COMPUTATIONAL COMPLEXITY OF SPARSE RATIONAL INTERPOLATION *

DIMA GRIGORIEV†, MAREK KARPINSKI‡, AND MICHAEL F. SINGER§

Abstract. The authors analyze the computational complexity of sparse rational interpolation, and give the first deterministic algorithm for this problem with singly exponential bounds on the number of arithmetic operations.

Key words. computational complexity, interpolation, sparse rational functions, arithmetic operations

AMS subject classifications. 68Q25, 68Q40, 68Q15, 26C15

Introduction. Given a black box to evaluate a t-sparse (a quotient of two t-sparse polynomials) n-variable rational function f with integer coefficients, we can find the coefficients and exponents appearing in a t-sparse representation of f using $(t^{(nt)} \log d)^{O(1)}$ black box evaluations and arithmetic operations, and with arithmetic depth $(nt \log d)^{O(1)}$, where d denotes the degree of t-sparse representation of f (see the theorem at the end of §4 for an exact statement of this result). Although these bounds involve the size of exponents, this dependency arises only at the end of our algorithm. The algorithm genuinely produces (i.e., produces in a way whose arithmetic complexity does not depend on the size of the coefficients of f or on the degree of f, [19]) a polynomial whose roots are p-powers (for some small p) of the exponents appearing in a t-sparse representation of f. All known algorithms to find the roots of this polynomial (even knowing that they are p-powers) have complexities that depend on the size of the roots. This dependency also occurs in algorithms for interpolating t-sparse polynomials (cf., [1]) for the same reason.

To find the exponents appearing in some t-sparse representation of a t-sparse univariate rational function $f(X)$, we proceed as follows: We consider representations of $f(X)$ of the form $(\sum_{i=1}^{t} a_i X^{\alpha_i})/(\sum_{i=1}^{t} b_i X^{\beta_i})$, where a_i, b_i, α_i, β_i are real numbers. Such a function is called a *real quasi-rational function.* Furthermore, we call such a representation minimal if it has a minimal number of nonzero terms in the numerator and denominator; it is called normalized if some term is 1. We show that there are only a finite number of minimal normalized representations and that the exponents must be integers. We are able to produce a system T of polynomial equalities and inequalities (whose coefficients depend on the values of $f(X)$ at $t^{O(t)}$ points) that determine all the possible values of any such α_i and β_i. Using the methods of [13], we can then find all α_i and β_i. To find the exponents when $f(X_1, \dots, X_n)$ is a multivariate polynomial, we show how to produce sufficiently many n-tuples of integers $(\nu_1, \dots, \nu_n)$ such that the exponents of f can be recovered from the exponents of all the $f(X^{\nu_1}, \dots, X^{\nu_n})$.

Complexity issues for t-sparse polynomial and rational function interpolation have been dealt with in several papers. Polynomial (black box) interpolation was studied in [1], [2], [9], [12], [17], [19], [27], and [28]. For bounded degree rational interpolation (when the bound on the degree is part of the input), see [15], [16], [25]. Approximative unbound interpolation also arises naturally in issues of computational learnability of sparse rational functions

(cf. [21]). The present authors have previously studied the problem of interpolation of rational functions in [10], but the algorithm presented there for finding the exponents had considerably worse complexity. The present paper significantly improves the results of that paper by introducing the notion of a minimal representation (allowing us to compute directly a finite set of possible exponents instead of just bounding them) and a new technique for reducing multivariate interpolation to univariate interpolation. As we shall see, these ideas give us a more efficient algorithm.

The rest of the paper is organized as follows: In §1 we give formal definitions of a quasi-rational function and related concepts and prove some basic facts about these functions. In §2 we introduce some useful linear operators on fields of these functions. We use these operators to derive criteria for a function to be t-sparse. In §3 we use these criteria to give an algorithm for t-sparse univariate interpolation. In §4 we again use these operators to show how multivariate interpolation can be reduced to univariate interpolation. Complexity analyses of the algorithms are also given in §§3 and 4.

1. Quasi-rational functions.

A finite sum

$$\sum_I c_I \mathbf{X}^I, \tag{1}$$

where $I = (\alpha_1, \dots, \alpha_n), \alpha_i \in \mathbb{C}$, $X^I = X^{\alpha_1} \cdot \dots \cdot X^{\alpha_n}$, $C_I \in \mathbb{C}$ is called a *quasipolynomial* of n variables. The set of quasipolynomials forms a ring under the obvious operations and we denote this ring by $\mathbb{C}\langle X_1, \dots, X_n\rangle$. The subring of quasipolynomials (1) with $\alpha_i \in \mathbb{R}$ and $c_I \in \mathbb{R}$ will be referred to as the ring of *real quasipolynomials* and will be denoted by $\mathbb{R}\langle X_1, \dots, X_n\rangle$. A ratio of two quasipolynomials (real quasipolynomials) is called a *quasi-rational function* (*real quasi-rational function*). The set of such functions forms a field that we denote by $\mathbb{C}\langle\langle X_1, \dots, X_n\rangle\rangle(\mathbb{R}\langle\langle X_1, \dots, X_n\rangle\rangle)$. Note that $\mathbb{Q}(X_1, \dots, X_n) \subset \mathbb{R}\langle\langle X_1, \dots, X_n\rangle\rangle$. We use the expressions *polynomial* or *rational function* in the usual sense (that is, for a quasipolynomial or quasi-rational function with nonnegative integer exponents in their terms).

We say that the quasipolynomial (1) is *t-sparse* if at most t of the c_I are nonzero. If a quasi-rational function f can be written as a quotient of a numerator that is t_1-sparse and a denominator that is t_2-sparse, then we say that f is *(t_1, t_2)-sparse*. For example, $(X^m - 1)/(X - 1) = X^{m-1} + \dots + 1$ is $(2, 2)$-sparse and also $(m, 1)$-sparse. If f is (t_1, t_2)-sparse but not $(t_1 - 1, t_2)$- or $(t_1, t_2 - 1)$-sparse, we say that f is *minimally (t_1, t_2)-sparse*. Note that the above example is both minimally (2.2)-sparse and minimally $(m, 1)$-sparse. We say that a representation $f = p/q$ is a minimal (t_1, t_2)-sparse representation if f is minimally (t_1, t_2)-sparse and p is t_1-sparse and q is t_2-sparse.

We will need a zero test for (t_1, t_2)-sparse rational functions. This is similar to the well-known zero test for t-sparse polynomials (cf., [1], [9], [11]). We assume that we are given a black box for an n-variable rational function f with integer coefficients in which we can put points with rational coefficients. The output of the black box is either the value of the function at this point or some special sign (e.g., "∞") if the denominator of the irreducible representation of the function vanishes at this point. (A representation $f = g/h$, $g, h \in \mathbb{C}[X_1, \dots, X_n]$, is irreducible if g and h are relatively prime.)

LEMMA 1. *Let f be a (t_1, t_2)-sparse rational function of n variables, let $p_1, \dots, p_n$ be n distinct primes, and let $P^j = (p_i^j, \dots, p_n^j) 1 \le j \le t_1 + t_2 - 1$. Then f is not identically zero if and only if the black box outputs a number different from* 0 *and* ∞ *at one of the points p^j.*

Proof. If $M_1, \dots, M_t$ are distinct positive numbers, then any $t \times t$ subdeterminant of the $r \times t$ matrix $(M_s^j)_{1 \le s \le t, 1 \le j \le r}$ is nonsingular (cf. [5]). Since the black box gives output based on an irreducible representation of f, we see that any zero of the denominator of such a representation is zero of the denominator of a (t_1, t_2)-sparse representation of f. Using the remark about the matrix (M_s^j) above we see that the denominator can vanish at (at most) $t_2 - 1$ of these points. A similar argument applies to the numerator. Therefore, the (t_1, t_2)-sparse function f is not identically zero if and only if the black box outputs a number different from 0 and ∞ at one of these points P^j.

We note that Lemma 1 is not true for quasi-rational functions. For example, let $p = 2$ and $f(X) = 1 - X^{\frac{2\pi\sqrt{-1}}{\log 2}}$. We then have that $f(2^i) = 0$ for all i. If one restricts oneself to real quasi-rational functions, then Lemma 1 is also not true for $n \geq 2$. To see this, let $f(X_1, X_2) = X_1^{\log_2 5} - X_2^{\log_3 5}$ and $p_1 = 2$, $p_2 = 3$. However, we do have a zero test for univariate real quasi-rational functions. We need such a test, which we state in the following lemma, for real quasipolynomials only.

LEMMA 2. *Let p be a positive real number and let $f \in \mathbb{R}\langle X\rangle$ be t-sparse. If $f(p^i) = 0$ for $i = 0, \ldots, t-1$, then $f \equiv 0$.*

Proof. Let $f = \sum_{i=1}^{t} a_i X^{\alpha_i}$, where $\alpha_i \neq \alpha_j$ for $i \neq j$. Since $f(p^i) = 0$ for $i = 0, \ldots, t-1$,

$$\begin{bmatrix} 1 & \cdots & 1 \\ p^{\alpha_1} & \cdots & p^{\alpha_t} \\ \vdots & \vdots & \vdots \\ (p^{\alpha_1})^{t-1} & & (p^{\alpha_t})^{t-1} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_t \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

Since the α_i are real, $p^{\alpha_i} \neq p^{\alpha_j}$ if $i \neq j$. Therefore, the above $t \times t$ matrix is nonsingular and so $a_1 = \cdots = a_t = 0$.

If f is a quasi-rational function, we call a representation $f = g/h$, $g, h \in \mathbb{C}\langle X_1, \ldots, X_n\rangle$ *normalized* if g or h contains the constant term 1. For an arbitrary representation $f = \tilde{g}/\tilde{h}$, there are a finite number of monomials M such that $(\tilde{g}/M)/(\tilde{h}/M)$ is normalized.

LEMMA 3. (a) *Assume that $p/q = \bar{p}/\bar{q}$ are normalized representations of a multivariate quasi-rational function and assume that p/q is a minimal (t_1, t_2)-sparse representation. Then the $\mathbb{Z}$-module generated by the exponent vectors of p and q is a submodule of the $\mathbb{Z}$-module generated by the exponent vectors of $\bar{p}$ and $\bar{q}$.*

(b) *There exist at most $(t_1 + t_2)^{O(t_1+t_2)}$ minimal (t_1, t_2)-sparse normalized representations. Furthermore, for given exponent vectors, the coefficients in the corresponding minimal representations are unique.*

(c) *Assume the same conventions as in* (a). *Then*

$$\max\{|\deg(p)|, |\deg(q)|\} \leq 2(t_1 + t_2) \max\{|\deg(\bar{p})|, |\deg(\bar{q})|\}.$$

Proof. Let $I_1, \ldots, I_{t_1}$ be the exponent vectors of p; $J_1, \ldots, J_{t_2}$ be the exponent vectors of q; and let $\{\bar{I}_i\}$ (respectively, $\{\bar{J}_j\}$) be the exponent vectors of $\bar{p}$ (respectively, $\bar{q}$). We define a weighted directed graph $\mathcal{G}$ in the following way: The vertices of $\mathcal{G}$ correspond to the $t_1 + t_2$ exponents of p/q. We join I_i and J_i if $I_i + \bar{J}_{j_1} = J_j + \bar{I}_{i_1}$ for some i_1, j_1 and assign the weight $\bar{I}_{i_1} - \bar{J}_{j_1}$ to the edge (I_i, J_j). We join I_i and I_{i_1} if $I_i + \bar{J}_j = I_{i_1} + \bar{J}_{j_1}$ for some $j \neq j_1$ and assign weight $\bar{J}_{j_1} - \bar{J}_j$ to the edge (I_i, I_{i_1}). Finally, we join J_j and J_{j_1} if $J_j + \bar{I}_i = J_{j_1} + \bar{I}_{i_1}$ for some $i \neq i_1$ and assign weight $\bar{I}_{i_1} - \bar{I}_i$ to the edge (J_j, J_{j_1}).

We claim that $\mathcal{G}$ is connected when viewed as an undirected graph. If not, let $\mathcal{G}_o$ be the connected component that contains the exponent vector $(0, \ldots, 0)$. One sees that the representation p_o/q_o obtained from p/q by deleting all terms with exponent vectors not belonging to this connected component equals $\bar{p}/\bar{q}$. This contradicts the minimality of p/q and proves the claim.

To prove (a) and (c), consider a spanning tree $\mathcal{T}$ of $\mathcal{G}$ and let $(0, \dots, 0)$ be the root of $\mathcal{T}$. Any exponent vector I_i (respectively, J_i) equals the sum of the weights along the unique path connecting I_i, (respectively, J_i) with the root and so lies in the module generated by the $\bar{I}_i$ and $\bar{J}_i$.

To prove (b), note that the spanning tree above uniquely determines the set of exponent vectors that can occur in p/q. Therefore, the number of exponent vectors in the numerator and denominator is at most the product of the number of such weighted trees and $\binom{t_1+t_2}{t_1}$ (the latter value being the number of choices of exponents for the numerator and denominator). The number of rooted trees with $(t_1 + t_2)$ vertices is at most $(t_1 + t_2)^{0(t_1+t_2)}$. For a fixed tree, the number of ways to assign weights of the above form from a fixed set $\{\bar{I}_i\}_{i=1}^{t_1} \cup \{\bar{J}_j\}_{j=1}^{t_2}$ can be bounded by $(t_1 + t_2)^{0(t_1+t_2)}$. Thus the number of exponent vectors can also be bounded by $(t_1 + t_2)^{0(t_1+t_2)}$.

We now prove the last statement of (b). Assume that $p_o/q_o = p/q$ are two different minimal (t_1, t_2)-sparse representations with the same exponent vectors in the corresponding numerators and denominators. For suitable $c \in \mathbb{C}$, $(p_o - cp)/(q_o - cq) = p/q$ is a representation that is either $(t_1 - 1, t_2)$- or $(t_1, t_2 - 1)$-sparse, contradicting the minimality of (t_1, t_2). This completes the proof of Lemma 3. □

We note that we do not know whether the above bound on the number of distinct minimal (t_1, t_2)-sparse representations is sharp. We have the following immediate consequence of Lemma 3(a).

COROLLARY 4. *Any normalized minimal (t_1, t_2)-sparse quasi-rational representation of a rational function has exponents that are integers.*

2. Linear operators.

2. Linear operators. In the following sections it will be useful to consider the actions of certain linear operators on fields of quasi-rational functions.

DEFINITION. (a) Let $p_1, \dots, p_n$ be distinct prime numbers, and let

$$D_n : \mathbb{C}\langle\langle X_1, \dots, X_n\rangle\rangle \to \mathbb{C}\langle\langle X_1, \dots, X_n\rangle\rangle$$

be the $\mathbb{C}$-linear operator defined by $D_n(X_i^{\alpha}) = p_i^{\alpha} X_i^{\alpha}$, where the number p_i^{α} is defined to be $e^{\alpha \log p_i}$ for some fixed branch of the logarithm. When $n = 1$ we will write $\mathbb{C}\langle\langle X\rangle\rangle$ instead of $\mathbb{C}\langle\langle X_1\rangle\rangle$ and D instead of D_1.

(b) Let $\mathcal{D} : \mathbb{C}\langle\langle X\rangle\rangle \to \mathbb{C}\langle\langle X\rangle\rangle$ be the $\mathbb{C}$-linear operator defined by

$$\mathcal{D}(X^{\alpha}) = X\frac{d}{dX}(X^{\alpha}) = \alpha X^{\alpha}.$$

We first note that given a black box for f, one can immediately construct a black box for $D_n f$. As we shall see below, this new black box will help us to interpolate f. D_n is used in a spirit similar to the prime power evaluation scheme of [1], [9], [11], and [12]. On the other hand, we know of no simple deterministic way of constructing a black box for $\mathcal{D}f$ given a black box for f, i.e., without first interpolating f. In this paper, our main use of $\mathcal{D}$ will be to prove that "faithful" mappings of multivariate (t_1, t_2)-sparse rational functions to univariate (t_1, t_2)-sparse rational functions are abundant. Note also that D_n is a homomorphism, i.e., $D_n(fg) = D_n(f)D_n(g)$ while $\mathcal{D}$ is a derivation, i.e., $\mathcal{D}(f)g + f\mathcal{D}(g)$. This difference will force us to deal with these operators separately. We begin by studying D_n.

LEMMA 5. (a) *Let $f \in \mathbb{C}(X_1, \dots, X_n)$, and assume that $D_n(f) = f$. Then $f \in \mathbb{C}$.*

(b) *Let $f \in \mathbb{R}\langle\langle X\rangle\rangle$ and assume that $D(f\ ) = f$. Then $f \in \mathbb{R}$.*

Proof. (a) If $D_n(f) = f$, then

$$F(X_1, \dots, X_n) = f(p_1X_1, \dots, p_nX_n) = f(p_1^2X_1, \dots, p_n^2X_n) = \cdots.$$

Lemma 1 implies that $f(X_1, \ldots, X_n) = f(X_1 Y_1, \ldots, X_n Y_n)$ for new variables $Y_1, \ldots, Y_n$. If $f = g/h$, let $g = \sum_I a_I \mathbf{X}^I, h = \sum_j b_J \mathbf{X}^J$. Comparing coefficients of the corresponding monomials in $\mathbf{X}$ and $\mathbf{Y}$ we have that, after a suitable reordering, $I_1 = J_1, I_2 = J_2, \ldots$ and $a_I b_J = a_J b_I$ for all I, J. Therefore, $f \in \mathbb{C}$.

(b) The proof is the same as in (a) using Lemma 2 instead of Lemma 1.

Note that Lemma 5(a) is not true for $f \in \mathbb{R}\langle\langle X_1, \ldots, X_n\rangle\rangle \subset \mathbb{C}\langle\langle X_1, \ldots, X_n\rangle\rangle, n \geq 2$. To see this, let $f = X_1^{\log_2 5} X_2^{-\log_3 5}$, $p_1 = 2$, $p_2 = 3$. Lemma 5(b) is not true for $f \in \mathbb{C}\langle\langle X\rangle\rangle$ since, for $p = 2$, $f = X^{\frac{2\pi\sqrt{-1}}{\log 2}}$ gives a counterexample.

LEMMA 6. (a) *If $y_1, \ldots, y_m \in \mathbb{C}(X_1, \ldots, X_n)$, then $y_1, \ldots, y_m$ are linearly dependent over $\mathbb{C}$ if and only if*

$$W_{D_n}(y_1, \ldots, y_m) = \det \begin{bmatrix} y_1 & \cdots & y_m \\ D_n y_1 & \cdots & D_n y_m \\ \vdots & \vdots & \vdots \\ D_n^{m-1} y_1 & \cdots & D_n^{m-1} y_m \end{bmatrix} = 0.$$

(b) *If $y_1, \ldots, y_m \in \mathbb{R}\langle\langle X\rangle\rangle$, then $y_1, \ldots, y_m$ are linearly dependent over $\mathbb{R}$ if and only if $W_{D_1}(y_1, \ldots, y_m) = 0$.*

Proof. (a) If $y_1, \ldots, y_m$ are linearly dependent over $\mathbb{C}$, then we clearly have $W_{D_n}(y_1, \ldots, y_m) = 0$. Now assume that $W_{D_n}(y_1, \ldots, y_m) = 0$. In this case there exist $f_1, \ldots, f_m \in \mathbb{C}(X_1, \ldots, X_n)$, not all zero, such that

$$f_1 y_1 + \cdots + f_m y_m = f_1 D_n y_1 + \cdots + f_m D_n y_m = \cdots = f_1 D_n^{m-1} y_1 + \cdots + f_m D_n^{m-1} y_m = 0.$$

We may assume $f_1 = 1$. Applying D_n to each of these equations, we have

$$D_n^i y_1 + D_n f_2 D^i y_2 + \cdots + D_n f_n D_n^i y_m = 0$$

for $i = 1, \ldots, n$. This implies that

$$(f_2 - D_n f_2) D_n^i y_2 + \cdots + (f_m - D_n f_m) D_n^i y_m = 0$$

for $i = 1, \ldots, n-1$. Either $f_i - D_n f_i = 0$ for $i = 2, \ldots, m$, in which case we are done by Lemma 5, or by induction there exist $\alpha_2, \ldots, \alpha_m \in \mathbb{C}$, not all zero, such that $\alpha_2 D_n y_2 + \cdots + \alpha_m D_n y_m = 0$. Therefore, $D_n(\alpha_2 y_2 + \cdots + \alpha_m y_m) = 0$, so $\alpha_2 y + \ldots + \alpha_m y_m = 0$. The proof of part (b) is similar and omitted.

Lemma 6 immediately implies the following criterion for a real quasi-rational function to be (t_1, t_2)-sparse.

LEMMA 7. (a) *Let $f \in \mathbb{C}(X_1, \ldots, X_n)$. f is (t_1, t_2)-sparse if and only if there exist $I_1, \ldots, I_{t_1}, J_1, \ldots, J_{t_2} \in \mathbb{Z}^n$, $I_i \neq I_j$, $J_i \neq J_j$ for $i \neq j$ such that*

$$W_{D_n}(\mathbf{X}^{I_1}, \ldots, \mathbf{X}^{I_{t_1}}, \mathbf{X}^{J_1} f, \ldots, \mathbf{X}^{J_{t_2}} f) = 0.$$

(b) *Let $f \in \mathbb{R}\langle\langle X\rangle\rangle$. f is (t_1, t_2)-sparse if and only if there exist $\alpha_1, \ldots, \alpha_{t_1}, \beta_1, \ldots, \beta_{t_2} \in \mathbb{R}$, $\alpha_i \neq \alpha_j$, $\beta_i \neq \beta_j$ for $i \neq j$ such that $W_D(X^{\alpha_1}, \ldots, X^{\alpha_{t_1}}, X^{\beta_1} f, \ldots, X^{\beta_{t_2}} f) = 0$.*

Proof. (a) f is (t_1, t_2)-sparse if and only if there exist $I_1, \ldots, I_{t_1}, J_1, \ldots, J_{t_2} \in \mathbb{Z}^n$, $I_i \neq I_j$, $J_i \neq J_j$ for $i \neq j$ and $a_1, \ldots, a_{t_1}, b_1, \ldots, b_{t_2} \in \mathbb{C}$, not all zero, such that $\sum_{i=1}^{t_1} a_i \mathbf{X}^{I_i} + \sum_{j=1}^{t_2} b_j \mathbf{X}^{I_j} f = 0$. By Lemma 6 this happens if and only if

$$W_{D_n}(\mathbf{X}^{I_1}, \ldots, \mathbf{X}^{I_{t_1}}, \mathbf{X}^{J_1} f, \ldots, \mathbf{X}^{J_{t_2}} f) = 0.$$

The proof of (b) is similar.

We now consider the other linear operator $\mathcal{D}$ on $\mathbb{C}\langle\langle X\rangle\rangle$. We will need results similar to Lemmas 5 and 6.

LEMMA 8. *If $f \in \mathbb{C}\langle\langle X\rangle\rangle$ and $\mathcal{D}f = 0$, then $f \in \mathbb{C}$.*

Proof. First assume that $f = \sum_{i=1}^{t} a_i X^{\alpha_i} \in \mathbb{C}\langle X\rangle$. If $0 = \mathcal{D}f = \sum_{i=1}^{t} a_i \alpha_i X^{\alpha_i}$, then $t = 1$ and $a_1 = 0$, so $f \in \mathbb{C}$.

Now let $f \in \mathbb{C}\langle\langle X\rangle\rangle$. f is minimally (t_1, t_2)-sparse for some (t_1, t_2). Let $f = g/h$ be a minimal (t_1, t_2)-sparse normalized representation. If $\mathcal{D}h = 0$, then we have just shown that $h \in \mathbb{C}$. Since $\mathcal{D}f = ((\mathcal{D}g)h - g\mathcal{D}h)/h^2 = (\mathcal{D}g)/h$, so $\mathcal{D}g = 0$. Therefore, $g \in \mathbb{C}$ and so $f \in \mathbb{C}$. We will, therefore, now assume that $\mathcal{D}h \neq 0$ and derive a contradiction. Since $(\mathcal{D}g)h - g\mathcal{D}h = 0$, we have $g/h = \mathcal{D}g/\mathcal{D}h$. Since g/h is normalized, $\mathcal{D}g/\mathcal{D}h$ is a $(t_1 - 1, t_2)$- or a $(t_1, t_2 - 1)$-sparse representation of f, a contradiction.

LEMMA 9. *If $y_1, \dots, y_m \in \mathbb{C}\langle\langle X\rangle\rangle$, then $y_1, \dots, y_m$ are linearly dependent over $\mathbb{C}$ if and only if*

$$W_{\mathcal{D}}(y_1, \dots, y_m) = \det \begin{bmatrix} y_1 & \cdots & y_m \\ \mathcal{D}y_1 & \cdots & \mathcal{D}y_m \\ \vdots & \vdots & \vdots \\ \mathcal{D}^{m-1}y_1 & \cdots & \mathcal{D}^{m-1}y_m \end{bmatrix} = 0.$$

Proof. Lemma 8 implies that $\mathbb{C}\langle\langle X\rangle\rangle$ is a differential field with constant subfield equal to $\mathbb{C}$. The result now follows from ([18, Thm. 3.7]).

3. Univariate interpolation. Lemma 7 in §2 allows us to characterize (t_1, t_2)-sparse rational functions and is the basis of the following algorithm for finding the exponents of a sparse univariate rational function.

Assume we are given a black box to evaluate a univariate rational function $f \in \mathbb{Q}(X)$, and assume we are told that it is minimally (t_1, t_2)-sparse. (The general case, in which we are told only that it is (t_1, t_2)-sparse, is handled below.) Consider the expression

$$\begin{aligned} S(p^{\alpha_1}, \dots, p^{\alpha_{t_1}}, p^{\beta_1}, \dots, &\ p^{\beta_{t_2}},\ f(X), f(pX), \dots, f(p^{t_1+t_2-1}X)) \\ &= \frac{W_{\mathcal{D}}(X^{\alpha_1}, \dots, X^{\alpha_{t_1}}, X^{\beta_1} f, \dots, X^{\beta_{t_2}} f\ )}{X^{\alpha_1} \cdot \dots \cdot X^{\alpha_{t_1}} \cdot X^{\beta_1} \cdot \dots \cdot X^{\beta_{t_2}}}. \end{aligned}$$

Note that S is a polynomial in the indicated terms with integer coefficients. Replacing $p^{\alpha_1}, \dots, p^{\alpha_{t_1}}, p^{\beta_1}, \dots, p^{\beta_{t_2}}$ with new variables $Y_1, \dots, Y_{t_1+t_2}$, we get a polynomial $S(Y_1, \dots, Y_{t_1+t_2}, f(X), f(pX), \dots, f(p^{t_1+t_2-1}X))$ with at most $(t_1 + t_2)^{t_1+t_2}$ terms in the variables $Y_1, \dots, Y_{t_1+t_2}$ and multilinear in the black boxes $f(X), f(pX), \dots, f(p^{t_1+t_2-1}X)$. Since we are looking for the exponents of a normalized minimal (t_1, t_2)-sparse representation of f, we may assume $Y_1 = 1$. By Lemma 7(b) $(0, \alpha_2, \dots, \alpha_{t_1}, \beta_1, \dots, \beta_{t_2}) \in \mathbb{R}^{(t_1+t_2)}$ will be a vector of such exponents if and only if

$$(2) \qquad S(1, p^{\alpha_2}, \dots, p^{\alpha_{t_1}},\ p^{\beta_1}, \dots, p^{\beta_{t_2}},\ f(X), f(pX), \dots) = 0$$

$$(3) \qquad 0 \neq \alpha_i \neq \alpha_j, \qquad \beta_i \neq \beta_j \quad \text{for} \quad i \neq j.$$

Observe that S as a rational function from $\mathbb{R}(X)$ is $((t_1 + t_2)^{2(t_1+t_2)}, t_2^{t_1+t_2})$-sparse, hence by Lemma 1, condition (2) is equivalent to the condition that S is either ∞ or 0 for $X =$

$p^i, i = 0, \dots, 2(t_1 + t_2 + 1)^{2(t_1+t_2)} - 1$. For at least $(t_1 + t_2 + 1)^{2(t_1+t_2)}$ of these points (being independent from $\alpha_2, \dots, \beta_{t_2}$), S will be zero. Using the black box for $f(X)$, we can determine a system T consisting of $(t_1+t_2+1)^{2(t_1+t_2)}$ equations in the unknowns $Y_2, \dots, Y_{t_1+t_2}$ of degree at most $(t_1 + t_2)$; of inequalities $1 \neq Y_i \neq Y_j \neq 1, 2 \leq i < j \leq t_1$, $Y_i \neq Y_j, t_1 < i < j \leq t_1 + t_2$; and of inequalities $Y_2 \geq 1, \dots, Y_{t_1+t_2} \geq 1$ that is equivalent to (2), (3) (for $Y_2 = p^{\alpha_2}, \dots, Y_{t_1+t_2} = p^{\beta_{t_2}}$). By Lemma 3(b), T has a finite number of solutions in $\mathbb{R}^{t_1+t_2-1}$. Note that Corollary 4 implies that these solutions are integers. We can apply the algorithm of [13], [14] (cf. also [1]) to this system and find these solutions with $\left((t_1 + t_2)^{(t_1+t_2)} \log d\right)^{O(1)}$ arithmetic operations and depth $((t_1 + t_2) \log d)^{O(1)}$, where d is the maximum of the exponents $\alpha_2, \dots, \beta_{t_2}$. Note that the algorithm of [13], [14] will yield a polynomial satisfied by these p-powers with $(t_1 + t_2)^{O(t_1+t_2)}$ arithmetic operations and $(t_1+t_2)^{O(1)}$ depth. As we noted in the introduction, the dependence on d of the final complexity is introduced when we find the roots of this polynomial. One can find these roots as in [23] or more simply by considering the powers of p that divide the coefficients. We remark that this algorithm also implies that there are at most $(t_1 + t_2)^{O(t_1+t_2)}$ solutions [cf. Lemma 3(b)] and that these solutions $p^{\alpha_2}, \dots, p^{\beta_{t_2}}$ are bounded by $p^d \leq \exp(M(t_1 + t_2)^{O(t_1+t_2)})$, where M is bound on the bitsize of the values yielded by the black box when we evaluate $f(p^{i+j})$ for $i = 0, \dots, t_1 + t_2 - 1$, $j = 0, \dots, 2(t_1 + t_2 + 1)^{2(t_1+t_2)} - 1$. Hence, the exponents $\alpha_2, \dots, \beta_{t_2}$ of the rational function f do not exceed $d \leq M(t_1 + t_2)^{O(t_1+t_2)}$. Notice that the algorithm can find the exponents $\alpha_2, \dots, \beta_{t_2}$ in $\left((t_1 + t_2)^{(t_1+t_2)} \log d\right)^{O(1)}$ arithmetic operations with the depth $((t_1 + t_2) \log d)^{O(1)}$.

We can find the coefficients by solving a system of linear equations gotten from

$$\left(\sum_{i=1}^{t_2} b_i X^{\beta_i}\right) f(X) = \sum_{i=1}^{t_1} a_i X^{\alpha_i}$$

by letting $X = p^j$, $j = 0, 1, \dots, t_1 + t_2 - 1$. Note that Lemma 3(b) implies that this system will have a unique solution. This can be found with $(t_1 + t_2)^{O(1)}$ arithmetic operations with depth $(\log(t_1 + t_2))^{O(1)}$, since to set up this system one has to compute powers p^{α_i}, p^{β_j}, which were computed above.

Turning to the general case, where we are told only that f is (t_1, t_2)-sparse, we proceed as follows: We consider all pairs (t_1', t_2') with $1 \leq t_1' \leq t_1, 1 \leq t_2' \leq t_2$ and use the above algorithm for these pairs. The first time that the above algorithm yields a nonempty set of solutions, we are guaranteed that, for this (t_1', t_2'), f has a minimal (t_1', t_2')-sparse representation and that the algorithm has yielded the exponents and the coefficients.

4. Multivariate interpolations. Let $f(X_1, \dots, X_n) \in \mathbb{Q}(X_1, \cdots, X_n)$ be a minimally (t_1, t_2)-sparse rational function given by a black box. We shall show in this section how the problem of finding the exponent vectors of f can be reduced to the univariate case. In particular, we shall show that the set of vectors $\boldsymbol{\nu} = (\nu_1, \dots, \nu_n) \in \mathbb{C}^n$ such that $f_{\boldsymbol{\nu}}(X) = f(X^{\nu_1}, \dots, X^{\nu_n})$ is not minimally (t_1, t_2)-sparse is a small set V. We will then show that if we find the exponents of $f_{\boldsymbol{\nu}}$ for sufficiently many $\boldsymbol{\nu} \notin V$, then we can recover the exponents appearing in f.

LEMMA 10. *Let $f(X_1, \dots, X_n)$ be a minimally (t_1, t_2)-sparse rational function and let $\nu_1, \dots, \nu_n \in \mathbb{C}$ be linearly independent over $\mathbb{Z}$. Then $f(X^{\nu_1}, \dots, X^{\nu_n})$ is minimally (t_1, t_2)-sparse.*

Proof. Let $\tilde{p}(X)/\tilde{q}(X)$ be a minimally $(\tilde{t}_1, \tilde{t}_2)$-sparse representation of $f(X^{\nu_1}, \dots, X^{\nu_n})$ with $\tilde{t}_1 \leq t_1, \tilde{t}_2 \leq t_2$. By Lemma 3(a), we may assume that $\tilde{p}, \tilde{q} \in \mathbb{C}[X^{\nu_1}, \dots, X^{\nu_n}]$. Since the map sending X^{ν_i} to X_i induces an isomorphism of $\mathbb{C}(X^{\nu_1}, \dots, X^{\nu_n})$ onto $\mathbb{C}(X_1, \dots, X_n)$, we get a $(\tilde{t}_1, \tilde{t}_2)$-sparse representation of $f(X_1, \dots, X_n)$. Therefore, $\tilde{t}_1 = t_1$, and $\tilde{t}_2 = t_2$.

LEMMA 11. *Let f be a minimally (t_1, t_2)-sparse rational function with integer coefficients. The set V of vectors $\boldsymbol{\nu} \in \mathbb{C}^n$ such that $f_{\boldsymbol{\nu}}$ is not minimally (t_1, t_2)-sparse lies in the union of at most $(t_1 + t_2)^{O((t_1+t_2)n)}$ hyperplanes determined by linear forms with integer coefficients.*

Proof. We will first show that V is defined by a set of polynomial equalities and inequalities with coefficients in $\mathbb{Q}$ (i.e., V is a $\mathbb{Q}$-constructible set). Let $V_1, \dots, V_n$ be variables. We shall write down conditions on $V_1, \dots, V_n$ so that $f(X^{V_1}, \dots, X^{V_n})$ is $(t_1 - 1, t_2)$-sparse. These conditions will be used to determine a set $\mathcal{W}^{(1)}$. Similar conditions can be derived for $f(X^{V_1}, \dots, X^{V_n})$ to be $(t_1, t_2 - 1)$-sparse and used to determine a set $\mathcal{W}^{(2)}$. Thus $\mathcal{W} = \mathcal{W}^{(1)} \cup \mathcal{W}^{(2)}$. Lemma 9 implies that $f(X^{V_1}, \dots, X^{V_n})$ is $(t_1 - 1, t_2)$-sparse if and only if there exist $\alpha_1, \dots, \alpha_{t_1-1}, \beta_1, \dots, \beta_{t_2} \in \mathbb{C}$ such that $\alpha_i \neq \alpha_j$, $\beta_i \neq \beta_j$ for $i \neq j$, and

$$\begin{aligned} & S_{\mathcal{D}}\left(\alpha_1, \dots, \alpha_{t_1-1}, \beta_1, \dots, \beta_{t_2}, f(X^{V_1}, \dots, X^{V_n}), \dots, \mathcal{D}^{t_1+t_2-2} f(X^{V_1}, \dots, X^{V_n})\right) \\ (4) \qquad & = \frac{W_{\mathcal{D}}(X^{\alpha_1}, \dots, X^{\alpha_{t_1}-1}, X^{\beta_1} f(X^{V_1}, \dots, X^{V_n}), \dots, X^{\beta_{t_2}} f(X^{V_1}, \dots, X^{V_n}))}{X^{\alpha_1} \cdot \dots \cdot X^{\alpha_{t_1-1}} \cdot X^{\beta_1} \cdot \dots \cdot X^{\beta_{t_2}}} \\ & = 0. \end{aligned}$$

When we clear the denominator of (4), we will get a linear function in expressions of the form $X^{\Sigma a_i V_i}$ with coefficients C_a, where $a = (a_1, \dots, a_n) \in \mathbb{Z}^n$, that are polynomials in $\alpha_1, \dots, \alpha_{t_1-1}, \beta_1, \dots, \beta_{t_2}, V_1, \dots, V_n$ with integer coefficients. Observe that there are at most $(t_1 + t_2)^{O(t_1+t_2)}$ distinct powers $X^{\Sigma a_i V_i}$ that can appear.

For any pair $\sum a_i V_i$, $\sum b_i V_i$ of distinct exponents, let $L_{a,b} = \sum (a_i - b_i) V_i$. Lemma 9 states that for any choice $(\nu_1, \dots, \nu_n) \in \mathbb{C}^n$ such that $L_{a,b}(\nu_1, \dots, \nu_n) \neq 0$, f is $(t_1 - 1, t_2)$-sparse if and only if there exist $\alpha_1, \dots, \alpha_{t_1-1}, \beta_1, \dots, \beta_{t_2} \in \mathbb{C}$ such that all the C_a considered above vanish. Let Φ be the formula, from the language of algebraically closed fields, with bound variables $\alpha_1, \dots, \alpha_{t_1-1}, \beta_1, \dots, \beta_{t_2}$ and free variables $V_1, \dots, V_n$, that express this latter statement. This formula contains at most $(t_1 + t_2)^{O(t_1+t_2)}$ polynomials, each of degree at most $(t_1 + t_2)^2$.

Applying the results of [6] (see also [4]), we can eliminate quantifiers and get a quantifier-free formula Ψ in variables $V_1, \dots, V_n$ equivalent to Φ. Furthermore, the polynomials occurring in Ψ have degrees at most $(t_1 + t_2)^{O((t_1+t_2)n)}$ and there are at most $(t_1 + t_2)^{O((t_1+t_2)n)}$ of these. This formula determines a constructible set $\mathcal{W}_0 \subset \mathbb{C}^n$. As it was shown previously, the symmetric difference $(\mathcal{W}^{(1)} \backslash \mathcal{W}_0) \cup (\mathcal{W}_0 \backslash \mathcal{W}^{(1)})$ lies in a union of all $(t_1 + t_2)^{O(t_1+t_2)}$ hyperplanes of the kind $L_{a,b}$ for the integer vectors a, b considered above. From Lemma 10, we know that for each point $(\nu_1, \dots, \nu_n) \in \mathcal{W}$ there exists a relation $\sum_{i=1}^n \gamma_i \nu_i = 0$ for suitable integers $\gamma_1, \dots, \gamma_n$ not all zero. From Lemma 12 of the appendix we know that each irreducible component of $\mathcal{W}_0$ (and also of $\mathcal{W}$) lies in a hyperplane. Therefore, $\mathcal{W}$ lies in the union of at most $(t_1 + t_2)^{O((t_1+t_2)n)}$ hyperplanes determined by linear forms with integer coefficients.

We now proceed to describe an algorithm to find p-powers of the exponents of a minimally (t_1, t_2)-sparse normalized rational function f.

For any $c > 0$ using the construction from ([11] or [12], Lem.), one can explicitly produce, for suitable $c_1 > 0$, $c_2 > 0$, $N = (t_1 + t_2)^{c_1(t_1+t_2)n}$ vectors $\boldsymbol{\nu}^{(i)} = (\nu_1^{(i)}, \dots, \nu_n^{(i)})$, $1 \leq i \leq N$, where the integers $1 \leq \nu_j^{(i)} \leq (t_1 + t_2)^{c_2(t_1+t_2)_n}$ such that for any family of $(t_1 + t_2)^{c(t_1+t_2)n}$ hyperplanes (containing the origin) at least n of these vectors lie in none of these hyperplanes and any n of these vectors are linearly independent. We take $c > 0$ such that the number of hyperplanes in Lemma 11 is at most $(t_1 + t_2)^{c(t_1+t_2)n}$ (so for the algorithm we have only to estimate explicitly constant c once and forever) and apply to this c the construction mentioned above. For each of the vectors $\boldsymbol{\nu}^{(i)}$ produced in this way, use the algorithm from §3 to find $t_1^{(i)} \leq t_1$, $t_2^{(i)} \leq t_2$ such that the rational function $f_{\boldsymbol{\nu}^{(i)}} \in \mathbb{Q}(X)$ has a minimal $(t_1^{(i)}, t_2^{(i)})$-sparse representation. By Lemma 11 and the construction of the $\boldsymbol{\nu}^{(i)}$, there exist at least n vectors among the $\boldsymbol{\nu}^{(i)}$ (without loss of generality we let them be $\boldsymbol{\nu}^{(1)}, \dots, \nu^{(n)}$) such that $f_{\boldsymbol{\nu}^{(i)}}$ is minimally (t_1, t_2)-sparse for all $1 \le i \le n$. Using the algorithm from §3 we find p-powers of the exponents of all normalized (t_1, t_2)-sparse representations of $f_{\boldsymbol{\nu}^{(i)}}$ for each $1 \le i \le n$ (recall that there are at most $(t_1 + t_2)^{O(t_1+t_2)}$ of these). For each $f_{\boldsymbol{\nu}^{(i)}}$, $1 \le i \le n$, pick out one set of such p-powers of the exponents $p^{\alpha_1^{(i)}}, \dots, p^{\alpha_{t_1}^{(i)}}, p^{\beta_1^{(i)}}, \dots, p^{\beta_{t_2}^{(i)}}$. For each i, $1 \le i \le n$, we also pick out two permutations $\pi^{(i)} \in \mathcal{S}_{t_1}$ and $\sigma^{(i)} \in \mathcal{S}_{t_2}$, where $\mathcal{S}_m$ is the permutation group on m elements. For every j_i, $1 \le j_1 \le t_1$, the algorithm solves the p-power form of a linear system

$$p^{\sum_{k=1}^{n} \nu_k^{(i)} Y_k^{(j_1)}} = p^{\alpha^{(i)}_{\pi^{(i)}(j_1)}} \tag{5}$$

$$1 \le i \le n$$

and for every j_2, $1 \le j_2 \le t_2$ a system

$$p^{\sum_{k=1}^{n} \nu_k^{(i)} Z_k^{(j_2)}} = p^{\beta^{(i)}_{\sigma^{(i)}(j_2)}} \tag{6}$$

$$1 \le i \le n.$$

Using [22] the algorithm produces the inverse matrix $(\mu_k^{(i)}/\mu)$, where $\mu_k^{(i)}$, $\mu \in \mathbb{Z}$, to $n \times n$ matrix $(\nu_k^{(i)})$, which is invertible because of the construction of the vectors $\nu^{(i)}$. Then

$$p^{\mu Y_k^{(j_1)}} = p^{\sum_{1 \le i \le n} \mu_k^{(i)} \alpha^{(i)}_{\pi^{(i)}(j_1)}}$$

and the algorithm computes the right side of this equality. The algorithm also computes $p^{\mu Z_k^{(j_2)}}$. The vectors $\mathbf{Y}^{(1)} = (Y_1^{(1)}, \dots, Y_n^{(1)}), \dots, \mathbf{Y}^{(t_1)} = (Y_1^{(t_1)}, \dots, Y_n^{(t_1)})$ and $\mathbf{Z}^{(1)} = (Z_1^{(1)}, \dots, Z_n^{(1)}), \dots, \mathbf{Z}^{(t_2)} = (Z_1^{(t_2)}, \dots, Z_n^{(t_2)})$ are considered as candidates for being exponent vectors in the numerator and denominator of a (t_1, t_2)-sparse representation of f. The algorithm represents them by $p^{\mu Y_k^{(j_1)}}$, $p^{\mu Z_k^{(j_2)}}$. The algorithm tests whether $\mathbf{Y}^{(j)} \ne \mathbf{Y}^{(l)}$, $\mathbf{Z}^{(j)} \ne \mathbf{Z}^{(l)}$ for $j \ne 1$. Then the algorithm tests whether these candidates fit. For this aim consider the linear system

$$\textstyle\sum_{1 \le i \le t_1} \phi_i p_1^{\mu Y_1^{(i)} l} \cdots p_n^{\mu Y_n^{(i)} l} = \sum_{1 \le i \le t_2} \psi_i p_1^{\mu Z_1^{(i)} l} \cdots p_n^{\mu Z_n^{(i)} l} f(p_1^{\mu l}, \dots, p_n^{\mu l}), \tag{7}$$

$$1 \le l \le 2(t_1 + t_2)^2$$

in the unknown coefficients ϕ_i, ψ_i of the (t_1, t_2)-sparse representations of f currently being tested. (In (7) we skip the equations for which $f(p_1^{\mu l}, \dots, p_n^{\mu l}) = \infty$.) Lemma 1 implies that (7) is solvable if and only if exponent vectors $\mathbf{Y}^{(j)}$, $\mathbf{Z}^{(j)}$ fit. Here we apply Lemma 1 but probably not to rational functions, since the exponents $Y_k^{(i)}$, $Z_k^{(i)}$ could be rational; it is, however, still valid when the variables $X_i \to \bar{X}_i^{\mu l}$, $1 \le i \le n$ are replaced.) If (7) is solvable, then $Y_k^{(i)}$, $Z_k^{(i)}$ are integers because of Lemma 3(a). Moreover, it has a unique solution by Lemma 3(b). This completes the description of the algorithm for f as minimally (t_1, t_2)-sparse. To treat the case when we are told only that f is (t_1, t_2)-sparse, we proceed as in §3.

Now we proceed to the complexity bounds. Let us assume we are given the black box for a (t_1, t_2)-sparse rational function. The algorithm produces $(t_1 + t_2)^{O((t_1+t_2)n)}$ integer vectors $\boldsymbol{\nu}^{(i)}$

and, for each of these, applies the algorithm from §3 to the univariate rational function $f_{\nu^{(i)}}$. This part of the algorithm requires $\left((t_1+t_2)^{(t_1+t_2)n}\log d\right)^{O(1)}$ arithmetic operations with depth $((t_1+t_2)n\log d)^{O(1)}$. The algorithm then selects, for each i, $1\le i\le n$, some (t_1,t_2)-sparse representation of $f_{\nu^{(i)}}$ and also two permutations $\pi^{(i)}, \sigma^{(i)}$. This is again within the same bounds. The algorithm then solves $(t_1+t_2)^{O((t_1+t_2)n)}$ p-power forms of linear systems of type (5) and (6). To invert $n\times n$ matrix $(\nu_k^{(i)})$, $n^{O(1)}$ arithmetic operations are used with depth $\log^{O(1)} n$. Since $\mu_k^{(i)}, \mu \le (t_1+t_2)^{O((t_1+t_2)n^2)}$ computation of p^{μ}, $p^{\mu Y_k^{(j_1)}}$, $p^{\mu Z_k^{(j_2)}}$ can be done within the same complexity bounds. The same applies to solving system (7). If we are told only that f is (t_1,t_2)-sparse, the additional search required by the algorithm does not change the complexity.

We are also able to give some bounds on the degree d of a sparse representation. Assume that A is a bound for all the exponents $\alpha_j^{(i)}$, $\beta_j^{(i)}$ found for the univariate rational functions $f_{\nu^{(i)}}$ (such a bound can be found using the techniques of §3). We can then bound d by looking at p-power forms of the linear systems (5) and (6); in fact, $d\le A(t_1+t_2)^{O((t_1+t_2)n^2)}$. Thus, we can formulate the main result of the paper, which is given in the following theorem.

THEOREM. (a) *One can construct some (t_1,t_2)-sparse representation*

$$\sum_{1\le i\le t_1} a_i X_1^{j_1^{(i)}}\cdots X_n^{j_n^{(i)}} \Big/ \sum_{1\le i\le t_2} b_i X_1^{k_1^{(i)}}\cdots X_n^{k_n^{(i)}}$$

of (t_1,t_2)-sparse rational function f in $\left((t_1+t_2)^{(t_1+t_2)n}\log d\right)^{O(1)}$ arithmetic operations with the depth $((t_1+t_2)n\log d)^{O(1)}$.

(b) *The exponents $j_l^{(i)}, k_l^{(i)}$ do not exceed $d\le M(t_1+t_2)^{O((t_1+t_2)n^2)}$, where M is the bound on bitsizes of all the outputs of applications of a black box during the computation.*

Appendix. For the convenience of the reader, we give a short proof of the result about complex varieties that was needed in the proof of Lemma 11. This result is true for varieties over any algebraically closed field of characteristic 0, but the proof is more complex and depends on the Hilbert Irreducibility Theorem instead of on elementary topological notions.

LEMMA 12. *Let $\mathcal{W}$ be an irreducible constructible set in $\mathbb{C}^n$ (i.e., a constructible set whose Zariski closure is irreducible). Assume that for each $\nu=(\nu_1,\dots,\nu_n)\in\mathcal{W}$ there exist $\gamma_1,\dots,\gamma_n\in\mathbb{Z}$, not all zero, such that $\sum_{i=1}^n\gamma_i\nu_i=0$. Then there exist $\tilde\gamma_1,\dots,\tilde\gamma_n\in\mathbb{Z}$, not all zero, such that $\sum_{i=1}^n\tilde\gamma_i\nu_i=0$ for all $(\nu_i,\dots,\nu_n)\in\mathcal{W}$.*

Proof. If $\mathcal{W}$ has dimension 0, then it is a point and we are done. Therefore, assume $\dim\mathcal{W}>0$ and let $\overline{\mathcal{W}}$ be its Zariski closure. Since $\mathcal{W}$ is constructible, it can be written as a finite union of sets $\mathcal{W}_i$, each of which is Zariski open in its Zariski closure $\overline{\mathcal{W}_i}$. Since $\mathcal{W}$ is irreducible, we must have that for some i, $\overline{\mathcal{W}}=\overline{\mathcal{W}_i}$. Therefore $\mathcal{W}$ contains a set $\mathcal{D}$ that is Zariski open in $\overline{\mathcal{W}}$. Since the nonsingular points of $\overline{\mathcal{W}}$ are Zariski dense, there exists a point $\nu\in\mathcal{W}$ that is nonsingular in $\overline{\mathcal{W}}$ (i.e., a point where the Jacobian of a suitable system of defining equations has maximal rank). We select a sufficiently small ε such that $\mathcal{W}_\varepsilon=\mathcal{W}\cap\{\mathbf{x}\mid\|\mathbf{x}-\nu\|\le\varepsilon\}$ will be closed in the usual topology and contain an open subset of $\mathcal{W}$. For each $(\gamma_1,\dots,\gamma_n)\in\mathbb{Z}^n$, not all γ_i zero, let $H_{\gamma_1,\dots,\gamma_n}=\{(\nu_1,\dots,\nu_n)\in\mathcal{W}\mid\sum_{i=1}^n\gamma_i\nu_i=0\}$. Since $\mathcal{W}_\varepsilon$ is closed, the Baire Category Theorem ([24, p. 139]) implies that for some $(\tilde\gamma_1,\dots,\tilde\gamma_n)$, $H_{\tilde\gamma_1,\dots,\tilde\gamma_n}$ contains an open subset of $\mathcal{W}_\varepsilon$ (and so, of $\mathcal{W}$). Therefore, $\dim(H_{\tilde\gamma_1,\dots,\tilde\gamma_n}\cap\overline{\mathcal{W}})=\dim\overline{\mathcal{W}}$. Since $\overline{\mathcal{W}}$ is irreducible, we must have $\dim(H_{\tilde\gamma_1,\dots,\tilde\gamma_n}\cap\overline{\mathcal{W}})=\overline{\mathcal{W}}$ (cf. [26, p. 54]) so $\overline{\mathcal{W}}\subseteq H_{\tilde\gamma_1,\dots,\tilde\gamma_n}$.

Acknowledgment. We are indebted to Volker Strassen for motivating the problem and a number of stimulating discussions.

TIGHT UPPER AND LOWER BOUNDS ON THE PATH LENGTH OF BINARY TREES*

ALFREDO DE SANTIS† AND GIUSEPPE PERSIANO‡

Abstract. The *external path length* of a tree T is the sum of the lengths of the paths from the root to each external node. The *maximal path length difference*, Δ, is the difference between the lengths of the longest and shortest such paths.

Tight lower and upper bounds are proved on the external path length of binary trees with N external nodes and maximal path length difference Δ is prescribed.

In particular, an upper bound is given that, for each value of Δ, can be exactly achieved for infinitely many values of N. This improves on the previously known upper bound that could only be achieved up to a factor proportional to N. An elementary proof of the known upper bound is also presented as a preliminary result.

Moreover, a lower bound is proved that can be exactly achieved for each value of N and $\Delta \leq N/2$.

Key words. binary search trees, path length

AMS subject classifications. 68P05, 68P10

1. Introduction. Binary trees constitute the most important and widely used data structure for the storage and retrieval of information. The cost of accessing information stored in a node is proportional to the distance of the node from the root. An important measure of efficiency, often considered with respect to a binary tree T, is its *external path length* $\text{EXTERNAL}(T)$, which is the sum of the distances of the external nodes from the root as this is related to the average cost of an unsuccessful search in the tree T. Moreover, the external path length of T is related to the internal path length $\text{INTERNAL}(T)$, which is the sum of the distances of the internal nodes from the root and corresponds to the average cost of a successful search in the tree T.

It is well known that the external path length of a binary tree with N external nodes is $\Theta(N \lg N)$ in the best case but can be as bad as $\Theta(N^2)$ in the worst case. The large gap between the best and the worst cases motivates the study of this important quantity when some additional information about the tree is available. Nievergelt and Wong [7] proposed an upper bound for the external path length of a tree T in terms of the number of external nodes and the maximum weight balance of all its subtrees. More recently, Klein and Wood [5] obtained an upper bound that requires much less information about the tree. Namely, they derived an upper bound on the external path length of a T in terms of N, the number of external nodes, and Δ, the maximum of the differences of the lengths of the paths from the root to each external node. In the case $\Delta \leq \sqrt{N}$, they also constructed trees whose external path length is within $O(N)$ from their upper bound.

In this paper we continue and extend the work of [5]. We present an upper bound on the external path length of binary trees with N nodes and maximum path length difference Δ and construct an infinite class of trees whose external path length matches our bound exactly. Moreover, we present a lower bound on the external path length of these trees. For the case $\Delta \leq N/2$, there exist trees whose external path length matches exactly our bound.

1.1. Organization of the paper and summary of the results. In this paper we study the path length of (N, Δ)-trees, which are extended binary trees with N external nodes and maximum path difference Δ.

In §2 we set up our notation and recall some elementary facts about binary trees.

In §3, we present our upper bounds. As a preliminary result, in §3.1 we give a simple derivation of the upper bound presented in [5]. In §3.2 we improve on this result by giving a better bound that, for *each* Δ, can be exactly achieved for infinitely many N.

In §4 we present our lower bound. We exactly compute, for each N and $\Delta \leq N/2$, the external path length of the tree with shortest external path length. Our lower bound is the first lower bound to improve on the banal lower bound obtained by considering the binary tree with external nodes on two consecutive levels, which has the shortest external path length among the trees with the same number of external nodes.

2. Background and notation.

2. Background and notation. In this section we set up our notation and recall some elementary facts about binary trees.

We denote the set of the natural numbers by $\mathcal{N}$, the set of the positive natural numbers by $\mathcal{N}^+$, and the set of the positive real numbers by $\mathcal{R}^+$. The writing $\lceil x \rceil$ denotes the least integer greater than or equal to x. Throughout this paper, the writing $\lg x$ denotes the logarithm to base 2 of x.

All the trees considered in this paper are *extended binary trees*. An *extended binary tree* is obtained from a binary tree by adding special nodes, the *external nodes*, so that every node in the binary tree has exactly two children. The originary nodes of the binary tree are also called internal nodes.

We say that an external node e is at level l of a tree T if the length of the (unique) path from the root to e is l. Let T have N external nodes at levels $l_1, \ldots, l_N$. Then, the *external path length* of T, $\textsc{External}(T)$, is defined as

$$\textsc{External}(T) = \sum_{i=1}^{N} l_i.$$

The internal path length of a tree $\textsc{Internal}(T)$ is defined as the sum of the levels of the *internal* nodes.

The *maximum path length difference* of T, $\textsc{Fringe}(T)$, is defined as

$$\textsc{Fringe}(T) = \max_{1 \leq i \leq N} l_i - \min_{1 \leq j \leq N} l_j.$$

Also, a level l (other than the last one) is said to be *dense* if it has more than one external node, while the last level is dense if it has more than two external nodes. An (N, Δ)-tree is a binary tree with N external nodes and maximum path length difference Δ.

For $2 \leq \Delta \leq N - 2$ define $epl(N, \Delta)$ and $\textsc{Epl}(N, \Delta)$ as

$$epl(N, \Delta) = \min_{T \text{ is a } (N, \Delta)\text{-tree}} \textsc{External}(T)$$

and

$$\textsc{Epl}(N, \Delta) = \max_{T \text{ is a } (N, \Delta)\text{-tree}} \textsc{External}(T).$$

In this paper we give bounds on $epl(N, \Delta)$ and $\textsc{Epl}(N, \Delta)$. We restrict our attention to the cases when $2 \leq \Delta \leq N - 2$ since if $\Delta > N - 2$ then there exists no (N, Δ)-tree and the cases $\Delta = 0, 1$ can be completely characterized (see §4).

The following is a simple and well-known result about extended binary trees (see, e.g., [4]) that will be extensively used in the sequel.

FACT 2.1 (Kraft equality). *Let $l_1, \dots, l_N$ be a sequence of positive integers. Then there exists an extended binary tree with N external nodes at levels $l_1, \dots, l_N$ if and only if $\sum_{i=1}^{N} 2^{-l_i} = 1$.*

We shall say that a (N, Δ)-tree T has *configuration* $(L; a_0, a_1, \dots, a_{\Delta})$ if

1. $a_0, a_\Delta \geq 1$;
2. T has a_i external nodes at level $L + i, 0 \leq i \leq \Delta$; and
3. $\sum_{i=0}^{\Delta} a_i = N$.

Two (N, Δ)-trees with the same configuration are said *isomorphic*, as for our purposes they are the "same" tree. In what follows, we will omit L from a configuration when it is either clear from the context or immaterial.

3. Upper bounds.

In this section we present upper bounds on $\text{EPL}(N, \Delta)$. The problem of computing $\text{EPL}(N, \Delta)$ can be stated as follows:

Find the maximum of $\sum_{i=1}^{N} l_i$ subject to

1. $l_i \in \mathcal{N}^+$ for $i = 1, \dots, N$;
2. $\sum_{i=1}^{N} 2^{-l_i} = 1$; and
3. $\max_i l_i - \min_j l_j = \Delta$.

Because of the constraints $l_i \in \mathcal{N}^+$, finding the exact maximum does not appear to be an easy task.

3.1. A simple proof of a known upper bound.

Recently, Klein and Wood [5] proved the following upper bound on $\text{EPL}(N, \Delta)$.

BOUND 1.

$$\text{EPL}(N, \Delta) \leq N(\lg N + \Delta - \lg \Delta - \Psi(\Delta))$$

where

$$\Psi(\Delta) = \lg e - \lg \lg e - \frac{\Delta}{2^{\Delta} - 1} - \lg\left(1 - \frac{1}{2^{\Delta}}\right) \geq 0.6622,$$

and e is the base of the natural logarithm.

In [5], the bound above is derived by first proving that the external path length is related to the ratio of the geometric and the harmonic means of certain integers and then applying a theorem by Specht [8]. In this section, we re-derive Bound 1 using only elementary calculus.

We obtain an upper bound on $\text{EPL}(N, \Delta)$ by allowing the l_i's to range over the real numbers.

To this end, for $2 \leq \Delta \leq N - 2$, we define $M(N, \Delta, x)$ as the maximum of $\sum_{i=1}^{N} l_i$ over the sequences $l_1, \dots, l_N$ satisfying the following constraints

1. $l_i \in \mathcal{R}^+$, for $i = 1, 2, \dots, N$;
2. $\sum_{i=1}^{N} 2^{-l_i} = 1$; and
3. $x \leq l_i \leq x + \Delta$, for $i = 1, 2, \dots, N$.

A triplet (N, Δ, x) for which there exists a sequence $l_1, \dots, l_{N}$ that satisfies the three constraints above is called *admissible*.

It is clear that an upper bound on the external path length of binary trees is given by

$$\text{EPL}(N, \Delta) \leq \max\{M(N, \Delta, x) | (N, \Delta, x) \text{ is admissible and } x \in \mathcal{R}^+\}. \tag{1}$$

The following lemma gives a useful characterization of the maximum $M(N, \Delta, x)$.

LEMMA 3.1. *Let (N, Δ, x) be an admissible triplet. The maximum $M(N, \Delta, x)$ is achieved by a sequence $l_1, l_2, \ldots, l_n$ where all the l_i's, but at most one, are equal either to x or $x + \Delta$.*

Proof. Assume, by way of contradiction, that the maximum is reached by $l'_1, l'_2, \ldots, l'_N$ such that $x < l'_1 \le l'_2 < x + \Delta$. Fix $\epsilon > 0$, and define the sequence $l''_1, l''_2, \ldots, l''_N$ as

$$l''_i = \begin{cases} l'_1 - \delta & \text{if } i = 1, \\ l'_2 + \epsilon & \text{if } i = 2, \\ l'_i & \text{otherwise,} \end{cases}$$

where δ is chosen so that the Kraft equality holds; that is, $2^{-l''_1} + 2^{-l''_2} = 2^{-l'_1} + 2^{-l'_2}$ and thus $\delta = \lg(1 + 2^{l'_1 - l'_2}(1 - 2^{-\epsilon}))$. Notice that for sufficiently small values of ϵ (i.e., $\epsilon < \min\{x + \Delta - l'_2, l'_1 - x\}$), l''_1 and l''_2 are both in $[x, x + \Delta]$. Since the function $x - \lg(1 + 2^{l'_2 - l'_1}(1 - 2^{-x}))$ is increasing in x and is equal to 0 for $x = 0$, it is positive for $x > 0$, and thus $\epsilon > \delta$ holds. Therefore, if $\epsilon < \min\{x + \Delta - l'_2, l'_1 - x\}$, the sequence $l''_1, \ldots, l''_N$ satisfies the three constraints in the definition of $M(N, \Delta, x)$ and $\sum_{i=1}^{N} l''_i > \sum_{i=1}^{N} l'_i$, contradicting the maximality of $l'_1, \ldots, l'_N$. □

The following lemma provides an upper bound on the maximum $M(N, \Delta, x)$.

LEMMA 3.2. *Let (N, Δ, x) be an admissible triplet. Then*

$$M(N, \Delta, x) \le Nx + \Delta \frac{N - 2^x}{1 - 2^{-\Delta}}.$$

Proof. By Lemma 3.1, the maximum is achieved when $l_1 = \cdots = l_m = x + \Delta$, $l_{m+1} = x + y$ and $l_{m+2} = \cdots = l_N = x$, for some $1 \le m \le N$ and $0 \le y < \Delta$. By the Kraft equality, we get

$$\frac{m}{2^{x+\Delta}} + \frac{1}{2^{x+y}} + \frac{N - m - 1}{2^x} = 1,$$

from which we see that m is uniquely specified by N, Δ, y, and x. The maximum $M(N, \Delta, x)$ is thus given by

$$\begin{aligned} M(N, \Delta, x) &= n = m(x + \Delta) + (x + y) + (N - m - 1)x \\ &= m\Delta + Nx + y \\ &= Nx + \Delta \frac{N - 2^x}{1 - 2^{-\Delta}} + y - \Delta \frac{1 - 2^{-y}}{1 - 2^{-\Delta}}. \end{aligned}$$

The function $f(y) = y - \Delta(1 - 2^{-y})/(1 - 2^{-\Delta})$ is a convex function of y with $f(0) = 0$ and $f(\Delta) = 0$. Thus $f(y) \le 0$ for $0 \le y \le \Delta$. Hence the lemma is proved. □

We are now ready to prove Bound 1.

THEOREM 3.3.

$$\mathrm{EPL}(N, \Delta) \le N(\lg N + \Delta - \lg \Delta - \Psi(\Delta))$$

where

$$\Psi(\Delta) = \lg e - \lg \lg e - \frac{\Delta}{2^\Delta - 1} - \lg\left(1 - \frac{1}{2^\Delta}\right),$$

and e is the base of the natural logarithm.

Proof. Combining Lemma 3.2 and (1) we get

$$EPL(N, \Delta) \le \max_{x \in \mathcal{R}^+} \left\{ Nx + \Delta \frac{N - 2^x}{1 - 2^{-\Delta}} \right\}. \tag{2}$$

The function to maximize is a concave function of x. It can easily be seen, using elementary calculus, that it reaches its maximum (for fixed values of N and Δ) at $x_{\max} = \lg N + \lg(1 - 2^{-\Delta}) + \lg\lg e - \lg \Delta$. Substituting this into (2) we get Bound 1. □

3.2. An improved upper bound achievable by infinitely many values. In the previous section all maximizations were carried over the real numbers. Now, we show that by restricting x to be an integer we get a better bound. The bound presented in this section improves on Bound 1 on two accounts: first, it is more accurate; second, for *each* value of Δ, it can be exactly achieved for infinitely many values of N.

BOUND 2. Let $L = \lceil \lg(N(1 - 2^{-\Delta})/\Delta) \rceil$. Then

$$\text{EPL}(N, \Delta) \leq NL + \Delta \frac{N - 2^L}{1 - 2^{-\Delta}}.$$

Moreover, for each Δ there exists an infinite subset $\mathcal{N}_\Delta \subseteq \mathcal{N}$ such that for each $N \in \mathcal{N}_\Delta$ there exists a (N, Δ)-tree $T_{(N,\Delta)}$ with

$$\text{EXTERNAL}(T_{(N,\Delta)}) = NL + \Delta \frac{N - 2^L}{1 - 2^{-\Delta}}.$$

Proof. From the analysis in §3.1, it is clear that an upper bound on the external path length of binary trees is given by

$$\text{EPL}(N, \Delta) \leq \max_{x \in \mathcal{N}^+} M(N, \Delta, x).$$

From Lemma 3.2 we get

$$\text{EPL}(N, \Delta) \leq \max_{x \in \mathcal{N}^+} \Phi_{N,\Delta}(x)$$

where

$$\Phi_{N,\Delta}(x) = Nx + \Delta \frac{N - 2^x}{1 - 2^{-\Delta}}.$$

Let $\overline{x} \in \mathcal{N}^+$ be an integer at which $\Phi_{N,\Delta}(x)$ is maximum; i.e,

$$\Phi_{N,\Delta}(\overline{x}) = \max_{x \in \mathcal{N}^+} \Phi_{N,\Delta}(x). \tag{3}$$

As $\Phi_{N,\Delta}(x)$ is a concave function of x, any integer $\overline{x}$ such that

$$\Phi_{N,\Delta}(\overline{x}) \geq \max\left\{\Phi_{N,\Delta}(\overline{x} + 1), \Phi_{N,\Delta}(\overline{x} - 1)\right\}$$

satisfies (3). From the definition of $\Phi_{N,\Delta}(x)$, we obtain that any $\overline{x}$ such that

$$N \frac{1 - 2^{-\Delta}}{\Delta} \leq 2^{\overline{x}} \leq 2N \frac{1 - 2^{-\Delta}}{\Delta}$$

satisfies (3). However, $N(1 - 2^{-\Delta})/\Delta$ is not an integer power of 2; if it were equal to 2^z, for some $z \in \mathcal{N}^+$, then $2^\Delta - 1$ would be a factor of $\Delta 2^{z-\Delta}$, thus of Δ, which is impossible. Hence, the above inequalities uniquely determine $\overline{x}$ as $\overline{x} = \lceil \lg(N(1 - 2^{-\Delta})/\Delta) \rceil$, proving the bound.

Now, we prove that the bound is achievable. Let Δ and x be positive integers such that $2 \leq \Delta \leq x$. Set

$$h_{\Delta,x}(y) = \lg\left(\frac{1-2^{-\Delta}}{\Delta}(2^x + y(2^\Delta - 1))\right).$$

The function $h_{\Delta,x}$ enjoys the following three properties.

(a) $h_{\Delta,x}(1) < x$. Indeed, this inequality is equivalent to

$$2^x > (2^\Delta - 1)^2/(2^\Delta(\Delta - 1) + 1)$$

that is satisfied for $x \geq \Delta$.

(b) $h_{\Delta,x}(2^x - 1) > x$. Indeed, this can be written as

$$2^x > (2^\Delta - 1)^2/(2^\Delta(2^\Delta - 1 - \Delta))$$

that is satisfied for $x \geq \Delta \geq 2$.

(c) $h_{\Delta,x}(y+1) < h_{\Delta,x}(y) + 1$, for $y = 1, 2, \ldots, 2^x - 1$. Indeed, simple algebra shows that it is equivalent to $y > 1 - 2^x/(2^\Delta - 1)$, which holds for $y \geq 1$.

Because of the above three properties, for each $\Delta \geq 2$ and $x \geq \Delta$, there exists some $y_{\Delta,x} \in \{1, 2, \ldots, 2^x - 1\}$ such that $h_{\Delta,x}(y_{\Delta,x}) < x < h_{\Delta,x}(y_{\Delta,x}) + 1$. (Actually, there can be several such $y_{\Delta,x}$'s; for instance, if $\Delta = 5$ and $x = 10$, all integers $s \in [53, 137]$ satisfy $h_{5,10}(s) < 10 < h_{5,10}(s) + 1$.)

For each $\Delta \geq 2$, consider the infinite set $\mathcal{N}_\Delta = \{N : \exists L \geq \Delta \text{ s.t. } N = 2^L + (2^\Delta - 1)y_{\Delta,L}\}$. Fix Δ and $N \in \mathcal{N}_\Delta$, and consider the (N, Δ)-tree T with $2^L - y_{\Delta,L}$ external nodes at level L and $y_{\Delta,L}2^\Delta$ at level $L + \Delta$, where L is such that $N = 2^L + (2^\Delta - 1)y_{\Delta,L}$. First of all, such a tree exists. In fact, as $y_{\Delta,L} \leq 2^L - 1$, it follows $2^L - y_{\Delta,L} > 0$ and the Kraft equality is satisfied. From the definition of $y_{\Delta,L}$ we obtain

$$h_{\Delta,L}(y_{\Delta,L}) \leq L \leq h_{\Delta,L}(y_{\Delta,L}) + 1,$$

and by the definition of the function $h_{\Delta,L}$

$$\lg\left(N\frac{1-2^{-\Delta}}{\Delta}\right) \leq L \leq \lg\left(N\frac{1-2^{-\Delta}}{\Delta}\right) + 1,$$

from which $L = \lceil \lg(N(1-2^{-\Delta})/\Delta) \rceil$ follows.

We now compute $\text{External}(T)$ which turns out to be exactly as in Bound 2. In fact, one has that

$$\begin{aligned}\text{External}(T) &= L(2^L - y_{\Delta,L}) + y_{\Delta,L}2^\Delta(L + \Delta)\\ &= NL + y_{\Delta,L}\Delta 2^\Delta\\ &= NL + \Delta\frac{N - 2^L}{1 - 2^{-\Delta}}.\end{aligned}$$

□

It is clear that Bound 2 is more accurate than Bound 1. In fact, for every $\Delta \geq 2$ and $N \geq \Delta$, (1) is the absolute maximum of the function $\Phi_{N,\Delta}(x) = Nx + \Delta(N - 2^x)/(1 - 2^{-\Delta})$, while (2) is the maximum of the same function subject to the additional constraint $x \in \mathcal{N}^+$.

Example 1. As an example, consider the case $\Delta = 5$. There are binary trees which satisfy Bound 2 with equality for $N = 2^L + 31y$, where $L = 10$ and $y = 53, \ldots, 137$, $L = 11$ and $y = 105, \ldots, 274$, $L = 12$ and $y = 209, \ldots, 549$, $L = 13$ and $y = 418, \ldots, 1099$, and so on for all larger L.

Example 2. By plugging $\Delta = 2$ into Bound 2, we obtain that

$$EPL(N, 2) \leq \left\lfloor (\lceil \lg (3N) \rceil - 3)\, N + \frac{8N - 2^{\lceil \lg(3N) \rceil}}{3} \right\rfloor .$$

Actually, it can be proved that the above bound is tight for all values of N (see [2], [3]).

Example 3. As a simple application of the Bound 2, we derive an upper bound on the internal path length of red-black trees. The class of red-black trees constitutes an important class of balanced binary trees that guarantee a worst-case search cost of $2\log(N + 1)$. The bound we obtain is, up to terms of lower order, equal to the one presented in [1] that was proved to be asymptotically tight.

The bound is obtained by observing that a red-black tree has FRINGE $\leq \log(N + 1)$ and that Bound 2 is increasing in Δ.

BOUND 3. Let T be a red-black tree with N internal nodes. Then

$$\text{INTERNAL}(T) \leq (N + 1)(2\lg(N + 1) - \lg\lg(N + 1) + O(1)).$$

We refer the reader to [3] for a proof of the above bound.

4. Lower bound. In this section we present a lower bound that can be exactly achieved for $N \geq 4$ and $2 \leq \Delta \leq N/2$.

Before dealing with the general case, let us briefly discuss the cases $\Delta = 0$ and $\Delta = 1$ (see [6] for a more complete treatment). The case $\Delta = 0$ is easily settled: a $(N, 0)$-tree exists if and only if N is a power of 2, in which case the N external nodes are located at level $\lg N$ and the tree is unique. On the other hand, a $(N, 1)$-tree exists if and only if N is not a power of 2, in which case it is unique. The external nodes of the *unique* $(N, 1)$-tree are located at levels $\lceil \lg N \rceil - 1$ and $\lceil \lg N \rceil$, and its external path length is $N(\lceil \lg N \rceil + 1) - 2^{\lceil \lg N \rceil}$. The following property of $(N, 1)$-trees can be easily proved using the Kraft equality.

LEMMA 4.1. *If the $(N, 1)$-tree exists and has $c > 0$ external nodes at level $\lceil \lg N \rceil - 1$ then $N + c$ is a power of 2 and, due to $c < N$, none of the integers in $[N, N + c - 1]$ is a power of 2.*

Let us now consider the case $\Delta \leq N/2$ and $N \geq 4$. We start by characterizing the (N, Δ)-trees with minimum external path length. As we will prove in Theorem 4.5, such trees belong to a class of (N, Δ)-trees with a particular structure. Then we compute the external path length of the trees with such a structure and obtain a lower bound by minimizing the so obtained external path lengths.

LEMMA 4.2. *Let T be a (N, Δ)-tree with minimum external path length and configuration $(L; a_0, \ldots, a_\Delta)$. Then*

1. *T has at most two dense levels. Moreover, if T has two dense levels, then these two levels are consecutive.*

2. *If level $L + i$ is dense, for some $1 < i \leq \Delta$, then $a_j = 0$ for all $0 < j < i - 1$.*

Proof. We only prove 1, as the proof of 2 is similar. Assume, by way of contradiction, that T is a tree with two nonconsecutive dense levels and minimum external path length. That is, $a_i, a_k \geq 2$, for $i + 1 < k < \Delta$ (the case in which one of the two dense levels is the last one is similar). Now, consider the tree T' with configuration $(L; a'_0, a'_1, \ldots, a'_\Delta)$ where

$$a'_j = \begin{cases} a_i - 1 & \text{if } j = i, \\ a_j + 3 & \text{if } j = k - 1 = i + 1, \\ a_{i+1} + 2 & \text{if } j = i + 1 \text{ and } j \neq k - 1, \\ a_{k-1} + 1 & \text{if } j = k - 1 \text{ and } j \neq i + 1, \\ a_k - 2 & \text{if } j = k, \\ a_j & \text{otherwise.} \end{cases}$$

T' is still an (N, Δ)-tree and has external path length

$$\text{EXTERNAL}(T') = \text{EXTERNAL}(T) + i + 1 - k < \text{EXTERNAL}(T).$$

Thus T cannot have minimum external path length.

Now, it is immediate that there cannot be more than two intermediate levels with more than one external node even if they are consecutive. In fact, suppose that three levels have more than one external node. Then, obviously, at least two of them must be nonconsecutive. □

Before going any further, let us introduce the following notation. An (N, Δ)-tree of *type* $(L; \geq b_0, a_1, \ldots, a_\Delta)$ has an unspecified, but greater than or equal to b_0, external node at level L; more precisely, it has configuration $(L; a_0, a_1, \ldots, a_\Delta)$ for some $a_0 \geq b_0$. We shall say that an (N, Δ)-tree has type $(L; a_0^{b_0}, a_1^{b_1}, \ldots, a_k^{b_k})$ if it has a_0 external nodes on each of the first b_0 levels, a_1 external nodes on each of the following b_1 levels, and so on; that is, it has configuration

$$(L; \underbrace{a_0, \ldots, a_0}_{b_0 \text{ times}}, \underbrace{a_1, \ldots, a_1}_{b_1 \text{ times}}, \ldots, \underbrace{a_k, \ldots, a_k}_{b_k \text{ times}}).$$

The symbols $\leq a^b$ and $\geq a^b$ denote respectively b levels each of which have no more than a external nodes and no less than a external nodes. As done with the configuration, we will omit L and just say that a tree is of type $(a_0^{b_0}, a_1^{b_1}, \ldots, a_k^{b_k})$ whenever L is either clear from the context or immaterial.

LEMMA 4.3. *Let T be a tree of type $(L; \geq 0^a, \leq 1^b, 2)$. Then if level $L + a'$, with $a' > a$, contains an external node then all levels $L + a' + 1, \ldots, L + a' + b - 1$ contain exactly one external node each; that is, T is of type $(L; \geq 0^{a'-1}, 1^{a+b-a'+1}, 2)$.*

Proof. Consider the grandparent e of the two external nodes at level $L + a + b$. This node has two children, one of which is the internal node which is the parent of the two external nodes at level $L + a + b$. Now, the other child of e cannot be an internal node as this would imply either that level $L + a + b$ has more than two external nodes or that some successive level has some external nodes. Thus, level $L + a + b - 1$ has exactly one external node. We can prove by induction that this is the case also for levels $L + a + b - 2, \ldots, L + a' + 1$, thus proving the lemma. □

We are now ready to characterize completely the configuration of (N, Δ)-trees with minimum external path length. In fact, in Theorem 4.5 we will prove that such a tree must be an (N, Δ, a)-tree defined as follows.

DEFINITION 4.4. For $N \geq 4$, $2 \leq \Delta \leq N - 2$, and $-1 \leq a \leq \min\{\Delta - 2, \lg N - 1\}$ we define an (N, Δ, a)-tree as follows.

1. An $(N, \Delta, -1)$-tree is an (N, Δ)-tree of type $(\geq 1, \geq 0, 1^{\Delta-2}, 2)$.

2. Let $0 \leq a \leq \min\{\Delta - 3, \log N - 2\}$. An (N, Δ, a)-tree is an (N, Δ)-tree of type $(1, 0^a, \geq 0, \geq 0, 1^{\Delta-(a+3)}, 2)$.

3. If $\Delta - 2 \leq \log N - 1$, an $(N, \Delta, \Delta - 2)$-tree is an (N, Δ)-tree of type $(1, 0^{\Delta-2}, \geq 0, \geq 2)$.

Remark. Notice that in the above definition we have not considered the case $a > \log N - 1$. In fact, a tree of type $(L; 1, 0^a, \geq 0, \geq 0, 1^{\Delta-(a+3)}, 2)$ contains at least $2^{L+a+1} - 2^{a+1}$ external nodes. But $L \geq 1$, and thus $2^{a+1} \leq N$, from which $a \leq \lg N - 1$.

Also notice that using the Kraft equality it is easy to see that the (N, Δ, a)-tree, if it exists, is unique. See also the discussion following Lemma 4.6.

THEOREM 4.5. *For $N \geq 4$, $2 \leq \Delta \leq N - 2$, if T is an (N, Δ)-tree with minimum external path length then T is an (N, Δ, a)-tree for some a, $-1 \leq a \leq \min\{\Delta - 2, \lg N - 1\}$.*

Proof. In view of Lemma 4.2, an (N, Δ)-tree with minimum external path length has at most two dense levels and the levels preceding the dense levels (except for the very first one) are all empty.

We consider first the case in which there are two dense levels. If the dense levels are the first two levels, then, because of Lemma 4.3, the tree is of type $(\geq 2, \geq 2, 1^{\Delta-2}, 2)$ and thus is an $(N, \Delta, -1)$-tree. Instead, if the last two levels are dense, then the tree is of type $(1, 0^{\Delta-2}, \geq 2, > 2)$ and is thus an $(N, \Delta, \Delta - 2)$-tree. Finally, if the two dense levels are intermediate then, because of Lemma 4.3, the tree is of type $(1, 0^a, \geq 2, \geq 2, 1^{\Delta-(a+3)}, 2)$, for some a, and thus is an (N, Δ, a)-tree.

Consider now the case in which there exists only one single dense level. Then, if this level is the first, the tree is an $(N, \Delta, -1)$-tree; if it is the last level then the tree is an $(N, \Delta, \Delta - 2)$-tree; otherwise the tree is an (N, Δ, a)-tree for some $0 \leq a \leq \min\{\Delta - 3, \lg N - 2\}$. □

LEMMA 4.6. (a) *For* $0 \leq a \leq \Delta - 3$, *the* $(X, 1)$*-tree* U *with configuration* $(L; a_0, a_1)$, *where* $a_0 \geq 2^{a+1}$, *exists if and only if there exists an* $(X - 2^{a+1} + \Delta - a - 1, \Delta)$*-tree* T *with configuration* $(L - (a + 1); 1, 0^a, a_0 - 2^{a+1}, a_1 - 1, 1^{\Delta-(a+3)}, 2)$.

(b) *The* $(X, 1)$*-tree* U *with configuration* $(L; a_0, a_1)$ *exists if and only if there exists an* $(X + \Delta - 1, \Delta)$*-tree* T *with configuration* $(L; a_0, a_1 - 1, 1^{\Delta-2}, 2)$.

(c) *The* $(X, 1)$*-tree* U *with configuration* $(L; a_0, a_1)$, *where* $a_0 \geq 2^{\Delta-1}$, *exists if and only if there exists an* $(X - 2^{\Delta-1} + 1, \Delta)$*-tree* T *with configuration* $(L - (\Delta - 1); 1, 0^{\Delta-2}, a_0 - 2^{\Delta-1}, a_1)$.

Proof. We prove only part (a) of the lemma, the proofs of parts (b) and (c) being very similar.

For brevity, we denote the configuration of T by $(L - (a + 1); c_0, c_1, \ldots, c_\Delta)$ and $\Delta - a - 2$ by b. First, all the c_i are nonnegative integers if and only if $a_0 \geq 2^{a+1}$. Moreover,

$$\begin{aligned}\sum_{i=0}^{\Delta} \frac{c_i}{2^{L-(a+1)+i}} &= \frac{1}{2^{L-(a+1)}} + \frac{a_0 - 2^{a+1}}{2^L} + \frac{a_1 - 1}{2^{L+1}} + \sum_{i=2}^{b} \frac{1}{2^{L+i}} + \frac{2}{2^{L+b+1}} \\ &= \frac{a_0}{2^L} + \frac{a_1}{2^{L+1}} - \frac{1}{2^{L+1}} + \frac{1}{2^L}\left(\frac{1}{2} - \frac{1}{2^b}\right) + \frac{2}{2^{L+b+1}} \\ &= \frac{a_0}{2^L} + \frac{a_1}{2^{L+1}}.\end{aligned}$$

By using the Kraft equality, the existence of one of the two trees implies that both sums are equal to 1 and thus both trees exist. □

The above lemma implies that, for fixed N, Δ, and a, there exists a unique (N, Δ, a)-tree. In fact, for each a, Lemma 4.6 naturally defines an invertible mapping on trees with $\Delta = 1$ to trees with greater Δ. Therefore, if for some N, Δ, and a there are two (nonisomorphic) (N, Δ, a)-trees, then by inverting the mapping we would construct two (nonisomorphic) trees with $\Delta = 1$ and the same number of external nodes, which is not possible.

The next lemma gives necessary and sufficient conditions for the existence of the (N, Δ, a)-tree and computes its external path length. To this aim, we define the function $F(a, N, \Delta)$ as follows:

$$\begin{aligned}F(a, N, \Delta) = N\Big(\lceil \lg X(a, N, \Delta) \rceil + 1\Big) - 2^{\lceil \lg X(a,N,\Delta) \rceil} + 2^{a+2} + \frac{a(a+1)}{2} \\ + \frac{\Delta(\Delta - 3)}{2} - a\Delta - 2,\end{aligned}$$

where

$$X(a, N, \Delta) = N - \Delta + 2^{a+1} + a + 1.$$

LEMMA 4.7. *For $N \geq 4$, $2 \leq \Delta \leq N - 2$, and $-1 \leq a \leq \min\{\Delta - 2, \log N - 1\}$, the (N, Δ, a)-tree exists if and only if the interval $[X(a, N, \Delta), X(a, N, \Delta) + 2^{a+1} - 1]$ does not contain any power of 2, in which case its external path length is $F(a, N, \Delta)$.*

Proof. We will prove the lemma for $0 \leq a \leq \min\{\Delta - 3, \log N - 1\}$. The cases $a = -1$ and $\Delta - 2 < \log N - 1$ can be proved in a similar way.

Suppose that the interval $[X(a, N, \Delta), X(a, N, \Delta) + 2^{a+1} - 1]$ does not contain any power of 2. Then, by Lemma 4.1 and since $N = X(a, N, \Delta) - 2^{a+1} + \Delta - a - 1$, the unique $(X(a, N, \Delta), 1)$-tree has at least 2^{a+1} external nodes on its first level. Therefore, the hypothesis of part (a) of Lemma 4.6 holds and, thus, the (N, Δ, a)-tree exists. The other implication is proved in a similar way.

To compute the external path length of the (N, Δ, a)-tree, we use Lemma 4.6. The configuration of the (N, Δ, a)-tree, and thus its external path length, is completely determined by the configuration of the corresponding $(X, 1)$-tree. It can be expressed as a function of L, a_0, and a_1, which, in turn, depend only on the value X. We can thus compute the external path length of the (N, Δ, a)-tree, that a tedious computation shows to be exactly $F(a, N, \Delta)$. □

We next study the behavior of the external path length of the (N, Δ, a)-tree, for fixed N and Δ. We will see that the external path length of the (N, Δ, a)-tree is a bitonic function of a; that is, it is nonincreasing up to a certain value $\alpha(\Delta)$ of a and then it is nondecreasing. $\alpha(\Delta)$ is the integer part of the unique solution to the equation $x + 2^{x+1} = \Delta$, $x \in \mathcal{R}$. It is easily seen that $\alpha(\Delta)$ is equal to either $\lfloor \lg \Delta \rfloor - 2$ or $\lfloor \lg \Delta \rfloor - 1$.

LEMMA 4.8. *Let $N \geq 4$, $2 \leq \Delta \leq N - 2$, and $0 \leq a \leq \min\{\Delta - 2, \lg N - 1\}$. If the $(N, \Delta, a - 1)$-tree exists then*

$$F(a, N, \Delta) \begin{cases} \leq F(a - 1, N, \Delta) & \text{if } a \leq \alpha(\Delta), \\ \geq F(a - 1, N, \Delta) & \text{if } a > \alpha(\Delta). \end{cases}$$

Proof. The difference $F(a - 1, N, \Delta) - F(a, N, \Delta)$ is equal to

$$N\Big(\lceil \lg X(a - 1, N, \Delta) \rceil - \lceil \lg X(a, N, \Delta) \rceil\Big) + 2^{\lceil \lg X(a, N, \Delta) \rceil} - 2^{\lceil \lg X(a-1, N, \Delta) \rceil}$$
$$+ \Delta - 2^{a+1} - a.$$

By hypothesis the $(N, \Delta, a - 1)$-tree exists. Therefore, by Lemma 4.7, the interval

$$[X(a - 1, N, \Delta), X(a - 1, N, \Delta) + 2^a - 1]$$

does not contain any power of 2.

If $X(a - 1, N, \Delta) + 2^a$ is a power of 2 then

$$\lceil \lg X(a - 1, N, \Delta) \rceil = \lg(X(a - 1, N, \Delta) + 2^a)$$

and

$$\begin{aligned} \lceil \lg X(a, N, \Delta) \rceil &= \left\lceil \lg\left(X(a - 1, N, \Delta) + 2^a + 1\right) \right\rceil \\ &\qquad \text{(from the definition of } X(a - 1, N, \Delta)) \\ &= \lg(X(a - 1, N, \Delta) + 2^a) + 1. \end{aligned}$$

Therefore,

$$F(a - 1, N, \Delta) - F(a, N, \Delta) = -N + X(a - 1, N, \Delta) + 2^a + \Delta - 2^{a+1} - a = 0,$$

and the lemma is proved.

Let us consider now the case when $X(a-1, N, \Delta) + 2^a$ is not a power of 2. In this case we have

$$\begin{aligned}\lceil \lg X(a, N, \Delta)\rceil &= \left\lceil \lg\left(X(a-1, N, \Delta) + 2^a + 1\right)\right\rceil \\ &= \lceil \lg (X(a-1, N, \Delta))\rceil \\ &\qquad \text{(as the interval } [X(a-1, N, \Delta), X(a-1, N, \Delta) + 2^a] \\ &\qquad \text{does not contain any power of 2.)}\end{aligned}$$

Therefore,

$$F(a-1, N, \Delta) - F(a, N, \Delta) = \Delta - (a + 2^{a+1}).$$

Now, if $a \leq \alpha(\Delta)$ then $a + 2^{a+1} \leq \Delta$ and $F(a, N, \Delta) \leq F(a-1, N, \Delta)$. On the other hand, if $a > \alpha(\Delta)$ then $a + 2^{a+1} > \Delta$ and $F(a, N, \Delta) > F(a-1, N, \Delta)$. □

LEMMA 4.9. *Let $N \geq 4$, $2 \leq \Delta \leq N-2$, and $1 \leq a \leq \min\{\Delta - 2, \lg N - 1\}$. If the $(N, \Delta, a-1)$-tree does not exist and the (N, Δ, a)-tree and the $(N, \Delta, a-2)$-tree exist, then*

$$F(a, N, \Delta)\begin{cases} \leq F(a-2, N, \Delta) & \text{if } a \leq \alpha(\Delta), \\ \geq F(a-2, N, \Delta) & \text{if } a > \alpha(\Delta).\end{cases}$$

Proof. The proof of this lemma is very similar to that of the previous lemma and is omitted. We refer the reader to [3] for a complete proof. □

LEMMA 4.10. *Let $N \geq 4$, $\Delta \leq N/2$, and $\alpha = \alpha(\Delta)$. If the (N, Δ, α)-tree does not exist, then both the $(N, \Delta, \alpha - 1)$-tree and the $(N, \Delta, \alpha + 1)$-tree exist.*

Proof. As the (N, Δ, α)-tree does not exist, then, by Lemma 4.7, the interval

$$[X(\alpha, N, \Delta), X(\alpha, N, \Delta) + 2^{\alpha+1} - 1]$$

contains a power of 2 and the previous power of 2 is in the interval

$$\left[\frac{X(\alpha, N, \Delta)}{2}, \frac{X(\alpha, N, \Delta) + 2^{\alpha+1} - 1}{2}\right].$$

The interval

$$[X(\alpha - 1, N, \Delta), X(\alpha - 1, N, \Delta) + 2^{\alpha} - 1]$$

does not contain any power of 2, and thus the $(N, \Delta, \alpha - 1)$-tree exists, since $X(\alpha - 1, N, \Delta) + 2^{\alpha} - 1 < X(\alpha, N, \Delta)$ and

$$X(\alpha - 1, N, \Delta) > \frac{X(\alpha, N, \Delta) + 2^{\alpha+1} - 1}{2}.$$

The first inequality follows from the definition of $X(a, N, \Delta)$, while the second is equivalent to $N - \Delta > 2^{\alpha+1} - \alpha$. As $\Delta \leq N/2$ and $\alpha \leq \log \Delta - 1$, the above inequality holds, thus proving that the $(N, \Delta, \alpha - 1)$-tree exists.

The existence of the $(N, \Delta, \alpha + 1)$-tree is established in a similar way. □

We can summarize the above lemmata by saying that if the (N, Δ, α)-tree exists, that is, if the interval $[X(\alpha, N, \Delta), X(\alpha, N, \Delta) + 2^{\alpha+1} - 1]$ does not contain any power of 2, then *epl*$(N, \Delta) = F(\alpha, \Delta, N)$. When the (N, Δ, α)-tree does not exist, then, by Lemma 4.10, both the $(N, \Delta, \alpha - 1)$-tree and the $(N, \Delta, \alpha + 1)$-tree exist and the minimum path length is obtained by either one.

We have thus proved the following:

BOUND 4. For all $N \geq 4$ and $\Delta \leq N/2$,

$$epl(N, \Delta) = \begin{cases} F(\alpha, \Delta, N) & \text{if } [X(\alpha, N, \Delta), X(\alpha, N, \Delta) + 2^{\alpha+1} - 1] \\ & \quad \text{does not contain any power of 2,} \\ F(\alpha + 1, \Delta, N) & \text{if } F(\alpha + 1, \Delta, N) \leq F(\alpha - 1, \Delta, N), \\ F(\alpha - 1, \Delta, N) & \text{otherwise,} \end{cases}$$

where α is the integer part of the (unique) solution of the equation $x + 2^{x+1} = \Delta$,

$$X(a, N, \Delta) = N - \Delta + 2^{a+1} + a + 1,$$

and

$$F(a, N, \Delta) = N\Big(\lceil \lg X(a, N, \Delta) \rceil + 1\Big) - 2^{\lceil \lg X(a,N,\Delta) \rceil} + 2^{a+2}$$
$$+ \frac{a(a+1)}{2} + \frac{\Delta(\Delta - 3)}{2} - a\Delta - 2.$$

UNIQUE BINARY-SEARCH-TREE REPRESENTATIONS AND EQUALITY TESTING OF SETS AND SEQUENCES*

RAJAMANI SUNDAR[†] AND ROBERT E. TARJAN[‡]

Abstract. This paper studies the problem of representing sets over an ordered universe by unique binary search trees, so that dictionary operations can be performed efficiently on any set. Although efficient randomized solutions to the problem are known, its deterministic complexity has been open. The paper exhibits representations that permit the execution of dictionary operations in optimal deterministic time when the dictionary is sufficiently sparse or sufficiently dense. The results demonstrate an exponential separation between the deterministic and randomized complexities of the problem.

Unique representations are applied to obtain efficient data structures for maintaining a dynamic collection of sets/sequences under queries that test the equality of a pair of objects. The data structure for set equality testing tests equality of sets in constant time and processes set updates in $O(\log m)$ amortized time and $O(\log m)$ space, where m denotes the total number of updates performed. It is based on an efficient implementation of cascades of CONS operations on uniquely stored S-expressions. The data structure for sequence equality testing tests equality of sequences in constant time and processes updates in $O(\sqrt{n}\log m + \log m)$ amortized time and $O(\sqrt{n})$ amortized space where n denotes the length of the sequence that is updated and m denotes the total number of updates performed.

1. Introduction.

A *unique representation* of an abstract data type (e.g., a dictionary) by a concrete data type (e.g., a binary search tree) consists of a one-to-one mapping of values of the abstract data type (ADT) into values of the concrete data type (CDT) and an implementation of the ADT operations by the CDT that *preserves* this mapping. A CDT implementation of an ADT operation that changes an ADT value v to a value w *preserves* this mapping if the implementation changes the image of v into the image of w. In this paper we are interested in devising unique representations of dictionaries by binary search trees that support dictionary operations (i.e., searches, insertions, and deletions of elements) efficiently and in applying our unique representations to equality testing of sets and sequences.

Unique representations arise in the contexts of incremental evaluation and implementation of high-level programing techniques. Incremental evaluation [14], [15] is the technique of efficiently updating the value of a function when the input changes. A simple idea to speed up incremental evaluation is to remember the results of previous function calls and thereby avoid recomputation. If the input domain is uniquely represented and input data objects are *stored uniquely*, then it becomes easy to check whether the function has already been evaluated on a given input. In this context *unique storage* of data objects means that instances of the same data object created at different times are all represented physically by the same storage structure. Modern programming languages, such as SETL, support high-level data types, such as sets and sequences, and permit testing whether two such objects are equal. Equality testing

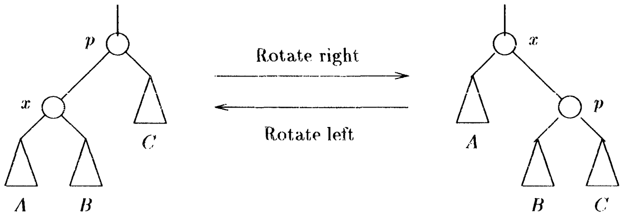

FIG. 1. *Rotation in a binary tree.*

can be implemented in constant time by devising a unique representation for the data type and uniquely storing concrete data values.

We define some basic concepts. A *dictionary* is a set of items selected from a totally ordered universe on which membership queries and update operations that insert or delete items can be performed. We can represent a dictionary by a binary tree containing one item per node, with the items arranged in symmetric order: each item in the tree is larger than the items in its left subtree and smaller than the items in its right subtree. This data structure is called a *binary search tree.* A binary search tree is represented in storage as a collection of records, one per node, with a pointer to the record corresponding to the root. Each record has a key field, left and right child pointers, and a fixed number of additional information and pointer fields. A *rotation* of an edge $[x, p]$ in a binary tree, where p is the parent of x, is a transformation that makes x the parent of p by transferring one of the subtrees of x to p; see Fig. 1.

We review previous work on unique representations. Snyder [18] studied unique representations of sets over an ordered universe by search trees so that, for each set size, all sets of that size have the same underlying tree. Search trees can be updated in various ways; in Snyder's work search trees are updated by changing the pointers of a set of nodes. For his class of unique representations Snyder showed that $\Theta(\sqrt{n})$ time is necessary and sufficient to perform a dictionary operation, where n is the dictionary size. Munro and Suwanda [13] studied how to implicitly represent sets over an ordered universe by an array so that, for each set size, all sets of that size satisfy a unique partial order on the array locations. They showed that $\Theta(\sqrt{n})$ time is necessary and sufficient to perform dictionary operations by using their representations. Recent work has focused on randomized unique representations. Pugh [14] and Pugh and Tietelbaum [15] gave efficient randomized unique representations for sets, sequences, and other abstract data types. Aragon and Seidel [3] gave a randomized binary-search-tree data structure that has the unique representability property and supports dictionary operations in $O(\log n)$ randomized time.

This paper studies the deterministic complexity of uniquely representing a dictionary over an ordered universe U by a binary search tree. We explore the following methods of updating a binary search tree during an insertion or deletion:

1. Performing a sequence of rotations: In this method we update the binary search tree representing the dictionary by using the traditional algorithms for binary-search-tree insertion and deletion [11], but we permit arbitrary rotations to be performed on the tree before and after so that the final tree correctly represents the updated dictionary.

2. Nondestructive updating through CONS operations: In this method we perform a sequence of dictionary operations on the null tree, and we maintain all the trees created by the operations performed so far and their subtrees. An update operation constructs a new tree by accessing some of its subtrees from the existing collection of trees and creating the remaining subtrees from the accessed subtrees, proceeding bottom-up. Also, an update operation may create any number of additional trees that may be needed in the future. A

CONS operation is used to create a new tree, given its left and right subtrees and root item. This operation parallels the CONS operation on S-expressions occurring in LISP [1]. A unique binary-search-tree representation that can be updated efficiently by means of CONS operations can be used to devise a data structure for maintaining a collection of sets/sequences under equality tests. In order to perform equality tests quickly, we assign *signatures* to binary search trees representing sets/sequences so that identical trees get identical signatures. Since we are using a unique representation, two sets/sequences are equal if and only if their binary search trees are identical, in other words, if their signatures are identical. A CONS operation computes the signature of a new tree it creates by matching it in the current collection of trees. If there is an identical tree in the collection, its signature is assigned to the new tree; otherwise, a new signature is assigned. CONS operations are the expensive part of the data structure since they have to search in the collection of trees. At present we do not know whether CONS operations can be implemented in constant time; later in this section we discuss the fastest known methods of implementing CONS operations. In our unique representation we define the cost of an update operation as the number of CONS operations performed instead of as the actual time taken. This is reasonable since CONS operations are the bottleneck in equality testing data structures and since we do not know their exact complexity.

For each updating method we seek representations that permit efficient implementation of the dictionary by using that method. Since $2n - 2$ rotations suffice to transform any n-node binary tree into any other n-node binary tree (see [7], [17]), any unique binary-search-tree representation supports dictionary operations in $O(n)$ time when rotations are used. We provide a representation that supports searches in $O(\log n)$ time and updates in $O(\sqrt{n})$ CONS operations.

We prove lower bounds on the complexity of any unique binary-search-tree representation that apply to sparse dictionaries (sets that are small compared to the universe). The lower bounds are derived for the following cost metric. The *cost* of an update using one of the aforementioned methods is, respectively, the number of rotations or the number of CONS operations. The *cost* of searching for an item in a binary search tree is 1 plus the depth of the item in the tree. Under the assumption that the dictionary is sparse, we show that the $O(n)$ and $O(\sqrt{n})$ upper bounds mentioned in the last paragraph are optimal. Our proof technique also extends Snyder's $\Omega(\sqrt{n})$ lower bound in the pointer-changes model to unique representations in which sets of equal cardinality need not have the same underlying tree. In light of Aragon and Seidel's representation, these lower bounds imply an exponential separation between the deterministic and randomized complexities of the problem. The sparseness assumption in the lower bounds is essential since we construct a representation that requires $O(\log |U|)$ cost per dictionary operation using any update strategy. This representation is optimal on dense dictionaries.

We apply unique representations to the problems of equality testing of sets and sequences.

Set equality testing problem: Maintain a collection of sets over an ordered universe under the operations i) EQUAL(S, T)—test whether sets S and T are equal, ii) INSERT(S, x, T)—create a new set T by inserting element x into set S, and iii) DELETE(S, x, T)—create a new set T by deleting element x from set S. Initially, the collection consists of only the empty set.

Sequence equality testing problem: Maintain a collection of sequences over an ordered universe under the operations i) EQUAL(S, T)—test whether sequences S and T are equal, ii) INSERT(S, i, x, T)—create a new sequence T by inserting element x into sequence S as the ith element between old positions $i - 1$ and i, and iii) DELETE(S, i, T)—create a new set T by deleting the ith element of sequence S. Initially, the collection consists of only the null sequence.

For both problems we are interested only in data structures that test equality in constant time. Wegman and Carter [20] proposed a randomized signature-based scheme for set equality testing that requires only constant time per operation but errs with a small probability. Pugh [14] and Pugh and Tietelbaum [15] gave randomized solutions to both problems that require $O(\log n)$ expected time and $O(\log n)$ expected space per update operation, where n denotes the size of the set or sequence. Their data structures also support more powerful operations (for instance, union and intersection of sets) efficiently. For sequence equality testing, however, the logarithmic bound is valid only if the sequences do not contain repeated elements. Yellin [23] provided a deterministic solution for set equality testing that requires $O(\log^2 m)$ time and $O(\log m)$ space per update operation, where m denotes the total number of updates.

We devise a data structure for set equality testing with $O(\log m)$ amortized time and $O(\log m)$ space per update. The data structure is based on a solution to a more fundamental problem involving S-expressions. S-expressions [1] constitute the staple data type of the programming language LISP. An *S-expression* is either an *atom* (signifying a number or a character string) or a pair of S-expressions. An atom is represented by a node in storage, and a pair is represented by a node with left and right pointers that point to nodes representing the component S-expressions. We store S-expressions uniquely, i.e., all instances of an S-expression are represented by a single node. CONS(s_1, s_2) returns the S-expression $(s_1.s_2)$. A *casade* of CONS operations is a sequence of CONS operations such that the result of each CONS operation is an input to the next CONS operation. For instance,

$$\begin{aligned} s_1 &:= \textsc{Cons}(s_0, t_0), \\ s_2 &:= \textsc{Cons}(t_1, s_1), \\ s_3 &:= \textsc{Cons}(t_2, s_2), \\ &\ \vdots \\ s_f &:= \textsc{Cons}(s_{f-1}, t_{f-1}) \end{aligned}$$

is a cascade of f CONS operations. The S-expression problem in question is to devise a data structure for efficiently implementing cascades of CONS operations on uniquely stored S-expressions.

Unique storage of S-expressions makes CONS operations expensive. Single CONS operations can be implemented in $O(\sqrt{\log F})$ time and $O(1)$ amortized space or, alternatively, in $O(1)$ time and $O(F^\epsilon)$ space, where F denotes the total number of CONS operations performed and ϵ is any positive constant. This implementation is based on Willard's data structure [22] for maintaining a dictionary in a small universe. Universal hashing [4] and dynamic perfect hashing [8] offer alternative implementations that require $O(1)$ randomized amortized time and $O(1)$ amortized space per CONS operation.

We develop a data structure that performs a cascade of f CONS operations in $O(f + \log m_c)$ amortized time, where m_c denotes the total number of cascades performed. The total space used is proportional to the number of distinct S-expressions present. When sets are represented by binary tries, an update operation translates into a cascade of at most $\log m$ CONS operations and requires $O(\log m)$ amortized time when this data structure is used. Many list-oriented functions in functional languages (LISP, for instance) involve cascades of CONS operations and can be implemented efficiently by using this method. Function APPEND is a typical example:

$$\begin{aligned} &\textsc{Append}([v_1, v_2, \ldots, v_k], [w_1, w_2, \ldots, w_l]) \equiv \\ &s_1 \quad := \textsc{Cons}(v_k, [w_1, w_2, \ldots, w_l]), \\ &s_2 \quad := \textsc{Cons}(v_{k-1}, s_1), \\ &\quad\ \vdots \\ &\textbf{Result} := \textsc{Cons}(v_1, s_{k-1}). \end{aligned}$$

Sequence equality testing can be solved in $O(n+\log m)$ amortized time and $O(1)$ space per update operation by maintaining sequences in a lexicographic search tree [16]. Here n denotes the length of the sequence that is updated and m denotes the total number of updates. Our solution to this problem requires $O(\sqrt{n \log m} + \log m)$ amortized time and $O(\sqrt{n})$ amortized space per update operation. When sequences are free from repetitions, sequence equality testing is equivalent to set equality testing. This follows from the representation of sets by sorted sequences and the representation of sequences by sets of ordered pairs of adjacent elements. Therefore, sequence equality testing becomes truly hard only when sequences have repetitions.

Recently, Andersson and Ottmann [2] have studied unique representation of a dictionary by directed graphs with nodes of bounded outdegree. Their class of unique digraph representations encompasses Snyder's and our classes of unique representations. They prove a tight bound of $\Theta(n^{1/3})$ on the time required by dictionary operations using their unique digraph representations. Unfortunately, their unique representation cannot be used to test equality of sets/sequences in constant time because the representation is updated through arbitrary pointer changes instead of through CONS operations; in order to transform a unique representation into an equality-testing data structure it should be updated by using CONS operations alone.

It might be possible to solve the sequence equality problem efficiently by devising a unique representation of sequences by bounded-outdegree directed acyclic graphs (DAG's) that can be quickly updated through CONS operations when elements are inserted into or deleted from sequences. It is natural to ask whether there is a unique DAG representation of sequences that can be updated in $O(\text{polylog}(n))$ CONS operations; n denotes the length of the updated sequence. We study the complexity of unique DAG representation of sequences in which all sequences of the same length are represented by the same underlying DAG and show that update operations in these representations require $\Omega(\sqrt{n}/\log n)$ CONS operations. Hence this restricted class of unique DAG representations cannot lead to a fast data structure for sequence equality testing. Our lower bound extends to arbitrary unique DAG representations of sequences if the underlying universe is sufficiently large.

The paper is organized as follows. Section 2 describes the results on unique binary-search-tree representations. Sections 3 and 4, respectively, describe the data structures for set and sequence equality testing. Section 5 describes the lower-bound result for unique DAG representations of sequences. Section 6 poses open problems.

2. Unique binary-search-tree representations.

In this section we describe the optimal representations for sparse and dense dictionaries and establish the lower bounds for representing sparse dictionaries.

2.1. An optimal representation for sparse dictionaries.

We describe a representation that allows search in $O(\log n)$ time and permits updating the binary search tree in $O(\sqrt{n})$ CONS operations. We represent the dictionary by an almost complete binary search tree. Specifically, if $n = 2^{i_1} + 2^{i_2} + \cdots + 2^{i_k}$, such that $i_1 > i_2 > \cdots > i_k$, then the binary search tree representing an n-element dictionary comprises a k-node right path, with a sequence of k complete binary trees of respective sizes $2^{i_1} - 1, 2^{i_2} - 1, \ldots, 2^{i_k} - 1$ hanging off of it; see Fig. 2a.

In order to be able to update the tree efficiently, we store some additional information. Define a *j-run* to be a subset of $2^j - 1$ adjacent elements in the dictionary; a *j-tree* is a complete binary search tree representing a j-run. For each $j = 1, 2, \ldots, \lfloor \log n/2 \rfloor$ we store the j-trees of the dictionary in a sorted list. This list is simply a doubly linked list of the roots of the j-trees; the subtrees of the j-trees are represented by pointers to the roots of these subtrees in the list of $(j-1)$-trees; see Figs. 2b and 2c. When n has the form $2^{2i} - 2^i + k$, where $1 \le k < 2^i$, in addition to the preceding lists we also store a sorted list of i-trees

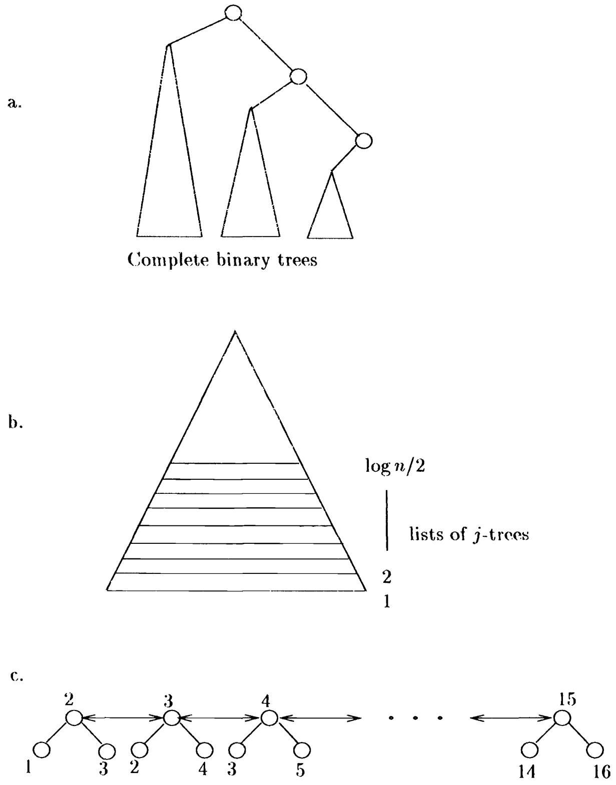

FIG. 2. *a. An almost complete binary tree having $2^{i_1} + 2^{i_2} + 2^{i_3}$ elements, where $i_1 > i_2 > i_3$. b. Lists of j-trees. c. List of 2-trees in the representation of set* $\{1, 2, \ldots, 16\}$.

($i = \lfloor \log n/2 \rfloor + 1$) corresponding to the first $k2^i$ i-runs. When an insertion causes n to increase from $2^{2i} - 1$ to 2^{2i} (causing $\lfloor \log n/2 \rfloor$ to increase by 1), this list becomes the list of $\lfloor \log n/2 \rfloor$-trees. This completes our representation; the storage used is $O(n \log n)$.

It is obvious that this representation supports search in $O(\log n)$ time. To insert a new element x we first locate the position of x in the list of 1-trees by searching the tree from top to bottom, then update the lists of trees, proceeding bottom-up, and then create the rest of the tree from trees in the updated lists. Updating the list of j-trees, for any j, involves locating and deleting at most $2^j - 2$ j-trees corresponding to old j-runs that contain the predecessor as well as the successor of x and inserting in their place at most $2^j - 1$ j-trees corresponding to new j-runs that contain x. We locate the j-trees to be replaced by starting at the j-tree encountered while searching for element x in the tree and traversing the list of j-trees left and right; this takes $O(2^j)$ time. We create a new j-tree by performing a CONS operation on two $(j-1)$-trees that are its subtrees and its root item. If n is of the form $2^{2i} - 2^i + k$, where $1 \leq k < 2^i$, we also extend the size of the list of i-trees from $k2^i$ to $(k+1)2^i$ by creating at most 2^i new i-trees. The list of j-trees can be updated in $O(2^j)$ time plus $O(2^j)$ CONS operations once the list of $(j-1)$-trees has been updated. The total cost of updating the lists of trees is at most $O(2 + 2^2 + \cdots + 2^{\lfloor \log n/2 \rfloor + 1}) = O(\sqrt{n})$. To create the rest of the tree we need to create the nodes of the tree at levels $\lfloor \log n/2 \rfloor + 1, \lfloor \log n/2 \rfloor + 2, \ldots, \lfloor \log n \rfloor + 1$ and the nodes on the right path of the tree. We traverse the nodes of the old tree at these levels, not on the right path, in postorder and replace them with nodes of the new tree by using

CONS operations. This gives us the subtrees of the right path of the new tree at the upper-half levels. We locate the subtrees of the right path at the lower-half levels in the updated lists of trees by traversing these lists top-down and left-to-right in staircase fashion. The subtrees of the right path of the new tree are all available now, so we create this path from bottom to top. It is easy to see that only $O(\sqrt{n})$ CONS operations are performed during an insertion and only $O(\sqrt{n})$ extra work is performed in addition to the CONS operations; the storage used is $O(\sqrt{n})$. Deletion in analogous.

2.2. Lower bounds for sparse dictionaries. Our lower bounds are proved by using Ramsey's theorem [10], [12].

RAMSEY'S THEOREM. *Let n, k, and $s \geq n$ be arbitrary positive integers, and let U be an arbitrary set. There exists a number $R_n(k, s)$ with the following property: if $|U| \geq R_n(k, s)$, then for any partition of the n-subsets of U into k classes there is an s-subset S all of whose n-subsets lie in a single class.*

It is known that $R_n(k, s) = T_n(O(\log(ks)))$ [10], [12], where $T_n(x)$ is the tower function

$$\left.2^{2^{\cdot^{\cdot^{2^x}}}}\right\}n.$$

First, we state a lower bound for updating the tree by means of rotations. Let $b_n = \binom{2n}{n}/(n+1)$ denote the number of distinct n-node binary trees [11]. Let n and d be positive integers, and let U be an ordered universe of size at least $R_n(b_n, n+1)$. For any unique binary-search-tree representation of subsets of U, we have the following trade-off between search and update times.

THEOREM 1. *If the n-subsets of U are represented by binary search trees of height at most d, then there is an n-subset on which an update operation requires $\Omega(n - 2d)$ rotations.*

The theorem implies that a dictionary operation requires $\Omega(n)$ time in the worst case if the dictionary is sufficiently sparse and rotations are used to update the tree. It is easy to show that the trade-off given by the theorem is optimal, up to a constant factor. The Ramsey number $R_n(b_n, n+1)$ is at most $T_{n+1}(cn)$, for some constant c. Therefore, the trade-off is valid when the dictionary size is at most $(1 - o(1)) \log^* |U|$.

The next theorem gives the lower bound on the cost of updating the tree by using CONS operations.

THEOREM 2. *Let n and $m \geq 2n$ be positive integers, and let U be an ordered universe of size at least $R_n(b_n, m)$. For any unique binary-search-tree representation of subsets of U there is a sequence of m update operations that involves only subsets of size at most n and causes $\Omega(m\sqrt{n})$ CONS operations to be performed.*

Snyder [18] showed a lower bound of $\Omega(\sqrt{n})$ on the worst-case cost of a dictionary operation when updates are implemented through pointer changes. His lower bound is restricted to the class of unique binary-search-tree representations in which all sets of equal cardinality have the same underlying tree. When the dictionary is sufficiently sparse, the lower bound can be extended to the class of all unique binary-search-tree representations by using Ramsey's theorem. The way to accomplish this is illustrated by the proofs of Theorems 1 and 2.

Proof of Theorem 1. By Ramsey's theorem there is a subset $S = \{x_1, x_2, \ldots, x_{n+1}\}$ of U all of whose n-subsets are represented by a single underlying binary tree, say, B. We claim that at least $n - 1 - 2d$ rotations are necessary to transform set $S_1 = \{x_1, x_2, \ldots, x_n\}$ into set $S_2 = \{x_2, x_3, \ldots, x_{n+1}\}$. The claim is proved by using Wilber's method [21] of deriving lower bounds on rotations in binary trees.

Consider an n-node binary tree T whose nodes are labeled from 1 to n in symmetric order. An interval $[i, j]$ of nodes of T is a *block* of T. Any block $[i, j]$ of T induces a binary tree,

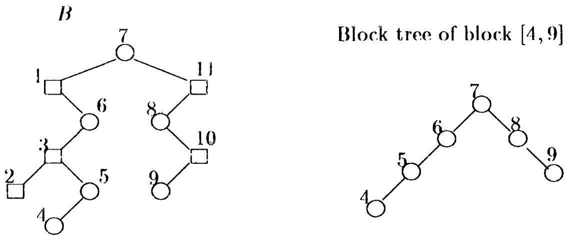

FIG. 3. *Block tree.*

called the *block tree* of block $[i,\ j]$, obtained by contracting all edges of T having an endvertex outside the block; see Fig. 3.

A rotation on T propagates into a rotation on a block tree of T only if both nodes of the rotation lie in the block tree; otherwise, the block tree is unaffected. Let $T_{\min}$ denote the binary tree obtained by deleting the minimum element of T (equivalently, the block tree of block $[2, n]$ in T). Define $T_{\max}$ similarly. Let $d_{\min}(T)$ and $d_{\max}(T)$ denote, respectively, the depths of the minimum and maximum elements of T.

LEMMA 1. *For any binary tree T, at least $|T| - 1 - d_{\min}(T) - d_{\max}(T)$ rotations are necessary to transform $T_{\min}$ into $T_{\max}$.*

Proof. The lemma is proved by induction on $|T|$.

Basis. $|T| \leq 2$: Easy.

Induction step. $|T| \geq 3$: Let x denote (the symmetric order number of) the node in T that is closest to the root and that is not the maximum or the minimum element. Let L and R denote, respectively, the block trees of blocks $[1, x]$ and $[x, |T|]$ in T. Divide the nodes of $T_{\min}$ and $T_{\max}$ into a left block $[1, |L| - 1]$ and a right block $[|L|, |T| - 1]$. Then the left block trees of $T_{\min}$ and $T_{\max}$ are respectively, $L_{\min}$ and $L_{\max}$; see Fig. 4.

By the inductive hypothesis at least $|L| - 1 - d_{\min}(L) - d_{\max}(L)$ left block rotations must be performed to transform $L_{\min}$ into $L_{\max}$. Similarly, at least $|R| - 1 - d_{\min}(R) - d_{\max}(R)$ right block rotations are needed to transform the right block tree $R_{\min}$ of $T_{\min}$ into the right block tree $R_{\max}$ of $T_{\max}$. Hence the total number of rotations necessary to transform $T_{\min}$ into $T_{\max}$ is at least $|T| - 1 - d_{\min}(L) - d_{\max}(L) - d_{\min}(R) - d_{\max}(R)$. The rest of the proof breaks up into three cases according to the position of x in T.

Case 1. x is the root of T: In this case we have

$$d_{\min}(L) = d_{\min}(T), \quad d_{\max}(L) = d_{\min}(R) = 0, \quad d_{\max}(R) = d_{\max}(T).$$

The inductive hypothesis follows from these relations.

Case 2. x is the only child of the root: The root must be either the minimum or the maximum element. Without loss of generality, assume that the root is the minimum element. We have

$$d_{\min}(L) = d_{\min}(R) = d_{\min}(T) = 0, \quad d_{\max}(L) = 1, \quad d_{\max}(R) = d_{\max}(T) - 1.$$

The inductive hypothesis follows.

Case 3. x is the only grandchild of the root: The minimum and the maximum elements of T constitute the root and its only child. Without loss of generality, let the minimum element be the root and let the maximum element be its child. We have

$$d_{\min}(L) = d_{\min}(R) = d_{\min}(T) = 0, \quad d_{\max}(L) = d_{\min}(R) = d_{\max}(T) = 1.$$

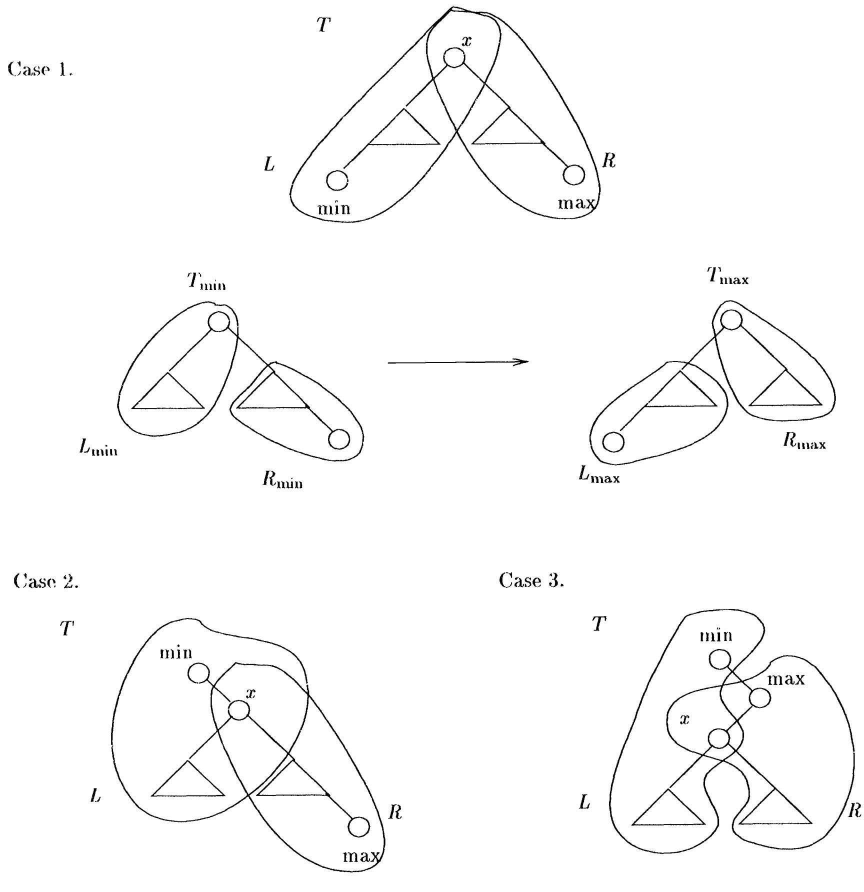

FIG. 4.

Since the roots of T_{min} and T_{max} are from different blocks, in addition to left and right block rotations, at least one rotation involving nodes from both blocks must be performed in transforming T_{min} into T_{max}. The inductive hypothesis follows from this observation and the preceding relations. □

When set S_1 is transformed into set S_2, the block tree induced by subset $\{x_2, x_3, \ldots, x_n\}$ is transformed from B_{min} into B_{max}. By Lemma 1 it follows that at least $n - 1 - 2d$ rotations are required to transform S_1 into S_2.

Consider transforming S_1 into S_2 by deleting x_1 and inserting x_{n+1}. The insertion of x_{n+1} into set $\{x_2, x_3, \ldots, x_n\}$ and the deletion of x_{n+1} from set S_2 are inverse transformations and require the same number of rotations. Hence $\Omega(n - 2d)$ rotations are necessary for either the deletion of x_1 from set S_1 or the deletion of x_{n+1} from set S_2. □

Proof of Theorem 2. By Ramsey's theorem there is a subset $S = \{x_1, x_2, \ldots, x_m\}$ of U all of whose n-subsets are represented by the same underlying binary tree. Let T denote an n-subset of S, to be specified later. The lower-bound construction inserts the elements of T into the null tree, one by one, and then performs $m - n$ updates on the resulting tree by repeating the following cycle of operations sufficiently many times:

1. Repeat $\sqrt{n} - 1$ times: Delete the minimum element of the tree and insert a fresh element from S that is larger than the maximum element of tree. Throughout this construction, by fresh element we mean an element that has never been in the tree before.

2. Replace the elements of the tree with symmetric order numbers $\sqrt{n}, 2\sqrt{n}, \ldots, n$ by fresh elements from S that occupy the same symmetric order positions in the tree.

This completes the construction. We now define set T and the fresh elements inserted into the tree during the construction. Execute the construction, treating all elements used as indeterminants, and determine their partial ordering. Next, assign specific values to these elements from set S to fit the partial order.

An iteration of the cycle performs $4\sqrt{n} - 2$ update operations on the tree (the first step performs $2(\sqrt{n} - 1)$ update operations; the second step performs $2\sqrt{n}$ update operations). Since $m - n \geq m/2$ update operations are performed during all iterations of the cycle, it follows that the number of iterations is at least $m/(8\sqrt{n})$. We claim that an iteration of the cycle creates n new trees. This would imply that at least $m\sqrt{n}/8$ new trees are created during the entire construction and would prove the theorem. Let us prove the claim. For $i = 1, 2, \ldots, \sqrt{n}$ let v_i denote the highest node of the tree with symmetric order number in the interval $[(i-1)\sqrt{n} + 1, i\sqrt{n}]$. Consider an iteration of Step 1 of the cycle. The subtrees of nodes $v_1, v_2, \ldots, v_{\sqrt{n}}$ after the iteration are all different from the subtrees of the tree at any time before the iteration; this is caused by the leftward movement of the fresh elements inserted during the preceding cycle. Since Step 1 is iterated $\sqrt{n} - 1$ times, it follows that $n - \sqrt{n}$ new trees are created during this step. Step 2 creates $\sqrt{n}$ new trees, so it follows that n new trees are created during an iteration of the cycle. The proof of the claim is complete; Theorem 2 follows. □

2.3. An optimal representation for dense dictionaries. Aragon and Seidel's representation [3] creates trees of height at least $\sqrt{|U|}$ in the worst case. They choose a static, random priority for each element in the universe and represent a set of items by the binary search tree that is heap-ordered according to priorities. It is well known [12] that any sequence of $p^2 + 1$ numbers contains a monotone subsequence of length at least $p + 1$. If we consider the longest monotone subsequence of the sequence of priorities of elements in the universe, then the representation of the set corresponding to this subsequence has height at least $\sqrt{|U|}$. Therefore, Aragon and Seidel's representation requires $\Omega(\sqrt{|U|})$ time in the worst case to perform a dictionary operation. Furthermore, since it is possible to assign priorities to elements of the universe so that the longest monotone subsequence has length at most $\sqrt{|U|} + 1$, there is a static priority representation in which trees have height $O(\sqrt{|U|})$. This representation allows dictionary operations to be performed in $O(\sqrt{|U|})$ time.

We describe a more efficient representation, based on binary tries [11], that allows dictionary operations to be performed in $(O \log |U|)$ time. Assume that $U = [1, 2^p]$, and let S denote the set being represented. If $S \subseteq [1, 2^{p-1}]$, then S is represented in U by the tree representing it in the universe $[1, 2^{p-1}]$. Otherwise, let $r = \min(S \bigcap [2^{p-1} + 1, 2^p])$. Then, r is the root of the tree representing S, and its left and right subtrees are, respectively, the trees representing subsets $S \bigcap [1, 2^{p-1}]$ and $S \bigcap [r + 1, 2^p]$ in the universes $[1, 2^{p-1}]$ and $[2^{p-1} + 1, 2^p]$. The height of the resulting tree is at most $\log |U|$. To insert a new element x, we compare x with the root of the tree, say, r. Let $2^{i-1} < r \leq 2^i$. We distinguish the following cases:

Case 1. $x > 2^i$: Make x the tree root with the old tree as the left subtree.

Case 2. $r < x \leq 2^i$: Insert x into the right subtree recursively.

Case 3. $2^{i-1} + 1 \leq x < r$: Place x at the tree root, substituting item r, and insert r into the right subtree recursively.

Case 4. $x \leq 2^{i-1}$: Insert x into the left subtree recursively.

Deletion is analogous to insertion. It is easy to see that each operation requires only $O(\log |U|)$ rotations or CONS operations.

3. Set equality testing. In this section we describe a data structure for set equality testing with $O(\log m)$ amortized time and $O(\log m)$ space per update operation, where m denotes the total number of updates. The elements seen so far are numbered in serial order and define the current universe $U = [1, |U|]$. Each set is represented by a binary trie [11] in this universe. The binary trie representing a set S is an S-expression that stores the elements of S as atoms and is defined recursively. Let $2^p < |U| \leq 2^{p+1}$. A singleton set is represented by an atom, and the empty set is represented by the atom NIL. If $|S| \geq 2$, then S is represented by a pair $(s_1.s_2)$, where s_1 and s_2 are, respectively, the S-expressions representing subsets $S \cap [1, 2^p]$ and $S \cap [2^p + 1, |U|]$ in their respective subuniverses. We store S-expressions uniquely so that two sets are equal if and only if their S-expressions are represented by the same node. Unique storage of S-expressions makes CONS operations expensive. Fortunately, a set update operation translates into a cascade of at most $\log |U| \leq \log m$ CONS operations, which can be implemented in $O(\log m)$ amortized time and $O(\log m)$ space by using the method described in the following.

We now describe an efficient data structure for performing cascades of CONS operations on uniquely stored S-expressions. The data structure requires $O(f + \log m_c)$ amortized time to perform a cascade of f CONS operations, where m_c denotes the total number of cascades performed. Consider the collection of nodes representing S-expressions. Number the nodes serially in order of creation. Say node p is a *parent* of node v if p points to v. Each node, say, v, maintains a set *parents*(v) of all its parents. Each parent $p \in$ *parents*(v) is assigned a key equal to (serial#(w),b), where w is the other node (besides v) pointed to by p, and b equals 0 or 1 depending on whether the left pointer of p points to v or not. To perform a CONS operation on two nodes v and w, we search set *parents*(v) under key (serial#(w),0) and return the matching parent (or, alternatively, we search the set parents(w,0) under key (serial#(v),1)). If there is no matching parent, we create a new node p with pointers to v and w, set *parents*(p) to empty, insert p into *parents*(v) and *parents*(w), and return p. In a cascade of CONS operations we implement each CONS operation by searching in the set of parents of the node returned by the previous CONS operation.

We represent each set *parents*(v) by a binary search tree and use the splay algorithm [16] to perform searches. Insertion of a new item by using splay is implemented as follows. Maintain a pointer to the maximum item in the tree (in addition to the root pointer). If the inserted item is larger than the current maximum item, insert it as the right child of the maximum item. Otherwise, insert the item into the tree in the standard way and splay at the item. The two types of insertions are called *passive* and *active*, respectively. We implement passive insertions more efficiently since they are more numerous than active insertions.

The following theorem summarizes the performance of the data structure.

THEOREM 3. *The amortized cost of a cascade of f* CONS *operations is $O(f + \log m_c)$, where m_c is the total number of cascades performed on S-expressions.*

Before proving the theorem, we need a few lemmas. The following technical lemma uses the notion of blocks in a binary tree introduced in the proof of Theorem 1 and occurs implicitly in the work of Cole, Mishra, Schmidt, and Siegel [6].

LEMMA 2. *Consider a binary tree partitioned into blocks whose items have been assigned arbitrary nonnegative weights such that every block has positive weight (the weight of a block is the sum of the weights of items in the block). Let n denote the number of nodes in the tree, and let n_b denote the number of blocks. The cost of a sequence of m splays performed on the roots of the blocks is $O(m + n + \sum_{j=1}^{m} \log(W/w_j) + \sum_{i=1}^{n_b} \log(W/\bar{w}_i))$, where W is the total weight of all the items, w_j is the weight of the block of the jth accessed item, and $\bar{w}_i$ is the weight of the ith block of the tree.*

Proof. Assign potentials to all nodes in the tree as described by Cole, Mishra, Schmidt, and Siegel [6, §2], and analyze splays by using their analysis of global insertions. (An account of this analysis can also be found in Cole [5].) The amortized cost of splaying at the root of a block with weight w is $O(1 + \log(W/w))$, and the drop in potential over the entire sequence is $O(\sum_{i=1}^{n_b} \log(W/\bar{w}_i) + n)$. The result follows. □

The next lemma bounds the cost of the sequence of operations performed on a single parent set and is the key step in the analysis.

LEMMA 3. *Consider a sequence of insertions and searches performed on an (initially empty) binary search tree by using splays. Let f_i be the number of searches of item i, F be the total number of searches, n_a be the number of active insertions, and n be the total number of insertions. The cost of this sequence if $O(n + n_a \log n_a + F + \sum_{f_i \geq 1} f_i \log(F/f_i))$.*

Proof. We modify the sequence by preinserting all items into the initial tree according to their order of arrival (without splaying). On this tree we perform the searches and simulate the insertions. Active insertions are simulated by splaying at the corresponding items, and passive insertions are simply ignored. We obtain a sequence of splays corresponding to active insertions and searches (*active* splays and *hot* splays, respectively). It suffices to bound the cost of this sequence.

We bound the cost of this sequence by partitioning the tree into blocks and applying Lemma 2. Partition the tree into blocks as follows. Call the items accessed by active and hot splays *active* and *hot*, respectively. Every active or hot item forms a singleton block. Each nonempty interval of nodes between consecutive singleton blocks forms a *passive* block. Choose an item from each passive block, and call it the *block representative*. Note that n_a is the number of active items. The weight of item i is defined by

$$\left\{\begin{array}{ll} f_i & \text{if the item is hot,} \\ F/(n_a + 1) & \text{if the item is active but not hot,} \\ 0 & \text{if the item is in a passive block} \\ & \qquad \text{but not the representative.} \end{array}\right.$$

The representatives of $n_a + 1$ passive blocks are assigned a weight of $F/(n_a + 1)$ each, and the representatives of the remaining passive blocks are placed in one-to-one correspondence with the set of hot items and assigned the weights of their mates. The total weight of the tree is at most $4F$. If Lemma 2 is applied, the cost of the sequence of splays is

$$\begin{aligned} O\Bigg(& n_a + F + n + \sum_{f_i \geq 1} f_i \log\left(\frac{4F}{f_i}\right) + n_a \log(4(n_a + 1)) \\ & +2\left(\sum_{f_i \geq 1} \log\left(\frac{4F}{f_i}\right)\right) + (2n_a + 1)\log(4(n_a + 1))\Bigg) \\ = O & \left(n + n_a \log n_a + F + \sum_{f_i \geq 1} f_i \log\left(\frac{F}{f_i}\right)\right). \end{aligned}$$ □

Remark. The lemma is an extension of Sleator and Tarjan's static optimality theorem [16]. The theorem is restricted to sequences of searches in which all items of the tree are accessed at least once. Use of the analysis of Cole, Mishra, Schmidt, and Siegel [6] is what made our extension possible.

LEMMA 4. *Consider a digraph $G = (V, E)$, and consider a collection of walks in G. Let F_e be the number of traversals of edge e in the walks, F_v be $\sum_{(v,w)\in E} F_{(v,w)}$, for any vertex v, W_v be the number of walks originating at vertex v, and id_v be indegree$(v) + 1$. Then,*

$$\sum_{(v,w)\in E} F_{(v,w)} \log\left(\frac{F_v}{F_{(v,w)}}\right) \leq \sum_{v\in V} F_v \log id_v + \sum_{F_v \geq 1} W_v \log F_v.$$

Proof. Let $\bar{F}_{(v,w)}$ be $F_{(v,w)}$ minus the number of walks with (v, w) as the last edge. Then,

$$\begin{aligned}
\sum_{(v,w)\in E} F_{(v,w)} \log\left(\frac{F_v}{F_{(v,w)}}\right) &= \sum_{F_v\geq 1} F_v \log F_v + \sum_{(v,w)\in E} F_{(v,w)} \log\left(\frac{1}{F_{(v,w)}}\right) \\
&\leq \sum_{F_v\geq 1} W_v \log F_v + \sum_{(x,v)\in E} \bar{F}_{(x,v)} \log F_v \\
&\quad + \sum_{(v,w)\in E} \bar{F}_{(v,w)} \log\left(\frac{1}{F_{(v,w)}}\right) \\
&= \sum_{F_v\geq 1} W_v \log F_v + \sum_{F_w\geq 1} \sum_{(v,w)\in E} \bar{F}_{(v,w)} \log\left(\frac{F_w}{\bar{F}_{(v,w)}}\right) \\
&\leq \sum_{F_v\geq 1} W_v \log F_v + \sum_{w\in V} F_w \log id_w,
\end{aligned}$$

where the first inequality holds because $x \log(1/x)$ is decreasing in $[1/e, \infty]$ and the second follows from the entropy inequality. □

Proof of Theorem 3. Consider a sequence of m_c cascades of CONS operations comprising F CONS operations totally. The cost of a cascade of f CONS operations is $O(f)$ plus the cost of operations on parent sets. During any cascade of CONS operations, there are at most two active insertions into parent sets. These insertions are performed when the first node is created by the cascade, and all subsequent insertions are passive. Thus out of at most $2F$ insertions into parent sets during the entire sequence of cascades, at most $2m_c$ are active. Applying Lemma 3 to the sequence of insertions and searches performed on each parent set and summing the costs over all parent sets, we see that the total cost of parent set operations is

$$O\left(F + m_c \log m_c + \sum_{\text{nodes } v} \sum_{i\in parents(v)\wedge f_i\geq 1} f_i \log\left(\frac{F(v)}{f_i}\right)\right),$$

where $F(v)$ denotes the total number of searches performed on *parents*(v) and f_i denotes the number of searches of item i among these. The double summation bounds the total cost of all searches performed on the parent sets. We bound the summation, in turn, by using Lemma 4. The collection of nodes at the end of the sequence of cascades induces a directed graph with the nodes as vertices and edges from nodes to their parents. The indegree of each node in the graph is at most 2. For each edge (v, w) define $F_{(v,w)}$ to be the number of searches of node w performed on *parents*(v). Delete all edges e such that $F_e = 0$. If Lemma 4 is applied to the resulting graph, the summation is bounded by $F \log 3 + m_c \log m_c$. It follows that the cost of the sequence of cascades is $O(F + m_c \log m_c)$. The theorem follows. □

4. Sequence equality testing. In this section we describe a data structure for sequence equality testing with $O(\sqrt{n} \log m + \log m)$ amortized time and $O(\sqrt{n})$ amortized space per update, where n denotes the length of the sequence that is updated and m denotes the total number of updates. We represent a sequence by an almost complete binary tree analogous to the set representation described in §2.1. The ith node of the tree in symmetric order stores the ith element of the sequence. A j-run is a subsequence of $2^j - 1$ adjacent elements in the sequence. For each $j \leq \lfloor \log n/2 \rfloor$ we maintain a list of j-trees representing the j-runs of the sequence; this will allow us to update a sequence by creating $O(\sqrt{n})$ new trees through CONS operations. In this representation a node can belong to several sequences and hence can have left and right pointers corresponding to several lists of j-trees. This makes navigation through the list of j-trees of a particular sequence expensive. We make the data structure persistent so that it permits efficient navigation. A data structure is *fully persistent* [9] if it maintains all versions of the data structure created by the update operations so far and permits accesses and updates (that create new versions) to any existing version. Driscoll, Sarnak, Sleator, and Tarjan [9] show how to make a purely pointer-based data structure that has nodes of constant bounded indegree and constant bounded number of access points fully persistent by weakening the time and space per update operation to amortized bounds (the original bounds must be worst case). Their method is to split a node when it has to maintain too many fields corresponding to different versions of the data structure. In our data structure, nodes have indegree at most 4 since a node has at most two parents and at most two adjacent nodes in its list of j-trees that point to it. Also, the data structure is always accessed from the root of the binary tree. Therefore, it can be made fully persistent by using their technique. The persistent data structure maintains the representations of all sequences created so far and permits navigating in and updating any of them. The data structure supports an update operation on a sequence in $O(\sqrt{n})$ amortized time plus the time needed for $O(\sqrt{n})$ CONS operations.

We now discuss how to test equality of sequences by using this data structure. Two sequences are equal if and only if their binary trees are isomorphic; here we define *isomorphic trees* as trees having the same shape and the same labels on the nodes. To facilitate isomorphism testing of binary trees, we serially number each class of isomorphic binary trees in order of creation and store the serial number of a binary tree at its root. Two sequences are equal if and only if their binary trees have identical serial numbers. When a node of the persistent data structure is split, its serial number is stored in the resulting nodes. Let us see how to compute the serial number of a new tree created by a CONS operation. Number all elements seen so far in serial order, and store them in a balanced search tree so that the serial number of an element can be computed in $O(\log m)$ time. Associate with each tree a triple (l, r, x) of serial numbers of its two subtrees and root element. If the triple of the new tree equals the triple of some existing tree, its serial number is obtained from the serial number of the matching tree. Otherwise, the new tree forms a new isomorphism class, so it is assigned the next available serial number. We have reduced the computation of the serial number of a new tree to testing membership of its triple in the collection of triples of all the trees. The collection of triples associated with the trees is a subset of $[1, cm^{3/2}] \times [1, cm^{3/2}] \times [1, m]$ for some constant c. Willard [22] gives a data structure for maintaining a dictionary over an ordered universe U in $O(\sqrt{\log |U|})$ time and $O(1)$ amortized space per operation. If the collection of triples is maintained by using this data structure, the serial number of a new tree can be computed in $O(\sqrt{\log m})$ time and $O(1)$ amortized space. Willard's data structure requires a priori knowledge of the universe size. If the number of updates is not known a priori, we estimate this quantity tentatively and, whenever the actual number of updates overshoots the estimate, we square the estimate and reconstruct the data structure. This increases the amortized time per dictionary operation in Willard's data structure by only a constant factor.

The persistent data structure, in conjunction with the data structure for serial number computation, solves the sequence equality testing problem. The cost of testing equality of two sequences is $O(1)$. The amortized time to update a sequence of length n is $O(\sqrt{n \log m} + \log m)$; the amortized space required is $O(\sqrt{n})$.

5. Unique DAG representation of sequences. In this section we study unique representations of sequences by DAG's with nodes of bounded outdegree that are updated by using CONS operations. We show that any representation that represents all sequences of the same length by the same underlying DAG requires $\Omega(\sqrt{n}/\log n)$ CONS operations per update operation.

We describe our class of unique DAG representations. A *unique* DAG *representation* of sequences over a universe represents sequences by rooted, ordered DAGs with nodes of bounded outdegree. A DAG is a *rooted* DAG if all nodes of the DAG are reachable from a single node that is called the *root*. An *ordered* DAG is one in which the outgoing edges of any node are ordered. Let G be an ordered DAG, and let x be a node of the DAG with a sequence of outgoing edges $(x, y_1), (x, y_2), \ldots, (x, y_k)$. Node y_k is called the ith *outneighbor* of x. Represent a sequence of length n by an n-node rooted, ordered DAG whose nodes have outdegree at most c, and store the elements of the sequence, one element per node, in a way that is unique to the sequence; c is a fixed constant, independent of n. A unique DAG representation also has an additional property that makes it useful for equality testing: the representation represents distinct sequences by nonisomorphic DAG's; *nonisomorphic* DAG's are DAG's that either have different shapes or have different arrangements of elements in nodes. A collection of sequences is represented by a common DAG that contains the DAG's representing the individual sequences as its subgraphs. When a new sequence is created from an existing sequence by inserting or deleting an element, the DAG representing the new sequence is created by accessing some of its nodes from the common pool and creating the remaining nodes bottom-up from the accessed nodes. An update operation is also permitted to create any additional nodes that may be needed in the future. A CONS operation is used to create a new node given its element and its outneighbors. The cost of an update operation equals the number of CONS operations performed.

We seek a unique DAG representation of sequences that permits sequences to be updated in $O(\text{polylog}(n))$ CONS operations; n denotes the length of the updated sequence. Such a representation might lead to a polylogarithmic-time data structure for sequence equality testing. We study a restricted class of unique DAG representations, called *length-unique* DAG representations. A unique DAG representation is *length-unique* if it represents sequences of the same length by a fixed underlying DAG and it arranges the elements of these sequences in the nodes of the DAG according to a fixed permutation. Our main result in this section is the following theorem.

THEOREM 4. *Let n and $m \geq n$ be positive integers, and let U be a universe of size at least m. For any length-unique* DAG *representation of sequences over U, there is a sequence of m update operations on sequences of length at most n that causes $\Omega(m\sqrt{n}/\log n)$* CONS *operations to be performed.*

This lower bound says that the complete-binary-tree representation of sequences used in our sequence equality data structure is optimal, up to a log factor, among the class of length-unique DAG representations. The log factor in the denominator of the lower bound arises for a technical reason; we believe that the lower bound holds even without it. The lower bound can be extended to arbitrary unique DAG representations if the underlying universe is sufficiently large, with the help of Ramsey's theorem. This is not a direct consequence of Theorem 4, but it follows because the proof of the theorem also works for unique representations that represent sorted sequences of each length (not all sequences) over an ordered universe by a fixed underlying DAG, according to a fixed permutation.

The proof of the theorem uses two technical combinatorial lemmas. The first one concerns integer sequences. Define the *slope* of an integer sequence $a_1, a_2, \ldots, a_n$ to be $(a_n - a_1)/n$. Define the *sum* of two sequences $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$ to be the sequence $a_1+b_1, \ldots, a_n+b_n$.

LEMMA 5. *Every sequence of n integers has a subsequence of length $n/(5\log n)$ that is the sum of an increasing sequence with slope at most $5\log n$ and a sequence of distinct elements.*

Proof of Lemma 5. The proof idea is that perturbing the sequence by a random linearly growing sequence gives a sequence with many distinct elements. Let $\bar{a} = (a_1, a_2, \ldots, a_n)$ be the sequence we want to decompose. Select a random number k from $\{1, 2, \ldots, n\}$. Define a sequence $\bar{r} = (r_1, \ldots, r_n)$ by $r_i = \lfloor ik/n \rfloor$. The sequence has slope at most 1. We claim that the sequence $\bar{d} = (a_1 - r_1, \ldots, a_n - r_n)$ is likely to have at least $n/(5 \log n)$ distinct elements. This would give the lemma.

Let us prove the preceding claim. Let p denote the number of distinct elements in sequence $\bar{d}$, and let $k_1, k_2, \ldots, k_p$ denote the respective numbers of occurrences of these p elements in $\bar{d}$. For a fixed pair of integers i, j such that $1 \le i < j \le n$ let us compute the probability of the event $d_i = d_j$.

$$\begin{aligned}
\Pr[d_i = d_j] &= \Pr[a_i - r_i = a_j - r_j] \\
&= \Pr[a_j - a_i = \lfloor jk/n \rfloor - \lfloor ik/n \rfloor] \\
&\le \Pr[a_j - a_i - 1 < (j-i)k/n < a_j - a_i + 1] \\
&= \Pr[n(a_j - a_i - 1)/(j-i) < k < n(a_j - a_i + 1)/(j-1)] \\
&\le 2/(j-i).
\end{aligned}$$

We estimate the expected value of $\sum_i k_i^2$.

$$\begin{aligned}
E\left[\sum_i k_i^2\right] &= 2E\left[\sum_i \binom{k_i}{2}\right] + n \\
&= 2\left(\sum_{i<j} \Pr[d_i = d_j]\right) + n \\
&\le 2\left(\sum_{i<j} \frac{2}{j-i}\right) + n \\
&\le 5n \log n.
\end{aligned}$$

We estimate $E[p]$ as follows:

$$\sum_i k_i^2 \ge \left(\sum_i k_i\right)^2 / p = n^2/p$$

by the Cauchy–Schwarz inequality. Hence,

$$E\left[\sum_i k_i^2\right] \ge E[n^2/p] \ge n^2/E[p]$$

by Jenson's inequality. It follows that $E[p]$ is at least $n/(5 \log n)$, completing the proof of the claim. The proof of the lemma is complete. □

The second technical lemma used in proving Theorem 4 concerns DAG's. Let G be a rooted, ordered DAG with node set $\{1, 2, \ldots n\}$. We say that two nodes v and w of G are *shape-isomorphic* if the subgraphs of G rooted at v and w are isomorphic as unlabeled, ordered diagraphs. We say that two nodes v and w are *rank-isomorphic* if the subgraphs of G rooted at v and w are shape-isomorphic and the shape-ismorphism between these subgraphs maps the ith largest labeled nodes in the subgraphs to each other, for all i.

LEMMA 6. *Let G be a rooted, ordered* DAG *with node set $\{1, 2, \ldots n\}$. There exist node triples $(u_1, v_1, w_1), (u_2, v_2, w_2), \ldots, (u_p, v_p, w_p)$ in G, where $p = \sqrt{n}/(12(c+1))$, and c is an upper bound on the outdegree of the nodes of G, such that all of the following hold*:

1. $|w_i - v_i| \ge \sqrt{n}$ *for all* i.
2. *Either* $v_i < w_i$ *for all* i *or vice versa.*

3. $|v_i - v_j| \geq \sqrt{n}$ *for all* $i \neq j$.

4. v_i *and* w_i *are descendants of* u_i *for all* i.

5. *If* u_i *and* u_j *are rank-isomorphic, then the isomorphism between the subgraphs rooted at these nodes matches* (v_i, w_i) *and* (v_j, w_j).

Proof of Lemma 6. We construct the desired node triples by using the following algorithm. We call a DAG node *narrow* if the labels of any two of its descendants differ by less than $2\sqrt{n}$; otherwise, we call the node *wide*. We call a DAG node *i-narrow* if it is the descendant of a narrow node that is the ith outneighbor of some wide node. Since every node is either wide or i-narrow for some i, it follows that either there are at least $n/(c+1)$ wide nodes or there are $n/(c+1)$ i-narrow nodes for some i. We consider the two cases separately:

Case 1. The number of wide nodes is at least $n/(c+1)$: We scan the wide nodes, one by one, marking them and simultaneously creating node triples (u_i, v_i, w_i) that satisfy Conditions 1, 3, 4, and part of Condition 5 of the lemma. Initially, none of the wide nodes is marked. Each scan step picks an unmarked wide node u, it adds a new triple (u, u, w), where w is the descendant of u whose label differs from u's label by the maximum amount, and it marks u as well as all wide nodes whose labels differ from u's label by less than $\sqrt{n}$. The scan continues until all wide nodes are marked. Since each scan step marks at most $2\sqrt{n} - 1$ wide nodes and there are at least $n/(c+1)$ wide nodes to be marked totally, the total number of scan steps as well as the total number of triples created is at least $\sqrt{n}/(2(c+1))$. The set of triples satisfies Conditions 1, 3, and 4 of the lemma. Instead of Condition 5, the triples satisfy the following weaker condition: For two triples (u_i, v_i, w_i) and (u_j, v_j, w_j) such that u_i and u_j are rank-isomorphic, the isomorphism between the subgraphs rooted at u_i and u_j always matches v_i and v_j but matches w_i and w_j only if $v_i - w_i$ and $v_j - w_j$ have the same sign. We can make the triples satisfy Conditions 2 and 5 by eliminating at most half of them.

Case 2. The number of i-narrow nodes is at least $n/(c+1)$ for some i: We create the triples by scanning the wide nodes in a way analogous to Case 1. Each scan step picks a wide node u whose ith outneighbor, say, v, is an unmarked narrow node, it creates a new triple (u, v, w) where w is the descendant of u whose label differs from v's label by the maximum amount, and it marks v as well as all i-narrow nodes whose labels differ from v's label by less than $\sqrt{n}$. When the scan terminates, the ith outneighbors of all wide nodes that are narrow nodes are marked. Hence at the end of the scan, for every i-narrow node, say, x, there is a marked i-narrow node whose label differs from x's label by less than $2\sqrt{n}$; in fact, there is a triple (u, v, w) such that x's label differs from v's label by at most $3\sqrt{n} - 2$. For any triple (u, v, w) there are at most $6\sqrt{n} - 3$ i-narrow nodes whose labels differ from v's label by at most $3\sqrt{n} - 2$. It follows that the total number of triples created is at least $\sqrt{n}/6(c+1))$. We eliminate at most half of these triples in order to make then satisfy Conditions 2 and 5 of the lemma.

This completes the description of the algorithm. The algorithm creates at least $\sqrt{n}/12(c+1))$ node triples that satisfy the conditions of the lemma. □

Let us prove Theorem 4. The proof involves extending the ideas used in the proof of the lower bound for unique binary-search-tree representations (Theorem 2) in a nonobvious way. We would like to motivate the proof, first, by mentioning some preliminary approaches that do not work. Following the proof of Theorem 2 we can try to devise an adversary operation sequence consisting only of substitutions of elements in the sequence and shift operations that shift the entire sequence to the left or right by one position. This approach does not work since there is a unique binary-tree representation of sequences that processes substitutions and shifts in $O(\log n)$ CONS operations. This representation represents a sequence by a complete binary tree and arranges the elements in the tree according to the bit-reversal permutation; that is, the ith element of the sequence is stored in the node with symmetric order number equal to the reverse of the binary representation of i. We leave the proof that the representation works as an exercise. Another class of adversary operation sequences to try are those consisting of substitutions and shifts of a fixed segment of the sequence. This approach also does not give the lower bound we are aiming at since there is a unique binary-tree representation that supports substitutions and shifts of any fixed segment of the sequence in $O(n^{1/3})$ CONS operations; we leave this representation as an exercise. Hence the only adversaries that have a chance of giving a $\sqrt{n}$ lower bound are ones that shift several different segments of the sequences in an intermixed fashion.

Proof of Theorem 4. We devise an adversary that performs a sequence of $O(n)$ operations involving sequences of length n and causes the performance of $\Omega(n\sqrt{n}/\log n)$ CONS operations. The theorem will follow immediately once we have such an adversary. The adversary partitions the sequence into about $\sqrt{n}$ adjacent blocks, each consisting of $\sqrt{n}$ adjacent positions, and performs an intermixed sequence of *global shift* operations that shift the entire sequence to the right by inserting a new element at the left end and deleting the rightmost element and *local shift* operations that shift an individual block to the left by inserting a new element at the right end and deleting the leftmost element of the block. The global and local shift operations will be so designed that a specific set of $\sqrt{n}/\log n$ nodes of the DAG representing the sequence will have to be re-created during most global shift operations.

We define a set of $\sqrt{n}/\log n$ nodes of the DAG representing the sequences that the adversary will cause to be re-created many times during the adversary operation sequence. Let G be the DAG representing sequences of length n. We label the nodes of G by the positions in a sequence of length n to which they correspond. From now on, we will refer to nodes of G by their labels (or positions in a sequence of length n). By Lemma 6 there is a set of node triples $(u_1, v_1, w_1), \ldots, (u_p, v_p, w_p)$, for some $p = \Omega(\sqrt{n})$, such that the five conditions of the lemma are satisfied. Without loss of generality, we can strengthen the second condition of the lemma and assume that $v_i < w_i$ for all i. We call each node triple (u_i, v_i, w_i) a *tripole*; v_i and w_i are called the *minus pole* and the *plus pole* of the tripole, respectively, and u_i is called its *head*. We delete all the tripoles with minus poles in the set $\{1, 2, \ldots, p\sqrt{n}/2\}$ and use only the remaining tripoles; the number of remaining tripoles is at least $p/2$. We renumber the remaining tripoles from 1 to a number $q \geq p/2$ in ascending order of their minus poles. Consider the sequence of lengths of the tripoles $\{w_i - v_i \mid i = 1, 2, \ldots, q\}$. By Lemma 5 this sequence has a subsequence of $w_{i_1} - v_{i_1}, \ldots, w_{i_r} - v_{i_r}$, where $r = q/(5\log q)$, that is the sum of a sequence of integers $0 \leq s_1 \leq \cdots \leq s_r \leq q$ and a sequence of distinct positive integers. We delete all tripoles whose indices are not in the set $\{i_1, i_2, \ldots, i_r\}$ and renumber the remaining tripoles from 1 to r in ascending order of their minus poles.

Our next task is to define the adversary operation sequence so that the nodes $u_1, u_2, \ldots, u_r$ will be re-created many times. The idea is to send many distinct pairs of sequence elements into nodes v_i and w_i of G.

Partition the positions of a sequence of length n into $p/2$ blocks $B_1, B_2, \ldots, B_{p/2}$ each consisting of $\sqrt{n}$ adjacent positions and a block $B_{p/2+1}$ consisting of the remaining positions $\{p\sqrt{n}/2+1, \ldots, n\}$. For a set of integers S, define $S+i$ to be the set $\{x+i \mid x \in S\}$. Suppose we color the positions in each of the blocks either red or blue; for each block, all the positions in the block get the same color. For a tripole (u, v, w) and a block B_i, for some $i \leq p/2$, we say that the tripole-block pair $((u, v, w), B_i)$ is *compatible* if the positions in B_i are all red positions and the positions in $(B_i + (w - v))$ are all blue positions. We seek a coloring of the blocks that has a large number of compatible tripole-block pairs. A random coloring of the blocks achieves this. So let us randomly color the positions in each of the blocks $B_1, \ldots, B_{p/2}$ either red or blue with probability 1/2, independent of the other blocks; block $B_{p/2+1}$ alone is always colored blue. The probability that a fixed tripole-block pair is compatible is at least

1/8. It follows that the expected number of compatible tripole-block pairs is at least $pr/16$. We conclude that there is a coloring of the blocks that has at least $pr/16 = \Omega(n/\log n)$ compatible tripole-block pairs.

The significance of the coloring of the blocks and of the notion of compatible tripole-block pairs is the following. The red blocks are the blocks that undergo local shift operations, and the blue blocks are the blocks that remain static during the adversary operation sequence. A red block gets repeatedly shifted to the right through global shift operations. When the block sweeps through a minus pole position v corresponding to a compatible tripole (u, v, w), the head node u of the tripole gets re-created $\sqrt{n}$ times. Since there are $\Omega(n/\log n)$ compatible tripole-block pairs, we will get $\Omega(n\sqrt{n}/\log n)$ total node creations during the adversary operation sequence.

We describe the adversary. Let us assume that the universe is totally ordered. The adversary initially creates a sorted sequence of n elements in the universe, partitions it into $p/2+1$ red/blue blocks as described previously, and repeats the following operation sequence n times:

1. *Local shift*: For each block of red positions that is immediately followed by a minus pole position of a tripole do the following. Let i be the index of the tripole (recall that the tripoles are numbered from 1 to r in ascending order of their minus poles). Perform $s_i - s_{i-1}$ left-shift operations on the red block; assume $s_0 = 0$. Each left-shift operation deletes the smallest element of the block and inserts a fresh largest element at the other end while maintaining the sortedness of the whole sequence; here a fresh element is an element that was never in the sequence before.

2. *Global shift*: Shift the entire sequence one position to the right by deleting the largest element and inserting a fresh smallest element at the other end. This operation also shifts the blocks and their coloring one position to the right; it does not assign a color to the new first position.

The total number of operations performed by the adversary is $O(n)$.

Let us analyze this adversary. We will show that for any compatible tripole-block pair $((u, v, w), B)$ and element x within block B, a new copy of node u is created when element x moves to position v in the sequence. It will follow that $\Omega(n\sqrt{n}/\log n)$ CONS operations are performed in creating new copies of the head nodes. Let x be an element of a block B, and let (u_i, v_i, w_i) and (u_j, v_j, w_j) be tripoles that are compatible with B. Let $G_i(u_i)$ $(G_j(u_j))$ be the subgraph rooted at node $u_i(u_j)$ when element x reaches position $v_i(v_j)$ of the sequence. We claim $G_i(u_i)$ and $G_j(u_j)$ are not identical, that is, either their shapes are different or they have different arrangements of elements in their nodes. Let us prove this claim. If the two subgraphs are not shape-isomorphic, there is nothing to prove. If they are shape-isomorphic alone, not rank-isomorphic, then since the elements of the sequence are sorted, the arrangements of elements in the two subgraphs must be different. The last case to handle is when $G_i(u_i)$ and $G_j(u_j)$ are rank-isomorphic. In this case the elements stored in positions w_i and w_j, respectively, at the times when x is at positions v_i and v_j, respectively, are different. This is ensured by the shift operations ($s_j - s_i$ in number) performed on B between these two times and by the positions w_i and w_j lying in blue blocks at these respective times. It follows that the subgraphs are not identical, proving the claim. Hence, for each compatible tripole-block pair $((u, v, w), B)$ and element x within B, a new copy of node u is created when element x moves to position v in the sequence. Some $\sqrt{n}$ elements that are ever in B reach position v of the sequence during the adversary operation sequence. Hence the total number of copies of the head nodes of the tripoles that are created during the adversary operation sequence is at least $pr\sqrt{n}/16 = \Omega(n\sqrt{n}/\log n)$. The theorem follows. □

6. Open problems.

Our work raises some interesting open problems:

1. Our proofs of the lower bounds for unique binary-search-tree representations use Ramsey's theorem; as a consequence, they require the universe to be extremely large relative to the dictionary ($|U|$ must be at least a tower of n 2's). If $|U|$ is only exponential in n, do the lower bounds still hold?

2. Is there a data structure for performing CONS operations on S-expressions in constant amortized time and constant amortized space, in general?

3. Prove (or disprove) that the problem of maintaining sets over a small, finite universe U under the complete repertoire of set operations (i,e., union, intersection, difference, etc.) has no *efficient* solution. An *efficient* solution is one that implements all set operations in $O(\text{polylog}(|U|))$ time.

4. Is there a data structure for sequence equality testing with $O(\text{polylog}(n))$ time and space per update operation, where n is the length of the updated sequence? If we are willing to use randomization and tolerate a probability of error in answering queries, then this can be achieved by representing sequences by using the standard signature method of taking the remainder modulo a randomly chosen prime. View each sequence as the base-m representation of a number, where m is the total number of update operations performed on the sequences. The resulting numbers are at most m^m each. Choose a random prime p in the range $[m^{3+c} \log m, 2m^{3+c} \log m]$, where c is a constant, and define the signature of a sequence s to be $s \bmod p$. Then, any particular set of m sequences will be assigned distinct signatures with probability at least $1 - 1/m^c$. In order to efficiently update the signature of a sequence we represent a sequence by the leaves of a balanced binary search tree (in left-to-right order) and store at each node the signature of the subsequence corresponding to its subtree. Leaving mundane details to the reader, we see that the resulting data structure requires only $O(\log m)$ time and space per update operation and errs during a sequence of operations with probability at most $1/m^c$. Alternatively, Sundar [19] gives an error-free randomized representation of sequences that supports joins/splits in $O(\log^2 n)$ expected time/space.

5. Is there a unique representation of sequences over $\{0, 1\}$ of DAG's by bounded outdegree that can be updated in $O(\text{polylog}(n))$ CONS operations, where n is the length of the updated sequence?

Acknowledgment. We thank Mike Fredman for valuable discussions.

A COMPLEXITY INDEX FOR SATISFIABILITY PROBLEMS*

E. BOROS[†], Y. CRAMA[‡], P. L. HAMMER[§], AND M. SAKS[¶]

Abstract. This paper associates a linear programming problem (LP) to any conjunctive normal form ϕ, and shows that the optimum value $Z(\phi)$ of this LP measures the complexity of the corresponding *SAT* (Boolean satisfiability) problem. More precisely, there is an algorithm for *SAT* that runs in polynomial time on the class of satisfiability problems satisfying $Z(\phi) \leq 1 + \frac{c \log n}{n}$ for a fixed constant c, where n is the number of variables. In contrast, for any fixed $\beta < 1$, *SAT* is still NP complete when restricted to the class of CNFs for which $Z(\phi) \leq 1 + (1/n^{\beta})$.

Key words. Boolean satisfiability, polynomial algorithms, NP completeness

AMS subject classifications. 90C09, 68Q15, 68T99

1. Introduction.

We consider Boolean formulae in *conjunctive normal form* (CNF), that is, formulae of the type

$$\phi(x_1, \ldots, x_n) = \bigwedge_{k=1}^{m} \left(\bigvee_{i \in P_k} x_i \bigvee_{i \in N_k} \overline{x}_i \right), \tag{1}$$

where $x_1, \ldots, x_n$ are Boolean variables, $\overline{x}_1, \ldots, \overline{x}_n$ are their *complements*, and $P_1, \ldots, P_m$, $N_1, \ldots, N_m$ are subsets of $\{1, \ldots, n\}$ satisfying $P_k \bigcap N_k = \emptyset$ for $k \in [m] = \{1, \ldots, m\}$. Each of the terms $C_k = \bigvee_{i \in P_k} x_i \bigvee_{i \in N_k} \overline{x}_i$ for $k \in [m]$ is called a *clause* of ϕ, and the quantity $|P_k \bigcup N_k|$ is called the *degree* of the clause. The *degree* of ϕ is the maximum degree of its clauses. The *size* of ϕ, denoted $|\phi|$, is the sum of the degrees of its clauses. The *satisfiability problem* for ϕ is to determine whether or not ϕ is *satisfiable*, i.e., whether or not there is an assignment $(a_1, \ldots, a_n) \in \{0, 1\}^n$ to the variables such that

$$\phi(a_1, \ldots, a_n) = 1. \tag{2}$$

The satisfiability problem is well known to be NP complete, even when the input is restricted to the class of degree 3 CNFs [3]. It is solvable in polynomial (linear) time in $|\phi|$ when ϕ is restricted to belong to the class of degree 2, or *quadratic* CNFs [1], [3], [5], and when ϕ is restricted to the class of *Horn* CNFs, i.e., to CNFs that satisfy $|P_k| \leq 1$ for all $k \in [m]$ [4], [6], [7].

The *complexity index* of the CNF ϕ (or of (2)) is the optimal value $Z(\phi)$ of the linear programming problem

$$Z(\phi) = \min Z \tag{3}$$

such that

$$(4)\qquad \sum_{i\in P_k}\alpha_i + \sum_{i\in N_k}(1-\alpha_i) \le Z \qquad (k = 1,\dots,m), \text{ and}$$

$$(5)\qquad 0 \le \alpha_i \le 1 \qquad (i = 1,\dots,n).$$

We refer to the above linear program as $LP(\phi)$. We call a CNF *q-Horn* if its complexity index is at most 1. It is easy to verify that both the quadratic and the Horn forms are in this class. Q-Horn formulae were introduced in [2].

The purpose of this paper is to show that the complexity index sharply delineates between classes of "easy" and "hard" satisfiability problems. In particular, we shall see that, for any fixed $\varepsilon > 0$, the class of satisfiability problems with complexity index smaller than $1+\varepsilon$ forms an NP-complete class. This is to be contrasted with the fact that the satisfiability problem for a q-Horn formula is polynomially solvable, as shown in [2] (see also §2). To express our results more precisely, let us introduce one more definition.

Given a function $f\colon \mathbf{N}_+ \to \mathbf{R}$, we define the problem $SAT(f)$ as follows:
Instance: a CNF formula $\phi(x_1,\dots,x_n)$ with $Z(\phi) \le f(n)$.
Question: is ϕ satisfiable?

We shall prove:

THEOREM 1.1. *$SAT(1+\frac{c\log n}{n})$ is polynomially solvable for all $c \in \mathbf{R}$.*

THEOREM 1.2. *$SAT(1+(1/n^{\beta}))$ is NP complete for all $\beta < 1$.*

Theorem 1.2 implies, in particular, that $SAT(1+\varepsilon)$ is NP complete for any fixed $\varepsilon > 0$. Theorems 1.1 and 1.2 follow from more general results that will be stated and proved in §§3 and 4.

2. Preliminaries. If ϕ is a Boolean formula on variable set X, and W is a subset of variables, we define the *reflection* of ϕ with respect to W to be the formula ϕ_W obtained from ϕ by complementing all occurrences of the variables in W. We say that ϕ and ψ are *congruent* if $\psi = \phi_W$ for some subset W. Trivially, two congruent formulae are either both satisfiable or not.

Suppose that ϕ is a Boolean formula and $T = (Z, \alpha_1,\dots,\alpha_n)$ is a solution to $LP(\phi)$. Let W be the set of variables x_j such that $\alpha_j < 1/2$. If $W = \emptyset$ we say that the solution $S(\phi)$ is *aligned*. Otherwise, if we define $\beta_j = 1-\alpha_j$ for $j \in W$ and $\beta_j = \alpha_j$ otherwise, then $S = (Z, \beta_1,\dots,\beta_n)$ is an aligned solution to $LP(\phi_W)$. We refer to the pair (ϕ_W, S) as the *aligned reflection* of (ϕ, T).

We now review some basic facts about q-Horn formulae (more details on this topic can be found in [2]). A *QHY-partition* for the CNF ϕ is a partition of the variables into three disjoint sets Q, H, and Y that satisfy the following conditions:

1. No clause contains more than two variables (complemented or uncomplemented) from Q.
2. Every clause contains at most one uncomplemented variable from H.
3. Every clause containing an uncomplemented variable from H contains no variables from Q.

If $Y = \emptyset$ then we say that (Q, H) is a *QH-partition.* It is easy to see that if ϕ has a QH-partition then ϕ is q-Horn, by setting $\alpha_j = 1/2$ for each $x_j \in Q$ and $\alpha_j = 1$ for each $x_j \in H$. More generally, ϕ is q-Horn if it is congruent to a formula that admits a QH-partition. Conversely, if ϕ is q-Horn, then ϕ is congruent to a formula ψ with aligned solution $S = (Z, \alpha_1,\dots,\alpha_n)$ with $Z \le 1$. Setting Q to be the set of variables with $\alpha_j = 1/2$ and H to be the set of variables with $\alpha_j > 1/2$, yields a QH-partition of ψ. Thus we have:

THEOREM 2.1 [2]. *A Boolean formula is q-Horn if and only if it is congruent to a formula that admits a QH-partition of its variables.*

In particular, this implies that quadratic, Horn, and so-called renamable or disguised Horn formulae [8] are q-Horn.

THEOREM 2.2 [2]. *Given a QH-partition of ϕ, there is an algorithm that tests satisfiability of ϕ in time $O(|\phi|)$.*

We describe this algorithm informally and leave the details of the linear time implementation to the reader.

Phase 1: While there is a clause involving exactly one variable, assign to this variable the 0-1 value required to satisfy the clause; if some clause becomes unsatisfiable due to such successive assignments, then stop : the CNF is not satisfiable.
Phase 2: Assign the value 0 to all remaining variables in H.
Phase 3: Solve the remaining (quadratic) satisfiability problem.

Finally, we note a corollary to Theorem 2.2.

COROLLARY 2.3. *Given a QHY-partition (Q, H, Y) of ϕ, there is an algorithm that tests satisfiability of ϕ in time $O(|\phi|2^{|Y|})$.*

Proof. Each of the $2^{|Y|}$ assignments A to the variables of Y determines a Boolean function ϕ_A on variable set $Q \bigcup H$. Trivially, ϕ is satisfiable if and only if at least one of the functions ϕ_A is satisfiable. It is easy to see that (Q, H) is a QH-partition of each of the ϕ_A, so each of these satisfiability problems can be solved in time $O(|\phi|)$ by Theorem 2.2. □

3. A simple satisfiability algorithm. In this section, we prove Theorem 1.1 by describing a simple algorithm for satisfiability, whose running time on any n-variable CNF ϕ is bounded above by $2^{6n\epsilon(\phi)}|\phi| + p(|\phi|)$, where $p(\cdot)$ is a polynomial function, and where

$$\epsilon(\phi) = \begin{cases} 0 & \text{if } Z(\phi) \leq 1, \\ Z(\phi) - 1 & \text{if } Z(\phi) > 1. \end{cases}$$

This implies that the algorithm runs in polynomial time on the set of SAT instances with $Z(\phi) \leq 1 + \frac{c \log n}{n}$.

The first step of the algorithm is to compute a solution $S = (Z, \alpha_1, \dots, \alpha_n)$ to $LP(\phi)$. By replacing the pair (ϕ, S) by its aligned reflection, we may assume that $\alpha_j \geq 1/2$ for each $j \in [n]$. The running time of this first step is bounded by a polynomial function of $|\phi|$.

The second part of the algorithm is provided by:

THEOREM 3.1. *There is a polynomial time algorithm A, which takes as input a CNF $\phi(x_1, \dots, x_n)$ and an aligned solution $S = (Z, \alpha_1, \dots, \alpha_n)$ to $LP(\phi)$ and produces a QHY-partition of the variables such that $|Y| < 6n\epsilon(\phi)$.*

The third and final part of the algorithm is now provided by Corollary 2.3: given a QHY-partition with $|Y| < 6n\epsilon(\phi)$, the satisfiability problem for ϕ can be solved in time $O(|\phi|2^{6n\epsilon(\phi)})$.

Proof of Theorem 3.1. If $Z \leq 1$ then ϕ is q-Horn and we are done. So suppose that $Z > 1$ and set $\epsilon = Z - 1$ $(= \epsilon(\phi))$. If J is an interval, let X_J denote the set of variables x_j for which $\alpha_j \in J$. Define $L = \frac{1-\epsilon}{2}$ and $R = \frac{2+2\epsilon}{3}$. We will need the following lemma.

LEMMA 3.2. *Let a and b be real numbers such that $(a, b) \subseteq (L, R)$ and $b - a > \epsilon$. Then $Q = X_{[1/2, a]}$, $H = X_{[b, 1]}$, and $Y = X_{(a, b)}$ is a QHY-partition of the variables.*

Proof. It suffices to check the three defining conditions of a QHY-partition.

To verify Condition 1, assume (for contradiction) that for some k, $P_k \cup N_k$ contains the indices, say u, v, and w, of three variables of Q. Then for this clause we obtain the following contradiction:

$$\sum_{i\in P_k}\alpha_i + \sum_{i\in N_k}(1-\alpha_i) \geq (1-\alpha_u)+(1-\alpha_v)+(1-\alpha_w) > 3(1-(R-\epsilon)) = 1+\epsilon.$$

To verify Condition 2, assume (for contradiction) that for some clause of index k there are two variables $x_u, x_v \in H$ such that $u \in P_k$ and $v \in P_k$. Then again we have a contradiction:

$$\sum_{i\in P_k}\alpha_i + \sum_{i\in N_k}(1-\alpha_i) \geq \alpha_u + \alpha_v \geq 2b > 2(L+\epsilon) = 1+\epsilon.$$

To verify Condition 3, assume (again for contradiction) that for a clause of index k, there are variables $x_u \in Q$ and $x_v \in H$, such that $u \in P_k \cup N_k$ and $v \in P_k$. Then for this clause, we obtain the contradiction:

$$\sum_{i\in P_k}\alpha_i + \sum_{i\in N_k}(1-\alpha_i) \geq (1-\alpha_u)+\alpha_v \geq (1-a)+b > 1+\epsilon. \qquad \square$$

To complete the proof of Theorem 3.1, we use Lemma 3.2 to find a QHY-partition with Y sufficiently small. Select p to be the largest integer such that $\Delta = \frac{R-L}{p}$ is greater than ϵ. For $q \in \{0, 1, \ldots, p\}$, set $c_q = L + q\Delta$. For each $q \in [p]$, the pair c_{q-1}, c_q satisfies the hypotheses on a, b in Lemma 3.2. Thus it is possible to construct a QHY-partition with $Y = X_{(c_{q-1},c_q)}$, for any $q \in [p]$. Because the intervals (c_{q-1}, c_q) are disjoint, one of them satisfies $|X_{(c_{j-1},c_j)}| \leq n/p$. The definition of p implies that $p+1 \geq \frac{R-L}{\epsilon} > 1 + \frac{1}{6\epsilon}$, and hence $\frac{n}{p} \leq 6\epsilon n$.

It remains to observe that we must have $p \leq n$, which implies that the index j such that $|X_{(c_{j-1},c_j)}|$ is smallest can be found in linear time. This is true since if $p > n$ then one of the sets $X_{(c_{q-1},c_q)}$ is empty and there would exist a QHY-partition with $Y = \emptyset$, contradicting the fact that $Z(\phi) > 1$, i.e., that ϕ is not a q-Horn formula. $\square$

4. Proof of Theorem 1.2. Theorem 1.2 will follow easily from the following:

THEOREM 4.1. *Given a positive integer t and a CNF $\phi(x_1, \ldots, x_n)$ of degree d, $d \geq 3$, a CNF ψ on $(1+t)n$ variables such that*

(i) *ϕ is satisfiable if and only if ψ is satisfiable, and*

(ii) $Z(\psi) \leq 1 + (1-\frac{2}{d})\frac{1}{t}$,

can be constructed in time polynomial in t and $|\phi|$.

Proof. Let ϕ be given by (1). Let ψ be the CNF on variable set $\{y_{ij} | 1 \leq i \leq n, 0 \leq j \leq t\}$ whose clauses are:

$$\bigvee_{i\in P_k} y_{io} \bigvee_{i\in N_k} \bar{y}_{it} \qquad (k = 1, \ldots, m), \tag{6}$$

$$\bar{y}_{ij} \bigvee y_{i,j+1} \qquad (i = 1, \ldots, n;\ j = 0, \ldots, t-1), \text{ and} \tag{7}$$

$$y_{io} \bigvee \bar{y}_{it} \qquad (i = 1, \ldots, n). \tag{8}$$

Clauses (7) and (8) ensure that in any satisfying assignment of ψ, $y_{io} = y_{i1} = \ldots = y_{it}$ for each $i \in [n]$. Identifying $y_{io}, \ldots, y_{it}$ with x_i, one easily concludes that ϕ is satisfiable if and only if ψ is satisfiable.

To show that $Z(\psi) \leq 1 + (1-\frac{2}{d})\frac{1}{t}$, let us define

$$\alpha_{ij} = \frac{1}{d} + \left(1 - \frac{2}{d}\right)\frac{j}{t}, \qquad (i = 1, \ldots, n;\ j = 0, \ldots, t).$$

Consider now a clause of type (6). Since $\alpha_{io} = \frac{1}{d}$ and $\alpha_{it} = 1 - \frac{1}{d}$, we obtain

$$\sum_{i \in P_k} \alpha_{io} + \sum_{i \in N_k} (1 - \alpha_{it}) = |P_k \bigcup N_k| \frac{1}{d} \leq 1.$$

Similarly, for the clauses of type (8),

$$\alpha_{io} + (1 - \alpha_{it}) = \frac{2}{d} < 1.$$

Finally, for the clauses of type (7)

$$(1 - \alpha_{ij}) + \alpha_{i,j+1} = 1 + \left(1 - \frac{2}{d}\right) \frac{1}{t}. \qquad \square$$

Proof of Theorem 1.2. Recall that the satisfiability problem for CNFs of degree 3 (3-SAT) is NP complete. Let r be a positive integer. By Theorem 4.1, there is a polynomial time reduction that maps any CNF ϕ of degree 3 on p variables to a CNF ψ on $n = p^{r+1} + p$ variables with $Z(\psi) \leq (1 + 1/3p^r)$. For a fixed $\beta < 1$ we choose $r = \lceil \frac{\beta}{1-\beta} \rceil$, which implies

$$n^\beta = (p^{r+1} + p)^\beta \leq (2p^{r+1})^\beta < 3p^{(r+1)\beta} \leq 3p^r,$$

and therefore $Z(\psi) \leq 1 + (1/n^\beta)$. Thus any instance of 3-SAT can be reduced in polynomial time to an instance of SAT$(1 + (1/n^\beta))$, implying the theorem. $\square$

THE SET UNION PROBLEM WITH UNLIMITED BACKTRACKING*

ALBERTO APOSTOLICO[†], GIUSEPPE F. ITALIANO[‡], GIORGIO GAMBOSI[§], AND MAURIZIO TALAMO[¶]

Abstract. An extension of the disjoint set union problem is considered, where the extra primitive backtrack(i) can undo the last i unions not yet undone. Let n be the total number of elements in all the sets. A data structure is presented that supports each union and find in $O(\log n/\log\log n)$ worst-case time and each backtrack(i) in $O(1)$ worst-case time, irrespective of i. The total space required by the data structure is $O(n)$. A byproduct of this construction is a partially persistent data structure for the standard set union problem, capable of supporting union, find, and find-in-the-past operations, each in $O(\log n/\log\log n)$ worst-case time. All these upper bounds are tight for the class of separable-pointer algorithms as well as in the cell probe model of computation.

Key words. disjoint set union, deunion, unlimited backtrack, design and analysis of algorithms

AMS subject classification. 68C25

1. Introduction.

The disjoint *set union problem* has been studied extensively during the past two decades [1], [2], [5], [10], [19], [20], [22]. The problem consists of maintaining an efficient internal representation for a dynamic partition of an n-element set S that undergoes a sequence of operations of the following kinds:

- union(A, B, C): combine the two subsets of S named, respectively, A and B into a new set named C.
- find(x): return the name of the unique subset of S that currently contains the element x.

Initially, the partition of S consists of the n singleton sets $\{1\}, \{2\}, \ldots, \{n\}$, and the name of set $\{i\}$ is i. Various conventions can be made about the way in which the name C is chosen in a union, and they give rise to a small number of variations of the problem. Typically, the name of every set at any time is maintained to coincide with the name (an integer in $[1, n]$) of one of the elements of that set. Also, the name C in a union is usually one of the names of the two input sets. Along these lines, C can be rigidly identified with A, or it can be left unspecified and result in either A or B at runtime, depending on the details of the implementation of a union. All such classes of restrictions do not affect the substance of the set union problem, but they allow the withdrawal of the third argument C from the format of a union. Throughout this paper we reason in terms of the primitive union(A, B), which combines the two subsets named A and B into a new set named either A or B.

The most efficient algorithms for the set union problem were devised by Tarjan and van Leeuwen [19], [22]. Such algorithms run in $O(n+m\alpha(m+n, n))$ time on a sequence consisting of at most $n-1$ unions and m finds. Here α is a functional inverse of the Ackermann function. No better performance is possible for the class of *separable-pointer algorithms* [20], [22], i.e., in the *pointer-machine* [12], [18], [20] model of computation. The storage of a pointer machine consists of an unbounded collection of records connected by pointers. Each record can contain an arbitrary amount of additional information, but no arithmetic is allowed in the computation of the address of a record. Separable-pointer algorithms must obey the following rules [2], [20]:

(i) The operations must be performed on line.

(ii) Each set element is a node of the data structure. There can also be additional nodes.

(iii) (*Separability*) After each operation the data structure can be partitioned into subgraphs such that each subgraph corresponds exactly to a current set. No edge leads from a subgraph to another.

(iv) To perform find(x) the algorithm obtains the node v containing x and follows paths starting from v until it reaches the node that contains the name of the corresponding set.

(v) During any operation the algorithm may insert or delete any number of edges. The only restriction is that rule (iii) must hold after each operation.

Recently, Fredman and Saks [5], [6] showed that even in the powerful *cell-probe* model of computation, which encompasses the power of a random-access machine, no better performance than $O(n + m\alpha(m + n, n))$ is possible for a sequence of n unions and m finds.

Despite the low amortized [21] bounds, Blum [2] showed that the worst-case bound per operation for the set union problem is $O(\log n / \log\log n)$.[1] Also, this upper bound is known to be tight for the class of separable-pointer algorithms [2] and in the cell-probe model of computation [6].

In recent years, some variants of the set union problem have been considered, where individual unions or sequence of unions can be backtracked upon [7], [8], [13], [15], [24]. Such extensions are motivated by problems arising in the memory management by Prolog interpreters [9], [13], [14], [23], in the incremental execution of logic programs [15], and in the implementation of search heuristics for resolution [11], [17]. Along these lines, Mannila and Ukkonen [13] proposed the *set union problem with backtracking*, where a third operation, *deunion*, which undoes the last union not yet undone, is introduced.

Westbrook and Tarjan [24] proved that any separable-pointer algorithm for the set union problem with backtracking requires $\Omega(m \log n / \log\log n)$ time in performing a sequence of m find, union, and deunion operations. They also gave several algorithms with $O(\log n / \log\log n)$ amortized running time, thus matching this lower bound. The overall space required by these algorithms is $O(n)$ [24].

An extension of the set union problem with backtracking is considered in [7], [8]. In this extension a real number is assigned to each union as the *weight* of that union, and it is possible to backtrack either to the union of maximal weight or to a generic union performed in the past. This extension has both a *static* [7] and a *dynamic* [8] version, depending on whether or not the weights can be dynamically updated. Both versions can be solved in $O(\log n)$ worst-case time per operation and in $O(n)$ overall space [8]. Also, this upper bound is tight for the class known as *non-separable-pointer algorithms* [16].

In this paper we consider a generalization of set union with backtracking where, in addition to the usual union and find operations, a primitive backtrack(i) that undoes the last i unions not yet undone is introduced. We call this problem the *set union problem with unlimited backtracking*. An efficient solution to this problem is desirable in several applications, notably, in the implementation of search heuristics for Prolog interpreters [9], [11], [17], [23]. In that framework, sequences of unions correspond to unifications between terms [14], and a multiple deunion would enable one to quickly recover from an unsuccessful search by returning to one of the most promising states among those examined so far.

Since backtrack(1) is simply a deunion operation, the algorithms in [24] can be easily adapted to handle unlimited backtracks, within the same amortized time and space performance. If, however, backtrack(i) is regarded as a single operation, then such an implementation requires $\Omega(n)$ time in the worst case.

[1] Throughout this paper all logarithms are taken to the base 2, unless explicitly noted otherwise.

Our implementation of the set union problem with unlimited backtracking takes worst-case time $O(\log n/\log\log n)$ for each union or find operation and constant time for each backtrack(i), irrespective of i. We use $O(n)$ overall space. Clearly, the $\Omega(\log n/\log\log n)$ per-operation lower bounds of [2] and [6] still hold for our problem, so that our bound is tight both in the separable-pointer and cell-probe models of computation.

A byproduct of our construction is a partially persistent [4] data structure that supports each union, find, and find-in-the-past operation in $O(\log n/\log\log n)$ worst-case time, with $O(n)$ space usage. This is faster than the bound achieved in [15], but the specifications of a union used in [15] are slightly different.

2. Union-find with deunion. As mentioned in [24], the data structure proposed by Blum [2] could be easily adapted to support deunions in $O(\log n/\log\log n)$ time per operation and in overall space $O(n)$. In this section we carry out the details of this extension that will serve as a basis for the subsequent developments. We start by recalling the tree structure used in [2].

For any $k \geq 2$ a k-UF *tree* is a rooted tree T such that

(i) the root has at least two children;
(ii) each internal node has at least k children;
(iii) all leaves are at the same level.

Clearly, the height of a k-UF tree with n leaves is bounded by $\lceil\log_k n\rceil$. We say that a node of a k-UF tree is *slim* if it has fewer than k children and is *fat* otherwise. A consequence of the aforementioned definitions is that only the root of a k-UF tree can be slim. Disjoint sets are represented by k-UF trees as follows. The elements of the set are stored in the leaves, and the name of the set is stored in the root. Furthermore, the root also contains the height of the tree and a bit specifying whether it is fat or slim.

A find(x) is performed by first climbing up the tree from the leaf containing x and then returning the name stored in the root. This takes $O(\log_k n)$ time.

To perform union(A, B) for two nonsingleton sets A and B, we need access to the roots r_A and r_B of the corresponding k-UF trees T_A and T_B. Blum assumed that his algorithm obtained r_A and r_B in constant time, prior to performing a union(A, B). If this is not possible, r_A and r_B can be obtained by means of two finds (i.e., find(A) and find(B)), because of the property that the name of a set is one of the elements of that set. Once r_A and r_B are available, the two k-UF trees T_A and T_B are combined as follows.

Assume without loss of generality that height(T_B) $\leq$ height(T_A). Let v be the node on the path from the rightmost leaf of T_A to r_A such that the subtree of T_A rooted at v has the same height as T_B. Node v is found by starting at r_A and then following the leftmost downward branch of each node for exactly height(T_A)$-$ height(T_B) steps. After node v is reached, the manipulations to be performed depend on the type of union, according to the following.

Type 1 — Root r_B is fat (i.e., has no fewer than k children), and v is not the root of T_A. Then r_B is made a sibling of v.

Type 2 — Roots r_A and r_B are fat, and v is the root of T_A. A new (slim) root r is created and both r_A and r_B are made children of r.

Type 3 — This type covers all remaining possibilities. Specifically, if root r_B is slim, then the children of r_B are made the rightmost children of v. If root r_B is fat, then, since we are not in type 1 or 2, we have that $v = r_A$ and v is slim. In this case all the children of r_A are made rightmost children of r_B.

Note that new arcs are created only as part of a type 1 or 2 union. Type 3 unions involve instead what we call *redirecting* existing arcs. We make the assumption that the node representing a singleton set is a fat node. From now on, we fix $k = \lceil\log n/\log\log n\rceil$. This choice of k is motivated by the following theorem by Blum [2].

THEOREM 2.1 [2]. UF *trees support either union or find in* $O(\log n/\log\log n)$ *time and* $O(n)$ *space.*

Blum [2] proved also that this bound is tight for the class of separable-pointer algorithms. Recently, this result was extended to the cell-probe model of computation by Fredman and Saks [6].

THEOREM 2.2 [2], [6]. *Any separable-pointer algorithm for the disjoint set union problem has single-operation worst-case time complexity* $\Omega(\log n/\log\log n)$. *The same lower bound holds in the cell-probe model of computation.*

A UF tree can be easily adapted to support deunions. We list the few upgrades needed. The resulting structure will be called a DUF *tree*. For each node v the children of v are also linearly ordered from left to right in a doubly linked list. Two DUF trees T_A and T_B are combined in much the same way as UF trees, except that type 3 unions are now expanded as follows. Assume root r_B is slim. All the children of r_B are made the rightmost children of v. The arc connecting the leftmost child of r_B to v is marked a *separator*, and the label of r_B (i.e., the old name of the set represented by T_B) is recorded in that arc. Similar manipulations are performed when r_A is slim.

Because of the linear order on the children of each node, each union can be implicitly described by its *characteristic arc*, defined as follows. The characteristic arc of a type 1 union is $(r_B, \text{parent}(v))$. The characteristic arc of a type 2 union is (r_A, r). Finally, the characteristic arc of a type 3 union is the separator associated with that union. With the help of a stack P, characteristic arcs allow quick deunions to be performed. Following each union, a pointer to its characteristic arc is pushed onto P, along with the type identifier (1, 2, or 3) of that union. Type 1 and type 2 unions are then easily undone in constant time, following the pointer to the characteristic arc. To undo a type 3 union we access the separator pointed to by the top of the stack and disconnect this arc and all the arcs to its right. All the nodes so detached from the tree are made children of a new root to which the name stored in the separator is assigned. By the definition of type 3 union, this requires $O(k)$ time. Note that $O(n)$ nodes and arcs can be in the structure at any time. The stack records correspond to unions not yet undone, and there can be at most $n - 1$ such unions. Therefore, the total space required is $O(n)$. In conclusion, the following theorem holds.

THEOREM 2.3. DUF *trees support each union, find, and deunion in* $O(\log n/\log\log n)$ *time and* $O(n)$ *space.*

3. Upgrading DUF trees. In the set union problem with unlimited backtracking, deunions are replaced by backtracks: for any integer $i \geq 0$ backtrack(i) undoes the last i valid unions performed. Backtrack(i) is performed on DUF trees in $O(i\ \log n/\log\log n)$ time, simply by carrying out i deunions as described in §2. This is clearly undesirable, since i can be $\Theta(n)$. On the other hand, as long as we insist on deleting arcs the moment that they are invalidated by backtracking (i.e., in the *eager* mode [24]) the cost of backtrack(i) is $\Omega(i)$, since at least one arc must be removed for each erased union. To sidestep this lower bound, the removal of arcs invalidated by backtracking must be deferred to some possible future operation. This mode of operation is called *lazy*. In a strict sense, the lazy approach infringes on the separability condition stated in the introduction. However, the substance of that condition would still be met if one maintains that an arc is never traversed once it is invalidated (see, e.g., [24]). Our approach guarantees this fact and thus does not depart substantially from the separability assumption.

In what follows we present a data structure suitable for storing a collection of disjoint sets in such a way that the identity of each set in the collection is preserved. We call this data structure a k-BUF tree or, with the implicit assumption that $k = \lceil\log n/\log\log n\rceil$, simply a BUF tree. We will show that BUF trees support union and find in $O(\log n/\log\log n)$ time and backtrack(i) in constant time, independent of i.

We begin by describing the main features of BUF trees and by highlighting the associated implementation of the union, find, and backtrack operations. BUF trees retain the basic structure of DUF trees but differ from them primarily because of some implicit attributes defined on the arcs. With BUF trees a union is still performed according to one of three different patterns of management, as with DUF trees. In particular, we will have that type 1 and type 2 unions *create* new arcs, whereas type 3 unions only *redirect* already existing arcs. With BUF trees, however, a union must perform some additional manipulations on arcs, besides those pertaining to the mere aggregation of the two input subsets. In the following we say that an arc e is *handled* by a certain union only if e is either created or redirected by that union during the aggregation stage of that union. The main difference with DUF trees is that now, because of the lazy approach, we allow arcs and separators to possibly survive in the data structure also after the union that introduced them has been invalidated by backtracking. At any given time we call a union *valid* if it has not yet been undone by backtracks, and we call it *void* otherwise. We further partition void unions as follows. A void union is *persisting* if the arcs handled by that union have not yet been actually removed from the data structure, and it is *dissolved* otherwise. This classification of unions induces a corresponding taxonomy on arcs and separators as follows. In a BUF tree an ordinary arc can be *live*, *dead*, or *cheating*, and a separator arc can be, in addition, either *active* or *inactive*. Informally, live arcs represent connections not yet invalidated by backtracks; this happens when the last union that handled them is still valid. Dead arcs instead represent connections that, although still in the structure, only await destruction; this happens when the first union that created them is a void persisting union. Between live and dead arcs lie cheating arcs. They occur when the first union that created them is valid but the last union that handled them is a persisting type 3 union. Therefore, they represent faulty connections that do not have to be destroyed but have only to be replaced by the corresponding correct connections. As in DUF trees, separators are associated with type 3 unions. At any given time a separator is *active* if its associated union is valid and is inactive otherwise. A node of a BUF tree is *live* if there is at least one live arc entering it and is *persisting* otherwise. In analogy with the nodes of DUF trees, the live nodes of BUF trees can be *slim* or *fat*, but this is decided based only on the number of live arcs entering each node. Specifically, a node is slim if the number of live arcs entering it is less than k and is fat if the number of live arcs entering it is at least k.

Assume that we perform an intermixed sequence σ of union, find, and backtrack operations starting from the initial partition of S into n singletons. The partition of S that results from σ is the same as that produced by applying to S, in the same order as in σ, only those unions that are valid (i.e., not undone by backtracks) at the completion of σ. The subsequence of σ consisting only of unions that are still valid by the end of σ (i.e., by neglecting the unions made void by backtracking) is called the *virtual sequence of unions*. The following rules ensure that at any time each currently valid union u is assigned a unique integer $\text{ord}(u)$ representing the ordinal number of u in the current virtual sequence of unions:

(i) The first union performed gets ordinal number 1.

(ii) When a union is made void by backtracking, it relinquishes its ordinal number.

(iii) A new union gets an ordinal number equal to 1 plus the ordinal number of the last valid union performed.

At some point of the execution of σ, let $i_{\max}$ be the ordinal number of the last valid union performed so far. Backtrack(i) consists of removing the effect of the last i valid unions, that is, the effect of the last i unions in the current virtual sequence of unions. We perform backtrack(i) simply by setting $i_{\max} = \max\{i_{\max} - i, 0\}$, i.e., in constant time irrespective of i. This implementation of backtrack does not affect any arc in the forest, but its effect is implicitly recorded in the change of status of some arcs and separators. Part or all of these arcs might be removed or redirected later, while subsequent union operations are performed. In any event, we need to ensure the consistency of the forest of trees under this newly introduced operation. By the forest being consistent we mean that each tree in the forest stores a collection of sets in the current partition in such a way that, for any x, a find(x) executed as specified in the following correctly returns the name of the set currently containing x. We refer to the consistency of the forest as Invariant 0. The complete specification of this invariant requires some additional notions.

First, each arc e in a BUF tree T has two unions associated with it, as follows. The first union, denoted first_ union(e), is the union that created e. The second union, last_ union(e), is the last union not yet actually undone (i.e., either a valid or a persisting union) that handled e. We will maintain that ord(first_ union(e)) $\leq$ ord(last_ union(e)) for every arc e. In a consistent BUF tree an arc e is *dead* if and only if first_union(e) is void (i.e., e has to be destroyed since it gives a connection made void by some intervening backtrack). Similarly, arc e is cheating if and only if first_union(e) is valid and last_union(e) is void (i.e., e gives a faulty connection and hence has to be replaced but not completely destroyed). Finally, e is *live* (i.e., it gives a connection not yet affected by backtracking) if and only if last_union(e) is still valid. In addition to first_union and to last_union, each separator s also has associated the type 3 union that made it a separator. In the following, such a union will be referred to as separate_ union(s). A separator s is active if and only if separate_union(s) is valid and is inactive otherwise.

To complete our description of a consistent BUF tree T, let $S_1, S_2, \ldots, S_p$ be the disjoint sets stored in T. We specify the mapping from the set of leaves of T to the set of names of $S_1, S_2, \ldots, S_p$. Let x be a leaf of T and also a member of the set S_q, $1 \leq q \leq p$. Let Y be the name of S_q. Ascend from x towards the root of T following live arcs until a node without an outgoing live arc is met. Call this node apex(x). In a consistent BUF tree an apex falls always in one of the following three classes.

1. *Live apex* — There is no arc leaving apex(x), i.e., apex(x) is the root r of T. We will maintain that the name Y of S_q is stored in r.

2. *Dead apex* — The arc leaving apex(x) is dead. We will maintain that the name of S_q is stored in apex(x).

3. *Cheating apex* — The arc e leaving apex(x) is cheating. In this case we will maintain that at least one inactive separator falls within $k - 1$ arcs to the left of e and that the name of S_q is stored in the rightmost such separator.

The preceding description explains how a find is performed on a BUF tree. Throughout the sequence of union, find, and backtrack operations we need to maintain the forest of BUF trees in such a way that any arbitrary find would give a consistent answer. We formalize this condition as Invariant 0.

INVARIANT 0 (*find consistency*). Prior to the execution of each operation of a sequence σ of operations and for every element x of S, the following holds. If apex(x) is either dead or live, then the name of the set containing x is stored in apex(x). If apex(x) is cheating, then the name of the set containing x is stored in the rightmost inactive separator to the left of apex(x), and such a separator falls within $k - 1$ arcs to the left of apex(x).

The following fact is an immediate consequence of Invariant 0.

FACT 3.1. BUF *trees support each find operation in time $O((k+h)t)$, where t is the time needed to test the status of an arc and h is the maximum length of an ascending path from a leaf x to its apex in the tree.*

In the following sections we show that it is possible to implement BUF trees in such a way that t is $O(1)$ and h is $O(\log_k n)$. This immediately yields the claimed $O(\log n/ \log\log n)$ time bound for each find.

We now examine what is involved in performing union operations. Let A and B be two different subsets of the partition of S, such that $A \neq B$. In the collection of BUF trees that represents this partition, let T_1 and T_2 be the trees storing, respectively, A and B. We remark that two disjoint sets can happen to be stored in the same tree, so that T_1 and T_2 may coincide even if $A \neq B$. The first task of union(A, B) consists of finding in T_1 and T_2 the roots of the smallest subtrees that store, respectively, A and B. These roots are located by performing two finds. The associated subtrees have to be detached from their host trees and then combined into a single tree. Once the two subtrees have been located and detached, their unification requires a treatment quite similar to that of the union procedure described for DUF trees in §2. The most delicate part of the process, however, is in the first stage. The correctness of the two initial finds depends on our ability to preserve Invariant 0 through each union, find, and backtrack. This is discussed in the next sections.

4. Dominance trees and the procedure Restore. As said, we follow the lazy approach of undoing unions made void by backtracks not immediately, but rather during the execution of subsequent unions. Within the claimed time bounds, however, a single union cannot undo *all* the currently persisting unions. On the other hand, this is also not strictly necessary. What is necessary for a union is to undo all the persisting unions that undermine its own consistent execution, along with the validity of Invariant 0 on the resulting forest of BUF trees. It turns out that such a reduced task can be performed within the claimed time and space bounds, at the expense of some additional bookkeeping.

Our technique consists of maintaining the edges in every BUF tree T grouped into clusters, a *cluster* being defined as a maximal set E of consecutive sibling arcs with the property that last_union is the same for all the elements of E. We will maintain that the size of any cluster is at most $k - 1$ at any given time. At any point in the computation, a cluster is persisting if the field *last* common to its arcs exceeds the current value of $i_{\max}$ (i.e., if the last_union of its arcs is void), and it is live otherwise. This section describes the structure of such clusters and then details the operation of a procedure, called Restore, that will carry out a recurrent subtask of our BUF-tree implementation of a union. In informal terms, the task of Restore is that of removing all dead arcs from the input cluster, and then partitioning the remaining arcs in a certain number of smaller, yet live clusters. We will see that any union involves at most a constant number of calls to Restore and that the cost of each such call is $O(\log n / \log\log n)$ time.

Before describing the structural properties of clusters, we need to make some additional assumptions on the structure of BUF trees. To each arc e, two integers first(e) and last(e) are assigned. They represent, respectively, the ordinal number given to first_union(e) and to last_union(e). Besides first(s) and last(s), each separator s contains the following additional information. An attribute separate(s) is the ordinal number given to separate_union(s). Furthermore, label(s) is the name destroyed by separate_union(s), and number(s) is the total number of arcs moved during the execution of separate_union(s). These latter arcs will be maintained to fall immediately to the right of s. Since separate_union(s) is a type 3 union, number(s)$< k$. By the definition of a cluster, all the edges in a cluster E have the same value of *last* field. We refer to last(E) as the value shared by the last fields of all the arcs in E.

For each node v, fat(v) is the ordinal number of the last union that made v a fat node, provided that the effects of that union have not been actually removed from the data structure (i.e., that union is not a dissolved union). If no such union exists, then fat(v) is undefined. According to this convention, a slim node that was once fat may have a defined fat number. In addition to Invariant 0, we will maintain the invariants given below.

INVARIANT 1 (the $i_{\max}$ invariant). At any time, the following properties hold. For every arc e in a BUF tree, arc e is dead if and only if $i_{\max} <$ first(e), is cheating if and only if first$(e) \leq i_{\max} <$ last(e), and is live if and only if $i_{\max} \geq$ last(e). If, in addition, e is a separator, then e is inactive if and only if $i_{\max} <$ separate(e) and e is active if and only if $i_{\max} \geq$ separate(e). For every node v in the tree such that fat(v) is defined, fat$(v) \leq i_{\max}$ if and only if v is fat.

Maintaining Invariant 1 enables us to test the status of an arc in constant time. One more important consequence of this invariant is that either all arcs in a cluster are live or none is. Let now e and f be two arcs in a cluster E. We write $e < f$ if e precedes f in the left-to-right order, and we denote by $|f - e|$ the number of consecutive arcs between e and f (including both). If s is a separator in E, then we say that s *dominates* f if and only if $s < f$ and $|f - s| \leq$ number(s). We maintain also the following invariant.

INVARIANT 2 (the nesting invariant). Let E be a cluster. If $|E| = 1$, then the only element of E is not a separator. Assume now $|E| > 1$. Then, if the leftmost arc of E is a separator, say, s, then separate$(s) =$ last(s) and number$(s) = |E|$. If the leftmost arc of E is not a separator, then $|E| = 2$, E is the leftmost one among its sibling clusters, and E contains no other separators. In general, if s' and s'' are any two separators in E and s' dominates s'', then s' also dominates any arc e dominated by s''.

The nested structure of a cluster E delimited by a left separator is described in detail with the aid of a rooted, ordered tree called the *dominance tree* $D(E)$ of E. The leaves of $D(E)$ in preorder correspond bijectively to the arcs of E (including separators) from left to right; the internal vertices of $D(E)$ correspond bijectively to the separators. Thus, given a simple arc e in E, there is only one leaf ℓ in $D(E)$ corresponding to e, while there is a leaf ℓ and also an internal vertex v in $D(E)$ in correspondence with each separator of $D(E)$. If s is such a separator, then ℓ is the leftmost leaf in the subtree of $D(E)$ rooted at v.

The main feature of $D(E)$ is the following. Let ℓ be the leaf of $D(E)$ that corresponds to arc $e \in E$. Then, the internal vertices on the path from ℓ to the root of $D(E)$ correspond to the separators that dominate e, in the same succession as such separators are met in E starting from e and scanning E from right to left (see Fig. 1). In the following we will not distinguish between an arc or separator of E and its corresponding vertex in $D(E)$ whenever our meaning is made clear by the context.

Besides representing the nestings of separators, dominance trees encapsulate some monotonicity properties that form the object of our next invariant. Specifically, each vertex v in a dominance tree $D(E)$ gets assigned an integer $r(v)$ $(1 \leq r(v) \leq n)$, with the following meaning. If v is a leaf, then $r(v) =$ first(v). If v is an internal vertex (hence it maps a separator), then $r(v) =$ separate(v). We now consider all the arcs entering a node in a BUF tree as partitioned into clusters, and we assign similar numbers, denoted by R, to such clusters. Specifically, if either E is the leftmost cluster or $|E| = 1$, then $R(E) =$ first(e), where e is the leftmost arc in E. Otherwise, $R(E)$ is separate(s), where s is the separator that coincides with the leftmost arc in E (cf. Invariant 2). The numbers assigned in this way to the vertices of dominance trees and clusters of arcs entering a node will satisfy the monotonicity condition given below.

INVARIANT 3 (the monotonicity invariant). Let the dominance tree $D(E)$ of cluster E be defined. Hence $|E| > 1$. Then the two leftmost children of each internal vertex of $D(E)$ are always two leaves. Moreover, every internal node s (which must correspond to a separator) has number(s) equal to the number of leaves of the subtree of $D(E)$ rooted at s. Furthermore, if v and v' are sibling vertices of $D(E)$ with $v < v'$, then one of the following two cases applies: (i) if v and v' are the two leftmost vertices among their siblings (and thus leaves by the preceding part of this invariant) with $v < v'$, then $r(v) = r(v')$; (ii) otherwise, $r(v) < r(v')$. We also have that if p is the parent of v, then $r(p) > r(v)$. The individual clusters entering a slim node of a BUF tree obey the following rules. The leftmost cluster of arcs entering a slim node

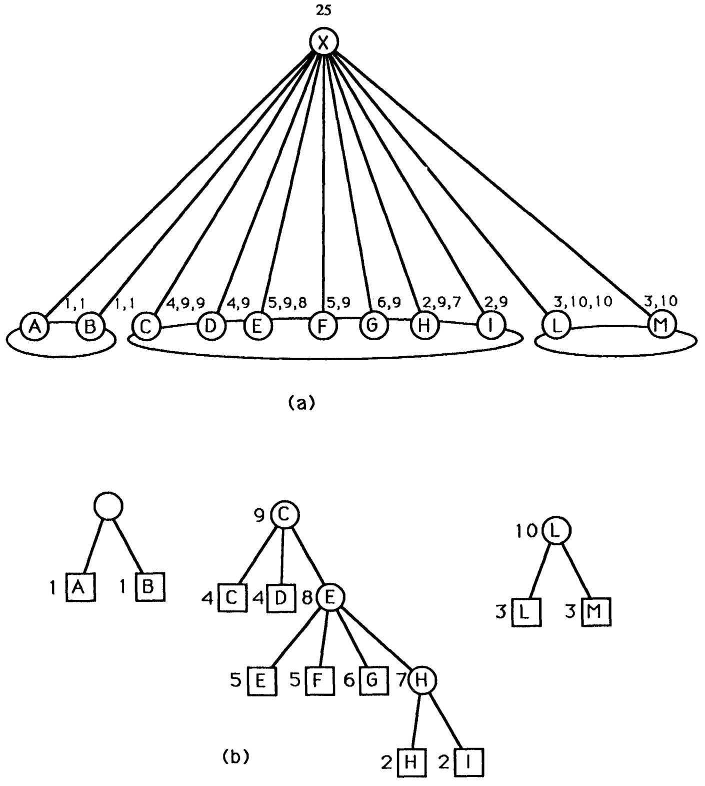

FIG. 1. BUF *trees and dominance trees.* (a) *The* BUF *tree produced for* $k > 10$, *by applying to an initial singleton partition the ordered sequence of unions*: union(A, B), union(H, I), union(L, M), union(C, D), union(E, F), union(F, G), union(F, I), union(D, G), union(A, E), union(B, L). *The first two numbers at the bottom right of each arc represent, respectively, the* first *and* last *field for that arc. Separators are also labeled with a third number, representing their* separate *field. This sequence produces* 3 *clusters and the* 4 *separators* (C, X), (E, X), (H, X), *and* L, X). contains two arcs and no separators. Furthermore, if E and E' are clusters of arcs entering the same slim node and E is on the left of E', then $R(E) < R(E')$.

As one of the consequences of Invariant 3 we get that if f is an arc dominated by a separator s, then first(f) < separate(s). Our last two invariants are as follows.

INVARIANT 4 (the slim compression invariant). The live arcs entering any slim node are leftmost among their siblings and have nondecreasing last fields, from left to right. For fat nodes this property holds for all the arcs that were directed to that node while the node was slim, including the arcs that made the node fat.

The slim compression invariant enables us to decide in $O(k)$ time whether a node is slim or fat simply by examining the at most k leftmost arcs entering that node.

INVARIANT 5 (the numbering invariant). For any integer i, $1 \leq i \leq n - 1$, there are either at most two sibling arcs with first field equal to i or at most one arc with separate field equal to i. Moreover, there are at most $k - 1$ sibling arcs with last field equal to i, and such arcs are in a cluster. Let E be this cluster. If E contains only one arc e, then first(e) = last(e). If $|E| > 1$, then the first two arcs of E have the same first field, the second arc of E is not a separator, and the remaining arcs possibly existing in E have first fields different from that of the first two arcs. Moreover, if the leftmost arc of E is not a separator, then $|E| = 2$ and the first fields of its two arcs are equal to their last fields. Otherwise, each arc in E has last field strictly greater than first field, and the leftmost arc has separator field equal to i. Finally, given i we can access in constant time the arcs with first field equal to i or with separator field equal to i.

The numbering invariant guarantees that the size of each cluster is at most $k - 1$ and that no two distinct clusters can have arcs with identical last fields. The last part of the invariant implies that a singleton cluster or a cluster not delimited by a left separator cannot contain cheating arcs. Thus such types of clusters contain either live or dead arcs.

We are now ready to describe how a persisting cluster of m arcs is detached from its host BUF tree in $O(m)$ time, maintaining Invariants 0–5 on the resulting dismembered structure. This is accomplished by the procedure Restore, which takes as input some arc e and an integer value $i_{\max}$. The specific tasks of Restore are as follows:

1. to identify the cluster E containing e;

2. to delete the dead arcs possibly existing in E;

3. to redirect the cheating arcs possibly existing in E towards newly introduced roots, in such a way that, by letting F be the forest of trees into which T has been dismembered, the following hold: (3.1) F represents, through Invariant 0, precisely the same collection of subsets of S formerly represented by T, and (3.2) all nondead arcs of E become live arcs in F.

To analyze what is involved in a Restore(e, $i_{\max}$), let E be the cluster containing e. If e is already live, then, by the $i_{\max}$ invariant, so are all the other arcs in E, so that Restore does not need to do anything. Henceforth we assume last(e) $> i_{\max}$, i.e., e is either cheating or dead. Then, by the definition of cluster, there cannot be any live arc in E. To deal with the most general case, assume that $D(E)$ is defined (i.e., E has a left separator) and let ℓ be a leaf of $D(E)$. With reference to the BUF tree T containing E, let v be the node from which arc ℓ originates, and let T' be the subtree of T rooted at v. Assume that ℓ is a dead arc of E. By Invariant 0 any leaf of T' connected to v by a path consisting solely of live arcs belongs currently to the set whose name is stored in v. Thus Restore can accomplish its task just by deleting ℓ. Assume now that ℓ is a cheating arc, and let as(ℓ) and is(ℓ) be, respectively, the highest active and lowest inactive separator on the path from ℓ to the root of $D(E)$. Observe that Invariants 2 and 5 guarantee that is(ℓ) is always defined in the case being considered. In the following, the expression "to the left of" is used to mean "to the left of and including."

LEMMA 4.1. *In E,* is(ℓ) *is the rightmost inactive separator to the left of ℓ.*

Proof. The assertion follows trivially from the definition of $D(E)$ if ℓ itself is an inactive separator in E. Thus we concentrate on the case where ℓ is not an inactive separator. Assume for a contradiction that the rightmost inactive separator to the left of ℓ in E is some s' such that $s' \neq$ is(ℓ) and $s' \neq \ell$ (see Fig. 2). By Invariant 2 and our choice of is(ℓ), separator s' cannot be on the path from ℓ to the root of $D(E)$ and thus does not dominate ℓ. Since s' falls in E between is(ℓ) and ℓ and since is(ℓ) dominates ℓ, then is(ℓ) dominates s', whence s' must lie in the subtree of $D(E)$ rooted at is(ℓ). Since s' is to the left of ℓ in E and $s' \neq \ell$, then in such a subtree of $D(E)$ we have that s' or an ancestor of s' is a left sibling of either ℓ or an ancestor of ℓ. Then let v stand for s' or the ancestor of s', and let v' stand for ℓ or the ancestor of ℓ, according to the case. By Invariant 3 and the $i_{\max}$ invariant, s' being an inactive separator implies that v is an inactive separator. By the same invariants, if v' is not ℓ, then v' is an active separator. If v' is an active separator, then always, by Invariant 3, $r(v) \leq r(v')$, whence v' active forces v to be active too, a contradiction. If v' coincides with ℓ, then the fact that ℓ is a cheating arc (i.e., first(ℓ) $\leq i_{\max}$), along with the conditions $r(v') =$ first(ℓ), $r(v) =$ separate(v), and $r(v) \leq r(v')$ (cf. Invariant 3), leads again to the contradiction that v is inactive. □

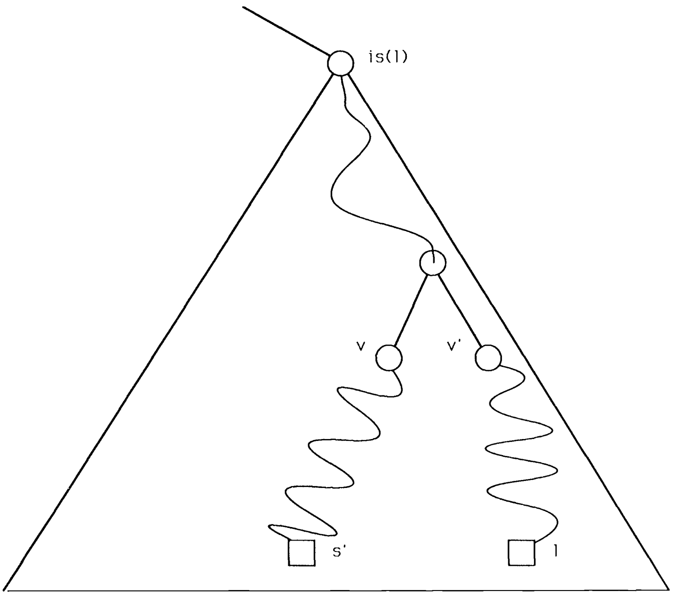

FIG. 2. *Illustration of Lemma* 4.1.

LEMMA 4.2. *If* as(ℓ) *is defined, then* as(ℓ) *is a direct son of* is(ℓ). *Moreover, the subtree of* $D(E)$ *rooted at* as(ℓ) *does not contain any inactive separator.*

Proof. If as(ℓ) and is(ℓ) are both defined, then from the fact that as(ℓ) is active and is(ℓ) is inactive we get that separate(as(ℓ)) < separate(is(ℓ)). By Invariant 3 is(ℓ) is then an ancestor of as(ℓ). That as(ℓ) is a son of is(ℓ) then follows straightforwardly from their respective definitions. The second part of the claim is an easy consequence of Invariant 3. □

Once $D(E)$ is given, it is easier to specify the operation of Restore so as to carry out tasks 1–3 consistently with Invariant 0. For this, let $E = \{e_1, e_2, \ldots, e_h\}, h < k$, be the cluster handled by Restore, and let x_i, $1 \leq i \leq h$, be the node of the BUF tree T from which arc e_i originates. As already observed, if one of the e_i's is live, then all the e_i's are live and Restore can terminate without affecting the structure of T. Assume therefore that E contains only cheating and dead arcs. The only leaves of T for which something must change are those whose previous apex was one of the x_i's. If x_i was a dead apex, then Restore will make x_i a live apex by simply deleting e_i. In this way the name of the set of leaves having apex in x_i remains the same. If x_i was cheating, then Restore will move the arc e_i to a new root with name label(is(e_i)) and will reset the last field of e_i to separate(as(e_i)). By Lemma 4.1, is(e_i) is the rightmost inactive separator to the left of e_i, so that also in this case all the nodes with apex x_i preserve their name. Each one of the aforementioned cases can be handled trivially in $O(k)$ time, but Restore must update *all* the arcs of E within this bound. The main handle for this is given by the nested structure of $D(E)$. To clarify this point, we describe a computation on $D(E)$ that we call Dismember (see Fig. 3).

The goal of Dismember is threefold. First, it will disconnect from its father every internal node of $D(E)$ that corresponds to an inactive separator. Thus in the forest of trees produced by Dismember no internal vertex other than a root can be an inactive separator. Second, Dismember will delete every leaf corresponding to a dead arc. Finally, Dismember will reset the last field of every surviving leaf ℓ to the separate field of the highest active separator on the path from ℓ to the root of $D(E)$ if such a separator exists and to first(ℓ) otherwise. Thus

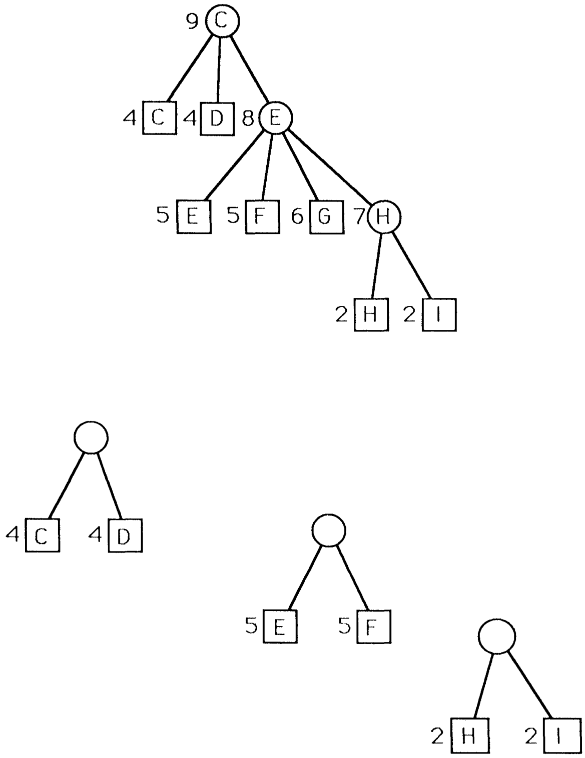

FIG. 3. *The effect of a dismember with* $i_{\max} = 5$ *on the second cluster of Fig.* 1(b).

there will be only live leaves in the output forest. Observe that these goals are unambiguous and mutually consistent, in force of Lemmas 4.1 and 4.2. The computation can be scheduled according to the preorder visit of the vertices of $D(E)$. It starts thus at the root of $D(E)$ and proceeds with the help of a stack P, which is used to store the inactive separators encountered in the visit. An inactive separator s is pushed onto P the first time it is visited and is popped from P immediately after all nodes in the subtree rooted at s have been handled. When a separator is popped from P, it is also disconnected from its father in $D(E)$ and it relinquishes its attributes as a separator in E. Assume that separator s was just pushed onto P. The computation considers all the children of s from left to right. If the child being considered is a leaf, then its last field is immediately updated. If it is an active separator, then Dismember visits the subtree of $D(E)$ rooted at such a separator updating all leaves in that subtree. Finally, if the child being considered is an inactive separator, then it is pushed onto P and the computation proceeds recursively on the children of such a separator.

It is clear that Dismember takes time $O(|E|)$. Assume that whenever Dismember deletes a leaf of $D(E)$ it also removes the corresponding arc of E. This accomplishes subtask 2 of Restore. The following few extra manipulations on the forest at the outset of Dismember suffice to accomplish subtask 3. First, for each tree D in that forest, the root x of a new BUF tree is created. Next, the arcs of E that are mapped into the leaves of D are considered in their left-to-right order, and each arc is redirected to x in succession, along with its applicable attribute fields (i.e., first and last and, for separators, also label, separate, and number). The only exception to this rule is represented by the leftmost arc, which corresponds to the leftmost leaf of D and also to the root of D. This arc surrenders its separator attributes, thus relinquishing its status as a separator, but its label field is stored into node x. The remaining separators are active, and they retain their attributes. Observe, incidentally, that the number field of each such separator is still consistent, in force of the second part of Lemma 4.2 (no pruning of $D(E)$ takes place below an active separator). At this point Lemma 4.1 and Invariant 0 yield that subtask 3.1 of Restore is accomplished provided only that every surviving arc of E is live. Recall that the only field changed by Dismember is the last field of cheating leaves and their associated separators. Specifically, the last field of a leaf ℓ is set equal to separate(as(ℓ)) if as(ℓ) is defined and is set equal to first(ℓ) otherwise. Invariant 3 guarantees then that every leaf of D has become live in this way, which accomplishes subtask 3.2.

We now consider subtask 1, and we also dispose of the cases where $D(E)$ is not defined. Clearly, Restore(e, $i_{\max}$) can check the status of e in constant time by the $i_{\max}$ invariant. For live e the procedure does nothing more. Thus we concentrate on the cases where e is either dead or cheating. By Invariant 5 and the definition of a cluster, the cluster E containing e is formed by at most $k - 1$ arcs. Thus E can be identified trivially in $O(k)$ time by checking the last fields of the arcs in an interval containing e and of size at most $k + 1$. If E is not delimited by a left separator, then (cf. Invariant 5 and the comment following it) we have $|E| = 2$, and the arcs in E are dead. The procedure deletes these two arcs and terminates, in constant time.

As is easily checked, there is no need to maintain dominance trees explicitly. The traversal of $D(E)$ performed by Dismember can be simulated by scanning E from left to right with an auxiliary stack. The stack is used as before to store the separators encountered in the scanning, a separator being kept in the stack until all the arcs within its dominion have been updated. Although $D(E)$ is not given explicitly, the procedure can use some easy bookkeeping on the number fields of the separators in order to detect the condition that the dominion of a separator has been exhausted. In conclusion, we can record the following theorem.

THEOREM 4.3. *There is an implementation of* Restore(e, $i_{\max}$) *that takes time* $O(k)$.

We now show that Restore preserves our invariants.

THEOREM 4.4. *The procedure* Restore *maintains Invariants* 0–5.

Proof. Let $E = \{e_1, e_2, \ldots, e_h\}, h < k$, be the cluster handled by Restore, and let x_i, $1 \leq i \leq h$, be the node of the BUF tree T from which arc e_i originates. Since Restore does nothing if one (hence every) e_i is live, we assume henceforth that E contains only cheating and dead arcs.

That Invariant 0 is maintained by Restore follows straightforwardly from the discussion preceding Theorem 4.3. That discussion also shows that Restore preserves the part of Invariant 1 that involves $i_{\max}$. Consider now the part of Invariant 1 that involves the fat field. Since all newly introduced nodes are slim by construction, these nodes do not have a defined fat field. The only other node of T whose fat field could be possibly affected by Restore is the node v that the arcs in the cluster E were entering prior to Restore. Since the arcs of E are not live, however, they did not contribute in any way to the fatness of v (only live arcs do). Since the procedure does not change the value of $i_{\max}$, then v will remain slim or fat after Restore, consistent with before.

To discuss the next invariants, consider the forest of trees produced by Dismember. We have already seen that every nontrivial tree in such a forest represents a collection of formerly cheating arcs of E that were changed into live arcs. We show now that Restore has actually done more than just resuscitate those arcs. Specifically, we claim that every nontrivial tree in the forest produced by Restore represents a collection of live clusters that obey, with their associated dominance trees, every applicable property in Invariants 2–5.

For this, let D be one of the trees produced by Dismember, and let s be the inactive separator of E that corresponds to the root of D. Consider the children of s in $D(E)$, from left to right. The first observation is that if s became the root of nontrivial tree D, then s has at least two children and the two leftmost children of s in D are precisely the two leftmost children of s in $D(E)$. In fact, let ℓ and ℓ' be the two leftmost children of s in $D(E)$. Then, Invariant 3 guarantees that first$(\ell) =$ first(ℓ'). If ℓ and ℓ' are both dead, then they are deleted. However, no sibling of ℓ in $D(E)$ could be a live leaf or an active separator in this case because of the monotonicity of the r-values prescribed by Invariant 3 for ℓ and its siblings. Hence s could not be the root of a tree in the forest built by Dismember. Assume now that ℓ and ℓ' are cheating. Then, as(ℓ) and as(ℓ') are not defined and is$(\ell) =$ is$(\ell') = s$. In this case s will be the root of a tree, within which ℓ and ℓ' will still be the two leftmost children of the root. Thus s has at least two children in D, and such children are leaves of D. These two leaves form the leftmost cluster in the new BUF tree created by Restore. By the horizontal monotonicity of Invariant 3, the size of this cluster is 2. By the operation of Restore, neither arc in the cluster is a separator. This cluster complies with every applicable part of Invariants 2–5.

The other children of the root s of D are either leaves or active separators that did not fall within the dominion of any other active separators of E. Let s' be one such child of s, and consider the two possible cases below.

Case 1: s' is a leaf. Then Dismember set last(s') = first(s'). Recall that, in $D(E)$, first(s') = $r(s')$. If s'' is the immediate right sibling of s', then $r(s'') > r(s')$ by Invariant 3. Hence s' becomes a singleton cluster in D, with R-number equal to the old r-number of s'.

Case 2: s' is an active separator of E. Recall that Dismember assigns to s' and all of its descendants a last field equal to separate(s') and leaves number(s') untouched. The subset of E that is represented by the leaves of D forms a cluster delimited by a left separator and with a consistent separator nesting. The R-number of such a cluster is the old r-number of s'. Clearly, the subtree of D rooted at s' is the consistent dominance tree of such a cluster.

In view of Lemmas 4.1 and 4.2, the preceding analysis shows that Invariant 2 is preserved by Restore. Since no number field or r-number is altered, then the part of Invariant 3 that concerns these fields and numbers is preserved. By the operation of Restore, the leaves in the subtrees rooted at the children of s will be directed towards the same root of a newly created BUF tree. Our analysis of cases 1 and 2 displays that the monotonicity of the r-numbers on the children of s before Dismember guarantees the monotonicity of the R-values of clusters entering this root. With regard to the node of the BUF tree that the arcs of E entered before Restore, clearly, the R-values of the former siblings of E were not affected, whence their relative order is preserved. Thus Invariants 2 and 3 are thoroughly maintained.

We now turn to Invariant 4. Since $|E| < k$ and all the redirected arcs will enter new nodes, no fat node is introduced by Restore. The novel slim nodes vacuously comply with Invariant 4 since all arcs entering them are live. The nondecreasing ordering of the last fields of such arcs is secured by Invariant 3. In fact, the new last fields are former r-numbers (i.e., either separate or first fields, depending on the type of node—an internal active separator or a leaf—encountered by Dismember), and these r-numbers obeyed Invariant 3. Consider now the BUF-tree node v that arcs in E entered before Restore. The only situation under which such arcs are disconnected from v is when they are not live. But in such a situation the arcs of E did not contribute in any way to the fatness or slimness of v. Thus Restore also preserves Invariant 4.

Finally, we deal with Invariant 5. Recall that Restore does not introduce new values for either first or separate fields. Furthermore, all the redirected arcs that get the same last field are siblings because of the implementation of Restore and do not exceed $k - 1$ since $|E| < k$ by hypothesis. We have seen that a new cluster E' created by Restore contains only one arc ℓ only if ℓ was a leaf in the input dominance tree $D(E)$ and as(ℓ) was not defined. In this case last(ℓ) was updated by Restore to first(ℓ), consistent with Invariant 5. A new cluster E', $|E'| > 1$, without a left separator is created by Restore only when the two leftmost leaves of $D(E)$ are encountered, and such leaves are assigned identical last and first fields. Otherwise, if $|E'| > 1$, E' was obtained as a subtree of $D(E)$ rooted at some active separator s. In this case, since Invariant 3 is already established, it follows that the two leftmost arcs in E' have the same first field and that the second arc in E' is not a separator. We have also seen that in this case all the arcs in E' get separate(s) as their new last field and that such a new last field is greater then all their first fields, also by Invariant 3. By definition of dominance tree, the leftmost arc in E' is the separator s. Thus for every leaf ℓ in E' we get that last(ℓ) = separate(s) as prescribed by Invariant 5. In conclusion, Invariant 5 is also preserved. □

Before we continue with our discussion it is instructive to revisit the outline of a BUF-tree union given at the end of §3. In that outline we said that a necessary preliminary stage of a union(A, B) consists of locating and detaching the roots of the two subtrees that contain A and B. But our description of Restore implies that in general the procedure also locates and detaches other trees that are not needed in the union. This is necessary in order to maintain a consistent record of the history encoded in the nested structure of clusters. Detaching only the subtrees of the BUF trees that are needed to perform the current union besets the consistency of the clusters that account for those subtrees at that moment. In particular, an edge e could be subtracted from the dominion of some separators without those separators becoming aware of this fact. This would infringe on the consistency of the number fields that are affected by the loss of e, thus undermining the consistency of future detachments.

5. Union-Find with unlimited backtracking. In this section we show that BUF trees support any union or find in $O(\log n / \log\log n)$ worst-case time and that they backtrack(i) in constant time, irrespective of i.

We study unions first. In terms of BUF trees, union(A, B) transforms the current input forest F of BUF trees into a new forest F' that meets the following specifications. First, F' represents, through Invariant 0, the same partition of S as F, except for the fact that A and B are consolidated into a single set. Second, Invariants 1–5 still hold on F'. Before proving this we describe how to support union(A, B).

To deal with the most general case, we assume that A and B are stored in two subtrees of some BUF tree(s) in F. The management of simpler cases is similar and will be omitted. Recall that union(A, B) must increment $i_{\max}$ by 1, the updated value of $i_{\max}$ being assigned to this union as its ordinal number. This increment of $i_{\max}$ may infringe on Invariant 5. To restore this invariant the procedure must remove from the forest F possibly existing arcs either with first field or separate field equal to $i_{\max}$. By Invariant 5 there were originally either at most two sibling arcs e' and e'' with first field equal to $i_{\max}$ or at most one arc e''' with separate field equal to $i_{\max}$, and such arcs can be accessed in constant time. The procedure deletes these arcs by means of either a Restore(e', $i_{\max}$) or a Restore(e''', $i_{\max}$), depending on the case. As a result, the forest F is transformed into an equivalent forest F'' no arc of which is labeled $i_{\max}$. By Theorems 4.3 and 4.4, F'' still satisfies Invariants 0–5, and F'' was produced in $O(k)$ time.

The next task consists of locating in F'', from input A and B, both apex(A) and apex(B). This stage is accomplished by performing two finds at a cost $O(k + h)$ (cf. Invariant 0) in the worst case, where h is the maximum possible length for a path originating at a leaf in a BUF tree and containing only live arcs. Clearly, Invariants 0–5 are not affected by this stage.

Next, union(A, B) transforms F'' into an equivalent forest F''' with the property that apex(A) and apex(B) are live in F'''. If we let e_A and e_B be the arcs, respectively leaving apex(A) and apex(B), this involves the two calls Restore(e_A, $i_{\max}$) and Restore(e_B, $i_{\max}$). Thus F''' is produced in $O(k)$ time, and it meets Invariants 0–5 because of Theorems 4.3 and 4.4.

Now let T_A and T_B be the BUF (sub)trees of F''' storing, respectively, A and B, and let r_A and r_B be their respective roots. The final task of union(A, B) is that of combining T_A and T_B into a single (sub)tree, thus producing the final forest F'. Assume without loss of generality that height$(T_B) \leq$ height(T_A). Observe that height(T_A) cannot exceed h since there is a live path from leaf A to r_A. Our BUF-tree union locates a live node v in T_A having the same height as r_B. This takes $O(h)$ steps, e.g., by retracking the find that produced r_A for height(T_B) steps. The procedure now selects one of the following three modes of operations, in analogy with a DUF-tree union.

Type 1 — r_B is fat and $v \neq r_A$. Root r_B is made a sibling of v, according to the following rule. If parent(v) is fat, r_B is made the rightmost child of parent(v). If parent(v) is slim, r_B is attached to the right of the rightmost live arc entering parent(v). At this point it is set first$((r_B, \text{parent}(v)))$ = last$((r_B, \text{parent}(v)))$ = $i_{\max}$. Finally, fat(parent(v)) is set to $i_{\max}$ if appropriate.

Type 2 — r_B and $v = r_A$ are both fat nodes. A new node r is created, and the name of r is copied from the name of either r_A or r_B. Next, both r_A and r_B are made children of r, thereby relinquishing their respective names. Finally, first$((r_A, r))$, first$((r_B, r))$, last$((r_A, r))$, and last$((r_B, r))$ are all set to $i_{\max}$.

Type 3 — This type covers all remaining possibilities, i.e., either root r_B is slim or root $v = r_A$ is slim. We describe only how the case of a slim r_B is handled, the other case being symmetric. By proceeding from left to right, every live child x of r_B is made a child of v, with the following policy. If v is fat, the newcomer arcs will be the rightmost arcs entering v. If v is slim, these arcs will be the rightmost live arcs entering v. The arc s connecting the leftmost child of r_B to v is marked a separator with separate$(s) = i_{\max}$. Moreover, the old name of r_B is stored into label(s), and number(s) is set to the total number of arcs moved. For every redirected arc e, last(e) is set to $i_{\max}$. Finally, fat(v) is set to $i_{\max}$ if appropriate.

To complete the management of union(A, B), a pointer indexed by $i_{\max}$ is directed towards the arc(s) (cf. type 1 or 2) or separator (type 3) introduced by the procedure. The fatness of a node can be tested in $O(k)$ time by a walk starting at its leftmost child (cf. Invariant 4).

We now prove the following lemma.

LEMMA 5.1. *Let h be the maximum possible length for a path originating at a leaf in a* BUF *tree and containing only live arcs. The preceding implementation of* union(A, B) *requires $O(k + h)$ time and preserves Invariants* 0–5.

Proof. The time bound is immediate from the preceding discussion. Therefore, we are left to show that a union preserves all the invariants. Since the three initial possible calls to Restore preserve the invariant, it is enough to show that the invariants are preserved after any of the three types of manipulations. Consider first type 1 and type 2 unions. They introduce new clusters with one and two arcs, respectively.

To see that find consistency is maintained, observe that only nodes in A and B may have their apex changed. If this change occurs, the new apex will be live and it will consistently store the name of $A \cup B$.

Consider now the $i_{\max}$ invariant. The only arcs for which something has changed are the newly introduced arcs: they are at most two, have last value equal to $i_{\max}$, and are live. Also, the last part of Invariant 1 still holds. For this, consider first a type 1 union, which introduces only the arc $(r_B, \text{parent}(v))$. The field fat(parent(v)) is unaffected if either parent(v) was fat or parent(v) was slim and did not become fat through the union. If, on the other hand, union(A, B) made parent(v) fat, then we have seen that it also sets fat(parent(v))= $i_{\max}$, thus preserving the last part of Invariant 1. In the case of a type 2 union, the new node r is introduced, and r is reached by the two arcs $((r_A, r)$ and $(r_B, r))$. Node r is thus slim, and fat(r) is, consistently, undefined. This completes the analysis of Invariant 1 for type 1 and type 2 unions.

Consider now the impact on Invariant 2 of type 1 and type 2 unions. A new cluster E with $|E| > 1$ can be created only by a type 2 union. In this case E does not contain any separator, and, having no siblings, it is vacuously the leftmost cluster. If E has only one arc, then E has been created by a type 1 union. Again, E contains no separators.

Invariants 3 and 4 are trivially maintained by a type 2 union, as well as by a type 1 union, the new arc introduced by which enters a fat parent(v). Consider now a type 1 union, the new arc introduced by which reaches a slim parent(v). In this case the new arc $e = (r_B,$ parent$(v))$ is inserted immediately after the rightmost live arc entering parent(v), and we have first$(e) =$ last$(e) = i_{\max}$. Thus first(e) will be larger than the first and separate fields of all of its left siblings, which consist only of live arcs or active separators in force of the slim compression and numbering invariants. Similarly, last(e) will be larger than the last field of every left sibling of e.

It is easily checked that a type 1 or type 2 union also maintains Invariant 5.

We turn now to type 3 unions. Let $e_i = (x_i, v)$, $1 \leq i \leq h < k$, be the arcs redirected by union(A, B) as they appear in the forest F'. Clearly, Invariant 0 is still valid in F'. In fact, the only nodes of F that had their apex changed are the nodes the old apex of which was one of the x_i's. The procedure provided for these nodes to have a new and consistent live apex.

The arcs $e_1, e_2, \ldots, e_h$ are live and have last field equal to $i_{\max}$. Moreover, separate$(e_1) = i_{\max}$, and e_1 is an active separator. The fat field of node v is correctly updated following a type 1 or type 3 union. Thus Invariant 1 is preserved.

A type 3 union introduces one new cluster $E = \{e_1, e_2, \ldots e_h\}$ by ordered aggregation of the clusters of edges entering a slim node of F'''. In the new cluster E the leftmost edge e_1 is made a separator. Furthermore, the last field of all the arcs in E will be set to $i_{\max}$, and therefore last$(E) =$ separate(e_1), as required by Invariant 2. Since Invariant 2 was valid in F''' for each one of the individual clusters contributing to E, number$(e_1) = |E|$. Thus E satisfies Invariant 2. By reasoning along the same lines, it is easy to check that E also satisfies Invariants 3 and 4.

The first part of Invariant 5 is preserved by the first call to Restore, while the rest of this invariant follows from the validity of Invariant 3 at the inception of the union. □

We now focus on the BUF-tree implementation of backtracks.

LEMMA 5.2. *For any values of* $i_{\max}$ *and* i*,* backtrack(i) *can be performed on a forest of* BUF *trees in constant time, preserving Invariants* 0–5.

Proof. As said, backtrack(i) is performed by setting $i_{\max} = \max(i_{\max} - i, 0)$, i.e., in constant time for any value of i. Hence we need to prove only that backtrack(i) maintains Invariants 0–5. Since the effect of a backtrack is null unless the value of $i_{\max}$ is altered, we can safely assume $i_{\max} - i \geq 0$. Then, we may regard a backtrack(i) as a sequence of i consecutive backtrack(1), and we need to prove only that if Invariants 0–5 were valid before performing a backtrack(1), they are still valid immediately afterwards. To fix the ideas, let $i_{\max}^{\text{old}}$ and $i_{\max}^{\text{new}} = i_{\max}^{\text{old}} - 1$ be the values of $i_{\max}$ immediately before and after backtrack(1), respectively.

We distinguish two cases, depending on the type of union undone. Let u be this union, and let A and B be the two sets unified by u.

If u is a type 1 or 2 union, then u introduced at most two arcs and such arc(s) are now made dead by the backtrack. Assume, for generality, that two arcs, say, $e_1 = (x_1, v)$ and $e_2(x_2, v)$, were introduced by u. Clearly, first(e_1) = first(e_2) = $i_{\max}^{\text{old}} > i_{\max}^{\text{old}} - 1 = i_{\max}^{\text{new}}$; hence these arcs become consistently dead. If e_1 and e_2 were cheating, then their death did not affect the fatness of v. If they were live, then v may have become, from fat, slim. But this implies that u was the last surviving union that made v fat; whence after backtrack fat$(v) = i_{\max}^{\text{old}}$ exceeds $i_{\max} = i_{\max}^{\text{new}}$. Since no arc other than e_1 and e_2 is affected by this backtrack, this guarantees the validity of Invariant 1.

Invariant 0 is also preserved. In fact, the only leaves the apex of which was possibly changed are those ending up with apex at either x_1 or x_2. The union operation u that the backtrack is voiding, however, did not delete the old names A and/or B stored in these nodes.

The leaves in the subtrees rooted at x_1 and/or x_2 are thus given back the old name A and/or B. This consistently reflects that u was made void.

The slim compression invariant is propagated by the validity, prior to backtrack(1), of Invariant 4 itself and of the part of Invariant 3 that concerns the R-numbers of clusters entering slim nodes. No part of Invariant 2, 3, or 5 is affected by a backtrack operation, so that these invariants are maintained too.

Assume now that u is of type 3, and let $e_1 = (x_1, v)$, $e_2 = (x_2, v), \dots, e_h = (x_h, v)$, with $h \leq k$, be the arcs issued by u. By hypothesis, the last field of these arcs was equal to $i_{\max}^{\text{old}}$ prior to backtrack and therefore is strictly larger than $i_{\max}^{\text{new}} = i_{\max}^{\text{old}} - 1$. Hence these arcs become consistently cheating (recall that, by Invariant 5, the first field of each arc in a cluster is strictly smaller than the last field of that arc). Since these arcs were live, v may become, from fat, slim. This means that u was the last surviving union that made v fat, and therefore $\text{fat}(v) = i_{\max}^{\text{old}}$ is now greater than $i_{\max}^{\text{new}}$. This settles Invariant 1.

Clearly, only the leaves that, prior to operation u, had apex at one of the x_i's are affected by the backtrack. By the structure of a type 3 union, however, the name of each such leaf was stored in label(e_1) as part of the execution of u. Having assumed Invariant 3 valid prior to the backtrack, we are guaranteed that, afterwards, e_1 is the rightmost inactive separator to the left of each e_i, $1 \leq i \leq h$. Thus Invariant 0 is preserved. Slim compression descends from the validity of Invariants 2 and 5 and of Invariant 4 itself prior to backtrack(1), while Invariants 2, 3, and 5 are all maintained vacuously. □

In order to prove our claimed time bounds, we show now that, at any time in a BUF-tree forest, the length of a path consisting of live arcs cannot exceed $O(\log_k n)$. This clearly establishes our bound for finds, and it combines with Lemma 5.1 to yield an identical bound for the union. Our desired property shall follow from the following lemma.

LEMMA 5.3. *At any time and for every arc* $e = (x, v)$ *in a* BUF-*tree forest, if* x *is not a leaf, then* $\text{fat}(x)$ *is defined and, moreover,* $\text{fat}(x) < \text{first}(e)$.

Proof. We proceed by induction on the number of operations performed. Initially there are n singleton trees and the claim holds vacuously since there are no arcs and no fat nodes in the structure.

Assuming now that the claim holds before the ith operation, $i \geq 1$, we prove that it also holds afterwards. The proof is straightforward in the case of finds and backtracks since these operations do not alter any of the parameters in the claim. Thus we concentrate on unions.

Then let the ith operation be union(A, B), where A and B are two arbitrary sets in the current partition of S.

We first show that the procedure Restore preserves the property of the claim. To see this, let $E = e_1, e_2, \dots, e_h$, $1 \leq h < k$, be the cluster of arcs managed by a Restore. As we know (see Invariant 1 and the definition of cluster), either all arcs in E are live or none is. Since Restore does nothing on live arcs, we concentrate on the case where E contains a mixture of dead and cheating arcs. We need to show that the claim holds after Restore for the arcs in E only, since every other arc or node was not affected.

Let x_i $(1 \leq i \leq h)$ be the node from which the arc e_i originated immediately prior to Restore. By the inductive hypothesis, $\text{fat}(x_i) < \text{first}(e_i)$ $(i = 1, 2, \dots, h)$. We now distinguish two cases for each arc e_i in E, depending on whether e_i is dead or cheating. If arc e_i is dead, then Restore simply deletes e_i, leaving a BUF tree rooted at x_i. The nodes of such a BUF tree still satisfy the invariant, by the inductive hypothesis. If, on the other hand, arc e_i is cheating, then by Invariant 1 $\text{first}(e_i) \leq i_{\max}$. By assumption $\text{fat}(x_i) < \text{first}(e_i)$, so that $\text{fat}(x_i) < i_{\max}$. As a consequence, the union that made x_i fat is still valid and therefore x_i is still fat. The procedure Restore redirects e_i to a new node, as explained in its description, which does not modify $\text{fat}(x_i)$ and $\text{first}(e_i)$. Since $\text{fat}(x_i)$ and $\text{first}(e_i)$ remain unchanged for each re-directed cheating arc e_i, the claim holds after Restore for every such arc. The nodes introduced by Restore are slim nodes and thus do not have a defined fat field. Clearly, no arc leaves such newly created nodes. In conclusion, Restore maintains our claim.

Recall that Restore is called for three times at the beginning of a union, the second and third time in order to produce the two trees T_A and T_B. We need now to show that the unification of T_A and T_B preserves the claim. Let r_A and r_B be the respective roots of T_A and T_B, and let $i_{\max}$ be the ordinal number of the present union. As usual, we distinguish three types of unions.

If a type 1 union is performed, then r_B is fat and therefore by Invariant 1 $\text{fat}(r_B) < i_{\max}$. A new arc e leaving from r_B is introduced, and $\text{first}(e)$ is set to $i_{\max}$. As a consequence, $\text{fat}(r_B) < \text{first}(e)$. Since this is the only change in the data structure, the claim is maintained.

If a type 2 union is performed, then r_A and r_B are both fat. Therefore, $\text{fat}(r_A) < i_{\max}$ and $\text{fat}(r_B) < i_{\max}$. The only change in the data structure is that a new node r and two new arcs (r_A, r) and (r_B, r) are introduced. Since $\text{first}(r_A, r) = \text{first}(r_B, r)$ is set to $i_{\max}$, then $\text{fat}(r_A) < \text{first}(r_A, r)$ and $\text{fat}(r_B) < \text{first}(r_B, r)$. Hence the claim is maintained.

If a type 3 union is performed, then either r_A is slim or r_B is slim. Assume to fix the ideas that r_B is slim. Then, at most $k - 1$ nodes (i.e., all the children x of r_B for which the arc (x, r_B) is live) are given a new parent v, but neither the first field of the redirected arcs (x, r_B) nor the fat field of the previous children of r_B is affected. As a consequence, we have only to check that the node v still fulfills the claim. If v was fat, then $\text{fat}(v) < i_{\max}$, and, by the inductive hypothesis, the arc leaving v (if any) had first field greater than $\text{fat}(v)$. If v was slim and there is no arc leaving v, then the claim will trivially still hold for v. Assume now that v is slim and there is an arc e leaving v. Then we claim that e must be dead. In fact, assume by contradiction that e is either live or cheating. This implies that, because of Invariant 1, $\text{first}(e) < i_{\max}$ and, because of the inductive assumption, $\text{fat}(v) < \text{first}(e) < i_{\max}$, which contradicts the hypothesis of v being slim. Therefore, the arc e leaving v must be dead. By Invariant 1 this is equivalent to saying that $\text{first}(e) > i_{\max}$. If the new children of v do not make it fat, then $\text{fat}(v)$ remains unchanged and the claim still trivially holds for v by propagation of the inductive hypothesis. On the other hand, if because of the type 3 union being performed v becomes fat, then $\text{fat}(v)$ changes to $i_{\max}$. But since e is dead, then $\text{first}(e) > i_{\max}$ and therefore $\text{fat}(v) < \text{first}(e)$. As a consequence, v will fulfill the claim in this case, too.

This completes the induction step of the union operation and establishes the lemma. □

Remark. The crucial implication of Lemma 5.3 is that live arcs can originate only from either leaves or fat nodes. Therefore, in any path composed only of live arcs, only the node at the top can be slim. Since, by definition, all arcs traversed by find(x) except the last one are live, it follows that a find(x) encounters only fat nodes on the path from x to apex(x), with the only possible exception of apex(x) itself. Then let $x = v_0, v_1, v_2, \ldots, v_{h-1}, v_h = \text{apex}(x)$ be the ordered sequence of nodes visited by a generic find(x) while climbing a path of length h up to apex(x). Then v_{h-1} has at least k live edges entering it, i.e., at least k fat children. Iterated application of Lemma 5.3 to these children, their own children, and so on yields that there are at least k^{h-1} leaves connected to v_{h-1} by means of paths consisting only of live edges. Since $k^{h-1} \leq n$, it follows that h is $O(\log_k n)$.

THEOREM 5.4. BUF *trees support each union and find in* $O(\log n / \log \log n)$ *time and support* backtrack(i) *in* $O(1)$ *time, irrespective of* i. *The overall space required is* $O(n)$.

Proof. The time bounds follow from Lemmas 5.1, 5.2, and 5.3. The space complexity of the data structure is dictated by the maximum number of arcs that may be present in it at any given time. New arcs are introduced only by unions, and each union can introduce at most two arcs. However, we have seen that when a union getting ordinal number i is performed, the arcs possibly created by a past union with the same ordinal number are removed from the data structure. This guarantees that at any time at most $2(n-1)$ arcs may exist in the data structure. If persisting nodes are removed as soon as there are no edges entering them, then the total space required by the data structure is $O(n)$. □

6. Conclusion. We have introduced a data structure for the efficient management of set union with unlimited backtracking. Our approach stays within the guidelines of separable-pointer algorithms if one only relaxes the separability condition to an extent that is deemed acceptable [24]. Our per-operation worst-case bounds are tight both for this model and for the more powerful cell-probe model of computation.

BUF trees also represent a partially persistent [4] data structure to be used in the following variant of the set union problem. In this variant the set union is defined as usual, but a find operation is formatted as find(x, k), where x is the name of an element of S and k is a nonnegative integer not exceeding the ordinal number of the last union so far performed. The task of find(x, k) is to return the name of the subset that contained the element x at the time when only the first k unions had been performed. To perform a find(x, k) on a BUF tree it is sufficient to temporarily set $i_{\max}$ to $i_{\max} - k$ and then proceed as per an ordinary find(x).

Acknowledgments. Moti Yung read an early version of this paper and gave several useful comments. A referee pointed out that a partially persistent set union algorithm for the RAM with logarithmic word size was recently given in [3].

THE PROFILE MINIMIZATION PROBLEM IN TREES*

DAVID KUO† AND GERARD J. CHANG†

Abstract. The profile minimization problem is to find a one-to-one function f from the vertex set $V(G)$ of a graph G to the set of all positive integers such that $\sum_{x \in V(G)} \{f(x) - \min_{y \in N[x]} f(y)\}$ is as small as possible, where $N[x] = \{x\} \cup \{y : y \text{ is adjacent to } x\}$ is the closed neighborhood of x in G. This paper gives an $O(n^{1.722})$ time algorithm for the problem in a tree of n vertices.

AMS subject classifications. 05C78, 05C85, 68R10

1. Introduction. The profile minimization problem was introduced by [5], [6] as a technique for handling sparse matrices. For instance, in the finite element method [8], [9], we want to solve a system of linear equations $Ax = b$ where A is a sparse symmetric $n \times n$ matrix. Suppose for each row i, $a_{ii} \neq 0$ and p_i is the position of the first non-zero element in this row. We call

$$w_i = i - p_i = i - \min\{j : a_{ij} \neq 0\}$$

the *width* of row i, and call

$$P(A) = \sum_{i=1}^{n} w_i$$

the *profile* of matrix A. To store A, we need only store $w_i + 1$ elements in each row i, which are from position p_i to position i. The total amount of storage for this scheme is then $P(A) + n$. In order to reduce the amount of storage, we need only permute the rows and columns of A simultaneously such that the resulting matrix has minimum profile, i.e., we need to find a permutation matrix Q such that the profile $P(QAQ^t)$ is minimized.

We can reformulate this problem in terms of graphs. Associate the matrix A with a graph G such that $V(G) = \{v_1, v_2, \ldots, v_n\}$ and $E(G) = \{(v_i, v_j) : i \neq j \text{ and } a_{ij} \neq 0\}$. Note that

$$P(A) = \sum_{i=1}^{n} w_i = \sum_{i=1}^{n} \left(i - \min_{v_j \in N[v_i]} j \right),$$

where $N[v_i] \equiv \{v_i\} \cup \{v_j : v_i \text{ is adjacent to } v_j\}$ is the *closed neighborhood* of v_i in G. The row and column permutation Q corresponds to a one-to-one function f from $V(G)$ onto $\{1, 2, \ldots, n\}$ and $P(QAQ^t) = \sum_{x \in V(G)} (f(x) - \min_{y \in N[x]} f(y))$. This motivates the definition of the profile of a graph given below.

For technical reasons, however, we shall give a slightly more general definition than that described in the previous paragraph. A *labeling* of a graph G is a one-to-one function f from the vertex set $V(G)$ to the set of all positive integers. A labeling is *simple* if it maps $V(G)$ onto $\{1, 2, \ldots, |V(G)|\}$. For a labeling f, the *profile-width* of a vertex x is defined as

$$w_f(x) = f(x) - \min_{y \in N[x]} f(y).$$

†Institute of Applied Mathematics, National Chiao Tung University, Hsinchu 30050, Taiwan, Republic of China (gjchang@cc.nctu.edu.tw).

The *profile of G with respect to f* is

$$P_f(G) = \sum_{x \in V} w_f(x)$$

and the *profile* of G is

$$P(G) = \min\{P_f(G) : f \text{ is a labeling of } G\}.$$

A labeling f is *optimal* if $P_f(G) = P(G)$.

The purpose of this paper is to study the *profile minimization problem*, i.e., the problem of determining the profile $P(G)$ of a graph G, from an algorithmic point of view. The profile minimization problem is analogous to the *linear arrangement problem*, which is to find a labeling f of a graph G such that $\sum\{|f(x) - f(y)| : (x, y) \text{ is an edge in } G\}$ is minimized (see [1], [3], [7]). Reference [5] proved that the profile minimization problem is equivalent to the problem of interval graph completion, which is known to be NP-complete even when G is stipulated to be an edge graph (see [4]). The main result of this paper is to give an $O(n^{1.722})$ time algorithm for the problem when G is a tree of n vertices.

The rest of this paper is organized as follows. In §2, we establish several basic properties that motivate the development of our algorithm. In particular, we prove that for a tree T there exists a basic path $\alpha(x, y)$ such that $P(T) = P(T - \alpha(x, y)) + |E(T)|$. So the problem becomes that of finding a path $\alpha(x, y)$ such that $P(T - \alpha(x, y))$ is minimized. For the purposes of recurrence, we also introduce the problem of finding a path $\alpha(x, y)$ such that $P(T - \alpha(x, y))$ is minimized, with the boundary condition that y is fixed. In order to determine the basic path, §3 develops theorems that narrow the possibilities for the basic path. For instance, we prove that $\alpha(x, y)$ contains centroids of the tree. This also means that the number of vertices of each component of $T - \alpha(x, y)$ is no more than half the number of vertices of T. This is important in determining the speed of our recursive algorithm. Section 4 uses these results to design an algorithm, and §5 analyzes the time complexity of the algorithm.

2. Motivating properties. This section shows the existence of a basic path $\alpha(x, y)$ such that $P(T) = P(T - \alpha(x, y)) + |E(T)|$ and introduces the problem of finding a minimum such path with the boundary condition that y is fixed. The following properties are obvious and their proofs are omitted.

PROPOSITION 2.1. *An optimal labeling of a connected graph G maps $V(G)$ onto a set of consecutive integers.*

PROPOSITION 2.2 ([5]). *If H is a subgraph of G, then $P(H) \leq P(G)$.*

PROPOSITION 2.3 ([5]). *If G has m components $G_1, G_2, \ldots, G_m$, then $P(G) = \sum_{i=1}^{m} P(G_i)$.*

We can in fact assume that an optimal labeling of a graph is simple even if it is not connected. Suppose T is a tree of n vertices. For any leaf x and any vertex y in T, consider the unique (x, y)-path $\alpha(x, y) = (v_0, v_1, \ldots, v_r)$, where $v_0 = x$ and $v_r = y$. Suppose that for each i, $1 \leq i \leq r$, $T - \alpha(x, y)$ has n_i components $T_{i1}, T_{i2}, \ldots, T_{in_i}$ each with a vertex v_{ij} adjacent to v_i in T (see Fig. 2.1). Let f_i be an optimal simple labeling of $F_i = \cup_{1 \leq j \leq n_i} T_{ij}$. We consider a simple labeling f_{xy} defined by

$$f_{xy}(v) = \begin{cases} 1 & \text{if } v = v_0, \\ f_{xy}(v_{i-1}) + f_i(v) & \text{if } v \in V(F_i), \\ f_{xy}(v_{i-1}) + |V(F_i)| + 1 & \text{if } v = v_i. \end{cases}$$

See Fig. 2.2 for an example of f_{xy} with $\alpha(x, y) = (a, b, c, d)$. Note that the numbers beside the vertices are their labels. Then

$$w_{f_{xy}}(v_0) = 0,$$
$$w_{f_{xy}}(v_i) = f_{xy}(v_i) - f_{xy}(v_{i-1}) = |V(F_i)| + 1 \quad \text{for } 1 \le i \le r,$$

and

$$w_{f_{xy}}(v) = w_{f_i}(v) \quad \text{for } v \in V(F_i).$$

Consequently

$$\begin{aligned} P_{f_{xy}}(T) &= \sum_{i=1}^{r}(|V(F_i)| + 1 + P(F_i)) \\ &= |E(T)| + \sum_{i=1}^{r} P(F_i) \qquad (2.1) \\ &= |E(T)| + \sum_{i=1}^{r}\sum_{j=1}^{n_i} P(T_{ij}). \end{aligned}$$

We call $\alpha(x, y)$ the *basic path* (with respect to the labeling f_{xy}). Note that

$$1 = f_{xy}(v_0) < f_{xy}(v_1) < \cdots < f_{xy}(v_r) = n.$$

In general, an optimal labeling of a tree is of this type.

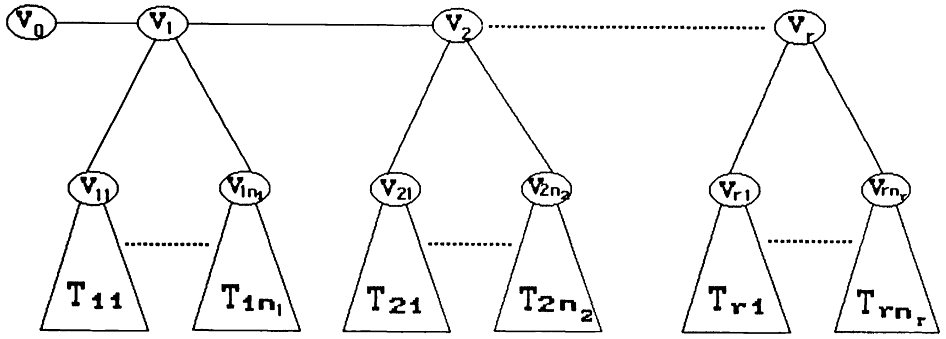

FIG. 2.1. *Tree T.*

THEOREM 2.4. *If f is an optimal labeling of a tree T of n vertices, then $f = f_{xy}$ where $x = f^{-1}(1)$ is a leaf and $y = f^{-1}(n)$ is adjacent to at most one non-leaf vertex.*

Proof. Let $\alpha(z, u) = (v_0, v_1, \ldots, v_r)$ be a longest path containing both x and y, say, $x = v_s$ and $y = v_t$ for $0 \le s < t \le r$. Note that since r is the maximum, v_0 and v_r are leaves. In this case $n_r = 0$ and $P_{f_{zu}}(T) = P_{f_{zu'}}(T)$, where $u' = v_{r-1}$.

Suppose T and $\alpha(z, u)$ are as shown in Fig. 2.1. Let $f_{ij} = f|_{V(T_{ij})}$ be the labeling f restricted on $V(T_{ij})$. Then, by definition,

$$P(T) = P_f(T) \ge \sum_{i=0}^{r} w_f(v_i) + \sum_{i=1}^{r}\sum_{j=1}^{n_i} P_{f_{ij}}(T_{ij}). \qquad (2.2)$$

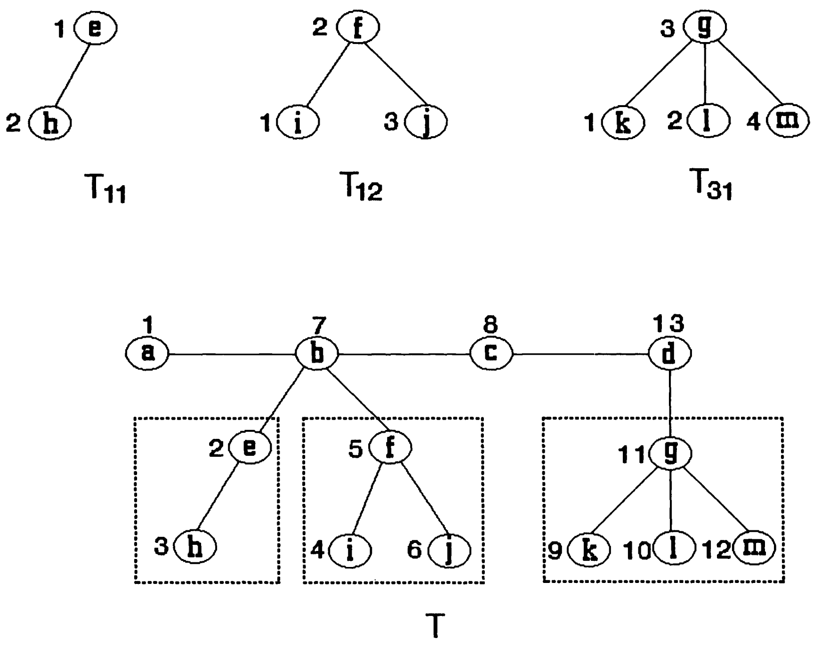

FIG. 2.2. *An example of f_{xy}.*

Note that

$$(2.3)\qquad \sum_{i=0}^{r} w_f(v_i) \ge \sum_{i=s+1}^{t} w_f(v_i) \ge \sum_{i=s+1}^{t} \{f(v_i) - f(v_{i-1})\} = n - 1 = |E(T)|.$$

Consequently, by (2.1),

$$(2.4)\qquad P(T) \ge |E(T)| + \sum_{i=1}^{r} \sum_{j=1}^{n_i} P(T_{ij}) = P_{f_{zu}}(T) \ge P(T).$$

Therefore, all inequalities in (2.2) to (2.4) are equalities. This implies the following:

(1) each f_{ij} is an optimal labeling for T_{ij},

(2) $w_f(v_0) = w_f(v_1) = \cdots = w_f(v_s) = 0$,

(3) $w_f(v_{t+1}) = w_f(v_{t+2}) = \cdots = w_f(v_r) = 0$,

(4) $f(v_{i-1}) = \min_{y \in N[v_i]} f(y)$ for $s + 1 \le i \le t$.

Statement (2) implies that $s = 0$, otherwise $w_f(v_{s-1}) = f(v_{s-1}) - f(v_s) > 0$. That is, $x = z$, which is a leaf. Statement (3) implies that $r-1 \le t$, otherwise either $f(v_{t+1}) > f(v_{t+2})$ or $f(v_{t+1}) < f(v_{t+2})$, i.e., either $w_f(v_{t+1}) > 0$ or $w_f(v_{t+2}) > 0$. So either $y = u$ or $y = u'$. In the former case, $y = u$ is a leaf. In the latter case, $y = u'$ is adjacent to at most one non-leaf vertex, otherwise we can choose a longer $\alpha(z, u)$. In this case, since $P_{f_{zu'}}(T) = P_{f_{zu}}(T)$, we replace u by u' and assume $y = u$. Note that in this case $n_r > 0$. So, now $\alpha(x, y) = \alpha(z, u)$. Finally, statement (4) implies the following:

(5) $1 = f(v_0) < f(v_1) < \cdots < f(v_r) = n$,

(6) $f(v_{i-1}) < f(v_{ij})$ for $1 \le i \le r$ and $1 \le j \le n_i$.

On the other hand, statement (1) and Proposition 2.1 imply that each $f(V(T_{ij}))$ contains consecutive integers. From this, together with statements (5) and (6), we obtain $f = f_{zu} = f_{xy}$. □

COROLLARY 2.5. *For any tree T there is an optimal labeling f_{xy} in which both x and y are leaves.*

From now on, all optimal labelings we consider are as specified in Corollary 2.5. The path $\alpha(x, y)$ is called a *basic path* for $P(T)$.

Theorem 2.4 and (2.1) tell us that in order to find the profile of a tree T we need only find a basic path $\alpha(x, y)$ whose deletion results in a forest with the smallest possible profile.

For technical reasons, we now consider the following restricted path deletion problem. Suppose y is a fixed vertex in tree T; find a path $\alpha(x, y)$ ending at y such that $P(T - \alpha(x, y))$ is minimum. We use $P'(T, y)$ to denote this minimum value. We also call $\alpha(x, y)$ the *basic path* for $P'(T, y)$.

Suppose f_{xy} is an optimal labeling of T and the tree T is as shown in Fig. 2.1. Denote by ${}^kT$ (respectively T^k) the subtree of T that contains $v_0, v_1, \ldots, v_k, F_1, \ldots, F_k$ (respectively $v_k, \ldots, v_r, F_k, \ldots, F_r$). From Theorem 2.4 and (2.1), we obtain the following corollary.

COROLLARY 2.6. *For a basic path $(v_0, v_1, \ldots, v_r)$ for $P(T)$, the following hold:*

(1) $(v_0, v_1, \ldots, v_k)$ *is a basic path for* $P'({}^kT, v_k)$ *and* $P'({}^kT, v_k) = \sum_{i=1}^{k} P(F_i) = \sum_{i=1}^{k} \sum_{j=1}^{n_i} P(T_{ij})$ *for* $1 \le k \le r$.

(2) $(v_k, v_{k+1}, \ldots, v_r)$ *is a basic path for* $P'(T^k, v_k)$ *and* $P'(T^k, v_k) = \sum_{i=k}^{r} P(F_i) = \sum_{i=k}^{r} \sum_{j=1}^{n_i} P(T_{ij})$ *for* $1 \le k \le r$.

(3) $P(T) = |E(T)| + P'({}^sT, v_s) + P'(T^t, v_t) + \sum_{i=s+1}^{t-1} P(F_i)$ *for* $1 \le s < t \le r$.

PROPOSITION 2.7. $P(T) \le P'(T, y) + |E(T)|$ *for any vertex y in T.*

3. Main theorems. This section develops theorems that restrict the possibilities of the basic paths for $P(T)$ and $P'(T, y)$. In particular, the basic path $\alpha(x, y)$ for $P(T)$ contains the centroids of T. We also prove that the basic path for $P'(T, u)$ is either $\alpha(x, u)$ or $\alpha(y, u)$, and the deletion of the basic path for $P'(T, u)$ from T results in a forest each of whose components has at most $2|V(T)|/3$ vertices. These results are the keystone of our algorithm for the profile maximization problem.

A *centroid* of a tree of n vertices is a vertex whose deletion results in a forest each of whose components has at most $\lfloor \frac{n}{2} \rfloor$ vertices. It is well known that a tree has either exactly one centroid or exactly two adjacent centroids (see [2]). A "from leaves to center" method can be employed to derive the centroids of a tree. This method requires linear time.

THEOREM 3.1. *Any basic path $\alpha(x, y)$ for $P(T)$ contains all centroids of T.*

Proof. Suppose there is a centroid of T not in the basic path

$$\alpha(x, y) = (x, \ldots, v_1, u, v_2, \ldots, y).$$

Then T is of the form shown in Fig. 3.1, with $|V(T')| \ge n/2$ where $n = |V(T)|$. By Corollary 2.6 (3), we have

$$(3.1) \qquad P(T) = |E(T)| + P'(T_1, v_1) + P'(T_2, v_2) + \sum_{i=3}^{k} P(T_i) + P(T').$$

Up to a symmetric argument, we may assume that $|V(T_1)| \le |V(T_2)|$. Let $\alpha(z, v)$ be a basic path for $P(T')$. Corollary 2.6 (3) and Proposition 2.2 give

$$(3.2) \qquad P(T') \ge |E(T')| + P'(T_a, a) + P'(T_b, b) + \sum_{j=1}^{m} P(F_j).$$

We also assume that $|V(T_a)| \le |V(T_b)|$. Now consider the labeling f_{vy} for T. By (2.1) and Corollary 2.6, we have

(3.3)

$$P_{f_{vy}}(T) = |E(T)| + P'(T_b, b) + P'(T_2, v_2) + P(T_a) + \sum_{j=1}^{m} P(F_j) + P(T_1) + \sum_{i=3}^{k} P(T_i).$$

Equations (3.1) to (3.3) together lead to that $|E(T')| \le P(T_a) - P'(T_a, a) + P(T_1) - P'(T_1, v_1)$. Then $|E(T')| \le |E(T_a)| + |E(T_1)|$ by Proposition 2.7. Thus

$$\begin{aligned} |E(T_1)| &\ge |E(T')| - |E(T_a)| \\ &> |E(T')|/2 \qquad (\text{since } |E(T_a)| \le |E(T_b)| \text{ and } T' - (T_a \cup T_b) \ne \emptyset) \\ &\ge (n - |E(T')|)/2 \qquad (\text{since } |E(T')| \ge n/2) \\ &\ge |E(T_1)| \qquad (\text{since } |E(T_1)| \le |E(T_2)|), \end{aligned}$$

which is a contradiction. □

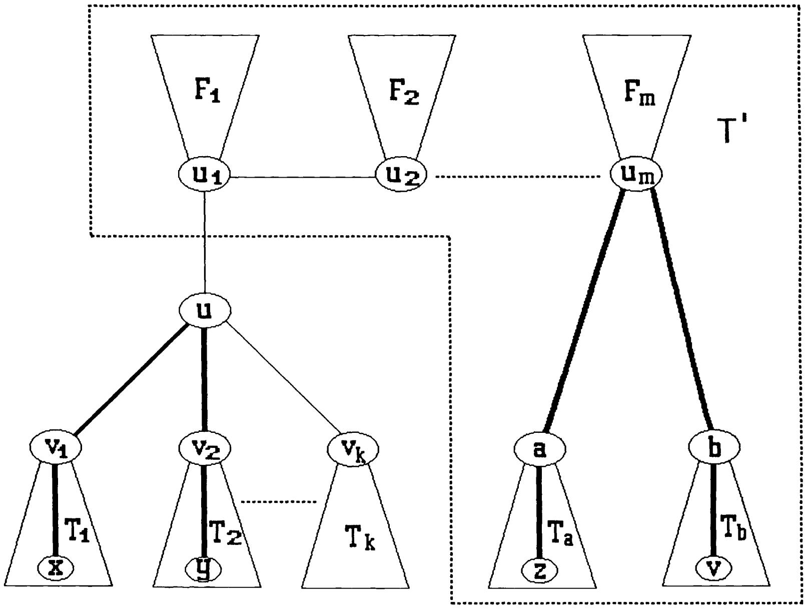

FIG. 3.1.

Similar arguments lead to the following theorem.

THEOREM 3.2. *Suppose y is a fixed vertex of a tree T of n vertices. For any basic path $\alpha(xy)$ of $P'(T, y)$, every component of $T - \alpha(x, y)$ has at most $2n/3$ vertices.*

Proof. The proof of this theorem is exactly the same as that for Theorem 3.1, except now we assume $|E(T')| > 2n/3$ and $|E(T_a)| \le |E(T_b)|$, and there is no assumption that $|E(T_1)| \le |E(T_2)|$. However, we still have $|E(T')| \le |E(T_a)| + |E(T_1)|$. Then

$$\begin{aligned} |E(T_1)| &\ge |E(T')| - |E(T_a)| \\ &\ge |E(T')|/2 \qquad (\text{since } |E(T_a)| \le |E(T_b)|) \\ &> n - |E(T')| \qquad (\text{since } |E(T')| > 2n/3) \\ &\ge |E(T_1)|, \end{aligned}$$

which is a contradiction. □

Figure 3.2 gives an example in which a basic path $\alpha(x, y)$ for $P'(T, y)$ does not contain the centroid z of T.

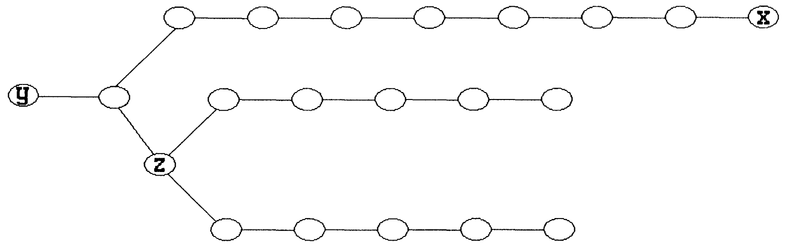

FIG. 3.2.

THEOREM 3.3. *If $\alpha(x, y)$ is a basic path for $P(T)$ and u is a fixed vertex in T, then either $\alpha(x, u)$ or $\alpha(y, u)$ is a basic path for $P'(T, u)$.*

Proof. Suppose $\alpha(x, y) = (x, \ldots, v_1, u_1, v_2, \ldots, y)$ and $(u_1, u_2, \ldots, u_r = u)$ is the unique path from $\alpha(x, y)$ to u, as shown in Fig. 3.3. Let $\alpha(z, u)$ be a basic path for $P'(T, u)$.

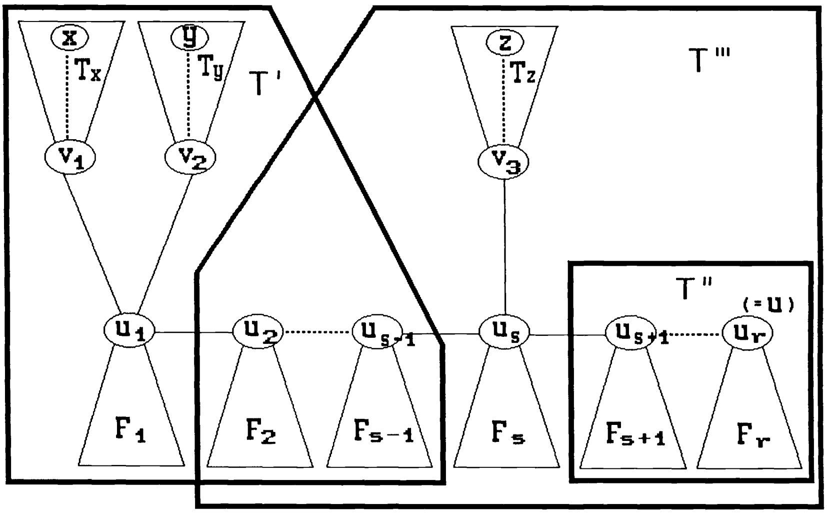

FIG. 3.3.

Case 1. $z \in V(T_x)$. In this case, $u_s = u_1$, $v_3 = v_1$, and $T_z = T_x$. By Corollary 2.6 (1), $\alpha(x, v_1)$ is a basic path for $P'(T_x, v_1)$, and so $P(T_x - \alpha(x, v_1)) \leq P(T_z - \alpha(z, v_3))$. Then

$$\begin{aligned}P'(T, u) &= P(T - \alpha(z, u))\\ &= P(T_z - \alpha(z, v_3)) + P(T_y) + \sum_{i=1}^{r} P(F_i)\\ &\geq P(T_x - \alpha(x, v_1)) + P(T_y) + \sum_{i=1}^{r} P(F_i)\\ &= P(T - \alpha(x, u)).\end{aligned}$$

Hence $\alpha(x, u)$ is also a basic path for $P'(T, u)$.

Case 2. $z \in V(T_y)$. By a similar argument, $\alpha(y, u)$ is also a basic path for $P'(T, u)$.

Case 3. $z \notin V(T_x)$ and $z \notin T(T_y)$. Let T', T'', and T''' be subtrees, as shown in Fig. 3.3. Note that in the case of $s = 1$, $T' = T_x \cup T_y$ is not a tree. Now

$$P(T - \alpha(z, u)) = P'(T_z, v_3) + P(T') + \sum_{i=s}^{r} P(F_i). \tag{3.4}$$

Note that $P'(T_z, v_3) = P(T_z - \alpha(z, v_3))$. By Proposition 2.2, we have

$$P(T') \geq P(T_x) + P(T_y) + \sum_{i=1}^{s-1} P(F_i). \tag{3.5}$$

Since $\alpha(x, y)$ is a basic path for $P(T)$, we have $P_{f_{xz}}(T) \geq P_{f_{xy}}(T)$. By (2.1) and Corollary 2.6 (3) we have

$$\begin{aligned} &|E(T)| + P(T_x - \alpha(x, v_1)) + P(T_y) + \sum_{i=1}^{s} P(F_i) + P(T'') + P(T_z - \alpha(z, v_3)) \\ &\geq |E(T)| + P'(T_x, v_1) + P'(T_y, v_2) + P(F_1) + P(T'''). \end{aligned} \tag{3.6}$$

Note that $P'(T_x, v_1) = P(T_x - \alpha(x, v_1))$. Again, by Proposition 2.2,

$$P(T''') \geq \sum_{i=2}^{s} P(F_i) + P(T_z) + P(T''). \tag{3.7}$$

Equations (3.4) to (3.7) together lead to

$$P(T - \alpha(z, u)) \geq P'(T_y, v_2) + P(T_x) + \sum_{i=1}^{r} P(F_i) + P(T_z) = P(T - \alpha(y, u)).$$

Hence $\alpha(y, u)$ is a basic path for $P'(T, u)$. □

4. The algorithm. We can use the theorems in §3 to design an efficient algorithm for the profile minimization problem in a tree T. By Theorem 3.1, the basic idea of our algorithm is to find a centroid z first in linear time. Suppose $T - z = \cup_{1 \leq i \leq m} T_i$, where u_i is the only vertex of T_i that is adjacent to z in T (see Fig. 4.1). To use Corollary 2.6 (3), we need to find all

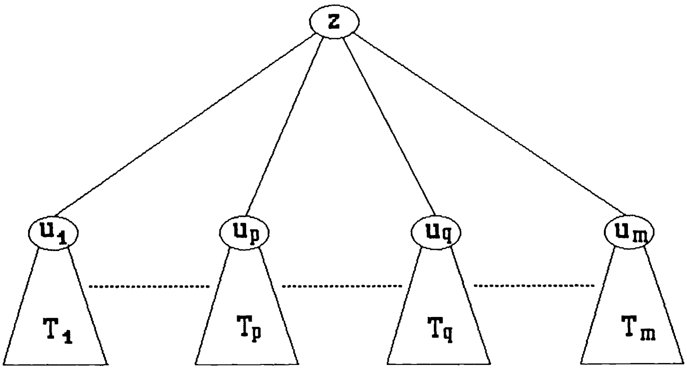

FIG. 4.1.

profiles $P(T_i)$ and $P'(T_i, u_i)$ recursively. In the following, Algorithm PROFILE finds $P(T)$ and Algorithm PROFILE1 finds $P'(T, u)$. Note that, in order to make use of Theorem 3.3, Algorithm PROFILE not only has to output the value $P(T)$ but also a basic path.

ALGORITHM PROFILE
Input: A tree T of n vertices.
Output: A basic path $\alpha(x, y) = (v_0, v_1, \ldots, v_r)$ for $P(T)$ and the values $P(T)$ and $P(T_{ij})$ for $1 \le i \le r-1$ and $1 \le j \le n_i$.
Method:

```
1. find a centroid $z$ of $T$.
2. let $T - z = \cup_{1 \le k \le m} T_k$ and $z$ be adjacent to $u_k \in V(T_k)$ for $1 \le k \le m$.
3. for each $1 \le k \le m$, recursively call PROFILE for $T_k$ to get a basic path $\alpha(x_k, y_k)$
   and values $P(T_k)$ and $P(T_{kij})$, where $T_{kij}$ are the components of $T_k - \alpha(x_k, y_k)$.
4. for each $1 \le k \le m$, recursively call PROFILE1 for $(T_k, u_k)$ to get a basic path
   $\alpha(z_k, u_k)$ and values $P'(T_k, u_k)$ and $P(T'_{kij})$, where $T'_{kij}$ are the components of $T_k -$
   $\alpha(z_k, u_k)$.
5. let $P(T) = n + \min_{1 \le p < q \le m}\{P'(T_p, u_p) + P'(T_q, u_q) + \sum_{i \ne p,q}(T_i)\}$, where $p^*$ and
   $q^*$ attain the above minimum.
6. let $\alpha(x, y) = \alpha(z_{p^*}, u_{p^*}) + z + \alpha(u_{q^*}, z_{q^*})$.
7. combine profiles $P(T_{p^*ij})$, $P(T_k)$ for $k \ne p^*, q^*$, and $P(T_{q^*ij})$ to get profiles $P(T_{ij})$.
```

To find $P'(T, u)$, we note that by Theorem 3.3, either $\alpha(x, u)$ or $\alpha(y, u)$ is a basic path for $P'(T, u)$. So we consider the configuration in Fig. 3.3 with T_z omitted.

ALGORITHM PROFILE1
Input: Tree T of n vertices with a basic path $\alpha(x, y) = (v_0, v_1, \ldots, v_r)$ for $P(T)$ and the values $P(T_{ij})$ for $1 \le i \le r-1$ and $1 \le j \le n_i$. u is a fixed vertex in T.
Output: A basic path $\alpha(z, u) = (v'_0, v'_1, \ldots, v'_{r'})$ for $P'(T, u)$ and the values $P'(T, u)$ and $P(T'_{ij})$ for $1 \le i \le r'$ and $1 \le j \le n'_i$.
Method:

```
1. identify the path $(u_1, u_2, \ldots, u_r)$ as in Fig. 3.3.
2. recursively use PROFILE to solve $P(T_x)$, $P(T_y)$, $P(F_i)$ (in fact $P(T_{ij})$ for each
   component in $F_i$) for $1 \le i \le r$.
3. $a = P'(T_x, v_1) + P(T_y) + \sum_{i=1}^{r} P(F_i)$,
   $b = P'(T_y, v_2) + P(T_x) + \sum_{i=1}^{r} P(F_i)$,
   where $P'(T_x, v_1)$ and $P'(T_y, v_2)$ can be computed from the input values $P(T_{ij})$.
4. $P'(T, u) = \min\{a, b\}$.
   if $a \le b$ then $z = x$ else $z = y$.
5. combine part of the profiles $P(T_{ij})$, $P(T_x)$, or $P(T_y)$, and $P(F_i)$ to get profiles $P(T'_{ij})$.
```

5. Time complexity. This section shows that the time complexities of the above two algorithms are $O(n^{1.722})$. Let $f(n)$ (respectively, $g(n)$) be the time complexity for Algorithm PROFILE (respectively, PROFILE1).

In Algorithm PROFILE, Step 3 (respectively, 4) needs $\sum_{i=1}^{m} f(n_i)$ (respectively, $\sum_{i=1}^{m} g(n_i)$) time, where $n_i = |V(T_i)|$ for $1 \le i \le m$. All other steps need $O(n)$ time. Note that for Step 5 we only have to find the smallest and the second smallest values of $P'(T_i, w_i) - P(T_i)$. Therefore

$$(5.1) \qquad f(n) = \sum_{i=1}^{m}\{f(n_i) + g(n_i)\} + c_1 n,$$

where

$$\sum_{i=1}^{m} n_i = n - 1 \quad \text{and} \quad n_i \le n/2 \quad \text{for} \quad 1 \le i \le m.$$

Similarly, in Algorithm PROFILE1, Step 2 needs $\sum_{i=1}^{m} f(n_i)$ time and all other steps need $O(n)$ time. Thus, by Theorem 3.2,

$$g(n) = \sum_{i=1}^{m} f(n_i) + c_2 n, \tag{5.2}$$

where

$$\sum_{i=1}^{m} n_i \le n - 1 \quad \text{and} \quad n_i \le 2n/3 \quad \text{for} \quad 1 \le i \le m.$$

To solve (5.1) and (5.2), we first choose a number $\sigma > 1$, which is very close to 1, say, $\sigma = 1.001$. Then choose $1 < \lambda < 2$ such that

$$\epsilon = \left(\frac{2}{3}\right)^{\lambda} + \left(\frac{1}{3}\right)^{\lambda} < 1$$

and

$$\delta = (1 + \sigma\epsilon)2\left(\frac{1}{2}\right)^{\lambda} < 1.$$

Note that a simple computer program gives that $\lambda = 1.722$ for $\sigma = 1.001$.

THEOREM 5.1. *There exists a constant c such that $f(n) \le cn^{\lambda}$ and $g(n) \le c\sigma\epsilon n^{\lambda}$ for all n, i.e., $f(n) = O(n^{\lambda})$ and $g(n) = O(n^{\lambda})$.*

Proof. The proof is by induction on n. Assume that there exists a constant c such that $f(n') \le cn'^{\lambda}$ and $g(n') \le c\sigma\epsilon n'^{\lambda}$ for all $n' < n$. We also assume that $c \ge c_1/(1-\delta)$ and $c \ge c_2/(\sigma - 1)\epsilon$.

For $0 < a \le b$, consider the function $h(x) = (b+x)^{\lambda} + (a-x)^{\lambda} - b^{\lambda} - a^{\lambda}$ where $0 \le x \le a$. Note that $h'(x) = \lambda(b+x)^{\lambda-1} - \lambda(a-x)^{\lambda-1} \ge 0$. So h is an increasing function and then $h(x) \ge h(0) = 0$ for $0 \le x \le a$. Thus

$$b^{\lambda} + a^{\lambda} \le (b+x)^{\lambda} + (a-x)^{\lambda} \quad \text{for} \quad 0 \le x \le a \le b. \tag{5.3}$$

By (5.1) and the induction hypothesis, we have $f(n) \le c(1+\sigma\epsilon)\sum_{i=1}^{m} n_i^{\lambda} + c_1 n$ where $\sum_{i=1}^{m} n_i = n - 1$ and $n_i \le n/2$ for $1 \le i \le m$. Repeatedly apply (5.3) to get $\sum_{i=1}^{m} n_i^{\lambda} \le \left(\frac{n}{2}\right)^{\lambda} + \left(\frac{n}{2} - 1\right)^{\lambda}$. Therefore $f(n) \le c(1+\sigma\epsilon)2\left(\frac{1}{2}\right)^{\lambda} n^{\lambda} + c_1 n = c\delta n^{\lambda} + c_1 n$. By the choice of c, $c_1 n \le c(1-\delta)n \le c(1-\delta)n^{\lambda}$. Then $f(n) \le cn^{\lambda}$.

By (5.2) and the induction hypothesis, we have $g(n) \le c\sum_{i=1}^{m} n_i^{\lambda} c_2 n$ where $\sum_{i=1}^{m} n_i \le n - 1$ and $n_i \le 2n/3$ for $1 \le i \le m$. Repeatedly apply (5.3) to get $\sum_{i=1}^{m} n_i^{\lambda} \le (2n/3)^{\lambda} + \left(\frac{n}{3}\right)^{\lambda} = \epsilon n^{\lambda}$. Also, by the choice of c, $c_2 n \le c(\sigma - 1)\epsilon n \le c(\sigma - 1)\epsilon n^{\lambda}$. Then $g(n) \le c\epsilon n^{\lambda} + c(\sigma - 1)\epsilon n^{\lambda} = c\sigma\epsilon n^{\lambda}$. □

MODIFICATIONS OF COMPETITIVE GROUP TESTING*

D.-Z. DU[†‡], G.-L. XUE[†], S.-Z. SUN[†] AND S.-W. CHENG[†]

Abstract. Many fault-detection problems fall into the following model: There is a set of n items, some of which are defective. The goal is to identify the defective items by using the minimum number of tests. Each test is on a subset of items and tells whether the subset contains a defective item or not. Let $M_\alpha(d, n)(M_\alpha(d \mid n))$ denote the maximum number of tests for an algorithm α to identify d defectives from a set of n items provided that d, the number of defective items, is known (unknown) before the testing. Let $M(d, n) = \min_\alpha M_\alpha(d, n)$. An algorithm α is called a *competitive algorithm* if there exist constants c and a such that for all $n > d > 0$, $M_\alpha(d \mid n) \leq cM(d, n) + a$. This paper confirms a recent conjecture that there exists a bisecting algorithm A such that $M_A(d \mid n) \leq 2M(d, n) + 1$. Also, an algorithm B such that $M_B(d \mid n) \leq 1.65M(d, n) + 10$ is presented.

Key words. group testing, competitive algorithm

AMS subject classification. 68P10

1. Introduction.

A feature of on-line problems [12], [15] is that information about input is not completely given at the beginning but is collected during the process of seeking a solution. This feature makes an optimal solution very hard to attain; an option is to consider competitive algorithms, which take responsibility for producing a reasonable solution. A similar situation occurs in some searching problems.

Consider a set of n items. Some items are *defective*, and others are *good*. The problem is to identify the defective items by a sequence of tests. Each test is on a subset of items and tells us whether the subset contains a defective item or not. In the former case the subset is said to be *contaminated*, and in the latter case the subset is said to be *pure*. The problem has applications in high-speed computer networks [4], string pattern recognition [11], medical examination [5], and quantity searching [3]. It also occurs in statistics [16], information theory [8], and related areas [1], [2], [10]. In the literature, the problem has been named *group testing*. It has two categories based on whether the tests have errors or are error free [3], [14]. In this paper we study error-free tests.

A classic model for such a searching problem is to assume that the number of defective items is known. This assumption is somewhat artificial since in practice this number is usually unknown *a priori* and it can be known only after testing. If the number of defective items is unknown at the beginning, how do we design and analyze algorithms? Motivated by the study of on-line problems [12], [15], Du and Hwang [7] proposed the concept of competitive algorithms for the group-testing problem.

Let $N_\alpha(s \mid d, n)(N_\alpha(s \mid n))$ be the number of tests that an algorithm α spends on a sample s of n items under the condition that d, the number of defective items, is known (unknown). Denote

$$M_\alpha(d, n) = \max_{s \in \mathcal{A}(n,d)} N_\alpha(s \mid d, n),$$

$$M(d, n) = \min_\alpha M_\alpha(d, n),$$

$$M_\alpha(d \mid n) = \max_{s \in \mathcal{A}(n,d)} N_\alpha(s \mid n),$$

when $\mathcal{A}(n, d)$ is the set of samples of n items containing d defective items. An algorithm α is called a *c-competitive* algorithm if there exists a constant a such that for $0 < d < n$, $M_\alpha(d \mid n) \leq c \cdot M(d, n) + a$. Note that in the definition we exclude two cases, $d = 0$ and $d = n$, because $M(0, n) = M(n, n) = 0$. A c-competitive algorithm for a constant c is simply called a competitive algorithm, and c is called the *competitive ratio* of the algorithm.

Du and Hwang [7] proposed a bisecting algorithm with competitive ratio 2.75 and conjectured that there exists a bisecting algorithm A such that $M_A(d \mid n) \leq 2M(d, n) + 1$ for $1 \leq d \leq n - 1$. Soon thereafter, Bar-Noy, Hwang, Kessler, and Kutten [4] discovered a doubling algorithm D such that $M_D(d \mid n) \leq 2M(d, n) + 5$ for $1 \leq d \leq n - 1$. In this paper we confirm Du and Hwang's conjecture by presenting a bisecting algorithm A such that $M_A(d \mid n) \leq 2M(d, n) + 1$. Also, we present an algorithm B such that $M_B(d \mid n) \leq 1.65M(d, n) + 10$.

2. Preliminaries. The analysis of competitive group testing involves both lower-bound and upper-bound problems. In this section we list some results about the lower bound for $M(d, n)$ that will be used in other sections.

There are $\binom{n}{d}$ samples for n items containing d defectives. Each test divides those samples into two sets. Therefore, we have the following information lower bound.

LEMMA 2.1. *For* $n > d > 0$

$$M(d, n) \geq \left\lceil \log_2 \binom{n}{d} \right\rceil \geq d \log_2 \frac{n}{d}.$$

A more useful bound derived from the aforementioned information lower bound is stated in the next lemma.

LEMMA 2.2. *For* $0 < d < \rho n$, $\rho \in (0, 1)$,

$$M(d, n) \geq d \left(\log_2 \frac{n}{d} + \log_2(e\sqrt{1 - \rho}) \right) - 0.5 \log_2 d - 0.5 \log_2(1 - \rho) - 1.568.$$

Proof. Note that the information lower bound is $\log_2 \binom{n}{d}$ for $M(d, n)$. since $n/d < (n - i)/(d - i)$ for $0 < i < d$, we have $M(d, n) \geq d \log_2(n/d)$. Now, we use Stirling's formula, $n! = \sqrt{2\pi n}(n/e)^n e^{\epsilon/(12n)} (0 < \epsilon < 1)$ [13], to obtain the following estimation.

$$\begin{aligned}\binom{n}{d} &\geq \sqrt{\frac{n}{2\pi d(n - d)}} \left(\frac{n}{d}\right)^d \left(\frac{n}{n - d}\right) n - d \exp\left(-\frac{1}{12d} - \frac{1}{12(n - d)}\right) \\ &> \frac{1}{\sqrt{d}} \left(\frac{n}{d}\right)^d \left[\left(1 + \frac{d}{n - d}\right)^{(n-d)/d+0.5}\right]^d \left(\frac{n}{n - d}\right)^{-0.5d+0.5} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{6}\right) \\ &> \frac{1}{\sqrt{d}} \left(\frac{n}{d}\right)^d (e\sqrt{1 - \rho})^d (1 - \rho)^{-0.5} 2^{-1.568}.\end{aligned}$$

Thus

$$M(d, n) > d \left(\log_2 \frac{n}{d} + \log_2(e\sqrt{1 - \rho}) \right) - 0.5 \log_2 d - 0.5 \log_2(1 - \rho) - 1.568. \qquad \square$$

Applying Lemma 2.2 to the case of $\rho = 8.21$, we have the following.

COROLLARY 2.3. *For* $0 < d < (8/21)n$

$$M(d, n) \geq d \left(\log_2 \frac{n}{d} + 1.096 \right) - 0.5 \log_2 d - 1.222.$$

Sometimes the information lower bound is too rough. Then the bound in the following lemma may be useful. This lemma can be found in [9].

LEMMA 2.4. *For* $1 \leq d \leq n-1$

$$M(d,n) \geq \min\left\{n-1, \max_{0\leq k<d}\left[\left\lceil \log \binom{n-k}{d-k}\right\rceil + 2k\right]\right\}.$$

Hu, Hwang, and Wang [9] conjectured that for $n \leq 3d$, $M(d,n) = n-1$. Du and Hwang [6] obtained the following from Lemma 2.4.

LEMMA 2.5. *If* $n > d \geq (8/21)n$, *then* $M(d,n) = n-1$.

3. Tight bound for bisecting. Let S be a set of n items. The principle of the bisecting algorithm is that at each step, if a contaminated subset X of S is discovered, then X is bisected and the resulting two subsets X' and X'' are tested. The method of bisecting will affect the competitive ratio. Here, we choose X' to contain $2^{\lceil \log_2 |X| \rceil - 1}$ items and $X'' = X \backslash X'$, where $|X|$ denotes the number of elements in X.

```
Algorithm A;
      input $S$;
      $G := \theta$; {a container of good items}
      $D := \theta$; {a container of defective items}
      TEST($S$);
      if $S$ is pure then $G := S$ and $Q := \theta$
         else $Q := \{S\}$;
      repeat
         choose the frontier element $X$ of queue $Q$;
         bisect $X$ into $X'$ and $x''$;
         TEST($X'$);
         if $X'$ is contaminated then TEST($X''$);
         {If $X'$ is pure, then it is known that $X''$ is contaminated.}
         for $Y := X'$ and $X''$ do begin
            if $Y$ is pure then $G := G \cup Y$;
            if $Y$ is a contaminated singleton then $D := D \cup Y$;
            if $Y$ is contaminated but not a singleton
               then put $Y$ into the rear of queue $Q$
         end-for;
       until $Q = \theta$
end-algorithm.
```

We will show the following.

THEOREM 3.1. *For* $1 \leq d \leq n-1$

$$M_A(d \mid n) \leq 2M(d,n) + 1. \tag{1}$$

A binary tree is a rooted tree with the property that each *internal node* has exactly two sons. A node is said to be the kth level of the tree if the path from the root to the node has length $k-1$. So the root is on the first level. Let i be the number of nodes in a binary tree, and let j be the number of internal nodes in the tree. It is well known that $i = 2j+1$.

Let T denote a binary tree with nodes denoted by X's in Algorithm A such that two nodes X' and X'' are sons of X if and only if they are obtained by bisecting X. Note that each leaf of T must identify at least one item. So T has at most n leaves. It follows that T has at most $2n-1$ nodes. Therefore, $M_A(d \mid n) \leq 2n-1$. By Lemma 2.5 if $d/n \geq 8/21$, then

$M_A(d \mid n) \le 2M(d,n) + 1$. Before proving Theorem 3.1 for $d/n < 8/21$, let us first show some lemmas.

For convenience we assume that the value of function $d \log_2 \frac{n}{d}$ at $d = 0$ is 0 because $\lim_{d \to 0} d \log_2 \frac{n}{d} = 0$. The following lemma is an important tool for our analysis.

LEMMA 3.2. *Let $d = d' + d''$ and $n = n' + n''$, where $d' \ge 0, d'' \ge 0, n' > 0$, and $n'' > 0$. Then*

$$d' \log_2 \frac{n'}{d'} + d'' \log_2 \frac{n''}{d''} \le d \log_2 \frac{n}{d}.$$

Proof. Note that $(d^2/dx^2)(-x \log_2 x) = -\frac{1}{x \ln 2} < 0$ for $x > 0$. So $-x \log_2 x$ is a concave function. Thus

$$\begin{aligned} d' \log_2 \frac{n'}{d'} + d'' \log_2 \frac{n''}{d''} &= n \left(\frac{n'}{n} \frac{d'}{n'} \log_2 \frac{n'}{d'} + \frac{n''}{n} \frac{d''}{n''} \log_2 \frac{n''}{d''} \right) \\ &\le n \left(\frac{d}{n} \log_2 \frac{n}{d} \right) \\ &= d \log_2 \frac{n}{d}. \qquad \square \end{aligned}$$

Clearly, when n is a power of 2, the analysis is relatively easy. So we first study this case.

LEMMA 3.3. *Let n be a power of 2. Then for $1 \le d \le n$*

$$M_A(d \mid n) \le 2d \left(\log_2 \frac{n}{d} + 1 \right) - 1.$$

Proof. Consider the binary tree T defined before Lemma 3.2. Clearly, every internal node must be contaminated and there exist exactly d contaminated leaves. Next, we count how many contaminated nodes we can have. Denote $u = \lceil \log_2 n \rceil$, $v = \lceil \log_2 d \rceil$, and $v' = v - \log_2 d$. Then the tree T has $u + 1$ levels, and the ith level contains 2^{i-1} nodes. Note that each level has at most d contaminated nodes and the $(v+1)st$ level is the first level that has at least d nodes. Thus the number of contaminated nodes is at most

$$\begin{aligned} \sum_{i=1}^{v} 2^{i-1} + (u - v + 1)d &= 2^v - 1 + d \left(\log_2 \frac{n}{d} + 1 - v' \right) \\ &= -1 + d \left(\log_2 \frac{n}{d} + 1 - v' + 2^{v'} \right) \\ &\le -1 + d \left(\log_2 \frac{n}{d} + 2 \right). \end{aligned}$$

The last inequality sign holds since $f(v') = -v' + 2^{v'}$ is a convex function of v' and v' is between 0 and 1. Thus T has at most $-1 + d(\log_2 \frac{n}{d} + 1)$ internal nodes and hence at most $2d(\log_2 \frac{n}{d} + 1) - 1$ nodes. $\square$

According to the way the bisection was done, each level of T contains at most one node that is a set whose size is not a power of 2. This property plays an important role in the following.

LEMMA 3.4. *For $0 \le d \le n$*

$$M_A(d \mid n) \le 2d \left(\log_2 \frac{n}{d} + 1 \right) + 1.$$

Proof. We prove the lemma by induction on n. For $n = 1$ the proof is trivial. For $n > 1$ let S be the set of n items. If $d = 0$, then one test is sufficient so that the lemma holds obviously. If $d > 0$, then we consider two cases corresponding to S' and S'' that are obtained by bisecting S.

Case 1. S' is contaminated. Since the number of items in S' is a power of 2, Algorithm A spends at most $2d'(\log_2(|S'|/d') + 1) - 1$ tests on S', where d' is the number of defective items in S'. Let d'' be the number of defective items in S''. By the induction hypothesis, Algorithm A spends at most $2d''(\log_2(|S''|/d'') + 1) + 1$ tests. Adding one for testing S, we obtain that the total number of tests is at most

$$2d'\left(\log_2\frac{|S'|}{d'} + 1\right) + 2d''\left(\log_2\frac{|S''|}{d''} + 1\right) + 1 \leq 2d\left(\log_2\frac{n}{d} + 1\right) + 1.$$

Case 2. S' is pure. In this case Algorithm A spends a test on S' and at most $2d(\log_2\frac{|S''|}{d} + 1) + 1$ tests on S''. So, adding one more test for S, we obtain that the total number of tests is at most

$$2 + 2d\left(\log_2\frac{|S''|}{d} + 1\right) + 1 = 2d\left(\log_2\frac{2|S''|}{d} + 1\right) + 1$$
$$\leq 2d\left(\log_2\frac{n}{d} + 1\right) + 1. \qquad \square$$

To prove Theorem 3.1, by the remark that we made after the proof of Theorem 3.1, we need only to consider the case for which $d/n < 8/21$. In this case, by Corollary 2.3 we have

$$M(d,n) > d\left(\log_2\frac{n}{d} + 1.096\right) - 0.5\log_2 d - 1.222.$$

Thus by Lemma 3.4

$$M_A(d\,|\,n) \leq 2M(d,n) + 2(0.5\log_2 d + 1.222 - 0.096d) + 1.$$

Let us look at the function $h(d) = 0.5\log_2 d - 0.096d$. $h'(d) = \frac{0.5}{d\cdot\ln 2} - 0.096$. So $h(d)$ is decreasing for $d \geq 8$. We want $h(d) \leq -1.222$. This yields $d \geq 41$. Therefore, for $d \geq 41$, $M_A(d\,|\,n) \leq 2M(d,n) + 1$.

Next, we use a more accurate analysis to deal with the case of $1 \leq d \leq 41$.

Define

$$f(n,d) = \frac{\binom{n}{d}\sqrt{2}}{\left(\frac{n}{d}\right)^d 2^d}. \tag{2}$$

If $f(n,d) > 1$, then from Lemma 3.4 and the information lower bound for $M(d,n)$ it is easy to see that

$$M_A(d\,|\,n) < 2M(d,n) + 2.$$

Since both sides of the inequality are integers, we have

$$M_A(d\,|\,n) \leq 2M(d,n) + 1.$$

Next, we study the case of $f(n,d) \leq 1$.

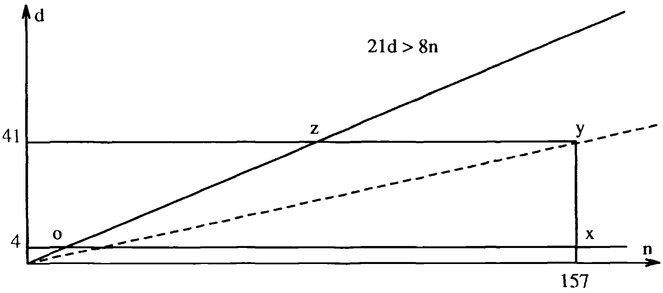

FIG. 1. *All (n, d) for $f(n, d) \leq 1$ are contained in the polygon oxyz.*

Consider the following ratio:

$$\frac{f(n, d+1)}{f(n, d)} = \frac{n-d}{2n}\left(1 + \frac{1}{d}\right)^d.$$

It is easy to see that

$$\frac{n-d}{2n} \cdot e > \frac{f(n, d+1)}{f(n, d)} > \frac{n-d}{2n}\left(\frac{d}{d+1}\right)^{1/2} \cdot e.$$

Thus we have the following lemma.

LEMMA 3.5. *For $\frac{d}{n} \geq 1 - \frac{2}{e}$, $f(n, d)$ is decreasing with respect to d. For $\frac{d}{n} \leq 1 - \frac{2}{e}\sqrt{(d+1)/d}$, $f(n, d)$ is increasing with respect to d.*

This lemma tells us the behavior of function $f(n, d)$ with respect to d. Next, we study its behavior with respect to n. Consider

$$g(n, d) = \frac{f(n+1, d)}{f(n, d)} = \frac{\frac{n+1}{n-d+1}}{\left(\frac{n+1}{n}\right)^d}.$$

Note that

$$\frac{g(n, d+1)}{g(n, d)} = \frac{n(n-d+1)}{(n+1)(n-d)} \geq 1$$

because

$$n(n-d+1) - (n+1)(n-d) = d.$$

Moreover, $g(n, 1) = 1$. Thus for $d \geq 1$, $g(n, d) \geq 1$. Therefore, we have the following lemma.

LEMMA 3.6. *For $d \geq 1$, $f(n, d)$ is increasing in n.*

From Lemmas 3.5 and 3.6 we see that if $f(n^*, d^*) > 1$, then for every $n \geq n^*$ and $(1 - \frac{2}{e}\sqrt{d/(d-1)})n + 1 \geq d \geq d^*$, $f(n, d) > 1$. Note that $f(157, 5) > 1$ and $(1 - \frac{2}{e}\sqrt{41/40}) \cdot 157 + 1 > 41$. It follows that for $n \geq 157$ and $d \geq 5$, $f(n, d) > 1$ (see Fig. 1). Unfortunately, the preceding argument does not help in the case of $d \leq 4$. In fact, it is easy to prove that for $1 \leq d \leq 4$, $f(n, d) < 1$. Actually, we need a more accurate upper bound for $M_A(d \mid n)$ for $1 \leq d \leq 4$. The details can be found in Appendix 1. Now, the remainder is a finite set of pairs (n, d)'s located in the polygon $oxyz$ as shown in Fig. 1.

For such finitely many pairs we compute $M_A(d \mid n)$ by the following formula:

$$M_A(d \mid n) = \max_{0 \le d' \le d} \{1 + M_A(d' \mid n') + M_a(d'' \mid n'')\}, \tag{3}$$

$$M_A(0 \mid n) = 1, \tag{4}$$

$$M_A(1 \mid n) = 2\lceil \log n \rceil + 1, \tag{5}$$

where $n' = 2^{\lceil \log n \rceil - 1}$, $n'' = n - n'$, and $d'' = d - d'$. We also compute a lower bound of $M(d, n)$ by the following formula:

$$\ell(d, n) = \min \left\{ n - 1, \max_{0 \le k < d} \left[\left\lceil \log \binom{n-k}{d-k} \right\rceil + 2k \right] \right\}.$$

Comparing two computational results, we find that $M_A(d \mid n) \le 2\ell(d, n) + 1$. (We can save some computation by a careful analysis; see Appendix 2 for details). This completes the proof of Theorem 3.1. □

4. 1.65-Competitive algorithm. Bar-Noy, Hwang, Kessler, and Kutten [4] discovered another way to design a competitive group-testing algorithm. Their basic idea is as follows. Because d, the number of defective items, is unknown, the algorithm tries to estimate the value of d. If d is small, the algorithm would like to find large pure sets, whereas if d is large, the algorithm would like to find small contaminated sets. To produce this behavior, the algorithm uses a doubling strategy. It tests a disjoint set of size $1, 2, \ldots, 2^i$ until a contaminated set is found. Namely, the first i sets are pure and the last set is contaminated. So the algorithm finds $1 + 2 + \cdots + 2^{i-1} = 2^i - 1$ good items and a contaminated set of size 2^i by using $i + 1$ tests. Next, the algorithm identifies a defective item from the contaminated item by a binary search with i tests as follows.

```
**Procedure** DIG($X$);
    **repeat**
        $X' := \lceil |Y|/2 \rceil$ items from $X$;
          TEST($X'$);
          **if** $X'$ is contaminated **then** $X := X'$
             **else** $X := X \backslash X'$;
                  $S := S \backslash X'$;
                  $G := G \cup X'$;
    **until** $X$ is a singleton;
    $S := S \backslash X$;
    $D := D \cup X$;
**end-procedure**;
```

Thus, the algorithm used a total of $2i + 1$ tests and identified 2^i items.

Here, we introduce a new idea as follows: Instead of testing disjoint sets of size $1, \ldots, 2^i$, the algorithm tests disjoint sets of size $1+2$, $4+8, \ldots, 2^i + 2^{i+1}$ for even i until a contaminated set is found. In this way the algorithm detects $2^i - 1$ good items by using $i/2$ tests instead of i tests. However, it found a contaminated set of size $3 \cdot 2^i$ instead of 2^i, which requires only one more test on a subset of size 2^i in order to reduce the contaminated set to either size 2^i or size 2^{i+1} with 2^i more good items. This idea is an extension of an idea given in [4] for combining the first two tests to further combining.

Let us first describe a procedure for three items, which is given in [4]. The input for this procedure is a contaminated set of three items. With two tests the procedure identifies either two defective items or at least one good item and one defective item.

```
Procedure 3-TEST({$x$, $y$, $z$});
    TEST($x$);
    TEST($y$);
    if $x$ is defective then $D := D \cup \{x\}$
        else $G := G \cup \{x\}$;
    if $y$ is defective then $D := D \cup \{y\}$
        else $G := G \cup \{y\}$;
    if $x$ and $y$ both are good
        then $S := S \backslash \{x, y, z\}$
             $D := D \cup \{z\}$
        else $S := S \backslash \{x, y\}$;
end-procedure;
```

An extension of Procedure 3-TEST is as follows. The input is a contaminated set of $3 \cdot 2^k$ items ($k > 0$). The procedure first finds either a contaminated set of size 2^k or a pure set of size 2^k and a contaminated set of size 2^{k+1} and then digs out a defective item from the resultant contaminated set.

```
Procedure 3-SET-TEST($X$);
    $X' := \min(2^k, |X|)$ items from $X$;
    TEST($X'$);
    if $X'$ is contaminated
        then $X := X'$
        else $X := X \backslash X'$
             $G := G \cup X'$
             $S := S \backslash X'$;
    DIG($X$);
end-procedure
```

Now, we describe the main body of the algorithm.

```
Algorithm B;
    input $S$;
    $D := \emptyset$;
    $G := \emptyset$;
    while $|S| \geq 3$ do
        $k := 0$;
        repeat {jumping process}
            $X := \min(2^k + 2^{k+1}, |S|)$ items from $S$;
            TEST($X$);
            if $X$ is pure then $G := G \cup X$
                                $S := S \backslash X$
                                $k := k + 2$;
            if $k = 10$ then TEST($S$)
                             if $S$ is pure then $G := G \cup S$
                                                 $S := \emptyset$;
            until $X$ is contaminated;
            if $k = 0$ then 3-TEST($X$);
            if $k > 0$ then 3-SET-TEST($X$);
        end-while;
        while $S \neq \emptyset$ do
            $x :=$ an item from $S$;
            TEST($x$);
            if $x$ is good then $G := G \cup \{x\}$;
            if $x$ is defective then $D := D \cup \{x\}$;
            $S := S \backslash \{x\}$;
        end-while;
end-algorithm
```

Next, we analyze Algorithm B in a way similar to that in §3.

LEMMA 4.1. $M_B(d\,|\,n) \leq 1.65d(\log_2 \frac{n}{d} + 1.031) + 5$.

Proof. We prove the lemma by induction on d. For $d = 0$, since the algorithm will test S when $k = 10$, it takes at most five tests to find that S is pure. Thus $M_B(0\,|\,n) \leq 5$.

For $d > 0$ suppose that the first time that the computation goes out from the jumping process is with $k = i$. So a contaminated set X of size at most $2^i + 2^{i+1}$ (i is even) and $2^i - 1$ good items are found with $i/2 + 1$ tests. Next, consider three cases.

Case 1. $i = 0$. Procedure 3-TEST identifies either two defective items or at least one good item and one defective item by two tests. Applying the induction hypothesis to the remaining $n - 2$ items, we obtain that in the former subcase the total number of tests is at most

$$\begin{aligned} &3 + 1.65(d-2)\left(\log_2 \frac{n-2}{d-2} + 1.031\right) + 5 \\ &= 1.5 \cdot 2\left(\log_2 \frac{2}{2} + 1\right) + 1.65(d-2)\left(\log_2 \frac{n-2}{d-2} + 1.031\right) + 5 \\ &\leq 1.65d\left(\log_2 \tfrac{n}{d} + 1.031\right) + 5; \end{aligned}$$

in the latter subcase the total number of tests is at most

$$\begin{aligned} &3 + 1.65(d-1)\left(\log_2 \frac{n-2}{d-1} + 1.031\right) + 5 \\ &= 1.5(\log_2 2 + 1) + 1.65(d-1)\left(\log_2 \frac{n-2}{d-1} + 1.031\right) + 5 \\ &\leq 1.65d\left(\log_2 \frac{n}{d} + 1.031\right) + 5. \end{aligned}$$

Case 2. $2 \leq i \leq 8$. Procedure 3-SET-TEST finds either one defective item by using at most $i + 1$ tests or one defective item and 2^i good items by using at most $i + 2$ tests. In the former subcase the total number of identified items is 2^i and the total number of tests for detecting them is at most

$$(i/2 + 1) + (i + 1) \leq 1.65(\log_2 2^i + 1.031);$$

in the latter case the total number of identified items is 2^{i+1} and the total number of tests for identifying them is at most

$$(i/2+1)+(i+2) \leq 1.50(\log_2 2^{i+1}+1).$$

Applying the induction hypothesis to the remaining unidentified items and using Lemma 3.2, we can obtain the upper bound $1.65d(\log_2 \frac{n}{d}+1.031)+5$ for the total number of tests.

Case 3. $i \geq 10$. This case is similar to Case 2. The difference is that the algorithm uses one more test for testing on S when $i = 10$. So, corresponding to the two subcases in Case 2, we have that in the former subcase the total number of tests for identifying $2^i - 1$ good items and one defective item is at most

$$(i/2+1)+(i+2) \leq 1.65(\log_2 2^i + 1.031);$$

in the latter subcase the total number of tests for identifying 2^{i+1} good items and one defective item is at most

$$(i/2+1)+(i+3) \leq 1.65(\log_2 2^{i+1}+1.031).$$

The proof is completed by applying the induction hypothesis to the remaining unidentified items and using Lemma 3.2. □

LEMMA 4.2. *For* $0 \leq d \leq n$, $M_B(d \mid n) \leq 1.5n$.

Proof. We prove the lemma by induction on d. For $d = 0$ the algorithm needs one test when $n \leq 3$, two tests when $4 \leq n \leq 15$, and at most five tests when $n > 16$, so that $M_B(0 \mid n) \leq 1.5n$. For $d > 0$ suppose that the first time that the computation goes out from the jumping process is with $k = i$. So a contaminated set X of size at most $2^i + 2^{i+1}$ (i is even) and $2^i - 1$ good items are found with $i/2+1$ tests. Next, we follow the trace of the proof of the last lemma to verify that in each case the number of tests is at most 1.5 times the number of identified items.

Case 1. $i = 0$. Two items were identified by using three tests.

Case 2. $2 \leq i \leq 8$. Either 2^i items were identified by using $1.5i+2$ tests or 2^{i+1} items were identified by using $1.5i+3$ tests. Since $i \geq 2$, $1.5i+2 \leq 1.5 \cdot 2^i$ and $1.5i+3 \leq 1.5 \cdot 2^{i+1}$.

Case 3. $i \geq 10$. Either 2^i items were identified by using $1.5i+3$ tests or 2^{i+1} items were identified by using $1.5i+4$ tests. Since $i \geq 10$, $1.5i+3 \leq 1.5 \cdot 2^i$ and $1.5i+4 \leq 1.5 \cdot 2^{i+1}$.

The proof is completed by applying the induction hypothesis to the remaining unidentified items and adding the bound to the inequality in each of the cases or subcases. □

THEOREM 4.3. *For* $1 \leq d \leq n-1$, $M_B(d \mid n) \leq 1.65M(d,n)+10$.

Proof. If $d/n \geq 8/21$, then $M(d,n) = n-1$. The theorem then follows from Lemma 4.2. If $d/n < 8/21$, then by Lemma 4.1 and Corollary 2.3 we have

$$M_B(d \mid n) \leq 1.65M(d,n)+5+1.65(0.5\log_2 d - 0.065d+1.222).$$

Denote $h(d) = 0.5\log_2 d - 0.065d$. Then $h(d)$ increases for $d \leq 11$ and decreases for $d \geq 12$. Thus $h(d) \leq \max(h(11), h(12)) \leq 1.015$. Hence $M_B(d \mid n) \leq 1.65M(d,n)+9.3$. □

By modifying Algorithm B, the competitive ratio could be further improved to approach 1.5. The modification can be done through studying the competitive group testing for a small number of items. For example, if instead of Procedure 3-TEST we use a procedure for testing 12 items, the competitive ratio can be decreased to be less than 1.6. However, how to push the competitive ratio down from 1.5 is unknown.

Appendix 1: Proof of Theorem 3.1 for $1 \le d \le 4$. Let us prove the following lemmas.

LEMMA 3.7.

$$\begin{aligned} M_A(1\,|\,2^u) &= 2u+1 \quad \textit{for } u \ge 0, \\ M_A(2\,|\,2^u) &= 4u-1 \quad \textit{for } u \ge 1, \\ M_A(3\,|\,2^u) &= 6u-5 \quad \textit{for } u \ge 2, \\ M_A(4\,|\,2^u) &= 8u-9 \quad \textit{for } u \ge 2. \end{aligned}$$

Proof. We prove the lemma by induction on u. It is easy to check each initiation. For induction we employ formulae (3), (4), and (5) to yield the following:

$$\begin{aligned} M_A(1\,|\,2^u) &= 1 + M_A(1\,|\,2^{u-1}) + M_A(0\,|\,2^{u-1}) \\ &= 1 + 2(u-1) + 1 + 1 \\ &= 2u+1, \\ M_A(2\,|\,2^u) &= \max(1 + M_A(2\,|\,2^{u-1}, 1 + 2M_A(1\,|\,2^{u-1}))) \\ &= \max(4u-4, 4u-1) \\ &= 4u-1, \\ M_A(3\,|\,2^u) &= \max(1 + M_A(3\,|\,2^{u-1}), 1 + M_A(1\,|\,2^{u-1}) + M_A(2\,|\,2^{u-1})) \\ &= \max(6u-10, 6u-5) \\ &= 6u-5, \\ M_A(4\,|\,2^u) &= \max_{0\le d'\le 4}(M_A(d'\,|\,2^{u-1}) + M_A(4-d'\,|\,2^{u-1})) \\ &= \max(8u-17, 8u-11, 8u-9) \\ &= 8u-9. \qquad \square \end{aligned}$$

LEMMA 3.8. *Let* $u+1 = \lceil \log n \rceil$, $v = \lceil \log(n-2^u) \rceil$, *and* $w = \lceil \log(n - 2^u - 2^{v-1}) \lceil$. *Then*

$$\begin{aligned} &M_A(1\,|\,n) \le 2(u+1)+1, \\ &M_A(2\,|\,n) \le \max(4u+1, 2(u+v+1)+1), \\ &M_A(3\,|\,n) \le \max(6u-3, 4u+2v+1), \\ &M_A(4\,|\,n) \le \max(8u-7, 6u+2v-3, 4u+4v-3, 4u+2v+2w+1). \end{aligned}$$

Proof. Use the recursive formula (3), and note that $M_A(d\,|\,n-2^u) \le M_A(d\,|\,2^v)$. □

Now, we prove Theorem 3.1 in the case of $1 \le d \le 4$ as follows. Note that u and v are defined the same as in Lemma 3.8.

For $d = 1$, $M_A(1\,|\,n) \le 2(u+1)+1 = 2M(1,n)+1$.

For $d = 2$, if $v < u$, then $M_A(2\,|\,n) \le 4u+1$ and

$$M(2,n) \ge \left\lceil \log \binom{n}{2} \right\rceil \ge \left\lceil \log \frac{(2^u+1)2^u}{2} \right\rceil = 2u.$$

So $M_A(2\,|\,n) \le 2M(2,n)$. If $u = v$, then $M_A(2\,|\,n) = 2(2u+1)+1$ and

$$\begin{aligned} M(2,n) &\ge \left\lceil \log \binom{n}{2} \right\rceil \\ &\ge \left\lceil \log \frac{(2^u+2^{u-1}+1)(2^u+2^{u-1})}{2} \right\rceil \\ &\ge \lceil \log(2^{2u}+2^{2u-3}) \rceil = 2u+1. \end{aligned}$$

Thus (1) holds.

For $d = 3$ verification is trivial for $u = 1$. Next, we consider $u \ge 2$. If $v < u$, then $M_A(3\,|\,n) \le 2(3u-2)+1$ and

$$\begin{aligned} M(3,n) &\ge \left\lceil \log \binom{n}{3} \right\rceil \\ &\ge \left\lceil \log \frac{(2^u+1)2^u(2^u-1)}{6} \right\rceil \\ &\ge \lceil \log((2^u+1)2^{2u-3}) \rceil \\ &\ge 3u-2. \end{aligned}$$

Thus (1) holds. If $u = v$, then $M_A(3\,|\,n) \le 6u+1$ and

$$\begin{aligned} M(3,n) &\ge \left\lceil \log \binom{n}{3} \right\rceil \\ &\ge \left\lceil \log \frac{(2^u+2^{u-1}+1)(2^u+2^{u-1})(2^u+2^{u-1}-1)}{6} \right\rceil \\ &\ge \lceil \log((2^{2u+1}+2^{2u-2}-1)2^{u-2}) \rceil \\ &\ge 3u. \end{aligned}$$

For $d = 4$ it is trivial to verify (1) for $u = 1$ and 2. Next, consider $u \ge 3$. If $v < u$ and $w < u-1$, then $M_A(4\,|\,n) \le 2(4u-3)+1$ and

$$\begin{aligned} \left\lceil \log \binom{n}{4} \right\rceil &\ge \left\lceil \log \frac{(2^u+1)2^u(2^u-1)(2^u-2)}{8 \cdot 3} \right\rceil \\ &= \left\lceil \log \frac{(2^{3u}-2^{2u}-2^{u-1}+1)2^{u-2}}{3} \right\rceil \\ &\ge 4u-3. \end{aligned}$$

Thus (1) holds. If $u = v$ and $w < u - 1$, then $M_A(4 \,|\, n) \le 2(4u - 2) + 1$ and

$$\begin{aligned}
\left\lceil \log \binom{n}{4} \right\rceil &\ge \left\lceil \log \frac{(2^u + 2^{u-1} + 1)(2^u + 2^{u-1})(2^u + 2^{u-1} - 1)(2^u + 2^{u-1} - 2)}{8 \cdot 3} \right\rceil \\
&\ge \left\lceil \log \frac{((2^u + 2^{u-1})^2 - 1)((2^u + 2^{u-1} - 1)^2 - 1)}{3 \cdot 8} \right\rceil \\
&\ge \left\lceil \log \left(\frac{2^{2u+1} + 2^{2u-2} - 1}{3} \cdot \frac{2^{2u+1} + 2^{2u-2} - 2^u - 2^{u-1}}{8} \right) \right\rceil \\
&\ge \left\lceil \log((2^{2u-1} + 1)2^{2u-2}) \right\rceil \\
&\ge 4u - 2.
\end{aligned}$$

So (1) holds. If $w = u - 1$, then we must have $u = v$ and $M_A(4 \,|\, n) \le 2(4u - 1) + 1$. Note that $n \ge 2^u + 2^{u-1} + 2^{u-2} + 1$. Thus

$$\begin{aligned}
\left\lceil \log \binom{n}{4} \right\rceil &\ge \left\lceil \log \frac{((2^u + 2^{u-1} + 2^{u-2})^2 - 1)((2^u + 2^{u-1} + 2^{u-2} - 1)^2 - 1)}{3 \cdot 8} \right\rceil \\
&\ge \left\lceil \log \left(\frac{2^{2u+1} + 2^{2u} + 2^{2u-4} - 1}{3} \cdot \frac{2^{2u+1} + 2^{2u} + 2^{2u-4} - 2^u - 2^{u-1} - 2^{u-2}}{8} \right) \right\rceil \\
&\ge \left\lceil \log((2^{2u} + 1)2^{2u-2}) \right\rceil \\
&\ge 4u - 1.
\end{aligned}$$

Therefore, (1) holds.

Appendix 2: Proof of Theorem 3.1 for $5 \le d \le 40$. To save some computation, let us first compute $n_d = \min\{n \mid f(n, d) > 1\}$ for $5 \le d \le 40$, where $f(n, d)$ is the function defined by (2). The result is shown in the following.

$$\begin{array}{llllll}
n_5 = 73, & n_6 = 44 & n_7 = 38, & n_8 = 37, & n_9 = 37, & n_{10} = 37, \\
n_{11} = 39, & n_{12} = 40, & n_{13} = 42, & n_{14} = 43, & n_{15} = 45, & n_{16} = 47, \\
n_{17} = 49, & n_{18} = 50, & n_{19} = 52, & n_{20} = 54, & n_{21} = 56, & n_{22} = 58, \\
n_{23} = 60, & n_{24} = 62, & n_{25} = 64, & n_{26} = 66, & n_{27} = 68, & n_{28} = 70, \\
n_{29} = 72, & n_{30} = 74, & n_{31} = 76, & n_{32} = 78, & n_{33} = 80, & n_{34} = 82, \\
n_{35} = 84, & n_{36} = 86, & n_{37} = 88, & n_{38} = 90, & n_{39} = 92, & n_{40} = 94.
\end{array}$$

From the preceding equations we see that for $21 \le d \le 40$, $d/n_d \ge 8/21$. Therefore, for $21 \le d \le 40$, (1) holds. Now, for $5 \le d \le 20$ and $(21/8)d < n < n_d$ we compute $M_a(d \,|\, n)$ and $\ell(d, n)$. The results are given in Table 1 and show that $M_A(d \,|\, n) \le 2\ell(d, n) + 1$.

TABLE 1

THE COMPLEXITY OF DECISION VERSUS SEARCH*

MIHIR BELLARE[†] AND SHAFI GOLDWASSER[‡]

Abstract. A basic question about NP is whether or not search reduces in polynomial time to decision. This paper indicates that the answer is negative: Under a complexity assumption (that deterministic and nondeterministic double-exponential time are unequal) a language in NP for which search does not reduce to decision is constructed.

These ideas extend in a natural way to interactive proofs and program checking. Under similar assumptions, the authors present languages in NP for which it is harder to prove membership interactively than it is to decide this membership, and languages in NP that are not checkable.

Key words. NP-completeness, self-reducibility, interactive proofs, program checking, sparse sets, quadratic residuosity

AMS subject classifications. 68Q15, 03D15, 94A60

1. Introduction.

The work on interactive proofs brought back to light a basic question: How powerful does a prover need to be to convince a verifier of membership in a language L? Clearly, the prover needs at least the power to decide the language for himself. The question we focus on is whether this is enough.

There are interactive proofs known for complete problems in NP, $P^{\#P}$, and PSPACE where it is sufficient for the prover to be able to decide membership in the language. Such power is also sufficient for almost all of the languages in IP that have been closely examined (specifically, the languages of graph isomorphism, graph nonisomorphism [GMW], and quadratic nonresiduosity [GMR]). On the other hand, all known interactive proofs for complete languages for coNP require the prover to do more than decide membership in the language. Similarly, all known interactive proofs for the language of quadratic residuosity require the prover to do more than decide quadratic residuosity.

As we will see, this is essentially a generalization of the old question of whether search problems reduce to their decision counterpart for NP. Namely is computing a witness for membership in $L \in$ NP any harder than establishing the existence of such a witness? For NP-complete problems it is well known that the answer is no: given an oracle for membership a witness can be computed in polynomial time. But for general $L \in$ NP the problem remains open.

In this paper we use natural complexity assumptions to indicate that proving membership may be harder than deciding it. As a first example we look at decision versus search in NP. We then turn to interactive proofs and finally apply the same ideas to derive results on the difficulty of program checking.

Let us proceed to describe our results in detail.

1.1. Decision versus search in NP.

Before we can present our results, we need to say what we mean by "search," "decision," and the "reduction" of the former to the latter. We will

*Received by the editors March 23, 1992; accepted for publication (in revised form) August 21, 1992. These results appeared in preliminary form in [BG]. Later, merged with [BF], they appeared in [BBFG].

keep the discussion here informal; for formal definitions we refer the reader to §2.1. We start with some terminology.

Suppose $\rho(\cdot, \cdot)$ is a polynomial-time computable binary relation. We let $\rho(x) = \{w : \rho(x, w) = 1\}$ be the set of all ρ-witnesses for x. We say that ρ is an NP-relation if there exists a constant c such that for all $x \in \{0, 1\}^*$ it is the case that $\rho(x) \subseteq \{0, 1\}^{|x|^c}$. We let $L_\rho = \{x \in \{0, 1\}^* : \rho(x) \neq \emptyset\}$.

Now let $L \subseteq \{0, 1\}^*$ be a language. We say that ρ defines L if $L = L_\rho$. Clearly, $L \in$ NP if and only if there exists an NP-relation that defines L. It is important to note, however, that for any particular NP language L, there are many (different) NP-relations that define it.

Associated to any NP language L is a (single) decision problem and a class of search problems. The decision problem is, of course, just the problem of deciding membership in L. As for the search problems, there is one for each NP-relation that defines L, and the search problem corresponding to a particular NP-relation ρ that defines L is the following: given $x \in L$, find a ρ-witness for x. For example, if L is SAT, then the decision problem is to decide whether or not a given formula is satisfiable. One of the associated search problems is to determine a truth assignment of a given satisfiable formula (but there are other associated search problems as well).

We are interested in defining what it means for search to reduce to decision for L. As a means for obtaining the definition and understanding the issues involved, we begin by discussing a less general notion: that of reducing search to decision for an NP-relation ρ (defining L).

Fix a particular NP-relation ρ that defines L. We say that "search reduces to decision for ρ" if the search problem for ρ is solvable in polynomial time, given an oracle for the decision of $L = L_\rho$. More precisely, search reduces to decision for ρ if there exists a polynomial-time oracle machine W such that for all $x \in L$ it is the case that $W^L(x)$ (the output of W with oracle L and input x) is a ρ-witness for x. Intuitively, the search problem for ρ is no harder than the decision problem for the corresponding language.

We are now ready to state what it means for search to reduce to decision for a *language* $L \in$ NP. We recall that there are many different NP-relations defining L. In general, search might reduce to decision for some of these and not for others. Our definition is to say that search reduces to decision for L as long as there is *some* NP-relation ρ (defining L) such that search reduces to decision for ρ. In other words, we say that search reduces to decision for L as long as at least one of the (many different) search problems associated to the decision problem for L is no harder than this decision problem.

The motivation for this definition, which stems from the question of whether proving membership can be harder than deciding it, will become clearer as we go on. For the moment, it is more important to stress the generality of our definition and the strength of negative conclusions that are based on it. In particular, to say that search does *not* reduce to decision for a particular language L (as in the conclusion of the theorem that follows) is to make a strong statement indeed, because it means that for *all* ρ defining L it is the case that search does not reduce to decision for ρ. That is, *all* the search problems corresponding to the decision problem of L are harder than this decision problem. In particular, the existence of a language for which search does not reduce to decision certainly implies the existence of an NP-relation for which search does not reduce to decision.

To state the theorem we first need the following definitions:

$$\mathrm{EE} = \bigcup_{c \geq 0} \mathrm{DTIME}(2^{c2^n}) \quad \text{and} \quad \mathrm{NEE} = \bigcup_{c \geq 0} \mathrm{NTIME}(2^{c2^n}).$$

THEOREM 1.1. *Suppose EE $\neq$ NEE. Then there is a language in* NP *for which search does not reduce to decision.*

Note that the conclusion (of Theorem 1.1) implies P $\neq$ NP. Whether the assumption could be reduced to P $\neq$ NP (or even E $\neq$ NE) remains an open question.

We note that if L is NP-complete, then for *any* NP-relation ρ that defines L, it is the case that search reduces to decision for ρ (a consequence of the self-reducibility and NP-completeness of SAT as well as certain features of the proof of Cook's theorem [Co]; this is one of the most basic and well-known facts in the theory of computation). In particular, by our definition search certainly reduces to decision for any NP-complete language. So the hard problems (from the point of view of search versus decision) will necessarily be non-NP-complete. In particular, the language of the conclusion of Theorem 1.1 is not NP-complete.

The decision-versus-search question has attracted the attention of researchers ever since NP was introduced (we survey some of the work on this subject in §1.5). However, we note that previous work has focused on the question of whether search reduces to decision for NP-relations (not NP-languages), and the conclusions have been weaker than ours.

1.2. Competitive proof systems: The natural extension. NP represents the simplest kind of proof system. An NP proof system for L is defined by a polynomial time verifier V. This verifier talks to a prover who, on an input x common to both parties, is allowed to send the verifier a single message of length polynomial in $n = |x|$. As a function of this message and the common input, the verifier decides whether or not to accept (this decision of the verifier is a polynomial-time binary predicate ρ evaluated on the common input and the prover's message). In the case that $x \in L$ there must exist some *deterministic* prover P who can convince the verifier to accept (this is the *completeness* condition). In the case that $x \notin L$ no prover should be able to convince the verifier to accept (this is the *soundness* condition). We usually specify an NP proof system by a pair (P, V), where P is a prover satisfying the completeness condition. Clearly, $L \in$ NP if and only if it possesses an NP proof system.

How powerful need the prover P be in an NP proof system for L? It is clear the prover must have at least the ability to decide L for himself. Let us call an NP proof system (P, V) *competitive* if this minimal ability is also sufficient; more precisely, (P, V) is competitive if P runs in polynomial time given an oracle for L. It now becomes clear that the question of whether or not search reduces to decision for $L \in$ NP captures the computational difficulty of the prover's task under this competitive measure of complexity. More precisely, we observe that L has a competitive NP proof system if and only if search reduces to decision for L. Thus Theorem 1.1 indicates that there is a language $L \in$ NP to give an NP proof of which any prover must use power over and above that necessary to decide L.

NP proof systems, however, are very restrictive. It becomes natural to ask, would the prover's task be alleviated if the parties were allowed interaction and the proof was now only required to be correct with high probability? In other words, we now consider interactive proofs (see [GMR]). We recall that in an interactive proof both parties are allowed to be probabilistic and the parties are allowed to exchange messages, for a polynomial number of rounds, before the verifier decides whether or not to accept. Completeness and soundness are required to hold only with high probability (see §4.1 for precise definitions). Let us call an interactive proof system competitive if the prover[1] runs in probabilistic polynomial time, given access to L as an oracle. Then does every language in NP (and more generally in IP) have a competitive interactive proof? In other words, does the extra leeway provided by interaction and randomness reduce the burden on the prover, or does the discrepancy between proving and deciding remain even if coins and interaction are allowed?

Quadratic residuosity provides a telling example. Let QR $= \{(x, N) : \exists y \in Z_N^* \text{ s.t. } x \equiv y^2 (\text{mod } N)\}$, and let QNR $= \{(x, N) : \neg\exists y \in Z_N^* \text{ s.t. } x \equiv y^2 (\text{mod} N)\}$. Search is not known

[1] The prover here refers, of course, to the "honest" prover of the completeness condition; the soundness condition of the proof system is, as usual, required to hold with respect to any (computationally unbounded) prover.

to reduce the decision for QNR; in all known NP proof systems for QNR the prover requires the ability to factor N, and factoring is not known to be reducible to quadratic residuosity. Yet, we do know of *interactive* proofs for membership in QNR where it suffices for the prover to be able to tell membership in QR (i.e., QNR does have competitive interactive proofs) [GMR]. On the other hand, there is no known interactive proof for QR where it suffices for the prover to be able to decide membership in QR (i.e., QR is *not* known to have a competitive interactive proof).

Our next result indicates that, in general, interaction and randomness will not make the prover's task easier. More precisely, we indicate that not all languages in NP have competitive interactive proofs. Letting BPEE denote the class of languages recognized with bounded error by a probabilistic TM running in time 2^{c2^n} for some constant $c \geq 0$, we have the following theorem.

THEOREM 1.2. *If* NEE $\not\subseteq$ BPEE, *then there is a language in* NP *that does not have a competitive interactive proof.*

The complexity of a prover in an interactive proof system is a basic question that is attracting a fair amount of attention (see §1.5). The notion of competitive interactive proofs that we introduce provides an new angle from which to understand this question; whereas past work has focused on providing upper bounds on the complexity of provers, we are instead trying to understand the comparative complexity of proving versus deciding.

1.3. Program checking. We briefly mention our results on program checking that are in the same vein as the preceding.

Blum and Kannan [BK] introduced the notion of program checkers (see §5 for full definitions). Negative results in this domain begin with Yao [Ya], who presented a language in deterministic space $2^{n^{\log\log n}}$ that does not have a checker. Beigel and Feigenbaum [BF] and Krawczyk [Kr] improved this to deterministic space $n^{\log^* n}$. The question of whether there are languages of reasonable complexity that are not checkable was answered by Beigel and Feigenbaum [BF] under an assumption: they showed there was one such in NP provided that nondeterministic *triple* exponential time is not contained in bounded probabilistic *triple* exponential time. We improve the assumption to *double* exponential time. Namely, we have the following.

THEOREM 1.3. *If* NEE $\not\subseteq$ BPEE, *then there is a language in* NP *that does not have a checker.*

1.4. A natural candidate? Clearly, it would be most interesting to exhibit an example of a *natural* problem in NP for which there are no competitive interactive proofs. A candidate example—as we indicated in §1.2—is the quadratic residuosity problem. Let us consider the interactive proofs known for membership both in QR and QNR in more detail.

First, for membership of (x, N) in QNR, the following protocol is repeated k times (see [GMR]). The verifier tosses a coin $c \in \{0, 1\}$. If $c = 1$, then the verifier sends the prover $z = xr^2 \bmod N$ for random $r \in Z_N^*$; else the verifier sends the prover $z = r^2 \bmod N$ for random $r \in Z_N^*$. The prover is then asked to guess the value of c. If the prover guesses correctly in each repetition of the protocol, then the verifier accepts. Clearly, if $(x, N) \in$ QNR, then $c = 1$ if and only if $(z, N) \notin$ QR. Thus it is sufficient for the prover to be able to determine membership in QR in order to guess c, and the prover is competitive. On the other hand, if $(x, N) \notin$ QNR, then the probability that the verifier accepts is no greater than 2^{-k}.

How about proving that $(x, N) \in$ QR? A simple proof would be the factorization of N or a $y \in Z_N^*$ such that $x \equiv y^2 \pmod N$. In fact, all known interactive proofs of this fact require the ability to factor N. Because we do not know whether factoring reduces to deciding quadratic residuosity, it remains an intriguing open problem whether membership in QR can be interactively proved by a probabilistic polynomial-time prover with access to a QR oracle. In particular, if the answer to this question were negative, we would get the following interesting number-theoretic implication: integer factorization is not polynomial-time reducible to deciding quadratic residuosity.

We note that there are special classes of integers N for which $(x, N) \in \mathrm{QR}$ can be interactively proved be a probabilistic polynomial-time prover with access to a QR oracle. For example, this can be done when N is the product of a constant number of primes (see §6).

1.5. Related work. We discuss related work on decision versus search and the complexity of provers.

1.5.1. Decision versus search for NP. The decision-versus-search question has attracted the attention of researchers ever since NP was introduced. It has been studied in many different contexts and from many angles, and, in particular, many results have indicated that for NP, search is likely to be harder than decision. We stress that all these results are about search versus decision for NP-relations, not NP-languages. So, in that sense, the conclusions are weaker than ours.

Let us now describe some of this work. In what follows we let ρ denote a polynomial-time computable binary predicate.

Valiant [Va] appears to have been the first to indicate that there are NP-relations ρ for which search is unlikely to reduce to decision; specifically, assuming $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$, he presents a particular NP-relation ρ with the property that search does not reduce to decision for ρ. However, the underlying language L_ρ in Valiant's result is easy; in fact, it equals $\{0, 1\}^*$. Borodin and Demers [BD] strengthen Valiant's result in this regard by showing that under the same assumption there is an NP-relation ρ for which $L_\rho \in \mathrm{NP} - \mathrm{P}$, but search still does not reduce to decision for ρ. Hartmanis and Hemachandra [HH] present results similar to Valiant's but assume $\mathrm{P} \neq \mathrm{UP} \cap \mathrm{coUP}$.

Impagliazzo and Naor [IN] indicate that, at least in relativized worlds, the assumption $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$ is not necessary for the conclusion of Valiant's result. More precisely, they present a relativized world in which $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$, but there exists an NP-relation ρ such that $L_\rho = \{0, 1\}^*$ and search does not reduce to decision for ρ.

The assumption $\mathrm{P} \neq \mathrm{NP}$ suffices to indicate that the usual method of self-reduction (in which one constructs a witness bit by bit, given an oracle for the language) may not always work: Selman [Se] shows that under this assumption there is an NP-relation ρ for which $L_\rho \in \mathrm{NP} - \mathrm{P}$, but, given a pair of strings (x, u) and an oracle for L_ρ, it is impossible to decide in polynomial time whether or not there is an extension of u that is a ρ-witness for x.

We stress again that none of the preceding work addresses the problem we consider. These other authors focus on NP-relations, asking whether there exist (specific) NP-relations ρ for which it is impossible to reduce the search problem for ρ to the corresponding decision problem for L_ρ. We focus on NP languages, asking whether there exists a language L for which, for *any* associated search problem ρ, it is impossible to reduce the search problem for ρ to its corresponding decision.

1.5.2. Decision versus search in other settings. The usual reduction of search to decision has a strong sequential flavor, and Karp, Upfal, and Wigderson [KUW] investigate the degree to which this is necessary. Ben-David, Chor, Goldreich, and Luby [BCGL] investigate the decision-versus-search question in the context of the average-case complexity. Impagliazzo and Tardos [IT] consider the decision-versus-search question in the exponential case and present an oracle relative to which $\mathrm{E} = \mathrm{NE}$, but there is an exponential-time binary predicate whose search problem is not solvable in exponential time.

1.5.3. The complexity of provers. Several recent works present results on the complexity of provers in interactive proofs. Let us describe some of them.

Shamir's [Sh] result implies that polynomial-space provers suffice to prove PSPACE languages. The best upper bound on the complexity of a prover of a coNP language, due to Lund, Fortnow, Karloff, and Nisan [LFKN], is probabilistic, polynomial time with a #P oracle.

Bellare and Petrank [BP] investigate the complexity of zero-knowledge (ZK) provers and indicate that such provers can be reasonably efficient; specifically, they show that any language possessing a statistical ZK interactive proof possesses one with a prover that is a probabilistic, polynomial-time machine with access to an NP oracle.

In the case of multiple-prover proofs, Babai, Fortnow, and Lund [BFL] show that exponential-time provers suffice for exponential-time languages.

We stress that all these works are concerned with upper bounding the complexity of provers in an absolute sense. The model of competitive interactive proofs that we introduce here is for the purpose of studying the complexity of provers in a different way, namely, in terms of the comparative complexity of proving versus deciding.

1.5.4. Recent work. Independently of this work, Impagliazzo and Sudan [IS] show that if NE $\neq$ coNE, then there is a language in NP for which search does not reduce to decision. Here the conclusion is the same as in Theorem 1.1, but the assumption is different (and not known to be either weaker or stronger). They also show that if E $\neq$ NE, then there is an NP-relation ρ for which search does not reduce to decision; this is the same conclusion as in the aforementioned result of Borodin and Demers [BD] but under an assumption that is different from that of [BD] (but, again, not known to be either weaker or stronger). Finally, Spielman [Sp] has constructed an uncheckable set in $\sum_2^{\mathrm{P}}$ under the assumption that $\sum_2^{\mathrm{E}} \neq \Pi_2^{\mathrm{E}}$.

1.6. Relations to other notions. We focus in this paper on (competitive) interactive proofs and checking. Related notions are function-restricted interactive proofs [BK], multiple-prover interactive proofs [BGKW], and coherence [Ya]. Here we discuss how these notions relate to ours and also how our results impinge on them. First, let us list (the complexity classes corresponding to) the notions in this area.

1.6.1. The complexity classes in this area. The following are the (main) complexity classes on which the ensuing discussion will focus.

$$\begin{aligned}
\mathrm{compNP} &= \{L : L \text{ has a competitive NP-proof system}\}\\
&= \{L \in \mathrm{NP} : \text{ search reduces to decision for } L\},\\
\mathrm{IP} &= \{L : L \text{ has an interactive proof system}\},\\
\mathrm{compIP} &= \{L : L \text{ has a competitive interactive proof system}\},\\
\mathrm{frIP} &= \{L : L \text{ has a function-restricted interactive proof system}\},\\
\mathrm{MIP} &= \{L : L \text{ has a multi-prover interactive proof system}\},\\
\mathrm{Check} &= \{L : L \text{ is checkable}\},\\
\mathrm{Coh} &= \{L : L \text{ is coherent}\}.
\end{aligned}$$

1.6.2. Function-restricted interactive proofs. Function-restricted interactive proof systems are a variant of interactive proof systems introduced by Blum and Kannan [BK]. Like competitive interactive proofs, they make the restriction that the honest prover be a probabilistic, polynomial-time machine with access to an oracle for the language in question. But, in contrast to competitive interactive proofs, they also restrict the dishonest prover. Specifically, they ask that a dishonest prover be a function from verifier messages to strings. In particular, the response of the dishonest prover to a verifier message is not allowed to depend on previous questions of the verifier (that is, its messages are independent of the history).

As we will see (Lemma 4.3) it is the case that comIP $\subseteq$ frIP. Blum and Kannan also established that Check $\subseteq$ frIP. On the other hand, on the basis of the techniques of [FRS] one can show that frIP $\subseteq$ MIP.

Function-restricted interactive proofs were introduced in order to relate program checking to interactive proofs. We introduce competitive interactive proofs to address the question of how much power is necessary for the honest prover to prove membership interactively; whence it is imperative to not weaken the definition of interactive proofs by making assumptions on the power of the dishonest prover. However, we use the notion of function-restricted proof systems to provide a unified treatment of our results. We establish the main technical lemmas needed for our proofs in terms of the equivalent notion of "deciders" (see §3) and then use these lemmas to derive our results on competitive interactive proofs and checking in a simple way. In particular (improving [BF]; see the following), we do show that if NEE $\not\subseteq$ BPEE, then there is a language in NP $-$ frIP.

1.6.3. Competitive multiple-prover proofs. One could define competitive multi-prover proofs. However, using techniques of [FRS], one can show that the corresponding class of languages is identical to frIP.

1.6.4. Coherence. The notion of coherence was introduced by Yao [Ya]. Informally, a language L is *coherent* if the membership of x in L can be decided in probabilistic polynomial time and bounded error by a machine (called the "examiner") that has access to L as an oracle but is allowed to query this oracle only on points different from x. If L is not coherent, we say it is incoherent. Beigel and Feigenbaum [BF] prove the existence of incoherent languages in NP under the assumption that nondeterministic *triple* exponential time is not contained in bounded probabilistic *triple* exponential time. Since checkable languages and languages in frIP are coherent (see [Ya], [BF]), they thereby establish the existence of uncheckable languages in NP, and languages in NP $-$ frIP, under the same assumption.

One can show that if search reduces to decision for L or if L has a competitive interactive proof, then also L is coherent. So the construction of incoherent sets yields negative results about these notions as well. However, the fact that our stronger results on all these notions (namely, decision versus search, competitive interactive proofs, checking, and function-restricted proofs) are obtained more directly (i.e., avoiding incoherence) indicates that coherence may not be the best approach to negative results in this area.

We note that, intuitively, coherence has a flavor different from that of the other notions we have considered; whereas the common underpinning of these others is the notion of a proof (interactive or noninteractive), coherence is not a form of proof. Indeed, the examiner gives no proof that $x \in L$—there is no guarantee as to what would happen if the examiner is run with an oracle different from L. It is by exploiting this prooflike quality of the notions we consider that we are able to derive results that are stronger than those derived by the coherence approach.

In this context we note also that one can separate the classes of checkable and coherent languages inside NP, assuming NEE $\not\subseteq$ BPEE (see Theorem 5.4).

1.6.5. Summary. We summarize relationships among the various complexity classes we have discussed. First, we introduce some notation. We define the triple-exponential time class

$$\mathrm{NEEE}^* = \bigcup_{c\geq 0} \mathrm{NTIME}(2^{2^{2^{n^c}}}).$$

Similarly, we let BPEEE* denote the class of languages recognized with bounded error by a probabilistic Turing machine (TM) running in time $2^{2^{2^{n^c}}}$ for some constant $c \geq 0$. The following inclusions are known or are easily derived from known techniques:

(1) compNP $\subseteq$ NP $\cap$ compIP.

(2) NP $\cup$ compIP $\subseteq$ IP $\subseteq$ MIP.

(3) compIP $\cup$ Check $\subseteq$ frIP $\subseteq$ MIP $\cap$ Coh.

Under the assumption NEE $\not\subseteq$ BPEE we establish the following:

(4) NP is not contained in any of the following: compNP, compIP, Check, frIP.

(5) NP $\cap$ Coh is not contained in any of the following: compNP, compIP, Check, frIP.

For the results of line (4), see Theorems 2.9, 4.4, 5.3, and 3.6. For those of line (5), see (Theorem 5.4 and) the discussion at the end of §5. Finally under the assumption NEEE* $\not\subseteq$ BPEEE* [BF], establish the following:

(6) NP $\not\subseteq$ Coh.

2. Decision versus search in NP. In this section, we present a simple construction of a language in NP for which search does not reduce to decision if it is assumed that EE $\neq$ NEE. In later sections we will extend the argument to interactive proofs and program checking. Let us begin with the definitions.

2.1. Definitions. The goal of this section is to make precise what we mean by "search reduces to decision for an NP language L." Since the issues were discussed at length in §1.1, we will here be brief, stating the (formal) definitions and limiting the discussion to essentials.

It is convenient to proceed in steps. We begin by defining NP-relations and saying what it means for search to reduce to decision for them. We then use this to say what it means for search to reduce to decision for an NP language.

DEFINITION 2.1. Let $\rho(\cdot, \cdot)$ be a polynomial-time computable binary relation, and let $x \in \{0, 1\}^*$. We let $\rho(x) = \{w \in \{0, 1\}^* : \rho(x, w) = 1\}$ and call the members of this set *ρ-witnesses* for x. We say that ρ is an *NP-relation* if there exists a constant $c \in \mathbf{N}$ such that for all $x \in \{0, 1\}^*$ it is the case that $\rho(x) \subseteq \{0, 1\}^{|x|^c}$. The *language defined by* ρ is $\{x \in \{0, 1\}^* : \rho(x) \neq \emptyset\}$ and is denoted L_ρ.

Note that if ρ is an NP-relation, then $L_\rho \in$ NP.

Notation. If $W(\cdot)$ is an oracle machine, then $W^L(x)$ denotes the output of W with oracle $L \subseteq \{0, 1\}^*$ and input $x \in \{0, 1\}^*$.

We now say what it means for search to reduce to decision for an NP-relation. An equivalent formulation of the definition that follows appears in [BD].

DEFINITION 2.2. Suppose ρ is an NP-relation and $W(\cdot)$ is a polynomial-time oracle machine. Let $L = L_\rho$. We say that W is a *ρ-witness finder* if for each $x \in L$ it is the case that $W^L(x) \in \rho(x)$. We say that *search reduces to decision for* ρ if there exists a ρ-witness finder.

Note that the witness finder is not restricted to any particular method (for example, it is not required that the length of queries be decreasing with time). Rather, any polynomial-time computation is allowed. This strengthens negative results.

We now wish to say what it means for search to reduce to decision for an NP-*language* (as opposed to an NP-relation). Begin with the following terminology.

DEFINITION 2.3. Suppose ρ is an NP-relation and $L \subseteq \{0, 1\}^*$ is a language. We say that *ρ defines L* if $L = L_\rho$.

Clearly, $L \in$ NP if and only if there exists an NP-relation that defines L. However, for any particular language $L \in$ NP there may be many different NP-relations that define L. If L is NP-complete, then search reduces to decision for *any* of these NP-relations. However, if L is not NP-complete, then search might reduce to decision for some of them but not for others.

In defining what it means for search to reduce to decision for L we have chosen to be liberal: we ask only that there be *some* NP-relation ρ defining L for which search reduces to decision.

DEFINITION 2.4. Suppose $L \subseteq \{0, 1\}^*$. We say that *search reduces to decision for* L if there exists an NP-relation ρ such that ρ defines L and search reduces to decision for ρ.

As we indicated in §1, our definition is motivated by interactive proofs and the question of whether proving membership is harder than deciding it. Proving membership in L is easy (in the sense that L has a competitive NP-proof system) as long as search reduces to decision for *some* NP-relation defining L, so that we are led to Definition 2.4. We note, in this context, that there are languages (such as $\{0, 1\}^*$) that are easy but that have an associated search problem that is hard [Va], and we certainly do not wish to think of search as being harder than decision for these languages. Appropriately, search does not reduce to decision for these languages according to our definition.

Finally, we note that the existence of a language for which search does not reduce to decision does, of course, imply the existence of an NP-relation for which search does not reduce to decision, so that negative results under our definition are stronger than those that simply conclude the existence of NP-relations for which search is harder than decision.

Whenever ρ is understood, we will say "witness" or "witness finder" rather than "ρ-witness" or "ρ-witness finder."

2.2. Uniformly log-sparse languages. Our proof will use languages that combine logarithmic sparseness with the property that it be possible to efficiently identify a logarithmic-sized superset of the strings below any given length. Let us proceed to the formal definitions.

DEFINITION 2.5. The *census function* $\mu_L : \mathbf{N} \to \mathbf{N}$ of $L \subseteq \{0, 1\}^*$ of a language L is defined by $\mu_L(n) = \sum_{i=0}^{n} |L \cap \{0, 1\}^i|$. We say that L is *log-sparse* if $\mu_L(n) = O(\log n)$.

That is, $\mu_L(n)$ is the number of strings in L that have length $\leq n$, and a language is log-sparse if it contains at most $O(\log n)$ strings of length at most n. Log-sparse languages are used in [HSI], where they are called "super-sparse."

The next definition formalizes the idea of being able to efficiently identify some superset of a language and then specifies the notion of uniform log-sparseness in which we are interested.

DEFINITION 2.6. We say that $C \subseteq \{0, 1\}^*$ is a *candidate selector* for L if C is polynomial-time decidable and $L \subseteq C$. We say that a language L is *uniformly log-sparse* if it has a log-sparse candidate selector.

As we will see in §2.3, the interest of uniformly log-sparse languages is that they form a class for which the problem of reducing search to decision is particularly hard. Let us end this section by stating a lemma that we will use later. This lemma generalizes work of Hartmanis, Sewelson, and Immerman [HSI], who show that there is a log-sparse language in NP − P if EE ≠ NEE.[2] Log-sparseness is weaker than uniform log-sparseness in that no candidate selector is required, but it is easy to see that a uniform log-sparseness language in NP − P nonetheless exists under the same assumption. For completeness we provide a sketch of the (entirely standard) proof.

LEMMA 2.7. *If* EE ≠ NEE, *then there is a uniformly log-sparse language in* NP − P.

Proof. We use a standard downward-separation argument. Assume EE ≠ NEE and suppose $L' \in$ NEE − EE. Define $L = \{y.0^{g(|y|)-|y|} : y \in L'\}$, where $g(k) = 2^{2^k}$. We claim that L is uniformly log-sparse and $L \in$ NP − P.

Define A to be the logarithm that on input $x \in \{0, 1\}^n$ behaves as follows. If n is not in the range of g, then A outputs 0. Else it computes $k = g^{-1}(n)$ and outputs 1 if and only if

[2] Hartmanis, Sewelson, and Immerman [HSI] claim the converse as well, but Allender [Al] points out that their proof is flawed and that the theorem cannot be proved by using techniques that relativize.

the last $n - k$ bits of x are zero. Then $C = \{x : A(x) = 1\}$ is a candidate selector for L, and $\mu_C(n) \le 2^{1+g^{-1}(n)} = O(\log n)$, so that L is uniformly log-sparse.

The fact that $L \in \mathrm{NP} - \mathrm{P}$ follows directly from the fact that $L' \in \mathrm{NEE} - \mathrm{EE}$. □

2.3. A language for which search does not reduce to decision. The following, which is the main lemma of this section, shows that the reduction of search to decision for a uniformly log-sparse language is possible only in the trivial case for which the language is already in P.

LEMMA 2.8. *Suppose L is a uniformly log-sparse language for which search reduces to decision. Then $L \in \mathrm{P}$.*

Proof. By assumption there exists an NP-relation ρ and a polynomial-time oracle machine W such that ρ defines L and W is a ρ-witness finder. We will construct a polynomial-time machine M that decides L. We begin by describing the idea informally.

The idea is to use W as a subroutine to find a witness. The difficulty is, of course, that W makes oracle queries about L itself. Not having access to an oracle for L, our machine M certainly cannot correctly answer these queries. To see how it can nonetheless exploit W, suppose for a moment that W is guaranteed to make only one oracle query in its entire computation on input x. Then M can try both possible answers. That is, it branches into a pair of parallel computations. In the first it answers the query by 0, in the second it answers it by 1, and in both it then runs W until W halts. Clearly, $x \in L$ if and only if at least one of these runs outputs a witness, and the strategy is polynomial time.

This idea extends to W making $O(\log n)$ queries. In reality, however, W could make polynomially many queries, so that this strategy is not efficient. This is the point at which we invoke the uniform log-sparseness of L (which we have not used so far). This implies that there are really only $O(\log n)$ effective queries that W can make; since W can write down only queries of polynomial length, we can use the log-sparse candidate selector of L to identify a set of at most $O(\log n)$ strings that include all the strings in L that W could possibly query, and we need branch only on these.

With this overall strategy in mind let us now specify the operation of M more precisely. Since ρ is an NP-relation, there exists a constant $c \in \mathrm{N}$ such that for all $x \in \{0, 1\}^*$ it is the case that $\rho(x) \subseteq \{0, 1\}^{|x|^c}$. We can assume that there is a constant $d > 0$ such that on any input $x \in \{0, 1\}^*$ the machine W will halt in $\le d|x|^d$ steps and output a string of length $|x|^c$, regardless of how the oracle queries of W are answered. We also assume (without loss of generality) that all queries made by W are distinct. Let C be a log-sparse candidate selector for L. Now, on input $x \in \{0, 1\}^n$ the machine M behaves as follows:

(1) M runs W on input x. Each time W makes an oracle query q, the machine M provides a response as follows:

(1.1) If $q \notin C$, then M responds with 0.

(1.2) Else it continues by trying in parallel both possible answers 0 and 1. That is, M branches into two parallel computations. In the first it lets the response to q be 0, and in the second it lets the response to q be 1. It then continues to run W in each computation.

In this manner M generates a number of parallel computations. After dn^d steps all of these computations have halted and each has yielded an n^c-bit output (the output of W).

(2) M now examines the set of outputs from the previous step. It accepts if at least one of these outputs w satisfies $\rho(x, w) = 1$ and rejects otherwise.

This completes the description of the machine M. The fact that it works should be clear, but for completeness let us spell it out.

First, to see that M accepts x if and only if $x \in L$, it suffices to check that on at least one of the parallel computations all oracle queries are correctly (that is, according to L) answered.

But Step (1.1) is obviously correct by definition of the candidate selector and in step (1.2) everything is being tried, so that one of the runs will certainly end up having all the right query answers.

The next thing to check is whether M runs in polynomial time. It suffices to show that the total number of parallel computations is $n^{O(1)}$. For this it suffices to show that the number of branches on any path is $O(\log n)$. We now argue the latter. First note that any query q has length at most dn^d (the running time of W). But branching occurs only when $q \in C$, and we have assumed that all W's queries are distinct. So the number of times branching occurs is at most the size of $\{q \in C : |q| \leq dn^d\}$, which is at most $\mu_C(dn^d) = O(\log n)$. This completes the proof. □

We can now put the pieces together to obtain the following result.

THEOREM 2.9. *If* EE $\neq$ NEE, *then there exists a language in* NP *for which search does not reduce to decision.*

Proof. By Lemma 2.7 there exists a uniformly log-sparse language $L \in$ NP $-$ P. By Lemma 2.8 search cannot reduce to decision for L. □

Note that the fact that search does not reduce to decision for L implies that L is not NP-complete. The existence of a non-NP-complete language in NP $-$ P can, however, be established by assuming only P $\neq$ NP (see [La]).

3. Deciders and their properties. Before extending the ideas of the previous section to interactive proofs and checking, we pause to develop some technical material. This material will be useful in proving the results of later sections. In particular, we introduce the notion of a decider, which will enable us to give a unified and more concise treatment of the rest of the results of this paper. We begin with the definition.

DEFINITION 3.1. Let D be a probabilistic, polynomial-time oracle machine. We say that D is a decider for language L if for each $x \in \{0, 1\}^*$ the following are true:

(1) If $x \in L$, then $D^L(x)$ accepts with probability $\leq 2/3$.

(2) If $x \notin L$, then the probability that $D^A(x)$ accepts is $\leq 1/3$ for all oracles A.

We note that L has a decider if and only if it is in function-restricted IP (see [BK]). So deciders are just a way of characterizing languages in frIP. They can also be viewed as checkers for YES instances. They are weaker that multiple-prover interactive proofs: the results of [FRS] imply that if L has a decider, then it has a multiple-prover interactive proof. For us the motivation of Definition 3.1 is to generalize the notion of a witness finder in the light of our proof of Lemma 2.8. The property of the witness finder that was important in that proof was that it was correct for $x \in L$ as long as oracle queries were answered correctly (i.e., according to L), and it was correct for $x \notin L$ no matter how oracle queries were answered. As for a witness finder, correctness of the decider on inputs $x \in L$ is guaranteed (except here only with high probability) as long as oracle queries are correctly answered. On the other hand, if $x \notin L$, then again correctness is guaranteed with high probability, *no matter how oracle queries are answered.* As we will see, these properties will suffice for us to approximately extend Lemma 2.8 to Lemma 4.3.

The error probability of 1/3 in Definition 3.1 is not always sufficient. It is convenient also to define the following.

DEFINITION 3.2. Let D be a probabilistic, polynomial-time oracle machine. We say that D is a *strong decider* for L if for each $x \in \{0, 1\}^*$ the following are true:

(1) If $x \in L$, then $D^L(x)$ accepts with probability $\geq (1 - 2^{-|x|})$.

(2) If $x \notin L$, then the probability that $D^A(x)$ accepts is $\leq 2^{-|x|}$ for all oracles A.

Standard error reduction, of course, says that strong deciders exist whenever deciders exist. For completeness let us state this as a proposition and provide a sketch of the proof.

PROPOSITION 3.3. *If L has a decider, then it has a strong decider.*

Proof. Let D be a decider for L. We define machine D' as follows. On input x, machine D' runs D on input x a total of $m = O(n)$ times, each time with independent coin tosses. The oracle queries made by D' are answered by D' by way of his own oracle (that is, if D makes oracle query q, then D' makes oracle query q and provides the answer received to D). D' outputs the majority vote of the outputs of D in the m trials. To see that D' is a strong decider for L, let $X_1^A, \dots, X_m^A$ denote the sequence of random variables representing the outcomes of D with oracle A in these successive trials. These are independent, and for each $i = 1, \dots, m$ they satisfy $\Pr[X_i^L = 1] \geq 2/3$ in the case that $x \in L$, and they satisfy $\Pr[X_i^A = 1] \leq 1/3$ for all oracles A in the case that $x \notin L$. An application of standard Chernoff bounds yields the desired conclusions. □

We saw in §2 that reducing search to decision for uniformly log-sparse languages is hard. Here we show that these same languages also do not have deciders unless they are in BPP.

LEMMA 3.4. *Suppose L is uniformly log-sparse and has a decider. Then* $L \in$ BPP.

Proof. By Proposition 3.3, L has a strong decider D. We show how to use D to construct a BPP machine M to decide L. The idea is very much the same as that in the proof of Lemma 2.8, with the decider here playing the role that the witness finder played in that proof. That is, on input x the machine M will run D on input x and will answer its oracle queries according to the same rules as those used in the proof of Lemma 2.8. M accepts if and only if the decider accepts on at least one of the parallel computations. The main difference (with respect to Lemma 2.8) lies in the fact that there is no way to tell whether a particular output of the decider is correct (in Lemma 2.8 one can always check whether or not the output of the witness finder is really a witness). Instead, the correctness of the procedure follows from the fact that the error probability of D is very small (2^{-n}). Details follow.

Let d be a constant such that D always halts in $\leq dn^d$ steps on inputs of length n. Let C be the log-sparse candidate selector for L. We assume without loss of generality that all oracle queries made by D are distinct. On input $x \in \{0, 1\}^n$ the machine M behaves as follows:

(1) M runs D on input x. Each time D makes an oracle query q, the machine M provides a response as follows:

(1.1) If $q \notin C$, then D responds with 0.

(1.2) Else it continues by trying in parallel both possible answers 0 and 1. That is, M branches into two parallel computations. In the first it lets the response to q be 0, and in the second it lets the response to q be 1. It then continues to run W in each computation.

In this manner M generates a number of parallel computations. After dn^d steps all of these computations have halted and each has yielded an output of 1 or 0 (the output of D).

(2) M now examines the set of outputs from the previous step. It accepts if at least one of these outputs is 1.

Since the answers in one of these parallel computations correspond to L, machine M accepts with probability $\geq (1 - 2^{-n})$ if $x \in L$. Now suppose $x \notin L$. Let $Q = \{q \in C : |q| \leq dn^d\}$, and let $\mathcal{A}$ denote the set of all subsets of Q. Each parallel computation of M corresponds to running D with some oracle $A \in \mathcal{A}$. It follows that the probability that M accepts is at most $\sum_{A \in \mathcal{A}} \Pr[D^A \text{ accepts}]$. By assumption D is a strong decider for L, so that we can bound this by $|\mathcal{A}| \cdot 2^{-n}$. But we claim that $|\mathcal{A}| \leq n^{O(1)}$, and so the probability that M accepts is $o(1)$, completing the proof. To justify the claim, note that $|\mathcal{A}| \leq 2^{|Q|}$ and $|Q| \leq \mu_C(dn^d) = O(\log n)$. □

Recall that BPEE denotes the class of languages accepted in time 2^{c2^n} for some constant $c \geq 0$ by a probabilistic machine with bounded error. By an argument analogous to that used in the proof of Lemma 2.7 we can show the following.

LEMMA 3.5. *If* NEE $\not\subseteq$ BPEE, *then there exists a uniformly log-sparse language in* NP − BPP.

Combining this with Lemma 3.4, we obtain the following theorem, which we will use in the next two sections.

THEOREM 3.6. *If* NEE $\not\subseteq$ BPEE, *then there exists a language in* NP *that does not have a decider.*

We remarked earlier that L has a decider if and only if $L \in$ frIP, and so Theorem 3.6 says that NEE $\not\subseteq$ BPEE implies NP $\not\subseteq$ frIP. In later sections we will use Theorem 3.6 to show that (NEE $\not\subseteq$ BPEE implies) NP $\not\subseteq$ compIP and check by showing that languages in compIP and Check have deciders (see Lemmas 4.3 and 5.2).

4. Competitive interactive proofs.

We begin by recalling the notion of an interactive proof. We then define competitive interactive proofs and present our results.

4.1. Interactive proofs.

Interactive proofs are extensions of NP ones, so let us begin by recalling the latter. An NP proof system for a language L is defined by a polynomial-time *verifier* V. We imagine this verifier talking to a prover. The parties receive a common input x, and the prover's goal is to convince the verifier to accept. To this end he is allowed to send the verifier a (single) message of length $n^{O(1)}$. The verifier's decision as to whether or not to accept is made as a function of the common input and this message (since the verifier is deterministic, this decision is a polynomial-time binary predicate ρ evaluated on the common input and the prover's message). In the case that $x \in L$ we ask that there exist some *deterministic* prover P who can convince the verifier to accept (this is the completeness condition). In the case that $x \notin L$ no prover should be able to convince the verifier to accept (this is the soundness condition). We usually specify an NP proof system as a pair (P, V), where P is a prover satisfying the completeness condition. Clearly, $L \in$ NP if and only if it possesses an NP proof system.

Interactive proofs, which were introduced by Goldwasser, Micali, and Rackoff [GMR], are a natural extension of such NP proof systems. Both parties are now allowed to be probabilistic. Moreover, they are allowed to interact (that is, they exchange messages for a polynomial number of rounds, and it is only at the end of this exchange that V decides whether or not to accept). We say that (P, V) is an interactive proof for a language L if (1) on common input a string in L, it is possible for P to induce V to accept with high probability, and (2) on common input a string not in L, there is no prover who can prevent V from rejecting with high probability.

Let us now proceed more formally. A party A in an interactive proof may be viewed as a (probabilistic) function of the common input and the conversion so far. The outcome of this function on input x (the common input) and c (transcript of conversation so far), which we denote by $A(x, c)$, is the next message computed by A (and sent to the other party).[3] We assume that the transcript of the conversation at any point may be uniquely parsed into its constituent messages. We may discuss the complexity of such parties in the usual way, viewing them as being computed by (probabilistic) TM's. For example, the verifier is a party computable by a probabilistic, polynomial-time TM. Complexity is measured as a function of the length of the common input (which we usually denote by n). The total number of moves (a move consists of a party computing and sending a message) as well as the length of all messages are assumed to be bounded by a polynomial in n. At the end of the interaction, the verifier accepts or rejects by applying a (deterministic) binary predicate to the common input and transcript of conversation. Suppose a prover A interacts with a verifier B on common

[3] When we say that this function is probabilistic, we mean that to any x, c party A actually associates a distribution on strings and $A(x, c)$ is a random element of this distribution.

input x. The "probability that B accepts in its interaction with A on common input x" is the probability the B accepts given the common input x and transcript $\alpha_1\beta_1 \cdots \alpha_{g-1}\beta_{g-1}\alpha_g$ chosen according to the following experiment: $\alpha_1 = A(x, \lambda)$, $\beta_1 = B(x, \alpha_1)$, $\alpha_2 = A(x, \alpha_1\beta_1)$, $\beta_2 = B(x, \alpha_1\beta_1\alpha_2), \ldots, \alpha_g = A(x, \alpha_1\beta_1 \cdots \alpha_{g-1}\beta_{g-1})$. (Here $g = g(n)$ is the total number of moves, λ is the empty string, and we are assuming for simplicity that A speaks first and last. The probabilities are over the random choices of both parties in this conversation.)

DEFINITION 4.1 (interactive proofs [GMR]). Let (P, V) be a pair of (probabilistic) functions. We say that (P, V) is an interactive proof system for language L if V is probabilistic, polynomial time and the following hold:

(1) For every $x \in L$ the probability that V accepts in its interaction with P on common input x is $\geq 2/3$.

(2) For every $x \notin L$ and every function $\hat{P}$ the probability that V accepts in its interaction with $\hat{P}$ on common input x is $\leq 1/3$.

The first condition is the completeness condition, and the second is the soundness condition.

We note the strength of the soundness condition: the quantification is over all functions $\hat{P}$ (we call them "cheating" or "dishonest" provers), even noncomputable ones.

We note that an NP proof system is a special kind of interactive proof system. Specifically, an NP proof system is an interactive proof system (P, V) in which both P and V are deterministic, the interaction is restricted to a single message from the prover to the verifier, and the probabilities in the completeness and soundness conditions are 1 and 0 (rather than $2/3$ and $1/3$), respectively. The addition of interaction and randomness, however, seems to add significantly to the language-recognition power of the system. It was established by Lund, Fortnow, Karloff, and Nisan [LFKN] that IP (the class of languages possessing interactive proofs of membership) contains the polynomial-time hierarchy, and Shamir [Sh] extended this to show that IP equals PSPACE.

4.2. Competitive interactive proofs. A basic complexity-theoretic question is to determine how efficient the prover P can be in an interactive proof (P, V) of a language L. Certainly, the prover would need at least the ability to decide the language himself. We define a competitive interactive proof system as one where the prover is allowed no more than this. Specifically, he must run in probabilistic polynomial time given access to L as an oracle. As we will see, competitive interactive proofs represent the natural generalization of the problem of decision versus search.

DEFINITION 4.2. Let P be a probabilistic polynomial-time oracle machine, and let V be a probabilistic polynomial-time machine. We say that (P, V) is a *competitive interactive proof system* for a language L if the following hold:

(1) For every $x \in L$ the probability that V accepts in its interaction with P^L on common input x is $\geq 2/3$.

(2) For every $x \notin L$ and every interactive TM $\hat{P}$ the probability that V accepts in its interaction with $\hat{P}$ on common input x is $\leq 1/3$.

The first condition is the completeness condition, and the second is the soundness condition. We call P a *competitive prover.*

We note that the soundness condition remains the same as in the definition of interactive proofs. In particular, we do not restrict the computational power of the cheating prover $\hat{P}$ in the case of $x \notin L$. Our goal is to understand the difficulty of providing a correct proof, and unrestricted soundness would appear to be an inherent property of proofs.

Competitive NP proof systems are defined in the natural way. That is, a *competitive* NP *proof system* is a competitive interactive proof system in which both parties are deterministic, the interaction is restricted to a single message from the prover to the verifier, and the probabilities in the completeness and soundness conditions are 1 and 0 (rather than 2/3 and 1/3), respectively. Equivalently, it is an NP proof system in which the prover is restricted to polynomial time plus an oracle for L. We now note that search reduces to decision for L if and only if L has a competitive NP proof system (the prover in the competitive NP proof system corresponds to the witness finder). It is in this sense that competitive interactive proofs are the natural extension of the problem of decision versus search.

4.3. An NP language not possessing a competitive interactive proof. In §2 we presented a language $L \in$ NP for which search is unlikely to reduce to decision. In other words, L is unlikely to have a competitive NP proof system. The truth, however, is that proving membership in NP languages remains hard even when interaction and randomness are allowed: we will show here that there is probably an NP language that does not even have a competitive interactive proof system. Given the results of §3 we need only the following lemma, which shows that any language possessing a competitive interactive proof also has a decider (or, equivalently, that compIP $\subseteq$ frIP).

LEMMA 4.3. *Suppose L has a competitive interactive proof system. Then it has a decider.*

Proof. Let (P, V) be a competitive interactive proof for L. We note that in probabilistic polynomial time we can run both P and V. So given an oracle A, the machine D on input x can sample the space of conversations between P^A and V on input x and accept if and only if the conversation obtained is accepting. Details follow.

Let $r(n)$ denote (a polynomial bound on) the number of coin tosses used by P and V on any input of length n. D picks, uniformly at random, an $r(n)$-bit string R_P and an $r(n)$-bit string R_V. D now runs P and V on common input x, using R_P as the coins for P and R_V as the coins for V. That is, assuming for example that P sends the first message, D would run P (with coins R_P) to get P's first message. D would then run V (with coins R_V) to get the response, and so on. Oracle queries made by P in this process are answered by D by way of his own oracle (that is, if P makes oracle query q, the D makes oracle query q and provides the answer he receives to P). Eventually D obtains the output of V (1 if V accepts and 0 otherwise) and outputs this value. Given any particular oracle A, it is the case that $D^A(x)$ is a 0/1 random variable, and clearly the probability that it is 1 equals the probability that V accepts in its interaction with P^A on common input x. By the assumption that (P, V) was a competitive interactive proof for L it follows that $\Pr[D^L(x) = 1] \geq 2/3$ in the case that $x \in L$ and that $\Pr[D^A(x) = 1] \leq 1/3$ for all oracles A in the case that $x \notin L$. □

Combining Lemma 4.3 and Theorem 3.6 yields the theorem.

THEOREM 4.4. *If* NEE $\not\subseteq$ BPEE, *then there exists a language in* NP *that does not have a competitive interactive proof.*

We note that we have done more than simply show that interactive proofs may be more powerful than competitive ones, because the language L of Theorem 4.4 is in NP, a subclass of IP that possesses particularly simple interactive proofs. To show only that interactive proofs are more powerful than competitive ones, it would suffice to present a language in IP (but not necessarily in NP) that does not have a competitive interactive proof. This can be done under weaker assumptions, by an extension of the same argument we used previously. For example, let

$$\text{EESPACE} = \bigcup_{c \geq 0} \text{SPACE}(2^{c2^n}).$$

Then we can show that if EESPACE $\not\subseteq$ BPEE, then there exists a language in IP that does not possess a competitive interactive proof.

In general, to construct a language L that lies in some particular complexity class C but does not possess a competitive interactive proof, it suffices to assume that the "double-exponential counterpart" of C is not contained in BPEE. We put the phrase "double-exponential counterpart" in quotation marks because it, of course, does not always make sense (many classes have no such counterpart). But there are many natural classes (such as those used here) for which this paradigm does make sense.

4.4. Zero-knowledge aspects. The competitive aspects of zero-knowledge proofs may also be worth investigating. To initiate such an investigation, let us try to discuss briefly what one can easily infer from known work and what are the open questions.

Do NP languages have competitive zero-knowledge interactive proofs? In general, of course, they probably do not since by Theorem 4.4 they probably do not even have competitive interactive proofs (let alone ZK ones). An appropriate question then is whether NP languages that possess competitive interactive proofs also possess competitive zero-knowledge interactive proofs. The answer depends on the kind of zero-knowledge one considers and on the kind of cryptographic assumptions one is willing to make.

Let us first consider computational ZK. The result of Goldreich, Micali, and Wigderson [GMW] implies that NP-complete languages have competitive ZK interactive proofs, given the existence of one-way functions (more generally, it implies that if search reduces to decision for L, then L has a competitive ZK interactive proof, given the existence of one-way functions). We do not know whether the assumption that there exist one-way functions suffices to show that *any* language that possesses a competitive interactive proof also possesses a competitive ZK interactive proof. But we do know that the latter conclusion may be established with stronger assumptions such as the existence of ideal secure circuit evaluation or the existence of oblivious transfer. This follows from the result of Kilian [Ki] (and we refer the reader to that paper for details on what exactly are these assumptions).

All statistical ZK languages known to possess competitive interactive proofs are also known to possess statistical ZK competitive interactive proofs (these languages are graph isomorphism [GMW], graph nonisomorphism [GMW], and quadratic nonresiduosity [GMR]). We do not, of course, know whether or not quadratic residuosity has a competitive statistical ZK interactive proof, given that we do not know whether or not it has a competitive interactive proof at all.

5. Program checking. Blum and Kannan [BK] introduce the notion of program checkers. Informally, a checker for a function f is a probabilistic, polynomial-time oracle machine that receives as an oracle a program P that purports to compute f. The checker also receives an input x. If the program is entirely correct (that is, $P(y) = f(y)$ for all y), then the checker is supposed to accept with high probability. However, if the program disagrees with f on the particular input x provided to the checker, then the checker should reject with high probability. The definition follows. We note that by a "program" we mean a deterministic machine that halts on all inputs. We also recall that the characteristic function of a language L is the function $\chi_L : \{0, 1\}^* \to \{0, 1\}$ defined by $\chi_L(x) = 1$ if $x \in L$ and 0 otherwise.

DEFINITION 5.1 [BK]. Let C be a probabilistic polynomial-time oracle TM. C is a *checker* for $f : \{0, 1\}^* \to \{0, 1\}$ if for all programs P and all $x \in \{0, 1\}^*$ the following hold:

(1) If $P(y) = f(y)$ for all $y \in \{0, 1\}^*$, then $C^P(x)$ accepts with probability $\geq 2/3$.

(2) If $P(x) \neq f(x)$, then the probability that $C^P(x)$ accepts is $\leq 1/3$.

We say C is a checker for a language L if it is a checker for the characteristic function of L. L is *checkable* if it has a checker.

The definition is close in spirit to that of (competitive) interactive proofs, but there are two important differences. First, unlike interactive proofs, checking is a symmetric notion in which the checker for language L must be able to determine that P is correct on x not only when $x \in L$ but also when $x \notin L$. Second, programs are history-independent objects, whereas (cheating) provers are not. Thus if L and $\bar{L}$ both have competitive interactive proofs, then L has a checker, whereas we do not know whether or not every checkable language has a competitive interactive proof.

Checkers are also related to multiple-prover interactive proofs [BGKW]. In particular, results of [FRS] imply that the class of languages that possess checkers is contained in MIP $\cap$ coMIP (where MIP is the class of languages possessing multiple-prover interactive proofs of membership). We note that MIP = NEXP by the result of [BFL].

Blum and Kannan [BK] showed that Check = frIP $\cap$ cofrIP. It follows that checkable languages have deciders. For completeness, however, let us see this directly.

LEMMA 5.2. *Suppose L has a checker. Then it has a decider.*

Proof. Let C be a checker for L. Let D be the probabilistic polynomial-time oracle machine that on input x works as follows. D begins by querying its oracle with the string x. If the oracle returns 0, then D rejects. Else it runs C on input x, uses its own oracle (denoted A) to answer C's oracle queries, and accepts if and only if C accepts. We claim that D is a decider for L. To see this we need to check that for each $x \in \{0, 1\}^*$ the two conditions of Definition 3.1 hold. The first condition is clear. To see that the second is true, suppose $x \notin L$, and suppose first that $A(x) = 0$. In this case D rejects with probability 1. Now suppose $A(x) = 1$. Then the probability that D accepts is at most 1/3 because C is a checker. □

Combining Lemma 5.2 and Theorem 3.6 yields the theorem.

THEOREM 5.3. *If* NEE $\not\subseteq$ BPEE, *then there exists a language in* NP *that is not checkable.*

Similarly, if EESPACE $\not\subseteq$ BPEE, then there exists a language in PSPACE that is not checkable.

We recall that a language L is *coherent* if the membership of x in L can be decided in probabilistic polynomial time and bounded error by a machine (called the *examiner*) that has access to L as an oracle but is allowed to query this oracle only on points different from x. If L is not coherent, we say it is incoherent. Previous negative results on checking were established by first exhibiting incoherent sets and then exploiting Yao's observation that any incoherent set is uncheckable (see [Ya], [BF]). We note that our (stronger) results are obtained more directly. Moreover, our techniques indicate that even within NP the class of coherent sets could be much larger than the class of checkable ones. Let us sketch why this is so.

The disjoint union of languages A and B, denoted $A \oplus B$ is $\{0x : x \in A\} \cup \{1x : x \in B\}$; this construct is widely used in complexity theory (see, e.g., [BD], [HH]). It is easy to see (see [BF]) that $L \oplus L$ is coherent for any language L. It is also easy to see that the transformation $L \mapsto L \oplus L$ preserves many complexity characteristics of L, for example, membership in NP, compNP, compIP, Check, frIP. In particular, combining this observation with Theorem 5.3 yields the claimed separation.

THEOREM 5.4. *If* NEE $\not\subseteq$ BPEE, *then there exists a language in* NP *that is coherent but not checkable.*

6. Towards competitive proofs for quadratic residuosity. In this section we return to the unresolved question of whether the language of quadratic residuosity has a competitive interactive proof system, and we present a special case of the problem for which competitive proofs are possible.

6.1. Definitions. We will be looking at *promise* problems rather than problems of language membership. The difference is that in the former we begin with a promise that the input already belongs to some set, and we have only to "decide" whether or not it falls in a given subset of this set. Such problems have been considered in many works; see, e.g., [ESY]. The formalization we use is different from (but equivalent to) the ones used in these works and is as follows. The problem is specified by a pair of disjoint sets (A, B). Intuitively, the input is promised to be in $A \cup B$, and we have to decide whether it is in A or in B. Corresponding to promise problems are promise oracles that are guaranteed to be correct only when the promise is true.

DEFINITION 6.1. *A promise problem* is a pair of disjoint sets (A, B). *A promise oracle* (for a promise problem (A, B) is an oracle that given a query q returns 1 if $q \in A$ and 0 if $q \in B$.

Note that whereas promise problems are, intuitively, easier than language-recognition problems, promise oracles are correspondingly weaker than (normal) oracles. In particular, a promise oracle for (A, B) is weaker than an oracle for just A (or B) in that its response on queries outside $A \cup B$ is indeterminate.

A competitive interactive proof for a promise problem (A, B) is just an interactive proof that $x \in A$ given that $x \in A \cup B$ and having the property that the competitive prover gets only a promise oracle for (A, B). The more formal definition follows.

DEFINITION 6.2. Let P be a probabilistic polynomial-time oracle machine, and let V be a probabilistic polynomial-time machine. We say that (P, V) is a competitive interactive proof for promise problem (A, B) if the following hold:

(1) For every $x \in A$ and every promise oracle O for (A, B), the probability that V accepts in its interaction with P^O on common input x is $\geq 2/3$.

(2) For every $x \in B$ and every interactive TM $\hat{P}$, the probability that V accepts in its interaction with $\hat{P}$ on common input x is $\leq 1/3$.

6.2. Results. We recall that $x \in Z_N^*$ is a *quadratic residue* (or *square*) mod N if $x \equiv y^2$ (mod N) for some $y \in Z_N^*$ and a *quadratic nonresidue* (or *nonsquare*) mod N otherwise. Also, recall from §1.2 that

$$\mathrm{QR} = \{(x, N) : x \text{ is a square mod } N\},$$

$$\mathrm{QNR} = \{(x, N) : x \text{ is a nonsquare mod } N\}.$$

The special case we are interested in is when N is the product of a constant number of distinct odd primes. To be more precise, first define

$$\mathrm{QR}_s = \{(x, N) \in \mathrm{QR} : N \text{ is a product of } s \text{ distinct odd primes}\},$$

$$\mathrm{QNR}_s = \{(x, N) \in \mathrm{QNR} : N \text{ is a product of } s \text{ distinct odd primes}\}.$$

We will present a competitive interactive proof that $(x, N) \in \mathrm{QR}_s$, given that it is already in $\mathrm{QR}_s \cup \mathrm{QNR}_s$. Note that QR_s and QNR_s are not complements of each other, so that, formally, we are talking of a competitive interactive proof for the promise problem $(\mathrm{QR}_s, \mathrm{QNR}_s)$ in the sense of Definition 6.2.

THEOREM 6.3. *Let s be an integer* ≥ 1. *Then the promise problem* $(\mathrm{QR}_s, \mathrm{QNR}_s)$ *possesses a competitive interactive proof.*

In related work, Kompella and Adleman [KA] present checkers for this same special case of quadratic residuosity when the modulus is the product of a constant number of primes (i.e., they present checkers for the promise problem $(\mathrm{QR}_s, \mathrm{QNR}_s)$). Their construction does not, however, extend to competitive interactive proofs, because the correctness of their checker uses the fact that a program (in contrast to a cheating prover) is history independent.

To prove Theorem 6.3 we begin by recalling some basic number-theoretic facts. We refer the reader to [An], [NZ] for number-theoretic background and justification of these facts.

For $x \in Z_N^*$ we let $Q_N(x) = 0$ if x is a quadratic residue mod N, and we let $Q_N(x) = 1$ otherwise. Suppose $N = p_1 \cdots p_s$, where $p_1, \ldots, p_s$ are distinct odd primes. Define the binary relation ($\simeq$) on Z_N^* by

$$x \simeq y \quad \text{iff } \forall i : 1 \leq i \leq s : Q_{p_i}(x \bmod p_i) = Q_{p_i}(y \bmod p_i).$$

This is an equivalence relation. The equivalence class of x under this relation (namely, $\{y \in Z_N^* : x \simeq y\}$) is called its *residue class.* The product xy mod N of two elements $x, y \in Z_N^*$ is a square mod N if x, y are from the same residue class and is a nonsquare mod N otherwise. The total number of residue classes is 2^s, and they are all of the same size. We will denote them by $R_N^1, \ldots, R_N^{2^s}$, with the convention that the last $R_N^{2^s}$, is the class of quadratic residues mod N.

We recall that there exists a competitive interactive proof for quadratic nonresiduosity. We will exploit this fact by reducing the proof of $(x, N) \in \mathrm{QR}_s$ to a polynomial number of proofs of nonresiduosity in such a way that the prover need use only probabilistic, polynomial time and a promise oracle for $(\mathrm{QR}_s, \mathrm{QNR}_s)$. The first step is the following definition.

DEFINITION 6.4. Let N be a product of s distinct odd primes, and let $t = 2^s$. We call a vector $(y_1, \ldots, y_{t-1}) \in (Z_N^*)^{t-1}$ *representative* of Z_N^* if the following conditions hold:

(1) y_i is a nonsquare mod N for each $i = 1, \ldots, t-1$.

(2) $y_i y_j$ mod N is a nonsquare mod N for each pair of indices i, j satisfying $1 \leq i < j \leq t-1$.

This leads us to a way to reduce a residuosity test to a collection of nonresiduosity tests as long as we are in possession of a representative vector.

PROPOSITION 6.5. *Let N be a product of s distinct odd primes, and let $x \in Z_N^*$. Suppose $\vec{y} = (y_1, \ldots, y_{t-1})$ is representative of Z_N^* (where $t = 2^s$). Then $(x, N) \in \mathrm{QR}_s$ if and only if xy_i* mod *N is a nonsquare mod N for each $i = 1, \ldots, t-1$.*

Proof. xy_i mod N will be a nonsquare mod N for each $i = 1, \ldots, t-1$ if and only if its residue class differs from the residue class of y_i for each $i = 1, \ldots, t-1$. But since $\vec{y}$ is representative, this happens if and only if x is a square mod N. □

To use this, however, we have to be able to get representative vectors. It suffices to show how the prover can construct a representative vector and then convince the verifier that it is indeed representative, all by using only probabilistic, polynomial time and a promise oracle for $(\mathrm{QR}_s, \mathrm{QNR}_s)$.

PROPOSITION 6.6. *There is a probabilistic, polynomial-time oracle machine R that on input $(x, N) \in \mathrm{QR}_s \cup \mathrm{QNR}_s$ and access to a promise oracle for $(\mathrm{QR}_s, \mathrm{QNR}_s)$ outputs either a representative vector for Z_N^* or the special symbol $\perp$, with the probability of the latter event being at most* $1/4$.

Proof. R picks at random $\vec{y}_1, \ldots, \vec{y}_m \in (Z_N^*)^{t-1}$, where $t = 2^s$ and m is a constant to be defined later. For each $i = 1, \ldots, m$ the machine R then uses the promise oracle to test whether or not the conditions of Definition 6.4 hold for $\vec{y}_i$. If some vector $\vec{y}_i$ passes the test, then the first such vector is output. If all vectors fail the test, then R outputs $\perp$. The probability that a particular vector passes the test is $(t-1)!/t^{t-1}$, which is a positive constant. So it suffices to choose m to be a constant such that

$$\left[1 - \frac{(t-1)!}{t^{t-1}}\right]^m \leq \frac{1}{4}.$$

(A (crude) calculation shows that $m = O((2e)^t)$ suffices.) That R runs in probabilistic, polynomial time is clear. □

We can now proceed to describe the protocols. We begin by recalling (following [GMR]) the basic (competitive) protocol to prove nonresiduosity.

PROTOCOL QNR.

Input: (x, N) and 1^k

(V1) V picks at random $c_1, \dots, c_k \in \{0, 1\}$ and $r_1, \dots, r_k \in Z_N^*$, sets $z_i = x^{c_i} r_i^2 \bmod N$ (for $i = 1, \dots, k$), and sends $z_1, \dots, z_k$ to P.

(P1) P sets d_i to 0 if z_i is a quadratic residue mod N and to 1 otherwise (for $i = 1, \dots, k$) and sends $d_1, \dots, d_k$ to V.

(V2) V accepts if and only if $c_i = d_i$ for all $i = 1, \dots, k$.

PROPOSITION 6.7. *Protocol* QNR *has the following properties*:

(1) *If* $(X, N) \in$ QNR, *then the probability that* V *accepts in its interaction with* P *is* 1.

(2) *If* $(x, N) \notin$ QNR, *then for any* $\hat{P}$ *the probability that* V *accepts in its interaction with* $\hat{P}$ *is* $\leq 2^{-k}$.

(3) P *is competitive* (*that is, it runs in probabilistic, polynomial time, given an oracle for* QNR).

Proof. The first two items follow from basic properties of modular residues, and we refer the reader to [GMR] for proofs. The last item is clear. □

We now proceed to the competitive interactive proof for QR_s. We will use Protocol QNR as a subprotocol.

PROTOCOL QR(s)

Input: $(x, N) \in \mathrm{QR}_s \cup \mathrm{QNR}_s$

Notation: We let $t = 2^s$.

(P1) P runs the algorithm of Proposition 6.6 and sends the output to V.

(V1) If V receives $\perp$ from P, then it rejects. If instead it receives a vector $\vec{y} = (y_1, \dots, y_{t-1}) \in (Z_N^*)^{t-1}$, then the parties proceed to the next step.
Subprotocol: P uses Protocol QNR (with security parameter k set to 2) to prove the following to V:
(1) y_i is a nonsquare mod N for each $i = 1, \dots, t-1$.
(2) $y_i y_j$ mod N is a nonsquare mod N for each pair of indices i, j satisfying $1 \leq i < j \leq t-1$.
(3) $x y_i$ mod N is a nonsquare mod N for each $i = 1, \dots, t-1$.
(This is a total of $(t-1)(t+2)/2$ invocations of the QNR protocol.)

(V2) V accepts if and only if each of the preceding subproofs was accepting.

The correctness of the protocol follows from the results established in the preceding. Details follow.

Suppose $(x, N) \in \mathrm{QR}_s$. Proposition 6.6 implies that the parties get a representative vector and proceed to the subprotocol with probability $\geq 3/4$. Definition 6.4 and Proposition 6.5 imply that the inputs to the nonresiduosity subproofs are all indeed nonsquares mod N, and thus Proposition 6.7 implies that these subproofs all succeed with probability 1. So V accepts with probability $\geq 3/4$.

Suppose $(x, N) \in \mathrm{QNR}_s$. If $\hat{P}$ sends $\perp$ in its first step, then V rejects; so suppose $\hat{P}$ sends a vector $\vec{y} = (y_1, \dots, y_{t-1}) \in (Z_N^*)^{t-1}$. If $\vec{y}$ is not representative, then by Definition 6.4 either there is an i such that y_i is a square mod N or there is a pair $i < j$ such that $y_i y_j$ mod N is a square mod N. In either case the corresponding nonresiduosity subproof fails with probability $\geq 3/4$, and V rejects. So suppose $\vec{y}$ is representative. But the Proposition 6.5 implies there is an i such that $x y_i$ mod N is a square mod N. So the corresponding nonresiduosity subproof fails with probability $\geq 3/4$, and V again rejects.

The competitiveness of P follows from Propositions 6.6 and 6.7.

The reason this does not extend to arbitrary N is, of course, that the number of residue classes is in general exponential in the length of N, and in polynomial time we could not even write down a representative list. On the other hand, working through the proofs shows that the result does extend to the case for which $s : \mathbf{N} \rightarrow \mathbf{N}$ is a polynomial-time-computable function of N that is bounded above by $\lg \lg \lg N = \lg \lg |N|$. For simplicity we have stuck to the case of constant s.

Clearly, the weakness of this result is in the promise that N is already a product of (exactly) s odd primes; this is what may be hard to prove competitively if one wants a competitive interactive proof of QR.

7. Open questions. *Quadratic residuosity.* We think that the most interesting open question is whether or not the language of quadratic residuosity has a competitive interactive proof. Conditional results on the subject would also be interesting; for example, could one show that if quadratic residuosity has a competitive interactive proof, then factoring is reducible (in probabilistic, polynomial time) to deciding quadratic residuosity? (Note that an affirmative answer to this last question would imply that if QR has a competitive interactive proof, then it has an NP proof through the simple factorization witness.)

Reducing assumptions. Another open question is whether one can reduce the assumptions required for our results. In particular, can one show that there is a language for which search does not reduce to decision given P $\neq$ NP or even E $\neq$ NE? Or could cryptographic assumptions such as the existence of one-way functions be used to establish the existence of languages in IP that do not have competitive interactive proofs?

Other settings. What is the relationship of decision to search in the context of optimization problems and approximation algorithms, and does search reduce to decision in this setting? For example consider the traveling salesman problem. Let $\omega(G)$ denote the weight of an optimal tour on a (weighted) graph G, and suppose $\mu \geq 1$ is a constant. Suppose A is an oracle satisfying $\omega(G) \leq A(G) \leq \mu \cdot \omega(G)$ for all graphs G. Is there a polynomial-time procedure that with oracle access to A and input G, outputs a tour (in G) of weight at most $\mu \cdot \omega(G)$?

Perfect completeness. An interactive proof (P, V) for L is said to have perfect completeness if the probability of acceptance in the completeness condition is 1. We know that any language L possessing an interactive proof also possesses one with perfect completeness [FGMSZ]. Does any language possessing a competitive interactive proof also possess a competitive interactive proof with perfect completeness? (One of the motivations for this question is the fact that our competitive proof for the special case of quadratic residuosity in §6 does not possess perfect completeness.)

Zero knowledge. We discussed the open questions in §4.4.

Acknowledgments. Many people pointed out to us the error in [HSI]: we thank Eric Allender, Juris Hartmanis, Jack Lutz, and Osamu Watanabe in this regard. We thank Muli Safra, Lance Fortnow, and Jack Lutz for helpful discussions, and we thank Silvio Micali for suggesting the term "competitive interactive proofs." We thank Oded Goldreich for many helpful comments on this paper. We thank Satish Thate for drawing our attention to the results of [La] mentioned in §2. Finally, we thank a pair of (anonymous) referees for many valuable comments on the paper.

HOMEOMORPHISM OF 2-COMPLEXES IS GRAPH ISOMORPHISM COMPLETE *

JOHN SHAWE-TAYLOR[†] AND TOMAŽ PISANSKI[‡]

Dedicated to A.W. Tucker

Abstract. It is shown that the problem of determining whether two 2-complexes are homeomorphic is isomorphism-complete.

Key words. 2-complex, homeomorphism, graph, isomorphism, computational complexity, simplicial complex, triangulation

AMS subject classifications. 57M20, 57Q15, 68 15, 68Q25, 68R10

1. Introduction. There has been much interest focused on the position of GRAPH ISOMORPHISM in the complexity hierarchy. As yet it has neither been shown to be in P or to be NP-complete. As such it is one of the few "classical" problems that have not been classified as either "easy" or "hard". Various adaptations of the problem have been classified as NP-complete, while for others polynomial algorithms have been found. For example, Luks [4] has shown that if the valency is bounded by a constant then the problem is in P, while Lubiw [3] and others have considered slight adaptations that result in the problem becoming NP-complete. Thus subgraph isomorphism is NP-complete, as is the problem of determining the existence of an isomorphism with restrictions and the existence of a fixed point free automorphism.

The above considerations have led to the introduction of the class ISOMORPHISM-complete, which has been studied by Booth and Colbourn [1] and Lubiw [3]. They have identified a number of problems in this class—among others, automorphism with a fixed number of restrictions, finding generators of Aut(G), calculating $|\mathrm{Aut}(G)|$, Automorphism with 1 edge fixed, and so on. This paper extends the class of ISOMORPHISM-complete to include a new problem with a novel flavor—namely, 2-complex homeomorphism or homeomorphism between the carriers of 2-complexes. This problem has not been previously studied in the context of complexity theory, though it was shown to be decidable by Whittlesey [9], who worked under A. W. Tucker on this problem.

The paper is organized as follows. In §2 we introduce the definitions of the various structures and classes and state the main theorem and some known results that we will require. Section 3 develops the techniques that we require to complete our algorithm and proof. This is then presented in §4. We finish with some conclusions and directions for future research.

2. Definitions. In order to reduce a 2-complex homeomorphism to an isomorphism oracle, we will build a canonical invariant for a 2-complex. The invariant structure will be a labeled graph, which will encapsulate sufficient information for the construction of a topological space homeomorphic to the original complex. This will enable the definition of an algorithm to determine whether two complexes are homeomorphic. The algorithm first constructs the invariant graph for both complexes and then tests, using the isomorphism oracle, whether the two graphs obtained are isomorphic.

Note that a related problem of determining whether two complexes have isomorphic fundamental groups is algorithmically unsolvable. It reduces to the well-known word problem for group presentations.

DEFINITION 1. A set X together with a collection $\mathcal{O}$ of subsets of X is a *topological space* if $\mathcal{O}$ contains $\emptyset$ and X and is closed under finite intersections and arbitrary unions of sets. The collection $\mathcal{O}$ are termed *open* sets.

A mapping h between two topological spaces X and Y is a *homeomorphism* if it is a bijection on both elements and open sets.

It should be noted that the definition of topology and, in particular, the Euclidean topologies considered in simplicial complexes are not finite or even countably infinite and so are not obviously open to combinatorial manipulation. This is even more apparent in the case of homeomorphisms of 2-complex carriers, which are not a priori constrained by the finite descriptions that we give of a complex. The results obtained here show that not only can we find a finite combinatorial way of describing the topologies considered, but that it enables us to assess the computational complexity of the homeomorphism problem for 2-complexes. In this context it is worth mentioning that changes in the precise combinatorial description used would affect the details of the algorithm and construction, but the significance of the results is not in the detailed choice of representation, but in the fact that the topological properties can be captured at all and, in particular, in such a way that the computational complexity can be determined.

We begin with the definition of a (purely) 2-dimensional complex. We will follow the notation and definitions of Gross and Tucker [2].

DEFINITION 2. A k-simplex is the convex hull of $k + 1$ affinely independent points in Euclidean n-space.

A *geometric simplicial complex* K is a finite collection of simplices in $\mathcal{R}^n$ satisfying two conditions:

1. Every face of every simplex in K is a simplex of K.
2. The intersection of any two simplices in K is a simplex in K.

The *carrier* of a simplicial complex K is the topological space with point set $|K| = \bigcup_{S \in K} S$.

An *abstract simplicial complex* $K = (V, C)$ is a finite set V together with a collection C of subsets of V whose union is V and which is closed under taking subsets.

The *dimension* of a complex is the dimension of the largest simplex or the size of the largest subset in the collection C minus one.

A *purely k-complex* is a simplicial complex for which each simplex is contained in a k-dimensional simplex (each subset is contained in a subset of size $k + 1$).

A *triangulation* of a topological space X is a homeomorphism h from the carrier of a simplicial complex K to the space X.

Every geometric simplicial complex gives rise to an abstract simplicial complex by taking the sets to be the vertices of simplices. Likewise for every abstract simplicial complex a geometric complex can be constructed so that the simplices correspond to the subsets of the abstract complex. The corresponding dimensions of the abstract and geometrical complexes agree, and one is a pure k-complex if and only if the other is. Further, if two geometrical complexes have the same abstract complex, they are homeomorphic. In view of the close relation between an abstract and geometrical complex, we will use the term complex ambiguously to refer to either. In fact, we extend this ambiguity to the carriers of complexes and hence to spaces that have a triangulation.

In this paper we are interested in (≤ 2)-dimensional complexes. We now state our main result.

THEOREM 2.1. *Homeomorphism of* 2*-complexes is graph isomorphism complete.*

Proof. We must show that homeomorphism of 2-complexes is equivalent to graph isomorphism modulo polynomial time reductions.

Given an instance of graph isomorphism, we can view the graph as a 2-complex by placing a distinct label on all the 2-valent vertices. The complexes constructed will be homeomorphic if and only if the the original graphs were isomorphic.

The reverse direction of the proof will require significantly more effort. □

To motivate our approach we first consider what is known about simpler complexes and their carriers.

Example 1. 1. *Closed surfaces* can be constructed from polygons so that all edges involved are identified in pairs and the resulting space is connected. Each surface can be characterized by a single integer (or a pair of an integer (*genus*) and a bit (*orientability type*)). Hence homeomorphism involves computing the genus and orientability. This can be done using Euler's formula for the genus and by attempting to fix an orientation.

2. *Disconnected closed surfaces.* Finite number of surfaces. Homeomorphism can be decided as above followed by a comparison of two sets of numbers.

3. *Surfaces with boundary.* They can be characterized by a triple: *genus, orientability type, number of boundary components.* Homeomorphism involves computing the genus, orientability, and number of boundary components. This can again be done using a straightforward algorithm. This characterization can be extended to the disconnected case as above.

We now introduce some more definitions that will prove useful in our reduction.

DEFINITION 3. Each graph G and a natural number d give rise to a d-complex $K(G, d)$ so that each k-clique $(0 < k \leq d + 1)$ determines a $(k - 1)$-simplex, and the incidence relation is defined in the obvious way.

For a vertex v of a complex K we define

- Star(v) to be the minimal subcomplex of K that contains every simplex incident with v;
- Link(v) to be the maximal subcomplex of Star(v) that does not contain v itself.

For a vertex v of a graph G, Link(v) is defined to be Link$(K(G, 2))$ and is the graph induced by G on the neighbors of v in G.

For a complex K, K^k is the collection of all simplices of K with dimension less than or equal to k. K^k is called the *k-skeleton* of K. In the case of the 1-skeleton K^1, we also view it as a graph.

A triangulation K of a d-dimensional topological space is called *clean* if $K(K^1, d)$ is homeomorphic to K.

For triangulations of 2-complexes, being clean is equivalent to saying that not only is each face a triangle but also each triangle (of the 1-skeleton) is a face. If a triangulation that is not clean is given, we need only take a subdivision (see below) to ensure that there are no longer any triangles in the 1-skeleton that are not faces in the complex. Hence, every 2-complex admits a clean triangulation.

Example 2. Clean triangulations are nice because we can use them to characterize various types of complexes just by looking at the Link(v) of each vertex v of its 1-skeleton.

- 0-*Dimensional complexes.* All links are void.
- 1-*Dimensional complexes.* Each link is an empty graph or void.
- *Purely* 1-*dimensional complexes.* Each link is an empty graph.
- *Closed surfaces.* Connected graph. Each link is a cycle.
- (*Disconnected*) *closed surfaces.* Each link is a cycle.
- *Surfaces with boundary.* Each link is either a cycle or a path.
- *Pseudosurfaces.* Each link is a union of cyles.
- *Pseudosurfaces with boundary.* Each link is a union of cycles and paths.

In order to obtain a clean triangulation it is sometimes necessary to subdivide a given triangulation. We therefore introduce the concept of a subdivision.

DEFINITION 4. The *subdivision* of a complex K' is a complex K with $|K'| = |K|$, and for each simplex s of K there exists a simplex s' of K' such that $s \subseteq s'$.

The definition of subdivision is given for a geometric complex, though a corresponding interpretation for abstract complexes is immediate. Note that this implies the triangles of the original complex have been subdivided to form a number of triangles in the subdivision, namely, those contained in the original triangle. Likewise, the edges have been subdivided, and of course the subdivision is compatible with that on triangles incident with the edge. For an example see the Su functions in Fig. 3. The subdivision process also provides an answer to whether two complexes with homeomorphic carriers are related in any way. In the 2-dimensional case this was answered by Papakyriakopoulos [6], see also Gross and Tucker [2, pp. 97–98].

THEOREM 2.2. *If two 2-complexes K_1 and K_2 have homeomorphic carriers, then they have a common subdivision.*

Purely 2-dimensional complexes are complexes in which each point and line are contained in a 2-dimensional object. A triangulation of such a complex can be given as a collection of triples of points that constitute the triangles of the triangulation, with the understanding that the points and lines of each triangle are also in the complex.

In the next section we will construct a combinatorial description of purely 2-complexes starting from a clean triangulation. We will show that the description obtained is independent of the triangulation used, hence by the above theorem making it a combinatorial invariant under homeomorphism of purely 2-complexes.

3. Combinatorial description of 2-complexes. In this section we will describe a method of decomposing a complex K into a collection of surfaces with boundaries, together with information about how to reconstruct K from those surfaces. This will enable a complete description of K by a labeled graph. We will show that each homeomorphism type of a 2-complex corresponds uniquely to a particular labeled graph.

We begin by describing the algorithm for decomposing a purely 2-complex K.

ALGORITHM 1. *Complex Splitting Algorithm.*

Input: Clean triangulation T of a complex K is given as a set of triples of vertices.

Algorithm:

Stage 1: The triangles are completely dismantled in a new triangulation $\mathrm{Sp}_1(T)$ (see Fig. 1), obtained from T by taking the vertex set

$$\{(v, t) | v \text{ is a vertex of } T \text{ lying in triangle } t\ \}$$

and triangles

$$\{\{(v_1, t), (v_2, t), (v_3, t)\} | t = \{v_1, v_2, v_3\} \text{ is a triangle of } T\}.$$

Stage 2: The second stage of the process is to reidentify vertices that lie on parts of the complex that are locally a simple surface to create a triangulation $\mathrm{Sp}(T)$. The collection of triangles remains the same. Vertices (v, t) and (v', t') will be reidentified if and only if the following two conditions hold (see Fig. 1):

(i) $v = v'$,

(ii) there is a sequence of triangles of T, $t = t_1, t_2, \ldots, t_n = t'$ and vertices $v_1, \ldots, v_{n-1}$, such that the edge $\{v, v_j\}$ is contained in precisely two triangles t_j and t_{j+1}, $j = 1, 2, \ldots, n-1$.

Output: The triangulation obtained is denoted by $\mathrm{Sp}(T)$.

It corresponds to reidentifying copies of vertices where a vertex in its link has valency two, but note that we reidentify vertices at the center of the link. The only vertices of T that

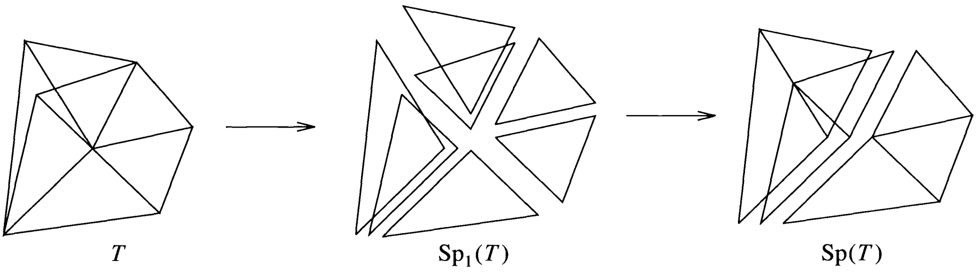

FIG. 1. *Stages in the splitting algorithm.*

are not split in $\mathrm{Sp}(T)$ are those whose Link is a simple circuit. This motivates the following definition.

DEFINITION 5. A vertex of a pure 2-complex is called *simple* if its link consists of a simple circuit. A vertex is called *splitting* if it is not simple.

PROPOSITION 3.1. *After the above splitting operation the complex obtained is a collection of surfaces possibly with boundaries.*

Proof. Consider a vertex (v, t) of the complex created. The vertices in $\mathrm{Link}(v, t)$ in the new complex are

$$\begin{aligned}\{(u, s) \quad | \quad & \exists n \geq 1, \text{ vertices } v_0, \ldots, v_{n-1}, \\ & \text{and triangles } t = t_1, \ldots, t_n = s = \{v, u, v_{n-1}\} \\ & \text{such that for } 1 \leq \ell \leq n-1, \{v, v_\ell\} \text{ lies in precisely } t_\ell \text{ and } t_{\ell+1} \ \}.\end{aligned}$$

Clearly, these vertices form either a path or a circuit, so by the result mentioned in the first section, the complex is a collection of surfaces possibly with boundaries. □

There is, however, a danger that information may be lost in the splitting operation as the next example shows.

Example 3. *Two sphere example.* Consider the triangulation (see Fig. 2)

$$\{\{123\}, \{134\}, \{124\}, \{234\}, \{126\}, \{125\}, \{156\}, \{256\}\}.$$

This is a 2-complex made of two tetrahedrons identified along the edge $\{12\}$. After the splitting operation all but the vertices 1 and 2 are completely reidentified since they are simple vertices. The copies of vertex 1 for triangles $\{156\}$, $\{125\}$, and $\{126\}$ are all reidentified to a vertex that we will denote 1_{56} since vertices 5 and 6 both have degree 2 in Link(1). Similarly the copies of vertex 1 for triangles $\{123\}$, $\{124\}$, and $\{134\}$ are identified to a vertex 1_{34}. Hence, in the split complex there are two copies of vertex 1 (1_{56} and 1_{34}) and similarly two copies of vertex 2 (denoted 2_{56} and 2_{34} using a similar notation, where the indices refer to neighbors in the split complex). So the triangles of the split complex are

$$\begin{gathered}\{\{1_{56}2_{56}6\}, \{1_{56}2_{56}5\}, \{1_{56}56\}, \{2_{56}56\}, \\ \{1_{34}2_{34}4\}, \{1_{34}2_{34}3\}, \{1_{34}34\}, \{2_{34}34\}\},\end{gathered}$$

which is a complex consisting of two disjoint tetrahedra.

The problem with this example is that exactly the same split complex *and* the same linking information obtained from the split vertices would have been obtained from two spheres with just the two anomalous points identified (and no points on the line $\{12\}$ joining them). The type of anomaly of the above example will occur if there are links with only one vertex having

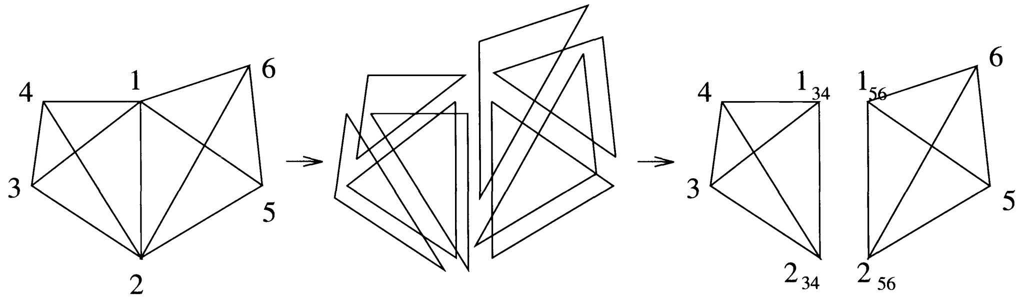

FIG. 2. *Splitting of Example* 3.

valency greater than two and if two such vertices are adjacent in the triangulation. We can remove the problem by taking a subdivision of the complex. In the two spheres example the new vertex on the edge joining the two anomalous vertices would be (two copies of) a split vertex in the case of two spheres joined on a line and two distinct vertices in the case of two spheres joined at two points. The standard pattern for a link is a number of paths between two vertices. This fact motivates the following definition.

DEFINITION 6. A vertex will be termed *standard* if its link consists of a number of paths joining two distinct vertices. Simple vertices are a special case of standard vertices. Nonstandard vertices are called *anomalous* vertices.

We will call a triangulation in which anomalous vertices are adjacent an *anomalous* triangulation.

The problem with anomalous triangulations can, however, be avoided by taking a subdivision of a triangulation in which anomalous vertices are adjacent. To see this is the case we will show that no new vertex of a subdivision is an anomalous vertex. The new vertices lie in the middle of edges or triangles of the old triangulation. For vertices in the middle of an old triangle the new vertex has link a simple circuit and so is not anomalous. For vertices in the middle of an old edge, let the old edge lie on $p \geq 1$ triangles. Therefore, the link of the new vertex consists of p paths between two vertices (the two vertices at the end of the edge of the old triangulation). Hence, the new vertices are not anomalous. We have proved the following lemma.

LEMMA 3.2. *Let $Su(T)$ be a subdivision of a triangulation T. Then $Su(T)$ is not an anomalous triangulation.*

The first stage in our proof that the surfaces and boundary regluing information will characterize the original complex will be to show that homeomorphic complexes give rise to the same collection of surfaces with boundaries after splitting, if we start with nonanomalous triangulations. We begin with a useful lemma.

LEMMA 3.3. *Let $s = \{v_1, v_2, v_3\}$ and $t = \{v_1, v_2, v_4\}$ be two adjacent triangles in a triangulation in which v_1 is a standard vertex. The vertices (v_1, s) and (v_1, t) will be reidentified in the split complex if and only if the edge $\{v_1, v_2\}$ is contained only in s and t.*

Proof. Since v_1 is a standard vertex, its link consists of a number of paths joining two distinct vertices. If $\{v_1, v_2\}$ is contained only in s and t, then by the definition of the second stage of the splitting algorithm, Algorithm 1, the vertices (v_1, s) and (v_1, t) will be reidentified in the split complex. Suppose now that (v_1, s) and (v_1, t) are reidentified in the second stage of the splitting algorithm. If v_2 has degree greater than 2, then v_3 and v_4 must be on distinct paths joining the two vertices of degree greater than 2 in Link(v_1). It is also possible that one of v_3 or v_4 is the second vertex with degree greater than 2. In either case there will be no path involving only vertices of degree two from v_3 to v_4 in Link(v_1) contradicting the reidentification. We conclude that the edge $\{v_1, v_2\}$ is contained only in s and t. □

PROPOSITION 3.4. *For a nonanomalous triangulation of a pure 2-complex the splitting operation commutes with subdivision.*

Proof. Let T be a triangulation of a complex K with no adjacent pair of vertices both anomalous. Let $\mathrm{Su}(T)$ be a subdivision of T. Hence, we must show that $\mathrm{Sp}(\mathrm{Su}(T)) = \mathrm{Su}(\mathrm{Sp}(T))$, where it is understood that the same subdivision is performed on the triangles of $\mathrm{Sp}(T)$ as was performed on T (see Fig. 3).

Since triangles are preserved by the splitting operation, there is clearly a natural mapping τ from the triangles of $\mathrm{Sp}_1(\mathrm{Su}(T))$ to the triangles of $\mathrm{Su}(\mathrm{Sp}(T))$; see Fig. 3. Further, all the vertices in the triangles of $\mathrm{Sp}_1(\mathrm{Su}(T))$ are distinct, so τ induces a mapping

$$\mathrm{vert} : V(\mathrm{Sp}_1(\mathrm{Su}(T))) \to V(\mathrm{Su}(\mathrm{Sp}(T))),$$

where $V(T)$ is the set of vertices of a complex T. To complete the proof we must show that for $(u, s), (u, t) \in V(\mathrm{Sp}_1(\mathrm{Su}(T)))$, $\mathrm{vert}(u, s) = \mathrm{vert}(u, t) \Leftrightarrow (u, s)$ and (u, t) are identified in the second stage of Algorithm 1, i.e., in $\mathrm{Sp}(\mathrm{Su}(T))$. This will imply that the mapping vert induces a triangle-preserving bijection between $\mathrm{Sp}(\mathrm{Su}(T))$ and $\mathrm{Su}(\mathrm{Sp}(T))$.

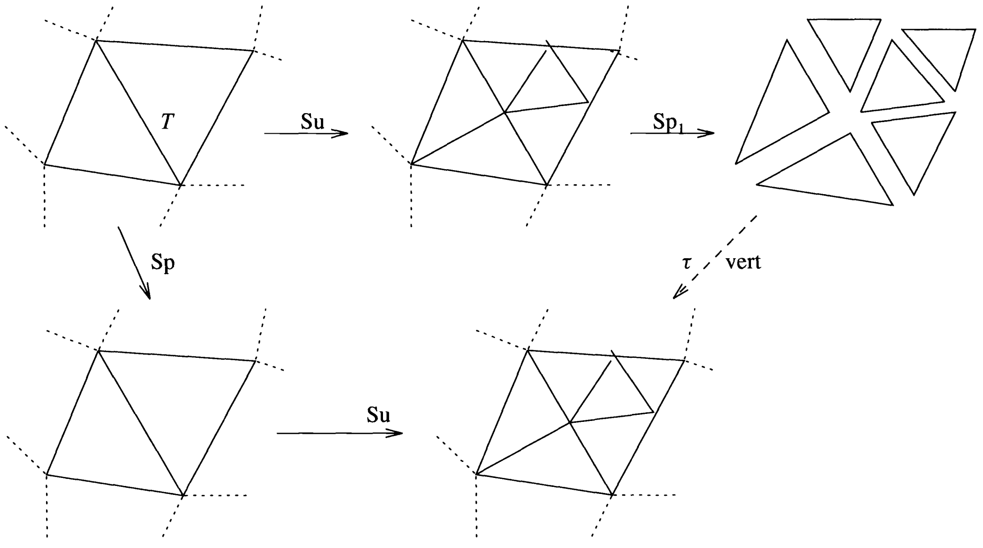

FIG. 3. *Subdivision and splitting in Proposition* 3.5.

CLAIM. *For* $(u, s), (u, t) \in V(\mathrm{Sp}_1(\mathrm{Su}(T)))$, $\mathrm{vert}(u, s) = \mathrm{vert}(u, t) \Leftrightarrow (u, s) \equiv (u, t)$ *in* $\mathrm{Sp}(\mathrm{Su}(T))$.

($\Leftarrow$) First observe that it will be sufficient to show that the property holds for (u, s), (u, t), where s and t are triangles sharing a common edge $\{u, v\}$ in $\mathrm{Su}(T)$, since the full reidentification is the transitive closure of this type of identification. If s and t both lie in the same triangle of T, the edge $\{u, v\}$ lies only in s and t, so (u, s) and (u, t) are identified. But in this case $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$ as required. Suppose therefore that s and t lie in distinct triangles s' and t' respectively of T. The edge $\{u, v\}$ is therefore contained in an edge $\{u', v'\}$ that lies in both s' and t'. If u is a standard vertex and (u, s) and (u, t) are identified, then by Lemma 3.3 $\{u, v\}$ lies only in s and t. Hence, $\{u', v'\}$ lies only in s' and t'. This means that (u', s') and (u', t') are identified in $\mathrm{Sp}(T)$. Likewise, (v', s') and (v', t') are identified and so the copy of the vertex u associated with s in $\mathrm{Su}(\mathrm{Sp}(T))$ is the same as that associated with t, giving $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$ as required. Consider finally the case when u is an anomalous vertex. In this case, by the comment after Definition 6, it must be a vertex of the triangulation T. Again assume that s (t) lies in a triangle s' (t') of T. If (u, s) and (u, t) are identified,

$$\exists s = t_1, t_2, \dots, t_n = t \text{ and } v_1, \dots, v_{n-1},$$

such that $\{u, v_i\}$ lies in precisely two triangles t_i, t_{i+1}. Let the triangle t_i be contained in the triangle t_i' of T. Note that for some i we may have $t_i' = t_{i+1}'$. Where $t_i' \neq t_{i+1}'$, the two triangles meet in an edge $\{u, v_i'\}$ containing $\{u, v_i\}$ and contained only in t_i' and t_{i+1}'. We therefore have a sequence of triangles that indicates (u, s') and (u, t') are identified in $\mathrm{Sp}(T)$. Hence, $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$, as required.

($\Rightarrow$) We consider the case now when two vertices (u, s) and (u, t) in $\mathrm{Sp}_1(\mathrm{Su}(T))$ are not identified in $\mathrm{Sp}(\mathrm{Su}(T))$. We must show that in this case $\mathrm{vert}(u, s) \neq \mathrm{vert}(u, t)$. By the argument at the beginning of the proof of the claim, the fact that the two vertices are not identified implies that s and t must lie in distinct triangles s' and t' of T. We will assume that $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$ and obtain a contradiction. We distinguish two cases according to whether u is a vertex of T or not. If u is a vertex of T, $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$ implies (u, s) and (u, t) are the same vertex in $\mathrm{Su}(\mathrm{Sp}(T))$, which implies that (u, s') and (u, t') were identified in $\mathrm{Sp}(T)$. But this implies the existence of a sequence of triangles $s' = t_1', \dots, t_k' = t'$ with t_i' and t_{i+1}' sharing a common edge containing u and contained only in t_i' and t_{i+1}'. We can therefore find a sequence of triangles

$$s = t_{1,1}, \dots, t_{1,n_1}, t_{2,1}, \dots, t_{k-1,n_{k-1}}, t_{k,1}, \dots, t_{k,n_k} = t$$

with $t_{i,j}$ contained in t_i' and each adjacent pair in the sequence sharing a common edge containing u and unique to the pair in $\mathrm{Su}(T)$. This implies that (u, s) and (u, t) are identified in $\mathrm{Sp}(\mathrm{Su}(T))$, a contradiction.

Finally consider the case when u is not a vertex of T. We must have u contained in an edge $\{u', v'\}$ of T since s and t are in distinct triangles of T. We again assume $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$ and obtain a contradiction. The edge $\{u', v'\}$ of the triangles s' and t' must have been identified in $\mathrm{Sp}(T)$, or we would not have $\mathrm{vert}(u, s) = \mathrm{vert}(u, t)$. But this implies that both (u', s'), (u', t') and (v', s'), (v', t') were identified. Since T does not have adjacent anomalous vertices, we may assume without loss of generality that u' is a standard vertex. By Lemma 3.3, the edge $\{u', v'\}$ is contained only in s' and t'. Now we may find a sequence of triangles

$$s = s_1, \dots, s_\ell, t_1, \dots, t_k = t,$$

with s_i (t_i) contained in s' (t') and each adjacent pair sharing a common edge unique to them which contains u. For all but s_ℓ and t_1 this follows as the two triangles are contained in the same triangle of T, while for s_ℓ and t_1 the common edge is contained in $\{u', v'\}$, which is common to only s' and t'. We conclude that (u, s) and (u, t) are identified, a contradiction. This completes the proofs of the claim and the proposition. □

COROLLARY 3.5. *The collection of surfaces obtained by the splitting operation are invariant under subdivision of the original complex provided it was not anomalous.*

Proof. By the proposition the subdivision operation commutes with the splitting operation when the original complex is not anomalous. But we know that the collection of surfaces is invariant under subdivision, so if we apply the subdivision first (i.e., to the original complex) and then perform the splitting operation, we do not affect the collection of surfaces that is obtained. □

COROLLARY 3.6. *Any two homeomorphic 2-complexes K_1 and K_2 with any nonanomalous triangulations T_1 and T_2 respectively give rise to the same collection of surfaces with boundaries after splitting.*

Proof. Since K_1 and K_2 are homeomorphic, there is a subdivision T_1' of T_1 and subdivision T_2' of T_2 such that T_1' and T_2' are isomorphic. But by Corollary 3.5, the collection of surfaces created by splitting is invariant under subdivision, so T_1 and T_2 give rise to the same collection. □

Each component surface created by splitting a triangulation T corresponds uniquely to some closed (compact) orientable or nonorientable surface with a finite number of holes with boundaries.

ALGORITHM 2. *Graph Construction Algorithm.*
Input: The split triangulation $\mathrm{Sp}(T)$ of a triangulation T together with the triangulation T.
Algorithm: We create a labeled graph $G(T)$ to represent how components of $\mathrm{Sp}(T)$ arose from T.

Stage 1: The component surfaces of the triangulation $\mathrm{Sp}(T)$ are classified according to genus, orientability type, and number of boundary components. Each of the component surfaces will be represented in $G(T)$ by a vertex (vertices of layer one) labeled with the genus and orientability.

Stage 2: The vertices of layer 2 of $G(T)$ will consist of vertices for each vertex of $\mathrm{Sp}(T)$ that arose from a splitting vertex. These vertices are interconnected if they are adjacent in $\mathrm{Sp}(T)$ and are connected to the vertex for the component in which they lie. Hence each boundary of a surface will correspond to a circuit of vertices all adjacent to the surface's vertex in the graph.

Stage 3: Finally there is a layer of vertices corresponding to each splitting vertex of the original complex. These vertices are connected to all the vertices in layer 2 that arose from them.
Output: The labeled graph $G(T)$.

For a vertex v of layer two we will denote by $\mathrm{sib}(v)$ the set of vertices in layer two connected to the same vertex in layer three, that is, the set of vertices arising from the same splitting vertex.

LEMMA 3.7. *Given the triangulation* $\mathrm{Sp}(T)$ *created by the splitting of a triangulation* T, *and the labeled graph* $G(T)$ *defined above, we can reconstruct* T.

Proof. We can clearly reconstruct the vertices of T; they are the vertices of $\mathrm{Sp}(T)$ with identifications performed between those having a common neighbor in the third layer of $G(T)$. As each triangle of T mapped to a unique triangle in $\mathrm{Sp}(T)$, we can also reconstruct the triangles of T once the vertex identification has been made. □

COROLLARY 3.8. *Given only the labeled graph* $G(T)$ *we can reconstruct a complex that is homeomorphic to* T.

Proof. We can construct a triangulation T_0 of the surfaces with boundaries given by the labeled vertices of $G(T)$, which will be homeomorphic to $\mathrm{Sp}(T)$. Moreover, we can ensure that the number of vertices around each boundary corresponds to the number of vertices in the circuit for that boundary in $G(T)$ and that isolated images of splitting vertices in $\mathrm{Sp}(T)$ correspond to vertices of the triangulation T_0. Let $\phi : \mathrm{Sp}(T) \longrightarrow T_0$ be a homeomorphism that maps the boundary vertices and lines as well as the isolated vertices of $G(T)$ to the corresponding vertices and lines of T_0. We can construct a topological space from T_0 using the same procedure as outlined in the lemma, that is, topologically identifying vertices arising from the same splitting vertex and lines arising from the same lines of T. The space created will be a triangulation $T_0^\dagger$ such that $\mathrm{Sp}(T_0^\dagger) = T_0$. Because we have identified closed subsets of points in the topological space, we can lift the homeomorphism ϕ to a homeomorphism $\phi^\dagger : T \longrightarrow T_0^\dagger$. This completes the proof. □

We now introduce a simplification procedure for the graph $G(T)$, which will be shown to give a canonical graph for each homeomorphism class of complex.

ALGORITHM 3. *Simplification Algorithm.*

Input: The graph $G(T)$ arising from a triangulation T.

Algorithm: The following simplification is applied to all vertices of the second layer of $G(T)$ until no change occurs during a complete sweep.

- Given a vertex v of layer two in $G(T)$. For each neighbor u of v with u in layer two, if sib(u) can be paired with sib(v), so that each pair is adjacent in $G(T)$, we identify each of these pairs, the vertices u and v, and their respective neighbours in layer three. The edges from identified vertices are left incident with the new vertex, even if this creates a multiple edge. If two vertices connected by a pair of edges are identified then the new vertex retains a loop.

Output: The simplified graph $\hat{G}(T)$.

The order in which the vertices are scanned does not alter the effect of the algorithm. This is because if a pair of vertices can be merged the merging of any other pair of vertices will not alter this fact (unless of course it corresponds to the same merge) even if one of the vertices merged was from the pair. We will denote by $\hat{G}(T)$ the graph obtained from applying the algorithm to the graph $G(T)$ of a triangulation T.

PROPOSITION 3.9. *Let $\{u, v\}$ be an edge of a nonanomalous triangulation T. Then if T' is the triangulation obtained from T by subdividing the edge $\{u, v\}$, then $\hat{G}(T) = \hat{G}(T')$.*

Proof. First, by Corollary 3.10, subdivision does not affect the collection of surfaces with boundaries that are obtained. Hence, we need only check that the structure of the graphs $\hat{G}(T)$ and $\hat{G}(T')$ are the same.

We consider cases according to the number p of triangles containing the edge $\{u, v\}$. If this number is two then the new vertex v' has Link(v') a simple circuit and so is not a splitting vertex. It therefore does not feature in $G(T')$, which is unchanged from $G(T)$.

If $\{u, v\}$ lies on one triangle, then the new vertex v' has one copy of itself in $G(T')$ adjacent to a copy of u and a copy of v in the boundary of one of the surfaces. If one of u and v only has one copy, then the copy of v' can merge with that vertex under the algorithm given above. We can therefore reduce $G(T')$ to $G(T)$ by one simplification. It follows that $\hat{G}(T) = \hat{G}(T')$. However, w.l.o.g. let v be nonanomalous. Since the edge $\{u, v\}$ lies on one triangle, the vertex u has degree one in Link(v). It therefore follows that Link(v) is a path both in T and T' and therefore that v has only one copy in Sp(T') as required.

Finally consider the case when $\{u, v\}$ lies on $p > 2$ triangles $t_1, \ldots, t_p$. The new vertex v' will split into p copies in Sp(T'). Assume that v is not anomalous. Since the edge $\{u, v\}$ lies on p triangles, u has degree p in Link(v). Therefore, Link(v) is a collection of p paths joining two vertices of degree p both in T and T'. Therefore, the vertex v also splits into p copies in Sp(T'), each of which is adjacent to one of the copies of v' in $G(T')$. It follows that the copies of v and v' can be merged using the above algorithm, again reducing $G(T')$ to $G(T)$ by one simplification. □

COROLLARY 3.10. *If two complexes K_1 and K_2 are homeomorphic and we choose nonanomalous triangulations T_1 of K_1 and T_2 of K_2, then $\hat{G}(T_1) = \hat{G}(T_2)$.*

Proof. Since the triangulations T_1 and T_2 are of homeomorphic 2-complexes, there exists a subdivision T_1' of T_1 and a subdivision T_2' of T_2 such that T_1' and T_2' are isomorphic. By the proposition

$$\hat{G}(T_1) = \hat{G}(T_1') = \hat{G}(T_2') = \hat{G}(T_2),$$

as required. □

Our program of classification of 2-complexes will be complete if we can prove the converse of the above corollary, namely, that given any two complexes K_1, K_2 and nonanomalous triangulations T_1, T_2 of them, such that $\hat{G}(T_1) = \hat{G}(T_2)$, then K_1 is homeomorphic to K_2. This will clearly follow from the following proposition.

PROPOSITION 3.11. *Given a graph $\hat{G}(T)$ arising from a triangulation T, we can construct a topological space V from $\hat{G}(T)$ such that V is homeomorphic to T.*

Proof. In Corollary 3.6 we saw how a complex could be reconstructed from $G(T)$ and that the proof that the reconstructed complex was homeomorphic to T was topological. In this proof we will do the same thing for $\hat{G}(T)$ or rather for each simplification stage of $G(T)$. Let $G(T) = G_1, \dots, G_k = \hat{G}(T)$ be one of the sequences of graphs obtainable when simplifying $G(T)$ to $\hat{G}(T)$. For each G_i, $i = 1, \dots, k$, we will construct a topological space. First, however, take a fixed collection S of surfaces with boundaries and the correct number of isolated points dictated by the layer one structure of the graphs. Note that this does not change in the simplification process since the number of circuits attached to each surface remains the same even when the number of vertices on a circuit is reduced to two or one (a loop will represent a boundary circuit). Now choose the correct number of points on the boundaries of S, one for each vertex in the corresponding boundary circuit of $G(T)$. The surface with the chosen points will be called S_1. Given the surface collection S_i, $i = 1, \dots, k-1$, which will be the surface S with points chosen on the boundary for each vertex of the corresponding circuit in G_i, we construct S_{i+1} from S_i by deleting one of each pair of points corresponding to pairs of vertices that are identified in the simplification of G_i to G_{i+1}. We will prove that we can perform the topological identification of the points and lines of S_i that are identified by the third layer structure of G_i to create a topological space V_i and, furthermore, that it is homeomorphic to T.

By Corollary 3.6 V_1 is homeomorphic to T, while we will take V to be V_k. Note that the construction of V_k is not affected by our knowledge of $G(T)$; so if we prove this result, it will follow that whatever S_k we chose, the resulting space V will be homeomorphic to T. We will proceed by induction. The base case is Corollary 3.6.

Suppose that we have constructed the space V_{i-1}. Let u_j, v_j, $j = 1, \dots, m$, be the pairs of vertices identified as mergeable in G_{i-1} to give G_i, and suppose w.l.o.g. that those corresponding to u_j were deleted from S_{i-1}. Let w_j be the other neighbor of u_j on its boundary (note that w_j could in some cases be v_j). Since the lines of S_{i-1} could be identified to create the space V_{i-1}, all of the u_j, v_j, and w_j were identified amongst themselves, and the collections of edges

$$\{\{u_j, w_j\}\}_{j=1}^m \quad \text{and} \quad \{\{u_j, v_j\}\}_{j=1}^m$$

were also identified. But then the edges $\{v_j, w_j\}$ of S_i can also be identified by the same recipe and in such a way that the chosen points u_j are identified amongst themselves. The space V_i created along with the other identifications performed on S_{i-1} is then homeomorphic to V_{i-1}.

This completes the proof. □

4. Proof of main result. We are now ready to prove our main result.

Proof of Theorem 2.1. We are given two 2-complexes and are required to reduce the problem of deciding whether they are homeomorphic to an isomorphism oracle. We first perform a subdivision so that any singular simplices are removed. Singular simplices are those in which two distinct faces are identified. A subdivision will always remove this type of singularity. A further subdivision will ensure that the triangulation is not anomalous as guaranteed by Lemma 3.2. The next stage is to separate the purely 2-dimensional part of the complex from any lower-dimensional simplices. Zero-dimensional simplices that are not part of a one-dimensional simplex can be counted and, provided there are the same number in both complexes, can be ignored. The set of one-dimensional simplices that are not edges of two-dimensional simplices form a number of graphs, which may or may not be connected to two-dimensional simplices. Those that are not connected to any 2-dimensional simplices can be treated as a single graph in both complexes, and after removing 2-valent vertices we may call the graph isomorphism oracle to decide whether they are homeomorphic. This will be a necessary condition for the two complexes as a whole to be homeomorphic.

Finally we consider those component graphs that are connected to 2-dimensional simplices. These are disconnected from the 2-dimensional part of the complex, but the points of attachment are labeled. We are left with a purely 2-dimensional complex, with a number of labeled points. We perform the construction of the combinatorial invariant using Algorithms 1, 2, and 3 described in the previous section with two slight adaptations. The first adaptation concerns the transfer of labeled points into the graph $G(T)$. For such points that are not on a boundary in the split complex an extra vertex is created in layer two of the graph $G(T)$ connected to the vertex in layer one corresponding to its surface. This vertex will for the time being receive the point's label. For points that lie on a boundary the corresponding vertex of layer three receives the point's label.

The second adaptation concerns the simplification algorithm and requires that labeled vertices cannot be concatenated during the simplification process.

Once the simplified graph $\hat{G}(T)$ has been created we connect the graph sections that were removed from the original complex back onto the vertices with corresponding labels in $\hat{G}(T)$ after concatenating any 2-valent vertices in these graph sections. We then call the graph isomorphism oracle to decide if the two graphs are isomorphic. The fact that the vertices of layer one are labeled ensures that any isomorphism will be an isomorphism of the graphs created from the 2-complexes, together with a homeomorphism of the graph sections retained from the original complex. Hence, by the results of the previous section, the graphs will be isomorphic if and only if the original 2-complexes are homeomorphic. It therefore only remains to show that the reduction algorithm can be performed in polynomial time. □

PROPOSITION 4.1. *Algorithms* 1, 2, *and* 3 *run in time polynomial in the size of the triangulation* T.

Proof. Stage 1 of Algorithm 1 consists of a simple manipulation and can clearly be performed in polynomial time. Stage 2 requires examining pairs of vertices which arose from the same original vertex. By initially labeling edges that appear in only two triangles, this computation becomes equivalent to finding the connected components of a graph and is clearly polynomial.

Stage 1 of Algorithm 2 is a standard computation, while Stages 2 and 3 are straightforward translations using only local information about the connectivity of splitting vertices. All three stages clearly involve only polynomial time computations.

During all but the last sweep of the simplification algorithm (Algorithm 3) the number of vertices in the graph is reduced by at least three. Clearly the number of reductions is therefore at most a third of the total number of vertices in the original graph, which is in turn bounded by the number of vertices and triangles in the original triangulation. It remains therefore to show that each sweep of the algorithm requires at most polynomial time. Checking pairs of vertices for concatenation involves looking at all pairs of adjacent vertices in layer two and examining their sibling sets. The matching of the sibling sets can be checked simply because each sibling has only two neighbors in layer two that are candidate siblings for the second vertex. This computation can clearly be performed in polynomial time. The actual vertex deletion is also a local operation and can be performed in constant time. □

5. Conclusions. We have considered the problem of determining whether two 2-complexes are homeomorphic and investigated its position in the complexity hierarchy. Whereas the closely related problem of determining whether two complexes have isomorphic fundamental groups is algorithmically unsolvable, we have shown that the problem of 2-complex homeomorphism is not only decidable but of equivalent complexity to graph isomorphism modulo polynomial time reductions.

From a practical point of view there exist very efficient heuristic algorithms for testing whether two graphs are isomorphic [5]. Our reduction will therefore facilitate efficient testing of 2-complex homeomorphism.

From a theoretical point of view our results suggest that the problem of 2-complex homeomorphism may be of interest in the on-going investigation of the precise status of graph isomorphism in the complexity hierarchy. We feel that future research could profitably consider which variations of 2-complex homeomorphism retain the same complexity status, which become NP-complete, and which, if any, become undecidable. Some results in this area have been obtained recently. For example, Thomassen has shown that deciding the genus of a graph is NP-complete [8]. This would parallel the studies performed on the complexity status of variants of graph isomorphism, but in the case of 2-complex homeomorphism there is the additional attraction that a closely related problem has already been shown to be undecidable.

ON COLLISION-FREE PLACEMENTS OF SIMPLICES AND THE CLOSEST PAIR OF LINES IN 3-SPACE*

MARCO PELLEGRINI†

Abstract. The problem of detecting efficiently whether a query simplex is *collision-free* among polyhedral obstacles is considered. If n is the number of vertices, edges, and faces of the polyhedral obstacles, and m is the amount of storage allocated for the data structure ($n^{1+\epsilon} \leq m \leq n^{4+\epsilon}$), it is possible to solve collision-free placements queries for simplices in time $O(n^{1+\epsilon}/m^{1/4})$ for any $\epsilon > 0$, where the constants depend on ϵ. In order to solve this problem the authors develop data structures to detect on-line intersections of query half planes with sets of lines and segments.

Some nearest-neighbor problems for objects in 3-space are also considered. Given a set of n lines in 3-space, the shortest vertical segment between any pair of lines is found in randomized expected time $O(n^{8/5+\epsilon})$ for every $\epsilon > 0$. The longest connecting vertical segment is found in time $O(n^{4/3+\epsilon})$. The shortest connecting segment is found in time $O(n^{5/3+\epsilon})$.

AMS subject classification. 68U05

1. Introduction.

1.1. Collision-free placements of simplices.

Detecting intersections of objects is a basic problem in computational geometry [PS85], [Ede87], [Meh84]. While intersection problems on the plane are more or less solved, for their three-dimensional counterpart fewer results are known. Intersection of *convex polyhedra* in 3-space can be detected in time logarithmic in the total number n of vertices, faces, and edges, using data structures of linear size [CD80], [DK83], [DK90]. Non-convex polygonal objects in 3-space are much harder from a computational point of view. If we have two *terrains* with the same vertical direction, Chazelle et al. [CEGS89a] solve the intersection-detection problem in time $O(n^{4/3+\epsilon})$. In [MS85] the case of one convex and one non-convex polyhedra is considered. If we have two non-convex polyhedra or any set of non-convex polyhedra, we can solve the intersection-detection problem in time $O(n^{8/5+\epsilon})$ [Pel91b].

In this paper we are interested in detecting the intersection of a query simplex among a set of (possibly intersecting) non-convex polyhedral obstacles. We allow preprocessing of the obstacles and we answer on-line intersection queries in sublinear time. For this problem, a simple-minded extension of the approach of [CD80], [DK90] requires testing each obstacle with the query simplex independently. In the worst case we would have a linear number of simplex-obstacle pairs to consider. The intersection-detection results in [CEGS89a, Pel91b] are inherently off-line and do not immediately imply a solution for our on-line query problem.

The solution of this intersection-detection problem allows us to determine efficiently whether a placement of a polyhedral object of constant complexity within polyhedral obstacles is collision-free. Finding collision-free placements for objects is a basic problem for applications in robotics. There are many results for several variations of the free-placement problem (e.g., finding a collision-free path, finding the placement of the largest copy, etc.) for

*Received by the editors April 13, 1992; accepted for publication (in revised form) September 15, 1992. A preliminary version of this paper appeared with the title "Incidence and nearest neighbor problems for lines in 3-space" in the Proceedings of the 8th ACM Symposium on Computational Geometry, Berlin, Germany, 1992. This research was initiated while the author was visiting the International Computer Science Institute in Berkeley.

a polygonal object amidst polygonal obstacles *in the plane* (see [LS87b], [LS87a], [GSS88], [KS88], [HO89], [CK89], [FHS89], [Tol91]; see [SS89] for a survey).

In [Hal91] some motion planning problems for systems with three degrees of freedom are considered. In this case the robot is mapped as a point in a suitable three-dimensional parametric space and the obstacles are mapped as surfaces within this space. Also, recent work of Aronov and Sharir [AS90], [AS92] on the complexity of a cell in an arrangement of triangles in 3-space has applications to this kind of problem.

The main result of the paper is the following (Theorem 7): given a set of polyhedral obstacles with n vertices, edges, and faces, we can build a data structure using m units of storage, with $n^{1+\epsilon} \leq m \leq n^{4+\epsilon}$, such that for any query simplex we can determine in time $O(n^{1+\epsilon}/m^{1/4})$ whether the simplex is collision-free.[1]

To our knowledge no previous sublinear algorithm for collision-free placement queries among several non-convex polyhedra has been known.

In three-dimensional space, free-placement problems have a high intrinsic combinatorial complexity; therefore we tackle the simple problem of building a data structure for free-placement queries. On the other hand, our data structure is powerful because *both* the placement (six degrees of freedom) *and* the shape (as long as it is of constant complexity) of the robot are part of the query.

We consider first a solution which, at the expense of large storage, answers the queries in logarithmic time. Applying the methods in [CSW90], [Mat91], [AM92a] (see also [AS91a]), we obtain a space/query-time trade-off.

In [Pel91b], [AS91a] algorithms for the following problem are presented: given a set of triangles, count (or report) the triangles intersected by any query ray or segment. One of the main building blocks for our collision-free data structure is a solution for the *dual problem*: given a set of segments in 3-space, count (or report) the segments intersected by any query triangle. Dobkin and Edelsbrunner in [DE84] solve the problem of counting the number of segments intersected by a query *plane*, but their approach does not seem to extend to query *half planes*. Our approach is based on reducing the problem to *half-space range searching* and it attains the goal of a data structure for half plane queries. Once we have the solution for half-planes, it easily extended to triangle queries.

1.2. The closest pair of lines in 3-space. Arrangements of lines in 3-space have been studied recently in computational geometry (e.g., [CEGS89a], [Pel90], [Pel91b], [PS92], [AS91a], [dBHO$^+$91], [CEG$^+$90]). Some of the problems concerning lines can be classified as "incidence" or "order" problems. For example, the *relative orientation* of lines in space [CEGS89a] is exploited in [CEGS89a], [Pel91b], [dBHO$^+$91] to solve ray-shooting problems, and in this paper to answer collision-free queries. Problems that involve a metric on the set of lines in R^3 can be classified as "neighbor" problems.

If a robot does not intersect any obstacle, the next natural question is to find the obstacle *closest to the robot.* Thus, we are led to consider "neighbor" problems in 3-space. Neighbor problems for sets of points have been extensively studied in computational geometry [Vai89], [AESW91], [PS85] also in connection with the well-studied *Voronoi Diagrams* (see [Aur91] for a survey). Much less is known about neighbor problems in higher dimensional spaces *for objects which are not points.*

Neighbor problems for polyhedral objects in 3-space such as lines, segments, and polyhedra are important for applications not only in robotics, but also for three-dimensional very large scale integration and computer-assisted design. In these two areas we often need to enforce a minimum separation distance among three-dimensional objects.

[1] All the bounds presented hold for every $\epsilon > 0$ and the multiplicative constants depend on ϵ.

In §§4.2 and 4.3 we describe algorithms for solving a few neighbor problems on lines in 3-space. We are interested in finding the shortest segment connecting two lines in a set of lines, under a variety of constraints. We give algorithms to find the *shortest vertical segment* connecting two elements in a set of lines or segments which runs in $O(n^{8/5+\epsilon})$ expected time. Surprisingly, we prove an expected time bound for finding the *longest vertical segment* that is only $O(n^{4/3+\epsilon})$. We find the shortest segment connecting two lines in a set of n lines in $O(n^{5/3+\epsilon})$ expected time.

All the neighbor problems considered in this paper can be easily solved in $O(n^2)$ time. For some of the problems slightly sub-quadratic algorithms have been known. For the special case of the shortest vertical distance between two sets of edges of non-intersecting polyhedral terrains Chazelle et al. [CEGS89a] give an $O(n^{4/3+\epsilon})$ randomized expected time algorithm. The problem of the minimum vertical separation for segments was solved in [CS88] in time $O(n^{1.99987})$. The method in [CS88] maps a segment into a point in six-dimensional space. Using the representation in [CS88] and the more recent decomposition technique of [CEGS89b], it is possible to obtain a time bound of roughly $O(n^{2-1/9}) = O(n^{1.8889})$.

Independently, Guibas, et al. [Gui91] have considered the problem of finding the closest pair of lines, obtaining an $O(n^{5/3+\epsilon})$ algorithm. More recently, Chazelle et al. [CEGS92] have improved the running time to $O(n^{8/5+\epsilon})$.

The main strategy used in this paper to solve closest pair problems is to build first a data structure to answer closest line queries. In a second stage we transform the method for solving on-line queries into an off-line method by batching the queries. Because the on-line data structures can have a *multilayer structure* [Meh84], we develop in §4.1 a general method called *nested batching technique*, which is of independent interest (for more applications see [Pel92]).

The paper is organized as follows. In §2 we give an overview of the geometric techniques used to obtain the results. In §3 we discuss the problem of detecting efficiently whether a placement of a simplex is collision-free. Section 4 deals with several neighbor problems: finding the shortest and longest vertical segments and finding the shortest segment in a set of lines.

2. Geometric and algorithmic preliminaries. In this section we survey some geometric and algorithmic results which lay the groundwork for the main results of the subsequent sections.

2.1. Arrangements. A finite set H of hyperplanes in R^d defines a decomposition of R^d into cells of various dimensions, which is called the *arrangement* $\mathcal{A}(H)$ of H [Ede87]. If $|H| = n$, the maximum number of cells in $\mathcal{A}(H)$ is $O(n^d)$ and the arrangement $\mathcal{A}(H)$ can be computed in optimal $O(n^d)$ time [EOS86]. One d-dimensional cell of $\mathcal{A}(H)$ is bounded by $O(n^{\lfloor d/2 \rfloor})$ cells of any dimension [Ede87].

Similarly, a set V of real semi-algebraic varieties in R^d decomposes R^d into cells of various dimensions, which is called the *arrangement* $\mathcal{A}(V)$ of V [CEGS89b]. In [CEGS89b], Chazelle et al. describe a method for building a point-location data structure for the arrangement of n algebraic varieties of fixed maximum degree in R^d. For $d \geq 3$, the data structure has size $O(n^{2d-3+\epsilon})$ and it can be built in $O(n^{2d-3+\epsilon})$ randomized expected time or $O(n^{2d+1})$ deterministic time. The query time is $O(\log n)$.

2.2. Random sampling and cuttings. Given a random sample R of a set of hyperlanes H, with $|R| = r \leq n$, let us consider the arrangement $\mathcal{A}(R)$. A triangulation $\Delta\mathcal{A}(R)$ is a subdivision of each cell of $\mathcal{A}(R)$ into simplices such that the vertices of each simplex are vertices of $\mathcal{A}(R)$. The number of simplices in $\Delta\mathcal{A}(R)$ is $O(r^d)$. The random sampling theory of Clarkson [Cla87] states that with probability at least 1/2 the interior of each simplex

$s \in \Delta\mathcal{A}(R)$ does not meet more than $O(n/r \log r)$ hyperplanes of H. A set as $\Delta\mathcal{A}(R)$ is called a *cutting* for H.

Given H, we can build a data structure that uses $Cn^{d+\epsilon}$ storage, for each $\epsilon > 0$, where the constant C depends on ϵ, such that a query point is located in $\mathcal{A}(H)$ in $O(\log n)$ time [Cla87]. This data structure is built in expected time $O(n^{d+\epsilon})$ [Cla87].

For $d = 2$ Matoušek [Mat90] gives a deterministic method that, for a parameter $r < n$, subdivides the plane into $O(r^2)$ triangles in time $O(nr)$ such that the interior of each triangle meets only n/r lines in H.

For a set V of n algebraic varieties of fixed degree in R^d, $d > 2$, Chazelle et al. [CEGS89b] prove that a R^d can be decomposed into $O(r^{2d-3}\beta(r))$ cells of constant descriptive complexity, where $\beta(\cdot)$ is a sub-logarithmic function, and each cell intersects no more than $O(n/r \log r)$ surfaces in V.

These results on cuttings are the basis of many divide-and-conquer algorithms in computational geometry (see [Aga91] for a survey).

2.3. On-line and off-line point location. The algorithms of [Cla87] and [CEGS89b] solve, in logarithmic time, on-line point location problems in arrangments of hyperplanes or algebraic varieties of fixed degree. In several applications the queries are given off-line and we can batch them in order to speed up the overall computation.

In [EGS90], Edelsbrunner et al. give a method for batched point-location that is generalized in §4.1 to deal with a vast class of off-line point location problems. Given n surfaces and m points, we compute properties of the points that depend only on the locations of these points with respect to the arrangement of the given surfaces in expected time $O(m^{a/(a+1)}n^{a/(a+1)} + m^{1+\epsilon} + n^{1+\epsilon})$, where a is a characteristic parameter of the problem.

To apply this technique an important requirement is the ability to map data and queries as point or surfaces, via dual transformations.

Geometric dual transformations [Ede87], [EMP$^+$82] are pairs of functions: one function maps points to surfaces (hyperplanes) and the second function maps surfaces (hyperplanes) to points in R^d. Duality mappings preserve incidence and order relations.

2.4. Halfspace range searching. A problem intimately connected to the point-location problem is the half-space range searching problem. Given a set S of n points in R^d, build a data structure such that, for every query half-space h^+, the number of points in $S \cap h^+$ is computed efficiently. This problem is solved in [CSW90], [Mat91] using *partition trees*. In a partition tree, each node is associated with a region in R^d such that only a fraction of the children intersect the hyperplane h supporting the query half-space. During the query we retrieve the number of points of S within the regions associated with children not intersected by h and we recurse the query on the children intersected by h. Partition trees are quite versatile and they can be used to set up multilevel data structures.

2.5. Multilevel data structures. Multilevel data structures are a basic paradigm in computational geometry [Meh84]. They are used to search for elements satisfying a complex property. Usually the complex property is split into elementary properties and each elementary property is tested at a specific level of the data structure. For example, in [CSW90], [Mat91] sets of points are organized in multilevel partition trees to answer simplex range queries, where each level of the data structure tests the position of the data points with respect to the hyperplane spanning a facet of the simplex. We have this fundamental theorem in [CSW90].

THEOREM 1 ([CSW90]). *Simplex range searching in n points in R^d can be performed in $O(n^{1+\epsilon}/m^{1/d})$ query time, for every $\epsilon > 0$, using a data structure of size m (for any m between n and n^d), which can be computed in $O(m^{1+\epsilon})$ randomized expected time.*

Matoušek in [Mat91], using a different partition scheme, is able to make the preprocessing deterministic and to reduce the query time to $O(n \log^{O(1)} n/m^{1/d})$.

2.6. Parametric search. In some of the algorithms for nearest neighbor problems on lines we use Megiddo's parametric search technique [Meg83], [Col87]. Roughly speaking, this technique transforms an algorithm to test a property into an algorithm to find the minimum value of a parameter for which the property is true, under quite general conditions.

More formally, suppose we have an algorithm P' to compute a predicate $P(i, t)$, which depends on an input i and a real parameter t. The algorithm P' only uses the parameter t to perform branching tests based on the evaluation of fixed degree polynomials that depend on i and t. Moreover, suppose that the predicate $P(i, t)$ is monotone in t, meaning that for increasing values of t, it never switches from false to true.

Megiddo's parametric search technique is a method that transforms P' into an algorithm P'' for finding the minimum value of t for which the predicate $P(i, t)$ is true.

As an intermediate step of the transformation, we need a parallel version of the program P', which we call $\mathcal{P}$. The parallel time is $T_{\mathcal{P}}$ and the number of processors is p. The new algorithm P'' simulates sequentially $\mathcal{P}$ without specifying the value of t. When each of the p processors is stopped at a branching step that requires the evaluation of a polynomial in t, we compute all the roots of the polynomials at the branching steps and we sort them. Then we use the sequential algorithm P' to perform a binary search on the sequence of roots in order to find the interval where the minimum value t^* lies. Once we have this interval, we can compute the sign of the branching polynomials at t^*. The algorithm branches accordingly to these values. The algorithm completes the simulation and determines a final interval whose left endpoint is exactly t^*. The total time of the simulation is given by $O(pT_{\mathcal{P}} + T_{P'}T_{\mathcal{P}} \log p)$.

Applications of Megiddo's parametric search to geometric problems are in [AASS90], [AM92b], [CEGS92].

2.7. Plücker coordinates of lines. To solve problems on lines and polyhedra we use the *Plücker coordinates* of lines. Algorithmic uses of Plücker coordinates can be found in [CEGS89a] and in [Pel91a], [PS92]; a classical treatment of Plücker coordinates can be found in [Som51].

A point in real three-dimensional space has Cartesian coordinates (x, y, z) and homogeneous coordinates (x_0, x_1, x_2, x_3). The relations between the two systems of coordinates are given by the following equations: $x = x_1/x_0$, $y = x_2/x_0$, and $z = x_3/x_0$. Two points $x = (x_0, x_1, x_2, x_3)$ and $y = (y_0, y_1, y_2, y_3)$ in three-dimensional homogeneous coordinates define a line l in 3-space. The six quantities

$$\xi_{ij} = x_i y_j - x_j y_i \quad \text{for} \quad ij = 01, 02, 03, 12, 23, 31$$

are called *Plücker coordinates* of the line l (oriented from x to y). They correspond to the two-by-two minors of the two-by-four matrix formed by the coordinates of the point x (on the first row) and y (on the second row).

The six parameters are not independent; they must satisfy the following equation (whose solution set constitutes the Plücker hypersurface of Klein quadric or Grassman manifold $\mathcal{F}_4^2$ [Sto89], [Som51]):

$$(1) \qquad \prod \; : \; \xi_{01}\xi_{23} + \xi_{02}\xi_{31} + \xi_{03}\xi_{12} = 0.$$

The incidence relation between two lines l and l' can be expressed using the Plücker coordinates of l and l'. Let a_1, b_1 (respectively, a_2, b_2) be two points on l (respectively, l') oriented as l (respectively, l'). The incidence between l and l' is expressed as the vanishing of the determinant of a four-by-four matrix whose rows are the coordinates of a_1, b_1, a_2, b_2 in this order from top to bottom:

$$\text{(2)} \qquad \begin{vmatrix} a_{10} & a_{11} & a_{12} & a_{13} \\ b_{10} & b_{11} & b_{12} & b_{13} \\ a_{20} & a_{21} & a_{22} & a_{23} \\ b_{20} & b_{21} & b_{22} & b_{23} \end{vmatrix} = 0.$$

If we expand the determinant according to the two-by-two minors of the sub-matrix formed by the coordinates of the points a_1, b_1 and the minors of the sub-matrix formed by the points a_2, b_2, we obtain the following equation in which only Plücker coordinates are involved:

$$\text{(3)} \qquad \xi_{01}\xi'_{23} + \xi_{02}\xi'_{31} + \xi_{03}\xi'_{12} + \xi'_{01}\xi_{23} + \xi'_{02}\xi_{31} + \xi'_{03}\xi_{12} = 0.$$

Let us introduce two mappings: $\pi \; : \; l \to \pi(l)$ maps a line in $\mathcal{R}^3$ to a hyperplane in $\mathcal{P}^5$ (five-dimensional oriented projective space) whose plane coordinates are the Plücker coordinates of l appropriately reordered. $p \; : \; l \to p(l)$ maps a line in $\mathcal{R}^3$ to a point in $\mathcal{P}^5$ whose coordinates are the Plücker coordinates of the line. The incidence relation between the two lines l, l' (expressed by (3)) can be reformulated as an incidence relation between points and hyperplanes in $\mathcal{P}^5$. Equation 3 can be rewritten in the form $\pi_l(p_{l'}) = 0$, which is equivalent to requiring point $p(l')$ to belong to hyperplane $\pi(l)$. Computations that are standard in real spaces can be done in oriented projective spaces using a method in [Sto89].

For any given pair of lines l and l' the sign of the quantity $\pi_l(pl')$ is called the *relative orientation* of l and l', denoted by $l \diamond l'$.

2.8. Lines in space. In a seminal paper [CEGS89a], Chazelle, et al. use Plücker coordinates to obtain several results on problems involving polyhedral terrains in 3-space.

One of the problems discussed in [CEGS89a] is the following: given a set $\mathcal{L}$ of n lines in $\mathcal{R}^3$, build a data structure so to answer efficiently whether a query line l is above every line in $\mathcal{L}$. They give a data structure of size $O(n^{2+\epsilon})$ to answer such queries in time $O(\log n)$. Because this data structure is the point of departure of the present article from previous work, we discuss it in full detail.

Given two non-vertical lines l and l', l is above l' if there exists a vertical line meeting both lines and the intersection with l is above the intersection with l'. The objective is to express the *above* relation in terms of relative orientation. Let us consider the line λ parallel to l and passing through the point $z_\infty = (0, 0, 1, 0)$. The line l' is *above* l if it is "between" l and λ, therefore we require that

$$\text{(4)} \qquad l' \diamond l = -l' \diamond \lambda.$$

Thus, we need to check the consistency of two linear inequalities. Let $\mathcal{L} = \{l_1, \ldots, l_n\}$ be a set of n *oriented lines*. And let λ_i be the line parallel to l_i and through the point z_∞. Given query line l, we first test if it is *consistently oriented* with respect to $\mathcal{L}$, that is if $l \diamond \lambda_i = -1$ for all i. For a line l that is consistently oriented the aboveness test reduces to test membership of its corresponding Plücker point in the intersection of n Plücker halfspaces.

Chazelle et al. also observe that to decide if a line l is consistently oriented it is sufficient to project l and $\mathcal{L}$ on the xy-plane and to test if the projection of l is clockwise with respect to the projections of all lines in $\mathcal{L}$. Thus, there are $2n$ ways to orient the lines in $\mathcal{L}$ consistently such that any l is consistently oriented exactly for one orientation of $\mathcal{L}$.

3. An incidence problem in 3-space.

3.1. Redefining the *above* relation. Our first objective is to redefine the *above* relation between lines in a form more suitable for algorithmic applications. We do so by generalizing in a more algebraic context the steps of the algorithm in §2.8.

Let us fix once and for all an orthogonal reference frame in 3-space with unit vectors $(\vec{i}, \vec{j}, \vec{k})$ forming a positively oriented triple according to the skew rule. And let (x, y, z) be the coordinates of a generic point in this reference frame.

Given a line l, a vector $\vec{v}$, and a line l' in R^3 we say that l is *above* l' in direction $\vec{v}$ (namely $above(l, l', \vec{v}\,)$) if moving l in direction $\vec{v}$ we eventually intersect l'.

When $\vec{v}$ is a vector parallel to the $-\vec{k}$-axis, we are in the situation described in [CEGS89a]. In [CEGS89a] the condition for a line to be above another line was given by the relative orientation of the two lines in Plücker space and by the relative orientation of the projections of the two lines on the xy-plane. Let us define oriented lines by ordered pairs of points in 3-space: $l = (a, b)$ and $l' = (a', b')$; then the relative orientation of the projections of l and l' on the xy-plane is equivalent to testing if the triple $(a - b, a' - b', \vec{v}\,)$ is oriented as $(\vec{i}, \vec{j}, \vec{k})$. This, in turn, is equivalent to computing the sign of the following determinant:

$$tsp(l, l', \vec{v}\,) = sign \begin{vmatrix} a_x - b_x & a_y - b_y & a_z - b_z \\ a'_x - b'_x & a'_y - b'_y & a'_z - b'_z \\ 0 & 0 & 1 \end{vmatrix},$$

which is the triple scalar product of the vectors $a - b$, $a' - b'$, and $(0, 0, 1)$. We can generalize the notion of relative orientation by making the "vertical direction" part of the query. If the vertical direction is specified by a variable vector $\vec{v}$, the relative orientation is still the sign of the triple scalar product of $(a - b, a' - b', \vec{v}\,)$:

$$(5) \qquad tsp(l, l', \vec{v}) = \text{sign} \begin{vmatrix} a_x - b_x & a_y - b_y & a_z - b_z \\ a'_x - b'_x & a'_y - b'_y & a'_z - b'_z \\ v_x & v_y & v_z \end{vmatrix}$$

Considering the signs $(+1, -1)$ as boolean values, we prove the following technical lemma:

LEMMA 1. $above(l, l', \vec{v}\,) = tsp(l, l', \vec{v}\,)\ xor(l \diamond l')$.

Proof. (i) If $\vec{v} = -\vec{k}$, then clearly $tsp(l, l', \vec{v}) = l' \diamond \lambda$, by the discussion in [CEGS89a]. Because l is above l' if and only if the two sides of (4) have different values the lemma is proved.

(ii) If $\vec{v} \neq -\vec{k}$, then we can apply a rigid transformation to our reference frame which takes $-\vec{k}$ into $\vec{v}$. It is easy to check that such transformation does not change the value of $l \diamond l'$ and $tsp(l, l', \vec{v}\,)$; therefore we are back to case (i) and the lemma is proved. □

We say that a line l is above a set $\mathcal{L}$ in direction $\vec{v}$ if it is above every line in $\mathcal{L}$, namely $above(l, \mathcal{L}, \vec{v}\,)$. From Lemma 1 we have

$$(6) \qquad above(l, \mathcal{L}, \vec{v}\,) = \bigwedge_{i=1,n} tsp(l, l_i, \vec{v}\,)\ xor(l \diamond l_i).$$

3.2. Half-plane intersection queries on lines. The determinant in (5) can be expanded in a bilinear form in terms of the two-by-two minors of the last two rows and the one-by-one minors of the first row. Let us define $\pi'(l) = (a_x - b_x, a_y - b_y, a_z - b_z)$ and $p'(l', \vec{v}) = (u_{yz}, u_{zx}, u_{xy})$, where $u_{ij} = (a'_i - b'_i)v_j - (a'_j - b'_j)v_i$.

We can think of $p'(l', \vec{v})$ as a point in oriented projective 2-space $\mathcal{P}^2$ and of $\pi'(l)$ as a hyperplane in the same space. The value of $tsp(l, l', \vec{v})$ is just the sign of the inner product of $\pi'(l)$ and $p'(l', \vec{v})$. The value of $tsp(l, l', \vec{v})$ is also the sign of the polynomial defining $\pi'(l)$ evaluated at $p'(l', \vec{v})$.

THEOREM 2. *Given a set $\mathcal{L}$ of n lines, there is a data structure $D(\mathcal{L})$ of size $O(n^{2+\epsilon})$ that in time $O(\log n)$, for a query pair $(l', \vec{v})$, determines if l' is above $\mathcal{L}$ in direction $\vec{v}$.*

Proof. We number the lines in $\mathcal{L}$ from 1 to n obtaining a sequence of lines $L = [l_i]$. We construct the arrangement $\mathcal{A}'(\mathcal{L})$ of the hyperplanes in $\{\pi'(l) | l \in \mathcal{L}\}$. Consider a cell c of $\mathcal{A}'(\mathcal{L})$ and a point $q \in c$. We define as the *sign sequence* of the cell c the sequence $[\text{sign}(\pi'(l) \cdot q) | l \in L]$. We build for each region c a Plücker polytope using the negated sign sequence c as a guide for choosing the correct side of the Plücker hyperplanes.

Let $(l', \vec{v})$ be a query pair. First we locate the cell c in the arrangement $\mathcal{A}'(\mathcal{L})$ containing $p'(l', \vec{v})$. Then, we test for inclusion of the Plücker point $p(l')$ in the Plücker polyhedron associated with c.

In order to obtain a space-efficient data structure, we use a a plane partition approach to construct the arrangement in $\mathcal{P}^2$. Using the method in [Mat91], we partition the plane into $O(r^2)$ regions such that each region is cut by no more than n/r hyperplanes $\pi'(l)$. For at most $O(n)$ hyperplanes π' not cutting through a region c, we build a corresponding point-in-polytope query data structure in Plücker space at the expense of at most $O(n^{2+\epsilon})$ storage (see [CEGS89a], [Pel90]). Then we recurse the construction in each region on the hyperplanes cutting through. The storage $S(n)$ needed to construct the data structure satisfies the following inequality:

$$S(n) \leq cr^2 S(n/r) + cr^2 O(n^{2+\epsilon}). \tag{7}$$

The solution is $S(n) = O(n^{2+\epsilon})$. By choosing $r = n^{\nu}$ for an appropriate value of ν, and by adding planar point location data structures, we can achieve $O(\log n)$ query time. Note that the data structure itself does not depend on any specific direction $\vec{v}$. □

COROLLARY 1. *Given a set $\mathcal{L}$ of n lines, there is a data structure $D(\mathcal{L})$ of size $O(n^{2+\epsilon})$ that in time $O(\log n)$, for a query half plane h, determines if h intersects* 0 (*or all*) *lines in $\mathcal{L}$.*

Proof. If a line l is above all lines in $\mathcal{L}$ along a direction $\vec{v}$, then the half plane defined by l and $-\vec{v}$ does not intersect any line in $\mathcal{L}$. Conversely, the half plane defined by l and $\vec{v}$ intersects all lines in $\mathcal{L}$. Here we consider lines parallel to the half plane h as intersecting h (at infinity). □

COROLLARY 2. *Given a set H of n half planes, there is a data structure $D(H)$ of size $O(n^{2+\epsilon})$ that in time $O(\log n)$, for a query line l, determines if l intersects* 0 (*or all*) *half planes in H.*

Proof. A pair $(l', \vec{v})$ determines a half plane h in 3-space. We can think of $p'(l', \vec{v})$ as a hyperplane in $\mathcal{P}^2$ and $\pi'(l)$ as a point in $\mathcal{P}^2$. We build the data structure of Theorem 2 reversing the roles of hyperplanes and points in $\mathcal{P}^2$. For a query line l we can detect efficiently if any line l_i stored in the data structure hits l when moved in the associated direction $\vec{v}_i$. This is equivalent to detecting an intersection of l with all the half planes stored in the data-structure. If a line l hits all the opposite half planes defined by l_i and $-\vec{v}_i$, then it misses all the half planes defined by l_i and $\vec{v}_i$. □

The data structure of Corollary 2 is a generalization of the data structure in [CEGS89a], which can detect intersections of lines and *vertical* half planes only. A data structure solving the same problem of Corollary 2 is in [AM92b].

3.3. Triangle intersection queries on segments. Let S be a set of segments in 3-space. We build a multilevel data structure to solve the following problem: count the number of segments in S intersected by a query triangle. The general strategy is the following. Let t be a query triangle and let $\mathrm{aff}(t)$ be the plane spanning t. The first level of the data structure detects the segments of S which are intersected by $\mathrm{aff}(t)$. Those segments meeting $\mathrm{aff}(t)$ can be extended into full lines without introducing new intersections. The next three levels of the data structure are associated with the three edges of t. For each edge of t we consider the line spanning it and the half plane of $\mathrm{aff}(t)$ based on that line and containing t. We select the lines that meet this query half plane. At the bottom of the multilevel data structures we count exactly the number of segments meeting t. Now we formalize the above strategy and we give bounds on the storage and query time.

THEOREM 3. *Given a set $\mathcal{L}$ of n lines, there is a data structure $D(\mathcal{L})$ of size $O(n^{4+\epsilon})$ that in time $O(\log n)$, for a query half plane h, counts the number of lines in $\mathcal{L}$ intersected by h.*

Proof. We follow the same general approach as in the data structure of Theorem 2. The main difference is that for each planar region we associate a point-location data structure for the whole zone of the Plücker surface in the arrangement of Plücker hyperplanes [Pel91b]. This data structure requires $O(n^{4+\epsilon})$ storage and we can locate a point within the Plücker arrangement in time $O(\log n)$. We prestore in each cell the number of data lines that satisfy the *above* condition with respect to the line supporting the query half plane. We solve the same problem recursively on each planar region relatively to the lines such that $\pi'(l)$ crosses the planar region. The total storage is $O(n^{4+\epsilon})$ and the total query time is $O(\log n)$. □

THEOREM 4. *Given n segments there is a data structure of size $O(n^{4+\epsilon})$ that counts segments intersected by a query triangle in time $O(\log n)$.*

Proof. We dualize every segment in S into a double spatial wedge using a standard point-plane duality $\mathcal{D}$ [Ede87]. Detecting the segments intersected by the plane $\mathrm{aff}(T)$ is equivalent to locate the dual point $\mathcal{D}(\mathrm{aff}(t))$ in the arrangement $\mathcal{A}(\mathcal{D}(S))$ of the wedges.

When we have obtained the set of segments intersected by $\mathrm{aff}(t)$ as the disjoint union of sets stored in the first level of the data structure, we can extend the segments into lines without introducing any new intersection.

We consider now t as the intersections of three half planes in 3-space. In the next three levels of the data structure we store the lines supporting the segments and we build half plane–line intersection data structures of Theorem 3. At the last level, we can count the number of segments intersecting t. The total storage is $O(n^{4+\epsilon})$ as follows from solving a sequence of inequalities similar to (7) and the query time is $O(\log n)$. □

We can also report the intersections in time $O(\log n + k)$, using $O(n^{4+\epsilon})$ storage, where k is the output size.

3.4. Linear storage and sublinear query time. In the previous section we have reduced the problem of counting the number of segments of S intersected by a query triangle to the problem of locating several query points within several arrangements of hyperplanes (Plücker hyperplanes in Plücker space or lines on a parametric plane). By doing so, we compute efficiently, during the query, the relative position of the points with respect to the hyperplanes stored in the data structure.

As a matter of fact we could have interpreted the data structure as storing points and the query as half space range queries. The final result is the same (i.e., checking the sign of polynomials), but the preprocessing is quite different because the data structure can now be constructed using less storage at the expenses of an increased query time.

We can rebuild the whole multilevel data structure of §3.3 using a *half space range searching approach* [CSW90], [AS91a], [Mat91], [AM92a] rather than the point-location approach. The half space range query approaches in [CSW90], [Mat91] use a point location data structure as a subroutine, and in §3.3 we have developed such subroutine for the triangle query problem.

When solving the half space range problem in Plücker space, we have to take into account the presence of the Plücker hypersurface. We have the property that all Plücker points are on the Plücker hypersurface and all Plücker hyperplanes are tangent to the Plücker surface. Adapting the analysis of the data structure in [Mat91] to this special case and using a result in [APS91], Agarwal and Matoušek prove the following lemma:

LEMMA 2 ([AM92a]). *Given n Plücker points it is possible to solve half space range searching problems with Plücker hyperplanes using m storage, with* $n^{1+\epsilon} < m < n^{4+\epsilon}$, $O(m)$ *expected preprocessing time and* $(n^{1+\epsilon}/m^{1/4})$ *query time.*

As in [CSW90], [Mat91] it is possible to trade storage and query time. Using Lemma 2 and the analysis in [AS91a], Agarwal and Matoušek obtain the following result for ray-shooting on a set of triangles in 3-space:

THEOREM 5 ([AM92a]). *Given n triangles in three-dimensional space and any* $\epsilon > 0$, *one can preprocess them in randomized expected time* $O(m)$ *into a data structure of size* $O(m)$, *for* $n^{1+\epsilon} < m < n^{4+\epsilon}$, *so that for a query ray* ρ, *the first triangle met by* ρ *can be computed in time* $O(n^{1+\epsilon}/m^{1/4})$.

Lemma 2 applied to the analysis of §3.3 gives the following theorem:

THEOREM 6. *Given a set of n segments we can build a data structure using m units of storage, with* $n^{1+\epsilon} \leq m \leq n^{4+\epsilon}$, *such that for any query triangle t we can count in time* $O(n^{1+\epsilon}/m^{1/4})$ *the number of esgments intersected by t.*

Theorem 6 is an essential ingredient in the proof of the main theorem of the paper.

THEOREM 7. *Given a set of polyhedral obstacles with n edges, faces, and vertices, we can build a data structure using m units of storage with* $n^{1+\epsilon} \leq m \leq n^{4+\epsilon}$ *such that for any query simplex s we can determine in time* $O(n^{1+\epsilon}/m^{1/4})$ *whether s is collision-free.*

Proof. Assume that we are given a set of polyhedral objects with a total of n edges and a simplex s in 3-space. We have to consider only four collision cases. For each collision case we describe a data structure that answers whether the query simplex s generates a collision of that type.

(i) *An object is completely contained in s.* We select one arbitrary point of each obstacle thus obtaining a set P of at most n points in R^3. We build a data structure D_1 for simplex range searching on P using the methods in [CSW90], [Mat91], which satisfies the stated bound. We use the simplex s to query D_1. If any point of P is in s, then we have a clash of type (i).

(ii) *An edge of s meets a face of same object.* We take the facets of the obstacles and we triangulate them, obtaining a set T of $O(n)$ triangles in 3-space. We build a data structure D_2 for ray-shooting on T using the method in [AS91a] and its improvement in [AM92a]. We take for each vertex v of s the rays from v containing the edges of s incident to v. Using the data structure D_2, we determine the first triangle intersected by each ray. If for some ray the intersection point is closer to v than the second endpoint of the segment spanned by this ray, then we have a collision of type (ii). We have a constant number of ray-shooting queries for each simplex s. The preprocessing and the query time are those stated Theorem 5.

(iii) *A face of s meets an edge of some object.* We take the edges of the obstacles obtaining a set S of $O(n)$ segments in 3-space. We build a data structure D_3 for answering triangle-intersection queries, using the method of Theorem 6. In turns we take the facets of s and we count the number of segments intersected by each facet. If we detect some intersection we have a collision of type (iii).

(iv) *The query simplex s is completely contained within a polyhedral obstacle.* This case is checked by using the data structure D_2 for ray-shooting queries. We take a ray ρ from an arbitrary point of s in an arbitrary direction. If no obstacle is hit the simplex is not contained in any obstacle. Otherwise, we obtain the first facet t hit by ρ. If locally the ray ρ hits t from the interior of the object containing t, then we have a collision of type (iv).

Collision cases (i), (ii), (iii), and (iv) cover all possible collisions between a simplex and a set of polyhedral obstacles. □

4. Neighbor problems for lines in space. To solve neighbor problems on a set of lines in 3-space, we use the following general strategy. Given a set of lines $\mathcal{L}$ we build a data structure $D(\mathcal{L})$ that efficiently answers nearest-line queries for any query line l. The second step is to balance the preprocessing time and the query time by batching the queries, which we know in advance, over the data structure $D(\mathcal{L})$.

On an abstract level we can think that a query is a pair $(l, \mathcal{L})$, where l is any line and $\mathcal{L}$ a set of lines. Solving the query is equivalent to computing the truth value of a conjunction of several predicates that depend on l and on the elements of $\mathcal{L}$. The data structure $D(\mathcal{L})$ allows us to find the truth value of many predicates efficiently in an implicit way and therefore allows us to solve the query problem. Once we have the data structure $D(\mathcal{L})$, we can produce its batched version in a quite general way, which we call *nested batching technique*. This technique is a generalization of an approach to batching computations in [EGS88]. This technique has been used in several recent papers (e.g., [Pel90], [AS91b]) where the underlying predicate has only one conjunct. In [Pel91b] the technique has been used for a formula with two conjuncts. Here we generalize it in an abstract setting for any constant number of conjuncts.

4.1. The nested batching technique. Let $\mathcal{A}$ and $\mathcal{B}$ be two classes of geometric objects and $A \subset \mathcal{A}$ and $B \subset \mathcal{B}$ two finite subsets. Our goal is to compute efficiently $|C_k(A, B)| = |\{(a, b) \in A \times B | F(a, b)\}|$, where $F(a, b) = \wedge_{j=1,k} C_j$ is a conjunction of a constant number k of elementary conditions. Each elementary condition C_j is of the form $S_a^j(p_b^j) > 0$, where $S_a^j(\,.\,)$ is a polynomial whose structure depends on j and $\mathcal{A}$ and whose coefficients depend only on $a \in \mathcal{A}$. Also, p_b^j is a tuple of real numbers depending only on $b \in B$. Moreover, we require that we can rewrite C_j in the dual form $S_b^j(p_a^j) > 0$, where $S_b^j(\,.\,)$ is a polynomial whose structure depends on j and $\mathcal{B}$, whose coefficients depend only on $b \in B$. Also, p_a^j is a tuple of real numbers depending only on $a \in A$. For technical reasons we assume that $C_0 =$ *TRUE*. If $S_a^j(p_b^j) > 0$ we say that the *point* p_b^j is on the *positive side* of the *surface* $S_b^j(\,.\,) = 0$. From now on we will use the terms *point* and *surface* in this context. Note that, for a given j, an element $a \in A$ (respectively, $b \in B$) is mapped to a point or to a surface. We call the point and the surface *dual* to one another.

The following conditions must be also satisfied:

(I) Given a family of surfaces $\{S_a^j(x) = 0 | a \in A\}$ there is a constant $d'(\mathcal{A}, j)$ such that the space underlying the family of surfaces can be partitioned into $M_j'(r) = O(r^{d'(\mathcal{A},j)} \log^{O(1)} r)$ cells of constant descriptive complexity such that each cell meets at most $|A|/r \log r$ surfaces in the family. Moreover, we assume that this decomposition can be computed in expected time $O(|A|r^{O(1)})$.

(II) Given a family of surfaces $\{S_b^j(x) = 0 | b \in B\}$ there is a constant $d(\mathcal{B}, j)$ such that the space underlying the family of surfaces can be partitioned into $M_j(r) = O(r^{d(\mathcal{B},j)} \log^{O(1)} r)$ cells of constant descriptive complexity such that each cell meets at most $|B|/r \log r$ surfaces in the family. Moreover, we assume that this decomposition can be computed in expected time $O(|B|r^{O(1)})$.

Conditions (I) and (II) can be rephrased requiring that there is a $1/r$*-cutting* of a certain size for the arrangement of surfaces (see [Aga91] for a survey on cuttings). To be more precise, we require a cutting covering the portion of space where the query points are confined. If we do not have any condition on the points then the whole space must be covered. If the points are constrained to lie on a surface or within a convex polyhedron, only the surface or the polyhedron must be covered.

Let $d_j = \max\{d'(\mathcal{A}, j), d(\mathcal{B}, j)\}$ and let $d = \max_j d_j$. We will refer to d as the *characteristic dimension of the formula F*, while d_j is the *characteristic dimension of the elementary conjunct C_j*.

Let $T_j(m, n)$ be the time needed to determine the number of pairs $(a, b) \in A \times B$ satisfying the conditions associated with the elementary conjuncts form 1 to j, that is the time to compute $|\mathcal{C}_j(A, B)| = |\{(a, b) \in A \times B| \wedge_{i=1,j} C_i\}|$. We set $M(r) = \max_j\{M_j(r), M'_j(r)\}$. Just to give some examples, for lines and points on the plane we obtain $M'_j(r) = M_j(r) = r^2$ simple regions. For surfaces and points used in §4.3, we obtain $M_j(r) = M'_j(r) = r^4\beta(r)$ simple regions, using the technique in [CEGS89b], where $\beta(r)$ is a sub-logarithmic function. For Plücker points in an arrangement of Plücker hyperplanes we obtain $M_j(r) = M'_j(r) = r^4 \log r$, from a result in [APS91], because we need to cover only the Plücker hypersurface.

LEMMA 3. *Given a set A and B as above, let $|A| = n$ and $|B| = m$. For every $0 \leq j \leq k$, we can build in time $O(n^{d+\epsilon})$ a data structure such that, for every $b \in B$, $|\mathcal{C}_j(\{b\}, A)|$ can be computed in time $O(\log^j n)$.*

Proof. Let $T_j(n)$ be the time needed to build the data structure up to level j. We prove the claim by induction on j. For $j = 0$, $T_0(n) = O(1)$ therefore the lemma is satisfied. Assume $j > 0$. Applying property (I) for a value of r constant from n and m, we compute a decomposition of the space into $M'_j(r)$ elementary cells each one intersected by no more than $n/r \log r$ surfaces in $\{S^j_a = 0|a \in A\}$. For each elementary cell we select a point in its interior and we compute the set S^+_τ of surfaces not intersecting the region τ and in positive position with respect to τ. We associate the cardinality of S^+_τ with the region and we recurse this construction. Also, for each region τ and for all the elements $a \in A$ whose corresponding surface is in S^+_τ, we build the data structure to compute $\mathcal{C}_{j-1}$, which can be built in time $T_{j-1}(n)$. The total time and space for this construction satisfies the recurrence

$$T_j(n) \leq M'_j(r)T_j(n/r \log r) + M'_j(r)T_{j-1}(n) + O(nr^{O(1)} + nM'_j(r)),$$

$$T_j(O(1)) = O(1).$$

Since $M'(r) \leq r^d \log^{O(1)} r$ and assuming by induction hypothesis that $T_{j-1} = O(n^{d+\epsilon})$, the solution to this recurrence is $T_j(n) = O(n^{d+\epsilon})$.

Given a query point p we locate by exhaustive search the region τ containing it. Then we recurse on the two data structures associated with τ. At the last level we collect the counters of the positive regions and we sum them up to form the final result. The query time $Q_j(n)$ satisfies this recurrence:

$$Q_j(n) \leq Q_j(n/r \log r) + Q_{j-1}(n) + O(M'(r)).$$

Assuming by induction hypothesis that $Q_{j-1} = O(\log^{j-1} n)$, we obtain the solution is $Q_j(n) = O(\log^j(n))$. □

From Lemma 3 easily follows Lemma 4.

LEMMA 4. *If $m \geq n^d$ then, for every $j \leq k$, $|\mathcal{C}_j(B, A)|$ can be computed in time $O(m^{1+\epsilon})$.*

Let us suppose now that $m \leq n^d$. We dualize points and surfaces at level j, and we compute the partition (II) for a constant value of r. For each cell τ of the partition we have a set of n_τ points contained it and a set of m_τ surfaces cutting through. By the property (II), $m_\tau \leq cm/r \log r$ for some constant c. For each cell τ the relative sign of the points in τ and the surfaces outside τ is similar for each point in τ. This implies that in time $O(m)$ we can determine for all points in τ and for most surfaces the truth value of the predicate associated with the jth level. For the surfaces intersecting τ we proceed recursively. Let $T_j(m,n)$ be the time needed to compute $|\mathcal{C}_j(B,A)|$. From the above discussion $T_j(m,n)$ satisfies this recurrence:

$$T_j(m,n) \le \sum_{\tau} T_j(m_\tau, n_\tau) + M(r)(m+n) + M(r)T_{j-1}(m,n_\tau) + O(mr^{O(1)}). \tag{8}$$

The following is the main theorem of this section.

THEOREM 8. *For any ϵ and $\delta \le \epsilon/d$,*

$$T_j(m,n) = D_j n^{d/(d+1)+\epsilon} m^{d/(d+1)} + B_j m^{1+\delta} + A_j n \log^{(1+j)} m$$

where D_j, B_j, A_j depend on ϵ and δ.

Proof. The proof is an induction on j and n inspired by similar argument is in [EGS88].

For $j = 0$, $C_0 = \mathit{TRUE}$ is satisfied by nm pairs. The product is computed in constant time. We consider $j > 0$ and we use the inductive hypothesis on T_{j-1}. Equation (8) becomes

$$\begin{aligned} T_j(m,n) \le & \sum_{\tau} T_j(m_\tau, n_\tau) + O(mr^{O(1)}) \\ & + M(r)(D_{j-1}n^{d/(d+1)+\epsilon}m^{d/(d+1)} + B_{j-1}m^{1+\delta} + A_{j-1}n\log^{1+(j-1)} m) \\ & + M(r)(m+n). \end{aligned} \tag{9}$$

For any fixed pair δ, ϵ, with $\delta \le \epsilon/d$ we choose a value of r, constant from n and m, depending on ϵ and δ. The actual dependency of r on ϵ and δ will be defined along with the proof. If $m \ge n^d$ then, from Lemma 4, $T_j(m,n) \le cm^{1+\delta}$ and the theorem is proved assuming $B_j \ge c$. Suppose $m \le n^d$. In this case

$$m^{1+\delta} = m^{d/(d+1)} m^{1/(d+1)+\delta} \le m^{d/(d+1)} n^{d/(d+1)+d\delta}. \tag{10}$$

First notice that at each level of the recursion the term $M(r)n + M(r)A_{j-1}n\log^j m$ in (9) contributes $O(n\log^j m)$ on one level of the recursion; and there are at most $O(\log m)$ levels. This is a consequence of the fact that the objects in A (whose counter is n) are represented as points. The objects in B (which are counted in m) are represented as surfaces. The overall contribution of this term is $O(n\log^{j+1} m)$. It is sufficient to drop this term from the recursion (9) and prove that the modified inequality for a new unknown function $T'_j(m,n)$.

$$\begin{aligned} T'_j(m,n) \le & \sum_{\tau} T'_j(m_\tau, n_\tau) + M(r)m \\ & + M(r)(D_{j-1}m^{d/(d+1)}n^{d/(d+1)+\epsilon} + B_{j-1}m^{1+\delta}) + O(mr^{O(1)}) \end{aligned} \tag{11}$$

satisfies the bound

$$T'_j(m,n) = D_j m^{d/(d+1)} n^{d/(d+1)+\epsilon} + B_j m^{1+\delta}.$$

Choosing B_j and D_j large enough so that the bound holds for small valus of m and n, we apply the inductive argument on $T'_j(m_\tau, n_\tau)$.

$$\begin{aligned} T'_j(m,n) \le & \sum_{i=1}^{M(r)} \left[D_j m_i^{d/(d+1)} n_i^{d/(d+1)+\epsilon} + B_j m_i^{1+\delta} \right] \\ & + M(r)m + M(r)D_{j-1}m^{d/(d+1)}n^{d/(d+1)+\epsilon} + M(r)B_{j-1}m^{1+\delta} + O(mr^{O(1)}), \end{aligned}$$

but $\sum_{i=1,M(r)} m_i^{1+\delta} \le [M(r)c\log^{1+\delta} r/r^{1+\delta}]m^{1+\delta}$. We can sum up terms in m and $m^{1+\delta}$, set $E = B_jM(r)c\log^{1+\delta} r/r^{1+\delta} + M(r) + M(r)B_{j-1} + O(r^{O(1)})$, and use inequality (10). We obtain

$$T_j'(m,n) \le \left[D_j \sum_{i=1}^{M} m_i^{d/(d+1)} n_i^{d/(d+1)+\epsilon} + Em^{d/(d+1)} n^{d/(d+1)+d\delta} \right].$$

Now we eliminate the summation using first the bound on m_i and then the Hölder-Minkowsky inequality [Mit70].

$$\begin{aligned}\sum_{i=1}^{M(r)} m_i^{d/(d+1)} n_i^{d/(d+1)+\epsilon} &\le [(c'\log r/r)m]^{d/(d+1)} \sum_{i=1}^{M(r)} n_i^{d/(d+1)+\epsilon} \\ &\le [c'\log r/r]^{d/(d+1)} m^{d/(d+1)} M(r)^{1/(d+1)-\epsilon} n^{d/(d+1)+\epsilon}.\end{aligned}$$

Assuming $\epsilon \ge d\delta$, we obtain, for some constant c''

$$T_j'(m,n) \le [D_jc''\log^{d/(d+1)} r/r^{d/(d+1)} M(r)^{1/(d+1)-\epsilon} + E]m^{d/(d+1)} n^{d/(d+1)+\epsilon}. \tag{12}$$

Recalling that $M(r) = r^d \log^{O(1)} r$ the coefficient becomes

$$\begin{aligned}&D_jc''\log^{d/(d+1)} r/r^{d/(d+1)} M(r)^{1/(d+1)-\epsilon} + E \\ &= D_jc''\log^{d/(d+1)} r \log^{O(1)/(d+1)-\epsilon} r (1/r)^{d\epsilon} + E.\end{aligned}$$

If we choose r sufficiently large so that the constant in (12) is less than $[D_j/2 + E]$, and if we choose $D_j = 2E$, we obtain

$$T_j'(m,n) \le D_j m^{d/(d+1)} n^{d/(d+1)+\epsilon}$$

which completes the proof. □

It is also easy to show the following corollary.

COROLLARY 3. *It is possible to report the set $C_k(A, B)$ in time $T_k(m,n) + |C_k(A, B)|$.*

COROLLARY 4. *Under the assumption that the cuttings at* (I) *and* (II) *for a constant value of r can be computed in parallel using polylogarithmic time and linearly many processors, then $|C_k(A, B)|$ can be computed in parallel using $O(T_k(m,n))$ processors and polylogarithmic parallel time.*

Proof. The algorithms of Lemma 3 and of Theorem 8 are based on taking a sample of the surfaces and computing a cutting. For each cell in the cutting we find the points within the region, the surfaces intersecting the region and the surfaces on the positive side of the region. Corresponding to every phase of the sequential algorithm we allocate a processor for each pair point-region and for each pair surface-region. In constant time we can determine the input to the next phase. The number of processors we use is bounded by the number of pairs, which in turn is bounded by the sequential time. The parallel time is bounded by the number of phases of the sequential algorithm. This fact, with the hypothesis that we can compute cuttings in polylogarithmic time, gives us a total polylogarithmic query time. □

If we use Clarkson's random sampling techniques [Cla87] to compute the cuttings at (I) and (II), then it is easy to check that constant parallel time and a linear number of processors is sufficient for the construction.

4.2. Finding the shortest vertical segment. We apply the general nested batching technique to the problem of finding the minimum length vertical segment whose endpoints are on two distinct lines of $\mathcal{L}$.

LEMMA 5. *Given a non-vertical line l and a set of non-vertical lines $\mathcal{L}$, the line in $\mathcal{L}$ with the shortest vertical connecting segment to l is the first line hit by l when translated downward or upward.*

Proof. It follows from elementary geometry. □

Our approach to the problem is to find for each line $l \in \mathcal{L}$ the first lines in $\mathcal{L}$ intersected when translating l upward and downward. If l meets more than one line simultaneously, we record only one line. Clearly we produce no more than a $O(n)$ pairs of lines, which we check for the minimum vertical segment in time $O(n)$. In order to find the set of pairs of lines, we use the following theorem from [CEGS89a].

THEOREM 9 ([CEGS89a]). *Given a set $\mathcal{L}$ of n lines in R^3 and any $\epsilon > 0$, we can preprocess $\mathcal{L}$ into a data structure whose storage is $O(n^{2+\epsilon})$, so that for any query line l we can decide whether l is above all lines in $\mathcal{L}$ in $O(\log n)$ time and, if so, find the line $l' \in \mathcal{L}$ hit first by l when translated downward.*

The difference between Theorem 9 and the result discussed in §2.8 is a subtle but important one. The data structure is based on locating Plücker points of the query line in a given Plücker polytope formed by the hyperplanes associated with the data lines in $\mathcal{L}$. The point location data structure is built by taking a random sample of the hyperplanes and by triangulating the interior of the resulting polytope. In order to obtain the result of §2.8 any triangulation would do. For the result of Theorem 9 Chazelle et al. carefully devise a triangulation so that, for every "triangle" produced, any Plücker point in the "triangle" would hit the same line in the random sample when translated downward. During the point location query we collect at most a logarithmic number of candidate data lines. Then in extra logarithmic time we select the data line immediately below the query line.

First we establish the following theorem.

THEOREM 10. *Given a set $\mathcal{L}$ of n lines in R^3 and any $\epsilon > 0$, we can preprocess $\mathcal{L}$ into a data structure whose storage is $O(n^{4+\epsilon})$, so that for any query line l we can find in $O(\log^2 n)$ time the line $l' \in \mathcal{L}$ hit first by l when translated downward (or upward).*

Proof. Using a data structure similar to that of Theorem 3, we can determine for a query line the lines in $\mathcal{L}$ above and below it. For these lines, which are represented as a disjoint union of canonical sets, we apply the result of Theorem 9. We obtain a data structure that for every query line l gives us the line in $\mathcal{L}$ immediately above and the line immediately below. The storage $S(n)$ used by the data structure satisfies the following inequality:

$$S(n) \leq r^4 S(n/r \log r) + r^4 n^{2+\epsilon}$$

from which we have $S(n) = O(n^{4+\epsilon})$. □

4.2.1. The batching technique and the shortest vertical segment.

THEOREM 11. *Given n lines in 3-space it is possible to find the shortest vertical connecting segment in $O(n^{8/5+\epsilon})$ randomized expected time for any $\epsilon > 0$, where the multiplicative constant depends on ϵ.*

Proof. We divide the set of lines $\mathcal{L}$ into two sets L_1 and L_2 of roughly equal size. We solve the problem recursively for the two sets and then we consider the bichromatic problem (i.e., finding the minimum distance between a line in L_1 and a line in L_2). The total complexity is dominated by the solution for the bichromatic case.

We now apply the nested batching technique of §4.1 to the data structure of Theorem 10 (Corollary 3). L_1 is used as our data set of lines and L_2 as the query set for the algorithm of Theorem 10.

At the first level of the data structure, we have to compute the predicate $tsp(l, l', \vec{v})$, where $\vec{v}$ is the vertical direction. The characteristic dimension of this test is $d_1 = 1$ (the vector $\vec{v}$ is fixed). At the second level we locate Plücker points in an arrangement of Plücker hyperplanes. From results in [APS91] we have characteristic dimension for this test $d_2 = 4$. At the last level we use the special cutting of Theorem 9 with characteristic dimension $d_3 = 2$. At the last level, by locating the Plücker points within the regions of the cutting, we are able to find also the closest data line.

By applying the nested batching method to the data structure of Theorem 10, we would like to obtain for each line in L_1 the line in L_2 with the shortest vertical segment. Unfortunately the batched nested method does not quite produce such set of pairs.

At the second level of the algorithm we have sets of Plücker hyperplanes $H(M_\sigma)$ and sets of Plücker points $P(N_\sigma)$ such that the relative orientation is known and uniform (i.e., all lines in M_σ are above all lines in N_σ). By batching the algorithm of Theorem 9 on M_σ as data and N_σ as points, we obtain a set $\mathcal{Q}$ of pairs of lines, where each line in N_σ is associated to the line in M_σ immediately below. But, in order to use the nested batching technique, we must sometimes flip the roles of data and queries. Reversing the role of M_σ and N_σ, we obtain a set of pairs $\mathcal{Q}'$. The two sets $\mathcal{Q}$ and $\mathcal{Q}'$ can be very different one from the other. On the other hand if $(l, l') \in \mathcal{Q}$ is the pair of lines with minimum connecting vertical segment, then (l', l) is an element of $\mathcal{Q}'$ and it is the pair of lines with minimum connecting vertical segment in $\mathcal{Q}'$. Reversing the role of the two sets of lines, we do not loose the information about the minimum connecting segment and the algorithm produces the correct answer. The time bound follows from Theorem 8. □

We now extend the result of Theorem 11 to segments. It is enough to solve the bichromatic version of the problem where we are given two sets of segments R (red) and B (blue). The main idea is to find a set Σ of pairs of sets (R_σ, B_σ) with the following properties:

(a) For every σ, $R_\sigma \subseteq R$ and $B_\sigma \subseteq B$.

(b) Every pair of red, blue segments whose xy-projections intersect is represented in one and only one pair σ.

(c) The xy-projection of every segment in R_σ intersects the xy-projection of every segment in B_σ.

For each pair σ we can safely extend the segments into full lines without introducing new vertical segments. We use the result of Theorem 11 on each pair and pick the minimum among the partial results.

In order to find such set Σ, we need a few auxiliary definitions. Given a segment s on the plane, let l_s be the line supporting s, $rph(s)$ the right endpoint and $lhp(s)$ the left endpoint. $Slope(l)$ is the slope of line l.

LEMMA 6. *Two segments s_1 and s_2 on the plane intersect if and only if $l(s_1)$ meets s_2 and $l(s_2)$ meets s_1.*

LEMMA 7. *A line l meets a segment s in either of these two cases:*

(A) $(Slope(l) < Slope(l_s)) \wedge (lph(s)\ below\ l) \wedge (rhp(s)\ above\ l)$

(B) $(Slope(l) > Slope(l_s)) \wedge (lhp(s)\ above\ l) \wedge (rhp(s)\ below\ l)$

Proof. Follows from elementary geometry. □

COROLLARY 5. *Given n segments in 3-space it is possible to find the shortest vertical connecting segment in $O(n^{8/5+\epsilon})$ randomized expected time for any $\epsilon > 0$, where the multiplicative constant depends on ϵ.*

Proof. We build a multilevel data structure using the nested batching technique in order to find pairs of red-blue segments whose xy-projection satisfies the properties of Lemma 6 and Lemma 7. At the first level we compare the slopes of the segments. This gives us a test of characteristic dimension $d = 1$. Once we have groups of segments whose relative slope is uniform, we can test at the next levels the above/below relations using standard point/line duality in dimension $d = 2$. At the last level we obtain pairs of sets of segments (blue and red) such that all red segments meet all blue segments. We can extend the corresponding red-blue segments in 3-space into full lines without introducing any new and potentially dangerous candidates for the minimum vertical connecting segment test. At the last level we therefore add a data structure similar to those of Theorem 11. The characteristic dimension of the whole data structure is therefore dominated by $d = 4$. The time bound derives from the application of the nested batching technique of Theorem 8. □

4.2.2. Finding the longest vertical segment. Suppose we want to find the *longest* among the vertical segments connecting two lines in $\mathcal{L}$. Although this problem has a formulation similar to finding the *shortest* vertical segment, we obtain an asymptotically faster algorithm.

THEOREM 12. *Given a set $\mathcal{L}$ of n lines in R^3, the maximum length vertical segment connecting two lines in $\mathcal{L}$ can be found in $O(n^{4/3+\epsilon})$ randomized expected time.*

Proof. We partition $\mathcal{L}$ into two subsets, L_1 and L_2, of equal size and we solve the problem recursively in each set. It is thus enough to solve the bichromatic case. Suppose without loss of generality the pair (l_1, l_2), with $l_1 \in L_1$ and $l_2 \in L_2$, achieves the maximum and moreover l_1 is above l_2. Let δ be the value of the maximum. If we shift every line in L_1 downward of a distance δ, we obtain a new set L'_1. From the fact that δ is the maximum distance follows that every line in L'_1 is below every line in L_2. The two sets L'_1 and L_2 satisfy the towering property (see [CEGS89a]), which can be tested in $O(n^{4/3+\epsilon})$ randomized expected time. This algorithm can be seen as a special instance of the nested batching technique of §4.1. In this case we have a first level to test the *tsp* condition with characteristic dimension $d_1 = 1$ and a second level to test the relative orientation with characteristic dimension $d_2 = 2$. The algorithm for testing the towering property can be used as the oracle of Megiddo's parametric search method. A parallel version of the oracle can be devised using the inherent tree-structure of the nested batching scheme of §4.1, as shown in Corollary 4. We obtain logarithmic parallel time using no more than $O(n^{4/3+\epsilon})$ processors. The parametric search approach allows us to find the value of δ that is the maximum bichromatic distance. □

The result of Theorem 12 extends, with the same time bound, to sets of segments, since the characteristic dimension of each level is no more than $d = 2$, as follows from Lemma 6 and 7 and from the algorithm to test the towering property [CEGS89b].

4.3. Finding the shortest segment. Given a set $\mathcal{L}$ of n lines in R^3 the problem is to find the shortest segment connecting two lines. A more formal statement of the problem is the following: compute $\text{Min}(\mathcal{L})$, where

$$\text{Min}(\mathcal{L}) = \min_{l',l\in\mathcal{L},1\neq l'} \min_{p\in l,q\in l'} |\bar{pq}|.$$

Computing $\text{Min}(\mathcal{L})$ fits nicely into the general schema of Megiddo's parametric search. Given a set $\mathcal{L}$ of n lines in R^3 we partition $\mathcal{L}$ into two disjoint sets R (red) and B (blue) of roughly $n/2$ lines each. If $T(n)$ is the time of the algorithm for finding the closest pair, we have the following recursive inequality:

$$T(n) \leq 2T(n/2) + T'(n/2, n/2)$$

where $T'(n, m)$ is the time sufficient to solve the bichromatic version of the problem (i.e., find the shortest segment connecting a "red" line with a "blue" line).

Let us denote as $P'(R, B, t)$ the program that, given a set R of red lines and a set B of blue lines, counts the number of red lines at distance less than t from any blue line. Clearly

$P'(R, B, t)$ is monotone in t. Using a method in [Pel91b], we can easily check if $P'(R, B, 0) = 0$. Finding the shortest bichromatic distance is equivalent to finding the minimum value of t such that $P'(R, B, t) > 0$.

4.3.1. The oracle. In this subsection we give the algorithm underlying the program $P'(R, B, t)$. The problem of counting pairs of lines within distance t can be seen as the problem of counting the number of intersections among the set R of lines and the set B' of cylinders of radius t whose axes are lines in B.

LEMMA 8. *Given a set of n lines and a set of m cylinders of the same radius, there is an algorithm that counts all line-cylinder intersections in time*:

$$Am^{5/6}n^{5/6+\epsilon} + Bm^{1+\epsilon} + Cn\log^2 m,$$

where the constants A, B, and C depend on ϵ.

Proof. A line l in 3-space is representable in a canonical way as the intersection of a plane parallel to the x-axis and of a plane parallel to the y-axis.[2]

$$y = az + b.$$

$$x = cz + d.$$

The four numbers (a, b, c, d) uniquely represent a line in 3-space. Thus we can map a line l to a point $p(l)$ in real parametric space R^4. A cylinder c of fixed radius t is representable in a canonical way as a point $p(c)$ in real parametric space R^4 (as a matter of fact we need only to map the axis of the cylinder).

Given a line l we define as the dual surface of l the set $S(l)$ of all the points $p(c)$ where c is a cylinder of radius t tangent to l. Clearly $S(l)$ is an algebraic variety (of co-dimension 1) in R^4. In particular there is a polynomial $q_l(\cdot)$ such that $S(l) = \{x \in R^4 | q_l(x) = 0\}$. Symmetrically we define as the dual surface of the cylinder c the set $S(c)$ of the points $p(l)$ where l is tangent to c. Again $S(c)$ is an algebraic variety of co-dimension 1. And we know there exists a polynomial $r_c(\cdot)$ such that $S(c) = \{x \in R^4 | r_c(x) = 0\}$. The relative position of the point $p(l)$ and surface $S(c)$ determines whether l meets c or not.

Using the data structure in [CEGS89b], we can locate the points $p(l)$ in the arrangement of algebraic surfaces $S(c)$. The size is $O(n^{2d-3+\epsilon})$. The query time is $O(\log n)$. We apply the batching argument developed in §4.1 for locating m points in an arrangement of n surfaces. The time bound follows from the batching technique. □

THEOREM 13. *Given n lines in 3-space, it is possible to find the shortest connecting segment in $O(n^{5/3+\epsilon})$ randomized expected time for any $\epsilon > 0$, where the multiplicative constant depends on ϵ.*

Proof. The algorithm of Lemma 8 (based on the data structure in [CEGS89b]) and on the nested batching technique has a tree structure of logarithmic depth. It is relatively easy to transform the sequential algorithm into a parallel algorithm using Corollary 4, as required by Megiddo's technique. □

The oracle used in Theorem 13 is a counting oracle that counts the number of intersections. In order to solve the closest line problem it is sufficient for the oracle to test whether the number of incidences is greater than 0. It is likely that such an algorithm can attain a better asymptotic bound than the counting oracle. Such improved bound would imply a faster algorithm for finding the closest line. The improved time bound of [CEGS92] is based on a similar observation.

[2] We cannot represent horizontal lines but, with a suitable space transformation, we can make sure that we do not have any.

5. Conclusions and open problems. Solving problems on lines in 3-space is often a necessary ingredient for solving problems on sets of polyhedra in 3-space. In this paper we solved an on-line intersection query problem for lines and half planes in 3-space, which is an essential ingredient of a fast method for collision-free placement queries amidst polyhedral obstacles in 3-space. In the same spirit, we gave algorithms for solving a few neighbor problems on lines in 3-space. Here are a few open questions: Is it possible to extend the solution of neighbor problems of lines to segments and polyhedra? How can we combine neighbor information and collision-free placements to plan a collision-free movement of a polyhedral object in a polyhedral environment? Is it possible to have a dynamic (under insertions and deletions) version of the data structure of Theorem 7? An initial result in the direction of solving this last question is in [AM91].

6. Acknowledgments. I thank Subhash Suri for proposing the problem of finding the closest pair of lines and Raimund Seidel, Micha Sharir, and Leonidas Guibas for useful discussions. I also thank Pankaj Agarwal for his comments on an early version of the paper and Professor Julian Ullmann for his comments.

FAT TRIANGLES DETERMINE LINEARLY MANY HOLES*

JIŘÍ MATOUŠEK†‡2, JÁNOS PACH§¶3, MICHA SHARIR§134, SHMUEL SIFRONY§, AND EMO WELZL‡24

Abstract. The authors show that for every fixed $\delta > 0$ the following holds: If F is a union of n triangles, all of whose angles are at least δ, then the complement of F has $O(n)$ connected components and the boundary of F consists of $O(n \log \log n)$ straight segments (where the constants of proportionality depend on δ). This latter complexity becomes linear if all triangles are of roughly the same size or if they are all infinite wedges.

Key words. combinatorial geometry, computational geometry, Davenport Schinzel sequences, union of geometric figures, fat triangles

1. Introduction. The problem studied in this paper is to obtain sharp upper bounds on the combinatorial complexity of the union of n geometric figures in the plane. This problem arises in many applications. For example, in motion planning for systems with two degrees of freedom, one constructs the two-dimensional configuration space of the system as the complement of the union of n "forbidden regions," each representing the space of placements of the system in which a collision occurs between two specific system and obstacle features (see [9], [14] for details). It has also been observed recently that families of figures, with the property that the union of any subfamily has small combinatorial complexity, have several additional useful properties. For example, they admit efficient output-sensitive hidden surface removal algorithms (when these figures lie at various heights and are viewed from a point far below them) [20]. Also one can obtain sharp bounds on the number of "k-sets" in an arrangement of such figures [19] and an efficient algorithm for "point-stabbing" queries in a collection of such figures (where one has to report all figures containing a query point) [19].

The simplest example of a family with the above property is a collection of half planes, each bounded by a line, or more generally by a pseudoline. A more interesting example is a family of *pseudodisks*, i.e., figures with the property that the boundaries of each pair of them intersect in at most two points. It was shown in [14] that the boundary of the union of n pseudodisks consists of at most $6n - 12$ connected pieces of the boundaries of the given figures (a special case of this result has also been obtained in [8]). Another case was studied in [4] and involved a family of figures, each bounded between a portion of the x-axis and a curve lying above the axis and delimited by two points on the axis, with the property that any pair of these curves intersect in at most 3 points. It was shown that the combinatorial complexity of the union of n such figures is $O(n\alpha(n))$, where $\alpha(n)$ is the inverse Ackermann's function.

As all these examples indicate, the property of having a union of small combinatorial complexity somehow seems to require that the boundaries of any pair of the given figures intersect in a small number (1, 2, or 3) of points. When the allowed number of intersections becomes 4 or more, there are sets of n triangles whose union has quadratic complexity. However, one observes that to attain quadratic complexity, it seems to be essential that the triangles be very narrow and many must have an angle that tends to 0 as n increases.

The purpose of this paper is to show that if this is not allowed—namely, if we are given a collection of triangles that are "fat"—then indeed the combinatorial complexity of their union is small.

Statement of results. We call a triangle T *δ-fat*, if each angle of T is at least δ. By a *figure* we mean a (closed) region in the plane, bounded by a closed Jordan curve or by an unbounded Jordan arc.

Let $\mathcal{F}$ be a finite family of figures. A *hole* of $\mathcal{F}$ is a connected component of the complement of the union of the figures of $\mathcal{F}$. The number of holes of $\mathcal{F}$ will be denoted by $\mathrm{H}(\mathcal{F})$.

A point of the boundary of the union of a family $\mathcal{F}$ is called a *corner* of $\mathcal{F}$ if it is a point of intersection between the boundaries of two figures in $\mathcal{F}$. The *boundary complexity* of $\mathcal{F}$ (denoted by $\mathrm{BC}(\mathcal{F})$) will be the number of corners of $\mathcal{F}$; note that we do not count vertices (if any) of the figures of $\mathcal{F}$ as corners — their number is usually small and presents no problems in the analysis. An *edge* of $\mathcal{F}$ is a connected portion of the boundary of the union of $\mathcal{F}$ contained in the boundary of a single figure between two adjacent corners.

Our main results are the following theorems:

THEOREM 1.1. *For any fixed $\delta > 0$, every family $\mathcal{F}$ of n δ-fat triangles has $O(n)$ holes, with the constant of proportionality depending on δ.*

Using this theorem in combination with the Combination Lemma of Edelsbrunner et al. [6] (reviewed in the next section), we will show in §4 the following

THEOREM 1.2. *For any fixed $\delta > 0$, the boundary complexity of every family $\mathcal{F}$ of n δ-fat triangles is $O(n \log\log n)$ (again, the constant of proportionality depends on δ). On the other hand, there exist such families (even with $\delta = 60°$) whose boundary complexity is $\Omega(n\alpha(n))$.*

In the special case when the triangles in our family all have roughly the same size, the boundary complexity becomes linear (in the statement of the theorem, $\mathrm{diam}(T)$ denotes the diameter of triangle T):

THEOREM 1.3. *Let $\delta > 0$ and $0 < c \leq C$ be fixed numbers. Let $\mathcal{F}$ be a family of n δ-fat triangles, such that $c \leq \mathrm{diam}(T) \leq C$ for every triangle $T \in \mathcal{F}$. Then the boundary complexity of $\mathcal{F}$ is $O(n)$ (with the constant of proportionality depending on δ and on C/c). The boundary complexity is also linear for a family of δ-fat wedges (regions bounded between a pair of rays with a common endpoint).*

Related results have been recently obtained by Alt et al. [2], where the complexity of fat objects was first considered. They showed, among other results, that the boundary complexity of the union of n δ-fat double wedges is $O(n)$. They have also shown that the number of holes (and the boundary complexity) of the union of n triangles, each of which is homothetic either to a fixed triangle T or to the reflection of T, is linear. These results are special cases of the results that we obtain in this paper.

2. Preliminaries. In this section we review two basic results concerning arrangements of certain types of figures, which will be needed in the subsequent analysis. The first result, adapted from [6], is stated here in a more specialized form, which nevertheless follows easily from the original version of [6].

LEMMA 2.1 (Combination Lemma [6]). *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be families of figures, whose boundaries are polygons with n_1 and n_2 sides in total. Then*

$$\mathrm{BC}(\mathcal{F}_1 \cup \mathcal{F}_2) \leq \mathrm{BC}(\mathcal{F}_1) + \mathrm{BC}(\mathcal{F}_2) + O(n_1 + n_2 + \mathrm{H}(\mathcal{F}_1 \cup \mathcal{F}_2)).$$

The next lemma follows from a more general statement about pseudodisks, [14], [8]. However, for the sake of completeness we present the simple proof for the special case we need here (two figures are called *homothetic*, if one can be obtained from the other by translation and scaling).

LEMMA 2.2. *For a family $\mathcal{F}$ of n pairwise homothetic triangles we have* $\mathrm{BC}(\mathcal{F}) \leq 6n$.

Proof. Let us first observe that the boundaries of two homothetic triangles cross in at most two points. Consider now a corner w of $\mathcal{F}$, which is the intersection of two edges e and e' of two of the triangles. Each edge has one direction at the corner in which the edge 'disappears' locally into the respective other triangle. Let v and v' be the vertices incident to the edges in those distinguished directions. Note that either v or v' must be covered by the respective other triangle. Indeed, in order for v to lie outside, the edge e must create another boundary crossing, and similarly for v'; thus, if both v and v' are not covered, we get at least three boundary crossings, which is impossible. If v is covered, the corner w is the last corner on e in the direction toward v (since, by convexity, the whole portion between w and v is covered); an analogous statement holds for v'.

We charge the corner to the pair (e, v), if v lies in the other triangle, and to the pair (e', v'), otherwise. We have seen that each such pair can be charged at most once, so the number of corners is at most twice the number of vertices, namely, $6n$. (Note that this bound holds even if we also count in the boundary complexity the triangle vertices on the boundary. □

3. Bounding the number of holes. In this section we prove Theorem 1.1, that is, we show that a set of δ-fat triangles has at most a linear number of holes.

Passing to canonical triangles. The first step in the proof is to transform the given collection $\mathcal{F}$ to another collection consisting of *canonical triangles* so that the number of holes in the new collection is not much different than the number of holes of $\mathcal{F}$. Specifically, we have

LEMMA 3.1 (Canonization Lemma). *For each $\delta > 0$ there exists a positive constant $c = c(\delta) = O(1/\delta)$, such that if $\mathcal{F}$ is a family of n δ-fat triangles, then there exists families $\mathcal{F}_1, \ldots, \mathcal{F}_c$ consisting of $O(n)$ triangles in total, such that each $\mathcal{F}_i$ is a family of $\delta/4$-fat homothetic triangles and*

$$\mathrm{H}(\mathcal{F}) \leq \mathrm{H}(\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_c) + O(n).$$

The canonization is achieved by producing triangles which have edges from some fixed finite set of directions $D(\delta) = \{0, \hat{\delta}, 2\hat{\delta}, \ldots, (k_\delta - 1)\hat{\delta}\}$, where $k_\delta = \lceil 4\pi/\delta \rceil$ and $\hat{\delta} = 2\pi/k_\delta$. The set $D(\delta)$ has the property that every angle of at least $\delta/2$ contains a direction in $D(\delta)$.

LEMMA 3.2. *Let $\delta > 0$. Any δ-fat triangle can be expressed as the union of three $(\delta/2)$-fat triangles T_1, T_2, T_3, such that two of the sides of each T_i have directions in $D(\delta)$, while the third is a side of T.*

Proof. Let T be a δ-fat triangle with vertices A, B, C, and let O be the center of its inscribed circle (which is also the intersection of the angle bisectors, see Fig. 1). Hence each of the angles OAC, OBC is at least $\delta/2$. We can thus find a point Q in the triangle, such that the point O lies in the triangle ABQ and the segments AQ and BQ have directions in $D(\delta)$. Such a point Q determines the triangle $T_1 = ABQ$, and T_2, T_3 can be constructed in an analogous manner for the two other sides of T. □

In the first stage of canonization, we replace each triangle in $\mathcal{F}$ by three "semi-canonical" triangles as in the preceding lemma. In a second stage we shrink each of the new triangles until it becomes the union of two "fully canonical" triangles. This is shown in the following lemma.

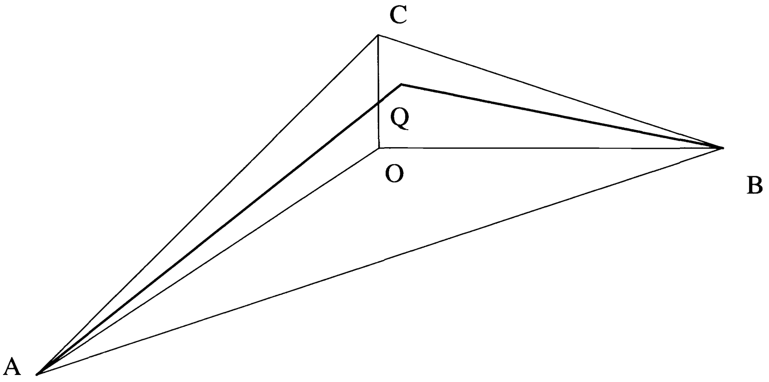

FIG. 1. *First stage of canonization.*

LEMMA 3.3 (Shrinking Lemma). *Let $\mathcal{F}$ be a family of n triangles. Let $\mathcal{F}^\star$ arise from $\mathcal{F}$ by replacing each triangle $T = ABC$ in $\mathcal{F}$ by the union of two triangles ABX, AYC, such that X lies on AC and Y lies on AB (see Fig. 2). Then*

$$\mathrm{H}(\mathcal{F}) \leq \mathrm{H}(\mathcal{F}^\star) + 3n.$$

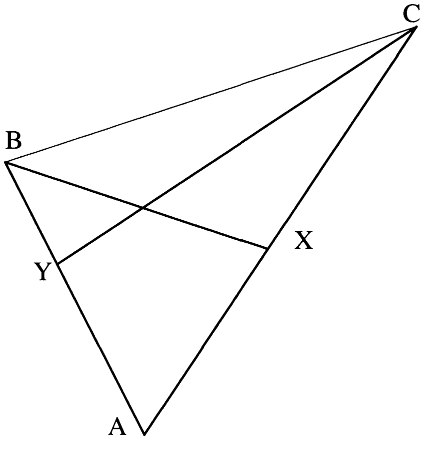

FIG. 2. *Second stage of canonization.*

Proof. Since the union of $\mathcal{F}^\star$ is contained in the union of $\mathcal{F}$, the only way in which the number of holes of $\mathcal{F}$ might decrease as we pass from $\mathcal{F}$ to $\mathcal{F}^\star$ is when a pair of holes are merged together to form a single hole. Let us imagine that every triangle ABC of $\mathcal{F}$ shrinks into the corresponding figure of $\mathcal{F}^\star$ by a continuous deformation, during which the side BC is deformed into an outward-concave curve γ, e.g., in the manner depicted in Fig. 3.

During this shrinking process, two holes of $\mathcal{F}$ may be merged to form a new hole only when a vertex of some other triangle is passed by γ and appears on the boundary of the union of the shrinking family of figures. Each such event decreases the number of holes by 1, and we can charge this event to the newly appearing vertex. Note that this event is irreversible—once a vertex has appeared on the boundary of our family, it will never be covered again, so there are at most $3n$ such events during the entire shrinking process, hence the number of holes could not have decreased by more than $3n$. □

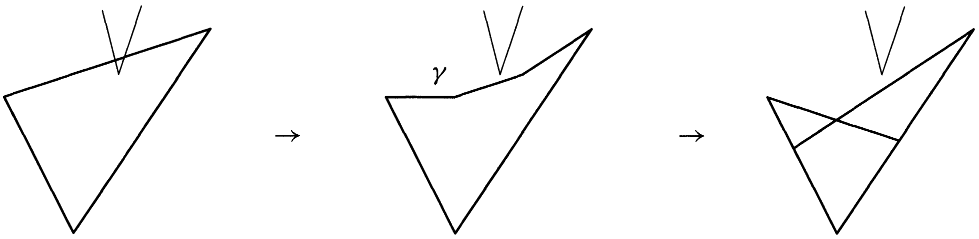

FIG. 3. *Shrinking a triangle.*

Now the proof of Lemma 3.1 is easy. First we replace, using Lemma 3.2, each triangle of the original family $\mathcal{F}$ by the union of a triple of semicanonical triangles, each having two sides in the set of canonical directions. Then we replace each semicanonical triangle ABC by a pair of triangles ABX, AYC as in Lemma 3.3 so that each side of the new triangles has a direction in a fixed finite set of directions and one angle in each triangle is exactly $\hat{\delta}$ (the angle at vertex B and C, respectively); thus the final triangles fall already into a constant number of families of homothetic triangles). We can apply the shrinking of Lemma 3.3 once more to ensure that we have a set of at most $12n$ triangles, where two angles are $\hat{\delta}$. That is, the triangles fall now in $2k_{\delta} = O(1/\delta)$ homothetic classes. Lemma 3.3 is easily seen to imply that at most $O(n)$ holes can be lost in both shrinking processes, since the number of triangles (and so the number of vertices) is linear. □

Boundary complexity for a pair of homothetic families. By the Canonization Lemma 3.1, it suffices to bound the number of holes of a union of a constant number of families, each consisting of homothetic $\hat{\delta}$-fat triangles. For simplicity of exposition, we will continue to denote $\hat{\delta}$ by δ. If $\mathcal{F} = \mathcal{F}_1 \cup \cdots \cup \mathcal{F}_c$, then any corner of $\mathcal{F}$ must be a corner of some family of the form $\mathcal{F}_i \cup \mathcal{F}_j$, for $1 \leq i, j \leq c$ (this also includes corners that arise within a single family $\mathcal{F}_i$), thus

$$\mathrm{BC}(\mathcal{F}) \leq \sum_{i,j} \mathrm{BC}(\mathcal{F}_i \cup \mathcal{F}_j).$$

Therefore, Theorem 1.1 will be proved if we prove the following:

LEMMA 3.4. *Let* $\delta > 0$ *be fixed. Let* $\mathcal{F}_1$ *and* $\mathcal{F}_2$ *be families of triangles, each consisting of* n δ*-fat homothetic triangles. Then* $\mathrm{BC}(\mathcal{F}_1 \cup \mathcal{F}_2) = O(n)$ *(with a constant of proportionality that depends on* δ*).*

Proof. Let us put $\mathcal{F} = \mathcal{F}_1 \cup \mathcal{F}_2$. We will bound the number of edges of the union F of $\mathcal{F}$. Let us call the edges of the union F_i of $\mathcal{F}_i$ the *superedges* of $\mathcal{F}_i$, $i = 1, 2$. If e is an edge of F lying on a superedge s of a triangle T of $\mathcal{F}_i$, we call s the *supporting superedge*, T the *supporting triangle*, and $\mathcal{F}_i$ the *supporting family* of e.

By Lemma 2.2, we know that the boundary complexity of $\mathcal{F}_1$ and of $\mathcal{F}_2$ are linear; i.e., the number of superedges is linear in n.

Call an edge e of F *trivial* if e is the first or the last edge of F along its supporting superedge. The number of trivial edges is therefore $O(n)$.

Since edges of F have only six possible directions, it suffices to bound the number of nontrivial edges with one fixed direction. Fix such a direction d, and let e be a nontrivial edge of F having direction d. Suppose e is supported by the family $\mathcal{F}_2$. The edge e is adjacent to two edges f and f', whose respective supporting triangles T and T' belong to the other family $\mathcal{F}_1$ and are thus homothetic. Let s and s' be the supporting superedges of f and f', respectively.

Call the pair (s, s') an *active pair* of superedges, if they are connected by an edge e as above; we will refer to e as an edge *belonging* to (s, s').

We claim that the number of active pairs is $O(n)$. Indeed, the superedges of $\mathcal{F}_1$ are nonintersecting and each active pair is visible from each other in direction d. The number of such visible pairs is linear; this can be seen by sweeping a line in direction d across the plane or by applying a graph planarity argument.

The proof will therefore be finished if we prove the following:

LEMMA 3.5. *Let (s, s') be an active pair of superedges; then the number of nontrivial edges belonging to (s, s') is bounded by a constant (depending on δ).*

Proof. Let T and T' be the triangles supporting s and s', respectively (see Fig. 4). Consider all the edges belonging to the active pair (s, s'), which, by our convention, are all assumed to have direction d; without loss of generality we assume that d is horizontal and that T lies to the left of T' (see Fig. 4). Without loss of generality, we may also assume that the corresponding holes of $\mathcal{F}$ lie below these edges.

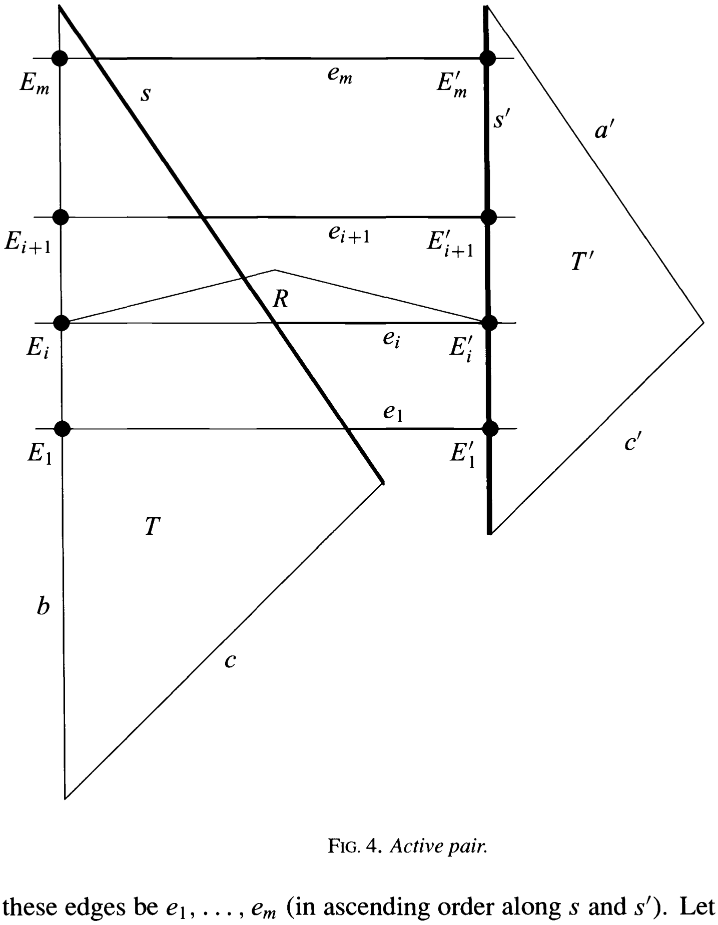

FIG. 4. *Active pair.*

Let these edges be $e_1, \ldots, e_m$ (in ascending order along s and s'). Let b denote the side of T parallel to s', and let a' denote the side of T' parallel to s. Without loss of generality we may assume that the projection of s in direction d on the line containing b is contained in b (and similarly for a' and s').

For each edge e_i let us denote the intersections of its superedge with the edges b, s' by E_i, E'_i, respectively (see Fig. 4; these intersections exist by the assumption just made and because each e_i is nontrivial and thus penetrates through both T and T'). Consider the parallelogram

$E_1 E_m E'_m E'_1$. The angle $E_1 E_m E'_1$ is at least δ; hence, $|E_1 E'_1| \geq \gamma \cdot |E_1 E_m|$, where $\gamma > 0$ is a constant depending on δ.

Consider an edge e_i and its supporting triangle T_i. This triangle must contain both points E_i and E'_i. The key observation is that T_i cannot intersect the segment $E_{i+1} E'_{i+1}$, simply because $E_{i+1} E'_{i+1}$ is part of a superedge and T_i belongs to the same family as $E_{i+1} E'_{i+1}$.

Since T_i is δ-fat, it must contain the triangle R with base $E_i E'_i$ and angles δ at the vertices E_i and E'_i, so R also does not intersect $E_{i+1} E'_{i+1}$. This means that the length of the segment $E_i E_{i+1}$ is at least a constant fraction (depending on δ) of the length of $E_i E'_i$ and, hence, also of $E_1 E_m$. This implies that the number m of nontrivial edges belonging to the active pair (s, s') is bounded by a constant. □

Remark. A more detailed analysis in the previous lemma shows that the constant claimed is $O(1/\delta^2)$. That is, if we denote the cardinality of $\mathcal{F}_i$ by n_i, then $\mathrm{BC}(\mathcal{F}_1 \cup \mathcal{F}_2) = O(n_i + n_j + \min\{n_i, n_j\}/\delta^2)$. This gives a bound of $O(cn/\delta^2) = O(n/\delta^3)$ for $\mathrm{H}(\mathcal{F})$ (for the original family $\mathcal{F}$). Summing up, we have at most $O(n/\delta^3)$ holes in the union of n δ-fat triangles. This is probably not tight in terms of δ; the best lower bound we can derive is $\Omega(n/\delta)$.

In closing this section, we note that Lemma 3.4 has the following corollary, which may be of independent interest. Call a family of triangles *c-oriented* if the orientations of the edges of the triangles are drawn from a fixed set of c orientations; see [10], [11], [18], [22] for several studies of c-oriented polygons.

COROLLARY 3.6. *The boundary complexity of a family of n c-oriented triangles is $O(n)$, where the constant of proportionality depends on c and the minimum angle between any two of the c given orientations.*

Remark. The weaker result of Alt et al. [2] is also a special case of this corollary.

4. The boundary complexity of the union of fat triangles. In this section we analyze the boundary complexity of the union of n fat triangles. We rely on the results of the preceding section concerning the number of holes, on the Combination Lemma 2.1, and on a special way of decomposing the given collection of triangles into subcollections, each having a union with small boundary complexity.

Proof of Theorem 1.2. Let $\mathrm{BC}(n)$ denote the maximum possible boundary complexity of a family of n δ-fat triangles. Let $\mathcal{F}$ be such a family. Applying the first canonization step in the proof of Theorem 1.1, we replace $\mathcal{F}$ by a constant number of subfamilies, each consisting of triangles that have two sides with fixed orientations. By further refining this partitioning, we can also assume that within each subfamily the orientations of the third edges of the triangles all lie within some small angular interval, of length, say 1°. Note that the number of subfamilies is still a constant and that the overall union of all subfamilies is equal to the union of $\mathcal{F}$. We will show that the boundary complexity of the union of the triangles in the ith subfamily is $O(n_i \log\log n_i)$, where n_i is the number of triangles in the subfamily. The Combination Lemma 2.1 then implies that the boundary complexity of the union of all triangles is $O(n \log\log n)$, as asserted.

Thus, from now on, we consider a single subfamily, which, for simplicity, we also denote by $\mathcal{F}$. By applying an appropriate affine transformation, we can assume that each triangle is a right triangle with one horizontal edge and one vertical edge, that these edges meet in the lower-left vertex of the triangle, and that the hypotenus of the triangle has orientation between, say, 134 and 136 degrees (so the triangle is nearly isosceles).

Our first step is to partition $\mathcal{F}$ into $O(\log n)$ subfamilies so that the boundary complexity of each subfamily is almost linear in the number of triangles it contains.

LEMMA 4.1. *If all triangles in $\mathcal{F}$ have the form assumed above and meet a common horizontal line, then* $\mathrm{BC}(\mathcal{F}) = O(n \cdot 2^{\alpha(n)})$, *where $\alpha(n)$ is the inverse Ackermann function.*

Proof. Without loss of generality, assume the line is the x-axis. For each triangle $T \in \mathcal{F}$ let T^+ denote its portion above the x-axis and T^- denote its portion below the x-axis. The boundary complexity of $\mathcal{F}$ is clearly bounded by the sum of the boundary complexities of the union of the triangles T^+ and of the union of the trapezoids T^-. The boundary complexity of the upper triangles T^+ is $O(n)$—if we direct all edges toward the x-axis, then, as is easily seen, every corner is the last corner (in this direction) for one of its two edges.

As to the lower trapezoids T^-, we first decompose each T^- into two interior-disjoint portions, one being an axis-parallel rectangle and the other being a right, nearly isosceles triangle with a horizontal edge and a vertical edge whose top vertex lies on the x-axis; see Fig. 5.

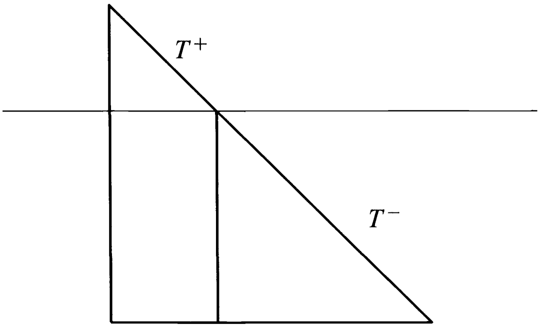

FIG. 5. *A triangle cut by a horizontal line.*

It suffices to show that the boundary complexity of the union of the family $\mathcal{F}^-$ consisting of these new triangles is $O(n \cdot 2^{\alpha(n)})$, because the boundary complexity of the union of the rectangles is trivially linear and the Combination Lemma 2.1 implies that merging the rectangles with the triangles of $\mathcal{F}^-$ yields a joint boundary complexity that is proportional to the complexity of $\mathcal{F}^-$. We therefore restrict our attention only to the union of $\mathcal{F}^-$.

CLAIM 1. A horizontal edge of a triangle T in $\mathcal{F}^-$ can be incident to at most four hole corners.

Proof. Let e be the given edge, and let $e' = XY$ be an interval along e that appears on the boundary of the union and is not the leftmost such interval along e. The left endpoint X of e' is the intersection of e with the hypotenus of another triangle T', and our assumption concerning e' implies that the vertical edge of T' also cuts e. See Fig. 6. Let the top angles of T, T' be α, α' respectively, and let the length of the vertical edge of T be h; let g denote the intersection $e \cap T'$.

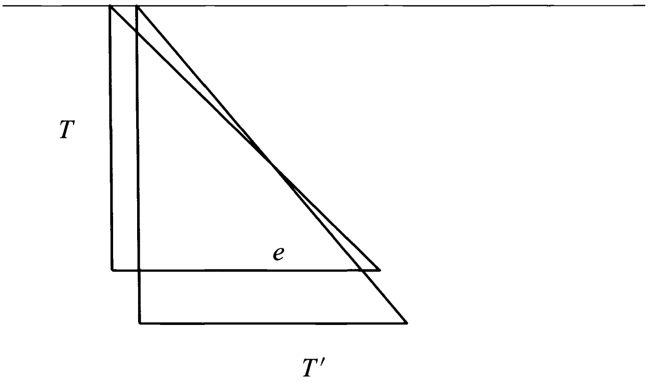

FIG. 6. *Two "interleaving" triangles.*

We have $|e| = h \tan\alpha$ and $|g| = h \tan\alpha'$. Thus $|g|/|e| = \tan\alpha'/\tan\alpha$ is very close to 1; in particular, it is greater than 1/2. This shows that the interval e' is unique and so that e can contain at most two intervals that bound holes, namely, e' and another leftmost interval. This completes the proof of the claim. □

CLAIM 2. The total number of hole corners that are incident to either a horizontal edge or to a vertical edge is $O(n)$.

Proof. Claim 1 implies that the number of hole corners along horizontal edges is $O(n)$. Let e be a vertical edge, and let e' be an interval along e bounding a hole. It is easily verified that the top endpoint of e' must be incident to a horizontal edge. The claim is now immediate. □

It therefore remains to consider only hole corners formed by intersections of two hypotenuses of the triangles of $\mathcal{F}^-$. We order these corners in lexicographical order so that $c_1 \prec c_2$ if, for $c_1 = (x_1, y_1)$ and $c_2 = (x_2, y_2)$, either $x_1 < x_2$ or $x_1 = x_2$ and $y_1 < y_2$. This is clearly a linear order.

Our strategy is to transform this sequence of corners to a *Davenport Schinzel sequence* of order 4 [1], [12], which will then yield the asserted bound on the boundary complexity of $\mathcal{F}^-$. (Recall that a Davenport Schinzel sequence of order 4 is a sequence that does not have any two equal adjacent elements and does not contain as a (not necessarily contiguous) subsequence an alternation $a \cdots b \cdots a \cdots b \cdots a \cdots b$ of length 6 between any two distinct symbols a and b.) To this end, we divide each hypotenus at its midpoint into two subsegments of equal length, which we refer to as its top part and bottom part, respectively. For each corner c consider the hypotenus incident to c and appearing along the hole just below c; c is *associated* with the part (top or bottom) of that hypotenus, to which it is incident. See Fig. 7.

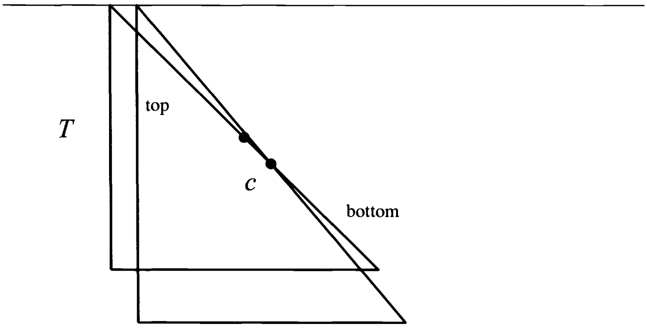

FIG. 7. *The corner c is associated with the bottom part of the triangle T.*

We proceed through the ordered sequence of corners and form a sequence U, consisting of all associated appearances of the top or bottom hypotenus parts in the order that the corresponding corners are encountered. Thus U is composed of at most $2n$ distinct symbols.

CLAIM 3. The number of appearances of bottom parts in U is at most n, and the number of pairs of equal consecutive elements in U is $O(n)$.

Proof. We first show that no bottom part of a hypotenus can appear twice in U. Indeed, let T be a triangle with a hypotenus h and c be a hole corner of the kind we consider that is associated with the bottom part of h. Thus there exists another triangle T' whose hypotenus meets T at c and has a smaller slope than h. A calculation similar to that in the proof of Claim 1 shows that the next higher appearance of h along a hole must already appear on its top part. This establishes the first assertion of the claim.

Next consider adjacent equal elements of U. Suppose a hypotenus h of some triangle T appears twice consecutively in U. Thus h contains two subintervals e, e' that bound holes.

But then the bottom endpoint c of the higher of these two intervals must be incident to a vertical edge (otherwise c is incident to some other hypotenus h', which necessarily appears in U between the two appearances of h). The claim is thus an immediate consequence of Claim 2. □

We can therefore delete from U all bottom appearances and then delete one of each pair of equal consecutive elements. The new sequence $U^\star$ consists of only top hypotenus parts (so it is composed of at most n distinct symbols), has no pair of equal adjacent elements, and satisfies $|U| = |U^\star| + O(n)$.

We claim that $U^\star$ is indeed a Davenport Schinzel sequence of order 4. That is, we have to show that $U^\star$ cannot contain an alternating subsequence of the form $a \cdots b \cdots a \cdots b \cdots a \cdots b$, where a and b are top parts of the hypotenuses of two distinct respective triangles, T, R.

Suppose to the contrary that such an alternation exists. We distinguish between two cases:

CASE I. *T and R intersect in at most two points.* This can happen in one of the four schematic forms shown in Fig. 8.

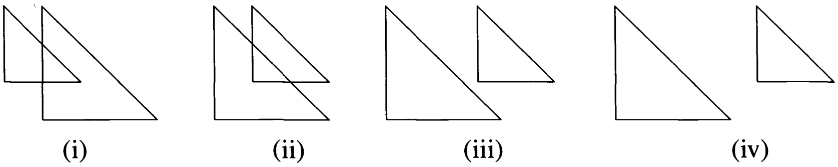

FIG. 8. *Two triangles of $\mathcal{F}^-$ intersecting in at most 2 points.*

Cases (i) and (iv) are easy, because they allow no alternation of a and b in U, as is easily checked. In case (ii) let us first assume that a is the top part of the hypotenus of the left triangle. Note that all appearances of a between the first and last appearances of b correspond to corners that lie in the vertical strip spanned by the right triangle R. Let p and q be two subintervals of a that give rise to two such appearances of a. Then it is easily seen that there must exist another triangle Q that cuts the hypotenus of T in some interval between p and q; see Fig. 9. Denote the top angles of triangles T, R, Q by $\alpha, \alpha', \alpha''$, respectively. Let d' denote the length of the vertical edge of R, let d_0 denote the vertical distance between the bottom endpoint of p and the top endpoint of q, and let d denote the vertical distance from the top endpoint of q to the x-axis; see Fig. 9.

Simple trigonometric calculations show that

$$d \tan \alpha'' = d_0 \tan \alpha < d' \tan \alpha'$$

and

$$d_0 + d' < d,$$

which is clearly impossible, since all three angles $\alpha, \alpha', \alpha''$ are close to 45°.

This argument implies that, between the first and last appearance in $U^\star$ of the hypotenus of the right triangle, there can be at most one appearance of the hypotenus of the left triangle. Thus the maximum length of an alternation between a and b in $U^\star$ is 5 (in the form $a \cdots b \cdots a \cdots b \cdots a$). If a is the top part of the hypotenus of the right triangle, the above analysis shows that the longest possible alternation is now only $a \cdots b \cdots a \cdots b$. Exactly the same analysis applies in case (iii).

CASE II. *T and R intersect in four points.* This is depicted in Fig. 10. Again without loss of generality we can assume that T is the triangle whose top vertex lies to the left of that of R (otherwise, as above, the maximum possible alternation will be shorter).

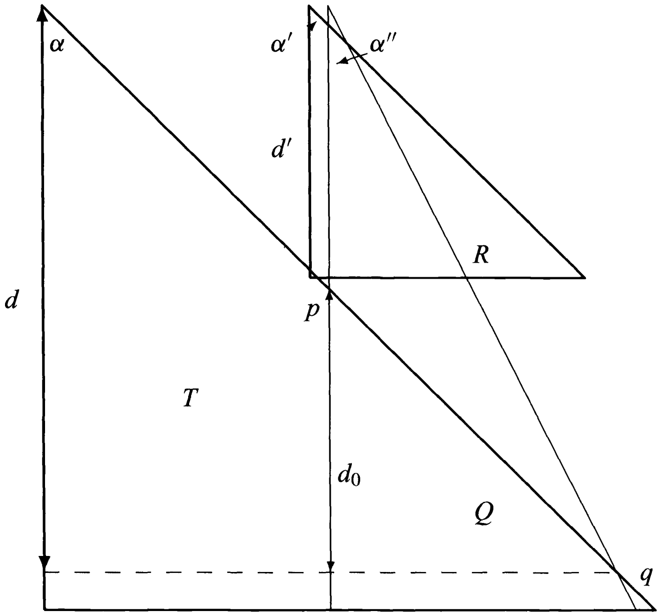

FIG. 9. *Case* I(ii) *of the proof.*

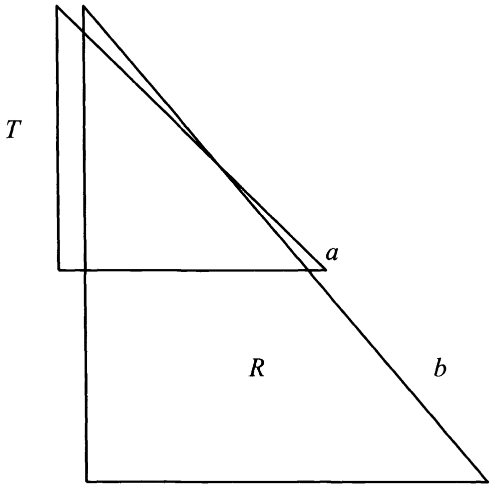

FIG. 10. *Case* II *of the proof.*

Note that the second appearance of a in the alternation must be to the right of the intersection point of the two hypotenuses, which implies that the two last appearances of b in the alternation must occur below the horizontal edge of T. But then, arguing as in the proof of Claim 1, it is easy to show that the last occurrence of a in the alternation must be at the bottom part of the hypotenus, contrary to assumption. Thus the alternation is impossible.

Hence $U^\star$ is indeed a Davenport Schinzel sequence of order 4 composed of at most n distinct symbols, so its length is at most $O(n \cdot 2^{\alpha(n)})$ [1]. This is also an upper bound on the length of U, and this clearly completes the proof of the lemma. □

We now decompose $\mathcal{F}$ as follows. We first find a horizontal line ℓ with the property that the number of triangles in $\mathcal{F}$ lying completely above ℓ and the number of triangles lying completely below ℓ are both at most $n/2$. Let $\mathcal{F}_1$ denote the subfamily of triangles of $\mathcal{F}$ intersecting ℓ. We apply the same procedure to the two subfamilies of $\mathcal{F}$ consisting respectively of the triangles lying above ℓ and of those lying below ℓ. For each of these subfamilies we find a "halving" horizontal line as above and define $\mathcal{F}_2$ to be the collection of triangles in these subfamilies which intersect one of these halving lines. We are now left with four subfamilies, each of which is next halved by a line, and $\mathcal{F}_3$ consists of the remaining triangles that intersect one of these lines. Continuing in this fashion, we obtain a decomposition of $\mathcal{F}$ into $O(\log n)$ subfamilies, $\mathcal{F}_1, \mathcal{F}_2, \ldots$, and the preceding lemma is easily seen to imply that the boundary complexity of each subfamily $\mathcal{F}_i$ is $O(n_i \cdot 2^{\alpha(n_i)})$, where $n_i = |\mathcal{F}_i|$.

We now apply the Combination Lemma 2.1 in a tree-like fashion. That is, we merge the subfamilies $\mathcal{F}_i$ two at a time, then merge each of the resulting collections two at a time, and so on, until all subfamilies are merged together. At each step, when merging two subfamilies $\mathcal{G}_1, \mathcal{G}_2$ to form a combined subfamily $\mathcal{G}$, we have

$$\mathrm{BC}(\mathcal{G}) \leq \mathrm{BC}(\mathcal{G}_1) + \mathrm{BC}(\mathcal{G}_2) + O(n_1 + n_2) ,$$

where n_i is the size of $\mathcal{G}_i$, for $i = 1, 2$. This is an immediate consequence of the Combination Lemma and of the fact that the number of holes of $\mathcal{G}$ is $O(n_1 + n_2)$. Since the depth of the tree representing these merges is $O(\log \log n)$ and the sum of the boundary complexities of the individual subfamilies $\mathcal{F}_i$ is $O(n \cdot 2^{\alpha(n)})$, it follows easily that $\mathrm{BC}(\mathcal{F}) = O(n \log \log n)$.

To obtain the lower bound in Theorem 1.2, take a collection of n line segments whose lower envelope consists of $\Omega(n\alpha(n))$ subsegments [23]. Flatten the collection in the y-direction until all segments have almost horizontal slope. Then replace each segment e by an equilateral triangle lying above e and having e as one of its sides. It is easily checked that the boundary complexity of the union of these triangles is $\Omega(n\alpha(n))$. □

Remark. By modifying the above lower bound construction and exploiting the special structure of the construction in [23], one can also obtain a collection of n equilateral triangles, whose union has $\Theta(n)$ holes, so that no triangle appears more than once along the boundary of any single hole, and yet the overall boundary complexity is $\Omega(n\alpha(n))$.

Proof of Theorem 1.3. Recall that the theorem asserts that if $\mathcal{F}$ is a family of n δ-fat triangles with $c \leq \mathrm{diam}(T) \leq C$ for all $T \in \mathcal{F}$, then $\mathrm{BC}(\mathcal{F}) = O(n)$, with the constant of proportionality depending on δ and C/c. Let $\mathcal{F}$ be such a family of triangles. We choose a real number D that satisfies the following two conditions:

(i) No square with side D is intersected by more than two sides of any triangle from $\mathcal{F}$.

(ii) The diameter of any triangle of $\mathcal{F}$ is at most a constant multiple of D.

The existence of such a D is guaranteed by the assumptions on $\mathcal{F}$; the constant factor in condition (ii) is easily seen to be of the form $\frac{C}{c}\phi(\delta)$, for an appropriate function ϕ.

Let us cover the plane by a grid of squares with side length D. By the choice of D, every triangle of $\mathcal{F}$ intersects at most a constant number of squares of this grid. We claim that the boundary complexity of $\mathcal{F}$ inside each grid square is linear in the number of triangles intersecting that square, and this will imply that the total boundary complexity of $\mathcal{F}$ is $O(n)$.

Let us consider a fixed square Q of the grid. For each triangle $T \in \mathcal{F}$, at most two sides of T intersect Q; hence, there exists a wedge (angle) W_T such that $Q \cap W_T = Q \cap T$. Let us consider the family

$$\mathcal{W} = \{W_T \ : \ T \in \mathcal{F},\ T \cap Q \neq \emptyset\}.$$

The boundary complexity of $\mathcal{W}$ is an upper bound for the complexity of the part of the boundary of $\mathcal{F}$ inside Q. Adapting Theorem 1.1 to the special case of wedges, it is easily seen that the family $\mathcal{W}$ has a linear number of holes. We claim that $\mathcal{W}$ can be partitioned into a constant number of subfamilies $\mathcal{W}_1, \ldots, \mathcal{W}_c$, each of which has a linear boundary complexity. Applying the Combination Lemma 2.1 (as in the preceding proof) a constant number of times, we obtain a linear bound on the boundary complexity of $\mathcal{W}$. (This part of the proof also establishes the second assertion in Theorem 1.3 concerning the complexity of the union of fat wedges.)

We may assume that the apex angle of each wedge of $\mathcal{W}$ is at least δ (this is obvious for triangles having two sides intersecting Q; for triangles with only one intersecting side, the choice of the apex and its angle are fairly arbitrary). It follows that there exists a fixed set of a constant number $c = O(1/\delta)$ of canonical orientations (e.g., $\delta/2$ apart from each other) so that each wedge in $\mathcal{W}$ contains a ray emerging from its apex and having one of these canonical orientations. We thus choose the decomposition $\mathcal{W} = \mathcal{W}_1 \cup \cdots \cup \mathcal{W}_c$ so that for all wedges in the same subfamily, the corresponding rays are all in the same (canonical) direction. It is well known that the boundary complexity of each subfamily $\mathcal{W}_i$ of wedges is linear. Indeed, if the common ray direction is assumed to be the negative y-direction, the boundary of the union of $\mathcal{W}_i$ is the upper envelope of the collection of rays that bound these wedges, and it is known that the complexity of such an envelope is linear (see, e.g., [5]). This finishes the proof of Theorem 1.3. □

5. Extensions, applications, and open problems. We have so far shown that the union of n δ-fat triangles has a linear number of holes and that its boundary complexity is $O(n \log\log n)$ and can be $\Omega(n\alpha(n))$. In this section we consider several extensions of these results, mention some applications, and conclude with some open problems.

Constructing the union of fat triangles. First we note that one can also calculate efficiently the union of such a family $\mathcal{F}$. The following algorithm, adapted from [14], can be used. Partition $\mathcal{F}$ into two subfamilies of roughly $n/2$ triangles each. Recursively calculate the union F_1 of $\mathcal{F}_1$ and the union F_2 of $\mathcal{F}_2$. Then merge the two unions by the line-sweeping procedure of Chazelle and Edelsbrunner [3] or of Mairson and Stolfi [15]. This computes all k intersections between the boundaries of F_1 and of F_2 in time $O(N \log N + k)$, where N is the overall size of F_1 and of F_2. But each such intersection is easily seen to be a corner of the overall union of $\mathcal{F}$, so by Theorem 1.2 we have that both N and k are bounded by $O(n \log\log n)$. This easily implies that we can construct the union of $\mathcal{F}$ from F_1 and F_2 in time $O(n \log n \log\log n)$, so the overall running time of this algorithm is $O(n \log^2 n \log\log n)$. We thus have

THEOREM 5.1. *One can calculate the union of n δ-fat triangles in $O(n \log^2 n \log\log n)$ time and $O(n \log\log n)$ storage (where the constant of proportionality depends on δ).*

Remark. One should contrast the problem of explicit construction of the union of a collection of figures to that of computing various measures of the union, such as its area or the length of its boundary. Such measures can be calculated efficiently for the case of axis-parallel rectangles, not necessarily δ-fat [17]. However, such efficient procedures are not known for general non-δ-fat collections. For δ-fat collections they are immediate by-products of the algorithm given above.

Recently, after the original submission of the paper, Miller and Sharir [16] obtained an improved randomized incremental algorithm for computing the union of n fat triangles, using $O(n \cdot 2^{\alpha(n)} \log n)$ expected time and storage.

General "fat" objects. We can also extend our results to families of polygons, which can be expressed as the union of a constant number of δ-fat triangles. Some "fatness" condition is clearly essential for such a result to hold, since one can form a quadratic number of holes with very narrow objects. Moreover, the following example shows that even when the polygons appear to be fat in an intuitive sense, they can still form quadratically many holes, so a stronger condition, such as imposed above, has to be enforced.

EXAMPLE 5.2. There exists a family of n similar convex figures (actually regular polygons), for each of which the ratio between the radii of the circumscribed and inscribed circles is less than 2 and which determine $\Omega(n^2)$ holes.

Proof. We will construct a family of $2n$ regular n-gons. Let us choose a regular n-gon $A = A_1A_2 \cdots A_n$. On each of its sides, A_iA_{i+1}, choose $n+1$ equidistant points $B_{i,0} = A_i, B_{i,1}, \ldots, B_{i,n-1}, B_{i,n} = A_{i+1}$. The first half of our family consists of n regular n-gons $C_1, C_2, \ldots, C_n$, where $C_j = B_{1,j}B_{2,j} \cdots B_{n,j}$. The second half of the family consists of n regular n-gons $D_1, \ldots, D_n$, where D_i arises as a mirror image of A, reflected around the side A_iA_{i+1}. This family determines quadratically many holes. □

Remarks. (1) This example is somewhat misleading because we ignore here the overall description complexity of the polygons C_i, D_i (which is itself quadratic). We include this example only to demonstrate that one needs to be careful in the definition of fatness if one wishes to extend the results of this paper to more complex figures than triangles.

(2) The reason for the large complexity in this example is that the boundaries of the convex figures intersect in many points per pair. It remains to investigate what happens if we consider a family of fat objects, such that the number of intersections of boundaries of any pair is bounded by a constant.

Applications. As briefly mentioned in the introduction, the fact that the boundary complexity of a family of fat triangles is small has various combinatorial and algorithmic consequences. So far these applications were limited to the case of pseudodisks and to a few other favorable cases mentioned in the introduction. These applications can now be extended to the case of fat triangles. We list some of them as corollaries of the bounds obtained in the preceding sections and omit the proofs, which are easily obtained by adapting the earlier proofs cited below.

COROLLARY 5.3. *Let $T_1, \ldots, T_n$ be n δ-fat triangles lying in three-dimensional space in arbitrary horizontal planes and viewed from a point at $z = -\infty$. Then one can perform hidden surface removal for this scene in time $O(n^{3/2} \log n (\log\log n)^{1/2} + k)$, where k is the size of the resulting "visibility map."*

Proof. See [20]. □

Remark. Recently, after the original submission of this paper, this result has been significantly improved in [13]. The algorithm presented there is also based on the results of this paper, and its running time is $O((n \log\log n + k)\log^2 n)$.

COROLLARY 5.4. *Let $T_1, \ldots, T_n$ be n δ-fat triangles in the plane, and let $k \leq n-2$ be an integer. The number of intersection points of the boundaries of these triangles which are covered by at most k other triangles is $O(nk \log\log \frac{n}{k})$.*

Proof. See [19]. □

COROLLARY 5.5. *Let $T_1, \ldots, T_n$ be n δ-fat triangles in the plane. One can preprocess them by a randomized algorithm, whose expected running time is $O(n \log^2 n \log\log n)$, into a data structure of size $O(n \log n \log\log n)$, so that, given any query point z, all k triangles containing z can be reported in (worst-case) time $O((k+1)\log n)$.*

Proof. See [19]. □

Remark. The bounds stated in the preceding theorems follow from the bound $O(n \log\log n)$ on the boundary complexity of a collection of fat triangles. Since we believe that this bound is not tight (see below), we expect corresponding improvements in the bounds of the preceding theorems. We also note that the running time of the algorithm of Corollary 5.5 can be slightly improved by the recent technique of [16] mentioned above.

Recently, the results of this paper have been applied in [21] to obtain efficient algotihms for motion planning among fat obstacles.

Open problems. The main open problem that arises is to close the gap between the upper and lower bounds on the maximum boundary complexity of a union of n δ-fat triangles. We venture the conjecture that the correct bound is indeed $O(n\alpha(n))$. It is annoying that we were unable to prove this even in the special case of Lemma 4.1.

Another problem is to calibrate the dependence of the constants of proportionality in the various bounds obtained above in terms of δ so that sharp bounds can be obtained also in cases where δ does depend on n. Some progress toward this goal was recently achieved in [7].

Finally, it is challenging to extend the results of this paper to three dimensions. For example, can one show that the boundary complexity of the union of n arbitrary cubes (or of 'fat' simplices) in 3-space is close to *quadratic* in n (as opposed to a trivial cubic upper bound)?

THREE-DIMENSIONAL STATISTICAL DATA SECURITY PROBLEMS[*]

ROBERT W. IRVING[†] AND MARK R. JERRUM[‡]

Abstract. Suppose there is a three-dimensional table of cross-tabulated nonnegative integer statistics, and suppose that all of the row, column, and "file" sums are revealed together with the values in some of the individual cells in the table. The question arises as to whether, as a consequence, the values contained in some of the other (suppressed) cells can be deduced from the information revealed.

The corresponding problem in two dimensions has been comprehensively studied by Gusfield [*SIAM J. Comput.*, 17 (1988), pp. 552–571], who derived elegant polynomial-time algorithms for the identification of any such "compromised" cells, and for calculating the tightest bounds on the values contained in all cells that follow from the information revealed. In this note it is shown, by contrast, that the three-dimensional version of the problem is NP-complete.

It is also shown that if the suggested row, column, and file sums for an unknown three-dimensional table are given, with or without the values in some of the cells, the problem of determining whether there exists any table with the given sums is NP-complete. In the course of proving these results, the NP-completeness of some constrained Latin square construction problems, which are of some interest in their own right, is established.

Key words. data security, NP-complete problems, Latin squares

1. Introduction.

Problems of statistical data security in two dimensions have been studied extensively—see [1] for some indications of early work and [3], [4], and [6] for some recent developments. In this note, we study the obvious extension of the problem to three dimensions, raised as an open problem by Gusfield [3], and show that, as is the case in a variety of other contexts, problems that are solvable in polynomial time in the two-dimensional case become NP-complete when extended to three dimensions.

Consider a three-dimensional table D, of size $n \times n \times n$, of nonnegative integer values $D(i, j, k)$, $(1 \leq i, j, k \leq n)$. The table entries $D(i, j, k)$ for fixed i, k and $1 \leq j \leq n$ constitute a *row* of the table, for fixed j, k and $1 \leq i \leq n$ a *column* of the table, and for fixed i, j and $1 \leq k \leq n$ a *file* of the table.

Envisage that a particular table D represents a collection of cross-tabulated statistical data, and that the row, column, and file sums of D are to be disclosed together with the values contained in some of the cells. However, other cells may contain sensitive values that are therefore to be suppressed; the question arises as to whether knowledge of the row, column, and file sums together with the disclosed cells will (a) essentially fix the values of one or more of the suppressed cells and (b) allow such values to be deduced in reasonable (say, polynomial) time (say, by an adversary). A suppressed cell that has the same value in all legal tables, i.e., all tables satisfying the row, column, and file sums and containing the disclosed values, is said to be *compromised.* A suppressed cell that is not compromised is said to be *protected.*

In the case of the corresponding two-dimensional problem, Gusfield [3] gives a $O(n^3)$ algorithm to identify all the fixed cells and to calculate their values. In [3] and [4], Gusfield also describes polynomial-time algorithms to calculate the tightest bounds on the protected cells. As part of this work, a $O(n^3)$ algorithm is presented for the identification of a legal solution in the two-dimensional case. In this context, it turns out that the obvious necessary conditions for a legal solution—namely, that the sums of the row and column sums should be equal and that each row and column sum should be at least equal to the sum of the disclosed entries in that row or column—are also sufficient for the existence of a legal solution.

By contrast, in the three-dimensional case, we shall show that the obvious necessary two-dimensional conditions on the row, column, and file sums are not sufficient to guarantee the existence of a legal solution, and indeed that the problem of determining whether a legal solution exists is NP-complete. This result holds even in the interesting special case in which all the cells are suppressed; in other words, if we are given the row, column, and file sums, and are asked whether a legal solution exists. We shall then proceed to show that the NP-completeness of the existence problem also implies the NP-completeness of the problem of identifying compromised cells, at least in the general case where some cells may be revealed.

The NP-completeness proofs involve consideration of special cases that are equivalent to two-dimensional problems of Latin square construction, which are of some interest in their own right. For instance, we show that a special case of the problem of the existence of a legal solution is equivalent to the problem of constructing an $n \times n$ Latin square given independent restricted choices for the various entries, and that this Latin square construction problem is itself NP-complete.

2. Formal statement of the problem. Throughout, we assume that, unless otherwise stated, the row, column, and file indices i, j, and k range over the values $1, \ldots, n$ wherever appropriate. Suppose that for a given $n \times n \times n$ table D of nonnegative integers, and for each i, j, k, the row, column, and file sums are denoted by $R(i, k)$, $C(j, k)$, and $F(i, j)$, respectively. In other words,

$$R(i,k) = \sum_{j=1}^{n} D(i,j,k), \tag{1}$$

$$C(j,k) = \sum_{i=1}^{n} D(i,j,k), \tag{2}$$

$$F(i,j) = \sum_{k=1}^{n} D(i,j,k). \tag{3}$$

If we represent the set of suppressed cells by S, i.e., $S = \{(i, j, k) : D(i, j, k)$ not disclosed$\}$, then we can calculate the reduced row, column, and file sums, namely,

$$R^*(i,k) = R(i,k) - \sum_{j:(i,j,k)\notin S} D(i,j,k), \tag{4}$$

$$C^*(j,k) = C(j,k) - \sum_{i:(i,j,k)\notin S} D(i,j,k), \tag{5}$$

$$F^*(i,j) = F(i,j) - \sum_{k:(i,j,k)\notin S} D(i,j,k). \tag{6}$$

We are now in a position to state formally the problem that we wish to pursue.

2.1. Three-dimensional statistical data—legal solutions (3DSDLS).

Instance: A positive integer n, nonnegative integer values $R^*(i, k)$, $C^*(j, k)$, and $F^*(i, j)$, and a subset S of N^3, where $N = \{1, 2, \ldots, n\}$.

Question: Does there exist an assignment of nonnegative values to $D(i, j, k)$ for $(i, j, k) \in S$ such that

$$\sum_{j=1}^{n} D(i,j,k) = R^*(i,k), \tag{7}$$

$$\sum_{i=1}^{n} D(i, j, k) = C^*(j, k), \tag{8}$$

$$\sum_{k=1}^{n} D(i, j, k) = F^*(i, j), \tag{9}$$

where each sum is taken over values $(i, j, k) \in S$?

It is immediate that, in order for a solution to exist, the sums of the R^*, C^*, and F^* values must all be identical and satisfy constraints imposed by consideration of the two-dimensional "slices" of the table, namely,

$$\sum_{k=1}^{n} R^*(i, k) = \sum_{j=1}^{n} F^*(i, j) \quad (1 \leq i \leq n), \tag{10}$$

$$\sum_{i=1}^{n} F^*(i, j) = \sum_{k=1}^{n} C^*(j, k) \quad (1 \leq j \leq n), \tag{11}$$

$$\sum_{j=1}^{n} C^*(j, k) = \sum_{i=1}^{n} R^*(i, k) \quad (1 \leq k \leq n). \tag{12}$$

To see that these necessary conditions are by no means sufficient for the existence of a legal solution, we consider an example in which $n = 2$ and all cells are suppressed.

Example. It may be checked easily by exhaustive search that the 3DSDLS instance shown in Fig. 1, in which the row, column, and file sums appear as labels on the appropriate arrows, admits no legal solution, although the necessary two-dimensional conditions are satisfied.

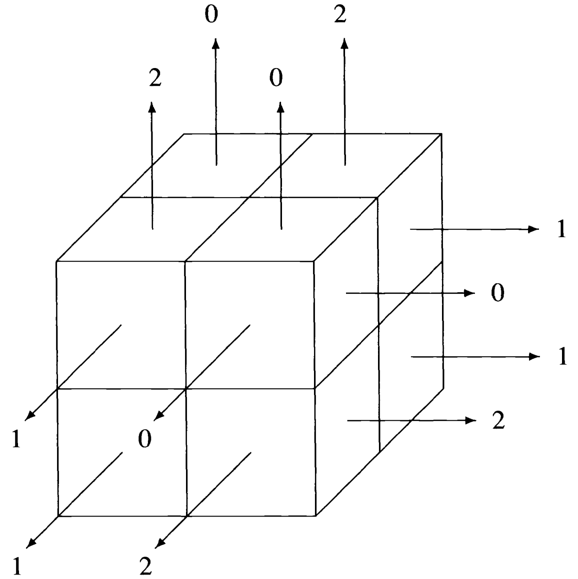

FIG. 1. *An instance of* 3DSDLS *of size* 4 *with no legal solution.*

In order to show that the 3DSDLS problem is NP-complete, we shall restrict our attention to a special case, which can be interpreted as the problem of constructing a Latin square given restricted choices for the various entries. This special case involves setting $R^*(i, k) = C^*(j, k) = F^*(i, j) = 1$ for all values of i, j, and k. If we define

$$S(i, j) = \{k : (i, j, k) \in S\},$$

then our task is to find a suppressed cell in each file, i.e., an element in $S(i, j)$, which can be given the value 1, subject to the constraint that no two cells can be chosen from the same row and no two can be chosen from the same column. It should be clear that this can be interpreted as the problem of constructing a Latin square of size $n \times n$ where the choice of element in position (i, j) is restricted to the set $S(i, j)$.

2.2. Latin square construction (LSC).

Instance: A positive integer n, and for each i, j, a subset $S(i, j)$ of $\{1, \dots, n\}$.

Question: Does there exist a Latin square X of size $n \times n$ such that, for all i, j, $X(i, j) \in S(i, j)$?

Example. The first array below constitutes a "yes"-instance of LSC of size 4, with underlined entries indicating one solution. On the other hand, exhaustive search will reveal that the second array constitutes a "no"-instance.

$$\begin{array}{llll} \{3, \underline{4}\} & \{\underline{1}, 2\} & \{1, \underline{3}, 4\} & \{1, \underline{2}\} \\ \{\underline{2}, 4\} & \{1, \underline{3}\} & \{\underline{1}, 2\} & \{3, \underline{4}\} \\ \{\underline{1}, 3\} & \{2, \underline{4}\} & \{1, \underline{2}\} & \{1, \underline{3}, 4\} \\ \{1, 2, \underline{3}\} & \{\underline{2}, 3\} & \{3, \underline{4}\} & \{\underline{1}, 2, 3\} \end{array} \qquad \begin{array}{llll} \{1, 2\} & \{1, 3\} & \{2, 4\} & \{3, 4\} \\ \{3, 4\} & \{2, 4\} & \{1, 2\} & \{1, 3\} \\ \{1, 2\} & \{3, 4\} & \{1, 3\} & \{2, 4\} \\ \{3, 4\} & \{1, 2\} & \{3, 4\} & \{1, 2\} \end{array}$$

Clearly a proof of NP-completeness for LSC implies that the more general 3DSDLS problem is NP-complete also.

3. NP-completeness of LSC. In preparation for the proof of NP-completeness of LSC, we need to investigate the conditions under which a Latin rectangle may be extended to a larger Latin rectangle or to a full Latin square. The following result is well known—see [5] or [7].

LEMMA 3.1. *An arbitrary Latin rectangle of size $m \times n$ $(m < n)$ over a ground-set of size n may be extended by the addition of $n - m$ additional rows to form a Latin square of size $n \times n$.*

In addition, we need a sufficient condition for a $p \times q$ Latin rectangle to be extendable to an $n \times q$ Latin rectangle. The following result may not be the best possible, but it will suffice for our purposes.

LEMMA 3.2. *Suppose that L is a Latin rectangle of size $p \times q$ with elements chosen from a ground-set of size n, and suppose that $n \geq p + 2q - 2$. Then L can be extended to a Latin rectangle of size $n \times q$.*

Proof. Suppose that the first j columns of L have already been extended to length n, where $0 \leq j \leq q - 1$; we show that the $(j + 1)$th column can also be extended to length n.

Consider a bipartite graph G with vertex set $V = U \cup W$. In U there are $s = n - p$ vertices, one for each of rows $p + 1, \dots, n$ in the rectangle, and in W there are n vertices, one for each element of the ground-set, which we may take to be $\{1, \dots, n\}$. Vertices $u \in U$ and $w \in W$ are joined if and only if element w already appears neither in column $j + 1$ nor in row u (and therefore w is a candidate for position (u, j) in the rectangle). It is clear that the $(j + 1)$th column can be extended to length n if and only if the graph G has a matching of size s.

By Hall's theorem, G will have a matching of size s provided that, for each k $(1 \leq k \leq s)$, the vertices in every k-subset of U are collectively adjacent to at least k vertices in W. We consider two cases:

Case (a) $k > j$. In this case, no element can appear in all the k rows corresponding to the k vertices of U. Hence, these k vertices are collectively adjacent to all n vertices in W, except for the p vertices corresponding to the elements in column $j + 1$, therefore, to $n - p$ vertices. Since $n - p \geq k$, the required condition for a matching of size s is met.

Case (b) $k \leq j$. In this case, it is possible that the k rows have up to k elements in common, so that the best we can claim is that the k vertices in U are collectively adjacent to at least $n - p - k$ vertices in W. Nonetheless, since $n - p \geq 2(q - 1)$, $q - 1 \geq j$, and $j \geq k$, it follows that $n - p - k \geq k$, and the required condition is again satisfied.

Hence, by Hall's theorem, G has a matching of size s, and therefore the $(j + 1)$th column can be extended to length n as claimed. □

We are now in a position to prove the NP-completeness of our Latin square construction problem LSC.

THEOREM 3.3. *Latin square construction is NP-complete.*

Proof. Membership in NP is immediate, for we need simply guess an element $X(i, j) \in S(i, j)$ for each i, j, and it is straightforward to verify, in polynomial time, whether the resulting square X is a Latin square.

To show that LSC is NP-complete, we describe a polynomial-time transformation from the known NP-complete problem 3-Satisfiability (3-SAT)—see [2].

Given an instance of 3-SAT involving m variables $v_1, v_2, \ldots, v_m$ and n clauses $C_1, C_2, \ldots, C_n$, we construct an instance of LSC of size $2mn$, which admits a Latin square if and only if the original 3-SAT instance is satisfiable. Corresponding to each v_k there are precisely $2n$ elements in the ground-set S for the derived instance of LSC, denoted by $u_{kl}, \overline{u}_{kl}$ $(1 \leq l \leq n)$. It remains to describe the sets $S(i, j)$ $(1 \leq i, j \leq 2mn)$.

For $1 \leq k \leq m$, $1 \leq l \leq n$, we define

$$\begin{aligned} S((k-1)n + l, 1) &= \{u_{kl}, \overline{u}_{kl}\}, \\ S((k-1)n + l, 2) &= \{u_{kl}, u_{k,l+1}\}, \\ S((k-1)n + l, 3) &= \{u_{k,l+1}, \overline{u}_{k,l}\}, \end{aligned}$$

where here, and subsequently, $l + 1$ is taken modulo n in the range $[1, n]$.

For $1 \leq l \leq n$ we define

$$S(mn + l, 1) = \{w_{1l}, w_{2l}, w_{3l}\},$$

where

$$w_{hl} = \begin{cases} u_{kl} & \text{if the } h\text{th literal in } C_l \text{ is } v_k, \\ \overline{u}_{kl} & \text{if the } h\text{th literal in } C_l \text{ is } \overline{v}_k. \end{cases}$$

Finally, for all subscript pairs i, j not covered by the above, we set $S(i, j) = S$. It is clear that the entire construction can be carried out in time bounded by a polynomial in the length of the original 3-SAT expression.

We now have to establish that the derived instance of LSC admits the construction of a $2mn \times 2mn$ Latin square if and only if the original instance of 3-SAT has a satisfying assignment.

Suppose first that the LSC instance admits a Latin square X. For a given value of k, consider positions $(k - 1)n + l, t$ $(1 \leq l \leq n, 1 \leq t \leq 3)$ in the square. It is straightforward to verify that there are just two possibilities, either

$$\text{(a)} \qquad \begin{aligned} X((k-1)n+l,1) &= \overline{u}_{kl},\\ X((k-1)n+l,2) &= u_{kl},\\ X((k-1)n+l,3) &= u_{k,l+1} \end{aligned}$$

for all l $(1 \leq l \leq n)$, or

$$\text{(b)} \qquad \begin{aligned} X((k-1)n+l,1) &= u_{kl},\\ X((k-1)n+l,2) &= u_{k,l+1},\\ X((k-1)n+l,3) &= \overline{u}_{kl} \end{aligned}$$

for all l $(1 \leq l \leq n)$.

We assign variable v_k to be true or false accordingly as Case (a) or Case (b) applies.

Now, for each l, $1 \leq l \leq n$, we consider $X(mn+l,\, 1)$. Because X is a Latin square, we must have $X(mn+l,\, 1)$ equal to w_{hl}, where w_{hl} represents a true literal; otherwise, by (a) and (b) above, we would have $X(mn+l,\, 1) = X((k-1)n+l,\, 1)$ for some k. So, in the derived assignment, every clause contains at least one true literal, showing that the original instance of 3-SAT is satisfiable.

On the other hand, suppose that the instance of 3-SAT is satisfiable, and consider a particular satisfying assignment. If v_k is true in this assignment, we choose

$$\begin{aligned} X((k-1)n+l,1) &= \overline{u}_{kl},\\ X((k-1)n+l,2) &= u_{k,l},\\ X((k-1)n+l,3) &= u_{k,l+1} \end{aligned}$$

for all l $(1 \leq l \leq n)$, while if v_k is false, we choose

$$\begin{aligned} X((k-1)n+l,1) &= u_{kl},\\ X((k-1)n+l,2) &= u_{k,l+1},\\ X((k-1)n+l,3) &= \overline{u}_{kl} \end{aligned}$$

for all l $(1 \leq l \leq n)$.

Further, for $1 \leq l \leq n$, we choose

$$X(mn+l,1) = w_{hl},$$

where w_{hl} is a true literal in clause C_l, and

$$\begin{aligned} X(mn+l,2) &= \overline{u}_{1,l+1},\\ X(mn+l,3) &= \begin{cases} u_{1,l+1} & \text{if } v_1 \text{ is false},\\ \overline{u}_{1,l+2} & \text{if } v_1 \text{ is true}. \end{cases} \end{aligned}$$

It is straightforward to verify that this gives a Latin rectangle of size $(m+1)n \times 3$. Provided $(m-1)n \geq 4$, which can be assumed without loss of generality, the condition of Lemma 3.2

is satisfied; this Latin rectangle can then be extended, first, to form a Latin rectangle of size $2mn \times 3$, and then, by Lemma 3.1, to form a Latin square of size $2mn \times 2mn$, bearing in mind that $S(i, j) = S$ for all outstanding positions (i, j). □

In view of the earlier observation that LSC is a special case of 3DSDLS, we have the following corollary.

COROLLARY 3.4. 3DSDLS *is NP-complete, even in the special case where all the row, column and file sums are* 1.

4. The special case of all cells suppressed. We now consider the interesting special case of 3DSDLS in which all cells are suppressed. This special case is a natural problem in its own right, which we refer to as the 3D contingency table problem (3DCT).

4.1 Three-dimensional contingency tables (3DCT).

Instance: A positive integer n, and for each i, j, k, nonnegative integer values $R(i, k)$, $C(j, k)$, $F(i, j)$.

Question: Does there exist an $n \times n \times n$ contingency table X of nonnegative integers such that

$$\textstyle\sum_{j=1}^{n} X(i, j, k) = R(i, k),$$

$$\textstyle\sum_{i=1}^{n} X(i, j, k) = C(j, k),$$

$$\textstyle\sum_{k=1}^{n} X(i, j, k) = F(i, j)$$

for all i, j, k?

We now establish the NP-completeness of 3DCT even in the special case where all the R, C, and F values are 0 or 1. This we achieve by viewing this special case as a two-dimensional partial Latin square construction problem, and by showing that there is a polynomial-time transformation from the basic Latin square construction problem, already known to be NP-complete, to this new problem.

The partial Latin square construction problem is specified in the following section.

4.2 Partial Latin square construction (PLSC).

Instance: A positive integer n, subsets $R(i)$ and $C(j)$ of $N = \{1, \ldots, n\}$ for each i, j, and a subset $\mathcal{N}$ of N^2 such that (a) $|R(i)| = |k : (i, k) \in \mathcal{N}|$, and (b) $|C(j)| = |k : (k, j) \in \mathcal{N}|$.

Question: Does there exist a partial Latin square X with

(i) $X(i, j)$ defined for all $(i, j) \in \mathcal{N}$;

(ii) $X(i, j) \in R(i) \cap C(j)$ for all such (i, j)?

Note that it follows at once that, in a "yes" instance of PLSC, (a) $k \in R(i) \Rightarrow X(i, j) = k$ for some j, and (b) $k \in C(j) \Rightarrow X(i, j) = k$ for some i.

Example. In Fig. 2, the sets $R(i)$ and $C(j)$ appear to the left of the rows and above the columns, respectively; the set $R(i) \cap C(j)$ appears in position (i, j); cells corresponding to pairs $(i, j) \notin \mathcal{N}$ contain the symbol —; and the underlined elements indicate that this is a "yes"-instance of the problem.

Our first objective is to show that the special case of 3DCT in which the row, column, and file sums are all 0 or 1 can be interpreted as an instance of PLSC. Given such an instance of 3DCT of size n with row, column, and file sums $R(i, k)$, $C(j, k)$, and $F(i, j)$, define

$$\begin{aligned} \mathcal{N} &= \{(i, j) : F(i, j) = 1\}, \\ R(i) &= \{k : R(i, k) = 1\}, \\ C(j) &= \{k : C(j, k) = 1\}. \end{aligned}$$

	$\{1,3\}$	$\{1,2,4\}$	$\{3,4\}$	$\{1,2,3,4\}$
$\{1,2,3\}$	—	$\underline{1}, 2$	$\underline{3}$	$1, \underline{2}, 3$

FIG. 2. *An instance of* PLSC *of size* 4.

The set $\mathcal{N}$ represents the set of files with sum equal to 1. The sole position in such a file, say, file (i, j), occupied by a 1 must correspond to both a row with sum equal to 1—i.e., an element of $R(i)$—and a column with sum equal to 1—i.e., an element of $C(j)$. It follows that a solution to the given instance of the special case of 3DCT corresponds exactly to a solution of the derived instance of PLSC.

We are now in a position to establish the NP-completeness of PLSC.

THEOREM 4.1. *The partial Latin square construction problem* (PLSC) *is* NP-*complete.*

Proof. Membership in NP is immediate, since we can guess an element in the ground-set for each cell in the set $\mathcal{N}$ and verify in polynomial time that the various row and column constraints are satisfied. To prove NP-completeness, we describe a polynomial-time transformation from the basic Latin square construction problem (LSC), already known to be NP-complete by Theorem 3.3.

Given a positive integer n and sets $S(i, j) \subseteq N = \{1, \ldots, n\}$ forming an instance of LSC, we construct an instance of PLSC over the same ground-set N but of increased size $n' = n + \sum_{ij} |S(i, j)|$. The set of free cells $\mathcal{N}$ is defined as a disjoint union of n^2 component sets $\mathcal{N}_{ij}$, which are constructed as follows. Let λ, μ be mappings from N^2 to $\{n + 1, n + 2, \ldots, n'\}$ satisfying

(i) $\mu(i, j) - \lambda(i, j) + 1 = |S(i, j)|$, for all $i, j \in N$;

(ii) the intervals $\{[\lambda(i, j), \mu(i, j)] \; : \; i, j \in N\}$ form a partition of the set $\{n + 1, n + 2, \ldots, n'\}$. (The notation $[a, b]$ denotes the set of all integers not less than a and not greater than b.)

For each i, j in the range $1 \leq i, j \leq n$, define

$$\mathcal{N}_{ij} = [l, m] \times [l, m] \cup \{(i, l), (l, j)\} - \{(l, l)\},$$

where $l = \lambda(i, j)$ and $m = \mu(i, j)$; the set of free cells is then $\mathcal{N} = \bigcup_{ij} \mathcal{N}_{ij}$. Figure 3 is a pictorial representation of a typical component set $\mathcal{N}_{ij}$.

We now specify the row and column sets. For k in the range $1 \leq k \leq n$, set $R(k) = C(k) = N$. For k outside this range, i.e., for $n+1 \leq k \leq n'$, let $i, j \in N$ be the unique integers satisfying $\lambda(i, j) \leq k \leq \mu(i, j)$, and set $R(k) = C(k) = S(i, j)$. It can be checked that R, C, and $\mathcal{N}$ together form a consistent instance of PLSC. This completes the construction.

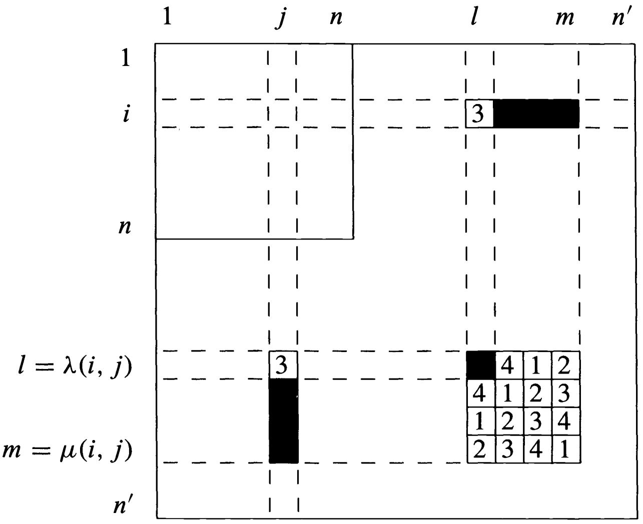

FIG. 3. *The set $\mathcal{N}_{ij}$, and a possible numbering when $S(i, j) = \{1, 2, 3, 4\}$.*

To verify the construction, we must show that the derived instance of PLSC admits a solution if and only if the original instance of LSC does. Suppose first that the LSC instance admits a Latin square X, so that $X(i, j) \in S(i, j)$ for all i, j. We shall construct a partial Latin square Y consistent with the derived instance of PLSC, i.e., satisfying $Y(i, j) \in R(i) \cap C(j)$ for all $(i, j) \in \mathcal{N}$.

It is enough to describe the restriction of Y to a typical component set $\mathcal{N}_{ij}$, since $\mathcal{N}$ is a disjoint union of such sets. Let $l = \lambda(i, j)$, $m = \mu(i, j)$, and $s = |S(i, j)|$. We consider the domain $\mathcal{N}_{ij}$ in two parts: the square with missing corner cell $[l, m] \times [l, m] - \{(l, l)\}$, and the two isolated cells (i, l) and (l, j). On the isolated cells, we simply take $Y(i, l) = Y(l, j) = X(i, j)$. In order to deal with the square, imagine that the missing corner cell is temporarily reinstated. Define Y on this completed square so that the resulting $s \times s$ table of values forms a Latin square over the ground-set $S(i, j)$, with $Y(l, l) = X(i, j)$. Then simply remove the cell (l, l) from the domain of definition of Y. Figure 3 is intended to illustrate how the restriction of Y to the set $\mathcal{N}_{ij}$ might appear in the case $S(i, j) = \{1, 2, 3, 4\}$.

It may readily be checked that $Y(i, j) \in R(i) \cap C(j)$ for all cells $(i, j) \in \mathcal{N}$. The only other condition we must verify is that Y is indeed a partial Latin square, i.e., that no row or column of Y contains a duplicate value. By symmetry, we need only check this condition for the rows. For i in the range $n + 1 \leq i \leq n'$, the fact that row i of Y cannot contain duplicate values is clear by construction. So suppose $1 \leq i \leq n$, which is the only other possibility. Row i of the derived instance of PLSC contains precisely n cells that are elements of $\mathcal{N}$, and these correspond to the n cells forming row i in the original instance of LSC. Y assigns to each of the n cells in the PLSC instance the same value that X assigns to the corresponding cell in the LSC instance, and these n values must all be distinct. Thus we have shown that the PLSC instance admits a solution if the LSC instance does.

For the converse, suppose that the derived PLSC instance admits a partial Latin square Y that is consistent with the various row and column constraints. We shall construct a Latin square X consistent with the original instance of LSC. Consider the restriction of Y to the set $\mathcal{N}_{ij}$, for some $1 \leq i, j \leq n$. As before, let $l = \lambda(i, j)$ and $m = \mu(i, j)$. The restriction of Y to the array of cells $[l, m] \times [l, m]$ forms a Latin square on ground-set $S(i, j)$ with the top left corner cell removed. The values $Y(i, l)$ and $Y(l, j)$ must both equal the missing element of this Latin square, and hence $Y(i, l) = Y(l, j) \in S(i, j)$. Now set $X(i, j)$ equal to $Y(i, l)$.

Since the individual cell constraints are clearly satisfied, it only remains to show that X is indeed a Latin square, i.e., that no row or column of X contains duplicate values. By symmetry, we need only check this condition for rows. But the n values occurring in the ith row of X are equal, by construction, to the n corresponding values occurring in the ith row of Y. Hence the ith row of X cannot contain duplicate values. We have thus demonstrated that the LSC instance admits a solution if the PLSC instance does. This completes the validation of the reduction. □

COROLLARY 4.2. 3DCT *is* NP-*complete, even in the special case where all the row, column and file sums are* 0 *or* 1.

5. NP-completeness of identifying compromised cells. We now consider the question of identifying the compromised cells in the general three-dimensional problem. In other words, if we are given a particular legal solution to an instance of 3DSDLS, and we focus attention on a particular (suppressed) cell, we wish to establish whether there exists a second solution in which that cell holds a different value. We shall show that determining whether a particular cell is compromised is also an NP-complete problem.

First, we give a formal description of the problem.

5.1. Three-dimensional statistical data—compromised cells (3DSDCC).

Instance: A positive integer n, a subset S of N^3, where $N = \{1, \dots, n\}$, nonnegative integer values $D(i, j, k)$ for each $(i, j, k) \in S$, and a particular triple $(i_0, j_0, k_0) \in S$.

Question: Does there exist a set of nonnegative integer values $D'(i, j, k)$ $((i, j, k) \in S)$ such that

(i) $\sum_{i=1}^n D'(i, j, k) = \sum_{i=1}^n D(i, j, k)$,

(ii) $\sum_{j=1}^n D'(i, j, k) = \sum_{j=1}^n D(i, j, k)$,

(iii) $\sum_{k=1}^n D'(i, j, k) = \sum_{k=1}^n D(i, j, k)$,

and

(iv) $D'(i_0, j_0, k_0) \neq D(i_0, j_0, k_0)$,

where all sums are taken over $(i, j, k) \in S$?

As was the case with our earlier problem, we prove 3DSDCC NP-complete by considering a special case that we can interpret in terms of Latin squares. Again, this is the special case in which all the row, column, and file sums are equal to 1. As earlier, we can interpret any solution to such an instance as a Latin square X of size $n \times n$ in which $X(i, j) \in S(i, j)$, where $S(i, j) = \{k : (i, j, k) \in S\}$.

In fact, the NP-completeness of the Latin square nonuniqueness problem that we are about to describe has a slightly stronger consequence than we need, namely, that the problem of determining whether there is any legal solution, other than the one given, is NP-complete. The NP-completeness of 3DSDCC follows at once from this, for if we had a polynomial-time algorithm for the latter problem, we could apply it at most a polynomial number of times to determine whether there is any other legal solution.

5.2. Latin square nonuniqueness (LSNU).

Instance: A positive integer n, subsets $S(i, j)$ of $N = \{1, \dots, n\}$ for each i,j, and a Latin square X of size $n \times n$ with $X(i, j) \in S(i, j)$ for all i, j.

Question: Does there exist a Latin square X' of size $n \times n$ such that $X'(i, j) \in S(i, j)$ for all i, j, and $X' \neq X$?

As observed above, the NP-completeness of 3DSDCC will follow from the NP-completeness of LSNU. Before proving this result, we need some further notation and a lemma.

For arbitrary values of i, j $(1 \leq i, j \leq 2n)$, we write $p(i, j)$ for the value of $i + j - 1$ taken mod$n$ in $[1, n]$, so that, clearly, $p(i, j + n) = p(i, j)$.

LEMMA 5.1. *For fixed i, let*

$$S(j) = \begin{cases} \{p(i,j), p(i,j)+n\} & (1 \le j \le n), \\ \{p(i,j), p(i,j+1)+n\} & (n+1 \le j \le 2n). \end{cases}$$

Then the sets $S(j)$ $(1 \le j \le 2n)$ have exactly two sets of distinct representatives, namely, $s(j)$ and $t(j)$ defined by

$$s(j) = \begin{cases} p(i,j) & (1 \le j \le n), \\ p(i,j+1)+n & (n+1 \le j \le 2n) \end{cases}$$

and

$$t(j) = \begin{cases} p(i,j)+n & (1 \le j \le n), \\ p(i,j) & (n+1 \le j \le 2n). \end{cases}$$

Proof. First of all we observe the following intersections:

$$\begin{aligned} S(j) \cap S(j+n) &= \{p(i,j)\} && (1 \le j \le n), \\ S(j+1) \cap S(j+n) &= \{p(i,j+1)+n\} && (1 \le j \le n), \end{aligned}$$

where $j+1$ is taken mod$n$ in $[1,n]$. So, if we choose $p(i,1)$ as the representative for $S(1)$, we are forced to choose $p(i,2)+n$ as the representative for $S(n+1)$, which in turn forces us to choose $p(i,2)$ as the representative for $S(2)$, and so on, leading to the system s defined above. On the other hand, if we choose $p(i,1)+n$ as the representative for $S(1)$, we are forced to choose $p(i,2n)$ as the representative for $S(2n)$, which in turn forces us to choose $p(i,n)+n$ as the representative for $S(n)$, and so on, leading to the system t defined above. These are the only two possibilities. □

The following further lemma is analogous to the previous one.

LEMMA 5.2. *For fixed j, let*

$$S(i) = \begin{cases} \{p(i,j), p(i,j)+n\} & (1 \le i \le n), \\ \{p(i,j), p(i+1,j)+n\} & (n+1 \le i \le 2n). \end{cases}$$

Then the sets $S(i)$ $(1 \le i \le 2n)$ have exactly two sets of distinct representatives, namely, $s(i)$ and $t(i)$ defined by

$$s(i) = \begin{cases} p(i,j) & (1 \le i \le n), \\ p(i+1,j)+n & (n+1 \le i \le 2n) \end{cases}$$

and

$$t(i) = \begin{cases} p(i,j)+n & (1 \le i \le n), \\ p(i,j) & (n+1 \le i \le 2n). \end{cases}$$

THEOREM 5.3. *Latin square nonuniqueness is NP-complete.*

Proof. Membership in NP is immediate. We need merely guess values $X'(i, j) \in S(i, j)$ for each (i, j), and easily verify in polynomial time that X' is a Latin square, and that $X' \neq X$.

To prove NP-completeness, we describe a polynomial-time transformation from LSC, known to be NP-complete by Theorem 3.3, to LSNU.

Given an instance of LSC of size n with ground-set $\{1, \ldots, n\}$ and subsets $S(i, j)$ $(1 \leq i, j \leq n)$, we construct from it an instance of LSNU of size $2n$, with ground-set $\{1, \ldots, 2n\}$ and subsets $S'(i, j)$ $(1 \leq i, j \leq 2n)$ as follows.

We set

$$S'(i, j) = \begin{cases} S(i, j) \cup \{p(i, j) + n\} & \text{for } 1 \leq i, j \leq n\,, \\ \{p(i, j), p(i, j) + n\} & \text{for } n + 1 \leq i \leq 2n, 1 \leq j \leq n, \\ & \text{and } 1 \leq i \leq n, n + 1 \leq j \leq 2n, \\ \{p(i, j), p(i - 1, j) + n\} & \text{for } n + 1 \leq i, j \leq 2n. \end{cases}$$

The Latin square for this instance of LSNU is defined by

$$X(i, j) = \begin{cases} p(i, j) + n & \text{for } 1 \leq i, j \leq n\,, \\ p(i, j) & \text{for } n + 1 \leq i \leq 2n, 1 \leq j \leq n, \\ & \text{and } 1 \leq i \leq n, n + 1 \leq j \leq 2n, \\ p(i - 1, j) + n & \text{for } n + 1 \leq i, j \leq 2n. \end{cases}$$

Verification that X is a Latin square and that $X(i, j) \in S(i, j)$ for all i, j is straightforward.

We now show that there is a Latin square X' with $X'(i, j) \in S(i, j)$ for all i, j, and X' nonidentical to X if and only if the original instance of LSC is solvable, and indeed if this is the case then $X'(i, j) \neq X(i, j)$ for all i, j.

First of all, if the LSC instance is solvable, with $n \times n$ Latin square Y, $Y(i, j) \in S(i, j)$ $(1 \leq i, j \leq n)$, we may choose

$$X'(i, j) = \begin{cases} Y(i, j) & \text{for } 1 \leq i, j \leq n, \\ p(i, j) + n & \text{for } n + 1 \leq i \leq 2n, 1 \leq j \leq n, \\ & \text{and } 1 \leq i \leq n, n + 1 \leq j \leq 2n, \\ p(i, j) & \text{for } n + 1 \leq i, j \leq 2n. \end{cases}$$

to give a $2n \times 2n$ Latin square X', with $X'(i, j) \neq X(i, j)$ for all i, j.

On the other hand, let us consider the circumstances under which a different $2n \times 2n$ Latin square may exist. If for some (i_0, j_0), $X'(i_0, j_0) \neq X(i_0, j_0)$, then it is immediate that $X'(i', j') \neq X(i', j')$ for some (i', j') with $1 \leq i' \leq n, n + 1 \leq j' \leq 2n$. By Lemma 5.1, it follows that $X'(i, j) \neq X(i, j)$ for all i, j $(n + 1 \leq i \leq 2n, 1 \leq j \leq 2n)$. A further application of Lemma 5.2 reveals that this is true also for $1 \leq i \leq n, n + 1 \leq j \leq 2n$. Hence, in order that X' may be a Latin square, every value $X'(i, j)$ $(1 \leq i, j \leq n)$ must belong to $S(i, j)$, and therefore these values constitute a Latin square for the original instance of LSC. □

Finally, we consider the special case in which all cells are suppressed. This version of the problem can be expressed as described in the following section.

5.3. Contingency table nonuniqueness (CTNU).

Instance: A positive integer n and an $n \times n \times n$ table X of nonnegative integers.

Question: Does there exist an $n \times n \times n$ table $X'(\neq X)$ such that X' and X have identical row, column, and file sums?

Superficially, this version of the problem might appear easier than the general 3DS-DCC problem. For example, the existence of nonzero entries in positions (i, j, k'), (i, j', k), (i', j, k), and (i', j', k') for some i, i', j, j', k, k' would constitute an obvious sufficient condition for a "yes" answer—these entries could be reduced by 1 and the entries in positions (i, j, k), (i, j', k'), (i', j, k'), and (i', j', k) increased by 1 to give a second legal solution.

However, contingency table nonuniqueness is still NP-complete, as we now show. We first of all observe, in the same spirit as previously, that the special case of CTNU in which all row, column and file sums are 0 or 1 can be phrased as a partial Latin square problem, as follows.

5.4. Partial Latin square nonuniqueness (PLSNU).

Instance: A positive integer n, subsets $R(i)$ and $C(j)$ of $N = \{1, \ldots, n\}$ for each i, j, a subset $\mathcal{N}$ of N^2 such that (a) $|R(i)| = |k : (i, k) \in \mathcal{N}|$, and (b) $|C(j)| = |k : (k, j) \in \mathcal{N}|$, and values $X(i, j)$ for all $(i, j) \in \mathcal{N}$ satisfying

(i) $X(i, j) \in R(i) \cap C(j)$;

(ii) $i \neq i' \Rightarrow X(i, j) \neq X(i', j)$;

(iii) $j \neq j' \Rightarrow X(i, j) \neq X(i, j')$.

Question: Do there exist values $X'(i, j)$ for all $(i, j) \in \mathcal{N}$ satisfying (i), (ii), and (iii) above, such that $X'(i_0, j_0) \neq X(i_0, j_0)$ for some i_0, j_0?

THEOREM 5.4. CTNU *is* NP-*complete.*

Proof. Membership in NP is obvious, since we can guess X' and easily verify the required conditions in polynomial time.

The key to the proof of NP-completeness is the observation that the polynomial-time transformation from LSC to PLSC given in the proof of Theorem 4.1 can, with relatively minor adjustments, be made parsimonious, i.e., so that there is a one-to-one correspondence between solutions to the original LSC instance and solutions to the derived PLSC instance. Hence, this parsimonious version gives us a polynomial-time transformation from LSNU to PLSNU, and in view of Theorem 5.3, establishes the NP-completeness of the latter problem. It remains to describe the details of this parsimonious transformation.

Define n', λ, and μ as in the proof of Theorem 4.1; recall that n' denotes the size of the derived instance of PLSC. As before, the set $\mathcal{N}$ of free cells is constructed as a disjoint union of component sets $\mathcal{N}_{ij}$. For each i, j in the range $1 \leq i, j \leq n$ define

$$\mathcal{N}_{ij} = \{(k, l), (k, k), (l, k) : l + 1 \leq k \leq m\} \cup \{(i, l), (l, j)\},$$

where $l = \lambda(i, j)$ and $m = \mu(i, j)$. (Note that at this point the construction diverges somewhat from that employed in the proof of Theorem 4.1.) As before we define $\mathcal{N} = \bigcup_{ij} \mathcal{N}_{ij}$.

We now specify the row and column sets. For k in the range $1 \leq k \leq n$, set $R(k) = C(k) = N$. For k outside this range, i.e., for $n + 1 \leq k \leq n'$, let $i, j \in N$ be the unique integers satisfying $\lambda(i, j) \leq k \leq \mu(i, j)$. Let $l = \lambda(i, j)$, $m = \mu(i, j)$, $s = |S(i, j)|$, and let $\{v_1, \ldots, v_s\}$ be an enumeration of the elements of the set $S(i, j)$. Then define

$$R(k) = C(k) = \begin{cases} S(i, j), & \text{if } k = l; \\ \{v_{k-l}, v_{k-l+1}\}, & \text{otherwise.} \end{cases}$$

It can be checked that R, C, and $\mathcal{N}$ together form a consistent instance of PLSC. This completes the construction. Figure 4 is intended to illustrate a fragment of the derived instance of

PLSC, and features the rows and columns that lie within the range $[l, m]$. (The conventions employed here are the same as those of Fig. 2.) For this example, we have again taken $S(i, j) = \{1, 2, 3, 4\}$. The intention is that this 4×4 square should replace the 4×4 square at the bottom-right corner of Fig. 3.

	$\{1,2,3,4\}$	$\{1,2\}$	$\{2,3\}$	$\{3,4\}$
$\{1,2,3,4\}$	—	$\underline{1}, 2$	$\underline{2}, 3$	$3, \underline{4}$
$\{1,2\}$	$\underline{1}, 2$	$1, \underline{2}$	—	—
$\{2,3\}$	$\underline{2}, 3$	—	$2, \underline{3}$	—
$\{3,4\}$	$3, \underline{4}$	—	—	$\underline{3}, 4$

FIG. 4. *A fragment of the derived instance of* PLSC.

The verification of the reduction relies on the following observation. Let Y be any partial Latin square that is consistent with the derived instance of PLSC. Consider the restriction of Y to the set $\mathcal{N}_{ij}$. Recall that $\{v_1, \dots, v_s\}$ is an enumeration of the set $S(i, j)$, and suppose that $Y(i, l) = v_t$. Observe that column l of Y is completely forced: from cell $(l+1, l)$ to cell (m, l) the entries must read $v_1, v_2, \dots, v_{t-1}, v_{t+1}, v_{t+2}, \dots, v_s$; these entries constrain the diagonal, which from cell $(l + 1, l + 1)$ to cell (m, m) must read $v_2, v_3, \dots, v_t, v_t, v_{t+1}, \dots, v_{s-1}$; these in turn constrain row l, which from cell $(l, l + 1)$ to (l, m) must read $v_1, v_2, \dots, v_{t-1}$, $v_{t+1}, v_{t+2}, \dots, v_s$. Figure 4 illustrates the pattern that emerges when $v_1 = 1$, $v_2 = 2$, $v_3 = 3$, $v_4 = 4$, and $t = 3$.

It follows from this chain of reasoning that $Y(l, j) = v_t = Y(i, l)$. Moreover, once $Y(i, j)$ has been chosen, there is precisely one way to extend Y to the remaining cells in $\mathcal{N}_{ij}$. Armed with this observation, the validation of the reduction proceeds as in the proof of Theorem 4.1; the reduction is clearly parsimonious. □

6. The case of "slice" sums. In an alternative extension to three dimensions of the original two-dimensional problem, suppose that we are given the sums of all two-dimensional "slices" of a three-dimensional table rather than the sums of the one-dimensional rows, columns, and files. In practice, for example, we might be given the row and column sums for three two-dimensional tables relating each pair of three distinct attributes of a population. Such a population could be represented in a three-dimensional table relating all three attributes, and the row and column sums for the two-dimensional tables would translate into the sums of the two-dimensional slices in the three-dimensional table.

The question arises as to the status, in this context, of problems corresponding to those investigated in earlier sections when row, column, and file sums are given. We conclude by summarizing the main results that hold for this version of the problem. They are again NP-completeness results, with the notable exception of the contingency table problem.

Consider an $n \times n \times n$ table D of nonnegative integer values $D(i, j, k)$, and define the slice sums

$$X(i) = \sum_{j,k} D(i, j, k),$$

$$Y(j) = \sum_{i,k} D(i, j, k),$$

$$Z(k) = \sum_{i,j} D(i, j, k).$$

The following theorem and corollary are analogous to the results established by Gusfield in [3, §5] and can be proved by similar methods, with a simple induction argument replacing the use of network flow.

THEOREM 6.1. *Suppose that, for each i, j, k, we are given nonnegative integer values $X(i)$, $Y(j)$, $Z(k)$ such that $\sum_i X(i) = \sum_j Y(j) = \sum_k Z(k) = T$. Then there exists a table D for which $X(i)$, $Y(j)$, and $Z(k)$ are the slice sums. Furthermore, the tightest upper and lower bounds on the value of $D(i, j, k)$ are* $\min(X(i), Y(j), Z(k))$ *and* $\max(0, X(i) + Y(j) + Z(k) - 2T)$, *respectively.*

COROLLARY 6.2. *In the context of the previous theorem, only the cells in the slice with the largest sum can have a nonzero lower bound, and this can happen only if that slice has sum $> 2T/3$.*

The results of the above theorem contrast with the NP-completeness of the corresponding problem when row, column, and file sums are given (3DCT) and perhaps give us some hope that, when the values of some cells are revealed as well as the slice sums, there may be polynomial-time algorithms to determine a legal solution and to identify compromised cells. However, this turns out not to be so.

As far as finding a legal solution is concerned, it is not hard to see that the special case in which all slice sums over suppressed cells are equal to 1 is just the three-dimensional matching problem, which is well known to be NP-complete [2].

Finally, the problem of identifying compromised cells in this context can be proved NP-complete by a reduction and argument similar to, but easier than, that used in the proof of Theorem 5.3.

AN NC ALGORITHM FOR SCHEDULING UNIT-TIME JOBS WITH ARBITRARY RELEASE TIMES AND DEADLINES*

GREG N. FREDERICKSON† AND SUSAN H. RODGER‡

Abstract. The problem of scheduling n unit-time jobs with real-valued release times and deadlines is shown to be in NC. The solution is based on characterizations of a canonical schedule and best subset of jobs to be scheduled in a given time interval. The algorithm runs on a CREW PRAM in $O((\log n)^2)$ time and uses $O(n^4/\log n)$ processors.

Key words. parallel algorithm, scheduling, release time, deadline

1. Introduction. A major goal in the study of parallel algorithms is the elucidation of the underlying combinatorial structure of problems. A wealth of insight has been generated by designing parallel algorithms for problems in such areas as graph theory, algebra and arithmetic, and computational geometry [KR]. To a lesser extent, parallel algorithms have been reported in scheduling theory [DUW], [HM1], [HM2]. In this paper we focus on a fundamental problem in scheduling theory and identify significant features of it that lead to an NC algorithm. The problem is to find a schedule for a set of jobs on a single processor, where the jobs each have unit-time processing requirements and real-valued release times and deadlines.

Our problem is intermediate in conceptual difficulty between the following two variations. The first variation has integral release times and deadlines in addition to unit processing times, and can be solved sequentially by the earliest-deadline-first rule [H] and in parallel by a parallel implementation of this rule [AGK], [DS], [R]. The second variation has unequal processing times, and has been shown to be NP-complete [GJ]. Our problem was posed as open in [GJ] as to whether it is polynomially solvable or NP-complete. It was shown in [C], [S1] that the problem is polynomially solvable, and an $O(n \log n)$-time algorithm was presented in [GJST]. Polynomial-time algorithms for finding a multiprocessor schedule were given in [S2] and [SW]. These approaches appear inherently sequential, and the problem is challenging in a parallel regimen for the following reason. Since the release times and deadlines are arbitrary real values, the appropriate scheduling choice at a given time might be to schedule no job and allow some fraction of idle time until another job's release time is reached. These choices can be affected by jobs whose release times and deadlines are far from such a decision point, making it difficult to resolve such choices "locally." We show how to work around this difficulty, and present an algorithm that uses $O((\log n)^2)$ time and $O(n^4/\log n)$ processors on a CREW PRAM.

We sketch our approach briefly and indicate the features that make this approach possible. The set of jobs is partitioned into subsets based on their release times, such that each subset has associated with it a time interval, which contains the release times of the jobs in the subset. For each such interval, a "best" set of jobs is tentatively chosen, from among those jobs assigned to the interval, to be scheduled within the interval. This best set is such that the jobs that are not chosen have the largest deadlines among all such sets. (These notions are defined precisely

later.) A balanced binary tree structure is imposed on the intervals, taking as leaves of the tree the intervals from earliest to latest, and having the nonleaf nodes represent new intervals that span the intervals of their children. The algorithm then sweeps up through the tree, computing best sets. For two consecutive time intervals I_1 and I_2, where I_1 precedes I_2, the set of jobs tentatively chosen to be scheduled in the spanning interval I is generated (roughly) as follows. This set will include the set of jobs tentatively chosen for I_1 plus a best set selected from jobs chosen from I_2 unioned with jobs not chosen from I_1.

This basic approach is fairly straightforward, but its correctness is not. Choosing best sets allows maximum flexibility in scheduling, since the jobs not chosen to be scheduled in the interval must be scheduled at a later time. But it is far from obvious that such best sets exist for any given time interval. We show in a lengthy proof by contradiction that best sets do in fact exist. The proof uses a nonobvious measure of the size of a problem. Furthermore, it is not obvious that the set of jobs not chosen in I_2 would also not be chosen in I. The correctness of this assertion depends on an involved proof by contradiction that is similar to the proof of the existence of a best set.

There is a crucial feature of our solution that we have not yet discussed. In order to be able to insert idle time into the schedule, each time interval mentioned above must actually represent a family of $O(n^2)$ time intervals, whose starting times differ by less than 1, and whose ending times differ by less than 1. In combining sets of chosen jobs for the families of intervals for I_1 and I_2, each interval in the family for I results from considering $O(n)$ combinations of individual intervals, one from I_1 and one from I_2. Some of the combinations do not necessarily result in a schedule. To test feasibility, we use what we call a "template." A template is formed using the set of jobs whose deadlines are in the given interval. From among all sets of these jobs that can be scheduled within the interval, the template is the set of deadlines that is smallest among such sets of jobs. We prove that such a template exists. The proof yields an elegant mirror-image approach to computing the set.

Our paper is organized as follows. In §2 we prove the existence of a canonical form for schedules, which is based on certain types of time intervals that we identify. In §3 we extend our characterizations to prove the existence of best sets and establish properties that lead to their fast computation. In §4 we present our NC algorithm in its entirety and analyze its performance.

2. Properties of intervals and schedules. In this section we identify a canonical form for schedules that we use in our parallel divide-and-conquer algorithm. The canonical form contains two types of time intervals induced by a set of jobs. In a "prime interval," certain jobs must be scheduled within the interval, and these jobs can always be tightly packed together. We identify a maximal set of prime intervals that are "compatible," called "cover intervals." The intervals that fall between consecutive cover intervals, called "gaps," are the more difficult to schedule. When no additional jobs can be scheduled in a gap, then the jobs can be tightly packed together in two groups, separated by a section of free space in which no job is scheduled. We show that for every schedule, there is a corresponding canonical schedule. This notion of a canonical schedule forms the basis of further characterizations in §3.

We first define some basic terms and establish some simple properties. Each job i has a release time r_i, a deadline d_i, and it should be processed for one unit of time in the interval $[r_i, d_i)$. The interval is closed on the left end to indicate that the job can start at r_i, and the interval is open on the right end to indicate that the job should be completed by d_i. Let s_i be the start time of job i and c_i be the completion time of job i, $c_i = s_i + 1$. The interval $[s_i, c_i)$ represents the time job i is processed. A *schedule* is an assignment of start times to jobs, such that the difference between the start times of any two jobs is at least one and for each job i,

$r_i \le s_i$ and $c_i \le d_i$. A set of jobs can be *scheduled in an interval* $[a, b)$ if and only if there is a schedule of the jobs such that for each job i, $s_i \ge a$ and $c_i \le b$.

Our approach is based on considering time intervals with certain interesting properties. We say that a job i is *contained* in an interval $[a, b)$ if and only if $a \le r_i$ and $d_i \le b$. We consider intervals $[a, b)$ such that $a = r_i$ for some job i contained in $[a, b)$ and $b = d_j$ for some job j contained in $[a, b)$. An interval $[a, b)$ has *looseness* x if and only if there are precisely $b - a - x$ jobs contained in it. If any interval has negative looseness, then no schedule is possible. We shall assume for the remainder of this section that all intervals have nonnegative looseness.

We are now ready to define an interval such that the jobs contained within it are easy to identify and easy to schedule. A *constrained interval* is an interval whose looseness is less than 1. A *prime interval* is a constrained interval $[a, b)$ such that there is no constrained interval $[a', b')$ properly contained in $[a, b)$. Figure 1(a) shows a set of jobs. Each job is represented by an interval in which the left endpoint is its release time and the right endpoint is its deadline. There are quite a few constrained intervals in Fig. 1(a). One constrained interval is [7.2, 11.1), which contains three jobs, 4, 5, and 6, and has looseness 0.9. It is not a prime interval because the constrained interval [8.0, 10.4) is contained in it. The prime intervals in Fig. 1(a) are [8.0, 10.4), [13.0, 15.6), and [13.6, 16.3).

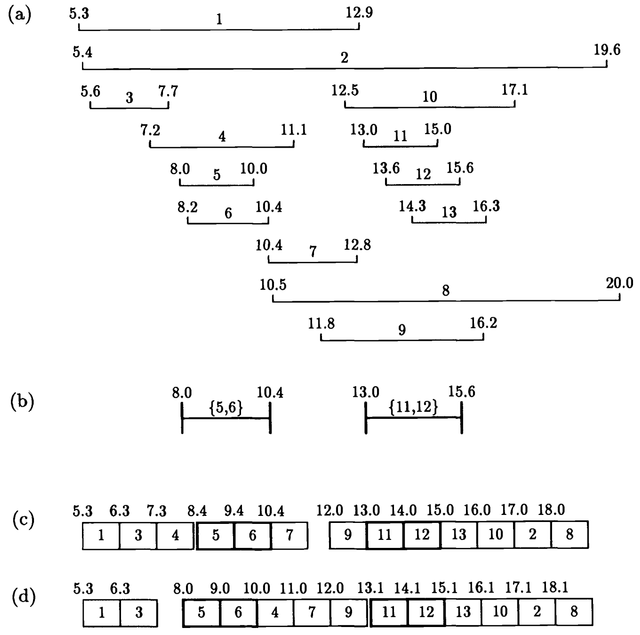

FIG. 1. (a) *A set of jobs with release times and deadlines*; (b) *A cover for this set of jobs*; (c) *A schedule for anchored gaps* [5.3, 8.4), [10.4, 13.0) *and* [15.0, 20.0); (d) *A schedule for anchored gaps* [5.3, 8.0), [10.0, 13.1), *and* [15.1, 20.0).

A prime interval is useful, because the jobs that must be scheduled within the interval can be packed tightly together with no free space between them and with a variable amount of free space on either end of the interval. We prove this in the following lemma.

LEMMA 2.1. *Let $[a, b)$ be a prime interval with looseness x. For any y, $0 \le y \le x$, the jobs contained in $[a, b)$ can be scheduled in the interval $[a + y, b - x + y)$.*

Proof. Suppose that the jobs contained in $[a, b)$ cannot be scheduled in the interval $[a + y, b - x + y)$ for some value y, $0 \leq y \leq x$. Without loss of generality, assume that $a + y$ is an integer. (Otherwise, we can subtract $a + y - \lfloor a + y \rfloor$ from all values to generate an equivalent problem.) For each job i contained in $[a, b)$, set $r_i' = \lceil r_i \rceil$, and $d_i' = \lfloor d_i \rfloor$. The resulting jobs are called *modified*. Since all r_i' and d_i' are integers, and there is no schedule for the modified jobs, then there must be an interval $[a', b')$ properly contained in $[a, b)$, with a' and b' integers, such that there are at least $b' - a' + 1$ modified jobs contained in $[a', b')$. Let a'' be the earliest release time of an original job whose corresponding modified job is contained in $[a', b')$, and let b'' be the latest deadline of an original job whose corresponding modified job is contained in $[a', b')$. Then there are at least $b' - a' + 1$ original jobs in the interval $[a'', b'')$, which is of length $b'' - a'' < (b' + 1) - (a' - 1) = b' - a' + 2$. Thus the interval $[a'', b'')$ has looseness less than 1, i.e., it is a constrained interval. Furthermore, interval $[a'', b'')$ is properly contained in $[a, b)$, for the following reason. Since $b' - a' + 1 \leq (b - x + y) - (a + y)$, and a', b', $a + y$ and $b - x + y$ are all integers, either $a' \geq a + y + 1$ or $b' \leq b - x + y - 1$. Thus either $a'' > a' - 1 \geq a + y$ or $b'' < b' + 1 \leq b - x + y$, and it follows that $[a'', b'')$ is properly contained in $[a, b)$. This is a contradiction to the original assumption that $[a, b)$ is a prime interval. It follows that the original jobs can be scheduled in $[a + y, b - x + y)$. □

Within isolated prime intervals, jobs are easy to schedule, but when these intervals overlap, a schedule in one interval affects the schedule in the other. Two prime intervals $[a, b)$ and $[a', b')$, with $a < a'$, are *compatible* if and only if $b - a' < 2$. If two prime intervals are compatible, then they do not contain a common job. This can be shown as follows. Suppose each interval contained job i. Then $a' \leq r_i < d_i \leq b$, which implies that $d_i - r_i < 2$, and thus $[r_i, d_i)$ would be a constrained interval contained inside an interval $[a, b)$ claimed to be prime. This is not possible.

Because of the incompatibility of certain prime intervals, we focus on a subset of the set of all prime intervals. A maximal set of prime intervals that are pairwise compatible is a *cover* for the set of jobs. A cover is shown in Fig. 1(b). Jobs 5 and 6 must be scheduled in [8.0, 10.4) (indicated by {5, 6} in the figure), and jobs 11 and 12 must be scheduled in [13.0, 15.6). Not all prime intervals are compatible. The prime interval [13.6, 16.3) is not part of the cover since [13.0, 15.6) and [13.6, 16.3) are not compatible. Both of these prime intervals contain job 12. For any two compatible prime intervals that overlap, the jobs in the prime interval with the smaller left endpoint are scheduled before the jobs in the other prime interval. For example, if job 4 in Fig. 1 had deadline 8.6, then there would be an additional prime interval in the cover, [7.2, 8.6), that contains job 4. The compatible prime intervals [7.2, 8.6) and [8.0, 10.4) overlap, so job 4 would have to be scheduled before jobs 5 and 6.

The precise scheduling of jobs contained in the prime intervals of a cover, called *cover intervals*, is dependent on the scheduling of the jobs not contained in those intervals. Given a cover, let $[a, b)$ and $[a', b')$ be two consecutive cover intervals. The *gap* between intervals $[a, b)$ and $[a', b')$ is the interval $[a'', b'')$, where $a'' = a + \lfloor b - a \rfloor$ and $b'' = b' - \lfloor b' - a' \rfloor$. The value a'' is the theoretically earliest possible time after a at which a job not contained in $[a, b)$ can be started in a schedule, and b'' is the latest possible time before b' at which a job not contained in $[a', b')$ can be completed. Note that if the looseness of $[a, b')$ is 0, then gap $[a'', b'')$ constitutes the empty interval. Of course, whether a job can actually start at a'' in a schedule depends on whether the jobs contained in $[a, b)$ are scheduled to complete by a''. It is important to maintain this flexibility in the definition of a gap. If two cover intervals overlap, then in any schedule the gap between them will either be empty or will contain precisely one job, which is not contained in either of the cover intervals. If $b'' - a'' < 1$, then in any schedule a job that is not contained in a cover interval will not be scheduled in the gap.

For uniformity, we require that each gap is always surrounded by two cover intervals. This is easily taken care of by adding a cover interval with looseness 0 at the beginning and end of the schedule. Let $r_{\min}$ be the minimum release time and $d_{\max}$ the maximum deadline in the problem. Two new jobs are introduced, job $n+1$ with $r_{n+1} = r_{\min} - 1$ and $d_{n+1} = r_{\min}$, and job $n+2$ with $r_{n+2} = d_{\max}$ and $d_{n+2} = d_{\max} + 1$. This forces two new cover intervals, $[r_{n+1}, d_{n+1})$ and $[r_{n+2}, d_{n+2})$, to be included in the cover. Clearly, the original n jobs can be scheduled if and only if the new set of $n+2$ jobs can be scheduled. In Fig. 1, two additional jobs would be added on the ends of the overall interval, job 14 with $r_{14} = 4.3$ and $d_{14} = 5.3$ and job 15 with $r_{15} = 20.0$ and $d_{15} = 21.0$. This would result in cover intervals on the ends of the overall interval; these are not shown.

We restrict our attention to specific subintervals of gaps. For a given cover, let $[a, b)$ and $[a', b')$ be two consecutive cover intervals with looseness x and x', respectively. An *anchored gap* is an interval $[a'', b'')$, where $b - x \leq a'' \leq b$, $a' \leq b'' \leq a' + x'$, a'' differs from some release time by an integer, and b'' differs from some release time by an integer. At least one anchored gap $[b - x, a' + x')$ for gap $[b, a')$ exists, since the looseness of $[a, b')$ is by assumption at least 0. If $x + x' = 0$ and $b = a'$, then we say that there is one anchored gap for gap $[b, a')$, namely $[b, a')$, which is empty. Since each of a'' and b'' can be one of at most n values, there are at most n^2 anchored gaps for any gap.

If there is a schedule of jobs in an anchored gap that almost fills the anchored gap, then there is a schedule in which the jobs are packed together in two groups with free space between the two groups. For a given schedule, a *hole* in an anchored gap $[a'', b'')$ is a nonempty interval $[a''', b''')$ contained in $[a'', b'')$, such that no jobs are scheduled in $[a''', b''')$ and both $a''' - 1$ and b''' are start times for jobs in the schedule.

LEMMA 2.2. *For any set of jobs that has a schedule S, and for any cover for the set of jobs, there is a schedule S' such that for each anchored gap $[a, b)$ that has $\lfloor b - a \rfloor$ jobs scheduled within it, there is at most one hole in the anchored gap.*

Proof. Let $[a, b)$ be an anchored gap in S that has $\lfloor b - a \rfloor$ jobs scheduled in it. We claim that there is a schedule of the jobs in the anchored gap such that there is only one hole within it. The proof of the claim is by induction on h, the number of jobs scheduled between first and last holes in $[a, b)$. For the basis, with $h = 0$, the claim is trivially satisfied. For the induction step, with $h > 0$, assume that the claim holds whenever there are fewer than h jobs scheduled between the first and last holes of $[a, b)$. Let $[a_1, b_1)$ be the first hole in $[a, b)$ and let $[a_l, b_l)$ be the last hole in $[a, b)$. We shall show that some of the jobs scheduled in $[b_1, a_l)$ can be scheduled starting at a_1 or finishing at b_l, thus reducing the number of jobs scheduled between the first and last holes.

For each job i scheduled in $[b_1, a_l)$, temporarily reset the release time r_i to be $r'_i = \max\{r_i, a_1\}$ and the deadline d_i to be $d'_i = \min\{d_i, b_l\}$. Since each such job i is scheduled in $[b_1, a_l)$, the schedule would still be valid if we had reset r_i to be $\max\{r_i, b_1\}$ and d_i to be $\min\{d_i, a_l\}$. Since $a_1 < b_1$ and $b_l > a_l$, the resetting we actually do is no more restrictive, and thus the schedule is still valid. Let $a' = \min\{r'_i\}$ and $b' = \max\{d'_i\}$. Since $[a, b)$ contains $\lfloor b - a \rfloor$ jobs, and $(b_1 - a_1) + (b_l - a_l) < 1$, we have $(b_1 - a') + (b' - a_l) < 1$. Thus $[a', b')$ is a constrained interval with respect to the modified release times and deadlines. Note that if both $a' > a_1$ and $b' < b_l$, then $[a', b')$ would be a constrained interval with respect to the original release times and deadlines, and would be compatible with all cover intervals, a contradiction to the cover being maximal.

Without loss of generality, assume $a' = a_1$. (The argument for $b' = b_l$ is similar.) Now identify the smallest value $b'' < b'$ such that $[a_1, b'')$ is a constrained interval with respect to the modified release times and deadlines. Any interval that is a constrained interval with respect to the modified release times and deadlines and is contained within $[a', b')$ must have either a' or b' as an endpoint. Thus $[a_1, b'')$ does not properly contain a constrained interval, and is thus a prime interval with respect to the modified release times and deadlines. The set of jobs whose scheduled positions in S overlap with $[a_1, b'')$ is precisely the set of jobs contained in $[a_1, b'')$ with respect to the modified release times and deadlines. By Lemma 2.1, this set of jobs can be scheduled in $[a_1, a_1 + \lfloor b'' - a_1 \rfloor)$. The remaining jobs are scheduled as they were in S. Thus the first hole will now begin at $a_1 + \lfloor b'' - a_1 \rfloor$ rather than a_1, and there will be $h - \lfloor b'' - a_1 \rfloor$ jobs between the first and last holes. By the induction hypothesis, the jobs in $[a, b)$ can be rescheduled to yield just one hole. This completes the proof of the claim.

The proof of the lemma follows by handling in turn each anchored gap $[a, b)$ that has $\lfloor b - a \rfloor$ jobs scheduled in it and has more than one hole. □

A schedule of the jobs for the anchored gaps [5.3, 8.4), [10.4, 13.0), and [15.0, 20.0) is shown in Fig. 1(c). A schedule of the jobs for anchored gaps [5.3, 8.0), [10.0, 13.1), and [15.1, 20.0) is shown in Fig. 1(d). Lemma 2.2 is illustrated by these schedules. In each anchored gap the jobs can be scheduled so that there is at most one hole within the gap. Note that there is no schedule when the first anchored gap is [5.3, 8.2). This follows since jobs 3 and 4 would have to be scheduled in the first anchored gap, and jobs 1, 7, 9, 11, 12, and 13 would have to be scheduled by 16.3, with 16.2 being the earliest at which they could all be finished. But then job 10 cannot start before 16.2, and thus cannot finish by its deadline.

We now show that if there is a schedule, then there is a schedule such that the jobs are nicely packed and the starting times of the jobs are convenient values. Given a set J of jobs, a *breakpoint* is any number x such that for some job j, $x - r_j$ is an integer. Given a cover, those jobs that must be scheduled within the cover intervals are called *cover jobs*, and those jobs that are scheduled within anchored gaps are called *gap jobs*. A *canonical schedule* is a schedule in which each job starts at a breakpoint, the cover jobs are scheduled tightly together within the cover intervals, and there is at most one hole in any anchored gap $[a, b)$ in which $\lfloor b - a \rfloor$ gap jobs are scheduled. We show in the next theorem that we can restrict our algorithm to finding a canonical schedule.

THEOREM 2.1 (canonical schedule). *For any set of jobs that has a schedule and for any cover for the set of jobs, there is a corresponding canonical schedule.*

Proof. Consider any schedule S and any cover for the set of jobs. Consider any cover interval $[a, b)$ with looseness x. The jobs contained in $[a, b)$ will be the only jobs completely scheduled in $[a, b)$, since $x < 1$. Let $a + y$ be the earliest start time of any of these jobs. By Lemma 2.1, the jobs contained in $[a, b)$ can be scheduled in $[a + y, b - x + y)$, which means that they are scheduled without any free space between them. It follows that there is a schedule S' such that for each cover interval, the cover jobs are scheduled without any free space between them within the cover interval. Given S', Lemma 2.2 establishes that there is a schedule S'' such that there is only one hole in each anchored gap $[a, b)$ that has $\lfloor b - a \rfloor$ jobs scheduled in it.

We derive a canonical schedule S''' from S'' that preserves the same order of the jobs, though it may shift their start times. For this discussion, consider there to be one additional hole, that starts when the last job completes. Consider the first hole $[a_1, b_1)$ in the schedule, and let J_1 be the set of jobs with start times before a_1. Let y_1 be the maximum value that can be subtracted from the start of each job in J_1 such that a schedule still remains. Subtract y_1 from each such start time. Clearly, some job in J_1 is starting at its release time, and all the rest start at a time that differs from this time by an integer. For each succeeding hole $[a_i, b_i)$, $i > 1$, let J_i be the set of jobs scheduled between this hole and the preceding one. Let y_i be the maximum value that can be subtracted from the start of each job in J_i such that a schedule still remains. Subtract y_i from each such start time. Clearly, either some job in J_i is starting at its release time, or the start time of the first job in J_i equals the completion time of the last job in J_{i-1}. In the latter case, each job starts at a time that differs from some release time by an integer, by transitivity. Thus each job in S''' starts at a time that differs from some job's release time by an integer. It follows that S''' is a canonical schedule. □

By Theorem 2.1, we can limit deadlines to being breakpoints. Thus we may assume as preprocessing that each deadline d_j is reset to the largest breakpoint no larger than d_j. Alternatively, breakpoints could be defined in terms of deadlines, and each release time r_j could be reset to the smallest breakpoint no smaller than r_j.

Consider the schedules in Figs. 1(c) and 1(d). In both schedules, the cover jobs are tightly scheduled together within the cover intervals, and there is at most one hole in any anchored gap. Since $r_1 = 5.3$, $r_7 = 10.4$, and $r_{11} = 13.0$, every job in the schedule in Fig. 1(c) starts at a breakpoint. Thus the schedule in Fig. 1(c) is canonical. However, since there is no job whose release time has fractional part .1, the schedule in Fig. 1(d) is not canonical.

3. Best r-sets, best d-sets, and templates.

The characterization of canonical schedules in the last section is not sufficient for designing a fast parallel algorithm. In particular, no method is implied to choose an appropriate set of jobs to be scheduled in a gap, and no method is identified for choosing suitable endpoints of a gap, in the case that its bracketing cover intervals have nonzero looseness. In this section we discuss the existence and computation of what we shall define as a "best r-set," a best choice of a subset of jobs to be scheduled in an interval. To make best r-sets unique, we shall transform problem instances so that all release times are distinct and all deadlines are distinct. A best r-set is easy to compute when the interval is a gap, but is more complicated to compute when the interval contains a collection of gaps and cover intervals. In the latter case, we first establish the existence of the best r-set, and then show how to select a subset of the jobs that will form the best r-set if there is a schedule. To identify suitable endpoints for a gap, all possible choices can be considered, with a test performed to determine if the selected jobs can be scheduled. We examine what we call a "modified mirror image problem," and identify a template of deadlines that represents the minimum set of deadlines that will result in a schedule. The template can be compared to a set of selected jobs to determine if the endpoints were suitable.

We first discuss a transformation that will give us uniqueness with respect to the best sets that we shall introduce shortly. Let a set of jobs be *simple* if all release times are distinct and all deadlines are distinct. Given a set of jobs for which a schedule exists, we can reset release times and deadlines so as to make the set of jobs simple. While either of the following operations applies, perform it. If $r_j = r_k$ and $d_j \leq d_k$ for jobs j and k, then reset r_k to be $r_j + 1$. If $r_j < r_k$ and $d_j = d_k$, then reset d_j to be $d_k - 1$. Clearly, performing these operations does not affect whether or not a schedule exists. We assume for the remainder of this section that the set of jobs in the problem instance has been transformed so as to be simple.

We first introduce the notion of feasibility with respect to an interval, and then we define what we call an r-set. Let J be a set of jobs, and $[a, b)$ an interval. Recall that a job is contained in an interval $[a, b)$ if $r_j \geq a$ and $d_j \leq b$. Let $J[a, b)$ be the subset of all jobs in J that are contained in $[a, b)$. A set J is $[a, b)$*-feasible* if there is a schedule for $J[a, b)$. If there is no schedule for $J[a, b)$, then there cannot be a schedule for J. We next consider a partition of J based on release times. Let $J_r[a, b)$ be the subset of all jobs j in J such that $r_j \in [a, b)$. Note that $J[a, b) \subseteq J_r[a, b)$. A set A is an *r-set* for $[a, b)$ with respect to J if and only if J is $[a, b)$-feasible and A is a subset of $J_r[a, b)$ such that $J[a, b) \subseteq A$ and the jobs in A can be scheduled in $[a, b)$. We choose the name r-set, where r denotes release time, to emphasize that jobs are partitioned by their release times.

Since some r-sets are better than others when constructing a schedule, we define the notion of a "best" r-set. Consider an interval $[a, b)$. Clearly, the jobs that are contained in $[a, b)$ must be scheduled in $[a, b)$. We would also like to schedule as many additional jobs as possible, and choose those jobs to be as preferable as possible. For those jobs with release times in $[a, b)$ but with deadlines greater than b, it is preferable to choose to schedule in $[a, b)$ those jobs with the smallest deadlines that can be scheduled. This strategy allows the jobs that are not chosen to have a better chance of being scheduled in a later time interval, since they have larger deadlines. For any set A of jobs, let $d(A)$ denote the (multi)set of deadlines of jobs in A. We define the partial order relation $\preceq$ on (multi)sets of values. If X and Y are two sets of values, then $X \preceq Y$ if and only if for $i = 1, 2, \ldots, \min\{|X|, |Y|\}$, $x_i \leq y_i$, where x_i is the ith smallest value in X and y_i is the ith smallest value in Y. Thus we prefer a set A of jobs over a set B of jobs with respect to their deadlines if and only if $d(A) \preceq d(B)$. If we deal with a set of jobs in which all deadlines are distinct, equality between equal-cardinality subsets A and B will hold if and only if they are identical. An r-set A for $[a, b)$ with respect to J is a *best r-set* for $[a, b)$ with respect to J if and only if for any other r-set B for $[a, b)$ with respect to J, $d(A) \preceq d(B)$ and $|A| \geq |B|$. If J is simple, then A is a unique best r-set.

We discuss examples of best r-sets, using the set of jobs in Fig. 1(a). There are 6 jobs whose release times lie in [5.3, 8.2], jobs 1, 2, 3, 4, 5, and 6. We do not consider jobs 5 and 6 since they obviously cannot be scheduled within this interval. Job 3 is contained in [5.3, 8.2), and thus must be in any r-set. Jobs 3 and 4 form the best r-set for [5.3, 8.2) as $d(\{3, 4\}) \preceq d(B)$, for B that is any of $\{3\}$, $\{1, 3\}$, and $\{2, 3\}$. Similarly, jobs 7 and 9 form the best r-set for [10.2, 13.0). The best r-set for [15.0, 20.0) is empty since there are no jobs with a release time in the interval.

We discuss the existence and computation of the best r-set for two types of intervals, the simpler interval that does not contain a constrained interval and the more complex interval that can contain constrained intervals. The first type corresponds to an anchored gap in our algorithm, and the second type corresponds to what we will call an anchored multiple gap, which we consider in the combining step of our algorithm.

We first discuss the existence and computation of the best r-set with respect to a set J of jobs for an interval $[a, b)$ that contains no constrained intervals. Clearly, J is $[a, b)$-feasible. Computing the best r-set for $[a, b)$ is straightforward. We define the *discrete earliest deadline rule* applied to the jobs in $J_r[a, b)$ as follows. For each job i, let r_i' be the smallest value no smaller than r_i such that $b - r_i'$ is an integer. Then apply the earliest deadline first rule using modified release times on the interval $[b - \lfloor b - a \rfloor, b)$. Using the earliest deadline first rule results in a set of jobs A such that $d(A) \preceq d(B)$ and $|A| \geq |B|$ for any subset B of $J_r[a, b)$ that can be scheduled in $[a, b)$.

LEMMA 3.1. *Let J be a set of jobs, and $[a, b)$ an interval, such that there is no constrained interval contained in $[a, b)$. The subset of $J_r[a, b)$ scheduled in $[a, b)$ by the discrete earliest deadline rule is a best r-set for $[a, b)$ with respect to J.*

Proof. Consider any subset A of $J_r[a, b)$ that can be scheduled in $[a, b)$. We generate a set A' of jobs with modified release times so that each differs from b by an integer. For each job $j \in A$, define job $j' \in A'$ such that $d_{j'} = d_j$ and $r_{j'}$ is the smallest value no smaller than r_j such that $b - r_{j'}$ is an integer. We show that A' can be scheduled in $[a, b)$. Suppose that no schedule of all jobs in A' is possible. Then there is an interval $[a', b')$ that contains more than $\lfloor b' - a' \rfloor$ jobs with respect to A'. Let $a'' = \min\{r_j | j \in A, j'$ is the corresponding job in A', $r_{j'} \geq a'$ and $d_j' \leq b'\}$. Since $r_j' - r_j < 1$ for each $j \in A$ and corresponding $j' \in A'$, $(a' - a'') < 1$. Thus there are at least $\lfloor b' - a' \rfloor + 1 = \lfloor b' - a'' - (a' - a'') \rfloor + 1$ $\geq \lfloor b' - a'' - 1 \rfloor + 1 = \lfloor b' - a'' \rfloor$ jobs contained in $[a'', b')$ with respect to A. Since $J_r[a, b)$ can be scheduled in $[a, b)$, there are at most $\lfloor b' - a'' \rfloor$ jobs contained in $[a'', b')$ with respect to A. Thus $[a'', b')$ is a constrained interval with respect to A, which is a contradiction to the assumption that $[a, b)$ does not contain a constrained interval. Thus it follows that all jobs in

A' can be scheduled. Thus modifying release times as in the discrete earliest-deadline-first rule does not eliminate any r-set A. Once all release times are modified, the problem is equivalent to a problem in which all release times and deadlines are integers. Then choosing the jobs with earliest-deadlines-first clearly produces a best r-set. □

We now discuss the existence of a best r-set for an interval that can contain constrained intervals. A *multiple gap* is an interval $[a, b)$ such that a is the left endpoint of a gap, b is the right endpoint of a different gap, and thus there is at least one cover interval within $[a, b)$. An *anchored multiple gap* is an interval $[a, b)$ such that a is the left endpoint of an anchored gap, b is the right endpoint of a different anchored gap, and thus there is at least one cover interval within $[a, b)$. Our algorithm will compute best r-sets, if they exist, for certain anchored multiple gaps. We now prove the existence of the best r-set for an unrestricted interval $[a, b)$ and an $[a, b)$-feasible set of jobs that is simple.

THEOREM 3.1 (best r-set). *Let $[a, b)$ be an interval, and J be an $[a, b)$-feasible set of jobs that is simple. Then there is a (unique) best r-set for $[a, b)$ with respect to J.*

Proof. The proof is by contradiction.

We define an *r-problem* P to consist of an interval $[a, b)$ and an $[a, b)$-feasible set of jobs J with distinct release times and distinct deadlines. Define a *P-breakpoint* to be either a or a breakpoint with respect to J. For any interval $[a, b)$, $a < b$, define $b \ominus a$, the *size* of $[a, b)$, to be the number of distinct P-breakpoints that lie in this interval. (We view the operation $\ominus$ as discretized subtraction, and use the symbol $\ominus$ as we would the minus sign. Thus we assume that the first operand is no smaller than the second.) Let the *size* of job i be the size of the interval $[r_i, d_i)$. Then the *size* of P is the size of interval $[a, b)$ plus the sum of the sizes of all jobs in J plus the sum of the product of sizes for all pairs of jobs in J:

$$size(P) = (b \ominus a) + \sum_{i \in J} (d_i \ominus r_i) + \sum_{i,j \in J,\ j \neq i} (d_i \ominus r_i) * (d_j \ominus r_j).$$

We consider an r-problem P, consisting of interval $[a, b)$ and set J of jobs, that is of smallest size among those r-problems that do not satisfy the theorem. Since P is of smallest size, $J_r[a, b) = J$. We shall eliminate all but two r-sets from consideration, and deduce various properties about schedules for these r-sets. We then use these properties to generate a contradiction.

Note that some job j in J has release time a, otherwise there would be a corresponding smaller r-problem P', consisting of interval $[a', b)$ and set of jobs J, where a' is the next P-breakpoint after a. P' is a smaller r-problem than P, so P' would have a best r-set A' in interval $[a', b)$. The set A' would be the best r-set for P in interval $[a, b)$, which is a contradiction to the assumption that there is no best r-set in P. Thus, there is some job j with $r_j = a$.

We restrict our attention to two r-sets in P as follows. Consider all r-sets in $[a, b)$ that have every schedule in $[a, b)$ starting at a. Then any such r-set must contain job j, and j is scheduled starting at a in such a schedule. We infer a smaller r-problem P' with interval $[a + 1, b)$ and set of jobs $J - \{j\}$. There is a best r-set A' for P'. Let $A_1 = A' \cup \{j\}$. A_1 is an r-set for P. We next consider all r-sets in $[a, b)$ that have some schedule in $[a, b)$ that does not start at a. Let a' be the next breakpoint after a. We infer a smaller r-problem P'' with interval $[a', b)$ and set of jobs J. (Note that job j will not be in any r-set for P''.) There is a best r-set A_2 for P''. This set A_2 is an r-set for P.

Any r-set A for P must satisfy either $d(A_1) \preceq d(A)$ and $|A_1| \geq |A|$, or $d(A_2) \preceq d(A)$ and $|A_2| \geq |A|$, since any schedule for A in $[a, b)$ either starts at a or it does not start at a. Thus we can confine our attention to the r-sets A_1 and A_2. Note that each job in J must appear in either A_1, A_2, or both. Otherwise we could remove such a job and get a smaller r-problem. The smaller r-problem would have a best r-set, which would then be the best r-set for P, a contradiction. By Theorem 2.1, canonical schedules exist for A_1 and A_2. Let S_1 be a canonical schedule for A_1 in $[a, b)$, and S_2 be a canonical schedule for A_2 in $[a', b)$. We note several properties of S_1 and S_2.

CLAIM 3.1. *Every job that is scheduled in both S_1 and S_2 starts at its release time in one of the schedules and completes at its deadline in the other schedule. If a job is scheduled in just one of S_1 and S_2, then the job starts at its release time in that schedule, and its deadline is greater than b.*

Proof of claim. Let k be a job in J that is scheduled in either S_1, S_2, or both. Let s_k be k's earliest starting time in the two schedules. Suppose $r_k < s_k$. We generate a new r-problem P' by resetting r_k to s_k. Note that resetting r_k does not generate any new breakpoints, since choosing S_1 and S_2 to be canonical schedules guarantees that s_k is a breakpoint. Also note that if this causes J to no longer be simple, we can just apply the appropriate operations to reset release times. P' is a smaller r-problem since the size of job k (and possibly some other jobs) has been reduced. Since P' is smaller than P, there is a best r-set A' in P'. Schedules S_1 and S_2 are both schedules in P'. Thus A_1 and A_2 are both r-sets in P', so $d(A') \preceq d(A_1)$ and $|A'| \geq |A_1|$, and $d(A') \preceq d(A_2)$ and $|A'| \geq |A_2|$. Thus A' is the best r-set for P, which is a contradiction to the assumption that there is no best r-set in P. Thus $r_k = s_k$ for all k in J.

Suppose that k is scheduled in both S_1 and S_2 and let c_k be k's latest completion time in the two schedules. Suppose $d_k > c_k$. We generate a smaller r-problem P' by resetting d_k to c_k. Again we perform any additional operations needed to keep J simple. Since P' is smaller than P, there is a best r-set A' in P'. Note that any job other than k whose deadline is reset must have its deadline be at most b, and is thus in every r-set for P and for P'. Since both A_1 and A_2 also contain any job whose deadline is reset, $d(A') \preceq d(A_1)$ for P' if and only if $d(A') \preceq d(A_1)$ for P, and similarly for A' and A_2. Also note that $|A'| \geq |A_1|$ and $|A'| \geq |A_2|$. Since for any r-set A for P, either $d(A_1) \preceq d(A)$ or $d(A_2) \preceq d(A)$, A' is a best r-set for P, which is a contradiction to the assumption that there is no best r-set in P. Thus $d_k = c_k$ for all k in J.

Suppose job k is scheduled in just one of S_1 and S_2. Since $J = J_r[a, b)$ and J is $[a, b)$-feasible, any job in J with deadline at most b must be scheduled in both S_1 and S_2. Since job k is not in both S_1 and S_2, $d_k > b$. This completes the proof of Claim 3.1.

In the remainder of the proof, if resetting a release time or deadline causes J to no longer be simple, we apply the appropriate operations, as in the proof of the last claim, to make J simple once again. We note that whenever a deadline is changed, the job will appear in every corresponding r-set. Thus comparisons between the deadlines of r-sets using $\preceq$ are not affected.

For schedule S_p, where $p = 1$ or $p = 2$, and for any job h in J that is scheduled in S_p, let s_h^p be the start time of h in S_p and c_h^p be the completion time of h in S_p. We say that the scheduled position of a job g in S_1 *overlaps* that of job h in S_2 if and only if $\max\{s_g^1, s_h^2\} < \min\{c_g^1, c_h^2\}$.

CLAIM 3.2. *For any job that is scheduled in both S_1 and S_2, its scheduled positions in the two schedules overlap.*

Proof of claim. Suppose the claim is false. Let k be the job with the smallest deadline that is scheduled in both S_1 and S_2 such that its scheduled positions in the two schedules do not overlap.

We introduce five transformations for generating smaller r-problems that result in contradictions. The first is called an *exchange-d* transformation. Let g and h be jobs in J with $r_h < r_g$, $d_h < d_g$, and $s_h^p < s_g^p \leq s_h^{3-p}$, where $p = 1$ or $p = 2$. By Claim 3.1, it follows that $s_h^p = r_h$, $s_g^p = r_g$, $c_h^{3-p} = d_h$, and $c_g^{3-p} = d_g$. We transform r-problem P into a new r-problem P' by replacing jobs h and g with jobs h' and g', where $r_{h'} = r_h$, $d_{h'} = d_g$, $r_{g'} = r_g$, and $d_{g'} = d_h$. We call this transformation an exchange-d, because we exchange the deadlines for h and g. Schedules S_{3-p} and S_p for P are easily transformed into corresponding schedules

S'_{3-p} and $S_p{}'$ for P' in the following way. Schedule S'_{3-p} will be the same as S_{3-p}, except that g' will be in the position of h, and if g is in S_{3-p} then h' will be in the position of g. Schedule S'_p will be the same as S_p, except that h' will be in the position of h, and g' in the position of g. Thus the sets A'_{3-p} and A'_p corresponding to A_{3-p} and A_p are r-sets in P'. Figure 2 illustrates the exchange-d transformation of a problem P (which has schedules S_1 and S_2) into a problem P' (which has schedules S'_1 and S'_2). The release time-deadline intervals for the relevant jobs are also shown.

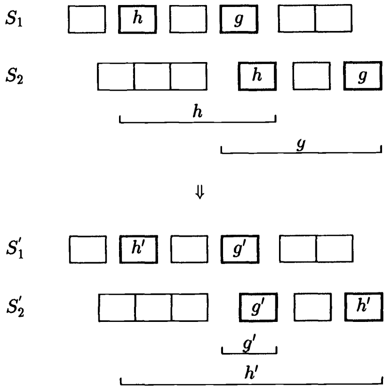

FIG. 2. *An exchange-d transformation.*

A schedule S' in P' can be transformed to a schedule S in P in the following way. Any job in S' that is not h' or g' is scheduled in the same position in S. Note that g' must be scheduled in S', and h' may or may not be scheduled in S'. If h' is scheduled overlapping in $[r_{h'}, r_{g'})$, then h is scheduled in S in the position of h' in S' and g is scheduled in S in the position of g' in S'. Otherwise, h is scheduled in S in the position of g' in S', and if h' is scheduled in S', then g is scheduled in S in the position of h' in S'. Any set A in P whose corresponding set A' in P' is an r-set in P' is itself an r-set in P. The size of P' is smaller than the size of P since

$$\begin{aligned}(d_g \ominus r_h) * (d_h \ominus r_g) &< ((d_g \ominus r_h) * (d_h \ominus r_g)) + ((d_g \ominus d_h) * (r_g \ominus r_h))\\ &= ((d_g \ominus r_h) * (d_h \ominus r_g)) + (d_g \ominus d_h) * ((d_g \ominus r_h) - (d_g \ominus d_h) - (d_h \ominus r_g))\\ &= ((d_g \ominus r_h) - (d_g \ominus d_h)) * ((d_h \ominus r_g) + (d_g \ominus d_h))\\ &= (d_h \ominus r_h) * (d_g \ominus r_g).\end{aligned}$$

Thus P' has a best r-set A', which is at least as large as any r-set of P. For set B as any of A_{3-p}, A_p or A, h is in B if and only if g' is in B', and g is in B if and only if h' is in B'. Thus for set B as any of A_{3-p}, A_p or $A, d(B) \preceq d(B')$ and $d(B') \preceq d(B)$. Since $d(A') \preceq d(A'_{3-p})$ and $d(A') \preceq d(A'_p)$, we have $d(A) \preceq d(A_{3-p})$ and $d(A) \preceq d(A_p)$, and thus A is a best r-set for P, which is a contradiction to the assumption that P does not have a best r-set. Thus whenever an exchange-d transformation can be applied, a contradiction can be achieved. This concludes the discussion of an exchange-d transformation.

The second transformation is called a *compress* transformation. Let g and h be jobs in J with $c_g^p = s_h^p$, $c_g^{3-p} = s_h^{3-p}$, and $s_h^p \leq s_h^{3-p} < c_h^p$, where $p = 1$ or $p = 2$. By Claim 3.1, it follows that $s_g^p = r_g$, $s_h^p = r_h$, $c_g^{3-p} = d_g$, and $c_h^{3-p} = d_h$. We generate a new r-problem P' in which the jobs g and h are compressed into one job h' such that $r_{h'} = r_h$ and $d_{h'} = d_h$. For any job i with $r_i < r_g$, reset r_i to $r_i + 1$. For any job i with $d_i < d_g$, reset d_i to $d_i + 1$. Reset a to $a + 1$. Note that the sets A'_{3-p} and A'_p in P' that correspond to A_{3-p} and A_p in P are r-sets in P'. The new r-problem P' is smaller than P since there is one fewer job, $(b \ominus a)$ is smaller, and $(d_i \ominus r_i)$ is no larger for any remaining job i. Thus P' has a best r-set A'. Let $A = A' \cup \{g, h\} - \{h'\}$. Then A is an r-set for P and is of maximum size among r-sets for P. Note that any job other than g or h that has its deadline changed must be in every r-set for P' and in every r-set for P. By Claim 3.1, $d_g < b$. It follows that $d(A) \preceq d(A_{3-p})$ and $d(A) \preceq d(A_p)$. Thus A is a best r-set for P, which is a contradiction to our initial assumption. Thus whenever a compress transformation can be applied, a contradiction can be achieved. Figure 3 illustrates the compress transformation.

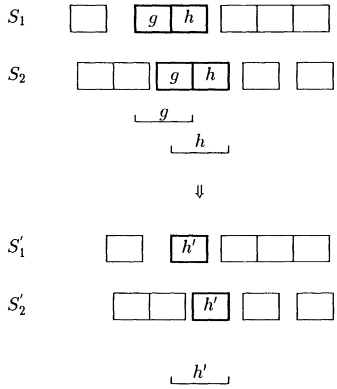

FIG. 3. *A compress transformation.*

The third transformation is a variation of the compress, called an *inverted compress*. Let g and h be jobs in J with $c_g^p = s_h^p$, $c_h^{3-p} = s_g^{3-p}$, and $s_g^p \leq s_h^{3-p} < c_g^p$, where $p = 1$ or $p = 2$. We generate a new r-problem P' in which the jobs g and h are compressed into one job h' such that $r_{h'} = s_h^p$ and $d_{h'} = d_g$. For any job i with $r_i < r_g$, reset r_i to $r_i + 1$. For any job i with $d_i < c_h^{3-p}$, reset d_i to $d_i + 1$. Reset a to $a + 1$. In a fashion analogous to that of the compress transformation, a contradiction can be achieved whenever an inverted compress transformation can be applied. Figure 4 illustrates the inverted compress transformation.

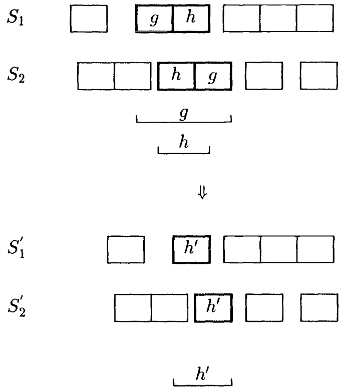

FIG. 4. *The inverted compress transformation.*

The fourth transformation is called an *increase-r* transformation. Let g and h be jobs in J with g scheduled before h in S_p, $c_g^p < s_h^p$, no other job scheduled between g and h in S_p, and $c_g^p < d_g$, where $p = 1$ or $p = 2$. By Claim 3.1, $r_g = s_g^p$. We reset r_g to be the next larger breakpoint, giving a smaller r-problem P', for which there would be a best r-set. This set would also be a best r-set for P, contradicting our initial assumption about P. Thus whenever an increase-r transformation can be applied, a contradiction can be achieved.

The fifth transformation is called a *decrease-d* transformation. Let g and h be jobs in J with g scheduled before h in S_p, $c_g^p < s_h^p$, no other job scheduled between g and h in S_p, and $r_h < s_h^p$, where $p = 1$ or $p = 2$. By Claim 3.1, $d_h = c_h^p$. We reset d_h to be the next smaller breakpoint, giving a smaller r-problem P', for which there would be a best r-set. Since job h must be in any r-set for P, changing its deadline does not affect whether or not an r-set is the best r-set for P. Hence the best r-set for P' would also be the best r-set for P, contradicting our initial assumption about P. Thus whenever a decrease-d transformation can be applied, a contradiction can be achieved.

We now proceed with a case analysis. Assume that $c_k^2 \le s_k^1$. (The argument for $c_k^1 \le s_k^2$ is essentially the same.) By Claim 3.1, $r_k = s_k^2$ and $d_k = c_k^1$. Suppose as Assumption (a1) that there is no job scheduled in S_2 during any part of the interval $[s_k^1, c_k^1)$. This case is illustrated in Fig. 5(a). Only the relevant jobs are shown. Then we can reset r_k to be s_k^1 and get a smaller r-problem P', for which A_2 can still be scheduled, with job k in interval $[s_k^1, c_k^1)$. This would mean that there would be a best r-set for P'. This set would also be the best r-set for P, contradicting the assumption about P. Thus (a1) cannot hold, and there is a job h that is scheduled in S_2 during some part of the interval $[s_k^1, c_k^1)$.

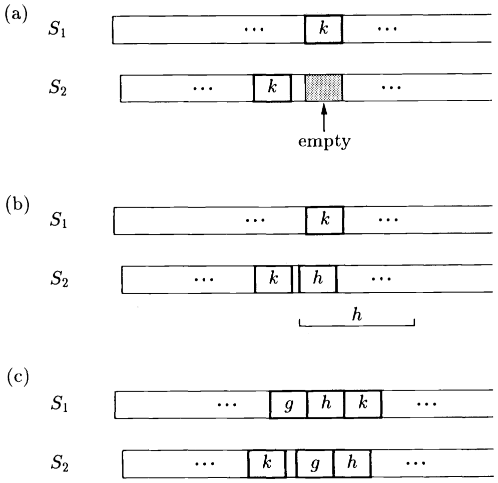

FIG. 5. *Selected cases in the proof of Claim* 3.2. (a) *Assumption* (a1); (b) *Assumptions* (a2) *and* (a2.1); (c) *Assumptions* (a2), (a2.2), *and* (a2.2.1).

Either $s_h^2 \le s_k^1 < c_h^2 \le c_k^1$, or both $s_k^1 < s_h^2 < c_k^1 < c_h^2$ and there is no job i such that $s_i^2 \le s_k^1 < c_i^2$. Suppose as (a2) that $s_h^2 \le s_k^1 < c_h^2 \le c_k^1$. By Claim 3.1 either $r_h = s_h^2$ or $d_h = c_h^2$. Suppose as (a2.1) that $r_h = s_h^2$. This case is illustrated in Fig. 5(b). Then an exchange-d transformation can be applied to jobs h and k. Thus (a2.1) does not hold, and $r_h \ne s_h^2$.

Thus we have that $d_h = c_h^2$. Since deadlines are distinct, $d_h < d_k$. Since k is the job with the smallest deadline whose positions in S_1 and S_2 do not overlap, job h is scheduled in positions in S_1 and S_2 that overlap. Thus job h is the job that precedes k in S_1. Furthermore, $c_h^1 = s_k^1$, since otherwise we could apply an increase-r transformation. Let g be the job that precedes job h in S_2. We have that $c_g^2 = s_h^2$, since otherwise we could apply a decrease-d transformation. Either $g \ne k$ or $g = k$. Suppose as (a2.2) that $g \ne k$. Either $d_g = c_g^2$ or $r_g = s_g^2$. Suppose as (a2.2.1) that $d_g = c_g^2$. This case is illustrated in Fig. 5(c). By choice of job k, the positions of g in S_1 and S_2 overlap. Thus job g is the job that precedes h in S_1. Furthermore, $c_g^1 = s_h^1$, since otherwise we could apply an increase-r transformation. A compress transformation can now be applied to jobs g and h. Thus (a2.2.1) does not hold, and $r_g = s_g^2$. Then $s_g^1 \geq c_k^1$ and $r_k < r_g$. An exchange-d operation can now be applied to jobs k and g. Thus (a2.2) does not hold, so $g = k$. Since $g = k$, we can apply an inverted compress transformation for k and h, which leads to a contradiction.

Thus (a2) does not hold, which means that there is a job h such that $s_k^1 < s_h^2 < c_k^1 < c_h^2$ and there is no job i such that $s_i^2 \leq s_k^1 < c_i^2$. Let job m be the job that precedes job h in S_2. Since there is no job i such that $s_i^2 \leq s_k^1 < c_i^2$, $c_m^2 < s_h^2$. We have that $r_h = s_h^2$, since otherwise we could apply a decrease-d transformation on jobs m and h. Let job l be the job that precedes job k in S_1. Note that $c_l^1 = s_k^1$, since otherwise we could apply a decrease-d transformation on jobs l and k. Also, $d_l < d_k$, since otherwise we could apply an exchange-d transformation for k and l. By choice of k, the scheduled positions of l in S_1 and S_2 overlap, and since there is no job i such that $s_i^2 \leq s_k^1 < c_i^2$, it follows that $m = l$. Since there is no job i such that $s_i^2 \leq s_k^1 < c_i^2$, we have $c_l^2 \leq s_k^1$, which means that $c_l^2 \leq c_l^1$, from which it follows that $d_l = c_l^1$. Then $c_l^2 = c_l^1$, since otherwise we could apply an increase-r transformation to l and h. Since $c_l^1 = d_l$ and $c_l^2 = c_l^1$, it follows that $s_l^2 = s_l^1$.

Let g be the job that precedes job l in S_2. Either $g = k$ or $g \neq k$. Suppose as (a3) that $g = k$. This case is illustrated in Fig. 6(a). We must have $c_g^2 = s_l^2$, since otherwise we could apply an increase-r transformation for g and l. We can then apply an inverted compress transformation for k and l. This transformation leads to a contradiction. Thus (a3) does not hold, and $g \neq k$. Let f be the job that immediately precedes job l in S_1. Either $f = g$ or $f \neq g$. Suppose as (a4) that $f = g$. This case is illustrated in Fig. 6(b). It follows that $r_g = d_g - 1$, by an argument similar to the one that showed that $r_l = d_l - 1$. We can then apply a modified compress transformation to g and l, with the only difference being the following. For any i with $r_i < r_g$, reset r_i to $r_i + r_l - r_g$. For any i with $d_i < d_l$, reset d_i to $d_i + r_l - r_g$. This leads to a contradiction.

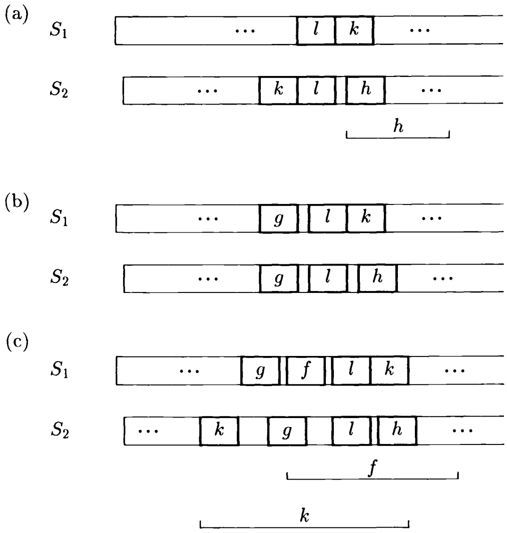

FIG. 6. *Selected cases in the proof of Claim* 3.2. (a) *Assumption* (a3); (b) *Assumption* (a4); (c) *Final contradiction.*

Thus (a4) does not hold, and $f \neq g$. Either $s_g^2 = r_g$ or $c_g^2 = d_g$. Suppose $s_g^2 = r_g$. Then we can perform an exchange-d operation on jobs g and k, which leads to a contradiction.

Thus $c_g^2 = d_g$. By choice of k the positions of g in S_1 and S_2 overlap, which means that the positions of f in S_1 and S_2 cannot overlap. This case is illustrated in Fig. 6(c). Thus $s_f^1 = r_f$ and $d_f > d_k$. But then we can reset d_k to be c_f^1 and r_f to be s_k^1. This gives a smaller r-problem P', which will thus have a best r-set. It follows that this set will also be a best r-set for P, a contradiction. At this point, all cases have been exhausted. Thus there can be no job k whose scheduled positions in S_1 and S_2 do not overlap. This completes the proof of Claim 3.2.

We are now ready to generate the contradiction to the assumption that the theorem does not hold. Let j be the job scheduled at a in S_1 and let h be the first job scheduled in S_2. If $j = h$, then we generate a new r-problem P' by deleting h and resetting a to $a + 1$. Then P' is smaller than P and thus it has a best r-set A'. Let $A = A' \cup \{h\}$. Then $d(A) \preceq d(A_1)$ and $|A| \geq |A_1|$, and $d(A) \preceq d(A_2)$ and $|A| \geq |A_2|$, which yields a contradiction, so $j \neq h$. Since no other job in S_2 can overlap j in S_1, job j is not in S_2, by Claim 3.2. Either $s_h^2 \geq c_j^1$ or $s_h^2 < c_j^1$. If $s_h^2 \geq c_j^1$, then $A_2 \cup \{j\}$ can be scheduled in $[a, b)$, since j can be scheduled in $[a, a + 1)$ and A_2 can be scheduled in $[a + 1, b)$. But this would contradict A_2 being an r-set for P. Thus $s_h^2 < c_j^1$. It follows that $s_h^2 = r_h$. Either h is scheduled in S_1 or it isn't. If h is not scheduled in S_1, then $d_h > b$. We generate a new r-problem P' by removing j and h and resetting a to $a + 1$. In a similar manner to the argument above, this yields a contradiction. If h is scheduled in S_1, then $s_h^1 < c_h^2$. Since $d_j > b$, we generate a new r-problem P' by removing h and resetting r_j to $r_j + 1$ and a to $a + 1$. In a similar manner to the argument above, this yields a contradiction. At this point we have exhausted all cases. The theorem that there is a best r-set for $[a, b)$ then follows . □

COROLLARY 3.1.1. *Let $[a, b)$ be an interval, and J be an $[a, b)$-feasible set of jobs with distinct deadlines. Then there is a (unique) best r-set for $[a, b)$ with respect to J.*

Proof. If deadlines are distinct, then there do not exist two different subsets A and B of jobs such that $d(A) \preceq d(B)$ and $d(B) \preceq d(A)$. If there are any jobs in J with the same release time, do the following. For the subset of jobs in J with release times less than a, arbitrarily reset all release times to be distinct values less than a. This cannot change any r-set for $[a, b)$. Next, perform the appropriate operations to reset release times until all remaining release times are distinct. Note that a best r-set for $[a, b)$ will remain a best r-set for $[a, b)$. By Theorem 3.1 there will be a unique best r-set for $[a, b)$ in the transformed problem. Thus there will be a unique best r-set for $[a, b)$ in the original problem. □

We consider the problem of determining a best r-set for an anchored multiple gap, given the best r-sets for two adjacent anchored multiple gaps that span it. We first consider the simpler problem of recomputing the best r-set for an interval $[a, b)$ when one additional job with release time a is inserted into the set of jobs. We show that if the best r-set for $[a, b)$ changes at all, then the only change is that the new job replaces one of the jobs in the best r-set.

LEMMA 3.2. *Let $[a, b)$ be an interval, and J and $J' = J \cup \{j'\}$ be $[a, b)$-feasible sets of jobs with distinct deadlines, where j' is a job not in J with $r_{j'} = a$. Let A_1 be the best r-set with respect to J, and A_2 the best r-set with respect to J'. Then $A_2 \subseteq A_1 \cup \{j'\}$.*

Proof. The proof is by contradiction and is similar in structure to the proof of Theorem 3.1. We first note that by Corollary 3.1.1, best r-sets A_1 and A_2 exist.

We define an *r^+-problem* P to consist of an interval $[a, b)$, a set of jobs J, and an additional job $j' \notin J$ with $r_{j'} = a$ such that $J' = J \cup \{j'\}$ is $[a, b)$-feasible. We define P-breakpoint, size of an interval, and size of a job as in the proof of Theorem 3.1. The size of r$^+$-problem P is the size of interval $[a, b)$ plus the sum of the sizes of all jobs in J' plus the sum of the product of sizes of all pairs of jobs in J'.

We consider an r$^+$-problem P, consisting of interval $[a, b)$, set J of jobs, and additional job j', that is of smallest size among those r$^+$-problems that do not satisfy the lemma. Since

P is of smallest size, $J_r[a, b) = J$ and $J'_r[a, b) = J'$. Suppose that $A_2 \not\subseteq A_1 \cup \{j'\}$. Clearly, $j' \in A_2$, since otherwise $A_2 = A_1$.

Let S_1 be any schedule for A_1, and S_2 be any schedule for A_2. We note several properties of S_1 and S_2.

CLAIM 3.3. *Every job that is scheduled in both S_1 and S_2 starts at its release time in one of the schedules and completes at its deadline in the other schedule. Job j' completes in S_2 at its deadline. If a job in J is scheduled in just one of S_1 and S_2, then the job starts at its release time in that schedule, and its deadline is greater than b.*

Proof of claim. Let j be a job in J that is scheduled in either S_1, S_2, or both. Let s_j be j's earliest starting time in the two schedules. Suppose $r_j < s_j$. We generate a new r$^+$-problem P' by resetting r_j to s_j. Clearly A_1 is the best r-set in P' with respect to J and A_2 is the best r-set in P' with respect to J'. P' is a smaller r$^+$-problem since the size of job j has been reduced. Since P' is smaller than P, $A_2 \subseteq A_1 \cup \{j'\}$, which contradicts the assumption that P does not satisfy the lemma. Thus $r_j = s_j$.

Suppose that job j is scheduled in both S_1 and S_2 and let c_j be j's latest completion time in the two schedules. Suppose $d_j > c_j$. We generate a new r$^+$-problem P' by resetting d_j to c_j. If this causes two jobs to have the same deadline, then apply the appropriate operation to reset deadlines, as was discussed in the proof of Theorem 3.1. Any job whose deadline is changed must have its deadline be at most b, and thus will be in every r-set for P' with respect to J and with respect to J', and similarly for P. Thus A_1 and A_2 remain best r-sets for P' with respect to J and J', respectively. Since P' is smaller, it follows that $A_2 \subseteq A_1 \cup \{j'\}$, which gives a contradiction. Thus $d_j = c_j$.

If job j' completes in S_2 before its deadline, then $d_{j'}$ can be reset to $c_{j'}$. Note that this does not affect the comparisons for best r-set A_2, since j' is in A_2. This once again gives a smaller r$^+$-problem, yielding a contradiction.

Suppose job $j \in J$ is scheduled in one of S_1 and S_2. Since $J = J_r[a, b)$ and J is $[a, b)$-feasible, any j in J with deadline at most b must be scheduled in both S_1 and S_2. Since job j is not in both S_1 and S_2, $d_j > b$. This completes the proof of the claim.

CLAIM 3.4. *For any job in J that is scheduled in both S_1 and S_2, their scheduled positions in the two schedules overlap.*

Proof of claim. The proof of this claim is similar to the proof of Claim 3.2 in Theorem 3.1, but in this lemma we are addressing r$^+$-problems and derive contradictions to the assumption of this lemma. The proof of this claim is a straightforward transformation of the proof of Claim 3.2, and is omitted.

We are now ready to generate the contradiction to the assumption that the lemma does not hold. Suppose j' is not the last job scheduled in S_2. Let h be the last job scheduled in S_2 and k be the last job scheduled in S_1. If $k = h$, then we can generate a smaller r$^+$-problem by deleting this job and subtracting 1 from b, and thus achieve a contradiction. Thus, $k \neq h$. Suppose $s_k^1 \geq s_h^2$. Then $s_k^1 = r_k$ and $d_k > b$. If $d_h > b$, then replace h by k in S_2, and generate a smaller r$^+$-problem, since there is one less job, and achieve a contradiction. Thus $d_h \leq b$, which means that the job scheduled before k in S_1 is h. But then we can generate a smaller r$^+$-problem by removing h, resetting the release time of k to $r_k - 1$, and resetting the interval to $[a, b - 1)$. This again leads to a contradiction. The argument is similar if $s_k^1 < s_h^2$.

Thus j' is the last job scheduled in S_2. Let h be the first job scheduled in S_2 and k be the first job scheduled in S_1. If $k = h$, then we can generate a smaller r$^+$-problem, which gives a contradiction, so $k \neq h$. Suppose $s_h^2 \leq s_k^1$. Then $s_h^2 = r_h$ and $d_h > b$. Then h and j' can be swapped in S_2 and the r_h reset to $s_{j'}^2$ before the swap. The size of a job has been reduced, resulting in a smaller r$^+$-problem, which gives a contradiction, so $s_h^2 > s_k^1$. Then, $d_k > b$. If $d_h > b$, then again, h and j' can be swapped in S_2, generating a smaller r$^+$-problem, which leads to a contradiction. Thus, $d_h \leq b$, which means that the second job scheduled in S_1 is h. But this leads to a smaller r$^+$-problem. This achieves the final contradiction, as we have shown that $s_h^2 \leq s_k^1$, $s_h^2 \geq s_k^1$, and $s_h^2 \neq s_k^1$. Thus, all jobs except $j' \in S_2$ appear in S_1. □

We now consider recomputing the best r-set when a set of additional jobs is introduced. We show that a job that is not in the original best r-set cannot appear in the recomputed best r-set.

THEOREM 3.2. *Let $[a, b)$ be an interval, and J' and $J \subset J'$ be $[a, b)$-feasible sets of jobs with distinct deadlines, and where each job $j' \in J' - J$ has $r_{j'} = a$. Let A_1 be the best r-set with respect to J, and let A_2 be the best r-set with respect to J'. Then $A_2 \subseteq A_1 \cup (J' - J)$.*

Proof. We first note that by Corollary 3.1.1, best r-sets A_1 and A_2 exist. Our proof is by induction on $|J' - J|$. For the basis, we have $|J' - J| = 1$. The basis case holds by Lemma 3.2. For the induction step, we have $|J' - J| > 1$. Assume as the induction hypothesis that the theorem holds for all values smaller than $|J' - J|$. Let j' be a job in $J' - J$. Let A_1 be the best r-set for $[a, b)$ with respect to J. By the induction hypothesis, the best r-set A_2 for $[a, b)$ with respect to $J' - \{j'\}$ satisfies $A_2 \subseteq A_1 \cup ((J' - J) - \{j'\})$. By Lemma 3.2, the best r-set A_3 for $[a, b)$ with respect to J' satisfies $A_3 \subseteq A_2 \cup \{j'\}$, which implies $A_3 \subseteq A_1 \cup (J' - J)$. □

In the last part of this section we concentrate on computing the best r-sets for intervals that contain cover intervals. As shown in Lemma 3.1, an interval $[a, b)$ that has no constrained interval contained within it (and hence no cover interval contained within it) is $[a, b)$-feasible and the corresponding schedule can be computed easily using the discrete earliest deadline rule. Determining $[a, b)$-feasibility is more involved when the interval contains cover intervals because we do not know in advance when the first job of a cover interval should be started. For certain choices of the starting time of the first job in a cover interval, there may be no schedule. Our approach is to consider all possible starting times of an appropriate cover interval, and compute a set of jobs that is the best r-set if the set is $[a, b)$-feasible. Then the $[a, b)$-feasibility of the set can be tested by comparing the set of deadlines for a certain subset of its jobs with a "template" generated from a "mirror-image problem." The template is composed of the smallest allowable deadlines for jobs that can be scheduled in an appropriate portion of $[a, b)$.

First we define the notions of d-set, best d-set, and template. Let $[a, b)$ be an interval, J a set of jobs, and $J_d[a, b)$ be the subset of all jobs j in J such that $d_j \in (a, b]$. The set A is a *d-set* for $[a, b)$ with respect to J if and only if J is $[a, b)$-feasible and A is a subset of $J_d[a, b)$ that includes all jobs in $J[a, b)$, and the jobs in A can be scheduled in $[a, b)$. We choose the name d-set, where d denotes deadline, to stress the partitioning of jobs by their deadlines. A d-set A for $[a, b)$ with respect to J is a *best d-set* for $[a, b)$ with respect to J if for any other d-set B for $[a, b)$ with respect to J, $d(A) \preceq d(B)$ and $|A| \geq |B|$. The set of deadlines of the best d-set for $[a, b)$ with respect to J is called a *template* for $[a, b)$ with respect to J.

We discuss examples of templates using the set of jobs in Fig. 1(a). There are six jobs whose deadlines lie within (15.0, 20.0], jobs 2, 8, 9, 10, 12, and 13. Job 12 is not considered further since it cannot be scheduled within the interval. The best d-set for [15.0, 20.0) consists of the four jobs 2, 8, 9, and 10. Thus the template for [15.0, 20.0) is the set {16.2, 17.1, 19.6, 20.0}, consisting of the deadlines of jobs 2, 8, 9, and 10. The deadline of job 13 is not in the template since only one of jobs 9 and 13 can be scheduled in [15.0, 16.4), and job 13 has a later deadline. Similarly, the template for [5.3, 8.2) consists of the deadline of job 3, and the template for [10.2, 13.0) consists of the deadlines of jobs 7 and 1.

A template can be used to test for feasibility as follows. Let $[a, b)$ and $[a', b')$ be two consecutive anchored multiple gaps, where $a' - b$ equals the number of jobs in the cover interval separating them. Suppose that J is $[a, b)$-feasible, $[a', b')$-feasible, and $[b, a')$-feasible. We want to determine if there is a schedule of jobs contained in $[a, b')$ that has $a' - b$ cover jobs scheduled in $[b, a')$. (This is a constrained type of $[a, b')$-feasibility.) Let B be all jobs that are contained in $[a, b')$ except those in the best r-set for $[a, b)$ and those to be scheduled in $[b, a')$. Let A be the best d-set for $[a', b')$ with respect to J. Then there is a desired schedule if and only if $d(A) \preceq d(B)$ and $|B| \leq |A|$. A proof of this claim can be sketched as follows. Clearly, there is a schedule of jobs contained in $[a, b')$ that has $a' - b$ cover jobs scheduled in $[b, a')$ if and only if B can be scheduled in $[a', b')$. Suppose B can be scheduled in $[a', b')$. Then B is a d-set for $[a', b')$. Since A is a best d-set, $d(A) \preceq d(B)$ and $|B| \leq |A|$. Suppose $d(A) \preceq d(B)$ and $|B| \leq |A|$. Since A is a d-set, every job contained in $[a', b')$ is a member of A. By definition, every job contained in $[a', b')$ is a member of B. All remaining jobs in either A or B have a release time earlier than a'. Thus given a schedule for A, a schedule for B can be constructed as follows. Any job contained in $[a', b')$ is in the same position in the schedule for B as in the schedule for A. Let A' and B' be the remaining sets of jobs. Since $|B| \leq |A|$, we have $|B'| \leq |A'|$. Schedule the job in B' with the ith largest deadline in the position that the job in A' with the ith largest deadline was scheduled. Thus B can be scheduled in $[a', b')$.

We illustrate how a template is used. Consider the set of jobs in Fig. 1(a), but with $r_9 = 12.1$. The best r-set for anchored multiple gap $[5.3, 13.0)$ will have jobs 1 and 3 scheduled in the gap $[5.3, 8.0)$, and jobs 4, 7, and 2 in gap $[10.0, 13.0)$. It is not possible to schedule the remaining jobs 8, 9, 10, and 13 in $[15.0, 20.0)$. Job 13, with second smallest deadline, has a deadline smaller than the second smallest value, 17.1, in the template. Since $\{9, 10, 2, 8\} \not\preceq \{9, 13, 10, 8\}$, there is no schedule for this choice of anchored gaps.

We next discuss how the existence of best r-sets relates to the existence of best d-sets. Given a set J of jobs that constitute a problem P, the *mirror-image* problem P^M is defined as follows. For each job i in J with release time r_i and deadline d_i, there is a job i in J^M with release time $r_i^M = r_{\min} + (d_{\max} - d_i)$ and deadline $d_i^M = d_{\max} - (r_i - r_{\min})$. It would be convenient if i were in the best d-set in P^M if and only if i were in the best r-set in P. Unfortunately, this is not the case, since in both problems P and P^M, the relation $\preceq$ is applied to sets of deadlines. We show the existence of the best d-set below in Theorem 3.3, and also show how to generate it using a modified mirror-image problem.

THEOREM 3.3 (best d-set). *Let $[a, b)$ be an interval. Let J be an $[a, b)$-feasible set of jobs that is simple. Then there is a best d-set for $[a, b)$ with respect to J.*

Proof. Let $[a, b)$ be an interval, J an $[a, b)$-feasible set of jobs, and let P be a *d-problem* consisting of finding the best d-set for the interval $[a, b)$ with respect to J, if such a set exists. We generate a new d-problem $\widehat{P}$ with job set $\widehat{J}$ in the following way. For each job $j \in J$ with release time r_j and deadline d_j there is a job j in $\widehat{J}$ with deadline $\widehat{d_j} = d_j$ and release time $\widehat{r_j} = r_j$ if $r_j \geq a$, and $\widehat{r_j} = a - (\widehat{d_j} - a)$ otherwise. It follows that the release times $\widehat{r_j}$ in $\widehat{P}$ are all distinct, as are the deadlines $\widehat{d_j}$. The d-problem $\widehat{P}$ is to find the best d-set for the interval $[a, b)$ with respect to $\widehat{J}$. A set is the best d-set for P if and only if it is the best d-set for $\widehat{P}$, since the only differences in jobs in J and $\widehat{J}$ are modified release times that are outside of the interval $[a, b)$. The release times are modified in such a way that for any two jobs j and k in J with $r_j, r_k < a$, if $d_j < d_k$, then $\widehat{r_j} > \widehat{r_k}$.

Let $\widehat{P}^M$ be an r-problem formed by taking the mirror image of d-problem $\widehat{P}$, as follows. For each job j let release time $r_j^M = \widehat{r}_{\min} + (\widehat{d}_{\max} - \widehat{d_i})$ and deadline $d_i^M = \widehat{d}_{\max} - (\widehat{r_i} - \widehat{r}_{\min})$. Let $a^M = \widehat{r}_{\min} + (\widehat{d}_{\max} - b)$ and $b^M = \widehat{d}_{\max} - (a - \widehat{r}_{\min})$. Since J is $[a, b)$-feasible, $\widehat{J}$ is $[a, b)$-feasible, and $\widehat{J}^M$ is $[a^M, b^M)$-feasible. Thus there is an r-set for $[a^M, b^M)$ with respect to $\widehat{J}^M$. Since the release times $\widehat{r_j}$ in $\widehat{P}$ are distinct, and the deadlines $\widehat{d_j}$ are also distinct, it follows that the release times r_j^M in $\widehat{P}^M$ are distinct, and the deadlines d_j^M are also distinct. By Theorem 3.1, there is a best r-set for $[a^M, b^M)$ with respect to $\widehat{J}^M$. This best r-set is equivalent to the best d-set for $[a, b)$ with respect to $\widehat{J}$, which is equivalent to the best d-set for $[a, b)$ with respect to J. □

The proof of Theorem 3.3 identifies a method for computing d-sets. When an interval $[a, b)$ does not contain a prime interval, computing the best d-set for it is easy. As in the previous proof, modify the release times of the jobs, transform the problem into a mirror-image problem, and compute an r-set using the discrete earliest deadline rule. This best r-set is equivalent to the best d-set in the original problem.

When an interval $[a, b)$ does contain a prime interval, we can construct its best d-set by combining the best d-sets of two subproblems. We need a lemma similar to Theorem 3.2, which applied to r-sets. Let J be a set of jobs whose maximum deadline is $d_{\max}$, where $d_{\max} > b$. We wish to consider the case when jobs in $J_d[b, d_{\max})$ would be forced to complete by time b. Let $\tilde{b} = b + \lfloor d_{\max} - b \rfloor + 1$. Let the *b-extension of* J be the set J^b of jobs $\{j_i \mid i = 1, \ldots, \tilde{b} - b\}$ with $d_{j_i'} = b + i$ and $r_{j_i'} = d_{j_i'} - 1$. When $J \cup J^b$ is $[a, \tilde{b})$-feasible, any schedule must have the interval $[b, \tilde{b})$ scheduled with jobs only in J^b, and all jobs in J must be scheduled to complete by b. The set J^b is an artifice that allows us to conveniently discuss how a best choice of a set scheduled for $[a, b)$ would differ from a best d-set for $[a, b)$.

LEMMA 3.3. *Let $[a, b)$ be an interval, and J a set of jobs such that $J \cup J^b$ is $[a, \tilde{b})$-feasible and simple. Let A_1 be the best d-set for $[a, b)$ with respect to J, and let A_2 be the best d-set for $[a, \tilde{b})$ with respect to $J \cup J^b$. Then $A_2 - J^b \subseteq A_1 \cup J_d[b, d_{\max})$.*

Proof. The proof is similar to that of Theorem 3.3 except that it appeals to Theorem 3.2 rather than Theorem 3.1. Let $\widehat{J'}$ be the subset of J whose deadlines are greater than a, with release times and deadlines modified as follows. For each job $j \in J$ with $d_j \geq a$, there is a job j in $\widehat{J'}$ with deadline $\widehat{d_j} = \min\{d_j, b\}$ and release time $\widehat{r_j} = r_j$ if $r_j \geq a$, and $\widehat{r_j} = a - (d_j - a)$ otherwise. Note that all $\widehat{r_j}$ will be distinct. Let $\widehat{J}$ be the subset of $\widehat{J'}$ corresponding to the subset $J_d[a, b)$ of J. Let $a^M = \widehat{r}_{\min} + (\widehat{d}_{\max} - b)$ and $b^M = \widehat{d}_{\max} - (a - \widehat{r}_{\min})$. Let $\widehat{J'}^M$ be the mirror-image set of jobs corresponding to $\widehat{J'}$, and $\widehat{J}^M$ be the mirror-image subset of jobs corresponding to $\widehat{J}$. Since $J \cup J^b$ is $[a, \tilde{b})$-feasible, $\widehat{J'}$ is $[a, b)$-feasible, and $\widehat{J'}^M$ is $[a^M, b^M)$-feasible. Thus $\widehat{J}^M$ is $[a^M, b^M)$-feasible, and there is an r-set for $[a^M, b^M)$ with respect to $\widehat{J}^M$. Note that all $\widehat{d}_j^M$ will be distinct, since all $\widehat{r_j}$ are distinct. By Corollary 3.1.1, there is a best r-set $\widehat{A}_1^M$ for $[a^M, b^M)$ with respect to $\widehat{J}^M$, and a best r-set $\widehat{A}_2^M$ for $[a^M, b^M)$ with respect to $\widehat{J'}^M$. By Theorem 3.2, $\widehat{A}_2^M \subseteq \widehat{A}_1^M \cup (\widehat{J'}^M - \widehat{J}^M)$. Best r-set $\widehat{A}_1^M$ is equivalent to best d-set $\widehat{A}_1$ for $[a, b)$ with respect to $\widehat{J}$, which is equivalent to best d-set A_1 for $[a, b)$ with respect to J. Best r-set $\widehat{A}_2^M$ is equivalent to a subset $\widehat{A}_2 \subseteq \widehat{J'}$. Since the best d-set A_2 for $[a, \tilde{b})$ with respect to $J \cup J^b$ must contain all of J^b, and any schedule for A_2 must schedule every job in $A_2 - J^b$ to complete by b, $\widehat{A}_2$ is equivalent to $A_2 - J^b$. The theorem then follows. □

The computation of best d-sets for intervals that contain prime intervals is similar to the computation of r-sets, and will be discussed in more detail in the next section.

4. The NC algorithm. In this section we describe a parallel divide-and-conquer algorithm on a CREW PRAM for determining if there is a schedule, and if so, generating it. The algorithm consists of four steps, plus a preprocessing step. The preprocessing step replaces the original set of jobs with an equivalent set of jobs, in which all release times are distinct, all deadlines are distinct, and each deadline is a breakpoint. The first step uses the characterization of §2 to form a cover and to label the jobs as either cover jobs or gap jobs. Then the jobs are partitioned, with each job assigned to either a cover interval or a gap based on release times. A second partition is also generated, based on deadlines. The second step imposes a balanced binary tree structure on the problem, with the leaves representing gaps in order from earliest to latest, and with each nonleaf node representing a multiple gap containing the gaps represented by its leaf descendants. The characterizations of §3 are used to compute best r-sets and best d-sets for anchored gaps and anchored multiple gaps corresponding to the tree nodes. If there is a best r-set that includes all jobs, then there is a schedule; otherwise the algorithm halts. If a schedule exists, then the third step obtains a schedule of the gap jobs by starting with the largest anchored multiple gap and its best r-set, and repeatedly splitting anchored multiple gaps and their corresponding set of jobs into two constituent anchored multiple gaps and a cover interval, until only anchored gaps and their corresponding sets remain. The jobs within each of these sets can easily be scheduled within their assigned anchored gap. Given the endpoints of the anchored gaps, the fourth step schedules the cover jobs in the cover intervals, using Lemma 2.1. We discuss each step carefully and analyze its time and processor requirements.

The preprocessing step first makes every deadline a breakpoint. For each job j, the fractional parts $u_j = r_j - \lfloor r_j \rfloor$ and $v_j = d_j - \lfloor d_j \rfloor$ of its release time and deadline are determined. The multiset of values u_j is then sorted. For each j, a binary search is performed in the sorted list to find the largest u_i no larger than v_j. (If there is no such u_i, then u_i is taken to be -1 plus the largest value in the list.) Then d_j is reset to be $d_j - v_j + u_i$.

Next the preprocessing step increases certain release times so that all release times are distinct, and decreases certain deadlines so that all deadlines are distinct. As stated in §3, we want to perform the following operations repeatedly, while they apply. If $r_j = r_k$ and $d_j \leq d_k$ for jobs j and k, then reset r_k to be $r_j + 1$. If $r_j < r_k$ and $d_j = d_k$, then reset d_j to be $d_k - 1$. We first describe how to handle all instances of the release time modifications in parallel, and then all instances of the deadline modifications.

First we describe how to make all release times distinct. For each release time r_j, its fractional part $u_j = r_j - \lfloor r_j \rfloor$ is extracted. The multiset of the values u_j are then sorted. Then the jobs j are partitioned into sets R_u such that $u_j = u$. For each set R_u, the following is done. The parallel version of the discrete earliest deadline first rule [AGK, R] is applied to the set. If no schedule is possible, then our algorithm halts with failure. Otherwise reset the release time of job j to be its starting time in the schedule.

To make all deadlines distinct first convert the problem into a mirror-image problem. The release time r_j^M for job j in P^M is set to $r_{\min} + (d_{\max} - d_j)$, and the deadline d_j^M for job j in J^M is set to $d_{\max} - (r_j - r_{\min})$. Then the above algorithm for resetting release times is run, but without resetting the release times. Instead, the deadline of job j is reset to $d_j - (s_j - (r_{\min} + d_{\max} - d_j)) = d_{\max} + r_{\min} - s_j$, where s_j is the starting time of job j in the corresponding schedule for the mirror-image problem.

LEMMA 4.1. *Given a set J_0 of n unit-time jobs with arbitrary release times and deadlines, an equivalent simple set J with all deadlines being breakpoints can be found in $O(\log n)$ time using $O(n)$ processors.*

Proof. The correctness of the above procedure is established as follows. By Theorem 2.1, deadlines need only be breakpoints. Next consider generating simple set J. When applying the first of the above operations, the only jobs that can have equal release times at some point are those that have an equal fractional part. The discrete earliest deadline rule schedules correctly for any set of jobs, all of whose release times differ from some value by an integral amount. The discrete earliest deadline rule always schedules a job at the earliest possible release time, subject to no other job being available and having an earlier deadline. Thus the starting time of the job corresponds to the release time generated by the repeated application of the above operation. The application of the discrete earliest deadline rule to the mirror-image problem gives a schedule in which every job starts as late as possible. Correctness then follows.

We analyze the resource bounds as follows. Sorting will use $O(\log n)$ time on $O(n)$ processors, and performing n binary searches in parallel, as well as the parallel version of the discrete earliest deadline rule [AGK], [R], will use the same resources. □

The first step identifies subproblems that can be solved independently. The subproblems are formed by finding a cover and its associated gaps, and partitioning the jobs into sets that are associated with either a cover interval or a gap. The cover is found by forming the set of all possible constrained intervals and then deleting those that are neither prime nor compatible. First the constrained intervals are identified. For each pair consisting of a release time r_i and a deadline d_j, where $r_i < d_j$, let $n_{i,j}$ be the number of jobs contained in this interval. If $d_j - r_i < n_{i,j}$, then the algorithm halts, as no schedule exists. If $d_j - r_i - n_{i,j} < 1$, then $[r_i, d_j)$ is a constrained interval. Second, for each release time r_i, if there is more than one constrained interval starting at r_i, then all such intervals except for the one with the smallest deadline are deleted. Similarly, for each deadline d_j, if there is more than one constrained interval ending at d_j, then all such intervals except for the one with the largest release time are deleted. At most n constrained intervals will remain.

Third, the prime intervals are identified. Each constrained interval is compared with every other constrained interval and deleted if it contains such an interval. The fourth step is to form a cover. The prime intervals $[a_i, b_i)$ are sorted on the values a_i. Since no interval is contained in another, they are also sorted by b_i. For each $[a_i, b_i)$ binary search is used to determine the prime interval $[a_j, b_j)$ with $i < j$ such that $[a_i, b_i)$ and $[a_j, b_j)$ are compatible and for any k, $i < k < j$, $[a_i, b_i)$ and $[a_k, b_k)$ are not compatible. Using recursive doubling, a maximal set of prime intervals that are compatible is identified, and those prime intervals that are not compatible with one of the selected prime intervals are deleted. The remaining prime intervals constitute a cover.

Having identified a cover, the gaps are then identified. The set of jobs are then partitioned in the two partitions as follows. Any job contained in a cover interval is a cover job, and is assigned to the cover interval in both partitions. The remaining jobs are gap jobs, and are assigned as follows. For the partition based on release times, if the release time of a gap job falls within a gap, then the job is assigned to that gap. Otherwise, the gap job is called *anomalous*, and it is assigned to the cover interval containing its release time. For the partition based on deadlines, if the deadline of a gap job falls within a gap, then the job is assigned to that gap; otherwise, the gap job is assigned to the cover interval containing its deadline.

LEMMA 4.2. *Given a set of n unit-time jobs with arbitrary release times and deadlines, a cover can be computed in $O(\log n)$ time using $O(n^2/\log n)$ processors.*

Proof. The correctness of the above procedure follows from the definition of a cover. We next analyze the time complexity. Assuming that jobs are indexed by nondecreasing deadlines, the $n_{i,j}$ are computed as follows. Let $v_{i,j}$ indicate whether job j lies within $[r_i, d_j)$, so $v_{i,j} = 1$ if $r_j \geq r_i$ and $v_{i,j} = 0$ if $r_j < r_i$. The $n_{i,j}$ are computed by performing a prefix sum over the $v_{i,j}$'s, $n_{i,j} = v_{i,1} + v_{i,2} + \ldots + v_{i,j}$. Using Brent's Theorem [B], this uses $O(n^2/\log n)$ processors. Reducing the number of constrained intervals under consideration to at most n also uses $O(n^2/\log n)$ processors. Assigning one processor to $\log n$ pairs of constrained intervals, identifying prime intervals and finding a compatible set uses $O(n^2/\log n)$ processors. Each of the above activities uses $O(\log n)$ time. □

We next discuss the second step in our algorithm. It first imposes a balanced binary tree structure on the problem, with the leaves representing gaps in order from earliest to latest, and with each nonleaf node representing a multiple gap containing the gaps represented by its leaf descendants. It then computes best r-sets and best d-sets, if they exist, for anchored gaps and anchored multiple gaps corresponding to the tree nodes, using a bottom-up sweep through the tree. The final result at the root of the tree will be the best r-set and the best d-set for $[r_{\min}, d_{\max})$. The best r-sets are in sorted order by deadlines, not in scheduled order, so that they can be merged with other best r-sets quickly. Best d-sets are also in sorted order by deadlines.

We first discuss computing best r-sets and best d-sets for anchored gaps. Let $[a, b)$ be a gap, preceded by a cover interval of looseness x and followed by a cover interval of looseness x'. Associated with gap $[a, b)$ are the anchored gaps $[a_i, b_h)$, where $a_i \in [a, a + x)$, and

$b_h \in (b - x', b]$, and a_i and b_h are breakpoints. Assume that the a_i, and also the b_h, are indexed in increasing order. Thus there are at most n^2 anchored gaps associated with each gap. Consider one anchored gap $[a_i, b_h)$ associated with gap $[a, b)$. Recall that $J_r[a, b)$ is the set of gap jobs assigned to gap $[a, b)$ in the release time partition. We shall understand $J_r[a_i, b_h)$ to be $J_r[a, b)$. (For any job assigned to $[a, b)$ whose release time is less than a_i, we are implicitly assuming that its release time is modified to be a_i for anchored gap $[a_i, b_h)$, for the purposes of computing best r-sets. We make a similar assumption for any anchored multiple gap that starts at a_i.) A similar understanding applies for $J_d[a_i, b_h)$ and the deadline partition. For each anchored gap $[a_i, b_h)$ and set of jobs $J_r[a_i, b_h)$, the best r-set for $[a_i, b_h)$, denoted $J_r^*[a_i, b_h)$, is computed. Those jobs from $J_r[a_i, b_h)$ that are not chosen for $J_r^*[a_i, b_h)$ are placed into $J_r^-[a_i, b_h)$, the set of remaining jobs not chosen yet. Similarly, considering the jobs $J_d[a_i, b_h)$, the best d-set for $[a_i, b_h)$, denoted $J_d^*[a_i, b_h)$, is computed and the remaining jobs from $J_d[a_i, b_h)$ not chosen for $J_d^*[a_i, b_h)$ are placed into $J_d^-[a_i, b_h)$.

There is no need to compute the best r-set for each of the at most n^2 anchored gaps, since there are at most $2n$ distinct best r-sets for these anchored gaps. For a given b_h and all possible a_i, there are at most two distinct best r-sets for all of the corresponding anchored gaps $[a_i, b_h)$. All these intervals consider the same set of jobs, but the larger intervals might be able to schedule one more job than the smaller intervals. This follows since $\lfloor b_h - a_1 \rfloor \leq \lfloor b_h - a_k \rfloor + 1$, where a_k is the largest a_i. If there are two best r-sets, then there is some a_l such that all $[a_i, b_h)$, $i \leq l$, have the same best r-set, and all $[a_i, b_h)$, $i > l$, have the other best r-set. The two best r-sets can be found by computing best r-sets for $[a_1, b_h)$ and $[a_k, b_h)$ using the discrete earliest deadline rule. Computing at most $2n$ best r-sets instead of n^2 best r-sets reduces the number of processors needed for this activity by a factor of n.

We show how to compute best r-sets for anchored gaps contained in gap $[a, b)$. First compute $J_r^*[a_1, b_h)$ for all valid indices h. Apply the parallel version of the discrete earliest deadline rule [AGK], [R] for the jobs in $J_r[a_1, b_h)$ and the interval $[a_1, b_h)$. Set $J_r^-[a_1, b_h)$ to $J_r[a_1, b_h) - J_r^*[a_1, b_h)$. In the same manner, compute $J_r^*[a_k, b_h)$ and $J_r^-[a_k, b_h)$ for all valid indices h, where k is the largest index for the a_i. The set $J_r^*[a_i, b_h)$ is set to $J_r^*[a_1, b_h)$ if $\lfloor b_h - a_i \rfloor = \lfloor b_h - a_1 \rfloor$; otherwise it is set to $J_r^*[a_k, b_h)$. In the first case, $J_r^-[a_i, b_h) = J_r^-[a_1, b_h)$ and in the second case $J_r^-[a_i, b_h) = J_r^-[a_k, b_h)$. These additional best r-sets and remaining sets do not need to be computed as they are just duplicates of other sets.

In a similar manner, the best d-sets for anchored gaps contained in gap $[a, b)$ are computed. For a given a_i, there are at most two best d-sets. The release times of each job $j \in J_d[a_i, b_h)$ with $r_j < a_i$ is reset to $a_i - (d_j - a_i)$, the mirror image of this problem is formed, and then solved by the discrete earliest deadline first rule. The maximum number of jobs that can be scheduled in $[a_i, b_h)$ is stored as $C[a_i, b_h)$. For anchored gap $[a_i, b_h)$, this value is $\lfloor b_h - a_i \rfloor$.

LEMMA 4.3. *For all anchored gaps, determining best r-sets and best d-sets whenever they exist uses $O(\log n)$ time and $O(n^2)$ processors.*

Proof. Correctness of the above procedure follows from Lemma 3.1, Theorem 3.3, and the above discussion. To analyze the time and processor complexity, let the lth gap have n_l jobs associated with it. A best r-set or best d-set is computed for at most $2n$ anchored gaps. The parallel version of the discrete earliest deadline rule [AGK], [R] uses $O(\log n)$ time and $O(n)$ processors to schedule n jobs. Thus computing one best r-set or one best d-set in parallel takes $O(\log n_l)$ time and $O(n_l)$ processors, so the total number of processors needed to compute the $2n$ best r-sets for the lth gap is $O(n * n_l)$. Since $n = n_1 + n_2 + \ldots + n_g$, the total number of processors for all gaps is $O(n^2)$. □

We next discuss computing best r-sets and best d-sets for anchored multiple gaps. Let $[a, b')$ be a multiple gap composed of the two consecutive gaps and/or multiple gaps $[a, b)$ and $[a', b')$. In general multiple gaps overlap their two surrounding cover intervals, so that the cover interval between $[a, b)$ and $[a', b')$ is not $[b, a')$. For convenience we shall abuse our notation slightly and refer to this cover interval as $[b, a')$. Assume that best r-sets and best d-sets have already been computed for all anchored multiple gaps associated with $[a, b)$ and $[a', b')$. Let $[a_i, b_h)$ be an anchored multiple gap for $[a, b)$, and let $[a'_g, b'_f)$ be an anchored multiple gap for $[a', b')$, where $a'_g - b_h$ equals the number of cover jobs contained in the cover interval $[b, a')$, and such that $J_r^*[a_i, b_h)$ and $J_r^*[a'_g, b'_f)$ exist. Among r-sets of $[a_i, b'_f)$ that have a schedule in which a cover job starts at b_h, if one exists, let $J_r^{*h}[a_i, b'_f)$ be the best such r-set for $[a_i, b'_f)$. Define $J_d^{*h}[a_i, b'_f)$ similarly. Let $J_r^{-h}[a_i, b'_f) = J_r[a_i, b'_f) - J_r^{*h}[a_i, b'_f)$, and similarly for $J_d^{-h}[a_i, b'_f)$. For every pair $[a_i, b_h)$ and $[a'_g, b'_f)$ such that $a'_g - b_h$ equals the number of cover jobs contained in $[b, a')$, sets $J_r^{*h}[a_i, b'_f)$ and $J_d^{*h}[a_i, b'_f)$ are computed if they exist. Then, for each anchored multiple gap $[a_i, b'_f)$ of multiple gap $[a, b')$, the various values of b_h are examined, and from among the corresponding $J_r^{*h}[a_i, b'_f)$, if there are any, the best r-set is identified as $J_r^*[a_i, b'_f)$. Then $J_r^-[a_i, b'_f)$ is chosen to be the corresponding $J_r^{-h}[a_i, b'_f)$. Similarly, from among the corresponding $J_d^{*h}[a_i, b'_f)$, if there are any, the best d-set is identified as $J_d^*[a_i, b'_f)$. The value $C[a_i, b'_f)$ is set to $C[a_i, b_h) + (a'_g - b_h) + C[a'_g, b'_f)$.

We next discuss how to compute $J_r^{*h}[a_i, b'_f)$ if it exists. Note that $J_r^*[a_i, b_h) \subseteq J_r^{*h}[a_i, b'_f)$, since the jobs in $J_r^*[a_i, b_h)$ can be scheduled in the $[a_i, b_h)$ portion of $[a_i, b'_f)$, and none of the jobs from $J_r^*[a'_g, b'_f)$ or $J_r^-[a'_g, b'_f)$ can be considered in $[a_i, b_h)$. Since the set of cover jobs of a cover interval is unaffected by the exact positioning of the gaps on either side of it, we let $J^*[b, a')$ be the set of cover jobs contained in $[b, a')$ and let $J_r^-[b, a')$ be the set of anomalous gap jobs whose release times lie in $[b, a')$. Clearly, $J^*[b, a') \subseteq J_r^{*h}[a_i, b'_f)$. We now focus on computing the jobs for the $[a'_g, b'_f)$ portion of $J_r^{*h}[a_i, b'_f)$. Let $J' = J_r^*[a'_g, b'_f) \cup J_r^-[a_i, b_h) \cup J_r^-[b, a')$. Let J'' be the $\min\{|J'|, C[a'_g, b'_f)\}$ jobs with smallest deadlines from set J'. If $d(J_d^*[a'_g, b'_f)) \preceq d(J')$ and there are no more than $|J_d^*[a'_g, b'_f)|$ jobs in J' with deadlines at most b'_f, then the jobs in J'' can be scheduled within $[a'_g, b'_f)$. In this case, $J_r^{*h}[a_i, b'_f) = J_r^*[a_i, b_h) \cup J^*[b, a') \cup J''$, and $J_r^{-h}[a_i, b'_f) = J_r^-[a'_g, b'_f) \cup (J' - J'')$. Otherwise there is no schedule using anchored multiple gap $[a_i, b'_f)$ and starting a cover job at b_h.

We next discuss how to compute $J_d^{*h}[a_i, b'_f)$ if it exists. Clearly, $J_d^*[a'_g, b'_f) \subseteq J_d^{*h}[a_i, b'_f)$, and $J^*[b, a') \subseteq J_d^{*h}[a_i, b'_f)$. We now focus on computing the jobs for the $[a_i, b_h)$ portion of $J_d^{*h}[a_i, b'_f)$. Let $J' = J_d^*[a_i, b_h) \cup J_d^-[a'_g, b'_f) \cup J_d^-[b, a')$. A set $\widehat{J}$ with the following modified release times is generated as follows. For each job $j \in J'$, let $\hat{r}_j$ be the modified release time and let r_j be the original release time. If r_j is less than a_i then $\hat{r}_j$ is set to $a_i - (d_j - a_i)$, otherwise $\hat{r}_j$ is set to r_j. Then $\widehat{J}$ is sorted by modified release times. The $\min\{|J'|, C[a_i, b_h)\}$ jobs in $\widehat{J}$ with largest modified release times are identified, with J'' being the set of corresponding jobs in J'. If $J_r^{*h}[a_i, b'_f)$ exists, then $J_d^{*h}[a_i, b'_f) = J'' \cup J_d^*[a'_g, b'_f) \cup J^*[b, a')$, and $J_d^{-h}[a_i, b'_f) = J_d^-[a_i, b_h) \cup (J' - J'')$. Otherwise, there is no set $J_d^{*h}[a_i, b'_f)$.

This step is complete when it has been determined if there is an r-set for the root of the tree. If there is an r-set for $[r_{\min}, d_{\max})$, then a schedule of the jobs exists.

LEMMA 4.4. *For all anchored multiple gaps, computing best r-sets and best d-sets whenever they exist uses $O((\log n)^2)$ time and $O(n^4/\log n)$ processors.*

Proof. As the crucial step in computing $J_r^{*h}[a_i, b'_f)$, consider the computation of J''. Since none of the jobs in J' can be scheduled in $[a_i, b_h)$, those jobs with release times less than a'_g can have their release times reset to a'_g. By Theorem 3.2, if J' is $[a'_g, b'_f)$-feasible, then there is a best r-set for $[a'_g, b'_f)$ that will contain no jobs from $J_r^-[a'_g, b'_f)$. It follows that the computation of $J_r^{*h}[a_i, b'_f)$ is correct. A similar argument using Lemma 3.3 establishes the correctness of the computation of $J_d^{*h}[a_i, b'_f)$.

We next consider time and processor complexity. Let $[a, b)$ and $[a', b')$ be the multiple gaps associated with two sibling nodes, and let there be n_l gap jobs whose release time lies within $[a, b')$. There are at most n^2 anchored multiple gaps $[a_i, b_h)$ for $[a, b)$. Each anchored multiple gap $[a_i, b_h)$ must be matched against an anchored multiple gap $[a'_g, b'_f)$ for $[a', b')$, where $a'_g - b_h$ equals the number of cover jobs that lie within the cover interval that lies between these anchored multiple gaps. Thus for any anchored multiple gap $[a_i, b_h)$, there are at most n anchored multiple gaps $[a'_g, b'_f)$ with which it must be checked. Thus at most n^3 pairs of anchored multiple gaps $[a_i, b_h)$ and $[a'_g, b'_f)$ must be checked. Each pair of anchored multiple gaps $[a_i, b_h)$ and $[a'_g, b'_f)$ can be checked in $O(\log n)$ time using $n_l / \log n$ processors. Since the sum of n_l for all gaps at one level of the tree is $O(n)$, the total number of processors needed is $n^4 / \log n$. Since there are at most $\log n$ levels in the tree, the total time for this activity is $O((\log n)^2)$. □

We next discuss the third step in our algorithm. With respect to the balanced binary tree structure imposed on the previous step, this step selects one anchored multiple gap or anchored gap for each node in the tree, along with a corresponding set of jobs, using a top-down pass through the tree. We call these anchored multiple gaps and anchored gaps *selected multiple gaps* and *selected gaps*, respectively. We call the set $J^*[a_i, b_h)$ that corresponds to a selected multiple gap or selected gap $[a_i, b_h)$ the *selected set* for $[a_i, b_h)$. The final result is a partition of the gap jobs into selected sets for anchored gaps, from which a schedule of the gap jobs within selected gaps is obtained.

This step begins by noting that $[r_{\min}, d_{\max})$ is a selected multiple gap, and the best r-set for $[r_{\min}, d_{\max})$ is a selected set for $[r_{\min}, d_{\max})$. Let $[a, b')$ be a multiple gap, and $[a, b)$ and $[a', b')$ its two constituent gaps or multiple gaps, based on the structure of the binary tree. Let $[a_i, b'_f)$ be the selected multiple gap for $[a, b')$. Let $[a_i, b_h)$ and $[a'_g, b'_f)$ be anchored multiple gaps for the multiple gaps $[a, b)$ and $[a', b')$, respectively. This step considers the at most n pairs such that $a'_g - b_h$ is equal to the number of cover jobs that are contained in the cover interval that lies between $[a_i, b_h)$ and $[a'_g, b'_f)$. Each pair $[a_i, b_h)$ and $[a'_g, b'_f)$ is examined to determine if there is a partition of $J^*[a_i, b'_f)$ into two sets such that the first can be scheduled in $[a_i, b_h)$ and the second can be scheduled in $[a'_g, b'_f)$. A pair is then chosen for which there is such a partition, with the first set being $J^*[a_i, b_h)$, and the second set being $J^*[a'_g, b'_f)$.

We next discuss how to test a given pair $[a_i, b_h)$ and $[a'_g, b'_f)$ to see if there is the desired partition of $J^*[a_i, b'_f)$. First, all gap jobs in $J^*[a_i, b'_f)$ that could be scheduled in $[a_i, b_h)$ are identified. Let J' be the set of all jobs in $J^*[a_i, b'_f)$ whose release times are less than a_i. Let $J'' = (J^*[a_i, b'_f) \cap J^*_r[a_i, b_h)) \cup J'$. Let J''' be the $\min\{|J''|, C[a_i, b_h)\}$ jobs of J'' with smallest deadlines. If $d(J^*_d[a_i, b_h)) \preceq d(J''')$, then the jobs in J''' can be scheduled within $[a_i, b_h)$. Let $J'''' = J^*[a_i, b'_f) - J^*[b, a') - J'''$ be the set of jobs that must be scheduled in $[a'_g, b'_f)$. If $d(J^*_d[a'_g, b'_f)) \preceq d(J'''')$ and the number of jobs in J''' with deadline at most b'_f is at most $|J^*_d[a'_g, b'_f)|$ and $|J''''| \leq C[a'_g, b'_f)$, then the jobs in J'''' can be scheduled within $[a'_g, b'_f)$. If both tests succeed then $[a_i, b_h)$ and $[a'_g, b'_f)$ can be selected, and $J^*[a_i, b_h)$ and $J^*[a'_g, b'_f)$ would be J''' and J'''', respectively.

LEMMA 4.5. *Given best r-sets and best d-sets for all anchored gaps and anchored multiple gaps for which these sets exist, identifying selected gaps and selected multiple gaps and the corresponding selected sets uses* $O((\log n)^2)$ *time and* $O(n^2 / \log n)$ *processors.*

Proof. We first discuss correctness. Since $J^*[a_i, b'_f)$ exists, there must be some choice of b_h such that there is a partition of $J^*[a_i, b'_f) - J^*[b, a')$ into two sets that can be scheduled in $[a_i, b_h)$ and $[a'_g, b'_f)$, respectively. Suppose we are examining such a choice b_h. We verify that we make this partition correctly. It does not alter the results to assume that any job in J' has modified release time a_i. By Theorem 3.2, there is a best r-set for $[a_i, b_h)$ with respect to J (with modified release times) that contains only jobs in $J' \cup J^*_r[a_i, b_h)$. By the approach that we employ in the algorithm, a job in $J_r^*[a_i, b_h)$ will be found in $J^*[a_i, b'_f)$ unless there is a corresponding job with release time before a that has replaced it. Thus $|J''| \geq |J_r^*[a_i, b_h)|$. Thus given $J^*[a_i, b'_f)$, our algorithm makes a best choice of jobs to be scheduled in $[a_i, b_h)$.

We next analyze the time and processors used to determine $J^*[a_i, b_h)$ and $J^*[a'_g, b'_f)$. At most n pairs $[a_i, b_h)$ and $[a'_g, b'_f)$ are checked, and these can all be checked in $O(\log n)$ time using $O(n\ |J^*[a_i, b'_f)|\ / \log n)$ processors. Thus $O(n^2/ \log n)$ processors are used for one level in the tree. The time for each level is $O(\log n)$ and there are at most $\log n$ levels in the tree, so the total time is $O((\log n)^2)$. □

We next discuss scheduling the gap jobs in gaps. For each gap, there is a selected gap and a corresponding selected set. Unfortunately, the jobs in the selected set are in sorted order by deadlines, not in scheduled order. The schedule of jobs in the selected set is computed using a modified earliest deadline algorithm.

Let $[a_i, b_h)$ be the selected gap of gap $[a, b)$, with corresponding selected set $J^*[a_i, b_h)$. The location of the first hole in $[a_i, b_h)$ is determined, and $J^*[a_i, b_h)$ is partitioned into two sets of jobs, those jobs that will be scheduled before the first hole in the gap, and those jobs that will be scheduled after the first hole. If $|J^*[a_i, b_h)| = \lfloor b_h - a_i \rfloor$, then there is only one hole, otherwise there can be several holes. To compute the position of the first hole, the smallest c is found such that there is no job available to be scheduled at position $a_i + c$. Thus the starting position of the first hole is at $a_i + c$. The c jobs with release times at most $a_i + c - 1$ are scheduled, using the discrete earliest deadline algorithm [AGK], [R]. Then the remaining $\lfloor b_h - a_i \rfloor - c$ jobs in $[b_h - (\lfloor b_h - a_i \rfloor - c), b_h)$ are scheduled, again using the discrete earliest deadline algorithm.

LEMMA 4.6. *Computing the schedule of the jobs in selected sets within their selected gaps uses $O(\log n)$ time and $O(n)$ processors.*

Proof. First we discuss correctness. By definition of selected set, a schedule exists. There are c jobs with release time at most $a_i + c - 1$. The discrete earliest deadline algorithm schedules these jobs in $[a_i, a_i + c)$. The remaining jobs must be scheduled in $[a_i + c, b_h)$. Since there is a schedule of these jobs within this interval, we may reset any deadline greater than b_h to be b_h. If any constrained interval is created, it must end at b_h. Consider such a constrained interval $[a'', b_h)$ that contains no other such constrained interval. Only the jobs contained in this interval can be scheduled so as to overlap with interval $[b_h - \lfloor b_h - a'' \rfloor, b_h)$. By Lemma 2.1, these jobs can be scheduled in $[b_h - \lfloor b_h - a'' \rfloor, b_h)$. The same argument may be applied inductively to any remaining jobs and interval $[a_i + c, b_h - \lfloor b_h - a'' \rfloor)$. All such jobs scheduled start at a time that differs from b_h by an integer. When no constrained intervals remain, the remaining jobs can be scheduled by the discrete earliest deadline rule to also satisfy this requirement. But then there exists a schedule of remaining jobs in which all jobs start at a time that differs from b_h by an integer. The discrete earliest deadline rule will find such a schedule.

Next we analyze the time and processors used. The first hole in the lth gap is computed by sorting the jobs in nondecreasing release time order, and performing a prefix sum on the number of release times less than or equal to unit spaced positions in the interval. This takes $O(\log n_l)$ time and $O(n_l)$ processors, where n_l is the number of jobs to be scheduled in the selected gap. Applying the parallel earliest deadline algorithm to the two pieces of the gap also takes $O(\log n_l)$ time and $O(n_l)$ processors. Computing one schedule for each gap in parallel takes $O(\log n)$ time and $O(n)$ processors. □

The fourth step in the algorithm schedules the cover jobs. The choice of selected gaps dictates the position of the cover jobs within the cover intervals. By Lemma 2.1, there is a schedule with the jobs packed tightly together. Let $[a, b)$ and $[a', b')$ be consecutive gaps, and $[a_i, b_h)$ and $[a'_g, b'_f)$ the corresponding selected gaps. Consider the cover interval $[b, a')$.

Note that $a'_g - b_h = |J^*[b, a')|$. The discrete earliest deadline algorithm is applied to the set $J^*[b, a')$ in interval $[b_h, a'_g)$.

LEMMA 4.7. *Scheduling the cover jobs within the cover intervals takes $O(\log n)$ time and uses $O(n)$ processors.*

Proof. The parallel earliest deadline algorithm [AGK], [R] applied to the ith cover interval that contains n_l jobs takes $O(\log n_l)$ time and uses $O(n_l)$ processors. Thus computing the schedule for all cover intervals in parallel takes $O(\log n)$ time and $O(n)$ processors. □

We summarize the performance of the algorithm below.

THEOREM 4.1. *Given n unit-time jobs with arbitrary release times and deadlines, there is a CREW PRAM algorithm that determines if there is a schedule of the jobs on a single processor, and if so, it produces a schedule. The algorithm uses $O((\log n)^2)$ time and $O(n^4/(\log n))$ processors.*

Proof. By Theorem 2.1, if there is a schedule, then there is a canonical schedule. The discussion accompanying the description of the algorithm in this section, plus the correctness within Lemmas 4.2 through 4.7, establish that the algorithm computes a canonical schedule whenever one exists. The time and processor complexities follow from Lemmas 4.2 through 4.7. □

Suppose k is the number of distinct fractional parts of the release times. The algorithm uses fewer than $\Theta(n^4/(\log n))$ processors if k is $o(n)$. The number of starting positions for anchored gaps is thus reduced to k. If there are fewer distinct fractional parts of the deadlines, then breakpoints can be based on deadlines, as discussed at the end of §2. Let k be the minimum of the number of distinct fractional parts of release times and the number of distinct fractional parts of deadlines.

COROLLARY 4.1.1. Given n unit-time jobs with arbitrary release times and deadlines, there is a CREW PRAM algorithm that determines if there is a schedule of the jobs on a single processor, and if so, it produces a schedule. If k is the minimum of the number of distinct fractional parts of release times and the number of distinct fractional parts of deadlines, then the algorithm uses $O((\log n)^2)$ time and $O(k^3n/(\log n) + n^2/(\log n)^2)$ processors.

Proof. Finding a cover can be done in $O((\log n)^2)$ time using just $O(n^2/(\log n)^2)$ processors, by having each of the processors simulate $\log n$ processors in the algorithm stated earlier. Similarly, computing best r-sets and best d-sets for anchored gaps can be done in $O((\log n)^2)$ time using $O(kn/\log n)$ processors. Computing best r-sets and d-sets for anchored multiple gaps takes $O((\log n)^2)$ time and uses $O(k^3n/(\log n))$ processors. Determining selected gaps and selected multiple gaps uses $O(kn/\log n)$ processors and $O((\log n)^2)$ time. Scheduling the gap jobs and the cover jobs uses $O(\log n)$ time and $O(n)$ processors. □

BROADCASTING AND GOSSIPING IN DE BRUIJN NETWORKS*

JEAN-CLAUDE BERMOND† AND PIERRE FRAIGNIAUD‡

Abstract. Communication schemes based on *store and forward* routing, in which a processor can communicate simultaneously with all its neighbors (in parallel) are considered. Moreover, the authors assume that sending a message of length L from a node to a neighbor takes time $\beta + L\tau$. The authors give efficient *broadcasting* and *gossiping* protocols for the de Bruijn networks. To do this, *arc-disjoint spanning trees* of small depth rooted at a given vertex in de Bruijn digraphs are constructed.

Key words. broadcasting, gossiping, interconnection networks, de Bruijn graphs, disjoint spanning trees

AMS subject classifications. 68E10, 94, 05C05, 05C35

1. Introduction. In the design and use of parallel computers, different elements are important. Among them are the topology of the interconnection network and the communication scheme. In this paper, we focus on communication problems. Important cases appearing in parallel algorithms are

Broadcasting: send a message from a given vertex to all the vertices, also called *OTA* (one-to-all).

Gossiping: send messages from all the vertices to all the other vertices, also called *ATA* (all-to-all) or total exchange.

An important literature on graph theory concerning this problem assumes that the communication cost is a constant and that only one port can be used by a processor at a given time (see the survey [15]). Here we consider the *store and forward* model, in which a vertex can simultaneously send and receive (eventually) *different* messages to and from all its neighbors. Indeed, this communication possibility corresponds to existing parallel computers (hypercubes and transputer-based machines). Moreover, the neighbor-to-neighbor communication time depends on a latency, or start-up time β, and on a data transfer time per element, or propagation time τ ($\frac{1}{\tau}$ is the bandwidth of a link). Sending a message of length L to a neighbor takes time $T = \beta + L\tau$ [20], [28], [31].

The hypothesis stating that processors are able to communicate simultaneously through all their ports is well known [20], [28], [31]. Many parallel computers satisfy this hypothesis. However, note that if the number of communication ports of a vertex is large, the start-up time (and in a less significant way, the propagation time) may grow with the number of ports used simultaneously [11]. We do not consider this problem in this paper. The reader is referred to [12] for a survey of broadcasting algorithms under several hypotheses. Note also that there exist other models of routing, such as *circuit-switched* or *wormhole* routing [8], [21]; however, in the case of intensive communications such as broadcasting or gossiping, they do not seem to offer any significative advantages over the *store and forward* model [30].

Clearly, the broadcasting and gossiping protocols depend on the topology of the interconnection network. The choice of this topology is critical in the design of parallel computers. Different goals can be pursued to increase the performance and minimize the cost. These goals can be expressed in terms of the graph (or digraph) that represents the interconnection network. The vertices of the graph correspond to processors, and the edges (or arcs) correspond to communication links between processors.

An important constraint claimed by many authors [7], [8], [17] is that very large-scale integration (VLSI) computing systems are wire limited, which corresponds to a fixed small degree in the associated graph. Furthermore, in the model of store and forward routing, the total transmission time depends on the diameter, which should be as small as possible. Thus, it is important to have graphs with a small diameter and a fixed degree. This is not the case for the hypercube, since the degree and diameter increase as the logarithm of the number of processors, or for the multidimensional meshes or torus, since they have diameters that are too large.

Two well-known topologies are the Kautz and de Bruijn networks, which have many interesting properties [6], [29]. In particular, these networks interconnect considerably more processors than the usual topologies, and they have small diameters and small and fixed degrees. Therefore the aim of this paper is to find efficient broadcasting and gossiping protocols in the de Bruijn digraph. Classical broadcasting in de Bruijn digraphs using the assumption of a constant communication time and the possibility of sending a message to at most one neighbor at any time has been considered in [5], [16].

This paper is organized as follows. In §2 we recall some definitions about directed graphs. In §3 we compute lower bounds and explain possible communication protocols for broadcasting in a given network. We show that an efficient way uses the construction of arc-disjoint spanning trees. Section 4 describes the de Bruijn graphs and digraphs and introduces some notation. Section 5 proposes arc-disjoint spanning trees of the de Bruijn digraphs, which can be used to perform asymptotically optimal broadcasting. In §6 a fast, greedy, gossiping algorithm is given. Section 7 explains how to translate the proposed algorithms from the de Bruijn digraphs to the undirected de Bruijn graphs. Finally, §8 concludes the paper.

2. Notation. A network of n processors is usually modeled by a graph or a digraph $G = (V, E)$ of order n. Three kinds of communication links are usually used.

1. Monodirectional links: messages can only be transferred in one direction. The network is modeled by a digraph.

2. Bidirectional *half duplex* links: such links can be used at a given time in at most one direction. The network is modeled by a graph.

3. Bidirectional*full duplex* links: each link can be simultaneously used in both directions. The network is modeled by a *symmetric* digraph.

In this paper we will consider digraphs only (symmetric or not), either corresponding to networks with monodirectional links, or networks with bidirectional *full duplex* links. In a digraph there is an arc from a node u to a node v only if u is able to send a message directly to v.

Let $d(u, v)$ be the distance between the vertices u and v, that is, the length of a shortest path from u to v. We will use $ecc(u)$ to denote the eccentricity of the vertex u, that is, $\max_{v \in V} d(u, v)$, and use D for the diameter of the digraph, that is, $\max_{u \in V} ecc(u)$. We will use "shortest-paths spanning tree rooted at r" to denote breadth first search tree rooted at r. In such a tree, the path from r to any other vertex v is a shortest path. Note that the depth of such a tree is $ecc(r)$.

Let $d^+(u)$ (resp. $d^-(u)$) denote the out-degree (or in-degree) of the vertex u, that is, the number of outgoing (or incoming) arcs from (or to) u. If the digraph is regular then all the vertices have the same out- and in-degree d. Otherwise $d^+_{\max}$ denotes the maximum out-degree over all the vertices (similar definitions are derived for $d^-_{\max}$, $d^+_{\min}$, and $d^-_{\min}$). Let $m^+(S, V - S)$ be the number of arcs going from S to $V - S$ and let $c_G(r) = \min_{S \neq V | r \in S} m^+(S, V - S)$. $c_G(r)$ can be regarded as the minimum number of arcs that must be deleted to make at least one vertex not reachable from r. Another interpretation of $c_G(r)$ is that there exist $c_G(r)$ arc-disjoint paths from r to any vertex of G. Moreover, $c_G(r)$ is the maximum number of such paths that are arc disjoint (Menger's theorem). Let λ be the arc connectivity of G, that is $\lambda = \min_{r \in V} c_G(r)$. Note that $d^+(r) \geq c_G(r) \geq \lambda$.

Finally, we will use $b_G(r)$ to denote the minimum time of any broadcast initiated by a vertex r of G, and use g_G for the minimum time of any gossiping on G.

3. Broadcasting in networks.

3.1. Lower bounds. Recall that the communication time to send a message of length L from a node to a neighbor is of the form $\beta + L\tau$. Following [20], [31], we can obtain two different lower bounds by considering the total start-up time or the total data transfer time. First the broadcasting time $b_G(r)$ is at least $ecc(r)\beta$. Consider now a subset S of V containing r such that $m^+(S, V - S) = c_G(r)$, and let u be a vertex of $V - S$. The total bandwidth of the arcs between S and $V - S$ is $c_G(r)/\tau$ and therefore the minimum time to send the message from r to u is at least $(L/c_G(r))\tau$.

PROPOSITION 3.1. *In a digraph G, the time to broadcast a message of length L from a node r is at least* $\max(ecc(r)\beta, (L/c_G(r))\tau)$.

For example, in a D-cube used in full duplex mode, $c_G(r) = d^+(r) = d^-(r) = D$, and $ecc(r) = D$. We obtain $b_{D-\text{cube}}(r) \geq \max(D\beta, \frac{L}{D}\tau)$, which is the bound proposed by Johnsson and Ho in [20].

3.2. Communication protocols. There exist different ways to perform broadcasting from an originator r. The efficiency of these protocols depends on the ratio $\frac{\beta}{L\tau}$. The first protocol simply uses a shortest-paths spanning tree. The broadcasting time is $ecc(r)(\beta + L\tau)$ because there exists at least one vertex at distance $ecc(r)$ from r. If $L\tau \ll \beta$, this time is of the order $\beta ecc(r)$ approaching the lower bound and so we cannot do better.

In contrast, if $L\tau \gg \beta$, this time is of the order $L\tau ecc(r)$, which is far from the lower bound $L\tau/c_G(r)$. In case of long messages, we can improve the total time by cutting the messages in smaller packets. A classical technique is pipelining. Suppose we cut the message into $\frac{L}{B}$ packets of length B and send the packets one after each other on a shortest-paths spanning tree. The broadcasting time is $ecc(r)(\beta + B\tau)$ for the first packet to reach a farthest node, plus $(\frac{L}{B} - 1)(\beta + \beta\tau)$ for the other $\frac{L}{B} - 1$ packets following the first one to reach a farthest node. Hence the total time is $(\beta + B\tau)(ecc(r) + \frac{L}{B} - 1)$. This time is optimized by choosing $B_{\min} = \sqrt{L\beta/(ecc(r) - 1)\tau}$, its value being $(\sqrt{L\tau} + \sqrt{(ecc(r) - 1)\beta})^2$. If $L\tau$ is large compared with β, we have now a time of the order $L\tau$. Thus we have earned a factor of $ecc(r)$, but are still far from the lower bound.

Another technique consists of finding p spanning trees rooted at r and pairwise arc disjoint. We cut the message into blocks, each of size $\frac{L}{p}$, and send each block on a different spanning tree. Suppose the maximum depth of the spanning trees is h, then the broadcasting time is $h(\beta + \frac{L}{p}\tau)$. This technique has been used for networks such as hypercubes [20], folded hypercubes [18], star graphs, and k-ary hypercubes [25]. See [12] for a survey. Moreover, we can use the following theorem of graph theory by Edmonds [10] (see Lovász [24] for a short proof).

THEOREM 3.2 (Edmonds). *The maximum number of pairwise arc-disjoint spanning trees rooted at a vertex r is equal to $c_G(r)$.*

We can use these $c_G(r)$ spanning trees to obtain a broadcasting time $h(\beta + (L/c_G(r))\tau)$. Here again, if $L\tau \gg \beta$, we have a time of order $(hL/c_G(r))\tau$ saving a factor of $c_G(r)$ when h is close to $ecc(r)$.

Finally, we can combine the two techniques of pipelining and arc-disjoint spanning trees. With packets of size B, we obtain a time $h(\beta + B\tau)$ so that the first packet reaches a farthest node in the deepest spanning tree, plus $(L/(c_G(r)B) - 1)(\beta + B\tau)$ for the other $L/(c_G(r)/B) - 1$

packets following the first one to reach this farthest node. Hence the total time is $(\beta + B\tau)(h + L/(c_G(r)B) - 1)$. An optimal choice of the size B of the packets gives a broadcasting time $(\sqrt{L\tau/c_G(r)} + \sqrt{(h-1)\beta})^2$.

THEOREM 3.3. *If the maximum depth of $c_G(r)$ arc disjoint spanning trees rooted at a vertex r is h, then there exists a protocol of broadcasting from r whose time is* $(\sqrt{L\tau/c_G(r)} + \sqrt{(h-1)\beta})^2$.

If $L\tau \gg \beta$, we have a time of order $L\tau/c_G(r)$, matching the lower bound. If β and $L\tau$ are of the same order of magnitude, we have to balance the effects of the number of spanning trees and the depth of these trees, respectively. Ideally we want to find many spanning trees ($c_G(r)$ if possible) of maximum depth as small as possible. In the case of regular classical networks, $c_G(r) = \lambda = d$ and $ecc(r) = D$, and the best we can hope to find is d arc-disjoint spanning trees with a depth of at most $D + 1$. Our aim will be to construct arc-disjoint spanning trees of the de Bruijn networks. Note that for the two-dimensional torus, this problem has been completely solved [26].

Let us finish this section with some remarks.

1. Instead of using arc-disjoint spanning trees, we could use time-disjoint diffusion trees (meaning that at a given time, one arc is used in at most one diffusion tree). However, these trees are more difficult to find and do not allow pipelining.
2. There exists algorithms for finding arc-disjoint spanning trees of any given digraph, but the complexities of these algorithms are high, and there is no good bound on the depth of the trees obtained. So it is interesting to give explicit constructions.
3. It is possible to do the same study for the *half duplex* communication mode. See [14], [22], [27] for results on edge-disjoint spanning trees of an undirected graph.

4. de Bruijn digraphs. The de Bruijn digraph $B(d, D)$ [9] is a digraph in which the vertices are the words of length D on an alphabet of d letters (for instance $\{0, \ldots, d-1\}$). There is an arc from a vertex $x = (x_1, \ldots, x_D)$ to a vertex y if the $D-1$ first letters of y are equal to the $D-1$ last letters of x. That is, there is an arc from $x = (x_1, \ldots, x_D)$ to all the vertices $(x_2, \ldots, x_D, \alpha)$, $\alpha \in \{0, \ldots, d-1)\}$. Therefore, each node of $B(d, D)$ has an out and in degree d and it is easy to check that the diameter is D, and for every vertex r of $B(d, D)$, $c_G(r) = \lambda = d - 1$. The number of vertices is $n = d^D$. Figure 1 shows $B(2, D)$ with $D = 1, 2, 3$.

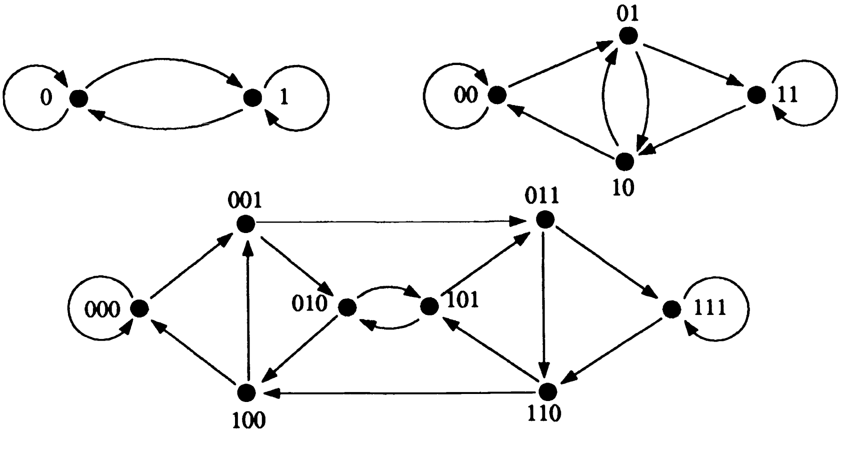

FIG. 1. $B(2, 1)$, $B(2, 2)$, *and* $B(2, 3)$.

One can note that, for a fixed degree d, the number of vertices of these digraphs is of the same asymptotic order as the directed Moore bound (which is equal to $d^D + d^{D-1} + \cdots + d^2 + d + 1$). Another important remark is that the degree and the diameter of these digraphs are independent and adjustable parameters.

The corresponding undirected graphs $UB(d, D)$ are built by omitting the direction of the arcs.

Remark. If we do not consider the loops, all the vertices $(\alpha, \alpha, \ldots, \alpha, \alpha)$ of $B(d, D)$ have in- and out-degree $d - 1$. Many solutions are proposed in the literature [2] to modify the de Bruijn graphs to make them regular, but we do not consider them in this paper. Indeed, links can be added to nodes of degree strictly less than the maximum degree to communicate with external devices such as front-end processors and peripherals.

In the following section, we use the notations $x = (x_1, \ldots, x_D)$ for a vertex of $B(d, D)$ and $e = [x_1, \ldots, x_D, \alpha]$ for the arc $(x_1, \ldots, x_D) \rightarrowtail (x_1, \ldots, x_D, \alpha)$. The capital letter W will represent any sequence of letters, and $|W|$ the length of this sequence.

5. Arc-disjoint spanning trees of the de Bruijn digraph. The main purpose of this section is to construct for a given vertex r of a de Bruijn digraph a set of $c_G(r) = d - 1$ arc-disjoint spanning trees all rooted at this vertex.

We will extensively use the *shortest-paths spanning tree* (or breadth first search tree). The shortest directed path from a vertex x to a vertex y is obtained by determining the longest sequence, common to the end of x and to the beginning of y. Suppose that this longest sequence is of length $D - h$ and of the form $z_1, \ldots, z_{D-h}$ and let $x = (x_1, \ldots, x_h, z_1, \ldots, z_{D-h})$ and $y = (z_1, \ldots, z_{D-h}, y_1, \ldots, y_h)$. Then the distance between x and y is h, and the unique shortest path between x and y contains successively the vertices

$$(1) \qquad \begin{aligned} x^0 &= x \\ x^1 &= (x_2, \ldots, x_h, z_1, \ldots, z_{D-h}, y_1) \\ &\ldots \\ x^i &= (x_{i+1}, \ldots, x_h, z_1, \ldots, z_{D-h}, y_1, \ldots, y_i),\ 1 < i < h \\ &\ldots \\ x^h &= y. \end{aligned}$$

Figure 2 shows the two shortest-paths spanning trees rooted respectively at (000) and (111) in $B(2, 3)$. One can see that they are arc disjoint.

FIG. 2. *Two shortest-paths spanning trees in* $B(2, 3)$.

PROPOSITION 5.1. *The d shortest-paths spanning trees of the de Bruijn digraph, rooted respectively at the vertices $(\alpha, \ldots, \alpha)$, $\alpha = 0, \ldots, d-1$, are pairwise arc disjoint.*

Proof. Two arcs of different trees are of the form $[\alpha, \ldots, \alpha, W_1]$ and $[\beta, \ldots, \beta, W_2]$, with $|W_i| \leq D, i = 1, 2$. Hence, they are disjoint if $\alpha \neq \beta$. □

Thus, assuming that each of these nodes is connected to an external device, it is possible to load data from the front end to the parallel multiprocessor using d arc-disjoint spanning trees, with a bandwidth d/τ. This is a main point: de Bruijn graphs ensure high bandwidth between any external device and the multiprocessor. We show in the following how to ensure high bandwidth communications within the network.

It is more difficult to find arc-disjoint spanning trees of small depth all rooted at the same vertex in a de Bruijn digraph. It might be worth noting at this point that Imase et al. [19] have built $d-1$ arc-disjoint *paths* of length $\leq D+1$ between any two nodes to study the vulnerability of the de Bruijn digraph. Unfortunately, their construction cannot be used to find arc-disjoint spanning trees rooted at the same vertex.

Finally, let us note that we cannot construct more than $d-1$ arc-disjoint spanning trees rooted at a given vertex due to the presence of loops at the vertices $(\alpha, \ldots, \alpha), \alpha = 0, \ldots, d-1 (c_G(r) = \lambda = d-1)$.

First we present a simple construction of $d-1$ arc-disjoint spanning trees rooted at a given vertex of the form $(\alpha, \alpha, \ldots, \alpha, \alpha)$ with $\alpha \in \{0, \ldots, d-1\}$. Next we generalize this construction.

PROPOSITION 5.2. For all $\alpha \in \{0, \ldots, d-1\}$, *there exist $d-1$ arc-disjoint spanning trees of optimal depth $D+1$ rooted at vertex $(\alpha, \alpha, \ldots, \alpha, \alpha)$ of $B(d, D)$.*

Proof. Let $\alpha \in \{0, \ldots, d-1\}$. With each $\nu \in \{0, \ldots, d-1\}$, $\nu \neq \alpha$ we associate a tree T_ν consisting of the arc from $(\alpha, \ldots, \alpha)$ to $(\alpha, \ldots, \alpha, \nu)$ and the shortest-paths spanning tree rooted at $(\alpha, \ldots, \alpha, \nu)$ from which the vertex $(\alpha, \ldots, \alpha)$ which is a leaf, is deleted. Let $\nu \neq \mu$, and consider any arc $e_\nu = [\alpha, \ldots, \alpha, \nu, W_1]$ from T_ν and any arc $e_\mu = [\alpha, \ldots, \alpha, \mu, W_2]$ from T_μ where $0 \leq |W_i| \leq D, i = 1, 2$. The letters α, ν, μ are all distinct, thus $e_\nu \neq e_\mu$ and T_ν and T_μ are arc disjoint.

It is easy to verify that the depth of these trees is $D+1$. This is optimal since there is only one path of length $\leq D$ from $(\alpha, \ldots, \alpha)$ to any vertex $(x_1, \ldots, x_D), x_1, \neq \alpha$. □

THEOREM 5.3. *For any vertex u of $B(d, D)$, there exist $d-1$ arc-disjoint spanning trees rooted at u of depth at most $D+2k+1$, where k is the length of the second longest subsequence of identical letters in u, that is, of depth at most $D + 2\lfloor \frac{D}{2} \rfloor + 1$.*

Proof. Let $u = (u_1, \ldots, u_D)$ be a given node of $B(d, D)$. We construct $d-1$ arc-disjoint spanning trees rooted at u in two steps. First we will use the shortest-paths trees rooted at vertices at distance $k+1$ from u where k depends on the form of u. Then, if an arc is common to two trees, we will remove this arc from one tree and replace it with another arc that does not appear elsewhere. During all these replacements we will keep the tree structure. We give an example of two arc-disjoint spanning trees of $B(3, 2)$ rooted at $(1, 0)$.

1. *Definition of k and α:* Let us consider a longest subsequence of u consisting of identical letters, and let α be this letter. Let k be the length of the second longest subsequence of identical letters. For example, if $u = (0, 0, \ldots, 0, 0)$, then $\alpha = 0$ and $k = 0$; if $u = (0, 0, 0, 1, 1, 1)$, then $\alpha = 0$ or 1 and $k = 3$; if $u = (0, 0, 0, 1, 1, 2, 2)$, then $\alpha = 0$ and $k = 2$; if $u = (0, 1, 0, 1, 0, 1)$, then $\alpha = 0$ or 1 and $k = 1$. For $u = (1, 0)$, $k = 1$ and we choose $\alpha = 0$.

2. *Definition of T_ν, $\nu \neq \alpha$:* For all $\nu \in \{0, \ldots, d-1\}$, $\nu \neq \alpha$, we build a tree T_ν. We start with the shortest-path P_ν between $u = (u_1, \ldots, u_D)$ and the node $(u_{k+2}, \ldots, u_D, \nu, \ldots, \nu)$ where the letter ν is repeated $k+1$ times, and we add the shortest-paths tree rooted at

$(u_{k+2}, \ldots, u_D, \nu, \ldots, \nu)$. Then we delete from it all the vertices appearing in P_ν (except $(u_{k+2}, \ldots, u_D, \nu, \ldots, \nu)$) and the subtrees rooted at them, and we reattach these subtrees directly to P_ν. Thus we have obtained a spanning tree T_ν rooted at u. In $B(3, 2)$, from $u = (1, 0)$ and our choice of $\alpha = 0$, there are two paths P_1 and P_2:

$$P_1 = (1, 0) \longrightarrow (0, 1) \longrightarrow (1, 1),$$
(2)
$$P_2 = (1, 0) \longrightarrow (0, 2) \longrightarrow (2, 2),$$

and the two trees T_1 and T_2 are shown in Fig. 3 (T_1 is the black tree, and T_2 is the grey tree). They are not disjoint, since $(1, 0) \longrightarrow (0, 2)$ belongs to both trees.

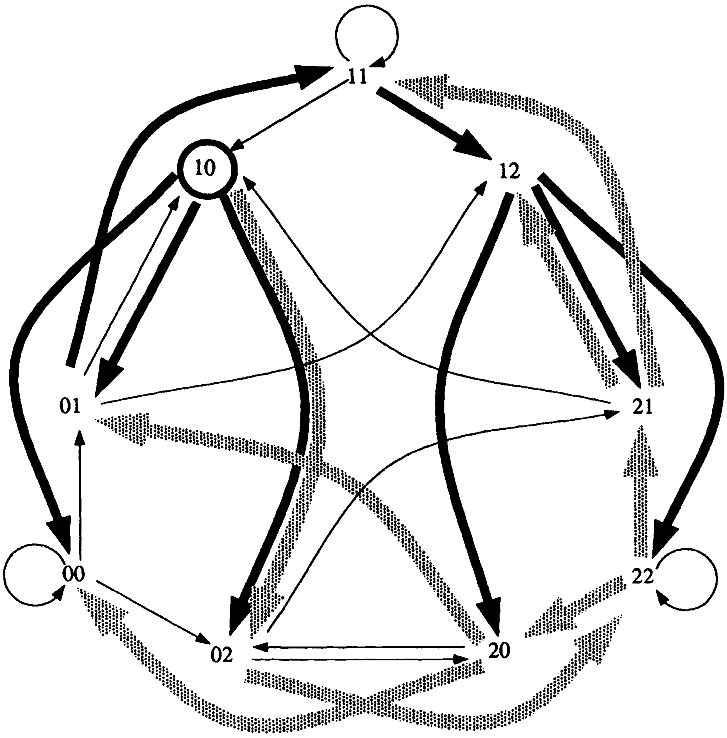

FIG. 3. *Construction of two arc-disjoint spanning trees rooted at* (10) *in* $B(3, 2)$.

3. *Definition of* T'_ν, $\nu \neq \alpha$: An arc of T_ν is of the form

(a) $$e_\nu = \left[u_i, \ldots, u_D, \underbrace{\overbrace{\nu, \ldots, \nu}^{\leq k+1}}_{\geq 1} \right] \text{ if it belongs to } P_\nu,$$

(b) $$\text{otherwise } e_\nu = \left[u_i, \ldots, u_D, \overbrace{\nu, \ldots, \nu}^{k+1}, W \right] \text{ where } W \text{ is non-empty and } i \leq D,$$

(c) $$\text{or } e_\nu = \left[\underbrace{\overbrace{\nu, \ldots, \nu}^{\leq k+1}}_{\geq 1}, W \right] \text{ where } W \text{ is non-empty.}$$

Let $\mu \neq \nu$ and $e_\nu = e_\mu$ where e_ν and e_μ are arcs of T_ν and T_μ, respectively. Since $\mu \neq \nu$, e_ν and e_μ cannot be both of type (a) or both of type (c). Suppose e_ν is of type (a) or (b), and e_μ of type (b). Then $e_\nu = [u_i, \dots, u_D, \nu, \dots, \nu, W]$ where W may be empty (and there may be less than $k+1$ consecutive letters ν), and

$$e_\mu = \left[u_j, \dots, u_D, \overbrace{\mu, \dots, \mu}^{k+1}, W' \right]$$

where W' is non-empty and $j \leq D$. If W is empty (type (a)), then, since $\mu \neq \nu$, there are $k+1$ consecutive letters μ in the subword $u_i, \dots, u_D$, contradicting the definition of k as $\mu \neq \alpha$. If W is non-empty, then we can suppose without loss of generality that $j > i (i \neq j$ since $\mu \neq \nu)$. Thus, as before, there would be $k+1$ consecutive letters μ in the subword $u_i, \dots, u_D$, a contradiction. Note that the same argument shows that e_μ cannot be of type (c) with $k+1$ letters μ at the beginning.

Thus exactly one arc is of type (c) with not more than k identical letters at the beginning. Suppose without loss of generality that it is $e_\mu = [\mu, \dots, \mu, W]$ (W is non-empty). Moreover, this arc is also of type (a) or (b) in T_ν, that is, of the form $[u_i, \dots, u_D, \nu, \dots, \nu, W']$ (W' may be empty), $\nu \neq \mu$. We denote this kind of arc e^ν_μ. Such an arc satisfies

$$\begin{aligned} e^\nu_\mu &= [\mu, \dots, \mu, W],\ W \text{ non-empty} \\ &= [u_i, \dots, u_D, \nu, \dots, \nu, W'],\ W' \text{ can be empty.} \end{aligned} \tag{3}$$

We will replace this arc in T_μ by the arc f^ν_μ which is obtained from e^ν_μ by replacing the first occurrence of μ by α.

Let us call T'_μ the new graph obtained from T_μ by doing all the possible replacements.

In the example in Fig. 3, the arc $[1, 0, 2]$ belongs to both T_1 and T_2. This arc, denoted e^2_1, is of type (c) since it can be written $[1, W]$ (an arc of T_1) and of type (a) since it can be written $[u_1, u_2, 2]$ (an arc of T_2). This arc is replaced in T_1 by the arc $f^2_1 = [\alpha, W] = [0, 0, 2]$ to build T'_1. The other tree is not modified: $T'_2 = T_2$. One can check on Fig. 3 that T'_1 and T'_2 are arc disjoint.

4. *The T'_μ, $\mu \neq \alpha$ are arc disjoint*: The arc f^ν_μ comes from the replacement of $e_\mu = e_\nu$ and so can be written

$$\begin{aligned} f^\nu_\mu &= [\alpha, \mu, \dots, \mu, W],\ W \text{ non-empty} \\ &= [\alpha, u_{i+1}, \dots, u_d, \nu, \dots, \nu, W'],\ W' \text{ can be empty.} \end{aligned} \tag{4}$$

First, let us show that $f^\nu_\mu \neq f^{\nu'}_{\mu'}$ for all $\mu \neq \mu'$. Necessarily, $\nu \neq \nu'$, otherwise there would be two arcs entering to the same node in T_ν, namely $e^\nu_\mu = [\mu X]$ and $e^\nu_{\mu'} = [\mu' X]$ where $X = (u_{i+1}, \dots, u_D, \nu, \dots, \nu, W')$. We have

$$\left\{ \begin{aligned} f^\nu_\mu &= [\alpha, u_{i+1}, \dots\dots, u_D, \nu, \dots, \nu, W], \\ f^{\nu'}_{\mu'} &= [\alpha, u_{j+1}, \dots\dots, u_D, \nu', \dots, \nu', W'], \end{aligned} \right. \tag{5}$$

with at least one ν and one ν'. Without loss of generality, we can suppose that $j > i$ (therefore $i + 1 \leq D$), W' is non-empty, otherwise W would also be empty and this would imply $\nu = \nu'$. Therefore $f^{\nu'}_{\mu'}$ contains a subsequence of $k+1$ letters ν'. Thus $\alpha, u_{i+1}, \dots, u_D$ contains also a subsequence of $k+1$ letters ν' contradicting the definition of k (since $\alpha \neq \nu'$).

Finally, f_μ^ν cannot be an arc of T_γ, $\gamma \neq \mu$. Indeed, assume that $f_\mu^\nu = e_\gamma$:

$$f_\mu^\nu = [\alpha, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W] \tag{6}$$

and

$$e_\gamma = \begin{cases} [u_j, \dots, u_D, \gamma, \dots, \gamma] \text{ (type (a))} \\ \text{or} \\ [u_j, \dots, u_D, \gamma, \dots, \gamma, W'] \text{ (type (b))} \\ \text{or} \\ [\gamma, \dots, \gamma, W''] \text{ (type (c)).} \end{cases} \tag{7}$$

The arc e_γ cannot be of type (c) because $\gamma \neq \alpha$. If $\gamma \neq \nu$, a similar argument shows that there is a subsequence of $k + 1$ letters γ or ν in $u = (u_1, \dots, u_D)$ contradicting the definition of k. But $\gamma = \nu$ implies that the node $(u_{i+1}, \dots, u_D, \nu, \dots, \nu, W)$ is reached in T_ν by the arc $[\alpha, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W]$. This is impossible since it is reached in T_ν by the arc $e_\nu = [u_i, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W] = e_\mu^\nu$, and $u_i \neq \alpha$ since $e_\mu^\nu = [\mu, \dots]$.

5. *The T'_μ, $\mu \neq \alpha$ are connected*: It suffices to show that the path in T'_μ from the root to the tail of the new arc $[\alpha, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W']$ is identical to the corresponding path in T_μ. Suppose that some arc of this path has been modified. Then it must be of the form $[\mu, \dots, \mu, \alpha, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W'']$ (because the path must reach the tail of $[\alpha, u_{i+1}, \dots, u_D, \nu, \dots, \nu, W']$), and it must also be of the form $[u_j, \dots, u_D, \gamma, \dots, \gamma, W''']$ for some $\gamma \neq \mu$.

If $\gamma \neq \nu$, then a similar argument as before shows that there is a subsequence of $k + 1$ letters γ or ν in $u = (u_1, \dots, u_D)$ contradicting the definition of k. So $\gamma = \nu$, but it again implies a contradiction with the definition of k by looking carefully at the positions of u_i in the two forms of the arc and noting that $\nu \neq \alpha$, $u_i \neq \alpha$, and $u_i \neq \nu$ (recall that in fact $u_i = \mu$).

6. *The depth of the T'_μ is at most $D + 2\lfloor \frac{D}{2} \rfloor + 1$*: The path from the root to any vertex in T_μ is of length at most $k + 1 + D$. In the replacement process, we might attach at most one (by step 5) subtree of depth at most $k - 1$. Indeed, the root of this subtree is the head of an arc e_μ^ν, which is (by step 3) of the type (c) but cannot contain more than k letters μ. Altogether the total depth is at most $k + 1 + D + 1 + k - 1 = D + 2k + 1$. We always have $k \leq \lfloor \frac{D}{2} \rfloor$. □

The proof of Theorem 5.3 is constructive and gives a method to construct arc-disjoint spanning trees of $B(d, D)$. With the notation of the proof, first find α and k. Next build the $d - 1$ shortest-paths trees rooted at the $d - 1$ vertices $(u_{k+2}, \dots, u_D, \nu, \dots, \nu)$, $\nu \neq \alpha$ (where the letter ν is repeated $k + 1$ times). Finally, correct the trees following the described rule. Concerning the depth, note that $k = \lfloor \frac{D}{2} \rfloor$ is a worst case that occurs with a small probability. In general, k is much smaller than $\lfloor \frac{D}{2} \rfloor$, hence the depth of the arc-disjoint spanning trees is much smaller than $D + 2\lfloor \frac{D}{2} \rfloor + 1$. For instance, if the root is $u = (\alpha, \alpha, \dots, \alpha, \alpha)$, our construction is the one given in Proposition 5.2 and we have a depth of $D + 1$.

COROLLARY 5.4. *Let r be any node of $B(d, D)$. There exists a protocol of broadcasting from r whose time is at most $(\sqrt{L\tau/(d - 1)} + \sqrt{2DB}\,)^2$.*

For a large message, this time is of the same order as the lower bound given by Proposition 3.1, i.e., $b_{B(d,D)}(r) \geq \max(D\beta, L\tau/(d - 1)\tau)$.

6. Gossiping in networks. First we consider a given digraph $G = (V, E)$ of diameter D and minimum in-degree $d^-_{\min} = \min_{u \in V} d^-(u)$, and next we study the particular case of the de Bruijn digraph. Gossiping is broadcasting from all the nodes. We assume that all the messages are of the same length L.

6.1. General lower bounds. Since during any gossiping all the nodes must perform a broadcast, the total start-up time is at least $\max_{r\in V} ecc(r)\beta = D\beta$. Let u be any node of V and S be a set of vertices not containing u. All the $|S|$ messages initiated by the vertices in S must reach u through $m^+(S, V - S)$ communication links, hence the total propagation time is at least

$$\max_{u\in V}\max_{S\neq\emptyset\,|\,u\notin S}\frac{|S|L}{m^+(S, V - S)}\tau. \tag{8}$$

For instance, choosing $S = V - \{u\}$ the total propagation time is at least

$$\max_{u\in V}((n-1)L/d^-(u))\tau = ((n-1)L/d^-_{\min})\tau.$$

PROPOSITION 6.1. *In a digraph G of minimum in-degree $d^-_{\min}$ and diameter D, the gossiping time is at least $g_G \geq \max(D\beta, ((n-1)L/d^-_{\min})\tau)$.*

Note that we cannot obtain a lower bound by adding the two lower bounds (start-up and propagation time) [13], [31].

According to the above reasoning and particularly to (8), a good gossiping algorithm might proceed in D steps, ensuring that for any set of vertices S maximizing the ratio $|S|/m^+(S, V - S)$, the messages crossing from S to $V - S$ use the $m^+(S, V - S)$ links with a well-balanced load of the messages on the links. Johnsson and Ho [20] and MacKenzie and Seidel [25] show that this is possible for hypercubes and star graphs, respectively. We will show that this is also possible for the de Bruijn digraphs.

6.2. Gossiping in digraphs. We give below a simple greedy algorithm that appears to reach an optimal propagation time in the de Bruijn digraph. More details concerning the algorithm and its extensions can be found in [3], [4], [23]. We define the receiving phase as follows: receive while data arrive through any link and while all the links have not transmitted at least one message. With this convention, we describe following gossiping algorithm.

ALGORITHM (the algorithm is given for a processor u)
Step $i (1 \leq i \leq D)$:

i. Form a message called *New* consisting of all the messages u has not already sent (at step 1, *New* will consist of the message of u itself). Send *New* to all the out-neighbors of u.
ii. Wait until you receive all the messages from your in-neighbors.

Note that to ensure that the algorithm works, u has to send a message at each phase i. If u has not received any new messages at phase $i - 1$, it can send an empty message or a special one.

The algorithm applied to the de Bruijn digraph is shown in Fig. 4. (The messages are numbered with the name of the processor in decimal arithmetic.)

The following lemma shows that the algorithm realizes the total exchange of the messages in D steps and will enable us to compute an upper bound of the gossiping time.

LEMMA 6.2. *At step i, each processor p forwards all the messages from all processors p' such that there exists a shortest path of length $i - 1$ from p' to p $(d(p', p) = i - 1)$.*

Proof. Let us call P_i the property "*at step i, each processor p forwards all the messages from all processors p' such that $d(p', p) = i - 1$.*" We proceed by induction. P_1 is true. Assume that P_j is true for all $j < i$. During step $i - 1$, each processor q sends to all its

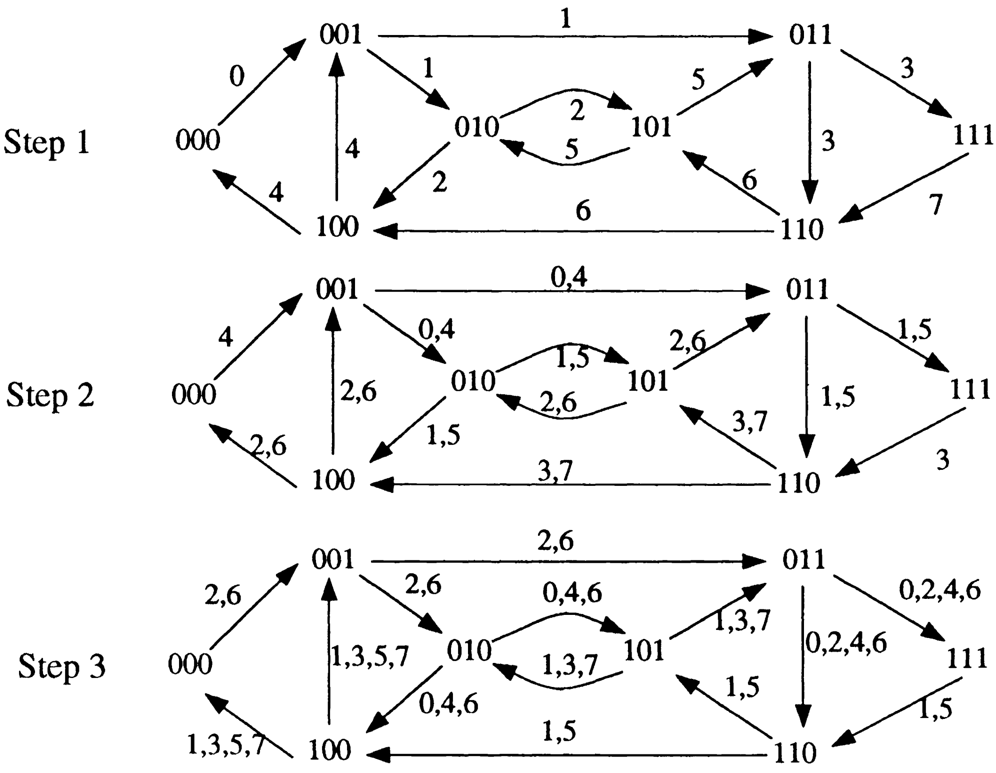

FIG. 4. *Gossiping in* $B(2,3)$.

neighbors all the messages from processors p' such that $d(p', q) = i - 2$ by the induction hypothesis. Thus all the messages from processors p' such that $d(p', p) \leq i - 1$ have been received by p at the end of step $i - 1$. During step i, p forwards messages from processors p' such that $d(p', p) = i - 1$ since it had already forwarded those from processors p' such that $d(p', p) < i - 1$ by hypothesis. Thus P_i is true. □

Let $d^-_{\max}$ be the maximum in-degree of the considered network. From a processor p, there are at most $(d^-_{\max})^i$ processors p' such that $d(p', p) = i$; thus the maximum time of step i of the greedy algorithm is less than $\beta + (d^-_{\max})^{i-1}L\tau$ assuming that all messages are of same length L. Hence:

$$\begin{aligned} T_{Greedy} &\leq \sum_{i=1}^{D} \left(\beta + (d^-_{\max})^{i-1}L\tau\right) \\ &= D\beta + \frac{(d^-_{\max})^D - 1}{d^-_{\max} - 1}L\tau. \end{aligned} \tag{9}$$

THEOREM 6.3. *In any digraph G of diameter D and maximum in-degree $d^-_{\max}$, there exists a protocol of gossiping whose running time is at most*

$$D\beta + \frac{(d^-_{\max})^D - 1}{d^-_{\max} - 1}L\tau.$$

For short messages, the greedy algorithm runs in $\Theta(D\beta)$, which is optimal. But depending on the considered network, the upper bound of the greedy algorithm cost can be far from the lower bound of the time to gossip. However, we will show in the next section that, for the de Bruijn digraph, this upper bound is of the same order as the lower bound for large messages.

6.3. Gossiping in de Bruijn digraphs. For a de Bruijn digraph $B(d, D)$, $d^-_{\min} = d - 1$, thus $g_G \geq (n - 1/d - 1)L\tau$. Moreover, $d^-_{\max} = d$ and $n = d^D$, thus the greedy algorithm applied to the de Bruijn digraph has a complexity $T_{Greedy} \leq D\beta + (n - 1/d - 1)L\tau$.

COROLLARY 6.4. *In the de Bruijn digraph $B(d, D)$, there exists a protocol of gossiping whose running time is at most $D\beta + (n - 1/d - 1)L\tau$.*

For large messages, this protocol is of the same order as the lower bound. Moreover, for any length of message, it is at most two times slower than an optimal algorithm since the lower bound given by Proposition 6.1 is $\max(D\beta, ((n - 1)L/d - 1)\tau)$. Note that Fig. 4 shows that there may exist a dissymmetry on the load of the arcs during each step of the greedy algorithm. Moreover, note that there are small redundancies in the transmission of the data. Hence, it may be possible to decrease the global cost by a small amount.

7. Case of undirected graphs. Designers prefer to construct networks based on undirected graphs. Indeed, layouts of mono- and bidirectional links are of the same complexity. If there is a link between u and v, then a message can be sent directly from u to v and from v to u. Recall that if only one of these messages can be sent at any given time, it is a *half duplex* mode of communication. Otherwise it is a *full duplex*. Here we are interested in the full duplex communication mode and so it is better to think in terms of symmetric digraphs. We can therefore apply the results above. We will now examine only what is happening for the undirected de Bruijn graph $UB(d, D)$.

A node $u = (u_1, \ldots, u_D) \in UB(d, D)$ is linked with $(u_2, \ldots, u_D, \alpha)$ and $(\alpha, u_1, \ldots, u_{D-1})$. A very important point is that we do not remove any of the double bidirectional links between nodes. For instance, (010) is linked twice in $UB(2, 3)$ with (101) by two bidirectional links. The maximum degree of $UB(d, D)$ is $2d$, but its minimum degree is $2d - 2$. We will use $UB^*(d, D)$ to denote the symmetric digraph obtained from $UB(d, D)$.

7.1. Broadcasting. Consider the set T_v of $d - 1$ arc-disjoint trees as constructed in §5. They use the arcs of $UB^*(d, D)$ in only one direction. Moreover, we can consider another family S_v of $d - 1$ arc-disjoint spanning trees by using right shifts instead of left shifts. Therefore, we have constructed a family of $2d - 2$ arc-disjoint spanning trees of $UB^*(d, D)$ of depth h at most $2D + 1$. Thus using Theorem 3.3, we have:

COROLLARY 7.1. *In any symmetric de Bruijn graph $UB^*(d, D)$ there exists a protocol whose broadcasting time is at most $(\sqrt{L\tau/2d - 2} + \sqrt{2D\tau})^2$.*

For large messages, this time is of the same order as the lower bound given by Proposition 3.1, i.e., $b_{UB^*(d,D)}(r) \geq \max(D\beta, (L/2d - 2)\tau)$.

7.2. Gossiping. We easily deduce from the greedy algorithm of §6 a greedy algorithm for $UB^*(d, D)$. Each message is divided into two parts. One part is diffused using the original gossiping (with left shifts), whereas the second part is diffused performing a similar gossiping with right shifts. The complexity is then:

$$\begin{aligned} T_{Greedy} &\leq \sum_{i=1}^{D} \left(\beta + d^{i-1}\frac{L}{2}\tau\right) \\ &= D\beta + \frac{d^D - 1}{d - 1}\frac{L}{2}\tau \qquad (10) \\ &= D\beta + \frac{n - 1}{2d - 2}L\tau. \end{aligned}$$

COROLLARY 7.2. *In the de Bruijn graph $UB^*(d, D)$, there exists protocol of gossiping whose running time is at most $D\beta + \frac{n-1}{2d-2}L\tau$.*

As for $B(d, D)$, for large messages this protocol is of the same order as the lower bound, and for any length of messages it is at most two times slower than an optimal algorithm since the lower bound given by Proposition 6.1 is $g_{UB^*(d,D)} \geq \max(D\beta, \frac{(n-1)L}{2d-2}\tau)$.

8. Conclusion. The de Bruijn digraphs (or undirected graphs) are a good family for performing broadcasting or gossiping. Our broadcasting and gossiping algorithms have propagation times that reach the optimal order for large messages. To do this, we have constructed a family of arc-disjoint spanning trees. These trees have a small depth and are easy to construct when the root is a vertex of the form $(\alpha, \dots, \alpha)$. This confirms the interest of using these vertices as gates with the outside world. It will be interesting to improve the depth of the spanning trees constructed in general. It remains to study the same problem for other families such as Kautz digraphs or generalized de Bruijn or Kautz graphs. Finally, the general problem of bounding the maximum depth of arc-disjoint spanning trees in general graphs is interesting in itself and, as far as we know, algorithms for constructing arc-disjoint spanning trees of minimum depth have not been yet proposed (this problem has been proved to be NP-complete by Noga Alon; see sketch of his proof in [1]).

Acknowledgments. We are grateful to Joseph Peters and Dominique Sotteau for many helpful discussions and remarks.

A LINEAR-TIME ALGORITHM FOR THE HOMOTOPIC ROUTING PROBLEM IN GRID GRAPHS*

MICHAEL KAUFMANN† AND KURT MEHLHORN‡

Abstract. The paper considers the problem of finding edge-disjoint paths between pairs of vertices in a finite grid graph. The homotopy class for each path to be routed is prespecified. A very fast algorithm that guarantees to find a solution for any solvable homotopic routing problem is given.

Key words. algorithms, homotopic routing, edge-disjoint paths, VLSI-theory

AMS subject classifications. 68Q25, 68U05

1. Introduction. We give a linear time algorithm for the homotopic routing problem in grid graphs.

Problem: Homotopic Routing Problem in Grid Graphs (HRP)
Input: A grid graph R and nets $q_1, \dots, q_k$.
Output: Pairwise edge-disjoint grid paths $p_1, \dots, p_k$ such that p_i is homotopic to q_i, $1 \le i \le k$, or an indication that no such paths exist. □

The *planar rectangular grid consists* of vertices $\{(x, y); x, y \in \mathbb{Z}\}$ and edges $\{((x, y), (x', y')); |x - x'| + |y - y'| = 1\}$. A *grid graph* $R = (V, E)$ is a finite subgraph of the planar rectangular grid. We call a bounded face F of R trivial if it has exactly four vertices on its boundary and nontrivial otherwise. We muse M to denote the set of nontrivial bounded faces together with the unbounded face F_{ext} and $\mathcal{O}$ to denote the union of the interiors of the faces in M. A nontrivial face is also called a hole.

A path p is a continuous function $p : [0, 1] \to \mathbb{R}^2 - \mathcal{O}$. A path p is called a *net* if $\{p(0), p(1)\} \subseteq V \cap \partial\mathcal{O}$ where $\partial\mathcal{O}$ is the boundary of $\mathcal{O}$. Two paths p and q are *homotopic*, denoted $p \sim q$, if there is a continuous function $F : [0, 1] \times [0, 1] \to \mathbb{R}^2 - \mathcal{O}$ such that $F(0, x) = p(x)$ and $F(1, x) = q(x)$ for all $x, 0 \le x \le 1$, and $F(t, 0) = p(0)$ and $F(t, 1) = p(1)$ for all $t, 0 \le t \le 1$. A path p is called a *grid path* if $p(x)$ belongs to R for all x.

Figure 1 gives an example of an HRP. For the algorithmic treatment, we assume that the nets $q_1, \dots, q_k$ are grid paths and use n to denote the number of vertices of R plus the total number of edges in the paths q_i. The integer n is called the size of the HRP. We use $\mathcal{N}$ to denote the set $\{q_1, \dots, q_k\}$ of nets.

THEOREM 1. *Let $P = (R, \mathcal{N})$ be an even bounded HRP of size n.*

(a) *P is solvable if and only if* $\text{fcap}(X) \ge 0$ *for every cut X.*

(b) *In time $O(n)$ one can decide whether P has a solution and also construct a solution if it does.* □

Part (a) of this theorem was shown in [KM2] and later extended by [Sh]. The paper [KM2] also presents an $O(n^2)$ algorithm. In the present paper we give a new algorithm with linear running time.

A *cut* C is a simple path in $\mathbb{R}^2 - \mathcal{O} - V$ with its endpoints in $\partial\mathcal{O}$. The *capacity* $\text{cap}(C)$ of a cut C is the number of intersections with edges of R. If C is a cut and p is a path then $\text{cross}(p, C)$ is the number of intersections with edges p and C and $\text{mincross}(p, C) =$

min{cross (q, D); $q \sim p$, $D \sim C$}. Finally, the *density* dens(C) of cut C is defined by

$$\text{dens}\,(C) = \sum_{p \in \mathcal{N}} \text{mincross}(p, C)$$

and the *free capacity* fcap (C) is given by

$$\text{fcap}(C) = \text{cap}(C) - \text{dens}(C).$$

A cut C is *saturated* if fcap$(C) = 0$ and *oversaturated* if fcap$(C) < 0$. An HRP is *even* if fcap(C) is even for every cut C.

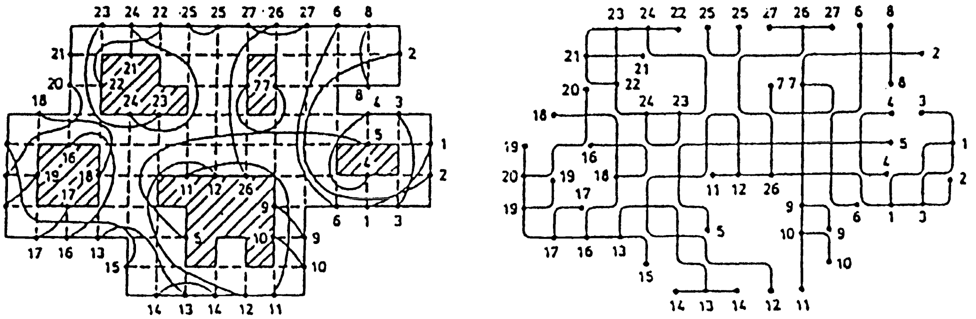

FIG. 1.

Let v be a vertex in R. We denote the degree of v by deg(v) and the number of nets having v as endpoint by ter(v). An HRP is *bounded*, if deg(v) + ter$(v) \leq 4$ for all vertices v, and *weakly bounded* if deg$(v) = 4$ implies ter$(v) = 0$.

There are many previous papers on finding edge-disjoint paths in grid graphs and general planar graphs, e.g., [PL], [F], [MP], [NSS], [KM1], [KM2], [BM], [K], [Sh]. The present paper extends the work in [KM2]. We refer the reader to [KM2] for a discussion of the relationship between VLSI-design and homotopic routing problems.

This paper is organized as follows. In §2 we describe the algorithm and in §3 we prove its correctness. The algorithm is similar in spirit to the algorithm in [KM2], but differs in many details. In particular, its correctness does not follow from [KM2]. In §4 we then describe the linear time implementation of the algorithm. Weinelt [W] has implemented the algorithm; Fig. 1 has been produced by his program.

2. The algorithm. In this section we describe an algorithm for the homotopic routing problem in grid graphs. Recall that we are given a grid graph R and nets $p_1, \dots, p_k$ and that our goal is to shift the nets $p_1, \dots, p_k$ into pairwise edge-disjoint grid paths. Our algorithm works iteratively. In each iteration we consider an edge e of R and decide whether to use it for some net and if so for which one. If e is to be used for net p then we choose suitable nets p^1 and p^2 with $p \sim p^1 e p^2$ and replace net p by the three nets p^1, e, and p^2. The edge e is then used to route the net e in the obvious way. Thus, each iteration discards one edge of R and hence there are $O(n)$ iterations. In §4 we show how to implement the algorithm such that each iteration takes amortized time $O(1)$.

For the algorithm we need some further concepts.

DEFINITION 1. *For a path p the canonical representation* can(p) *is the shortest path homotopic to p.*

Note that can(p) is composed of straight-line segments.

DEFINITION 2. (a) *A path p is called a prefix of path q if there is a monotone function $t : [0, 1] \to [0, 1]$ with $t(0) = 0$ such that $p(x) = q(t(x))$ for all x.*

(b) *The reversal p^{-1} of path p is defined by $p^{-1}(x) = p(1 - x)$ for $0 \leq x \leq 1$.*

(c) *If p and q are paths, then $p \approx q$ if either $p \sim q$ or $p^{-1} \sim q$.*

(d) *For a path p, we define* source$(p) = p(0)$ *and* target$(p) = p(1)$.

(e) *For a point v, $x(v)$ and $y(v)$ denote the x- and y-coordinate of point v, respectively.*

DEFINITION 3. *Let p and q be nontrivial paths with the same source s and let s lie on the boundary of a unique hole F. Then p is said to be* right *of q, if either*

- can(p) = can(q) *or*
- can(p) *is a proper prefix of* can(q) *and there is a hole to the right of* can(q) *at point* target(can(p)) *or*
- can(q) *is a proper prefix of* can(p) *and there is a hole to the left of* can(p) *at point* target(can(q)) *or*
- can(p) *and* can(q) *have no nontrivial common prefix and for every sufficiently small circle K around s there is a counterclockwise scan of K intersecting first ∂F, then* can(p), *then* can(q), *and finally again ∂F or*
- can(p) *and* can(q) *have a maximal common nontrivial prefix r, i.e.,* can$(p) = rp^1$, can$(q) = rq^1$ *and p^1 and q^1 have no nontrivial common prefix, and for every sufficiently small circle K around* target(r) *there is a counterclockwise scan of K intersecting first r, then p^1, and finally q^1.*

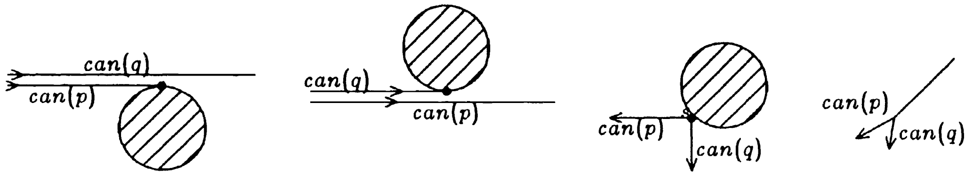

FIG. 2. *An illustration of the four cases in Definition* 3.

Figure 2 illustrates the various cases of Definition 3. The relation *left* is defined analogously. Both relations are clearly transitive.

DEFINITION 4. (a) *A path p is* x-monotone *if x*(target(p)) $\leq x$(source(p)) *and for every vertical line L the intersection $p \cap L$ is a segment, i.e., x-monotone paths travel from right to left.*

(b) *The* monotone prefix pref(p) *of a net p is the maximal x-monotone prefix of* can(p).

(c) *Let p and q be nets with a common source s and let s lie on the boundary of a unique hole. Then p is* quasi-right *of q if either* pref(q) *is trivial or* pref(p) *and* pref(q) *are nontrivial and* pref(p) *is right of* pref(q).

Remark. The ordering right played an important role in the algorithm of [KM2]. In this paper we use the ordering quasi-right instead. This is one of the sources for the improved running time.

DEFINITION 5. *A cut C is called* vertical *if it is a vertical straight-line segment.*

The algorithm is given as Program 1. In this program, *top* always denotes the largest y-coordinate of any vertex of R, *Top* is the subgraph spanned by the vertices with y-coordinate equal to *top*, and a *segment* is a connected component of *Top*. An endpoint of a segment is called *exposed* if it is not the terminal of any net. The endpoints of a segment are also called *corners* of the segment. Finally, *Rim* is the closed region above the horizontal line $y = top - 1$. In the formulation of Program 1 we assumed that the lowest numbered case for which the precondition is satisfied is executed, i.e., if e.g., case 4.3 is taken, then cases 1, 2, 3, 4.1, and 4.2 do not apply. In cases 4.2 and 5.1 the concept of rightmost decomposition is used, which we now define.

DEFINITION 6. *Let $e = (b, a)$ with b the left neighbor of a be an edge in row Top and let X be the vertical cut through e. Let C be the set of nets p with* $\text{mincross}(p, X) > 0$. *For $p \in C$ an* admissible *decomposition is a triple (p^1, e, p^2) such that $p \approx p^1ep^2$ and* $\text{mincross}(p^1, X) + \text{mincross}(p^2, X) = \text{mincross}(p, X) - 1$. *A triple (p^1, e, p^2) is called a* rightmost *decomposition with respect to X if it is an admissible decomposition of a net $p \in C$ and p^2 is quasi-right of q^2 for any admissible decomposition (q^1, e, q^2).*

PROGRAM 1.

3. Proof of correctness. This section is divided into two subsections. In the first subsection we collect some useful facts about cuts and in the second subsection we argue the correctness of the routing algorithm.

3.1. Some facts about cuts.

DEFINITION 7. *A cut $C : [0, 1] \to \mathbb{R} - \mathcal{O} - V$ is called* straight *if the function C is linear and it is called* almost-straight *if it is either straight or if the line segment connecting $C(0)$ and $C(1)$ is contained in the boundary of a nontrivial face, the functions $C|[0, \frac{1}{2}]$ and $C|[\frac{1}{2}, 1]$ are linear, there is no vertex of R contained in the interior of the triangle $C(0)C(\frac{1}{2})C(1)$, and no edge of R is intersected more than once by C. A cut C is called* Manhattan *if it consists of horizontal and vertical straight-line segments. For a cut C,* Manhattan(C) *is a Manhattan cut intersecting the same edges as C.*

DEFINITION 8. *A tuple $(p_1, \ldots, p_k)$ is called* straight-line decomposition *of p if* can(p) $= p_1 \cdots p_k$ *and each p_i is a maximal straight-line segment contained in* can(p). *Each p_i is called a straight-line piece of p.*

LEMMA 1. (a) *Let P be weakly bounded. Then the cut condition holds if it holds for all almost-straight cuts.*

(b) *Let P be bounded. Then* fcap(C) > 0 *for every cut C that is almost-straight but not straight. Also, the cut condition holds if it holds for straight cuts.*

(c) *Let p be a net and C a cut. Then* cross(p, C) $\equiv$ mincross(p, C) mod 2.

(d) *Let $(p_1, \ldots, p_k)$ be the straight-line decomposition of p and let C be a straight cut. Then* mincross(p, C) $= \sum_{i=1}^{k}$ cross(p_i, C).

(e) *Let P be a bounded problem satisfying the cut condition and let C be a saturated Manhattan path in P. Then consecutive turns of C are in alternate directions.*

(f) *Let P be bounded. If there is an oversaturated straight cut in P, then there is either an oversaturated horizontal or vertical cut in P or an oversaturated straight cut intersecting only edges incident to vertices of degree* 4.

Proof. (a) This is the content of §3 of [Sh].

(b) Let C be almost-straight but not straight. Then the line segment connecting $C(0)$ and $C(1)$ passes through exactly cap(C) $- 2$ vertices, all of which have degree 3. Hence dens(C) $\leq$ cap(C) $- 2$. The second part now follows from part (a).

(c) This is Lemma 7 of [KM2].

(d) Since $p \sim$ can(p) $= p_1 p_2 \cdots p_k$, we have mincross(p, C) $\leq \sum_i$ cross(p_i, C). Let us assume mincross(p, C) $< \sum_i$ cross(p_i, C). Then there are (x_1, λ_1), (x_2, λ_2) such that $x_i \neq x_2$, $\lambda_1 \neq \lambda_2$, and can(p)$|[x_1, x_2] \sim C|[\lambda_1, \lambda_2]$. Since can($p$) is a shortest path homotopic to p and since C is a straight-line segment, we conclude that can(p)(x_1) and can(p)(x_2) must lie on the same segment p_i. So p_i is a subpath of C and hence C passes through a vertex of R, a contradiction.

(e) This is Lemma 12a, Claim 1 of [KM2].

(f) This is Lemma 12b of [KM2]. Note that this lemma state in the terminology of that paper that there is either an oversaturated 0-bend or an oversaturated 1-bend cut connecting two concave corners. The latter gives rise to a straight cut intersecting only edges incident to vertices of degree 4. □

3.2. Correctness of the algorithm. All of the actions in our algorithm fall under the following paradigm. For a certain edge e and a certain net p we choose p^1 and p^2 such that $p \approx p^1 e p^2$, replace p by p^1 and p^2 and discard e; operations 4.1, 4.2, and 5.2 can be viewed as repeated application of this basic action. It is convenient to view the basic step as to consist of two substeps.

substep A: replace p by the three nets p^1, e, and p^2.

substep B: remove edge e and net e.

The further outline of the correctness proof is as follows. We first deal with substep B in Lemma 2, then show in Lemma 3 that substep A generates even problems satisfying the degree constraints postulated in the premise of Lemma 3, and finally show in Lemmas 4 to 10 that operations 1 to 5.2 preserve the cut condition. In the proofs of these lemmas we will frequently use part (a) of Theorem 1, i.e., the present paper does not give an alternative proof of part (a).

LEMMA 2. *Let $P = (R, \mathcal{N})$ be an even routing problem satisfying the cut condition, and let e be an edge in the boundary of $\mathcal{O}$ as well as a net in $\mathcal{N}$. Assume further that* $\text{ter}(v) + \deg(v) \leq 4$ *for all vertices except the endpoints of e and* $\text{ter}(v) + \deg(v) \leq 6$ *for the two endpoints of e. Then removing edge e and net e yields an even, bounded problem satisfying the cut condition.*

Proof. Let us use P' to denote the modified problem. P' is certainly bounded. If there is a cut of capacity one through e, then P' is also even and satisfies the cut condition. So let us assume that there is a trivial face F incident to e in P. Let $R' = R - e, \mathcal{N}' = \mathcal{N} - e$ and let Y' be any straight cut in R'. If Y' is also a cut in P, then $\text{dens}'(Y') = \text{dens}(Y')$ and $\text{cap}'(Y') = \text{cap}(Y')$ where dens′ and cap′ are computed with respect to P'. If, on the other hand, Y' ends in F then we can extend Y' to a cut in P with $\text{cap}(Y) = \text{cap}'(Y') + 1$ and $\text{dens}(Y) = \text{dens}'(Y') + 1$. Thus $\text{fcap}'(Y') = \text{fcap}(Y) \geq 0$. □

LEMMA 3. *Substep* A *generates even problems satisfying the degree constraints postulated in the premise of Lemma* 2.

Proof. The claim about the degree contraints is obvious. For the evenness let C be any cut and let $p \sim p^1 e p^2$. Then

$$\begin{aligned} \text{mincross}(p, C) &= \text{mincross}(p^1 e p^2, C) \\ &= \text{cross}(p^1 e p^2, C) \bmod 2 \qquad \text{by Lemma 1(c)} \\ &= [\text{cross}(p^1, C) + \text{cross}(e, C) + \text{cross}(p^2, C)] \bmod 2 \\ &= [\text{mincross}(p^1, C) + \text{mincross}(e, C) + \text{mincross}(p^2, C)] \bmod 2 \end{aligned}$$

by Lemma 1(c). Thus evenness is preserved. □

LEMMA 4. *Operations* 1 *and* 2 *preserve the cut condition.*

Proof. Obvious. □

LEMMA 5. *Operation* 3 *preserves the cut condition.*

Proof. In operation 3 there are nets p and q incident to the right corner b of a segment with p quasi-right of q. We replace p by e and p^1, where $e = (b, a)$, a is the left neighbor of b, and $p \approx ep^1$. Assume, for the sake of a contradiction, that there is an oversaturated almost-straight cut C in the modified problem. The cut C must go through edge e since otherwise its density is not affected by the action. Also $\text{mincross}(e, C) = 1$ and $\text{mincross}(p^1, C) = \text{mincross}(p, C) \pm 1$. Thus the density of C is increased by at most 2 and hence C must be saturated in the original problem. Thus C must be straight by Lemma 1(b) and $\text{mincross}(p^1, C) = \text{mincross}(p, C) + 1$. Since the original problem has a solution in which then necessarily net q uses edge e, we conclude $\text{mincross}(q^1, C) = \text{mincross}(q, C) - 1$ where $q \approx eq^1$. Let $(p_1, \ldots, p_h)$ and $(q_1, \ldots, q_k)$ be the straight-line decompositions of p and q, respectively. Then p_1 does not intersect C since $p_1 \cdots p_k$ is a shortest path homotopic to p, $\text{mincross}(p, C) = \sum_i \text{cross}(p_i, C)$ by Lemma 1(d), and $\text{mincross}(p^1, C) = \text{mincross}(p, C) + 1$, and q_1 intersects C for analogous reasons.

Case A. $\lfloor x(\text{target}(C)) \rfloor \leq \lfloor x(\text{source}(C)) \rfloor$: Then p_1 is not right of q_1 and hence p is not quasi-right of q.

Case B. $\lfloor x(\text{target}(C))\rfloor > \lfloor x(\text{source}(C))\rfloor$: Consider the cut D indicated in Fig. 3. Then D is saturated, since $\text{mincross}(p, D) = \text{mincross}(p, C) + 1$ and $\text{mincross}(q, D) = \text{mincross}(q, C) - 1$. Also, Manhattan ($D$) makes two consecutive turns into the same direction, a contradiction to Lemma 1(e). □

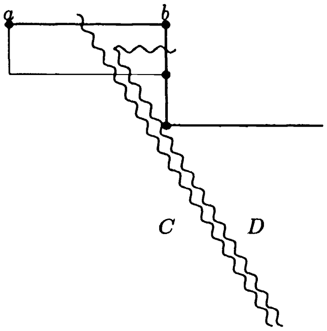

FIG. 3.

LEMMA 6. *Operation* 4.1 *preserves the cut condition. This is even true if the right corner of S is not exposed.*

Proof. In operation 4.1 there is a net p with $\text{can}(p) \subseteq S$. Then $\text{mincross}(p, C) = \text{cross}(\text{can}(p), C)$ for every straight cut C. Hence, deleting the net p and discarding all edges in $\text{can}(p)$ preserves the cut condition. □

LEMMA 7. *Operation* 4.2 *preserves the cut condition.*

Proof. In operation 4.2 the right corner of S is exposed and the left corner of S is not exposed. Furthermore, there is no net p with $\text{can}(p) \subseteq S$ and hence the horizontal cut Y, which cuts off the segment S, is saturated. Note that there are exactly $\text{cap}(Y)$ terminals above segment Y and that each terminal contributes one to the density of Y. Let b be the right corner of S, let $e = (b, a)$ be the horizontal edge incident to b, and let X be the vertical cut through e. In operation 4.2 the cut X is saturated. Let (p^1, e, p^2) be the rightmost decomposition of any net with respect to X.

CLAIM 1. $\text{can}(p^2) \subseteq S$.

Proof. Let $e' = (c, b)$ be the vertical edge incident to b. Consider any solution to the original problem. Then there must be a net, say q, which uses the edges e' and e, i.e., the solution path can be written $q^1e'eq^2$. Furthermore, since there are exactly $\text{cap}(Y)$ terminals in S, contributing one each to the density, we conclude that $\text{mincross}(q^2, Y) = 0$. Thus $\text{can}(q^2) \subseteq S$. Next observe that p^2 is quasi-right of q^2, since (p^1, e, p^2) is a rightmost decomposition with respect to X, and hence $\text{can}(p^2) \subseteq S$. □

Let P' be the problem obtained by replacing p by p^1 and ep^2. It suffices to show that P' satisfies the cut condition, since the deletion of net ep^2 and all edges in $\text{can}(ep^2)$ is covered by Lemma 6. So assume that there is an oversaturated straight cut C in P'. By Lemma 1(f) we may assume that C is either vertical or horizontal or a straight cut intersecting only edges incident to vertices of degree 4. Since $\text{cross}(ep^2, C) \leq 1$, $p^1 \approx ep^2p^{-1}$ and hence $\text{mincross}(p^1, C) \leq \text{cross}(\text{can}(p), C) + \text{cross}(ep^2, C) \leq \text{mincross}(p, C) + 1$, we conclude $\text{fcap}(C) = 0, \text{fcap}'(c) = -2$, $\text{mincross}(ep^2, C) = 1$, and $\text{mincross}(p^1, C) = \text{mincross}(p, C) + 1$. From $\text{mincross}(ep^2, C) = 1$ we conclude that C must intersect an edge of segment S and hence must be vertical.

Since $\text{mincross}(p, X) > 0$, we can write $\text{can}(p) = r^1r^2$ where $x(\text{source}(r^2)) = x(b)$, $\text{cross}(r^2, X) = 1$, and the vertical segment s^1 connecting $\text{source}(r^2)$ to b is contained in R. Then $p^1 \sim r^1s^1$ and hence $\text{mincross}(p^1, C) \leq \text{cross}(r^1s^1, C) = \text{cross}(r^1, C) = \text{cross}(\text{can}(p), C) - 1 = \text{mincross}(p, C) - 1$. Thus $\text{fcap}'(C) = \text{fcap}(C)$ for any vertical cut, a contradiction. □

LEMMA 8. *Operation* 4.3 *preserves the cut condition.*

Proof. The precondition is almost as in operation 4.2; however, the vertical cut X through $e = (b, a)$ is not saturated. Let p be a net which has a as a terminal. Let $p \approx (a, b)p^1$ and replace p by (a, b) and p^1.

Assume that there is an oversaturated straight cut C with respect to the modified problem P'; note that P' is bounded. Then C must intersect the edge (a, b), since otherwise its density is not affected by the action, and $\text{fcap}(C) = 0$. Next observe that P' is bounded and hence by Lemma 1(f) we may assume that C is vertical, i.e., $C = X$. This contradicts $\text{fcap}(C) = 0$. □

LEMMA 9. *Operation* 5.1 *preserves the cut condition.*

Proof. Let X be the shortest saturated vertical cut intersecting an edge in S, let $e = (b, a)$ be the edge in S intersected by X with b being the right neighbor of a, and let $p \approx p^1ep^2$ be a net crossing X such that either $\text{can}(p^1) \subseteq Rim$ or (p^1, e, p^2) is the rightmost decomposition with respect to X. We replace p by p^1, e, and p^2.

The following claim will be useful.

CLAIM 2. *In P there is no saturated nonvertical cut through edge e.*

Proof. Assume that there is such a Manhattan cut C'. By Lemma 1(e) we may assume that C' turns in alternate directions. Assume also that the first segment C_1' of C' is maximal in length. We now distinguish cases. Assume first that C' has only 1 bend or C_1' intersects less that $\text{cap}(X) - 1$ edges.

We move the vertical part of C' intersecting e so as to make the cut C' shorter. Then one of the following situations must arise (see Fig. 4). Either we split the cut at some point into several cuts or we move the vertical part beyond the end of segment S. In the first case one of the parts is a saturated vertical cut intersecting S and being shorter than X; in the second case an oversaturated cut is obtained since the corners of S are exposed. In both cases, we have a contradiction. We conclude that C_1 intersects $\text{cap}(X) - 1$ edges and C' has more than 1 bend; i.e., the situation is as shown in Fig. 5.

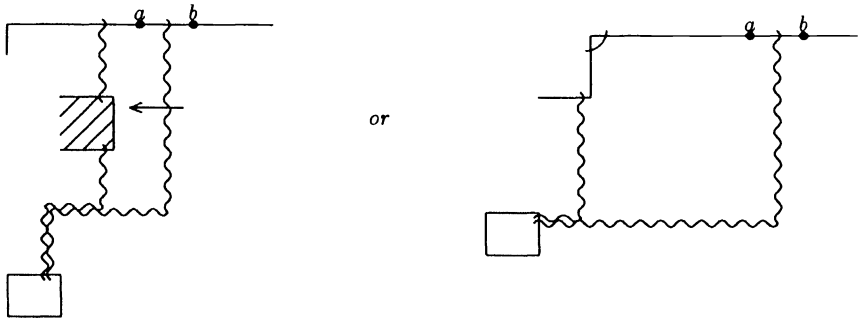

FIG. 4. *Illustrating the first case in the proof of Claim* 2.

We now move the first horizontal part of C' down by one unit, and in this way split C' into several cuts, which are all saturated in P. Hence one of them is oversaturated in P'. But the topmost cut ($= X$) is saturated in P' and the free capacities of all other cuts do not change, since they do not interfere with cut X. □

We now return to the discussion of operation 5.1. Assume that there is an oversaturated cut C with respect to the modified problem P'. Since $\text{mincross}(p, X) > 0$, we can write

$\text{can}(p) = r^1fr^2$ where $x(\text{source}(f)) = x(b), x(\text{target}(f)) = x(a)$, and the straight-line segments s^1 connecting source(f) to b and s^2 connecting a to target(f) are contained in R. Then $p \sim s^1r^1, p^2 \sim r^2s^2$, and $f \sim s^1es^2$. Also, $\text{mincross}(p^1, C)+ \text{mincross}(e, C)+ \text{mincross}(p^2, C) \leq \text{cross}(r^1s^1, C) + \text{cross}(e, C) + \text{cross}(s^2r^2, C) = \text{cross}(r^1fr^2, C) + \text{cross}(s^1es^2, C) - \text{cross}(f, C) \leq \text{mincross}(p, C) + 2$. We conclude that $\text{cross}(s^1es^2, C) = 2$, $\text{fcap}(C) = 0$ and $\text{fcap}'(C) = -2$. Hence C is straight by Lemma 1(b).

Case A. C intersects e: Claim 2 and the fact that $\text{fcap}(C) = 0$ and C is straight imply that C is vertical. Thus $C = X$, a contradiction.

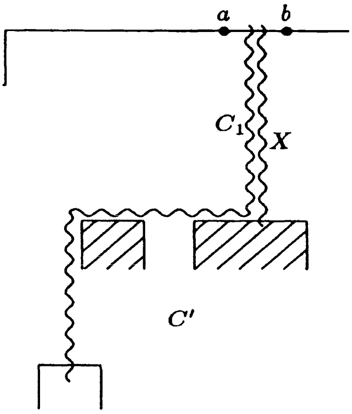

FIG. 5.

Case B. C does not intersect e. Then C must intersect s^1 and s^2 and hence C and X intersect in a single point.

Case B1. $\text{can}(p^1) \subseteq Rim$. Then C must intersect $\text{can}(p^1)$ because otherwise $\text{mincross}(p^1e, C)+\text{mincross}(p^2, C) = \text{mincross}(p^2, C) \leq \text{cross}\,(e^{-1}(\text{can}(p^1))^{-1}\text{can}(p), C) \leq \text{cross}(\text{can}(p), C)$, and hence $\text{fcap}'(C) = \text{fcap}(C)$. Let $C' \sim C$ be a Manhattan cut with $\text{cap}(C') = \text{cap}(C)$. Assume first that C' is a straight horizontal cut. Then $C' = Y$, where Y is defined as in Lemma 7, and hence $f\text{cap}(C') \geq 2$, a contradiction. We conclude that C' contains at least one vertical segment. Since $\text{can}(p^1) \subseteq Rim$, C intersects $\text{can}(p^1)$, s^1, and s^2, C is straight, and since the corners of all segments in *Top* are exposed, we may assume without loss of generality (w.l.o.g.) that C' starts with a vertical segment and turns right. Thus if we move that vertical segment by one unit to the left, the capacity of the cut cannot increase. Also, since the corners of all segments are exposed when case 5 applies, the density of the cut cannot decrease and hence the cut stays saturated in P (or even becomes oversaturated in P'). As we move the vertical part further to the left either one of the following three situations must arise (see Fig. 6). Either, we obtain an oversaturated cut in P or a nonvertical saturated cut through e or the cut is split into several cuts at least one of which is saturated in P and oversaturated in P'. In all three cases we have a contradiction; this is obvious in the first case, follows from Claim 2 in the second case, and follows in the third case form the observation that none of the resulting cuts can simultaneously intersect s^1, s^2, and $\text{can}(p^1)$.

Case B2. (p^1, e, p^2) is the rightmost decomposition with respect to X. Consider the cuts Z_1 and Z_2 shown in Fig. 7. Let Z_1' be a shortest path homotopic to Z_1. Z_1' is a polygonal path that bends at the corners of some holes. We split Z_1' at these corners and obtain straight cuts $Z_{11}', \ldots, Z_{1k_1}'$ (see Fig. 8). In a similar way we obtain $Z_{21}', \ldots, Z_{2k_2}'$ from Z_2.

CLAIM 3. $\text{fcap}(X) + \text{fcap}(C) \geq \sum_{i=1}^{k_1} \text{fcap}(Z_{1i}') + \sum_{i=1}^{k_2} \text{fcap}(Z_{2i}')$.

Proof. It is clear that $\text{cap}(X) + \text{cap}(C) \geq \sum_{i=1}^{k_1} \text{cap}(Z_{1i}' + \sum_{i=1}^{k_2} \text{cap}(Z_{2i}')$. It therefore

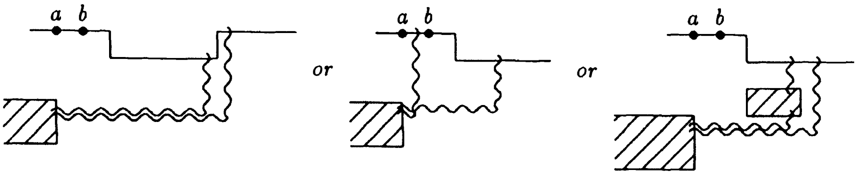

FIG. 6.

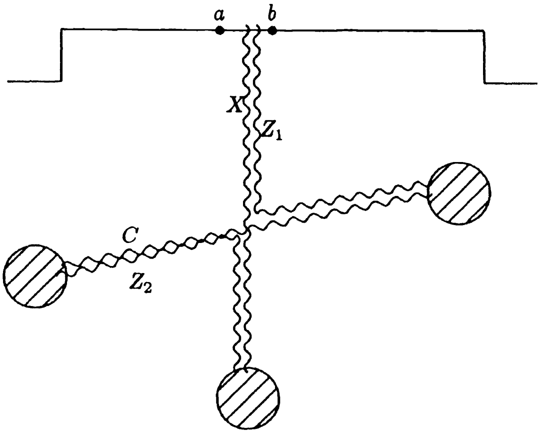

FIG. 7. *X and C produce* Z_1 *and* Z_2.

suffices to show that $\text{cross}(s, X) + \text{cross}(s, C) \leq \sum_{i=1}^{k_1} \text{cross}(s, Z'_{1i}) + \sum_{i=1}^{k_2} \text{cross}(s, Z'_{2i})$ where s is any straight-line piece of a net $q \in \mathcal{N}$. Divide the plane by the lines supporting X and C into four regions as shown in Fig. 9. Then all pieces s contribute the same amount to both sides except those having one endpoint in region D and one endpoint in region F. Such segments contribute 2 to the left hand side and 0 to the right hand side.

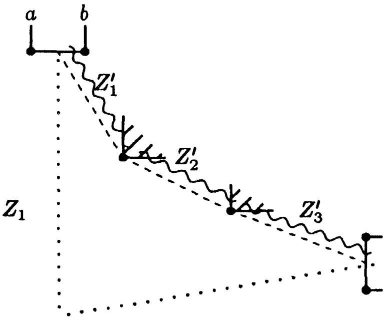

FIG. 8.

We now show that there is no such segment. Assume otherwise. Let q be a net such that $\text{cap}(q) = q'sq''$ contains an elementary piece s, which has its source in F and its target in D. Let $s = s's''s'''$ where $x(\text{source}(s'')) = x(b)$ and $x(\text{target}(s'')) = x(a)$; let l_1 and l_2 be the paths parallel to X and connecting source(s'') with b and a with target(s''), respectively. Then $q \approx q's'l_1el_2s'''q''$, $\text{mincross}(q', X) = \text{mincross}(q's'l_1, X)$ and $\text{mincross}(q'', X) = \text{mincross}(l_2s'''q'', X)$, i.e., $(q's'l_1, e, l_2s'''q'')$ is a decomposition of q with respect to X. Also,

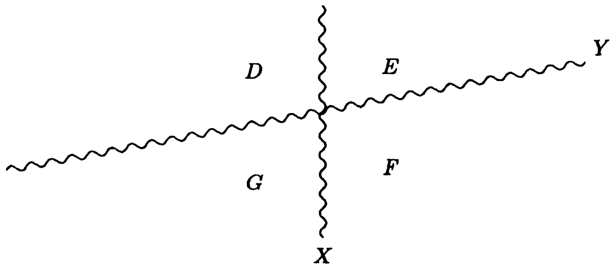

FIG. 9. *The four regions D, E, F, and G.*

$l_2 s''' q''$ is quasi-right of p_2, since the first elementary piece of p_2 ends in G, a contradiction. □

Claim 3 implies that either one of the cuts $Z'_{1i}, 1 \le i \le k_1$, or $Z'_{2i}, 2 \le i \le k_2$, is oversaturated, a contradiction to the assumption that P satisfies the cut condition, or that all of them are saturated. In the latter case, Z'_{11}, a nonvertical straight cut through e, is saturated, a contradiction to Claim 2. The discussion of case B is now completed and Lemma 9 is shown. □

LEMMA 10. *Operation* 5.2 *preserves the cut condition.*

Proof. When operation 5.2 is applied, both corners of S are exposed and there is no saturated vertical cut through any edge of S. Let a and b be the two corners of S. We add the nets p and q with $p(\lambda) = q(\lambda) = a\lambda + (1 - \lambda)b$ for $0 \le \lambda \le 1$. Let P' be the modified problem and assume that there is an oversaturated cut C in P'. Then C must intersect S and C was saturated in P. Since P' is bounded, we may assume that C is vertical by Lemma 1(f), a contradiction. □

4. A linear time implementation. In this section we describe a linear time implementation of our algorithm. In the first part of the section we introduce the required data structures and in the second part we realize the algorithm using these data structures. The first part consists of two interleaved sections: the description of the abstract and the description of the concrete data structure. In the abstract data part we use objects like sequences and sets and operations on these objects and in the concrete part we show how to realize these operations. The concrete part is interleaved with the abstract part.

4.1. The data structure. We first discuss the representation of the routing region. We assume that the vertices and the vertical cuts are numbered 1, 2, 3, ... The numbering of the cuts is such that for each x-coordinate the cuts with the x-coordinate are numbered by consecutive numbers from top to bottom. We identify vertices and cuts with their number. We specify the routing region by storing the neighbors for each vertex.

Concrete. We have four arrays l, r, u, d. For $1 \le v \le |V|, l[v]$ is the (number of the) left neighbor of v; similarly for r, u, and d. We also have two arrays X and Y that give the coordinates of every vertex. □

Let v be any vertex. Then $L(1, v)(L(2, v)$, respectively) is the closest vertex with the same y-coordinate as v to the left of v, which can be reached from v by a straight-line grid path and which is incident to a vertical boundary edge from below and from above, respectively. $R(i, v)$, $U(i, v)$, and $D(i, v), i = 1, 2$ are defined analogously with left replaced by right, above, and below, respectively.

Concrete. We have another four arrays L, R, U, and D. The array L can be initialized in linear time by scanning each row of the routing region from left to right. Similarly, for R, U, and D. □

We turn to the representation of nets next.

DEFINITION 9. (a) *Let p be a net. Then* rightmost p *is a shortest grid path homotopic to p, which is right of any other shortest grid path homotopic to p.* leftmost(p) *is defined analogously.*

(b) *Let p be a net. The monotone decomposition of p is $(p_1, \ldots, p_k)$ where* $\mathrm{can}(p) = p_1 \cdots p_k$, *and p_i is either a maximal vertical segment or a maximal subpath not containing a vertical segment.*

(c) *The representative of p is* $\mathrm{rep}(p) = p'_1 \cdots p'_k$ *where $(p_1, \ldots, p_k)$ is the monotone decomposition of p and*

$$p'_i = \begin{cases} p_i & \text{if } p_i \text{ is vertical,} \\ \text{rightmost } (p_i) & \text{if } x(\text{target}(pi)) < x(\text{source}(p_i)), \\ \text{leftmost}(p_i) & \text{if } x(\text{target}(p_i)) > x(\text{source}(p_i)). \end{cases}$$

(d) *The bend sequence $b_s(p)$ of p is the sequence $v_0, \ldots, v_k$ of vertices such that*

(1) *v_0 and v_k are the terminals of p;*

(2) *$v_1, \ldots, v_{k-1}$ are consecutive bends of* $\mathrm{rep}(p)$*;*

(3) *if $v_0 \notin Rim \cap \partial F_{\mathrm{ext}}$, then v_1 is the first bend of* $\mathrm{rep}(p)$ *and if $v_0 \in Rim \cap \partial F_{\mathrm{ext}}$, then v_1 is the first bend not contained in Rim. Similarly, if $v_r \notin Rim \cap \partial F_{\mathrm{ext}}$, then v_{r-1} is the last bend of* $\mathrm{rep}(p)$ *and if $v_r \in Rim \cap \partial F_{\mathrm{ext}}$, then v_{r-1} is the last bend not contained in Rim.*

Remark. In the bend sequence of a path we suppress the bends contained in Rim, since these bends appear and disappear as we process the top row. It would therefore be very costly to treat them like the other bends. Figure 10 shows the representative of a net and its bend sequence.

In the input, a net is given as a grid path. The representative of a path can be computed in time proportional to its length by walking along the path and looking for shortcuts using the arrays L, R, U, and D.

This can be seen as follows. In a first walk along the path, a shortest path homotopic to the net is computed (the task is here to remove U-turns which are not forced by a hole).

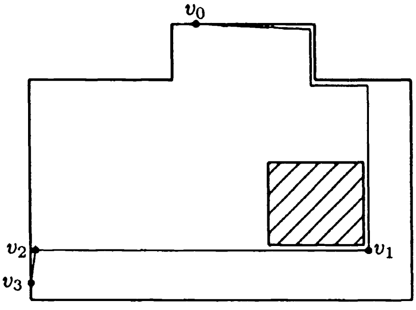

FIG. 10.

In a second walk along the path, the path is decomposed into montone pieces and the pieces are shifted appropriately. All of this takes linear time in the length of the path.

The bend sequence can be computed from the representative by inspecting the initial and final segments of it. Altogether, all representatives and bend sequences can be computed in linear time.

A *crossing* is an intersection between a representative and a vertical cut. Every crossing belongs to two sequences as we describe next.

Let p be a net, let $v_0, \ldots, v_k$ be the bend sequence of p and let $c_1, \ldots, c_m$ be the crossings of rep(p) with vertical cuts in the order in which they occur on rep(p). For $0 \leq i < k$, define the c-sequence of (v_i, v_{i+1}) as the subsequence of crossings that occur between v_i and v_{i+1}.

Let C be any vertical cut. The r-sequence of C is any ordering $c_1, \ldots, c_p$ of the crossings with C satisfying the following three properties: Let $e = (b, a)$, with a the left neighbor of b be the topmost edge intersected by C, and let (p_i^1, e, p_i^2) be an admissible decomposition of net p_i corresponding to crossing c_i, $1 \leq i \leq m$. Then

(1) (*rim property*) There is an integer $k(C) \geq 0$ such that $i \leq k(C)$ implies can $(p_i^1) \subseteq$ *Rim*;

(2) (*ordering property*) If $k(C) < i < j$, then p_i^2 is quasi-right of p_j^2;

(3) (*consistency property*) If D is a vertical cut in the column to the left of C, $k(C) < i < j$ and p_i and p_j also cross D, then $k(D) < i' < j'$ where c_i' is the next crossing of p_i and D and c_j' is the next crossing of p_j and D.

Remark. Initially, we will have $k(C) = 0$, for all C. Then (2) states that the r-sequence of C reflects the ordering quasi-right and (3) states that the orderings for adjacent cuts are consistent with one another. We are not able to maintain (2) and (3) with $k(C) = 0$ for all C. One of the difficulties is case 4.3. In the situation of Fig. 11 the new crossing of p with X would have to be inserted somewhere into the r-sequence of X.

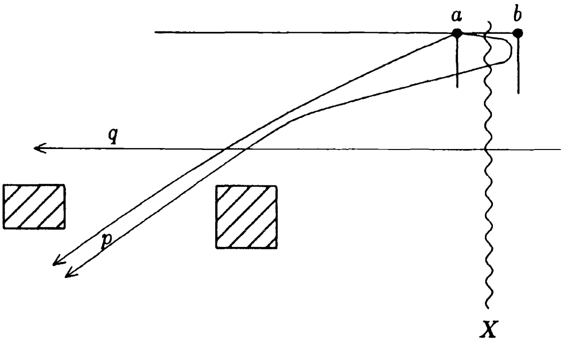

FIG. 11.

We will instead add it to the front of the sequence and increase $k(X)$ by one. In this way (1), (2), and (3) are maintained with small cost. However, the ordering quasi-right in cases 3, 4.2, and 5.1 is now harder to compute. In case 3 we solve this problem by basing the decision on cuts that do not intersect the *Rim* and hence have $k(C) = 0$; in case 4.2 we use the fact that can$(ep^2) \subseteq$ *Top* for the rightmost decomposition (p^1, e, p^2), and in case 5.1 we can always take the first element of the r-sequence. The details are given below.

We call $c_1, \ldots, c_{k(C)}$ the *rim-part* and $c_{k(C)+1}, \ldots, c_m$ the *non-rim-part* of the r-sequence of C.

Concrete. A bend sequence is realized as a doubly linked list (see Fig. 12). The elements of the list are vertices and representatives of c-sequences. Each c-sequence is a doubly linked list of crossings; a crossing is represented by a record to be described below. The representative of a c-sequence points to the first and the last item of the c-sequence. An r-sequence is represented as a singly linked list. There is an array rheads[ ] of list headers for the r-sequences. rhead[i] points to the first element of the r-sequence for cut i. We describe below how this data structure is initialized.

There are several functions that can be applied to crossings and c-sequences. For a crossing c, Findrep(c) returns the representative of the c-sequence to which c belongs, Findcut(c) returns the number of the cut whose r-sequence contains c, Above(c, d) yields true for two crossings c, d belonging to the same r-sequence if c is in front of d in the sequence, Split(c) splits the c-sequence containing the crossing c after c and returns the representatives of the two resulting sequences, Addleft(r, c) and Addright(r, c) add the crossing c to the c-sequence with representative r, Delete(c) deletes the crossing c from the c-sequence containing it, and Access&Split(r, x) splits the c-sequence with representative r after the crossing with x-coordinate x and returns the representatives of the resulting c-sequences.

FIG. 12.

Concrete. We realize a crossing as a record consisting of the following fields: Two pointers *csuc* and *cpred* for the c-sequence; a pointer *rsuc* for the r-sequence; an integer *cutnumber*, which is the number of the cut containing the crossing; an integer *rank*; and various other fields, which are used to realize the other operations. We postulate that the rank field increases along any r-sequence and hence Above takes time $O(1)$. Findcut also takes time $O(1)$ by virtue of the cutnumber field. The operations Findrep, Split, Addleft, Addright, Delete, and Access&Split comprise the data type *splittable list.* It is shown in [Schw] that splittable lists can be implemented such that all operations have amortized cost $O(1)$. The implementation combines the level-linked trees of [HMRT] with the split-find data structures of [GT], [IA].

We are now ready to describe the initialization of the data structure. We number the cuts from left to right and for each x-coordinate from top to bottom. The c-sequences are easily computed in linear time. The r-sequences are computed as follows. We scan the layout region from left to right. When we reach a certain column, the r-sequences for all cuts to the left of the column are already computed, and ranks are assigned to all crossings in these r-sequences. We now show how to compute the r-sequences for all cuts immediately to the right of the column in time proportional to the length of the column (see Fig. 13).

Consider any cut C to the right of the current column. We first divide the set of crossings with C into three parts: the U-, D- and L-parts; the U-part and D-part consist of all crossings with nets that either terminate in the current column on a module that touches the current column from the right and lies above C or below C, respectively, or that have the next crossing with a cut above C or below C, respectively; and the L-part consists of all other crossings. The r-sequence of C can then be obtained by concatenating an appropriate ordering of the U-part with an appropriate ordering of the L-part with an appropriate ordering of the D-part.

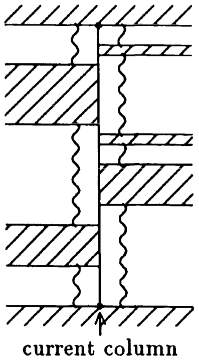

FIG. 13.

We show how to order the L-parts. We first construct a list L consisting of the topmost vertex of the current column, followed by the r-sequence of the first cut to the left of the column, followed by the terminals on the first module touching the current column from the left, followed by the r-sequence of the second cut, ..., and then number the elements of this list in increasing order. We then go through the L-parts of all cuts C and generate for each crossing c with C, say with rep(p), a pair consisting of

- the number of the cut C
- the rank in L of the crossing or terminal adjacent to c in rep(p).

We sort these pairs by bucket sort in time proportional to the length of the column. This gives us the desired ordering of the L-parts, the U- and D-parts can be ordered in a similar way. The ranks are now assigned by numbering the crossings in each q-sequence in increasing order. Altogether we have now shown how to compute the r-sequences of all cuts in linear time.

We finally store for each cut its free capacity (array freecap[ ]). We also have an array satcut[1...] of pointers. The element satcut[i] points to a doubly linked list of all saturated vertical cuts of length i intersecting row *top*. Each saturated cut points to its position on the satcut lists (array satpos[...]). We also keep the nonempty entries of the array *satcut* in a linked list (see Fig. 14). This finishes the description of the data structure.

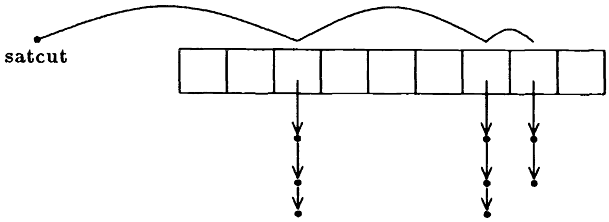

FIG. 14.

4.2. The algorithm. We work through the routing region from top to bottom. Suppose that we are just beginning to process row *top*. Let us also assume that we have the data structure described in §1 available.

Step 1 (*Cuts of capacity one*). A cut of capacity one is necessarily saturated and hence the cuts of capacity one intersecting row *top* are all contained in the list satcut[1]. Let C be any cut in satcut[1], let (a, b) be the edge in row top intersected by C, and let c be the crossing on the r-list of C. Let c be on the c-sequence of bends u and v. Note that we can find u and v in time $O(1)$ using operation Findrep. We split (operation Split) the c-sequence of u and v at the crossing c and introduce a and b as new terminals (see Fig. 15).

At this point we have created two nets, say p_1 and p_2, with terminals in row *top*. If either u or v was a terminal of its net then the bend sequences of p_1 and p_2 are correctly computed by the splitting process. If neither u or v was a terminal, then we have to update the bend sequences of p_1 and p_2 as follows. Follow the bend sequence until a vertex, say w, which is not in Rim is encountered, delete the vertices before w and concatenate the appropriate c-sequences. If l vertices were deleted then $l + 1$ c-sequences have to be concatenated. We concatenate these sequences by adding (operation Add) the items on the second, third, ..., sequence to the first sequence one by one. Note that a crossing can be added at most once to a c-sequence because it belongs to a c-sequence incident to a terminal after the addition. Hence the total cost of additions is linear.

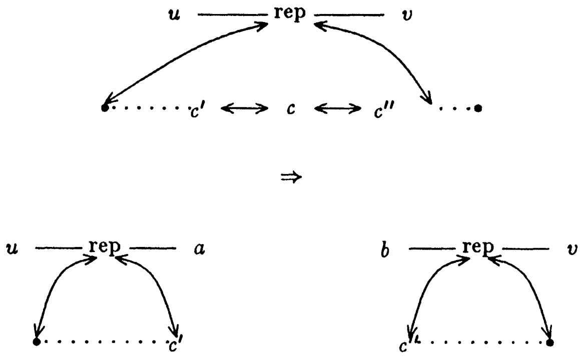

FIG. 15.

Step 2 (*No cuts of capacity one*). All cuts of capacity one are processed. We scan row *top* from left to right and construct four sets of segments. The set RS, LS, and FS, contains all segments where the right corner is not exposed, the right corner is exposed but the left corner is not exposed, and both corners are exposed, respectively. The set TS contains all segments consisting of a single vertex.

We now discuss cases 2 to 5 of the routing algorithm.

Case 2 applies whenever $TS \neq \emptyset$. Let $S \in TS$ be a segment, let b be the single vertex in S, let p be the net incident to b, and let a be the lower neighbor of b. We replace b by a on the bend sequence of p and delete the edge $e = (b, a)$. This takes constant time.

Case 3 applies whenever $TS = \emptyset$ and $RS \neq \emptyset$. Let S be any segment in RS, let b be the right corner of S, let a be the left neighbor of b, and let p and q be the two nets with terminal b. Let v_1 and w_1 be the vertices following b on the bend sequences of p and q, respectively.

Case A. At least one of the nets p and q leaves the column of b to the left. This can be checked in time $O(1)$ by inspecting the first crossing of p and q. We may assume w.l.o.g. that p leaves the column of b to the left. If q does not then p is quasi-right of q. So let us suppose that q also leaves the column of b to the left. If v_1 and w_1 are different or v_1 and w_1 are equal and at least one is a terminal or at least one of the nets makes a left turn at v_1, then it is easy to decide whether p is quasi-right of q using the coordinates of v_1 and w_1. So let us assume that v_1 and w_1 are equal and both nets make a right turn at v_1. In this case both nets enter the bend point v_1 from above. Let c and d be the crossings following v_1 on p and q, respectively, and let C be the cut containing c and d. Then C does not intersect row *top* and hence p is quasi-right of q if c is above d in the r-sequence of C. In either case we have shown that the test whether p is quasi-right of q takes time $O(1)$.

Lėt w.l.o.g. p be quasi-right of q. We replace b by a on the bend sequence of p and delete (operation Delete) the first crossing from the first c-sequence of p. We also replace b by its lower neighbor on the bend sequence of q. Finally, we mark (array mark) the cut, say X, through the edge (a, b) as processed, add it to the set of marked cuts, delete X from its satcut-list, if it is on one, and insert it into the satcut-list of one smaller index. All of this takes time $O(1)$.

Remark. The mark on cut X indicates that X does not start in row *top* anymore. The mark bit will be used in case 5. The set of marked cuts is used to unmark the marked cuts again when row *top* is completely processed.

If p terminates in b, then we remove S from RS and add it to LS or FS whatever is appropriate (a segment is stored as a pair of vertices and hence this is an $O(1)$ decision). If p does not terminate in b, then S stays in RS.

Case B. p and q leave the column of b to the right. Let c and d be the first crossings of p and q and let C and D be the cuts crossed. If $C \neq D$, then it is easy to decide whether p is quasi-right of q. We may assume w.l.o.g. that p is quasi-right of q in this case. If $C = D$, then p is quasi-right of q and q is quasi-right of p. We may assume w.l.o.g. that either c belongs to the rim-part of the r-sequence of C or that both c and d belong to the non-rim-part and d is above c.

We replace b by a on the bend sequence of p, add the crossing of p and X, where X is the vertical cut through edge (a, b), as first element of the rim-part of the r-sequence of X if c belongs to the rim-part of C and as first element of the non-rim-part otherwise (this preserves the ordering property and the consistency property) and add the crossing to the appropriate c-sequence. We also decrease the free capacity of X by two. If X becomes saturated then we add X to the appropriate satcut-list and mark X. The appropriate satcut-list is determined by linear search in time proportional to the length of X. Since every cut becomes saturated at most once, the total cost of adding saturated cuts to satcut-lists is linear.

Case 4 applies whenever $TS = RS = \emptyset$ and $LS \neq \emptyset$. Let S be any segment in LS. The right corner of S is exposed and the left is not.

Case 4.1: There is a net p with $\text{can}(p) \subseteq S$. Let p be the one with leftmost right terminal.

We can find p as follows. We search through the segment starting in the left corner of S. For every vertex v encountered we inspect the bend sequence of the net incident to v and determine in time $O(1)$ whether v qualifies as vertex t. Thus t can be found in time proportional to its distance from the left corner of S.

We route as shown in Fig. 16. All cuts between s and t are marked and moved to the satcut-list of one smaller index, if saturated. Also, all crossings of net p are removed. Also the terminal is changed for each net incident to vertices between s and t, segment S is removed from LS, segment S' is added to LS, and segment S'' is added to FS.

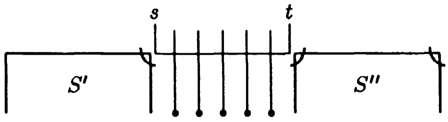

FIG. 16. *Both corners of S'' are exposed and the right corner of S' is exposed.*

Note that the cost of this action is proportional to the length of S' plus the number of edges deleted from the routing region. Since case 4.1 does not again apply to segment S', rather S' is completed by cases 4.2 and 4.3, the total time spent in case 4.1 is linear.

Cases 4.2 and 4.3: There is no net contained in S. Let b be the right corner of S, let a be the left neighbor of b and let X be the vertical cut through (a, b).

Case 4.2: X is saturated. Let p be the quasi-rightmost net across X. We have shown in §3 that p has a terminal s in segment S. We can find p as follows: We start in the right corner of S and walk to the left. For each terminal encountered in the walk we check whether the associated net crosses X by examining its bend sequence. This takes time $O(1)$ per terminal. The first net encountered which crosses X is the desired net p. We route p along the top row (see Fig. 17), route all nets between S and the right corner of S down by one unit, update the data structure as in case 4.1, and put S' on LS.

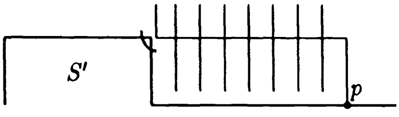

FIG. 17.

Note that case 4.2 or 4.3 applies again to S'. The time required is proportional to the number of edges deleted from the routing region.

Case 4.3: X is not saturated. Let p be the net with terminal a. We route p form a to b and then down by one unit (see Fig. 18).

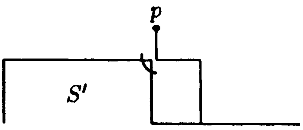

FIG. 18.

If p did not go across X before the action (inspect the first crossing of the net p), then we add a crossing as first element of the rim-part of the r-sequence of X (this preserves the ordering and the consistency property), decrease the free capacity of X by two, and add X to a satcut-list if X became saturated. All of this takes time $O(1)$ if X did not become saturated and time $O(1+$ length of $X)$ otherwise. Thus the total time spent in case 4.3 is linear. Also case 4.2 or 4.3 applies again to segment S'.

Case 5 applies whenever $TS = LS = RS = \emptyset$ and $FS \neq \emptyset$.

We keep a pointer P to the satcut-lists with the following semantics. If the pointer points to list satcut[i] then all cuts in satcut[j], $j < i$, and all cuts preceding the item pointed to in satcut[i] are marked.

We advance P until it points to an unmarked cut. This takes time $O(1)$ per move of P. Note that all cuts added to the satcut-lists during the execution of cases 2, 3, and 4 are marked and hence P never has to be reset. Also the total length of the satcut-list is at most the number of edges in rows top and $top - 1$ and hence the total time spent on advancing P is linear.

Case 5.1: Let X be the saturated cut found, and let (a, b) be the edge in row top intersected by X. Clearly, X is a shortest vertical cut intersecting an edge of the segment containing edge (a, b). Let c be the first crossing on the r-list of C. Let c be on the c-sequence of u and v. Note that we can find u and v in time $O(1)$ using Findrep. Figure 19 shows how the representatives of the nets p^1 and p^2 look like. The bend sequences of p^1 and p^2 can be found as follows.

Let y be the y-coordinate of vertices u and v. Then the bends of p^1 and p^2 are readily determined by inspecting the L- and R-values of all vertices w which lie below a in rows $top, top - 1, \ldots, y$. This takes time $O(1 + top - y)$; since the sum of the lengths of the representatives of p^1 and p^2 exceeds the length of the representative of p by $2(top - y)$, we can account for the cost by the length increase; note that the total length of the canonical representatives is always bounded by the size of the routing region.

At this point we have computed the bend sequences of p^1 and p^2. We then split the c-sequence of u and v at the appropriate places using the operation Access&Split. This takes amortized time $O(1)$ for each Access&Split and hence the cost is easily accounted for.

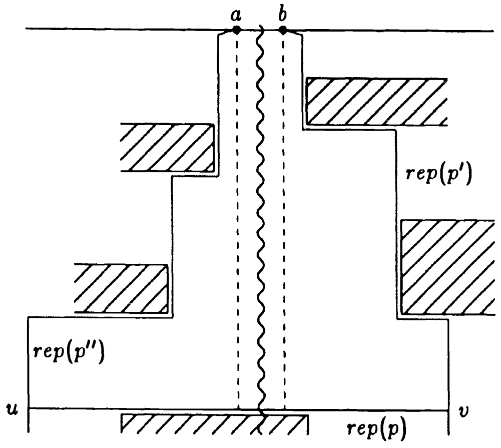

FIG. 19.

Finally, we observe that the ordering and consistency property is preserved.

Case 5.2 (no saturated cut found): Let S be any segment in FS. We route as shown in Fig. 20.

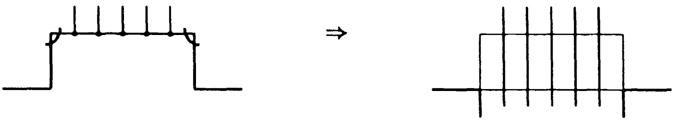

FIG. 20.

All cuts between s and t have their free capacity reduced by two and are added to a *satcut*-list if necessary. This completes the description of the various cases of the routing algorithm.

Suppose now that we processed row *top* completely. We unmark all cuts using the set of marked nets in time proportional to their number, decrease *top* by one, go through *Top* and adjust bend-sequences as described in case 1, and are ready for processing the new row *top*.

This completes the proof of the main theorem.

SOME RESULTS ON ELUSIVE GRAPH PROPERTIES*

EBERHARD TRIESCH†

Abstract. This article proves several graph properties to be elusive. Two of the main results are

1. If $\mathcal{P}$ is a decreasing graph property containing no graph of girth smaller than 5, then $\mathcal{P}$ is elusive.
2. The property of having matching number at most k, $k < \lfloor |V|/2 \rfloor$, is elusive.

The proofs are all based on a topological method developed by Kahn, Saks, and Sturtevant.

Key words. monotone graph property, elusive, recognition complexity, girth, matching

AMS subject classifications. 68Q05, 68R05, 05C25

1. Introduction.

Let T be a finite set and $\mathcal{P}$ a property of subsets of T, i.e., $\mathcal{P} \subset 2^T$, the power set of T. Imagine two players $\mathcal{A}$ (*Algy*) and $\mathcal{S}$ (*Strategist*). Player $\mathcal{A}$ wants to learn from $\mathcal{S}$ whether an unknown set $X \subset T$ is in $\mathcal{P}$ or not by asking him questions of the form *Is* $x \in X$? ($x \in T$). The goal of $\mathcal{A}$ is to minimize the number of questions, but $\mathcal{S}$ wants to force $\mathcal{A}$ to ask as many questions as possible. If both players play optimally from their point of view, then the number of questions that are asked in the game is called the *recognition complexity* of $\mathcal{P}$ (also, *Boolean decision tree complexity*) and is denoted by $c(\mathcal{P})$. If $\mathcal{S}$ can force $\mathcal{A}$ to probe all elements of T, then $\mathcal{P}$ is called *elusive* (also, *evasive*).

The recognition complexity has been studied by various authors during the last 15 years (see all the references except [5], [10], [11], and [14]) and has turned out to be especially interesting for the case that T equals $V^{(2)}$, the set of two-element subsets of some finite set V. In this case the subsets of T can be interpreted as graphs with vertex set V. A *graph property* is a subset $\mathcal{P} \subset 2^T$, $T = V^{(2)}$, such that $\mathcal{P}$ contains with each graph G also each isomorphic copy of G (with vertex set V). A graph property $\mathcal{P}$ is called *nontrivial* if $\mathcal{P} \neq \emptyset$, $\mathcal{P} \neq 2^T$. It is called *decreasing* if, for each $G \in \mathcal{P}$, all subgraphs of G (with vertex set V) are contained in $\mathcal{P}$, *increasing* if $2^T \setminus \mathcal{P}$ is decreasing and *monotonic* if it is increasing or decreasing. In 1973, Rosenberg [12] conjectured that there exists some $\gamma > 0$ such that

$$c(\mathcal{P}) \geq \gamma n^2$$

for all nontrivial graph properties $\mathcal{P}$, $n = |V|$.

Meanwhile, there exist many counterexamples to the conjecture (see [2]). Together with Aanderaa, he modified his conjecture as follows.

There exists $\gamma > 0$ *such that for all nontrivial monotonic graph properties* $\mathcal{P}$ *we have* $c(\mathcal{P}) \geq \gamma n^2$.

This conjecture was proved by Rivest and Vuillemin [13] in 1975 with $\gamma = 1/16$. Kleitman and Kwiatkowski [8] improved the value of γ from 1/16 to 1/9 for n large. Then, in 1984, Kahn, Saks, and Sturtevant [9] proved that $c(\mathcal{P}) \geq \binom{n}{2} + o(n^2)$, which is strong support for the following conjecture of Karp that is still unresolved.

All nontrivial monotonic graph properties are elusive.

In fact, Kahn, Saks, and Sturtevant proved Karp's conjecture in case n is a prime power. Their method (which comes from algebraic topology) was applied by King [7] to digraph properties and by Yao [17] to monotone bipartite graph properties. We now use their method in a different way to obtain some new results, e.g., the theorem that all decreasing graph properties containing no graphs with cycles of length 3 or 4 are elusive.

*Received by the editors January 21, 1991; accepted for publication (in revised form) July 28, 1992.

2. Tools from algebraic topology. From now on, we assume that $\mathcal{P}$ is a monotone nontrivial graph property.

Because $c(\mathcal{P}) = c(2^T \backslash \mathcal{P})$, it suffices to study decreasing graph properties. But a decreasing graph property is an (abstract) simplicial complex. Hence, its *Euler characteristic* $\chi(\mathcal{P})$ is defined as

$$\chi(\mathcal{P}) := \sum_{i=1}^{|T|} (-1)^{i-1} a_i,$$

where $a_i := a_i(\mathcal{P}) := |\{X \in \mathcal{P} : |X| = i\}|$.

Now if G is an abelian group (here, $G = \mathbf{Z}$ or $G = \mathbf{Z}/p\mathbf{Z}$, p prime), the complex is called *G-acyclic* if

$$H_0(\mathcal{P}, G) = G \quad \text{and} \quad H_i(\mathcal{P}, G) = 0 \quad \text{for } i > 0,$$

where $H_i(\mathcal{P}, G)$ denotes the i-dimensional homology group of $\mathcal{P}$ with respect to G. Kahn, Saks, and Sturtevant established the following connection between complexity theory and algebraic topology.

THEOREM 1. *If $\mathcal{P}$ is not elusive, then it is $\mathbf{Z}_p$-acyclic for all primes p.*

Denote by $\mathcal{G}$ the set of all finite groups G containing a normal p-subgroup G_1, $G_1 \trianglelefteq G$, such that the factor group G/G_1 is cyclic. If G is a permutation group on T leaving $\mathcal{P}$ invariant, we define the simplicial complex $\mathcal{P}_G$ with vertex set $T_G := \{B \in \mathcal{P} : B \text{ orbit of } G\}$ by

$$\{B_1, \ldots, B_k\} \in \mathcal{P}_G :\Longleftrightarrow B_1 \cup \cdots \cup B_k \in \mathcal{P}.$$

Now the following theorem of Smith [14] and Olivier [11] is the essential tool in [9] and in what follows.

THEOREM 2. *If $G \in \mathcal{G}$ is a permutation group on T leaving the $\mathbf{Z}_p$-acyclic complex $\mathcal{P}$ invariant, then*

$$\chi(\mathcal{P}_G) = 1.$$

3. Some applications. We start by deriving some information about a cyclic group acting on $V^{(2)}$.

LEMMA 1. *Let $V := \mathbf{Z}_n := \mathbf{Z}/n\mathbf{Z}$ and $\tau : \mathbf{Z}_n \to \mathbf{Z}_n : x \to x + 1$. The group $G := \langle \tau \rangle$ generated by τ acts canonically on $V^{(2)}$ and the following statements about the orbits of G hold.*

(i) *If n is odd, $V^{(2)}$ decomposes into $(n-1)/2$ orbits of cardinality n.*

(ii) *If n is even, $V^{(2)}$ decomposes into $(n/2 - 1)$ orbits of cardinality n and one orbit of cardinality $n/2$.*

(iii) *The set of edges $\{\{0, j\} : 1 \le j \le \lfloor n/2 \rfloor\}$ is a system of distinct representatives for the orbits of G.*

(iv) *Denote by $D_j^n = D_j$ the orbit of $\{0, j\}$ and by $F_j^n = F_j$ the corresponding graph (V, D_j). Then F_j is the vertex disjoint union of s_j cycles of length r_j, where $s_j :=$ $\gcd(j, n)$ and $r_j := n/s_j$, $(1 \le j < n/2)$. For n even we have $F_{n/2} \simeq \frac{n}{2} K_2$. The components of F_j are the sets $M_{j,i}^n := M_{j,i} := \{x \in \mathbf{Z}_n : x \equiv i \bmod s_j\}, 0 \le i < s_j, 1 \le j \le \lfloor n/2 \rfloor$.*

Proof. We have $G = \langle \tau \rangle = \{\tau^j : 0 \le j < n\}$ and $\tau^j(x) = x + j, 0 \le j < n$. An edge $\{x, y\} \in V^{(2)}$ is a fixed point of τ^j if and only if $\{x + j, y + j\} = \{x, y\}$. This is certainly true for $j = 0$. For $0 < j < n$ we must have $x + j = y$ and $y + j = x$; hence, $x + y + 2j = x + y$ and therefore $2j = 0$ (in $\mathbf{Z}_n$), i.e., n is even and $j = n/2$. It is easy to see that there are exactly $n/2$ edges $\{x, y\}$ in $V^{(2)}$ such that $x + \frac{n}{2} = y$ and $y + \frac{n}{2} = x$.

From Burnside's Lemma we infer that the number of orbits is

$$\frac{1}{n}\sum_{0\leq j<n} (\#\text{ fixed points of } \tau^j \text{ in } V^{(2)}),$$

which equals $\frac{1}{n}\binom{n}{2} = \frac{n-1}{2}$ if n is odd and $\frac{1}{n}\left(\binom{n}{2} + \frac{n}{2}\right) = \frac{n}{2}$ if n is even.

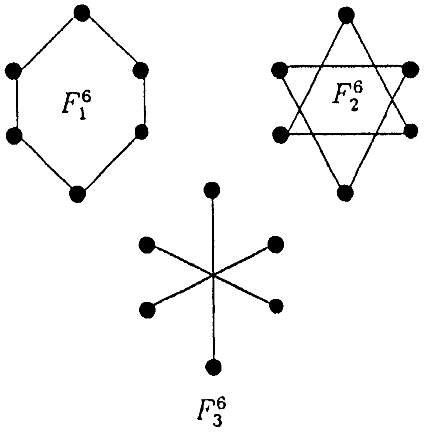

FIG. 1. *The orbits of Lemma* 1 *for* $n = 6$.

If $\{x, y\}$ and $\{x', y'\}$ are in the same orbit, then $x - y = \pm(x' - y')$. Hence, the edges $\{0, j\}$, $1 \leq j \leq \lfloor n/2 \rfloor$, belong to different orbits and (because we know the number of orbits) form a system of distinct representatives for the orbits and (iii) follows. To complete the proof of (i) and (ii), we note that $|D_j|$ is the index of the stabilizer of $\{0, j\}$ and hence (cf. the argument at the beginning of the proof)

$$|D_j| = \begin{cases} n & \text{for } j < n/2 \\ n/2 & \text{for } n \text{ even and } j = n/2. \end{cases}$$

Now G is a subgroup of the automorphism group $\operatorname{Aut}(F_j)$ of F_j and hence $\operatorname{Aut}(F_j)$ acts transitively on the vertices of F_j. We conclude that F_j is a regular graph of degree 2 for $j < n/2$ and of degree 1 for $j = n/2$. Hence, $F_{n/2} \simeq \frac{n}{2}K_2$ and F_j is a disjoint union of cycles for $j < n/2$. The cycle in F_j containing $\{0, j\}$ consists of the edges $\{0, j\}, \{j, 2j\}, \ldots, \{(r_j - 1)j, 0\}$ with

$$r_j = \min\{x \in \mathbf{Z} : x \geq 1, xj \equiv 0 \bmod n\}.$$

Again by the transitivity of $\operatorname{Aut}(F_j)$ on V, all cycles of F_j have the same length r_j and their number is $s_j = \gcd(j, n)$.

Finally, we note that x and y are joined by a path in F_j if and only if there exists some positive $k \in \mathbf{Z}$ such that $\tau^{kj}(x) = y$, i.e., if and only if there exists some $z \in \mathbf{Z}_n$ such that $x - y = zj$, which holds if and only if $x \equiv y \bmod \gcd(j, n)$. This proves (iv). □

Recall that the *girth* of a graph is the length of its shortest cycle (the girth of a forest being defined as ∞). We can now prove Theorem 3.

THEOREM 3. *Suppose $\mathcal{P}$ is a decreasing* (*nontrivial*) *graph property such that all graphs of $\mathcal{P}$ have girth greater than* 4. *Then $\mathcal{P}$ is elusive.*

Proof. If n is a power of 2, then elusiveness follows from the (more general) results in [9] (Karp's conjecture for prime powers). Hence, we may assume that some odd prime p divides n, $n = pm$ say, and $V = \mathbf{Z}_p \times \mathbf{Z}_m$. Let $G := \langle\tau\rangle$, the group generated by $\tau : \mathbf{Z}_p \to \mathbf{Z}_p : x \to x + 1$ and $H := \langle\sigma\rangle$, where $\sigma : \mathbf{Z}_m \to \mathbf{Z}_m : y \to y + 1$. Recall that the *wreath product* $G \wr H$ is a permutation group on V defined as follows:

$$G \wr H := \{(f; \pi) | f : \mathbf{Z}_m \to G, \pi \in H\}.$$

For $(i, j) \in V$ and $(f; \pi) \in G \wr H$, we have

$$(f; \pi)(i, j) := (f(\pi(j))(i), \pi(j)),$$

$G \wr H$ contains the normal subgroup

$$G_1 := \{(f; 1_H) | f : \mathbf{Z}_m \to G\},$$

which is isomorphic to the m-fold direct product $G^m = G \times \cdots \times G$. Hence, G_1 is a p-group and we have $(G \wr H)/G_1 \simeq H$. It follows that $G \wr H$ is in $\mathcal{G}$.

Now suppose there was a nonelusive graph property $\mathcal{P}$ that contained graphs of girth greater than 4 only. By Theorems 1 and 2 we must have

$$\chi(\mathcal{P}_{G\wr H}) = 1.$$

To obtain a contradiction, we consider two cases.

(a) $p = 3$. The orbit of an edge joining two vertices in some set $V_i := \mathbf{Z}_p \times \{i\}, i \in \mathbf{Z}_m$, is isomorphic to mK_3, the graph consisting of m disjoint triangles, by Lemma 1 and the action of the wreath product. But K_3 has girth 3. The orbit of an edge joining vertices in V_i and $V_j (i \neq j)$ is easily seen to contain the complete bipartite graph $K_{3,3}$ as a subgraph that has girth 4. We infer that $\mathcal{P}_G$ is empty, a contradiction.

(b) $p > 3$. Similarly to (a), the orbits of edges joining nodes in V_i and V_j, $i \neq j$, are easily seen to contain some complete bipartite graph $K_{p,p}$ that has girth 4 and therefore cannot be contained in $\mathcal{P}$. The orbits of edges joining two points in V_i are isomorphic to mC_p, the graph consisting of m disjoint copies of the p-cycle C_p, and there are $(p - 1)/2$ such orbits (cf. Lemma 1 and the action of the wreath product). We claim that the union of two such orbits contains a 4-cycle. It obviously suffices to show that each union $F_j \cup F_k$, $1 \leq j < k \leq (p - 1)/2$, contains a 4-cycle (notation of Lemma 1). But for each $x \in \mathbf{Z}_p$ the vertices $x, x + j, x + j + k, x + k$ lie on a 4-cycle in $F_j \cup F_k$ (in this order). It follows that $\chi(\mathcal{P}_{G\wr H}) = (p - 1)/2 > 1$, again a contradiction. □

COROLLARY 1. *Suppose $\mathcal{P}_k$ consists of all graphs having girth at least k. Then $\mathcal{P}_k$ is elusive for all $k \geq 4$.*

Proof. The case $k = 4$ (triangle-free graphs) was proved by Bollobás by exhibiting an explicit strategy for player $\mathcal{S}$ that forces $\mathcal{A}$ to probe all edges (cf. [3]). For $k > 4$ we apply Theorem 3. □

The next theorem is easy to prove.

THEOREM 4. *Suppose $\mathcal{P}$ is a decreasing property such that each graph in $\mathcal{P}$ has minimum degree at most one. Then $\mathcal{P}$ is elusive.*

Proof. Without loss of generality suppose that $n = |V|$ is not a power of two. Obviously, it suffices to exhibit a permutation group G on V such that each graph with nonempty edge set that is invariant under G has minimum degree at least two. For n odd, a transitive cyclic group will do by Lemma 1. For n even, n contains an odd prime divisor by assumption. Hence, we can choose a wreath product as in Theorem 3. □

We are now going to prove elusiveness for some graph properties that are often considered in graph theory.

THEOREM 5. *Let $\mathcal{P}_k$ denote the set of graphs with vertex set V and maximum degree at most k. Then $\mathcal{P}_k$ is elusive for $0 \le k \le n-2$.*

Proof. Suppose first that n is odd. We choose a cyclic and transitive permutation group on V (without loss of generality $V = \mathbf{Z}_n$ and $G = \langle \tau \rangle$ as in Lemma 1). Obviously, $G \in \mathcal{G}$. Now suppose that $\mathcal{P}_k$ is not elusive. By Theorem 2, $\chi((\mathcal{P}_k)_G) = 1$. A union $\bigcup_{i=1}^{m} F_{j_i}$ of distinct orbits is in $\mathcal{P}_k$ if and only if $m \le \lfloor k/2 \rfloor =: u$. Hence, letting $t := (n-1)/2$, we have

$$1 - \chi((\mathcal{P}_k)_G) = \sum_{i=0}^{u} (-1)^i \binom{t}{i}$$

$$= \sum_{i=0}^{u} (-1)^i \left[\binom{t-1}{i-1} + \binom{t-1}{i} \right]$$

$$= (-1)^u \binom{t-1}{u} \neq 0$$

because $t - 1 = (n-3)/2 \ge \lfloor k/2 \rfloor$ for n odd, $k \le n-2$, a contradiction.

Now assume that n is even. If k is even we can proceed completely analogous to the preceding case choosing $V := \mathbf{Z}_n$, $G := \langle \tau \rangle$ as in Lemma 1. Again, a union of distinct orbits is in $\mathcal{P}_k$ if and only if $m \le k/2$. Letting $t := n/2$, $u := k/2$ we get

$$1 - \chi((\mathcal{P}_k)_G) = (-1)^u \binom{t-1}{u} \neq 0.$$

If k is odd, which implies $k \le n-3$, we let $V := \{a\} \dot{\cup} \mathbf{Z}_{n-1}$ and $G := \langle \tau \rangle$, where $\tau(a) := a$ and $\tau(x) := x + 1$ for $x \in \mathbf{Z}_{n-1}$. The orbits of G on $V^{(2)}$ are the sets D_j^{n-1}, $1 \le j \le \frac{n}{2} - 1$ and $D_0 := \{\{a, j\} : j \in \mathbf{Z}_{n-1}\}$. Because $k \le n-3$, no graph in $\mathcal{P}_k$ contains all the edges in D_0. Now elusiveness follows just as in the first part of the proof. □

Denoting by $\Delta(H)$ and $\delta(H)$ the maximal and minimal degree of a graph H, respectively, we obtain the following.

COROLLARY 2. *The graph properties $\{H : \Delta(H) \ge k\}$ and $\{H : \delta(H) \ge k\}$ are elusive for $1 \le k \le n-1$; $\{H : \delta(H) \le k\}$ is elusive for $0 \le k \le n-2$.*

Proof. If $\mathcal{P}$ is a graph property, denote by $\mathcal{P}^*$ the set $\{H = (V, E) : \bar{H} := (V, V^{(2)} \setminus E) \in \mathcal{P}\}$. It is well known that $c(P) = c(P^*) = c(2^T \setminus \mathcal{P})$ (cf. [15]). Hence, the result follows from Theorem 5. □

Suppose $H = (V, E)$ is a graph. A *matching* of H is a set M of edges ($M \subset E$) such that no two of them have an endpoint in common. A vertex x is covered by M if x is an endpoint of one of the edges in M. A matching covering all the nodes in V is called a *perfect matching*. (Equivalently, we say that H has a *1-factor*.) H is called *factor-critical* if $H - x$, the graph obtained from H by deleting the vertex x, has a *1-factor* for all $x \in V$. The *matching number* $\nu(H)$ of H is the maximum cardinality of a matching in H. The following lemma is well known (cf. [10, Ex. 3.2.5 and Thm. 5.5.24]).

LEMMA 2. *Suppose H is a graph whose automorphism group is transitive on the vertices. Then each component of H is either factor-critical or contains a 1-factor.*

As an application, we get the following.

LEMMA 3. *Let n, p, m, G, H, and $V = \mathbf{Z}_p \times \mathbf{Z}_m$ be defined as in the proof of Theorem* 1 *except that the prime $p = 2$ is allowed. Then the following results hold for an arbitrary orbit B of $G \wr H$ acting on $V^{(2)}$:*

(i) *In case $p = 2$, the graph (V, B) contains a* 1*-factor.*

(ii) *In case $p > 2$, the inequality $2\nu((V, B)) \geq n - m$ holds.*

Proof. Note that the orbit B of an edge e in $V^{(2)}$ is obtained as follows: if e joins two vertices in some set $V_i := \mathbf{Z}_p \times \{i\}$, then (V, B) is isomorphic to mK_2 in case $p = 2$ and to mC_p for $p > 2$. Hence, the result is clear in this case.

If e joins vertices in different V_i's, in V_0 and V_j say, consider the orbit D_j^m (and the corresponding graph F_j^m) of H acting on $\mathbf{Z}_m$. Then (V, B) arises from F_j^m by substituting the set V_i for each $i \in \mathbf{Z}_m$ and joining vertices in V_i and V_k if and only if $i \neq k$ and i and k are joined in F_j^m (see Figs. 1 and 2). It is clear that (V, B) satisfies the hypothesis of Lemma 2. Hence, for $p = 2$, each component has an even number of vertices and thus contains a perfect matching. For $p > 2$, just note that the number of components of (V, B) is $\gcd(j, m) \leq m/2$ and that each component either has a 1-factor or is factor-critical. □

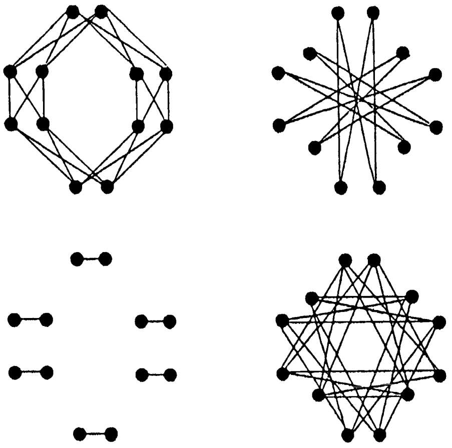

FIG. 2. *The orbits of $G \wr H$ on* $(\mathbf{Z}_2 \times \mathbf{Z}_6)^{(2)}$.

THEOREM 6. *Suppose k is a natural number satisfying $k < \lfloor n/2 \rfloor$ and denote by $\mathcal{P}_k$ the property*

$$\mathcal{P}_k := \{H : H \text{ is a graph with vertex set } V \text{ and } \nu(H) \leq k\}.$$

Then $\mathcal{P}_k$ is elusive.

Proof. If n is even, $n = 2m$ say, we choose a wreath product $G \wr H$ on $V := \mathbf{Z}_2 \times \mathbf{Z}_m$ as in Lemma 3. By Lemma 3(i), no orbit graph (V, B) is in $\mathcal{P}_k$ and thus $\chi((\mathcal{P}_k)_{G \wr H}) = 0$, which implies that $\mathcal{P}_k$ is elusive.

Now assume that n is odd, n no prime power. Hence, $n \geq 15$ and n has a prime divisor $q \geq 5$. By choosing again a wreath product $G \wr H$ of transitive cyclic groups on $\mathbf{Z}_q \times \mathbf{Z}_{n/q}$, we see that $\chi((\mathcal{P}_k)_{G \wr H}) = 0$ if $2k \leq n - \frac{n}{q} = n(1 - \frac{1}{q})$. So suppose that $2k > n(1 - \frac{1}{q}) \geq \frac{4}{5}n$. By Bertrand's postulate (cf. [5, p. 71]), we can choose a prime number p satisfying $n/3 < p \leq 2n/3$. (Note that p does not divide n.) We write $V = U \dot{\cup} W$ with $|U| = p$ and $|W| = n - p$. Because $|W|$ is even, we identify W with $\mathbf{Z}_2 \times \mathbf{Z}_{(n-p)/2}$ and choose a wreath product of cyclic groups as above on W and call that group G'. On U, we choose a cyclic transitive permutation group G'' and let $G := G' \times G''$. Recall that G' has a normal subgroup G_1' of order 2^r, $r := (n-p)/2$, and $G'/G_1' \simeq \mathbf{Z}_r$. Hence, G_1' is normal in G and $G/G_1' \simeq (G'/G_1') \times G'' \simeq \mathbf{Z}_r \times \mathbf{Z}_p \simeq \mathbf{Z}_{rp}$ because p and r are relatively prime. We conclude that $G \in \mathcal{G}$.

Now, the action of G on $V^{(2)}$ yields the following orbits:

(a) The orbits of G' on $W^{(2)}$, $W_1, \ldots, W_s$. By Lemma 3(i), each graph (W, W_i) has a 1-factor ($s = \lfloor r/2 \rfloor + 1$).

(b) The orbits $U_1, \ldots, U_t$ of G'' on $U^{(2)}$, where each graph (U, U_j) is a p-cycle ($t = (p-1)/2$).

(c) The orbit $B := \{\{u, w\} : u \in U, w \in W\}$.

Because $k < \lfloor n/2 \rfloor$, no graph $(V, W_i \cup U_j)$ is in $\mathcal{P}_k$. From $2k > \frac{4}{5}n > \frac{2}{3}n \geq \max(p, n-p)$, we infer that each of the graphs (V, W_i), (V, U_j) is in $\mathcal{P}_k$, $(1 \leq i \leq s, 1 \leq j \leq t)$. For (V, B), we have the following two cases.

(i) $k < \min(p, n-p)$. Then $(V, B) \notin \mathcal{P}_k$, implying

$$\chi((\mathcal{P}_k)_G) = \sum_{i=1}^{s}(-1)^{i-1}\binom{s}{i} + \sum_{j=1}^{t}(-1)^{j-1}\binom{t}{j} = 1 + 1 = 2,$$

and hence $\mathcal{P}_k$ is elusive.

(ii) $k \geq \min(p, n-p)$. Suppose first that $p = \min(p, n-p)$. Because $2k < n$ and $p + (n-p) = n$, we must have $k < n - p$. Thus, all graphs $(V, B \cup C)$, where C is a union of some of the orbits $U_1, \ldots, U_t$, are in $\mathcal{P}_k$. On the other hand, all graphs $(V, B \cup W_i)$, $(1 \leq i \leq s)$ have matching number $(n-1)/2$ and therefore are not in $\mathcal{P}_k$. We conclude that

$$\chi((\mathcal{P}_k)_G) = \sum_{i=1}^{s}(-1)^{i-1}\binom{s}{i} + \sum_{j=1}^{t}(-1)^{j-1}\binom{t}{j} + \sum_{j=0}^{t}(-1)^{j}\binom{t}{j} = 1 + 1 + 0 = 2.$$

Hence, $\mathcal{P}_k$ is not elusive. The case $n - p = \min(p, n-p)$ is similar.

This completes the proof. □

Again, the corresponding result for the properties $\{H : \nu(H) \geq k\}$ follows by taking complements.

The proof of our final result uses the same construction as the proof of Theorem 5 and is therefore left to the reader.

THEOREM 7. *For k even, $k < n$, denote by $\mathcal{P}_k$ the set of all graphs on V having a k-factor, i.e., a k-regular spanning subgraph. Then $\mathcal{P}_k$ is elusive.*

We conclude by mentioning that there are several important monotone graph properties that have not been shown to be elusive to the knowledge of the author. Two examples are *Hamiltonicity* and *k-connectedness* for $k \geq 3$.

Acknowledgments. I thank W. Obershelp for introducing me to the topic and for some very helpful discussions. I also thank the referee who helped to improve the article by several constructive suggestions.

CLOSENESS OF NP-HARD SETS TO OTHER COMPLEXITY CLASSES*

BIN FU[†] AND HONG-ZHOU LI[‡]

Abstract. Let A be a language and C be a class of languages. A is said to be *s-C-close* (*s-C-outside-close*) if there exists $B \in C$ such that $\| (A \bigtriangleup B)^{\leq n} \| \leq s(n)$ (and $A \subseteq B$). If A is *q-C-close* (*q-C-outside-close*) for some polynomial q then it is simply said that A is *C-close* (*C-outside-close*). The following results are shown in this paper.

(1) No *NP-hard* set can be *coNP-close* unless $NP = coNP$.

(2) No *NP-hard* set can be *R-close* unless $NP = R$.

(3) No *NP-hard* set can be $O(\log n)$*-UP-close* unless $NP = FewP$.

(4) No *NP-hard* set can be $O(\log n)$-$C_=P$*-close* unless $NP \subseteq C_=P$.

(5) No *NP-hard* set can be *UP-outside-close* unless $NP = FewP$.

(6) No *NP-hard* set can be $C_=P$*-outside-close* unless $NP \subseteq C_=P$.

Key words. symmetric difference, sparse sets, *NP-hard* sets

AMS subject classification. 68C25

1. Introduction.

Research about the connection and difference between complexity classes are two main research lines in complexity theory. In recent years investigations about many counting classes have revealed surprising connections between complexity classes. In this paper we pay attention to the difference between *NP* and other complexity classes. We study whether an *NP-hard* set can be approximated sufficiently by the sets in other complexity classes.

Yesha [17] first considered measuring the similarity of two sets A and B by the density of their symmetric difference $A \bigtriangleup B$. Yesha [17] and Schöning [10] defined two sets A and B to be *s-close* to each other if for each n, $\| (A \bigtriangleup B)^{\leq n} \| \leq s(n)$. Can a *NP-hard* set be polynomially close to some set in P? Yesha and Schöning provided only partial answers to this question. Yesha proved that no *NP-hard* sets can be $O(\log \log n)$*-close* to any set in P unless $P = NP$. Schöning showed that no paddable *NP-hard* sets can be polynomially close to any set in P unless $P = NP$. Watanabe [16] showed that if $NP \subseteq P_{1-tt}(sparse)$ then $NP = R$. The question was not settled until Ogiwara and Watanabe [9] showed that if $NP \subseteq P_{btt}(sparse)$ then $P = NP$; the result follows since any set that is close to a set in P is $1 - tt$ reducible to a sparse set. Recently Fu [5] investigated lower bounds of closeness between many complexity classes. He showed that if an *NP-hard* set is the union of a set in $P_{btt}(sparse)$ and set A, then $NP \subseteq P_{dtt}(A)$. Thus no *NP-hard* set can be the union of a sparse set and a set in *coNP* (*FewP*) unless $NP = coNP$ ($NP = FewP$).

In this paper, we investigate the closeness between *NP-hard* sets and the sets of some other complexity classes such as *UP*, *coNP*, $C_=P$, and R. In order to characterize the conditions necessary for an *NP-hard* set to have a small density symmetric difference with a set A, we introduce two reductions: $\leq^P_{d\text{-maj}}$ and $\leq^P_{d\text{-conj}}$, both of which are positive truth-table reductions [11]. We show that if an *NP-hard* set can be polynomially close ($O(\log n)$*-close*) to set A then $NP \subseteq P_{d\text{-maj}}(A)$ (respectively, $NP \subseteq P_{d\text{-conj}}(A)$), and if *NP-hard* set H is a subset of A and A-H is sparse then $NP \subseteq P_{d\text{-conj}}(A)$.

2. Preliminaries. We fix $\Sigma = \{0, 1\}$ as our alphabet . By "string" we mean an element of Σ^*. For a string x in Σ^*, $\mid x \mid$ denotes the length of x. We consider a standard canonical order on Σ^*. For any strings x and y, x is canonically smaller than y (write $x \leq y$) if either (1) $\mid x \mid < \mid y \mid$, or (2) $\mid x \mid = \mid y \mid$ and if there exists some k, $1 \leq k \leq \mid x \mid$, such that (for all $i : 1 \leq i < k[x_i = y_i]$ and $x_k = 0 \wedge y_k = 1$), where x_i is the ith symbol of the string x. For an $S \subseteq \Sigma^*$, the cardinality of S is denoted by $\parallel S \parallel$; set $S^{=n}(S^{\leq n})$ consists of all words of length $= n(\leq n)$ in S. In particular, we let $\Sigma^n = \{x : x \in \Sigma^*$ and $\mid x \mid = n\}$ and $\Sigma^{\leq n} = \{x : x \in \Sigma^*$ and $\mid x \mid \leq n\}$. Let $x, y \in \Sigma^*$; we define the interval $[x, y] : [x, y] = \{z : x \leq z \leq y$ and $z \in \Sigma^*\}$.

Let $[a, b]$ and $[c, d]$ be two disjoint intervals; we say $[a, b] \leq [c, d]$ if $b \leq c$. We use λ to denote the null string. N represents the set $\{0, 1, 2, \ldots\}$.

We use the pairing function $\langle . , . \rangle : \Sigma^* \times \Sigma^* \longrightarrow \Sigma^*$. It is convenient to assume that for any x, y in Σ^*, $\mid < x, y > \mid \leq 2(\mid x \mid + \mid y \mid)$.

Our computation model is the Turing machine. Now we involve the following complexity classes: P (respectively, NP) denotes the class of languages accepted by deterministic (respectively, nondeterministic) Turing machines in polynomial-time. PF denotes the class of polynomial-time computable functions. $coNP = \{\Sigma^* - A : A \in NP\}$. UP [14] denotes the class of languages accepted by polynomial-time nondeterministic Turing machines that have at most one accepting path on each input. $FewP$ [1] represents the class of languages accepted by polynomial-time nondeterministic Turning machines that have at most polynomial number of accepting paths on each input. $C_=P$ was defined by Wagner [15]. A language L belongs to $C_=P$ if and only if there exists a polynomial-time nondeterministic Turing machine M such that $x \in L$ if and only if the number of accepting paths is equal to the number of rejecting paths. R (see [2]) represents one-sided bounded error probability complexity classes.

It is well known that $P \subseteq UP \subseteq FewP \subseteq NP$ and $P \subseteq R \subseteq NP$. In [13] relativizations are presented under which the classes NP and $C_=P$ are incomparable.

We now define some notions of polynomial-time reducibilities.

A $\leq_m^P$-reduction of A to B is a polynomial-time computable function f such that for each $x \in \Sigma^*, x \in A \Longleftrightarrow f(x) \in B$.

A $\leq_{k-tt}^P$-reduction of A to B is a pair $\langle f, g \rangle$ of polynomial-time computable functions such that the following hold for each $x \in \Sigma^*$: (1) $f(x) = \langle x_1, \ldots, x_k \rangle$ is an ordered k-*tuple* of strings, (2) $g(x)$ is a k-argument truth-table: $\{0, 1\}^k \longrightarrow \{0, 1\}$, (3) $x \in A \Longleftrightarrow g(x)(\chi_B(x_1), \ldots, \chi_B(x_k)) = 1$,where χ_B is the characteristic function of the set B.

A $\leq_{btt}^P$-reduction of A to B is a $\leq_{k-tt}^P$-reduction of A to B for some integer k.

A $\leq_{dtt}^P$-reduction of A to B is a polynomial-time computable function f such that for each $x \in \Sigma^*$, $f(x)$ is a list of strings in Σ^* and $x \in A \Longleftrightarrow$ one of the strings of $f(x)$ is in B.

A $\leq_{d-\mathrm{maj}}^P$-reduction of A to B is a polynomial-time computable function f such that for each $x \in \Sigma^*$, $f(x) = \langle C_1, \ldots, C_k \rangle$, where C_i is a list of strings in Σ^* and $x \in A \Longleftrightarrow \parallel B \bigcap C_i \parallel > \parallel C_i \parallel /2$ for some $i \leq k$.

A $\leq_{d-\mathrm{conj}}^P$-reduction of A to B is a polynomial-time computable function f such that for each $x \in \Sigma^*$, $f(x) = \langle C_1, \ldots, C_k \rangle$, where C_i is a list of strings in Σ^* and $x \in A \Longleftrightarrow C_i \subseteq B$ for some $i \leq k$.

A $\leq_{tt}^P$-reduction of A to B is a pair of polynomial-time computable functions $\langle f, g \rangle$ such that for each $x \in \Sigma^*$, $f(x) = \langle x_1, \ldots, x_k \rangle$, $g(x)$ is a polynomial-time boolean circuit with k inputs, and $x \in A \Longleftrightarrow g(x)(\ \chi_B(x_1), \ldots, \chi_B(x_k)) = 1$.

For a boolean circuit $C : \{0, 1\}^k \longrightarrow \{0, 1\}$, if for any two k-tuples of $\{0, 1\} : \langle a_1, \ldots, a_k \rangle$ and $\langle b_1, \ldots, b_k \rangle$, with for all $i \leq k\ (a_i \leq b_i)$, $C(a_1, \ldots, a_k) = 1$ implies $C(b_1, \ldots, b_k) = 1$, then we say C is positive.

If $A \leq_{tt}^P B$ via $\langle f, g \rangle$ and for each $x \in \Sigma^*$ $g(x)$ is positive, then we say $A \leq_{ptt}^P B$. The reduction $\leq_{ptt}^P$ is called a positive truth-table reduction.

Let C be a class of languages, and let $\leq_r^P$ be a type of reduction (e.g., $r = m, btt, k-tt, ptt$, etc.). Then for any $A \subseteq \Sigma^*$, we define $A \in P_r(C)$ if and only if $A \leq_r^P B$ for some B in C. If every language in C is *$\leq_r^P$-reducible* to H, then we say H is *C-r-hard*.

For any set $A \subseteq \Sigma^*$, we say A is sparse if there exists a polynomial p such that $\| A^{\leq n} \| \leq p(n)$ for every $n \in N$. Let languages $A, B \subseteq \Sigma^*$; we define $A \triangle B = (A - B) \cup (B - A)$. The function $\mathrm{dist}_{A,B} : N \longrightarrow N$ is called the distance function of A and B, where $\mathrm{dist}_{A,B}(n) = \| (A \triangle B)^{\leq n} \|$. Let C be a class of languages, and let function $s : N \longrightarrow N$; A is said to be *s-C-close* (*s-C-outside-close*, *s-C-inside-close*) if there exists $B \in C$ such that $\mathrm{dist}_{A,B}(n) \leq s(n)$ (and $A \subseteq B$, $B \subseteq A$ respectively). If A is *q-C-close* (*q-C-outside-close*, *q-C-inside-close*) for some polynomial q then we simply say A is *C-close* (*C-outside-close*, *C-inside-close*). We assume all polynomials involved in this paper are monotonic.

3. Closeness to *NP-m-hard* sets. In this section we study whether an *NP-hard* set can be *$s(n)$-close* to some other complexity classes for some slowly increasing function $s(n)$. First we develop a useful technical lemma that generalizes many results.

LEMMA 3.1. *Let H be NP-m-hard, $K \in NP$, $A \subseteq \Sigma^*$, and $\mathrm{dist}_{A,H}(n) \leq s(n)$, where $s(n)$ is a nondecreasing function in PF. There exists a polynomial $p_0(n)$ such that for every polynomial-time computable function $h(n) > 2s(p_0(n))$ there is an algorithm that has the following properties for input x of length n:*

(1) *The algorithm either accepts x or outputs a series of sets: $G_1, \ldots, G_{e_x}$, where $\| G_e \| \leq h(n)$ and $G_e \subseteq \Sigma^{\leq p_0(n)}$ for all $e \leq e_x$.*

(2) *$x \in K \Longleftrightarrow$ (the algorithm accepts x) or ($\| A \bigcap G_e \| > s(p_0(n))$ for some $e \leq e_x$).*

(3) *If $\| \overline{A} \bigcap G_e \| > s(p_0(n))$ for all e with $\| G_e \| = h(n)$, then $x \in K \Longleftrightarrow$ the algorithm accepts x.*

(4) *The algorithm will stop in $p_1(h(n)) + p_1(n)$ steps, where $p_1(n)$ is a polynomial.*

Proof. Since $K \in NP$, there exist a set $C \in P$ and a polynomial $r(n)$ such that $x \in K \Longleftrightarrow$ there exists $w (w \in \Sigma^{\leq r(|x|)} \wedge \langle x, w \rangle \in C)$. We define the left set $L(C, r)$ as in [9]:

$L(C, r) = \{\langle x, y \rangle : (y \in \Sigma^{\leq r(|x|)}) \wedge (\text{there exists } w \in \Sigma^{\leq r(|x|)} (y \leq w)) \wedge (\langle x, w \rangle \in C)\}$.

It is easy to see $L(C, r) \in NP$. Because H is *NP-m-hard*, there exists a function $f \in PF$ such that $L(C, r) \leq_m^P H$ via f. Let f be computable in polynomial-time $t(n)$. For a fixed $x \in \Sigma^*$, if there exists a $w \in \Sigma^{\leq r(|x|)}$ such that $\langle x, w \rangle \in C$, then we let $w_{\max}$ be the largest such string. □

Let $p_0(n) = t(2(n + r(n)))$.

ALGORITHM.

Input x of length n.

Let $U_0 := \{[\lambda, 1^{r(n)}]\}$. $e := 0$.

Repeat

Let $[a_1, b_1], [a_2, b_2], \ldots, [a_k, b_k]$ be all the intervals in U_e.

It will follow that these intervals are all disjoint.

U_e is partitioned into the blocks $U_{e,1}, U_{e,2}, \ldots$, which satisfy the following three conditions.

(1) $U_e = U_{e,1} \cup U_{e,2} \cup \cdots \cup U_{e,m_e}$, where m_e is the number of blocks.

(2) Any two intervals $[a, b]$, $[a', b']$ in U_e are in the same block if and only if $f(\langle x, a \rangle) = f(\langle x, a' \rangle)$.

(3) For any two blocks $U_{e,i}, U_{e,j}$, $i < j$, $[a_i^{(0)}, b_i^{(0)}] < [a_j^{(0)}, b_j^{(0)}]$, where $[a_i^{(0)}, b_i^{(0)}]$ and $[a_j^{(0)}, b_j^{(0)}]$ are the least intervals (leftmost intervals) of $U_{e,i}$ and $U_{e,j}$ respectively.

Let $[a_i^{(1)}, b_i^{(1)}]$ be the largest interval (rightmost interval) in $U_{e,i}$ ($i \leq m_e$).

$V_e := \{[a_i^{(1)}, b_i^{(1)}] : i \leq h(n)\}$

$G_e := \{f(\langle x, a_i^{(1)} \rangle) : a_i^{(1)}$ is the left point of one of the intervals in $V_e\}$

```
    $U_{e+i} := \bigcup_{t\in V_e}\{t_1, t_2 : t_1, t_2$ are the first and last half of $t$ respectively$\}$
    $e := e + 1$
Until all the intervals in $U_e$ are of width 1
$e_x := e - 1$ {For $e$ was added an extra one before exiting the cycle}
If There is $b \in \bigcup_{t\in U_{e_x}}$ such that $\langle x, b\rangle \in C$.
Then Accept $x$.
Else Output: $G_1, \ldots, G_{e_x}$.
End of the Algorithm.
```

Claim 1. (i) For all $e \le e_x$, there are at most $2h(n)$ intervals in U_e. (ii) The cycle of the algorithm will not be repeated more than $r(n)+1$ times. (iii) $G_e \subseteq \Sigma^{\le p_0(n)}$ and $\| G_e \| \le h(n)$. (iv) $\| G_e \| = \| V_e \|$.

Proof of Claim 1. From the algorithm (i), (ii), and (iv) hold clearly. We must only prove (iii). For each interval $[c_i, d_i]$ in V_e, $[c_i, d_i] \subseteq [\lambda, 1^{r(n)}]$. Hence $| c_i | \le r(n)$ and $| \langle x, c_i\rangle | \le 2(n+ | c_i |) \le 2(n + r(n))$. Because f is computable in time t, $| f(\langle x, c_i\rangle) | \le t(2(n + r(n))) = p_0(n)$. So $G_e \subseteq \Sigma^{\le p_0(n)}$. □

Claim 2. If for some $e \le e_x$, $\| G_e \bigcap A \| > s(p_0(n))$, then $x \in K$.

Proof of Claim 2. Clearly for any two different intervals $[c_i, d_i]$, $[c_j, d_j]$ in V_e, they belong to different blocks $U_{e,i}$, $U_{e,j}$ respectively. Thus $f(\langle x, c_i\rangle) \ne f(\langle x, c_j\rangle)$. By Claim 1 (iii) $G_e \subseteq \Sigma^{\le p_0(n)}$. Since $\| (A \bigtriangleup H)^{\le p_0(n)} \| \le s(p_0(n))$ and $\| G_e \bigcap A \| > s(p_0(n))$, $H \bigcap G_e \ne \emptyset$, and there are some $c_i \in \Sigma^{\le r(n)}$ with $f(\langle x, c_i\rangle) \in H$. So $x \in K$. □

Claim 3. Let $e \le e_x$. If $\| G_e \| < h(n)$, then $w_{\max}$ is in an interval of $U_e \Longleftrightarrow w_{\max}$ is in an interval of V_e.

Proof of Claim 3. We assume that $w_{\max}$ is in one of the intervals of the block U_{e,i_0} ($i_0 \le m_e$). For any two intervals $[c, d]$, $[c', d']$ in the same block, $f(\langle x, c\rangle) = f(\langle x, c'\rangle)$. So $w_{\max}$ must be in $[a_{i_0}^{(1)}, b_{i_0}^{(1)}]$, which is the largest interval in U_{e,i_0}.

By Claim 1 (iv) $\| V_e \| = \| G_e \| < h(n)$; thus $\| V_e \| = m_e$. For every block $U_{e,i}$ ($i \le m_e$), its largest interval $[a_i^{(1)}, b_i^{(1)}]$ belongs to V_e. Hence $w_{\max}$ belongs to an interval in V_e. □

Claim 4. Let $e \le e_x$. If $\| G_e \bigcap \overline{A} \| > s(p_0(n))$, then $w_{\max}$ is in an interval of $U_e \Longleftrightarrow$ $w_{\max}$ is in an interval of V_e.

Proof of Claim 4. If $\| G_e \| < h(n)$, this claim holds by Claim 3. We only discuss the case $\| G_e \| = h(n)$. By Claim 1 (iv), $\| G_e \| = \| V_e \|$. We assume that $w_{\max}$ is in one of the intervals of the block U_{e,i_0} ($i_0 \le m_e$). By the same reasons as Claim 3 $w_{\max}$ must be in $[a_{i_0}^{(1)}, b_{i_0}^{(1)}]$. By Claim 1 (iii), $G_e \subseteq \Sigma^{\le p_0(n)}$. Since $\| (A \bigtriangleup H)^{\le p_0(n)} \| \le s(p_0(n))$ and $\| G_e \cap \overline{A} \| > s(p_0(n))$, we can conclude that $\overline{H} \bigcap G_e \ne \emptyset$, and there are some intervals $[c_{i_1}, d_{i_1}]$ in V_e such that $f(\langle x, c_{i_1}\rangle) \notin H$. Thus we have $i_1 \le h(n)$ with $f(\langle x, a_{i_1}^{(0)}\rangle) \notin H$ and $w_{\max} < a_{i_1}^{(0)}$. So $i_0 < i_1 \le h(n)$ and $w_{\max}$ belongs to an interval in V_e. □

Claim 5. If $\| G_e \bigcap \overline{A} \| > s(p_0(n))$ for all $e \le e_x$ with $\| G_e \| = h(n)$, then $x \in K \Longleftrightarrow$ the algorithm accepts x.

Proof of Claim 5. By the algorithm and Claim 4. □

Claim 6. $x \in K \Longleftrightarrow$ (The algorithm accepts x) or ($\| A \bigcap G_e \| > s(p_0(n))$ for some $e \le e_x$).

Proof of Claim 6. $\Longleftarrow$ By algorithm and Claim 2 it is easy to see.

$\Longrightarrow$ Let $x \in K$. We assume that the algorithm does not accept x.

It is impossible that $\| G_e \| < h(n)$ for all $e \le e_x$, otherwise the algorithm will accept x by Claim 3.

It is also impossible that $\| \overline{A} \bigcap G_e \| > s(p_0(n))$ for all $e \le e_x$ with $\| G_e \| = h(n)$, otherwise the algorithm will accept x by Claim 5.

Therefore, there exists an $e \le e_x$ such that $\| \overline{A} \bigcap G_e \| \le s(p_0(n))$ and $\| G_e \| = h(n)$. Hence $\| A \bigcap G_e \| = \| G_e \| - \| \overline{A} \bigcap G_e \| \ge h(n) - s(p_0(n)) > s(p_0(n))$. □

The following claim is easy to verify from the algorithm, so we do not prove it here.

Claim 7. For some polynomial $p_1(n)$, the algorithm will stop in $p_1(h(n)) + p_1(n)$ steps.

This finishes the proof of Lemma 3.1.

Now we state several consequences of our main lemma, which examine the difference *NP* and other complexity classes.

THEOREM 3.2. *Let H be NP-m-hard. If* $H \triangle A$ *is sparse, then* $NP \subseteq P_{d-\text{maj}}(A)$.

Proof. Let K be *NP-m-complete* and $s(n)$ be a polynomial such that $\text{dist}_{A,H}(n) \le s(n)$. By Lemma 3.1 we get a polynomial $p_0(n)$. Let $h(n) = 2s(p_0(n)) + 1$. From Lemma 3.1(2) it is easy to see that $K \le^P_{d-\text{maj}} A$. So $NP \subseteq P_{d-\text{maj}}(A)$. □

It is well known that the class *coNP* is closed under positive truth-table reductions [11]. Since $\le^P_{d-\text{maj}}$ is a special kind of positive reduction, we have the following result.

COROLLARY 3.3. *Let H be NP-m-hard. If H is coNP-close, then NP = coNP.*

It is easy to see that R (see [2]) is closed under positive truth-table reductions. So we also have the following corollary.

COROLLARY 3.4. *Let H be NP-m-hard. If H is R-close, then NP =R.*

Unfortunately we do not know whether *UP*, *FewP*, or $C_=P$ is closed under $\le^P_{d-\text{maj}}$-reductions. Thus, we cannot obtain the similar results for *UP*, *FewP*, or $C_=P$.

THEOREM 3.5. *Let H be NP-m-hard and* $A \subseteq \Sigma^*$. *If* $\text{dist}_{A,H}(n) = O(\log n)$, *then NP* $\subseteq P_{d-\text{conj}}(A)$.

Proof. Let K be *NP-m-complete*. Since $\| (H \triangle A)^{\le n} \| \le c \cdot \log n + c$ for some $c > 0$, let $s(n) = c \cdot \log n + c$. Now use Lemma 3.1 and let $h(n) = 2s(p_0(n)) + 1$. Clearly $h(n) = O(\log n)$. By Lemma 3.1(2) we have $x \in K \iff$ (The algorithm accepts x) or $(\| G_e \bigcap A \| > s(p_0(n))$ for some $e \le e_x$). Since $\| G_e \bigcap A \| > s(p_0(n)) \iff$ there exists $G((G \subseteq G_e) \wedge (\| G \| = s(p_0(n)) + 1) \wedge (G \subseteq A))$.

So $(\| G_e \bigcap A \| > s(p_0(n))$ for some $e \le e_x) \iff$ there exists $e \le e_x$ there exists $G((G \subseteq G_e) \wedge (\| G \| = s(p_0(n)) + 1) \wedge (G \subseteq A))$.

Since $\| G_e \|$ is $O(\log n)$, the number of subsets of G_e is bounded by a polynomial. Therefore, $K \in P_{d-\text{conj}}(A)$.

Hence $NP \subseteq P_{d-\text{conj}}(A)$. □

COROLLARY 3.6. *Let H be NP-m-hard. If H is* $O(\log n)$*-UP-close, then NP = FewP.*

LEMMA 3.7. $C_=P$ *is closed under* $\le^P_{d-\text{conj}}$*-reductions.*

Proof. Clearly, $A \le^P_{d-\text{conj}} B$ implies that there exists a C such that $A \le^P_{dtt} C$ and $C \le_{ctt} B$. Since $C_=P$ is closed under both $\le^P_{dtt}$- and $\le^P_{ctt}$-reductions (see [4]), it is easy to see that the lemma holds. □

COROLLARY 3.8. *Let H be NP-m-hard. If H is* $O(\log n)$*-*$C_=$ *P-close, then NP* $\subseteq C_=P$.

THEOREM 3.9. *Let H be NP-m-hard and A be a language. If* $H \subseteq A$ *and* $A - H$ *is sparse, then* $NP \subseteq P_{d-\text{conj}}(A)$.

Sketch of Proof. The proof of this theorem is very similar to that of Lemma 3.1, except let $h(n) = s(p_0(n)) + 1$ and replace Claim 4 and Claim 6 by the following Claim 4′ and Claim 6′ respectively. □

Claim 4′. Let $e \le e_x$. If $G_e \bigcap \overline{A} \neq \emptyset$, then $w_{\max}$ is in an interval of $U_e \iff w_{\max}$ is in an interval of V_e.

Proof of Claim 4′. Since $G_e \bigcap \overline{A} \neq \emptyset$ and $H \subseteq A$, we have some interval $[c_i, d_i]$ in V_e such that $f(\langle x, c_{i_1}\rangle) \notin H$. As in Claim 4 $w_{\max}$ is in an interval of $U_e \iff w_{\max}$ belongs to an interval in V_e. □

Claim 6′. $x \in K \iff$ (The algorithm accepts x) or ($G_e \subseteq A$ and $\| G_e \| = h(n)$ for some $e \le e_x$).

From Theorem 3.9 , Lemma 3.6, and Lemma 3.9 we have:

COROLLARY 3.10. *Let H be NP-m-hard. If H is UP-outside-close, then NP = FewP.*

COROLLARY 3.11. *Let H be NP-m-hard. If H is $C_=P$-outside-close, then $NP \subseteq C_=P$.*

We left some open problems:

1. Does $NP \neq coNP(NP \neq R)$ imply that for any *NP-m-hard* set H and $A \in coNP$ (respectively, R), $A \triangle H$ is not in $P_{btt}(sparse)$?

2. Does $FewP \neq NP$ imply that for any *NP-m-hard* set H and $A \in FewP$, $A \triangle H$ is not sparse?

3. Does $UP \neq NP$ imply that for any *NP-m-hard* set H, H is not *UP-inside-close*?

Acknowledgments. We would like to thank Professor Shouwen Tang for his encouragement in this research. The first author also thanks Professor Qiongzhang Li for his encouragement during this research and Mr. Tian Liu for his valuable suggestions for the earlier version of this paper [6]. We thank Mr. Anjiang Ma for his patience in typing this paper and the unknown referees for their suggestions for improving our presentation.

COMPLEXITY-RESTRICTED ADVICE FUNCTIONS*

JOHANNES KÖBLER† AND THOMAS THIERAUF‡

Abstract. The authors consider uniform subclasses of the nonuniform complexity classes defined by Karp and Lipton [L'Enseign. Math., 28 (1982)] via the notion of advice functions. These subclasses are obtained by restricting the complexity of computing correct advice. Also, the effect of allowing advice functions of limited complexity to depend on the input rather than on the input's length is investigated. Among other results, using the notions described above, new characterizations of (a) $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$, (b) NP with a restricted access to an NP oracle, and (c) the odd levels of the boolean hierarchy are given.

As a consequence, it is shown that every set that is nondeterministically truth-table reducible to SAT in the sense of Rich [J. Comput. System Sci., 38 (1989), pp. 511–523] is already deterministically truth-table reducible to SAT. Furthermore, it turns out that the NP reduction classes of bounded versions of this reducibility coincide with the odd levels of the boolean hierarchy.

Key words. nonuniform complexity classes, advice classes, optimization functions, restricted oracle access, sparse NP sets, relativization, boolean hierarchy, truth-table reducibility

AMS subject classification. 68Q15

1. Introduction.

In their fundamental paper, Karp and Lipton [23] introduced the notion of advice functions and investigated nonuniform complexity classes which they denoted by $\mathcal{C}/\mathcal{F}$, where $\mathcal{C}$ is a class of sets and $\mathcal{F}$ is a class of (advice) functions. A typical class is P/poly, where poly is the set of polynomially length bounded functions. The interest in P/poly stems from the fact that it consists exactly of the languages that can be computed by polynomially size-bounded circuits [34].

Intuitively, a set A is in $\mathcal{C}/\mathcal{F}$, if A can be solved by a machine of type $\mathcal{C}$ that gets, in addition to the input x, the advice $f(x)$, where f is a function in $\mathcal{F}$ depending only on the length of x. Many researchers have considered nonuniform classes where the function class $\mathcal{F}$ is defined by a quantitative length restriction such as poly and log (see, e.g., [3], [5], [23], [36]). Note that for such $\mathcal{F}$ there are nonrecursive functions in $\mathcal{F}$, and therefore $\mathcal{C}/\mathcal{F}$ contains nonrecursive languages.

Here, we consider uniform language classes obtained by imposing complexity bounds on the advice functions. Note that Kämper [22] investigates refinements of the original $\mathcal{C}/\mathcal{F}$ definition by delimiting the complexity of proof sets, i.e., special sets of correct advice. In contrast to this, we directly bound the complexity of computing correct advice. With this concept, we are able to show characterizations as well as finer distinctions of several complexity classes. For example, we show that the class $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ coincides with the class $\mathrm{NP}/\mathrm{OptP}[O(\log n)]$, a subclass of NP/ log, where correct advice is computable by an OptP function [29], i.e.,

$$\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}} = \mathrm{NP}/\mathrm{OptP}[O(\log n)]. \tag{1.1}$$

One can interpret equality (1.1) as stating that (exactly) the languages in $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ can be computed in the following way: on input x of length n, at first an $\mathrm{OptP}[O(\log n)]$ precomputation takes place that gets as input only 1^n. The (logarithmically length-bounded) output

of this precomputation is then passed along with x to the subsequent NP computation, which decides the membership of x.

Motivated by the relativized separation of P and NP of Baker, Gill, and Solovay [2] (exploiting the fact that an NP oracle machine can ask superpolynomially many queries), Book, Long, and Selman [11] introduced restricted relativizations of NP by bounding the number of oracle queries in various ways. Subsequently, Long [32] investigated the relationship between restricted access of nondeterministic machines to an oracle and full access to a sparse oracle set. Let NP_R^A be the class of all languages whose membership in NP^A is witnessed by an oracle machine such that the number of potential oracle queries in A (asked on some oracle) is polynomially bounded. From this definition, it is clear that $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ is contained in $\mathrm{NP}_R^{\mathrm{NP}}$. Since also coNP is contained in $\mathrm{NP}_R^{\mathrm{NP}}$, $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ and $\mathrm{NP}_R^{\mathrm{NP}}$ are different unless the polynomial hierarchy collapses [21]. By considering the proof of equality (1.1), we will see that if we let the $\mathrm{OptP}[O(\log n)]$ advice function depend not only on the length of the input but on the input itself, we get a characterization of $\mathrm{NP}_R^{\mathrm{NP}}$. This leads us to define the class $\mathcal{C}//\mathcal{F}$, which is defined in the same way as $\mathcal{C}/\mathcal{F}$ but with the advice functions depending on the input. Thus, we obtain the following characterization of $\mathrm{NP}_R^{\mathrm{NP}}$:

$$(1.2) \qquad \mathrm{NP}_R^{\mathrm{NP}} = \mathrm{NP}//\mathrm{OptP}[O(\log n)].$$

The characterizations (1.1) and (1.2) give insight into the difference between restricted access to NP oracles and full access to sparse NP sets.

It seems that the notion of $\mathcal{C}//\mathcal{F}$ is an appropriate concept for studying different kinds of truth-table reducibilities. Let χ_k^{SAT} be the k-ary characteristic function of SAT. Then $\mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ is the class of sets that are k-truth-table reducible to some NP set. It is known that these classes are interleaved with the levels of the boolean hierarchy: $\mathrm{NP}(k) \subseteq \mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP} \subseteq \mathrm{NP}(k+1)$ for all $k \geq 1$ [28]. Since $\mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ is closed under complementation, these classes are all different unless the boolean hierarchy collapses.

$\mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ is the class of sets that are k-truth-table reducible to some NP set, where the evaluator is an NP machine. These classes turn out to coincide with the odd levels of the boolean hierarchy, giving an interesting characterization of the levels of the boolean hierarchy in terms of reduction classes,

$$\mathrm{NP}(2k+1) = \mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}.$$

Furthermore, we show that $\mathrm{NP}(2k+1) = \mathrm{NP}_{k\text{-tt}}^{\mathrm{NP}}$, where $\mathrm{NP}_{k\text{-tt}}^{\mathrm{NP}}$ is the class of sets that are nondeterministically k-truth-table reducible to a set in NP in the sense of [35][1], whereas in the unbounded case all sets nondeterministically truth-table reducible to SAT are already deterministically truth-table reducible to SAT, i.e., $\mathrm{NP}_{\mathrm{tt}}^{\mathrm{NP}} = \mathrm{P}_{\mathrm{tt}}^{\mathrm{NP}}$. The latter result also holds for the strong nondeterministic truth-table reducibility $\leq_{\mathrm{tt}}^{\mathrm{SN}}$ introduced by Long [31], i.e., we show that $\{A \mid A \leq_{\mathrm{tt}}^{\mathrm{SN}} \mathrm{SAT}\} = \{A \mid A \leq_{\mathrm{tt}}^{\mathrm{P}} \mathrm{SAT}\}$.

The paper is organized as follows. Section 2 introduces notation and gives basic definitions. In §3 we prove the aforementioned characterizations of $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ and $\mathrm{NP}_R^{\mathrm{NP}}$ and show that changing from $\mathrm{OptP}[O(\log n)]$ to the larger function class FewOptP (containing all functions whose membership in OptP is witnessed by an NP transducer that generates only polynomially many different outputs) does not increase the power of $\mathrm{NP}/\mathrm{OptP}[O(\log n)]$ and $\mathrm{NP}//\mathrm{OptP}[O(\log n)]$.

In §4 we separate some of these complexity classes in relativized world, the main result is a separation of $\mathrm{P}/\mathrm{OptP}[O(\log n)]$ and $\mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}[O(\log n)]}$.

[1] By requiring the NP generator to be single valued, Rich [35] has modified the nondeterministic truth-table reducibility originally defined by Ladner, Lynch, and Selman [30].

In §5 we give several characterizations of certain levels of the boolean hierarchy in terms of various complexity restricted advice function classes.

2. Preliminaries and notation. All languages considered here are over the alphabet $\Sigma = \{0, 1\}$. For a string $x \in \Sigma^*$, $|x|$ denotes its length. We assume the existence of a pairing function $\langle \cdot, \cdot \rangle : \Sigma^* \times \Sigma^* \rightarrow \Sigma^*$ that is computable in polynomial time and has inverses also computable in polynomial time. $\langle \cdot, \cdot \rangle$ can be extended to encode finite sequences $(x_1, \dots, x_k)$ of strings into a string $\langle x_1, \dots, x_k \rangle \in \Sigma^*$. For a set A, $|A|$ denotes its cardinality. The complement $\Sigma^* - A$ of A is denoted by $\overline{A}$. $A^{\leq n}$ is the set of all strings in A of length less than or equal to n.

A language S is *sparse* if there is a polynomial p such that for all n the number of words in S up to length n is at most $p(n)$. Let SPARSE be the class of all sparse languages. A set T is *tally* if T is a subset of 1^*. Let TALLY be the class of all tally sets.

We assume that the reader is familiar with (nondeterministic, polynomial-time bounded, oracle) Turing machines and complexity classes (see [4], [36]). FP is the class of functions computable by a deterministic polynomial-time bounded Turing transducer. An *NP transducer* is a nondeterministic polynomial-time bounded Turing machine T that on every branch either accepts and writes a binary number on its output tape or rejects. The set of outputs generated by T on input x is denoted by $\mathrm{out}_T(x)$.

Krentel [29] defines an *NP metric Turing machine* to be an NP transducer that accepts on every branch. For an NP metric Turing machine T and an input $x \in \Sigma^*$ let $\max_T(x)$ $[\min_T(x)]$ be the maximum [minimum] output generated by T on input x on any accepting computation of T. The class OptP [29] of optimization functions is defined as

$$\mathrm{OptP} = \{\max_T, \min_T \mid T \text{ is an NP metric Turing machine}\}.$$

For a class $\mathcal{R}$ of functions on the natural numbers (called restricting functions), we define the subclass

$$\mathrm{OptP}[\mathcal{R}] = \{f \in \mathrm{OptP} \mid \exists r \in \mathcal{R} \, \forall x \in \Sigma^* : |f(x)| \leq r(|x|)\}$$

containing all optimization functions $f \in \mathrm{OptP}$ such that the length of $f(x)$ in binary representation is bounded by a function from $\mathcal{R}$.

$\mathrm{P}^{\mathrm{NP}[\mathcal{R}]}$ denotes the class of sets whose membership in P^{NP} can be witnessed by an oracle machine M making for some $r \in \mathcal{R}$ at most $r(n)$ many queries on inputs of length n. In the case that $\mathcal{R}$ is a singleton set $\{r\}$ we simply write $\mathrm{OptP}[r]$ and $\mathrm{P}^{\mathrm{NP}[r]}$, respectively. Throughout the paper we assume that for every restricting function r the function $x \mapsto r(|x|)$ is computable in polynomial time.

Karp and Lipton [23] introduced the notion of advice functions in order to define nonuniform complexity classes. For a class $\mathcal{C}$ of sets and a class $\mathcal{F}$ of functions from Σ^* to Σ^* let $\mathcal{C}/\mathcal{F}$ be the class of sets A such that there is a set $B \in \mathcal{C}$ and a function $h \in \mathcal{F}$ such that for all $x \in \Sigma^*$,

$$x \in A \Leftrightarrow \langle x, h(1^{|x|}) \rangle \in B.$$

Note that the advice function h depends only on the length of x. By canceling this restriction we obtain the class $\mathcal{C}//\mathcal{F}$ of all sets A such that there is a set $B \in \mathcal{C}$ and a function $h \in \mathcal{F}$ such that for all $x \in \Sigma^*$,

$$x \in A \Leftrightarrow \langle x, h(x) \rangle \in B.$$

By definition, $\mathcal{C}/\mathcal{F}$ is a subset of $\mathcal{C}//\mathcal{F}$ for each class of sets $\mathcal{C}$ and each class of functions $\mathcal{F}$, which fulfills the condition that if $h \in \mathcal{F}$ then also $x \mapsto h(1^{|x|}) \in \mathcal{F}$. Special advice function classes considered in the literature are poly $= \{h : \Sigma^* \rightarrow \Sigma^* \mid$ there exists a polynomial p such that for all x, $|h(x)| \leq p(|x|)\}$ and log $= \{h : \Sigma^* \rightarrow \Sigma^* \mid |h(x)| = O(\log(|x|))\}$.

3. $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ versus $\mathrm{NP}_R^{\mathrm{NP}}$. In this section we show that the class $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ can be characterized as the class $\mathrm{NP}/\mathrm{OptP}[O(\log n)]$, i.e., the class of sets that are accepted by an NP machine with advice of a logarithmically length-bounded OptP function. Further, it turns out that the related class $\mathrm{NP}_R^{\mathrm{NP}}$ (see definition below) coincides with $\mathrm{NP}//\mathrm{OptP}[O(\log n)]$. For the latter two classes we can show that they are also equal to $\mathrm{P}//\mathrm{OptP}[O(\log n)]$, which, by a result of Krentel [29], is identical to $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$.

DEFINITION 3.1 [11]. *For any oracle Turing machine M and any string $x \in \Sigma^*$ let $Q(M, A, x)$ be the set of all oracle queries that M may ask on input x using oracle A, i.e., the set of all strings $y \in \Sigma^*$ such that in some computation of M on input x under oracle A the oracle is queried about y. $Q(M, x)$ is the set of all oracle queries of M on input x using any oracle, i.e., $Q(M, x) = \bigcup_{A\subseteq\Sigma^*} Q(M, A, x)$.*

For any set A, $\mathrm{NP}_R(A)$ is the class of sets $L \in \mathrm{NP}(A)$ whose membership is witnessed by a machine M such that the number of potential oracle queries in A is polynomially bounded, i.e., there exists a polynomial p such that $|Q(M, x) \cap A| \leq p(|x|)$ for all x.

Our first theorem states that if a language L is accepted by an NP oracle machine M using an NP oracle A in such a way that the number of potential oracle queries that are in A is polynomially bounded, then L is in $\mathrm{NP}//\mathrm{OptP}[O(\log n)]$, i.e., membership in L can be tested by an NP machine which gets along with the input the value of an $\mathrm{OptP}[O(\log n)]$ function. In the special case that A is sparse this containment can be strengthened to $\mathrm{NP}/\mathrm{OptP}[O(\log n)]$, i.e., for all inputs of the same length the advice function yields the same result. The proof is by a census argument similar to that used by Hemachandra [18] and Kadin [21].

THEOREM 3.2. (i) $\mathrm{NP}_R^{\mathrm{NP}} \subseteq \mathrm{NP}//\mathrm{OptP}[O(\log n)]$,

(ii) $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}} \subseteq \mathrm{NP}/\mathrm{OptP}[O(\log n)]$.

Proof. Let $L = L(M, A)$ for an NP machine M and an oracle A in NP, and let p be a polynomial that bounds the running time of M.

To show (i) let r be a polynomial such that $|Q(M, x) \cap A| \leq r(|x|)$ for all x. An NP machine knowing the size of the set $Q(M, x) \cap A$ can guess this set (note that it is an NP problem to decide for two given strings x and y whether y is in $Q(M, x) \cap A$). Define the function

$$h(x) = |Q(M, x) \cap A|$$

and the set

$$B = \{\langle x, k\rangle \mid \exists X \subseteq Q(M, x) \cap A : |X| = k \text{ and } x \in L(M, X)\}.$$

Then $B \in \mathrm{NP}$ and $h \in \mathrm{OptP}[O(\log |x|)]$, since $h(x)$ is the maximum output of the following algorithm:

```
On input $x$ guess $k \leq r(|x|)$ and $x_1 < \cdots < x_k \in \Sigma^{\leq p(|x|)}$;
if $x_1, \ldots, x_k \in Q(M, x) \cap A$, then output $k$, else output 0.
```

Now, it holds for all $x \in \Sigma^*$ that $x \in L$ if and only if $\langle x, h(x)\rangle \in B$. Therefore, L is in $\mathrm{NP}//\mathrm{OptP}[O(\log n)]$.

For (ii) let A be a sparse set, and let r be a polynomial such that $|A^{\leq p(n)}| \leq r(n)$ for all n. Define the function

$$h(x) = |A^{\leq p(|x|)}|$$

and the set

$$B = \{\langle x, k\rangle \mid \exists X \subseteq A^{\leq p(|x|)} : |X| = k \text{ and } x \in L(M, X)\}.$$

By an argument similar to that in the proof of (i), $x \in L$ if and only if $\langle x, h(1^{|x|})\rangle \in B$. This shows that L is in NP/OptP[$O(\log n)$]. □

Combining Theorem 3.2 (ii) with the result of Balcázar and Schöning [5] that NP/log ∩ coNP $\subseteq$ $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ (see also [3]), it follows that for every coNP set in NP/log correct advice can already be computed by an OptP function.

COROLLARY 3.3. NP/log ∩ coNP $=$ NP/OptP[$O(\log n)$] ∩ coNP.

To show the reverse containments of Theorem 3.2, we make use of the following lemma. It states that every OptP function h can be computed by a deterministic polynomial-time oracle machine by asking $|h(x)|$ many queries to an NP oracle.

LEMMA 3.4 [29]. OptP[r] $\subseteq$ $\mathrm{FP}^{\mathrm{NP}[r]}$ *for any restricting function r.*

COROLLARY 3.5. (i) $\mathrm{NP}_R^{\mathrm{NP}} = $ NP//OptP[$O(\log n)$],

(ii) $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}} = \mathrm{NP}^{\mathrm{NP}\cap\mathrm{TALLY}} =$ NP/OptP[$O(\log n)$].

Proof. By Theorem 3.2, it only remains to show the inclusions from right to left.

To show (i), let L be in NP//OptP[$O(\log n)$] via an NP machine N and an optimization function h. Then L can be accepted by an NP machine M that computes deterministically by binary search the value of h according to Lemma 3.4 asking $O(\log n)$ many queries to an NP oracle and then simulates N without asking further oracle queries. Since $Q(M, x)$ is polynomially bounded, it follows that L is in $\mathrm{NP}_R^{\mathrm{NP}}$.

If h is a function that depends only on the length of its argument, then $h(x)$ can be computed by binary search using the tally NP set $T = \{1^{\langle n,k\rangle} \mid k \leq h(1^n)\}$. This proves (ii). □

Note that the above proof shows that every language in NP//OptP[$O(\log n)$] (and thus in $\mathrm{NP}_R^{\mathrm{NP}}$) can in fact be accepted by an NP oracle machine M such that $Q(M, x)$ is polynomially bounded.

In the next lemma, we show that an NP computation getting along with the input the value function $h(x)$ of an OptP can be transformed into a P computation on the cost of adding one bit to $h(x)$. Note that this bit actually depends on x even if $h(x)$ only depends on the length of x.

LEMMA 3.6. NP//OptP[r] $\subseteq$ P//OptP[$r + 1$] *for any function r.*

Proof. Let L be in NP//OptP[r], witnessed by an NP set B and an OptP[r] function $h = \max_T$ for some NP metric machine T. Define the OptP[$r + 1$] function

$$h'(x) = \begin{cases} h(x)1 & \text{if } \langle x, h(x)\rangle \in B, \\ h(x)0 & \text{otherwise.} \end{cases}$$

Then it holds for all x that $\langle x, h(x)\rangle \in B \Leftrightarrow \langle x, h'(x)\rangle \in B'$, where the set $B' = \{\langle x, k\rangle \mid k \text{ is odd}\}$ is in P. The case that $h = \min_T$ can be proved analogously. □

Combining Corollary 3.5(i) and Lemma 3.6 we obtain a further characterization of the class $\mathrm{NP}_R^{\mathrm{NP}}$ and that it is closed under complementation. Note that P//OptP[$O(\log n)$] $=$ $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$ [29].

COROLLARY 3.7. $\mathrm{NP}_R^{\mathrm{NP}} = $ P//OptP[$O(\log n)$].

COROLLARY 3.8. $\mathrm{NP}_R^{\mathrm{NP}}$ *is closed under complementation.*

Remark 3.9. The results stated in Corollary 3.5 can be extended to the classes of the polynomial-time hierarchy [37]. In order to do so, we define restricted relativizations of the Σ-levels of the polynomial hierarchy. $\Sigma_{k,R}^{\mathcal{C}}$ is the class of all sets L accepted by a k-alternating polynomial-time Turing machine [16] using an oracle A from $\mathcal{C}$ such that $|Q(M, x) \cap A|$ is polynomially bounded. Then, the results stated in Corollary 3.5 can be extended to

$$\begin{aligned} \Sigma_k^{\Sigma_k\cap\mathrm{SPARSE}} &= \Sigma_k/\mathrm{Opt}\,\Sigma_{k-1}[O(\log n)], \\ \Sigma_{k,R}^{\Sigma_k} &= \Sigma_k//\mathrm{Opt}\,\Sigma_{k-1}[O(\log n)] = \mathrm{P}^{\Sigma_k[O(\log n)]}, \end{aligned}$$

where Opt $\mathcal{C}$ is the class of optimization functions computable by an NP transducer using some oracle in the class $\mathcal{C}$. Since $\Sigma_k/\mathrm{Opt}\,\Sigma_{k-1}[O(\log n)]$ is included in $\mathrm{P}^{\Sigma_k[O(\log n)]}$, this sharpens the recent result in [13] that $\Sigma_k^{\Sigma_k \cap \mathrm{SPARSE}} \subseteq \mathrm{P}^{\Sigma_k[O(\log n)]}$.

Remark 3.10. The advice (even depending on the input) provided by an OptP[$O(\log n)$] function does not increase the power of the probabilistic class PP: PP//OptP[$O(\log n)$] = PP. This follows from the result by Toda [40] that $\mathrm{PP}_R^{\mathrm{NP}} = \mathrm{PP}$, since PP//OptP[$O(\log n)$] coincides with the class $\mathrm{PP//FP}^{\mathrm{NP}[O(\log n)]}$ (see Lemma 3.4) that is clearly contained in $\mathrm{PP}_R^{\mathrm{NP}}$.

Next, we consider uniform subclasses of P/log and P/poly. Whereas the proof of Corollary 3.5(ii) also yields the inclusion of P/OptP[$O(\log n)$] in $\mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}[O(\log n)]}$, the census technique of Theorem 3.2 cannot be applied to obtain the reverse containment. The next theorem is proved by constructing (long enough initial segments of) a sparse NP set by an OptP computation. The underlying technique was used by Mahaney [33] to show that $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}} \subseteq \mathrm{P}^{\mathrm{NP}}$.

THEOREM 3.11. $\mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}} \subseteq \mathrm{P/OptP}$.

Proof. Let $L = L(M, S)$ for a P machine M and a sparse NP set S. Let p and r be polynomials such that p bounds the running time of M and $|S^{\le n}| \le r(n)$. Define $h(x) = \langle S^{\le p(|x|)}\rangle$. Then $h \in$ OptP, since $h(x)$ is the maximum output of the following algorithm:

```
On input $1^n$ guess $k \le r(p(n))$ and $x_1 < \cdots < x_k \in \Sigma^{\le p(|x|)}$;
if $x_1, \ldots, x_k \in S$, then output $\langle x_1, \ldots, x_k\rangle$, else output 0.
```

Now the computation of M using oracle S on input x can be simulated by a P machine answering oracle questions according to the set $h(1^{|x|})$. □

Let FewOptP be the class of functions $f \in$ OptP computed by an NP transducer that produces at most a polynomial number of different outputs. Clearly, OptP[$O(\log n)$] $\subseteq$ FewOptP, and obviously, this is a proper inclusion.

However, as shown by the next theorem, the classes NP/OptP[$O(\log n)$] and NP//OptP[$O(\log n)$] remain unchanged when the function class OptP[$O(\log n)$] is replaced by the larger class FewOptP.

THEOREM 3.12. (i) NP//FewOptP = P//FewOptP = P//OptP[$O(\log n)$],

(ii) NP/FewOptP = NP/OptP[$O(\log n)$].

Proof. Let L be a set in NP//FewOptP via $A \in$ NP and $f \in$ FewOptP. Let T be an NP metric machine for f, i.e., $f = \max_T$ (the proof for $f = \min_T$ is similar), and the number of different outputs of T is polynomially bounded. Define the function

$$h(x) = |\mathrm{out}_T(x)|$$

and the set

$$B = \{\langle x, m\rangle \mid \exists z_1 < \cdots < z_m \in \mathrm{out}_M(x) : \langle x, z_m\rangle \in A\}.$$

It is easy to see that $h \in$ OptP[$O(\log n)$] and $B \in$ NP. Now x is in L if and only if $\langle x, h(x)\rangle$ is in B, and therefore L is in NP//OptP[$O(\log n)$] = P//OptP[$O(\log n)$]. The latter equality follows from Corollaries 3.5(i) and 3.7. The proof of (ii) is analogous, we only have to replace $\mathrm{out}_T(x)$ by $\mathrm{out}_T(1^{|x|})$. □

The technique used in the previous proof cannot be applied to show that the classes P/OptP[$O(\log n)$] and P/FewOptP are equal. However, the proof of P/OptP[$O(\log n)$] $\subseteq \mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}[O(\log n)]}$ (using binary search, see the proof of Corollary 3.5(ii) can be refined to show the following theorem. It states that a set in P/FewOptP can be decided in polynomial time by querying a sparse NP oracle (polynomially often).

THEOREM 3.13. $\mathrm{P/FewOptP} \subseteq \mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}}$.

Proof. Let f be in FewOptP, and let T be an NP transducer computing f. Using the sparse NP set

$$S = \{\langle 1^n, m, i, z\rangle \mid \exists z_1 < \cdots < z_m \in \mathrm{out}_T(1^n)\ \exists z' :\ z z' = z_i\}$$

as oracle, $f(x)$ can be computed in polynomial time by determining first $|\mathrm{out}_T(1^n)|$ and then applying a prefix search to find the optimum value in $\mathrm{out}_T(1^n)$. □

The known relationships of the language classes considered in this section are summarized in Fig. 3.1.

FIG. 3.1. *Inclusion structure of some considered complexity classes; thick lines indicate that there are relativized separations* (*see* §4).

4. Relativized separations. Since Baker, Gill, and Solovay [2] separated P from NP relative to some oracle, relativizations have been an important subject in complexity theory. In this section, we discuss which of the inclusions in Fig. 3.1 are strict, at least in some relativized world.

Since there are nonrecursive sets in P/poly and in NP/poly, these two classes are clearly different from all other (recursive) classes considered here. Whether there are any other strict inclusions in the diagram of Fig. 3.1 is not known. For some of the inclusions, however, the question whether they are proper can be linked to central open problems in complexity theory.

For example, by the result of Karp, Lipton, and Sipser (see [23]) that $\mathrm{NP} \subseteq \mathrm{P/poly}$ implies the collapse of the polynomial hierarchy to its second level, it follows that if $\mathrm{PH} \neq \Sigma_2$, then

NP is not contained in any of the classes on the left column of Fig. 3.1. Since this holds in all relativized worlds, and since there exists an oracle separating PH from Σ_2 [24], it follows that relative to this oracle all the inclusions between the first and the second column are proper.

Similarly, using the result of Kadin [21] that coNP $\subseteq$ $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}}$ implies PH $=$ $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$, it follows that if PH $\neq$ $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$, then $\mathrm{NP}^{\mathrm{NP}\cap\mathrm{SPARSE}} \neq \mathrm{P}^{\mathrm{NP}[O(\log n)]}$. Since, as it is easily seen, the inclusion coNP $\subseteq$ NP/OptP implies PH $=$ P^{NP}, we can state the following theorem.

THEOREM 4.1. PH $\neq \mathrm{P}^{\mathrm{NP}} \Rightarrow$ NP/OptP $\neq$ P//OptP.

Furthermore, by the recent result of Toda [39] that PH $\subseteq \mathrm{P}^{\mathrm{PP}}$, it follows that $\mathrm{P}^{\mathrm{NP}[O(\log n)]} \neq$ PP and $\mathrm{P}^{\mathrm{NP}} \neq$ PP//OptP unless PH $= \mathrm{P}^{\mathrm{NP}}$.

Beigel [7] constructed an oracle A such that $\mathrm{P}^{\mathrm{NP}^A} - \mathrm{PP}^A \neq \emptyset$. Since $\mathrm{P}^{\mathrm{NP}[O(\log n)]} \subseteq$ PP [9], oracle A also separates $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$ and P^{NP} (for a direct proof see [14]).

Cai et al. [15] showed the existence of an oracle A such that relative to A the boolean hierarchy is infinite, i.e., $\forall k : \mathrm{NP}^A(k) \neq \mathrm{coNP}^A(k)$. In fact, Cai et al. construct the oracle A in such a way that, for all k, some *tally* test language $L_k(A)$ is in $\mathrm{coNP}^A(k) - \mathrm{NP}^A(k)$. Because it holds for every oracle set B that

$$\mathrm{NP}^B(2^k - 1) \cup \mathrm{coNP}^B(2^k - 1) \subseteq \mathrm{P//OptP}^B[k] \subseteq \mathrm{NP}^B(2^k)$$

[8], [28], [43], it follows that $L_{2^k-1}(A) \in \mathrm{P//OptP}^A[k] \cap \mathrm{TALLY} \subseteq \mathrm{P/OptP}^A[k]$, i.e.,

$$\exists A \ \forall k \geq 1 : \mathrm{P/OptP}^A[k] - \mathrm{NP}^A(2^k - 1) \neq \emptyset.$$

Since P/OptP$[k]$ is contained in the 2^kth level of the boolean hierarchy, this result is optimal.

Clearly, if the boolean hierarchy is proper, it does not have complete sets. Since the class P/OptP$[O(\log n)]$ has complete sets, it is not contained in BH in any relativized world where the boolean hierarchy is infinite, i.e.,

$$\exists A : \mathrm{P/OptP}^A[O(\log n)] - \mathrm{BH}^A \neq \emptyset.$$

The main result in this section is a separation of the classes P/OptP$[O(\log n)]$ and $\mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}[O(\log n)]}$. In fact, we show that for any fixed polynomial q there is a relativization such that NP contains sparse sets that are not in the nonuniform class P/q (defined as $\mathrm{P}/\{h \mid |h(x)| \leq q(|x|)\}$).

THEOREM 4.2. *For every polynomial q there exists a set A such that*

$$(\mathrm{NP}^A \cap \mathrm{SPARSE}) - \mathrm{P}^A/q \neq \emptyset.$$

Proof. For an arbitrary set A we define a sparse set $L(A) \in \mathrm{NP}^A$ as follows. For a given n and a suitable chosen function $l(n)$, we partition the $2^{l(n)}$ words of length $l(n)$ into $q(n) + 1$ intervals (with respect to the lexicographic ordering) $I_1^{l(n)}, \ldots, I_{q(n)+1}^{l(n)}$ such that

$$|I_k^{l(n)}| \geq \left\lfloor \frac{2^{l(n)}}{q(n)+1} \right\rfloor \quad \text{for } k = 1, \ldots, q(n) + 1.$$

For each interval containing a word in A, we put a word into $L(A)$: let $w_1^n, w_2^n, \ldots$ be an enumeration of Σ^n in lexicographic order, and let $l(n) = n + q(n)$. Define the NP^A set

$$L(A) = \{w_k^n \mid n \geq 1, \ 1 \leq k \leq q(n) + 1 \text{ and } I_k^{l(n)} \cap A \neq \emptyset\}.$$

Clearly, there are at most $q(n) + 1$ words of length n in A, i.e., $L(A)$ is sparse. Now we construct a set A in stages such that $L(A) \notin \mathrm{P}/q$. Let $M_1, M_2, \ldots$ be an enumeration of all polynomial-time bounded Turing machines with running times $p_1, p_2, \ldots$, respectively.

Stage 0. $A := \emptyset$; $n_0 := \min\{n \mid \forall m \geq n : \ q(m) < 2^m\}$.

Stage $s \geq 1$. Choose n_s minimal such that $n_s > \max\{p_i(n_{s-1}) \mid i < s\}$ and $2^{n_s} > 2\, p_s(n_s)\,(q(n_s)+1)^2$.

The algorithm in Fig. 4.1 determines the words of length $l(n_s)$ that are included in A. This is done by diagonalizing against machine M_s and all potential advice for M_s on an input of length n_s.

```
ADVICE := $\Sigma^{\leq q(n_s)}$;
(* ADVICE contains all potential advice against that we have to diagonalize *)
QUERY := $\emptyset$;
(* In QUERY we freeze the oracle queries of $M_s$ during the construction *)
for $k := 1$ to $q(n_s) + 1$ do
  ACC := $\{a \in$ ADVICE $\mid M_s^A(w_k^{n_s}, a)$ accepts $\}$;
  REJ := ADVICE − ACC;
  if |ACC| ≥ |REJ| then
    (* $I_k^{l(n_s)} \cap A$ remains empty, i.e., no word in ACC is advice for $w_k^{n_s}$ *)
    ADVICE := REJ;
    QUERY := QUERY $\cup \bigcup_{a \in \mathrm{ACC}} Q(M_s, A, \langle w_k^{n_s}, a\rangle)$ ;
  else
    (* put a word in $I_k^{l(n_s)} \cap A$, i.e., no word in REJ is advice for $w_k^{n_s}$ *)
    ADVICE := ACC;
    QUERY := QUERY $\cup \bigcup_{a \in \mathrm{REJ}} Q(M_s, A, \langle w_k^{n_s}, a\rangle)$ ;
    choose a $y \in I_k^{l(n_s)}$−QUERY;
    $A := A \cup \{y\}$
  end (* if *)
end (* for *).
```

FIG. 4.1. *Algorithm used in the proof of Theorem* 4.2.

Let M be any P machine. We show that M, taking advice of any q-length bounded function, does not accept $L(A)$. Let s be an index such that $M = M_s$. There are $2^{q(n_s)+1} - 1$ potential words as advice for M_s on inputs of length n_s (that are stored in ADVICE). Each execution of the for-loop diagonalizes against at least half of the possible advice for M_s. Since $\log(2^{q(n_s)+1} - 1) \leq q(n_s) + 1$, ADVICE becomes empty at the end of the algorithm. The construction further guarantees that for every advice a, $|a| \leq q(n_s)$, there exists a $k \leq q(n_s)+1$ such that

$$\langle w_k^{n_s}, a\rangle \in L(M_s, A) \Leftrightarrow w_k^{n_s} \notin L(A).$$

Therefore, it suffices to show that the algorithm can always find a $y \in I_k^{l(n_s)}$– QUERY. In every execution of the for-loop and for every advice no more than $p_s(n_s)$ words are added to the set QUERY, i.e.,

$$\mid \text{QUERY} \mid \leq (q(n_s) + 1)\, 2^{q(n_s)+1}\, p_s(n_s).$$

Thus, we have for $1 \leq k \leq q + 1$,

$$\begin{aligned} |I_k^{l(n_s)} - \text{ QUERY} \mid &\geq |I_k^{l(n_s)}| - \mid \text{QUERY} \mid \\ &\geq \left\lfloor \frac{2^{n_s+q(n_s)}}{q(n_s)+1} \right\rfloor - (q(n_s)+1)\, 2^{q(n_s)+1}\, p_s(n_s) \end{aligned}$$

$$\begin{aligned} &\geq \frac{2^{q(n_s)+1}(2^{n_s-1}-(q(n_s)+1)^2\,p_s(n_s))}{q(n_s)+1}-1 \\ &\geq \frac{2^{q(n_s)+1}}{q(n_s)+1}-1 \quad \text{[by choice of } n_s\text{]} \\ &> 0. \quad \square \end{aligned}$$

COROLLARY 4.3. $\exists A : (\mathrm{NP}^A \cap \mathrm{SPARSE}) - \mathrm{P}^A/\log \neq \emptyset$.

Using a "Kolmogorov-argument", Corollary 4.3 was already shown by Hemachandra [19]. An immediate consequence of Corollary 4.3 is the existence of an oracle separating $\mathrm{P}/\mathrm{OptP}[O(\log n)]$ and $\mathrm{P}^{\mathrm{NP}\cap\mathrm{SPARSE}[O(\log n)]}$.

COROLLARY 4.4. $\exists A : \mathrm{P}^A/\mathrm{OptP}^A[O(\log n)] \neq \mathrm{P}^{\mathrm{NP}^A\cap\mathrm{SPARSE}[O(\log n)]}$.

5. Bounded advice versus the boolean hierarchy. The boolean hierarchy is the smallest class of sets that contains NP and is closed under union, intersection, and complementation. The levels of the boolean hierarchy are obtained by applying a fixed number of boolean operations to NP sets. In this section, we give several characterizations of the odd levels of the boolean hierarchy. First, we show that NP machines that get as advice the value of the k-ary characteristic function χ_k^{SAT} of SAT, where χ_k^{SAT} is evaluated on a k-tuple that is computed from the input by an FP function, accept exactly the languages in the $(2k+1)$th level of the boolean hierarchy. The same is true if the advice consists only of the information of how many out of k words that are produced from the given input by an FP function are in SAT.

Cai et al. [15] give several characterizations of the boolean hierarchy; we take the following one.

DEFINITION 5.1. *A set L is in the* kth level $\mathrm{NP}(k)$ of the boolean hierarchy *if there exist sets $L_1, \dots, L_k \in$* NP *such that*

$$L = \begin{cases} (L_1 - L_2) \cup \cdots \cup (L_{k-2} - L_{k-1}) \cup L_k & \text{if } k \text{ is odd,} \\ (L_1 - L_2) \cup \cdots \cup (L_{k-1} - L_k) & \text{if } k \text{ is even.} \end{cases}$$

The union $\bigcup_{k\geq 1} \mathrm{NP}(k)$ *of all the levels of the boolean hierarchy is denoted by* BH.

For a set A, χ^A denotes the characteristic function of A. χ_k^A is the k-ary characteristic function of A, $\#_k^A$ gives the number out of k words, which are in A, and $\oplus_k^A$ is the parity of this number, i.e.,

$$\begin{aligned} \chi_k^A(x_1,\dots,x_k) &= \chi^A(x_1)\dots\chi^A(x_k), \\ \#_k^A(x_1,\dots,x_k) &= \sum_{i=1}^{k}\chi^A(x_i), \\ \oplus_k^A(x_1,\dots,x_k) &= \#_k^A(x_1,\dots,x_k) \bmod 2. \end{aligned}$$

The unbounded version of χ_k^A is $\chi_\omega^A = \bigcup_{k\geq 1}\chi_k^A$.

Clearly, every set $L \in \mathrm{NP}(k)$ is k-truth-table reducible to SAT, i.e., $L \in \mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ (here and in the following, the composition operator $\circ$ takes precedence over $//$). Every set that is k-truth-table reducible to SAT is in $\mathrm{NP}(k+1)$ ([28], see also [8]); thus

$$\mathrm{NP}(k) \subseteq \mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP} \subseteq \mathrm{NP}(k+1). \tag{5.1}$$

Since $\mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ is closed under complementation, the classes in (5.1) are all different unless BH (and therefore PH [20]) collapses [15]. It is interesting to note that a P machine needs only to know the parity of the number of k queries in SAT in order to decide a set in $\mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ ([43], see also [8]),

$$\mathrm{P}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP} = \mathrm{P}//\#_k^{\mathrm{SAT}} \circ \mathrm{FP} = \mathrm{P}// \oplus_k^{\mathrm{SAT}} \circ \mathrm{FP}. \tag{5.2}$$

We show in the next theorem that the first equality in (5.2) also holds for the nondeterministic counterparts of these classes, which furthermore coincide with the $(2k+1)$th level of the boolean hierarchy. Since, as it is easily seen, $\mathrm{NP}// \oplus_k^{\mathrm{SAT}} \circ\mathrm{FP}$ is contained in $\mathrm{P}//\chi_{k+2}^{\mathrm{SAT}} \circ \mathrm{FP}$, we cannot replace P by NP, for $k \geq 2$, in the second equality of (5.2), unless BH, and thus PH, collapse. It is an open question whether also the classes $\mathrm{NP}// \oplus_k^{\mathrm{SAT}} \circ\mathrm{FP}$ characterize some levels of the boolean hierarchy.

We denote the bitwise ordering on strings of the same length by $\preceq$, i.e., $a_1 \dots a_k \preceq b_1 \dots b_k$, if $a_i \leq b_i$ for $i = 1, \dots, k$.

THEOREM 5.2. $\mathrm{NP}(2k+1) = \mathrm{NP}//\#_k^{\mathrm{SAT}} \circ \mathrm{FP} = \mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ *for all* $k \geq 0$.

Proof. Let L be in $\mathrm{NP}(2k+1)$. Then there exist sets $L_1, \dots, L_{2k+1} \in \mathrm{NP}$ such that $L = (L_1 - L_2) \cup \cdots \cup (L_{2k-1} - L_{2k}) \cup L_{2k+1}$. Define the function

$$f(x) = \sum_{i=1}^{k} \chi^{L_{2i}}(x),$$

and let A be the set defined as

$$\begin{aligned} \langle x, m\rangle \in A \quad \Leftrightarrow \quad & x \in L_{2k+1} \text{ or there exist } I \subseteq \{2i \mid x \in L_{2i}\} \text{ and } j \leq k \\ & \text{such that } |I| = m,\ x \in L_{2j-1}, \text{ and } 2j \notin I. \end{aligned}$$

Clearly, $f \in \#_k^{\mathrm{SAT}} \circ \mathrm{FP}$, $A \in \mathrm{NP}$, and it holds that $x \in L$ if and only if $\langle x, f(x)\rangle \in A$. To see this, observe that there is exactly one set $I \subseteq \{2i \mid x \in L_{2i}\}$ of cardinality $f(x)$, namely, $I = \{2i \mid x \in L_{2i}\}$. Therefore, $L \in \mathrm{NP}//\#_k^{\mathrm{SAT}} \circ \mathrm{FP}$.

It is clear that $\mathrm{NP}//\#_k^{\mathrm{SAT}} \circ \mathrm{FP} \subseteq \mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$. It remains to show that $\mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP} \subseteq \mathrm{NP}(2k+1)$. For this we adapt a proof technique used by Buss and Hay [14]. Let L be in $\mathrm{NP}//\chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$, i.e., there exist a set $A \in \mathrm{NP}$ and a function $f \in \mathrm{FP}$ such that $x \in L$ if and only if $\langle x, \chi_k^{\mathrm{SAT}}(f(x))\rangle \in A$. For $m \geq 0$, consider the NP sets

$$\begin{aligned} B_m &= \{x \mid \#_k^{\mathrm{SAT}}(f(x)) \geq m\}, \\ A_m &= \left\{ x \mid \exists a = a_1 \dots a_k \in \Sigma^k : \sum_{i=1}^{k} a_i = m,\ a \preceq \chi_k^{\mathrm{SAT}}(f(x)), \text{ and } \langle x, a\rangle \in A \right\}. \end{aligned}$$

It is easy to see that $A_m \subseteq B_m$ and $B_{m+1} \subseteq B_m$. Furthermore, $B_m - B_{m+1} = \{x | \#_k^{\mathrm{SAT}}(f(x)) = m\}$ and $A_m - B_{m+1} = \{x \in B_m - B_{m+1} \mid \langle x, \chi_k^{\mathrm{SAT}}(f(x))\rangle \in A\}$. The latter equality follows from the fact that for any $x \in B_m - B_{m+1}$, there is only one string $a \in \Sigma^k$ containing m 1's and fulfilling $a \preceq \chi_k^{\mathrm{SAT}}(f(x))$, namely, $a = \chi_k^{\mathrm{SAT}}(f(x))$. Therefore, $x \in L$ if and only if $x \in A_m - B_{m+1}$, for some $m \leq k$. Since $B_{k+1} = \emptyset$, it follows that $L = (A_0 - B_1) \cup \cdots \cup (A_{k-1} - B_k) \cup A_k$. □

Hemachandra [18] (see also Buss and Hay [14]) has shown that the classes $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$ and $\mathrm{P}//\chi_\omega^{\mathrm{SAT}} \circ \mathrm{FP}$ coincide. By a slight modification in the above proof we get the following corollary, yielding a further characterization of $\mathrm{P}^{\mathrm{NP}[O(\log n)]}$.

COROLLARY 5.3. $\mathrm{P}//\chi_\omega^{\mathrm{SAT}} \circ \mathrm{FP} = \mathrm{NP}//\chi_\omega^{\mathrm{SAT}} \circ \mathrm{FP}$.

Beigel [8] shows that $\mathrm{P}//\mathrm{OptP}[k] = \mathrm{P}//\chi_{2^k-1}^{\mathrm{SAT}} \circ \mathrm{FP}$. From Theorem 5.2 and the following Theorem 5.4, it follows that this equation remains valid when P is replaced by NP. Theorem 5.4 restates an observation in [26] that $\#_{2^k-1}^{\mathrm{SAT}}$ is complete for $\mathrm{OptP}[k]$.

THEOREM 5.4 [26]. $\mathrm{OptP}[k] = \#_{2^k-1}^{\mathrm{SAT}} \circ \mathrm{FP} \cup \#_{2^k-1}^{\overline{\mathrm{SAT}}} \circ \mathrm{FP}$ *for all* $k \geq 0$.

COROLLARY 5.5. $\mathrm{NP}(2^{k+1} - 1) = \mathrm{NP}//\mathrm{OptP}[k]$ *for all* $k \geq 0$.

Ladner, Lynch, and Selman [30] transformed the recursion-theoretic truth-table reducibility into complexity theory. They also give a definition of a nondeterministic truth-table reduction in the following way: A is nondeterministically truth-table reducible to B if there exists an NP transducer G (the *generator*) and an NP machine E (the *evaluator*) such that for every x,

$$\begin{aligned} x \in A \Leftrightarrow {} & \text{there exists a branch of } G(x) \text{ yielding an output} \\ & y = \langle y_1, \ldots, y_k \rangle \text{ such that } E(x, \chi_\omega^B(y_1, \ldots, y_k)) \text{ accepts.} \end{aligned}$$

It is known that this definition is equivalent with the nondeterministic Turing reducibility [30] and therefore does not lead to a new reducibility notion. We modify the above definition by restricting the generator G to be a *single-valued* NP transducer, i.e., the output must be the same on every accepting branch. Let NPSV be the set of functions computed by single-valued NP transducers [11].

This reducibility first appeared in [11] (there denoted by NP.UNIF.ALL) and was explicitly called *nondeterministic truth-table reducibility* by Book and Ko [10]. Subsequently, Book and Tang [12] and Rich [35] introduced the following terminology.

DEFINITION 5.6. *A set A is* nondeterministically truth-table reducible *to B ($A \leq_{\mathrm{tt}}^{\mathrm{NP}} B$), if $A \in \mathrm{NP}//\chi_\omega^B \circ \mathrm{NPSV}$. A is* nondeterministically k-truth-table reducible *to B ($A \leq_{k\text{-tt}}^{\mathrm{NP}} B$), if $A \in \mathrm{NP}//\chi_k^B \circ \mathrm{NPSV}$. For a class $\mathcal{C}$ of sets let $\mathrm{NP}_{\mathrm{tt}}^{\mathcal{C}}$ be the class $\{A \mid \exists\, B \in \mathcal{C} : A \leq_{\mathrm{tt}}^{\mathrm{NP}} B\}$ of all sets $\leq_{\mathrm{tt}}^{\mathrm{NP}}$-reducible to some set in $\mathcal{C}$, and let $\mathrm{NP}_{k\text{-tt}}^{\mathcal{C}} = \{A \mid \exists\, B \in \mathcal{C} : A \leq_{k\text{-tt}}^{\mathrm{NP}} B\}$.*

In [11], it is shown that there exist recursive sets A and B such that $A \leq_T^{\mathrm{NP}} B$ and $A \not\leq_{\mathrm{tt}}^{\mathrm{NP}} B$. This means that $\leq_{\mathrm{tt}}^{\mathrm{NP}}$ is properly stronger than $\leq_T^{\mathrm{NP}}$. The question whether $\leq_{\mathrm{tt}}^{\mathrm{P}}$ is properly stronger than $\leq_{\mathrm{tt}}^{\mathrm{NP}}$ is equivalent to the P =?NP problem [11], [35]. However, as we will see in Corollary 5.8, every set A that is nondeterministically truth-table reducible to some NP complete set B is also deterministically truth-table reducible to B, i.e., B is NP complete and

$$A \leq_{\mathrm{tt}}^{\mathrm{NP}} B \Rightarrow A \leq_{\mathrm{tt}}^{\mathrm{P}} B.$$

Thus, we have the surprising result that while the definition in [30] of a nondeterministic truth-table reduction was too weak, the definition of Rich seems to be too strong to yield a new reduction class between $\{L \mid L \leq_{\mathrm{tt}}^{\mathrm{P}} \mathrm{SAT}\}$ and $\{L \mid L \leq_T^{\mathrm{NP}} \mathrm{SAT}\}$. As a further consequence of Theorem 5.7, we get a characterization of the odd levels of the boolean hierarchy in terms of the nondeterministic k-truth-table reducibility notion.

THEOREM 5.7. (i) $\chi_k^{\mathrm{SAT}} \circ \mathrm{NPSV} = \chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$ *for all $k \geq 1$,*
(ii) $\chi_\omega^{\mathrm{SAT}} \circ \mathrm{NPSV} \subseteq \mathrm{FP}_{\mathrm{tt}}^{\mathrm{SAT}}$.

Proof. To see (i) let f be in NPSV and define the NP set

$$A = \{\langle x, m \rangle \mid \exists z_1, \ldots, z_k : f(x) = (z_1, \ldots, z_k) \text{ and } z_m \in \mathrm{SAT}\}.$$

Then $\chi_k^{\mathrm{SAT}}(f(x)) = \chi_k^A(\langle x, 1 \rangle, \ldots, \langle x, k \rangle)$ for all x, and thus, $\chi_k^{\mathrm{SAT}} \circ f \in \chi_k^A \circ \mathrm{FP} \subseteq \chi_k^{\mathrm{SAT}} \circ \mathrm{FP}$.

For the proof of (ii) define the NP set

$$B = \{\langle x, k, m, b \rangle \mid \exists z_1, \ldots, z_k : f(x) = (z_1, \ldots, z_k) \text{ and } b \leq \chi^{\mathrm{SAT}}(z_m)\}$$

and observe that $\chi_\omega^{\mathrm{SAT}}(f(x))$ can be read off B's answers to the parallel queries $\langle x, k, m, b \rangle$, for $k = 1, \ldots, p(|x|)$, $m = 1, \ldots, k$, and $b = 0, 1$, where p is a polynomial bounding the running time of the NP transducer that computes f. □

COROLLARY 5.8. (i) $\mathrm{NP}(2k + 1) = \mathrm{NP}_{k\text{-tt}}^{\mathrm{NP}}$, *for all $k \geq 1$,*
(ii) $\mathrm{P}_{\mathrm{tt}}^{\mathrm{NP}} = \mathrm{NP}_{\mathrm{tt}}^{\mathrm{NP}}$.

Remark 5.9. Book and Tang [12] especially consider the $O(\log n)$ bounded version $\leq_{\log n\text{-tt}}^{\mathrm{NP}}$ of the nondeterministic truth-table reduction obtained by logarithmically bounding the number of queries produced by the NPSV generator. It follows from (appropriately modified versions of) Theorem 5.7, Corollary 5.3, and Lemma 3.6 that

$$\mathrm{NP}^{\mathrm{NP}}_{\log n\text{-tt}} = \mathrm{P}^{\mathrm{NP}}_{\log n\text{-tt}} = \mathrm{P}^{\mathrm{NP}[O(1)+\log\log n]}.$$

This class is also considered by Wagner [42] (there denoted by $\mathrm{P}^{\mathrm{NP}}_{||}[O(\log n)]$), who shows that it coincides with the class of languages that are full-truth-table reducible[2] to SAT. As a consequence, it follows that $A \leq^{\mathrm{NP}}_{\log n\text{-tt}}$ SAT if and only if A is full-truth-table reducible to SAT.

Remark 5.10. Book and Tang [12] generalized the nondeterministic truth-table reducibility to a Σ_k truth-table reducibility by giving the generator and the evaluator access to a Σ_{k-1} oracle: A is Σ_k truth-table reducible to B ($A \leq^{\Sigma_k}_{\mathrm{tt}} B$) if $A \in \Sigma_k // \chi^B_\omega \circ \mathrm{NPSV}^{\Sigma_{k-1}}$. For a class $\mathcal{C}$ of sets let $\Sigma^{\mathcal{C}}_{k,\mathrm{tt}}$ be the class $\{A \mid \exists B \in \mathcal{C} : A \leq^{\Sigma_k}_{\mathrm{tt}} B\}$. Then Corollary 5.8(ii) generalizes to

$$\Sigma^{\Sigma_k}_{k,\mathrm{tt}} = \mathrm{P}^{\Sigma_k}_{\mathrm{tt}} = \mathrm{P}^{\Sigma_k[O(\log n)]},$$

i.e., every set that is Σ_k truth-table reducible to a set in Σ_k is already (deterministically) truth-table reducible to a set in Σ_k.

Thierauf [38] showed that allowing the generator in the nondeterministic truth-table reduction to produce polynomially many different outputs (i.e., to compute an NPPV function [11]) does not increase the class of sets reducible to SAT.

THEOREM 5.11 [38]. *Let L be a set, G an* NPPV *transducer, and E an* NP *set such that*

$$x \in L \Leftrightarrow \exists \langle y_1, \ldots, y_k\rangle \in \mathrm{out}_G(x) : \ \langle x, \chi^{\mathrm{SAT}}_\omega(y_1, \ldots, y_k)\rangle \in E.$$

Then L is in $\mathrm{P}^{\mathrm{NP}}_{\mathrm{tt}}$.

We end this section by proving that also the strong nondeterministic truth-table reducibility, introduced by Long [31], when applied to SAT, is only as powerful as $\leq^{\mathrm{P}}_{\mathrm{tt}}$. As in the definition of Ladner, Lynch, and Selman [30], the generator in a strong nondeterministic truth-table reduction can produce exponentially many different outputs, but the evaluator either has to accept all the outputs or it has to reject all of them.

DEFINITION 5.12 [31]. *A is* strongly nondeterministically truth-table reducible *to B ($A \leq^{\mathrm{SN}}_{\mathrm{tt}} B$) if there is an* NP *transducer G and a* P *machine E such that for all x the set $\mathrm{out}_G(x)$ is nonempty, and for all $\langle y_1, \ldots, y_k\rangle$ in $\mathrm{out}_G(x)$, $E(x, \chi^B_\omega(y_1, \ldots, y_k)) = \chi^A(x)$. For a class of sets $\mathcal{C}$ we denote by* $\mathrm{SN}^{\mathcal{C}}_{\mathrm{tt}}$ *the class $\{A \mid \exists B \in \mathcal{C} : A \leq^{\mathrm{SN}}_{\mathrm{tt}} B\}$.*

Clearly, $\leq^{\mathrm{SN}}_{\mathrm{tt}}$ lies in strength between $\leq^{\mathrm{P}}_{\mathrm{tt}}$ and $\leq^{\mathrm{NP}}_{T}$. Long [31] showed that $\leq^{\mathrm{SN}}_{\mathrm{tt}}$ is properly stronger than $\leq^{\mathrm{NP}}_{T}$ by constructing two sets A and B such that $A \not\leq^{\mathrm{SN}}_{\mathrm{tt}} B$ and $A \leq^{\mathrm{NP}}_{T} B$. The question whether $\leq^{\mathrm{P}}_{\mathrm{tt}}$ is properly stronger than $\leq^{\mathrm{SN}}_{\mathrm{tt}}$ is closely related to two major open questions in complexity theory [31]:

$$\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP} \ \Rightarrow\ \leq^{\mathrm{P}}_{\mathrm{tt}} \neq \leq^{\mathrm{SN}}_{\mathrm{tt}} \ \Rightarrow\ \mathrm{P} \neq \mathrm{NP}.$$

THEOREM 5.13. $\mathrm{SN}^{\mathrm{NP}}_{\mathrm{tt}} = \mathrm{P}^{\mathrm{NP}}_{\mathrm{tt}}$.

Proof. Let L be in $\mathrm{SN}^{\mathrm{NP}}_{\mathrm{tt}}$ via a generator G, an evaluator E, and a set $A \in$ NP. In order to decide membership of a given input x, it suffices to find out whether there is some output $\langle y_1, \ldots, y_k\rangle$ of $G(x)$ such that E accepts $\langle x, \chi^A_\omega(y_1, \ldots, y_k)\rangle$. But this becomes an NP problem, provided that the maximum number $\#^A_\omega(y_1, \ldots, y_k)$ of yes-answers from A over all outputs $\langle y_1, \ldots, y_k\rangle$ of $G(x)$ is given along with the input x.

[2] A set A is full-truth-table reducible [28], [14] to a set B if there is a function $g \in$ FP such that for all x, $g(x)$ is of the form $\langle a_0 \ldots a_{2^m-1}, y_1, \ldots, y_m\rangle$, where $a_i \in \{0, 1\}$ $(0 \leq i \leq 2^m - 1)$ and $y_i \in \Sigma^*$ $(1 \leq i \leq m)$, and it holds that $x \in A \Leftrightarrow a_j = 1$, where j is the number whose binary representation is given by $\chi^B_\omega(y_1, \ldots, y_m)$.

More precisely, define the function

$$h(x) = \max\{\#^A_\omega(y_1, \ldots, y_k) \mid \langle y_1, \ldots, y_k\rangle \in \mathrm{out}_G(x)\},$$

and let B be the set defined as

$$\langle x, m\rangle \in B \quad \Leftrightarrow \quad \exists a = a_1 \ldots a_k \in \Sigma^k \ \exists \langle y_1, \ldots, y_k\rangle \in \mathrm{out}_G(x) : \\ \sum_{i=1}^{k} a_i = m, \quad a \preceq \chi^A_\omega(y_1, \ldots, y_k) \text{ and } E(x, a) = 1.$$

Then $h \in \mathrm{OptP}[O(\log n)]$ and $B \in \mathrm{NP}$, and it holds for all x that $x \in L$ if and only if $\langle x, h(x)\rangle \in B$, i.e., L is in $\mathrm{NP}//\mathrm{OptP}[O(\log n)] = \mathrm{P}//\mathrm{OptP}[O(\log n)]$. □

Note that by the above proof, Theorem 5.13 remains true if the evaluator E is allowed to be an NP machine.

DETERMINISTIC SIMULATIONS OF PRAMS ON BOUNDED DEGREE NETWORKS*

KIERAN T. HERLEY†‡ AND GIANFRANCO BILARDI†§

Abstract. The problem of simulating a PRAM with n processors and memory size $m \geq n$ on an n-node bounded degree network is considered. A deterministic algorithm is presented that simulates an arbitrary PRAM step in $O((\log n \log m)/\log\log n)$ time in the worst case on an expander-based network. By extending a previously established lower bound, it is shown that the proposed simulation is optimal whenever $\Omega(n^{1+\epsilon}) \leq m \leq O(2^{(\log n)^{\alpha}})$ for some positive real constants ϵ and α.

1. Introduction.

Parallel random access machines (PRAMs) play a central role in the study of parallel computation and in the development of parallel algorithms [KR90]. A PRAM is essentially a set of synchronous processors connected to a shared memory. The basic feature of the PRAM is that references to distinct memory cells can be made simultaneously by different processors. A number of different variants of the PRAM model have been proposed [FW78], [Gol78], [Sch80], [LPV81], [SV81], [Kuc82], [Sni85], [BH85] that allow simultaneous references to the same memory cell in varying degrees. By ignoring several of the constraints that arise in the physical realization of a multiprocessor, the PRAM model provides an attractive framework for algorithm design. However, the running time of an algorithm on a PRAM may be a poor estimate of its performance on a realistic multiprocessor [Sny86].

Two important constraints not captured by PRAMs but shared by most realistic parallel machines are as follows: (i) the granularity of the memory (the memory is partitioned into banks or modules, each of which can respond to only one request per machine cycle), and (ii) the fact that the individual components of the machine (processors and memory modules) can be connected directly only to a small number of other components. The Bounded degree network (BDN) of processors and memory modules captures both constraints and hence is a more realistic model of parallel computers than the PRAM. A BDN consists of a synchronous collection of nodes, each equipped with a processor and a private local memory. Each node is connected to a constant number (independent of machine size) of other nodes by means of bidirectional communication channels. It is natural to wonder how well a PRAM computation can be simulated by a suitably chosen BDN. This question has received considerable attention in the literature, and we briefly review some of the results here.

Several researchers have observed that simulating a PRAM whose memory size m is linear in the number of processors n is essentially a routing problem (see [LPV81], [BH85], for example). The idea is that each node in the simulating network holds $O(1)$ PRAM memory cells; accessing a cell involves communicating with the node that holds it. In this paper we focus on the simulation of PRAMs where m, the memory size, is significantly larger than n, the number of PRAM processors. We will refer to such a PRAM as an (n, m)-PRAM. In this

case the chief obstacle to efficient simulation is *congestion*. Since only a single value can be accessed from any particular memory module in one BDN machine cycle, the simulation algorithm must limit the amount of information accessed from each node.

One approach, proposed in [MV84] and further developed subsequently in a series of papers [Upf84], [LPP88], [KU88], [LMR88], [Val88], [Ran91], distributes the address space of the PRAM among the modules of the BDN according to some suitably chosen hash function. The objective is to ensure that, with high probability, the congestion at any node of the network is low, and hence performance is good. In particular [Ran91] proposes a protocol for an n-node butterfly network that simulates T steps of an (n, m)-PRAM in $O(T \log n)$ time, with high probability, assuming that m is polynomial in n. The protocol is deterministic, except for the random choice of the hash function that defines the address map.

Another approach, also proposed in [MV84], relies on representing the contents of a PRAM memory cell by using several BDN cells. This approach forms the basis for a number of deterministic simulation schemes [UW87], [AHMP87], [LPP90] including the one proposed in this paper. The goal of these schemes is to provide good *worst-case* performance.

In [UW87], a scheme is advanced to simulate an arbitrary step of an (n, m)-PRAM $(m \geq n)$ by an n-node BDN in time $O(\log n \log m \log\log m)$. Nodes of the BDN consist of a RAM processor and a memory module. They are interconnected as in the graph (V, E_{AKSL}), Leighton's modification of the AKS sorting network [AKS83], [Lei85]. This time bound was subsequently improved to $O(\log n \log m)$ in [AHMP87] and is further improved to $O(\log n \log m / \log\log n)$ in the present paper. Our network is also an n-node BDN, $(V, E_{\text{exp}} \cup E_{\text{AKSL}} \cup E_{\text{tree}})$ where (V, E_{exp}) is a graph based on square-root expanders [PU89], [LPS86], (see also [LPS88]) and (V, E_{tree}) is a complete binary tree. A simulation with a running time of $O(\log^2 n/\log\log n + \log(m/n)\log n)$ has been obtained in [HMP89], which matches the performance of our scheme only for $m = n^{1+O(1/\log\log n)}$.

An $\Omega((\log n \log m)/\log\log m)$ lower bound for the time to simulate a step of an (n, m)-PRAM by an n-node BDN was established independently in [AHMP87] and [KU88] assuming that, for some positive constant ϵ, $\Omega(n^{2+\epsilon}) \leq m \leq 2^{O(\sqrt{n \log n})}$. By refining the proof technique of [AHMP87] and [KU88], we obtain a lower bound of $\Omega((\log(m/n))^2/\log\log(m/n))$ for $m \leq O(n^{2+\epsilon})$. A similar result has been obtained in [HMP89]. The performance of the simulation described in this paper matches the cited lower bound as long as $\Omega(n^{1+\epsilon}) \leq m \leq O(2^{(\log n)^\alpha})$, for some positive real constants ϵ and α.

The lower bounds just mentioned are based on the so-called point-to-point assumption, technically defined in §5. Essentially, it is assumed that when storing a new value of a PRAM variable in different memory locations, a BDN processor needs to issue a distinct message for each location. There is really no reason why a simulation should be restricted in this way. Nevertheless, the lower bound is interesting for the following reasons. All the simulations cited above are essentially point to point. At least for the range of m where the simulations of this paper are optimal, the lower bound indicates that the only hope for an improvement lies in "combining" techniques for messages from the same source carrying the same information. Moreover, even with the point-to-point limitation, the lower bound arguments are not straightforward, and they provide valuable insights on the problem. A recent study reports an $\Omega(\log m)$ lower bound that does not rely on the point-to-point assumption [HMP89].

In [LPP90] a PRAM simulation is presented on a BDN consisting of an $n \times n$ mesh-of-trees [Lei84], [NMB83], where the n roots of the trees are RAM processors, while the other $\Theta(n^2)$ nodes are packet-switching elements. The scheme is attractive for the regularity and simplicity of the interconnection. For m polynomial in n, a PRAM step is simulated in time $O(\log^2 n/\log\log n)$, the same as that achieved by our simulation for this range of m.

However, it should be noted that the use of $\Theta(n^2)$ nodes, albeit mere switches, makes the cited lower bound inapplicable to the mesh-of-trees.

Even under the point-to-point assumption, optimal simulations are not known for small memory ($m < O(n^{1+\epsilon})$), or for very large memory ($m > \Omega(2^{(\log n)^{\alpha}})$). For small memory, simulations faster than those given in this paper have been proposed in [Her89].

Deterministic PRAM simulations on BDNs typically lead to a BDN memory size considerably larger than m, the PRAM memory size. There are two reasons for this phenomenon: (a) several copies of each PRAM variable are kept in the BDN, and (b) the memory map indicating the location of such copies needs to be stored. Simulations using only $O(1)$ copies per variable have been proposed in [HP89] for a mesh-of-trees interconnection. Memory maps with substantially more compact representations than those previously considered are discussed in [Her90].

In most of the studies referred to above, the number n of nodes in the BDN is assumed to be proportional to the number of processors in the PRAM being simulated and is independent of the size m of the PRAM memory. It is certainly of interest to investigate simulations where the size of the BDN is allowed to depend on both n and m. In this direction it is worth mentioning the scheme of [Vis84], which has running time $O(\log n + \log m)$ on a BDN of $O(n \log n + m \log m)$ nodes.

The remainder of this paper is organized as follows. Section 2 is devoted to the formulation of the problem. Section 3 discusses the memory organization, i.e., the method by which the memory of the PRAM is represented by the memory of the BDN. Introducing the graph-theoretic notion of generalized expander, we investigate the trade-off between the number of copies and memory congestion in organizations of the type proposed in [UW87]. The choice of an appropriate point in this trade-off is critical in order to balance the work needed to extract the relevant information from the memory modules with the work needed to route this information to the intended processors. Section 4 describes and analyzes the memory access algorithm. Section 5 is devoted to lower bounds. Section 6 concludes the paper by indicating a number of interesting open problems.

2. Problem formulation. We consider an (n, m)-PRAM with processors, P_1^{PRAM}, P_2^{PRAM}, …, P_n^{PRAM} sharing a set U of m memory cells, which will also be referred to as *variables*. Our goal is to simulate such a PRAM by a BDN of n nodes (P_1, M_1), (P_2, M_2), …, (P_n, M_n) where P_i is a RAM processor and M_i is a memory module. We are interested in simulation algorithms that are deterministic and on line, i.e., the simulation of a step is independent of future steps.

We assume that the instruction to be executed by PRAM processor P_i^{PRAM} at a given step is available to the corresponding BDN processor P_i at the beginning of the simulation of this step. Since simulation of arithmetic and logical operations is straightforward, we can regard a generic PRAM step simply as an n-tuple of memory accesses. A memory access can either be of the form read(u), $(u \in U)$, which results in the contents of the memory cell u being copied into a distinguished register of the executing processor, or of the form write(u, x), ($u \in U$, x an integer value), which results in the integer value x being written to memory cell u. For simplicity we assume that all the accesses in a given step are of the same t;pe (read or write).

In any simulation scheme, upon termination of the simulation of a given PRAM step, the state of the PRAM memory must be uniquely reconstructible from the state of the BDN memory. The method chosen for representing the state of the PRAM memory by the state of the BDN memory is referred to as the *memory organization*. The algorithm that probes the state of the BDN memory when simulating a read step and that modifies it when simulating a write step is called the *memory access algorithm*.

A simulation scheme is *consistent* if, after the simulation of an arbitrary sequence of PRAM steps, the simulation of a step where processor P_i^{PRAM} executes read(u) results in loading the distinguished register of P_i with the correct value of u. The latter is of course the value assigned to u by the latest instruction of the form write(u, x).

In the next two sections we describe and analyze a new simulation scheme. Section 3 is devoted to the memory organization, and §4 to the memory access algorithm.

3. Memory organization. The idea of replicating data to enhance its accessibility is widely used in the field of distributed computing [Gif79], [Tho79]. Upfal and Wigderson [UW87] proposed a memory organization where, for each PRAM variable $u \in U$, the BDN maintains $2c - 1$ copies in the memory modules of a set $\Gamma(u) = \{\gamma_1(u), \gamma_2(u), \ldots, \gamma_{2c-1}(u)\}$ of distinct nodes. Their scheme adheres to the following read/write discipline. Each copy contains a value and a timestamp indicating the time at which that copy was last written. When simulating a step where u is written, at least c copies of u are updated. When simulating a step where u is read, at least c copies of u are retrieved: the one with the most recent timestamp is guaranteed to contain the correct value of u. We will adopt the same read/write discipline.

In the memory organizations employed in our simulation the location of the copies of a particular variable does not vary with time. This type of memory organization can be modelled conveniently by a bipartite graph $G = (U, V, E)$ where U is the set of PRAM variables, V is the set of the nodes of the BDN, and an edge (u, v) represents the fact that the node v contains a copy of the variable u.

Let $S \subseteq U$ and let $F \subseteq E$ have exactly k edges incident upon each $u \in S$. We call F a *k-bundle* for S. We say that the subset of V on which the edges of F are incident is a *k-neighborhood* of S and denote it by $\Gamma_F(S)$. When the read/write discipline scheme described above is adopted, the simulation of a PRAM step accessing the variables of S requires that the BDN access all the copies of some c-bundle, say F. Clearly, this takes at least $c|S|/|\Gamma_F(S)|$ time, since at least $c|S|$ copies have to be accessed from $|\Gamma_F(S)|$ modules. It is desirable to have a memory organization with large c-neighborhoods. The preceding remarks motivate the following definition.

DEFINITION 1. *A bipartite graph $G = (U, V, E)$ with $|U| = m$ and $|V| = n$, and with each node in U having degree d is a (λ, d, c, σ)-generalized expander if, for every $S \subseteq U$ such that $|S| \leq \sigma n$ and for every c-bundle F of S, $|\Gamma_F(S)| \geq \lambda c|S|$.*

Clearly, $c \leq d \leq n$, $\lambda \leq 1$, and $\sigma \leq 1/\lambda c$ are necessary conditions for the existence of a (λ, d, c, σ)-generalized expander. The next theorem establishes the existence of certain types of generalized expanders. (The proof is based on standard types of counting arguments and can be skipped without loss of continuity.)

THEOREM 1. *Let $g_0(\lambda) \triangleq (4e^{1+\lambda})^{2/(1-\lambda)}$. For every n, m, λ, g, and c with $m \geq n$, $\lambda < 1$, $2c - 1 \leq n$, $g_0(\lambda) < g \leq 3\lambda g_0(\lambda)m/n$, and $c \geq (2/(1 - \lambda)) \log(3\lambda m/n)/ \log(g/g_0(\lambda))$, there exists a $(\lambda, 2c - 1, c, 1/\lambda cg)$-generalized expander $G = (U, V, E)$ with $|U| = m$ and $|V| = n$.*

Proof. Let $B_{m,n,2c-1}$ be the class of all bipartite graphs $G = (U, V, E)$ with *labeled* nodes and *unlabeled* edges such that $|U| = m$, $|V| = n$, and each node of U has degree $2c - 1$. Note that $|B_{m,n,2c-1}| = \binom{n}{2c-1}^m$. Let η be the fraction of graphs in $B_{m,n,2c-1}$ that are *not* $(\lambda, 2c - 1, c, 1/\lambda cg)$-generalized expanders. We will show that $\eta < 1/2$.

We begin by observing that, if $G \in B_{m,n,2c-1}$ is not a $(\lambda, 2c - 1, c, 1/\lambda cg)$-generalized expander, then there exists a triple (S, W, F) with the following properties: (i) $S \subseteq U$, $|S| \leq n/\lambda cg$; (ii) $W \subseteq V$, $|W| = \lceil \lambda c|S| - 1 \rceil$; (iii) $F \subseteq E$ is a c-bundle of S such that $\Gamma_F(S) \subseteq W$. We shall call such a triple a *witness*. If we let f_s be the fraction of all graphs in $B_{m,n,2c-1}$ having a witness (S, W, F) with $|S| = s$, then we can bound η as follows:

$$\eta \leq \sum_{1 \leq s \leq n/\lambda cg} f_s. \tag{1}$$

We now claim that

$$f_s < \binom{m}{n}\binom{n}{\lceil \lambda cs - 1\rceil}\binom{2c-1}{c}^s \left\{ \frac{\binom{\lceil \lambda cs-1\rceil}{c}}{\binom{n}{c}} \right\}^s . \tag{2}$$

Standard combinatorial arguments show that there are $\binom{m}{s}$ ways of choosing S, $\binom{n}{\lceil \lambda cs-1\rceil}$ ways of choosing W,

$$\binom{\lceil \lambda cs - 1\rceil}{c}^s$$

ways of choosing F, and a fraction

$$\left\{ \binom{2c-1}{c} \Big/ \binom{n}{c} \right\}^s$$

of the graphs in $B_{m,n,2c-1}$ for which triple (S, W, F) is a witness. Then, simple arithmetic yields (2). Use of the inequalities $\binom{m}{s} < (em/s)^s$, $\binom{n}{\lceil \lambda cs-1\rceil} < (en/\lambda cs)^{\lambda cs}$, $\binom{2c-1}{c} < 2^{2c}$, and $\binom{\lceil \lambda cs-1\rceil}{c}/\binom{n}{c} < (\lambda cs/n)^c$ in (2) yields (after some manipulations)

$$f_s < \left\{ \frac{ecm}{n} \left[4e^{\lambda} \lambda^{(1-\lambda)} (cs/n)^{1-\lambda-1/c} \right]^c \right\}^s .$$

Making use of the bounds $ec \le e^c$, and $cs/n \le 1/\lambda g$ (from $s \le n/\lambda cg$), we have

$$f_s < \left\{ \frac{\lambda m}{n} \left[4e^{1+\lambda} (1/g)^{1-\lambda-1/c} \right]^c \right\}^s .$$

From $c \ge (2/(1-\lambda)) \log(3\lambda m/n)/\log(g/g_0(\lambda))$, and $g \le 3\lambda g_0(\lambda) m/n$, we have $c \ge 2/(1-\lambda)$, and hence $1 - \lambda - 1/c \ge (1-\lambda)/2$. Since $g > g_0(\lambda) > 1$, we can reformulate the expression for f_s as

$$f_s < \left\{ \frac{\lambda m}{n} \left[4e^{1+\lambda} (1/g)^{(1-\lambda)/2} \right]^c \right\}^s$$

which can be rewritten as

$$f_s < \left\{ \frac{\lambda m}{n} \left[\frac{g_0(\lambda)}{g} \right]^{(1-\lambda)c/2} \right\}^s ,$$

where $g_0(\lambda) = (4e^{1+\lambda})^{2/(1-\lambda)}$. If $c \ge (2/(1-\lambda)) \log(3\lambda m/n)/\log(g/g_0)$, then $f_s < 1/3^s$, and, from (1), $\eta < \frac{1}{2}$. □

Upfal and Wigderson [UW87] established the existence of a family of $(\lambda, 2c-1, c, 1/(2c-1))$-generalized expanders for every $\lambda < 1/(8e^4)$, and $c \ge \beta \log m$, for some suitable constant $\beta > 0$. These expanders and similar ones define the memory organizations used in [UW87], [AHMP87], [LPP90].

Theorem 1 demonstrates that $c = \lceil (2/(1-\lambda)) \log(3\lambda m/n)/\log(g/g_0) \rceil$ is sufficient to guarantee the existence of $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expanders. A natural question is whether such a large value of c is really necessary. As shown in Proposition 1 below, the answer is positive, at least if the expansion property applies to reasonably large subsets of U. We first prove a simple lemma, essentially a rephrasing of the definition of generalized expander, also needed for Lemma 2.

Henceforth, when referring to a $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expander, we shall assume the quantity $n/\lambda cg$ is an integer. This condition can always be met by increasing g slightly, without altering the results in any essential way.

LEMMA 1. *Let $G = (U, V, E)$ be a $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expander. If $S \subseteq U$ and $F \subseteq E$ defines a c-neighborhood $\Gamma_F(S)$ of size smaller than n/g, then $|S| \leq |\Gamma_F(S)|/\lambda c$.*

Proof. Suppose, by way of contradiction, that $|S| > |\Gamma_F(S)|/\lambda c$, that is, $|\Gamma_F(S)| < \lambda c|S|$. By Definition 1, it follows that $|S| > n/\lambda cg$. Let S' be a subset of S of size $n/\lambda cg$ and let $\Gamma_{F'}(S')$ be the c-neighborhood of S' contained in $\Gamma_F(S)$. Again by Definition 1 we have that $|\Gamma_F(S)| \geq |\Gamma_{F'}(S')| \geq \lambda cn/\lambda cg = n/g$, which is a contradiction. □

PROPOSITION 1. *If $G = (U, V, E)$ is a $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expander, with $|U| = m$, $|V| = n$, λ a fixed constant such that $0 < \lambda < 1$, and $n/cg \geq 4$, then $c = \Omega(\log(\lambda m/n)/\log g)$.*

Proof. Consider some $W \subseteq V$. We say that W *confines* $u \in U$ if $\Gamma(u) \subseteq W$. A simple combinatorial argument given in both [MV84] and [UW87] shows that the subsets of V of size w confine an average of $m\binom{n-2c+1}{w-2c+1}/\binom{n}{w} = m[w]_{2c-1}/[n]_{2c-1}$ variables apiece. (Here $[a]_b$ denotes $a(a-1)(a-2)\cdots(a-b+1)$.) In particular some set $W \subseteq V$ of size w will confine a set S with at least $\lceil m[w]_{2c-1}/[n]_{2c-1}\rceil$ variables. Choose $w = \lceil n/g - 1\rceil < n/g$ and let W and S be chosen as above. Then we have $\Gamma(S) \subseteq W$, and (by Lemma 1) $|S| \leq n/\lambda cg$; it follows that $\lceil m[w]_{2c-1}/[n]_{2c-1}\rceil \leq n/\lambda cg$. The latter inequality implies that $[n]_{2c-1}/[w]_{2c-1} > \lambda m/n$. Considering that $[n]_{2c-1} < n^{2c-1}$, and that $[w]_{2c-1} \geq (w/2)^{2c-1}$ (from $n/cg \geq 4$), we have $(2n/w)^{2c-1} > \lambda m/n$. From the definition of w, with some manipulations, we obtain $c = \Omega(\log(\lambda m/n)/\log g)$. □

One important facet of Theorem 1 lies in the introduction of the parameter g, which controls a trade-off between the number of copies and the largest set of variables for which expansion can be guaranteed. In fact the size of the smallest set of modules containing a given number of variables depends strongly on the value of c: the smaller this value the smaller the set of modules. Roughly speaking, increasing g reduces the number of copies to be processed during the simulation of a PRAM step, but creates higher congestion at memory modules, thereby making the job of accessing those copies more difficult.

Consider now a memory organization represented by a bipartite graph $G = (U, V, E)$ and let $S \subseteq U$ be a set of PRAM variables to be accessed. The copies of the variables in S will be distributed among the BDN nodes with node $v \in V$ containing $s_v \overset{\Delta}{=} |\{(u, v) : u \in S, (u, v) \in E\}|$ copies. We are interested in analyzing the effect of accessing $\min(s_v, q)$ copies from each node $v \in V$, as a function of the integer q. This operation, which we denote by Decimate(S, q), will form the basis of the memory access protocol to be described in the next section.

At any given instant, the variables of S can be partitioned into two sets: those for which at least c copies have been accessed, which we will call the *dead* variables, and the remaining ones, which we call the *live* variables. Dead variables play no further role in the simulation since enough copies have been accessed to effect either a read or write. For the live variables, more copies need to be accessed. Therefore, we are interested in bounding the size of the set of variables left alive after Decimate(S, q).

Formally, the set of copies accessed by Decimate(S, q) is represented by a set of edges $E' \subseteq E$ such that if $(u, v) \in E'$ then $u \in S$, and for each $v \in V$, there are exactly $\min(s_v, q)$ edges in E' incident upon v. Then, L is the subset of the nodes of S with degree at least c in the graph $(U, V, E - E')$.

LEMMA 2. *Suppose a memory organization has the structure of $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expander $G = (U, V, E)$. Let $k = \lceil |S|/(n/\lambda cg)\rceil$, and let $S \subseteq U$ be a set of variables. Then, if $q \geq 2k/\lambda$, the set L of variables remaining alive after* Decimate(S, q) *satisfies the relation*

$$|L| \leq \left\lceil \frac{2(1-\lambda)/\lambda}{q-2k} \right\rceil |S|. \tag{3}$$

Proof. The set S can be partitioned into k subsets $S_1, S_2, \ldots, S_k$, each of size no larger than $n/\lambda cg$. For $i = 1, 2, \ldots, k$, let $F_i \subseteq E$ be the set of edges incident upon nodes of S_i. Then F_i can be partitioned into $F_{i,1}$ and $F_{i,2}$ so that $\Gamma_{i,1} \triangleq \Gamma_{F_{i,1}}(S_i)$ is a c-neighborhood of S and $\Gamma_{i,2} \triangleq \Gamma_{F_{i,2}}(S_i)$ is a $(c-1)$-neighborhood of S. From the expansion property, we have that $|\Gamma_{i,1}| \geq \lambda c|S_i|$ and $|\Gamma_{i,2}| \geq (\lambda c - 1)|S_i|$. The latter relation is obtained considering that, by adding to $F_{i,2}$ one incident edge for each node in S_i, one obtains a c-neighborhood for S_i with at most $|S_i|$ nodes more than $\Gamma_{i,2}$ and at least $\lambda c|S_i|$ nodes in all. We now form, for each $i = 1, 2, \ldots, k$ and $j = 1, 2$, the set $F'_{i,j}$ by (arbitrarily) selecting for each node of $\Gamma_{i,j}$ one edge of $F_{i,j}$ incident upon it. Let $F = \cup_{i=1}^{k} \cup_{j=1}^{2} F'_{i,j}$. By construction, no more than $2k$ edges of F are incident upon any $v \in V$. Hence, the number of copies accessed by Decimate(S, $2k$) is at least

$$\begin{aligned}
|F| &= \sum_{i=1}^{k}\sum_{j=1}^{2} |F'_{i,j}| \\
&= \sum_{i=1}^{k}\sum_{j=1}^{2} |\Gamma_{i,j}| \\
&\geq \sum_{i=1}^{k} (\lambda c|S_i| + (\lambda c - 1)|S_i|) \\
&\geq (2\lambda c - 1)|S|.
\end{aligned}$$

Now let $H = \{v : s_v > q\}$. Each node in H contains at least $q - 2k + 1$ copies of variables in S in addition to those accessed by Decimate(S, $2k$). Considering that there is a total of $(2c-1)|S|$ copies of the variables in S, we obtain

$$(q - 2k + 1)|H| + (2\lambda c - 1)|S| \leq (2c - 1)|S|,$$

or equivalently

$$|H| \leq [2(1-\lambda)c/(q - 2k + 1)]|S|. \tag{4}$$

Given that, by assumption, $q \geq 2k/\lambda$ we have that $|H| < n/g$.

Since the copies of the live variables L not accessed by Decimate(S, q) are all in H, H must contain a c-bundle D of L. Then since $|\Gamma_D(L)| \leq |H| < n/g$, we have from Lemma 1 that $|L| \leq |H|/\lambda c$. This latter relation combined with Equation (4) yields the desired bound on $|L|$. □

We shall call the quantity $|L|/|S|$ the *survival factor* of the operation Decimate(S, q), which is the building block of the memory access protocol described in the next section. In contrast, the protocol of [UW87] is built around a procedure which, although implemented differently, has the same effect as a decimation with a constant survival factor.

Intuitively, the advantage of a smaller survival factor can be understood as follows. From standard considerations on the diameter of an n-node BDN it is clear that any implementation of decimation will require $\Omega(\log n)$ time in the worst case. However, it will be shown in the next section that $O(\log n)$ time is essentially sufficient for the execution of a Decimate(S, $O(\log n)$), as long as $|S| \leq n/(2c-1)$. From Lemma 2 we can see that, for $|S| \leq n/(2c-1)$, choosing $g = \log n$ and q a suitable multiple of g yields a survival factor of $O(1/\log n)$. The smaller the survival factor, the fewer decimations required to access all the variables. By accessing more information per unit time than the algorithm of [UW87], our algorithm succeeds in accessing the referenced variables more quickly. A similar observation is also employed in the scheme of [LPP90]. In a sense, the memory organization of [UW87] was chosen to minimize the amount of information to be extracted from any individual node in the machine. However, when related to the BDN model, this is not the dominant cost in their algorithm. Our choice of memory organization balances the work of extracting information from individual nodes with that of moving information around the machine.

4. The memory access algorithm. In this section we describe a memory access algorithm for the simulation of one step of an (n, m)-PRAM. Let λ be a constant satisfying $0 < \lambda < 1$. We assume that the memory organization is a $(\lambda, 2c-1, c, 1/\lambda cg)$-generalized expander with $c = \Theta(\log(m/n)/\log g)$. The parameter g will be specified later. It is further assumed that each node of the BDN stores in its local memory a table giving for each PRAM variable u the nodes $\gamma_1(u), \gamma_2(u), \ldots, \gamma_{2c-1}(u)$ containing copies of u. The BDN has the structure $(V, E_{\text{exp}} \cup E_{\text{AKSL}} \cup E_{\text{tree}})$, where (V, E_{exp}) is a certain expander graph to be specified later, (V, E_{AKSL}) is the graph underlying Leighton's modification of the AKS sorting network [AKS83] [Lei85], and (V, E_{tree}) is a complete binary tree with n nodes.

Let X be the set of PRAM variables to be accessed in a given PRAM step. The goal of the simulation is to access a majority of the copies of each variable in X. We shall describe the algorithm for simulating a read step, the algorithm for a write step being very similar. It is assumed that the read step is of the exclusive read variety, i.e., no two processors attempt to read the same variable. This is not an essential restriction. As already noted in several earlier studies [UW87], [AHMP87], [KU88], any concurrent read step may be reduced to an exclusive read step by means of established techniques as sketched in the Appendix.

A high level description of the memory access algorithm follows.

I. For each processor P_i generate u_i, the name of the variable it wishes to read. Let $X = \{u_1, \ldots, u_n\}$ denote the set of referenced variables.
II. For each P_i access at least c copies of u_i.
III. At P_i, select the value from the returned packet(s) with the most recent timestamp as the result of read(u_i).

Steps I and III are straightforward and are accomplished in $O(1)$ and $O(c)$ time, respectively. We focus our attention on Step II. It will be implemented as a sequence of decimations, the first one applied to the set X, and the remaining decimations each applied to the set of variables left alive by the previous decimation.

Let S be a subset of U of size at most n. The procedure Decimate(S, q) may be specified as follows: (i) S is a variable parameter denoting the set of live variables; (ii) the second argument q is a value parameter of type integer; (iii) the execution of Decimate(S, q) will cause $\min(s_v, q)$ packets destined for node v to reach that node and to be returned to their respective origins, with the appropriate values and timestamps (s_v denotes the number of copies of variables in S contained in node v); (iv) the value of S is modified by the execution of Decimate(S, q) so that, upon termination, S represents the set of live variables.

In terms of procedure Decimate, Step II of the memory access algorithm can be written as follows. Let S initially represent the set of referenced variables X.

```
for $h$ := 1 to $H$ do
        Decimate$(S, q_h)$
```

The values of $q_1, q_2, \ldots, q_H$ and H will be specified later so that after the Hth iteration S is empty, i.e., all the variables in X have been accessed.

The implementation of Decimate involves manipulating and routing sets of request packets. In the next subsection we review two routing results. The first is a *balancing* algorithm that takes a set of packets distributed among the nodes of a bounded degree network and redistributes them so that each node holds the same number. The second algorithm is a generalized routing algorithm. The implementation of Decimate in terms of these primitives is presented in the subsequent subsection. The final subsection provides an analysis of the running time of the entire memory access algorithm.

4.1. Generalized routing and balancing. The *(N, K_1, K_2)-routing problem* involves routing N packets in a network of n processors subject to the constraint that no node is the source of more than K_1 packets or the destination of more than K_2 packets. Peleg and Upfal [PU87], [PU89] formulated this problem and developed a network and a routing algorithm with an optimal number of communication steps. In the BDN model, the algorithm of [PU89] solves any instance of the (n, K_1, K_2)-routing problem in $O(\log n + K_1 + K_2 + \log(k_1 + K_2)\log n)$ time on a network with a particular expander-based structure. These results are generalized in [PU87] to handle sets of size N larger than n. In [Her91] the following result is established, which attains a lower bound of [PU87].

LEMMA 3. *There is an n-node* BDN $(V, E_{\text{exp}} \cup E_{\text{AKSL}})$ *and a deterministic algorithm that routes any instance of the (N, K_1, K_2)-routing problem in $O(\lceil N/n \rceil \log n + K_1 + K_2)$ time.*

From Lemma 3 one obtains a simple PRAM simulation scheme by distributing the PRAM variables evenly among the nodes of the BDN, with at most $\lceil m/n \rceil$ per node. Then, a write step is essentially an instance of $(n, 1, \lceil m/n \rceil)$-routing, and a read step can be implemented by means of a $(n, 1, \lceil m/n \rceil)$-routing step followed by an $(n, \lceil m/n \rceil, 1)$-routing step. These observations lead to the following result.

PROPOSITION 2. *An arbitrary step of a* PRAM *with n processors and $m \geq n$ memory cells can be simulated by the* BDN $(V, E_{\text{exp}} \cup E_{\text{AKSL}})$ *in $O(\log n + \min(n, m/n))$ time.*

In essence, the algorithm of [PU89] (as well as its refinement in [Her89]) reduces an instance of the generalized routing problem to a partial permutation routing problem by means of *balancing* (referred to as *token distribution* in [PU89]). Balancing involves redistributing a set of packets initially scattered unevenly among the nodes of a BDN so that each node has the same number. Formally, a *distributed set* $\hat{Z} \overset{\Delta}{=} (Z, f)$ is a set Z of packets distributed among the nodes of the BDN with packet $z \in Z$ at node $f(z)$. The *degree* $\Delta(\hat{Z})$ of $\hat{Z}$ is the maximum number of packets assigned by f to any one node. The set $\hat{Z}$ is *balanced* if it has degree $\lceil |Z|/n \rceil$. A distributed set $\hat{Z} = (Z, f)$ of packets, labeled with integer values, is said to be *balancesorted* if it is balanced and the packets with the $\lceil |Z|/n \rceil$ smallest keys lie in node 1, the next $\lceil |Z|/n \rceil$ next smallest lie in node 2, and so on. The following result is established in [Her91].

LEMMA 4. *There exists an n-node* BDN $(V, E_{\text{exp}} \cup E_{\text{AKSL}})$ *and a deterministic algorithm that balancesorts any distributed set $\hat{Z} = (Z, f)$ in $O(\lceil |Z|/n \rceil \log n + \Delta(\hat{Z}))$ time.*

4.2. Implementation of Decimate. The algorithm outlined in this subsection is based on the following primitives: sorting, parallel prefix, balancing, and the generalized routing mentioned in the previous subsection. The underlying network has the structure $(V, E_{\text{exp}} \cup E_{\text{AKSL}} \cup E_{\text{tree}})$ and was chosen to support these primitives as efficiently as possible. The algorithm can be adapted to any other architecture that supports these primitives.

Recall that at any given point in the computation S represents the set of live variables. The overall idea is as follows. For each $v \in V$, we *select* exactly $d_v \overset{\Delta}{=} \min(s_v, q)$ of the s_v requests directed at module v. The selected packets are routed to their respective destinations, where they are loaded with the appropriate values and then routed back to their origins. The details follow.

```
Decimate($S, q$)
1. For each $u_i \in S$ and each $j \in \{1, \dots, 2c - 1\}$ generate a request packet containing
   an origin $P_i$, a destination $\gamma_j(u_i)$, the label $u_i$ itself, and fields to store a value and a
   timestamp of the copy of $u_i$ contained in node $\gamma_j(u_i)$.
2. Sort the request packets by destination.
3. Select $d_v$ request packets from those with destination $v$; discard the others.
4. Route the selected request packets to the corresponding nodes.
5. Load values and timestamps into request packets.
6. Route the selected requests (now satisfied) back to their origins.
7. Let each origin $P_i$ count the number of packets received during Step 6 and, if they are
   at least $c$ in number, mark $u_i$ dead and remove the corresponding packets from the set
   of request packets.
```

LEMMA 5. *Decimate*(S, q) *can be implemented on the* BDN $(V, E_{\text{exp}} \cup E_{\text{AKSL}} \cup E_{\text{tree}})$ *with running time* $O(\lceil c|S|/n \rceil \log n + c + q)$.

Proof. First, Steps 1, 5, and 7 are sequential computations and can be performed locally at each node in $O(c)$, $O(q)$, and $O(c)$ time, respectively.

Step 2 consists of balancing and sorting a distributed set of size no larger than $(2c - 1)|S|$ and with at most $2c - 1$ elements per node. By Lemma 4, this operation takes $O(\lceil c|S|/n \rceil \log n + c)$ time.

Step 3 can be reduced to a parallel prefix computation [KRS85] on a sequence of length $(2c - 1)|S|$ as follows. Following Step 2, the packets are arranged in increasing order of destination, and so those with a common destination v form a contiguous subsequence σ_v. Using parallel prefix it is possible to number the packets in sequence σ_v with the numbers $1, \dots, s_v$. Those with numbers at most q are selected; the other are discarded. All of this can be executed on (V, E_{tree}) in $O(\lceil c|S|/n \rceil + \log n)$ time.

Step 4 involves routing $(2c - 1)|S|$ packets with at most $2c - 1$ per source and at most q per destination. This is an instance of the $((2c - 1)|S|, 2c - 1, q)$-routing problem, which by Lemma 3 takes $O(\lceil c|S|/n \rceil \log n + c + q)$ time. Similarly, Step 6 is an instance of the $((2c - 1)|S|, q, c)$-routing problem and has the same running time.

The contributions of the various steps add up to the stated running time. □

4.3. Simulation time. In this subsection we establish the following result.

THEOREM 2. *An arbitrary step of an* (n, m)-PRAM *with* $m \geq n$ *can be simulated by the* BDN $(V, E_{\text{exp}} \cup E_{\text{AKSL}} \cup E_{\text{tree}})$ *in* $O((\log n \log m)/ \log \log n)$ *time.*

Proof. From Proposition 2, if $m \leq (n \log n)/(3\lambda g_0(\lambda))$, then the simulation can be done in $O(\log n)$ time, and Theorem 2 is established. Therefore, we can assume that $m > (n \log n)/(3\lambda g_0(\lambda))$, and thus we can choose $g = \log n$ without violating the constraint of Theorem 1 that $g \leq 3\lambda g_0(\lambda) m/n$.

Also, if $m \geq (n/3\lambda)2^{n(1-\lambda)/4}$, then $\log m = \Omega(n)$ and Theorem 2 again follows from Proposition 2. Therefore, we can assume that $m < (n/3\lambda)2^{n(1-\lambda)/4}$. For $g = \log n$ and n large enough (such that $\log n \geq 2g_0(\lambda)$), the upper bound on m guarantees that the condition $2c - 1 \leq n$ of Theorem 1 is satisfied, so that we are entitled to assume the existence of the generalized expander underlying our simulation.

We have already seen that Steps I and III of the memory access algorithm can be completed in $O(c)$ time, so we now turn our attention to the running time of Step II, which consists of a sequence of H decimations with parameters $q_1, q_2, \dots, q_H$. Let L_h be the set of live variables after the hth decimation.

For the first decimation, applied to the set S of PRAM variables ($|S| \leq n$), we choose $q_1 = \lceil (4/\lambda) \lceil \lambda c g \rceil \rceil + 1$. Then, $q_1 \geq 2k/\lambda$ with $k = \lceil (|S|/n) \lambda c g \rceil \leq \lceil \lambda c g \rceil$, and by Lemma 2, $|L_1| \leq n/\lambda c g$. By Lemma 5, this decimation runs in $O(cg + c \log n)$ time.

For the remaining decimations, we choose $q_2 = q_3 = \cdots = q_H = \lceil g2(1-\lambda)/\lambda + 2\rceil$. By Lemma 2, considering that $k = \lceil(|L_h|/n)\lambda cg\rceil \leq \lceil(|L_1|/n)\lambda cg\rceil \leq 1$, for $h \geq 2$ we have $|L_h| \leq |L_{h-1}|/g$. Thus, for $h \geq 2$, $|L_h| \leq |L_1|/g^{h-1} \leq n/\lambda cg^h$. Choosing $H = \lceil \log n/\log g\rceil + 1$ ensures that $L_H = \emptyset$.

By Lemma 5, the hth decimation applied to a set of at most $|L_{h-1}|$ variables runs in time $O(\log n + c + g)$ for each $h \geq 2$.

The total time for Step II, and indeed for the entire simulation, is $O(cg + c\log n + (\log n + c + g)(\log n/\log g))$. Using the choice $g = \log n$ and recalling that $c = \Theta(\log(m/n)/\log g)$, we arrive at the result claimed above. □

5. Lower bound. We begin by stating the assumptions that underlie the known lower bounds as well as the refinement presented here. For a more extended discussion of some points the reader is referred to [AHMP87].

The (n, m)-PRAM to be simulated is of the exclusive-read exclusive-write (EREW) variety, that is, concurrent access to the same memory cell by two different processors is disallowed. Lower bounds for the EREW PRAM clearly apply if concurrent access is allowed.

The PRAM computation to be simulated is an arbitrary sequence of PRAM instructions. Each PRAM instruction consists of either an arbitrary n-tuple of reads or an arbitrary n-tuple of writes. In the lower bound arguments, it is essential that a sequence of $\Omega(m/n)$ instructions be considered and that the addresses to be accessed at each instruction be chosen independently of those in other instructions. In this sense, the sequence is straight-line. The lower bounds do not necessarily apply to sequences generated by running a fixed-sized program on a large enough input. Throughout this section the term *instruction* will be used to refer to the individual steps of a PRAM computation. The term BDN step will refer to a single machine cycle of the underlying n-node BDN.

The simulation is *on line*, in the sense that each PRAM instruction is made known to the BDN only after the simulation of the previous read instructions has been completed.

As for the memory organization, it is assumed that, at any given time, for each PRAM variable u there is a set $C(u)$ of BDN memory cells where the current (last written) value of u is available. The set $C(u)$ is allowed to change with time, even during the simulation of instructions that do not write u. If $u \neq u'$, it is assumed that $C(u)$ and $C(u')$ do not overlap. Thus, at a given time a memory cell can hold the value of at most one variable. The cells in $C(u)$ are sometimes referred to as the valid copies of u.

The memory access protocol is *point to point* in the following sense. If a PRAM processor writes a variable u, then the corresponding BDN node must send a distinct message (with the value to be assigned to u) to each of the BDN nodes containing a cell in $C(u)$. The crucial restriction is that messages directed to different nodes can not be combined, even if they share a portion of their paths. No such assumption is made for read instructions (the lower bound is based only on the fact that at least *one* valid copy must be accessed for each variable read).

The following result was established independently in [AHMP87] and [KU88]:

THEOREM 3. *For all real constants $\epsilon > 0$, and $\epsilon' > 0$, if $m = \Omega(n^{2+\epsilon})$ and $T \geq (1+\epsilon')\lceil m/n\rceil$, then the worst-case simulation time for a straight-line program running for T steps on an* EREW (n, m)-PRAM *is*

$$\Omega\left(T \min\left[\sqrt{n\log n}, \frac{\log m \log n}{\log\log m}\right]\right),$$

for any on-line point-to-point simulation of the PRAM *by an n-processor bounded degree network.*

Under the same assumption, by refining the proof technique of [AHMP87], [KU88], we can extend the lower bound to the range $n \leq m \leq n^{2+\epsilon}$.

THEOREM 4. *For all real constants $\epsilon > 0$, and $\epsilon' > 0$, if $2n < m \leq n^{2+\epsilon}$ and $T \geq (1+\epsilon')\lceil m/n \rceil$, then the worst-case simulation time for a straight-line program running for T steps on an* EREW (n, m)-PRAM *is*

$$\Omega\left(T\frac{\log^2(m/n)}{\log\log(m/n)}\right),$$

for any on-line point-to-point simulation of the PRAM *by an n-processor bounded degree network.*

We first review the ideas behind the proof of Theorem 3 and then indicate the modifications necessary to obtain Theorem 4. For ease of reference, we will use the same notation as in [AHMP87].

The key idea of the approach is the notion of redundancy defined below. Let $G = (V, E)$ be the graph representing the structure of the network. Let d denote the maximum degree of the nodes in the underlying BDN, and let ρ denote the quantity $\lfloor \log(m/2n)/(2\log d) \rfloor - 1$. For each node $v \in V$, let $B(v)$ represent the set $\{x : \delta(v,x) \leq \rho\}$ of nodes where δ is the usual graph-theoretic distance.

Let Γ_u^t denote the set of nodes which contain a valid copy of the variable u at the start of the simulation of the tth instruction of the PRAM program. The *redundancy* of a variable u is defined as follows:

$$r_u^t \triangleq \min_{v \in V} |\Gamma_u^t / B(v)|.$$

The average redundancy over the entire set of variables is $r^t \triangleq \sum_{u \in U} r_u^t / m$.

Intuitively, the average redundancy measures the "accessibility" of the variables: the lower the average redundancy, the harder it will be to simulate read instructions. The following lemma gives a quantitative formulation of this phenomenon.

LEMMA 6. *If $n \leq m \leq n^2$, and the average redundancy before the simulation of a read instruction is r, then there exists a set of n variables that will require $g(r) = \Omega((m/2n)^{1/(8r+2)})$* BDN *steps to read.*

Proof. First observe that if $m < 4d^4 n$, then we are claiming that $g(r) = \Omega(1)$, which is clearly true. Thus we may assume that $m \geq 4d^4 n$, which implies $\rho = \lfloor \log(m/2n)/(2\log d) \rfloor - 1 \geq 1$. Also, $|B(v)| \leq d^{\rho+1} \leq (m/2n)^{1/2}$, for all $v \in V$. Let Γ_x be the set of BDN nodes that contain a valid copy of variable $x \in U$ at the beginning of the instruction being considered, and let $r_x = \min_{v \in V} |\Gamma_x / B(v)|$ be the redundancy of x. Let $U' = \{x \in U : r_x \leq 2r\}$. Clearly $|U'| \geq m/2$. Partition U' into disjoint sets X_v, $v \in V$, so that $X_v \subseteq \{x \in U' : r_x = |\Gamma_x / B(v)|\}$. (Note that some of the X_v may be empty.) We will deal separately with the case $r < \frac{1}{2}$ and the case $r \geq \frac{1}{2}$.

If $r < \frac{1}{2}$, then all the elements of U' have redundancy 0, since each individual variable has redundancy strictly less than one and individual variables can only have integral redundancies. Consider a ball $B(v)$ such that $|X_v|$ is as large as possible, which implies that $|X_v| \geq \lceil m/2n \rceil$. Reading the $\lceil m/2n \rceil$ variables in X_v will clearly require at least

$$\frac{|X_v|}{|B(v)|} \geq \frac{\lceil m/2n \rceil}{(m/2n)^{1/2}} = \Omega((m/2n)^{1/2})$$

steps.

Now suppose that $r \geq \frac{1}{2}$. Without loss of generality we assume that $r \leq (\log(m/2n) - 2)/8$, since otherwise the bound claimed for $g(r)$ is $g(r) = \Omega(1)$ which is obvious. Let $L \subseteq V$ be the set of indices of the $\lceil n/(m/2n)^{1/2+1/8r} \rceil$ largest X_v, and let $X_L = \cup_{v \in L} X_v$. Clearly

$|X_L| \geq (m/2n)|L| \geq n(m/2n)^{1/2-1/8r}$. We also let $B_L = \cup_{v \in L} B(v)$. By the definition of L above, $|L|$ can be expressed in the form $|L| = n/(m/2n)^{1/2+1/8r} + \alpha$, for some real α satisfying $0 \leq \alpha < 1$. Thus

$$|B_L| \leq |L|(m/2n)^{1/2} = \frac{n}{(m/2n)^{1/8r}} + \alpha(m/2n)^{1/2} < \frac{2n}{(m/2n)^{1/8r}},$$

where we have made use of the relations $\alpha < 1, r \geq \frac{1}{2}$, and $m \leq n^2$.

Now for any $W \subseteq V$, let $A_W = \{x \in X_L \ : \ \Gamma_x \subseteq B_L \cup W\}$. Recall that each variable in U' has redundancy at most $2r$ and hence at most $\lfloor 2r \rfloor$. A simple combinatorial argument given in [AHMP87] establishes the following: for any k with $\lfloor 2r \rfloor \leq k \leq n$, there is a subset W of V with $|W| = k$ and

$$|A_W| \geq |X_L| \binom{n - \lfloor 2r \rfloor}{k - \lfloor 2r \rfloor} \Big/ \binom{n}{k} \geq |X_L| \left(\frac{k - \lfloor 2r \rfloor + 1}{n} \right)^{\lfloor 2r \rfloor}.$$

We now choose

$$k = \left\lceil \lfloor 2r \rfloor - 1 + n(m/2n)^{-(1/2-1/8r)(1/\lfloor 2r \rfloor)} \right\rceil.$$

Straightforward manipulations making use of the assumptions $m \leq n^2$ and $r \leq (\log(m/2n) - 2)/8$ show that $k \leq n$. Use of the chosen value of k in the lower bound for $|A_W|$ yields $|A_W| \geq n$. Then we can choose the set of variables to be read in the current instruction as any n-element subset of A_W. Since all of the valid copies of these variables are contained in $|B_L \cup W| \leq |B_L| + |W|$ nodes, it follows that the simulation of that read instruction (in the case where $r \geq \frac{1}{2}$) will require at least

$$\frac{n}{|B_L| + k} = \Omega\left(\min\left(\frac{n}{2r}, \left(\frac{m}{2n}\right)^{(\frac{1}{2} - \frac{1}{8r})\frac{1}{\lfloor 2r \rfloor}}, \quad \left(\frac{m}{2n}\right)^{1/8r} \right) \right) = \Omega\left(\left(\frac{m}{2n}\right)^{1/8r} \right)$$

time. Combining the results for the two subcases $r < \frac{1}{2}$ and $r \geq \frac{1}{2}$, we obtain the stated result. □

A similar lemma, with a different form of g, was obtained in [AHMP87], [KU88] for $m = \Omega(n^{2+\epsilon})$. The two key refinements of the proof technique that enable its application to the range of m in Lemma 6 are the following: (i) the value of ρ is chosen as a function of both m and n, instead of just n, and (ii) in constructing the set of variables that are hard to read, the union of several balls is considered, rather than just one ball.

The next lemma relates the average redundancy to the time spent to simulate the write instructions.

LEMMA 7. *Consider an interval during which an n-node* BDN *simulates a sequence of* (n, m)-PRAM *instructions such that each of the m variables is written at least once. The average redundancy r at the end of the interval and the length t of the interval satisfy the relation*

$$t \geq \rho r m/n. \tag{5}$$

Proof. As a simple consequence of its definition, the redundancy r_u of variable u at the end of the interval is at most the number of copies that are at a distance greater than ρ from the last processor that has written u. Due to the point-to-point assumption, at least ρr_u processor steps can be charged to variable u. Then, (5) follows from the observations that $rm = \sum_{u \in U} r_u$, and that at most tn processor steps are executed in the given interval. □

Proof of Theorem 4. We assume throughout the proof that $2n \leq m \leq n^2$, so that we can invoke Lemma 6. The result for the range $n^2 \leq m \leq n^{2+\epsilon}$, with ϵ a fixed positive constant, trivially follows from the case $m = n^2$.

We define an *adversary program* consisting of $\lceil m/n \rceil + \tau$ PRAM instructions. The first $\lceil m/n \rceil$ are write instructions that initialize all the PRAM variables. The remaining are read instructions chosen according to Lemma 6 so that each require at least $g(r)$ BDN steps to simulate.

Let t_i be the time when the BDN begins to simulate the ith read instruction, assuming that the simulation of the adversary program starts at time 1 and ends at time T_{sim}. Let r^i be the average redundancy at time t_i. Finally, let

$$\begin{aligned} r^* &= \left(\frac{\log(m/2n)}{2\log\log(m/2n) - \log\log\log(m/2n)} - 2 \right) /8 \\ &= \Omega(\log(m/2n)/\log\log(m/2n)), \end{aligned}$$

and observe that

$$g(r^*) = \Omega\left((m/2n)^{1/(8r^*+2)}\right) = \Omega\left(\log^2(m/2n)/\log\log(m/2n)\right).$$

We consider two complementary cases:

1. For some $i \in \{1, 2, \ldots, \tau\}$, $r^i \geq r^*$. Then, from Lemma 7,

$$T_{\text{sim}} \geq t_i \geq \rho r^* m/n = \Omega((m/n)\log^2(m/2n)/\log\log(m/2n)). \tag{6}$$

2. For all $i \in \{1, 2, \ldots, \tau\}$, $r^i < r^*$. Then, from Lemma 6, each read instruction requires at least $g(r^*)$ steps to simulate; hence,

$$T_{\text{sim}} = \Omega(\tau \log^2(m/2n)/\log\log(m/2n)). \tag{7}$$

If $\tau = \lceil \epsilon' m/n \rceil$ with $0 < \epsilon' < 1$, then Theorem 4 follows from the combination of (6) and (7).

The extension to any $\epsilon' > 1$ is easily obtained by applying the above considerations to the concatenation of $\lfloor (1+\epsilon')/2 \rfloor$ blocks, each with the structure of the $2\lceil m/n \rceil$ instruction adversary program defined above. □

A comparison of the lower bound of Theorem 4 with the upper bound provided by Theorem 2 shows that the simulations of §4 are optimal whenever $\Omega(n^{1+\epsilon}) \leq m \leq O(2^{(\log n)^{\alpha}})$ for some positive constants ϵ and α, as claimed in the introduction.

It should be noted that, for $m < n2^{\sqrt{O(\log n \log\log n)}}$, the lower bound of Theorem 4 is weaker than the straightforward $\Omega(T \log n)$ lower bound based on diameter considerations.

6. Conclusions. In this paper optimal point-to-point simulations have been given for a wide range of the memory size m. It is natural to try to close the gap between upper and lower bounds for the remaining values of m. Other important problems related to deterministic PRAM simulations on BDNs are the explicit construction of generalized expanders for the memory organization, the characterization of the complexity of non–point-to-point memory access protocols, and the development of simulations on BDNs with a simpler structure than those proposed in this paper, possibly avoiding the AKS network.

7. Appendix. The techniques of §4 applied to the problem of simulating a step of an exclusive read exclusive write PRAM in which the referenced variables are assumed to be distinct. In this appendix we extend these techniques to handle the concurrent access PRAMs.

In a concurrent read concurrent write PRAM a number of processors may read, or attempt to write to, the same variable in a single PRAM step. For the purposes of this appendix we will assume that in the event of concurrent writes the lowest numbered processor succeeds. The techniques outlined below may be modified to handle other variants of concurrent write PRAMs without too much difficulty. Techniques similar to those outlined here have been employed (implicitly or explicitly) in most of the earlier studies cited in the Introduction (see also [Vis83]). (The terminology of leaders and followers used below is borrowed from [LPP90], which contains a detailed description of the reduction of concurrent access steps to exclusive access steps for the mesh of trees architecture.)

We focus initially on the problem of concurrent read PRAMs and discuss concurrent write PRAMs at the end of the section. Let u_i denote the PRAM variable referenced by the ith PRAM processor P_i^{PRAM}. The variables $u_1, \ldots, u_n$ need not be distinct. To complete this PRAM step a copy of the value of variable u_i must be routed to the ith BDN processor P_i which simulates P_i^{PRAM}. This may be accomplished as follows.

1. Let P_i generate a token labeled with u_i and P_i.

2. For each referenced variable choose one token from among those that refer to it as a *leader*, all other tokens referring to that variable are *followers*.

3. Load each leader token with the value of the corresponding variable.

4. Distribute the value of each leader to its followers and return all tokens to the processors that generated them.

Step 1 requires $O(1)$ time to complete.

Step 2 may be implemented as follows.

(i) Sort the tokens by variable name. (Tokens referring to the same variable are ordered by processor number.)

(ii) For each processor P_i compare the token it holds with that held by P_{i-1}. If the two tokens refer to the same variable let P_i mark its token as a follower; otherwise mark it as a leader. (The token held by P_1 should be marked as a leader.)

Once the tokens have been sorted by variable name, all those referring to the same variable are grouped together in consecutively numbered processors. The token in the lowest numbered processor in each group is chosen as the leader and the others are marked as its followers. The sorting step involves sorting n packets and can be completed in $O(\log n)$ time. The comparison of adjacent tokens will involve a permutation routing step which can also be completed in $O(\log n)$ time.

For each referenced variable there is exactly one leader token. Thus Step 3 is essentially an exclusive read step and so can be completed in $O(\log n \log m / \log\log n)$ time by the results of §4.

Note that following the completion of Step 3 the tokens occupy the same processors they occupied before that step. At this point each leader token is labeled with the value of the appropriate variable which must now be distributed to the followers of that token. Each group of tokens (a leader and its followers) corresponding to a particular variable occupy a contiguous group of processors $P_a, \ldots, P_b$ where P_a holds the leader. Assign a value v_i to each processor as follows. If the token at that processor is a leader then v_i is the value loaded into that token during Step 3; otherwise the v_i is taken to the zero. For each group of processors $P_a, \ldots, P_b$ compute the quantities $w_i = \sum_{k=a}^{i} v_k$ and deposit each w_i in processor P_i. This can be accomplished using a prefix computation as shown in [Sch80] (p. 491) (where the problem is known as the summing-by-groups problem). This step also requires $O(\log n)$ time. It can easily be seen that each w_i within a group is equal to v_a the value of the leader of that group. The various tokens can be routed back to the processors that originated them in $O(\log n)$ time using a permutation routing step.

Summing the contribution of the various steps, it can be seen that any concurrent read PRAM step can be completed in $O(\log n \log m / \log\log n)$ time.

To simulate a concurrent write step execute Steps 1 to 3 of the above with the following modifications. First, each token is marked with the value to be written to the variable in question. Step 3 is an exclusive write step. By the reasoning given above it can be seen that all three steps can be concluded in $O(\log n \log m / \log\log n)$ time.

Acknowledgments. We are greatly indebted to the two referees for their patience and thoroughness in reading an earlier error-filled version of this manuscript. Their numerous valuable suggestions have greatly enhanced the readability of this paper. We also would like to thank Paul Bay for his comments on an earlier version of the manuscript.

LOWER BOUNDS FOR RANDOMIZED k-SERVER AND MOTION-PLANNING ALGORITHMS*

HOWARD KARLOFF†, YUVAL RABANI‡, AND YIFTACH RAVID‡

Abstract. In this paper, the authors prove lower bounds on the competitive ratio of randomized algorithms for two on-line problems: the k-server problem, suggested by Manasse, McGeoch, and Sleator [*Competitive algorithms for on-line problems*, J. Algorithms, 11 (1990), pp. 208–230], and an on-line motion-planning problem due to Papadimitriou and Yannakakis [*Shortest paths without a map*, Lecture Notes in Comput. Sci. 372, Springer-Verlag, New York, 1989, pp. 610–620]. The authors prove, against an oblivious adversary,

1. an $\Omega(\log k)$ lower bound on the competitive ratio of any randomized on-line k-server algorithm in any sufficiently large metric space,
2. an $\Omega(\log \log k)$ lower bound on the competitive ratio of any randomized on-line k-server algorithm in any metric space with at least $k + 1$ points, and
3. an $\Omega(\log \log n)$ lower bound on the competitive ratio of any on-line motion-planning algorithm for a scene with n obstacles.

Previously, no superconstant lower bound on the competitive ratio of randomized on-line algorithms was known for any of these problems.

Key words. competitive analysis, k-server problem, on-line algorithm, motion planning

AMS subject classifications. 68Q25, 93C85

1. Introduction.

On-line algorithms handle sequences of events, each event being handled before future events are known. Among the on-line problems recently studied are paging (Sleator and Tarjan [ST]), on-line vertex coloring (Lovász, Saks, and Trotter [LST]), metrical task systems (Borodin, Linial, and Saks [BLS]), the k-server problem (Manasse, McGeoch, and Sleator [MMS]), layered graph traversal (Baeza-Yates, Culberson, and Rawlins [BCR] and Papadimitriou and Yannakakis [PY]), and on-line motion-planning [PY].

Sleator and Tarjan [ST] suggested comparing on-line algorithms not to each other but to an optimal off-line algorithm that knows the entire sequence in advance. This approach is called *competitive analysis*. We say a (randomized) on-line algorithm A is *c-competitive* if there is a constant a dependent on the initial configuration but independent of the event sequence so that, for all event sequences σ, the (expected) cost incurred by A on σ is at most a plus c times the optimal cost to handle σ. The infimum of all c such that A is c-competitive is A's *competitive ratio*.

In the case of a randomized algorithm it is important to define accurately the power of the adversary (see Raghavan and Snir [RS] and Ben-David et al. [BBKTW]). The *adaptive off-line* adversary may adapt the sequence of requests it produces to the random choices made to date by the on-line algorithm and then pay for the entire sequence optimally. Ben-David et al. show that randomization against this adversary does not improve on-line performance compared with deterministic algorithms [BBKTW]. The *adaptive on-line* adversary adapts the request sequence to the on-line algorithm's random choices. However, it must serve each request before the on-line algorithm serves it, and therefore the cost of this adversary might be far from optimal. Ben-David et al. show that randomization against this adversary cannot help much. If there exists a c-competitive randomized algorithm against an adaptive on-line adversary, then there exists a c^2-competitive deterministic algorithm [BBKTW]. This paper

deals with the *oblivious* adversary, the weakest of the three and the "traditional" adversary. In contrast to adaptive adversaries, the oblivious adversary must fix the sequence of requests in advance and then pay for it optimally. Randomization can be used by the on-line algorithm to "hide" its choices from the oblivious adversary.

We study the k-server and motion-planning problems. In the *k-server problem*, k servers move among the points of a metric space $\mathcal{M}$, serving requests. A *request* is a point of $\mathcal{M}$. To *serve* the request means to move a server to the request site. The algorithm pays a price equal to the distance moved. Requests are served *on-line*. This means that each request is served before future requests are known. Manasse et al. proved that in every metric space on at least $k+1$ points there is a lower bound of k on the competitive ratio of any deterministic on-line k-server algorithm [MMS]. This lower bound is also applicable for randomization against adaptive adversaries but not for randomization against an oblivious adversary. Manasse et al. also conjectured that for every metric space and every k, there is a deterministic k-competitive on-line algorithm [MMS]. They proved their conjecture for $k = 2$ and for $k = n - 1$, where n is the cardinality of the (finite) metric space. This conjecture was proven for uniform metric spaces [ST] and for the infinite metric space that is isomorphic to the real line by Chrobak et al. [CKPV]. Chrobak and Larmore [CL] generalized the result to infinite metric spaces that are isomorphic to trees. Deterministic competitive algorithms for all metric spaces and all k were given by Fiat, Rabani, and Ravid [FRR]. Grove [Ge] proved that the so-called Harmonic randomized server algorithm, suggested by Raghavan and Snir [RS], is competitive for all k.

A searcher in the on-line motion-planning model of Papadimitriou and Yannakakis [PY] is a point particle that starts at a point s in the Euclidean plane and moves to a known target. In our version of the problem, the target is a vertical line, and the searcher need only reach a point of his own choosing on it. However, the plane is peppered with stationary open rectangular obstacles that are disjoint from each other and from the source s and target t. Each rectangle has integral side lengths. The searcher can "see" only those obstacles that are connected by an obstacle-free line segment to the searcher's position. We compare the cost incurred by the searcher to the length of a shortest obstacle-free source-target path, which is the cost incurred by an optimal algorithm that sees the entire scene. Papadimitriou and Yannakakis gave an $\Omega(\sqrt{n})$ lower bound on the ratio between the cost of a deterministic on-line algorithm and the optimal cost in a scene containing n rectangles [PY].

The use of randomization against an oblivious adversary has indeed led to superior algorithms. Fiat et al. exhibited a randomized paging algorithm with a competitive ratio bounded by $2\mathcal{H}_k$, where $\mathcal{H}_k = 1 + \frac{1}{2} + \cdots + \frac{1}{k} \sim \ln k$ [FKLMSY] (a different algorithm was subsequently proven $\mathcal{H}_k$-competitive by McGeoch and Sleator [MS]). This is to be contrasted with the lower bound of k for a deterministic paging algorithm. Fiat et al. also proved a lower bound of $\mathcal{H}_k$ for the competitive ratio of randomized paging algorithms [FKLMSY]. They conjectured that $\mathcal{H}_k$ is an upper bound for all metric spaces and all k. This conjecture was disproved by Karlin et al. [KMMO], who exhibited a family of 3-point metric spaces and a lower bound approaching $\frac{e}{e-1} > 1.5 = \mathcal{H}_2$ for the competitive ratio of any randomized 2-server algorithm for those metric spaces.

Vishwanathan showed how to color 3-colorable graphs on-line with only $O(\sqrt{n \log n})$ colors [Vn], a great improvement over the $O((n \log\log\log n)/\log\log n)$ bound of [LST]. An exponential improvement in the performance of algorithms that traverse certain layered graphs was exhibited by Fiat et al. [FFKRRV].

No superconstant lower bound was known for the competitive ratio of general metric spaces (with at least $k+1$ points). Indeed, several researchers conjectured that constant-competitive randomized k-server algorithms exist for certain infinite metric spaces. No superconstant lower bound for the on-line motion-planning problem was known either.

We prove two k-server lower bounds:

1. The competitive ratio of any randomized k-server algorithm for any sufficiently large metric space is $\Omega(\log k)$.

2. The competitive ratio of any randomized k-server algorithm for *any* metric space with at least $k + 1$ points is $\Omega(\log \log k)$.

In light of the [FKLMSY] algorithm, the first result is tight to within a constant factor.

Blum, Raghavan, and Schieber [BRS] used randomized k-server algorithms to construct randomized on-line motion-planning algorithms. Instead, we adapt randomized k-server lower bounds to prove a lower bound for the on-line motion-planning problem:

3. The competitive ratio of any randomized motion-planning algorithm is $\Omega(\log \log n)$, where n is the number of obstacles in the scene.

The proof of the first result goes as follows. First, we prove that for a *superincreasing* metric space $\mathcal{M}(k)$, a metric space on $\{z_0, z_1, \ldots, z_k\}$ with the distance from z_i to z_{i+1} much greater than that from z_{i-1} to z_i, no sublogarithmic competitive ratio is possible. This part of the proof generalizes techniques of Karlin et al. [KMMO]. Next, we prove a "Ramsey-like" theorem for metric spaces: every sufficiently large metric space $\mathcal{M}$ contains a $(k + 1)$-point subspace resembling either the superincreasing metric space or the uniform metric space. From the $\Omega(\log k)$ lower bounds for the superincreasing and uniform metric spaces we construct an $\Omega(\log k)$ lower bound for $\mathcal{M}$.

For $(k + 1)$-point metric spaces, we will use the Ramsey-like theorem to generate a set $\mathcal{S}$ of $s + 1$ points (where $s = \lceil \sqrt{\lg(k + 1)} \rceil$) that resembles either the superincreasing or uniform metric space. The $k - s$ servers initially on the $k - s$ points outside of $\mathcal{S}$ can be fixed at their initial locations by replacing a request to a point $z \in \mathcal{S}$ by a long sequence of requests to z and all the points outside of $\mathcal{S}$. Thus the on-line algorithm can be forced to use only s servers on the specified $s + 1$ points. We can use the first result to get an $\Omega(\log s)$ bound, and this is $\Omega(\log \log k)$.

The idea for the motion-planning result is to construct an obstacle scene in which the distance moved by an on- or off-line server to reach the target is approximately the cost incurred by a k-server algorithm when serving a sequence of requests in a metric space that resembles $\mathcal{M}(k)$. The lower bound for $\mathcal{M}(k)$ will yield a lower bound on the competitive ratio of motion-planning algorithms.

2. The superincreasing metric space.

Define $c_1 = 1$, and let

$$c_i = c_{i-1} \left[1 + 1/(2e^{2c_{i-1}} - 1) \right]$$

for $i \geq 2$.

DEFINITION. *Let $k \geq 0$, and let $\mathcal{M}(k)$ be a metric space on $k + 1$ points $z_0, z_1, z_2, \ldots, z_k$. Suppose that there are integers $d_1 < d_2 < d_3 < \cdots < d_k$ so that $d_1 = 1$ and that for $i < j$,* $\operatorname{dist}(z_i, z_j) = d_j$. *Then the sequence $d_1, d_2, d_3, \ldots, d_k$ and the metric space $\mathcal{M}(k)$ are called* superincreasing *if $d_i \geq (4c_{i-1}e^{2c_{i-1}})d_{i-1}$ for every $i \geq 2$.*

We will often use $\mathcal{M}(k)$ to mean any superincreasing metric space on $k + 1$ points.

For the metric space $\mathcal{M}(k)$, we prove that $c_k - 1$ is a lower bound on the competitive ratio of any on-line (randomized) k-server algorithm.

The following lemmas show that c_k is $\Theta(\log k)$.

LEMMA 2.1. *$c_k > \frac{1}{2} \ln k$ for all k.*

Proof. The definition of c_i gives the following:

$$c_k - c_{k-1} = \frac{c_{k-1}}{2e^{2c_{k-1}} - 1},$$

or

$$(c_k - c_{k-1})(2e^{2c_{k-1}} - 1) = c_{k-1} \geq 1,$$

or

$$(c_k - c_{k-1})e^{2c_{k-1}} \geq \tfrac{1}{2}.$$

Now, if f is a nondecreasing continuous function and $x_1 < x_2 < \cdots < x_r$, then

$$\int_{x_1}^{x_r} f(x)\,dx \geq \sum_{i=2}^{r} (x_i - x_{i-1}) f(x_{i-1}).$$

Thus

$$\int_{c_1}^{c_k} e^{2x}\,dx \geq \sum_{j=2}^{k} (c_j - c_{j-1}) e^{2c_{j-1}} \geq \frac{k-1}{2}.$$

Therefore,

$$\frac{e^{2c_k} - e^{2c_1}}{2} \geq \frac{k-1}{2},$$

$$e^{2c_k} \geq e^2 + (k-1) > k, \qquad 2c_k > \ln k, \qquad c_k > \tfrac{1}{2}\ln k. \qquad \square$$

LEMMA 2.2. *For all k, $c_k \leq 1 + 1.5 \ln k$.*

Proof. For all y, $1 + y \leq e^y$. Therefore, $1 + y \leq 2e^{2y}$ for all $y \geq 0$.

$$1 + c_{k-1} \leq 2e^{2c_{k-1}},$$

$$c_{k-1} \leq 2e^{2c_{k-1}} - 1.$$

Therefore,

$$\frac{c_{k-1}}{2e^{2c_{k-1}} - 1} \leq 1,$$

$$c_k - c_{k-1} = \frac{c_{k-1}}{2e^{2c_{k-1}} - 1} \leq 1.$$

Therefore, $c_k \leq k$ for all k.

$$\begin{aligned}
(c_k - c_{k-1})2e^{2c_{k-1}} &= c_{k-1} + (c_k - c_{k-1}) = c_k,\\
(c_k - c_{k-1})2e^{2c_k} &\leq (c_k - c_{k-1})2e^{2+2c_{k-1}}\\
&= e^2(c_k - c_{k-1})2e^{2c_{k-1}}\\
&= e^2 c_k \leq ke^2.
\end{aligned}$$

Therefore,

$$(c_k - c_{k-1})2e^{2c_k} \le ke^2,$$

$$(c_k - c_{k-1})e^{2c_k} \le \frac{ke^2}{2}.$$

If f is continuous and nondecreasing and $x_1 < x_2 < \cdots < x_r$, then

$$\int_{x_1}^{x_r} f(x)\,dx \le \sum_{i=2}^{r}(x_i - x_{i-1})f(x_i).$$

Hence

$$\int_{c_1}^{c_k} e^{2x}\,dx \le \sum_{i=2}^{k}(c_i - c_{i-1})e^{2c_i} \le \sum_{i=2}^{k}\frac{ke^2}{2} \le \frac{k^2e^2}{2}.$$

Thus

$$\frac{e^{2c_k} - e^{2c_1}}{2} \le \frac{k^2e^2}{2},$$

so that

$$e^{2c_k} \le e^2 + k^2e^2 = e^2(k^2+1).$$

Hence

$$c_k \le \frac{2 + 3\ln k}{2} = 1 + 1.5\ln k. \qquad \square$$

Let us generalize the k-server problem. The *multipoint k-server problem* is the problem of serving requests each of which consists of a *set* of at most k points. (A request to $\{z\}$ will be abbreviated as z.) To serve the request means to move one or more servers so that *all* the points in the requested set are covered. We will only study multipoint k-server problems on $(k+1)$-point metric spaces. This allows us to assume without loss of generality that the algorithm is *lazy*—it never moves more than one server to serve a request, and if the requested set is already covered, it does nothing.

In $\mathcal{M}(k)$, let τ_i be the set $\{z_1, z_2, z_3, \ldots, z_i\}$. Let γ_i be the set $\{z_0, z_1, z_2, \ldots, z_{i-1}\}$. Let $N_1, N_2, N_3, \ldots$ denote the integer sequence $N_1 = 2$ and $N_i = (2d_i)N_{i-1} + 2$ for $i \ge 2$.

Fix k and a lazy, randomized multipoint k-server algorithm A for $\mathcal{M}(k)$. If $1 \le i \le k$, say a request sequence σ is *i-convergent for A*, or simply *i-convergent*, if A covers τ_i with probability 1 just after σ is served.

LEMMA 2.3. *For each $1 \le i \le k$, for each i-convergent request sequence σ for $\mathcal{M}(k)$, there is a request sequence Δ with the following properties*:

1. *Δ consists of a request sequence for $\mathcal{M}(i-1)$ preceded immediately by a request to z_0 and followed immediately by a request to τ_i. (Thus $\sigma\Delta$ is i-convergent.)*
2. *The length of Δ is at most N_i.*
3. *Suppose A serves request sequence $\sigma\Delta$. Let $s_1, s_2, \ldots, s_i$ be the servers that occupy $\{z_1, z_2, \ldots, z_i\}$ just after σ is served, s_j occupying z_j. Let $t = P[z_0$ is vacant just after A has served $\sigma\Delta]$. Define the i-*cost *of Δ to be the cost incurred*

by $s_1, s_2, \ldots, s_i$ during the time A is serving the Δ of $\sigma\Delta$. Let $w \in \{1, 2, \ldots, 2d_i\}$ be the optimal cost of serving Δ by an i-server algorithm whose servers start on $\{z_1, \ldots, z_i\}$. Then the expected i-cost of Δ is at least $c_i wt$.

Intuitively, the reason why such a costly sequence Δ exists is that the on-line algorithm does not know in advance how many requests in $\mathcal{M}(i-1)$ will be given before the request to τ_i. Suppose that z_0 is vacant prior to the arrival of Δ. If only a few requests in $\mathcal{M}(i-1)$ appear, it makes little sense to move a server on one of the distant points $\{z_i, \ldots, z_k\}$ and pay a high price. If there are many requests, however, a distant server must be moved in order to avoid indefinitely having to shuffle $i-1$ servers among the i points of $\mathcal{M}(i-1)$.

To prove Lemma 2.3, we need a technical lemma, the proof of which appears in the appendix.

LEMMA 2.4. *Let $2 \le i \le k$. Let ℓ be an integer, $\ell \ge c_{i-1}$. Let $d \ge 4c_{i-1}e^{2c_{i-1}}\ell$ be an integer. Let $w_1, w_2, \ldots, w_Q \in \{1, 2, \ldots, 2\ell\}$ where Q satisfies $\sum_{i=1}^{Q-1} w_i < 2d \le \sum_{i=1}^{Q} w_i$. Let $p_1, p_2, \ldots, p_{Q-1} \in [0, 1]$.*

Then either

$$d + c_{i-1} \sum_{s=1}^{Q-1} p_s w_s \ge c_i(2d)$$

or there is an $h \in \{1, 2, \ldots, Q-1\}$ such that

$$d(1-p_h) + c_{i-1} \sum_{s=1}^{h} p_s w_s \ge c_i \sum_{s=1}^{h} w_s.$$

Proof of Lemma 2.3. By induction on i.

Basis: $i = 1$. Let $\Delta = z_0 z_1$. The optimal cost w of serving Δ by a 1-server algorithm whose server starts on z_1 is 2. Algorithm A leaves z_0 vacant after serving $\sigma\Delta$ with probability t, so with probability at least t server s_1 must have served both requests, incurring an expected i-cost of at least $2t = c_i wt$.

Inductive Step: $i > 1$. Let σ be an i-convergent request sequence for $\mathcal{M}(k)$. It is also $(i-1)$-convergent. By induction, there is a request sequence Δ_1 (of length at most N_{i-1}) consisting of a request sequence for $\mathcal{M}(i-2)$ preceded by a request to z_0 and followed by a request to τ_{i-1} such that the following holds. If A serves $\sigma\Delta_1$, the expected $(i-1)$-cost incurred while serving Δ_1 is at least $c_{i-1}w_1t_1$ (where $w_1 \in \{1, 2, \ldots, 2d_{i-1}\}$ is the optimal cost of serving Δ_1 with $i-1$ servers and t_1 is the probability that z_0 is vacant after $\sigma\Delta_1$ is served).

Since $\sigma\Delta_1$ is $(i-1)$-convergent, we can apply induction again. Thus there is a Δ_2 (of length at most N_{i-1}) consisting of a request sequence for $\mathcal{M}(i-2)$ preceded by a request to z_0 and followed by a request to τ_{i-1} such that the following holds. If A serves $\sigma\Delta_1\Delta_2$, the expected $(i-1)$-cost incurred while serving Δ_2 is at least $c_{i-1}w_2t_2$ (where $w_2 \in \{1, 2, \ldots, 2d_{i-1}\}$ is the optimal cost of serving Δ_2 with $i-1$ servers and t_2 is the probability that z_0 is vacant after $\sigma\Delta_1\Delta_2$ is served).

Since $\sigma\Delta_2$ is $(i-1)$-convergent, we can apply induction again. Thus there is a Δ_3 (of length at most N_{i-1}) consisting of a request sequence for $\mathcal{M}(i-2)$ preceded by a request to z_0 and followed by a request to τ_{i-1} such that the following holds. If A serves $\sigma\Delta_1\Delta_2\Delta_3$, the expected $(i-1)$-cost incurred while serving Δ_3 is at least $c_{i-1}w_3t_3$ (where $w_3 \in \{1, 2, \ldots, 2d_{i-1}\}$ is the optimal cost of serving Δ_3 with $i-1$ servers and t_3 is the probability that z_0 is vacant after $\sigma\Delta_1\Delta_2\Delta_3$ is served).

Repeat this process, getting $\Delta_1, \Delta_2, \ldots, \Delta_Q$ and $w_1, w_2, \ldots, w_Q$ such that $w_1 + w_2 + \cdots + w_Q \geq 2d_i$ but $w_1 + \cdots + w_{Q-1} < 2d_i$. Now change Δ_Q—replace it by $\Delta_Q \gamma_i$.

Let "time j" mean "just after $\sigma\Delta_1 \cdots \Delta_j$ has been served." Let $t_j = P[z_0$ is vacant at time $j]$. Let $u_j = P[z_i$ is vacant at time $j]$, and let $r_j = t_j + u_j$, the probability that either z_0 or z_i is vacant at time j. Because $r_j = P[z_{i+1}, z_{i+2}, \ldots, z_k$ are occupied at time $j]$ (even for $j = Q$), we have $r_1 \geq r_2 \geq \cdots \geq r_Q$. Let

$$q_j = \begin{cases} u_j/r_j & \text{if } r_j \neq 0, \\ 1 & \text{otherwise.} \end{cases}$$

Note that $r_j q_j = u_j$ always. The expected $(i-1)$-cost of phase $j < Q$ is at least

$$c_{i-1} w_j t_j = c_{i-1} w_j (r_j - u_j) = c_{i-1} w_j r_j (1 - q_j).$$

Clearly $t_Q = 0$. Therefore, $r_Q = u_Q$, so $q_Q = 1$. (Of course, the expected $(i-1)$-cost of phase Q is at least $0 = c_{i-1} w_Q r_Q (1 - q_Q)$.) $\Delta_1\Delta_2 \cdots \Delta_Q$ is a request sequence for $\mathcal{M}(i-1)$ preceded by a request to z_0.

Choose $1 \leq h \leq Q$. The expected cost incurred by s_i to serve $\Delta_1\Delta_2 \cdots \Delta_h \tau_i$ (after A has already served σ) is at least $d_i u_h$, since z_i is occupied just after σ is served. Thus the expected i-cost, if we have $h \leq Q$ phases, is at least

$$\begin{aligned} d_i u_h + \textstyle\sum_{j=1}^{h} c_{i-1} w_j r_j (1 - q_j) &\geq r_h (d_i q_h) + c_{i-1} r_h \textstyle\sum_{j=1}^{h} w_j (1 - q_j) \\ &= r_h \left(d_i q_h + c_{i-1} \textstyle\sum_{j=1}^{h} w_j (1 - q_j)\right) \end{aligned}$$

and $q_Q = 1$. When $h = Q$, this last quantity is

$$r_Q \left(d_i + c_{i-1} \sum_{j=1}^{Q-1} w_j (1 - q_j)\right).$$

By Lemma 2.4, with $\ell = d_{i-1}$, $d = d_i$, and $p_s = 1 - q_s$ for all s, either

$$d_i + c_{i-1} \sum_{j=1}^{Q-1} w_j (1 - q_j) \geq c_i (2d_i)$$

or there is an $h \in \{1, 2, \ldots, Q-1\}$ such that

$$d_i q_h + c_{i-1} \sum_{j=1}^{h} w_j (1 - q_j) \geq c_i \sum_{j=1}^{h} w_j.$$

In the former case, the optimal cost incurred by an adversary having i servers in serving $\Delta_1\Delta_2 \cdots \Delta_Q \tau_i$ after serving σ equals $2d_i$. A's expected i-cost to serve the same sequence after serving σ is at least $r_Q[c_i(2d_i)]$. Let $\Delta = \Delta_1\Delta_2 \cdots \Delta_Q \tau_i$. If z_0 is vacant after $\sigma\Delta$ is served, then either z_0 or z_i is vacant after $\sigma\Delta_1\Delta_2 \cdots \Delta_Q$ is served. Thus the probability t that z_0 is vacant after $\sigma\Delta$ is served is at most r_Q, and therefore Δ suffices, since Δ's length is at most $(2d_i)N_{i-1} + 2 = N_i$. ($Q \leq 2d_i$ since $w_j \geq 1$ for all j.)

In the latter case, the optimal cost incurred by an i-server adversary in serving $\Delta_1\Delta_2 \cdots \Delta_h \tau_i$ after serving σ is at most $\sum_{j=1}^{h} w_j$. A's expected i-cost to serve the same sequence after serving σ is at least $r_h c_i \sum_{j=1}^{h} w_j$. Let $\Delta = \Delta_1\Delta_2 \cdots \Delta_h \tau_i$. If z_0 is vacant after $\sigma\Delta$ is served, then either z_0 or z_i is vacant after $\sigma\Delta_1\Delta_2\cdots\Delta_h$ is served. Thus the probability t that z_0 is vacant after $\sigma\Delta$ is served is at most r_h, and therefore Δ suffices. □

We use the notation $\mathrm{OPT}(\sigma)$ to denote the optimal off-line multipoint cost to serve σ, and we use $A(\sigma)$ to denote the (random) cost of our on-line multipoint algorithm A to serve σ.

THEOREM 2.5. *For all r, there is a multipoint request sequence σ_r of length at most rN_k and optimal cost at least r such that*

$$E[A(\sigma_r)] \geq c_k \cdot \mathrm{OPT}(\sigma_r).$$

Proof. Take $i = k$. Build request sequence $\sigma_r = \Delta_1\Delta_2\Delta_3\cdots\Delta_r$ via repeated applications of Lemma 2.3, by constructing Δ_1, then Δ_2, then Δ_3, and so on. Each Δ_j has length at most N_k. The optimal cost of serving Δ_j with k servers is $w_j \geq 1$. Each time the lemma is applied, $t = 1$.

$$\mathrm{OPT}(\sigma_r) = w_1 + w_2 + \cdots + w_r.$$

(We have equality because each Δ_j ends with τ_k.) The expected value of $A(\sigma_r)$ is at least $c_k w_1 + c_k w_2 + \cdots + c_k w_r = c_k \cdot \mathrm{OPT}(\sigma_r)$. □

COROLLARY 2.6. *There is no c-competitive multipoint k-server algorithm for $\mathcal{M}(k)$ if $c < c_k$.*

DEFINITION. *Let $\mathcal{M}$ be a metric space on the $k+1$ points $\{z_0, z_1, \ldots, z_k\}$. Let $S \subsetneq \mathcal{M}$, $S \neq \emptyset$. Say an S-*request *is a sequence of requests to all $|S|$ points in S, one at a time, in increasing order by index.*

DEFINITION. *Let $\mathcal{M}$ be a metric space on the $k+1$ points $\{z_0, z_1, \ldots, z_k\}$. We say a (single-point) server algorithm A for $\mathcal{M}$ is finitely converging if it has the following property. Let α be a request sequence, and let $S \subsetneq \mathcal{M}$, $S \neq \emptyset$. If A serves a sequence consisting of α followed by enough S-requests, then at the end all the points in S are occupied with probability one.*

LEMMA 2.7. *Let $\mathcal{M}$ be a metric space on $k+1$ points. If there is a lazy, c-competitive, finitely converging algorithm for the single-point k-server problem on $\mathcal{M}$, then there is a lazy, c-competitive multipoint k-server algorithm for $\mathcal{M}$.*

Proof. Suppose A is a lazy, finitely converging c-competitive k-server algorithm for $\mathcal{M}$. We argue that there is a lazy, c-competitive multipoint k-server algorithm B for $\mathcal{M}$. Let σ be a multipoint request sequence for $\mathcal{M}$. B simulates A on a single-point request sequence σ' for $\mathcal{M}$. B constructs σ' on the fly by replacing a request to the set S in σ by a long sequence of S-requests. The.number of these S-requests is chosen so large that A is known to cover S with probability one after serving the S-requests. Further, the number is chosen so large that even the adversary is known to cover S afterward.

To serve a request to S, B flips coins for A and "watches" A's behavior on the long string of S-requests. At the end, B moves to A's configuration by moving at most one server.

Let OPT and OPT′ denote the optimal costs of a multipoint and single-point request sequence, respectively. $B(\sigma) \leq A(\sigma')$ and hence

$$E[B(\sigma)] \leq E[A(\sigma')] \leq c \cdot \mathrm{OPT}'(\sigma') + a$$

for a suitable a. But $\mathrm{OPT}(\sigma) = \mathrm{OPT}'(\sigma')$, and thus B is a lazy, c-competitive, multipoint k-server algorithm for $\mathcal{M}$. □

THEOREM 2.8. *There is no lazy, finitely converging c-competitive algorithm for the single-point k-server problem on $\mathcal{M}(k)$ if $c < c_k$.*

Proof. Follows from Corollary 2.6 and Lemma 2.7. □

Now we relate finitely converging and nonfinitely converging algorithms.

LEMMA 2.9. *Suppose that A is a lazy, c-competitive k-server algorithm for a $(k+1)$-point metric space M. Then there is a lazy, finitely converging $(c+1)$-competitive k-server algorithm A' for M.*

Proof sketch. Let the points of M be ordered $z_0, z_1, \ldots, z_k$. Without loss of generality, suppose that the minimum nonzero distance in M equals one and the maximum distance equals, say, D. Choose $a \geq 0$ such that $E[A(\sigma)] \leq c \cdot \mathrm{OPT}(\sigma) + a$ for all σ.

At all times, A' simulates either A or the deterministic, lazy, k-competitive algorithm BAL of [MMS], initially the former. A long sequence of S-requests will ensure that A fails to occupy all the points of S with probability approaching zero, for otherwise it could not be competitive. (Indeed, enough S-requests will ensure that any given competitive algorithm, on-line or off-line, occupies S with probability approaching one. The adversary himself can be forced to occupy S in this way.)

At all times, A' attempts to write the list of requests seen to date, including the current request, as τS^L, where

$$L = L(\tau) = 1 + \lceil k^2 D|\tau|^2(c|\tau| + 2cD + a)\rceil.$$

(Here, S represents an S-request.) If it fails, it simply flips coins and serves the request as A would have. If it succeeds—and in this case τ and S are unique—A' flips its coins to simulate A on the current request. If the coin flips dictate that A move to a configuration covering S, A' continues to mimic A. Otherwise, A' switches to BAL in a lazy way, never to return to A. If the next $|S|$ requests are an S-request, then L is so large that after those requests are served A' covers S. Thus A' covers S with probability one by the time it has served τS^{L+1}.

It is not hard to prove that L is so large that the probability that A' switches to BAL when the list of requests seen to date is of the form τS^L is at most $1/(k^2 D|\tau|^2)$. Therefore, the probability that A' ever switches to BAL is at most $\sum_{l=1}^{\infty} 1/(k^2 D l^2) \leq 2/(k^2 D)$. Now $A'(\sigma) = A(\sigma)$ if A' never switches to BAL, and $A'(\sigma) \leq A(\sigma) + (D + \mathrm{BAL}(\sigma))$ if A' does switch.

$$\begin{aligned} D + \mathrm{BAL}(\sigma) &\leq D + \left(k \cdot \mathrm{OPT}(\sigma) + \binom{k}{2} D\right) \\ &\leq k \cdot \mathrm{OPT}(\sigma) + (k^2/2)D. \end{aligned}$$

Therefore,

$$\begin{aligned} E[A'(\sigma)] &\leq E[A(\sigma)] + (k \cdot \mathrm{OPT}(\sigma) + \frac{k^2}{2} D) \cdot P[A' \text{ switches to BAL}] \\ &\leq E[A(\sigma)] + \frac{2}{kD} \cdot \mathrm{OPT}(\sigma) + 1 \\ &\leq E[A(\sigma)] + (\mathrm{OPT}(\sigma) + 1) \\ &\leq (c+1) \cdot \mathrm{OPT}(\sigma) + (a+1). \qquad \Box \end{aligned}$$

THEOREM 2.10. *There is no c-competitive algorithm A for the single-point k-server problem on $\mathcal{M}(k)$ if $c < c_k - 1$.*

Proof. Lemma 2.9 proves that the existence of a c-competitive algorithm implies the existence of a lazy, finitely converging $(c+1)$-competitive algorithm. Theorem 2.8 completes the proof. □

3. Ramsey theory for metric spaces. This section deals with the structure of metric spaces. Theorem 3.2 shows that every metric space of cardinality n contains either a roughly uniform subset of at least $\frac{1}{2}\lg n$ points or an approximately superincreasing sequence of $\Omega((\lg n)/\lg\lg n)$ points.

LEMMA 3.1. *Let $\mathcal{M}$ be a metric space on n points, $w(e)$ denoting the length of edge e, and let $c > 1$ be a real. $\mathcal{M}$ contains either*:

1. *a subset S of size at least $s = \lg n$ such that the distances within S differ by no more than a factor of c^2 or*

2. *a point P and a subset T of size at least $t = n/\lg n$ such that $P \notin T$ and*

$$\frac{\min_{x\in T} d(x, P)}{\max_{x,y\in T} d(x, y)} \geq \frac{c}{4} - \frac{1}{2}.$$

Proof. We may assume $n \geq 3$. Label edge e with $\lfloor \log_c w(e) \rfloor$. Let j be the largest label, and call those edges labeled j or $j-1$ *large* and the rest, if any, *small*. Build a graph G on the points of $\mathcal{M}$: $\{u, v\} \in E(G)$ if and only if $\{u, v\}$ is small in $\mathcal{M}$. The value of d, a nonnegative real, will be chosen later.

If every vertex in G has degree at most d, then G has an independent set S of size at least $n/(d+1)$. (The greedy independent set algorithm generates such an S.) If u and v are distinct points of S, $\{u, v\}$ is large. But the lengths of two large edges cannot differ by more than a factor of c^2.

Otherwise, some vertex v has degree exceeding d. Let $\{a, b\}$ be the longest edge in the metric space, labeled so that $d(a, v) \geq d(b, v)$; $d(a, v) \geq \frac{1}{2}d(a, b) \geq \frac{1}{2}c^j$. Let T be v together with its neighborhood in G. All edges between points in T are of length less than $2c^{j-1}$. If $x \in T$,

$$d(a, x) \geq d(a, v) - d(v, x) \geq \tfrac{1}{2}c^j - c^{j-1}.$$

Thus

$$\frac{\min_{x\in T} d(x, a)}{\max_{x,y\in T} d(x, y)} \geq \frac{c^j/2 - c^{j-1}}{2c^{j-1}} = \frac{c}{4} - \frac{1}{2}.$$

We have found either a set S of size at least $n/(d+1)$ whose interpoint distances differ by at most a factor of c^2 or a set T for which

$$\frac{\min_{x\in T} d(x, a)}{\max_{x,y\in T} d(x, y)} \geq \frac{c}{4} - \frac{1}{2}$$

with $|T| > 1 + d$. Taking $d = (n/\lg n) - 1$ and $P = a$, the proof is complete. □

THEOREM 3.2. *Let $\mathcal{M}$ be a metric space on n points, and let $c > 1$. $\mathcal{M}$ contains either*

1. *a subset of size at least $\frac{1}{2}\lg n$ whose interpoint distances differ by at most a factor of c^2 or*

2. *a sequence of distinct vertices $P_1, P_2, \ldots, P_t$ for $t = \lceil \frac{1}{2}(\lg n)/\lg\lg n \rceil - 1$ such that*

$$\frac{\min_{j>i} d(P_j, P_i)}{\max_{j>i+1} d(P_j, P_{i+1})} \geq \frac{c}{4} - \frac{1}{2}$$

for $i = 1, 2, \ldots, t-2$.

Proof. Construct a sequence of metric spaces $\mathcal{M} = \mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3, \ldots, \mathcal{M}_r$ and a set of points $P_1, P_2, \ldots, P_{r-1}$ (P_i in $\mathcal{M}_i$) as follows. Apply Lemma 3.1 to $\mathcal{M}_i$. If case 1 is true (where $n = |\mathcal{M}|$, not $|\mathcal{M}_i|$), halt. If case 2 is true but T has fewer than $\sqrt{n}$ points, halt without constructing $\mathcal{M}_{i+1}$. Otherwise, let P_i be the point P of case 2 and $\mathcal{M}_{i+1}$ be the metric space induced by T.

If case 1 is ever true, we have a set of at least $\lg \sqrt{n} = \frac{1}{2} \lg n$ points within the current metric space whose interpoint distances differ by at most c^2. Otherwise, since

$$|\mathcal{M}_{i+1}| \geq \frac{|\mathcal{M}_i|}{\lg |\mathcal{M}_i|} \geq \frac{|\mathcal{M}_i|}{\lg n},$$

the number r of metric spaces we construct satisfies $n/(\lg n)^r < \sqrt{n}$, i.e., $r > \frac{1}{2}(\lg n)/\lg\lg n$. The $r-1$ P's satisfy condition 2 above. □

4. General lower bounds.

LEMMA 4.1. *Let $\mathcal{M}$ and $\mathcal{M}'$ be two metric spaces defined on the same set of points with distance functions d and d', respectively. Let $b \geq 1$. Suppose that for every two points x, y, $d'(x, y) \leq d(x, y) \leq b \cdot d'(x, y)$. Let c be a lower bound on the competitive ratio for $\mathcal{M}'$. Then c/b is a lower bound on the competitive ratio for $\mathcal{M}$.*

Proof. The cost of serving σ in $\mathcal{M}$ is bounded above and below by b times and one times the cost of serving it in $\mathcal{M}'$, respectively. □

LEMMA 4.2. *Let $b \geq 1$, and let $\mathcal{M}$ be a metric space where*

$$\frac{\max_{x,y\in\mathcal{M}} \operatorname{dist}(x, y)}{\min_{x\neq y\in\mathcal{M}} \operatorname{dist}(x, y)} \leq b.$$

Then the competitive ratio for any randomized on-line k-server algorithm for $\mathcal{M}$ is at least $\mathcal{H}_k/b$, where $\mathcal{H}_k = 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{k}$ is the kth harmonic number.

Proof. Scale the distances in $\mathcal{M}$ so that the minimum nonzero distance is 1. Apply Lemma 4.1 and the lower bound of $\mathcal{H}_k$ for a uniform metric space [FKLMSY]. □

LEMMA 4.3. *Let $\mathcal{M}$ be a metric space defined on the $k + 1$ points $\{x_0, \ldots, x_k\}$ by the distance function d, which satisfies*:

1. $d(x_0, x_1) = 1$ *and*
2. *for every i, $1 < i \leq k$,*

$$\frac{\min_{j<i} d(x_j, x_i)}{\max_{j<i-1} d(x_j, x_{i-1})} \geq 8c_{i-1}e^{2c_{i-1}}.$$

Then $(c_k - 1)/4$ is a lower bound on the competitive ratio of any on-line randomized k-server algorithm serving requests in $\mathcal{M}$.

Proof. For all i, $1 \leq i \leq k$, define $a_i = \lceil \min_{0\leq j<i} d(x_j, x_i)\rceil$. Conditions 1 and 2 imply that the sequence $a_1, a_2, \ldots$ is superincreasing. Let $\mathcal{M}'$ be the superincreasing metric space defined on $\{x_0, \ldots, x_k\}$ by setting $\operatorname{dist}(x_j, x_i) = a_i$ for $j < i$. It is not hard to prove that $\frac{1}{2}a_i \leq \operatorname{dist}(x_j, x_i) \leq a_1 + a_2 + \cdots + a_i \leq 2a_i$ for all $j < i$. Theorem 2.10 and Lemma 4.1 complete the proof. □

LEMMA 4.4. *Let $t > 2$, and let $P_0, P_1, \ldots, P_{t-1}$ be a sequence of points in a metric space such that* $\operatorname{dist}(P_0, P_1) = 1$ *and for every i, $1 < i \leq t - 1$,*

$$\frac{\min_{j<i} \operatorname{dist}(P_j, P_i)}{\max_{j<i-1} \operatorname{dist}(P_j, P_{i-1})} \geq 2.$$

If $r > 1$, then there is a subset $\{Q_0, Q_1, \dots, Q_{u-1}\}$ of size $u \geq t/(1 + \lg r)$ so that for every i, $1 < i \leq u$,

$$\frac{\min_{j<i} \operatorname{dist}(Q_j, Q_i)}{\max_{j<i-1} \operatorname{dist}(Q_j, Q_{i-1})} \geq r.$$

Proof sketch. Take every $\lceil \lg r \rceil$th point of the P's. □

THEOREM 4.5. *If $n = |\mathcal{M}|$ is sufficiently large, then there is a lower bound of $\Omega(\log k)$ on the competitive ratio of any randomized on-line k-server algorithm for $\mathcal{M}$.*

Proof. Apply Theorem 3.2 to $\mathcal{M}$ with $c = 10$. If case 1 holds and $\frac{1}{2} \lg n \geq k+1$, we apply Lemma 4.2 to obtain a lower bound of $\mathcal{H}_k/100$. So suppose case 2 holds. Lemma 2.2 implies that $c_i \leq 1 + 1.5 \ln i$, so that $8c_i e^{2c_i} \leq 8(1 + 1.5 \ln i)e^2 i^3$. Define $r = 8(1 + 1.5 \ln k)e^2 k^3$. If

$$\frac{\lceil \frac{1}{2}(\lg n)/\lg\lg n \rceil - 1}{1 + \lg r} \geq k + 1,$$

then Theorem 3.2 and Lemmas 4.3 and 4.4 give us a lower bound of $\frac{1}{4}(c_k - 1) \geq \frac{1}{8} \ln k - \frac{1}{4}$. It is clear that there is a polynomial $p(k)$ so that if $n \geq 2^{p(k)}$, then

$$\frac{\lceil \frac{1}{2}(\lg n)/\lg\lg n \rceil - 1}{1 + \lg r} \geq k + 1. \qquad \square$$

THEOREM 4.6. *For any metric space with at least $k + 1$ points, there is a lower bound of $\Omega(\log\log k)$ on the competitive ratio of every randomized on-line k-server algorithm.*

Proof. Let $\mathcal{M}$ be a metric space on exactly $k + 1$ points. (Ignore any others.) Let $s = \lceil \sqrt{\lg(k + 1)} \rceil$. The technique of Theorem 4.5 can be used to construct an $(s + 1)$-point metric space $\mathcal{S}$ within $\mathcal{M}$ whose interpoint distances either differ by at most a factor of 100 or which "grow" by at least a factor of s^4. (This holds for sufficiently large k.) In either case we have a lower bound of $f(s)$ on the competitive ratio of any randomized s-server algorithm for $\mathcal{S}$, where $f(s)$ is $\Omega(\log s)$ and hence $\Omega(\log\log k)$. However, the algorithm has k servers, not s.

Suppose there is a lazy, finitely converging c-competitive k-server algorithm for $\mathcal{M}$. Then by Lemma 2.7 we infer that there is a lazy, c-competitive multipoint k-server algorithm A for $\mathcal{M}$. Then there is a c-competitive s-server algorithm A' for $\mathcal{S}$: A' simply replaces a request to $z \in \mathcal{S}$ by a request to the set $\{z\} \cup (\mathcal{M} - \mathcal{S})$ and feeds the request to A. Neither A nor the adversary will ever move any server initially outside of $\mathcal{S}$. It follows easily that A' is a c-competitive s-server algorithm for $\mathcal{S}$. However, for $c < f(s)$, this cannot be. Now Lemma 2.9 tells us that no $(f(s) - 1)$-competitive k-server algorithm for $\mathcal{M}$ can exist, finitely converging or not. □

5. On-line motion planning. In this section we study the on-line motion-planning problem of Papadimitriou and Yannakakis, as described in the introduction. [PY] proved that no deterministic search strategy achieves a constant ratio. In this section we prove that even a randomized searcher cannot achieve a constant ratio. Rather, the ratio must grow with the number of obstacles.

Let $d_1, d_2, d_3, \dots, d_k$ be a superincreasing sequence of integers. Set $d_0 = 0$. Define a new metric space $\mathcal{M}'(k)$ on $\{z_0, z_1, \dots, z_k\}$ by identifying z_i with the point d_i on the real line as $\operatorname{dist}(z_i, z_j) = |d_i - d_j|$.

THEOREM 5.1. *For all multipoint k-server algorithms A for $\mathcal{M}'(k)$, for all r, there is a request sequence σ_r of optimal cost at least r and of length at most rN_k such that*

$$E[A(\sigma_r)] \geq \frac{c_k}{2} \cdot \mathrm{OPT}(\sigma_r).$$

Proof. Let A be a multipoint k-server algorithm for $\mathcal{M}'(k)$. Let A' be the algorithm for $\mathcal{M}(k)$ that mimics the behavior of A on $\mathcal{M}'(k)$. Each distance in $\mathcal{M}'(k)$ is between one half and one times the corresponding distance in $\mathcal{M}(k)$. It follows that

$$E[A(\sigma)] \geq \tfrac{1}{2} E[A'(\sigma)]$$

for all σ. By Theorem 2.5, for each r there is a request sequence σ_r' for $\mathcal{M}(k)$ of optimal cost at least r and of length at most rN_k such that

$$E[A'(\sigma_r)] \geq c_k \cdot \mathrm{OPT}(\sigma_r').$$

The optimal cost of σ_r' in $\mathcal{M}(k)$ is at least its optimal cost in $\mathcal{M}'(k)$. We may set $\sigma_r = \sigma_r'$. □

Let $N = N_k$. Fix a randomized searching algorithm. For scenes with at most $(k+2)N+2$ obstacles, we will prove a lower bound of $\Omega(\log k)$ on the performance ratio.

Choose k. Let $h = N + 1$. We first build a collection of $(k + 2)N + 2$ open rectangles as follows. For each $i = 1, 2, \ldots, N$, place k rectangles of width one in the region $\{(x, y) | i-1 \leq x < i\}$ known as *column* i. The jth rectangle C_{ij} $(1 \leq j \leq k)$ runs from $y = d_{j-1}h$ to $y = d_j h$. These k rectangles cover the region $\{(x, y) | i-1 < x < i, 0 < y < hd_k\}$. Now add a rectangle C_{i0} of width one and infinite height just below C_{i1} and add a rectangle $C_{i,k+1}$ of the same size as C_{i0} just above C_{ik}. Now add one infinite open rectangle L covering all of the plane to the left of these $(k+2)N$ rectangles. To their right add an infinite rectangle R covering everything to the right. Now we need to shift the rectangles slightly. Define $\epsilon_i = 2^{-i}$ and slide upward by ϵ_i all $k + 2$ rectangles in column i, $1 \leq i \leq N$.

To summarize, the final positions of the rectangles are as follows: For $1 \leq j \leq k$,

$C_{ij} = \{(x, y) | i - 1 < x < i, d_{j-1}h + \epsilon_i < y < d_j h + \epsilon_i\}$,
$C_{i0} = \{(x, y) | i - 1 < x < i, y < \epsilon_i\}$, and
$C_{i,k+1} = \{(x, y) | i - 1 < x < i, y > hd_k + \epsilon_i\}$.

These rectangles together with L and R cover all but a set of measure 0 of the entire plane.

The input consists of a sequence $\sigma_1, \sigma_2, \ldots, \sigma_N$, chosen in advance, with $\sigma_i \subsetneq \{0, 1, \ldots, k\}$ and $\sigma_i \neq \emptyset$ for all i. In column i, $1 \leq i \leq N$, the adversary "fuses" rectangles C_{ij} and $C_{i,j+1}$ for all $j \in \sigma_i$. The searcher's origin s is $(0, \epsilon_1)$, and his target is the vertical line $x = N$.

As soon as the searcher first reaches column i, i.e., his x-coordinate first reaches $i - 1$, the adversary tells him σ_i. The slight vertical displacement between columns $i - 1$ and i prevents the searcher from learning anything about σ_i before he enters column i.

Against these possible inputs, we can convert any searching algorithm to an algorithm A of no greater cost with this property:

- As soon as the searcher's x-coordinate reaches $i - 1$ (and he learns σ_i), he chooses a column-i rectangle C_{ij} with $0 \leq j \leq k$ and $j \notin \sigma(i)$. (The choice of $j \in \{0, 1, \ldots, k\}$ is random and probably not uniform.) Because $j \notin \sigma(i)$, rectangle C_{ij} has not been fused with its neighbor above. The searcher then moves vertically to the upper-left corner of C_{ij} and then one unit rightward.

Let $a_i \notin \sigma_i$ be the searcher's random choice of j in column i, and let $a_0 = 0$. His cost of moving from the upper-right corner $(i-1, d_{a_{i-1}}h + \epsilon_{i-1})$ of $C_{i-1,a_{i-1}}$ to the upper-right corner $(i, d_{a_i}h + \epsilon_i)$ of C_{i,a_i} is at least $h|d_{a_i} - d_{a_{i-1}}|$. His total cost is therefore at least $h\sum_{i=1}^{N}|d_{a_i} - d_{a_{i-1}}|$. The random choice of $a_i \notin \sigma_i$ depends only on $\sigma_1, \sigma_2, \ldots, \sigma_i$. This is precisely the situation of a randomized multipoint k-server algorithm that serves N multipoint requests in $\mathcal{M}'(k)$ and starts with its "hole" at d_0: d_{a_i} is the location of the algorithm's "hole" after serving the ith request σ_i. We will view A as a multipoint k-server algorithm for $\mathcal{M}'(k)$.

Given $\sigma_1, \ldots, \sigma_N$, set $b_0 = 0$ and let $b_1, b_2, \ldots, b_N$ be the optimal way to serve requests $\sigma_1, \ldots, \sigma_N$ in $\mathcal{M}'_k$. In other words, $b_1, b_2, \ldots, b_N$ minimizes $\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|$ subject to the constraint $b_i \notin \sigma_i$ for all i. Then the length of the shortest obstacle-free $s - t$ path is at most

$$\sum_{i=1}^{N}[1 + 2^{-i} + h|d_{b_i} - d_{b_{i-1}}|] < N + 1 + h\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|.$$

By Theorem 5.1 applied to A with $r = 1$, there is a request sequence σ of length at most N such that

$$E[A(\sigma)] \geq \frac{c_k}{2} \cdot \mathrm{OPT}(\sigma).$$

(Theorem 5.1 goes through even if A knows the length of the request sequence in advance.) For that sequence,

$$\frac{E[\sum_{i=1}^{N}|d_{a_i} - d_{a_{i-1}}|]}{\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|} \geq \frac{c_k}{2}.$$

Thus

$$\begin{aligned}\frac{E[h\sum_{i=1}^{N}|d_{a_i} - d_{a_{i-1}}|]}{N+1+h(\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|)} &= \frac{hE[\sum_{i=1}^{N}|d_{a_i} - d_{a_{i-1}}|]}{h(1+\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|)}\\ &\geq \frac{E[\sum_{i=1}^{N}|d_{a_i} - d_{a_{i-1}}|]}{2\sum_{i=1}^{N}|d_{b_i} - d_{b_{i-1}}|}\\ &= \frac{c_k}{4}.\end{aligned}$$

With at most $2 + (k+2)N$ rectangles, we have proven a lower bound of $c_k/4$, which is $\Omega(\log k)$. If desired, each of the rectangles with an infinite side length can be replaced by a rectangle with finite but very large dimensions.

We choose

$$d_k = \lceil 4c_{k-1}e^{2c_{k-1}} \rceil d_{k-1}$$

for all $k \geq 2$ and $d_1 = 1$. A simple calculation yields $N_k \leq 4^k(d_1 d_2 \cdots d_k)$, $d_k \leq k^{10}d_{k-1}$, and $N_k \leq 4^k(k!)^{10k}$. This means that we have a lower bound of $(\ln\ln n)/24$, n being the number of rectangles, for infinitely many n.

6. Acknowledgments. We are grateful to Prabhakar Raghavan for inspiring us to seek a general k-server lower bound, to Lyle McGeoch for his help in fixing a mistake, to Mario

Szegedy for simplifying the proof of Lemma 3.1, and to Dean Foster and Amos Fiat for their helpful remarks.

7. Appendix. Let $\beta \geq 1$ be a real, and let $\ell \geq \beta$ be a positive integer. Let $d \geq 4\beta e^{2\beta}\ell$ be an integer. Let $w_1, w_2, \ldots, w_Q \in \{1, 2, \ldots, 2\ell\}$ where Q satisfies $\sum_{i=1}^{Q-1} w_i < 2d \leq \sum_{i=1}^{Q} w_i$.

We prove a lower bound on the solution of the following linear program LP$_1$:

Find $p_1, p_2, \ldots, p_{Q-1}, \gamma$ so as to minimize γ subject to

$$d(1 - p_t) + \beta \cdot \sum_{s=1}^{t} p_s w_s \leq \gamma \cdot \sum_{s=1}^{t} w_s \quad \text{for } t = 1, \ldots, Q-1$$

$$d + \beta \cdot \sum_{s=1}^{Q-1} p_s w_s \leq \gamma \cdot 2d,$$

and

$$0 \leq p_s \leq 1 \quad \text{for } s = 1, \ldots, Q-1.$$

We first prove that the solution of the linear program LP$_2$:

Find $r_1, r_2, \ldots, r_{2d-2\ell}, \gamma$ so as to minimize γ subject to

$$d(1 - r_j) + \beta \cdot \sum_{i=1}^{j} r_i \leq \gamma \cdot (j + 2\ell) \quad \text{for } j = 1, \ldots, 2d - 2\ell$$

and

$$d + \beta \cdot \sum_{i=1}^{2d-2\ell} r_i \leq \gamma \cdot 2d$$

is a lower bound on the solution of LP$_1$. Then we prove that the solution of the linear program LP$_3$:

Find $t_1, t_2, \ldots, t_{2d-2\ell}, \gamma$ so as to minimize γ subject to

$$d(1 - t_j) + \beta \cdot \sum_{i=1}^{j} t_i = \gamma \cdot (j + 2\ell) \quad \text{for } j = 1, \ldots, 2d - 2\ell$$

and

$$d + \beta \cdot \sum_{i=1}^{2d-2\ell} t_i \leq \gamma \cdot 2d$$

is a lower bound on the solution of LP$_2$. LP$_2$ and LP$_3$ are identical, except that the first $2d - 2\ell$ inequalities in LP$_2$ are equalities in LP$_3$.

LEMMA 7.1. *The solution of* LP$_2$ *is a lower bound on the solution of* LP$_1$.

Proof. Suppose $p_1, \ldots, p_{Q-1}, \gamma$ is a feasible solution to LP$_1$. Then the assignment

$$\begin{aligned} r_1 &= p_1 \\ r_2 &= p_1 \\ &\vdots \end{aligned}$$

$$\begin{aligned} r_{w_1} &= p_1 \\ r_{w_1+1} &= p_2 \\ r_{w_1+2} &= p_2 \\ &\vdots \\ r_{w_1+w_2} &= p_2 \\ &\vdots \\ r_{w_1+\cdots+w_{Q-2}+1} &= p_{Q-1} \\ r_{w_1+\cdots+w_{Q-2}+2} &= p_{Q-1} \\ &\vdots \\ r_{w_1+\cdots+w_{Q-1}} &= p_{Q-1} \end{aligned}$$

and γ is a solution to LP$_2$. (Because $w_1 + w_2 + \cdots + w_{Q-1} \geq 2d - 2\ell$, we have constructed at least as many r's as we need, maybe more.) □

LEMMA 7.2. *The solution of* LP$_3$ *is a lower bound on the solution of* LP$_2$.

Proof. Suppose $r_1, r_2, \ldots, r_{2d-2\ell}, \gamma$ is a feasible solution to LP$_2$. Define $R_0 = 0$ and $R_j = r_1 + r_2 + \cdots + r_j$, $1 \leq j \leq 2d - 2\ell$. Then

$$d(1 - R_j + R_{j-1}) + \beta R_j \leq \gamma(j + 2\ell)$$

for $1 \leq j \leq 2d - 2\ell$ and

$$d + \beta R_{2d-2\ell} \leq \gamma \cdot 2d.$$

Therefore,

$$d - R_j(d - \beta) + dR_{j-1} \leq \gamma(j + 2\ell),$$

which is equivalent to

$$R_j \geq \frac{d}{d - \beta} R_{j-1} + \frac{d - \gamma(j + 2\ell)}{d - \beta}.$$

Also $R_{2d-2\ell} \leq d(2\gamma - 1)/\beta$. Now define $T_0 = 0$ and

$$T_j = \frac{d}{d - \beta} T_{j-1} + \frac{d - \gamma(j + 2\ell)}{d - \beta}$$

if $1 \leq j \leq 2d - 2\ell$ so that

$$d(1 - T_j + T_{j-1}) + \beta T_j = \gamma(j + 2\ell)$$

for $1 \leq j \leq 2d - 2\ell$. An easy inductive proof shows that $T_j \leq R_j$ for all j. Thus

$$T_{2d-2\ell} \leq R_{2d-2\ell} \leq d(2\gamma - 1)/\beta.$$

Define $t_j = T_j - T_{j-1}$ for $j = 1, 2, \ldots, 2d - 2\ell$. For $1 \leq j \leq 2d - 2\ell$,

$$\begin{aligned} d(1 - t_j) + \beta(t_1 + t_2 + \cdots + t_j) &= d(1 - T_j + T_{j-1}) + \beta T_j \\ &= \gamma(j + 2\ell). \end{aligned}$$

Also

$$T_{2d-2\ell} = t_1 + t_2 + \cdots + t_{2d-2\ell} \le d(2\gamma - 1)/\beta.$$

This means that $t_1, t_2, \ldots, t_{2d-2\ell}, \gamma$ is a feasible solution to LP$_3$. □

LEMMA 7.3. *If $t_1, t_2, \ldots, t_{2d-2\ell}, \gamma$ is a solution to* LP$_3$, *then*

$$\gamma \ge \beta\left[1 + 1/(2e^{2\beta} - 1)\right].$$

Proof. We have $d(1 - t_1) + \beta t_1 = \gamma(1 + 2\ell)$, i.e.,

$$t_1 = \frac{d - \gamma(1 + 2\ell)}{d - \beta}.$$

For $j = 2, 3, \ldots, 2d - 2\ell$,

$$d(1 - t_j) + \beta \cdot \sum_{i=1}^{j} t_i = \gamma \cdot (j + 2\ell),$$

$$d(1 - t_{j-1}) + \beta \cdot \sum_{i=1}^{j-1} t_i = \gamma \cdot (j - 1 + 2\ell).$$

Subtracting, $d(t_{j-1} - t_j) + \beta t_j = \gamma$, or

$$t_j = \frac{d}{d - \beta} t_{j-1} - \frac{\gamma}{d - \beta},$$

$j = 2, 3, \ldots, 2d - 2\ell$. An easy proof verifies that

$$t_j = \frac{\gamma}{\beta} - \left(\frac{\gamma}{\beta} + 2\gamma\frac{\ell}{d} - 1\right)\left(\frac{d}{d - \beta}\right)^j$$

for $j = 1, 2, \ldots, 2d - 2\ell$. We now use this assignment in the last constraint of LP$_3$ to get

$$d + \gamma(2d - 2\ell) + \beta\left(1 - \frac{\gamma}{\beta} - 2\gamma\frac{\ell}{d}\right)\sum_{i=1}^{2d-2\ell}\left(\frac{d}{d - \beta}\right)^i \le \gamma \cdot 2d.$$

But

$$\sum_{i=1}^{2d-2\ell}\left(\frac{d}{d - \beta}\right)^i = \frac{d}{\beta} \cdot \left[\left(\frac{d}{d - \beta}\right)^{2d-2\ell} - 1\right] = \frac{d}{\beta}(D - 1)$$

where $D = (d/(d - \beta))^{2d-2\ell}$. Therefore,

$$d + \gamma(2d - 2\ell) + \beta\left(1 - \frac{\gamma}{\beta} - 2\ell\frac{\gamma}{d}\right)\left[\frac{d}{\beta}(D - 1)\right] \le \gamma(2d),$$

$$d + \gamma(2d - 2\ell) + d\left(1 - \frac{\gamma}{\beta} - 2\ell\frac{\gamma}{d}\right)(D - 1) \le \gamma(2d),$$

$$d(1 + D - 1) + \gamma(-2\ell - \left(\frac{d}{\beta} + 2\ell\right)(D - 1)) \le 0,$$

$$dD \leq \gamma \left(2\ell + (D-1)\left(\frac{d}{\beta} + 2\ell\right)\right),$$

$$\gamma \geq \frac{Dd}{2\ell + (D-1)(\frac{d}{\beta} + 2\ell)} = \frac{Dd\beta}{2\ell\beta + (D-1)(d + 2\ell\beta)}$$

$$= \frac{Dd\beta}{2\ell\beta + Dd - d + D2\ell\beta - 2\ell\beta},$$

$$\gamma \geq \beta \left[\frac{Dd}{Dd - d + D(2\ell\beta)}\right] = \beta \left[\frac{Dd - d + D(2\ell\beta) + [d - D(2\ell\beta)]}{Dd - d + D(2\ell\beta)}\right]$$

$$= \beta \left[1 + \frac{d - D(2\ell\beta)}{Dd - d + D(2\ell\beta)}\right] = \beta \left[1 + \frac{1 - 2\beta D\ell/d}{D(1 + 2\beta\ell/d) - 1}\right].$$

Now

$$D = \left(\frac{d}{d-\beta}\right)^{2d-2\ell} = \left(1 + \frac{\beta}{d-\beta}\right)^{2d-2\ell} \leq e^{\beta(2d-2\ell)/(d-\beta)}.$$

Because $(2d - 2\ell)/(d - \beta) \leq 2$, $D \leq e^{2\beta}$. But

$$\gamma \geq \beta \left[1 + \frac{1 - 2\beta\ell D/d}{D(1 + 2\beta\ell/d) - 1}\right].$$

As D increases, the bracketed quantity decreases. Therefore,

$$\gamma \geq \beta \left[1 + \frac{1 - 2\beta\ell e^{2\beta}/d}{e^{2\beta} - 1 + e^{2\beta}(2\beta\ell/d)}\right].$$

Because $d \geq 4\beta e^{2\beta}\ell$, $2\beta\frac{\ell}{d}e^{2\beta} \leq 1/2$. Thus

$$\gamma \geq \beta \left[1 + \frac{1 - 1/2}{e^{2\beta} - 1 + 1/2}\right] = \beta \left[1 + \frac{1}{2e^{2\beta} - 1}\right]. \qquad \square$$

LEMMA 7.4. *The optimal value of* LP_1 *is at least*

$$\beta\left[1 + 1/(2e^{2\beta} - 1)\right].$$

Proof. The lemma follows from Lemmas 7.1, 7.2, and 7.3. □

Proof of Lemma 2.4. If Lemma 2.4 is not true, then

$$d + c_{i-1} \sum_{s=1}^{Q-1} p_s w_s < c_i(2d)$$

and

$$d(1-p_h)+c_{i-1}\sum_{s=1}^{h} p_s w_s < c_i \sum_{s=1}^{h} w_s$$

for all h, $1 \le h \le Q-1$. In this case, there is a $C < c_i$ such that

$$d + c_{i-1}\sum_{s=1}^{Q-1} p_s w_s \le C(2d)$$

and

$$d(1-p_h)+c_{i-1}\sum_{s=1}^{h} p_s w_s \le C \sum_{s=1}^{h} w_s$$

for all h, $1 \le h \le Q-1$. This contradicts Lemma 7.4 if we set $\beta = c_{i-1}$ and $\gamma = C$, since then

$$\beta\left[1+1/(2e^{2\beta}-1)\right] = c_i. \qquad \square$$

AN ALPHABET INDEPENDENT APPROACH TO TWO-DIMENSIONAL PATTERN MATCHING[*]

AMIHOOD AMIR[†], GARY BENSON[‡], AND MARTIN FARACH[§]

Abstract. There are many solutions to the string matching problem that are strictly linear in the input size and independent of alphabet size. Furthermore, the model of computation for these algorithms is very weak: they allow only simple arithmetic and comparisons of equality between characters of the input. In contrast, algorithms for two-dimensional matching have needed stronger models of computation, most notably assuming a totally ordered alphabet. The fastest algorithms for two-dimensional matching have therefore had a logarithmic dependence on the alphabet size. In the worst case, this gives an algorithm that runs in $O(n^2 \log m)$ with $O(m^2 \log m)$ preprocessing.

The authors show an algorithm for two-dimensional matching with an $O(n^2)$ text-scanning phase. Furthermore, the text scan requires no special assumptions about the alphabet, i.e., it runs on the same model as the standard linear-time string-matching algorithm. The pattern preprocessing requires an ordered alphabet and runs with the same alphabet dependency as the previously known algorithms.

Key words. multidimensional matching, period, string

AMS subject classifications. 68Q05, 68Q20, 68Q25

1. Introduction. The classical *string-matching problem* has as its input a *text* string T of length n and a *pattern* string P of length m. The elements in the text and pattern are taken from an alphabet set Σ and σ_P is the number of distinct characters in pattern P, so in particular, $\sigma_p \leq \min\{|\Sigma|, m\}$. We will in general drop the subscript P and simply refer to σ. The output is all text locations i where there is a character-by-character match with the pattern, i.e., $T[i + j - 1] = P[j]$, $j = 1, \ldots, m$.

String matching is one of the most widely studied problems in computer science [13]. Fischer and Paterson [12] gave a convolutions-based solution of time complexity $O(n \log m \log \sigma)$ word operations ($O(n \log m \log \log m \log \sigma)$ bit operations). Karp, Miller, and Rosenberg [17] gave a parallelizable label-doubling algorithm with complexity $O(n \log m)$. Knuth, Morris, and Pratt [19] gave the first linear-time solution. A heuristically improved algorithm was presented by Boyer and Moore [10]. Galil and Seiferas [15] showed a real-time algorithm using a constant number of registers. The Knuth, Morris, and Pratt and Galil and Seiferas algorithms have time complexity $O(n)$, are alphabet independent, and use a weak model of computation where only equality of symbols is tested.

Karp and Rabin [18] devised a *randomized* linear-time algorithm in a stronger arithmetic model. They generate a large random prime number as well as use arithmetic operations (e.g., multiplication, modulo) on the characters. Vishkin [24] introduced a deterministic sampling scheme that allowed using the "signature" idea in a deterministic weak model.

In recent years there has been growing interest in multidimensional pattern matching, largely motivated by problems in low-level image processing [23]. Various algorithms exist for the *exact two-dimensional matching* problem. The exact two-dimensional matching problem is defined similarly to the string-matching problem but the text and pattern are rectangular matrices rather than strings. For simplicity's sake we assume that T is an $n \times n$ matrix and P is an $m \times m$ matrix, although our results apply to rectangular matrices as well.

Baker [8] and, independently, Bird [9] used the Aho and Corasick [1] dictionary matching algorithm to obtain a $O(n^2 \log \sigma)$ algorithm for the exact two-dimensional matching problem. Their model requires a totally ordered alphabet (since it uses the Aho and Corasick algorithm as a subroutine), and so the time is dependent on the alphabet size. For an unbounded alphabet, their algorithm's time is $O(n^2 \log m)$. Two other algorithms for exact two-dimensional matching appear in [6] and [4]. They both use subword trees and run in time $O(n^2 \log \sigma)$. Note that while these algorithms require no arithmetic operations on the characters, they all assume a total ordering on their alphabets and make order comparisons in addition to checking equality of characters. A convolutions-based method was suggested by Amir and Landau [5]. There the time is $O(\sigma n^2 \log m)$ word operations in an arithmetic model (or also $O(n^2\sqrt{m} \log m)$). The Karp and Rabin algorithm also generalizes to two dimensions but, as we noted before, it is a randomized algorithm with a relatively powerful arithmetic model. Other algorithms with good average case complexities and strong computational models are given in [26] and [7].

In this paper we present what is, to our knowledge, the first deterministic algorithm for two-dimensional exact matching where the text scanning is alphabet independent and thus truly linear. Moreover, our algorithm is comparison based using a weak model of computation. During the text scan, the only character comparisons made are of the equality type, thus the model is weaker than in the above-mentioned two-dimensional matching algorithms. As opposed to previous algorithms, our algorithm is inherently two-dimensional, and uses a novel technique in two-dimensional matching—*two-dimensional periodicity*, as introduced by Amir and Benson in [2].

1.1. The two-dimensional periodicity idea. A periodic pattern contains locations, other than the origin, where the pattern can be superimposed on itself without mismatch. Suppose our pattern is *non-periodic*, i.e., there are no such locations, other than the origin. We could then narrow down the number of *potential candidates* for a pattern appearance in the text in a fashion that ensures that all such candidates are "sufficiently far" from each other. Verification of a candidate could then be done in the naive character-by-character comparison, but the time would still be linear because the candidates do not overlap.

The problem with implementing this idea is that there is no guarantee that the pattern is non-periodic. Indeed it has been shown [2] that there are four different types of two-dimensional periodicity and that a pattern may contain many locations where it can superimpose on itself without mismatch. Moreover, it is not possible to subdivide all patterns into non-periodic subunits, as is the case with one-dimensional strings. In this paper, we make use of the very strong property that superimposable patterns can not disagree in the area of overlap, and we present a new method for exploiting the pattern's periodicity.

In contrast, previous algorithms have, to a lesser or greater degree, shared a common weakness. They all treat a matrix as a *set* of rows, rather than as a sequence of rows. That is, they only consider periodicity one dimension at a time. Thus, while exploiting periodicity *within* rows, information about periodicity *among* rows is disregarded. The extra log factor can be seen as a way to recompute information that was discarded in earlier stages of the algorithm. Our unified approach to two-dimensional periodicity allows us to use all periodicity information throughout the text-scanning algorithm.

Our algorithm consists of a *pattern analysis* stage and a *text-scanning* stage. In the pattern analysis we construct a WITNESS array that allows a constant time decision of whether two overlapping pattern appearances conflict. This stage is done in time $O(m^2 \log \sigma)$, $O(m^2 \log m)$ in the worst case, and assumes an ordered alphabet. Note that very recently, there have been several advances in two-dimensional string matching. In [14] and independently in [3], it was shown how to compute a witness table in $O(m^2)$ using the unordered alphabet model of computation.

The text-scanning stage has two phases, the *compatibility phase* and the *verification phase*. We begin by assuming that the pattern could occur anywhere in the text. In the compatibility phase we eliminate candidate locations until all remaining candidates agree on the expected text characters. We are left with potential candidates that are all *compatible* with each other. In the verification phase we verify which of these potential candidates are indeed a match. The entire text-scanning stage is done in time $O(n^2)$.

The paper is organized as follows. The pattern analysis is described in §2. Section 3 consists of the text scan.

2. Pattern preprocessing. The idea of array overlap or *periodicity* and the pattern preprocessing algorithm are given in [2]. For completeness, we review the algorithm here. Our goal is to determine where two copies of an array A can overlap without conflict. Such sites are called *sources* (Fig. 1). For each location that is not a source, there exists a *witness* that proves that the overlapping copies of A mismatch.

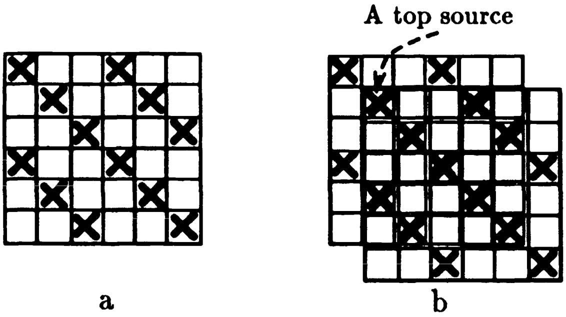

FIG. 1. (a) *An array A.* (b) *A overlaps itself without a mismatch.*

Given two copies of an $m \times m$ array $A[1, \ldots, m; 1, \ldots, m]$ one directly on top of the other, the two copies are said to be *in register* when all of the corresponding elements in the area of overlap contain the same symbol. Clearly, A is in register with itself when $A[1, 1]$ is aligned with $A[1, 1]$. If we can slide the upper copy over the lower copy to a point where the copies are again in register, then at least one of the corner elements $A[1, 1]$ or $A[m, 1]$ in one copy overlaps an element of the other copy. If the overlapping corner is $A[1, 1]$ then we have a *top source*. Otherwise, we have a *bottom source*.

We want to fill out two WITNESS arrays. For each location $A[i, j]$, TOP-WITNESS$[i, j]$ $= (m + 1, m + 1)$ if A is in register with itself when element $A[1, 1]$ overlaps element $A[i, j]$. Otherwise, TOP-WITNESS$[i, j] = (r, c)$ where (r, c) identifies some mismatch. Specifically $A[r, c] \neq A[i + r - 1, j + c - 1]$ (Fig. 2). BOTTOM-WITNESS$[i, j]$ is filled out similarly except element $A[m, 1]$ overlaps element $A[i, j]$.

2.1. The pattern preprocessing algorithm. Our pattern preprocessing algorithm (Algorithm A) makes use of two algorithms (Algorithms 1 and 2) from [21] which are themselves variations of the KMP algorithm [19] for string matching. Algorithm 1 takes as input a pattern string w of length m and builds a table $lppattern[1, \ldots, m]$ where $lppattern[i]$ is the length of the longest prefix of w starting at w_i. Algorithm 2 takes as input a text string t of length n and the table produced by Algorithm 1 and produces a table $lptext[1..n]$ where $lptext[i]$ is the length of the longest prefix of w starting at t_i.

The idea behind Algorithm A is the following. We convert the two-dimensional problem into a problem on strings (Fig. 3). Let the array A be processed column by column and suppose we are processing column j. Assume we can convert the block $A[1..m, j..m]$ into a string

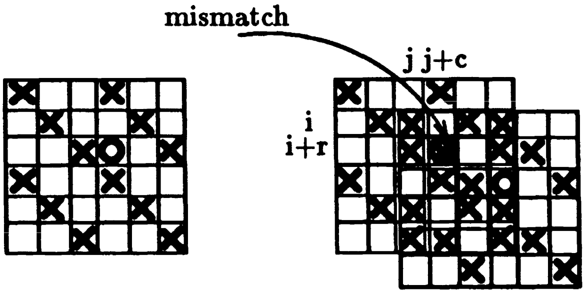

FIG. 2. *The WITNESS table gives the location of a mismatch (if one exists) for two overlapping copies of the pattern. Here TOP-WITNESS*$[i, j] = (r + 1, c + 1)$.

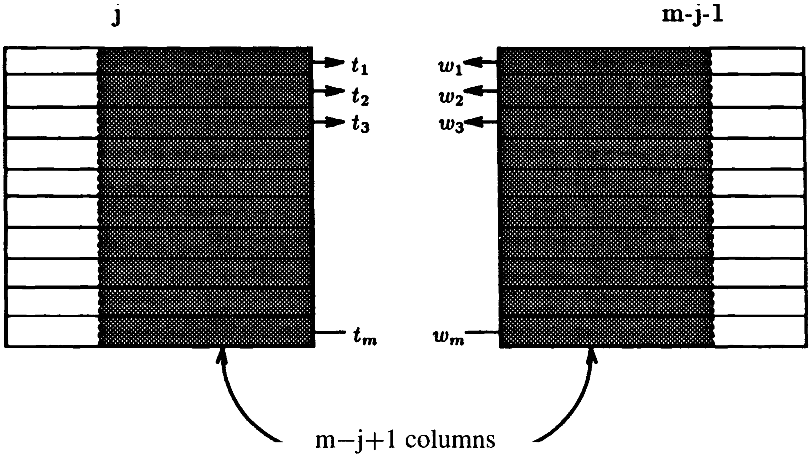

FIG. 3. *Representing a block of the array by a string. For the preprocessing algorithm,* $T_j = t_1, \ldots, t_m$ *is the text and* $W_j = w_1, \ldots, w_m$ *is the pattern.*

$T_j = t_1, \ldots, t_m$ where t_i represents the suffix of row i starting in column j. This will serve as the text string. Assume also that we can convert the block $A[1..m, 1..m - j + 1]$ into a string $W_j = w_1, \ldots, w_m$ where w_i represents the prefix of row i of length $m - j + 1$. This will serve as the pattern string. Now, use Algorithm 1 to produce the table *lppattern* for W_j and Algorithm 2 to produce the table *lptext* for T_j. If the longest prefix of the pattern in the text starting at t_i runs through the last row of the text ($lptext[i] = m - i + 1$), then $A[i, j]$ is a source. If the longest prefix stops before the last row ($lptext[i] < m - i + 1$), then there is a mismatch between the prefix of row $lptext[i]$ and the suffix of row $i + lptext[i]$. We need merely locate the mismatch to obtain the witness. In order to treat the suffix and prefix of a row as a single character, we will build a *suffix tree* for the array.

A suffix tree is a compacted trie of the suffixes of a string ([22], [25]). The suffix tree is perhaps the most widely used data structure in string matching. A thorough description of suffix trees and their properties appears in [11]. We note that since a suffix tree is a trie, each node v has associated with it some string $S(v)$. In [20], it was pointed out that if l is the least common ancestor (LCA) of two nodes v and w, then $S(l)$ is the longest common prefix of $S(v)$ and $S(w)$. In [16], an algorithm was given that preprocesses a tree in linear time and answers LCA queries in constant time. Thus a suffix tree, in conjunction with LCA queries, is a powerful tool for comparing the substrings of a string.

ALGORITHM A. *For building witness array*

Step A.1: Build a suffix tree by concatenating the rows of the array. Preprocess the suffix tree for least common ancestor queries in order to answer questions about the length of the common prefix of any two suffixes.

Step A.2: For each column j, fill out TOP-WITNESS for column j:

- Step A.2.1: Use Algorithm 1 to construct the table *lppattern* for $W_j = w_1 \dots w_m$. Character w_i is the *prefix* of row i of length $m - j + 1$. We can answer questions about the equality of two characters by consulting the suffix tree. If the length of the common prefix of the two characters is at least $m - j + 1$ then the characters are equal.
- Step A.2.2: Use Algorithm 2 to construct the table *lptext* for $T_j = t_1 \dots t_m$. Character t_i is the *suffix* of row i starting in column j (also of length $m - j + 1$). Again we test for equality by reference to the suffix tree.
- Step A.2.3: For each row i, if $lptext[i] = m - i + 1$ then we have found a source and TOP-WITNESS$[i, j] = (m + 1, m + 1)$ otherwise, using the suffix tree, compare the suffix of row $i + lptext[i]$ starting in column j with the prefix of row $lptext[i]$. The length l of the common prefix will be less than $m - j + 1$, and TOP-WITNESS$[i, j] = (lptext[i], l + 1)$.

Step A.3: Repeat step 2 for BOTTOM-WITNESS by building the automatons and processing the columns from the bottom up.

THEOREM 2.1. *Algorithm* A *runs in time* $O(m^2 \log \sigma)$.

Proof. The suffix tree construction [25] takes time $O(m^2 \log \sigma)$ while the preprocessing for least common ancestor queries [16] can be done in time linear in the size of the array. Queries to the suffix tree are processed in constant time. The tables *lppattern* and *lptext* can be constructed in time $O(m)$ [21]. For each of m columns, we construct two tables so the total time for steps 2 and 3 is $O(m^2)$. The total complexity of the pattern preprocessing is therefore $O(m^2 \log \sigma)$. □

3. Text processing. Text processing is accomplished in two stages: candidate consistency and candidate verification. A *candidate* is a location in the text where the pattern may occur. We denote a candidate with origin at text location $T[r, c]$ by (r, c). We say that two candidates (r, c) and (x, y) are *consistent* if they expect the same text characters in their region of overlap (two candidates with no overlap are trivially consistent). In terms of witnesses, two candidates are consistent if they have no witness, i.e., if $r \leq x$ and $c \leq y$ then *TOP-WITNESS*$[x - r + 1, y - c + 1] = (m + 1, m + 1)$. If $r > x$ and $c \leq y$ then *BOTTOM-WITNESS*$[m - r + x, y - c + 1] = (m + 1, m + 1)$. We use the shorthand $(r, c) \sim (x, y)$ to mean that the candidates (r, c) and (x, y) are consistent. If the two candidates are inconsistent, then we write $(r, c) \not\sim (x, y)$.

Initially, we have no information about the text and therefore all text locations are candidates. However, not all text locations are consistent. During the candidate consistency phase, we eliminate candidates until all remaining candidates are pairwise consistent. During the candidate verification phase, we check the candidates against the text to see which candidates represent actual occurrences of patterns. We exploit the consistency of the surviving candidates to rule out large sets of candidates with single text comparisons (since all consistent candidates expect the same text character).

3.1. Candidate consistency. As stated above, the goal of the *candidate consistency algorithm* presented in this subsection is to produce a set of candidates for the given text such that the candidates are all consistent.

We begin with some transitivity lemmas for the $\sim$ relation.

LEMMA 3.1. *For any* $1 \le r_1 \le r_2 \le r_3 \le n$ *and for any* $1 \le c_1 \le c_2 \le c_3 \le n$, *if* $(r_1, c_1) \sim (r_2, c_2)$ *and* $(r_2, c_2) \sim (r_3, c_3)$, *then* $(r_1, c_1) \sim (r_3, c_3)$.

Proof. Suppose that $(r_1, c_1) \not\sim (r_3, c_3)$. Then, there exists an $x \le m - r_3 + r_1$ and a $y \le m - c_3 + c_1$ such that $P[x, y] \ne P[x + r_3 - r_1, y + c_3 - c_1]$. But $r_3 \ge r_2$ so $x + r_3 \ge r_2$ and $m \ge x + r_3 - r_1 \ge r_2 - r_1$. Similarly, $m \ge y + c_3 - c_1 \ge c_2 - c_1$. Since $(r_1, c_1) \sim (r_2, c_2)$, we have that $P[x + r_3 - r_1, y + c_3 - c_1] = P[x + r_3 - r_2, y + c_3 - c_2]$. A similar argument shows that $P[x, y] = P[x + r_3 - r_2, y + c_3 - c_2]$ since $(r_3, c_3) \sim (r_2, c_2)$. We conclude that $P[x, y] = P[x + r_3 - r_1, y + c_3 - c_1]$. This is a contradiction. Therefore $(r_3, c_3) \sim (r_1, c_1)$. □

LEMMA 3.2. *For any* $1 \le r_1 \le r_2 \le r_3 \le n$ *and for any* $1 \le c_3 \le c_2 \le c_1 \le n$, *if* $(r_1, c_1) \sim (r_2, c_2)$ *and* $(r_2, c_2) \sim (r_3, c_3)$, *then* $(r_1, c_1) \sim (r_3, c_3)$.

Proof. The proof is analogous to that of Lemma 3.1. □

3.1.1. A one-dimensional consistency algorithm.

Let c be some column of the text. Initially, all positions in this column are candidates. We would like to remove candidates until all candidates within the column are consistent. Further, we would like to preserve any candidate that might actually represent an occurrence of the pattern in the text. Thus, we will only remove candidates when we find some specific text location with which they mismatch. The idea of Algorithm B is the following. Suppose we have eliminated inconsistent candidates from the last i rows of column c. The surviving candidates are placed on a list. Notice that by Lemma 3.1, if the candidate in row $n - i$ is consistent with the top candidate on the list, it is consistent with all of them. This check takes constant time using the witness array. This principle is used to produce an $O(n)$ algorithm for column consistency.

ALGORITHM B. *Eliminate inconsistent candidates within a column*

```
Step B.1: Get column number, $c$.
Step B.2: We create a doubly linked list, $S$, of consistent candidates in column
$c$. Initialize $S$ by adding candidate $(n - m + 1, c)$ to the top of $S$.
Step B.3: For row $r = n - m$ to 1 do:
    Step B.3.1: Let $(x, c)$ be the top candidate in $S$. Test if candidates $(r, c)$
    and $(x, c)$ are consistent by reference to the witness arrays:
      * If $(r, c) \sim (x, c)$, then add $(r, c)$ to the top of $S$.
```

If the two candidates under consideration are consistent, then they need not be compared with any other candidates on S. This is because, by Lemma 3.1, consistency within a single column is transitive.

```
      * If $(r, c) \not\sim (x, c)$ then use the witness character in the text to eliminate
        at least one of the candidates. If $(x, c)$ is eliminated, remove it from
        $S$ and if $(r, c)$ is not eliminated, repeat step B.3.1 with the new top
        candidate in $S$. If no candidates remain in $S$, add $(r, c)$ to $S$.
```

Clearly, if the two candidates are inconsistent, they can't both match the text. Thus the inappropriate one is eliminated.

```
Step B.4.3: Return $S$.
```

THEOREM 3.3. *Algorithm* B *is correct and runs in time* $O(n)$.

Proof. The correctness of the algorithm follows largely from the comments within the algorithm and from Lemma 3.1.

For the complexity bound, note that S can be initialized in constant time. For each row r in the for loop, there is at most one successful test of consistency. For each unsuccessful test, a candidate is eliminated, either the candidate (r, c) or the top candidate in S. Since the number of candidates is bounded by n the total time is $O(n)$. □

3.1.2. A two-dimensional consistency algorithm. We use the above algorithm as an initial "weeding out" of candidates so that we get a list for each column of consistent candidates. In the two-dimensional consistency algorithm, we start with the rightmost column, which we know to be consistent, and add one column at a time from right to left. We will maintain the following loop invariant: $P(i) \equiv$ the candidates remaining in columns $i, \ldots, n$ are all pairwise consistent.

No candidates can occur in columns $n - m + 2, \ldots, n$ so $P(n - m + 2), \ldots, P(n)$ are trivially satisfied. As noted above, by calling Algorithm B with value $n - m + 1$ we are assured of $P(n - m + 1)$. The approach of the algorithm below is to quickly ensure $P(i)$ once $P(i + 1)$ is known. When $P(1)$ holds, we are done. We use a similar idea to that of Algorithm B. We first have a phase where we make sure that each candidate is consistent with all candidates above and to the right. A symmetric phase makes sure that candidates below and to the right are consistent, thus assuring $P(i)$. To reduce the work, we note that during the first phase, we need only compare a candidate on column i with the leftmost surviving candidate in each row above it. To further reduce the work, once a candidate in column i is found to be consistent with candidates above it, all lower candidates in column i are also consistent (see Fig. 4).

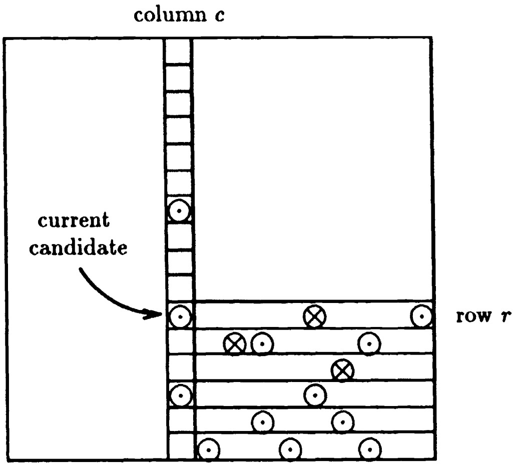

FIG. 4. *In the bottom-up scan, the current candidate in column c need only be tested against the leftmost candidates (marked by ⊗) in rows $r + m, \ldots, r$ that have not already been tested by candidates below c.*

```
ALGORITHM C. Candidate consistency
    Step C.1: For $i \leftarrow 1$ to $n - m + 1$ do $C_i \leftarrow$ Call Algo B($i$)
    Step C.2: For $i \leftarrow 1$ to $n - m + 1$ do initialize $R_i$ to be an empty list of candidates
    for each row $i$.
    Step C.3: Put the candidates on $C_{n-m+1}$ onto their appropriate $R_i$ lists.
    Step C.4: For $i \leftarrow n - m$ downto 1 do
  Add one row at a time, making sure that it is consistent with all candidates added so far.
        Step C.4.1: Call Bottom-Up($i$)
  Make sure that all candidates in column $i$ are consistent with all candidates below them
  in columns $i + 1, \ldots, n$.
        Step C.4.2: Call Top-Down($i$)
  Make sure that all candidates in column $i$ are consistent with all candidates above them
  in columns $i + 1, \ldots, n$.
```

```
        Step C.4.3: Add surviving candidates from column $i$ to the appropriate
        $R_j$ lists.
```

We describe procedure Bottom-Up only, since procedure Top-Down is symmetric.

```
Procedure C1. Bottom-Up(c)
    Step C1.1: Initialize: $cur$ gets bottom value from $C_c$. $row \leftarrow n - m + 1$ is a
    pointer to the last row compared so far.
    Step C1.2: While not at the top of $C_c$ do
        Step C1.2.1: If $cur$ is consistent with leftmost item on $R_{row}$ or $R_{row}$ is
        empty, then $row \leftarrow row - 1$.
```

We compare the current candidate with the leftmost candidate in some row row below it. If they are consistent, then by Lemma 3.1, all candidates above cur on C_c are also consistent with all candidates on R_{row}, *even if cur is later deleted as inconsistent with another candidate.* We need not consider that row again.

```
        Step C1.2.2: If $cur$ is not consistent with leftmost item on $R_{row}$, then find
        a witness to their inconsistency. Check which of them has a mismatch
        against the text. If the leftmost item on $R_{row}$ has a mismatch, remove
        that candidate from its list. If $cur$ has a mismatch, set $cur$ to the next
        item above $cur$ on $C_c$.
```

We remove the candidate that has a mismatch against the text. If the item in R_{row} is removed, then we still need to check if cur is consistent with the remaining candidates in that row. Thus, we don't need to update any pointers. Otherwise, if cur is removed, we move up in C_c. We don't need to change row because of the comment above. None of the rows below row need to be compared against the new candidate cur since we already know they are consistent.

```
        Step C1.2.3: If the $row$ counter points to a row above $cur$'s row, set $cur$
        to the next candidate above $cur$ in $C_c$.
```

THEOREM 3.4. *Algorithm* C *is correct and runs in* $O(n^2)$.

Proof. As in Algorithm B, no candidate is removed unless a mismatch is found against the text. Therefore, no valid candidates are removed.

To show that at the end of the algorithm, only mutually consistent candidates are left on the R_i lists (and on the C_i), we pick two arbitrary surviving candidates (r_1, c_1) and (r_2, c_2) such that $c_1 < c_2$. We have two cases.

Case $r_1 \leq r_2$: We show this case by induction. Suppose that after processing column $c_1 + 1$ that $P(c_1 + 1)$ holds. The base case is true by Theorem 3.3. Let (r_2, c') be the leftmost candidate such that $c' > c_1$ and c' appears on R_{r_2} after processing column c_1. By Lemma 3.1, we need only show that $(r_1, c_1) \sim (r_2, c')$ since $(r_2, c') \sim (r_2, c_2)$.

Let (r', c_1) be the last candidate with which (r_2, c') was compared during *Bottom-Up*(c_1).

CLAIM 3.4.1. $r' \geq r_1$ *and* $(r', c_1) \sim (r_2, c')$.

Proof. Suppose that $(r', c_1) \not\sim (r_2, c')$. Then we either delete (r', c_1) or (r_2, c') from the candidate list. If we remove (r_2, c') from the list, then we would compare the next candidate on R_{r_2} with (r', c_1), thus violating the assumption that (r_2, c') was the leftmost candidate compared with a c_1 candidate. If we remove (r', c_1), then we would compare (r_2, c') with the next candidate above (r', c_1), thus violating the assumption that (r', c_1) was the last candidate on column c_1 with which (r_2, c') was compared.

To show that $r' \geq r_1$ we observe that if $r_1 > r'$, then we couldn't have compared (r_2, c') with (r', c_1) without first comparing (r_1, c_1) with (r_2, c'). Since they both survived, they would have had to have been consistent. But then we never would have compared (r_2, c') with (r', c_1) at all. □

Finally, we know that $(r_1, c_1) \sim (r', c_1)$, $(r', c_1) \sim (r_2, c')$, $(r_2, c') \sim (r_2, c_2)$ and that $r_1 \leq r' \leq r_2$ and that $c_1 \leq c' \leq c_2$. So by Lemma 3.1, we have proved the case.

Case $r_1 > r_2$: This case is very similar to the one above, however, we refer the reader to procedure Top-Down rather than Bottom-Up and Lemma 3.2 rather than Lemma 3.1.

The argument that shows the running time to be $O(n^2)$ is similar to the complexity analysis in Theorem 3.3. We observe that during Bottom-Up (and Top-Down) in each, comparison of candidates results in the removal of a candidate (which can only happen n^2 times in all calls to these procedures), or in the *cur* pointer being decremented (respectively, incremented). This can only happen $O(n)$ time each time Bottom-Up (respectively, Top-Down) is called, and they are each called $O(n)$ times. Therefore the complexity is $O(n^2)$. □

3.2. Candidate verification. All remaining candidates are now mutually consistent. Each text element $t = T[r, c]$ may be contained by several candidates, the *relevant* candidates. However, consistent candidates that share the same text element must agree on the expected character in that element. This leads to the following crucial observation. Every element in T can be labeled as either *true* or *false*, where *true* means that it equals the unique pattern symbol expected by all relevant candidates, and *false* in all other cases. Thus, every text element needs to be compared to a *single* pattern element, and every candidate source that contains a *false* element within it is not a pattern appearance and can be discarded.

The candidate verification algorithm follows:

ALGORITHM D. *Candidate verification*

Step D.1: Mark every text location $T[r, c]$ with a *pattern coordinate pair* $\langle i, j\rangle$, where $\langle i, j\rangle$ are the coordinates of the pattern element $P[i, j]$ with which $T[r, c]$ should be compared.

There may be several options for some locations, namely, the position of the scanned text element relative to each of its relevant candidates. However, any will do since all candidate sources are now consistent. If a location is not contained in any candidate source it is left unmarked. We will later see how this step is implemented (Procedure D1).

Step D.2: Compare each text location $T[r, c]$ with $P[i, j]$, where $\langle i, j\rangle$ is the pattern coordinate pair of $T[r, c]$. If $T[r, c] = P[i, j]$ then label $T[r, c]$ as *true*, else label it *false*.

Step D.3: Flag with a *discard* every candidate that contains a *false* location within its bounds.

This flagging is done by the same method as in step D.1.

Step D.4: Discard every candidate source flagged with a *discard*. The remaining candidates represent all pattern appearances.

Our only remaining task is to show how to mark the text elements with the appropriate pattern coordinate pairs. We adopt the popular sports fan's technique—*the wave.*

Starting at the top (left) of each column (row), a wave is propagated going down (to the right) as follows. The first element stands and waves its pattern coordinate pair, if such exists. This nudges the neighbor below (to the right of) it to jump and raise its own pair. If it does not have a pair, it borrows its antecedent's pair, incrementing by 1 its row (column) coordinate, to adjust for its position relative to the same source. If the pair assigned to some position exceeds the size of the pattern, that position is left unmarked.

Thus in two sweeps of the text, column waves and row waves, each text element is given an appropriate pattern coordinate pair. Details of the wave follow:

Procedure D1. *The wave*

Step D1.1: **Initialization:** Mark every candidate origin with $\langle 1, 1\rangle$.

Step D1.2: **Column Waves:** For each column c, and for all positions r from 1 to n in column c do the following step: If $T[r, c]$ does not have a pair, and $T[r - 1, c]$ has pair $\langle i, j\rangle$ with $i < m$ then assign to $T[r, c]$ the pair $\langle i + 1, j\rangle$.

Step D1.3: **Row Waves:** For each row r, and for all positions c from 1 to n in row r do the following step: If $T[r, c]$ does not have a pair, and $T[r, c-1]$ has pair $\langle i, j\rangle$ with $j < m$ then assign to $T[r, c]$ the pair $\langle i, j+1\rangle$.

A similar version of the wave can be used to flag candidates with *discard.* What is propagated there is the *discard* flag, along with a counter pair to make sure the *discard* flag doesn't get propagated too far. The propagation is bottom-up in the columns and then from right to left within the rows.

THEOREM 3.5. *Algorithm* D *is correct and runs in time* $O(n^2)$.

Correctness. The only non-trivial fact is that the wave correctly marks all elements. We need the following terminology. If (r, c) is a candidate, we refer to the candidate origin $T[r, c]$ as a *source.* Let (r, c) be a candidate containing position $T[r+i, c+j]$. Then j is the *column distance* and i is the *row distance* between $T[r+i, c+j]$ and the source for (r, c). The *column-close* candidates containing location $T[r, c]$ have sources whose column distance to $T[r, c]$ is minimal. The *closest* candidate containing location $T[r, c]$ is the column-close candidate whose source has smallest row distance to $T[r, c]$.

CLAIM 3.5.1. *The pattern coordinate pair marked by Procedure* D1 *in location* $T[r, c]$ *is the pair* $\langle i, j\rangle$ *where* $(r-i+1, c-j+1)$ *is the closest source to* $T[r, c]$.

Proof. By induction on the column distance of the closest source. For column distance 0 the column wave assures that the marked pair is $\langle i, 1\rangle$ where i is the row distance to the closest source $+1$. Assuming that for every text element whose column distance to its closest source is d, the marked pair is correct, it is easy to see that the row wave will ensure correct marking of all elements with column distance $d+1$ to the closest source.

Time. Each of the steps of Algorithm D is easily implementable in time $O(n^2)$. Note that, in each of steps D.1 and D.4, there is a single call to Procedure D1, which clearly takes $O(n^2)$ time. □

4. Conclusion. While string matching is extremely well studied and understood, multidimensional matching has been somewhat neglected. This neglect does not stem from lack of practical motivation but may be attributed to the fact that string-matching techniques do not easily generalize to higher dimensions.

We feel that an inherently multidimensional approach is likely to produce better results. This paper is a step along the way. All previously known algorithms for exact two-dimensional matching pushed string-matching techniques as tools for solving the two-dimensional case. However, none succeeded in achieving results similar to the string-matching case. Our new idea of analyzing periodicity in two dimensions has been useful in improving results of the most basic two-dimensional task—that of exact matching.

TRADING SPACE FOR TIME IN UNDIRECTED *s*-*t* CONNECTIVITY*

ANDREI Z. BRODER†, ANNA R. KARLIN‡, PRABHAKAR RAGHAVAN§, AND ELI UPFAL¶

Abstract. Aleliunas et al. [20th Annual Symposium on Foundations of Computer Science, IEEE Computer Society Press, Los Alamitos, CA, 1979, pp. 218–223] posed the following question: "The reachability problem for undirected graphs can be solved in log space and $O(mn)$ time [m is the number of edges and n is the number of vertices] by a probabilistic algorithm that simulates a random walk, or in linear time and space by a conventional deterministic graph traversal algorithm. Is there a spectrum of time-space trade-offs between these extremes?" This question is answered in the affirmative for sparse graphs by presentation of an algorithm that is faster than the random walk by a factor essentially proportional to the size of its workspace. For denser graphs, this algorithm is faster than the random walk but the speed-up factor is smaller.

Key words. space-time tradeoff, connectivity testing, parallel random walks

AMS subject classifications. 05C40, 05C85, 60J15, 68Q25

1. Motivation and results.

We consider the problem of s-t connectivity on an undirected graph (USTCON). Given a graph G with n vertices and m edges, and given two vertices s and t of G, we are to decide if s and t are in the same connected component. We are interested in space-bounded algorithms for USTCON, which is an important problem in the study of space-bounded complexity classes [3], [8]. Throughout this paper, we assume that our workspace takes the form of p registers, each capable of storing a $\log n$-bit number.

There are two well-known approaches to solving USTCON: via a deterministic graph search on G (e.g., depth-first search), and via a simulation of a random walk on G [1]. (The standard random walk on G is the stochastic process associated with a particle moving from vertex to vertex according to the following rule: if d_i is the degree of vertex i then the probability of a transition from vertex i to vertex j is $1/d_i$ if $\{i, j\}$ is an edge in G and 0 otherwise.)

The first approach can be implemented to run in time $O(m)$ using space $O(n)$. The latter requires space $O(1)$, and has been shown to decide USTCON in time $O(mn)$ with one-sided error (i.e., if s and t are in the same connected component, the algorithm outputs YES with probability at least 0.5; if they are in different components, the algorithm outputs NO). For both these algorithms, the product of time and space is $O(mn)$.

Given space that is insufficient for depth-first search, can we decide USTCON faster than via a random walk? More precisely, given space $p \leq n$, can we bridge the gap between the depth-first search and the random walk by devising an algorithm that runs in time $O(mn/p)$? Considering the time-space product achieved at the two extremes, this seems a likely conjecture.

In this paper we present an algorithm that runs in time $O(m^2 \log^5 n/p)$ in space $O(p)$. Therefore, for linear-sized graphs (i.e., $m = O(n)$), it achieves the bound conjectured above within a poly-log factor. For denser graphs, our algorithm does not achieve the bound, but it is faster than the random walk for m/p sufficiently small.

The informal description of the algorithm is as follows.

```
Algorithm STConn.
    1. Repeat $O(\log n)$ times
        (a) Choose $p$ random vertices according to the stationary distribution of the random
            walk on $G$. (The stationary distribution of the random walk is $\pi_v = d_v/(2m)$
            where $d_v$ is the degree of vertex $v$.) Call these vertices, together with $s$ and $t$,
            leaders.
        (b) Repeat $O(\log n)$ times: Starting from each leader, take a random walk of length
            $\tau_1 = O(m^2/p^2 \log^3 n)$. If such walks connect two leaders, then mark them and
            all the other leaders known to be connected to them, as belonging to the same
            component. If at any point $s$ and $t$ are marked as being in the same component,
            then stop and report "connected."
    2. Report "probably not connected."
End STConn.
```

A more precise description of the algorithm is given in §3. Clearly the space required is $O(p)$ and the time required is $O(m^2 \log^5 n/p)$. (The leaders are marked via a standard union-find algorithm.) Notice that this algorithm resembles standard search when $p = n$ and the random walk when $p = 0$. (However, throughout this paper we shall assume $p > 0$.)

There are three facts that must be proven in order to show that this algorithm works. The first is to show that a set of p random walks of length τ_1, one from each of the randomly chosen leaders, visits all the vertices of a connected graph with high probability. Otherwise an adversary could choose s and t among those vertices unlikely to be visited from the other leaders and conceivably foil the algorithm. In other words, we need to derive a bound on the expected time required by p parallel and independent random walks to cover the graph, a problem of interest in its own right. Typically, results about graph coverage rely heavily on the long-run behavior of the corresponding Markov chain and its convergence to a limit distribution. Here we must prove something about short-term behavior of the Markov chain and coverage of local neighborhoods in a graph.

The second fact to prove is that if s and t are in the same component and enough leaders are chosen within that component, then with high probability s and t are linked up after a small number of walks from each leader. Coverage of the graph as described above does not ensure linkage, since s and t may be visited only by walks from two disjoint sets of leaders that are never linked. Furthermore, all the vertices in G could be visited by the walks even with s and t in different components.

The third fact to show is that, with high probability, within $O(\log n)$ choices of the set of leaders, the component containing s and t gets enough leaders at least once.

To aid the intuition of the reader, let us consider the case when G is a simple path on n vertices. For p leaders chosen at random, with high probability, the maximum gap between two leaders is no more than $n \ln n/p$; the expected time to cover this maximum gap is $\Theta(n^2 \log^2 n/p^2)$. Hence $O(\log n)$ trials (random walks of length $O(n^2 \log^2 n/p^2)$ from each leader) will almost surely cover all the gaps between them for a total of $\Theta(n^2 \log^3 n/p)$ steps. Thus each leader "discovers" its closest neighbor leader in both directions, and therefore all leaders are marked as being in the same component.

Extending this technique to even 3-regular graphs requires considerably more complicated machinery and the general bound is weaker. (In particular, the walks need to have length $O(n^2 \log^5 n/p^2)$ and we need to try $O(\log n)$ choices for leaders.)

Our main results are:

THEOREM 2.4. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a subset of p vertices chosen at random according to the stationary distribution. Let $S_v(t)$ denote the set of vertices seen in a random walk of length t starting at v. Define the random variable C_p by*

$$C_p = \inf\{t \ : \ \bigcup_{l \in L} S_l(t) = V\},$$

that is, C_p is the time needed for p parallel random walks to visit all the vertices in the graph. Then

$$\mathbf{E}(C_p) = O\left(\frac{m^2 \log^3 n}{p^2}\right).$$

THEOREM 3.1. *There is an algorithm that, given an undirected graph G with n vertices and m edges, and given two vertices s and t of G, decides* USTCON *with one-sided error using space p and time $O(m^2 \log^5 n/p)$. If s and t are in the same connected component, the algorithm outputs YES with probability $1 - O(n^{-1})$, otherwise it outputs NO.*

Remark. The algorithm mentioned in Theorem 3.1 runs in time, that is, within a $\log^5 n$ factor of our target time-bound of $O(mn/p)$ for linear-sized graphs. It is conceivable that a better analysis would lead to a similar algorithm with a lower overhead factor; however, the path example shows that a factor of $\log^3 n$ is inherent to our approach.

2. Covering a graph with p random walks. In this section we derive an upper bound on the time taken by p parallel and independent walks to cover the graph (Theorem 2.4).

We denote by $\{v, w\}$ the undirected edge between vertices v and w and by $[v, w]$ its directed version. For the purposes of the proof, we need to look at the random walk in two ways: first, as a Markov chain $X(t)$ where each state is a vertex in G (the vertex process); second, as a Markov chain $Y(t)$ where each state is a directed edge (the edge process). The transition rule for the vertex process is that if $X(t) = v$, then $X(t+1)$ is equally likely to be any of the neighbors of vertex v. The edge process is defined by $Y(t) = [X(t-1), X(t)]$, $t \geq 1$. The stationary distribution of the vertex process, denoted π, is given by $\pi_v = d_v/(2m)$ where d_v is the degree of the vertex v, and the stationary distribution of the edge process, denoted π', is given by $\pi'_{[v,w]} = 1/(2m)$.

Let $N_v(u, T)$ (respectively, $N_v([u, w], T)$) be the number of visits to the vertex u (respectively, traversals of $[u, w]$) in a random walk of length T starting at v. (By definition, $N_v(v, 0) = 0$.) Let $S_v(T)$ (respectively, $E_v(T)$) be the set of vertices (edges) visited in a random walk of length T starting at v. Finally, let $H_v(u)$ (respectively, $H_v([u, w])$ be the first time the vertex u (the edge $[u, w]$) is encountered by a random walk starting from v. (We define $H_v(v)$ to be $1/\pi_v$, i.e., the return time to v.) For all of these random variables, a replacement of the subscript v with the subscript π (respectively, $[v, w]$) denotes a random walk starting at the stationary distribution (respectively, the directed edge $[v, w]$).

LEMMA 2.1. *Let G be a connected, undirected graph on n vertices. Consider a random walk of length τ starting from the stationary distribution. Then for every directed edge $[v, w]$,*

$$\Pr\Big([v, w] \in E_\pi(\tau)\Big) \geq \frac{\mathbf{E}\Big(N_\pi([v, w], \tau)\Big)}{1 + \mathbf{E}\Big(N_{[v,w]}([v, w], \tau)\Big)}.$$

Proof. Clearly

$$\begin{aligned}\mathbf{E}\Big(N_\pi([v, w], \tau)\Big) &= \textstyle\sum_{1 \leq t \leq \tau} \Pr\Big(H_\pi([v, w]) = t\Big)\Big(1 + \mathbf{E}\Big(N_{[v,w]}([v, w], \tau - t)\Big)\Big) \\ &\leq \Pr\Big(H_\pi([v, w]) \leq \tau\Big)\Big(1 + \mathbf{E}\Big(N_{[v,w]}([v, w], \tau)\Big)\Big).\end{aligned}$$

But $\Pr\Big(H_\pi([v, w]) \leq \tau\Big) = \Pr\Big([v, w] \in E_\pi(\tau)\Big)$, yielding the lemma. □

LEMMA 2.2. *Let G be a connected, undirected graph with n vertices and m edges. Then for every directed edge $[v, w]$,*

$$\mathbf{E}\Big(N_{[v,w]}([v, w], \tau)\Big) \le \frac{\tau}{2m} + \gamma\sqrt{\tau \ln n},$$

where γ is an absolute constant.

Proof. We consider the edge process Y_t. From standard results in renewal theory [9, Thm. 3.7.1] we obtain that

$$\text{(1)} \qquad \mathbf{E}\Big(N_{[v,w]}([v, w], \tau)\Big) = \pi'_{[v,w]}\Big(\tau + \mathbf{E}\Big(H_{Y_{[v,w]}(\tau)}([v, w])\Big)\Big) - 1.$$

Clearly

$$\text{(2)} \qquad \mathbf{E}\Big(H_{Y_{[v,w]}(\tau)}([v, w])\Big) = \mathbf{E}\Big(H_{X_w(\tau)}(v)\Big) + \mathbf{E}\Big(H_v([v, w])\Big).$$

Let $d(x, y)$ be the distance (the length of the shortest path) between two vertices x and y in G. Let c be a sufficiently large constant.

We first bound $\mathbf{E}\Big(H_{X_w(\tau)}(v)\Big)$ using the fact that $d(X_w(\tau), w)$ is not likely to be more than $c\sqrt{\tau \ln n}$, for some $c > 0$ such that $c\sqrt{\tau \ln n}$ is an integer. By the law of total probability

$$\text{(3)} \qquad \begin{aligned} &\mathbf{E}\Big(H_{X_w(\tau)}(v)\Big) = \\ &\mathbf{E}\Big(H_{X_w(\tau)}(v) \mid d(X_w(\tau), v) \le c\sqrt{\tau \ln n}\Big) \Pr\Big(d(X_w(\tau), v) \le c\sqrt{\tau \ln n}\Big) \\ &+ \mathbf{E}\Big(H_{X_w(\tau)}(v) \mid d(X_w(\tau), v) > c\sqrt{\tau \ln n}\Big) \\ &\times \Pr\Big(d(X_w(\tau), v) > c\sqrt{\tau \ln n}\Big). \end{aligned}$$

Since $d(X_w(\tau), v) \le 1 + d(X_w(\tau), w)$, we obtain from the main result of [4] that

$$\text{(4)} \qquad \begin{aligned} \Pr\Big(d(X_w(\tau), v) > c\sqrt{\tau \ln n}\Big) &\le \Pr\Big(d(X_w(\tau), w) \ge c\sqrt{\tau \ln n}\Big) \\ &\le \sum_{x : d(w,x) \ge c\sqrt{\tau \ln n}} 2\left(\frac{\pi_x}{\pi_w}\right)^{\frac{1}{2}} \exp\left(-\frac{d(w, x)^2}{2\tau}\right) \\ &\le 3n^{\frac{1}{2}} \exp\left(-\frac{c^2 \tau \ln n}{2\tau}\right) \le \frac{1}{n^3}, \end{aligned}$$

for a sufficiently large c.

For any two vertices x and y in the same component we can apply the bound implicitly proven in [1]

$$\text{(5)} \qquad \mathbf{E}\Big(H_x(y)\Big) \le 2md(x, y) \le n^3.$$

Plugging equation (5) and equation (4) in equation (3) we obtain that

$$\text{(6)} \qquad \mathbf{E}\Big(H_{X_w(\tau)}(v)\Big) \le 2cm\sqrt{\tau \ln n} + 2.$$

Turning to the second term of the right side of equation (2), we observe that

$$\mathbf{E}\Big(H_v([v,w])\Big) \le 2m+1, \tag{7}$$

because the expected time to return to v given that v was left through an edge other than $[v,w]$ is at most $2m/(d_v-1)$ and the expected number of returns to v before exiting through $[v,w]$ is d_v-1. (The former fact follows from $2m/d_v = \mathbf{E}(H_v(v)) \ge (d_v-1)/d_v \cdot \mathbf{E}(H_v \mid v \text{ not left via } [v,w])$.)

Combining equations (6), (7), and (2), we obtain that

$$\mathbf{E}\Big(H_{Y_{[v,w]}(\tau)}([v,w])\Big) \le 2cm\sqrt{\tau \ln n} + 2m + 3.$$

Finally, from equation (1), because $\pi'_{[v,w]} = 1/(2m)$ for any edge $[v,w]$

$$\mathbf{E}\Big(N_{[v,w]}([v,w],\tau)\Big) \le \frac{\tau}{2m} + c\sqrt{\tau \ln n} + O(1).$$

From here, the lemma follows with an appropriate value for γ. □

LEMMA 2.3. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p vertices (called leaders) in G chosen independently according to the stationary distribution. For every constant $c_1 > 0$ there exists a constant c_2 such that for every directed edge $[v,w]$, a set of p walks of length $c_2 m^2 \ln^3 n/p^2$, one from each of the leaders, satisfies*

$$\Pr\Big([v,w] \in \bigcup_{l \in L} E_l(c_2 m^2 \ln^3 n/p^2)\Big) \ge 1 - \frac{1}{n^{c_1}}.$$

Proof. For $p = O(\log n)$ the conclusion is obvious. For larger p we start from

$$\Pr\Big([v,w] \notin \bigcup_{l \in L} E_l(\tau)\Big) = \prod_{l \in L} \Pr\Big([v,w] \notin E_l(\tau)\Big),$$

and, since each vertex l is chosen independently according to the stationary distribution, Lemma 2.1 gives us a bound on $\Pr([v,w] \notin E_l(\tau))$. By Lemma 2.2 and because $\mathbf{E}\Big(N_\pi([v,w],\tau)\Big) = \tau/2m$, there exists a constant $c_3 > 0$ such that

$$\Pr\Big([v,w] \notin \bigcup_{l \in L} E_l(\tau)\Big) \le \left(1 - \frac{c_3\sqrt{\tau}}{m\sqrt{\ln n}}\right)^p,$$

provided that $\tau = O(m^2 \log n)$. Now taking $\tau = c_2 m^2 \ln^3 n/p^2$ yields the result. □

THEOREM 2.4. *Let $G = (V,E)$ be a connected, undirected graph with n vertices and m edges. Let L be a subset of p vertices chosen at random according to the stationary distribution. Let $S_v(t)$ denote the set of vertices seen in a random walk of length t starting at v. Define the random variable C_p by*

$$C_p = \inf\{t : \bigcup_{l \in L} S_l(t) = V\},$$

that is, C_p is the time needed for p parallel random walks to visit all the vertices in the graph. Then

$$\mathbf{E}(C_p) = O\left(\frac{m^2 \log^3 n}{p^2}\right).$$

Proof. Corollary of Lemma 2.3. □

In fact Lemma 2.3 implies the stronger result that the time needed for p parallel random walks to traverse every edge in the graph is $O\big(m^2 \log^3 n/p^2\big)$.

3. An algorithm for USTCON in $O(p)$ space. We now present the algorithm for USTCON using $O(p)$ space. As a subroutine, we use a standard Union/Find algorithm.

We use three constants, k_1, k_2, and k_3, in the description of the algorithm, which must be chosen sufficiently large. The choice of these constants determines the error probability of the algorithm. For ease of reference, we note here that k_1 is the constant c_2 of Lemma 2.3, Theorem 4.1, and Corollary 4.2, k_2 is the constant c_2 of Lemma 4.6, and k_3 is bound in Theorem 4.7.

```
algorithm STConn;
begin
  do $k_3 \ln n$ times begin
    Let $L$ be a set of $p$ elements of $V$, chosen independently at
      random according to the stationary distribution;
    $L := L \bigcup \{s, t\}$;
    (* Set($l$) are the leaders known to be connected to leader $l$ *)
    for every $l$ in $L$ do Set($l$) := $\{l\}$;
    do $k_2 \ln n$ times begin
      for every $l$ in $L$ do begin
        Take a random walk $X_l(t)$, starting at $l$, of length
          $k_1 m^2 \ln^3 n/p^2$.
        At each step, if $X_l(t) \in L$ then
          Union(Find($X_l(t)$), Find($l$));
      end ;
    end ;
    if Find($s$) =Find($t$)
      then return ("YES: $s$ and $t$ are connected")
  end ;
return ("NO: $s$ and $t$ don't seem to be connected") end .
```

THEOREM 3.1. *Given an undirected graph G with n vertices and m edges, and given two vertices s and t of G, the algorithm* **STConn** *decides* USTCON *with one-sided error using space $O(p)$ and time $O(m^2 \log^5 n/p)$.*

Proof. Choosing a random set of p vertices according to the stationary distribution can be done in $O(m)$ steps using $O(p \log n)$ random bits and $O(p)$ space. Since only $O(p)$ space can be used to store L and do lookups on, a binary search tree or a perfect hash function must be used. (Constructing a perfect hash function for storing L requires expected time $O(p)$ [6].) If the unions are weighted and each union causes path compression on all elements of the set, then each find has cost $O(1)$. Since at most $O(n)$ non-trivial unions are performed, the cost of all the unions is $O(n \log n)$. Performing all $O(\log n)$ random walks of length $O(m^2 \log^3 n/p^2)$ takes time $O(m^2 \log^4 n/p^2)$ per leader for a total of $O(m^2 \log^4 n/p)$ time. Since this is also the total number of finds and lookups performed, this is the running time of each execution of the outermost loop. □

Remark. Note that this algorithm is easily parallelizable using p processors and $O(p)$ space. The parallel hashing scheme described in [7] can be used to implement a parallel version of this algorithm that runs on p processors, $n^\epsilon \leq p \leq n^{1-\epsilon}$, $\epsilon > 0$, that are connected by a bounded degree network. Briefly, storing the leader set using parallel hashing allows for the p processors to execute parallel unions and parallel finds in time $O(p^{\epsilon'})$ for any $\epsilon' > 0$, and consequently the random walks from each of the leaders can be executed in parallel. The resulting parallel implementation of the **STConn** algorithm runs in time $O(m^{2+\epsilon''}/p^2)$ ($\epsilon'' > \epsilon'$).

4. The correctness of STConn. Because our algorithm has one-sided error, it suffices to analyze its correctness in the case when s and t are in the same component of G. If G is actually connected, the results of §2 show that, in one pass through the inner loop of **STConn**, every edge is traversed with high probability. From this, it is possible to deduce that every leader is discovered by some leader. As mentioned earlier, however, this is not enough to prove that s and t become linked. The rest of this section shows that s and t will be "linked up" with high probability after $O(\log n)$ passes through the inner loop.

THEOREM 4.1. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders, each chosen at random according to the stationary distribution. Then for any $c_1 > 0$ there is a constant $c_2 > 0$ such that*

$$\Pr(L \cap S_{[v,w]}(c_2 m^2 \ln^3 n/p^2) \neq \emptyset) \geq 1 - \frac{1}{n^{c_1}},$$

where $S_{[v,w]}(T)$ denotes the set of distinct vertices visited in a T step random walk starting at $[v, w]$.

Proof. The proof is very similar to that of Lemma 2.3. As before the case $p = O(\log n)$ is trivial.

Let e be a directed edge chosen uniformly at random. By a proof virtually identical to that of Lemma 2.1,

$$\Pr(e \in E_{[v,w]}(\tau)) \geq \frac{\mathbf{E}(N_{[v,w]}(e, \tau))}{1 + \mathbf{E}(N_e(e, \tau))}.$$

Obviously, if e is chosen uniformly at random then

$$\mathbf{E}(N_{[v,w]}(e, \tau)) = \frac{\tau}{2m}.$$

By Lemma 2.2

$$\mathbf{E}(N_e(e, \tau)) \leq \frac{\tau}{2m} + \gamma\sqrt{\tau} \ln n.$$

Hence, for e chosen uniformly at random, there exists a constant c_3 such that

$$\Pr(e \in E_{[v,w]}(c_2 m^2 \ln^3 n/p^2)) \geq c_3 \frac{\ln n}{p},$$

provided that $P = \Omega(\log n)$.

In order to choose a leader according to the stationary distribution, one can choose a directed edge e uniformly at random and let the leader be the head of e. Since the probability of reaching a leader is greater than or equal to the probability of traversing the edge chosen to determine it, we obtain that

$$\Pr(L \cap S_{[v,w]}(c_2 m^2 \ln^3 n/p^2) = \emptyset) = (1 - \Pr(e \in E_{[v,w]}(c_2 m^2 \ln^3 n/p^2)))^p \leq \frac{1}{n^{c_1}},$$

for a sufficiently large c_2. □

COROLLARY 4.2. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders chosen at random according to the stationary distribution. Then for any $c_1 > 0$ there is a constant $c_2 > 0$ such that*

$$\Pr(L \cap S_s(c_2 m^2 \ln^3 n/p^2) \neq \emptyset) \geq 1 - \frac{1}{n^{c_1}}$$

and

$$\Pr(L \cap S_t(c_2 m^2 \ln^3 n/p^2) \neq \emptyset) \geq 1 - \frac{1}{n^{c_1}}.$$

Let L be any set of p leaders. We say the set L is *good* if for an absolute constant k_1 (determined in Lemma 4.3 below) the following two properties hold.

Property 1. The probability that a set of p independent random walks of length $\tau = \frac{1}{2}k_1 m^2 \ln^3 n/p^2$, one from each leader in L, traverses every edge in G is at least $1 - 1/n^3$.

Property 2. For every edge $[v, w] \in G$, the probability that a random walk of length τ starting from $[v, w]$ visits some leader in L is at least $1 - 1/n^3$.

LEMMA 4.3. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders chosen uniformly at random according to the stationary distribution. Then* $\Pr(L \text{ is good}) \geq 1 - 2/n$.

Proof. Say that a set of random walks, one from each of the leaders, is unsuccessful for $[v, w]$ if $[v, w]$ is not visited by any of them. Letting $c_1 = 6$ in Lemma 2.3 , we see that at most $1/n^3$ of the possible leader sets can have probability greater than $1/n^3$ of yielding unsuccessful random walks for any fixed $[v, w]$. Similarly, letting $c_1 = 6$ in Theorem 4.1, we see that at most $1/n^3$ of the possible leader sets have probability greater than $1/n^3$ of remaining undiscovered in a random walk of length τ from any fixed edge $[v, w]$. The probability that a leader set is not good is bounded by the sum of the probabilities that it isn't good because it violates properties 1 or 2. Since there are less than $n^2/2$ edges, the probability that a leader set is bad is bounded by $1/n$. The constant k_1 is determined by the requirements of Lemma 2.3 and Theorem 4.1. □

LEMMA 4.4. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders chosen uniformly at random according to the stationary distribution. Suppose that L is a good set of leaders. Let A and B be a partition of L into two nonempty subsets. Consider a random walk of length* 2τ *from each of the leaders in L. Then the probability that some leader in A is visitedfrom some leader in B or vice versa is greater than* 1/18.

Proof. (Unless stated otherwise, all edges referred to in this proof are directed.) We assign to each edge in the graph two labels: a "To" label T and a "From" label F. These labels are subsets of the set $\{A, B\}$. By definition, $A \in T(e)$ (respectively, $B \in T(e)$) if the probability that e is visited by a walk of length τ emanating from one of the leaders in A (respectively, a walk from one of the leaders in B) is at least 1/3. Analogously, $A \in F(e)$ (respectively, $B \in F(e)$) if the probability that some leader in A (respectively, B) is visited in a random walk of length τ starting from e is at least 1/3.

Properties 1 and 2 of good leader sets imply that for each edge neither label is empty. We now consider four cases.

Case 1. There is some edge $[v, w]$ with $A \in F([v, w])$ and $B \in T([v, w])$ or vice versa. Then with probability $\geq$ 1/3 edge $[v, w]$ is visited by one of the random walks of length τ originating in A and with probability $\geq$ 1/3 a leader in B is visited in the remaining at least τ steps. Hence, with probability $\geq$ 1/9 a leader in B is visited from a leader in A. After eliminating this case, the only remaining possibility is that for every edge $F([v, w]) = T([v, w]) = \{A\}$ or $F([v, w]) = T([v, w]) = \{B\}$.

Case 2. There is some undirected edge $\{v, w\}$ such that $F([v, w]) = T([v, w]) = \{A\}$, and $F([w, v]) = T([w, v]) = \{B\}$. Then with probability $\geq$ 1/3, $[v, w]$ is visited by one of the walks of length τ originating in A and hence the vertex v is visited by one of these walks with probability $\geq$ 1/3. Since a leader in B is visited from $[w, v]$ in τ steps with probability $\geq$ 1/3, a leader in B is visited from v in τ steps with probability $\geq$ 1/3. Hence with probability $\geq$ 1/9 a leader in B is visited from a leader in A.

Case 3. No label in the graph contains A or no label in the graph contains B. Without loss of generality, consider the first of the two conditions. Then every edge directed towards leaders in A, has a "To" label of B. Therefore, with probability $\geq 1/3$, each such edge is visited by one of the random walks of length τ originating in B and a leader in A is immediately visited. Hence, with probability $\geq 1/3$, a leader in A is visited from a leader in B.

Case 4. For each undirected edge $\{v, w\}$, we have $T([v, w]) = F([v, w]) = T([w, v]) = F([w, v]) = \{A\}$ or we have $T([v, w]) = F([v, w]) = T([w, v]) = F([w, v]) = \{B\}$. Since case 3 does not hold and the graph is connected, there must be a vertex v that is simultaneously the endpoint of some all-A labeled edge and some all-B labeled edge. Assume without loss of generality that at least 1/2 of the undirected edges with one endpoint at v have all their labels equal to B. Then since some edge $[w, v]$ has an A T-label, with probability $\geq 1/3$ v is visited in the first τ steps of the random walks originating at A. Since the majority of edges leaving v have a B F-label, with probability $\geq 1/2$ one of these edges will be traversed and then with probability $\geq 1/3$, a leader in B will be reached during the remaining at least τ steps. Hence with probability $\geq 1/18$ a leader in B is visited from a leader in A. □

We say that a subset of leaders forms a component if, during some prior phase of the algorithm, they have all been connected up with one another. During a particular phase, we say that a component C is *successful* if it discovers some other component or some other component discovers it. The previous lemma proves that, if the leader set is good, every component has probability at least 1/18 of being successful. The next lemma shows that the number of separate components decreases exponentially with the number of phases.

LEMMA 4.5. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders chosen uniformly at random according to the stationary distribution. Suppose that L is a good leader set. Let N_i be the number of components after the ith phase. Then there exist constants α and β, with $0 < \alpha, \beta < 1$, such that if $N_i > 1$ then*

$$\Pr(N_{i+1} > \beta N_i) \leq \alpha.$$

Proof. Plainly, N_{i+1} equals N_i minus the number of non-redundant links formed in phase i. Since the number of such links formed in phase i exceeds one-half the number of successful components, and the previous lemma shows that the probability that a component is successful is at least 1/18,

$$\mathbf{E}(\text{number of links formed in phase } i) \geq \frac{1}{2 \cdot 18} N_i.$$

Hence,

$$\mathbf{E}(N_{i+1}) \leq (1 - \frac{1}{36})N_i$$

and so there is a positive constant $\beta < 1$ such that

$$\Pr(N_{i+1} > \beta N_i) \leq \alpha. \qquad □$$

LEMMA 4.6. *Let G be a connected, undirected graph with n vertices and m edges. Let L be a set of p leaders chosen uniformly at random according to the stationary distribution. Suppose that L is a good leader set. Let N_i be the number of components after the ith phase. Then for any constant $c_1 > 0$, there is a constant $c_2 > 0$ such that*

$$\Pr(N_{c_2 \ln n} > 1) \leq \frac{1}{n^{c_1}}.$$

Proof. We say that a phase is successful if $N_{i+1} \leq \beta N_i$. Since the leader set is fixed and good, successive phases are independent (the random walks are independent), and by the previous lemma, phase i has probability greater than $1-\alpha$ of being successful for each i. But the probability that $N_{c_2 \ln n}$ is greater than 1 is bounded by the probability that there are fewer than $\ln_{1/\beta} n$ successful phases out of $c_2 \ln n$ phases. This in turn is bound by the probability that there are fewer than $\ln_{1/\beta} n$ successes in $c_2 \ln n$ Bernoulli trials with probability greater than $1-\alpha$ of success, which by Chernoff's bound is less than $1/n^{c_1}$, for appropriately chosen c_2. □

THEOREM 4.7. *The algorithm* **STConn** *decides* USTCON *using space $O(p)$ and time $O((m^2 \log^5 n)/p)$ with one-sided error. If s and t are in the same connected component, the algorithm fails to output YES with probability $O(n^{-1})$; if s and t are in different components, it outputs NO.*

Proof. If the graph consists of a single connected component, then we need only consider one execution of the outer loop of the algorithm, wherein the algorithm can fail to output YES when it should if either the leader set is not good or the leader set is good but the number of components did not reduce to 1. By Lemma 4.3, the former has probability at most $1/n$, and by Lemma 4.6 the latter, when choosing the constant k_3 appropriately, has probability at most $1/n$, and so the theorem follows in this case.

The other case is when s and t are in a single component C containing $\tilde{n}$ vertices and $\tilde{m}$ edges. If $m^2/p^2 > \tilde{m}\tilde{n}$ or $\tilde{n} < \ln^{3/2} n$, then in $k_3 \ln n$ random walks of length $k_1 m^2 \ln^3 n/p^2$ starting from s, the vertex t will be seen with overwhelming probability, since the expected cover time of the component is bounded by $2\tilde{m}\tilde{n}$ [1].

Otherwise, if $m^2/p^2 < \tilde{m}\tilde{n}$, the algorithm can fail to output YES when it should, if either none of the $c_0 \ln n$ selections of leaders include enough leaders that are in the component C, or if some selection of leaders includes enough leaders in C but the associated random walks do not succeed in connecting s to t. For the latter case, we observe that, in each of the $c_0 \ln n$ executions of the outer loop of the algorithm, the expected number of leaders that are chosen from C is $\tilde{p} = p\tilde{m}/m$. If $\tilde{p}/2$ leaders are indeed chosen from C, then since

$$\tau = \frac{c_3 m^2 \ln^3 n}{p^2} = \frac{c_3 \tilde{m}^2 \ln^3 n}{\tilde{p}^2},$$

the analysis given for a single connected graph on $\tilde{n}$ vertices and $\tilde{m}$ edges with $\tilde{p}$ leaders yields a failure probability of $O(\tilde{n}^{-1}) = o(1)$. To bound the probability that a leader selection is not sufficiently dense, we note that the probability that fewer than $\tilde{p}/2$ leaders are chosen from C is bounded by the probability of fewer than $\tilde{p}/2$ successes in p trials with probability $\tilde{m}/m$ of success. By standard bounds, this probability is at most

$$e^{-\frac{1}{8}p\frac{\tilde{m}}{m}} \leq e^{-\frac{1}{8}\sqrt{\frac{\tilde{m}}{\tilde{n}}}} \leq c$$

for some constant $c < 1$ (since $m/p < \sqrt{\tilde{m}\tilde{n}}$). Therefore, the probability that a single execution of the outermost loop fails is bounded by $c + o(1)$, and hence the overall probability of failure is bounded by $O(n^{-1})$, for a sufficiently large constant k_3. □

5. Open problems. Can the bound on the parallel cover time given in Theorem 2.4 be improved? Note that we bound the cover time for all vertices by bounding the cover time for all edges. It is not clear that this is necessary.

Theorem 3.1 shows that for p slightly larger than the average degree m/n, our algorithm runs faster than the random walk. Devising an algorithm that runs in time $O(mn \log^k n/p)$ is perhaps the most interesting open problem.

There is no fundamental reason why our upper bound is the best possible. We thus hope that this work will spark interest in proving a time-space tradeoff for USTCON, even in a restricted model of space-bounded computation such as the JAGs of Cook and Rackoff [5]. Beame et al. [2] give a number of time-space tradeoffs for structured models based on automata that traverse graphs. For one natural variant that admits implementations of our algorithms, they show that the product of time and space is $\Omega(n^2)$ for d-regular graphs ($d \geq 3$), and is $\Omega(mn)$ for non-regular graphs.

Acknowledgments. We are grateful to Lyle Ramshaw for a thorough reading of the manuscript and many useful comments and corrections. We also thank Larry Ruzzo and Martin Tompa for their many comments and suggestions, and also the anonymous referees.

BOUNDS ON THE COSTS OF MULTIVALUED REGISTER IMPLEMENTATIONS*

SOMA CHAUDHURI[†] AND JENNIFER L. WELCH[‡]

Abstract. A fundamental aspect of any concurrent system is how processes communicate with each other. Ultimately, all communication involves concurrent reads and writes of shared memory cells, or *registers*. The stronger the guarantees provided by a register, the more useful it is to the user, but the harder it may be to implement in practice. This paper considers the problem of implementing a k-ary regular (respectively, safe) register out of binary regular (respectively, safe) registers, assuming a single writer. While algorithms have been developed previously for these problems, no nontrivial lower bounds were known. The cost measures considered here are the number of physical registers and the number of reads and writes on the physical registers required to implement the logical register. Tight bounds are obtained on the cost measures in many cases, and interesting trade-offs between the cost measures are identified. The lower bounds are shown using information-theoretic techniques. Two new algorithms are presented that improve on the costs of previously known algorithms: the *hypercube* algorithm implements a k-ary safe register out of binary safe registers, requiring only one physical write per logical write; and the *tree* algorithm implements a k-ary regular register out of binary regular registers, requiring only $\lceil \log k \rceil$ physical operations per logical operation. Both algorithms use novel combinatorial techniques.

1. Introduction.

A fundamental aspect of any concurrent system is how processes communicate with each other. Ultimately, all communication involves concurrent accesses to shared memory cells, or registers. The stronger the guarantees provided by the shared memory, the more useful it is to the user, but the harder it may be to implement in practice. Thus it is of interest to determine which types of registers can implement which other types. Many such implementations are known, e.g., [1], [2], [6], [7], [10], [11], [12], [13], [15], [16], [17], among many others.

The contribution of this paper is to study the *costs* of implementing one type of register (the *logical* register) out of registers of another type (the *physical* registers). Cost measures considered are the number of physical registers and the number of operations on the physical registers used to perform the operations of the implemented register. Bounds on the number of physical operations can be used to obtain time bounds for the logical operations in terms of the time taken by the physical operations.

A *register* is a shared variable or memory cell that supports concurrent reading and writing by a collection of processing entities. The operations of reading and writing are not instantaneous; instead, they have duration in time, from a starting point to an ending point. Although each entity accessing a register is assumed to issue operations sequentially, operations on behalf of different entities can overlap in time.

A variety of types of registers can be defined, differing in several dimensions, including the number of concurrent readers supported, the number of concurrent writers supported, the number of values the register can take on, and the strength of the consistency guarantees provided in the presence of concurrent operations. Throughout this paper we assume there

is only one writer, leaving three parameters of interest: the number of readers, the number of values, and the consistency guarantees. We distinguish between 1-reader registers and n-reader registers, for $n > 1$, and between binary registers and k-ary registers, for $k > 2$. (A k-ary register can take on k different values.)

Lamport [6] defines three consistency guarantees of increasing strength, namely, safe, regular, and atomic. Roughly speaking, a read of a *safe* register always returns the most recent value written to the register, unless the read overlaps with a write, in which case any legal value of the register can be returned. A read of a *regular* register always returns the most recent value written, unless the read overlaps one or more writes, in which case it returns either the old value or one of the values written by an overlapping write. An *atomic* register provides the illusion, via the values returned by read operations, that each operation happens at a single instant in time within its range, i.e., that the operations are totally ordered. In this paper, we only consider safe and regular registers. In particular, we consider the problem of implementing an n-reader k-ary regular (respectively, safe) register out of n-reader binary regular (respectively, safe) registers.

We study the costs incurred by these implementations. Let M, R, and W be the minima, over all implementations between two particular types of registers, of the number of physical registers, the maximum number of physical operations in a logical read, and the maximum number of physical operations in a logical write, respectively. Our algorithms will involve no physical reads in a logical write and no physical writes in a logical read. Our lower bound results give bounds on the number of physical reads per logical read, and the number of physical writes per logical write. These are stronger results than just giving bounds on the number of physical operations per logical action.

Our results are summarized in Tables 1 and 2. Table 1 gives the bounds when all algorithms are considered. Table 2 gives the bounds when certain classes of algorithms are considered, as specified by the column labeled S—namely, 1-write algorithms, c-write algorithms, and $\lceil \log k \rceil$-register algorithms. (All logarithms are base 2.)

For implementing a k-ary safe register out of binary safe registers, we show tight bounds of $R = \lceil \log k \rceil$, $W = 1$, and $M = \lceil \log k \rceil$. The upper bound of 1 on W is obtained from a new algorithm, which we call the *hypercube* algorithm. The best previous upper bound on W was $\lceil \log k \rceil$ [6]. These three optimal bounds are not obtained simultaneously in a single algorithm, and in fact, we show some nontrivial trade-offs between the three cost measures.

For implementing a k-ary regular register out of binary regular registers, we show the tight bound that $R = \lceil \log k \rceil$, and the bounds $1 \leq W \leq \lceil \log k \rceil$, and $\max\{\lceil \log k \rceil + 1, 2(\log k) - \log\log k - 2\} \leq M \leq \min\{k - 1, n(3 \log k + 68)\}$, where n is the number of readers of the logical register. The upper bounds on R and W are simultaneously achieved by a new algorithm, which we call the *tree* algorithm. We also present some lower bounds on R and M that follow if we restrict attention to implementations that use only a small constant number of physical writes per logical write.

The lower bounds in Table 1 for safe registers and those on R and W for regular registers are obvious from information-theoretic considerations. All of the remaining lower bounds are new. Little previous work has been done concerning lower bounds or trade-offs for register implementations. One such previous result is in [6], where it is shown that in any implementation of an atomic register using regular registers, a read of the logical register must involve a write to a physical register. Tromp [13] uses this result to show that three binary safe registers are necessary to construct a binary atomic register.

In §2 we present our model and some results for all implementations. Section 3 considers safe registers and §4 considers regular registers. We conclude in §5 with some open questions.

2. Preliminaries. In this section, we give formal definitions for the types of registers that we will study (n-reader, k-ary, safe, and regular), describe the rules we impose on implementing

one type of register with another, and define the cost measures we will use. Then we present some definitions and lemmas that are true for implementations between any types of registers.

2.1. Model. We use a simplified form of the I/O automaton model [9] to describe our system.

To implement a logical register with value set V, where $|V| = k$, we compose a collection of physical registers X_j, $1 \le j \le m$, each with value set $\{0, 1\}$, a collection of read processes RP_i, $1 \le i \le n$, and a single write process WP. The read and write processes implement the protocols used by the readers and writer of the logical register. Each such protocol consists of accessing certain of the physical registers and doing some local computation.

Communication between these components takes place via **actions**. Each action is an output of one component (the component that generates it) and an input to another component. Components are modeled as state machines in which actions trigger transitions. Components have no control over when inputs occur and thus must have a transition for every input in every state. Components do have control over when outputs occur; if an output labels a transition from a state, then the output is **enabled** in that state.

An **execution** of the implementation consists of a sequence in which state tuples (one entry for the state of each component) and actions alternate, beginning with a tuple of initial states. For each action π in the execution, π must be enabled in the preceding state of the component for which it is an output. In the following state tuple, the states of the two components for which π is an input and an output must change according to the transition functions, while the remaining components' states are unchanged.

A **schedule** is the sequence of actions in an execution.

The **logical actions** are READ(i), RETURN(i, v), WRITE(v), and ACK, $1 \le i \le n$ and $v \in V$. READ(i) is an input to RP_i from the outside world; RETURN(i, v) is an output from RP_i to the outside world. WRITE(v) is an input to WP from the outside world and ACK is an output from WP to the outside world. Although we do not explicitly model the outside world with a component, we do assume that for each i, the outside world and RP_i cooperate so that READs and RETURNs strictly alternate, beginning with a READ, and analogously for WP.

[1] $k - 1$ if k is a power of 2; k otherwise.

The **physical actions** are $\text{read}_j(i)$, $\text{return}_j(i, v)$, $\text{write}_j(v)$, and ack_j. The subscript j is between 1 and m; it indicates that X_j is the physical register being read or written. The parameter v is either 0 or 1 and indicates the value being read from or written to X_j. For a fixed j, the parameter i for reads and returns ranges over some subset of $\{0, \ldots, n\}$ of size at most n; this subset indicates which of the read and write processes read X_j. (The value 0 indicates WP.) For a fixed j, there is no parameter i for writes and acks, since there is a unique read or write process that writes X_j.

A READ(i) and its following RETURN(i, v) form a **logical operation**, as do a WRITE(v) and its following ACK. **Physical operations** are defined analogously. An operation is **pending** if its first half is present but not its second half.

We assume that the read and write processes cooperate with the physical registers so that for each i, $0 \leq i \leq n$, and each j, $1 \leq j \leq m$, $\text{read}_j(i)$ and $\text{return}_j(i, *)$ alternate beginning with a read, and analogously for writes. We also assume that no read or write process has a physical operation pending unless it has a logical operation pending.

Each physical register X_j satisfies this liveness property: Immediately after an input action occurs, the matching output is enabled.

A **safe** physical register satisfies the **Safe Property**: For every physical read operation that does not overlap a physical write operation, the value returned is the value written by the most recent physical write operation. If there is no preceding write operation, then it returns the initial value.

A **regular** physical register satisfies the **Regular Property**: Every physical read operation returns a value written by an overlapping write operation or by the most recent preceding write (or the initial value if there is no preceding write).

The read and write processes must work together to implement a logical register. The liveness property for a logical register differs from that for a physical register, as discussed below. A safe (respectively, regular) logical register satisfies the safe (respectively, regular) property, as defined for physical registers, replacing "physical" with "logical."

The liveness property for a logical register is that the implementation must be **wait-free**, meaning that in every finite execution, if a logical operation by RP_i (respectively, WP) is pending, then there is a finite sequence of actions involving only RP_i (respectively, WP) that finishes the operation. Our algorithms actually provide a bounded number of actions, while our lower bounds hold for algorithms satisfying the weaker definition.

A natural question that may arise is why the liveness property is different for physical and logical registers. The wait-free definition for the logical register implies that every logical operation must complete using only physical operations initiated by that logical operation. In the case of the physical register, where we don't model the "internal" actions, this wait-free property reduces to the physical liveness property given.

We now define the cost measures.

Consider two register types, physical and logical, and let A be an algorithm for a physical-to-logical register implementation. Let M_A be the number of physical registers used in A, let R_A be the maximum number of physical operations performed during any logical READ in any execution of A, and let W_A be the maximum number of physical operations performed during any logical WRITE in any execution of A. Given a set S of physical-to-logical register implementations, let M_S be the minimum of M_A over all $A \in S$, R_S be the minimum of R_A over all $A \in S$, and W_S be the minimum of W_A over all $A \in S$. (If $S = \emptyset$, then M_S, R_S, and W_S are infinity.) Finally, let $M = M_S$, $R = R_S$, and $W = W_S$, where S is the set of all physical-to-logical register implementations (for these two types). (The physical and logical register types are implicit parameters to M, R, and W.)

In the rest of this paper, we derive upper and lower bounds on M, R, and W, and trade-offs between them, for different physical and logical register types.

These bounds on R and W can be converted into time bounds for performing logical operations as follows. Suppose we know bounds R_l, R_u, W_l, and W_u such that $R_l \leq R \leq R_u$ and $W_l \leq W \leq W_u$. Let r be an upper bound on the time to read a physical register and let w be an upper bound on the time to write a physical register. Let s be an upper bound on the time for a read or write process to perform an action once it becomes enabled. Our upper bounds on R and W come from algorithms, all of which have the property that no logical READ involves a physical write and no logical WRITE involves a physical read. Since we assume that all physical operations are enclosed within logical operations and that only one physical operation can be pending at a time, we deduce that an upper bound on the worst case time to perform a READ of a logical register that is implemented with physical registers is $R_u(r + s) + s$. Similarly, an upper bound on the worst case time to perform a WRITE of a logical register that is implemented with physical registers is $W_u(w + s) + s$. Our lower bounds on R and W do not assume that logical READs do not involve physical writes, or that logical WRITEs do not involve physical reads, and thus they imply analogous lower bounds on the worst case times.

2.2. General results. Given a finite schedule σ of an algorithm A, let the **configuration** of σ be the tuple of sets of "possible values" of the physical registers at the end of the schedule, i.e., if X_i is the ith physical register, then the ith element of the configuration is the set of all values that could be returned by a physical read of that register at that point, according to the safe/regular property. A configuration is **stable** if each element of the tuple is a singleton set. Thus it can be represented as $x_1 \ldots x_m$, where x_i is the value of register X_i for all i. The **initial configuration** is the (stable) configuration of the empty schedule, consisting of the initial value of each physical register.

Let $\mathcal{WO}$ (for "write-only") be the set of all schedules of A in which only WP takes steps and no physical write is pending. Let $\mathcal{S} = \{C : C$ is the configuration of some $\sigma \in \mathcal{WO}\}$. It is easy to see that all configurations in $\mathcal{S}$ are stable.

For each i, define $L_i : \mathcal{S} \to V$ as follows. $L_i(C)$ is the logical value returned by RP$_i$ when RP$_i$ starts in its local initial state, the physical registers have the values specified in C, and no other read or write process takes a step.

What we would like is a function that returns the value of the logical register when the physical registers are in a given configuration. However, an arbitrary algorithm may have different protocols for different read processes (necessitating our use of a subscript on L), and it may use the history of the read process to determine what value is returned. Thus it might be the case that RP$_i$ returns different values at different times in an execution, even given the same configuration. In order to accommodate such algorithms, we define each L_i specifically when RP$_i$ has taken no steps yet.

The next lemma states that L_i is well defined, i.e., that the current configuration (values of the physical registers) and nothing else determines the value of the logical register (as perceived by RP$_i$). This can be shown by a simple induction on the length of the execution.

LEMMA 2.1. *For any algorithm A, the function L_i is well defined for all i.*

Let $\mathcal{WOC}$ (for "write-only, completed") be the set of all schedules of A in which only WP takes steps and no *logical* WRITE is pending. Let $\mathcal{T} = \{C : C$ is the configuration of some $\sigma \in \mathcal{WOC}\}$. It is easy to see that $\mathcal{T} \subseteq \mathcal{S}$. Every configuration in $\mathcal{T}$ is defined to be a **terminal** configuration.

The next lemma states that if no read process has taken any steps and no logical WRITE is in progress, then each L_i is equal to the value of the most recent WRITE to the logical register.

LEMMA 2.2. *For any algorithm A, if σ is in $\mathcal{WOC}$ with configuration C, then, for all i, $L_i(C)$ equals the value of the most recent* WRITE *(the initial value if σ is empty).*

The previous lemma implies that all the L_i's must agree whenever the argument is in the set $\mathcal{T}$. Thus we define $L : \mathcal{T} \to V$ to be $L(C) = L_i(C)$ for any i. It is easy to see that for each $v \in V$, there is a $C \in \mathcal{T}$ such that $L(C) = v$.

In most of our proofs, we only need to consider situations in which no logical WRITE is pending, and thus we can use the notation L. However, in a few places (notably Lemmas 4.4 and 4.5), we must consider what happens in the middle of a logical WRITE, and thus we must use a specific L_i (we choose L_1 for concreteness).

3. k-ary safe register from binary safe registers. We consider the problem of implementing an n-reader, k-ary, safe register out of n-reader, binary, safe registers, for any $n \geq 1$, where $k > 2$. Subsection 3.1 is devoted to proving tight, independent bounds on R, W, and M. In §3.2, we present an algorithm A such that $W_A = 1$. We also show some nice combinatorial properties related to one-write algorithms. Subsection 3.3 discusses algorithms that allow c physical accesses per logical WRITE. We also give some additional trade-offs between the cost measures.

Let the value set of the logical register be $V = \{0, \ldots, k-1\}$ with initial value $v_0 \in V$.

3.1. Independent bounds. The following theorem gives matching upper and lower bounds on R, W, and M.

THEOREM 3.1. *The implementation of an n-reader, k-ary, safe register by n-reader, binary, safe registers gives the following independent bounds*: $R = \lceil \log k \rceil$, $W = 1$, *and* $M = \lceil \log k \rceil$.

Proof. The upper bounds on R and M follow from the binary representation algorithm in [6] described below. The upper bound on W follows from our hypercube algorithm presented in §3.2. The lower bounds on W and M are obvious.

We now show the lower bound on R. For each $v \in V$, there is a schedule σ_v of A of the form

$$\text{WRITE}(v)\ \alpha_v\ \text{ACK READ}(1)\ \beta_v\ \text{RETURN}(1, v),$$

where α_v consists solely of actions of WP and contains no ACK, and β_v consists solely of actions of RP_1 and contains no RETURN.

By the definition of read processes, for all distinct v and w, $\beta_v \neq \beta_w$ and the maximal common prefix of β_v and β_w is immediately followed by a return(0) action from some physical register X in β_v and by a return(1) action from X in β_w (or vice versa); that is to say, RP_1 does the same thing in β_v and β_w until it reads a different value. Let γ_v be the sequence of physical values read in β_v, for all v.

Thus, if $v \neq w$, then the sequence γ_v of physical values read in β_v is not equal to the sequence γ_w of physical values read in β_w. There are k distinct sequences of physical values corresponding to the γ_v's, i.e., k binary strings. Thus at least one string, say that corresponding to γ_v, must have length at least $\lceil \log k \rceil$, implying that β_v contains at least $\lceil \log k \rceil$ physical reads. □

The **binary representation algorithm** in [6] implements an n-reader, k-ary, safe register out of $\lceil \log k \rceil$ n-reader, binary, safe registers. The write process writes the binary representation of the logical value into the physical registers. Each read process reads all the physical registers and returns the logical value whose binary representation was read, as long as the value is less than k. Otherwise, it returns any value less than k. This algorithm implies that $R \leq \lceil \log k \rceil$, $W \leq \lceil \log k \rceil$, and $M \leq \lceil \log k \rceil$. By Theorem 3.1, the number of registers and number of physical reads in the binary representation algorithm are both optimal.

The **unary representation algorithm** presented next shows that $W \leq 2$. There are $k-1$ physical registers, $X_1, \ldots, X_{k-1}$. Logical value 0 is represented when all registers are 0.

Logical value $v \neq 0$ is represented when X_v is 1 and the other registers are 0. Each read process reads registers X_1, X_2, and so on, in order, until reading a 1, and RETURNs logical value v, where X_v is the register that returned 1. If no register returns 1, then 0 is RETURNed. To WRITE logical value v, assuming w is the old value of the logical register, the write process writes 0 to X_w if $w \neq 0$, and writes 1 to X_v if $v \neq 0$.

In the next subsection, we will present an algorithm which brings down the number of physical writes per logical WRITE to 1.

3.2. One-write algorithms. In this subsection, we discuss the class of one-write algorithms. We show that their existence depends on satisfying a combinatorial coloring property of hypercubes.

Figure 1 presents our new **hypercube algorithm**, which shows that $W \leq 1$; it relies on a function f, which will be defined shortly. For now, assume that k is a power of 2. Later we will show how to remove this restriction.

```
Physical Registers: $X_1, \ldots, X_{k-1}$, initially $f(X_1 \ldots X_{k-1}) = v_0$ and $X_j = 1$ for at most one $j$
Read Process RP$_i$, $1 \leq i \leq n$: variables $x_1, \ldots, x_{k-1}$
        READ($i$):
                for $j := 1$ to $k - 1$ do $x_j :=$ read $X_j$ endfor
        RETURN($i$, $f(x_1 \ldots x_{k-1})$)
Write process WP: variables $x_1, \ldots, x_{k-1}$, initially $x_j$ equals the initial value of $X_j$ for all $j$
        WRITE($v$):
                if $v \neq f(x_1 \ldots x_{k-1})$ then
                        write $\overline{x_j}$ to $X_j$, where $j$ is such that $f(x_1 \ldots x_{j-1}\overline{x_j}x_{j+1} \ldots x_{k-1}) = v$
                        $x_j := \overline{x_j}$
                endif
        ACK
```

FIG. 1. *Hypercube algorithm.*

We notice an interesting relationship between the correctness of the hypercube algorithm and coloring the nodes of a $(k - 1)$-dimensional hypercube with k colors such that each node has a neighbor with each of the $k - 1$ colors other than its own. The following definition and lemmas formalize this idea. (Nodes are labeled with $(k - 1)$-bit strings, the colors are elements of V, and the function is the coloring.)

A function g is said to have the **rainbow-coloring property** if $g : \{0, 1\}^{k-1} \rightarrow V$ such that for all $x \in \{0, 1\}^{k-1}$, and for all $v \in V$, if $v \neq g(x)$, then there exists $y \in \{0, 1\}^{k-1}$ such that $v = g(y)$ and x and y differ in exactly one bit. That is, every node x has a neighboring node with every color other than x's color.

Lemma 3.2 states that if the function f used in the algorithm has the rainbow-coloring property, the hypercube algorithm correctly implements a k-ary safe register using binary safe registers such that each logical WRITE requires one physical write. The rainbow-coloring property ensures that each READ RETURNs the correct value if it does not overlap a WRITE.

LEMMA 3.2. *If function f has the rainbow-coloring property, then the hypercube algorithm is correct.*

We define a function $f : \{0, 1\}^{k-1} \rightarrow V$ for use in the algorithm. Lemma 3.3 shows that f has the rainbow-coloring property. For positive integer $i < k$, let $bin(i)$ be the binary representation of i in $\log k$ bits (remember that k is a power of 2). For $x \in \{0, 1\}^{k-1}$, let x_i be the ith bit of x, i.e., $x = x_1 x_2 \ldots x_{k-1}$. For all $x \in \{0, 1\}^{k-1}$, we define $f(x)$ to be the element of V whose binary representation is $\bigoplus_{x_i=1} bin(i)$, where $\oplus$ represents exclusive-or. This expression consists of $\log k$ bits and thus represents a value in the range 0 to $k - 1$, i.e., a value in V.

The intuition behind the coloring function f is that we want to go from a $(k - 1)$-bit string, the label of a node in the hypercube, to a $(\log k)$-bit string, indicating one of k colors. Given a node with label x, the color assigned is the one whose binary representation is equal to the exclusive-or of the set of $bin(i)$, for all i such that $x_i = 1$. Note that if two nodes x and y differ in the single bit i, then $f(x) \oplus f(y) = bin(i)$. So, given the color of a node x, we can derive the color of any adjacent node y in a consistent manner.

Given this definition of f, the initial values of the physical registers are all 0, except that if $v_0 \neq 0$ then $X_{v_0} = 1$. The computation of j in the writer's code is $bin(j) = bin(v) \oplus bin(f(x_1 \ldots x_{k-1}))$.

LEMMA 3.3. *The function f defined for the hypercube algorithm (when k is a power of 2) has the rainbow-coloring property.*

Proof. First we must show that for all $x, y \in \{0, 1\}^{k-1}$ that differ in exactly one bit, $f(x) \neq f(y)$. Suppose x and y differ in bit i. Then $f(x) \oplus f(y) = bin(i)$. Since $bin(i) \neq 0^{\log k}$, we are done. Second we must show that for all $x, y, z \in \{0, 1\}^{k-1}$ such that $y \neq z$ and y and z both differ from x in exactly one bit, $f(y) \neq f(z)$. This can be shown similarly. These two facts together show that f has the rainbow-coloring property. □

Figure 2 illustrates how our algorithm works in the simple case where $k = 4$. Our hypercube is then a three-dimensional cube, whose vertices can be colored with four colors, r, b, g, and y. Note that the coloring satisfies the rainbow-coloring property.

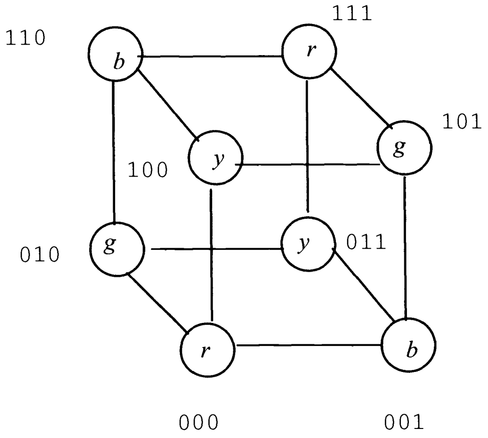

FIG. 2. *An example illustrating the hypercube algorithm.*

Combining Lemmas 3.2 and 3.3 shows that the hypercube algorithm is a one-write algorithm (using $k - 1$ registers) if k is a power of 2. To obtain a one-write algorithm for values of k that are not powers of 2, we modify the power-of-2 hypercube algorithm for $m - 1$ physical registers, where $m = 2^{\lceil \log k \rceil}$, i.e., m is the smallest power of 2 larger than k. The modification is to change the RETURN statement to be RETURN(min$\{k - 1, f(x_1 \ldots x_{m-1})\}$). This implementation of a k-ary register by binary registers will not cause the binary registers to take on all possible 2^{m-1} values, i.e., no stable configuration of the algorithm will be mapped to a value that is out of the range of the logical register. However, a slow read process, which overlaps a number of writes, might (spuriously) observe a configuration corresponding to a value larger than $k - 1$, thus necessitating the modification. Thus we have shown the following theorem.

THEOREM 3.4. *The hypercube algorithm correctly implements a k-ary safe register using binary safe registers.*

The following theorem summarizes our results for the class of 1-write algorithms.

THEOREM 3.5. *Let S be the set of algorithms A such that $W_A \leq 1$. Then*

(i) $k - 1 \leq R_S \leq 2^{\lceil \log k \rceil} - 1$,

(ii) $M_S = k - 1$, *if k is a power of* 2, *and*

(iii) $k \leq M_S \leq 2^{\lceil \log k \rceil} - 1$, *if k is not a power of* 2.

Proof. All the upper bounds follow from the hypercube algorithm. The rest of the proof concerns the lower bounds.

Choose an algorithm $A \in S$. Let C_{v_0} be the initial configuration. For all $v \neq v_0$, let C_v be the configuration of a schedule in $\mathcal{WOC}$ of the form WRITE(v) α_v ACK, where α_v contains no ACK. Since α_v only contains one physical write, C_{v_0} and C_v differ in a single bit, say that for physical register X_v.

Since there are $k - 1$ choices for $v \neq v_0$, there are at least $k - 1$ physical registers. Since A was chosen arbitrarily, $M_S \geq k - 1$. The improved lower bound of k for M_S when k is not a power of 2 follows from Lemmas 3.6 and 3.7.

To show $R_S \geq k - 1$, we assume, for contradiction, that $R_A < k - 1$. Consider the schedule READ(1) β RETURN(1, v_0), where β consists solely of actions of RP$_1$ and contains no RETURN. β contains a sequence of less than $k - 1$ physical reads. Let X_v (as defined above) be one of the physical registers not read in β; note that $v \neq v_0$. Since C_{v_0} differs from C_v in the value of register X_v and nowhere else, an easy induction on the length of β shows that WRITE(v) α_v ACK READ(1) β RETURN(1, v_0) is a schedule of A, violating the safe property since $v \neq v_0$. We therefore have a contradiction, implying $R_A \geq k - 1$. □

We now consider the number of registers when k is not a power of 2. Lemma 3.6, which is the converse of Lemma 3.2, shows that the existence of a function with the rainbow-coloring property is necessary for the existence of a one-write algorithm using $k - 1$ registers. Lemma 3.7, which is the converse of Lemma 3.3, shows that when k is not a power of 2, no function with the rainbow-coloring property can exist. Together, these two lemmas imply that if k is not a power of 2, then any one-write algorithm must use more than $k - 1$ registers.

LEMMA 3.6. *If there is an algorithm A with $W_A = 1$ and $M_A = k - 1$, then there exists a function with the rainbow-coloring property.*

Proof. We show that L has the rainbow-coloring property. Recall that L maps $\mathcal{T}$, the set of terminal configurations, to V. We know $\mathcal{T}$ is not empty. Choose any configuration $C \in \mathcal{T}$. Let v be the color of C under L. Every neighbor of C is also in $\mathcal{T}$ and has a unique color different from C's color, since there are only $k - 1$ registers and $k - 1$ possibilities for the next value not to be v. To finish the proof, we note that $\mathcal{T} = \{0, 1\}^{k-1}$, since every neighbor of a terminal configuration is also a terminal configuration. □

LEMMA 3.7. *If k is not a power of* 2, *then there is no function with the rainbow-coloring property.*

Proof. Assume in contradiction that there is a function f with the rainbow-coloring property. Choose any color, say blue, and let b be the number of nodes colored blue by f. Let B be the set of edges in the hypercube that have one endpoint colored blue and one endpoint not colored blue. Since each nonblue node is adjacent to exactly one blue node and there are $2^{k-1} - b$ nonblue nodes, $|B|$ must be $2^{k-1} - b$. However, since each blue node is adjacent to $k - 1$ nonblue nodes and there are b blue nodes, $|B|$ must be $b(k - 1)$. The implication is that $2^{k-1} - b = b(k - 1)$, implying $2^{k-1} = kb$. This implies that k divides 2^{k-1}, contradicting the fact that k is not a power of 2. □

In this subsection, we showed that the existence of a one-write implementation of a k-ary safe register was based on solving an underlying combinatorial problem. Specifically, a one-write algorithm using $k-1$ physical registers exists if and only if we can color a $(k-1)$-dimensional hypercube with k colors such that each node has a neighbor with every color other than its own. We can generalize this to any number of physical registers as follows. A one-write algorithm using m registers exists if and only if we can *partially* color an m-dimensional hypercube with k colors, such that each *colored* node has a neighbor with every color other than its own. By a partial coloring, we mean a coloring where not all nodes of the graph need to be colored.

Lemmas 3.3 and 3.7 imply that there is rainbow-coloring of the $(k-1)$-dimensional hypercube if and only if k is a power of 2. Kant and van Leeuwen [5] have independently shown the same result. Their proof uses notions from coding theory and is based on showing a correspondence between 1-error-correcting codes and these colorings. They applied this result to the file distribution problem.

3.3. c-write algorithms and trade-off results. As we showed for 1-write algorithms, the problem of implementing c-write algorithms can also be shown to have a corresponding parallel in a combinatorial problem. Here, we are interested in a partial coloring of the m-dimensional hypercube such that for each colored node, there exists a node of every other color *within a distance of c* from this node.

This combinatorial characterization also helps us obtain lower bounds for M and R. For example, we know that for there to exist a one-write algorithm that uses m physical registers, there must be a configuration C_0 that differs from $k-1$ different configurations C_v in exactly one bit. Since each configuration is represented in m bits, this says that there is a binary string of length m that differs from $k-1$ different strings of the same length in exactly one bit. To satisfy this combinatorial property, we require that $m \geq k-1$. This sequence of reasoning was implicit in the proof of Theorem 3.5.

Along similar lines, for there to exist a c-write algorithm that uses m registers, there must exist a binary string of length m which differs from $k-1$ different strings of the same length in *at most c* bits.

We formalize this property in Lemma 3.8 and Theorems 3.10 and 3.11. These theorems give lower bounds on M and R for c-write algorithms, i.e., algorithms that use a small bounded number of physical writes per logical WRITE.

The next result is Theorem 3.12, which gives trade-offs on W versus R and M. An application of this result is to give upper bounds on M and R for c-write algorithms.

The final result in this subsection, Theorem 3.13, states that if no more than $\lceil \log k \rceil$ registers are used, then some WRITE must write at least $\lceil \log k \rceil$ physical registers.

LEMMA 3.8. *Given any binary string x of length m, if there are at least k distinct strings of length m which differ from x in at most c bits, where $c \leq (\log k)/3$, then $m \geq (c!k/2)^{1/c}$.*

Proof. Let x be a string of length m. The number of distinct strings of length m that differ from x in at most c bits is

$$\binom{m}{0} + \binom{m}{1} + \binom{m}{2} + \cdots + \binom{m}{c}.$$

Since we know that there are at least k such distinct strings, we have $\sum_{i=0}^{c} \binom{m}{i} \geq k$. We obtain the following upper bound on $\binom{m}{i}$, for all i: $\binom{m}{i} = \frac{m(m-1)(m-2)\cdots(m-i+1)}{i!} \leq m^i/i!$. To get an upper bound on the entire summation, we need the following claim, which is taken from [14]. First, we introduce some notation. Let $s_{m,j}$ denote $\sum_{i=0}^{j} \binom{m}{i}$. Let $b_{m,i}$ denote $\binom{m}{i}$.

CLAIM 3.9. *If $1 \leq j \leq m/3$, then $s_{m,j} \leq 2b_{m,j}$.*

Proof. We compute a lower bound for $b_{m,j}/b_{m,j-1} = \frac{m-j+1}{j}$. Note that $\frac{m-j+1}{j}$ is larger than 2 for $j \leq m/3$. Therefore, for $j \leq m/3$, $b_{m,j}/b_{m,j-1} > 2$. The remaining proof is by induction.

Inductive hypothesis: $s_{m,j} \leq 2b_{m,j}$ for $j \leq m/3$.

Basis: For $j = 1$ (assume $m \geq 3$), $s_{m,0} = b_{m,0} = 1$ and $b_{m,1} = m$. Therefore, $s_{m,1} = m + 1$ and $s_{m,1} \leq 2b_{m,1}$.

Inductive step: Let the inductive hypothesis hold for all l such that $l < j \leq m/3$. We show that it holds for j. By the inductive hypothesis, $s_{m,j-1} \leq 2b_{m,j-1}$. Note that $s_{m,j} = s_{m,j-1} + b_{m,j}$. This implies that $s_{m,j} \leq 2b_{m,j-1} + b_{m,j}$. Also, we showed earlier that $2b_{m,j-1} \leq b_{m,j}$. Therefore, $s_{m,j} \leq b_{m,j} + b_{m,j} = 2b_{m,j}$. □

The above claim holds for $j = c$ since we know that $m \geq \log k$ (it takes $\log k$ bits to represent k distinct values), and this implies that $c \leq m/3$. Now, using the above claim and our previous upper bound for $\binom{m}{i}$, we have $\sum_{i=0}^{c} \binom{m}{i} \leq 2\binom{m}{c} \leq 2m^c/c!$. So, $k \leq 2m^c/c!$; by manipulating this inequality, we get $m \geq (c!k/2)^{1/c}$. □

THEOREM 3.10. *For all algorithms A, if $W_A = c$, where $c \leq (\log k)/3$, then $M_A \geq (c!k/2)^{1/c}$.*

Proof. Given an algorithm A such that $W_A = c$, where $c \leq (\log k)/3$, let C_{v_0} be the initial configuration. Then $L(C_{v_0}) = v_0$. For all $v \neq v_0$, the schedule σ_v of the form WRITE(v) α_v ACK yields the terminal configuration C_v. Since each WRITE can initiate at most c physical writes, each C_v differs in at most c bits from C_{v_0}.

Since there are k values v, there must be at least k terminal configurations C_v differing in at most c bits from C_{v_0}. The number of registers used in the algorithm is M_A. Each terminal configuration is therefore a binary string of length M_A. Therefore, there are at least k strings of length M_A which differ in at most c bits from C_{v_0}. Since, $c \leq (\log k)/3$, Lemma 3.8 applies, and we have the result $M_A \geq (c!k/2)^{1/c}$. □

THEOREM 3.11. *For all algorithms A, if $W_A = c$, where $c \leq (\log k)/3$, then $R_A \geq (c!k/2)^{1/c}$.*

Proof. For any algorithm A, where $W_A \leq c$, consider the following schedules, for all v,

$$\text{WRITE}(v)\ \alpha_v\ \text{ACK READ}(1)\ \beta_v\ \text{RETURN}(1, v),$$

where α_v and β_v contain only physical actions. We claim that for some v, β_v initiates at least $(c!k/2)^{1/c}$ physical reads. We prove this by contradiction.

Suppose, for every v, β_v initiates at most p physical reads where $p < (c!k/2)^{1/c}$. Let ρ_v be the sequence of values read, in order, on accessing any given register *for the first time* in β_v. Note that we don't include values obtained from registers which have been read before or been written before in β_v. Clearly, $|\rho_v| \leq p$.

First we assume that the initial configuration is the zero-vector. Therefore, the initial values of all the physical registers are 0. Since α_v contains at most c physical writes, there can be at most c 1's in ρ_v. Clearly, each ρ_v is distinct. Otherwise, if for some v, v' such that $v \neq v'$, $\rho_v = \rho_{v'}$, then a READ in both cases would RETURN the same value, which would be a contradiction. Therefore, $\{\rho_v | v \in V\}$ is a set of k distinct strings of length at most p that differ from the zero-vector in at most c bits. Since $p < (c!k/2)^{1/c}$, this contradicts Lemma 3.8.

In the general case where the initial configuration is *not* the zero-vector, we can no longer claim that ρ_v contains at most c 1's. We therefore define the string δ_v, for every v, as follows. For every bit in ρ_v, if the value is the *same* as the initial value of the register read, place the bit 0 in δ_v. If the value is *different* from the initial value of the register read, place the bit 1 in δ_v. Since α_v contains at most c writes, δ_v can contain at most c 1's. Also, each δ_v is distinct. Now, the same argument as in the previous paragraph holds, with δ_v substituted for ρ_v.

Therefore, for some v, β_v initiates at least $(c!k/2)^{1/c}$ physical reads. This gives our lower bound for R_A. □

Theorem 3.12 presents bounds on the costs of algorithms that are a hybrid of the binary and unary representation algorithms. Using this theorem, we can derive upper bounds on M

and R for c-write algorithms. Theorem 3.13 concerns bounds on W for algorithms that use $\lceil \log k \rceil$ physical registers.

The binary representation algorithm yields an upper bound of $\lceil \log k \rceil$ for R, W, and M. The unary representation algorithm brings down the upper bound for W to 2, while pushing up the bounds for R and M to $\Omega(k)$. This suggests a trade-off between these measures. We can construct a class of algorithms, by borrowing from the two previously mentioned algorithms, that have bounds on R_A and M_A varying from $\Theta(\log k)$ to $\Theta(k)$ and bounds on W_A varying from $\Theta(\log k)$ to $\Theta(1)$.

THEOREM 3.12. *For any m, $1 \leq m \leq k$, there is an algorithm A such that $R_A = \Theta(\log m + k/m)$, $M_A = \Theta(\log m + k/m)$, and $W_A = \lceil \log m \rceil + 2$.*

Proof. We implement our k-ary register by combining an a-ary register and a b-ary register as follows. Let a be the smallest power of 2, which is at least as large as m, i.e., $a = 2^{\lceil \log m \rceil}$. Let $b = \lceil k/a \rceil$. We implement an a-ary register by the *binary* representation method, and a b-ary register by the *unary* representation method. Both these methods have been described earlier. Let the values represented by the a-ary register be in $A = \{1, \ldots, a\}$ and the values represented by the b-ary register be in $B = \{1, \ldots, b\}$. We obtain an ab-ary register by combining these two registers, where the ab values represented are in $A \times B$. Note that $ab \geq k$, so we have our k-ary register.

We consider the bounds of our combination register. The a-ary register uses $\lceil \log m \rceil$ registers and $\lceil \log m \rceil$ physical operations per logical operation. The b-ary register uses $\lceil k/a \rceil$ registers, $\lceil k/a \rceil$ physical reads per logical READ, and 2 physical writes per logical WRITE. Therefore, the total number of registers used is $\lceil \log m \rceil + \lceil k/2^{\lceil \log m \rceil} \rceil$. This is also the number of physical reads per logical READ. There are $\lceil \log m \rceil + 2$ physical writes per logical WRITE. This gives the combined bounds claimed by our theorem. □

The preceding theorem helps us to derive upper bounds for M_S and R_S, where S is the class of c-write algorithms. Choose $m = 2^{c-2}$. Since $c \leq \log k$, it follows that $m \leq k$ and Theorem 3.12 applies. Therefore, there exists an algorithm A such that

(i) $W_A = c$,
(ii) $R_A = c - 2 + \lceil k/2^{c-2} \rceil$, and
(iii) $M_A = c - 2 + \lceil k/2^{c-2} \rceil$.

We thus have the corresponding upper bounds for R_S and M_S, where S is the class of c-write algorithms. Clearly, the upper bounds obtained earlier for the class of 1-write algorithms also hold for c-write algorithms. These new bounds surpass the earlier bounds when $c \geq 3$.

The next theorem states that if an algorithm uses only $\lceil \log k \rceil$ physical registers, then some logical WRITE must use at least $\lceil \log k \rceil$ physical writes.

THEOREM 3.13. *For any algorithm A, if $M_A \leq \lceil \log k \rceil$, then $W_A \geq \lceil \log k \rceil$.*

Proof. Let A be an algorithm with $M_A = \lceil \log k \rceil$. (We have already shown M_A cannot be smaller.) Since the physical registers are binary, $|\mathcal{T}| \leq 2^{\lceil \log k \rceil}$. Recall that for all $v \in V$, there is an $x \in \mathcal{T}$ with $L(x) = v$.

Let U be the subset of $\mathcal{T}$ such that x is in U if and only if there is no $y \neq x$ in $\mathcal{T}$ such that $L(y) = L(x)$. Thus for each configuration x in U, x is the only terminal configuration which has the logical value $L(x)$.

CLAIM 3.14. *There is an $x \in U$ such that $\overline{x} \in \mathcal{T}$. ($\overline{x}$ is the binary string that differs from x in every bit.)*

Proof. Suppose there is no such x. Let $|U| = l$. Each element of U corresponds to a distinct element of V, accounting for l elements of V. The remaining $k - l$ elements of V are represented among the configurations of $\mathcal{T}$ that are not in U and are not the inverse of an element of U. There are at most $2^{\lceil \log k \rceil} - 2l$ of these configurations. There are at least two of these configurations for each remaining element of V. Thus $2^{\lceil \log k \rceil} - 2l \geq 2(k - l)$, which implies $\lceil \log k \rceil \geq \log k + 1$, a contradiction. □

Choose $x \in U$ such that $\overline{x} \in \mathcal{T}$. Let σ be a schedule in $\mathcal{WOC}$ with configuration $\overline{x}$. Suppose $L(x) = v$. Then there is a schedule τ in $\mathcal{WOC}$ of the form σ WRITE(v) α ACK, where α contains no ACK. The configuration of τ must be x since $x \in U$. Thus α contains at least $\lceil \log k \rceil$ writes, and $W_A \geq \lceil \log k \rceil$. □

4. k-ary regular register from binary regular registers. We now shift our attention to regular registers. We would like to implement an n-reader, k-ary, regular register using n-reader, binary, regular registers. Binary regular registers and binary safe registers have the same power. In other words, one can be implemented from the other using one physical register per logical register, at most one physical write per logical WRITE, and one physical read per logical READ [6].

As with safe registers, the problem of implementing k-ary regular registers can also be shown to have a parallel in a combinatorial problem. If there exists an algorithm to implement a k-ary regular register that uses m binary registers, then there is a partial k-coloring of an m-dimensional hypercube with the following restriction. For each colored vertex v, let c be its color. Then, for each color c_i such that $c_i \neq c$ (there are $k - 1$ such colors), there exists a path in the hypercube from v to some vertex v_i with color c_i *all of whose intermediate vertices are colored* c.

This characterization takes care of a slow WRITE that overlaps a number of READs. The path corresponds to the intermediate configurations reached during a WRITE. It makes sure that whatever value is RETURNed by a READ that sees an intermediate configuration preserves the regular property of registers. Note, however, that while this restriction is necessary for an algorithm, it is not sufficient. This is because the restriction doesn't take care of the problem of a slow READ overlapping a number of WRITEs, as we will show later. In particular, our hypercube algorithm for safe registers satisfies this characterization, but cannot be used to implement a regular register. Therefore, this characterization may help us get a lower bound for this problem, but not an upper bound.

Subsection 4.1 shows our independent bounds on R, W, and M. Subsection 4.2 contains our trade-off results. As before, we let $V = \{0, \ldots, k - 1\}$.

4.1. Independent bounds. The following theorem establishes the independent bounds achieved for this problem.

THEOREM 4.1. *The implementation of an n-reader, k-ary, regular register by n-reader, binary, regular registers gives the following independent bounds*:

(i) $R = \lceil \log k \rceil$,

(ii) $1 \leq W \leq \lceil \log k \rceil$, *and*

(iii) $\max\{\lceil \log k \rceil + 1, \lceil 2 \log k - \log \log k \rceil - 2\} \leq M \leq \min\{k - 1, n(3 \log k + 68)\}$.

Proof. The lower bound for R follows directly from a similar proof as the one for safe registers. The lower bound for W is obvious. The lower bound for M is shown in Lemmas 4.4 and 4.5.

The upper bounds on R and W appear simultaneously in the tree algorithm, presented below. However, this algorithm uses $k-1$ physical registers. Lamport [6] describes a complex composition of implementations to achieve an algorithm using $n(3 \log k + 68)$ 1-reader physical registers (recall that n is the number of readers for the logical register). It is unknown whether a better result, for example without the factor of n, is possible by taking advantage of the additional power when the physical registers are n-reader. □

The **modified unary algorithm** is a simple algorithm in [6] that gives upper bounds of $W \leq k$, $R \leq k$ and $M \leq k$. Given registers $X_0, \ldots, X_{k-1}$, the index of the lowest indexed register that has the value 1 determines the k-ary value represented. A READ operation reads $X_0, X_1, \ldots$, in order, until a 1 is returned. It subsequently RETURNs v, where the 1 was read from X_v. A WRITE(v) operation writes 1 in register X_v, and then writes 0 in $X_{v-1}, \ldots, X_0$, in order. (It is possible to optimize the algorithm so as to remove register X_{k-1}.)

Our hypercube algorithm, which we used to implement a k-ary safe register from binary safe registers, cannot be used to implement a k-ary regular register. The reason for this is as follows. In case of a slow READ that overlaps a number of WRITEs, the physical reads initiated by the READ may return a set of register values that do not represent a configuration that occurred during the course of the READ. Thus a logical value may be RETURNed that does not correspond to a value written by an overlapping or last preceding WRITE. A stronger result, stating that no 1-write algorithm using $k - 1$ registers can implement a k-ary regular register from binary regular registers, is proven in Theorem 4.6.

We now present our new **tree algorithm**, which gives the improved bounds of $R \leq \lceil \log k \rceil$, $W \leq \lceil \log k \rceil$, and $M \leq k - 1$. The registers are the nodes in a binary tree. The tree represents a sort of binary search conducted by the READ operation to find the value written. The READ takes a path from the root to a leaf, while the WRITE follows a path starting from a leaf to the root. The path in the tree taken by the READ, along with the values it reads, uniquely defines the value read.

The tree representation of the registers is described as follows. Given any binary tree of k leaves, the internal nodes of the tree correspond to the registers, while the leaves correspond to the k-ary values. Let the leaves of the tree be labeled in some arbitrary manner by the k values in V.

Let v_0 be the initial value of the logical register. The initial values of the physical registers are those that would result from starting with all 0's in the physical registers and then executing a single WRITE(v_0) operation described as follows.

A WRITE(v) operation writes into the set of registers that form the path from the leaf labeled v to the root, beginning with the parent of the leaf, following the path, and ending with the root. The value written to the ith node on the path is 0 (respectively, 1) if the $(i - 1)$-st node on the path is the left (respectively, right) child.

A READ operation reads a set of registers that form a path from the root to a leaf labeled v, for some v, beginning with the root. Suppose the ith node read has value 0 (respectively, 1). If its left (respectively, right) child is a leaf, then v is RETURNed, where v is the label of the leaf. Otherwise, the left (respectively, right) child of the ith node is the $(i + 1)$-st node read.

We just showed that any binary tree with k leaves completely specifies our algorithm. Simple results in graph theory imply that for any k, there exists a binary tree with k leaves, $k - 1$ internal nodes, and height $\lceil \log k \rceil$ (the number of edges in the longest path from the root to a leaf). To obtain the desired complexity bounds, we base our algorithm on one of these trees. Since only internal nodes correspond to registers, $M_A = k - 1$, $R_A \leq \lceil \log k \rceil$, and $W_A \leq \lceil \log k \rceil$.

Figure 3 illustrates a 7-ary register with value 3. The path marked on the tree corresponds to the physical registers read by a logical READ operation.

If k is a power of 2, the registers and values form a *complete* binary tree of height $\log k$. We describe the algorithm, for this special case, formally in Fig. 4. Let $v_m v_{m-1} \ldots v_1$ be the binary representation of the k-ary value v, where $m = \log k$. The root register is labeled with the empty string ϵ. For each register labeled with the binary string l, the strings $l0$ and $l1$ are the labels of its left and right children, respectively. Let the initial value of the logical register be v_0 with its binary representation being $v_{0,m} v_{0,m-1} \ldots v_{0,1}$. Then the initial value of the physical register labeled $v_{0,m} \ldots v_{0,p+1}$ is $v_{0,p}$, for all $p \in \{1, \ldots, m\}$. All other physical registers have initial value 0.

Here, the $\log k$ physical values read by the READ operation form the binary representation of the k-ary number. Clearly, the algorithm has the bounds stated.

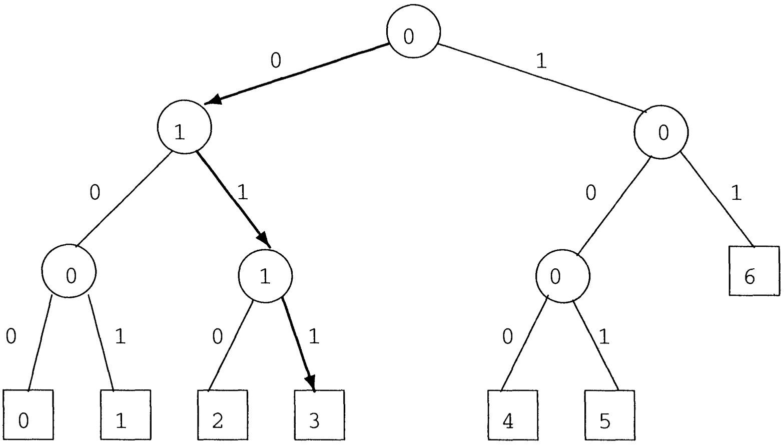

FIG. 3. *An example illustrating the tree algorithm.*

```
To WRITE($v$),
for $p$ := 1 to $m$ do
    write $v_p$ to register $v_m \ldots v_{p+1}$
ACK
```

```
To READ,
for $p$ := $m$ to 1 do
    $v_p$ := read register $v_m \ldots v_{p+1}$
RETURN($v_m \ldots v_1$)
```

FIG. 4. *Tree algorithm for k a power of 2.*

In order to prove the correctness of the tree algorithm, we need some definitions and a lemma. We define a physical read r to **reflect** a physical write w, in a given schedule, if r and w access the same physical register, and either (1) w completely precedes r, or (2) w and r overlap and r returns the value that w writes. We say that a logical READ R **notices** a logical WRITE W if R contains a physical read that reflects a physical write contained in W.

LEMMA 4.2. *Given any schedule of the tree algorithm, and any* READ *R in the schedule, R* RETURNs *the value written by the last* WRITE *W that R notices (note that there is a total order among the* WRITE *operations). If no such* WRITE *exists, R* RETURNs *the initial value.*

Proof. Let R be a READ in some schedule. Suppose R notices no WRITEs. Then every physical read r initiated by R returns the initial value of the physical register read. Therefore, R RETURNs the initial value of the logical register.

Otherwise, R notices some WRITEs. Let W be the last WRITE that R notices. Let s be the last register read by R such that R's read from s reflects W's write to s. Clearly, R reads the value b written by W into s. Otherwise, there is a later WRITE W_1 such that W_1 writes s and R notices W_1; which contradicts the fact that W is the last WRITE that R notices.

Without loss of generality, let $b = 0$. (The argument for $b = 1$ is identical by replacing "left" in the following discussion with "right.")

We claim that s is the last register read by R. Suppose not. Then, R next reads the register t corresponding to the left son of s. Since W wrote b in register s, it must have earlier written to register t. This contradicts the definition of s.

Now, the left son of s must be a leaf node. Let v be the label of this leaf node. Clearly, v is RETURNed by R. Since W writes b into s, the logical value written by W is v. □

THEOREM 4.3. *The tree algorithm implements a k-ary regular register using binary regular registers.*

Proof. We need to argue that our logical k-ary register behaves correctly; i.e., given that our algorithm is implemented using regular binary physical registers, it actually implements a regular k-ary register. Clearly the algorithm has the wait-free property.

Given any schedule, and any READ R in that schedule, we need to prove that R RETURNs the value of one of the WRITE operations it overlaps with or the last preceding WRITE W_1 (or the initial value, in the case that no WRITE completely precedes R). We consider two cases.

Case 1: R notices no WRITEs. Since R reads the root node, and any WRITE must write into the root node, it follows that no WRITE completely precedes R. By Lemma 4.2, R RETURNs the initial value, and this satisfies regularity.

Case 2: R notices some WRITEs. Let W_1 be the last WRITE that R notices. By Lemma 4.2, R RETURNs the value written by W_1. We show that W_1 either overlaps with R or is the last WRITE preceding R. This would satisfy regularity.

Clearly, W_1 cannot completely follow R, since, by the definition of *notice*, W_1 contains a physical write that either precedes or overlaps a physical read contained in R. The only other case to consider is that W_1 precedes another WRITE W_2, which completely precedes R. Since W_1 is the last WRITE that R notices, R does not notice W_2. Since W_2 completely precedes R, R must read the root node after W_2 writes into it, which implies that R does notice W_2. This gives a contradiction. Therefore, W_1 either overlaps with R or is the last WRITE preceding R. □

The tree algorithm simultaneously gives us the best bounds we have for this problem. If the frequencies of READs and WRITEs of all the k values were known in advance, then the number of accesses per READ or WRITE could be optimized by organizing the binary registers as a Huffman tree. For a discussion of Huffman codes, see Hamming [4].

We present our lower bounds for M as follows. Both of the bounds we obtain are significant for different values of k. The bound of Lemma 4.5 supersedes the bound of Lemma 4.4 for $k \geq 55$.

LEMMA 4.4. $M \geq \lceil \log k \rceil + 1$.

Proof. Choose any algorithm A. We assume, for contradiction, that $M_A = \lceil \log k \rceil$. Note that the lower bound for M of $\lceil \log k \rceil$, proved for safe registers, holds here as well. For all $v \in V$, there is a schedule σ_v of A in $\mathcal{WOC}$ of the form WRITE(v) α_v ACK, where α_v contains no ACK. Let C_v be the configuration of σ_v; it is easy to see that C_v is stable.

Choose $v \in V$. For each $w \in V$, $w \neq v$, there is a schedule σ_{vw} in $\mathcal{WOC}$ of the form WRITE(v) α_v ACK WRITE(w) β_{vw} ACK, where β_{vw} contains no ACK. Let C_{vw} be the configuration of σ_{vw}; it is easy to see that C_{vw} is stable.

Since only WP takes steps in σ_{vw} and physical writes are done serially, β_{vw} goes through a sequence of stable configurations (corresponding to schedules in $\mathcal{WO}$). By Lemma 2.2, $L_1(C_{vw}) = w$ and $L_1(C_v) = v$. Since $w \neq v$ and L_1 is a function by Lemma 2.1, $C_{vw} \neq C_v$. Thus a stable configuration is reached in β_{vw} that is different than C_v. Let D_{vw} be the first such configuration. D_{vw} and C_v differ in a single bit, i.e., in the value of a single register.

Since there are only $\lceil \log k \rceil$ bits in each configuration, there are only $\lceil \log k \rceil$ configurations that differ in a single bit from C_v. Since there are $k - 1$ values in V different than v, there exist distinct w and u in V such that $D_{vw} = D_{vu}$. Call this configuration D_v. By regularity, $L_1(D_{vw}) \in \{v, w\}$ and $L_1(D_{vu}) \in \{v, u\}$. Thus $L_1(D_v) = v$.

Since $L_1(C_v) = v$, all the C_v's are distinct. Since $L_1(D_v) = v$, all the D_v's are distinct. It is easy to see that $C_v \neq D_w$ for all v and w. Thus there are at least $2k$ distinct stable configurations, requiring at least $\lceil \log k \rceil + 1$ registers. Therefore, we have a contradiction. □

LEMMA 4.5. $M \geq \lceil 2 \log k - \log \log k \rceil - 2$.

Proof. Choose any algorithm A. Let d be the number of registers used in the algorithm.

For all $v \in V$, there is a schedule σ_v of A in $\mathcal{WOC}$ of the form WRITE(v) α_v ACK, where α_v contains no ACK. Let C_v be the configuration of σ_v; it is easy to see that C_v is stable. Clearly, $L_1(C_v) = v$.

We claim that for any two k-ary values v and w, there exists a pair of stable configurations D_v and D_w that differ in exactly one bit such that $L(D_v) = v$ and $L(D_w) = w$. Suppose not. Then, consider the schedule σ_{vw} in $\mathcal{WOC}$ of the form σ_v WRITE(w) β_{vw} ACK, where β_{vw} contains no ACK. Let the configuration of σ_{vw} be D_{vw}. The configuration of σ_v is C_v. Note that D_{vw} is a stable configuration and $L_1(D_{vw}) = w$. Consider the sequence of stable configurations reached by the schedule σ_{vw} starting from C_v and ending at D_{vw}. By the assumption, there exists a stable configuration D_x in the sequence such that $L_1(D_x) = x$ but $x \neq v$ and $x \neq w$. A READ starting at D_x would therefore RETURN x, which violates regularity. This gives a contradiction.

Recall that $\mathcal{S}$ is the set of all configurations resulting from schedules in $\mathcal{WO}$ (only WP takes steps and no physical write is pending). Let c_v be the number of stable configurations C in $\mathcal{S}$ such that $L_1(C) = v$, for each k-ary value v. Let $c = \min\{c_x | x \in V\}$, and let $v \in V$ be such that $c = c_v$. For each value w such that $w \neq v$, there are stable configurations D_v and D_w in $\mathcal{S}$ that differ in exactly one bit such that $L_1(D_v) = v$ and $L_1(D_w) = w$. Since each stable configuration C, such that $L_1(C) = v$, has d neighbors, and there are $(k - 1)$ values w, it follows that $cd \geq k - 1$. Since there are k different values and at most 2^d possible stable configurations, $ck \leq 2^d$. Solving the two inequalities, we obtain that $k^2 - k \leq d\,2^d$, which implies that $2(\log k) \leq d + \log d + 1$, for $k \geq 2$. The last inequality implies that $d \geq 2(\log k) - \log\log k - 2$. □

4.2. Trade-offs. We have the following lower bounds for R and M relating to one-write algorithms. In particular, we show that any one-write algorithm for this problem would require at least k registers. In other words, our hypercube algorithm for safe registers does not work for regular registers.

THEOREM 4.6. *For all algorithms A, if $W_A = 1$ then $R_A \geq k - 1$ and $M_A \geq k$.*

Proof. The lower bound for R_A follows from a similar proof as the one for safe registers. By using a similar argument, we can actually make the additional claim that every READ reads at least $k - 1$ distinct physical registers. We use this claim in the following proof of the bound for M_A.

To show $M_A \geq k$, suppose in contradiction that a one-write algorithm A exists that uses $k - 1$ registers. Then Lemma 3.6 carries over from the safe case, implying that the function L has the rainbow-coloring property. Let C_0 be the initial configuration; clearly, $L(C_0) = v_0$. Consider the following schedule α: READ(1) δ RETURN(1, v_0), where δ consists only of physical actions taken by RP$_1$. We claim that δ does not contain any physical write.

CLAIM 4.7. *The sequence of actions δ does not contain a physical write.*

Proof. Suppose δ does contain a physical write, i.e., $\delta = \delta_1$ write$_i(b)$ δ_2, where δ_1 contains no physical write. Then, there is a schedule of the form

READ(1) δ_1 write$_i(b)$ δ_2 RETURN(1, v_0) READ(1) δ' RETURN(1, v_0),

where δ' contains only physical actions. Let C_1 be the configuration that differs from C_0 only in position i. Then $L(C_1) = v$, for some $v \neq v_0$.

Consider the schedule WRITE(v) γ ACK, where γ contains only physical actions of WP. Then γ consists of a single physical write, to register i (as well as possibly some physical reads). An easy induction shows that

READ(1) δ_1 WRITE(v) γ ACK write$_i(b)$ δ_2 RETURN(1, v_0) READ(1) δ' RETURN(1, v_0)

is a schedule, since there is no physical write in δ_1 and the physical write within the logical

WRITE is "obliterated" by $\text{write}_i(b)$. This violates regularity because the second READ should RETURN v, not v_0. □

Now, we continue with the proof of the theorem. Pick two distinct registers (call them registers i and j) that are read in schedule α.

We define C_1 to be the stable configuration that differs from C_0 in position j, C_3 to be the stable configuration that differs from C_0 in position i, and C_2 to be the stable configuration that differs from C_0 in positions i and j. For all $l \in \{1, 2, 3\}$, C_l is a terminal configuration. Let $L(C_l) = v_l$. It is easy to verify that v_0, v_1, v_2, and v_3 are distinct values in V. Suppose, without loss of generality, that the initial value of both registers i and j is 0. Figure 5 illustrates the relation between the four configurations defined. Adjacent configurations differ in a single bit. The label on the edge between two configurations corresponds to the particular bit in which they differ.

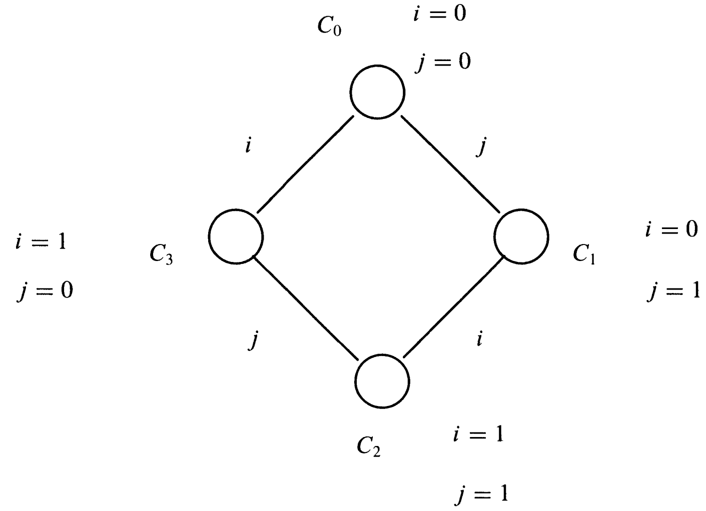

FIG. 5. *Relationship between the four configurations.*

Now, consider the sequences of actions, specified in Table 3, which can be applied at a configuration C_{start} and results in the configuration C_{finish}.

TABLE 3
Sequences for proof of Theorem 4.6.

C_{start}	sequence β	C_{finish}
C_0	$\beta_{01} = \text{WRITE}(v_1)\ \gamma_{01}\ \text{write}_j(1)\gamma'_{01}$ ACK	C_1
C_1	$\beta_{12} = \text{WRITE}(v_2)\ \gamma_{12}\ \text{write}_i(1)\gamma'_{12}$ ACK	C_2
C_2	$\beta_{23} = \text{WRITE}(v_3)\ \gamma_{23}\ \text{write}_j(0)\gamma'_{23}$ ACK	C_3
C_3	$\beta_{32} = \text{WRITE}(v_2)\ \gamma_{32}\ \text{write}_j(1)\gamma'_{32}$ ACK	C_2
C_2	$\beta_{21} = \text{WRITE}(v_1)\ \gamma_{21}\ \text{write}_i(0)\gamma'_{21}$ ACK	C_1

We claim that if we have a schedule σ with the configuration C_{start} and no pending WRITE, we can concatenate an appropriate sequence of actions β (from Table 3) to σ to obtain the schedule σ' with the configuration C_{finish}. The sequence β is a single logical WRITE which consists of a single physical write (and possibly some physical reads)—thus none of the γ_{ab}'s contain any physical writes. It is easy to see that each β exists.

We create a new sequence α' by taking α and inserting certain sequences at certain points, according to the following rules. First, we insert β_{01} immediately before READ(1), resulting in configuration C_1. Then, immediately before each read$_j$ of RP$_1$, if the configuration is C_1, we insert $\beta_{12}\beta_{23}$, resulting in configuration C_3. Immediately before each read$_i$ of RP$_1$, if the configuration is C_3, we insert $\beta_{32}\beta_{21}$, resulting in configuration C_1.

To see that α' is a schedule, it is sufficient to observe that the only time the configuration changes within the schedule is when a sequence β_{ab} is inserted. This follows from the fact, proven in Claim 4.7, that α contains no physical writes. In particular, inserting β_{01} changes the configuration to C_1, inserting $\beta_{12}\beta_{23}$ changes the configuration to C_3, and inserting $\beta_{32}\beta_{21}$ changes the configuration to C_1. We can prove, by a simple induction, that the configuration reached by any prefix of schedule α' up to a read$_i$ by RP$_1$ is always C_1. Similarly, the configuration reached by any prefix of schedule α' up to a read$_j$ by RP$_1$ is always C_3. Therefore, read$_i$ and read$_j$ always return the value 0. It follows that v_0 is the value RETURNed by the READ(1) in the schedule α'. Since, to satisfy regularity, the READ should RETURN v_1, v_2, or v_3, we have a contradiction. □

We conclude this section with a trade-off result relating to a constant number of writes. This follows from the identical result derived in the safe case.

THEOREM 4.8. *For all algorithms A, if $W_A = c$, where $c \leq (\log k)/3$, then $M_A \geq (c!k/2)^{1/c}$ and $R_A \geq (c!k/2)^{1/c}$.*

5. Conclusion. We have demonstrated upper and lower bounds on the number of physical registers, the number of physical reads in a logical read, and the number of physical writes in a logical write, for a variety of multivalued register implementations. In many cases, our bounds are tight. Some of our upper bounds follow from two new algorithms that we present, one for implementing a k-ary safe register out of binary safe registers, and another for implementing a k-ary regular register out of binary regular registers. We also presented several interesting trade-offs between these cost measures, for implementing k-ary registers out of binary registers. The bounds on the number of physical operations can be converted into bounds on the time to perform the logical operations, in terms of the time for the physical operations.

Future work includes finding such bounds for more algorithms, in particular, those involving atomic registers and multi-writer registers. The bounds in this paper on W and M for implementing a k-ary regular register out of binary regular registers are not tight. (Current work shows that the tight bound for W is 1, i.e., that there exists a 1-write algorithm for a k-ary regular register [3].) A final question is what difference does it make, if any, if clocks are available to the read and write processes?

Acknowledgments. We would like to thank Brian Coan for the proof of Lemma 3.7. Akhilesh Tyagi suggested the combinatorial techniques required in proving Theorems 3.10 and 3.11. We are grateful to Hagit Attiya, Paul Beame, Richard Ladner, Mike Saks, Martin Tompa, and George Welch for many helpful conversations that improved some of the results and presentation. The notes [8] from the Distributed Algorithms class taught by Nancy Lynch at MIT served as a useful survey and tutorial of earlier work. The anonymous referees made helpful comments that improved the presentation.

PARALLEL INFORMATION DISSEMINATION BY PACKETS*

A. BAGCHI[†][‡], E. F. SCHMEICHEL[§], AND S. L. HAKIMI[†][¶]

Abstract. Each vertex of an undirected graph possesses a piece of information that must be sent to every other vertex. They communicate by sending bounded size packets of messages from one vertex to another. The authors describe parallel algorithms, which accomplish the desired tasks for six prominent architectures. The algorithms are optimal, or nearly so, in every case.

Key words. parallel gossiping, interprocessor communication, algorithms for parallel communication on networks

AMS subject classification. F.2.2

1. Introduction. One of the most important issues in parallel and distributed computing is the issue of communication among the processors. In this paper we will consider a communication problem in networks (or graphs) that is usually termed "gossiping" and that abstracts a large class of communication problems in distributed systems. In the standard gossiping problem, each vertex of a connected graph G begins with a unique piece of information (its message), and the goal is to disseminate this message to every other vertex in the graph. (The precise model of communication for accomplishing this will be discussed in the next paragraph.) Gossiping provides a suitable framework in which to study a number of important issues related to communication in multiprocessor systems. Clearly, gossiping problems arise naturally in studying such matters as load balancing, congestion control, synchronization, and billing. More broadly, the gossiping problem is an abstraction of communication that arises in a large class of distributed computation problems. Thus, optimal solutions to gossiping provide a lower bound for the communication complexity of such problems. Often, the solution to a problem in distributed systems is essentially a solution of gossiping using a different communication model [3], [14]. In addition, the efficiency of an optimal time algorithm for gossiping on a particular topology is a useful measure of that graph's parallel communication capability when viewed as an interconnection network.

Because of its wide applicability and interesting theoretical aspects, gossiping problems have been studied by many researchers. An excellent survey of previous work on gossiping and related problems is provided by Hedetniemi, Hedetniemi, and Liestman [9].

There are two prominent models of communication used in the study of gossiping problems: the telephone model and the mail (or telegraph) model. We may think of each edge (x, y) in a connected graph G as providing a two-way communication link between the end vertices x and y. In the telephone model, communication between x and y can take place in both directions simultaneously; that is, in a single call, x and y may exchange all the messages they possess. By contrast, in the mail model, communication between x and y takes place in only one direction at a time. Thus, in a single transmission x may send y a letter containing all messages known to x, or vice versa, but both letters cannot be sent during the same transmission. In either model, when x and y are communicating with each other, it is assumed that neither is involved in any other activity in the network. In this paper, we will exclusively use the mail model of communication.

In the earliest work on gossiping, the objective was to accomplish gossiping using the minimum number of telephone calls or letters. Let G denote any connected graph with $n \geq 4$ vertices. Bumby [5] and Kleitman and Shearer [10] showed that $2n-4$ (respectively, $2n-3$) telephone calls are both necessary and sufficient to complete gossiping in G if G contains (respectively, does not contain) a cycle of length 4. Conversely, Harary and Schwenk [8] showed that in the mail model of communication, $2n-2$ letters are both necessary and sufficient to complete gossiping in G. A generalization of these results in which the edges are assigned weights has been considered by Wolfson and Segall [14].

The minimum number of telephone calls or letters needed to gossip in a graph G is, however, an inherently sequential measure of the difficulty of gossiping in G. In the sequel, we will instead measure optimality in terms of the overall finishing time, allowing many of the transmissions to occur in parallel. More precisely, we will assume that any set of transmissions (x_1, y_1), (x_2, y_2), ... that form an independent set of edges (i.e., a matching) in G could be performed simultaneously. We will call such a set of simultaneously performed transmissions a *round*, and our goal will be to accomplish gossiping in G in as few rounds as possible, regardless of the number of transmissions actually used.

All previous work on parallel gossiping has assumed transmissions of *unbounded* length; i.e., a vertex is allowed to send everything it knows to an adjacent vertex in a single transmission. The earliest important work considered parallel gossiping in complete graphs using the mail model of communication. Entringer and Slater [6] gave an algorithm to gossip in K_n with unbounded length letters in $\log_\phi n + 5 \doteq 1.44 \log_2 n + 5$ rounds, where $\phi = (1+\sqrt{5})/2$. Later, Even and Monien [7] showed that this number of rounds was optimal to within a small additive constant. In [1], the authors studied parallel gossiping with unbounded length letters in other prominent families of graphs (e.g., trees, hypercubes, and cycles) and presented nearly optimal algorithms for each of the architectures considered. Several of the results in [1] were subsequently improved by Krumme and by Krumme, Cybenko, and Venkataraman [11], [12].

Our goal in this paper is to study parallel gossiping in the mail model of communication with transmissions of *bounded* length. Thus, we will think of each transmission as a letter (or packet) of fixed size. For uniformity, we will assume that the message of each vertex has size 1. As will be seen, the constraint of fixed packet size renders the parallel gossiping problem substantially more challenging. However, the number of rounds required to gossip with fixed size packets in a network is a more realistic measure and gives a good estimate of the real time needed to disseminate information in the network.

It is known [1] that determining the optimal number of rounds for gossiping with unbounded size packets in general graphs is NP-hard; almost certainly, the problem remains NP-hard with packets of fixed size, although this problem remains open. This suggests two directions in which we might profitably proceed. One is the development of efficient approximation algorithms for parallel gossiping with fixed size packets. The other is to consider parallel gossiping with fixed size packets in specific families of graphs (architectures). We have chosen the latter direction in this paper. In particular, we will consider parallel gossiping with fixed size packets in complete graphs, hypercubes, paths, grids, cycles, and binary trees—the latter architecture being by far the most difficult. The algorithms we give will be optimal in the number of rounds, or nearly so, in every case.

While the focus of our paper is on parallel algorithms that assume an observer with global knowledge of the graph, we wish to point out that all of our algorithms can nonetheless be readily implemented as distributed algorithms. In particular, the algorithms for hypercubes and binary trees could be directly incorporated for use in a distributed system. Further consideration of this possibility is left to the reader.

2. Parallel gossiping algorithms using bounded size packets. Let $g(p, G)$ denote the number of rounds needed to gossip in $G = (V, E)$ using packets of size p, assuming all initial messages have size 1. Before considering the various architectures, we state an easy lower bound on $g(p, G)$ that is nonetheless quite useful.

THEOREM 1.

$$g(p, G) \geq \frac{|V|(|V| - 1)}{p\lfloor \frac{V}{2} \rfloor},$$

and the inequality is strict for $p > 1$.

Proof. Each vertex must receive $|V| - 1$ messages, and so $|V|(|V| - 1)$ messages must be received altogether by the vertices. But in a single round, at most $p\lfloor \frac{|V|}{2} \rfloor$ messages altogether can be received. Thus we obtain $g(p, G) \geq |V|(|V| - 1)/p\lfloor \frac{|V|}{2} \rfloor$.

We note that the inequality in Theorem 1 is strict if $p > 1$, since no vertex can send p messages in the first round. □

We now consider how to gossip with fixed size packets in various prominent architectures.

Complete graphs. We begin with the case $p = 1$, which will also prove useful for the general case. Let $\chi'(G)$ denote the edge chromatic number of G.

LEMMA 1.

$$g(1, K_n) = \begin{cases} 2(n-1), & n \text{ even}, \\ 2n, & n \text{ odd}. \end{cases}$$

Proof. Edge color K_n with $\chi'(K_n)$ colors. Then we use the following simple procedure:

```
for $j = 1$ to $\chi'(K_n)$ do
  for each edge $(v, w)$ colored $j$ do in parallel
    begin
      $v$ sends his initial message to $w$ during round $2j - 1$;
      $w$ sends his initial message to $v$ during round $2j$;
    end.
```

This completes gossiping in $2\chi'(K_n)$ rounds. The fact that

$$\chi'(K_n) = \begin{cases} n-1, & n \text{ even}, \\ n, & n \text{ odd} \end{cases}$$

is well known [4].

On the other hand, by Theorem 1 we have

$$g(1, K_n) \geq \frac{n(n-1)}{\lfloor n/2 \rfloor} = \begin{cases} 2(n-1), & n \text{ even}, \\ 2n, & n \text{ odd}. \end{cases} \qquad \square$$

We now turn to the case $p > 1$. It will be convenient to partition the vertices of K_n into $\lceil n/p \rceil$ "row sets" $R_1, R_2, \ldots, R_{\lceil n/p \rceil}$, where we assume $|R_i| = p$, for $1 \leq i \leq \lceil n/p \rceil - 2$ and $|R_i| \geq \frac{p}{2}$, for $\lceil n/p \rceil - 1 \leq i \leq \lceil n/p \rceil$. If the vertices in R_i are say $\{v_{i,1}, v_{i,2}, \ldots\}$, we define the p "column sets" $C_1, \ldots, C_p$ by $C_j = \{v_{1,j}, v_{2,j}, \ldots\}$. Note that $C_j = \lceil n/p \rceil$, for $1 \leq j \leq \frac{p}{2}$; see Fig 1. Our gossiping algorithm is now easily described.

		C_1 ↓	C_2 ↓	C_3 ↓	C_4 ↓	C_5 ↓
R_1	→	$v_{1,1}$	$v_{1,2}$	$v_{1,3}$	$v_{1,4}$	$v_{1,5}$
R_2	→	$v_{2,1}$	$v_{2,2}$	$v_{2,3}$	$v_{2,4}$	$v_{2,5}$
R_3	→	$v_{3,1}$	$v_{3,2}$	$v_{3,3}$	$v_{3,4}$	
R_4	→	$v_{4,1}$	$v_{4,2}$	$v_{4,3}$		

FIG. 1. *Partitioning K_{17} for $p = 5$.*

```
algorithm {gossiping in $K_n$ with $p$ packets}
begin
(1) for $i = 1$ to $\lceil n/p \rceil$ do in parallel gossip in $R_i$;
(2) for $j = 1$ to $p$ do in parallel gossip in $C_j$;
    {if $|C_j| = \lceil n/p \rceil$, then each node in $C_j$ knows the cumulative message after (2)}
(3) for $i = 1$ to $\lceil n/p \rceil$ do in parallel
        for $j = 1$ to $\lfloor p/2 \rfloor$ do in parallel
           begin
           (i) $v_{i,j}$ sends $v_{i,j+\lceil p/2 \rceil}$ (if the latter exists) a packet containing the messages
               in $R_{\lceil n/p \rceil - 1}$;
           (ii) $v_{i,j}$ sends $v_{i,j+\lceil p/2 \rceil}$ (if the latter exists) a packet containing the messages
               in $R_{\lceil n/p \rceil}$
           end
end. {gossiping in $K_n$ with $p$ packets}
```

It is easy to verify that the algorithm completes gossiping in a correct way.

For the analysis, note that since $|R_i| \leq p$ for all i, we can use the algorithm of Entringer and Slater [6] to complete Step (1) in $\log_\phi p + 5 = 1.44 \log_2 p + 5$ rounds. Each node begins Step (2) knowing $\leq p$ messages, which all can fit in a single packet. So for gossiping in C_j, we can apply the result in Lemma 1 when $p = 1$ in an obvious way. Thus Step (2) takes at most $2|C_j| \leq 2\lceil n/p \rceil \leq 2\left(\frac{n}{p} + 1\right)$ rounds. Finally Step (3), if needed, takes two rounds. In summary, we obtain the following theorem.

THEOREM 2. $g(p, K_n) \leq \frac{2n}{p} + 1.44 \log_2 p + O(1)$.

We now show that the above algorithm is optimal to within a small constant number of rounds.

THEOREM 3. $g(p, K_n) > \frac{2n}{p} + 1.44 \log_2 p - 3$.

Proof. At any time during the running of an algorithm, let the *knowledge vector* be the n-vector whose ith component is the number of messages known to the ith vertex at that time. Let $\overline{v}_t$ denote the knowledge vector after t rounds, so that initially the knowledge vector is $\overline{v}_0 = \langle 1, 1, \ldots, 1 \rangle$. At the conclusion, the knowledge vector will be $\langle n, n, \ldots, n \rangle$.

Consider the earliest round r at which the "total knowledge" (i.e., the L_1-norm of the knowledge vector) is at least pn. Since $\|v_r\|_1 \geq pn$, it follows easily that the euclidean norm $\|\overline{v}_r\|_2 \geq \|\langle p, p, \ldots, p \rangle\|_2 = p\sqrt{n}$. Since $\|\overline{v}_0\|_2 = \sqrt{n}$, we see that the euclidean norm of the knowledge vector increases by a factor of at least p during the first r rounds.

LEMMA. (Even and Monien [7]). *In a single round, the euclidean norm of the knowledge vector increases by a factor of at most ϕ.*

Sketch of Proof of the Lemma (when n is even). Let $\overline{v}_t = \langle x_1, x_2, \ldots, x_n \rangle$. By suitably permuting the indices, we may assume that $\overline{v}_{t+1} = \langle x_1+x_2, x_2, x_3+x_4, x_4, \ldots, x_{n-1}+x_n, x_n \rangle$; i.e., $\overline{v}_{t+1} = A\overline{v}_t$, where

$$A = \begin{pmatrix} \begin{matrix} 1 & 1 \\ 0 & 1 \end{matrix} & & 0 \\ & \ddots & \\ 0 & & \begin{matrix} 1 & 1 \\ 0 & 1 \end{matrix} \end{pmatrix}.$$

Thus $\|\overline{v_{t+1}}\|_2 \leq \|A\|_2 \|\overline{v_t}\|_2$, where

$$\|A\|_2 = \sup_{\overline{x} \neq \overline{0}} \frac{\|A\overline{x}\|_2}{\|\overline{x}\|_2}$$

denotes the euclidean norm of A. But it is well known [13] that $\|A\|_2 = \sqrt{|\lambda_{\max}\left(A^TA\right)|}$. Since

$$A^TA = \begin{pmatrix} \begin{matrix} 1 & 1 \\ 1 & 2 \end{matrix} & & 0 \\ & \ddots & \\ 0 & & \begin{matrix} 1 & 1 \\ 1 & 2 \end{matrix} \end{pmatrix}$$

has maximum eigenvalue $\frac{1}{2}(3+\sqrt{5})$, we obtain $\|A\|_2 = \phi$, completing the proof of the lemma when n is even. For n odd, we refer the reader to [7].

It follows immediately from the lemma that $r \geq \lceil \log_\phi p \rceil$. Thus after $\lceil \log_\phi p \rceil - 1$ rounds the total knowledge is less than pn. So after the first $\lceil \log_\phi p \rceil - 1$ rounds, the total knowledge must increase by more than $n^2 - pn$. Since the total knowledge increases by at most $p\lfloor n/2 \rfloor$ per round, it follows that after the first $\lceil \log_\phi p \rceil - 1$ rounds, we need more than $(n^2 - pn)/p\lfloor n/2 \rfloor \geq \frac{2n}{p} - 2$ additional rounds. Thus $g(p, K_n) > \frac{2n}{p} + \log_\phi p - 3 > \frac{2n}{p} + 1.44 \log_2 p - 3$. □

Hypercubes. Let Q_d denote the d-dimensional hypercube with $n = 2^d$ vertices. We think of the vertices of Q_d in the usual way, as d-tuples of 0's and 1's, with two vertices adjacent if they differ in exactly one component. Let us say an edge (v, w) belongs to dimension j if v and w differ in the jth coordinate. We have the following easy algorithm for gossiping in Q_d.

```
algorithm {gossiping in $Q_d$ with $p$ packets}
  begin
    for $j = 1$ to $d$ do
      for all edges $(v, w)$ belonging to dimension $j$ do in parallel
        begin
          $v$ sends $w$ all messages known to $v$ using $\lceil 2^{j-1}/p \rceil$ rounds;
          $w$ sends $v$ all messages known to $w$ but not yet known to $v$
            using $\lceil 2^{j-1}/p \rceil$ rounds;
        end
  end. {gossiping in $Q_d$ with $p$ packets}
```

The correctness of the algorithm is immediate. The algorithm requires

$$2\sum_{j=1}^{d}\lceil 2^{j-1}/p\rceil \le 2\sum_{j=1}^{d}\left(\frac{2^{j-1}}{p}+1\right)=2\left[\frac{n}{p}\left(\sum_{j=1}^{d}\frac{1}{2^{d-j+1}}\right)+d\right]$$
$$=\frac{2n}{p}+2\log_2 n-\frac{2}{p}$$

rounds. If p is a power of 2, say $p = 2^c$, then the number of rounds becomes

$$2\sum_{j=1}^{d}\lceil 2^{j-1}/p\rceil = 2c+2\sum_{j=c+1}^{d} 2^{j-c-1} = 2\left(c+2^{d-c}-1\right)=\frac{2n}{p}+2\log_2 p-2.$$

By way of comparison, we have $g(p, Q_d) \ge g(p, K_n) > \frac{2n}{p} + 1.44\log_2 p - 3$. Thus our algorithm is close to optimal for gossiping in Q_d, especially when p is a power of 2.

We summarize our results.

THEOREM 4. (i) $g(p, Q_d) \le \frac{2n}{p} + 2\log_2 n - \frac{2}{p}$.

(ii) *If p is a power of* 2, *then* $g(p, Q_d) \le \frac{2n}{p} + 2\log_2 p - 2$.

Paths. Let P_n denote the path with n vertices. We begin by showing that for $p = 4$ (and a priori $p > 4$), we can gossip in P_n in $\text{diam}(P_n) + O(1)$ rounds; this is clearly optimal up to an additive constant since $g(p, G) \ge \text{diam}(G)$ for any p and G.

Let $p = 4$, and for simplicity of presentation assume $n \equiv 2 \pmod 8$; the modifications needed for other values of n will be easy.

Partition the vertices of P_n into $\frac{n-2}{4}$ groups of four vertices each, and one group of two vertices (the center two vertices), as shown in Fig. 2. Call the edge immediately to the left of the center edge the *crossover edge*.

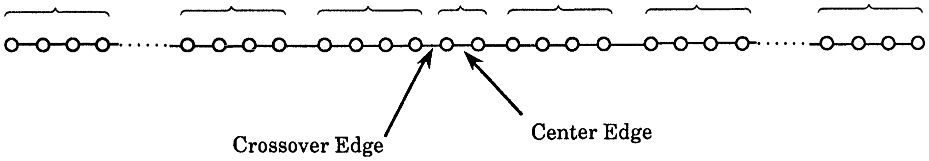

FIG. 2. *Groups for path algorithm, $p \ge 4$.*

Consider any group that occurs to the right of the crossover edge. A packet will begin at the right vertex of the group, and then move steadily to the left (except for "collisions" with other packets, as discussed below). We will call such a packet a *major packet.* It will pick up the messages of the vertices in its own group and proceed to the left endpoint of the path without picking up any additional messages. Similarly, a *minor packet* will begin at the left endpoint of this group and move steadily to the right in a similar way, picking up only the messages in its own group. There are symmetric definitions for a major and minor packet for each group to the left of the crossover edge.

The protocol when collisions occur between packets moving in opposite directions is as follows:

(1) A major packet is never delayed by a minor packet; the minor packet waits two rounds for the major packet to pass.

(2) When two major packets collide, the one that started farther from the crossover edge has priority, and the other waits two rounds until it passes.

It is readily checked that for two packets moving to the right, the one that started farther to the right will always remain ahead, i.e., packets moving to the right will not "pile up." The same holds for any two packets moving left.

Since the major packet from the right end vertex is never delayed, it follows by the above paragraph that all left-moving packets will have reached their destination in $\mathrm{diam}(P_n)$ rounds. The major packet from the left end vertex is delayed only by a collision with the major packet from the right end vertex. Thus all packets moving right will reach their destination in just $\mathrm{diam}(P_n) + 2$ rounds.

Consider now the case when $p = 3$; we assume for simplicity that $n \equiv 2 \pmod 6$. We use the above approach, except that we change the size of the large groups from 4 to 3 and delay the start of the major packets. In particular, if the major packets to the right of the crossover edge are ordered by increasing distance from the crossover edge, then the start of the jth major packet to the right is delayed $j - 1$ rounds. (The intuition is to create the same spread between the left-moving major packets that we had when the large groups had size 4). Similarly, we delay the start of the jth major packet to the left of the crossover edge by j rounds. In particular, the major packets at the end vertices of the path are delayed by $\frac{n}{6} + O(1)$ rounds. The minor packets start as soon as possible, and the protocol for collisions is exactly as above. Thus we have $g(3, P_n) \leq \frac{7}{6}n + O(1)$.

For $p = 1$ and 2, we use a different strategy; for simplicity of presentation we assume n is even. The idea is to take a census at the $(\frac{n}{2} + 1)$th vertex from the left end (denoted v_0 in the sequel) and then to broadcast from v_0 the messages from each half of the path to the other half. At the same time, we disseminate the messages of the vertices in each half to the other vertices in the same half. We illustrate the method for $p = 1, n = 6$ and $p = 2, n = 8$ in Fig. 3, in which the number(s) above an arrow indicates the number of the unit(s) whose messages are being sent.

For $p = 1$, it takes $n - 1$ rounds to complete a census at v_0, another $n + 1$ rounds until v_0 sends out its final packet (v_0 needs to send its own message in both directions), and a final $\frac{n}{2} - 2$ rounds until the last packet sent by v_0 reaches its final destination. Thus $g(1, Pn) \leq \frac{5}{2n} + O(1)$.

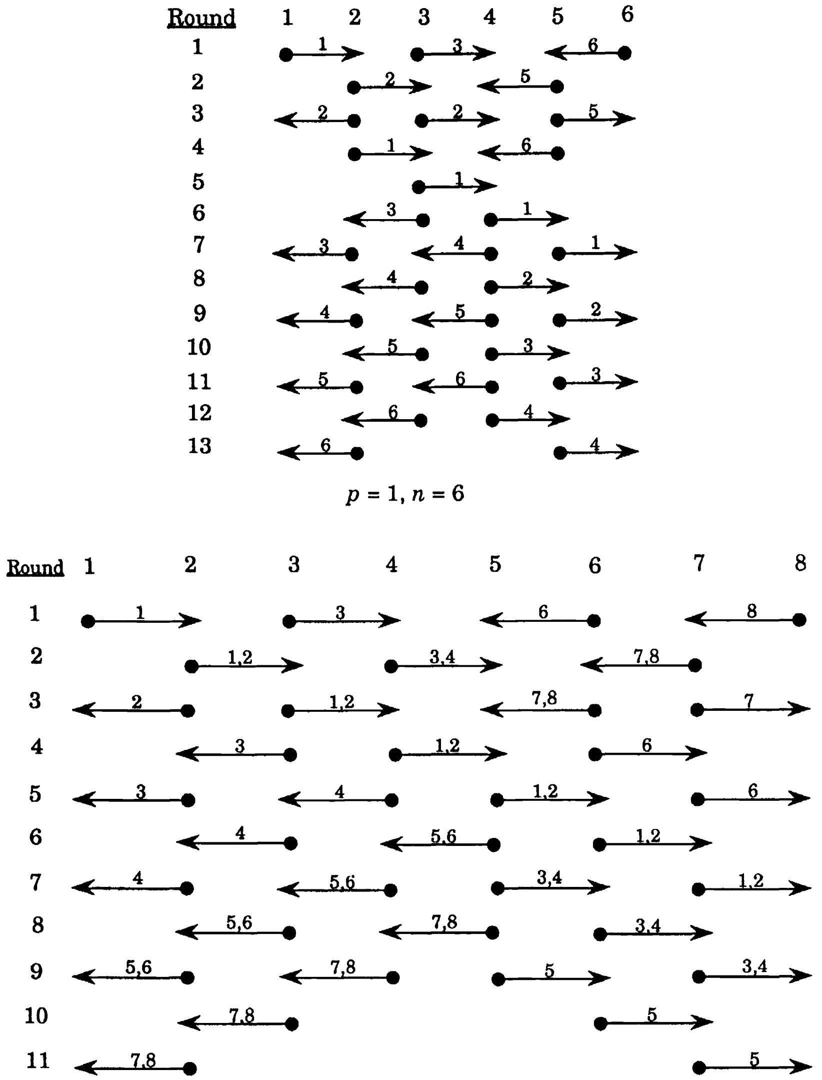
For $p = 2$, it takes $\frac{n}{2}$ rounds to complete a census at v_0, $\frac{n}{2} + 1$ more rounds until v_0 sends out its last packet, and a final $\frac{n}{2} - 2$ rounds until this last packet reaches its final destination. Thus $g(2, P_n) \leq \frac{3}{2n} + O(1)$.

We now show that these upper bounds for $g(p, P_n)$ are optimal to within a small additive constant. For $p \geq 4$, this is immediate. For $p \leq 3$, the optimality follows by the following result.

LEMMA 2.

$$g(p, P_n) \geq \left\lceil \frac{n-1}{p} \right\rceil + \left\lceil \frac{n+1}{p} \right\rceil + \left\lceil \frac{n}{2} - 2 \right\rceil .$$

Proof. Let v_0 be a centermost vertex on P_n. Note that v_0 needs to receive at least $\lceil (n-1)/p \rceil$ crucial packets (i.e., packets bringing v_0 a new message) and to send $\geq \lceil (n+1)/p \rceil$ crucial packets (i.e., packets bringing the recipient a new message). Clearly the last crucial packet sent by v_0 must occur after the last crucial packet received by v_0, and so the last crucial packet sent by v_0 cannot occur before round $\lceil (n-1)/p \rceil + \lceil (n+1)/p \rceil$. But the last crucial packet sent by v_0 contains a message that needs $\geq \frac{n}{2} - 2$ rounds to reach the appropriate end vertex of the path. This proves the lemma. □



$p = 1, n = 6$

$p = 2, n = 8$

FIG. 3.

We summarize our results as follows.

THEOREM 5.

$$g(p, P_n) = \begin{cases} 5/2n + O(1), & p = 1, \\ 3/2n + O(1), & p = 2, \\ 7/6n + O(1), & p = 3, \\ \operatorname{diam}(P_n) + O(1), & p \geq 4. \end{cases}$$

Rectangular grids. Let $G_{m,n}$ denote the grid with m rows and n columns. Since $G_{m,n}$ contains mn vertices, it follows by Theorem 3 that $g(p, G_{m,n}) > \frac{2mn}{p} + 1.44 \log_2 p$. A natural way to gossip in $G_{m,n}$ would be: "Gossip in each of the columns in parallel, and then gossip in each of the rows in parallel." Such an approach uses $\frac{5}{2}\frac{mn}{p}$ rounds. This bound can be asymptotically improved. We present below a slightly more complex algorithm which yields $g(p, G_{m,n}) \leq \frac{2mn}{p} + O(m+n)$.

We begin with the following result.

LEMMA 3. *For n odd*, $g(1, G_{3,n}) \leq 6n+2$.

Proof. Let $n = 2k+1$. Label the units in row r by $\mu_{(r-1)n+1}, \dots, \mu_{rn}$ from left to right, for $r = 1, 2, 3$. We will term a unit μ_i odd (respectively, even) if i is odd (respectively, even). Note that there are $3k+2$ odd units and $3k+1$ even units.

If we delete any odd unit from G, the resulting graph is Hamiltonian. In fact, for each unit μ_i, $i = 1, 3, 5, \dots, 2n+1$, $G - \mu_i$ contains a unique directed Hamiltonian cycle, denoted C_i, which contains the directed path $\mu_{3n}, \mu_{3n-1}, \mu_{3n-2}, \dots, \mu_{2n+1}$. The algorithm will employ only the cycles $C_1, C_3, C_5, \dots, C_{2n-1}$. We note two useful facts about this collection of cycles:

(1) Let μ_i be any even unit. The even unit which immediately follows μ_i on C_j is the same for all $j = 1, 3, 5, \dots, 2n-1$.

(2) Let μ_i be any odd unit. The even units which immediately precede and follow μ_i on $C_j (j \neq i)$ are the same for all $j = 1, 3, 5, \dots, 2n-1$ with $j \neq i$.

The algorithm is conveniently described in two stages. During the first (second) stage, each unit will learn the message of all the even (odd) units.

Stage 1 will begin with the following $6k$ rounds.

```
for $i = 0$ to $k - 1$ do
begin
    during rounds $6i + 1$ and $6i + 3$, every even unit transmits the last message it
        learned to the following (odd) unit on $C_{2i+1}$;
    during rounds $6i + 2$ and $6i + 4$, every odd unit transmits the last message it
        learned to the following (even) unit on $C_{2i+1}$;
    {during these four rounds, we use the cycle $C_{2i+1}$ which omits an odd unit
        in the first row}
    during round $6i + 5$, every even unit transmits the last message it learned to
        the following (odd) unit on $C_{n+2i+2}$;
    during round $6i + 6$, every odd unit transmits the last message it learned to
        the following (even) unit on $C_{n+2i+2}$;
    {during these two rounds, we use the cycle $C_{n+2i+2}$ which omits an odd unit
        in the second row}
end
```

It is easy to see by (1) that after these $6k$ rounds, every even unit knows the messages of all the other even units. Similarly by (2), after $6k$ rounds each odd unit in the first (respectively, second, third) row knows the messages of all the even units with at most two (respectively, one, zero) exceptions. Thus we can easily finish Stage 1 in three additional rounds, for a total of $6k+3$.

In Stage 2, we disseminate the messages of the odd units. In the first round we use C_1, letting each odd unit (except μ_1) send its message to an even unit. We then use a scheme analogous to the one above, with four rounds on C_{n+2}, two rounds on C_3, four rounds on C_{n+4}, two rounds on C_5, etc. The key change is that μ_1, which belongs to all these cycles except the initial C_1, delays sending the message just received from μ_{n+1} for two rounds. In particular, μ_1 sends its own message at round 3. So Stage 2 is analogous to Stage 1 except for this two-round delay. It follows that Stage 2 can be completed in $6k+5$ rounds, and so altogether we can gossip in $G_{3,n}$ in just $12k+8 = 6n+2$ rounds as asserted. □

The algorithm is now quite easy to describe. First gossip in each of the columns in parallel; this takes $\leq \frac{5}{2}m + O(1)$ rounds, by Theorem 5. Next, partition the rows into sets of two consecutive rows {Row 1, Row 2}, {Row 3, Row 4}, ..., with a final set of three rows if n is odd. For each pair {Row $2j-1$, Row $2j$}, note that the vertices in the odd (respectively, even) positions in Row $2j-1$ (respectively, Row $2j$) together know all the messages. These vertices are darkened in Fig. 4. It is now easy to complete gossiping in these two rows in $2n\lceil m/p \rceil \leq 2n\left(\frac{m}{p}+1\right)$ rounds, using the directed cycle in Fig. 4 and moving the m messages which begin at each darkened vertex one position along the cycle every $\lceil m/p \rceil$ rounds.

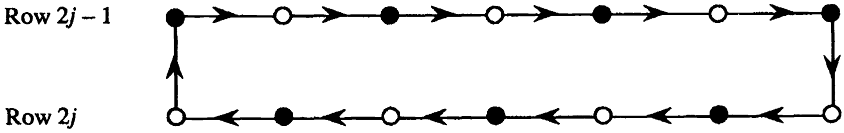


FIG. 4.

For the final set of three rows (if it exists), we assign, to each of the three vertices in a column, $\lceil m/3 \rceil$ messages from that column in the original grid so that together these three vertices are assigned all m original messages from that column. We now simulate the algorithm in Lemma 3 in an obvious way, simulating each transmission in the Lemma by $\lceil m/3p \rceil$ transmissions here. We thus complete gossiping in the final three rows in $(6n+2)\cdot\lceil m/3p \rceil = \frac{2mn}{p} + O(m+n)$ rounds. We have thus proved Theorem 6.

THEOREM 6. $g(p, G_{m,n}) \leq \dfrac{2mn}{p} + O(m+n)$.

Cycles. Let C_n denote the cycle on n vertices. It will be convenient to consider the case when p is even first.

We begin by noting that

$$g(2, C_n) = \begin{cases} n, & n \text{ even}, \\ n+1, & n \text{ odd}; \end{cases}$$

we leave the easy proof of this to the reader, mentioning only that the lower bound follows from the remark following Theorem 1. Suppose therefore that $p \geq 4$. For simplicity of explanation, let us also assume for the moment that p divides n. Label the vertices of C_n in clockwise order as $v_{11}, v_{12}, \ldots, v_{1p}, v_{21}, v_{22}, \ldots, v_{2p}, \ldots, v_{n/p,1}, \ldots, v_{n/p,p}$. We define group j to be the vertices with first index j. We now give a high level description of our gossiping algorithm for C_n under these assumptions. For each j, $1 \leq j \leq n/p$, a packet will begin at $v_{j,1}$ (respectively, $v_{j,p}$) and move clockwise (respectively, counterclockwise), first picking up all the messages of the vertices in group j and then continuing without picking up additional messages to the vertex which is, roughly, diametrically opposite the vertex $v_{j,p/2}$. We illustrate the movement of these two packets in Fig. 5. Whenever two packets moving in opposite directions "collide," we delay each packet one round in allowing the other packet to pass. If a packet moved without collisions, it would take exactly $\frac{n}{2}+\frac{p}{2}-1$ rounds to reach its final destination. But each packet will collide with $\leq \frac{n}{p}$ packets moving in the opposite direction. Thus $g(p, C_n) \leq \frac{n}{2}+\frac{n}{p}+\frac{p}{2}-1$ when p is even and $p|n$.

If p does not divide n, we instead partition C_n into $\lceil n/p \rceil$ groups of consecutive vertices, each group containing at most p, but at least 2, vertices. We then mimic the algorithm above, holding up packets as they are about to exit groups with $\geq p$ vertices so that all packets leave the

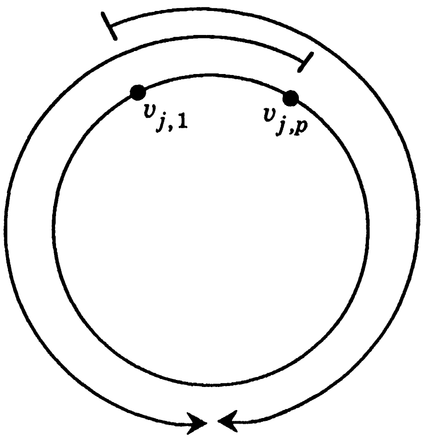

FIG. 5.

groups in synchrony. With this approach, it is easy to see that $g(p, C_n) \leq \lceil n/2 \rceil + \lceil n/p \rceil + \frac{p}{2} - 1$ for any even p.

Consider now the case when p is odd. For $p = 1$, it is easy to show that

$$g(1, C_n) = \begin{cases} 2n - 2, & n \text{ even}, \\ 2n, & n \text{ odd}. \end{cases}$$

For $p \geq 3$, we simply define the packet size to be $p - 1$ (even) and apply the algorithm above. We summarize our result below.

THEOREM 7.

(i) $g(1, C_n) = \begin{cases} 2n - 2, & n \text{ even}, \\ 2n, & n \text{ odd}. \end{cases}$

(ii) $g(p, C_n) \leq \begin{cases} \left\lceil \frac{n}{2} \right\rceil + \left\lceil \frac{n}{p} \right\rceil + \frac{p}{2} - 1, & \text{if } p \text{ is even}, \\ \left\lceil \frac{n}{2} \right\rceil + \left\lceil \frac{n}{p-1} \right\rceil + \frac{p-1}{2} - 1, & \text{if } p > 1 \text{ is odd}. \end{cases}$

Although the bound above is tight for $p = 1$ and 2, the only lower bound we have when $p \geq 3$ is the trivial $g(p, C_n) \geq 1 + \operatorname{diam}(C_n) = 1 + \lfloor n/2 \rfloor$.

Binary trees. Let B_n denote the complete binary tree on n vertices. We begin by describing an easy algorithm for gossiping in B_n. Color the edges of B_n with three colors, say $\{0, 1, 2\}$. If $r \equiv j (\text{mod } 3)$, the edges colored j will be termed *active* during round r. Throughout the algorithm each node v will maintain a queue $Q(v)$ which initially contains just v's message. As usual, each node also maintains a list of all messages received in its local memory, which is separate from the queue. As messages arrive at v from v's sons, they are inserted in $Q(v)$ in the order received. Let $f(v)$ denote the father of v in B_n. Suppose $(v, f(v))$ is active during round r. If $Q(v)$ is nonempty, then v sends $f(v)$ the first $\min\{p, |Q(v)|\}$ messages in $Q(v)$ in a packet to $f(v)$. Otherwise, if $f(v)$ knows any messages not yet known to v, then $f(v)$ sends v a packet containing as many messages, not yet known to v, as possible. The algorithm halts when each unit knows all the messages. Our goal is to show that this algorithm is optimal to within $O(1)$ rounds if n is sufficiently large relative to p.

We will establish the following upper bound for the running time of the algorithm.

THEOREM 8. *If $p \geq 2$ and $n \geq 4p^{3/2\log_\phi 2}$, the above algorithm uses at most $\frac{3n}{p} + 2\log_2 n + \log_\phi p + O(1)$ rounds.*

Although the algorithm given above is quite easy, the proof of Theorem 8 is rather involved. Before formally establishing the complexity of the algorithm, we will informally discuss the execution of the algorithm and the ideas behind the analysis.

Let r_1 and r_2 denote the two sons of the root $f(r_1)$. Suppose the edge $(r_1, f(r_1))$ is colored 1. It is easily checked that in rounds $1, 4, 7, \ldots, r_1$ sends to $f(r_1)$ packets containing $1, \min\{p, 6\}, \min\{p, 26\}, \ldots,$ messages, respectively. There is a similar pattern for the number of messages sent by any vertex u to $f(u)$ in successive early transmissions. We will establish that if n is large enough in terms of p, then r_1 sends a packet with $\min\{p, 2F_{3k+1}\}$ messages to $f(r_1)$ during round $3k + 1$, for $k = 1, 2, \ldots,$ until r_1 sends $f(r_1)$ at most one final packet with $< p$ messages, where F_j is the jth Fibonacci number. Once r_1 has sent $f(r_1)$ all the messages in the subtree T_{r_1} of T rooted at r_1, then $f(r_1)$ starts sending r_1 the messages from $T_{r_2} \cup \{f(r_1)\}$. Using the above facts, it is easy to show that the root and both of its sons will have learned the cumulative message by round $R + O(1)$, where $R = \frac{3n}{p} + \log_\phi p$.

Now consider vertex x in Fig. 6. Vertex x must receive from x_1 and x_2 all the messages in subtrees T_1 and T_2, respectively. Once x knows all the messages in T_1 (respectively, T_2), x begins sending to x_1 (respectively, x_2) the messages from subtree T_2 (respectively, T_1). Meanwhile, x continues to send messages from $T' = T_1 \cup T_2 \cup \{x\}$ to $f(x) = x_3$. When x_3 knows all the messages from T', it starts sending to x the messages from $T - T'$. Once x starts receiving these messages, it sends them down to x_1 and x_2. Note that if x has finished sending all the messages from T_1 (respectively, T_2) to x_2 (respectively, x_1) before receiving any message from x_3, then the messages from x_3 will encounter no delay at x. If each downward moving packet encountered no delay at any vertex in the tree, then of course gossiping would be completed in $R + 2\log_2 n + O(1)$ rounds. It will be shown, however, that the total delay encountered by any packet moving down the tree is just $O(1)$ rounds, and thus the desired bound of $R + 2\log_2 n + O(1)$ rounds will be established.

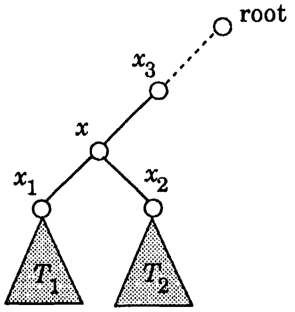

FIG. 6.

To establish a delay of $O(1)$ rounds on any downward moving packet, we will first study the number of messages that are sent by a vertex v to $f(v)$ in successive transmissions (the so-called "upsequence" of the edge $(v, f(v))$). It will be shown that there are only a few types of upsequences. One possible upsequence occurs if v sends $f(v)$ first some packets containing less than p messages, then a series of full packets (containing p messages), and finally at most one packet with less than p messages. We mentioned above that the two edges incident to the root will have this type of upsequence if n is sufficiently large. Indeed, this will be the upsequence of any edge $(v, f(v))$ that is "high enough" in the tree (i.e., the distance h from v

to its leaf descendants is large enough). On the other hand, if this is not the upsequence type of $(v, f(v))$, then we will show that v will have completed sending all messages in T_v to $f(v)$ by round $2h + 3$. Once $f(v)$ knows the messages in T_v, $f(v)$ begins sending the messages from $T - T_v$ to v in packets containing p messages, and v will know the cumulative message by round $R + 2\log_2(n - h) + O(1)$.

Before giving the actual proof, it will be useful to develop a number of lemmas. On any edge e of B_n, packets are first sent upward (towards the root) and then downward later on. The first lemma concerns the number of messages which are sent upward on e in successive packets.

LEMMA 4. *Suppose a packet is sent upward on e during round r containing $up_e(r)$ messages. If $up_e(r) > up_e(r+3)$, then $up_e(r+3) > up_e(r+6) > \cdots$, as long as packets are being sent upward on e.*

Proof. For any edge e, let $r(e)$ denote the first round r in which $up_e(r) < up_e(r-3)$. It is easy to see that if e_1, e_2 are two edges colored the same with e_1 higher in the tree than e_2, then $r(e_1) \geq r(e_2)$.

We now proceed by induction on the height of the edge e above the leaves. Suppose the lemma holds for all edges of height at most h, and let $e = e_0$ have height $h + 1$, with say $r(e_0) = r + 3$. We need to show that $up_e(r+3) > up_e(r+6)$.

We see clearly in Fig. 7 that $r(e_1) \leq r + 2$ or $r(e_2) \leq r + 2$ or both. Without loss of generality suppose $r(e_1) \leq r+2$ and color$(e_1) \equiv r + 1 \pmod 3$. By the induction hypothesis

$$(1) \qquad up_{e_1}(r+1) > up_{e_1}(r+4).$$

Suppose (again, see Fig. 7) that color$(e_0) =$ color(e_3) and color$(e_1) =$ color(e_4). By the observation in the preceding paragraph $r(e_3) \leq r(e_0)$ and $r(e_4) \leq r(e_1)$. Thus

$$(2) \qquad up_{e_3}(r) > up_{e_3}(r+3),$$

$$(3) \qquad up_{e_4}(r+1) > up_{e_4}(r+4).$$

From (2) and (3) we get

$$(4) \qquad up_{e_2}(r+2) > up_{e_2}(r+5),$$

and from (1) and (4) we get the desired result. □

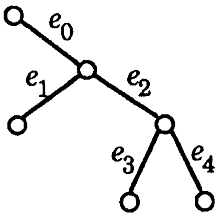

FIG. 7.

Given an edge e colored 0, we call the sequence $(up_e(3), up_e(6), \ldots)$ the *upsequence* of e. Analogous definitions give the upsequence of edges colored 1 or 2. By Lemma 4, the upsequence of each edge is one of the following three types. (We use formal language notation to describe the three types, letting ϵ denote the empty string, and $(<p)$ denote the set of positive integers less than p.)

(1) All-partial: $(<p)^*(<p)$,
(2) Good: $(<p)^*p^*p\{<p, \epsilon\}$,
(3) Bad: $(<p)^*p^*p(<p)^*(<p)^2$.
We will call an edge all-partial, good, or bad according to the type of its upsequence.

Our immediate goal is to show that we can bound the height (above the leaves) of bad edges in B_n in terms of p. As we shall see, if $n \geq 4p^{3/2 \log_\phi 2}$ then no bad edge will occur more than halfway up the tree.

Consider a message m moving towards the root. We identify two kinds of delays it can encounter, say at vertex u, along the way.

(1) Blocking delay: after m reaches u, it is *not* sent to $f(u)$ at the first opportunity $(u, f(u))$ becomes active. (There are at least p messages in $Q(u)$ ahead of m.)

(2) Coloring delay: after m arrives at u, it is sent to $f(u)$ at the first opportunity $(u, f(u))$ becomes active, but this is *two* rounds after m arrives at u. (This delay of one round is entirely due to the coloring of the edges incident to u.)

The following will be useful.

LEMMA 5. *If $(u, f(u))$ is bad, then the last message u sends $f(u)$, say m_{last}, did not encounter any blocking delay before reaching $f(u)$.*

Proof. Suppose v is a descendant of u at which m_{last} encounters a blocking delay.

CLAIM 1. *$(v, f(v))$ is good.*

Proof. If $(v, f(v))$ were bad, then the last two packets sent upward on $(u, f(u))$ were not full. The first of these packets cleared all messages at v waiting to be sent to v. Since m_{last} is in the following packet sent up by v, it could not have encountered a blocking delay at v, a contradiction. □

CLAIM 2. *If $(v, f(v))$ is good, all the edges in the path from v to $f(u)$ must also be good. In particular, $(u, f(u))$ would be good, a contradiction.*

Proof. Let $(w, f(w))$ be the first bad edge we come to as we move upward from v to $f(u)$. Let x, y denote the sons of w, with m_{last} sent upward along (x, w). Then (y, w) must send its last packet upward to w before x does. Moreover, since (x, w) is good, the upward packet on (x, w) before the one containing m_{last} must be full. It follows easily now that $(w, f(w))$ would be good, a contradiction. This proves Claim 2, and completes the proof of Lemma 5. □

Lemma 5 implies that if $(u, f(u))$ is bad, then all messages in the subtree T_u rooted at u will reach $f(u)$ within at most $2h + 3$ rounds, where h denotes the height of u (the distance from u to a leaf descendant), since the last message of T_u to reach u encounters only coloring delays before arriving at u.

We next establish an upper bound on the number of messages that are sent upward on an edge during round r. This bound will be useful in the sequel.

LEMMA 6. *During round $r \geq 2$, an upward packet on $(u, f(u))$ contains at most $2F_r$ messages, where F_r denotes the rth Fibonacci number, with equality if h (the height of u) is at least r.*

Proof. It is easy to see that during rounds 1, 2, and 3, a unit can send at most 1, 2, and 4 messages, respectively. In round $r \geq 4$, a unit can send at most $\min\{p, |\text{Messages learned in rounds } r-1 \text{ and } r-2|\}$. Thus if M_r denotes the maximum number of messages which can be sent upward on an edge at round r, then M_r satisfies $M_r \leq M_{r-1} + M_{r-2}$, $M_2 = 2$, $M_3 = 4$. Thus, $M_r \leq 2F_r$ for $r \geq 2$. □

Let us assume now that $(u, f(u))$ is bad, and that u has height h. We saw above that u will send to $f(u)$ all the messages in T_u, of which there are $2^{h+1} - 1$, within $2h + 3$ rounds. On the other hand, u could send $f(u)$ at most

$$\frac{\phi^2 p + 1}{\sqrt{5}} + \left\lceil \frac{(2h+3) - \log_\phi p}{3} \right\rceil p$$

messages during the first $2h + 3$ rounds. (Simply note that if $(u, f(u))$ has color c, then by Lemma 6 u could send $f(u)$ at most

$$\sum_{j=0}^{\lfloor(\log_\phi p-c)/3\rfloor} 2F_{3j+c} \le 1 + \sum_{k=1}^{\lfloor\log_\phi p\rfloor} F_k = F_{\lfloor\log_\phi p\rfloor+2} < \frac{1}{\sqrt{5}}\left(\phi^{\lfloor\log_\phi p\rfloor+2} + 1\right) \le \frac{\phi^2 p + 1}{\sqrt{5}}$$

messages during the first $\log_\phi p$ rounds.) But this implies that we must have

$$\frac{\phi^2 p + 1}{\sqrt{5}} + \left\lceil \frac{(2h+3) - \log_\phi p}{3} \right\rceil p > 2^{h+1} - 1 \tag{5}$$

in order to have a bad edge $(u, f(u))$ with u at height h. But if $n \ge 4p^{3/2\log_\phi 2}$, it is easily checked that (5) fails to hold for $h > \frac{1}{2}\log_2 n$. In other words, there will be no bad edges in the top half of the tree. In particular, both edges incident to the root will be good.

The following fact is easy to verify (formally by induction on h): Let u be any node of height h. Then, by the end of round $2h + 3$, either u has sent $f(u)$ a full packet or u has completed sending up packets to $f(u)$.

Let us call a good edge $(u, f(u))$ *complete* if u sends $f(u)$ exactly $2F_r$ messages in every round r during which $(u, f(u))$ is active prior to sending $f(u)$ a first full packet. Otherwise, we call a good edge $(u, f(u))$ *incomplete*.

Proof of Theorem 8. Assume for now that both good edges incident to the root are complete. (We will show in a moment that this is true.) Then the root will learn the cumulative message within $\log_\phi p + \left\lceil \frac{3n}{2p} \right\rceil + O(1)$ rounds. Within $\left\lceil \frac{3n}{2p} \right\rceil$ more rounds, both sons of the root will also know the cumulative message, and so both sons will have learned the cumulative message by round $R + O(1)$, where $R = \frac{3n}{p} + \log_\phi p$. To complete the proof, we will show that each u will learn the cumulative message by round $R + 2(\log_2 n - h) + O(1)$, where h denotes the height of u. The proof is by induction on $\log_2 n - h$; the case $\log_2 n - h = 1$ is given above.

Consider an edge $(u, f(u))$, where u has height h. If $f(u)$ does not always have a full backlog of messages to send u once u has completed sending messages upward, then clearly u will learn the cumulative message at most two rounds after $f(u)$ does. So by the induction hypothesis, u will learn the cumulative message by round $R + 2(\log_2 n - h) + O(1)$. Therefore, we assume in the sequel that u always has a backlog of messages to send u once u completes sending messages up to u.

We now consider three cases.

Case 1. $(u, f(u))$ is complete.

Let u be a descendant of the son r_1 of the root, and for the moment assume $(u, f(u))$ and (r_1, root) are colored the same. Let k_1 (respectively, n_1) denote the number of packets (respectively, messages) which are sent from u to $f(u)$ prior to the first full packet. Then the total number of packets sent across the edge $(u, f(u))$ is

$$k_1 + \left\lceil \frac{2^{h+1} - 1 - n_1}{p} \right\rceil + \left\lceil \frac{n - 2^{h+1}}{p} \right\rceil.$$

On the other hand, the total number of packets sent across (r, root) will be

$$k_1 + \left\lceil \frac{(n-1)/2 - n_1}{p} \right\rceil + \left\lceil \frac{n/2}{p} \right\rceil.$$

These two quantities differ by $O(1)$, and thus u will know the cumulative message by round $R + O(1)$. The argument remains essentially unchanged if $(u, f(u))$ and (r, root) are colored differently.

Case 2. $(u,\ f(u))$ is incomplete.

By the fact given above, u must have sent its first full packet to $f(u)$ by round $2h+3$. Thus the number of rounds before u learns the cumulative message is at most

$$3\left\lceil\frac{2^{h+1}-1}{p}\right\rceil+3\left\lceil\frac{n-2^{h+1}+1}{p}\right\rceil.$$

We would be done if we had

$$R+2(\log_2 n-h)\geq(2h+3)+3\left\lceil\frac{2^{h+1}-1}{p}\right\rceil+3\left\lceil\frac{n-2^{h+1}+1}{p}\right\rceil$$

or $2\log_2 n\geq 4h-\log_\phi p$. However, $h<\log_\phi p$ (or else $2F_h>p$ and u would have sent $2F_r$ messages to $f(u)$ in each round r prior to sending the first full packet, contradicting the fact that $(u,\ f(u))$ is incomplete). Thus, it suffices to have $2\log_2 n\geq 3\log_\phi p$, or $n\geq p^{3/2\log_\phi 2}$, which we have by assumption.

Case 3. $(u,\ f(u))$ is bad or all-partial.

Then u will have completed sending messages up to $f(u)$ within $2h+3$ rounds. So the number of rounds before u learns the cumulative message will be

$$(2h+3)+3\left\lceil\frac{2^{h+1}-1}{p}\right\rceil+O(1).$$

We would be done if we had

$$R+2(\log_2 n-h)\geq 2h+3\left\lceil\frac{n-2^{h+1}}{p}\right\rceil.$$

Since $R\geq\left\lceil\frac{3n}{p}\right\rceil$, it follows easily that the desired inequality will be true if $h\leq\frac{1}{2}\log_2 n$. But if $n\geq 4p^{3/2\log_\phi 2}$ and u has height h, we have argued that $(u,\ f(u))$ cannot be bad if $h>\frac{1}{2}\log_2 n$. The same argument shows that $(u,\ f(u))$ cannot be all-partial if $h>\frac{1}{2}\log_2 n$. Thus $h\leq\frac{1}{2}\log_2 n$ as desired.

This completes the proof of Theorem 8. □

We now establish a lower bound for the number of rounds needed to gossip in B_n using size p packets. It matches the upper bound in Theorem 8 to within $O(1)$ rounds.

THEOREM 9. $g(p,\ B_n)\geq\frac{3n}{p}+2\log_2 n+\log_\phi p-O(1)$.

Proof. In what follows, we assume no vertex receives the same message twice. Clearly this is no loss in generality.

Let x denote a son of the root of B_n, and let T_1, T_2, T_3 denote the binary subtrees of B_n as shown in Fig. 8.

Consider any round r_0 after which x knows $<p$ messages, including his own. We begin with two useful facts concerning round r_0.

(1) After round r_0, x must still receive $>\lceil(n-1)/p\rceil-1$ packets.

Proof of (1). After round r_0, x must still receive

$$\geq\sum_{i=1}^{3}\left\lceil\frac{|\text{Messages in } T_i \text{ not known to } x \text{ after round } r_0|}{p}\right\rceil$$

$$\geq\left\lceil\frac{1}{p}\sum_{i=1}^{3}|\text{Messages in } T_i \text{ not known to } x \text{ after round } r_0|\right\rceil$$

$$>\left\lceil\frac{1}{p}(n-1-p)\right\rceil=\left\lceil\frac{n-1}{p}\right\rceil-1.\qquad\square$$

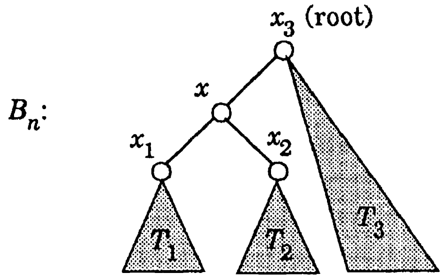

FIG. 8.

(2) After round r_0, x must still send

$$\geq \sum_{i=1}^{3} \left\lceil \frac{n - |T_i|}{p} \right\rceil - 3$$

packets.

Proof of (2). After round r_0, x still needs to send

$$\geq \sum_{i=1}^{3} \left\lceil \frac{|n - |T_i| \text{ messages in } T_i \text{ not known to } x_i \text{ after round } r_0|}{p} \right\rceil$$
$$\geq \sum_{i=1}^{3} \left\lceil \frac{n - |T_i|}{p} \right\rceil - 3 \text{ packets,}$$

since each x_i knows less than p messages outside of T_i after round r_0. □

We observe that

$$\sum_{i=1}^{3} \left\lceil \frac{n - |T_i|}{p} \right\rceil - 3 = 2\left\lceil \frac{3n+3}{4p} \right\rceil + \left\lceil \frac{n-1}{2p} \right\rceil - 3 = \frac{2n}{p} - O(1).$$

Moreover, we note that the last message sent by x must follow the last message received by x. Finally, it can be seen that the last message sent by x needs at least $2\log_2 n - O(1)$ rounds to reach all the leaves of the T_i to which it is sent.

In summary, we see that

$$g(p, B_n) \geq r_0 + \left\lceil \frac{n-1}{p} \right\rceil - 1 + \frac{2n}{p} - O(1) + 2\log_2 n - O(1)$$
$$= r_0 + \frac{3n}{p} + 2\log_2 n - O(1).$$

So, to complete the proof, it suffices to show that there exists a value of r_0 satisfying

(3) $r_0 \geq \log_\phi p - O(1)$.

Proof of (3). To prove (3), let m_r denote the maximum number of messages, including its own, that the root of a binary tree could know after r rounds. It is easy to see that m_r satisfies the recurrence relation $m_r = m_{r-1} + m_{r-2} + 1, m_0 = 1, m_1 = 2$. (Intuitively, one should get as many messages as possible to the jth son of the root, for $j = 1$ and 2, in $r - j$ rounds, and then use round $r - 1$ (respectively, r) to have the second (respectively, first) son send everything it knows to the root. The addition of 1 is for the root's own message.) Solving this recurrence yields $m_r = F_{r+3} - 1$, where F_k is the kth Fibonacci number.

Consider now the earliest round at which x could know $\geq p$ messages, including its own. It is easy to verify that after r rounds, x could know at most $m_{r-4} + m_{r-2} + m_{r-1} + 2 = F_{r-1} + F_{r+1} + F_{r+2} - 1 = 3F_{r+1} - 1$ messages (see Fig. 9).

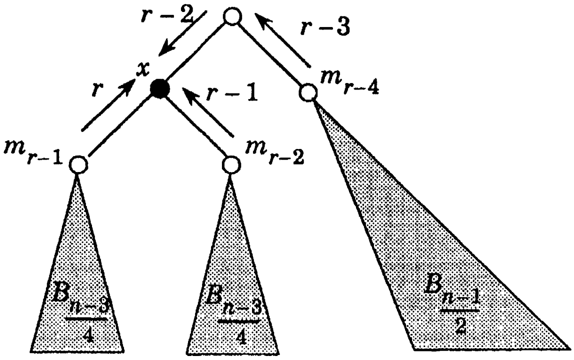

FIG. 9.

Thus, for x to know $\geq p$ messages, we need $\geq r$ rounds, where r satisfies $3F_{r+1} - 1 \geq p$, or $\phi^r \geq F_{r+1} \geq (p+1)/3$, or $r \geq \log_\phi((p+1)/3) \geq \log_\phi p - 3$. Thus, we can take $r_0 \geq \log_\phi p - O(1)$ as asserted. This proves (3), and completes the proof of Theorem 9. □

GENERATING LINEAR EXTENSIONS FAST*

GARA PRUESSE† AND FRANK RUSKEY‡

Abstract. One of the most important sets associated with a poset $\mathcal{P}$ is its set of linear extensions, $E(\mathcal{P})$. This paper presents an algorithm to generate all of the linear extensions of a poset in constant amortized time, that is, in time $O(e(\mathcal{P}))$, where $e(\mathcal{P}) = |E(\mathcal{P})|$. The fastest previously known algorithm for generating the linear extensions of a poset runs in time $O(n \cdot e(\mathcal{P}))$, where n is the number of elements of the poset. The algorithm presented here is the first constant amortized time algorithm for generating a "naturally defined" class of combinatorial objects for which the corresponding counting problem is #P-complete. Furthermore, it is shown that linear extensions can be generated in constant amortized time where each extension differs from its predecessor by one or two adjacent transpositions. The algorithm is practical and can be modified to count linear extensions efficiently and to compute $P(x < y)$, for all pairs x, y, in time $O(n^2 + e(\mathcal{P}))$.

Key words. poset, linear extension, transposition, combinatorial Gray code

AMS subject classifications. 05C45, 06A05, 06A06, 68Q25

1. Introduction.

One definition of the adverb "fast" is "in quick succession" (Webster's Collegiate Dictionary [1]). The purpose of this paper is to show that the linear extensions of a partially ordered set (poset) can be generated fast—so fast, in fact, that no algorithm can be faster, up to constant factors. Furthermore, the constants involved are very small and our algorithms extend the practical range of posets for which extensions can be generated and counted.

Linear extensions are of great interest to computer scientists because of their relation to sorting and scheduling problems. For example, there are many NP-complete one-processor scheduling problems with precedence constraints [13], and one obvious way of solving such problems is by generating all linear extensions of the precedence constraints and picking the best extension. Linear extensions are also of interest to combinatorists because of their relation to counting problems [2], [21]. Our results can be used to generate efficiently the standard Young Tableau of a given shape, alternating permutations, and any of the many other combinatorial objects that can be viewed as linear extensions of particular posets.

Given a poset $\mathcal{P}$, two questions naturally arise. The *generation question* asks whether the linear extensions, $E(\mathcal{P})$, of $\mathcal{P}$ can be efficiently generated. The *counting question* asks whether $e(\mathcal{P})$, the size of the set $E(\mathcal{P})$, can be efficiently determined. The recent result of Brightwell and Winkler [4], that the counting question is #P-complete, indicates that the counting question may be no easier than the generation question. We give the best possible answer to the generation question in the sense that our algorithm generates $E(\mathcal{P})$ in time complexity $O(e(\mathcal{P}))$ (aside from a small amount of preprocessing).

We say that a generation algorithm runs in *constant amortized time* if it runs in time $O(N)$, where N is the number of objects generated. In the case of linear extensions we assume that a unit cost oracle that takes two poset elements a and b and returns whether $a \prec b$ or not is available. We also assume that the poset elements have been labeled in a particular manner, to be described later. This labeling can be carried out in time $O(n^2)$ on an n element poset. Aside from the space used for the poset, the amount of space required by our algorithm is

$O(n)$. No constant amortized time generation algorithm was previously known for a class of combinatorial objects for which the corresponding counting problem is #P-complete.

The problem of generating the linear extensions of a poset has been considered by Knuth and Szwarcfiter [12], Varol and Rotem [24], and Kalvin and Varol [11]. In these papers the term "topological sorting" is used instead of "linear extension." The most efficient of these algorithms appears to be that of Varol and Rotem [24], whose time complexity is given as $O(n \cdot e(\mathcal{P}))$ in [11], where n is the number of elements in the poset. It is worth noting that the Varol and Rotem algorithm is very simple and elegant and quite efficient in practice. The only algorithm of which we are aware for counting linear extensions of arbitrary posets is that of Wells [25], but it appears to be difficult to analyze. For particular classes of posets, such as series-parallel or bounded width, efficient algorithms for counting are known (see, e.g., Bouchitte and Habib [3]).

2. Strategy and definitions. A popular strategy for efficiently generating some set of combinatorial objects is to insist that successive objects in the listing differ by some small and prescribed way. Listings of combinatorial objects that have this property are called (generalized or combinatorial) Gray codes. For example, the binary-reflected Gray codes yield a method for generating all the n-bit strings such that each bit string differs from its predecessor by the flipping of one bit. Gray codes have been found for several classes of combinatorial objects; many of these are described in Wilf [26].

We will regard linear extensions as permutations of the elements of the poset. When generating various classes of permutations, the most common "closeness" criteria is that successive permutations differ by a transposition of two of their elements; sometimes this is further restricted to a transposition of adjacent elements only. The well-known algorithm of Steinhaus [22], Johnson [10], and Trotter [23] provides a Gray code listing of all the $n!$ permutations of n elements where each permutation differs from its predecessor by a transposition of two adjacent elements. Thus we say that the $n!$ permutations can be *generated by* (*adjacent*) *transpositions*. The permutations of an n-set correspond to the linear extensions of the poset that is an n element antichain.

In general, it is not always possible to generate the linear extensions of a poset by transpositions, adjacent or not—for example, the linear extensions of the poset consisting of two nontrivial chains and only if n and m are both odd [5], [6], [16]. Thus, the linear extensions of the poset in Fig. 1 (two 2-element chains) cannot be generated by transpositions. The linear extensions of some classes of posets have been shown to be generable by transpositions (see [18], [15], [20]). It is an open problem to characterize the posets that have this property. Even when the linear extensions of a family of posets can be generated by transpositions, a fast algorithm to perform the generation may not exist.

The basic strategy of our initial algorithm is to generate each linear extension twice, where each extension is flagged plus or minus. The algorithm keeps track of the signs of the extensions and only "outputs" the plus extensions. Thus, in a sense, this algorithm falls into the class of generation algorithms that generate more objects than those that are actually output.

We now introduce our terminology and notation.

A poset (or partially ordered set) $\mathcal{P}$ is a reflexive, transitive, and antisymmetric relation $R(\mathcal{P})$ on a set $S(\mathcal{P})$. An ordered pair $(a, b) \in R(\mathcal{P})$ is denoted $a \preceq_{\mathcal{P}} b$ or, when it will not lead to confusion, simply $a \preceq b$. By $a \prec b$ we mean $a \preceq b$ and $a \neq b$. An element a is *minimal* in $\mathcal{P}$ if there is no element b such that $b \prec a$. Let $\text{Min}(\mathcal{P})$ denote the set of minimal elements of $\mathcal{P}$. If $a \prec b$ and there does not exist a c in $S(\mathcal{P})$ such that $a \prec c \prec b$, then we say that b *covers* a. Let $\text{Cover}(a)$ denote the set of elements that cover a. Elements a and b are said to be *incomparable* if $a \npreceq b$ and $b \npreceq a$. We write $a \parallel b$ to indicate that a and b are incomparable. If no pair of elements of $S(\mathcal{P})$ are incomparable, then $\mathcal{P}$ is a *total ordering*. If $\mathcal{P}$ is a total ordering on $S(\mathcal{P}) = \{x_1, x_2, \ldots, x_n\}$ such that $x_i \prec x_j$ if and only if $i < j$, then we sometimes use $x_1 x_2 \cdots x_n$ to denote $\mathcal{P}$. An *extension* of $\mathcal{P}$ is a poset $\mathcal{Q}$ such that $S(\mathcal{P}) = S(\mathcal{Q})$, and $R(\mathcal{P}) \subseteq R(\mathcal{Q})$. An extension of $\mathcal{P}$ which is a total ordering is called a *linear extension* of $\mathcal{P}$. Let $E(\mathcal{P})$ denote the set of linear extensions of $\mathcal{P}$, and let $e(\mathcal{P})$ denote $|E(\mathcal{P})|$. We let $\pm E(\mathcal{P})$ denote $\{+l, -l \mid l \in E(\mathcal{P})\}$.

The *height*, $h(x)$, of an element x is the average position that it occupies in a linear extension. Thus, a minimum element has height 1, a maximum element has height $|S(\mathcal{P})|$, and if $\mathcal{P}$ is an antichain then all elements have height $(|S(\mathcal{P})| + 1)/2$. The probability that x precedes y is denoted $P(x < y)$; it is the number of extensions in which x precedes y divided by the total number of extensions. In connection with sorting algorithms it is desirable to find pairs of elements x and y where $P(x < y)$ is close to 1/2.

For $T \subseteq S(\mathcal{P})$, we let $\mathcal{P} \backslash T$ denote the poset on the set $S(\mathcal{P}) \backslash T$ with the relations set $R(\mathcal{P}) \cap (S(\mathcal{P}) \backslash T)^2$. Suppose a and b are incomparable elements of $S(\mathcal{P})$ such that a has the same relationship to all other elements of $S(\mathcal{P})$ as b; more precisely, suppose that, for all $c \in S(\mathcal{P})$, $c \prec a$ if and only if $c \prec b$ and $a \prec c$ if and only if $b \prec c$. Then a and b are called *siblings*. For posets $\mathcal{P}$ and $\mathcal{Q}$, if $R(\mathcal{P}) \cup R(\mathcal{Q})$ is antisymmetric, then we let $\mathcal{P} + \mathcal{Q}$ denote the poset on the set $S(\mathcal{P}) \cup S(\mathcal{Q})$ with the relation set that is the transitive closure of $R(\mathcal{P}) \cup R(\mathcal{Q})$. For example, $\mathcal{P} + abc$ is the poset on the set $S(\mathcal{P}) \cup \{a, b, c\}$ with the relation set that is the transitive closure of $R(\mathcal{P}) \cup \{(a, b), (b, c)\}$. If $\mathcal{P} + \mathcal{Q} = \mathcal{P}$, then we say $\mathcal{P}$ *induces* $\mathcal{Q}$. For example, if $\mathcal{P} + abc = \mathcal{P}$, then $\{(a, b), (b, c)\} \subseteq R(\mathcal{P})$, and every linear extension of $\mathcal{P}$ has $a \prec b \prec c$; therefore, we say $\mathcal{P}$ induces abc. For element disjoint total orders $\alpha, \beta, \gamma, \delta$, we let $\alpha(\beta + \gamma)\delta$ denote the poset $\alpha\beta\delta + \alpha\gamma\delta$.

Consider the graph that has $E(\mathcal{P})$ as its vertex set, such that two vertices are adjacent in the graph whenever the corresponding linear extensions differ by a single transposition. This graph is called the *transposition graph* of the poset $\mathcal{P}$ and is denoted $G(\mathcal{P})$. The subgraph of $G(\mathcal{P})$ on the same vertex set but containing only the edges that correspond to adjacent transpositions is called the *adjacent transposition graph* and is denoted $G'(\mathcal{P})$. Generating the linear extensions of $\mathcal{P}$ by (adjacent) transpositions is equivalent to finding a Hamiltonian path in the graph $G(\mathcal{P})$ $(G'(\mathcal{P}))$. Figure 1 shows a poset and its transposition graph. If α and β are linear extensions of $\mathcal{P}$, then by $D(\alpha, \beta)$ we denote the distance in $G(\mathcal{P})$ from α to β and by $D'(\alpha, \beta)$ we denote the corresponding distance in $G'(\mathcal{P})$.

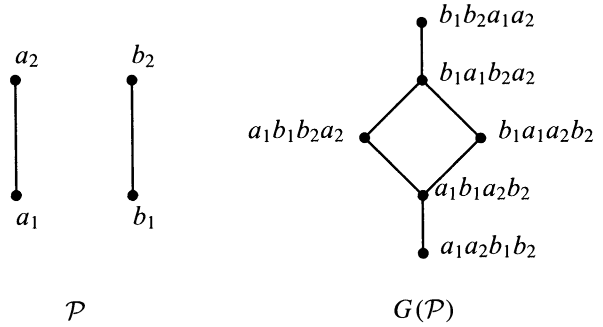

FIG. 1. *A poset and its transposition graph.*

Transposition graphs are bipartite and connected. If the partite sets of $G(\mathcal{P})$ are not the same size, then there is no Hamiltonian cycle through the graph; if the difference in the size of the partite sets is more than one, there is no Hamiltonian path through the graph and thus the linear extensions of $\mathcal{P}$ cannot be generated by transpositions. Ruskey [17] conjectures that this necessary condition for the existence of a Hamiltonian path is also sufficient, suggesting a possible characterization of the posets whose linear extensions can be generated by transpositions. In Fig. 1, the partite sets have a size difference of two, so the linear extensions of that poset cannot be generated by transpositions.

If G is a graph, then let $G \times K_2$ be the graph that results from taking two copies of G and adding the edges that correspond to an isomorphism between the two copies. To differentiate between the copies of G, we will prefix the vertices of one copy of G with "+" and the other with "$-$". For example, Fig. 2 shows $G(\mathcal{P}) \times K_2$, where $\mathcal{P}$ is the poset shown in Fig. 1.

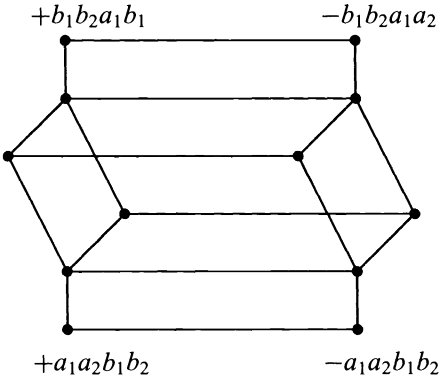

FIG. 2. *The graph* $G(\mathcal{P}) \times K_2$.

A lemma that will be useful in later sections can be stated as follows.

LEMMA 2.1. *If a and b are siblings in* $\mathcal{P}$, *then* $G(\mathcal{P}) \cong G(\mathcal{P} + ab) \times K_2$.

Proof. Observe that $E(\mathcal{P}) = E(\mathcal{P} + ab) \cup E(\mathcal{P} + ba)$. For any linear extension l of $\mathcal{P}$, transposing a and b in l yields another linear extension of $\mathcal{P}$. Therefore, the operation that transposes a and b in a linear extension provides an isomorphism between $G(\mathcal{P} + ab)$ and $G(\mathcal{P} + ba)$. □

If $e(\mathcal{P}) = 1$ (i.e., if $\mathcal{P}$ is a total order), $G(\mathcal{P}) \times K_2$ is an edge. For the purpose of inductively showing the existence of Hamiltonian cycles, we consider this graph to have a Hamiltonian cycle, since it has a Hamiltonian path such that the endpoints are adjacent.

3. The graph $G'(\mathcal{P}) \times K_2$ is Hamiltonian. The proof that $G'(\mathcal{P}) \times K_2$ is Hamiltonian forms the basis of the efficient algorithm to be presented in the next section. That this is true for a certain kind of poset, called a B-poset, was shown by Pruesse and Ruskey [15], and this result will be used in the proof of the general case.

DEFINITION 3.1. A *B-poset* is a poset $\mathcal{P}$ whose elements can be partitioned into two disjoint chains, $x_1 \prec x_2 \prec \cdots \prec x_n$ and $y_1 \prec y_2 \prec \cdots \prec y_m$, such that $y_j \not\preceq x_i$ for all i and j, where $1 \le i \le n$ and $1 \le j \le m$.

An example of a B-poset is shown in Fig. 3. Note that $\kappa = x_1x_2\cdots x_ny_1y_2\cdots y_m$ is a linear extension of any B-poset. The extension κ is called the *canonical linear extension* of a B-poset. Define $mr(x_i)$ to be the largest index j such that $x_i \parallel y_j$; if $x_i \prec y_1$, then $mr(x_i) = 0$. For the B-poset of Fig. 3, $mr(a) = 4$ and $mr(b) = 7$.

The following lemma was proved in [15].

LEMMA 3.2. *Let* $\mathcal{P}$ *be a B-poset. Then there exists a Hamiltonian cycle in* $G'(\mathcal{P}) \times K_2$ *that uses the edge* $[+\kappa, -\kappa]$.

Figure 4 shows the graph $G'(\mathcal{P}) \times K_2$, where $\mathcal{P}$ is the B-poset shown in Fig. 3. The edges corresponding to the isomorphism between the two copies of $G'(\mathcal{P})$ have been omitted for the

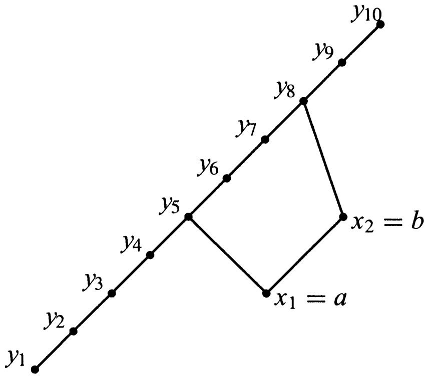

FIG. 3. *A B-poset.*

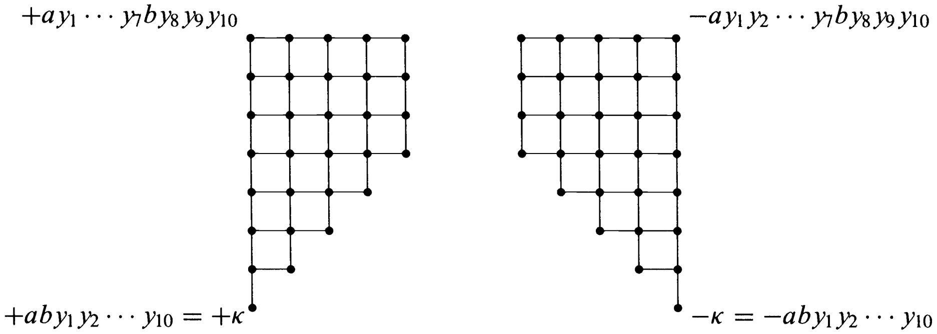
sake of clarity. One can think of traveling up a vertical edge as transposing $b = x_2$ with its neighbor on the right and traveling along a horizontal edge as transposing $a = x_1$ with one of its neighbors. A Hamiltonian path between $+\kappa$ and $-\kappa$ is shown in Fig. 5. All B-posets used in the remainder of the paper have $n = 2$; we call these *2B-posets.*



$+ay_1 \cdots y_7by_8y_9y_{10}$
$-ay_1y_2 \cdots y_7by_8y_9y_{10}$
$+aby_1y_2 \cdots y_{10} = +\kappa$
$-\kappa = -aby_1y_2 \cdots y_{10}$

FIG. 4. *The graph $G'(\mathcal{P}) \times K_2$.*

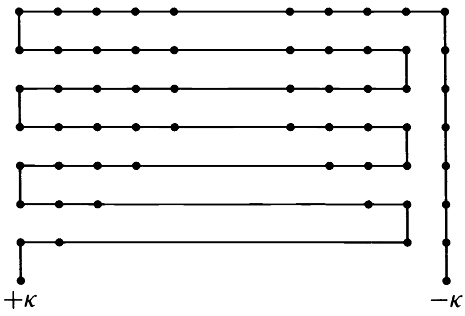


FIG. 5. *A Hamiltonian cycle through $G'(\mathcal{P}) \times K_2$.*

A graph similar to that shown in Fig. 4 arises whenever $a \parallel y_1$; we call this the *typical case.* If $a \prec y_1$ then $G'(\mathcal{P})$ is a path; we call this the *atypical case.* In other words, the typical case occurs when $mr(a) > 0$ and the atypical case occurs when $mr(a) = 0$.

THEOREM 3.3. *For every poset $\mathcal{P}$, the graph $G'(\mathcal{P}) \times K_2$ is Hamiltonian.*

Proof. The proof of the theorem is by induction on $|S(\mathcal{P})|$. For the base cases of the induction, $\mathcal{P}$ is the poset on zero or one element; in both of these cases $G'(\mathcal{P}) \times K_2$ is an edge.

Suppose $|S(\mathcal{P})| > 1$. If $\mathcal{P}$ has a unique minimum a, then $G'(\mathcal{P}) \cong G'(\mathcal{P}\backslash\{a\})$, and by the inductive hypothesis $G'(\mathcal{P}\backslash\{a\}) \times K_2$ is Hamiltonian.

Otherwise, let $\mathcal{P}$ have two minimal elements a and b. By the inductive hypothesis, the graph $G'(\mathcal{P}\backslash\{a, b\}) \times K_2$ has a Hamiltonian cycle H'. Replace each signed linear extension $+\alpha_i$ on H' with $ab\alpha_i$; replace each linear extension $-\alpha_i$ with $ba\alpha_i$. The result is a cycle $\beta_1, \beta_2, \dots, \beta_M$, where $M = 2 \cdot e(\mathcal{P}\backslash\{a, b\})$, in $G'(\mathcal{P}) \times K_2$, which visits exactly those linear extensions in which a and b precede all other elements of $S(\mathcal{P})$. That is, this cycle visits all the linear extensions of

$$\mathcal{P}' = \mathcal{P} + \sum_{x \in S(\mathcal{P})\backslash\{a,b\}} ax + bx.$$

The poset $\mathcal{P}'$ is $\mathcal{P}$ extended so that a and b are covered by every other element of $\operatorname{Min}(\mathcal{P})$.

For each $\beta_i = x_i y_i \zeta_i$, where $x_i = a$, $y_i = b$ or $x_i = b$, $y_i = a$, the poset $\mathcal{P} + x_i y_i + \zeta_i$ is a B-poset. By Lemma 3.2, there is a Hamiltonian path through $G'(\mathcal{P} + x_i y_i + \zeta_i) \times K_2$ from $+\beta_i$ to $-\beta_i$. We substitute the occurrence of β_i with this path in H', for each odd i. For each even i, we substitute the reverse of this path for the occurrence of β_i. Call the resulting walk H.

To prove that H is a Hamiltonian cycle through $G'(\mathcal{P}) \times K_2$, it is necessary to show that every vertex on the cycle H is a linear extension of $\mathcal{P}$; this is true, since $E(\mathcal{P}') \subseteq E(\mathcal{P})$, and hence each B-poset generated is an extension of $\mathcal{P}$. It is also necessary to show that for each linear extension l of $\mathcal{P}$, $+l$ and $-l$ both occur exactly once on H. Suppose l induces the order xy on $\{a, b\}$ and the order ζ on $S(\mathcal{P})\backslash\{a, b\}$. Then $xy\zeta$ is a linear extension of $\mathcal{P}'$, and l is a linear extension of the B-poset $\mathcal{P} + xy + \zeta$; also, every other B-poset that is generated either does not induce the order xy or does not induce the order ζ. Therefore, $+l$ and $-l$ are generated only during the generation of $E(\mathcal{P} + xy + \zeta)$; i.e., each $+l$ and $-l$ are generated exactly once. □

Observe that the reference to Lemma 3.2 in the preceding proof was not strictly necessary because the B-posets that occur are all 2B-posets. In the "typical" case, the cycle of Fig. 5 could be used; in the "atypical" case the cycle is obvious (move b to the right as far as possible, change signs, and then move the b back to the left). If $mr(b)$ is even, the cycle of Fig. 5 is slightly different and uses the edge $[+a\gamma b, -a\gamma b]$, where $\gamma = y_1 y_2 \cdots y_m$. These cycles are used in the algorithm of the following section.

COROLLARY 3.4. *If $\mathcal{P}$ is a poset with a pair of siblings, then $G(\mathcal{P})$ is Hamiltonian.*

Proof. Suppose $\mathcal{P}$ has a pair of siblings a, b. By Theorem 3.3, $G'(\mathcal{P} + ab) \times K_2$ is Hamiltonian; therefore, $G(\mathcal{P} + ab) \times K_2$ is Hamiltonian. Hence by Lemma 2.1, $G(\mathcal{P})$ is Hamiltonian. □

It is an open problem to determine whether $G'(\mathcal{P})$ is Hamiltonian, where $\mathcal{P}$ is a poset with a pair of siblings.

4. The algorithm. The proof of Theorem 3.3 is constructive. In this section, we present the recursive algorithm implicit in the inductive proof. The algorithm runs in *constant amortized time*, i.e., generating all the linear extensions of a poset $\mathcal{P}$ takes time $O(e(\mathcal{P}))$.

We first give an overview of the algorithm and use a small example to give a general description of how it works. We then give the details of the algorithm and a proof of its correctness.

The algorithm is an *in-place* algorithm; it maintains an array `le`, which contains the current linear extension, and maintains a variable `IsPlus`, which keeps track of the sign

("+" or "−"). We go from one linear extension to the next by making changes to the array or reversing the sign.

The main procedure used by the algorithm, which we call GenLE, is recursive and basically follows the path indicated in Fig. 5. Every level of the recursion has an associated pair of minimal elements of the current subposet. For example, in the poset shown in Fig. 1, a_1, b_1 are a pair of minimal elements of $\mathcal{P}_1 = \mathcal{P}$ and a_2, b_2 are a pair of minimal elements of $\mathcal{P}_2 = \mathcal{P}_1 \backslash \{a_1, b_1\}$. These pairs are determined by some preprocessing, which will be described later.

The procedures Move and Switch are used to change the current linear extension. They operate in $O(1)$ time as follows.

Switch(i): If $i = 0$, then the sign is changed; that is, IsPlus is changed. If $i > 0$, then a_i and b_i are transposed.

Move(x,left): This call transposes x with the element on its left.

Move(x,right): This call transposes x with the element on its right.

Each time a new linear extension l of $\mathcal{P}_i$ is generated by the call GenLE(i) (i.e., each time Move or Switch is called), GenLE(i-1) is called; the call GenLE(i-1) moves $a_1, b_1, \ldots, a_{i-1}, b_{i-1}$ in all possible ways through l, while maintaining the order $a_{i-1} \prec b_{i-1}$ (or $b_{i-1} \prec a_{i-1}$, depending on their order at the point of calling GenLE(i-1)). If $i = 1$, then GenLE(i-1) does nothing.

For example, starting with $+a_1b_1a_2b_2$ and executing the calling sequence GenLE(2), Switch(2), GenLE(2) on the poset shown in Fig. 1 leads to the trace of calls shown in Fig. 6.

Procedure Call	**Linear Extension**
	$+a_1b_1a_2b_2$
GenLE(2)	
GenLE(1)	
Move($b_1, \rightarrow$)	$+a_1a_2b_1b_2$
Switch(0)	$-a_1a_2b_1b_2$
Move($b_1, \leftarrow$)	$-a_1b_1a_2b_2$
Switch(1)	$-b_1a_1a_2b_2$
GenLE(1)	
Switch(0)	$+b_1a_1a_2b_2$
Switch(2)	$+b_1a_1b_2a_2$
GenLE(2)	
GenLE(1)	
Move($a_1, \rightarrow$)	$+b_1b_2a_1a_2$
Switch(0)	$-b_1b_2a_1a_2$
Move($a_1, \leftarrow$)	$-b_1a_1b_2a_2$
Switch(1)	$-a_1b_1b_2a_2$
GenLE(1)	
Switch(0)	$+a_1b_1b_2a_2$

FIG. 6. *The trace of the calling sequence for the poset of Fig.* 1.

We now follow with the details of our implementation. The reader should refer to the Pascal procedure GenLE of Fig. 8.

The implementation of the algorithm maintains four global arrays: array le is the linear extension; array li is its inverse. Arrays a and b store the elements a_i and b_i. In our discussion of the algorithm, a_i and b_i are considered fixed at the outset and unchanging throughout the run of the algorithm. The arrays will be maintained so that a[i] always contains the value of the leftmost of the ith pair and `b[i]` contains the rightmost. Also, the current sign, either plus (+) or minus (−), is maintained.

The boolean function `Right(x)` is used to determine whether the element `x` can move to the right. It operates in $O(1)$ time as follows:

`Right(b[i])`: Returns true only if `b[i]` is incomparable with the element to its right in the array `le`.

`Right(a[i])`: Returns true only if `a[i]` is incomparable with the element to its right in the array `le` and the element to the right is not `b[i]`.

We now describe our preprocessing. We successively strip off pairs a_i, b_i of minimal elements for $i = 1, 2, \ldots$ until there are no elements left. If a unique minimum element is encountered then it is simply deleted and does not become part of a pair. Let `MaxPair` be the index of the last pair of minimal elements we strip from $\mathcal{P}$, the remainder of $\mathcal{P}$ being a total ordering or empty. This preprocessing is detailed in Fig. 7. Note that `MaxPair` is not uniquely determined by the poset but that it depends on the order in which the elements are stripped from $\mathcal{P}$.

```
$i \leftarrow j \leftarrow 0$;
$\mathcal{Q} \leftarrow \mathcal{P}$;
while $S(\mathcal{Q}) \neq \emptyset$ do
    if $\mathcal{Q}$ has exactly one minimal element $x$ then begin
        $j \leftarrow j + 1$;
        $le[j] \leftarrow x$;
        $\mathcal{Q} \leftarrow \mathcal{Q} \backslash \{x\}$;
    end else begin
        let $a', b'$ be any two minimal elements of $\mathcal{Q}$;
        $i \leftarrow i + 1$;
        $j \leftarrow j + 2$;
        $a[i] \leftarrow a'$;
        $b[i] \leftarrow b'$;
        $le[j-1] \leftarrow a'$;
        $le[j] \leftarrow b'$;
        $\mathcal{Q} \leftarrow \mathcal{Q} \backslash \{a', b'\}$;
    end {else}
end {while}
MaxPair $\leftarrow i$;
```

FIG. 7. *The preprocessing routine.*

We say the linear extension l is in *proper order up to i* if for all $1 \leq j \leq i$ the elements a_j and b_j are adjacent in l and if l induces the orders $a_1 a_2 \cdots a_i a_h$ and $a_1 a_2 \cdots a_i b_h$ for all h, where $i < h \leq$ `MaxPair`. The initial linear extension of the listing must be properly ordered up to `MaxPair`; the preprocessing of Fig. 7 does this.

Assuming that `Right( b[MaxPair+1] )` is false, the initial call is simply `GenLE( MaxPair + 1 )`; this is the same as the following procedure calls, which we call the *calling sequence.*

```
GenLE( MaxPair ); Switch( MaxPair ); GenLE( MaxPair );
```

The algorithm consists of executing the preprocessing, setting `IsPlus` to plus (+), and then executing the calling sequence.

A Pascal procedure implementing `GenLE` is given in Fig. 8. We now prove the following theorem.

THEOREM 4.1. *The algorithm* `GenLE` *generates the linear extensions along a Hamiltonian path in* $G'(\mathcal{P}) \times K_2$.

```
procedure GenLE ( i : integer );
var mrb,mra,mla,x : integer;  typical : boolean;
begin
if i > 0 then begin
  GenLE( i-1 );
  mrb := 0;   typical := false;
  while Right( b[i] ) do begin
     mrb := mrb + 1;
     Move( b[i], riht );  GenLE( i-1 );
     mra := 0;
     if Right( a[i] ) then begin
        typical := true;
        repeat
           mra := mra + 1;
           Move( a[i], riht );  GenLE( i-1 );
        until not Right( a[i] );
     end {if};
     if typical then begin
        Switch( i-1 );  GenLE( i-1 );
        if odd( mrb ) then mla := mra - 1 else mla := mra + 1;
        for x := 1 to mla do begin
           Move( a[i], left );  GenLE( i-1 );
        end;
     end {if};
  end {while};
  if typical and odd( mrb )
     then Move( a[i], left )
     else Switch( i-1 );
  GenLE( i-1 );
  for x := 1 to mrb do begin
     Move( b[i], left );  GenLE( i-1 );
  end;
end {if};
end {GenLE};
```

FIG. 8. *Pascal procedure* GenLE.

Proof. In order to prove the theorem, we first prove the following proposition.

PROPOSITION 4.2. *Let the linear extension in array* `le` *be* $\xi = \delta a_i b_i \gamma$, *and let* ξ *be properly ordered up to* i. *Then for each linear extension* $l \in E(\mathcal{P} + a_i b_i + \gamma)$, `GenLE(i)` *generates each of* $+l$, $-l$ *exactly once. Furthermore, if* $i = 1$ *then the last extension generated is* $-\xi$, *and if* $i > 1$ *then the last extension generated is* $+\xi'$, *where* ξ' *differs from* ξ *by a transposition of* a_{i-1} *and* b_{i-1}.

Proof. The proof proceeds by induction on i. If $i = 1$, the recursive calls `GenLE(0)` do nothing, `Switch(0)` just changes the sign, and δa_1 is induced by $\mathcal{P}$.

It is easy to confirm that the algorithm in Fig. 8, when stripped of its recursive calls and in which `Switch` just changes the sign, simply follows the path indicated in Fig. 2. In this case, `GenLE(1)` just finds a Hamiltonian path from $+\xi$ to $-\xi$ through $G'(\mathcal{Q}) \times K_2$, where $\mathcal{Q}$ is the 2B-poset $\mathcal{P} + a_1 b_1 + \gamma$.

If $i > 1$, then assume without loss of generality that the sign in storage when `GenLE` is invoked is "+". There are α, β, γ such that $+\xi = +\alpha a_{i-1} b_{i-1} \beta a_i b_i \gamma$. Because of the way the preprocessing selects the pairs a_j, b_j, we are assured that $\mathcal{P}$ induces the order $\beta(a_i + b_i)$ (of course, β could be empty).

As mentioned before, the basic structure of the algorithm, stripped of recursive calls, follows the Hamiltonian path in a 2B-poset as indicated in Fig. 2, where `Switch` now transposes a_{i-1} and b_{i-1}; therefore, it generates

$$+E' = +E(\mathcal{P} + \alpha(a_{i-1} + b_{i-1})\beta(a_i b_i + \gamma)).$$

Each linear extension in $+E'$ is properly ordered up to $i - 1$.

As each such linear extension $+l = +\alpha a_{i-1} b_{i-1} \beta\zeta$ (or $+l' = +\alpha b_{i-1} a_{i-1}\beta\zeta$), where $\zeta \in E(a_i b_i + \gamma)$, is generated, GenLE(i-1) is called on $+l$. By the inductive hypothesis, that call generates $\pm E(\mathcal{P} + a_{i-1}b_{i-1} + \beta\zeta)$ (or $\pm E(\mathcal{P} + b_{i-1}a_{i-1} + \beta\zeta)$, respectively), starting at $+l$ and ending at $+l'$ if $i > 2$, and ending at $-l$ if $i = 2$. Since there are an even number of vertices in the product of the graph with an edge, there are an even number of calls to GenLE(i-1). Thus if $i > 2$ then the sign of the final permutation is unchanged, and if $i = 2$ then the relative ordering of a_{i-1} and b_{i-1} is unchanged. The union over all such ζ is

$$\pm E(\mathcal{P} + a_{i-1}b_{i-1} + a_i b_i + \gamma) \cup \pm E(\mathcal{P} + b_{i-1}a_{i-1} + a_i b_i + \gamma) = \pm E(\mathcal{P} + a_i b_i + \gamma). \qquad \square$$

Let a, b be a[MaxPair], b[MaxPair] respectively, and suppose the calling sequence is executed on the preprocessed poset $\mathcal{P}$. By the proposition, the first call to GenLE generates $\pm E(\mathcal{P} + ab)$; then a and b are transposed, and then $\pm E(\mathcal{P} + ba)$ is generated. Therefore, $E(\mathcal{P})$ is generated, and the theorem is proved. □

In analyzing the time complexity of the algorithm, we assume that Right, Switch, and Move can be implemented in constant time. This is easily accomplished as long as the inverse li of le is maintained. Each call to Move and Switch generates one more linear extension. Observe that the call GenLE(i) generates at least two calls to GenLE(i-1). Each iteration of a while-loop or for-loop in the algorithm executes a Move, thereby generating a linear extension. The only occasion in which GenLE can be recursively called and no linear extension generated is when $i = 0$, and this happens at most once per linear extension generated. Therefore, the algorithm runs in constant time per linear extension, when generating $\pm E(\mathcal{P})$. By suppressing the linear extensions which are prefixed with "$-$", we generate $E(\mathcal{P})$ in constant amortized time. Another way to think of the preceding argument is to consider the underlying computation tree, where each internal node is a recursive call and each leaf is a linear extension. The total amount of computation can be apportioned so that each node is assigned a constant amount of computation. Since each internal node has at least two children, the number of leaves is greater than the number of internal nodes and, therefore, the total amount of computation is proportional to the number of leaves.

Observe that the generation of the minus ("$-$") vertices only occurs when $i = 1$ in Algorithm GenLE. This suggests that $i = 1$ be treated as a special case and that minus ("$-$") vertices be omitted entirely by simply skipping to the next plus ("+") vertex. If this is done, then it saves some computation, but the same list of extensions is produced as before, and successive extensions can differ by a large number of transpositions.

If one only wants to compute the number of extensions, then some computation can be saved by only computing the number of vertices at the $i = 1$ level of the recursion, and not generating the extensions explicitly, i.e., never moving a_1 and b_1. The number of vertices (extensions) can be determined from $mr(a) =$ mra and $mr(b) =$ mrb; the number is $(mr(a) + 1)[mr(b) + 1 - mr(a)/2]$. Furthermore, $mr(a)$ and $mr(b)$ change by at most unity from one extension to the next, since only adjacent transpositions are used. This leads to an algorithm whose running time is $O(e(\mathcal{P} \setminus \{a_1, b_1\}))$. In general, we have

$$2 \cdot e(\mathcal{P} \setminus \{a_1, b_1\}) \leq e(\mathcal{P}) \leq n(n-1) \cdot e(\mathcal{P} \setminus \{a_1, b_1\}).$$

The lower bound is attained when $a_1 \prec c$ and $b_1 \prec c$ for all elements c of $\mathcal{P} \setminus \{a_1, b_1\}$. The upper bound is attained when a_1 and b_1 are maximal, as well as minimal.

5. Gray codes for linear extensions. We now show that linear extensions can be listed so that successive extensions differ by at most a few adjacent transpositions. We first show the existence of such listings and then how to modify the results of the previous sections to show that the set of linear extensions of a poset can be listed so that successive extensions differ by only one or two adjacent transpositions. Let us say that an ordering $\alpha_1, \alpha_2, \dots, \alpha_{e(\mathcal{P})}$ of the extensions of $\mathcal{P}$ has *delay C* if $D'(\alpha_i, \alpha_{i+1}) \le C$ for all $0 \le i < e(\mathcal{P})$, where $\alpha_0 = \alpha_{e(\mathcal{P})}$. Thus we are going to show the existence of a delay 2 ordering of $E(\mathcal{P})$. Furthermore, such a listing can be done in constant amortized time. The existence of a delay 3 ordering is not difficult to show.

If G is a graph then by G^k we denote the graph with the same vertex set as G but which has an edge between every pair of vertices that are connected by a path of length at most k in G. In other words, if M is the incidence matrix of G, then M^k is the incidence matrix of G^k, where arithmetic is done mod 2. The *cube* of G is G^3, and the *square* of G is G^2. A poset $\mathcal{P}$ has a delay k ordering if and only if $G'(\mathcal{P})^k$ is Hamiltonian. A result of Sekanina [19] is that the cube of every connected graph is Hamiltonian. Since $G'(\mathcal{P})$ is always connected, $G'(\mathcal{P})^3$ is Hamiltonian and a delay 3 ordering exists.

The graph $G'(\mathcal{P})$ is not always 2-connected; otherwise the existence of a delay 2 ordering would by implied by a result of Fleischner [7], which states that the square of every 2-connected graph is Hamiltonian.

Even though $G'(\mathcal{P})$ is not in general 2-connected, the posets with 2-connected transposition graphs are easy to characterize. First, consider the question of which transposition graphs have pendant vertices. If $\mathcal{P}$ consists of two disjoint chains, then $G'(\mathcal{P})$ has two pendant vertices; if $\mathcal{P}$ is a B-poset and is not the disjoint union of two chains, then $G'(\mathcal{P})$ has one pendant vertex; otherwise, $G'(\mathcal{P})$ has no pendant vertices.

LEMMA 5.1. *For every poset $\mathcal{P}$, the graph $H(\mathcal{P})$ is 2-connected, where $H(\mathcal{P})$ is $G'(\mathcal{P})$ minus any pendant vertices.*

This may be proved by showing that every pair of incident edges of $H(\mathcal{P})$ is on a 4-, 6-, or 8-cycle. This lemma does not help us in finding an efficient algorithm for listing a delay 2 ordering of $E(\mathcal{P})$. Instead, we prove it by applying Theorem 3.3 and the following lemma.

LEMMA 5.2. *If G is bipartite and $G \times K_2$ is Hamiltonian, then G^2 is Hamiltonian.*

Proof. Let G be a bipartite graph on n vertices, and let

$$(v_1, x_1), (v_2, x_2), \dots, (v_{2n}, x_{2n})$$

be a Hamiltonian cycle through $G \times K_2$, where $v_i \in V(G)$ and $x_i \in V(K_2) = \{1, 2\}$, for all i, $1 \le i \le 2n$. Consider the sequence of vertices $S = v_2, v_4, \dots, v_{2n}$.

Since G is bipartite, so is $G \times K_2$; thus the vertices of S are all the vertices of one partite set of $G \times K_2$. Also, for a vertex u of G, $(u, 1)$ and $(u, 2)$ are adjacent and therefore are in different partite sets of $G \times K_2$. Therefore, each vertex of G appears exactly once in S. For each i, the vertices v_i and v_{i+2} are either of distance one in G (if $x_i \ne x_{i+2}$) or of distance two in G (if $x_i = x_{i+2}$). Therefore, S is a Hamiltonian cycle in G^2. □

We conjecture that Lemma 5.2 may be extended to graphs that are not bipartite.

CONJECTURE 5.3. *If $G \times K_2$ is Hamiltonian, then G^2 is Hamiltonian.*

A graph is in class $\mathcal{H}(s, t)$ if it has a closed walk that visits every vertex at least s times and at most t times. (See [8], [14].) Thus $\mathcal{H}(1, 1)$ is the class of Hamiltonian graphs. Observe that if $G \times K_2$ is Hamiltonian, then $G \in \mathcal{H}(1, 2)$ (just consider the walk that results when the two copies of G are identified). The converse is not true; if G is the triangle with a pendant edge added to each vertex, then $G \in \mathcal{H}(1, 2)$ but $G \times K_2$ is not Hamiltonian. Theorem 3.3

shows that for every poset $\mathcal{P}$, the graph $G'(\mathcal{P})$ is in $\mathcal{H}(1, 2)$. In general, these graphs are not Hamiltonian. We make a conjecture.

CONJECTURE 5.4. *If $G \in \mathcal{H}(1, 2)$, then G^2 is Hamiltonian.*

The example of $K_{2,6}$ shows that the converse of the conjecture is false.

The proof of Lemma 5.2 is constructive; applying that construction to $G'(\mathcal{P})$ yields the following result.

THEOREM 5.5. *The linear extensions of any poset can be generated with delay* 2 *in constant amortized time.*

Proof. We run the Algorithm `Genle` given in Fig. 8, but instead of suppressing the linear extensions with a negative sign we suppress every other linear extension; i.e., if we generate the list $l_1, l_2, l_3, l_4, l_5, \ldots,$ then we output the list $l_1, l_3, l_5, \ldots.$ By the proof of Lemma 5.2, this is a delay 2 listing of the linear extensions. It has the same running time as `Genle`, i.e., constant amortized time. □

In the remainder of this section we discuss how to use the algorithm to compute $P(x < y)$ and $h(x)$. We use the version of `GenLE` that generates each extension exactly twice, where each successive extension differs by an adjacent transposition from its predecessor. We first discuss how to compute $P(x < y)$.

Let us define an xy-run to be a maximal sequence of successive extensions where x precedes y. We maintain two arrays of integers, call them S and T. The value of $S[x, y]$ is the sum of the lengths of the previous xy-runs. The value of $T[x, y]$ is the iteration at which the current xy-run started. At each iteration, exactly one adjacent pair, say xy, is transposed. If this occurs at the tth iteration, then $S[x, y]$ is incremented by $t - T[x, y]$ and $T[y, x]$ is set to t. At the termination of the algorithm, $P(x < y)$ is $S[x, y]$ divided by $2e(\mathcal{P})$. Since only a constant amount of update is done at each iteration, the total computation is $O(n^2 + e(\mathcal{P}))$.

To compute $h(x)$ we proceed in a similar fashion. An x-run is a maximal sequence of extensions in which x occupies the same position. Here the value of $S[x]$ is the weighted sum of the lengths of the previous x-runs and $T[x]$ is the iteration at which the current x-run started. At each iteration exactly one adjacent pair, say xy, is transposed. If this occurs at the tth iteration, then for $z = x, y$, $S[z]$ is incremented by $p[z] * (t - T[z])$ and $T[z]$ is set to t, where $p[z]$ is the position that z occupied in the extension. At termination the value of $h(x)$ is $S[x]$ divided by $2e(\mathcal{P})$.

6. Concluding remarks.

The algorithm given in §6 generates the linear extensions of a poset in constant amortized time, an improvement over the $O(n)$ amortized time algorithm of [11], which is the fastest previously known algorithm. A further refinement to the work presented here would be to generate the linear extensions by a "loopfree" algorithm (i.e., constant computation in the worst case in producing a new extension from the current one).

We have fully implemented the counting and generating algorithms in C and found them to be quite efficient in practice. On a Sun SPARCstation SLC, the program generated the 2,702,765 extensions of a 12-element fence poset in 4.2 seconds. These extensions are counted by the Euler numbers; counting took 1.7 seconds. The 199,360,981 extensions of a 14-element fence were counted in 91 seconds and generated in 281 seconds. The 2,674,440 extensions of the 2 by 14 grid were generated in 8.3 seconds. These extensions are counted by the Catalan numbers.

Enumeration of the linear extensions of a poset has recently been shown to be #P-complete. The algorithm in §3 constitutes the first constant amortized time algorithm for generating a naturally defined class of combinatorial objects where the associated counting problem is #P-complete. This leads to some interesting questions about the complexity of generating other combinatorial objects for which counting is #P-complete.

Do all #P-complete problems admit constant amortized time generation algorithms? In asking this question we assume that an initial object has been supplied as part of the input. For example, for Hamiltonian cycles the input would consist of a graph G and a Hamiltonian cycle in G; similarly, in this paper we have assumed that $12 \cdots n$ is a linear extension of the input poset.

Intuitively, if the existence question is difficult (NP-complete), then the generation question will be difficult as well, but we have not answered, or even formalized, this intuition. Even if the existence question is easy (in P), there are many problems for which the complexity of generating is unknown. For example, can the ideals of a given input poset be generated in constant amortized time? Counting ideals is #P-complete, but finding an ideal is trivial. What about generating the spanning trees of a graph in constant amortized time? Finding a spanning tree and counting the number of such trees are both in P, but no one has discovered a constant amortized time algorithm for generating the spanning trees. Is there, in fact, any interesting relationship between constant amortized time generation algorithms and the complexity of existence and/or counting? Some related questions, for various polynomial time complexity measures (instead of constant amortized time), were considered by Johnson, Yannakakis, and Papadimitriou [9].

Acknowledgments. We would like to thank Derek Corneil, Mike Fellows, and Carla Savage for helpful discussions, Malcolm Smith for work on the figures, and especially Ken Wong for implementing the algorithms and carefully reading the manuscript.

Note added in proof. As was pointed out by L. Babai (private communication), it is easy to contrive a #P-complete object that can be generated quickly by starting with a #P-complete object and pumping up the number of instances by taking the union with an easily counted and easily generated but more numerous object. For example, given a poset $\mathcal{P}$ on n vertices, consider the set $\{x : x \text{ is an ideal of } \mathcal{P}\} \cup \{x : x \subseteq [n^2]\}$. This set is #P-complete to count and, given an appropriate representation, is easy to generate in constant amortized time.

A counterexample on twenty-four vertices to Conjectures 5.3 and 5.4 has recently been found by J. van den Heuvel (private communication).

RANDOMIZED PARALLEL ALGORITHMS FOR MATROID UNION AND INTERSECTION, WITH APPLICATIONS TO ARBORESENCES AND EDGE-DISJOINT SPANNING TREES*

H. NARAYANAN†, HUZUR SARAN‡, AND VIJAY V. VAZIRANI‡

Abstract. The strong link between matroids and matching is used to extend the ideas that resulted in the design of random NC (RNC) algorithms for matching to obtain RNC algorithms for the matroid union, intersection, and matching problems, and for linearly representable matroids. As a consequence, RNC algorithms for the well-known problems of finding an arboresence and a maximum cardinality set of edge-disjoint spanning trees in a graph are obtained. The key tools used are linear algebra and randomization.

Key words. parallel algorithms, randomized algorithms, graph algorithms, matroids

1. Introduction.

We obtain random NC (RNC) algorithms for the fundamental problems of matroid union and matroid intersection, for linearly representable matroids.

A key step in the matroid union algorithm is a simple method, using randomization, for obtaining a linear representation for the union (it is well known that the union will be a matroid, and will also be linearly representable). Once this is done, it is straightforward to find a maximal independent set in the union matroid. This set is partitioned into independent sets in the corresponding matroids using our RNC matroid intersection algorithm.

An RNC algorithm for the matroid intersection problem, which is a generalization of bipartite matching, is obtained using the Binet-Cauchy Theorem and the Isolating Lemma of [MVV]. Similar techniques, together with a theorem of Lovász [Lo2], yield an RNC algorithm for the matroid matching problem as well. This problem, also called the matroid parity problem, generalizes matroid intersection and general graph matching.

Using the matroid union and intersection algorithms, we obtain RNC algorithms for the matroid covering and packing problems. For the case of a graphic matroid, these correspond to the well-known problems of finding an arboresence in a graph (i.e., the minimum number of forests that cover all edges), and of finding a maximum cardinality set of edge-disjoint spanning trees in a graph. The latter has applications to fault tolerant communications [IR], [Gu]. It also has applications in the analysis of electric networks [IF], [OIW] and in the study of rigidity of structures [LY].

The first polynomial time algorithms for matroid union and matroid intersection were given by Edmonds [Ed1], and Lovász [Lo2] gave the first such algorithm for the matroid matching problem for linearly representable matroids.

Our results draw on the ideas used in the design of RNC algorithms for the maximum matching problem [KUW1], [MVV]. Broadly speaking, the solution for matching consisted of taking the problem into linear algebra, and the use of randomization for extracting a maximum matching. Indeed, we are also forced to work within the realm of linear algebra; our results hold only for linearly representable matroids. However, since almost all useful matroids have this property, this is not a major restriction.

It is interesting to see matroid theory and the matching problem playing their typical roles once again—the former unifies and generalizes concepts, and the latter "serves as an archetypical example of how a 'well-solvable' problem can be studied" (quoted from [LP]).

2. Preliminaries.

Let us first review some basic definitions and notation from matroid theory; details may be found in [Ai], [La], [We].

‡Department of Computer Science and Engineering, Indian Institute of Technology, Delhi 110016, India.

A *matroid* M is a finite set $S = \{e_1, \dots, e_n\}$ together with a collection $\mathcal{I}$ of subsets of S (called *independent sets*) such that the following conditions hold.

1. $\emptyset \in \mathcal{I}$.
2. If $X \in \mathcal{I}$ and $Y \subseteq X$ then $Y \in \mathcal{I}$.
3. If $U, V \in \mathcal{I}$ with $|U| = |V| + 1$ then there exists $x \in U - V$ such that $V \cup \{x\} \in \mathcal{I}$.

A subset of S that is not independent is called *dependent*. The *rank* of a set $A \subseteq S$, denoted by $\rho(A)$, is the cardinality of a maximal independent subset of A. The rank of the matroid M is the rank of S. A maximal independent set of M is called a *base*. A fundamental consequence of the matroid axioms is that all bases of a matroid have the same cardinality, thus every maximal independent set is actually maximum.

A matrix B over a field F is a *linear representation* of M if there is a one-to-one correspondence between the elements of S and the columns of B, such that a subset of S is independent in M if and only if the corresponding set of columns of B is independent over F. If the rank of M is r then B need only have r rows. A matroid M is said to be *linearly representable* over F if there exists such a matrix.

For convenience, we will restrict our attention to matroids that are linearly representable over the rationals; it is easy to check that our results are valid as long as $|F|$ is large enough as a function of n and r. Henceforth, "representable" will mean "representable over $\mathbf{Q}$."

Given a graph G, the matroid $\hat{G}$ obtained by taking S to be the set of edges of G and $\mathcal{I}$ to be the forests of G, is called a *graphic* matroid. Every base of $\hat{G}$ corresponds to a spanning forest in G. It is easily seen that if we delete any one row of the vertex-edge incidence matrix of G, we obtain a linear representation of $\hat{G}$ over $GF(2)$. A linear representation of $\hat{G}$ over $\mathbf{Q}$ is obtained by changing one 1 to a -1 in each column of the above matrix.

The *dual* of a matroid M, denoted by M^*, is the matroid whose independent sets are $\{X : \exists B \text{ a base of } M \text{ such that } X \subseteq S - B\}$ i.e., the independent sets of M^* are the subsets of complements of bases in M.

Given a set S and a partition $S_1, S_2, \dots, S_k$ of S, the matroid obtained by taking $\mathcal{I} = \{I \subseteq S : |I \cap S_j| \leq 1, 1 \leq j \leq k\}$ is called a *partition* matroid. It is easily seen that partition matroids are linearly representable (pick k linearly independent vectors and let all elements in S_i be represented by the ith vector).

Let $M_1, M_2, \dots, M_k$ be matroids on S. Let $\mathcal{I} = \{X : X = X_1 \cup \dots \cup X_k$ such that X_i is independent in $M_i, 1 \leq i \leq k\}$. Then $\mathcal{I}$ is the collection of independent sets of a matroid on S. We call this matroid the *union* of $M_1, \dots, M_k$ and denote it by $\bigvee_{i=1}^k M_i$. If X is an independent set in $\bigvee_{i=1}^k M_i$, then a partition of X into sets $X_1, \dots, X_k$ such that X_i is independent in M_i is called a *proper* partition of X.

The intersection of matroids can be defined analogously. However, the collection of sets so obtained does not form the independent sets of a matroid. As a consequence, a maximal set in this collection need not be maximum. The problem of finding a maximum cardinality set in the intersection of two matroids is called the *matroid intersection* problem.

The *matroid matching problem* is: given matroid $M = (S, \mathcal{I})$, and a partition of S into pairs $(x_1, x_2), \dots, (x_{2n-1}, x_{2n})$, pick the largest number of pairs so that the picked elements form an independent set.

The (i, j)th entry of a $n \times n$ matrix A will be denoted by $A(i, j)$ and its determinant will be denoted by $|A|$:

$$|A| = \sum_{\sigma} \text{sign}(\sigma)\text{value}(\sigma)$$

Here, the sum is taken over all permutations of $\{1, \dots, n\}$, sign(σ) is $+1$ if σ is even and -1 if σ is odd, and value$(\sigma) = \prod_{i=1}^n A(i, \sigma(i))$.

In this paper, we state all our results assuming the arithmetic CREW PRAM model of computation [KR]. The arithmetic operations we require are addition, multiplication, and subtraction of $O(n)$ bit numbers, where n is the size of the ground set. We use $M(n)$ to denote the number of processors required to multiply two $n \times n$ matrices in $O(\log n)$ time, $M(n) = o(n^{2.376})$ [CW].

3. Obtaining a representation for the union matroid. If matroids $M_1, M_2, \ldots, M_k$ over set S are linearly representable, then the union $\bigvee_{i=1}^{k} M_i$ is also linearly representable. However, the standard way of constructing such a representation does not seem to be parallelizable. We first give an *RNC* algorithm for constructing a linear representation of the union of k matroids, for any $k \geq 1$.

We will give details for $k = 2$; the generalization will be obvious. Let the ranks of M_1 and M_2 be r_1 and r_2, respectively. Let A_1 be an $r_1 \times n$ matrix representing M_1 and A_2 be an $r_2 \times n$ matrix representing M_2. Obtain A'_2 from A_2 by multiplying the columns of A_2 by distinct variables $x_1, x_2, \ldots, x_n$, i.e., $A'_2(i, j) = A_2(i, j) \cdot x_j$. It is easy to verify that a set of columns of A'_2 is independent if and only if the corresponding set of columns of A_2 is independent. (Linear independence for matrices containing variables is defined in a natural way, using operations over the field of multivariate polynomials.)

Define B, an $(r_1 + r_2) \times n$ matrix, whose first r_1 rows are the same as the rows of A_1 and the last r_2 rows are the same as the rows of A'_2, i.e.,

$$B(i, j) = \begin{cases} A_1(i, j) & \text{if } i \leq r_1, \\ A'_2(i - r_1, j) & \text{otherwise.} \end{cases}$$

LEMMA 3.1. *A set $S' \subseteq S$ is independent in $M_1 \vee M_2$ if and only if the corresponding columns of B are linearly independent.*

Proof. Let us first state a key property of matrix B that makes the lemma hold. Let C be a $(k + l) \times (k + l)$ submatrix of B that picks k rows from A_1 and l rows from A'_2, and some set of $k + l$ columns. Corresponding to a set of l of these columns, we define a $k \times k$ submatrix C_1 and an $l \times l$ submatrix C_2 of C as follows: C_2 consists of l rows of A'_2 and these l columns, and C_1 consists of the unpicked rows and columns of C. Let the indices of the l columns of C_2 be $i_1, \ldots, i_l$ in B. Consider $|C| = \sum_{\pi} \text{sign}(\pi)\text{value}(\pi)$, where as usual, the sum runs over all permutations π mapping rows of C onto columns of C. Let P be the set of permutations mapping rows of C_1 onto columns of C_1, and rows of C_2 onto columns of C_2. Then it is easy to check that

$$\sum_{\pi \in P} \text{sign}(\pi)\text{value}(\pi) = |C_1||C_2|;$$

this term is of the form $cx_{i_1}, \ldots, x_{i_l}, c \in \mathbf{Q}$. Furthermore, a monomial of this form is not generated by any permutation $\pi \notin P$. Therefore, if C_1 and C_2 are both non-singular then so is C. Similarly, if C is non-singular then for a suitable choice of $i_1, \ldots, i_l$ (corresponding to a monomial with non-zero coefficient in $|C|$), C_1 and C_2 must be non-singular.

The rest of the proof is now straightforward. Suppose $S' \subseteq S$ is independent in $M_1 \vee M_2$. Let (S_1, S_2) be a proper partition of S', and let $|S_1| = k$ and $|S_2| = l$. Then the columns of $A_1(A'_2)$ corresponding to $S_1(S_2)$ are linearly independent, and one can pick $k(l)$ rows to get a $k \times k(l \times l)$ non-singular matrix $C_1(C_2)$. Then by the above stated property, the $(k+l) \times (k+l)$ matrix C consisting of all the picked rows and columns is non-singular. Hence the columns of B corresponding to the elements of S' are linearly independent.

To prove the other direction, pick a maximal non-singular square submatrix, C, of the linearly independent columns of B. The columns in C correspond to some set $S' \subseteq S$. By the above-stated property, there exist non-singular submatrices C_1 and C_2 of C. These yield a partition of S' into (S_1, S_2) such that S_i is independent in M_i, $i = 1, 2$. This implies that S' is independent in $M_1 \vee M_2$. □

The construction given above clearly generalizes to k matroids $M_1, \dots, M_k$ of rank $r_1, \dots, r_k$: multiply the columns of $M_2, \dots, M_k$ with distinct variables, $x_1, \dots, x_{(k-1)n}$, and "stack up" the resulting matrices, together with M_1, to obtain an $(r_1 + \cdots + r_k) \times n$ matrix B. Since matroid union is associative, the proof that this construction works follows immediately using induction.

LEMMA 3.2. *Given matroids $M_1, \dots, M_k$, the matrix B obtained above is a linear representation of $\bigvee_{i=1}^{k} M_i$.*

We next show, using randomization, how to obtain a linear representation of $\bigvee_{i=1}^{k} M_i$ using only rational entries, i.e., with no variables.

LEMMA 3.3. *Let $\tilde{B}$ be obtained from B by substituting each indeterminate randomly and independently from $\{1, \dots, 2n\binom{n}{n/2}\}$. Then*

$$Pr\left[\tilde{B} \text{ is a linear representation of } \bigvee_{i=1}^{k} M_i\right] > \frac{1}{2}$$

Proof. Note that it is enough to show that our substitution maintains the independence of every base of B. Let the rank of the union matroid be r. Then, it can have at most $\binom{n}{r}$ distinct bases. Corresponding to each base β there is an $r \times r$ non-singular submatrix, C_β, of B. Consider the polynomial

$$p = \Pi_\beta |C_\beta|,$$

where the product is taken over all bases of B. The degree of p is no more than $\binom{n}{r} r$. Now it is enough to obtain a substitution for the indeterminates such that p evaluates to a non-zero value. By Lemma 3.4, it is sufficient to substitute for the variables randomly and independently from the integers $\{1, 2, \dots, 2r\binom{n}{r}\}$, i.e., using $O(n)$ bits for each number, since $2r\binom{n}{r} \leq 2n2^n$. □

LEMMA 3.4. [Sc], [Zi] *Let $p(x_1, x_2, \dots, x_n)$ be a non-trivial polynomial of degree d over field F and let $S \subseteq F$. If $x_1, x_2, \dots, x_n$ are randomly and independently chosen from S then,*

$$Pr[\textit{the substitution is a zero of } p] \leq d/|S|.$$

Hence we get the following theorem.

THEOREM 3.5. *Given the linear representations of k matroids $M_1, M_2, \dots, M_k$ with ranks $r_1, r_2, \dots, r_k$, there is an RNC^0 algorithm for obtaining a representation of the union using $n(\sum_{i=1}^{k} r_i) \leq n^2 k$ processors.*

Once we have a representation, $\tilde{B}$, for the union matroid $M = \bigvee_{i=1}^{k} M_i$, we can find the lexicographically first base, I, for M by finding the lexicographically first base of $\tilde{B}$. The lexicographically first base of a matrix can be obtained in NC^2 by computing in parallel the rank of first i columns, for $i = 1, \dots, n$, and choosing indices where rank increases. We get the following corollary.

COROLLARY 3.6. *Given k matroids $M_1, \dots, M_k$ via their linear representations over $\mathbf{Q}$, there is an RNC^2 algorithm that uses $O(\max\{kn^2, nM(n)\})$ processors for obtaining the lexicographically first maximal independent set in the union $\bigvee_{i=1}^{k} M_i$.*

Remark. Notice that even if the random substitution was a zero of p, if a set of columns is independent in $\tilde{B}$ then it must be independent in B. Therefore I is guaranteed to be independent in M.

Next we would like to obtain a proper partition of I. For this we need a parallel algorithm for the matroid intersection problem.

4. Matroid intersection and matroid matching.

4.1. Matroid intersection. We use the Isolating Lemma of [MVV] and the Binet-Cauchy Theorem to obtain an RNC algorithm to compute the maximum cardinality set in the intersection of two matroids. Recall that the Binet-Cauchy Theorem states that, given two $n \times m$ matrices A and B,

$$|AB^T| = \sum_{\alpha} |A_\alpha||B_\alpha|$$

where the sum is taken over all possible ways, α, of choosing n columns out of m, and by $A_\alpha(B_\alpha)$ we mean the $n \times n$ submatrix of $A(B)$ consisting of columns chosen by α.

We shall need the following slightly modified version of the Isolating Lemma (this is a straightforward extension of the original lemma).

LEMMA 4.1 (Isolating Lemma [MVV]). *Let $(X, \mathcal{F})$ be a set system, where $X = \{x_1, x_2, \ldots, x_n\}$ and $\mathcal{F} \subseteq 2^X$ is a family of subsets of X. Let $\{c_1, c_2, \ldots, c_n\}$, $c_i \in \mathbf{Q}$ be a set of initial weights on the x_i's. Pick $w_1, w_2, \ldots, w_n$ randomly and independently from $[1, \ldots, 2n]$. Define the weight of x_i to be $c_i + w_i$, and let the weight of a set be the sum of the weights of its elements. Then,*

$$Pr[\exists \textit{ unique minimum weight set in } \mathcal{F}] \geq \frac{1}{2}.$$

THEOREM 4.2. *There is an RNC^2 algorithm using $O(n^{4.5})$ processors for the matroid intersection problem for linearly representable matroids.*

Proof. Let the two matroids M_1 and M_2 be represented by the matrices A and B, respectively. Without loss of generality assume that A and B have the same number of rows, say r (since the smaller matrix can be padded with rows of zeroes). In general, the required maximum cardinality subset of S may have fewer than r elements; if so, by the Binet-Cauchy Theorem $|AB^T| = 0$, and we get no information from this determinant. We shall overcome this problem by first augmenting A and B with extra columns. Let $e_1, e_2, \ldots, e_r$ be the unit vectors over $\mathbf{Q}^r$. Obtain $r \times r^2$ matrices C and D such that for each $1 \leq i, j \leq r$, there is an index $1 \leq k \leq r^2$, such that the kth column of C is e_i and the kth column of D is e_j.

Let $[A, C]$ represent the $r \times (n + r^2)$ matrix whose first n columns are the same as those of A, and the last r^2 columns are the same as those of C. Similarly, obtain $[B, D]$. The augmented matrices have the following property: any subset of indices from $[1, \ldots, n]$ such that the corresponding columns are linearly independent both in A and in B can be extended to a set of r indices from $[1, \ldots, n + r^2]$ such that the corresponding columns are linearly independent both in $[A, C]$ and $[B, D]$.

Randomly and independently pick $w_1, \ldots, w_{n+r^2}$ from $[1, \ldots, 2(n+r^2)]$. For $1 \leq i \leq n$, multiply the ith column of $[A, C]$ by x^{w_i}, and for $n + 1 \leq i \leq r^2 + n$, multiply the ith column of $[A, C]$ by $x^{w_i + 2r(n+r^2)}$ to obtain a new $r \times (n + r^2)$ matrix E. Compute $|E[B, D]^T|$. This can be done in NC^2 using $O(n^{4.5})$ processors (see [BCP]).

We now apply the Isolating Lemma. Here the set system, X, consists of the set of $n + r^2$ indices and $\mathcal{F}$ consists of all choices of r indices such that the corresponding columns are independent both in $[A, C]$ and in $[B, D]$. Then with probability at least 1/2, the minimum weight set of indices, α, is unique for the chosen weight distribution, and has weight w_α. By the Binet-Cauchy Theorem $|E[B, D]^T| \not\equiv 0$, since the coefficient of the minimum power of x (i.e., x^{w_α}) is non-zero. The minimum weight set of indices α can be obtained as follows:

```
For $i=1$ to $n+r^2$, in parallel do:
    decrease $w_i$ by 1, keeping the
    rest of the weights unchanged,
    and compute $|E[B,D]^T|$. If
    the coefficient of $x^{w_\alpha}$ changes,
    then pick index $i$.
end;
```

The weight of any column of C is greater than the sum of weights of all columns of A, irrespective of the random choices made. Therefore, α must pick as many indices from $[1,\dots,n]$ as possible. Hence, the subset of α in the range $[1,\dots,n]$ will constitute a maximum cardinality subset of S that is independent in both matroids. □

Remark. The algorithm given above extends to the weighted matroid intersection problem, provided the weights are given in unary. Let the ith element of the ground set have weight W_i; find a minimum weight maximum cardinality set in the intersection of the two matroids. In this case, we multiply the ith column of $[A,C]$ by $x^{w_i+2(n+r^2)W_i}$ for $1 \le i \le n$, and by $x^{w_i+2r(n+r^2)W}$ for $n < i \le n+r^2$, where W is the weight of the heaviest ground set element. Extending this to the case of binary weights is left open.

4.2. Matroid matching. In this section we shall give an RNC algorithm for the *matroid matching problem* for linearly representable matroids: given m pairs of vectors over $\mathbf{Q}^{2n}$, $\{a^{(1)},b^{(1)}\},\dots,\{a^{(m)},b^{(m)}\}$, pick the largest number of pairs so that the picked vectors are linearly independent. Let us first define the *wedge product* of vectors a, b over $\mathbf{Q}^{2n}$ as an $2n \times 2n$ matrix A such that

$$A(i,j) = a_ib_j - a_jb_i.$$

Denote this by $(a \wedge b)$. We will need the following theorem of Lovász.

THEOREM 4.3. [Lo2], [LP]. *Let* $\{a^{(1)},b^{(1)}\},\dots,\{a^{(m)},b^{(m)}\}$ *be pairs of vectors over* $\mathbf{Q}^{2n}$. *Then there exists a set of n pairs whose union is a basis iff* $|B| \not\equiv 0$, *where*

$$B = \sum_{i=1}^{m}(a^{(i)} \wedge b^{(i)})x_i.$$

Here the x_i's are distinct indeterminates.

THEOREM 4.4. *There is an* RNC^2 *algorithm using* $O(n^{4.5})$ *processors for the matroid matching problem for linearly representable matroids.*

Proof. As in Theorem 4.1, we will first deal with the issue that there may not be n pairs (a_i,b_i) whose union is a basis, by throwing in $\binom{2n}{2}$ additional pairs of vectors. Let $e_1,\dots,e_{2n}$ be the unit vectors in $\mathbf{Q}^{2n}$. The added vectors are chosen in such a way that for every pair of indices (i,j), $1 \le i < j \le 2n$, (e_i,e_j) is included.

As before, as a result of the augmentation, any subset of the original m pairs that are linearly independent can be extended to n pairs using the added pairs. Let

$$B = \sum_{i=1}^{m+\binom{2n}{2}} (a^{(i)} \wedge b^{(i)})x_i.$$

Randomly and independently pick $w_1,\dots,w_{m+\binom{2n}{2}}$ from $[1,\dots,2(m+\binom{2n}{2}))]$. For $1 \le i \le m$, substitute $x_i = x^{w_i}$, and for $m+1 \le i \le m+\binom{2n}{2}$, substitute $x_i = x^{w_i+2n(m+\binom{2n}{2}))}$, and compute $|B|$.

Note that B is skew-symmetric, and hence $|B| = (pf(B))^2$, where $pf(B)$ is the pfaffian of B. Lovàsz [Lo2] shows that $pf(B)$ is linear in each of the variables x_i and each monomial in the polynomial $pf(B)$ is the product of n distinct variables x_i. We will now apply the Isolating Lemma with X as the set of $m + \binom{2n}{2}$ indices, and $\mathcal{F}$ consisting of all choices of n indices such that the corresponding monomial has non-zero coefficient in $pf(B)$. Then, after the random substitution given above, with probability at least $\frac{1}{2}$, there is a unique term having the minimum power of x (say x^w) in $pf(B)$. Consequently, the polynomial $|B|$ will also contain a unique term having minimum power of x, x^{2w}. Hence $|B| \not\equiv 0$. The indices contributing to this term can be obtained as in Theorem 4.1, by decreasing w_i by 1 in parallel for each i. By the choice of weights, the number of indices in the range $[1, \ldots, m]$ is maximized. Hence, this set of indices is a solution to the matroid matching problem. □

As in the case of matroid intersection, the above algorithm extends to the weighted problem, if the weights are given in unary. Once again, the weighted matroid matching problem for binary weights is left open.

5. Partitioning the independent set. Suppose set I is independent in $M_1 \vee M_2$. In this section, we show how to obtain a proper partition of I.

5.1. Obtaining a representation for the dual matroid. First, we need a parallel algorithm for obtaining a representation of the dual matroid. The standard method parallelizes in a straightforward manner; essentially, it involves finding a base for the null-space of A, where A is a $r \times n$ matrix representing M. Denote the submatrix of A consisting of the first r (last $n-r$) columns of A by $A_1(A_2)$. The columns of A can be permuted in NC to ensure that A_1 is non-singular.

```
For each $n-r$ dimensional unit vector $e_i$,
$1 \leq i \leq n-r$ in parallel do:
  Compute $x_i = -A_1^{-1}A_2e_i$.
  Output the $n$ dimensional vector
    whose first $r$ components
    consist of $x_i$ and the remaining
    $n-r$ components consist of $e_i$.
end;
```

Let C be the matrix consisting of these $n-r$ n-dimensional column vectors (in any order). Then $B = C^T$ is a linear representation for M^* [We]. Since matrix inversion is in NC^2 (see [Cs]) we get the following lemma.

LEMMA 5.1. *There is an NC^2 algorithm using $O(nM(n))$ processors for obtaining the linear representation of the dual, M^*, of a linearly representable matroid M.*

5.2. The partitioning algorithm. We may assume without loss of generality that I is the ground set for M_1 and M_2 (if not, we can restrict M_1 and M_2 to I, and pick only the corresponding columns of matrices A and B). The partitioning algorithm is as follows:

```
1. Find a representation $B^*$ for $M_2^*$.
2. Apply the matroid intersection algorithm on $A$ and $B^*$.
3. Let $I_1$ be the set found in step 2.  Output $(I_1, I_2)$ where
   $I_2 = I - I_1$.
```

LEMMA 5.2. *Assuming that the matroid intersection algorithm in step* 2 *is successful, (I_1, I_2) is a proper partition of I.*

Proof. It is sufficient to prove that I_2 is independent in M_2, since clearly I_1 is independent in M_1. Since I_1 is independent in M_2^*, I_2 contains a base of M_2. We will finish the proof by showing that $|I_2|$ must equal the cardinality of a base of M_2.

Let (I_1', I_2') be a proper partition of I that maximizes $|I_2'|$. Then I_2' must be a base of M_2; if not, we should be able to move an element from I_1' to I_2' (note that $I_1' \cup I_2'$ is the ground set of M_2). Clearly, I_1' is independent in M_1 and M_2^*. Therefore $|I_1| \geq |I_1'|$, and so $|I_2| \leq |I_2'|$. Since I_2 contains a base of M_2, we have that $|I_2| = |I_2'|$. The lemma follows. □

When we are given I over $M_1 \vee M_2 \vee \cdots \vee M_k$ using the previous algorithm, we can first partition it into I_1 and I_2 such that I_1 is independent in $M_1 \vee \cdots \vee M_{k/2}$ and I_2 is independent in $M_{k/2+1} \vee \cdots \vee M_k$. For this, we need to construct representations for the two matroids $M_1 \vee \cdots \vee M_{k/2}$ and $M_{k/2+1} \vee \cdots \vee M_k$. Clearly, this just involves choosing the appropriate rows of the representation of $M_1 \vee M_2 \vee \cdots \vee M_k$. Now recursively, in parallel, solve the problem for I_1 and I_2. Note that this will take at most $\log n$ iterations of the above algorithm.

THEOREM 5.3. *There is an RNC^3 algorithm using $O(n^{4.5})$ processors for the following problem. Given matroids $M_1, \ldots, M_k$, via their linear representations and an independent set I in $\bigvee_{i=1}^k M_i$, find a proper partition of I.*

6. Covering and packing problems. We give RNC algorithms for solving the covering and packing problems for a linearly representable matroid M. Let M^k denote $\bigvee_{i=1}^k M$.

The *matroid covering problem* is: Find a minimum cardinality collection $\mathcal{C}$ of independent sets in M such that $\bigcup_{X \in \mathcal{C}} X = S$. Let $|\mathcal{C}| = k$, then $k \leq n$, assuming that there are no trivial elements in S (i.e., elements that participate in no independent set). Clearly $k = \min\{i : \rho(M^i) = n\}$. Thus, we can carry out a binary search in the interval $[1, \ldots, n]$ to obtain k. This would involve at most $\log n$ iterations of the matroid union algorithm. We can then partition S into k independent sets using the algorithm of Theorem 5.1 to get the required cover.

THEOREM 6.1. *There is an RNC^3 algorithm using $O(n^{4.5})$ processors for obtaining a minimum cardinality cover by independent sets of a linearly representable matroid M.*

Since the graphic matroid of a graph is linearly representable (see §2), we get the following corollary.

COROLLARY 6.2. *There is an RNC^3 algorithm using $O(n^{4.5})$ processors for obtaining an arboresence of a graph G.*

The *matroid packing problem* is: Find a maximum cardinality set of mutually disjoint bases of M. Let k be the cardinality of this set and r be the rank of M. Clearly, $k = \max\{i : \rho(M^i) = ri\}$, and $k \leq \lfloor n/r \rfloor$. To find k, we can do a binary search over the range $1, \ldots, \lfloor n/r \rfloor$. A partition of any base of M^k will then give the required set of bases.

THEOREM 6.3. *There is an RNC^3 algorithm using $O(n^{4.5})$ processors for obtaining a maximum cardinality set of disjoint bases of a linearly representable matroid M.*

COROLLARY 6.4. *There is an RNC^3 algorithm using $O(n^{4.5})$ processors for finding a maximum cardinality set of edge-disjoint spanning trees of a graph G.*

7. Las Vegas extensions. The algorithms presented so far have all been Monte Carlo, i.e., they work with probability at least $\frac{1}{2}$. We now give parallel algorithms for verifying the solutions obtained, thereby giving their Las Vegas extensions, i.e., the running time of the algorithm is probabilistic; however, it is guaranteed to produce the correct solution.

The matroid intersection algorithm can be made Las Vegas as follows. Suppose the intersection computed is I. Now for each element $e \in S - I$, check using Edmonds' matroid intersection algorithm whether the set can be augmented with e (this will be a transitive closure computation in an appropriately defined graph, see [PS]). If this fails for each element, then I is the largest set in this intersection.

Next, we make the matroid union algorithm Las Vegas. Let I be the lexicographically first maximal independent set found in $M_1 \vee \cdots \vee M_k$, and Let $I_1, \ldots, I_k$ be the partition of I obtained. Notice that randomization is used at two points: in finding I, and in partitioning it. Because of Remark 3.1, I must be independent, though it may not be the lexicographically first maximal independent set. We can verify this solution as follows:

1. Verify that I_i is independent in M_i, $1 \leq i \leq k$; if not, halt. This can be done easily since linear representations of M_i are available. (Notice that a failure here indicates a bad choice in the randomization done in the partitioning phase. Hence, if this test is passed, then the partitioning of I is correct.)

2. Verify that I is the lexicographically first maximal independent set of $M_1 \vee \cdots \vee M_k$ as follows: Let $e_1, \ldots, e_n$ be the ordering on the elements of S, and let $I^{(i)}$ denote the restriction of I to $\{e_1, \ldots, e_i\}$. It is sufficient to verify that for each i, $1 \leq i < n$: if $e_{i+1} \notin I$ then $I^{(i)} \cup \{e_{i+1}\}$ is dependent in the union matroid. This can be done in parallel for each i, as in the matroid intersection case given above. Notice that a partition of $I^{(i)}$ is available.

We next turn to covering. Suppose our algorithm found that $k = \min\{i : S \text{ is independent in } M^i\}$. Now we only need to verify that S is not independent in M^{k-1}. This can easily be done by finding a maximal independent set in M^{k-1}. Finally, the quantity k returned by the packing procedure can be verified by checking if $\rho(M^{k+1}) < r(k+1)$, where r is the rank of M. We leave the open problem of obtaining a Las Vegas extension for the matroid matching problem.

8. Discussion and open problems. (1) Our results hold only for linearly representable matroids. Although almost all interesting matroids have this property, it is still interesting to check whether there exist fast parallel algorithms for the matroid union and intersection problems when the matroids are not linearly representable. We may assume that a rank oracle or an independence oracle is given for the matroids. In the sequential setting, either of these oracles suffices for running Edmonds' algorithms. The importance of linear representability to algorithm design has been noted previously. For example, Lovász [Lo1] has given a polynomial time algorithm for the matroid matching problem if the given matroid has a linear representation; however, the general problem is not polynomial time solvable [Lo1], [JK] (interestingly, this result does not depend on the $P \neq NP$ hypothesis). In the spirit of [Lo1], [JK] can one prove negative results in the parallel setting? For other work along these lines see [KUW2].

(2) The ideas in this paper can also be applied to finding branching(s) in digraphs. In a directed graph $G = (V, E)$, a *branching rooted at vertex* v is an acyclic subgraph of G in which v has indegree zero, and every other vertex has indegree one.

Lovász [Lo3] gives an NC^2 algorithm for finding a branching in a directed graph. It is well-known that sequentially a branching can be found using matroid intersection. Let us first remark that our parallel matroid intersection algorithm gives an RNC^2 algorithm for finding a branching, although the algorithm in [Lo3] is superior not only because it is deterministic, but also because it uses fewer processors. The advantage of the matroid approach is that it extends to the problem of obtaining k edge-disjoint branchings rooted at v, using the following theorem.

THEOREM 8.1. [Ed2] *A set $E' \subseteq E$ can be partitioned into k edge-disjoint branchings rooted at v if and only if*

(i) *when considered as a set of undirected edges, E' can be partitioned into k spanning trees,*

(ii) *every vertex other than v has indegree k.*

Let M be the graphic matroid on E obtained by ignoring edge directions, and let P be the partition matroid on E where the elements of the ith partition are the edges that point into the vertex i. To find a set E' (if it exists) of edges that can be partitioned into k edge-disjoint branchings rooted at v, obtain a maximum cardinality set in the intersection of M^k and P^k. The problems of partitioning E' into k branchings, and of making this algorithm Las Vegas are left as open problems.

(3) What is the parallel complexity of finding

(a) a lexicographically first intersection of two matroids

(b) a lexicographically first maximum cardinality intersection of two matroids.

Special cases of (a) and (b) are lexicographically first maximal and maximum matching, respectively, in bipartite graphs. Analogous problems can also be stated for the graphic matroid. Finding a lexicographically first maximal matching is known to be CC-complete. On the other hand, the parallel complexity of lexicographically first maximum matching is unresolved. Is problem (a) CC-complete?

Acknowledgments. We wish to thank Prasoon Tiwari and Umesh Vazirani for valuable discussions during which a restricted version of Theorem 4.1 was obtained. Also we would like to thank Naveen Garg, Samir Khuller, Shachin Maheshwari, Sachin Patkar, Milind Sohoni, and Prakash Sunderasan for useful discussions.

ON THE CONSECUTIVE-RETRIEVAL PROBLEM*

R. SWAMINATHAN† AND DONALD K. WAGNER‡

Abstract. A {0, 1}-matrix M has the *consecutive-retrieval property* if there exists a tree T such that the vertices of T are indexed on the rows of M and the columns of M are the incidence vectors of the vertex sets of paths of T. If such a T exists, then T is a *realization* for M. In this paper, an $O(r^2c)$ algorithm is presented to determine whether a given standard, $r \times c$ matrix has the consecutive-retrieval property and, if so, to construct a realization.

Key words. consecutive-retrieval property, tree realization, matrix decomposition, polynomial-time algorithm

AMS subject classifications. 05C05, 68P20

1. Introduction. A {0, 1}-matrix M has the *consecutive-retrieval property* if there exists a tree T such that the vertices of T are indexed on the rows of M and the columns of M are the incidence vectors of the vertex sets of paths of T. (Note that not every path of T needs to correspond to a column of M.) If such a T exists, then T is a *realization* for M and M is *consecutive-retrieval graphic* (abbreviated *cr-graphic*). The *consecutive-retrieval problem* is to determine whether a given {0, 1}-matrix M is cr-graphic and, if so, to construct a realization. This paper presents an $O(r^2c)$ algorithm for the consecutive-retrieval problem, where the given matrix is a standard, $r \times c$ {0, 1}-matrix.

The consecutive-retrieval problem defined above was introduced by Tanaka [20] as a generalization of versions of the problem defined by Ghosh [9] and Lipski [15].

The problem defined by Ghosh is as follows. Let R be a set of *records*, and let $\mathcal{Q}$ be a collection of subsets of R called *queries*. The problem is to determine whether the members of R can be arranged linearly in storage locations in such a way that the members of each $Q \in \mathcal{Q}$ are stored in consecutive locations. One advantage of such a storage arrangement is that any query can be retrieved from storage using just two parameters, namely, a pointer to the beginning of the query and the number of records in the query. Ghosh's problem can be rephrased in the terminology of the present paper as follows. Let M be a matrix, the columns of which are the incidence vectors of the members of $\mathcal{Q}$. Then the problem is to determine whether there exists a path P such that the vertices of P are indexed on the rows of M and the columns of M are the incidence vectors of the vertex sets of subpaths of P. Thus, the consecutive-retrieval problem defined above is an extension of Ghosh's problem from paths to trees. Different aspects of Ghosh's problem have been studied by Ghosh [10], [11], [12], Gupta [13], Kou [14], Patrinos and Hakimi [18], and Waksman and Green [25].

A different rephrasing of Ghosh's problem is that of determining whether the rows of M can be permuted such that the ones in each column occur consecutively. A matrix admitting such a permutation is called a *consecutive-ones matrix*. Such matrices were introduced by Fulkerson and Gross [7], [8] and studied further in Tucker [22], [23], Nakano [16], [17], and Booth and Lueker [4]. In particular, Booth and Lueker gave a linear-time algorithm (linear in the number of nonzeros) for determining whether a given matrix is a consecutive-ones matrix.

Lipski [15] generalized Ghosh's problem as follows. For a given {0, 1}-matrix M, Lipski's problem is that of determining whether there exists an arborescence T such that the vertices of T are indexed on the rows of M and each column of M is the incidence vector of the

vertex set of a directed path of T. Thus, the consecutive-retrieval problem of this paper is an undirected version of Lipski's problem. As in Ghosh's problem, if M represents a set of queries, then each query can be retrieved from the arborescence T using just two parameters, the end of the corresponding directed path and its length. Truszczyński [21] gave an $O(c^3 + c^2r)$ algorithm for determining whether M admits such an arborescence. Dietz, Furst, and Hopcroft [5] improved this to linear time. An almost-linear-time algorithm and several different applications of the problem are provided by the authors in [19].

Observe that if a cr-graphic matrix represents a set of queries, then each query can be retrieved from a realization T using just four parameters as follows. First, assign directions to the edges of T so as to make it an arborescence. Then any path of T is either a directed path of the arborescence or is the union of two directed paths. Since each of these directed paths can be retrieved using just two parameters, any path of T corresponding to a query can be retrieved with just four.

An edge analogue of the consecutive-retrieval problem has previously been studied. Define a $\{0, 1\}$-matrix M to be *edge-tree graphic* if there exists a tree T such that the columns of M are the incidence vectors of the edge sets of paths of T. If such a T exists, then T is an *edge-tree realization* for M. The *edge-tree realization problem* is that of determining whether a given matrix M is edge-tree graphic and, if so, to construct an edge-tree realization. A polynomial-time algorithm for this problem was first devised by Tutte [24]. Several other algorithms have been developed, the most efficient of which are the almost-linear-time algorithms of Bixby and Wagner [2] and Fujishige [6].

The algorithm presented here for the consecutive-retrieval problem is reminiscent of Tutte's algorithm [24] for the edge-tree realization problem. The basic idea of the present algorithm is as follows. The algorithm consists of two phases, a decomposition phase followed by a composition phase. In the decomposition phase, the matrix M is recursively decomposed into smaller matrices with the final set of matrices each having exactly one row. Such matrices are obviously cr-graphic. The composition phase starts with realizations of these one-rowed matrices and undoes the recursion of the first phase in an attempt to construct a realization of M.

The remainder of the paper is outlined as follows. Section 2 develops the decomposition phase of the algorithm, and §3 develops the composition phase. Section 4 combines these results to yield an algorithm for the consecutive-retrieval problem.

Undefined graph-theoretic terminology is consistent with Bondy and Murty [3]. With respect to the main algorithm and its subroutines described in the remaining sections, the data structures required are standard and so are not stressed in the derivation of the complexity bound. In particular, it is assumed that matrices are stored in a column-by-column fashion and that the nonzero positions for a given column are stored in a linked list. Graphs are stored by keeping the set of ends for each edge. In all stated complexity results, r is the number of rows of the given matrix, c is the number of columns, and n is the number of nonzeros.

2. A matrix decomposition. In this section, a matrix decomposition is described. This decomposition is first described independently of the consecutive-retrieval problem. Then the decomposition and corresponding composition results are related to the consecutive-retrieval problem.

A $\{0, 1\}$-matrix M is *standard* if $M = (I, N)$, where I denotes an identity matrix of appropriate size. Associated with a matrix M is a bipartite graph $B(M)$ defined as follows. The vertex set of $B(M)$ is $R(M) \cup C(M)$, where $R(M)$ denotes the index set of the rows of M and $C(M)$ denotes the index set of the columns of M, and $i \in R(M)$ and $j \in C(M)$ are adjacent in $B(M)$ if and only if the ij-entry of M is nonzero. The vertex set of a component of B induces a unique submatrix of M, called a *component* of M. The matrix M is *connected* if it has exactly one component.

Let M be a connected, standard $\{0, 1\}$-matrix, and let $B := B(M)$ be its associated bipartite graph. Let D be a proper subset of $C(M)$. If $B \setminus D$ is disconnected and no vertex of $R(M)$ is isolated in $B \setminus D$, then D is a *disconnecting set* (abbreviated *d-set*) of M. A d-set is *minimal* if it does not properly contain a d-set.

LEMMA 2.1. *Let $M = (I, N)$ be a connected $\{0, 1\}$-matrix. If M has at least two rows, then M has a minimal d-set. Moreover, every minimal d-set of M is contained in $C(N)$, and a minimal d-set can be computed in $O(n)$ time.*

Proof. Let $B := B(M)$, and let the vertex set of B be $R \cup C$, where $R := R(M)$ and $C := C(M)$. Let D be a minimal subset of C such that $B \setminus D$ is disconnected. (Since B is bipartite and M has at least two rows, such a set D exists.)

Suppose that D contains an element of $C(I)$, say u. Observe that u has degree one in B. Thus, $B \setminus (D - \{u\})$ is disconnected, a contradiction to the minimality of D. Thus, $D \subseteq C(N)$.

Consider any vertex $v \in R$ in $B \setminus D$. Since $D \subseteq C(N)$, v is adjacent, in $B \setminus D$, to a vertex in $C(I)$. Therefore, no vertex of R is isolated in $B \setminus D$. Thus, D is a d-set of M. Moreover, by the choice of D, it is a minimal d-set of M.

Now, let D be a minimal d-set of M. As above, if D contains an element u of $C(I)$, then $B \setminus (D - \{u\})$ is disconnected, which implies that $D - \{u\}$ is a d-set. Thus, every minimal d-set is contained in $C(N)$.

From the above, it follows that a minimal d-set of M can be found by computing a minimal subset D of C such that $B \setminus D$ is disconnected. This can be done as follows. Choose any $v \in R$. Let $u \in C$ index the identity column such that u and v are adjacent in B. Then u has degree one in B. Thus, v is a cut vertex of B. Let $B_1, \dots, B_t$ be the blocks (i.e., maximal 2-connected subgraphs) of B that contain v, and let $H_1, \dots, H_t$ be the maximal edge-disjoint connected subgraphs of B such that B_i is a subgraph of H_i for $1 \le i \le t$. Since M has at least two rows, it can be assumed without loss of generality that $|V(H_1)| \ge 3$. Let D' be the set of vertices of H_1 adjacent to v. Then D' is a d-set; it is a minimal d-set if $H_1 \setminus D'$ is connected. In the case that $H_1 \setminus D'$ is not connected, let K a component of $H_1 \setminus D'$ that has the fewest neighbors in D'; let D be this set of neighbors. Then D is the required set.

Constructing B requires $O(n)$ time by scanning each column of M, and finding the blocks of B requires $O(n)$ time using the algorithm of Aho, Hopcroft, and Ullman [1] designed for this purpose. Constructing the subgraphs $H_1, \dots, H_t$ and the set D' also takes $O(n)$ time. Finally, computing the components of $H_1 \setminus D'$ and constructing the set D require $O(n)$ time. □

Let D be a minimal d-set of a connected, standard matrix M. Let $R_1, \dots, R_t$ and $C_1, \dots, C_t$ be the partitions of $R(M)$ and $C(M) - D$ induced by the components of $B(M) \setminus D$. For $1 \le i \le t$, define M_i to be the submatrix of M having row set R_i and column set $C_i \cup D$. Then $\{M_1, \dots, M_t\}$ is a *simple decomposition* of M with respect to D. A matrix picture of a simple decomposition is given in Fig. 2.1. Observe that each M_i is a connected, standard matrix.

$$M = \left[\begin{array}{ccc|ccc|c} I_1 & & 0 & N_1 & & 0 & D_1 \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & & I_t & 0 & & N_t & D_t \end{array}\right] \qquad M_i = \left[\begin{array}{c|c|c} I_i & N_i & D_i \end{array}\right]$$

FIG. 2.1. *Matrix picture of a simple decomposition.*

Applying the notion of a simple decomposition recursively leads to the following definition. A *decomposition tree* associated with M is an arborescence $\mathcal{T}$ such that: (i) the vertex set of $\mathcal{T}$ is a collection of $\{0, 1\}$-matrices with the root of $\mathcal{T}$ equal to M, (ii) the set of children of a vertex is a simple decomposition of the vertex, and (iii) each vertex of outdegree zero is a matrix having exactly one row. Observe that associated with each vertex having outdegree greater than one is a minimal d-set, namely, the minimal d-set with respect to which the set of children of the vertex is a simple decomposition.

THEOREM 2.2. *Let M be a standard, connected $\{0, 1\}$-matrix. Then any decomposition tree associated with M has $O(r)$ vertices. Moreover, a decomposition tree can be computed in $O(rn)$ time.*

Proof. By Lemma 2.1, a minimal d-set can be computed in $O(n)$ time. Therefore, it suffices to show that any decomposition tree, say $\mathcal{T}$, associated with M has $O(r)$ vertices. This is done by showing by induction that $\mathcal{T}$ has at most $2r - 1$ vertices.

If $r = 1$, then $\mathcal{T}$ has exactly one vertex. Thus, assume $r \geq 2$. Let $\{M_1, \ldots, M_t\}$ be a simple decomposition of M, and let r_i be the number of rows of M_i for $1 \leq i \leq t$. By induction, any decomposition tree associated with M_i has at most $2r_i - 1$ vertices.

Let $\mathcal{T}_1, \ldots, \mathcal{T}_t$ be the components of the arborescence obtained by deleting M from $\mathcal{T}$ such that M_i is a vertex of $\mathcal{T}_i$. Then $\mathcal{T}_i$ is a decomposition tree associated with M_i. Therefore, the tree $\mathcal{T}$ has at most $\sum_{i=1}^{t} (2r_i - 1) + 1$ vertices. Since $\sum_{i=1}^{t} r_i = r$ and $t \geq 2$, the result follows. □

The above decomposition is now related to cr-graphic matrices. Recall that the decomposition applies only to connected, standard matrices. Clearly, a matrix M is cr-graphic if and only if the standard matrix (I, M) is cr-graphic. Thus, nothing is lost by the restriction to standard matrices. Moreover, the following proposition reduces the analysis of the consecutive-retrieval problem to the connected case.

PROPOSITION 2.3. *Let M be a $\{0, 1\}$-matrix, and let $\{M_1, \ldots, M_t\}$ be the set of components of M. Then M is cr-graphic if and only if $M_1, \ldots, M_t$ are cr-graphic.*

Proof. Suppose that M is cr-graphic, and let T be a realization of M. Consider a component M_1 of M, and let T_1 be the subgraph of T induced by $R(M_1)$.

Let $c \in C(M_1)$. Then $c \in C(M)$. Let P be the vertex set of the path of T for which column c of M is the incidence vector. Since M_1 is a component of M, all of the vertices of P are vertices of T_1. Thus, P is the vertex set of a path in T_1, which implies that column c of M_1 is the incidence vector of P in T_1. Thus, if T_1 is a tree, then T_1 is a realization of M_1. Since T_1 is a subgraph of a tree, it is a tree if it is connected. If T_1 is not connected, then there exists a partition of its vertex set, say $\{V_1, V_2\}$, such that no vertex set of a path corresponding to a column of M_1 has nonempty intersection with both V_1 and V_2. It follows that M_1 is not connected, a contradiction.

Suppose that $M_1, \ldots, M_t$ are cr-graphic with respective realizations $T_1, \ldots, T_t$. Let v_i be a vertex of T_i for $1 \leq i \leq t$. Define T to be the tree obtained from $T_1, \ldots, T_t$ be adding $v_1v_2, v_2v_3, \ldots, v_{t-1}v_t$ as edges. Then the tree T is a realization of M. □

Let G be a connected graph, and let T be a spanning tree of G. Then the ordered pair (G, T) is a *graph-tree pair* (abbreviated *gt-pair*). For each edge e of G not in T, there exists a unique cycle in $T \cup \{e\}$, called a *fundamental cycle* of (G, T).

Let M be a connected, standard, cr-graphic matrix, and let T be a realization of M. For each column c, add an edge c joining the two ends of the corresponding path in T and call the resulting graph G. The gt-pair (G, T) is a *graph-tree realization* (abbreviated *gt-realization*) of M. Observe that in solving the consecutive-retrieval problem, it is sufficient to construct a gt-pair that is a gt-realization of the matrix.

The next sequence of results relates a simple decomposition of a matrix M to a gt-realization (G, T) of M.

LEMMA 2.4. *Let M be a cr-graphic matrix, and let (G, T) be a gt-realization of M. Then M is connected if and only if G is 2-edge connected.*

Proof. Suppose M is not connected. Then the associated bipartite graph is not connected. This implies that there exists a partition $\{V_1, V_2\}$ of the vertex set of G such that the vertex set of every fundamental cycle of (G, T) is contained in either V_1 or V_2. It follows that either G is disconnected or has a cut edge. Thus, G is not 2-edge connected.

By reversing the above argument, if G is not 2-edge connected, then M is not connected. □

Let H be a connected graph, and let K be the set consisting of the cut edges of H. Then, each component of $H \setminus K$ is a 2-*block* of H. Observe that each 2-block of H is 2-edge connected.

Let M be a connected, standard, cr-graphic matrix, and let (G, T) be a gt-realization of M. Lemmas 2.1 and 2.4 imply that a minimal d-set of M corresponds to a minimal subset D of $E(G) - T$ such that $G \setminus D$ has at least two 2-blocks.

LEMMA 2.5. *Let M be a connected, standard, cr-graphic matrix, and let (G, T) be a gt-realization of M. Let D be a minimal d-set of M, and let $H_1, \dots, H_t$ be the 2-blocks of $G \setminus D$. Let H be the graph obtained from G by contracting the edges of $\bigcup_{i=1}^{t} E(H_i)$, and let $P := H \setminus D$. Then P is a path with at least two vertices. Moreover, in H, the ends of every edge in D are coincident with the ends of P.*

Proof. Clearly, P is a tree with at least two vertices. Let J be a 2-block of $G \setminus D$ that corresponds to a vertex of degree one in P. Let D' be the subset of the edges of D that have an end in $V(J)$. Then D' is a d-set, and by minimality, $D' = D$. It follows that P has exactly two vertices of degree one and thus is a path. Moreover, every edge of D has its ends coincident, in H, with those of P. □

Let (G, T) be a gt-pair in which G is 2-edge connected, and let M be a matrix for which (G, T) is a gt-realization. Let D be subset of $E(G) - T$ such that D is a minimal d-set of M. Let $\{H_1, \dots, H_t\}$ be the 2-blocks of $G \setminus D$ such that H_1 and H_t correspond to the end vertices of the path specified by Lemma 2.5. Then H_1 and H_t each have exactly one vertex of attachment in $G \setminus D$. Consider H_1, and let x denote its vertex of attachment. By Lemma 2.5, each edge of D has exactly one of its ends in H_1. For edge $e \in D$, denote this end by $H_1(e)$. Let G_1 be the graph obtained from H_1 by adding the edges of D such that $e \in D$ has ends $H_1(e)$ and x in G_1. Define the graph G_t in an analogous fashion. Now, consider one of the remaining 2-blocks, say H_j for some $j \in \{2, \dots, t-1\}$. Then H_j has two vertices of attachment, say u and v, with the possibility that $u = v$. For each $j \in \{2, \dots, t-1\}$, define G_j to be the graph obtained from H_j by adding the edges of D such that every edge of D has ends u and v in G_j. Finally, for $1 \le i \le t$, define $T_i := T \cap E(G_i)$. Then $(G_1, T_1), \dots, (G_t, T_t)$ are the *D-components* of (G, T); (G_1, T_1) and (G_t, T_t) are the *end* D-components. Observe that if $\{M_1, \dots, M_t\}$ is a simple decomposition of M with respect to D, then for each $i \in \{1, \dots, t\}$, there exists a $j \in \{1, \dots, t\}$ such that $V(G_i) = R(M_j)$. Thus, by suitably ordering the $M_1, \dots, M_t$, it can be assumed that $V(G_i) = R(M_i)$ for $1 \le i \le t$.

LEMMA 2.6. *Let M be a connected, standard, cr-graphic matrix, and let $\{M_1, \dots, M_t\}$ be a simple decomposition of M with respect to D. Let (G, T) be a realization of M, and let $\{(G_1, T_1), \dots, (G_t, T_t)\}$ be the D-components of (G, T) with $V(G_i) = R(M_i)$ for $1 \le i \le t$. Then, for $1 \le i \le t$, (G_i, T_i) is a gt-realization of M_i.*

Proof. By Lemma 2.5, every edge of G not in T is either an edge of D or has both of its ends in G_i for some $i \in \{1, \dots, t\}$. Also by Lemma 2.5 and the definition of the D-components, for a given edge e of G_i not in T_i, the vertex set of the fundamental cycle of

(G_i, T_i) that contains e is the restriction of the vertex set of the fundamental cycle of (G, T) that contains e to the vertex set of G_i. From the definition of simple decomposition, it follows that each column of M_i is the restriction of a column of M to the row set of M_i. The result follows. □

A set D of edges in a graph G is a *single star* if there exists at least one vertex of G to which all of the edges of D are incident; each such vertex is an *end* of D. Note that some of the edges in D might be loops. A set D of edges in a graph G is a *double star* if there exist at most two vertices of G to which the edges of D are incident. Note that these two vertices can be identical. Observe that every double star is also a single star. Also, observe that in the definition of the D-components above, the set D is a single star in G_1 and G_t and is a double star in $G_2, \ldots, G_{t-1}$.

The composition of gt-pairs is now examined. Let $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ be a set of gt-pairs, and let D be a subset of $\bigcap_{i=1}^{t} E(G_i)$. Then $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is *mergeable* with respect to D if: (i) $V(G_i) \cap V(G_j) = \emptyset$ for $1 \leq i < j \leq t$, (ii) $D \cap T_i = \emptyset$ for $1 \leq i \leq t$, (iii) D is a single star in $G_1, \ldots, G_t$, and (iv) D is a double star in at least $t-2$ of $G_1, \ldots, G_t$.

Consider a mergeable set of gt-pairs with respect to a set D. An ordering of the members of this mergeable set is *feasible* if D is a double star in the second through the penultimate gt-pairs (actually, the graphs of the gt-pairs) of the ordering. Every mergeable set has a feasible ordering.

Let $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ be a mergeable set with respect to a set D, and suppose $(G_1, T_1), \ldots, (G_t, T_t)$ is a feasible ordering. A sequence $X := x_1, \ldots, x_{2t-2}$ is a *merging sequence* for $(G_1, T_1), \ldots, (G_t, T_t)$ and D if D is a single star of (G_1, T_1) with end x_1, D is a single star of (G_t, T_t) with end x_{2t-2}, and, for $2 \leq i \leq t-1$, D is a double star of (G_i, T_i) with ends x_{2i-2} and x_{2i-1}. Note that for a given feasible ordering, there can exist several merging sequences. However, given a mergeable set and a merging sequence, there exists exactly one corresponding feasible ordering. Thus, it is well defined to associate a merging sequence directly with a mergeable set.

Let $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ be a mergeable set with respect to a set D, and let $X = x_1, \ldots, x_{2t-2}$ be an associated merging sequence such that x_1 is a vertex of G_1, x_{2t-2} is a vertex of G_t, and x_{2i-2} and x_{2i-1} are vertices of G_i for $2 \leq i \leq t-1$. A gt-pair (G, T) is constructed as follows. For $f \in D$, if f is not a loop of G_1, then let $u(f)$ denote the end of f different from x_1; otherwise, let $u(f) = x_1$. For $f \in D$, if f is not a loop of G_t, then let $v(f)$ denote the end of f different from x_{2t-2}; otherwise, let $v(f) = x_{2t-2}$. Define G to be the graph obtained from $G_1 \setminus D, \ldots, G_t \setminus D$ by adding the edges of D such that $f \in D$ has ends $u(f)$ and $v(f)$ and by adding new edges $e_1, \ldots, e_{t-1}$ such that e_i has ends x_{2i-1} and x_{2i}. Define $T := \{\bigcup_{i=1}^{t} T_i\} \cup \{\bigcup_{i=1}^{t-1} \{e_i\}\}$. Then (G, T) is the *mergence* of $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ with respect to D and X. Observe that $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is precisely the set of D-components of (G, T).

LEMMA 2.7. *Let M be a standard, connected, cr-graphic matrix, and let $\{M_1, \ldots, M_t\}$ be a simple decomposition of M with respect to a minimal d-set D. For $1 \leq i \leq t$, let (G_i, T_i) be a gt-realization of M_i. Suppose $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is mergeable with respect to D. Then, the mergence of $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ with respect to D and any merging sequence is a gt-realization for M.*

Proof. Let (G, T) denote the mergence of $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ with respect to D and some merging sequence.

Consider a column d of M. If $d \notin D$, then d is exactly in one M_i, so by Lemma 2.6, column d of M_i is the incidence vector of the vertex set of a fundamental cycle, say C_d, in (G_i, T_i). Observe that the mergence maintains C_d, and thus, C_d is a fundamental cycle in (G, T). If $d \in D$, then d is partitioned into t subcolumns such that subcolumn d_i is in exactly one M_i. Moreover, each d_i is the incidence vector of the vertex set of some fundamental cycle C_{d_i} of (G_i, T_i). Again, from the definition of the mergence, $\bigcup_{i=1}^{t} V(C_{d_i})$ is the vertex set of a fundamental cycle of (G, T) whose corresponding incidence vector is d. Thus, every column of M is the incidence vector of the vertex set of a fundamental cycle of (G, T).

Observe that the number of fundamental cycles of (G, T) is equal to the number of columns of M. It follows that the vertex set of every fundamental cycle of (G, T) has its incidence vector as a column of M. □

Lemmas 2.6 and 2.7 can be combined to yield the following result, which motivates the algorithm for solving the consecutive-retrieval problem.

THEOREM 2.8. *Let M be a connected, standard matrix, and let $\{M_1, \ldots, M_t\}$ be a simple decomposition of M with respect to a minimal d-set D. Then M is cr-graphic if and only if $M_1, \ldots, M_t$ are cr-graphic and have gt-realizations such that the set of these gt-realizations is mergeable with respect to D.*

3. Composition. The purpose of this section is to develop the theory used to carry out the composition phase of the algorithm. The idea is as follows. Let M be a connected, standard $\{0, 1\}$-matrix, and suppose that it is desired to determine whether M is cr-graphic. Let $\mathcal{T}$ be a decomposition tree of M. Each vertex of $\mathcal{T}$ of outdegree zero is a matrix having exactly one row. Such matrices are evidently cr-graphic; in fact, they have unique gt-realizations. At a general stage of the composition phase, a vertex N of $\mathcal{T}$ is considered. Suppose that all of the children of N in $\mathcal{T}$ have been found to be cr-graphic, and let $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ be gt-realizations for the children of N. If $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is mergeable, then, by Lemma 2.7, a gt-realization of N can be obtained by first choosing a merging sequence and then constructing the resulting mergence. In this case, this process can be repeated at another vertex of $\mathcal{T}$. However, it might be the case that $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is not mergeable. Unfortunately, if this happens, then it does not necessarily follow that N is not cr-graphic. It might be the case that $\{(G_1, T_1), \ldots, (G_t, T_t)\}$ is an unsuitable set of gt-realizations for the children of N. That is, there might exist another set of gt-realizations of the children of N that is mergeable. In particular, if M is cr-graphic, then it follows from Lemma 2.6 that a mergeable set of gt-realizations exists. Thus, it is sufficient to find a mergeable set of gt-realizations of the children of N or to show that no such set exists.

Observe that the choice of the set of gt-realizations of the children of N (and the corresponding merging sequence) not only determines the gt-realization of N but also affects those of the ancestors of N in $\mathcal{T}$. Therefore, in order to make a judicious choice for the gt-realizations for the children of N, one must take into account information about the minimal d-sets associated with N and all of its ancestors in $\mathcal{T}$. The following set of definitions are aimed at making these ideas precise.

Let M be a connected, standard matrix, and let $\mathcal{T}$ be a decomposition tree of M. Let N be a vertex of $\mathcal{T}$ different from M, and let P be the (M, N)-dipath of $\mathcal{T}$. Let $M_1, \ldots, M_m$ be the vertex set of P in the order specified by P. Then M_{i+1} is a member of a simple decomposition of M_i with respect to some minimal d-set of M_i, say D_i. Define the ordered set $\Sigma := (D_1, \ldots, D_{m-1})$ to be the *decomposer* of N with respect to $\mathcal{T}$. The *critical decomposer* of N is the subset $\{D_i \in \Sigma | D_i \subseteq C(N)$ and $D_i - D_j \neq \emptyset$ for every $m-1 \geq j > i\}$. The *decomposer* and *critical decomposer* of M are defined to be the empty set.

Observe that if N' is the parent of N in $\mathcal{T}$, then $(D_1, \ldots, D_{m-2})$ is the decomposer of N'. Moreover, if Ω is the critical decomposer of N, then the critical decomposer of N' is obtained from Ω by first deleting D_{m-1} and then adding the members of $\{D_i \in \Sigma | D_i \subseteq D_{m-1}$ and $D_i - D_j \neq \emptyset$ for every $m-2 \geq j > i\}$ and the members of $\{D_i \in \Sigma | D_i - C(N) \neq \emptyset, D_i \subseteq C(N')$, and $D_i - D_j \neq \emptyset$ for every $m-2 \geq j > i\}$.

Let (G, T) be a gt-pair. Let $\Omega = \{D_1, \dots, D_m\}$ be a set of subsets of $E(G) - T$ such that, for $1 \leq i \leq m$, D_i is a single star of G. Define $V_\Omega := \{v \in V(G) | v$ is an end of some $D_i \in \Omega\}$. A *labeling* of (G, T) with respect to Ω is a function L that maps elements of V_Ω into subsets of Ω such that each $D_i \in L(v)$ for some v and if $D_i \in L(v)$, then v is an end of D_i. If $D_i \in L(v)$ for some $v \in V_\Omega$, then v is D_i*-labeled* by L. A labeling L is *consistent* with respect to Ω if it satisfies properties (C1) and (C2) below.

(C1) For every $1 \leq i < j \leq m$, if $e \in D_i \cap D_j$ and e is not a loop, then no end of e is both D_i-labeled and D_j-labeled by L.

(C2) For every $1 \leq i \leq m$, if D_i is a double star and $D_i \cap D_j = \emptyset$ for all $j \neq i$, then both ends of D_i are D_i-labeled by L.

If (G, T) has a consistent labeling with respect to Ω, then (G, T) is *consistent* with respect to Ω.

In the context of the composition phase of the algorithm described at the beginning of this section, consistent labelings are used as follows. As before, let N be a vertex of the decomposition tree $\mathcal{T}$ associated with M, and let $\{(G_1, T_1), \dots, (G_t, T_t)\}$ be gt-realizations of the children of N. Assume that each (G_i, T_i) has a consistent labeling, say L_i, with respect to the critical decomposer of the corresponding vertex in $\mathcal{T}$. Then $L_1, \dots, L_t$ are used to construct an appropriate merging sequence for $\{(G_1, T_1), \dots, (G_t, T_t)\}$. In particular, it will be seen that if D is the minimal d-set associated with N and $D \in L_i(x)$ for some $x \in V(G_i)$, then x is a good vertex to put in the merging sequence.

The next result says that if M is cr-graphic, then a consistent labeling does, in fact, exist.

LEMMA 3.1. *Let M be a connected, standard, cr-graphic matrix, and let $\mathcal{T}$ be a decomposition tree of M. Let N and N' be vertices of $\mathcal{T}$ such that N' is a child of N, and let D be the minimal d-set associated with N. Let Ω and Ω' be the respective critical decomposers of N and N'. Let (H, S) and (H', S') be respective gt-realizations of N and N' such that (H', S') is a D-component of (H, S). If (H, S) is consistent with respect to Ω, then (H', S') is consistent with respect to Ω'.*

Proof. Since (H, S) is consistent with respect to Ω, every member of Ω is a single star of H. Observe that $\Omega' \subseteq \Omega \cup \{D\}$. From the definition of the D-components, it follows that every member of Ω' is a single star of H'. Now, let L be a consistent labeling of (H, S) with respect to Ω. It suffices to construct a consistent labeling, say L', of (H', S') with respect to Ω'. This is done by specifying $L'(v)$ for each vertex v of H' that is an end of some member of Ω' in H'. Let v be such a vertex, and choose $D' \in \Omega'$ such that v is an end of D' in H'. If $D' \neq D$ and $D' \in L(v)$, then define D' to be a member of $L'(v)$. If $D' = D$ and v is not an end of D in H, then define D to be a member of $L'(v)$. Finally, if $D' = D$, v is an end of D in H, and either D is a set of loops of H' incident to v or D is a double star of H' and $D \cap D'' = \emptyset$ for all $D'' \in \Omega' - \{D\}$, then define D to be a member of $L'(v)$.

It is claimed that L' defined above is a consistent labeling of (H', S') with respect to Ω'. The first step is to show that L' is a labeling. Let $D' \in \Omega' - \{D\}$. It follows from the definition of the D-components that every end of D' in H is also an end of D' in H'. Since L is a labeling, it follows that $D' \in L(v)$ for some end v of D' in H'. From the definition of L', $D' \in L'(v)$. Also from the definition of L' and the D-components, it follows that $D \in L'(v)$ for some end v of D in H'. Thus, L' is a labeling.

The next step is to show that (C1) and (C2) are satisfied by L' and Ω'. Consider (C1), and let D' and D'' be members of Ω' that have a common edge, say $e = uv$, that is not a loop of H'. Moreover, assume $L'(v)$ contains both D' and D''. Since e is not a loop of H', it is not a loop of H. Assume, without loss of generality, $D'' \neq D$. Since $D'' \in L'(v)$, it follows from the definition of L' that $D'' \in L(v)$. Thus, v is an end of D'' in H, which implies that v is an end of e in H. If $D' \neq D$, then similarly $D' \in L(v)$, which is a contradiction to (C1).

Thus, $D' = D$. Now, from the definition of L', it follows that v is not an end of D in H. The definition of the D-components together with the facts that v is an end of e in H, v is an end of D in H', but v is not an end of D in H imply that e is a loop of H', a contradiction.

Finally, consider (C2). Let D' be a member of Ω' such that D' is a double star in H' and $D' \cap D'' = \emptyset$ for all $D'' \in \Omega' - \{D'\}$. If $D' = D$, then the definition of L' implies that both ends of D' in H' are D'-labeled, as required. If $D' \neq D$, then D' is a double star of H and $D' \cap D'' = \emptyset$ for $D'' \in \Omega - \{D'\}$. Since L is consistent, both ends of D' in H are D'-labeled by L. It follows that both ends of D' in H' are D'-labeled by L', as required. □

The next set of results is aimed at proving the converse of Lemma 3.1. For this purpose, the following notations are fixed for the remainder of the section. Let M be a connected, standard $\{0, 1\}$-matrix, and let $\mathcal{T}$ be a decomposition tree of M. Let N be a vertex of $\mathcal{T}$, and let $N_1, \dots, N_t$ be the children of N in $\mathcal{T}$. Let D be the minimal d-set associated with N, and let $\Omega, \Omega_1, \dots, \Omega_t$ be the critical decomposers of $N, N_1, \dots, N_t$, respectively. Throughout the remainder of the section, $N_1, \dots, N_t$ are assumed to be cr-graphic and have gt-realizations that are consistent with respect to their respective critical decomposers. In particular, for $1 \leq i \leq t$, let (H_i, S_i) denote a gt-realization of N_i, and let L_i be a consistent labeling of (H_i, S_i) with respect to Ω_i. On occasion, N is assumed to be cr-graphic. In this case, (G, T) denotes a gt-realization of N and $(G_1, T_1), \dots, (G_t, T_t)$ are the D-components of (G, T). By Lemma 2.6, $(G_1, T_1), \dots, (G_t, T_t)$ are also gt-realizations of $N_1, \dots, N_t$. By the definition of the D-components, D is a double star in at least $t - 2$ of $G_1, \dots, G_t$.

Under the assumption that M is cr-graphic, Lemmas 3.2 to 3.4 establish the existence of a special type of merging sequence for $\{(H_1, S_1), \dots, (H_t, S_t)\}$ with respect to $L_1, \dots, L_t$ and D. Lemmas 3.5–3.8 then show that the resulting mergence is consistent with respect to Ω. This is done algorithmically; Procedures LABEL1, LABEL2, and LABEL3 construct a consistent labeling from $L_1, \dots, L_t$.

LEMMA 3.2. *If N is cr-graphic, then $\{(H_1, S_1), \dots, (H_t, S_t)\}$ is mergeable.*

Proof. By assumption, each (H_i, S_i) is consistent with respect to Ω_i. From the definition of consistency, D is a single star in each of $H_1, \dots, H_t$. Thus, it suffices to show that D is a double star in at least $t - 2$ of $H_1, \dots, H_t$.

As observed, D is a double star in at least $t - 2$ of $G_1, \dots, G_t$. Since (H_i, S_i) and (G_i, T_i) are both gt-realizations of the matrix N_i, it follows that if D is a double star in G_i, then it is a double star of H_i. □

For $1 \leq i \leq t$, define (H_i, S_i) to be an *end piece* of $\{(H_1, S_1), \dots, (H_t, S_t)\}$ with respect to D if either D is a single star and not a double star of H_i or D is a double star of H_i and $D' \cap D \neq \emptyset$ for some $D' \in \Omega_i - \{D\}$.

LEMMA 3.3. *If M is cr-graphic, then at most two of* $\{(H_1, S_1), \dots, (H_t, S_t)\}$ *are end pieces with respect to D.*

Proof. Since M is cr-graphic, repeated application of Lemma 2.6 implies that N is cr-graphic with gt-realization (G, T). It is shown that if (H_i, S_i) is an end piece of $\{H_1, \dots, H_t\}$, then (G_i, T_i) is an end D-component of (G, T). Since (G, T) has exactly two end D-components, the result follows.

Suppose that (H_i, S_i) is an end piece for some $i \in \{1, \dots, t\}$. If D is a single star and not a double star of H_i, then D is a single star and not a double star of G_i, which implies that (G_i, T_i) is an end D-component of (G, T). Now suppose that D is a double star of H_i and that $D' \cap D \neq \emptyset$ for some $D' \in \Omega_i - \{D\}$. Since Ω_i is a critical decomposer, $D' - D \neq \emptyset$. Since $D' \in \Omega_i$, D' is a single star of G_i. Since $D' - D \neq \emptyset$, there exists an edge e of $D' - D$ that, in G, has both ends in $V(G_i)$. Since $D' \cap D \neq \emptyset$, there exists an edge f of G in $D' \cap D$. By repeated application of Lemma 3.1, (G, T) is consistent with respect to Ω. Since $D' \in \Omega$, it is a single star of G. Thus, e and f are adjacent in G. It follows that (G_i, T_i) is an end D-component of (G, T). □

A feasible ordering of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ is *good* if none of the second through penultimate gt-pairs in the ordering is an end piece of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$. If M is cr-graphic, then Lemma 3.3 implies that $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ has a good ordering. A merging sequence $X = x_1, \ldots, x_{2t-2}$ for a good ordering of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ is *good* with respect to $L_1, \ldots, L_t$ and D if $D \in L_i(x_j)$ whenever $x_j \in V(H_i)$. As before, it is well defined to associate a good merging sequence directly with a mergeable set; the associated unique ordering of the mergeable set is necessarily good. The next result shows that there exists a good merging sequence.

LEMMA 3.4. *If M is cr-graphic, then there exists a good merging sequence for $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ with respect to $L_1, \ldots, L_t$ and D.*

Proof. By Lemma 3.3, it can be assumed that $(H_1, S_1), \ldots, (H_t, S_t)$ is a good ordering of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$. Since L_1 is consistent, there exists a vertex $x_1 \in V(H_1)$ such that $D \in L_1(x_1)$. Similarly, there exists a vertex $x_{2t-2} \in V(H_t)$ such that $D \in L_t(x_{2t-2})$. Now, consider $i \in \{2, \ldots, t-1\}$. Since $(H_1, S_1), \ldots, (H_t, S_t)$ is a good ordering, D is a double star of H_i. Moreover, since (H_i, S_i) is not an end piece, $D \cap D' = \emptyset$ for all $D' \in \Omega_i - \{D\}$. If the ends of D in H_i are x_{2i-2} and x_{2i-1}, then property (C2) of the consistency of L_i implies that $D \in L_i(x_{2i-1})$ and $D \in L_i(x_{2i-2})$. Thus, the sequence $x_1, \ldots, x_{2t-2}$ is a good merging sequence. □

The remainder of the section assumes that $\{H_1, \ldots, H_t\}$ is mergeable. If M is cr-graphic, then Lemmas 2.6 and 3.2 imply that this is indeed the case. The following notations are fixed: X denotes a merging sequence of $\{(H_1, S_1), \ldots, (H_, S_t)\}$ with respect to $L_1, \ldots, L_t$ and D, and (H, S) is the mergence of $\{(H_1, S_1), \ldots, (H_, S_t)\}$ with respect to D and X. In the case that M is indeed cr-graphic, it is further assumed that X is a good merging sequence, the existence of which is provided by Lemma 3.4. Finally, it is also assumed that the ordering of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ corresponding to X is given by $(H_1, S_1), \ldots, (H_t, S_t)$. The next lemma establishes a necessary condition for the existence of a consistent labeling of (H, S) with respect to Ω.

LEMMA 3.5. *If M is cr-graphic, then every member of Ω is a single star in H.*

Proof. Let $D' \in \Omega$. Since M is cr-graphic, Lemma 2.6 implies that N is also cr-graphic. Moreover, Lemma 3.1 implies that (G, T) is consistent with respect to Ω. Thus, D' is a single star of G. It follows that $D' \subseteq E(G_i)$ for some $i \in \{1, \ldots, t\}$. Thus, either $D' \in \Omega_i$ for some $i \in \{1, \ldots, t\}$ or $D' \subseteq D$.

First, suppose that $D' \in \Omega_i$ for some $i \in \{1, \ldots, t\}$. Since L_i is a consistent labeling of (H_i, S_i) with respect to Ω_i, there exists a vertex $v \in V(H_i)$ such that $D' \in L_i(v)$. Moreover, v is an end of D' in H_i. If $D \cap D' = \emptyset$, then it follows directly from the definition of the mergence that D' is a single star in H with v as an end. Thus, assume $D \cap D' \neq \emptyset$. Then (H_i, S_i) is an end piece. Moreover, by (C1), either $D \notin L_i(v)$ or every edge of $D \cap D'$ is a loop of H_i. In either case, from the definition of the mergence, it follows that D' is a single star in H.

Next, suppose that $D' \subseteq D$. Let v be an end of D' in G. Then v is a vertex of one of the end D-components of (G, T), say (G_j, T_j) for some $j \in \{1, \ldots, t\}$. It follows that D' is a double star of G_j. By definition, D, and therefore D', is a double star in all of the nonend D-components of (G, T). Thus, D' is a double star in at least $t-1$ of $G_1, \ldots, G_t$, which implies that D' is a double star in at least $t-1$ of $H_1, \ldots, H_t$. Now, from the definition of the mergence, D' is a single star in H. □

The construction of a consistent labeling of (H, S) with respect to Ω is done in three stages. Define $\Sigma_1 := (\Omega_1 \cup \cdots \cup \Omega_t) - \{D\}$. Define Σ_2 to be those members of Ω that are contained in D and are not a double star in H. (By Lemma 3.5, each member of Σ_2 is a single star in H.) Finally, define Σ_3 to be those members of Ω that are contained in D and are a double star in H. Then $\Omega = \Sigma_1 \cup \Sigma_2 \cup \Sigma_3$. Moreover, Σ_1, Σ_2, and Σ_3 are pairwise disjoint. Define $\{\Sigma_1, \Sigma_2, \Sigma_3\}$ to be the *principal partition* of Ω. A consistent labeling of (H, S) with respect to Ω is constructed by first constructing a consistent labeling of (H, S) with respect to Σ_1, then to $\Sigma_1 \cup \Sigma_2$, and finally to $\Sigma_1 \cup \Sigma_2 \cup \Sigma_3$. The following procedure provides the first construction.

```
Procedure LABEL1.
Input: $(H, S)$, $\Sigma_1$, and $L_1, \dots, L_t$.
Output: A labeling $L$ of $(H, S)$ with respect to $\Sigma_1$.
Step 1 : For each $v \in V(H)$ that is an end of some member of $\Sigma_1$, set
    $L(v) \leftarrow \emptyset$.
Step 2 : For each $D' \in \Sigma_1$ and each $v \in V(H)$ that is an end of $D'$, if
    $D' \in L_i(v)$ for some $i \in \{1, \dots, t\}$, then set $L(v) \leftarrow L(v) \cup \{D'\}$.
```

LEMMA 3.6. *The output L of Procedure* LABEL1 *is a labeling of (H, S) with respect to Σ_1. Moreover, if M is cr-graphic, then L is consistent.*

Proof. Since $L_1, \dots, L_t$ are labelings, it follows that L is a labeling. Thus, assuming that M is cr-graphic, it suffices to show that properties (C1) and (C2) are satisfied.

Consider (C1), and let D' and D'' be members of Σ_1 such that D' and D'' have a nonloop edge $e = uv$ of H in common. Now, suppose that D' and D'' are both members of $L(v)$. Thus, v is an end of D' and D'' in H. It follows that there exists an $i \in \{1, \dots, t\}$ such that D' and D'' are members of Ω_i. From the definition of L, it follows that D' and D'' are both members of $L_i(v)$. Since L_i is a consistent labeling of (H_i, S_i) with respect to Ω_i, it follows that e is a loop of H_i. Thus, $e \in D$ and $i \in \{1, t\}$. Without loss of generality, assume $i = 1$.

Since D' and D'' are in Ω_1, $D' - D$ and $D'' - D$ are nonempty. Since e is a loop at v in H_1, it is a loop at v in G_1. Therefore, v is an end of both D' and D'' in G_1. It now follows from the definition of D-components of (G, T) that v is the unique end of both D' and D'' in G. Thus, in any labeling of (G, T) with respect to Ω, D' and D'' violate property (C2). Thus, (G, T) has no consistent labeling with respect to Ω, contradicting Lemma 3.1.

Now, consider (C2). Let $D' \in \Sigma_1$ be such that D' is a double star of H and $D' \cap D'' = \emptyset$ for all $D'' \in \Sigma_1 - \{D'\}$. Observe that $D' \cap D = \emptyset$. Thus, D' is a double star in H_i for some $i \in \{1, \dots, t\}$. Moreover, D' has the same set of ends in H_i as it does in H. Since $\Omega_i - \{D\} \subseteq \Sigma_1$, it follows that $D' \cap D'' = \emptyset$ for all $D'' \in \Omega_i - \{D'\}$. Therefore, by (C2), both ends of D' in H_i are D'-labeled by L_i. By Procedure LABEL1, both ends of D' in H are D'-labeled by L, as required. □

The following procedure extends the labeling L to a consistent labeling with respect to $\Sigma_1 \cup \Sigma_2$.

```
Procedure LABEL2.
Input: $(H, S)$, $\Sigma_2$, and the labeling $L$ that is the output of LABEL1.
Output: A labeling $L$ of $(H, S)$ with respect to $\Sigma_1 \cup \Sigma_2$.
Step 1 : For each $v \in V(H)$ that is an end of some member of $\Sigma_2$ but not
    an end of any member of $\Sigma_1$, set $L(v) \leftarrow \emptyset$.
Step 2 : For each $D' \in \Sigma_2$, let vertex $v$ be its unique end in $H$ and set
    $L(v) \leftarrow L(v) \cup \{D'\}$.
```

LEMMA 3.7. *The output L of Procedure* LABEL2 *is a labeling of (H, S) with respect to $\Sigma_1 \cup \Sigma_2$. Moreover, if M is cr-graphic, then L is consistent.*

Proof. Since the input to Procedure LABEL2 is a labeling, it is evident that the output is a labeling. Thus, assuming that M is cr-graphic, it suffices to show that (C1) and (C2) are satisfied. Since (C2) is satisfied by the input to the procedure, it is also satisfied by the output because no member of Σ_2 is a double star. Thus, consider (C1).

Suppose that there exist D' and D'' in $\Sigma_1 \cup \Sigma_2$ having a nonloop edge e of H in common, and suppose that D' and D'' are both members of $L(v)$, where v is an end of e in H. By Lemma 3.6, at most one of D' and D'' is in Σ_1. Without loss of generality, assume $D'' \notin \Sigma_1$.

First, consider the case when $D' \in \Sigma_1$. Since $D'' \in \Sigma_2$, $D'' \subseteq D$. Since v is an end of e in H and $e \in D$, v is a vertex of either H_1 or H_t. Without loss of generality, assume the former. Since D'' is not a double star in H, there exists an edge $f \in D''$ in H that is not parallel to e. Since $D' \in L(v)$, v is an end of D' in H. Thus, $D' - D$ is contained in the edge set of H_1. Observe that e and f are parallel in H_1. A contradiction is obtained by showing that they are not parallel in G_1. By Lemma 3.1, (G, T) is consistent with respect to Ω. Thus, D' and D'' are single stars of G. Let e have ends x and y in G. Since $D' - D \subseteq E(H_1)$, $D' - D \subseteq E(G_1)$. Since $D' \in \Sigma_1$, $D' - D \neq \emptyset$. It follows that (G_1, T_1) is an end D-component of (G, T), and x (say) is a vertex of G_1. Moreover, y is a vertex of the end D-component of (G, T) different from (G_1, T_1). Therefore, x is the unique end of D' in G and so is D'-labeled by any consistent labeling of (G, T) with respect to Ω. By consistency, x is not D''-labeled by any such labeling. Therefore, y is D''-labeled by any consistent labeling of (G, T) with respect to Ω. Thus, y is an end of D'' in G. Since e and f are not parallel in H, they are not parallel in G. Therefore, x is not an end of f in G. It follows that e and f are not parallel in G_1, as required.

Second, consider the case that D' and D'' are both members of Σ_2. Thus, both are contained in D and neither is a double star of H. Let f be an edge of D' that is not parallel to e in H, and let g be an edge of D'' that is not parallel to e in H. By the consistency of (G, T) with respect to Ω, the respective ends of D' and D'' in G are in different end D-components of (G, T). It follows that f and g are not parallel in either end D-component of (G, T). Thus, f and g are parallel in precisely $t - 2$ of the D-components of (G, T). This is a contradiction since f and g are parallel in $t - 1$ of $\{(H_1, S_1), \dots, (H_t, S_t)\}$; in particular, f and g are parallel in each of $\{(H_2, S_2), \dots, (H_{t-1}, S_{t-1})\}$ and the member of $\{(H_1, S_1), (H_t, S_t)\}$ that contains the vertex v. □

The final step is to extend the output L of Procedure LABEL2 to a consistent labeling of (H, S) with respect to Ω. The idea is as follows. Recall that each member of Σ_3 is a double star of H contained in D. Consider a graph $I := I(H, \Sigma_3)$, the vertex set of which is Σ_3 and the edge set of which is defined by declaring two members of Σ_3 to be adjacent if they have an edge of H in common. Consider a component J of I. Then there exist distinct vertices of H, say u and v, such that every member of Σ_3 that is a vertex of J is a double star with ends u and v. Now, suppose that the consistent labeling L of (H, S) with respect to $\Sigma_1 \cup \Sigma_2$ has been extended to $\Sigma_1 \cup \Sigma_2 \cup \{D'\}$ for some $D' \in V(J)$, and suppose that under this extension $D' \in L(u)$. Consider a member $D'' \in V(J)$ that is adjacent to D' in J. Then, if L is extended to include D'', it must be that $D'' \in L(v)$, for otherwise L would violate (C1). More generally, if $D'' \in V(J) - \{D'\}$ and some path in J from D' to D'' has an odd number of edges, then $D'' \in L(v)$; otherwise $D'' \in L(u)$. (It follows that if a consistent labeling exists, then the graph I is bipartite.) The following procedure makes these ideas precise. For any two vertices D' and D'' in the same component of I, let $d(D', D'')$ denote the number of edges in a shortest path from D' to D'' in I.

```
Procedure LABEL3.
Input: $(H, S)$, $\Sigma_3$, and the labeling $L$ that is the output of LABEL2.
Output: A labeling $L$ for $(H, S)$ with respect to $\Omega$.
Step 1: For each $v \in V(H)$ that is an end of some member of $\Sigma_3$ but not an
    end of any member of $\Sigma_1 \cup \Sigma_2$, set $L(v) \leftarrow \emptyset$.
Step 2 : Compute $I := I(H, \Sigma_3)$, and let $\mathcal{I}$ be the set of components of $I$.
Step 3 : If $\mathcal{I} = \emptyset$, then output $L$ and stop; otherwise, choose $J \in \mathcal{I}$.
```

Step 4 : Determine whether there exists a vertex D' of J that has an edge in common with a member D^* of $\Sigma_1 \cup \Sigma_2$; if so, let u' be an end of D' such that $D^* \notin L(u')$. Otherwise, let D' be an arbitrary vertex of J, and let u' be an end of D'. In either case, let v' be the end of D' different from u'.
Step 5 : For each $D'' \in V(J)$ such that $d(D', D'')$ is even, set $L(u') \leftarrow L(u') \cup \{D''\}$. For each $D'' \in V(J)$ such that $d(D', D'')$ is odd, set $L(v') \leftarrow L(v') \cup \{D''\}$. If D' is the unique vertex of J and D' does not have an edge in common with any member of $\Sigma_1 \cup \Sigma_2$, then set $L(v') \leftarrow L(v') \cup \{D'\}$. Set $\mathcal{I} \leftarrow \mathcal{I} - \{J\}$, and go to Step 3.

LEMMA 3.8. *The output L of Procedure* LABEL3 *is a labeling of* (H, S) *with respect to* Ω. *Moreover, if M is cr-graphic, then L is consistent.*

Proof. The first step is to verify that the output L is a labeling of (H, S) with respect to Ω. In particular, it must be verified that each member D' of Ω is in $L(v)$ for some vertex $v \in V(H)$ that is an end of D'. By Lemma 3.7, this is true for $D' \in \Sigma_1 \cup \Sigma_2$. Now, consider Σ_3, and in particular, consider a component J of the graph I computed in Step 2. The key point is to show that the vertex u' defined in Step 4 exists. Suppose that there exists $D' \in V(J)$ and $D^* \in \Sigma_1 \cup \Sigma_2$ such that D' and D^* have an edge in common. Since $D^* \in \Sigma_1 \cup \Sigma_2$, either D^* is a single star and not a double star or it is a double star not contained in D. Since D' is a double star contained in D, it has an end that is not an end of D^*. Therefore, the vertex u' exists. Given that u' exists, then Step 5 evidently assigns each vertex D'' of J to some appropriate $L(v)$. Therefore, L is a labeling of (H, S) with respect to Ω.

The next step is to verify the consistency of L in the case that M is cr-graphic. By Lemma 3.7 and Step 5, property (C2) is evidently satisfied. Consider property (C1). First, observe that it is sufficient to show that property (C1) is satisfied by L for pairs of members from $\Sigma_1 \cup \Sigma_2 \cup V(J)$ for each component J of I.

Let J be a component of I, and let u and v be the ends of some member (and therefore, every member) of $V(J)$ in H. Let x and y be the analogous vertices in G. Since every member of $V(J)$ is contained in D, $u \in V(H_1)$ (say) and $v \in V(H_t)$. Similarly, x and y are contained in the respective vertex sets of the end D-components of (G, T). Without loss of generality, assume that if (G_1, T_1) is an end D-component of (G, T), then $x \in V(G_1)$, and if (G_t, T_t) is an end D-component, then $y \in V(G_t)$. By Lemma 3.1, (G, T) has a consistent labeling with respect to Ω, say L'.

First, suppose that no member of $V(J)$ has an edge of H in common with a member of $\Sigma_1 \cup \Sigma_2$. Then, by Lemma 3.7, L satisfies property (C1) with respect to $\Sigma_1 \cup \Sigma_2 \cup V(J)$ if and only if it satisfies property (C1) with respect to $V(J)$. Let D' be the member of $V(J)$ chosen in Step 4. Observe that the graph I is identical to the analogous graph for G and Σ_3; that is, $I = I(G, \Sigma_3)$. Observe that if $D' \in L'(x)$ (say), then, for any $D'' \in V(J)$, $D'' \in L'(y)$ if and only if $d(D', D'')$ is odd. It follows that either $L(u) \cap V(J) = L'(x) \cap V(J)$ and $L(v) \cap V(J) = L'(y) \cap V(J)$ or $L(u) \cap V(J) = L'(y) \cap V(J)$ and $L(v) \cap V(J) = L'(x) \cap V(J)$. Since L' satisfies property (C1) with respect to $V(J)$, so does L.

The case when some member of $V(J)$ has an edge in common with a member of $\Sigma_1 \cup \Sigma_2$ is similar but more complicated. The following claim is used. Let D' and D^* be as in Step 4. Then either $D^* \in L(u)$ or $D^* \in L(v)$. The claim is that if $D^* \in L(u)$ (respectively, $L(v)$), then $D^* \in L'(x)$ (respectively, $L'(y)$).

First, suppose that $D^* \in \Sigma_1$. Then $D^* - D \neq \emptyset$ and $D^* \cap D \neq \emptyset$. It follows that D^* has a unique end in H and this end is either u or v. If it is u, then $D^* \in L(u)$ and $D^* - D \subseteq E(H_1)$. Thus, $D^* - D \subseteq E(G_1)$, from which it follows that (G_1, T_1) is an end D-component of (G, T). Moreover, since x is a vertex of G_1 in this case, it is the unique end of D^* in G. Thus, $D^* \in L'(x)$, as required. Similarly, if v is the unique end of D^* in H, then $D^* \in L(v)$, from which is follows that $D^* \in L'(y)$.

Second, suppose that $D^* \in \Sigma_2$. By definition of Σ_2, D^* is a single star, but not a double star, in H. Thus, either u or v is the unique end of D^* in H. Consider the former case. Then $D^* \in L(u)$. Since u is the unique end of D^* in H, D^* is a double star in H_1 and a single star, but not a double star, in H_t. Thus, D^* is a double star in G_1 and a single star, but not a double star, in G_t. It follows that (G_t, T_t) is an end D-component of (G, T) and that y is not an end of D^* in G. This implies that $D^* \in L'(x)$. Similarly, $D^* \in L(v)$ implies $D^* \in L'(y)$. Thus, the claim is proved.

The claim is now used to prove that L satisfies property (C1) with respect to $\Sigma_1 \cup \Sigma_2 \cup V(J)$. Let D' and D^* be as in Step 4. From the claim it follows that if D' is added to $L(u)$ (respectively, $L(v)$) in Step 5, then $D' \in L'(x)$ (respectively, $L'(y)$). Since $I = I(G, \Sigma_3)$, if $D'' \in V(J)$ is added to $L(u)$ (respectively, $L(v)$) in Step 5, then $D'' \in L'(x)$ (respecuvely, $L'(y)$). Since L' satisfies property (C1) with respect to $\Sigma_1 \cup \Sigma_2 \cup V(J)$, the claim implies that L also does. □

The final result of the section is a complexity analysis of Procedures LABEL1, LABEL2, and LABEL3.

LEMMA 3.9. *Procedures* LABEL1, LABEL2, *and* LABEL3 *each requires $O(rc)$ time.*

Proof. Consider Procedure LABEL1. Step 1 requires determining the ends, in H, of each member of Σ_1. Given that the ends of each edge of H are stored with the edge name, determining the ends of $D' \in \Sigma_1$ can be done in $O(|D'|)$ time. Evidently, $|D'| \leq c$. Since Σ_1 is a subset of a decomposer, $|\Sigma_1| \leq r$. Thus, Step 1 requires $O(rc)$ time.

Observe that each vertex of H is in exactly one of $H_1, \dots, H_t$. It follows that for each v that is the end of some member of Σ_1 in H, $L(v) = L_i(v)$ for some $i \in \{1, \dots, t\}$. Thus, Step 2 of the procedure amounts to creating a copy of $L_i(v)$ for each vertex v that is an end of some member of Σ_1. Since each member of Σ_1 has at most two ends, this copying requires $O(|\Sigma_1|)$ time. Thus, Step 2 requires $O(r)$ time.

Consider Procedure LABEL2. The main work is in determining the end, in H, of each member in Σ_2. As in Procedure 1, this requires $O(rc)$ time.

Consider Procedure LABEL3. By the above argument, the initialization in Step 1 requires $O(rc)$ time. Step 2 requires the construction of the graph $I := I(H, \Sigma_3)$. This can be done in $O(rc)$ time as follows. First, construct the union of the members of Σ_3 by scanning each member. Then, for each edge of the union, find the members of Σ_3 that contain it. Each step so far requires $O(rc)$ work. For each pair of members of Σ_3 that contain a given edge of H, an edge of I is constructed. Since there can be at most $O(r^2)$ edges in I, this last step requires $O(r^2)$ work.

Since the graph I has $O(r^2)$ edges, its components can be computed in $O(r^2)$ time. The next step is to determine, for each component J of I, whether some member of $V(J)$ has an edge of H in common with some member of $\Sigma_1 \cup \Sigma_2$. Using a procedure similar to that of the previous paragraph, this can be done in $O(rc)$ time. Thus, the D' and D^* required in Step 4 for each component J can be found in this time. For each component J, the numbers $d(D', D'')$ needed in Step 5 can be computed by breadth-first search applied to J. This requires $O(|E(J)|)$ time for each component J and so requires $O(r^2)$ time overall. □

4. The main algorithm. This section contains the main algorithm, a proof of its correctness, and its time complexity analysis.

Algorithm MAIN.
Input: A standard, connected $r \times c$ $\{0, 1\}$-matrix M.
Output: A gt-realization of M or the conclusion that M is not cr-graphic.
Step 1 : Compute a tree decomposition $\mathcal{T}$ of M, and then for each vertex of $\mathcal{T}$, compute the associated critical decomposer. Let h be the height of $\mathcal{T}$,

and for $0 \leq i \leq h$, compute the set $\Pi_i := \{N \in V(\mathcal{T}) \mid$ the distance from the root of $\mathcal{T}$ to N is $i\}$.

Step 2 : For each $N \in \Pi_h$, construct a consistent gt-realization of N and a corresponding consistent labeling with respect to the critical decomposer of N. Set $i \leftarrow h - 1$.

Step 3 : Choose $N \in \Pi_i$, and let D be the associated minimal d-set. Let $N_1, \ldots, N_t$ be the children of N. Let $(H_1, S_1), \ldots, (H_t, S_t)$ be respective gt-realizations that have been constructed, and, for $1 \leq i \leq t$, let L_i be the labeling of (H_i, S_i) with respect to the critical decomposer of N_i that has been constructed.

Step 4 : If $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ is not mergeable, then stop with the conclusion that M is not cr-graphic. If $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ has more than two end pieces, then stop with the conclusion that M is not cr-graphic. If there does not exist a good merging sequence for $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ with respect to $L_1, \ldots, L_t$ and D, then stop with the conclusion that M is not cr-graphic; otherwise construct such a sequence X, and let (H, S) be the mergence of $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ with respect to D and X.

Step 5 : Compute the principal partition of the critical decomposer of N, and apply Procedures LABEL1, LABEL2, and LABEL3 to compute a labeling L of (H, S) with respect to the critical decomposer of N.

Step 6 : If N is the root of $\mathcal{T}$, then stop with (H, S) as the output. Otherwise, set $\Pi_i \leftarrow \Pi_i - \{N\}$. If $\Pi_i = \emptyset$, then set $i \leftarrow i - 1$. Go to Step 3.

THEOREM 4.1. *Algorithm* MAIN *is correct.*

Proof. Suppose that M is cr-graphic. Each member of Π_h is a matrix with one row. Each such matrix is evidently cr-graphic and has a unique gt-realization that is consistent with respect to the associated critical decomposer. Thus, Step 2 is correct. The gt-realizations and the labelings in Step 3 are evidently well defined when $i = h - 1$, and given that Steps 4–6 are correct, they are well defined for all $i \in \{0, \ldots, h - 2\}$. Moreover, since M is cr-graphic, Step 5 and Lemmas 3.6–3.8 imply that each of the labelings L_i in Step 3 is a consistent labeling. Also since M is cr-graphic, Lemmas 3.2–3.4 imply that Step 4 constructs both a good merging sequence X for $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ and the resulting mergence (H, S). By Lemma 2.7, (H, S) is a gt-realization of N. Thus, in Step 6 when N is the root of $\mathcal{T}$ (i.e., $N = M$), (H, S) is a gt-realization of M, as required.

In the case that M is not cr-graphic, Lemma 2.6 implies that for some N chosen in Step 3, the corresponding set of gt-realizations $\{(H_1, S_1), \ldots, (H_t, S_t)\}$ of its children is not mergeable. Therefore, the algorithms correctly stops in Step 4. □

THEOREM 4.2. *The time complexity of Algorithm* MAIN *is* $O(r^2c)$.

Proof. By Theorem 2.2, the time complexity for computing a decomposition tree $\mathcal{T}$ in Step 1 is $O(rn)$, which is $O(r^2c)$ since $n \leq rc$. The computation of $\Pi_1, \ldots, \Pi_h$ can easily be incorporated into the computation of $\mathcal{T}$ within the same time bound. For future use, it is convenient to also keep track of the set of minimal d-sets associated with the vertices of $\mathcal{T}$ that contain a given column of M. These sets are easily constructed during the computation of $\mathcal{T}$.

The computation of the critical decomposer associated with each vertex of $\mathcal{T}$ can be done as follows. First, for each pair of minimal d-sets (from the set of minimal d-sets associated with the vertices of $\mathcal{T}$), compute the corresponding intersection. This requires $O(c)$ time per pair since each minimal d-set has at most c elements. By Theorem 2.2, $\mathcal{T}$ has $O(r)$ vertices, so finding the collection of all such intersections requires $O(r^2c)$ work. Given the critical decomposer associated with a vertex N of $\mathcal{T}$, the critical decomposer of one of its children N'

in $\mathcal{T}$ can be found by first adding the minimal d-set D associated with N and then by deleting the members that are subsets of D together with the members that are not subsets of $C(N')$. For the child N', deletions of the first and second kind each require $O(rc)$ work; deletions of the first kind can be done using the collection of intersections, and deletions of the second kind can be done by comparing each of the remaining members to $C(N')$. Thus, to find the collection of critical decomposers for the vertex set of $\mathcal{T}$ requires $O(r^2c)$ work.

In Step 2, gt-realizations for the members of Π_h are constructed. There are r such members, one for each row of M. Each such gt-realization has exactly one vertex and at most c edges. Thus, construction of the set of gt-realizations requires $O(rc)$ work. Given the critical decomposer of a particular gt-realization, a consistent labeling can be computed in $O(r)$ time since each critical decomposer has at most r members. Thus, the total work for constructing the set of consistent labelings is $O(r^2)$.

In Step 4, determining whether the given set is mergeable can be done by checking the ends of each edge of D in each of the gt-pairs in the set. Since D has at most c elements and there exist at most r gt-pairs, this requires $O(rc)$ time. The next part of Step 4 requires checking to see if (H_i, S_i) is an end piece, for $1 \leq i \leq t$. Let $\Omega_1, \dots, \Omega_t$ be the respective critical decomposers of $N_1, \dots, N_t$. Observe that for $i \neq j$, $\Omega_i - \{D\}$ is disjoint from $\Omega_j - \{D\}$. It follows that determining which of $(H_1, S_1), \dots, (H_t, S_t)$ are end pieces can be done in $O(rc)$ time by determining the sets $D' \cap D$ for each $D' \in (\Omega_1 - \{D\}) \cup \cdots \cup (\Omega_t - \{D\})$. Given that there exist at most two end pieces, an ordering of $(H_1, S_1), \dots, (H_t, S_t)$ so that the resulting ordered set is good is easily found. The next part of Step 4 is constructing a good merging sequence, if one exists. This can be done by first determining the ends of D in each H_i and then by checking, for each end v of D in H_i, whether $D \in L_i(v)$. Since $|D| \leq c$, finding its ends in a given H_i requires $O(c)$. Since $t \leq r$, this requires $O(rc)$ overall. Scanning the appropriate $L_i(v)$ requires $O(r)$ work since the union of all such $L_i(v)$ has $O(r)$ members. Thus, a good merging sequence, if one exists, can be found in $O(rc)$ time. The final part of Step 4 is the construction of (H, S). This can be done by deleting D from each of $(H_1, S_1), \dots, (H_t, S_t)$, adding edges joining consecutive vertices in the merging sequence, and then adding the edges of D with the appropriate ends. Since $|D| \leq c$ and $t \leq r$, this step requires $O(rc)$ work.

Step 5 first computes the principal partition of the critical decomposer Ω of N. This can be done by first determining, for each member of Ω, whether it is in the critical decomposer of one of the children of N. This requires $O(r^2)$ work since $|\Omega| \leq r$ and the cardinality of the union of the critical decomposers of the children of N is $O(r)$. For a member of Ω that is not in one of the critical decomposers of the children of N, it needs to be determined whether it is a double star of H. For a given member, this can be done in $O(c)$ time by finding the ends of each edge in the member. Since Ω has at most r members, the total work for this part is $O(rc)$, so the principal partition can be found in $O(rc)$. Step 5 then applies Procedures LABEL1, LABEL2, and LABEL3, which is $O(rc)$ by Lemma 3.9.

Step 6 ensures that each of Steps 3–5 is executed at most $O(r)$ times, once for each vertex of $\mathcal{T}$. Thus, Algorithm MAIN requires $O(r^2c)$ time. □

POLYNOMIAL ROOT-FINDING ALGORITHMS AND BRANCHED COVERS*

MYONG-HI KIM† AND SCOTT SUTHERLAND†

Abstract. A family of root-finding algorithms is constructed that combines knowledge of the branched covering structure of a polynomial with a path-lifting algorithm for finding individual roots. In particular, the family includes an algorithm that computes an ϵ-factorization of a polynomial of degree d that has an arithmetic complexity of $\mathcal{O}\big(d(\log d)^2|\log\epsilon| + d^2(\log d)^2\big)$. At the present time, this complexity is the best known in terms of the degree.

Key words. Newton's method, approximate zeros, arithmetic complexity, path-lifting method, branched covering

AMS subject classifications. primary 68Q25; secondary 58C10, 65H05, 30C15, 58F08

Introduction. The problem of devising optimal methods for numerically approximating the roots of a polynomial has been of interest for several centuries, and is far from solved. There are numerous recent works on root-finding algorithms and their cost, for example, the work of Jenkins and Traub [JT70], Renegar [Ren87], Schönhage [Sch82], and Shub and Smale [SS85], [SS86], [Sma85]. This list is far from complete; the reader should refer to the aforementioned papers as well as [DH69] for more detailed background. The work in this paper is most closely related to that of Smale.

Our algorithm computes an approximate factorization of a given polynomial (that is, it approximates all the roots). In constructing it, we combine global topological information about polynomials (namely, that they act as branched covers of the Riemann Sphere) with a path-lifting method for finding individual roots. Utilizing this global information enables us to use fewer operations than applying the path-lifting method to each root sequentially.

Renegar's algorithm in [Ren87] approximates all d roots of a given polynomial using $\mathcal{O}\big(d^3\log d + d^2(\log d)(\log|\log\epsilon|)\big)$ arithmetic operations in the worst case. He has shown that the factor of $\log|\log\epsilon|$ in the complexity is the best possible if one restricts to the operations $+$, $-$, $\times$, and $\div$. This algorithm has a component (the Shur-Cohn algorithm) that requires exact computation and so is not suitable for an analysis of bit complexity, that is, one that accounts for rounding errors introduced by finite precision. In [Pan87], Pan gives a different algorithm that slightly improves the complexity to $\mathcal{O}\big(d^2\log d\log|\log\epsilon|\big)$; this algorithm also operates effectively as a parallel algorithm.

Schönhage [Sch82] gives an algorithm that produces an ϵ-factorization with a bit complexity of $\mathcal{O}\big(d^3\log d + d^2|\log\epsilon|\big)\log(d|\log\epsilon|)\log\log(d|\log\epsilon|)$, via the "splitting circle method." Note that the customary parameter for bit length of the coefficients does not appear in the complexity. This is because, as Schönhage states, for fixed degree d and output precision ϵ, there is a number s_0 for which "the input [coefficients] a_ν can be restricted to complex integer multiples of 2^{-s_0} without loss of generality." In [Ren87], it is stated that Schönhage believes that, if exact arithmetic is used, this method "should yield a complexity bound [in ϵ] of $\mathcal{O}(d^\alpha\log|\log\epsilon|)$, most likely with $\alpha \le 3$."

Smale's path lifting algorithm in [Sma85] approximates a single root of the polynomial with a worst case arithmetic complexity of $\mathcal{O}\big(d(\log d)|\log\epsilon| + d^2(\log d)^2\big)$, and an average complexity of $\mathcal{O}\big(d^2 + d|\log\epsilon|\big)$. One good feature of this line of work is that it is stable under round-off error. In [Kim89a], Kim shows that if f and f' are computed with relative error 10^{-3} until an approximate zero (see §1.2) is reached, then the algorithm behaves exactly the same.

*Received by the editors July 8, 1991; accepted for publication March 25, 1993. Part of this work was done while the first author was at Bellcore, Morristown, New Jersey. An earlier version of this paper was circulated with the title "Parallel Families of Polynomial Root-Finding Algorithms."

†Institute for Mathematical Sciences, State University of New York at Stony Brook, Stony Brook, New York 11794-3600 (myonghi@math.sunysb.edu and scott@math.sunysb.edu).

A recent series of papers by Shub and Smale [SS93a], [SS93b], [SS93c], [SS93d] generalizes the path lifting algorithm to systems of homogeneous polynomials in several variables.

The algorithm presented here exploits the branched covering structure of a polynomial to choose good starting points for a variant of Smale's algorithm, and we obtain a worst-case arithmetic complexity of $\mathcal{O}\big(d(\log d)|\log\epsilon| + d^2(\log d)^2\big)$ to compute an ϵ-factorization. In a subsequent paper, we shall compute the bit complexity of this algorithm. Because of the stability mentioned in the previous paragraph and the ability to exploit bounds on the variation of f and f', we hope to achieve results comparable to Schönhage's.

At first glance, it may appear that our complexity results are inferior to some of those above in terms of ϵ. However, in practice there is usually a relationship between the degree d and the desired precision ϵ. In particular, if we have $\epsilon \geq 2^{-d}$, then the complexity of our algorithm compares favorably with all of those mentioned above. Furthermore, our algorithm is simple to implement and is numerically very stable.

Our algorithm is suitable for some amount of parallelization, but has a sequential component of $\mathcal{O}(d + |\log\epsilon|)$ operations. However, we think of this algorithm as acting on d points simultaneously, and techniques that evaluate a polynomial at d points (see [BM75], for example) are used to cut the cost involved. Of course, the algorithm can be implemented on a sequential machine while still taking advantage of these techniques. In fact, evaluation of the polynomial is the only point at which we need to use asymptotic estimates to achieve the stated complexity; the other places where we use asymptotic estimates are only for ease of expositon.

The reader should also see the papers [BFKT88], [BT90], [Nef90] for fully parallel algorithms for solving polynomials with integer coefficients. In [BFKT88], it is shown that if all roots of the polynomial are real, this problem is in NC. Neff extends this result to allow complex roots in [Nef90].

This paper is structured as follows. In §1, after some background material, we recall the "path lifting method" of Smale and present a version of the relevant theorem (our Theorem 1.5) that improves the constants involved somewhat. We then discuss how we can exploit the branched-covering structure of a polynomial to choose initial points for the algorithm, many of which will converge to roots. We close the section with a brief explanation of how to construct families of algorithms that locate $\frac{d}{n}$ roots at a time, for various values of n.

Section 2 presents an explicit algorithm for a specific family, which locates $\frac{d}{2}$ points at a time. Our main theorem, Theorem 2.1, states that this algorithm always terminates with an ϵ-factorization of the input polynomial, and gives a bound on the number of arithmetic operations required in the worst case. As a corollary, the algorithm can be used to locate all d roots of the polynomial to within ϵ with a complexity of $\mathcal{O}\big(d^2(\log d)|\log\epsilon| + d^2(\log d)^2\big)$. In the subsequent sections, each component of the algorithm is analyzed, and the relevant lemmas are proven. Finally, we tie all the components together and prove the main theorem.

1. Preliminaries.

1.1. Root and coefficient bounds. Given a polynomial $\phi(z) = \sum_{i=0}^{d} a_i z^i$, with $a_i \in \mathbb{C}$, it is our goal to determine an approximate factorization of ϕ, that is, approximations $\hat{\xi}_i$ to the actual roots ξ_i of ϕ so that $\|\phi(z) - \prod(z - \hat{\xi}_i)\| < \epsilon$. The norm we shall use here is the max-norm, that is, $\|\phi\| = \max|a_j|$. A related problem is to ensure that $|\xi_i - \hat{\xi}_i| < \epsilon'$; there are well-known estimates giving the relationship between ϵ and ϵ', so solving one problem essentially solves the other.

In order to have an estimate on the complexity of a root-finding algorithm, we need a compactness condition on the space of polynomials. This can be done either by placing conditions of the location of the roots or on the coefficients; such bounds are interrelated.

Since our goal is to minimize a functional norm, it seems most natural to place our conditions on the coefficients. We shall assume our input polynomial ϕ is an element of the family

$$\mathcal{P}_d(1) = \left\{ z^d + \sum_{j=0}^{d-1} a_j z^j, \text{ with } |a_j| \le 1 \right\}.$$

This is the same space as used by Smale and others [SS85], [Sma81], [Sma85]. One can always transform an arbitrary polynomial into an element of $\mathcal{P}_d(1)$: if $p(z) = \sum_{i=0}^{d} b_i z^i$, and $B = \max |b_j/b_d|^{1/(d-j)}$, then $p(Bz)/B^d \in \mathcal{P}_d(1)$.

One should not confuse this family with the degree d polynomials whose roots are in the unit disk, although unfortunately this space is also often denoted by $\mathcal{P}_d(1)$ (for example, in [Fri90] and [Ren87]).

There are a number of estimates that relate the coefficients of a polynomial to a bound on the modulus of the zeros (see [Hen74] or [Mar66], for example). Such an estimate is important to us, since although membership in $\mathcal{P}_d(1)$ is not preserved under deflation (division of factors), bounds on the modulus of the roots are. We state one such bound here (Corollary 6.4k of [Hen74]).

LEMMA 1.1. *All the zeros of the polynomial $z^d + \sum_{j=0}^{d-1} a_j z^j$ lie within the open disk with center* 0 *and radius*

$$2 \max_{0 \le j < d} |a_j|^{1/(d-j)}.$$

As an immediate consequence, we see that the roots of a polynomial in $\mathcal{P}_d(1)$ lie within $\mathbb{D}_2$.

1.2. Approximate zeros. Our algorithm uses a path lifting method (see below) to get close to the roots of our polynomial, and then uses the standard Newton's method to further refine these approximations. This is done because Newton's method converges very quickly in a neighborhood of a simple root, but can fail for some initial points outside this neighborhood. One of the authors [Sut89] has shown how one can guarantee convergence of Newton's method, but a bound on the arithmetic complexity has not been computed. Instead, we use the more certain path lifting method as described in §1.3; this allows an explicit computation of the complexity.

Following Smale [Sma81], we call a point z_0 an *approximate zero* if Newton's method converges rapidly (that is, quadratically) when started from z_0. Such terminology is reasonable, because given such a point, we can quickly obtain an approximation of a root to arbitrary precision.

DEFINITION 1.2. *Let f be a polynomial and let z_n be the nth iterate under Newton's method of the point z_0, that is, $z_n = z_{n-1} - f(z_{n-1})/f'(z_{n-1})$. Then we say that z_0 is an approximate zero of f if, for all $n > 0$ we have*

$$|z_n - \zeta| \le 8 \left(\frac{1}{2}\right)^{2^n} |z_0 - \zeta|,$$

for some root ζ of f.

Notice that this definition is never satisfied in the neighborhood of a multiple root of f, since the convergence of Newton's method is asymptotically linear there. In our algorithm, we perturb the polynomial slightly to ensure that we always have simple zeros. Refer to §§2.1 and 2.3 for more details.

Kim [Kim88] and Smale [Sma86] have developed readily tested criteria for determining, based on the values of the derivatives $f^{(k)}(z)$, when a point z is an approximate zero. These can be extended to a much more general setting, namely for f a mapping between Banach spaces. The following is essentially Theorem A of [Sma86].

LEMMA 1.3. *Let*

$$\alpha_f(z) = \max_{k>1} \left|\frac{f(z)}{f'(z)}\right| \left|\frac{f^{(k)}(z)}{k!\,f'(z)}\right|^{1/(k-1)}.$$

If $\alpha_f(z) < \frac{1}{8}$, *then* z *is an approximate zero of* f.

We will find the following also very useful.

LEMMA 1.4. *Let* $f(z)$ *be a polynomial and* z *be a complex number so that* $f'(z) \neq 0$, *and let* $R_f(z)$ *be the radius of convergence of the branch of the inverse* f_z^{-1} *which takes* $f(z)$ *to* z. *If*

$$\frac{|f(z)|}{R_f(z)} < \frac{1}{10},$$

then z *is an approximate zero of* f. *Furthermore, if we have* $|f(z)|/R_f(z) < \frac{1}{32}$, *then* $\alpha_f(z) < \frac{1}{8}$.

Remark. If Smale's mean value conjecture holds (see [Sma81], [Tis89]), then the hypotheses of the lemma imply that $\alpha_f(z) < \frac{1}{8}$.

Proof. The first result is a consequence of the proof of Theorem 4.4 of [Kim88], and the second is an immediate consequence of Corollary 4.3 of the same paper. This, in turn, uses the Extended Loewner's Theorem in [Sma81]. □

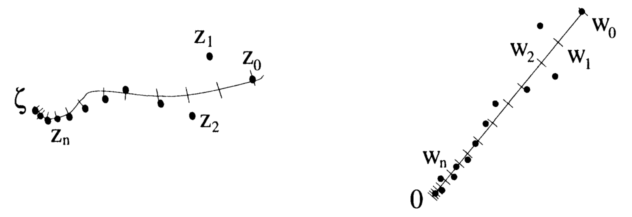
1.3. The path lifting method. Here we review the path lifting method, which forms the core of our iteration scheme. This method is sometimes referred to as a "generalized Euler method" or "modified Newton's method"; we prefer the term "path lifting method" as it is the most descriptive (to us, anyway). This method appears in the work of Smale [Sma85], although the version we present here is slightly different and we present another proof of the relevant theorem, which is quite simple. It should be emphasized that the path lifting method, like Newton iteration, is an algorithm for finding a *single* root of a polynomial; we discuss how to combine these to find all roots in §1.5 below.

We think of a polynomial f as a map from the *source space* to the *target space*; that is, $f : \mathbb{C}_{\text{source}} \to \mathbb{C}_{\text{target}}$. Given an initial value z_0 in the source space, we connect its image $w_0 = f(z_0)$ to 0 in the target space, and then lift this ray under the proper branch of f^{-1} to a path connecting z_0 with a root ζ of f. Of course, we don't explicitly know this inverse, but if the path in the target space stays well away from the critical values of f, the local inverse map $f_{z_0}^{-1}$ is well-defined on a neighborhood of the ray. Even if the path *does* contain critical values, a local inverse can still be defined for some z_0. See §1.4.

The basic idea of the path lifting method is to take a sequence of points w_n along the ray in the target space, with $w_0 = f(z_0)$. We then construct a sequence of points z_n in the source space so that $f(z_n)$ is near w_n in the target. See Fig. 1.1. This is done using a single step of Newton's method to solve $f(z) = w_n$ with z_{n-1} as the starting point. That is,

$$z_n = z_{n-1} - \frac{f(z_{n-1}) - w_{n-1}}{f'(z_{n-1})}.$$

This construction will converge to a root ζ in the source space if there is a wedge about the ray in the target space on which there is a well-defined branch of the inverse f_ζ^{-1}, and if the w_n are chosen properly (in a way that depends on the angle of the wedge). The larger the wedge about the ray, the faster the method converges. We now state the exact theorem, although we shall defer the proof until §2.3.



source space

target space

FIG. 1.1. *The source and target spaces in the path lifting method. In the source space, each z_i is indicated by a black dot, and $f(z_i)$ is indicated by a black dot in the target space. Similarly, the w_i are indicated by tick marks in the target space, and $f^{-1}(w_i)$ by ticks in the source space.*

Notation. By a wedge $\mathcal{W}_{A,w}$, we mean the set

$$\{z \mid 0 < |z| < 2|w|, \ \arg w - A < \arg z < \arg w + A\}.$$

THEOREM 1.5. *Suppose that the branch of the inverse $f_{z_0}^{-1}$ is analytic on a wedge $\mathcal{W}_{A,w_0}$, with $0 < A \le \frac{\pi}{2}$, and let $h \le \frac{\sin A}{19}$. Suppose also that $|f(z_0) - w_0| < h|w_0|/2$, and define*

$$w_n = (1-h)^n w_0, \qquad z_{n+1} = z_n - \frac{f(z_n) - w_{n+1}}{f'(z_n)}.$$

Then $|f(z_n) - w_n| \le h|w_n|/2$ and $z_{n+1} \in f_{z_0}^{-1}\left(\mathcal{W}_{A,w_n}\right)$.

It should be noted that this theorem is a slight improvement of Smale's Theorem A in [Sma85]. His proof is valid for all angles, but is stated only for $A = \frac{\pi}{12}$ with $h = \frac{1}{98}$, and for $A = \frac{\pi}{4}$ with $h = \frac{1}{32}$. For $A = \frac{\pi}{12}$ we can take take $h = \frac{1}{74}$, and for $A = \frac{\pi}{4}$, $h = \frac{1}{27}$ is adequate.

1.4. Branched covers, inverse functions, and all that. If f is a polynomial of degree d, then $f : \mathbb{C} \to \mathbb{C}$ is a branched covering with branch points at the critical points θ_i of f. If z is a regular point of f, that is, $f'(z) \ne 0$, then there is a well-defined inverse function f_z^{-1} so that $f_z^{-1}(f(z)) = z$.

In any neighborhood of a critical point of f, there cannot be a single valued inverse; however, the behavior at such points is well understood. Let θ be a critical point of multiplicity $k-1$. Then we have

$$f(z) - f(\theta) = (z-\theta)^k g(z), \qquad \text{where} \quad g(\theta) \ne 0.$$

One can then define k branches of the inverse that are analytic on a small slit disk about $f(\theta)$. We may, of course, choose any slit that connects $f(\theta)$ to the boundary of the disk. The reader is referred to a complex analysis text for further details (for example, see [Ahl79]).

Let $\{\zeta_j\}$ be the d roots of f, represented with multiplicity. If ζ_j is a simple root, denote by $f_{\zeta_j}^{-1}$ or f_j^{-1} the unique branch of the inverse of f that takes 0 to ζ_j. On the other hand, if ζ_j is a multiple root, we let $f_{\zeta_j}^{-1} = f_j^{-1}$ be one of the branches of the inverse that take 0 to ζ_j, taking care to account for all such branches exactly once. This can be done, since if ζ is a root of multiplicity $k \ge 2$, it is also a critical point of multiplicity $k-1$, and so there are k branches of the inverse.

We now analytically continue each of the f_j^{-1} to a maximal starlike domain Ω_j in the target space; that is, we attempt to extend each f_j^{-1} along open rays from 0. When doing this, it is useful to think of the target space as consisting of d copies of $\mathbb{C}$, with a single f_j^{-1} associated with each one. When does the analytic continuation fail? Precisely when the inverse image of a ray encounters a critical point of f. Refer to Fig. 1.2.

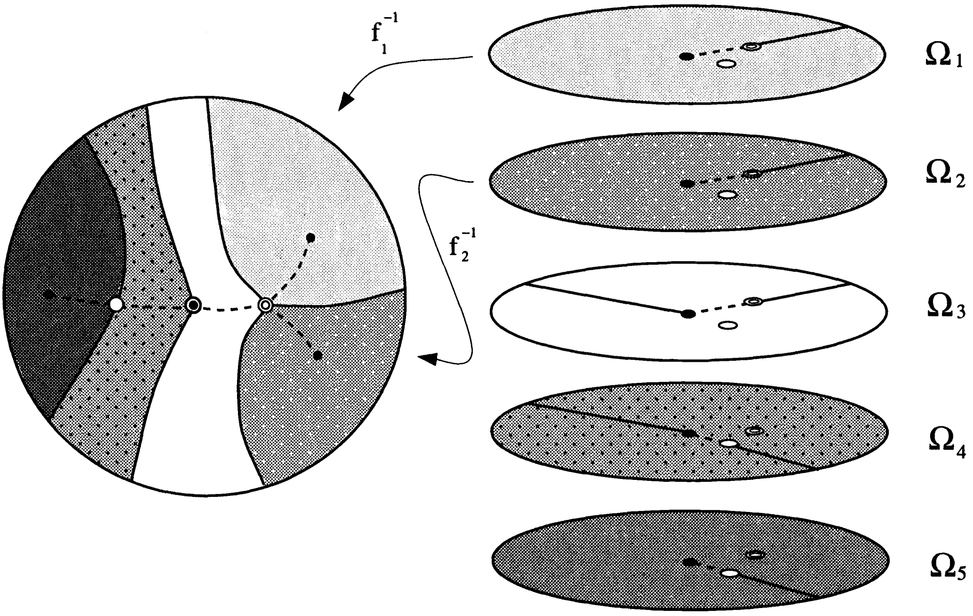


FIG. 1.2. *The Ω_j in the target space (on the right), and the corresponding source space, for a degree 5 polynomial with a double root (black dot inside a white dot) and a critical point of multiplicity 2 (double white dot). The other critical point is marked by a single white dot, and the roots by black dots. The cuts in the Ω_j are represented by black radial lines.*

At this point, it may be useful to consider the Newton vector field given by

$$\dot{z} = -f(z)/f'(z).$$

Let $\varphi_t(z)$ be the solution curve with initial condition $\varphi_0(z) = z$. Then we have

$$f(\varphi_t(z)) = e^{-t} f(z);$$

that is, f maps solution curves of the Newton vector field to rays in the target space. Notice that the singularities of the vector field occur precisely at the points where $f'(z) = 0$. The solution curves $\varphi_t(z)$ which have singularities play an important role here: they divide the source space into regions on which f is injective. Refer to [Shu83], [STW88], [Sma85] for more details on the behavior of the solution curves. Applying the path lifting method can be viewed as attempting to follow the solution curves to the flow φ_t.

When constructing the Ω_j, we continue f_j^{-1} radially outward until a critical point θ is encountered in the source space. We then exclude the ray $\{rf(\theta) \mid r \geq 1\}$ from Ω_j, and continue by moving along rays that avoid the cut. Notice that when we encounter a critical point θ of multiplicity $k-1$, we need to slit at most k of the Ω_j starting at $f(\theta)$. Also, note that some of the Ω_j may already be slit at $f(\theta)$, since there may be another critical point whose image lies on the same ray.

We now count the number of such cuts: f has $d-1$ critical points (with multiplicity), and a critical point of multiplicity $k-1$ can cause at most k cuts. This means we have at most

$2(d-1)$ cuts, distributed through the d copies of the target space. Note that if Ω_j contains some wedge W, then f_j^{-1} is analytic on W. The following counts the number of Ω_j which contain wedges of a given size.

LEMMA 1.6. *Let m be an integer, and divide $\mathbb{C}$ into m wedges*

$$W_{n,m} = \left\{ w \;\middle|\; \frac{2n\pi}{m} < \arg w < \frac{2(n+1)\pi}{m} \right\} \qquad n = 0, \dots, m-1.$$

For each wedge $W_{n,m}$, let $N(n,m)$ be the number of Ω_j that contain the sector $W_{n,m}$, and let $N(m) = \max_{0 \le n < m} N(n,m)$. Then

$$N(m) \ge d - \left\lfloor \frac{2(d-1)}{m} \right\rfloor.$$

Proof. Since we have $2(d-1)$ cuts and m wedges W_n, at least one of the wedges has no more than $\frac{2(d-1)}{m}$ cuts. Since there are d Ω_js, we have the result. □

COROLLARY 1.7. *$N(d) = d$, $N(3) \ge \frac{d}{3}$, and $N(4) \ge \frac{d}{2}$.*

Proof. Application of the formula above gives the result for $N(3)$ and $N(4)$, and yields $N(d) \ge d-1$. However, since each critical point causes at least two cuts, it is not possible to have a wedge cut only once. Thus, the value $d-1$ is not permissible for $N(d)$, giving $N(d) = d$. □

1.5. Families of root-finding methods. We now use the result of Lemma 1.6 to construct families of root-finding algorithms. Recall that the modified Newton method described in §1.3 works when there is an Ω_j containing a wedge about our initial value $f(z_0)$; the larger the wedge, the faster the method converges.

For each family, we start with md points in the source space placed around a circle that contains all the roots. We think of this as m sets of d initial points, and choose them so that the image of each set lies well inside each of the m sectors $W_{n,m}$ in the target space. Then by Lemma 1.6, one of the m sets of points will contain at least $N(m)$ elements whose images are each in a "good wedge," that is, they lie in some Ω_j. As a consequence, iterating these points under the path lifting method will locate at least $N(m)$ roots of the polynomial.

Particular families of interest are $m = d$, which gives the algorithm discussed in [Kim89b], and $m = 4$, on which we focus our attention here. The basic idea of all of the algorithms is this: obtain md "good" initial points and apply the path lifting method to d of them at a time. If, after a prescribed number of iterations, we have found approximation to at least $N(m)$ roots (counting multiplicity), we deflate the polynomial (that is, divide out the approximated roots) and repeat the process on the result. If not, we try again with the next set of d points. Note that we are guaranteed success by the time we try the mth set.

The remainder of the paper consists of a detailed description and analysis of the algorithm for $m = 4$. Most of what follows can be readily adapted to the other families as well.

2. A root-finding algorithm.

2.1. Statement of the algorithm and main theorem. Here we present our root-finding algorithm for the family $m = 4$. The presentation is structured as a main routine and several subroutines, which do most of the work.

Notation. Throughout this section, we shall denote matrices, vectors, and sets in uppercase calligraphic type, and their elements in subscripted lowercase type. For example, x_j is the jth element of the vector $\mathcal{X}$. We shall also use the notation $\lfloor x \rfloor$ to denote the least integer in x, sometimes also called `floor(x)`.

The main routine merely inputs the desired polynomial and precision, rescales it so the roots lie in the disk of radius $\frac{1}{2}$, then repeatedly calls a subroutine to halve the number of unknown roots (counted with multiplicity) and deflate. We do the rescaling in order to easily bound the error introduced by the FFT deflation. The set Λ contains all the approximations found by the ith stage.

Note that the algorithm is given for an arbitrary monic polynomial, since only minor changes are required to normalize the input polynomial. If it is assumed that the input polynomial is already in $\mathcal{P}_d(1)$, we can take $f_0(z) = \phi(4z)/4^d$ and $\tau = 32\epsilon/7^{d+3}$.

```
Main Routine

Input monic polynomial $\phi(z) = \sum_{i=0}^{d} a_i z^i$ and desired precision $\epsilon$.
Let $f_0(z) = \phi(Kz)/K^d$, with $K = 4 \max |a_j|^{\frac{1}{d-j}}$.
Let $\tau = \frac{\epsilon}{2K^d} (4/7)^{d+3}$.
Let $i = 0$ and $\Lambda = \emptyset$.
While $\#(\Lambda) < \deg(\phi)$
    Let $(f_{i+1}, \Lambda_i) =$ get-half-roots-and-deflate($f_i, \tau$).
    Let $\Lambda = \Lambda \cup \Lambda_i$.
    Increment $i$.
End While.
Output $K\Lambda$.
```

The function get-half-roots-and-deflate takes as input a normalized polynomial f and precision τ. It returns a set of points y_j that approximate at least half of the roots of f (with multiplicity) and a new polynomial $\tilde{f}$ that we obtain by deflation. These satisfy $\| f(z) - \tilde{f}(z) \prod (z - y_j) \| < 2\tau$. We should point out here that we are actually finding approximate zeros of $f - \vec{\tau}$, where $|\vec{\tau}| = \tau$, which depends on ϵ. When the translation is in the proper quadrant, this will ensure that the relevant roots of $f - \vec{\tau}$ are simple, so that we have approximate zeros in a neighborhood. This allows us to obtain the right number of approximations to a multiple root, without worrying about winding number arguments or the like. We emphasize again that τ is chosen as a function of ϵ, and is small enough that the approximation polynomial has negligible errors in the non-constant terms.

The matrix $\mathcal{Z}$ consists of 4 rows of d "good" initial conditions, with $|z_{j,k}| = \frac{3}{2}$ and $\arg f(z_{j,k}) \approx 2\pi i j/4$. We use $\mathcal{Z}_j$ to represent the jth row.

```
function get-half-roots-and-deflate($f, \tau$)

Let $d = \deg f$.
Let $\mathcal{Z}$ =choose-4d-good-initial-points($f$).
For $j = 1$ to 4 do
    Let $\mathcal{Y} =$ iterate-PLM($f, \mathcal{Z}_j, j, \tau$).
    Let $\psi = f - \tau e^{2\pi i j/4}$.
    Let $\mathcal{X} =$ select-approx-zeros($\psi, \mathcal{Y}$).
    Let $\mathcal{W} =$ polish-roots($\psi, \mathcal{X}, \tau$).
    Let $\mathcal{V} =$ weed-out-duplicates($\psi, \mathcal{W}$).
    If $\#(\mathcal{V}) \geq d/2$ then
        Let $\tilde{f} =$ deflate($\psi, \mathcal{V}$).
        Return $(\tilde{f}, \mathcal{V})$.
    End if.
End for.
```

```
Print "We have proven this statement will not be reached. Check your code."
Abort.
```

The function `choose-4d-good-initial-points` gives us our 4 sets of d initial values on the circle of radius $\frac{3}{2}$. The sets have the property that elements of the same set are mapped to points with approximately the same argument, and elements of distinct sets are mapped to points in different quadrants of the target space. There are several different ways to accomplish this, and other methods can slightly decrease the number of operations required in `iterate-PLM`. Please refer to the remarks in §2.2 for more details.

```
function choose-4d-good-initial-points($f$)

Let $N = 676 \deg f$.
For $k = 1$ to $N$
    Let $\omega_k = \frac{3}{2}e^{2\pi ik/N}$.
End For.
For $j = 1$ to 4
    Let $\mathcal{Z}_j$ be the union of the $\omega_k$ for which $\arg f(\omega_k) \leq 2\pi/j$ and $\arg f(\omega_{k+1}) > 2\pi/j$.
End For.
Return($\mathcal{Z}$).
```

From our sets of initial points $\mathcal{Z}_j$, we obtain our approximate zeros via the routine `iterate-PLM`. This applies the path lifting method to f for an appropriate number of steps. For simplicity, we present a scalar version here. However, there are well-known methods for evaluating the same polynomial f at m different points ($m \geq d$) in $\mathcal{O}\big(m(\log d)^2\big)$ arithmetic operations; refer to §4.5 of [BM75]. When computing the complexity in §2.7, we assume such methods are used. Note that this algorithm can be easily implemented on either a vector or parallel computer, so that one can iterate the d elements of $\mathcal{Z}_j$ simultaneously. Also note that if Smale's mean value conjecture holds, the extra iteration to obtain $\hat{z}$ is not needed; z_N is good enough. See the remarks following Lemma 1.4.

```
function scalar-iterate-PLM($f, z_0, j, \tau$)

Let $w_0 = |f(z_0)|e^{j\pi i/2}$.
Let $h = 1/27$.
Let $N = \left\lfloor \dfrac{\log_2(\tau/|w_0|)}{\log_2(26/27)} \right\rfloor$.
For $n = 1$ to $N$
    Let $w_n = (1-h)w_{n-1}$.
    Let $z_n = z_{n-1} - \dfrac{f(z_{n-1}) - w_i}{f'(z_{n-1})}$.
End for.
Let $\hat{z} = z_N - \dfrac{f(z_N) - \tau e^{j\pi i/2}}{f'(z_N)}$.
Return($\hat{z}$).
```

The next routine takes the output of `iterate-PLM` and uses the α function (defined in Lemma 1.3) to remove those elements that are not approximate zeros. Although the test $\alpha < \frac{1}{8}$ is sufficient, it is not a necessary condition. However, if the image of the initial points $\mathcal{Z}_j$ lie in a "good quadrant," we know by Lemma 2.5 below that we will have $\alpha < \frac{1}{8}$ for at least half of them, and so we are not in danger of discarding too many points.

```
function select-approx-zeros($\psi, \mathcal{Y}$)

Let $\mathcal{X} = \emptyset$.
For $j = 1$ to $\#(\mathcal{Y})$
    If $\alpha_\psi(y_j) < \frac{1}{8}$, then let $\mathcal{X} = \mathcal{X} \cup \{y_j\}$.
End For.
Return($\mathcal{X}$).
```

Once we have found approximate zeros for at least half of the roots of f_i (by applying `iterate-PLM` to at most 4 sets $\mathcal{Z}_j$), we further refine them by "polishing" with regular Newton's method. As in `iterate-PLM`, fast polynomial evaluation techniques can be used, but we present a scalar version here for simplicity.

```
function scalar-polish-roots($\psi, x_0, \tau$)

Let $M = 1 + \lfloor \log_2 \log_2 \left(64d(7/4)^d\right) / \tau \rfloor$.
For $n = 1$ to $M$
    Let $x_n = x_{n-1} - \dfrac{\psi(x_{n-1})}{\psi'(x_{n-1})}$.
End For.
Return($x_M$).
```

Finally, we remove from the set of approximations any points that approximate the same root of ψ. We do this by taking the approximation that minimizes $|\psi|$, and then making a pass through the rest of them and accepting only those that approximate different roots from the ones previously accepted.

```
function weed-out-duplicates($\psi, \mathcal{W}$)

Sort $\mathcal{W}$ so that $|\psi(w_1)| \leq |\psi(w_2)| \leq \ldots \leq |\psi(w_n)|$.
Let $\mathcal{V} = \{w_1\}$.
For $j = 2$ to $\#(\mathcal{W})$
    If $|w_j - v| > 3|\psi(w_j)|/|\psi'(w_j)|$ for all $v \in \mathcal{V}$, then let $\mathcal{V} = \mathcal{V} \cup \{w_j\}$.
End For.
Return($\mathcal{V}$).
```

At this point we have found approximations to at least half of the roots of f_i. We divide them out to obtain a new polynomial f_{i+1} of smaller degree, using a standard technique involving the finite Fourier matrix.

```
function deflate($\psi, \mathcal{V}$)

Let $n = \deg \psi - \#\mathcal{V}$.
Let $\omega = e^{2\pi i/(n+1)}$.
Let $p(z) = \prod_{k=1}^{\#\mathcal{V}} (z - v_k)$.
Let $\mathcal{M}^{-1}$ be the inverse of the $n \times n$ Fourier matrix. That is, $m_{j,k} = \omega^{-jk}/n$.
Let $\mathcal{P}$ be the column vector with entries $p_j = \dfrac{\psi(\omega^j)}{p(\omega^j)}$, $j = 0, \ldots, n$.
Let $\mathcal{Q} = \mathcal{M}^{-1}\,\mathcal{P}$.
Let $q(z) = \sum_{j=0}^{n} q_j z^j$.
Return($q$).
```

We now state our main theorem, which essentially says that the algorithm just presented works.

THEOREM 2.1. *Given a monic polynomial $\phi(z)$ of degree d and $\epsilon > 0$, the algorithm presented in this section will always terminate with d points $\lambda_1, \dots, \lambda_d$ that satisfy*

$$\|\phi(z) - \prod_{j=1}^{d}(z - \lambda_j)\| < \epsilon.$$

For $\phi \in \mathcal{P}_d(1)$, the worst case arithmetic complexity of this algorithm is

$$\mathcal{O}\big(d(\log d)^2 |\log \epsilon| + d^2(\log d)^2\big).$$

COROLLARY 2.2. *Let ϕ and ϵ be as in the theorem, and denote the roots of ϕ by ξ_j, represented with multiplicity. Then the algorithm can be used to produce the approximations λ_j satisfying*

$$|\xi_j - \lambda_j| < \epsilon,$$

with a worst-case arithmetic complexity of

$$\mathcal{O}\big(d^2(\log d)^2 |\log \epsilon| + d^2(\log d)^2\big).$$

Proof. This is an immediate consequence of the fact that if f and g are in $\mathcal{P}_d(1)$ with $\|f - g\| < (\epsilon/8d)^d$, then the roots of f and g are at most ϵ apart (See [Kim89b]). □

We prove the theorem as a series of lemmas in the following sections. There is a rough correspondence between the sections and the routines in the algorithm. Finally, we summarize all of these lemmas and give the proof in §2.8.

2.2. Selection of initial points. For each intermediate polynomial f_i, we need to select four sets of ($\deg f_i$) points at which to begin our iteration. These must be chosen so that the elements of each set map very near the same point in the target space, and the images of elements in successive groups are approximately $\frac{1}{4}$-turn apart. This can be accomplished either by evaluating f_i at a large number of points spaced around a circle in the source space, and then selecting from those, or by taking a much smaller number (perhaps as few as $4d$) of points and adjusting them with either a standard or modified Newton's method. The arithmetic complexity of either comes out much the same; we opt for the former method because of its conceptual simplicity.

The following lemma gives us bounds on how much the argument in the target space can vary between points around a circle containing all the roots in the source space. Using this, we see how many points are required to obtain our "good" points.

LEMMA 2.3. *Suppose all of the roots ζ of a polynomial f of degree d lie in $\mathbb{D}_R(0)$, and let*

$$\omega_m = 2R\,\mathrm{e}^{\frac{2\pi i m}{nd}}.$$

Then

$$\left|\arg \frac{f(\omega_{m+1})}{f(\omega_m)}\right| \le \frac{4\pi}{n}.$$

Proof. This argument appears in [Ren87, Lem. 7.1], although in a somewhat different form. We present an adapted version here. The idea is quite simple. Since

$$\arg \frac{f(\omega_{m+1})}{f(\omega_m)} = \arg \frac{\prod_{i=1}^{d}(\omega_{m+1} - \zeta_i)}{\prod_{i=1}^{d}(\omega_m - \zeta_i)} = \sum_{i=1}^{d} \arg \frac{\omega_{m+1} - \zeta_i}{\omega_m - \zeta_i},$$

we merely bound the angles in the source space and add them up.

Note that each root $|\zeta_i| < R$ and $|\omega_m| = 2R$, so

$$\begin{aligned}\left|\arg \frac{\omega_{m+1} - \zeta_i}{\omega_m - \zeta_i}\right| &\le 2\arctan \frac{|\omega_{m+1} - \omega_m|/2}{2R\cos\frac{\pi}{nd} - R} \\ &\le 2\arctan \frac{2R\sin\frac{\pi}{nd}}{2R(\cos\frac{\pi}{nd} - \frac{1}{2})} \\ &\le \frac{4\pi}{nd}.\end{aligned}$$

Refer to Fig. 2.1. Summing the d terms gives the result. □

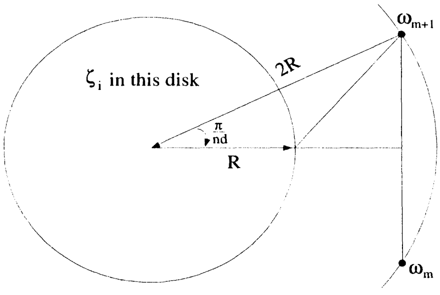

FIG. 2.1. *Calculation of the upper bound on the variation of argument in the target space. This picture is in the source space.*

From Theorem 1.5, for $h = \frac{1}{27}$ we require that our initial points be within $\sin^{-1}(\frac{h}{2}) < \frac{\pi}{169}$ of the central ray, so we start with $676d$ points equally spaced around the circle of radius $\frac{3}{2}$. We then evaluate the polynomial at each of them, and select four sets of d points whose arguments are closest to 0, $\frac{\pi}{2}$, π, and $\frac{3\pi}{2}$, respectively. For each of these, we take the initial target point w_0 to be the projection of its image onto the real or imaginary axis.

Remark. Some amount of computation can be saved if we use the same w_0 for all d elements of a given set of initial points, rather than just points with the same argument. This would make the computation of the w_n a scalar rather than a vector operation, that is, w_n would only need to be computed once for each group of d points. However, in order to do this, we must ensure that the images of each z_j in a set have approximately the same modulus as well as argument. This is best accomplished using some sort of Newton's method.

If an initial Newton's method is used, one can also choose a much smaller number of trial points ω_i. Such a method should converge well, since all the critical points of $f(z) - w_0$ are inside $\mathbb{D}_R$, while the roots of $f(z) - w_0$ and the ω_i are well outside.

2.3. Iteration of the path lifting method. In this section, we analyze the behavior of applying the path lifting method to a single well-chosen initial value z_0.

We first prove the theorem as promised in §1.3, and then we show that after a specified number of iterations, the result will be an approximate zero. Before doing this, we shall state the relevant special case of of [Kim88, Thm. 3.2], which gives a lower bound on how far a point moves under Newton's method.

LEMMA 2.4. *Let $\hat{z} = z - g(z)/g'(z)$, with $r = |g(z)|/R_g(z) < 0.148$, where $R_g(z)$ is the radius of convergence of g_z^{-1} as a power series based at z. Then*

$$\left|\frac{g(\hat{z})}{g(z)}\right| \leq B(r) \qquad where \qquad B(r) = 2r\frac{(1+r)^3}{(1-r)^5}.$$

Given this lemma, the proof of Theorem 1.5 is quite simple. Note that each step of the iteration in Theorem 1.5 corresponds to Newton's method applied to $f(z) - w_{n+1}$ at z_{n-1}.

THEOREM 1.5. *Suppose that the branch of the inverse $f_{z_0}^{-1}$ is analytic on a wedge $\mathcal{W}_{A,w_0}$, with $0 \leq A \leq \frac{\pi}{2}$, and let $h \leq \frac{\sin A}{19}$. Suppose also that $|f(z_0) - w_0| < h|w_0|/2$, and define*

$$w_n = (1-h)^n w_0, \qquad z_{n+1} = z_n - \frac{f(z_n) - w_{n+1}}{f'(z_n)}.$$

Then $|f(z_n) - w_n| \leq h|w_n|/2$ and $z_{n+1} \in f_{z_0}^{-1}\left(\mathcal{W}_{A,w_n}\right)$.

Proof. We shall prove this by induction. All that is required is to establish the conclusion, given that $|f(z_{n-1}) - w_{n-1}| < h|w_{n-1}|/2$.

Note that

$$|f(z_{n-1}) - w_n| \leq |f(z_{n-1}) - w_{n-1}| + |w_{n-1} - w_n| \leq 3h|w_{n-1}|/2,$$

and that

$$R_{f-w_n}(z_{n-1}) = R_f(z_{n-1}) \geq |w_n| \sin A - h|w_n|/2.$$

Since $h \leq \frac{\sin A}{19}$, we can apply Lemma 2.4 with $g(z) = f(z) - w_n$ and $r = \frac{3}{37}$ to obtain

$$\left|\frac{f(z_n) - w_n}{w_n}\right| = \left|\frac{f(z_n) - w_n}{f(z_{n-1}) - w_n}\right| \cdot \left|\frac{f(z_{n-1}) - w_n}{w_{n-1}(1-h)}\right| \leq B(r)\frac{3h}{2(1-h)}.$$

Because $B(\frac{3}{37}) < (1-h)/3$, we have our conclusion. □

Remark. The denominator of 19 in the upper bound on h can be relaxed only slightly in this proof. If we take $h \leq \frac{\sin A}{k(A)}$, then $k(A)$ is a monotonically increasing function, with $18.3096 \leq k(A) \leq 18.895$. Also, if $A > \frac{\pi}{2}$, we can take $h = \frac{1}{19}$.

We apply the path lifting method until we have an approximate zero, at which time we can use the standard Newton iteration. Since we are interested in finding τ-roots of f, we stop the iteration once we have an approximate zero for $f - \tau\frac{w_0}{|w_0|}$. Note that, as discussed in §2.1, this translation is necessary, since there are no approximate zeros in a neighborhood of a multiple root. Having approximate zeros for the perturbed polynomial gives us the following bound on the number of iterations required, and enables the weeding out of duplicates.

LEMMA 2.5. *Let $h \leq \frac{\sin A}{19}$, with w_i and z_i as in Theorem 1.5. If*

$$N = \left\lfloor \frac{\log_2(\tau/|w_0|)}{\log_2(1-h)} \right\rfloor,$$

then z_N is an approximate zero for $f - \tau\frac{w_0}{|w_0|}$. Furthermore, if

$$\hat{z} = z_N - \frac{f(z_N) - \tau\frac{w_0}{|w_0|}}{f'(z_N)}$$

then we have $\alpha(\hat{z}) \leq \frac{1}{8}$.

Proof. For notational convenience, set $\vec{\tau} = \tau\frac{w_0}{|w_0|}$.

By assumption, $f_{z_0}^{-1}$ is analytic on the wedge $\mathcal{W}_{A,w_0}$, and the initial point z_0 is close enough to w_0 that we can apply Theorem 1.5. Note that if N is as specified, we have

$$\tau \leq |w_N| \leq \frac{\tau}{1-h},$$

since $|w_N| = (1-h)^N|w_0|$ by definition. Also, $|f(z_N) - w_N| \leq h|w_N|/2$. Refer to Fig. 2.2.

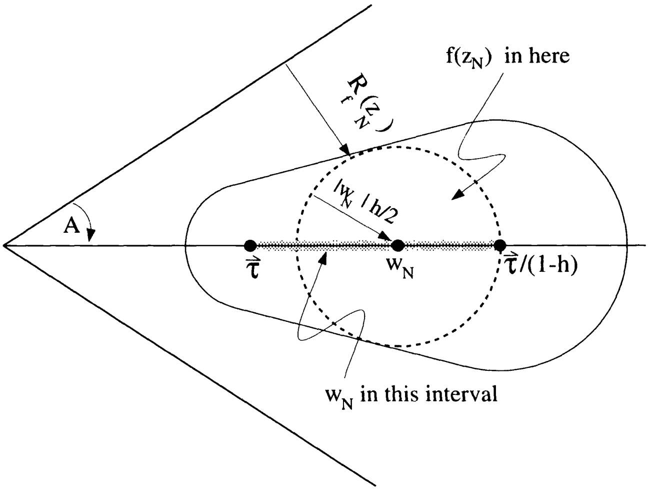

FIG. 2.2. *The locations of w_N and $f(z_N)$ in the target space when z_0 is in a "good quadrant."*

In order to conclude that z_N is an approximate zero, we need to show that we have $|f(z_N) - \vec{\tau}|/R_f(z_N) < \frac{1}{10}$, where $R_f(z_N)$ is the radius of convergence of $f_{z_N}^{-1}$. Consider $f(z_N)$ in some circle of radius $h|w|/2$, where $\arg w = \arg w_0$, and $|w| > \tau$. Then we have

$$\frac{|f(z_N) - \vec{\tau}|}{R_f(z_N)} \leq \frac{|w| + h|w|/2 - \tau}{|w|\sin A - h|w|/2} = \frac{2+h}{2\sin A - h} - \frac{\tau}{|w|(\sin A - h/2)}.$$

The maximum of this quantity occurs when $|w|$ is as large as possible, which in our case is $|w| = \tau/(1-h)$. Hence

$$\frac{|f(z_N) - \vec{\tau}|}{R_f(z_N)} \leq \frac{3h}{2\sin A - h} \leq 3/37 < 1/10.$$

By Lemma 1.4, z_N is an approximate zero of $f(z) - \vec{\tau}$.

In order to ensure that $\alpha < \frac{1}{8}$, we need to apply Newton's method once. Set

$$\hat{z} = z_N - \frac{f(z_N) - \vec{\tau}}{f'(z_N)}.$$

Then this point satisfies

$$\frac{\left|f(\hat{z}) - \vec{\tau}\right|}{|f(z_N) - \vec{\tau}|} \leq B(3/37) \leq 0.31271,$$

and so

$$\left|f(\hat{z}) - \vec{\tau}\right| \leq 0.31271\,(|f(z_N) - w_N| + |w_N| - \tau) \leq 0.31271\frac{3h\tau}{2(1-h)} \leq \frac{\tau\sin A}{39}.$$

This gives us

$$\frac{|f(\hat{z}) - \vec{\tau}|}{R_f(\hat{z})} \le \frac{\tau \sin A/39}{\tau \sin A - \tau \sin A/39} = 1/38.$$

As a consequence of Lemma 1.4, we have $\alpha(\hat{z}) < \frac{1}{8}$. □

2.4. Refinement of the root approximations. The routine `iterate-PLM` outputs a set of points $\mathcal{Y} = \{y_1, y_2, \ldots, y_d\}$ that may be approximate zeros for $\psi(z) = f(z) - \vec{\tau}$. We can use α_ψ (see Lemma 1.3) to choose those y_i that are indeed approximate zeros; we discard those y_i for which $\alpha_\psi(z) > \frac{1}{8}$. As a consequence of Lemmas 1.4 and 2.5, those y_i that started in the "good sector" will not be discarded.

In addition, we also want to ensure that we approximate each root only once (counted with multiplicity). Lemma 2.7 gives us conditions that allow us to weed out any duplicates; the proof relies on a variant of the Koebe Distortion Theorem which we quote here from [Kim88, Lem. 3.3].

LEMMA 2.6. *Let g be univalent on $\mathbb{D}_R(z)$. Then for any $s < 1$, we have*

$$\mathbb{D}_{tR}(g(z)) \subset g(\mathbb{D}_{sR}(z)) \subset \mathbb{D}_{uR}(g(z)),$$

where $t = s|g'(z)|/(1+s)^2$ and $u = s|g'(z)|/(1-s)^2$.

LEMMA 2.7. *Suppose that y_1 and y_2 are approximate zeros of $\psi(z)$, with $|\psi(y_1)| \ge |\psi(y_2)|$, and $R_\psi(y_j) \ge 12\psi(y_j)$, where $R_\psi(y_j)$ is the radius of convergence of $\psi_{y_j}^{-1}$. Then y_1 and y_2 approximate the same simple root ξ of ψ if and only if*

$$|y_1 - y_2| < \left|\frac{3\psi(y_1)}{\psi'(y_1)}\right|.$$

Proof. If y_1 and y_2 approximate the same simple root, then we have $\psi_{y_1}^{-1} = \psi_{y_2}^{-1}$. Since $|\psi(y_1) - \psi(y_2)| \le 2|\psi(y_1)|$, we have $\psi(y_2) \in \mathbb{D}_{2|\psi(y_1)|}(\psi(y_1))$. Thus we can apply Lemma 2.6 with $g = \psi^{-1}$, which is univalent on the disk of radius $R = 12|\psi(y_1)|$. Taking $s = \frac{1}{6}$, we have

$$\psi^{-1}\left(\mathbb{D}_{2|\psi(y_1)|}(\psi(y_1))\right) \text{ contained in the disk of radius } \frac{72|\psi(y_1)|}{25|\psi'(y_1)|} \text{ about } y_1,$$

so

$$|y_1 - y_2| < \frac{3|\psi(y_1)|}{|\psi'(y_1)|}.$$

For the other direction, we apply the Koebe $\frac{1}{4}$-Theorem (or Lemma 2.6 with $s = 1$; it is the same thing) to see that $\psi_{y_1}^{-1}\left(\mathbb{D}_{12|\psi(y_1)|}(\psi(y_1))\right)$ contains the disk of radius $3|\psi(y_1)|/|\psi'(y_1)|$ about y_1. Thus, if the distance between y_1 and y_2 is less than this amount, we must have $\psi_{y_1}^{-1}(\psi(y_2)) = y_2$, that is, y_1 and y_2 approximate the same root of ψ. □

Remark. Note that $\alpha_\psi(z) < \frac{1}{8}$ is not sufficient to imply that the hypotheses of Lemma 2.7 are satisfied, since this only gives $R_\psi(z) \ge 4|\psi(z)|/3$. However, if Newton's method is applied to such a point at least 3 times, the value of $|\psi|$ will decrease by at least $\frac{1}{128}$, and so the lemma can be applied. Since we need to "polish" the approximations with Newton's method in order to control the error in the deflation, we do that before weeding out the duplicates. The total number of iterations of Newton's method required is calculated in §2.6, but it is greater than three in all cases. In practice, one should probably perform the weeding in the routine `select-approx-zeros`, in order to avoid polishing points that will be discarded later.

2.5. Deflation of intermediate polynomials. Here we compute an explicit bound on the error introduced by the deflation step. We start with a polynomial ψ which has roots $\{\xi_j\}_{j=1,\dots,d}$, and a set of approximations to these roots that we denote by $\{v_k\}_{k=1,\dots,n}$ with $n \leq d$. We then use polynomial interpolation via the discrete Fourier matrix to obtain a polynomial q of degree $d-n$ so that

$$\psi(z) \approx p(z)q(z), \qquad \text{where} \qquad p(z) = \prod_{k=1}^{n}(z - v_k).$$

In this section, we estimate $\|\psi(z) - p(z)q(z)\|$, as well as the accumulated error in repeating this process until $q(z)$ is a constant.

Recall that the finite Fourier matrix $\mathcal{M}$ has as its j, kth entry the jkth power of a primitive $d+1$st-root of unity. That is,

$$m_{j,k} = \omega^{jk} = \mathrm{e}^{2\pi \mathrm{i} jk/(d+1)} \qquad j,k = 0,\dots,d.$$

Then one can readily see that if $f(z) = \sum_{j=0}^{d} a_j z^j$ and $\mathcal{A}$ is the column vector of the coefficients of f, then the product $\mathcal{MA}$ will be the vector $\mathcal{B}$ whose jth entry is the value of $f(\omega^j)$. Also, given the values of f evaluated at the powers of ω, we can easily compute the coefficients of f as the product $\mathcal{M}^{-1}\mathcal{B}$.

Our first lemma gives us estimates on the size of the error caused by a single deflation. As is common with this sort of thing, the proof is neither terribly entertaining or enlightening.

LEMMA 2.8. *Suppose $\psi(z) = \prod_{j=1}^{d}(z-\xi_j)$, with $|\xi_j| < \frac{3}{4}$, factors as $\psi(z) = P(z)Q(z)$, where $\deg(P) = n < d$ and $\deg(Q) = m = d-n$. Let $p(z) = \prod_{j=1}^{n}(z - v_j)$, with $|\xi_j - v_j| < \delta < 1/8d^2$, and define $q(z)$ and $r(z)$ by $\psi(z) = p(z)q(z) + r(z)$, where q is found by polynomial interpolation as described above. Then*

$$\begin{aligned} \|P(z) - p(z)\| &< 8n\delta\,(7/4)^n \\ \|Q(z) - q(z)\| &< 8m\delta\,(7/4)^m \\ \|r(z)\| &< 8d\delta\,(7/4)^d\,. \end{aligned}$$

Proof. Let $\omega = \mathrm{e}^{2\pi\mathrm{i}/(n+1)}$, and let $\mathcal{B}$ be the vector with entries $b_j = P(\omega^j) - p(\omega^j)$, for $0 \leq j \leq n$. Note that

$$\begin{aligned} b_j &= \prod_{k=1}^{n}(\omega^j - \xi_k) - \prod_{k=1}^{n}(\omega^j - v_k) \\ &= \left(\prod_{k=1}^{n}(\omega^j - \xi_k)\right)\left(1 - \prod_{k=1}^{n}\frac{\omega^j - v_k}{\omega^j - \xi_k}\right) \\ &= \left(\prod_{k=1}^{n}(\omega^j - \xi_k)\right)\left(1 - \prod_{k=1}^{n}\left(1 + \frac{\xi_k - v_k}{\omega^j - \xi_k}\right)\right). \end{aligned}$$

Also note that

$$\frac{1}{4} < |\omega^j - \xi_k| < \frac{7}{4} \qquad \text{and} \qquad \left|\frac{\xi_k - v_k}{\omega^j - \xi_k}\right| \leq 4\delta.$$

Since $4\delta \leq 1/2d^2 < 1/2n^2$, we have $(1+4\delta)^n \leq 8n\delta + 1$, and so

$$|b_j| < (7/4)^n\big((1+4\delta)^n - 1\big) < 8n\delta\,(7/4)^n.$$

Thus

$$\|P(z) - p(z)\| = \|\mathcal{M}^{-1}\mathcal{B}\| \leq \|\mathcal{B}\| < 8n\delta\,(7/4)^n.$$

We have a similar computation for the bound on $\|Q - q\|$: Let $\eta = e^{2\pi i/(m+1)}$ and let $\mathcal{C}$ be the vector with entries $c_j = Q(\eta^j) - q(\eta^j)$, $j = 0, \dots, m$. Then

$$c_j = \frac{\psi(\eta^j)}{P(\eta^j)} - \frac{\psi(\eta^j)}{p(\eta^j)} = \frac{\psi(\eta^j)}{P(\eta^j)}\left(1 - \frac{P(\eta^j)}{p(\eta^j)}\right) = Q(\eta^j)\left(1 - \prod_{k=1}^{m}\frac{\eta^j - v_k}{\eta^j - \xi_k}\right).$$

As in the case of $P(z) - p(z)$, we obtain

$$\|Q(z) - q(z)\| = \|\mathcal{M}^{-1}\mathcal{C}\| \leq \|\mathcal{C}\| < 8m\delta\,(7/4)^m.$$

Finally, for the bound on $\|r(z)\|$, note that $r(z) = P(z)Q(z) - p(z)q(z)$. If we write $r(z) = \sum_{j=0}^{d} r_j z^j$, $P(z) = \sum_{j=0}^{d} P_j z^j$, and so on, then we have

$$r_j = \sum_{k=0}^{j} P_{j-k}Q_k - \sum_{k=0}^{j} p_{j-k}q_k = \sum_{k=0}^{j}\big(q_k(P_{j-k} - p_{j-k}) - P_{j-k}(Q_k - q_k)\big).$$

Since $|\xi_j| < \frac{3}{4}$, we have the following crude bounds on the coefficients of P and q:

$$|P_{j-k}| \leq (7/4)^n \qquad \text{and} \qquad |q_j| \leq (7/4)^m.$$

Combining this with the bounds on $\|P - p\|$ and $\|Q - q\|$, we get

$$\begin{aligned} |r_j| &\leq \sum_{k=0}^{j}\big(8m\delta\,(7/4)^m\,(7/4)^n + 8n\delta\,(7/4)^n\,(7/4)^m\big) \\ &\leq 8jd\delta\,(7/4)^d \\ &\leq 8d^2\delta\,(7/4)^d. \qquad \square \end{aligned}$$

Now that we have bounds on the error in one step of deflation, we can bound the error introduced by repeated deflation. We assume that our initial polynomial f has roots in $\mathbb{D}_{1/2}$ so that we can ensure that the roots of the subsequent polynomials f_k remain in $\mathbb{D}_{3/4}$ as required by Lemma 2.8.

LEMMA 2.9. *Suppose* $f(z) = \prod_{j=1}^{d}(z - \zeta_j)$, *with* $|\zeta_j| < \frac{1}{2}$. *Let* $f_0 = f$, *and define*

$$f_k(z) = p_{k+1}(z)f_{k+1}(z) + r_{k+1}(z)$$

for $0 < k < m - 1$, *where* p_j, f_j, *and* r_j *are determined by polynomial interpolation as in Lemma* 2.8, *with* $f_m(z) = 1$. *Suppose also that* $\deg r_{k+1} < \deg f_k = d_k$, *and that*

$$\|r_k\| < \min\left(\frac{1}{4(4d)^d}, \mu(4/7)^{d+3}\right).$$

Then

$$\|f - p_1p_2\cdots p_m\| < \mu.$$

Furthermore, if we have $d_k \leq d_{k-1}/2$ *and* $\mu \leq (7/16)^d$, *we need only require that* $\|r_k\| < \mu(4/7)^{d+3}$.

Proof. Note that $f - p_1p_2\cdots p_m = p_1\cdots p_m r_{m-1} + \cdots + p_1r_2 + r_1$, and so

$$\|f - p_1p_2\cdots p_m\| \leq \|p_1\cdots p_{m-1}\|\|r_{m-1}\| + \cdots + \|p_1\|\|r_2\| + \|r_1\|.$$

First, we show that $\|p_1\cdots p_k\| \leq (7/4)^{\deg p_1\cdots p_k}$. We shall use induction to show that the roots of $p_1\cdots p_k$ are always in the circle of radius $\frac{1}{2}+\frac{k}{4d} < \frac{3}{4}$. On the circle $|z| = \frac{1}{2}+\frac{k}{4d}$, we have

$$|f_{k-1}(z) - p_k(z)f_k(z)| \leq \|r_k\| \sum_{j=0}^{\deg r_k} |z|^j \leq \frac{d}{(4d)^d(2d-k)} \leq \frac{1}{(4d)^d} \leq |f_{k-1}(z)|,$$

and so by Rouché's Theorem the roots of p_kf_k lie inside $\mathbb{D}_{\frac{1}{2}+\frac{k}{4d}}$. Thus the roots of $p_1p_2\cdots p_k$ also lie in this disk, and so the coefficients are less than $(7/4)^{\deg p_1\cdots p_k}$.

Since $\deg p_1p_2\cdots p_k < d-(m-k)$, we can conclude that

$$\begin{aligned}\sum_{k=1}^{m-1} \|p_1p_2\cdots p_k\|\|r_{k+1}\| &\leq \sum_{k=1}^{m-1} (7/4)^{d-(m-k)}\,(4/7)^{d+3}\,\mu \\ &\leq \frac{4}{3}\,(7/4)^{d+2}\,(4/7)^{d+3}\,\mu \\ &< \mu.\end{aligned}$$

If we require that $d_k \leq d/2^k$, that is, we find at least half of the roots at each step, then we can relax the restriction on $\|r_k\|$ somewhat. If we have $\|r_k\| \leq 1/(4\cdot 4^d)$, then we can use Rouché's Theorem as before to show that the roots of p_kf_k are in the disk of radius $C_k = \frac{1}{2}+\frac{1}{2}\sum_{n=1}^k 2^{-2^k} < 3/4$. Note that for $|z| = C_k$, we have

$$|f_{k-1}(z)| \geq (C_k - C_{k-1})^{d_{k-1}} \geq \left(\frac{1}{2\cdot 2^{2^k}}\right)^{d/2^{k-1}} \geq 1/4^d.$$

Applying almost the same argument as before, we have

$$|f_{k-1}(z) - p_k(z)f_k(z)| \leq \|r_k\| \sum_{j=0}^{\deg r_k} |z|^j \leq \frac{1}{4^d} \leq |f_{k-1}(z)|.$$

Since $\|r_k\| < \mu(4/7)^{d+3} < 1/(4\cdot 4^d)$, we are done. □

2.6. Controlling the error. In this section, we compute the size of τ that we can use to ensure we have an ϵ-factorization of ψ. The following very simple proposition shows that if the norms of two polynomials are close, so are the norms of the rescaled versions. This gives us the relationship between ϵ and the number μ used in Lemma 2.9.

PROPOSITION 2.10. *Suppose that ϕ is a monic polynomial with all its roots in $\mathbb{D}_R$, so that the roots of $f(z) = (2R)^{-d}\phi(2Rz)$ are in $\mathbb{D}_{1/2}$. Then if $\|f - p\| \le \epsilon$, we have*

$$\left\|\phi(z) - (2R)^d p\left(\frac{z}{2R}\right)\right\| \le (2R)^d \epsilon.$$

Proof. Let $f(z) = \sum a_j z^j$ and $p(z) = \sum b_j z^j$. Then $\phi(z) = \sum (2R)^{d-j} a_j z^j$ and $(2R)^d p\left(\frac{z}{2R}\right) = \sum (2R)^{d-j} b_j z^j$. Since $\max|\sum (2R)^{d-j}(a_j - b_j)| \le (2R)^d |a_j - b_j|$, we have our claim. □

Our input polynomial ϕ is in $\mathcal{P}_d(1)$ and f is the rescaled polynomial as in the previous proposition, so $R = 2$. Then an ϵ-factorization of ϕ corresponds to an $\epsilon/4^d$-factorization of f, so we take $\mu = \epsilon/4^d$.

In order to properly approximate the roots of f, we need to ensure that the remainder r_k (as in Lemma 2.9) at the kth step satisfies $\|r_k\| < 2\tau$, where $\tau = (4/7)^{d+3}\mu/2 = 32\epsilon/7^{d+3}$.

At each stage, we translate f_k by τ, and ensure that the error introduced by the deflation of the translated polynomial is no more than τ. By Lemma 2.8, we need the root distance between translated polynomial and the deflated polynomial to satisfy

$$\delta \le \frac{\tau}{8d}\left(\frac{4}{7}\right)^d.$$

Then we will have

$$\|r_k\| = \|f_{k-1} - p_k f_k\| \le \|(f_{k-1} - \vec{\tau}) - p_k f_k\| + \|(f_{k-1} - \vec{\tau}) - f_{k-1}\| \le \tau + \tau.$$

In order to achieve the root distance less than δ, we apply Newton's method to the approximate zeros found by the routine `iterate-PLM` (see Lemma 2.5). Since each point z is an approximate zero to the root ξ of the translated polynomial, we have by Definition 1.2

$$\delta \le 8\left(\frac{1}{2}\right)^{2^n} |z - \xi|.$$

Thus iterating Newton's method $\log_2 \log_2(\frac{8}{\delta})$ times, as is done in `polish-roots`, will give the desired result.

2.7. Arithmetic complexity. In this section we count the number of arithmetic operations involved in using the algorithm to obtain an ϵ-factorization of a polynomial in $\mathcal{P}_d(1)$.

In the main routine, we rescale the polynomial and then call `get-half-roots-and-deflate` at most $\log_2 d$ times, since at least half of the roots are found in each call.

- The cost of rescaling is $2d$ multiplications.
- Each call to `get-half-roots-and-deflate` calls the routine `choose-4d-good-initial-points` once, and makes at most four calls to each of `iterate-PLM`, `select-approx-zeros`, `polish-roots`, and `weed-out-duplicates`, and one call to `deflate`. As before, we denote the degree of the input polynomial by d and the degree of the kth intermediate polynomial by d_k.
  - The routine `choose-4d-good-initial-points` involves evaluation of f_k at $676d_k$ points, and $676d_k$ comparisons. Since we can evaluate f_k at m points with a cost of $\mathcal{O}\big(m(\log d_k)^2\big)$ operations (see [BM75]), this gives a total of $\mathcal{O}\big(d_k(\log d_k)^2\big)$ operations.
  - For `iterate-PLM`, each iteration evaluates

$$z_n - \frac{f(z_n) - w_{n+1}}{f'(z_n)}$$

at d_k points, which costs $\mathcal{O}\big(d_k(\log d_k)^2\big)$. This is done N times, where $N < 27\log\left(\frac{|w_0|}{\tau}\right)$. Note that since the roots of f are in $\mathbb{D}_{3/4}$ and $|z_0| = \frac{3}{2}$, we have $|w_0| = |f_k(z_0)| \leq (9/4)^{d_k}$. Since $\tau = 32\epsilon/7^{d+3}$, we have $N = C_1(d + |\log\epsilon|)$ for some constant C_1. This gives a total of

$$\mathcal{O}\big((d+|\log\epsilon|)(d_k(\log d_k)^2)\big)$$

operations.

- For `select-approx-zeros`, we need to evaluate α at d_k points, which requires evaluation of all the derivatives of f. This requires $\mathcal{O}\big(d_k^2(\log d_k)^2\big)$ operations.
- The routine `polish-roots` performs M iterations of Newton's method at d_k points. Since $M = C_2(\log d + \log|\log\epsilon|)$ for some constant C_2, we have a total operation count of

$$\mathcal{O}\big((d_k(\log d_k)^2)(\log d + \log|\log\epsilon|)\big).$$

- `Weed-out-duplicates` requires a sort of at most d_k points, which costs $\mathcal{O}(d_k\log d_k)$, and evaluation of f and f' at d_k points. Thus the total cost of this routine is $\mathcal{O}\big(d_k(\log d_k)^2\big)$.
- Lastly, `deflate` costs $\mathcal{O}\big(d_k(\log d_k)^2\big)$ operations.

Thus the overall cost of each call to `get-half-roots-and-deflate` is dominated by that of `iterate-PLM`, and is at most $\mathcal{O}\big(d_k(\log d_k)^2(d+|\log\epsilon|)\big)$ operations. Since $d_{k+1} \leq d_k/2$, we have a total cost of at most

$$\mathcal{O}\big(d^2(\log d)^2 + d(\log d)^2|\log\epsilon|\big)$$

operations to obtain an ϵ-factorization of the polynomial.

2.8. Summary and proof of main theorem. At this point, we have actually already proven Theorem 2.1, but we would like to tie together the various steps involved. Just to refresh your memory, this theorem says, in essence, that our algorithm always produces an ϵ-factorization with the stated complexity.

Recall that the algorithm performs the approximate factorization in stages using the routine `get-half-roots-and-deflate`; at the kth step, we produce a function f_k and sets of approximations Λ_j so that

$$f(z) \approx f_k(z)\prod_{\lambda_i\in\Lambda}(z-\lambda_i),$$

where $\Lambda = \bigcup_{j\leq k}\Lambda_j$. In order to prove Theorem 2.1, we need to show that the number of approximations found at the kth stage $(\#\Lambda_k)$ is at least $(\deg f_{k-1})/2$, and that $\|f(z) - f_k(z)\prod_{\lambda_i\in\Lambda}(z-\lambda_i)\| \leq \epsilon/4^d$. Given this, the complexity calculation in the previous section will apply, and we shall have the result.

First, note that as a consequence of Lemma 1.6, there will always be a quarter-plane in the target space on which at least $d_k/2$ branches of f_k^{-1} are defined. This means that if we start with d_k points z_j that are well-spaced in the source space (so that each sheet in the target space is represented), then for at least half of them there will be a branch of the inverse $f_{z_j}^{-1}$ defined on the entire quadrant, and $f_{z_i}^{-1} \neq f_{z_j}^{-1}$. For these points z_j, if we ensure that $f(z_j)$ is close enough to the center line of the quadrant, at least half of them will satisfy the hypothesis of Theorem 1.5 and so the routine `iterate-PLM` will produce approximations to each of the corresponding $d_k/2$ roots of f_k (with multiplicity). Such initial points z_j will be produced by `choose-4d-good-initial-points`, as was shown in §2.2. As a consequence of Lemma 2.5, the good approximations `iterate-PLM` are approximate zeros of $\psi = f_k - \vec{\tau}$, with $\alpha_\psi < \frac{1}{8}$. As was discussed in §2.4, application of the routines `select-approx-zeros` and `weed-out-duplicates` will select exactly one representative for each approximated root of ψ, giving at least $d_k/2$ such approximations λ_j. This selection is necessary since some of the initial z_j that did not satisfy the hypothesis of Theorem 1.5 may still have converged.

As was shown in §2.6, the approximations produced yield an $\epsilon/4^d$-factorization, since the each the λ_i are made sufficiently close to the roots of ψ by the routine `polish-roots`, and $\|\psi - f_k\|$ is sufficiently small. This completes the proof of Theorem 2.1.

COMPUTING AND VERIFYING DEPTH ORDERS*

MARK DE BERG†, MARK OVERMARS†, AND OTFRIED SCHWARZKOPF†

Abstract. A depth order on a set of line segments in 3-space is an order such that line segment a comes before line segment a' in the order when a lies below a' or, in other words, when there is a vertical ray that first intersects a' and then intersects a. Efficient algorithms for the computation and verification of depth orders of sets of n line segments in 3-space are presented. The algorithms run in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If all line segments are axis-parallel or, more generally, have only a constant number of different orientations, then the sorting algorithm runs in $O(n \log^3 n)$ time and the verification takes $O(n \log^2 n)$ time. The algorithms can be generalized to handle triangles and other polygons instead of line segments. They are based on a general framework for computing and verifying linear orders extending implicitly defined binary relations.

Key words. computational geometry, depth orders, three dimensions, linear extensions of partial orders

AMS subject classification. 68Q25

1. Introduction.

Hidden surface removal is an important problem in computer graphics. In a typical setting, we are given a set of nonintersecting polyhedral objects in 3-space and a view point and want to compute which parts of the objects can be seen from the view point.

An efficient way of solving this problem is the *painter's algorithm*; see, for example, [10]. In this algorithm one tries to "paint" the objects in a back-to-front order onto the screen. Thus the objects in the front are painted on top of the objects in the back, resulting in a correct view of the scene. Such a back to front ordering is called a *depth order* of the set of objects. Note that a depth order does not always exist, since there can be *cyclic overlap* among the objects, as is the case for the three triangles shown in Fig. 1. A closely related approach uses a binary space partition tree to obtain a displaying order for the objects in a scene [11]. A binary space partition (BSP) cuts the objects in such a way that there is a depth order in any direction. Unfortunately, the number of fragments and, hence, the size of the resulting BSP tree can be as large as $\Omega(n^2)$ [20]. Hence, this approach can be very wasteful if there is no cyclic overlap in the viewing direction.

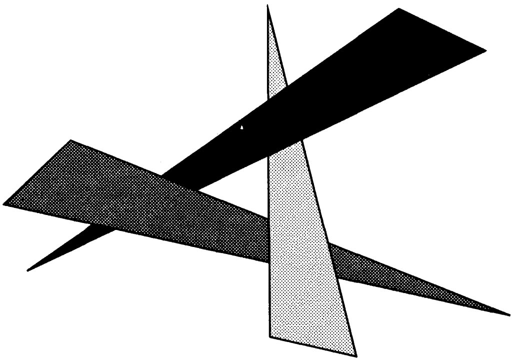

FIG. 1. *Cyclic overlap among triangles.*

The view of a scene consists of a subdivision of the viewing plane into maximal connected regions such that in each region either (some portion of) a single object can be seen or no

object is seen. Sometimes it is necessary to compute a combinatorial representation of this so-called *visibility map*. Note that the painter's algorithm does not give us such a combinatorial representation. The combinatorial complexity of the visibility map of a set of objects with n edges in total varies between $O(1)$ and $\Omega(n^2)$. Hence, it would be nice to have an *output-sensitive* algorithm, that is, an algorithm whose running time is dependent on the complexity of the visibility map. Almost all output-sensitive algorithms known to date require that a depth order on the objects is given; see, for example, [14], [16], [19], [21]. Only the recent algorithms of [8], [9] do not need a depth order. The implementation of the latter algorithms, however, is much easier when a depth order is known.

It is thus important to be able to compute depth orders efficiently. This problem was studied by Chazelle et al. [5]. When the objects are lines in 3-space, they noted that a depth order can be obtained by a standard sorting algorithm, because any two lines can be compared (assuming no two have parallel projections). If there is cyclic overlap, however, then the outcome of the sorting algorithm is not a valid depth order. Verifying whether a depth order is valid is no trivial matter though; in [5], Chazelle et al. presented an $O(n^{4/3+\varepsilon})$ time algorithm to verify a given depth order of a set of lines. When the objects are line segments in 3-space, the problem becomes much harder, since not every pair of line segments can be compared. For this case, the best algorithm that was known runs in time $O(n \log n + k)$, where k is the number of intersections in the projection plane, or, in other words, the number of pairs that can be compared directly [5], [18]. Note that k can be $\Theta(n^2)$ and, hence, that the worst-case running time of these algorithms is $\Theta(n^2)$. Even for the case of axis-parallel line segments, it was an open problem to find a depth order in $o(n^2)$ time [21].

In this paper we show that a depth order for a set of line segments in 3-space can be computed in subquadratic time. More specifically, we give an algorithm that computes a depth order in time $O(n^{4/3+\varepsilon})$. We also present an algorithm that verifies a given order in $O(n^{4/3+\varepsilon})$ time. When the line segments are c-oriented, that is, they have only c different orientations for some constant c, then the sorting algorithm runs in $O(n \log^3 n)$ time and verification takes $O(n \log^2 n)$ time. Note that axis-parallel line segments are 3-oriented. The results can be generalized to depth orders for sets of triangles, or other polygons, instead of line segments.

The algorithms that we give are surprisingly simple. They are based on a general framework for computing a linear order extending a relation $(S, \prec)$. It is easy to compute an order in time that is linear in the number of pairs that are related; to this end one sorts the directed graph $\mathcal{G} = (S, E)$ topologically, where $(a, a') \in E$ if and only if $a \prec a'$. This is the approach taken in [5], [18] to sort a set S of n line segments: first compute all pairs of line segments that are related—this can be done in $O(n \log n + k)$ time by computing all intersections in the projection plane—and then sort the corresponding graph $\mathcal{G}$ in $O(n + k)$ time. Note that if $(S, \prec)$ does not contain a cycle then the sorting will succeed, otherwise some cycle will be detected in the graph $\mathcal{G}$. We show that it is not necessary to compute the full graph corresponding to $(S, \prec)$. All that is needed is to have a data structure that answers the following question: Given an element $a \in S$, return a predecessor of a and a successor of a, if they exist. The data structure should allow for the deletion of an element a in S in sublinear time. In cases where the relation is given implicitly—such as for depth orders—this is often possible. Our algorithm uses an interesting form of divide-and-conquer, where the divide-step does not need to be balanced. In fact, the more unbalanced it is, the better the running time of the algorithm.

There is some previous work on the computation of a linear order that extends a partial order. This work is also in the context of depth orders, in particular, depth orders in two-dimensional space [12], [13], [23] and depth orders for spheres in 3-space [22]. Unfortunately, the solutions given in these papers do not generalize to our setting. Of related interest is also a paper by Kenyon-Mathieu and King [15], who describe an algorithm that verifies whether a given partial order holds on n elements from an unknown total order.

The rest of this paper is organized as follows. In §2 we present our general framework for computing a linear order extending a relation $(S, \prec)$, and in §3 we give an algorithm to verify a given order. In §4 we show how to use these results to compute or verify a depth order for a set of line segments (or triangles, or polygons) in 3-space. We make some concluding remarks in §5.

2. Computing linear extensions. Let $\prec$ be a binary relation defined on a set S of n elements. Note that $\prec$ is not necessarily a partial order, since we do not assume transitivity. This will be useful in our application. In this section it is shown how to compute a linear order extending $(S, \prec)$ or to decide that $(S, \prec)$ contains a cycle. Thus we want to compute an order $a_1, \ldots, a_n$ on the elements in S such that $a_i \prec a_j$ implies $i < j$. The algorithm that we will give for this problem needs a data structure $\mathcal{D}_\prec$ for storing a subset $S' \subseteq S$ that can return a predecessor in S' of a query element $a \in S$. More formally, QUERY$(a, \mathcal{D}_\prec)$ returns an element $a' \in S'$ such that $a' \prec a$ or *NIL* if there is no such element. We call such a query a *predecessor query*. Similarly, we need a structure $\mathcal{D}_\succ$ for *successor queries*. To make our algorithm efficient, the structures should allow for efficient deletions of elements from S' and the preprocessing time should not be too high.

Let us define $\prec_*$ to be the transitive closure of $\prec$ and $\succ_*$ to be the transitive closure of $\succ$. The basic strategy of the algorithm is divide and conquer: we pick a pivot element $a_{\mathrm{piv}} \in S$, partition the remaining elements into a subset $S_\prec$ of elements a that must come before a_{piv} in the order because $a \prec_* a_{\mathrm{piv}}$ and a subset $S_\succ$ of elements that must come after a_{piv} in the desired order because $a_{\mathrm{piv}} \prec_* a$, and recursively sort these sets. Note that not every pair of elements is comparable under $\prec_*$. Hence, except for the subsets $S_\prec$ and $S_\succ$, there is a third subset $S_\approx$ of elements that cannot be compared to a_{piv} under $\prec_*$. This subset should be sorted recursively as well. To find the subsets $S_\prec$ and $S_\succ$ efficiently, the data structures $\mathcal{D}_\prec$ and $\mathcal{D}_\succ$ are used. Consider the subset $S_\prec$. By querying $\mathcal{D}_\prec$ with element a_{piv}, we can find an element a such that $a \prec a_{\mathrm{piv}}$. We delete a from $\mathcal{D}_\prec$ to avoid reporting it more than once and query once more with a_{piv}. Continuing in this manner until the answer to the query is *NIL*, we can find all elements $a \in S$ such that $a \prec a_{\mathrm{piv}}$. However, we want to find all elements a such that $a \prec_* a_{\mathrm{piv}}$. Thus we also have to query $\mathcal{D}_\prec$ with the elements a that we have just found, query with the new elements that we find, and so forth. Whenever we find an element, it is deleted from $\mathcal{D}_\prec$ and we query with it until we have found all predecessors of it (that have not been found before). This way we can compute the set $S_\prec$ with a number of queries in $\mathcal{D}_\prec$ that is linear in the size of $S_\prec$. Notice that when we find a_{piv} as an answer to a query, there must be a cycle in the relation. The subset $S_\succ$ can be found in a similar way, using the data structure $\mathcal{D}_\succ$. The subset $S_\approx$ contains the remaining elements.

There is one major problem with this approach: we cannot ensure that the partitioning is balanced, that is, that the sets $S_\prec$, $S_\succ$, and $S_\approx$ have about the same size. Fortunately, we can circumvent this if we make the following two observations. First, we note that we need not treat the subset $S_\approx$ separately. We can put the elements of $S_\approx$ in either $S_\prec$ or $S_\succ$, as long as we do it consistently, that is, as long as we put all elements in the same set. It seems that this only makes things worse because the partitioning gets more unbalanced. But now we observe that it is enough to find the smaller of the two subsets $S_\prec$ and $S_\succ$. The remaining elements—which can be elements of $S_\approx$—are all put into one set. It is possible to find the smaller of the two subsets $S_\prec$ and $S_\succ$—without computing the complete larger set as well—with a number of queries that is linear in its size, by doing a "tandem search": alternatingly, find an element of $S_\prec$ and an element of $S_\succ$ until the computation of one of the two subsets has been completed. Thus we partition S into two subsets in time that is dependent on the size of the smaller of the two subsets. This means that the more unbalanced the partitioning is, the faster it is performed, leading to a good worst-case running time for the algorithm. There is one problem left that we have not addressed so far: we cannot afford to build the data structures that we need for the recursive call for the large set from scratch. Fortunately, we can obtain these structures from those that we have at the end of the tandem search by reinserting and deleting certain elements.

The algorithm for computing an ordering on $(S, \prec)$ first builds the data structures $\mathcal{D}_\prec$ and $\mathcal{D}_\succ$ on the set S and then calls the procedure ORDER, with the set S and these two data structures as arguments. Below follows a detailed description of this procedure, whose output is a linear order extending $(S, \prec)$ if one exists, and which detects a cycle otherwise. The algorithm maintains two queues $\mathcal{Q}_\prec$ and $\mathcal{Q}_\succ$, which store the elements of $S_\prec$ (respectively, $S_\succ$) for which we have not yet found all predecessors (respectively, successors). The procedure ENQUEUE adds an element to a queue. Similarly, DEQUEUE deletes an element from the queue. An element a is deleted from the data structure $\mathcal{D}_\prec$ by calling DELETE(a, $\mathcal{D}_\prec$); a deletion from $\mathcal{D}_\succ$ is performed with a similar call. To delete all elements in a set A, we simply write DELETE(A, $\mathcal{D}_\prec$).

The two main steps in the algorithm are steps 4 and 5. In step 4 of the algorithm the tandem search is performed; step 4(i) computes a new element of $S_\prec$, and step 4(ii) computes a new element of $S_\succ$. In step 5 the two sets that result from the partitioning are sorted recursively; to this end we first construct the data structures that are needed in the recursive calls. For the larger of the two sets the new data structures are obtained from the existing data structures, and for the smaller set the data structures are built from scratch.

```
ORDER(S,$\mathcal{D}_\prec$, $\mathcal{D}_\succ$)
1. **if** $|S| > 1$ **then** perform steps 2–6 **else** stop ($S$ is already sorted).
2. Make $S_\prec \leftarrow \emptyset$ and $S_\succ \leftarrow \emptyset$, and initialize two empty queues $\mathcal{Q}_\prec$ and $\mathcal{Q}_\succ$.
3. Pick an arbitrary pivot element $a_{\text{piv}} \in S$; ENQUEUE($a_{\text{piv}}$, $\mathcal{Q}_\prec$); ENQUEUE($a_{\text{piv}}$, $\mathcal{Q}_\succ$).
4. **while** both $\mathcal{Q}_\prec$ and $\mathcal{Q}_\succ$ are nonempty
   **do** (i) $a \leftarrow$ DEQUEUE($\mathcal{Q}_\prec$); $a' \leftarrow$ QUERY($a$, $\mathcal{D}_\prec$).
          **if** $a' \neq NIL$
          **then if** $a' = a_{\text{piv}}$
                 **then** Stop and report that there is a cycle.
                 **else** ENQUEUE($a$, $\mathcal{Q}_\prec$) ; ENQUEUE($a'$, $\mathcal{Q}_\prec$); DELETE($a'$, $\mathcal{D}_\prec$).
                      $S_\prec \leftarrow S_\prec \cup \{a'\}$.
       (ii) Compute a new element $a' \in S_\succ$ in a similar way, using $\mathcal{Q}_\succ$ and $\mathcal{D}_\succ$.
5. **if** $\mathcal{Q}_\prec$ is empty (hence, $S_\prec$ is the smaller set)
   **then** Reinsert the elements of $S_\succ$ into $\mathcal{D}_\succ$.
        DELETE($S_\prec \cup \{a_{\text{piv}}\}$, $\mathcal{D}_\succ$); DELETE($a_{\text{piv}}$, $\mathcal{D}_\prec$).
        Build new predecessor and successor structures $\mathcal{D}'_\prec$ and $\mathcal{D}'_\succ$ for the set $S_\prec$.
        ORDER($S_\prec$, $\mathcal{D}'_\prec$, $\mathcal{D}'_\succ$).
        ORDER($S - \{a_{\text{piv}}\} - S_\prec$, $\mathcal{D}_\prec$, $\mathcal{D}_\succ$).
   **else** Compute the data structures for the recursive calls as above, reversing the
        roles of $S_\prec$, $\mathcal{D}_\prec$ and $S_\succ$, $\mathcal{D}_\succ$, and sort $S_\succ$ and $S - S_\succ - \{a_{\text{piv}}\}$ recursively.
6. Concatenate $S_\prec$, $a_{\text{piv}}$, and $S_\succ$ to form the ordered list for $S$.
```

The following lemma proves the correctness of our algorithm.

LEMMA 2.1. *Procedure* ORDER *outputs a linear order extending* $(S, \prec)$ *if it exists and detects a cycle otherwise.*

Proof. It is straightforward to see that the algorithm never claims to have found a cycle that does not exist. It remains to show that if ORDER outputs a list $a_1, \ldots, a_n$ then this list is a correct ordering. Assume for a contradiction that $a_i \succ a_j$ for some $i < j$. Then, at some stage of the algorithm, a_i must have been put into $S_\prec$, whereas a_j was put into $S_\succ$, or a_i was put into $S_\prec$ and a_j was the pivot element a_{piv}, or a_i was the pivot element a_{piv} and a_j was put into $S_\succ$. The second and third case both imply that there is a cycle containing a_{piv}, and we can easily verify that step 3 never fails to discover a cycle containing the pivot element. We thus consider the first case: If $\mathcal{Q}_\prec$ is empty after step 3 then all predecessors of a_i have been found, including a_j. Hence, a_j would have been put into $S_\prec$ instead of $S_\succ$. (It may also happen that a_j is put into both sets, but in that case the algorithm would have reported a cycle containing the pivot element.) Similarly, if $\mathcal{Q}_\succ$ is empty then a_i would have been put into $S_\succ$. □

Next we prove a bound on the running time of the algorithm. Let us for the sake of simplicity assume that the query time of $\mathcal{D}_\prec$ and the query time of $\mathcal{D}_\succ$ are equal, and let this time be denoted by $Q(n)$. Similarly, let the time to build these structures on n elements be $B(n)$, and let $D(n)$ denote the time for a deletion.

LEMMA 2.2. *The procedure* ORDER *runs in* $O\left([B(n) + n(Q(n) + D(n))]\log n\right)$ *time. The running time reduces to* $O\left(B(n) + n[Q(n) + D(n)]\right)$ *if* $B(n)/n + Q(n) + D(n) = \Omega(n^\alpha)$ *for some constant* $\alpha > 0$.

Proof. Since all other operations in the procedure can be done in constant time, the time that we spend is dominated by the operations on the structures $\mathcal{D}_\prec$ and $\mathcal{D}_\succ$. Furthermore, if the size of the smaller of the two subsets $S_\prec$ and $S_\succ$ is m, then we perform at most $2m + 2$ queries and deletions on these structures in step 4 of the procedure. Restoring a data structure to a situation from the past, which we do in step 5, can be done without extra asymptotic overhead if we record all the changes. Finally, we perform m deletions in step 5, and we build new data structures for the smaller set. This adds up to $B(m) + O(1 + m)[Q(n) + D(n)]$ in total for the partitioning.

Next we argue that $m \leq n/2$ if the partitioning is successful, that is, if no cycle is found at this point. Suppose that $m > n/2$. Then there must be an element $a \in S_\prec \cap S_\succ$. But this means that a_{piv} will be found as a predecessor or a successor (whichever happens first) and a cycle is detected. Trivially, an unsuccessful partitioning happens at most once, giving a one-time cost of $O(n[Q(n) + D(n)])$.

It follows that the total running time $T(n)$ can be bounded by the recursion

$$T(n) \leq \max_{0 \leq m \leq n/2} \{B(m) + O(1 + m)[Q(n) + D(n)] + T(m) + T(n - m - 1)\},$$

which solves to the claimed time. □

Combining the two lemmas above, we obtain the following theorem.

THEOREM 2.3. *The procedure* ORDER *runs in* $O\left([B(n) + n(Q(n) + D(n))]\log n\right)$ *time and outputs an ordered list if* $(S, \prec)$ *does not contain a cycle or finds a cycle otherwise. The running time reduces to* $O\left(B(n) + n[Q(n) + D(n)]\right)$ *if* $B(n)/n + Q(n) + D(n) = \Omega(n^\alpha)$ *for some constant* $\alpha > 0$.

Remark. With a little extra effort, the algorithm can output a witness cycle, when $(S, \prec)$ cannot be ordered. To this end, we keep track of the successor (predecessor) of each element that we put into $S_\prec$ ($S_\succ$). This extra information enables us to "walk back" when we find a_{piv} in step 3 of the algorithm and report the elements of the cycle.

3. Verifying linear extensions. In this section it is shown how to verify a given order for a relation $(S, \prec)$. Notice that different orders can be valid for $(S, \prec)$, so it does not suffice to compute a valid order and compare it to the given order. The algorithm uses a straightforward divide-and-conquer approach. It relies on the existence of a data structure $\mathcal{D}_\prec$ for predecessor queries. Unlike in the previous section, however, this data structure need not be dynamic. The algorithm we describe next has a list $\mathcal{L} = \{a_1, \ldots, a_n\}$ as input. For this list we have to test whether it corresponds to a valid order. It will report that $\mathcal{L}$ is not sorted or run quietly when $\mathcal{L}$ is a valid ordering for $(S, \prec)$.

```
VERIFY($\mathcal{L}$)
if $|\mathcal{L}| > 1$
then Let $\mathcal{L}_1 = \{a_1, \ldots, a_{\lfloor n/2 \rfloor}\}$ and $\mathcal{L}_2 = \{a_{\lfloor n/2 \rfloor + 1}, \ldots, a_n\}$.
     Build a data structure $\mathcal{D}_\prec$ for predecessor queries on $\mathcal{L}_2$.
     for $i = 1$ to $\lfloor n/2 \rfloor$
     do if QUERY($a_i, \mathcal{D}_\prec$)$\neq$ NIL
        then Stop and report that $\mathcal{L}$ is not sorted
     VERIFY($\mathcal{L}_1$); VERIFY($\mathcal{L}_2$)
```

The correctness of the procedure is proved as follows. If $\mathcal{L}$ does not correspond to a valid order, then, by definition, there are elements a_i, a_j such that $a_i \prec a_j$ and $i > j$. Now either $i > \lfloor n/2 \rfloor$ and $j \leq \lfloor n/2 \rfloor$, or $i, j \leq \lfloor n/2 \rfloor$, or $i, j > \lfloor n/2 \rfloor$. The first case is tested by querying with the elements of $\mathcal{L}_1$ in the data structure $\mathcal{D}_\prec$, and the second and third possibilities are tested with the recursive calls for $\mathcal{L}_1$ and $\mathcal{L}_2$, respectively. The following theorem is now straightforward. As before, $B(n)$ denotes the time needed to build the structure $\mathcal{D}_\prec$ on a set of n elements, and $Q(n)$ denotes the query time.

THEOREM 3.1. *The procedure* VERIFY *verifies in* $O([B(n) + nQ(n)] \log n)$ *time whether a list* $\mathcal{L}$ *corresponds to an order for* $(S, \prec)$. *The running time of the procedure reduces to* $O\,(B(n) + nQ(n))$ *if* $B(n)/n + Q(n) = \Omega(n^\alpha)$ *for some constant* $\alpha > 0$.

Remark. Observe that if the procedure reports that $\mathcal{L}$ is not ordered, then it can report a witness pair a_i, a_j of elements such that $i < j$ and $a_j \prec a_i$. If the structure $\mathcal{D}_\prec$ is dynamic, then the algorithm can even report all conflicting pairs. When we test an element $a_i \in \mathcal{L}_1$, we just remove each element $a_j \in \mathcal{L}_2$ that conflicts with a_i from $\mathcal{D}_\prec$ and report the pair a_i, a_j, until no more conflicting elements are found. Then we reinsert the elements of $\mathcal{L}_2$ into $\mathcal{D}_\prec$ and test the next element of $\mathcal{L}_1$ in the same way.

4. Application to depth orders.

4.1. Depth orders for line segments. Let S be a set of n line segments in 3-space, and let $\vec{d}$ be the viewing direction. (The adaptation of the algorithms to "perspective depth orders," that is, depth orders with respect to a point, is straightforward.) We want to find a depth order on S for direction $\vec{d}$. In other words, we want to find a linear order extending the relation $(S, \prec)$, where $a \prec a'$ when there is a ray into direction $\vec{d}$ that first intersects line segment a' and then intersects line segment a. When $a \prec a'$, we say that a lies *behind* a' or that a' lies *in front of* a. Observe that $\prec$ is not necessarily a transitive relation. To apply Theorem 2.3, we need dynamic data structures that store a set $S' \subset S$ of line segments and enable us to find a line segment in S' lying behind (respectively, in front of) a query line segment. Define the *curtain* of a line segment into direction $\vec{d}$ to be the set of points q in 3-space such that there is a ray into direction $\vec{d}$ that first intersects a and then intersects q. If we want to find a line segment in S' lying in front of a query line segment a, we just have to check whether a intersects one of the curtains hanging from the line segments in S' and report the line segment holding that curtain. See Fig. 2. Finding a line segment lying behind a query line segment can be done in a similar way. Agarwal and Matoušek [2] have shown that intersection queries in a set of n curtains can be answered in time $O(n^{1/3})$ with a structure that uses $O(n^{4/3+\varepsilon})$ space and has an amortized update time of $O(n^{1/3+\varepsilon})$. (Note that the fact that the update time is amortized does not cause any difficulties for the analysis of the time bound.) If both the line segments holding the curtains and the query line segments are c-oriented, that is, they have only c different orientations for some constant c, then queries can be answered in time

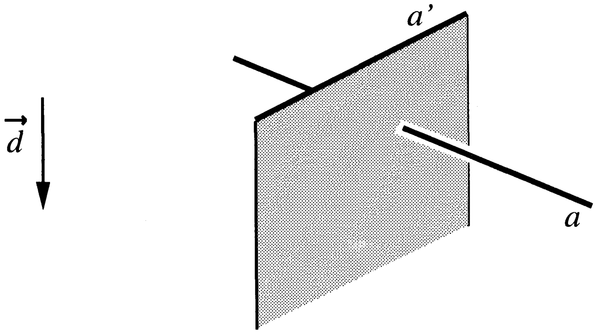

FIG. 2. *Line segment a lies behind line segment a′ and, hence, intersects its curtain.*

$O(\log^2 n)$ with a structure using $O(n \log n)$ space and with $O(\log^2 n)$ update time; see de Berg [7]. Combining this with Theorem 2.3 gives us the following result.

THEOREM 4.1. *Given a set S of n line segments in 3-space and a viewing direction $\vec{d}$, one can compute a depth order on S for direction $\vec{d}$ or decide that there is cyclic overlap among the line segments, in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the line segments are c-oriented then the time bound improves to $O(n \log^3 n)$.*

To verify a given depth order for a set of line segments in 3-space, we use the results of §3. In the general case, we again use Agarwal and Matoušek's structure for predecessor and successor queries. In the c-oriented case, we can use a more efficient structure than we used for computing depth orders: because the structure need not be dynamic, we can use the structure of de Berg and Overmars [9], which has $O(\log n)$ query time and $O(n \log n)$ preprocessing time. We immediately obtain the following theorem.

THEOREM 4.2. *It is possible to verify a depth order on a given set S of n line segments in 3-space for a viewing direction $\vec{d}$ in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the line segments are c-oriented then the time bound improves to $O(n \log^2 n)$.*

4.2. Depth orders for triangles. To extend our results to triangles instead of line segments, we only need to adapt the data structures for predecessor and successor queries. Let us discuss the structure for successor queries; to obtain a structure for predecessor queries we only have to reverse the roles of "behind" and "in front of."

A triangle t is in front of another triangle t' if and only if at least one of the following conditions holds: (i) an edge of t is in front of an edge of t', (ii) t is in front of a vertex of t', or (iii) a vertex of t is in front of t'. (A vertex v is in front of a triangle t' if there is a ray into the viewing direction that first intersects v and then intersects t'.) We already know how to find the triangles t' that satisfy condition (i) for a query triangle t. The triangles satisfying conditions (ii) and (iii) can be found as follows. Consider condition (ii) and assume, to simplify the description, that the viewing direction is the negative z-direction. Project all vertices onto the xy-plane, and let $\bar{t}$ be the projection onto the xy-plane of a query triangle t. To find a vertex in front of t we select all vertices whose projections are contained in $\bar{t}$ in a small number of groups; for such a group we can think of t as being a plane, and the question becomes that of reporting a point in a half-space in 3-space. The latter query can be answered in $O(\log n)$ time, using the half-space emptiness structure of Agarwal et al. [1]. This structure uses $O(n^{1+\varepsilon})$ preprocessing and has $O(n^{\varepsilon})$ update time. The selection can be done using a three-level partition tree: each level filters out those vertices lying on the appropriate side of the line through one of the three edges of $\bar{t}$. We use the partition tree of Matoušek [17], which allows for queries and updates in time $O(n^{1/3})$ (respectively, $O(n^{1/3+\varepsilon})$), and which uses $O(n^{4/3+\varepsilon})$ preprocessing time and space. Because the preprocessing and the query times in such a multi-level partition tree are essentially determined by the least efficient level, the preprocessing time, query time, and update time of the total structure remain $O(n^{4/3+\varepsilon})$, $O(n^{1/3})$, and $O(n^{1/3+\varepsilon})$, respectively. See [2], [3], [6], [17] for further details on the analysis of multilevel partition trees. The structure for condition (iii) is the same (up to some dualizations) as the structure for (ii) that we just described. We conclude that a dynamic structure for predecessor queries in a set of triangles exists with $O(n^{1/3})$ query and $O(n^{1/3+\varepsilon})$ update time, using $O(n^{4/3+\varepsilon})$ preprocessing time and space.

For the c-oriented case, where the edges of the triangles have only c different orientations for some constant c, we can use structures from [7]. There it is shown that a vertex in front of a c-oriented query triangle can be found in $O(\log^3 n)$ time, with a structure that uses $O(n \log^2 n)$ space and has $O(\log^3 n)$ update time. A triangle in front of a query vertex can be found in $O(\log^2 n \log\log n)$ time, using $O(n \log^2 n)$ space and with $O(\log^2 n \log\log n)$ update time. Furthermore, finding a vertex in front of an axis-parallel rectangle can be done with a structure whose query and update time are $O(\log^2 n)$.

The above combined with Theorems 2.3 and 3.1 lead to the following result.

THEOREM 4.3. *Given a set S of n triangles in 3-space and a viewing direction $\vec{d}$, one can compute a depth order on S for direction $\vec{d}$ or decide that there is cyclic overlap among the triangles, in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the triangles are c-oriented then the time bound improves to $O(n \log^4 n)$, and if the objects are axis-parallel rectangles then the algorithm takes $O(n \log^3 n \log\log n)$ time.*

To verify a given depth order for an arbitrary set of triangles, we use the same structures as for computing a depth order. In the c-oriented case, however, we can save some logarithmic factors by using static structures instead of dynamic ones. In the algorithm of §3 we have to test whether the triangles in a list $\mathcal{L}_1$ do not lie in front of any triangle in a list $\mathcal{L}_2$. Testing whether there is an edge of a triangle in $\mathcal{L}_1$ that lies in front of an edge of a triangle in $\mathcal{L}_2$ can be done in $O(n \log n)$ time, as in §4.1. To test for conflicts corresponding to conditions (ii), we build a structure on the triangles in $\mathcal{L}_1$ that reports the first triangle that is hit by a query ray starting from infinity into the viewing direction. Next, we shoot rays from infinity into the viewing direction toward each vertex of all triangles in $\mathcal{L}_2$; when we know the first triangle that is hit by the ray toward a certain vertex, we can decide if there is any triangle in front of the vertex. There exists a structure that answers these ray shooting queries in $O(\log n)$ time, after $O(n \log n)$ preprocessing [9]. Hence, in $O(n \log n)$ time we can decide if there is a triangle in $\mathcal{L}_1$ that is in front of some vertex of a triangle in $\mathcal{L}_2$. To test condition (iii) we build a similar structure on the triangles in $\mathcal{L}_2$ (only this time for query rays into the opposite viewing direction), and we query with vertices of triangles in $\mathcal{L}_1$. This leads to the following theorem.

THEOREM 4.4. *It is possible to verify a given depth order on a set S of n triangles in 3-space for a direction $\vec{d}$ in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the triangles are c-oriented then the time bound improves to $O(n \log^2 n)$.*

4.3. Extension to polygons. Consider the case where we want to compute a depth order for a set of polygons in 3-space, instead of a set of triangles. Let n be the total number of vertices of the polygons. First, we triangulate every polygon, which can be done in $O(n)$ time in total [4]. Observe that one polygon is behind another polygon if and only if one of the triangles in the triangulation of the first polygon is behind one of the triangles of the second polygon. Hence, we can use the same data structures as before to find predecessors and successors. However, if the polygons do not have constant complexity, then there is a slight problem; the triangles that correspond to the same polygon must stay together in the ordering, so when we find one triangle as a predecessor or successor we have to report the other triangles as well. This is problematic, because the number of other triangles can be large. Suppose that during our tandem search we suddenly have to add a very large polygon to one of the subsets; if we find out in the next step that the other subset is complete, then we have spent a lot of time that we cannot charge to the smaller subset. An elegant solution to this problem can be obtained if we realize that we can choose any particular pivot element we like. Hence, we can choose the polygon with the largest complexity as pivot element. The tandem search for the sets $S_{\prec}$ and $S_{\succ}$ now proceeds as follows. We find successors and predecessors using the data structures for triangles. However, when we find a large polygon for, say, $S_{\prec}$, we first allow $S_{\succ}$ to catch up. Thus we search for successors until the complexity of $S_{\succ}$—that is, the total number of vertices of all polygons in $S_{\succ}$—is greater than the complexity of $S_{\prec}$. When this happens, we start querying for predecessors again, and so forth, until one of the subsets is completed. This way the extra work that we have to do, caused by adding a large polygon to what turns out to be the larger set, is bounded by the time spent on one polygon. Since the pivot polygon is chosen to be the largest polygon in the set, we can charge this extra work to the pivot polygon. Clearly, each polygon is charged at most once this way, because in the recursive calls we do not consider the pivot element anymore. Thus the asymptotic running time of the algorithm remains the same, and we have the following theorem.

THEOREM 4.5. *Given a set S of polygons in 3-space with n vertices in total and a viewing direction $\vec{d}$, one can compute a depth order on S for direction $\vec{d}$ or decide that there is cyclic overlap among the polygons, in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the polygons are c-oriented then the time bound improves to $O(n \log^4 n)$, and if the polygons are axis-parallel then the algorithm takes $O(n \log^3 n \log\log n)$ time.*

The adaptation of the verification procedure to polygons is fairly straightforward, and we leave it as an (easy) exercise to the reader.

THEOREM 4.6. *It is possible to verify a given depth order on a set S of polygons in 3-space with n vertices in total, for a viewing direction $\vec{d}$, in time $O(n^{4/3+\varepsilon})$, for any fixed $\varepsilon > 0$. If the polygons are c-oriented then the time bound improves to $O(n \log^2 n)$.*

5. Concluding remarks. We have shown that it is possible to compute a depth order for a set of line segments in 3-space in subquadratic time. More specifically, a depth order can be computed in $O(n^{4/3+\varepsilon})$ time in the general case and in $O(n \log^3 n)$ time in the c-oriented case. It is also possible to verify a given depth order, and the results can be extended to polygons instead of line segments. Our algorithms are based on a general framework to compute or verify a linear order extending an implicitly defined binary relation, which might have other applications as well.

When a depth order is needed as input to a hidden surface removal algorithm, we are not done if we detect a cycle: the cycles should be removed by cutting the objects into smaller pieces. Moreover, we would like to use as few cuts as possible. As mentioned in the introduction, binary space partitions are a way of cutting the objects to obtain a depth order, but there is no guarantee that the number of pieces in this scheme is small [20]. We leave the computation of the minimum (or a small) number of cuts as an open problem. See [5] for an initial study of these problems.

ERRATUM: OPTIMAL PARALLEL RANDOMIZED ALGORITHMS FOR THREE-DIMENSIONAL CONVEX HULLS AND RELATED PROBLEMS*

JOHN H. REIF† AND SANDEEP SEN‡

A portion of the appendix to "Optimal Parallel Randomized Algorithms for Three-Dimensional Convex Hulls and Related Problems," by John H. Reif and Sandeep Sen [SIAM J. Comput., 21 (1992), pp. 466–485] was inadvertently deleted when the article was printed. The appendix appears here in its entirety.

A. Appendix. We say a random variable X upper-bounds another random variable Y (equivalently Y lower bounds X) if for all x such that $0 \leq x \leq 1$, $\text{Prob}(X \leq x) \leq \text{Prob}(Y \leq x)$.

A Bernoulli trial is an experiment with two possible outcomes, success and failure. The probability of success is p.

A binomial variable X with parameters (n, p) is the number of successes in n independent Bernoulli trials, the probability of success in each trial being p. The *probability mass function* of X can be easily seen to be

$$\text{Prob}(X \leq x) = \sum_{k=0}^{x} \binom{n}{k} p^k (1-p)^{n-k}.$$

The tail end of the binomial distribution can be bounded by *Chernoff* bounds. In particular the following approximations due to Angluin and Valiant are frequently used:

$$\text{Prob}(X \geq m) \leq \left(\frac{np}{m}\right)^m e^{m-np} \tag{1}$$

$$\text{Prob}(X \leq m) \leq \left(\frac{np}{m}\right)^m e^{-np+m} \tag{2}$$

$$\text{Prob}(X \leq (1-\epsilon)pn) \leq \exp(-\epsilon^2 np/2) \tag{3}$$

$$\text{Prob}(X \geq (1+\epsilon)np) \leq \exp(-\epsilon^2 np/3) \tag{4}$$

for all $0 < \epsilon < 1$. The last two bounds actually follow from the Chernoff bounds, which (for a discrete distribution) can be stated as

$$\text{Prob}[A \geq x] \leq z^{-x} G_A(z)$$

where $G_A(z)$ is the probability generating function.

To minimize the bound we substitute $z = z_o$, which minimizes the right side expression.

Proof. (Lemma 10): Consider the generalized Chebychev's inequality

$$\text{Prob}\{|X| \geq t\} \leq \frac{E(\phi(X))}{\phi(t)}.$$

Using $\phi(t) = t^{2k}$ and substituting $X - E[X]$ for X and setting t to be equal to μ, we get

$$\text{Prob}\{|X - E[X]| \geq E[X]\} \leq \frac{E[(X - E[X])^{2k}]}{E^{2k}[X]}.$$

‡Department of Computer Science, Duke University, Durham, North Carolina, 27706. Present address, Department of Computer Science and Engineering, Indian University of Technology, New Delhi, 110016, India.

Let us focus on the numerator. We shall show that it is $O(\mu^k)$ and the lemma follows. Since $E[X] = \sum_{i=1}^{n} E[X_i]$, we can write $(X - E[X])^{2k}$ as $(\sum_{i=1}^{n} X_i - E[X_i])^{2k}$. In the multinomial expansion, all the terms containing $X_i - E[X_i]$ (for any i) as a factor vanish because of the $2k$-way independence property.

There are $\binom{n}{c} \cdot \binom{2k-1}{c-1}$ terms that have c distinct non-unit product terms of the form $(X_j - E[X_j])^i$ such that $i > 0$ and $\sum i = 2k$. Also note that

$$\begin{aligned} E[(X_j - E[X_j])^i] &= (1-p)(-p)^i + p(1-p)^i \\ &\leq p^i + p \\ &= p(1 + p^{i-1}) \\ &\leq 2p. \end{aligned}$$

We can factor out p so that we can write the coefficient of n^c as $p^c \cdot f(k)$, where f is a function independent of n and can be absorbed in the big-O notation. From our observation about the first-order terms (which vanish), the maximum value of c is k. The numerator can be bound by the asymptotically dominating term $O(n^k \cdot p^k) = O(\mu^k)$. Since the denominator is μ^{2k}, the lemma follows. □

TOP-BOTTOM ROUTING AROUND A RECTANGLE IS AS EASY AS COMPUTING PREFIX MINIMA*

OMER BERKMAN†, JOSEPH JÁJÁ‡, SRIDHAR KRISHNAMURTHY§, RAMAKRISHNA THURIMELLA¶, AND UZI VISHKIN||

Abstract. A new parallel algorithm for the prefix minima problem is presented for inputs drawn from the range of integers $[1..s]$. For an input of size n, it runs in $O(\log\log\log s)$ time and $O(n)$ work (which is optimal). A faster algorithm is presented for the special case $s = n$; it runs in $O(\log^* n)$ time with optimal work. Both algorithms are for the Priority concurrent-read concurrent-write parallel random access machine (CRCW PRAM). A possibly surprising outcome of this work is that, whenever the range of the input is restricted, the prefix minima problem can be solved significantly faster than the $\Omega(\log\log n)$ time lower bound in a decision model of parallel computation, as described by Valiant [SIAM J. Comput., 4 (1975), pp. 348–355].

The top-bottom routing problem, which is an important subproblem of routing wires around a rectangle in two layers, is also considered. It is established that, for parallel (and hence for serial) computation, the problem of top-bottom routing is no harder than the prefix minima problem with $s = n$, thus giving an $O(\log^* n)$ time optimal parallel algorithm for the top-bottom routing problem. This is one of the first nontrivial problems to be given an optimal parallel algorithm that runs in sublogarithmic time.

Key words. parallel algorithms, VLSI routing, prefix minima, PRAM algorithms

AMS subject classifications. 68Q10, 68Q25

1. Introduction.

The prefix minima problem is defined as follows. Given an array of integers $A = [a_1, a_2, \ldots, a_n]$ drawn from the range of integers $[1..s]$, find for each i, $1 \le i \le n$, the minimum over the prefix $a_1, a_2, \ldots, a_i$. We give two parallel algorithms for the problem: An $O(\log\log\log s)$ time algorithm using $n/\log\log\log s$ processors and $O(ns^\epsilon)$ space, and an $O(\log^* n)$[1] time algorithm using an optimal number of processors and linear space when the input is drawn from the range of integers $[1..n]$ (i.e., $s = n$).

We demonstrate the power of prefix minima by giving a nontrivial application—the top-bottom routing around a rectangle in two layers. The routing problem is defined as follows. We are given a rectangle $\mathcal{R}$ and a set of n two-terminal nets with each net having exactly one terminal on the top and one terminal on the bottom of $\mathcal{R}$. Find a routing around $\mathcal{R}$, in the standard two-layer model that uses the minimum number of total tracks. We give an $O(\log^* n)$ time algorithm for this routing problem using an optimal number of processors. Our time bound compares favorably with time bounds of previous algorithms. Additionally, the algorithm presented in this paper is quite elegant and relatively simple.

The main model of parallel computation that is used in this paper is the concurrent-read concurrent-write (CRCW) parallel random access machine (PRAM). We assume that if several processors attempt to write at the same memory location the processor with minimum

[1] $\log^* n = \text{minimum}\{i \mid \log^{(i)}(n) \le 1\}$ where $\log^{(i)}$ denotes the ith iterate of log (i.e., $\log^{(1)}(n) = \log n$ and $\log^{(i)}(n) = \log(\log^{(i-1)}(n))$ for $i \ge 2$.)

index succeeds (the so-called PRIORITY CRCW PRAM). An *optimal* parallel algorithm is an algorithm whose time-processor product matches the sequential complexity of the problem (which in this paper is always linear in the size of the input). An *ultimate* theoretical goal, that is, often unattainable, is to design constant-time optimal parallel algorithms. Seeking to get as close as possible to accomplishing this goal is an interesting research goal.

Valiant [12] gave an $\Omega(\log\log n)$ time lower bound for computing the maximum of n elements using n processors in a comparison model of parallel computation. The same lower bound applies for a PRAM assuming the input is drawn from a large domain (see [8] and [9]). Our result shows that this lower bound does not apply when the input range is restricted. Computing the parity of n bits needs $\Omega(\log n/\log\log n)$ time using a polynomial number of processors [2]. Since parity is such a simple problem, it is interesting to demonstrate that other interesting and nontrivial problems can be solved extremely fast. Recently, Berkman and Vishkin [4] have shown that several interesting functions could be computed in time that is significantly faster than the lower bound for parity, e.g., in inverse-Ackermann time. See also the survey [13]. The results of this paper also contribute in this direction. Furthermore, the top-bottom routing problem is one of the most involved problems for which a sublogarithmic optimal parallel algorithm presently exists.

The previous algorithms for the prefix minima problem run in $O(\log\log n)$ time using an optimal number of processors ([3] and [11]). This upper bound cannot be improved when the input range is unrestricted because of the lower-bound by Valiant. Our prefix minima algorithm has already been used by Matias and Viskin [7] as an important subroutine in designing an $O(\log^* n)$ time algorithm for generating a random permutation.

The top-bottom routing problem is one of the important subproblems encountered by very large scale integration (VLSI) circuit designers during the layout of a chip. This problem and its variations, arise in hierarchical approaches to VLSI layout. It should be emphasised, though, that the top-bottom routing is a restricted version of the problem of routing wires around multiple rectangles, which is the general routing problem. Indeed, the former problem can be considered a "very" simple case of the latter problem, which is itself NP-hard. Nevertheless, a study of the top-bottom routing problem provides new insights into the general problem and hence an efficient parallel algorithm for this problem could conceivably be a part of the software for computer-aided design tools.

While our algorithm is the first parallel algorithm, several authors have studied this problem in the sequential context. Baker [1], and Sarrafzadeh and Preparata [10] give a simple linear-time algorithm for this problem. However, the layout resulting from their algorithms is not optimal. On the other hand, the known algorithms that achieve optimality in the layout area for this problem are unsatisfactory for other reasons. LaPaugh's algorithm [6] is computationally expensive: it takes $O(n^3)$ time. The algorithm of Gonzalez and Lee [5], although it runs in $O(n)$ time, is quite involved.

2. Top-bottom routing.

2.1. Preliminaries and notation. Given a grid structure, let $\mathcal{R}$ be an $l \times h$ rectangle with sides on grid-line segments. Let $\mathcal{N}$ be $\{N_1, N_2, \ldots, N_s\}$. Each N_i (referred to as a **net**) consists of a pair of grid points (referred to as **terminals**) $N_i = \{a_{i_1}, a_{i_2}\}$, where terminal a_{i_1} (referred to as a **top terminal**) is on the top boundary of $\mathcal{R}$, and terminal a_{i_2} (referred to as a **bottom terminal**) is on the bottom boundary of $\mathcal{R}$. The *top-bottom routing problem* is to specify a path along grid-line segments, that connects for each N_i both its terminals. The layout (routing) should be such that the paths (wires) are outside $\mathcal{R}$ and should satisfy the constraints of a given routing model. We consider the *standard two-layer model*, where the horizontal segments of a wire are on one layer and the vertical segments are on the other. The segments of two different wires in any one layer are allowed no contact with one another, but wires running on different layers are allowed to cross without being connected. When a connection is desired at a grid point between a horizontal and a vertical segment of the same wire, it is achieved by an explicit connection (referred to as a *via*). The problem is to find such a routing around $\mathcal{R}$, that uses the minimum number of horizontal grid-line segments (referred to as **tracks**). There are two frequently used facts about routing we assume in this paper; the proofs of these facts are either straightforward or in [1], [6], [5]: (1) Minimizing the total number of horizontal tracks also minimizes the total area used by the layout, since each net increases the width of the layout by one unit. (2) There is an optimal routing such that each net uses exactly four bends or vias.

We elaborate on the definition of the problem. Assume the input is given as follows: two arrays $T = [t_1, t_2, \ldots, t_n]$ and $B = [b_1, b_2, \ldots, b_n]$ that contain net numbers as they appear at the top and bottom of $\mathcal{R}$ in left-to-right order. Without loss of generality (wlog), assume that $T = [t_1, t_2, \ldots, t_n] = [1, 2, \ldots, n]$ and B is a permutation of the numbers $1, 2, \ldots, n$. Note that any routing solution uses at least n horizontal tracks. Figure 1a demonstrates a solution for a problem with $n = 4$. The wire that leaves top-terminal 1 takes a vertical track upwards for one unit-length, connects to the horizontal track layer and takes a horizontal track left-bound for two units, and connects to the vertical track layer and takes a vertical track downwards for $h + 3$ units (recall that h is the height of the rectangle). A total of $h + 4$ horizontal tracks are used in the routing shown in Fig. 1a. It is easy to argue that in general $h + n$ is the minimal number of horizontal tracks possible for the routing problem. We ignore the horizontal tracks occupied by the rectangle and say that the number of horizontal tracks used by the above routing equals four.

A routing will be represented by two sets of edges: the *top* edges and the *bottom* .edges between nets in the array B (observe that array T is not needed). Each net in B is an endpoint of at most one top edge and at most one bottom edge.

- A **top edge** (b_k, b_l) means that nets b_k and b_l share the same track at the top and thus implies **directions** for b_k and b_l: if $b_k < b_l$, the direction of the net b_k is counter clockwise (CC) and that of b_l is clockwise (C); if $b_k > b_l$, the direction of b_k is C and that of b_l is CC. Observe that this is the direction as we traverse the path of the net from its top terminal to its bottom terminal.
- A **bottom edge** (b_i, b_j) means that b_i and b_j share the same track at the bottom and thus implies directions of b_i and b_j: if $i < j$, the direction of b_i is CC and that of b_j is C; if $i > j$, the direction of b_i is C and that of b_j is CC (see Fig. 1b).

A routing is *inconsistent with respect to* k, $1 \le k \le n$, if the direction implied by the top edge of a net b_k is C (respectively, CC) and the direction implied by the bottom edge of net b_k is CC (respectively, C); otherwise it is *consistent with respect to* k. A routing is **consistent** if it is consistent with respect to every k, $1 \le k \le n$.

An equivalent formulation of the consistency issue follows. Consider the complete undirected graph whose vertices are the nets. A **matching** in this graph consists of any subset of the edges such that no two of them share an endpoint. The set of top edges, denoted M_1, induces a matching; similarly the set of bottom edges, M_2, induces a matching. We define this pair of matchings M_1 and M_2 to be *consistent with respect to* a net b_i if, whenever $(b_i, b_j) \in M_1$ and $(b_i, b_k) \in M_2$, $b_i < b_j$ if and only if b_i appears before b_k in B (i.e., $i < k$). (M_1 and M_2 are also consistent with respect to b_i if b_i is unmatched in M_1 or in M_2.) A pair of matchings is called *consistent* if it is consistent with respect to each b_i. Our problem is to find a consistent pair of matchings M_1 and M_2 on B such that $|M_1| + |M_2|$ is a maximum.

Figure 1b shows an example of a consistent routing. For instance, for $b_2 = 2$, the top edge leads to $b_3 = 1$, implying a CC direction for net b_3 and a C direction for net b_2 (since $b_3 < b_2$). The bottom edge for b_2 leads to $b_1 = 3$, implying a CC direction for net b_1 and a C direction for net b_2 (since b_1 occurs before b_2 in B).

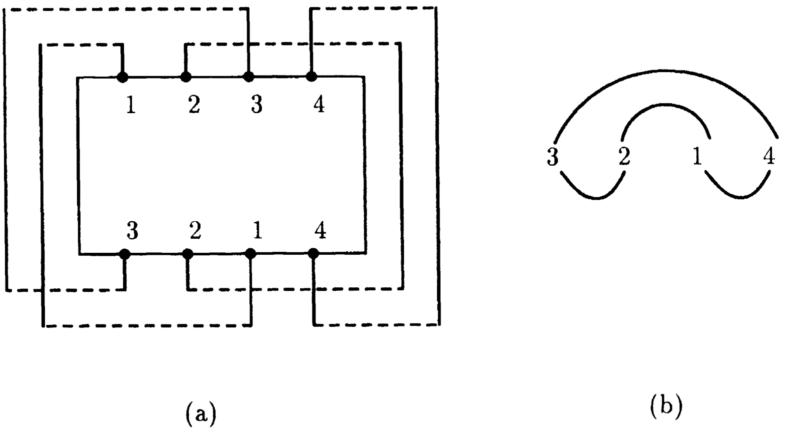

FIG. 1. *An example of top-bottom routing.* (a) *Actual routing.* (b) *Routing representation.*

Given such a representation with k_1 top edges and k_2 bottom edges, it is straightforward to assign tracks sequentially to the nets and thereby construct the actual routing. (Parallel track assignment is handled later.) The total number of tracks used at the top is $n - k_1$ and the total number of tracks used at the bottom is $n - k_2$. An optimal routing is thus a routing that maximizes $k_1 + k_2$.

2.2. An easy upper bound of n + 1 tracks. The proof of the following theorem provides an exceptionally simple algorithm. Its simplicity is particularly remarkable since the algorithm achieves the same number of tracks as in the pair up algorithms of Baker [1], and in Sarrafzadeh and Preparata [10], which are much more involved. Our method has the additional advantage that it can be implemented in constant time using n processors.

THEOREM 2.1. *A routing of the nets that uses a total of $n + 1$ tracks on the top and bottom parts of $\mathcal{R}$ can always be constructed.*

Proof. Let $B = [b_1, b_2, \ldots, b_n]$ be the bottom array. The set of top edges is given by (b_{2i}, b_{2i+1}), for $i = 1, 2, \ldots, \lfloor (n-1)/2 \rfloor$. The set of bottom edges is $(b_1, \max(b_2, b_3))$, $(\min(b_{2i}, b_{2i+1}), \max(b_{2i+2}, b_{2i+3}))$ for $i = 1, 2, \ldots, \lfloor (n-3)/2 \rfloor$. If n is an even integer, add also the bottom edge $(\min(b_{n-2}, b_{n-1}), b_n)$. When n is an odd integer, we have $(n-1)/2$ top edges and $(n-1)/2$ bottom edges. When n is even, we have $(n/2) - 1$ top edges and $n/2$ bottom edges. In both cases, the total number of tracks is $n + 1$.

It can be easily verified that the resulting routing is consistent. □

COROLLARY 2.2. *An $(n + 1)$-track routing solution can be obtained in sequential linear time and in $O(1)$ time with n processors on an exclusive-read exclusive-write* (EREW) PRAM.

Figure 2 gives examples of $(n + 1)$-track routing solutions.

2.3. Can we do better than n + 1? An $(n + 1)$-track routing solution always exists as shown above. It is easy to see that when n is odd this solution is optimal. Therefore, for the rest of the section assume n is even.

We describe a necessary and sufficient condition for the routing problem to have an n track solution.

DEFINITION 1. *A bottom array $B = \{b_1, b_2, \ldots, b_n\}$ is said to be* **unbalanced** *if there exists an odd integer i, such that the minimum over the prefix $\{b_1, b_2, \ldots, b_i\}$ is larger than the maximum over the suffix $\{b_{i+1}, b_{i+2}, \ldots, b_n\}$. (Alternatively, since B is a permutation of $1, 2, \ldots, n$ we can say that B is unbalanced if there exists an odd integer i such that the subarray $\{b_1, b_2, \ldots, b_i\}$ is a permutation of the numbers $\{n - i + 1, n - i + 2, \ldots, n\}$.) The array B is said to be* **balanced** *otherwise.*

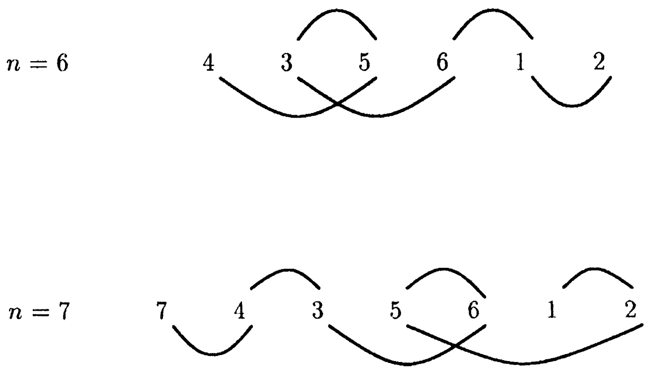

FIG. 2. $(n + 1)$*-track routing solutions.*

THEOREM 2.3. *Given an array B representing a top-bottom routing problem, an n track routing solution exists if and only if array B is balanced.*

Proof (*only if*). The proof is by contradiction. Assume B is unbalanced and let i be an odd integer such that the subarray $\{b_1, b_2, \ldots, b_i\}$ is a permutation of the numbers $\{n - i + 1, n - i + 2, \ldots, n\}$. Assume that the routing problem has an n track solution represented by $n/2$ top edges and $n/2$ bottom edges. At least $\lceil \frac{i}{2} \rceil$ nets from the subarray $\{b_1, b_2, \ldots, b_i\}$ must have a bottom edge with a net that lies to their right (in array B). On the other hand, at the top there exists a subset of nets $\{c_1, c_2, \ldots, c_{\lceil \frac{i}{2} \rceil}\} \subset \{n - i + 1, n - i + 2, \ldots, n\}$ such that each c_j, $j = 1, 2, \ldots, \lceil \frac{i}{2} \rceil$, shares a track with a net b_k where $b_k < c_j$. The direction implied for each of these $\lceil \frac{i}{2} \rceil$ nets is C. Since i is odd the direction assignments implied by these two sets of top and bottom edges results in a conflicting direction assignment for at least one net. This gives us the contradiction.

(*if*). Assume B is balanced. We construct an n track routing solution. We leave it to the reader to verify that the routing is consistent whenever we show how to assign directions to the nets. Denote by PMIN(i) the minimum over the prefix $\{b_1, b_2, \ldots, b_i\}$ and by SMAX(i) the maximum over the suffix $\{b_i, b_{i+1}, \ldots, b_n\}$ for $1 \leq i \leq n$.

We prove, inductively, that for an odd integer $i = 1, 3, \ldots, n - 1$, the sequence $\{b_1, b_2, \ldots, b_i, \text{SMAX}(i + 1)\}$ has an $i + 1$ track routing solution.

Basis. $i = 1$; Since B is balanced, $b_1 < \text{SMAX}(2)$ and a two track routing solution is given by the bottom edge $(b_1, \text{SMAX}(2))$ and the top edge $(b_1, \text{SMAX}(2))$.

Inductive step. Given an $(i - 1)$-track solution for $\{b_1, b_2, \ldots, b_{i-2}, \text{SMAX}(i - 1)\}$ we construct an $(i + 1)$-track solution for the sequence

$$\{b_1, b_2, \ldots, b_{i-2}, b_{i-1}, b_i, \text{SMAX}(i + 1)\}.$$

Case 1. $\text{SMAX}(i - 1) = \text{SMAX}(i + 1) = s$. We have a bottom edge (b_l, s) for some $l \leq i - 2$ in the inductively assumed $i - 1$ track solution. Replace this bottom edge by the following three edges: bottom edge $(b_l, \max(b_{i-1}, b_i))$, top edge (b_{i-1}, b_i), and bottom edge $(\min(b_{i-1}, b_i), s)$. The resulting set of top and bottom edges gives an $(i + 1)$-track solution for $\{b_1, b_2, \ldots, b_{i-2}, b_{i-1}, b_i, s\}$ (see Fig. 3).

Case 2. $\text{SMAX}(i - 1) \neq \text{SMAX}(i + 1)$. This implies that either $\text{SMAX}(i - 1) = b_{i-1}$ or $\text{SMAX}(i - 1) = b_i$. Assume $\text{SMAX}(i - 1) = b_{i-1}$ (the case $\text{SMAX}(i - 1) = b_i$ can be handled similarly). Let $p = \text{PMIN}(i)$. Since B is balanced, $p < \text{SMAX}(i + 1)$.

Case 2.1. $p = b_i$. We add a bottom edge $(b_i, \text{SMAX}(i+1))$ and a top edge $(b_i, \text{SMAX}(i+1))$, which gives an $(i + 1)$-track solution (see Fig. 4).

(b)

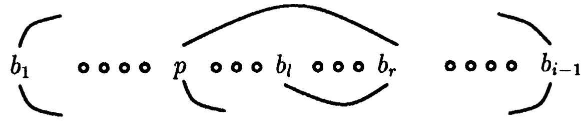
FIG. 4. (a) *Inductively assumed* $(i-1)$*-track solution.* (b) $(i+1)$*-track solution.*

Case 2.2. $p \neq b_i$. We know that $b_{i-1} > b_i$ (since SMAX$(i-1) = b_{i-1}$). Thus $p \neq b_{i-1}$. It follows that there exists j, $1 \leq j \leq i-2$, such that $b_j = p$. We have a top edge (p, b_r), for some $r \leq i-1$ in the inductively assumed $i-1$ track solution. We also have a bottom edge

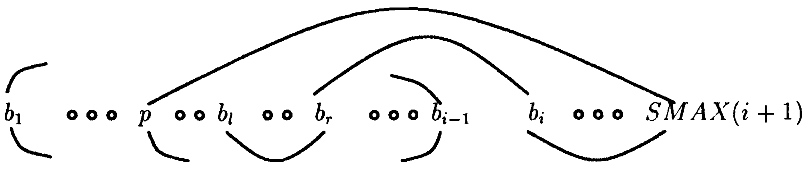
(b_l, b_r), for some $l \leq i-1$ (actually $l < r$ since the direction implied by the top edge (p, b_r) for net b_r is C).

Case 2.2.1. $b_r > b_i$. The top edge (p, b_r) is replaced by the following three edges: top edge $(p, \text{SMAX}(i+1))$, bottom edge $(\text{SMAX}(i+1), b_i)$, and top edge (b_i, b_r). This gives an $(i+1)$-track solution (see Fig. 5).



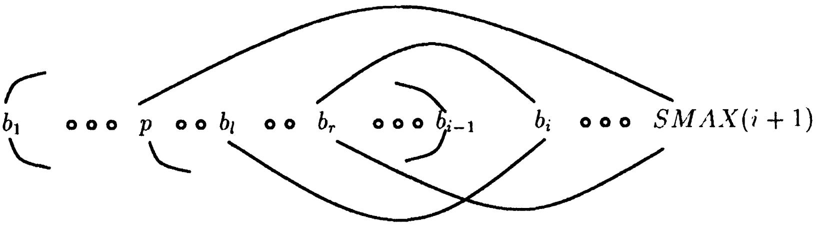
(a)

FIG. 5. (a) *Inductively assumed* $(i-1)$*-track solution.*



(b)

FIG. 5. (b) $(i+1)$*-track solution for* $b_i < b_r$.



(c)

FIG. 5. (c) $(i+1)$*-track solution for* $b_i > b_r$.

Case 2.2.2. $b_r < b_i$. We replace the top edge (p, b_r) and the bottom edge (b_r, b_l) by the following four edges: top edge $(p, \text{SMAX}(i+1))$, bottom edge $(\text{SMAX}(i+1), b_r)$, top edge (b_r, b_i), and bottom edge (b_i, b_l). Note that this is the only case in which the direction of any net is reversed with respect to its direction in the inductively assumed solution. This again gives an $(i+1)$-track solution (see Fig. 5). □

Given a bottom array B representing an instance of a top-bottom routing problem, we have the following theorem.

THEOREM 2.4. *An optimal routing solution can be constructed in sequential linear time.*

Proof. It is straightforward to verify whether array B is balanced. If B is unbalanced, then the optimal solution needs $n + 1$ tracks and Theorem 2.1 gives the construction of such a solution. Otherwise, the constructive proof of Theorem 2.3 gives an algorithm that finds an n track solution in linear time. □

2.4. Parallel algorithm. In this subsection we present a parallel version of the optimal routing algorithm discussed above.

Assume that the given input array $B = [b_1, b_2, \ldots, b_n]$ is balanced. To simplify the presentation of the algorithm we define an operation SWAP on array B. Given two indices i and j in the array, SWAP(i, j) swaps the contents of locations i and j in B. We show later, as a part of the correctness proof of our algorithm, that the directions assigned for the nets for the array after a SWAP operation can also be used for the array before the SWAP operation. First, we do the following preprocessing.

A balanced array $B = [b_1, b_2, \ldots, b_n]$ is said to satisfy the **even>odd property** if $b_{2i} > b_{2i+1}$ for all i, $1 \leq i < n/2$ in B. We use the SWAP operation, if necessary, to make the array satisfy the above property. That is, for every $1 \leq i < n/2$, if $b_{2i} < b_{2i+1}$, then SWAP$(2i, 2i + 1)$. For convenience, we continue to refer to the swapped array as B also.

Next find all prefix minima and suffix maxima with respect to B and put them in arrays PMIN and SMAX, respectively. For each odd integer i, if $b_i =$ PMIN(i) mark location i by "P." Similarly, for each even integer i, if $b_i =$ SMAX(i) mark location i by "S."

As a final part of the preprocessing step we further limit the input array to satisfy the **SP-free property**: for each even j, $2 \leq j < n$, either j is not marked S or $j + 1$ is not marked P. This is achieved by partitioning the input array as follows. Simultaneously, for every even integer j, if location j is marked "S" and location $j + 1$ is marked "P," then split array B between locations j and $j + 1$. These simultaneous splits partition array B into several contiguous subarrays.

CLAIM 2.5. *Each subarray after the above partition is even in length and is balanced. Furthermore, it satisfies*: (i) *the SP-free property, and* (ii) *the even > odd property.*

Proof. Each subarray after the partition is such that the first and last elements of the subarray are marked P and S, respectively. It is easy to see that each subarray satisfies the SP-free property and the even>odd property. Also, each subarray is of even length because markings S and P occur at an even and odd positions of the array, respectively. To prove that each subarray is balanced, we note that for each location in the subarray, its prefix minimum (resp. suffix maximum) with respect to the subarray is equal to its prefix minimum (resp. suffix maximum) with respect to B. Since B is balanced, it follows that the resulting subarrays are also balanced. □

Let $D = [d_1 \ldots d_m]$ be a subarray obtained after the preprocessing. The rest of the algorithm is devoted to solving the matching problem with respect to each such subarray separately. We note that array D is not a permutation of the numbers $1 \ldots m$. However, the crucial information about array D (namely, the marks "P" and "S") is already known and thus there is no need to compute prefix-minima or suffix-maxima with respect to D. We describe the algorithm below.

Algorithm *Parallel Top-Bottom Routing.*

Input: A balanced array D satisfying the even > odd property and the SP-free property. Also, the marks P and S for the elements of D.

Output: The directions C and CC for each of the elements of D.

1. (*Extract PS-pairs.*) Locate all pairs (d_l, d_r), $3 \leq l < r \leq m - 2$, such that d_l is marked "P," d_r is marked "S," and there is no element d_k, $l < k < r$, such that d_k is marked. Such a pair is called a **PS-pair**.

2. (*Handle PS-pairs.*) Consider first the case where there are no PS-pairs. For such a case add the top edge (d_1, d_m), and bottom edges (d_1, d_2) and (d_{m-1}, d_m) and proceed to Step 3. For the rest of this step we assume that there exists at least one PS-pair. We add the following edges:
   (a) (*Chain all outside neighbors of each PS-pair.*) For each PS-pair (d_l, d_r), add the top edge (d_{l-1}, d_{r+1}). Further, if $d_{l-1} < d_{r+1}$ then SWAP$(l - 1, r + 1)$. Add the bottom edges (d_{l-2}, d_{l-1}) and (d_{r+1}, d_{r+2}) (see Fig. 6a).
   (b) (*Chain all PS-pairs.*)
      (i) (*Attach at the extremes.*) Let (d_{l_1}, d_{r_1}) and (d_{l_2}, d_{r_2}) be the first and last PS-pairs in D. Add top edges (d_1, d_{r_1}) and (d_{l_2}, d_m). Add bottom edges (d_1, d_2) and (d_{m-1}, d_m) if no such edges exist from Step 2a (see Fig. 6b).
      (ii) (*Attach the middle pairs.*) For each two consecutive PS-pairs $(d_{l_\alpha}, d_{r_\alpha})$ and $(d_{l_\beta}, d_{r_\beta})$, add a top edge $(d_{l_\alpha}, d_{r_\beta})$. For each PS-pair (d_l, d_r), add bottom edges (d_l, d_{l+1}) and (d_{r-1}, d_r) (see Fig. 6c).
3. (*Pair-up the rest of the elements, each to its neighbor, based on their position: even to odd at the top and odd to even at the bottom.*) Add the following edges:
   Add top edges (d_{2j}, d_{2j+1}), $1 \leq j \leq (m/2) - 1$ unless either d_{2j} or d_{2j+1} have top edges from Step 2. Also add bottom edges (d_{2j-1}, d_{2j}), $2 \leq j \leq (m/2) - 1$ unless either d_{2j-1} or d_{2j} have bottom edges from Step 2.

FIG. 6. *Handling of PS-pairs.*

Next, we argue the correctness of this algorithm. It follows from Step 3 that every element is paired up. We divide the remaining proof into two categories. First, we show that if an attempt is made by the algorithm to add an edge for an element of D at a particular stage, then that element is "available" to be paired up, i.e., no edge was added to that element of D by a step prior to the current one. The second part of the correctness argument consists of showing that the routing resulting from the algorithm is consistent (for the array before as well as after the SWAP operations).

2.4.1. Correctness I: no conflicts.

PROPOSITION 2.6. *Following the preprocessing, the outside neighbors d_{l-1} and d_{r+1} of any PS-pair (d_l, d_r) are unmarked (i.e., they are not marked neither "P" nor "S").*

Proof. Consider any PS-pair (d_l, d_r) and its outside neighbors d_{l-1} and d_{r+1}. Since $l-1$ is even, d_{l-1} cannot be marked "P." In addition since array D is SP-free, and d_l is marked "P," it implies that d_{l-1} cannot be marked "S." Similarly we can prove that d_{r+1} in unmarked. □

CLAIM 2.7. *The top and bottom edges added in Step* 2b(ii) *never conflict with an edge added in Step* 2a *(that is, if a top (bottom) edge (u, v) is added in Step* 2b(ii), *neither u nor v have top (bottom) edges from Step* 2a).

Proof. For top edges the claim follows directly from Proposition 2.6. Consider any PS-pair (d_l, d_r). The bottom edges that are added in Step 2a are (d_{l-2}, d_{l-1}) and (d_{r+1}, d_{r+2}). We prove the claim with respect to elements d_{l-2} and d_{l-1} (similar arguments work for d_{r+1} and d_{r+2}). We use three facts. (1) Elements d_{l-1} and d_{l-2} are not part of any PS-pairs. (2) At least one of the elements corresponding to a bottom edge added in Step 2b(ii) belong to a PS-pair. (3) All bottom edges that are added in Step 2b(ii) are of the form (d_{2j-1}, d_{2j}). Using fact (3) we conclude that the only possible edge that might have been added to d_{l-2} or d_{l-1} in Step 2b(ii) is (d_{l-2}, d_{l-1}). However, facts (1) and (2) together imply that such an edge cannot be added in Step 2b(ii). We are left to show why fact (1) is correct (facts 2 and 3 are obvious). Element d_{l-1} is unmarked (Proposition 2.6) and cannot be a part of any PS-pair. If element d_{l-2} is marked, it can only be marked "P." Thus the only way in which d_{l-2} can be a part of a PS-pair is if d_{l-1} is marked "S," which is not possible (Proposition 2.6). □

PROPOSITION 2.8. *Whenever an existing bottom edge in Step* 2b *and in Step* 3 *prevents us from connecting two elements u and v by a bottom edge, then both u and v are endpoints of existing bottom edges. Similarly in Step* 3, *if an existing top edge prevents us from connecting two elements u and v by a top edge, then both u and v are endpoints of existing top edges.*

Proof. We consider the top edges and the bottom edges separately.

(i) The proposition is trivial with respect to bottom edges: All bottom edges (u, v) are of the form (d_{2j-1}, d_{2j}) for some j, $1 \leq j \leq m/2$. Hence, in either Step 2b or Step 3, if we are prevented from connecting two elements u and v by a bottom edge, it implies that u and v are already connected to each other by an existing bottom edge.

(ii) All top edges (u, v) added in Step 3 are of the form (d_{2j}, d_{2j+1}), for some j, $1 \leq j \leq (m/2) - 1$. Prior to Step 3, whenever we add a top edge matching an element at i with an element at j, where i is even $(i < n)$, and j is odd $(j > 1)$, we also add top edges for the elements at $i + 1$ and $j - 1$ (this includes both cases $i < j$ and $i > j$). Hence if we are prevented from connecting two elements u and v by a top edge in Step 3, it implies that both u and v are endpoints of existing top edges. □

2.4.2. Correctness II: routing consistency.

The following proposition is useful for the later proofs.

PROPOSITION 2.9. *Given any two consecutive PS-pairs $(d_{l_\alpha}, d_{r_\alpha})$ and $(d_{l_\beta}, d_{r_\beta})$, we have $d_{l_\alpha} < d_{r_\beta}$. In addition, $d_1 < d_{r_1}$ and $d_{l_2} < d_m$. (If there are no PS-pairs then $d_1 < d_m$.)*

Proof. Consider the smallest index $i > r_\alpha$ that is marked P. The maximal element in the suffix $[i-1,\ldots,m]$ is d_{r_β}. The minimal element in the prefix $[1,\ldots,i-2]$ is d_{l_α}. (To see these, recall the SP-free property and the definition of PS-pairs.) Since D is balanced, $d_{l_\alpha} < d_{r_\beta}$. Similarly, we can prove that $d_1 < d_{r_1}$ and $d_{l_2} < d_m$. □

CLAIM 2.10. *The matchings corresponding to the top and bottom edges added in Step* 2a *are consistent with respect to d_{l-1} and d_{r+1}, for all PS-pairs (d_l, d_r) in D.*

Proof. We show that the matching is consistent with respect to d_{l-1}. Similar arguments work for d_{r+1}. From Step 2a, d_{l-1} has top edge (d_{l-1}, d_{r+1}) and bottom edge (d_{l-2}, d_{l-1}). Since $d_{l-1} > d_{r+1}$ (after the SWAP operation), the matchings corresponding to these edges are consistent in the swapped array D. It remains to prove that these matchings are consistent in array D before the SWAP of Step 2a. Consider the bottom edge (d_{l-2}, d_{l-1}). The elements at locations $l-2$ and $l-1$ could have changed their locations by this SWAP operation. Notice, however that all SWAP operations performed in this step are of the form SWAP(r, s) where r is even, s is odd and $r < s$. Since $l-1$ is even and $l-2$ is odd, it follows that element d_{l-1} must have been in location $\geq l-1$ and element d_{l-2} must have been in location $\leq l-2$ before the SWAP. Thus the matching is consistent with respect to d_{l-1} also before the SWAP. □

CLAIM 2.11. *The matchings resulting from the top and bottom edges added in Step* 2b *are consistent with respect to d_l and d_r for all PS-pairs (d_l, d_r) in D (and also with respect to d_1 and d_m).*

Proof. From Proposition 2.9 it is easy to see that the matchings are consistent with respect to the swapped array D. We show that neither d_l nor d_{l+1} are affected by the SWAP (of Step 2a). This will imply that the matchings are consistent also with respect to array D before the SWAP. Element d_l is unaffected by the SWAP operation since it is marked "P." For d_{l+1} to be affected d_{l+2} must be marked "P." If $l+1 = r$ then $l+2$ cannot be marked "P" because of the SP-free property. If $l+1 < r$ then $l+2$ cannot be marked "P" since otherwise (d_l, d_r) would not have been a PS-pair. Similarly, we can show that d_{r-1} and d_r are not affected by the SWAP operation. □

CLAIM 2.12. *The matchings resulting from the edges added in Step* 3 *are consistent with respect to both d_{2j} and d_{2j+1} for $1 \leq j \leq (m/2)-1$.*

Proof. For array D after the SWAP of Step 2a, the claim follows from the even > odd property. Since all SWAP operations of Step 2a are of the form SWAP(r, s) where r is even, s is odd, and $r < s$, it follows that element d_{2j} must have been in location $\geq 2j$ and d_{2j+1} must have been in location $\leq 2j+1$ before the SWAP operation. Thus the matchings are consistent also with respect to the original array D. □

MAIN CLAIM. *Steps* 1 *to* 5 *result in a consistent pair of matchings M_1 and M_2 for D, such that $|M_1| = |M_2| = m/2$.*

Proof. The Main Claim follows from Claims 2.10, 2.11, and 2.12. □

THEOREM 2.13. *M_1 and M_2 are the needed matchings on B (recall that B is the original array for which D is a subarray).*

Proof. From the Main Claim above, matchings M_1 and M_2 are consistent with respect to D and hence are also consistent with respect to array B obtained after the SWAP performed in the preprocessing step. Since our algorithm never puts a bottom edge matching the element at b_{2i} with the element at b_{2i+1}, for $1 \leq i < n/2$, matchings M_1 and M_2 are consistent also with respect to the original array B. □

2.4.3. Complexity and implementation.

THEOREM 2.14. *The optimal routing algorithm runs in $O(\log^* n)$ time using $O(n)$ operations on the* CRCW PRAM.

Proof. By Theorem 3.4 below we can solve the prefix-minima (or suffix-maxima) problem in $O(\log^* n)$ time and $O(n)$ operations. Remaining nontrivial implementation details are extracting PS-pairs (in Step 3), finding in each SP-free subarray the first and last PS-pairs (needed for Step 2b(i)), and finding consecutive PS-pairs (in Step 2b(ii)). Given the array D with the marks "P" and "S" it is easy to see that each of these problems can be solved using the nearest-one algorithm of [4] in $O(\alpha(n))$ time with an optimal number of processors, and thus also in $O(\log^* n)$ time with an optimal number of processors. In fact it turns out that the prefix-minima and suffix-maxima information suffices for solving each of these three subproblems in $O(1)$ time using n processors (we omit the details). All other steps of the algorithm need $O(1)$ time and $O(n)$ operations.

Finally, we need to compute for each net its actual track number on the top and bottom of the rectangle. The track numbers for each net at the top can be obtained as follows. Observe that at the end of Step 3 of the algorithm, all top edges in D, match an element at i with an element at j where i is even and j is odd and $d_i > d_j$. This pair of elements is assigned track number $i/2$, with the element at location j having direction CC and the element at location i having direction C. Clearly this track assignment is unique for the matchings induced by each top edge. The track assignment at the bottom can be done in a similar manner by observing that at the end of Step 3 of the algorithm all bottom edges are of the form (d_{2j-1}, d_{2j}) for all $j, 1 \leq j \leq m/2$. □

3. The prefix-minima problem.

In this section we present a fast parallel algorithm for the prefix-minima problem: Given an array of integers $A = [a_1, a_2, \ldots, a_n]$ drawn from the range of integers $[1..s]$, find for each i, $1 \leq i \leq n$ the leftmost minimal element over the prefix $[a_1, a_2, \ldots, a_i]$.

We give two main results; both are optimal parallel algorithms. The first is a triply-logarithmic time algorithm for an arbitrary input range size s, and the second is an algorithm that runs in $O(\log^* n)$ time when s is equal to n.

We start by reducing the prefix-minima problem to the problem of finding critical elements, which is defined below. Later we give an algorithm for the problem of finding critical elements.

Finding critical elements. Given is an array of integers $A = [a_1, a_2, \ldots, a_n]$ drawn from the range of integers $[1..s]$. An element a_i, $1 \leq i \leq n$ is **critical** if $a_i < a_j$, for every j, $1 \leq j < i$. The problem is to find all critical elements in A.

The reduction. Given some element a_i, $1 \leq i \leq n$, let $c(i) \leq i$ be the maximal index such that $a_{c(i)}$ is critical. Note that a_{c_i} is the leftmost minimal element over the prefix $a_1, a_2, \ldots, a_i$. Thus, given all critical elements in A, the prefix-minima problem is equivalent to finding for each i, $1 \leq i \leq n$, the index $c(i)$. This computation can be done using the nearest-one algorithm of [4] in $O(\alpha(n))$ time (where $\alpha(n)$ is the inverse of Ackermann's function) using an optimal number of processors (and thus also in $O(\log^* n)$ time using an optimal number of processors).

3.1. Overview.

Our main tool is a basic algorithm for finding critical elements that evolves in two directions giving the two main results mentioned above.

This basic algorithm runs in time $O(1)$ using $n \log s$ processors and $O(s)$ space for an input of length n, drawn from the range of integers $[1..s]$.

Stages in the description of the triply-logarithmic algorithm.

(1) The basic algorithm.

(2) Reducing the space of the basic algorithm.

For any constant $0 < \epsilon < 1$, the resulting algorithm runs in time $O(1)$ using $\epsilon n \log s$ processors and $O(ns^\epsilon)$ space.

(3) The optimal triply-logarithmic algorithm.

The algorithm runs in $O(\log\log\log s)$ time using $n/\log\log\log s$ processors and $O(ns^\epsilon)$ space.

Stages in the description of the $O(\log^* n)$ time algorithm.

(1) The basic algorithm.

(2) An $O(\log^* s)$ time algorithm.

The algorithm uses $s + n\log^* n$ processors and $O(n+s)$ space for an input of length n, drawn from the range of integers $[1..s]$. It is obtained by a recursive application of the basic algorithm.

(3) The optimal $O(\log^* n)$ time algorithm.

The algorithm runs in $O(\log^* n)$ time using $n/\log^* n$ processors and $O(n)$ space for an input of length n, drawn from the range of integers $[1..n]$ (i.e., $s = n$).

3.2. The basic constant-time algorithm. Assume for simplicity that $s = 2^\alpha$ for some integer $\alpha > 0$.

THEOREM 3.1. *The algorithm for finding critical elements below runs in $O(1)$ time using $n\log s$ processors and $O(s)$ space.*

Step 1. Build a complete binary tree, T, whose leaves are the integer values $1, 2, \ldots, s$. Let 1 be the level of the leaves and $\log s + 1$ be the level of the root.

Let v be a node of T and let the interval of integers $[i, \ldots, j]$ be its leaves; denote by $l(v)$ the minimum index k, $1 \le k \le n$ in A such that $i \le a_k \le j$. Sometimes, we use the notation $l[i, \ldots, j]$ instead of $l(v)$. No ambiguity will arise.

Example. Let $A = [a_1, a_2, a_3, a_4] = [4, 3, 1, 8]$; $s = 8$ and T is given in Fig. 7. Now $l(a) = 3, l(b) = l(e) = l(g) = 1$, and $l(d) = l(f) = 4$ ($l(c)$ is undefined).

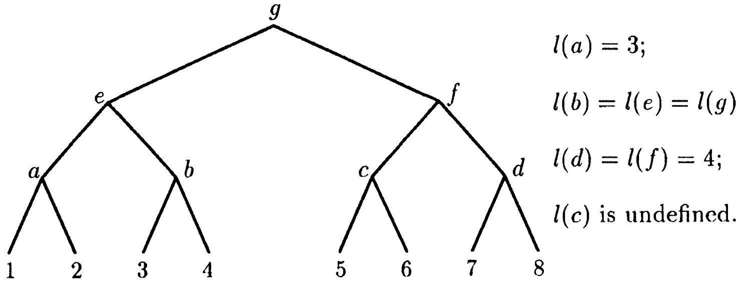

FIG. 7. *The tree T and its l-values.*

We allocate $\log s + 1$ processors to each element a_i in A, a processor for each ancestor of the *value* a_i in T (note that a node of T is defined to be one of its own ancestors).

Step 2. Compute $l(v)$ for each node v in T as follows. Each element a_i tries to write $l(v) := i$ for each ancestor v of the value a_i in T. (If two or more elements attempt to write at the same location, the element with minimal index in A succeeds.)

The computation in Step 3 below relies on the following two facts: (1) For every i, $1 \le i \le n$, a_i is critical if and only if there is no $j < i$ such that $a_j \le a_i$. To state the second fact we need the following definition. An interval of integers $[i, \ldots, j]$ is a *canonical interval* if there is a node of T such that the integer values $\{i, \ldots, j\}$ are all its leaves. (2) For every k, $1 \le k \le s$, the interval of integers $[1, \ldots, k]$ can be represented as a (disjoint) union of $\log s$ canonical intervals.

Step 3. For each element a_i test (in constant-time) whether it is critical, as follows. First, check whether $l(a_i) = i$. If not (implying that there exist an element a_j such that

$a_j = a_i$ and $j < i$) conclude that element a_i is not critical. If yes, consider the interval of integers $[1, 2, \ldots, a_i - 1]$ and take the $\leq \log s$ canonical intervals $[i_1, \ldots, j_1], [i_2, \ldots, j_2] \ldots [i_{\log s}, \ldots, j_{\log s}]$, whose union represents this interval. If $l[i_k, \ldots, j_k] < i$ for some k, $1 \leq k \leq \log s$, we conclude that a_i is not critical. Otherwise a_i is critical.

Assignment of the $\log s$ processors of a_i to the canonical intervals in Step 3 in constant time is standard, and is therefore omitted.

3.3. The optimal triply-logarithmic algorithm.

LEMMA 3.2. *There is an algorithm for finding critical elements that runs in $O(1)$ time using $n \log s$ processors and $O(ns^{\epsilon})$ space for any given constant ϵ, $0 < \epsilon < 1$.*

The algorithm that realizes the lemma above is based on adding a variant of the Radix sort idea, where the most significant bits are handled first, to the basic algorithm above. For details the reader is referred to the appendix.

THEOREM 3.3. *There is an algorithm for finding critical elements that runs in $O(\log\log\log s)$ time using an optimal number of processors and $O(ns^{\epsilon})$ space.*

The proof of the above theorem is easy. Partition the input array A into successive subarrays of $\log s$ elements each. Within each subarray find critical elements using a doubly-logarithmic optimal algorithm for prefix minima (see [3], for instance). This takes $O(\log\log\log s)$ time using $n/\log\log\log s$ processors. Each of these $n/\log s$ subarrays contributes its minimum to form an array B of elements. Informally, we finish by applying the algorithm of Lemma 3.2 to B to obtain the claimed bounds.

3.4. An optimal $O(\log^* n)$ time algorithm. In this subsection we consider the special case where the elements of the array A are restricted to the range of integers $[1..n]$. Unfortunately, we do not see a way to use the ideas introduced below to get a faster algorithm for a general domain s. The reason is that the number of processors we use is almost as large as the size of the domain (see, e.g., Lemma 3.5, where more than s processors are used).

THEOREM 3.4. *The algorithm below finds critical elements in $O(\log^* n)$ time using $n/\log^* n$ processors and linear space.*

In order to prove the above theorem we first prove the following lemma concerning a general input range $[1..s]$.

LEMMA 3.5. *There is an algorithm for finding critical elements that runs in $O(\log^* s)$ time using $s + n\log^* n$ processors and $O(n + s)$ space.*

Proof of Lemma 3.5. We begin with a high-level description followed by implementation details.

Step 1. For each k, $1 \leq k \leq s/\log s$, we select as a **representative** of the range of integers $[(k-1)\log s + 1..k \log s]$, the leftmost element a_i in A which belongs to the range (if such an element a_i exists). The number of selected representatives is at most $s/\log s$. We refer to a representative which is a critical element in A as a **critical representative**. To avoid confusion we note here that the computation below is done with respect to the original array A (and not with respect to any array of representatives).

Step 2. Find all critical representatives in A.

For i, $1 \leq i \leq n$, let left(i) denote the maximum index such that $a_{\text{left}(i)}$ is a critical representative and left$(i) < i$. Similarly, let right(i) denote the minimum index such that $a_{\text{right}(i)}$ is a critical representative and right$(i) > i$.

Step 3. For each element a_i, $1 \leq i \leq n$, find left(i) and right(i).

Consider some critical representative a_i in A. An element a_r, $i < r <$ {right(i), is critical if and only if a_r is critical in the subarray $a_i, a_{i+1}, \ldots, a_{\text{right}(i)-1}$ of A. Let $k = \lceil a_i/\log s \rceil$. In Step 4 below we finish the computation of critical elements in A by finding all critical elements in subarray $a_i, a_{i+1}, \ldots, a_{\text{right}(i)-1}$, for every critical representative a_i *separately*. The range of the elements for each of these separate subproblems is $[(k-1)\log s + 1..k \log s]$ (elements not in this range are not critical and can be given a dummy value of $k \log s$). For convenience we will view the range as $[1..\log s]$.

Step 4. Apply (recursively) Steps 1 to 4 to solve each of the separate subproblems.

Below we show how each of Steps 1 to 3 can be implemented in $O(1)$ time using $s + n \log^* n$ processors and $O(s+n)$ space. With respect to Step 4, we show how to allocate processors and space for each of the separate subproblems within the same time, processors and space bounds as Steps 1 to 3. After $\log^* s$ iterations of Steps 1 to 4 the size of the range for each of the separate subproblems is constant and the critical elements for each of these subproblems can be found in $O(1)$ time. Hence the whole algorithm takes $O(\log^* s)$ time, using $s + n \log^* n$ processors and $O(s+n)$ space. □

Implementation details.

Step 1. We use an auxiliary array B of size $s/\log s$. A processor that we allocate to each element a_i, $1 \le i \le n$, tries to write $B(\lceil a_i/\log s \rceil) := i$; The processor of a_i succeeds if and only if a_i is the leftmost element in A that belongs to the range of integers $[(\lceil a_i/\log s\rceil - 1)\log s + 1..\lceil a_i/\log s\rceil \log s]$.

Step 2. We apply the basic constant-time algorithm, but only with respect to the representatives (that is, among the elements of A we allocate processors to the representatives only). This takes $O(1)$ time using $s/\log s \cdot \log s = s$ processors and $O(s)$ space. Allocating $\log s$ processors to each representative as required by the basic constant-time algorithm is done using the array B obtained in Step 1 above.

Step 3. We use an auxiliary array $C = (c_1, c_2, \ldots, c_n)$ of bits that are all zeros initially. Each critical representative a_i, $1 \le i \le n$ writes $c_i := 1$. The problem then is to find the nearest ones (to the left and right) for each element in C. This can be done in $O(1)$ time using $n \log^* n$ processors using the nearest-one algorithm of [4].

Step 4. Consider the subproblem of finding all critical elements in the subarray $a_i, a_{i+1}, \ldots, a_{\mathrm{right}(i)-1}$ for some critical representative a_i in A. Allocating $(\mathrm{right}(i) - i)\log^* n$ processors (though only $(\mathrm{right}(i)-i)\log^*(\mathrm{right}(i)-i)$ are needed) and $O(\mathrm{right}(i)-i)$ space to this subproblem can be done using the output of Step 3. Allocating an additional $\log s$ processors and $O(\log s)$ space can be done using the array B that was computed in Step 1.

Proof of Theorem 3.4. We start with n elements, each assuming an integer value in the range $[1..n]$. The index of each element is an integer in the domain $[1\ldots n]$. Step 1 below reduces the size of the domain (of indices) from n to $n/(\log^* n)^2$. Step 2 reduces the size of the range (of values) from n to $n/(\log^* n)^2$. Step 3 applies the algorithm of Lemma 3.5 to find all critical elements in the reduced problem. Step 4 extends the solution of the reduced problem for finding all critical elements with respect to A.

Step 1. Partition the input array A into successive subarrays of $(\log^* n)^2$ numbers each. Find the minimum element in each subarray and put these minima in an array A' of size $n/(\log^* n)^2$. This step can be done in $O(\log^* n)$ time using $n/\log^* n$ processors.

Step 2. For each k, $1 \le k \le n/(\log^* n)^2$ we select as a representative of the range of integers $[(k-1)(\log^* n)^2+1..k(\log^* n)^2]$, the leftmost element a'_i in A' that belongs to the range. Get A'' from A' by replacing the value of the representative of $[(k-1)(\log^* n)^2+1..k(\log^* n)^2]$ by k; the value of nonrepresentatives will be set by default to $n/(\log^* n)^2$, which is large enough not to affect the computation.

Step 3. Find all critical elements in A''. By Lemma 3.5 this takes $O(\log^* x)$ time using $x + x\log^* x$ processors and $O(x+x)$ space, where $x = n/(\log^* n)^2$, or $O(\log^* n)$ time, using $n/\log^* n$ processors and at most $O(n)$ space.

Step 4. Mark in A every critical element of A''. Using the nearest-one algorithm of [4], find for each element a_i of A the nearest marked element to its left and the nearest marked element to its right (denoted $a_{\text{left}(i)}$ and $a_{\text{right}(i)}$, respectively, as before). This can be done in $O(\log^* n)$ time using an optimal number of processors.

We characterize the cases in which a_i is a critical element. Let the value of $a_{\text{left}(i)}$ be in the range of integers $[(k-1)(\log^* n)^2 + 1..k(\log^* n)^2]$ for some k.

Case 1. a_i and $a_{\text{right}(i)}$ do not belong to the same subarray (of size $(\log^* n)^2$). Observe that (a) a_i must be at least $(k-1)(\log^* n)^2 + 1$, and (b) a_i is a critical element if for every j, $left(i) \leq j < i, a_i < a_j$. (Checking whether condition (b) holds is called TEST 1, below.)

Case 2. a_i and $a_{\text{right}(i)}$ belong to the same subarray. Observe that (a) If $a_i \leq (k-1)(\log^* n)^2$, then it is a critical element (with respect to A) if it is a critical element with respect to its subarray. (Checking whether a_i is a critical element with respect to its own subarray is called TEST 2, below.) (b) If $a_i > (k-1)(\log^* n)^2$, then it is a critical element (with respect to A) if the following two conditions hold: (i) a_i is a critical element with respect to its subarray (can be checked by TEST 2), and (ii) for every j, left$(i) \leq j < i, a_i < a_j$ (TEST 1).

To complete the description of the algorithm, we show how to perform TEST 1 and TEST 2.

Step 5.1. Perform a prefix minimum computation with respect to each subarray of size $(\log^* n)^2$. This can be done in time $O(\log^* n)$ using $\log^* n$ processors. This provides for TEST 2 whenever needed.

Step 5.2. For every marked element, we will have a "bulletin board" $B[1 \ldots (\log^* n)^2]$ of size $(\log^* n)^2$. For every element a_i, we do the following. Let the value of $a_{\text{left}(i)}$ be in the range of integers $[(k-1)(\log^* n)^2 + 1..k(\log^* n)^2]$ for some k. If a_i is in this range, then the index i is written into $B(a_i - (k-1)(\log^* n)^2)$ using the convention that the smallest among the indices attempted to be written there is actually written (B is the bulletin board of $a_{\text{left}(i)}$). Then find critical elements with respect to each bulletin board. Finally, conclude that a_i passes TEST 1 if $B(a_i - (k-1)(\log^* n)^2) = i$ and is a critical element.

Overall Step 5 takes $O(\log^* n)$ time using $n/\log^* n$ processors and linear space. □

Appendix. Implementing Radix prefix minima. The appendix connects to its reference in §3.

High-level description. We use a variant of the Radix sort idea, where the most significant bits are handled first. The binary representation of each a_k, $1 \leq k \leq n$, needs $\log s$ bits. For each i, $0 \leq i \leq 1/\epsilon$ let a_k^i be the number represented by the $i\epsilon \log s$ most significant bits of a_k. Let A^i be the array $(a_1^i, \ldots, a_n^i)$. We find critical elements with respect to A in $1/\epsilon$ stages.

Guided by Radix sort, we compute in stage i, $1 \leq i \leq 1/\epsilon$, critical elements with respect to A^i. In addition we have a flag for each element that determines whether the element is still a **candidate** for becoming critical. An element a_j is a candidate after stage i if (1) it has not yet been identified to be critical after stage i, and (2) its leftmost $i\epsilon \log s$ bits are the same as those of the nearest critical element to its left (implying that later stages may still find a_j to be a critical element).

Base of the inductive construction. a_1 is the only critical element with respect to A^0. All other elements are candidates. (The reason is that a_k^0, $1 \leq k \leq n$ is an empty prefix of a_k.) This is the input to stage $i = 1$.

The inductive construction. We describe stage i, where the critical elements with respect to array A^{i-1} are "refined" into critical elements with respect to array A^i. Consider an interval $[\beta, \ldots, \gamma]$ of A such that a_β and a_γ are adjacent critical elements in A^{i-1} (that is, for every j, $\beta < j < \gamma$, a_j is not critical in A^{i-1}). Element a_j, $\beta < j < \gamma$, is critical in A^i if the following two conditions hold: (i) it is a candidate after stage $i-1$; and (ii) it is critical in the subarray $[a_\beta^i, \ldots, a_{\gamma-1}^i]$. Condition (i) can be verified from the output of stage $i-1$. To verify condition (ii) with respect to any j, $\beta < j < \gamma$, we find all critical elements in $[a^i_\beta, \dots, a^i_{\gamma-1}]$. For this we need only consider the ith $\epsilon \log s$ bits of the elements in $[a^i_\beta, \dots, a^i_{\gamma-1}]$. The reason is that the first $(i-1)\epsilon \log s$ bits are the same for all candidates (noncandidates can be given a default value of s^ϵ). This is done using the basic constant-time algorithm.

The output of the last stage (stage $1/\epsilon$) results in finding all critical elements with respect to A.

4. Implementation details. (1) In stage i we need to find for each element in A the nearest critical elements (with respect to A^{i-1}) to its left and right. This is done using the nearest-one algorithm of [4] in $O(1)$ time using $n \log^* n$ processors, which we can assume is at most $n \log s$ processors for the following reason. If $n \log^* n > n \log s$ then $s \leq \log n$. In such a case, the prefix-minima problem can be solved in constant time using n processors using a (single) "bulletin board" of values. This bulletin board is of size $\log n$ and the prefix-minima problem with respect to it can be solved in constant time using $\log^2 n$ processors.

(2) Allocation of processors and space to each subproblem with respect to an interval $[\beta, \dots, \gamma]$ is done as follows: We allocate $\log s$ processors and s^ϵ space to each entry in A. For the subproblem associated with interval $[\beta, \dots, \gamma]$, we use only the space allocated to entry β.

(3) Application of the basic constant-time algorithm to the ith $\epsilon \log s$ bits of $[a^i_\beta, \dots, a^i_{\gamma-1}]$ takes $O(1)$ time using $(\gamma - \beta + 1)\epsilon \log s$ processors and s^ϵ space. Overall, the running time is $O(1)$ using $\epsilon n \log s$ processors and ns^ϵ space.

FASTER APPROXIMATION ALGORITHMS FOR THE UNIT CAPACITY CONCURRENT FLOW PROBLEM WITH APPLICATIONS TO ROUTING AND FINDING SPARSE CUTS*

PHILIP KLEIN[†], SERGE PLOTKIN[‡], CLIFFORD STEIN[§] AND ÉVA TARDOS[¶]

Abstract. This paper describes new algorithms for approximately solving the concurrent multicommodity flow problem with uniform capacities. These algorithms are much faster than algorithms discovered previously. Besides being an important problem in its own right, the uniform-capacity concurrent flow problem has many interesting applications. Leighton and Rao used uniform-capacity concurrent flow to find an approximately "sparsest cut" in a graph and thereby approximately solve a wide variety of graph problems, including minimum feedback arc set, minimum cut linear arrangement, and minimum area layout. However, their method appeared to be impractical as it required solving a large linear program. This paper shows that their method might be practical by giving an $O(m^2 \log m)$ expected-time randomized algorithm for their concurrent flow problem on an m-edge graph. Raghavan and Thompson used uniform-capacity concurrent flow to solve approximately a channel width minimization problem in very large scale integration. An $O(k^{3/2}(m+n\log n))$ expected-time randomized algorithm and an $O(k \min\{n, k\}(m+n\log n)\log k)$ deterministic algorithm is given for this problem when the channel width is $\Omega(\log n)$, where k denotes the number of wires to be routed in an n-node, m-edge network.

1. Introduction.

The multicommodity flow problem involves shipping several different commodities from their respective sources to their sinks in a single network with the total amount of flow going through an edge limited by its capacity. The amount of each commodity we wish to ship is called the *demand* for that commodity. An optimization version of this problem is the *concurrent flow* problem in which the goal is to find the maximum percentage z such that at least z percent of each demand can be shipped without violating the capacity constraints. Here we consider the concurrent flow problem with unit capacities. Observe that in this case, the problem is equivalent to the problem of finding a flow (disregarding capacities) that minimizes the maximum total flow on any edge (the *congestion*). Let m, n, and k be, respectively, the number of edges, nodes, and commodities for the input network.

In this paper, we give algorithms that, for any positive ϵ, find a solution whose congestion is no more than $(1+\epsilon)$ times the minimum congestion. Our algorithms significantly improve the time required for finding such approximately optimal solutions.

One contribution of this paper is the introduction of a randomization technique useful in iterative approximation algorithms. This technique enables each iteration to be carried out much more quickly than by using known deterministic methods.

Part of our motivation in developing algorithms for concurrent flow derives from two important applications, finding sparsest cuts and finding a very large scale integration (VLSI) routing that minimizes channel width.

Leighton and Rao [14] showed how to use the solution of a unit-capacity concurrent flow problem to find an approximate "sparsest cut" of a graph. As a consequence, they and other researchers have developed polylog-times-optimal approximation algorithms for a wide variety of graph problems, including minimum area VLSI layout, minimum cut linear arrangement, minimum feedback arc set [14], optimal linear and higher-dimensional arrangement [7], minimum chordal fill [9], and single-processor scheduling [17].

The computational bottleneck of the method of Leighton and Rao is solving a unit-capacity concurrent flow problem with $O(n)$ commodities, each with unit demand. They appealed to linear programming techniques to show that the problem can be solved in polynomial time. The new approximation algorithm greatly improves the resulting running time.

THEOREM 1.1. *For any fixed $\epsilon > 0$, a $(1+\epsilon)$-factor approximation to the unit-capacity, unit-demand concurrent flow problem can be found by a randomized algorithm in $O((k+m)m\log m)$ expected time, where the constant depends on ϵ.*

As an application of this result we substantially reduce the time required for Leighton and Rao's method.

THEOREM 1.2. *An $O(\log n)$-factor approximation to the sparsest cut in a graph can be found by a randomized algorithm in expected $O(m^2 \log m)$ time.*

Previous to our work, the best algorithm for this problem and a running time of $O(n^{4.5}\sqrt{m}\log n)$ [21] and made use of linear programming techniques and fast matrix multiplication.

Another application of our approximation algorithm is to VLSI routing in graphs. Raghavan and Thompson [16] and Raghavan [15] considered the problem of routing two-terminal nets (essentially wires) in a graph so as to minimize approximately the *channel width*, i.e., the maximum number of nets routed through an edge. The computational bottleneck in their algorithms is solving a unit-capacity concurrent flow problem. Their algorithms require a better than constant ϵ approximation to the concurrent flow problem. In fact, the algorithm of Theorem 1.1 is a *fully polynomial approximation* algorithm, i.e., its running time depends polynomially on ϵ^{-1}.

THEOREM 1.3. *For any positive $\epsilon < 1$ that is at least inverse polynomial in n, a $(1+\epsilon)$-factor approximation to the unit-capacity concurrent flow problem can be found by a randomized algorithm in expected time $O((\epsilon^{-1}k + \epsilon^{-3}m)(m\log n + n\log^2 m))$ and by a deterministic algorithm in time $O((k+\epsilon^{-2}m)k(m\log m + n\log^2 m))$.*

An application of the algorithm of Theorem 1.3 is a significant improvement in the time needed to solve Raghavan and Thompson's problem.

THEOREM 1.4. *If $w_{\min}$ denotes the minimum achievable channel width and $w_{\min} = \Omega(\log m)$, a routing of width $w_{\min} + O(\sqrt{w_{\min}\log n})$ can be found by a randomized algorithm in expected time $O(k^{3/2}(m + n\log n))$ and by a deterministic algorithm in time $O(k\min\{n,k\}(m+n\log n)\log k)$.*

Our algorithms compare favorably to previous work. The concurrent flow problem can be formulated as a linear program in $O(mk)$ variables and $O(m+nk)$ constraints (see, for example, [18]). Linear programming can be used to solve the problem optimally in polynomial time. Kapoor and Vaidya [8] gave a method to speed up the matrix inversions involved in Karmarkar type algorithms for multicommodity flow problems; combining their technique with Vaidya's new linear programming algorithm using fast matrix multiplication [21] yields a time bound of $O(k^{3.5}n^3\sqrt{m}\log(nD))$ for the unit-capacity concurrent flow problem with integer demands (where D denotes the sum of the demands) and an $O(\sqrt{m}k^{2.5}n^2 \log(n\epsilon^{-1}D))$ bound for the approximation problem.

Shahrokhi and Matula [18] gave a combinatorial fully polynomial approximation scheme for the unit-capacity concurrent flow problem (which they called the concurrent flow problem with uniform capacities). Their algorithm runs in $O(nm^7\epsilon^{-5})$ time.

Our approach to solving concurrent flow problems is a modification of the framework originated by Shahrokhi and Matula [18]. The idea is to use a length function on the edges to reflect congestion and iteratively reroute flow from long (more congested) paths to short (less congested) paths. Our approach differs from that of Shahrokhi and Matula in several ways. We develop a framework of *relaxed optimality conditions* that allows us to measure the congestion on both a local and a global level, thereby giving us more freedom in choosing which flow paths to reroute at each iteration. We exploit this freedom by using a faster *randomized* method for choosing flow paths. In addition, this framework also allows us to achieve greater improvement as a result of each rerouting. In Table 1, we give upper bounds on the running times for our algorithms. Our actual bounds are slightly better than those in the table and are given in more detail in the remainder of the paper. Note that by use of various combinations of our techniques, we can obtain slightly better bounds than those stated in Theorems 1.1 and 1.3.

TABLE 1

Upper bounds on the running times of our algorithms. The actual bounds are slightly better.

Algorithm type	Running Time
Randomized, fixed ϵ	$O(m(k+m)\log n)$
Deterministic, fixed ϵ	$O(mk(k+m)\log n)$
Randomized, $1 < \epsilon < \frac{1}{\text{poly}(n)}$	$O(\epsilon^{-3}m(k+m)\log^2 n)$
Deterministic, $1 < \epsilon < \frac{1}{\text{poly}(n)}$	$O(\epsilon^{-2}mk(k+m)\log^2 n)$

An earlier version of this paper has appeared in [11]. In the earlier version the case when both the capacities and the demands are uniform was considered separately from the more general case when only the capacities are assumed to be uniform. The earlier version presented a fast algorithm for the first case and a factor of $\epsilon^{-1}m$ slower one for the more general case. In this version we extend the algorithm for the uniform demand case to work for the more general case with at most a logarithmic slowdown.

In subsequent work building on that described here, Leighton et al. [13] gave a fast approximation algorithm for concurrent flow with arbitrary capacities. That algorithm is faster than ours when the number of commodities is less than $\sqrt{m}$. It makes use of the randomized technique introduced in this paper. Also, in subsequent work, Goldberg [4] and Grigoriadis and Khachiyan [6] showed that by a modification of the randomized technique, one can reduce the running time's dependence on ϵ for both our algorithm and that of Leighton et al.

2. Preliminaries and definitions. In this section we define the concurrent flow problem, introduce our notation, and give some basic facts regarding the problem. Concurrent flow is a variant of multicommodity flow, and we start by giving a formal definition of the latter.

The multicommodity flow problem is the problem of shipping several different commodities from their respective sources to their sinks in a single network, while obeying capacity constraints. More precisely, an instance of the multicommodity flow problem consists of an undirected graph $G = (V, E)$, a nonnegative capacity $\text{cap}(vw)$ for every edge $vw \in E$, and a specification of k commodities, numbered 1 through k. The specification for commodity i consists of a source-sink pair $s_i, t_i \in V$ and a nonnegative integer demand $d(i)$. We will denote the maximum demand by $d_{\max}$, the total demand $\sum_i d(i)$ by D, the number of nodes by n, the number of edges by m, and the number of different sources by k^*. Notice that $k^* \leq n$. For notational convenience we assume that $m \geq n$ and that the graph G has no parallel edges. If there is an edge between nodes v and w, this edge is unique by assumption, and we denote it by vw. Note that vw and wv denote the same edge.

A *flow* f_i in G from node s_i to node t_i can be defined as a collection of paths from s_i to t_i, with associated real values. Let $\mathcal{P}_i$ denote a collection of paths from s_i to t_i in G, and let $f_i(P)$ be a nonnegative value for every P in $\mathcal{P}_i$. The *value* of the flow thus defined is $\sum_{P \in \mathcal{P}_i} f_i(P)$, which is the total flow delivered from s_i to t_i. The amount of flow through an edge vw is

$$f_i(vw) = \sum \{f_i(P) \ : \ P \in \mathcal{P}_i \text{ and } vw \in P\}.$$

A *feasible multicommodity flow* f in G consists of a flow f_i from s_i to t_i of value $d(i)$ for each commodity $1 \leq i \leq k$. We require that $f(vw) \leq \text{cap}(vw)$ for every edge $vw \in E$, where we use $f(vw) = \sum_{i=1}^{k} f_i(vw)$ to denote the total amount of flow on the edge vw.

We consider the optimization version of the multicommodity flow problem, called the *concurrent flow problem* and first defined by Shahrokhi and Matula [18]. In this problem the objective is to compute the maximum possible value z such that there is a feasible multicommodity flow with demands $z \cdot d(i)$ for every $1 \leq i \leq k$. We call z the *throughput* of the multicommodity flow. An equivalent formulation of the concurrent flow problem is to compute the maximum z such that there is a feasible flow with demands $d(i)$ and capacities $\text{cap}(vw)/z$.

In this paper we shall focus exclusively on the special case of *unit capacities*, in which all edge-capacities are equal. The problem of finding a maximum throughput z can be reformulated in this special case as follows: ignore capacities, and find a multicommodity flow f that satisfies the demands and minimizes $|f| = \max_{vw \in E} \{f(vw)\}$, the maximum total flow on any edge.

A multicommodity flow f satisfying the demands $d(i)$ is *ϵ-optimal* if $|f|$ is at most a factor $(1+\epsilon)$ more than the minimum possible $|f|$. The *approximation problem* associated with the unit-capacity concurrent flow problem is to find an ϵ-optimal multicommodity flow f. We shall assume implicitly throughout that ϵ is at least inverse polynomial in n and at most $1/10$. These assumptions are not very restrictive as they cover practically every case of interest. To find an ϵ-optimal flow where $\epsilon \geq 1/10$, one can just find a $1/10$-optimal flow. To find an ϵ-optimal flow when $1/\epsilon$ is greater than any polynomial in n, one can run our algorithm. It will work for arbitrarily small ϵ, however, the running time will be slower than the time bounds given, as we will need to manipulate numbers whose size is exponential in the input. However, if this amount of accuracy is desired, it is more sensible and efficient to use any polynomial time linear programming algorithm to solve the problem exactly.

One can define the analogous problem for directed graphs. Our algorithms, and the corresponding time bounds, easily extend to the directed case by replacing (undirected) edges by (directed) arcs and paths by directed paths. Henceforth, we will concentrate only on the undirected case.

Linear programming duality gives a characterization of the optimum solution to the concurrent flow problem. Let $\ell : E \rightarrow \mathbf{R}$ be a nonnegative *length* function. For nodes $v, w \in V$ let $\text{dist}_\ell(v, w)$ denote the length of the shortest path from v to w in G with respect to the length function ℓ. For a path P we shall use $\ell(P)$ to denote the length of P. We shall use $|\ell|_1$ to denote $\sum_{vw \in E} \ell(vw)$, the sum of the length of the edges. The following theorem is a special case of the linear programming duality theorem (see, for example, [18]).

THEOREM 2.1. *For a multicommodity flow f satisfying the demands $d(i)$ and a length function ℓ,*

$$
(1)\qquad
\begin{aligned}
|f||\ell|_1 \geq \sum_{vw\in E} f(vw)\ell(vw) &= \sum_{i=1}^{k}\sum_{vw\in E}\ell(vw)f_i(vw)\\
&= \sum_{i=1}^{k}\sum_{P\in\mathcal{P}_i}\ell(P)f_i(P) \geq \sum_{i=1}^{k}\operatorname{dist}_\ell(s_i,t_i)d(i).
\end{aligned}
$$

Furthermore, a multicommodity flow f minimizes $|f|$ if and only if there exists a nonzero length function ℓ for which all of the above terms are equal.

The optimality (complementary slackness) conditions given by linear programming can be reformulated in terms of conditions on edges and paths.

THEOREM 2.2. *A multicommodity flow f has minimum $|f|$ if and only if there exists a nonzero length function ℓ such that*

(1) *for every edge $vw \in E$ either $\ell(vw) = 0$ or $f(vw) = |f|$, and*

(2) *for every commodity i and every path $P \in \mathcal{P}_i$ with $f_i(P) > 0$ we have $\ell(P) = \operatorname{dist}_\ell(s_i, t_i)$.*

The goal of our algorithms is to solve the approximation problem, i.e., to find a multicommodity flow f and a length function ℓ such that the largest term, $|f||\ell|_1$, in (1) is within a $(1+\epsilon)$ factor of the smallest term, $\sum_i \operatorname{dist}_\ell(s_i,t_i)d(i)$. In this case, we say that f and ℓ are ϵ-optimal. Note that if f and ℓ are ϵ-optimal, then clearly f is ϵ-optimal. In fact, a multicommodity flow f is ϵ-optimal if and only if there exists a length function ℓ such that f and ℓ are ϵ-optimal.

3. Relaxed optimality conditions. Theorems 2.1 and 2.2 give two (apparently) different characterizations of exact optimality. Our goal is to find a flow that satisfies a relaxed version of Theorem 2.1. In order to do so, we will introduce a relaxed version of Theorem 2.2, the complementary slackness conditions of linear programming. We will then show that these *relaxed optimality conditions* are sufficient to show that the first and last terms in (1) are within a $(1+\epsilon)$ factor, and hence the flow f is ϵ-optimal. Our notion of relaxed optimality is analogous to the notion of ϵ-optimality used by Goldberg and Tarjan in the context of the minimum-cost flow problem [5].

Let $\epsilon > 0$ be an error parameter, f a multicommodity flow, and ℓ a length function. Throughout this section we shall use ϵ' to denote $\frac{\epsilon}{7}$. We say that a path $P \in \mathcal{P}_i$ for a commodity i is *ϵ-good* if

$$\ell(P) - \operatorname{dist}_\ell(s_i,t_i) \leq \epsilon'\ell(P) + \epsilon'\frac{|f|}{\min\{D, kd(i)\}}|\ell|_1$$

and *ϵ-bad* otherwise. The intuition is that a flow path is ϵ-good if it is short in either a relative or an absolute sense, i.e., either it is almost as short as the shortest possible (s_i,t_i)-path or it is at most a small fraction of $|\ell|_1$. We use this notion in defining the following *relaxed optimality conditions* (with respect to a flow f, a length function ℓ, and an error parameter ϵ):

(R1) For every edge $vw \in E$ either $\ell(vw) \leq \frac{\epsilon'}{m}|\ell|_1$ or $f(vw) \geq |f|/(1+\epsilon')$.

$$
(\text{R2})\qquad \sum_{i=1}^{k}\sum_{\substack{P\in\mathcal{P}_i\\ P\ \epsilon\text{-bad}}} f_i(P)\ell(P) \leq \epsilon'\sum_{i=1}^{k}\sum_{P\in\mathcal{P}_i} f_i(P)\ell(P).
$$

The first condition says that every edge either has a length that is a small fraction of the sum of the lengths of all edges or is almost saturated. The second condition says that the amount of flow that is on ϵ-bad paths, i.e., long paths, contributes a small fraction of the sum $f\cdot\ell$.

The next two lemmas show that the relaxed optimality conditions are sufficient to imply ϵ-optimality. We will first show that Condition (R1) implies that the first two terms in (1) are close. Then we will show that the two conditions together imply that the first and last terms in (1) are close. Thus we can conclude that the relaxed optimality conditions are sufficient to imply ϵ-optimality.

LEMMA 3.1. *Suppose a multicommodity flow f and a length function ℓ satisfy relaxed optimality condition* (R1). *Then*

$$(1-\epsilon')|f||\ell|_1 \le (1+\epsilon')\sum_{vw} f(vw)\ell(vw). \tag{2}$$

Proof. We estimate $|f||\ell|_1 = \sum_{vw}|f|\ell(vw)$ in two parts. The first part is the sum of the terms contributed by edges that satisfy $|f| \le (1+\epsilon')f(vw)$. This part of the sum is clearly at most $(1+\epsilon')\sum_{vw} f(vw)\ell(vw)$. If vw is an edge whose contribution is not counted in the first part, then, by assumption, $\ell(vw) \le (\epsilon'/m)|\ell|_1$. Therefore, the sum of all other terms is at most $\epsilon'|f||\ell|_1$. Thus, $|f||\ell|_1 \le (1+\epsilon')\sum_{vw} f(vw)\ell(vw) + \epsilon'|f||\ell|_1$. This implies the lemma. □

THEOREM 3.2. *Suppose f and ℓ and ϵ satisfy the Relaxed Optimality Conditions* (R1) *and* (R2). *Then f is ϵ-optimal, i.e., $|f|$ is at most a factor* $(1+\epsilon)$ *more than the minimum possible.*

Proof. We need to estimate the ratio of the terms in inequality (1) of Theorem 2.1. Lemma 3.1 estimates the ratio of the first two terms. We shall use this in estimating the ratio of the first and the last terms.

Consider the penultimate term in (1). We break this sum, $\sum_i \sum_{P\in\mathcal{P}_i} \ell(P)f_i(P)$, into two parts: the sum over ϵ-good paths and the sum over ϵ-bad paths. Relaxed optimality condition (R2) gives us an upper bound of $\epsilon'\sum_i\sum_{P\in\mathcal{P}_i}\ell(P)f_i(P)$ on the sum over the ϵ-bad paths, and the definition of an ϵ-good path gives us the following bound on the sum over the ϵ-good paths:

$$\sum_{i=1}^{k} \sum_{\substack{P\in\mathcal{P}_i\\ P\ \epsilon\text{-good}}} f_i(P)\ell(P)$$
$$\le (1-\epsilon')^{-1}\sum_i\sum_{P\in\mathcal{P}_i}\left(\mathrm{dist}_\ell(s_i,t_i)f_i(P) + \epsilon'\frac{|f|}{\min\{D,kd(i)\}}|\ell|_1 f_i(P)\right).$$

Observing that $(\min\{D,kd(i)\})^{-1} \le D^{-1} + (kd(i))^{-1}$ and $\sum_{P\in\mathcal{P}_i} f_i(P) = d(i)$, we can bound the sum over the ϵ-good paths by

$$\sum_{i=1}^{k} \sum_{\substack{P\in\mathcal{P}_i\\ P\ \epsilon\text{-good}}} f_i(P)\ell(P)$$
$$\le (1-\epsilon')^{-1}\left(\sum_i \mathrm{dist}_\ell(s_i,t_i)d(i) + \sum_i \epsilon'|f||\ell|_1 d(i)\left(\frac{1}{D}+\frac{1}{kd(i)}\right)\right)$$
$$= (1-\epsilon')^{-1}\left(\sum_i \mathrm{dist}_\ell(s_i,t_i)d(i) + \sum_i \epsilon'|f||\ell|_1\left(\frac{d(i)}{D}+\frac{1}{k}\right)\right).$$

Now observe that there are exactly k commodities and $\sum_i d(i) = D$, so the last term sums to exactly $2\epsilon'|f||\ell|_1$. This gives that

$$\sum_{i=1}^{k} \sum_{\substack{P \in \mathcal{P}_i \\ P\ \epsilon\text{-good}}} f_i(P)\ell(P) \leq (1-\epsilon')^{-1}\left(\sum_i \text{dist}_\ell(s_i, t_i)d(i) + 2\epsilon'|f||\ell|_1\right).$$

Combining the bounds on the sum over ϵ-bad and ϵ-good paths we get

$$\begin{aligned}\sum_i \sum_{P\in\mathcal{P}_i} \ell(P)f_i(P) &\leq (1-\epsilon')^{-1}\sum_{i=1}^{k} \sum_{\substack{P \in \mathcal{P}_i \\ P\ \epsilon\text{-good}}} f_i(P)\ell(P) \\ &\leq (1-\epsilon')^{-2}\sum_i \text{dist}_\ell(s_i, t_i)d(i) + 2(1-\epsilon')^{-2}\epsilon'|f||\ell|_1.\end{aligned}$$

By the middle equations in Theorem 2.1, $\sum_i \sum_{P\in\mathcal{P}_i} \ell(P)f_i(P)$ is equal to $\sum_{vw\in E} f(vw)\ell(vw)$. Lemma 3.1 gives a bound on $\sum_{vw\in E} f(vw)\ell(vw)$ in terms on $|f||\ell|_1$. Combining these inequalities and rearranging terms we get

$$\left(\frac{(1-\epsilon')^2}{1+\epsilon'} - \frac{2\epsilon'}{1-\epsilon'}\right)|f||\ell|_1 \leq \frac{1}{1-\epsilon'}\sum_i \text{dist}_\ell(s_i, t_i)d(i).$$

Combining the fractions and dropping low-order terms we get that

$$|f||\ell|_1 \leq \frac{1+\epsilon'}{1-5\epsilon'}\sum_i \text{dist}_\ell(s_i, t_i)d(i).$$

The assumption that $\epsilon \leq 1/10$ implies that $\epsilon' \leq 1/70$, which in turn implies that the factor $(1+\epsilon')/(1-5\epsilon')$ is less than $(1+7\epsilon') = (1+\epsilon)$. We combine this bound with inequality (1) to complete the proof. □

In the next two sections, we will focus on algorithms that achieve the relaxed optimality conditions.

4. Generic rerouting. In this section, we describe the procedure REDUCE that is the core of our approximation algorithms and prove bounds on its running time. Given a multicommodity flow f, procedure REDUCE modifies f until either f becomes ϵ-optimal or $|f|$ is reduced below a given target value. The approximation algorithms presented in the next two sections repeatedly call procedure REDUCE to decrease $|f|$ by a factor of 2, until an ϵ-optimal solution is found.

The basic step in our algorithms is choosing a flow path and rerouting some flow from this path to a "better" path. This step closely resembles the basic step in the algorithm of Shahrokhi and Matula [18]. The main differences are in the way we choose the paths and in the amount of flow that is rerouted at each iteration.

The key idea is to measure how good the current flow is by using the notion of ϵ-optimality, described in the previous section. Given a flow f and a value α to be determined later, we use a length function defined by $\ell(vw) = e^{\alpha f(vw)}$, which reflects the congestion of the edge vw. In other words, the length of an edge depends on the flow carried by the edge. Given an input ϵ, our algorithms gradually update f until f and ℓ (defined by the above formula) become ϵ-optimal. Each update is done by choosing an ϵ-bad flow path, rerouting some flow from this path to a much shorter path (with respect to ℓ), and recomputing the length function. We will prove below that the parameter α in the definition of length can be selected so that relaxed optimality condition (R1) is always satisfied. Through iterative reroutings of flow, we gradually enforce relaxed optimality condition (R2). When both relaxed optimality conditions are satisfied then Theorem 3.2 can be used to infer that f is ϵ-optimal.

For simplicity of presentation, we shall assume for now that the value of the length function $\ell(vw) = e^{\alpha f(vw)}$ at an edge vw can be computed in one step from $f(vw)$ and represented in a single computer word. In §4.3 we will remove this assumption and show that it is sufficient to compute an approximation to this value and show that the time required for computing a sufficiently good approximation does not change the asymptotic running times of our algorithms.

Procedure REDUCE (see Fig. 1) takes as input a multicommodity flow f, a target value τ, an error parameter ϵ, and a flow quantum σ_i for each commodity i. We require that each flow path comprising f_i carries flow that is an integer multiple of σ_i. The procedure repeatedly reroutes σ_i units of flow from an ϵ-bad path of commodity i to a shortest path. We will need a technical *granularity condition* that σ_i is small enough for every i to guarantee that approximate optimality is achievable through such reroutings. In particular, we assume that upon invocation of REDUCE, for every commodity i we have

$$\sigma_i \le \epsilon^2 \frac{\tau}{102 \log(7m\epsilon^{-1})}. \tag{3}$$

Upon termination, the procedure outputs an improved multicommodity flow f such that either $|f|$ is less than the target value τ or f is ϵ-optimal. (Recall that we have assumed that $\epsilon \le 1/10$.)

In the remainder of this section, we analyze the procedure REDUCE shown in Fig. 1. First, we show that throughout REDUCE f and ℓ satisfy relaxed optimality condition (R1). Second, we show that if the granularity condition is satisfied, the number of iterations in REDUCE is small. Third, we give an even smaller bound on the number of iterations for the case in which the flow f is $O(\epsilon)$-optimal upon invocation of REDUCE. This bound will be used in §5 to analyze an ϵ-scaling algorithm presented there. Fourth, we describe efficient implementations of procedure FINDPATH.

```
REDUCE($f$, $\tau$, $\epsilon$, $\sigma_i$ for $i = 1, \dots, k$)
$\alpha \leftarrow (7+\epsilon)\tau^{-1}\epsilon^{-1}\log(7m\epsilon^{-1})$.
While $|f| \ge \tau$ and $f$ and $\ell$ are not $\epsilon$-optimal,
  For each edge $vw$, $\ell(vw) \leftarrow e^{\alpha f(vw)}$.
  Call FINDPATH($f$, $\ell$, $\epsilon$) to find an $\epsilon$-bad flow path $P$ and a short path $Q$
    with the same endpoints as $P$.
  Reroute $\sigma_i$ units of flow from $P$ to $Q$.
Return $f$.
```

FIG. 1. *Procedure* REDUCE.

4.1 Bounding the number of iterations of REDUCE.

LEMMA 4.1. *If f is a multicommodity flow and $\alpha \ge (7+\epsilon)|f|^{-1}\epsilon^{-1}\log(7m\epsilon^{-1})$, then the multicommodity flow f and the length function $\ell(vw) = e^{\alpha f(vw)}$ satisfy relaxed optimality condition* (R1).

Proof. Assume $|f| - f(v,w) \ge \frac{\epsilon}{7} f(v,w)$ for an edge $vw \in E$, and let ϵ' denote $\frac{\epsilon}{7}$. Observe that $|\ell|_1 \ge e^{\alpha|f|}$. Hence, we have

$$\frac{|\ell|_1}{\ell(v,w)} \geq \frac{e^{\alpha|f|}}{e^{\alpha f(v,w)}} \geq \frac{e^{\alpha|f|}}{e^{\alpha|f|(1+\epsilon')^{-1}}} = e^{\alpha|f|\epsilon'(1+\epsilon')^{-1}}.$$

We can use the bound on α in the statement of the lemma to conclude that this last term is at least $\frac{7m}{\epsilon}$. Thus, $\ell(vw) \leq \frac{\epsilon}{7m}|\ell|_1$. □

At the beginning of REDUCE, α is set equal to $(7+\epsilon)\tau^{-1}\epsilon^{-1}\log(7m\epsilon^{-1})$. As long as $|f| \geq \tau$, the value of α is sufficiently large, so by Lemma 4.1, relaxed optimality condition (R1) is satisfied. If we are lucky and relaxed optimality condition (R2) is also satisfied, then it follows that f and ℓ are ϵ-optimal. Now we show that if (R2) is not satisfied, then we can make significant progress. Like Shahrokhi and Matula, we use $|\ell|_1$ as a measure of progress.

LEMMA 4.2. *Suppose σ_i and τ satisfy the granularity condition. Then rerouting σ_i units of flow from an ϵ-bad path of commodity i to the shortest path with the same endpoints decreases $|\ell|_1$ by*

$$\Omega\left(\frac{\sigma_i}{\min\{D, kd(i)\}}|\ell|_1 \log m\right).$$

Proof. Let P be an ϵ-bad path from s_i to t_i, and let Q be a shortest (s_i,t_i)-path. Let $A = P - Q$ and $B = Q - P$. The only edges whose length changes due to the rerouting are those in $A \cup B$. The decrease in $|\ell|_1$ is $\ell(A) + \ell(B) - e^{-\alpha\sigma_i}\ell(A) - e^{\alpha\sigma_i}\ell(B)$, which can also be written as

$$(1-e^{-\alpha\sigma_i})(\ell(A)-\ell(B)) - (1-e^{-\alpha\sigma_i})(e^{\alpha\sigma_i}-1)\ell(B).$$

The granularity condition, the definition of α, and the assumption that $\epsilon \leq 1/10$ imply that $\alpha\sigma_i \leq \frac{7+\epsilon}{102}\epsilon \leq \epsilon/7 \leq 1/70$. For $0 \leq x \leq \frac{1}{70}$, we have $e^x \geq 1+x$, $e^x \leq 1+\frac{141}{140}x$, and $e^{-x} \leq 1-\frac{139}{140}x$. Thus the decrease is at least

$$\frac{139}{140}\alpha\sigma_i\,(\ell(A)-\ell(B)) - (\alpha\sigma_i)\left(\frac{141}{140}\alpha\sigma_i\right)\ell(B).$$

Now, observe that $\ell(A)-\ell(B)$ is the same as $\ell(P)-\ell(Q)$ and that $\ell(Q) = \mathrm{dist}_\ell(s_i,t_i)$. Also $\ell(B) \leq \ell(P)$. This gives a lower bound of

$$\frac{139}{140}\alpha\sigma_i\,(\ell(P)-\mathrm{dist}_\ell(s_i,t_i)) - \left(\frac{141}{140}\alpha^2\sigma_i^2\right)\ell(P).$$

But P is ϵ-bad, so this must be at least

$$\frac{139}{140}\alpha\sigma_i(\epsilon'\ell(P) + \epsilon'\frac{|f|}{\min\{D,kd(i)\}}|\ell|_1) - \frac{141}{140}\alpha^2\sigma_i^2\ell(P)$$

$$= \frac{139}{140}\alpha\sigma_i\epsilon'\ell(P) - \frac{141}{140}\alpha^2\sigma_i^2\ell(P) + \frac{139}{140}\alpha\epsilon'|f|\frac{\sigma_i}{\min\{D,kd(i)\}}|\ell|_1.$$

We have seen that $\frac{7+\epsilon}{102}\epsilon \geq \alpha\sigma_i$, which implies that $139\epsilon' \geq 141\alpha\sigma_i$, and therefore the first term dominates the second term. Thus the third term gives a lower bound on the decrease in $|\ell|_1$.

Substituting the value of α and using the fact that during execution of REDUCE we have $\tau \leq |f|$ yields the claim of the lemma. □

The following theorem bounds the number of iterations in REDUCE.

THEOREM 4.3. *If, for every commodity i, τ and σ_i satisfy the granularity condition and $|f| = O(\tau)$ initially, then the procedure* REDUCE *terminates after*

$$O(\epsilon^{-1} \max_i \frac{\min\{D, kd(i)\}}{\sigma_i})$$

iterations.

Proof. Theorem 3.2 implies that if f and ℓ satisfy the relaxed optimality conditions, then they are ϵ-optimal. By Lemma 4.1, relaxed optimality condition (R1) is maintained throughout all iterations. The fact that f is not yet ϵ-optimal implies that condition (R2) is not yet satisfied. Hence there exists an ϵ-bad path for FINDPATH to find. A single rerouting of flow from an ϵ-bad path of commodity i to a shortest path results in a reduction in $|\ell|_1$ of at least

$$\Omega\left(\frac{\sigma_i}{\min\{D, kd(i)\}}|\ell|_1 \log(m\epsilon^{-1})\right).$$

Since $1 - x < e^{-x}$, it follows that every

$$O\left(\max_i \frac{\min\{D, kd(i)\}}{\sigma_i} \log^{-1}(m\epsilon^{-1})\right)$$

iterations reduce $|\ell|_1$ by at least a constant factor.

Next we bound the number of times $|\ell|_1$ can be reduced by a constant factor. Let f' denote the input multicommodity flow. For every edge vw, $f'(vw) \leq |f'|$. Hence after we first assign lengths to edges, the value of $|\ell|_1$ is at most $me^{\alpha|f'|}$. The length of every edge remains at least 1, so $|\ell|_1$ is always at least m. Therefore, $|\ell|_1$ can be reduced by a factor of e at most $\alpha|f'|$ times, which is $O(\epsilon^{-1} \log(m\epsilon^{-1}))$ by the assumption that $f = O(\tau)$ and the value of α. This proves that REDUCE terminated in the claimed number of iterations. □

THEOREM 4.4. *Suppose that the input flow f is $O(\epsilon)$-optimal, σ and τ satisfy the granularity condition, and $|f| = O(\tau)$ initially. Then the procedure* REDUCE *terminates after*

$$O\left(\max_i \frac{\min\{D, kd(i)\}}{\sigma_i}\right)$$

iterations.

Proof. Again let f' denote the input multicommodity flow. The assumption that f' is $O(\epsilon)$-optimal implies that $|f'| \leq (1 + O(\epsilon))|f|$ for *every* multicommodity flow f. Therefore, the value of $|\ell|_1$ is never less than $e^{(1+O(\epsilon))^{-1}\alpha|f'|}$. As in Theorem 4.3, the initial value of $|\ell|_1$ is at most $me^{\alpha|f'|}$, so the number of times $|\ell|_1$ can be reduced by a constant factor is $O(\alpha\epsilon|f'| + \log m)$, which is $O(\alpha\epsilon|f'|)$ by the choice of α and τ. The theorem then follows as in the proof of Theorem 4.3. □

4.2. Implementing an iteration of REDUCE. We have shown that REDUCE terminates after a small number of iterations. It remains to show that each iteration can be carried out quickly. REDUCE consists of three steps—computing lengths, executing FINDPATH, and rerouting flow. We discuss computing lengths in §4.3. In this section, we discuss the other two steps.

We now consider the time taken by procedure FINDPATH. We will give three implementations of this procedure. First, we will give a simple deterministic implementation that runs in $O(k^*(m + n \log n) + n \sum_i (d(i)/\sigma_i))$ time, then a more sophisticated implementation that runs in time $O(k^*n\log n + m(\log n + \min\{k, k^*\log d_{\max}\}))$, and finally a randomized implementation that runs in expected $O(\epsilon^{-1}(m + n\log n))$ time. All of these algorithms use the shortest-paths algorithm of Fredman and Tarjan [3] that runs in $O(m + n\log n)$ time.

To find a bad flow path deterministically, we first compute, for every source node s_i, the length of the shortest path from s_i to every other node v. This takes $O(k^*(m + n\log n))$ time. In the simplest implementation we then compute the length of every flow path in $\mathcal{P}$ and compare its length to the length of the shortest path to decide if the path is ϵ-bad. There could be as many as $\sum_i (d(i)/\sigma_i)$ flow paths, each consisting of up to n edges; hence, computing these lengths takes $O(n\sum_i(d(i)/\sigma_i))$ time.

To decrease the time required for FINDPATH we have to find an ϵ-bad path, if one exists, without computing the length of so many paths. Observe that if there is an ϵ-bad flow path for commodity i, then the longest flow path for commodity i must be ϵ-bad. Thus, instead of looking for an ϵ-bad path in $\mathcal{P}_i$ for some commodity i, it suffices to find an ϵ-bad path in the directed graph obtained by taking all flow paths in $\mathcal{P}_i$ and treating the paths as directed away from s_i. In order to see if there is an ϵ-bad path we need to compute the length of the longest path from s_i to t_i in this directed graph. To facilitate this computation we shall maintain that the directed flow graph is acyclic.

Let G_i denote the flow graph of commodity i. If G_i is acyclic, an $O(m)$ time dynamic programming computation suffices to compute the longest paths from s_i to every other node. Suppose that in an iteration we reroute flow from an ϵ-bad path from s_i to t_i, in the flow graph G_i. We must first update the flow graph G_i to reflect this change. Second, the update might introduce directed cycles in G_i, so we must eliminate such cycles of flow. We use an algorithm due to Sleator and Tarjan [19] to implement this process. Sleator and Tarjan gave a simple $O(nm)$ algorithm and a more sophisticated $O(m\log n)$ algorithm for the problem of converting an arbitrary flow into an acyclic flow.

Note that eliminating cycles only decreases the flows on edges, so it cannot increase $|\ell|_1$. Thus our bound on the number of iterations in REDUCE still holds.

We compute the total time required for each iteration of REDUCE as follows. In order to implement FINDPATH, we must compute the shortest path from s_i to t_i in G and the longest path from s_i to t_i in G_i for every commodity i, so the time required is $O(k^*(m+n\log n)+km)$. Furthermore, after each rerouting, we must update the appropriate flow graph and eliminate cycles. Elimination of cycles takes $O(m\log n)$ time. Combining these bounds gives an $O(k^*n\log n + m(k + \log n))$ bound on the running time of FINDPATH.

In fact, further improvement is possible if we consider the flow graphs of all commodities with the same source and same flow quantum σ_i together. Let $G_{v,\sigma}$ be the directed graph obtained by taking the union of all flow paths $P \in \mathcal{P}_i$ for a commodity i with $s_i = v$ and $\sigma_i = \sigma$, treating each path as directed away from v. If $G_{v,\sigma}$ is acyclic, an $O(m)$ time dynamic programming computation suffices to compute the longest paths from v to every other node in $G_{v,\sigma}$.

During our concurrent flow algorithm all commodities with the same demand will have the same flow quantum. To limit the different flow graphs that we have to consider we want to limit the number of different demands. By decomposing demand $d(i)$ into at most $\log d(i)$ demands with source s_i and sink t_i we can assume that each demand is a power of 2. This way the number of different flow graphs that we have to maintain is at most $k^*\log d_{\max}$.

LEMMA 4.5. *The total time required for deterministically implementing an iteration of* REDUCE *(assuming that exponentiation is a single step) is* $O(k^*n\log n + m(\log n + \min\{k, k^*\log d_{\max}\}))$.

Next, we give a randomized implementation of FINDPATH that is much faster when ϵ is not too small; this implementation seems simple enough to be practical. If f and ℓ are not ϵ-

optimal, then relaxed optimality condition (R2) is not satisfied, and thus ϵ-bad paths contribute at least an $\frac{\epsilon}{7}$-fraction of the total sum $\sum_i \sum_{P\in\mathcal{P}_i} \ell(P) f_i(P)$. Therefore, by randomly choosing a flow path P with probability proportional to its contribution to the above sum, we have at least an $\frac{\epsilon}{7}$ chance of selecting an ϵ-bad path. Furthermore, we will show that we can select a candidate ϵ-bad path according to the right probability in $O(m)$ time. Then we can compute a shortest path with the same endpoints in $O(m + n \log n)$ time. This enables us to determine whether or not P was an ϵ-bad path. Thus we can implement FINDPATH in $O(\epsilon^{-1}(m+n \log n))$ expected time.

The contribution of a flow path P to the above sum is just the length of P times the flow on P, so we must choose P with probability proportional to this value. In order to avoid examining all such flow paths explicitly, we use a two-step procedure, as described in the following lemma.

LEMMA 4.6. *If we choose an edge vw with probability proportional to $\ell(vw) f(vw)$ and then select a flow path among paths through this edge vw with probability proportional to the value of the flow carried on the path, then the probability that we have selected a given flow path P is proportional to its contribution to the sum $\sum_i \sum_{P\in\mathcal{P}_i} \ell(P) f_i(P)$.*

Proof. Let $B = \sum_i \sum_{P\in\mathcal{P}_i} \ell(P) f_i(P)$. Select an edge vw with probability $f(vw)\ell(vw)/B$. Once an edge vw is selected, choose a path $P \in \mathcal{P}_i$ through edge vw with probability $\frac{f_i(P)}{f(vw)}$. Consider a commodity i and a path $P \in \mathcal{P}_i$.

$$Pr(P \text{ chosen}) = \sum_{vw\in P} Pr(vw \text{ chosen}) \times \frac{f_i(P)}{f(vw)} = \sum_{vw\in P} \frac{f(vw)\ell(vw)}{B} \times \frac{f_i(P)}{f(vw)}$$

$$= \sum_{vw\in P} \frac{\ell(wv) f_i(P)}{B} = \frac{f_i(P)\ell(P)}{B}. \qquad \square$$

Choosing an edge with probability proportional to $\ell(vw) f(vw)$ can easily be done in $O(m)$ time. In order to choose with the right probability a flow path going through that edge, we need a data structure to organize these flow paths. For each edge we maintain a balanced binary tree with one leaf for each flow path through the edge, labeled with the flow value of that flow path. Each internal node of the binary tree is labeled with the total flow value of its descendent leaves. The number of paths is polynomial in n and ϵ^{-1}; therefore, using this data structure, we can randomly choose a flow path through a given edge in $O(\log n)$ time.

In order to maintain this data structure, each time we change the flow on an edge, we must update the binary tree for that edge, at a cost of $O(\log n)$ time. In one iteration of REDUCE the flow only changes on $O(n)$ edges; therefore, the time to do these updates is $O(n \log n)$ per call to FINDPATH, which is dominated by the time to compute single-source shortest paths.

We have shown that if relaxed optimality condition (R2) is not satisfied, then, with probability of at least $\epsilon/7$, we can find an ϵ-bad path in $O(m + n \log n)$ time. FINDPATH continues to pick paths until either an ϵ-bad path is found or $7/\epsilon$ trials are made. Observe that given that f and ℓ are not yet ϵ-optimal (which implies that condition (R2) is not yet satisfied), the probability of failure to find an ϵ-bad path in $7/\epsilon$ trials is bounded by $1/e$. Thus, in this case, REDUCE can terminate, claiming that f and ℓ are ϵ-optimal with probability of at least $1 - 1/e$. Computing lengths and updating flows can each be done in $O(n \log n)$ time, thus we get the following bound:

LEMMA 4.7. *One iteration of* REDUCE *can be implemented randomly in time* $(\epsilon^{-1}(m + n \log n))$ *time* (*assuming that exponentiation is a single step*).

The randomized algorithm as it stands is *Monte Carlo*; there is a nonzero probability that REDUCE erroneously claims to terminate with an ϵ-optimal f. To make the algorithm *Las Vegas* (never wrong, sometimes slow), we introduce a deterministic check. If FINDPATH fails to find an ϵ-bad path, REDUCE computes the sum $\sum_i \text{dist}_\ell(s_i, t_i)d(i)$ to the required precision and compares it with $|f||\ell|_1$ to determine whether f and ℓ are really ϵ-optimal. If not, the loop resumes. The time required to compute the sum is $O(k^*(m + n\log n))$, because at most k^* single-source shortest path computations are required. The probability that the check must be done t times in a single call to REDUCE is at most $(e^{-1})^{t-1}$, so the total expected contribution to the running time of REDUCE is at most $O(k^*(m + n\log n))$.

Recall that the bound on the number of iterations of REDUCE is greater than

$$\max_i \frac{\min\{D, kd(i)\}}{\sigma_i},$$

which in turn is at least k. Since in each iteration we carry out at least one shortest path computation, the additional time spent on checking does not asymptotically increase our bound on the running time for REDUCE.

We conclude this section with a theorem summarizing the running time of REDUCE for some cases of particular interest. For all of these bounds the running time is computed by multiplying the appropriate time for an iteration of REDUCE by the appropriate number of iterations of REDUCE. These bounds depend on the assumption that exponentiation is a single step. In §4.3 we shall show that the same bounds can be achieved without this assumption. We shall also give a more efficient implementation for the case when ϵ is a constant.

THEOREM 4.8. *Let $f = O(\tau)$ and τ and σ_i satisfy the granularity condition. Let*

$$H(k, d, \sigma) = \max_i \frac{\min\{D, kd(i)\}}{\sigma_i},$$

and let $\hat{k} = \min\{k, k^* \log d_{\max}\}$. Then the following table contains running times for various implementations of procedure REDUCE *(assuming that exponentiation is a single step).*

	Randomized Implementation	Deterministic Implementation
$1 \le \epsilon \le \frac{1}{poly(n)}$	$O\left(\epsilon^{-2}(m + n\log n)H(k, d, \sigma)\right)$	$O\left(\epsilon^{-1}H(k, d, \sigma)\right.$ $\left.[k^*n\log n + m(\log n + \hat{k})]\right)$
$1 \le \epsilon \le \frac{1}{poly(n)}$, f is $O(\epsilon)$-opt.	$O\left(\epsilon^{-1}(m + n\log n)H(k, d, \sigma)\right)$	$O\left(H(k, d, \sigma)\right.$ $\left.[k^*n\log n + m(\log n + \hat{k})]\right)$

4.3. Further implementation details. In this section, we will show how to get rid of the assumption that exponentiation can be performed in a single step. We will also give a more efficient implementation of the procedure REDUCE for the case when ϵ is fixed.

4.3.1. Removing the assumption that exponentiation can be performed in $O(1)$ time. To remove the assumption that exponentiation can be performed in $O(1)$ time, we will need to do two things. First we will show that it is sufficient to work with edge-lengths $\hat{\ell}(vw)$ that are approximations to the actual lengths $\ell(vw) = e^{\alpha f(vw)}$. We then show that computing these approximate edge-lengths does not change the asymptotic running times of our algorithms.

The first step is to note that in the proof of Lemma 4.2, we never used the fact that we reroute flow onto a *shortest* path. We only need that we reroute flow onto a *sufficiently short* path. More precisely, it is easy to convert the proof of Lemma 4.2 into a proof for the following claim.

LEMMA 4.9. *Suppose σ_i and τ satisfy the granularity condition, and let P be an ϵ-bad flow path of commodity i. Let Q be a path connecting the endpoints of P such that the length of Q*

is no more than $\epsilon'\ell(P)/2 + \epsilon'\frac{|f|}{D}|\ell|_1/2$ *greater than the length of the shortest path connecting the same endpoints. Then rerouting* σ_i *units of flow from path* P *to* Q *decreases* $|\ell|_1$ *by*

$$\Omega\left(\frac{\sigma_i}{\min\{D, kd(i)\}}|\ell|_1 \log m\right).$$

We will now show that in order to compute the lengths of paths up to the precision given in this lemma, we only need to compute the lengths of edges up to a reasonably small amount of precision.

By Lemma 4.9, the length of a path can have a rounding error of $\epsilon'\frac{|f|}{D}|\ell|_1/2$. Each path has at most n edges, so it will suffice to ensure that each edge has a rounding error of $\frac{1}{n}(\epsilon'\frac{|f|}{D}|\ell|_1/2)$. We will now bound this quantity. $|f|$ is the maximum flow on an edge and hence must be at least as large as the average flow on an edge, i.e., $|f| \geq \sum_{vw} f(vw)/m$. Every unit of flow contributes to the total flow on at least one edge, and hence $\sum_{vw} f(vw) \geq D$, and combining with the previous equation, we get that $|f|/D \geq 1/m$. $|\ell|_1$ is at least as big as the length of the longest edge, i.e., $|\ell|_1 \geq e^{\alpha|f|}$. Plugging in these bounds we see that it suffices to compute with an error of at most $(\epsilon'/nm)e^{\alpha|f|}$. Each edge has a positive length of at most $e^{\alpha|f|}$ and can be expressed as $e^{\alpha|f|}\rho$, where $0 < \rho \leq 1$. Thus we need to compute ρ up to an error of ϵ'/nm. To do so, we need to compute $O(\log(\epsilon^{-1}nm))$ bits, which by the assumption that ϵ is inverse polynomial in n is just $O(\log n)$ bits.

By using the Taylor series expansion of e^x, we can compute one bit of the length function in $O(1)$ time. Therefore, to compute the lengths of all edges at each iteration of REDUCE, we need $O(m \log n)$ time. In the deterministic implementation of REDUCE each iteration takes at least $\Omega(m \log n)$ time (the time required for cycle cancelling); therefore, the time spent on computing the lengths is dominated by the running time of an iteration.

The approximation above depends on the current value of $|f|$, which may change after each iteration. It was crucial that we recomputed the lengths of every edge in every iteration. The time to do so, $O(m \log n)$, would dominate the running time of the randomized implementation of REDUCE. (Recall that the randomized implementation does not do cycle cancelling.) Thus, we need to find an approximation that does not need to be recomputed at every iteration. We will choose one that does not depend on the current $|f|$ and hence will only need to be updated on the $O(n)$ edges on which the flow actually changes. We proceed to describe such an approximation that will depend on τ rather than $|f|$.

Throughout REDUCE all edge length are at most $e^{O(\alpha\tau)}$ and at least one edge has length more than $e^{\alpha\tau}$. Therefore, $|\ell|_1$ is at least $e^{\alpha\tau}$, and by the same argument as for the deterministic case $O(\epsilon^{-1} \log n)$ bits of precision suffice throughout REDUCE. When we first call REDUCE, we must spend $O(\epsilon^{-1}m \log n)$ time to compute all the edge lengths. For each subsequent iteration, we only need to spend $O(\epsilon^{-1}n \log n)$ time updating the $O(n)$ edges whose length have changed. Since each iteration of REDUCE is expected to take $O(\epsilon^{-1}(m + n \log n))$ time to compute shortest paths in FINDPATH, the time for updating edges is dominated by the time required by FINDPATH. While it appears that the time to compute initially all the edge lengths may dominate the time spent in one invocation of REDUCE, we shall see in §5 that whenever any of our algorithms calls REDUCE, it will have at least $\Omega(\log n)$ iterations. Each iteration is expected to take at least $\Omega(\epsilon^{-1}m)$ time to compute the shortest paths in FINDPATH. Therefore, the time spent on initializing lengths will be dominated by the running time of REDUCE.

Note that in describing the randomized version of FINDPATH in Lemma 4.6, we assumed we knew the exact lengths. However, by using the approximate lengths we do not significantly change a path's apparent contribution to the sum $\sum_i \sum_{P\in\mathcal{P}_i} \ell(P)f_i(P)$. Hence we do not significantly reduce the probability of selecting a bad path.

Thus we have shown that without any assumptions, REDUCE can be implemented deterministically in the same time as is stated in Theorem 4.8. Although for the randomized version, there is additional initialization time, for all the algorithms in this paper the initialization time is dominated by the time spent in the iterations of REDUCE.

THEOREM 4.10. *The times required for the deterministic implementations of procedure* REDUCE *stated in Theorem* 4.8 *hold without the assumption that exponentiation is a single step. The time required by the randomized implementations increases by an additive term of* $O(\epsilon^{-1}m \log n)$ *without this assumption.*

4.3.2. Further improvements for fixed ϵ. In this section we show how one can reduce the time per iteration of REDUCE for the case in which ϵ is a constant. First we show how using approximate lengths can reduce the time required by FINDPATH; we use an approximate shortest-paths algorithm that runs in $O(m + n\epsilon^{-1})$ time. Then we give improved implementation details for an iteration of REDUCE to decrease the time required by other parts of REDUCE.

We will describe how, given the lengths and an ϵ-bad path P from s to t, we can find a path Q with the same endpoints such that $\ell(Q) \leq \text{dist}_\ell(s,t) + \epsilon'\ell(P)/2$ in $O(m+n\epsilon^{-1})$ time. First, we discard all edges with length greater than $\ell(P)$, for they can never be in a path that is shorter than P (if P is a shortest path between s and t, then P is not an ϵ-bad path). Next, on the remaining graph, we compute shortest paths from s using approximate edge-lengths

$$\tilde{\ell}(v,w) = \frac{\epsilon'\ell(P)}{2n}\left\lceil \ell(vw)\frac{2n}{\epsilon'\ell(P)}\right\rceil,$$

thus giving us $\text{dist}_{\tilde{\ell}}(s,t)$, an approximation of $\text{dist}_\ell(s,t)$, the length of the actual shortest (s,t)-path. There are at most $n-1$ edges on any shortest path, and for each such edge, the approximate length is at most $\epsilon'\ell(P)/2n$ more than the actual length. Thus we know that

$$\text{dist}_{\tilde{\ell}}(s,t) \leq \text{dist}_\ell(s,t) + n\frac{\epsilon'\ell(P)}{2n} = \text{dist}_\ell(s,t) + \frac{\epsilon'\ell(P)}{2}$$

Further, since each shortest path length is an integer multiple of $\epsilon'\ell(P)/2n$ and no more than $\ell(P)$, we can use Dial's implementation of Dijkstra's algorithm [2] to compute $\text{dist}_{\tilde{\ell}}(s,t)$ in $O(m + n\epsilon^{-1})$ time.

Implementing FINDPATH with this approximate shortest path computation directly improves the time required by a deterministic implementation of REDUCE. The randomized implementation of FINDPATH with approximate shortest path computation requires $O(\epsilon^{-1}(m + n\epsilon^{-1}))$ expected time. In order to claim that an iteration of REDUCE can be implemented in the same amount of time, we must handle two difficulties: updating edge lengths and updating each edge's table of flow paths when flow is rerouted. Previously, these steps took $O(n \log n)$ time, which was dominated by the time for FINDPATH. We have reduced the time for FINDPATH, so the time for these steps now dominates. We show how to carry out these steps in $O(n)$ time. For the first step, we show that a table can be precomputed so that each edge length can be updated in constant time. For the second step, we sketch a three-level data structure that allows selection of a random flow path through an edge in $O(n)$ time and allows constant-time addition and deletion of flow paths.

Say that before computing the length $e^{\alpha f(vw)}$, we were to round $\alpha f(vw)$ to the nearest multiple of ϵ/c, for some constant c. This will introduce an additional multiplicative error of $1 + O(\epsilon/c)$ in the length of each edge and hence an additional multiplicative error of $1 + O(\epsilon/c)$ on each path. However, by arguments similar to the previous subsection, this will still give us a sufficiently precise approximation.

Now we will show that by rounding in this way there are a small enough number of possible values for $\ell(vw)$ that we can just compute them all at the beginning of an iteration of REDUCE and then compute the length of an edge by simply looking up the value in a precomputed table. The largest value of $\alpha f(vw)$ we will ever encounter is $O(\epsilon^{-1} \log n)$. Since we are only concerned with multiples of ϵ/c, there is a total of only $O(\epsilon^{-2} \log n)$ values that we will ever encounter. At the beginning of each iteration, we can compute each of these numbers to a precision of $O(\log n)$ bits in $O(\epsilon^{-2} \log^2 n)$ time. Once we have computed all these numbers, we can compute the length of an edge by computing $\alpha f(vw)$, truncating to a multiple of ϵ/c, and then looking up the value of $\ell(vw)$ in the table. This takes $O(1)$ time. Thus for constant ϵ, we are spending $O(\log^2 n + m) = O(m)$ time per iteration.

Now we address the problem of maintaining, for each edge, the flow paths going through that edge. Henceforth we will describe the data structure associated with a single edge. First suppose that all the flow paths carry the same amount of flow, i.e., σ_i is the same for each. In this case, we keep pointers to the flow paths in an array. We maintain that the array is at most one-quarter empty. It is then easy to select a flow path in constant expected time randomly; one randomly chooses an index and checks whether the corresponding array entry has a pointer to a flow path. If so, select that flow path. If not, try another index.

One can delete flow paths from the array in constant time. If one maintains a list of empty entries, one can also insert in constant time. If the array gets too full, copy its contents into a new array of twice the size. The time required for copying can be amortized over the time required for the insertions that filled the array. If the array gets too empty, copy its contents into a new array of half the size. The time required for copying can be amortized over the time required for the deletions that emptied the array. (See, for example, [1], for a detailed description of this data structure.)

Now we consider the more general case, in which the flow values of flow paths may vary. In this case, we use a three-level data structure. In the top level, the paths are organized according to their starting nodes. In the second level, the paths with a common starting node are organized according to their ending nodes. The paths with the same starting and ending nodes may be assumed to belong to the same commodity and hence all carry the same amount of flow. Thus these paths can be organized using the array as described above.

The first level consists of a list; each list item specifies a starting node, the total flow of all flow paths with that starting node, and a pointer to the second-level data structure organizing the flow paths with the given starting node. Each second-level data structure consists of a list; each list item specifies an ending node, the total flow of all flow paths with that ending node and the given starting node, and a pointer to the third-level data structure, the array containing flow paths with the given starting and ending nodes.

Now we analyze the time required to maintain this data structure. Adding and deleting a flow path takes constant time. Choosing a random flow path with the right probability can be accomplished in $O(n)$ time. First we randomly choose a value between 0 and the total flow through the edge. Then we scan the first-level list to select an appropriate item based on the value. Next we scan the second-level list pointed to by that item and select an item in the second-level list. Each of these two steps takes $O(n)$ time. Finally, we select an entry in the third-level array. In the third-level array, all the flows have the same σ_i; thus, this can be accomplished in $O(1)$ expected time by the scheme described above.

So we have shown that for constant ϵ, each of the three steps in procedure REDUCE can be implemented in $O(m)$ expected time, thus yielding the following theorem.

THEOREM 4.11. *Let $f = O(\tau)$ and τ and σ_i satisfy the granularity condition. Let*

$$H(k, d, \sigma) = \max_i \frac{\min\{D, kd(i)\}}{\sigma_i},$$

and let $\hat{k} = \min\{k, k^* \log d_{\max}\}$. *For any constant* $\epsilon > 0$ *the procedure* REDUCE *can be implemented in randomized* $O(m H(k, d, \sigma))$ *and in deterministic* $O(H(k, d, \sigma) m(\log n + \hat{k}))$ *time.*

5. Concurrent flow algorithms. In this section, we give approximation algorithms for the concurrent flow problem with uniform capacities. We describe two algorithms: CONCURRENT and SCALINGCONCURRENT. CONCURRENT is simpler and is best if ϵ is constant. SCALINGCONCURRENT gradually scales ϵ to the right value and is faster for small ϵ.

Algorithm CONCURRENT (see Fig. 2) consists of a sequence of calls to procedure REDUCE described in the previous section. The initial flow is constructed by routing each commodity i on a single flow path from s_i to t_i. Initially, we set $\sigma_i = d(i)$. Before each call to REDUCE we divide the flow quantum σ_i by 2 for every commodity where this is needed to satisfy the granularity condition (3). Each call to REDUCE modifies the multicommodity flow f so that either $|f|$ decreases by a factor of 2 or f becomes ϵ-optimal. (The procedure REDUCE can set a global flag to indicate whether it has concluded that f is ϵ-optimal.) In the latter case our algorithm can terminate and return the flow. As we will see, $O(\log m)$ calls to REDUCE will suffice to achieve ϵ-optimality.

```
CONCURRENT($G, \epsilon, \{d(i), (s_i, t_i) : 1 \le i \le k\}$)
For each commodity $i$: $\sigma_i \leftarrow d(i)$, create a simple path from $s_i$ to $t_i$ and route $d(i)$ flow on it.
$\tau \leftarrow |f|/2$.
While $f$ is not $\epsilon$-optimal,
  For every $i$,
    Until $\sigma_i$ and $\tau$ satisfy the granularity condition,
      $\sigma_i \leftarrow \sigma_i/2$.
  Call REDUCE ($f, \tau, \epsilon, d$).
  $\tau \leftarrow \tau/2$.
Return $f$.
```

FIG. 2. *Procedure* CONCURRENT.

THEOREM 5.1. *The algorithm* CONCURRENT *finds an* ϵ*-optimal multicommodity flow in* $O((\epsilon^{-1}k + \epsilon^{-3}m)(k^* n \log n + m(\log n + \min\{k, k^* \log d_{\max}\})) \log n)$ *or in expected time* $O((k\epsilon^{-2} + m\epsilon^{-4})(m + n \log n) \log n)$.

Proof. Immediately after the initialization we have $|f| \le D$. To bound the number of phases we need a lower bound on the minimum value of $|f|$. Observe that for every multicommodity flow f, the total amount of flow in the network is D. Every unit of flow contributes to the total flow on at least one of the edges, and hence $\sum_{vw \in E} f(vw) \ge D$. Therefore,

$$|f| \ge D/m. \tag{4}$$

This implies that the number of iterations of the main loop of CONCURRENT is at most $O(\log m)$. By Theorems 4.3 and 4.8, procedure REDUCE invoked during a single iteration of CONCURRENT first spends $O(m \log n)$ time initializing edge lengths and then executes

$$O\left(\epsilon^{-1} \max_i \frac{\min\{D, kd(i)\}}{\sigma_i}\right)$$

iterations. Throughout the algorithm for every i σ_i is either equal to $d(i)$ or is $\Theta(\epsilon^2 \tau / \log(m\epsilon^{-1}))$. In the first case,

$$\frac{\min\{D, kd(i)\}}{\sigma_i} = \frac{\min\{D, kd(i)\}}{d(i)} = \min\left\{\frac{D}{d(i)}, k\right\} \le k.$$

In the second case

$$\frac{\min\{D, kd(i)\}}{\sigma_i} = \min\{D, kd(i)\}\,\epsilon^{-2}\tau^{-1}\log(m\epsilon^{-1}) \le \epsilon^{-2}\frac{D}{\tau}\log(m\epsilon^{-1}).$$

Thus the total number of iterations of the loop of REDUCE is at most $O(\epsilon^{-1}(k + \epsilon^{-2}\frac{D}{\tau}\log(m\epsilon^{-1}))$, and the time spent on the initialization of the edge length is dominated. The value τ is halved at every iteration; therefore, the total number of calls required for all iterations is at most $O(\epsilon^{-1}k\log n)$ plus twice the number required for the last iteration of CONCURRENT. It follows from (4) that τ is $\Omega(\frac{D}{m})$, and the total number of iterations of the loop of REDUCE is at most $O(\epsilon^{-1}k\log n + \epsilon^{-3}m\log n)$. □

Consider the special case when ϵ is constant. We use the version of REDUCE implemented with an approximate shortest path computation and apply the bounds of Theorem 4.11 combined with a proof similar to that of Theorem 5.1 to get the following result:

THEOREM 5.2. *For any constant $\epsilon > 0$, an ϵ-optimal solution for the unit-capacity concurrent flow problem can be found in $O(m(k + m)\log^2 n)$ expected time by a randomized algorithm and in $O(m(k + m)(\log n + \min\{k, k^*\log d_{\max}\})\log n)$ time by a deterministic algorithm.*

If ϵ is less than a constant, we use the algorithm SCALINGCONCURRENT, shown in Fig. 3. It starts with a large ϵ and then gradually scales ϵ down to the required value. More precisely, algorithm SCALINGCONCURRENT starts by applying algorithm CONCURRENT with $\epsilon = \frac{1}{10}$. SCALINGCONCURRENT then repeatedly divides ϵ by a factor of 2 and calls REDUCE. After the initial call to CONCURRENT, f is $\frac{1}{10}$-optimal, i.e., $|f|$ is no more than twice the minimum possible value. Therefore, $|f|$ cannot be decreased below $\tau/2$, and every subsequent call to REDUCE returns an ϵ-optimal multicommodity flow (with the current value of ϵ). As in CONCURRENT, each call to REDUCE uses the largest flow quantum σ permitted by the granularity condition (3).

```
ScalingConcurrent($G$, $\epsilon'$, $\{d(i), (s_i, t_i) : 1 \le i \le k\}$)
$\epsilon \leftarrow \frac{1}{10}$.
Call Concurrent($G$, $\epsilon$, $\{d(i), (s_i, t_i) : 1 \le i \le k\}$), and let $f$ be the resulting flow.
  $\tau \leftarrow \tau/2$.

While $\epsilon > \epsilon'$,
  $\epsilon \leftarrow \epsilon/2$,
  For every $i$,
    Until $\sigma_i$ and $\tau$ satisfy the granularity condition,
      $\sigma_i \leftarrow \sigma_i/2$.
  Call Reduce ($f$, $\tau$, $\epsilon$, $\sigma$).
Return $f$.
```

FIG. 3. *Procedure* SCALING CONCURRENT.

THEOREM 5.3. *The algorithm* SCALINGCONCURRENT *finds an ϵ-optimal multicommodity flow in expected time $O((k\epsilon^{-1} + m\epsilon^{-3}\log n)(m + n\log n))$.*

Proof. As is stated in Theorem 5.2, the call to procedure CONCURRENT takes $O(km\log n + m^2\log m)$ time and returns a multicommodity flow f that is $\frac{1}{10}$-optimal; hence, $|f|$ is no more than twice the minimum. Therefore every subsequent call to REDUCE returns an ϵ-optimal multicommodity flow f.

The time required by one iteration is dominated by the call to REDUCE. The input flow f of REDUCE is 2ϵ-optimal, so, by Theorems 4.8 and 4.10, the time required by the randomized implementation of REDUCE is

$$O\left(\epsilon^{-1}(m + n\log n)\max_i \frac{\min\{D, kd(i)\}}{\sigma_i}\right).$$

We have seen that

$$\max_i \frac{\min\{D, kd(i)\}}{\sigma_i}$$

is at most $O(k + \epsilon^{-2}m\log m)$. The value of ϵ is reduced by a factor of two in every iteration. Therefore, the total time required for all iterations is at most twice the time required by the last iteration. The last iteration takes $O((k + \epsilon^{-2}m\log n)(\epsilon^{-1}(m + n\log n)))$ time, which proves the claim. □

Consider an implementation of CONCURRENT or SCALINGCONCURRENT with the deterministic version of REDUCE. The time required by FINDPATH does not depend on ϵ, so we cannot claim that the time is bounded by at most twice the time required for the last call to REDUCE. Since there are at most $\log\epsilon^{-1}$ iterations, we have the following theorem.

THEOREM 5.4. *An ϵ-optimal solution to the unit-capacity concurrent flow problem can be found deterministically in time $O(km\log^2 n + (k\log\epsilon^{-1} + \epsilon^{-2}m\log n)$ $(k^*n\log n + m(\log n + \min\{k, k^*\log d_{\max}\})))$.*

6. Two applications. In this section we describe two applications of our unit-capacity concurrent flow algorithm. The first application is to implement efficiently Leighton and Rao's sparsest cut approximation algorithm [14], and the second application is to minimize approximately channel width in VLSI routing; the second problem was considered by Raghavan and Thompson [16] and Raghavan [15].

We start by reviewing the result of Leighton and Rao concerning finding an approximately sparsest cut in a graph. For any partition of the nodes of a graph G into two sets A and B, the associated *cut* is the set of edges between A and B, and $\delta(A, B)$ denotes the number of edges in that cut. A cut is *sparsest* if $\delta(A, B)/(|A||B|)$ is minimized. Leighton and Rao [14] gave an $O(\log n)$-approximation algorithm for finding the sparsest cut of a graph. By applying this algorithm they obtained polylog-times-optimal approximation algorithms for a wide variety of NP-complete graph problems, including minimum feedback arc set, minimum cut linear arrangement, and minimum area layout.

Leighton and Rao exploited the following connection between sparsest cuts and concurrent flow. Consider an *all-pairs* multicommodity flow in G, where there is a unit of demand between every pair of nodes. In a feasible flow f, for any partition $A \cup B$ of the nodes of G, a total of at least $|A||B|$ units of flow must cross the cut between A and B. Consequently, one such edge must carry at least a $|A||B|/\delta(A, B)$ flow for the sparsest cut $A \cup B$. Leighton and Rao prove an approximate max-flow, min-cut theorem for the all-pairs concurrent flow problem, by showing that in fact this lower bound for $|f|$ is at most an $O(\log n)$ factor below the minimum value. Their approximate sparsest-cut algorithm makes use of this connection. More precisely given a nearly optimal length function (dual variables) they show how to find a partition $A \cup B$

that is within a factor of $O(\log n)$ of the minimum value of $|f|$ and, hence, of the value of the sparsest cut.[1]

The computational bottleneck of their method is solving a unit-capacity concurrent flow problem, in which there is a demand of 1 between every pair of nodes. In their paper, they appealed to the fact that concurrent flow can be formulated as a linear program and hence can be solved in polynomial time. A much more efficient approach is to use our unit-capacity approximation algorithm. The number of commodities required is $O(n^2)$. Leighton [12] has discovered a technique to reduce the number of commodities required. He shows that if the graph in which there is an edge connecting each source-sink pair is an expander graph, then the resulting flow problem suffices for the purpose of finding an approximately sparsest cut. (We call this graph the *demand graph.*) In an expander we have:

> For any partition of the node set into A and B, where $|A| \leq |B|$, the number of commodities crossing the associated cut is $\theta(|A|)$.

Therefore, the value of $|f|$ for this smaller flow problem is $\Omega(|A|/\delta(A, B))$. Since $|B| \geq n/2$, it follows that $n|f|$ is $\Omega(|A||B|)/\delta(A, B))$. The smaller flow problem essentially "simulates" the original all-pairs problem. Moreover, Leighton and Rao's sparsest-cut algorithm can start with the length function for the smaller flow problem in place of that for the all-pairs problem. Thus Leighton's idea allows one to find an approximate sparsest cut after solving a much smaller concurrent flow problem. If one is willing to tolerate a small probability of error in the approximation, one can use $O(n)$ randomly selected source-sink pairs for the commodities. It is well known how to select node pairs randomly so that, with high probability, the resulting demand graph is an expander.

By Theorem 5.2, algorithm CONCURRENT takes expected time $O(m^2 \log^2 m)$ to find an appropriate solution for this smaller problem.

THEOREM 6.1. *An $O(\log n)$-factor approximation to the sparsest cut in a graph can be found by a randomized algorithm in $O(m^2 \log^2 m)$ time.*

The second application we discuss is approximately minimizing channel width in VLSI routing. Often a VLSI design consists of a collection of modules separated by channels; the modules are connected by wires that are routed through the channels. For purposes of regularity the channels have uniform width. It is desirable to minimize that width in order to minimize the total area of the VLSI circuit. Raghavan and Thompson [16] give an approximation algorithm for minimizing the channel width. They model the problem as a graph problem in which one must route wires between pairs of nodes in a graph G so as to minimize the maximum number of wires routed through an edge. To solve the problem approximately, they first solve a concurrent flow problem where there is a commodity with demand 1 for each path that needs to be routed. An optimal solution f_{opt} fails to be a wire routing only in that it may consist of paths of *fractional* flow. However, the value of $|f_{\text{opt}}|$ is certainly a lower bound on the minimum channel width. Raghavan and Thompson give a randomized method for converting the fractional flow f_{opt} to an integral flow, increasing the channel width only slightly. The resulting wire routing f achieves channel width

$$|f| \leq |f_{\text{opt}}| + O(\sqrt{|f_{\text{opt}}| \log n}), \tag{5}$$

[1] Their algorithm also works for edge-weighted graphs; weights translate to edge capacities in the corresponding concurrent flow problem.

which is at most $w_{\min} + O(\sqrt{w_{\min}\log n})$, where $w_{\min}$ is the minimum width. In fact, the constant implicit in this bound is quite small. Later Raghavan [15] showed how this conversion method can be made deterministic.

The computational bottleneck is, once again, solving a unit-capacity concurrent flow problem. Theorems 5.3 and 5.4 are applicable and yield good algorithms. But if $w_{\min}$ is $\Omega(\log n)$, we can do substantially better.[2] In this case, a modified version of our algorithm ScalingConcurrent directly yields an integral f satisfying (5), although the big-Oh constant is not as good as that of [16].

Consider the procedure ScalingConcurrent. It consists of two parts. First the procedure Concurrent is called with $\epsilon = \frac{1}{10}$ to achieve $\frac{1}{10}$-optimality. Next, ScalingConcurrent repeatedly calls Reduce, reducing the error parameter ϵ by a factor of two every iteration, until the required accuracy is achieved. The demands are the same for every commodity; hence, σ_i is independent of i, and we shall denote it by σ.

We claim that if $w_{\min} = \Omega(\log n)$, then σ, which is initially 1 for this application, need never be reduced. Consequently, there remains a single path of flow per commodity, and the randomized conversion method of Raghavan and Thompson becomes unnecessary. We show that these paths constitute a routing with width $w_{\min} + O(\sqrt{w_{\min}\log n})$.

First suppose the call to Concurrent terminates because the granularity condition becomes false. At this point, we have that

$$1 > \epsilon^2\tau/(51\log(7m\epsilon^{-1})). \tag{6}$$

We have that $\tau \geq |f|/2$ and $\epsilon = \frac{1}{10}$, and therefore $|f| = O(\log n)$. By our assumption $w_{\min} = \Omega(\log n)$, and hence $|f| \leq w_{\min} + O(\sqrt{w_{\min}\log n})$.

Now assume that the call to Concurrent terminates with a $\frac{1}{10}$-optimal flow. We proceed with ScalingConcurrent. It terminates when the granularity condition becomes false, at which point inequality (6) implies that $\epsilon^2 = O((\log m)/\tau)$. The flow f is ϵ-optimal and integral. So $|f| \leq w_{\min} + O(w_{\min}\sqrt{(\log m)/\tau})$. Since $\tau = |f|/2 \geq w_{\min}/2$, this bound on $|f|$ is at most $w_{\min} + O(\sqrt{w_{\min}\log m})$, as required.

Theorem 6.2. *If $w_{\min}$ denotes the minimum possible width and $w_{\min} = \Omega(\log m)$, a routing of width $w_{\min} + O(\sqrt{w_{\min}\log n})$ can be found by a randomized algorithm in expected time $O(km\log n\log k + k^{3/2}(m + n\log n)/\sqrt{\log n})$ and by a deterministic algorithm in time $O(k\log k(k^*n\log n + mk^* + m\log n))$.*

Proof. We have shown that algorithm ScalingConcurrent finds the required routing if it is terminated as soon as the granularity condition becomes false with $\sigma = 1$. Now we analyze the time required.

We have $D = k$ and $d(i) = 1$ for every i, and throughout the algorithm we have $\sigma_i = 1$ for every i. The number of calls to Reduce during Concurrent is $O(\log k)$ (initially $|f| \leq k$, and it never gets below 1 with $\sigma = 1$). Therefore, the number iterations of the loop of Reduce required during Concurrent is $O(k\log k)$. Next we proceed with ScalingConcurrent. The number of iterations is at most $O(\log k)$, because ϵ is reduced by a factor of two each iteration, starts at $\frac{1}{10}$, and never gets below $1/k$. Each iteration is a call to Reduce, which in turn results in $O(k)$ iterations of the loop of Reduce.

The time required by one iteration of the loop deterministically is $O(k^*n\log n + m(k^* + \log m))$, and the total time to find a good routing of wires is $O(k\log k(k^*n\log n + mk^* + m\log n))$.

The expected time required by the randomized implementation of Reduce is $O(m\log n + k\epsilon^{-1}(m + n\log n))$. The total expected time required by Concurrent is $O(mk\log k\log n)$.

[2] This is the case of most interest, for if $w_{\min}$ is $O(\log n)$, then the error term in (5) dominates $w_{\min}$.

After the call to CONCURRENT ϵ decreases by a factor of two each iteration, it follows that the total expected time required for all iterations is $O(m \log n \log \epsilon^{-1})$ plus twice the time for the last call to REDUCE. During the last call to REDUCE, $\epsilon^{-1} = O(\sqrt{k/\log n})$, so the time required for all iterations is $O(km \log n \log k + k^{3/2}(m + n \log n)/\sqrt{\log n})$. This time dominates the time required by CONCURRENT since $w_{\min} = \Omega(\log n)$ implies $k = \Omega(\log n)$. □

THE EXTENDED LOW HIERARCHY IS AN INFINITE HIERARCHY*

MING-JYE SHEU† AND TIMOTHY J. LONG‡

Abstract. Balcázar, Book, and Schöning introduced the extended low hierarchy based on the Σ-levels of the polynomial-time hierarchy as follows: for $k \geq 1$, level k of the extended low hierarchy is the set $EL_k^{P,\Sigma} = \{A \mid \Sigma_k^P(A) \subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT})\}$. Allender and Hemachandra and Long and Sheu introduced refinements of the extended low hierarchy based on the Δ- and Θ-levels, respectively, of the polynomial-time hierarchy: for $k \geq 2$, $EL_k^{P,\Delta} = \{A \mid \Delta_k^P(A) \subseteq \Delta_{k-1}^P(A \oplus \mathrm{SAT})\}$ and $EL_k^{P,\Theta} = \{A \mid \Theta_k^P(A) \subseteq \Theta_{k-1}^P(A \oplus \mathrm{SAT})\}$. This paper shows that the extended low hierarchy is properly infinite by showing, for $k \geq 2$, that $EL_k^{P,\Sigma} \subsetneqq EL_{k+1}^{P,\Theta} \subsetneqq EL_{k+1}^{P,\Delta} \subsetneqq EL_{k+1}^{P,\Sigma}$. The proofs use the circuit lower bound techniques of Håstad and Ko. As corollaries to the constructions, for $k \geq 2$, oracle sets B_k, C_k, and D_k, such that $\mathrm{PH}(B_k) = \Sigma_k^P(B_k) \supsetneqq \Delta_k^P(B_k)$, $\mathrm{PH}(C_k) = \Delta_k^P(C_k) \supsetneqq \Theta_k^P(C_k)$, and $\mathrm{PH}(D_k) = \Theta_k^P(D_k) \supsetneqq \Sigma_{k-1}^P(D_k)$ are obtained.

1. Introduction.

The low and high hierarchies in NP were introduced by Schöning in order to understand the internal structure of NP [Sch83]. The low hierarchy starts at P and grows "upward" toward the NP-complete sets, while the high hierarchy starts with the complete sets in NP and grows "downward" toward P. More formally, set A is in level k of the *low hierarchy* if $\Sigma_k^P(A) = \Sigma_k^P$, and A is in level k of the *high hierarchy* if $\Sigma_{k+1}^P = \Sigma_k^P(A)$. Many interesting sets have been located in these hierarchies: $\leq_T^P$-complete sets and $\leq_T^{SN}$-complete sets for NP form the first two levels of the high hierarchy, while sparse NP sets, NP sets with small circuits, and graph isomorphism have been placed in various levels of the low hierarchy.

These hierarchies were first extended to sets outside of NP by Balcázar, Book, and Schöning [BBS86]. In particular, they defined the *extended low hierarchy* as follows: set A is in level k of the extended low hierarchy if $\Sigma_k^P(A) \subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT})$. Once again, many interesting classes of sets have been located in the extended low hierarchy, such as sparse sets, sets with small circuits, and general left cuts of real numbers. Recently, refinements of the extended low hierarchy based on the Δ-classes and Θ-classes of the polynomial-time hierarchy were introduced by Allender and Hemachandra [AH92] and by Long and Sheu [LS91], respectively. Many of the sets previously located in the extended low hierarchy were more carefully and precisely located in new levels of the refined extended low hierarchy.

An interesting open question is whether the low hierarchy or the extended low hierarchy consists of an infinite number of distinct levels. This question is of interest for several reasons. If these hierarchies are properly infinite, then they provide a natural formal framework for categorizing and comparing the relative "power and complexity" of sets: sets at higher levels of the low hierarchy are more "complicated" than sets at lower levels. But more importantly, for the low hierarchy, if it contains at least two distinct levels, then $\mathrm{P} \neq \mathrm{NP}$. We also note that it is not even known if the low hierarchy is properly infinite under very natural assumptions, such as the polynomial-time hierarchy consisting of an infinite number of distinct levels.

For the extended low hierarchy, the situation is somewhat different. In proving optimal lower bounds for the extended low hierarchy, Allender and Hemachandra [AH92] constructed a sparse set that is not in $EL_2^{P,\Sigma}$, level two of the extended low hierarchy based on the Σ-levels

*Received by the editors August 26, 1991; accepted for publication (in revised form) December 21, 1992. This work was supported in part by National Science Foundation grant CCR-8909071.

‡Department of Computer and Information Science, The Ohio State University, Columbus, Ohio 43210.

of the polynomial-time hierarchy. Since it is known that all sparse sets are in $EL_3^{P,\Theta}$, the third level of the extended low hierarchy based on the Θ-levels of the polynomial-time hierarchy, this shows that the extended low hierarchy has at least two distinct levels up through $EL_3^{P,\Theta}$. However, it was not known if the extended low hierarchy has distinct levels beyond $EL_3^{P,\Theta}$.

In this paper we show that the extended low hierarchy is in fact a properly infinite hierarchy. Specifically, we prove that

$$\forall k \geq 2,\ EL_k^{P,\Sigma} \subsetneq EL_{k+1}^{P,\Theta} \subsetneq EL_{k+1}^{P,\Delta} \subsetneq EL_{k+1}^{P,\Sigma},$$

where $EL_k^{P,\Sigma}$ ($EL_k^{P,\Delta}$, $EL_k^{P,\Theta}$) denotes level k of the extended low hierarchy based on the Σ-levels (Δ-levels, Θ-levels, respectively) of the polynomial-time hierarchy. This is the first example of a low hierarchy in complexity theory that has been shown to be properly infinite.

Our proofs follow the circuit lower bound techniques from Yao [Yao85], Håstad [Has87], and Ko [Ko89]. Of particular interest for us is Ko's result that there are sets relative to which the polynomial-time hierarchy collapses to any finite level:

$$\forall k \geq 1, \exists A\ [\mathrm{PH}(A) = \Sigma_k^P(A) \neq \Sigma_{k-1}^P(A)].$$

Note that A is in level $k+1$ of the extended low hierarchy based on Σ-levels of the polynomial-time hierarchy and is not likely to be in level k of the extended low hirarchy. The condition for A not being in level k of the extended low hierarchy is as follows:

$$\mathrm{PH}(A) = \Sigma_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT}).$$

Thus, a direct modification of Ko's proofs yields that every Σ-level of the extended low hierarchy is distinct. In this paper we are able to extend Ko's collapsing results to Δ- and Θ-levels of relativized polynomial-time hierarchies.

In §3, we extend Yao and Håstad's separation results by showing the existence of oracle sets A, B, and C such that for all $k \geq 2$, $\Delta_k^P(A) \neq \Sigma_k^P(A)$, $\Theta_k^P(B) \neq \Delta_k^P(B)$, and $\Sigma_{k-1}^P(C) \neq \Theta_k^P(C)$. In order to obtain our results, we introduce, for the first time, circuit models for the Δ- and Θ-classes of relativized polynomial-time hierarchies. In §4, we combine the separation results of §3 with encoding techniques to construct oracles D_k, E_k, and F_k such that

$$\forall k \geq 1\ \exists D_k\ [\mathrm{PH}(D_k) = \Sigma_k^P(D_k) \not\subseteq \Delta_k^P(D_k \oplus \mathrm{SAT})],$$

$$\forall k \geq 2\ \exists E_k\ [\mathrm{PH}(E_k) = \Delta_k^P(E_k) \not\subseteq \Theta_k^P(E_k \oplus \mathrm{SAT})],$$

and

$$\forall k \geq 2\ \exists F_k\ [\mathrm{PH}(F_k) = \Theta_k^P(F_k) \not\subseteq \Sigma_{k-1}^P(F_k \oplus \mathrm{SAT})].$$

These results show that every level of the extended low hierarchy is distinct. Immediate corollaries are the existence of oracles G_k, H_k, and I_k, for all $k \geq 2$, such that $\mathrm{PH}(G_k) = \Sigma_k^P(G_k) \neq \Delta_k^P(G_k)$, $\mathrm{PH}(H_k) = \Delta_k^P(H_k) \neq \Theta_k^P(H_k)$, and $\mathrm{PH}(I_k) = \Theta_k^P(I_k) \neq \Sigma_{k-1}^P(I_k)$. These corollaries answer open questions posed by Ko [Ko89].

2. Preliminaries.

2.1. Basic definitions and notation.

Σ denotes an arbitrary alphabet of size at least two. For $x \in \Sigma^*$, $|x|$ denotes the length of x, with λ denoting the string of length 0. For a set A over Σ, $\overline{A}$ denotes its complement $\Sigma^* - A$, and for a class of sets $\mathcal{C}$, co-$\mathcal{C}$ denotes the set of complements of the elements of $\mathcal{C}$. For arbitrary sets A and B, $A \oplus B = \{0x \mid x \in A\} \cup \{1x \mid$

$x \in B\}$. Let $\| A \|$ denote the cardinality of a set A, and let $\| A^{\leq n} \|$ denote the cardinality of $A^{\leq n}$; that is, the cardinality of A restricted to strings of length at most n.

$L(M)$ denotes the set accepted by Turing machine M, and $L(M, A)$ denotes the set accepted by an oracle Turing machine M using oracle set A. The classes P and NP have their standard definitions. P(A) and NP(A) are the A-relativized versions of P and NP. For each oracle set A, we define the set $K(A)$ as follows: for a nondeterministic oracle machine M_i, a string x, and an integer j, let $\langle i, x, 1^j \rangle \in K(A)$ if and only if the nondeterministic machine M_i, using A as the oracle, accepts x in at most j steps. It is well known that, for every set A, $K(A)$ is $\leq_m^P$-complete for NP(A).

2.2. Polynomial-time hierarchy. The classes of the polynomial-time hierarchy are $\{\Sigma_k^P, \Pi_k^P, \Delta_k^P, \Theta_k^P \mid k \geq 0\}$, where

$$\Sigma_0^P = \Pi_0^P = \Delta_0^P = \Theta_0^P = \text{P}, \text{ and for } k \geq 0,$$

$$\Sigma_{k+1}^P = \text{NP}(\Sigma_k^P),$$

$$\Pi_{k+1}^P = \text{co-}\Sigma_{k+1}^P, \Delta_{k+1}^P = \text{P}(\Sigma_k^P),$$

and

$$\Theta_{k+1}^P = \Theta(\Sigma_k^P).^1$$

Sets in the polynomial-time hierarchy relative to A have also been characterized in terms of polynomial bounded quantification over predicates in P(A) [Sto76], [Wra76]. We adopt the following definitions from [Ko89]. A predicate σ of a set variable A and a string variable x is called a polynomial-time predicate, or a P^1-predicate, if there exist an oracle machine M and a polynomial p such that p bounds the running time of M, and for all sets A and all strings x, M^A accepts x if and only if $\sigma(A; x)$ is true. Thus, a set B is in P(A) if and only if there exists a P^1-predicate σ such that for all x, $x \in B \Leftrightarrow \sigma(A; x)$ holds.

Define the $\Sigma_0^{P,1}$-predicates to be the P^1-predicates. For each $k \geq 1$, define a $\Sigma_k^{P,1}$-predicate to be any predicate of the form:

$$(\exists y_1, |y_1| \leq p(|x|))(\forall y_2, |y_2| \leq p(|x|)) \cdots (Q_k y_k, |y_k| \leq p(|x|))\, \sigma(A; \langle x, y_1, \ldots, y_k \rangle),$$

where σ is a P^1-predicate, p is a polynomial, and Q_k is $\exists$ if k is odd and Q_k is $\forall$ if k is even. Without loss of generality, we assume that p also bounds the running time of the oracle machine M that decides σ with oracle A. The classes of the relativized polynomial-time hierarchy (PH(A)) can be defined as follows:

$$\Sigma_k^P(A) = \{L \mid (\exists \Sigma_k^{P,1}\text{-predicate } \tau)[x \in L \Leftrightarrow \tau(A; x)]\},$$

$$\Pi_k^P(A) = \text{co-}\Sigma_k^P(A),$$

$$\Delta_{k+1}^P(A) = \text{P}(\Sigma_k^P(A)),$$

and

$$\Theta_{k+1}^P(A) = \Theta(\Sigma_k^P(A)), \text{ for } k \geq 0.$$

It is known that for each level of the relativized polynomial-time hierarchy, there is a $\Sigma_k^P(A)$-complete set. These complete sets can be defined inductively as follows: Let $K^1(A) = K(A)$ and $K^k(A) = K(K^{k-1}(A))$ for $k > 1$. Then for each $k \geq 1$ and each set A, $K^k(A)$ is complete for $\Sigma_k^P(A)$.

[1] The Θ operator is defined as follows: for any class C, a set $L \in \Theta(C)$ if and only if there are a deterministic polynomial time oracle machine M and a set $A \in C$ such that $L = L(M, A)$ and, on any input x, M makes at most $O(\log |x|)$ queries to A.

2.3. Circuits. A circuit is a rooted tree, where each nonleaf node is associated with a gate. In this paper, we use four types of gates: AND, OR, MaxOdd, and XOR. For a MaxOdd gate, let its input lines from left to right be $b_0, b_1, \ldots, b_n$. A MaxOdd gate outputs 1 if and only if i is odd, where b_i is the rightmost input line with input 1. A MaxOdd gate outputs 0 if all the inputs are 0. An XOR gate outputs 1 if and only if the number of its 1-inputs is odd. The fanins of all the gates are unlimited. Each leaf of a circuit is associated with a constant 0, a constant 1, a variable x, or a negated variable $\overline{x}$. The *size* of a circuit C is defined to be the number of gates in C. Given a circuit C with only AND and OR gates, its dual circuit $\hat{C}$ is defined inductively as follows: the dual of a constant or a variable is its negation, and the dual of a circuit C that is an OR (AND) of n children C_i, $1 \leq i \leq n$, is the AND (OR) of $\hat{C}_i$, $1 \leq i \leq n$.

A circuit computes a function on its variables in the obvious way. Each variable is represented by v_z for some string $z \in \Sigma^*$. Let V be the set of variables in a circuit C. A *restriction* ρ of a circuit C is a mapping from V to $\{0, 1, *\}$. Let $C\lceil_\rho$ denote the circuit C' obtained from C by replacing each variable x with $\rho(x) = 0$ by 0 and each y with $\rho(y) = 1$ by 1. If a restriction ρ maps no variables to $*$, we say ρ is a complete assignment for the variables of C. Also, we say a restriction ρ *completely determines* C if $C\lceil\rho$ computes a constant function 0 or 1.[2] For any set $A \subseteq \Sigma^*$, the natural assignment ρ_A on all variables v_z, $z \in \Sigma^*$ is: $\rho_A(v_z) = 1$ if $z \in A$ and $\rho_A(v_z) = 0$ if $z \notin A$. For any pair of sets B_1, B_0, with $B_1 \cap B_0 = \emptyset$, the assignment ρ_{B_1,B_0} on all variables v_z, $z \in \Sigma^*$, is $\rho_{B_1,B_0}(v_z) = 1$, if $z \in B_1$, $\rho_{B_1,B_0}(v_z) = 0$, if $z \in B_0$, and $\rho_{B_1,B_0}(v_z) = *$, if $z \notin B_1 \cup B_0$.

Note that applying a restriction ρ to a circuit C and its dual circuit $\hat{C}$ results in another pair of dual circuits. This can be expressed by the following proposition.

PROPOSITION 2.1. *Let C be a circuit with only AND and OR gates, and let $\hat{C}$ be the dual circuit of C. Let ρ be a restriction of C. Then $\hat{C}\lceil_\rho$ is the dual circuit of $C\lceil_\rho$.*

Random restrictions of circuits were first introduced by Furst, Saxe, and Sipser [FSS81]. We use two probability spaces of restrictions $R^+_{q,\mathcal{B}}$ and $R^-_{q,\mathcal{B}}$ from [Has87], as well as the restriction $g(\rho)$, where $\rho \in R^+_{q,\mathcal{B}}$ or $R^-_{q,\mathcal{B}}$. Let $\mathcal{B} = \{B_j\}_{j=1}^r$ be a partition of variables in a circuit C, and let q be a value between 0 and 1. To define a random restriction ρ in $R^+_{q,\mathcal{B}}$, for each B_j, $1 \leq j \leq r$, let $s_j = *$ with probability q and let $s_j = 0$ with probability $1 - q$. Then, independently, for each variable $x \in B_j$, let $\rho(x) = s_j$ with probability q and $\rho(x) = 1$ with probability $1 - q$. Next, for each $\rho \in R^+_{q,\mathcal{B}}$, define a restriction $g(\rho)$ such that for all B_j with $s_j = *$, let V_j be the set of all variables in B_j that are given value $*$ by ρ. $g(\rho)$ selects one variable y in V_j and gives value $*$ to y and value 1 to all other variables in V_j. The probability space $R^-_{q,\mathcal{B}}$ and $g(\rho)$ are defined analogously by interchanging the roles of 0 and 1.

Circuits can be used to describe the computation of oracle machines on input strings [FSS81]. The following proposition is taken from Ko [Ko89].

PROPOSITION 2.2 [Ko89]. *Let M be a deterministic oracle machine with runtime $\leq p(n)$, where p is a polynomial. Then, for each x, there is a depth-2 circuit $C = C_{M,x}$ satisfying the following properties*:

(1) *C is an* OR *of* AND*s*;

(2) *the top fanin of C is $\leq 2^{p(|x|)}$ and the bottom fanin of C is $\leq p(|x|)$; and*

(3) *for any set A, $C\lceil_{\rho_A} = 1$ if and only if $M^A(x)$ accepts.*

Intuitively, each AND gate of C represents one of the accepting computation paths of M on input x, where the variables of the AND gate represent the query strings and answers of that path. It is not difficult to see that the above proposition also holds if we require that the circuit C be an AND of ORs.[3]

[2] Note that a restriction that is not a complete assignment may still completely determine C.

[3] Since M is a deterministic oracle machine, there is a determinisitc oracle machine M' such that M' behaves exactly like M except reversing accept/reject at the end of the computation. The desired AND of ORs circuit is the dual circuit of the circuit obtained from M' by Proposition 2.2.

We call a depth-$(k+1)$ circuit a Σ_k-circuit if it has alternating OR and AND gates, starting with a top OR gate. A $\Sigma_k(m)$-circuit (Fig. 1) is a Σ_k-circuit such that

(1) the number of gates at level 1 to level $k-1$ is bounded by 2^m,

and

(2) fanins at level $k+1$ are $\leq m$.

Note that there is no restriction in fanin at level k. A depth-$(k+1)$ circuit is a Π_k-circuit ($\Pi_k(m)$-circuit) if its dual circuit is a Σ_k-circuit ($\Sigma_k(m)$-circuit). Now we can translate $\Sigma_k^{P,1}$-predicates to circuits.

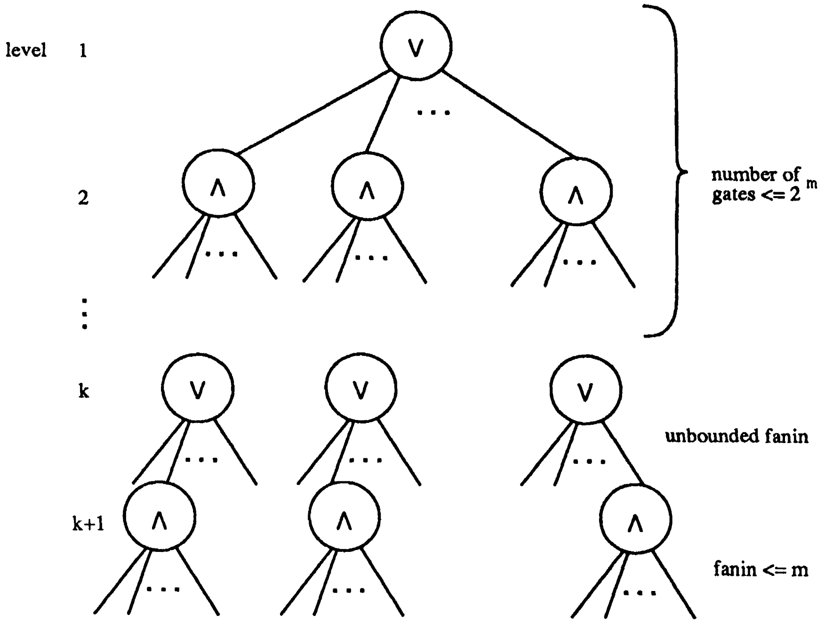

FIG. 1. *A $\Sigma_k(m)$-circuit.*

PROPOSITION 2.3 [Ko89]. *Let $k \geq 1$. For every $\Sigma_k^{P,1}$-predicate τ there is a polynomial q such that for every x, there exists a $\Sigma_k(q(|x|))$-circuit $C_{\tau,x}$, having the property that for any set A, $C_{\tau,x}\lceil_{\rho_A} = 1$ if and only if $\tau(A; x)$ is true. Also, for each variable v_z ($\overline{v_z}$) in $C_{\tau,x}$, $|z| \leq q(|x|)$.*

Sipser [Sip83] introduced a family of functions f_k^n, $n \geq 1$, $k \geq 1$, computed by special types of circuits. Håstad later introduced a modified family of f_k^n functions [Has87], and Ko, still later, introduced a further modification of the f_k^n functions in constructing oracles that separate and collapse relativized polynomial-time hierarchies [Ko89]. We will use Ko's defnition of f_k^n functions as well as introducing similar functions that will be used in our separation results in the next section. These circuits and their functions are pictured in Figs. 2, 3, and 4.

DEFINITION 2.4 [Ko89]. *For each $n \geq 1$ and $k \geq 1$, a C_k^n circuit is a depth-k circuit such that*:

(1) *C_k^n has alternating OR and AND gates, with a top OR gate*;

(2) *all the fanins of C_k^n are exactly n, except the bottom fanins, which are exactly $\sqrt{n}$*; *and*

(3) *each leaf of C_k^n is a unique positive variable.*

We let f_k^n denote the function computed by C_k^n.

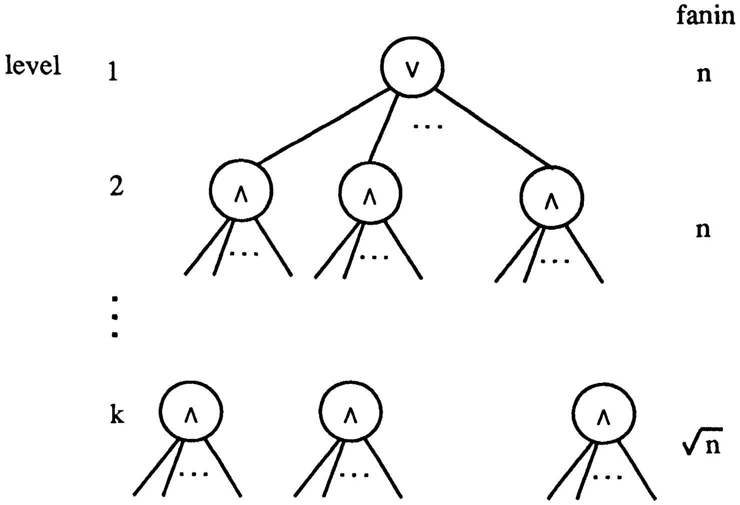

FIG. 2. *A C_k^n circuit.*

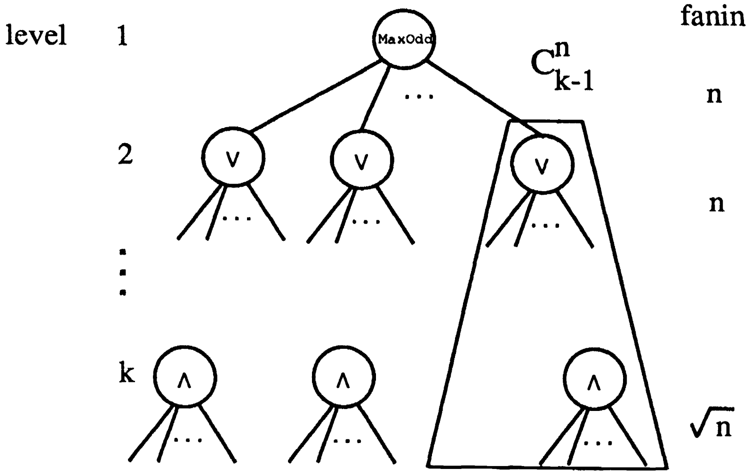

FIG. 3. *An H_k^n circuit.*

DEFINITION 2.5. (1) *For each $n \geq 1$ and $k \geq 1$, an H_k^n circuit is a depth-k circuit with a top* MaxOdd *gate having fanin exactly n such that each subcircuit of the top* MaxOdd *gate is a C_{k-1}^n circuit computing an f_{k-1}^n function and that all the variables in H_k^n are unique. We let h_k^n denote the function computed by H_k^n.*

(2) *For each $n \geq 1$ and $k \geq 1$, a D_k^n circuit is a depth-k circuit with a top* XOR *gate having fanin exactly* 2 *such that each subcircuit of the top* XOR *gate is a C_{k-1}^n circuit computing an f_{k-1}^n function and that all the variables in D_k^n are unique.*

We let l_k^n denote the function computed by D_k^n.

Before ending this section, we state some important lemmas, including the switching lemma on constant-depth circuits from Håstad [Has87].

LEMMA 2.6 (Switching Lemma) [Has87]. *Let G be an* AND *of* OR*s with bottom fanin $\leq t$, and let $\mathcal{B} = \{B_j\}$ be a partition of the variables in G. Then, for a random restriction ρ*

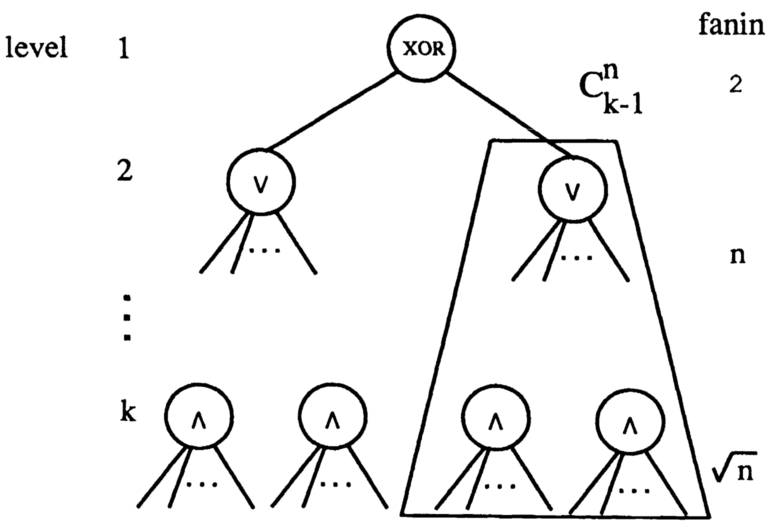

FIG. 4. *A D^n_k circuit.*

from $R^+_{q,\mathcal{B}}$, $Pr(G\lceil_{\rho g(\rho)}$ is not equivalent to a circuit of OR *of* AND*s with bottom fanin $\le s$) is bounded by α^s, where $\alpha < 6qt$. The above probability also holds with $R^+_{q,\mathcal{B}}$ replaced by $R^-_{q,\mathcal{B}}$ or with G being an* OR *of* AND*s circuit to be converted to an* AND *of* OR*s circuits.*

The next lemma is a generalized form of the switching lemma.

LEMMA 2.7 [Has87, Ko89]. *Let $\{C_i\}^n_{i=1}$ be a collection depth-*2 AND-of-OR *and* OR-of-AND *circuits, where the bottom fanin of each C_i is $\le t$. Let V be the set of the variables in $\{C_i\}^n_{i=1}$, and let $\mathcal{B} = \{B_j\}$ be a partition of the variables in V. q is a number between* 0 *and* 1 *and ρ is a random restriction from $R^+_{q,\mathcal{B}}$ or $R^-_{q,\mathcal{B}}$. The probability that every $C_i\lceil_{\rho g(\rho)}$, which is an* AND-of-OR *or* OR-of-AND, *can be converted to a* OR-of-AND *or* AND-of-OR, *respectively, with bottom fanin $< s$ is greater than* 2/3, *if $n \le 1/(3\alpha^s)$, where $\alpha < 6qt$.*

The importance of the switching lemma is that a depth-$(k + 1)$, $k \ge 2$, alternating OR-AND-gate circuit, with small bottom fanins, can be converted to an equivalent depth-k alternating OR-AND-gate circuit, with small bottom fanins. This "shrinking" effect is done by converting the bottom 2-level OR-of-AND (AND-of-OR) subcircuits to AND-of-OR (OR-of-AND) subcircuits and then collapsing the AND (OR) gates at level k and $k - 1$ of the circuit. Our next lemma is a formal statement of this shrinking effect.

LEMMA 2.8. *For each $k \ge 2$, let $\{C_i\}^n_{i=1}$ be a collection of $\Sigma_k(\gamma)$-circuits and $\Pi_k(\gamma)$-circuits. Let V be the set of the variables in $\{C_i\}^n_{i=1}$, and let $\mathcal{B} = \{B_j\}$ be a partition of the variables in V. Let q be a number between* 0 *and* 1, *and let ρ be a random restriction from $R^+_{q,\mathcal{B}}$ or $R^-_{q,\mathcal{B}}$. The probability that every $\Sigma_k(\gamma)$-circuit and every $\Pi_k(\gamma)$-circuit, after applying the random restriction ρ, can be converted to an equivalent $\Sigma_{k-1}(\gamma)$-circuit and an equivalent $\Pi_{k-1}(\gamma)$-circuit is greater than* 2/3, *if $n \le 1/(3(2\alpha)^\gamma)$ where $\alpha < 6q\gamma$.*

Lemmas 2.9 and 2.10 show the effects of a random restriction $\rho \in R^+_{q,\mathcal{B}}$ or $R^-_{q,\mathcal{B}}$ on the circuits that compute f^n_k, h^n_k, and l^n_k functions. The effect of random restrictions on the circuits computing f^n_k functions is due to Håstad [Has87]. Lemma 2.9 shows that a random restriction $\rho \in R^+_{q,\mathcal{B}}$ (or $R^-_{q,\mathcal{B}}$, depending on whether k is odd or even) transforms a circuit computing f^n_k (h^n_{k+1}, or l^n_{k+1}), to a circuit computing a function very close to f^n_{k-1} (h^n_k, or l^n_k). Lemma 2.10 is a stronger form of Lemma 2.9. All proofs follow easily from the proofs in [Ko89].

LEMMA 2.9. *For each $k \ge 2$, there exists an integer n_k such that the following hold for all*

$n \geq n_k$: Let C be a C_k^n circuit computing an f_k^n function (an H_{k+1}^n circuit computing an h_{k+1}^n function, or a D_{k+1}^n circuit computing an l_{k+1}^n function), let $q = n^{-1/3}$, and let ρ be a random restriction from $R_{q,\mathcal{B}}^+$ if k is even or from $R_{q,\mathcal{B}}^-$ if k is odd. The probability that $C\lceil_{\rho g(\rho)}$ contains a subcircuit computing an f_{k-1}^n function (an h_k^n function, or an l_k^n function, respectively) is greater than $2/3$.

LEMMA 2.10. *For each $k \geq 2$, let $\{C_i\}_{i=1}^t$ be t C_k^n circuits, each computing a function f_k^n, with pairwise disjoint variables. Let $q = n^{-1/3}$. If $t \leq 2^{\delta n^{1/6}}$ with $\delta < 1$, then for sufficiently large n, there exists a restriction ρ from $R_{q,\mathcal{B}}^+$ if k is even or from $R_{q,\mathcal{B}}^-$ if k is odd, such that every $C_i\lceil_{\rho g(\rho)}$, $1 \leq i \leq t$, contains a subcircuit that computes an f_{k-1}^n function. This is also holds for H_{k+1}^n and D_{k+1}^n circuits and h_{k+1}^n and l_{k+1}^n functions.*

3. Separation results for relativized polynomial-time hierarchies. Yao and Hastad [Yao85], [Has87] proved the existence of oracles, relative to which, the polynomial-time hierarchy has an infinite number of distinct levels. In this section, we further separate the Σ-, Δ-, and Θ-classes of relativized polynomial-time hierarchies. Our separating results show that there is an oracle A such that for all $k \geq 2$, $\Sigma_{k-1}^P(A) \subsetneq \Theta_k^P(A) \subsetneq \Delta_k^P(A) \subsetneq \Sigma_k^P(A)$. Although Yao and Hastad's results imply part of our separation results, we show different proofs here and will make use of them in the later sections.

3.1. Separating Δ-classes and Σ-classes in relativized polynomial-time hierarchies. In this section, we show that there exists a recursive oracle A such that for all $k \geq 2$, $\Sigma_k^P(A) \neq \Delta_k^P(A)$. We will find, for each $k \geq 2$, a set $L_k^A \in \Sigma_k^P(A)$ such that $L_k^A \notin \Delta_k^P(A)$. By dovetailing the diagonalization for each $k > 0$, the oracle set A can be constructed so that $\Delta_k^P(A) \subsetneq \Sigma_k^P(A)$ for all $k > 0$. Note that when $k = 1$, separation of $\Sigma_1^P(A)$ and $\Delta_1^P(A)$ was already done in [BGS75].

In order to use the circuit lower bound techniques, we need to define circuits for $\Delta_k^P(A)$. Consider a deterministic polynomial-time bounded oracle machine M using oracle set B. On any input x, we can perform computations of M on x. By Proposition 2.2, there is a two-level OR-of-ANDs circuit $C_{M,x}$ such that $x \in L(M, B)$ if and only if $C_{M,x}\lceil_{\rho_B} = 1$. Each AND gate of $C_{M,x}$ represents an accepting computation path of T, relative to some oracle. The fanins (variables) of each AND gate are the query strings in the corresponding computation path of T. For the convenience of discussion, we will label each AND gate with $p(|x|)$ bits, where p is the polynomial bound of the running time of M on any input x. For each label $l = b_1 \ldots b_{p(|x|)}$, b_i represents the answer of the ith query string in the corresponding computation path: $b_i = 1$ if and only if the answer to the ith query string is YES. It is not difficult to see that every two labels are distinct and that for any two labels l and l' with same prefix $b_1 \ldots b_i$, $1 \leq i < p(|x|)$, the corresponding computation paths π_l and $\pi_{l'}$ have the same query strings $q_1, \ldots, q_{i+1}$.

Now if we replace B by $K^{k-1}(A)$, then the language accepted by M is in $\Delta_k^P(A)$. As stated in §2, for each variable z of the form $\langle i, y, 1^j \rangle$, there are a polynomial q and a $\Sigma_{k-1}(q(|z|))$-circuit $C_{K^{k-1},z}$ such that $z \in K^{k-1}(A)$ if and only if $C_{K^{k-1},z}\lceil_{\rho_A} = 1$. We then replace each positive variable v_z of $C_{M,x}$ by $C_{K^{k-1},z}$ if z is of the correct syntactic form or by 0 if z is not of the correct syntactic form. For each negative variable v_z of $C_{M,x}$, we replace it by the dual circuit of $C_{K^{k-1},z}$ if z is of the correct syntactic form or by 1 if z is not of the correct syntactic form. The entire circuit consists of $k+2$ levels. Now we formally define, for $k \geq 2$, $\Delta_k(m)$-circuits.

DEFINITION 3.1. *For $k \geq 2$, C is a $\Delta_k(m)$-circuit if and only if*

(1) *C has $k + 2$ levels; and the top gate is an* OR *with fanin $\leq 2^m$;*

(2) *the gates on the second level are* AND *gates with fanins $\leq m$;*

(3) *each* AND *gate G_j at the second level has a distinct label of m bits, $b_1 \ldots b_m$, and if $b_i = 1$ then the ith subcircuit from the left of G_j is a $\Sigma_{k-1}(m)$-circuit, and if $b_i = 0$ then the ith subcircuit from the left of G_j is a $\Pi_{k-1}(m)$-circuit;*

(4) *for any two* AND *gates G_j and G_n, labeled l_j and l_n, at the second level, if the first r bits, $r < m$, of labels l_j and l_n are the same, then the first r subcircuits from the left of G_j and G_n are the same*; *and*

(5) *for any two* AND *gates G_j and G_n, labeled l_j and l_n, at the second level, if the first bit from the left of l_j and l_n, where l_j and l_n differ, is b_r, $r \leq m$, then the rth subcircuits from the left of G_j and G_n are dual circuits.*

The following lemma states that for all $k \geq 2$ and for any arbitrary set A, if $L \in \Delta_k^P(A)$, then there is a Δ_k-circuit C such that $x \in L \Leftrightarrow C\lceil_{\rho_A} = 1$.

LEMMA 3.2. *Let $k \geq 2$. For every set $L \in \Delta_k^P(A)$, there is a polynomial q such that for every input string x, there is a corresponding $\Delta_k(q(|x|))$-circuit $C_{L,x}$ such that $x \in L \Leftrightarrow C_{L,x}\lceil_{\rho_A} = 1$.*

Our goal is, for every $k \geq 2$, to find a set A such that $\Sigma_k^P(A)$ properly contains $\Delta_k^P(A)$. First, for fixed $k \geq 1$, define the language

$$L_k^A = \{x0^{kn} \mid |x| = 2n, (\exists y_1, |y_1| = n)(\forall y_2, |y_2| = n) \cdots (Q_k y_k, |y_k| = n) 0xy_1y_2 \ldots y_k \in A\},$$

where Q_k is $\exists$ if k is odd and Q_k is $\forall$ if k is even. It is clear that $L_A \in \Sigma_k^P(A)$.

Let $M_1, M_2, \ldots$ be an effective enumeration of deterministic polynomial-time bounded oracle machines with running time bounded by polynomials $p_1, p_2, \ldots$, respectively. The construction of set A is by stages. Let $t(n)$ denote the maximum length of strings in A or $\overline{A}$ decided by stage n. Let $D(n)$, the diagonalization area for stage n, be the set $\{x \in \Sigma^* \mid t(n-1) + 1 \leq |x| \leq t(n)\}$. At stage n of the construction, we will find a witness 0^m, m is a multiple of $k+2$, such that, $0^m \in L_k^A \Leftrightarrow 0^m \notin L(M_n, K^{k-1}(A))$; that is, at each stage $n > 0$, we want to satisfy the following requirement R_n:

$$R_n : (\exists x = 0^m)(\exists B \subseteq D(n))[0^m \in L_k^B \Leftrightarrow 0^m \notin L(M_n, K^{k-1}(A'))],$$

where $A' = A(n-1) \cup B$ and $A(n-1)$ denotes the strings in A decided prior to stage n. Let C_0 be the obvious k-level circuit for the predicate $0^m \in L_k^B$. C_0 contains a subcircuit that computes a $f_k^{2^{m/(k+2)}}$ function. By Lemma 3.2, there exist a polynomial q and a $\Delta_k(q(m))$-circuit C_n that corresponds to the computation of the machine M_n on input 0^m with oracle $K^{k-1}(A)$. Since the length of query strings to A in the circuit C_n is bounded by $q(m)$, we let $t(n) = q(m)$. The requirement R_n can then be rewritten as

$$R'_n : (\exists x = 0^m)(\exists B \subseteq D(n))[C_0\lceil_{\rho_B} = 1 \Leftrightarrow C_n\lceil_{\rho_{A'}} = 0],$$

where $A' = A(n-1) \cup B$. Now let $s_k(v)$ be the minimum r such that a $\Delta_k(r)$-circuit can compute an f_k^v function. That requirement R'_n can be satisfied follows from the following lower bound on $s_k(v)$.

THEOREM 3.3. *For all $k \geq 2$, for sufficiently large v, $s_k(v) \geq \delta v^{1/5}$, where $\delta = 1/48$.*

Proof. The proof is by induction on k. For the base case of $k = 2$, let C_2^v be a circuit computing f_2^v; that is, C_2^v is an OR of v AND's, each having fanin $= \sqrt{v}$. Let C be a $\Delta_2(r)$-circuit, with $r < \delta v^{1/5}$. We will show that C does not compute f_2^v; that is, we will find a restriction ρ such that $C_2^v\lceil_\rho \neq C\lceil_\rho$.

Consider C, a $\Delta_2(r)$-circuit. Recall that, for each AND gate g_l at second level of C, g_l is labeled with r bits, $b_{l_1}b_{l_2}\cdots b_{l_r}$, and if $b_{l_i} = 1$, then the ith subcircuit from the left of g_l is a $\Sigma_1(r)$-circuit, and if $b_{l_i} = 0$, then the ith subcircuit from the left of g_l is a $\Pi_1(r)$-circuit. Also, for any other AND gate $g_{l'}$ at the second level with label $b_{l'_1}b_{l'_2}\ldots b_{l'_r}$, where $b_{l_j} = b_{l'_j}$ for $1 \leq j < i$ and $b_{l_i} \neq b_{l'_i}$, the ith subcircuits of g_l and g'_l are dual circuits. Thus, if we find a restriction ρ that makes the ith subcircuit of g_l output 1, then the ith subcircuit of $g_{l'}$ will output 0 by Proposition 2.1. Therefore, the entire subcircuit g'_l at level 2 of C can be replaced by a constant 0. By making assignments to at most r^2 variables, we will be able to determine completely the output of C while the output of C_2^v remains undetermined.

The process of finding an appropriate assignment of variables starts by fixing the leftmost subcircuit of each second-level AND gate of C. Note that there is a single $\Sigma_1(r)$ circuit C_1 such that the leftmost subcircuit of each second-level AND gate of C is one of C_1 or $\hat{C}_1$. If C_1 can be forced to output 1 by assigning at most r variables (recall that C_1 is an OR of ANDs, each AND with fanin at most r), then this is done. Then, all second level AND gates of C with C_1 as the leftmost subcircuit are modified by replacing C_1 with 1, and all second level AND gates of C with $\hat{C}_1$ as the leftmost subcircuit are removed from C. On the other hand, if C_1 cannot be forced to output 1, then $\hat{C}_1$ will always output 1 regardless of assignments to variables. In this case, all second-level AND gates of C with $\hat{C}_1$ as the leftmost subcircuit are modified by replacing $\hat{C}_1$ with 1, all second-level AND gates of C with C_1 as the leftmost subcircuit are removed from C, and no assignments are made. In either case, all second-level AND gates that now remain in C had the same leftmost subcircuit, either C_1 or $\hat{C}_1$, which is now replaced by 1. This implies that there is a single $\Sigma_1(r)$ circuit C_2 such that the second subcircuit of each remaining second-level AND gate of C is one of C_2 or $\hat{C}_2$. Hence, we can repeat the same process with C_2, then with some C_3, etc., until some C_r. At this point, at most r^2 variables will have been assigned and the output of C is completely determined. Since $r^2 \leq (\delta v^{1/5})^2 < \sqrt{v}$ for sufficiently large v, there is no bottom AND gate G of C_2^v such that $G\lceil_\rho = 1$. Also, since the top fanin of C_2^v is v, there is some bottom AND gate G' of C_2^v such that no variables of G' have been decided in the previous process; that is, we can find a restriction ρ such that

$$(\#) \qquad C\lceil_\rho \neq * \quad \text{and} \quad C_2^v\lceil_\rho = *.$$

Thus, C cannot compute a function f_2^v when the size of C is less than $\delta v^{1/5}$. This establishes the base case for the inductive proof of Theorem 3.3.

Our induction hypothesis is that for some fixed $k' \geq 2$ and for sufficiently large v, $s_{k'}(v) \geq \delta v^{1/5}$; that is, for sufficiently large v, if C is a $\Delta_{k'}(r)$-circuit with $r < \delta v^{1/5}$, then C does not compute the function $f_{k'}^v$. For the induction step, consider $k = k' + 1 > 2$. Consider a C_k^v-circuit that computes an f_k^v function. Let $q = v^{-1/3}$ and let $\mathcal{B} = \{B_j\}$, where B_j is the set of variables of the bottom AND gate H_j of C_k^v. By way of contradiction, assume that there exists a circuit C, that is, a $\Delta_k(r)$-circuit with $r < \delta v^{1/5}$, computing the function f_k^v. We will argue that after applying a random restriction ρ from $R_{q,\mathcal{B}}^+$, if k is even, or from $R_{q,\mathcal{B}}^-$, if k is odd, to C, the resulting circuit $C\lceil_{\rho g(\rho)}$ is a $\Delta_{k-1}(r)$-circuit with $r < \delta v^{1/5}$ that computes the function f_{k-1}^v, which contradicts our induction hypothesis.

To apply the induction hypothesis, we need to verify that

(1) with a high probability, $C\lceil_{\rho g(\rho)}$ is equivalent to a $\Delta_{k-1}(r)$-circuit,

and

(2) with a high probability, $C_k^v\lceil_{\rho g(\rho)}$ contains a subcircuit computing the function f_{k-1}^v.

Part (1) is proved by Lemma 2.8. To apply Lemma 2.8, let us choose $\gamma = \delta v^{1/5}$. We have $\alpha < 6q\gamma = 1/8 \cdot v^{-2/15}$. By definition, the total number of $\Sigma_k(r)$-circuits and $\Pi_k(r)$-circuits in a $\Delta_k(r)$-circuit is bounded by $r \cdot 2^r \leq 2^{2r}$. Thus, we only need to show that $2^{2r} < 2^{2\gamma} \leq 1/(3(2\alpha)^\gamma)$. We have

$$2^{2\gamma} \cdot 3(2\alpha)^\gamma = 3 \cdot (8\alpha)^\gamma \leq 3 \cdot (v^{-2/15})^\gamma \leq 1$$

for sufficiently large v. This proves part (1). Part (2) was proved in Lemma 2.9. This completes the proof of Theorem 3.3. □

To satisfy requirement R_n', notice that C_n is a $\Delta_k(q(m))$-circuit corresponding to the predicate $0^m \in L(M_n, K^{k-1}(A))$ and that C_0, corresponding to the predicate $0^m \in L_k^A$, contains a subcircuit that computes an $f_k^{2^{m/(k+2)}}$ function. Thus, we need to choose an integer

m so large such that $q(m) < (1/48) \cdot 2^{m/5(k+2)}$ and that Theorem 3.3 holds for $s_k(2^{m/(k+2)})$. We now have the desired theorem.

THEOREM 3.4. *There exists an oracle A such that for all $k \geq 1$, $\Delta_k^P(A) \subsetneq \Sigma_k^P(A)$.*

3.2. Separating Θ-classes and Δ-classes in relativized polynomial-time hierarchies. In this section, we show that there exists a recursive oracle A such that for all $k \geq 2$, $\Theta_k^P(A) \neq \Delta_k^P(A)$. We will find, for each $k \geq 2$, a set $L_{\text{odd},k}^A \in \Delta_k^P(A)$ and that $L_{\text{odd},k}^A \notin \Theta_k^P(A)$. Again, by dovetailing the diagonalization for each $k \geq 2$, the oracle set A can be constructed so that $\Theta_k^P(A) \subsetneq \Delta_k^P(A)$ for all $k \geq 2$.

We will again use circuit lower bound techniques to prove this separation. Similarly to finding special circuits that represent sets in $\Delta_k^P(A)$, we need special circuits that represent sets in $\Theta_k^P(A)$. Consider a deterministic polynomial-time bounded oracle machine M using oracle set B and, on any input x, the query tree T that represents all the possible computations of M on x. Since there are at most $O(\log |x|)$ queries in any one computation path, the total number of possible paths is bounded by a polynomial $p(|x|)$. Thus, we can define $\Theta_k(m)$-circuits in a manner that is similar to the definition of $\Delta_k(m)$-circuits.

DEFINITION 3.5. *For $k \geq 2$, C is a $\Theta_k(m)$-circuit if and only if:*

(1) *C has $k+2$ levels, and the top gate is an* OR *with fanin $\leq m$;*

(2) *the gates on second level are* AND *gates with fanins $\leq \log m$;*

(3) *each* AND *gate G_j at the second level has distinct label of $n = \log m$ bits, $b_1 \ldots b_n$, and if $b_i = 1$ then, the ith subcircuit from the left of G_j is a $\Sigma_{k-1}(m)$-circuit, and if $b_i = 0$, then the ith subcircuit from the left of G_j is a $\Pi_{k-1}(m)$-circuit;*

(4) *for any two* AND *gates G_j and G_n, labeled l_j and l_n, at the second level, if the first r bits, $r < \log m$, of labels l_j and l_n are the same, then the first r subcircuits from the left of G_j and G_n are the same; and*

(5) *for any two* AND *gates G_j and G_n, labeled l_j and l_n, at the second level, if the first bit from the left of l_j and l_n where l_j and l_n differ is b_r, $r \leq \log m$, then the rth subcircuits from the left of G_j and G_n are dual circuits.*

LEMMA 3.6. *Let $k \geq 2$. For every set $L \in \Theta_k^P(A)$, there is a polynomial q such that for every input string x, there is a corresponding $\Theta_k(q(|x|))$-circuit $C_{M,x}$ such that $x \in L \Leftrightarrow C_{M,x}\lceil_{\rho_A} = 1$.*

To separate $\Theta_k^P(A)$ and $\Delta_k^P(A)$, for all $k \geq 2$, we define

$$L_{\text{odd},k}^A = \{x0^{kn} \mid |x| = n, \text{ and } \max\{y \mid |y| = |x|, xy\,0^{(k-1)n} \in L_{k-1}^A\} \text{ has odd parity}\}.$$

Recall that L_{k-1}^A, as defined in §3.1, is a set in $\Sigma_{k-1}^P(A)$; thus $L_{\text{odd},k}^A$ is in $\Delta_k^P(A)$ using a binary search algorithm. The setup of the diagonalization is similar to the one in §3.1 with functions $t(n)$ and $D(n)$. For each stage $n > 0$ of the construction, we want to satisfy the following requirement R_n:

$$R_n : (\exists x = 0^m)(\exists B \subseteq D(n))[0^m \in L_{\text{odd},k}^B \Leftrightarrow 0^m \notin L(M_n, K^{k-1}(A'))],$$

where $A' = A(n-1) \cup B$ and $A(n-1)$ denotes the strings in A decided prior to stage n, and M_n is the nth Θ_k^P oracle machine making at most $\log(p_n(m))$. Note that the predicate "$0^m \in L_{\text{odd},k}^B$" can be represented by a k-level circuit with a top MaxOdd gate having fanin $2^{m/(k+1)}$. Each top level subcircuit, C_y, of MaxOdd contains a $C_{k-1}^{2^{m/(k+1)}}$-subcircuit computing an $f_{k-1}^{2^{m/(k+1)}}$ function, where y corresponds to the y in the definition of $L_{\text{odd},k}^B$. Also, the subcircuits C_y will be arranged, in lexicographic order on y, from left to right as the children of the top MaxOdd gate. Let C_0 be the corresponding k-level circuit for the predicate $0^m \in L_{\text{odd},k}^B$. C_0 contains an $H_k^{2^{m/(k+1)}}$ subcircuit that computes an $h_k^{2^{m/(k+1)}}$ function.

By Lemma 3.6, there exist a polynomial q and a $\Theta_k(q(m))$-circuit C_n corresponding to the the machine M_n on input 0^m, with oracle $K^{k-1}(A)$. We let $t(n) = q(m)$. The requirement

R_n can then be rewritten as

$$R'_n : (\exists x = 0^m)(\exists B \subseteq D(n))[C_0\lceil_{\rho_B}= 1 \Leftrightarrow C_n\lceil_{\rho_{A'}}= 0],$$

where $A' = A(n-1) \cup B$.

Now let $s_k(v)$ be the minimum r for a $\Theta_k(r)$-circuit to compute an h_k^v function. The following lower bound on $s_k(v)$ shows that the requirement R'_n can be satisfied.

THEOREM 3.7. *For all $k \geq 2$, for sufficiently large v, $s_k(v) \geq \delta v^{1/5}$, where $\delta = 1/24$.*

Proof. Again, the proof is by induction on k. For the base case of $k = 2$, let H_2^v be an MaxOdd of v subcircuits, each computing a function f_1^v. Let C be a $\Theta_2(r)$-circuit, with $r < \delta v^{1/5}$. We need to show that C does not compute the same function as H_2^v; that is, we will find a restriction ρ such that $H_2^v\lceil_\rho \neq C\lceil_\rho$.

Consider C, the $\Theta_2(r)$-circuit. Accounting for the fact that some Σ_1- and Π_1-circuits are duals, there are at most $r < \delta v^{1/5}$ many different Σ_1-circuits and Π_1-circuits in C. (It is easy to see this by looking at the query tree of a Θ_2^P oracle machine.) During the construction of A at stage n, we will put strings into A step by step. At each step we place some strings into A in order to flip-flop the output of $H_2^v\lceil_{\rho_A}$. During the same step, at least one of the Σ_1-circuits (or Π_1-circuits) of C will be fixed to have output 1 (or 0) by assigning variables to A only. Since there are only $r < \delta v^{1/5}$ many different Σ_1-circuits and Π_1-circuits, we will eventually fix the output of C after at most $r + 1 \leq \delta v^{1/5}$ flip-flops of H_2^v. We argue that, after this process, we are still able to flip-flop the output of H_2^v as we desire. Thus, we can find the needed restriction. Now we present this flip-flop process.

Process FF:

```
$B :=$ the variables of the leftmost OR gate of $H_2^v$; $\overline{B} := \emptyset$;
while $C\lceil_{\rho_B}= H_2^v\lceil_{\rho_B}$ do
    if there is some $\Sigma_1$-circuit $C_j$ of $C$ with $C_j\lceil_{\rho_B}= 1$ then
        for all $\Sigma_1$-circuits $C_j$ of $C$ with $C_j\lceil_{\rho_B}= 1$ do
            Fix the output of one AND gate $G$ of $C_j$ to be 1 with restriction $\rho_B$
            by assigning all negative variables of $G$ to $\overline{B}$
        end(* for *)
    end(* if *)
    if there is some $\Pi_1$-circuit $C'_j$ of $C$ with $C'_j\lceil_{\rho_B}= 0$ then
        for all $\Pi_1$-circuits $C'_j$ of $C$ with $C'_j\lceil_{\rho_B}= 0$ do
            Fix the output of one OR gate $G'$ of $C'_j$ to be 0 with restriction $\rho_B$
            by assigning all positive variables of $G'$ to $\overline{B}$
        end(* for *)
    end(* if *)
    Find the leftmost subcircuit $H_i$ of $H_2^v$ such that $H_i\lceil_{\rho_B}= 0$.
    Let $V$ be the set of variables in $H_i$ that are not in $\overline{B}$. Let $B := B \cup V$.
end(* while *)
```

We now carefully analyze **Process FF**. Initially, B contains the variables in the leftmost OR gate of H_2^v and $\overline{B}$ is empty. We have $H_2^v\lceil_{\rho_B}= 0$. If $H_2^v\lceil_{\rho_B}\neq C\lceil_{\rho_B}$, then we are done. Otherwise, we will try to fix the output of some of the Σ_1-circuits or Π_1-circuits of C. To make sure that we only reserve polynomial many strings in the entire process, we only consider fixing the output of Σ_1-circuits to be 1 and the output of Π_1-circuits to be 0. This process is done in the following steps: for all the Σ_1-circuits C_j of C such that $C_j\lceil_{\rho_B}= 1$, fix the output of one of C_j's bottom AND gates G to be 1 with restriction ρ_B. If we assign all the negative variables in G to $\overline{B}$, then we will preserve the output of C_j in later steps. Note that the positive variables of G are already in B since G is an AND gate and $G\lceil_{\rho_B}$ outputs 1. In later steps, we will never reassign the variables in B or $\overline{B}$. Also, for each Σ_1-circuit, there are at most r

many variables that are assigned to $\overline{B}$ in this process. We carry out a similar process for the Π_1-circuits C'_j of C to obtain $C'_j\lceil_{\rho_B}= 0$.

The next step in **Process FF** is to "flip-flop" the output of H_2^v. This is done by adding the free variables of the leftmost subcircuit H_i of H_2^v such that $H_i\lceil_{\rho_B}= 0$. We will assure that there are always some free variables in H_i that are not in $\overline{B}$. This will flip-flop H_i's output between 0 and 1, and the output of the other OR gates in H_2^v remains unchanged (recall that all variables in H_2^v are unique). As output of H_2^v is flip-flopped, if the output of $C\lceil_{\rho_B}$ does not flip-flop, we are done. *Otherwise, if $C\lceil_{\rho_B}$ also flip-flops its output, there must be some Σ_1-circuits (Π_1-circuits) that output* 0 (1) *in the previous iteration but then change their outputs to* 1 (0). This is because Σ_1-circuits outputting 1 and Π_1-circuits outputting 0 are already fixed. In this case, we repeat the same process. Note that at each iteration of the process, at least one Σ_1- or Π_1-circuit is fixed.

Now we argue that the variables reserved in $\overline{B}$ will not make any H_i's of H_2^v permanently output 0; that is, flip-flopping the output of H_2^v is always possible. Observe the following two facts.

(1) There are at most $r < \delta v^{1/5}$ Σ_1-circuits and Π_1-circuits in C. Thus, after at most $r + 1$ iterations, the while-loop in **Process FF** terminates.

(2) There are v subcircuits of the top MaxOdd gate of H_2^v and each subcircuit is an OR of $\sqrt{v}$ inputs.

Since we assign at most r variables to $\overline{B}$ for each Σ_1-circuit and Π_1-circuit, there are, by fact (1), at most $r(r + 1) \leq (\delta v^{1/5})^2 < \sqrt{v}$ variables reserved to $\overline{B}$ during **Process FF**. Thus, none of the H_i's of H_2^v will permanently output 0 based on assignments to $\overline{B}$. Finally, since there are at most $r + 1 \leq v^{1/5}$ iterations of the while-loop and since H_2^v can flip-flop at least v times, we then conclude that there is a pair of finite sets B and $\overline{B}$ that

$$(*) \qquad C\lceil_{\rho_{B,\overline{B}}}\neq * \quad \text{and} \quad H_2^v\lceil_{\rho_{B,\overline{B}}}= *.$$

This completes the base case of $k = 2$.

Our induction hypothesis is that for some fixed $k' \geq 2$ and for sufficiently large v, $s_{k'}(v) \geq \delta v^{1/5}$; that is, for sufficiently large v, if C is a $\Theta_{k'}(r)$-circuit with $r < \delta v^{1/5}$, then C does not compute the function $h_{k'}^v$. For the induction step, consider $k = k' + 1 > 2$. Consider an H_k^v-circuit that computes an h_k^v function. Let $q = v^{-1/3}$ and let $\mathcal{B} = \{B_j\}$, where B_j is the set of variables of the bottom AND gate G_j of H_k^v. By way of contradiction, assume that there exists a circuit C, that is, a $\Theta_k(r)$-circuit with $r < \delta v^{1/5}$, computing the function h_k^v. We will argue that after applying a random restriction from $R_{q,\mathcal{B}}^+$, if k is odd or from $R_{q,\mathcal{B}}^-$, if k is even, to C, the resulting circuit $C\lceil_{\rho g(\rho)}$ is a $\Theta_{k-1}(r)$-circuit with $r < \delta v^{1/5}$ that computes the function h_{k-1}^v, which contradicts our induction hypothesis.

To apply the induction hypothesis, we need to verify that

(1) with a high probability, $C\lceil_{\rho g(\rho)}$ is equivalent to a $\Theta_{k-1}(r)$-circuit,

and

(2) with a high probability, $H_k^v\lceil_{\rho g(\rho)}$ contains a subcircuit computing the function h_{k-1}^v.

Again, part (1) is proved by the Lemma 2.8. To apply Lemma 2.8, we choose $\gamma = \delta v^{1/5}$. We have $\alpha < 6q\gamma = 1/4 \cdot v^{-2/15}$. The total number of $\Sigma_{k-1}(r)$-circuits and $\Pi_{k-1}(r)$-circuits of C is bounded by $r \cdot \log r \leq 2^r < 2^\gamma$. To apply Lemma 2.8, we need to show that $2^\gamma \leq 1/(3(2\alpha)^\gamma)$. We have

$$2^\gamma \cdot 3(2\alpha)^\gamma = 3(4\alpha)^\gamma \leq 3(v^{-2/15})^\gamma \leq 1,$$

for sufficiently large v. This proves part (1). Part (2) follows from Lemma 2.9. This completes the proof of Theorem 3.7. □

To satisfy requirement R'_n, we need to choose an integer m so large that Theorem 3.7 holds for $s_k(2^{m/(k+1)})$ and such that $q(m) < (1/24) \cdot 2^{m/5(k+1)}$.

THEOREM 3.8. *There exists an oracle A such that for all $k \geq 2$, $\Theta_k^P(A) \subsetneq \Delta_k^P(A)$.*

3.3. Separating Σ-classes and Θ-classes in relativized polynomial-time hierarchies. In this section, we show that there exists a recursive oracle A such that for all $k \geq 2$, $\Sigma_{k-1}^P(A) \neq \Theta_k^P(A)$. We will find, for each $k \geq 2$, a set $L_{\mathrm{xor},k}^A \in \Theta_k^P(A)$ such that $L_{\mathrm{xor},k}^A \notin \Sigma_{k-1}^P(A)$. Once again, by dovetailing the diagonalization for each $k \geq 2$, the oracle set A can be constructed so that $\Sigma_{k-1}^P(A) \subsetneq \Theta_k^P(A)$ for all $k \geq 2$.

To separate $\Sigma_{k-1}^P(A)$ and $\Theta_k^P(A)$, for all $k \geq 2$, we define

$$L_{\mathrm{xor},k}^A = \{x0^{kn} \mid |x| = n, \text{ and exactly one of } 0^n x 0^{(k-1)n} \text{ or } 1^n x 0^{(k-1)n} \text{ is in } L_{k-1}^A\},$$

where L_{k-1}^A is a set in $\Sigma_{k-1}^P(A)$, as defined in §3.1. Thus $L_{\mathrm{xor},k}^A$ is in $\Theta_k^P(A)$.

The setup of the diagonalization is similar to the one in §3.1. For each stage $n > 0$, we want to satisfy the following requirement R_n:

$$R_n : (\exists x = 0^m)(\exists B \subseteq D(n))[0^m \in L_{\mathrm{xor},k}^B \Leftrightarrow \sigma_n(A; 0^m) \text{ is false }],$$

where σ_n is the nth $\Sigma_{k-1}^{P,1}$-predicate. Note that the predicate "$0^m \in L_{xor,k}^B$?" can be represented by a k-level circuit with a top XOR gate having fanin of 2. Each subcircuit of the XOR gate contains a $C_{k-1}^{2^{m/(k+1)}}$-subcircuit computing an $f_{k-1}^{2^{m/(k+1)}}$ function. Let C_0 be the corresponding k-level circuit for the predicate $0^m \in L_{\mathrm{xor},k}^B$. C_0 contains a $D_k^{2^{m/(k+1)}}$-subcircuit that computes an $l_k^{2^{m/(k+1)}}$ function.

By Lemma 2.3, there exist a polynomial q and a $\Sigma_{k-1}(q(m))$-circuit C_n corresponding the predicate $\sigma_n(A; 0^m)$. Again, let $t(n) = q(m)$. The requirement R_n can then be rewritten as

$$R_n' : (\exists x = 0^m)(\exists B \subseteq D(n))[C_0\lceil_{\rho_B} = 1 \Leftrightarrow C_n\lceil_{\rho_{A'}} = 0],$$

where $A' = A(n-1) \cup B$ and $A(n-1)$ is the set of strings in A decided prior to stage n. Now let $s_k(v)$ be the minimum r such that a $\Sigma_{k-1}(r)$-circuit can compute an l_k^v function. The following lower bound on $s_k(v)$ shows that the requirement R_n' can be satisfied.

THEOREM 3.9. *For all $k \geq 2$, for sufficiently large v, $s_k(v) \geq \delta v^{1/3}$, where $\delta = 1/12$.*

Proof. Again, the proof is by induction on k. For the base case of $k = 2$, let D_2^v be an XOR of 2 subcircuits D_1 and D_2, each computing an f_1^v function. Let C be a $\Sigma_1(r)$-circuit, where $r < \delta v^{1/3}$. We will find a restriction ρ such that $C\lceil_\rho \neq *$ and $D_2^v\lceil_\rho = *$.

Let v_1 be the leftmost variable of D_1. Initially, let $B = \overline{B} = \emptyset$. Let $\rho_\emptyset$ denote the restriction that assigns 0 to all the variables, let $\rho_{\{v_1\}}$ denote the restriction that assigns 1 to v_1 and 0 to all the other variables, and let $\rho_{\emptyset, \Sigma^* - \{v_1\}}$ denote the restriction that assigns $*$ to v_1 and assigns 0 to all the other variables. There are three cases:

Case 1. $C\lceil_{\rho_\emptyset} = 1$. In this case, there must be an AND gate G of C with only negative variables. Assign all the variables in G to $\overline{B}$. The number of variables being assigned is bounded by $r < \delta v^{1/3} < \sqrt{v}$. Thus, neither D_1 nor D_2 will be forced to output a constant by $\rho_{B,\overline{B}}$ and $D_2^v\lceil_{\rho_{B,\overline{B}}} = *$, where $B = \emptyset$.

Case 2. $C\lceil_{\rho_\emptyset} = 0$ and $C\lceil_{\rho_{\{v_1\}}} = 0$. In this case, changing the assignment of v_1 from 0 to 1 does not change the output of $C\lceil_{\rho_\emptyset}$. Thus, $C\lceil_{\rho_{\emptyset,\Sigma^*-\{v_1\}}} = 0$. $D_2^v\lceil_{\rho_{\emptyset,\Sigma^*-\{v_1\}}} = *$ since the output of $D_2^v\lceil_{\rho,\Sigma^*}$ can be set to 1 by assigning 1 to variable v_1 or left at 0 by assigning 0 to v_1.

Case 3. $C\lceil_{\rho_\emptyset} = 0$ and $C\lceil_{\rho_{\{v_1\}}} = 1$. In this case, there is an AND gate G of C that outputs 1 by $\rho_{\{v_1\}}$. Since v_1 is the only variable that is assinged 1 by $\rho_{\underline{\{v_1\}}}$, all the other variables in G must be negative variables. Assign all negative variables to $\overline{B}$ and assign v_1 to B. Since the number of negative variables is bounded by $r < \delta v^{1/3} < \sqrt{v}$ and since only one positive variable has been assigned, it is easy to see that $C\lceil_{\rho_{B,\overline{B}}} = 1$ and $D_2^v\lceil_{\rho_{B,\overline{B}}} = *$.

Our induction hypothesis is that for some fixed $k' \geq 2$ and for sufficiently large v, $s_{k'}(v) \geq \delta v^{1/3}$; that is, for sufficiently large v, if C is a $\Sigma_{k'-1}(r)$-circuit with $r < \delta v^{1/3}$, then C does not comupte the function $l^v_{k'}$. For the induction step, consider $k = k' + 1 > 2$. Consider a D^v_k-circuit that computes an l^v_k function. Let $q = v^{-1/3}$ and let $\mathcal{B} = \{B_j\}$, where B_j is the set of variables of the bottom AND gate G_j of D^v_k. By way of contradiction, assume that there exists a circuit C, that is, a $\Sigma_{k-1}(r)$-circuit with $r < \delta v^{1/3}$, computing the function l^v_k. We will argue that after applying a random restriction from $R^+_{q,\mathcal{B}}$, if k is odd, or from $R^-_{q,\mathcal{B}}$, if k is even, to C, the resulting circuit $C\lceil_{\rho g(\rho)}$ is a $\Sigma_{k-2}(r)$-circuit with $r < \delta v^{1/3}$ that computes the function l^v_{k-1}, which contradicts our induction hypothesis.

For induction step, let C be a $\Sigma_{k-1}(r)$-circuit and let D^v_k be the circuit computing an l^v_k function. To apply the induction hypothesis, we need to verify that

(1) with a high probability, $C\lceil_{\rho_{\rho,g(\rho)}}$ is equivalent to a $\Sigma_{k-2}(r)$-circuit, and

(2) with a high probability, $D^v_k\lceil_{\rho g(\rho)}$ contains a subcircuit computing the function l^v_{k-1}.

Part (1) is proved by Lemma 2.7. To apply Lemma 2.7, we choose $\gamma = \delta v^{1/3}$. We have $\alpha < 6q\gamma = 1/2$. The total number of depth-2 subcircuits at the bottom level of C is bounded by its size $2^r < 2^\gamma$. We need to show that $2^\gamma \leq 1/(3 \cdot \alpha^\gamma)$. We have

$$2^\gamma \cdot 3 \cdot \alpha^\gamma = 3(2\alpha)^{\delta v^{1/3}} \leq 1,$$

for sufficiently large v. Part (2) follows from Lemma 2.9. This completes the proof of Theorem 3.9. □

To satisfy requirement R'_n, we need to choose an integer m so large that Theorem 3.9 holds for $s_k(2^{m/(k+1)})$ and such that $q(m) < (1/12) \cdot 2^{m/3(k+1)}$.

THEOREM 3.10. *There exists an oracle A such that for all $k \geq 2$, $\Sigma^P_{k-1}(A) \subsetneq \Theta^P_k(A)$.*

The constructions of Theorems 3.3, 3.7, and 3.9 can all be dovetailed to obtain the following:

THEOREM 3.11. *For all $k \geq 2$, there exists an oracle A such that $\Sigma^P_{k-1}(A) \subsetneq \Theta^P_k(A) \subsetneq \Delta^P_k(A) \subsetneq \Sigma^P_k(A)$.*

4. The extended low hierarchy has an infinite number of distinct levels. An interesting question is whether the low hierarchy or the extended low hierarchy consists of an infinite number of distinct levels. The existence of an infinite number of distinct levels in the low hierarchy not only implies that P $\neq$ NP but also provides a natural complexity categorization of sets in NP: sets at the higher levels of the low hierarchy are more "complicated" than sets at the lower levels. It is interesting to note that there exists an oracle set relative to which the low hierarchy is a properly infinite hierarchy and that there also exists an oracle set relative to which the low hierarchy has a finite number of distinct levels [Ko91].

The situation is different for the extended low hierarchy. In proving optimal lower bounds for the extended low hierarchy, Allender and Hemachandra [AH92] constructed a sparse set that is not in $EL^{P,\Sigma}_2$, level 2 of the extended low hierarchy based on the Σ-levels of the polynomial-time hierarchy. It is known that sparse sets are in $EL^{P,\Theta}_3$, level 3 of the extended low hierarchy based on the Θ-levels of the polynomial-time hierarchy. This shows that the extended low hierarchy has at least two distinct levels.

In this section, we show that the extended low hierarchy actually consists of an infinite number of distinct levels. Our theorems are motivated by the observation that there are hard sets in the extended low hierarchy. As noted in [BBS86], any PSPACE complete set, for example, is in the extended low hierarchy. Sets, like hard sets, that can collapse the polynomial-time hierarchy to a fixed level, but no lower, are candidates for sets separating various levels of the extended low hierarchy.

To better understand why this happens, first consider the definition of the extended low hierarchy.

DEFINITION 4.1 [BBS86], [AH92], [LS91].(1) *For each* $k \geq 1$, $EL_k^{P,\Sigma} = \{A \mid \Sigma_k^P(A) \subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT})\}$.

(2) *For each* $k \geq 2$, $EL_k^{P,\Delta} = \{A \mid \Delta_k^P(A) \subseteq \Delta_{k-1}^P(A \oplus \mathrm{SAT})\}$.

(3) *For each* $k \geq 2$, $EL_k^{P,\Theta} = \{A \mid \Theta_k^P(A) \subseteq \Theta_{k-1}^P(A \oplus \mathrm{SAT})\}$.

Proposition 4.2 shows the basic relationships between the levels of the extended low hierarchy.

PROPOSITION 4.2 [AH92], [LS91]. (1) *For each* $k \geq 1$, $EL_k^{P,\Sigma} \subseteq EL_{k+1}^{P,\Theta} \subseteq EL_{k+1}^{P,\Delta} \subseteq EL_{k+1}^{P,\Sigma}$.

(2) $EL_1^{P,\Sigma} = EL_2^{P,\Theta} = EL_2^{P,\Delta}$.

The following observation is very useful: for all $k \geq 1$ and for all sets A,

(1) $\Sigma_k^P(A) \subseteq \Sigma_k^P(A \oplus \mathrm{SAT}) \subseteq \Sigma_{k+1}^P(A)$,

(2) $\Delta_k^P(A) \subseteq \Delta_k^P(A \oplus \mathrm{SAT}) \subseteq \Delta_{k+1}^P(A)$,

(3) $\Theta_{k+1}^P(A) \subseteq \Theta_{k+1}^P(A \oplus \mathrm{SAT}) \subseteq \Theta_{k+2}^P(A)$.

Thus, if a set A is so powerful that $\Sigma_{k+1}^P(A)$ collapses to $\Sigma_k^P(A)$, then A, by definition, is in the extended low hierarchy. This also holds for Δ-levels and Θ-levels of the polynomial-time hierarchy as well. We express this property in the following proposition.

PROPOSITION 4.3. (1) $\forall k \geq 0, \forall A\ [\Sigma_{k+1}^P(A) \subseteq \Sigma_k^P(A) \Rightarrow A \in EL_{k+1}^{P,\Sigma}]$.

(2) $\forall k \geq 1, \forall A\ [\Delta_{k+1}^P(A) \subseteq \Delta_k^P(A) \Rightarrow A \in EL_{k+1}^{P,\Delta}]$.

(3) $\forall k \geq 1, \forall A\ [\Theta_{k+1}^P(A) \subseteq \Theta_k^P(A) \Rightarrow A \in EL_{k+1}^{P,\Theta}]$.

The proofs of our main theorems, separating the levels of the extended low hierarchy, are motivated by Ko's recent result that, for each $k \geq 1$, there exists an oracle set relative to which the polynomial-time hierarchy has exactly k levels [Ko89]:

$$\forall k \geq 1, \exists A\ [\mathrm{PH}(A) = \Sigma_k^P(A) \supsetneq \Sigma_{k-1}^P(A)].$$

Note that this result strongly suggests that the Σ-levels of the extended low hierarchy are all distinct. Specifically, if $\mathrm{PH}(A) = \Sigma_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT})$, then $A \in EL_{k+1}^{P,\Sigma} - EL_k^{P,\Sigma}$. It is a simple matter to modify Ko's result to show that the Σ-levels of the extended low hierarchy are all distinct. We significantly extend Ko's work by showing that each of the levels of the extended low hierarchy are distinct; that is,

$$\forall k \geq 2, EL_k^{P,\Sigma} \subsetneq EL_{k+1}^{P,\Theta} \subsetneq EL_{k+1}^{P,\Delta} \subsetneq EL_{k+1}^{P,\Sigma}.$$

4.1. Separating $EL_k^{P,\Sigma}$ and $EL_k^{P,\Delta}$. In this section, we will separate $EL_k^{P,\Sigma}$ and $EL_k^{P,\Delta}$ for each $k \geq 2$; that is, for arbitrary $k \geq 2$, we will construct a set A such that $A \in EL_k^{P,\Sigma}$ and $A \notin EL_k^{P,\Delta}$. From Proposition 4.3, we know that if $\Sigma_k^P(A) \subseteq \Sigma_{k-1}^P(A)$, then A is in $EL_k^{P,\Sigma}$. To separate $EL_k^{P,\Sigma}$ and $EL_k^{P,\Delta}$, we need to show that $\Delta_k^P(A) \not\subseteq \Delta_{k-1}^P(A \oplus \mathrm{SAT})$. Since $\Sigma_{k-1}^P(A) \subseteq \Delta_k^P(A)$, we will construct a set A such that $\mathrm{PH}(A)$ collapses to $\Sigma_{k-1}^P(A)$ and $\Sigma_{k-1}^P(A) \not\subseteq \Delta_{k-1}^P(A \oplus \mathrm{SAT})$. As a result, $\Delta_k^P(A) \not\subseteq \Delta_{k-1}^P(A \oplus \mathrm{SAT})$. For the case of $k = 2$, it is known that there exists an oracle A such that $\mathrm{PH}(A) = \mathrm{NP}(A) \neq \mathrm{P}(A)$ [BGS75]. A direct modification yields that $\mathrm{PH}(A) = \mathrm{NP}(A) \not\subseteq \mathrm{P}(A \oplus \mathrm{SAT})$. The case of $k \geq 3$ is handled in the following theorem.

THEOREM 4.4. *For every recursive set B, and for each $k \geq 2$, there exists a recursive set A such that* $\mathrm{PH}(A) = \Sigma_k^P(A) \not\subseteq \Delta_k^P(A \oplus B)$.

Proof. Our proof will again use circuit lower bound techniques. For arbitrary $k \geq 2$, we need to collapse $\mathrm{PH}(A)$ to $\Sigma_k^P(A)$ and at the same time separate $\Sigma_k^P(A)$ and $\Delta_k^P(A \oplus B)$. To collapse PH to $\Sigma_k^P(A)$, we will encode the $\Sigma_{k+1}^P(A)$ complete set $K^{k+1}(A)$ into a set in $\Sigma_k^P(A)$. To separate $\Delta_k^P(A \oplus B)$ and $\Sigma_k^P(A)$, we will use the set L_k^A defined in the previous section:

$$L_k^A = \{x0^{kn} \mid |x| = 2n, (\exists y_1, |y_1| = n)(\forall y_2, |y_2| = n) \cdots (Q_k y_k, |y_k| = n) 0xy_1y_2 \ldots y_k \in A\}.$$

For each $k \geq 1$, define the predicate

$$\tau_k(A; x) \equiv (\exists y_1, |y_1| = n) \cdots (Q_k y_k, |y_k| = n)\ 1xy_1y_2 \ldots y_k \in A,$$

where $|x| = 2n$. Thus, for each x of length $2n$, the value of $\tau_k(A; x)$ only depends on strings in A of length $(k+2)n+1$. Note that $\tau_k(A; x)$ is false if $|x|$ is odd. It is easy to verify that $\tau_k(A; x)$ is a $\Sigma_k^{P,1}$-predicate. Also, it is clear that, for any pair of strings x and y, whether $x \in L_k^A$ and $\tau_k(A; y)$ are true depends on the membership in A of different strings.

The construction of A will make sure that for all strings $x \in \Sigma^*$, $x \in K^{k+1}(A) \Leftrightarrow \tau_k(A; x0^{|x|})$. Thus, $\mathrm{PH}(A) = \Sigma_{k+1}^P(A) = \Sigma_k^P(A)$. We will also construct A so that $L_k^A \notin \Delta_k^P(A \oplus B)$. More specifically, A will be constructed by stages. Let $M_1, M_2, \ldots$ be an effective enumeration of deterministic polynomial time-bounded oracle machines. The setup of $t(n)$ and $D(n)$ is similar to that in the previous section. Let m be a multiple of $k+2$. At stage n of the construction, we will find an assignment of strings to A and $\overline{A}$ so that $0^m \in L_k^A$ if and only if $0^m \notin L(M_n, K^{k-1}(A \oplus B))$. In stage n, we also "$\Sigma_k^P(A)$-encode" into A strings $x \in K^{k+1}(A)$, $t(n-1)+1 \leq (k+2)\cdot|x|+1 \leq t(n)$, such that $x \in K^{k+1}(A) \Leftrightarrow \tau_k(A; x0^{|x|})$. The encoding is divided into two steps: before and after finding the witness 0^m separating $\Sigma_k^P(A)$ and $\Delta_k^P(A \oplus B)$. In the first step, we "$\Sigma_k^P(A)$-encode" into A all the strings $x \in K^{k+1}(A)$, where $t(n-1)+1 \leq (k+2)\cdot|x|+1 < m$. In the second step, we "$\Sigma_k^P(A)$-encode" into A all the strings $x \in K^{k+1}(A)$, where $m \leq (k+2)\cdot|x|+1 \leq t(n)$.

Let C_x be the circuit corresponding to the predicate $\tau_k(A; x0^{|x|})$, and let C_0 be the circuit corresponding to the predicate $0^m \in L_k^A$. Also, by Lemma 3.2, there is a polynomial q and a corresponding $\Delta_k(q(m))$-circuit C_n such that $C_n \lceil \rho_{A\oplus B} = 1$ if and only if $0^m \in L(M_n, K^{k-1}(A \oplus B))$. We let $t(n) = q(m)$. Note that C_n can be simplified to another $\Delta_k(q(m))$-circuit C_n' by the following replacements:

(1) all the variables v_z in the leaves of C_n having the form $z = 1z'$ are replaced by 1 if $z' \in B$ and by 0 if $z' \notin B$, and

(2) all the variables v_z of the form $z = 0z'$ are replaced by $v_{z'}$.

Thus, for any set A, and a fixed set B, $C_n \lceil_{\rho_{A\oplus B}} = C_n' \lceil_{\rho_A}$ and $C_n' \lceil_{\rho_A} = 1$ if and only if $0^m \in L(M_n, K^{k-1}(A \oplus B))$.

The requirement for stage n can be described as

$$\begin{aligned} R_n : (\exists B_0, B_1 \subseteq D(n))[&B_0 \cap B_1 = \emptyset,\ C_n' \lceil_{\rho_{B_1, B_0}} \neq *, \text{ and for all } x, \\ &t(n-1) < (k+2)|x|+1 < m,\ C_x \lceil_{\rho_{B_1, B_0}} = 1 \Leftrightarrow x \in K^{k+1}(A(n-1) \cup B_1), \\ &\text{and } C_0 \lceil_{\rho_{B_1, B_0}} = C_x \lceil_{\rho_{B_1, B_0}} = *, \text{ for all } x, m \leq (k+2)|x|+1 \leq t(n)], \end{aligned}$$

where ρ_{B_1, B_0} is the restriction that v_z is 1 if $z \in B_1$ and v_z is 0 if $z \in B_0$. Construction of A at stage n is done by the following steps.

Step 1. For all the strings x, $t(n-1) < (k+2)|x|+1 < m$, assign strings to $A(n)$ and $\overline{A(n)}$ such that $\tau_k(A; x0^{|x|})$ is true if and only if $x \in K^{k+1}(A)$.

Step 2. Replace all the variables in C_n' that are in $A(n)$ by 1 and replace those in $\overline{A(n)}$ by 0. The resulting circuit, let's still call it C_n', remains a $\Delta_k(q(m))$-circuit.

Step 3. Find a pair of finite sets B_1 and B_0 that satisfy the requirement R_n. Assign variables in B_1 to $A(n)$ and assign variables in B_0 to $\overline{A(n)}$.

Step 4. For all the strings x, $m \leq (k+2)|x|+1 \leq t(n)$, assign remaining free strings to $A(n)$ and $\overline{A(n)}$ such that $\tau_k(A; x0^{|x|})$ is true iff $x \in K^{k+1}(A)$. If there are still remaining free strings of length between $t(n-1)+1$ and $t(n)$, assign them to $\overline{A(n)}$. Go to the next stage.

The key step is Step 3. The following lemma guarantees that the requirement R_n can be satisfied at Step 3.

LEMMA 4.5. *For all $k \geq 2$, let $\{C_i\}_{i=1}^t$ be t circuits, each computing a function f_k^v, with pairwise disjoint variables. Let C be a $\Delta_k(r)$-circuit. If $t \leq 2^{\delta v^{1/6}}$ and $r \leq \delta v^{1/5}$, with*

$\delta = 1/48$, *then for sufficiently large* v, *there exists a restriction* ρ *such that* $C\lceil_\rho \neq *$ *and* $C_i\lceil_\rho = *$ *for all* $i = 1, \ldots, t$.

Proof. The proof is by induction on k. For the case of $k = 2$, the proof is similar to the proof of Theorem 3.3. Recall that in the proof of Theorem 3.3, we found a restriction ρ such that $C\lceil_\rho \neq *$ and $C_2^v\lceil_\rho = *$, where C is an $\Delta_2(r)$-circuit with $r < \delta v^{1/5}$ and C_2^v computes an f_2^v function. (See (#) in the proof of Theorem 3.3.) The number of strings that we added to the oracle set was at most $r^2 \leq (\delta v^{1/5})^2 < \sqrt{v}$. Here, every C_i, $1 \leq i \leq t$, is an OR of v AND gates, each of fanin $\sqrt{v}$. Therefore, the same restriction ρ satisfies that $C_i\lceil_\rho = *$, for all $i, 1 \leq i \leq t$.

For the induction step, consider any $k > 2$. As in the proof of Theorem 3.3, proceeding by contradiction, we need to verify that (1) with a high probability, $C\lceil_{\rho g(\rho)}$ is equivalent to a $\Delta_{k-1}(r)$-circuit, and (2) with a high probability, $C_i\lceil_{\rho g(\rho)}$ contains a subcircuit computing the function f_{k-1}^v for all $i = 1, \ldots, t$. Part (1) is identical to that in the proof of Theorem 3.3. Part (2) follows from Lemma 2.10. □

It is easy to see that C_0 contains a $C_k^{2^{m/(k+2)}}$-subcircuit computing an $f_k^{2^{m/(k+2)}}$ function. Also, for all x, $m \leq (k+2)|x| + 1 \leq t(n)$, C_x contains a subcircuit computing $f_k^{2^{m/(k+2)}}$. There are at most $2^{q(m)}$ many such C_x. To satisfy requirement R_n, we need to choose an integer m so large that $q(m) \leq (1/48)2^{m/6(k+2)}$. Thus, there exists an oracle set A such that $\Sigma_{k+1}^P(A) = \Sigma_k^P(A)$ and $\Sigma_k^P(A) \not\subseteq \Delta_k^P(A \oplus B)$, for each $k \geq 2$. This completes the proof of Theorem 4.4.

COROLLARY 4.6. *For each* $k \geq 2$, $EL_k^{P,\Delta} \subsetneq EL_k^{P,\Sigma}$.

Proof. As a point of interest, recall that $EL_2^{P,\Delta} = EL_1^{P,\Sigma}$ by Proposition 4.2. For $k = 2$, a direct modification of Baker, Gill, and Solovay's proof [BGS75] yields the existence of an oracle A such that PH(A) = NP(A) $\neq$ P($A \oplus$ SAT). For $k > 2$, just let B be SAT in Theorem 4.4. □

COROLLARY 4.7. *For each* $k \geq 1$, *there exists an oracle set A such that* $\Delta_k^P(A) \subsetneq \Sigma_k^P(A) =$ PH(A) = PSPACE(A).

Proof. Simply replace the complete set $K^{k+1}(A)$ by a complete set for PSPACE(A), and let $B = \emptyset$ in the proof of Theorem 4.4. □

Ko also constructed an oracle set relative to which the polynomial-time hierarchy has a finite number of levels and is properly contained in PSPACE [Ko89]. By combining his proof techniques with those in Theorem 4.4, we have the following corollary:

COROLLARY 4.8. *For each* $k \geq 1$, *there exists an oralce set A such that* $\Delta_k^P(A) \subsetneq \Sigma_k^P(A) =$ PH(A) $\subsetneq$ PSPACE(A).

4.2. Separating $EL_k^{P,\Delta}$ and $EL_k^{P,\Theta}$. In this section, we will separate $EL_k^{P,\Delta}$ and $EL_k^{P,\Theta}$ for each $k \geq 3$. The setup is similar to that in §4.1 for arbitrary $k \geq 2$, we will construct a set A such that PH(A) = $\Delta_k^P(A) \not\subseteq \Theta_k^P(A \oplus \text{SAT})$. As a result, $A \in EL_{k+1}^{P,\Delta}$ and $A \notin EL_{k+1}^{P,\Theta}$.

THEOREM 4.9. *For every recursive set B, and for each* $k \geq 2$, *there exists an oracle set A such that* PH(A) = $\Delta_k^P(A) \not\subseteq \Theta_k^P(A \oplus B)$.

Proof. To collapse PH to $\Delta_k^P(A)$, we will encode the $\Sigma_k^P(A)$ complete set $K^k(A)$ into a set in $\Delta_k^P(A)$. To separate $\Delta_k^P(A)$ and $\Theta_k^P(A \oplus B)$, we will use the set $L_{odd,k}^A \in \Delta_k^P(A)$ defined in the previous section:

$$L_{\text{odd},k}^A = \{x0^{kn} \mid |x| = n, \text{ and } \max\{y \mid |y| = |x|, xy0^{(k-1)n} \in L_{k-1}^A\} \text{ has odd parity}\}.$$

Now define the set

$$\hat{L}_{\text{odd},k}^A = \{x \mid \max\{y \mid |y| = |x| \text{ and } \tau_{k-1}(A; xy) \text{ is true }\} \text{ has odd parity}\},$$

where τ_{k-1} is the predicate from §4.1. Notice that for each x of length n, whether $x \in \hat{L}_{\text{odd},k}^A$ only depends on membership of strings in A of length $(k+1)n + 1$.

It is easy to verify that $\hat{L}^A_{\mathrm{odd},k}$ is in $\Delta^P_k(A)$: just use binary search querying a set in $\Sigma^P_{k-1}(A)$. Also, it is clear that, for any pair of strings x and y, whether $x \in L^A_{\mathrm{odd},k}$ and $y \in \hat{L}^A_{\mathrm{odd},k}$ are true depends on the membership of different strings in A.

The rest of the proof is very similar to that in §4.1. A is constructed by stages. The setup of $m, t(n)$, and $D(n)$ is similar to that in §3.2. At stage n of the construction, we will find an assignment of strings to A and $\overline{A}$ so that $0^m \in L^A_{\mathrm{odd},k}$ if and only if $0^m \notin L(M_n, K^{k-1}(A \oplus B))$, where M_n is the nth machine in an enumeration of $\Theta^P_k(A \oplus B)$. In stage n, we "$\Delta^P_k(A)$-encode" into A any strings $x \in K^k(A)$, $t(n-1)+1 \leq (k+1)\cdot|x|+1 \leq t(n)$, such that $x \in K^k(A) \Leftrightarrow x \in \hat{L}^A_{\mathrm{odd},k}$.

Again, let C_x be the circuit corresponding to the predicate $x \in \hat{L}^A_{\mathrm{odd},k}$, and let C_0 be the circuit corresponding to the predicate $0^m \in L^A_{\mathrm{odd},k}$. Also, by Lemma 3.6, there is a polynomial q and a corresponding $\Theta_k(q(m))$-circuit C_n such that $C_n\lceil_{\rho_{A\oplus B}}= 1$ if and only if $0^m \in L(M_n, K^{k-1}(A \oplus B))$. Let $t(n) = q(m)$. Simiar to §4.1, C_n can be simplified to a $\Theta_k(q(m))$-circuit C'_n such that $C_n\lceil_{\rho_{A\oplus B}}= C'_n\lceil_{\rho_A}$ for arbitrary set A and a fixed set B. The requirement of stage n can be described as

$$\begin{aligned}R_n : (\exists B_0, B_1 \subseteq D(n))[&B_0 \cap B_1 = \emptyset, C'_n\lceil_{\rho_{B_1,B_0}} \neq *, \text{ and for all } x,\\ &t(n-1) < (k+1)|x|+1 < m, C_x\lceil_{\rho_{B_1,B_0}} = 1 \Leftrightarrow x \in K^k(A(n-1) \cup B_1),\\ &\text{and } C_0\lceil_{\rho_{B_1,B_0}} = C_x\lceil_{\rho_{B_1,B_0}} = *, \text{ for all } x, m \leq (k+1)|x|+1 \leq t(n)],\end{aligned}$$

where ρ_{B_1,B_0} is the restriction that v_z is 1 if $z \in B_1$ and v_z is 0 if $z \in B_0$. Steps in construction of A at stage n are essentially the same as that in §4.1. The following lemma ensures that the requirement R_n can be satisfied.

LEMMA 4.10. *For all $k \geq 2$, let $\{C_i\}^t_{i=1}$ be t circuits, each computing an h^v_k function, with pairwise disjoint variables. Let C be a $\Theta_k(r)$-circuit. If $t \leq 2^{\delta v^{1/6}}$ and $r \leq \delta v^{1/5}$, with $\delta = 1/24$, then for sufficiently large n, there exists a restriction ρ such that $C\lceil_\rho \neq *$ and $C_i\lceil_\rho = *$ for all $i = 1, \ldots, t$.*

Proof. Again, the proof is by induction on k. The base case of $k = 2$ is proved similarly to the proof of Theorem 3.7. Recall that in **Process FF**, we flip-flopped the output of an H^v_k circuit computing an h^v_k function by adding to the oracle set the variables in the leftmost undecided OR gate of H^v_k. We then find a restriction ρ such that $C\lceil_\rho \neq *$ and $H^v_2\lceil_\rho = *$ (see (∗) in the proof of Theorem 3.7). Here we have t many H^v_k circuits. We can easily modify **Process FF** such that at each step of flip-flop we add to the oracle set the variables of the leftmost undecided OR gate of C_i, for all $1 \leq i \leq t$. It is not difficult to see that, by a similar argument, we can find a restriction ρ such that $C\lceil_\rho \neq *$ and $C_i\lceil_\rho = *$ for all $1 \leq i \leq t$.

For the induction step, consider any $k > 2$. As in the proof of Theorem 3.7, proceeding by contradiction, we need to verify that (1) with a high probability, $C\lceil_{\rho g(\rho)}$ is equivalent to a $\Theta_{k-1}(r)$-circuit, and that (2) with a high probability, $C_i\lceil_{\rho g(\rho)}$ contains a subcircuit computing the function h^v_{k-1} for all $i = 1, \ldots, t$. Part (1) is identical to that in the proof of Theorem 3.7 and part (2) is proved by Lemma 2.10. □

Note that C_0 contains an $H^{2^{m/(k+1)}}_k$- subcircuit computing a function $h^{2^{m/(k+1)}}_k$. Also, for all $x, m \leq (k+1)|x|+1 \leq t(n)$, C_x contains a subcircuit computing $h^{2^{m/(k+1)}}_k$. There are at most $2^{q(m)}$ many such C_x. To satisfy requirement R_n, we need to choose an integer m so large that $q(m) \leq (1/24)2^{m/6(k+1)}$. Thus, there exists an oracle set A such that $\Sigma^P_k(A) = \Delta^P_k(A)$ and $\Delta^P_k(A) \not\subseteq \Theta^P_k(A \oplus B)$, for each $k \geq 2$. This completes the proof of Theorem 4.9.

COROLLARY 4.11. *For each $k \geq 3$, $EL^{P,\Theta}_k \subsetneq EL^{P,\Delta}_k$.*

Proof. Simply replace B by SAT in the proof of Theorem 4.9. □

COROLLARY 4.12. *For each $k \geq 2$, there exists an oracle set A such that $\Theta^P_k(A) \subsetneq \Delta^P_k(A) =$* PH$(A) =$ PSPACE(A).

Proof. Simply replace $K^k(A)$ by a complete set for PSPACE(A) and replace B by the empty set in the proof of Theorem 4.9. □

COROLLARY 4.13. *For each* $k \geq 2$, *there exists an oracle set A such that* $\Theta_k^P(A) \subsetneq \Delta_k^P(A) = \mathrm{PH}(A) \subsetneq \mathrm{PSPACE}(A)$.

4.3. Separating $EL_k^{P,\Theta}$ and $EL_{k-1}^{P,\Sigma}$. In this section, we will find a recursive set A that is in $EL_k^{P,\Theta}$ but not in $EL_{k-1}^{P,\Sigma}$ for each $k \geq 3$. The setup is similar to that in §§4.1 and 4.2: for each $k \geq 2$, we construct a set A such that $\mathrm{PH}(A) = \Theta_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus \mathrm{SAT})$. Thus, A is in $EL_{k+1}^{P,\Theta}$ and not in $EL_k^{P,\Sigma}$. We first prove the following theorem.

THEOREM 4.14. *For every recursive set B, for each* $k \geq 2$, *there exists a recursive set A such that* $\mathrm{PH}(A) = \Theta_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus B)$.

Proof. Recall that $L_{\mathrm{xor},k}^A = \{x0^{kn} \mid |x| = n$, and exactly one of $0^n x 0^{(k-1)n}$ or $1^n x 0^{(k-1)n}$ is in $L_{k-1}^A\}$. Define the following language:

$$\hat{L}_{\mathrm{xor},k}^A = \{x \mid \text{ exactly one of } \tau_{k-1}(A; 0^{|x|}x) \text{ or } \tau_{k-1}(A; 1^{|x|}x) \text{ is true } \},$$

where τ_k is defined in the previous section. It is easy to see that both $L_{\mathrm{xor},k}^A$ and $\hat{L}_{\mathrm{xor},k}^A$ are in $\Theta_k^P(A)$. A will be constructed so that $L_{\mathrm{xor},k}^A \notin \Sigma_{k-1}^P(A \oplus B)$ and so that for all x, $x \in K^k(A) \Leftrightarrow x \in \hat{L}_{\mathrm{xor},k}^A$. It will follow that $\mathrm{PH}(A) = \Theta_k^P(A)$ and $\Theta_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus B)$.

The setup of the construction of A, as well as m, $t(n)$, and $D(n)$ are the same as in §§4.1 and 4.2. At stage n of the construction, we will ensure that for all x, $t(n-1) < (k+1)|x|+1 \leq t(n)$, $x \in K^k(A) \Leftrightarrow x \in \hat{L}_{\mathrm{xor},k}^A$. Let C_0 be the circuit corresponding to the predicate $0^m \in L_{\mathrm{xor},k}^A$ and for all x, $t(n-1) < (k+1)|x|+1 \leq t(n)$, let C_x represent the circuit corresponding to the predicate $x \in \hat{L}_{\mathrm{xor},k}^A$. Let $\sigma_1, \sigma_2, \ldots$ be an enumeration of $\Sigma_{k-1}^{P,1}$-predicates. By Lemma 2.3, there exist a polynomial q and a $\Sigma_{k-1}(q(m))$-circuit C_n corresponding to the nth predicate σ_n. We let $t(n) = q(m)$. Using the same replacement technique as in the §4.1, C_n can be simplified to a Σ_{k-1}-circuit C_n' such that $C_n \lceil_{\rho_{A\oplus B}} = C_n' \lceil_{\rho_A}$ for arbitrary set A and a fixed set B. The requirement R_n of stage n of the construction is

$$\begin{aligned} R_n : (\exists B_0, B_1 \subseteq D(n))[&B_0 \cap B_1 = \emptyset, C_n' \lceil_{\rho_{B_1,B_0}} \neq *, \text{for all } x, \\ &t(n-1) < (k+1)|x| + 1 < m, C_x \lceil_{\rho_{B_1,B_0}} = 1 \Leftrightarrow x \in K^k(A(n-1) \cup B_0), \\ &\text{and } C_0 \lceil_{\rho_{B_1,B_0}} = C_x \lceil_{\rho_{B_1,B_0}} = *, \text{ for all } x, m \leq (k+1)|x| + 1 \leq t(n)], \end{aligned}$$

where ρ_{B_1,B_0} is the restriction that v_z is 1 if $z \in B_1$ and v_z is 0 if $z \in B_0$. The steps in the construction of A at stage n are essentially the same as that in §4.1. We need the following lemma to ensure that R_n will can be satisfied at stage n.

LEMMA 4.15. *For all* $k \geq 2$, *let* $\{C_i\}_{i=1}^t$ *be t circuits, each computing an* l_k^v *function, with pairwise disjoint variables. Let C be a* $\Sigma_{k-1}(r)$*-circuit. If* $t \leq 2^{\delta v^{1/6}}$ *and* $r \leq \delta v^{1/3}$, *with* $\delta = 1/12$, *then for sufficiently large n, there exists a restriction* ρ *such that* $C\lceil_\rho \neq *$ *and* $C_i \lceil_\rho = *$ *for all* $i = 1, \ldots, t$.

Proof. The proof is by induction on k. To prove the base case of $k = 2$, let us consider circuits C and C_i for all $i = 1, \ldots, t$. C is an OR of AND's with bottom fanin $\leq r$. C_i is an XOR of two subcircuits, each computing an f_1^v function. Note that all the leaves of all C_i's are unique positive variables. Let v_i be the leftmost variable in C_i, $1 \leq i \leq t$, and let $V = \{v_i \mid 1 \leq i \leq t\}$.

Let F denote the variables that are assigned 1, and let $\overline{F}$ denote the variables that are assigned 0. Initially, both F and $\overline{F}$ are empty. We will first present the algorithm for constructing F and $\overline{F}$ and then show that the restriction $\rho_{F,\overline{F}}$ is the desired restriction. Recall that $\rho_\emptyset$ is the restriction that assigns 0 to all variables.

```
Process F:
        $F = \overline{F} = \emptyset$.
        if $C\lceil_{\rho_{\emptyset}} = 1$ then
                Choose one AND gate of $C$ with all negative variables; Assign
                all the variables to $\overline{F}$
        else
                if there is an $S \subseteq V$ such that $C\lceil_{\rho_S} = 1$ then
                        Select such an $S$;
                        Choose one AND gate $D$ of $C$ such that $D\lceil_{\rho_S} = 1$;
                        Assign all negative variables in $D$ to $\overline{F}$ and assign all positive
                        variables in $D$ to $F$
                else
                        $F = \emptyset, \overline{F} = \Sigma^* - V$.
                end(* if *)
        end(* if *)
```

We now argue the correctness of **Process F**. Consider the first case when $F = \emptyset$ and $C\lceil_{\rho_{\emptyset}} = 1$. Since C is a circuit of an OR of AND gates, there must exist an AND gate D in C such that D contains only negative variables. Put all the variables in D into $\overline{F}$ to preserve the the output of C. We have $C\lceil_{\rho_{F,\overline{F}}} = 1$. Note that the number of variables in D is $\leq r \leq \delta v^{1/3} < \sqrt{v}$, thus $C_i\lceil_{\rho_{F,\overline{F}}} = *$, for all $i = 1, \ldots, t$. In this case, $\rho_{F,\overline{F}}$ is the desired restriction.

On the other hand, if $C\lceil_{\rho_{\emptyset}} = 0$, then we choose some j many different v_i's and put these variables into S. Suppose, for all the different choices of S, $C\lceil_{\rho_S}$ remains 0. Then we know that for all 2^t possible S, $C\lceil_{\rho_S} = 0$, and, for each C_i, $C_i\lceil_{\rho_S} = 1$ if and only if $v_i \in S$. This implies that we can arbitrarily force any combination of C_i's to output 1 or 0, by choice of S, without changing the output of C. Thus, $C\lceil_{\rho_{\emptyset,\Sigma^*-V}} = 0$ and $C_i\lceil_{\rho_{\emptyset,\Sigma^*-V}} = *$, for all $1 \leq i \leq t$. Let $F = \emptyset$ and $\overline{F} = \Sigma^* - V$ and $\rho_{F,\overline{F}}$ is the desired restriction.

The last case is that there is an S such that $C\lceil_{\rho_S} = 1$. In this case, fix an AND gate D of C such that $D\lceil_{\rho_S} = 1$. We reserve the output of C by assigning the negative variables in D to $\overline{F}$ and the positive variables in D to F. Note that each positive variable in D is in S since D is an AND gate and $D\lceil_{\rho_S} = 1$. Also important is that for any restriction ρ_S, there is only one positive variable in C_i that is assigned 1 by ρ_S. The number of variables in $\overline{F}$ is bounded by $r \leq \delta v^{1/3} < \sqrt{v}$. Thus, $C\lceil_{\rho_{F,\overline{F}}} = 1$ and $C_i\lceil_{\rho_{F,\overline{F}}} = *$ for all $1 \leq i \leq t$. In summary, there is a pair of finite sets F and $\overline{F}$ such that $F \cap \overline{F} = \emptyset$, $C\lceil_{\rho_{F,\overline{F}}} \neq *$, and $C_i\lceil_{\rho_{F,\overline{F}}} = *$ for all i, $1 \leq i \leq t$.

Finally, the induction step is proved by Lemma 2.7 and Lemma 2.10. □

Note that C_0 contains a subcircuit computing an $l_k^{2^{m/(k+1)}}$ function. Also, for all x, $m \leq (k+1)|x| + 1 \leq t(n)$, C_x contains a subcircuit computing an $l_k^{2^{m/(k+1)}}$ function. To satisfy requirement R_n, we only need to choose an integer m so large that $t(n) \leq (1/12)2^{m/6(k+1)}$. We then conclude that there exists an oracle set A such that $\Sigma_k^P(A) = \Theta_k^P(A)$ and $\Theta_k^P(A) \not\subseteq \Sigma_{k-1}^P(A \oplus B)$, for each $k \geq 2$. This completes the proof of Theorem 4.14.

COROLLARY 4.16. *For each* $k \geq 3$, $EL_{k-1}^{P,\Sigma} \subsetneq EL_k^{P,\Theta}$.

Proof. Simply replace B by SAT in the proof of Theorem 4.14. □

COROLLARY 4.17. *For each* $k \geq 2$, *there exists an oracle set* A *such that* $\Sigma_{k-1}^P(A) \subsetneq \Theta_k^P(A) = \mathrm{PH}(A) = \mathrm{PSPACE}(A)$.

Proof. Simply replace $K^k(A)$ by a complete set for PSPACE(A) and replace B by the empty set in the proof of Theorem 4.14. □

COROLLARY 4.18. *For each* $k \geq 2$, *there exists an oracle set* A *such that* $\Sigma_{k-1}^P(A) \subsetneq \Theta_k^P(A) = \mathrm{PH}(A) \subsetneq \mathrm{PSPACE}(A)$.

COMPLEXITY OF NETWORK RELIABILITY AND OPTIMAL RESOURCE PLACEMENT PROBLEMS*

DONALD B. JOHNSON† AND LARRY RAAB‡

Abstract. A fundamental problem of distributed system design in an existing network where components can fail is finding an optimal location at which to place a resource. This paper proves exactly how hard this placement problem is under the measure of data availability. Specifically, it shows that the optimal placement problem for availability is #*P*-complete, a measure of intractability at least as severe as *NP*-completeness. To obtain these results, the environment in which a distributed system operates is modelled by a *probabilistic graph*, which is a set of fully reliable vertices representing sites and a set of edges representing communication links, each operational with a rational probability. Finding the optimal placement in a probabilistic graph is proved to be #*P*-complete by giving a sequence of Turing reductions from #Satisfiability. This result is generalized to networks in which each site and each link has an independent, rational operational probability and to networks in which all the sites or all the links have fixed, uniform operational probabilities. Given the anticipated computational difficulty of finding an exact solution, the requirements for effective, practical approximation methods are discussed.

Key words. #*P* complexity class, resource placement, database, simulation, networks, reliability graph

AMS subject classifications. 68Q25, 68P15, 68M15

1. Introduction.

Determining the optimal placement of a resource, be it a file, database, or data object, is one of the most well-studied problems in computer science. Research into the "file assignment problem," or FAP as it is now known, [3], [8], dates back to Chu in 1969 [4] and even earlier when viewed as the single commodity warehouse problem (see, for example, [19]).

Our interest in this placement problem is motivated by our work with database replica control protocols [15], [17], [16]. These protocols attempt to increase the accessibility of a data object by replicating that object throughout the network. Our work has shown that, given the database consistency constraints, there is a nontrivial bound on the benefits of replication over an optimally located nonreplicated data object [17]. Thus, it is natural to attempt a complexity characterization, which we present in this paper.

The most general form of the optimal placement problem is as follows: given a set of sites, communication links, rational reliability probabilities on both the sites and links, and a distribution of access requests, find the *optimal* site. A site x is **optimal** if and only if placing the resource at site x maximizes *availability*. **Availability** is defined as the probability that an access request, when submitted according to an access request distribution, arrives at a site that can communicate with site x. A rational reliability ρ for a site (and similarly for a link) is the steady-state probability that the site is operational. Therefore, $\rho = \frac{\text{MTTF}}{\text{MTTF+MTTR}}$, where MTTF is the mean time to failure for a site and MTTR is the mean time to recovery for a site.

Thus, the optimal location at which to place the sole copy of a resource in a distributed environment is a function of the network topology, the site and link reliabilities, and the access request distribution. We show that since the underlying graph reliability problems are #*P*-complete, so also is this **optimal placement** problem. #*P*-complete implies, among other things, that an efficient (polynomial) solution to this problem can be found only if $P = NP$ [22]. In this paper we prove that the simplified problem, where the sites are infallible, links operate with probability ρ, and the access request distribution is uniform, is #*P*-complete.

*Received by the editors May 26, 1992; accepted for publication (in revised form) November 30, 1992.

We call this the **simplified model** and call the graph representing such a network a **probability graph**. Using the simple technique of restriction [10], this result generalizes to include networks in which each site and each link has an independent, rational operational probability, to networks with fixed, uniform site reliabilities, and to arbitrary access request distributions.

We begin by listing each of the problems that we use to prove our #*P*-completeness result. Each of these problems is an interesting probability graph problem in its own right. In §4, we prove that each of these problems are #*P*-complete. We also generalize the main complexity result to include classes of networks with nonuniform link reliabilities and networks with uniform, fixed site reliabilities. This latter class includes such networks as radio broadcast networks [1] and single-bus networks like Ethernet. Having proven this problem computationally difficult, we have little hope of finding an efficient, exact solution. Therefore, we conclude with a discussion of practical methods for approximating the optimal copy placement.

2. Related work.

As mentioned above, determining the optimal placement is one of the most well-studied problems in computer science. Our work differs from all others of which we are aware in that we wish to optimize the availability measure, the probability that an access request arrives at a site that can contact the resource. In addition, we show that this problem is $\#P$-complete, not NP-complete as is frequently shown for other location problems, and is, therefore, at least as "hard" as NP-complete problems and may well be "harder" [10].

In [7], Dowdy and Foster present a survey of research dealing with FAP, including a description of fourteen models and a list of twenty-one others. More recent models with approximate solutions are discussed in [11]. Although the models vary considerably, they all attempt to minimize some cost measure (such as storage or communication cost) or maximize throughput. Although some of these models include an availability constraint, they neither maximize availability nor define it as we have here.

Related work also appears in the context of network reliability computations. In 1965 Kiryukhin investigated the optimal placement of a given number of communication links relative to the availability measure. Having simplified the problem by considering only paths of length less than three, Kiryukhin presented a nonlinear programming solution. See [9] and [25] for more detailed discussions.

Rosenthal provides the first NP-hardness result for these network reliability problems [20]. His proof reduces the Steiner Tree problem to the computation of the probability that a specified subset of a graph is connected. NP-hardness has also been shown for determining whether two sites are connected [24] and whether all sites are connected [13], [18]. A survey of these results and related approximation algorithms can be found in [5].

3. Problem definitions.

In this section, we define each of a sequence of combinatorial problems that we use to prove that finding the optimal location of a single copy is #*P*-complete. In [23] Valiant defined the class of problems called #*P* and showed #SAT to be #*P*-complete using a modification of Cook's construction for SAT [6]. In [24] Valiant showed that CONNECTEDNESS is also #*P*-complete. The other three problems are shown to be #*P*-complete with respect to Turing reductions in §4. In Table 1 we define the terms and notation we use.

We maximize availability by maximizing $\mathcal{E}\,[v]$, the expected size of the group containing a site v. $\mathcal{E}\,[v]/n$ is the availability achieved on a network with n sites and a single copy located at site v, since, in this simplified model, access requests are submitted uniformly at random, and only requests submitted to sites within the group containing v will be granted. Therefore, site v is an **optimal location** if and only if $\mathcal{E}\,[v] \geq \mathcal{E}\,[u]$ for all sites u.

In the problems that follow, we use the phrase "the expected group size of vertex v," meaning the expected number of sites in the group containing v. Also, if more than one vertex

TABLE 1

Notation and Terminology

- $G = (V, E)$ is a graph of vertices V and undirected edges E. G represents a network with sites V and bidirectional communication links E.
- n and m denote $|V|$ and $|E|$, respectively, when $G = (V, E)$ is clear from the context.
- $\rho = p/q$ is the rational link reliability, where $0 \le \rho \le 1$ and $\gcd(p, q) = 1$.
- A **group** is a maximal set of connected vertices. Groups comprising a probability graph change over time due to component failures and recoveries.
- $\mathcal{E}_G[v]$ is the expected size of the group (i.e., number of vertices in the group) containing vertex v in probability graph G. We will simply say $\mathcal{E}[v]$ when G is clear from the context.
- $\mathcal{P}r(S)$ is the probability that the logical statement S is true.
- $\mathcal{P}r(S|T)$ is the conditional probability that the logical statement S is true given that the logical statement T is true.
- $\overline{S}$ is the negation of the logical statement S; therefore, $\mathcal{P}r(\overline{S}) = 1 - \mathcal{P}r(S)$.
- $c(u, w)$ is the logic statement "vertices u and w are connected." The probability graph containing u and w will be clear from context.

has maximal expected group size, OPTLOC may return any one of these vertices.

1. **#SAT** (#SAT)
   INSTANCE: A logical formula F in n variables.
   QUESTION: How may different truth assignments that satisfy F are there to the n variables?
2. **CONNECTEDNESS** (CON)
   INSTANCE: A probability graph $G = (V, E)$ and vertices $v_1, v_2 \in V$.
   QUESTION: What is the probability that vertices v_1 and v_2 are connected?
3. **EXPECTED SIZE** (EXPSZ)
   INSTANCE: A probability graph $G = (V, E)$ and vertex $v \in V$.
   QUESTION: What is the expected group size of vertex v?
4. **BOUNDED EXPECTED SIZE** (BEXPSZ)
   INSTANCE: A probability graph $G = (V, E)$, vertex $v \in V$, and a rational number B.
   QUESTION: Has v expected group size greater than or equal to B?
5. **OPTIMAL LOCATION** (OPTLOC)
   INSTANCE: A probability graph $G = (V, E)$.
   QUESTION: Which $v \in V$ has the largest expected group size?

4. Reductions. In this section, we either prove or cite proofs for each of the problems defined in the previous section. The first two problems are covered elsewhere and citations are given. The remaining three problems are shown to be *#P*-complete. We include a subsection with two related lemmas that are used in §4.3. Again, see Table 1 for an explanation of the terms and notation.

4.1. Preliminary reductions.

THEOREM 4.1. #SAT *is #P-complete.*

Proof. In [6] Cook proved that SAT is *NP*-complete. Valiant modified Cook's proof to show that #SAT is *#P*-complete [23]. □

THEOREM 4.2. CON *is #P-complete.*

Proof. A reduction from #SAT to CON is given by Valiant in [24]. □

THEOREM 4.3. EXPSZ *is #P-complete.*

Proof. Let $G = (V, E)$ be a probability graph. Then it is not difficult to show that the expected size of the group containing $v \in V$, $\mathcal{E}[v]$, is equal to $\sum_{w \in V} \mathcal{P}r\big(c(v, w)\big)$. Thus

EXPSZ is in $\#P$ since we can solve EXPSZ with $|V|$ queries to an CON oracle, and CON is in $\#P$.

We show that EXPSZ is $\#P$-hard using a Turing reduction from EXPSZ to CON. We solve CON by calculating the expected group size of a vertex in each of two networks.

Let $G = (V, E)$ and $u, v \in V$ be an instance of CON.

Let $G' = (V', E')$, where $V' = V \cup \{u'\}$ and $V' = V \cup \{(u, u')\}$, where u' is a new vertex not in V. Then

$$\begin{aligned}\mathcal{E}_{G'}[v] &= \sum_{w\in V'} \mathcal{P}r\big(c(v,w)\big)\\ &= \mathcal{P}r\big(c(v,u')\big) + \sum_{w\in V} \mathcal{P}r\big(c(v,w)\big)\\ &= \rho\, \mathcal{P}r\big(c(v,u)\big) + \sum_{w\in V} \mathcal{P}r\big(c(v,w)\big)\\ &= \rho\, \mathcal{P}r\big(c(v,u)\big) + \mathcal{E}_G[v].\end{aligned}$$

Therefore, $\mathcal{P}r\big(c(v,u)\big) = \frac{1}{\rho}\Big(\mathcal{E}_{G'}[v] - \mathcal{E}_G[v]\Big)$, and calculating $\mathcal{E}_G[v]$ must be $\#P$-complete since calculating $\mathcal{P}r\big(c(v,u)\big)$ is $\#P$-complete. □

THEOREM 4.4. BEXPSZ *is #P-complete.*

Proof. Clearly BEXPSZ is in $\#P$ since we can solve BEXPSZ with one query to an EXPSZ oracle, and EXPSZ is in $\#P$.

We show that BEXPSZ is $\#P$-hard using a Turing reduction from EXPSZ to BEXPSZ.

Let $G = (V, E)$ and vertex $v \in V$ be an instance of the EXPSZ problem, that is, we wish to determine C, the expected size of the group containing vertex v. Let $n = |V|$ and $m = |E|$. Then there are 2^m possible graph states, and the probability of any one state with k operational links, $0 \leq k \leq m$, is $\rho^k(1-\rho)^{m-k}$. Therefore, C, $1 \leq C \leq n$, is a multiple of $1/q^m$ and is one of nq^m possible values. (Recall from Table 1 that q is an integer equal to $p \cdot \rho$.) Suppose, then, that we have an oracle that can solve BEXPSZ. Then we can use a binary search procedure to query this oracle until we find the exact value of C. This can be done in $a \leq \lceil \log(nq^m) \rceil$ queries. Since $m \leq n(n-1)/2$, $a \leq \lceil \log(nq^{n(n-1)/2}) \rceil = O(n^2)$.

Since EXPSZ is $\#P$-complete, and since we can solve EXPSZ with a polynomial number of queries to a BEXPSZ oracle, it must be that BEXPSZ is $\#P$-hard. □

4.2. Related lemmas. We simplify the task of proving that OPTLOC is $\#P$-complete by establishing two lemmas. The first lemma states that the expected group size of vertex v in graph G, $\mathcal{E}_G[v]$, is at least as large as the expected group size of any other vertex u, $\mathcal{E}_G[u]$, times the probability the v and u are connected.

LEMMA 4.5. *Let $G = (V, E)$ be a probability graph and $u, v \in V$. Then $\mathcal{E}_G[v] \geq \mathcal{P}r\,(c(v,u))\ \mathcal{E}_G[u]$.*

Proof.

$$\begin{aligned}\mathcal{E}_G[v] &= \textstyle\sum_{w\in V} \mathcal{P}r(c(v,w))\\ &\geq \textstyle\sum_{w\in V} \mathcal{P}r(c(v,u) \text{ and } c(u,w))\\ &= \mathcal{P}r(c(v,u))\ \textstyle\sum_{w\in V} \mathcal{P}r(c(u,w) \mid c(v,u))\\ &\geq \mathcal{P}r(c(v,u))\ \textstyle\sum_{w\in V} \mathcal{P}r(c(u,w))\\ &= \mathcal{P}r(c(v,u))\ \mathcal{E}_G[u]. \quad \square\end{aligned}$$

The following lemma states that, for any integer $c \geq |V|$, we can make any vertex $v \in V$ the *optimal* vertex by adding $\lceil (c+1)/\rho \rceil$ vertices, each adjacent to v.

LEMMA 4.6. *Let $G = (V, E)$ be a probability graph and $v \in V$. Let $G' = (V', E')$, where $V' = V \cup \{x_i \mid 1 \leq i \leq \lceil (c+1)/\rho \rceil\}$ and $E' = E \cup \{(v, x_i) \mid 1 \leq i \leq 2c+2\}$. For any integer $c \geq |V|$, v is the unique optimal vertex in G'.*

Proof. Let w be some vertex in $V - v$.

$$\begin{aligned} \mathcal{E}_{G'}[v] &= \mathcal{E}_G[v] + \rho\lceil (c+1)/\rho \rceil \quad \text{since link reliabilities} = \rho. \\ &\geq \mathcal{P}r(c(v,w))\,\mathcal{E}_G[w] + \rho\lceil (c+1)/\rho \rceil \quad \text{by 4.5.} \\ &> \mathcal{E}_G[w] + \mathcal{P}r(c(v,w))\,\rho\lceil (c+1)/\rho \rceil \\ &\qquad \text{since } 0 \leq \mathcal{P}r(c(v,w)) \leq 1 \text{ and } \mathcal{E}_G[w] < \rho\lceil (c+1)/\rho \rceil. \\ &= \mathcal{E}_{G'}[w] \quad \text{since all paths from } w \text{ to any } x_i \text{ pass though } v. \qquad \square \end{aligned}$$

4.3. Primary reduction. In this section, we use the previous reductions and lemmas to prove that optimally placing a single copy is $\#P$-complete.

THEOREM 4.7. OPTLOC *is $\#P$-complete.*

Proof. Clearly OPTLOC is in $\#P$ since we can solve OPTLOC using one query to an EXPSZ oracle for each $v \in V$, and EXPSZ is in $\#P$.

We show that OPTLOC is $\#P$-hard using a polynomial time reduction from BEXPSZ to OPTLOC, that is we show that we can solve the BEXPSZ problem using a machine for solving the OPTLOC problem.

Let $G_v = (V_v, E_v)$, A, $v \in V_v$ be an instance of the BEXPSZ problem, with $n = |V_v|$ and $m = |E_v|$. We will use OPTLOC to determine in polynomial time whether or not $\mathcal{E}[v] \geq A$.

We know that $\mathcal{E}[v] = \sum_{k=0}^{m} d_k \rho^k (1-\rho)^{m-k}$, where each d_k is the sum of the sizes of the groups containing site v in all states with exactly k operational links. This can be rewritten as $\sum_{k=0}^{m} \sum_{j=0}^{m-k} \binom{m-k}{j} d_k (-1)^{m-k-j} \rho^{m-j}$, using the binomial theorem. If we subtract 1 (since site v is always operational), and we subtract $D'\rho$ for as large an integer D' as possible, we are left with a positive rational number D'' less than ρ. Thus we can rewrite $\mathcal{E}[v]$ as $1 + D'\rho + \sum_{i=2}^{m} d_i \rho^i$, where each d_i is a nonnegative integer less than q (i.e., $\sum_{i=2}^{m} d_i \rho^i$ is the base-ρ expansion of D'').

We would like to express A in the same manner, as 1 plus $A'\rho$ plus a base ρ expansion of $A - 1 - A'\rho$. But this expansion may not terminate in base-ρ. Instead we define B, a terminating approximation of A, such that $\mathcal{E}[v] \geq A$ if and only if $\mathcal{E}[v] \geq B$. We form B simply by truncating A after the mth place and adding ρ^m if $B \neq A$. Thus for some sequence of positive integers b_i each less than q,

$$B = 1 + B'\rho + \sum_{i=2}^{m} b_i \rho^i.$$

We give the reduction below, an explanation following the reduction, and an example in Fig. 1.

4.3.1. Reduction.

Let $G_u = (V_u, E_u)$ where

$V_u = \{u\} \cup \{u_i | 1 \leq i \leq B'\}$,

$E_u = \{(u, u_i) | 1 \leq i \leq B'\}$.

Let $G'_v = (V'_v, E'_v)$ where

$V'_v = V_v \cup \{v_{i,j,k} | 1 < i \leq m \text{ and } 1 \leq j \leq b_i \text{ and } 1 \leq k \leq i-1\}$,

$E'_v = E_v \cup \{(v, v_{i,j,1}) | 1 < i \leq m \text{ and } 1 \leq j \leq b_i\}$

$\cup \{(v_{i,j,k}, v_{i,j,k+1}) | 1 < i \leq m \text{ and } 1 \leq j \leq b_i \text{ and } 1 \leq k < i-1\}$.

FIG. 1. *This figure represents the graph G given an initial graph G_v with $\rho = \frac{1}{2}$ and $B = 3\frac{5}{64}$. (Therefore, $B' = 4$, $b_1 = b_2 = b_3 = b_5 = 0$, and $b_4 = b_6 = 1$.) The name of each of the intermediate graphs is given near the portion of G that was introduced by that intermediate graph. (Note that vertex v is in G_v, although this is not evident from the figure.)*

Let $G'_u = (V'_u, E'_u)$ where
$V'_u = V_u \cup \{u_{i,j,k} \mid 1 < i \leq m$ and $1 \leq j \leq b_i$ and $1 \leq k \leq i\}$,
$E'_u = E_u \cup \{(u, u_{i,j,1}) \mid 1 < i \leq m$ and $1 \leq j \leq b_i\}$
$\cup\{(u_{i,j,k}, u_{i,j,k+1}) \mid 1 < i \leq m$ and $1 \leq j \leq b_i$ and $1 \leq k < i\}$.

Let $c = \max(\ |V'_v|\ ,\ |V'_u|\ )$.

Let $G''_v = (V''_v, E''_v)$ where
$V''_v = V'_v \cup \{w_i \mid 1 \leq i \leq \lceil (c+1)/\rho \rceil\}$,
$E''_v = E'_v\{(v, w_i) \mid 1 \leq i \leq \lceil (c+1)/\rho \rceil\}$.

Let $G''_u = (V''_u, E''_u)$ where
$V''_u = V'_u \cup \{x_i \mid 1 \leq i \leq \lceil (c+1)/\rho \rceil\}$,
$E''_u = E'_u \cup \{(u, x_i) \mid 1 \leq i \leq \lceil (c+1)\rho \rceil\}$.

Let $G'''_v = (V'''_v, E'''_v)$ where
$V'''_v = V''_v \cup \{y_i \mid 1 \leq i \leq m+1\}$,
$E'''_v = E''_v \cup \{(y_i, y_{i+1}) \mid 1 \leq i \leq m\} \cup \{(v, y_1)\}$.

Let $G_u''' = (V_u''', E_u''')$ where
$V_u''' = V_u'' \cup \{z_i \mid 1 \le i \le m\}$,
$E_u''' = E_u'' \cup \{(z_i, z_{i+1}) \mid 1 \le i \le m-1\} \cup \{(u, z_1)\}$.

Let $G = (V, E)$ where
$V = V_v''' \cup V_u'''$,
$E = E_v''' \cup E_u''' \cup \{(u, v)\}$.

$\mathcal{E}[v] \ge B$ if and only if v is the optimal vertex in G. Since the size of V is less than $2q(1/\rho+1)|E_v|^2 + 2|E_v| + (31/\rho+1)|V_v| + 51/\rho$, the size of G is polynomial in the size of G_v. Therefore, OPTLOC is #P-hard since BEXPSZ is #P-hard.

4.3.2. Explanation and correctness. Clearly, $\mathcal{E}[v] \ge B$ if and only if $\mathcal{E}[v]+d \ge B+d$, for some rational term d, which we describe later. We, therefore, build a graph G_u' with optimal vertex u and $\mathcal{E}_{G_u'}[u] = B + d$. At the same time we form G_v' by augmenting G_v such that $\mathcal{E}_{G_v'}[v] = \mathcal{E}_{G_v}[v] + d$. We then augment both G_u' and G_v', forming G_u'' and G_v'', respectively, to ensure that either u or v or both are the optimal vertices in both G_u'' and G_v''. We then augment both G_u'' and G_v'', forming G_u''' and G_v''', respectively, to ensure that u and v do not have the same expected size. At this point, $\mathcal{E}_{G_v}[v] \ge B$ if and only if v is the optimal vertex in $(V_u''' \cup V_v''', E_u''' \cup E_v''' \cup \{(u, v)\})$.

Since the expected number of operational links from u to some u_i is $B'\rho$,

$$\mathcal{E}_{G_u}[u] = 1 + B'\rho.$$

Connecting a vertex to a "chain" of k vertices increases the expected size of the group containing that vertex by $\sum_{1\le j\le k} \rho^j$. We form G_v' from G_v by adding b_k chains of length $k-1$ for every $b_k \ge 1$. Therefore,

$$\mathcal{E}_{G_v'}[v] = \mathcal{E}_{G_v}[v] + \sum_{b_i \ge 1} \sum_{j=1}^{i-1} b_i \rho^j.$$

Likewise, we form G_u' from G_u by adding b_k chains of length k for every $b_k \ge 1$. Adding a chain of length k to G_u' and of length $k-1$ to G_v' produces a net increase of $b_k\rho^k$ in the difference between $\mathcal{E}_{G_u'}[u]$ and $\mathcal{E}_{G_v'}[v]$. Therefore,

$$\begin{aligned}\mathcal{E}_{G_u'}[u] &= 1 + B'\rho + \sum_{b_i \ge 1} \sum_{j=1}^{i} b_i \rho^j \\ &= 1 + B'\rho + \sum_{b_k \ge 1} b_i \rho^i + \sum_{b_i \ge 1} \sum_{j=1}^{i-1} b_i \rho^j \\ &= B + \sum_{b_i \ge 1} \sum_{j=1}^{i-1} b_i \rho^j.\end{aligned}$$

Now $\mathcal{E}_{G_v}[v] \ge B$ if and only if $\mathcal{E}_{G_v'}[v] \ge \mathcal{E}_{G_u'}[u]$. But OPTLOC tells which vertex is optimal in the entire graph, not which of u and v is better. Therefore, we must ensure that either u or v is the optimal vertex. Clearly, $\mathcal{E}_{G_v'}[v] \ge 1$ and $\mathcal{E}_{G_v'}[t] \le c$ for all $t \in V_v'$. By adding $\lceil (c+1)/\rho \rceil$ neighbors to v, we increase the expected group size of v by $\rho\lceil (c+1)/\rho \rceil$ and ensure, by 4.6, that v is the optimal vertex in G_v''. Likewise for u in G_u'. Therefore,

$$\mathcal{E}_{G''_v}[v] = \mathcal{E}_{G'_v}[v] + \rho\left\lceil (c+1)/\rho \right\rceil = \mathcal{E}_{G_v}[v] + \sum_{b_i \geq 1} \sum_{j=1}^{i-1} b_i \rho^j + \rho\left\lceil (c+1)/\rho \right\rceil,$$

$$\mathcal{E}_{G''_u}[u] = \mathcal{E}_{G'_u}[u] + \rho\left\lceil (c+1)/\rho \right\rceil = B + \sum_{b_i \geq 1} \sum_{j=1}^{i-1} b_i \rho^j + \rho\left\lceil (c+1)/\rho \right\rceil.$$

Now $\mathcal{E}_{G_v}[v] \geq B$ if and only if v is the optimal vertex in $(V''_u \cup V''_v, E''_u \cup E''_v)$, provided $\mathcal{E}_{G''_v}[v] \neq \mathcal{E}_{G''_u}[u]$. If, however, $\mathcal{E}_{G''_v}[v] = \mathcal{E}_{G''_u}[u]$, or equivalently $\mathcal{E}_{G_v}[v] = B$, we cannot be sure which of u and v will be called *optimal*, since OPTLOC, is indifferent in this case. Therefore, we introduce G'''_v and G'''_u such that

$$\begin{aligned}
\mathcal{E}_{G'''_v}[v] &= \mathcal{E}_{G''_v}[v] + \sum_{j=1}^{m+1} \rho^j \\
&= \mathcal{E}_{G_v}[v] + \sum_{b_i \geq 1} \sum_{j=1}^{i-1} b_i \rho^j + \rho\left\lceil (c+1)/\rho \right\rceil + \sum_{j=1}^{m} \rho^j + \rho^{m+1}, \\
\mathcal{E}_{G'''_u}[u] &= \mathcal{E}_{G''_u}[u] + \sum_{j=1}^{m} \rho^j \\
&= B + \sum_{b_i \geq 1} \sum_{j=1}^{i-1} b_i \rho^j + \rho\left\lceil (c+1)/\rho \right\rceil + \sum_{j=1}^{m} \rho^j.
\end{aligned}$$

Since B is a multiple of $1/q^m$, $\mathcal{E}_{G_v}[v] \geq B$ if and only if v is the optimal vertex in $(V''_u \cup V''_v, E''_u \cup E''_v)$.

We form G by connecting G'''_u and G'''_v with an edge from u to v. Clearly, "optimality" is preserved.

Therefore, $\mathcal{E}_{G_v}[v] \geq B$ iff v is the optimal vertex in G, and G can be achieved in time polynomial in the size of G_v. Since BEXPSZ is #P-hard, OPTLOC, is also #P-hard. □

4.4. Generalizing. Since probability graphs model a subset of the networks with arbitrary, nonuniform link reliabilities and networks with both fallible sites and fallible links, the #P-completeness result of the previous section applies to these more complex networks. Also, AboElFotoh and Colbourn have shown the #P-completeness of the CON problem where vertices, rather than edges, are subject to failure [1]. Using this result, the proof given in this paper can easily be modified to include radio broadcast networks and other networks modeled by graphs with fallible vertices and infallible edges. This also includes single, bus networks like Ethernet, where the link reliability can be factored out of the availability equation.

5. Concluding remarks. Although #P-complete in general, the determination of the optimal location for the resource is solvable for some systems. Since often a network for an existing database is built incrementally around the database, the current location may be optimal. As is shown in [2], [5], [12], [21], the single copy availability can be efficiently determined for regular network topologies, such as ring, single-bus, fully connected, and for series-parallel networks. Since, for these topologies, the single copy availability can be calculated in polynomial time by calculating the expected group size, $\mathcal{E}[v] = \sum_{u \in V} \mathcal{P}r\big(c(v, u)\big)$, for each site in V, the placement problem can be solved in polynomial time. It may also be possible to solve efficiently the placement problem for networks with fixed, deterministic routing algorithms, since the number of possible paths connecting two sites may not be a function of the size of the network, or the paths may be mutually independent.

Although calculating the expected group size is feasible in some special cases, it may be unnecessary to do so in real systems. Instead, each site could record the actual number of access requests submitted to sites within its group, and the site with the largest number can be made the location of the copy. (Requiring that a site record the number of access requests, rather than the number of sites, accommodates a nonuniform access request distribution.) This method maximizes availability because the number of access requests "seen," that is, those requests submitted within a site's group, is the same as the number of access requests that would be granted if the resource were located at that site, since communication is symmetric.

If the past network performance and the access request distribution are indicative of future behavior, this technique will lead to optimal copy placement. This method does not require a priori knowledge of the network topology, hardware reliability, or access request distribution, and it adjusts automatically to unanticipated changes in any of the these system parameters. These characteristics are precisely those necessary for any protocol that hopes to relocate an object as an access distribution change. Preliminary simulation work with this method has been encouraging [14].

In summary, we have analyzed a fundamental problem that seeks the optimal location for resources. Here optimality is obtained, not by minimizing a cost metric, but by maximizing availability, that is, the probability that an arbitrary access request is submitted to a site connected to the resource. We have shown that this optimal placement problem and two related network reliability problems are #P-complete and, therefore, likely to be computationally tractable only in very small networks. Given the increasing importance of distributed computing environments, the development of practical and efficient on-line approximation techniques is an important area for further research.

POLYNOMIAL ALGORITHMS FOR HAMILTONIAN CYCLE IN COCOMPARABILITY GRAPHS*

JITENDER S. DEOGUN† AND GEORGE STEINER‡

Abstract. Finding a Hamiltonian cycle in a graph is one of the classical NP-complete problems. Complexity of the Hamiltonian problem in permutation graphs has been a well-known open problem. In this paper the authors settle the complexity of the Hamiltonian problem in the more general class of cocomparability graphs. It is shown that the Hamiltonian cycle existence problem for cocomparability graphs is in P. A polynomial time algorithm for constructing a Hamiltonian path and cycle is also presented. The approach is based on exploiting the relationship between the Hamiltonian problem in a cocomparability graph and the bump number problem in a partial order corresponding to the transitive orientation of its complementary graph.

Key words. Hamiltonian path, Hamiltonian cycle, cocomparability graphs, partial order, bump number

AMS subject classifications. 05C85, 05C45, 06A06, 68R10, 68Q20

1. Introduction.

The *Hamiltonian cycle* problem is one of the classical NP-complete problems [6], [13] on graphs. The *Hamiltonian problem* remains NP-complete even on such special classes as planar 3-connected graphs [6], bipartite graphs [16], split graphs [7], edge graphs [2], planar bipartite graphs [11], circle graphs [3], and grid graphs [11]. Relatively few classes of graphs are known for which the problem has a polynomial time solution. These include 4-connected planar graphs [8] and interval graphs [14]. The *Hamiltonian cycle* has been a well-known open problem for permutation graphs for several years [12]. In this paper we solve the Hamiltonian Path and Hamiltonian Cycle problems for a more general class of graphs known as cocomparability graphs.

It is shown that the Hamiltonian cycle existence and construction problems for cocomparability graphs have a polynomial solution. In the process we identify necessary and sufficient conditions for the existence of a Hamiltonian path or cycle in a cocomparability graph. An $O(n^3)$ time complexity algorithm for constructing a Hamiltonian cycle is also presented. Our solution method is based on exploiting the strong connection between the Hamiltonian problems in a cocomparability graph and the bump number problem in a partial order corresponding to a transitive orientation of its complementary graph. Determining whether a cocomparability graph has a Hamiltonian cycle will be referred to as the *existence problem*, and the problem of finding a Hamiltonian cycle, when it exists, is referred to as the *construction problem.* The Hamiltonian path problem on cocomparability graphs is solved using the bump number algorithm in [4], and the same approach is used for the Hamiltonian completion problem, that is, the problem of finding the minimum number of edges that should be added to make a non-Hamiltonian cocomparability graph Hamiltonian [4]. Polynomial algorithms for finding the bump number of a partial order were recently reported [10], [17], here we use the results from [10].

The paper is organized as follows: §2 contains the preliminary definitions and the most important features of the bump number algorithm that are used in this paper. In §3 we show that the bump number problem is strongly related to the *Hamiltonian path* problem in cocomparability graphs. This is followed by technical results on *"critical"* elements in *"auxiliary"*

partial orders. The critical elements play a crucial role in the solution of the existence problem for a cocomparability graph. Our main results are presented in §4, where we show that a cocomparability graph has a Hamiltonian cycle exactly if a transitive orientation of its complementary graph has no critical element. An $O(n^3)$ algorithm for solving the existence problem in cocomparability graphs is contained in §5. This is followed by a much more elaborate $O(n^3)$ algorithm, which solves the Hamiltonian cycle construction problem in a cocomparability graph.

2. Preliminary definitions and results. For the standard graph-theoretic and order-theoretic notions not mentioned here we refer the reader to [1] and [7]. Throughout the paper we consider only finite, simple, undirected graphs. Let $G = (V, E)$ be a graph with vertex set V and edge set E, and let $|V| = n$. For any $A \subseteq V$, the *subgraph* induced by A, $G[A]$ is the graph with vertex set A and those edges from E that have both their endpoints in A. For $G = (V, E)$, its *complementary graph* $G^c = (V, E^c)$ has vertex set V and edge set $E^c = V \times V - E$. A *path* in a graph is a set of vertices $\{x_1, x_2, x_3, \ldots, x_{k-1}, x_k\}$ such that $(x_i, x_{i+1}) \in E$, $1 \leq i \leq k-1$. A *cycle* in a graph is defined similarly except that in a cycle $x_1 = x_k$. We will also view paths or cycles as the collection of their edges, when this is more convenient. A path (cycle) is called *Hamiltonian* if its edges cover all the vertices in G exactly once. It is easy to show that the following monotonicity property holds.

PROPERTY 2.1. *If $G = (V, E)$ has no Hamiltonian path (cycle) and $G' = (V, E')$ with $E' \subseteq E$, then G' has no Hamiltonian path (cycle) either.*

A partial order is denoted by $P = (V, <_P)$, where V is the (finite) ground set of elements or vertices and $<_P$ is an order relation, i.e., an irreflexive, antisymmetric and transitive binary relation. The elements of the order relation $(a, b) \in <_P$ for $a, b \in V$ are written as $a <_P b$ with the usual interpretation.

We say that a is *covered* by b (denoted $a <\cdot\, b$) if $a <_P b$ and there is no $c \in V$ with $a <_P c <_P b$. Two elements $a, b \in V$ are *comparable* in P if either $a <_P b$ or $b <_P a$. Otherwise they are said to be *incomparable* and denoted by $a \,||_P\, b$. A graph $G = (V, E)$, whose edges are exactly the comparable pairs in a partial order P on V, is called a *comparability graph*. A graph G is a *cocomparability graph* if its complementary graph G^c has a transitive orientation, corresponding to the comparability relations in a partial order, denoted by P_G. A cocomparability graph G has as many partial orders P_G, as is the number of transitive orientations of G^c. However, a partial order P uniquely determines its comparability graph and, thus, its cocomparability graph denoted by $G(P)$ and $G^C(P)$, respectively.

Interval orders are the partial orders whose ground set is a family of closed intervals on the real line, with $[a, b] < [c, d]$ in the partial order if $b < c$ as numbers. The cocomparability graphs of interval orders are the *interval graphs. Permutation graphs* are exactly those graphs that are both comparability and cocomparability graphs [7]. The Hamiltonian problem for permutation graphs has been a well-known open problem [12]. In this hierarchy interval graphs represent the largest class for which the Hamiltonian cycle problem was known to be polynomially solvable [14] until now. In this paper, we extend the polynomial solvability of the Hamiltonian cycle problem to the class of cocomparability graphs, which properly includes the class of interval graphs as well as the class of permutation graphs. Thus, the class of cocomparability graphs is a significantly larger class of graphs for which the Hamiltonian problem can be solved. Cocomparability graphs also represent a large class over which many domination problems are known to be polynomially solvable [15].

A set of pairwise incomparable elements in a partial order is called an *antichain*. For $A, B \subseteq V$, disjoint subsets of V, $A <_P B$ means that $a <_P b$ for all $a \in A$, $b \in B$. A *linear order* is a partial order without incomparable elements. A *linear extension* of a partial order $P = (V, <_P)$ is a linear order $L = (V, <_L)$ that *extends* P, i.e., $a <_P b$ implies $a <_L b$

for all $a, b \in V$. We will write linear orders as $L = x_1x_2 \ldots x_n$, where the sequence from left to right defines the order relation $<_L$, i.e., $x_1 <_L x_2 <_L \ldots <_L x_n$. Two consecutive elements x_i, x_{i+1} of L are separated by a bump if $x_i <_P x_{i+1}$. The total number of bumps in L is denoted by $b(L, P)$. The *bump number* $b(P)$ of P is the minimum number of bumps in some linear extension, i.e.,

$$b(P) = \min\{b(L, P) \mid L \text{ is a linear extension of } P\}.$$

A linear extension L of P with $b(L, P) = b(P)$ is called *(bump-)optimal.* It was proved in [5], [9] that the bump number is a *comparability invariant*, i.e., partial orders with the same comparability graph have the same bump number too.

The bump number algorithm [10] is of the *primal-dual* type. This means that it constructs simultaneously a primal solution, a solution of the original minimization problem, and a dual solution, a solution of an associated maximization problem — the *dual* problem. The optimality of both primal and dual solutions is proven by showing that their objective values are equal. In our context a *primal solution* corresponds to a *linear extension L* of P, and its objective value is given by $b(L, P)$. The *dual solutions* correspond to *special* partial orders P^* *contained* in $P = (V, <_P)$. *Containment* is defined with respect to inclusion of the order relations, i.e., $P^* = (V, <_{P^*})$ is *contained* in $P = (V, <_P)$ (or, equivalently, P *contains* or *extends* P^*) if $a <_{P^*} b$ implies $a <_P b$ for all $a, b \in V$. We denote containment by $P^* \subseteq P$. It is easy to see that the bump number is nondecreasing with respect to containment, that is,

$$(1) \qquad P^* \subseteq P \quad \text{implies} \quad b(P^*) \leq b(P).$$

The *special* partial orders are defined as follows. For natural numbers $r \geq 1$ and $s \geq 0$, the class $\psi_{r,s}(V)$ consists of all partial orders $P = (V, <_P)$ for which there is a partition of V into $r + 1$ sets $U, A_1, \ldots, A_r$ such that

$$(2) \qquad |A_i| \geq 1, \quad i = 1, \ldots, r; \qquad |U| = s,$$

and

$$(3) \qquad a <_P b \quad \text{iff} \quad a \in A_i, b \in A_j, \text{ and } i < j.$$

In other words, every partial order in $\psi_{r,s}(V)$ is a parallel composition (disjoint sum) of s isolated elements and the series composition (ordinal sum) of the antichains $A_1, \ldots, A_r$. The partial orders from the classes $\psi_{r,s}(V)$ were called *generalized weak orders* in [10]. It can easily be seen that $b(P) = \max\{0, r - 1 - s\}$ for any $P \in \psi_{r,s}(V)$.

THEOREM 2.2 ([10]). *For any partial order P,*

$$\max\{b(P^*) | P^* \subseteq P, P^* \text{ a generalized weak order}\}$$
$$= \min\{b(L, P) | L \text{ a linear extension of } P\}.$$

Our algorithm for the Hamiltonian cycle problem on cocomparability graphs uses a slightly modified version of the bump number algorithm. The modified algorithm is presented in the appendix. The reader interested in more detail is referred to [10]. Here we describe only some salient features of the modified version of the bump number algorithm that are essential to our treatment of the Hamiltonian problem. The bump number algorithm is a greedy algorithm that traverses the given partial order $P = (V, <_P)$ in a "layered" fashion and avoids creating bumps as long as possible. Originally, P is given by a directed covering graph (Hasse diagram) with layers $H_0, H_1, \ldots, H_h$ in which each element is on the highest possible layer. Following this layered scheme the maximal elements are on the highest layer

H_h (where h is the height of P), and elements covered by some element in layer H_i are on layer $H_{i-1}, i = 1, \ldots, h$. The algorithm traverses the layers $H_0, H_1, \ldots, H_h$ one after the other in increasing order, starting with layer H_0. Since each H_i is an antichain of P, a bump can only occur at the transition between adjacent layers H_{i-1}, H_i. On leaving the current layer H_{i-1}, a bump is avoided if there are points a, b with

$$\text{(A.1)} \qquad a \in H_{i-1}, b \in H_j \quad \text{with } j \geq i, a \,||_P\, b, \text{ and } b \,||_P\, v \text{ for all } v \in H_i.$$

In this case, b can be placed right after a in a linear extension of P. A pair (a, b) fulfilling (A.1) is called a *transition* from H_{i-1} into H_j. If $j > i$, b is said to be *pulled down* from layer H_j in order to enable a non-bump transition to H_i, and the element b is called a *bump cutter*. Pulling down b from H_j will make H_j smaller for later steps of the algorithm. This is expressed by updating the layers accordingly. So throughout the algorithm $H'_0 = H_0, H'_1, \ldots, H'_h$ denote the current layers, where $H'_i \subseteq H_i$ denotes the set of elements that are still remaining on H_i, i.e., have not been pulled down.

The algorithm looks for transitions from the current layer H'_{i-1}, while observing three "greedy" choice rules. These rules define the layer from which b should be taken, and if there are several possible b's on that layer, specify which b to choose (or rather, not to choose). A transition $(a, b) \in H'_{i-1} \times H'_j$ is called *close* if H'_j is the closest layer above the current layer H'_{i-1} for which a transition from H'_{i-1} exists; if $j = i$, then we call the transition *short*. Then the choice rules are as follows:

Rule 1: Prefer close transitions (a, b) from H'_{i-1}.

Rule 2: Among several close transitions $(a_1, b_1), \ldots, (a_k, b_k)$ from H'_{i-1} to H'_j, with $j > i$, prefer (a_r, b_r) such that b_r is not on a close transition (b_r, c) from the layer H'_j.

Rule 3: Among several short transitions $(a_1, b_1), \ldots, (a_k, b_k) \in H'_{i-1} \times H'_i$ prefer (a_1, b_1) and (a_2, b_2) such that $b_1 \neq b_2$ and a_1 and a_2 are not the endpoints of chosen transitions to H'_{i-1}.

Rule 1 reflects that elements b' from higher layers with $a \,||_P\, b'$ might still be used for transitions (a', b') at later stages, while Rule 2 reflects that (b_r, c) might still be used when layer H_j is reached. Rule 3 tries to use *independent* pairs of short transitions, i.e., transitions whose endpoints are all different. It may be noted that this is a modification to the original algorithm in [10].

In going from layer H'_{i-1} to H'_i, the algorithm first looks for a transition $(a, b) \in H'_{i-1} \times H'_i$ (thus fulfilling Rule 1). If the element b is the same in all such transitions, the algorithm chooses an arbitrary such pair (a, b), and the element b is also called a bump cutter. Otherwise it reserves two transitions $(a, b), (a', b') \in H'_{i-1} \times H'_i$ with $b \neq b'$; if, in addition, a and a' can be chosen so that $a \neq a'$ and one or both are not endpoints of reserved transitions to H'_{i-1}, then they are selected this way (thus fulfilling Rule 3). The final choice between (a, b) and (a', b') is made later. If no transition $(a, b) \in H'_{i-1} \times H'_i$ exists, the algorithm looks for a transition $(a, b) \in H'_{i-1} \times H'_j$ with $j > i$ and, if there is one, chooses one according to Rules 1 and 2. Finally, if there is no transition (a, b) from H'_{i-1} to any $b \in H'_j, j \geq i$, the algorithm will create a bump in going from H'_{i-1} to H'_i.

When the choice of the transition is definite (i.e., all transitions $(a, b) \in H'_{i-1} \times H'_i$ have the same endpoint b or there is only one transition (a, b) into levels higher than H_i), then the linear extension to be constructed will take $H'_{i-1} - \{a\}$ in some permutation, then a followed by b, and then $H'_i - \{b\}$ in some permutation. The definite choice of a will then serve as the starting point for a backward procedure to make the final choice for the transitions between previous layers if the choice was delayed. In that case, the choice of a being the last element of H'_{i-1} determines the delayed choice of the transition from H'_{i-2} to H'_{i-1}. One of the two reserved transitions will not have a as second element, and this one is taken. Applying this principle recursively backward over all delayed decisions, the linear extension is constructed.

From now on, we will use the terminology used in the Algorithm bumpno (see the appendix), and whenever we refer to bump-optimal linear extensions, we will mean those "layered" extensions that could be generated by Algorithm bumpno. We will always use L to represent such a bump optimal linear extension. Define the intervals $L[x, u] = \{y| \, x \leq_L y \leq_L u\}$, $L| \, u = \{y| \, y \leq_L u\}$, and $u| \, L = \{y|u <_L y\}$. We will also use $G|u$ to denote the subgraph induced from G by the elements in $L|u$, for a given bump-optimal L of P_G. In the context of Hamiltonian cycles, we will use $L[x, u]$ to also denote the set of edges (v, w) if $v <\cdot_L w$ and $v, w \in L[x, u]$. The notation $HC(v, w)$ will be used to denote a Hamiltonian cycle that contains the edge (v, w), and if $v <\cdot_L w$, then v will always be the first endpoint shown for the edge (v, w).

3. Hamiltonian paths, cycles, and critical elements. The following result was proved in [4], but we include it here with a short proof, because this serves as a basis for the rest of the developments in the paper.

THEOREM 3.1. *A cocomparability graph $G = (V, E)$ has a Hamiltonian path if and only if $b(P_G) = 0$.*

Proof. If $b(P_G) = 0$, then the covering pairs in any bump-optimal linear extension of P_G form a Hamiltonian path in G. If $b(P_G) > 0$, then, by Theorem 2.2, P_G contains a generalized weak order $P_{r,s}$ with $b(P_G) = r - 1 - s$. Furthermore, it can easily be seen that, since $r - 1 - s > 0$, $G^C(P_{r,s})$ has no Hamiltonian path. Let E' be the edge set of $G^C(P_{r,s})$; then $E \subseteq E'$ and, by the monotonicity Property 2.1, G cannot have a Hamiltonian path. □

Based on the above proof, Theorem 3.1 also implies the following duality result:

COROLLARY 3.2. *A cocomparability graph $G = (V, E)$ has no Hamiltonian path if and only if there exists a generalized weak order $P_{r,s}$ on V such that $G^C(P_{r,s})$ has no Hamiltonian path and E is contained in E', the edge set of $G^C(P_{r,s})$.*

Naturally, since the existence of a Hamiltonian cycle also implies the existence of a Hamiltonian path, $b(P_G) = 0$ is a necessary condition for a cocomparability graph G to have a Hamiltonian cycle. This in itself is not sufficient, however, and our aim in the remainder of this section is to identify additional, necessary, and sufficient conditions.

DEFINITION 3.3. *An element $x \in V$ is called* critical *if $b(P_G - x) = b(P_G) + 1$, where $P_G - x$ is the subposet of P_G induced by $V - \{x\}$.*

LEMMA 3.4. *If $b(P_G) = 0$ and P_G has a critical element x, then G has no Hamiltonian cycle.*

Proof. Since x is critical, $b(P_G - x) = 1$. By Theorem 2.2 $P_G - x$ contains a generalized weak order $P_{r,s}$ with $r - 1 - s = 1$. Let $P_{r,s+1}$ be the disjoint union of $P_{r,s}$ and x (i.e., adding back x without any comparability relations). It is clear that $G^C(P_{r,s+1})$ is a graph with no Hamiltonian cycle.

However, G is contained in $G^C(P_{r,s+1})$; therefore, by the monotonicity Property 2.1 G has no Hamiltonian cycle. □

This lemma gives the first indication that the existence or nonexistence of critical elements plays a crucial role in determining whether a cocomparability graph has a Hamiltonian cycle. Naturally, the elements that are not on the entry or exit transition to or from a layer can always be removed from a layered optimal linear extension, without creating bumps, so they can never be critical.

DEFINITION 3.5. *An element $x \in H'_j$ is called* potentially critical *if x is the entry or exit point to or from H'_j in every optimal linear extension.*

LEMMA 3.6. *If $|H'_j| > 2$ and $x \in H'_j$ is the entry point to H'_j in every optimal linear extension, then x is critical.*

Proof. Suppose x is not critical; then there exists a linear extension L' of $P_G - x$ with $b(P_G - x) = b(L') = b(P_G)$. Let $a, b \in H'_j$ be the first and second elements, respectively, from H'_j in L'. Now, we want to insert x in L' between a and b without increasing the bump number. However, there may exist a $v \in H'_{j-1}$ such that $v < x$ in P_G but incomparable with every other element of H'_j and thus could appear after b in L'. But it is easy to see that such a v can be moved before a in L' without adding bumps. So we can assume that every element of H'_{j-1} is before a in L'. Thus x can be inserted between a and b in L'. This again adds no bumps and results in an optimal linear extension of P_G in which x is *not* the entry point into H'_j. □

The situation is somewhat more complicated if all optimal linear extensions *exit* a layer H'_j via the same point x, as it is indicated in Fig. 1. It is easy to see that every optimal linear extension of the P_G in Fig. 1 will exit H'_1 via x, but x is not critical because the linear extension $L' = badcefg$ of $P_G - x$ has no bumps. The point $e \in H_0$, which is below x but incomparable to every other point of H_1, moved up to become the exit point from $H_0 \cup (H_1 - x)$ in L'.

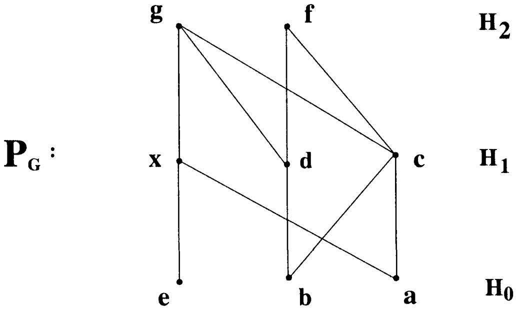

FIG. 1.

LEMMA 3.7. *Suppose that* $|H'_j| > 1$ *and* $x \in H'_j$ *is the only exit point for transitions from* H'_j; *then either* x *is critical or in every optimal linear extension of* $P_G - x$ *the exit point from* $H'_{j-1} \cup H'_j - x$ *is an* $e \in H'_{j-1}$ *such that* $e < x$ *and* $e \not< v$ *for* $v \in H'_j - x$ *in* P_G.

Proof. If x is not critical, then there is a linear extension L' of $P_G - x$ with $b(L') = b(P_G - x) = b(P_G)$. If L' exited $H'_{j-1} \cup H'_j - x$ via a $d \in (H'_j - x)$, then the subposet induced by the points in $L|x$ must have an optimal linear extension L_d; ending in d, we could replace its initial segment (up to d) by L_d, resulting in an optimal linear extension of P_G in which H'_j does not exit via x, a contradiction. Therefore, L' must exit $H'_{j-1} \cup H'_j - x$ via an $e \in H'_{j-1}$, which moved up to the jth layer after deleting x. □

If a layer H'_i, $|H'_i| \geq 2$, has two points x, y such that every short transition from H'_{i-1} to H'_i ends in x or y and every short transition from H'_i to H'_{i+1} starts in x or y, then x and y are also potentially critical, since in every optimal linear extension both x and y will have to be an entry or exit point (with these roles possibly interchanged in different linear extensions).

If a layer H'_i has two points x, y that are endpoints of short transitions from H'_{i-1} and two points v, w that are starting points of short transitions to H'_{i+1} with $|\{x, y, v, w\}| > 2$, then we can always construct an optimal linear extension L in which any designated point of H'_i can be made a nonentry and nonexit point, e.g., second from H'_i in L. Thus, a layer with this property cannot contain potentially critical points.

LEMMA 3.8. (1) *If* H'_i $(0 < i < h)$ *is not the bottom layer of a closed set,* $|H'_i| > 2$, *and it has exactly two points* x, y *that are the only endpoints for transitions from* H'_{i-1} *to* H'_i *as well as the only starting points for transitions between* H'_i *and* H'_{i+1}, *then* x *and* y *are critical.*

(2) *Let $|H_i'| \geq 2$, and let $x \in H_i$ be the only starting point of transitions from H_i'. If there is no $e \in H_{i-1}'$ that could move up to this layer when x is deleted and that is also the starting point of a transition to some H_j' $(j > i)$, then x is critical.*

Proof. (1) Since $|H_i'| > 2$, there exists a $c \in H_i' - \{x, y\}$ and c is above every element in H_{i-1}'. So if we delete x, the only entry point for a transition into H_i' is y. But then we have no transition from H_i' to H_{i+1}'; therefore, $b(P_G - x) > b(P_G)$. The proof is similar for $b(P_G - y)$.

(2) If we delete x from P_G, there is no element left that could serve as the starting point of a transition from H_i to H_{i+1}'; therefore, $b(P_G - x) > b(P_G)$. □

Consider a generalized weak order $P_{r,s}$ with $r - 1 - s \geq 0$ and its set of isolated elements $U \neq \emptyset$. Since $r - 1 - s \geq 0$, every element of U is used as a bump cutter in a bump-optimal linear extension of $P_{r,s}$. Therefore, every $u \in U$ must be critical. This observation yields:

LEMMA 3.9. *If $b(P_G) = 0$ and P_G contains a generalized weak order $P_{r,s}$ such that $r - 1 - s = 0$ and $s > 0$, then P_G has a critical element and G has no Hamiltonian cycle.*

The lemma means that the existence of a Hamiltonian cycle in G implies not only $b(P_G) = 0$ but also that the bump number algorithm must produce a dual order for P_G that is simply an antichain on V. This can happen if either the bump number algorithm uses the procedure `close` only once at the end (i.e., the dual order is built only by the successive applications of the procedure `grow`) or `close` is used more than once but all antichains in the dual order get eventually combined into a single antichain by the procedure `collapse`. In the following we deal with these two cases separately.

4. Hamiltonian cycles.

4.1. Strictly grown orders. In the first case the dual order is *strictly grown*, i.e., the bump number algorithm has always found at least two transitions into the next layer with different endpoints.

Case 1*a*. In this subcase the starting points of the transitions are also different, i.e., we have two independent transitions between each pair of consecutive layers, and these independent transitions cover at least 3 points on every layer, except the top and bottom ones. In this situation we can easily construct a Hamiltonian cycle in G using this set R of reserved transitions. First we find two node-disjoint paths between the top and bottom layers of P_G by the following procedure.

```
procedure twopaths($P_G$; $R$)
    1. Start by choosing one of the reserved transitions from $H_0'$ to $H_1'$.
    2. Suppose $(a,b) \in H_i' \times H_{i+1}'$ was the last transition chosen. If $H_{i+1}'$ is the top layer, then the selected transitions and edges form a path $\pi_1$ and go to 3. If $b$ is the starting point of a reserved transition $(b,c)$ to the next layer, $H_{i+2}'$, then choose $(b,c)$ and repeat Step 2; otherwise choose a reserved transition $(d,e) \in H_{i+1}' \times H_{i+2}'$ with the restriction that $d$ is not the end point of a reserved transition from $H_i'$ to $H_{i+1}'$. Connect $(a,b)$ and $(d,e)$ adding the horizontal edge $(b,d) \in H_{i+1}' \times H_{i+1}'$ from $G$. Repeat Step 2.
    3. The remaining reserved transitions (after adding some $(u,v) \in H_i' \times H_i'$ type horizontal edges from $G$, if necessary) form a path $\pi_2$ from the top layer to $H_0$.
```

The fact that this procedure will construct two node-disjoint paths between the top and bottom layers follows from the observation that after each execution of Step 2 there will be exactly one reserved transition left to and from each intermediate layer and none of these cover points that are covered by transitions in π_1. Furthermore, since each intermediate layer had at least 3 points on the reserved transitions, at least one of π_1 or π_2 must contain a horizontal edge $(u, v) \in H_i' \times H_i'$ for each intermediate layer H_i'. This means that any points $w \in H_i'$, missed by both π_1 and π_2, can be inserted between these u and v. Finally the Hamiltonian cycle in G can be completed by connecting the end of π_1 to the start of π_2 in H_h' and the end of π_2 to the start of π_1 in H_0' and by inserting any missed points from H_0 or H_h by horizontal edges in the corresponding layers.

The entire construction is illustrated in an example in Fig. 2. Suppose the transition $(1, 4) \in \pi_1$ was chosen. Since the node 4 is also the start of a transition, (4, 7) is added to π_1. After this, (6, 9) and (8, 11) are the next available reserved transitions, but (8, 11) cannot be chosen since 8 is the end point of the transition (3, 8); thus, (6, 9) is added to π_1 with (7, 6) joining it to the earlier built part. In the next iteration (9, 13) must be chosen since 9 is both the end and start of a reserved transition. In the last iteration through Step 2 both transitions (12, 17) and (16, 19) are available, so choose, say (16, 19), and join it to π_1 by (13, 16). This completes $\pi_1 = (1, 4, 7, 6, 9, 13, 16, 19)$. The remaining reserved transitions along with the horizontal edges (12, 15), (10, 11), and (3, 5) form $\pi_2 = (17, 12, 15, 10, 11, 8, 3, 5, 2)$. The only point missed from an intermediate layer is 14. Since both π_1 and π_2 have a horizontal edge from the layer of 14, we insert 14, say, between 13 and 16, in π_1. Finally, π_1 and π_2 are combined into the Hamiltonian cycle HC = (1, 4, 7, 6, 9, 13, 14, 16, 19, 18, 20, 17, 12, 15, 10, 11, 8, 3, 5, 2, 1), after including the points 18 and 20, missed from H_h'.

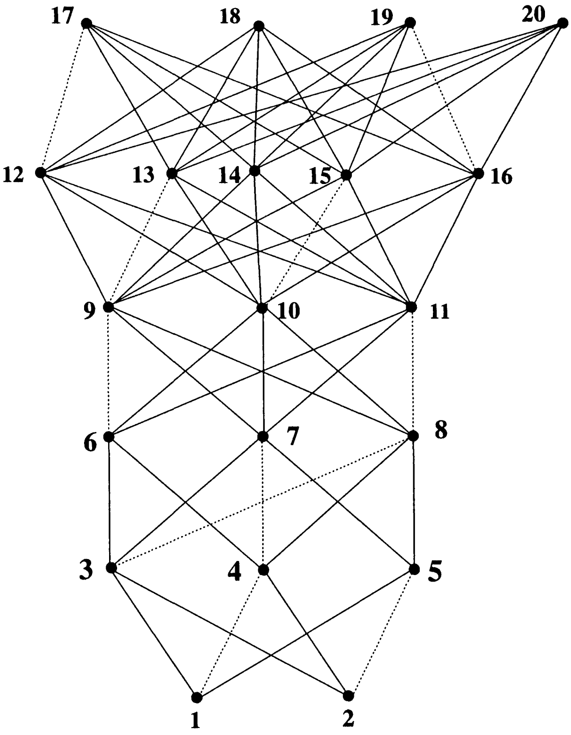

FIG. 2. *P_G with reserved transitions represented by dotted lines.*

Remark: We note that since missed points from H_0' or H_h' can be inserted in any order at the end, we can assume without loss of generality that if $a, b \in H_h'$ (or H_0'), such that at most one of them is on a reserved transition, then HC(G) will contain the edge (a, b). For example, the HC(G) constructed in the example contains the horizontal edges (19, 18), (18, 20), and (20, 17), but by changing the order of insertions it could be made to go through either one of the edges (19, 20) or (18, 17). The only horizontal edge it is forced to avoid is (17, 19), the edge connecting the endpoints of the reserved transitions. This is an important property of the Hamiltonian cycle constructed, which will be used later.

Case 1*b*. In this subcase there are two independent transitions between each pair of consecutive layers, but there is an intermediate layer H_i' where all transitions end and start in the same two points x and y. Applying the procedure `twopaths` would still yield two node-disjoint paths π_1 and π_2, the same way as in Case 1a. If $|H_i'| = 2$, then we can again use the same method as before to construct a Hamiltonian cycle, but if H_i' contains a third point c, then both π_1 and π_2 would miss c and neither one of them has a horizontal edge in the layer H_i', where c could be inserted later. This situation is illustrated in Fig. 3.

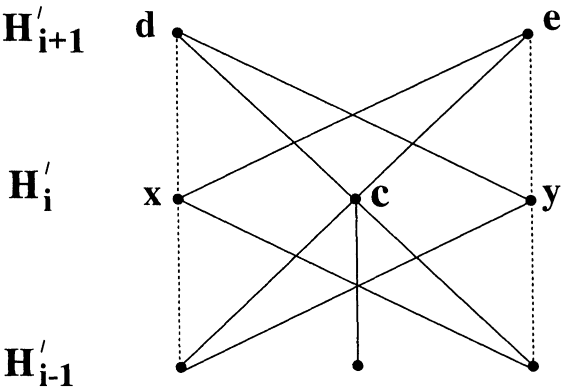

FIG. 3. *A Type* 1 *blocker.*

LEMMA 4.1. *Let G be a cocomparability graph. Suppose that $b(P_G) = 0$ and P is strictly grown. Let H_i' with $|H_i'| > 2$ be an intermediate layer that contains two points x and y such that there are transitions both ending and starting only in the points x and y, implying that every other point $c \in H_i'$ is above every element in H_{i-1}' and below every element in H_{i+1}'. If P_G^{i+1} denotes the restriction of P_G to $H_0' \cup H_1' \cup \cdots \cup H_{i+1}'$, then x and y are critical in P_G^{i+1}.*

Proof. The lemma is a direct consequence of Lemma 3.8(1) applied to P_G^{i+1}. □

We will refer to a layer H_i that satisfies the conditions of Lemma 4.1 as a *Type* 1 *blocker*. Of course, the existence of such a blocker does not necessarily preclude the existence of a Hamiltonian cycle in G, as it may be possible to pull down some other element, from a layer above H_{i+1}, that could play the role of a bump cutter between H_i and H_{i+1} in $P_G - x$ or $P_G - y$. Therefore, the elements x and y of Lemma 4.1 are *potentially critical*, as defined earlier, but whether these are critical or not really depends on the rest of P_G.

Case 1*c*. In this subcase there is a layer H_i, with $|H_i'| \geq 2$ and element $x \in H_i'$ such that all short transitions from H_i' to H_{i+1}' start in x. This situation is depicted in Fig. 4. In this case the procedure `twopaths` could not find two node-disjoint paths between H_0' and H_h'. We will refer to the layer H_i' with these properties as a *Type* 2 *blocker*. The element x of a Type 2 blocker may or may not be critical (cf. Lemma 3.7 and Lemma 3.8(2)), as it may be possible to pull down some other element, from a layer above H_{i+1}, to act as a bump cutter between H_i and H_{i+1} in $P_G - x$. In another situation, as shown in the second example of

Fig. 4, an element $e \in H'_{i-1}$, that can move up "to act" as a bump cutter between H'_i and H'_{i+1} in $P_G - x$ may exist. Therefore, the element x is only potentially critical.

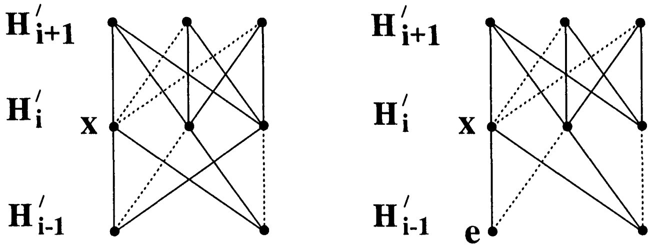

FIG. 4. *Type* 2 *blockers.*

We will use HP(u, v) to denote a Hamiltonian path between vertices u and v in a graph to be specified. Similarly HC(u, v) is used to denote a Hamiltonian cycle that includes edge (u, v). The following technical lemma will be used repeatedly.

LEMMA 4.2. *Let G_1 and G_2 be two graphs having exactly two common vertices u and v. Let $G = G_1 \cup G_2$ be the graph whose vertex set and edge set is the union of those in G_1 and G_2. If* $\mathrm{HP}_1(u, v)$ *and* $\mathrm{HP}_2(u, v)$ *are Hamiltonian paths in G_1 and G_2, respectively, then* $\mathrm{HC} = \mathrm{HP}_1(u, v) \cup \mathrm{HP}_2(u, v)$ *is a Hamiltonian cycle in G. Similarly, if* $\mathrm{HC}_1(u, v)$ *and* $\mathrm{HC}_2(u, v)$ *are Hamiltonian cycles in G_1 and G_2 respectively, then* $\mathrm{HC} = \mathrm{HC}_1(u, v) \cup \mathrm{HC}_2(u, v) - \{(u, v)\}$ *is a Hamiltonian cycle in G. Furthermore,* $\mathrm{HP}_1(u, v) \cup \mathrm{HC}_2(u, v) - \{(u, v)\}$ *and* $\mathrm{HC}_1(u, v) - \{(u, v)\} \cup \mathrm{HP}_2(u, v)$ *are also Hamiltonian cycles in G.*

Proof. Obvious. □

THEOREM 4.3. *Let G be a cocomparability graph. Suppose that $b(P_G) = 0$ and P_G is strictly grown. G has a Hamiltonian cycle if and only if P_G has no critical element.*

Proof. In one direction the theorem follows from Lemma 3.4. For the other direction, assume that P_G has no critical element. We use induction on the number of blockers. If P_G has no blockers, then we have Case 1a and a Hamiltonian cycle can be constructed as described earlier. In correspondence with our remark at the end of Case 1a, we make our inductive hypothesis slightly stronger than what is stated in the theorem:

Inductive hypothesis. Suppose $b(P_G) = 0$, the dual order is strictly grown, and P_G has no critical element and at most m blockers. If $c, x \in H'_0$ such that at most one of them is on a reserved transition, then there is a Hamiltonian cycle HC(c, x) in G.

Let us consider now a P_G satisfying the assumptions of the theorem. Further assume that P_G has no critical element and $m + 1$ blockers. Let H'_i be the lowest level blocker in P_G .

Case i. *The lowest level blocker H'_i is of Type* 1 *with potentially critical elements x and y.* Without loss of generality (wlog) let L be an optimal linear extension of P_G in which x is the last element from H'_i. Since x is not critical, there is a linear extension L' of $P_G - x$ such that $b(P_G - x) = b(L') = 0$. Every $v \in H'_i - \{x, y\}$ is above every element of H'_{i-1} and below every element of H'_{i+1}, so L' must use y as its entry point to H'_i. Therefore, there must exist a $u \in H'_j\ (j > i + 1)$ that acts as a bump cutter between H'_i and H'_{i+1} in L', and this vertex u can be used to bypass H'_i in our Hamiltonian cycle. First we note that the bypass element u must be incomparable to every point occurring between x and u in L, i.e., $v \not< u$ in P_G for every $v \in H'_k\ (i < k \leq j)$. Let $c \in H'_i - \{x, y\}$ be the last element from H'_i in L'. We can assume that x covers c in L. The subposet induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_i$ has no blockers and satisfies the earlier discussed Case 1a, thus there is a Hamiltonian cycle $\mathrm{HC}_1(c, x)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_i$ from G. Furthermore, $\mathrm{HC}_2(c, x) = \{(c, x), L[x, u], (u, c)\}$ is also a cycle and, by Lemma 4.2, $\mathrm{HC}_3 = \mathrm{HC}_1(c, x) \cup HC_2(c, x) - \{(c, x)\}$ is a Hamiltonian cycle in the subgraph $G|u$.

If H'_j is not a blocker, then we can always rearrange L (and HC_3) so that u is the second element from H'_j in L. (We will call this a *rearrangement of Type* 1). If a denotes the element covered by u in this rearranged L, then HC_3 contains the edge (a, u). The subgraph induced by $H'_j \cup H'_{j+1} \cup \cdots \cup H'_h$ satisfies the assumptions of the inductive hypothesis with fewer than $m + 1$ blockers and u is not a potentially critical element (H'_j has none), so there is a $\mathrm{HC}_4(a, u)$ in this subgraph. By Lemma 4.2 again, $\mathrm{HC} = \mathrm{HC}_3(a, u) \cup HC_4(a, u) - \{(a, u)\}$ is a Hamiltonian cycle in G.

If H'_j is a Type 2 blocker and u is its potentially critical element, then we cannot have an $e \in H'_{j-1}$ (with $e < u$ in P_G) that could move up to the jth level in $P_G - u$ to act as exit point from this level in the sense of Lemma 3.7 because of our observation that the bypass element u is incomparable to every point between x and itself. Therefore, since u is not critical, there must be an $a \in H'_j - u$ that is the starting point of a transition from H'_j to some $v \in H'_k$ ($k > j + 1$). If a is the only such starting point and, in addition, $|H'_j| > 2$, then a and u cannot be the only endpoints for short transitions between H'_{j-1} and H'_j because this would make them critical by Lemma 3.8(1). So irrespective of the size of H'_j (even if $|H'_j| = 2$) we can assume that L (and HC_3) can be rearranged so that a is covered by u in L. (We will call this a *rearrangement of Type* 2). Therefore, (a, u) will be an edge in the rearranged HC_3. On the other hand, the subgraph induced by $\{a, u\} \cup H'_{j+1} \cup \cdots \cup H'_h$ satisfies the assumptions of the inductive hypothesis with at most m blockers, so there is an $\mathrm{HC}_4(a, u)$ in it. By Lemma 4.2, $\mathrm{HC} = \mathrm{HC}_3(a, u) \cup \mathrm{HC}_4(a, u) - \{(a, u)\}$ is a Hamiltonian cycle in G.

If H'_j is a Type 2 blocker but u is not its potentially critical element, then let x' be its potentially critical element and three subcases exist. In the first subcase $|H'_j| > 2$ and there is an $a \in H'_j - x'$ that acts as exit point from H'_j in the bump-free linear extension L' of $P_G - x'$. It may be noted that the existence of L' is guaranteed since x' is not critical. Since $|H'_j| > 2$, if $a \neq u$, then we can assume that u is not the entry point to H'_j in L by Lemma 3.6 and we can rearrange L so that u covers a in L (a rearrangement of Type 2). If u is the only possible exit point from $H'_j - x'$ (i.e., $a = u$) in L', then x' and u are the only exit points from H'_j and by Lemma 3.8(1) there must be an $a \in H'_j - \{x', u\}$ that can be the entry point to H'_j in L. Rearrange L and HC_3 so that a is covered by u in L. In either case this leads to an HC_3 that contains the edge (a, u). Let B denote the set of points following u in L. The subposet induced by $\{a, u\} \cup B$ satisfies the assumptions of the inductive hypothesis with at most m blockers. Therefore, there is an $\mathrm{HC}_4(a, u)$ in its cocomparability graph. Thus $\mathrm{HC} = \mathrm{HC}_3(a, u) \cup \mathrm{HC}_4(a, u) - \{(a, u)\}$ is a Hamiltonian cycle in G. In the second subcase $|H'_j| = 2$ ($H'_j = \{x', u\}$) and u acts as the exit point from H'_j in the bump-free linear extension L' of $P_G - x'$. The subposet $\{u, x'\} \cup B$, where $B = u \mid L$, satisfies the assumptions of the inductive hypothesis with at most m blockers, so there is an $\mathrm{HC}_4(u, x')$ in its cocomparability graph. By rearranging the segment $L|x'$ we can make u the last point from H'_j. Using this rearranged segment for rearranging HC_3 we can make $(x', u) \in \mathrm{HC}_3$. Then $\mathrm{HC} = \mathrm{HC}_3 \cup \mathrm{HC}_4(u, x') - \{(u, x')\}$ is a Hamiltonian cycle in G. In the third subcase, irrespective of the size of H'_j, an $e \in H'_{j-1}$ acts as the exit point from the jth layer in the bump-free linear extension of $P_G - x'$, in the sense of Lemma 3.7. Since e must be incomparable to every $v \in H'_j - x'$, we can rearrange L so that e is covered by u in L. (We call this a *rearrangement of Type* 3). The resulting HC_3 will have (e, u) as an edge. Let $B = u|L$. If we delete the comparability relation (e, x') in the subposet $\{e, u\} \cup B$, then it will satisfy the assumptions of the inductive hypothesis with at most m blockers, so there is an $\mathrm{HC}_4(e, u)$ in its comparability graph. (It is clear that x' and e will be the endpoints of reserved transitions used in HC_4, so e and x' will not be neighbors in HC_4). Therefore, $\mathrm{HC} = \mathrm{HC}_3(e, u) \cup \mathrm{HC}_4(e, u) - \{(e, u)\}$ is a Hamiltonian cycle in G.

If H'_j is a Type 1 blocker, then we can assume wolg that u is the exit point from H'_j in L. Accordingly, HC_3 is a Hamiltonian cycle on the subgraph $G|u$ induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_j$. Since H'_j is a Type 1 blocker, we can repeat the argument used for bypassing H'_i — since u is not critical, there is a $u' \in H'_k$ $(k > j+1)$ that acts as bump cutter between H'_j and H'_{j+1} in a bump-free linear extension L'' of $P_G - u$. If H'_k is not a blocker or it is a Type 2 blocker, then we have reduced this case to one of those discussed earlier. On the other hand, if H'_k is a Type 1 blocker again, then we can repeat the bypassing argument for it too. After a finite number of repetitions we either must cover the whole graph G by the Hamiltonian cycle or end up using a bump cutter either from a nonblocker layer or from a Type 2 blocker.

Case ii. *The lowest level blocker H'_i is of Type* 2, *with potentially critical element x.* Let L be an optimal linear extension of P_G. Since x is not critical, there is a linear extension L' of $P_G - x$ with $b(P_G - x) = b(L') = 0$. Let $u \in H'_j$ $(j \geq i+1)$ be the first (the bypass) element in L' from above H'_i, and let c be the element covered by u in L'.

If $c \in H'_i$ and $H'_i = \{x, c\}$, then there is a $\mathrm{HC}_1(c, x)$ in the subgraph of G induced by $L|x$, since this subgraph has no blocker. If $c \in H'_i$ and $|H'_i| > 2$, then every $d \in H'_i - \{c, x\}$ is before c in L', by definition, so there is a transition from H'_{i-1} to H'_i with some endpoint $d \in H'_i - \{c, x\}$. Using this as one of the reserved transitions in the application of `twopaths` to the poset induced by $H'_0 \cup H'_1 \cup \cdots \cup (H'_i - x)$ means that at most one of c and x may lie on another reserved transition. Therefore, by our remark at the end of Case 1a, there is a $\mathrm{HC}_1(c, x)$ in the subgraph G^i, induced by $L|x$.

If $c \in H'_{i-1}$ then c is not comparable to any element in $H'_i - x$. Since every $d \in H'_i - x$ is before c in L', by definition, there is a $c' \in (H'_{i-1} - c)$ and $d \in (H'_i - x)$ such that (c', d) is a short transition between H'_{i-1} and H'_i. If c and c' are not the only endpoints of short transitions between H'_{i-2} and H'_{i-1} or $H'_{i-1} = H'_0$ or $|H'_{i-1}| = 2$, then, by our remark at the end of Case 1a, there is a $\mathrm{HC}_0(c, c')$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1}$. If $|H'_{i-1}| > 2$, $i - 1 > 0$, and every $v \in H'_{i-1} - \{c, c'\}$ is above every element of H'_{i-2}, then one of these v must be the starting point of a short transition into H'_i, since otherwise the layer H'_{i-1} would be a Type 1 blocker (contradicting that H'_i is the lowest level blocker, see Fig. 5), and this v can play the role of c' in the previous sentence. In summary, there must exist an $\mathrm{HC}_0(c, c')$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1}$, such that c' is the starting point of a short transition (c', d) to H'_i and c is not comparable to any element in $H'_i - x$. $\mathrm{HC}_0(c, c')$ can be enlarged into an $\mathrm{HP}_1(c, x)$ of $G|x$ by inserting d, followed by $H'_i - \{x, d\}$ in any order, and finally x between c' and c. We will refer to this sequence of operations as a *rearrangement of Type* 4.

If $c \in H'_i$, then it can be assumed that c is covered by x in L by Lemma 3.6 (c cannot be the only entry point to H'_i if $|H'_i| > 2$). Therefore, $\mathrm{HC}_2(c, x) = \{(c, x)\} \cup L[x, u] \cup \{(u, c)\}$ is a cycle and $\mathrm{HC}_3 = \mathrm{HC}_1(c, x) \cup$ $\mathrm{HC}_2(c, x) - \{(c, x)\}$ is a Hamiltonian cycle in $G|u$. If $c \in H'_{i-1}$, then $\mathrm{HP}_2(c, x) = L[x, u] \cup \{(u, c)\}$ is a path and $\mathrm{HC}_3 = \mathrm{HP}_1(c, x) \cup HP_2(c, x)$ is a Hamiltonian cycle in $G|u$. In either one of the previous situations HC_3 can be enlarged into a Hamiltonian cycle in G, by a construction identical to the one used in Case i; therefore, we do not repeat it here. □

We also note that we proved a bit more than the existence of a Hamiltonian cycle in G. Because of its importance in the remainder of the paper, we state this stronger result as a separate corollary:

COROLLARY 4.4. *Suppose $b(P_G) = 0$, P_G is strictly grown, and P_G has no critical element. If $x \in H'_i$ is the exit point from H'_i in the optimal linear extension L, $c \in H'_i$ is not potentially critical, and there is a transition (c, u) from H'_i to $u \in H'_j$ $(j > i)$, then there is a Hamiltonian cycle $HC_1(c, x)$ in the subgraph of G induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_i$ and there is a $HC_2(c, x)$ in the subgraph of G induced by $\{c, x\} \cup H'_{i+1} \cup \cdots \cup H'_h$.*

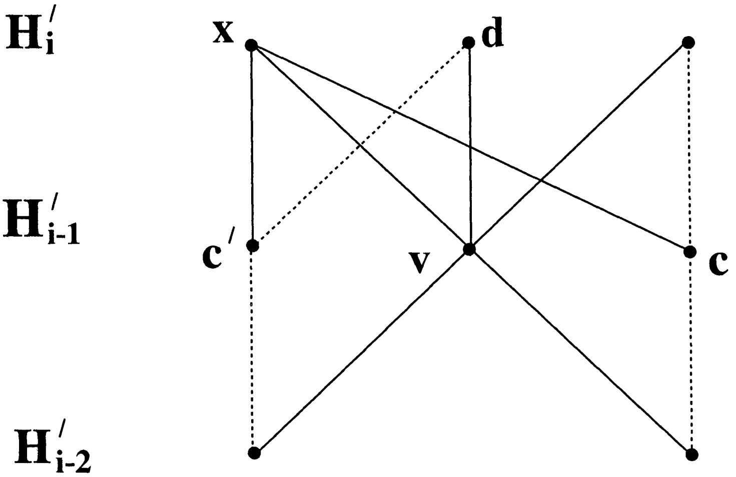

FIG. 5.

As we have seen, even though a strictly grown partial order may contain blockers, when the potentially critical elements in a blocker are not critical, we can include in a Hamiltonian cycle the elements of such a blocker. We will refer to this as the blocker being *bypassed* and will call the element u the *bypass element* for the blocker.

In Fig. 6 we show a P_G satisfying the conditions of Theorem 4.3. In this poset H_2 is a Type 1 blocker and H_4, H_6, H_{10} are Type 2 blockers. Suppose bumpno has found for P_G the bump-free linear extension L = 1, 2, 3, ..., 37, 38, 39. The first blocker is H_2, so applying twopaths to $H_0 \cup H_1 \cup H_2$ we get HC$_1$ = (2, 1, 5, 6, 7, 8, 4, 3, 2). The element $x = 8$ is not critical because we have the transition (7, 15) with $u_1 = 15$ as a bypass element for H_2. Using $L[8, 15]$, we have HC$_2$(7, 8) = (7, 8, 9, 10, 11, 12, 13, 14, 15, 7). Since $(7, 8) \in$ HC$_1$, no rearrangement is necessary, and we get HC$_3$ = HC$_1 \cup$ HC$_2$(7, 8) $-$ {(7, 8)} = (2, 1, 5, 6, 7, 15, 14, 13, 12, 11, 10, 9, 8, 4, 3, 2). The bypass element $u_1 = 15$ is the potentially critical element of the Type 2 blocker H_4. The transition (14, 19) could be used to exit from $H_4 - \{15\}$ in $P_G - \{15\}$. Therefore, the subgraph G_1 and subposet induced by {14, 15, 16, 17, 18, ..., 39} satisfy the conditions of Theorem 4.3 (if the original P_G satisfied them), with L_1 = 14, 15, 16, 17, ..., 38, where L_1 is the same as L after 17. We should find a Hamiltonian cycle, containing the edge (14, 15), on this subgraph. The point 15 is potentially critical in the bottom layer {14, 15} of this subposet, but the transition (14, 19) bypasses it. This gives HC$_4$ (14, 15) = (15, 16, 17, 18, 19, 14, 15), with bypass element u_2 = 19. This u_2 is the entry point in L to the Type 2 blocker H_6, but it is not the only possible entry to H_6, so it does not have to be critical. We can rearrange L_1 so that $u_2 = 19$ becomes the second point in it from H_6. The new L_1 = 14, 15, 16, 18, 17, 20, 19, 21, ..., 38, which follows the old L_1 after 21. The resulting rearrangement of HC$_4$ yields a new HC$_4$(14, 15) = (15, 16, 18, 17, 20, 19, 14, 15), which now contains the additional point 20. To bypass the Type 2 blocker H_6, we can use the bypass element $u_3 = 25$, which is the endpoint of the transition (19, 25) between $H_6 - \{21\}$ and H_7. The subgraph G_2 and corresponding subposet induced by $H_6 \cup H_7 \cup \cdots \cup H_{13}$ satisfy the conditions of Theorem 4.3 if G_1 satisfied them, with L_2 = 20, 19, 21, ..., 38, where L_2 follows the pattern in L_1 after 21. We should find a Hamiltonian cycle, containing the edge (20, 19), in G_2. Building our cycle in G_2 to the bypass element $u_3 = 25$ yields HC$_5$ (20, 19) = (19, 20, 21, 22, 23, 24, 25, 19). The bypass element $u_3 = 25$ is the entry point to H_8. We can make u_3 the second point in L_2 by rearranging L_2 to 20, 19, 21, 22, 23, 24, 27, 25, 26, 29, 28, 30, ..., 38, where it follows the old L_2 after 30, and the new HC$_5$ (20, 19) = (19, 20,

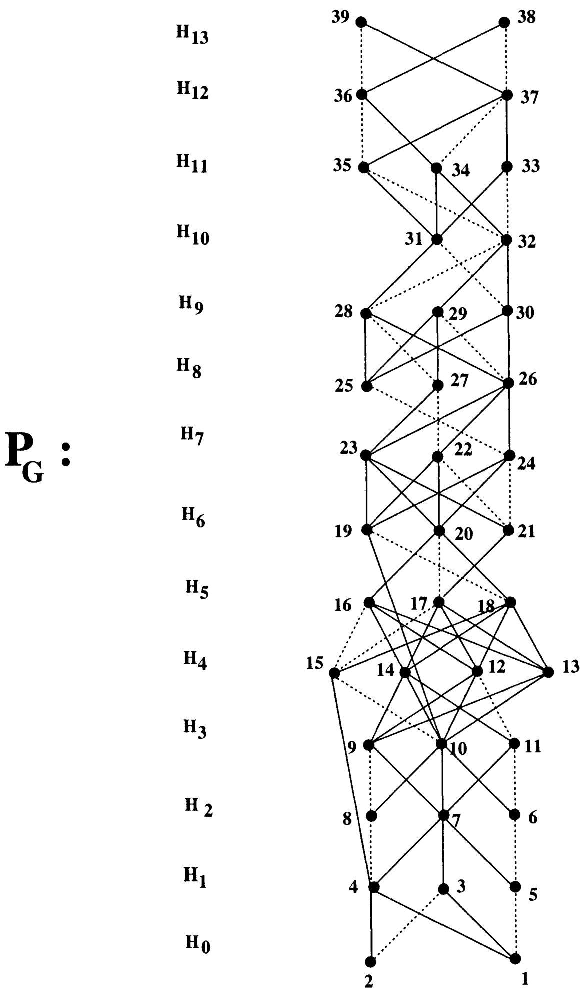

FIG. 6. *An example of the construction in strictly grown orders.*

21, 22, 23, 24, 27, 25, 19). The subgraph G_3 and subposet induced by $H_8 \cup H_9 \cup \ldots \cup H_{13}$ satisfy the conditions of Theorem 4.3, if G_2 satisfied them, with $L_3 = 27, 25, 26, 29, 28, 30, \ldots, 38$, where L_3 follows the pattern in L_2 after 30. We should find a Hamiltonian cycle, containing the edge (25, 27), in G_3. Building our cycle in G_3 yields HC_6 (25, 27) = (25, 27, 28, 32, 31, 30, 29, 26, 25). We reached the Type 2 blocker H_{10}, but, this time, there is no transition starting in H_{10} to bypass its potentially critical point 32. On the other hand, the element $e = 29$ could move up to become the exit point from $H_{10} - \{32\}$. We can rearrange L_3 so that 32 is covering e. The new $L_3 = 26, 25, 27, 28, 30, 31, 29, 32, \ldots$, with no change after 32, and HC_6 becomes HP_6 (29, 32) = (29, 26, 25, 27, 28, 30, 31, 32). By deleting the comparability relationship $29 < 32$, 29 moves up to H_{10}. The subgraph G_4 and subposet induced by $\{29, 32\} \cup H_{11} \cup \cdots \cup H_{13}$ satisfy the conditions of Theorem 4.3 if G_3 satisfied them, with $L_4 = 29, 32, 33, \ldots, 38$, where L_4 follows the pattern of L_3 after 33. We should find a Hamiltonian path from 29 to 32 in G_4. Building our path in G_4 yields HP_7 (29, 32) = (29, 33, 34, 37, 38, 39, 36, 35, 32). All that is left is to combine the Hamiltonian cycles and paths generated into a cycle in G. Let

$$\begin{aligned}
\mathrm{HC}_8 &= \mathrm{HP}_6 \cup \mathrm{HP}_7 &&= (29, 33, 34, 37, 38, 39, 36, 35, 32,\\
&&&\quad 31, 30, 28, 27, 25, 26, 29);\\
\mathrm{HC}_9 &= \mathrm{HC}_8 \cup \mathrm{HC}_5 - \{(25, 27)\} &&= (29, 33, 34, 37, 38, 39, 36, 35, 32,\\
&&&\quad 31, 30, 28, 27, 24, 23, 22, 21, 20,\\
&&&\quad 19, 25, 26, 29);\\
\mathrm{HC}_{10} &= \mathrm{HC}_9 \cup \mathrm{HC}_4 - \{(20, 19)\} &&= (29, 33, 34, 37, 38, 39, 36, 35, 32,\\
&&&\quad 31, 30, 28, 27, 24, 23, 22, 21, 20,\\
&&&\quad 17, 18, 16, 15, 14, 19, 25, 26, 29);\\
\mathrm{HC} &= \mathrm{HC}_{10} \cup \mathrm{HC}_3 - \{(15, 14)\} &&= (29, 33, 34, 37, 38, 39, 36, 35, 32,\\
&&&\quad 31, 30, 28, 27, 24, 23, 22, 21, 20,\\
&&&\quad 17, 18, 16, 15, 7, 6, 5, 1, 2, 3, 4,\\
&&&\quad 8, 9, 10, 11, 12, 13, 14, 19, 25, 26, 29);
\end{aligned}$$

HC is a Hamiltonian cycle in G.

4.2. Collapsed dual orders. As we have seen before, certain (bypass) elements can be used to grow a Hamiltonian cycle beyond a blocker in strictly grown orders. The situation is quite similar for bump cutters: Suppose we have grown our Hamiltonian cycle $\mathrm{HC}_1(c_1, x)$ to include the top layer of closed set A_k, with x being the exit point in L from H_i', the top layer of A_k. If the bump cutter u_k is not critical, then there is a bump-free linear extension L' of $P_G - u_k$. (In the following discussion an indexed u_k always refers to the (kth) bump cutter between A_{k-1} and A_k). This L' must use a $u \in u_k|L$ as a bypass element; i.e., if u is the first element from $u_k|L$ in L', then u must be the endpoint of a transition (c, u) for some $c \in H_i'$, where c is the exit point from H_i' in L'. If we can rearrange L and $\mathrm{HC}_1(c_1, x)$ so that c moves into the position immediately before x, i.e., we get $\mathrm{HC}_1(c, x)$, then $\mathrm{HC}_u = \mathrm{HC}_1(c, x) \cup L[x, u] \cup \{(u, c)\} - \{(c, x)\}$ is a Hamiltonian cycle in $G|u$, that is, HC_1 was enlarged to include u_k and points beyond u_k .

The next lemma states some important properties for bypass elements.

LEMMA 4.5. *Suppose H_i' is either a blocker or the top layer of a closed set A_k and x is the exit point from H_i' in L. If u is the bypass element for the blocker H_i' or the bump cutter u_k, then*:

(a) *If u is used to bypass the bump cutter u_k, then u is incomparable to every point that is between u_k and itself in L; if u is used to bypass the blocker H_i', then u is incomparable to every point that is between x and itself in L.*

(b) *If $u \in H_j'$, then $|H_j'| \geq 2$ and H_j' is not the bottom layer of a closed set.*

(c) *If $u \in H_j'$, then H_j' cannot be a Type 1 blocker if there is a $v \in H_{j-1}'$ with $v < u$ in P_G.*

Proof. Part (a) follows from the fact that u is the endpoint of a transition between H_i' and H_{i+1}'.

A layer H_j' can have one point only if it is the bottom layer of a closed set (otherwise the bumpno algorithm would have made its single element a bump cutter). If H_j' were the bottom layer of a closed set, then for every $w \in H_j'$ and $v \in H_{j-1}'$ we have $v < w$ in P_G. Since $j - 1 \geq i$, by (a) this shows that the bypass element u could not have come from a bottom layer H_j'.

Suppose H_j' is a Type 1 blocker and there is a $v \in H_{j-1}'$ with $v < u$ in P_G. This is in contradiction with (a) again, proving (c). □

The next two lemmas discuss rearrangements that involve the bypass element.

LEMMA 4.6. *Suppose we have constructed an* $\mathrm{HC}_1(c_1, x)$ *on* $G|x$, *where* x *is the exit point in* L *from a layer* H_i' *that was either a blocker or the top layer of a closed set* A_k; $\mathrm{HC}_1(c_1, x)$ *was enlarged into an* $\mathrm{HC}_u = \mathrm{HC}_1(c_1, x) \cup \mathrm{HC}_2(c_1, x) - \{(c_1, x)\}$, *where* $\mathrm{HC}_2(c_1, x) = \{(c_1, x), L[x, u], (u, c_1)\}$ *with a bump cutter* $u = u_j \in U$ $(j > k)$ *the bypass element* (*for the blocker* H_i' *or the bump cutter* u_k). *Let* H_t' $(t > i)$ *be the top layer of the closed set* A_j, *and let* d *be the point covered by* u_j *in* L *and* c *be the entry point to* H_t' *in* L. *Then* L *and* HC_u *can be rearranged so that* c *is the exit from* H_t' *in* L, u *covers* c *in* L *and* (c, u) *is an edge in* HC_u.

Proof. By Lemma 4.5, u must be incomparable to every point in H_t', in particular, to c. From the bump number algorithm we know that L can be rearranged, so that c becomes its exit point from H_t', without affecting its optimality. How does this rearrangement affect HC_u? If H_t' is also the bottom layer of the closed set A_j, then the bump cutter u_{j-1} is incomparable to every element of H_t', so we can simply exchange c and d in L and HC_u. Otherwise, if H_t' was entered via the short transition (e_1, c), with $e_1 \in H_{t-1}'$, then making c the exit point from H_t' forces us to use a different entry point, but there must exist another short transition (e_2, v_1) between H_{t-1}' and H_t' to a $v_1 \in H_t' - c$, since H_t' was reached by a `grow` step by Lemma 4.5(b). If $e_3 \neq e_2$ was the entry point to H_{t-1}' in L, then we can easily make e_2 the exit point from H_{t-1}' and rearrange L and HC_u between e_3 and u in the following order: e_3, $H_{t-1}' - \{e_3, e_2\}$ in any order, followed by $e_2, v_1, H_t' - \{v_1, c\}$ in any order, and followed by c. If e_2 was the entry point to H_{t-1}' in L, then making it the exit from H_{t-1}' forces us to use a different entry point. However, following an argument similar to the one above, there is a $v_2 \in H_{t-1}' - e_2$ such that there is a transition (e_3, v_2) between H_{t-2}' and H_{t-1}', and so on. Inductively carrying on with this, we either reach a layer where we are not forced to make further changes or reach the blocker layer H_i' for which u was used as the bypass element. (If we reach H_i' by these forcings, then all layers between H_i' and H_t' must either be Type 1 blockers or be of size 2.) If H_i' was a Type 2 blocker, with x its potentially critical (exit) element, then the forced changing of the entry point to H_{i+1}' to a, say, $e_r \in H_{i+1}'$, does not force further changes since x must be the starting point for the transition ending in e_r. Suppose now that H_i' was a Type 1 blocker itself, with potentially critical elements x and y, with x being the exit from H_i' in L. If $\mathrm{HC}_1(c_1, x)$ reached x as a bypass element, then, by Lemma 4.5(c), x must be incomparable (in P_G) to every $v \in H_{i-1}'$; therefore, H_{i-1}' cannot be a blocker; if $\mathrm{HC}_1(c_1, x)$ reaches x by an application of the algorithm `twopaths`, then H_{i-1}' cannot be a blocker because, to bypass it, HC_1 would have had to reach at least u. Let $e_r, e_{r+1} \in H_{i-1}' (e_r \neq e_{r+1})$ be the starting points of the transitions (e_r, y) and (e_{r+1}, x). Forcing y to be the exit point from H_i' forces us to change L, to make it use (e_{r+1}, x) instead of (e_r, y) between H_{i-1}' and H_i'. This, however, forces no further changes, since either H_{i-1}' is the bottom layer of A_j or by `rules 1` and `2` of `bumpno` L must have used a transition (a, b) from H_{i-2}' to H_{i-1}', with $b \in H_{i-1}' - \{e_r, e_{r+1}\}$. In any case the set of reserved transitions used by `twopaths` does not change, we only have to change $\mathrm{HC}_1(c_1, x)$ into an $\mathrm{HC}_1(c_1, y)$ by moving c_1 to become a neighbor of y instead of a neighbor of x (by the proper selection of horizontal edges in H_i'). This $\mathrm{HC}_1(c_1, y)$ can be continued by combining it with a new $\mathrm{HC}_2(c_1, y) = \{(c_1, y), L[y, u], (u, c_1)\}$, using the rearranged L. In this L the point c in the statement of the lemma is the exit point from H_t', and (c, u) is an edge as required. □

LEMMA 4.7. *Suppose we have constructed an* $\mathrm{HC}_1(c_1, x)$ *on* $G|x$, *where* x *is the exit point in* L *from a layer* H_i' *that was either a blocker or the top layer of a closed set* A_k; $\mathrm{HC}_1(c_1, x)$ *was enlarged into an* $\mathrm{HC}_u = \mathrm{HC}_1(c_1, x) \cup \mathrm{HC}_2(c_1, x) - \{(c_1, x)\}$, *where* $\mathrm{HC}_2(c_1, x) = \{(c_1, x), L[x, u], (u, c_1)\}$ *with* $u \in H_j'$ *the bypass element* (*for the blocker* H_i' *or the bump cutter* u_k). *If* H_j' *is a Type* 2 *blocker and* u *is not its potentially critical* (*exit*) *point, then* $|H_j'| > 2$, *and* L *and* HC_u *can be rearranged so that* u *becomes the second point from* H_j' *in* L.

Proof. Suppose that, contrary to the lemma, $H'_j = \{x', u\}$ with x' its potentially critical (exit) element. If H'_j was entered in L via a transition (e_1, u) from some $e_1 \in H'_{j-1}$, then $e_1 < x'$ in P_G, since otherwise we should have $e_1 \in H'_j$ by the definition of the layers. On the other hand, there is an $e_2 \in H'_{j-1}$ with (e_2, x') a transition, since H'_j was reached by a `grow` step by Lemma 4.5(b). If $x <_L e_2$, then (e_2, u) is also a transition, by Lemma 4.5(b), which would make $e_2 \in H'_j$. If $x \not<_L e_2$, then $i = j-1$, and H'_i cannot be the top layer of a closed set or a Type 1 blocker, it can be only a Type 2 blocker. In this case, however, (x, x') and (x, u) would be transitions from H'_{j-1} to H'_j, contradicting that $x \in H'_{j-1}$. So $|H'_j| > 2$ and $x' \neq u$ is its exit point. If u is not the entry point to H'_j in L, then u can be freely moved to be second from H'_j in L. If u was the entry point, then, by Lemma 3.6, there must be an alternative optimal linear extension in which u is not the entry point to H'_j. This means that there is a $d \in H'_j - \{x', u\}$ and $c \in H'_{j-1}$ with (c, d) a transition. We can rearrange L so that it uses d for entry to H'_j and u follows d in L. This may force backward changes in the transitions used earlier, but it can be proved, by using essentially the same argument as in the proof of the previous lemma, that the 'chain' of forcings would have to end at or before reaching H'_i. This means that these changes could affect only the HC_2 of the lemma but not HC_1. Accordingly, the rearrangement of L can easily be incorporated into HC_u. □

In this section we deal with orders that were *not* strictly grown, but we state our main theorem so that it includes the strictly grown case too:

THEOREM 4.8. *Let G be a cocomparability graph. Then G has a Hamiltonian cycle if and only if $b(P_G) = 0$ and P_G has no critical element.*

Proof. Theorem 3.1 and Lemma 3.4 prove that both conditions are necessary. To prove that they are also sufficient we use induction on the number of closed sets created by the bump number algorithm. If $m = 1$ (i.e., dual order is strictly grown), then Theorem 4.3 proves sufficiency.

Inductive hypothesis: If $b(P_G) = 0$, P_G has no critical element, and its dual order has at most m closed sets, then G has a Hamiltonian cycle. Furthermore, if $c, x \in H_0$ are not both potentially critical, then G has a Hamiltonian cycle that contains the edge (c, x).

Consider now a P_G that satisfies the conditions of the theorem and whose dual order has $m+1$ closed sets, $A_1, A_2, \ldots, A_{m+1}$ with bump cutters $u_1, u_2, \ldots, u_m$ between them.

Case 1. There is a blocker in A_1 that cannot be bypassed by using an element from A_1, i.e., the blocker contains an element that is critical in the subposet induced by A_1. (Note that a blocker can never be the top layer of a closed set, by definition.) Let $H'_i \subseteq A_1$ be the one of these blockers that is on the lowest level, and let $x \in H'_i$ be the last element from H'_i in an optimal linear extension L of P_G. Since x is not critical, there is a linear extension L' of $P_G - x$ such that $b(L') = 0$. Let c be the last element in L' from $H'_{i-1} \cup H'_i$ and u be the (bypass) element immediately following it. If $u \in A_1$ were true, then this u could be used to bypass the blocker H'_i within A_1, so $u \in V - A_1$, i.e., there is no transition from $H'_i - x$ to any layer of A_1 above H'_i.

Case 1a. H'_i is a Type 1 blocker.

By Corollary 4.4 there is a $\mathrm{HC}_1(c, x)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1} \cup H'_i$. On the other hand, $\mathrm{HC}_2(c, x) = \{(c, x), L[x, u], (u, c)\}$ is a cycle too, so $\mathrm{HC}_u = \mathrm{HC}_1(c, x) \cup \mathrm{HC}_2(c, x) - \{(c, x)\}$ is a Hamiltonian cycle in $G|u$, bypassing the blocker H'_i.

Case 1b. H'_i is a Type 2 blocker.

If $c \in H'_i$, then by Corollary 4.4 there is a $\mathrm{HC}_1(c, x)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_i$. $\mathrm{HC}_1(c, x)$ can be enlarged into a Hamiltonian cycle HC_u of $G|u$ the same way as in Case 1a.

If $c \in H'_{i-1}$, then c is not comparable to any element in $H'_i - x$. Since every $v \in H'_i - x$ is before c in L', by definition, there is a $c' \in (H'_{i-1} - c)$ and $d \in (H'_i - x)$ such that (c', d)

is a short transition between H'_{i-1} and H'_i. If c and c' are not the only endpoints of short transitions from H'_{i-2} to H'_{i-1}, or $H'_{i-1} = H_0$, or $|H'_{i-1}| = 2$, then, by Corollary 4.4, there is a $\mathrm{HC}_0(c', c)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1}$. If $|H'_{i-1}| > 2$, $i - 1 > 0$, and every $v \in H'_{i-1} - \{c, c'\}$ is above every element of H'_{i-2}, then one of these v must be the starting point of a short transition into H'_i, since otherwise the layer H'_{i-1} would be a Type 1 blocker that could not be bypassed within A_1, contradicting the assumption that H'_i is on the lowest level of these blockers. So one of the $v \in H'_{i-1} - \{c, c'\}$ could play the role of c' above. In summary, there is a $\mathrm{HC}_0(c', c)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1}$ such that c' is the starting point of a short transition (c', d) to H'_i and c is not comparable to any element in $H'_i - x$. $\mathrm{HC}_0(c', c)$ can be enlarged into a $HP_1(c, x)$ of $G|x$ by inserting d, $H'_i - \{x, d\}$, and x between c' and c. $\mathrm{HP}_1(c, x)$ can be enlarged into a Hamiltonian cycle HC_u of $G|u$ the same way as in Case 1a.

Case 2. There is no blocker that cannot be bypassed within A_1. Let H'_i be the top layer of A_1 and $x \in H'_i$ the last element from H'_i in an optimal linear extension L of P_G. Since u_1, the bump cutter between A_1 and A_2, is not critical, there is a linear extension L' of $P_G - u_1$ with $b(L') = 0$. Let $c \in H'_i$ be the last element in L' from H'_i and $u \in V - \{A_1 \cup u_1\}$ be the element immediately following it.

Case 2a. If $x \neq c$, then, by Corollary 4.4, there is a $\mathrm{HC}_1(c, x)$ in the subgraph induced by A_1. $\mathrm{HC}_2(c, x) = \{(c, x)\} \cup L[x, u] \cup \{(u, c)\}$ is also a cycle, so $\mathrm{HC}_u = \mathrm{HC}_1(c, x) \cup HC_2(c, x) - \{(c, x)\}$ is a Hamiltonian cycle in the subgraph $G|u$.

Case 2b. If x and c cannot be made different, i.e., for all possible choices of L and L' they always exit H'_i through the same $x = c$, then by Lemma 3.7 there must be an $e \in H'_{i-1'}$, which would move up to become the exit point from $H'_{i-1} \cup H'_i - x$ if x was deleted from P_G. It also follows that there is a, possibly new, bypass element $u \in V - A_1$, with (e, u) a transition and u immediately following e in an optimal linear extension L'' of $P_G - x$. We show that e cannot be potentially critical: Since e is the exit point from $H'_{i-1} \cup H'_i - x$ in L'', e is incomparable to every $v \in H'_i - x$ and there must be at least one transition from $H'_{i-1} - e$ to $H'_i - x$, say (f, f'). So H'_{i-1} cannot be a Type 2 blocker. Suppose H'_{i-1} is a Type 1 blocker with potentially critical elements e and f. By Lemma 3.8(1) e and f would have to be critical in the poset induced by A_1, contradicting the assumption that every blocker within A_1 can be bypassed within A_1. So e is not a potentially critical element (and H'_{i-1} is not a blocker), and therefore, there is an optimal linear extension L of P_G in which e is the second last element from H'_{i-1} with a $g \in H'_{i-1}$ the exit point. By Corollary 4.4 there is a $\mathrm{HC}_1(e, g)$ in the subgraph induced by $H'_0 \cup H'_1 \cup \cdots \cup H'_{i-1}$. $\mathrm{HC}_2(e, g) = \{(e, g), L[g, u], (e, u)\}$ is also a cycle, and $\mathrm{HC}_u = \mathrm{HC}_1(e, g) \cup \mathrm{HC}_2(e, g) - \{e, g\}$ is a Hamiltonian cycle in the subgraph $G|u$.

Combining all the above cases, we have shown the existence of a Hamiltonian cycle HC_u in the subgraph $G|u$. We also note that the bypass element u was always chosen by the linear extension L', and therefore, it must be the closest (lowest level) bypass element available. In the remainder of the proof we show how to enlarge this HC_u into a Hamiltonian cycle of G using the inductive hypothesis. Let B denote the set of elements following u in L.

Case i. The element u in HC_u is one of the bump cutters, say, $u = u_j$.

Let H'_t be the top layer in A_j and $y \in H'_t$ be the element immediately preceding u_j in L. Since u_j is not critical, there is a linear extension L' of $P_G - u_j$ with $b(L') = 0$. Let $c \in H'_t$ be the last element in L' from A_j.

If $u_j = u_1$ (this can happen only if HC_u was constructed earlier under Case 1 of the proof), then there must be a transition from a $v \in A_1$ to a (lowest level) $w \in A_k (k > 1)$, since otherwise the dual order of P_G could not have been collapsed. Since (v, w) is not a short transition, there must also exist a transition from the top layer of A_1 to w (otherwise transitivity would preclude (v, w) being a transition), so we assume, without the loss of generality, that $v \in H'_t$. Furthermore, since $u_j = u_1$ was the bypass element for a blocker, u_1 must be incomparable to every element of H'_t, in particular, to v. We can assume, without the loss of generality, that the optimal linear extension L, which we used to construct HC_u, had v as its last element from H'_t. Therefore, (v, u_1) was an edge in HC_u. $\mathrm{HC}_2(v, u_1) = \{(v, u_1), L[u, w], (w, v)\}$ is a cycle, and $\mathrm{HC}_w = \mathrm{HC}_u \cup \mathrm{HC}_2(v, u_1) - \{(v, u_1)\}$ is a Hamiltonian cycle in the subgraph $G|w$. If $w = u_j$ for some j, then we have $j > 1$. If $w \in H'_j$ for some j, then we have a cycle that reached into a layer above H'_t and this situation will be dealt with under Case ii.

So if our HC_u goes to a bump cutter $u = u_j$, we can now assume that $j > 1$. If $y = c$, then the subposet induced by $(y, u_j) \cup B$ has no critical element, bump number 0, and fewer than $m + 1$ closed sets, so by the inductive hypothesis there is a $\mathrm{HC}(y, u_j)$ in the subgraph induced by these elements. By Lemma 4.2 $\mathrm{HC} = \mathrm{HC}_u \cup \mathrm{HC}(y, u_j) - \{(y, u_j)\}$ is a Hamiltonian cycle in G.

If $y \neq c$ and c was the entry point to H'_t in L, then, by Lemma 4.6, L and HC_u can be rearranged so that c becomes the exit point from H'_t in L and we have the previous case again. If $y \neq c$ and c was not the entry point to H'_t in L, then c can be freely moved in L so that c becomes the exit point from H'_t in L ($u = u_j$ is not comparable to any element of H'_t since u was a bypass element for something below the layer H'_t, so $c \parallel u_j$ in P_G). Thus, we have the case of the previous paragraph again.

Case ii. The bypass element u is not one of $\{u_1, u_2, \ldots, u_m\}$ and $u \in H'_j$.

By Lemma 4.5(b) $|H'_j| \geq 2$ and we can repeat the argument used to continue the cycle HC_3 in Case i of the proof of Theorem 4.3. The only change needed is replacing the inductive hypothesis with the current one and using the argument to continue the current HC_u instead of HC_3 of the proof of Theorem 4.3. Therefore, we omit the details. □

Since there are very few known necessary and sufficient conditions for a graph to have a Hamiltonian cycle, we feel it is important to relate Theorem 4.8 in graph-theoretic terms:

COROLLARY 4.9. *A cocomparability graph $G = (V, E)$ has a Hamiltonian cycle if and only if*

(1) *G has a Hamiltonian path*;

(2) *For every $v \in V$ the subgraph $G - v$ induced by $V - \{v\}$ has a Hamiltonian path.*

Proof. The corollary is a direct consequence of Theorems 3.1 and 4.8. □

5. The algorithms. Theorem 4.8 means that we can easily state an algorithm for the *Hamiltonian Cycle Decision* problem on cocomparability graphs.

ALGORITHM 5.1.

```
procedure hamiltonian_cycle ($G$)
    Input:    A cocomparability graph $G$.
    Output:   YES if $G$ has a Hamiltonian cycle, NO otherwise.
    Step 1.   Find a transitive orientation of $G^C$ and
              call it $P_G$.
    Step 2.   Call bumpno($P_G$)
              If $b(P_G) > 0$ or ($b(P_G) = 0$ but the dual order is not
                  collapsed into a single antichain) then output
                  ''NO'' and STOP.
    Step 3.   For each potentially critical element $x \in P_G$ do;
                  Call bumpno($P_G - x$)
                  If $b(P_G - x) > 0$ then output ''NO'' and STOP.
              end;
    Step 4.   Output ''YES'' and STOP.
```

THEOREM 5.2. *Algorithm* 5.1 *solves the Hamiltonian Cycle Decision problem for a cocomparability graph G in $O(hn^2)$ time and $O(n^2)$ space, where n is the number of vertices in G and h is the height of P_G, that is, the size of a largest independent set of G.*

Proof. The correctness of the algorithm is a direct consequence of Theorem 3.1, Lemma 3.4, and Theorem 4.8.

The claimed complexity follows from the following observations: G^C and a transitive orientation for it can be found in $O(n^2)$ time and space [18]. The bumpno algorithm for P_G requires at most $O(n^2)$ time and space [10]. It is clear that P_G has at most h blockers or bump cutters, so it can have at most $O(h)$ potentially critical elements. Calling bumpno for all $P_G - x$, where x is potentially critical, will require $O(hn^2)$ time and $O(n^2)$ space. □

Algorithm 5.1 solves the *Hamiltonian Cycle Decision* problem but does not find such a cycle in case the answer is YES. In the remainder of this section we present an algorithm that also constructs a Hamiltonian cycle, if it exists.

Algorithm 5.3 starts with preprocessing steps, which identify certain cases when G cannot have a Hamiltonian cycle. After this the algorithm calls the main procedure hamiltonian, which takes its detailed (layered) input from bumpno and starts the construction of a Hamiltonian cycle layer by layer, by the previously defined procedure twopaths. The procedure twopaths builds two parallel paths through the layers in G until it either reaches the top layer H_h' or a blocker layer H_i' or the bump cutter u_1. In the first case the two independent paths can easily be joined into a Hamiltonian cycle in G. In the second case the two independent paths are joined into a Hamiltonian cycle covering the subgraph induced by $H_0' \cup H_1' \cup \cdots \cup H_i'$ and the procedure bypass1 or bypass2 is called depending on whether H_i' is a Type 1 or Type 2 blocker. In the third case the two independent paths are joined into a Hamiltonian cycle of the subgraph induced by the first closed set A_1 and the procedure bypass3 is called.

The procedure bypass1 (H_i'; x, y, $\mathrm{HC}_1(c_1, x)$) looks for a bypass element u that can be used to grow the current cycle HC_1 beyond the layer H_i'. If such u does not exist, then the potentially critical elements x, y in H_i' are critical and G has no Hamiltonian cycle. If a bypass element is found, then HC_1 is enlarged into an HC_u, covering all the points in $G|u$.

The procedure bypass2 (H_i'; x, $\mathrm{HC}_1(c_1, x)$) looks for a bypass element u that can be used to grow the current cycle HC_1 beyond the Type 2 blocker H_i'. If no u is found, then the potentially critical (exit) point x from H_i' is critical and G has no Hamiltonian cycle. If a bypass element is found, then HC_1 is enlarged into an HC_u, covering $G|u$.

The procedure bypass3 (H_i'; x, u_k, $\mathrm{HC}_1(c, x)$) looks for a bypass element u that can be used to grow the current cycle beyond the closed set A_k (i.e., bypass the bump cutter u_k). If such u does not exist, then the bump cutter u_k is critical and G has no Hamiltonian cycle. If a bypass element is found, then HC_1 is enlarged into an HC_u, covering $G|u$.

All three bypass procedures return the control to the main procedure, hamiltonian, which either completes the cycle if the top layer H_h' has been reached or calls the procedure continue1 (if the bypass element u was a bump cutter itself) or the procedure continue2 (if the bypass element u came from a layer H_j').

The procedure continue1 ($\mathrm{HC}_1(c_1, u_j)$, H_t') tries to grow the cycle beyond the bypass element $u = u_j$. This is done by either directly finding a new bypass element u for u_j or by recursively calling the procedure hamiltonian to find a Hamiltonian cycle on the subgraph induced by $\{c_1, u\} \cup B$, where B is the set of elements not covered by HC_1. In the first case, if the cycle can be directly grown beyond u, this is done and control is returned to the calling program (hamiltonian). If the cycle cannot be grown directly, then hamiltonian is called on the subgraph induced by $\{c_1, u_j\} \cup B$ and it will either find a critical element in this subgraph (which will be a critical element in G) or it will return a Hamiltonian cycle on this subgraph, which also contains the edge (c_1, u_j) and, so, can be combined with our original $\mathrm{HC}_1(c_1, u_j)$ into a Hamiltonian cycle of G.

The procedure `continue2` ($\mathrm{HC}_1(c_1, u)$, H'_j) tries to grow the cycle beyond the bypass element u and its layer H'_j. It tries to grow the cycle directly, as above, or by calling `bypass1` or `bypass2` or it recursively calls the procedure `hamiltonian` on the appropriately defined subgraph. The procedure `hamiltonian` then either returns some critical element in the subgraph, which is also critical in P_G, or a Hamiltonian cycle of the subgraph, which can be combined with the original $\mathrm{HC}_1(c_1, u)$ into a Hamiltonian cycle of G.

ALGORITHM 5.3.

```
procedure hamiltonian_cycle_construct ($G$)
   Input :  A cocomparability graph $G$.
   Output:  A Hamiltonian cycle in $G$ or ''$b(P_G) > 0$'' or some
                critical elements which show that $G$ has no
                Hamiltonian cycle.

   (Steps 1–3 are preprocessing steps.)

   Step 1.  Find a transitive orientation of $G^C$ and call it $P_G$.
   Step 2.  Call bumpno($P_G$).
            If $b(P_G) > 0$ or ($b(P_G) = 0$ but the dual order is not
                collapsed into a single antichain then output
                ''$G$ has no Hamiltonian cycle'' output
                ''$b(P_G) > 0$'' or any bump cutter as critical
                and STOP.
   Step 3.  ($b(P_G) = 0$ and the dual order was collapsed into a single antichain.
                Suppose that procedure bumpno has created $m + 1$ closed
                sets $A_1, A_2, \dots, A_{m+1}$ and $m$ bump cutters $u_1, u_2, \dots, u_m$ during
                its execution. Recapture all the closed sets created by bumpno,
                before collapsing.)
            For i = 0 to $m$ do;
                Put $A_{m+1-i} := A_{m+1-i} - \bigcup_{j=1}^{m-i}(A_j \cup U_j)$.
   Step 4.  Call procedure hamiltonian ($V$).
```

PROCEDURE 5.4.

```
procedure hamiltonian ($V$; $v, w$)
   Input :  A partial order $P_G$ (of a cocomparability graph $G$)
                on the set $V$. The decomposition of $P_G$ into
                closed sets $A_1$, $A_2, \dots, A_{m+1}$ and bump cutters
                $U = \{u_1, u_2, \dots, u_m\}$, a bump-optimal linear
                extension $L$ of $P_G$, the modified layers
                $H'_0, H'_1, \dots, H'_h$. A set $R$ of pairs of reserved
                independent transitions between every
                pair of consecutive layers, up to the first
                blocker layer, in the lowest closed set $A_1$.
                The blocker layers with their potentially
                critical elements identified. Optional input
                is $v, w \in H'_0$. ( When they are included,
                this signals that we want a Hamiltonian
                cycle containing edge $(v, w)$.)
```

```
Output:  A Hamiltonian cycle in $G$ or some critical
             elements in $P_G$, precluding the existence
             of such cycle.
Step 1.  If $A_1 = H'_0$ then go to Step 6.
         If $A_1$ contains no blockers then let $i$ be the
             index of its top layer $H'_i$, otherwise let i be
             the index of its lowest level blocker $H'_i$.
         Call twopaths ($H'_0 \cup H'_1 \cup \cdots \cup H'_i; R$)
         Connect the endpoints of the paths $\pi_1$ and $\pi_2$ in
             $H'_0$ and $H'_i$ to form $\mathrm{HC}_1$. Insert all the
             points missed, by both $\pi_1$ and $\pi_2$,
             in a horizontal edge in their layer
             ($\mathrm{HC}_1$ must contain a horizontal edge in every layer.)
         If the optional $v, w \in H'_0$ were specified then
             modify $\mathrm{HC}_1$ so that $(v, w)$ is an edge in $HC_1$.

There are 4 cases treated in Steps 2–5.

Step 2.  ($H'_i$ is a Type 1 blocker with potentially critical elements $x$ and $y$)
         Call bypass1 ($H'_i; x, y, \mathrm{HC}_1(c_1, x)$)
         Go to Step 7.
Step 3.  ($H'_i$ is a Type 2 blocker with potentially critical element $x$)
         Call bypass2 ($H'_i;\ x, \mathrm{HC}_1(c_1, x)$)
         Go to Step 7.
Step 4.  ($H'_i$ is the top layer of a closed set and $P_G$ is not strictly grown)
         Let $x$ be the last element from $H'_i$ in $L$ and $u_j$ its
         cover in $L$.
         Call bypass3 ($H'_i; x, u_j, \mathrm{HC}_1(c_1, x)$)
         Go to Step 7.
Step 5.  ($P_G$ is strictly grown)
         Go to Step 9.
Step 6.  ($A_1 = H'_0$) Let $x$ be the last element from $H'_0$ in $L$.
         If $|H'_0| > 1$ and $c_1$ is the point covered by $x$ in $L$
             then find a Hamiltonian cycle $\mathrm{HC}_1(c_1, x)$ in the
             (complete) graph induced by $H'_0$.
             Call bypass3 ($H'_0; x, u_1, \mathrm{HC}_1(c_1, x)$)
         else ($x$ is the only point in $H'_0$) put $\mathrm{HC}_1 := \emptyset$
             Call bypass3 ($H'_0; x, u_1, \mathrm{HC}_1$).
Step 7.  (The point $u$ is the last (bypass) element reached by our cycle)
         If $u \in H'_h$ then go to Step 8.
         If $u = u_j \in U$ then call continue1 ($\mathrm{HC}_1(c_1, u)$, $H'_t$)
             ($H'_t$ is the top layer of $A_j$)
         else ($u \in H'_j$ for some $j < h$)
             call continue2 ($\mathrm{HC}_1(c_1, u)$, $H'_j$)
         Repeat Step 7.
Step 8.  (We have reached the top layer $H'_h$)
         If $u$ is the last point in $L$ then go to Step 9.
         (At this stage $u$ cannot be the only entry point to $H'_h$, as this would
                mean $v < w$ for every $v \in H'_{h-1}$ and $w \in H'_h - u$, contradicting
                that the dual order of $P_G$ was collapsed into a single antichain
                in our preprocessing. Since we always try to make the bypass
                element $u$ the second one from its layer in $L$, this must be
                the case here too.)
            Insert the remaining elements from $H'_h - \{c_1, u\}$ in
                $\mathrm{HC}_1(c_1, u)$ between $c_1$ and $u$.
Step 9.     If $\mathrm{HC}_1$ contains all layers then output $\mathrm{HC}_1$ as a
                Hamiltonian cycle in $G$ and STOP, otherwise
                return $\mathrm{HC}_1$ to the calling procedure.
END;
```

PROCEDURE 5.5.

```
procedure bypass1 ($H'_i$; $x, y, \mathrm{HC}_1(c_1, x)$)
($H'_i$ is a Type 1 blocker with critical elements $x$ and $y$, $(c_1, x)$ is a horizontal edge
    in $\mathrm{HC}_1$ )
  Step 1.   Let $B = x|L$. Find a highest level $u \in B$ with $(c_1, u)$
                a transition. If no such $u$ exists then go to
                Step 2, otherwise go to Step 3.
  Step 2.   Find a highest level $u \in B$ with $(a, u)$ a transition
                for some $a \in H'_i - \{x, y\}$. If no such $u$ exists then
                output''$x$ and $y$ are critical'' and STOP.
            Rearrange $L$ and $\mathrm{HC}_1(c_1, x)$ so that $(a, x)$ becomes an
                edge in both (i.e., move $a$ between $c_1$ and $x$ by a
                rearrangement of Type 2).
                Put $c_1 := a$.
  Step 3.   If $u \notin U$ (i.e., $u \in H'_j$ for some $j \geq i + 1$) then modify
                $L$ (if possible) so that $u$ is the second point
                from $H'_j$ in $L$.
                (If this rearrangement of Type 1 is not possible then
                $H'_j$ must be a blocker itself and it will be determined
                later — in the procedure continue2 — whether this
                blocker can be bypassed too. This comment also
                applies in the remaining procedures where this type
                of rearrangement is attempted unsucessfully.)
  Step 4.   Let $a$ be the element covered by $u$ in $L$.
            Put $\mathrm{HC}_2(c_1, x) := \{(c_1, x), L[x, u], (u, c_1)\}$;
                $\mathrm{HC}_1(a, u) := \mathrm{HC}_1(c_1, x) \cup \mathrm{HC}_2(c_1, x) - \{(c_1, x)\}$; $c_1 := a$.
  END;
```

PROCEDURE 5.6.

```
procedure bypass2 ($H'_i$; $x, \mathrm{HC}_1(c_1, x)$)
($H'_i$ is a Type 2 blocker with potentially critical (exit) element $x$.)
  Step 1.   Let $B = x|L$. Find a highest level $u \in B$ with $(c_1, u)$
                a transition. If no such $u$ exists go to
                Step 2, otherwise go to Step 8.
  Step 2.   Find a highest level $u \in B$ with $(a, u)$ a transition
                for some $a \in H'_i - \{x, c_1, y\}$, where $y$ is the entry
                point to $H'_i$ in $L$. If no such $u$ exists go to
                Step 3, otherwise go to Step 7.
Step 3.  Find a highest level $u \in B$ with $(y, u)$ a transition.
             If no such $u$ exists then go to Step 4,
             otherwise go to Step 6.
Step 4.  Find a highest level $u \in B$ with ($(e, u)$ a transition
             to $u$, $e \in H'_{i-1}$, $e < x$ in $P_G$ and $e$ is incomparable
             to every other $v \in H'_i$). If no such $u$ exists
             then output ''$x$ is critical'' and STOP.
Step 5.  Rearrange $L$ and $\mathrm{HC}_1(c_1, x)$ by moving $e$ immediately
             before $x$ and performing the implied changes
             both in $L$ and $\mathrm{HC}_1$ in the sense of a
             rearrangement of Type 4. This results in
             a $\mathrm{HP}_1(e, x)$.
         If $u \notin U$ (i.e., $u \in H'_j$ for some $j > i$) then make
             $u$ the second point in $L$ from $H'_j$, if possible.
             Let $a$ be the element covered by $u$ in $L$ and
             $\mathrm{HP}_2(x, e) := L[x, u] \cup \{(u, e)\}$.
         Put $\mathrm{HC}_1(a, u) := \mathrm{HP}_1(e, x) \cup \mathrm{HP}_2(x, e), c_1 := a$ and go to END.
Step 6.  Find a $d \in H'_i - \{x, y\}$ with $(c, d)$ a transition for some
             $c \in H'_{i-1}$. If no such $d$ exists then output
             ''$x$ is critical'' and STOP,
             (we do not need to consider Step 4 here because the
             nonexistence of $d$ implies the nonexistence of $e$ in Step 4),
             otherwise rearrange $L$ and $\mathrm{HC}_1$ by moving $y$
             immediately before $x$ in $L$, making $d$ the
             entry point to $H'_i$ in $L$ and all the implied
             changes like in a rearrangement of
             Type 2.
         Put $c_1 := y$ and go to Step 8.
Step 7.  Move $a$ between $c_1$ and $x$ in both $L$ and $\mathrm{HC}_1$ and put
             $c_1 := a$.
Step 8.  If $u \notin U$ (i.e., $u \in H'_j$ for some $j > i$) then make $u$
             the second element from $H'_j$ in $L$, if possible.
         Let a be the element covered by $u$ in $L$.
             Let $\mathrm{HC}_2(c_1, x) := \{(c_1, x), L[x, u], (u, c_1)\}$.
             Put $\mathrm{HC}_1(a, u) := HC_1(c_1, x) \cup \mathrm{HC}_2(c_1, x) - \{(c_1, x)\}; c_1 := a$.
END;
```

PROCEDURE 5.7.

```
procedure bypass3 ($H'_i$; $x, u_k, \mathrm{HC}_1(c_1, x)$)
($H'_i$ is the top layer in the closed set $A_k$, $x$ is its last element in $L$, $x$ covers $c_1$ in $L$ and
    $u_k$ is the bump cutter between $A_k$ and $A_{k+1}$.)
  Step 1.  If $A_1 = H'_i = \{x\}$ then find a highest level
               $u \in V - \{x, u_1\}$ with $(x, u)$ a transition
               ($u$ must exist since the dual order was collapsed),
               otherwise go to Step 4.
               If $u \in \{u_2, u_3, \ldots, u_m\}$ go to Step 3,
               otherwise go to Step 2.
  Step 2.  ($u \in H'_j$ for some $j > i$): Modify $L$ (if possible)
               so that $u$ is the second point from $H'_j$ in $L$
               (rearrangement of Type 1).
```

```
Step 3.  Let $a$ be the element immediately preceding $u$ in $L$.
             Put $\mathrm{HC}_1(a,u) := \{L[x,u], (u,x)\}$, $c_1 := a$ and go to END.
Step 4.  (HC$_1$ has reached $H_i'$ but not beyond.)
         Find a highest level
             $u \in A_{k+1} \cup u_{k+1} \cup A_{k+2} \cup u_{k+2} \cup \cdots \cup A_{m+1}$
             with $(c_1,u)$ a transition from $H_i'$. If no such $u$
             exists then go to Step 5. If $u \in H_j'$ for some $j$
             then modify $L$ (if possible) to make $u$ the
             second point from $H_j'$ in $L$ (rearrangement of Type 1).
         Put $\mathrm{HC}_1(a,u) := \mathrm{HC}_1(c_1,x) \cup L[x,u] \cup \{(u,c_1)\} - \{(c_1,x)\}$
             and $c_1 := a$, where $a$ is the point immediately
             before $u$ in $L$. Go to END.
Step 5.  Find a highest level $u \in A_{k+1} \cup u_{k+1} \cup \cdots \cup A_{m+1}$ with
             $(c,u)$ a transition for some $c \in H_i' - \{x,y\}$, where
             $y$ is the entry point to $H_i'$ in $L$. If no such
             $u$ exists then go to Step 6. If $u \in H_j'$ for some
             $j$ then modify $L$ (if possible) to make $u$ the
             second point from $H_j'$ in $L$ (rearrangement of Type 1).
         Move $c$ between $c_1$ and $x$ both in $L$ and $\mathrm{HC}_1(c_1,x)$ .
         Put $\mathrm{HC}_1(a,u) := \mathrm{HC}_1(c,x) \cup L[x,u] \cup \{(u,c)\} - \{(c,x)\}$
             and $c_1 := a$, where $a$ is the point immediately
             preceding $u$ in $L$. Go to END.
Step 6.  Find a $u \in A_{k+1} \cup u_{k+1} \cup \cdots \cup A_{m+1}$ with $(y,u)$ a transition.
             If no such $u$ exists then go to Step 7.
             If $|H_i'| > 2$ then modify $L$ and $\mathrm{HC}_1(c_1,x)$, so that
             a $d \in H_i' - \{x,y\}$ is used as entry point to $H_i'$
             in $L$ and $\mathrm{HC}_1$ and move $y$ immediately before
             $x$ in both $L$ and $\mathrm{HC}_1$ (like in a rearrangement of Type 2),
             otherwise if no such $d$ exists then output
             ''$x$ and $y$ are critical'' (by Lemma 3.8(1) )
             and STOP.
         Put $c_1 := y$. If $u \in H_j'$ for some j then modify $L$
             (if possible) to make $u$ the second point from
             $H_j'$ in $L$ (rearrangement of Type 1).
         Put $\mathrm{HC}_1(a,u) := \mathrm{HC}_1(c_1,x) \cup L[x,u] \cup \{(u,c_1)\} - \{(c_1,x)\}$
             and $c_1 := a$, where $a$ is the point immediately
             preceding $u$ in $L$. Go to END.
Step 7.  ($x$ is the only exit point from $H_i'$):
         Find a highest level $u \in A_{k+1} \cup\ u_{k+1} \cup \cdots \cup A_{m+1}$ with
             $(e,u)$ a transition for some $e \in H_{i-1}'$ with the
             properties $e < x$ and $e$ incomparable to every
             point between $e$ and $x$ in $L$. If no such $e$
             and $u$ exist then output ''$x$ is critical''
             (by Lemma 3.7) and STOP. Otherwise modify $L$
             so that $e$ moves up to become the immediate
             predecessor of $x$ in $L$ and correspondingly,
             $\mathrm{HC}_1(c,x)$ is replaced by $\mathrm{HP}_1(e,x)$ (rearrangement of
             Type 4). If $u \in H_j'$ for some $j$ then modify $L$
```

```
            (if possible) to make $u$ the second point from
            $H'_j$ in $L$ (rearrangement of Type 1).
        Put $\mathrm{HC}_1(a,u) := \mathrm{HP}_1(e,x) \cup L[x,u] \cup \{(u,e)\}$ and $c_1 := a$,
            where $a$ is the point covered by $u$ in $L$.
END;
```

PROCEDURE 5.8.

```
procedure continue1 ($\mathrm{HC}_1(c_1,u_j)$, $H'_t$)
(Our cycle has reached the bump cutter $u_j$, using it as a bypass element. $H'_t$ is
the top layer of $A_j$, $c_1 \in H'_t$ is the point covered by $u_j$ in $L$. )
    Step 1.  Let $B = u_j|L$. Find a highest level $u \in B$ with $(c_1,u)$
                 a transition. If no such $u$ exists then go to
                 Step 3. If $u \notin U$ then rearrange $L$ so that $u$ is
                 the second point from its layer in $L$
                 (if possible).
    Step 2.  Put $\mathrm{HC}_2(c_1,u_j) := L[c_1,u] \cup \{(u,c_1)\}$, $\mathrm{HC}_1(a,u) := \mathrm{HC}_1(c_1,u_j) \cup$
                 $\mathrm{HC}_2(c_1,u_j) - \{(c_1,u_j)\}$, $c_1 := a$, where $a <_L u$.
                 Go to END.
    Step 3.  If $H'_t = \{c_1\}$ then output ''$u_j$ is critical'' (there is
                 no transition from $H'_t$ up if we delete $u_j$) and STOP.
             Find a highest level $u \in B$ and $c \in H'_t - \{c_1\}$ with $(c,u)$
                 a transition. If no such $u$ exists then output
                 ''$u_j$ is critical'' and STOP.
             If $u \notin U$ then rearrange $L$ so that $u$ is the second
                 point from its layer in $L$ (if possible).
                 If $c$ is not the entry point to $H'_t$ in $L$ then
                 go to Step 4.
             Rearrange $L$ and $\mathrm{HC}_1(c_1,u_j)$ to make $c$ the exit
                 point from $H'_t$ in $L$ in the sense of Lemma 4.6.
                 (The resulting $\mathrm{HC}_1$ will have $(c,u_j)$ as edge.)
             Go to Step 5.
    Step 4.  Rearrange $L$ and $\mathrm{HC}_1(c_1,u_j)$ to make $c$ the exit point
                 from $H'_t$ in $L$ and $(c,u_j) \in \mathrm{HC}_1$.
    Step 5.  Put $\mathrm{HC}_2(c,u_j) := \mathrm{HC}_1$.
             Call hamiltonian ($\{c,u_j\} \cup B$) (the returned $\mathrm{HC}_1$ will
             contain $(c,u_j)$).
                 Put $\mathrm{HC} := \mathrm{HC}_1 \cup \mathrm{HC}_2(c,u_j) - \{(c,u_j)\}$.
             Output HC as a Hamiltonian cycle for $G$ and STOP.
    END;
```

PROCEDURE 5.9.

```
procedure continue2 ($\mathrm{HC}_1(c_1,u)$, $H'_j$)
(Our cycle $\mathrm{HC}_1(c_1,u) = \mathrm{HC}_u$ has reached $u \in H'_j$ as a bypass element, $|H'_j| \geq 2$
    must hold.)
    Step 1.  Let $B = u|L$. Find a highest level $w \in B$ with $(c_1,w)$
                 a transition.
             If no such $w$ exists then go to Step 2. If $w \notin U$
                 try to make it the second point in $L$ from
                 its layer, (if possible). Let
```

```
                $\mathrm{HC}_2(c_1, u) := L[c_1, w] \cup \{(w, c)\}$,
                $\mathrm{HC}_1(a, w) := \mathrm{HC}_1(c_1, u) \cup \mathrm{HC}_2(c_1, u) - \{(c_1, u)\}, c_1 := a$,
                where $a$ is the element covered by $w$ in $L$.
                Go to END.
Step 2.     If $u$ is the second point in $L$ from $H'_j$ then go to
            Step 3. ($u$ could not be made the second point from $H'_j$ in $L$,
                so $u$ must be the entry or exit for $H'_j$ and $H'_j$ must be a blocker.)
            If $u$ is the potentially critical exit element from
            the Type 2 blocker $H'_j$ then
                call bypass2 ($H'_j$; $u, \mathrm{HC}_1(c_1, u)$).
                Go to END.
            If $H'_j$ is a Type 1 blocker and $u$ is incomparable to
                every $v \in H'_{j-1}$ in $P_G$ then rearrange $L$ and $\mathrm{HC}_1$
                so that $u$ becomes the exit point from $H'_{j-1}$
                in $L$.
                Call bypass1($H'_j$; $u, y, \mathrm{HC}_1(c_1, u)$), where $y$ is the
                    other possible exit from $H'_j$.
                Go to END.
            ($u$ is the entry point to $H'_j$ in $L$, $|H'_j| > 2$ by Lemma 4.7 and $u$
                could not be made second from $H'_j$ in $L$.)
                Output ``$u$ is critical'' (by Lemma 3.6) and STOP.
Step 3.     If $H'_j$ is a Type 2 blocker and $|H'_j| > 2$ then go to
                Step 4.
            Call hamiltonian ($H'_j \cup B; c_1, u$) (It returns an $\mathrm{HC}_1(c_1, u)$.)
            Put $\mathrm{HC} := \mathrm{HC}_u \cup \mathrm{HC}_1(c_1, u) - \{(c_1, u)\}$, output HC for $G$
                and STOP.
Step 4.     ($H'_j$ is a Type 2 blocker and $u$ is neither the entry point to it
                nor the exit from it in $L$.)
            Let $x'$ be the (only) exit from $H'_j$ in $L$. Find a
                highest level $w \in B$ with $(a, w)$ a transition for
                some $a \in H'_j - \{u, x'\}$. If no such $w$ exists then
                go to Step 5. Rearrange $L$ and $\mathrm{HC}_u$ so that $u$
                covers $a$ in $L$ and $(a, u) \in \mathrm{HC}_u$ (Type 2 rearrangement).
            Call hamiltonian ($\{a, u\} \cup B; a, u$) ($\mathrm{HC}_1(a, u)$ is the cycle
                returned.)
            Put $\mathrm{HC} := \mathrm{HC}_u \cup \mathrm{HC}_1(a, u) - \{(a, u)\}$, output HC for
                $G$ and STOP.
Step 5.     Find a highest level $w \in B$ with $(e, w)$ a transition
                between the $j$th and (j+1)st layer in $P_G - x'$
                (i.e., $e < x'$, $e \in H'_{j-1}$, and $e$ incomparable to every point in
                $H'_j - \{x'\}$). If no such $w$ and $e$ exist then output
                ``$x'$ is critical'' and STOP.
            Rearrange $L$ and $\mathrm{HC}_u$ so that $e$ is covered by $u$
                in $L$ (make $e$ the exit from $H'_{j-1}$ and $u$ the
                entry to $H'_j$ in $L$), and $(e, u)$ becomes an edge
                in $\mathrm{HC}_u$ (Type 3 rearrangement).
                Put $B := u|L$, using the rearranged $L$.
```

```
        Call hamiltonian ($\{e,u\} \cup B; e, u$) ($\mathrm{HC}_1(e,u)$ is returned.)
        Put $\mathrm{HC} := \mathrm{HC}_u(e,u) \cup \mathrm{HC}_1(e,u) - \{(e,u)\}$, output HC for $G$
            and STOP.
END;
```

Let us consider the application of Algorithm 5.3 to the example shown in Fig. 7. Although the bumpno algorithm creates, during its execution, the closed sets $A_1, A_2, \ldots, A_6$ and bump cutters $u_1, u_2, \ldots, u_5$, eventually all these get collapsed into a single antichain. (The transition (4,13) collapses $A_1 \cup A_2 \cup u_1 \cup u_2 \cup H_3' \cup H_4'$ into a single antichain A_3, which is grown to include H_5'. Following this, the transition (26, 31) collapses $A_6 \cup u_5 \cup A_5$ into a single antichain A_5, which has the endpoint of the transition (14, 30) between A_3 and A_6, causing the whole dual order to collapse into a single antichain $A_1 = \{1, 2, \ldots, 33\}$.) In Step 3 Algorithm 5.3 recaptures the original $A_1, A_2, \ldots, A_6$, which are shown in Fig. 7. Suppose the optimal linear extension created by the algorithm bumpno is $L = 1, 2, 3, 5, 4, 8, 7, 6, 9, 10, 11, 13, 12, 14, 15, 16, 19, 18, 17, 20, 21, 22, 24, 23, 27, 26, 25, 30, 29, 28, 31, 32, 33$. The algorithm bumpno would also identify the Type 1 blocker H_7' (with potentially critical elements 20 and 22) and the Type 2 blockers H_2' and H_4' with potentially critical elements 6 and 12, respectively.

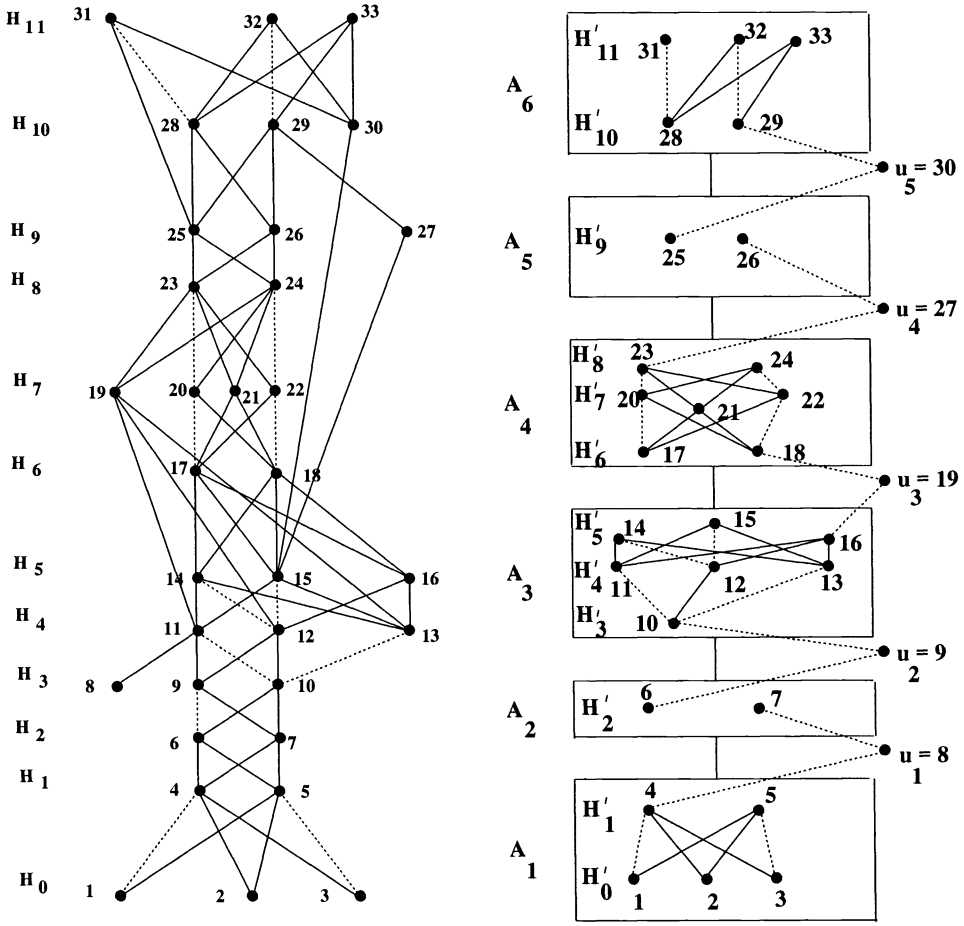

FIG. 7. *An example for the application of Algorithm* 2.

Applying `hamiltonian` to P_G starts by calling `twopaths` ($H'_0 \cup H'_1$; R), where the reserved transitions are $R = \{(1,4),(3,5)\}$. This returns HC$_1$ = (1, 2, 3, 5, 4, 1). Since H'_1 is not a blocker, it calls `bypass3` (H'_1; 4, 8, HC$_1$(5, 4)) to bypass the bump cutter $u_1 = 8$. This finds $u = 13$ as the highest level bypass element with the transition (5, 13) and enlarges HC$_1$ into HC$_1$ (11, 13) = (1, 2, 3, 5, 13, 11, 10, 9, 6, 7, 8, 4, 1). After returning to `hamiltonian`, since the bypass element u is not a bump cutter, it calls `continue2` (HC$_1$ `(11, 13),` H'_4). This identifies $B = 13 \mid L = \{12, 14, 15, \ldots, 33\}$. No transition exists from $c_1 = 11$ to B, H'_4 is a Type 2 blocker with potentially critical $x' = 12$, and no transition exists from $H'_4 - \{11, 12\} = \{13\}$ to B. The element $e = 10$ is identified as the start of the transition (10, 14) to $w = 14 \in B$. By a Type 3 rearrangement of L we make $e = 10$ the exit from H'_3 and $u = 13$ the entry to H'_4. This results in L = 1, 2, 3, 5, 4, 8, 7, 6, 9, 10, 13, 11, 12, …, with no change after 12, and HC$_1$ = (1, 2, 3, 5, 13, 10, 9, 6, 7, 8, 4, 1). The element 11 gets added to B. After this `hamiltonian` ($\{10, 13\} \cup B$; 10, 13) is called, with L_1 = 10, 13, 11, 12, …, continued as L after 12. This calls `twopaths` ($H'_3 \cup H'_4$; R), where the reserved transitions are $R = \{(10,11),(10,13)\}$. This returns HC$_2$ = (10, 11, 12, 13, 10). After this `bypass2` (H'_4; 12, HC$_2$(11, 12)) is called, which identifies the transition (10,14) to bypass x = 12, with u = 14 the bypass element and $e = 10$ moving up to replace x in $P_G - x$. By a rearrangement of Type 4, $e = 10$ is moved immediately before $x = 12$ in L_1 and HC$_2$, "taking" also 13 with it (to keep the edge (10, 13)), resulting in L_1 = 11, 13, 10, 12, … and HP_2(10, 12) = (10, 13, 11, 12). (Note that (10, 12) is a bump in L_1, and correspondingly (10, 12) is not an edge in G.) The bypass element $u = 14$ is not the second point from H'_5 in L_1, so L_1 is rearranged (by a Type 1 rearrangement) into L_1 = 11, 13, 10, 12, 15, 14, 16, 19, …. HP$_3$(12, 10) $= L_1[12, 14] \cup (14, 10) =$ (12, 15, 14, 10) is constructed and is combined into HC$_2$(15, 14) $= HP_2$(10, 12) ∪ HP$_3$(12, 10) = (10, 13, 11, 12, 15, 14, 10). Returning to `hamiltonian, continue2` (HC$_2$(15, 14), H'_5) is called. B is set to $B = \{16, 19, 17, 18, 20, 21, \ldots, 33\}$. The bypass element $u = 14$ is second from H'_5 in L_1, so `hamiltonian` ($H'_5 \cup B$; 14, 15) is called with L_2 = 15, 14, 16, 19, …. This constructs HC$_3$ = (14, 15, 16, 14) and calls `bypass3` (H'_5; 16, 19, HC$_3$(14, 15)). This finds the highest level bypass element $u = u_5 = 30$ with the transition (14, 30). Using this u, we enlarge our cycle into HC$_3$(14, 15) = (14, 15, 16, 19, 18, 17, 20, 21, 22, 24, 23, 27, 26, 25, 30, 14) and return to `hamiltonian`, which calls `continue1` (HC_3(25, 30), H'_9). (Note that 27 was also available to bypass $u_3 = 19$, but 30 being from a higher layer, choosing 30 speeds up the algorithm. We also bypassed the Type 1 blocker H_7 in the process). B is set to $B = \{29, 28, 31, 32, 33\}$. The bypass element $u = 31$ with the transition (26, 31) is identified. L_2 is rearranged into L_2 = 15, 14, 16, 19, 18, 17, 20, 21, 22, 24, 23, 27, 26, 25, 30, 28, 29, 32, 31, 33 to make u = 31 the second point from H'_{11} in L_2 . As $c = 26$ is the entry point to H'_9 in L_2, we rearrange L_2 , in the sense of Lemma 4.6, into L_2 = 15, 14, 16, 19, 18, 17, 20, 21, 22, 24, 23, 27, 25, 26, 30, 28, 29, 32, 31, 33 to make 26 the exit point from H'_9. This rearrangement results in HC$_3$(26, 30) = (14, 15, 16, 19, 18, 17, 20, 21, 22, 24, 23, 27, 25, 26, 30, 14). `hamiltonian` ($\{26, 30\} \cup B$) is called with L_3 = 26, 30, 28, 29, 32, 31, 33, which, after a call to `bypass3` ($\{26\}$; 26, 30, ϕ), returns HC$_4$(26, 30) = (26, 30, 28, 29, 32, 33, 31, 26). All is left is to combine the cycles constructed:

$$\begin{aligned}
\mathrm{HC}_5 &= \mathrm{HC}_3(26,30) \cup \mathrm{HC}_4(26,30) - \{(26,30)\} \\
&= (14, 15, 16, 19, 18, 17, 20, 21, 22, 24, 23, \\
&\qquad 27, 25, 26, 31, 33, 32, 29, 28, 30, 14) \\
\mathrm{HC}_6 &= \mathrm{HC}_2(14,15) \cup \mathrm{HC}_5 - \{(14,15)\} \\
&= (10, 13, 11, 12, 15, 16, 19, 18, 17, 20, \\
&\qquad 21, 22, 24, 23, 27, 25, 26, 31, 33, \\
&\qquad 32, 29, 28, 30, 14, 10)
\end{aligned}$$

$$\begin{aligned}\mathrm{HC} &= \mathrm{HC}_1(10,13) \cup \mathrm{HC}_6 - \{(10,13)\}\\ &= (1,2,3,5,13,11,12,15,16,19,18,17,\\ &\qquad 20,21,22,24,23,27,25,26,31,33,\\ &\qquad 32,29,28,30,14,10,9,6,7,8,4,1)\end{aligned}$$

THEOREM 5.10. *Algorithm* 5.3 *solves the* Hamiltonian Cycle Construction problem *for a cocomparability graph G in $O(hn^2)$ time and $O(n^2)$ space, where n is the number of vertices in G and h is the size of a largest independent set in G.*

Proof. The correctness of the algorithm follows from Lemmas 3.4 to 3.9, 4.5 to 4.7 and Theorem 4.8. The only change in the algorithm, from the development of the previous results, is that instead of using the bumpno algorithm on $P_G - x$ to find a bypass element u for the potentially critical element x, we look for a *highest level* bypass element u *directly*. This means that the bypass element we find may not be the same as what bumpno would have found. The reason for looking for a highest level bypass element is that this way our Hamiltonian cycle is grown faster, by possibly reaching higher levels in fewer iterations. Once we have grown the Hamiltonian cycle into an HC_u covering $G|u$, for any bypass element u, by Lemma 3.4, it follows that the subposet $L|u$ cannot have critical elements, even though we may not have directly tested all its potentially critical elements.

For the space complexity of the algorithm we note that all the information needed and generated by bumpno can be clearly stored in $O(n^2)$ space.

To prove the claimed time complexity we make the following observations: G^{C} and the transitive orientation P_G can be found in $O(n^2)$ time [18]. The bumpno algorithm for P_G needs at most $O(n^2)$ time [10]. It is clear that P_G has at most $O(h)$ blockers or bump cutters, so the procedures bypass1, bypass2, bypass3, continue1 *and* continue2 can be called at most $O(h)$ times. A single execution of any of these can clearly be done in $O(n^2)$ time. □

We note that a careful implementation of the algorithm could result in a version with $O(n^2)$ time complexity, by exploiting the fact that each transition present in P_G would have to be looked at at most two times (once when searching for an appropriate transition, and possibly the second time when rearrangements are performed). We omitted this from the statement of the theorem, because proving it would require a much more detailed statement of the algorithm. Finally, we also note that the Hamiltonian cycle constructed by the algorithm is "layered" in a certain sense: it enters each layer H_i' at most twice.

6. Appendix.

ALGORITHM 6.1.

```
algorithm bumpno($P$)
    Step 1:  (Initialization):
                 Let $H_0, \dots, H_h$ be the initial layers of $P$. Put
                 $H_i' := H_i (i = 0, \dots, h), l := 1, k := 0$. open($A_l$), put $k := 1$.
    Step 2:  (Termination condition):
                 If $k = h$, close($A_l, a$) with any maximal $a \in A_l$ and
                 terminate. Then the concatenation $L = L_1 U_1 L_2 \dots$
                 $U_{l-1} L_l$ is an optimal linear extension and
                 $A_1, \dots, A_l$ and $U$ define the contained
                 generalized weak order $P^*$.
    Step 3:  (Search for transitions from $H_{k-1}'$):
                 Search for transitions $(a_{k-1}, u_{k-1})$ from $H_{k-1}'$ to
                 $H_j'$ with $j \geq k$ according to RULE 1, RULE 2, and
                 RULE 3. There are 4 cases that are treated in
                 Steps 4-7.
```

```
Step 4:  (There are two or more transitions into $H'_k$ with
           different endpoints): Then grow($A_l$). If there
           is a transition $(a,b)$ from some $a \in \bigcup_{i=1}^{l-1} A_i$ to
           some $b \in H'_k$ (which can only happen if $l > 1$),
           then collapse($A_l$) and put $l := t$ (a value returned
           by collapse). Put $k := k+1$ and go to Step 2.
Step 5:  (All transitions into $H'_k$ have the same endpoint):
           Let $(a_{k-1}, u_{k-1})$ be such a transition. Then
           close($A_l, a_{k-1}$), put $H'_k := H'_k - \ \{u_{k-1}\}, U_l := \{u_{k-1}\}, l := l+1$,
           and open($A_l$). Then open returns $A_l = H'_k$. If
           there is a transition $(a,b)$ from some $a \in \bigcup_{i=1}^{l-1} A_i$
           to some $b \in H'_k$ then collapse($A_l$) and put $l := t$
           (a value returned by collapse). Put $k := k+1$
           and go to Step 2.
Step 6:  (There are only transitions into higher layers $H'_j$, $j > k$) :
           Choose such a transition $(a_{k-1}, u_{k-1})$ with
           $u_{k-1} \in H_j$ according to RULE 1 and RULE 2.
           Then close($A_l, a_{k-1}$), put $H'_j := H'_j - \{u_{k-1}\}$,
           $U_l := \{u_{k-1}\}$, open($A_{l+1}$), put $l := l+1, k := k+1$
           and go to Step 2.
Step 7:  (There is no transition at all): Then close($A_l, a$)
           with any maximal $a \in A_l$ , put $U_l := \phi$ (this means
           that a bump is created), open($A_{l+1}$) put $l : l+1$,
           $k := k+1$, and go to Step 2.
```

The change in bumpno, in comparison to the original algorithm in [10], is the addition of RULE 3 for breaking ties between short transitions. Clearly this does not affect its correctness or complexity. The procedure open initializes the new antichain and creates data structures necessary for storing the information.

PROCEDURE 6.2.

```
procedure open($A_l$).
        Put $A_l^1 := \phi, A_l^2 := H'_k$ (where $U_0 = \phi$), and $A_l := A_l^1 \cup A_l^2$ .
        Create a list list($A_l^2$) for transitions to be stored,
        create a list list($A_l^1$) for storing a linear exten-
        sion $L_l^1$ of $A_l^1$ (for the case that $A_l^1$ becomes nonempty).
```

The procedure grow(A_l) is rather simple and just keeps track of the information needed to construct the linear extension of A_l upon closing. Note that grow is the only step in the algorithm where A_l^2 is enlarged.

PROCEDURE 6.3.

```
procedure grow($A_l$).
        Put the two transitions $(a_{k-1}, u_{k-1}), (a'_{k-1}, u'_{k-1})$
        with $u_{k-1} \neq u'_{k-1}$ on list($A_l^2$). Put $A_l^2 := A_l^2 \cup H'_k$.
```

The procedure `close` constructs a linear extension of A_l according to the information stored in list(A_l^1) and list(A_l^2).

PROCEDURE 6.4.

```
procedure close($A_l, a$).
          Construct a linear extension $L_l$ of $A_l$ without
          bumps with last element $a$.
          Put the set $A_l$ on list closedsets. If $k < h$ then put
          the bump cutter $u_l$ on list bumpcutters.
          (These lists are constructed because they are needed
          to reconstruct collapsed closed sets.)
```

The procedure `collapse` is applied when the layer H_k' that is to be added to A_l or A_{l+1} is not above some previous antichain A_i. This can only occur if H_k' contains endpoints of transitions from previous layers contained in previous antichains. Loosely speaking, `collapse` joins as many antichains A_i and associated sets U_i below A_l to the A_l^1 — part of A_l as necessary to ensure that $A_1 < A_2 < \ldots < A_l$ holds at all the time and updates the associated linear extension L_l^1 of A_l^1. Note that `collapse` is the only part in the algorithm where A_l^1 is enlarged.

In looking for the *range* over which the collapsing has to take place, a certain closure operation is used. First, all transitions (a, b) to all $b \in H_k'$ are considered and if $a \in A_i$, $i < l$, then $A_i \cup U_i$ is added to A_l. Then the same is done for transitions (a, b) with $b \in U_j$ for all added U_j, iterating in this fashion through $l-1, l-2, \ldots$ until we find the first (largest) t for which there is no transition from $\bigcup_{j=1}^{t-1} A_j$ to $A_l^{\text{new}} = A_l^{\text{old}} \cup U_{l-1} \cup A_{l-1} \cup \cdots \cup U_t \cup A_t$.

PROCEDURE 6.5.

```
procedure collapse($A_l$).
          Find, in the order $l-1, l-2, \ldots$ the first index $t$
          such that if $(a,b)$ is a transition with $b \in H_k' \cup (\bigcup_{i=t}^{l-1} U_i)$
          then $a \notin \bigcup_{j=1}^{t-1} A_j$. Enlarge $A_l^1$ by putting $A_l^1 := A_l^1 \cup \{\bigcup_{i=t}^{l-1}(A_i$
          $\cup U_i)\}$ and update the linear extension $L_l^1$ by letting
          $L_t U_t L_{t+1} U_{t+1} \ldots L_{l-1} U_{l-1}$ precede the old $L_l^1$.
          Store the new $L_l^1$ in list($L_l^1$). Finally, return $t$.
```

It was shown in [10] that t can be characterized as the largest index fulfilling $\bigcup_{j=1}^{t-1} A_j <_P \bigcup_{j=t}^{l} (A_j \cup U_j)$. For more detail and examples we refer the reader to [10].

PACKET TRANSMISSION IN A NOISY-CHANNEL RING NETWORK*

VICTOR PESTIEN†, S. RAMAKRISHNAN†, AND DILIP SARKAR†

Abstract. Assume that n stations, each with a buffer to hold only one packet at a time, are connected as a ring and that data packets are transmitted counterclockwise. A station will attempt to transmit a packet to the next station only if (i) it has a packet to send and (ii) the next station's buffer is empty. The communication channels connecting the stations are noisy, and there is a fixed probability p $(0 < p < 1)$ of error-free transmission of a packet from one station to the next in one attempt.

An exact expression for the long-run average time for a packet to go around the ring is derived. (A special case of this answers a question raised by Berman and Simon in [*Proc. 20th ACM Symp. on Theory of Computing*, ACM Press, 1988, pp. 66–77].) For fixed n and p, the throughput of the system is maximum when the number of packets is an integer closest to $n/2$.

Key words. ring network, packet communication, equilibrium distribution, Markov chain

1. Introduction.

Local area networks are a subject of increasing importance for efficient data communication. A ring network is a particularly attractive local area network, since its architecture uses simple control software and interfaces. In a unidirectional ring network, the host computers are connected to the network via ring interface hardware. Each interface is called a station in the ring. A station transmits its message to the next station in the ring, and the message circulates around the network until it reaches the destination station where it is forwarded to the host computer. The interface hardware can identify messages intended for its host. A host may transmit its packet by passing it to its attached station using one of several standard protocols (see Tanenbaum [6]).

In this paper, we study the asymptotic average rate of transmission of packets of messages in a ring network. We assume that a station can store only one packet of a message at a time in its buffer. Thus, a station can transmit a packet to the next station if the next station has an empty buffer. During transmission, a packet can become corrupted in the channel. In other words, the transmission channel is not noise-free. Assume that there is a probability p of error-free transmission in one attempt. If a packet is corrupted during transmission, it must be retransmitted. Also assume that all the stations synchronously attempt to transmit packets.

We assume that there is a fixed interval of time between consecutive transmission attempts. Within this interval, each station will determine the status of the buffer of the next station, attempt transmission, and receive acknowledgment. We further assume that the transmission of the acknowledgment is error-free. This assumption is harmless since the size of the acknowledgment packet is very small compared to the size of a packet of information, and hence it can be encoded using some error-correcting code.

This paper illustrates how the theory of Markov chains could be naturally used to model and analyze a computing problem. In §2 the system is formalized as a Markov chain and its equilibrium distribution is obtained. This distribution is then used in §3 to calculate the asymptotic average cycle time of a packet. In §4, the condition for maximizing throughput is established. Throughput of the system is the expected number of packets successfully transmitted from one station to the next in one unit of time. Section 5 gives some concluding remarks and discusses connections with the work of Berman and Simon [1].

2. Stationary probability distribution.

Consider n *stations* arranged in a circle. We assume that the stations are numbered $0, 1, \dots, n-1$. Also, for any integer j, by *station* j, we

*Received by the editors July 12, 1989; accepted for publication (in revised form) January 19, 1993.

†Department of Mathematics and Computer Science, University of Miami, Coral Gables, Florida 33124-4250.

shall mean the station j mod n. Suppose there are k packets ($k < n$) that are to be transmitted counterclockwise around the circle under the following conditions:

(i) packets can move only at discrete times $t = 1, 2, \ldots$;

(ii) at every time instant t, each packet is at some station and there is at most one packet at each station;

(iii) at every time instant t and for every integer j, a packet located at station j can move only if station $(j + 1)$ does not have a packet; if it *can* move, it *will* move, independently of other packets that can move, with probability p $(0 < p < 1)$ to station $(j + 1)$, and it will stay at station j with probability $(1 - p)$.

We want to calculate the long-run average speed with which a packet goes around the circle. We shall formalize this stochastic process as a discrete-time Markov chain with stationary transition probabilities. (All the definitions and results from the theory of Markov chains that we shall need can be found in Chung [2] or Feller [3].)

Given a time instant, we say that the *local state* of a station is

$$\begin{cases} 1 & \text{if it has a packet at that instant,} \\ 0 & \text{if it does not.} \end{cases}$$

The state space S of our Markov chain consists of n-tuples $s = (s_0, \ldots, s_{n-1})$, where s_j is the local state of station j. Formally,

$$S = \{s \in \{0, 1\}^n : \text{ exactly } k \text{ coordinates of } s \text{ are } 1\}.$$

For $s \in S$ and for any integer j, by s_j we shall mean the $(j \bmod n)$th coordinate of s. For $s \in S$ and any integer j, we say that j is an *opportunity station* of state s if $s_j s_{j+1} = 10$; and we say that j is a *post-opportunity station* of state s if $s_j s_{j+1} = 01$. An opportunity station j is one that has a packet that can move in a one-step transition to station $j + 1$ since there is no packet at station $j + 1$, while a post-opportunity station is one from which a packet may have just moved to station $j + 1$. Let

$$\mathrm{OPP}(s) = \{j : 0 \le j \le n - 1 \text{ and } j \text{ is an opportunity station of state } s\}$$

and

$$\mathrm{POSTOPP}(s) = \{j : 0 \le j \le n - 1 \text{ and } j \text{ is a post-opportunity station of state } s\}.$$

The states that can result from a state s after a one-step transition are in one-to-one correspondence with subsets of OPP(s), the subset identifying the stations from which a packet actually moves. If $A \subseteq \mathrm{OPP}(s)$, the state s^A that will result from s when A is the set of stations from which packets have just moved is described formally as follows:

(i) for $j \in A$, $s_j^A s_{j+1}^A = 01$;

(ii) if s_j^A is not specified by (i), then $s_j^A = s_j$.

The entries of the transition matrix P of our Markov chain are defined by

$$P(s, s^A) = p^{|A|}(1 - p)^{|\mathrm{OPP}(s)| - |A|}, \tag{2.1}$$

for $s \in S$ and $A \subseteq \mathrm{OPP}(s)$. ($|\cdot|$ denotes cardinality.) All other entries of the transition matrix are zero.

Thus for each $s \in S$, $P(s, s')$ is nonzero for exactly $2^{|\mathrm{OPP}(s)|}$ states s'. However, given states $s, s' \in S$, it can easily be verified that in $2n$ one-step transitions, s can be transformed into s' with positive probability. Thus the Markov chain with transition matrix P is irreducible. It is also positive recurrent, because the set S is finite. Therefore, as is well known, there is a unique stationary probability distribution for P, i.e., there is a unique vector π on S such that

$$\pi(s) = \sum_{s' \in S} \pi(s') P(s', s) \quad \text{for all } s \in S, \tag{2.2}$$

$$\pi(s) > 0 \quad \text{for all } s \in S, \tag{2.3}$$

and

$$\sum_{s \in S} \pi(s) = 1. \tag{2.4}$$

The stationary probability distribution of P can thus be obtained by first getting a vector that satisfies (2.3) and (2.2) and then normalizing it.

Let γ be the vector on S defined by

$$\gamma(s) = (1-p)^{-|\mathrm{OPP}(s)|}. \tag{2.5}$$

THEOREM 2.1. *The vector γ defined by* (2.5) *satisfies* (2.3) *and* (2.2) *for the matrix P defined by* (2.1).

Proof. Plainly, since $0 < p < 1$, γ satisfies (2.3). To verify (2.2), given $s \in S$, by the definition of P, the summation on the right side of (2.2) need be taken only over those $s' \in S$ such that for some $A \subseteq \mathrm{OPP}(s)$, $s = (s')^A$. In such a case, $A \subseteq \mathrm{POSTOPP}(s)$. Moreover, given $s \in S$ and $A \subseteq \mathrm{POSTOPP}(s)$, there is a unique state s' satisfying $(s')^A = s$. We shall denote this state by s^{-A}. With this notation (2.2) can be rewritten as follows:

$$\gamma(s) = \sum_{A \subseteq \mathrm{POSTOPP}(s)} \gamma(s^{-A}) P(s^{-A}, s) \quad \text{for all } s \in S. \tag{2.6}$$

The proof of (2.6) will use the following two lemmas.

LEMMA 2.2. *If $s \in S$, then*

$$|\mathrm{OPP}(s)| = |\mathrm{POSTOPP}(s)|.$$

Proof. For $j \in \mathrm{OPP}(s)$, let j' be the largest integer such that $s_i = 0$ for $j < i \leq j'$ and let $j'' = j' \bmod n$. It is easy to see that the pairing of j and j'' gives a one-to-one correspondence between $\mathrm{OPP}(s)$ and $\mathrm{POSTOPP}(s)$. □

LEMMA 2.3. *If $s \in S$ and $A \subseteq \mathrm{POSTOPP}(s)$, then*

$$\gamma(s^{-A})\ P(s^{-A}, s) = \left(\frac{p}{1-p}\right)^{|A|}.$$

Proof. Since $(s^{-A})^A = s$ by definition, we have

$$\begin{aligned}\gamma(s^{-A})\ P(s^{-A}, s) &= (1-p)^{-|\mathrm{OPP}(s^{-A})|} \cdot p^{|A|} \cdot (1-p)^{|\mathrm{OPP}(s^{-A})|-|A|} \\ &= \left(\frac{p}{1-p}\right)^{|A|}. \quad \square\end{aligned}$$

We now finish the proof of Theorem 2.1 by verifying (2.6). Note that

$$\begin{aligned}
&\sum_{A\subseteq \mathrm{POSTOPP}(s)} \gamma(s^{-A})\cdot P(s^{-A},s)\\
&= \sum_{A\subseteq \mathrm{POSTOPP}(s)} \left(\frac{p}{1-p}\right)^{|A|} \quad \text{[by Lemma 2.3]}\\
&= \sum_{\ell=0}^{|\mathrm{POSTOPP}(s)|} \binom{|\mathrm{POSTOPP}(s)|}{\ell}\left(\frac{p}{1-p}\right)^{\ell}\\
&= \left(1+\frac{p}{1-p}\right)^{|\mathrm{POSTOPP}(s)|} \quad \text{[by the binomial theorem]}\\
&= (1-p)^{-|\mathrm{POSTOPP}(s)|}\\
&= (1-p)^{-|\mathrm{OPP}(s)|} \quad \text{[by Lemma 2.2].}
\end{aligned}$$

The proof of Theorem 2.1 is thus complete. □

COROLLARY 2.4. *If π is defined by*

$$\pi(s)=\frac{\gamma(s)}{\sum_{s'\in S}\gamma(s')}, \tag{2.7}$$

where γ satisfies (2.5), *then π is the unique stationary probability distribution of the Markov chain with transition probability matrix P.*

3. Average cycle time. A natural measure of the progress of the system is the number of packet movements. In a one-step transition from state s to state s', this is the number of opportunity stations of s that successfully transmit a packet and hence are post-opportunity stations of s', i.e.,

$$|\mathrm{OPP}(s)\cap \mathrm{POSTOPP}(s')|.$$

Of course, such a transition would have positive probability only when $s'=s^A$ for some $A\subseteq \mathrm{OPP}(s)$; and in such a case $|\mathrm{OPP}(s)\cap\mathrm{POSTOPP}(s')|=|A|$. If $s^0,s^1,\dots,s^t,\dots$ denote the sequence of states generated by our Markov chain (s^t is the state at time instant t), the long-run average time per unit progress is

$$\lim_{t\to\infty}\frac{t}{\sum_{i=1}^t|\mathrm{OPP}(s^{i-1})\cap\mathrm{POSTOPP}(s^i)|}. \tag{3.1}$$

Using the strong law of large numbers for Markov chains, one can show (see below) that with probability one,

$$\lim_{t\to\infty}\frac{t}{\sum_{i=1}^t|\mathrm{OPP}(s^{i-1})\cap\mathrm{POSTOPP}(s^i)|}=\frac{1}{p\sum_{s\in S}\pi(s)|\mathrm{OPP}(s)|}. \tag{3.2}$$

Since the long-run average cycle time for a packet, to be denoted by TIME(n,k,p), can be defined to be equal to the long-run average time for nk units progress of the system, we have

$$\mathrm{TIME}(n,k,p)=\frac{nk}{pE(|\mathrm{OPP}|)}, \tag{3.3}$$

where $E(|\mathrm{OPP}|)=\sum_{s\in S}|\mathrm{OPP}(s)|\pi(s)$, the expected number of opportunities under π.

To see how the strong law is used to calculate the limit in (3.1), it helps to consider the associated Markov chain, with state space $S\times S$, which generates the sequence of states

$$(s^0,s^1),(s^1,s^2),\dots,(s^{t-1},s^t),\dots.$$

It is easily verified that this Markov chain has stationary distribution π^* defined by

$$\pi^*(s, s') = \pi(s)P(s, s'),$$

where π and P are defined by (2.7) and (2.1), respectively. By an application of the strong law (Chung [2, Theorem 2, §I.15]), the limit (3.1) can now be seen to equal, with probability one,

$$\frac{1}{\sum_{(s,s')\in S\times S} |\mathrm{OPP}(s) \cap \mathrm{POSTOPP}(s')|\pi^*(s, s')}.$$

This is the same as

$$\begin{aligned}
&\frac{1}{\sum_{s\in S}\sum_{A\subseteq \mathrm{OPP}(s)} |A|\pi(s)P(s, s^A)}\\
&= \frac{1}{\sum_{s\in S}\pi(s)\sum_{\ell=1}^{|\mathrm{OPP}(s)|}\ell\binom{|\mathrm{OPP}(s)|}{\ell}p^{\ell}(1-p)^{|\mathrm{OPP}(s)|-\ell}}\\
&= \frac{1}{\sum_{s\in S}\pi(s)p|\mathrm{OPP}(s)|}\\
&= \frac{1}{p\cdot\sum_{s\in S}\pi(s)|\mathrm{OPP}(s)|},
\end{aligned}$$

where the second-to-last equality holds because the inner sum is a binomial expectation. The verification of (3.2) is now complete.

The following proposition calculates $E(|\mathrm{OPP}|)$ explicitly in terms of n, k, and p.

PROPOSITION 3.1.

$$E(|\mathrm{OPP}|) = \frac{\sum_{\ell=1}^{\min(k,n-k)}\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}{\sum_{\ell=1}^{\min(k,n-k)}\frac{1}{\ell}\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}. \tag{3.4}$$

Proof. Since $k < n$, for every $s \in S$ there must exist j such that $s_j s_{j+1} = 10$. Hence $|\mathrm{OPP}(s)| \geq 1$. Moreover,

$$\mathrm{OPP}(s) \subseteq \{j : 0 \leq j \leq n-1 \text{ and } s_j = 1\},$$

so $|\mathrm{OPP}(s)| \leq k$. Further,

$$\{j+1 : j \in \mathrm{OPP}(s)\} \subseteq \{i : 1 \leq i \leq n \text{ and } s_i = 0\},$$

so $|\mathrm{OPP}(s)| \leq n - k$. We have thus shown that

$$1 \leq |\mathrm{OPP}(s)| \leq \min(k, n-k)$$

for each $s \in S$. For each integer ℓ such that $1 \leq \ell \leq \min(k, n-k)$, let $S_\ell = \{s \in S : |\mathrm{OPP}(s)| = \ell\}$. By Corollary 2.4, we have

$$\begin{aligned}
E(|\mathrm{OPP}|) &= \frac{\sum_{s\in S}|\mathrm{OPP}(s)|\gamma(s)}{\sum_{s\in S}\gamma(s)}\\
&= \frac{\sum_{\ell=1}^{\min(k,n-k)}\ell|S_\ell|(1-p)^{-\ell}}{\sum_{\ell=1}^{\min(k,n-k)}|S_\ell|(1-p)^{-\ell}}.
\end{aligned}$$

The proof will be complete if we can show that

$$|S_\ell| = \frac{n}{\ell}\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1} \quad \text{for } 1 \le \ell \le \min(k, n-k). \tag{3.5}$$

Note that every $s \in S$ is the concatenation of an alternating sequence of nonempty blocks of 0's and nonempty blocks of 1's, so $s \in S_\ell$ if and only if it has one of the following four possible forms:

(i) s is the concatenation of an alternating sequence of ℓ nonempty blocks of 1's and ℓ nonempty blocks of 0's (where s starts with a block of 1's);

(ii) s is the concatenation of an alternating sequence of $\ell + 1$ nonempty blocks of 1's and ℓ nonempty blocks of 0's (where s starts with a block of 1's);

(iii) s is the concatenation of an alternating sequence of ℓ nonempty blocks of 0's and ℓ nonempty blocks of 1's (where s starts with a block of 0's);

(iv) s is the concatenation of an alternating sequence of $\ell + 1$ nonempty blocks of 0's and ℓ nonempty blocks of 1's (where s starts with a block of 0's).

Since any string of length a can be partitioned into b nonempty blocks in $\binom{a-1}{b-1}$ ways and since each $s \in S$ has k 1's and $(n-k)$ 0's, we have

$$\begin{aligned} |S_\ell| &= \binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1} + \binom{k-1}{\ell}\binom{n-k-1}{\ell-1} \\ &\quad + \binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1} + \binom{k-1}{\ell-1}\binom{n-k-1}{\ell} \\ &= \left(1 + \frac{k-\ell}{\ell} + 1 + \frac{n-k-\ell}{\ell}\right)\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1} \\ &= \frac{n}{\ell}\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}. \end{aligned}$$

(Similar counting arguments are discussed in detail in Johnson and Kotz [4], for example.) □

THEOREM 3.2.

$$\text{TIME}(n, k, p) = \frac{nk}{p} \frac{\sum_{\ell=1}^{\min(k,n-k)} \frac{1}{\ell} \cdot \binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}{\sum_{\ell'=1}^{\min(k,n-k)} \binom{k-1}{\ell'-1}\binom{n-k-1}{\ell'-1}(1-p)^{-\ell'}}. \tag{3.6}$$

Proof. This is an immediate consequence of (3.3) and Proposition 3.1. □

4. Optimum throughput. Given a station j, if $P(\text{TRANS at } j)$ denotes the probability, under the stationary distribution π, that a packet gets transmitted to station $(j+1)$, then

$$P(\text{TRANS at } j) = p \cdot \pi\{s \in S : j \in \text{OPP}(s)\}.$$

Since $\pi\{s \in S : j \in \text{OPP}(s)\}$ is independent of j, so is $P(\text{TRANS at } j)$, and we can denote it simply by $P(\text{TRANS})$. It now follows that

$$n \cdot P(\text{TRANS}) = p \sum_{j=0}^{n-1} \pi\{s \in S : j \in \text{OPP}(s)\}.$$

Therefore,

$$n \cdot P(\text{TRANS}) = p \cdot E(|\text{OPP}|). \tag{4.1}$$

The last equality is seen by expressing $|\text{OPP}|$ as a sum of n 0–1 valued random variables. Either of the equivalent expressions in (4.1) can be taken as the definition of the "throughput" of the system.

We now solve the following optimization problem. For fixed n and p we determine the value of k that maximizes $P(\text{TRANS})$. Hence, we determine the value of k that maximizes throughput.

THEOREM 4.1. *Let n, a positive integer, and p, a real number such that $0 < p < 1$, be fixed. Then as a function of k, $P(TRANS)$ is maximized at k_0, where*

$$k_0 = \begin{cases} \frac{n}{2} & \text{if } n \text{ is even,} \\ \frac{n-1}{2} \text{ or } \frac{n+1}{2} & \text{if } n \text{ is odd.} \end{cases} \tag{4.2}$$

The proof of Theorem 4.1 relies on a lemma.

LEMMA 4.2. *Let μ_1 and μ_2 be functions defined on $\{1, \dots, L\}$, where L is a positive integer such that*

(i) $\mu_i(\ell) \geq 0$ *for all ℓ and for $i = 1, 2$;*

(ii) $\mu_i(\ell) = 0$ *implies $\mu_i(\ell') = 0$ for all $\ell' \geq \ell$ and for $i = 1, 2$;*

(iii) $\sum_{\ell=1}^{L} \mu_i(\ell) = 1$, *for $i = 1, 2$; and*

(iv) $\mu_1(\ell + 1)/\mu_1(\ell) \geq \mu_2(\ell + 1)/\mu_2(\ell)$ *for all ℓ such that $\mu_1(\ell) > 0$ and $\mu_2(\ell) > 0$.*

Let φ be a nondecreasing function on $\{1, \dots, L\}$. Then

$$\sum_{\ell=1}^{L} \varphi(\ell)\mu_1(\ell) \geq \sum_{\ell=1}^{L} \varphi(\ell)\mu_2(\ell).$$

[*Remark.* This elementary lemma is a special case of a well-known result in the monotone likelihood ratio theory in statistics (see Lehmann [5, §3.3]). However, for completeness, we include a proof.]

Proof. Let ℓ_0 be the least integer in $\{1, \dots, L\}$ such that $\mu_1(\ell_0) \geq \mu_2(\ell_0)$. Such an integer must exist because of hypothesis (iii). Now hypotheses (iv), (ii), and (i) imply that

$$\mu_1(\ell) \geq \mu_2(\ell) \quad \text{for all } \ell \geq \ell_0. \tag{4.3}$$

If $\ell_0 = 1$, then by (iii) and (4.3), $\mu_1(\ell) = \mu_2(\ell)$ for all ℓ and the assertion of the lemma is true. If $\ell_0 \geq 2$,

$$\begin{aligned}
&\sum_{\ell=1}^{L} \varphi(\ell)[\mu_1(\ell) - \mu_2(\ell)] \\
&= \sum_{\ell=1}^{\ell_0-1} \varphi(\ell)[\mu_1(\ell) - \mu_2(\ell)] + \sum_{\ell=\ell_0}^{L} \varphi(\ell)[\mu_1(\ell) - \mu_2(\ell)] \\
&\geq \varphi(\ell_0 - 1) \cdot \sum_{\ell=1}^{\ell_0-1} [\mu_1(\ell) - \mu_2(\ell)] + \varphi(\ell_0) \sum_{\ell=\ell_0}^{L} [\mu_1(\ell) - \mu_2(\ell)] \\
&\qquad\qquad\qquad\qquad\qquad\qquad \text{[since } \varphi \text{ is nondecreasing]} \\
&= [\varphi(\ell_0) - \varphi(\ell_0 - 1)] \sum_{\ell=\ell_0}^{L} [\mu_1(\ell) - \mu_2(\ell)] \quad \text{[by (iii)]} \\
&\geq 0 \quad \text{[by (4.3)]}. \qquad \square
\end{aligned}$$

Proof of Theorem 4.1. Because of (4.1) and (3.4), maximizing $P(\text{TRANS})$ is equivalent to minimizing

$$\sum_{\ell=1}^{\min(k,n-k)} \frac{1}{\ell} \cdot \frac{\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}{\sum_{\ell'=1}^{\min(k,n-k)}\binom{k-1}{\ell'-1}\binom{n-k-1}{\ell'-1}(1-p)^{-\ell'}}.$$

For each positive integer $k < n$, define

$$\mu_k(\ell) = \frac{\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}{\sum_{\ell'=1}^{\min(k,n-k)}\binom{k-1}{\ell'-1}\binom{n-k-1}{\ell'-1}(1-p)^{-\ell'}} \tag{4.4}$$

if $1 \leq \ell \leq \min(k, n-k)$ and define $\mu_k(\ell) = 0$ if $\min(k, n-k) < \ell \leq \min(k_0, n-k_0)$.

Since k_0 satisfies (4.2), it follows that for $k < n$ the functions μ_{k_0} and μ_k satisfy hypotheses (i), (ii), and (iii) of Lemma 4.2. Also,

$$\frac{\mu_k(\ell+1)}{\mu_k(\ell)} = \frac{\binom{k-1}{\ell}\binom{n-k-1}{\ell}(1-p)^{-\ell-1}}{\binom{k-1}{\ell-1}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}} = \frac{k(n-k)-\ell n+\ell^2}{\ell^2}\cdot\frac{1}{1-p}$$

for $1 \leq \ell < \min(k, n-k)$. Therefore,

$$\frac{\mu_{k_0}(\ell+1)}{\mu_{k_0}(\ell)} \geq \frac{\mu_k(\ell+1)}{\mu_k(\ell)}$$

for all $k < n$ and for all ℓ satisfying $1 \leq \ell \leq \min(k, n-k)$. Thus hypothesis (iv) of Lemma 4.2 is also satisfied. So by applying Lemma 4.2 to the nondecreasing function φ defined by $\varphi(\ell) = -\frac{1}{\ell}$, we obtain

$$\sum_{\ell=1}^{\min(k_0,n-k_0)} \frac{1}{\ell}\mu_{k_0}(\ell) \leq \sum_{\ell=1}^{\min(k,n-k)} \frac{1}{\ell}\mu_k(\ell) \quad \text{for all } k < n.$$

This completes the proof of the theorem. □

5. Concluding remarks.

5.1. A bound for TIME(2N,N,1/2). In Berman and Simon [1], the question of obtaining an exact expression for TIME($2N$, N, $1/2$) was raised. Of course, Theorem 3.2 gives the answer. Although the expression (3.6) in Theorem 3.2 is complicated, here is an easy argument to show that

$$\text{TIME}\left(2N, N, \frac{1}{2}\right) \leq \frac{4}{p}N.$$

If μ_p denotes the function defined by the right side of (4.4) when $k = N$ and $n = 2N$ and μ_0 denotes this function when, in addition, $p = 0$, then Lemma 4.2 can be applied routinely to show that

$$\sum_{\ell=1}^{N}\frac{1}{\ell}\mu_p(\ell) \leq \sum_{\ell=1}^{N}\frac{1}{\ell}\mu_0(\ell).$$

Hence

$$
\begin{aligned}
\mathrm{TIME}(2N, N, p) &= \frac{2N^2}{p}\sum_{\ell=1}^{N}\frac{1}{\ell}\mu_p(\ell) \\
&\le \frac{2N^2}{p}\sum_{\ell=1}^{N}\frac{1}{\ell}\mu_0(\ell) \\
&= \frac{2N}{p}\frac{\sum_{\ell=1}^{N}\frac{N}{\ell}\cdot\binom{N-1}{\ell-1}\binom{N-1}{\ell-1}}{\sum_{\ell'=1}^{N}\binom{N-1}{N-\ell'}\binom{N-1}{\ell'-1}} \\
&= \frac{2N}{p}\frac{\sum_{\ell=1}^{N}\binom{N}{N-\ell}\binom{N-1}{\ell-1}}{\sum_{\ell'=1}^{N}\binom{N-1}{N-\ell'}\binom{N-1}{\ell'-1}} \\
&= \frac{2N}{p}\cdot\frac{\binom{2N-1}{N-1}}{\binom{2N-2}{N-1}} \\
&\le \frac{4}{p}N.
\end{aligned}
$$

5.2. Asymptotics. The expression for TIME(n, k, p) given by (3.6) is hard to evaluate if k and $n-k$ are large. We tried approximating it by the technique of moment-generating functions as follows:

Rewrite (3.6) as

$$
\mathrm{TIME}(n, k, p) = \frac{nk}{p}\cdot\frac{\sum_{\ell=1}^{\min(k,n-k)}\binom{k}{k-\ell}\binom{n-k-1}{\ell-1}(1-p)^{-\ell}}{\sum_{\ell'=1}^{\min(k,n-k)}\ell'\binom{k}{k-\ell'}\binom{n-k-1}{\ell'-1}(1-p)^{-\ell'}}. \tag{5.1}
$$

Consider now an urn with k red balls and $(n-k-1)$ black balls. Let X denote the number of black balls drawn when $(k-1)$ balls are drawn from the urn, one by one, without replacement. If $t = (1-p)^{-1}$, we may now write (5.1) as

$$
\begin{aligned}
\mathrm{TIME}(n, k, p) &= \frac{nk}{p}\frac{E(t^{X+1})}{E((X+1)t^{X+1})} \quad \text{[where } E \text{ denotes expectation]} \\
&= \frac{nk}{p}\frac{E(t^{X+1})}{t\cdot\frac{d}{dt}[E(t^{X+1})]}.
\end{aligned}
$$

This last expression can be approximated by regarding the hypergeometric random variable X to be approximately normally distributed. In particular, this technique yields for TIME($2N$, N, p) the approximation

$$
\frac{N}{p}\cdot\frac{1}{\frac{1}{2N}+\frac{1}{4}-\frac{1}{16}\ln(1-p)}.
$$

While this approximation seems to work reasonably well for $p \le 0.5$ as compared to simulated values, it is very poor for values of p close to 1.

It would be desirable to derive a closed-form expression for the limit of

$$\frac{n}{\text{TIME}(n, k, p)}$$

as n approaches ∞, k approaches ∞, and $\frac{k}{n}$ approaches α where $0 < \alpha < 1$. In the particular case where $\alpha = 1/2$, Berman and a referee have conjectured that this limit equals $1 - \sqrt{1 - p}$.

Acknowledgments. Shortly after we obtained our results, L. A. Shepp obtained (3.6) independently. A referee provided a number of detailed comments that led to a substantial change in style as well as shortening of an earlier version.

SUBQUADRATIC SIMULATIONS OF BALANCED FORMULAE BY BRANCHING PROGRAMS *

JIN-YI CAI[†] AND RICHARD J. LIPTON[‡]

Abstract. This paper considers Boolean formulae and their simulations by bounded width branching programs. It is shown that every balanced Boolean formula of size s can be simulated by a constant width (width 5) branching program of length $s^{1.811\cdots}$. A lower bound for the translational cost from formulae to permutation branching programs is also presented.

Key words. branching programs, Boolean formulae, Boolean circuits, group theory

AMS subject classifications. 68Q15, 68Q25

1. Introduction.

In a beautiful paper, Barrington [B] showed that the class of languages recognized by (nonuniform) NC^1 circuits (fan-in 2, depth $O(\log n)$ on n inputs) is identical to the class recognized by bounded width branching program with polynomial length. His main motivation was to resolve a conjecture that had been made by Borodin et al. [BDFP]. They had conjectured the opposite is true, namely, that bounded width computations requires exponential length to simulate NC^1; in particular, the majority function requires exponential length.

Barrington showed that any balanced Boolean formula of depth d can be recognized by a branching program of width 5 and length $(2^d)^2$. Thus, if an NC^1 function is represented by a balanced tree of depth d (so the size s of the tree is roughly 2^d), then the length of the branching program will be s^2, quadratic in the size of the tree. (For simplicity, we assume our balanced trees are fully balanced binary trees, as in Barrington's paper. Although our construction works for trees not fully balanced, the estimate of the length is more complicated.) Barrington's work has been generalized by Ben-Or and Cleve [BC] to algebraic formulae. Their simulation, which uses a construction similar to Barrington's, also has a quadratic increase in the length.

The first set of results in this paper is to improve on the upper bound established by Barrington. We show that, for width 5 branching programs, the exponent 2 in Barrington's construction can be improved to 1.811.... Then in §5 we present a lower bound on the translational cost from formulae to branching programs over any finite groups.

Our primary motivation for this work is to study branching programs and the important class NC^1 [Pi][Co]. If we can shed further light on the relationship between branching programs and the class NC^1 in the attempt to lower the exponent of the cost of simulating NC^1 by branching programs, the study will have proved to be worthwhile.

Specifically, we would like to sharpen the estimate of the translational cost from Boolean formulae to branching programs. The class of balanced Boolean formulae of polynomial size is the same as NC^1; thus, this also provides improved simulation of NC^1 by branching programs, although in general, another polynomial factor will appear [Sp], just as in Barrington's simulation. For the class of balanced Boolean formulae, one referee points out that, in fact, people have thought that the quadratic bound of Barrington was optimal, before the current paper. Also, understanding how to encode information into simple groups may help shed light

onto why no construction seems possible in solvable groups. These questions are intimately related to constant depth circuits with modulo p gates for a fixed finite set of primes p.

Unlike Barrington's construction, our branching programs in this paper use subprograms that are not restricted to have only two output values for intermediate steps, although the final output is still Boolean. The question of this so-called "weak" versus "strong" representation, namely, whether the less restrictive weak representation (with possibly more than two output values in intermediate steps) is more powerful than strong representation (with exactly two outputs), has been of interest in other upper/lower bound proofs. The present paper provides quantitative evidence that, for branching programs, indeed the less restrictive representation is more powerful.

There already has been some extension of our work since a preliminary version [CL] of this paper appeared in FOCS '89. Cleve [Cl] has proved one of our original conjectures: that indeed the exponent can be reduced to $1 + \varepsilon$ at the cost of increased (depending on ε but still constant) width for the simulating branching program. The width achieved is rather large, and the theoretical question of whether the increase is necessary is still open.

Our lower bound takes a first step toward this direction. Using a Ramsey-type argument, we show that over any finite group there must be a superlinear increase in the length in general. We establish the first superlinear lower bound for a class of branching programs that compute functions with linear formula size.

2. Preliminaries. The branching program model is a generalization of the binary decision tree model. We consider a branching program as given by a leveled directed acyclic graph. It has a "start" node. All links point from nodes of one level to the next, and all nodes of the last level are terminal nodes, labeled *accept* or *reject*. Each nonterminal node is labeled by a Boolean variable and has two links labeled *true* or *false*. A setting of the Boolean variables determines a unique path from the start node to a terminal node. The complexity measures are its width and length (see [B] for details).

We assume our NC^1 circuits are given by balanced binary trees of depth $O(\log n)$. In this paper, we speak of "size" as the tree size, or formula size, and circuits as balanced Boolean formulae. In case the tree is not balanced, one can always balance the tree (at the cost of a polynomial blow up of the circuit size). It is also well known that any NC^1 circuit can be simulated by a Boolean formula of polynomial size. Note that the quadratic cost of Barrington's simulation is also measured in terms of the balanced binary tree size of the circuit. To compare the cost of our simulation with that of Barrington's, we just consider balanced Boolean formulae.

We use some elementary notions and results of group theory; they can be found in any standard textbook in that subject (e.g., [H]).

3. A subquadratic simulation. We first review Barrington's construction [B]. Suppose an AND gate, $f \wedge g$, is given. Let's represent the truth values of f and g (true or false) by some elements of a finite simple group in such a way that the AND gate $f \wedge g$ can be represented likewise. This can be accomplished as follows. Represent "f = true" by some 5-cycle $a \in A_5$ and "f = false" by the identity $1 \in A_5$, where A_n is the alternating group on n letters. Represent g by some $b \in A_5$ and 1 likewise. Call the representation α and β, respectively. Consider the commutator $[\alpha, \beta]$, namely, the representation $\alpha\beta\alpha^{-1}\beta^{-1}$, where say, $\alpha^{-1} = a^{-1}$ or 1 depending on "f = true" or "f = false," respectively. Because the identity 1 commutes with any element of the group, we see immediately that the commutator evaluates to 1 if $f \wedge g$ is false. The commutator construction is completed by choosing a and b carefully so that the commutator $[a, b]$ is yet another 5-cycle. The case with an OR gate is dual. It should be clear how this can be translated to a statement about width 5 branching programs.

We note that by using a commutator at every level of a Boolean formula, the overhead is quadratic, that is, for a Boolean formula of size s, the length of the simulating branching program using this construction has length s^2.

We shall first give some intuitive ideas leading toward a subquadratic simulation of a Boolean formula. Without loss of generality, we assume our Boolean formulae are given by binary trees of depth $O(\log n)$ and the AND and OR gates alternate at every level. We indicate the modifications needed when the Boolean formulae do not conform to the requirements of strict alternation.

Again, assume we are given $f \wedge g$. It is apparent that if we solely depend on commutators, we necessarily end up with a quadratic blowup. On the other hand, with any simulation (without global reconfiguration), the best one can hope for is linear (or close to) linear overhead. If we simply concatenate the branching programs representing f and g, in other words, if we multiply the respective representations instead of forming their commutator, we get the optimal linear overhead. However, over a group, this necessarily will produce multiple representations for $f \wedge g$ for (at least) one of the truth values. This cannot be continued indefinitely, as the sets of representatives for true and false must be kept disjoint. Thus, it appears that certain "cleanup" steps must be taken.

We show that by carefully combining multiplication with commutators, one can simulate a Boolean formula more efficiently, that is, with a simulation of subquadratic length.

Any balanced Boolean formula of depth d can be expressed as $u \wedge (v \vee (x \wedge y))$, $u \vee (v \vee (x \wedge y))$, $u \vee (v \wedge x \wedge y)$, or $u \vee (v \vee x \vee y)$ or their duals, where u is of depth $d-1$, v is of depth $d-2$, and x and y are of depth $d-3$, respectively.

Let $F = u \wedge (v \vee (x \wedge y))$. Let $a = (1\ 4\ 2\ 3\ 5)$, $b = (1\ 2\ 3\ 4\ 5)$, $c = (1\ 4\ 3\ 5\ 2)$, and $d = (1\ 5\ 2\ 4\ 3)$. The following relations can be easily verified:

$$[a, b] = aba^{-1}b^{-1} = (1\ 4\ 2\ 3\ 5)(1\ 2\ 3\ 4\ 5)(5\ 3\ 2\ 4\ 1)(5\ 4\ 3\ 2\ 1) = (1\ 2\ 5\ 3\ 4) = c^{-1},$$

$$[a, b^2] = ab^2a^{-1}b^{-2} = (1\ 4\ 2\ 3\ 5)(1\ 3\ 5\ 2\ 4)(5\ 3\ 2\ 4\ 1)(4\ 2\ 5\ 3\ 1) = (1\ 3\ 2),$$

$$[a, b^2][a, b]^{-1} = [a, b^2]c = (1\ 3\ 2)(1\ 4\ 3\ 5\ 2) = (1\ 5\ 2\ 4\ 3) = d,$$

$$[c, d] = (1\ 4\ 3\ 5\ 2)(1\ 5\ 2\ 4\ 3)(2\ 5\ 3\ 4\ 1)(3\ 4\ 2\ 5\ 1) = (1\ 2\ 4\ 5\ 3).$$

These identities have the following implications. If we represent the truth value of x and y by 1 (if it is true) and b (if it is false) and if we multiply the representations, we get 1 if $x \wedge y$ is true and b or b^2 otherwise. Now let's represent the truth value of v by 1 (if it is true) and a (if it is false) and form the commutator of the representations of v and of $x \wedge y$ and then form the product of this commutator with $[a, b]^{-1} = c = (1\ 4\ 3\ 5\ 2)$. We call this last multiplication a *shift*. As a result, we get c if $v \vee (x \wedge y)$ is true and 1 or d otherwise. Finally, if we represent u by d (if it is true) and 1 (if it is false) and form the commutator of the representations of $v \vee (x \wedge y)$ and u, we end up with a nice clean form: $[c, d] = (1\ 2\ 4\ 5\ 3)$ if $F = u \wedge (v\ \vee (x \wedge y))$ is true and 1 otherwise.

It should be clear that the shift step does not cost anything in the branching program length, as $[a, b] = (1\ 2\ 5\ 3\ 4)$ is a constant and can be absorbed in the previous transition step in the branching program involving a variable.

By recursively applying the construction, we can get the following estimate. Suppose x, y, v, and u respectively represent circuits of depth k, k, $k+1$, and $k+2$ and of size 2^k, 2^k, 2^{k+1}, and 2^{k+2}, and let ℓ_i be the respective lengths of the branching programs. Then we have

$$\ell_{k+3} = 2(\ell_{k+2} + 2(\ell_{k+1} + (\ell_k + \ell_k))).$$

Let $\ell_i = 2^i \ell'_i$, then

$$\ell'_{k+3} = \ell'_{k+2} + \ell'_{k+1} + \ell'_k.$$

We have the characteristic equation

$$\lambda^3 = \lambda^2 + \lambda + 1.$$

By Cardan's formula [J], we can solve this equation exactly, with the only real root

$$\lambda = \frac{1}{3}(1 + (19 + 3\sqrt{33})^{1/3} + (19 - 3\sqrt{33})^{1/3}) \approx 1.839\ldots.$$

Thus, the construction here achieves a subquadratic blowup of $O(s^{1+\log_2 \lambda}) \approx O(s^{1.879\ldots})$.

We also remark that had the function F been $u \vee (v \vee (x \wedge y))$, we would not have to carry out the shift step in the above construction. Notice that if we simply form the commutator of the representations of v and of $x \wedge y$, we get 1 if $v \vee (x \wedge y)$ is true and $[a, b] = (1\ 2\ 5\ 3\ 4)$ or $[a, b^2] = (1\ 3\ 2)$ otherwise. We represent u by 1 or $(1\ 3\ 2)^{-1}(1\ 2\ 5\ 3\ 4) = (1\ 5\ 3\ 2\ 4)$ (in case it is true or false) and form the commutator of the representations of u and of $v \vee (x \wedge y)$, and we have 1 if F is true and

$$[(1\ 5\ 3\ 2\ 4), (1\ 2\ 5\ 3\ 4)] = [(1\ 5\ 3\ 2\ 4), (1\ 3\ 2)] = (1\ 2\ 3\ 4\ 5)$$

if F is false.

Moreover, given $F = u \vee (x \wedge (y \wedge z))$ or $F' = u \vee (x \vee (y \vee z))$, we have the following construction that performs even better. (These 4 cases are exhaustive, using duality.)

Let

$$a = (1\ 3\ 4\ 2\ 5), \qquad a' = (1\ 4\ 2\ 3\ 5), \qquad b = (1\ 4\ 5\ 2\ 3),$$

$$b' = (1\ 2\ 4\ 5\ 3), \qquad c = (1\ 2\ 5\ 3\ 4), \qquad c' = (1\ 3\ 4\ 2\ 5),$$

and

$$\gamma = aa' = bb' = cc' = aba'b' = aca'c' = bcb'c' = (1\ 5\ 4\ 3\ 2),$$

$$\delta = abca'b'c' = (1\ 3\ 4\ 2\ 5).$$

If we consider $a_x b_y c_z a'_x b'_y c'_z$, where $a_x = 1$ if x is true and $a_x = a$ if x is false, similarly for the others, we have:

$$a_x b_y c_z a'_x b'_y c'_z = \begin{cases} 1 & \text{if } x = y = z = 1, \\ \delta = (1\ 3\ 4\ 2\ 5) & \text{if } x = y = z = 0, \\ \gamma = (1\ 5\ 4\ 3\ 2) & \text{otherwise.} \end{cases}$$

For $F = u \vee (x \wedge y \wedge z)$, we represent u by 1 or $\gamma^{-1}\delta = (1\ 5\ 3\ 2\ 4)$ (true or false, respectively), and we have

$$[\gamma, \gamma^{-1}\delta] = [\delta, \gamma^{-1}\delta] = (1\ 2\ 4\ 5\ 3).$$

For $F' = u \vee (x \vee y \vee z)$, we represent u by 1 or γ (true or false, respectively), and we have

$$[\gamma, \delta] = (1\ 4\ 2\ 3\ 5).$$

(This is even slightly better in complexity with a growth of $s^{1.842\cdots}$. We omit the details. For simplicity we do not consider the strict requirements on alternation and multiple fan-in in the remainder of this paper to avoid tedious case analysis. Thus, we assume our tree is balanced and alternate at each level.)

4. Iterated simulation. In this section we indicate an improvement of the construction given in the last section. Again let us look at $F = u \wedge (v \vee (x \wedge y))$. The simple observation is that in the above construction when we have represented $v \vee (x \wedge y)$ by c if it is true and 1 or d if it is false, we can relax somewhat on the representation of u. More specifically, if we have $u = u_1 \vee u_2$, we may represent both u_1 and u_2 by d (true) and 1 (false) and then simply form the multiplication of the representation. This gives us the representation for u as d or d^2 when u is true and 1 otherwise. Now because all powers of d commute, we still get 1 if F is false. However, if F is true we get either

$$[c, d] = (1\ 2\ 4\ 5\ 3) \quad \text{or} \quad [c, d^2] = (2\ 3\ 4).$$

We note that the situation is exactly the same as what we have before in $v \vee (x \wedge y)$. More exactly, after a conjugation, we have the exact dual case as in the representation for $v \vee (x \wedge y)$ just before the shift. (We recall that a shift is free.) Specifically, the pairs a, b and c, d are conjugate to each other by the same conjugation. Let $\alpha = (1\ 4\ 2)$. Conjugation by α gives $c^\alpha = \alpha^{-1} c \alpha = (4\ 2\ 3\ 5\ 1) = a$ and $d^\alpha = (4\ 5\ 1\ 2\ 3) = b$ and thus $[c, d]^\alpha = [a, b]$ and $[c, d^2]^\alpha = [a, b^2]$. (Just like a shift, a conjugation is merely a renaming of the states of the branching program, and thus it is free. But unlike a shift, a conjugation is a simultaneous renaming of the input as well as the output states, and thus in the actual construction of the branching program, the conjugation does not even need to be carried out. We include them in the exposition only to show that inductively the construction can be carried out.)

Of course, now it is natural to iterate on this. Let h_i and h'_i be circuits of depth $k + i$ and $g_{i+1} = h_i \circ h'_i$, where $\circ = \wedge$ if i is even and $\vee$ if i is odd, and $0 \le i \le m - 2$ for some $m \ge 2$. Let f_1 be a circuit of depth $k + 1$ and $f_{i+2} = f_{i+1} \circ g_{i+1}$, where $\circ = \vee$ if i is even and $\wedge$ if i is odd. Finally, let $F_{m+1} = f_m \circ g_m$, where g_m is a circuit of depth $k + m$ and $\circ = \wedge$ if m is even and $\vee$ if m is odd. Our simulation will carry multiple values as we move up the tree. But in the last step we bring it back to the form of single-valued representation in both cases, true or false.

We have the following recurrence relation where ℓ_i denotes the length of a branching program simulating a circuit of depth i and size 2^i.

$$\ell_{k+m+1} = 2(\ell_{k+m} + 2(2\ell_{k+m-2} + \cdots + 2(2\ell_{k+1} + 2(2\ell_k + \ell_{k+1}))\ldots)),$$

or

$$\ell_{k+m+1} = 2^1 \ell_{k+m} + \sum_{i=3}^{m+1} 2^i \ell_{k+m+1-i} + 2^m \ell_{k+1}.$$

Simplifying a bit, let $\ell_i = 2^i \ell'_i$, we have

$$\ell'_{k+m+1} = \ell'_{k+m} + \sum_{i=3}^{m+1} \ell'_{k+m+1-i} + \ell'_{k+1},$$

which has a characteristic equation

$$\chi_{m+1}(\lambda) = \lambda^{m+1} - \left(\lambda^m + \sum_{i=3}^{m+1} \lambda^{m+1-i} + \lambda\right) = 0.$$

LEMMA 4.1. *Each χ_i has a unique positive root $\lambda_i, i \geq 3$. Furthermore, the set $\{\lambda_i\}$ forms a monotonic decreasing sequence with limit*

$$\lambda_* = \frac{1}{3}\left(2 + \left(\frac{25}{2} + \frac{3}{2}\sqrt{69}\right)^{1/3} + \left(\frac{25}{2} - \frac{3}{2}\sqrt{69}\right)^{1/3}\right) \approx 1.7549\ldots.$$

This implies the following theorem.

THEOREM 4.2. *Every balanced Boolean formula of size s can be simulated by a width 5 permutation branching program of length $O(s^{1+\log_2 \lambda_* + o(1)}) \approx O(s^{1.811\ldots})$. Thus, exponent of the simulation is at most 1.811....*

Proof of the lemma. It is easy to verify that $\chi_3(\lambda) = \lambda^3 - \lambda^2 - \lambda - 1$ has a unique real root at $\lambda_3 = \frac{1}{3}(1 + (19 + 3\sqrt{33})^{1/3} + (19 - 3\sqrt{33})^{1/3}) \approx 1.839\ldots$ by Cardan's formula.

Furthermore, χ_3 has a unique local maximum at $-\frac{1}{3}$ of $\chi_3(-\frac{1}{3}) = -\frac{22}{27}$ and a unique local minimum at 1 of $\chi_3(1) = -2$; thus, $\chi_3(\lambda) < 0$ for $\lambda < \lambda_3$ and monotonic increasing for $\lambda > 1$.

Let

$$\lambda_* = \frac{1}{3}\left(2 + \left(\frac{25}{2} + \frac{3}{2}\sqrt{69}\right)^{1/3} + \left(\frac{25}{2} - \frac{3}{2}\sqrt{69}\right)^{1/3}\right) \approx 1.7549\ldots$$

be the unique real root of $\chi_*(\lambda) = (\lambda - 1)^2\lambda - 1$ (Cardan's formulas). Inductively, we assume that χ_m has a unique positive real root λ_m, $\lambda_* < \lambda_m < \cdots < \lambda_3$, and, moreover, χ_m is monotonic increasing for $\lambda > \lambda_*$, and $\chi_m(\lambda) < 0$ for $0 < \lambda < \lambda_m$.

Let

$$\Delta_m(\lambda) = \chi_{m+1}(\lambda) - \chi_m(\lambda) = \lambda^{m-2}((\lambda - 1)^2\lambda - 1) = \lambda^{m-2}\chi_*(\lambda). \tag{1}$$

It follows, by the definition of λ_*, that $\Delta_m(\lambda) > 0$ for $\lambda > \lambda_*$ and $\Delta_m(\lambda) < 0$ for $0 < \lambda < \lambda_*$. Furthermore, it can be verified directly that $\Delta'_m(\lambda) > 0$ for $\lambda > \lambda_*$.

Thus, $\chi_{m+1}(\lambda) = \chi_m(\lambda) + \Delta_m(\lambda) < 0$ for $0 < \lambda \leq \lambda_*$ and monotonic increasing for $\lambda > \lambda_*$; therefore, $\chi_{m+1}(\lambda)$ has a unique positive real root λ_{m+1}, $\lambda_* < \lambda_{m+1} < \lambda_m < \cdots < \lambda_3$. Moreover, $\chi_{m+1}(\lambda) < 0$ for $0 < \lambda < \lambda_{m+1}$. The induction is completed.

It follows that $\lim \lambda_m$ exists. Let $\lambda^* = \lim \lambda_m$. We claim $\lambda^* = \lambda_*$. Suppose not; thus, $\lambda_* < \lambda^*$. By (1), $\chi_m(\lambda_*)$ is some negative constant $-c$ independent of m.

It is easy to show, by directly taking and estimating the derivative on χ_{m+1}, that for all $\lambda > \lambda_*$,

$$\chi'_{m+1}(\lambda) \geq \lambda^m + m\chi_m(\lambda) \geq \lambda_*^m - mc,$$

which tends to infinity as $m \to \infty$.

However, by the intermediate value theorem, for all m, there exists $\tilde{\lambda}_m \geq \lambda_*$, such that the value of $\chi'_m(\lambda)$ at $\tilde{\lambda}_m$ is bounded above:

$$\chi'_m(\tilde{\lambda}_m) = \frac{\chi_m(\lambda_m) - \chi_m(\lambda_*)}{\lambda_m - \lambda_*} \leq \frac{c}{\lambda^* - \lambda_*}.$$

This contradiction shows that $\lim \lambda_m = \lambda_*$. □

5. A superlinear lower bound. We turn our attention to lower bounds in this section. In particular, we ask what is the minimum length of a branching program for functions with linear formula size. In this section we present a lower bound of $\Omega(n \log\log n)$ for the translational cost from NC^1 circuits to permutation branching programs over any finite group. This bound is the first known lower bound for the translational cost.

Several super linear lower bounds are known for branching programs. Chandra, Furst, and Lipton [CFL] showed that the function $\sum_i x_i = n/2$ requires $\Omega(nw(n))$ in the length of any bounded-width branching program, where $w(n)$ is the inverse function of the van der Waerden numbers. Pudlák [Pu] proved an $\Omega(n \log\log n / \log\log\log n)$ lower bound for threshold functions. A lower bound of $\Omega(n \log n)$ for symmetric Boolean functions was achieved by Ajtal et al [Aj]. However, it is not known whether any lower bound applies to functions with linear circuit size. See also [B2] and [BT] for lower bounds for branching programs over specific groups such as S_3 and some solvable groups. Our bound is the first over an arbitrary finite group.

Our lower bound applies only to permutation branching programs and not to (unrestricted) branching programs in general. In fact, we establish the $\Omega(n \log\log n)$ lower bound for the AND function $\bigwedge_{i+1}^{n} x_i$, which has a trivial width two branching program of length n. Our proof is Ramseyian; a similar method has been used in [AM].

THEOREM 5.1. *Any permutation branching program computing the function* AND $\bigwedge_{i=1}^{n} x_i$ *requires length* $\Omega(n \log\log n)$.

Let a permutation branching program over a finite group G be given that computes the logical AND function of n Boolean variables $x_1, x_2, \dots, x_n$.

We assume the branching program has the following normal form

$$BP(x_1, x_2, \dots, x_n) = g_1(x_{i_1}) g_2(x_{i_2}) \dots g_L(x_{i_L}).$$

(See [B2].) Thus, for each step, the transition depends on one Boolean variable x. Furthermore, if x is true, then the transition is identity $g_k(1) = 1$, and if x is false, then the transition is some element of the group G, $g_k(0) = g_k \in G$. Without loss of generality, every permutation branching program can be brought to this form without any increase of length.

We prove a lower bound on the length L of the branching program. Let n_k denote the number of variables that occur exactly k times in the branching program, then $\sum_{k\geq 1} n_k = n$ and $\sum_{k\geq 1} kn_k = L$. If $\sum_{k\geq(\log_3\log_3 n)/2} n_k \geq n/2$, then we are done: $L \geq (n \log\log n)/4$. We assume $\sum_{k<(\log_3\log_3 n)/2} n_k \geq n/2$, and thus there exists $k < (\log_3\log_3 n)/2$, $n_k \geq n/\log_3\log_3 n$. Set all other variables to true, we get a branching program on n_k variables, each variable appears exactly k times, where $k < (\log_3\log_3 n)/2$. Denote $N = n_k$.

Let ℓ_{ij} be the location of the jth appearance of the ith variable x_i. By renaming variables if necessary, we assume that the first appearances are in order, that is,

$$\ell_{11} < \ell_{21} < \cdots < \ell_{N1}.$$

Consider the second appearances of these variables. We select a subset of the variables of cardinality $\geq N^{1/3}$, such that the second appearances of these variables are nicely correlated to the first appearances of the same variables. More precisely, we show that there exists a subsequence $i_1 < i_2 < \cdots < i_m$ of $1, 2, \dots, N$, where $m \geq N^{1/3}$, such that one of the following three alternatives hold:

(1) $\ell_{i_1 2} > \ell_{i_2 2} > \cdots > \ell_{i_m 2}$, or

(2) $\ell_{i_1 2} < \ell_{i_2 2} < \cdots < \ell_{i_m 2}$ and $\ell_{i_1 2} > \ell_{i_m 1}$, or

(3) $\ell_{i_1 1} < \ell_{i_1 2} < \ell_{i_2 1} < \ell_{i_2 2} < \cdots < \ell_{i_m 1} < \ell_{i_m 2}$.

For any sequence of integers, it is well known that we can first obtain either a monotonic decreasing subsequence of length $m' \geq N^{1/3}$ or a monotonic increasing subsequence of length

$m' \geq N^{2/3}$ of the sequence $\ell_{12}, \ell_{22}, \ldots, \ell_{N2}$. If the subsequence is monotonic decreasing, then the first altenative holds.

Suppose it is monotonic increasing. By setting all the other variables to true and by renaming the variables, we may assume the subsequence is $\ell_{12} < \ell_{22} < \cdots < \ell_{m'2}$. For $1 \leq i \leq m'$, let $p(i) = \max\{p \mid \ell_{i2} > \ell_{p1}\}$, that is, the relative place of ℓ_{i2} in the first sequence. Clearly, $p(i) \geq i$ for all i, and $1 \leq p(1) \leq \cdots \leq p(m') = m'$. Now we ask the key question: Is there an i, $1 \leq i \leq m'$, such that $p(i) - i \geq \sqrt{m'}$? If so, then we choose the subset as those with indices between i and $p(i)$:

$$\ell_{i2} < \ell_{i+12} < \cdots < \ell_{p(i)2},$$

and $\ell_{i2} > \ell_{p(i)1}$. Thus, the second alternative holds.

Now suppose the answer is no, that is, for all i, $p(i) - i < \sqrt{m'}$. Then we are going to select our subsequence greedily as follows: Let $q(i) = p(i) + 1$, and

$$i_j = q^{(j-1)}(1), \qquad 1 \leq j \leq \sqrt{m'},$$

where $f^{(k)}$ denotes the kth iterate of a function f. That all i_j, $1 \leq j \leq \sqrt{m'}$, are no greater than m', and thus well defined, is a consequence of our hypothesis for all i, $p(i) - i < \sqrt{m'}$. This implies the third alternative and completes the proof of our claim.

Now one can iterate this process. Suppose s iterations are done, and $N' \geq N^{1/3^s}$ variables remain. Inductively, every successive sequence (consisting of the rth occurrence, $1 < r \leq s$, of the remaining variables) is related to its previous sequences similarly as in that between the first and the second sequence just shown. In fact, we can group together those successive sequences related as in alternative 3, namely

$$\ell_{i_1 r} < \ell_{i_1 r+1} < \cdots < \ell_{i_1 r'} < \ell_{i_2 r} < \ell_{i_2 r+1} < \cdots < \ell_{i_2 r'} < \cdots < \ell_{i_m r} < \ell_{i_m r+1} < \cdots < \ell_{i_m r'},$$

or its reverse,

$$\ell_{i_1 r} > \ell_{i_1 r+1} > \cdots > \ell_{i_1 r'} > \ell_{i_2 r} > \ell_{i_2 r+1} > \cdots > \ell_{i_2 r'} > \cdots > \ell_{i_m r} > \ell_{i_m r+1} > \cdots > \ell_{i_m r'}.$$

Call any maximal such internal $\{j | r \leq j \leq r'\}$ a block.

We focus on the last block, say starting from $t + 1$ to s. By renaming the variables, we assume inductively $x_1, x_2, \ldots, x_{N'}$ are remaining, and

$$\ell_{1,t+1} < \ell_{1,t+2} < \cdots < \ell_{1s} < \ell_{2,t+1} < \ell_{2,t+2} \cdots < \ell_{2s} < \cdots < \ell_{N',t+1} < \ell_{N',t+2} < \cdots < \ell_{N's},$$

and, if $t > 0$, the tth and $t + 1$st sequence are related as in alternative (1) or (2). (The other alternative of reversing all $<$ to $>$ in the above ℓ-sequence is symmetric.)

We will select a subsequence of $\ell_{1s+1}, \ldots, \ell_{N's+1}$, indexed by $i_1 < i_2 < \cdots < i_m$, where $m \geq N'^{1/3}$, such that one of the following three alternatives is true:

(1) $\ell_{i_1 s+1} > \ell_{i_2 s+1} > \cdots > \ell_{i_m s+1}$, or

(2) $\ell_{i_1 s+1} < \ell_{i_2 s+1} < \cdots < \ell_{i_m s+1}$ and $\ell_{i_1 s+1} > \ell_{i_m s}$, or

(3) $\ell_{i_1 t+1} < \ell_{i_1 t+2} < \cdots < \ell_{i_1 s} < \ell_{i_1 s+1} < \ell_{i_2 t+1} < \ell_{i_2 t+2} < \cdots < \ell_{i_2 s} < \ell_{i_2 s+1} < \cdots < \ell_{i_m t+1} < \ell_{i_m t+2} < \cdots < \ell_{i_m s} < \ell_{i_m s+1}$.

The proof is identical to the base case, and we will not repeat it here.

Because $k < (\log_3 \log_3 n)/2 < \log_3 \log_3 N$, the process can be iterated k times. We end up with k sequences each of which has $n' \geq N^{1/3^k}$ variables, and the branching program computes the AND function of these variables (all others are set to true). Moreover, all adjacent blocks of sequences are related in one of three ways as above. Clearly, any block can be collapsed to just one sequence. After the collapse (and renaming the variables) we have $k' \leq k$ sequences, and the branching program looks like

$$S_1 S_2 \dots S_{k'},$$

where each S_j is either

$$g_{1j}(x_1) g_{2j}(x_2) \dots g_{n'j}(x_{n'}),$$

or

$$g_{n'j}(x_{n'}) g_{n'-1j}(x_{n'-1}) \dots g_{1j}(x_1).$$

Consider the map F from $1 \leq i \leq n'$ to $G^{k'}$:

$$i \mapsto \langle s_1(i), s_2(i), \dots, s_{k'}(i) \rangle,$$

where

$$s_j(i) = g_{1j} g_{2j} \cdots g_{ij},$$

in the first case of S_j, or

$$s_j(i) = g_{ij} g_{i-1,j} \cdots g_{1j},$$

in the second case of S_j. (Recall that $g_{\sigma j} = g_{\sigma j}(0) \in G$.)

Because $k < (\log_3 \log_3 n)/2$ and $N \geq \frac{n}{\log_3 \log_3 n}$, it follows easily that[1] $n' \geq N^{1/3^k} > |G|^{k'}$; thus, $F(i) = F(i')$ for some $i < i'$ by the pigeonhole principle. Therefore, for all j, $g_{i+1\,j} \cdots g_{i'j} = 1 \in G$, or $g_{i'j} \cdots g_{i+1\,j} = 1 \in G$, which ever the case may be. This implies that the original branching program evaluates to 1 when all variables (after renaming) between x_{i+1} and $x_{i'}$ are set to false and others set to true. Hence it does not compute the AND function. This completes the proof of our lower bound.

The method we used here to prove our $\Omega(n \log \log n)$ lower bound has been used by Barrington and Straubing to obtain several other lower bounds [BS].

6. Open problems. There are many unanswered questions raised here. We mentioned in the beginning of the paper that Cleve [Cl] has proved the following theorem, which was the first conjecture in the preliminary version of this paper.

THEOREM 6.1 (Cleve). *For any $\epsilon > 0$, an NC^1 circuit of size s can be simulated by a width $2^{2^{O(1/\epsilon)}}$ (permutation) branching program of length $O(s^{1+\epsilon})$.*

In view of this, it is natural to define *Barrington's constants* $\mathcal{B}_k$, for each width k, that is, $\mathcal{B}_k$ is the infimum of $\mathcal{B}$ such that any NC^1 circuit of size s can be simulated by a width k (permutation) branching program of length $O(s^{\mathcal{B}})$. We conjecture that these Barrington's constants are greater than one (and hence nontrivial).

[1] Let $c = |G|$, a constant. Because $k < (\log_3 \log_3 n)/2$, $3^k < \sqrt{\log_3 n}$. As $N \geq \frac{n}{\log_3 \log_3 n}$,

$$\begin{aligned} N \cdot \log_3 \log_3 n &\geq n \\ &\geq c^{\frac{\sqrt{\log_3 n}\, \log_3 \log_3 n}{2}} + \log_c \log_3 \log_3 n \\ &> c^{\frac{\log_3 \log_3 n}{2} \cdot 3^k} \cdot \log_3 \log_3 n. \end{aligned}$$

Thus, $N^{1/3^k} > c^{\frac{\log_3 \log_3 n}{2}} > c^k \geq c^{k'}$, for large n.

CONJECTURE 6.2. *Width k (permutation) branching programs simulating any NC^1 circuit of size s requires length $\Omega(s^{1+\epsilon_k})$, for some $\epsilon_k > 0$.*

Our lower bound in §5 can be viewed as the first step toward settling this conjecture. If this conjecture is true, one may further inquire the exact order of growth of these *Barrington's constants* $\mathcal{B}_k$. The best known bound for $\mathcal{B}_5$ is 1.811 .... It is not clear what to expect in general. A tight simulation of circuits by branching programs could offer the possibility of proving lower bounds for circuits size, whereas a reasonable width could be valuable in hardware design pertaining reconfigurable chips.

Acknowledgments. We thank Sandeep Bhatt, Walter Feit, Mike Fischer, Merrick Furst, Roger Howe, Herb Scarf, and George Seligman for helpful conversations. We thank the two anonymous referees for many comments.
