5.1. *For n sufficiently large, any oblivious* PRIORITY *algorithm that solves a chaining problem of size n in k steps requires $\Omega(nI_{k+1}(n))$ processors.*

Proof: Fix n. Let $G_{A,n}$ be the graph for algorithm A, which terminates in k read-write steps, and let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be the input and the output vertices of $G_{A,n}$. Let H be the set of leaves of $T_k(l)$ defined in the previous section, with $l = \lfloor \frac{I_k(n)-1}{2} \rfloor \ge \frac{I_k(n)}{3}$. Fix $h \in H$ and let $p(h) = \frac{1}{c_1(h)\dots c_k(h)}$. Pick U, a random subset of $[n]$, by picking each element of $[n]$ independently with probability $p(h)$. Consider the partial input $B = b_1 \dots b_n$, $b_i = 0$ if $i \in [n] - U$, and $b_i = *$ if $i \in U$. Fix the values of the input vertices of $G_{A,n}$ as indicated by B. For a vertex v of $G_{A,n}$ let f_v denote the indegree of v. Let V_j denote the set of vertices at level $2j$, $0 \le j \le k$. Call a vertex $v \in V_j$, $1 \le j \le k-1$, *high degree* if $f_v > c_j(h)$.

Consider a high-degree vertex $(c, 2j)$ which is not fixed for B, and let $(p, 2j-1)$ be the highest priority processor that writes to $(c, 2j)$ over all inputs consistent with B, i.e., there is a setting for the variables $\{b_i \mid i \in U\}$ so that p writes to c at step j. The state of p can be affected only by those input vertices that can reach $(p, 2j-1)$. Modify B and the input vertex settings so that over all inputs consistent with the new B, $(p, 2j-1)$ writes some fixed value to $(c, 2j)$. Now $(c, 2j)$ is fixed for B, since $(p, 2j-1)$ will override any other processor that writes. If no processor writes to $(c, 2j)$, then modify B by setting to 0 all the variables that reach $(c, 2(j-1))$. Then $(c, 2(j-1))$ is fixed, and so is $(c, 2j)$. Call this operation *fixing* a vertex.

Carry out the following two-step procedure on $G_{A,n}$.

(A) For j starting at 1 and going up to $k-1$, fix all the high-degree vertices in V_j.

(B) For i starting at 1 and going up to n, if $i \in U$, set all the input vertices (with value $*$) that can reach y_i through low-degree vertices to the value 1, except x_i.

We claim that at the end of this procedure all the undefined input vertices are fixed, except possibly one. To see this, suppose more than one input vertex is undefined. Set all to 1 except the leftmost undefined input vertex x_i. Let this partial input be C. Let x_j be the first input vertex to the right of x_i that has the value 1. Clearly, x_j exists and $i, j \in U$. Since x_i was not set in step (B), x_i does not reach y_j through low-degree vertices. However, for the two inputs consistent with C, only vertices reachable from x_i through low-degree vertices can have different values, since the high-degree vertices are fixed. Hence the state of y_j remains fixed over both inputs, an error.

Write $E_{A,B}$ for the expected number of input bits that are set during this process. By the above argument, $E_{A,B} \geq E(|U|) - 1 \geq np(h) - 1$. We now obtain an upper bound for $E_{A,B}$.

Note that when fixing $v \in V_j$, all the high-degree vertices in V_i, $1 \leq i < j$ have already been fixed. Thus, the only variables that affect the contents of v are the undefined variables that can reach v through low-degree vertices. Hence $D_v := E(\text{number of inputs set to fix } v \in V_j) \leq E(\text{number of undefined inputs that can reach } v \text{ through low-degree vertices}) \leq f_v 2c_{j-1}(h)2c_{j-2}(h)\dots 2c_1(h)p(h)$. When we actually fix $v \in V_j$, we either fix the state of the highest priority processor, p, that writes to v, or if no processor writes, we fix v', the vertex that represents the same memory cell as v at the previous time step. The number of inputs fixed is at most the number of inputs that reach either of the two through low-degree vertices, i.e., at most $2c_{j-1}(h)2c_{j-2}(h)\dots 2c_1(h) = 2^{j-1}c_1(h)\dots c_{j-1}(h)$.

For a high-degree vertex $v \in V_j$, D_v is at most the minimum of these two quantities, i.e., $D_v \leq 2^{j-1}c_1(h)\dots c_{j-1}(h)\min[f_v p(h), 1]$. The expected number of bits set during (A) is the sum of the expected number of bits set while fixing each high-degree vertex, i.e., $E_A := E(\text{number of bits set during (A)}) \leq \sum_{j=1}^{k-1}\sum_{v\in X(j)} D_v$, where $X(j) = \{v \in V_j \mid c_j(h) < f_v\}$. Thus,

$$E_A \leq \sum_{j=1}^{k-1}\sum_{X(j)} D_v \leq \sum_{j=1}^{k-1}\sum_{X(j)} 2^{j-1}c_1(h)\dots c_{j-1}(h)\min[f_v p(h), 1].$$

We now upper bound E_B, the expected number of inputs set during step (B). Let y_j be an output vertex and let $S = \{x_i \mid x_i \text{ can reach } y_j \text{ through low-degree vertices and } i \in U,\ i \neq j\}$. As before, $|S| \leq f_{y_j}2c_{k-1}(h)2\dots c_1(h)$. For $x_i \in S$, P(x_i is set while processing y_j in step (B))$\leq$ P($i \in U$ and $j \in U$). Since $i \neq j$, the events $i \in U$ and $j \in U$ are independent and P($i \in U$ and $j \in U$) $= p(h)^2$. Hence E(number of inputs set while processing y_j in step (B)) $\leq f_{y_j}2c_{k-1}(h)2\dots c_1(h)p(h)^2$. As before, E_B is the sum, over all output vertices y_i, $i \in U$, of these expectations. So $E_B \leq \sum_{v\in V_k} 2^{k-1}f_v c_1(h)\dots c_{k-1}(h)p(h)^2$. Clearly, $E_{A,B} = E_A + E_B$. Thus,

$$\sum_{j=1}^{k-1}\sum_{X(j)} 2^{j-1}\min\left[\frac{f_v}{c_j(h)\dots c_k(h)}, c_1(h)\dots c_{j-1}(h)\right]$$

$$+ \sum_{v\in V_k} 2^{k-1}\frac{f_v}{c_k(h)}p(h) \geq E_A + E_B = E_{A,B} \geq np(h) - 1.$$

Multiplying both sides by $c_k(h)$, summing over $h \in H$, and interchanging the order of summation, we get

$$\sum_{j=1}^{k-1}\sum_{v\in V_j}\sum_{Y(v,j)} 2^{j-1}\min\left[\frac{f_v}{c_j(h)\dots c_{k-1}(h)}, c_1(h)\dots c_{j-1}(h)c_k(h)\right] + \sum_{v\in V_k}\sum_{h\in H} 2^{k-1} f_v p(h)$$
$$\geq \sum_{h\in H}\left[\frac{n}{c_1(h)\dots c_{k-1}(h)} - c_k(h)\right],$$

where $Y(v, j) = \{h \in H \mid c_j(h) < f_v\}$.

Let $Z(v, j) = \{h \in H \mid c_j(h) < f_v \leq c_1(h)\dots c_k(h)\}$ and $W(v, j) = \{h \in H \mid c_1(h)\dots c_k(h) < f_v\}$. Notice that $Y(v, j)$ is the disjoint union of $Z(v, j)$ and $W(v, j)$. Using this observation and rewriting, we get

$$\sum_{j=1}^{k-1}\sum_{v\in V_j} 2^{j-1}\sum_{Z(v,j)}\frac{f_v}{c_j(h)\dots c_{k-1}(h)} + \sum_{j=1}^{k-1}\sum_{v\in V_j} 2^{j-1}\sum_{W(v,j)} c_1(h)\dots c_{j-1}(h)c_k(h)$$
$$+\sum_{v\in V_k} 2^{k-1}\sum_{h\in H}\frac{f_v}{c_1(h)\dots c_k(h)} \geq \sum_{h\in H}\left[\frac{n}{c_1(h)\dots c_{k-1}(h)} - c_k(h)\right]. \tag{2}$$

Before simplifying this further, we observe that the sum of the indegrees of all the cell vertices is bounded by the number of edges and that the number of cell vertices is bounded by $2k^2P$, i.e.,

$$\sum_{j=1}^{k-1}\sum_{v\in V_j} f_v \leq 6k^2P, \tag{3a}$$

$$\sum_{j=1}^{k-1}\sum_{v\in V_j} 1 \leq 2k^2P. \tag{3b}$$

We now separately bound each of the terms of the left-hand side (LHS) of (2), which we call (I), (II), and (III), respectively. (I) can be written as the sum of two terms by separating vertices of degree greater than $I_{k+1}(n)$ and others. Thus,

$$\text{(I)} = \sum_{j=1}^{k-1}\sum_{v\in V_j,\ f_v\leq I_{k+1}(n)} 2^{j-1}\sum_{Z(v,j)}\frac{f_v}{c_j(h)\dots c_{k-1}(h)}$$
$$+\sum_{j=1}^{k-1}\sum_{v\in V_j,\ f_v> I_{k+1}(n)} 2^{j-1}\sum_{Z(v,j)}\frac{f_v}{c_j(h)\dots c_{k-1}(h)}.$$

Using (1h) and (3b) to bound the first term and (1g) and (3b) to bound the second, we find

$$\text{(I)} \leq 2^{k-1}(I_{k+1}(n))^2\cdot 2k^2P + 2^{k-1}\cdot 2\cdot 6k^2P.$$

Using (1e) and (3a) to simplify (II) we get

$$\text{(II)} \leq 2^{k-1}\cdot 2\cdot 6k^2P.$$

Term (III) can be estimated using (1d) and (3a), yielding

$$\text{(III)} \le 2^{k-1} \cdot 2 \cdot 6k^2 P.$$

The right-hand side (RHS) of equation (2) can be estimated using (1f) and (1c) to give

$$\text{RHS} \ge n\frac{I_k(n)}{3} - 2n.$$

Thus, rewriting (2) and simplifying yields

$$P = \Omega\left(\frac{nI_k(n)}{2^k k^2 (I_{k+1}(n))^2}\right) = \Omega(nI_{k+1}(n)). \qquad \square$$

6. Nonoblivious lower bounds. The techniques used in the lower bounds for oblivious algorithms may extend to nonoblivious algorithms. We conjecture similar lower bounds for all algorithms but are able to prove it only for the case $k = 2$. ($k = 1$ is easy.) Although the following theorem may be proved using computations similar to those used in the oblivious case, we use simpler computations that we hope are more illuminating. We associate a graph $G_{A,B}$ with a nonoblivious algorithm A and partial input B. As before, $G_{A,B}$ will have levels of vertices $(c, 2j)$ and $(p, 2j+1)$, $0 \le j \le k-1$. The edges are defined by the following.

$(c, 2j) \to (p, 2j+1)$: if for some input vector consistent with B, at step $j+1$, processor p reads cell c.

$(p, 2j+1) \to (c, 2(j+1))$: if for some input vector consistent with B, at step $j+1$, processor p writes to cell c.

$(p, 2j+1) \to (p, 2(j+1)+1)$.

Note that in this case we do not have edges from cell vertices to cell vertices.

For v a vertex of $G_{A,B}$ define $S_B(v)$ as before.

THEOREM 6.1. *Any* PRIORITY PRAM *algorithm that solves the chaining problem in* 2 *steps requires* $\frac{1}{8}n(\log n)^{1/2}$ *processors.*

Proof. Let $P \le \frac{1}{8}n(\log n)^{1/2}$ be the number of processors used by A. Suppose A terminates in two steps. $G_{A,B}$ consists of five levels (numbered 0,...,4) of vertices. Let $e_{B,i}$, $1 \le i \le 4$ be the set of edges between level $i-1$ and level i in $G_{A,B}$. It is easily seen that for any partial input B, $|e_{B,1}| \le P$ and $|e_{B,2}| \le 2P$.

Let $1 \le i \le 2P$, $D_i = \{v \mid v$ is a level 2 vertex with indegree $\ge i\}$, and $d_i = |D_i|$. Then we have $\sum_{i=1}^{2P} d_i \le 2P \le \frac{1}{4}n(\log n)^{1/2}$. Let $z = 2^{(\log n)/2}$. If $\forall i$, $1 \le i \le z$, $d_i > n/(2i(\log n)^{1/2})$ then $\sum_{i=1}^{z} d_i > \frac{1}{4}n(\log n)^{1/2}$, so $\exists i_0$, $1 \le i_0 \le z$ such that $d_{i_0} \le n/(2i_0(\log n)^{1/2})$.

Let $v \in D_{i_0}$ and consider the highest priority processor p that has an edge to v. The state of this processor depends only on one input bit. We set this input bit so that p writes to v. Let B be the partial input so defined. Clearly $|S_B(v)| = 1$, so v is fixed. In this manner, fix all the vertices in D_{i_0}, and let C be the partial input obtained by this procedure. The number of bits set in C is at most d_{i_0}, since, fixing each vertex in D_{i_0} involves setting at most one bit.

All the level 2 vertices of $G_{A,C}$ that are not fixed are written to by less than i_0 processors, each in at most two states. The different things that can be written to the vertex are the (at most) two values that each processor may write, and, in case no processor writes, the (at most) two values that it initially contained. Hence $\forall v$, $|S_C((v, 2))| \le 2(i_0 - 1) + 2 = 2i_0$. Since $\forall p$, $|S_C((p, 1))| \le 2$, and each processor reads a vertex that can have at most $2i_0$ different values written, the number of states of a processor is bounded by the product of the two, i.e., $\forall p$, $|S_C((p, 3))| \le 4i_0$.

Let $y_1, \ldots, y_n$ be the output vertices of $G_{A,C}$. Suppose $r = d_{i_0} \le n/(2i_0(\log n))^{1/2}$ bits $(c_{l_1}, \ldots, c_{l_r})$ have been set in C. Define $l_0 = 0$ and $l_{r+1} = n+1$. Consider m, j such that $l_j < m < l_{j+1}$. Since all the bits between c_{l_j} and c_m are undefined, y_m may have, as its final value, any one of $l_j, l_j + 1, \ldots, m - 1$, or 0, so $|S_C((y_m, 4))| \geq m - l_j + 1$. Thus $\sum_{l_j<m<l_{j+1}} |S_C((y_m, 4))| \geq \frac{1}{2}(l_{j+1} - l_j + 1)(l_{j+1} - l_j) - 1 \geq \frac{1}{2}(l_{j+1} - l_j)^2$. Since $\sum_{j=1}^{r}(l_{j+1} - l_j) \geq n$, a simple minimization shows that

$$\sum_{j=0}^{r} \sum_{l_j<m<l_{j+1}} |S_C((y_m, 4))| \geq \frac{n^2}{2(r+1)}. \tag{4}$$

For $e \in e_{C,4}$, an edge from $(p, 3)$ to $(c, 4)$, let $g(e)$ be the number of different values that p writes to c over all inputs consistent with C. For any output vertex $(y, 4)$, let e_y be the set of edges into $(y, 4)$. The number of different values that can be written to $(y, 4)$ is bounded by the number of values that different processors can write via edges in e_y plus the number of values it had before (in the case that no processor writes). Hence $S_C((y, 4)) \leq \sum_{e\in e_y} g(e) + S_C((y, 2)) \leq \sum_{e\in e_y} g(e) + 2i_0$, which yields

$$S_C((y, 4)) - 2i_0 \leq \sum_{e\in e_y} g(e). \tag{5}$$

For any processor $(p, 3)$, the total number of different values it can write over all edges leading out of it is bounded by $S_c((p, 3)) \leq 4i_0$. Summing this quantity over all processors gives an upper bound on the number of different values that can be written via edges in $e_{C,4}$. Thus

$$4i_0 P \geq \sum_{e\in e_{C,4}} g(e) \geq \sum_{i=1}^{n} \sum_{e\in e_{y_i}} g(e).$$

From equation (5), we get

$$4i_0 P \geq \sum_{i=1}^{n}(|S_C((y_i, 4))| - 2i_0) \geq \sum_{j=0}^{r} \sum_{l_j<m<l_{j+1}} |S_C((y_m, 4))| - \sum_{i=1}^{n} 2i_0.$$

Finally, from equation (4), we get

$$4i_0 P \geq \frac{n^2}{2(r+1)} - 2i_0 n.$$

Since $r \leq n/(2i_0(\log n)^{1/2})$, this yields

$$P \geq \frac{1}{4}n(\log n)^{\frac{1}{2}} - \frac{n}{2} > \frac{1}{8}n(\log n)^{\frac{1}{2}}, \text{ a contradiction.} \qquad \square$$

7. Conclusion and open problems.

We have shown that oblivious chaining with n processors is $\Theta(\alpha(n))$ time. This leaves open the question of whether an $O(1)$ time nonoblivious algorithm exists. Recently, Chaudhuri and Radhakrishnan [9] settled this question, showing an $\Omega(\alpha(n))$ lower bound for any chaining algorithm using $O(n)$ processors.

Using randomization, better performance may be achieved in some situations. Raman [17] gave a randomized algorithm that runs in $O(1)$ time if the number of 1s in the input is not too large. We conjecture that for arbitrary inputs, constant-time chaining is not possible, even using randomization.

Appendix.

LEMMA A.1 *The maximum product of labels along a path from the root to a leaf of $T_k(l)$ is at most $A(k, 2l)$.*

Proof. Let $B(k, l)$ be the maximum product of labels on a path from the root to a leaf in $T_k(l)$. Define the following auxiliary family of trees $S_k(l)$. The definition of $S_k(l)$ is the the same as $T_k(l)$ except that the first edge created at each level has the label l (instead of 1). Let $C(k, l)$ be the maximum product of labels on a path from the root to a leaf of $S_k(l)$. Then

$$B(k, l) \leq C(k, l) \leq B(k, 2l) \tag{6}$$

since we can find a subtree of $S_k(l)$ isomorphic to $T_k(l)$, such that the labels on each edge are greater than or equal to the labels on the corresponding edges of $T_k(l)$. The second inequality holds for the same reasoning with $T_k(2l)$ and $S_k(l)$.

We will now show by induction on k and l that $B(k, l) \leq A(k, 2l)$ for $k, l \geq 1$.

It is easy to see that $\forall i \geq 1,\ B(i, 1) \leq A(i, 2)$, and $\forall j \geq 1,\ B(1, j) \leq A(1, 2j)$.

Assume $B(k, l) \leq A(k, 2l)\, \forall k$ if $l \leq j$ and $\forall l$ if $k \leq i$. We shall show that $B(i+1, j+1) \leq A(i+1, 2(j+1))$ for $i, j \geq 1$.

$B(i+1, j+1)$ may be written as the product of the label on the edge to the rightmost child of the root, which is $2B(i+1, j)$, and the maximum product of labels in the subtree below the rightmost child of the root. The labels on the leftmost edges in this subtree are all at most $2B(i+1, j)$, thus the maximum product of labels is at most the maximum product of labels in $S_i(2B(i+1, j))$, i.e., $C(i, 2B(i+1, j))$. Hence, using (6) gives

$$B(i+1, j+1) \leq 2B(i+1, j)C(i, 2B(i+1, j)) \leq 2B(i+1, j)B(i, 4B(i+1, j)).$$

From the definition of $B(i, j)$, for $i \geq 1$, $B(i, j+1) \geq 2B(i, j)$ and hence, for $x \geq 0$, $B(i, j+x) \geq xB(i, j)$, which yields

$$2B(i+1, j)B(i, 4B(i+1, j)) \leq B(i, 6B(i+1, j)) \leq A(i, 12A(i+1, 2j))$$

where the last inequality follows from the induction hypothesis. Finally, observe that $i+1 \geq 2$ and $2j \geq 4$. It can be proved by induction that for such i, j, $12A(i+1, 2j) \leq A(i+1, 2j+1)$, and hence

$$A(i, 12A(i+1, 2j)) \leq A(i, A(i+1, 2j+1)) \leq A(i+1, 2(j+1)). \qquad \square$$

LEMMA A.2 *Proofs of inequalities* (1a)–(1e).

Proof. (1a): Obvious.

(1b): By Lemma A.1 and the choice of l, (1b) holds.

(1c): It is easy to see that the labels on edges to leaves of the tree increase by a factor of two as we move from left to right along the leaves of the tree. Thus the sum is a geometric series with the stated bound.

(1d): The sum is dominated term-by-term by the series $\sum_{h \in H} \frac{1}{c_k(h)}$, whose sum is at most 2.

(1e): Consider the sum as it is formed by going through the vertices from left to right. Since the last factor in each product increases by a factor of two and the other factors do not decrease, each term is at least twice the previous term. Since the last term is at most y the series has a sum of at most $2y$. $\square$

LEMMA A.3 *Inequality* (1f) *holds.*

Proof. Let $0 \leq i \leq k$, H_i be the set of vertices at level i of the tree and for $h \in H_i$ let $c_1(h), \ldots, c_i(h)$ be the labels on the unique path from the root to h. Then we have

$$\begin{aligned}\sum_{h\in H}\frac{1}{c_1(h)\dots c_{k-1}(h)} &= \sum_{h\in H_k}\frac{1}{c_1(h)\dots c_{k-1}(h)}\\ &= \sum_{h\in H_{k-1}}\frac{1}{c_1(h)\dots c_{k-1}(h)}c_{k-1}(h)\\ &= \cdots\\ &= \sum_{h\in H_1} 1 = l \geq \frac{I_{k+1}(n)}{3}. \qquad \square\end{aligned}$$

Acknowledgments. I am grateful to Ravi Boppana for introducing me to the work in [6] and [11], and for many helpful discussions. I am indebted to Jaikumar Radhakrishnan for the simple proof of the upper bound and for innumerable insightful comments.

REQUIREMENTS FOR DEADLOCK-FREE, ADAPTIVE PACKET ROUTING*

ROBERT CYPHER† AND LUIS GRAVANO‡

Abstract. This paper studies the problem of deadlock-free packet routing in parallel and distributed architectures. Three main results are presented. First, it is shown that the standard technique of ordering the buffers so that every packet always has the possibility of moving to a higher-ordered buffer is not necessary for deadlock freedom. Second, it is shown that every deadlock-free, adaptive packet routing algorithm can be restricted, by limiting the adaptivity available, to obtain an oblivious algorithm which is also deadlock-free. Third, it is shown that any packet routing algorithm for a cycle or torus network which is free of deadlock and which uses only minimal length paths must require at least three buffers in some node. This matches the known upper bound of three buffers per node for deadlock-free, minimal packet routing on cycle and torus networks.

Key words. deadlock, packet routing, store-and-forward routing, adaptive routing, networks, buffer requirements, lower bounds, parallel algorithms

1. Introduction.

This paper studies the problem of deadlock-free packet routing in parallel and distributed architectures. A wide range of packet routing algorithms with differing properties and costs has been proposed [1]–[10], [12]–[14], [16]–[21], [23], [24]. In this paper we will focus on a particularly simple and important class of routing algorithms which we will call *buffer-reservation* algorithms. A buffer-reservation algorithm consists of rules that specify to which buffers a packet may move based solely on the buffer currently holding the packet, the packet's source node, and the packet's destination node. A packet is allowed to move from its current buffer to any other buffer at any time, provided that the other buffer is empty and that the move is allowed by the routing algorithm. Buffer-reservation algorithms can be implemented efficiently in hardware because they require only local information to make routing decisions, are inherently asynchronous and therefore do not require a global clock, and do not require the creation or exchange of any special packets containing only control information. Furthermore, adaptive buffer-reservation algorithms allow packets to avoid congestion, thus permitting high throughput in the network. As a result of these advantages, buffer-reservation algorithms have been widely studied and implemented.

The primary disadvantage of buffer-reservation techniques is that they require that each node contain some minimum number of buffers. Although a great deal of research has been devoted to the problem of minimizing the storage requirements of buffer-reservation algorithms [4], [7], [8], [10], [12], [14], [16], [19], [21]–[24], very little is known in terms of lower bounds on the storage which is required by such algorithms. Our goal in this paper is to characterize the properties which these algorithms must have in order to be free of deadlock and to use these properties to prove lower bounds on storage requirements.

One well-known technique for proving freedom from deadlock is to order the buffers so that every packet always has the possibility of moving to a higher-ordered buffer [12]. Providing such an ordering of the buffers is the standard technique for proving freedom from deadlock and has been used by many researchers [4], [7], [8], [10], [12], [14], [16], [19], [21], [23], [24]. Therefore, it seems plausible that the existence of such an ordering of the buffers is a necessary condition for freedom from deadlock. In fact, in the special case of oblivious buffer-reservation algorithms, Toueg and Steiglitz have shown that the existence of such an ordering of the buffers *is* necessary for deadlock freedom [22]. However, in this paper we

‡Department of Computer Science, Stanford University, Stanford, California 94305.

will present an adaptive buffer-reservation algorithm which is provably free of deadlock and for which no ordering of the buffers can be defined such that every packet always has the possibility of moving to a higher-ordered buffer. Thus, in the case of adaptive routing, the technique of ordering the buffers is sufficient but not necessary for avoiding deadlock.

On the other hand, we will prove that every deadlock-free, adaptive buffer-reservation algorithm can be restricted, by limiting the adaptivity available, to obtain an oblivious algorithm which is also deadlock-free. As a result, we will be able to use lower bounds on the storage requirements of oblivious routing algorithms to obtain lower bounds on the storage requirements of adaptive routing algorithms. In particular, we will show that any adaptive buffer-reservation algorithm for a cycle or torus network which is free of deadlock and which uses only minimal length paths must require at least three buffers in some node. This matches the known upper bound of three buffers per node for deadlock-free, minimal routing on cycle [11] and torus networks [4].

The remainder of this paper is organized as follows. Definitions and a formal description of the routing model are given in §2. Section 3 presents an example of a deadlock-free, adaptive routing algorithm in which it is impossible to order the buffers so that every packet always has the possibility of moving to a higher ordered buffer. The fact that every deadlock-free, adaptive buffer-reservation algorithm can be restricted to obtain a deadlock-free, oblivious algorithm is proven in §4. Lower bounds on the storage requirements for deadlock-free minimal buffer-reservation algorithms are given in §5. Some conclusions and open problems are presented in §6.

2. Preliminaries. We will view a routing network as being an undirected graph in which the nodes represent processors and the edges represent communication links. Each node contains a set of buffers, one of which will be called an *injection buffer*, another one of which will be called a *delivery buffer*, and the remainder of which will be called *standard buffers*. Packets can enter the routing network only by being placed in an empty injection buffer in their source node, and they can be removed from the network only when they are in the delivery buffer of their destination node. We will assume throughout that each buffer can hold exactly one packet and that the number of buffers is finite.

Given the buffer in which a packet is currently stored and the packet's source and destination nodes, a *routing algorithm* specifies a set of buffers to which the packet may be moved. More formally, the *color* of a packet is the pair (s, d) where s is the packet's source node and d is the packet's destination node. We will say that a buffer has color c if it contains a packet with color c. A routing algorithm A is a function which associates a set of buffers, called a *waiting set*, with each possible buffer and color pair (q, c). The waiting set which A associates with the pair (q, c) will be denoted $A(q, c)$. All of the buffers in a waiting set $A(q, c)$ must either be in the node which contains q or in neighboring nodes (that is, nodes that are connected by an edge to the node containing q).

If $q_2 \in A(q_1, c)$, then it is required that q_1 is not a delivery buffer and that q_2 is not an injection buffer. Furthermore, if q_2 is a delivery buffer and if $c = (s, d)$, then it is required that q_2 is in node d. Finally, and if either q_1 is an injection buffer or q_2 is a delivery buffer, then q_1 and q_2 must be in the same node. Thus injection and delivery buffers are used only for placing new packets in the network and for removing packets once they have reached their destination.[1]

The routing algorithm operates asynchronously. A packet with color c may move from a buffer q_1 to any empty buffer $q_2 \in A(q_1, c)$ at any time, and a new packet with an arbitrary

[1] It should be noted that the injection and delivery buffers are introduced only to simplify the description of the model, and that they need not be physically present in an actual routing network.

destination may be placed in an empty injection buffer at any time. Packets may be transmitted in either store-and-forward [19] or virtual cut-through [15] mode. The only requirement is that when a packet is moved from one buffer to another, it occupies both of the buffers for a finite amount of time, and after a finite amount of time the former buffer becomes empty.

A routing algorithm is *oblivious* if every waiting set contains at most one buffer, and it is *adaptive* otherwise. ("Oblivious" and "adaptive" routing algorithms have also been referred to as "static" and "dynamic" routing algorithms.) Routing algorithm A is a *restriction* of routing algorithm B if and only if for every pair (q, c), $A(q, c) \subseteq B(q, c)$, and for some pair (q, c), $A(q, c) \neq B(q, c)$. A routing algorithm is *minimal* if every packet is routed from its source node to its destination node while visiting the minimum number of nodes possible. Note that the concept of minimality is based on the number of nodes visited, rather than the number of buffers visited.

Given a routing algorithm A, a *buffer q is reachable* by a packet with color $c = (s, d)$ if and only if there exists some path $q_0, q_1, \dots, q_k$ such that q_0 is the injection buffer in node s, $q_k = q$, and for all i, $1 \leq i \leq k$, $q_i \in A(q_{i-1}, c)$. A *configuration T* is a nonempty set of buffers S such that each buffer q in S is either empty or has some color c. The set of buffers S will be called the *critical set* of the configuration T. Given a configuration T with critical set S and given any buffer $q \in S$, the notation $T(q)$ will denote q's color in configuration T (or the value "empty" if it does not contain a packet). A *configuration is reachable* if and only if it is possible to start with an empty network and to route packets so as to obtain the configuration.

A *deadlock configuration* for a routing algorithm A is a configuration with a critical set S such that none of the buffers in S is a delivery buffer, none of the buffers in S is empty, and for each buffer q in S, q has color c where $A(q, c) \subseteq S$. A routing algorithm is *deadlock-free* if and only if it has no reachable deadlock configuration. It is straightforward to verify that this definition of deadlock-freedom does in fact correspond to the impossibility of obtaining deadlock when using the given routing algorithm. Finally, given any two configurations T' and T'' with critical sets S' and S'', respectively, $T' \oplus T''$ will denote the configuration T with critical set $S = S' \cup S''$ in which for each buffer $q \in S'$, $T(q) = T'(q)$, and for each buffer $q \in S'' \setminus S'$, $T(q) = T''(q)$. Thus $T' \oplus T''$ is obtained by taking configuration T' and adding to it all of those buffers in T'' which are not also in T'.

3. Deadlock freedom without ordering buffers. In this section we will show that the standard technique of ordering the buffers so that every packet always has the possibility of moving to a higher ordered buffer is not necessary for the prevention of deadlock in buffer-reservation algorithms. In particular, we will give a simple example of an adaptive buffer-reservation algorithm which is provably free of deadlock and has no such ordering of the buffers.

The example is routing algorithm A shown in Fig. 1, in which each circle represents a buffer and each arc represents a possible move between buffers. There are three injection buffers labeled I_1, I_2, and I_3, and three delivery buffers labeled D_1, D_2, and D_3. In addition, there are six standard buffers labeled X_1, X_2, X_3, Y_1, Y_2, and Y_3. We will consider only three colors of packets, namely C_1, C_2, and C_3, where packets with color C_i, $1 \leq i \leq 3$, are injected in buffer I_i and delivered from buffer D_i. The label associated with each arc specifies which color packets are allowed to make the given move between buffers. For example, $A(I_1, C_1) = \{X_1\}$, $A(X_1, C_1) = \{X_2, Y_1\}$, and $A(X_1, C_2) = \{X_3\}$. Of course, a complete routing algorithm would provide routes for packets with other colors. In particular, note that for each other color (s, d), it would be possible to add a dedicated path of buffers from the injection buffer in s to the delivery buffer in d. These dedicated paths would not change the deadlock or buffer ordering properties of the example, and they would allow packets to be routed from each injection buffer to each delivery buffer. Finally, note that routing algorithm A does not include an assignment of buffers to nodes, but the creation of such an assignment is straightforward.

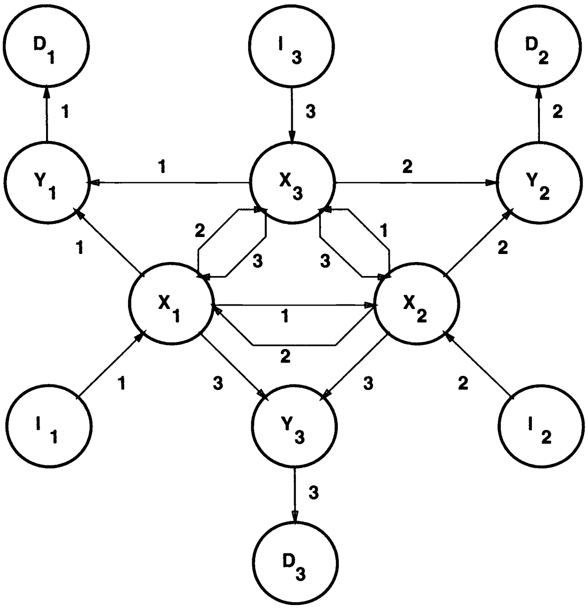

FIG. 1. *A deadlock-free, adaptive routing algorithm A for which the technique of ordering the buffers cannot be used to prove freedom from deadlock.*

LEMMA 3.1. *The routing algorithm A shown in Fig.* 1 *is free of deadlock.*

Proof. Assume for the sake of contradiction that deadlock is possible, in which case there must be some reachable deadlock configuration with a nonempty critical set S that does not contain any delivery buffers. Note that Y_1, Y_2, and Y_3 cannot appear in S because they are only reachable by packets which are able to move directly to a delivery buffer. Also, note that if injection buffer I_i, $1 \leq i \leq 3$ is in S, then buffer X_i must also be in S. Therefore, at least one of the buffers X_i must be in S. Because none of the buffers Y_i is in S, it follows that if X_1 is in S it must have color C_2 in the deadlock configuration; if X_2 is in S it must have color C_1 in the deadlock configuration; if X_3 is in S it must have color C_3 in the deadlock configuration. Note that X_3 must be in S, because otherwise either X_1 or X_2 must be in S, and $X_3 \in A(X_1, C_2)$ and $X_3 \in A(X_2, C_1)$. Because $X_1 \in A(X_3, C_3)$ and $X_2 \in A(X_3, C_3)$, both X_1 and X_2 must be in S. Therefore, the deadlock configuration must include a C_2 packet in X_1 and a C_1 packet in X_2. However, it is impossible to simultaneously route a C_2 packet to X_1 and a C_1 packet to X_2, so the deadlock configuration is not reachable, which is a contradiction. □

LEMMA 3.2. *There is no ordering of the buffers shown in Fig.* 1 *such that every packet always has the possibility of moving to a higher-ordered buffer.*

Proof. Assume for the sake of contradiction that such an ordering is possible. Note that X_1 is reachable by a packet with color C_2 and $A(X_1, C_2) = \{X_3\}$ and that X_2 is reachable by a packet with color C_1 and $A(X_2, C_1) = \{X_3\}$. Therefore, buffer X_3 must be higher ordered than both X_1 and X_2. However, X_3 is reachable by a packet with color C_3 and $A(X_3, C_3) = \{X_1, X_2\}$, so either X_1 or X_2 (or both) must be higher ordered than X_3, which is a contradiction. □

Combining the two previous lemmas yields the following theorem.

THEOREM 3.3. *There exists an adaptive routing algorithm which is free of deadlock, and for which there is no ordering of the buffers such that every packet always has the possibility of moving to a higher-ordered buffer.*

4. Restrictions of adaptive routing algorithms. In this section we will show that every deadlock-free, adaptive packet routing algorithm can be restricted to obtain an oblivious algorithm which is also deadlock-free. The proof will depend on the following lemma.

LEMMA 4.1. *Let A be any deadlock-free, adaptive routing algorithm, let q_1 be any buffer, and let c_1 be any color such that $|A(q_1, c_1)| \geq 2$. Let q_2 be any buffer such that $q_2 \in A(q_1, c_1)$, and let B be the restriction of A obtained by removing q_2 from the waiting set associated with (q_1, c_1). If B is subject to deadlock, then there must exist some reachable deadlock configuration for B in which buffer q_1 contains a packet with color c_1.*

Proof. Because B is subject to deadlock, there must exist some configuration T which is a reachable deadlock configuration for B. Because B is a restriction of A, it follows that configuration T is also reachable by A. However, A is deadlock-free, so T must not be a deadlock configuration for A. Therefore, buffer q_1 must have color c_1 in configuration T. □

THEOREM 4.2. *Given any adaptive, deadlock-free routing algorithm A, there exists an oblivious, deadlock-free routing algorithm B which is a restriction of A.*

Proof. Assume for the sake of contradiction that the claim is false. Then there must exist some adaptive, deadlock-free routing algorithm A such that every routing algorithm A' which is a restriction of A is subject to deadlock. Let A be such a deadlock-free routing algorithm, q_1 be any buffer, and c_1 be any color such that $|A(q_1, c_1)| \geq 2$. Let q_2 and q_3 be any distinct buffers such that $q_2 \in A(q_1, c_1)$ and $q_3 \in A(q_1, c_1)$, let A' be the restriction of A obtained by removing q_2 from the waiting set associated with (q_1, c_1), and let A'' be the restriction of A obtained by removing q_3 from the waiting set associated with (q_1, c_1). It follows from Lemma 4.1 that there exists a configuration T' (similarly, T'') which is a reachable deadlock configuration for A' (similarly, A'') and in which buffer q_1 contains a packet with color c_1. Let $T = T' \oplus T''$ and let S be the critical set of T. Let R be the configuration which also has critical set S but in which all of the buffers are empty. Note that the following properties hold.

Property 1: The set S is the critical set of both configuration T and configuration R.

Property 2: Configuration R is a reachable configuration for A.

Property 3: Every buffer q in R is either empty or has a color c such that $A(q, c) \subseteq S$.

Property 4: Every buffer q in T has a color c such that q is reachable by a packet with color c.

Property 5: Configuration T is a deadlock configuration for A.

Also note that Property 5 implies that S does not contain any delivery buffers.

We will define an algorithm for transforming R and T while maintaining Properties 1–5. The algorithm will repeatedly add packets to empty buffers in R until none of the buffers in R is empty. At this point R will be a reachable deadlock configuration, which will be the desired contradiction.

The algorithm for transforming R and T consists of repeatedly performing the following subroutine until R contains no empty buffers. The subroutine consists of two halves. In the first half, we will pick an arbitrary buffer in R which is empty and we will fill it. We will then extend both T and R so that the selected buffer is filled in R and so that Properties 1, 2, and 4 hold. In the second half, we will extend both T and R still further so that Properties 1–5 hold. The two halves of the subroutine operate as follows.

First, select an arbitrary buffer q which is empty in R. Let $c = T(q)$ and note that $A(q, c) \subseteq S$ (from Property 5). Because buffer q is reachable by some packet p with color c (from Property 4), there must exist a simple path from p's injection buffer to buffer q. Define the configuration P in which the critical set consists of all of those buffers that appear in this simple path, and in which all of the buffers in the critical set contain a packet with color c. Transform R to become the configuration obtained by adding P and R (that is, perform the assignment $R \leftarrow P \oplus R$), transform T to become the configuration obtained by adding P and T (that is, perform the assignment $T \leftarrow P \oplus T$), and let S be the critical set of the transformed configurations R and T. This completes the first half of the subroutine.

At this point, Property 1 clearly holds. Also, Property 2 holds because it is possible to first route packets with the desired colors to all of the nonempty buffers in R which are not in P and to then fill the buffers in P with packets with color c. Furthermore, Property 4 holds because all of the buffers in P are reachable by packets with color c. Finally, note that S does not contain any delivery buffers because configuration P does not contain any delivery buffers. However, Properties 3 and 5 may not hold, because it is possible that some of the packets in P have waiting sets that include buffers which are not in S.

The second half of the subroutine repeatedly adds buffers to T and R until Properties 1–5 hold. First, select an arbitrary buffer q' in the simple path described above such that $A(q', c) \not\subseteq S$ (if such a buffer exists). Let q'' be the successor of q' in the simple path described above (note that q'' must exist if q' exists, because $A(q, c) \subseteq S$ so $q' \neq q$). Let A' be the restriction of A obtained by removing q'' from the waiting set associated with (q', c). It follows from Lemma 4.1 that there exists a configuration D which is a reachable deadlock configuration for A' and in which buffer q' contains a packet with color c. Let D' be the configuration with the same critical set as D but in which all of the buffers are empty. Transform R to become the configuration obtained by adding R and D' (that is, perform the assignment $R \leftarrow R \oplus D'$), transform T to become the configuration obtained by adding T and D (that is, perform the assignment $T \leftarrow T \oplus D$), and let S be the critical set of the transformed configurations R and T. Repeat this procedure of selecting a buffer q' in the simple path such that $A(q', c) \not\subseteq S$ and transforming R, T, and S until no such buffer q' exists. When no such buffer q' exists, the second half of the subroutine is completed. At this point return from the subroutine.

It is clear that the transformations performed in the second half of the subroutine maintain Properties 1, 2, and 4. Furthermore, upon returning from the subroutine Property 3 must hold because for each buffer q' in the simple path described above, $A(q', c) \subseteq S$. Finally, upon returning from the subroutine Property 5 must hold because S does not contain any delivery buffers and for each buffer q in T with color c, $A(q, c) \subseteq S$. Therefore, all of Properties 1–5 hold upon returning from the subroutine.

Note that any buffer in R which was nonempty before calling the subroutine will again be nonempty after calling the subroutine. Finally, note that following the call to the subroutine, R contains at least one additional nonempty buffer. Because the number of buffers is finite, this procedure must terminate, at which point R is both reachable by A (from Property 2) and a deadlock configuration for A (from Property 3 and from the fact that R contains neither empty buffers nor delivery buffers), which is a contradiction. □

5. Minimal routing in cycle and torus networks. In this section we will prove lower bounds on the number of buffers per node that are required for deadlock-free, minimal routing in cycle and torus networks. Our approach will be to first prove a lower bound on the buffer requirements of deadlock-free, minimal, oblivious routing algorithms for cycle networks. We will then use this lower bound, along with Theorem 4.2 and the fact that a torus network can be decomposed into disjoint cycles, to obtain a lower bound on the buffer requirements of deadlock-free, minimal routing algorithms for both cycle and torus networks. Of course, it should be recalled that we are concerned solely with buffer-reservation algorithms, and that other types of deadlock-free routing algorithms for cycle networks have been created [10],

[20], [23]. However, these other types of routing algorithms have fundamentally different properties. For example, buffer insertion rings [20] can provide high throughput, but they are poorly suited to the creation of minimal routing algorithms for torus networks.

LEMMA 5.1. *Let routing algorithm A be any deadlock-free, minimal, and oblivious routing algorithm for a cycle network with n nodes. The cycle network must contain at least* $3n - 30$ *standard buffers.*

Proof. Because A is deadlock-free and oblivious, it follows that there exists an ordering of the buffers such that every packet visits the buffers in ascending order [22]. Let $k = \lfloor n/2 \rfloor - 1$ (so either $n = 2k + 2$ or $n = 2k + 3$). We will say that a packet is routed in the *clockwise* direction if it visits buffers in nodes of the form i, $(i + 1) \bmod n$, $(i + 2) \bmod n, \ldots, j$, and in the *counterclockwise* direction otherwise. Note that for each node i, $0 \le i < n$, algorithm A routes packets from node i to node $(i + k) \bmod n$ in the clockwise direction. Therefore, for each node i, $0 \le i < n$, there must exist an ascending sequence of standard buffers $s_{i,i}\ , s_{i,(i+1)\mathrm{mod}n}\ , \ \ldots\ , s_{i,(i+k)\mathrm{mod}n}$, where each buffer of the form $s_{i,j}$ is located in node j (for example, let $s_{i,j}$ be the highest ordered standard buffer in node j which is visited by a packet with source node i and destination node $(i + k) \bmod n$). For each i, $0 \le i < n$, let $S_i = s_{i,i}\ , s_{i,(i+1)\mathrm{mod}n}\ , \ \ldots\ , s_{i,(i+k)\mathrm{mod}n}$ denote the ascending sequence of standard buffers beginning in node i. Let $h = n - 1 - k$, note that $S_h = s_{h,h}\ , s_{h,h+1}\ , \ \ldots\ , s_{h,n-1}$, and note that S_0 and S_h are disjoint.

We will say that a sequence of buffers is a *clockwise increasing* (similarly, *counterclockwise increasing*) sequence if when the buffers are visited in ascending order, the nodes containing the buffers are visited in clockwise (counterclockwise) order. We will show that there must exist at most three mutually disjoint clockwise increasing sequences of buffers, the total length of which is at least $n + k$. There are two cases, which follow.

Case 1. There exists a clockwise increasing sequence of standard buffers $X = x_0\ , x_1\ , \ \ldots\ , x_{n-1}$ such that for each i, $0 \le i < n$, x_i is located in node i. In this case, we have two subcases.

Case 1(a). There exists an a, $0 \le a \le n - 1$, such that S_a and X are disjoint. In this case, the two disjoint clockwise increasing sequences are S_a and X, and their total length is $n + k + 1$.

Case 1(b). For each i, $0 \le i \le n - 1$, S_i and X intersect. In this case, let a be the largest value of i, $0 \le i \le n - 1$, such that there exists a value $i' \ge i$ where $s_{i,i'} = x_{i'}$. Let a' be any value such that $a' \ge a$ and $s_{a,a'} = x_{a'}$. Let $b = (a + 1) \bmod n$ and let b' be any value such that $s_{b,b'} = x_{b'}$. Note that $a' \ge a \ge k \ge b'$. Let Y be the sequence

$$s_{b,b}\ , \ \ldots\ , s_{b,b'-1}\ , x_{b'}\ , \ \ldots\ , x_{a'}\ , s_{a,a'+1}\ , \ \ldots\ , s_{a,(a+k)\mathrm{mod}n}.$$

The sequence Y is clockwise increasing and has length $n + k$.

Case 2. There does not exist such a sequence X. In this case, we have two subcases.

Case 2(a). There exists an a, $0 \le a \le h$, such that S_a and S_0 are disjoint and such that S_a and S_h are disjoint. In this case, the three disjoint clockwise increasing sequences are S_0, S_a, and S_h, and their total length is $3k + 3 \ge n + k$.

Case 2(b). For each i, $0 \le i \le h$, either S_i and S_0 intersect or S_i and S_h intersect, but not both. In this case, let a be the largest value of i in the range $0 \le i \le h$ such that S_i and S_0 intersect. Let a' be any value such that $s_{a,a'} = s_{0,a'}$. Let $b = a + 1$ and let b' be any value such that $s_{b,b'} = s_{h,b'}$ (note that such a b' must exist because of the definition of a and the fact that S_h does not intersect S_0). Let Y be the sequence

$$s_{0,0}\ , \ \ldots\ , s_{0,a'-1}\ , s_{a,a'}\ , \ \ldots\ , s_{a,a+k}$$

and let Z be the sequence

$$s_{b,b}\ ,\ \dots\ ,\ s_{b,b'}\ ,\ s_{h,b'+1}\ ,\ \dots\ ,\ s_{h,n-1}.$$

Note that Y and Z are clockwise increasing sequences and that they must be disjoint (because otherwise there would exist a clockwise increasing sequence X spanning all of the nodes). Also, note that the length of Y is $a + k + 1$ and the length of Z is $n - a - 1$, so their total length is $n + k$.

Thus, in any case there must exist at most three mutually disjoint clockwise increasing sequences of buffers, the total length of which is exactly $n+k$. An analogous argument can be used to show that there must exist at most three mutually disjoint counterclockwise increasing sequences of buffers, the total length of which is exactly $n + k$.

Now consider an arbitrary clockwise increasing sequence of buffers Y and an arbitrary counterclockwise increasing sequence of buffers Z. Assume that Y and Z intersect at some buffer a and again at some higher ordered buffer b, let Y' be the subsequence of Y starting at a and ending immediately before b, and let Z' be the subsequence of Z starting at a and ending immediately before b. The total length of Y' and Z' must be at least n, because every node other than the node containing b must contain at least one buffer from either Y' or Z', and the node containing a must contain at least one buffer from both Y' and Z'. Now assume that Y and Z intersect x times and for $1 \leq i < x$ let Y_i denote the subsequence of Y starting at their ith point of intersection and ending immediately before their i + 1st point of intersection, let Y_x denote the subsequence of Y of length 1 consisting of their xth point of intersection, and let Z_i subsequences be defined analogously. Then for $1 \leq i < x$, the total length of Y_i and Z_i must be at least n, and the total length of Y_x and Z_x must be 2, so the total length of Y and Z must be at least $(x - 1)n + 2$.

As a result, a clockwise increasing sequence of buffers of length at most $n + k$ and a counterclockwise increasing sequence of buffers of length at most $n+k$ can intersect in at most three buffers. Therefore, it follows that the entire collection of clockwise increasing sequences and counterclockwise increasing sequences contains at least $(n + k) + (n + k) - (3 * 9) = 2n + 2k - 27 \geq 3n - 30$ distinct buffers. □

THEOREM 5.2. *Let routing algorithm A be any deadlock-free, minimal routing algorithm for a cycle network with* 31 *or more nodes or for a torus network in which at least one of the dimensions is of length* 31 *or greater. The cycle or torus network must contain at least one node which has three or more standard buffers.*

Proof. The claim for a cycle network follows immediately from Theorem 4.2 and Lemma 5.1. The claim for a torus network follows from Theorem 4.2, Lemma 5.1, and the observation that a torus can be decomposed into disjoint cycles such that all minimal length paths between pairs of nodes within a cycle lie within the cycle. □

6. Conclusions and open problems. This paper has examined the characteristics which an adaptive packet routing algorithm must have in order to be free of deadlock. In particular, we have shown that an adaptive packet routing algorithm may be free of deadlock even though it is impossible to order the buffers so that every packet always has the possibility of moving to a higher-ordered buffer. On the other hand, we have shown that every deadlock-free, adaptive buffer-reservation algorithm can be restricted to obtain a deadlock-free oblivious algorithm. We have also used this fact to show lower bounds on the storage requirements of minimal, deadlock-free routing algorithms for cycle and torus networks.

These results suggest a number of natural open problems. It would be interesting to obtain lower bounds on the storage requirements of minimal, deadlock-free routing algorithms for different topologies, including hypercube-derivative networks such as de Bruijn and butterfly networks. It would also be interesting to see whether or not any networks exist for which these lower bounds on storage requirements are nonconstant. Finally, the problem of characterizing the properties of deadlock-free wormhole routing algorithms remains open.

ON LANGUAGES REDUCIBLE TO ALGORITHMICALLY RANDOM LANGUAGES*

RONALD V. BOOK†

Abstract. In this paper languages "bounded reducible" to *algorithmically random languages* are studied; these are the languages whose characteristic sequences are algorithmically random (as defined by Martin-Löf [*Inform. and Control*, 9 (1966), pp. 602–619]); here RAND denotes the class of algorithmically random languages. The reducibilities $\leq^{\mathcal{R}}$ are very general but are defined so that if $A \in \mathcal{R}(B)$, then there is a machine M with the properties that $L(M, B) = A$ and every computation of M relative to any oracle halts.

Book, Lutz, and Wagner [*Math. Systems Theory*, 27 (1994), pp. 201–209] studied ALMOST-$\mathcal{R}$, defined to be $\{A \mid$ for almost every B, $A \leq_{\mathcal{R}} B\}$. They showed that ALMOST-$\mathcal{R} = \mathcal{R}(\text{RAND}) \cap \text{REC}$, where REC denotes the class of recursive languages, so that ALMOST-$\mathcal{R}$ is the "recursive part" of $\mathcal{R}(\text{RAND})$. In this paper this characterization is strengthened by showing that for *every* $B \in \text{RAND}$, ALMOST-$\mathcal{R} = \mathcal{R}(B) \cap \text{REC}$. A pair (A, B) of languages is an *independent pair* of algorithmically random languages if $A \oplus B \in \text{RAND}$. In this paper it is shown that for every $\mathcal{R}$ and for every independent pair (A, B), ALMOST-$\mathcal{R} = \mathcal{R}(A) \cap \mathcal{R}(B)$.

1. Introduction.

Within computational complexity theory there has been a growing interest in probabilistic algorithms (or probabilistic machines) and randomness. Probabilistic machines incorporate randomness into their underlying logic, so that randomization is part of the internal calculation. Just as in the case of nondeterministic machines, there are examples where probabilistic algorithms can solve problems much faster than is known to be possible by deterministic algorithms. Hence, these concepts have received a great deal of attention.

In structural complexity theory "random oracles" have been studied when using the method of reducibilities to compare complexity classes. Many of the results are stated in terms of a relationship being true for "almost every oracle." (See [Amb86], [BG81], [Cai89], [NW88].) The results given there suggest that one might consider a (nicely behaved) reducibility or a relativization of a complexity class, say $\mathcal{R}$, and define a class ALMOST-$\mathcal{R}$ as $\{B \mid$ for almost every language A, $B \in \mathcal{R}(A)\}$. For example, if $\mathcal{R}$ is the reducibility $\leq^{\text{P}}_{\text{T}}$, then ALMOST-$\mathcal{R}$ is the class BPP, and if $\mathcal{R}$ is the reducibility $\leq^{\text{NP}}_{\text{T}}$, then ALMOST-$\mathcal{R}$ is the class AM. Properties of ALMOST-$\mathcal{R}$ for appropriate reducibilities $\mathcal{R}$ were studied by Book, Lutz, and Wagner [BLW94].

In this context one must consider the class of "algorithmically random" languages of Martin-Löf [Mar66]. As Ko [Ko92], [Ko86] has observed, the notion of algorithmic randomness is the strongest definition of random languages (or sequences) that is widely accepted as *the* definition of randomness. Book, Lutz, and Wagner showed that for appropriate reducibilities $\mathcal{R}$, a recursive language A is in ALMOST-$\mathcal{R}$ if and only if there is an algorithmically random language B such that $A \in \mathcal{R}(B)$, so that ALMOST-$\mathcal{R} = \mathcal{R}(\text{RAND}) \cap \text{REC}$, where REC denotes the class of recursive languages, and ALMOST-$\mathcal{R}$ represents the recursive part of $\mathcal{R}(A)$.

The principal results of the present paper are two additional characterizations of ALMOST-$\mathcal{R}$, each of which is strong.

The random oracle characterization. For every $B \in$ RAND, ALMOST-$\mathcal{R} = \mathcal{R}(B) \cap$ REC (Theorem 3.5).

The independent pair characterization. For every pair (A, B) of languages such that $A \oplus B \in$ RAND, ALMOST-$\mathcal{R} = \mathcal{R}(A) \cap \mathcal{R}(B)$ (Theorem 4.2).

2. Preliminaries. For the most part our notation is standard, following that used by Balcázar, Díaz, and Gabarró [BDG88], [BDG90]. We assume that the reader is familiar with the standard recursive reducibilities and the variants obtained by imposing resource bounds such as time or space on the algorithms that compute these reducibilities.

A *word* (string) is an element of $\{0, 1\}^*$. The length of a word $w \in \{0, 1\}^*$ is denoted $|w|$. For a set A of strings and an integer $n > 0$, let $A^{\leq n} = \{x \in A \mid |x| \leq n\}$.

The power set of a set A is denoted by $\mathcal{P}(A)$.

Let c_A be the characteristic function of A. The *characteristic sequence* χ_A of a language A is the infinite sequence $c_A(x_0)c_A(x_1)c_A(x_2)\ldots$, where $\{x_0, x_1, x_2, \ldots\} = \{0, 1\}^*$ in lexicographical order. We freely identify a language with its characteristic sequence and the class Ω of all languages on the fixed finite alphabet $\{0, 1\}$ with the set $\{0, 1\}^\omega$ of all such infinite sequences; the usage is based on context so that there will be no ambiguity on the part of the reader.

If X is a set of strings (i.e., a language) and $\mathbf{C}$ is a set of sequences (i.e., a class of languages), then $X \cdot \mathbf{C}$ denotes the set $\{w\xi \mid w \in X, \ \xi \in \mathbf{C}\}$.

For each string w, $\mathbf{C}_w = \{w\} \cdot \{0, 1\}^\omega$ is the *basic open set* defined by w. An *open set* is a (finite or infinite) union of basic open sets, i.e., a set $X \cdot \{0, 1\}^\omega$ where $X \subseteq \{0, 1\}^*$. (This definition gives the usual product topology, also known as the Cantor topology, on $\{0, 1\}^\omega$.) A *closed set* is the complement of an open set. A class of languages is *recursively open* if it is of the form $X \cdot \{0, 1\}^\omega$ for some recursively enumerable set $X \subseteq \{0, 1\}^*$. A class of languages is *recursively closed* if it is the complement of some recursively open set.

We assume an effective enumeration of the recursively enumerable languages as $W_1, W_2, \ldots$.

For a class $\mathbf{C}$ of languages we write Prob[$\mathbf{C}$] for the probability that $A \in \mathbf{C}$ when A is chosen by a random experiment in which an independent toss of a fair coin is used to decide whether a string is in A. This probability is defined whenever $\mathbf{C}$ is measurable in the usual product topology of $\{0, 1\}^*$. In particular, if $\mathbf{C}$ is a countable union or intersection of (recursively) open or closed sets, then $\mathbf{C}$ is measurable and so Prob[$\mathbf{C}$] is defined. Note that there are only countably many recursively open sets, so every intersection of recursively open sets is a countable intersection of such sets, and hence is measurable; similarly every union of recursively closed sets is measurable. Notice that the statement "almost every B is in $\mathbf{C}$" corresponds to the more formal statement "Prob$[\{B \mid B \in \mathbf{C}\}] = 1$."

A class $\mathbf{C}$ is *closed under finite variation* if $A \in \mathbf{C}$ holds whenever $B \in \mathbf{C}$ and A and B have finite symmetric difference. A class $\mathbf{C}$ is *closed under finite translation* if for all $y \in \{0, 1\}^*$ and all $A \subseteq \{0, 1\}^\omega$, $\{y\} \cdot A \in \mathbf{C}$ implies $A \in \mathbf{C}$.

The Kolmogorov 0–1 law says that every measurable class $\mathbf{C} \subseteq \{0, 1\}^\omega$ that is closed under finite variation has either measure 0 or measure 1.

3. The random oracle characterization. The definition of an "algorithmically random" language is due to Martin-Löf [Mar66]. A class $\mathbf{C}$ is called a *constructive null set* if there is a total recursive function g with the properties that for every k we have the following.

(i) $\mathbf{C} \subseteq W_{g(k)} \cdot \{0, 1\}^\omega$, and

(ii) Prob$[W_{g(k)} \cdot \{0, 1\}^\omega] \leq 2^{-k}$.

Hence, every constructive null set has measure 0. Let NULL be the union of all constructive null sets, and let RAND $=_{df}$ $\{0, 1\}^\omega$ − NULL be the class of *algorithmically random* languages. Since NULL is a countable union of measure 0 sets, we have Prob[NULL] $= 0$ and, consequently, Prob[RAND] $= 1$.

No recursively enumerable language is in RAND.

Since we are concerned with the use of oracles, we consider complexity classes that can be specified so as to "relativize." But we want to do this in a more general setting than reducibilities computed in polynomial time, and so we introduce a few definitions.

Assume a fixed enumeration $M_0, M_1, M_2, \ldots$ of deterministic oracle Turing machines.

A *relativized class* is a function $\mathbf{C} : \mathcal{P}(\{0,1\}^*) \longrightarrow \mathcal{P}(\mathcal{P}(\{0,1\}^*))$. A *recursive presentation* of a relativized class $\mathbf{C}$ of languages is a total recursive function $f : \mathbf{N} \longrightarrow \mathbf{N}$ such that for every language A and every $i \geq 0$, $M_{f(i)}(A)$ halts on every computation and $\mathbf{C}(A) = \{L(M_{f(i)}(A)) \mid i \in \mathbf{N}\}$. A relativized class is *recursively presentable* if it has a recursive presentation.

Notice that if for every A and every i, $M_{f(i)}(A)$ halts on every computation, then $M_{f(i)}()$ has a running time that is bounded above by a recursive function.

A *reducibility* is a relativized class. A *bounded reducibility* is a relativized class that is recursively presentable. If $\mathcal{R}$ is a reducibility, then we use the notation $A \leq^{\mathcal{R}} B$ to indicate that $A \in \mathcal{R}(B)$. In addition we write $\mathcal{R}^{-1}(A)$ for $\{B \mid A \leq^{\mathcal{R}} B\}$. Typical bounded reducibilities include $\leq_m^{\mathrm{P}}, \leq_{btt}^{\mathrm{P}}, \leq_T^{\mathrm{P}}, \leq_T^{\mathrm{NP}}, \leq_T^{\mathrm{SN}}, \leq_m^{\mathrm{logspace}}$, etc. The relations $\leq_m$ and $\leq_T$ are reducibilities that are not bounded.

If $\mathcal{R}$ is a reducibility and $\mathbf{C}$ is a set of languages, write $\mathcal{R}(\mathbf{C})$ for $\bigcup_{A \in \mathbf{C}} \mathcal{R}(A)$.

A reducibility $\mathcal{R}$ will be called *appropriate* if (i) it is bounded, (ii) for any language A, $\mathcal{R}(A)$ is closed under finite variation, and (iii) for any language A, $\mathcal{R}^{-1}(A)$ is closed under finite translation and under finite variation.

The reader should note that the reducibilities commonly used in structural complexity meet the conditions for being appropriate.

There are characterizations of complexity classes in terms of RAND. This follows from the next fact.

PROPOSITION 3.1 [BLW94]. *If $\mathcal{R}$ is an appropriate reducibility, then the inverse image $\mathcal{R}^{-1}(B)$ of a recursive language B is a union of recursively closed sets.*

For each reducibility $\mathcal{R}$, define $\mathsf{ALMOST}\text{-}\mathcal{R} = \{A \mid \mathrm{Prob}[\{B \mid A \in \mathcal{R}(B)\}] = 1\}$. Let REC denote the class of recursive languages.

PROPOSITION 3.2 [BLW94]. *If $\mathcal{R}$ is an appropriate reducibility, then* $\mathsf{ALMOST}\text{-}\mathcal{R} = \mathcal{R}(\mathrm{RAND}) \cap \mathrm{REC}$.

Simple examples of characterizations of complexity classes given by Proposition 3.2 are the following:

(a) $\mathrm{P} = \mathrm{P}_{btt}(\mathrm{RAND}) \cap \mathrm{REC} = \mathsf{ALMOST}\text{-}\mathrm{P}_{btt}$ [Amb86], [BG81];

(b) $\mathrm{BPP} = \mathrm{P}_T(\mathrm{RAND}) \cap \mathrm{REC} = \mathsf{ALMOST}\text{-}\mathrm{P}_T$ [Amb86], [BG81];

(c) $\mathrm{AM} = \mathrm{NP}_T(\mathrm{RAND}) \cap \mathrm{REC} = \mathsf{ALMOST}\text{-}\mathrm{NP}_T$ [NW88];

(d) $\mathrm{PH} = \mathrm{PH}(\mathrm{RAND}) \cap \mathrm{REC} = \mathsf{ALMOST}\text{-}\mathrm{PH}$ [NW88];

(e) $\mathrm{PSPACE} = \mathrm{PQH}(\mathrm{RAND}) \cap \mathrm{REC} = \mathsf{ALMOST}\text{-}\mathrm{PQH}$, where $A \leq^{\mathrm{PQH}} B$ if and only if $A \in \mathrm{PH}(\mathrm{QBF} \oplus B)$ [BW81], [BBS85].

Proposition 3.2 shows that for appropriate $\mathcal{R}$, $\mathsf{ALMOST}\text{-}\mathcal{R}$ is precisely the "recursive part" of $\mathcal{R}(\mathrm{RAND})$. Since this work is part of the general study of complexity classes, it is particularly significant that $\mathsf{ALMOST}\text{-}\mathcal{R}$ is the recursive part of $\mathcal{R}(\mathrm{RAND})$.

By definition of $\mathsf{ALMOST}\text{-}\mathcal{R}$, a language L is in $\mathsf{ALMOST}\text{-}\mathcal{R}$ if and only if $\mathrm{Prob}[\{J \mid L \in \mathcal{R}(J)\}] = 1$. By Proposition 3.1, for any recursive L, $\mathrm{Prob}[\{J \mid L \in \mathcal{R}(J)\}] = 1$ if and only if there exists $J \in \mathrm{RAND}$ such that $L \in \mathcal{R}(J)$. Thus, $\mathsf{ALMOST}\text{-}\mathcal{R} \subseteq \mathcal{R}(\mathrm{RAND})$, and a recursive language L is in $\mathsf{ALMOST}\text{-}\mathcal{R}$ if and only if there exists $J \in \mathrm{RAND}$ such that $L \in \mathcal{R}(J)$; hence, $\mathsf{ALMOST}\text{-}\mathcal{R} = \cup_{B \in \mathrm{RAND}}(\mathcal{R}(B) \cap \mathrm{REC})$. This statement can be strengthened.

Kautz [Kau91] has developed a number of results about RAND. A modification of one of his results leads to a variation on Proposition 3.2.

LEMMA 3.3. *If* $\mathbf{X}$ *is recursively open,* $\text{Prob}[\mathbf{X}] < 1$, *and* $\mathbf{X}$ *is closed under finite translation, then* $\mathbf{X} \cap \text{RAND} = \emptyset$.

Proof. Assume that $\mathbf{X}$ is recursively open, $\text{Prob}[\mathbf{X}] < 1$, $A \subseteq \{0, 1\}^\omega$, and $A \in \mathbf{X}$. Since $\mathbf{X}$ is closed under finite translation, for all $w \in \{0, 1\}^*$, $A = \{w\} \cdot B$ implies $B \in \mathbf{X}$. It suffices to show that $A \notin \text{RAND}$.

Fix a positive integer r such that $\text{Prob}[\mathbf{X}]^r < 1/2$. Since $\mathbf{X}$ is recursively open, there is a recursively enumerable (r.e.) set C such that C is an instantaneous code (i.e., a prefix-free code) and $\mathbf{X} = C \cdot \{0, 1\}^\omega$. For each $j \in \mathbf{N}$, let $C^j = \{w_1 w_2 \cdots w_j \mid \text{each } w_i \in C\}$. Then each C^j is r.e. and there is a total recursive function g such that $W_{g(k)} = C^{rk}$ for all $k \in \mathbf{N}$.

We show that $\{A\} \subseteq W_{g(k)} \cdot \{0, 1\}^\omega$ and for each k, $\text{Prob}[W_{g(k)} \cdot \{0, 1\}^\omega] < 2^{-k}$. This implies that $\{A\}$ is a constructive null set so that $A \notin \text{RAND}$.

For the first, it suffices to prove that $A \in C^j \cdot \{0, 1\}^\omega$ for all $j \in \mathbf{N}$. This can be done by induction. It is trivial for $j = 0$. Assume that $A \in C^j \cdot \{0, 1\}^\omega$ for some j. Then $A = \{w\} \cdot B$ for some $w \in C^j$ and $B \subseteq \{0, 1\}^\omega$. By choice of A, $B \in \mathbf{X}$ and so $B = \{v\} \cdot B'$ for some $v \in C$ and $B' \subseteq \{0, 1\}^\omega$. Then $A = \{wv\} \cdot B'$ and $wv \in C^{j+1}$, so $A \in C^{j+1} \cdot \{0, 1\}^\omega$.

For the second, notice that $\text{Prob}[W_{g(k)} \cdot \{0, 1\}^\omega] = \text{Prob}[C^{rk} \cdot \{0, 1\}^\omega] = (\text{Prob}[C \cdot \{0, 1\}^\omega])^{rk} = (\text{Prob}[\mathbf{X}])^{rk} < (1/2)^k = 2^{-k}$. □

The following is a simple version of a result of Kautz [Kau91].

THEOREM 3.4. *Let* $\mathbf{X}$ *be a class that is closed under finite translation and finite variation. If* $\mathbf{X}$ *is an intersection of recursively open sets or a union of recursively closed sets, then* $\mathbf{X} \cap \text{RAND} = \emptyset$ *or* $\text{RAND} \subseteq \mathbf{X}$.

Proof. If $\mathbf{X}$ is closed under finite variation, then by the Kolmogorov 0–1 law, $\text{Prob}[\mathbf{X}] = 0$ or $\text{Prob}[\mathbf{X}] = 1$. If $\text{Prob}[\mathbf{X}] = 1$, then $\text{RAND} \subseteq \mathbf{X}$ (Corollary 3 of [BLW94]).

If $\text{Prob}[\mathbf{X}] = 0$, then $\mathbf{X} = \bigcap_{k=0}^{\infty} Y_k$ for some choice of recursively open Y_i, $i \geq 0$. Since $\text{Prob}[\mathbf{X}] = 0$, there exists $m \in \mathbf{N}$ such that the set $\mathbf{Y} = \bigcap_{k=0}^{m} Y_k$ has $\text{Prob}[\mathbf{Y}] < 1$. This set $\mathbf{Y}$ is recursively open. Let $A \in \mathbf{X}$. Then every tail of A is in $\mathbf{X} \subseteq \mathbf{Y}$ so that by Lemma 3.3, $A \notin \text{RAND}$. Hence, $\mathbf{X} \cap \text{RAND} = \emptyset$. □

Now we have the strong variation on Proposition 3.2.

THEOREM 3.5 (the random oracle characterization). *If* $\mathcal{R}$ *is an appropriate reducibility, then for every* $B \in \text{RAND}$, $\textsf{ALMOST-}\mathcal{R} = \mathcal{R}(B) \cap \text{REC}$.

Proof. Since $\textsf{ALMOST-}\mathcal{R} = \mathcal{R}(\text{RAND}) \cap \text{REC}$, it is trivial that for every $B \in \text{RAND}$, $\mathcal{R}(B) \cap \text{REC} \subseteq \textsf{ALMOST-}\mathcal{R}$.

To see that the converse is true, choose any $L \in \textsf{ALMOST-}\mathcal{R}$; then since we have $L \in \textsf{ALMOST-}\mathcal{R}$, $L \in \text{REC}$ and $\text{Prob}[\mathcal{R}^{-1}(L)] = 1$. As an appropriate reducibility, $\mathcal{R}$ is bounded so that $\mathcal{R}^{-1}(L)$ is a union of recursively closed sets (Proposition 3.1) that is closed under finite translation and finite variation. Since $\text{Prob}[\mathcal{R}^{-1}(L)] = 1$, it follows by Theorem 3.4 that $\text{RAND} \subseteq \mathcal{R}^{-1}(L)$. This implies that for every $B \in \text{RAND}$, $L \in \mathcal{R}(B)$; since $L \in \text{REC}$, this shows that $L \in \mathcal{R}(B) \cap \text{REC}$. Hence, $\textsf{ALMOST-}\mathcal{R} \subseteq \mathcal{R}(B) \cap \text{REC}$. □

COROLLARY 3.6. *Let* $\mathcal{R}$ *be an appropriate reducibility.*

(a) *Language* $A \in \textsf{ALMOST-}\mathcal{R}$ *if and only if* A *is recursive and for every* $B \in$ RAND, $\text{A} \in \mathcal{R}(B)$.

(b) *For every two languages* $C, D \in \text{RAND}$, $\textsf{ALMOST-}\mathcal{R} \subseteq \mathcal{R}(C) \cap \mathcal{R}(D)$.

Theorem 3.5 shows that for any two languages C, D in RAND, the recursive part of $\mathcal{R}(C)$ is precisely the same as the recursive part of $\mathcal{R}(D)$ since both are equal to $\textsf{ALMOST-}\mathcal{R}$. Thus, no specific language in RAND plays a special role as an oracle for any language in $\textsf{ALMOST-}\mathcal{R}$.

Theorem 3.5 generalizes the characterization of BPP due to Lutz [Lut92]. Notice that it follows immediately from the definitions (without using Theorem 3.5) that for every $B \in$ RAND, $\text{P} = \text{P}_{\text{btt}}(B) \cap \text{REC}$ and $\text{PH} = \text{PH}(B) \cap \text{REC}$, but no similar characterizations are known for classes of the form $\textsf{ALMOST-}\mathcal{R}$ without using Theorem 3.5.

4. The independent pair characterization. The theory of reducibilities has been used successfully in complexity theory to find upper bounds on the complexity of various languages. When a language A is known to be reducible to a language B, then it is sometimes the case that the inherent computational complexity of A can be bounded above by some function that bounds the inherent computational complexity of B. What can be said when language B is in RAND? It is known [Gac86] that for every language A, there is a language $B \in$ RAND such that A is Turing reducible to B. Thus, simply knowing that a language is reducible to language in RAND tells one nothing about the computational complexity of the given language. In addition, knowing that a reduction of A to B, $B \in$ RAND, is witnessed by a machine whose running time is bounded by some total recursive function still does not guarantee that A is recursive or is in some specific complexity class; this follows from the fact that if the reduction is reflexive, then B is reducible to itself within the same time bound. Recall that no recursively enumerable language (hence, no recursive language) can be in RAND.

One approach to gaining information about the complexity of the languages reducible to a language in RAND is to consider appropriate reducibilities as described in §3. Thus, consider the case where A is in ALMOST-$\mathcal{R}$ for some appropriate $\mathcal{R}$. Then A is recursive and there is a language $B \in$ RAND such that $A \in \mathcal{R}(B)$. This is enough to show that there is an upper bound on the complexity of A which depends only on the reducibility $\mathcal{R}$, that is, for every $B \in$ RAND and every $A \in \mathcal{R}(B)$, there is a machine that recognizes A and whose running time is bounded above by $f_{\mathcal{R}}$. This fact follows from a straightforward simulation based on the definition of $\mathcal{R}$ as a bounded reducibility. Hence, it is stated without proof, leaving the details as an exercise.

THEOREM 4.1. *For any appropriate reducibility $\mathcal{R}$, there is a total recursive function $f_{\mathcal{R}}$ that depends only on $\mathcal{R}$ such that every language in* ALMOST-$\mathcal{R}$ *can be recognized deterministically in time bounded by $f_{\mathcal{R}}$.*

Now we consider a special type of algorithmically random language.

Let $\mathcal{R}$ be a reducibility and $\mathbf{C}$ a class of languages. A pair (A, B) of languages is an *$\mathcal{R}$-minimal pair for* $\mathbf{C}$ if $A \notin \mathbf{C}$, $B \notin \mathbf{C}$, and for every language D, $D \in \mathcal{R}(A)$ and $D \in \mathcal{R}(B)$ imply $D \in \mathbf{C}$. (See [Amb87].)

Most of the research on minimal pairs that has been carried out in complexity theory has focused on minimal pairs for well-studied classes like P and NP with respect to reducibilities computed in polynomial time (for examples, see [Amb87], [Bre78], [Lad75], [Sch84]). However, this topic has arisen in the context of random oracles [Amb86] and [TW89]. Recently, Lutz [Lut92] developed a characterization of languages in BPP in terms of "independent pairs of algorithmically random languages," a characterization that can be put into the framework of minimal pairs and that here is generalized to every class of the form ALMOST-$\mathcal{R}$ for every appropriate $\mathcal{R}$.

Let A and B be languages such that $A \oplus B \in$ RAND. Then (A, B) is an *independent pair of algorithmically random languages.* (Here, $A \oplus B$ denotes the "join" of A and B, $A \oplus B = \{0x, 1y \mid x \in A,\ y \in B\}$.)

In the present paper we abbreviate the name as "independent pair."

Lutz observed that choosing A and B independently from Ω is equivalent to choosing the pair (A, B) from the product space $\Omega \times \Omega$ with the probability distribution given by $\text{Prob}[X \times Y] = \text{Prob}[X] \cdot \text{Prob}[Y]$ for all $X, Y \in \Omega$. Thus, almost every pair of languages is an independent pair, that is, $\text{Prob}[\{(A, B) \mid (A, B) \text{ is an independent pair}\}] = 1$.

Since $A \oplus B \in$ RAND implies that both A and B are in RAND, the name "independent pair of algorithmically random languages" is justified. Note that there exist $A, B \in$ RAND such that $A \oplus B \notin$ RAND; an example is $A \oplus \overline{A}$ where $A \in$ RAND.

Now we have the second variation on Proposition 3.2.

THEOREM 4.2 (the independent pair characterization). *Let $\mathcal{R}$ be an appropriate reducibility. For every independent pair (A, B),* $\mathsf{ALMOST}\text{-}\mathcal{R} = \mathcal{R}(A) \cap \mathcal{R}(B)$.

Proof. To show that $\mathcal{R}(A) \cap \mathcal{R}(B) \subseteq \mathsf{ALMOST}\text{-}\mathcal{R}$, it suffices to show that every independent pair is an $\mathcal{R}$-minimal pair for $\mathsf{ALMOST}\text{-}\mathcal{R}$. The proof is generalization of the proof of the main result of Lutz [Lut92]. Since Lutz was discussing only polynomial time-bounded Turing reducibilities, that proof must be altered for general appropriate reducibilities $\mathcal{R}$.

Let (A, B) be an independent pair. Let D be a language such that $D \in \mathcal{R}(A)$ and $D \in \mathcal{R}(B)$. Assume that $D \notin \mathsf{ALMOST}\text{-}\mathcal{R}$. The desired result follows by proving that $\{A \oplus B\}$ has a constructive null cover and so $A \oplus B$ is not algorithmically random.

Let M_a, M_b be machines witnessing $D \in \mathcal{R}(A)$ and $D \in \mathcal{R}(B)$. Since $\mathcal{R}$ is a bounded reducibility, one can assume that there exist total recursive functions f_a and f_b bounding the running times of M_a and M_b. Fix a strictly increasing function g such that for all x, $g(|x|) \geq \max\{f_a(|x|), f_b(|x|)\}$. Then for all x and all strings y that are query strings in either M_a's or M_b's computation on x, $|y| \leq g(|x|)$. For each natural number n, let $K(n) = 2^{g(n)} - 1$ and $N(n) = 2K(n) + 1$. In this proof certain subsets of $\{0, 1\}^{<g(n)}$ will be discussed; let $u, v \in \{0, 1\}^{K(n)}$ denote the characteristic strings of sets $U, V \subseteq \{0, 1\}^{<g(n)}$, respectively, and let $u \oplus v \in \{0, 1\}^{N(n)}$ denote the characteristic string of $U \oplus V$.

Now the proof follows that of Lutz.

Since (A, B) is an independent pair, both A and B are in RAND. By Corollary 3.6(b), this means that $\mathsf{ALMOST}\text{-}\mathcal{R} \subseteq \mathcal{R}(A) \cap \mathcal{R}(B)$. Hence, $\mathsf{ALMOST}\text{-}\mathcal{R} = \mathcal{R}(A) \cap \mathcal{R}(B)$. □

Lutz [Lut92] showed that for every independent pair (A, B), $\mathrm{BPP} = \mathrm{P}_T(A) \cap \mathrm{P}_T(B)$. That result appears to be the first characterization of this form for any class of the form $\mathsf{ALMOST}\text{-}\mathcal{R}$ for any specific appropriate $\mathcal{R}$.

From the fact that almost every pair of languages is an independent pair, it follows that for every $A \in$ RAND, (A, B) forms an independent pair for almost every language B.

Notice that for every $A \in$ RAND, there exist $B \in$ RAND such that (A, B) is *not* an independent pair and for some $\mathcal{R}$, $\mathcal{R}(A) \cap \mathcal{R}(B) \neq \mathsf{ALMOST}\text{-}\mathcal{R}$. For example, if $A \in$ RAND, then $\overline{A} \in$ RAND, but $A \oplus \overline{A} \notin$ RAND. For a reducibility like $\leq^{\mathrm{P}}_{\mathrm{T}}$, notice that $\mathrm{P}_T(A) = \mathrm{P}_T(\overline{A})$ so that $\mathrm{BPP} \neq \mathrm{P}_T(A) \cap \mathrm{P}_T(\overline{A})$.

As noted in §3, for every two languages C, D in RAND and every appropriate $\mathcal{R}$, the recursive part of $\mathcal{R}(C)$ is equal to the recursive part of $\mathcal{R}(D)$. This does not imply that $\mathcal{R}(C) = \mathcal{R}(D)$. For if $C \oplus D \in$ RAND, then $\mathcal{R}(C) \cap \mathcal{R}(D) \subseteq$ REC so that $\mathcal{R}(C) \cap \mathcal{R}(D)$ is properly included in both $\mathcal{R}(C)$ and $\mathcal{R}(D)$. But neither $\mathcal{R}(C)$ nor $\mathcal{R}(D)$ is included in REC so this implies that $\mathcal{R}(C) \neq \mathcal{R}(D)$. Thus, for every C, $\mathcal{R}(C) \neq \mathcal{R}(D)$ for almost every $D \in$ RAND.

As a more concrete application of Theorem 4.2, recall Theorem 5.2(c) of Tang and Watanabe [TW89]: for almost every pair (T_1, T_2) of tally sets, $BP \cdot \Sigma_k^P = \Sigma_k^P(T_1) \cap \Sigma_k^P(T_2)$. It has been an open question whether this result can be extended to pairs (A, B) of languages over $\{0, 1\}^*$ instead of over $\{0\}^*$. It is known [NW88] that $BP \cdot \Sigma_k^P = \mathsf{ALMOST}\text{-}\Sigma_k^P$ for every $k \geq 0$, and that almost every pair (A, B) is an independent pair.

COROLLARY 4.3. *For almost every pair (A, B) of languages,* $\mathsf{ALMOST}\text{-}\Sigma_k^{\mathrm{P}} = \Sigma_k^{\mathrm{P}}(A) \cap \Sigma_k^{\mathrm{P}}(B)$.

Lutz (personal communication) observed that for the well-studied complexity classes, this is the first result where the probabilistic result did not precede the more abstract result, that is, it was not known that $\mathrm{Prob}[\{(A, B) \mid \Sigma_k^P(A) \cap \Sigma_k^P(B) = BP \cdot \Sigma_k^P\}] = 1$ until Theorem 4.2 was established.

5. Remarks. These results give new characterizations of classes of the form $\mathsf{ALMOST}\text{-}\mathcal{R}$. Perhaps the most interesting applications (in terms of current interest) are the following:

(a) For every $B \in$ RAND, AM = NP(B) ∩ REC.

(b) For every pair (C, D) of languages such that $C \oplus D \in$ RAND, AM = NP(C) ∩ NP(D).

(c) For every $B \in$ RAND, ALMOST-PSPACE = PSPACE(B) ∩ REC.

(d) For every pair (C, D) of languages such that $C \oplus D \in$ RAND, we have ALMOST-PSPACE = PSPACE(C) ∩ PSPACE(D).

Characterizations (c) and (d) are of particular interest since no intrinsic characterization of ALMOST-PSPACE is known.

It should be noted that in Theorems 3.5 and 4.2, the reducibilities are bounded. If this condition is omitted, then things change. For example, let us write $A \in$ REC(B) if $A \leq_T B$. Then REC(RAND) ∩ REC = REC and ALMOST-REC = REC. In addition, Kautz (personal communication) has observed that a result of Kucera [Kuc86] (also see Chapter III of [Kau91]) shows that there exist languages A and B in RAND such that REC is a proper subset of REC(A) ∩ REC(B). Thus, the independent pair characterization requires that the reducibility be bounded.

Acknowledgments. I wish to thank Steven Kautz, Ker-I Ko, Jack Lutz, Elvira Mayordomo, and Greg Perkins for their helpful suggestions.

A FAST ALGORITHM FOR OPTIMUM HEIGHT-LIMITED ALPHABETIC BINARY TREES*

LAWRENCE L. LARMORE† AND TERESA M. PRZYTYCKA‡

Abstract. In this paper, an $O(nL \log n)$-time algorithm is presented for construction of an optimal alphabetic binary tree with height restricted to L. This algorithm is an alphabetic version of the Package Merge algorithm, and yields an $O(nL \log n)$-time algorithm for the alphabetic Huffman coding problem. The Alphabetic Package Merge algorithm is quite simple to describe, but appears hard to prove correct.

Garey [*SIAM J. Comput.*, 3 (1974), pp. 101–110] gives an $O(n^3 \log n)$-time algorithm for the height-limited alphabetic binary tree problem. Itai [*SIAM J. Comput.*, 5 (1976), pp. 9–18] and Wessner [*Inform. Process. Lett.*, 4 (1976), pp. 90–94] independently reduce this time to $O(n^2 L)$ for the alphabetic problem. In [*SIAM J. Comput.*, 16 (1987), pp. 1115–1123], a rather complex $O(n^{3/2} L \log^{1/2} n)$-time "hybrid" algorithm is given for length-limited Huffman coding. The Package Merge algorithm, discussed in this paper, first appeared in [*Tech. Report*, 88-01, ICS Dept. Univ. of California, Irvine, CA], but without proof of correctness.

Key words. optimal tree, weighted binary tree

1. Introduction.

The classic *prefix-free binary coding* problem, also called the *Huffman coding* problem, was introduced, and definitively solved, by Huffman in 1952 [9]. Given a set of items ("symbols"), $A_1, \dots A_n$, where each symbol A_i has an associated "frequency," $a_i \geq 0$, find a binary string for each symbol, $code(A_i)$, minimizing the *expected code length*

$$\sum_{i=1}^{n} a_i |code(A_i)|,$$

where $|w|$ refers to the length of a string w, subject to the *prefix property*—i.e., no $code(A_i)$ is a prefix of any other $code(A_j)$. We refer to codes with the prefix property as *Huffman* codes.

The prefix property enables a bit string to be uniquely decoded. Huffman's algorithm computes a Huffman code of minimal expected length in $O(n \log n)$ time, but only linear time if the symbols are already sorted by frequency.

The "alphabetic" version of the problem introduces the one additional restriction that $code(A_i) < code(A_j)$ if $i < j$, where the relation "<" on strings refers to lexical ordering. $O(n \log n)$-time algorithms for the alphabetic problem have been given by Hu and Tucker and by Garsia and Wachs [5], [7], [8].

These algorithms, as well as subsequent algorithms for additional variations of the problem, make use of the *binary tree* representation of prefix-free codes.

The set of all bit strings (i.e., strings over {0,1}) is an infinite binary tree, where the empty string is the root, and the left and right children of any string w are $w0$ and $w1$, respectively. Any code with the prefix property can be mapped to the (finite) binary tree consisting of all $code(A_i)$ and all ancestors of those bit strings. The symbol A_i is then considered to be attached to the leaf $code(A_i)$. Note that the depth of a symbol in the tree is precisely the length of its code string.

Thus, the alphabetic Huffman coding problem is equivalent to the optimal binary search tree problem with the restriction that all data are in the leaves [8], [11]. In this paper, we refer to that problem as the *alphabetic binary tree* problem.

When the problem is expressed in terms of trees, we usually say *weighted depth* or *weighted path length* instead of *expected code length.*

The input for one instance of the alphabetic binary tree problem is a list of nonnegative *weights*, $w_1, \dots w_n$, and the output is a full binary tree[1] with n leaves, represented by its list of leaf depths, called its *leaf sequence*, $\ell_1, \dots \ell_n$, chosen so that the weighted depth $\sum_{i=1}^n w_i \ell_i$ is minimized.

1.1. Length-limited Huffman coding. The *length-limited Huffman coding* problem is introduced by Gilbert [6]. This is the Huffman coding problem with the restriction that every code string $code(A_i)$ must have length no greater than a given constant L. (In an application, L might be the size of a register.)

The alphabetic version of length-limited Huffman coding is equivalent to the optimal binary search tree problem with all data in the leaves, where the height of the tree is restricted. It is the latter formulation that we use in this paper, which we refer to as the *height-limited alphabetic binary tree* problem.

Previous results. Garey [4] gives an $O(n^2 \log n)$-time algorithm for the length-limited Huffman coding problem, and an $O(n^3 \log n)$-time algorithm for the height-limited alphabetic binary tree problem.

Itai [10] and Wessner [16] independently reduce this time to $O(n^2 L)$ for the alphabetic problem, essentially by showing that Garey's monotonicity lemma extends to the alphabetic case. Lemma 8.1 in this paper is a generalization of Garey's monotonicity lemma.

In [12], a rather complex $O(n^{3/2} L \log^{1/2} n)$-time "hybrid" algorithm is given for length-limited Huffman coding.

In [13] and [14], the *Package Merge* algorithm is introduced for length-limited Huffman coding. A radical departure from the dynamic programming methods of [4], [10], [12], and [16], the $O(nL)$-time Package Merge algorithm returns to the original greedy approach of Huffman's algorithm [9].

The alphabetic version of the Package Merge algorithm, an $O(nL \log n)$-time algorithm for the alphabetic Huffman coding problem, and the subject of this paper, is quite simple to describe (see §2), but appears hard to prove correct. The algorithm first appeared in [13] and [15], but without proof of correctness.

In this paper, we describe the Package Merge algorithm for a more general problem, which we call the *weighted binary tree* problem.

An instance of the weighted binary tree problem consists of a doubly indexed *weight matrix* $w_{i,\ell}$, for $i = 1, \dots n$, and $\ell = 0, \dots L$, for some given $L \geq \lceil \log_2 n \rceil$, such that

(i) $w_{i,0} = 0$,

(ii) $w_{i,\ell+1} \geq w_{i,\ell}$ [monotonicity condition],

(iii) $2w_{i,\ell} \leq w_{i,\ell-1} + w_{i,\ell+1}$ [concavity condition].

The *cost* of a binary tree $\mathcal{T}$ with respect to a weight matrix $\{w_{i,\ell}\}$ is defined to be

$$|\mathcal{T}| = \sum_{i=1}^{n} w_{i,\ell_i},$$

where $\ell_1, \dots, \ell_n$ is the leaf sequence of $\mathcal{T}$. The problem is to find the tree $\mathcal{T}$ with minimal cost, given the weight matrix. We call such a tree *optimal.*

[1] A nonempty binary tree where every nonleaf node has two children. Henceforth, in this paper, we assume that all binary trees are full.

Note that the condition that $w_{i,0} = 0$ is really no restriction. A matrix $\{w_{i,\ell}\}$ without that condition can be replaced by a matrix having that condition, by the transformation $w'_{i,\ell} = w_{i,\ell} - w_{i,0}$, preserving monotonicity and concavity. Costs of trees are changed by a constant, so optimality is preserved.

The height-limited alphabetic binary tree problem reduces to the weighted binary tree problem by letting $w_{i,\ell} = \ell w_i$ for all $\ell \leq L$.

1.2. Overview of the paper. The paper is organized as follows. In §2, we give a brief but complete description of the Package Merge algorithm with no attempt to prove correctness. In §3, we introduce a new geometric interpretation of binary trees and forests, show its relation to the traditional interpretation, and prove some of its properties. In §4, we extend this geometric interpretation to weighted binary trees and forests and show a method of constructing optimal weighted binary trees (the Package Search algorithm). In §§5 and 6, we prove properties of the technique that leads to the efficient implementation of the Package Search algorithm, the Package Merge algorithm.

A different, naturally parallelizable implementation of the Package Search algorithm will be a subject of a separate paper.

2. The Package Merge algorithm. In this section, we present a complete description of the Package Merge algorithm.

Let $w_{i,\ell}$, for $i = 1, \ldots n$, and $\ell = 0, \ldots L$, for $L \geq \lceil \log_2 n \rceil$, be an instance of the weighted binary tree problem, as defined in §1.1.

We define a *tile* to be an ordered pair of integers (i, ℓ) such that $i \in [1, n]$ and $\ell \in [0, L]$. The tile (i, ℓ) is said to have *index* i, *level* ℓ, and *width* $2^{-\ell}$. We define the *weight* of (i, ℓ) to be $w_{i,\ell} - w_{i,\ell-1}$ for $\ell > 0$, and zero if $\ell = 0$. We define the *tag value* of (i, ℓ) to be $n\ell + i$. If A is a set of tiles, define its weight, denoted $|A|$, to be the sum of the weights of its members. The width of A is defined to be the sum of the widths of its members. Define the *tag value* of A to be the maximum tag value of any of its members.[2] Finally, define the index of A to be the minimum of the indices of its members.

If $\mathcal{T}$ is any binary tree, with leaf sequence $\ell_1, \ldots \ell_n$, we define the *associated set of tiles* to be

$$\mathit{skyline}(\mathcal{T}) = \{(i, \ell) : \ell \in [0, \ell_i]\}$$

which has width $(2n - 1)$ and weight equal to $\mathit{cost}(\mathcal{T})$. (We use the word "skyline" because if that set of tiles is inverted, it consists of a set of adjacent columns of various heights and the same base, like buildings in the skyline of a city. See §3.)

The Package Merge algorithm operates by finding $\mathit{skyline}(\mathcal{T})$, the minimal weight set of tiles which has width $(2n - 1)$, subject to the condition that it is a *geometric tree*, as defined in §3. (The set of tiles generated by the Package Merge algorithm will always satisfy this condition.) $\mathcal{T}$ can then be recovered from $\mathit{skyline}(\mathcal{T})$.

We recall the Hu–Tucker algorithm [8] for constructing a minimal alphabetic binary tree. Initially, there is a list of n "square nodes," each of which has a *weight*. The algorithm consists of $(n - 1)$ steps. During each step, two nodes are combined to form a new "round" node, whose weight is equal to the sum of the weights of its children. This new "round" node is inserted in place of its left child, and the two children are deleted from the list.

In the Hu–Tucker algorithm, two nodes are said to be "tentatively connected" if there is no "square" node strictly between them in the list. During each step, the two nodes that are combined are those of minimal total weight subject to the condition that they are tentatively

[2] Tag values are used only to break ties.

connected. This construction gives rise to a binary tree, $\mathcal{T}'$. The final step of the Hu–Tucker algorithm recovers the optimal alphabetic tree, $\mathcal{T}$, from $\mathcal{T}'$. The depth ℓ_i of the ith item in $\mathcal{T}$ equals the depth of the ith "square" node in $\mathcal{T}'$. We refer the reader to [8] for details.

The Package Merge algorithm has many features in common with the Hu–Tucker algorithm. "Square" nodes of Hu–Tucker correspond to tiles in the Package Merge algorithm, and "round" nodes correspond to *packages*. A level-ℓ *package*, where ℓ is a nonnegative integer, is a certain kind of tile set that has at least two members, and whose width is $2^{-\ell}$. (A precise definition will be given in §3.2.) Packages and tiles are together called *items*.

The first step of the algorithm is to let F^L be the list of all level-L tiles, ordered by index. Then, starting with $\ell = L - 1$ and ending with $\ell = 0$, *optimal packages* of level ℓ are formed by combining the items in $F^{\ell+1}$ according to certain rules. These optimal level-ℓ packages are then merged with the list of level-ℓ tiles to form F^ℓ, a list ordered by index, where a tile is always in front of a package of the same index.

The *packaging* step, which occurs at each of the L levels, consists of as many as $(n - 1)$ steps in which two level-$(\ell + 1)$ items are selected, then combined to form a level-ℓ package. The two items are then deleted from $F^{\ell+1}$. The rule is to select that pair of smallest total weight, subject to the condition that the pair is "tentatively connected." A pair of items in $F^{\ell+1}$ is *tentatively connected* if there is no tile which is strictly between them in the list. Since items are deleted as they are selected, there will always be at least one tentatively connected pair if the list has at least two items.

Note that there can be at most one item left in $F^{\ell+1}$ at the end of the packaging step. This item, which we call an "orphan," is simply discarded.

The set *skyline*$(\mathcal{T})$ will be simply the union of the items in F^0, from which $\mathcal{T}$ can be easily recovered.

Ties are broken using the tag values. In particular, if two items have equal weight, that with the higher tag value is considered heavier.

The Package Merge algorithm is illustrated in Figs. 1 and 2. We give a pseudo-code below.

```
ALGORITHM Package Merge (L)
1. For all $\ell \in [1, L]$, $F^\ell \leftarrow$ all level-$\ell$ tiles
2. $F^0 \leftarrow$ empty list
3. for $\ell = L - 1$ downto 0 do
      3.1. while $|F^{\ell+1}| \geq 2$ do
               3.2.1. $(p_1, p_2) \leftarrow$ least weight tentatively connected pair in $F^{\ell+1}$
               3.2.2. $p \leftarrow p_1 \cup p_2$
               3.2.3. insert $p$ into $F^\ell$
               3.3.4. delete $p_1, p_2$ from $F^{\ell+1}$
4. skyline$(\mathcal{T}) \leftarrow$ union of all members of $F^0$
5. Recover $\mathcal{T}$ from skyline$(\mathcal{T})$
```

The question of whether the Package Merge algorithm is correct if ties are broken arbitrarily is open.

We suggest using a list of mergeable priority queues to represent $F^{\ell+1}$. A pair of items will be tentatively connected if and only if they are both in the same priority queue. Using this data structure, it takes $O(\log n)$ time to select the minimal weight, tentatively connected pair. Since that selection must occur at most $(n - 1)$ times on each of L levels, the time complexity of the Package Merge algorithm is $O(nL \log n)$.

3. Geometric trees. In this section, we introduce a new geometric interpretation of binary trees and forests, and show its relation to the traditional interpretation.

FIG. 1. *Constructing skyline*$(\mathcal{T})$.

Consider an $n \times (L + 1)$ rectangle in the plane, divided into unit squares which we call *tiles*. (See Fig. 3.) A "geometric tree" or "geometric forest" will be defined to be a certain kind of connected union of tiles. We refer to the tile in the ℓth row and the ith column as $s_{i,\ell}$, and we say that $s_{i,\ell}$ has *index* i and *level* ℓ. We adopt the conventions that levels range from 0 to L, from the top down, while indices range from 1 to n, from left to right.

Two tiles are *adjacent* if they share a boundary edge, not just a corner. Thus, $s_{i,\ell}$ is adjacent to $s_{i+1,\ell}$ and to $s_{i,\ell+1}$, but not to $s_{i+1,\ell+1}$. A *path of tiles* is a sequence of tiles in

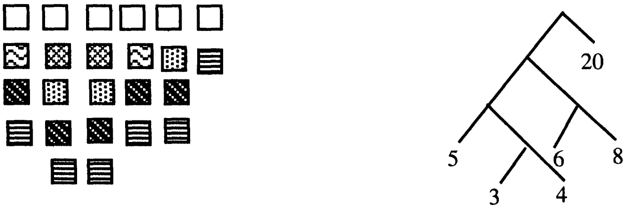

FIG. 2. *Recovering the tree $\mathcal{T}$ from skyline($\mathcal{T}$).*

which consecutive tiles are adjacent. We say that a set of tiles A is *connected* if for any two tiles $a_1, a_2 \in A$ there exists a path of tiles between a_1 and a_2 that is entirely contained in A.

For any $M \leq N$ and any set of tiles S, we define $S_{[M,N]}$ to be the set of all members of S whose indices are in the interval $[M, N]$. Formally,

$$S_{[M,N]} = \{s_{i,\ell} \in S \mid M \leq i \leq N\}.$$

DEFINITION. *We define a skyline at level ℓ (or level-ℓ skyline, for short) to be a connected set of tiles A such that*

1. *A contains no tile at any level $\ell' < \ell$, and*
2. *if $s_{i,\ell'+1} \in A$ for any $\ell' \geq \ell$, then $s_{i,\ell'} \in A$.*

A skyline looks like an upside-down bar graph. It consists of one or more columns of tiles which are adjacent in the horizontal dimension, such that the top tile of each column is at the same level (see Fig. 3).

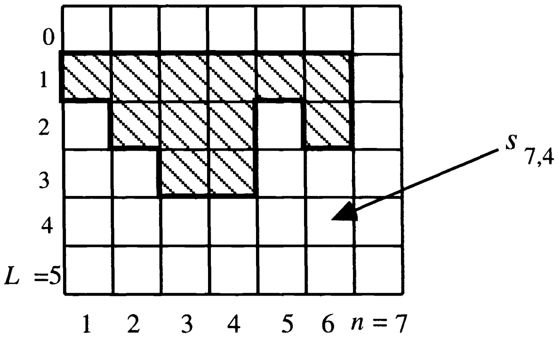

FIG. 3. *A skyline of level* 1.

For any ℓ, we define B^ℓ to be the set of all level-ℓ tiles. The *base* of a level-ℓ skyline A is defined to be the set of all its level-ℓ tiles, i.e., $A \cap B^\ell$. By connectivity, this base will always consist of a contiguous partial row of tiles $s_{M,\ell}, \ldots s_{N,\ell}$. We call $[M, N]$ the *base interval* of A, and we say that A has *base length* $(N - M + 1)$. We also say that A is a skyline *over* $[M, N]$.

Certain skylines will be called *geometric trees*, and certain ones will be called *geometric forests*. These concepts are invariant under translation up, down, or sideways, but not under rotation.

We give a recursive definition of a *geometric forest*, and a *geometric tree* is simply a geometric 1-forest.

DEFINITION. (i) A level-ℓ tile is a level-ℓ geometric tree.

(ii) A level-ℓ skyline which is the exact union of k level-ℓ geometric trees is a level-ℓ geometric k-forest.

(iii) If A is a level-$(\ell + 1)$ geometric 2-forest over $[M, N]$, then $A \cup B^{\ell}_{[M,N]}$ is a level-ℓ geometric tree.

Note that a geometric k-forest A is simply the disjoint union of k geometric trees that have adjacent bases.

The following lemma follows immediately from the above definition.

LEMMA 3.1. *If A is a level-$(\ell + 1)$ skyline over $[M, N]$, then $A \cup B^{\ell}_{[M,N]}$ is a level-ℓ geometric k-forest if and only if A is a level-$(\ell + 1)$ geometric $2k$-forest.*

Usage of the words "tree" and "forest" is justified by the following correspondence lemma.

LEMMA 3.2. *There is a one-to-one correspondence between level-ℓ geometric k-forests over $[M, N]$ and ordered k-forests of size*[3] *$(N - M + 1)$ and height at most $(L - \ell)$, as follows: If F is a geometric k-forest over $[M, N]$, then F corresponds to the forest $\mathcal{F}$ whose leaf sequence is $\ell_M, \ell_{M+1,\dots\ell_N}$, where $\ell_i + \ell$ is the greatest level of any tile in F of index i.*

Although somewhat complex in its statement, Lemma 3.2 follows immediately from the inductive definition of geometric forest. We omit the proof.

If $\mathcal{F}$ is an ordered k-forest of height h and size $(N - M + 1)$, we define the *level-ℓ representation of $\mathcal{F}$ over $[M, N]$* to be the geometric k-forest at level ℓ over $[M, N]$ that corresponds to $\mathcal{F}$ under Lemma 3.2, which exists and is unique provided $(\ell + h) \leq L$.

Figure 4 shows a binary tree, a forest, and their corresponding geometric tree and forest.

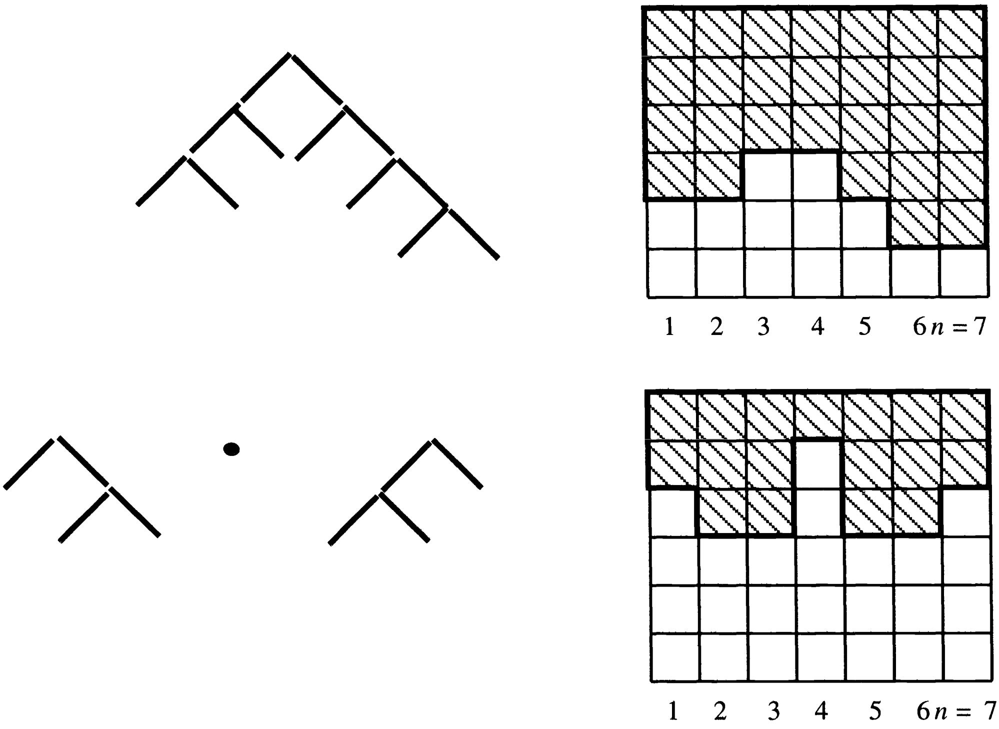

FIG. 4. *A binary tree, a forest, and their corresponding geometric tree and forest.*

[3] The *size* of a tree or forest is defined to be the number of leaves.

Henceforth, we say "tree" and "forest" instead of "geometric tree" and "geometric forest," provided the meaning is clear from context.

The recursive definitions of geometric "tree" and "forest" above allow us to build up geometric trees and forests out of smaller ones in ways which are analogous to the usual building of binary trees and binary forests out of smaller ones. But we can also build them by a radically different method—which is the essence of this paper—by changing a geometric k-forest into a geometric $(k-1)$-forest by adding an appropriate set of tiles, which we will call a *package*.

Before plunging into formalism, we ask the reader to examine Fig. 5, which shows a geometric 3-forest of size 7, which has been changed into a geometric 2-forest, also of size 7, by the addition of some tiles. It is important to note that this mutation is quite different from the usual recursive construction—the leaves of the middle tree have been divided among the two trees of the new forest.

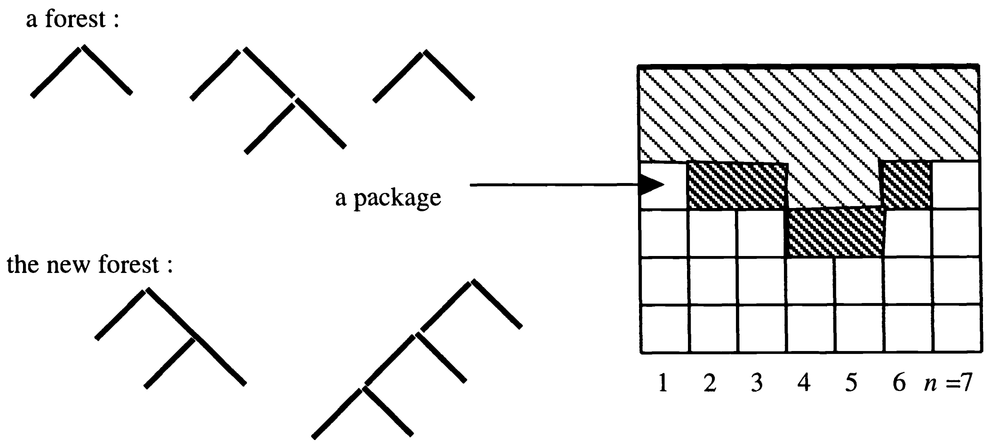

FIG. 5. *Changing a* 3*-forest into a* 2*-forest by adding a* package.

3.1. Boundaries, spanning, gaps, and cuts. If A is a nonempty set of tiles, we define *lboundary* (A) to be the smallest index of any tile which is a member of A, and we define *rboundary* (A) to be the largest index of any tile which is a member of A.

We also say that A *spans* an index r if $r \in [\mathit{lboundary}\ (A), \mathit{rboundary}\ (A)]$.

Let $\ell' \geq \ell$. We say that a set of tiles A is *level-ℓ' connected* with respect to a level-ℓ skyline Q over $[M, N]$ if

1. $A \cap Q = \emptyset$.
2. $A \cup Q$ is a level-ℓ skyline over $[M, N]$.
3. For any two tiles $a_1, a_2 \in A$ there exists a path of tiles between a_1 and a_2 that is entirely contained in $A \cup Q$, and which uses no tiles at level ℓ' or above.[4]

Remark 3.3. *If a set of tiles A is level-ℓ' connected with respect to two level-ℓ skylines, Q and Q', where $\ell' \geq \ell$, then A is level-ℓ' connected with respect to $Q \cap Q'$.*

Thus, if A is level-ℓ' connected with respect to some level-ℓ skyline Q, and if A spans r, then $s_{r,\ell'+1} \in A \cup Q$.

If Q is a level-ℓ skyline, we say that r is a *gap* of Q if $r \in [\mathit{lboundary}\ (Q), \mathit{rboundary}\ (Q)]$ and $s_{r,\ell+1} \notin Q$. If r is one of the boundary values, we say that the gap is *external*, otherwise *internal* (see Fig. 6).

[4] To be consistent with our figures, levels which are less are called "higher."

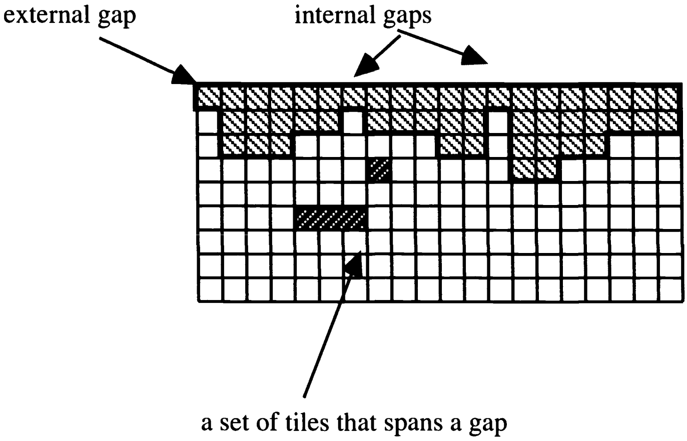

FIG. 6. *Internal and external gaps and a set of tiles that spans a gap.*

Let F be a k-forest over $[M, N]$. We define the *cuts* of F to be the right boundaries of the trees which form F. Formally, if F is the disjoint union of geometric trees $T_1, \ldots T_k$ (from left to right) at the same level as F, define $c_m(F) = \mathit{rboundary}\ (T_m)$. We also let $c_0(F) = M - 1$. We say that $(M - 1)$ and $c_k(F) = N$ are the *external* cuts of F, and that the others are *internal* cuts.

$F_{[c_s(F)+1, c_t(F)]}$ is a $(t - s)$-forest (which we call a *subforest* of F) at the same level as F, for $0 \leq s \leq t \leq k$.

LEMMA 3.4 (gap implies two cuts). *A geometric forest F has a gap at r if and only if it has cuts at $(r - 1)$ and at r.*

Proof. By the recursive definition, no tree of base length more than 1 can have a gap. If r is a gap of F, then $s_{r,\ell}$ must be one of the constituent trees of F, hence there must be a cut on either side of it. The converse follows from the fact that the only trees of base length 1 are singleton tiles. □

3.2. Packages, glue packs, and parse trees. We now give jointly recursive (but still fairly simple) definitions of two concepts: *level-ℓ item over* $[M, N]$ and *level-ℓ package over* $[M, N]$.

DEFINITION. A *level-ℓ item over* $[M, N]$ is either a level-ℓ package over $[M, N]$ or a tile $s_{i,\ell}$ where $M \leq i \leq N$. A *level-ℓ package over* $[M, N]$ is the disjoint union of two level-$(\ell+1)$ items over $[M, N]$.

Any item p can be represented with the help of a binary tree $T(p)$, called the *parse tree* of the item. The nodes of $T(p)$ are subsets of p which are themselves items at various levels. The root of $T(p)$ is p. If p is a tile, $T(p)$ has just one node. If p is a level-ℓ package consisting of the disjoint union of level-$(\ell + 1)$ items p_1, p_2, then $T(p_1)$ and $T(p_2)$ are the left and right subtrees. Note that the construction of $T(p)$ is not unique, as there may be more than one way to represent a package as the union of two items.

We warn the reader that, in spite of the similarity of the recursive definitions, items are radically different from geometric trees. In particular, they need not be connected. There is a relationship between the two concepts, though. We shall see that every level-ℓ geometric k-forest of base length d is the disjoint union of precisely d level-ℓ tiles and $(d - k)$ level-ℓ packages.

The essence of the Package Merge algorithm is to build "optimal" packages at each level ℓ by combining level-$(\ell + 1)$ tiles and optimal level-$(\ell + 1)$ packages. The optimal level-0 tree over $[1, n]$ will then be B^0, together with the disjoint union of precisely $(n - 1)$ optimal level-0 packages. The tree corresponding to this optimal geometric tree is the solution to the problem, i.e., the minimal cost tree.

DEFINITION. Let Q be a level-ℓ skyline over $[M, N]$ and p be a level-ℓ' item, $\ell' \geq \ell$, over $[M, N]$, disjoint from Q. Then p is called a *level-ℓ' glue-pack* for Q if and only if p is level-ℓ' connected with respect to Q and one of the following two conditions holds:

(i) p is a tile;

(ii) $p = p_1 \cup p_2$, where p_1 is a level-$(\ell' + 1)$ glue-pack with respect to Q, and p_2 is a level-$(\ell' + 1)$ glue-pack with respect to $Q \cup p_1$.

Figure 7 shows an example of a package that is a glue-pack with respect to a polygon and an example of a package that is not a glue-pack with respect to that polygon.

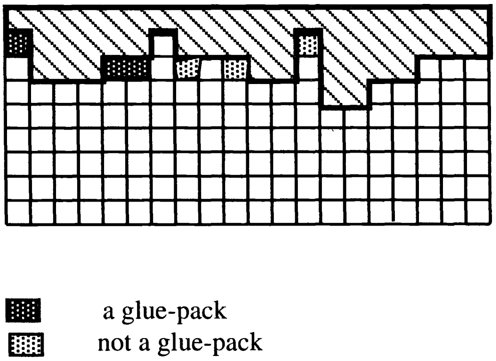

FIG. 7. *Examples of a package that is a is a glue-pack and another that is not a glue-pack with respect to a skyline.*

If p is a glue-pack with respect to some polygon Q then a parse tree for p implied by the definition of a glue-pack is called a *normal parse tree with respect to Q*. Formally, if p is a package, and if p_1, p_2 are as given in the definition, then the left and right subtrees of the normal parse tree of p must be a normal parse tree for p_1 with respect to Q, and a normal parse tree for p_2 with respect to $Q \cup p_1$, respectively. (In spite of this restriction, a normal parse tree need not be unique.)

Immediately from the definition of a glue-pack we have the following lemmas, which can be proved by induction on the parse tree of a glue-pack, using Remark 3.3.

LEMMA 3.5. *If $A \subseteq B$ are skylines, and if p is a glue-pack with respect to A and is disjoint from B, then p is a glue-pack with respect to B.*

LEMMA 3.6. *If A and B are skylines, and if p is a glue-pack with respect to A and also with respect to B, then p is a glue-pack with respect to $A \cap B$.*

LEMMA 3.7. *If p is any package such that $p_{[M,N]} = p$, then p is a glue-pack over a skyline A if and only if p is a glue-pack over $A_{[M,N]}$.*

LEMMA 3.8. *If $\ell' > \ell$, p is a level-ℓ' glue-pack with respect to a level-ℓ skyline Q over $[M, N]$, and if either $\ell' > (\ell + 1)$ or p is not a tile, then p is also a level-ℓ' glue-pack with respect to $\left(Q - B^{\ell}\right) \cup B_{[M,N]}^{(\ell+1)}$.*

Informally, the lemma below states that if p is a glue-pack that spans a gap, then it must "fill" the gap, and cannot extend beyond both boundaries of the gap.

LEMMA 3.9 (gap-filling property). *If Q is a skyline that does not contain the tile $s_{i,\ell+1}$, and if p is a level-ℓ glue-pack with respect to Q, then we have what follows.*

1. *If p spans i, then either $p = s_{i,\ell}$ or $s_{i,\ell+1} \in p$.*
2. *Either rboundary $(p) \leq i$ or lboundary $(p) \geq i$.*

Proof. The proof is by induction on the number of tiles in p. If p is a tile, the result is trivial, so assume p is a package. Let p_1, p_2 be the children of p in its parse tree. If p does not span i, the result is trivial, so assume p spans i. Since $Q \cup p$ is a skyline, $s_{i,\ell+1} \in p$, since otherwise $Q \cup p$ would not be level-ℓ connected. We can let $p_1 = s_{i,\ell+1}$. Since p_2 is a glue-pack with respect to $Q \cup p_1$ which does not contain $s_{i,\ell+2}$, the inductive hypothesis guarantees that either *rboundary* $(p_2) \leq i$ or *lboundary* $(p_2) \geq i$, and we are done. □

We now present the main result of this section.

THEOREM 3.10. *If Q is a level-ℓ k-forest over $[M, N]$ where $k > 1$ and p is a level-ℓ glue-pack with respect to Q, then $Q \cup p$ is a level-ℓ $(k - 1)$-forest over $[M, N]$.*

Proof. We prove the theorem by backwards induction on the level, ℓ, and within each level by induction on the base length.

If $\ell = L$ then $B^{\ell}_{[M,N]}$ is the only level-ℓ forest over $[M, N]$. Similarly, for any ℓ, if $M = N$ then $s_{M,\ell}$ is the only level-ℓ forest over $[M, N]$. Thus, if $\ell = L$ or the base length is 1, the theorem holds vacuously.

The method we use for the inductive step is to break Q into three subforests (a subforest can be empty) by using two cuts. One subforest F' (say, an s-forest) spans p, and the other two (say, an a-forest F'' and a b-forest F''', where $a + s + b = k$) are to the left and right of F' and are unaffected by p. We show that $F' \cup p$ is an $(s - 1)$-forest over the same base interval as F', and thus $F \cup p = F'' \cup (F' \cup p) \cup F'''$ is a $(k - 1)$-forest.

Assume that the statement of the theorem is true for all $\ell' > \ell$ and, within ℓ, for all M', N' such that $(N' - M') < (N - M)$. Let Q be a level-ℓ k-forest over $[M, N]$. Let p be a level-ℓ glue-pack with respect to Q. Note that p cannot be a tile since it must be disjoint from Q. Let $T(p)$ be a normal parse tree for p, and let p_1, p_2 be the left and right children of p in this parse tree.

Consider the following three cases, illustrated in Fig. 8.

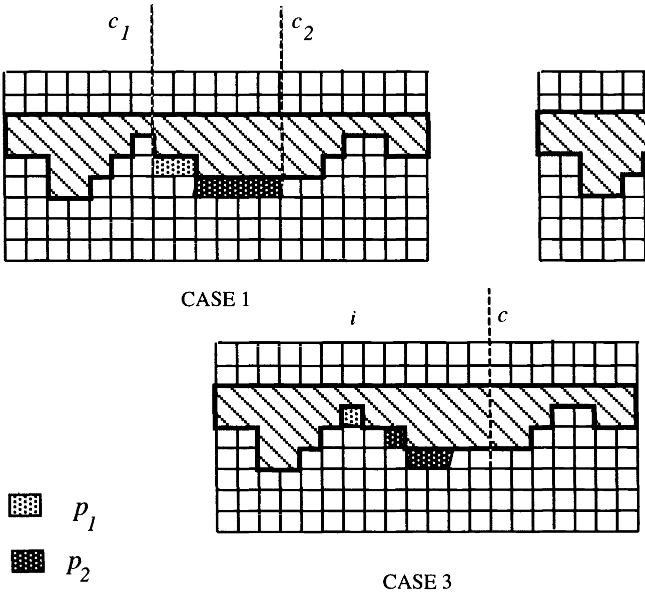

FIG. 8. *The three cases considered in the proof of Theorem* 3.10.

Case 1. Both p_1 and p_2 are level-$(\ell + 1)$ packages. Let c_1 be the largest cut that is less than *lboundary* $(p_1 \cup p_2)$ and let c_2 be the smallest cut that is greater than or equal to

$rboundary(p_1 \cup p_2)$. Let $F' = Q_{[c_1+1,c_2]}$. Since $p_1 \cup p_2$ is level-ℓ connected with respect to Q, we have, by Lemma 3.9, that Q has no gaps between c_1 and c_2. Thus, by Lemma 3.1, $F' - B^\ell$ is a level-$(\ell + 1)$ $2s$-forest. By the definition of a glue-pack, p_1 is a level-$(\ell + 1)$ glue-pack with respect to $F' - B^\ell$ and p_2 is a level-$(\ell + 1)$ glue-pack with respect to $(F' - B^\ell) \cup p_1$.

By the inductive hypothesis, $(F' - B^\ell) \cup p_1$ is a level-$(\ell + 1)$ $(2s - 1)$-forest over $[c_1 + 1, c_2]$, and $(F - B^\ell) \cup p_1 \cup p_2 = (F - B^\ell) \cup p$ is a level-$(\ell + 1)$ $(2s - 2)$-forest over the same base interval. By Lemma 3.1, $F' \cup p_1 \cup p_2 = F' \cup p$ is an $(s - 1)$-forest over $[c_1 + 1, c_2]$, and therefore $Q \cup p$ is a level-ℓ $(k - 1)$-forest over $[M, N]$.

Case 2. Both p_1 and p_2 are level-$(\ell+1)$ tiles. Let $p_1 = s_{i,\ell+1}$ and $p_2 = s_{j,\ell+1}$, and $i < j$. Then $(i - 1)$, i, $(j - 1)$, and j are cuts of Q, by Lemma 3.4. Let $F' = Q_{[i,j]}$. Then $Q_{[i+1,j-1]}$ is an $(s - 2)$-forest. By Lemma 3.1, $Q_{[i+1,j-1]} - B^\ell$ is a level-$(\ell + 1)$ $(2s - 4)$-forest over $[i + 1, j - 1]$, and thus $(Q_{[i+1,j-1]} - B^\ell) \cup p_1 \cup p_2 = (F' - B^\ell) \cup p_1 \cup p_2 = (F' - B^\ell) \cup p$ is a level-$(\ell + 1)$ $(2s - 2)$-forest over $[i, j]$.

By Lemma 3.1, $F' \cup p$ is a level-ℓ $(s - 1)$-forest over $[i, j]$. Thus $Q \cup p$ is a level-ℓ $(k - 1)$-forest over $[M, N]$.

Case 3. One of the p_i is a level-$(\ell + 1)$ tile and the other is a level-$(\ell + 1)$ package. We can assume that p_1 is a tile (let $p_1 = s_{i,\ell+1}$) and that p_2 is a package.

Then i is a gap of Q and $(i - 1)$ and i are cuts, by Lemma 3.4. By Lemma 3.9, either $rboundary(p_2) \leq i$ or $lboundary(p_2) \geq i$. Without loss of generality, the second case holds. Let c be the smallest cut of Q that is greater than or equal to *rboundary* (p_2), and let $F' = Q_{[i,c]}$. Then $Q_{[i+1,c]}$ is a level-ℓ $(s - 1)$-forest, hence, by Lemma 3.1, $Q_{[i+1,c]} - B^\ell$ is a level-$(\ell + 1)$ $(2s - 2)$-forest over $[i + 1, c]$, and $\left(Q_{[i+1,c]} - B^\ell\right) \cup s_{i,\ell+1}$ is a level-$(\ell + 1)$ $(2s - 1)$-forest over $[i, c]$. From Lemma 3.8, p_2 is a glue-pack with respect to $\left(Q_{[i+1,j]} - B^\ell\right) \cup s_{i,\ell+1}$. By the inductive hypothesis, $\left(Q_{[i+1,c]} - B^\ell\right) \cup s_{i,\ell+1} \cup p_2 = \left(Q_{[i+1,c]} - B^\ell\right) \cup p$ is a level-$(\ell + 1)$ $(2s - 2)$-forest over $[i, c]$. Thus, by Lemma 3.1, $F' \cup p$ is a level-ℓ $(s - 1)$-forest over $[i, c]$ and $Q \cup p$ is a level-ℓ $(k - 1)$-forest over $[M, N]$.

This concludes the proof of Theorem 3.10. □

4. Geometric weighted trees.

In this section we give a polygonal interpretation of weighted binary forests.

We define an instance of the *geometric tree* problem to consist of integers $n \geq 1$ and $L \geq \log_2 n$, and an assigned *weight* to every tile, as defined in §3. (For each $i \in [1, n]$ and each $\ell \in [0, L]$, we write $|s_{i,\ell}|$ to be the weight of $s_{i,\ell}$.) The weight function must satisfy

(i) $|s_{i,\ell}| \geq 0$ [nonnegativity], and

(ii) $|s_{i,\ell+1}| \geq |s_{i,\ell}|$ [monotonicity].

The problem is to find a level-0 geometric tree over $[1, n]$ which has minimum total weight.

To simplify our presentation we assume that the following hypothesis holds:

(iii) If $A \neq B$ are sets of tiles, then $|A| \neq |B|$ [uniqueness hypothesis].

We will show in §7 that the general case reduces to the case where the uniqueness hypothesis holds. Specifically, in case two sets of tiles have the same weight, we break the tie in a consistent way by imagining that each tile has a certain "infinitesimal" additional weight.

4.1. Reduction.

The weighted binary tree problem reduces to the geometric tree problem, as follows. Let $|s_{i,\ell}|$ be defined to be $w_{i,\ell} - w_{i,\ell-1}$ for $\ell > 0$, and let $|s_{i,0}| = 0$.

Nonnegativity and monotonicity follow from monotonicity and concavity, respectively, for the weighted binary tree problem.

The fact that this gives a true reduction comes from the following lemma, which follows immediately from the definition of the level-0 representation of a tree.

LEMMA 4.1. *The cost of a binary tree is equal to the weight of its level*-0 *representation over* $[1, n]$.

4.2. Optimal forests. Henceforth in this section, we assume that we are given an instance of the geometric tree problem which satisfies the uniqueness hypothesis.

Define the *optimal level-ℓ k-forest over* $[M, N]$ (denoted $F[M, N, k, \ell]$) to be that unique level-ℓ k-forest over $[M, N]$ of minimal weight, defined if and only if

$$(N - M + 1)2^{\ell-L} \leq k \leq (N - M + 1).$$

LEMMA 4.2. *Any subforest of an optimal forest is optimal.*

Proof. If $F[M, N, k, \ell]$ contains a nonoptimal subforest over a subinterval $[M', N']$, simply replace that subforest by the appropriate optimal forest and obtain an improvement of $F[M, N, k, \ell]$, which is a contradiction. □

We will also need the following lemma, whose proof is fairly complex, but related to the various "monotonicity" lemmas of [1], [4], [10]–[12], [16], and [17].

LEMMA 4.3 (interleaving property). *If M, N, k, ℓ are given where $1 \leq M < N \leq n$, $0 \leq \ell \leq L$, $(N - M + 1)2^{\ell-L} \leq k \leq N - M$, and $0 \leq m \leq k$, then*

$$c_m(F[M, N, k + 1, \ell]) \leq c_m(F[M, N, k, \ell]) \leq c_{m+1}(F[M, N, k + 1, \ell]).$$

The proof of Lemma 4.3 is given in §8.

The interleaving property has a number of immediate corollaries which allow us to relate the shapes of $F[M, N, k + 1, \ell]$ and $F[M, N, k, \ell]$.

LEMMA 4.4. *If $F[M, N, k, \ell]$ has a gap at r, then $F[M, N, k + 1, \ell]$ has a gap at r.*

Proof. By Lemma 3.4, we can write

$$\begin{aligned} c_{m-1}(F[M, N, k, \ell]) &= r - 1, \\ c_m(F[M, N, k, \ell]) &= r. \end{aligned}$$

By Lemma 4.3, $c_m(F[M, N, k + 1, \ell])$ is equal to either $(r - 1)$ or r. Those two cases are seen to be equivalent by using the natural left–right symmetry of the entire problem. Thus, without loss of generality, we may assume that $c_m(F[M, N, k + 1, \ell]) = r$. By Lemma 4.2, $F[M, N, k + 1, \ell]_{[M,r]} = F[M, r, m, \ell] = F[M, N, k, \ell]_{[M,r]}$. By Lemma 3.4, we are done. □

LEMMA 4.5. *If $F[M, N, k + 1, \ell]$ has an internal gap at r, $F[M, N, k, \ell]$ and $F[M, N, k + 1, \ell]$ have a common internal cut, either at $(r - 1)$ or at r.*

Proof. By Lemma 3.4, we can write

$$\begin{aligned} c_{m-1}(F[M, N, k + 1, \ell]) &= r - 1, \\ c_m(F[M, N, k + 1, \ell]) &= r. \end{aligned}$$

By Lemma 4.3, $c_{m-1}(F[M, N, k, \ell])$ is equal to either $(r - 1)$ or r. □

LEMMA 4.6. *If $F[M, N, k, \ell]$ and $F[M, N, k + 1, \ell]$ have a common cut, c, then either*

$$F[M, N, k, \ell]_{[M,c]} = F[M, N, k + 1, \ell]_{[M,c]}$$

or

$$F[M, N, k, \ell]_{[c+1,N]} = F[M, N, k + 1, \ell]_{[c+1,N]}.$$

Proof. Write $c = c_m(F[M, N, k, \ell])$. If $c = c_m(F[M, N, k + 1, \ell])$, then, by Lemma 4.2,

$$F[M, N, k, \ell]_{[M,c]} = F[M, N, k + 1, \ell]_{[M,c]}.$$

If $c = c_{m+1}(F[M, N, k+1, \ell])$, then, by Lemma 4.2,

$$F[M, N, k, \ell]_{[c+1,N]} = F[M, N, k+1, \ell]_{[c+1,N]}.$$

By Lemma 4.3, there are no other possibilities. □

THEOREM 4.7 (inclusion property). *For any M, N, k, ℓ such that $1 \leq M < N \leq n$, $0 \leq \ell \leq L$, and $(N - M + 1)2^{\ell - L} \leq k \leq N - M$,*

$$F[M, N, k, \ell] = F[M, N, k+1, \ell] \cup p$$

where p is the smallest weight level-ℓ package which is a glue-pack with respect to $F[M, N, k, \ell]$.

We will prove the inclusion property by backwards induction on ℓ. Thus we need to examine the dependency between optimal level-$(\ell + 1)$ forests and optimal level-ℓ forests. Such a dependency is given in Lemmas 4.8, 4.10, and 4.11 and illustrated in Fig. 9 (a), (b), and (c).

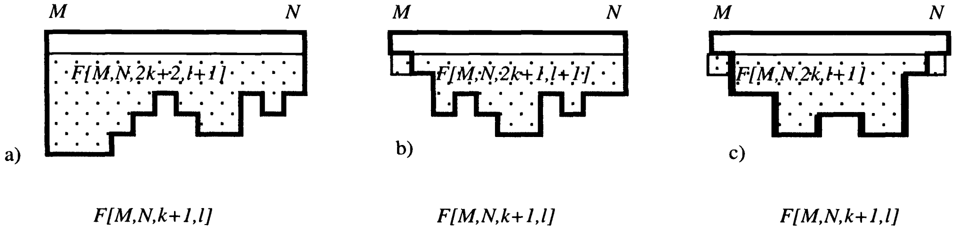

FIG. 9. *Illustration of Lemmas* 4.8, 4.10, *and* 4.11.

LEMMA 4.8. *If $F[M, N, k+1, \ell]$ does not have gaps, then $F[M, N, 2k+2, \ell+1] = F[M, N, k+1, \ell] - B^\ell$.*

Proof. If not, by Lemma 3.1, $F[M, N, 2k+2, \ell+1] \cup B^\ell_{[M,N]}$ would be a level-ℓ $(k+1)$-forest over $[M, N]$ of smaller weight than $F[M, N, k+1, \ell]$, a contradiction. □

For the proofs of Lemmas 4.10 and 4.11, we will need the following technical lemma.

LEMMA 4.9. *If F is any level-ℓ k-forest over $[M, N]$ which does not have a gap at r, where $r = M$ or $r = N$, then there exists a level-ℓ $(k+1)$-forest $F' \subseteq F$ over $[M, N]$ such that $|F'| < |F - s_{r,\ell}|$.*

Proof. Without loss of generality, $r = M$. Consider the binary forest $\mathcal{F}$ represented by the level-ℓ forest F (see Fig. 10 (a)). The first leaf, v_M, of $\mathcal{F}$ has depth $d \geq 1$. Let v be the sibling of v_M. Remove v_M from $\mathcal{F}$ together with its parent and promote the sibling of v_M (and all its descendants) one level up (see Fig. 10 (b)). The resulting binary forest has k trees. Now we add the single-element tree containing just the leaf v_M at the front of this forest. The new binary forest, which we refer to as $\mathcal{F}'$, has $(k+1)$ trees. Let F' be the level-ℓ representation of $\mathcal{F}'$ over $[M, N]$ (see Fig. 10 (c)). We consider how F' differs from F.

Removing the leaf v_M from $\mathcal{F}$ corresponds to deleting the column of all tiles of index M from the geometric representation, F. Promoting all descendants of v corresponds to deleting the bottom (i.e., greatest level) tile of F of each index in the interval $[M+1, M+t]$, where t is the number of leaves in the subtree rooted at v.

Reinserting v_M as a tree of size 1 corresponds to reinserting the tile $s_{M,\ell}$. F' can thus be obtained from F by removing a set of tiles, that contains, in particular, $s_{M,\ell+1}$. Since $|s_{M,\ell}| \leq |s_{M,\ell+1}|$, we are done. □

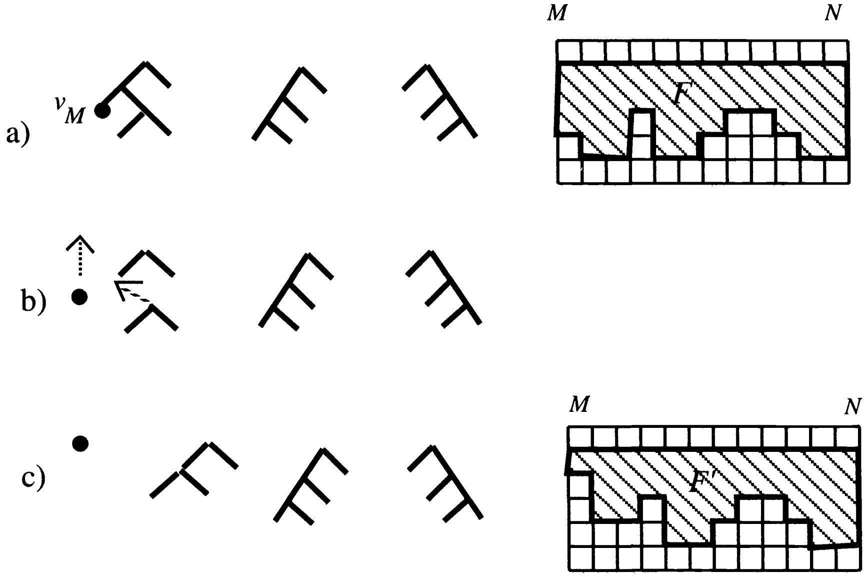

FIG. 10. *Illustration of the proof of Lemma* 4.9.

LEMMA 4.10. *If $F[M, N, k+1, \ell]$ has one external gap at r (note $r = M$ or $r = N$) and no other gaps, then*

$$F[M, N, 2k+1, \ell+1] = \left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup s_{r,\ell+1}.$$

Proof. Without loss of generality, $r = M$. Assume that the equality in the statement of the lemma is not true. Since the right-hand side of that inequality is a level-($\ell+1$) $(2k+1)$-forest over $[M, N]$ that is not optimal, we have

$$\left|\left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup s_{M,\ell+1}\right| > |F[M, N, 2k+1, \ell+1]|.$$

Thus,

$$|F[M, N, k+1, \ell]| > \left|\left(F[M, N, 2k+1, \ell+1] \cup B^{\ell}\right) - s_{M,\ell+1}\right|.$$

If $F[M, N, 2k+1, \ell+1]$ has a gap at M, then $\left(F[M, N, 2k+1, \ell+1] \cup B^{\ell}\right) - s_{M,\ell+1}$ is a $(k+1)$-forest over $[M, N]$, which is a contradiction, since it cannot have smaller weight than the optimal forest. Otherwise, by Lemma 4.9, there exists a level-($\ell+1$) $(2k+2)$-forest F' over $[M, N]$ such that

$$\left|F[M, N, 2k+1, \ell+1] - s_{M,\ell+1}\right| > \left|F'\right|.$$

Therefore

$$|F[M, N, k+1, \ell]| > \left|F' \cup B^{\ell}_{[M,N]}\right|$$

which is a contradiction, since $F' \cup B^{\ell}_{[M,N]}$ is a $(k+1)$-forest over $[M, N]$, which cannot have smaller weight than the optimal forest. □

LEMMA 4.11. *If $F[M, N, k+1, \ell]$ has two external gaps and no internal gap then*

$$\left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup s_{M,\ell+1} \cup s_{N,\ell+1} = F[M, N, 2k, \ell+1].$$

Proof. Assume that the equality in the statement of the lemma is not true. Since the left-hand side of that inequality is a level-$(\ell+1)$ $2k$-forest over $[M, N]$ that is not optimal, we have

$$\left|\left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup s_{M,\ell+1} \cup s_{N,\ell+1}\right| > |F[M, N, 2k, \ell+1]| \,.$$

Thus,

$$|(F[M, N, k+1, \ell])| > \left|\left(F[M, N, 2k, \ell+1] - s_{M,\ell+1} - s_{N,\ell+1}\right) \cup B^{\ell}_{[M,N]}\right| .$$

If $F = F[M, N, 2k, \ell+1]$ has gaps at both M and N, then

$$\left(F[M, N, 2k, \ell+1] - s_{M,\ell+1} - s_{N,\ell+1}\right) \cup B^{\ell}_{[M,N]}$$

is a $(k+1)$-forest over $[M, N]$, which is a contradiction, since it cannot have smaller weight than the optimal forest. Otherwise, without loss of generality, F has no gap at M. By Lemma 4.9, there exists a level-$(\ell+1)$ $(2k+1)$-forest F' over $[M, N]$ such that $\left|F - s_{M,\ell+1}\right| > \left|F'\right|$.

We now consider two cases, depending on whether F' has a gap at N. Suppose F' has a gap at N. Then $\left|\left(F' - s_{N,\ell+1}\right) \cup B^{\ell}_{[M,N]}\right| < |F[M, N, k+1, \ell]|$ which is a contradiction, since $\left(F' - s_{N,\ell+1}\right) \cup B^{\ell}_{[M,N]}$ is a $(k+1)$-forest over $[M, N]$, which cannot have smaller weight than the optimal forest.

Suppose F' has no gap at N. By Lemma 4.9, there exists a level-$(\ell+1)$ $(2k+2)$-forest F'' over $[M, N]$ such that $\left|F' - s_{N,\ell+1}\right| > \left|F''\right|$. Then $\left|F'' \cup B^{\ell}_{[M,N]}\right| < |F[M, N, k+1, \ell]|$ which is a contradiction, since $F'' \cup B^{\ell}_{[M,N]}$ is a $(k+1)$-forest over $[M, N]$, which cannot have smaller weight than the optimal forest.

This concludes the proof of Lemma 4.11. □

Using Lemma 4.4, we can summarize the results of Lemmas 4.8, 4.10, and 4.11 in the following corollary.

LEMMA 4.12. *If $F[M, N, k+1, \ell]$ does not have internal gaps then*

$$\left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup B^{(\ell+1)}_{[M,N]}$$

and

$$\left(F[M, N, k, \ell] - B^{\ell}\right) \cup B^{(\ell+1)}_{[M,N]}$$

are optimal level-$(\ell+1)$ forests.

Now we are ready to conclude the proof of the inclusion property.

Proof (of Theorem 4.7). As in the proof of the Theorem 3.10, we prove the inclusion property by backwards induction on the level, ℓ, and within each level by induction on the base length. If $\ell = L$, then $F[M, N, M-N+1, L]$ is the only level-L forest over $[M, N]$. The only forests of base length 1 are singleton tiles. Thus, for $\ell = L$ or $N = M$, the theorem holds.

Assume that the theorem holds for all $\ell' > \ell$ and, within ℓ, for all $[M', N']$ such that $N' - M' < N - M$. We consider four cases depending on relative shapes of $F[M, N, k+1, \ell]$ and $F[M, N, k, \ell]$.

Case 1. $F[M, N, k, \ell]$ and $F[M, N, k+1, \ell]$ have a common internal cut, c.

In this case, by Lemma 4.6, $F[M, N, k, \ell]$ and $F[M, N, k+1, \ell]$ are identical on one side, say the left side, of the cut. Thus, for some k',

$$F[M, N, k, \ell]_{[c+1,N]} = F[c+1, N, k', \ell]$$

and

$$F[M, N, k+1, \ell]_{[c+1,N]} = F[c+1, N, k'+1, \ell].$$

By the inductive hypothesis,

$$F[c+1, N, k', \ell] = F[c+1, N, k'+1, \ell] \cup p,$$

where p is a level-ℓ glue-pack with respect to $F[c+1, N, k'+1, \ell]$. Thus p is also a level-ℓ glue-pack with respect to $F[M, N, k+1, \ell]$. Furthermore,

$$F[M, N, k, \ell] = F[M, N, k+1, \ell] \cup p.$$

Case 2. $F[M, N, k+1, \ell]$ does not have a gap.

From Lemma 4.4 it follows that $F[M, N, k, \ell]$ also does not have a gap. By Lemma 4.8 we have

$$F[M, N, k+1, \ell] - B^{\ell} = F[M, N, 2k+2, \ell+1]$$

and

$$F[M, N, k, \ell] - B^{\ell} = F[M, N, 2k, \ell+1].$$

By the inductive hypothesis we have

$$F[M, N, 2k, \ell+1] = F[M, N, 2k+2, \ell+1] \cup p_1 \cup p_2$$

where p_1 and p_2 are level-$(\ell+1)$ items such that p_1 is a glue-pack with respect to $F[M, N, 2k+2, \ell+1]$ and p_2 is a glue-pack with respect to $F[M, N, 2k+1, \ell+1] \cup p_1$. Since $F[M, N, k+1, \ell]$ does not have gaps, p_1 is a level-$(\ell+1)$ glue-pack with respect to $F[M, N, k+1, \ell]$, p_2 is a level-$(\ell+1)$ glue-pack with respect to $F[M, N, k+1, \ell] \cup p_1$, and $p_1 \cup p_2$ is level-ℓ connected with respect to $F[M, N, k+1, \ell]$. Therefore

$$F[M, N, k, \ell] - F[M, N, k+1, \ell] = p_1 \cup p_2$$

and $p_1 \cup p_2$ is a glue-pack with respect to $F[M, N, k+1, \ell]$.

Case 3. $F[M, N, k+1, \ell]$ has exactly one external gap.

By symmetry, we may assume that the one external gap of $F[M, N, k+1, \ell]$ is at M.

We first show that we may assume that $F[M, N, k+1, \ell]$ has only one gap and that $F[M, N, k, \ell]$ has no gaps. If $F[M, N, k+1, \ell]$ has an internal gap, then we can reduce to Case 1 by Lemma 4.5. If $F[M, N, k, \ell]$ has a gap at M, then M is a common internal cut, and we again reduce to Case 1. By Lemma 4.4, $F[M, N, k, \ell]$ cannot otherwise have a gap.

By Lemma 4.8 we have

$$F[M, N, k, \ell] - B^{\ell} = F[M, N, 2k, \ell+1]$$

and by Lemma 4.10 we have

$$\left(F[M, N, k+1, \ell] - B^{\ell}\right) \cup s_{r,\ell+1} = F[M, N, 2k+1, \ell+1].$$

Thus

$$F[M, N, k, \ell] = F[M, N, k+1, \ell] \cup s_{r,\ell+1} \cup p_2,$$

where $p_2 = F[M, N, 2k, \ell + 1] - F[M, N, 2k + 1, \ell + 1]$ is a level-$(\ell + 1)$ glue-pack with respect to $F[M, N, 2k + 1, \ell + 1]$. Thus p_2 is a level-$(\ell + 1)$ glue-pack with respect to $F[M, N, k + 1, \ell] \cup s_{r,\ell+1}$. Since $F[M, N, k + 1, \ell]$ does not have an internal gap, $p = p_2 \cup s_{r,\ell+1}$ is level-ℓ connected with respect to $F[M, N, k + 1, \ell]$ and therefore is a level-ℓ glue-pack with respect to $F[M, N, k + 1, \ell]$.

Case 4. $F[M, N, k + 1, \ell]$ has two external gaps.

As in the previous case, we assume that $F[M, N, k + 1, \ell]$ does not have internal gaps and that $F[M, N, k, \ell]$ does not have any gaps, since otherwise the problem can be reduced to Case 1. By Lemma 4.8 we have

$$F[M, N, k, \ell] - B^{\ell} = F[M, N, 2k, \ell + 1]$$

and by Lemma 4.11 we have

$$\left(F[M, N, k + 1, \ell] - B^{\ell}\right) \cup s_{M,\ell+1} \cup s_{N,\ell+1} = F[M, N, 2k, \ell + 1].$$

Thus

$$F[M, N, k, \ell] = F[M, N, k + 1, \ell] \cup s_{M,\ell+1} \cup s_{N,\ell+1}.$$

Note that $s_{M,\ell+1} \cup s_{N,\ell+1}$ is a glue-pack with respect to $F[M, N, k + 1, \ell]$. The result follows.

This concludes the proof of Theorem 4.7. □

4.3. The Package Search algorithm. Theorem 4.7 gives us the first hint leading to an algorithm for construction of an optimal alphabetic height-restricted tree. Namely, we need to find the smallest weight package that is a level-0 glue-pack with respect to B^0. This gives us the optimal height-restricted $(n - 1)$-forest. Then we find the smallest weight package that is a glue-pack with respect to that forest. This leaves us with the optimal height-restricted $(n - 2)$-forest. We repeat this step until we construct the optimal tree.

Theorem 4.7 gives rise to the following definition.

DEFINITION. *For any M, N, r, ℓ such that*

$$1 \leq M < N \leq n,\ 0 \leq \ell \leq L,\ \textit{and}\ 1 \leq r \leq N - M - \lceil (N - M + 1)2^{\ell - L} \rceil,$$

define the optimal level-ℓ package of rank r over $[M, N]$, $p^{\ell}_{[M,N]}(r)$, to be the difference

$$p^{\ell}_{[M,N]}(r) = F[M, N, N - M - r + 1, \ell] - F[M, N, N - M - r + 2, \ell].$$

An optimal level-ℓ item is defined to be either an optimal level-ℓ package or a level-ℓ tile.

With the above definition, the algorithm described informally at the beginning of this section can be described as follows:

ALGORITHM 1. **Package Search (L)**

```
1. $F^{\ell} := B^{\ell}$;
2. for $r := 1$ to $n - \lceil n2^{\ell-L} \rceil - 1$ do
   2.1. find $p^{\ell}_{[1,n]}(r)$;
   2.2. $F^{\ell} := F^{\ell} \cup p^{\ell}_{[1,n]}(r)$.
```

The most difficult step of the above algorithm is step 2.1, in which we find the optimal level-ℓ package of rank r, $p^{\ell}_{[1,n]}(r)$. In the next section we will examine properties of optimal packages that lead to an efficient implementation of this step. In fact, we shall find that optimal level-0 packages over the interval $[1, n]$ can be constructed recursively from optimal packages of lower levels over the same interval. Consequently, in our implementation we use only optimal packages over interval $[1, n]$. However we shall find the more general definition given in this section convenient in the inductive proofs of basic properties of optimal packages.

5. Monotonicity and decomposition properties of optimal packages. In this section, we continue to assume that the uniqueness hypothesis of §4 holds.

The basic difficulty of the Package Search algorithm presented in the previous section is to describe an efficient implementation of step 2.1, in which we find the optimal level-ℓ package, $p^{\ell}_{[1,n]}(r)$, i.e., the smallest weight level-ℓ package that forms a glue-pack with respect to F^{ℓ}. Thus, we need more information about the structure of optimal glue-packs. Their basic properties are given in the theorem below.

THEOREM 5.1 (main theorem). *Given M, N, r, ℓ, if $1 \leq M < N \leq n$, $0 \leq \ell \leq L$, and $1 \leq r \leq N - M - \lceil (N - M + 1)2^{\ell - L} \rceil$, then we have the following items.*

1. *The decomposition property*:

   1.1 *$p^{\ell}_{[M,N]}(r)$ is the smallest weight union of two level-$(\ell+1)$ items that are optimal over $[M, N]$ which is level-ℓ connected with respect to $F[M, N, N - M - r + 2, \ell]$.*

   1.2 *$p = p^{\ell}_{[M,N]}(r)$ has a normal parse tree with both children of p being optimal level-$(\ell + 1)$ items and the right child being heavier than the left child.*

2. *The monotonicity property*:

   If $r > 1$, then $\left|p^{\ell}_{[M,N]}(r-1)\right| < \left|p^{\ell}_{[M,N]}(r)\right|$.

3. *The package span property*:

   Write $p = p^{\ell}_{[M,N]}(r)$. If $i \in [lboundary(p), rboundary(p)]$ then $|p| > \left|s_{i,\ell+1}\right|$.

Proof. The proof is by triple induction: within an interval on the rank, r, of an optimal level-ℓ package, within the level, on the base length of the interval, and backwards induction on the level ℓ.

Formally, our inductive hypothesis is that the statement of the theorem holds for any of the following three "predecessor" situations:

(i) The same values for $[M, N]$ and ℓ, and a smaller value for r.

(ii) The same value for ℓ, a proper subinterval $[M', N']$ for $[M, N]$, and any value for r.

(iii) If $\ell < L$: $(\ell + 1)$ for ℓ, and any values for $[M, N]$ and r.

For $\ell = L$, the result follows vacuously from the fact that there are no level-L packages.

Assuming the inductive hypothesis, we first prove the decomposition property, then the monotonicity property, and finally the package span property.

The following lemma will be used in the proof of the decomposition property and the monotonicity property.

LEMMA 5.2. *Suppose Q is a skyline, and that p and q are level-$(\ell + 1)$ items which are optimal over $[M, N]$ such that q is a glue-pack with respect to Q, p is a glue-pack with respect to $Q \cup q$, and $|p| < |q|$. Then p is a glue-pack with respect to Q, and q is a glue-pack with respect to $Q \cup p$.*

Proof. The second part of the conclusion follows immediately from Lemma 3.5. Thus, we need only show that p is a glue-pack with respect to Q. If p is a tile, this is trivial, so assume p is a package. The remainder of the proof is in two cases, depending on whether q is a tile or a package.

Suppose q is a tile, say, $s_{i,\ell+1}$. By Lemma 3.9, p cannot span i, since otherwise it must contain $s_{i,\ell+2}$, which is at least as heavy as q. Without loss of generality, *lboundary* $(p) > i$. Applying Lemma 3.7 twice, we see that p is a glue-pack with respect to $(Q \cup q)_{[i+1,N]} = Q_{[i+1,N]}$, and thus also with respect to Q.

Suppose q is a package. Let $F = F[M, N, N - M - t + 2, \ell + 1]$, where t is that rank for which $p = p^{\ell+1}_{[M,N]}(t)$. By the definition of optimal package, p is a glue-pack with respect to F. By monotonicity at level $(\ell + 1)$, which follows from part (iii) of the inductive hypothesis, $q = p^{\ell+1}_{[M,N]}(t')$ for some $t' > t$, hence $q \cap F = \emptyset$. By Lemma 3.6, p is a glue-pack with respect to $F \cap (Q \cup q) = F \cap Q$. By Lemma 3.5, p is a glue-pack with respect to Q. □

5.1. The proof of the decomposition property. Let $p = p^{\ell}_{[M,N]}(r)$ for $\ell < L$, and let p_1, p_2 be the children of p in its normal parse tree. We need only prove that p_1 and p_2 can be chosen to be level-$(\ell + 1)$ optimal items over $[M, N]$, since the other parts of the decomposition property then follow by the definition of $p^{\ell}_{[M,N]}(r)$ and by Lemma 5.2. If both p_1 and p_2 are tiles, the decomposition property follows immediately. Thus, we can assume that at least one of them, namely p_2, is a level-$(\ell + 1)$ package.

By the definition of an optimal level-ℓ package over $[M, N]$ of rank r, we have

$$p = F[M, N, N - M - r + 1] - F[M, N, N - M - r + 2].$$

Let i be the largest integer such that i is a gap of $F[M, N, N - M - r + 2]$ and $i \leq$ *lboundary* (p). Let $i = M$ if such a gap does not exist. Let j be the smallest integer such that j is a gap of $F[M, N, N - M - r + 2]$ and $j \geq rboundary(p)$. Let $j = N$ if such a gap does not exist.

We note that p is an optimal package over $[i, j]$. If q were a better choice of level-ℓ glue-pack over $[i, j]$, then, by Lemma 3.7, q would also be a better choice of level-ℓ glue-pack over $[M, N]$, so p would not be optimal over $[M, N]$.

We consider two cases: when $[i, j] = [M, N]$ and $[i, j] \neq [M, N]$.

If $[i, j] = [M, N]$ then, by the definition of i and j, $F[M, N, N - M - r + 2]$ has no internal gaps. Thus, by Corollary 4.12,

$$F_1 = \left(F[M, N, N - M - r + 2, \ell] - B^{\ell}\right) \cup B^{\ell+1}_{[M,N]}$$

and

$$F_2 = \left(F[M, N, N - M - r + 1, \ell] - B^{\ell}\right) \cup B^{\ell+1}_{[M,N]}$$

are optimal forests over $[M, N]$. If neither p_1 nor p_2 is a tile, then

$$p = p_1 \cup p_2 = F_2 - F_1.$$

By the definition of an optimal package, F_2 is obtained from F_1 by adding two level-$(\ell + 1)$ optimal packages over $[M, N]$. Thus, p_1 and p_2 can be chosen to be optimal over $[M, N]$, and we are done.

If p_1 is a tile, then

$$p_2 = F_2 - F_1.$$

Thus, by the definition of an optimal package, p_2 is an optimal level-$(\ell + 1)$ package over $[M, N]$, and we are done.

This concludes the proof of the decomposition property for the case when $[M, N] = [i, j]$.

Assume now that $[i, j]$ is a proper subinterval of $[M, N]$. Let

$$F = \left(F[M, N, N - M - r + 2, \ell] - B^{\ell}\right) \cup B^{\ell+1}_{[M,N]}.$$

By part (i) of the inductive hypothesis, F is a union of level-$(\ell + 1)$ items which are optimal over $[M, N]$.

By Lemmas 4.2, 4.4, and 4.12, since $F[M, N, N - M - r + 2, \ell]_{[i,j]}$ does not have internal gaps, $F_{[i,j]}$ and $F_{[i,j]} \cup p$ are optimal $(\ell + 1)$-forests over $[i, j]$.

Thus, if p_1 is a tile, then $F_{[i,j]} \cup p = F_{[i,j]} \cup p_2$, hence p_2 is optimal over $[i, j]$. If p_1 is a package, then p_1, p_2 can be chosen to be optimal over $[i, j]$. By Lemma 5.2, $|p_1| < |p_2|$. For $i = 1, 2$, let P_i be the union of all level-$(\ell + 1)$ packages of weight less than $|p_i|$ which are optimal over $[M, N]$. Let $F_i = P_i \cup B^{\ell+1}_{[M,N]}$, which is an optimal level-$(\ell + 1)$ forest, by monotonicity at level $(\ell + 1)$. We will prove the following two claims:

Claim 1. If p_1 is a package, then $(F_1)_{[i,j]} = F_{[i,j]}$.

Claim 2. If p_1 is an optimal item over $[M, N]$, then $(F_2)_{[i,j]} = F_{[i,j]} \cup p_1$.

We conclude the proof of the decomposition property, assuming Claims 1 and 2.

If p_1 is a tile, it is optimal. If p_1 is a package, let q_1 be the minimal level-$(\ell+1)$ glue-pack with respect to F_1. By definition of optimal package, q_1 is an optimal level-$(\ell + 1)$ package over $[M, N]$, and $|q_1| \geq |p_1|$, since otherwise $q_1 \subseteq P_1$. By Lemma 3.7 and Claim 1, p_1 is a glue-pack with respect to F_1, thus $|p_1| \geq |q_1|$, since otherwise q_1 would not be minimal. By the uniqueness hypothesis, $p_1 = q_1$. Thus, p_1 is an optimal level-$(\ell + 1)$ package over $[M, N]$.

Let q_2 be the minimal level-$(\ell+1)$ glue-pack with respect to F_2. By definition of optimal package, q_2 is optimal over $[M, N]$, and $|q_2| \geq |p_2|$, since otherwise $q_2 \subseteq P_2$. By Lemma 3.7 and Claim 2, p_2 is a glue-pack with respect to F_2, thus $|p_2| \geq |q_2|$, since otherwise q_2 would not be minimal. By the uniqueness hypothesis, $p_2 = q_2$. Thus, p_2 is an optimal level-$(\ell + 1)$ package over $[M, N]$.

Thus, the decomposition property holds if Claims 1 and 2 are true. It remains only to prove those claims.

We will use the following notation:

We define a COS (COS = *Component Of Subforest*) *over* $[M', N']$ to be an optimal level-$(\ell+1)$ forest over a subinterval $[M', N'] \subseteq [M, N]$ which is the disjoint union of level-$(\ell+1)$ items which are optimal over $[M, N]$.

In particular, if either $M' = M$ or M' is a gap of $F[M, N, N - M - r + 2, \ell]$, and if either $N' = N$ or N' is a gap of $F[M, N, N - M - r + 2, \ell]$, then $F_{[M',N']}$ is a COS.

LEMMA 5.3. *If Q is a* COS *over $[M', N'] \subseteq [M, N]$, then those level-$(\ell + 1)$ items in Q which are optimal over $[M, N]$ are also optimal items over $[M', N']$.*

Proof. We only need to consider packages, since tiles are automatically optimal items. Write $Q = B^{\ell+1}_{[M',N']} \cup q_1 \cup q_2 \cup \cdots \cup q_m$, where each q_t is a level-$(\ell + 1)$ package which is optimal over $[M, N]$, and where $|q_t| < |q_{t+1}|$. We prove $q_t = p^{\ell+1}_{[M',N']}(t)$ for each t. Suppose this is not the case. Pick the smallest t for which $q_t \neq q'_t = p^{\ell+1}_{[M',N']}(t)$. Since Q is the optimal $(N' - M' - m + 1)$-forest at level $(\ell+1)$ over $[M', N']$, it contains $p^{\ell+1}_{[M',N']}(t')$ for all $t' \in [1, m]$. Hence, in particular, it contains q'_t. Let F_t be the level-$(\ell + 1)$ forest over $[M, N]$ consisting of $B^{\ell+1}_{[M,N]}$ together with all level-$(\ell + 1)$ packages of weight less than $|q_t|$ which are optimal over $[M, N]$. By monotonicity at level $(\ell + 1)$, F_t is an optimal forest over $[M, N]$, and q_t is the smallest level-$(\ell + 1)$ glue-pack with respect to F_t.

Let $H = B^{\ell+1}_{[M',N']} \cup q_1 \cup \cdots \cup q_{t-1} = F[M', N', N' - M' - t + 2, \ell + 1]$, an optimal level-$(\ell + 1)$ forest over $[M', N']$. Since q'_t is disjoint from $H = F_t \cap Q$ and is a subset of Q, it is disjoint from F_t. Since q'_t is level-$(\ell + 1)$ connected with respect to H, it is level-$(\ell + 1)$ connected with respect to F_t, since $H \subseteq F_t$. Thus, q'_t is a level-$(\ell + 1)$ glue-pack with respect to F_t, and by optimality of q_t and uniqueness, $|q'_t| > |q_t|$.

On the other hand, q_t is level-$(\ell + 1)$ connected with respect to both F_t and Q, hence also with respect to H, by Remark 3.3. Since q_t is disjoint from H, it is a glue-pack with respect to H, contradicting the minimality of q'_t. □

Let Q be a COS over $[M', N']$, and q' be the smallest weight level-$(\ell + 1)$ glue-pack with respect to Q. Note that q' is optimal over $[M', N']$. Define $SE(Q)$ to be the union of all level-$(\ell+1)$ packages, x, which are optimal over $[M, N]$ and satisfy the following conditions:

(i) $|x| \leq |q'|$;

(ii) $x \cap Q = \emptyset$;

(iii) $x_{[M',N']} \neq \emptyset$.

Define $S(Q)$ to be to be the union of all level-$(\ell+1)$ packages, x, which are optimal over $[M, N]$ and satisfy the following conditions:

(i) $|x| < |q'|$;
(ii) $x \cap Q = \emptyset$;
(iii) $x_{[M',N']} \neq \emptyset$.

Define $G(Q)$ to be the union of all level-$(\ell+1)$ packages, x, which are optimal over $[M, N]$ and satisfy the following conditions:

(i) $|x| > |q'|$;
(ii) $x \subseteq Q$.

LEMMA 5.4. *If Q is a* COS *over $[M', N'] \subseteq [M, N]$, q' is the smallest weight level-$(\ell+1)$ glue-pack with respect to Q, and q is the least weight member of $SE(Q)$, then $q_{[M',N']} = q$ implies that $q = q'$.*

Proof. If $[M', N'] = [M, N]$, then the lemma is trivial since q' is optimal over $[M', N'] = [M, N]$. Thus, we can assume $[M', N']$ is a proper subinterval of $[M, N]$. Let F_q be the level-$(\ell+1)$ forest over $[M, N]$ consisting of $B^{\ell+1}_{[M,N]}$ together with all level-$(\ell+1)$ packages of weight less than $|q|$ which are optimal over $[M, N]$. By monotonicity at level $(\ell+1)$, F_q is an optimal forest over $[M, N]$, and q is the smallest level-$(\ell+1)$ glue-pack with respect to F_q.

By Lemma 5.3, we can write $Q = B^{\ell}_{[M',N']} \cup q_1 \cup \cdots \cup q_m$, where each q_t is a level-$(\ell+1)$ package which is optimal over both $[M, N]$ and $[M', N']$, and $q_t = p^{\ell+1}_{[M',N']}(t)$. Note $q' = p^{\ell+1}_{[M',N']}(m+1)$, and thus $|q_t| < |q'|$ for all t, by the monotonicity property over $[M', N']$ implied by part (iii) of the inductive hypothesis.

Let $Q' = (F_q)_{[M',N']}$. By the minimality of q, $Q' \subseteq Q$. Since q is the smallest weight glue-pack with respect to F_q and $q_{[M',N']} = q$, it follows that q is a glue-pack with respect to Q', by Lemma 3.7. Since $Q' \subseteq Q$, by Remark 3.3, we know q is ℓ-connected with respect to Q. Since $q \cap Q = \emptyset$, q is a glue-pack with respect to Q. Therefore $|q| \geq |q'|$. By definition of $SE(Q)$, $|q| \leq |q'|$. By the uniqueness hypothesis, $q' = q$. □

Since $F_{[i,j]}$ is a COS over $[i, j]$, we can rewrite Claim 1 as follows.

Claim 1′. If p_1 is a package then $S(F_{[i,j]}) = \emptyset$ and $G(F_{[i,j]}) = \emptyset$.

Since p_1 is optimal over $[i, j]$, and since $F_{[i,j]} \cup p_1$ is a COS over $[i, j]$ if p_1 is optimal over $[M, N]$, we can rewrite Claim 2 as follows:

Claim 2′. If p_1 is an optimal item over $[M, N]$, then $S(F_{[i,j]} \cup p_1) = \emptyset$ and $G(F_{[i,j]} \cup p_1) = \emptyset$.

LEMMA 5.5. *Suppose Q is a* COS *over $[M', N'] \subseteq [M, N]$. Then $G(Q) = \emptyset$.*

Proof. By Lemma 5.3, $Q = B^{\ell+1}_{[M',N']} \cup q_1 \cup \cdots \cup q_m$, where $q_1, \ldots q_m$ are level-$(\ell+1)$ items, each of which is optimal over both $[M, N]$ and $[i, j]$. Let q be the smallest weight glue-pack with respect to Q. By the monotonicity property at level $(\ell+1)$ over $[i, j]$ implied by part (iii) of the inductive hypothesis, all q_t have weight less than $|q|$. Equivalently, $G(Q) = \emptyset$. □

By Lemma 5.5, Claims 1′ and 2′ are equivalent to the following two claims.

Claim 1″. If p_1 is a package, then $S(F_{[i,j]}) = \emptyset$.

Claim 2″. If p_1 is an optimal item over $[M, N]$, then $S(F_{[i,j]} \cup p_1) = \emptyset$.

We now finish the proof of Theorem 5.1 by proving Claims 1″ and 2″. First note that Lemma 5.4 immediately implies the following corollary.

COROLLARY 5.6. *Let Q be a* COS *over $[M', N'] \subseteq [M, N]$. Let q be the smallest weight member of $SE(Q)$, if one exists. Then $q_{[M',N']} = q$ implies $S(Q) = \emptyset$.*

We break the argument into two cases: when p_1 is a tile and p_2 is a package, and when both p_1 and p_2 are packages.

Case 1. Consider first the case when p_1 is a tile. In this case we need to prove only Claim 2$''$. By the gap-filling property (Lemma 3.9), $p_1 = s_{i,\ell+1}$ or $p_1 = s_{j,\ell+1}$. Assume, without loss of generality, that the first case holds. Note that $F = F \cup p_1$ and $F_{[i,j]} = F_{[i,j]} \cup p_1$. Suppose $S(F_{[i,j]}) \neq \emptyset$. Let q be the smallest weight member of $S(F_{[i,j]})$. By Corollary 5.6, $q_{[i,j]} \neq q$. Thus q must span an external gap of $F_{[i,j]}$, either i or j. If q spans j then, by the package span property on level $(\ell + 1)$, implied by part (iii) of the inductive hypothesis, $|s_{j,\ell+2}| < |q|$. Thus, by the monotonicity property of the weight function, $|s_{j,\ell+1}| < |q|$. By minimality of q', $|q| < |p_2|$. Thus $p_1 \cup s_{j,\ell+1} = s_{i,\ell+1} \cup s_{j,\ell+1}$ is a level-ℓ glue-pack with respect to $F[M, N, N - M - r + 2, \ell]$ of weight less than $|p|$, contradicting the minimality of p.

Thus we can assume that q spans i. Let k be the greatest integer smaller than i such that $F[M, N, N - M - r + 2, \ell]$ has a gap at k. If no such gap exists, let $k = M$.

Note that if k is a gap of $F[M, N, N - M - r + 2, \ell]$, then there does not exist an optimal package over $[M, N]$ of weight less than or equal to $|q|$ that spans k, since otherwise, by the package span property at level $(\ell + 1)$, and by the monotonicity property of the weight function, $s_{k,\ell+1} \cup s_{i,\ell+1}$ is a glue-pack with respect to $F[M, N, N - M - r + 2, \ell]$ of weight less than $|p|$, contradicting the minimality of p.

By Lemmas 4.2, 4.12, and part (ii) of the inductive hypothesis, $F_{[k,i]}$ is a COS over $[k, i]$.

Let q' be the smallest weight level-$(\ell + 1)$ package optimal over $[M, N]$ not in F such that $|q'| \leq |q|$ and $q'_{[k,j]} \neq \emptyset$. The existence of q' follows from the existence of q. Since q is a minimal weight package of $S(F_{[i,j]})$, *rboundary*$(q') < i$ (otherwise $q' \neq q$ and $q' \subseteq S(F_{[i,j]})$). Since q' does not span k, *lboundary*$(q') > k$. Thus $q'_{[k,i]} = q'$. By Lemma 5.4, q' is a glue pack with respect to $F_{[k,i]}$. Therefore $s_{i,\ell+1} \cup q'$ is a glue-pack with respect to $F[M, N, N - M - r + 2, \ell]$ of weight less than $|p|$, contradicting the minimality of p.

Case 2. Assume now that both p_1 and p_2 are level-$(\ell + 1)$ packages over $[M, N]$. We need to prove both Claim 1$''$ and Claim 2$''$. First we prove Claim 1$''$, i.e., that $S(F_{[i,j]}) = \emptyset$. Assume $S(F_{[i,j]}) \neq \emptyset$. Let q be the smallest weight member of $S(F_{[i,j]})$. By Corollary 5.6, $q_{[i,j]} \neq q$. Thus q must span an external gap of $F_{[i,j]}$ at i or j. Without loss of generality, q spans i. By the package span property at level $(\ell + 1)$, $|q| > |s_{i,\ell+2}| \geq |s_{i,\ell+1}|$. Thus $|p_1| > |s_{i,\ell+1}|$ and therefore $|p_2| > |s_{i,\ell+1}|$. This implies that $s_{i,\ell+1} \cup p_1$ is a glue-pack with respect to $F_{[i,j]}$ of weight less than $|p|$, contradicting the minimality of p.

It remains to prove Claim 2$''$ for the case when p_1, p_2 are both level-$(\ell + 1)$ packages and under the assumption that Claim 1 is true. Assume that the claim is false, i.e., $S(F_{[i,j]} \cup p_1) \neq \emptyset$. Let q be the smallest weight optimal level-$(\ell + 1)$ package over $[M, N]$ in $S(F_{[i,j]} \cup p_1)$. By Corollary 5.6, $q_{[i,j]} \neq q$, and therefore q must span an external gap of $F_{[i,j]}$ at i or j. Without loss of generality, q spans i. By the package span property at level $(\ell + 1)$, $|q| > |s_{i,\ell+1}| \geq |s_{i,\ell+1}|$, hence $|p_2| > |s_{i,\ell+1}|$. But this implies that $s_{i,\ell+1} \cup p_1$ is a glue-pack with respect to $F_{[i,j]}$ of weight less than $|p|$, contradicting the minimality of p.

This finishes the proof of the decomposition property.

5.2. The proof of the monotonicity property. Let $F = F[M, N, N - M - r + 3]$. Let $q = p^{\ell}_{[M,N]}(r - 1)$, and $p = p^{\ell}_{[M,N]}(r)$, and suppose that $|q| \geq |p|$. By the uniqueness hypothesis, $|q| > |p|$. Let p_1, p_2 be the children of p in its normal parse tree, and let q_1, q_2 be the children of q in its normal parse tree. By the decomposition property, and by Lemma 5.2, we may assume that p_1 is the left child of p, q_1 is the left child of q, $|q_1| < |q_2|$, and $|p_1| < |p_2|$. Thus, $|p_1| < |q_2|$.

If $q_1 \cup p_1$ were a glue-pack for F, it would be lighter than q, contradicting the minimality of q. Thus, it cannot be a glue-pack. But we know that q_1 is a glue-pack with respect to F, since q is a glue-pack with respect to F. We also know that p_1 is a glue-pack with respect to $F \cup q_1$, by Lemma 5.2, since $|p_1| < |q_2|$ and p_1 is a glue-pack with respect to $F \cup q_1 \cup q_2$.

Thus, there must be a gap of F that separates q_1 from p_1, say at i. Without loss of generality, *rboundary* $(p_1) > i$ and *lboundary* $(q_1) < i$.

By Lemma 3.9, either $q_2 = s_{i,\ell+1}$ or *rboundary* $(q_2) < i$.

Case 1. Suppose *rboundary* $(q_2) < i$. By Lemma 3.9 and the fact that p_1 lies entirely to the right of i, we have *lboundary* $(p) \geq i$. Thus, $p_{[i,N]} = p$. Applying Lemma 3.7 twice, we see that p is a glue-pack with respect to $(F \cup q)_{[i,N]} = F_{[i,N]}$, and thus also with respect to F, contradicting the minimality of q.

Case 2. Suppose $q_2 = s_{i,\ell+1}$. If *lboundary* $(p_2) > i$, then $p_{[i+1,N]} = p$. Applying Lemma 3.7 twice, we see that p is a glue-pack with respect to $(F \cup q)_{[i+1,N]} = F_{[i+1,N]}$, and thus also with respect to F, contradicting the minimality of q. Thus, *lboundary* $(p_2) \leq i$.

Recall that p_1 is a glue-pack with respect to $F \cup q$. Recall also that $(p_1)_{[i,N]} = p_1$. Applying Lemma 3.7 twice, we see that p_1 is a glue-pack with respect to $(F \cup q)_{[i,N]} = F_{[i,N]} \cup q_2$, and thus also with respect to $F \cup q_2$. Since it is a tile, q_2 is a glue-pack with respect to F. If q_2 and p_1 are not level-ℓ connected with respect to F, they must be separated by a gap, say at j, where $i < j <$ *lboundary* (p_1). By Lemma 3.9, *lboundary* $(p) \geq j$, hence *lboundary* $(p_2) \geq j > i$, contradiction. Thus, $q_2 \cup p_1$ is a glue-pack with respect to F, which must be heavier than q, since q is minimal. It follows that $|q_1| < |p_1|$. From the fact that $|p| < |q|$, we can then conclude that $|p_2| < |q_2|$.

Now p_2 is a level-$(\ell+1)$ glue-pack with respect to $F \cup q \cup p_1$, which does not contain $s_{i,\ell+2}$. By Lemma 3.9, p_2 cannot span i, since then it would contain $s_{i,\ell+2}$, which is at least as heavy as q_2 by monotonicity of weights. The only remaining possibility is that *rboundary* $(p_2) < i$, i.e., $(p_2)_{[M,i-1]} = p_2$. Applying Lemma 3.7 twice, we see that p_2 is a glue-pack with respect to $(F \cup q \cup p_1)_{[M,i-1]} = (F \cup q_1)_{[M,i-1]}$, and thus also with respect to $F \cup q_1$.

If q_1 and p_2 were separated by a gap of F, say j, then $j < i$, since both q_1 and p_2 extend to the left of i. If q_1 is to the left of j, then that gap separates q_1 from q_2, contradicting the fact that q is a glue-pack of F, while if p_2 is to the left of j, then that gap (which is still a gap of $F \cup q$) separates p_2 from p_1, contradicting the fact that p is a glue-pack of $F \cup q$. Thus, $q_1 \cup p_2$ is a glue-pack with respect to F. By minimality of q, $|q_2| < |p_2|$, contradicting the fact that $|p_2| < |q_2|$.

This finishes the proof of the monotonicity property.

5.3. The proof of the package span property. Suppose $i \in [lboundary(p), rboundary(p)]$. If $F[M, N, N - M - r + 2, \ell]$ has a gap at i, then the result follows from Lemma 3.9. Otherwise, $s_{i,\ell+1} \in p^{\ell}_{[M,N]}(t)$ for some $t < r$, and $\left|s_{i,\ell+1}\right| < \left|p^{\ell}_{[M,N]}(t)\right| < |p|$ by the monotonicity property.

This concludes the proof of Theorem 5.1. □

6. The Package Merge algorithm. Recall that our technique of constructing the optimal forest described in the Package Search algorithm is to compute all level-0 optimal packages. By the decomposition property (Theorem 5.1, part 1), we know that an optimal level-ℓ package is a union of two optimal level-$(\ell + 1)$ items. More precisely, in order to find the optimal package, $p^{\ell}_{[1,n]}(r)$, in each iteration of the inner loop of the Package Search algorithm, we need to find the minimum weight pair of optimal level-$(\ell + 1)$ items over $[1, n]$ that are level-ℓ connected with respect to $F[1, n, n - r + 2, \ell]$. This restricts our search domain to $O(n^2)$ pairs.

In this section we show that we can further restrict the search domain by considering only pairs of optimal items that are "tentatively connected," a notion first introduced by Hu and Tucker [8], and generalized in this paper.

(Since, by Theorem 5.1, we need only consider optimal items over the interval $[1, n]$, we refer to optimal items over the interval $[1, n]$ simply as "optimal items" throughout this section.)

DEFINITION. *Suppose that Q is a skyline. We say that two sets of tiles, p_1, p_2 are* tentatively connected with respect to Q *if Q has no gaps in the interval*

$$[min(lboundary\ (p_1), lboundary\ (p_2)) + 1, max(lboundary\ (p_1), lboundary\ (p_2)) - 1].$$

The main result of this section is stated in the following theorem.

THEOREM 6.1. *Let F be a level-ℓ optimal forest over $[1, n]$ and p_1, p_2 be the smallest total weight pair of optimal level-$(\ell + 1)$ items that are tentatively connected with respect to F. Then $p_1 \cup p_2$ is the minimal weight level-ℓ glue-pack with respect to F.*

First, we examine the properties of the minimum weight pair of level-$(\ell + 1)$ optimal items that are tentatively connected with respect to a level-ℓ optimal forest.

LEMMA 6.2. *Let Q be a level-ℓ skyline over $[1, n]$ that is a union of B^ℓ and level-$(\ell + 1)$ optimal items. Let $p \not\subseteq Q$ be an optimal level-$(\ell + 1)$ package that is not a glue-pack with respect to Q. Then there exists an optimal level-$(\ell + 1)$ item $q \not\subseteq Q$, such that $|q| < |p|$ and p, q are tentatively connected with respect to Q.*

Proof. Assume first that p spans a gap of Q. Let $r_1, r_2, \ldots, r_k$, where $r_t < r_{t+1}$, be the gaps of Q spanned by p. Then p and $s_{r_1,\ell}$ are tentatively connected with respect to Q. By the package span property (Theorem 5.1, part 3), $|p| > |s_{r_1,\ell}|$.

Suppose p does not span a gap of Q. Let $[i, j] = [lboundary\ (p), rboundary(p)]$. Let $F = F[1, n, n - t + 1, \ell + 1]$, where t is that index for which $p = p^{\ell+1}_{[1,n]}(t)$. By the definition of optimal package, p is a level-$(\ell + 1)$ glue-pack with respect to F. By Lemma 3.5, p is a glue-pack with respect to $F \cup Q$. By the monotonicity property (Theorem 5.1, part 2), F is the union of $B^{\ell+1}$ and all optimal level-$(\ell + 1)$ packages of weight less than $|p|$. We next show that there is some optimal level-$(\ell + 1)$ package $q' \not\subseteq Q$ such that $|q'| < |p|$ and q' has some tiles in the interval $[i, j]$. Suppose there is no such q. Then, since p spans no gap of F, this implies that $(F \cup Q)_{[i,j]} = Q_{[i,j]}$. Applying Lemma 3.7 twice, we see that p is a level-$(\ell + 1)$ glue-pack with respect to Q, contradicting our hypothesis.

We consider two cases: when q' spans a gap of Q, and when it does not.

Case 1. If q' does not span a gap of Q, then $p \cup q'$ also does not span a gap, and therefore p and q' are tentatively connected. This implies the lemma with $q = q'$.

Case 2. Assume that q' spans at least one gap of Q. Let $r_1, r_2, \ldots, r_k$, where $r_t < r_{t+1}$, be the gaps of Q spanned by q'. If $r_1 \leq i$, let r be the greatest r_t such that $r_t \leq i$, and then Q has no gaps in the interval $[r + 1, i - 1]$. Otherwise, let $r = r_1$, and then Q has no gaps in the interval $[i + 1, r - 1]$.

Thus, p and $s_{r,\ell+1}$ are tentatively connected with respect to Q. By the Package Span property, $|s_{r,\ell+1}| < |q'|$, thus $|s_{r,\ell+1}| < |p|$. This implies the lemma with $q = s_{r,\ell+1}$.

This concludes the proof of Lemma 6.2. □

Proof (of Theorem 6.1). Let p be the minimal weight level-ℓ glue-pack with respect to F. By Theorem 5.1, $p = p_1 \cup p_2$, where p_1, p_2 are optimal level-$(\ell + 1)$ items which must be tentatively connected, since otherwise $F \cup p$ would not be level-ℓ connected.

Let p_1, p_2 be the smallest pair of optimal level-$(\ell + 1)$ items that are tentatively connected with respect to F. Let $|p_1| < |p_2|$. By Lemma 6.2, p_1 is a glue-pack with respect to F (otherwise p_1, p_2 would not be the minimal pair).

We need to prove that p_2 is a level-$(\ell + 1)$ glue-pack with respect $F \cup p_1$. If p_2 is a tile, we are done. We can thus assume that p_2 is a package. Suppose p_2 is not a level-$(\ell + 1)$ glue-pack with respect to $F \cup p_1$. If $F \cup p_1$ has a gap at $i_2 = lboundary\ (p_2)$, then $s_{i_2,\ell+1}$, p_1 form a tentatively connected pair of total weight smaller than the pair p_1, p_2, contradicting the minimality of that pair. Otherwise, by Lemma 6.2, choose an optimal level-$(\ell + 1)$ item, $q \not\subseteq F \cup p_1$, such that $|q| < |p_2|$ and q and p_2 are tentatively connected with respect to $F \cup p_1$.

It is a routine matter of checking cases to verify that p_1 and q are tentatively connected, contradicting the minimality of the pair p_1, p_2. □

We now describe the Package Merge implementation of the Package Search algorithm introduced in §4.3. Each iteration of the main loop makes use of a data structure (the details of which are described below) which holds all optimal items (tiles, as well as packages produced during the previous iteration) and which allows rapid retrieval of the minimal tentatively connected pair.

During each iteration of the inner loop, the minimal tentatively connected pair of optimal level-$(\ell + 1)$ items is deleted from the data structure, and their union forms an optimal level-ℓ package.

Correctness of the implementation follows immediately from Theorem 6.1.

ALGORITHM 2. **Package Merge (L)**

```
1. for $\ell = L - 1$ downto 0 do
    1.1. $F^\ell \leftarrow B^\ell$;
    1.2. Initialize the data structure to be all optimal level-$(\ell + 1)$ items;
    1.3. for $r := 1$ to $n - \lceil n2^{\ell - L} \rceil - 1$ do
        1.3.1. $p_1, p_2 \leftarrow$ the minimal weight pair of tentatively connected
               optimal items;
        1.3.2. $p^\ell_{[1,n]}(r) \leftarrow p_1 \cup p_2$;
        1.3.3. $F^\ell := F^\ell \cup p^\ell_{[1,n]}(r)$;
        1.3.4. Delete $p_1$ and $p_2$ from the data structure;
2. compute the (standard) tree representation of $F^0$.
```

6.1. The data structure. The data structure consists of *local* priority queues C_0, $C_1, \ldots C_n$, where each C_i contains optimal level-$(\ell + 1)$ items prioritized by weight, together with a *global* priority queue G containing pairs of optimal level-$(\ell + 1)$ items, prioritized by total weight.

We refer to an item (that is, an optimal level-$(\ell + 1)$ item) as *unused* if it is still in the data structure, and *used* if it is not, i.e., it has already been chosen as one of the two halves of an optimal level-ℓ package.

At any given time, every unused tile is a member of exactly two of the local priority queues, while every unused package is a member of exactly one of the local priority queues.

The data structure is initialized by letting C_0 consist only of $s_{1,\ell+1}$, C_n consist only of $s_{n,\ell+1}$, and, for $i \in [1, n - 1]$, C_i consist of $s_{i,\ell+1}$, $s_{i+1,\ell+1}$, and all optimal level-$(\ell + 1)$ packages whose *lboundary* is equal to i. G will, at all times, contain the minimal pair of items from each local priority queue that has at least two items. Initially, G has $(n - 1)$ members, namely the pairs $\{s_{i,\ell+1}, s_{i+1,\ell+1}\}$ for all $i \in [1, n - 1]$.

At any time, any two unused items will be tentatively connected if and only if they are members of the same local priority queue. Thus, the minimal tentatively connected pair will always be the minimal item of G.

Deletion of the minimal pair of items is implemented as follows. Each of the two items is deleted from each of the local priority queues that it belongs to: one if a package, two if a tile. Deletion of a tile from two local priority queues causes the two queues to be merged. For each of the one, two, or three old local priority queues which have been modified, minimal pairs must be deleted from G (not necessarily the "deletemin" operation) and a new minimal pair for the new local priority queue is computed and inserted into G.

Time Complexity. Initializing the data structure requires $O(n)$ time. Each deletion from the data structure takes $O(\log n)$ time. Thus, the overall time complexity of the algorithm is $O(nL \log n)$.

7. Appendix: Resolving ties.

At some step during the execution of the Package Merge algorithm, there may be more than one choice of tentatively connected pairs that have minimum total weight. We proved correctness of the algorithm under the assumption that this never occurs—in fact, we made the even stronger assumption that the uniqueness hypothesis (introduced in §4) holds. In this section we show that this assumption is unnecessary.

In practice, the Package Merge algorithm works by resolving all ties according to specific rules given in this section. The correctness of this method is proved by showing that it is equivalent to increasing the weight of each tile by an "infinitesimal" amount, where the "infinitesimals" are chosen so as to guarantee the uniqueness hypothesis, without violating the monotonicity condition on tile weights.

7.1. Resolve a tie by choosing the smallest tag.

We assign each tile a unique positive integral *tag* value, taking care that the tags of tiles of the same index are monotone in the level. For example, the tile $s_{i,\ell}$ could be assigned the tag value $n\ell + i$. Each nonempty set of tiles will be assigned the largest tag value of any of its member tiles.

If at any time during execution of the Package Search algorithm, or its implementation, the Package Merge algorithm, there is a choice among two sets of tiles of the same actual weight, the set with the smaller tag value will be treated as the one of smaller weight.

This technique requires a slight clarification, since the algorithm requires searching for the least-weight set of tiles which has a certain property, and it could be that two or more such sets have the same tag value, as they could have tiles in common. If p and q are sets of tiles which have the same weight, and if the algorithm requires choosing the one of smaller weight, we choose p if and only if the tag value of $p - q$ is less than the tag value of $q - p$. These cannot be equal, since $p - q$ and $q - p$ must be disjoint.

Keeping track of tag values for all the sets concerned does not increase the asymptotic time complexity of the Package Merge algorithm, since it only requires storing one additional integer with each optimal item, and using this tag to break ties in the priority queues. Within each priority queue, the least-weight pair is still obtained by combining the two items of smallest weight, where "smallest" is now unambiguous, using the tie-breaker. Finding that priority queue which has the smallest least-weight pair is also easy using the tie-breaker.

7.2. Infinitesimal penalties.

Let $\epsilon > 0$ be a real number so small that, if A, B are any sets of tiles such that $|A| < |B|$, then $|A| + \epsilon < |B|$. (Since there are finitely many sets of tiles, such an ϵ must exist.) For each tile s, let $t(s)$ be the tag value of s. Let T be an integer larger than the largest tag value of any tile, and let each tile s be assigned the *fictitious* weight $|s| + \epsilon \cdot 2^{t(s)-T}$. If A and B are sets of tiles, we say that $A \prec B$ if the fictitious weight of A is less than the fictitious weight of B.

Remark 7.1. If A and B are sets of tiles, then we have the following properties.

1. Uniqueness: If $A \neq B$, then $A \prec B$ or $B \prec A$.
2. Consistency: If $|A| < |B|$, then $A \prec B$.
3. Same as tag scheme: If $|A| = |B|$, then the tie-breaking scheme of §7.1 will pick A to be the "lesser weight" if and only if $A \prec B$.
4. Nonnegativity: The fictitious weight of any set of tiles is nonnegative.
5. Monotonicity: For any $1 \leq i \leq n$ and any $0 \leq \ell < L$, $s_{i,\ell} \prec s_{i,\ell+1}$.

Thus, using fictitious weights instead of actual weights causes the uniqueness hypothesis to hold, without losing the needed conditions of nonnegativity and monotonicity introduced in §4, and the tie-breaking scheme always chooses that set which has the lighter fictitious weight.

Furthermore, at the end of the algorithm, when the optimal level-0 tree (i.e., tree of least fictitious weight) over $[1, n]$ is found, we are guaranteed that this geometric tree has the least actual weight, and hence represents an optimal solution to the original weighted binary tree problem.

8. Appendix: Proof of the interleaving property. In this section we give a proof of Theorem 4.3. The proof is very similar to proofs given in [1]–[4], [10]–[12], [16], and [17].

LEMMA 8.1 (Monge property of optimal forests). *If* $1 \le M \le M' \le N \le N' \le n$, $0 \le \ell \le L$, *and* $(N' - M + 1)2^{\ell - L} \le k \le (N - M' + 1)$, *then*

$$|F[M, N, k, \ell]| + |F[M', N', k, \ell]| \le |F[M, N', k, \ell]| + |F[M', N, k, \ell]| .$$

Proof. The proof is by backwards induction on ℓ, and for given ℓ, by induction on k.

We first note that if $M = M'$ or $N = N'$, both sides of the inequality are the same, so the result is trivial. Thus, without loss of generality, $M < M'$ and $N < N'$.

If $\ell = L$ the result is vacuous, since no k satisfies the condition.

Suppose $k > 1$. Let $c = c_{k-1}(F[M', N, k, \ell])$ and $c' = c_{k-1}(F[M, N', k, \ell])$. We consider two cases: $c \le c'$ and $c > c'$. If $c \le c'$, the inductive hypothesis gives us

$$|F[M, c, k-1, \ell]| + |F[M', c', k-1, \ell]| \le |F[M, c', k-1, \ell]| + |F[M', c, k-1, \ell]| .$$

Thus

$$\begin{aligned} &|F[M, N, k, \ell]| + |F[M', N', k, \ell]| \\ &\le |F[M, c, k-1, \ell]| + |F[c+1, N, 1, \ell]| + |F[M', c', k-1, \ell]| + |F[c'+1, N', 1, \ell]| \\ &\le |F[M, c', k-1, \ell]| + |F[c'+1, N', 1, \ell]| + |F[M', c, k-1, \ell]| + |F[c+1, N, 1, \ell]| \\ &= |F[M, N', k, \ell]| + |F[M', N, k, \ell]| . \end{aligned}$$

If $c \ge c'$, the inductive hypothesis gives us

$$|F[c'+1, N, 1, \ell]| + |F[c+1, N', 1, \ell]| \le |F[c'+1, N', 1, \ell]| + |F[c+1, N, 1, \ell]| .$$

Thus

$$\begin{aligned} &|F[M, N, k, \ell]| + |F[M', N', k, \ell]| \\ &\le |F[M, c', k-1, \ell]| + |F[c', N, 1, \ell]| + |F[M', c, k-1, \ell]| + |F[c+1, N', 1, \ell]| \\ &\le |F[M, c', k-1, \ell]| + |F[c'+1, N', 1, \ell]| + |F[M', c, k-1, \ell]| + |F[c+1, N, 1, \ell]| \\ &= |F[M, N', k, \ell]| + |F[M', N, k, \ell]| . \end{aligned}$$

Finally, suppose $k = 1$, $\ell < L$. We consider two cases: $M' < N$, and $M' = N$. If $M' < N$, then, by the inductive hypothesis,

$$|F[M, N, 2, \ell+1]| + |F[M', N', 2, \ell+1]| \le |F[M, N', 2, \ell+1]| + |F[M', N, 2, \ell+1]| .$$

Let $c = c_1(F[M', N, 2, \ell+1])$, and let $c' = c_1(F[M, N', 2, \ell+1])$. By symmetry, we can assume without loss of generality that $c \le c'$. Thus, since

$$|B^{\ell}_{[M,N]}| + |B^{\ell}_{[M',N']}| = |B^{\ell}_{[M,N']}| + |B^{\ell}_{[M',N]}|$$

we have

$$\begin{aligned} &|F[M, N, 1, \ell]| + |F[M', N', 1, \ell]| \\ &= |F[M, N, 2, \ell+1]| + |B^{\ell}_{[M,N]}| + |F[M', N', 2, \ell+1]| + |B^{\ell}_{[M',N']}| \\ &\le |F[M, N', 2, \ell+1]| + |B^{\ell}_{[M,N']}| + |F[M', N, 2, \ell+1]| + |B^{\ell}_{[M',N]}| \\ &= |F[M, N', 1, \ell]| + |F[M', N, 1, \ell]| . \end{aligned}$$

In the case $M' = N$, we need an additional lemma.

LEMMA 8.2. *If* $L - \ell - 1 \geq \log_2 n$ *then*

$$|F[M, N, 1, \ell]| + |s_{N,\ell+1}| \leq \left|F[M, N, 1, \ell + 1] \cup B^{\ell}_{[M,N]}\right|.$$

Proof. Let ℓ_i be the greatest level of any tile of index i in $F[M, N, 1, \ell]$. Then

$$\left|F[M, N, 1, \ell + 1] \cup B^{\ell}_{[M,N]}\right| - |F[M, N, 1, \ell]| \geq \sum_{i=M}^{N} |s_{i,\ell_i+1}|$$

which is at least $|s_{N,\ell+1}|$. □

We return to the proof of Lemma 8.1. Let $c = c_1(M, N', 2, \ell + 1)$. We assume that $c \geq N$. (The case where $c < N$ is symmetric.) By the inductive hypothesis,

$$|F[M, N, 1, \ell + 1]| + |F[N, c, 1, \ell + 1]| \leq |s_{N,\ell+1}| + |F[M, c, 1, \ell + 1]|.$$

Then, by Lemma 8.2, we have

$$\begin{aligned}
&|F[M, N, 1, \ell]| + |F[N, N', 1, \ell]| \\
&\leq |F[M, N, 1, \ell]| + |F[N, c, 1, \ell + 1]| + |F[c + 1, N', 1, \ell + 1]| + \left|B^{\ell}_{[N,N']}\right| \\
&\leq \left|B^{\ell}_{[M,N]}\right| + |F[M, N, 1, \ell + 1]| - |s_{N,\ell+1}| \\
&+ |F[N, c, 1, \ell + 1]| + |F[c + 1, N', 1, \ell + 1]| + \left|B^{\ell}_{[N,N']}\right| \\
&\leq |F[M, c, 1, \ell + 1]| + \left|B^{\ell}_{[M,N]}\right| + |F[c + 1, N', 1, \ell + 1]| + \left|B^{\ell}_{[N,N']}\right| \\
&= |F[M, N', 1, \ell]| + |s_{N,\ell}|.
\end{aligned}$$

This concludes the proof of Lemma 8.1. □

We are now ready to give the proof of the interleaving property.

LEMMA 8.3 (interleaving property). *For* M, N, k, ℓ, *if* $1 \leq M < N \leq n$, $0 \leq \ell \leq L$, $(N - M + 1)2^{\ell-L} \leq k \leq N - M$, *and* $0 \leq m \leq k$, *then*

$$c_m(F[M, N, k + 1, \ell]) \leq c_m(F[M, N, k, \ell]) \leq c_{m+1}(F[M, N, k + 1, \ell]).$$

Proof. It suffices to show that $c_m(F[M, N, k, \ell]) \leq c_{m+1}(F[M, N, k + 1, \ell])$. The other inequality is symmetric.

Let $c = c_{m+1}(F[M, N, k + 1, \ell])$ and $c' = c_m(F[M, N, k, \ell])$. Suppose $c' < c$.

Let $M' = c_1(F[M, N, k + 1, \ell])$. By Lemma 4.2,

$$F[M', N, k, \ell] = F[M, N, k + 1, \ell]_{[M',N]}.$$

Thus, $c = c_m(F[M', N, k, \ell])$.

By the uniqueness hypothesis,

$$\begin{aligned}
|F[M, c', m, \ell]| + |F[c' + 1, N, k - m, \ell]| &< |F[M, c, m, \ell]| + |F[c + 1, N, k - m, \ell]|, \\
|F[M', c, m, \ell]| + |F[c + 1, N, k - m, \ell]| &< |F[M', c', m, \ell]| + |F[c' + 1, N, k - m, \ell]|.
\end{aligned}$$

Adding the two inequalities and cancelling, we obtain

$$|F[M, c', m, \ell]| + |F[M', c, m, \ell]| < |F[M, c, m, \ell]| + |F[M', c', m, \ell]|,$$

which contradicts Lemma 8.1. This concludes the proof of the interleaving property. □

Acknowledgment. We wish to thank the referee for devoting the very substantial amount of time that was necessary to review this paper, and for giving us so many valuable suggestions.

IMPROVED ALGORITHMS FOR LINEAR INEQUALITIES WITH TWO VARIABLES PER INEQUALITY*

EDITH COHEN† AND NIMROD MEGIDDO‡

Abstract. The authors show that a system of m linear inequalities with n variables, where each inequality involves at most two variables, can be solved in $\tilde{O}(mn^2)$ time (we denote $\tilde{O}(f) = O(f \operatorname{polylog} n \operatorname{polylog} m)$) deterministically, and in $\tilde{O}(n^3 + mn)$ expected time using randomization. Parallel implementations of these algorithms run in $\tilde{O}(n)$ time, where the deterministic algorithm uses $\tilde{O}(mn)$ processors and the randomized algorithm uses $\tilde{O}(n^2 + m)$ processors. The bounds significantly improve over previous algorithms. The randomized algorithm is based on novel insights into the structure of the problem.

1. Introduction.

In this paper we consider the following class of linear systems.

DEFINITION 1.1. *A* TVPI *system is a system of linear inequalities where each inequality involves at most two variables. (I.e., a system of the form* $\boldsymbol{Ax} \le \boldsymbol{b}$ *, where* $\boldsymbol{A} \in R^{m\times n}$ *is a matrix,* $\boldsymbol{b} \in R^m$ *is a real vector, and each row of* $\boldsymbol{A}$ *contains at most two nonzero entries.) We denote the number of inequalities by m, and the variables by* $x_1, \ldots, x_n$*. We denote by* $F = \{\boldsymbol{x} \in R^n | \boldsymbol{Ax} \le \boldsymbol{b}\}$ *the set of feasible solutions. A* TVPI *system is called* monotone *if the two nonzero entries in each row have opposite signs. See Fig.* 1 *for an example of a* TVPI *system.*

Our goal is to either find a point that satisfies all the inequalities or conclude that no such point exists. The structure of TVPI systems enables us to obtain specialized algorithms that are faster than known algorithms for solving general linear systems. The algorithms given here can also be adapted to find a solution that minimizes or maximizes a specific variable. We summarize previous work on solving TVPI systems. Shostak [17] characterized the set of solutions of TVPI systems and gave an algorithm that is exponential in the worst case. Nelson [16] gave an $n^{O(\log n)}$ algorithm. Aspvall and Shiloach [3] and Aspvall [2] proposed algorithms that perform $O(mn^3 I)$ and $O(mn^2 I)$ arithmetic operations, respectively, where I is the size of the binary encoding of the problem. Megiddo [15] proposed the first strongly polynomial time algorithm for the problem, which performs $O(mn^3 \log m)$ operations. The parallel implementation of Megiddo's algorithm runs in $O(n^3 \log m)$ time using $O(m)$ processors.

The algorithms presented here improve the sequential and parallel time bounds. We give an $O\left(mn^2(\log m + \log^2 n)\right)$ time deterministic algorithm, which has a parallel implementation that runs in $O\left(n(\log m + \log^2 n)\right)$ time using $O(mn)$ processors. An additional improvement is obtained through using randomization: We give an algorithm that runs in $O\left(n^3 \log n + mn(\log^5 n + \log m \log^3 n)\right)$ expected time. A parallel implementation runs in $O\left(n(\log^5 n + \log^3 n \log m)\right)$ expected time using $O(n^2 + m)$ processors. The space requirement of the algorithms presented here is $O(n^2 + m)$. The effort involved in translating these

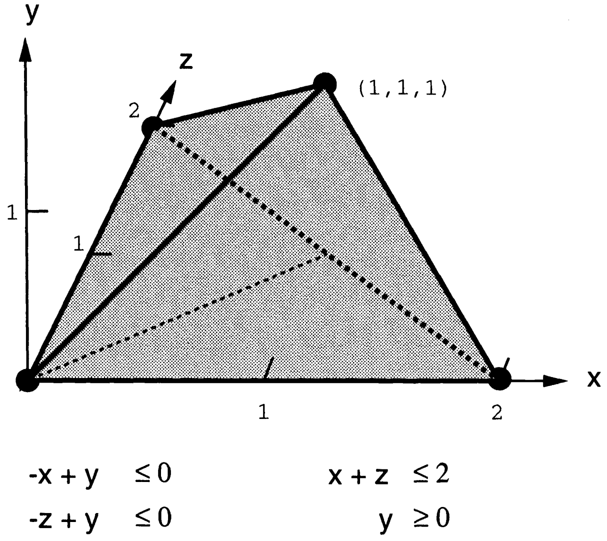

FIG. 1. *An example of a* TVPI *system with three variables.*

algorithms into actual programs is about the same as in the previously known algorithms, and the hidden constants in the time bounds are still reasonable. Subsequent to our work, Hochbaum and Naor [12] found a new $O(mn^2 \log m)$ deterministic algorithm for the problem. Their algorithm, however, runs in $O(n^2 \log m)$ time in parallel, and it does not seem possible to combine it with the randomized approach to yield algorithms with better expected time.

Section 2 gives the preliminaries. We give a characterization of polyhedra defined by TVPI systems. We represent a TVPI system by a directed multigraph with $2n$ vertices and $2m$ edges. The edges have linear functions of a single variable as "weights," and the weight of a path is interpreted as compositions of the weights along the path's edges. We review a result of Shostak [17] that relates weights of directed cycles and paths in this multigraph to bounds on the feasible region. We also discuss some subproblems and show how to solve them by performing a "Bellman-Ford shortest-path"-type computation on the representing multigraph where initial numerical values are assigned to vertices and "adding" an edge weight is replaced by substituting the current value at the vertex in the linear function comprising the edge weight (hence by an $O(mn)$ sequential algorithm, or by an $O(n)$ time parallel algorithm using $O(m)$ processors). In particular we discuss the subproblem of *locating a value*: For a numerical value ξ and $1 \leq i \leq n$, decide whether a TVPI system with the addition of a constraint of the form $x_i \geq \xi$ or $x_i \leq \xi$ remains feasible. An $O(mn)$ algorithm for locating a value was given by Aspvall and Shiloach [3].

In §3 we introduce a framework for solving TVPI systems that amounts to performing a "Floyd-Warshall all-pairs shortest-path"-type computation where resolving comparisons is replaced by locating values. This formulation enables us to reduce solving TVPI systems to performing $\tilde{O}(m + n^3)$ operations for the Floyd-Warshall-type computation and in addition solving a polylogarithmic number of instances of the more general subproblem of *locating a pool of values*: For numerical values $\xi_1, \ldots, \xi_n$ choose bounds $s_1, \ldots, s_n$, where $s_i \in \{x_i \geq \xi_i, x_i \leq \xi_i\}$, such that the system with the additional constraints $s_1, \ldots, s_n$ remains feasible. Obviously, a pool of values can be located by n sequential applications of an algorithm that locates a single value. This yields an $O(mn^2)$ time sequential algorithm that in parallel, runs in $O(n^2)$ time using $O(m)$ processors. The latter yields a $\tilde{O}(mn^2)$ deterministic algorithm for solving TVPI systems.

In §4 we present better algorithms for locating a pool. We first give an algorithm that improves the parallel running time to $O(n)$ using $O(mn)$ processors. This algorithm enables us to obtain a $\tilde{O}(n)$ parallel deterministic running time (using $O(mn)$ processors) for solving TVPI systems. Section 4 also contains an overview of a two stage $\tilde{O}(mn)$ time randomized algorithm. In parallel, the randomized algorithm runs in $\tilde{O}(n)$ time and uses $O(m)$ processors. This algorithm enables us to obtain the stated randomized bounds for solving TVPI systems. The randomized algorithm constitutes the most novel and the most technically difficult part of this work. Sections 5 and 6 are concerned with the details of the two stages.

In §7 we discuss the special structure of monotone systems. These systems are of special interest since the linear programming duals of generalized transshipment problems are monotone. In [4] and [7] the authors exploited this relationship and presented algorithms for generalized network flow problems (see also Adler and Cosares [1]).

Section 8 contains concluding remarks and a discussion of open problems.

2. Preliminaries.

Consider two two-variable inequalities that share a common variable. In some cases, these inequalities can be combined to yield a new two-variable inequality that is implied by the previous two. For example, the inequalities $x_1 \leq 2x_2 - 4$ and $x_2 \leq 4x_3 + 5$ can be combined to yield $x_1 \leq 8x_3 + 6$. The inequalities $x_1 \leq 2x_2 - 4$ and $x_2 \geq 4x_3 + 5$, however, cannot be combined in a similar fashion. The notion of combining inequalities was first discussed by Shostak [17] and used in all succeeding works. A TVPI system was represented by a multigraph where nodes correspond to variables and inequalities correspond to edges. Each set of inequalities that can be combined as described above to yield a new inequality forms an *admissible* path in this multigraph [17]. We find it more convenient to consider a slightly different graph (the *associated graph* of a system), in which there is an exact correspondence between directed paths and new inequalities that can be obtained as above. Cycles in the associated graph yield bounds on variables. Obviously, the new inequalities and bounds that are obtained by combining inequalities are implied by the original system. Shostak proved that the converse is also true: The tightest bounds on variables that can be obtained from simple cycles and paths define the bounding box of the feasible region. The current paper, like much previous work (see [3], [2], [15], and [17]), makes use of Shostak's result.

2.1. The associated graph.

We represent a TVPI system by a set of n intervals and a directed multigraph with $2n$ nodes and $2m$ edges. The graph is a natural representation of the system, where variables correspond to vertices and two-variable inequalities to edges between vertices of the participating variables. A formal definition of the associated graph follows.

DEFINITION 2.1. *Suppose we are given a* TVPI *system as in Definition* 1.1. *Without loss of generality, assume that the inequalities with a single variable* (bounds) *are summarized in the form of intervals* $S_i = [a_i, b_i]$ $(-\infty \leq a_i \leq b_i \leq \infty,\ i = 1, \dots, n)$. *We consider a directed multigraph* $G = (V, E)$ *as follows. For each variable* x_i, *there are two vertices in* G *associated with* x_i, *namely,* $V = \overline{V} \cup \underline{V}$ *where* $\overline{V} = \{\overline{v}_i \mid i = 1, \dots, n\}$ *and* $\underline{V} = \{\underline{v}_i \mid i = 1, \dots, n\}$. *For* $u \in V$, *we define* $u^{-1} \in V$ *as follows. If* $u = \underline{v}_i \in \underline{V}$, *then* $u^{-1} = \overline{v}_i$, *and if* $u = \overline{v}_i \in \overline{V}$, *then* $u^{-1} = \underline{v}_i$. *The edges of* G *are associated with the inequalities that involve exactly two variables. Note that each such inequality can be written in the form*

$$\gamma x_i \leq \alpha x_j + \beta,$$

where either $\gamma = 1$ *and* $\alpha \neq 0$ *or* $\gamma = -1$ *and* $\alpha > 0$. *Each such inequality is represented by two edges, where each edge* e *is labeled with a certain linear function* f_e *as follows*:

1. *If* $\alpha > 0$ *and* $\gamma = 1$, *we have an edge* $e = (\overline{v}_j, \overline{v}_i)$ *labeled* $f_e(x) = \alpha x + \beta$ *and an edge* $e^{-1} = (\underline{v}_i, \underline{v}_j)$ *labeled* $f_{e^{-1}}(x) = \frac{1}{\alpha}x - \frac{\beta}{\alpha}$.
2. *If* $\alpha < 0$ *and* $\gamma = 1$, *we have an edge* $e = (\underline{v}_j, \overline{v}_i)$ *labeled* $f_e(x) = \alpha x + \beta$ *and an edge* $e^{-1} = (\underline{v}_i, \overline{v}_j)$ *labeled* $f_{e^{-1}}(x) = \frac{1}{\alpha}x - \frac{\beta}{\alpha}$.
3. *If* $\alpha > 0$ *and* $\gamma = -1$, *we have an edge* $e = (\overline{v}_j, \underline{v}_i)$ *labeled* $f_e(x) = -\alpha x - \beta$ *and an edge* $e^{-1} = (\overline{v}_i, \underline{v}_j)$ *labeled* $f_{e^{-1}}(x) = -\frac{1}{\alpha}x - \frac{\beta}{\alpha}$.

See Fig. 2 *for an example of such a system and the associated graph. See Fig.* 3 *for the associated graph of the system shown in Fig.* 1. *We assume throughout this paper that a* TVPI *system is given by the associated graph and set of intervals.*

$$\begin{array}{llll}
(1.) & y & \le & x+2 \\
(2.) & y & \ge & x \\
(3.) & y & \ge & -x \\
(4.) & y & \le & -x+2
\end{array}$$

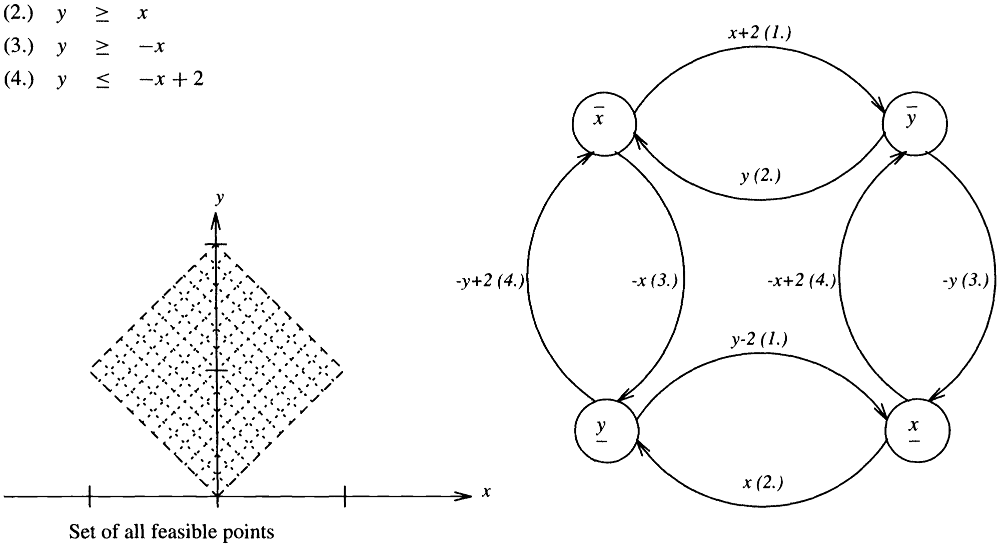

FIG. 2. *An example of a system of inequalities and the associated graph.*

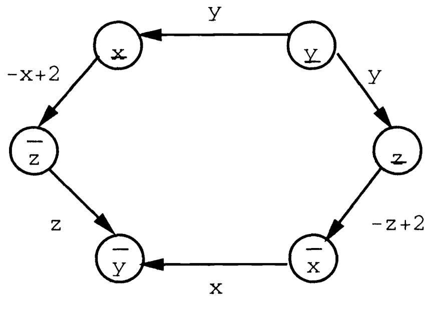

FIG. 3. *The associated graph of the* TVPI *system of Fig.* 1.

For any one-to-one function f let f^{-1} denote the inverse function. In particular, if $f(x) = \alpha x + \beta$ and $\alpha \ne 0$, then $f^{-1}(x) = \frac{1}{\alpha}x - \frac{\beta}{\alpha}$. Note that for all $e \in E$, $f_{e^{-1}} = f_e^{-1}$.

Let G be as in Definition 2.1. A linear function associated with an edge (u, w) corresponds to an inequality in the original system: Suppose that $u \in \{\underline{v}_i, \overline{v}_i\}$; if $w = \overline{v}_j$ the inequality is $x_j \le f_e(x_i)$, and if $w = \underline{v}_j$ the inequality is $x_j \ge f_e(x_i)$. We define the linear function associated with a directed path p from u to w. The corresponding two-variable inequality that results from treating the path as an edge (u, w), is implied by the original system.

DEFINITION 2.2. *Let $p = (e_1, \dots, e_k)$ be a (directed) path in G.*

1. *For any path p, we define a linear function f_p, where $f_p = f_{e_k} \circ \cdots \circ f_{e_1}$. Note that if both ends of p lie either in $\overline{V}$ or in $\underline{V}$ then f_p is increasing. Otherwise, f_p is decreasing.*
2. *We denote by p^{-1} the path $p = (e_k^{-1}, \dots, e_1^{-1})$. Note that $f_{p^{-1}} = f_p^{-1}$ and hence the two paths p, p^{-1} correspond to the same inequality.*

Consider, for example, the directed path from $\underline{y}$ to $\overline{z}$ in the graph of Fig. 3. The linear function associated with this path is $f = 2 - y$, and the corresponding inequality is $z \le 2 - y$.

In particular, Definition 2.2 applies to cycles (closed paths). Cycles play a special role since they give a relation that involves a single variable, from which a bound on this variable can be deduced. This is formalized in the following definition.

DEFINITION 2.3. *We refer to a path that starts and ends at vertices from $\{v, v^{-1}\}$ as a* cycle. *A path from v to v is a* closed cycle, *and to a path from v to v^{-1} is an* open cycle.

1. *Let c be a cycle starting at one of the vertices $\overline{v}_i$ and $\underline{v}_i$, and ending at a vertex $\overline{v}_i$ (resp., $\underline{v}_i$). Let f_c be the associated linear function. The bound on x_i implied by the cycle c follows from the inequality $x \le f_c(x)$ (resp., $x \ge f_c(x)$). Obviously, the implied inequality must hold for all feasible points. Note that if a cycle c starts at $\overline{v}_i$ and ends at $\underline{v}_i$ (resp., starts at $\underline{v}_i$ and ends at $\overline{v}_i$), then f_c is decreasing. Hence c implies a lower bound (resp., an upper bound) on x_i.*
2. *We say that the cycle c* contradicts *a value ξ_i of $\overline{v}_i$ (resp., $\underline{v}_i$) if the bound implied by c is of the form $x_i \ge \alpha$ (resp., $x_i \le \alpha$) whereas $\xi_i < \alpha$ (resp., $\xi_i > \alpha$).*

Consider, as an example, the graph of Fig. 2 and the cycle that consists of the path from $\underline{x}$ to $\overline{x}$. The function associated with this cycle is $f = -x + 2$ and the bound implied by the cycle is $x \le -x + 2$ (i.e., $x \le 1$).

2.2. Pushing bounds along edges. We maintain numerical values associated with the vertices of G: The value associated with $\overline{v}_i$ (resp., $\underline{v}_i$) is denoted by $\overline{x}_i$ (resp., $\underline{x}_i$). Intuitively, $\overline{x}_i$ and $\underline{x}_i$ correspond to upper and lower bounds, respectively, on the value of the variable x_i. We say that ξ is *tighter* than μ as a value of $\overline{x}_i$ (resp., $\underline{x}_i$), if $\xi < \mu$ (resp., $\xi > \mu$). We introduce the following operation that considers an edge $e = (u, v)$ and updates the bound associated with v, as implied by the inequality associated with e and the bound associated with u.

DEFINITION 2.4. *A* push *through an edge e is defined as the following operation:*

1. *If $e = (\overline{v}_j, \overline{v}_i)$, $\overline{x}_i \leftarrow \min\{\overline{x}_i, f_e(\overline{x}_j)\}$.*
2. *If $e = (\underline{v}_j, \underline{v}_i)$, $\underline{x}_i \leftarrow \max\{\underline{x}_i, f_e(\underline{x}_j)\}$.*
3. *If $e = (\overline{v}_j, \underline{v}_i)$, $\underline{x}_i \leftarrow \max\{\underline{x}_i, f_e(\overline{x}_j)\}$.*
4. *If $e = (\underline{v}_j, \overline{v}_i)$, $\overline{x}_i \leftarrow \min\{\overline{x}_i, f_e(\underline{x}_j)\}$.*

A push is said to be essential *if it actually modifies the value of $\underline{x}_i$ or $\overline{x}_i$.*

PROPOSITION 2.5. *Suppose $\underline{x}_i$ and $\overline{x}_i$ $(i = 1, \dots, n)$ are initialized to some values and X is the set of vectors $\boldsymbol{x} = (x_1, \dots, x_n)^T$ that* (i) *satisfy all the given inequalities and* (ii) *$\underline{x}_i \le x_i \le \overline{x}_i$ $(i = 1, \dots, n)$. The set X is invariant under pushes.*

Proof. Consider any $\boldsymbol{x} \in X$ and a push through an edge $e = (\overline{v}_j, \overline{v}_i)$. (The arguments for the other cases are similar.) Since $\boldsymbol{x}$ is a feasible solution we have $x_i \le f_e(x_j)$. Note that f_e is an increasing function when both ends of e lie either in $\overline{V}$ or in $\underline{V}$. Hence, from $x_j \le \overline{x}_j$, it follows that $x_i \le f_e(\overline{x}_j)$. Since $x_i \le \overline{x}_i$, we have $x_i \le \min\{\overline{x}_i, f_e(\overline{x}_j)\}$.

It is easy to see that a vector $\boldsymbol{x}$ solves a given TVPI system if and only if (i) $x_i \in S_i$ $(i = 1, \dots, n)$ and (ii) the set of values $\overline{x}_i = \underline{x}_i = x_i$ $(i = 1, \dots, n)$ is invariant under pushes.

We define a new operation that amounts to assigning simultaneously at all vertices the tightest values that could be obtained by applying pushes (see Definition 2.4).

DEFINITION 2.6. *Consider the graph G with some set of values at the vertices, $\underline{x}_i = \underline{x}_i^k$, $\overline{x}_i = \overline{x}_i^k$ $(i = 1, \ldots, n)$. A* push phase *on G is assigning, at the respective vertices, the set of values $\underline{x}_i^{k+1}$, $\overline{x}_i^{k+1}$ $(i = 1, \ldots, n)$ defined as follows:*

$$\overline{x}_i^{k+1} \leftarrow \min\left\{\overline{x}_i^k, \min_{e\in\text{in}\{\overline{v}_i\}}\left\{f_e(\overline{x}_j^k) \text{ if } e = (\overline{v}_j, \overline{v}_i), \text{ or } f_e(\underline{x}_j^k) \text{ if } e = (\underline{v}_j, \overline{v}_i)\right\}\right\},$$

$$\underline{x}_i^{k+1} \leftarrow \max\left\{\underline{x}_i^k, \max_{e\in\text{in}\{\underline{v}_i\}}\left\{f_e(\overline{x}_j^k) \text{ if } e = (\overline{v}_j, \underline{v}_i), \text{ or } f_e(\underline{x}_j^k) \text{ if } e = (\underline{v}_j, \underline{v}_i)\right\}\right\}.$$

Performing a *push phase* is computationally similar to a single phase of the Bellman-Ford shortest-path algorithm. It takes $O(m)$ time sequentially; $O(\log\log n)$ time using $O(m)$ processors or $O(1)$ expected time using $O(m)$ processors by a randomized algorithm on a CRCW PRAM; and $O(\log m)$ deterministic time using $O(m)$ processors on a CREW PRAM. (See [13].)

We use push phases as a basic operation in algorithms presented later. When repeated applications of push phases are performed, the initial set of values is denoted by $\underline{x}_i = \underline{x}_i^0$, $\overline{x}_i = \overline{x}_i^0$ $(i = 1, \ldots, n)$ and the respective values of $\underline{x}_i$ and $\overline{x}_i$ after the termination of the kth push phase are denoted by $\underline{x}_i^k$ and $\overline{x}_i^k$.

DEFINITION 2.7. *Suppose that a sequence of push phases is performed. Consider pairs consisting of a value and a vertex of the form $(\underline{x}_j^k, \underline{v}_j)$ or $(\overline{x}_j^k, \overline{v}_j)$ (where $k \geq 0$ and $1 \leq j \leq n$). The* predecessor *of a pair (ξ, v) is the pair (ξ', v') such that $e = (v', v)$ is the edge through which the essential push determined the value ξ, and $\xi' = f_e^{-1}(\xi)$ is the corresponding value at v'. If the predecessor is not uniquely defined we choose arbitrarily among the qualified pairs. A pair (ξ, v) does not have a predecessor if and only if ξ is the initial value at v.*

The essential path *of a pair (ξ, v) as above consists of the sequence of pairs $(\xi_1, v_1), \ldots, (\xi_\ell, v_\ell)$ and the corresponding sequence of edges $e_1, \ldots, e_{\ell-1}$ such that* (i) *(ξ_i, v_i) is the predecessor of (ξ_{i+1}, v_{i+1}) and e_i is the edge through which the essential push occurs $(i = 1, \ldots, \ell - 1)$,* (ii) *$(\xi_\ell, v_\ell) = (\xi, v)$, and* (iii) *$(\xi_1, v_1)$ does not have a predecessor.*

It is easy to see that the essential paths that correspond to $(\underline{x}_i^\ell, \underline{v}_i)$ and $(\overline{x}_i^\ell, \overline{v}_i)$ $(i = 1, \ldots, n)$ can be found within the same time bounds of performing ℓ push phases, simply by keeping track of all essential push operations.

We extend the notion of a push through an edge to directed paths. Let $p = (e_1, \ldots, e_k)$ be a (directed) path in G. A *push along p* is defined to be the composition of k successive pushes, through the edges $e_1, \ldots, e_k$. It is easy to see that for every $\ell \geq 0$ and a vertex v, after a sequence of ℓ push phases, the value at v is exactly the tightest between the initial value at v and the values obtained by pushing corresponding initial values at vertices along paths of size at most k that are going into v.

2.3. Properties of the feasible region. We discuss the relation between the bounds of the interval of feasible values of a variable and the tightest bounds implied by directed cycles. We first give the following definitions.

DEFINITION 2.8.

1. *For each variable x_i, let $[\underline{x}_i^*, \overline{x}_i^*]$ be the set of values in $[a_i, b_i]$ that are not contradicted by any simple cycle. Note that the two cycles c and c^{-1} imply the same bound. It follows that in order to find $\overline{x}_i^*$ (resp., $\underline{x}_i^*$), it suffices to consider cycles ending at $\overline{v}_i$ (resp., $\underline{v}_i$).*
2. *For $1 \leq i \leq n$ denote by $[x_i^{\min}, x_i^{\max}] \subseteq [\underline{x}_i^*, \overline{x}_i^*]$ the largest interval such that* (1) *for all $1 \leq j \leq n$ and for all simple paths p from a vertex $\overline{v}_j$ (resp., $\underline{v}_j$) to $\overline{v}_i$, we*

have $x_i^{\max} \leq f_p(\overline{x}_j^*)$ (*resp.*, $x_i^{\max} \leq f_p(\underline{x}_j^*)$) *and* (2) *for all* $1 \leq j \leq n$ *and for all simple paths* p *from a vertex* $\overline{v}_j$ (*resp.*, $\underline{v}_j$) *to* $\underline{v}_i$ *we have* $x_i^{\min} \geq f_p(\overline{x}_j^*)$ (*resp.*, $x_i^{\min} \geq f_p(\underline{x}_j^*)$).

3. *An interval* $I \subset R$ *is* infeasible *with respect to the variable* x_i *if* $I \cap [x_i^{\min}, x_i^{\max}] = \emptyset$. *A value* $\overline{x}_i$ (*resp.*, $\underline{x}_i$) *is* infeasible *if* $\overline{x}_i < x^{\min}$ (*resp.*, $\underline{x}_i > x^{\max}$).
4. *A value* $\overline{x}_i$ (*resp.*, $\underline{x}_i$) *is* consistent with an interval $[a, b]$ *if* $\overline{x}_i \geq b$ (*resp.*, $\underline{x}_i \leq a$). *A value* $\overline{x}_i$ (*resp.*, $\underline{x}_i$) *is* consistent *if* $\overline{x}_i \geq x_i^{\max}$ (*resp.*, $\underline{x}_i \leq x_i^{\min}$).

REMARK 2.9. *When the values* $\overline{x}_i^*$ *and* $\underline{x}_i^*$ $(i = 1, \ldots, n)$ *are given, we can compute* $x_i^{\min}$ *and* $x_i^{\max}$ *as follows. Initialize the values at the vertices to be* $\overline{x}_i^0 = \overline{x}_i^*$ *and* $\underline{x}_i^0 = \underline{x}_i^*$ $(i = 1, \ldots, n)$. *Perform* $2n$ *push phases. It follows from Definition* 2.8 *part* 2 *that* $x_i^{\min} = \underline{x}_i^n$ *and* $x_i^{\max} = \overline{x}_i^n$. *This procedure runs in* $O(mn)$ *time and is used in Megiddo's algorithm* [15].

For example, the TVPI system of Fig. 2 has $[\underline{x}^*, \overline{x}^*] = [-1, 1] = [x^{\min}, x^{\max}]$, and $[\underline{y}^*, \overline{y}^*] = [0, 2] = [y^{\min}, y^{\max}]$. The TVPI system of Fig. 3 has $[\underline{x}^*, \overline{x}^*] = [\underline{z}^*, \overline{z}^*] = [-\infty, +\infty]$, $[\underline{y}^*, \overline{y}^*] = [y^{\min}, y^{\max}] = [0, 1]$, and $[x^{\min}, x^{\max}] = [z^{\min}, z^{\max}] = [0, 2]$.

The following key observation is due to Shostak.

PROPOSITION 2.10 [17]. *If the system is feasible, then for all* $1 \leq i \leq n$, *the interval* $[x_i^{\min}, x_i^{\max}]$ *is the projection of the set of solutions on the* x_i *axis. Otherwise, for some* $1 \leq i \leq n$, $x_i^{\min} > x_i^{\max}$.

The proof follows from considering the possible structure of minimal sets of inequalities that imply a bound on a variable. Proposition 2.10 and the procedure described in Remark 2.9 assert that in order to find a feasible solution it suffices to consider all *simple* cycles in the associated graph. Shostak presented an exponential time algorithm that essentially examines all directed simple cycles [17].

The following corollary states that if two bounds are feasible separately but not simultaneously, then there exists a simple path that implies an inequality which asserts that the bounds are not simultaneously feasible.

COROLLARY 2.11. *Let* S *be a set of* TVPI *constraints and* $s_1 \in \{x_i \geq \alpha, x_i \leq \alpha\}$, $s_2 \in \{x_j \geq \beta, x_j \leq \beta\}$ *be two bounds. Let* $u_i = \overline{v}_i$ *if* s_1 *is an upper bound, and* $u_i = \underline{v}_i$ *otherwise*; *let* $u_j = \overline{v}_j$ *if* s_2 *is an upper bound, and* $u_j = \underline{v}_j$ *otherwise. Suppose* $S \cup \{s_1\}$, *and* $S \cup \{s_2\}$ *are feasible systems, but* $S \cup \{s_1, s_2\}$ *is not feasible. Under the above conditions the following holds. There exists a simple path* p *from* u_i *to* u_j^{-1} *such that* (i) $f_p(\alpha) < \beta$, *if* s_2 *is a lower bound, and* (ii) $f_p(\alpha) > \beta$, *if* s_2 *is an upper bound. Moreover, if* p *is the tightest* (*simple*) *path from* u_i *to* u_j^{-1} *relative to* $x_i = \alpha$, *then if* s_2 *is an upper* (*resp.*, *lower*) *bound,* $x_j = f_p(\alpha)$ *is the smallest* (*resp.*, *largest*) *value of* x_j *subject to* $S \cup \{s_1\}$.

Proof. Suppose that both s_1, s_2 are upper bounds (the proof for the other cases is similar). Consider $a_j \equiv x_j^{\min}$ under the system $S \cup \{s_1\}$ and $a_j' \equiv x_j^{\min}$ under the system S. We have $a_j' \leq \beta$ and $a_j > \beta$. By definition, $x_j^{\min}$ is either implied (a) by a cycle or a cycle and a path (i.e., implied only by inequalities that involve exactly two variables), or (b) a (possibly empty) directed simple path (i.e., by a single variable inequality). Since the system S contains the same two variable inequalities as $S \cup \{s_1\}$, a_j is determined by a system of type (b) consisting of the bound s_1 and a simple path p.

2.4. Characterizations of TVPI polyhedra. Proposition 2.10 relates the bounding box of the feasible region to the associated graph. We give several characterizations for polyhedra that comprise sets of solutions of TVPI systems (TVPI *polyhedra*). Polyhedra that cannot be expressed as such are *non*-TVPI *polyhedra*.

PROPOSITION 2.12. *Consider a polyhedron* $P \subset R^n$. *The following statements are equivalent*:

1. *The polyhedron* P *is a* TVPI *polyhedron.*

2. *For a bounded convex set $P' = P \cap B'$, where B' is a box, denote $a_i = \min_{x \in P'} x_i$, $b_i = \max_{x \in P'} x_i$ $(i = 1, \ldots, n)$, and denote by $B = \text{X}_{i=1}^{n}[a_i, b_i]$*[1] *the tightest bounding box for P'. Every P' as above is such that $\frac{1}{2}\boldsymbol{a} + \frac{1}{2}\boldsymbol{b} \in P'$.*
3. *Every set S of bounds (i.e., conditions of the form $x_i \geq \alpha$, $x_i \leq \alpha$, $x_i = \alpha$) has the following property. Denote by $B_S \in R^n$ the set of all feasible vectors for S. $P \cap B_S = \emptyset$ if and only if there exists a set $S' \subset S$, where $|S'| \leq 2$ such that $P \cap B_{S'} = \emptyset$.*
4. *Same as property 3, but S contains only equalities.*

In analysis done later in this paper we make use of the fact that property 1 implies 3. The other characterizations are presented for the sake of interest and completeness.

Proof. We first show that property 1 implies properties 2–4.

1 ⇒ 2 Was proved by Lueker, Megiddo, and Ramachandran [14].

1 ⇒ 3 Suppose P is a TVPI polyhedron. Let S_P be a set of TVPI constraints that define P and let $P_i = [\hat{x}_i^{\min}, \hat{x}_i^{\max}]$ $(i = 1, \ldots, n)$ be the corresponding projections. Let S be a set of bounds such that the combined TVPI system $S_P \cup S$ is infeasible. Note that the associated graphs of S_P and $S_P \cup S$ are identical. Denote by $x_i^{\min}, x_i^{\max}$ $(i = 1, \ldots, n)$ the bounds defined by the system $S \cup S_P$. By definition, each of $x_i^{\min}, x_i^{\max}$ $(i = 1, \ldots, n)$ that does not coincide with the respective end point of the interval P_i, is determined by a single bound from S and a simple path. Proposition 2.10 implies that the system $S_P \cup S$ is infeasible if and only if for some variable x_i, $x_i^{\min} > x_i^{\max}$. Hence at least one of the two bounds $x_i^{\min}, x_i^{\max}$ does not coincide with an end point of P_i. Consider the bounds $S' \subset S_P \cup S$ $(|S'| \leq 2)$ that determine $x_i^{\min} > x_i^{\max}$. Obviously, the system $S_P \cup S'$ is infeasible.

3 ⇒ 4 Obvious.

It remains to prove that either one of properties 2–4 implies property 1. Note that properties 1–4 are invariant under scalings and translations of coordinates.

Figure 4 provides an example of a non-TVPI polyhedron. It is easy to see that for this polyhedron property 2 does not hold (consider the bounding box $0 \leq x \leq 1$, $0 \leq y \leq 1$, $0 \leq z \leq 1$), and property 4 does not hold (consider $S = \{x = 0, y = 0, z = 0\}$).

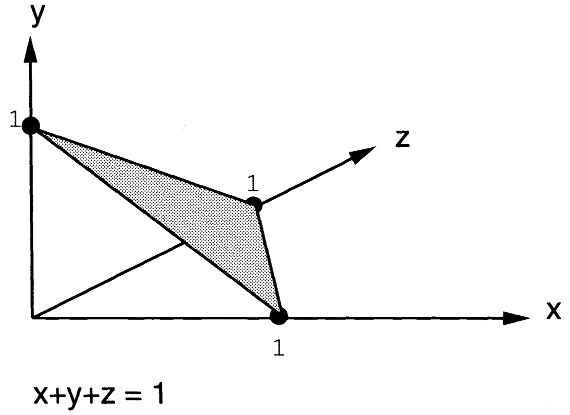

FIG. 4. *An example of a non-*TVPI *polyhedron.*

Assume that P is a non-TVPI polyhedron. If P is full dimensional, there exists at least one face F such that the equation of the hyperplane H constituting the affine hull of F involves

[1] $\text{X}_{i=1}^{n}[a_i, b_i]$ denotes the Cartesian product of the intervals $[a_i, b_i]$ $(i = 1, \ldots, n)$.

more than two variables. Without loss of generality (by permuting and scaling coordinates) we can assume that the equation is $\sum_{i=1}^{\ell} x_i = c$ (where $\ell \geq 3$ and $c \in R$), and for all points $\boldsymbol{x} \in P$, $\sum_{i=1}^{\ell} x_i \leq c$. Note that $P \cap H$ is full dimensional in H. Define $\hat{\boldsymbol{x}}$ to be some point in rel int $P \cap H$. If P is not full dimensional, consider a set of equations defining the affine hull of P. Consider a representation of P by the equalities $x_i = f_i(x_1, \ldots, x_{n'})$ $(i \geq n')$ for some $n' < n$ and a set of inequalities on $x_1, \ldots, x_{n'}$. Denote by $P' \subset R^{n'}$ the polyhedron defined by these inequalities. The representation is chosen such that P' is full dimensional. If one of the equations involves more than two variables assume (by permuting and scaling coordinates) that it has the form $x_\ell = -\sum_{i=1}^{\ell-1} x_i + c$. Define $(\hat{x}_1, \ldots, \hat{x_\ell})$ to be some point in rel int P'. If none of the equations involves more than two variables, then at least one face F of P' involves more than two variables. Using similar considerations to the ones used above, we assume without loss of generality that the equation defining the affine hull of F is $\sum_{i=1}^{\ell} x_i = c$, and for all points $\boldsymbol{x} \in P$, $\sum_{i=1}^{\ell} x_i \leq c$. Note that $P' \cap H$ is full dimensional in H. Define $\hat{\boldsymbol{x}}$ to be some point in rel int $P' \cap H$.

4 ⇒ 1 By definition of $\hat{\boldsymbol{x}}$, there exists a small enough $\epsilon \geq 0$ such that for $i = 1, \ldots, \ell$, there exists $\boldsymbol{x}^i \in P$ such that $x_i^i = \hat{x}_i - (\ell - 1)\epsilon$, and $x_j^i = \hat{x}_j + \epsilon$ $(j = 1, \ldots, i-1, i+1, \ldots, \ell)$. Consider the set of equations $S = \{x_j = \hat{x_j} + \epsilon \mid j = 1, \ldots, \ell\}$. Obviously, there is no point in P that satisfies S. On the other hand, there is a point that satisfies every subset of $\ell - 1 \geq 2$ constraints. Hence, property 4 does not hold for P.

2 ⇒ 1 By definition of $\hat{\boldsymbol{x}}$, there exists a small enough $\epsilon \geq 0$ such that for $i = 1, \ldots, \ell$, there exists $\boldsymbol{x}^i \in P$ such that $x_i^i = \hat{x}_i + (\ell - 1)\epsilon$, and $x_j^i = \hat{x}_j - \epsilon$ $(j = 1, \ldots, i-1, i+1, \ldots, \ell)$. Consider the box B defined by the intervals $[\hat{x}_j - \epsilon, \hat{x}_j + (\ell - 1)\epsilon]$ $(i = 1, \ldots, \ell)$. Since $\boldsymbol{x}^i \in B \cap P$, B is a bounding box for $B \cap P$. However, there is no $\boldsymbol{x} \in P$ for which $x_j = \hat{x}_j + (\ell - 2)\epsilon/2$ $(j = 1, \ldots, \ell)$. It follows that property 2 does not hold for P.

2.5. Classifying and locating values. We discuss two procedures that are used later in the paper and are based on repetitive applications of push phases and examining essential paths.

One of the procedures solves the following problem.

PROBLEM 2.13 [*Locate a value*]. *For a given* TVPI *system, a number* ξ, *and a variable* x_i, *locate* ξ *with respect to the interval* $[x_i^{\min}, x_i^{\max}]$, *that is, decide whether* (i) $\xi_i < x_i^{\min}$, (ii) $\xi_i > x_i^{\max}$, *or* (iii) $\xi_i \in [x_i^{\min}, x_i^{\max}]$.

We refer to solving Problem 2.13 as *locating* the value ξ_i. Aspvall and Shiloach [2], [3] proved the following.

PROPOSITION 2.14. *Problem* 2.13 *can be solved in* $O(mn)$ *operations.*

Aspvall and Shiloach utilized this result to solve TVPI systems: By solving instances of Problem 2.13, their algorithm conducts a binary search that finds a point $\xi_i \in [x_i^{\min}, x_i^{\max}]$ $(1 \leq i \leq n)$. They showed that finding such a point ξ_i can be done in $O(mnI)$ operations where I is the number of bits in the binary representation of the input. This yielded their $O(mn^2I)$ algorithm for TVPI systems: The algorithm performs n steps, where in step i a point $\xi_i \in [x_i^{\min}, x_i^{\max}]$ is found, and the equation $x_i = \xi_i$ is added to the system. If the original system is feasible, then $\boldsymbol{\xi} \in F$.

In §3 we present a $\tilde{O}(mn^2)$ deterministic algorithm for solving TVPI systems, that is based on locating values in the time bounds stated in Proposition 2.14. The material contained in the remainder of the current section is needed for achieving the randomized sequential bound of $\tilde{O}(n^3 + mn)$ and parallel time bounds of $\tilde{O}(n)$, and hence, it is not needed for the reading of §3. In the rest of the section we first characterize the possible structures of minimal subsystems that certify the infeasibility of values ("*certificates*"). We then classify infeasible values according to the types of their certificates. We also present a generic algorithm that performs a sequence of push phases for a given set of initial values. This algorithm maintains essential paths and tests for cycles in these paths. We apply this algorithm to solve both the value location problem and the *reveal* problem that is defined later.

Certificates of infeasibility. Suppose an interval $I = [a, b]$ is infeasible with respect to x_i (equivalently, either $[-\infty, b]$ or $[a, \infty]$ is infeasible). It follows from Proposition 2.10 that there exists a vertex w, a simple path p from $u \in \{\underline{v}_i, \overline{v}_i\}$ to w, and a disjoint simple cycle c starting at w such that the bound on w implied by c and the path p produce a bound on x_i that does not intersect I. Note that the path p and the cycle c comprise a minimal subsystem that implies the infeasibility of I. Also note that the cycle c may be empty, in which case the infeasibility follows from the path p and a bound on the variable associated with w. We refer to such a system as a *certificate* for I. If c is a closed cycle we say that the certificate is *closed*. If c is open or empty, we say that the certificate is *open*. When we refer to a certificate, we interchangeably mean the set of edges $E' = p \cup c$, the set E'^{-1} of the reversed edges, or the corresponding set of inequalities.

Classifying values. We classify values of variables according to the types of their certificates. Consider an interval I with respect to x_i. If I has a closed certificate we say that I is *strongly infeasible.* If only open certificates exist, we say that I is *weakly infeasible.* Otherwise, if no certificate exists, $I \cap [x_i^{\min}, x_i^{\max}] \neq \emptyset$ and we say that I is feasible. In particular these definitions apply when I consists of a single point. For $1 \leq i \leq n$, we denote by $[x_i^{\min *}, x_i^{\max *}]$ the set of all feasible and weakly infeasible values of x_i. Note that $x_i^{\min *}$, $x_i^{\max *}$ $(1 \leq i \leq n)$ are independent of the single variable inequalities.

We motivate distinguishing strongly and weakly infeasible values. We shall see that weakly infeasible values can be identified by applying push phases (at most $2n$ times) until for some $1 \leq i \leq n$ we have $\underline{x}_i > \overline{x}_i$. Strongly infeasible values are trickier to identify. Merely applying push phases is not enough. We need to keep track of essential paths, detect cycles in these paths, and compute the corresponding bounds.

We extend the definitions of the concepts above from intervals to values at vertices of G: A property (having a closed/open certificate, weak/strong infeasibility) holds for a value ξ at a vertex $\underline{v}_i$ (resp., $\overline{v}_i$) if it holds for the interval $[\xi, \infty]$ (resp., $[-\infty, \xi]$) with respect to x_i.

We present two corollaries of Propositions 2.5 and 2.10. Consider a feasible TVPI system and the associated graph. Suppose a sequence of push phases is performed.

COROLLARY 2.15. *If the values at the vertices are initially consistent (see Definition 2.8), they remain consistent after any number of push operations.*

COROLLARY 2.16. *Consider a vertex $u = \underline{v}_i$ (resp., $u = \overline{v}_i$) and a value $\xi = \underline{x}_i^{\ell}$ (resp., $\xi = \overline{x}_i^{\ell}$) for some ℓ. Let (ξ_j, v_j) $(j = 1, \ldots, k \leq \ell)$, where $(\xi_k, v_k) \equiv (\xi, u)$, be the pairs comprising the essential path (see Definition 2.6) associated with (ξ, u). If ξ is infeasible (resp., strongly infeasible) at u, then each of the pairs (ξ_j, v_j) $(1 \leq j < k)$ is such that ξ_j is an infeasible (resp., strongly infeasible) value of v_j.*

Consider an essential path that contains a closed cycle (a vertex appears more than once). The following proposition enables us to extract information from the cycle. It states that either all values following the start pair of the cycle are consistent (the path does not add information) or all values preceding the last pair of the cycle are strongly infeasible (an infeasible value is detected). Moreover, by considering the updating cycle we can determine which of the two situations occurs.

PROPOSITION 2.17. *Let ξ be a value at $u = \overline{v}$ (resp., $u = \underline{v}$). Suppose a closed cycle c, that starts and ends at u, is such that $f_c(\xi) < \xi$ (resp., $f_c(\xi) > \xi$). Then, either* (i) *ξ is strongly infeasible at u and the cycle c is a closed certificate, or* (ii) *if $F \neq \emptyset$, ξ is consistent at u.*

Proof. The bound implied by the cycle c is $f_c(y) \geq y$ (resp., $f_c(y) \leq y$). It suffices to show that it holds either (i) only for values y such that $y > \xi$ (resp., $y < \xi$), and hence ξ is strongly infeasible, or (ii) only for values y such that $y \leq \xi$ (resp., $y \geq \xi$) and hence, ξ is consistent. The function $f_c(y) - y$ is linear and thus can change sign only once. It cannot be a nonpositive (resp., nonnegative) constant, since this contradicts $f_c(\xi)$ being tighter than ξ. If the function is a negative (resp., positive) constant, the cycle implies that the system is infeasible (and therefore ξ is contradicted by the cycle). Otherwise, consider the value y^* such that $f_c(y^*) = y^*$. The bound implied by c is either $[-\infty, y^*]$ or $[y^*, \infty]$. Since ξ does not satisfy the bound inequality, it is not in this interval.

The following algorithm is applied to a set of values $\underline{x}_i^0, \overline{x}_i^0$ (for $1 \leq i \leq n$). The algorithm performs a sequence of push phases, and keeps track of essential paths. When the algorithm detects a nonsimple essential path, it either terminates or discards the path. If the algorithm terminates as a result of such a path, a closed certificate is found for one of the initial values. A vertex v is *active* at a particular point in the execution of the algorithm if the current value at v resulted from an essential path that is not discarded.

ALGORITHM 2.18 [*generic applications of push phases*].

1. *For* $i = 1, \ldots, n$, *initialize the values at* $\underline{v}_i$ *and* $\overline{v}_i$ *as* $\underline{x}_i^0$ *and* $\overline{x}_i^0$, *respectively.*
2. *For* $k = 1, \ldots, 2n$ *do steps* 3–7. *If the algorithm did not terminate, conclude that none of the initial values is strongly infeasible, and stop.*
3. *Perform a push phase. Denote the values at the vertices after the kth push phase by* $\underline{x}_j^k, \overline{x}_j^k$ $(1 \leq k \leq 2n)$.
   Keep track of all essential push operations that result from active vertices. If there are no such essential pushes or no active vertices, stop and conclude that none of the initial values is strongly infeasible.
   (*We assume that ambiguities about the edge that carried the essential push are resolved consistently according to some ordering on the edges.*)
4. *If* $k \neq 2^j$ *for all integers* j *and* $k \neq 2n$, *go to step* 3 (*next iteration*).
5. *Optional: If for some* j, $\underline{x}_j^k > \overline{x}_j^k$, *then stop.*
6. *For each active vertex* v, *let* p_v *be the essential path that corresponds to the last tightening of the value at* v.
   If p_v *contains a closed cycle* (*i.e., some vertex appears in more than one pair*), *execute the following subroutine* (step 7). *After considering all vertices, go to step* 3 (*next iteration*).
7. **Subroutine: Examine p_v.**
   Consider the last simple closed cycle c *on* p_v. *Denote by* u *the vertex where* c *starts and ends. Denote by* ξ *the value associated with* u *at its first occurrence on* c. *Check whether the bound implied by* c *contradicts* ξ. *If there is no contradiction,* ξ *is consistent* (*see Proposition* 2.17), *discard all essential paths originating from the first pair* (u, ξ) *of the cycle* c (*all correspond to consistent values according to Corollary* 2.15); *return. Otherwise, if* c *contradicts* ξ, ξ *is strongly infeasible. It follows from Corollary* 2.16 *that so are all values along the path* p_v *prior to the pair* $(u, f_c(\xi))$ (*the last occurrence of* u *on* p_v). *In particular, the initial value at the first vertex* w *of* p_v *is strongly infeasible. Terminate the execution of the algorithm.*

Complexity. The underlying computation of the algorithm is the Bellman-Ford single-source shortest-path computation [8], where we maintain information needed to construct the paths and test for cycles.

The algorithm terminates after $\ell \leq 2n$ iterations, in which case, it requires $O(m\ell)$ sequential time, and $O(\ell)$ expected time (or, $O(\ell \log\log m)$ deterministic time) using $O(m\ell)$ work on a CRCW PRAM.

If the algorithm terminates at step 7, it finds a closed certificate for the initial value at w. If the algorithm terminates during the ℓth iteration, the closed certificate found is of size $\theta(\ell)$.

PROPOSITION 2.19. *Consider an execution of Algorithm* 2.18, *where step* 5 *is skipped.*

1. *At least one of the initial values is strongly infeasible if and only if the algorithm terminates at step* 7.
2. *Suppose that exactly one of the initial values, ξ at the vertex w, is strongly infeasible. The algorithm terminates at step* 7 *with the same closed certificate regardless of the initial values at other vertices.*

Proof. We first prove part 1. The "if" direction is immediate. Suppose an initial value ξ at a vertex w has a closed certificate consisting of a path p of length $|p|$ to u_0 and a cycle c of length r that starts and ends at u_0. After at most $|p|$ iterations, the value at u_0 is at least as tight as $f_p(\xi)$ and hence, has a closed certificate consisting of c. Similarly, after $|p| + r$ iterations the same holds for all the vertices of c. Let $e_0, \dots, e_r$ and $u_0, \dots, u_r$, respectively, be the edges and vertices of c. We claim that all iterations for which $k \geq |p|$ result in an update of at least one of the values at $u_0, \dots, u_r$. Assume the claim is true. Assume to the contrary that the algorithm did not terminate at step 7. Therefore, it performs $2n$ iterations. It follows that at least one of the paths p_{u_j} $(1 \leq j \leq r)$ is of length $2n$, and hence, contains a closed cycle. Since the value at u_j is strongly infeasible, it follows from Corollary 2.16 that w or another vertex with a strongly infeasible initial value is the first vertex of p_{u_j}. It follows from Proposition 2.17 that each cycle in p_{u_j} contradicts the value at the start vertex. Hence, the algorithm terminates at step 7.

What remains is to prove the claim. Assume the contrary. Let $\xi_0, \dots, \xi_r$ be the respective values at $u_0, \dots, u_r$. In particular, none of the edges e_k $(0 \leq k \leq r)$ had an essential push. Hence, for all $j = 1, \dots, r$, $f_{e_j}(\xi_j)$ is not tighter than $\xi_{j+1 \bmod r}$. It follows that $f_{e_1 \cdots e_r}(\xi_0) = f_c(\xi_0)$ is no more tight than ξ_0. This is a contradiction for c being a closed certificate for ξ_0.

We prove part 2. Consider an initialization where ξ at w is the only strongly infeasible value. It follows from part 1 that the algorithm terminates in step 7, and finds an essential path p that starts at w and terminates in a closed cycle. All values along the path are strongly infeasible. Suppose that an initial path starting at a vertex other than w updates a value at a vertex in p. It follows from Corollary 2.16 that the updated value cannot be tighter or as tight as the value resulting from p. The proof follows. □

DEFINITION 2.20. *Suppose ξ is a strongly infeasible value at a vertex w. Consider an execution of Algorithm* 2.18 *where step* 5 *is skipped and ξ at w is the only strongly infeasible initial value* (*see Proposition* 2.19 *part* 2). *We refer to the unique closed certificate found by such an execution as* the certificate *of ξ.*

REMARK 2.21. *Consider a run of the algorithm where step* 5 *is performed.*

1. *Suppose that the algorithm terminates at step* 5, *where it detects $\underline{x}_j^k > \overline{x}_j^k$. Consider the initial pairs (u, ξ) and (w, μ) of the two essential paths that determined $(\underline{v}_j, \underline{x}_j^k)$ and $(\overline{v}_j, \overline{x}_j^k)$. It is not necessarily true that one of the initial pairs is infeasible. We can conclude, however, that the two corresponding bounds cannot be satisfied simultaneously by a feasible vector.*
2. *Consider a run of the algorithm where at least one of the initial values has an open certificate of size ℓ that contains a nontrivial cycle. The following is immediate: The algorithm terminates at either step* 7 *or step* 5 *within ℓ iterations.*

Locating a value. We apply Algorithm 2.18 to solve Problem 2.13.

Consider a value ξ_i. We show how to decide whether or not $\xi_i > x_i^{\max}$ (the case $\xi_i < x_i^{\min}$ is similar).

ALGORITHM 2.22 [*Locate a value with respect to* $x_i^{\max}$]. *Perform a run of Algorithm* 2.18, *where step* 5 *is enabled, for the following input of values*: $\underline{x}_j^0 = a_j$ *for* $j \neq i$, $\overline{x}_j^0 = b_j$ *for* $j = 1, \ldots, n$, *and* $\underline{x}_i^0 = \xi_i$.

Conclude as follows:

- *If the algorithm stopped at step* 3 (*no active vertices*), *determine that* $\xi_i \leq x_i^{\max}$.
- *If the algorithms stopped at step* 5, *consider the essential paths associated with* $\underline{x}_j^k > \overline{x}_j^k$. *If in neither path, the initial pair is* $(\underline{v}_i, \xi_i)$, *conclude that the system is infeasible. Otherwise, conclude that* $\xi_i > x_i^{\max}$.
- *Suppose the algorithm terminated at step* 7. *If* $w = \underline{v}_i$, *determine that* $\xi_i > x_i^{\max}$. *Otherwise, if* $w \neq \underline{v}_i$, *the system is infeasible.*
- *If the algorithm terminated at step* 2, *determine that* $\xi_i \leq x_i^{\max}$.

The correctness follows immediately from Proposition 2.19, part 1, and Remark 2.21.

Reveal a strongly infeasible value. We discuss applying Algorithm 2.18 to solve the following problem.

PROBLEM 2.23 [*reveal a strongly infeasible value*]. *Given are values* ξ_i, $a_i \leq \xi_i \leq b_i$ $(i \in I)$ *for the respective variables* x_i $(i \in I)$, *where* $I \subset \{1, \ldots, n\}$. *Do one of the following*:

1. *Conclude that all the values are feasible or weakly infeasible.*
2. *Find a strongly infeasible value* ξ_j *and a closed certificate.*

ALGORITHM 2.24 [*reveal*]. *Perform a run of Algorithm* 2.18, *where step* 5 *is skipped, for the input values:* $\overline{x}_i = \underline{x}_i = \xi_i$ $(i \in I)$, *and* $\overline{x}_i = b_i$, $\underline{x}_i = a_i$ $(i \notin I)$.

The following is a corollary of Proposition 2.19.

COROLLARY 2.25. *Algorithm* 2.24 *solves Problem* 2.23. *If none of the initial values is strongly infeasible, the algorithm requires* $O(mn)$ *operations. Otherwise, the algorithm terminates after* $\ell \leq 2n$ *iterations with a closed certificate of size* $\theta(\ell)$. *If exactly one of the values* ξ_i $(i \in I)$ *is strongly infeasible, the algorithm terminates with the same closed certificate regardless of the other values.*

3. The basic algorithm.

In this section we present a framework for solving TVPI systems. This framework allows us to state an algorithm for TVPI systems in terms of solving instances of Problem 2.13 (locating single values). The framework is stated in §3.1, and the correctness proof is given in §3.2. In §3.3 we reduce solving a TVPI system to locating $O(n(\log^2 n + \log m))$ values. Since locating a single value requires $O(mn)$ time ($O(n \log\log m)$ time using $O(mn)$ work on a CRCW PRAM), we obtain an $O(mn^2(\log^2 n + \log m))$ deterministic algorithm for solving TVPI systems (that runs in $\tilde{O}(n^2)$ time using $O(mn^2(\log^2 n + \log m))$ work on a CRCW PRAM). In §3.4 we introduce the problem of *locating a pool of values*. A key for further improvements is the reduction of solving a TVPI system to locating $O(\log^2 n + \log m)$ pools of values. A pool of values can be located naively by sequentially locating n single values. In §4 we present faster parallel and sequential algorithms for locating a pool, that yield better algorithms for solving TVPI systems.

3.1. The framework.

We first describe an idea introduced by Megiddo [15], which is the key in obtaining strongly polynomial time bounds. Consider the associated graph of some TVPI system. Every directed path in the associated graph corresponds to a two-variable inequality. Consider two inequalities that correspond to two paths between the same pair of vertices (v_i, v_j), where $v_i \in \{\overline{v}_i, \underline{v}_i\}$. These inequalities are linear, hence there exists a number a such that for all $xm_i \leq a$ one of the inequalities implies the other, and vice versa for $x_i \geq a$. If we focus only on feasible points $\boldsymbol{x}$ for which $x_i \geq a$ (similarly $x_i \leq a$), one of the inequalities is redundant. The algorithm eliminates paths and simultaneously restricts the feasible region. When "comparing" two paths, the decision about which one to eliminate is done as follows.

First, the number a, as above, is computed. The redundant path is determined by locating a with respect to feasible values of x_i (see Problem 2.13). Megiddo applied the above idea in an algorithm that basically performed n single-source shortest path Bellman-Ford type computations, where comparisons amount to locating values. The framework presented here is based on performing an all-pairs shortest path Floyd-Warshall [8] type computation that allows us to apply further ideas.

The following definition formalizes the concept of comparing paths.

DEFINITION 3.1.

1. *Suppose that p_1 and p_2 are two directed paths from u to v, and from v to w, respectively. Denote by $p_1 p_2$ the path from u to w obtained by concatenating p_1 and p_2.*
2. *Suppose that p_1 and p_2 are two paths from u to w. Let $I \subset R$ be an interval. We say that the path p_1 is at least as* tight *as p_2 relative to I (denote it by $p_1 \prec_I p_2$) if either $w \in \underline{V}$ and $f_{p_1}(\xi) \geq f_{p_2}(\xi)$ for all $\xi \in I$, or $w \in \overline{V}$ and $f_{p_1}(\xi) \leq f_{p_2}(\xi)$ for all $\xi \in I$.*
3. *Suppose $p_1, p_2, \ldots, p_k$ are paths from u to w. If for some i, $p_i \prec_I p_j$ for all j, we write $p_i = \min_{\prec_I}\{p_1, p_2, \ldots, p_k\}$. Note that when I is a single point, $\min_{\prec_I}$ is well defined.*

The algorithm maintains a set of intervals S_i $(1 \leq i \leq n)$, and a path p_{uw} from u to w for every pair of vertices (u, w). The algorithm runs in $\lceil \log_2 2n \rceil$ phases. During each phase, the paths and the intervals are considered for possible updates. Denote by S_i^k $(1 \leq i \leq n)$ and p_{uw}^k $(\{u, w\} \subseteq V)$ the intervals and paths, respectively, at the beginning of the kth phase. The algorithm has the following properties: (i) The set $\mathsf{X}_{i=1}^n S_i^k$ contains a feasible point, and (ii) the path p_{uw}^k is the tightest path from u to w, of length at most 2^k, relative to the interval S_i^k (where $u \in \{\overline{v}_i, \underline{v}_i\}$).

The algorithm is based on solving instances of the following problem.

PROBLEM 3.2. *Given are a graph G and a set of intervals $S_1, \ldots, S_n$ as in Definition 2.1. For every ordered pair $(u, v) \in V \times V$ of vertices we are given $p_{uv}^1, \ldots, p_{uv}^{k_{uv}}$, a collection of directed paths from u to v in G. The goal is to find a set of n intervals $I_1, \ldots, I_n$ and select a path $p_{uv}^* \in \{p_{uv}^1, \ldots, p_{uv}^{k_{uv}}\}$ for every pair (u, v) of vertices, where*

1. *$F \neq \emptyset \Rightarrow (\mathsf{X}_{i=1}^n I_i) \cap F \neq \emptyset$, and*
2. *$u \in \{\underline{v}_i, \overline{v}_i\} \Rightarrow p_{uv}^* = \min_{\prec_{I_i}}\{p_{uv}^1, \ldots, p_{uv}^{k_{uv}}\}$.*

We later suggest algorithms for Problem 3.2. The following algorithm uses it as a subroutine. It first initializes the tightest paths matrix by selecting the tightest edge out of every set of multiple edges (step 2). The rest of the algorithm consists of $\lceil \log 2n \rceil$ update phases of the tightest-paths matrix (step 4). During each phase, the algorithm considers n^2 sets of n paths (one for each pair of vertices). It then selects the tightest path in each set. In the last step, the tightest path matrix is used to compute a feasible vector.

ALGORITHM 3.3 [*Solve* TVPI *systems*].

1. *[Initialization] Construct S and G as in Definition 2.1.*
2. *[Initialize tightest paths matrix] For each pair of vertices consider the set of paths of length 1, i.e., all the multiple edges. Solve Problem 3.2 relative to these paths. For $(u, v) \in V \times V$: $p_{uv}^0 \leftarrow p_{uv}^*$. For $i = 1, \ldots, n$: $S_i \leftarrow S_i \cap I_i$, $S_i^0 \leftarrow S_i$.*
3. *For $k = 1, \ldots, \lceil \log_2 2n \rceil$, execute step 4. To continue, go to step 5.*
4. *For each pair $(u, v) \in V \times V$, consider the set of paths*

$$\left\{p_{uv}^{k-1}\right\} \cup \left\{p_{uw}^{k-1} p_{wv}^{k-1} | w \in V \setminus \{u, v\}\right\} .$$

Solve Problem 3.2 relative to these sets of paths.
For $(u, v) \in V \times V$: $p_{uv}^k \leftarrow p_{uv}^*$. For $i = 1, \ldots, n$: $S_i \leftarrow S_i \cap I_i$, $S_i^k \leftarrow S_i$.

5. *Denote* $p_{\underline{i}\,\underline{j}} \equiv p^{\lceil \log 2n \rceil}_{\underline{v}_i,\underline{v}_j}$, $p_{\underline{i}\bar{j}} \equiv p^{\lceil \log 2n \rceil}_{\underline{v}_i,\overline{v}_j}$, $p_{\bar{i}\underline{j}} \equiv p^{\lceil \log 2n \rceil}_{\overline{v}_i,\underline{v}_j}$, $p_{\bar{i}\bar{j}} \equiv p^{\lceil \log 2n \rceil}_{\overline{v}_i,\overline{v}_j}$ *(for* $1 \le i \le n$, $1 \le j \le n$*).*
   For $i = 1, \ldots, n$*:*
   $S_i \leftarrow S_i \cap \{x \mid f_{p_{\underline{i}\,\underline{i}}}(x) \le x\}$, $S_i \leftarrow S_i \cap \{x \mid f_{p_{\underline{i}\bar{i}}}(x) \ge x\}$, $S_i \leftarrow S_i \cap \{x \mid f_{p_{\bar{i}\underline{i}}}(x) \le x\}$.
6. *For* $i = 1, \ldots, n$, *compute intervals* $S'_i = [a'_i, b'_i]$ *as follows (where* $[a_j, b_j] = S_j$, *for* $1 \le j \le n$*):*

$$a'_i \leftarrow \max\left\{a_i, \max_j f_{p_{\bar{j}\underline{i}}}(b_j), \max_j f_{p_{\underline{j}\,\underline{i}}}(a_j)\right\},$$

$$b'_i \leftarrow \min\left\{b_i, \min_j f_{p_{\bar{j}\bar{i}}}(b_j), \min_j f_{p_{\underline{j}\bar{i}}}(a_j)\right\}.$$

7. *Compute a feasible solution* $\hat{\mathbf{x}}$ *as follows, for* $i = 1, \ldots, n$:

$$\hat{x}_i \in \left[\max\left\{a'_i, \max_{j<i} f_{p_{\bar{j}\underline{i}}}(\hat{x}_j), \max_{j<i} f_{p_{\underline{j}\,\underline{i}}}(\hat{x}_j)\right\}, \min\left\{b'_i, \min_{j<i} f_{p_{\bar{j}\bar{i}}}(\hat{x}_j), \min_{j<i} f_{p_{\underline{j}\bar{i}}}(\hat{x}_j)\right\}\right].$$

3.2. Correctness. We prove the following:

1. For $1 \le i \le n$, $S^0_i \supset S^1_i \supset \cdots \supset S^{\lceil \log_2 2n \rceil}_i \supset S'_i$.
2. If $\mathsf{X}^n_{i=1} S^0_i$ contains feasible points, then so do $\mathsf{X}^n_{i=1} S^k_i$ (for all $k > 0$) and $\mathsf{X}^n_{i=1} S'_i$.
3. p^k_{uw} ($u \in \{\underline{v}_i, \overline{v}_i\}$, $w \in V$) is the tightest path (relative to S^k_i) from u to w, of length less than or equal to 2^k.
4. If the system is feasible, the process described in step 7 results in a feasible vector $\hat{\mathbf{x}}$.

Claims 1 and 2 follow directly from the statement of the algorithm.

We prove Claim 3. Consider paths p_1, p_2 between the same pair of vertices. Assume they originate at $\{\underline{v}_j, \overline{v}_j\}$. It follows from the definition of $\prec$ that if $p_1 \prec p_2$ relative to S^k_j, then $p_1 \prec p_2$ relative to S^{k+1}_j. Consider paths of length at most 2^{k+1} from u to v. It suffices to show that when $p_{uv} = p_{uw}p_{wv}$ and $p'_{uv} = p'_{uw}p'_{wv}$, if $p_{uw} \prec_I p'_{uw}$ and $p_{wv} \prec_I p'_{wv}$, then $p_{uv} \prec_I p'_{uv}$. The latter is straightforward.

We prove Claim 4. We first show that $S'_i \subset [x^{\min}_i, x^{\max}_i]$ ($i = 1, \ldots, n$). We claim that $S^{\lceil \log 2n \rceil}_j \subset [\underline{x}^*_j, \overline{x}^*_j]$. If the latter holds, it follows from Proposition 2.10 that $S'_i \subset [x^{\min}_i, x^{\max}_i]$. Assume the contrary, that is, for some $1 \le j \le n$, $S^{\lceil \log 2n \rceil}_j \not\subset [\underline{x}^*_j, \overline{x}^*_j]$. Consider a point $\eta \in S^{\lceil \log 2n \rceil}_j \setminus [\underline{x}^*_j, \overline{x}^*_j]$. Assume that $\eta > \overline{x}^*_j$ (the case where $\eta < \underline{x}^*_j$ is similar). It follows that there exists a simple cycle c, such that either of the following is true:

1. The cycle c, starts and ends at $\overline{v}_j$, and is such that $f_c(\eta) < \eta$.
2. The cycle c, starts at $\underline{v}_j$ and ends at $\overline{v}_j$, and is such that $f_c(\eta) < \eta$.

Denote $c' = p_{\bar{j}\bar{j}}$ (for case (i)) and $c' = p_{\underline{j}\bar{j}}$ (for case (ii)). It follows from claim 3 that the cycle c' is the tightest simple cycle relative to $S^{\lceil \log 2n \rceil}_j$. Therefore, $f_{c'}(\eta) \le f_c(\eta)$. On the other hand, due to step 5 of the algorithm $f_{c'}(\eta) \ge \eta$. This is a contradiction. Thus we have shown that $S'_i \subset [x^{\min}_i, x^{\max}_i]$ ($i = 1, \ldots, n$).

We conclude the proof of Claim 4. Consider the computation performed in step 7. For $i = 1, \ldots, n$ consider the set of intervals $\hat{S}^i_\ell$ ($1 \le \ell \le n$) defined as follows. If $\ell < i$, $\hat{S}^i_\ell = \{\hat{x}_\ell\}$. Otherwise,

$$\hat{S}^i_\ell = \left[\max\left\{a'_\ell, \max_{j<i} f_{p_{\bar{j}\underline{\ell}}}(\hat{x}_j), \max_{j<i} f_{p_{\underline{j}\,\underline{\ell}}}(\hat{x}_j)\right\}, \min\left\{b'_\ell, \min_{j<i} f_{p_{\bar{j}\bar{\ell}}}(\hat{x}_j), \min_{j<i} f_{p_{\underline{j}\bar{\ell}}}(\hat{x}_j)\right\}\right].$$

We claim that for $i = 1, \ldots, n$ the following holds. For each $\mu \in \hat{S}^i_j$ there exists a feasible vector ξ, such that $\xi_j = \mu$ and $\xi_\ell \in \hat{S}^i_\ell$ ($\ell \ne j$). To conclude the proof of property 4, it suffices to prove the claim. We prove the claim by induction on i.

In the base case $\hat{S}^1_\ell = S'_\ell$ $(1 \le \ell \le n)$. We show that for every $\xi_j \in S'_j$ there exists a feasible solution $\boldsymbol{x}$ such that $x_j = \xi_j$ and $x_\ell \in S'_\ell$ for $\ell \ne j$. Assume the contrary. It follows from Proposition 2.12 that there exist two bounds $s_1 \in \{x_j \ge \xi_j, x_j \le \xi_j\}$ and $s_2 \in \{x_\ell \le b'_\ell, x_\ell \ge a'_\ell\}$ such that the system subject to $x_k \in S'_k$ $(1 \le k \le n)$ with the additional bounds s_1, s_2 is infeasible. Assume that s_1 is $x_j \ge \xi_j$ and s_2 is $x_\ell \le b'_\ell$ (the other cases are treated similarly). It follows from Corollary 2.11 that there exists a simple path p from $\overline{v}_\ell$ to $\overline{v}_j$ such that $f_p(b'_\ell) < \xi_j$. In contrast, it follows from property 3 and the computation of step 6 that $f_{p'}(b'_\ell) \ge b'_j$ for all paths p' from $\overline{v}_\ell$ to $\overline{v}_j$, hence a contradiction.

We prove the correctness of the induction step. Consider the step that determines $\hat{x}_i$. Assume that the claim is true for previous steps. The induction hypothesis asserts that subject to the constraints $x_\ell \in \hat{S}^i_\ell$ $(1 \le \ell \le n)$, we have $[x^{\min}_\ell, x^{\max}_\ell] = \hat{S}^i_\ell \equiv [\hat{a}^i_\ell, \hat{b}^i_\ell]$. For $1 \le \ell \le n$, let $\tilde{x}^{\min}_\ell$, $\tilde{x}^{\max}_\ell$ be the respective values of $x^{\min}_\ell$, $x^{\max}_\ell$ subject to $x_\ell \in \hat{S}^i_\ell$ $(1 \le \ell \le n)$ and the additional constraint $x_i = \hat{x}_i$. We need to show that for $1 \le \ell \le n$, $[\tilde{x}^{\min}_\ell, \tilde{x}^{\max}_\ell] = \hat{S}^{i+1}_\ell$. The direction $\hat{S}^{i+1}_\ell \supset [\tilde{x}^{\min}_\ell, \tilde{x}^{\max}_\ell]$ is obvious. Consider $\tilde{x}^{\max}_j$ (the arguments for $\tilde{x}^{\min}_j$ are similar). If $\tilde{x}^{\max}_j = \hat{b}^i_j$ we are done. Otherwise, it follows from Proposition 2.10 that there exists a simple path p from $v_i \in \{\overline{v}_i, \underline{v}_i\}$ to $\underline{v}_j$ such that $f_p(\hat{x}_i) = \tilde{x}^{\max}_j$. It follows from property 3 that either $p' = p_{\bar{i}\underline{j}}$ or $p' = p_{\underline{i}\underline{j}}$ is as tight as p. Hence $f_{p'}(\hat{x}_i) = \tilde{x}^{\max}_j = \hat{b}^{i+1}_j$.

REMARK 3.4. *Note that step 7 can be replaced by choosing* $\hat{x}_i = (a'_i + b'_i)/2$, $1 \le i \le n$. *This follows from the fact that for the system subject to* $x_i \in S'_i$ $1 \le i \le n$, *we have* $[x^{\min}_i, x^{\max}_i] = S'_i$ $(1 \le i \le n)$, *and from Proposition* 2.12 *part* 2.

3.3. Complexity of the naive implementation. The complexity is dominated by the calls to an algorithm for Problem 3.2. We present a naive algorithm for Problem 3.2 that is based on locating single values (see Problem 2.13). The algorithm consists of n sequential stages as follows. At the ith stage the interval I_i is computed and a tightest path is found for each of the $O(n)$ sets of paths that emanate from either one of $\{\underline{v}_i, \overline{v}_i\}$. In the proceeding stages we consider the system with the additional constraint $x_i \in I_i$.

For $1 \le i \le n$, denote by $k^{(i)} = \sum_u (k_{\overline{v}_i u} + k_{\underline{v}_i u})$, the number of paths emanating from $\{\underline{v}_i, \overline{v}_i\}$. We discuss stage i. We consider $O(n)$ sets of paths with the goal of choosing a tightest path in each set. This is done in $O(\log k^{(i)})$ iterations, where in each iteration the total number of paths that need to be considered reduces from r to $n + 3(r - n)/4$. Initially, $r = k^{(i)}$. After the stage terminates, $r = n$ and each set contains a single path (the tightest path). Each iteration is as follows. First, we pair up paths that belong to the same pair of vertices. Each such pair corresponds to a comparison between the two paths that needs to be resolved. For each pair, we compute the intersection of the two linear functions that correspond to the two paths. Each "comparison" amounts to locating the intersection point with respect to the interval $[x^{\min}_i, x^{\max}_i]$. We solve one instance of Problem 2.13 to locate the median of these $r/2$ intersections. By doing this, half the comparisons are resolved, and the number of remaining paths is at most $n + 3(r - n)/4$.

The following proposition is immediate. The parallel bounds follow from known parallel selection algorithms (see e.g., [13]).

PROPOSITION 3.5. *Stage i can be performed by an* $O(k^{(i)} + mn \log k^{(i)})$ *algorithm. A parallel algorithm runs in* $O(n \log m \log\log m \log k^{(i)})$ *determinisitc time* (*alternatively, by allowing randomization, in* $O(n \log k^{(i)})$ *expected time*) *using* $O(mn \log k^{(i)} + k^{(i)})$ *work on a CRCW PRAM.*

We discuss the resulting complexity of Algorithm 3.3. In step 2, the total number of paths $(\sum_{i=1}^n k^{(i)})$ is the number of edges in the graph. Hence the number of operations is $O(mn^2 \log m)$. In step 4, $k^{(i)} = O(n^2)$ $(1 \le i \le n)$. Hence, the number of operations in each execution of step 4 is $O(n^3 + mn^2 \log n)$. Step 4 is performed $\lceil \log_2 2n \rceil$ times. It follows that the total number of operations is $O\left(mn^2(\log m + \log^2 n)\right)$. On a CRCW PRAM the algorithm runs in $O\left(n^2(\log m + \log^2 n)\log m \log\log m\right)$ time (alternatively, by allowing randomization, in $O\left(n^2(\log m + \log^2 n)\right)$ expected time), using $O(mn^2(\log m + \log^2 n)$ work.

3.4. Solving TVPI systems by locating pools of values.

Consider the "naive" algorithm for solving Problem 3.2. The algorithm consists of n stages that are performed sequentially. We present a different algorithm that performs the stages "concurrently," where iterations of different stages are interleaving. The algorithm consists of $O(\max_{1 \le i \le n} \log k^{(i)})$ phases, where at phase i all the ith iterations of the n stages are performed.

An iteration of stage $1 \le j \le n$ amounts to locating a value of x_j. Performing a phase amounts to solving an instance of the following problem.

PROBLEM 3.6 [*Locate a pool of values*]. *Given are a graph G and a set of intervals $S_1, \ldots, S_n$ as in Definition* 2.1. *Also given are a set of values $\xi_i \in S_i$ $(i \in I)$ for the corresponding variables x_i $(i \in I)$, where $I \subset \{1, \ldots, n\}$. The goal is to find a set of intervals J_i $(i \in I)$, such that* (i) $F \neq \emptyset \Rightarrow F \cap \{x \in R^n | \bigwedge_{i \in I} x_i \in J_i\} \neq \emptyset$, *and* (ii) $\xi_i \notin$ interior J_i $(i \in I)$.

We give a more elaborate description of the algorithm that reduces Problem 3.2 to locating pools of values. The correctness is straightforward. The algorithms performs interleaving executions of the "n" stages. This is done in $O(\log \max_i k^{(i)})$ phases. Denote by $I \subset \{1, \ldots, n\}$ the set of stages that did not terminate at the current phase (initially, $I = \{1, \ldots, n\}$). Phase j is as follows:

1. For each $\ell \in I$: compute the value ξ_ℓ of x_ℓ arising from an iteration of stage ℓ. This computation takes $O(n + (3/4)^j \sum_{i \in I} k^{(i)})$ time, and takes, with optimal speedup, $O(\log \max_i k^{(i)} \log\log \max_i k^{(i)})$ deterministic time and constant expected time on a CRCW PRAM.
2. Locate the pool (solve Problem 3.6) ξ_ℓ $(\ell \in I)$. Let J_ℓ $(\ell \in I)$ be the intervals constituting the solution.
3. For $\ell \in I$, $S_\ell \leftarrow S_\ell \cap J_\ell$.

It follows that Problem 3.2 is reduced to solving $O(\max_i \log k^{(i)})$ instances of Problem 3.6 and $O(n \max_i \log k^{(i)} + \sum_{1 \le i \le n} k^{(i)})$ additional time. The problem of solving TVPI systems is therefore reduced to solving $O(\log^2 n + \log m)$ instances of Problem 3.6 and $O(m + n^3 \log n)$ additional computation. Note that, in parallel, the additional computation can be performed in $O(\log m \log\log m + \log^2 n \log\log n)$ time deterministically and in $O(\log n)$ expected time with optimal speedup.

Problem 3.6 can be solved naively by sequentially solving $|I|$ instances of Problem 2.13 (locating a single value). This requires mn^2 time, and $\tilde{O}(n^2)$ time in parallel. In §4 we give algorithms that improve over this bound.

4. Algorithms for locating a pool.

The problem of solving TVPI systems was reduced to locating $O(\log^2 n + \log m)$ pools (Problem 3.6) and $O(n^3 \log n + m)$ additional computation.

In §3.4 we showed that a pool can be located in mn^2 time, and $\tilde{O}(n^2)$ time in parallel. In this section we discuss two algorithms for locating a pool. In §4.1 we present an algorithm that runs in $O(mn^2)$ sequential time, and $\tilde{O}(n)$ time in parallel with optimal speedup. In §4.2 we overview a randomized $O(mn \log^3 n)$ expected time algorithm. A parallel implementation runs in $\tilde{O}(n)$ expected time using $O(m)$ processors. The details of the randomized algorithm are given in §§5 and 6.

4.1. $\tilde{O}(n)$ time using $O(n^2 m)$ work.

In this subsection we prove the following.

PROPOSITION 4.1. *Problem* 3.6 *can be solved on a CRCW PRAM in* $O(n \log\log m)$ *time* (*alternatively, by allowing randomization, in* $O(n)$ *expected time*) *using* $O(mn|I|)$ *work.*

COROLLARY 4.2. *Algorithm* 3.3 *has a parallel implementation on a CRCW PRAM that runs in* $O\left(n \log\log m(\log^2 n + \log m)\right)$ *time* ($O\left(n(\log^2 n + \log m)\right)$ *expected time if randomization is allowed*) *and performs* $O(mn(\log^2 n + \log m))$ *work.*

The following algorithm solves Problem 3.6 within the time bounds stated in Proposition 4.1.

ALGORITHM 4.3 [*Locate a pool*].

```
1. In parallel, locate (solve Problem 2.13) each of the values $\xi_i$ $(i \in I)$.
   For $i \in I$ do as follows:
     • If $\xi_i \geq x_i^{\max}$, determine $J_i \leftarrow \{z | z \leq \xi_i\}$.
     • If $\xi_i \leq x_i^{\min}$, determine $J_i \leftarrow \{z | z \geq \xi_i\}$.
   Let $I' \subset I$ be the set of indices such that $x_i^{\min} < \xi_i < x_i^{\max}$ $(i \in I')$.
2. For each $i \in I'$ perform the following computation:
   Initialize the values at the vertices of $G$ to $\overline{x}_i = \underline{x}_i = \xi_i$ and $\overline{x}_j = \infty$, $\underline{x}_j = -\infty$
   $(j \neq i)$. Apply $2n$ push phases. For $1 \leq j \leq n$ denote the final values at the nodes
   $\underline{v}_j$, $\overline{v}_j$, respectively, by $\underline{x}_j^i$, $\overline{x}_j^i$.
3. Construct a graph $H$ as follows: The graph $H$ has $|I'|$ nodes $w_i$ $(i \in I')$. There is
   an edge between $w_i$ and $w_j$ if and only if $\xi_j < \underline{x}_j^i$ or $\xi_j > \overline{x}_j^i$.
4. Compute a maximal independent set (corresponds to nodes $I^+ \subset I'$) in $H$.
   Choose intervals $J_i$ $(i \in I')$ as follows:
   If $i \in I^+$, $J_i \leftarrow \{\xi_i\}$.
   If $i \in I' \setminus I^+$, then
     • If $\min_{j \in I^+} \overline{x}_i^j < \xi_i$, $J_i \leftarrow \{z | z \leq \xi_i\}$.
     • If $\max_{j \in I^+} \underline{x}_i^j > \xi_i$, $J_i \leftarrow \{z | z \geq \xi_i\}$.
```

We prove the correctness of the algorithm. It follows from Corollary 2.11 that $F \cap \{x | x_i = \xi_i \wedge x_j = \xi_j\} \neq \emptyset$ if and only if $\underline{x}_j^i \leq \xi_j \leq \overline{x}_j^i$. Hence the graph H captures the dependencies between pairs of values. Proposition 2.12 (see equivalence of properties 1 and 4) implies that a set of single variable equations is feasible if and only if every pair is feasible. Hence, the set of intervals J_i $(i \in I')$ solves Problem 3.6.

4.2. Overview of a $\tilde{O}(mn)$ algorithm. In this subsection we present an overview of a faster randomized algorithm for locating a pool of values. A single value can be located in $O(mn)$ operations by using Algorithm 2.22. In the previous section we solved Problem 3.2 more efficiently by inferring from locating a value of one variable about other values of the same variable. To locate a set I of values of different variables, however, we still needed $O(mn|I|)$ operations. The randomized approach presented in this section enables us to infer about values of other variables as well, and in particular, locate a pool of values within $\tilde{O}(mn)$ operations.

We prove the following.

THEOREM 4.4. *Problem* 3.6 *can be solved sequentially in an expected number of* $O(mn \log^3 n)$ *operations and on a CRCW PRAM in* $O(n \log^3 n)$ *expected time using* $O(m)$ *processors.*

Consequently, TVPI systems can be solved in an expected number of

$$O\left(n^3 \log n + mn(\log^5 n + \log m \log^3 n)\right)$$

operations.

Consider a pool of values $\xi_1, \ldots, \xi_n$ for the corresponding variables. These values are classified into three groups as follows (see §2.5):

1. $\xi_i \in [x_i^{\min}, x_i^{\max}]$ (ξ_i is feasible).

2. $\xi_i \notin [x_i^{\min}, x_i^{\max}]$, but $\xi_i \in [x_i^{\min *}, x_i^{\max *}]$ (ξ_i is weakly infeasible).
3. $\xi_i \notin [x_i^{\min *}, x_i^{\max *}]$ (ξ_i is strongly infeasible).

We propose a two-stage algorithm for Problem 3.6. In the first stage the algorithm locates all the strongly infeasible values ξ_i $(i \in I')$, and determines whether $\xi_i < x_i^{\min *}$ or $\xi_i > x_i^{\max *}$. The respective intervals are determined to be $J_i = [-\infty, \xi_i]$ if $\xi_i > x_i^{\max *}$ and $J_i = [\xi_i, \infty]$ if $\xi_i < x_i^{\min *}$. In the second stage the algorithm solves an easier special case of Problem 3.6 where the values are guaranteed to be either feasible or weakly infeasible. In §5 we present an algorithm that solves the first stage and in §6 we present an algorithm for the second stage. These algorithms run in $O(mn \log^3 n)$ time, and in $O(n \log^3 n)$ parallel time using $O(m)$ processors on a CRCW PRAM.

By combining the above results we obtain algorithms for Problem 3.6 with the running times stated in Theorem 4.4.

5. Locating the strongly infeasible values.

We present an algorithm for the following problem.

PROBLEM 5.1 [*Determine the strongly infeasible values*]. *Given are values ξ_i $(i \in I)$ for the corresponding variables x_i $(i \in I)$, where $I \subset \{1, \dots, n\}$. The goal is to determine for each $i \in I$ whether $\xi_i < x_i^{\min *}$, $\xi_i > x_i^{\max *}$, or $\xi_i \in [x_i^{\min *}, x_i^{\max *}]$.* We prove the following.

PROPOSITION 5.2. *Problem* 5.1 *can be solved* (i) *sequentially, in an expected number of $O(mn \log^3 n)$ operations, and* (ii) *on a CRCW PRAM, in $O(n \log^3 n)$ expected time, using $O(m)$ processors.*

For purposes of analysis we classify the strongly infeasible values of variables according to the sizes of their certificates (see Definition 2.20).

DEFINITION 5.3. *A strongly infeasible value ξ_i of a variable x_i is ℓ* big *if the certificate is of size at most ℓ. A value is $(\ell_1, \ell_2]$ big if it is ℓ_2 big but not ℓ_1 big. We interchangeably refer to strongly infeasible values as* big. *Note that all strongly infeasible values are $2n$ big.*

We explain the motivation for this classification. The algorithm that determines all the big values is based on a tradeoff between the following two properties. These properties are stated more formally and proved later. The first one "favors" big values with small certificates: For any ℓ-big value ξ it takes $O(m\ell)$ operations (by using "reveal") to find the certificate. Hence, a decision procedure that locates an ℓ-big value requires only $O(m\ell)$ operations. The second property favors values with large certificates: We introduce the procedure "check" that considers a big value ξ along with an associated certificate E'. The "check" procedure can on average locate many other big values whose certificates intersect E'.

5.1. The algorithm.

The description of the algorithm includes calls to the following three procedures:

- The first procedure "reveal" (Problem 2.23) considers a set of k values, and either finds a big value that belongs to the set or concludes that all these values are feasible or weakly infeasible. Algorithm 2.24 solves "reveal." Recall (see Corollary 2.25) that the algorithm takes $O(mn)$ time. If the input set contains big values, the algorithm terminates after $O(m\ell)$ operations (where $\ell \leq n$) with a closed certificate of size $\theta(\ell)$. If the original set contained exactly one big value ξ_j, the certificate found by the algorithm is the certificate of ξ_j.
- The second procedure "check" considers an ℓ-big value and the corresponding certificate. The "check" procedure uses the certificate to produce upper and lower bounds on the feasible regions of other variables. These bounds enable us to make decisions regarding other values in the pool. An $O(m\ell)$ time "check" algorithm is given in §5.3. In §5.4 we discuss properties of the "check" algorithm. We show that at least half of the $(\ell, 2\ell]$-big values in the pool have the following property: When a "check"

is applied to any of them, it determines at least $\ell/(6n) - 1$ of the other $(\ell, 2\ell]$ big values in the pool.

- The third procedure considers the set of unlocated values I and computes a crude estimate r^* to the number of big values r. The estimate r^* is such that $1/2 \leq r^*/r \leq 2$ with probability at least $1/2$. In §5.5 we present an "estimate" algorithm that performs $O((\log\log n)^2)$ calls to the "reveal" procedure. The time complexity is dominated by these calls and hence is $O(mn(\log\log n)^2)$.

The following algorithm determines all big values in a pool of $|I| = \hat{n}$ values. The algorithm performs iterations where each iteration determines some of the big values. The set I and the number $\hat{n}$ are updated accordingly. Denote by $r \leq \hat{n}$ the (unknown) number of big values in I. Appropriate values for the constants C_1, C_2, and C are given later.

ALGORITHM 5.4 [*Determine all the big values*].

◇ *Loop A: Steps* 1–9

1. *Apply the "reveal" procedure to the set I. If there are no big values, stop.*
2. *Compute an estimate* r^* *for* r *such that with probability at least* $1/2$, $1/2 \leq r^*/r \leq 2$. *Reset the following two counters:* $tt \leftarrow 0$ [*number of operations*]; $tb \leftarrow 0$ [*number of big values discarded*] (*in the current iteration of Loop A*).

◇ *Loop B: Steps* 3–9

3. *If either* (i) $tb \geq r^*/4$ (*successful iteration of Loop A*), *or* (ii) $tt \geq Cmn\log^2 n$ (*unsuccessful iteration of Loop A*), *go to step* 1 (*next iteration*).
4. $b \leftarrow 0$ [*the number of big values discarded in the current iteration of Loop B*].
5. *If* $r^* \geq \hat{n}/4$, $s \leftarrow 1$. *Otherwise,* $s \leftarrow \lfloor \hat{n}/r^* \rfloor$. *Choose* $k = \lceil C_1 \log n \rceil$ *random samples* $S_1, \ldots, S_k$ *of size* s (*with replacements*) *from the pool* I.
6. *Execute "concurrently"* k *runs of "reveal"* (*see Algorithm* 2.24) *applied to the sets* $S_1, \ldots, S_k$ *as follows*:
7. *Initialize copy* i *according to the set of values* S_i. *Set* $\ell \leftarrow 0$ [*current phase number*]. *Set* $K \leftarrow \{1, \ldots, k\}$ [*set of "active" runs*].

◇ *Loop C: Steps* 8–9

8. *Perform an additional iteration* (*push phase*) *to the runs in* K. *Set* $\ell \leftarrow \ell + 1$. *Let* $K' \subset K$ *be the* (*possibly empty*) *subset of the runs for which certificates are found. Apply "check" operations to these certificates, and discard from* I *all the big values that are determined. Increment* b *and* tb *accordingly, and set* $K \leftarrow K \setminus K'$.
9. *If either* $\ell = 2n + 1$ *or* $b \geq \lceil C_2 \ell r^*/(n \log n) \rceil$ *then* $tt \leftarrow tt + C_1 \ell m \log n$, *go to step* 3 [*next iteration of Loop B*]. *Otherwise, go to step* 8.

In §5.2 we prove the following.

PROPOSITION 5.5. *There exist constants* C_1,C_2, *and* C *as follows. If the estimate* r^* *is such that* $1/2 \leq r^*/r \leq 2$, *then with probability at least* $1/2$, *the current iteration of Loop A terminates after determining* $r^*/4$ *big values* (*the iteration is successful*).

It follows that with probability at least $1/4$, each iteration of Loop A determines at least $1/8$ of the big values in the pool. Hence, the expected number of iterations performed until all big values are determined is $O(\log n)$. Each iteration of Loop A runs in $O(mn\log^2 n)$ time. Hence, the expected time in which Algorithm 5.4 terminates is $O(mn\log^3 n)$. This concludes the proof of Proposition 5.2.

REMARK 5.6. *Note that the computation of the estimate* r^* *in step* 2 *can be replaced by running Loop A with* $r^* = 2^1, 2^2, \ldots, 2^{\lfloor \log \hat{n} \rfloor}$. *This results in an additional* $\log n$ *factor in the worst-case time bound.*

5.2. Probability for a successful iteration of Loop A.

In this subsection we prove Proposition 5.5.

Denote by r_i ($i = 1, \dots, \lceil \log 2n \rceil$) the number of $(2^{i-1}, 2^i]$ big values in I.

DEFINITION 5.7. *A sample $S \subset I$ of values from the pool is* good *if the following three conditions hold*:

1. *The sample contains exactly one big value ξ_j. Denote the size of the certificate of ξ_j by $2^{i-1} < \ell \leq 2^i$.*
2. *ξ_j determines* (*using "check"*) *at least $2^{i-1} r_i/(6n)$ big values in I* (*including ξ_j itself*).
3. $r_i \geq r/(4\lceil \log 2n \rceil)$.

We claim that property (iii) holds for at least 3/4 of the big values. Let

$$L = \{1 \leq i \leq \lceil \log 2n \rceil \mid r_i < r/(4\lceil \log 2n \rceil)\} .$$

We need to show that $\sum_{i \in L} r_i < r/4$. The claim follows from the inequality

$$\sum_{i \in L} r_i/r < \sum_{i \in L} 1/(4\lceil \log 2n \rceil) = |L|/(4\lceil \log 2n \rceil) < 1/4 .$$

It follows from Theorem 5.17 in §5.4 that property (ii) holds for at least half the $(2^{i-1}, 2^i]$ big values (for all i). Hence, properties (ii) and (iii) hold for at least 3/8 of the big values.

The following proposition motivates the definition of good samples.

PROPOSITION 5.8. *Consider an application of the reveal algorithm to a good sample, followed by a check to the certificate found. There exists a number $\ell = 2^i$ ($1 \leq i \leq \lceil \log 2n \rceil$), such that by using $O(m\ell)$ operations we can locate at least $\lceil \ell r/(24n\lceil \log 2n \rceil)\rceil$ big values.*

Proof. Denote by ξ_j the big value in the sample, and let $\ell = 2^i$ be such that the size of the certificate of ξ_j is in $(2^{i-1}, 2^i]$. Consider an application of the reveal algorithm to the sample. It follows from Proposition 2.19, part 2 that the certificate is found within $O(m\ell)$ operations. A check procedure applied to the certificate locates at least $2^{i-1} r_i/(6n) - 1$ additional big values from the pool. Note that $r_i \geq r/(4\lceil \log 2n \rceil)$. Hence at least $\ell r/(24n\lceil \log 2n \rceil)$ big values are located.

PROPOSITION 5.9. *Consider an integer $s \geq 1$ such that* (i) $s = 1$ *if $r \geq \hat{n}/2$ and in some cases, when $r \geq \hat{n}/16$, and* (ii) *otherwise, $c = rs/\hat{n}$ is such that $0.25 \leq c \leq 2$. Consider a random sample $S \subset I$* (*with replacements*) *of s elements. In some cases, and only when $s - 1 \geq 4$, the random sample contains $s - 1$ elements. There exists a constant ρ_1 such that with probability at least ρ_1, S contains exactly one big value.*

Proof. If $|S| = s$, the probability that S contains exactly one big value is

$$P = s\frac{r}{\hat{n}}\left(1 - \frac{r}{\hat{n}}\right)^{s-1} .$$

If $s = 1$, then $16r \geq \hat{n}$ and hence $P \geq 1/16$. Otherwise, $2r < \hat{n}$, hence $c/s < 1/2$. We obtain that

$$P \geq c\left((1 - c/s)^{s/c}\right)^c (1 - c/s)^{-1} \geq c/4^c \geq 1/32 .$$

If $|S| = s - 1$, we have

$$P = (s - 1)\frac{r}{\hat{n}}\left(1 - \frac{r}{\hat{n}}\right)^{s-2} \geq ((s - 1)/s)c/4^c \geq (4/5)(1/32) .$$

Consider an iteration of Loop A. During iterations of Loop B, the number r of big values in the set I decreases, but the value of the estimate r^* is not updated. The iteration of Loop A terminates when $r^*/4$ big values are discovered. Therefore, if initially $1/2 \leq r^*/r \leq 2$, then during the iterations of Loop B we have $1/2 \leq r^*/r \leq 4$.

COROLLARY 5.10. *Suppose that* $1/2 \le r^*/r \le 4$, *and consider a random sample* $S \subset I$ (*with replacements*) *of size* s, *where* $s = 1$ *when* $r^* \ge \hat{n}/4$ *and* $s = \lfloor \hat{n}/r^* \rfloor$ *otherwise. The sample* S *is good with probability* $\rho \ge 3\rho_1/8$.

COROLLARY 5.11. *Let* $C_1 = -1/\ln(1-\rho)$. *Consider* $\lceil C_1 \log n \rceil$ *randomly chosen samples* (*with replacements*) *of size* s. *If* $1/2 \le r^*/r \le 4$, *the probability that none of the samples is good is smaller than* $1/n$.

Proof. The probability that no sample is good is $p = (1-\rho)^{\lceil C_1 \log n \rceil}$. It follows that $p \le 1/n$ when $C_1 \ge -1/\ln(1-\rho)$.

Assume that initially $1/2 \le r^*/r \le 2$. Choose $C_2 = 1/96$. We compute the expected number of steps performed until $r^*/4$ big values are located.

DEFINITION 5.12. *An iteration of Loop B is* beneficial *if* $b \ge \lceil C_2 \ell r^*/(n \log n) \rceil$ *when the iteration terminates* (*at* step 9).

PROPOSITION 5.13. *Consider an iteration of Loop B. If at least one of the samples is good, the iteration is beneficial.*

Proof. The proof follows from Proposition 5.8 and the fact that for $r^* \le 4r$,

$$\lceil C_2 \ell r^*/(n \log n) \rceil \le \lceil \ell r/(24n \lceil \log 2n \rceil) \rceil .$$

The counter tt is such that at the end of each iteration of Loop B, the running time so far of the current iteration of Loop A is $O(tt)$. A beneficial iteration increases tt in $C_1 m \ell \log n$ units (runs in time $O(C_1 m \ell \log n)$), and each unbeneficial iteration by $C_1 mn \log n$ units ($O(C_1 mn \log n)$ time). It follows from Proposition 5.13 and Corollary 5.11 that an expected number of $(n-1)/n$ of all iterations of Loop B are beneficial. Hence, the expected number of operations performed by unbeneficial iterations is not bigger than the expected number of operations performed by beneficial iterations.

To conclude the proof of Proposition 5.5, it suffices to count the expected number of operations performed by beneficial iterations (increase of the counter tt) until at least $r^*/4$ big values are located.

Denote by t_i ($i = 1, \ldots, \lceil \log n \rceil$) the number of beneficial iterations that ended within $(2^{i-1}, 2^i]$ phases. The total expected increase in the value of tt by beneficial iterations is

$$\Delta_{tt} \le C_1 \sum_{i=1}^{\lceil \log n \rceil} t_i 2^i m \log n .$$

The expected final value of tt (number of operations by beneficial and unbeneficial iterations) is $tt \le 2\Delta_{tt}$. At all iterations but the last we have

$$\sum_{i=1}^{\lceil \log n \rceil} (t_i C_2 2^{i-1} r^*/(n \log n)) \le r^*/4 .$$

Hence, after the last iteration, $\sum_{i=1}^{\lceil \log n \rceil} t_i 2^i \le n \log n/(2C_2) + n$. Therefore,

$$\Delta_{tt} \le ((C_1 + C_2)/(2C_2)) mn \log^2 n .$$

Thus, the expected final value of tt is

$$tt \le ((C_1 + C_2)/C_2) mn \log^2 n .$$

We choose $C = 2(C_1 + C_2)/C_2$. It follows that with probability $1/2$, at least $r^*/4$ of the big values are located before the value of tt reaches $Cmn \log^2 n$. This concludes the proof of Proposition 5.5.

5.3. The "check" procedure. In this subsection we give an algorithm for performing "checks." The "check" algorithm is applied to a $(2^{k-1}, 2^k]$-big value ξ_i and the certificate ξ_i, and provides information from which it can be concluded that certain other values are also big.

We explain how a closed certificate for a value of one variable is used to obtain information about other variables in the following remark.

REMARK 5.14. *Suppose ξ_i is a big value of x_i. The certificate G_i consists of a path from v_i to a vertex u and a cycle that starts and ends at u, such that $v_i = \underline{v}_i$ if $\xi_i > x_i^{\max *}$, and $v_i = \overline{v}_i$ if $\xi_i < x_i^{\min *}$. For a vertex w in G_i, define $\xi_i(w) = f_p(\xi_i)$, where p is the path in G_i from v_i to w. Define $\xi_i(v_i) = \xi_i$. It follows from Corollary 2.16 that for every vertex w of G_i, the value $\hat{\xi}_i(w)$ at w is strongly infeasible.*

The "check" algorithm is described below. The input is a $(2^{k-1}, 2^k]$-big value ξ_i of x_i along with the certificate G_i.

ALGORITHM 5.15 [*check*].

```
1. For each vertex $v \in G_i$, compute the big value $\xi(v)$ (as in Remark 5.14).
2. Initialize the values of $\overline{x}_1, \ldots, \overline{x}_n$ and $\underline{x}_1, \ldots, \underline{x}_n$ as follows. If $\overline{v}_j \in G_i$, set $\underline{x}_j = \xi_i(\overline{v}_j)$; otherwise, if $\overline{v}_j \notin G_i$, set $\underline{x}_j = -\infty$. If $\underline{v}_j \in G_i$, set $\overline{x}_j = \xi_i(\underline{v}_j)$; otherwise, if $\underline{v}_j \notin G_i$, set $\overline{x}_j = \infty$.
3. Perform $2^k$ push phases.
4. Make conclusions as follows. If for some value $\eta$ we have $\eta \geq \overline{x}_j$ (resp., $\eta \leq \underline{x}_j$), conclude that $\eta > x_j^{\max *}$ (resp., $\eta < x_j^{\min *}$).
```

The initial values at the vertices are consistent (see Remark 5.14), and hence (see Corollary 2.15), the final values are consistent. It follows that the conclusions made by the "check" algorithm are correct.

DEFINITION 5.16. *If in step 4 of Algorithm 5.15 we deduce that a value η is big, we say that ξ_i 2^k* locates *η.*

5.4. Properties of the "check" procedure. This subsection establishes the following theorem.

THEOREM 5.17. *Consider a collection of b $(2^{k-1}, 2^k]$-big values. At least half the values have the following property. If a "check" is applied to any of them, it results in 2^k locating at least $b2^{k-1}/(6n) - 1$ other values from the collection.*

The following proposition analyzes the dependencies among values of different variables.

PROPOSITION 5.18. *Let ξ_i and ξ_j be big values of x_i and x_j, respectively. Let the respective certificates G_i, G_j, and the nodes v_i, v_j be as in Remark 5.14. Suppose that $|G_i| \leq \ell$, $|G_j| \leq \ell$ for some ℓ. If the sets of vertices participating in G_i and G_j intersect, at least one of the values ξ_i and ξ_j is ℓ located by the other.*

Proof. Suppose $u \in \underline{V}$ (similar for $u \in \overline{V}$) participates both in G_i and in G_j. Let p_i be the directed path in G_i from v_i to u and let p_j be a directed path in G_j from v_j to u. (See Fig. 5 for an illustration, where $i = 1$ and $j = 2$.) We claim that if $f_{p_i}(\xi_i) \leq f_{p_j}(\xi_j)$, then ξ_i ℓ locates ξ_j; if $f_{p_j}(\xi_j) \leq f_{p_i}(\xi_i)$, ξ_j ℓ locates ξ_i. Assume that $f_{p_i}(\xi_i) \leq f_{p_j}(\xi_j)$, and consider an application of "check" to ξ_i. The "check" algorithm determines that $f_{p_i}(\xi_i)$ is a strongly infeasible value of u. The algorithm initializes u^{-1} to the consistent value $f_{p_i}(\xi_i)$ and applies ℓ push phases. Consider the path p_j^{-1} from u^{-1} to v_j^{-1}. Since $|p_j^{-1}| \leq \ell$, the value at v_j^{-1} after ℓ push phases must be at least as tight as $\xi_j^* \equiv f_{p_j^{-1}}(f_{p_i}(\xi_i))$. To conclude the proof, note that ξ_j^* is at least as tight as ξ_j at v_j^{-1}, since $\xi_j = f_{p_j^{-1}}(f_{p_j}(\xi_j))$ and we assumed that $f_{p_j}(\xi_j)$ is no more tight than $f_{p_i}(\xi_i)$ at u^{-1}. Hence ξ_i ℓ-locates ξ_j.

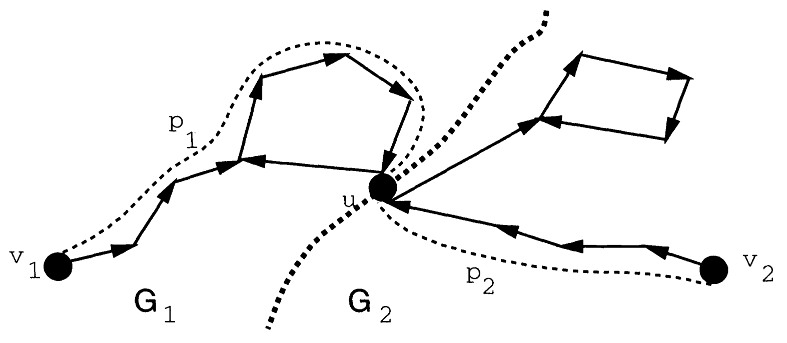

FIG. 5. *Dependence of intersecting certificates.*

DEFINITION 5.19. *Consider a pool of b* $(2^{k-1}, 2^k]$*-big values. The* influence *graph of this pool is defined as follows. Each big value in the pool corresponds to a vertex in the influence graph. If one value* 2^k *locates another, then there is a directed edge from the vertex of the former to the vertex of the latter.*

Theorem 5.17 is an immediate corollary of the following theorem.

THEOREM 5.20. *In the influence graph of a pool of b* $(2^{k-1}, 2^k]$*-big values, at least half of the vertices have an out degree greater than* $\frac{1}{6}b2^{k-1}/n - 1$. We first prove two propositions that are used in the proof of the theorem.

PROPOSITION 5.21. *In the intersection graph of b subsets of* $\{1, \ldots, n\}$ *with cardinality* ℓ*, the sum of the degrees is at least* $b^2\ell/n - b$.

Proof. Let s_i $(i = 1, \ldots, n)$ be the number of subsets containing i. Obviously, $\sum_{i=1}^n s_i = b\ell$. The sum of the degrees plus the number of vertices (subsets) is at least $\sum_{i=1}^n s_i^2/\ell$. This expression is minimized when $s_i \in \{\lfloor b\ell/n \rfloor, \lceil b\ell/n \rceil\}$ $(i = 1, \ldots, n)$. It follows that the sum of degrees is at most $\lceil b^2\ell/n \rceil - b$.

PROPOSITION 5.22. *In any orientation of the edges of the intersection graph of b subsets of* $\{1, \ldots, n\}$ *with cardinality* ℓ*, at least half the vertices have out degrees greater than* $\frac{1}{6}b\ell/n - 1$.

Proof. It follows from Proposition 5.21 that the sum of out degrees (i.e., the total number of edges) in any subgraph induced by b' vertices is at least $\frac{1}{2}(b'^2\ell/n - b')$. Suppose, to the contrary, that there exists a subset U of cardinality $|U| = b' = b/2$ where the out degree of each vertex is less than or equal to $\frac{1}{6}b\ell/n - 1$. The total number of edges (that equals the sum of out degrees) in the subgraph induced by these vertices is $\frac{1}{3}b'^2\ell/n - b'$, hence a contradiction since it is less that $\frac{1}{2}(b'^2\ell/n - b')$.

Proof of Theorem 5.20. The cardinality of a certificate of a $(2^{k-1}, 2^k]$-big value is greater than or equal to $\ell = 2^{k-1}$. It follows from Proposition 5.18 that if two big values have intersecting certificates, then in the influence graph there is an edge between the corresponding vertices. Hence, the influence graph contains an intersection graph of b subsets of $\{1, \ldots, n\}$ of cardinality ℓ. Thus, the proof follows from Proposition 5.22. □

5.5. Estimating the number of big values. In this subsection we prove the following proposition.

PROPOSITION 5.23. *An estimate* r^* *such that* $1/2 \le r^*/r \le 2$ *with probability at least* $1/2$*, can be found using* $O((\log\log n)^2)$ *"reveal" operations.* The problem of computing an estimate can be stated in the following terms. We are given a collection of $\hat{n}$ stones, where r of them are radioactive. The number r is not known. We are equipped with a primitive gauge that, when exposed to a set of stones, can determine if at least one of them is radioactive (i.e., "reveal" operation). A *good estimate* to the number of radioactive stones is a number r^* such that $1/2 \le r^*/r \le 2$. The goal is to compute a good estimate that is correct with probability at least 1/2, by using at most $O((\log\log\hat{n})^2)$ gauge readings. We first give some useful propositions.

PROPOSITION 5.24. *Denote by $p_0(s)$ the probability that a sample (with replacements) of size s contains no radioactive stones and let $c \equiv rs/\hat{n}$. Under these conditions,* (i) $c < \ln(1/p_0(s))$, *and* (ii) *if $r/\hat{n} \le 0.5$, $c \ge \log(1/p_0(s))/\log 4$.*

Proof.

$$p_0(s) = \left(1 - \frac{r}{\hat{n}}\right)^s = \left(\left(1 - \frac{r}{\hat{n}}\right)^{\frac{\hat{n}}{r}}\right)^c .$$

It follows that $p_0(s) < e^{-c}$ and if $r/\hat{n} \le 0.5$, $p_0 \ge 4^{-c}$.

COROLLARY 5.25. *Suppose $p_0(s)$ is known. We can conclude as follows:*

1. *If* $0.136 \le p_0(s) \le 0.5$, *then* $1/2 \le c \le 2$.
2. *If* $0.146 \le p_0(s) \le 0.49$, *then* $0.514 \le c \le 1.92$.
3. *If* $p_0(s) \le 0.156$, *then* $c \ge 1.34$.
4. *If* $p_0(s) \ge 0.48$, *then* $c \le 0.74$.

PROPOSITION 5.26. *Let B' be the random variable (r.v.) that corresponds to the number of non-radioactive samples out of $B = 5000(\lceil\log\log\hat{n}\rceil + 1)$ random samples of size s.*

$$\text{Prob}\left\{|B'/B - p_0(s)| \ge 0.01\right\} \le 1/(2\lceil\log\log\hat{n}\rceil + 2) .$$

Proof. B' is the number of successes of B Bernoulli trials with success probability $p_0(s)$, and hence, has a binomial distribution. Therefore B' has expected value $p_0(s)B$ and variance $Bp_0(s)(1 - p_0(s))$ (see [11] for background). It follows from Chebyshev inequality that $\text{Prob}\left\{|B' - p_0(s)B| \ge 0.01B\right\} \le 2500B/B^2 = 2500/B = 1/(2\lceil\log\log\hat{n}\rceil + 2)$.

Denote by $\boldsymbol{p}_0'(s)$ the r.v. B'/B, and by $p_0'(s)$ a value of $\boldsymbol{p}_0'(s)$.

Below we state an algorithm that computes the estimate r^*. For simplicity, we assume that $\hat{n}$ is a power of 2 (the general case can be handled by a small modification of the algorithm). The algorithm is based on performing a binary search on the $\log\hat{n} - 1$ possible estimate values $2^1, 2^2, \ldots, 2^{\log\hat{n}-1}$.

ALGORITHM 5.27 [*compute an estimate*].

```
1. If $p_0'(2) \le 0.35$, stop and return the estimate $r^* = 2^{\log\hat{n}-1}$.
2. Initialize $a = 1$, $b = \lfloor\log\hat{n}\rfloor$. Repeat step 3 until $a = b$. Return $r^* = \hat{n}/2^a$.
3. Set $j = \lceil(a + b)/2\rceil$, and $s = 2^j$.
     • If $0.146 \le p_0'(s) \le 0.49$, stop and return the estimate $r^* = \hat{n}/s$.
     • If $p_0'(s) < 0.146$, set $b = j$ and go to step 3.
     • If $p_0'(s) > 0.49$, set $a = j$ and go to step 3.
```

We show that with probability at least 0.5, $1/2 \le r^*/r \le 2$. Consider the first step. If $r \ge \hat{n}/2$, $p_0(2) \le 1/4$. Hence, $\text{Prob}\{p_0'(2) \le 0.35\} \ge 1 - 1/(2\lceil\log\log\hat{n}\rceil + 2)$. If $r < \hat{n}/4$, $p_0(2) > 9/16$. Hence, $\text{Prob}\{p_0'(2) < 0.35\} \le 1/(2\lceil\log\log\hat{n}\rceil + 2)$. It follows that if $r \ge \hat{n}/2$, the algorithm stops with a good estimate with probability at least $1 - 1/(2\lceil\log\log\hat{n}\rceil + 2)$. If $r \le \hat{n}/4$ the probability that the algorithm stops at Step 1 with a bad estimate is smaller than $1/(2\lceil\log\log\hat{n}\rceil + 2)$.

The algorithm performs at most $\lceil\log\log\hat{n}\rceil$ iterations of step 3. Each iteration terminates with a further restriction of the set $a, a+1, \ldots, b$. Consider a single iteration of step 3. Suppose that at the beginning of the iteration, at least one of the values $2^a, 2^{a+1}, \ldots, 2^b$ constitutes a good estimate. It follows from Proposition 5.26 that with probability $(1 - 1/(2\lceil\log\log\hat{n}\rceil + 2))$, $|p_0'(s) - p_0(s)| \le 0.01$. Assume that this is the case. Note that for $r^* = \hat{n}/s$ we have $c = r/r^*$. Therefore, it follows from Corollary 5.25 that when the iteration ends the modified interval $a, a + 1, \ldots, b$ is such that at least one of $2^a, 2^{a+1}, \ldots, 2^b$ is a good estimate.

Therefore, the probability that when the algorithm terminates 2^a is a good estimate is at least

$$(1 - 1/(2\lceil \log\log \hat{n}\rceil + 2))^{\lceil \log\log \hat{n}\rceil + 1} \geq 0.5 \,.$$

The algorithm performs $O(\log\log \hat{n})$ iterations, where each iteration computes an appropriate value of p_0'. Each iteration requires $O(\log\log \hat{n})$ "gauge readings" (see Proposition 5.26). Hence, the total number of "gauge readings" performed by the algorithm is $O((\log\log \hat{n})^2)$. This concludes the proof of Proposition 5.23.

6. Locating a pool of weakly infeasible values and feasible values. In this section we present an algorithm that asserts the following.

THEOREM 6.1. *Problem* 3.6, *where the values ξ_i $(i \in I)$ are guaranteed to be either feasible or weakly infeasible, can be solved* (i) *sequentially, in $O(mn \log^3 n)$ expected time, and* (ii) *on a CRCW PRAM, in $O(n \log^3 n)$ expected time, using $O(m)$ processors.*

The following is a key property of feasible and weakly infeasible values.

PROPOSITION 6.2. *Let ξ_i and ξ_j be feasible or weakly infeasible values of x_i and x_j, respectively. If there exists a path p from $v_j \in \{\underline{v}_j, \overline{v}_j\}$ to $v_i \in \{\underline{v}_i, \overline{v}_i\}$ such that $f_p(\xi_j)$ is at least as tight as ξ_i at the vertex v_i, there exists such a simple path p'.*

Proof. We assume that $v_j = \overline{v}_j$, $v_i = \overline{v}_i$. (The proof for the other cases is similar.) Consider the path p from v_j to v_i. Suppose a vertex u occurs more than once on p. Consider two of the occurrences of u. Let $p = p_1 p_2 p_3$, where p_1 is the prefix of p until the first occurrence and p_3 is the suffix of p starting from the second occurrence of u. If $f_{p_1 p_2}(\xi_j)$ is not tighter than $f_{p_1}(\xi_j)$ at u, the path $p' = p_1 p_3$ is at least as tight as p. Consider iterating the above process. It follows that there exists a path $\hat{p}$ from v_j to v_i that is at least as tight as p with respect to $x_j = \xi_j$, and when a vertex appears more than once, the value at subsequent occurrences is always tighter. We claim that each vertex may occur at most once in $\hat{p}$. Assume the contrary, and consider the first cycle c along $\hat{p}$. Let u be the vertex where c starts and ends, and let $p' = p_1 c$ be the corresponding prefix of $\hat{p}$. It follows from Proposition 2.17 that either $f_{p_1}(\xi_j)$ is strongly infeasible at u, or $f_{p_1}(\xi_j)$ is consistent at u. If $f_{p_1}(\xi_j)$ is strongly infeasible, then p' is a closed certificate for $[-\infty, \xi_j]$ with respect to x_j and we get a contradiction to the assumption that ξ_j is not strongly infeasible. Otherwise, $f_{p_1}(\xi_j)$ is consistent at u. It follows that for every prefix p_2 of $\hat{p}$ that contains p_1 and ends at a vertex u', the value $f_{p_2}(\xi_j)$ is consistent at u'. Consider the last cycle c' along $\hat{p}$, and let $p' = c' p_3$ be the corresponding suffix of $\hat{p}$. It follows that p' is a closed certificate for $[f_{\hat{p}}(\xi_j), \infty]$ at v_i^{-1}. Hence, since $\xi_i \geq f_{\hat{p}}(\xi_j)$, p' is a closed certificate for $[\xi_i, \infty]$. This is a contradiction to ξ_i not being strongly infeasible.

We present two procedures that are subroutines of the algorithm for locating a pool. The first procedure is applied to a subset of the values and returns a partial solution. The second procedure extends a partial solution as much as possible without restricting the feasible region further. We discuss the first procedure in detail. The input is a subset of values $\xi_i \in S_i$ $(i \in I')$, where $I' \subset I$. The procedure determines intervals J_i $(i \in I'')$, where $I'' \subset I'$ is a subset of the values in the input set. The intervals J_i $(i \in I'')$ constitute a partial solution for Problem 3.6, that is, there exists a set of intervals J_i $(i \in I \setminus I'')$ such that J_i $(i \in I)$ is a solution of Problem 3.6.

ALGORITHM 6.3 [*find a partial solution*].

```
1. Initialize the values at the vertices of $G$ as follows:
   $\overline{x}_i = \underline{x}_i = \xi_i$ $(i \in I')$, $\overline{x}_i = b_i$, $\underline{x}_i = a_i$ $(i \notin I')$,
2. Apply $2n$ push phases.
```

3. *For $i \in I'$ do as follows*:
   - *If* $\xi_i = \overline{x}_i = \underline{x}_i$, *set* $J_i = \{\xi_i\}$.
   - *If* $\xi_i = \overline{x}_i < \underline{x}_i$, *set* $J_i = [\xi_i, \infty]$.
   - *If* $\xi_i = \underline{x}_i > \overline{x}_i$, *set* $J_i = [-\infty, \xi_i]$.
   - *Otherwise,* J_i *is not determined.*

   Let $I'' \subset I'$ *be the set of all* $i \in I'$ *for which* J_i *is determined. For* $i \in I''$ *do:* $S_i \leftarrow S_i \cap J_i$.

Denote by F^* the feasible region prior to applying Algorithm 6.3. Consider an application of the algorithm. We show that if $F^* \neq \emptyset$ then the system remains feasible, that is, $F \neq \emptyset$. The following proposition proves a necessary condition for correctness: If $F^* \neq \emptyset$, then for all $i \in I''$, $F^* \cap \{x | x_i \in J_i\} \neq \emptyset$.

PROPOSITION 6.4. *Suppose* $\underline{x}_i = \xi_i$ *(resp.,* $\overline{x}_i = \xi_i$*) is weakly infeasible, and the certificate does not consist only from a bound and a simple path. There exists a simple path p from* $\underline{v}_i$ *to* $\overline{v}_i$ *(resp.,* $\overline{v}_i$ *to* $\underline{v}_i$*), such that* $f_p(\xi_i) < \xi_i$ *(resp.,* $f_p(\xi_i) > \xi_i$*).*

Proof. It suffices to prove the existence of a not necessarily simple path p with the above properties. The existence of a simple path would follow from Proposition 6.2. We assume $\underline{x}_i = \xi_i$ is weakly infeasible (the other case is proved similarly). There exists $1 \leq j \leq n$ and two simple paths emanating from $\underline{v}_i$, p_1 to $\overline{v}_j$ and p_2 to $\underline{v}_j$ such that $f_{p_1}(\xi_i) < f_{p_2}(\xi_i)$. Consider the path $p = p_1 p_2^{-1}$ from $\underline{v}_i$ to $\overline{v}_i$. We claim that $f_p(\xi_i) < \xi_i$. To prove the claim note that $f_p(\xi_i) = f_{p_2^{-1}} \circ f_{p_1}(\xi_i)$. Since the end vertices of p_2^{-1} both lie in $\underline{V}$, the function $f_{p_2^{-1}}$ is monotone increasing. Hence, $f_{p_2^{-1}} \circ f_{p_1}(\xi_i) < f_{p_2^{-1}} \circ f_{p_2}(\xi_i) = \xi_i$.

We show that the intervals J_i $(i \in I'')$ constitute a partial solution.

PROPOSITION 6.5. $F = F^* \cap \{x | \bigwedge_{i \in I''} x_i \in J_i\} \neq \emptyset$.

Proof. We first claim that J_i is feasible for all $i \in I''$. Consider $i \in I''$. If ξ_i is feasible the claim is immediate. Otherwise, assume to the contrary that $J_i = [\xi_i, \infty]$ (similar for $[-\infty, \xi_i]$) is weakly infeasible. If the certificate consists of a bound in S_j $(j \in I)$ and a simple path then, when the algorithm terminates, we have $\overline{x}_i < \xi_i$ (since the initialization is with values at least as tight as S_j $(j \in I)$). This is a contradiction. Otherwise, the certificate contains an open cycle. The contradiction follows from Proposition 6.4. This concludes the proof of the claim. In order to prove the proposition, Proposition 2.12, part 3 asserts that it suffices to show that for every pair $\{i, j\} \in I''$, $F^* \cap \{x | x_i \in J_i,\ x_j \in J_j\} \neq \emptyset$. The latter follows from Corollary 2.11.

We discuss the procedure that extends a partial solution. Suppose we applied Algorithm 6.3 and as a result, for $i \in I''$, we updated the intervals S_i and determined J_i. The following algorithm may determine the interval J_i for some additional values $i \in I \setminus I''$.

ALGORITHM 6.6 [*extend a partial solution*].

1. *Initialize the values at the vertices of G as follows.* $\underline{x}_i = a_i$ *and* $\overline{x}_i = b_i$ $(i \in I)$.
2. *Apply* $2n$ *push phases.*
3. *For* $i \in I \setminus I''$ *conclude as follows*:
   - *If* $\overline{x}_i \leq \xi_i$, *set* $J_i = \{-\infty, \xi_i\}$.
   - *If* $\underline{x}_i \geq \xi_i$, *set* $J_i = \{\xi_i, \infty\}$.

   Let $\hat{I}$ *be the set of all* $i \in I \setminus I''$ *such that* J_i *was determined.*
   For $i \in \hat{I}$ *do:* $S_i \leftarrow S_i \cap J_i$.

REMARK 6.7. *Proposition* 2.5 *asserts that the feasible region is not changed by the updates of the intervals* S_i *done by Algorithm* 6.6. *In particular, if the feasible region was nonempty prior to applying the algorithm it remains nonempty.*

6.1. The algorithm. The following algorithm considers feasible and weakly infeasible values ξ_i $(i \in I)$, and solves Problem 3.6 for these values. The solution consists of a set of intervals J_i $(i \in I)$. The algorithm performs iterations, where in each iteration some intervals J_i $(i \in I' \subset I)$ are determined. The intervals J_i $(i \in I')$ are incorporated into the system, we set $I \leftarrow I \setminus I'$, and the problem is reduced to locating the values ξ_i $(i \in I)$.

ALGORITHM 6.8 [*locate a pool*].

```
1. Repeat the following until $I = \emptyset$.
2. For $\ell = 1, 2, 4, \ldots, 2^{\lfloor \log |I| \rfloor}$, execute steps 3–5:
3. Choose (uniformly at random) $\ell$ elements from $I$. Let $I' \subset I$ be the set of chosen
   elements.
4. Apply Algorithm 6.3 to $I'$. The algorithm determines $J_i$ for $i \in I'' \subset I'$.
5. Apply Algorithm 6.6 and determine $J_i$ for additional values $\hat{I} \in I$. Set $I \leftarrow I \setminus$
   $\{I'' \cup \hat{I}\}$.
```

It follows from Proposition 6.5 and Remark 6.7 that if the problem was feasible, it remains feasible at any point during the execution of the algorithm. Hence, when the algorithm terminates, the intervals J_i $(i \in I)$ constitute a solution for Problem 3.6.

6.2. Complexity. For values ξ_i $(i \in I)$, consider a solution for Problem 3.6, that is, intervals J_i $(i \in I)$ such that $J_i \in \{[-\infty, \xi_i], [\xi_i, \infty]\}$ and $F \cap \{\boldsymbol{x} | \bigwedge_{i \in I} x_i \in J_i\} \neq \emptyset$. We designate vertices v_i $(i \in I)$ according to the choice of intervals J_i $(i \in I)$: If $J_i = [-\infty, \xi_i]$, $v_i = \overline{v}_i$. If $J_i = [\xi_i, \infty]$, $v_i = \underline{v}_i$.

We define a relation on the set I, with respect to the solution J_i $(i \in I)$:

DEFINITION 6.9. *Let $i \in I$, $j \in I$ be two elements.*

1. *We say that j* locates *i if there exists a path p from v_j to v_i such that $f_p(\xi_j)$ is at least as tight as ξ_i on v_i.*
2. *We say that i* interferes *with j if there exists a path p from v_i^{-1} to v_j^{-1} such that $f_p(\xi_i)$ is tighter than ξ_j on v_j^{-1}.*
3. *We define the relation $\prec$ on I as follows. $j \prec i$ if and only if i interferes with j. $j \preceq i$ if and only if j locates i. (Note that $j \prec i$ implies $j \preceq i$, and $j \preceq i \wedge i \npreceq j$ implies $j \prec i$.)*
4. *For an element $i \in I$, denote by* $\operatorname{pred}(i) = \{j \in I | j \preceq i\}$ *the set of elements that locate i, and by* $\operatorname{succ}(i) = \{j \in I | j \succ i\}$ *the set of elements that interfere with i.*

The following is a corollary of Proposition 6.2.

COROLLARY 6.10. *If a path p as in Definition* 6.9, *parts* 1 *and* 2 *exists, then there must exist a simple path with the same properties.*

The following proposition relates the locate and interfere relations to the algorithms presented earlier. The proof follows from Corollary 6.10.

PROPOSITION 6.11. *Let $i \in I$, $j \in I$ be two elements.*

1. *Suppose that j locates i. If $S_j \subset J_j$, then an application of Algorithm* 6.6 *would determine J_i.*
2. *Suppose that i interferes with j. Consider an application of Algorithm* 6.3 *where $\{i, j\} \subset I'$. The interval J_j will not be determined as a result of such a run. Moreover, if $j \in I'$, the interval J_j is determined in this run if and only if for all values $i \in I'$, i does not interfere with j.*

We characterize the values located in an iteration of Algorithm 6.8, in terms of pred and succ.

COROLLARY 6.12. *The following relations hold in an execution of Steps* 4–5: $I'' = \{k \in I' | \operatorname{succ}(k) \cap I' = \emptyset\}$ *and* $\hat{I} = \{k \in I \setminus I'' | \operatorname{pred}(k) \cap I'' \neq \emptyset\}$.

PROPOSITION 6.13. *The relation $\prec$ is a partial order on I.*

Proof. The transitivity of $\prec$ is immediate. We need to show that $\prec$ has no cycles. If there is a cycle, it follows from the transitivity that for some $j \in I$, j interferes with j. The path p is in this case a simple cycle that constitutes a closed certificate for ξ_j. This contradicts the assumption that ξ_j is not strongly infeasible.

Note that each iteration of steps 3–5 results in determining at least one interval, and therefore, the algorithm terminates within $O(n)$ iterations. In order to prove Theorem 6.1, however, we need to show that the expected number of iterations is only $O(\log^3 n)$.

Define $I^0 = \{i \in I | \mathrm{succ}(i) = \emptyset\}$.

PROPOSITION 6.14.

$$|I^0| + \sum_{i \in I \setminus I^0} \sum_{j \in \mathrm{succ}^{-1}(i)} 1/|\mathrm{succ}(j)| = |I|.$$

Proof. The sum is well defined since in each inner sum, $\{i\} \cup \mathrm{succ}(i) \subset \mathrm{succ}(j)$, and hence $|\mathrm{succ}(j)| \geq 2$. Note that

$$\sum_{i \in I \setminus I^0} \sum_{j \in \mathrm{succ}^{-1}(i)} 1/|\mathrm{succ}(j)| = \sum_{i \in I \setminus I^0} |\mathrm{succ}(i)|/|\mathrm{succ}(i)| = |I| - |I^0| .$$

Consider iterations of steps 2–5. For $k \geq 0$, denote by I_k, I_k^0, $\mathrm{succ}_k : I_k \to 2^{I_k}$, $\mathrm{pred}_k : I_k \to 2^{I_k}$, respectively, the contents of the sets I, I_k^0, and the corresponding succ and pred functions in the beginning of the kth iteration. For $k \geq 0$ and $i \in I_k$ we have $\mathrm{succ}_k(i) = \mathrm{succ}_0(i) \cap I_k$ and $\mathrm{pred}_k(i) = \mathrm{pred}_0(i)$ (since if $j \in \mathrm{pred}(i)$ is located, then so is i).

For $k \geq 0$, define

$$L_k = \left\{ i \in I_k \setminus I_k^0 | \sum_{j \in \mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \geq 1/4 \right\} .$$

PROPOSITION 6.15. *There exists a constant ρ_0 such that for every $k \geq 0$ and $i \in L_k \cup I_k^0$,* $\mathrm{Prob}\{i \notin I_{k+1}\} \geq \rho_0$.

Proof. Consider $i \in I_k^0$. It follows from Corollary 6.12 that if $i \in I'$ in some iteration of Steps 3–5, then i gets located. With probability at least 1/2, $i \in I'$ at the iteration where $\ell = 2^{\lfloor \log |I_k| \rfloor}$. Consider $i \in L_k$. For $0 \leq h \leq \lfloor \log |I_k| \rfloor$, denote

$$T_h = \{j \in \mathrm{succ}_k^{-1}(i) | 2^h \leq |I_k|/|\mathrm{succ}_k(j)| \leq 2^{h+1}\} .$$

It follows that

$$\sum_{0 \leq h \leq \lfloor \log |I_k| \rfloor} 2^h |T_h|/|I_k| \geq (1/2) \sum_{j \in \mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \geq 1/8 .$$

For $0 \leq h \leq \lfloor \log |I_k| \rfloor$, consider the iteration where $\ell = 2^h$. Consider an element $j \in T_h$. Note that $\{i\} \cup \mathrm{succ}_k(i) \subset \mathrm{succ}_k(j)$. Hence, $|\mathrm{succ}_k(j)| \geq 2$ and $\ell \leq |I_k|/|\mathrm{succ}_k(j)| \leq |I_k|/2$. Therefore, the probability that $\mathrm{succ}_k(j) \cap I' = \emptyset$ is at least

$$(1 - \ell/|I_k|)^{|\mathrm{succ}_k(j)|} \geq (1 - \ell/|I_k|)^{2|I_k|/\ell} \geq 1/16 .$$

Note that these probabilities are dependent for different elements of T_h. The probability that $j \in I'$ is at least $\ell/|I_k|$. These probabilities are independent for different elements of T_h. Using Corollary 6.12, it follows that the probability that i is not located in the iteration where $\ell = 2^h$ is at most

$$(1 - \ell/|I_k|)^{|T_h|} \leq ((1 - \ell/|I_k|)^{|I_k|/\ell})^{\ell |T_h|/|I_k|} \leq 4^{-2^h |T_h|/|I_k|} .$$

These probabilities are independent for different iterations. Hence, the probability that i is not located in any iteration is at most

$$\prod_{0\le h\le\lfloor\log|I_k|\rfloor} 4^{-2^h|T_h|/|I_k|} = 4^{-\sum_{0\le h\le\lfloor\log|I_k|\rfloor} 2^h|T_h|/|I_k|} \le 4^{-1/8} < 0.85\,.$$

Thus, i is located with probability at least 0.15.

PROPOSITION 6.16.

$$\sum_{i\in L_k}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \ge 3(|I_k|-|I_k^0|)/4\,.$$

Proof. The proof follows from Proposition 6.14 and from

$$\sum_{i\in I_k\setminus(I_k^0\cup L_k)}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \le (|I_k|-|I_k^0|-|L_k|)/4 \le (|I_k|-|I_k^0|)/4\,.$$

PROPOSITION 6.17. *Denote* $\rho_2=3\rho_0/8$ *and* $\rho_1=\rho_0/2$. *With probability at least* ρ_1,

$$|I_k^0\setminus I_{k+1}| + \sum_{i\in I_k\setminus(I_k^0\cup I_{k+1})}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \ge \rho_2|I_k|\,.$$

Proof. Consider the random variable

$$R = |I_k^0\setminus I_{k+1}| + \sum_{i\in L_k\setminus I_{k+1}}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)|\,.$$

Note that

$$\sum_{i\in I_k\setminus(I_k^0\cup I_{k+1})}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)| \ge \sum_{i\in L_k\setminus I_{k+1}}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)|\,.$$

Hence, it suffices to show that $\mathrm{Prob}\{R\ge\rho_2|I_k|\}\ge\rho_1$. It follows from Proposition 6.15 that the expected value of R is

$$E(R) \ge \rho_0|I_k^0| + \rho_0\sum_{i\in L_k}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)|\,.$$

The maximum value of R is at most

$$R_{\max} = |I_k^0| + \sum_{i\in L_k}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)|\,.$$

Note that

$$E(R) \le \mathrm{Prob}\{R<E(R)/2\}E(R)/2 + \mathrm{Prob}\{R\ge E(R)/2\}R_{\max}\,.$$

Therefore,

$$\mathrm{Prob}\{R\ge E(R)/2\} \ge E(R)/(2R_{\max}-E(R)) \ge E(R)/(2R_{\max}) \ge \rho_0/2\,.$$

It follows that with probability at least $\rho_0/2$,

$$R \ge \left(\rho_0|I_k^0| + \rho_0\sum_{i\in L_k}\sum_{j\in\mathrm{succ}_k^{-1}(i)} 1/|\mathrm{succ}_k(j)|\right)/2 \ge (\rho_0|I_k^0|+3\rho_o(|I_k|-|I_k^0|)/4)/2 \ge 3\rho_0|I_k|/8\,.$$

The second to last inequality follows from Proposition 6.16.

PROPOSITION 6.18. *Consider a sequence of* $h' \geq 4c_0/\rho_1\lceil\log_{c_1}|I_k|\rceil$ *iterations of steps* 2–5, *starting at the kth iteration, where* $c_0 \geq 1$ *and* $c_1 > 1$ *are constants that are specified below. With probability at least* $1/2$, $|I_{k+h'}| < (1-\rho_2/2)|I_k|$.

Proof. Let H be the set of all $1 \leq h \leq h'$ such that

$$|I^0_{k+h-1} \setminus I_{k+h}| + \sum_{i\in I_{k+h-1}\setminus(I^0_{k+h-1}\cup I_{k+h})}\ \sum_{j\in \mathrm{succ}^{-1}_{k+h-1}(i)} 1/|\mathrm{succ}_{k+h-1}(j)| \geq \rho_2|I_{k+h-1}|\,.$$

It follows from Proposition 6.17 that for $1 \leq h \leq h'$, $h \in H$ with probability at least ρ_1. Hence, using bounds on the binomial distribution, with probability $1-\exp(O(-h'\rho_1)) \geq 1/2$, $|H| \geq c_0\lceil\log_{c_1}|I_k|\rceil$. We assume that $|H| \geq c_0\lceil\log_{c_1}|I_k|\rceil$ and $|I_{k+h'}| \geq (1-\rho_2/2)|I_k|$ and obtain a contradicition. Consider $h \in H$. It follows, using Proposition 6.14, that

$$\begin{aligned}&|I^0_{k+h-1} \cap I_{k+h}| + \sum_{i\in I_{k+h}\setminus I^0_{k+h-1}}\ \sum_{j\in \mathrm{succ}^{-1}_{k+h-1}(i)} 1/|\mathrm{succ}_{k+h-1}(j)|\\ &= |I^0_{k+h-1} \cap I_{k+h}| + \textstyle\sum_{i\in I_{k+h}\setminus I^0_{k+h-1}} |\mathrm{succ}_{k+h}(i)|/|\mathrm{succ}_{k+h-1}(i)| < (1-\rho_2)|I_{k+h-1}|.\end{aligned}$$

We obtain that

$$\begin{aligned}\sum_{i\in I_{k+h}\setminus I^0_{k+h-1}} |\mathrm{succ}_{k+h}(i)|/|\mathrm{succ}_{k+h-1}(i)| &< (1-\rho_2)|I_{k+h-1}| - |I^0_{k+h-1}\cap I_{k+h}|\\ &\leq (1-\rho_2)|I_{k+h}|/(1-\rho_2/2) - |I^0_{k+h-1}\cap I_{k+h}|\,.\end{aligned}$$

Denote $\rho_3 = (1-\rho_2)/(1-\rho_2/2)$ and $\rho_4 = (1+\rho_3)/2$. Note that $\rho_3 < 1$ and $\rho_3 < \rho_4 < 1$. The number of elements in the summation that are not smaller than ρ_4 is less than

$$(\rho_3|I_{k+h}| - |I^0_{k+h-1}\cap I_{k+h}|)/\rho_4\,.$$

The number of elements in the summation is $|I_{k+h}\setminus I^0_{k+h-1}| = |I_{k+h}| - |I^0_{k+h-1}\cap I_{k+h}|$. Hence, more than

$$(1-\rho_3/\rho_4)|I_{k+h}| + (1/\rho_4 - 1)|I^0_{k+h-1}\cap I_{k+h}| \geq (1-\rho_3/\rho_4)|I_{k+h}|$$

elements are smaller than ρ_4. Using $|I_{k+h}| \geq (1-\rho_2/2)|I_k|$, it follows that after each iteration in H, for more than $(1-\rho_3/\rho_4)(1-\rho_2/2)|I_k|$ elements, the number of successors (size of succ_{k+h}) reduces by a factor of at least ρ_4. Let

$$c_0 = 1/((1-\rho_3/\rho_4)(1-\rho_2/2)) + 1$$

and $c_1 = (1-\rho_4)^{-1}$. The size of elements in the range of succ_k is bounded by I_k. Hence

$$|H| < c_0\lceil\log_{c_1}|I_k|\rceil\,,$$

which contradicts our assumption.

COROLLARY 6.19. *The expected number of iterations of steps* 2–5 *is* $O(\log^2 n)$.

Proof of Theorem 6.1. Algorithm 6.8 terminates with a correct solution. Each execution of Steps 2–5 amounts to $O(\log n)$ calls to Algorithms 6.3 and 6.6. Hence it follows from Corollary 6.19 that Algorithm 6.8 performs an expected number of $O(\log^3 n)$ applications of Algorithms 6.3 and 6.6. Recall that Algorithms 6.3 and 6.6 run in $O(mn)$ time sequentially, and on a CRCW PRAM, in $O(n)$ time using $O(m)$ processors. It follows that the expected running time of Algorithm 6.8 is as stated in the theorem. □

7. Monotone systems. Consider the following two operations on vectors in R^n:

$$\boldsymbol{x} \vee \boldsymbol{y} = (\max\{x_1, y_1\}, \dots, \max\{x_n, y_n\})^T \quad \text{(the } \textit{join} \text{ of } \boldsymbol{x} \text{ and } \boldsymbol{y}\text{)},$$
$$\boldsymbol{x} \wedge \boldsymbol{y} = (\min\{x_1, y_1\}, \dots, \min\{x_n, y_n\})^T \quad \text{(the } \textit{meet} \text{ of } \boldsymbol{x} \text{ and } \boldsymbol{y}\text{)}.$$

Consider a TVPI system as in Definition 1.1, where the matrix $\boldsymbol{A}^T$ (resp., $-\boldsymbol{A}^T$) is a *pre-Leontief* matrix, that is, each row of $\boldsymbol{A}$ contains at most one positive (resp., negative) entry. The set of solutions of such a system constitutes a semilattice relative to the $\vee$ (resp., $\wedge$) operation (see Cottle and Veinott [10]). It follows that if all the variables are bounded from above (resp., below), there exists a solution where all the variables are maximized (resp., minimized) simultaneously, hence, the vector $\boldsymbol{x}^{\max}$ (resp., $\boldsymbol{x}^{\min}$) is feasible. Also, the associated graph of such a system (see Definition 2.1) does not contain edges from $\underline{V}$ to $\overline{V}$ (resp., from $\overline{V}$ to $\underline{V}$).

A TVPI system where the two nonzero coefficients in each inequality have opposite signs (equivalently, both $\boldsymbol{A}^T$ and $-\boldsymbol{A}^T$ are pre-Leontief) is called *monotone*. The set of solutions of monotone systems constitutes a lattice relative to the $\vee$ and $\wedge$ operations. Note that the converse is also true: If a polyhedral set constitutes a lattice relative to the $\vee$ and $\wedge$ operations, then it can be represented as the set of solutions of some monotone system. This converse is a direct consequence of the following result due to Veinott [18]: a polyhedral set is a semilattice relative to the $\vee$ (resp., $\wedge$) operation if and only if it constitutes the set of solutions of some linear system $\boldsymbol{Ax} \leq \boldsymbol{b}$ (resp., $\boldsymbol{Ax} \geq \boldsymbol{b}$), where the matrix $\boldsymbol{A}^T$ (resp., $-\boldsymbol{A}^T$) is pre-Leontief. Consider, for example, the nonmonotone system in Fig. 6. The points (5, 1) and (3, 4) are feasible, but the point $(5, 1) \wedge (3, 4) = (3, 1)$ is not. Monotone systems are related to generalized network flow problems: The linear programming dual of the uncapacitated generalized transshipment problem is monotone. In [4] and [7] we present algorithms for generalized network flow problem that exploit this relationship.

$$\begin{array}{rcrl} y & - & 3x \leq & 0 \\ 8y & - & 3x \leq & 42 \\ -y & + & x \leq & 1 \\ -y & + & x \leq & -3 \end{array} \qquad \begin{array}{rcrl} 3y & - & 4x \leq & 0 \\ 5y & + & x \leq & 46 \\ -y & + & x \leq & 4 \\ -2y & + & 3x \leq & -7 \end{array}$$

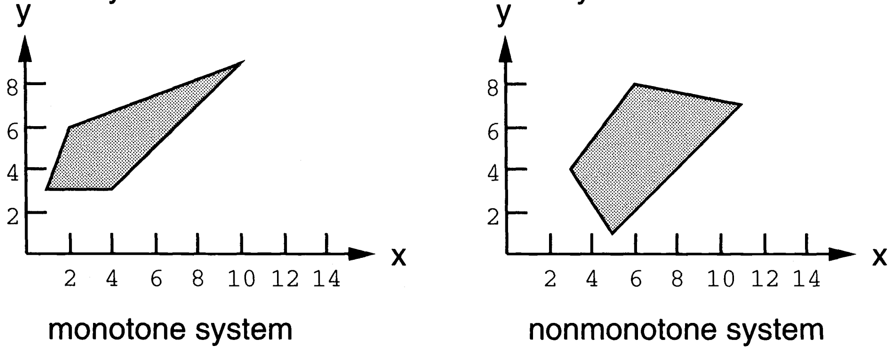

FIG. 6. *Examples of a monotone system and a nonmonotone system.*

The algorithms presented here for solving the feasibility of TVPI systems can be adapted to find the vectors $\boldsymbol{x}^{\min}$, $\boldsymbol{x}^{\max}$ for monotone systems. Note that in the associated graph of a monotone system there are no edges passing between the two sets of vertices $\overline{V}$ and $\underline{V}$. It follows that all certificates are either closed certificates or simple paths.

We consider an application of Algorithm 3.3 to a monotone system, with the goal of finding the point $\boldsymbol{x}^{\max}$. It suffices to rely on a simpler notion of locating values: *Locating* the value ξ means locating it with respect to $x_i^{\max}$ (rather than determining its position relative to $x_i^{\min}$ as well). Problem 3.6 amounts to the following.

PROBLEM 7.1 [*locate a pool of values*]. *Given are values ξ_i $(i \in I)$ for the corresponding variable x_i $(i \in I)$. Locate these values, i.e., determine if $\xi_i > x_i^{\max}$ $(i \in I)$. Choose intervals J_i $(i \in I)$ as follows. $J_i = [\xi_i, \infty]$, if $\xi_i \leq x_i^{\max}$ and $J_i = [-\infty, \xi_i]$, if $\xi_i \geq x_i^{\max}$ $(i \in I)$.*

It is easy to see that the intervals J_i are such that $\{x | \bigwedge_{i \in I} x_i \in J_i\}$ contains the simultaneous maximum.

Consider step 7 of Algorithm 3.3. The interval S_i' are feasible for x_i $(1 \leq i \leq n)$. Hence, for $1 \leq i \leq n, b_i' = x_i^{\max}$ (x_i is unbounded if and only if $b_i' = \infty$). If all variables are bounded, $\boldsymbol{b}' = \boldsymbol{x}^{\max}$. Otherwise, the algorithm supplies dependencies that allow us to compute feasible solutions when we determine some variables and maximize others.

REMARK 7.2. *An algorithm that computes $\boldsymbol{x}^{\max}$ (resp., $\boldsymbol{x}^{\min}$) for feasible monotone systems can be applied to compute $\boldsymbol{x}^{\max}$ (resp., $\boldsymbol{x}^{\min}$) for* TVPI *systems where the matrix $\boldsymbol{A}^T$ (resp., $-\boldsymbol{A}^T$) is pre-Leontief. Consider a system $\boldsymbol{Ax} \leq \boldsymbol{b}$ where at most one of the two nonzero coefficients in each row is positive. Obtain a monotone system $\boldsymbol{A}'\boldsymbol{x} \leq \boldsymbol{b}'$ by omitting all rows of $\boldsymbol{A}$ where there are two negative entries. Compute the vector $\boldsymbol{y}$ that maximizes all variables in the resulting monotone system. If the original system $\boldsymbol{Ax} \leq \boldsymbol{b}$ is feasible, $\boldsymbol{y}$ is the vector that maximizes all variables.*

8. Concluding remarks. In this paper we considered systems of linear inequalities, where each inequality has at most two nonzero coefficients (TVPI systems). We presented algorithms that solve the feasibility problem, that is, either find a point that satisfies all the inequalities or conclude that no such point exists. We gave a $\tilde{O}(mn^2)$ deterministic algorithm and a $\tilde{O}(n^3 + mn)$ expected time randomized algorithm. The complexities of the respective parallel implementations are: $\tilde{O}(n)$ time using $O(mn)$ processors, and $\tilde{O}(n)$ expected time using $O(n^2+m)$ processors. Although the analysis of these algorithms seems quite lengthy, the algorithms themselves are simple. The underlying computation amounts to the basic Bellman-Ford and Floyd-Warshall [8] shortest-path algorithms where only simple data structures are used. Our algorithms are strongly polynomial, that is, the number of operations does not depend on the size of input numbers. We comment that the size (number of bits) of the numbers generated by the algorithms is $O(nC)$, where C is the size of the largest coefficient in the input.

We give some comments and suggestions for further research:

The time complexity of the randomized algorithm involves many logarithmic factors ($\log^5 n$). We suspect that a more careful analysis may eliminate some of these factors. The constant factors in the algorithms of §5 are quite large, but probably can be reduced significantly. We believe that some appropriate version of the algorithms presented here could work well in practice. Another obvious question is whether the $\tilde{O}(n^3 + mn)$ bound can be achieved deterministically.

We discuss the possibility of improving over a $\tilde{O}(n^3 + mn)$ bound. The $\tilde{O}(n^3)$ factor results from the all-pairs shortest-paths Floyd-Warshall computation and is inherent from our basic framework. A different approach, however, may yield a $\tilde{O}(mn)$ algorithm. We note that more work efficient parallel all-pairs shortest-paths algorithms that are applicable for semirings, can be combined with our techniques (instead of the Floyd-Warshall algorithm) to obtain better bounds. In particular, a polylogarithmic time $f(m, n) = o(n^3)$ work all-pairs shortest-paths algorithm yields a $\tilde{O}(f(m, n) + mn)$ algorithm for solving TVPI systems. We comment that better bounds are obtained for TVPI systems where the associated graph has some special structure for which more work-efficient shortest-paths algorithms exist. When the associated graph has a separator decomposition using $O(n^\mu)$ size separators (e.g., planar graphs, k-dimensional grid graphs bounded on most dimensions, or bounded tree-width graphs), the corresponding TVPI systems can be solved in $\tilde{O}(n^{3\mu} + mn)$ time, using a shortest paths algorithm by the first author [5]. Consider, as an example, a TVPI system such that the variables correspond to vertices of a three-dimensional grid, and all inequalities are "local" (that is, for each inequality, the distance on the grid between the two vertices corresponding to the variables in the inequality is bounded by some constant). The associated graph has a separator decomposition using $O(n^{2/3})$ size separators, and hence, these TVPI systems can be solved in $\tilde{O}(mn)$ expected time.

The feasibility problem of monotone systems includes as a very special case the problem of detecting existence of negative weight directed cycles in a graph with n nodes, m edges, and real weights associated with the edges (using a well-known reduction). The best known bound for detecting negative weight cycles is $O(mn)$ and hence we believe it is unlikely that a $\tilde{o}(mn)$ algorithm exists for solving TVPI systems. We sketch the reduction. Consider a weighted graph $G = (V, E, w)$, where $w : E \to R$. The corresponding monotone system is as follows. For each node $v \in V$ assign a variable x_v. For each edge $e = (u, v) \in E$ assign the inequality $x_v - x_u \leq w(e)$. It follows from Proposition 2.10 that G contains a negative weight cycle if and only if the system is infeasible.

Our algorithms solve the feasibility problem of TVPI systems. They can be adapted, however, to (i) find a solution that maximizes a specific variable (ii) and find the lexicographic maximum. Questions that remain open regard finding an optimal solution relative to an arbitrary linear objective function. It is not known whether a strongly polynomial time algorithm exists for the problem, or whether we can achieve a time bound that is better than specializations of existing general LP algorithms. A partial result is due to Cosares [9], who showed that when the objective function has a fixed number of nonzero entries, the problem can be solved in strongly polynomial time bounds. The degree of the polynomial, however, grows linearly with the number of nonzero entries.

We discuss the parallel complexity of solving TVPI systems. Lueker, Megiddo, and Ramachandran [14] showed that the problem of finding an optimal solution relative to a general objective function is $\mathcal{P}$ complete. It is not known, however, whether the feasibility problem is $\mathcal{P}$ complete. The algorithms presented in this paper have a parallel running time of $\tilde{O}(n)$. This is the best known parallel time bound achievable by a polynomial number of processors. Lueker, Megiddo, and Ramachandran [14] gave an algorithm for the problem that runs in polylogarithmic time, but uses $n^{O(\log n)}$ processors.

Acknowledgments. The authors would like to thank the anonymous referee for very careful reading and many good suggestions for improving the presentation.
