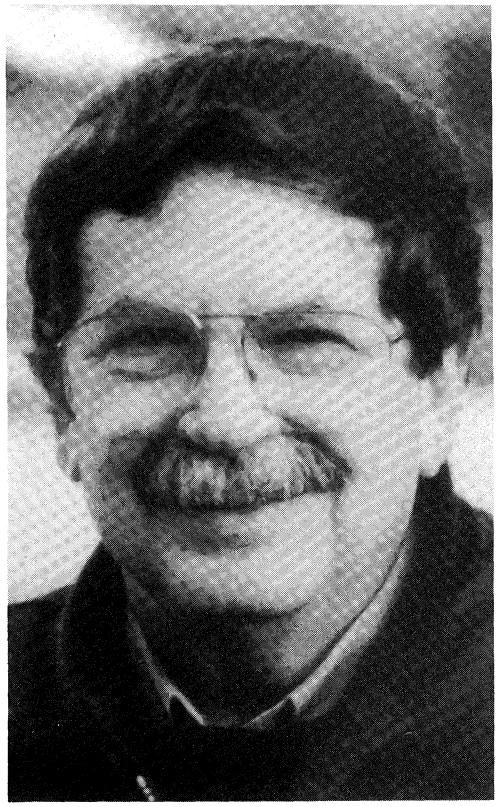
IN MEMORIAM
EUGENE L. LAWLER



Eugene L. Lawler died on September 2, 1994, at age 61, after an eight month battle with cancer. He is survived by his wife Marijke, his son Stephen, and his daughter Susan, son-in-law Matthew, and granddaughter Janna Rose Surprise. He will be dearly missed by his students, colleagues, and friends.

Gene obtained an A.M. at Harvard University in 1957 and was a Senior Electrical Engineer at Sylvania Electric Products in Needham, Massachusetts from 1959 until 1961. He went back to Harvard to obtain a Ph.D. in 1962. He taught at the University of Michigan in Ann Arbor from 1962 until 1970 and the University of California at Berkeley from 1971 until his death. He combined an illustrious career of highly influential research with a history of dedicated service to both universities. Throughout his career, Gene was an active member of the theoretical computer science community; he served on the editorial board of *SIAM Journal on Applied Mathematics* (1968–1972) as well as *SIAM Journal on Computing* (1972–1980).

For more than 30 years, Gene Lawler studied algorithmic issues in combinatorial optimization. His contributions were fundamental in giving the discipline the breadth and depth it has now attained. Of all of his work, his textbook *Combinatorial Optimization: Networks and Matroids* (1976) has had the most pronounced impact. It brought together the most important results in the area and is notable for its lucid writing style. It gave new clarity to both well-understood and not so well-understood results, brought the reader to the forefront of the field, and made the challenges of the future both apparent and accessible. It is one of the classics of the area and is as useful today as the day it was written. Another book, *The*

Traveling Salesman Problem: A Guided Tour of Combinatorial Optimization (1985), which he edited with three younger colleagues, also became a benchmark reference.

It is hard to separate Gene's contributions as an expositor from those as a researcher. His great gift in investigating a computational approach to a problem was his ability to extract the essential difficulty, achieve a deeper insight, and solve a more general problem in a simpler way. To some extent, his expository talent came from the relative difficulty he had in absorbing new ideas. In order for him to understand other people's work, especially when it was written in a complicated way, he often had to wrestle with it to arrive at a better understanding and a simplification of the result.

Gene's papers on branch-and-bound (with D. E. Wood) and dynamic programming (with J. M. Moore) are classics; the former, in fact, was selected as a citation classic in 1987. Rather than introducing radically new techniques, both papers brought a new level of usefulness and understanding to important algorithmic paradigms. Since the mid 1970s, Gene was particularly interested in sequencing and scheduling. Prior to his work, the area was a rather unmathematical hodgepodge, with little systematic understanding of the types of methods and techniques that could be used most effectively. Gene's work greatly stimulated and unified the area. His main unfinished project is the completion of a graduate textbook on scheduling. He made significant contributions to a wide variety of questions in the area of combinatorial optimization, which were influential in both the operations research and computer science communities. Most recently, he had turned his attention to combinatorial problems in computational biology, which is an area of growing importance.

As this summary of Gene's research contributions might suggest, he was a phenomenal educator. He could provide the intuition that made difficult results easily accessible. His appreciation of the difficulties of absorbing ideas to the point that one can go beyond them in some original way helped to make him a great advisor. He was constantly available for every new idea and always ready to interest his students in whatever he was currently thinking about.

Gene had an enormous influence on the atmosphere of the Computer Science Division at Berkeley. He never lost sight of the mission of a university and never backed away from difficult tasks. Gene was the social conscience of the Division. He helped the individual student fight the bureaucracy, reformed what the university taught and to whom it taught it, and made the university a more humane and more stimulating place to study. Last year he was awarded the Berkeley Citation, the campus' highest accolade.

Gene Lawler was a remarkable man who was ready to discuss intelligently almost any current issue, and who did so in a thought-provoking way. We will all miss him very much.

MATRIX TRANSFORMATION IS COMPLETE FOR THE AVERAGE CASE*

ANDREAS BLASS† AND YURI GUREVICH‡

Abstract. In the theory of worst case complexity, NP completeness is used to establish that, for all practical purposes, the given NP problem is not decidable in polynomial time. In the theory of average case complexity, average case completeness is supposed to play the role of NP completeness. However, the average case reduction theory is still at an early stage, and only a few average case complete problems are known. The first algebraic problem complete for the average case under a natural probability distribution is presented. The problem is this: Given a unimodular matrix X of integers, a set S of linear transformations of such unimodular matrices and a natural number n, decide if there is a product of $\leq n$ (not necessarily different) members of S that takes X to the identity matrix.

Key words. average case, decision problems, unimodular matrices, reduction, randomization

AMS subject classifications. 68Q15, 60C05, 15A36, 15A25

1. Introduction. The theory of NP completeness is very useful. It allows one to establish that certain NP problems are NP complete and therefore, for all practical purposes, not decidable in polynomial time (PTime). One way around the NP completeness phenomenon is to consider the given NP problem together with an appropriate probability distribution and seek a decision algorithm that runs quickly on average. This works very well for some problems (see [GS], for example), but some other randomized decision problems appear too difficult even on average. It would be very useful to generalize the theory of NP completeness to be able to establish that certain randomized decision problems are, for all practical purposes, not decidable quickly on average. This is the motivation for the theory of average case completeness.

Before we plunge into this theory, let us review briefly the NP completeness theory. The idea is that PTime algorithms are considered easy. In particular, PTime decidable NP problems are considered easy. One says that an NP problem Π_1 reduces to an NP problem Π_2 if there is a PTime algorithm R from instances of Π_1 to instances of Π_2 that takes positive instances to positive instances and negative instances to negative instances. Such an R is a many-one PTime reduction from Π_1 to Π_2. A PTime decision algorithm A for Π_2 gives rise to the PTime decision algorithm $R \circ A$ for Π_1. A decision problem is hard for NP (via many-one PTime reductions) if every NP problem reduces to it (by means of a many-one PTime reduction). A decision problem is complete for NP if it belongs to NP and is hard for NP. Most known natural NP problems are either PTime decidable or NP complete.

The theory of average case completeness was pioneered by Levin in [Le]. Levin replaced NP with the class RNP of NP problems with so-called PTime computable probability distributions [Le], [Gu1]. He generalized PTime computability to computability in time polynomial on average (APtime computability) and defined many-one PTime reductions of RNP problems. Then he established that a bounded version of the known tiling problem together with a natural probability distribution is complete for RNP via many-one PTime reductions. (That is, the randomized tiling problem belongs to RNP and every problem in RNP reduces to it via many-one PTime reductions.) Another RNP problem, implicitly present in [Le], is bounded halting, a bounded version of the standard halting problem together with natural probability distribution; this problem is explicitly defined and proved complete in [Gu1].

Some progress has been achieved in the meantime. In particular, the restriction to PTime computable distributions was liberalized [BCGL]; Levin's complete problems remained complete (we return to the issue of the liberalized RNP later in this introduction). The reduction theory has been revised [Gu1], [BCGL], [VL], [BG1], [BG2]. In particular, deterministic reductions, shown insufficient in [Gu1], have been replaced in [VL] by randomizing reductions; in other words, reduction algorithms have been allowed to flip coins. This tuning up of the reduction theory continues in this paper. In §§2–5 of this paper, we describe the current state of the reduction theory in full detail and in particular define a clean notion of randomized many-one reductions of randomized decision problems.

A number of additional natural RNP complete problem have been found [Gu1], [VL], [Gu2], [VR], but that number is still very small. Moreover, none of the known complete problems, however natural they are, arose in applications. All of them were designed especially for the purpose of finding additional average-case complete problems. Why have not more problems been found? It is possible that the reduction theory must be tuned up further. It is certainly true that establishing average-case completeness is much more difficult than establishing worst-case completeness; the range of an average-case reduction of a problem Π_1 to a problem Π_2 cannot comprise only very, very special instances of Π_2. What should be done? Consider the theory of undecidability or NP completeness. In either case, a rich collection of complete problems (complete for recursive enumerability via recursive reductions or NP complete, respectively) has been accumulated that are convenient for reductions to other problems. We need, it seems, to accumulate a rich collection of various average-case complete problems with the hope that these problems will be useful for further reductions. In this connection, Levin challenged Gurevich (who started his career an algebraist) to find an average-case complete problem of algebraic character. Such a problem was found in [Gu2]; this paper is a full version of the extended abstract [Gu2].

The matrix decomposition problem involves linear transformations of unimodular matrices. The *modular group* is the multiplicative group $\mathrm{SL}_2(Z)$ of two-by-two integer matrices of determinant 1 (*unimodular matrices*). The notion of linear transformation of $\mathrm{SL}_2(Z)$ does not seem to make sense because $\mathrm{SL}_2(Z)$ is not closed under addition, but this difficulty is not serious. Define a *linear transformation* of $\mathrm{SL}_2(Z)$ to be a function T from $\mathrm{SL}_2(Z)$ to $\mathrm{SL}_2(Z)$ such that $T(\sum X_i) = \sum T(X_i)$ whenever all the X_i and $\sum X_i$ are unimodular matrices. We show in §9 that a linear transformation T of $\mathrm{SL}_2(Z)$ uniquely extends to a linear transformation of all two-by-two integer (or even complex) matrices; this gives rise to the standard representation of T by a four-by-four integer matrix. Moreover we will describe a simple (certainly PTime) test to determine when a given four-by-four integer matrix represents a linear transformation of $\mathrm{SL}_2(Z)$. Identify linear transformations with the four-by-four integer matrices representing them.

Now we are ready to define our randomized decision problem. An instance of Matrix Transformation comprises three components: a unimodular matrix X, a finite set $\mathcal{S}$ of linear transformation of unimodular matrices, and a natural number n. The corresponding question is whether there exists a linear transformation $T \in \mathcal{S}^n$ such that $T(X)$ is the unit (or identity) matrix. Here $\mathcal{S}^n$ comprises products $T_1 \cdots T_m$ where $m \leq n$ and each $T_i \in \mathcal{S}$.

Define the size of an integer matrix (whether it is two-by-two or four-by-four) to be the length of the binary representation of the maximal absolute value of the entries. The size of an instance $(X, \mathcal{S}, n)$ is n plus the size of X plus the sum of the sizes of all members of $\mathcal{S}$.

The probability distribution on the instances is rather natural. The three components of a random instance $(X, \mathcal{S}, n)$ are chosen independently. The integer component n is chosen with respect to the default probability function $1/n(n+1)$. (The choice of the default distribution does not matter much [Gu1].) To choose the unimodular component X, first choose a positive

integer k with respect to the default distribution and then choose X randomly (with respect to the uniform probability distribution) among all unimodular matrices of size k. An auxiliary probability distribution on linear transformations is defined similarly; linear transformations of the same size have the same probability and the probability to have size k equals the default probability of k. Finally, the probability of $\mathcal{S}$ is proportional to the product of the probabilities of the members of $\mathcal{S}$. This completes the definition of Matrix Transformation.

We reduce Bounded Halting to Matrix Transformation and this way prove Matrix Transformation is complete for RNP via randomized many-one reductions. It remains complete under various restrictions on the cardinality of $\mathcal{S}$ and/or the number n; see §10 in this connection.

Actually, we prove only that Matrix Transformation is hard for RNP. It is obvious that (the unrandomized version of) Matrix Transformation is NP. Checking that the probability distribution is PTime is routine and we ignore it. We have already mentioned that the definition of RNP has been liberalized in [BCGL] by allowing more general distributions called *samplable*. Impagliazzo and Levin proved that every NP search problem with samplable distribution reduces via many-one PTime computable reductions to an NP search problem with PTime computable distribution [IL] (see also [BG2]). In an appropriate sense a search problem with a PTime computable distribution reduces to a decision problem with PTime computable distribution [BCGL]. Thus, Matrix Transformation is hard for the class of NP search problems with samplable distributions. Our reduction of Bounded Halting to Matrix Transformation can be easily modified to obtain a many-one randomized reduction of the search version of Bounded Halting to the search version of Matrix Transformation. Thus, the search version of matrix transformation is complete for the class of NP search problems with samplable distributions. The question remains whether Matrix Transformation (or Bounded Halting) is complete for the class of NP decision problems with samplable distributions. In the usual NP theory, decision problems are easily reducible to search problems. The situation is different in the average-case theory. We intend to consider these issues in [BG3].

A simpler version of Matrix Transformation is obtained by making $\mathcal{S}$ just a set of unimodular matrices and asking whether another unimodular matrix X can be represented as a product of at most n matrices from $\mathcal{S}$. This bounded version of the classical membership problem [Mi, p. 511] for $SL_2(Z)$ is NP complete; see § 11 in this connection. However, we do not think that the naturally randomized version of the bounded membership (§11) problem is complete for the average case. Indeed, there are indications that it is solvable in time polynomial on average. However, Venkatesan and Rajagopalan proved that the same problem for higher-dimension matrices is complete for the average case [VR].

Since we deal almost exclusively with randomized decision problems, the term "decision problem" will usually mean "randomized decision problem"; similarly, the term "search problem" will usually mean "randomized search problem."

2. Domains. As a general framework for the study of average case complexity, we use domains [Gu2], [BG1], [BG2].

DEFINITION 2.1. *A* domain X *consists of*

- *An underlying set, the* universe *of* X*, often called* X *as well, comprising strings in some alphabet* Σ_X;
- *A size function, assigning to each* $x \in X$ *a positive integer* $|x| = |x|_X$ *called the* size *of* x; *and*
- *A probability distribution* $\mathbf{P}_X$ *on* X.

We require elements of the domain to be strings in order to use the usual computation model based on the Turing machine. In the rest of the paper, an algorithm is a Turing machine. Traditional concepts of (worst-case) complexity are defined by means of the size function $|x|$. Concepts of average-case complexity are defined by averaging with respect to the probability

distribution $\mathbf{P}_X$. As was pointed out by Levin [Le] and discussed in some detail in [BCGL], [Gu1], the most obvious definition of the concept "polynomial time on average" has inappropriate consequences, and some care is needed to obtain a suitable definition. We use the following definition due to Levin [Le], as modified in [BG1] to allow ∞ as a value.

DEFINITION 2.2. *Let T be a function from a domain X to the interval $[0, \infty]$ of the real line augmented with ∞. T is* linear on average *if $T(x)/|x|$ has finite expectation,*

$$\mathop{\mathbf{E}}_{x} \frac{1}{|x|} T(x) = \sum_{x} \mathbf{P}_X(x) \frac{1}{|x|} T(x) < \infty,$$

and T is polynomial on average, *abbreviated AP, if it is bounded by a polynomial of a function that is linear on average. In other words, T is AP if, for some $\varepsilon > 0$,*

$$\mathop{\mathbf{E}}_{x} \frac{1}{|x|} (Tx)^{\varepsilon} = \sum_{x} \mathbf{P}_X(x) \frac{1}{|x|} (Tx)^{\varepsilon} < \infty\,.$$

We use the convention that $0 \cdot \infty = 0$; thus, an AP function can take the value ∞ but only at points of probability 0.

LEMMA 2.3 [Gu1].

- *If $\mathbf{E}(|T(x)| \mid |x| = l)$ is bounded by a polynomial of l, then T is AP.*
- *On any domain, the collection of AP functions is closed under addition and multiplication.*

DEFINITION 2.4. *A (deterministic) algorithm, taking elements of a domain X as inputs, is* polynomial time on average *or* AP time *if its running time on input x is an AP function of x.*

We consider the running time to be ∞ if the algorithm fails to terminate, so an AP time algorithm must terminate on all inputs of nonzero probability. In general, we take the point of view that instances of zero probability do not matter. By following that line consistently, which we try to do, we often have the luxury of throwing elements of zero probability out and supposing, when convenient, that no element of the domain X in question has zero probability or throwing elements of zero probability in and supposing, when convenient, that every string over Σ_X is an element of X. However, we do not go so far as to identify two domains if one of them is obtained from the other by eliminating some elements of zero probability.

In the case of domains with finitely many elements, it would be natural to call a domain uniform if all elements have the same probability. This definition makes no sense in the case of infinite domains, which is the only case of interest to us. Another natural way to define uniform domains requires a default probability distribution on positive integers; it is customary to assign the probability $1/n(n+1)$ to a positive integer n. The choice of the default probability distribution does not matter much; see [Gu1] in this connection.

DEFINITION 2.5. *PI is the domain of positive integers such that $|n| = n$ and the probability of any n is $1/[n(n+1)]$. The probability of a number n in PI is called the* default probability *of n.*

DEFINITION 2.6. *A domain is* uniform *if it has a finite number of elements of any given size, all elements of a given size have the same probability, and $\mathbf{P}\{x : |x| = n\}$ equals the default probability of n.*

Here are two examples of uniform domains.

DEFINITION 2.7. *BS is the uniform domain of nonempty binary strings where the size of a string is its length. FRACTION is the uniform domain of fractions a/b where a, b are relatively prime positive integers, $a \le b$ and the size of a/b is the length $\lceil \log_2(b+1) \rceil$ of the (shortest) binary notation for b.*

DEFINITION 2.8. *A domain Y with universe V is a* subdomain *of a domain X if V is a subset of (the universe of) X and $\mathbf{P}_X(V) > 0$ and $|x|_Y = |x|_X$, $\mathbf{P}_Y(x) = \mathbf{P}_X(x)/\mathbf{P}_X(V)$ for every $x \in V$. Y is also called the* restriction *$X|V$ of X to V.*

DEFINITION 2.9. *The direct product $X \times Y$ of domains X and Y is the domain of pairs (x, y), where $x \in X$ and $y \in Y$, such that $|(x, y)| = |x| + |y|$ and $\mathbf{P}(x, y) = \mathbf{P}_X(x) \times \mathbf{P}_Y(y)$.*

The direct product construction allows us to define powers $X^2, X^3, \ldots$ of a given domain X. Sometimes it is more natural to deal with subsets rather than sequences of elements of a given domain.

DEFINITION 2.10. *For each positive integer σ, $\mathrm{Set}_\sigma(X)$ is the domain of σ-element subsets S of a given domain X such that the size $|S| = \sum_{x\in S} |x|$ and the probability $\mathbf{P}(S)$ is proportional to the product $\prod_{x\in S} \mathbf{P}_X(x)$, i.e., $\mathbf{P}(S) \propto \prod_{x\in S} \mathbf{P}_X(x)$.*

There are various natural domains D of all finite nonempty subsets of a given domain X such that each $\mathrm{Set}_\sigma(X)$ is a subdomain of D.

DEFINITION 2.11. *$\mathrm{Set}(X)$ is the domain of nonempty subsets of X such that $|S| = \sum_{x\in S} |x|$ and $\mathbf{P}(S) \propto \prod_{x\in S} \mathbf{P}_X(x)$.*

We need to check that $\sum_S \mathbf{P}(S)$ converges. For each positive integer n, we have

$$1 = \left(\sum_{x\in X} \mathbf{P}(x)\right)^n = \sum_{x_1,\ldots,x_n\in X} \mathbf{P}(x_1)\cdots\mathbf{P}(x_n).$$

In the sum on the right, each $\mathbf{P}(S)$ occurs $n!$ times (and there are some additional terms with repeated x's). So $\sum_{S:\,|S|=n} \mathbf{P}(S) \le \frac{1}{n!}$.

Another possibility is to define a probability distribution on the collection of nonempty finite subsets of X that corresponds to the following experiment: first choose a positive integer n with respect to the default probability and then choose an n-element subset with respect to $\mathrm{Set}_n(X)$; call this alternative domain $\mathrm{Set}'(X)$.

In many respects, AP functions differ from polynomially bounded functions. Here is one illustration.

PROPOSITION 2.12. *For every countable family $\{f_1, f_2, \ldots\}$ of AP functions on BS there exists an AP function F on BS that is not majorized by any f_i.*

Proof. By induction on i, select elements x_i of BS such that

1. $|x_i| > |x_j|$ for all $j < i$, and
2. $2^{|x_i|} > f_i(x_i)$.

Such elements exist because each f_i is AP. Define

$$F(x) = \begin{cases} 2^{|x|} & \text{if } \exists i\,(x = x_i) \\ 0 & \text{otherwise.} \end{cases}$$

No f_i majorizes F because $F(x_i) > f_i(x_i)$. It remains to check that F is AP. We have

$$\sum_x \frac{1}{|x|} F(x)\mathbf{P}(x) \approx \sum_i \frac{1}{|x_i|} 2^{|x_i|} \frac{1}{|x_i|^2} 2^{-|x_i|} = \sum_i \frac{1}{|x_i|^3}$$

and the last sum is finite because all elements x_i are of different lengths. □

3. Domain reductions. In this section, we define and discuss many-one reductions, both deterministic and randomizing, between domains. These are the only sort of reductions used in this paper.

DEFINITION 3.1. *A function f from domain X to domain Y satisfies the* domination condition *if $\mathbf{P}_X[f^{-1}(fx)]/\mathbf{P}_Y(fx)$ is AP on X.*

COROLLARY 3.2. *An injective function f from domain X to domain Y satisfies the domination condition if and only if $\mathbf{P}_X(x)/\mathbf{P}_Y(fx)$ is AP on X.*

THEOREM 3.3 [BG1]. *Let f be an arbitrary function from a domain X to a domain Y. The following statements are equivalent:*

- *For every AP function T on Y, the composition $T \circ f$ is AP on X, and*
- *$|f(x)|_Y$ is AP on X and f satisfies the domination condition.*

This theorem, with T regarded as the running time of an algorithm on Y, suggests the following definition.

DEFINITION 3.4. *A* deterministic reduction *from a domain X to a domain Y is an AP time computable function f from X to Y such that $|f(x)|_Y$ is AP on X and f satisfies the domination condition.*

Such a reduction and an AP time algorithm on Y yield an AP time algorithm on X.

COROLLARY 3.5. *Deterministic reductions of domains compose. Therefore the relation of deterministic reducibility of domains is transitive.*

Also recall the two domains $\mathrm{Set}(X)$ and $\mathrm{Set}'(X)$ of finite nonempty subsets S of X defined above.

LEMMA 3.6. *The identity function reduces* $\mathrm{Set}(X)$ *to* $\mathrm{Set}'(X)$ *and* $\mathrm{Set}'(X)$ *to* $\mathrm{Set}(X)$.

Proof. The proof is obvious. □

LEMMA 3.7. *Let a function f reduce a domain X to a domain Y and suppose that f is one-to-one. Then, for each positive integer σ, the function*

$$F\{x_1, \ldots, x_\sigma\} = \{f(x_1), \ldots, f(x_\sigma)\}$$

reduces $\mathrm{Set}_\sigma(X)$ *to* $\mathrm{Set}_\sigma(Y)$.

Proof. Let σ be an arbitrary positive integer, $A = \mathrm{Set}_\sigma(X)$ and $B = \mathrm{Set}_\sigma(Y)$. It suffices to prove that F satisfies the domination condition. Since F is one-to-one, it suffices to prove that $\mathbf{P}_A(S)/\mathbf{P}_B(F(S))$ is AP on $\mathrm{Set}_\sigma(X)$.

Since f satisfies the domination condition, the ratio $\rho(x) = \mathbf{P}_X(x)/\mathbf{P}_Y(fx)$ is AP on X. Ignoring constant factors, we have

$$\frac{\mathbf{P}_A(S)}{\mathbf{P}_B(FS)} \approx \frac{\prod_{x\in S}\mathbf{P}_X(x)}{\prod_{x\in S}\mathbf{P}_Y(fx)} = \prod_{x\in S}\rho(x).$$

It remains to prove that the last product is AP on A.

Let δ witness that ρ is AP so that

$$\sum_{x\in X}\rho(x)^\delta \frac{1}{|x|}\mathbf{P}(x) < \infty.$$

It follows that

$$\sum_{x\in X}\rho(x)^{\delta/\sigma} \frac{1}{|x|^{1/\sigma}}\mathbf{P}(x) < \infty.$$

The terms where $\rho(x)\frac{1}{|x|} \le 1$ remain ≤ 1 and therefore sum up to at most 1, and the other terms become smaller. The number $\varepsilon = \delta/\sigma$ witnesses that $\prod_{x\in S}\rho(x)$ is AP on $\mathrm{Set}_\sigma(X)$. We have

$$\sum_S \left(\prod_{x\in S}\rho(x)\right)^\varepsilon \frac{1}{|S|}\prod_{x\in S}\mathbf{P}(x) \le \sum_S \prod_{x\in S}\frac{\rho(x)^\varepsilon \mathbf{P}(x)}{|x|^{1/\sigma}} \le \left[\sum_{z\in X}\frac{\rho(z)^\varepsilon \mathbf{P}(z)}{|z|^{1/\sigma}}\right]^\sigma < \infty.$$

The first of the three inequalities holds because the geometric mean $\prod_{x\in S}|x|^{1/\sigma}$ is bounded by the arithmetical mean of the same numbers $|x|$, which is bound by the size $|S|$. To prove the second inequality, note that every summand on the left-hand side is obtained when you multiply the σ copies of the infinite series. Concerning the third inequality, we have already checked that the infinite series in square brackets converges. It remains to apply Lemma 2.3. □

LEMMA 3.8. *Suppose that domains X and Y have the same universe and the same probability distribution. The identity function deterministically reduces X to Y if and only if the size function of Y is AP on X.*

Proof. Use Theorem 3.3. □

PROVISO 3.9. *Restrict attention to domains X such that the size function of X is AP on the domain X' obtained from X by redefining the size of a string as its length.*

COROLLARY 3.10. *A function f from a domain X to a domain Y reduces X to Y if and only if f is AP time computable and satisfies the domination condition.*

Proof. Let Y' be the domain obtained from Y by redefining the size as length. Since the length $\ell(f(x))$ of $f(x)$ is bounded by the time needed to compute $f(x)$, it is AP on X. Thus f reduces X to Y'. Now use Lemma 3.8 and the transitivity of the deterministic reducibility relation. □

Reductions are used in the usual way to define the notion of a complete problem in a complexity class, i.e., a problem in the class to which all problems in the class are reducible. Unfortunately, deterministic reductions are too weak to yield a good notion of completeness; see [Gu1] where it is shown that complete problems in this sense must (under the reasonable assumption that nondeterministic exponential time differs from deterministic exponential time) have special probability distributions (nonflat, in the terminology of [Gu1]). Therefore, we use the larger class, suggested in [VL], of randomizing reductions, i.e., we allow the computation of the reducing function to flip coins. To introduce randomizing reductions, we need some auxiliary notions.

Terminology and notation. A set S of binary strings satisfies the *prefix condition* if no string in S is a prefix of a different string in S. If Δ is a subset of the cartesian product $U \times V$ of sets U and V then, for each $x \in U$, $\Delta(x) = \{y : (x, y) \in \Delta\}$.

The notion of dilation was introduced in [Gu1] and used in [BG1], [BG2]. The idea is to combine the probability distribution on instances and the probability distribution of coin flips into one probability distribution. In the following definition, think of Δ as the set of pairs (x, s) where x is an input to a randomizing algorithm and s is a sequence of coin flips just sufficient to make that algorithm, with input x, produce an output.

DEFINITION 3.11 (cf. [Gu1], [BG1]). *A* dilation *of a domain X is a domain Δ such that*

- *the universe of Δ is a subset of $X \times BS$ such that, for every $x \in X$ of nonzero probability, $\Delta(x)$ is nonempty and satisfies the prefix condition*;
- *the size function $|(x, s)| = |x|$; and*
- *the probability distribution $\mathbf{P}(x, s) = \mathbf{P}(x)2^{-|s|}/\sum_{t\in\Delta(x)} 2^{-|t|}$.*

DEFINITION 3.12. *Let Δ be a dilation of a domain X. Then*

$$\text{Density}_\Delta(x) = \sum_{s\in\Delta(x)} 2^{-|s|} \quad \textit{and} \quad \text{Rarity}_\Delta(x) = \frac{1}{\text{Density}_\Delta(x)}.$$

Further, Δ is nonrare *if the rarity function $\text{Rarity}_\Delta(x)$ is AP on X. Δ is* almost total *if $\text{Rarity}_\Delta(x) = 1$ for every x of nonzero probability; in terms of coin flips, that means that, if we repeatedly flip a fair coin to produce a string of 0's and 1's, then, with probability 1, we will eventually obtain a string in $\Delta(x)$. Finally, Δ is* trivial *if, for every $x \in X$ of nonzero probability, $\Delta(x)$ contains the empty string (and therefore contains no other string).*

Theorem 3.3 generalizes to randomizing reductions.

THEOREM 3.13 [BG2]. *Suppose that Γ is a nonrare dilation of a domain X and f is a function from Γ to Y. Then the following statements are equivalent:*

- *$|f(x)|_Y$ is AP on Γ and f satisfies the domination condition;*
- *for every nonrare dilation Δ of Y and every AP function T on Δ, the composition $T(f(x,s),t)$ is AP on the dilation $\Gamma * \Delta$ of A that comprises pairs (x, st) such that $(x,s) \in \Gamma$ and $(f(x,s),t) \in \Delta$.*

DEFINITION 3.14. *A* (randomizing) reduction *of a domain X to a domain Y consists of a nonrare dilation Γ of X and a deterministic reduction f of Γ to Y.*

Randomizing reductions of domains compose in the following sense. If Γ and Δ are nonrare dilations of X and Y, respectively, and and if $f : \Gamma \longrightarrow Y$ and $g : \Delta \longrightarrow Z$ are randomizing reductions of X to Y and of Y to Z, then there is a composite reduction $g \circ f : \Gamma * \Delta \longrightarrow Z$ of X to Z. Here $\Gamma * \Delta$ is as in Theorem 3.13 and $g \circ f$ is defined by $(g \circ f)(x, st) = g(f(x,s),t)$ whenever $(x,s) \in \Gamma$ and $(f(x,s),t) \in \Delta$. (Although this composition is not the ordinary composition of functions, it does yield a category of domains and random functions.)

COROLLARY 3.15. *The relation of (randomized) reducibility is transitive.*

DEFINITION 3.16. *Let Σ be an alphabet. A* randomizing algorithm *on Σ^* is an algorithm A on $\Sigma^* \times BS$, but the two input strings, a string x over Σ and a binary string s, play different roles. The string x is viewed as the input, and the string s is viewed as a sequence of coin flips. It is supposed that A does not flip a coin unless the computation requires another random bit.*

DEFINITION 3.17. *A dilation Δ of a domain X is* (AP time) certifiable *if there exists a randomizing algorithm A on Σ_X^* such that*

- *for every $x \in X$ of nonzero probability and every binary string s, A outputs YES on input (x,s) if and only if $(x,s) \in \Delta$, and*
- *the computation time of A is AP on Δ.*

The need for certifiable reductions arises when dealing with decision problems. We consider algorithms that, given an input x of nonzero probability, produce a correct output on any random string $s \in \Delta(x)$ but may produce an incorrect output on $s \notin \Delta(x)$. When the correctness of the output cannot be verified efficiently, the certifiability of Δ will be needed to justify believing the output.

DEFINITION 3.18. *A reduction (Γ, f) of a domain X to a domain Y is* certifiable *if Γ is certifiable.*

LEMMA 3.19. *Certifiable reductions of domains compose.*

Proof. Chase the definitions and apply Theorem 3.3. □

As an example of how much easier it may be to deal with randomizing reductions, consider the problem of reducing BS to FRACTION. To avoid trivial solutions, like constant functions, let us require that different elements of BS are taken to different elements of FRACTION. The problem is easily solved with the help of randomization.

LEMMA 3.20. *There exists a randomized reduction (Γ, f) from BS to FRACTION such that $f(x_1,s_1) \neq f(x_2,s_2)$ whenever $x_1 \neq x_2$.*

Proof. $\Gamma(x)$ comprises all binary strings s of length $|x|$ such that the numbers (represented by binary strings) s and $1x$ are relatively prime. Since the chance that a random s is relatively prime to $1x$ is sufficiently large [HW], Γ is nonrare. $f(x,s) = s/1x$. □

4. Search problems.

DEFINITION 4.1. *A* (randomized) search problem SP(X, W) *is given by a domain X (of* instances*) and a PTime computable relation $W(x,w)$ (the* witness relation*) between elements of X and arbitrary strings in a fixed alphabet. The problem is: Given an instance x with $W(x) \neq \emptyset$, find an element of $W(x)$ (a* witness *for x).*

DEFINITION 4.2. SP(X, W) *is* AP time solvable *if there exist a nonrare dilation* Γ *of* $X|\{x : W(x) \neq \emptyset\}$ *and an AP time algorithm* M *on* Γ *that, given any* $(x, s) \in \Gamma$ *with* $\mathbf{P}_X(x) > 0$, *finds a witness for* x. *Such a pair* (Γ, M) *is called an* AP time solution *for* SP(X, W). *A solution* (Γ, M) *is* almost total *if* Γ *is so.*

This notion of AP solvability may seem weaker than it is.

THEOREM 4.3 [BG2]. *Every AP time solvable search problem* SP(X, W) *has an almost total solution.*

DEFINITION 4.4. *A* (randomizing) reduction *of* SP(X, U) *to* SP(Y, V) *consists of*

Dilation: *A nonrare dilation* Γ *of* X,

Instance transformer: *A deterministic reduction* f *of* Γ *to* Y, *and*

Witness transformer: *A PTime computable function* $g((x, s), v)$ *such that if* $s \in \Gamma(x)$ *and* $v \in V(f(x, s))$ *then* $g((x, s), v) \in U(x)$.

THEOREM 4.5 [BG2]. *The reducibility relation on search problems is transitive, and a problem* SP(X, U) *is solvable in AP time if it is reducible to some problem* SP(Y, V) *which is solvable in AP time.*

The notion of reduction allows us to define complete problems in the usual way. SP(X, W) is *complete* for a class $\mathcal{C}$ of search problems if it is in $\mathcal{C}$ and every problem in $\mathcal{C}$ reduces to it.

5. Decision problems.

DEFINITION 5.1. *A* (randomized) decision problem DP(X, P) *is given by a domain* X *of* instances *and a subset* P *of* X. *Instances in* P *are called* positive, *and instances in* $X - P$ *are called* negative. *The problem is: Given an instance* $x \in X$, *decide whether* x *is positive or negative.*

DEFINITION 5.2. *DP*(X, P) *is* AP time solvable (*or* AP time decidable) *if there exist a nonrare certifiable dilation* Γ *of* X *and an AP time algorithm* M *on* Γ *that, given any element* $(x, s) \in \Gamma$ *with* $\mathbf{P}_X(x) > 0$, *decides whether* x *is positive or negative. The pair* (Γ, M) *is an* AP time solution *for* DP(X, P). *A solution* (Γ, M) *for* DP(X, P) *is* almost total *if* Γ *is so.*

Note that certifiability is required, as we cannot check whether the output of M (yes or no) is correct. Contrast this with search problems where the assumed computability of the witness relation lets us check whether the output (an alleged witness) is indeed a witness and certifiability is therefore not required.

Again, the notion of AP time solution may seem weaker than it is.

THEOREM 5.3. *If* DP(X, P) *is AP time solvable then it has an almost total AP time solution.*

Proof. Let (Γ, M) be an AP time solution for a decision problem DP(X, P) and let A be a certifying algorithm for Γ. For each $s \in \Gamma(x)$, let s' be the computation of A on (x, s) and s'' be the computation of M on (x, s). Define

$$W = \{(x, (s, s', s'')) : (x, s) \in \Gamma\}.$$

Obviously, the relation W is PTime computable. (The intended algorithm for computing W uses A and M; we need not check $(x, s) \in \Gamma$ because this follows from $A(x, s)$ providing s'.) The dilation Γ and a combination of the algorithms A and M give an AP time solution for the search problem SP(X, W). By Theorem 4.3, this search problem has an almost total AP time solution (Δ, N). For each $(x, t) \in \Delta$ with $\mathbf{P}_X(x) > 0$, N outputs a triple $(s, s', s'') \in W$. By the definition of W, $s = s(t) \in \Gamma(x)$ and therefore $s(t)''$ is a computation of M deciding whether x is positive or negative.

The dilation Δ is certifiable. Given an instance x of nonzero probability and an arbitrary string t, the desired certifying algorithm A' runs N on (x, t). If a prefix t_0 of t belongs to $\Delta(x)$, N will produce an output on (x, t_0) and A' will output "yes" in the case where $t_0 = t$ or "no" in the case where t_0 is a proper prefix of t. Suppose that no prefix of t belongs to $\Delta(x)$.

Since Δ is almost total, both $t0$ and $t1$ are prefixes of strings in Δ. The computation of N on (x, t) will stop without producing any output, waiting for another random bit; in such a case A' will output "no."

Let N' be the modification of N that, given $(x, t) \in \Delta$ with $\mathbf{P}_X(x) > 0$, outputs only the result (yes or no) of the computation $s(t)''$. The pair (Δ, N') constitutes an almost total AP time solution for DP(X, P). □

Note the role of the certifying algorithm A. The certifiability of dilation was unnecessary in the case of search problems, but in the case of decision problems it plays an important role.

DEFINITION 5.4. *A* (randomizing) many-one reduction *of* DP(X, P) *to* DP(Y, Q) *comprises*

- *a nonrare certifiable dilation* Γ *of* X, *and*
- *a deterministic reduction* f *from* Γ *to* Y (*the* instance transformer) *satisfying the following* correctness property: *For all* $(x, s) \in \Gamma$,

$$f(x, s) \in Q \iff x \in P.$$

THEOREM 5.5. *The many-one reducibility relation on decision problems is transitive, and a problem* DP(X, P) *is AP time decidable if it reduces to some problem* DP(Y, Q) *that is AP time decidable.*

Proof. Use the fact, established in §3, that randomizing domain reductions compose. □

DEFINITION 5.6. *A many-one reduction* (Γ, f) *of* DP(X, P) *to* DP(Y, Q) *is* deterministic *if* Γ *is trivial. In this case, the reduction* (Γ, f) *is specified only by the instance transformer* f; Γ *may be identified with* X.

LEMMA 5.7. *The identity function deterministically reduces any decision problem* Π *to the decision problem* Π' *obtained from* Π *by redefining the size of a string as its length.*

Proof. Use Corollary 3.10. □

A decision problem is *hard* for a class $\mathcal{C}$ of decision problems if every problem in $\mathcal{C}$ reduces to it. A decision problem is *complete* for $\mathcal{C}$ if it belongs to $\mathcal{C}$ and is hard for $\mathcal{C}$.

RNP is the class of decision problems with PTime computable probability distributions. PTime computable distributions are defined in [Le] and analyzed in [Gu1].

6. Positive matrices. We now turn from the general theory of randomizing algorithms and reductions to the specific problem, Matrix Transformation, whose completeness for RNP we prove in § 10. We begin with information about unimodular matrices.

Call a unimodular matrix (i.e., an element of $\mathrm{SL}_2(Z)$, a two-by-two matrix with determinant 1) *positive* if it has no negative entries. Positive matrices form a monoid $PM = \mathrm{SL}_2(N)$. In this section, a column is a column of two relatively prime nonnegative integers; for notational simplicity, we view a positive matrix as the pair of its columns. If u is a column, let u_1 be the upper and u_2 the lower components of u. Partially order columns componentwise: $u \leq v$ if $u_1 \leq v_1$ and $u_2 \leq v_2$, and $u < v$ if $u \leq v$ and either $u_1 < v_1$ or $u_2 < v_2$. Define $\max(X)$ to be the maximal entry of a positive matrix X. In this section,

$$A_0 = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \quad \text{and} \quad B_0 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

LEMMA 6.1.

1. $(u, v) \times A_0 = (u + v, v)$, *and* $(u, v) \times B_0 = (u, u + v)$.
2. *If* A_0 *is a right divisor of a positive matrix* (u, v) *in* PM *then* $u > v$, *and if* B_0 *is a right divisor of* (u, v) *in* PM *then* $u < v$.
3. *If the maximal entry* m *of a matrix* (u, v) *appears in two or more places then* $m = 1$.

Proof. Part (1) is obvious, and (2) follows from (1).

(3) If m occurs twice in the same row or the same column, then it divides the determinant 1 and therefore $m = 1$. So assume this does not happen. If $v_1 = u_2 = m$ then the determinant cannot be positive. If $u_1 = v_2 = m$ then $1 = u_1v_2 - v_1u_2 \geq m^2 - (m-1)^2 = 2m - 1$ and therefore $m = 1$. □

The second statement of Lemma 6.1 implies that the monoid generated by the matrices A_0 and B_0 is free. This fact is noted in [Ei, Chap. VI, §12]. The following theorem should be known too, but we do not have an appropriate reference.

THEOREM 6.2. *The monoid PM is isomorphic to the monoid BS of binary strings. The two indecomposable nonunit elements are the matrices A_0 and B_0.*

Proof. Since A_0 and B_0 generate a free monoid, it suffices to prove that every nonunit positive matrix (u, v) is a product of matrices A_0 and B_0. Define weight$(u) = u_1 + u_2$ and weight$(u, v) =$ weight$(u)+$ weight(v). The proof is an induction on $s =$ weight(u, v). Since the entries of the main diagonal are not zero, $s \geq 2$.

The case $s \leq 3$ is easy: A_0 and B_0 are the only nonunit matrices of weight ≤ 3. Suppose that $s > 3$. Then $m = \max(u, v) > 1$. Exploiting the symmetry, we may suppose that m appears in u. If $u_1 = m$ then $1/m = (u_1v_2 - v_1u_2)/m > v_2 - u_2$ and therefore $u_2 \geq v_2$. Similarly, if $u_2 = m$ then $u_1 \geq v_1$. Thus, the column $u - v$ has nonnegative entries. The determinant of $(u - v, v)$ equals 1 and therefore $(u - v, v)$ is an element of $\mathrm{SL}_2(N)$. By the induction hypothesis, $(u - v, v)$ is a product of matrices A_0 and B_0. By Lemma 6.1(1), $(u, v) = (u - v, v) \times A_0$. □

COROLLARY 6.3. *If a positive matrix (u, v) is not the unit matrix then one of the two columns is greater than the other.*

Proof. The fact has been established in the proof of Theorem 6.2. □

Call the greater column of a nonunit positive matrix *major*; in the case of the unit matrix, call either column *major*. The other column of the matrix will be called *minor*.

LEMMA 6.4. *The major column and one bit indicating whether it is the first or the second column uniquely define the minor column.*

Proof. Without loss of generality, the given matrix (u, v) is not the unit matrix. It follows that both components of the major column are positive. By virtue of symmetry, suppose that u is the major column. We show that the minor column v is the least column such that $u_1v_2 - u_2v_1 = 1$. Let w be any column such that $u_1w_2 - u_2w_1 = 1$. Then $u_1(w_2 - v_2) = u_2(w_1 - v_1) = u_1u_2k$ for some k because u_1 and u_2 are relatively prime; hence $w_1 = v_1 + ku_1$ and $w_2 = v_2 + ku_2$. If $k < 0$ then either w_1 or w_2 is negative. Hence $k \geq 0$ and therefore $w_1 \geq v_1$, $w_2 \geq v_2$. □

LEMMA 6.5. *There exists a PTime algorithm that, given a column u, computes the minor column of the unique positive unimodular matrix with the first and major column u.*

Proof. Use the extended Euclid's algorithm [Kn1]. □

Remark 1. Instead of columns, we could use rows above in this section. This would cause some insignificant changes in Lemma 6.1 (for example, the first statement would say that $A_0 \times (u, v) = (u, u + v)$, and $B_0 \times (u, v) = (u + v, v)$ where u is the upper row of the given matrix and v is the lower row), but Corollary 6.3 and Lemma 6.4 remain true.

Let $\ell(n)$ be the length of the binary notation for n.

DEFINITION 6.6. *We define a domain structure on the monoid PM. It is the uniform domain with the size function $|X| = \ell(\max(X))$. Thus, PM is the monoid and domain of positive matrices.*

Strictly speaking, the elements of a domain should be strings. For this purpose, we may regard a matrix as a list of its entries in binary notation. Then Proviso 3.9 is satisfied.

LEMMA 6.7. *The relative probability* $\mathbf{P}_{\mathrm{PM}}[X \mid |X| = l] = \Theta(2^{-2l})$.

Proof. Let $g(l) \approx f(l)$ mean that $g(l) = \Theta(f(l))$, i.e., that there exist positive constants c, c', and l_0 such that $cf(l) \leq g(l) \leq c'f(l)$ for all $l \geq l_0$ [Kn2]. It suffices to prove that the number $N(l)$ of positive matrices of size l is $\Theta(2^{2l})$. Recall that $\phi(m)$ is the number of positive integers $n \leq m$ that are prime to m, and that $\Phi(m) = \phi(1) + \cdots + \phi(m) = 3m^2/\pi^2 + O(m \cdot \log m)$ [HW, Thm. 330]. Thus,

$$N(l) \approx \sum_{\ell(m)=l} \phi(m) \approx \Phi(2^l - 1) - \Phi(2^{l-1}) = \Theta(2^{2l}). \qquad \square$$

By Theorem 6.2, PM is isomorphic to BS as a monoid. There are exactly two isomorphisms of PM onto BS. One of them takes A_0 to 0 and B_0 to 1 while the other one takes A_0 to 1 and B_0 to 0. Let I be the isomorphism that takes A_0 to 0, and let J be the corresponding isomorphism I^{-1} from binary strings to PM. It is easy to check by induction on the length of the given string x that if x starts with a zero (respectively, one) then the lower (respectively, upper) row of $J(x)$ is major (see "transposed" Lemma 6.1 in Remark 6). Notice that the size of a matrix X may be quite different from the length of the corresponding string $I(X)$. It is easy to see that the isomorphism I is not computable in polynomial time: A matrix $A_0^n = \binom{1}{n}\ \binom{0}{1}$ is of size $\ell(n)$ whereas the string $0^n = I(A_0^n)$ is of length n.

LEMMA 6.8. *I is AP time computable.*

Proof. The following recursive algorithm computes $I(X)$. If X is the unit matrix then $I(X)$ is the empty string. Suppose that $X = (u, v)$ differs from the unit matrix. If u is the major column, $w = u - v$ and $z = I(w, v)$ then $I(X) = z0$, and if v is the major column, $w = v - u$ and $z = I(u, w)$ then $I(X) = z1$. The computation time of that algorithm is essentially proportional to $|I(X)|$, which is AP by Lemma 6.12. $\square$

The isomorphism J is PTime computable but $\mathbf{P}_{\mathrm{PM}}$ does not dominate $\mathbf{P}_{\mathrm{BS}}$ with respect to J and thus J fails to reduce BS to PM.

THEOREM 6.9. *$\mathbf{P}_{\mathrm{PM}}$ does not dominate $\mathbf{P}_{\mathrm{BS}}$ with respect to J.*

Proof. By contradiction, suppose that the function $g(x) = \mathbf{P}_{\mathrm{BS}}[x]/\mathbf{P}_{\mathrm{PM}}[Jx]$ is polynomial on average with respect to $\mathbf{P}_{\mathrm{BS}}$ and fix $\varepsilon > 0$ to witness that fact. Thus,

$$\infty > \sum_n \sum_{x:\,|x|=n} \frac{1}{n}(g(x))^{\varepsilon} \frac{1}{n(n+1)} 2^{-n},$$

so, as a function of n, the conditional expectation of $(g(x))^{\varepsilon}$ for strings of length n, $\sum_{x:\,|x|=n}(g(x))^{\varepsilon}2^{-n}$ is $o(n^3)$. We obtain the desired contradiction by proving that this expectation is not bounded by any polynomial of n.

Let $l = |Jx|$. By Lemma 6.7,

$$g(x) = \Theta(l^2 \cdot 2^{2l} \cdot n^{-2} \cdot 2^{-n}).$$

Let $s(x)$ be the sum of the entries of the major row of Jx. Clearly, $s(x) = \Theta(2^l)$. Hence it suffices to prove that the expectation $E_n = \sum_x [(s(x)^2/2^n)^{\varepsilon} \cdot 2^{-n}]$ of the function $[s(x)^2/2^n]^{\varepsilon}$ is not bounded by a polynomial of n. (The factor n^{-2} in $g(x)$ will not matter as it is the reciprocal of a polynomial, and l^2 will not matter as it is ≥ 1.) We may restrict our attention to $\varepsilon < 1/2$. Let y range over strings of length $n - 1$. $\square$

LEMMA 6.10. *There exists some $\alpha > 1$ such that every*

$$A(y) = (1/2)[s(y0)^{2\varepsilon} + s(y1)^{2\varepsilon}]/s(y)^{2\varepsilon} \geq \alpha 2^{\varepsilon}$$

Proof. Let $a > b$ be the two entries of the major row of $J(y)$, and $\gamma = b/a$. Then

$$A(y) = (1/2)[(2a+b)^{2\varepsilon} + (a+2b)^{2\varepsilon}]/(a+b)^{2\varepsilon} = (1/2)[(2+\gamma)^{2\varepsilon} + (1+2\gamma)^{2\varepsilon}]/(1+\gamma)^{2\varepsilon}.$$

Let $\delta = 1/(1+\gamma)$. Then $A(y) = (1/2)[(1+\delta)^{2\varepsilon} + (2-\delta)^{2\varepsilon}]$.

Consider the function $f(t) = t^{2\varepsilon}$ of a real variable t. The graph of f is concave because $f''(t) = 2\varepsilon(2\varepsilon - 1)t^{2\varepsilon-2} < 0$. Since $0 < \delta < 1$, the chord C between the points $(1+\delta, f(1+\delta))$ and $(2-\delta, f(2-\delta))$ lies strictly above the chord C_0 between the points $(1, f(1))$ and $(2, f(2))$. Further, the center of the interval $[1+\delta, 2-\delta]$ coincides with the center 1.5 of the interval $[1, 2]$, and therefore the center $(1.5, A(y))$ of C lies directly above the center $(1.5, [1+2^{2\varepsilon}]/2)$ of C_0. The arithmetical mean $[1+2^{2\varepsilon}]/2$ of numbers 1 and $2^{2\varepsilon}$ exceeds their geometrical mean 2^{ε}. Thus, $A(y) > [1+2^{2\varepsilon}]/2 > 2^{\varepsilon}$. The desired $\alpha = (1/2)[1+2^{2\varepsilon}]/2^{\varepsilon}$. □

We continue to prove Theorem 6.9. Let $A(y)$ and α be as in Lemma 6.10, and let x range over strings of length n and y over strings of length $n-1$. We have

$$E_n = \sum_x [(s(x)^2/2^n)^{\varepsilon} \cdot 2^{-n}] = 2^{-n\varepsilon} \cdot \sum_x [s(x)^{2\varepsilon} \cdot 2^{-n}] \geq 2^{-n\varepsilon} \cdot \sum_y [s(y)^{2\varepsilon} \cdot A(y) \cdot 2^{-(n-1)}].$$

By Lemma 6.10,

$$E_n \geq 2^{-n\varepsilon} \cdot \sum_y [s(y)^{2\varepsilon} \cdot \alpha 2^{\varepsilon} \cdot 2^{-(n-1)}] = \alpha \sum_y [(s(y)^2/2^{n-1})^{\varepsilon} \cdot 2^{-(n-1)}] = \alpha E_{n-1}.$$

It follows that E_n is $\Omega(\alpha^n)$ and therefore is not bounded by a polynomial of n. □

Recall the notion of a (simple) continued fraction [HW]. Here is an example:

$$\frac{81}{17} = 4 + \frac{13}{17} = 4 + \frac{1}{\left(\frac{17}{13}\right)} = 4 + \frac{1}{1+\frac{4}{13}} = 4 + \frac{1}{1+\frac{1}{\left(\frac{13}{4}\right)}} = 4 + \frac{1}{1+\frac{1}{3+\frac{1}{4}}} = [4, 1, 3, 4].$$

Similarly, every positive rational number r can be uniquely represented by a continued fraction $[a_l, \ldots, a_0]$ where a_l is a nonnegative integer, and each a_i with $0 < i < l$ is a positive integer, and a_0 is an integer ≥ 2 unless $l = 0$; the integers $a_i \geq 0$ are called partial quotients.

LEMMA 6.11. *Suppose that x is a nonempty binary string and let $m \leq n$ be the two entries of the major row of $J(x)$. Then $|x|$ equals the sum $s(n, m)$ of the partial quotients in the continued fraction for n/m.*

Proof. If $|x| = 1$ then $m = n = 1$ and $s(n, m) = 1 = |x|$. Suppose that $|x| > 1$. By virtue of symmetry, we may suppose that $x = y0$; the other case is similar. Let (i, j) be the major row of $J(y)$. By Lemma 6.1, the major row (n, m) of $J(x)$ is $(i+j, j)$. It suffices to prove that if $i \leq j$ then $s(n, m) = s(j, i) + 1$, and if $i \geq j$ then $s(n, m) = s(i, j) + 1$. Since $J(y)$ is not the unit matrix, neither i nor j is zero. In any case,

$$\frac{n}{m} = \frac{i+j}{i} = 1 + \frac{j}{i}.$$

If $i \leq j$ and $\frac{j}{i} = [a_l, \ldots, a_0]$ then $\frac{n}{m} = [a_l + 1, \ldots, a_0]$, so $s(n, m) = s(j, i) + 1$.

If $j \leq i$ and $\frac{i}{j} = [a_l, \ldots, a_0]$ then

$$\frac{n}{m} = 1 + \frac{1}{\left(\frac{1}{j}\right)} = [1, a_l, \ldots, a_0],$$

so $s(n, m) = s(i, j) + 1$. □

LEMMA 6.12. *$|I(X)|$ is AP on PM.*

Proof. Let $s(n, m)$ be as in Lemma 6.11. We use the following strong result of Yao and Knuth [YK]: $\sum_{m=1}^{m=n} s(n, m) = (6n/\pi^2)(\ln n)^2 + O(n(\log n)(\log\log n)^2) = \Theta(n(\log n)^2)$. Let X be a matrix of size $l > 0$, and let $a(X) < b(X)$ form the major row of the matrix X. Then $\sum_{X:\, b(X)=n} s(b(X), a(X)) = \Theta(n(\log n)^2)$. By Lemma 6.11 $\sum_{b(X)=n} |I(X)| = \Theta(n(\log n)^2)$ and therefore $\sum_{X:\, |X|=l} |I(X)| = \Omega(2^l \cdot l^2 2^l)$. Now use Lemma 6.7 to check that the expectation of $|I(X)|$ with respect to the conditional probability $\mathbf{P}_{\mathrm{PM}}[X \mid |X| = l]$ is bounded by a polynomial of l. It follows (see Lemma 2.3) that $I(X)$ is AP on PM. □

7. Positive matrix correspondence problem.

DEFINITION 7.1. *Let T be a nondeterministic Turing machine with binary input alphabet. The* bounded halting problem BH(T) *is the randomized decision problem with domain* BS × PI *such that an instance (x, n) is positive if and only if T has a halting computation of length $\leq n$ on x. Call an instance (x, n) of* BH(T) robust *if either T has a halting computation of length $\leq n$ on x or else T has no halting computation on x at all.* RBH(T) *is the restriction of* BH(T) *to robust instances.*

DEFINITION 7.2. *WBS is the domain of binary strings where $|x|$ is the length of x and $\mathbf{P}(x) = \mathbf{P}_{\mathrm{PM}}(Jx)$. Let T be a nondeterministic Turing machine with binary input alphabet. The* weird halting problem WH(T) *and its robust version* RWH(T) *are similar to* BH(T) *and* RBH(T) *except the domain is* WBS × PI *rather than* BS × PI.

LEMMA 7.3. *For a certain U,* RWH(U) *is hard for RNP.*

Proof. Some RBH(T) are RNP complete, by Corollary 1 of Theorem 1 in [Gu1]. (Actually, a slightly different version of bounded halting problems was considered in [Gu1]. It was supposed there that $n > |x|$ and $\mathbf{P}(x, n) \propto n^{-3}2^{|x|}$. However the same proof works. Also, the identity function deterministically reduces that older version of every RBH(T) to the new one.) Thus it suffices to reduce an arbitrary RBH(T) to an appropriate RWH(U). We will do just that.

One might be tempted to take $U = T$ and to use the identity mapping as a reduction. By Theorem 6.9, the identity function fails to do the job.

For every binary string s, let $N(s)$ be the integer with binary representation $1s$. If $N(s) = k$, let $S(k) = s$. Given a binary string y, the desired U computes $x = S(\max(J(y)))$, turns itself into T and then runs on input x. We construct a reduction (Γ, f) from RBH(T) to RWH(U). Here Γ is a dilation of BS × PI, and f is a function from Γ to WBS × PI.

Define $\Gamma(x, n)$ to comprise binary strings s of length $\geq |x| - 1$ such that $N(s)$ is prime to and less than $N(x)$. It is obvious that the dilation Γ is certifiable. By Theorem 328 in [HW], the number $\phi(k)$ of positive integers prime to and less than k is $\Omega(k/\log\log k)$. Note that, if j is relatively prime to k, then so is $k - j$. Thus, half of the integers counted by $\phi(k)$ are $\geq \frac{k}{2}$, and so the cardinality of $\Gamma(x, n)$ is $\geq \frac{1}{2}\phi(N(x))$. It follows that Γ is not rare:

$$\mathrm{Density}_\Gamma(x) = \sum_{s\in\Gamma(x)} 2^{-|s|} \geq \sum_{s\in\Gamma(x)} 2^{-|x|} = \Omega\left(\frac{1}{\log\log N(x)}\right) = \Omega\left(\frac{1}{\log|x|}\right).$$

By Lemma 6.4, for each $(x, n, s) \in \Gamma$, there exists a unique positive unimodular matrix $M(x, s)$ with first and major column $(N(x), N(s))$. View M as a function on Γ; we check that it reduces Γ to PM. By Lemma 6.5, the function M is PTime computable. To check the domination property, use Lemma 6.7 and the fact that M is injective.

The desired f is given by $f((x, n), s) = (y, t(x, s) + n)$ where $y = I(M(x, s))$ and $t(x, s)$ is the time that U needs to convert y into x. First, we check that f takes robust instances of BH(T) to robust instances of WH(U) and has the correctness property. By the definition of U, it halts on y if and only if T halts on x. Moreover, if T halts within $\leq n$ steps on x then U

halts within $t(x, s) + n$ steps on y. Now suppose that U halts on y. Then T halts on x. Since (x, n) is robust, T halts within n steps on x. Hence U halts within $t(x, s) + n$ steps on y.

Next, we check that f is AP time computable on Γ. We have to prove that y and $t(x, s)$ are computable in AP time relative to Γ. In the case of y this follows from the definition $y = I(M(x, s))$, the fact that M reduces Γ to PM, Lemmas 6.8 and 6.12 and Theorem 3.3. Now consider $t(x, s)$. It is the time that U needs to compute $x = S(\max(J(y)))$ from y, which is bounded by a polynomial of $|y|$ because J, max, and S are all PTime computable. So, by Lemma 2.3, $t(x, s)$ is AP on Γ. In addition, it is computable in AP time relative to Γ, because it can be computed by first computing y (which we already saw takes AP time) and then computing x from y while running a clock (which takes time essentially $t(x, s)$).

Finally, we check that f has the domination property. Notice that f is one-to-one, so we can use Corollary 3.2. In addition, the probability functions for WBS $\times$ PI and its restriction to robust instances differ by a constant factor, so we can compute with the former instead of the latter. We have

$$\frac{\mathbf{P}_\Gamma((x, n), s)}{\mathbf{P}_{\mathrm{WBS}\times\mathrm{PI}}(y, t(x, s) + n))} = \frac{\mathbf{P}_\Gamma((x, n), s)}{\mathbf{P}_{\mathrm{WBS}}(y)} \times (t(x, s) + n)(t(x, s) + n + 1).$$

The fraction on the right is AP on Γ because $\mathbf{P}_{\mathrm{WBS}}(y) = \mathbf{P}_{\mathrm{PM}}(M(x, s))$ and M has the domination property. Now use Lemma 2.3 and the fact that $t(x, s)$ is AP on Γ. □

The direct product PM $\times$ PM is a domain and monoid of positive matrix pairs; the multiplication of matrix pairs is componentwise: $(X_1, Y_1) \times (X_2, Y_2) = (X_1X_2, Y_1Y_2)$. If S is a set of positive matrix pairs, let S^n comprise products $P_1 \times \ldots \times P_m$ where $m \leq n$ and each $P_i \in S$. In the following definition, PMC stands for positive matrix correspondence.

DEFINITION 7.4. *For each positive integer* σ, PMC(σ) *is the decision problem with domain*

$$\mathrm{PM} \times \mathrm{Set}_\sigma(\mathrm{PM} \times \mathrm{PM}) \times \mathrm{PI},$$

where an instance (A, S, n) *is positive if and only if there exists a pair* (X, Y) *in* S^n *such that* $AX = Y$. *An instance* (A, S, n) *of* PMC(σ) *is* robust *if either* $AX = Y$ *for some pair* (X, Y) *in* S^n *or else the whole submonoid of* PM $\times$ PM *generated by* S *has no pair* (X, Y) *with* $AX = Y$. RPMC(σ) *is the restriction of* PMC(σ) *to robust instances* (A, S, n).

THEOREM 7.5. *Some* RPMC(σ) *is hard for RNP.*

Remark 2. Replacing PM with BS in the definition of RPMC(σ) gives a variant RPCP(σ) of the Post Correspondence Problem; this variant has been proved RNP complete for not too small σ in [Gu1]. (Actually, RPCP(σ) is slightly different from the version in [Gu1] but the difference is immaterial. For readers with §5.1 of [Gu1] before them, we indicate the changes needed in the completeness proof to cover our variant. Remove the clause L0 from the definition of $L(w)$ to obtain a reduced set $L'(w)$ of pairs. Instead of the instance $(L(w), p(m))$, use the instance $(ws_0, L'(w), p(m))$.) If we ignore probabilities and deal with decision problems only then the isomorphism J of §3 gives rise to a polynomial time reduction of RPCP(σ) to PMC(σ). Unfortunately, this reduction fails to have the domination property and it is difficult to alter in any way: The correctness property of the reduction is too closely related to fact that J is an isomorphism. Theorem 7.5 is not proved by a reduction from RPCP(σ), but the proof of completeness of RPCP(σ) is used in an essential way.

Proof of Theorem 7.5. Fix a Turing machine U witnessing Lemma 7.3. We will reduce RWH(U) to RPMC(σ) for appropriate σ. The variant RPCP(σ) of the Post Correspondence Problem was defined in a remark above. According [Gu1, §5] (with changes indicated in the remark), there exists a PTime reduction

$$F(x, n) = (xx', K(x), p(n))$$

of RBH(U) to some RPCP(σ) such that $|x'| = O(\log|xx'|)$ and $|K(x)| = O(\log|xx'|)$. (Concerning the size bounds, see in particular Lemma 5.1 in [Gu1].) Extend the isomorphism J to sequences of pairs of binary strings. The function

$$G(x, n) = (J(xx'), J(K(x)), p(n))$$

is the desired reduction of RWH(U) to RPMC(σ). Clearly, G is AP time computable and has the correctness property. Ignoring factors bounded by a polynomial of $|x| + n$ from above and by an inverse polynomial of $|x| + n$ from below, we have

$$\mathbf{P}_{\mathrm{RPMC}(\sigma)}[G(x, n)] \geq \mathbf{P}_{\mathrm{PM}}[J(x)] = \mathbf{P}_{\mathrm{RWH}}(x, n).$$

The inequality here depends on the fact that $|x'|$ and $|K(x)|$ are logarithmically small compared to $|x|$. This ensures that the entries in the matrices $J(K(x))$ have sizes logarithmic relative to $|x|$ and the entries in $J(xx') = J(x)J(x')$ have sizes $|J(x)| + O(\log|x|)$. These logarithms in the sizes contribute polynomials in $|x|$ as factors in the probabilities, and such factors are ignored. □

Remark 3. In [Gu2], Theorem 7.5 has been stated in a stronger form; instead of RPMC(σ) it referred to RPMC(σ, c) where the (A, S, n) were required to have $|S| = O(\log|A|)$. Our proof of the theorem does not establish the stronger result automatically. Although $|K(x)|$ is logarithmically small compared to $|x|$, we cannot conclude that $|J(K(x))|$ is logarithmically small compared to $|J(x)|$ or $|J(xx')|$, since J may shrink x or xx' much more than it shrinks $K(x)$. Since J shrinks only very few strings, the stronger form of the theorem may well be true, but we have not checked this since it does not seem to be worth the additional effort.

8. Matrix correspondence problem. In this section, a matrix is a unimodular matrix, a column is a column of two relatively prime (not necessarily positive) integers, and a matrix is seen as the pair of its columns. Call a matrix or a column positive (respectively, negative) if all its entries are nonnegative (respectively, nonpositive). If u is a column then u_1, u_2 are the upper and the lower entries of u, and $|u|$ is the positive column v such that $v_i = |u_i|$. Positive columns are ordered componentwise, as in §1. If u is a column then $\max(u) = \max(|u_1|, |u_2|)$. Any component of a column u with the absolute value $\max(u)$ is *major*, and the other component is *minor*. If X is a matrix (u, v) then $\max(X) = \max(\max(u), \max(v))$. Any entry of a matrix X with the absolute value $\max(X)$ is the *major* entry. If u, v are the two columns of a matrix X and $|u| > |v|$ then u is the *major* column and v is the *minor*; in the case of the unit matrix, both columns are *major* and both are *minor*.

LEMMA 8.1. *For every matrix* $X = (u, v)$,

1. *it is impossible that one of the numbers* u_1v_2, u_2v_1 *is positive and the other is negative. If they are both positive then* $|u_1v_2| - |u_2v_1| = 1$, *and if they are both negative then* $|u_2v_1| - |u_1v_2| = 1$;
2. *if* X *is not one of the following four matrices*

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} -1 & 0 \\ 1 & -1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

then either $(|u|) > (|v|)$ *or* $(|u|) < (|v|)$.

Proof. (1) If one of the numbers u_1v_2, u_2v_1 is positive and the other is negative then $|u_1v_2 - u_2v_1| \geq 1 + 1$ which is impossible. If the two numbers are positive then $|u_1v_2| - |u_2v_1| = u_1v_2 - u_2v_1 = 1$, and if the two numbers are negative then $|u_2v_1| - |u_1v_2| = u_1v_2 - u_2v_1 = 1$.

(2) Suppose that X is not one of the four matrices, and suppose that neither $|u| > |v|$ nor $|v| > |u|$. Without loss of generality, $|u_1| > |v_1|$ and $|u_2| < |v_2|$; otherwise replace (u, v)

with the matrix $(v, -u)$. Since X is neither the unit matrix nor its negative, either u_2 or v_1 is not zero. Hence $|u_1v_2| - |u_2v_1| \geq (|v_1| + 1)(|u_2| + 1) - |u_2v_1| = |u_2| + |v_1| + 1 \geq 2$ which contradicts (1). □

LEMMA 8.2. *If* $\max(u, v) > 1$ *then* (u, v) *has only one major entry.*

Proof. The proof is very similar to the proof of the second part of Lemma 6.1. There are some minor differences however, and—for the reader's convenience—we present the proof. By contradiction suppose that $m = \max(u, v) > 1$ but (u, v) has two or more major entries. If two major entries occur in the same row or column then m divides the determinant, which is impossible. Thus, there are exactly two major entries. Since (u, v) may be replaced with $(v, -u)$, we may suppose that the two major entries form the second diagonal, i.e., $|u_2| = |v_1| = m$. If $u_2v_1 > 0$ then the determinant is negative which is impossible. Hence $u_2v_1 < 0$. By Lemma 8.1, $u_1v_2 \leq 0$ and $1 = |u_2v_1| - |u_1v_2| \geq m^2 - (m-1)^2 = 2m - 1 \geq 3$, which is false. □

LEMMA 8.3. *For every two matrices* (u, v) *and* (u, v')*, there exists an integer* k*, such that* $v' = v + ku$.

Proof. $u_1v_2' - u_2v_1' = 1 = u_1v_2 - u_2v_1$ and therefore $u_1(v_2' - v_2) = u_2(v_1' - v_1) = u_1u_2k$ for some k. If neither component of u is zero, the claim is obvious. Suppose that one of the components of u is zero. By symmetry, let $u_1 = 0$. Then $v_1' = v_1$, $|u_2| = 1$ and the claim is clear. □

LEMMA 8.4. *Let* $X = (u, v)$ *be any matrix with* $\max(X) > 1$. *If* u *(respectively,* v*) is the major column of* X *then there exists exactly one additional matrix of the form* (u, v') *(respectively,* (u', v)*) where the column* v' *(respectively,* u'*) is minor. Moreover,* $v' = v \pm u$ *(respectively,* $u' = u \pm v$*). If the major column is positive or negative then one of the two possible minor columns is positive and the other one is negative.*

Proof. It suffices to consider the case when u is the major column because if (u, v) is a counterexample with the major column on the right then $(-v, u)$ is a counterexample with the major column on the left. Further, it suffices to consider the case when the major entry is positive because if (u, v) is a counterexample with a negative major entry then $(-u, -v)$ is a counterexample with a positive major entry. Let u_i be the major entry of u and (u, v') be another matrix with major column u. By Lemma 8.3, $v' = v + ku$ for some k. Since $u_i > 1$, $v_i \neq 0$. If $v_i > 0$ then $k = -1$, and if $v_i < 0$ then $k = 1$. Note also that if $v_i > 0$ (respectively, $v_i < 0$) then indeed u is the major column of the matrix $(u, v - u)$ (respectively, $(u, v + u)$). Now suppose that u is positive. Obviously, $u_1 > 0$ and $u_2 > 0$. By part 1 of Lemma 6.1, v is either negative or positive. If v is positive (respectively, negative) then v' is negative (respectively, positive). □

Let $SL_2(Z)$ denote not only the modular group but also the uniform domain of unimodular matrices with $|X| = \ell(\max(X))$.

LEMMA 8.5. *Let* $m > 1$ *and* X *be a random unimodular matrix with* $\max(X) = m$. *The probability that* X *is positive is* 1/8*, and the probability that* X *is the inverse of a positive matrix is* 1/8 *as well.*

Proof. Let S_0 be the collection of matrices X with $\max(X) = m$. The inverse of a matrix $\begin{pmatrix} a & c \\ b & d \end{pmatrix}$ is the matrix $\begin{pmatrix} d & -c \\ -b & a \end{pmatrix}$; thus $\max(X^{-1}) = \max(X)$ and therefore S_0 is closed under inversion. It follows that the number of positive matrices in S_0 equals the number of the inverses of positive matrices. Hence it suffices to prove only the first statement of the lemma.

Let S_1 be the collection of S_0 matrices X such that the major entry of X is positive. For every (u, v) in S_0, exactly one of the two matrices (u, v), $(-u, -v)$ belongs to S_1. It remains to prove that the probability of a random S_1 matrix being positive is 1/4.

Since the major entry of an S_1 matrix exceeds 1, the minor component of the major column is not zero. Let S_2 be the collection of S_1 matrices such that the minor component of the major

column is positive. For every S_1 matrix X, let X' be the result of multiplying by -1 the diagonal of X that contains the minor component of the major column. Exactly one of the two matrices X, X' belongs to S_2. It follows that S_2 contains exactly one half of the elements of S_1. It remains to prove that the probability of a random S_2 matrix being positive is 1/2. Now use Lemma 8.4. □

The direct product $\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z)$ is a domain and monoid of matrix pairs; the multiplication of matrix pairs is componentwise: $(X_1, Y_1) \times (X_2, Y_2) = (X_1X_2, Y_1Y_2)$. If S is a set of matrix pairs, let S^n comprise products $P_1 \times \cdots \times P_m$ where $m \leq n$ and each $P_i \in S$. Let σ be a positive integer. In the following definition, MC stands for Matrix Correspondence.

DEFINITION 8.6. *For each positive integer σ, $\mathrm{MC}(\sigma)$ is the decision problem with domain $\mathrm{SL}_2(Z) \times \mathrm{Set}_\sigma(\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z)) \times \mathrm{PI}$ where an instance (A, S, n) is positive if and only if there exists a pair $(X, Y) \in S^n$ such that $AX = Y$.*

Let σ witness Theorem 7.5.

THEOREM 8.7. *$\mathrm{MC}(\sigma)$ is hard for RNP. Moreover, so is its restriction to the subdomain of those instances (A, S, n) where each pair in S consists of positive matrices.*

Proof. The identity function reduces $\mathrm{PMC}(\sigma)$ to the desired restriction of $\mathrm{MC}(\sigma)$ and therefore to $\mathrm{MC}(\sigma)$ itself. To check the domination property, use Lemmas 3.7 and 8.5. □

9. Linear transformations of the modular group.

THEOREM 9.1. *Suppose that $T : \mathrm{SL}_2(Z) \to \mathrm{SL}_2(Z))$ is linear in the sense that, if $X = \sum_{i=1}^{k} Y_i$ with X and all Y_i in $\mathrm{SL}_2(Z)$, then $T(X) = \sum_{i=1}^{k} T(Y_i)$. Then there exist B and C in $\mathrm{SL}_2(Z)$ such that either, for all $X \in \mathrm{SL}_2(Z)$, $T(X) = BXC$ or, for all such X, $T(X) = BX^tC$ where the superscript t denotes transpose.*

Proof. We first normalize T so that $T(I) = I$, where I is the identity matrix. If the given T does not fix I, then we consider T' given by $T'(X) = T(I)^{-1}T(X)$, and we observe that the hypotheses of the theorem about T imply the same hypotheses about T' and the conclusion about T' (with $C = B^{-1}$) implies the same conclusion about T. Thus we may as well work with T', which fixes I, instead of T. So, from now on, we assume that $T(I) = I$.

Notation. $\mathrm{M}_2(Q)$ (respectively, $\mathrm{M}_2(C)$) is the vector space of two-by-two matrices with rational (respectively, complex) entries. As usual, $\mathrm{SL}_2(Q)$ (respectively, $\mathrm{SL}_2(C)$) is the multiplicative group of two-by-two matrices X with rational (respectively, complex) entries such that $\det(X) = 1$.

Our next goal is to show that the linearity hypothesis on T implies that T can be extended to a linear transformation (in the usual sense) on $\mathrm{M}_2(Q)$. Let $\mathcal{B}$ be the set of the following four matrices in $\mathrm{SL}_2(Z)$:

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = I, \quad \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 \\ -1 & 0 \end{pmatrix}.$$

It is easy to see that every matrix in the standard basis for $\mathrm{M}_2(Q)$

$$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$$

is a linear combination (with integer coefficients) of the $\mathcal{B}$ matrices, so that $\mathcal{B}$ is a basis for $\mathrm{M}_2(Q)$. There is no question what the linear extension of T should be; it is the unique linear transformation $\bar{T}$ that agrees with T on these four basis matrices. Our task is to show that it agrees with T on the other matrices in $\mathrm{SL}_2(Z)$ as well. Any $\mathrm{SL}_2(Z)$ matrix X is a linear combination, with rational coefficients, of the four $\mathrm{SL}_2(Z)$ matrices in the basis; to show that $T(X) = \bar{T}(X)$, it suffices to prove that $T(X)$ is the similar linear combination of T-images of the four matrices. Thus, it suffices to show that any linear dependence relation with rational

coefficients that holds between some matrices in $SL_2(Z)$ also holds between their T-images. Furthermore, we may suppose that the coefficients are integers (since we can multiply by a common denominator of the rational coefficients) and in fact that the coefficients are all ± 1 (as other coefficients can be replaced by repeated terms). Comparing what we need to prove with the hypothesis of the theorem, we find that we need only check that $T(-X) = -T(X)$ for all $X \in SL_2(Z)$. But this is easy; just apply the hypothesis to the linear relation $X = -X + X + X$.

From now on, we write T not only for the given function but also for the corresponding linear transformation of $M_2(Q)$ (called $\bar{T}$ above), and for the unique extension of this to a linear transformation of $M_2(C)$.

We note for future reference that if a matrix X from $M_2(C)$ has integer entries then so does $T(X)$. Indeed, this claim is true by hypothesis if X has determinant 1 and in particular for the four $\mathcal{B}$ matrices. By linearity of T, the claim follows for any X that is a linear combination with integer coefficients of $\mathcal{B}$ matrices. In particular the claim is true for the four matrices in the standard basis of $M_2(Q)$ and therefore it is true for all X in $M_2(C)$.

We also need that T preserves determinants, i.e., that $\det T(X) = \det(X)$ for all $X \in M_2(C)$. This is true by hypothesis if $X \in SL_2(Z)$, but some work will be needed to extend it to more general X.

Begin by considering $X \in M_2(Q)$. For such an X, the following two conditions are equivalent: (1) The determinant and the trace of X both vanish; (2) There are at least two distinct nonzero rational numbers r for which $I + rX \in SL_2(Z)$. This follows from the formula

$$\det(I + rX) = 1 + r \cdot \operatorname{tr}(X) + r^2 \cdot \det(X).$$

If (1) holds, then $I + rX$ has determinant 1 for all r, so we can satisfy (2) by taking any two r's for which the entries of rX are integers. Conversely, if (2) holds then we have two linear equations satisfied by the determinant and the trace of X, namely

$$r \cdot \operatorname{tr}(X) + r^2 \cdot \det(X) = 0$$

for each of the two r's. As the two equations are linearly independent, (1) follows.

It is clear, from inspection of condition (2), that if X satisfies it then so does $T(X)$. Thus, T maps the set N of matrices satisfying (2) or, equivalently, (1) into itself. T therefore also maps the linear span $\bar{N}$ of N into itself. Note that the trace of every $\bar{N}$ matrix is zero and that matrices with zero trace form a three-dimensional subspace of $M_2(Q)$. Since N contains the matrices

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad \text{and} \quad \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix},$$

it follows that $\bar{N}$ is exactly that three-dimensional subspace. In this three-dimensional vector space $\bar{N}$, N is a cone, the zero-set of the quadratic form det.

We check that, for some k, $\det(T(X)) = k \cdot \det(X)$ for all X of trace zero. Let X be

$$\begin{pmatrix} x & y \\ z & -x \end{pmatrix},$$

so that $\det(X) = -x^2 - yz$. As T is linear and det is quadratic,

$$\det(TX) = \alpha x^2 + \beta y^2 + \gamma z^2 + \delta xy + \varepsilon xz + \zeta yz$$

for some coefficients $\alpha, \beta, \gamma, \delta, \varepsilon, \zeta$. Since T maps N onto itself, $\det(TX) = 0$ if $\det(X) = 0$. Choose $y = x^2$ and $z = -1$ so that $\det(X) = 0$ and therefore $\det(TX) = 0$. We have that,

for all x, $\alpha x^2 + \beta x^4 + \gamma + \delta x^3 - \varepsilon x - \zeta x^2 = 0$, so that $\alpha = \zeta$ and $\beta = \gamma = \delta = \varepsilon = 0$. Thus, $\det(TX) = \alpha x^2 + \alpha yz = -\alpha \det(X)$.

Consider in particular the matrices

$$X = \begin{pmatrix} 0 & 3 \\ 1 & 0 \end{pmatrix} \quad \text{and} \quad 2I + X = \begin{pmatrix} 2 & 3 \\ 1 & 2 \end{pmatrix},$$

and note that X has trace zero while $2I + X \in \mathrm{SL}_2(Z)$. So we have

$$\begin{aligned} 1 &= \det(T(2I + X)) \\ &= \det(2I + T(X)) \\ &= 4 + 2 \cdot \mathrm{tr}(T(X)) + \det(T(X)) \\ &= 4 + 2 \cdot 0 + k \cdot \det(X) \\ &= 4 - 3k, \end{aligned}$$

so $k = 1$ and $\det(T(X)) = \det(X)$ for all rational X of trace zero.

For rational X of arbitrary trace, we can write $X = rI + Y$ where r is rational and $Y \in \bar{N}$. Then by what we have already proved, $T(Y)$ has trace zero and the same determinant as Y. So

$$\begin{aligned} \det(T(X)) &= \det(T(rI + Y)) \\ &= r^2 + r \cdot \mathrm{tr}(T(Y)) + \det(T(Y)) \\ &= r^2 + \det(Y) \\ &= \det(rI + Y) = \det(X). \end{aligned}$$

This shows that T preserves determinants of rational matrices. It follows that it preserves determinants of real matrices (by continuity) and of complex matrices (by analytic continuation). (Here is a more elementary argument. We have the equation $\det(T(X)) = \det(X)$ when all four entries are rational. If we let one entry, say the upper left one, vary over complex numbers while the other three entries remain fixed rational numbers, then the equation remains true because a polynomial equation in one variable that holds infinitely often must hold identically. Then we let another entry vary, while the remaining three stay fixed, one being an arbitrary complex number and the other two rational. Repeating the process for each entry in turn, we find that the equation holds for all complex values of the entries.)

Summarizing what we have achieved so far, we have a linear, determinant-preserving transformation T on $\mathrm{M}_2(C)$, which sends I to itself and sends integer matrices to integer matrices. Our immediate goal is to show that there is a matrix $B \in \mathrm{SL}_2(C)$ satisfying the conclusion of the theorem with $C = B^{-1}$ (as $T(I) = I$), not only for all $X \in \mathrm{SL}_2(Z)$ but for all $X \in \mathrm{M}_2(C)$. (This information is essentially contained in [W, pp. 19–21], but for the reader's convenience we give a different, more detailed proof.) Once this is done, we will complete the proof by showing that the entries of B must be integers.

Until we reach our intermediate goal, we shall be working in the complex vector space $\mathrm{M}_2(C)$, and it will be convenient to use the following basis for this space:

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad P = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \quad Q = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad R = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}.$$

The advantage of this basis is that the determinant is given by a very simple formula

$$\det(aI + pP + qQ + rR) = \det \begin{pmatrix} a + pi & q + ri \\ -q + ri & a - pi \end{pmatrix} = a^2 + p^2 + q^2 + r^2.$$

As T is linear and preserves determinants and I, it preserves eigenvalues; indeed, if $X - xI$ has determinant zero then so does $T(X - xI) = T(X) - xI$. In particular, $T\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ has eigenvalues 1 and 0; viewed as a transformation of 2-component vectors, it is a projection onto some line along some other line, which means that it has the form

$$T\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} p \\ q \end{pmatrix}(r \quad s) = \begin{pmatrix} pr & ps \\ qr & qs \end{pmatrix}$$

for some p, q, r, s. Furthermore, since the eigenvalues are 1 and 0, the trace is 1, so $pr + qs = 1$. This means that the matrix

$$A = \begin{pmatrix} p & -s \\ q & r \end{pmatrix}$$

has determinant 1. The transformation $X \mapsto AXA^{-1}$ sends I to itself and sends $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ to $\left(\begin{smallmatrix} pr & ps \\ qr & qs \end{smallmatrix}\right)$, just like T. So the linear transformation

$$T'(X) = A^{-1}T(X)A$$

preserves determinants and fixes both I and $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ and therefore also their linear combination P. If we achieve our intermediate goal for T', the same result will follow immediately for T. Indeed, if $T'(X) = BXB^{-1}$ then $T(X) = (AB)X(AB)^{-1}$, while if $T'(X) = BX^tB^{-1}$ then $T(X) = (AB)X^t(AB)^{-1}$. So we may work with T' instead of T.

Thus, we assume that T fixes both I and P. Furthermore, as T preserves the quadratic form det, it also preserves the associated bilinear form

$$\langle X, Y\rangle = \tfrac{1}{2}(\det(X + Y) - \det(X) - \det(Y)),$$

which has, relative to our chosen basis, the standard form

$$\langle aI + pP + qQ + rR, a'I + p'P + q'Q + r'R\rangle = aa' + pp' + qq' + rr'.$$

(Usually, complex linear spaces are equipped with inner products that are linear in one factor and conjugate-linear in the other. That is not the case here; our inner product is linear in both factors.)

As T preserves this inner product and fixes I and P, it must leave invariant the set of vectors orthogonal to both I and P, namely the linear span of Q and R. So we have $T(Q) = qQ + rR$ for some scalars q and r. Also, we have

$$1 = \det(Q) = \det(T(Q)) = \det(qQ + rR) = q^2 + r^2.$$

There is a complex number v such that $(v + (1/v))/2 = q$. (Just solve a quadratic equation for v; of course there is a second solution $1/v$.) Note that

$$\left[\frac{1}{2} = \left(v + \frac{1}{v}\right)\right]^2 + \left[\frac{1}{2i}\left(v - \frac{1}{v}\right)\right]^2 = 1 = q^2 + r^2,$$

so $r = \pm(v - (1/v))/2i$. Replacing v with $1/v$ if necessary, we can arrange that

$$q = \frac{1}{2}\left(v + \frac{1}{v}\right) \quad \text{and} \quad r = \frac{1}{2i}\left(v - \frac{1}{v}\right).$$

Let u be either of the square roots of v, and let

$$M = \begin{pmatrix} u & 0 \\ 0 & \frac{1}{u} \end{pmatrix}.$$

Note that

$$M \cdot \begin{pmatrix} x & y \\ z & w \end{pmatrix} \cdot M^{-1} = \begin{pmatrix} x & u^2 y \\ \frac{1}{u^2} z & w \end{pmatrix} = \begin{pmatrix} x & vy \\ \frac{1}{v} z & w \end{pmatrix}.$$

In particular, the transformation $X \mapsto MXM^{-1}$ fixes I and P (just as T does) and it sends $Q = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ to

$$\begin{aligned} \begin{pmatrix} 0 & v \\ -\frac{1}{v} & 0 \end{pmatrix} &= \frac{1}{2}\left(v + \frac{1}{v}\right)\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} + \frac{1}{2i}\left(v - \frac{1}{v}\right)\begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix} \\ &= qQ + rR \\ &= T(Q). \end{aligned}$$

So $T'(X) = M^{-1}T(X)M$ preserves determinants and fixes I, P, and Q. As before, it suffices to reach our intermediate goal for T' rather than T. So from now on we assume that T fixes I, P, and Q.

It follows that T fixes the subspace orthogonal to I, P, and Q, namely the subspace spanned by R. So $T(R)$ is a scalar times R, and the scalar can only be ± 1 because T preserves determinants. If the scalar is 1, then T fixes all four basis matrices, hence is the identity. If, on the other hand, the scalar is -1, then $T(X) = P^{-1}X^tP$, because the right side of this equation defines a linear transformation which, like T fixes I, P, and Q and reverses the sign of R. In either case, T has the required form, so we have achieved our intermediate goal.

We now return to the original T, normalized to fix I and extended to $\mathrm{M}_2(C)$, which we now know to have the form $T(X) = BXB^{-1}$ or $T(X) = BX^tB^{-1}$ for some $B \in \mathrm{SL}_2(C)$. We also know that if the entries of X are integers then so are those of $T(X)$. What we still need to show is that the entries of B are integers. Without loss of generality, we may suppose that $T(X) = BXB^{-1}$.

Let X be the matrix with a single entry equal to 1, say the entry in position i, j, and all other entries zero. Then the entries of $T(X)$, namely

$$(BXB^{-1})_{k,l} = B_{k,i}(B^{-1})_{j,l}$$

are integers for all k and l. But, as B has determinant 1, the entries of B^{-1} are the same as those of B, except for their signs and their positions in the matrices. Thus we see that the product of any two entries of B is an integer.

In particular, the square of each entry of B is an integer, so each entry is the product of an integer and (possibly) the square roots of certain distinct primes.

Suppose p is a prime whose square root occurs in one of the entries. Then $\sqrt{p}$ must occur in every entry, for the product of an entry containing $\sqrt{p}$ as a factor and another entry not containing it could never be an integer. So $\sqrt{p}$ occurs as a factor of every entry of B. But then p is a factor of $\det(B) = 1$. This contradiction shows that no square roots occur.

So every entry of B is an integer, and the proof is complete. □

We saw that an arbitrary linear transformation T over $\mathrm{SL}_2(Z)$ extends uniquely to a linear transformation over the vector space $M_2(R)$ of all four-by-four real matrices. Let $\mathrm{Mat}(T)$ be the matrix of (the extension of) T in the standard basis:

$$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

LEMMA 9.2. *We have*

$$T\begin{pmatrix} x_1 & x_2 \\ x_3 & x_4 \end{pmatrix} = \begin{pmatrix} y_1 & y_2 \\ y_3 & y_4 \end{pmatrix} \longleftrightarrow \mathrm{Mat}(T)\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix}.$$

Proof. The proof is obvious. □

The entries of $\mathrm{Mat}(T)$ are the entries of the four matrices obtained by applying T to the standard basis. By Theorem 9.1, these are integers.

By Theorem 9.1, there are unimodular matrices B and C such $T(X) = BXC$ for all unimodular matrices X or $T(X) = BX^tC$ for all unimodular matrices X. Call T *right* in the first case and *left* in the second. The determinant of $\mathrm{Mat}(T)$ is ± 1 because

$$\det(\mathrm{Mat}(T)) \times \det(\mathrm{Mat}(T^{-1})) = \det(T \times T^{-1}) = 1.$$

LEMMA 9.3. *Right transformations are exactly those with determinant* $+1$.

Proof. It suffices to prove that if T is right then $\det \mathrm{Mat}(T) = 1$, because a left T is the product of the transposing transformation (whose matrix has determinant 1) and a right transformation. So suppose that $T(X) = BXC$ for some unimodular matrices B, C and all unimodular (and therefore all two-by-two real matrices) X.

Now forget about unimodular matrices and think about real matrices. Every pair (B', C') of nonsingular two-by-two real matrices gives a linear transformation $T' = X \mapsto B'XC'$ over two-by-two real matrices that has an inverse, so that the matrix $\mathrm{Mat}(T')$ of T' in the standard bases is nonzero. Now continuously transform B and C to the unit matrix. In the process T is continuously transformed to the identity, whose matrix has determinant 1, and the determinant of T remains nonzero all the time. Therefore its initial value cannot be -1. □

LEMMA 9.4. *There is a PTime algorithm that, given a four-by-four integer matrix* M, *determines whether* $M = \mathrm{Mat}(T)$ *for some* T.

Proof. If $M = \mathrm{Mat}(T)$ then, by Theorem 9.1, there exist unimodular matrices B and C such that either $T(X) = BXC$ for all unimodular matrices X or $T(X) = BX^tC$ for all unimodular matrices X. We show how to find out whether there is a pair (B, C) satisfying the first condition and even how to find all pairs (B, C) satisfying the first condition. The case of the second condition is similar.

Suppose that $T(X) = BXC$ for all unimodular matrices X. Due to the unique extendibility of T, $T(X) = BXC$ for all two-by-two real matrices. Let

$$B = \begin{pmatrix} b_1 & b_2 \\ b_3 & b_4 \end{pmatrix}, \quad C = \begin{pmatrix} c_1 & c_2 \\ c_3 & c_4 \end{pmatrix}.$$

Computing the products BXC where X belongs to the standard basis and using Lemma 9.2, we have

$$M = \begin{pmatrix} b_1c_1 & b_1c_3 & b_2c_1 & b_2c_3 \\ b_1c_2 & b_1c_4 & b_2c_2 & b_2c_4 \\ b_3c_1 & b_3c_3 & b_4c_1 & b_4c_3 \\ b_3c_2 & b_3c_4 & b_4c_2 & b_4c_4 \end{pmatrix}.$$

Thus we can recover all b_i/b_j and all c_i/c_j. So we recover B and C up to scalar factor. We recover the scalar factor, except for the sign, using the equalities $\det(B) = \det(C) = 1$. It follows that the pair (B, C) is unique except for an over-all sign. □

10. Matrix transformation. In this section we prove that Matrix Transformation is hard for RNP.

For an arbitrary numerical matrix X, let $\max(X)$ be the maximal absolute value of the entries of X. Recall that $\ell(n)$ is the length of the binary notation for n and $\mathrm{Mat}(T)$ is the matrix of a linear transformation T.

DEFINITION 10.1. *LT (standing for "Linear Transformations") is the uniform domain of linear transformations of* $\mathrm{SL}_2(Z)$ *with* $|T| = \ell(\max(\mathrm{Mat}(T)))$.

It will be convenient to ignore the distinction between a linear transformation T over $\mathrm{SL}_2(Z)$ and its matrix $\mathrm{Mat}(T)$.

For all unimodular matrices B and C, let $T_{B,C}$ be the linear transformation $X \mapsto C^{-1}XB$.

LEMMA 10.2. *The function* $(B, C) \mapsto M_{B,C}$ *reduces the subdomain of positive pairs in* $\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z)$ *to LT.*

Proof. We need to check only that the function $f(B, C) = M_{B,C}$ has the domination property. Recall that the inverse of a matrix $\left(\begin{smallmatrix} a & c \\ b & d \end{smallmatrix}\right)$ is the matrix $\left(\begin{smallmatrix} d & -c \\ -b & a \end{smallmatrix}\right)$. It follows that $\max(f(B, C)) = \max(B) \times \max(C)$ and therefore $|B| + |C| - 1 \le |f(B, C)| \le |B| + |C|$.

Let $l = |f(B, C)|$, let M range over LT, and let B, C range over unimodular matrices. Using # as the cardinality symbol, we have

$$\begin{aligned} &\#\{M : |M| = l\} \le 2\#\{(B, C) : l \le |B| + |C| \le l + 1\} \\ &= \sum_{j=1}^{l+1} [\#\{B : |B| = j\} \times \#\{C : l - j \le |C| \le l - j + 1\}]. \end{aligned}$$

By Lemma 8.5, the number of unimodular matrices of size $m > 1$ is eight times the number of positive unimodular matrices of size m. According to Lemma 6.7, the later number is $\Theta(2^{2m})$. It follows that, modulo a constant factor,

$$\#\{M : |M| = l\} \le \sum_{l=1}^{l+1} 2^{2j} 2^{2l-2j} = 2^{2l}(l + 1).$$

We saw in the previous section that, for each M in LT, the pre-image of $f^{-1}(M)$ has at most two elements. It follows that, modulo bounded factors,

$$\frac{\mathbf{P}(f^{-1}f(B, C))}{\mathbf{P}(f(B, C))} \le \frac{2^{2l}(l + 1)}{2^{2l}} = l + 1 \le |(B, C)| + 1$$

which is AP on $\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z)$. □

If S is a subset of LT, let S^n be the set of products $T_m \cdots T_1$ where $m \le n$ and each $T_i \in S$. First we prove that an auxiliary version of matrix transformation is hard for RNP.

DEFINITION 10.3. *For each positive integer* σ, $\mathrm{MT}(\sigma)$ *is the decision problem with domain* $\mathrm{SL}_2(Z) \times \mathrm{Set}_\sigma(LT) \times PI$ *where an instance* (A, S, n) *is positive if and only if there exists* $T \in S^n$ *that transforms* A *to the unit matrix.*

THEOREM 10.4. *Some* $\mathrm{MC}(\sigma)$ *is hard for RNP.*

Proof. Let σ witness Theorem 8.7. We reduce the subdomain of $\mathrm{MC}(\sigma)$ described in Theorem 8.7 to $\mathrm{MC}(\sigma)$. If S is a sequence of positive matrix pairs, let S' be the result of replacing each pair (B, C) in S with the linear transformation $T_{B,C}(X) = C^{-1}XB$. The desired reduction is $f(A, S, n) = (A, S', n)$. To check the correctness property, note that $AB_1 \ldots B_m = C_1 \ldots C_m$ if and only if the transformation $T_{B_m,C_m} \ldots T_{B_1,C_1}$ takes A to the unit matrix.

It remains to check that f reduces the relevant subdomain of $\mathrm{SL}_2(Z) \times (\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z))^\sigma \times \mathrm{PI}$ to the domain $\mathrm{SL}_2(Z) \times (\mathrm{LT})^\sigma \times \mathrm{PI}$. It suffices to check that the function

$S \mapsto S'$ reduces $(\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z))^\sigma$ to LT^σ. By Lemma 3.7, it suffices to check that the function $(B, C) \mapsto T_{B,C}$ reduces $\mathrm{SL}_2(Z) \times \mathrm{SL}_2(Z)$ to LT. Now use Lemma 10.2. □

DEFINITION 10.5. *MT is the decision problem with domain* $\mathrm{SL}_2(Z) \times \mathrm{Set}(LT) \times PI$ *such that an instance* (A, S, n) *is positive if and only if there exists* $P \in S^n$ *with* $A = P(1)$.

COROLLARY 10.6. *MT is RNP complete.*

Proof. The identity function deterministically reduces $\mathrm{MT}(\sigma)$ to MT. We omit checking that MT is in RNP. □

Remark 4. Let $\pi(j)$ be any PTime computable nondecreasing function from positive integers to positive integers such that the inverse function $\pi^{-1}(j) = \min_i[\pi(i) \geq j]$ is polynomially bounded. For example, $\pi(j) = j$. The restriction of MT (respectively, $\mathrm{MT}(\sigma)$) to instances (A, S, n) with $n = \pi(|A|)$ remains RNP complete. The proof is the same proof except we start with the corresponding version of the bounded halting problem, which has been proved RNP complete in [Gu1, §9].

11. Bounded membership problem. In this section, we briefly consider a natural simplification of $\mathrm{MT}(\sigma)$ where the question is whether the given unimodular matrix X is a product of at most n factors taken from a given finite subset (assumed closed under inverses) of $\mathrm{SL}_2(Z)$. This is a bounded version of the membership problem [Mi] for $\mathrm{SL}_2(Z)$. We show that it is NP complete. It is interesting open problem whether a natural randomization of it is RNP complete. We begin with the analogous bounded version of the membership problem for the additive group of integers.

DEFINITION 11.1. Integer Sum *is the following* NP *problem:*

Instance: *A positive integer* K, *a finite set* S *of positive integers, and a positive integer* n.

Question: *Can* K *be represented as* $\sum_{i=1}^{m} \varepsilon_i b_i$ *where* $m \leq n$, *the numbers* b_i *are (not necessarily distinct) elements of* S, *and* $\varepsilon_i \in \{1, -1\}$?

The restriction n on the number of summands is important. It is easy to decide whether or not K can be represented as a sum of elements of $S \cup \{-b : b \in S\}$; just compute the greatest common divisor of the elements of S and check whether it divides K.

LEMMA 11.2. *Integer Sum is* NP *complete.*

The fact may be well known. It was not known to us. Suzanne Zeitman, a graduate student of Gurevich, proved the lemma.

Proof. The proof is by reduction from X3C, Exact Cover by 3-Sets [GJ], which is the following NP problem:

Instance: A positive integer q and a collection C of 3-element subsets of the set $\{1, 2, \ldots, 3q\}$.

Question: Is there an exact cover $C' \subseteq C$ for X (so that each element of X belongs to exactly one member of C')?

The transformation f we use resembles that used in the reduction of 3-Dimensional Matching to partition [GJ]. Given an instance (q, C) of X3C, let l be the length of the binary notation for q and B be the collection of binary strings of length $3ql$. View a B string as a sequence of $3q$ blocks (substrings) of length l. For each i, $1 \leq i \leq 3q$, let a_i be the integer represented by a B string with exactly one 1, which appears at the rightmost position of the ith block.

CLAIM 11.3. *If* $\sum_{i=1}^{3q} \alpha_i a_i = \sum_{i=1}^{3q} \beta_i a_i$ *and* $0 \leq \alpha_i, \beta_i \leq q$ *for each* i, *then* $\alpha_i = \beta_i$ *for each* i.

Proof. By the definition of l. □

Define

$$f(q, C) = (K, \{y(T) : T \in C\}, q),$$

where $K = \sum_{i=1}^{3q} a_i$ and each $y(T) = \sum_{i \in T} a_i$. If C' is an exact cover of C, then the cardinality of C' is q and K is represented as the sum of the q numbers $y(T)$ such that $T \in C'$.

Now suppose that $K = \sum_{j=1}^{m} \varepsilon_j y(T_j)$ where $m \leq q$ and $\varepsilon_j \in \{1, -1\}$ and $T_j \in C$. Then let $K^+ = \sum\{y(T_j) : \varepsilon_j > 0\} = \sum_{i=1}^{3q} \alpha_i a_i$ and $K^- = \sum\{y(T_j) : \varepsilon_j < 0\} = \sum_{i=1}^{3q} \gamma_i a_i$, so that $K^+ = K + K^-$. Clearly, $\alpha_i \leq m \leq q$. Similarly, $\gamma_i \leq q$. For each $T \in C$, let $z_i(T)$ equal 1 if $i \in T$ and equal 0 otherwise.

First consider the case $K^- = 0$. By Claim 11.3, we have that, for each i, $\sum_j z_i(T_j) = 1$. Thus, the sets T_j form an exact cover.

By contradiction, suppose that $K^- > 0$. Then the number of j's with $\varepsilon_j > 0$ is less than q and therefore there exists an i with $\alpha_i = 0$. Since $K^+ = K + K^-$, we have, by the claim, that $0 = \alpha_i = 1 + \gamma_i$ which is impossible. □

DEFINITION 11.4. *The* bounded membership problem *for the modular group, in short BM, is the following* NP *decision problem:*

Instance: *A unimodular matrix X, a finite set S of unimodular matrices and a positive integer n.*

Question: *Can X be represented as $\prod_{i=1}^{m} Y_i$ where $m \leq n$ and, for each i, either Y or Y^{-1} is in S?*

COROLLARY 11.5. *BM is* NP *complete.*

Proof. For each integer y, let

$$g(y) = \begin{pmatrix} 1 & y \\ 0 & 1 \end{pmatrix}.$$

If $g(y) = Y$ and $g(z) = Z$ then $g(y + z) = YZ$ and $g(-y) = Y^{-1}$. This gives rise to the following reduction of IS to BM:

$$F(K, S, n) = (g(K), \{g(y) : y \in S\}, n). \qquad \square$$

One natural way to randomize BM is to view the domain of BM as $\mathrm{SL}_2(Z) \times \mathrm{Set}(\mathrm{SL}_2(Z)) \times$ PI. The corresponding randomized decision problem is probably decidable in AP time.

Acknowledgments. We thank Suzanne Zeitman for allowing us to publish her proof that Integer Sum is NP complete. We thank Abraham Sharell, the team of Belanger and Wang, and the referees for pointing out various flaws in the previous versions of this paper.

TIGHTER LOWER BOUNDS ON THE EXACT COMPLEXITY OF STRING MATCHING*

RICHARD COLE†, RAMESH HARIHARAN†, MIKE PATERSON‡, AND URI ZWICK§

Abstract. This paper considers the exact number of character comparisons needed to find all occurrences of a pattern of length m in a text of length n using on-line and general algorithms. For on-line algorithms, a lower bound of about $(1 + \frac{9}{4(m+1)}) \cdot n$ character comparisons is obtained. For general algorithms, a lower bound of about $(1 + \frac{2}{m+3}) \cdot n$ character comparisons is obtained. These lower bounds complement an on-line upper bound of about $(1 + \frac{8}{3(m+1)}) \cdot n$ comparisons obtained recently by Cole and Hariharan. The lower bounds are obtained by finding patterns with interesting combinatorial properties. It is also shown that for some patterns off-line algorithms can be more efficient than on-line algorithms.

1. Introduction.

The classical *string matching* problem is the problem of finding all occurrences of a pattern $w[1 \ldots m]$ in a text $t[1 \ldots n]$. String matching is among the most extensively studied problems in computer science. A survey of the various algorithms devised for it can be found in [Ah90].

Among the most efficient algorithms devised for string matching are algorithms that gain information about the pattern and text only by performing comparisons between pattern and text characters. Such algorithms need not have any prior knowledge of the (possibly infinite) alphabet from which the pattern and text are drawn. We investigate the exact comparison complexity of string matching in this model and obtain lower bounds on the number of comparisons required (in the worst case). These lower bounds allow the algorithms to preprocess the pattern (but not the text). The lower bounds remain valid even if the algorithms do know the alphabet in advance, provided that the alphabet contains enough characters not appearing in the pattern.

Two kinds of comparison based algorithms have been studied. An *on-line* algorithm is an algorithm that examines text characters only in a window of size m sliding monotonically to the right; furthermore, the window can slide to the right only when all matching pattern instances to the left of the window or aligned with the window have been discovered. A general (or *off-line*) algorithm is an algorithm that can access both the pattern and the text in an unrestricted manner.

Perhaps the most widely known linear time algorithms for string matching are the Knuth–Morris–Pratt [KMP77] and Boyer–Moore [BM77] algorithms. We refer to them as the KMP and BM algorithms, respectively. The KMP algorithm makes at most $2n - m$ comparisons and this bound is tight. The exact complexity of the BM algorithm was an open question until recently. It was shown in [KMP77] that the BM algorithm makes at most $6n$ comparisons if the pattern does not occur in the text. Guibas and Odlyzko [GO80] reduced this to $4n$ under the same assumption. Cole [Cole91] finally proved an essentially tight bound of $3n - \Omega(n/m)$ comparisons for the BM algorithm, whether or not the pattern occurs in the text.

The versions of the KMP and BM algorithms considered in the preceding paragraph are comparison-based. It is interesting to note that both algorithms have variants that are not purely comparison-based and do not fall into the category of algorithms considered in this paper. The failure function of the KMP algorithm [KMP77] yields finite automata that perform string matching by reading each character exactly once. However, simulations of these automata require prior knowledge of the alphabet and the number of comparisons needed to simulate each transition depends on the alphabet size. Transitions can be simulated in unit time by using text characters to address an array of pointers, but this is not allowed in our model.

The standard BM algorithm [BM77] uses two shift functions to determine the distance to shift the pattern when a mismatch occurs. One of these shift functions, the *occurrence shift*, gives the rightmost position in the pattern in which the unmatched text character occurs. An efficient implementation of this shift function is again alphabet dependent. The second shift function used by the BM algorithm is comparison-based. The analysis of Cole [Cole91] shows that the occurrence shift function does not improve the worst-case behaviour of the BM algorithm. This occurrence shift function is very important in practice, however, as it ensures sublinear time in various probabilistic settings (see [BGR90]). For a study of how the KMP, BM, and other algorithms behave in practice the reader is referred to [HS91].

Apostolico and Crochemore [AC91] gave a simple variant of the KMP algorithm which makes at most $\frac{3}{2}n$ comparisons. Apostolico and Giancarlo [AG86] gave a variant of the BM algorithm which makes at most $2n - m + 1$ comparisons. Crochemore et al. [CCG92] showed recently that remembering just the most recently matched portion reduces the upper bound of BM from $3n$ to $2n$ comparisons.

Recently, Galil and Giancarlo [CGG90], [GG92] analyzed and modified a string matching algorithm designed by Colussi [Coll91] ; they showed that it makes at most $\frac{4}{3}n$ comparisons. In fact, [GG92] give this bound in a sharper form as a function of the period z of the pattern; the bound becomes $n+(n-m)\min\{\frac{1}{3}, \frac{\min\{z,m-z\}+2}{2m}\}$. Galil and Giancarlo [GG91] have also shown that any on-line algorithm for string matching must perform at least $\frac{4}{3}n - O(1)$ comparisons for some strings (the string `aba` is an example). It will be shown here that this lower bound also applies to general algorithms, if only pattern–text comparisons are allowed.

The algorithm of Galil and Giancarlo [GG92] is efficient for relatively short patterns. It may become inefficient for longer patterns. Breslauer and Galil [BG92] and Cole and Hariharan [CH92] have shown that the string matching problem becomes easier as the length of the pattern increases. Breslauer and Galil [BG92] developed an algorithm that performs at most $(1 + O(\frac{\log m}{m})) \cdot n$ character comparisons for texts of length n and patterns of length m. Cole and Hariharan [CH92] obtained an algorithm that performs at most $(1 + O(\frac{1}{m})) \cdot n$ comparisons. As we shall see, this is essentially tight.

Galil and Giancarlo [GG91] showed that any on-line algorithm must perform at least $(1 + \frac{2}{m+3}) \cdot n - O(1)$ comparisons for some patterns of odd length m, and that any (general) algorithm must perform at least $(1+\frac{1}{2m}) \cdot n - O(1)$ comparisons for some patterns of length m.

In this work we improve the lower bounds for both on-line and off-line algorithms. We also show that for certain patterns off-line algorithms can be more efficient than on-line algorithms. Some of our lower bounds apply in a model in which both text–text and pattern–text comparisons are allowed. We suspect that for some patterns text–text comparisons can improve the efficiency of string matching algorithms.

Our improved lower bounds are the following: For on-line algorithms that use only pattern–text comparisons, a lower bound of $(1 + \frac{16}{7m+27}) \cdot n - O(1)$ character comparisons is obtained, for $m = 16k + 19$ where $k \geq 1$. For on-line algorithms that are allowed to use both pattern–text and text–text comparisons, a lower bound of $(1 + \frac{9}{4(m+1)}) \cdot n - O(1)$ character comparisons is obtained for $m = 36k + 35$, where $k \geq 0$. For general off-line

algorithms that are allowed to use both pattern–text and text-text comparisons, a lower bound of $(1 + \frac{2}{m+3}) \cdot n - O(1)$ character comparisons is obtained for $m = 2k + 1$, where $k \geq 2$. We also get an off-line lower bound of $\frac{4}{3}n - O(1)$ character comparisons for $m = 3$ if only pattern–text comparisons are allowed.

The on-line lower bounds presented come very close to the on-line upper bound of $(1 + \frac{8}{3(m+1)}) \cdot n$ obtained by Cole and Hariharan [CH92]. The worst-case comparison complexity of string matching is therefore almost exactly determined. It is asymptotically of the form $(1 + \frac{d}{m}) \cdot n$ where for on-line algorithms $\frac{9}{4} \leq d \leq \frac{8}{3}$ and for general algorithms $2 \leq d \leq \frac{8}{3}$.

Our work builds on the work of Galil and Giancarlo [GG91]. Our point of view, however, is a bit different. Galil and Giancarlo [GG91] investigated the number of comparisons required only as a function of n, the text length, and m, the pattern length. We are interested in the number of comparisons required as a function of the text length and the specific pattern sought.

In the next section we explain, in more detail, the rules of the string matching game in the comparison model setting. In §3 we describe the adversary arguments that lie at the heart of our lower bounds proofs. The off-line lower bounds presented in §4 follow almost immediately from the arguments of §3. A specific lower bound is obtained for every pattern. This lower bound depends on the first and second periods of the pattern (see next section). These off-line lower bounds are shown to be tight for an interesting family of patterns. Exploiting the additional restrictions for on-line algorithms, we obtain, in §§5 and 6, improved on-line lower bounds. The lower bound of §5 depends again on the first and second periods of the patterns. Additional periods and more complicated combinatorial structures are used in §6. In §7 we obtain some on-line upper bounds (for strings of the form $\mathtt{a}^k\mathtt{ba}^\ell$) that match the on-line and some off-line lower bounds of §§4 and 5. Finally, in §8 we exhibit a pattern (abaa) for which an off-line algorithm (it is actually on-line with a small look-ahead) performs better than any on-line algorithm.

A preliminary version of this paper has appeared in [CHPZ93].

2. Preliminaries. The algorithms we consider are allowed to access the text and the pattern only through queries of the form "$t[i] = w[j]$?" or "$t[i] = t[j]$?". To each such query the algorithm is supplied with a "yes" or "no" answer. An algorithm is charged only for the queries it makes; all other computations are free of charge. Algorithms may adaptively choose their queries depending on the answers to earlier queries. An algorithm in this model may be viewed as a sequence of decision trees. Similar comparison models are used to study comparison problems such as sorting, searching, and selection.

For a string w, let $c(w)$ denote the minimal constant for which there exists a string matching algorithm that finds all occurrences of the pattern w in a text of length n using at most $c(w) \cdot n + o(n)$ comparisons (between text and pattern characters and between pairs of text characters). A variant of $c(w)$ is $c^*(w)$ in which the algorithm is not allowed to compare pairs of text characters. Obviously, $c(w) \leq c^*(w)$.

In the definition of $c(w)$ and $c^*(w)$, we allow unrestricted *off-line* algorithms that have random access to all the characters of the text. By contrast, we define $c_k(w)$ and $c_k^*(w)$ to be the corresponding minimal constants when the algorithms have access to the text only through a sliding window of size $|w|+k$ (where $|w|$ denotes the length of w). Furthermore, the algorithm is only allowed to slide the window past a text position when it has already reported whether an occurrence of the pattern starts at that text position. Algorithms using a sliding window of size $|w|$ (i.e., $k = 0$) are traditionally called *on-line* algorithms. We call algorithms that use larger windows *finite look-ahead* or *window* algorithms. Clearly $c(w) \leq c_k(w) \leq c_0(w)$ for any $k \geq 0$. We show in §8 that for some w and some k, $c_k(w) < c_0(w)$. More specifically, we show there that $c_4(\mathtt{abaa}) < c_0(\mathtt{abaa})$. This means that for some patterns, algorithms that use larger windows may be more efficient than all algorithms that use smaller windows. It is

still an open problem whether there exists a string w for which $c(w) < c_k(w)$ for every $k \geq 0$. That is, it is not known whether there exists strings for which an optimal off-line algorithm is better than any finite look-ahead algorithm. It is clear however that $c_k(w)$ is nonincreasing in k. The following lemma is also easily established.

LEMMA 2.1. *For any string w we have* $\lim_{k\to\infty} c_k(w) = c(w)$.

Proof. Let $c(n)$ be the number of comparisons required, in the worst case, to find all occurrences of w in a text of length n using an unrestricted algorithm. By the definition of $c(w)$ we get that $c(n) \leq c(w)\cdot n + d(n)$ where $d(n) = o(n)$. For every $k \geq 0$ consider now the following algorithm with look-ahead k. The algorithm finds all occurrences of w in its window of size $k + |w|$ using at most $c(k + |w|)$ comparisons. The window is then slid by $k + 1$ positions and the same process is repeated. The number of comparisons performed by this algorithm on a text of length n is at most

$$\left\lceil \frac{n}{k+1} \right\rceil \cdot c(k + |w|) \leq \hat{c}_k(w)\cdot n + \hat{d}_k(w),$$

where

$$\hat{c}_k(w) = \frac{k + |w|}{k+1} \cdot c(w) + \frac{d(k + |w|)}{k+1}$$

and $\hat{d}_k(w)$ is some constant (depending on w and k). In particular we get that $c_k(w) \leq \hat{c}_k(w)$. It is now easy to check that $\lim_{k\to\infty} \hat{c}_k(w) = c(w)$ and therefore $\lim_{k\to\infty} c_k(w) \leq c(w)$. It is clear however that $\lim_{k\to\infty} c_k(w) \geq c(w)$ and the required equality follows. □

It is easy to see that $1 \leq c(w) \leq c_0(w)$, $c^*(w) \leq c_0^*(w)$ for every string w. The KMP algorithm shows that $1 \leq c_0^*(w) \leq 2$, for every w. The algorithm of Galil and Giancarlo [GG92] shows that $1 \leq c_0^*(w) \leq \frac{4}{3}$, for every w. The algorithm of Breslauer and Galil [BG92] shows that $1 \leq c_0^*(w) \leq 1 + \frac{4\log_2 m+2}{m}$ for every string of length m. Finally, the algorithm of Cole and Hariharan [CH92] shows that $1 \leq c_0^*(w) \leq 1 + \frac{8}{3(m+1)}$ for every string w of length m. The algorithms (of [KMP77],[GG92],[BG92], and [CH92]) mentioned here are all on-line and they use only pattern–text comparisons.

Galil and Giancarlo [GG91] showed that $c_0^*(w) \geq c_0(w) \geq 1 + \frac{2}{m+3}$ for some patterns of odd length m. We show that for infinitely many values of m there exists strings of length m for which $c_0^*(w) \geq c_0(w) \geq 1 + \frac{9}{4(m+1)}$. We also show that for infinitely many values of m there exists strings of length m for which $c_0^*(w) \geq 1 + \frac{16}{7m+27}$. This shows that the algorithm of Cole and Hariharan is not far from being optimal. We further show that $c^*(w) \geq c(w) \geq 1 + \frac{2}{m+3}$ for some patterns of odd length $m \geq 5$, showing essentially that the lower bounds obtained by [GG91] for on-line algorithms also hold for general algorithms.

Let w be a string of length m. We say that z ($1 \leq z \leq m$) is *a period* of w if and only if $w[i] = w[i + z]$ for every $1 \leq i \leq m - z$. Let z_1 be the minimal period of w. (A minimal period exists since m is always a period of w.) Let z_2 be the minimal period of w which is not divisible by z_1. If such a second period does not exist we set $z_2 = \infty$. We call z_1 *the period* of w and z_2 *the second period* of w. Periodicity properties play a major role in the sequel.

It is well known (see, e.g., [KMP77]) that if z_1 and z_2 are periods of w and if $z_1 + z_2 \leq |w| + \gcd(z_1, z_2)$ then $\gcd(z_1, z_2)$ is also a period of w. If z_1 and z_2 are the first and second periods of w then $\gcd(z_1, z_2)$ is not a period of w and, as a consequence, $z_1 + z_2 \geq |w| + 2$.

3. Adversary arguments. Our lower bounds are derived using an adversary that fills in the text while answering the algorithm's queries. The adversary always "tiles" the text with (overlapping) occurrences of the pattern. Every character of the text eventually becomes part of an occurrence, which the algorithm must find. Consequently the algorithm must establish

the identity of each text character and it can achieve this only by getting at least one "yes" answer for each position. The adversary tries to avoid giving "yes" answers whenever possible. It gives a "yes" answer only when a "no" answer would either contradict a previous answer or prevent it from completely tiling the text. The arguments of this section are generalizations of similar arguments of Galil and Giancarlo [GG91].

The previous statement, that at least one "yes" answer must be obtained by the algorithm for each text position covered by an occurrence of the pattern, seems obvious. It is indeed immediate if only pattern–text comparisons are allowed. A slightly more complicated argument is needed to handle the possibility of text–text comparisons.

LEMMA 3.1. *A comparison based algorithm can be certain about the identity of s text characters in a text t only after receiving at least s "yes" answers.*

Proof. We construct a graph G which has one vertex for each text position and one vertex for each of the k distinct symbols which appear in the pattern w. Every edge in G corresponds to a "yes" answer received by the algorithm. If a "yes" answer was given to a query "$w[i] = t[j]$?" then an edge is added between the vertex corresponding to $t[j]$ and the vertex corresponding to the symbol at $w[i]$. If a "yes" answer was given to a query "$t[i] = t[j]$?" then an edge is added between the vertices corresponding to $t[i]$ and $t[j]$.

At any stage of the algorithm the graph G constructed so far represents the positive information known about the characters in the text. The text positions corresponding to vertices in components of G which contain a pattern symbol vertex are the only text positions where the identity of the character is known. Since the alphabet size is unlimited, the character at any other text position is not yet determined. Since a component of size p containing a pattern symbol vertex has $p - 1$ text vertices and at least $p - 1$ edges, the total numbers of known text positions is at most the total number of "yes" answers. □

Next we describe a scheme using which the adversary can give any algorithm a relatively large number of "no" answers. We begin with a simple example.

The pattern string is aba, and let $n = 3r + 1$ for some $r \geq 1$. We consider the family $\mathcal{F} = \{t_v : v \in \{0, 1\}^r\}$ of text strings of length n defined as follows. Place a's in positions $3j$, for $0 \leq j < r$, of all texts t_v. In positions $3j + 1, 3j + 2$ of t_v, put ba if $v_j = 0$ and ab if $v_j = 1$. (For simplicity, we number the positions here from 0.) This family may be depicted schematically as

$$\ldots \mathtt{a} \begin{matrix}\mathtt{ba}\\ \mathtt{ab}\end{matrix} \mathtt{a} \begin{matrix}\mathtt{ba}\\ \mathtt{ab}\end{matrix} \mathtt{a} \begin{matrix}\mathtt{ba}\\ \mathtt{ab}\end{matrix} \mathtt{a} \ldots .$$

Finding all occurrences of aba in a text string from $\mathcal{F}$ is equivalent to determining the index vector $v \in \{0, 1\}^r$. An adversary can force at least one "no" answer before revealing each bit of v.

The following definition generalises the properties of the example.

DEFINITION 3.2. Let w be a string. A family $\mathcal{F} = \{t_v : v \in \{0, 1\}^r\}$ of texts of length n is said to be *r-separating* for w if there exist distinct indices $u_1^0, \ldots, u_r^0, u_1^1, \ldots, u_r^1$ such that the following holds:

1. For every $v = (v_1, \ldots, v_r) \in \{0, 1\}^r$ and for every i, the text t_v contains an occurrence of w starting at position u_i^0 if and only if $v_i = 0$ and an occurrence of w at position u_i^1 if and only if $v_i = 1$.

2. The answer to any query of the form "$w[i] = t[j]$?" is either "yes" for all texts t_v, or "no" for all texts t_v, or "yes" for a text t_v if and only if $v_k = \varepsilon$, for some fixed $1 \leq k \leq r$ and $\varepsilon \in \{0, 1\}$.

3. The answer to a text–text query "$t[i] = t[j]$?" is either "yes" for all texts t_v, or "no" for all t_v, or "yes" for t_v if and only if $v_{k_1} = \varepsilon_1$, or "yes" for t_v if and only if $v_{k_1} \oplus v_{k_2} = \varepsilon_1$, or "yes" in t_v if and only if $v_{k_1} = \varepsilon_1$ and $v_{k_2} = \varepsilon_2$, for some fixed $1 \leq k_1, k_2 \leq r$ and $\varepsilon_1, \varepsilon_2 \in \{0, 1\}$. (If $\mathcal{F}$ contains only symbols from the pattern then 3. follows from 1. and 2.)

In the example given before Definition 3.2, there is no text–text query whose answer is "yes" if and only if $v_{k_1} = \varepsilon_1$ and $v_{k_2} = \varepsilon_2$, for some fixed $1 \leq k_1 \neq k_2 \leq r$ and $\varepsilon_1, \varepsilon_2 \in \{0, 1\}$. Such a situation may arise however for patterns w that contain more than two distinct characters.

We are now ready to prove the next lemma.

LEMMA 3.3. *If $\mathcal{F}$ is an r-separating family for w then, for any comparison-based algorithm for w, there exists a text $t_v \in \mathcal{F}$ for which the algorithm receives at least r "no" answers before being able to locate all the occurrences of w in t_v.*

Proof. The adversary maintains a set E containing linear equations over the binary field GF(2) in the variables $v_1, \ldots, v_r$. At any stage, there is at least one vector $v \in \{0, 1\}^r$ that satisfies all the equations of E, and if a vector $v \in \{0, 1\}^r$ satisfies all the equations of E then the text t_v is consistent with all answers given so far by the adversary. Further, the number of equations in E is at most the number of "no" answers given by the adversary. At the beginning $E = \phi$, and as no query has been made, all texts are still possible. This is how the adversary responds to a new query:

If the answer to the query is the same for all texts t_v for which v is a solution of E, the adversary responds with this common answer. The set E remains unchanged and all the invariants remain satisfied.

Otherwise, the adversary answers with a "no". It then adds an equation to E in the following way. As the answer to the current query is not the same for all the texts in $\mathcal{F}$, there exist, by Definition 3.2, either a single equation e_1 or two equations e_1 and e_2 such that the answer to the query is "yes" in t_v if and only if v satisfies e_1 or both e_1 and e_2.

If the answer to the query, according to t_v, is "yes" if and only if e_1 is satisfied, then $\overline{e_1}$, the equation obtained from e_1 by complementing its free coefficient, is added to E. If the answer to the query, according to t_v, is "yes" if and only if both e_1 and e_2 are satisfied, then at least one of e_1 and e_2 is independent of the equations of E, as otherwise the answer would have been the same for all surviving texts. If e_1 does not depend on E then the equation $\overline{e_1}$ is added to E, otherwise $\overline{e_2}$ is added. It is easy to verify that all the required invariants are still satisfied.

The algorithm's task is done only when there is a unique solution to E. This happens only when the set E contains at least r equations. An equation is added to E only as a result of a "no" answer. The adversary can therefore give the algorithm at least r "no" answers. □

Lemmas 3.1 and 3.3 can be combined together to give a lower bound of $n + r$ if, in every text t_v of the separating family $\mathcal{F}$ used in Lemma 3.3, every text position is covered by an occurrence of the pattern w. Such separating families will be constructed in the next section.

4. Off-line lower bounds.

THEOREM 4.1. *If w is a string and z_1, z_2 are its first and second periods then $c(w) \geq 1 + \frac{1}{z_1 + z_2}$.*

Proof. Assume without loss of generality that $n = r(z_1 + z_2) + |w|$ for some $r \geq 1$. For every $v \in \{0, 1\}^r$ construct a text t_v of length n in which, for every $0 \leq j < r$, occurrences of w start at $j(z_1 + z_2)$, and either at $j(z_1 + z_2) + z_1$ or $j(z_1 + z_2) + z_2$ according to whether $v_j = 0$ or $v_j = 1$. It is easy to verify that $\mathcal{F} = \{t_v : v \in \{0, 1\}^r\}$ is an r-separating family for w where $u_j^0 = j(z_1 + z_2) + z_1$ and $u_j^1 = j(z_1 + z_2) + z_2$, for $0 \leq j < r$. This construction is depicted in Fig. 1 (note that $z_1 + z_2 \geq |w| + 2$). Consider now a comparison-based algorithm A that finds all occurrences of w in a string of length n. According to Lemma 3.3, A gets at

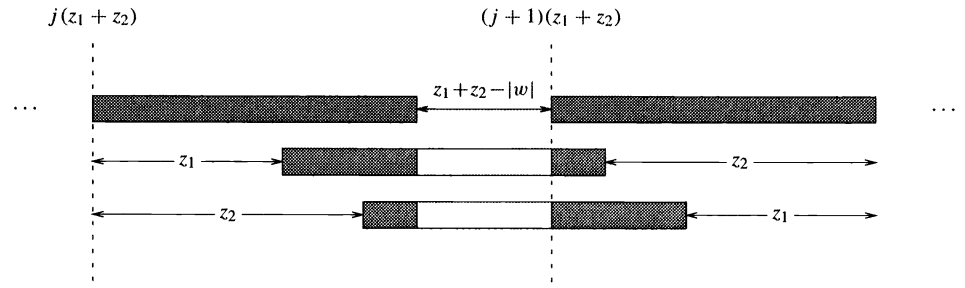

FIG. 1. *The configuration used to prove that* $c(w) \geq 1 + \frac{1}{z_1+z_2}$.

least r "no" answers for at least one text t_{v_0}, where $v_0 \in \{0,1\}^r$. It is also easy to see that every text t_v, and in particular t_{v_0}, is completely covered with occurrences of w. According to Lemma 3.1, A must therefore get at least n "yes" answers on t_{v_0}. In total, A must make, in the worst case, at least $n+r = (1+\frac{1}{z_1+z_2})n - \frac{|w|}{z_1+z_2}$ comparisons for a text of length n. □

As an example, note that for the string aba, $z_1 = 2$ and $z_2 = 3$ and therefore $c(\texttt{aba}) \geq \frac{6}{5}$. The separating family used to obtain this lower bound may be depicted as

$$\ldots \texttt{aba} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aba} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aba} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aba} \ldots .$$

This family has the property that, in every text of the family, every position is covered by an occurrence of aba. The separating family for aba given after Definition 3.2 did not have this property.

As a further example, note that for the string abaa we have $z_1 = 3$ and $z_2 = 4$, and therefore $c(\texttt{abaa}) \geq \frac{8}{7}$. In §8 it will be shown that this bound is tight, i.e., $c(\texttt{abaa}) = \frac{8}{7}$. We will see from Theorem 7.1 that $c_0(\texttt{abaa}) = \frac{5}{4}$. This provides an example of a string for which off-line algorithms can be more efficient than on-line algorithms.

THEOREM 4.2. *If w is a string, z_1, z_2 are its first and second periods, and $2z_2 - z_1 \leq |w|$ then $c(w) \geq 1 + \frac{1}{z_2}$.*

Proof. The proof is very similar to the proof of Theorem 4.1. A separating family, in which every text is *almost* completely tiled with occurrences of w, may be obtained this time without using occurrences of w that are common to all the texts of the family.

Assume that $n = rz_2 + |w| + z_1$ for some $r \geq 1$. For every $v \in \{0,1\}^r$, construct a text t_v of length n in which, for $0 \leq j < r$, occurrences of w start at jz_2 if $v_j = 0$ or at $jz_2 + (z_2 - z_1)$ if $v_j = 1$. It is again easy to check that $\mathcal{F} = \{t_v : v \in \{0,1\}^r\}$ is an r-separating family for w where this time $u_j^0 = jz_2$ and $u_j^1 = jz_2 + (z_2 - z_1)$, for every $0 \leq j < r$. The construction is depicted in Fig. 2. Note that if z_1, z_2 ($z_1 < z_2$) are periods of w then so is $2z_2 - z_1$. As $2z_2 - z_1 \leq |w|$, every position in a text t_v, except perhaps the first and last $z_2 - z_1$ positions, is covered by an occurrence of w. Thus, as in the proof of Theorem 4.1, we can show that any algorithm must perform, in the worst case, at least $n(1 + \frac{1}{z_2}) - O(|w|)$ comparisons. □

As an example, for the string aabaa we have $z_1 = 3$, $z_2 = 4$ and $2z_2 - z_1 \leq |w|$ and therefore $c(\texttt{aabaa}) \geq \frac{5}{4}$. The separating family used this time is

$$\ldots \texttt{aa} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aa} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aa} \begin{matrix}\texttt{ba}\\ \texttt{ab}\end{matrix} \texttt{aa} \ldots .$$

THEOREM 4.3. $c^*(\texttt{aba}) = \frac{4}{3}$.

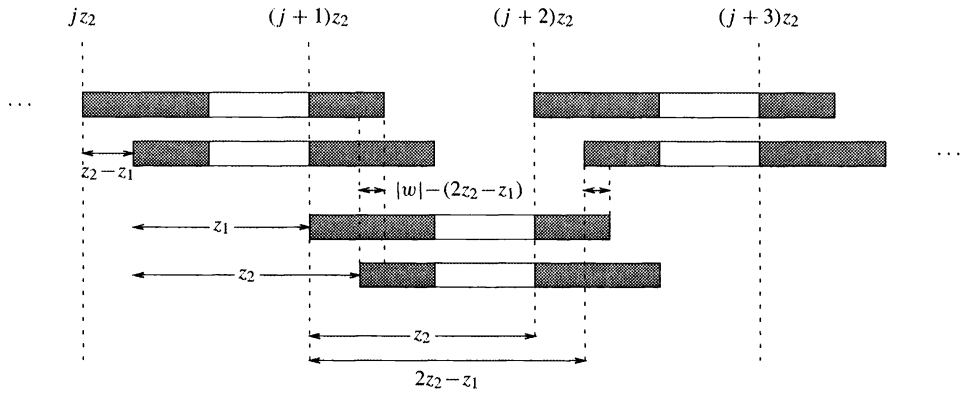

FIG. 2. *A configuration used to show that* $c(w) \geq 1 + \frac{1}{z_2}$.

Proof. The upper bound will follow from Theorem 7.1. The lower bound does not follow from Theorem 4.2 as the condition $2z_2 - z_1 \leq |w|$ is not satisfied. A specialized argument is needed in this case. The argument given here assumes that only pattern–text comparisons are allowed. It does not extend in a simple manner to the case in which both pattern–text and text–text comparisons are allowed.

The lower bound is obtained using the separating family for aba given after Definition 3.2. A complication arises, however, as texts in this family are not completely covered by occurrences of aba.

Assume that $n = 3r + 1$ for some $r \geq 1$. The adversary starts by putting a's in all text positions $3j$ for $0 \leq j < r$. It will set positions $3j + 1, 3j + 2$ to either ab or ba only after replying with a "no" to at least one query concerning these positions.

The adversary answers the queries of the algorithm in the following way. If the queried text position was already set by the adversary, the answer consistent with this setting is returned. If the query is "$t[3j + k] = \mathtt{a}$?" or "$t[3j + k] = \mathtt{b}$?" where $k = 1, 2$, and position $3j + k$ has not yet been set, the adversary responds with a "no". It then sets positions $3j + 1, 3j + 2$ to either ab or ba, whichever is consistent with its "no" answer.

All text positions of the form $3j + 1$ and $3j + 2$ will eventually be covered by occurrences of aba. The adversary therefore forces at least one "no" answer and two "yes" answers for each such pair. Positions of the form $3j$ are not necessarily covered by occurrences of aba. If, however, position $3j$ is not covered by such an occurrence, then positions $3j - 2, 3j - 1$ are set to ba and positions $3j + 1, 3j + 2$ are set to ab. An algorithm must still query position $3j$ at least once in such a case, to either verify or rule out an occurrence of aba starting at position $3j - 1$. This completes the proof. □

For a nonperiodic string w (i.e., a string with $z_1 = |w|$, $z_2 = \infty$), the above theorems give only the trivial lower bound, $c(w) \geq 1$. This bound is tight, however, as the many string matching algorithms (see, e.g., those of [Coll91],[GG91], and [CH92]) perform at most n comparisons when searching for a nonperiodic pattern in a text of length n.

As a corollary to Theorem 4.2 we get the following corollary.

COROLLARY 4.4. *For* $k, \ell \geq 2$ *we have* $c(\mathtt{a}^k\mathtt{ba}^\ell) \geq 1 + \frac{1}{\max\{k,\ell\}+2}$.

Proof. It is easy to check that the first and second periods of $w = \mathtt{a}^k\mathtt{ba}^\ell$ are $z_1 = \max\{k, \ell\} + 1$ and $z_2 = \max\{k, \ell\} + 2$ and that $2z_2 - z_1 = \max\{k, \ell\} + 3 \leq |w| = k + \ell + 1$. The claim follows immediately from Theorem 4.2. □

In §7 it will be shown that the bounds given in Corollary 4.4 are tight. They can even be matched using on-line algorithms. As a further corollary to Theorem 4.2 (or Corollary 4.4) we get the following corollary.

COROLLARY 4.5. *For every $m = 2k+1$, where $k \geq 2$, there exists a string $w_m (= \mathtt{a}^k\mathtt{b}\mathtt{a}^k)$ of length m such that any algorithm that finds all the occurrences of w_m in a text of length n must make at least $(1 + \frac{2}{m+3})n - O(1)$ comparisons in the worst case.*

We know (see the last paragraph of §2) that if z_1 and z_2 are the first and second periods of w then $z_1 + z_2 \geq |w| + 2$. As $z_2 \geq z_1 + 1$, we get that $z_2 \geq \lceil \frac{|w|+3}{2} \rceil$. Corollary 4.5 is therefore the strongest result of its kind implied by Theorem 4.2.

5. On-line lower bounds I. In this short section we show that the lower bound, $c(w) \geq 1 + \frac{1}{z_2}$, obtained for off-line algorithms only when $2z_2 - z_1 \leq |w|$, holds for on-line algorithms even if this condition does not hold.

THEOREM 5.1. *If w is a string and z_2 is its second period then $c_0(w) \geq 1 + \frac{1}{z_2}$.*

Proof. Suppose that an on-line algorithm has just found an occurrence of w in the text. The window will now be slid by at most z_1 positions to the right. Place two copies of w shifted by z_1 and z_2 positions below w, as shown in Fig. 3. Denote these copies by w' and w''. Since $z_2 - z_1$ is not a period of w, the two copies w' and w'' must disagree in at least one position after the end of the found occurrence of w. The adversary will extend the found occurrence of w by either w' or w'' in a way that will force the algorithm to get at least one "no" answer. If the algorithm makes a query whose answer is identical under both continuations, the adversary gives the algorithm this common answer. At some stage the algorithm has to make a query that distinguishes between the two incompatible continuations. No matter what this query is, the adversary answers it by "no". The adversary now chooses the continuation consistent with this "no" and answers all further questions accordingly, until the algorithm finds the chosen occurrence. By then the algorithm has either made at least $z_1 + 1$ queries and can slide the window by only z_1 positions, or has made at least $z_2 + 1$ queries and can slide the window by only z_2 positions. Note that to verify an occurrence of the pattern in the text, the algorithm must get at least one "yes" answer for each character of this occurrence. This process will be repeated again and again, forcing the algorithm to make at least $(1 + \frac{1}{z_2}) \cdot n - O(1)$ queries on a text of length n. □

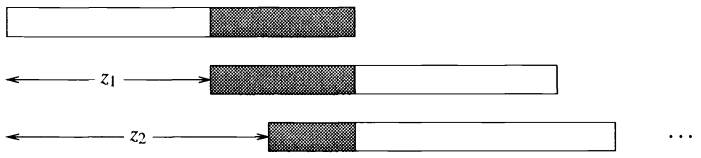

FIG. 3. *The configuration used to prove that $c_0(w) \geq 1 + \frac{1}{z_2}$.*

In the next section we obtain, using more complicated arguments, better lower bounds for on-line algorithms (see Corollaries 6.3 and 6.5).

6. On-line lower bounds II. In (the proof of) Theorem 5.1 it was shown that for every nonperiodic pattern the adversary can force any algorithm to make at least *one* mistake (i.e., get at least one "no" answer) for each occurrence of the pattern used in the tiling of the text. Now we show that for certain patterns the adversary can force any algorithm to make at least *two* mistakes for each such occurrence. The algorithm of Cole and Hariharan [CH92] makes at most two mistakes for each such occurrence, so no adversary can force all algorithms to make at least three mistakes for each occurrence of the tiling.

THEOREM 6.1. *Let w be a string of length m and let $z_1 < z_2 < \cdots < z_k$ be periods of w such that for every $1 \leq i < j \leq k$, $z_j - z_i$ is not a period of w.*

(i) *If none of the multisets $\{w[m + i - z_j] : 1 \leq j \leq k\}$ for $1 \leq i \leq z_1$ contains a character exactly $k - 1$ times, then $c_0^*(w) \geq 1 + \frac{2}{z_k}$.*

(ii) *If, in addition, none of the multisets* $\{(w[m+i_1-z_j], w[m+i_2-z_j]) : 1 \le j \le k\}$ *for* $1 \le i_1 < i_2 \le z_1$ *contains exactly* $k-1$ *equal pairs, then* $c_0(w) \ge 1 + \frac{2}{z_k}$.

Before proceeding with the proof of this theorem, we try to clarify the conditions appearing in it. Consider $k+1$ copies of w, positioned in an array of $k+1$ rows numbered $0, 1, \ldots, k$, and $m + z_k$ columns numbered $1, \ldots, m + z_k$, where the copy in the ith row is shifted z_i positions to the right with respect to the copy in the 0th row. Such arrays are depicted in Fig. 4(a) for the string $w_{10} = 1213451121$ with $z_1 = 7$, $z_2 = 9$, and $z_3 = 10$, and in Fig. 4(b) for the string $w_{12} = 121342531121$ with $z_1 = 9$, $z_2 = 11$, and $z_3 = 12$. A multiset $\{w[m+i-z_j] : 1 \le j \le k\}$ contains the k characters appearing in column $m+i$ of rows $1, \ldots, k$ in the array corresponding to w. The requirement in clause (i) above is that in each column that lies after the end of the copy of the 0th row, but at or before the end of all the other copies, no character appears in all but one of the rows. It is easy to check that in both cases depicted in Fig. 4 this condition is satisfied. Note that when $k = 3$ this condition requires that the three characters in such a column will either all be equal or all be distinct.

```
1213451121                  121342531121
      1213451121                  121342531121
        1213451121                  121342531121
         1213451121                  121342531121
```

(a) The set up $\langle w_{10}; 7, 9, 10\rangle$ (b) The set up $\langle w_{12}; 9, 11, 12\rangle$

FIG. 4. *Two simple setups in which Theorem* 6.1 *can be applied.*

To check the condition of clause (ii) above, one needs to look at pairs of such columns and compare the pair of characters appearing in each row. The number j of equal pairs is required to satisfy $j \ne k-1$. It is easily verified that this condition is satisfied in the array of $w_{10} = 1213451121$ but not in the array of $w_{12} = 121342531121$. Thus for w_{10} we obtain $c_0(w_{10}) \ge \frac{6}{5}$, while for w_{12} we can only infer $c_0^*(w_{12}) \ge \frac{7}{6}$.

Proof. The proof (of both statements) is a simple extension of the proof of Theorem 5.1. Suppose that an on-line algorithm has just found an occurrence of w in the text. The window can be slid at most z_1 positions to the right. Below w, place k copies of w shifted by $z_1, z_2, \ldots, z_k$ positions, respectively. (The reader may refer to Fig. 3 imagining that k instead of just two copies appear there.) Since none of $z_j - z_i$ is a period of w, each pair of copies must disagree in at least one position after the end of the found occurrence of w. The adversary will extend the found occurrence of w by one of the k copies in a way that will force the algorithm to get at least two "no" answers. If the algorithm asks a question whose answer under the above k continuations is the same, the adversary gives the algorithm this common answer. At some stage the algorithm has to make a query to which the answer is "yes" according to some of the continuations, and "no" according to the rest of them. The adversary will answer this query with a "no". Conditions (i) and (ii) imply that at least two continuations are consistent with this "no" answer. The adversary now gives the common answers to all queries that do not distinguish between the remaining continuations. At some stage the algorithm has to make another query to which both answers are possible. Again, the adversary answers this with a "no". At least one continuation is consistent with all the replies given by the adversary. The adversary chooses one of them and answers all subsequent queries accordingly, until the algorithm finds the next occurrence of w. By then the algorithm has made at least $z_i + 2$ queries, for some $1 \le i \le k$, and it can slide the window by only z_i positions. □

We will henceforth say that $\langle w; z_1, z_2, \ldots, z_k\rangle$ is a *setup* if w is a string, and $z_1 < z_2 < \cdots < z_k$ are periods of w, and none of $z_j - z_i$, for $i \neq j$, is a period of w. The string w_{10} is the shortest string for which a setup satisfying the conditions of Theorem 6.1 can be obtained. The string w_{12} is the shortest string for which a setup that satisfies condition (i), but not condition (ii), of Theorem 6.1 can be obtained. The two last statements were verified using a computer search.

We next show how to obtain from each setup satisfying the conditions of Theorem 6.1 an infinite sequence of such setups. This helps in the investigation of the asymptotic number of comparisons required as the length of the pattern strings tends to infinity. The infinite sequence is obtained by *padding* the basic setup.

Let u and v be strings. $\mathrm{pad}(u, v)$ denotes the string obtained by placing a copy of v before and after each character of u. Thus $\mathrm{pad}(121, 00) = 00100200100$ and in general $|\mathrm{pad}(u, v)| = (|u| + 1)(|v| + 1) - 1$.

THEOREM 6.2. *If $\langle w; z_1, \ldots, z_k\rangle$ is a setup satisfying the conditions of Theorem* 6.1 *and if $w_\ell = \mathrm{pad}(w, 0^\ell)$, then*

$$c_0(w_\ell) \geq 1 + \frac{2(|w|+1)}{z_k} \cdot \frac{1}{|w_\ell|+1} \quad .$$

Proof. If the setup $\langle w; z_1, \ldots, z_k\rangle$ satisfies the conditions of Theorem 6.1 then so does the setup $\langle w_\ell; (\ell+1)z_1, \ldots, (\ell+1)z_k\rangle$. To see this, note at first that $(\ell+1)z_i$ for $1 \leq i \leq k$ is indeed a period of $w_\ell = \mathrm{pad}(w, 0^\ell)$ and that none of $(\ell+1)(z_j - z_i)$ for $i \neq j$ is such a period. To verify the first condition of Theorem 6.1, note that every column in the setup $\langle w_\ell; (\ell+1)z_1, \ldots, (\ell+1)z_k\rangle$ is either a column of the setup $\langle w; z_1, \ldots, z_k\rangle$ or an all-zero column. The second condition is verified in a similar way. The statement of the theorem then follows from Theorem 6.1, applied to $\langle w_\ell; (\ell+1)z_1, \ldots, (\ell+1)z_k\rangle$, and from the fact that $1 + \frac{2}{(\ell+1)z_k} = 1 + \frac{2(|w|+1)}{z_k} \cdot \frac{1}{|w_\ell|+1}$. □

Theorem 6.2 motivates the search for setups $\langle w; z_1, \ldots, z_k\rangle$ satisfying the conditions of Theorem 6.1 for which $2(|w| + 1)/z_k$ is as high as possible. The best such setup that we have found with $k = 3$ is the following $\langle w_{35}; 25, 30, 32\rangle$:

```
12121121213412156781479121212112121
                        12121121213412156781479121212112121
                            12121121213412156781479121212112121
                              12121121213412156781479121212112121
```

For this setup, $2(|w| + 1)/z_k = \frac{9}{4}$. As a corollary to Theorem 6.2 we obtain the next corollary.

COROLLARY 6.3. *For every $m = 36k + 35$, where $k \geq 0$, there exists a string w_m of length m such that any on-line algorithm that finds all the occurrences of w_m in a text of length n must make at least $(1 + \frac{9}{4(m+1)})n - O(1)$ comparisons in the worst case.*

Using a computer enumeration we have verified that no better setup with $k = 3$ is possible with a pattern of length at most 250. However, better setups that satisfy the first condition of Theorem 6.1 can be obtained by using four instead of three overlaps.

Let

$$u_k = \left(\left((12)^k\,1\right)^2 3^3\right)^2 12 \left((12)^k\,1\right)^2 3^3 \left((12)^k\,1\right)^2 \quad .$$

The following lemma is easily verified.

LEMMA 6.4. *The setups $\langle u_k; 8k + 12, 12k + 17, 14k + 18, 14k + 20\rangle$ for $k \geq 1$ satisfy the first condition of Theorem* 6.1.

The setup $\langle u_1; 20, 29, 32, 34\rangle$ for example is

```
12112133312112133312121121333121121
                  12112133312112133312121121333121121
                          12112133312112133312121121333121121
                             12112133312112133312121121333121121
                               12112133312112133312121121333121121
```

As $|u_k| = 16k + 19$, we get as a corollary the following.

COROLLARY 6.5. *For every $m = 16k+19$, where $k \geq 1$, there exists a string $w_m (= u_k)$ of length m such that any on-line algorithm that uses only pattern–text comparisons to find all the occurrences of w_m in a text of length n must make at least $(1 + \frac{16}{7m+27})n - O(1)$ comparisons in the worst case.*

Corollary 6.5 is asymptotically better than Corollary 6.3 and it is the best on-line bound we have obtained. We have verified using a computer search that no better setup with four or five overlaps can be obtained using strings of length at most 250.

We believe that if $\langle w; z_1, \ldots, z_k \rangle$ is a setup satisfying the conditions of Theorem 6.1 then $|z_k| \geq \frac{7}{8}|w|$. If this is true, then the result of Corollary 6.5 is essentially the best that can be obtained using our methods.

7. On-line upper bounds. The next theorem exhibits an interesting family of strings for which Theorem 5.1 is tight.

THEOREM 7.1. *For every $k, \ell \geq 1$ we have $c_0(\mathtt{a}^k\mathtt{b}\mathtt{a}^\ell) = c_0^*(\mathtt{a}^k\mathtt{b}\mathtt{a}^\ell) = 1 + \frac{1}{\max\{k,\ell\}+2}$.*

Proof. The lower bound is a corollary of Theorem 5.1. A matching upper bound is fairly straightforward for the case $k \leq \ell$, but needs more care when $k > \ell$. We will describe an algorithm that works in both cases.

Algorithm for $\mathtt{a}^k\mathtt{b}\mathtt{a}^\ell$. The algorithm is described as a sequence of steps, in each of which a text character is compared to the aligned pattern character. In the case of a mismatch or if an occurrence of the pattern has been verified, the window is shifted along to the next position at which a pattern occurrence is possible. We represent the state of the algorithm before each step by an *information string* uxv, where $u \in \{0, \mathtt{a}\}^k$, $v \in \{0, \mathtt{a}\}^\ell$, and $x \in \{0, \mathtt{A}, \mathtt{b}\}$, describing (part of) the current knowledge the algorithm has about the text characters in the window. A "0" in the information string indicates that no information is available on the corresponding position. An "a" (or a "b") indicates that the character in that position is known to be an a (or a b). An "A" (or a "B") indicates that the character in the corresponding position is known *not* to be an a (or a b). The state can be written in the specified form because, after any necessary window shift, the information string must be consistent with the pattern. Our algorithm makes only "a?" and "b?" queries, and we *choose to forget* any negative information represented by "B". We shall call the $(k + 1)$-st position in the window the b-*position* and all the others a-*positions*. An a-position is always queried for an a. A b-position is always queried for a b.

In terms of the information strings, the algorithm is simply described.

```
IF there is some 0 in the information string
    THEN query the rightmost 0
    ELSE {x = A} query the b-position .
```

This procedure is repeated until the text string is exhausted. To prove the upper bound we first establish the following pair of invariants.

Invariants. (i) If $x = \mathtt{b}$ then $v = \mathtt{a}^\ell$.

(ii) If $x = 0$ then u does not contain the subword $\mathtt{a}^{\ell+1}$.

Invariant (i) holds because x can only become b after an information string of the form $u0\mathtt{a}^\ell$, and following any shift we again have $x \neq \mathtt{b}$.

For Invariant (ii), while $x = 0$ no tests in u are made, and the only a's shifted into u come from v. These are separated from the previous contents of u by the "x" of the previous information string.

Nearly all comparisons can be associated with text positions in the following way. Any query made at an a-position is associated with the corresponding text position. When $x = 0$ and the b-position is queried, a b result is associated with that text position. If the result is B then care is needed since, if $\ell < k$, this result will be represented as a 0 in u. However, in this case a shift of size $\ell + 1$ will be made and, by Invariant (ii), at least one 0 will be shifted out from the information string. The query is associated with the text character corresponding to any one such 0. The remaining case is when $x = \mathtt{A}$ and the b-position is queried. Such a query is not associated with any text position. We note that after such a query a shift of $1 + \max\{k, \ell\}$ is always made, and that the resulting information string will have $x = 0$. Since a window shift is made in any step which changes $x = 0$ to $x = \mathtt{A}$, clearly a cumulative shift of at least $2 + \max\{k, \ell\}$ positions must occur between any two such "extra" queries. The upper bound follows. □

As a corollary we get that Theorem 5.1 is also tight for all members of the $\mathtt{a}^k\mathtt{ba}^\ell$ family to which it can be applied.

COROLLARY 7.2. *For $k, \ell \geq 2$ we have* $c(\mathtt{a}^k\mathtt{ba}^\ell) = c_0^*(\mathtt{a}^k\mathtt{ba}^\ell) = 1 + \frac{1}{\max\{k,\ell\}+2}$.

8. Look-ahead is useful. In this section we present a string matching algorithm, specifically tailored for the string abaa. The algorithm uses a window of size eight and its performance matches the general lower bound obtained for abaa using Theorem 4.1. Thus, $\frac{8}{7} = c(\mathtt{abaa}) = c_4(\mathtt{abaa}) < c_0(\mathtt{abaa}) = \frac{5}{4}$ and abaa is therefore a string for which look-ahead is useful.

The abaa algorithm presented here sheds some light on the intricacy of optimal string matching algorithms. The description of it is quite complicated. Optimal algorithms for longer strings may have even more complicated descriptions.

Algorithm for the string abaa**.** The algorithm requires a window of size 8. A state of the algorithm is given as an information string $\sigma \in \cup_{k=1}^{8}\{0, \mathtt{a}, \mathtt{A}, \mathtt{b}, \mathtt{B}\}^k$, where σ represents information known about the text symbols in (a prefix of) the window. To describe the algorithm, we specify for each state the next query to be made, the amount of shift, and the next state corresponding to the two possible answers. We represent a? queries and b? queries by a single or double underline, respectively, under the appropriate symbol of the information string. For example, in state P in Table 1, an a? query is made at the fourth position in the window.

TABLE 1
The main transition table of the abaa *algorithm.*

state	inf. & query	transitions			
		match		mismatch	
		state	shift	state	shift
P	a00$\underline{0}$	R	0	Q	2
Q	$\underline{0}$A	T	0	U	2
R	a00a00$\underline{0}$	S	0	$Q \oplus F$	5
S	a00a00a$\underline{0}$	$P \oplus H$	7	$T \oplus G$	6
T	aA0$\underline{0}$	$P \oplus D$	3	Q	2
U	$\underline{0}$	P	0	U	1

For certain information strings, the task of finding all pattern occurrences decomposes into two logically disjoint tasks, checking occurrences in some finite prefix and checking in the remainder. Such a state is represented in the tables by a pair of states with the connective $\oplus$. For example, in state R of Table 1, if the seventh symbol is found not to be an a then it is sufficient to check separately for occurrences within the first five positions (state F) and in the text string beginning at the sixth position (state Q).

Table 2 shows, for each finite subproblem which arises in this way, the next query to be made and the number of queries required in the worst case to resolve that subproblem. The latter is computed recursively by following the transitions in Table 2. A "$\surd$" in Table 2 indicates that a full occurrence of the pattern has been found and the treatment of the current subproblem is finished. A "—" indicates that the treatment of the current subproblem has ended without finding such an occurrence.

TABLE 2
The secondary transition table of the abaa *algorithm.*

		new state		
state	inf. & query	match	mismatch	worst-case cost
A	a$\underline{0}$aa	$\surd$	—	1
B	ab$\underline{0}$a	$\surd$	—	1
C	a0a$\underline{0}$	A	—	2
D	a0$\underline{0}$a	A	—	2
E	a$\underline{0}$0aa	A	D	3
F	a$\underline{0}$0a0	C	D	3
G	a00a$\underline{0}$0a	$D \oplus B$	F	4
H	a00a$\underline{0}$0aa	$E \oplus A$	$D \oplus D$	5

In Table 1, the main part of the algorithm is presented. The graph showing the transitions between states of Table 1 is given in Fig. 5. The corresponding number of comparisons to make the transition and finish any consequent subproblem and the resulting shift are shown on each arrow. It can be verified that the worst case corresponds to iterating the cycle PRS, and this proves that $c_4(\texttt{abaa}) \leq \frac{8}{7}$.

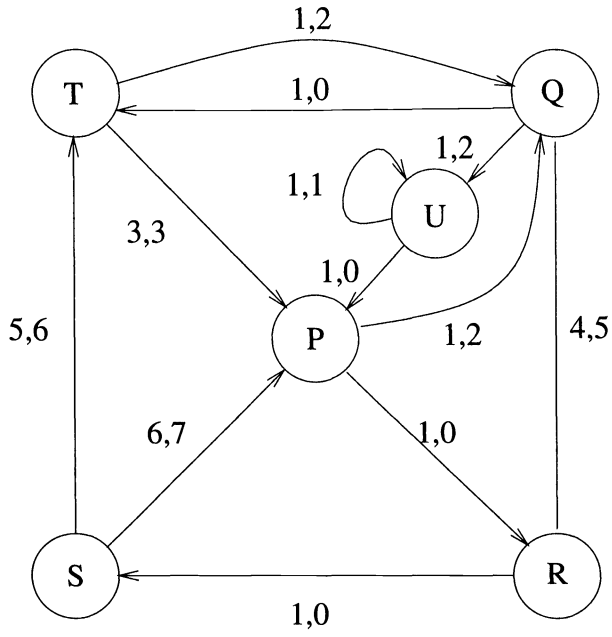

FIG. 5. *The transition diagram of the* abaa *algorithm.*

9. Concluding remarks. What is the hardest string to find? The perhaps disappointing answer is aba (or mum and dad and so on). We know that $c_0^*(\texttt{aba}) = \frac{4}{3}$ and that $c_0^*(w) \leq \frac{4}{3}$

for any string w [GG92]. We believe that $c_0^*(w) < \frac{4}{3}$ whenever $|w| \geq 4$ but this is not established yet (except for $|w| \geq 8$ [CH92]). This would imply that aba and its like are strictly the hardest strings to find. It is interesting to note that while we have shown here that $c^*(\texttt{aba}) = c_0^*(\texttt{aba}) = c_0(\texttt{aba}) = \frac{4}{3}$, the exact value of $c(\texttt{aba})$ is not known yet. We only know that $\frac{6}{5} \leq c(\texttt{aba}) \leq \frac{4}{3}$.

The task of computing the exact value of $c_0^*(w)$ or any of the other three variants, for every given pattern w, seems at present to be very hard. The constants $c_0^*(w)$, $c_0(w)$ can in principle be computed algorithmically since an on-line algorithm can have only a finite number of states representing the current information and only a finite number of possible next queries. Among optimal on-line algorithms for each w, there are some in which the next query depends only on the information state, and there is only a finite though huge number of different algorithms of this kind for every w. The task of finding $c(w)$ and $c^*(w)$ may be even harder. We do not know at present whether $c(w)$ and $c^*(w)$ are always rational, although it would be very odd if they were not.

A small gap still remains between our lower bounds and the upper bounds of Cole and Hariharan [CH92]. While closing this gap will have no practical value, we think that it may reveal many interesting properties of strings and string matching algorithms.

Acknowledgment. The authors thank an anonymous referee for suggestions which improved the paper.

Note added in proof. Shlomit Tassa and the last two authors have recently shown that $c(\texttt{aba}) \leq \frac{5}{4}$, thus proving that text–text comparisons can help.

PLANAR STRONG CONNECTIVITY HELPS IN PARALLEL DEPTH-FIRST SEARCH*

MING-YANG KAO†

Abstract. This paper proves that for a strongly connected planar directed graph of size n, a depth-first search tree rooted at a specified vertex can be computed in $O(\log^5 n)$ time with $n/\log n$ processors. Previously, for planar directed graphs that may not be strongly connected, the best depth-first search algorithm runs in $O(\log^{10} n)$ time with n processors. Both algorithms run on a parallel random access machine that allows concurrent reads and concurrent writes in its shared memory, and in case of a write conflict, permits an arbitrary processor to succeed.

Key words. linear-processor NC algorithms, graph separators, depth-first search, planar directed graphs, strong connectivity, bubble graphs, s-t graphs

AMS subject classifications. 68Q10, 05C99

1. Introduction.

Depth-first search is one of the most useful tools in graph theory [4], [34]. The *depth-first search problem* is the following: Given a graph and a distinguished vertex, construct a tree that corresponds to performing depth-first search in the graph starting from the given vertex.

The parallelization of depth-first search has been studied by numerous authors. Reif showed that lexicographic depth-first search is P-complete even for general undirected graphs [30]. For unordered depth-first search, Smith gave the first NC algorithm for planar undirected graphs [32]. The processor complexity of his algorithm was reduced to linear by He and Yesha [15]. Independently, Ja'Ja and Kosaraju [16] and Shannon [31] also achieved the same result. Aggarwal and Anderson gave a randomized NC algorithm for general undirected graphs [2]. The author studied the problem for directed graphs, and found an NC algorithm with n^4 processors for a planar directed graph of size n [17]. This was followed by the randomized NC algorithm of Aggarwal, Anderson, and Kao for general directed graphs [3].

Recently, Kao and Klein gave an algorithm that computes depth-first search trees in $O(\log^{10} n)$ time with n processors for planar directed graphs that may not be strongly connected [19].

This paper shows that for a strongly connected planar directed graph of size n, a depth-first search tree rooted a specified vertex can be computed in $O(\log^5 n)$ time with $n/\log n$ processors. This algorithm runs on a parallel random access machine that allows concurrent reads and concurrent writes in its shared memory, and in case of a write conflict, permits an arbitrary processor to succeed.

Both the algorithm of this paper and that of the author and Klein use directed graph separators defined by the author [17], and follow the framework of the randomized NC algorithm for general directed graphs [3]. The algorithm in this paper achieves a superior complexity by exploiting topological properties of strongly connected planar directed graphs. The strongly connected components of key subgraphs created in the course of the algorithm have very regular structures. A major task of the algorithm is to recursively maintain and utilize these structures.

This paper is organized as follows. Section 2 reviews basic definitions and relevant facts about planar directed graphs. Section 3 reports new results on computing strongly connected

components. Section 4 discusses directed graph separators; a more detailed discussion about separators is given in the Appendix. Section 5 details this paper's depth-first search algorithm for strongly connected planar directed graphs.

2. Basics of planar directed graphs. A *planar* directed graph is one that can be embedded on a plane such that the edges intersect only at common end vertices or start vertices [6], [7], [14], [35]. A *plane digraph* is a planar directed graph with a given planar embedding.

For subtle technical reasons, a planar graph in this paper may have multiple edges but does not have loop edges.

2.1. Strong graphs. For brevity, a strongly connected component of a directed graph is simply called a *strong component.* Similarly, a strongly connected plane digraph with at least one vertex is simply called a *strong graph.*

The goal of this paper is to efficiently compute a depth-first search spanning tree of a strong graph rooted at a specified vertex.

2.2. Faces, boundaries, and orientations. Let G be a connected plane digraph. If the vertices and edges of G are deleted from its embedding plane, then the plane is divided into disconnected regions. Exactly one of the regions is infinite; all others are finite. Each region is called a *face* of G. The infinite region is the *external* face; the finite regions are the *internal* faces.

Let f be a face of G. The *boundary* of f, denoted by $\mathcal{B}(f)$, is the set of edges and vertices surrounding f. If G contains at least two vertices, by its connectivity, $\mathcal{B}(f)$ can be arranged into a unique undirected cycle by having an observer stay inside f and walk around $\mathcal{B}(f)$ once. This cycle is called the *boundary* cycle of f. It may not be edge-simple.

Let e be a boundary edge of f. The *orientation* of e with respect to f is defined as follows:

- Case (1): f is the external face. The edge e is *positive* (respectively, *negative*) with respect to f if it points in the counterclockwise (respectively, clockwise) direction on the boundary cycle of f.
- Case (2): f is an internal face. The edge e is *positive* (respectively, *negative*) with respect to f if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of f.

2.3. Holes, boundaries, and orientations. Let G be a connected plane digraph. Let H be a connected subgraph of G. If the vertices and edges of H are removed from the embedding plane of G, then the plane is divided into disconnected regions. Exactly one of the regions is infinite; the others are all finite. Each region is called a *hole* of H. The infinite region is the *external* hole; the finite regions are the *internal* holes.

Let X be a hole of H. The *boundary* of X, denoted by $\mathcal{B}(X)$, is the set of vertices and edges surrounding X. If H contains at least two vertices, by its connectivity, $\mathcal{B}(X)$ can be arranged into a unique undirected cycle by having an observer stay inside X and walk around $\mathcal{B}(X)$ exactly once. This cycle is called the *boundary* cycle of X. It may not be edge-simple.

Let e be a boundary edge of X. The *orientation* of e with respect to X is defined as follows:

- Case (1): X is the external hole of H. The edge e is *positive* (respectively, *negative*) with respect to X if it points in the counterclockwise (respectively, clockwise) direction on the boundary cycle of X.
- Case (2): X is an internal hole of H. The edge e is *positive* (respectively, *negative*) with respect to X if it points in the clockwise (respectively, counterclockwise) direction on the boundary cycle of X.

2.4. Combinatorial embeddings and data structures. Let G be a connected planar directed graph. Algorithmically, a planar embedding of G is encoded by the boundary of its external face and the clockwise cyclic order of the edges incident with each vertex. Such an encoding is called a *combinatorial* planar embedding of G. Topologically, a planar embedding is uniquely specified by its corresponding combinatorial embedding.

The cyclic edge incidence in a combinatorial embedding is further encoded by the following data structure: For each vertex, there is a doubly linked circular list consisting of the edges incident with that vertex in the clockwise order. These lists can be used to efficiently trace the boundary cycles of the faces of G. They can also be used to trace the boundary cycles of the holes of a connected subgraph.

Given a connected planar directed graph of size n, a combinatorial planar embedding can be computed in $O(\log n)$ time with $n \log\log n / \log n$ processors on a deterministic Arbitrary-CRCW PRAM [29].

2.5. Planar embeddings induced by vertex contraction. In this paper, vertex contraction contracts only connected vertex subsets of a connected plane digraph. This ensures that planarity is preserved.

For technical reasons, all multiple edges created by vertex contraction are kept while all loop edges are deleted.

Let G be a connected plane digraph. Let H be the subgraph induced by a connected vertex subset of G. Let G' be the graph constructed from G by contracting H into a vertex H'. If H consists of at most one vertex, then G' and G are the same. Otherwise a planar embedding for G' is specified as follows:

- For every vertex $u \notin H$, the clockwise cyclic order of the edges incident with u is the same in G and G'.
- The edges around each nonempty hole X of H stay together around H', and their clockwise cyclic order around H' is the same as their cyclic order around the boundary cycle of X in the negative direction of X.
- All uncontracted edges on the boundary of the external face of G remain on that of G', and have the same orientations with respect to both external faces.
- If H contains a boundary vertex of the external face of G, then H' is on the boundary of the external face of G'.

In general such a planar embedding is not unique. Any planar embedding that fits this construction is suitable for the purposes of this paper.

LEMMA 2.1. *Given a connected plane digraph of size n, a planar embedding induced by contracting a disjoint family of connected vertex subsets can be computed in* $O(\log n)$ *time with* $n/\log n$ *processors.*

Remark. If vertex contraction is required to delete all multiple edges that it creates, then computing an induced embedding may take more than linear space to achieve $O(\log n)$ time on $n/\log n$ processors.

Proof. The edges around a new vertex of G' are collected by processing the doubly linked circular lists of the combinatorial embedding of G. The computation takes $O(\log n)$ time and $n/\log n$ processors, using optimal parallel algorithms for list ranking [5], [9], [13], prefix computation [23], [24], tree contraction [1], [8], [11], [10], [22], [27], [28], and planar connectivity [12]. □

3. New results for computing strong components. This section first reviews previous results on computing strong components and directed spanning trees, and then reports new results on how to compute the strong components of a graph that is obtained by deleting or contracting a subgraph.

3.1. Directed spanning trees.

THEOREM 3.1 [20]. *For a strong graph of size n, a directed spanning tree rooted at a specified vertex can be computed in $O(\log^2 n)$ time with $n/\log n$ processors on a deterministic* Arbitrary-CRCW PRAM.

3.2. Compactness and strong components. Let H_1 and H_2 be nonempty connected subgraphs of a connected plane digraph. H_1 *encloses* H_2 if H_2 is in an internal hole of H_1.

A *compact* strong component of a connected plane digraph is one that encloses no strong component. For a plane digraph that may not be connected, a strong component is *compact* if it is compact in the connected component that contains it.

THEOREM 3.2 [18]. *For a plane digraph of size n with α noncompact strong components, the strong components can be computed in $O(\lceil \log_2(\alpha+2) \rceil \cdot \log^2 n)$ time with $n/\log n$ processors on a deterministic* Arbitrary-CRCW PRAM.

3.3. Deleting a vertex subset from a strong graph. Let G be a directed graph. Let H be a subgraph or vertex subset of G. Let $G - H$ denote the graph obtained by removing from G the vertices in H and their incident edges.

THEOREM 3.3. *Assume that G is a strong graph of size n and H is a subgraph with γ connected components. Given $G - H$, the strong components of $G - H$ can be computed in $O(\lceil \log_2(\gamma+2) \rceil \cdot \log^2 n)$ time with $n/\log n$ processors.*

Proof. The noncompact strong components of $G - H$ can be counted using the three facts below. Let W be a noncompact strong component of $G - H$.

- By G's planarity and strong connectivity, at least one connected component of H is enclosed by W in G.
- By G's planarity, if some connected component of H is enclosed in G by both W and a distinct strong component W' of $G - H$, then one of W and W' encloses the other in G.
- By G's strong connectivity and planarity, some connected component H' of H is enclosed by W in G but not by any strong component of $G - H$ that is itself enclosed by W in G.

The mapping from W to H' is a one-to-one mapping from the noncompact strong components of $G - H$ to the connected components of H. Thus, $G - H$ has at most γ noncompact strong components, and this theorem follows from Theorem 3.2. □

3.4. Deleting an edge subset from a strong graph. Let G be a strong graph. Let U be a vertex subset of G. Let D be a subset of the edges in G incident with U. Let G' be the graph obtained by deleting from G the edges in D.

Let W be a connected subgraph of G. A vertex of G is *absorbed* by W in G if it either is a vertex in W or is enclosed by W in G.

THEOREM 3.4. *Let n be the size of G. Let ω be the number of vertices in U. Given G', the strong components of G' can be computed in $O(\lceil \log_2(2\omega+2) \rceil \cdot \log^2 n)$ with $n/\log n$ processors.*

Proof. The noncompact strong components of G' can be counted using the three facts below. Let W be a noncompact strong component of G'.

- By G's planarity and strong connectivity, some vertex in U is absorbed by W in G.
- By G's planarity, if some vertex in U is absorbed by both W and another strong component W' of G', then one of W and W' encloses the other in G.
- By G's strong connectivity and planarity, some $u \in U$ is absorbed by W in G but not by any strong component of G' that is itself enclosed by W in G, possibly except a unique component W'' that contains u as a boundary vertex of its external face.

The mapping from W to u maps at most two noncompact strong components, namely W and W'', of G' to u. Thus, G' has at most 2ω noncompact strong components, and this theorem follows from Theorem 3.2. □

3.5. Contracting connected vertex subsets in an acyclic graph. Let G be an acyclic connected plane digraph. Let H be a subgraph of G. Let G' be the graph obtained from G by contracting each connected component of H into a vertex.

THEOREM 3.5. *Assume that G is of size n and H has γ connected components. Given G', the strong components of G' can be computed in $O(\lceil \log_2(\gamma+2) \rceil \cdot \log^2 n)$ time with $n/\log n$ processors.*

Proof. Since a noncompact strong component has at least two vertices, by the acyclicity of G each noncompact strong component of G' contains at least one contracted connected component of H. Because two distinct strong components of G cannot contain the same contracted connected component of H, G' has at most γ noncompact strong components. This theorem then follows from Theorem 3.2. □

4. Directed graph separators. Intuitively, a *separator* of a graph is a subgraph whose removal disconnects the graph into small pieces [25], [26].

4.1. Cycle separators and k-path separators. Most of the works on parallel depth-first search rely on finding some form of graph separator. The algorithms for planar undirected graphs employ undirected cycle separators [15], [16], [32]. The algorithm for general undirected graphs uses path separators [2].

The notion of a directed graph separator was originally introduced for depth-first search in planar directed graphs [17]. It was then used for general directed graphs [3]. Here it is tailored for a strongly connected directed graph G:

- A vertex subset or subgraph is *heavy* (respectively, *light*) for G if it has more than (respectively, at most) two thirds of the vertices in G.
- A *separator* of G is a set S of vertices such that no strong component in $G - S$ is heavy for G.
- A *cycle* separator is a vertex-simple directed cycle whose vertices form a separator. A single vertex is considered a cycle of length zero. Thus, if the removal of a vertex separates a graph, the vertex is a cycle separator.
- For a positive integer k, a *k-path* separator is a set of k vertex-disjoint vertex-simple directed paths whose vertices form a separator. A 1-path separator is simply called a *path* separator.

The author showed that every directed graph has a directed path separator and a directed cycle separator [17]. These results are included in the Appendix. For a graph of size n, the proofs of these results yield a sequential algorithm that computes a path separator in optimal $O(n)$ time, and an algorithm that computes a cycle separator in $O(n \log n)$ time.

Aggarwal, Anderson, and Kao improved to $O(n)$ the sequential time for computing a directed cycle separator [3]. They also showed that computing cycle separators and computing depth-first search trees are NC-equivalent.

4.2. Computing cycle separators for strong graphs.

LEMMA 4.1. *Given a strong graph of size n, a two-path separator can be computed in $O(\log^2 n)$ time with $n/\log n$ processors.*

Proof. Let T be a directed spanning tree of the given graph. By the work of Lipton and Tarjan [25], there exist two vertices x and y such that the two tree paths of T from the root to x and from the root to y form a separator. A two-path separator is easily obtained from these tree paths. By Theorem 3.1, T can be computed in $O(\log n)$ time with $n/\log n$ processors. Then x and y can be found in $O(\log n)$ time with $n/\log n$ processors [21]. □

LEMMA 4.2. *Given a strong graph of size n, a path separator can be computed in* $O(\log^3 n)$ *time with* $n/\log n$ *processors.*

Proof. Let G be the given graph. First, use Lemma 4.1 to obtain a two-path separator for G, and then use the procedure MergeTwoPaths in Fig. 1 to compute a path separator. To combine P and Q, MergeTwoPaths first deletes the maximum subpath from the u_p-end of P while maintaining the separator property of P and Q. It then similarly processes Q so that the joining path R exists. The proof for the correctness of MergeTwoPaths is similar to that of Theorem A.2 in §A.3.

Procedure MergeTwoPaths
Input: a strong graph G, and a two-path separator $P = u_1, \ldots, u_p$ and $Q = v_1, \ldots, v_q$.
Output: a path separator S of G.
begin
1. Let s be the largest index such that some strong component Z_s of $G - (\{u_1, \ldots, u_{s-1}\} \cup Q)$ is heavy for G.
   (*Remark.* $u_s \in Z_s$.)
2. **if** s does not exist **then return** $S = Q$.
3. Let P' be the path $u_1, \ldots, u_s$.
   (*Remark.* P' and Q form a two-path separator.)
4. Let t be the smallest index such that some strong component Z_t of $G - (P' \cup \{v_{t+1}, \ldots, v_q\})$ is heavy for G.
   (*Remark.* $v_t \in Z_t$.)
5. **if** t does not exist **then return** $S = P'$.
6. Let Q' be the path $v_t, \ldots, v_q$.
   (*Remark.* P' and Q' form a two-path separator.)
7. Compute a directed path R in $Z_s \cup Z_t$ from u_s to v_t.
   (*Remark.* $Z_s \cup Z_t$ is strongly connected.)
8. Let S be the directed path formed by P', R, Q'.
   (*Remark.* S is vertex-simple.)
9. **return** S.

end.

FIG. 1. *A procedure for merging a two-path separator into a path separator.*

As for the complexity, it suffices to show that MergeTwoPaths runs in $O(\log^3 n)$ time with $n/\log n$ processors. Z_s, Z_t, s, and t are computed by binary search and Theorem 3.3 in $O(\log^3 n)$ time with $n/\log n$ processors. R is obtained by computing a divergent directed spanning tree rooted at u_s in the subgraph induced by $Z_s \cup Z_t$. This uses Theorem 3.1 and takes $O(\log^2 n)$ time with $n/\log n$ processors. Thus, the complexity of MergeTwoPaths is as stated. □

THEOREM 4.3. *Given a strong graph of size n, a cycle separator can be computed in* $O(\log^3 n)$ *time with* $n/\log n$ *processors.*

Proof. The proof is similar to those of Lemma 4.2 and Theorem A.2. □

5. Parallel depth-first search. Section 5.1 gives an overview of this paper's algorithm for performing depth-first search in a strong graph. Sections 5.2–5.6 discuss key techniques used in the algorithm. Section 5.8 details the algorithm.

5.1. An overview. Let G be a strong graph. Let r be a vertex in G. The goal is to construct a depth-first search spanning tree rooted at r for G. Such a tree will be recursively constructed using cycle separators.

First, compute a cycle separator of G. Then compute a path separator starting from r by finding a directed path from r to the cycle separator. This path and the cycle separator form a path separator S after an appropriate edge on the cycle separator is removed. S will be a branch of the final depth-first search tree.

Let $G' = G - S$, i.e., the remaining graph that is not searched by S. Suppose that the search is continued in G' starting from a vertex r' that is the end vertex of an edge pointing from the last vertex of S. This time the search recurses on the subgraph $B_{r'}$ that consists of all the vertices reachable from r' via directed paths in G'. The graph $B_{r'}$ is called a *dangling* subgraph. (See §5.5.)

Because S is a separator of G, the strong components of G' are all light for G. However, $B_{r'}$ may contain several such strong components. Consequently, $B_{r'}$ may still be too large for small depth recursion. To avoid this problem, a set of directed paths is removed from G such that the remaining directed graph has small dangling subgraphs. These removed paths will form a subtree, called a *partial* depth-first search tree, in the final depth-first search tree. (See §5.5.)

A dangling subgraph of a strong graph is a special kind of a graph called a *bubble* graph. The structures of a bubble graph can be exploited to efficiently process the dangling subgraphs. (See §5.2.)

A strong graph is in fact a special case of a bubble graph. The depth-first search algorithm in this paper actually takes a bubble graph as input, and computes a depth-first search tree by recursing on bubble subgraphs. (See §5.7.)

5.2. Bubble graphs. A strong component of a directed graph is a *sink* component if it has no outgoing edges to any other strong component.

Let B be a plane digraph. B is called a *bubble* graph rooted at a vertex r if the following conditions hold:

- Every vertex in B can be reached from r via directed paths.
- The vertex r is a boundary vertex of the external face of B, and every sink component of B contains at least one boundary vertex of the external face.

For example, since a strong graph is the only strong component of itself, it is trivially a bubble graph rooted at any boundary vertex of its external face.

From this point onwards, it is assumed that a bubble graph has a specified root. For brevity, that root will not be explicitly mentioned unless there is a risk of ambiguity.

LEMMA 5.1. *Let B be a bubble graph rooted at r. Let n be the size of B.*

1. *The strong components of B can be computed in $O(\log^2 n)$ time with $n/\log n$ processors.*
2. *A directed spanning tree of B rooted at r can be computed in $O(\log^2 n)$ time with $n/\log n$ processors.*

Proof. Statement 1 follows from Theorem 3.2 and the fact that a bubble graph has no noncompact strong components. To prove Statement 2, let B' be the strong graph obtained from B by adding a directed edge from each sink component of B to r via the external face of B. Note that a directed spanning tree of B' rooted at r is also one for B. The graph B' and a desired tree in B' can be computed by means of Statement 1 and Theorem 3.2, respectively, both within the desired complexity. □

5.3. Heavy bubble graphs and splitting components. For a directed graph G and a vertex subset (a vertex or a subgraph) H of G, let $\mathcal{R}(H, G)$ denote the set of vertices that H

can reach via directed paths in G. For all strong components W_1 and W_2 of G, W_2 is called a *descendant component* of W_1 if $W_1 \neq W_2$ and W_1 can reach W_2 via directed paths.

Let k be a positive integer. A bubble graph is called *k-heavy* (respectively, *k-light*) if it has more than (respectively, at most) k vertices. A strong component W of a k-heavy bubble graph B is a *k-splitting* component of B if $|\mathcal{R}(W, B)| > k$ and no descendant component of W satisfies this inequality.

The depth-first search algorithm of this paper will find a cycle separator of a k-splitting component of B, and then use the separator to break B into bubble subgraphs with smaller k-splitting components.

5.4. Computing a splitting component via *s-t* graphs. An acyclic plane digraph is called an *s-t* graph if it has a unique source and a unique sink, and they are on the boundary of its external face.

THEOREM 5.2. *Given a k-heavy bubble graph of size n, a k-splitting component can be computed in $O(\log^2 n)$ time with $n/\log n$ processors.*

Proof. Let B be a k-heavy bubble graph. A k-splitting component of B is computed by converting B into an *s-t* graph as follows.

- Let B_1 be the graph obtained by adding a vertex t in the external face of B and a directed edge pointing to t from each sink component of B.
- Let B_2 be the graph obtained from B_1 by contracting each strong component of B into a vertex. The vertices in B_2 are assigned weights. The weight of t is 0. For each vertex w that is contracted from a strong component W of B, the weight of w is the number of vertices in W.

Note that B_2 is an *s-t* graph. Its sink is t, and its source is contracted from the strong component of B that contains B's specified root.

By Lemmas 5.1(1) and 2.1, B_2 can be computed in $O(\log^2 n)$ time with $n/\log n$ processors. Next, the cardinality of $\mathcal{R}(W, B)$ for each strong component W of B is computed in $O(\log^2 n)$ time on $n/\log n$ processors by applying to B_2 a slight generalization of the descendant counting algorithm of Tamassia and Vitter for *s-t* graphs [33]. With the cardinality of $\mathcal{R}(W, B)$ computed, a k-splitting component of B is identified in a straightforward manner in $O(\log n)$ time with $n/\log n$ processors. □

5.5. Partial depth-first search trees and dangling subgraphs. Let B be a bubble graph. A *partial* depth-first search tree of B is a subtree of a depth-first search tree of B such that both trees are rooted at the specified root of B.

Let T be a partial depth-first search tree of B. Let $x_1, x_2, \ldots, x_t$ be the vertices of T listed in the postorder traversal sequence of depth-first search, i.e., in this sequence x_i is marked right after all its descendants in T are marked.

For each x_i, let $y_{i,1}, \ldots, y_{i,k_i}$ be the vertices that are not in T but are the end vertices of the edges pointing from x_i. The order of $y_{i,1}, \ldots, y_{i,k_i}$ is arbitrary. This is the postorder that will be used to search $B - T$ starting from x_i. A y vertex may have several different indices if it is adjacent from several x vertices.

The *dangling* subgraph of B, denoted by $\mathcal{D}(i, j)$, with respect to (i, j) and T is the subgraph induced by the vertices in $B - T$ that can be reached from $y_{i,j}$ but not from any y vertex before $y_{i,j}$ in the intended postorder traversal sequence of the y vertices, i.e., $\mathcal{D}(i, j) = \mathcal{R}(y_{i,j}, B - T) - \cup\{\mathcal{R}(y_{i',j'}, B - T) | i' < i \vee (i' = i \wedge j' < j)\}$.

For each nonempty $\mathcal{D}(i, j)$, the directed edge from x_i to $y_{i,j}$ is called the *dangling* edge associated with $\mathcal{D}(i, j)$.

The next two lemmas provide a natural way of extending T into a complete depth-first search tree by recursing on the nonempty dangling subgraphs in parallel.

LEMMA 5.3. *Let r be the specified root of B. Let H be a connected subgraph of B that contains r. Let u be a vertex that is not in H but is adjacent to or from H. Then the subgraph of B induced by $\mathcal{R}(u, B - H)$ is a bubble graph rooted at u.*

Proof. Let B_u be the subgraph of B induced by $\mathcal{R}(u, B - H)$. First, by the definition of B_u, the vertex u can reach every vertex in B_u via directed paths in B_u. Next, because r is a boundary vertex of the external face of B, by the connectivity of H and by the relationship of r, H, and u, the vertex u is a boundary vertex of the external face of B_u.

Let W be a sink component of B_u. The following discussion shows that W contains a boundary vertex of the external face of B_u. Because B is a bubble graph, B contains a directed path $Q = y_1, \ldots, y_s$ from W to a boundary vertex on the external face of B. There are two cases based on whether Q intersects H or not.

- Case (1): Q does not intersect H. Then Q lies in B_u. Because W is a sink component of B_u, the path Q lies in W. Therefore, W contains the last vertex of Q, which is a boundary vertex on the external face of B_u.
- Case (2): Q intersects H. Let y_s be the first vertex of Q that is in H. Because $r \in H$ is a boundary vertex on the external face of B, by the adjacency of H and y_{s-1}, the vertex y_{s-1} is a boundary vertex of the external face of B_u. Furthermore, because W is a sink component of B_u, the vertex y_{s-1} is in W. □

LEMMA 5.4. *Let Ω be the set of dangling subgraphs of B with respect to T. Let L be the set of the associated dangling edges. Then the following statements are true*:

1. *Each nonempty $\mathcal{D}(i, j)$ is a bubble graph rooted at $y_{i,j}$. Hence $y_{i,j}$ is chosen to be the specified root of $\mathcal{D}(i, j)$.*
2. *The dangling subgraphs are disjoint.*
3. *A depth-first search tree of B can be formed by T, L, and a depth-first search tree for each dangling subgraph with at least two vertices.*

Proof. The first statement is obtained by recursively applying Lemma 5.3. The other two statements are straightforward. □

5.6. Computing dangling subgraphs with respect to a path. This section shows how to compute the dangling subgraphs with respect to a partial depth-first search tree that is a path. The computation is based on two bisection strategies using the subroutines in Figs. 2 and 3.

5.6.1. Analyzing the subroutine in Fig. 2.

LEMMA 5.5. *Let Y be the set of the end vertices of the edges in B that point from P_1 to $B - P$. Then, $\mathcal{R}(Y, B - P) = W - \{w\}$.*

Proof. The proof has two directions.

$\mathcal{R}(Y, B - P) \subseteq W - \{w\}$: Let $y \in \mathcal{R}(Y, B - P)$. Then, $B - P_2$ contains a directed path Q_1 from P_1 to y. Note that Q_1 contains no edge from D. On the other hand, because A_1 is strongly connected, there is a directed path Q_2 from y to P such that Q_2 and P intersect at only one vertex. Because Q_2 contains no outgoing edges from P, it has no edge from D. Let Q be the directed path formed by Q_1 and Q_2. Because Q goes from P to P, it becomes a directed cycle in A_2 that contains w. Because Q contains no edge from D. it remains a directed cycle in A_3. Therefore, $y \in W - \{w\}$.

$\mathcal{R}(Y, B - P) \supseteq W - \{w\}$: Let $z \in W - \{w\}$. Then A_3 contains a vertex-simple directed path R_1 from w to z. Let R_2 be a directed path in A_1 that corresponds to R_1 and intersects P only at one vertex x. Note that x is the start vertex of R_1. Because A_1 is constructed by adding incoming edges to r and because the edges in D are removed from A_3, the vertex x is in P_1 and the edges of R_2 are in $B - P_2$. Therefore, $z \in \mathcal{R}(Y, B - P)$. □

LEMMA 5.6. *Let B be a bubble graph of size n. Then the procedure in Fig. 2 correctly computes an output as specified in $O(\log^2 n)$ time with $n/\log n$ processors.*

Procedure SubOneComputeDSG
Input: a bubble graph B rooted at r, and a vertex-simple directed path $P = x_p, \ldots, x_1$ with $x_p = r$ and $p \geq 2$.
Output: two graphs B_1 and B_2 constructed from B, and two paths $P_2 = x_p, \ldots, x_{\lceil p/2 \rceil + 1}$ and $P_1 = x_{\lceil p/2 \rceil}, \ldots, x_1$ with following properties:

1. B_1 and B_2 are bubble graphs rooted at $x_{\lceil p/2 \rceil}$ and x_p, respectively.
2. P_1 and P_2 are vertex-simple directed paths, respectively, in B_1 and B_2 starting from their specified roots.
3. The nonempty dangling subgraphs and the associated dangling edges of B with respect to P are exactly those of B_1 with respect to P_1 and those of B_2 with respect to P_2.
4. The total size of B_1 and B_2 is at most the size of B.

begin

1. Let $q = \lceil p/2 \rceil$.
2. Let P_1 be the subpath of P formed by $x_q, \ldots, x_1$.
3. Let P_2 be the subpath of P formed by $x_p, \ldots, x_{q+1}$.
4. Let D be the set of edges in B that point from P_2 to $B - P$.
5. **if** B is strongly connected
   then let $A_1 = B$
   else let A_1 be the graph obtained from B by adding a directed edge from each sink component to r via the external face of B.
6. Let A_2 be the graph obtained from A_1 by contracting P into a vertex w. (*Remark.* The edges in D are now outgoing edges of w.)
7. Let A_3 be the graph obtained from A_2 by deleting the edges in D.
8. Let W be the strong component in A_3 that contains w.
9. Let B_1 be the subgraph of B induced by $(W - \{w\}) \cup P_1$.
10. Let B_2 be the graph obtained from B by contracting $(W - \{w\}) \cup P_1 \cup \{x_{q+1}\}$ into x_{q+1}.
11. **return** B_1, B_2, P_1, and P_2.

end.

FIG. 2. *The first subroutine for computing dangling subgraphs.*

Proof. The second and the fourth output property of the procedure are straightforward. The other two properties are shown below.

- Property 1: By Lemma 5.5, B_1 is the subgraph of B induced by $\mathcal{R}(x_q, B - P_2)$. Therefore, by Lemma 5.3, B_1 is a bubble graph rooted at x_q. Then, because B_2 is obtained from a bubble graph by contracting a connected vertex subset, it is a bubble graph rooted at x_p.
- Property 3: By Lemma 5.5, the nonempty dangling subgraphs and the associated dangling edges of B with respect to P are exactly those of B_1 with respect to P_1 and those of $B - B_1$ with respect to P_2. Because $B - B_1$ may or may not be a bubble graph, B_1 is contracted instead of deleted. The contraction of B_1 into x_{q+1} may add new edges in B_2 from $B - (B_1 \cup P_2)$ to x_{q+1}. However, this contraction creates no new edges in B_2 from x_{q+1} to $B - (B_1 \cup P_2)$. Such edges would point from B_1

Procedure SubTwoComputeDSG
Input: a bubble graph B rooted at r with $k \geq 2$ edges outgoing from r.
Output: two graphs B_1 and B_2 constructed from B with the following properties:

1. B_1 and B_2 are bubble graphs rooted at r.
2. The nonempty dangling subgraphs and the associated dangling edges of B with respect to r are exactly those of B_1 and B_2 with respect to r, where r is considered as a path of a single vertex.
3. The outdegrees of r in B_1 and B_2 are at most $\lceil k/2 \rceil$ and $\lfloor k/2 \rfloor$, respectively.
4. The total size of B_1 and B_2 is at most the size of B.

begin

1. Let $h = \lceil k/2 \rceil$.
2. Let $y_1, \ldots, y_k$ be the k end vertices of the outgoing edges of r in B.
3. Let D be the set of the edges from r to $y_{h+1}, \ldots, y_k$ in B.
4. **if** B is strongly connected
   then let $A_1 = B$
   else let A_1 be the graph obtained from B by adding a directed edge from each sink component to r via the external face of B.
5. Let A_2 be the graph obtained from A_1 by contracting $\{r, y_1, \ldots, y_h\}$ into a vertex w.
   (*Remark.* The edges in D are now outgoing edges of w.)
6. Let A_3 be the graph obtained from A_2 by deleting the edges in D.
7. Let W be the strong component in A_3 that contains w.
8. Let B_1 be the subgraph of B induced by $(W - \{w\}) \cup \{r, y_1, \ldots, y_h\}$ without the edges in D.
9. Let B_2 be the graph obtained from B by contracting $(W - \{w\}) \cup \{r, y_1, \ldots, y_h\}$ into r.
10. **return** B_1 and B_2.

end.

FIG. 3. *The second subroutine for computing dangling subgraphs.*

and thus their end vertices would have been included in B_1. Therefore, contracting B_1 into x_{q+1} does not change the nonempty dangling subgraphs and the associated dangling edges of $B - B_1$ with respect to P_2.

As for the complexity, Steps 1–4 can be done in $O(\log n)$ time with $n/\log n$ processors. Step 5 can be done via Lemma 5.1(1) in $O(\log^2 n)$ time with $n/\log n$ processors. Step 6 is done via Lemma 2.1 in $O(\log n)$ time with $n/\log n$ processors. Step 7 can be done in $O(\log n)$ time with $n/\log n$ processors. Because A_1 is a strong graph, A_2 remains a strong graph. Because the edges of D are adjacent to w in A_2, by Theorem 3.4, W can be computed in $O(\log^2 n)$ time with $n/\log n$ processors. Step 9 can be done in $O(\log n)$ time with $n/\log n$ processors. Step 10 can be done via Lemma 2.1 in $O(\log n)$ time with $n/\log n$ processors. Thus, the total complexity of the procedure in Fig. 2 is as stated. □

5.6.2. Analyzing the subroutine in Fig. 3.

LEMMA 5.7. *Let B be a bubble graph of size n. Then the procedure in Fig. 3 correctly computes an output as specified in $O(\log^2 n)$ time with $n/\log n$ processors.*

Proof. The proof is similar to those of Lemmas 5.6 and 5.3. A subtle point is as follows. B_1 may contain some of $y_{h+1}, \ldots, y_k$. The dangling subgraphs of B with respect to such vertices are empty. Therefore, the edges in D can be deleted from B_1 without affecting its nonempty dangling subgraphs. This deletion ensures that the outdegree of r in B_1 is $\lceil k/2 \rceil$.

Remark. The procedure in Fig. 3 can be simplified by replacing Steps 5–9 with the following steps. This simplification decreases the apparent symmetry between the procedures in Figs. 2 and 3.

6′. Let A_3' be the graph obtained from A_1 by deleting the edges in D.
7′. Let W' be the strong component in A_3' that contains r.
8′. Let B_1 be the subgraph of B induced by W' without the edges in D.
9′. Let B_2 be the graph obtained from B by contracting B_1 into r. □

5.6.3. Computing dangling subgraphs. The next theorem uses the procedures in Figs. 2 and 3 to compute the nonempty dangling subgraphs with respect to a path.

THEOREM 5.8. *Let B be a bubble graph of size n. Let P be a vertex-simple directed path of B starting from its specified root. Then the nonempty dangling subgraphs and the associated dangling edges of B with respect to P can be computed in $O(\log^3 n)$ time with $n/\log n$ processors.*

Proof. The computation is divided into two phases:

- Phase 1 iteratively applies SubOneComputeDSG to B and P to bisect P. In $O(\log n)$ iterations, a collection of bubble subgraphs of B is obtained such that each subgraph B' contains only one vertex of P.
- Phase 2 iteratively applies SubTwoComputeDSG to each B' to bisect the outdegree of its root. In $O(\log n)$ iterations, a collection of even smaller bubble subgraphs of B is obtained. Each subgraph B'' is rooted at a vertex y. B'' either has exactly one outgoing edge from y or consists of only y. If B'' consists of only y, then its corresponding dangling subgraph of B is empty. Otherwise, $B'' - \{y\}$ is a nonempty dangling subgraph of B. Its associated dangling edge is the outgoing edge of y in B''.

The correctness and complexity of this computation follow directly from Lemmas 5.6 and 5.7. □

5.7. Parallel depth-first search in bubble graphs. Figure 6 details this paper's algorithm for performing depth-first search in a bubble graph. Its subroutines are described in Figs. 5 and 4.

LEMMA 5.9. *Assume that B is a bubble graph of size n. The procedure in Fig. 4 correctly computes an output as specified in $O(\log^3 n)$ time with $n/\log n$ processors.*

Proof. Let S' be the set of vertices in $S \cap W$. Assume that some dangling subgraph B' of B with respect to S is $2m/3$-heavy. Because B has at most m vertices, B' is the only $2m/3$-heavy dangling subgraph of B. Note that W is the only $2m/3$-splitting component of B included in the subgraph $\mathcal{R}(W, B)$. Thus, the $2m/3$-splitting components of B' must be strong components of $W - S'$. Then, because S' is a separator of W, the output property of the procedure holds.

As for the complexity of the procedure, Steps 1, 5, and 6 are obvious. Step 2 employs Theorem 5.2. Step 3 uses Theorem 4.3. Step 4 is done by means of Lemma 5.1(2). Steps 7 and 8 use Theorem 5.8. Thus, the total complexity is as stated. □

LEMMA 5.10. *Let B be a bubble graph of size n. The procedure in Fig. 5 correctly computes an output as specified in $O(\log^4 n)$ time with $n/\log n$ processors.*

Proof. At Step 2 in Fig. 5, by the output properties of SplitHeavyDSG, the $2m/3$-splitting components of the input bubble graph to each call of SplitHeavyDSG are all light subgraphs of a $2m/3$-splitting component of the input bubble graph to the previous call. Thus, the while loop at Step 2 iterates $O(\log n)$ time, and this lemma follows directly from Lemma 5.9. □

Procedure SplitHeavyDSG
Input: a positive integer m, and a $2m/3$-heavy bubble graph B that has at most m vertices.
Output: a partial depth-first search tree S of B, the set Δ of all dangling subgraphs of B with respect to S, and the set K of the associated dangling edges, where S satisfies either property below:

1. No subgraph in Δ is $2m/3$-heavy.
2. Some subgraph in Δ is $2m/3$-heavy and its $2m/3$-splitting components are all light subgraphs of a single $2m/3$-splitting component W of B.

begin

1. Let r be the specified root of B.
2. Let W be a $2m/3$-splitting component of B.
3. Let C be a directed cycle separator of W.
4. Let P be a vertex-simple directed path in B from r to C such that P and C intersect at only one vertex u.
5. Let e be the edge on C pointing to u.
6. Let S be the vertex-simple directed path formed by P and C without the edge e.
7. Let Δ be the set of dangling subgraphs of B with respect to S.
8. Let K be the set of the associated dangling edges.
9. **return** the tuple (S, Δ, K).

end.

FIG. 4. *A procedure for splitting a heavy dangling subgraph.*

THEOREM 5.11. *Let B be a bubble graph of size n. Let r be the specified root of B. Then a depth-first search tree of B rooted at r can be computed in $O(\log^5 n)$ time with $n/\log n$ processors on a deterministic* Arbitrary-CRCW PRAM.

Proof. The computation is done by the procedure in Fig. 6. This theorem then follows directly from Lemmas 5.4 and 5.10, and the fact that by the output property of ComputePartialTree, the depth of recursion of ComputeDFSTree is $O(\log n)$. □

5.8. Parallel depth-first search in strong graphs. The next theorem states the main result of this paper.

THEOREM 5.12. *Let G be a strong graph of size n. Let r be a vertex in G. Then a depth-first search spanning tree of G rooted at r can be computed in $O(\log^5 n)$ time with $n/\log n$ processors on a deterministic* Arbitrary-CRCW PRAM.

Proof. The external face of G can be changed so that r is a boundary vertex on that face. Then, by the strong connectivity of G, it is a bubble graph rooted at r. Therefore, this theorem follows from Theorem 5.11 and the fact that the external face can be changed in $O(\log n)$ time on $n/\log n$ processors using list ranking [5], [9], [13] and prefix computation [23], [24]. □

Appendix. All graphs have cycle separators. The following discussion uses depth-first search trees to compute graph separators [17].

A.1. Path and cycle separators of weighted graphs. A *weighted* graph is one with nonnegative vertex weights. To avoid triviality, assume that at least one vertex has a positive weight.

Procedure ComputePartialTree
Input: a bubble graph B with m vertices.
Output:
1. a partial depth-first search tree T of B such that all dangling subgraphs are $2m/3$-light;
2. the set Ω of the dangling subgraphs of B with respect to T.
3. the set L of the associated dangling edges.

begin
1. $(T, \Omega, L) \leftarrow$ SplitHeavyDSG(m,B).
2. **while** some $B' \in \Omega$ is $2m/3$-heavy **do**
   begin
   2-1. Delete B' from Ω.
   2-2. Delete the dangling edge of B' from L.
   2-3. Add the above edge to T to form a larger tree.
   2-4. $(S, \Delta, K) \leftarrow$ SplitHeavyDSG(m,B').
   2-5. Add S to T to form a larger tree.
   2-6. Add Δ to Ω.
   2-7. Add K to L.
   end.
3. **return** the tuple (T, Ω, L).

end.

FIG. 5. *A procedure for computing a partial depth-first search tree.*

Procedure ComputeDFSTree
Input: a bubble graph B with at least two vertices.
Output: a depth-first search tree T of B.
begin
1. $(T, \Omega, L) \leftarrow$ ComputePartialTree(B).
2. Add L to T to form a larger tree.
3. **for** each $B' \in \Omega$ with at least two vertices **do**
   begin
   3-1. $T' \leftarrow$ ComputeDFSTree(B').
   3-2. Add T' to T to form a larger tree.
   end.
4. **return** T.

end.

FIG. 6. *A procedure for computing a depth-first search tree.*

Let G be a weighted directed graph. Let H be a subgraph or vertex subset of G. Let $G - H$ be the subgraph obtained by removing the vertices in H and their incident edges.

Let $\mathcal{W}(H)$ be the total weight of H. The set H is called *heavy* for G if $\mathcal{W}(H) > \mathcal{W}(G)/2$.

Remark. The threshold for heaviness here is different from that in §4.1, which is 2/3.

A *separator* S of G is a vertex subset such that no strong component of $G - S$ is heavy for G. A *cycle* (respectively, *path*) separator is a vertex-simple directed cycle (respectively, path) such that its vertices form a separator.

For technical uniformity, a vertex is considered a trivial cycle. Thus, if a vertex forms a separator, it is a cycle separator. The empty set is considered both a trivial cycle and a trivial path. Thus, if the empty set forms a separator, it is a cycle separator as well as a path separator.

A.2. Computing path separators from depth-first search trees. The next theorem can be applied to a weighted undirected graph by substituting each undirected edge with a pair of directed edges.

THEOREM A.1. *Every weighted directed graph has a path separator.*

Proof. Let G be a weighted directed graph. Without loss of generality, assume that G is strongly connected. Otherwise, replace G with its maximum-weight strong component. Every path separator of that component is also one for G.

A path separator P for G is constructed as follows. Let T be a depth-first search spanning tree of G rooted at an arbitrary vertex r. Let $z_1, \ldots, z_n$ be the vertices of G in the corresponding depth-first search postorder. Let p be the smallest index with $\mathcal{W}(z_1)+\cdots+\mathcal{W}(z_p) \geq \mathcal{W}(G)/2$. Then, $\mathcal{W}(z_1) + \cdots + \mathcal{W}(z_{p-1}) < \mathcal{W}(G)/2$ and $\mathcal{W}(z_{p+1}) + \cdots + \mathcal{W}(z_n) \leq \mathcal{W}(G)/2$.

Let P be the tree path in T from r to z_p. Let $G_L = \{z_1, \ldots, z_{p-1}\}$. Let $G_R = G-(G_L \cup P)$. Note that $\mathcal{W}(G_L) < \mathcal{W}(G)/2$ and $\mathcal{W}(G_R) \leq \mathcal{W}(G)/2$.

P is shown to be a path separator as follows. Draw G on a plane in such a way that for all postorder indices i and j with $i > j$, the vertex z_i is either to the right of z_j or is an ancestor of z_j in T [4].

The vertex z_p either is an ancestor of or is to the right of every vertex in G_L because p is greater than the postorder indices of all vertices in G_L. Also, every vertex in G_R is to the right of z_p because the postorder indices of vertices in G_R are all greater than p and because P consists of z_p and all its ancestors. Therefore, every vertex in G_R is to the right of every vertex in G_L.

Because in depth-first search no edge points from left to right, every strong component of $G - P$ is either entirely in G_L or entirely in G_R. Thus, the weight of a strong component of $G - P$ is at most $\mathcal{W}(G_L)$ or $\mathcal{W}(G_R)$. □

A.3. Computing cycle separators from path separators. The next theorem can also be applied to a weighted undirected graph by edge substitution. Note that a separator obtained by the theorem actually consists of one of the following: no vertex, a single vertex, or at least three vertices. Thus it does not degenerate into an undirected edge after edge substitution is undone.

THEOREM A.2. *Every weighted directed graph has a cycle separator.*

Proof. Let G be a weighted directed graph. Let $P = u_1, \ldots, u_p$ be a path separator of G obtained by Theorem A.1.

P is converted into a cycle separator as follows. Let s be the largest index such that some strong component Z_s of $G - \{u_1, \ldots, u_{s-1}\}$ is heavy for G. Then $u_s \in Z_s$ because the path $u_1, \ldots, u_s$ is still a separator. If s does not exist, then the empty set is a trivial cycle separator. Otherwise, continue the conversion and let $P' = u_1, \ldots, u_s$.

Let t be the smallest index such that a strong component Z_t of $G - \{u_{t+1}, \ldots, u_s\}$ is heavy for G. Then $u_t \in Z_t$ because the path $u_t, \ldots, u_s$ is still a separator.

There are two cases based on whether $s = t$ or not. If $s = t$, then u_s is a trivial cycle separator. Otherwise, $u_t \notin Z_s$ and $u_s \notin Z_t$. Because Z_s and Z_t are heavy for G and are strongly connected, $Z_s \cap Z_t$ contains a vertex z such that there is a vertex-simple directed path

Q from u_s via $Z_s - Z_t$ to z and then via $Z_t - Z_s$ to u_t. Because $Z_s \cup Z_t$ contains none of $u_{t+1}, \ldots, u_{s-1}$, the path Q and the path $u_t, \ldots, u_s$ form a vertex-simple directed cycle with at least three vertices. This cycle is a separator because the path $u_t, \ldots, u_s$ is a separator. □

FAST PARALLEL COMPUTATION OF THE POLYNOMIAL REMAINDER SEQUENCE VIA BÉZOUT AND HANKEL MATRICES*

DARIO BINI† AND LUCA GEMIGNANI‡

Abstract. If $u(x)$ and $v(x)$ are polynomials of degree n and m, respectively, $m < n$, all the coefficients of the polynomials generated by the Euclidean scheme applied to $u(x)$ and $v(x)$ can be computed by using $O(\log^3 n)$ parallel arithmetic steps and $n^2/\log n$ processors over any field of characteristic 0 supporting FFT (Fast Fourier Transform). If the field does not support FFT the number of processors is increased by a factor of $\log\log n$; if the field does not allow division by $n!$ the number of processors is increased by a factor of n. This result is obtained by reducing the Euclidean scheme to computing the block triangular factorization of the Bezout matrix associated with $u(x)$ and $v(x)$. This approach is also extended to the evaluation of polynomial gcd (greatest common divisor) over any field of constants in $O(\log^2 n)$ steps with the same number of processors.

AMS subject classifications. 68Q25, 65Y05

1. Introduction.

Let

$$u(x) = \sum_{i=0}^{n} u_i x^i, \qquad v(x) = \sum_{i=0}^{n-1} v_i x^i$$

be two polynomials with coefficients in a field $\mathbf{F}$. The Euclidean scheme, applied to $u(x)$ and $v(x)$, generates a sequence of polynomials $r_i(x)$, $q_i(x)$, such that

$$\begin{aligned} &r_0(x) = u(x), \qquad r_1(x) = v(x) \\ &r_{i-1}(x) = r_i(x)q_i(x) - r_{i+1}(x), \qquad i = 1, \ldots, L, \end{aligned} \tag{1}$$

where $-r_{i+1}(x)$ is the remainder of the division of $r_{i-1}(x)$ and $r_i(x)$ and $r_L(x)$ is the greatest common divisor (gcd) of $u(x)$ and $v(x)$. If $\deg(r_i(x)) = n - i$, $i = 0, \ldots, n$, the Euclidean scheme is carried out in n steps and the quotients $q_i(x)$ are linear polynomials. We refer to this situation as the *normal case*.

The computation of the coefficients of the polynomials in (1) can be performed in $O(n^2)$ arithmetic operations by means of the synthetic division algorithm. Moreover, in the normal case this computation is asymptotically optimal since all the $n(n-1)/2$ coefficients of the polynomials $r_i(x)$ cannot be computed with less than $n(n-1)/2$ arithmetic operations.

The first polylogarithmic parallel solution to the Euclidean scheme computation was given in [7] (hereafter we assume the customary arithmetic PRAM model of parallel computation, where in each step each processor performs at most an arithmetic operation). The algorithm of [7], based on the theory of subresultants [8], [9], reduces the problem to computing n^2 determinants of size $O(n)$ in $O(\log^2 n)$ steps with $O(n^{\omega+2.5-\epsilon})$ processors, where $\omega < 2.38$ is the exponent of matrix multiplication complexity. In [18] the number of processors is reduced to $O(n^{\omega+1})$, but still obtains a processor-inefficient algorithm.

The first processor-efficient algorithm requiring $O(n^2)$ processor has been devised in [3] but only in the normal case and over fields of characteristic 0. This algorithm relies on an

interesting property that relates Hankel matrices (see the definition in §2) to the Euclidean scheme. We prove that in the normal case the Euclidean scheme computation is equivalent to computing the LU factorization of the Hankel matrix $H(u, v)$ generated by the rational function $v(x)/u(x)$. Other interesting properties relating structured matrices, the Euclidean scheme, and the gcd, have been proved in [1], [2], and [15].

In this paper we generalize the results of [3] to any field of constants $\mathbf{F}$ and to the abnormal case. By using suitable results from the theory of partial realizations (see [14] and Proposition 3.1), we prove that the coefficients of all the polynomials in (1) are univocally determined by any block LU factorization of the Hankel matrix $H(u, v)$ associated with $u(x)$ and $v(x)$ (compare Proposition 3.2), or more conveniently, by any block LU factorization of the matrix $JB(u, v)J$ where $B(u, v)$ is the Bézout matrix of $u(x)$ and $v(x)$ and J is the permutation matrix having 1 in the antidiagonal (see the definitions in §2 and relation (13) in §3). More specifically, if $JB(u, v)J = \hat{L}\hat{D}\hat{L}^T$ is such a factorization, then we prove that the entries of suitable columns of $\hat{L}$ coincide with the coefficients of the polynomials $r_i(x)$ of (1). Therefore, for any algorithm for computing the block LU factorization of the matrices $H(u, v)$ and $JB(u, v)J$ there is a corresponding algorithm for computing the coefficients of the polynomials generated by the Euclidean scheme that has the same computational cost.

In order to devise efficient algorithms for the block LU factorization of $JB(u, v)J$, we investigate suitable properties of the Schur complements of the leading principal submatrices of $JB(u, v)J$. In particular we prove that the Schur complement of the ith nonsingular leading principal submatrix of $JB(u, v)J$ is $JB'J$, where $B' = B(r_i, r_{i+1})$ is the Bézout matrix associated with the polynomials $r_i(x)$ and $r_{i+1}(x)$ of (1).

Based on these results, we devise a parallel algorithm for the computation of the block LU factorization of the matrix $JB(u, v)J$ over any field $\mathbf{F}$, in $O(\log^3 n)$ parallel steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors, where $p_{\mathbf{F}}(n) = 1$ if $\mathbf{F}$ supports FFT, $p_{\mathbf{F}}(n) = \log\log n$ otherwise, $q_{\mathbf{F}}(n) = 1$ if $\mathbf{F}$ allows division by $n!$, $q_{\mathbf{F}}(n) = n$ otherwise.

The algorithm, relying on the divide-and-conquer strategy, is based on the above property of the Schur complements, and on the recently devised techniques for Hankel-like and Toeplitz-like computations [4], [5], [20].

Concerned with the computation of the gcd of $u(x)$ and $v(x)$, we extend the results of [3] to any field of constant and to the case of Bézout matrices. We give a simpler proof of the results of [3] (see the next Proposition 3.6) characterizing gcd in matrix form. Moreover we prove that $\gcd(u(x), v(x))$ is univocally determined by a suitable vector in the kernel of the matrix $JB(u, v)J$ (see Corollary 3.1). Based on these results, we devise a parallel algorithm for the gcd computation in $O(\log^2 n)$ parallel steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors.

The use of Bézout matrices, rather than Hankel matrices, also leads to better upper bounds to the number of digits needed for the computation in the case of polynomials with integer or rational coefficients (see our comments in §4 and [5] and [13]).

The paper is organized as follows: in §2 we introduce the definitions and the tools needed for our analysis. In §3 we prove the theoretical results relating the Euclidean scheme and gcd computation to Hankel and Bézout matrices. Finally, in §4 we devise the algorithms for the block LU factorization of JBJ (Euclidean scheme computation) and for the computation of a vector in the kernel of JBJ (gcd computation), and perform their parallel cost analysis.

2. Preliminaries. Let $u(x) = \sum_{i=0}^{n} u_i x^i$ and $v(x) = \sum_{i=0}^{m} v_i x^i$ be two polynomials of degree n and m, respectively, where $m < n$. Let

$$f(z, w) = \sum_{i,j=0}^{+\infty} a_{i,j} z^i w^j$$

be a formal power series in the variables z and w. We associate with $f(z, w)$ the semi-infinite matrix $A = (a_{i,j})$, $i, j = 0, 1, \ldots$, and, for any natural n the $n \times n$ matrix $A_n = (a_{i,j})$, $i, j = 0, \ldots, n-1$, the *finite section* of A. We refer to $f(w, z)$ as to the *generating function* of A or of A_n. It is easy to check that

$$\frac{zu(z) - wu(w)}{z - w}$$

is the generating function of a *Hankel matrix*, that is, a matrix whose (i, j) entry is a function of $i + j$, $i, j = 0, 1, \ldots, n-1$.

Let Z be the *down-shift* matrix that has entries $z_{i,j} = 1$ if $i = j + 1$, $z_{i,j} = 0$ otherwise. Z is a special *Toeplitz matrix*. (A matrix is Toeplitz if its (i, j) entry is a function of $i - j$.)

The $n \times n$ matrix F_u obtained by replacing the last row of Z^T by the vector $(-u_0/u_n, \ldots, -u_{n-1}/u_n)^T$ is the *Frobenius (companion) matrix* associated with $u(x)$. We denote by $T(a_0, \ldots, a_{n-1})$ the lower triangular Toeplitz matrix having entries a_{i-j}, $i \geq j$.

The expression

$$\frac{u(z)v(w) - v(z)u(w)}{z - w}, \tag{2}$$

which is easily verified to be a polynomial in w and z, is called the *Bézoutian* of $u(x)$ and $v(x)$. The Bézoutian is a rather special bilinear form which appears in the context of the theory of equations, in stability theory, and in the classical elimination theory [16], [19], [11], [23]. The $n \times n$ matrix $B(u, v)$, whose generating function is (2), is called the *Bézout matrix* or, more simply the *Bézoutian* of $u(x)$ and $v(x)$. The following matrix representation of the Bézoutian [19] can easily be proved:

$$B(u, v) = -JT(v_n, \ldots, v_1)T^T(u_0, \ldots, u_{n-1}) + JT(u_n, \ldots, u_1)T^T(v_0, \ldots, v_{n-1}), \tag{3}$$

where J is the permutation matrix having 1 in the antidiagonal, i.e., its (i, j) entry is 1 for $j = n - i - 1$, $i, j = 0, \ldots, n-1$.

Remark 2.1 Given the mth row and the last row of $B(u, v)$, together with the entry $(0, 0)$ lying in the first row and in the first column of $B(u, v)$, it is possible to compute the coefficients of the polynomials $u_n v(x)$ and $u(x)/u_n$. In fact, if $m < n$, the last row of $B(u, v)$ is $u_n[v_0, \ldots, v_{n-1}]$, which defines the coefficients of $u_n v(x)$. Moreover, the mth row $\mathbf{b}^T$ of $B(u, v)$ is

$$\mathbf{b}^T = -v_m[u_0, \ldots, u_{n-1}] + [u_m, \ldots, u_n, 0, \ldots, 0] \begin{pmatrix} v_0 & \ldots & v_{n-1} \\ & \ddots & \vdots \\ O & & v_0 \end{pmatrix}, \tag{4}$$

and this relation can be used to express the coefficients of $u(x)/u_n$ as linear functions in u_{n-1}. Indeed, assume for simplicity that $u_n = 1$, so that the last row of $B(u, v)$ gives us the value of m and the coefficients $v_0, \ldots, v_m$. Moreover, rewrite (4) as an $n \times n$ system of linear equations:

$$[u_0, \ldots, u_{n-1}] \left(-v_m I_n + \begin{pmatrix} & & O & & O \\ v_0 & \ldots & v_m & & \\ & \ddots & & \ddots & \\ O & & v_0 & \ldots & v_m \end{pmatrix} \right)$$
$$= \mathbf{b}^T - [0, \ldots, 0, v_0, \ldots, v_{m-1}].$$

Remove the last equation of this linear system and consider the triangular Toeplitz system consisting of the last remaining $n-m$ equations. From the latter system, express $u_n, \ldots, u_{n-2}$ in terms of u_{n-1}. Substitute $u_m, \ldots, u_{n-1}$ in the first m equations and express them via u_{n-1}. Since we are given the entry in the first row and in the first column of $B(u, v)$, we may define the remaining unknown value u_{n-1}.

Another property, which directly follows from representation (3), is that the matrix $B(u, 1)$ is an upper triangular Hankel matrix:

$$B(u,1) = \begin{pmatrix} u_1 & u_2 & \cdots & u_n \\ u_2 & \iddots & \iddots & \\ \vdots & \iddots & O & \\ u_n & & & \end{pmatrix}.$$

Let h be a constant independent of n and L_i, U_i^T, $i = 1, \ldots, h$, be lower triangular Toeplitz matrices. Any matrix $A = \sum_{i=1}^{h} L_i U_i$ is called Toeplitz-like, any matrix $B = \sum_{i=1}^{h} J L_i U_i$ is called Hankel-like. From (3) it follows that $B(u, v)$ is a Hankel-like matrix.

Now consider the formal power series

$$\frac{v(x^{-1})}{xu(x^{-1})} = \sum_{i=0}^{+\infty} h_i x^i, \tag{5}$$

whose coefficients are related to the coefficients of $u(x)$ and $v(x)$ by the triangular Toeplitz system of equations

$$\begin{pmatrix} h_0 & & & \\ h_1 & h_0 & & \\ h_2 & h_1 & h_0 & \\ \ddots & \ddots & \ddots & \ddots \end{pmatrix} \begin{pmatrix} u_n \\ u_{n-1} \\ u_{n-2} \\ \vdots \end{pmatrix} = \begin{pmatrix} v_{n-1} \\ v_{n-2} \\ v_{n-3} \\ \vdots \end{pmatrix} \tag{6}$$

where we assume $v_i = 0$ for $i > m$. The above power series defines the $n \times n$ Hankel matrix $H(u, v)$, whose (i, j) entry is h_{i+j}, $i, j = 0, 1, \ldots, n-1$. Relation (6) immediately implies the following.

PROPOSITION 2.1. *For any pair of relatively prime polynomials $u(x)$, $v(x)$ of degree n and m, respectively, $m < n$, the matrix $H(u, v)$ is nonsingular, moreover, for any nonsingular $n \times n$ Hankel matrix H there exists a pair of relatively prime polynomials $u(x)$, $v(x)$, ($u(x)$ monic), of degree n and m, respectively, $m < n$, such that $H = H(u, v)$. The polynomials $u(x)$ and $v(x)$ are related to $H(u, v)$ by the following equation:*

$$H(u,v)(u_0, \ldots, u_{n-1})^T = -u_n(h_n, \ldots, h_{2n-1}),$$
$$(v_{n-1}, \ldots, v_0)^T = T(h_0, \ldots, h_{n-1})(u_n, \ldots, u_1)^T,$$

where h_{2n-1} is any number.

Proof. Observe that the first n equations of (6) allow us to express the coefficients of $v(x)$ in terms of the coefficients of $u(x)$. The remaining n equations constitute a system in the unknowns $u_0, \ldots, u_{n-1}$, whose matrix is $H(u, v)$, with known terms $-u_n(h_n, \ldots, h_{2n-1})^T$. Therefore, if $\det H(u, v) \neq 0$, then there exists unique (up to a scalar factor and once h_{2n-1} has been fixed) solution $u(x)$ to this system, and consequently, there exists unique polynomial $v(x)$. In this case $\gcd(u(x), v(x)) = 1$ otherwise the above linear system would have more than one solution. Vice versa, if $\det H(u, v) = 0$, the above system (with h_{2n-1} fixed) would

have more than one solution, say, $u(x)$, $v(x)$ and $a(x)$, $b(x)$ of degrees t, s, respectively, $s \leq t$. Therefore, from the relation

$$\frac{v(x^{-1})}{xu(x^{-1})} - \frac{b(x^{-1})}{xa(x^{-1})} = 0 \bmod x^{2n}$$

it follows that

$$v(x^{-1})a(x^{-1}) - u(x^{-1})b(x^{-1}) = 0 \bmod x,$$

that is, since the left-hand side is a polynomial in x^{-1} of degree at most $2n-1$ it follows that

$$v(x)a(x) - u(x)b(x) = 0,$$

hence $u(x)$ and $v(x)$ have a common nonconstant divisor. □

Remark 2.2. Let $H = H(u, v)$ be an $n \times n$ nonsingular Hankel matrix. Then $m = \deg v = n - k - 1$ if and only if $h_i = 0$, $i = 0, 1, \ldots, k-1$, $h_k \neq 0$, that is, if and only if $\det H_i = 0$, $i = 1, \ldots, k$, where H_i is the $i \times i$ leading principal submatrix of H.

We recall a classical result relating the matrices $H(u, v)$ and $B(u, v)$ [17], [16], [10].

PROPOSITION 2.2. *Let F_u be the $n \times n$ Frobenius matrix associated with the polynomial $u(x)$ of degree n. Let $v(x)$ be a polynomial of degree $m < n$. Then we have*

$$B(u, v) = B(u, 1)H(u, v)B(u, 1),$$

$$B(u, v) = B(u, 1)v(F_u),$$

moreover, if $u(x)$ and $v(x)$ are relatively prime then

$$B(u, k)H(u, v) = I,$$

where $v(F_u) = \sum_{i=0}^{m} v_i F_u^i$ and $k(x)$ is the polynomial of degree less than n such that $k(x)v(x) = 1 \bmod u(x)$.

Compare the first and second representations of $B(u, v)$ given in Proposition 2.2. Since $B(u, 1)$ is nonsingular it follows that

$$H(u, v) = (B(u, 1))^{-1} v(F_u^T). \tag{7}$$

If $H(u, v)$ is singular the above relation allows us to characterize the kernel of $H(u, v)$; in fact, the following result holds.

LEMMA 2.1. *Let $u(x)$ and $v(x)$ be two polynomials of degrees n and m, respectively, where $m < n$. Then $v(F_u^T)\mathbf{z} = \mathbf{0}$ if and only if $v(x)z(x) = 0 \bmod u(x)$, where $z(x) = \sum_{i=0}^{n-1} z_i x^i$. Therefore, $v(F^T)$ is singular if and only if $r(x) = \gcd(u(x), v(x))$ is a nonconstant polynomial. Moreover, if $u(x) = w(x)r(x)$, the null space of $v(F^T)$ is $\{\mathbf{z} \in \mathbf{C}^n : z(x) = p(x)w(x)\}$.*

Proof. Since $(F^T)^i \mathbf{e}^{(0)} = \mathbf{e}^{(i)}$, $i = 0, \ldots, n-1$ (where $\mathbf{e}^{(i)}$ denotes the ith column of the $n \times n$ identity matrix), the first column of $v(F^T)$ is $(v_0, v_1, \ldots, v_m, 0, \ldots, 0)^T$. Therefore, $v(F^T)\mathbf{z} = v(F^T)z(F^T)\mathbf{e}^{(0)} = s(F^T)\mathbf{e}^{(0)}$, where $s(x) = v(x)z(x) \bmod u(x)$ is a polynomial of degree less than n. Hence, $v(F^T)\mathbf{z} = \mathbf{0}$ if and only if $v(x)z(x) = 0 \bmod u(x)$. In particular, $z(x)$ must be a multiple of $w(x)$, i.e., there exists a polynomial $p(x)$ such that $z(x) = p(x)w(x)$. □

The above lemma will be used in order to characterize the polynomial gcd in terms of the Hankel matrix (Proposition 3.6).

3. Theoretical results. In this section we analyze correlations between the matrices $H(u, v)$, $B(u, v)$, and the coefficients of the polynomials generated by the Euclidean scheme applied to $u(x)$ and $v(x)$.

It is well known that Hankel matrices and their factorizations are related to the polynomial remainder sequences by means of the nonsymmetric Lanczos process for tridiagonalizing general non-Hermitian square matrices. (We refer the reader to [12] and [21] and to the references given there.) Here, we first recall a result of [14] which relates triangular factorization of Hankel matrices to orthogonalization processes. Then we will prove that suitable rows of the matrix $\tilde{L}^{-1}$ such that $H(u, k) = \tilde{L}\tilde{D}\tilde{L}^T$ is a block LDL^T factorization of $H(u, k)$ yield the coefficients of the remainders generated by the Euclidean scheme applied to $u(x)$ and $v(x)$. Here the polynomial $k(x)$ is the solution of the congruence $v(x)k(x) = 1 \bmod u(x)$. Then we prove that the matrix $\tilde{L}^{-1}$ can be obtained, bypassing the computation of $k(x)$ and the inversion of the matrix $\tilde{L}$, just by computing the L factor of the block LDL^T factorization of $JB(u, v)J$. Finally, by proving some properties of the Schur complements of the Bézout matrices, we arrive at the complete equivalence between the Euclidean scheme and the block LDL^T factorization of the matrix $JB(u, v)J$. We conclude this section by proving that the coefficients of $\gcd(u(x), v(x))$ can be directly obtained from a suitable vector in the kernel of $JB(u, v)J$.

Let us start by recalling the following basic result of [14].

PROPOSITION 3.1. *Let $H = (h_{i+j})$ be a semi-infinite Hankel matrix and H_n be its $n \times n$ finite section. Suppose that H_n is nonsingular and let $0 = m_0 < m_1 < \cdots < m_L = n$ be integers such that $\det H_{m_i} \neq 0$, $i = 1, \ldots, L$, $\det H_k = 0$, otherwise. Let $\delta_i = m_i - m_{i-1}$. Let $\mathcal{D}_n$ be the class of block diagonal matrices $\operatorname{diag}(T_1, \ldots, T_L)$ where T_i is a $\delta_i \times \delta_i$ lower triangular (with respect to the antidiagonal) Hankel matrix. Then we have the following results*:

(1) *There exists an upper triangular matrix R having unit diagonal entries, such that $R^T H_n R = D$, $D \in \mathcal{D}_n$. In particular one can choose*

$$R = \tilde{R} = (\mathbf{q}_0, Z\mathbf{q}_0, \ldots, Z^{\delta_1 - 1}\mathbf{q}_0, \mathbf{q}_1, Z\mathbf{q}_1, \ldots, Z^{\delta_2 - 1}\mathbf{q}_1, \ldots\ldots, Z^{\delta_L - 1}\mathbf{q}_{L-1}),$$

where Z is the down-shift matrix, $\mathbf{q}_0 = \mathbf{e}^{(0)}$, $\mathbf{q}_i^T = (\tilde{\mathbf{q}}_i^T, 1, \mathbf{0}^T)$, $\tilde{\mathbf{q}}_i = -H_{m_i}^{-1}(h_{m_i}, \ldots, h_{2m_i - 1})^T$, $i = 1, \ldots, L - 1$;

(2) *any upper triangular matrix $R = (\mathbf{r}_0, \mathbf{r}_1, \ldots, \mathbf{r}_{n-1})$, such that $R^T H_n R \in \mathcal{D}_n$, is such that $\mathbf{r}_{\delta_i} = \mathbf{q}_i$, where we assume $\delta_0 = 0$;*

(3) *set $Q_i(x) = (1, x, \ldots, x^{n-1})\mathbf{q}_i$, $i = 0, 1, \ldots, L$, where*

$$\mathbf{q}_L = -H_n^{-1} \begin{pmatrix} h_{n+1} \\ \vdots \\ h_{2n} \end{pmatrix},$$

and we have

$$\begin{aligned} &Q_i(x) = c_i(x)Q_{i-1}(x) - \theta_{i-1}Q_{i-2}(x), \qquad i = 1, \ldots, L, \\ &Q_0(x) = 1, \qquad Q_{-1}(x) = 0, \end{aligned}$$

where $c_i(x)$ are monic polynomials of degree δ_i and θ_{i-1} are constants $i = 1, \ldots, L$.

It is easy to show [12], [21] that the polynomials $Q_i(x)$, $i = 0, \ldots, L$, are orthogonal with respect to the symmetric bilinear form $\langle b(x), c(x)\rangle = \mathbf{b}^T H_n \mathbf{c}$, $b(x) = (1, x, \ldots, x^{n-1})\mathbf{b}$, $c(x) = (1, x, \ldots, x^{n-1})\mathbf{c}$ on the linear space of polynomials of degree less than n. This is the basic relationship between Hankel matrices and systems of orthogonal polynomials generated by three-term recurrence relations.

It is interesting to point out that the block triangular factorization of Proposition 3.1 is not generally unique.

Applying Proposition 3.1 to the matrix $H_n = H(u, v)$ it is possible to characterize the vectors $\mathbf{q}_i$ and, consequently, the polynomials $Q_i(x)$. We have, in fact, the following result.

PROPOSITION 3.2. *Let $u(x)$ and $v(x)$ be monic polynomials of degrees n and m, respectively, such that $n > m$, $\gcd(u(x), v(x)) = 1$. Then for the monic polynomials $Q_L(x)$, $Q_{L-1}(x)$ defined in Proposition* 3.1 *for $H = H(u, v)$, we have*

$$Q_L(x) = u(x), \qquad Q_{L-1}(x) = k^*(x),$$

where $k^*(x)$ is the monic polynomial associated with $k(x)$ (i.e., $k^*(x) = ck(x)$ for a nonzero constant c), and $k(x)v(x) = 1 \bmod u(x)$. Hence, the polynomials $Q_i(x)$, $i = 0, 1, \ldots, L$ are the monic polynomials associated with the polynomials obtained by applying the Euclidean scheme to $u(x)$ and $k(x)$.

Proof. For Proposition 2.2 we have

$$H(u, v)\mathbf{k} = \mathbf{e}^{(n-1)}, \quad \mathbf{k} = (k_0, \ldots, k_{n-1})^T, \quad k_i = 0, \ i > \deg\ k(x).$$

In particular, since

$$H_i(u, v)(k_0, \ldots, k_{i-1})^T = \mathbf{0}, \ i \geq 1 + \deg\ k(x) \tag{8}$$

(this condition does not apply if $\deg\ k(x) = n - 1$), we have

$$\det H_i = 0, \quad i = 1 + \deg\ k(x), \ldots, n - 1, \quad \det H_i \neq 0, \quad i = \deg\ k(x)$$

(for the uniqueness of $k(x)$), hence $\deg\ k(x) = m_{L-1}$; moreover,

$$H_{m_{L-1}}(k_0, \ldots, k_{m_{L-1}-1})^T = -k_{m_{L-1}}(h_{m_{L-1}}, \ldots, h_{2m_{L-1}-1})^T. \tag{9}$$

From parts (1) and (3) of Proposition 3.1 it follows that $Q_{L-1} = k^*(x)$. Now, let

$$\tilde{u}(x) = (x - \alpha)u(x), \qquad \tilde{v}(x) = (x - \alpha)v(x), \quad \alpha \in \mathbf{F}.$$

For Lemma 2.1 the vector $\mathbf{u} = (u_0, u_1, \ldots u_{n-1}, 1)^T$ generates the kernel of the matrix $H(\tilde{u}, \tilde{v})$. Thus, from $H(\tilde{u}, \tilde{v})\mathbf{u} = \mathbf{0}$ we obtain that

$$H(u, v)(u_0, \ldots, u_{n-1})^T = -(h_{n+1}, \ldots, h_{2n})^T,$$

that is, $u(x) = Q_L(x)$. □

The above results can be restated in the following way: Given two monic and relatively prime polynomials $u(x)$ and $v(x)$, the coefficients of the polynomials generated by the Euclidean scheme applied to $u(x)$ and $v(x)$ are given by suitable rows of the matrix $\tilde{L}^{-1}$, where $H(u, k) = \tilde{L}\tilde{D}\tilde{L}^T$ is a block triangular factorization of $H(u, k)$ and the polynomial $k(x)$ solves the congruence $v(x)k(x) = 1 \bmod u(x)$. It is easy to show that if $H(u, v) = LDL^T$ is a block triangular factorization of $H(u, v)$, then

$$H(u, k) = \tilde{L}\tilde{D}\tilde{L}^T, \quad \text{where } \tilde{L}^{-1} = JL^TB(u, 1), \quad \tilde{D}^{-1} = JDJ$$

is a block triangular factorization of $H(u, k)$. Therefore, the computation of the coefficients of all the polynomials generated in the Euclidean scheme, applied to the polynomials $u(x)$ and $v(x)$, is reduced to computing the block triangular factorization $H(u, v) = LDL^T$ and to

matrix-vector products with a lower triangular Hankel matrix. This way, unlike [3], we avoid the computation of the polynomial $k(x)$ and the inversion of the matrix L. Moreover, since

$$JB(u, v)J = JB(u, 1)H(u, v)B(u, 1)J, \tag{10}$$

the block triangular factorization of $H(u, v)$ can be obtained from the block triangular factorization of $JB(u, v)J = \hat{L}\hat{D}\hat{L}^T$. Indeed, we may choose $\tilde{L}^{-1} = J\hat{L}^T J$ (recall that the block LU factorization is not unique), therefore suitable columns of $\hat{L}$ give the coefficients of the polynomials generated by the Euclidean scheme.

Observe that the entries of $H(u, v)$ may grow exponentially with n, whereas the entries of $JB(u, v)J$ are bounded by $2n\mu\nu$, where μ and ν are upper bounds to the moduli of the coefficients of $u(x)$ and $v(x)$, respectively. Moreover, if $u(x)$ and $v(x)$ have integer coefficients then $JB(u, v)J$ has integer entries. This makes computing the block triangular factorization of $JB(u, v)J$ more convenient than computing the block triangular factorization of $H(u, v)$, and leads to an algorithm having a lower Boolean cost (see [5] and [13]).

The results proved so far imply the reduction of the Euclidean scheme computation to computing the block LDL^T factorization of $JB(u, v)J$. In order to devise efficient parallel algorithms for the computation of this factorization we will investigate suitable properties of the Schur complements of the nonsingular leading principal submatrices of $JB(u, v)J$.

Given the matrix

$$\begin{pmatrix} M & P \\ Q & R \end{pmatrix},$$

where M and R are square matrices and M is nonsingular, the Schur complement of M in A is the matrix $S = R - QM^{-1}P$. It is well known that if A is nonsingular then S is nonsingular and S^{-1} is the right lower corner submatrix of A^{-1}.

Now denote $(H(u, v))_i$, $(JB(u, v)J)_i$ the $i \times i$ leading principal submatrix of $H(u, v)$ and $JB(u, v)J$, respectively, and observe that in the hypotesis of Proposition 3.2, from Remark 2.2 we have

$$\det(H(u, v))_i = 0, \quad i = 1, \ldots, n - m - 1, \quad \det(H(u, v))_{n-m} \neq 0.$$

Therefore from (10) it follows that

$$\det(JB(u, v)J)_i = 0, \quad i = 1, \ldots, n - m - 1, \quad \det(JB(u, v)J)_{n-m} \neq 0. \tag{11}$$

We recall the following result of [22] concerning the generating function of the Schur complements.

LEMMA 3.1. *If Q is an $n \times n$ matrix having generating function*

$$\frac{a(z)b(w) - b(z)a(w)}{z - w}$$

and $\det Q_i = 0$, $i = 1, \ldots, t - 1$, $\det Q_t \neq 0$, *then the Schur complement of Q_t in Q has generating function*

$$\frac{a_t(z)b_t(w) - b_t(z)a_t(w)}{z - w},$$

where $a_t(z) = z^{-t}a(z)$ and $b_t(z)$ is defined by the recurrence

$$b_0(z) = b(z),$$
$$zb_{j+1}(z) = b_j(z) - a_t(z)\frac{b_j(0)}{a_t(0)}.$$

Applying Lemma 3.1 we prove the following basic result relating the Schur complement of the first nonsingular leading principal submatrix of $JB(u, v)J$ to the remainder $s(x)$ of the division of $u(x)$ and $v(x)$.

PROPOSITION 3.3. *Let S be the Schur complement of $(JB(u, v)J)_{n-m}$ in $JB(u, v)J$, then we have*

$$S = JB(v, s)J,$$

where $u(x) = q(x)v(x) - s(x)$, deg $s(x) < m$.

Proof. The generating function of $JB(u, v)J$ is easily verified to be

$$\frac{-\tilde{u}(z)\tilde{v}(w)w^{n-m} + \tilde{u}(w)\tilde{v}(z)z^{n-m}}{z - w},$$

where $\tilde{u}(z) = z^n u(z^{-1})$ and $\tilde{v}(z) = z^m v(z^{-1})$ are the reversed polynomials of $u(z)$, $v(z)$, respectively. Therefore, for Lemma 3.1, the generating function of the Schur complement S is given by

$$\frac{v_{n-m}(z)u_{n-m}(w) - u_{n-m}(z)v_{n-m}(w)}{z - w},$$

where $v_{n-m}(z) = \tilde{v}(z)$, and

$$\begin{aligned} &u_0(z) = \tilde{u}(z), \\ &zu_{j+1}(z) = u_j(z) - \tilde{v}(z)\tfrac{u_j(0)}{\tilde{v}(0)}, \quad j = 0, \ldots, n - m - 1. \end{aligned} \tag{12}$$

Now observe that the polynomials $u_j(z)$ in (12) have degrees $n - j$, $j = 0, \ldots, n - m$, and that $z^{n-j}u_j(z^{-1})$ are the polynomials obtained at the stage j of the synthetic polynomial division algorithm applied to $u(x)$ and $v(x)$, so that

$$u_{n-m+1}(z) = -\tilde{s}(z)z^{m-\deg s-1}, \quad u(z) = q(z)v(z) - s(z), \quad \deg s(z) < m.$$

Therefore

$$u_{n-m}(z) = z^{m-\deg s}\tilde{s}(z) + \beta\tilde{v}(z), \quad \beta = \frac{\tilde{u}_{n-m}(0)}{\tilde{v}(0)}.$$

Hence, the generating function of S is

$$\frac{-\tilde{v}(z)\tilde{s}(w)w^{m-\deg s} + \tilde{v}(w)\tilde{s}(z)z^{m-\deg s}}{z - w}$$

so that $S = JB(v, s)J$. □

Now consider the Schur complement S_k and S_{h+k} of A_k, A_{h+k}, respectively, in A, where A, A_k, A_{h+k}, are nonsingular matrices and A_k, A_{h+k} are the leading principal submatrices of A of dimension $k \times k$, $(h + k) \times (h + k)$, respectively. Since S_k^{-1} and S_{h+k}^{-1} are the right lower corner submatrices of A^{-1} of sizes $k \times k$ and $(h + k) \times (h + k)$, respectively, we have that S_{h+k} is the Schur complement of $(S_k)_h$ in S_k. Therefore we may inductively apply (11) and Proposition 3.3, obtaining the following proposition.

PROPOSITION 3.4. *Let $u(x)$ and $v(x)$ be monic polynomials of degrees n and m, respectively, such that $n > m$, $\gcd(u(x), v(x)) = 1$. Let $m_1 < \cdots < m_L = n$ be integers such that*

$$\det H_{m_i} \neq 0, \quad i = 1, \ldots, L, \quad \det H_j = 0, \quad j \neq m_i,$$

where the semi-infinite Hankel matrix H is generated by the power series (5). *Then*

$$\det(JB(u,v)J)_{m_i} \neq 0, \quad i = 1,\dots,L, \quad \det(JB(u,v)J)_j = 0, \quad j \neq m_i.$$

Morover, for the Schur complement S_{m_i} of $(JB(u,v)J)_{m_i}$ in $JB(u,v)J$ the following relation holds:

$$S_{m_i} = JB(r_i, r_{i+1})J,$$

where $r_i(x)$, $i = 1,\dots,L$ is the remainder sequence obtained by applying the Euclidean scheme to $u(x)$ and $v(x)$.

Remark 3.1. From the above result it follows that the nonsingular leading principal submatrices of $JB(u,v)J$ have sizes $m_i = n - \deg\ r_i(x)$.

Let $l_i = n - m_i + 1 = \deg\ r_i(x) + 1$ and $P_{m_i} = (JB(u,v)J)_{m_i}$ for $i = 1,\dots,L$. The following result relates the matrices P_{m_i}, $i = 1,\dots,L$ to the polynomials defining the Padé approximants of the power series (5).

PROPOSITION 3.5. *In the hypothesis of Proposition* 3.4, *we have*

$$P_{m_i} = T(u_n,\dots,u_{l_i})T(u^{(i)}_{m_i},\dots,u^{(i)}_1)^{-1}JB(u^{(i)},v^{(i)})JT(u^{(i)}_{m_i},\dots,u^{(i)}_1)^{-T}T(u_n,\dots,u_{l_i})^T,$$

where the polynomials $u^{(i)}(x)$, $v^{(i)}(x)$ are such that

$$H(u^{(i)},v^{(i)}) = (H(u,v))_{m_i}, \quad u^{(i)}(x) = \sum_{r=0}^{m_i} u^{(i)}_r x^r, \quad v^{(i)}(x) = \sum_{r=0}^{m_i-1} v^{(i)}_r x^r.$$

Proof. The proposition follows from the relation

$$P_{m_i} = (JB(u,v)J)_{m_i} = T(u_n\dots,u_{l_i})(H(u,v))_{m_i}T(u_n\dots,u_{l_i})^T$$

in the view of Proposition 2.2 and (10). □

Propositions 3.4 and 3.5 lead to the following block factorization of $JB(u,v)J$:

$$JB(u,v)J = \begin{pmatrix} P_{m_i} & X^T \\ X & W \end{pmatrix} = \begin{pmatrix} I & O \\ XP_{m_i}^{-1} & I \end{pmatrix}\begin{pmatrix} P_{m_i} & O \\ O & S_{m_i} \end{pmatrix}\begin{pmatrix} I & P_{m_i}^{-1}X^T \\ O & I \end{pmatrix}$$

$$= \begin{pmatrix} T & O \\ XP_{m_i}^{-1}T & I \end{pmatrix}\begin{pmatrix} JB(u^{(i)},v^{(i)})J & O \\ O & JB(r_i,r_{i+1})J \end{pmatrix}\begin{pmatrix} T^T & T^TP_{m_i}^{-1}X^T \\ O & I \end{pmatrix}, \tag{13}$$

where

$$S_{m_i} = W - XP_{m_i}^{-1}X^T = JB(r_i,r_{i+1})J, \quad T = T(u_n,\dots,u_{l_i})(B(u^{(i)},1))^{-1}J.$$

Proposition 3.4 and Remark 2.1 allow us to express the coefficient vector $\mathbf{r}_{i+1}$ of the $(i+1)$st remainder $r_{i+1}(x)$ as

$$\mathbf{r}_{i+1} = J(W - XP_{m_i}^{-1}X^T)J\mathbf{e}^{(n-m_i)},$$

that is, $\mathbf{r}_{i+1}$ can be computed by solving an $m_i \times m_i$ system with matrix P_{m_i}. Observe that P_{m_i} is the sum of products of pairs of triangular Hankel and Toeplitz matrices. Matrices having this structure are called Hankel-like matrices and have very strong computational properties [4], [5], [20].

In the case where the polynomials $u(x)$ and $v(x)$ have integer coefficients, the solution of the above Hankel-like system can be performed over the integers by multiplying both members by $\det P_{m_i}$. This way the polynomial $\det P_{m_i} r_{i+1}(x)$ has integer coefficients having moduli $O((2n\mu\nu)^{m_i})$. In the next section we will recursively apply (13) in order to compute the polynomials $r_i(x)$ with a low parallel cost

The assumption $\gcd(u(x), v(x)) = 1$ is no loss of generality. Indeed, it is easy to see that if $\gcd(u(x), v(x)) = r_L(x)$ the Euclidean remainder sequences $\{r_i(x)\}$ and $\{q_i(x)\}$ can be recovered by the polynomial sequences $\{\bar{r}_i(x)\}$ and $\{\bar{q}_i(x)\}$ generated by the Euclidean scheme applied to $u(x)/r_L(x)$ and $v(x)/r_L(x)$.

Let us conclude this section by analyzing the matrix formulation of computing gcd. The algorithm for the gcd computation given in [3] relies on the following characterization of gcd stated in terms of the Hankel matrix $H(u, v)$. Here we propose a different proof that does not make use of the zeros of the polynomials $u(x)$ and $v(x)$ as it is done in [3]; this allows us to extend the computation over any field of constants.

PROPOSITION 3.6. *Let $u(x)$, $v(x)$ be two monic polynomials of degrees n, m, respectively, $m < n$; $r(x) = \gcd(u(x), v(x))$ be a monic polynomial of degree $n - k$, and H_i be the $i \times i$ leading principal submatrix of $H(u, v)$. Then we have*

(a) $\operatorname{rank}(H(u, v)) = k$, $\det H_k \neq 0$, $\det H_i = 0$ *for* $i > k$,

(b) *if* $H_{k+1}\mathbf{w} = \mathbf{0}$, $\mathbf{w} = (w_i)_{i=0,\ldots,k}$, $w_k = 1$, *that is, if*

$$H_k \begin{pmatrix} w_0 \\ \vdots \\ w_{k-1} \end{pmatrix} = - \begin{pmatrix} h_k \\ \vdots \\ h_{2k-1} \end{pmatrix},$$

then

$$u(x) = r(x) \sum_{i=0}^{k} w_i x^i.$$

Proof. Assume that $u(x) = w(x)r(x)$ and $v(x) = t(x)r(x)$, so that $w(x)$ and $t(x)$ are relatively prime. From (7), we obtain that

$$H(u, v)\mathbf{z} = \mathbf{0} \quad \Longleftrightarrow \quad v(F_u^T)\mathbf{z} = \mathbf{0}.$$

So, the problem is reduced to analyzing the null space of $v(F_u^T)$. Now, by the virtue of Lemma 2.1, $v(F_u^T)\mathbf{z} = \mathbf{0}$ holds if and only if the polynomial $z(x) = \sum_{i=0}^{n-1} z_i x^i$ is such that $z(x) = p(x)w(x)$ for some polynomial $p(x)$. Since $\{z(x) : \quad z(x) = p(x)w(x), \deg p(x) \leq n-k-1\}$ is a linear space of dimension $n-k$, we have that rank $H(u, v) =$ rank $v(F^T) = k$. Moreover, by choosing $p(x) = x^j$, $j = 0, \ldots, n-k-1$, we satisfy the relations (a) and (b). □

From Lemma 2.1 and (10) it follows that Proposition 3.6 can be rewritten in terms of the Bézout matrix $B(u, v)$.

COROLLARY 3.1. *In the hypothesis of Proposition* 3.6 *we have*

(a) $\operatorname{rank}(B(u, v)) = k$, $\det(JB(u, v)J)_k \neq 0$, *and* $\det(JB(u, v)J)_i = 0$, $i > k$,

(b) *if* $(JB(u, v)J)_{k+1}\mathbf{y} = \mathbf{0}$, $\mathbf{y} = (y_0, \ldots, y_k)^T$, $y_k = 1$ *then*

$$u(x) = r(x) \sum_{i=0}^{k} w_i x^i,$$

where $\mathbf{w} = (B(u, 1)J)_{k+1}\mathbf{y}$, $\mathbf{w} = (w_0, \ldots, w_k)^T$, *and* $(JB(u, v)J)_i$ *denotes the* $i \times i$ *leading principal submatrix of* $JB(u, v)J$.

In the next section we will devise an algorithm for computing $\gcd(u(x), v(x))$ based on the above corollary.

4. The algorithms and their cost analysis. By using the results of §3 we devise new algorithms for the computation of polynomial gcd and of the coefficients of the polynomials generated in the Euclidean scheme.

We make use of the following computational results some of which have been recently proved in [4], [5], [6], [20]. In order to express the computational cost we use the functions $p_{\mathbf{F}}(n)$ and $q_{\mathbf{F}}(n)$, defined by $p_{\mathbf{F}}(n) = 1$ if the field $\mathbf{F}$ supports FFT, $p_{\mathbf{F}}(n) = \log\log n$ otherwise, $q_{\mathbf{F}}(n) = 1$ if $\mathbf{F}$ allows division by $n!$, $q_{\mathbf{F}}(n) = n$ otherwise.

Let $L_i, U_i^T, i = 1, \ldots, h$, be lower triangular Toeplitz matrices with entries in the field $\mathbf{F}$, where h is a constant independent of n. Consider the Hankel-like matrix $A = \sum_{i=1}^{h} JL_iU_i$. The matrix A is determined by its *displacement generator* made up by the set of vectors which are the first columns of the matrices L_i and U_i^T.

PROPOSITION 4.1. *For the Hankel-like matrix A the following computational results hold:*

- *The computation of* $r = \operatorname{rank}(A)$ *can be performed in* $O(\log^2 n)$ *parallel steps with* $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ *processors assuming the nonsingularity of the* $r \times r$ *leading principal submatrix of A.*
- *If A is nonsingular the solution of the linear system* $A\mathbf{x} = \mathbf{b}$ *can be performed in* $O(\log^2 n)$ *parallel steps with* $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ *processors. Moreover,* A^{-1} *is still a Hankel-like matrix and its displacement generator can be computed in* $O(\log^2 n)$ *parallel steps with* $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ *processors.*
- *The computation of the matrix-vector product* $A\mathbf{x}$ *can be performed in* $O(\log n)$ *parallel steps with* $np_{\mathbf{F}}(n)$ *processors.*
- *The product of Hankel-like matrices is still a Hankel-like matrix, its displacement generator can be computed in* $O(\log n)$ *parallel steps with* $np_{\mathbf{F}}(n)$ *processors.*
- *The computation of the quotient and remainder of the division of two polynomials of degree at most n can be performed in* $O(\log n \log\log n)$ *parallel steps with* $np_{\mathbf{F}}(n)$ *processors.*

Let us describe the algorithm for the computation of $\gcd(u(x), v(x))$. Without loss of generality we assume that $m < n$. If $m = n$ then we consider the polynomials $u(x)$ and $\hat{v}(x) = v(x) \bmod u(x)$.

ALGORITHM 4.1. *Computing* gcd.

Input: natural numbers m and n, $m < n$, and the coefficients $u_0, \ldots, u_n$, $v_0, \ldots, v_m$ of two polynomials $u(x) = \sum_{i=0}^{n} u_i x^i$, $v(x) = \sum_{i=0}^{m} v_i x^i$.

Output: The coefficients of $\gcd(u(x), v(x)) = r(x)$.

Computation:

1. Compute rank $B(u, v) = k$. Set $l = n - k + 1$.
2. Solve the $k \times k$ system $C\mathbf{y} = \mathbf{b}$, $\mathbf{y} = (y_{k-1}, \ldots, y_0)^T$, where $C = (JB(u, v)J)_k$ and

$$\mathbf{b} = T(u_n, \ldots, u_l)(v_l, \ldots, v_{n-2k})^T - T(v_n, \ldots, v_l)(u_l, \ldots, u_{n-2k})^T.$$

3. Compute $\mathbf{w} = (B(u, 1)J)_{k+1}(y_0, \ldots, y_k)^T$, $y_k = 1$.
4. Compute $r(x)$ such that $u(x) = r(x)w(x)$.

Corollary 3.1 implies the correctness of the algorithm. Moreover, observe that the matrix $JB(u, v)J$ satisfies the condition of Proposition 4.1. Therefore all the computation can be performed in $O(\log^2 n)$ parallel steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors.

In the view of Proposition 3.6 the above algorithm could be rewritten by replacing the matrix $JB(u, v)J$ with the Hankel matrix $H(u, v)$, the matrix C and the vector $\mathbf{b}$ at stage 2, with the matrix $(H(u, v))_k$ and the vector $(h_k, \ldots, h_{2k-1})^T$, respectively, obtaining the algorithm of [3]. However the entries of $H(u, v)$ may grow exponentially with n whereas the entries of $B(u, v)$ have moduli bounded by $\phi = 2n\mu\nu$, where $|u_i| \le \mu$, $|v_i| \le \nu$. Moreover,

if u and v have integer coefficients, then the matrix $B(u, v)$ has integer coefficients and all the computation can be kept within the integers.

It is possible to prove (see [5] and [13]) that if $u(x)$ and $v(x)$ have integer coefficients represented with d binary digits (bits), then the computation of Algorithm 4.1 can be performed with at most $O(n(d + \log n))$ bits. Moreover, if $u(x)$ and $v(x)$ have rational coefficients represented as pairs of d-digit integers, then $O(n^2(d + \log n)$ bits are sufficient to compute $\gcd(u, v)$ by using integer arithmetic.

ALGORITHM 4.2. *Computing the coefficients of the polynomials generated by the Euclidean scheme applied to $u(x)$ and $v(x)$ by means of the block triangular factorization of $JB(u, v)J$.*

Input: natural numbers m and n, and the coefficients $u_0, \ldots, u_n$, $v_0, \ldots, v_m$ of two polynomials $u(x) = \sum_{i=0}^{n} u_i x^i$, $v(x) = \sum_{i=0}^{m} v_i x^i$.

Output: The coefficients of the polynomials generated by the Euclidean scheme applied to $u(x)$ and $v(x)$.

Computation:

1. Compute $r(x) = \gcd(u(x), v(x))$ and replace $u(x)$, $v(x)$, n and m with $u(x)/r(x)$, $v(x)/r(x)$, $n - \deg r(x)$ and $m - \deg r(x)$, respectively.
2. If $n - m > n/2$ set $k = n - m$, otherwise compute rank $(JB(u, v)J)_{\lceil n/2 \rceil}$ and set $k = \text{rank } (JB(u, v)J)_{\lceil n/2 \rceil}$.
3. Let i be such that $k = m_i$ and factorize $JB(u, v)J$ as in (13). Compute

$$P_{m_i}^{-1}, \quad XP_{m_i}^{-1}, \quad S_{m_i} = W - XP_{m_i}^{-1}X^T$$

   and the coefficients of $r_i(x)$, $r_{i+1}(x)$, by using Proposition 3.4 and Remark 2.1.
4. Compute the coefficients of $u^{(i)}(x)$, $v^{(i)}(x)$ such that

$$H(u^{(i)}, v^{(i)}) = (H(u, v))_{m_i},$$

   that is, apply Proposition 2.1 to the matrix $(H(u, v))_{m_i}$, which is nonsingular for (10) and Remark 3.1.
5. Recursively apply Algorithm 4.2 to $JB(u^{(i)}, v^{(i)})J$, $JB(r_i, r_{i+1})J$, obtaining

$$JB(u^{(i)}, v^{(i)})J = L'D'L'^T, \qquad JB(r_i, r_{i+1})J = L''D''L''^T.$$

6. Set

$$L = \begin{pmatrix} I & O \\ XP_{m_i}^{-1} & I \end{pmatrix} \begin{pmatrix} T & O \\ O & I \end{pmatrix} \begin{pmatrix} L' & O \\ O & L'' \end{pmatrix}$$

   and obtain the coefficients of all the $r_i(x)$'s.
7. Recover the coefficients of the polynomial generated by the Euclidean scheme applied to $u(x)$ and $v(x)$, from the coefficients of the polynomial generated by the Euclidean scheme applied to $u(x)/r(x)$ and $v(x)/r(x)$.

The correctness of the algorithm follows from (13). Observe that stage 1 can be performed by Algorithm 4.1. Stage 2, which consists in the rank computation of a Hankel-like matrix, can be performed in $O(\log^2 n)$ steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors. Concerning the computation at stage 3 we observe that, since P_{m_i}, $P_{m_i}^{-1}$, $XP_{m_i}^{-1}$ and S_{m_i} are Hankel-like matrices, it is sufficient to compute only their displacement generators for the cost of $O(\log^2 n)$ steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors. Stage 4 is reduced to solving a Hankel system for the cost of $O(\log^2 n)$ steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors. At stage 6, $O(\log n)$ steps

with $n^2/\log n$ processors are sufficient to compute the triangular factor L; the same complexity bound applies to stage 7.

Therefore each recursive step of the algorithm can be performed in $O(\log^2 n)$ parallel steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors.

It is easy to check that $O(\log n)$ recursive steps are sufficient for the algorithm. In fact, from Remark 3.1 deg $r_i(x) = n - m_i$, and since deg $r_{i+1}(x) < n/2$ (i.e., $m_{i+1} > n/2$), then

$$\deg\ r_i(x) - \deg\ r_{i+1}(x) = m_{i+1} - m_i > n/2 - m_i.$$

Hence, by applying another recursive step to $JB(r_i, r_{i+1})J$ we obtain two diagonal blocks: the first of size $n/2 - m_i$ already factorized, the second of size $n/2$ (for simplicity we assume n even). Hence, the overall cost of Algorithm 4.2 is $O(\log^3 n)$ parallel steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors.

With the same cost it is possible to compute also all the polynomials generated by the extended Extended Euclidean Scheme (EES) by solving at most n linear systems defined by the same Toeplitz-like matrix. In fact the polynomials $s_i(x)$ and $t_i(x)$ generated by EES,

$$\begin{array}{llll} s_0(x) = 1, & s_1(x) = 0, & s_i(x) = & s_{i-2}(x) - q_i(x)s_{i-1}(x), \\ t_0(x) = 0, & t_1(x) = 1, & t_i(x) = & t_{i-2}(x) - q_i(x)t_{i-1}(x), \end{array} \quad i = 2, \ldots, L,$$

satisfy the equation

$$s_i(x)u(x) + t_i(x)v(x) = r_i(x), \quad i = 1, 2, \ldots, L. \tag{14}$$

Rewriting (14) in matrix form we obtain

$$R\begin{pmatrix} \mathbf{s}_i \\ \mathbf{t}_i \end{pmatrix} = \mathbf{r}_i, \qquad i = 1, 2, \ldots, L,$$

where $\mathbf{s}_i, \mathbf{t}_i, \mathbf{r}_i$ are the vectors associated with the polynomials $s_i(x)$, $t_i(x)$, and $r_i(x)$, respectively, filled with zeros up to the dimension m, n, $m+n$, respectively, and R is the $(m+n) \times (m+n)$ resultant (Sylvester) matrix of $u(x)$ and $v(x)$, that is, $R = [T_1|T_2]$, where T_1 and T_2 are Toeplitz matrices of sizes $(m+n) \times m$ and $(m+n) \times n$, respectively, with the first rows $(u_n, 0, \ldots, 0)$ and $(v_m, 0, \ldots, 0)$ and the first columns $(u_n, u_{n-1}, \ldots, u_0, 0, \ldots, 0)^T$ and $(v_m, v_{m-1}, \ldots, v_0, \ldots, 0)^T$, respectively.

We may assume without loss of generality $\gcd(u(x), v(x)) = 1$, otherwise we apply Algorithm 4.1. Therefore R is nonsingular and

$$\begin{pmatrix} \mathbf{s_i} \\ \mathbf{t_i} \end{pmatrix} = R^{-1}\mathbf{r_i}, \qquad i = 1, \ldots, L.$$

The matrix R is Toeplitz-like and the following relation holds [5]:

$$R^{-1} = L_1U_1 + L_2U_2,$$

where L_1, U_1, L_2, and U_2 are suitable triangular Toeplitz matrices. Then the computation of the vectors $\mathbf{s}_i, \mathbf{t}_i$, $i = 1, \ldots, L$ can be performed in two stages:

1. compute the matrices L_1, U_1, L_2, U_2,
2. compute $(L_1U_1 + L_2U_2)\mathbf{r}_i$, $i = 1, \ldots, L$.

Stage 1 can be performed for a cost of $O(\log^2 n)$ steps with $n^2 p_{\mathbf{F}}(n) q_{\mathbf{F}}(n)/\log n$ processors [5]. Stage 2 consists in computing L simultaneous matrix-vector products with a Toeplitz-like matrix, so that the overall cost of the EES is dominated by the cost of computing the polynomials $r_i(x)$.

A GRAPH-THEORETIC GAME AND ITS APPLICATION TO THE k-SERVER PROBLEM*

NOGA ALON†, RICHARD M. KARP‡, DAVID PELEG§, AND DOUGLAS WEST¶

Abstract. This paper investigates a zero-sum game played on a weighted connected graph G between two players, the *tree player* and the *edge player*. At each play, the tree player chooses a spanning tree T and the edge player chooses an edge e. The payoff to the edge player is $cost(T, e)$, defined as follows: If e lies in the tree T then $cost(T, e) = 0$; if e does not lie in the tree then $cost(T, e) = cycle(T, e)/w(e)$, where $w(e)$ is the weight of edge e and $cycle(T, e)$ is the weight of the unique cycle formed when edge e is added to the tree T. The main result is that the value of the game on any n-vertex graph is bounded above by $\exp(O(\sqrt{\log n \log\log n}))$. It is conjectured that the value of the game is $O(\log n)$.

The game arises in connection with the k-server problem on a *road network*; i.e., a metric space that can be represented as a multigraph G in which each edge e represents a road of length $w(e)$. It is shown that, if the value of the game on G is $Val(G, w)$, then there is a randomized strategy that achieves a competitive ratio of $k(1 + Val(G, w))$ against any oblivious adversary. Thus, on any n-vertex road network, there is a randomized algorithm for the k-server problem that is $k \cdot \exp(O(\sqrt{\log n \log\log n}))$ competitive against oblivious adversaries.

At the heart of the analysis of the game is an algorithm that provides an approximate solution for the *simple network design problem*. Specifically, for any n-vertex weighted, connected multigraph, the algorithm constructs a spanning tree T such that the average, over all edges e, of $cost(T, e)$ is less than or equal to $\exp(O(\sqrt{\log n \log\log n}))$. This result has potential application to the design of communication networks. It also improves substantially known estimates concerning the existence of a sparse basis for the cycle space of a graph.

1. Introduction.

Let G be a connected multigraph, and let w be a function from the edge set of G into the positive reals; $w(e)$ is called the *weight* of edge e. Consider a two-person zero-sum game between a *tree player* and an *edge player*. At each play the tree player chooses a spanning tree T and, simultaneously, the edge player chooses an edge e. The payoff $cost(T, e)$ is defined as follows. For an edge e that does not lie in the tree T, let $cycle(T, e)$ denote the weight of the unique cycle formed when edge e is added to the tree T. Then

$$cost(T, e) = \begin{cases} 0 & \text{if } e \text{ lies in the tree } T, \\ cycle(T, e)/w(e) & \text{otherwise.} \end{cases}$$

Our main interest is in determining the value of this game for particular weighted multigraphs, and in determining an upper bound on the value in terms of the number of vertices.

We introduce some standard terminology. A mixed strategy for the tree player is a probability distribution p over the spanning trees of G, assigning to each spanning tree T a probability $p(T)$; similarly, a mixed strategy for the edge player is a probability distribution q over the edges, assigning to each edge a probability $q(e)$. The min-max theorem of game theory tells us that

$$\min_p \max_q \sum_T \sum_e p(T)q(e)cost(T, e) = \max_q \min_p \sum_T \sum_e p(T)q(e)cost(T, e).$$

The common value of these two expressions is called the *value* of the game, and is denoted $Val(G, w)$. In the special *unweighted case* in which $w(e) = 1$ for all e, the value is denoted $Val(G)$.

Our main results with respect to the game are as follows:

- For every weighted n-vertex multigraph G, w,

$$Val(G, w) \leq \exp(O(\sqrt{\log n \log\log n})).$$

- There is an infinite sequence $\{G_n\}_{n\geq 1}$ of graphs such that G_n has n vertices and $Val(G_n) = \Omega(\log n)$.

We also provide a near-tight analysis of the game on several simple classes of graph topologies, including cycles, cycles with cross edges, grids and hypercubes.

At the heart of our analysis of the game on arbitrary multigraphs is an algorithm that provides an approximate solution for the *simple network design problem* of [JLR]. Specifically, for any n-vertex weighted, connected multigraph, our algorithm constructs a spanning tree T such that the average, over all edges e, of $cost(T, e)$ is less than or equal to $\exp(O(\sqrt{\log n \log\log n}))$. This algorithm provides us with a strategy for the tree player in the game. As a byproduct, our algorithm improves the main result of [SV] that deals with the choice of a sparse basis for the cycle space of a given graph. The authors of [SV] show that for every n-vertex graph there is a spanning tree so that the average length of a fundamental cycle is $O(\sqrt{n})$, whereas our result improves this estimate to $\exp(O(\sqrt{\log n \log\log n}))$.

A somewhat more general network design problem is the *optimum communication spanning tree problem* studied by Hu [Hu]. This problem extends the simple network design problem by introducing a *communication requirement matrix* on the vertices, and charging for each pair of vertices a cost proportional to their distance in the chosen spanning tree times their communication requirement. It can be shown that this seemingly more general problem is in fact reducible to the simple network design problem on multigraphs, so that any (approximate) solution for the latter problem can be translated into a solution for the former (with the same approximation ratio).

The game arises in connection with the k-server problem on a *road network*; i.e., a metric space that can be represented as a multigraph G in which each edge e represents a road of length $w(e)$. The class of these metric spaces seems to be one of the most natural ones for considering the k-server problem, as any real configuration of roads forms such a network. Note that any nontrivial road network has infinitely many points; a continuous circle, for example, can be represented by a road network with two vertices and two parallel edges joining them.

We show that if the value of the game on G is $Val(G, w)$, then there is a randomized strategy that achieves a competitive ratio of $k(1 + Val(G, w))$ against any oblivious adversary. Thus, on any n-vertex road network, there is a randomized algorithm for the k-server problem that is $k \cdot \exp(O(\sqrt{\log n \log\log n}))$ competitive against oblivious adversaries.

In addition, the spanning tree algorithm has potential application to the design of communication networks. Shortest-path trees are among the basic tools used in communication networks for various control tasks. Given a graph H, let $path(H, u, w)$ denote the weighted distance (i.e., the length of the shortest path) between u and w in H. A *shortest-path tree* for the graph H w.r.t. some vertex r is a tree T with the property that for every vertex v in H, its distance from r in T is the same as in H, i.e., $path(T, v, r) = path(H, v, r)$.

The obvious drawback of a shortest-path tree w.r.t. r is that while it yields optimal routes from r to any other node, the quality of the routes provided by the tree between other pairs of nodes may be poor. A natural measure for the quality of the path connecting nodes u, w in the tree T is its *stretch factor* (or dilation), defined as $path(T, u, w)/path(G, u, w)$. Classes of graphs for which there exist spanning trees with low worst-case stretch factor, termed *tree*

spanners, are studied in [Cai]. However, in general, looking for a tree with low worst-case stretch factor may be a hopeless task, since such a tree may not always exist. In particular, it is clear that there are graphs of diameter D for which any spanning tree incurs a worst-case stretch of $\Omega(D)$ for some pairs of nodes (the unit-weight cycle of two-D vertices is an example for such a graph). It may therefore be useful to look for trees that attempt to minimize the *average* stretch factor over all graph edges, or even over all pairs of vertices in the graph. This problem is referred to in [JLR] as the *simple network design problem*, and is shown therein to be NP hard. Our result provides a method for constructing such a tree, which in some cases may provide an attractive alternative to the standard shortest-path tree.

Let us comment that another viable alternative involves insisting on good bounds for the *worst-case* stretch, at the cost of allowing cycles in the spanning structure. It is known that for every graph there exist relatively sparse spanning subgraphs, termed *spanners*, guaranteeing this property [ADDJ], [PS], [PU]. However, the use of a *tree* as our spanning structure may sometimes be preferred due to its practical advantages, in terms of simplicity of the routing and control processes, lower total channel costs, and so on.

2. Basic examples. In this section we consider the game on several example graphs. The natural road networks that are not trees include cycles and grids. The solution of the game for the grid is difficult; asymptotics will appear in §6. Here we content ourselves with easier examples. A strategy for the edge player has value v if the minimum expected payoff for any tree against it is v, and a strategy for the tree player has value v if the maximum expected payoff against it for any edge is v; in other words, the value of a strategy is the payoff it ensures. The min-max theorem guarantees optimal strategies with the same value. Note that if the game has value v, then any choice given nonzero probability in the optimal strategy for one player must have expected payoff exactly v against the optimal strategy for the other player.

EXAMPLE 2.1. *The complete graph.* Let G be the unweighted n-vertex simple complete graph. If the edge player chooses uniformly among the edges, then selection of any tree will have probability $\frac{2}{n}$ of payoff 0 and probability $\frac{(n-2)}{n}$ of a positive payoff. The minimum positive payoff equals the length of the shortest cycle, which is 3. Therefore the expected payoff is at least $3 - \frac{6}{n}$. Equality holds only for the n-vertex stars, because other trees have fundamental cycles of lengths exceeding 3. If the tree player chooses uniformly among the n n-vertex stars, then any edge has probability $\frac{2}{n}$ of payoff 0 and probability $\frac{(n-2)}{n}$ of payoff 3, guaranteeing payoff at most $3 - \frac{6}{n}$. Hence uniform edge selection and uniform star selection are optimal strategies, and $Val(G) = 3 - \frac{6}{n}$. □

With arbitrary weights, the complete graph becomes rather complex. Therefore, let us consider simpler graphs and introduce weights.

EXAMPLE 2.2. *Cycles and multicycles.* If G is the n cycle, let T_i be the tree omitting edge i, and let w_i be the weight on edge i, with $W = \sum_i w_i$. If the tree player assigns probability $p_i = \frac{w_i}{W}$ to T_i, then every edge has expected payoff 1. If the edge player assigns probability $\frac{w_i}{W}$ to edge i, then every tree has expected payoff 1. Hence $Val(G, w) = 1$.

Now let G be the multigraph whose underlying simple graph is an n cycle, with G having n_i copies of edge i. Suppose that each copy of edge i has weight w_i, and let $W = \sum w_i$. Each tree consists of one copy of each of $n - 1$ edges. Let $\mathbf{T}_i$ denote the trees having no copy of edge i, and suppose these are chosen with equal probability totaling p_i. If $p_i = \frac{w_i}{W}$, as before, then the expected payoff for a copy of edge j is $1 + 2(1 - p_j)(1 - \frac{1}{n_j}) < 3$ (as in a multigraph, two parallel edges form a cycle of length 2). Hence $Val(G, w) < 3$. In fact, even for the unweighted case $Val(G)$ can be arbitrarily close to 3 when n and $\{n_i\}$ are appropriately chosen. In particular, if $w_i = 1$ and $n_i = m$ for all i, then when the edge player chooses edges uniformly the expected payoff of any tree is $1 + 2(1 - \frac{1}{n})(1 - \frac{1}{m})$, so $Val(G) \geq 3 - \frac{2}{n} - \frac{2}{m} + \frac{2}{nm}$. □

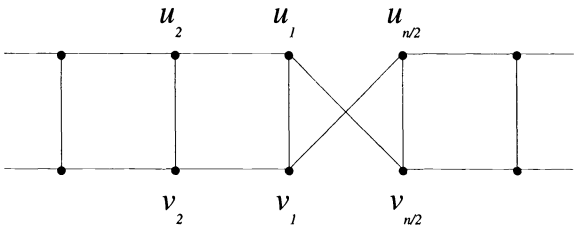

FIG. 1. *A portion of the twisted prism.*

In order to obtain higher values of the game for unweighted graphs, it is apparent that we need to have a substantial fraction of nontree edges, and that a large diameter will allow some of those edges to generate a large cost. (In any case, a small diameter leads to a small $Val(G)$.) The cycle meets the second criterion but fails the first, which suggests the following example.

EXAMPLE 2.3. *Cycles with diagonals.* Given n even, let G be the graph consisting of an n cycle C together with the chords joining antipodal points on the cycle. We prove $2-\frac{4}{3n} \le Val(G) \le 3-\frac{6}{n}$; we do not have an exact solution for this graph. The upper bound is achieved as follows. Let T be a tree consisting of a path of $\frac{n}{2}$ edges on C and the $\frac{n}{2}-1$ diagonals having one endpoint in the path. If the tree player plays the n rotations of T with equal probability, then the expected payoff of an edge of C is $0\cdot\frac{1}{2}+4\cdot(\frac{1}{2}-\frac{2}{n})+(\frac{n}{2}+1)\cdot(\frac{2}{n}) = 3-\frac{6}{n}$, and the expected payoff of a diagonal is $0\cdot(1-\frac{1}{n/2})+(n/2+1)\cdot\frac{1}{n/2} = 1+\frac{2}{n}$. This upper bound is not optimal, since in particular, the strategy of sticking to the edges of C (and choosing them uniformly) does not guarantee a payoff greater than 1 for the edge player.

The uniform edge strategy establishes the lower bound. A tree containing no diagonals has expected payoff $[n+(\frac{n}{2})(\frac{n}{2}+1)]\frac{2}{3n}$, which is quite large. (Indeed, such a tree is simply the cycle C except one of its edges. The cost of this edge with respect to the tree is n and the cost of each diagonal is $n/2+1$). For any other tree T, we claim there are at least two edges of C not in T that complete fundamental cycles of length at least $\frac{n}{2}+1$. Therefore, the expected cost of T is at least $[(\frac{n}{2}+1)2+4(\frac{n}{2}-1)]\frac{2}{3n} = 2-\frac{4}{3n}$ (since the cost of each nontree edge is clearly at least 4.) To prove the claim, view G as a Möbius band or twisted ladder (see Fig. 1); the cycle wraps around twice, and the diagonals become rungs of the ladder. Select a diagonal edge e in T. Label the vertices $u_1, \ldots, u_{n/2}$ counterclockwise from one end of e and $v_1, \ldots, v_{n/2}$ counterclockwise from the other end. Let F be the component of T containing e that is obtained from T by deleting either or both of $u_1v_{n/2}$ and $v_1u_{n/2}$ from T, if they are present. Let i [j] be the largest index such that $u_i \in F$ [$v_j \in F$]. Then $cost(T, u_iu_{i+1})$, $cost(T, v_jv_{j+1}) \ge \frac{n}{2}+1$, because the choice of i implies that the path in T between u_i and u_{i+1} must contain at least one of $\{u_k, v_k\}$ for each k in $\{i+1, \ldots, \frac{n}{2}, 1, \ldots, i\}$, and both of them for some k. This is similar for v_jv_{j+1}.

EXAMPLE 2.4. *Weighted cycle with diagonals.* Consider the graph G given in Example 2.3, but suppose the edges of C have weight 1 and the diagonals have weight $w > 1$. Assume that n is an even multiple of k. Let T_k be a tree obtained by taking $\frac{n}{2k}$ equally spaced diagonals, growing a path of length $\lceil\frac{k-1}{2}\rceil$ clockwise and $\lfloor\frac{k-1}{2}\rfloor$ counterclockwise from each endpoint of each diagonal taken, and adding cycle edges on one semicircle to connect these components. The cost of a nontree cycle edge is $2k+2w$, except for two edges with cost $\frac{n}{2}+w$. The total cost of a set of $k-1$ consecutive nontree diagonals is

$$2(k-1)+\frac{2}{w}\left[\binom{\lceil(k+1)/2\rceil}{2}+\binom{\lfloor(k+1)/2\rfloor}{2}\right] = 2(k-1)+\frac{1}{w}\lfloor\frac{k^2}{2}\rfloor.$$

If the rotations of T_k are selected with equal probability, then the expected cost of an edge of C is $\frac{1}{n}[(\frac{n}{2}+w)2+(2k+2w)(\frac{n}{2k}-1)] = 2+\frac{w}{k}-\frac{2k}{n}$. The expected cost of a diagonal (if k is even) is $2+\frac{k}{2w}-\frac{1}{k}$. If we choose $k \approx \sqrt{2}w$, then we obtain $Val(G, w) < 2.707\ldots$. □

All of our examples here have values bounded by constants. However, it is relatively easy to construct examples for which $Val(G) = \Omega(\log n)$. As is well known there are 4-regular graphs on n vertices with girth $c \log n$ (cf. [Bo], pp. 107–109). For any tree, the $n+1$ nontree edges each have cost at least $c \log n$. Hence against the uniform edge strategy every tree has expected cost at least $(\frac{c}{2}) \log n$. In §5, we will see that the N-vertex grid also has cost $\Theta(\log N)$.

3. An application: The *k*-server problem on an undirected network. Our game on graphs first suggested itself in connection with the *k-server problem*, which was introduced in [MaMcSl] and has been studied by many researchers. The problem is set in a metric space M and involves the use of k *servers* to process a sequence of *requests*. At any stage in the processing of the sequence of requests, each server is located at a point in M; the initial locations of the servers are stipulated as part of the problem. Each request is specified by a point $r \in M$. A request at r is processed by moving one of the servers from its present location to r; the cost of processing the request is the distance the server moves. A *deterministic on-line algorithm* is a deterministic rule for deciding which server to move in response to a request. The choice must be determined by the initial positions of the servers and the sequence of requests up to the present request. It is because the choice is not allowed to depend on knowledge of future requests that the algorithm is called on-line.

For any pair π, ρ, where π specifies the initial positions of the k servers and ρ specifies a finite sequence of requests, and for any deterministic on-line algorithm A, let $A(\pi, \rho)$ denote the cost that A incurs in processing the sequence of requests ρ, starting with the servers in the initial positions π. We may also associate with the pair π, ρ a real number $OPT(\pi, \rho)$ denoting the minimum possible cost of processing the request sequence ρ, starting with the servers in the k-tuple π of initial positions; $OPT(\pi, \rho)$ can be viewed as the cost that would be incurred by an *optimal off-line algorithm* that knew the entire request sequence, as well as the initial positions of the servers, in advance, and thus could determine the least expensive way of processing the entire request sequence.

Research on the k-server problem focuses on determining the factor in extra cost that a deterministic on-line algorithm must pay because of the handicap of making its decisions on-line, without knowing the future. This is formalized as follows. Let C be a positive constant. The deterministic on-line algorithm A is called *C-competitive* if there exists a positive constant a such that, for all pairs π, ρ,

$$A(\pi, \rho) \leq C \cdot OPT(\pi, \rho) + a.$$

In [MaMcSl] it is shown that for every positive integer k, every metric space M with at least $k+1$ distinct points, and every C less than k, there does not exist a C-competitive deterministic on-line algorithm. Thus, except in trivial cases, it is impossible to achieve a competitive factor less than k. On the other hand, in [FiRaRa] it is shown that for every positive integer k and every metric space M, there exists a C-competitive deterministic on-line algorithm for some C, where C depends on k but not on the metric space. Thus a bounded competitive factor is always achievable. Chrobak and Larmore [ChLa] consider a special type of metric space that might be called a *tree-like road network*. Such a network consists of a tree T in which each edge $\{u, v\}$ is an interval of length $w(u, v)$ between vertex u and vertex v. The metric space consists of the union of all these intervals. The distance between two points x and y is just the length of the unique simple path between x and y in the network. Chrobak and Larmore show constructively that for any tree-like road network, and any number of servers k, there is

a k-competitive deterministic on-line algorithm, matching the lower bound of k established in [MaMcSl].

It is also possible to consider randomized on-line algorithms, in which the server to move at each step is chosen by a random experiment which, of course, takes into account the initial positions of the servers, the sequence of requests up to the present one, and the choices made by the algorithm at previous steps. In the case of a randomized algorithm, the cost $A(\pi, \rho)$ is a random variable. In defining the competitive factor achieved by a randomized on-line algorithm, we view the request sequence as being specified by an *adversary* who is trying to foil the algorithm. We distinguish between two types of adversaries: the *oblivious adversary*, who specifies the entire sequence of requests in advance, and the *adaptive adversary*, who, in specifying the next request, can take into account the algorithm's responses to all previous requests. In this paper we restrict attention to oblivious adversaries. The randomized algorithm A is said to be *C-competitive* (against oblivious adversaries) if there exists a positive constant a such that for every k-tuple π of initial positions and every request sequence ρ,

$$E[A(\pi, \rho)] \leq C \cdot COST(\pi, \rho) + a,$$

where E denotes mathematical expectation. Several examples are known in which randomized algorithms can achieve a smaller competitive factor than deterministic ones [BBKTW], [BLS], [FKLMSY].

We consider the k-server problem on a class of metric spaces that generalize the tree-like road networks of [ChLa]. Such a space is specified by a multigraph G in which each edge e has a positive real weight $w(e)$. The edge $e = \{u, v\}$ may be viewed as an interval of length $w(e)$ between vertices u and v. The metric space $M(G, w)$ consists of the union of all these intervals; the distance between two points x and y is just the length of the shortest path between x and y; we shall sometimes refer to such a metric space as a *road network.*

The following theorem establishes a connection between our two-person game and the k-server problem on a road network.

THEOREM 3.1. *Let G be a multigraph and w a function assigning to each edge of G a positive real weight $w(e)$. Then for every k, there is a $k(1 + Val(G, w))$-competitive randomized on-line algorithm for the k-server problem on the road network $M(G, w)$.*

Proof. The algorithm is as follows.

- Using an optimal mixed strategy for the tree player in the game defined by G and w, select a spanning tree T in G.
- Along each edge e not in T, choose uniformly a random point $x(e)$, and place a "roadblock" at $x(e)$; more precisely, replace $e = \{u, v\}$ by two intervals $[u, x_1(e)$ and $[x_2(e), v]$, where $x_1(e)$ and $x_2(v)$ are new points, distinct from all points in the original metric space. The edge $[u, x_1(e)]$ is of the same length as the interval $[u, x(e)]$, and the interval $[x_2(e), v]$ is of the same length as the interval $[x(e), v]$. This transformation converts the original road network to a tree-like road network with the same set of points but a different distance function.
- Process the request sequence by executing the (deterministic) Chrobak–Larmore algorithm on this derived tree-like road network.

Let the random variable $A(\pi, \rho)$ denote the cost that the above randomized algorithm incurs in processing the request sequence π, starting from the initial server positions ρ. Let $OPT(\pi, \rho)$ denote the optimal off-line cost of processing ρ, starting from server positions π, on the road network defined by multigraph G and weight function w. Let the random variable $OPT'(\pi, \rho)$ denote the optimal off-line cost of processing ρ, starting from the server positions π, in the tree-like road network constructed by the algorithm. By the k-competitiveness of the Chrobak–Larmore algorithm, $A(\pi, \rho) \leq k \cdot OPT'(\pi, \rho) + a$. To complete the proof, we

shall show that

$$E[OPT'(\pi, \rho)] \leq (1 + Val(G, w))OPT(\pi, \rho). \tag{1}$$

Suppose that the tree player has selected a spanning tree T of G and then for each nontree edge e has placed a roadblock at a random point $x(e)$. Consider a particular sequence of moves on the original road network that processes the sequence of requests ρ starting from the initial k tuple of server positions π at cost $OPT(\pi, \rho)$. Let $\rho = \rho_1\rho_2 \ldots \rho_t$. For $i = 1, 2, \ldots, t$, let $x(i)$ be the index of the server that processes request i. Then it is possible to satisfy ρ on the derived tree-like road network by having server $x(i)$ process request ρ_i, for each i. The server may not be able to follow the same path it would have followed on the original network, because of the presence of roadblocks. However, the server can simulate the path it would have followed on the original road network, except that whenever it encounters a roadblock $x(e)$, it traverses the unique path in the tree-like road network between $x_1(e)$ and $x_2(e)$ in order to get to the other side of the roadblock. The cost of each such detour is $cycle(T, e)$, the weight of the unique cycle formed by the edge e with the tree T.

We now compute the expected cost of all the detours, given that the tree player uses an optimal mixed strategy. Let $p(T)$ be the probability that the tree player chooses spanning tree T. Let $d(e)$ be the distance that servers travel along edge e in a particular sequence of moves achieving cost $OPT(\pi, \rho)$ in the original network; then

$$\sum_e d(e) = OPT(\pi, \rho).$$

If $x(e)$ is a randomly chosen point along edge e, then the expected number of times that servers cross the point $x(e)$ is $\frac{d(e)}{w(e)}$. Each crossing of the point $x(e)$ requires a detour of cost 0 if e lies in T and $cycle(T, e)$ if e does not lie in T. Thus, the expected cost of detours associated with the edge e is exactly $d(e)cost(T, e)$, and the expected total cost of detours is

$$\sum_T \sum_e p(T)d(e)cost(T, e) = OPT(\pi, \rho) \sum_T \sum_e p(T)q(e)cost(T, e),$$

where

$$q(e) = \frac{d(e)}{OPT(\pi, \rho)}.$$

But since the sequence of numbers $\{q(e)\}$ constitutes a probability distribution, it follows that the expected sum of detours is bounded above by $OPT(\pi, \rho)Val(G, w)$, and hence (1) follows. □

COROLLARY 3.2. *There is a $2k$-competitive randomized algorithm on the circle.*

Proof. This follows immediately from Example 2.2 (or even from its special case corresponding to a cycle of two vertices). □

Note that as shown in [FRRS] there is a *deterministic* $O(k^3)$-competitive algorithm for the circle.

4. An optimization problem related to the tree game. In this section we introduce a natural optimization problem and show that it is closely related to our graph-theoretic game. Let G be a connected multigraph with edge multiset E and let w be a function that assigns to each edge e in G a positive weight $w(e)$. Assume that the edge weights are normalized so that the lightest edge has weight 1. For any spanning tree T of G, and any edge e of G, let $path(T, e)$ denote the weight of the path in T between the endpoints of e. Define

$$cost^*(T, e) = path(T, e)/w(e) .$$

Also, for every subset of edges E', denote

$$cost^*(T, E') = \sum_{e \in E'} cost^*(T, e).$$

Let $S(G, w, T) = cost^*(T, E)/|E|$. Let $S_{opt}(G, w) = \min_T S(G, w, T)$, where T ranges over all spanning trees of G. In the unweighted case, where $w(e) = 1$ for all e, we abbreviate $S(G, w, T)$ by $S(G, T)$ and $S_{opt}(G, w)$ by $S_{opt}(G)$. We shall show that the problem of finding a spanning tree that minimizes $S(G, w, T)$ is closely related to the problem of finding optimal strategies for the tree player and edge player in a variant of our tree game. In this new game, the payoff to the edge player when the edge player chooses edge e and the tree player chooses spanning tree T is $cost^*(T, e)$. Let the value of this game be denoted $Val^*(G, w)$. In the unweighted case, we abbreviate $Val^*(G, w)$ by $Val^*(G)$. Then, since $|cost(T, e) - cost^*(T, e)| \leq 1$ for every edge e, $|Val(G, w) - Val^*(G, w)| \leq 1$. Thus, our new game is very closely related to the original one.

Let G, w be a weighted multigraph. The operation of *replication* of an edge e replaces the edge e by one or more parallel edges of weight $w(e)$ between the endpoints of e. Any weighted multigraph created from G, w by a sequence of such operations is said to be *obtained from G, w by replication.*

THEOREM 4.1. *$Val^*(G, w) = \sup_{G', w'} S_{opt}(G', w')$, where G', w' ranges over all weighted multigraphs obtained from G, w by replication.*

Proof. Recall that

$$Val^*(G, w) = \max_q \min_p \sum_T \sum_e p(T)q(e)cost^*(T, e),$$

where q ranges over probability distributions for the edge player, and p over probability distributions for the tree player. For each fixed probability distribution q, $\sum_T \sum_e p(T)q(e)$ $cost^*(T, e)$ is minimized by a probability distribution p concentrated on one tree; this is an instance of the general observation that if one of the players in a zero-sum two-person game announces his mixed strategy, then the other player can play optimally by choosing a pure strategy. It follows that

$$Val^*(G, w) = \max_q \min_T \sum_e q(e)cost^*(T, e).$$

Now consider any weighted multigraph G', w' obtained from G, w by replication. Let $d(e)$ be the number of copies of edge e, and let $q(e)$ be $d(e)/(\sum_e d(e))$. Then q is a probability distribution, and

$$S_{opt}(G', w') = \min_T \sum_e q(e)cost^*(T, e).$$

It follows that $S_{opt}(G', w') \leq Val^*(G, w)$. Conversely, let q be the probability distribution for the edge player that maximizes $\min_T \sum_e q(e)cost^*(T, e)$. For any (large) integer M, let G^M, w^M be obtained from G, w by making $1 + \lfloor Mq(e) \rfloor$ copies of each edge e. Then clearly, as M tends to infinity, $S_{opt}(G^M, w^M)$ converges to $Val^*(G, w)$. The conclusion of the theorem follows. □

An *edge-transitive* graph is a graph G such that for any edges e, e' in G there is an automorphism σ in the automorphism group $\Gamma(G)$ such that σ takes the endpoints of e to the endpoints of e'. In the case of an unweighted edge-transitive graph, we prove that the optimization problem solves the game.

THEOREM 4.2. *If G is edge-transitive, then $Val^*(G) = S_{opt}(G)$.*

Proof. If the edge player plays each edge with equal probability, the expected payoff is at least $S_{opt}(G)$ for any tree. Let T be a tree with $S(G, T) = S_{opt}(G)$ and let $\mathbf{T}$ be the collection of images of T under the elements of $\Gamma(G)$. For each $T' \in \mathbf{T}$, let the probability of playing $\sigma(T)$ be $\frac{1}{|\Gamma(G)|}$ times the number of automorphisms σ such that $\sigma(T) = T'$.

We claim that the expected payoff for this tree strategy is $S_{opt}(G)$ for every edge, which completes the proof. Note that $cost^*(T, e) = cost^*(\sigma(T), \sigma(e))$. Also, Lagrange's theorem states that if a group ($\Gamma(G)$) acts on a set S (= $E(G)$), then the number of group elements taking $e \in S$ to any member of its orbit (including to itself) is the same. Hence the expected payoff for edge e is

$$\begin{aligned}\tfrac{1}{|\Gamma|}\textstyle\sum_\sigma cost^*(\sigma(T), e) &= \frac{1}{|\Gamma|}\sum_\sigma cost^*(T, \sigma^{-1}(e)) = \frac{1}{|\Gamma|}\frac{|\Gamma|}{|E|}\sum_{e'} cost^*(T, e') \\ &= S_{opt}(G). \qquad \square\end{aligned}$$

5. Upper and lower bounds for the tree game.

5.1. A lower bound. We begin with a lower bound on $Val^*(G)$.

THEOREM 5.1. *There exists a positive constant c such that for all n, there exists an n-vertex graph G_n such that $Val^*(G_n) \geq c \ln n$.*

Proof. The following is a known result in extremal graph theory (cf. [Bo], pp. 107–109): There exists a positive constant a such that for all n there exists an n-vertex graph G_n with $2n$ edges such that every cycle in G_n is of length at least $a \ln n$. Let T be any spanning tree in G. Then, for any nontree edge e, $cost^*(T, e) \geq a \ln n - 1$. Since more than half the edges are nontree edges, it follows that for every T, $\frac{1}{|E|}\sum_e cost^*(T, e) \geq \frac{1}{2}(a \ln n - 1)$. Thus $S_{opt}(G) \geq \frac{1}{2}(a \ln n - 1)$, and it follows from Theorem 4.1 that $Val^*(G) \geq \frac{1}{2}(a \ln n - 1)$. $\square$

We next give a preliminary result showing that for bounding $Val^*(G)$ from above, it is sufficient to consider multigraphs with at most $n(n+1)$ edges, counting multiplicities. (Note that in the context of the k-server problem we are really interested only in graphs. However, the construction technique employed in our proof makes it necessary to prove the result in the more general setting of multigraphs.)

LEMMA 5.2. *For every n-vertex multigraph G, w, there exists a multigraph G', w' on the same set of vertices and at most $n(n+1)$ edges such that $S_{opt}(G, w) \leq 2 \cdot S_{opt}(G', w')$.*

Proof. Let E be the edge multiset of G, and let E^{set} be the (maximal) set of distinct edges in E, where two edges are considered distinct if they don't have the same pair of endpoints. (That is, E^{set} contains a single representative edge uv for every pair of vertices u and v that are adjacent in G.) For each edge $e \in E^{set}$, let $d(e)$ be the number of copies of e in E, and let $w'(e)$ be the lowest weight of a copy of e in G, w. Then the cardinality of E (i.e., the total number of edges in G counting repetitions) is

$$|E| = \sum_{e \in E^{set}} d(e).$$

Consider a new multigraph G' with the same set of distinct edges, but with each edge e occurring $r(e)$ times instead of $d(e)$ times, where

$$r(e) = 1 + \left\lfloor \frac{d(e)|E^{set}|}{|E|} \right\rfloor . \tag{2}$$

Then the cardinality of the edge multiset E' of G' satisfies

$$|E'| = \sum_{e \in E^{set}} r(e) \leq |E^{set}| + \frac{|E^{set}|}{|E|}\sum_{e \in E^{set}} d(e) = 2|E^{set}| . \tag{3}$$

Since E^{set} contains at most one edge per pair of endpoints, including self-loops, it follows that G' has at most $n(n+1)$ edges, as required.

It remains to bound $S_{opt}(G', w')$. Combining (2) and (3) we get

$$r(e) \geq \frac{d(e)|E^{set}|}{|E|} \geq \frac{d(e)|E'|}{2|E|} . \tag{4}$$

The multigraph G' has a spanning tree T such that

$$S_{opt}(G', w') = \frac{1}{|E'|} \sum_{e \in E^{set}} r(e) cost^*(T, e, w') , \tag{5}$$

with the notation $cost^*(T, e, u)$ denoting $cost^*$ defined with respect to a weight function u. Using (4) and (5) and the choice of w', we find that

$$S_{opt}(G', w') \geq \frac{1}{2|E|} \sum_{e \in E^{set}} d(e) cost^*(T, e, w) .$$

But since T is a spanning tree of G as well as G', this last expression is at least $S_{opt}(G, w)/2$, so $S_{opt}(G, w) \leq 2S_{opt}(G', w')$. □

5.2. An upper bound for unweighted graphs: outline. Before we state and prove our upper bound for $S_{opt}(G, w)$ on general (weighted) graphs, it is instructive to sketch the construction in the simpler setting of an unweighted graph.

Our construction is based on the concepts of clusters and partitions. A *cluster* is a subset of the vertices whose induced subgraph is connected. A *partition* of a given graph $G = (V, E)$ is a collection of disjoint clusters whose union is V. The basic procedure used in the construction is a variant of the clustering algorithm of [Aw]. The construction involves a parameter x depending on n. This parameter is required to satisfy $x(n) > 1$ and be monotone increasing in n (with $x(n) \to \infty$), but its precise definition is left to be specified later. The output of the procedure is a partition of the given graph into clusters with low radii (specifically, radii at most $y(n) = O(x(n) \ln n)$), with the additional property that "most" of the graph edges are internal to clusters, and only a fraction of $1/x(n)$ of the edges connect endpoints in different clusters. We refer to edges of these two types as "internal" and "intercluster" edges, respectively.

A spanning tree can be built on the basis of such a partition as follows. First, construct a shortest-path spanning tree T_C (as defined earlier) for every cluster C in the partition. Note that since the partition is composed of disjoint clusters, these spanning trees form a spanning forest in the graph. Now connect the forest into a single tree by selecting a suitable tree of intercluster edges.

This last step can be carried out recursively. Given the partition, create an auxiliary *multigraph* $\tilde{G}$ by collapsing each cluster C into a single vertex v_C, and including an edge between two such vertices of $\tilde{G}$ for *each* original edge connecting these clusters. (Here is why it is useful to handle multigraphs in this algorithm, rather than simple graphs.) Next, apply the same procedure recursively to $\tilde{G}$, and obtain a tree $\tilde{T}$. The final tree T will consist of the union of $\tilde{T}$ and the trees T_C constructed for each cluster C.

Observe that internal edges will typically enjoy a lower cost than intercluster edges. This is because the path connecting the endpoints of an edge uw internal to a cluster C in the final tree T is the path connecting u and w on the tree T_C, and the partitioning algorithm guarantees that C has a low radius. In contrast, for an intercluster edge u_1u_2, where $u_1 \in C_1$ and $u_2 \in C_2$, the path connecting u_1 and u_2 in T is not simply the path connecting v_{C_1} and v_{C_2} in the tree $\tilde{T}$. Rather, this path is expanded when retracting from $\tilde{G}$ to G by replacing each vertex v_C on

it with an appropriate path segment on the internal tree T_C. This heavier cost for intercluster edges is compensated for by the fact that these edges are only a $1/x(n)$ fraction of the entire edge set, and therefore their contribution to the average cost is controllable.

The cost analysis is carried along the following lines. Let $f(n, m)$ be the maximum of $S(G, T)$ over all connected multigraphs G with up to n vertices and m edges, where T is the spanning tree of G constructed by the above algorithm. Then

$$f(n, m) \leq 2y(n) + \frac{1}{x(n)} \cdot f(n, m/x(n)) \cdot 5y(n) .$$

This inequality can be explained as follows. The first term in the right-hand side of the inequality denotes the contribution of the internal edges. This term is bounded above by $2y(n)$ since each cluster is of radius at most $y(n)$. The second term denotes the contribution of the intercluster edges. In this term, the factor $1/x(n)$ is an upper bound on the fraction of intercluster edges. The number of edges in $\tilde{G}$ is at most $m/x(n)$, thus the expected cost of an edge in $\tilde{G}$ is at most $f(n, m/x(n))$. Now consider an intercluster edge $e = uv$, and let $\tilde{\gamma}$ be the path connecting its endpoints in $\tilde{G}$, namely, $\tilde{\gamma} = (e_1, \ldots, e_q)$, where each $e_i = u_i v_i$ is an intercluster edge connecting the vertices $v_{C_{i-1}}$ and v_{C_i} in $\tilde{G}$, for $1 \leq i \leq q$, and $u \in C_0$ and $v \in C_q$. The path $\tilde{\gamma}$ can be expanded in G to a path γ connecting u and v, by taking the following steps:

1. inserting between e_i and e_{i+1} a subpath of the tree spanning C_i, connecting v_i and v_{i+1} (for $1 \leq i \leq q-1$),
2. inserting a subpath of the tree spanning C_0, connecting u and v_1, and
3. inserting a subpath of the tree spanning C_q, connecting v_q and v.

Each of these $q+1$ subpaths is of length at most $2y(n)$, namely, twice the radius of the corresponding cluster. Therefore the total length of the resulting path γ, for a given path $\tilde{\gamma}$ of length q, is at most $q + 2(q+1)y(n)$. Thus each connecting path in $\tilde{G}$ expands by a factor of at most $(q + 2(q+1)y(n))/q \leq 5y(n)$ in G. This accounts for the factor $f(n, m/x(n)) \cdot 5y(n)$ in the second term.

Finally, using the above inequality and choosing $x(n)$ optimally as $\exp(\sqrt{\ln n \ln\ln n})$, we find that $f(n) \leq \exp(O(\sqrt{\ln n \ln\ln n}))$.

5.3. An upper bound for weighted graphs: outline. For understanding the weighted case, it is convenient to think of the above algorithm as an iterative, rather than recursive one. From this point of view, think of the main clustering procedure as a "machine," to which the graph is "fed" for a number of iterations. In each iteration $j \geq 1$, the procedure constructs a partition for the current graph G_j (where G_1 is the original graph G), and then contracts the clusters into single vertices, thus creating the graph G_{j+1} to be processed in the next iteration. Each such iteration also reduces the number of "uncovered" edges by a factor of x, until all edges are "covered." (An edge is *covered* if it is internal to some cluster we have already constructed.)

Given this view of the partitioning process, one can analyze the radii of the clusters constructed at each iteration $j \geq 1$ (henceforth called "j clusters"). For that purpose, it is instructive to review the partitioning process in more detail. The partitioning procedure creates the clusters sequentially. Each cluster C is "grown" by starting at a single vertex, and successively merging it with layers of neighbouring vertices. This merging process is stopped once the number of outgoing edges of the current cluster C (namely, edges with one endpoint in C and one outside C) is at most a $1/x(n)$ fraction of the number of internal edges (namely, edges with both endpoints in C). As will be shown later on (in the formal proof for the weighted case), this merging process is bound to halt after adding no more than, say, $y(n)/3$ layers. Hence each j cluster has radius at most $y(n)/3$ *in the current graph* G_j. However,

in the original graph G, such j clusters have radius $r_j \leq y^{j+1}(n)$. This can be easily argued by noting that when a j cluster is constructed, each merged layer increases the radius by an additive factor of up to

$$1 + 2r_{j-1}, \tag{6}$$

where the 1 is contributed by the added edge, and the $2r_{j-1}$ by the diameter of the $(j-1)$ cluster corresponding to the endpoint of that edge in G_j. The bound on r_j follows inductively since at most $y(n)/3$ layers are merged.

Let us next outline the modifications needed for handling the weighted case. The main problem that needs to be overcome is that in this case, all edges cannot be treated alike, since when growing a cluster, a single layer merging step will increase the radius of the resulting cluster by the weight of the heaviest merged edge, rather than by just one, thus the radii of constructed clusters cannot be controlled.

The algorithm thus needs to be modified as follows. It is necessary to break the set of edges E into classes E_i, $i \geq 1$, according to weights, with E_i containing all edges whose weight is in the range $[y^{i-1}, y^i)$ for an appropriately chosen parameter $y = y(n, x)$ (with x a parameter to be determined in the same spirit as in the unweighted case). Intuitively, we would like to handle the lighter edges first. (We may, and will, assume that the minimum weight of an edge is 1.)

We now feed the classes E_i to the "machine" in a pipelined fashion, with overlaps. Namely, in iteration 1 only the edges of E_1 are considered, in the next iteration E_2 is added, and so on. In general, the class E_i is taken into consideration for the first time in the ith iteration, and is processed for the next $\rho = O(\ln n / \ln x)$ iterations, each reducing the number of unsatisfied edges in it by a factor of x, until the entire set E_i is exhausted.

A crucial point that must be explained at this point is the role of the parameter y in the construction. In the weighted case, this parameter has two different functions. The first is similar to the one it had in the unweighted case, i.e., it is (more or less) the radius increase bound for constructed clusters. That is, clusters constructed for the graph G_j in the jth iteration will have at most radius $y/3$ in G_j. The second function of the parameter y is governing the weight range of the edge classes.

The combination of these two functions implies that in the construction of new clusters during a given iteration j, there is a balance between the contributions to the radius made by previously constructed clusters and by new edges. This is what guarantees that cluster radii are properly bounded *in the original graph* G as well. Specifically, the radius of a j cluster (constructed in iteration j) is bounded by $r_j \leq y^{j+1}$. Formally, this can again be deduced inductively, noting that when a j cluster is constructed, each merged layer increases the radius by up to

$$y^j + 2r_{j-1} \leq 3y^j, \tag{7}$$

where (in analogy with (6)) the y^j is contributed by the added edge and the $2r_{j-1}$ by the diameter of the $(j-1)$ cluster corresponding to the endpoint of that edge in G_j, and $r_{j-1} \leq y^j$ follows by the inductive hypothesis. This, combined with the fact that at most $y/3$ layers are added, yields the desired bound of $r_j \leq y^{j+1}$ by induction.

5.4. The upper bound for weighted graphs: formal proof. We are now ready to formally state and prove the upper bound on S_{opt}.

THEOREM 5.3. *There exists a constant c such that for n sufficiently large, every n-vertex connected multigraph G and every weight function w satisfy* $S_{opt}(G, w) \leq \exp(c\sqrt{\log n \log\log n})$.

By Lemma 5.2, it suffices to prove the theorem for every n-vertex multigraph having at most $n(n+1)$ edges in its edge multiset.

We shall use an iterative construction to obtain a suitable spanning tree of G. Again, the construction involves a parameter $1 \leq x \leq n$ depending on n, to be fixed later. Define

$$\rho = \lceil \frac{3 \ln n}{\ln x} \rceil, \quad \mu = 9\rho \ln n, \quad y = x\mu.$$

Break the edge multiset E into subclasses E_i, for $i \geq 1$, according to weights, defining

$$E_i = \{e \mid w(e) \in [y^{i-1}, y^i)\}.$$

(Recall that the edge weights are normalized to be greater than or equal to 1.)

As described above, the algorithm proceeds in iterations. In each iteration j we compute some clusters in the graph G_j, and mark some of the edges as "covered." We then contract the clusters into single nodes, thus preparing the multigraph G_{j+1} for the next iteration.

More precisely, let E_i^j, for $i, j \geq 1$, denote the multiset of edges from E_i that are still uncovered at the beginning of iteration j. The purpose of the construction at iteration j is to partition the vertex set into disjoint clusters such that

- each cluster has a spanning tree of radius at most y^{j+1} in G;
- in every nonempty edge class E_i, $1 \leq i \leq j$, the fraction of intercluster edges is at most $1/x$; i.e., $|E_i^{j+1}| \leq |E_i^j|/x$.

Note that this definition for the purpose of an iteration, and particularly, restricting the second requirement to classes E_i for $i \leq j$, implies that iteration j need only consider (and process) edges from the edge multisets E_i for $i \leq j$, i.e., edges of weight less than y^j, and may ignore heavier edges. Avoiding heavier edges is crucial for guaranteeing the radius bound in the first requirement, as discussed earlier.

We next present the procedure used for forming the partition in iteration j. This procedure is a modified version of the clustering algorithm of [Aw]. The partition is constructed in a "greedy" fashion by a sequence of stages, each stage building a single cluster. After each stage, all the vertices of the graph that were included in the constructed cluster are eliminated from the graph.

Consider the beginning of a stage and let K be a connected component of the subgraph induced by the remaining vertices (i.e., the ones not yet included in any of the previously built clusters). Choose arbitrarily a "root vertex" u in K. Stratify the vertices and edges of K into layers according to their (unweighted) distance from u as follows. For each integer $\ell \geq 0$, let $V(\ell)$ be the set of vertices at (unweighted) distance ℓ from u in K (where the *unweighted distance* between two vertices is defined as the minimal number of edges in a path connecting them). Also let $E_i^j(\ell)$ be the set of edges of E_i^j that join a vertex in $V(\ell)$ with a vertex in $V(\ell) \cup V(\ell-1)$. Let ℓ^* be the least ℓ such that

$$(*) \qquad \forall 1 \leq i \leq j, \quad |E_i^j(\ell+1)| \leq \frac{1}{x}|E_i^j(1) \cup E_i^j(2) \cup \cdots \cup E_i^j(\ell)|.$$

Note that such ℓ always exists. The resulting cluster is the vertex set $V(1) \cup V(2) \cup \cdots \cup V(\ell^*)$. The vertices of this cluster are now eliminated from the graph, and the next stage is started. This process of cluster generation continues until the graph is exhausted (i.e., all vertices are assigned to clusters).

Let $x(n)$ be a function of n that will be specified later. The spanning tree T in an n-vertex multigraph G is constructed as follows:

- Set $j = 1$ and $G_j = G$.
- Set $x = x(n)$, ρ, μ, y, and the edge classes E_i, as defined above.
- While $\bigcup_i E_i \neq \emptyset$ do the following:
  1. Partition the vertex set of G_j into clusters as described above.
  2. Construct a shortest-path spanning tree T_C in each cluster C of G_j.
  3. Add each edge e of each of the constructed trees to the output tree T.
  4. Construct the next multigraph G_{j+1} by contracting each cluster C into a single vertex v_C, discarding internal edges from $\bigcup_i E_i$, and replacing each intercluster edge u_1u_2, for $u_1 \in C_1$ and $u_2 \in C_2$, by a new edge connecting the corresponding contracted vertices v_{C_1} and v_{C_2}.
  5. Set $j = j + 1$.

In order to analyze the output of our algorithm, we first bound the number of layers added to a cluster during the clustering process in some iteration j. This growth is bounded by showing that in iteration j, the only sets E_i^j considered by the algorithm (i.e., the only nonempty ones) are those satisfying $j - \rho \leq i \leq j$.

LEMMA 5.4. $|E_i^j| \leq |E_i|/x^{j-i}$ *for every* $1 \leq i \leq j$.

Proof. The claim follows from the fact that $|E_i^{j+1}| \leq |E_i^j|/x$ for every $1 \leq i \leq j$. To see this, note that by definition of the cluster construction process, each time a cluster is constructed in a connected component K, the number of edges of E_i^j connecting that cluster to the vertices of K not selected for inclusion is at most $\frac{1}{x}$ times the number of edges of E_i^j included in the cluster. Thus, in the entire graph the number of edges of E_i^j joining vertices in different clusters (constituting E_i^{j+1}) is at most $\frac{1}{x}$ times $|E_i^j|$. □

The above lemma enables us to bound the (weighted) radius of clusters generated during the execution.

LEMMA 5.5. *In iteration* j, *the radius of each cluster in* G *is bounded above by* y^{j+1}.

Proof. Let B_j denote the number of layers ℓ^* merged into any cluster in iteration j. We first prove that B_j is bounded above by

$$B_j \leq y/3 = 3\rho x \ln n. \tag{8}$$

To see this, note that by Lemma 5.4, $|E_i^{i+\rho}| = 0$ for every $i \geq 1$, which implies that the augmentation rule $(*)$ governing the addition of layers to the cluster need only consider edges from classes E_i^j for $j - \rho + 1 \leq i \leq j$. Each additional layer ℓ implies that some set $E_i^j(\ell)$ fails to satisfy this condition. Namely, for all ℓ such that $1 < \ell < \ell^*$, at least one i such that $j - \rho + 1 \leq i \leq j$ satisfies

$$|E_i^j(\ell)| > \frac{1}{x}|E_i^j(1) \cup E_i^j(2) \cup \cdots \cup E_i^j(\ell - 1)|.$$

Thus

$$|E_i^j(1) \cup E_i^j(2) \cup \cdots \cup E_i^j(\ell)| > \left(1 + \frac{1}{x}\right)|E_i^j(1) \cup E_i^j(2) \cup \cdots \cup E_i^j(\ell - 1)|.$$

Since there are at most ρ possible values of i, by the pigeonhole principle it follows that for ℓ^*, there exists at least one such i that caused the addition of a layer for at least $\lceil \ell^*/\rho \rceil$ times. This i satisfies

$$|E_i^j(1) \cup E_i^j(2) \cup \cdots \cup E_i^j(\ell^*)| \geq \left(1 + \frac{1}{x}\right)^{\lceil \ell^*/\rho \rceil}.$$

Since the number of edges in the multigraph is at most $n(n+1)$, it follows that, for n sufficiently large, $\ell^*/\rho \leq 3x \ln n$, so (8) is proved.

We now prove the main claim of the lemma, i.e., the bound on the radius of a cluster created in the jth iteration by induction on j. In order to analyze all iterations together (including also iteration 1), hypothesize iteration 0 as the one that yielded the initial graph G, with each vertex representing a cluster of radius 0 (thus trivially satisfying the inductive claim). Now for $j \geq 1$, suppose the claim holds up to $j-1$, and consider the jth iteration. At the beginning of the iteration, every vertex of the multigraph represents a cluster of radius up to y^j, by the inductive hypothesis. Also, every edge considered in iteration j is of length up to y^j. Hence in constructing a cluster, each additional layer contributes up to $3y^j$ to the radius. By inequality (8) above, the final radius is at most $3y^j \cdot y/3 = y^{j+1}$, as required. □

Using the above result we can bound the costs incurred by the edges, obtaining the following.

LEMMA 5.6. $cost^*(T, E) \leq 4x^2\mu^{\rho+1}|E|$.

Proof. Let H_i^j denote the set of edges from E_i that were covered during iteration j, i.e.,

$$H_i^j = E_i^j \setminus E_i^{j+1}.$$

We first claim that for every edge $e \in H_i^j$,

$$cost^*(T, e) = \frac{path(T, e)}{w(e)} \leq 2y^{j-i+2}. \tag{9}$$

To see this, note that since e is covered during iteration j, by the previous lemma $path(T, e) \leq 2y^{j+1}$, while on the other hand, $e \in E_i$ implies $w(e) > y^{i-1}$.

By Lemma 5.4,

$$|H_i^j| \leq |E_i^j| \leq |E_i|/x^{j-i}. \tag{10}$$

It follows from inequalities (9) and (10) that for every $1 \leq i \leq j$,

$$cost^*(T, H_i^j) \leq 2x^2\mu^{j-i+2}|E_i|. \tag{11}$$

Summing these costs over $i \leq j \leq i+\rho-1$, we get that

$$cost^*(T, E_i) \leq \sum_{j=i}^{i+\rho-1} cost^*(T, H_i^j) \leq 4x^2\mu^{\rho+1}|E_i|$$

for every $i \geq 1$. Summing the costs over all weight classes we get

$$cost^*(T, E) = \sum_{i=1} cost^*(T, E_i) \leq 4x^2\mu^{\rho+1}|E|,$$

and the lemma follows. □

It follows that the average spanning factor of the constructed tree T is bounded above by

$$S(G, w, T) \leq 4x^2\mu^{\rho+1} \leq 4x^2\left(\frac{27\ln^2 n}{\ln x}\right)^{1+\lceil \frac{3\ln n}{\ln x}\rceil}.$$

Selecting $x = \exp(\sqrt{\log n \log\log n})$ optimizes this bound on $S(G, w, T)$ as $S(G, w, T) \leq \exp(O(\sqrt{\log n \log\log n}))$. This completes the proof of Theorem 5.3. □

COROLLARY 5.7. *There exists a constant c such that for n sufficiently large, every n vertex connected multigraph G, w satisfies $Val^*(G, w) \leq \exp(c\sqrt{\log n \log\log n})$.*

Proof. By Theorem 4.1, $Val^*(G, w) = \max_{G',w'} S_{opt}(G', w')$, where G', w' ranges over all the weighted multigraphs obtained from G, w by replication. The claim thus follows from Theorem 5.3. □

We observe that the tree construction algorithm as described above can be used within a procedure (based on the ellipsoid algorithm) for implementing the first step in the online k-server algorithm of Theorem 3.1, yielding a polynomial-time algorithm for the problem; i.e., the optimal strategy for the tree player can, in fact, be efficiently approximated.

6. Grids and hypercubes. In this section, we discuss the value of the game on unweighted grids and hypercubes.

6.1. Upper bounds for d-dimensional grids. We consider the d-dimensional grid $G_{n,d}$ that is the Cartesian product of d n-vertex paths and has $N = n^d$ vertices. Formally, the vertex set of $G_{n,d}$ consists of all vectors of length d whose coordinates are in $\{1, \ldots, n\}$. The grid contains an edge uv if the vectors u and v differ in exactly one coordinate where their values differ by exactly 1.

A hypercube is edge-transitive, so $Val^*(G_{2,d}) = S_{opt}(G_{2,d})$. For $G_{n,2}$, the value of the game can be approximated by the optimal tree. To see this, note that the n by n discrete torus is edge-transitive. Any tree in the grid G is also a tree in the torus G'. If we choose a tree T in G with diameter less than αn, then $S(G', T) \leq S(G, T)(1 - \frac{1}{n}) + \alpha$. On the other hand, $Val^*(G') \geq Val^*(G)$, because the edge player on the torus has the option of playing only edges in the grid. The upper bound we obtain is independent of d.

THEOREM 6.1. *For the d-dimensional grid $G_{n,d}$ with $N = n^d$ vertices, $S_{opt}(G_{n,d}) < 2 \log N$.*

Proof. Suppose $n = 2^k$. For the upper bound, we construct a tree T_k in $G_{n,d}$ of diameter

$$d_k \leq (2d - 1)(2^k - 1) = (2d - 1)(n - 1)$$

such that $S(G_{n,d}, T_k) < 2d \log n = 2 \log N$. Partition the vertices of $G_{n,d}$ into 2^d subsets inducing copies of $G_{n/2,d}$. There is a unique d cube Q consisting of one vertex from each of these subsets. Form T_k by using a copy of T_{k-1} in each of the 2^d subsets and a spanning tree of diameter $2d - 1$ in Q (a breadth-first search tree from any vertex will do). Figure 2 illustrates the construction for $G_{8,2}$. We have $d_k \leq (2d - 1) + 2d_{k-1}$, with $d_0 = 0$. Hence $d_k \leq (2d - 1)(2^k - 1)$. Note that $G_{n,d}$ has $dn^{d-1}(n - 1) = dN(1 - \frac{1}{n})$ edges; let $N' = (\frac{n}{2})^d$. Also, the number of nontree edges that join the copies of $G_{n/2,d}$ is $dn^{d-1} - (2^d - 1)$. We thus have

$$S(G_{n,d}, T_k) \leq \frac{2^d \cdot dN'(1-\frac{2}{n}) S(G_{n/2,d}, T_{k-1}) + (dn^{d-1} - 2^d + 1)(d_k + 1)}{dN(1-\frac{1}{n})}$$

$$J < S(G_{n/2,d}, T_{k-1}) + \frac{(d_k+1)}{n-1} < S(G_{n/2,d}, T_{k-1}) + 2d.$$

Hence $S(G_{n,d}, T_k) < 2dk$. □

For the interesting special case of the hypercube $Q_d = G_{2,d}$, which is edge-transitive, we have a slightly better construction. This construction improves on the general case only by roughly a factor of four, but it is still of interest, since it is conjectured to be optimal.

THEOREM 6.2. $Val^*(Q_d) = S_{opt}(Q_d) \leq (d + 1)/2$.

Proof. Equality holds for $d = 1, 2$, with no choice of tree. For $d > 2$, construct a tree T_d by taking the optimal $d - 1$-dimensional tree T^* in copy A of Q_{d-1} and adding all edges between this and the other copy of Q_{d-1}. The edges in copy A have the same $cost^*$ as before,

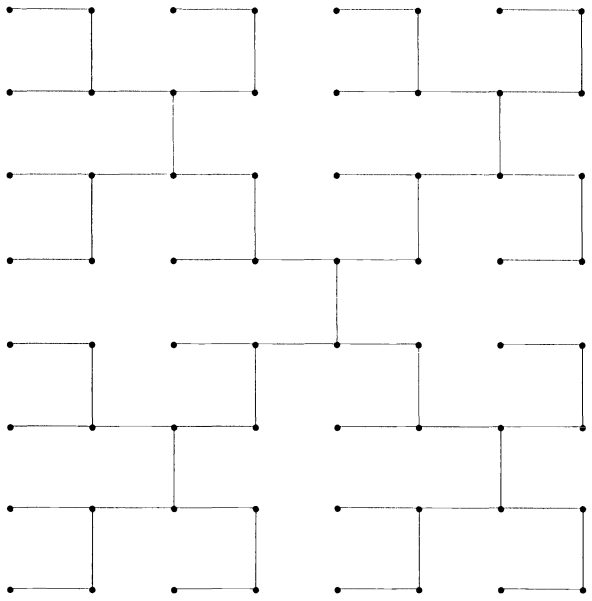

FIG. 2. *A spanning tree in* $G_{8,2}$.

and those between the copies have $cost^* = 1$. Each edge e in copy B corresponding to an edge e' in copy A has $cost^*(T_d, e) = cost^*(T^*, e') + 2$. We have

$$\begin{aligned} S_{opt}(Q_d) &\leq S(Q_d, T_d) \\ &= \frac{1}{(d2^{d-1})}\left((d-1)2^{d-2}(2 \cdot S_{opt}(Q_{d-1}) + 2) + 2^{d-1} \cdot 1\right). \end{aligned}$$

Hence $S_{opt}(Q_d) < \frac{d-1}{d} S_{opt}(Q_{d-1}) + 1$, implying the claim inductively. □

We believe that the general construction described above is essentially optimal for large n, with $S_{opt}(G_{n,d}) = 2\lg N + o(\lg N)$. In the following sections we prove only that $S_{opt}(G_{n,d}) \geq c \log N$ for some constant c.

6.2. Lower bounds for two-dimensional grids. For clarity, it is useful to first present the lower bound for the case of $d = 2$, showing $S_{opt}(G_{n,2}) \geq c\lg n + o(\lg n)$. For this we need several preliminary results.

LEMMA 6.3. *If A is a set of at least α^2 vertices in $G_{n,2}$, where $|A| \leq \frac{n^2}{2}$, then there are at least α rows that A intersects but does not fill or at least α columns that A intersects but does not fill.*

Proof. Suppose A intersects r rows and s columns, with $r \geq s$. Then $rs \geq \alpha^2$ implies $r \geq \alpha$, and the result holds for A unless A fills at least one row. If A does fill a row then $n = s \leq r$. Thus A intersects every row and every column. Now our goal is to prove that there are at least α rows that A does not fill or at least α columns that A does not fill. For this not to happen means that A fills more than $n - \alpha$ rows and more than $n - \alpha$ columns. This requires that A has more than $n^2 - \alpha^2$ vertices, which is impossible if $\alpha^2 \leq |A| \leq \frac{n^2}{2}$. □

LEMMA 6.4. *If A is a set of at least α^2 vertices in $G_{n,2}$, where $|A| \leq \frac{n^2}{2}$, and B is a set of at most four vertices in A, then there are at least $\frac{\alpha}{2}$ vertices in A that have neighbors outside A and have distance at least $\frac{\alpha}{16}$ from each vertex of B.*

Proof. The preceding lemma guarantees a set C of at least α vertices in A that are in distinct rows (or distinct columns) and have neighbors outside A. Since these are in distinct

rows, a vertex of B can be within distance $\frac{\alpha}{16}$ of at most $\frac{\alpha}{8}$ vertices in C. When we delete from C the vertices that are too close to B, at least $\frac{\alpha}{2}$ vertices remain. □

LEMMA 6.5. *If T is a spanning tree of $G_{n,2}$ and $1 \leq \alpha \leq \frac{n}{16}$, then there are at least $\frac{n^2}{64\alpha}$ edges e such that $path(T, e) > \frac{\alpha}{16}$.*

Proof. Since the grid has maximum degree 4, every subtree on $m > 1$ vertices in it (not necessarily spanning) has an edge whose deletion separates it into two smaller subtrees, each having at least $\frac{m-1}{4} \geq m/8$ of its vertices. Begin with T and successively delete edges from the biggest remaining component, always splitting that component as evenly as possible. Do this until $\lceil \frac{n^2}{8\alpha^2} \rceil - 1$ edges have been deleted and the number of pieces is $\lceil \frac{n^2}{8\alpha^2} \rceil$. On the average, the pieces have about $8\alpha^2$ vertices, with the smallest piece having at least α^2 vertices. To see this, note that at every stage, the largest piece has at most 8 times as many vertices as the smallest piece, because whenever there is a new smallest size it is at least $\frac{1}{8}$ of the old largest size. Minimizing x_1 subject to $x_1 \leq \cdots \leq x_m \leq 8x_1$ and $\sum x_i = M$ yields $x_1 = \frac{M}{8m-3}$, achieved when all the other variables are 8 times the smallest. Note also that the largest piece must have fewer than half the vertices as soon as more than 16 pieces are requested.

Since each deleted edge of T is incident to two pieces, the average number of deleted edges incident with a piece is less than 2. Hence at least half the pieces are incident with at most four deleted edges. (Since otherwise the number of deleted edges would be too large.) If A is the set of vertices of such a piece, let B be the vertices in A incident to these deleted edges. By the preceding lemma, A has at least $\frac{\alpha}{2}$ vertices having neighbors outside A whose distance from each vertex of B is at least $\frac{\alpha}{16}$. The edges leaving A from these vertices do not belong to T, since the only edges of T leaving A are incident to vertices of B. For any such edge e, we have $path(T, e) > \frac{\alpha}{16}$, since the path in T between the ends of e must contain a path in the piece of T induced by A from e to one of the vertices in B. Harvesting at least $\frac{\alpha}{2}$ endpoints of such edges from each of at least $\frac{n^2}{16\alpha^2}$ pieces of T (i.e., those pieces incident with at most 4 deleted edges), yields at least $\frac{n^2}{64\alpha}$ such edges, since we might have counted each edge twice. (Of course, $path(T, e) > \frac{\alpha}{8}$ for any edge we have counted twice, but we are not trying to optimize the constants here.) □

We are now ready to prove our lower bound.

THEOREM 6.6. $S_{opt}(G_{n,2}) \geq \frac{1}{2048} \ln n - O(1)$.

Proof. Given an arbitrary spanning tree T of $G_{n,2}$, the preceding lemma guarantees at least $\frac{n^2}{32\alpha}$ edges with $cost^*$ at least $\frac{\alpha}{16}$ for any $\alpha \leq \frac{n}{16}$. We now choose an edge e at random, defining a random variable X by $X = cost^*(T, e)$. We seek a lower bound on $E[X]$, the average $cost^*$ of an edge, since $S_{opt}(G_{n,2}) = E[X]$. We use the fact that, for a discrete random variable X attaining nonnegative integer values, we have $E[X] = \sum_{k \geq 1} Prob(X \geq k)$. For $k \leq \frac{n}{256}$, let $\alpha = 16k$. Then

$$Prob(X \geq k) \geq \frac{n^2}{1024k \cdot 2n(n-1)} > \frac{1}{2048}.$$

We thus obtain

$$E[X] > \frac{1}{2048} \sum_{k=1}^{\lfloor n/256 \rfloor} \frac{1}{k} \geq \frac{1}{2048} \ln n - O(1). \qquad \square$$

6.3. Lower bounds for d-dimensional grids. More generally, we prove that Theorem 6.1 is optimal, up to a constant factor, for all $n, d \geq 2$.

THEOREM 6.7. *There exists an absolute constant $c > 0$ such that for every $n, d \geq 2$, $S_{opt}(G_{n,d}) \geq cd \log n = c \log N$.*

The proof of Theorem 6.7 requires several preparations. We prove it for, say, $c = 10^{-10}$. (We note that we make no attempt to optimize the constants here and in the rest of the proof.) Clearly, with this value of c, if both n and d do not exceed 10^5 there is nothing to prove and hence we may assume that at least one of them does exceed 10^5, i.e.,

$$\max\{n, d\} \geq 10^5. \tag{12}$$

Suppose $n, d \geq 2$ and let $G = G_{n,d} = (V, E)$. Denote $M = \{1, 2, \ldots, n\}$. Recall that the vertices of G are naturally represented by all vectors of length d whose coordinates are in M. If uv is an edge of G, where $u, v \in V$, we say that the *direction* of the edge uv is i if i is the unique coordinate in which u and v differ. In the course of the proof we need to consider vectors whose coordinates except one are all determined. It is convenient to denote a nondetermined coordinate by the symbol $*$. Thus, for a subset $A \subset V$ and for a vector $v = (v_1, \ldots, v_d)$ with $v_i = *$ and $v_j \in M$ for all $j \neq i$, we say that A *intersects* the vector v if there is a $u \in A$ such that u coincides with v on all the coordinates but the ith (i.e., the projection of u on $\{1, \ldots, d\} \setminus \{i\}$ is equal to that of v). We say that A *properly intersects* v if A intersects v and also its complement $V \setminus A$ intersects v. Note that in this case there is at least one edge uw of G in direction i which joins a vertex u of A with a vertex w of $V \setminus A$, with the property that both u and w coincide with v on all coordinates but the ith.

We need the following lemma, proved in [CFGS]. (The proof in [CFGS] is given only for the case $n = 2$, but the same proof works for all integers n. See also [Al].)

LEMMA 6.8 [CFGS]. *Let $D = \{1, \ldots d\}$ be a finite set and let $B_1, \ldots, B_m$ be subsets of D such that each element of D belongs to at least k of the sets B_i. Let $\mathcal{F}$ be a family of vectors of length d whose coordinates, indexed by the elements of D, lie in $M = \{1, \ldots, n\}$. For each i, $1 \leq i \leq m$, let $\mathcal{F}_i$ denote the set of all projections of the vectors in $\mathcal{F}$ on B_i. Then*

$$|\mathcal{F}|^k \leq \prod_{i=1}^{m} |\mathcal{F}_i|. \qquad \square$$

Returning to the graph $G = (V, E)$ we now prove the following lemma.

LEMMA 6.9. *Suppose $A \subset V$, $|A| = x^d$, where $x \geq 1$ is not necessarily an integer. Let A_i denote the set of all vectors v such that A intersects v, where $v_i = *$ and $v_j \in M$ for all $j \neq i$. Let A_i' denote the set of all vectors v as above such that A properly intersects v. Then*

$$\sum_{i=1}^{d} |A_i| \geq dx^{d-1}$$

and

$$\sum_{i=1}^{d} |A_i'| \geq dx^{d-1}(1 - x/n).$$

Proof. Apply Lemma 6.8 to the grid $G_{n,d} = (V, E)$, where D is the set of d coordinates in the vectors of V. Specifically, set $\mathcal{F} = A$, $m = d$, $k = d - 1$ and $B_i = D \setminus \{i\}$. Clearly in this case $|\mathcal{F}_i| = |A_i|$ and hence, by the lemma

$$x^{d(d-1)} = |A|^{d-1} \leq \prod_{i=1}^{d} |A_i| \leq \left(\frac{1}{d} \sum_{i=1}^{d} |A_i| \right)^d.$$

This implies the first part of Lemma 6.9.

To prove the second part, observe that since $|A| = x^d$, A cannot intersect without properly intersecting more than x^d/n vectors v whose ith coordinate is $*$. Thus $|A_i'| \geq |A_i| - x^d/n$ for all i, and summation over $1 \leq i \leq d$ completes the proof of the lemma. □

Let v be a vertex of G, let y be a positive real, and suppose $i \in D = \{1, \ldots, d\}$. Let S denote the set of all vertices of G whose distance from v is less than $y(d-1)$ and let S_i denote the set of projections of the members of S on $D \setminus \{i\}$. Denote by $L(y, d)$ the maximum possible cardinality of S_i where the maximum is taken over all possible choices of v and i.

LEMMA 6.10. *For all* $y > 0$

$$L(y, d) \leq 2^{Min\{d-1, y(d-1)\}} \binom{d-1+(d-1)y}{d-1}. \tag{13}$$

Therefore, for all $y \geq 1$,

$$L(y, d) \leq (2e(y+1))^{d-1}$$

and for all $y \leq 1$

$$L(y, d) \leq (2e^2)^{(d-1)y},$$

where $e = 2.71828\ldots$ *is the basis of the natural logarithm.*

Proof. Suppose $v = (v_1, \ldots, v_d)$ and let F be a set of vertices of G whose distance from v is at most $y(d-1)$. Suppose, further, that no two members of F have the same projection on $D \setminus \{i\}$. Clearly, it suffices to show that the cardinality of F is at most the right-hand side of (13). If $u = (u_1, \ldots, u_d)$ is a member of F then, for each $j \neq i$, $u_j = v_j + \epsilon_j$, where $\sum_{j \neq i} |\epsilon_j| < y(d-1)$. The number of ways to choose the signs of all the ϵ_j-s which are not 0 is at most $2^{\min\{d-1, y(d-1)\}}$, since there are at most $\min\{d-1, y(d-1)\}$ such ϵ_j. The number of ways to choose the absolute values of the ϵ_js is less than the number of ways to write $y(d-1)$ as an ordered sum of d nonnegative integers (the first $d-1$ of which will serve as our numbers ϵ_j), and this is precisely the binomial coefficient $\binom{d-1+(d-1)y}{d-1}$. This completes the proof of (13). The other two estimates follow from this one by using the fact that $\binom{a}{b} \leq (ea/b)^b$ for all integers a and b and the fact that $(1 + \frac{1}{y})^y \leq e$. □

We can now return to the proof of Theorem 6.7. Let T be a spanning tree of $G = G_{n,d}$. Let x be a real number, $1.5 \leq x \leq \frac{3}{4}n$. By deleting edges of T we can break it into connected components each containing at most x^d and at least $\frac{x^d}{4d}$ vertices. (This is possible since the maximum degree of a vertex of G (and hence of a vertex of T) is at most $2d$, and thus if we repeatedly split T into connected components by always splitting the biggest remaining component as evenly as possible we will never have two components the ratio between the sizes of which exceeds $4d$.) It follows that the number t of connected components, and hence the number of deleted edges of T, does not exceed $\frac{4dn^d}{x^d}$. Let U denote the set of all end vertices of these deleted edges. Then $|U| \leq \frac{8dn^d}{x^d}$.

Let x_j denote the positive dth root of the number of vertices in the jth connected component, $(1 \leq j \leq t)$. Since $x_j \leq x \leq 0.75n$ for each j, Lemma 6.9 implies that the total number of edges of G emanating from the jth connected component to vertices in other components is at least $\frac{1}{4}dx_j^{d-1}$. Observe that if y is a real positive number and if an endpoint of such an edge is at distance at least $y(d-1)$ from all the vertices in U that lie in the same connected component as that endpoint then the length of the elementary cycle corresponding to this edge is greater than $y(d-1)$. This is because the elementary cycle has to contain a vertex in U. We next obtain a lower bound for the number of such edges. Let us fix a direction i and consider only edges in direction i. If we let A denote the set of vertices of the jth component C_j and

use the notation of Lemma 6.9, we conclude that there are at least $|A_i'|$ vertices in C_j whose projections on $D \setminus \{i\}$ are pairwise different, such that from each such vertex there is an edge in direction i emanating to another connected component. By the definition of $L(y, d)$, each vertex of U can be at distance less than $y(d-1)$ from no more than $L(y, d)$ such vertices. Summing over all t connected components and over all d directions we conclude that the number of edges that join distinct components whose elementary cycles have length that exceeds $y(d-1)$ is at least

$$\frac{1}{2}\sum_{j=1}^{t}\frac{1}{4}dx_j^{d-1} - |U|dL(y, d).$$

Since $|U| \leq 8dn^d/x^d$ and since the minimum possible value of $\sum_{j=1}^{t} x_j^{d-1}$ subject to the constraint that $x \geq x_j \geq 0$ and $\sum_{j=1}^{t} x_j^d = n^d$ is $\frac{n^d}{x^d}x^{d-1} = n^d/x$ we obtain the following lemma.

LEMMA 6.11. *For each spanning tree T in $G = G_{n,d}$ and for each real x, $1.5 \leq x \leq 0.75n$ and positive real y, the number of edges of G whose elementary cycles have length that exceeds $y(d-1)$ is at least*

$$\frac{dn^d}{8x} - L(y, d)8d^2\frac{n^d}{x^d}. \qquad \square$$

We can now prove Theorem 6.7. For technical reasons it is convenient to consider three possible cases, depending on the values of the parameters n and d.

Case I. $n \leq 80$.

In this case $d \geq 10^5$, by (12). Put $x = 1.5$, $y = 1/20$. By Lemma 6.10, $L(y, d) \leq (2e^2)^{0.05(d-1)} < 1.2^{d-1}$. Hence (since $x = 1.5$)

$$L(y, d)8d^2\frac{n^d}{x^d} < \left(\frac{12}{15}\right)^{d-1} 8d\frac{dn^d}{x} < \frac{dn^d}{16x}.$$

Therefore, by Lemma 6.11, there are at least $\frac{dn^d}{16x} = \frac{1}{24}dn^d$ edges whose cycles have length that exceeds $\frac{1}{20}(d-1)$, and since the total number of edges is $dn^{d-1}(n-1) < dn^d$ and the tree T was arbitrary we conclude that in this case $S_{opt}(G_{n,d}) \geq \frac{1}{480}(d-1) > cd\log n$, as needed.

Case II. $d \leq 20$.

In this case, which requires a little more work, $n \geq 10^5$, by (12). For each real x satisfying

$$1600 \leq x \leq \frac{3}{4}n, \tag{14}$$

define $y = x/1600$. By Lemma 6.10, $L(y, d) \leq (2e(y+1))^{d-1} < \frac{x^{d-1}}{160^{d-1}}$ and hence

$$L(y, d)8d^2\frac{n^d}{x^d} \leq \frac{8d}{160^{d-1}}\frac{dn^d}{x} \leq \frac{dn^d}{10x},$$

where here we applied the fact that $d \geq 2$.

It follows from Lemma 6.11 that at least a fraction $1/(40x)$ of the edges have cycles of length more than $x(d-1)/1600$, for each x satisfying (14). Therefore, if X is the random variable defined on the edges f of our graph G by letting $X(f)$ be the length of the elementary cycle of f divided by $d-1$, it follows that for each x satisfying (14), the probability $Prob(X \geq x/1600)$ is at least $1/(40x)$. Therefore, by defining $z = x/1600$ we conclude that for each

integer z satisfying $1 \leq z \leq \frac{3}{6400}n$, $Prob(X \geq z) \geq 1/(64000z)$. Thus the expectation of X is at least

$$\sum_{z=1}^{\lfloor 3n/6400 \rfloor} Prob(X \geq z) \geq \sum_{z=1}^{\lfloor 3n/6400 \rfloor} \frac{1}{64000z} \geq 10^{-6} \log n.$$

The average cost of an edge with respect to the tree T is $d-1$ times the expectation of X and hence we conclude that in this case $S_{opt}(G_{n,d}) \geq 10^{-6}(d-1)\log n > cd \log n$, as required.

Case III. $n > 80$ and $d > 20$.

For each real x, $30 \leq x \leq 0.75n$ define y by $y+1 = \frac{x}{4e}$. By Lemma 6.10, $L(y,d) \leq \frac{x^{d-1}}{2^{d-1}}$ and hence

$$L(y,d)8d^2\frac{n^d}{x^d} \leq \frac{8d}{2^{d-1}}\frac{dn^d}{x} < \frac{dn^d}{16x}.$$

Therefore, by Lemma 6.11, for every x, $30 \leq x \leq 0.75n$, with probability at least $1/(16x)$, the random variable X defined in the previous case exceeds $(x-4e)/(4e)$. As before (by letting $z = \lceil (x-4e)/4e \rceil$ take integer values) it follows that the expectation of this random variable is at least

$$\sum_{z \geq \lceil 30/(4e)-1 \rceil}^{\lceil 3n/(16e)-1 \rceil} \frac{1}{64e(z+1)} > 10^{-6} \log n,$$

and this implies that in this case too $S_{opt}(G_{n,d}) \geq cd \log n$ and completes the proof of Theorem 6.7. □

FINDING k CUTS WITHIN TWICE THE OPTIMAL*

HUZUR SARAN† AND VIJAY V. VAZIRANI†

Abstract. Two simple approximation algorithms for the minimum k-cut problem are presented. Each algorithm finds a k cut having weight within a factor of $(2 - 2/k)$ of the optimal. One algorithm is particularly efficient—it requires a total of only $n - 1$ maximum flow computations for finding a set of near-optimal k cuts, one for each value of k between 2 and n.

Key words. graph partitioning, minimum cuts, approximation algorithms

AMS subject classifications. 68Q20, 68Q25

1. Introduction.

The minimum k-cut problem is as follows: Given an undirected graph $G = (V, E)$ with nonnegative edge weights and a positive integer k, find a set $S \subseteq E$ of minimum weight whose removal leaves k connected components. This problem is of considerable practical significance, especially in the area of VLSI design. Solving this problem exactly is NP hard [GH], but no efficient approximation algorithms were known for it.

In this paper we give two simple algorithms for finding k cuts. We prove a performance guarantee of $(2 - 2/k)$ for each algorithm; however, neither algorithm dominates the other in all instances. One of our algorithms is particularly fast; it requires only $n - 1$ max flow computations, using the classic result of [GoHu]. In fact, within the same running time, this algorithm finds near-optimal k cuts for each k, $2 \leq k \leq n$. We also give a family of graphs that show that the bound of $(2 - 2/k)$ is tight for each algorithm. The problem of achieving a factor of $(2 - \epsilon)$, for some fixed $\epsilon > 0$, independent of k, seems to be difficult, and may possibly be intractable.

The minimum k-cut problem and its variants have been extensively studied in the past. For fixed k, polynomial time algorithms for solving the problem exactly have been discovered by [DJPSY] for planar graphs and by [GH] for arbitrary graphs. These algorithms have running times of $O(n^{ck})$, for some constant c, and $O(n^{k^2})$, respectively. More efficient algorithms for the case of planar graphs and $k = 3$ are given in [He] and [HS]. Polynomial time algorithms have also been developed for several variants [Ch], [Cu], and [Gu].

In [DJPSY], the complexity of multiway cuts is studied: Given an edge-weighted undirected graph with k specified vertices, find a minimum weight k cut that separates these vertices. They show that this problem is NP hard even when k is fixed, for $k \geq 3$. They also give an approximation algorithm that finds a solution within a factor of $(2 - 2/k)$ of the optimal, using k max-flow computations. Using their algorithm as a subroutine one can get a $(2 - 2/k)$ approximation algorithm for our problem; however this will require $\binom{n}{k}$ calls and is therefore not polynomial time in case k is not fixed.

We shall first present the more efficient algorithm, which we call EFFICIENT. The other algorithm is called SPLIT. We will actually establish the $(2 - 2/k)$ performance guarantee for a slight variant of EFFICIENT. The weight of the k cut found by this variant dominates the k cuts found by both EFFICIENT and SPLIT. Finally, we report on some preliminary results obtained by applying these techniques to the balanced graph partitioning problem.

2. Algorithm EFFICIENT.

Let $G = (V, E)$ be a connected undirected graph and let $wt : E \rightarrow \mathbf{Z}^+$ be an assignment of weights to the edges of G. We will extend the function wt to subsets of E in the obvious manner. A partition $(V', V - V')$ of V specifies a *cut*; the cut consists of all edges, S, that have one endpoint in each partition. We will denote a cut by the

*Received by the editors August 7, 1992; accepted for publication (in revised form) May 28, 1993.
†Department of Computer Science and Engineering, Indian Institute of Technology, New Delhi-110016, India.

set of its edges, S, and will define its *weight* to be $wt(S)$. For any set $S \subseteq E$, we will denote the number of connected components of the graph $G' = (V, E - S)$ by comps(S).

We will first find a k cut for a specified k. Our algorithm is based on the following greedy strategy: It keeps picking cuts until their union is a k cut and in each iteration it picks the lightest cut; in the original graph, that creates additional components.

Algorithm EFFICIENT:

1. For each edge e, pick a minimum weight cut, say, s_e, that separates the endpoints of e.
2. Sort these cuts by increasing weight, obtaining the list $s_1, \ldots, s_m$.
3. Greedily pick cuts from this list until their union is a k cut; cut s_i is picked only if it is not contained in $s_1 \cup \cdots \cup s_{i-1}$.

(Note: in case the algorithm ends with a cut B such that comps(B) $> k$, we can easily remove edges from B to get a cut B' such that comps(B') $= k$.)

Notice that since edge e is in s_e, $s_1 \cup \cdots \cup s_m = E$, and so this must be an n cut. Therefore, the algorithm will certainly succeed in finding a k cut.

Let $b_1, \ldots, b_l$ be the successive cuts picked by the algorithm. In the next lemma we show that with each cut picked we increase the number of components created, and hence the total number of cuts picked is at most $k - 1$.

LEMMA 2.1. *For each i, $1 \leq i < l$,* comps($b_1 \cup \cdots \cup b_{i+1}$) $>$ comps($b_1 \cup \cdots \cup b_i$).

Proof. Because of the manner in which EFFICIENT picks cuts, $b_{i+1} \not\subseteq (b_1 \cup \cdots \cup b_i)$. Let (u, v) be an edge in $b_{i+1} - (b_1 \cup \cdots \cup b_i)$. Clearly, u and v are in the same component in the graph obtained by removing the edges of $b_1 \cup \cdots \cup b_i$ from G, and they are in different components in the graph obtained by removing $b_1 \cup \cdots \cup b_{i+1}$ from G. Hence, the latter graph has more components. □

COROLLARY 2.2. *The number of cuts picked, l, is at most $k - 1$.*

Notice that at each step we are indeed picking the lightest cut that creates additional components: among all edges that lie within connected components, we choose the edge whose endpoints can be disconnected with the lightest of the cuts from the original graph.

The complexity of our algorithm is dominated by the time taken to find cuts $s_1, \ldots, s_m$. This can clearly be done with m max flow computations. A more efficient implementation is obtained by using Gomory–Hu cuts. Gomory and Hu [GoHu] show that there is a set of $n - 1$ cuts in G such that for each pair of vertices, $u, v \in V$, the set contains a minimum weight cut separating u and v; moreover, they show how to find such a set using only $n - 1$ max flow computations. The cuts $s_1, \ldots, s_m$ can clearly be obtained from such a set of $n - 1$ cuts.

Incorporating all this, we get a particularly simple description of our algorithm. First, notice that step 3 is equivalent to

3′. Find the minimum i such that comps($s_1 \cup \ldots \cup s_i$) $\geq k$. Output the k cut $s_1 \cup \ldots \cup s_i$.

Next, observe that when implemented with Gomory–Hu cuts, Algorithm EFFICIENT essentially boils down to the following:

1. Find a set of Gomory-Hu cuts in G.
2. Sort these cuts by increasing weight, obtaining the list $g_1, \ldots, g_{n-1}$.
3. Find the minimum i such that comps($g_1 \cup \ldots \cup g_i$) $\geq k$.

The algorithm extends in a straightforward manner to obtaining near-optimal k cuts for each k, $2 \leq k \leq n$, with the same set of Gomory–Hu cuts.

3. Performance guarantee for EFFICIENT. In this section we shall prove the next theorem.

THEOREM 3.1. *Algorithm EFFICIENT finds a k cut having weight within a factor of* $(2 - 2/k)$ *of the optimal.*

Let $b_1, \ldots, b_l$ be the successive cuts found by Algorithm EFFICIENT; $B = b_1 \cup \cdots \cup b_l$. Central to our proof is a special property of these cuts with respect to an enumeration of all cuts in G. Let $c_1, c_2, \ldots$ be such an enumeration, sorted by increasing weight, such that $b_1, \ldots, b_l$ appear in this order in the enumeration. Such an enumeration will be said to be *consistent* with the cuts $b_1, \ldots, b_l$. For any cut c in G, index(c) is its index in this enumeration.

The union property. Let $s_1, \ldots, s_p$ be a set of cuts in G, sorted by increasing weight. Pick any enumeration of all cuts in G, $c_1, c_2, \ldots$ that is consistent with $s_1, \ldots, s_p$. We will say that $s_1, \ldots, s_p$ satisfy the union property if, intuitively, w.r.t. any such enumeration, the union of the cuts in any initial segment of $c_1, c_2, \ldots$ is equal to the union of all cuts s_j contained in this initial segment. More formally, pick any consistent enumeration of all cuts in G, let i be any index, $1 \leq i \leq \text{index}(s_p)$, and let s_q be the last cut in the sorted order having index at most i. Then, $c_1 \cup \cdots \cup c_i = s_1 \cup \cdots \cup s_q$.

LEMMA 3.2. *The cuts* $b_1, \ldots, b_l$ *satisfy the union property.*

Proof. Suppose the cuts do not satisfy the union property. Then there is an enumeration of all cuts in G, $c_1, c_2, \ldots$, that is consistent with $b_1, \ldots, b_l$, and yet there is an index i, $i \leq \text{index}(b_l)$, such that

$$b_1 \cup \cdots \cup b_q \neq c_1 \cup \cdots \cup c_i,$$

where b_q is the last cut on our list having index at most i. The smallest such index will be referred to as the *point of discrepancy*. Let us fix an enumeration for which the point of discrepancy is maximum. Clearly, the point of discrepancy will have index less than index(b_l).

Let b_{q+1} be the next cut picked by our algorithm, and let index$(b_{q+1}) = j$. Because of the manner in which we fixed the enumeration, $wt(c_j) > wt(c_i)$ (otherwise we could interchange c_i and c_j, and obtain an enumeration in which discrepancy occurs at a larger index).

Clearly, $b_q \neq c_i$ and $c_1 \cup \cdots \cup c_{i-1} = b_1 \cup \cdots \cup b_q$. Let $e \in c_i - (c_1 \cup \cdots \cup c_{i-1})$. Then, $e \notin b_1 \cup \cdots \cup b_q$. Clearly, $wt(s_e) \leq wt(c_i)$, where s_e is a minimum weight cut that disconnects the endpoints of e. Now, our algorithm must pick edge e with a cut of weight at most $wt(s_e)$, and hence at most $wt(c_i)$. Since $wt(b_{q+1}) > wt(c_i)$, this means that $e \in b_1 \cup \cdots \cup b_q$, leading to a contradiction. □

Remark. Since $b_1, \ldots, b_l$ are drawn from $s_1, \ldots, s_m$, the latter cuts also satisfy the union property. For similar reasons, $g_1, \ldots, g_{n-1}$ satisfy the union property as well.

Let A be a minimum weight k cut in G. The second key idea in our proof is to view A as the union of k cuts as follows: Let $V_1, \ldots, V_k$ be the connected components of $G' = (V, E - A)$. Let a_i be the cut that separates V_i from $V - V_i$ for $1 \leq i \leq k$. Then $A = \bigcup_{i=1}^{k} a_i$. Notice that $\sum_{i=1}^{k} wt(a_i) = 2wt(A)$ (because each edge of A is counted twice in the sum). Assume without loss of generality that $wt(a_1) \leq wt(a_2) \leq \cdots \leq wt(a_k)$.

The $(2 - 2/k)$ bound is established by showing that the sum of weights of our cuts, $b_1, \ldots, b_l$ is at most the sum of weights of $a_1, \ldots, a_{k-1}$, i.e.,

$$\begin{aligned} wt(B) &\leq \sum_{i=1}^{l} wt(b_i) \leq \sum_{i=1}^{k-1} wt(a_i) \\ &\leq 2(1 - 1/k)wt(A), \end{aligned}$$

since a_k is the heaviest cut of A.

Actually, it will be simpler to prove a stronger statement. We will consider a slight variant of EFFICIENT that picks cuts with multiplicity; cut b_i will be picked t times if its inclusion created t additional components, i.e., if $(\text{comps}(b_1 \cup \ldots \cup b_i) - \text{comps}(b_1 \cup \ldots \cup b_{i-1})) = t$.

So, now we have exactly $k-1$ cuts; let us call them $b_1, \ldots, b_{k-1}$, to avoid introducing excessive notation. As before, $b_1, \ldots, b_{k-1}$ are sorted by increasing weight, and moreover we shall assume that cuts with multiplicity occur consecutively. We will show that

$$\sum_{i=1}^{k-1} wt(b_i) \leq \sum_{i=1}^{k-1} wt(a_i) \ldots (i).$$

For the rest of the proof, we will study how the cuts a_i's and b_j's are distributed in $c_1, c_2, \ldots$, an enumeration of all cuts in G w.r.t. which $b_1 \ldots b_{k-1}$ satisfy the union property. Denote by α_i the number of all cuts a_j that have index $\leq i$, i.e., $\alpha_i = |\{a_j | \text{ index}(a_j) \leq i\}|$. We will show that for each index i, $1 \leq i \leq \text{index}(a_{k-1})$, the number of cuts b_j having index $\leq i$ is at least α_i (of course, cuts b_j are counted with multiplicity). If so, there will be a 1–1 map from $\{b_1, \ldots b_{k-1}\}$ onto $\{a_1, \ldots, a_{k-1}\}$ such that if b_i is mapped onto a_j, then index $(b_i) \leq \text{index}(a_j)$. This will prove (i).

Two nice properties of the cuts a_i's and b_j's will help prove the assertion of the previous paragraph. Denote by A_i the union of all cuts a_j that have index $\leq i$, i.e., $A_i = \bigcup_{a_j:\text{index}(a_j)\leq i} a_j$. Similarly, let $B_i = \bigcup_{b_j:\text{index}(b_j)\leq i} b_j$.

The next lemma shows that for each index i, the cuts b_j are making at least as much progress as the cuts a_j's, where progress is measured by the number of components created.

LEMMA 3.3. *For each index i, $\text{comps}(A_i) \leq \text{comps}(B_i)$.*

Proof. The lemma is clearly true for $i > \text{index}(b_{k-1})$. For $i \leq \text{index}(b_{k-1})$, $B_i = c_1 \cup \cdots \cup c_i$, since the cuts $b_1, \ldots, b_{k-1}$ satisfy the union property. Therefore, $A_i \subseteq B_i$, and the lemma follows. □

It is easy to construct an example showing that each cut a_j may not necessarily create additional components. Yet, at each index i, the number of components created by the cuts a_j is at least $\alpha_i + 1$. This is established in the next lemma.

LEMMA 3.4. *For each i, $1 \leq i \leq \text{index}(a_{k-1})$, $\text{comps}(A_i) \geq \alpha_i + 1$.*

Proof. Corresponding to each cut a_j having index $\leq i$, the partition V_j will be a single connected component all by itself in the graph $G_i = (V, E - A_i)$. Let us charge a_j to this component of G_i. Since index $(a_k) > i$, the component of G_i containing V_k will not get charged. The lemma follows. □

At this point we have all the ingredients to finish the proof. Consider an index i, $1 \leq i \leq \text{index}(a_{k-1})$. By Lemma 3.4, $\text{comps}(A_i) \geq \alpha_i + 1$. This together with Lemma 3.3 gives $\text{comps}(B_i) \geq \alpha_i + 1$. For each additional component created by us, we have included a cut b_j (by including cuts with appropriate multiplicity), and thus it follows that the number of cuts b_j having index $\leq i$ is at least α_i. The theorem follows.

Remark. The proof given above shows that any set of cuts satisfying the union property will give a near-optimal k cut. This explains why the Gomory–Hu cuts work.

Clearly, the proof given above holds *simultaneously* for each value of k between 2 and n. Hence we get a set of near-optimal k cuts, $2 \leq k \leq n$. Notice that at the extremes, i.e., for $k = 2$ and $k = n$, we get optimal cuts.

THEOREM 3.5. *Algorithm EFFICIENT finds a set of k cuts, one for each value of k, $2 \leq k \leq n$; each cut is within a factor of $(2 - 2/k)$ of the optimal k cut. The algorithm requires a total of $n - 1$ max flow computations.*

Using the current best known max flow algorithm [GT], [KRT], our algorithm has a running time of $O(mn^2 + n^{3+\epsilon})$, for any fixed $\epsilon > 0$.

4. Algorithm SPLIT. Perhaps the first heuristic that comes to mind for finding a k cut is the following.

Algorithm SPLIT: Start with the given graph. In each iteration, pick the lightest cut in the current graph that splits a component, and remove the edges of this cut. Stop when the current graph has k connected components.

Notice that SPLIT, like EFFICIENT, is also a greedy algorithm. Whereas EFFICIENT picks a lightest cut in the original graph that creates additional components, SPLIT picks a lightest cut in the current graph.

SPLIT needs to find a minimum weight cut in each new component formed—this can be done using $n - 1$ max flow computations in a graph on n vertices. Hence SPLIT requires $O(kn)$ max flow computations to find a k cut.

We shall establish a $(2 - 2/k)$ performance guarantee for SPLIT as well. However, first let us point out that neither algorithm dominates the other. Consider the following graph on eight vertices, $\{a, b, c, d, e, f, g, h\}$. The edges and their weights are as follows.

$wt(a, b) = 3$,
$wt(a, c) = 3$,
$wt(b, d) = 7$,
$wt(c, e) = 7$,
$wt(d, e) = 10$,
$wt(d, f) = 4$,
$wt(f, g) = 5$,
$wt(g, h) = 5$,
$wt(e, h) = 4$.

Now, for $k = 3$, the cuts found by SPLIT and EFFICIENT have weights 13 and 14, respectively, but for $k = 4$, the weights are 20 and 19, respectively.

THEOREM 4.1. *The k cut found by Algorithm SPLIT has weight within a factor of $(2-2/k)$ of the optimal.*

Proof. In Theorem 3.1 we showed that a slight variant of EFFICIENT, that picks cuts with appropriate multiplicity, has a performance bound of $(2 - 2/k)$. We will now prove that the weight of the k cut found by SPLIT is dominated by the weight of the k cut found by this variant.

Let $b_1, \ldots, b_{k-1}$ be the cuts picked by the variant. Notice that since SPLIT picks a minimum weight cut in a component, it splits it into exactly two components. Therefore, SPLIT picks exactly $k - 1$ cuts, say, $d_1, \ldots, d_{k-1}$.

By induction on i, we will show that $wt(d_i) \leq wt(b_i)$ for $1 \leq i \leq k - 1$. The assertion is clearly true for $i = 1$. To show the induction step, first notice that $\text{comps}(d_1 \cup \cdots \cup d_i) = i + 1$ and $\text{comps}(b_1 \cup \cdots \cup b_{i+1}) \geq i + 2$. Therefore, there is a cut b_j, $1 \leq j \leq i + 1$, that is not contained in $(d_1 \cup \cdots \cup d_i)$. By the proof of Lemma 2.1, this cut will create additional components, and is available to SPLIT. Hence, SPLIT will pick a cut of weight at most $wt(b_j)$. Since $wt(b_j) \leq wt(b_{i+1})$, the assertion follows. □

5. Lower bound. We will show that the bounds established in Theorem 3.1 and Theorem 4.1 are tight in the following sense.

THEOREM 5.1. *For any ϵ, $0 < \epsilon \leq 1$, there is an infinite family of minimum k-cut instances (G, wt, k) such that the weight of the k cut found by each algorithm, EFFICIENT and SPLIT, lies in the range*

$$[(1 - \epsilon)(2 - 2/k)W,\ (2 - 2/k)W],$$

where W is the weight of an optimal k cut for the instance. Moreover, k is unbounded in this family.

Proof. The kth instance, in which we want to find a k cut, consists of a graph on $2k-1$ vertices, $V = \{u_1, \ldots, u_{k-1}, v_1, \ldots, v_k\}$. The only edges are (with weights specified)

$$\begin{aligned} wt(u_i, u_{i+1}) &= \beta \quad \text{for } 1 \le i \le k-2, \\ wt(u_{k-1}, v_1) &= \beta, \\ wt(v_i, v_{i+1}) &= \alpha \quad \text{for } 1 \le i \le k-1, \\ wt(v_1, v_k) &= \alpha, \end{aligned}$$

where α is a positive integer, and $\beta = 2\alpha(1-\epsilon)$.

The minimum k cut, A, picks all edges of weight α, and so $wt(A) = k\alpha$. Each algorithm, EFFICIENT and SPLIT, picks the k cut, B, consisting of all edges of weight β. So $wt(B) = (k-1)\beta = 2(k-1)\alpha(1-\epsilon)$. Hence

$$wt(B)/wt(A) = (2 - 2/k)(1-\epsilon).$$

This proves the theorem. □

6. Balanced graph partitioning. Given an edge-weighted graph, $G = (V, E)$, $wt : E \to \mathbf{Z}^+$, with an even number of vertices, the balanced graph partitioning problem asks for a partition of V into two sets, V_1 and V_2, each containing half the vertices, such that the weight of the cut separating V_1 and V_2 is minimized. This problem is NP hard [GJ]. It models realistic situations such as circuit partitioning and is frequently used in practice. (See [KL] for the well-known "swap" heuristic for this problem.) We give the first approximation algorithm for this problem; it achieves a performance ratio of $n/2$. The algorithm extends in a straightforward manner to the problem of partitioning the graph into k equal size pieces, for any fixed k. The performance ratio achieved for this problem is $(\frac{k-1}{k})n$. In the past, [LR] and [LMPSTT] have used multicommodity flow for obtaining a $\frac{1}{3}, \frac{2}{3}$ graph partition algorithm that is within an $O(\log n)$ factor of the best balanced partition (in a $\frac{1}{3}, \frac{2}{3}$ graph partition each side of the cut has between $\frac{1}{3}$ and $\frac{2}{3}$ fraction of the vertices).

Our algorithm uses the fact that there is a pseudopolynomial time algorithm for determining whether n given numbers $a_1, \ldots, a_n$ can be partitioned into two sets each of which adds up to $W/2$, where $\sum_{i=1}^{n} a_i = W$. This algorithm is based on a straightforward dynamic programming approach, and has a running time of $O(nW)$ [GJ]; if the answer is "yes," it finds a valid partition as well.

Balanced graph partitioning algorithm:

1. Find a set of Gomory-Hu cuts in G.
2. Sort these cuts by increasing weight, obtaining $g_1, \ldots, g_{n-1}$.
3. Find the minimum i such that the connected components of $G' = (V, E - (g_1 \cup \cdots \cup g_i))$ can be partitioned into two sets containing $\frac{n}{2}$ vertices each.

The complexity of our algorithm is dominated by step 1, since the total time required by step 3 is $O(n^3)$. We will use the following property of the partitioning problem to establish the bound of $n/2$.

LEMMA 6.1. *Let n be an even integer, and let $a_1, \ldots a_{(n/2)+1}$ be positive integers such that*

$$\sum_{i=1}^{\frac{n}{2}+1} a_i = n.$$

Then the answer to the partitioning problem is "yes."

Proof. Without loss of generality assume that the a_i's are sorted in decreasing order. Notice that in order to maintain a sum of n, if $a_1 = 2$ then $a_2 = \cdots = a_{(n/2)-1} = 2$ and $a_{n/2} = a_{(n/2)+1} = 1$. In this case, the a_i's can clearly be partitioned. In general, let k be the largest index such that $a_k > 1$, i.e., the last $\frac{n}{2} + 1 - k$ numbers are 1's. It is easy to see that the sizes of a_i's exceeding 2 determine the number of 1's in the following manner:

$$\sum_{i=1}^{k}(a_i - 2) = \left(\frac{n}{2} + 1 - k\right) - 2. \tag{1}$$

Now, associate $a_i - 2$ distinct 1's with each a_i that exceeds 2. By (1) this is feasible, and moreover exactly two 1's will be left over unassociated. For each a_i exceeding 2, we will include a_i in one partition and its associated 1's in the other partition. This effectively gives the former partition a weight of 2 more than the latter. Hence, once again we are essentially left with partitioning numbers of the form $2, 2, \ldots, 2, 1, 1$. □

As before, let $c_1, c_2, \ldots$ be an enumeration of all cuts in G, ordered by increasing weight, and let $B = g_1 \cup \cdots \cup g_i$ be the set of edges picked by our algorithm. Let c_k be the first cut in the enumeration that yields an optimal balanced partitioning of G.

LEMMA 6.2. $wt(B) \leq \frac{n}{2} wt(c_k)$.

Proof. As in Algorithm EFFICIENT, among the cuts $g_1, \ldots, g_i$, pick g_j iff it is not contained in $(g_1 \cup \cdots \cup g_{j-1})$. Let $b_1, \ldots, b_l$ be the cuts picked in this manner. Clearly, $B = b_1 \cup \cdots \cup b_l$. The proof is based on Lemma 3.2, i.e., the fact that the cuts $b_1, \ldots, b_l$ satisfy the union property. This and the fact that the components of $G' = (V, E - C)$ can certainly be partitioned into equal sized sets, for any set C containing c_k, imply that index$(b_l) \leq k$. Now by Lemma 2.1, $l \leq n - 1$, thereby giving a factor of $(n - 1)$. To achieve a better factor, notice that Lemma 6.1 implies that $l \leq n/2$. Therefore $wt(B) \leq \sum_{i=1}^{l} wt(b_i) \leq \frac{n}{2} wt(c_k)$. □

LEMMA 6.3. *The bound of $\frac{n}{2}$ is tight for our algorithm.*

Proof. As in Theorem 5.1, for any ϵ, $0 < \epsilon < 1$, we will give an infinite family of instances on which the cut found by our algorithm lies in the range $[(1 - \epsilon)\frac{n}{2} W, \frac{n}{2} W]$, where W is the weight of the optimal cut. The kth instance consists of a graph on $2k$ vertices $\{u, v, u_1 \ldots u_{k-1}, v_1, \ldots, v_{k-1}\}$, and edges (with weights) $wt(u_i, u) = \alpha, 1 \leq i \leq k - 1$, $wt(v_i, v) = \alpha, 1 \leq i \leq (k - 1)$, $wt(u, v) = \beta$, where $\alpha = (1 - \epsilon)\beta$. It is easy to see that our algorithm finds a cut of weight $k\alpha$, and the optimal cut has weight β. □

THEOREM 6.4. *The algorithm given above finds a balanced partitioning of an edge-weighted graph, using $n - 1$ max-flow computations. The weight of the cut found is within a factor of $n/2$ of the optimal. Moreover, the bound of $n/2$ is tight for our algorithm.*

7. Discussion and open problems. It will be interesting to see how Algorithms SPLIT and EFFICIENT compare in practice, even though neither algorithm dominates the other in worst-case performance. Our guess is that SPLIT will typically give lighter k cuts.

Notice that the graphs given in Theorem 5.1 help establish the $(2 - 2/k)$ lower bound for the k cut found for each k, $2 \leq k \leq (n + 1)/2$, where n is the number of vertices in the graph (n is odd), but not for higher values of k. Certainly, the bound of $(2 - 2/k)$ is not tight for $k = n$, since we get the optimal cut. Is there a better analysis of our algorithms for $k > n/2$?

Is there a better approximation algorithm for the minimum k-cut problem? We believe that the problem of achieving a factor of $(2 - \varepsilon)$, for some $\varepsilon > 0$, independent of k, is intractable. The minimum k-cut problem is MAX-SNP complete [Pa], and hence by the recent result of [ALMSS], achieving a factor of $1 + \varepsilon$, is NP complete for some $\varepsilon > 0$.

Our investigation of the balanced graph partitioning problems appears to be quite preliminary, and it should be possible to improve the bound. Interesting special cases are (a) the graph is planar, and (b) all edge weights are 1. Since the graphs used in Lemma 6.3 are planar,

the lower bound for our algorithm holds for case (a). It is easy to see that if ties are resolved arbitrarily in our algorithm, Lemma 6.3 holds for case (b) as well; however, this seems to be a small hurdle. It will also be useful to consider the version of the balanced graph partitioning problem in which vertices have weights; in this case the pseudopolynomial algorithm for partition will not be useful.

Finally, some of these methods may be useful for obtaining approximation algorithms for other NP-hard graph partitioning problems (see [GH] and [GJ]).

Acknowledgments. We wish to thank Fan Chung, Samir Khuller, Laszlo Lovasz, Milena Mihail, Christos Papadimitriou, Umesh Vazirani, and Mihalis Yannakakis for valuable discussions and comments.

THE SERIAL TRANSITIVE CLOSURE PROBLEM FOR TREES*

MARIA LUISA BONET† AND SAMUEL R. BUSS†

Abstract. The serial transitive closure problem is the problem, given a directed graph G and a list of edges, called closure edges, which are in the transitive closure of the graph, to generate all the closure edges from edges in G. A nearly linear upper bound is given on the number of steps in optimal solutions to the serial transitive closure problem for the case of graphs that are trees. "Nearly linear" means $O(n \cdot \alpha(n))$, where α is the inverse Ackermann function. This upper bound is optimal to within a constant factor.

Key words. transitive closure, graph algorithm, inverse Ackermann function, weak superconcentrators

AMS subject classifications. 68R10, 05C12, 05C85

1. Introduction.

A directed graph is transitive if, whenever there is an edge from a node X to a node Y and an edge from Y to Z, there is an edge from X to Z. The transitive closure of G is a smallest transitive, directed graph containing G. We write $X \rightarrow Y$ to indicate the presence of an edge from X to Y. It is easy to see that any edge in the transitive closure of a graph G can be obtained from the edges of G by a series of zero or more *closure steps*, which are inferences of the form

$$\frac{A \rightarrow B \qquad B \rightarrow C}{A \rightarrow C}.$$

In other words, if $A \rightarrow B$ and $B \rightarrow C$ are edges in the transitive closure of G, then $A \rightarrow C$ is too. This is because G plus the edges that can be derived by closure steps from edges in G both must be in any transitive graph containing G and also form a transitive graph on the nodes of G.

The serial transitive closure problem is the problem of deriving a given subset of edges, which we call "closure edges," in the transitive closure of a directed graph. A solution to the serial transitive closure problem is a sequence of closure steps that generates all of the given closure edges and the size of a solution is the number of closure steps in the solution. In this paper, we give upper and lower bounds on the size of optimal solutions to the serial transitive closure problems for directed graphs that are trees. It should be stressed that the set of closure edges can be any subset of the edges in the transitive closure of the graph (but not in the graph). The degenerate case of deriving a single closure edge $A \rightarrow B$ is quite simple, since the minimum number of closure steps required will be one less than the length of a shortest path from A to B. The general question of determining the optimal size of a solution is made difficult by the fact that, when a *set* of closure edges is being derived, it may be possible for individual closure steps to aid in the generation of multiple closure edges. In other words, it is not necessary to generate each closure edge independently. It is also important that the set of closure edges will, in general, not be *all* the edges in the transitive closure of the graph; the problem of deriving all the edges in the transitive closure of the graph is uninteresting because, in this case, exactly one closure step is needed per closure edge.

The authors' interest in the serial transitive closure problem arose in the study of the lengths of propositional proofs with and without the deduction rule. The serial transitive closure problem is directly related to the question of how efficiently Frege proof systems can simulate nested deduction Frege proof systems. More information on these proof systems and

the application of the serial transitive closure problem to proof lengths can be found in [2], [4], [3]. The present paper is an expansion of portions of [2], [4].

The serial transitive closure problem is potentially applicable to problems in networks. As an example, suppose a communication network is given where the nodes are, say, computers, and an edge from X to Y indicates that X is capable of sending messages to Y. Correspondingly, a set of closure edges is a set of edges of desired connections. If the closure edges are in the transitive closure of the network, then it is possible to establish the desired connections by having nodes relay messages (much like real-world nets such as Usenet). A closure step would correspond to determining that, since X can (indirectly) transmit to Y and Y can (indirectly) transmit to Z, X can indirectly transmit to Z. The size of a solution to the serial transitive closure problem would correspond to the number of indirect communication links that must be established to set up the desired connections. (It should be mentioned that this example completely glosses over important issues such as the bandwidth of the connections.)

The serial transitive closure problem is formally defined as follows.

Serial Transitive Closure Problem.

An *instance* consists of

- A directed graph G with m edges and
- A list of n *closure* edges $X_i \to Y_i$ $(i = 1, \ldots, n)$ that are in the transitive closure of G but not in G.

A *solution* is a sequence of edges $U_i \to V_i$ $(i = 1, \ldots, s)$ containing all n closure edges such that each $U_i \to V_i$ is inferred by a single closure step from earlier edges in the solution and/or edges in G. We call s the number of steps of the solution.

Note that the number of steps in a solution counts only closure steps and does not count edges that are already in G. A directed graph is a *tree* if it is a tree in the usual sense, with root at the top and with all edges directed downward or with all edges directed upward.

The outline of this paper is as follows. In §2, we state and prove the main results, which give near-linear upper bounds on size of solutions to the serial transitive closure problem for trees. Our near-linear upper bounds are of the form $O(n \cdot \alpha(n))$, where $\alpha(n)$ is the extremely slow-growing inverse Ackermann function. In §3 we show that the upper bound is optimal for trees, using a theorem used by Tarjan [13] for an algorithm for the Union-Find problem. It is not known whether our upper bound is optimal for the case where the directed graph G is linear, i.e., G is a tree with each nonleaf node having only one child. However, we argue at the end of §3 that our construction cannot be easily improved for the linear case, since our approach gives an explicit construction for weak superconcentrators and there is a lower bound on the size of constant depth superconcentrators [10] that prevents the possibility that a simple modification can lead to an improvement of our construction.

The methods of our paper do not apply to graphs that are not trees, and we do not know any nontrivial upper or lower bounds on the size of solutions of serial transitive closure problems for general graphs.

Our proof methods for our upper bounds (Theorem 2 through Corollary 2.8) are related to the constructions of weak superconcentrators by [6], [7], and are also similar to prior methods for creating algorithms for range queries on linear lists [15] and on free trees [8]. In fact, as one of the referees pointed out, it is possible to derive Corollary 2.8, as a corollary to the proofs (but not the theorems) contained in [15], [8]. Similar constructions have also been used for adding edges to trees to reduce their diameter [1]. However, it is useful to give direct proofs in this paper since the serial transitive closure problem is of independent interest (e.g., as applied in [4], [3]).

2. Upper bounds for trees. The "near-linear" upper bounds given below are stated in terms of extremely slow growing functions such as log^* and the inverse Ackermann function. The function $\log x$ is the real-valued base two logarithm function. The log^* function is defined so that $\log^* n$ is equal to the least number of iterations of the logarithm base 2, which, applied to n, yields a value < 2. In other words, $\log^* n$ is equal to the least value of k such that $n < 2^{2^{\cdot^{\cdot^{\cdot^{2}}}}}$ where there are k 2's in the stack. To get even slower growing functions, we define the $\log^{(*i)}$ functions for each $i \geq 0$. The $log^{(*0)}$ function is just the base 2 logarithm function rounded down to an integer and the $log^{(*1)}$ is just the log^* function. For $i > 1$, $log^{(*i)}(n)$ is defined to be equal to the least number of iterations of the $log^{(*i-1)}$ function, which, applied to n, yields a value < 2. The Ackermann function can be defined by the equations:

$$\begin{aligned} A(0, m) &= 2m, \\ A(n+1, 0) &= 1, \\ A(n+1, m+1) &= A(n, A(n+1, m)). \end{aligned}$$

It is well known that the Ackermann function is recursive but dominates eventually every primitive recursive function (see [9] for a proof). We next develop the basic properties of the Ackermann function and the $\log^*$ functions; see La Poutré [12] for a similar development (his function $\alpha(i, m)$ is equal to our $\log^{(*i-1)}(m)$).

It is is easy to see, by induction on n, that $A(n, 1) = 2$ for all n, because

$$A(n+1, 1) = A(n, A(n+1, 0)) = A(n, 1).$$

Also, by induction on m, we have $A(1, m) = 2^m$, since

$$A(1, m+1) = A(0, A(1, m)) = 2 \cdot A(1, m).$$

Likewise, $A(2, m) = 2^{2^{\cdot^{\cdot^{\cdot^{2}}}}}$ where there are m 2's in the stack, since

$$A(2, m+1) = A(1, A(2, m)) = 2^{A(2,m)}.$$

PROPOSITION 2.1. *For $n > 1$, $A(n, m)$ is the equal to the least i such that $\log^{(*n-1)}(i) = m$. Hence, $\log^{(*n-1)} A(n, m) = m$.*

Proof. The proof is by induction on n. By the above definitions and comments, the lemma holds for $n = 1, 2$. Fix n and assume, as the induction hypothesis for n, that for all i, m, if $A(n, m) \leq i < A(n, m+1)$, then $\log^{(*n-1)}(i) = m$. To prove the corresponding fact for $n+1$, we use induction on m. It is obvious for $m = 0$ since $A(n, 0) = 0$ and $A(n, 1) = 2$. For $m > 0$, we have that

$$\begin{aligned} \log^{(*n-1)} A(n+1, m) &= \log^{(*n-1)} A(n, A(n+1, m-1)) \\ &= A(n+1, m-1) \end{aligned}$$

and, in addition, that

$$\begin{aligned} \log^{(*n-1)}\Big(A(n+1, m+1) - 1\Big) &= \log^{(*n-1)}\Big(A(n, A(n+1, m)) - 1\Big) \\ &= A(n+1, m) - 1. \end{aligned}$$

The last equality is justified by the induction hypothesis that $A(n, A(n+1, m))$ is the least value i such that $\log^{(*n-1)}(i) = A(n+1, m)$. Thus we have shown that, if $A(n+1, m) \leq$

$k < A(n+1, m+1)$, then $A(n+1, m-1) \leq \log^{(*n-1)}(k) < A(n+1, m)$. If follows that, if $A(n+1, m) \leq k < A(n+1, m+1)$, then $\log^{(*n-1)}$ must be applied exactly m times to k to yield a value $< 2 = A(n+1, 1)$; i.e., that $\log^{(*n)}(k) = m$. □

PROPOSITION 2.2. *For $i \geq 1$, $\log^{(*i-1)}(i) \leq 3$.*

Proof. First observe that for all $i \geq 0$ and $x \geq 1$, we have $\log^{(*i)}(x) < x$. And for $i \geq 0$, $\log^{(*i)}(3) < 2$. We now prove the proposition by induction on i. The base case, $i = 1$, is obvious. For the induction step, we have that $\log^{(*i-1)}(i+1) \leq i$ by the first observation,and $\log^{(*i-1)}(i) \leq 3$ by the induction hypothesis. Thus three applications of $\log^{(*i-1)}$ suffice to take $i+1$ to a value less than 2. Hence $\log^{(*i)}(i+1) \leq 3$. □

DEFINITION. *The* inverse Ackermann *function α is defined so that $\alpha(n)$ is equal to the least value of i such that $A(i, i) > n$. Equivalently, $\alpha(n)$ is equal to the least i such that $\log^{(*i-1)} n < i$.*

MAIN THEOREM 2.3. *Let $i \geq 0$. If the directed graph G is a tree then the serial transitive closure problem has a solution with $O(n + m \log^{(*i)} m)$ steps.*

MAIN THEOREM 2.4. *If the directed graph G is a tree then the serial transitive closure problem has a solution with $O((n+m) \cdot \alpha(m))$ steps.*

Another definition of the inverse Ackermann function has been given by Tarjan [13] who defines

$$\alpha(m, n) = \text{least } i \geq 1 \text{s.t.} A(i, 4\lceil m/n \rceil) > \log n.$$

We will also prove below that for G a tree, the serial transitive closure has a solution with $O((n+m)\alpha(n+m, m))$ steps.

Theorem 2.7 below is a restatement of Theorem 2 with explicit constants. The rest of our upper bounds will be corollaries of Theorem 2.7.

For the proofs of our main theorems we may assume without loss of generality that G is a rooted tree with edges pointing away from the root. We always picture trees with the root at the top, except in the special case of one-trees, which have fanout 1, the root is to the left and edges point to the right. The concepts of *child, father, ancestor*, and *descendent* are defined as usual. The *size* of a tree is defined to be the number of edges in the tree (not the number of nodes). If a tree has e edges, then it has exactly $e+1$ nodes. We define a *subtree* of a tree T to be any connected subset of the edges of T and their endpoints so that, for all nodes X and Y in T, if X and Y have the same father, then X is in the subtree iff Y is in the subtree. A subtree is *unscarred* if it consists of all the edges below a given node in the tree. A subtree S may also be obtained by first removing some set of unscarred subtrees and then letting S consist of all the remaining edges below some given remaining node: S is said to have a *scar* at any of its leaf nodes that are roots of earlier removed (nontrivial) subtrees. Two subtrees are said to be *disjoint* if they have no edges in common; disjoint subtrees may share a single node since the root of one may be a scar of the other. If X is a node in T, then T_X denotes the subtree of T rooted at X. The *immediate subtrees* of a tree T are the maximal proper subtrees of T, i.e., the trees T_X for X a child of the root of T. The following lemma is well known: see, e.g., Brent [5].

LEMMA 2.5. *Let $N \geq 0$ and T be a tree with $\geq N$ edges. Then there is an unscarred subtree of T that has size $\geq N$ edges such that each of its immediate subtrees has $< N$ edges.*

Lemma 2.5 is easily proved by taking a minimal subtree with $\geq N$ edges. The next theorem restates and strengthens the case $i = 0$ of Theorem 2.3 with fairly tight bounds on the constants. The *log* function is base 2.

THEOREM 2.6. *If the directed graph G is a tree then the serial transitive closure problem has a solution with $n + m \cdot \lfloor \log m \rfloor$ closure steps.*

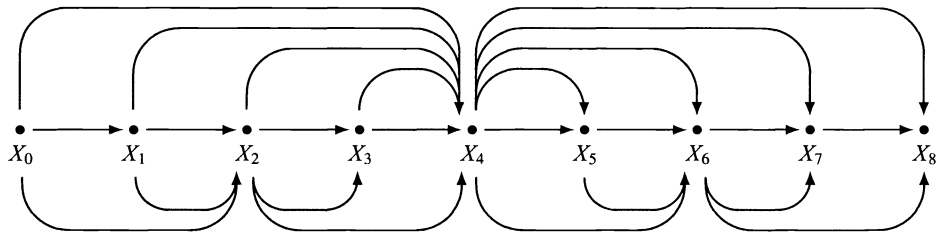

FIG. 1.

Proof. We will first derive $\leq m\lfloor \log m \rfloor$ edges, called *auxiliary edges*; each auxiliary edge will be obtained with a single closure step. The choice of auxiliary edges is independent of the closure edges; however, from the edges in G and the auxiliary edges each closure edge can be obtained with (at most) one additional closure step.

For illustration purposes, we first prove the theorem for G a one-tree and then do the general case. Although the general case includes the linear case, the proof of the linear case presents the main ideas more clearly.

Linear case. Assume G is a one-tree; that is, each node except the leaf has a single child. In this case we may assume the nodes of G are named $X_0, \ldots, X_m$ and that the edges of G are just $X_i \to X_{i+1}$ for $0 \leq i < m$. The auxiliary edges will be derived in rounds, the first round will in essence split G into two subtrees of $m/2$ edges, the second round splits G into four subtrees of $m/4$ edges, etc., for a total of $\lceil \log m \rceil - 1$ rounds. The process is illustrated for the case $m = 8$ in Fig. 1; the upper edges of Fig. 1 are derived in the first round and the lower edges in the second round.

Round 1. $X_{\lfloor m/2 \rfloor}$ is the midpoint of the one-tree G. The auxiliary edges added in round 1 are the edges of the form $X_j \to X_{\lfloor m/2 \rfloor}$ for $0 \leq j < \lfloor m/2 \rfloor$ and the edges of the form $X_{\lfloor m/2 \rfloor} \to X_k$ for $m/2 < k \leq m$. There are exactly m such edges and they can be derived with m closure steps if we derive them in the right order; namely, letting j range from $\lfloor m/2 \rfloor - 1$ down to 0 and letting k range from $\lfloor m/2 \rfloor + 1$ up to m. (Actually only $m - 2$ closure steps are needed since two of the auxiliary edges are already in G.)

Round 2. Round 1 split G into two halves; the midpoints of these two halves are $X_{\lfloor m/4 \rfloor}$ and $X_{\lfloor 3m/4 \rfloor}$. In round two, auxiliary edges to and from these midpoints are derived. Namely, (1) the edges $X_j \to X_{\lfloor m/4 \rfloor}$ with $j < \lfloor m/4 \rfloor$; (2) the edges $X_{\lfloor m/4 \rfloor} \to X_j$ with $\lfloor m/4 \rfloor < j \leq \lfloor m/2 \rfloor$; (3) the edges $X_j \to X_{\lfloor 3m/4 \rfloor}$ with $\lfloor m/2 \rfloor \leq j < \lfloor 3m/4 \rfloor$; and (4) the edges $X_{\lfloor 3m/4 \rfloor} \to X_j$ with $\lfloor 3m/4 \rfloor < j \leq m$. There are m such edges, and by deriving them in the right order, each can be obtained with a single closure step. (Again, taking into account duplicate edges, fewer than m closure steps are needed for round 2.)

Round ℓ. For round number ℓ we add auxiliary edges incident on the nodes $X_{\lfloor k \cdot m/2^\ell \rfloor}$ for odd values of k. Specifically, for each odd value $k < 2^\ell$ the following auxiliary edges are derived: (1) the edges $X_j \to X_{\lfloor k \cdot m/2^\ell \rfloor}$ for $\lfloor (k-1)m/2^\ell \rfloor \leq j < \lfloor k \cdot m/2^\ell \rfloor$ and (2) the edges $X_{\lfloor k \cdot m/2^\ell \rfloor} \to X_j$ for $\lfloor k \cdot m/2^\ell \rfloor < j \leq \lfloor (k+1)m/2^\ell \rfloor$. Again, there are exactly m such edges (some of them duplicates of edges from G and edges from earlier rounds); this is seen by using the obvious one-to-one correspondence with the edges of G. And by deriving them in the right order, each auxiliary edge is obtained with a single closure step.

Since there are exactly $\lceil \log m \rceil - 1$ rounds and fewer than m closure steps are needed in each round, it is clear that there are $\leq m\lfloor \log m \rfloor$ auxiliary edges and that the number of closure steps so far is bounded by $m\lfloor \log m \rfloor$.

Now we claim that each of the n closure edges can be obtained with at most a single closure step from the $m\lfloor \log m \rfloor$ auxiliary edges (of course some of the closure edges may also be auxiliary edges). To prove this, suppose $X_i \to X_j$ is a closure edge; of course, $i+1 < j$. Find the least value of ℓ such that for some odd k, $i \leq \lfloor k \cdot m/2^\ell \rfloor \leq j$. If either of the inequalities are actually equalities, then $X_i \to X_j$ is an auxiliary edge added in round ℓ and no additional closure step is needed. If both inequalities are strict, then $X_i \to X_{\lfloor k \cdot m/2^\ell \rfloor}$ and $X_{\lfloor k \cdot m/2^\ell \rfloor} \to X_j$ are both auxiliary edges and from these the closure edge $X_i \to X_j$ can be derived with one closure step.

It follows that all the closure and auxiliary edges are derived with fewer than $n + m\lfloor \log m \rfloor$ closure steps and Theorem 2.6 is proved for G a one-tree.

General case. The proof of Theorem 2.6 for G a tree uses a construction similar to the proof of the linear case. For the general case, we use Lemma 2.5 to split G into multiple subtrees of size less than half the size of G (one of these is scarred); then we similarily split these subtrees into subtrees of size less than one quarter the size of G, etc. As in the linear case, we derive auxiliary edges of G as we split G into subtrees; this process will be done in $\leq \log m$ rounds.

Round 1. By Lemma 2.5 there is a node X in G such that G_X has $\geq m/2$ edges, but the immediate subtrees of G_X have size $< m/2$ edges. Let $G_1, \ldots, G_k$ be the immediate subtrees of G_X. Let G_0 be the tree obtained by removing G_X from G; i.e., G_0 is the scarred subtree with root at the root of G and with a single scar at X.

During Round 1, the following auxiliary edges are derived: (1) for each ancestor Y of X the edge $Y \to X$ is an auxiliary edge, and (2) for each descendent Y of X the edge $X \to Y$ is an auxiliary edge. By deriving auxiliary edges in the correct order (namely, shorter edges first), only one closure step is needed for each auxiliary edge. There are at most m auxiliary edges and thus fewer than m closure steps are needed in round 1.

The subtrees $G_0, \ldots, G_k$ are disjoint and partition the nodes of G. They will be treated in the next round.

The total number of closure steps used to derive auxiliary edges in Round 2 is less than $\sum m_i < m$.

Round ℓ. The previous round $\ell - 1$ resulted in G being split into multiple, disjoint subtrees of size $\leq m/2^{\ell-1}$. In round ℓ, we separately consider each such subtree H which is of size $m_H \geq 2$ and process it in the manner of round 1. Since the subtree H is of size $m_H \geq 2$, Lemma 2.5 gives a node X in H such that H_X has size $\geq m_H/2$ and each of H_X's immediate subtrees have size $< m_H/2$. Now auxiliary edges are added from each ancestor of X in H to X and from X to each of its descendents in H; there are $\leq m_H$ such auxiliary edges and each can be added with at most one closure step. The immediate subtrees of H_X and the subtree H with H_X removed have size $\leq m_H/2$ and will be treated in next round.

Since the total size of all the disjoint subtrees is no more than m edges, fewer than m closure steps are used in this round.

The process of adding auxiliary edges ends when all the subtrees being considered have size < 2; namely after no more than $\lfloor \log m \rfloor$ rounds. Thus at most $m\lfloor \log m \rfloor$ closure steps are needed for deriving auxiliary edges.

As in the linear case, each of the n closure edges can be obtained with at most a single closure step from the $m\lfloor \log m \rfloor$ auxiliary edges. To prove this, suppose Y and Z are nodes in G and $Y \to Z$ is a closure edge; of course, Y is an ancestor of Z. Find the greatest value of ℓ, such that Y and Z are in the same subtree H considered during round ℓ. Of course, the nodes Y and Z are in different subtrees in the next round. Hence the node X chosen to split subtree H in round ℓ has Y as an ancestor and Z as a descendent (or possibly, $X = Y$ and

Z is a descendent of X). Thus the edges $Y \to X$ and $X \to Z$ are auxiliary edges derived during round ℓ and the closure edge can be added with a single further closure step.

Thus the total number of inference steps needed for a solution of the serial transitive closure problem is less than $n + m\lfloor \log m \rfloor$ and Theorem 2.6 is proved. □

The rest of proof of Theorem 2.3 proceeds by proving the following theorem by induction on i.

THEOREM 2.7. *Let $i \geq 0$. If the directed graph G is a tree then the serial transitive closure problem has a solution with $(1 + 2i)(n + m \log^{(*i)} m)$ steps.*

Proof. When $i = 0$, the theorem is just a restatement of Theorem 2.6. So fix $i \geq 1$ and assume the theorem holds for $i - 1$. We prove the theorem by splitting G into subtrees of size $\log^{(*i-1)} m$, adding auxiliary edges, and using the auxiliary edges to derive some of the closure edges; we iterate this process $\log^{(*i)} m$ many times, after which the subtrees all have size ≤ 1. The derivation of the closure edges from the auxiliary edges will depend on the induction hypothesis.

Let us begin by describing the reduction process, which will be used iteratively. The input to the reduction process is a subtree T of G; we assume T has $M > 1$ edges. The output of the reduction process will consist of a set of node-disjoint subtrees of T and the derivation of the closure edges whose endpoints are in T but are in different subtrees output by T. The reduction process has three steps:

Step 1. In the first step, T is partitioned into subtrees and auxiliary edges are derived.

By iteratively applying Lemma 2.5, T can be split into a finite set of subtrees $T_0, \ldots, T_k$ so that (1) the edges of the T_j's partition the edges of T; (2) for each $j > 0$, T_j has size $\geq \log^{(*i-1)} M$ edges; (3) for all $j \geq 0$, each immediate subtree of T_j has $< \log^{(*i-1)} M$ edges; and (4) T_0 has root at at the root of T and the rest of the T_j's have a root that is a scar of another subtree in the partition. Clearly there will be at most $\lceil M / \log^{(*i-1)} M \rceil$ many subtrees in the partition.

The following auxiliary edges are derived in Step 1: (1) for each T_j with root X, the edges $X \to Z$ for all other nodes Z of T_j are *auxiliary edges of the first kind*; and (2) for each j and p such that the root Y of T_p is a scar of T_j, the edges $X \to Y$ for all ancestors X of Y in T_j are *auxiliary edges of the second kind.* Figure 2 illustrates the choice of auxiliary

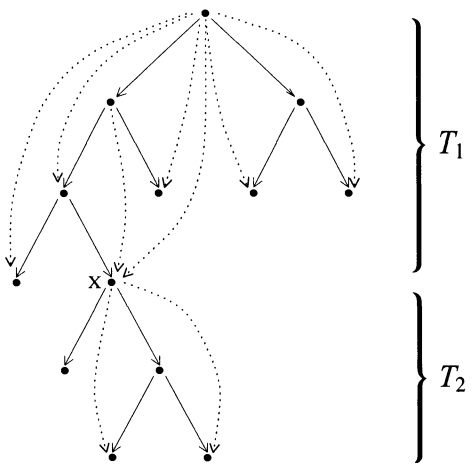

FIG. 2. *Node X is the root of T_2 and a scar of T_1. Hand-drawn edges are the auxiliary edges derived in Step* 1. *The edges of the second kind are the two edges with head X; one of these is also of the first kind.*

edges. It is easy to see that by deriving shorter edges first, each auxiliary edge can be derived by single closure step. Further, we claim that there are $\leq 2M$ auxiliary edges. It is easy to see that there $\leq M$ auxiliary edges of the first kind, since each node in T is at the head of at most one such auxiliary edge. To bound the edges of the second kind, note that if T_j has the root Y of T_p as a scar then the ancestors of Y in T_j consist of the root of T_j and some of the nodes in one of the immediate subtrees of T_j. The edge from the root of T_j to Y is also an edge of the first kind and has already been derived. Hence there are $< \log^{(*i-1)} M$ auxiliary edges from nodes inside T_j to Y. Also, the root of T_p cannot be the root of T (i.e., $p \neq 0$) so there are at most $M/\log^{(*i-1)} M$ different trees T_p to consider. Taking the product of the number of subtrees and the number of edges, we have that there are less than M auxiliary edges of the second kind.

Step 2. In this step we merely describe the output of the reduction process. The *output trees* are precisely the set of immediate subtrees of $T_0, \ldots, T_k$. Note that the output trees are disjoint and partition the nodes of T other than the root node of T, but do not contain all the edges of T. Each output tree has $< \log^{(*i-1)} M$ edges.

Step 3. In the third step we derive every closure edge $X \to Y$ with X and Y in T but in different output trees. Let N be the number of such closure edges. We derive these closure edges by setting up a new instance of the serial transitive closure problem and applying the induction hypothesis. The new instance will consist of a directed graph G', which has as nodes the roots of the trees $T_0, \ldots, T_k$ and has as edges the auxiliary edges from Step 1 that connect these roots. The closure edges of the new instance are the edges $X' \to Y'$, which are obtained by the following method: for each closure edge $X \to Y$ (of the original problem) such that X is a node in T_j and Y is a node in T_p with $j \neq p$, let Y' be the root of T_p and let X' be the (scarred) leaf of T_j such that Y is a descendent of X'. It will be important that $X \to X'$ and $Y' \to Y$ are auxiliary edges (of the second and first kind, respectively).

Clearly the new instance of the serial transitive closure problem has $< M/\log^{(*i-1)} M$ edges in G' and $\leq N$ closure edges. By the induction hypothesis, it has a solution of size less than or equal to

$$(1 + 2(i-1))\left[N + \frac{M}{\log^{(*i-1)} M} \log^{(*i-1)}\left(\frac{M}{\log^{(*i-1)} M}\right)\right],$$

which is trivially bounded by

$$(1 + 2(i-1)) \cdot [N + M].$$

Given a solution to the new serial transitive closure problem, for all X, X', Y, and Y' as above, we can derive the closure edge $X \to Y$ in two closure steps from the auxiliary edges $X \to X'$ and $Y' \to Y$ and the closure edge $X' \to Y'$ of the new problem.

To conclude the description of the reduction process, we note that the total number of closure steps needed in the reduction process is bounded by

$$2M + (1 + 2(i-1))(N + M) + 2N,$$

which is more suggestively written as

$$(1 + 2i)(N + M).$$

The overall procedure for proving Theorem 2.7 can now be very simply explained in terms of iterating the above reduction process.

Round 1. Apply the reduction process to the whole tree G. This derives n_1 closure edges (n_1 is the value of N from the reduction process) and outputs a set of subtrees of G

that partition the nonroot nodes of G and are each of size $< \log^{(*i-1)} m$ edges. The total number of closure steps in Round 1 is bounded by

$$(1 + 2i)(n_1 + m).$$

Round ℓ. The previous round generated a set of node-disjoint subtrees each of size less than

$$\underbrace{\log^{(*i-1)}(\log^{(*i-1)}(\cdots(\log^{(*i-1)}}_{\ell-1 \text{ times}}(m))\cdots)).$$

Apply the reduction process (Steps 1–3) to all of these subtrees that contain more than one edge; the overall result is that some number n_ℓ of closure edges are derived and that a set of node-disjoint output trees each of size less than

$$\underbrace{\log^{(*i-1)}(\log^{(*i-1)}(\cdots(\log^{(*i-1)}}_{\ell \text{ times}}(m))\cdots))$$

is generated. The total number of closure steps in round ℓ is less than

$$(1 + 2i)(n_\ell + m).$$

The rounds are iterated until all the subtrees have size ≤ 1; namely, in no more than $\log^{(*i)} m$ rounds. At the end every closure edge has been derived. The total number of closure steps used is bounded by

$$\sum_{\ell=1}^{\log^{(*i)} m} (1 + 2i)(n_\ell + m)$$

and since $\sum n_\ell = n$, the total number of closure steps is bounded by

$$(1 + 2i)(n + m \log^{(*i)} m).$$

That completes the proofs of Theorems 2.7 and 2.3. □

We are now ready to prove Main Theorem 2.4.

Proof. By Theorem 2.7, the serial transitive closure problem for the graph G has a solution with $O((1 + 2i)(n + m \log^{(*i)} m))$ steps, for any value of i. Let $i = \alpha(m)$: by the definition of the function α, we have $\log^{(*i-1)} m < i$. By Proposition 2.2, it follows that $\log^{(*i)} m \leq 4$. Hence the serial transitive closure problem of G has a solution of size bounded by

$$(1 + 2\alpha(m))(n + 4m) = O((n + m)\alpha(m)). \quad \square$$

We next give a bound on the number of steps in terms of Tarjan's inverse Ackermann function.

COROLLARY 2.8. *If the directed graph G is a tree then the serial transitive closure problem has a solution with $O((n + m)\alpha(n + m, m))$.*

Proof. We argue similarly to the above proof, but now let i equal $\max\{1, \alpha(n+m, m)\}$. Thus, by the definition of $\alpha(,)$, we have $A(i, 4\lceil(n+m)/m\rceil) > \log m$. By Proposition 2.1, $\log^{(*i-1)}(\log m) < 4\lceil(n+m)/m\rceil$, and hence $\log^{(*i)}(\log m) < 4\lceil(n+m)/m\rceil$. Since $i \geq 1$, $\log^{(*i)}(m) \leq 4\lceil(n+m)/m\rceil$. Thus, by Theorem 2.7, the serial transitive closure problem has a solution with size bounded by

$$(1 + 2\alpha(n + m, m))\left(n + m\left(4\left\lceil\frac{n+m}{m}\right\rceil\right)\right) = O((n + m)(\alpha(n + m, m)))$$

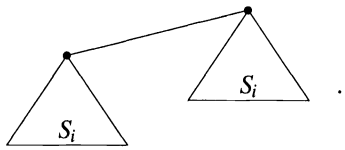
whenever $\alpha(n + m, m) > 0$. □

3. Lower bounds.

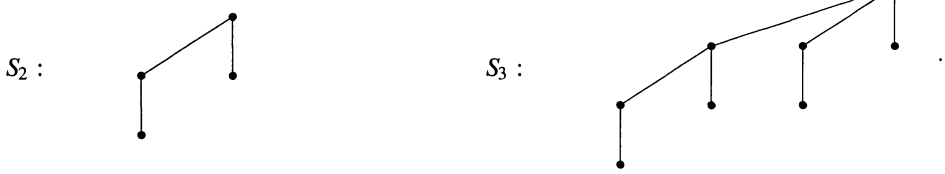
3.1. The lower bound for trees. In this section we prove that our method of solving the serial transitive closure problem for trees is optimal to within a constant factor; in particular, linear size solutions are not always possible. Our proof is based on a theorem of Tarjan [13] giving a lower bound on the worst case runtime of an algorithm for the union-find problem. Tarjan's lower bound applied only to a particular type of algorithm for the union-find problem (Tarjan [14], Fredman and Saks [11], and La Poutré [12] have since given lower bounds for a much wider class of algorithms). Essentially, Tarjan gave a lower bound for algorithms that rely exclusively on manipulating pointers (with certain constraints). Since the serial transitive closure problem is framed so as to deal only with edges and closure steps, it is not so surprising that we are able to modify Tarjan's original construction so as to give a lower bound for the serial transitive closure problem.

Our lower bound is obtained by constructing instances of the serial transitive closure problem that require at least $\frac{1}{25}(n+m)\cdot\alpha(n+m)$ closure steps in any solution. The construction is based on Tarjan's lower bound; we will review the relevant definitions and constructions but do not repeat Tarjan's proof.

Following Tarjan, define S_1 be the tree with two nodes: the root and one leaf. Define S_{i+1} to be the tree constructed by making two copies of S_i and making the root of one copy a child of the root of the other copy; pictorially, S_{i+1} is



For example, S_2 and S_3 are the trees



Clearly S_i has 2^i nodes of which 2^{i-1} are leaves. Let T be a tree. A *g-find* is a pair of nodes (a, b) in T such that b is a leaf and a is an ancestor of b. A (permissible) sequence of g-finds is a sequence (a_i, b_i) of g-finds such that the b_i's are distinct and such that, for all $i < j$, a_j is not a descendent of a_i. G is a *shortcut graph* of T if G is a directed graph on the nodes of T with each edge of T contained as a directed edge in T such that, if T is viewed as a directed graph with edges directed downward, the graph G is a subgraph of the transitive closure of T. If (a_i, b_i), $i = 1, \ldots, N$, is a sequence of g-finds, then the associated shortcut graphs $G_0, \ldots, G_N$ are defined by letting G_0 have the edges from T (directed downwards), and letting G_i be G_{i-1} plus all edges (c, d) such that c and d are on the path in T from a_i to b_i and such that d is a descendent of c. The *cost* of a particular g-find (a_i, b_i) in the sequence is defined to be the distance from a_i to b_i in the shortcut graph G_{i-1}.

Tarjan defines a version of the Ackermann function that is slightly different from ours; however, it is easy to see that Tarjan's Ackermann function equals ours, except for the values of $A(i, 0)$.

The next theorem of Tarjan will lead to our lower bounds.

THEOREM 3.1. *For all $k \geq 1$ and $i > A(4k, 4)$, there is a sequence of 2^{i-2} g-finds in S_i such that each g-find has cost $\geq k$.*

For a proof of Theorem 3.1, apply [13, Thm. 15] with $s = 1$. We can now prove our lower bound.

THEOREM 3.2. *Let $k \geq 1$. There is an instance of the serial transitive closure problem in which the graph G has $m = 2^{A(4k,4)+1}$ nodes and for which there are $n = 2^{A(4k,4)-1}$ closure edges such that any solution of of the serial transitive closure problem requires at least $(k-1) \cdot 2^{A(4k,4)-1}$ closure steps.*

Proof. Let the directed graph G be the tree S_i (with edges directed downward), where $i = A(4k, 4) + 1$. Clearly G has $m = 2^{A(4k,4)+1}$ nodes. The instance of the serial transitive closure problem is obtained by taking as closure edges, the $n = 2^{A(4k,4)-1}$ g-finds given by Theorem 3.1. Let $G_0, \ldots, G_n$ be the associated shortcut graphs.

We now must show that, because each g-find has cost k, any solution to this serial transitive closure problem requires at least $k-1$ steps per closure edge. To prove this, let $e_1, \ldots, e_s$ be a sequence of edges that comprise a solution to the serial transitive closure problem. For each $i \leq s$, define the *rank* of e_i to be the least value r_i such that e_i is an edge in G_{r_i}; let $r_i = n + 1$ if e_i is not in G_n. Now reorder the edges $e_1, \ldots, e_s$ according to their rank, keeping edges of the same rank in the same relative order. We claim that the reordered edges are also a solution to the serial transitive closure problem. This claim is easily proved by noting that if an edge $e_i = (c_1, c_2)$ is inferred from edges (c_1, c_3) and (c_3, c_2) and if e_i is in G_{r_i} then the other two edges must also be in G_{r_i} (by the definition of the shortcut graphs) and thus have ranks $\leq r_i$. Finally, we claim that that for all $r \leq n$ there are at least $k-1$ edges with rank r. To prove this, consider the edges of rank r; these edges are inferred by closure steps from the edges of rank $< r$ and one of the edges is the rth closure edge. But because the cost of the rth g-find is $\geq k$, at least $k-1$ closure steps are required to derive the rth closure edge from the edges of rank $< r$. □

Let $f(m, n)$ be the maximum number of edges required to solve serial transitive closure problems for *trees* with m edges and n closure edges.

LEMMA 3.3. *For infinitely many values of n, $f(4n-1, n) \geq \frac{n}{5}\alpha(5n)$.*

Proof. Let $k \geq 5$ and $n = 2^{A(4k,4)-1}$ and $i = A(4k, 4) + 1$. Since S_i has $4n$ nodes, it has $m = 4n - 1$ edges. By Theorem 3.2, $f(m, n) \geq (k-1)n$. It will suffice to show $\alpha(5n) \leq 5k - 5$. Now,

$$\begin{aligned} A(5k-5, 5k-5) &> A(5k-5, 5) \\ &= A(5k-6, A(5k-5, 4)) \\ &\geq A(5k-6, A(4k, 4)) \\ &> 2^{A(4k,4)+2} \qquad \text{since } 5k-6 > 2 \\ &> 5n \end{aligned}$$

from whence, by the definition of α, $\alpha(5n) \leq 5k - 5$. □

Since $m = 4n - 1$ and hence $5n > m + n$, the proof of Lemma 3.3 immediately implies the following result.

THEOREM 3.4. *$f(m, n) \geq \frac{1}{25}(n + m) \cdot \alpha(n + m)$ for infinitely many values of n with $m = 4n - 1$.*

3.2. Relations to weak superconcentrators. The above lower bound for the serial transitive closure problem applies to the case where G is a general tree. Essentially the same lower bound applies to binary trees, since any tree can be converted into a binary tree by expanding any node that has more than two children into multiple nodes with two children each. This expansion will at most double the number of edges in the tree and will not make the solutions to the serial transitive closure problem smaller.

However, we know of no way to extend the above argument to give a nonlinear lower bound for the size of solutions to the serial transitive closure problem for the case where the directed graph is linear, i.e., the case where each node in G has at most one incoming edge and at most one outgoing edge (this was the simple case considered in the preliminary portion of the proof of Theorem 2.6). On the other hand, there is a connection between constant depth weak superconcentrators and our proof of the main theorems, that suggests that our upper bound of $n \cdot \alpha(n)$ is the best that can be obtained for the linear case with our techniques. Namely, our proof of Theorem 2.7, for the case where G is linear, implicitly contains a construction of weak superconcentrators of optimal size (to within a constant factor). We outline this construction below; a similar construction has already been given by [6], [7].

It is also possible to use Yao's lower bound on the size of (t, m)-structures [15] to get a nonlinear lower bound on the number of auxiliary edges needed for our construction. However, the lower bounded obtained in this way is not as good as the lower bound we obtain below via weak superconcentrators.

We recall the definition of a weak superconcentrator. A network is a directed graph with nodes $a_0, \ldots, a_m$ designated as inputs and with nodes $b_0, \ldots, b_m$ designated as outputs. The inputs have no incoming edges and the outputs have no outgoing edges. A network is *synchronous* if it is possible to associate with each node a *depth*, such that each input has depth 0 and each edge in the network goes from a depth d node to a depth $d+1$ node, and such that the output nodes have a common depth. The depth of a synchronous circuit is defined to be the depth of the output nodes. The network is said to be a *weak* $(m+1)$*-superconcentrator* if the following property holds: if $0 \leq i_1 \leq j_1 < i_2 \leq j_2 < \ldots i_k \leq j_k \leq m$ are integers, then the network contains k many node-disjoint paths from a_{i_r} to b_{j_r}, for $r = 1, \ldots, k$. It is a theorem of Dolev, Dwork, Pippenger and Widgerson [10] that depth $2i + 2$ synchronous weak $(m + 1)$-superconcentrators must have at least $\Omega(m \log^{(*i)}(m))$ many nodes.[1] (Some related, but weaker, lower bounds are given by Bodlaender, Tel, and Santoro [1].)

Recall that in the proof of Theorem 2.7, we added auxiliary edges independently of the choice of closure edges and then derived the closure edges with the aid of the auxiliary edges. The net effect is, after the proof by induction has been unwound, that there were a total of $(1 + 2i)m \log^{(*i)}(m)$ auxiliary edges added such that, for any two nodes A and B with A an ancestor of B, there exists a path from A to B of length at most $(2i + 2)$.[2] This path consists entirely of auxiliary edges and edges in G, of course. We claim that these auxiliary edges can be made into a weak supercentrator of depth $(2i + 2)$. To do this we make $(2i + 3)$ disjoint copies of G, called $G_0, \ldots, G_{2i+2}$ and construct a network on the nodes in the union of these graphs.

To construct the weak $(m + 1)$-superconcentrator of depth $2i + 2$, let G be a linear tree with nodes $X_0, \ldots, X_m$ and edges $X_j \to X_{j+1}$, for $0 \leq j \leq m$. Form $(2i+3)$ disjoint copies of G denoted $G_0, \ldots, G_{2i+2}$ and let X_j^k be the copy of X_j in G_k. The weak superconcentrator will be a directed graph on the nodes X_j^k; the X_j^0's are the input nodes, the X_j^{2i+2}'s are the output nodes and each X_j^k will be of depth k. First, the weak superconcentrator will have the edges $X_j^k \to X_j^{k+1}$ for all j, k. There are obviously $2(i + 1)(m + 1)$ edges of this first kind. Second, the weak superconcentrator will have edges corresponding to the auxiliary edges from the proofs of Theorems 2.6 and 2.7. Recall that Theorem 2.7 was proved by

[1] The Ackermann function $A(i, x)$ used in [10] is the same as Tarjan's Ackermann function, and hence is the same as our $A(i, x)$ for $x \geq 1$. The function $\lambda(i, x)$ used in [10] satisfies $\log^{(*i)}(x) = \lambda(i + 1, x)$ for all $i \geq 0$ and $x > 0$.

[2] To justify the length $(2i + 2)$ recall that at most $(2i + 1)$ closure steps were needed to derive any possible closure edge from the auxiliary edges — this corresponds to a path of length $(2i + 2)$.

induction on i; by considering the auxiliary edges added to G in the proof of Theorem 2.6 and in all the induction steps of the proof of Theorem 2.7, it is easy to see that there are, in total, $\leq (1+2i)m \log^{(*i)} m$ auxiliary edges added to G. We must explain how the auxiliary edges are translated into edges in the weak superconcentrator — the essential idea is that each induction step of the proof of Theorem 2.7 adds two more layers of connections in the weak superconcentrator. To make this more precise, recall that in proving Theorem 2.7 for i we added $2m \log^{(*i)}(m)$ many auxiliary edges and invoked Theorem 2.7 for $i-1$ multiple times. If this proof by induction is "unwound," then each of these invocations of Theorem 2.7 for $i-1$ adds many auxiliary edges and further invokes Theorem 2.7 for $i-2$ multiple times, etc. The proof of Theorem 2.7 for $i=0$ was just the proof of Theorem 2.6 (in particular, the linear case); this of course also added auxilliary edges. Now consider all the auxiliary edges that are added during the unwinding of the proof of Theorem 2.7 for i; each auxiliary edge is associated with a value $i' \leq i$ by considering which case of Theorem 2.7 introduced the auxiliary edge (edges can be associated with more that one value of i' and in this case we count the edge multiple times). The weak superconcentrator contains all edges $X_j^{i-i'} \to X_s^{i-i'+1}$ and $X_j^{i+i'+1} \to X_s^{i+i'+2}$ where $X_j \to X_s$ is an auxiliary edge associated with i'. Since each auxiliary edge is put twice into the weak superconcentrator,[3] there are $2(1+2i)m \log^{(*i)}(m)$ such edges put into the network.

Thus, in total, there are only $O(i \cdot m \cdot \log^{(*i)} m)$ edges in the weak $(m+1)$-superconcentrator of depth $2i+2$. Hence our method of proof for the upper bound of Theorem 2.7 constructs optimal size weak superconcentrators and it seems, therefore, that no simple modification of the proof method can give a better upper bound for the linear case. Nonetheless, it is open whether our upper bound for the linear case of the serial transitive closure problem is optimal — for instance, it might be possible to give an improved construction by not choosing the auxiliary edges independently of the closure edges. The point is that it is not a priori necessary to construct a weak superconcentrator in order to get a solution to a particular instance of the serial transitive closure problem. The lower bound methods of [13] and [10] do not appear to give a definitive lower bound for the linear case.

Acknowledgments. We thank P. Pudlák for suggesting the connection to weak superconcentrators. We also thank one of the referees for bringing the works of Yao, Chazelle, and Bodlaender, Tel, and Santoro to our attention and suggesting some improvements to the paper, including Theorem 2.8.

NEW DECIDABILITY RESULTS CONCERNING TWO-WAY COUNTER MACHINES*

OSCAR H. IBARRA†, TAO JIANG‡, NICHOLAS TRAN§, AND HUI WANG¶

Abstract. The authors study some decision questions concerning two-way counter machines and obtain the strongest decidable results to date concerning these machines. In particular, it is shown that the emptiness, containment, and equivalence (ECE for short) problems are decidable for two-way counter machines whose counter is reversal-bounded (i.e., the counter alternates between increasing and decreasing modes at most a fixed number of times). This result is used to give a simpler proof of a recent result which shows that the ECE problems for two-way reversal-bounded pushdown automata accepting bounded languages (i.e., subsets of $w_1^* \dots w_k^*$ for some nonnull words $w_1, \dots, w_k$) are decidable. Other applications concern decision questions about simple programs. Finally, it is shown that nondeterministic two-way reversal-bounded multicounter machines are effectively equivalent to finite automata on unary languages, and hence their ECE problems are decidable also.

Key words. counter machines, decidability, emptiness problem, pushdown automata, simple programs

1. Introduction.

A fundamental decision question concerning any class C of language recognizers is whether there exists an algorithm to decide the following question: given an arbitrary machine M in C, is the language accepted by M empty? This is known as the emptiness problem (for C). Decidability (existence of an algorithm) of emptiness can lead to the decidability of other questions such as containment and equivalence (given arbitrary machines M_1 and M_2 in C, is the language accepted by M_1 contained (respectively, equal) to the language accepted by M_2) if the languages defined by C are effectively closed under union and complementation.

The simplest recognizers are the finite automata. It is well known that all the different varieties of finite automata (one-way, two-way, etc.) are effectively equivalent, and the class has decidable emptiness, containment, and equivalence (ECE, for short) problems.

When the two-way finite automaton is augmented with a storage device, such as a counter, a pushdown stack or a Turing machine tape, the ECE problems become undecidable (no algorithms exist). In fact, it follows from a result in [9] that the emptiness problem is undecidable for two-way counter machines even over a unary input alphabet. If one restricts the machines to make only a finite number of turns on the input tape, the ECE problems are still undecidable, even for the case when the input head makes only one turn [8]. However, for one-way counter machines, it is known that the equivalence (hence also the emptiness) problem is decidable, but the containment problem is undecidable [11]. The situation is different when we restrict both the input and counter. It has been shown that the ECE problems are decidable for counter machines with a finite-turn input and a reversal-bounded counter (the number of alternation between increasing and decreasing modes is finite, independent of the input) [8]. It is also known that the ECE problems are decidable for two-way counter machines with a reversal-bounded counter accepting bounded languages (subsets of $w_1^* \dots w_k^*$ for some nonnull words $w_1, \dots, w_k$) [6]. Note that these machines can accept fairly complex languages. For example,

it can recognize the language consisting of strings of the form 0^i1^j where i divides j. The decidability for the general case when the input is not over a bounded language was left open in [6]. We resolve this question here: We show that the ECE problems are decidable for two-way reversal-bounded counter machines. We believe this is the largest known class of machines, which are a natural generalization of the two-way finite automaton, for which the ECE problems are decidable. This result has some nice applications. We use it to give a simpler proof of a recent result that the ECE problems for two-way reversal-bounded pushdown automata accepting bounded languages (i.e., subsets of $w_1^* \dots w_k^*$ for some nonnull words $w_1, \dots, w_k$) are decidable. Other applications of this result concern decision questions about some special classes of simple programs.

Finally, we consider the nondeterministic version of reversal-bounded multicounter machines. We show that when the input alphabet is unary, these machines accept only regular languages. Since the proof is constructive, we obtain as corollaries that the ECE problems for these machines are also decidable. This resolves an open question raised in [5], where a similar result was shown for deterministic machines. This is the strongest result one can obtain since it is known that deterministic reversal-bounded 2-counter machines over $a_1^* \dots a_k^*$ (for distinct symbols $a_1, \dots, a_k$ for some k) can accept nonsemilinear sets and have an undecidable emptiness problem [8].

The rest of this paper is organized as follows. In §2, we show the decidability of the ECE problems for two-way reversal-bounded counter machines. We give the applications in §3. Finally, we show the effective equivalence of two-way reversal-bounded nondeterministic multicounter machines and finite automata over unary languages, along with the decidability of their ECE problems in §4.

In the remainder of this section, we define the models of computation of interest and related concepts. A *language* L is a subset of $\{0, 1\}^*$. A language is *strictly bounded* over k letters $a_1, a_2, \dots, a_k$ if it is a subset of $a_1^* a_2^* \dots a_k^*$. A language is *bounded* over k nonnull words $w_1, w_2, \dots, w_k$ if it is a subset of $w_1^* w_2^* \dots w_k^*$. A *counter machine* is a finite automaton augmented with a counter, whose value can be incremented, decremented, or tested for zero. An r-input reversal 2DCM is a two-way counter machine whose input head makes at most r reversals (but the counter is unrestricted). A two-way machine is *sweeping* if the input head reverses only on the endmarkers. 2DCM(c, r) denotes the class of deterministic machines having a two-way input head and c counters, each of which makes at most r reversals in any computation. 2NCM(c, r) denotes the corresponding nondeterministic class. 2DPDA(r) denotes the class of two-way deterministic pushdown automata whose pushdown stack makes at most r reversals. 2NPDA(r) denotes the nondeterministic class.

In the following sections, we will study the emptiness problems for the above machines on bounded languages. A straightforward argument shows that a machine of any type studied in this paper accepts a nonempty bounded language if and only if there is another machine of the same type that accepts a nonempty *strictly* bounded language. (Suppose a 2DCM(c, r) M accepts a nonempty bounded language $L \subseteq w_1^* w_2^* \dots w_k^*$. Let h be a homomorphism that maps each word w_i to a new letter s_i for $1 \leq i \leq k$. Then there is another 2DCM(c, r) M' that simulates M on w_i whenever it reads the letter s_i. Clearly, M' accepts $h(L)$.) So when we are dealing with the emptiness question for machines over bounded languages, we need only handle the case when the machines accept strictly bounded languages.

2. Reversal-bounded counter machines. It was shown in [8] that many decision problems such as emptiness, containment, and equivalence for the class 2DCM(c, r) for $c \geq 2$ and $r \geq 1$ are undecidable. The same paper raised the question of the decidability of these problems for 2DCM$(1, r)$ for $r \geq 1$. A partial answer was given in [6], where it was shown that the emptiness problem for 2DCM$(1, r)$ for $r \geq 1$ over bounded languages is decidable.

In this section we give a complete answer to this question; we show that the ECE problems for the class 2DCM(1, m), where $m \geq 1$, are decidable. First, we consider the emptiness problem and improve the result of Gurari and Ibarra by removing the requirement that the language be bounded.

THEOREM 2.1. *The emptiness problem for* 2DCM(1, r) *is decidable for every* $r \geq 1$.

Proof. Fix an $r \geq 1$, and let M be a 2DCM(1, r) with q states. We show that if $L(M) \neq \emptyset$, then M must accept an input in some bounded language over k words $w_1, w_2, \ldots, w_k$, where k and $w_1, w_2, \ldots, w_k$ depend only on M. Suppose M accepts some input x. Without loss of generality, we assume there are exactly $r + 1$ phases in the computation of M on x, such that in each phase the counter is either increasing or decreasing.

Define the *phase crossing sequence* C_i at the boundary of two input squares to be the sequence (s, d) of M's states and input head directions at the times the input head crosses this boundary during phase i. During an increasing phase, the input head crosses any boundary at most $2q$ times, or else M, being deterministic, would get into an infinite loop. Hence, there are at most $(2q)!$ different crossing sequences for an increasing phase. During a decreasing phase, the input head is allowed to go into a loop on the input tape (i.e., crosses some boundary, say b_0, twice in the same state and direction) until the counter becomes empty. In this case, the input head crosses each boundary in the loop $O(j)$ times, where j is the number of loop iterations. (A boundary is *in* the loop if it is crossed by the input head between two crossings of b_0 in the same state and direction.) Each boundary outside the loop is crossed at most a constant number of times.

Thus any crossing sequence during this phase can be written in the form $C_i = uv^j w$, where

1. no pairs of state and direction appear twice in u or v,
2. no pairs of state and direction appear in u *and* in v,
3. w is a prefix of v,
4. $|u| + |v| \leq 2q$.

Hence there are at most $(2q)! \cdot (2q)^2 \leq (2q + 2)!$ different crossing sequences during a decreasing phase. (Note that j is a fixed number for each phase.)

Define the *crossing sequence* at the boundary of two input squares to be the string $C_1\#C_2\#\cdots\#C_{r+1}$ of the phase crossing sequences at that boundary. From the above paragraph, we can see that the number of different crossing sequences is bounded by $c = [(2q + 2)!]^{r+1}$, which is independent of x. Hence we can rewrite x as $u_0v_1u_1 \ldots v_ku_k$, such that $0 \leq |u_j|, |v_j| \leq c$ for $j = 1, \ldots, k$ and the crossing sequences at the left and right boundaries of each v_j are identical. Call each v_j a *movable segment* and each u_j a *separator segment*. We say two movable segments v_m and v_n are of the same type if they are identical and have the same crossing sequences at the left and right boundaries. There are at most ct^{c+1} different types, where t is the size of the input alphabet.

We now transform x to another string x' by performing the following operation repeatedly on x. If $x = z_1v_1z_2v_2z_3$, where v_1 and v_2 are movable segments of the same type, then we rewrite x as $x' = z_1v_1v_2z_2z_3$, i.e., we group two movable segments of the same type together. If M were a DFA, it would be immediate that M accepts x iff it accepts x', because the crossing sequences of v_1 and v_2 are identical. However, the transposition may affect the counter value and alter the times and places of the counter reversals, so that the computations of M on x' may be completely different from the computation of M on x.

Fortunately, this situation cannot happen. In fact, each phase in the computation of M on x cannot end while the input head is reading $v_1z_2v_2$, since the crossing sequences of v_1 and v_2 are identical. This implies that transposing z_2 and v_2 does not affect the times and places of the counter reversals, nor does it affect the total net change to the counter value in each phase by the input segment $v_1z_2v_2$.

Hence, although the computations may not match step by step, each phase in the computation of M on x' ends with the same input head position (on z_1 or z_3), the same counter value, and the same state as with the corresponding phase of M on x. Thus, M accepts x iff M accepts x'.

Apply the same process of partitioning and transforming recursively on z_1 and z_2z_3 (at most $|x|$ times), so that at the end, x can be written as a bounded word $y \in w_1^*w_2^* \dots w_k^*$ where $|w_i| \leq c$, $k \leq ct^{c+1}$, c (hence k) is independent of x, and M accepts x iff M accepts y. But since the emptiness problem for 2DCM$(1, r)$ on bounded languages is decidable [6], the theorem follows. □

In contrast to Theorem 2.1 we state and briefly sketch the proof of the following result from [8].

THEOREM 2.2 [8]. *The emptiness problem for* 1*-input reversal* 2DCM *is undecidable.*

Proof. We reduce the emptiness problem for Turing machines to this problem. Given an arbitrary Turing machine M, we can find two 1DCM, M_1 and M_2, and a homomorphism g_1 such that $L(M) = g(L(M_1) \cap L(M_2))$. Furthermore, we can find a 1NCM M_3 such that $L(M_3) = L(M_2)^R$. By expanding the input alphabet with markers to dictate the nondeterministic choices of M_3, we can obtain a 1DCM M_4 and a homomorphism g_2 (which maps the markers to the null string and leaves the other symbols the same) such that $L(M_3) = g_2(L(M_4))$. We also modify M_1 to include markers in its alphabet; the resulting machine M_5 behaves like M_1 and ignores markers in its input.

From these constructions we have $L(M) = g_1g_2(L(M_5) \cap L(M_4)^R)$, and it is now trivial to construct from M_4 and M_5 a 1-input reversal 2DCM M' such that $L(M) = g_1g_2(L(M'))$. Since the emptiness problem for Turing machines is undecidable, so is the emptiness problem for 1-input reversal 2DCM. □

Next, we show the decidability the equivalence and containment problems. For every machine 2DCM$(1, r)$, we can construct an equivalent halting one. Below we prove that this is in fact true for every 2DCM(c, r). We first prove a lemma which shows how to modify a 2DFA to make it halt on every input. This lemma is slightly stronger than a similar result by Sipser [10], since our simulating 2DFA behaves exactly as the original machine until it detects that looping has occurred.

LEMMA 2.3. *For every* 2DFA N *we can construct an equivalent halting* 2DFA N' *such that on each input* N' *moves exactly like* N *until* N *enters a loop.*

Proof. Let $x = a_1a_2 \dots a_n$ be an input. For simplicity, assume N moves every step. For each i, $1 \leq i \leq n$, define a relation $R(i)$ as follows: For any two states p and q of N, the pair (p, q) is in $R(i)$ iff in state p, N will leave cell i to the right and return to cell i in state q the next time. Clearly N doesn't halt iff it moves to some cell i in state q and (q, q) is in the transitive closure of $R(i)$. We construct a 2DFA N' which simulates N and at the same time tries to construct the relation $R(i)$ for each cell being visited. To simplify the presentation, here we will allow N' to construct the relation $R(i)$ nondeterministically. The nondeterminism can be eliminated by the standard subset construction technique. Let δ_N be the transition function of N, and suppose N starts at cell 1.

N' initializes $R(1)$ to $\emptyset$. In general, suppose that N is at cell j. If N moves to the left, N' constructs deterministically $R(j-1)$ from the current $R(j)$ as follows. For each pair (p, q), N' puts (p, q) in $R(j-1)$ iff

1. $\exists s[\delta_N(p, a_{j-1}) = (s, right)\ \&\ \delta(s, a_j) = (q, left)]$, or
2. $\exists s_1, \dots, s_k[\delta_N(p, a_{j-1}) = (s_1, right), \delta_N(s_k, a_j) = (q, left)\ \&\ (s_1, s_2), \dots, (s_{k-1}, s_k) \in R(j)]$.

If N moves to the right, N' constructs (nondeterministically) $R(j+1)$ from the current $R(j)$ as follows: For each pair (p, q) in $R(j)$, M' guesses a sequence of distinct states

$s_1, \ldots, s_k$, such that $\delta_N(p, a_j) = (s_1, right)$ and $\delta_N(s_k, a_{j+1}) = (q, left)$, and puts all $(s_1, s_2), \ldots, (s_{k-1}, s_k)$ in $R(j+1)$. In doing this, N' also makes sure that no two pairs in the resulting $R(j+1)$ share the same first state. Moreover, N' also checks the validity of the current $R(j)$ and abandons the computation if some pair (p, q) in $R(j)$ is nonrealizable, i.e., $\delta_N(p, a_j) = (p', left)$ for some state p' or there exists no state q' such that $\delta_N(q', a_{j+1}) = (q, left)$.

N' halts if it detects that at some cell j, N is in state q and (q, q) is in current $R(j)$. Clearly, during the simulation, a relation $R(j)$ may contain some nonrealizable pairs. But it is not hard to see that these nonrealizable pairs will not cause a false loop detection. Thus we can establish the following claims. Suppose that N is at cell j.

1. If N is in state q and (q, q) is in the current $R(j)$, then N is in a loop.
2. Suppose that the rightmost cell that N has visited so far is cell k. Then for any pair (p, q) such that in state p, M will leave cell j to the right, stay in the cells $j+1$ through k, and return to cell j for the first time in state q, (p, q) is contained in $R(j)$.

Hence, N' can detect if N will enter a loop correctly. □

THEOREM 2.4. *For any c and $r \geq 1$, we can effective convert a* 2DCM(c, r) *to a* 2DCM(c, r) *that halts on every input.*

Proof. For simplicity, we prove the theorem for the case $c = 1$. The idea is the same for $c > 1$. Let M be a 2DCM$(1, r)$ machine. We construct an equivalent halting 2DCM$(1, r)$ machine M'. M' basically simulates M faithfully. We know that M can enter a loop only when (i) M is in an increasing phase or (ii) M is in an decreasing phase but the moves do not affect (i.e., really decrease) the counter. Call the latter a zero-decrease period. So besides simulating M, M' also checks if M will enter a loop in each increasing phase and each zero-decrease period. The fact that M' is able to realize this follows from the observation that M behaves like a 2DFA in an increasing phase and a zero-decrease period, and the above lemma. □

COROLLARY 2.5. *For each c, $\bigcup_r$* 2DCM(c, r) *is effectively closed under complementation, intersection, and union.*

COROLLARY 2.6. *The containment and equivalence problems for $\bigcup_r$* 2DCM$(1, r)$ *are decidable.*

Open Question: Is 2DCM(c, r) closed under union or intersection?

A related interesting halting result is given below, where 2DCM$(1, \infty)$ denotes a two-way deterministic 1-counter machine whose counter can make unrestricted (unbounded) number of reversals.

THEOREM 2.7. *Each* 2DCM$(1, \infty)$ *machine accepting a bounded language can be made halting.*

Proof. We first prove the theorem for unary languages. Let M be a 2DCM$(1, \infty)$ machine that accepts $L \subset a_1^*$. We construct a 2DCM$(1, \infty)$ M' that halts on all inputs and accepts the same language. We may assume that upon acceptance M halts in a unique accepting configuration.

First, observe that if M halts on some input x, then during the computation, the value of the counter cannot exceed $(q+1)|x|$, where q is the number of states of M. Otherwise, let t be the first time the counter value of M on input x reaches $(q+1)|x|$. For each value $v < (q+1)|x|$, let (q_v, i_v) be the state and the head position of M the last time the counter value reaches v before time t. Since there are at most $q|x|$ different combinations, there are two values v and w such that $q_v = q_w$ and $i_v = i_w$. But this implies that M will get into an infinite loop on x, contradicting the assumption that M halts on x. Second, we may assume M is normalized so that the input head moves from one endmarker to the other without reversing the direction in between.

M' starts with the unique accepting configuration of M and performs a Sipser search for the initial configuration. (A Sipser search performs a depth-first search on the connected component (actually a tree) that contains the unique accepting configuration of the computation graph of M on x. The vertices of the computation graph are the configurations, and the edges reflect the transition function of M. It was shown [10] that such a search does not use more space than originally required by M for space-bounded Turing machines. Here we adapt the technique to work for counter machines.)

During the search, whenever the input head of M' reaches an endmarker, then M' verifies that the counter value is at most $(q + 1)|x|$. If this is the case, M' continues the search; otherwise, M' abandons the current path of the search tree and continues with the next one. Because M' makes sure that the counter value is within bound, the number of nodes in the search tree is finite, and hence the Sipser search is guaranteed to halt. M' accepts iff the search fails. It is clear that M' accepts L and M' always halts.

The proof can be trivially extended to hold for strictly bounded languages over k letters for any $k > 1$. The simulating machine M' now performs the check whenever it reaches a boundary between the k segments of the input, instead of the endmarkers. A more involved argument is needed to show that the theorem holds for general bounded languages, since now there are many ways to partition the input into repetitions of the k basic words. M' needs to maintain in its finite control all possible partitions of the input in order to resume the computation after performing the check. □

We obtain from the above theorem the next corollary.

COROLLARY 2.8. *The class of* 2DCM(1, ∞) *on bounded languages is effectively closed under complementation, intersection, and union.*

Open Question: Is 2DCM(1, ∞) closed under complementation or union?

3. Some applications. We give three applications of Theorem 2.1 in this section. First we give a simpler proof of the decidability of the ECE problems concerning reversal-bounded deterministic pushdown automata on bounded languages. This result first appeared in [7] as a corollary of a rather difficult theorem.

THEOREM 3.1. *The emptiness problem for* 2DPDA(r) *for* $r \geq 1$ *on bounded languages is decidable.*

The proof follows from Theorem 2.1 and the following lemma.

LEMMA 3.2. *Let M be a* 2DPDA(r) *accepting a strictly bounded language over $a_1^* \dots a_k^*$. We can effectively construct a* 2DCM(1, r) *machine M' (not necessarily accepting the same language) such that $L(M)$ is empty iff $L(M')$ is empty.*

Proof. We may assume, without loss of generality, that on every step M pushes exactly one symbol on top of the stack, does not change the top of the stack, or pops exactly one symbol, i.e., M is not allowed to rewrite the top of the stack. In the discussion that follows, we assume M is processing an input that is accepted, i.e., the computation is halting.

A writing phase is a sequence of steps which starts with a push and the stack is never popped (i.e., the stack height does not decrease) during the sequence. A writing phase is periodic if there are strings u, v, w with v nonnull such that for the entire writing phase, the string written on the stack is of the form uv^iw for some i (the multiplicity) , and the configuration of M (state, symbol, top of the stack) just before the first symbol of the first v is written is the same as the configuration just before the first symbol of the second v is written. Note that w is a prefix of v. Clearly, a writing phase can only end when the input head reaches an endmarker or a boundary between the a_i's. A writing phase can only be followed by a popping of the stack (i.e., reversal) or another writing phase with possibly different triple (u, v, w).

By enlarging the state set, we can easily modify M so that all writing phases are periodic. One can easily verify that because M is reversal-bounded, there are at most a fixed number t of writing phases (in the computation), and t is effectively computable from the specification of M.

We now describe the construction of M'. Let $x = a_1^{i_1} \ldots a_k^{i_k}$ be the input to M. The input to M' is of the form: $y\#c_1\#c_2\# \ldots \#c_t$, where the c_i's are unary strings; y is x but certain positions are marked with markers $m_1, m_2, \ldots, m_t$. Note that a position of y can have 0, 1, ... at most t markers.

M' simulates M on the segment y ignoring the markers. The c_i's are used to remember the counter values. Informally, every time the counter enters a new writing phase, the machine "records" the current value of the counter by checking the c_i's.

M' begins by simulating M on y (ignoring the markers). When a writing phase is entered, M' records the triple (u_1, v_1, w_1) in its finite control and the multiplicity in the counter. Suppose M enters another writing phase. Then M' checks that the input head is on a symbol marked by marker m_1; hence M' can "remember" the input head position. (If it's not marked m_1, M' rejects.) Then it "records" the current value of the counter on the input by checking that the current value is equal to c_1. (If it's not, M' rejects.) M' restores the input head to the position marked m_1 and resets the counter to 0. It can then proceed with the simulation. Next time M' has to record the value of the counter, M' use the input marker m_2 and checks c_2, while storing the triple (u_2, v_2, w_2) in its finite control, etc. Popping of the stack is easily simulated using the appropriate triple (u, v, w) and the counter value. Note that if in the simulation of a sequence of pops, the counter becomes 0, M' must first retrieve the appropriate c_i (corresponding to the pushdown segment directly below the one that was just consumed) and restore it in the counter before it can continue with the simulation; retrieving and restoring the count in the counter requires the input head to leave the input position, but M' can remember the "new" position with a new "marker." If after a sequence of pops M enters a new writing phase before the counter becomes 0, the "residual" counter value is recorded as a new c_i like before. We leave the details to the reader. It is clear that M' in in 2DCM(1, r) for some r. □

Since the proof of Theorem 2.4 can be trivially modified to show that reversal-bounded 2DPDAs can be made halting, the class of languages they defined is effectively closed under complementation. Hence, we have the next corollary.

COROLLARY 3.3. *The containment and equivalence problems for* 2DPDA(r) *for* $r \geq 1$ *on bounded languages are decidable.*

As a second application, we use Theorem 2.1 to show the decidability of the emptiness problem for some classes of simple programs. The motivation for the following definition comes from the study of real-time verification [1].

DEFINITION 3.4. *A* simple program *P is a triple (V, X, I), where $V = \{A_1, A_2, \ldots, A_n\}$ is a finite set of* input variables, *$X \notin V$ is the* accumulator, *and $I = (i_1; i_2; \ldots; i_l)$ is a finite list of* instructions *of the following form*:

1. *label s:* $X \leftarrow X + A_i$
2. *label s:* $X \leftarrow X - A_i$
3. *label s: if* $X = 0$ *goto label t*
4. *label s: if* $X > 0$ *goto label t*
5. *label s: if* $X < 0$ *goto label t*
6. *label s: goto label t*
7. *label s: halt*

Note that the program is not allowed to change the value of an input variable.

DEFINITION 3.5. *For a program P, $EMPTY(P)$ = yes if there are integers (positive, negative, or zero) $a_1, a_2, \ldots, a_n$ such that P on this input halts; otherwise $EMPTY(P)$ = no. The emptiness problem for simple programs is deciding given P if $EMPTY(P)$ is yes.*

At present, we do not know if the emptiness problem for simple programs is decidable. However, for some special cases, we are able to show that the problem is decidable.

One such special case is a program whose accumulator crosses the 0 axis (alternates between positive values and negative values) at most k times for some positive integer k independent of the input. Call such a program *k-crossing*, and in general, a program *finite-crossing* if it is k-crossing for some $k \geq 1$.

For example, a program with three inputs A, B, C that checks the relation $A = (B - C)i$ for some i can operate as follows: Add A to the accumulator, and iterate adding B and subtracting C and checking if the accumulator X is zero after every iteration. (The program halts if X is zero and goes into an infinite loop if X is negative.) Although the accumulator alternates between increasing and decreasing modes arbitrarily many times (which depends on the input), the accumulator crosses the 0 axis at most once. So such a program is 1-crossing.

Although finite-crossing programs are quite powerful, there are programs that are not finite-crossing. Here is an example of a program whose accumulator alternates between positive and negative values an unbounded number of times:

```
    X = 0
a:  X = X + A
    if X = 0 goto c
    if X > 0 goto b
    goto d
b:  X = X − B
    if X = 0 goto c
    if X < 0 goto a
d:  goto e
e:  goto d
c:  halt
```

If $B = A + \sqrt{A}$, then there can be $\sqrt{A}$ alternations of the accumulator between positive and negative values.

Again, we apply Theorem 2.1 to show the emptiness problem for finite-crossing simple programs is decidable.

THEOREM 3.6. *The emptiness problem for finite-crossing simple programs is decidable, even when instructions of the form* $X \leftarrow X + 1$ *and* $X \leftarrow X - 1$, *are allowed.*

Proof. We give an algorithm to decide whether a finite-crossing simple program P halts on any input. Suppose P has l instructions and n input variables $A_1, A_2, \ldots, A_n$. Define the instantaneous description $(c_t, \text{sign}(X_t))$ of P at time t to be the label of the instruction being executed and the sign of the accumulator, which is either negative or nonnegative.

Consider a halting computation of P on some set of input values $a_1, a_2, \ldots, a_n$ as given by a sequence of IDs of P from start to finish. Since the accumulator of P alternates between positive and negative values at most k times for some $k \geq 1$, this computation can be divided into at most $k + 1$ phases such that every ID in a phase has the same second component. Because P is deterministic, some ID must be repeated after the first l steps in each phase, and hence the sequence of IDs in each phase can be written in the form of $uv^i w$, where each u, v, and w is a concatenation of at most l IDs.

Using this observation about finite-crossing simple programs, we construct a reversal-bounded counter machine M such that M accepts some input if and only if P halts on some input. Since M can make only a finite number of reversals on its counter, it cannot simulate P faithfully. Rather, M uses the "padding" technique described in Lemma 3.2. For each phase in

the computation of P, M precomputes the effect made on the counter by each possible loop v of instructions and "stores" it in the input, i.e., M verifies that its input is padded with this extra information. From then on, to simulate a loop M needs only add its corresponding net effect to the counter, and hence to simulate a phase, M needs at most a constant number of counter reversals. Also, to simulate the increment and decrement instructions, M introduces two new variables, a_+ and a_-, which hold $+1$ and -1, respectively. We give a precise description of the construction below.

M only accept inputs of the form $0^{a_1}\#0^{a_2}\#\ldots\#0^{a_n}\#0^{a_+}\#0^{a_-}\#0^{b_1}\#0^{b_2}\#\ldots\#0^{b_m}$, where $m = \sum_{i=1}^{l} i!$. M considers the first $n+2$ integers coded in its input to be the input values to P. The last m integers represent the net changes made to the accumulator by all possible loops of instructions of length at most l.

At the start of the computation, M verifies that its input has the desired form, and that the last m integers indeed represent the respective changes to the accumulator by a loop of instructions of length at most l, assuming the first n integers are the input values to P. Once this is verified, M proceeds to simulate P. Because the computation in each phase is periodic, M does not simulate P step by step once P gets into a loop of instruction. Instead, M records the loop in its finite control and then uses the corresponding value in the latter part of the input to make changes directly to the counter.

It is easy to see that M accepts some input iff P halts on some input. Furthermore, M makes at most $2l$ counter reversals in each phase and at most $2lm$ counter reversal in the initial verification process. Hence M makes at most $2l(k+1+m)$ counter reversals during the entire computation, and by Theorem 2.1 it is decidable whether $L(M) = \emptyset$. This proves the theorem. □

Remark. Allowing the use of "constant" instructions of the form $X \leftarrow X+1$ and $X \leftarrow X-1$ makes simple programs computationally more powerful. For example, the relation $R = \{A : 2|A\}$ can easily be verified by a finite-crossing program with constant instructions, but not by any program without constant instructions, even if it is not finite-crossing.

Although finite-crossing programs can check fairly complicated relations, they cannot verify multiplication and squaring.

Define MULT $= \{(A, B, C)|C = A * B\}$ and SQUARE $= \{(A, B)|B = A^2\}$.

CLAIM 3.7. MULT *and* SQUARE *cannot be verified by finite-crossing programs.*

Proof. We use the proof technique in [6]. It is known that there is a fixed polynomial $p(y, x_1, \ldots, x_t)$ with integer coefficients such that it is undecidable to determine for an arbitrary nonnegative integer m whether or not $p(m, x_1, \ldots, x_t)$ has a nonnegative integer solution in $x_1, \ldots, x_t$ [4].

Clearly, finite-crossing programs can do addition and subtraction. If MULT can be verified by a finite-crossing program, then we can effectively construct, for each m, a finite-crossing program P_m over $A_1, \ldots, A_t, B_1, \ldots, B_s$ (for some s) such that P_m halts on $A_1, \ldots, A_t$, $sB_1, \ldots, B_s$ for some $B_1, \ldots, B_s$ if and only if $p(m, A_1, \ldots, A_t) = 0$. P_m uses the programs for MULT, addition and subtraction. Since we can decide emptiness for finite-crossing programs, we can decide if the polynomial has a solution, which is a contradiction.

If SQUARE can be verified, then the relation $R = \{(A, B, C, D, E, F, G, H)|B = A^2, D = C^2, E = A+B, F = E^2, G = F-E, H = A*B\}$ can also be verified by a finite-crossing program. Thus MULT can effectively be verified. But we already know this is impossible. □

Although finite-crossing simple programs may seem equivalent at first glance to counter machines whose counters can become zero only a finite number of times regardless of its input (we call those *finite-reset* counter machines), the latter are in fact much more powerful computational devices. For example, there is a finite-reset counter machine M that accepts a

set S similar to MULT, namely, $S = \{0^x\#(0^y\#)^x : x, y \geq 1\}$. M first checks that its input is of the form $0^x\#0^{y_1}\#0^{y_2}\#\ldots\#0^{y_n}$ and that $n = x$. This requires 1 reset of the counter. Next M verifies that $y_1 \geq y_2$ by adding $1 + y_1 - y_2$ to its counter; M rejects if the counter resets to zero during this operation. Otherwise, $y_1 \geq y_2$ and M adds $2y_2 - y_1$ to the counter so that its value now becomes $1 + y_2$. Note that the counter does not reset during this operation. M now checks that $y_2 \geq y_3$ and so on, until it has verified that $y_1 \geq y_2 \geq \cdots \geq y_n$. Finally, M verifies that $y_1 = y_n$. It is easy to see that the whole computation requires only two resets of the counter.

It follows from the above remark that the emptiness problem for finite-reset counter machines is undecidable, because they can multiply and hence compute the value of any polynomial $p(y, x_1, x_2, \ldots, x_n)$ (see [3] for the proof of an analogous result). This contrasts with Theorem 3.6.

We can use the same technique in Theorem 3.6 to show that the emptiness problem is decidable for finite-reset counter machines on *strictly bounded languages* (and hence bounded languages also; see the remark at the bottom of §1). Each accepting computation of such a machine M can be divided into a finite number of phases at the times the counter value becomes zero. Since the language is strictly bounded, it is easy to see that the counter makes a reversal only at the boundary points, i.e., the endmarkers or the first symbols of each type. The computation in each phase then can be rewritten in the form uv^iw, such that the lengths of u, v, and w are bounded by some constant depending only M, and v starts and ends in the same state and on the same boundary point. Again, the number of different such v's is bounded by a constant. So we can construct a finite-reversal counter machine M', whose input is padded with the net change to the counter value by each possible loop v, such that $L(M)$ is empty iff $L(M')$ is. From this and Corollary 2.8, we have the following.

THEOREM 3.8. *The ECE problems for finite-reset counter machines over strictly bounded languages are decidable.*

It is interesting to note that there are strictly bounded languages that can be recognized by a finite-reset counter machine but not by any finite-reversal counter machine. One example is $L = \{0^a1^b2^c : a = n(b - c) \text{ for some } n \geq 0\}$.

There is a restricted class of simple programs allowing "nondeterminism" that arises in the theory of real-time verification [1], as seen in the following definition.

DEFINITION 3.9. *A* restricted nondeterministic simple program *is a simple program that allows more than one choice of instruction for each label and has the property that the accumulator X is nonnegative (nonpositive) after each instruction of the form $X \leftarrow X + A_i$ ($X \leftarrow X - A_i$).*

It is an open question whether the emptiness problem for this class of simple programs is decidable. However, we can show that the emptiness problem is decidable for restricted *deterministic* simple programs.

THEOREM 3.10. *The emptiness problem for restricted deterministic simple programs is decidable.*

Proof. We give an algorithm to decide whether a restricted deterministic simple program P halts on any input. Suppose P has l instructions and n input variables $A_1, A_2, \ldots, A_n$. Define the instantaneous description $(c_t, \text{sign}(X_t))$ of P at time t to be the label of the instruction being executed and the sign of the accumulator, which can be either positive, negative, or zero.

Consider a halting computation of P on some set of input values $a_1, a_2, \ldots, a_n$ as given by the sequence of IDs of P from start to finish. There can be at most l IDs with accumulator value zero, or else P would never halt. These IDs divide the computation into a finite number of phases. Because P is deterministic, some ID must be repeated after the first $2l$ steps in each phase, and furthermore, no $l + 1$ consecutive IDs in each phase can have the same first

component due to the constraint on the accumulator. Hence the sequence of IDs in each phase can be written in the form $uv^i w$, where each u, v, and w is a concatenation of at most $2l$ IDs.

Using this observation about restricted simple programs, we construct a reversal-bounded counter machine M such that M accepts some input if and only if P halts on some input, using the same technique of Theorem 3.6. We leave the details to the reader. □

We can allow comparisons between input variables and the emptiness problem still remains decidable.

COROLLARY 3.11. *The emptiness problem is decidable for finite-crossing simple programs and restricted deterministic simple programs which use additional instructions of the form*

if $p(A_i, A_j)$ **goto** *label,*

where A_i and A_j are input variables, and the predicate p is $|$ (for divides), $>$, $<$, or $=$.

Proof. Suppose P_1 is a finite-crossing simple program. We construct another program P_2 which precomputes all possible relations between the variables. P_2 consists of many segments, each of which simulates P_1 for the appropriate relations among the variables. After the preprocessing phase, P_2 jumps to the appropriate segment.

In the case of a restricted deterministic simple program P_1, the construction is similar, but because of the constraint on the accumulator, we need to use additional input variables to accomplish the testing of the relations. For example, suppose A and B are input variables, and we need to check whether $A|B$. In this case, we use an additional variable C storing the value $A + B$ which P_2 has to verify at the beginning. Then, P_2 executes the following code segment:

$X = B$
10: $X = X - C$
$X = X + B$
if $X = 0$ **goto** 20
if $X < 0$ **goto** 30
goto 10
20: A divides B
30: A does not divide B

X initially has the value $A - B$. Each iteration of the loop effectively adds A to X until $X = 0$ (A divides B) or $X < 0$ (A does not divide B). The resulting program P_2 may violate the constraint on the accumulator during this preprocessing phase, but only a constant number of times; however, the proof of Theorem 3.10 still applies. □

4. Nondeterministic reversal-bounded multicounter machines. We do not know if the emptiness problem for $\bigcup_r$ 2NCM(1, r) is decidable. In fact, the question is open even for $\bigcup_r$ 2NCM(1, r) machines accepting only bounded languages. However, we can show that the ECE problems are decidable for $\bigcup_c \bigcup_r$ 2NCM(c, r) on unary alphabet. More precisely, we prove that unary languages accepted by $\bigcup_c \bigcup_r$ 2NCM(c, r) machines are effectively regular. This settles a conjecture of Gurari and Ibarra [5]. In [5] it was only shown that unary languages accepted by $\bigcup_c \bigcup_r$ 2DCM(c, r) machines are effectively regular. Our technique is totally different. We first prove a lemma that characterizes regular unary languages.

LEMMA 4.1. *A unary language L is regular iff there is a constant c depending only on L such that for every $w = 0^x \in L$, $x > c$, there is some j, $1 \leq j \leq c$, such that $w' = 0^{jn}0^{x-j} \in L$ for all $n \geq 1$.*

Proof. The $\Rightarrow$ direction is immediate, since the stated condition is simply the condition of the pumping lemma for unary regular languages. Conversely, suppose L is a unary language

that satisfies the condition of the lemma. Partition L into c^2 subsets $L_{0,1}, L_{1,1}, \ldots, L_{c-1,c}$, so that $L_{i,j} = \{0^x \in L : j$ satisfies the condition for 0^x and $i = (x - j) \bmod j\}$. Then each $L_{i,j}$ is generated by its smallest element, and hence each $L_{i,j}$ and L is regular. □

THEOREM 4.2. *Every unary language accepted by a* 2NCM(c, r) *is regular for* $c, r \geq 1$.

Proof. It suffices to show the theorem for 2NCM(c, 1), since we can reduce the number of counter reversals by any 2NCM(c, r) to 1 by adding more counters. We first show the theorem for $c = 1$, using the characterization given in Lemma 4.1, and then extend the proof to the general case.

Suppose L is accepted by some 2NCM(1, 1) M with q states. To avoid stating unnecessary constants, we will use the word "bounded" in the following to mean "bounded by some constant depending only on q."

Let 0^x be in L, and let C be an accepting computation of M on 0^x. C has a *simple loop* if there are some $t_1 < t_2$ such that at times t_1 and t_2 M is in the same state and on the same input square, and furthermore M does not visit an endmarker during $[t_1, t_2]$. A simple loop is called *positive* or *negative* depending on the net change it makes to the counter value. C has a *sweep* if there are some $t_1 < t_2$ such that at times t_1 and t_2 M is on an endmarker, and M does not visit an endmarker during (t_1, t_2).

So given a computation C, we decompose C into sweeps of length $O(|0^x|)$ after first removing all simple loops. Since each boundary is crossed at most q times in each direction, the the number of different crossing sequences is bounded by $t = \sum_{i=0}^{2q}(2q)^i < (2q)^{2q+1}$, and so we can divide each sweep into a bounded number of clusters of identical movable segments (segments which have the same crossing sequences at both ends) separated by separator segments as explained in Theorem 2.1. Let b be the least common multiple of the lengths of all types of movable segments. After consolidating, we may assume that every movable segment has length b, and each sweep has exactly m movable segments for some $m = \Omega(|0^x|)$. (We consider sweeps that start and end on the same marker to have "empty" movable segments whose net change to the counter is zero.) We use $v(F)$ to denote the net change to the counter value by a computation fragment F (such as a loop or a sweep) of C. For example, $v(C) = 0$.

Suppose we add a segment of length b to the input 0^x. We can obtain from C an "almost" valid computation C' by duplicating one arbitrary movable segment in each sweep. (The simple loops are not affected since the input head never visits the endmarkers during a simple loop.) We call a set of movable segments obtained by taking one movable segment from each sweep a *cross section* E of C. A cross section E is called *positive* or *negative* depending on the sign of $v(E)$. Our strategy is to manipulate the sweeps, loops, and cross sections to obtain from C an accepting computation of M on 0^{x+kbn} for some bounded k and all $n \geq 1$.

We have the following seven cases.

1. C has a negative cross section and a positive cross section.

Let E^+ be the least positive cross section and E^- the least negative cross section. We claim $v(E^+)$ is bounded; otherwise, we can obtain another cross section E by replacing a movable segment in E by another choice in the same sweep with a smaller net change to the counter value. (We know such a sweep and a movable segment must exist, because there is a negative cross section.) We have $0 < v(E) < v(E^+)$, contradicting E^+'s minimality. The same applies for E^-. Letting $k = v(E^+) + |v(E^-)|$, we can obtain from C an accepting computation for 0^{x+kbn}, $n \geq 1$, by adding $|v(E^-)|n$ copies of cross section E^+ and $v(E^+)n$ copies of cross section E^-.

2. C has only positive cross sections, but also negative simple loops.

Let E be a positive cross section and K be a negative simple loop of C. From K we can obtain by cut-and-paste a new negative simple loop K' such that $v(K')$ is bounded. Letting

$k = |v(K')|$, we can obtain from C an accepting computation for 0^{x+kbn}, $n \geq 1$, by adding $|v(K')|n$ copies of cross section E and $v(E)n$ copies of simple loop K'.

3. C has only negative cross sections, but also positive simple loops. Symmetric to Case (2).

4. C has only positive cross sections, but also positive simple loops.

If C has only positive cross sections, then the number of sweeps in the decreasing phase cannot be bounded. To see this, recall that each sweep consists of m movable segments and some separator segments. Since C has only positive cross sections, we can choose any combination of movable segments (one in each sweep) and still have a positive cross section. Since there are $m \in \Omega(|0^x|)$ movable segments in each sweep, the net change to the counter values by the movable segments in all sweeps is $\Omega(|0^x|)$. If the number of sweeps in the decreasing phase is bounded, then the net change by the separator segments in those sweeps is $-O(1)$, not enough to make the final counter value of C zero. Hence C cannot be an accepting computation, a contradiction. So there is a sequence S of at most $2q + 1$ consecutive sweeps in the decreasing phase such that S starts and ends in the same state on the same endmarker, and $v(S) < 0$. Such a sequence is called a *sweep loop*.

Let E be a positive cross section and K be a positive simple loop of C. Again, we can assume that $v(K)$ is bounded. Let E' be the subset of movable segments of E that come from the sweeps in S, and let r be the least positive integer such that $v(K)v(E) + rv(K)(v(S) + v(K)v(E'))$ is negative. Letting $k = v(K)$, we can obtain from C an accepting computation for 0^{x+kbn}, $n \geq 1$, by adding $rv(K)n$ copies of the sweep loop S, $v(K)n$ copies of cross section E (E includes movable segments from the newly added copies of S), and $|v(E) + r(v(S) + v(K)v(E'))|n$ copies of simple loop K.

5. C has only negative cross sections, but also negative simple loops. Symmetric to case 4.

6. C has only positive cross sections, and no simple loops.

Since C has only positive cross section, again the number of sweeps in the decreasing phase cannot be bounded, and there is some negative sweep loop. We can assume that C has no sweep loops of net change $o(|0^x|)$. (Otherwise, we can obtain by cut-and-paste from such a sweep loop a new sweep loop S such that $v(S)$ is bounded. This sweep loop is in effect a simple loop, and we can proceed as in case 2 or 4.) Because the net change to the counter value in the decreasing phase is not bounded by $O(|0^x|)$ and there are no positive simple loops, the number of sweeps in the increasing phase cannot be bounded either, and there is also some positive sweep loop.

Let P be a positive sweep loop, and denote the net change by all separator segments in P by s_P. Select an arbitrary cross section of P (i.e., a set of movable segments in P, one from every sweep), and denote its net change by c_P. We can construct a new uniform sweep loop P' from P such that all cross sections of P' are the same, by replacing all movable segments in each sweep of P by the one selected for the cross section, and adding a extra copies, where a is a bounded number specified in the next paragraph. The net change by P' is $v(P') = (m + a)c_P + s_P$. Similarly, we can obtain a new uniform sweep loop N' from N such that the net change by N' is $v(N') = (m + a)c_N + s_N$, where c_N and s_N are defined analogously.

Now suppose we can find cross sections c_P and c_N such that $c_P s_N - c_N s_P$ is nonzero. Let a be $|c_P s_N - c_N s_P|$. Then $k = |gcd(v(P'), v(N'))|$ is bounded, since k must divide $c_P s_N - c_N s_P$, and c_P, c_N, s_P, s_N are all bounded. Hence, there are positive integers n_1, n_2 such that $n_1 v(P') + n_2 v(P') = -k$. In effect, we have a negative simple loop of net change $-k$. In this case, we can obtain from C an accepting computation for 0^{x+kbn}, $n \geq 1$, by adding $n_1 av(E)n/k$ copies of positive uniform sweep loop P', $n_2 av(E)n/k$ copies of negative

uniform sweep loop N', and *an* copies of a positive cross section E (E includes movable segments from the newly added sweep loops).

It remains to show that we can always choose the cross sections c_P and c_N so that $c_P s_N - c_N s_P$ is nonzero. Suppose not. Then all sweep loops in C must be uniform, i.e., there is only one unique cross section for each sweep loop, or else we can replace a single movable segment in one of the cross sections to make $c_P s_N - c_N s_P$ nonzero. Select arbitrarily a positive sweep loop J and a negative sweep loop K and discard $|c_K|$ copies of J and $|c_J|$ copies of K from C. Do this until it is no longer possible. At this point, either the number of positive sweep loops or the number of negative sweep loops is bounded. Note that the net change by all discarded sweep loops is zero, by our assumption.

If the number of negative sweep loops is bounded, then in fact the net change by all separator segments in C is $-O(1)$, not enough to offset the net change by all movable segments in C, which is $\Omega(|0^x|)$. So C cannot be an accepting computation, a contradiction. If the number of negative sweep loops is not bounded, then since the number of positive sweep loops is bounded, the total net change by the remaining sweeps must be negative (we noted earlier that the net change by a negative sweep loop is $-|\Omega(|0^x|)|$). Again, C cannot be an accepting computation, a contradiction.

7. C has only negative cross sections, and no simple loops. Symmetric to Case (6).

In all cases, we can find some bounded k such that 0^{x+kbn} is in L for all $n \geq 1$. Hence by Lemma 4.1, L is regular. This concludes the proof of the theorem for $c = 1$.

Now we show how to extend the above proof to the general case. Suppose L is accepted by some 2NCM(c, 1) M. Let 0^x be in L, and let C be an accepting computation of M on 0^x. We partition C into simple loops, movable segments, and sweeps as for the case of 2NCM(1, 1), except that now these units are defined relative to a single counter. So there are c different partitions of C, each concerning with net changes to only one counter and ignoring the other counters. Proceed as in the construction above to find the size of the segment to be added for each case, say $k_1 b$, $k_2 b$, ..., $k_c b$. Then the final input segment to be added is $k_1 k_2 \ldots k_c b^c$. □

The proof of Theorem 4.2 also works even if we shorten instead of lengthen the input. (In this case, we need to remove cross sections and simple loops but still *add* sweeps. We adjust the definitions to make sure that cross sections and simple loops always exist in multiple copies.) Thus, to decide whether a 2NCM(c, r) accept some input, we only need to check all inputs of length at most a bounded constant. Since the membership problem for 2NCM(c, r) is decidable [2], we have the following.

COROLLARY 4.3. *The ECE problems for* $\bigcup_c \bigcup_r$ 2NCM(c, r) *on unary alphabet are decidable.*

This is the strongest result one can obtain since it is known that deterministic reversal-bounded 2-counter machines over strictly bounded languages can accept nonsemilinear sets and have an undecidable emptiness problem [8].

ON THE OPTIMALITY OF RANDOMIZED α-β SEARCH *

YANJUN ZHANG†

Abstract. It is shown that the expected number of leaves evaluated by randomized α-β search for evaluating uniform game trees of degree d and height h is $O((B_d)^h)$, where $B_d = d/2 + \ln d + O(1)$. It was shown by Saks and Wigderson [*Proceedings of* 27th *Annual Symposium on Foundations of Computer Science* (1986), pp. 29–38] that the optimal branching factor of randomized algorithms for evaluating uniform trees of degree d is $B_d^* = (d - 1 + \sqrt{d^2 + 14d + 1})/4 = d/2 + O(1)$. As $B_d/B_d^* = 1 + O(\ln d/d)$, randomized α-β search is asymptotically optimal for evaluating uniform game trees as the degree of tree increases.

1. Introduction.

A *game tree* is a rooted tree in which the root is a MAX-node, the internal nodes at odd (even) distance from the root are MIN-nodes (MAX-nodes), and each leaf has a real value. The *value*, or *minimax value*, of a MAX-node (MIN-node) is recursively defined as the maximum (minimum) of the values of its children. The problem of game-tree evaluation is that of determining the value of the root of a game tree. Game-tree evaluation is used in computer programs for playing two-person games of perfect information such as chess and checkers.

The best known heuristic in practice for evaluating game trees is the α-β pruning procedure [4], which we shall call α-β *search*. The efficiency of α-β search lies in its ability to detect and prune away certain nodes whose values can no longer influence the value of the root. A *uniform* tree is a tree in which each internal node has the same number of children and each root-leaf path has the same number of nodes; for a uniform tree, the *degree* is the number of children of an internal node, and the *height* is the number of edges on a root-leaf path. Traditionally, the performance of α-β search has been analyzed on uniform game trees in the i.i.d. probabilistic model in which the values of leaves are drawn independently from the distribution of a certain random variable, and the complexity of a game-tree evaluation algorithm is the expected number of leaves evaluated by the algorithm. The *branching factor* of an algorithm is the asymptotic limit of the hth root of the expected number of leaves evaluated by the algorithm as the height of tree h increases.

It was shown by Knuth and Moore [4] that in the i.i.d. model the branching factor of a weaker version of α-β search using only "shallow cutoff" is $\Theta(d/\ln d)$ on uniform trees of degree d, and conjectured that the branching factor of α-β search remains $\Theta(d/\ln d)$. Their conjecture was confirmed by Baudet [1] (cf. [7, p. 294]). The exact value of the branching factor of α-β search on random uniform trees of degree d was shown by Pearl [6] to be $R_d^* = \frac{\xi_d}{1-\xi_d}$, where ξ_d is the positive root of $x^d + x - 1 = 0$ and $R_d^* = \frac{d}{\ln d}(1 + O(\frac{\ln\ln d}{\ln d}))$ (cf. [7, p. 267]). A year later, Tarsi [9] proved that branching factor R_d^* is best possible for evaluating random uniform trees in the i.i.d. model.

More recently, Saks and Wigderson [8] studied the game-tree evaluation by randomized algorithms. A randomized game-tree evaluation algorithm can make random choices during its execution in deciding which leaf to evaluate next, and the number of leaves evaluated on a fixed input instance is a random variable. The complexity of a randomized game-tree evaluation algorithm is the maximum of the expected number of leaves evaluated over all instances of game trees. The randomized complexity for game-tree evaluation is the minimum

of the complexity over all randomized game-tree evaluation algorithms. The chief advantage of randomized algorithms is that no probabilistic assumptions are imposed upon the input instances, as probabilistic assumptions may fail to reflect reality. Saks and Wigderson proved in [8] that the randomized complexity for evaluating uniform game trees of degree d and height h is $\Theta((B_d^*)^h)$, where $B_d^* = \left(d - 1 + \sqrt{d^2 + 14d + 1}\right)/4 = d/2 + 3/2 + O(d^{-1})$ is the optimal branching factor in the randomized model. The quantitative difference in optimal branching factors $B_d^* = d/2 + O(1)$ of the randomized model and $R_d^* = \Theta(d/\ln d)$ of the i.i.d. model demonstrates a fundamental difference in the two probabilistic models. Furthermore, they show that the optimal upper bound of $O((B_d^*)^h)$ is achieved by a randomized version of SCOUT, a game-tree evaluation algorithm studied by Pearl [5].[1] SCOUT is a quite different algorithm from α-β search; there is no dominating relation between SCOUT and α-β search in terms of the number of evaluated leaves. (See [7, pp. 246–250] for such examples.) The question of whether randomized α-β search is also optimal was not resolved by the work of Saks and Wigderson.

In this paper we show that randomized α-β search is asymptotically optimal for evaluating uniform game trees as the degree of tree increases. We show that the expected number of leaves evaluated by randomized α-β search for evaluating uniform game trees of degree d and height h is $O((B_d)^h)$, where $B_d = d/2 + O(\ln d)$, and $B_d/B_d^* = 1 + O(\ln d/d)$, where $B_d^* = d/2 + O(1)$ is the optimal branching factor. Our approach is similar to that used by Knuth and Moore for the analysis of α-β search in the i.i.d. model. Instead of a direct analysis of randomized α-β search, we shall analyze a weaker version of randomized α-β search using only shallow cutoff. We show that the randomized α-β search using only shallow cutoff achieves the claimed bound, thus asymptotically optimal as the degree of tree increases. It follows that randomized α-β search is also asymptotically optimal.

2. α-β search. The execution of α-β *search*[2] is a depth-first traversal of the input tree during which certain nodes are evaluated and others are pruned away, thus not evaluated. The pruned nodes are certified to have no influence on the value of the root. Let $\mathrm{val}(v)$ be the minimax value of node v. Each visited node v is evaluated upon the return of the traversal from the subtree rooted at that node with a *return value* $r(v)$, which may or may not be equal to $\mathrm{val}(v)$. The return value $r(v)$ is recursively defined as the leaf value of v if v is a leaf or the maximum (minimum) of the return values of the evaluated children of v if v is a MAX-node (MIN-node). The depth-first traversal of α-β search visits the children of a node in the left-to-right order. The *randomized* α-β *search* is an α-β search in which the children of a node are visited in a random order, independent of the order in which other nodes are visited.

The pruning mechanism of α-β search consists of two parameters, the α bound and the β bound. The *current value* of a MAX-node (MIN-node) v, denoted by $c(v)$, is the maximum (minimum) of the return values of the evaluated children of v. The current value of a node becomes its return value upon the evaluation of that node. Let $c(v) = -\infty(+\infty)$ for a MAX-node (MIN-node) v with no evaluated children. An *ancestor* of v is a node on the path between v and

[1] For the sake of completeness, we describe SCOUT in this footnote. SCOUT is a two-pass evaluation process that tests the usefulness of a node before deciding to evaluate or discard it. To evaluate a node v, SCOUT recursively evaluates a child u of v and sets $c(v) = \mathrm{val}(u)$. For each remaining child u' of v, SCOUT first tests whether $\mathrm{val}(u') > c(v)$ or $\mathrm{val}(u') < c(v)$ without determining the exact value of $\mathrm{val}(u')$; such a test can be done as an evaluation of an AND/OR tree of Boolean values. If $\mathrm{val}(u') > c(v)$ for a MAX-node v or $\mathrm{val}(u') < c(v)$ for a MIN-node v, then recursively evaluate u' and set $c(v) = \mathrm{val}(u')$; otherwise, discard u' without further evaluation. After all children of v are processed, $c(v)$ is returned (correctly) as $\mathrm{val}(v)$. SCOUT is also optimal in the i.i.d. model [7]. The randomized SCOUT in [8] is to randomly select the next child for testing and evaluation.

[2] In [4], α-β search is described by a recursive program $F2$ in the negmax format; the correctness of α-β search is proved via an invariant argument about program $F2$. For a node at which pruning occurs, $F2$ may compute a different value than the return value of that node defined in this paper.

the root, including v itself. The α *bound* of v is $\alpha(v) = \max\{c(w) \mid w \text{ is a MAX-ancestor of } v\}$ and the β *bound* of v is $\beta(v) = \min\{c(w) \mid w \text{ is a MIN-ancestor of } v\}$. During its traversal, α-β search maintains the α bound and β bound of the currently visited node. The *pruning rule* of α-β search is that the unevaluated children of a node v are pruned if $\alpha(v) \geq \beta(v)$. Pruning *occurs at* v if the unevaluated children of v are pruned but v itself is not. All children of the root r are evaluated, as r is a MAX-node and $\beta(r) = +\infty$ always.

In [4], Knuth and Moore described a weaker version of α-β search using only "shallow cutoff," which is given by program $F1$ together with a proof of correctness, and analyzed its asymptotic behavior for evaluating uniform random trees in the i.i.d. model. For any node v, define the *shallow* α*-bound* $\alpha'(v)$ and the *shallow* β*-bound* $\beta'(v)$ of v as follows. For root r, let $\alpha'(r) = c(r)$ and $\beta'(r) = +\infty$. For a MAX-node or MIN-node $v \neq r$, let w be the parent of v, and define $\alpha'(v) = c(v)$ and $\beta'(v) = c(w)$ if v is a MAX-node, or $\alpha'(v) = c(w)$ and $\beta'(v) = c(v)$ if v is a MIN-node. By definition, $\alpha'(v) \leq \alpha(v)$ and $\beta'(v) \geq \beta(v)$. Since $\alpha'(v) \leq \alpha(v)$ and $\beta'(v) \geq \beta(v)$, condition $\alpha'(v) \geq \beta'(v)$ guarantees the pruning criterion $\alpha(v) \geq \beta(v)$. The pruning occurring at v is called a *shallow cutoff* if $\alpha'(v) \geq \beta'(v)$; otherwise, it is a *deep cutoff*. Hence, the pruning at v is a shallow cutoff when pruning criterion $\alpha(v) \geq \beta(v)$ is satisfied by the current values of v and the parent of v. Figure 1 illustrates a shallow cutoff and a deep cutoff for game trees of degree 2. A basic fact about shallow cutoff is that a shallow cutoff cannot occur at a node that is evaluated first among its siblings. This is because the current value of the parent node of v will be either ∞ or $-\infty$ when v is evaluated first among its siblings, rendering the shallow cutoff condition $\alpha'(v) \geq \beta'(v)$ impossible. This fact will be used repeatedly in the later analysis.

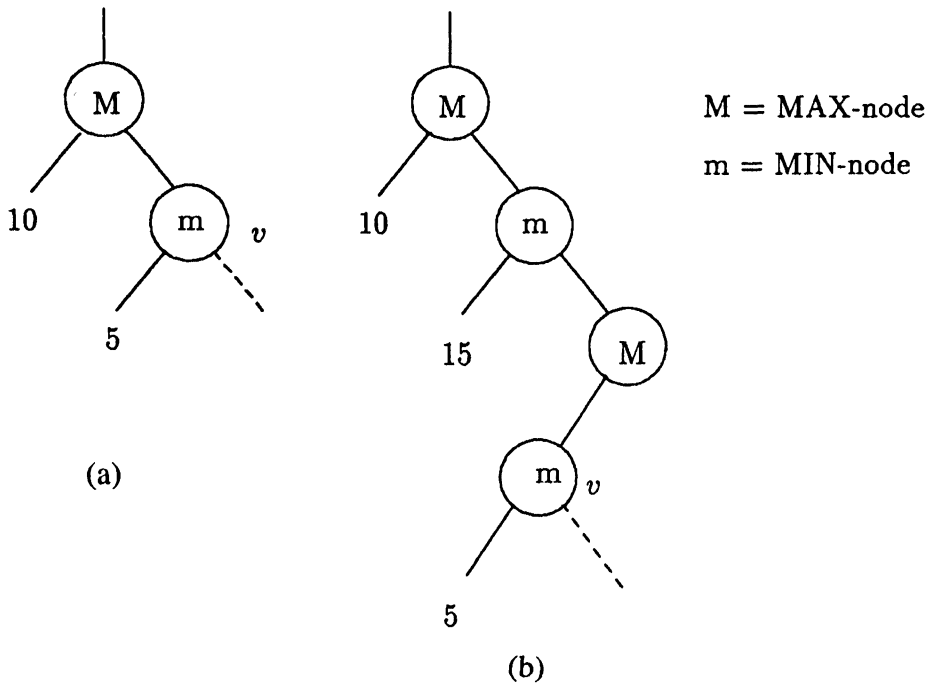

FIG. 1. (a) *a shallow cut at* v; (b) *a deep cut at* v. *In both* (a) *and* (b), $\alpha(v) \geq 10 > 5 \geq \beta(v)$.

We call the α-β search performing only shallow cutoffs *shallow* α-β *search*. A shallow α-β search in which the children of a node are visited in a random order is called *randomized*

shallow α-β search. We shall study shallow α-β search and randomized shallow α-β search in the next two sections.

We end this section with a useful characterization of α-β search. For a leaf u of a game tree, let $A(u)$ be the maximum of the values of all left siblings of a MIN-ancestor of u, and let $B(u)$ be the minimum of the values of all left siblings of a MAX-ancestor of u. Notice that $A(u)$ and $B(u)$ depend *statically* on the structure of the game tree and the minimax values of nodes. The following criterion for a leaf u to be evaluated by α-β search in terms of $A(u)$ and $B(u)$, in a similar way as the α bound and the β bound, was first shown in [2] and later in [1] (cf. [7, p. 239]).

THEOREM 1. *A leaf u is evaluated by α-β search if and only if $A(u) < B(u)$.*

3. Shallow α-β search. In this section we prove some basic properties of shallow α-β search, and show the domination of (randomized) α-β search over (randomized) shallow α-β search.

A fundamental relation between the return value $r(v)$, the minimax value $\mathrm{val}(v)$, and shallow bounds $\alpha'(v)$ and $\beta'(v)$ for any node v evaluated by shallow α-β search is given in Proposition 1. We note that neither (i) and (ii) of Proposition 1 holds in general for α-β search when deep cutoffs are used. The proof of Proposition 1 is not as straightforward as one may think, due to the fact that the return value of a node may differ from its minimax value. Proposition 1 also provides a proof of correctness of shallow α-β search.

PROPOSITION 1. *Suppose that a nonleaf node v is evaluated in a shallow α-β search. Then* (i) *if no pruning occurs at v, then* $\mathrm{val}(v) = r(v)$; *in particular,* $\mathrm{val}(r) = r(r)$ *where r is the root*; (ii) *if pruning occurs at v, then* $\mathrm{val}(v) \geq r(v) \geq \beta'(v)$ *if v is a MAX-node or* $\mathrm{val}(v) \leq r(v) \leq \alpha'(v)$ *if v is a MIN-node, where $\alpha'(v)$ and $\beta'(v)$ are, respectively, the shallow α bound and shallow β bound of v before the evaluation of v.*

Proof. We assume that v is a MAX-node. The case of a MIN-node v is symmetric. If pruning occurs at v, by the pruning rule, $r(v) = \alpha'(v) \geq \beta'(v)$, where $\beta'(v)$ is the current value of the parent of v. Observe that $\beta'(v)$ does not change during the evaluation of v, thus can be taken as being computed before the evaluation of v. This proves the second inequality $r(v) \geq \beta'(v)$ of (ii).

We shall prove (i) and the first inequality of (ii) by induction on the order of evaluation. Notice that (i) and (ii) hold for any evaluated leaf. Suppose that we have just evaluated v. We want to show that (i) and (ii) hold for v. Let $u_1, u_2, \ldots, u_{d'}$ be the set of evaluated children of v that were evaluated in that order. By induction, (i) and (ii) hold for $u_1, u_2, \ldots, u_{d'}$. Define a sequence of indices $i_j \leq d'$ as follows. Let $i_1 = 1$, and for $j \geq 1$, $i_{j+1} = \min\{k \leq d' \mid \mathrm{val}(u_k) > \mathrm{val}(u_{i_j})\}$, and i^* be the last i_j. By definition, $\mathrm{val}(u_{i_1}) < \mathrm{val}(u_{i_2}) < \cdots < \mathrm{val}(u_{i^*}) \leq \mathrm{val}(v)$, and if no pruning occurs at v, $\mathrm{val}(u_{i^*}) = \mathrm{val}(v)$. Hence, (i) and the first inequality of (ii) follow immediately if

$$r(v) = \mathrm{val}(u_{i^*}). \tag{1}$$

We shall prove the following statements (a) and (b) from which (1) follows immediately, given $r(v) = \max_{1 \leq k \leq d'}\{r(u_k)\}$.

(a) For $j \geq 1$, $\mathrm{val}(u_{i_j}) = r(u_{i_j})$.

(b) For $i_j < k < i_{j+1}$, $r(u_k) \leq r(u_{i_j})$ and for $i^* < k$, $r(u_k) \leq r(u_{i^*})$.

We prove (a) and (b) by induction on $k = 1, 2 \ldots, d'$. The basis of the induction is to show that $\mathrm{val}(u_1) = r(u_1)$. As u_1 is the first evaluated child of v, no pruning may occur at u_1. By induction of (i) on u_1, $\mathrm{val}(u_1) = r(u_1)$. We now assume inductively that (a) and (b) hold for all $u_{k'}$, where $k' < k$. Consider the MIN-node u_k. The shallow bound $\alpha'(u_k)$ before the evaluation of u_k is $\alpha'(u_k) = c(v) = \max_{k' < k}\{r(u_{k'})\}$. By induction of (a) and (b)

on $u_1, u_2, \ldots, u_{k-1}$, and the definition of indices i_j,

$$\alpha'(u_k) = \max_{k'<k}\{r(u_{k'})\} = \begin{cases} r(u_{i_j}) = \text{val}(u_{i_j}) & \text{if } i_j < k \le i_{j+1}, \\ r(u_{i^*}) = \text{val}(u_{i^*}) & \text{if } i^* < k. \end{cases} \tag{2}$$

Consider three cases of k.

Case 1. $k = i_{j+1}$, which is (a). In this case, we need to show $\text{val}(u_k) = r(u_k)$. By (2), $\alpha'(u_k) = \text{val}(u_{i_j}) < \text{val}(u_{i_{j+1}}) = \text{val}(u_k)$ before the evaluation of u_k. If pruning occurs at u_k, by induction of (ii) on u_k, we would have $\alpha'(u_k) \ge \text{val}(u_k)$—a contradiction. Hence, no pruning occurs at u_k, and by induction of (i) on u_k, $\text{val}(u_k) = r(u_k)$.

Case 2. $i_j < k < i_{j+1}$, the first case of (b). In this case, we need to show $r(u_k) \le r(u_{i_j})$. If no pruning occurs at u_k, by induction of (i), $\text{val}(u_k) = r(u_k)$. Since $i_j < k < i_{j+1}$, $\text{val}(u_k) \le \text{val}(u_{i_j}) = r(u_{i_j})$ by induction of (a) on u_{i_j}. So $r(u_k) \le r(u_{i_j})$ as desired. If pruning occurs at u_k, by induction of (ii), $r(u_k) \le \alpha'(u_k)$ before evaluation of u_k. By (2), $\alpha'(u_k) = r(u_{i_j})$. So again, $r(u_k) \le r(u_{i_j})$.

Case 3. $i^* < k$, the second case of (b). This case is identical to Case 2 with i^* in place of i_j. The induction on (a) and (b) is complete. □

The following proposition states that in shallow α-β search the current value of a node can be expressed in terms of minimax values of its evaluated children instead of their return values. This fact is critical to the later analysis.

PROPOSITION 2. *Let $D(v)$ be the set of children of v evaluated by shallow α-β search thus far. Suppose that $|D(v)| > 0$. Then $c(v) = \max_{u\in D(v)}\{\text{val}(u)\}$ if v is a MAX-node, or $c(v) = \min_{u\in D(v)}\{\text{val}(u)\}$ if v is a MIN-node, where $c(v)$ is the current value of v. Consequently, $c(v) \le \text{val}(v)$ if v is a MAX-node, or $c(v) \ge \text{val}(v)$ if v is a MIN-node.*

Proof. Assume that v is a MAX-node. We use induction on $|D(v)|$. In the basis case $|D(v)| = 1$, no pruning occurs at the first evaluated child u of v. By Proposition 1(i), $c(v) = r(u) = \text{val}(u)$. Assume inductively that $c(v) = \max_{u\in D(v)}\{\text{val}(u)\}$. Let MIN-node u' be the next evaluated child of v. By Proposition 1, if no pruning occurs at u', then $r(u') = \text{val}(u')$; otherwise, $\alpha'(u') = c(v) \ge r(u') \ge \text{val}(u')$. In either case, let $c'(v)$ be the current value of v after u' is evaluated, and we have $c'(v) = \max\{c(v), r(u')\} = \max\{c(v), \text{val}(u')\} = \max_{u\in D'(v)}\{\text{val}(u)\}$ where $D'(v) = D(v) \cup \{u'\}$. □

One can derive a criterion for a leaf u to be evaluated by shallow α-β search in terms of the static structure of the tree, similar to the one given in Theorem 1 in §2. Let v be an ancestor of leaf u. Define $A(v, u)$ (respectively, $B(v, u)$) to be the maximum (minimum) of the minimax values of the children of v that are left siblings to the child of v that is the ancestor of u if v is a MAX-node (MIN-node).

PROPOSITION 3. *A leaf u is not evaluated by shallow α-β search if and only if there are a MAX ancestor v of u and a MIN ancestor w of u where w is the parent of v or v is the parent of w such that $A(v, u) \ge B(w, u)$.*

Proof. Suppose that u is not evaluated by shallow α-β search. Let v be the ancestor of u at which pruning occurs. We may assume that v is a MAX-node. Upon pruning at v, $c(v) = \alpha'(v) \ge \beta'(v) = c(w)$, where w is the MIN parent of v, and the evaluated children of w (respectively, v) are exactly the left siblings of v (respectively, v', where v' is the child of v that is an ancestor of u). By Proposition 2, $c(v) = A(v, u)$ and $c(w) = B(w, u)$. Hence, $A(v, u) \ge B(w, u)$. On the other hand, suppose that u is evaluated by shallow α-β search. Let v be a MAX-ancestor of u and w a MIN-ancestor of u such that w is the parent of v or vice versa. Upon the evaluation of u, by Proposition 2, $A(v, u) = c(v) = \alpha'(v) < \beta'(v) = c(w) = B(w, u)$ if w is the parent of v, or $A(v, u) = c(v) = \alpha'(w) < \beta'(w) = c(w) = B(w, u)$ if v is the parent of w. In ether case, we have $A(v, u) < B(w, u)$. □

As a corollary, we conclude that α-β search performs no worse than shallow α-β search on any instance. This fact, though taken for granted in the literature, is not obvious because

the return values computed by shallow α-β search may be different than those computed by α-β search.

COROLLARY 1. *For any game tree T, we evaluate T by α-β search and again by shallow α-β search. If a leaf u is evaluated by α-β search, then u is also evaluated by shallow α-β search.*

Proof. The proof follows immediately from Proposition 3, Theorem 1, and the fact that $A(v, u) \leq A(u)$ and $B(v, u) \geq B(u)$. □

COROLLARY 2. *For any game tree T, let $R(T)$ and $R'(T)$ be the expected number of leaves evaluated by randomized α-β search and randomized shallow α-β search, respectively. Then $R(T) \leq R'(T)$.*

Proof. The proof follows immediately from Corollary 1 and the fact that the execution of randomized (shallow) α-β search is equivalent to the execution of deterministic (shallow) α-β search on the randomly permuted input tree. □

4. Randomized shallow α-β search. In this section we analyze the complexity of randomized shallow α-β search for evaluating uniform game trees. We show that the expected number of leaves evaluated by randomized shallow α-β search on any instance of uniform game tree of degree d and height h is $\Theta((B_d)^h)$, where $B_d = d/2 + \ln d + O(1)$.

We first state two probability facts about random permutations. In a permutation $(a_1, a_2, \ldots, a_n)$ of $\{1, 2, \ldots, n\}$, a_i is a *left-to-right maximum* if $a_i > a_j$ for all $j < i$. In other words, a_i is a left-to-right maximum if and only if position i contains the maximum among the values assigned to position $1, 2, \ldots, i$. For example, in permutation $(a_1, a_2, a_3, a_4, a_5) = (2, 1, 4, 5, 3)$, the left-to-right maxima are $a_1 = 2$, $a_3 = 4$ and $a_4 = 5$.

LEMMA 1. *The expected number of left-to-right maxima in a random permutation of $\{1, 2, \ldots, n\}$ is the nth harmonic number $H_n = 1 + \frac{1}{2} + \cdots + \frac{1}{n}$.*

Proof. The probability that position i of a random permutation contains the maximum among the values assigned to positions $1, 2, \ldots, i$ is $1/i$, as the maximum of these values is equally likely to be at any position of $1, 2, \ldots, i$. Hence, the expected number of left-to-right maxima is $H_n = \sum_{k=1}^{n} 1/k$. □

LEMMA 2. *In a random permutation of $n - 1$ white balls and one black ball, let W be the number of white balls proceeding the black ball in the permutation. Then $\Pr[W = k] = 1/n$ for $0 \leq k \leq n - 1$ and $E[W] = (n - 1)/2$.*

Proof. The black ball is equally likely to be at any position in a random permutation. The lemma follows. □

A critical notion in our analysis is that of "pruning information." By Proposition 2, $\alpha'(v) = c(v) \leq \text{val}(v)$ for a MAX-node v and $\beta'(v) = c(v) \geq \text{val}(v)$ for a MIN-node v, where $\alpha'(v)$ and $\beta'(v)$ are computed before evaluation of v. To meet the pruning condition $\alpha'(v) \geq \beta'(v)$, it must be the case that $\beta'(v) \leq \text{val}(v)$ for a MAX-node v and $\alpha'(v) \geq \text{val}(v)$ for a MIN-node v. We say v is *evaluated with pruning information* if, at the beginning of evaluation of v, $\beta'(v) \leq \text{val}(v)$ for a MAX-node v and $\alpha'(v) \geq \text{val}(v)$ for a MIN-node v; otherwise, v is *evaluated with no pruning information.* By Proposition 2, pruning may occur at v only if v is evaluated with pruning information. The root is evaluated with no pruning information. Clearly, pruning information may only help reduce the number of leaves evaluated. The following proposition characterizes the notion of pruning information.

PROPOSITION 4. *A nonleaf node v is evaluated with pruning information if and only if some sibling u of v has been evaluated such that $\text{val}(u) \leq \text{val}(v)$ if v is a MAX-node, or $\text{val}(u) \geq \text{val}(v)$ if v is a MIN-node.*

Proof. Suppose that a nonleaf v is evaluated with pruning information. Let w be the parent of v. Assume that v is a MAX-node. Then $c(w) = \beta'(v) \leq \text{val}(v)$. By Proposition 2,

$c(w) = \min\{\text{val}(u) | u \text{ is an evaluated sibling of } v\}$. Some sibling u of v with $\text{val}(u) \leq \text{val}(v)$ must have been evaluated. □

Let f_n (respectively, g_n) denote the maximum of expected number of leaves evaluated by randomized shallow α-β search on subtree H of height n over all subtrees H of height n in $T(d, h)$ under the condition that the the root of H is evaluated with no pruning information (respectively, with pruning information). By definition, $R'(T(d, h)) = f_h$ and $f_n \geq g_n$ for $0 \leq n \leq h$ with $f_0 = g_0 = 1$. We prove the following recurrence relation.

PROPOSITION 5. *For any n,* $1 \leq n \leq h$,

$$f_n \leq H_d f_{n-1} + (d - H_d) g_{n-1}, \tag{3}$$

$$g_n \leq (H'_d + 1) f_{n-1} + \left(\frac{d-1}{2} - H'_d\right) g_{n-1}, \tag{4}$$

where $H_d = 1 + \frac{1}{2} + \cdots \frac{1}{d}$ *and* $H'_d = \frac{1}{d}(H_1 + H_2 + \cdots + H_{d-1})$.

Proof. Let v be the root of a subtree of height n in $T(d, h)$. We may assume that v is a MAX-node. Let $u_1, u_2, \ldots, u_d$ be all d children of v arranged in the order such that $\text{val}(u_1) \leq \text{val}(u_2) \leq \cdots \leq \text{val}(u_d) = \text{val}(v)$. Suppose that v is evaluated with no pruning information. Then all children of v are evaluated. By Proposition 4, the child u_i, which is a MIN-node, is evaluated with no pruning information only if no sibling u of u_i with $\text{val}(u) \geq \text{val}(u_i)$ has already been evaluated, i.e., none of $u_{i+1}, u_{i+1}, \ldots, u_d$ and no u_j such that $j < i$ and $\text{val}(u_j) = \text{val}(u_i)$ has been evaluated. Hence, if u_i is evaluated with no pruning information, then u_i corresponds to a left-to-right maximum in a random permutation of $\{1, 2, \ldots, d\}$. Let R be the expected number of children of v evaluated with no pruning information. By Lemma 1, $R \leq H_d$. The expected number of children of v evaluated with pruning information is thus $d - R$. We have the following recurrence relation, noting $R \leq H_d$, $f_n \geq g_n$ and $(H_d - R)g_n \leq (H_d - R)f_n$:

$$\begin{aligned} f_n &\leq R f_{n-1} + (d - R) g_{n-1} \\ &= H_d f_{n-1} + (d - H_d) g_{n-1} - (H_d - R) f_{n-1} + (H_d - R) g_{n-1} \\ &\leq H_d f_{n-1} + (d - H_d) g_{n-1}, \end{aligned}$$

which is (3).

To analyze g_n, suppose that the MAX-node v is evaluated with pruning information. Then $\beta'(v) \leq \text{val}(v)$. Let $B = \{u_i \mid \text{val}(u_i) \geq \beta'(v)\}$, where u_i is a child of v, which is a nonempty set as $u_d \in B$ with $\text{val}(u_d) = \text{val}(v) \geq \beta'(v)$. By Proposition 2, $\alpha'(v) = c(v) = \max\{\text{val}(u) \mid u \text{ is an evaluated child of } v\}$. The pruning condition $\alpha'(v) \geq \beta'(v)$ holds if and only if some child of v in B is evaluated. Exactly one node in B is evaluated as the last evaluated child of v. Let W be the number of evaluated children of v before a child of v in B is evaluated. Viewing children of v in B as black balls and the other children of v as white balls in Lemma 2, we have $\Pr[W = k] \leq 1/d$ for $0 \leq k \leq d - 1$ and $E[W] \leq (d - 1)/2$.

The only evaluated child u in B, which is a MIN-node, is evaluated with no pruning information as, prior to the evaluation of u, $\alpha'(u) = c(v) = \max\{\text{val}(u_i) \mid u_i \text{ is an evaluated child of } v \text{ not in } B\} < \beta'(v) \leq \text{val}(u)$. Among the W evaluated children of v not in B, let R' be the expected number of nodes evaluated with no pruning information. Like we have argued previously, each of these evaluated nodes corresponds to a left-to-right maximum in a random permutation of $\{1, 2, \ldots, W\}$. By Lemma 1, $R' \leq H_k$ if $W = k$, and by conditioning on W,

$$R' \leq \sum_{k=1}^{d-1} H_k \Pr[W = k] \leq \frac{1}{d} \sum_{k=1}^{d-1} H_k = H'_d.$$

The expected number of children of v evaluated with pruning information is thus $E[W] - R'$. We have the following recurrence relation, noting $E[W] \leq (d-1)/2$, $R' \leq H'_d$, $f_n \geq g_n$,

$$\begin{aligned} g_n &\leq (R'+1)f_{n-1} + (E[W] - R')g_{n-1} \\ &= (H'_d + 1)f_{n-1} + (E[W] - H'_d)g_{n-1} - (H'_d - R')f_{n-1} + (H'_d - R')g_{n-1} \\ &\leq (H'_d + 1)f_{n-1} + \left(\frac{d-1}{2} - H'_d\right) g_{n-1}, \end{aligned}$$

which is (4). □

THEOREM 2. *Let $T(d,h)$ be any instance of a uniform game tree of degree $d \geq 2$ and height $h \geq 2$. Let $R'(T(d,h))$ be the expected number of leaves evaluated by randomized shallow α-β search for evaluating $T(d,h)$. Then*

$$R'(T(d,h)) = O((B_d)^h),$$

where, as a function of d,

$$B_d = \frac{d}{2} + \ln d + O(1).$$

Proof. Define $\lambda = H_d = \sum_{k=1}^{d} \frac{1}{k}$, $\mu = d - \lambda$, $\nu = 1 + H'_d = 1 + \frac{1}{d}\sum_{k=1}^{d-1} H_k$, and $\xi = \frac{d+1}{2} - \nu$. We rewrite the recurrence relations (3) and (4) in Proposition 5 as

$$\begin{aligned} f_n &\leq \lambda f_{n-1} + \mu g_{n-1}, \\ g_n &\leq \nu f_{n-1} + \xi g_{n-1}. \end{aligned}$$

Define $F_0 = 1 = f_0$, $G_0 = 1 = g_0$, and for $1 \leq n \leq h$,

$$F_n = \lambda F_{n-1} + \mu G_{n-1}, \tag{5}$$

$$G_n = \nu F_{n-1} + \xi G_{n-1}. \tag{6}$$

By a straightforward induction on n, we have for $0 \leq n \leq h$,

$$f_n \leq F_n. \tag{7}$$

By substituting (6) into (5), and noting $\mu G_{n-2} = F_{n-1} - \lambda F_{n-2}$ by (5), we obtain that for $1 \leq n \leq h$,

$$F_n = (\lambda + \xi)F_{n-1} + (\mu\nu - \lambda\xi)F_{n-2}. \tag{8}$$

The solution to recurrence relation (8) (cf. [3, §7.3]) is

$$F_n = \Theta((B_d)^n), \tag{9}$$

where B_d is the maximum of the two roots of the characteristic equation $x^2 = (\lambda + \xi)x + (\mu\nu - \lambda\xi)$ of recurrence relation (8).

To compute B_d, we calculate the following asymptotics. The harmonic number $H_d = \sum_{k=1}^{d} \frac{1}{k} = \ln d + \gamma + O(d^{-1})$, where $\gamma = .5772\ldots$, is the Euler's constant. Since $d! \sim (d/e)^d/\sqrt{2\pi d}$ and $\ln d! = d \ln d + O(1)$,

$$H'_d = \frac{1}{d}\sum_{k=1}^{d-1} H_k = \frac{1}{d}\sum_{k=1}^{d-1} \ln k + O(1) = \frac{1}{d}\ln d! + O(1) = \ln d + O(1).$$

Hence,

$$\begin{aligned}
\lambda &= H_d = \ln d + O(1),\\
\mu &= d - \lambda = d - \ln d + O(1),\\
\nu &= H'_d + 1 = \ln d + O(1),\\
\xi &= \frac{d+1}{2} - \nu = \frac{d}{2} - \ln d + O(1),\\
\lambda + \xi &= \frac{d}{2} + O(1),\\
\mu\nu - \lambda\xi &= \frac{d \ln d}{2} + O(d),\\
(\lambda + \xi)^2 + 4(\mu\nu - \lambda\xi) &= \left(\frac{d}{2}\right)^2 + 2d \ln d + O(d),\\
\sqrt{(\lambda + \xi)^2 + 4(\mu\nu - \lambda\xi)} &= \frac{d}{2} + 2 \ln d + O(1),
\end{aligned}$$

and finally

$$B_d = \frac{\lambda + \xi + \sqrt{(\lambda + \xi)^2 + 4(\mu\nu - \lambda\xi)}}{2} = \frac{d}{2} + \ln d + O(1).^3 \tag{10}$$

The theorem follows from the fact that $R'(T(d, h)) = f_h$, (7), (9), and (10). □

We now state the main result of this paper.

THEOREM 3. *Let $R(T(d, h))$ be the expected number of leaves evaluated by randomized α-β search for evaluating a uniform tree $T(d, h)$ of degree d and height h. Then for any $T(d, h)$,*

$$R(T(d, h)) = O((B_d)^h)$$

such that

$$\frac{B_d}{B_d^*} = 1 + O\left(\frac{\ln d}{d}\right),$$

where $B_d^* = \left(d - 1 + \sqrt{d^2 + 14d + 1}\right)/4 = d/2 + O(1)$ is the optimal branching factor of randomized algorithms for evaluating uniform game trees of degree d.

Proof. The proof is immediate from Theorem 2 and Corollary 2. □

We remark that by Theorem 3, randomized α-β search could be worse than an optimal randomized algorithm by a factor of $d^{O(h/d)}$ for evaluating uniform game trees of degree d and height h with a total of d^h leaves, as $B_d/B_d^* = 1 + O(\ln d/d) \sim e^{O(\ln d/d)} = d^{O(1/d)}$.

Finally, we show that the upper bound given in Theorem 2 on randomized shallow α-β search is tight. This is done by constructing an instance on which the upper bound is met. This amounts to a construction of an instance that makes the inequalities associated with f_n and g_n into equalities in the proof of Proposition 5. Let $T^*(d, h)$ be an instance of uniform game tree of degree d and height h formed by the following top-down construction. Suppose that we construct the subtree rooted at v of value val(v) that has d children $u_1, u_2, \ldots, u_d$ in the left-to-right order. We set the values of $u_1, u_2, \ldots, u_d$ by the following rules.

[3] A more precise expression is $B_d = \frac{d}{2} + \ln d + \frac{1}{2} + \gamma + O(d^{-1})$ where γ is the Euler's constant.

(i) v is a MAX-node. If v is the root or the first child of its parent, set $\text{val}(u_1) = \text{val}(v) > \text{val}(u_2) > \cdots > \text{val}(u_d)$; otherwise, let w be the parent of v and set $\text{val}(u_1) = \text{val}(v) > \text{val}(w) > \text{val}(u_2) > \cdots > \text{val}(u_d)$, where $\text{val}(v) > \text{val}(w)$ is guaranteed by the top-down construction.

(ii) v is a MIN-node. If v is the first child of its parent, set $\text{val}(u_1) = \text{val}(v) < \text{val}(u_2) < \cdots < \text{val}(u_d)$; otherwise, let w be the parent of v and set $\text{val}(u_1) = \text{val}(v) < \text{val}(w) < \text{val}(u_2) < \cdots < \text{val}(u_d)$ where $\text{val}(v) < \text{val}(w)$ is guaranteed by the top-down construction.

THEOREM 4. *Let $R'(T^*(d, h))$ be the expected number of leaves evaluated by randomized shallow α-β search for evaluating $T^*(d, h)$. Then $R'(T^*(d, h)) = \Theta((B_d)^h)$.*

Proof. The construction of $T^*(d, h)$ gives precisely the tree structure required to make the inequalities associated with f_n and g_n in the proof of Proposition 5 into equalities. The recurrence relations of (3) and (4) can be stated with equalities, and consequently $F_n = f_n$ in Theorem 2. Thus $R'(T^*(d, h)) = f_n = F_n = \Theta((B_d)^h)$ by Theorem 2. □

5. Conclusion. We have shown that the branching factor of randomized α-β search is asymptotically optimal for evaluating uniform game trees as the degree of tree increases. This conclusion is reached through an indirect analysis by showing that the branching factor of randomized shallow α-β search, a weaker version of randomized α-β search using only shallow cutoffs, is asymptotically optimal as the degree of tree increases. It remains a challenging problem to determine the branching factor of randomized α-β search for evaluating uniform trees of a fixed degree.

Acknowledgments. The author is grateful to a referee for suggesting improvements to the proofs, and also thanks Miklos Santha and Stephane Boucheron for their comments.

GREEDY PACKET SCHEDULING*

ISRAEL CIDON†, SHAY KUTTEN‡, YISHAY MANSOUR§, AND DAVID PELEG¶

Abstract. Scheduling packets to be forwarded over a link is an important subtask of the routing process in both parallel computing and in communication networks. This paper investigates the simple class of *greedy* scheduling algorithms, namely, algorithms that always forward a packet if they can. It is first proved that for various "natural" classes of routes, the time required to complete the transmission of a set of packets is bounded by the number of packets, k, and the maximal route length, d, for any greedy algorithm (including the arbitrary scheduling policy). Next, tight time bounds of $d + k - 1$ are proved for a specific greedy algorithm on the class of shortest paths in n-vertex networks. Finally, it is shown that when the routes are arbitrary, the time achieved by various "natural" greedy algorithms can be as bad as $\Omega(d\sqrt{k} + k)$, for any k, and even for $d = \Omega(n)$.

1. Introduction.

The task of managing the delivery of packets in a distributed communication network is intricate and complex. Consequently, many routing strategies incorporate design choices directed at simplifying the process. One prime example for this type of choice is the decision to create a clear distinction between two subtasks, namely, *route selection* and *packet scheduling*. The first subtask involves selecting for each packet the route it should use from its source to its destination. This selection is done in advance, before the packet actually leaves its source. The second subtask concerns the transmission stage itself, and involves deciding on the schedule by which the different packets are to be forwarded over each edge along their routes. At this stage, the packets are restricted to their predetermined routes, and cannot deviate from them. This paper concentrates on routing strategies adopting this separation, henceforth referred to as *fixed-route strategies*, and in particular on the scheduling subtask.

A second type of design choice, aimed at simplifying the scheduling process considerably, is to make scheduling decisions *locally* and per packet, rather than globally. The scheduling policy is thus restricted to the selection of local rules for managing the queues on outgoing links, namely, resolving the conflicts between the different packets that need to be advanced on the same outgoing edge. Intuitively, a *local* algorithm has the property that the rules used by a vertex in order to schedule awaiting packets rely only on information concerning these packets (typically contained in the packets' headers), such as the identity of the source and destination, the distance traversed by the packet so far, the arrival time at the current vertex, etc. In contrast, a global algorithm can base its decisions on additional global information on the status of the network, such as the current distribution of packets in the network and the routes of these packets.

Although the two design decisions discussed above may not generally lead to a globally optimal algorithm, they are both widely used. In fact, one of the main distributed network

strategies for packet routing is *virtual circuit* [CGKK], [Mar82], [BG87], which is based on fixing a predetermined *logical circuit* from the given end user to the given destination, and transmitting *all* packets between them on this circuit. Nonetheless, similar considerations apply also for the second common routing strategy, known as *datagram routing* [MRR80].

Fixed-route strategies are employed in communication networks such as Systems Network Architecture [Mar82], Advanced Peer to Peer Network [BGGJP85], and TYMNET [BG87]. In fact all the emerging integrated high-speed networks proposals such as the international Broadband ISDN (ATM) [CCITT90] and the IBM plaNET Gigabit network [CGGG92], are based on fixed routing strategies. As for the scheduling policy, most networks use a combination of first in, first out (FIFO), certain priority parameters, and flow control information, to determine the next packet to be forwarded. All of these mechanisms are "approximately" local (although flow control adds some global flavor). The main reasons for these choices are based on their advantages from an engineering point of view, namely, their simplicity and low complexity (compared to the global approach), which make them suitable for hardware implementation.

Packet scheduling algorithms for fixed-route strategies were studied by Leighton, Maggs, and Rao [LMR88]. Although motivated by routing problems in specific networks realizing parallel machines, their paper studies the problem on networks of arbitrary topology. The first result of [LMR88] is a proof that there exists a schedule that terminates in $O(d + c)$ time, where d is the maximal route length and c is the maximal congestion, i.e., the maximal number of packets that traverse any edge. However, it seems that determining this schedule requires a complex *centralized* computation, relying on global information. The paper provides also some *randomized* distributed protocols for the problem. These protocols are simple, online, and local (in the sense discussed above). The first applies to arbitrary sets of paths and requires $O(c+d \log |V|)$ time. The second protocol applies to the case when the paths are *leveled* with l levels. Informally, a set of paths is *leveled* if the vertices of the network can be partitioned into l levels in such a way that each edge of the paths connects two consecutive levels. The protocol completes the routing in $O(c+l+\log |V|)$ time. Both protocols of [LMR88] assume all packets start at the same time.

In contrast with both types of algorithms considered in [LMR88], in this paper we consider the complexity of *deterministic distributed* algorithms. In fact, we concentrate on a class of very simple on-line scheduling algorithms, termed *greedy* algorithms. A *greedy algorithm* is an algorithm satisfying the property that at each time unit, the set of packets that are forwarded is maximal, i.e., if there are messages waiting to be forwarded on some link then one of these messages is forwarded. Note that this also includes an algorithm that selects the message to be forwarded next on each link arbitrarily from among the waiting messages (or alternatively, allows an adversary to decide which packet will be sent next). The class of greedy policies is very natural [Ko78], and in fact, all packet scheduling policies used in practical packet switching networks of which we are aware fall in this class. It is interesting to note that the efficient algorithm of [LMR88] is not greedy.

In the upcoming sections we present several results concerning the behavior of greedy scheduling algorithms. We first look at some restricted path classes. To begin with, in §3 we show that for a *leveled* set of paths $\mathcal{P}$, the time required for delivering packet p_i by any greedy algorithm is bounded by $d_i + k - 1$, where d_i is the length of the route of packet p_i and k is the total number of packets. Note that in practical networks k might be much larger than c, hence the randomized algorithm of [LMR88] may perform better.

Our result for the leveled case implies the same result for the natural case of *unique subpaths*. A route collection $\mathcal{P}$ obeys the *unique subpaths* property if for every pair of vertices u and v, all the *subpaths* connecting them in any path of $\mathcal{P}$ are identical.

In §4 we consider the class of *shortest paths*. For this class, we present a strategy that guarantees a bound of $d_i + k - 1$ assuming all packets start at the same time. This strategy is based on advancing the packet that has progressed the least so far. A different strategy, based on fixed priorities, was independently proposed in [RVN90], and shown to yield the same bound. In an earlier version of this paper [CKMP90] we conjectured that the same bound is true for any greedy algorithm. This conjecture has recently been resolved in the affirmative [MP91].

We then turn to general route classes. In contrast with the special cases discussed above, we show in §5 that greedy algorithms might behave badly for an *arbitrary* set of paths. This is true even when we consider natural greedy schedulers, like fixed priority, FIFO, or preferring the packet that traversed the minimum (or maximum) distance so far. We show that in such a case the time may be $\Omega(d\sqrt{k} + k)$. These negative results hold even for the case where both $k = \Theta(|V|)$ and $d = \Theta(|V|)$. This strengthens the counter-examples given in [LMR88] for the case of long routes and a large number of packets.

2. Model. We view the communication network as a directed graph, $G = (V, E)$, where an edge (u, v) represents a bidirectional link connecting the processors u and v. We assume synchronous communication, i.e., the system maintains a global clock, characterized by the property that a packet sent at time t is received by time $t + 1$.

Next let us define formally the routing problem and its relevant parameters. The input to the problem is a collection $\mathcal{P}$ of k packets p_i and k associated routes ρ_i, $1 \leq i \leq k$. Packet p_i, marked by an identifier I_i, is originated at vertex A_i, its destination is B_i, and it is transmitted along the route ρ_i. We deal with vertex-simple (or loop-free) routes. The length of the route ρ_i is d_i, and we denote $d(\mathcal{P}) = \max_i\{d_i\}$.

Two packets are said to *collide* at time t if they are currently waiting at the same vertex to be sent over the same link. The scheduling algorithm has to decide at each time t which packet to forward at time t. (Note that the paths are fixed, and hence the algorithm has no choice with respect to the edges that a packet traverses.) Let τ_i^A denote the time at which packet p_i was sent from its originator A_i, and let τ_i^B denote the arrival time of p_i at its destination B_i. Let T_i denote the time elapsing from τ_i^A until τ_i^B, i.e., $T_i = \tau_i^B - \tau_i^A$. The *schedule time* of $\mathcal{P}$ is $T(\mathcal{P}) = \max_i\{T_i\}$.

Some of our results apply only to special path types. Below we characterize these route classes.

A set of paths $\mathcal{P}$ is leveled if there exists an assignment $level : V \to [1, \ldots, |V|]$, such that for each path $\rho = (v_1 \ldots v_l)$, $\text{level}(v_j) = \text{level}(v_{j-1}) + 1$. A directed graph is leveled if there exists an assignment $level$, such that for every directed edge (u, v), $\text{level}(u) + 1 = \text{level}(v)$. In a leveled directed graph, every set $\mathcal{P}$ of routes is leveled.

The path ρ_i is a *shortest path* if its length equals the distance between its endpoints A_i and B_i. A set of paths $\mathcal{P}$ is *shortest* if every path $\rho_i \in \mathcal{P}$ is a shortest path.

A set of paths $\mathcal{P}$ has the *unique subpaths* property if for every pair of vertices u and v, all the *subpaths* connecting them in any path of $\mathcal{P}$ are identical; that is, if both the routes ρ_i and ρ_j go through u and v, then the segments of the paths connecting u and v are identical.

3. Leveled routing. In this section we prove our first result, concerning greedy scheduling on leveled paths.

THEOREM 3.1. *Let $\mathcal{P}$ be a set of k leveled paths. Then for any greedy algorithm used for routing $\mathcal{P}$,*

1. *every packet p_i arrives within $T_i \leq d_i + k - 1$ time units, and*
2. *the algorithm has schedule time $T(\mathcal{P}) \leq d(\mathcal{P}) + k - 1$.*

Proof. For each packet p_i and $t \geq 0$, let $\text{level}(p_i, t)$ denote the number of the level where p_i resides at time t. A level L is said to be *occupied* at time t if there exists a packet p_i such

that level$(p_i, t) = L$. The proof is based on considering, for any $t \geq 0$, the set $\mathcal{L}(t)$ of levels that are occupied at time t. We shall argue that at every time unit there is some progress, in the sense that either the number of occupied levels grows, or the lowest occupied level (the one whose number is the smallest) becomes unoccupied.

For uniformity of presentation, we adopt the convention that at any time $t > \tau_i^B$ (the time p_i reaches its destination), level(p_i, t) is incremented by one. This can be thought of as if the packet continues progressing indefinitely along some path ρ_i' extended from the destination B_i and dedicated to it, and hence never collides afterwards. This does not restrict generality in any way, since such an extension ρ_i' of the packet's route has no influence on the routes of other packets, and the arrival time of the packet is still considered to be τ_i^B, the time it has reached its original destination B_i.

Consider the collection $\mathcal{L}(t)$ of occupied levels at time t. We break this collection into "blocks" of consecutive levels (separated by unoccupied levels). We define the following parameters for each packet p_i:

- $B(p_i, t)$ is the *block* of p_i at time t (i.e., the block containing level(p_i, t)).

Suppose that $B(p_i, t) = \{L, L+1, \ldots, H\}$. Then

- $\min(p_i, t) = L$.
- $\max(p_i, t) = H$.
- $\text{width}(p_i, t) = |B(p_i, t)| - 1 = \max(p_i, t) - \min(p_i, t)$ $(= H - L)$.

Note that the number of occupied levels at any given time t is bounded by the number of packets, $|\mathcal{L}(t)| \leq k$, and therefore the maximum block size satisfies

$$\text{width}(p_i, t) \leq k - 1. \tag{1}$$

CLAIM 3.2. $\max(p_i, t+1) - \max(p_i, t) \geq 1$ *for every* $t \geq 0$.

Proof. Since the algorithm is greedy, we are guaranteed that if the levels $L, L+1, \ldots, H$ are occupied at time t, then the levels $L+1, \ldots, H+1$ are occupied at time $t+1$. Also, $L \leq \text{level}(p_i, t) \leq H$ implies $L \leq \text{level}(p_i, t+1) \leq H+1$, and therefore $L+1, \ldots, H+1 \in B(p_i, t+1)$. This implies that $\max(p_i + 1, t) \geq H + 1$. □

COROLLARY 3.3. $T_i \leq \max(p_i, \tau_i^B) - \max(p_i, \tau_i^A)$. This corollary is complemented by the following claim which bounds the increase in $\max(p_i, t)$ from above.

CLAIM 3.4. $\max(p_i, \tau_i^B) - \max(p_i, \tau_i^A) \leq d_i + k - 1$.

Proof. Consider a packet p_i whose origin A_i is at level $L_A = \text{level}(p_i, \tau_i^A)$ and whose destination B_i is at level $L_B = \text{level}(p_i, \tau_i^B) = L_A + d_i$. Initially, $\max(p_i, \tau_i^A) \geq L_A$. On the other hand, upon arrival at the destination, $\max(p_i, \tau_i^B) = \min(p_i, \tau_i^B) + \text{width}(p_i, \tau_i^B) \leq L_B + \text{width}(p_i, \tau_i^B)$. Hence by (1) we have that $\max(p_i, \tau_i^B) - \max(p_i, \tau_i^A) \leq L_B + k - 1 - L_A = d_i + k - 1$. □

Combining Corollary 3.3 and Claim 3.4, we get $T_i \leq d_i + k - 1$. This completes the proof of part 1 of Theorem 3.1. Part 2 follows immediately from part 1. □

The natural class of paths with the unique subpaths property can be analyzed using the above theorem.

COROLLARY 3.5. *Let $\mathcal{P}$ be a set of k paths satisfying the unique subpaths property. Then for any greedy algorithm used for routing $\mathcal{P}$,*

1. *every packet p_i arrives within $T_i \leq d_i + k - 1$ time units, and*
2. *the algorithm has schedule time $T(\mathcal{P}) \leq d(\mathcal{P}) + k - 1$.*

Proof. We prove that the delay suffered by any packet p_i is no greater than in an execution on a leveled graph (with the same k and d_i). Consider subgraph G_i induced by the route of a particular packet p_i, and consider the subpaths of this single route which are traversed by other packets. Clearly, because of the unique subpath property each subpath is a consecutive segment of the original route, therefore, G_i is leveled. Consider an execution of of the schedule in the original graph $(\mathcal{P})$ and observe the subgraph G_i. Let τ_j^A in G_i be the time at which packet

p_j arrived to G_i (or p_i's route) in the above execution. Note that the schedules of p_i in G_i and in $\mathcal{P}$ are identical. Thus, by part 1 of Theorem 3.1 the delay suffered by p_i in the unique subpaths case is the same as the one in the leveled paths case we have constructed. □

4. Shortest path routing. In this section we consider a scheduling algorithm for the case in which each route ρ_i in the set $\mathcal{P}$ uses a shortest path from its origin to its destination. We shall assume that all packets start at the same time, i.e., $\tau_i^A = 0$ for $1 \leq i \leq k$. For every time $0 \leq t \leq T_i$, let $d_i(t)$ denote the distance traversed by p_i by time t (note that in particular, $d_i(T_i) = d_i$). If p_i and p_j "collide" at time t, the algorithm resolves the collision based on the distance traversed by the packets so far, breaking ties by packet identifiers. Thus the algorithm will prefer p_i iff

$$d_i(t) < d_j(t) \text{ or } (d_i(t) = d_j(t) \text{ and } I_i < I_j).$$

We refer to this algorithm as the *Min Went* algorithm. The rest of this section is devoted to proving the following theorem.

THEOREM 4.1. *If the set of paths $\mathcal{P}$ consists of shortest paths and $\tau_i^A = 0$ for $1 \leq i \leq k$ (i.e., all the packets start at the same time) then the Min Went scheduling algorithm guarantees*

1. *every packet p_i arrives at time $T_i \leq d_i + k - 1$.*
2. *the schedule time is $T(\mathcal{P}) \leq d(\mathcal{P}) + k - 1$.*

We begin the proof by pointing out the following trivial fact regarding the relationship between packets in consecutive collisions.

FACT 4.2. *If p_i and p_j collide twice (at times t_1 and t_2), then the relation between $d_i(t)$ and $d_j(t)$ is the same at both times.*

DEFINITION 4.3. *Given an execution of the algorithm the* collision relation *C is defined as the collection of all triples $\langle p_i, p_j, t\rangle$ such that at time t packets p_i and p_j collide (i.e., they are at the same vertex, waiting for the same edge), and p_i wins the collision resolution and gets to use the edge (at time t).*

Since only one packet can go on a specific edge at a time t we can deduce the following fact.

FACT 4.4. *For every p, t there is at most one triple $\langle p', p, t\rangle$ in C.*

Consider some packet p; without loss of generality we term it p_0. If this packet is never delayed, then $T_0 = d_0$ and we are done. Hence suppose the packet was delayed along its route. We now define a *delay sequence* for p_0. Let t_0 be the last time that packet p_0 was delayed. (Note that such a time exists since the delays are finite; a bound of $T(\mathcal{P}) \leq k \cdot d(\mathcal{P})$ on the scheduling time of any greedy algorithm is trivial.) Namely, there is a triple $\langle p_1, p_0, t_0\rangle$ in C, and there is no such triple for p_0 in later times $t > t_0$. (Recall that by Fact 4.4 there is only one such p_1.) Let t_1 be the last time p_1 was delayed before time t_0. Namely, there is a triple $\langle p_2, p_1, t_1\rangle$ and no such triple for p_1 in any time between t_1 and t_0. Continue the sequence in this way until reaching a packet p_ℓ that was not delayed prior to time $t_{\ell-1}$.

It is convenient to define also $t_{-1} = T_0$ (the arrival time of p_0) and $t_\ell = 0$ (the start time of p_ℓ).

We get a sequence $\mathcal{DS}$ of triples

$$\mathcal{DS} = \langle p_1, p_0, t_0\rangle, \langle p_2, p_1, t_1\rangle, \ldots, \langle p_\ell, p_{\ell-1}, t_{\ell-1}\rangle,$$

where $T_0 = t_{-1} > t_0 > t_1 > \cdots > t_{\ell-1} > t_\ell = \tau_\ell^A = 0$.

LEMMA 4.5. $T_0 \leq d_0 + \ell$.

Proof. By definition of the relation C and the Min Went scheduling, we have the inequalities

$$(X_j) \qquad d_{j+1}(t_j) \leq d_j(t_j) \qquad \text{for } j = 0, 1, \ldots, \ell - 1.$$

For $j = 0, \ldots, \ell$ let θ_j denote the segment of the route ρ_j traversed by p_j between the times t_j (when it "lost" in the collision resolution) and t_{j-1} (when it won), and let $\Delta_j = |\theta_j| = d_j(t_{j-1}) - d_j(t_j)$. Substitute this definition in the inequalities (X_j) to get

$$(Y_j) \qquad d_{j+1}(t_{j+1}) + \Delta_{j+1} \leq d_j(t_j) \qquad \text{for } j = 0, \ldots, \ell - 1.$$

We also have

$$(Y_{-1}) \qquad d_0(t_0) + \Delta_0 = d_0(t_{-1}) = d_0.$$

Summing the inequalities (Y_j) for $j = -1, 0, \ldots, \ell - 1$, and recalling that $d_\ell(t_\ell) = 0$, we get

$$(2) \qquad \Delta_0 + \Delta_1 + \cdots + \Delta_{\ell-1} + \Delta_\ell \leq d_0$$

We also construct a chain of equalities for the times involved in these collisions. Since packet p_j (for $0 \leq j \leq \ell - 1$) was delayed at time t_j but never delayed since that time until time t_{j-1}, we have

$$(Z_j) \qquad t_{j-1} = t_j + 1 + \Delta_j \qquad \text{for } j = 0, \ldots, \ell - 1.$$

We also have

$$(Z_\ell) \qquad t_{\ell-1} = d_\ell(t_{\ell-1}) = \Delta_\ell + t_\ell = \Delta_\ell$$

Combining the equalities (Z_j) for $j = 0, \ldots, \ell$ we get

$$(3) \qquad T_0 = t_{-1} = \Delta_0 + \Delta_1 + \cdots + \Delta_{\ell-1} + \Delta_\ell + \ell.$$

Combining equations (2) and (3), we get that $T_{i_0} \leq d_{i_0} + \ell$, and the lemma follows. □

In order to complete the proof of the theorem, it therefore remains to bound the length of the sequence $\mathcal{DS}$. This is done by proving the following claim.

LEMMA 4.6. *The packets p_j appearing in the triples of the sequence $\mathcal{DS}$ are all distinct.*

Proof. The proof is by a contradiction. Assume that some packet occurs twice in the sequence, for instance $p_m = p_r$ for $m > r$. (See Fig. 1.) By the structure of the sequence, every two consecutive packets are distinct, so necessarily $m \geq r + 2$. This means that the sequence contains a subcycle

$$\langle p_{r+1}, p_r, t_r\rangle, \ \langle p_{r+2}, p_{r+1}, t_{r+1}\rangle, \ldots, \langle p_{m-1}, p_{m-2}, t_{m-2}\rangle, \ \langle p_m, p_{m-1}, t_{m-1}\rangle = \langle p_r, p_{m-1}, t_{m-1}\rangle,$$

where $t_r > t_{r+1} > \cdots > t_{m-1}$, and $m \geq r + 2$.

We argue that among the inequalities (X_j), for $r \leq j \leq m - 1$, at least one of the inequalities is strict. Otherwise, all the collision resolutions in the cycle were made on the basis of packet identities, so $I_r = I_m < I_{m-1} < \cdots < I_{r+1} < I_r$, which is a contradiction. It follows that among the corresponding inequalities (Y_j), for $r \leq j \leq m - 2$, plus (X_{m-1}), at least one is strict. Combine these inequalities in a chain, to get

$$(4) \qquad d_m(t_{m-1}) + \Delta_{m-1} + \cdots + \Delta_{r+1} < d_r(t_r).$$

Finally, let $\bar{\theta}$ denote the segment of the route ρ_r traversed by p_r between the times t_{m-1} (when it won) and t_r (when it lost), and let $\bar{\Delta} = |\bar{\theta}| = d_r(t_r) - d_r(t_{m-1})$. We get that

$$\Delta_{m-1} + \cdots + \Delta_{r+1} < d_r(t_r) - d_r(t_{m-1}) = \bar{\Delta},$$

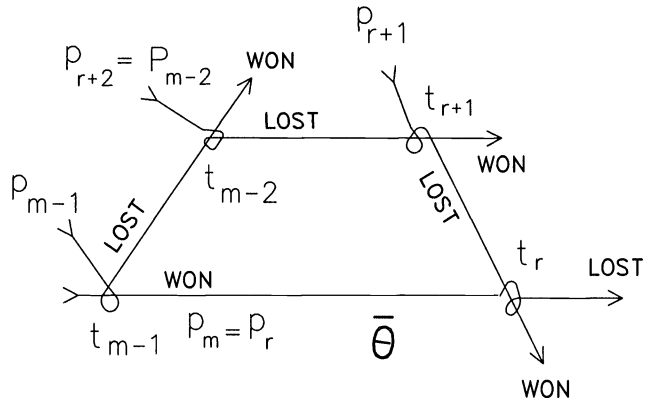

FIG. 1. *Cycle in delay sequence.*

or in other words, the segment $\bar{\theta}$ of ρ_r is not shortest; this is a contradiction to the assumption that all the paths in $\mathcal{P}$ are shortest paths. □

COROLLARY 4.7. *The sequence $\mathcal{DS}$ is of length $\ell \leq k - 1$.*

Combining this corollary with Lemma 4.5 completes the proof of part 1 of the theorem. Part 2 follows immediately.

5. Greedy algorithms in the general case. The purpose of this section is to demonstrate the fact that, unlike the case of leveled routes, for general route classes not every greedy algorithm delivers the messages fast. We start by constructing a directed graph and a set of paths, that will be used as building blocks for our main lower bound construction.

The construction is parameterized by two integers x and y. The constructed directed graph $G_{x,y}$ (see Fig. 2) is composed of a line of $2x + 1$ vertices, denoted by v_0, $v_{\langle 1,\mathtt{in}\rangle}$, $v_{\langle 1,\mathtt{out}\rangle}, \ldots, v_{\langle x,\mathtt{in}\rangle}, v_{\langle x,\mathtt{out}\rangle}$. In addition, each "in" vertex (i.e., $v_{\langle i,\mathtt{in}\rangle}$) is connected to its corresponding "out" vertex (i.e., $v_{\langle i,\mathtt{out}\rangle}$) also via a "detour" path of y vertices (denoted by L^i). Intuitively, the line is the "main" route; the L_i subgraphs are used to "side track" packets and delay them, thus causing them to collide repeatedly.

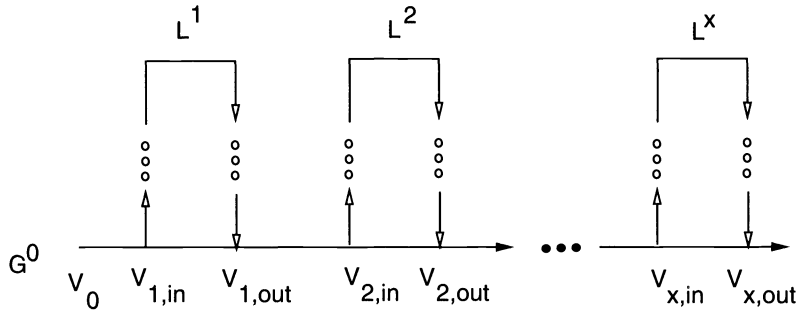

FIG. 2. *The graph $G_{x,y}$.*

A more formal construction follows. Define the graph $G_{x,y} = (V, E)$ to be the union of the subgraphs $G^0, L^1, \ldots, L^x, C$.

The vertices of the subgraph G^0 are

$$V(G^0) = \{1, \ldots, x\} \times \{\mathtt{in}, \mathtt{out}\} \cup \{v_0\},$$

and the edges are

$$E(G^0) = \{(v_{<i,\mathtt{out}>}, v_{<i+1,\mathtt{in}>}) \ : \ 1 \le i \le x-1\} \\ \cup \{(v_{<i,\mathtt{in}>}, v_{<i,\mathtt{out}>}) \ : \ 1 \le i \le x\} \\ \cup \{(v_0, v_{<1,\mathtt{in}>})\}.$$

The graph L is a straight line of y vertices and $y-1$ edges, i.e.,

$$V(L) = \{l_1, \ldots, l_y\} \quad \text{and} \quad E(L) = \{(l_i, l_{i+1}) \ : \ 1 \le i \le y-1\}.$$

For $1 \le i \le x$, the subgraph L^i is a copy of the graph L, with superscript i.

Finally, the edges in C connect the endpoints of each subgraph L^i to the corresponding vertices $v_{<i,\mathtt{in}>}$ and $v_{<i,\mathtt{out}>}$ on the path G^0:

$$C = \{(v_{<i,\mathtt{in}>}, l_1^i) \ : \ 1 \le i \le x\} \cup \{(l_y^i, v_{<i,\mathtt{out}>}) \ : \ 1 \le i \le x\}.$$

Let

$$G_{x,y} = G^0 \cup C \cup \bigcup_{1 \le i \le x} L^i.$$

The paths $\mathcal{P}_{x,y}$ are the following. All the paths start at vertex v_0, and proceed through $v_{<i,\mathtt{in}>}$ and $v_{<i,\mathtt{out}>}$, for $i = 1, \ldots, x$, ending at $v_{<x,\mathtt{out}>}$. There are two types of paths: a "long" path, pl, consisting of $x(y+2)$ edges, and a "short" one, ps, consisting of $2x$ edges. The "short" path ps travels directly through the graph G^0. The "long" path pl takes all the "detours" L^i, i.e., it travels from each "`in`" vertex $v_{<i,\mathtt{in}>}$ to the corresponding "`out`" vertex $v_{<i,\mathtt{out}>}$, via the path L_i. Formally, $ps = E(G^0)$, and

$$pl = \bigcup_{1 \le i \le x} E(L^i) \cup \{(v_{<i,\mathtt{out}>}, v_{<i+1,\mathtt{in}>}) \ : \ 1 \le i \le x-1\} \cup \{(v_0, v_{<1,\mathtt{in}>})\} \cup C.$$

Let us first illustrate the use of this construction by proving a weaker lower bound, and then proceed to our main lower bound. The scheduling policy that we use for the queue scheduling is a fixed priority. This lemma will later be used to prove our main lower bound.

LEMMA 5.1. *For any x and y, there exist a graph $G_{x,y}$ and a collection of $y+1$ paths $\mathcal{P}_{x,y}$, such that there is a packet that traverses a path of length $O(x)$ and requires $\Omega(xy)$ time under the fixed priority queueing policy.*

Proof. Given x and y, construct $G_{x,y}$ as above. The set $\mathcal{P}_{x,y}$ consists of $y+1$ paths, of which y are identical to the "long" path pl, and the remaining one is the "short" path ps. The last packet has the lowest priority. Note that whenever the low priority packet reaches an "`out`" vertex it is delayed y times, once by each other packet. It is also delayed y times in vertex v_0. Therefore, the total delay of this packet is $2x + xy$. □

The above lemma shows that for some packet the delay may be $\Omega(xy)$, even though the number of edges in its route is only $2x$. This lower bound can be strengthened in two respects. Note that in the above construction, some packets have routes of $\Omega(xy)$ edges, which is as high as the lower bound. Also, the number of vertices in the constructed graph is large (i.e., $\Omega(xy)$). In the setting of the next theorem, both the graph size and the route lengths are small relative to the derived lower bound.

THEOREM 5.2. *For every d and k there exist a graph $\mathcal{G}_{d,k}$ and a collection of k paths $\mathcal{P}$ whose schedule time under the fixed priority algorithm is $T(\mathcal{P}) = \Omega(d\sqrt{k})$, and $| V(\mathcal{G}_{d,k}) | = O(d)$.*

Proof. First we create a graph that achieves the delay bound, but has more vertices, and then we show how to reduce the number of vertices. Consider the graph $G_{x,y}$ defined in

Lemma 5.1, with the parameters $x = d/\sqrt{k}$ and $y = \sqrt{k}$. (We assume for simplicity that x and y are integral; if $x < 1$ then $k > d\sqrt{k}$, in which case the claim is trivial.) We take $\sqrt{k}$ copies of $G_{x,y}$, denoted by $G^i_{x,y}$, and connect the ith copy to the $(i+1)$st copy by identifying the last vertex of $G^i_{d,k}$ with the first vertex of $G^{i+1}_{d,k}$ (i.e., $v^i_{<x,\mathrm{out}>} \equiv v^{i+1}_0$).

We partition the packets into $\sqrt{k}$ groups of decreasing priorities; each group is of $\sqrt{k}$ packets. All packets go from $v^1_{<1,\mathrm{in}>}$ to $v^{\sqrt{k}}_{<\sqrt{k},\mathrm{out}>}$. The paths of all the packets within the same group are identical. The ith group traverses in G^j, $j \neq i$, the shortest path from the first vertex to the last vertex (i.e., ps). In G^i the packets traverse all the loops L^j (i.e., use pl). Note that all the paths are of the same length, which is $O(d)$.

Note that the packets in the ith group delay the packets in groups $j > i$ by $\Omega(d)$ time while traversing G^1 (and a similar thing happens as they traverse G^l for $l = 2, 3, \ldots, i-1$). This means that the last packet reaches its destination after $\Omega(d\sqrt{k})$ time.

The number of vertices in the construction so far is $O(d\sqrt{k})$. In order to reduce the number of vertices to $O(d)$ we modify the way in which we combine the $\sqrt{k}$ copies of $G_{x,y}$. For every i, we collapse the $\sqrt{k}$ subgraphs L^i in the graphs $G^1, \ldots, G^{\sqrt{k}}$ into a single copy, namely, L^i of G^1. See Fig. 3. □

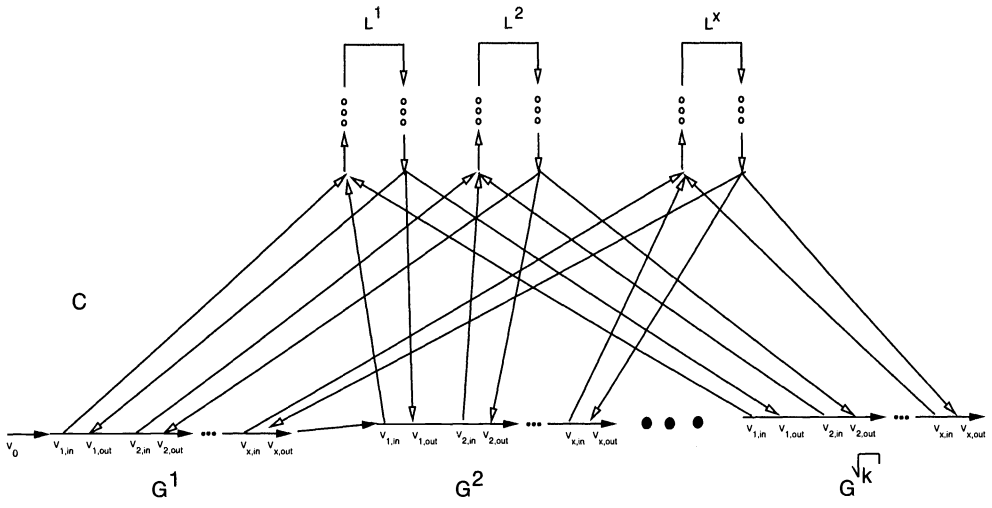

FIG. 3. *The graph* $\mathcal{G}_{d,k}$.

A similar, although somewhat more complicated proof can be constructed for other greedy algorithms, specifically the Min Went policy of §4, the analogous *Max Went* policy, or the *FIFO policy*, namely, the algorithm that resolves a collision between two packets in vertex v by sending the first to have arrived at v. Details can be found in [CKMP90].

Acknowledgment. We thank Amotz Bar-Noy for working with us in the early stages of this research. We are also grateful to the anonymous reviewers for their excellent comments and for simplifying some of the proofs, notably in §3.

OPTIMAL FILE SHARING IN DISTRIBUTED NETWORKS*

MONI NAOR† AND RON M. ROTH‡

Abstract. The following file distribution problem is considered: Given a network of processors represented by an undirected graph $G = (V, E)$ and a file size k, an arbitrary file $\mathbf{w}$ of k bits is to be distributed among all nodes of G. To this end, each node is assigned a memory device such that by accessing the memory of its own and of its adjacent nodes, the node can reconstruct the contents of $\mathbf{w}$. The objective is to minimize the total size of memory in the network. This paper presents a file distribution scheme which realizes this objective for $k \gg \log \Delta_G$, where Δ_G stands for the maximum degree in G: For this range of k, the total memory size required by the suggested scheme approaches an integer programming lower bound on that size. The scheme is also constructive in the sense that given G and k, the memory size at each node in G, as well as the mapping of any file $\mathbf{w}$ into the node memory devices, can be computed in time complexity which is polynomial in k and $|V|$. Furthermore, each node can reconstruct the contents of such a file $\mathbf{w}$ in $O(k^2)$ bit operations. Finally, it is shown that the requirement of k being much larger than $\log \Delta_G$ is necessary in order to have total memory size close to the integer programming lower bound.

1. Introduction.

Consider the following file distribution problem: A network of processors is represented by an undirected graph G. An arbitrary file $\mathbf{w}$ of a prescribed size k (measured, say, in bits) is to be distributed among all nodes of G. We are to assign memory devices to the nodes of G such that by accessing the memory of its own and of its adjacent nodes, each node can reconstruct the contents of $\mathbf{w}$. Given G and k, the objective is to find a *static* memory allocation to the nodes of G, independent of $\mathbf{w}$, as to minimize the total size of memory in the network. Although we do not restrict the file distribution or reconstruction algorithms to be of any particular form, we aim at simple and efficient ones.

The problem of file allocation in a network, i.e., of storing a file in a network so that every processor has "easy" access to the file, has been considered in many variants. (See [4] for a survey.) The specific version of reconstruction from adjacent nodes only has received attention in the form of *file segmentation*, where the task is to partition the file so that for each node u in the network, the union of the file segments stored at nodes adjacent to u is the complete file [4], [8], [13]. As we shall see, allowing more general reconstruction procedures than simply taking the union of file segments at adjacent nodes can result in a considerable savings of the total amount of memory required: Letting Δ_G denote the maximum degree of any node in G, the memory requirement of the best segmentation scheme can be $\Omega(\log \Delta_G)$ times larger than the optimal requirement in the general scheme; this bound is tight.

We start by deriving linear and integer programming lower bounds on the total size of memory required for any network G and file size k. We then present a simple scheme that attains these bounds for sufficiently large values of k. In this scheme, however, the file size k must be, in some cases, much larger than $\Delta_G \log \Delta_G$ in order to approach the abovementioned lower bounds. We regard this as a great disadvantage for two reasons: Such a scheme may turn out to be efficient only for large files and, even then, it requires addressing large units of

stored data each time a node accesses the file. Thus we devote considerable attention to the problem of finding a scheme that is close to the linear and integer programming bounds with a file size that is as small as possible.

Our main result is that the critical file size above which the linear or integer programming bounds can be approached is of the order of $\log \Delta_G$: We present a file distribution scheme for any network G and file size k of a total memory size that is within a multiplicative factor of $1 + \epsilon(G, k)$ from the linear programming bound, where $\epsilon(G, k)$ stands for a term which approaches zero as $k/\log \Delta_G$ increases. On the other hand, we present an inifinite sequence of network file-size pairs $\{(G_l, k_l)\}_{l=0}^{\infty}$ such that $k_l \geq \log \Delta_{G_l}$, and yet any file distribution scheme, when applied to a pair (G_l, k_l), requires memory size which is $1 + \delta(G_l, k_l)$ times larger than the integer (or linear) lower bound, with $\liminf_{l\to\infty} \delta(G_l, k_l) \geq \frac{1}{4}$. This proves that a file size of the order of $\log \Delta_G$ is indeed a critical point.

The rest of the paper is organized as follows. In §2 we provide the necessary background and definitions. In §3 we describe the linear and integer programming lower bounds and prove that the linear programming lower bound can be approached for large file sizes k. In §4 we prove our main result, namely, we present a file distribution scheme that approaches the linear programming bound as the ratio $k/\log \Delta_G$ increases. Finally, in §5 we exhibit the fact that a file size of $\log \Delta_G$ is a critical point, below which there exists infinite families of networks for which the linear and integer programming lower bounds cannot be attained.

2. Background and definitions. Throughout this paper we assume the underlying network to be presented by an undirected graph $G = (V, E)$, with a set of nodes $V = V_G$ and a set of edges $E = E_G$ such that

(i) G does not have parallel edges.

(ii) Each node contains a self loop. This stands for the fact that each node can access its own memory.

An undirected graph satisfying conditions (i) and (ii) will be referred to as a *network graph.*

Two nodes u and v in a network graph $G = (V, E)$ are adjacent if there is an edge in G connecting u and v. The adjacency matrix of a network graph $G = (V, E)$ is the $|V| \times |V|$ matrix $A_G = [a_{u,v}]_{u,v\in V}$, where $a_{u,v} = 1$ when u and v are adjacent, and $a_{u,v} = 0$ otherwise. Note that by definition of a network graph, every node $u \in V$ is adjacent to itself and thus $a_{u,u} = 1$.

For every $u \in V$, let $\Gamma(u)$ be the set of nodes that are adjacent to u in G. The degree of u is denoted by $\Delta(u) \triangleq |\Gamma(u)|$, and the maximum degree in G is denoted by $\Delta_G \triangleq \max_{u\in V} \Delta(u)$.

Two real vectors $\mathbf{y} = [y_i]_i$ and $\mathbf{z} = [z_i]_i$ are said to satisfy the relation $\mathbf{y} \geq \mathbf{z}$ if $y_i \geq z_i$ for all i. The scalar product $\mathbf{y} \cdot \mathbf{z}$ of these vectors is defined, as usual, by $\sum_i y_i z_i$. A real vector $\mathbf{y}$ is called nonnegative if $\mathbf{y} \geq \mathbf{0}$, where $\mathbf{0}$ denotes the all-zero vector. By the *norm* of a nonnegative vector $\mathbf{y}$ we mean the L_1-norm $\|\mathbf{y}\| \triangleq \mathbf{y} \cdot \mathbf{1}$, where $\mathbf{1}$ denotes the all-one vector.

Given a network graph $G = (V, E)$ and a positive integer k, a *file distribution protocol for* (G, k) is, intuitively, a procedure for allocating memory devices to the nodes of G and to map an arbitrary file $\mathbf{w}$ of size k into these memory devices such that each node u can reconstruct $\mathbf{w}$ by reading the memory contents at nodes adjacent to u.

More precisely, let $F_2 \triangleq GF(2)$, let $G = (V, E)$ be a network graph, and let k be a positive integer. For $u \in V$ and a real vector $\mathbf{z} = [z_u]_{u\in V}$ denote by $(A_G\mathbf{z})_u$ the uth entry[1] of $A_G\mathbf{z}$; this entry is equal to $\sum_{v\in\Gamma(u)} z_v$. A file distribution protocol χ for (G, k) is a list $(\mathbf{x}; [\mathcal{E}_u]_{u\in V}; [\mathcal{D}_u]_{u\in V})$, consisting of the following:

[1] As we have not defined any order on the set of nodes V, the order of entries in vectors such as $\mathbf{z}$ can be fixed arbitrarily. The same applies to rows and columns of the adjacency matrix A_G, or to subvectors such as $[z_v]_{v\in\Gamma(u)}$.

- *Memory allocation*, which is a nonnegative integer vector $\mathbf{x} = [x_u]_{u \in V}$; the entry x_u denotes the size of memory (in bits) assigned to node u;
- *encoding mappings:*

$$\mathcal{E}_u : F_2^k \to F_2^{x_u} \quad \text{for every } u \in V;$$

these mappings define the coding rule of any file $\mathbf{w}$ of size k into the memory devices at the nodes: the contents of the memory at node u is given by $\mathcal{E}_u(\mathbf{w})$;
- *decoding (reconstruction) mappings:*

$$\mathcal{D}_u : F^{(A_G \mathbf{x})_u} \to F_2^k \text{ for every } u \in V.$$

The memory allocation, encoding mappings, and decoding mappings satisfy the requirement

$$\mathcal{D}_u([\mathcal{E}_v(\mathbf{w})]_{v \in \Gamma(u)}) \equiv \mathbf{w}, \qquad \mathbf{w} \in F_2^k. \tag{1}$$

Equation (1) guarantees that each node u is able to reconstruct the value (contents) of any file $\mathbf{w}$ of size k out of the memory contents $\mathcal{E}_v(\mathbf{w})$ at nodes v adjacent to u.

The *memory size* of a file distribution protocol $\chi = (\mathbf{x}; [\mathcal{E}_u]_{u \in V}; [\mathcal{D}_u]_{u \in V})$ for (G, k) is defined as the norm $\|\mathbf{x}\|$ and is denoted $|\chi|$. That is, the memory size of a file distribution protocol is the total number of bits assigned to the nodes. The minimum memory size of any file distribution protocol for (G, k) is denoted by $M(G, k)$.

Example 1. The file segmentation method mentioned in §1 can be described as a file distribution protocol for (G, k) with memory allocation $\mathbf{x} = [x_u]_{u \in V}$ and associated encoding mappings $\mathcal{E}_u : F_2^k \to F_2^{x_u}$ of the form

$$\mathcal{E}_u : [w_1 w_2 \ldots w_k] \mapsto [w_{j(u;1)} w_{j(u;2)} \ldots w_{j(u;x_u)}],$$

where $0 < j(u; 1) < j(u; 2) < \cdots < j(u; x_u) \leq k$. For a node $u \in V$ to be able to reconstruct the original file $\mathbf{w}$, the mappings $\mathcal{E}_v$, $v \in \Gamma(u)$, must be such that every entry w_i of $\mathbf{w}$ appears in at least one $\mathcal{E}_v(\mathbf{w})$. This implies that the set of nodes S_i, which w_i is mapped to under the encoding mappings, must be a dominating set in G; that is, each node $u \in G$ is adjacent to some node in S_i. On the other hand, given a dominating set S in G, we can construct a file segmentation protocol for (G, k) of memory size $k \cdot |S| \leq k \cdot |V|$ (the case $S = V$ corresponds to simply replicating the original file $\mathbf{w}$ into each node in G).

A *file distribution scheme* is a function $(G, k) \mapsto \chi(G, k)$ which maps every network graph G and positive integer k into a file distribution protocol $\chi(G, k)$ for (G, k).

A file distribution scheme $(G, k) \mapsto \chi(G, k) = (\mathbf{x}; [\mathcal{E}_u]_{u \in V}; [\mathcal{D}_u]_{u \in V})$ is *constructive* if

(a) the complexity of computing the memory allocation $\mathbf{x}$ is polynomial in k and $|V|$;

(b) for every $\mathbf{w} \in F_2^k$, the complexity of computing the encoded values $[\mathcal{E}_u(\mathbf{w})]_{u \in V}$ is polynomial in the memory size $\|\mathbf{x}\|$;

(c) for every $u \in V$ and $\mathbf{c} \in F_2^{(A_G \mathbf{x})_u}$, the complexity of reconstructing $\mathbf{w} = \mathcal{D}_u(\mathbf{c})$ out of $\mathbf{c}$ is polynomial in the original file size k.

By computational complexity of a problem we mean the running time of a Turing machine that solves this problem.

Remark 1. In the definition of memory size of file distribution protocols we chose not to count the amount of memory required at each node u to store and run the routines which implement the decoding mappings $\mathcal{D}_u(\cdot)$. The reasoning for neglecting this auxiliary memory is that, in practice, there are a number of files (each, say, of the same size k) that are to be distributed in the network. The file distribution protocol can be implemented independently for each such file, using the *same* program and the same working space to handle all these files.

To this end, we might better think of k as the size of the smallest information unit (e.g., a word, or a record) that is addressed at each access to any file. From a complexity point of view, we would prefer k to be as small as possible. The motivation of this paper can be summarized as finding a constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$, which maintains a ratio of memory size to file size virtually equal to $\lim_{l\to\infty} M(G, l)/l$ for relatively small file sizes k.

Remark 2. One might think of a weaker definition for constructiveness by allowing nonpolynomial precomputation of $\mathbf{x}$ (item (a)) and, possibly, of other data structures which depend on G and k but not on $\mathbf{w}$ (e.g., calculating suitable representations for $\mathcal{E}_u$ and $\mathcal{D}_u$); such schemes may be justified by the assumption that these precomputation steps should be done once for a given network graph G and a file size k. On the other hand, items (b) and (c) in the constructiveness definition involve the complexity of the more frequent occasions when the file is encoded and—even more so—reconstructed. In this paper, however, we aim at finding file distribution schemes which are constructive in the way we have defined, i.e., in the strong sense: satisfying all three requirements (a)–(c).

We end this section by introducing a few terms which will be used in describing the mappings $\mathcal{E}_u$ and $\mathcal{D}_u$ of the proposed file distribution schemes. Let Φ be a finite alphabet of q elements. An (n, K) *code* C over Φ is a nonempty subset of Φ^n of size K; the parameter n is called the *length* of C, and the members of C are referred to as *codewords*. The *minimum distance* of an (n, K) code C over Φ is the minimum integer d such that any two distinct codewords in C differ in at least d coordinates.

Let C be an (n, K) code over Φ and let S be a subset of $\langle n\rangle \triangleq \{1, 2, \ldots, n\}$. We say that C is *separable with respect to* S if every two distinct codewords in C differ in at least one coordinate indexed by S. The next lemma follows directly from the definition of minimum distance.

LEMMA 1. *The minimum distance of an* (n, K) *code* C *over* Φ *is the minimum integer* d *for which* C *is separable with respect to every set* $S \subseteq \langle n\rangle$ *of size* $n - d + 1$.

Let q be a power of a prime. An (n, K) code C over a field $\Phi = GF(q)$ is *linear* if C is a linear subspace of Φ^n; in this case we have $K = q^k$, where k is the dimension of C. A generator matrix B of a linear (n, q^k) code C over Φ is a $k \times n$ matrix B over Φ whose rows span the codewords of C.

For a $k \times n$ matrix B (such as a generator matrix) and a set $S \subseteq \langle n\rangle$, denote by $(B)_S$ the $k \times |S|$ matrix consisting of all columns of B indexed by S. The following lemma is easily verified.

LEMMA 2. *Let* C *be an* (n, q^k) *linear code over a field* Φ, *let* B *be a generator matrix of* C, *and let* S *be a subset of* $\langle n\rangle$. *Then* C *is separable with respect to* S *if and only if* $(B)_S$ *has rank* k.

3. Lower bounds and the statement of the main result. In this section we first derive lower bounds on $M(G, k)$, i.e., on the memory size of any file distribution protocol for (G, k). Then we state our main result (Theorem 2), which establishes the existence of a constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$ that attains these lower bounds whenever $k \gg \log \Delta_G$. As the proof of Theorem 2 is somewhat long, it is deferred to §4. Instead, we present in this section a simple file distribution scheme which attains the lower bounds when $k = \Omega(\Delta_G^2 \log \Delta_G)$.

3.1. Lower bounds. Let $\mathbf{x} = [x_u]_{u\in V}$ be a memory allocation of some file distribution protocol for (G, k). Assigning x_u bits to each node $u \in V$, each node must "see" at least k memory bits at its adjacent nodes, or else (1) would not hold. Therefore, for every $u \in V$ we must have $\sum_{v\in\Gamma(u)} x_v \geq k$ or, in vector notation,

$$A_G\mathbf{x} \geq k \cdot \mathbf{1}.$$

Let $J(G, k)$ denote the minimum value attained by the following integer programming problem:

$$\text{IP}(G,k): \quad \begin{aligned} &J(G,k) = \min \|\mathbf{y}\|, \\ &\text{ranging over all integer } \mathbf{y} \text{ such that} \\ &A_G\mathbf{y} \leq k \cdot \mathbf{1} \quad \text{and} \quad \mathbf{y} \geq \mathbf{0}. \end{aligned}$$

Also, let ρ_G denote the minimum value attained by the following (rational) linear programming problem:

$$\text{LP}(G): \quad \begin{aligned} &\rho_G = \min \|\mathbf{z}\|, \\ &\text{ranging over all rational } \mathbf{z} \text{ such that} \\ &A_G\mathbf{z} \geq \mathbf{1} \quad \text{and} \quad \mathbf{z} \geq \mathbf{0}. \end{aligned} \tag{2}$$

The next theorem follows from the previous definitions, Example 1, and the fact that $J(G, 1)$ is the size of a (smallest) dominating set in G.

THEOREM 1. *For every network graph G and positive integer k,*

$$\rho_G \cdot k \leq J(G,k) \leq M(G,k) \leq k \cdot J(G,1) \leq k \cdot |V|.$$

We call $J(G, k)$ the *integer programming bound*, whereas $\rho_G \cdot k$ is referred to as the *linear programming bound.*

For $k = 1$, Theorem 1 becomes $M(G, 1) = J(G, 1)$. The problem of deciding whether a network graph G has a dominating set of size $\leq s$ is well known to be NP complete [6]. The next corollary immediately follows.

COROLLARY 1. *Given an instance of a network graph G and positive integers k and s, the problem of deciding whether there exists a file distribution protocol for (G, k) of memory size $\leq s$ (i.e., whether $M(G, k) \leq s$) is* NP *hard.*

Note that we do not know whether the decision problem of Corollary 1 is in NP (and therefore, whether it is NP complete) since it is unclear how to verify (1) in polynomial time, even when the encoding and decoding mappings are computable in polynomial time.

Remark 3. A result of Lovász [11] states that $J(G, 1) \leq \rho_G \log \Delta_G$; on the other hand, one can construct an infinite family of network graphs $\{G_l\}_l$ (such as the ones presented in §5) for which $J(G_l, 1) \geq \frac{1}{4}\rho_{G_l} \log_2 \Delta_{G_l}$ (see also [7]). In terms of file segmentation schemes (Example 1) this means that there always exists a file distribution protocol for (G, k) based on segmentation whose memory size, $k \cdot J(G, 1)$, is within a multiplicative factor of $\log_2 \Delta_G$ from the linear programming bound $\rho_G \cdot k$. Yet, on the other hand, there are families of network graphs for which such a multiplicative gap is definitive (up to a constant 4), even when k tends to infinity.

3.2. Statement of the main result. Corollary 1 suggests that it is unlikely that there exists an efficient algorithm for generating a file distribution scheme $(G, k) \mapsto \chi(G, k)$ with $|\chi(G, k)| = M(G, k)$. This directs our objective to finding a constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$ such that $|\chi(G, k)|/(\rho_G \cdot k)$ is close to 1 for values of k as small as possible.

More specifically, we prove the following theorem.

THEOREM 2. *There exists a constructive file distribution scheme* $(G, k) \mapsto \chi(G, k)$ *such that*

$$\frac{|\chi(G,k)|}{\rho_G \cdot k} = 1 + O\left(\max\left\{\frac{\log \Delta_G}{k}; \sqrt{\frac{\log \Delta_G}{k}}\right\}\right). \tag{3}$$

(The maximum in the right-hand side of (3) is determined according to whether k is smaller or larger than $\log \Delta_G$. Also, by Theorem 1, the ratios $|\chi(G,k)|/M(G,k)$, $M(G,k)/J(G,k)$, and $J(G,k)/(\rho_G \cdot k)$ all approach 1 when $k \gg \log \Delta_G$.)

In §4 we prove Theorem 2 by presenting an algorithm for generating a constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$ which satisfies (3); in particular, the computational complexity of the encoding mappings in the resulting scheme (item (b) in the constructiveness requirements) is $O(k \cdot |\chi(G,k)|)$, whereas applying the decoding mapping at each node (item (c)) requires $O(k^2)$ bits operations. Returning to our discussion in Remark 1, the complexity of these mappings suggests that the file size k should be as small as possible, still greater than $\log \Delta_G$. This means that files distributed in the network should be segmented into records of size $k = a \cdot \log \Delta_G$ for some (large) constant a, each record being encoded and decoded independently. Information can be retrieved from the file by reading whole records of size $a \cdot \log \Delta_G$ bits each, requiring $O(a^2 \log^2 \Delta_G)$ bit operations, whereby the ratio between the memory size required in the network and the file size k is at most $1 + O(1/\sqrt{a})$ times that ratio for $k \to \infty$.

Our file distribution algorithm is divided into two major steps.

Step 1. Find a memory allocation $\mathbf{x} = [x_u]_{u \in V}$ for (G, k) by finding an approximate solution to an integer programming problem; the resulting memory size $|\chi(G,k)| = \|\mathbf{x}\|$ will satisfy (3).

Step 2. Construct a set of $k \times x_u$ matrices B_u, $u \in V$, over F_2; these matrices define the encoding mappings $\mathcal{E}_u : F_2^k \to F_2^{x_u}$ by $\mathcal{E}_u : \mathbf{w} \mapsto \mathbf{w}B_u$, $u \in V$. The choice of the matrices B_u, in turn, is such that each $k \times (A_G\mathbf{x})_u$ matrix $[B_v]_{v \in \Gamma(u)}$ is of rank k, thus yielding decoding mappings $\mathcal{D}_u : F_2^{(A_G\mathbf{x})_u} \to F_2^k$, which satisfy (1).

3.3. File distribution scheme for large files. In this section we present a fairly simple constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$, for which

$$\frac{|\chi(G,k)|}{\rho_G \cdot k} = 1 + O\left(\frac{\Delta_G \cdot \log(\Delta_G \cdot k)}{k}\right).$$

Note that this proves Theorem 2 whenever $k = \Omega(\Delta_G^2 \log \Delta_G)$.

Given a network graph $G = (V, E)$ and a positive integer k, we first compute a memory allocation $\mathbf{x} = [x_u]_{u \in V}$ for (G, k) (Step 1 above). Let $\mathbf{z} = [z_u]_{u \in V}$ be an optimal solution to the linear programming problem LP(G) in (2). Such a vector $\mathbf{z}$ can be found in time complexity which is polynomial in $|V|$ (e.g., by using Karmarkar's algorithm [9]). Set $h \triangleq \lceil \log_2(\Delta_G \cdot k) \rceil$ and $l \triangleq \lceil k/h \rceil$, and define the integer vector $\mathbf{y} = [y_u]_{u \in V}$ by

$$y_u \triangleq \min\{l; \lfloor (l + \Delta_G) \cdot z_u \rfloor\}, \qquad u \in V.$$

Clearly, $\|\mathbf{y}\| \le \rho_G \cdot (l + \Delta_G)$; furthermore, since $A_G\mathbf{z} \ge \mathbf{1}$, we also have

$$(A_G\mathbf{y})_u \ge \min\{l; (l + \Delta_G)(A_G\mathbf{z})_u - \Delta_G\} \ge l, \qquad u \in V,$$

i.e., $A_G\mathbf{y} \ge l \cdot \mathbf{1}$. The memory allocation for (G, k) is defined by $\mathbf{x} \triangleq h \cdot \mathbf{y}$, and it is easy to verify that $\|\mathbf{x}\|/(\rho_G \cdot k) = 1 + O((\Delta_G/k)\log(\Delta_G \cdot k))$.

We now turn to defining the encoding and decoding mappings (Step 2). To this end, we first assign $\Delta_G \cdot l$ colors to the nodes of G, with each node u assigned a set C_u of y_u colors, such that $|\bigcup_{v\in\Gamma(u)} C_v| \geq l, u \in V$. In other words, we multicolor the nodes of G in such a way that each node "sees" at lease l colors at its adjacent nodes.

Such a coloring can be obtained in the following greedy manner: Start with $C_u \leftarrow \emptyset$ for every $u \in V$. Call a node u *saturated* if $|\bigcup_{v\in\Gamma(u)} C_v| \geq l$. (Hence, at the beginning all nodes are unsaturated, whereas at the end all of them should become saturated.) Scan each node $u \in V$ once, and, at each visited node u, redefine the set C_u to have y_u distinct colors not contained in sets C_v already assigned to nodes $v \in \Gamma(u')$ for all unsaturated nodes $u' \in \Gamma(u)$.

To verify that such a procedure indeed yields an all-saturated network, we first show that at each step there are enough colors to assign to the current node. Let $\sigma(u)$ denote the number of unsaturated nodes $u' \in \Gamma(u) - \{u\}$ when C_u is being redefined. Recalling that $y_v \leq l$ for every $v \in V$, it is easy to verify that the number of disqualified colors for C_u is at most $\sigma(u) \cdot (l-1) + (\Delta(u) - \sigma(u) - 1) \cdot l \leq \Delta_G l - l \leq \Delta_G l - y_u$. This leaves at least y_u qualified colors to assign to node u. We now claim that each node becomes saturated at some point. For if node u remained unsaturated all along, then the sets C_v, $v \in \Gamma(u)$, had to be disjoint; but in that case we would have

$$\left|\bigcup_{v\in\Gamma(u)} C_v\right| = \sum_{v\in\Gamma(u)} |C_v| = \sum_{v\in\Gamma(u)} y_u = (A_G\mathbf{y})_u \geq l,$$

contradicting the fact that u was unsaturated.

Let $\alpha_1, \alpha_2, \ldots, \alpha_{\Delta_G \cdot l}$ be distinct elements in $\Phi \triangleq GF(2^h)$, each α_j corresponding to some color j (note that $|\Phi| \geq \Delta_G \cdot k \geq \Delta_G \cdot l$). Given a file $\mathbf{w}$ of k bits, we group the entries of $\mathbf{w}$ into h tuples to form the coefficients of a polynomial $w(t)$ of degree $< \lceil k/h \rceil = l$ over Φ. We now compute the values $w_j = w(\alpha_j)$, $1 \leq j \leq \Delta_G \cdot l$, and store at each node $u \in V$ the values w_j, $j \in C_u$, requiring memory allocation of $x_u = h \cdot y_u$ bits. Since each u has access to images w_j of $w(t)$ evaluated at l distinct elements α_j, each node can interpolate the polynomial $w(t)$ and hence reconstruct the file $\mathbf{w}$.

The above encoding procedure can be described also in terms of linear codes (refer to the end of §2). Such a characterization will turn out to be useful in §§4 and 5. Let B_{RS} be an $l \times (\Delta_G l)$ matrix over $\Phi = GF(2^h)$ defined by $(B_{\mathrm{RS}})_{i,j} = \alpha_j^{i-1}$, $1 \leq i \leq l$, $1 \leq j \leq \Delta_G l$. For every node $u \in V$, let C_u be the set of colors assigned to u and let $B_u \triangleq (B_{\mathrm{RS}})_{C_u}$; that is, regarding C_u as a subset of $\{1, 2, \ldots, \Delta_G l\}$, B_u consists of all columns of B_{RS} indexed by C_u. The mappings $\mathcal{E}_u : F_2^k \to F_2^{x_u}$, or rather, $\mathcal{E}_u : \Phi^l \to \Phi^{y_u}$, are defined by $\mathcal{E}_u : \mathbf{w} \mapsto \mathbf{w}B_u$, $u \in V$, $\mathbf{w} \in \Phi^l$. The matrix B_{RS} is known as a generator matrix of a $(\Delta_G l, 2^{hl})$ generalized Reed–Solomon code over Φ [12, Chaps. 10–11]. Note that since all l columns in B_{RS} are linearly independent, every $l \times (A_G\mathbf{y})_u$ matrix $[B_v]_{v\in\Gamma(u)}$ has rank l, allowing each node u to reconstruct $\mathbf{w}$ out of $[\mathbf{w}B_v]_{v\in\Gamma(u)}$.

We remark that Reed–Solomon codes have been extensively applied to some other reconstruction problems in networks, such as Shamir's secret sharing [18] (see also [10] and [14]).

The file distribution scheme described in this section is not satisfactory when the file size k is, say, $O(\Delta_G)$, in which case the ratio $\chi(G,k)/(\rho_G \cdot k)$ might be bounded away from 1. This will be rectified in our next construction, which is presented in §4.

4. Proof of the main result. In this section we present a file distribution scheme which attains the memory size stated in Theorem 2. In §4.1 we present a randomized algorithm for finding a memory allocation by scaling and perturbing a solution to the linear programming problem LP(G) defined in (2). Having found a memory allocation $\mathbf{x}$, we describe in §4.2

a second randomized algorithm for obtaining the encoding and decoding mappings. Both algorithms are then derandomized in §4.3 to obtain a deterministic procedure for computing the file distribution scheme claimed in Theorem 2. In §4.4 we present an alternative proof of the theorem using the Lovász local lemma. In §4.5 we consider a variant of the cost measure used in the rest of the paper: Instead of looking for a near-optimal solution with respect to the total memory requirement of the system, we consider approximating the best solution such that the maximum amount of memory required in any node is close to the minimum feasible. This is done using the techniques of §4.4.

4.1. Step 1. Solving for a memory allocation. The goal of this section is to prove the following theorem. (Hereafter, e stands for the base of natural logarithms.)

THEOREM 3. *Given a network graph G and an integer m, let $\mathbf{z} = [z_u]_{u \in V}$ be a nonnegative real vector satisfying $A_G \mathbf{z} \geq \mathbf{1}$. Then there is a nonnegative integer vector $\mathbf{x}$ satisfying $A_G \mathbf{x} \geq m \cdot \mathbf{1}$ such that*

$$\frac{\|\mathbf{x}\|}{\|m \cdot \mathbf{z}\|} \leq 1 + c \cdot \max\left\{\frac{\log_e \Delta_G}{m}; \sqrt{\frac{\log_e \Delta_G}{m}}\right\} \tag{4}$$

for some absolute constant c.

In fact, we provide also an efficient algorithm to compute the nonnegative integer vector $\mathbf{x} = [x_u]_{u \in V}$ guaranteed by the theorem. The vector $\mathbf{x}$ will serve as the memory allocation of the computed file distribution protocol for an instance (G, k), where we will need to take m slightly larger than k in order to construct the encoding and decoding mappings in §4.2.

Theorem 3 is proved via a "randomized rounding" argument (see [15] and [17]): We first solve the corresponding linear programming problem LP(G) in (2) (say, by Karmarkar's algorithm [9]), and use the rational solution to define a probability measure on integer vectors that are candidates for $\mathbf{x}$. We then show that this probability space contains an integer vector $\mathbf{x}$, which satisfies the conditions of Theorem 3. Furthermore, such a vector can be found by a polynomial-time (randomized) algorithm. Note that if we are interested in a weaker result, where $\log |V|$ replaces $\log \Delta_G$ in Theorem 2 (or in Theorem 3), then a slight modification of Raghavan's lattice approximation method can be applied [15]. However, to prove Theorem 3 as is, we need a so-called "local" technique. One possibility is to use the "method of alteration" (see [19]), where a random integer vector selected from the above probability space is perturbed in a few coordinates so as to satisfy the conditions of the theorem. Another option is to use the Lovász local lemma. Both methods can be used to prove Theorem 3, and both can be made constructive and deterministic: The method of alteration can be used by applying the method of conditional probabilities (see Spencer [19, p. 31] and Raghavan [15]), and the local lemma can be used with Beck's method [2]. We show here the method of alteration, then present a second existence proof using the local lemma in §4.4.

Given a nonnegative real vector $\mathbf{z} = [z_u]_{u \in V}$ and a real number $\ell > 0$, define the vectors $\mathbf{s} = [s_u]_{u \in V}$ and $\mathbf{p} = [p_u]_{u \in V}$ by

$$s_u \triangleq \lfloor \ell \cdot z_u \rfloor \quad \text{and} \quad p_u \triangleq \ell \cdot z_u - s_u, \qquad u \in V; \tag{5}$$

note that $0 \leq p_u < 1$ for every $u \in V$. Let $\mathbf{Y} = [Y_u]_{u \in V}$ be a random vector of independent random variables Y_u over $\{0, 1\}$ such that

$$\text{Prob}\{Y_u = 1\} = p_u, \qquad u \in V, \tag{6}$$

and let $\mathbf{X} = [X_u]_{u \in V}$ be a random vector defined by

$$\mathbf{X} \triangleq \mathbf{s} + \mathbf{Y}. \tag{7}$$

Fix $\mathbf{a}$ to be a real vector in the unit hypercube $[0, 1]^{|V|}$ such that $\mathbf{a} \cdot \mathbf{z} \geq 1$. Since the expectation vector $E(\mathbf{Y})$ is equal to $\mathbf{p}$, we have

$$E(\mathbf{a} \cdot \mathbf{X}) = \mathbf{a} \cdot \mathbf{s} + \mathbf{a} \cdot \mathbf{p} = \ell \cdot \mathbf{a} \cdot \mathbf{z} \geq \ell.$$

In particular, if $\mathbf{z}$ is a rational vector satisfying $A_G \mathbf{z} \geq \mathbf{1}$, then

$$E(A_G \mathbf{X}) \geq \ell \cdot A_G \mathbf{z} \geq \ell \cdot \mathbf{1}.$$

Showing the existence of an instance of $\mathbf{X}$ which can serve as the desired memory allocation $\mathbf{x}$ makes use of the following two propositions. The proofs of these propositions are given in the Appendix, as similar statements can be found also in [15].

Throughout this section, $L\{\beta, \eta\}$ stands for $\max\{\log_e \beta; \sqrt{\eta \cdot \log_e \beta}\}$.

PROPOSITION 1. *Given a nonnegative real vector* $\mathbf{z}$ *and an integer* ℓ, *let* $\mathbf{X} = [X_u]_{u \in V}$ *be defined by* (5)–(7), *let* $\mathbf{a}$ *be a real vector in* $[0, 1]^{|V|}$ *such that* $\mathbf{a} \cdot \mathbf{z} \geq 1$, *and let* m *be a positive integer. There exists a constant* c_1 *such that for every* $\beta \geq 1$,

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{X} < m\} \leq \frac{1}{\beta}$$

whenever $\ell \geq m + c_1 \cdot L\{\beta, m\}$.

PROPOSITION 2. *Given a nonnegative real vector* $\mathbf{z}$ *and an integer* ℓ, *let* $\mathbf{X} = [x_u]_{u \in V}$ *be defined by* (5)–(7) *and let* $\mathbf{a}$ *be a real vector in* $[0, 1]^{|V|}$. *There exists a constant* c_2 *such that for every* $\beta \geq 1$.

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{X} > E(\mathbf{a} \cdot \mathbf{X}) + c_2 \cdot L\{\beta, E(\mathbf{a} \cdot \mathbf{X})\}\} \leq \frac{1}{\beta}.$$

Consider the following algorithm for computing a nonnegative integer vector $\mathbf{x}$ for an instance (G, m).

ALGORITHM 1.

1. *Set* $\beta = \beta_G \triangleq 2\Delta_G^2$ *and* $\ell = m + c_1 \cdot L\{\beta_G, m\}$.
2. *Solve the linear programming problem* LP(G) (*defined by* (2)) *for* $\mathbf{z}$.
3. *Generate an instance of the random vector* $\mathbf{X} = [s_u]_u + [Y_u]_u$ *as in* (5)–(7).
4. *The integer vector* $\mathbf{x} = [x_u]_{u \in V}$ *is given by*

$$x_u \triangleq \begin{cases} s_u + 1 & \text{if there exists } v \in \Gamma(u) \text{ with } (A_G \mathbf{X})_v < m, \\ s_u + Y_u & \text{otherwise.} \end{cases}$$

Theorem 3 is a consequence of the following lemma.

LEMMA 3. *The vector* $\|\mathbf{x}\|$ *obtained by Algorithm* 1 *satisfies inequality* (4) *with probability* $\geq \frac{1}{2} - (1/\beta_G)$.

Proof. Call a node v *deficient* if $(A_G \mathbf{X})_v < m$ for the generated vector $\mathbf{X}$. First note that x_u is either X_u or $X_u + 1$ and that

$$A_G \mathbf{x} \geq m \cdot \mathbf{1}; \tag{8}$$

in fact, for deficient nodes v we have $(A_G \mathbf{x})_v \geq \ell \cdot (A_G \mathbf{z})_v \geq \ell \geq m$.

Now by Proposition 1, for every node $v \in V$,

$$\text{Prob } \{ \text{ node } v \text{ is deficient } \} = \text{Prob } \{(A_G \mathbf{X})_v < m\} \leq \frac{1}{\beta_G}.$$

Hence, for each node $u \in V$,

$$\text{Prob}\{x_u = X_u + 1\} \leq \Delta_G \cdot \text{Prob}\{\text{node } v \text{ is deficient}\} \leq \frac{\Delta_G}{\beta_G} = \frac{1}{2\Delta_G}.$$

Therefore, the expected number of nodes u for which $x_u = X_u + 1$ is at most $(|V|/2\Delta_G)$ and, with probability at least $\frac{1}{2}$, there are no more than $|V|/\Delta_G$ such nodes u. Observing that

$$\|\mathbf{z}\| \geq \frac{1}{\Delta_G}\sum_{u\in V}(A_G\mathbf{z})_u \geq \frac{1}{\Delta_G}\sum_{u\in V}1 = \frac{|V|}{\Delta_G},$$

we thus obtain, with probability $\geq \frac{1}{2}$,

$$\|\mathbf{x}\| \leq \|\mathbf{X}\| + \frac{|V|}{\Delta_G} \leq \|\mathbf{X}\| + \|\mathbf{z}\|. \tag{9}$$

Recalling that $E(\|\mathbf{X}\|) = \ell \cdot \|\mathbf{z}\|$, we apply Proposition 2 with $\mathbf{a} = \mathbf{1}$ to obtain

$$\text{Prob}\{\|\mathbf{X}\| > \ell \cdot \|\mathbf{z}\| + c_2 \cdot L\{\beta_G, \ell \cdot \|\mathbf{z}\|\}\} \leq \frac{1}{\beta_G}. \tag{10}$$

Hence, by (8)–(10) we conclude that with probability $\geq \frac{1}{2} - (1/\beta_G)$, the integer vector $\mathbf{x}$ satisfies both

$$A_G\mathbf{x} \geq m \cdot \mathbf{1} \tag{11}$$

and

$$\begin{aligned}\|\mathbf{x}\| &\leq (\ell+1)\cdot\|\mathbf{z}\| + c_2 \cdot L\{\beta_G, \ell\cdot\|\mathbf{z}\|\}\\ &\leq (\ell+1)\cdot\|\mathbf{z}\| + c_2\cdot\|\mathbf{z}\|\cdot L\{\beta_G,\ell\}.\end{aligned}$$

The last inequality implies

$$\frac{\|\mathbf{x}\|}{\|\ell\cdot\mathbf{z}\|} \leq 1 + \frac{1}{\ell} + c_2\left(\frac{\log_e\beta_G}{\ell} + \sqrt{\frac{\log_e\beta_G}{\ell}}\right), \tag{12}$$

and the lemma now follows by substituting

$$\ell = m\cdot\left(1 + c_2\cdot\max\left\{\frac{\log_e\beta_G}{m}; \sqrt{\frac{\log_e\beta_G}{m}}\right\}\right)$$

and $\beta_G = 2\Delta_G^2$ in (12). □

Note that for $m = k + O(\log\Delta_G)$ we also have

$$\frac{\|\mathbf{x}\|}{\|k\cdot\mathbf{z}\|} = 1 + O\left(\max\left\{\frac{\log\Delta_G}{k}; \sqrt{\frac{\log\Delta_G}{k}}\right\}\right) \tag{13}$$

(compare with the right-hand side of (3)). The vector $\mathbf{x}$, computed for $m = k + O(\log\Delta_G)$, will serve, with a slight modification, as the memory allocation of $\chi(G,k)$. In §4.3 we shall apply the method of conditional probabilities to make Algorithm 1 deterministic.

4.2. Step 2. Defining the encoding mappings. Having found a memory allocation $\mathbf{x}$, we now provide a randomized algorithm for constructing the encoding and decoding mappings. The construction makes use of the following lemma.

LEMMA 4 [12, p. 444]. *Let* $\mathbf{S}$ *denote a random matrix, uniformly distributed over all* $k \times m$ *matrices over* F_2. *Then*

$$\text{Prob}\{\text{rank}(\mathbf{S}) = k\} = \prod_{i=0}^{k-1}(1 - 2^{i-m}) > 1 - 2^{k-m}.$$

Given an instance (G, k), let $\mathbf{x} = [x_u]_{u\in V}$ be the nonnegative integer vector obtained by Algorithm 1 for $m = k + 3\lceil \log_2 \Delta_G \rceil + 1$. The following algorithm computes for each node u a matrix B_u to be used for the encoding mappings.

ALGORITHM 2.

1. *For each* $u \in V$, *assign at random a matrix* $\mathbf{Q}_u$ *uniformly distributed over all* $k \times x_u$ *matrices over* F_2.

2. *For each* $u \in V$, *let* $\mathbf{S}_u \triangleq [\mathbf{Q}_v]_{v\in\Gamma(u)}$, *and define the encoding matrix* B_u *by*

$$B_u \triangleq \begin{cases} \mathbf{Q}_u & \text{if rank } (\mathbf{S}_u) = k, \\ I_k & \text{if rank } (\mathbf{S}_u) < k, \end{cases} \tag{14}$$

where I_k *stands for the* $k \times k$ *identity matrix.*

Note that each B_u is a $k \times \hat{x}_u$ binary matrix with

$$\hat{x}_u = \begin{cases} x_u & \text{if rank } (\mathbf{S}_u) = k, \\ k & \text{if rank } (\mathbf{S}_u) < k. \end{cases} \tag{15}$$

The vector $\hat{\mathbf{x}} \triangleq [\hat{x}_u]_{u\in V}$ will serve as the (final) memory allocation for $\chi(G, k)$. As we show later on in this section, the excess of $\|\hat{\mathbf{x}}\|$ over $\|\mathbf{x}\|$, if any, is small enough to let (13) hold also with respect to the memory allocation $\hat{\mathbf{x}}$. This will establish the memory size claimed in Theorem 2. The associated encoding mappings $\mathcal{E}_u : F_2^k \to F_2^{\hat{x}_u}$ are given by $\mathcal{E}_u : \mathbf{w} \mapsto \mathbf{w}B_u$, $u \in V$, and the overall process of encoding $\mathbf{w}$ into $[\mathcal{E}_u(\mathbf{w})]_{u\in V}$ requires $O(k \cdot \|\hat{\mathbf{x}}\|)$ multiplications and additions over F_2.

Recalling the definitions in §2, note that for each node u, the $k \times \|\hat{\mathbf{x}}\|$ matrix $B \triangleq [B_v]_{v\in V}$ is separable with respect to the set $\Gamma(u)$; that is, the rank of $(B)_{\Gamma(u)} = [B_v]_{v\in\Gamma(u)}$ is k. Therefore, each node u, knowing the values $[\mathcal{E}_v(\mathbf{w})]_{v\in\Gamma(u)} = [\mathbf{w}B_u]_{v\in\Gamma(u)}$, is able to reconstruct the file $\mathbf{w}$. To this end, node u has to process only k fixed coordinates of $\mathbf{w}(B)_{\Gamma(u)}$, namely, k coordinates which correspond to k linearly independent columns of $(B)_{\Gamma(u)}$. Let such a set of coordinates be indexed by the set T_u, $u \in V$. Assuming a "hard-wired" connection between node u and the k entries of $\mathbf{w}(B)_{\Gamma(u)}$ indexed by T_u, the decoding process at u sums up to multiplying the vector $\mathbf{w}(B)_{T_u} \in F_2^k$ by the inverse of $(B)_{T_u}$. Hence, the mappings $\mathcal{D}_u$, $u \in V$, are given by $\mathcal{D}_u(\mathbf{c}) = (\mathbf{c})_{T_u}((B)_{T_u})^{-1}$ for every $\mathbf{c} \in F^{(A_G\hat{\mathbf{x}})_u}$. The decoding process at each node thus requires $O(k^2)$ multiplications and additions over F_2. Note that in those cases where we set B_u in (14) to be the identity matrix, the decoding process is trivial, since the whole file is written at node u.

We now turn to estimating the memory size $\hat{\mathbf{x}}$. First note that for every node u, the matrix $\mathbf{S}_u$ is uniformly distributed over all $k \times (A_G\mathbf{x})_u$ matrices over F_2. Recalling that, by construction, $(A_G\mathbf{x})_u \geq m = k + 3\lceil \log_2 \Delta_G \rceil + 1$, we have, by Lemma 4,

$$\text{Prob}\{\text{rank } (\mathbf{S}_u) < k\} < 2^{k-m} \leq \frac{1}{2\Delta_G^3}.$$

Hence, the expected number of nodes for which $\hat{x}_u > x_u$ in (15) is at most $|V|/(2\Delta_G^3)$. Therefore, with probability at least $\frac{1}{2}$, there are no more than $|V|/\Delta_G^3$ nodes u whose memory allocation x_u has been increased to $\hat{x}_u = k$. Since $|V|/\Delta_G^3 \le \|\mathbf{z}\|/\Delta_G^2$, the total memory-size increase in (15) is bounded from above by $(k/\Delta_G^2)\|\mathbf{z}\|$. Hence, by (13),

$$\frac{\|\hat{\mathbf{x}}\|}{\|k \cdot \mathbf{z}\|} \le \frac{\|\mathbf{x}\| + (k/\Delta_G^2)\|\mathbf{z}\|}{\|k \cdot \mathbf{z}\|} = 1 + O\left(\max\left\{\frac{\log \Delta_G}{k}; \sqrt{\frac{\log \Delta_G}{k}}\right\}\right)$$

whenever $k = O(\Delta_G^2 \log \Delta_G)$. Recall that the construction of §3.3 covers Theorem 2 for larger values of k.

In §4.3 we apply the method of conditional probabilities (see [19, p. 31] and [15]) in order to make the computation of the matrices B_u deterministic.

Remark 4. It is worthwhile comparing the file distribution scheme described in §§4.1 and 4.2 with the scheme of §3.3, modified to employ Algorithm 1 on $(G, \lceil k/h \rceil)$, $h = \lceil \log_2(\Delta_G \cdot k) \rceil$, to solve for the memory allocation there. It can be verified that the resulting file distribution scheme is slightly worse than the one obtained here: Every term $\log \Delta_G$ in (3) should be changed to $\log(\Delta_G \cdot k) \log \Delta_G$. In particular, this method has critical file size of $\log^2 \Delta_G$.

4.3. A deterministic algorithm. We now show how to make Algorithms 1 and 2 deterministic using the method of conditional probabilities of Spencer [19, p. 31] and Raghavan [15], adapted to conditional expectation values. The idea of the method of conditional probabilities is to search the probability space defined by the random choices. At each iteration the probability space is bisected by setting one of the random variables. Throughout the search we estimate the probability of success, conditional on the choices we have fixed so far. The value of the next random variable is chosen as the one that maximizes the estimator function.

In derandomizing Algorithms 1 and 2 we employ as an estimator the expected value of the size of the allocation. At every step the conditional expectation for both possibilities for the value of the next random variable are computed and the setting that is smaller (thus increasing the probability of success) is chosen. Unlike Raghavan [15], we do not employ a "pessimistic estimator," but rather a conditional expectation estimator which is fairly easy to compute.

We start with derandomizing the computation of the (initial) memory allocation $\mathbf{x}$. Let $\mathbf{z} = [z_u]_u = [s_u + p_u]_u$, $\mathbf{X} = [X_u]_u$, and $\mathbf{x} = [x_u]_u$ be the vectors computed in the course of Algorithm 1. Recall that for every $u \in V$, the entry X_u is a random variable given by $X_u = s_u + Y_u$, with Prob $\{Y_u = 1\} = p_u$. Now,

$$\begin{aligned} E(\|\mathbf{x}\|) &= E(\|\mathbf{X}\|) + \sum_{u \in V} \text{Prob}\{x_u = X_u + 1\} \\ &\le E(\|\mathbf{X}\|) + \Delta_G \cdot \sum_{u \in V} \text{Prob}\{\text{ node } u \text{ is deficient }\} \\ &\triangleq \hat{E}. \end{aligned}$$

We refer to $\hat{E}$ as the *expectation estimator* for $\mathbf{x}$, and we have

$$\begin{aligned} E(\|\mathbf{x}\|) \le \hat{E} &= E(\|\mathbf{X}\|) + \Delta_G \cdot \sum_{u \in V} \text{Prob}\{(A_G\mathbf{X})_u < m\} \\ &= \ell \cdot \|\mathbf{z}\| + \Delta_G \cdot \sum_{u \in V} \text{Prob}\left\{\sum_{v \in \Gamma(u)} X_v < m\right\} \\ &\le \ell \cdot \|\mathbf{z}\| + \frac{|V|}{2\Delta_G} \le (\ell + \tfrac{1}{2}) \cdot \|\mathbf{z}\|. \end{aligned}$$

Comparing the last inequality with (12), it would suffice if we found a memory allocation whose size is at most $\hat{E}$. Note that $\hat{E}$ can be computed efficiently by calculating the expressions Prob $\{\sum_{v\in W_i} X_v < j\}$ for subsets W_i of $\Gamma(u)$ consisting of the first i nodes in $\Gamma(u)$ for $i = 1, 2, \ldots, \Delta(u) = |\Gamma(u)|$, and for $\sum_{u\in W} s_u \le j \le m$. Such a computation can be carried out efficiently by dynamic programming.

Let Y_1 denote the first entry of $\mathbf{Y} = \mathbf{X} - \mathbf{s}$ and define the conditional expectation estimators by

$$\hat{E}_b \triangleq E(\|\mathbf{X}\||Y_1 = b) + \Delta_G \cdot \sum_{u\in V} \text{Prob}\left\{\sum_{v\in\Gamma(u)} X_v < m|Y_1 = b\right\}, \qquad b = 0, 1.$$

Indeed, we have $E(\|\mathbf{x}\||Y_1 = b) \le \hat{E}_b$; furthermore, the two conditional expectation estimators $\hat{E}_0$ and $\hat{E}_1$ have $\hat{E}$ as a convex combination and, therefore, one of them must be bounded from above by $\hat{E}$. We set the entry Y_1 to the bit $y_1 = b$ for which $\hat{E}_b$ is the smallest. Note that, like $\hat{E}$, the conditional expectation estimators can be efficiently computed.

Having determined the first entry in $\mathbf{Y}$, we now reiterate this process with the second entry, Y_2, now involving the conditional expectation estimators $\hat{E}_{y_1,0}$ and $\hat{E}_{y_1,1}$. Continuing this way with subsequent entries of $\mathbf{Y}$, we end up with a nondecreasing sequence of conditional expectation estimators

$$\begin{aligned}(\ell + \tfrac{1}{2}) \cdot \|\mathbf{z}\| \ge \hat{E} \ge \hat{E}_{y_1} \ge \hat{E}_{y_1,y_2} \ge \cdots \ge \hat{E}_{y_1,y_2,\ldots,y_{|V|}} \\ \ge E(\|\mathbf{x}\||y_1 = y_1, Y_2 = y_2, \ldots, Y_{|V|} = y_{|V|}),\end{aligned}$$

thus determining the whole vector $\mathbf{Y}$, and therefore the vectors $\mathbf{X}$ and $\mathbf{x}$, the latter having memory size $\le (\ell + \frac{1}{2}) \cdot \|\mathbf{z}\|$.

We now turn to making the computation of the encoding mappings deterministic. Recall that Algorithm 2 first assigns a random $k \times x_u$ matrix $\mathbf{Q}_u$ to each node u. We may regard this assignment as an $\|\mathbf{x}\|$-step procedure, where at the nth step a random column of F_2^k is added to a node v with less than x_v already-assigned columns. Denote by $\mathbf{Q}_{u;n}$ the (partial) matrix at node $u \in V$ after the nth step. The assignment of the random matrices $\mathbf{Q}_u$ to the nodes of the network can thus be described as a random process $\{\mathbf{U}_n\}_{n=1}^{\|\mathbf{x}\|}$, where $\mathbf{U}_n = \{\mathbf{Q}_{u;n}\}_{u\in V}$ is a random column configuration denoting the contents of each node after adding the nth column to the network graph. We shall use the notation $\mathbf{U}_0$ for the initial column configuration where no columns have been assigned yet to any node.

Let $\mathbf{S}_u$ denote the random matrix $[\mathbf{Q}_v]_{v\in\Gamma(u)}$ (as in Algorithm 2) and let R be the number of nodes u for which rank $(\mathbf{S}_u) < k$. Recall that Algorithm 2 was based on the inequality

$$E(R) \triangleq E(R|\mathbf{U}_0) < \frac{|V|}{2\Delta_G},$$

which then allowed us to give a probabilistic estimate of $2E(R) < \frac{|V|}{\Delta_G}$ for the number of nodes u that required the replacement of $\mathbf{Q}_u$ by I_k. Instead, we compute here a sequence of column configurations $U_n = \{Q_{u;n}\}_{u\in V}$, $n = 1, 2, \ldots, \|\mathbf{x}\|$, such that

$$E(R|\mathbf{U}_n = U_n) \le E(R|\mathbf{U}_{n-1} = U_{n-1}); \tag{16}$$

in particular, we will have

$$E(R|\mathbf{U}_{\|\mathbf{x}\|} = U_{\|\mathbf{x}\|}) < \frac{|V|}{2\Delta_G},$$

i.e., the number of nodes u for which B_u is set to I_k in (14) is guaranteed to be less than $|V|/(2\Delta_G)$.

In order to attain the inequality chain (16) we proceed as follows: Let U_0 be the empty column configuration and assume, by induction, that the column configuration U_{n-1} has been determined for some $n \geq 1$. Let v be a node which has been assigned less than x_v columns in U_{n-1}. We now determine the column which will be added to v to obtain U_n. This is done in a manner similar to the process described before derandomizing Algorithm 1: Set the first entry, b_1, of the added column to be 0, assume the other entries to be random bits, and compute the expected value, E_0, of R conditioned on $\mathbf{U}_{n-1} = U_{n-1}$ and on $b_1 = 0$. Now repeat the process with b_1 being set to 1, resulting in a conditional expected value E_1 of R. Since the two conditional expected values E_0 and E_1 average to $E(R|\mathbf{U}_{n-1} = U_{n-1})$, one of them must be at most that average. The first entry b_1 in the column added to v is set to the bit b for which E_b is the smallest. This process is now iterated for the second bit b_2 of the column added to v, resulting in two conditional expected values $E_{b_1,0}$ and $E_{b_1,1}$ of R, the smaller of which determines b_2. Continuing this way, we obtain a sequence of conditional expected values of R,

$$E(R|\mathbf{U}_{n-1} = U_{n-1}) \geq E_{b_1} \geq E_{b_1,b_2} \geq \cdots \geq E_{b_1,b_2,\ldots,b_k},$$

thus determining the entire column added to v. Note that, indeed,

$$E(R|\mathbf{U}_n = U_n) = E_{b_1,b_2,\ldots,b_k} \leq E(R|\mathbf{U}_{n-1} = U_{n-1}),$$

in accordance with (16).

It remains to show how to compute the conditional expected values of R which are used to determine the column configurations U_n. It is easy to verify that for any event $\mathcal{A}$,

$$E(R|\mathcal{A}) = \sum_{u \in V} \text{Prob } \{ \text{ rank } (\mathbf{S}_u) < k|\mathcal{A}\}. \tag{17}$$

Hence, the computation of the conditional expected values of R boils down to the following problem:

Let $\mathbf{S}$ *denote a* $k \times m$ *random matrix over* F_2, *whose first* l *columns, as well as the first* t *entries in its* $(l+1)$*st column, are preset, and the rest of its entries are independent random bits with probability* $\frac{1}{2}$ *of being zero. What is the probability of* $\mathbf{S}$ *having rank* k?

Let H denote the $k \times l$ matrix consisting of the first l (preset) columns of such a random matrix $\mathbf{S}$. Denote by $\mathbf{T}$ the matrix consisting of the first $l+1$ columns of $\mathbf{S}$ and by $\mathbf{W}$ the matrix consisting of the last $m - l - 1$ columns of $\mathbf{S}$. Also let the random variable ρ denote the rank of $\mathbf{T}$. Clearly, ρ may take only two values, namely, rank (H) or rank $(H) + 1$. We now show that

$$\text{Prob } \{ \text{ rank } (\mathbf{S}) < k|\rho = r\} = 1 - \prod_{i=0}^{k-r-1} (1 - 2^{i+l+1-m}) < 2^{k+l+1-m-r}. \tag{18}$$

Indeed, without loss of generality assume that the first r rows of $\mathbf{T}$ are linearly independent. We assume that the entries of $\mathbf{W}$ are chosen randomly row by row. Having selected the first r rows of $\mathbf{W}$, we thus obtain the first r rows in $\mathbf{S}$ which, in turn, are linearly independent. Next we select the $(r+1)$st row in $\mathbf{W}$. Clearly, there are 2^{m-l-1} choices for such a row, out of which one row will result in an $(r+1)$st row in $\mathbf{S}$ which is spanned by the first r rows in $\mathbf{S}$. Hence, given that the first r rows in $\mathbf{W}$ have been set, the probability that the first $r+1$ rows in $\mathbf{S}$ will be linearly independent is $1 - 2^{l+1-m}$. Conditioning upon the linear independence of the first $r+1$ rows in $\mathbf{S}$, we now select the $(r+2)$nd row in $\mathbf{W}$. In this case there are two choices

of this row that yield an $(r+2)$nd row in $\mathbf{S}$ which is spanned by the first $r+1$ rows in $\mathbf{S}$. Hence, the probability of the first $r+2$ rows in $\mathbf{S}$ to be linearly independent (given the linear independence of the first $r+1$ rows) is $1-2^{l+2-m}$. In general, assuming linear independence of the first $r+i$ rows in $\mathbf{S}$, there are 2^i choices for the $(r+i+1)$st row of $\mathbf{W}$ that yield a row in $\mathbf{S}$ belonging to the linear span of the first $r+i$ rows in $\mathbf{S}$. The conditional probability for the first $r+i+1$ rows in $\mathbf{S}$ to be linearly independent thus becomes $1-2^{i+l+1-m}$. Equation (18) is obtained by reiterating the process for all rows of $\mathbf{W}$.

To complete the computation of the probability of $\mathbf{S}$ having rank k, we need to calculate the probability of ρ being $r = \text{rank}\ (H)$. Let H_t denote the first t rows of H with $r_t \triangleq \text{rank}\ (H_t)$ and let $\mathbf{c}$ denote the first t (preset) entries of the $(l+1)$st column of $\mathbf{S}$ (or of $\mathbf{T}$). We now show that

$$\text{(19)} \qquad \text{Prob}\ \{\rho = r = \text{rank}\ (H)\} = \begin{cases} 2^{r-r_t-k+t} & \text{if rank}\ ([H_t; \mathbf{c}]) = r_t, \\ 0 & \text{if rank}\ ([H_t; \mathbf{c}]) = r_t + 1. \end{cases}$$

We first perform elementary operations on the columns of H so that (i) the first r_t columns in H_t are linearly independent whereas the remaining $l-r_t$ columns in H_t are zero, and (ii) the first r columns in H are linearly independent whereas the remaining $l-r$ columns in H are zero. Now if $\mathbf{c}$ is not in the linear span of the columns of H_t, then $\rho = \text{rank}\ (\mathbf{T}) = \text{rank}\ (H) + 1$. Otherwise, there are 2^{r-r_t} ways to select the last $k-t$ entries of the $(l+1)$st column of $\mathbf{T}$ to have that column spanned by the columns of H: Each such choice corresponds to one linear combination of the last $r-r_t$ nonzero columns of H. Therefore, conditioning upon $\text{rank}\ ([H_t; \mathbf{c}]) = r_t$, the probability of having $\text{rank}\ (T) = \text{rank}\ (H)$ equals 2^{r-r_t-k+t}.

Equations (18) and (19) can be now applied to $\mathbf{S}_u$ to compute the right-hand side of (17), where $\mathcal{A}$ stands for the event of having $n-1$ columns in $\mathbf{U}_n$ set to U_{n-1}, and t bits of the currently added nth column set to $b_1, b_2, \ldots, b_t$.

4.4. Proof using the Lovász local lemma. In this section we present an alternative proof for the existence of a memory allocation $\mathbf{x}$ satisfying (3) and of $k \times x_u$ binary matrices B_u for the encoding mappings $\mathcal{E}_u : \mathbf{w} \mapsto \mathbf{w}B_u$, $u \in V$. The techniques used will turn out to be useful in §4.5. To this end, we make use of the following lemma.

LEMMA 5 (the Lovász local lemma [5], [19]). *Let $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ be events in an arbitrary probability space. Suppose that each event $\mathcal{A}_i$ is mutually independent of a set of all, but at most δ, events $\mathcal{A}_j$ and that* Prob $\{\mathcal{A}_i\} \le p$ *for all* $1 \le i \le n$. *If* $ep\delta < 1$, *then* Prob $\{\bigwedge_{i=1}^{n} \overline{\mathcal{A}_i}\} > 0$.

In most applications of the lemma (as well as in its use in the sequel), the $\mathcal{A}_i$'s stand for "bad" events; hence, if the probability of each bad event is at most p, and if the bad events are not terribly dependent of one another (in the sense stated in the lemma), there is a strictly positive probability that none of the bad events will occur. However, this probability might be exponentially small. Recently, Beck [2] has proposed a constructive technique that can be used in most applications of the lemma for finding an element of $\bigwedge_{i=1}^{n} \overline{\mathcal{A}_i}$ (see also [1]). We shall be mainly concentrating on an existence proof, as the construction will then follow by a technique similar to the one in [2].

We start by using the local lemma to present an alternative proof of Theorem 3. Given a network graph $G = (V, E_G)$ and an integer m, we construct a directed graph $H = (V, E_H)$ which satisfies the following four properties:

(i) There is an edge $u \to v$ in H whenever u is adjacent to v in G;
(ii) there are no parallel edges in H;
(iii) each node in H has the same in-degree $\Delta_H = O(\Delta_G)$;
(iv) each node in H has an out-degree which is bounded from above by $\Lambda_H = O(\Delta_G)$.

LEMMA 6. *A directed graph H satisfying* (i)–(iv) *always exists.*

Proof. When $\Delta_G > \frac{1}{2}|V|$ we take H as the complete graph (i.e., the adjacency matrix A_H is the all-one matrix and $\Delta_H = \Lambda_H = |V| < 2\Delta_G$). Otherwise, we construct H out of G as follows: Make every self loop in G a directed self loop in H, and change all other edges in G into two antiparallel edges in H. Finally, adjoin extra edges (not parallel to existing ones) to have in-degree $\Delta_H = \Delta_G$ and out-degree $\leq \Lambda_H = 2\Delta_G$ at each node in H. To realize this last step, we scan the nodes of H and add incoming edges to nodes whose in-degree is less than Δ_G—one node at a time. Let u be such a node and let $\overline{\Gamma}(u)$ be the set of nodes in H with no outgoing edges that terminate at u. We show that at least one of the nodes in $\overline{\Gamma}(u)$ has an out-degree less than $2\Delta_G$, thus allowing us to adjoin a new incoming edge to u from that node. The proof then continues inductively. Now, since the in-degree of each node in H at each stage is at most Δ_G, the total number of edges outgoing from nodes in $\overline{\Gamma}(u)$ is bounded from above by $\Delta_G \cdot (|V| - 1)$. On the other hand, $\overline{\Gamma}(u)$ contains at least $|V| - \Delta_G + 1$ nodes. Hence, there exists at least one node in $\overline{\Gamma}(u)$ whose out-degree is at most $(\Delta_G \cdot (|V| - 1))/(|V| - \Delta_G + 1)$; this number, in turn, is less than $2\Delta_G$ whenever $\Delta_G \leq \frac{1}{2}|V|$. □

Proof of Theorem 3 using the local lemma. Let $\mathbf{z}$ be a solution to the linear programming problem LP(G) of (2). By property (i), $\mathbf{z}$ satisfies the inequality $A_H\mathbf{z} \geq \mathbf{1}$. Redefine β_G to be $8e\Delta_G^2$ (and ℓ accordingly to be $m + c_1 \cdot L\{\beta_G, m\}$), and let $\mathbf{X}$ be obtained by (5)–(7). By Proposition 1 we have

$$\text{Prob}\,\{(A_G\mathbf{X})_u < m\} \leq \frac{1}{\beta_G}, \tag{20}$$

and by property (ii) and Proposition 2 we have

$$\text{Prob}\,\{(A_H\mathbf{X})_u > \ell \cdot (A_H\mathbf{z})_u + c_2 \cdot L\{\beta_G, \ell \cdot (A_H\mathbf{z})_u\}\} \leq \frac{1}{\beta_G} \tag{21}$$

for each node $u \in V$.

For every $u \in V$ define the event $\mathcal{A}_u$ as

$$\mathcal{A}_u \triangleq \left\{ \begin{array}{c} (A_G\mathbf{X})_u < m \\ \text{or} \\ (A_H\mathbf{X})_u > \ell \cdot (A_H\mathbf{z})_u + c_2 \cdot L\{\beta_G, \ell \cdot (A_H\mathbf{z})_u\} \end{array} \right\}. \tag{22}$$

By (20) and (21) it follows that Prob $\{\mathcal{A}_u\} \leq 2/\beta_G < 1/(4e\Delta_G^2)$. For every node u in H, denote by $\Gamma_{\text{out}}(u)$ the set of terminal nodes of the edges outgoing from u in H. Then, for every node u, the event $\mathcal{A}_u$ is mutually independent of all events $\mathcal{A}_v$ such that $\Gamma_{\text{out}}(u) \bigcap \Gamma_{\text{out}}(v) = \emptyset$. Hence, by properties (iii) and (iv), each $\mathcal{A}_u$ depends on at most $\Lambda_H(\Delta_H - 1) + 1 \leq 4\Delta_G^2$ events A_v and, therefore, by Lemma 5 there exists a nonnegative integer vector $\mathbf{x}$ satisfying both

$$(A_G\mathbf{x})_u \geq m \tag{23}$$

and

$$(A_G\mathbf{x})_u \leq \ell \cdot (A_H\mathbf{z})_u + c_2 \cdot L\{\beta_G, \ell \cdot (A_h\mathbf{z})_u\} \tag{24}$$

for all $u \in V$.

We now show that $\|\mathbf{x}\|$ satisfies the inequality

$$\frac{\|\mathbf{x}\|}{\|\ell \cdot \mathbf{z}\|} \leq 1 + c_2\left(\frac{\log_e \beta_G}{\ell} + \sqrt{\frac{\log_e \beta_G}{\ell}}\right). \tag{25}$$

By (24) and the fact that each node in H has in-degree Δ_H we have

$$\begin{aligned}\|\mathbf{x}\| &= \frac{1}{\Delta_H}\sum_{u\in V}(A_H\mathbf{x})_u \\ &\le \frac{\ell}{\Delta_H}\sum_{u\in V}(A_H\mathbf{z})_u + \frac{c_2}{\Delta_H}\sum_{u\in V} L\{\beta_G, \ell\cdot(A_H\mathbf{z})_u\} \\ &\le \ell\cdot\|\mathbf{z}\| + c_2\left(\frac{|V|}{\Delta_H}\log_e\beta_G + \frac{1}{\Delta_H}\sum_{u\in V}\sqrt{\ell\cdot(A_h\mathbf{z})_u\cdot\log_e\beta_G}\right).\end{aligned}$$

Now, by the Cauchy–Schwarz inequality,

$$\sum_{u\in V}\sqrt{(A_H\mathbf{z})_u} \le \sqrt{|V|}\cdot\sqrt{\sum_{u\in V}(A_H\mathbf{z})_u} = \sqrt{|V|\cdot\Delta_H\cdot\|\mathbf{z}\|}$$

and therefore

$$\|\mathbf{x}\| \le \ell\cdot\|\mathbf{z}\| + c_2\left(\frac{|V|}{\Delta_H}\log_e\beta_G + \sqrt{\frac{|V|}{\Delta_H}}\cdot\sqrt{\|\mathbf{z}\|\cdot\ell\cdot\log_e\beta_G}\right).$$

Inequality (25) is now obtained by bounding $|V|/\Delta_H$ from above by $\|\mathbf{z}\|$. Finally, Theorem 3 is a consequence of both (23) and (25). □

We now turn to defining the encoding and decoding mappings for a given instange (G, k). To this end, we shall make use of the following lemma.

LEMMA 7. *Let $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_t$ be subsets of $\langle n\rangle \stackrel{\Delta}{=} \{1, 2, \ldots, n\}$, each $\mathcal{S}_i$ of size $\ge s$, and no subset intersects more than δ subsets. Let q be a power of a prime and let k be a nonnegative integer satisfying*

$$e\cdot\delta\cdot q^{-s-1} < q^{-k}.$$

Then there exists an (n, q^k) linear code over $\Phi = GF(q)$, which is separable with respect to each $\mathcal{S}_i$.

Proof. We construct inductively $l \times n$ matrices B_l, $1 \le l \le k$, each generating a linear code which is separable with respect to every $\mathcal{S}_i$; that is, each $(B_l)_{\mathcal{S}_i}$ has rank l. Start with an all-one $1 \times n$ matrix B_1. As the induction step, assume that a matrix B_{l-1}, with the above property, has already been constructed for some $l \le k$. We are now to append at lth row to B_{l-1}.

Given such a matrix B_{l-1}, a row vector in Φ^n is "good" with respect to $\mathcal{S}_i$ if, when appended to B_{l-1}, it yields a matrix B_l such that $(B_l)_{\mathcal{S}_i}$ has rank l; otherwise, a row vector is "bad" with respect to that $\mathcal{S}_i$. Now, for each i, the row span of $(B_{l-1})_{\mathcal{S}_i}$ consists of q^{l-1} vectors in $\Phi^{|\mathcal{S}_i|}$; this means that the probability of a randomly selected row, being bad with respect to $\mathcal{S}_i$, is $q^{-|\mathcal{S}_i|+l-1} \le q^{-s-1+k} < 1/(e\cdot\delta)$. Similarly, if $\mathcal{S}_i \bigcap \mathcal{S}_j = \emptyset$, then the probability of a randomly selected row, being bad with respect to both $\mathcal{S}_i$ and $\mathcal{S}_j$, is $q^{-|\mathcal{S}_i|-|\mathcal{S}_j|+2(l-1)}$. Therefore, when $\mathcal{S}_i \bigcap \mathcal{S}_j = \emptyset$, the events "the row vector is bad with respect to $\mathcal{S}_i$" and "the row vector is bad with respect to $\mathcal{S}_j$" are independent; thus, by Lemma 5 we are guaranteed to have a row vector in Φ^n which is good with respect to every $\mathcal{S}_i$. This vector can now be appended to B_{l-1} to obtain a generator matrix B_l with $(B_l)_{\mathcal{S}_i}$ having rank l for all i. □

Let $\mathbf{x}$ be the integer vector guaranteed by Theorem 3 for $m = k + 2\lceil\log_2\Delta_G\rceil + 1$. Partition the set $\langle\|\mathbf{x}\|\rangle$ into $|V|$ (disjoint) subsets $\mathcal{Q}_u$ with $|\mathcal{Q}_u| = x_u$ and let $\mathcal{S}_u \stackrel{\Delta}{=} \bigcup_{v\in\Gamma(u)}\mathcal{Q}_v$, $u \in V$.

We have $|\mathcal{S}_u| = (A_G\mathbf{x})_u \geq m = k + 2\lceil \log_2 \Delta_G \rceil + 1$ and, therefore, $e \cdot \Delta_G^2 \cdot 2^{-|\mathcal{S}_u|-1} < 2^{-k}$. Furthermore, each $\mathcal{S}_u$ intersects at most $(\Delta_G - 1)^2 + 1$ sets $\mathcal{S}_v$; hence, by Lemma 7 there exists a linear $(\|\mathbf{x}\|, 2^k)$ code over F_2 which is separable with respect to each $\mathcal{S}_u$. For each $u \in V$ let $B_u \triangleq (B)_{\mathcal{Q}_u}$; i.e., B_u is the $k \times x_u$ matrix consisting of all columns of B indexed by $\mathcal{Q}_u$. We now use this to define the encoding and decoding mappings as in §4.2.

4.5. Variations on the memory cost measure. The techniques used in §4.4 can be adapted to obtain file distribution schemes $(G, k) \mapsto \chi(G, k)$ which are close to optimal with respect to other variants of the memory cost measure. For instance, consider the problem where for every instance (G, k), we are looking for a file distribution protocol $\chi(G, k)$ whose memory allocation $\mathbf{x}$ satisfies the following criteria:

(i) The largest component $x_{\max}$ of $\mathbf{x}$ is the smallest possible.

(ii) Among all file distribution protocols that satisfy (i), we take one whose memory size $\|\mathbf{x}\|$ is the smallest.

This variant of our original problem might suit cases where, say, each node in the network graph (as opposed to some "network manager") needs to pay for its own memory. Since the respective decision problem is NP complete, we need to look for approximations to the optimal solution.

Given a network graph $G = (V, E)$ and an integer k, we proceed as follows. Let $\Delta_{\min}$ be $\min_{u \in V} \Delta(u)$. It is clear that $\lceil k/\Delta_{\min} \rceil$ is a lower bound on the largest component of $\mathbf{x}$. Set $\alpha = \lceil k/\Delta_{\min} \rceil / k$ and consider the following linear program:

$$\text{LP}(G; \alpha): \quad \rho_{G;\alpha} = \min \|\mathbf{z}\|, \quad \text{ranging over all rational } \mathbf{z} = [z_u]_{u \in V} \text{ such that } A_G\mathbf{z} \geq \mathbf{1} \quad \text{and} \quad 0 \leq z_u \leq \alpha \quad \text{for every } u \in V. \tag{26}$$

Next, we set $\beta_G = 12e\Delta_G^2$, $m = k + 2\lceil \log_2 \Delta_G \rceil + 1$, and $\ell = m + c_1 \cdot L\{\beta_G, m\}$. Now let $\mathbf{X} = [X_u]_{u \in V}$ be obtained by (5)–(7) and redefine the events $\mathcal{A}_u$ in (22) as

$$\mathcal{A}_u \triangleq \left\{ \begin{array}{c} (A_G\mathbf{X})_u < m \\ \text{or} \\ X_u > \ell \cdot z_u + c_2 \cdot L\{\beta_G, \ell \cdot z_u\} \\ \text{or} \\ (A_H\mathbf{X})_u > \ell \cdot (A_H\mathbf{z})_u + c_2 \cdot L\{\beta_G, \ell \cdot (A_H\mathbf{z})_u\} \end{array} \right\}.$$

By (20) and (21) we have Prob $\{\mathcal{A}_u\} \leq 3/\beta_G < 1/(4e\Delta_G^2)$. Following along the lines of §4.4, the Lovász local lemma now guarantees a file distribution protocol with memory allocation $\mathbf{x}$ whose maximal component $x_{\max}$ and size $\|\mathbf{x}\|$ satisfy both

$$\frac{x_{\max}}{\alpha \cdot k} = 1 + O\left(\max\left\{\frac{\log \Delta_G}{k}; \sqrt{\frac{\log \Delta_G}{k}}\right\}\right)$$

and

$$\frac{\|\mathbf{x}\|}{\rho_{G;\alpha} \cdot k} = 1 + O\left(\max\left\{\frac{\log \Delta_G}{k}; \sqrt{\frac{\log \Delta_G}{k}}\right\}\right).$$

Both $x_{\max}$ and $\|\mathbf{x}\|$ approach their optimal values as k becomes larger than $\log \Delta_G$.

5. The integer programming bound is not tight. In §4 we presented an algorithm for finding a constructive file distribution scheme $(G, k) \mapsto \chi(G, k)$ such that the ratio between the memory size $|\chi(G, k)|$ and $\rho_G \cdot k$ approaches 1 as the ratio $k/\log \Delta_G$ tends to infinity. In this section we present a family of network graphs $\{G_l\}_{l=1}^{\infty}$ for which a file size of $\log \Delta_{G_l}$ is, indeed, a critical point: There exists a sequence of file sizes $k_l \geq \log_2 \Delta_{G_l}$, $l = 1, 2, \ldots$, for which the ratios $M(G_l, k_l)/J(G_l, k_l)$ (and, therefore, $M(G_l, k_l)/(\rho_{G_l} \cdot k_l)$) are bounded away from 1.

For integers m and l, $m \geq l$, define the network graphs $G_{m,l} = (V_{m,l}, E_{m,l})$ as follows: Let U_m be a set of m elements (say, $U_m = \langle m \rangle$) and let $\mathcal{W}_{m,l}$ consist of all subsets of U_m of size l. Set $V_{m,l} = U_m \bigcup \mathcal{W}_{m,l}$ and draw an edge between two nodes $u, v \in V_{m,l}$ in any of the following cases: (i) both u and v are in U_m (i.e., U_m is a clique); (ii) $u \in U_m$, $v \in \mathcal{W}_{m,l}$, and $u \in v$; (iii) $u = v$ (self loops).

First, we verify that $\rho_{G_{m,l}} = m/l$. Let $\mathbf{z} = [z_u]_{u \in V_{m,l}}$ be a nonnegative real vector satisfying $A_{G_{m,l}}\mathbf{z} \geq \mathbf{1}$ and $\|\mathbf{z}\| = \rho_{G_{m,l}}$. Without loss of generality, we can assume that $z_v = 0$ for every $v \in \mathcal{W}_{m,l}$; otherwise, "remove" the quantity z_v from such a node v and add it to the value z_u at some node $u \in \Gamma(v) - \{v\} \subseteq U_m$. This change results in a new nonnegative vector $\tilde{\mathbf{z}}$ with the same norm as $\mathbf{z}$ and which satisfies $A_{G_{m,l}}\tilde{\mathbf{z}} \geq \mathbf{1}$.

Now, rename the nodes of U_m to have $U_m = \langle m \rangle$ and $z_1 \leq z_2 \leq \cdots \leq z_m$. For the node $\langle l \rangle \in \mathcal{W}_{m,l}$ we have

$$\sum_{u=1}^{l} z_u = (A_{G_{m,l}}\mathbf{z})_{\langle l \rangle} \geq 1,$$

and, therefore, $z_u \geq z_l \geq 1/l$ for every node $u \geq l$ in U_m. Hence,

$$\rho_{G_{m,l}} = \|\mathbf{z}\| = \sum_{u=1}^{l} z_u + \sum_{u=l+1}^{m} z_u \geq 1 + \frac{m-1}{l} = \frac{m}{l}.$$

Setting $\mathbf{z} = [z_u]_{u \in V_{m,l}}$ to

$$z_u = \begin{cases} 1/l & \text{if } u \in U_m, \\ 0 & \text{otherwise,} \end{cases}$$

we obtain the equality $\rho_{G_{m,l}} = m/l$. Furthermore,

$$J(G_{m,l}, r \cdot l) = \rho_{G_{m,l}} \cdot r \cdot l = r \cdot m \tag{27}$$

for every positive integer r. A similar analysis for a similar set-covering problem appears also in [7].

In the forthcoming discussion we will be concentrating on two types of network graphs $G_{m,l}$, namely the following:

- $G_l \triangleq G_{2l,l}$, in which case $\rho_{G_l} = 2$ and

$$\log_2 \Delta_{G_l} = \log_2 \left(2l + \binom{2l-1}{l-1}\right) \leq 2l;$$

- $H_l \triangleq G_{2^l,l}$, in which case $\rho_{H_l} = 2^l/l$ and

$$\log_2 \Delta_{H_l} = \log_2 \left(2^l + \binom{2^l-1}{l-1}\right) \leq l^2, \qquad l \geq 2.$$

The proof of the next proposition makes use of the following known lemma.

LEMMA 8 (the sphere-packing or the Hamming bound [12, Chap. 1]). *Let Φ be an alphabet of q elements. There exists an (n, K) code of minimum distance $2t+1$ over Φ only if*

$$K \cdot \sum_{i=0}^{t} \binom{n}{i} (q-1)^i \leq q^n.$$

PROPOSITION 3. *For any fixed positive integer r,*

$$\lim_{l\to\infty} \frac{M(G_l, r\cdot l)}{\rho_{G_l}\cdot r\cdot l} = \lim_{l\to\infty} \frac{M(G_l, r\cdot l)}{J(G_l, r\cdot l)} \geq 1 + \frac{1}{2r}.$$

Proof. Set $k = rl$ for some positive integer r and let $\mathbf{x}$ be the memory allocation of a file distribution protocol χ for (G_l, k) of memory size $|\chi| = \|\mathbf{x}\| = M(G_l, k)$. We assume that $x_v = 0$ for every $v \in \mathcal{W}_{2l,l}$ and that the nodes of $U_{2l} = \langle 2l\rangle$ are renamed to have $x_1 \leq x_2 \leq \cdots \leq x_{2l}$. Letting $h \triangleq x_{l+2}$, we obtain

$$\begin{aligned} M(G_l, k) = \|\mathbf{x}\| &= \sum_{u=1}^{l} x_u + x_{l+1} + \sum_{u=l+2}^{2l} x_u \\ &\geq r\cdot l + r + (l-1)h, \end{aligned} \tag{28}$$

where the inequality follows from $\sum_{u=1}^{l} x_u = (A_{G_l}\mathbf{x})_{\langle l\rangle} \geq k = rl$ which, in turn, implies the inequalities $x_{l+1} \geq x_l \geq r$.

For a file $\mathbf{w} \in F_2^k$, let $\mathbf{c}_\mathbf{w}$ denote the encoded memory contents $[\mathcal{E}_u(\mathbf{w})]_{u=1}^{l+2}$ as determined by the file distribution protocol χ. We now regard the set

$$C \triangleq \{\mathbf{c}_\mathbf{w} \mid \mathbf{w} \in F_2^k\}$$

as an $(l+2, 2^k)$ code over an alphabet of $q \triangleq 2^h$ elements. The code C must be separable with respect to any subset of $\langle l+2\rangle$ of size l, or else there would be nodes in $\mathcal{W}_{2l,l}$ that could not reconstruct the file $\mathbf{w}$. Hence, by Lemma 1, the minimum distance of C is at least 3, which readily implies by Lemma 8 the inequality

$$2^k \cdot (1 + (l+2)(q-1)) \leq q^{l+2}.$$

Substituting $k = rl$ and $q = 2^h$, and noting that $2^h - 1 \geq 2^{h-1}$, we obtain,

$$(l+2)\cdot 2^{rl+h-1} \leq 2^{(l+2)h},$$

or

$$h \geq \left\lceil \frac{\log_2(l+2) + rl - 1}{l+1} \right\rceil = r + \left\lceil \frac{\log_2(l+2) - r - 1}{l+1} \right\rceil.$$

Hence, for fixed r and for sufficiently large l we must have $h \geq r+1$. Combining this lower bound on h with (28) yields the inequality

$$\lim_{l\to\infty} \frac{M(G_l, r\cdot l)}{J(G_l, r\cdot l)} \geq \lim_{l\to\infty} \frac{r(l+1) + (r+1)(l-1)}{2rl} = 1 + \frac{1}{2r}$$

which, with (27), concludes the proof. □

COROLLARY 2. *For* $k_l \triangleq 2l \geq \log_2 \Delta_{G_l}$,

$$\lim_{l\to\infty} \frac{M(G_l, k_l)}{\rho_{G_l} \cdot k_l} = \lim_{l\to\infty} \frac{M(G_l, k_l)}{J(G_l, k_l)} \geq \frac{5}{4}.$$

Corollary 2 exhibits the fact that a file size of $\log \Delta_{G_l}$ is a critical point in the following strong sense: For $k_l = 2l \geq \log_2 \Delta_{G_l}$, the size of any memory allocation for (G_l, k_l) must be bounded away from $\rho_{G_l} \cdot k_l$, not because of a gap between $J(G_l, k_l)$ and $\rho_{G_l} \cdot k_l$, but rather because of a gap between $M(G_l, k_l)$ and $J(G_l, k_l)$.

We point out that, as a counterpart of Proposition 3, we also have

$$\lim_{l\to\infty} \frac{M(G_l, r \cdot l)}{J(G_l, r \cdot l)} \leq 1 + \frac{2}{r},$$

the proof of which is based on the following result.

LEMMA 9 (the Gilbert–Varshamov bound [3, pp. 321–322]). *Let* Φ *be an alphabet of* q *elements and let* n, K, *and* d *be positive integers satisfying*

$$(K-1) \cdot \sum_{i=0}^{d-1} \binom{n}{i} (q-1)^i < q^n.$$

Then there exists an (n, K) *code of minimum distance* d *over* Φ.

Set $n = 2l$, $K = 2^{rl}$, $d = l + 1$, $h + r + 2$, and $q = 2^h$; these values satisfy the equality $K \cdot 2^n \cdot q^{d-1} = q^n$ and, therefore, by Lemmas 1 and 9 there exists a $(2l, 2^{rl})$ code C over F_2^h which is separable with respect to any subset of $\langle 2l \rangle$ of size l. Assign the coordinates (over F_2^h) of C to the nodes $u \in U_{2l}$ of G_l and map the files $\mathbf{w} \in F_2^{rl}$ into distinct codewords of C. This protocol allows every node in G_l to reconstruct any such file $\mathbf{w}$, requiring a total memory size of $2(r+2)l$ (compared to $J(G_l, r \cdot l) = 2rl$).

Remark 5. It can be readily verified that $J(G_{m,l}, k) \geq m - l + k$ for every m, l, and k, and, in particular, $J(G_l, 1) \geq l + 1 \geq \frac{1}{4}\rho_{G_l} \log_2 \Delta_{G_l}$. Hence, any file distribution protocol for (G_l, k) based on segmentation will be at least $\frac{1}{4}\log_2 \Delta_{G_l}$ times larger than the linear programming bound $\rho_{G_l} \cdot k$, *even when* k *tends to infinity* (see Example 1 and Remark 3).

For file sizes k which are smaller than $\log \Delta_G$, one can find examples where the ratio between $M(G, k)$ and $J(G, k)$ is even larger than stated in Proposition 3. We demonstrate this for the network graphs $H_l = G_{2^l,l}$ in the next proposition, making use of the following lemma.

LEMMA 10 (the Plotkin bound [3, p. 315]). *Let* C *be an* (n, K) *code of minimum distance* d *over an alphabet of* q *elements. Then*

$$\frac{1}{q} \leq 1 - \frac{d}{n}\left(1 - \frac{1}{K}\right).$$

PROPOSITION 4.

$$\frac{M(H_l, k)}{J(H_l, k)} \sim \begin{cases} 1 & \text{if } l|k \text{ and } k \geq l^2, \\ l^2/k & \text{if } l|k \text{ and } l \leq k < l^2, \\ k & \text{if } k < l, \end{cases}$$

where $f_l(k) \sim g_l(k)$ *stands for* $\lim_{l\to\infty} f_l(k)/g_l(k) = 1$ *uniformly on* k.

In particular, when $k = l$, the ratio $M(H_l, k)/J(H_l, k)$ is approximately l which, in turn, is at least $\sqrt{\log_2 \Delta_{H_l}}$.

Proof. We distinguish between the three ranges of k stated in the proposition.

Case 1. $k = rl$ for some integer $r \geq l$. By (27) we have $J(H_l, k) = \rho_{H_l} \cdot k = r \cdot 2^l$. In fact, we also have $M(H_l, k) = J(H_l, k)$: Since $r \geq l$, we can construct a $(2^l, 2^{rl})$ generalized Reed–Solomon code C_{RS} over $GF(2^r)$, which is separable with respect to any subset of $\langle 2^l \rangle$ of size l [12, Chaps. 10–11] (compare with §3.3). Assign the coordinates, over $GF(2^r)$, of C_{RS} to the nodes $u \in U_{2^l}$ of H_l and map the files $\mathbf{w} \in F_2^k$ into distinct codewords of C_{RS}. By the separability of C_{RS} every node in H_l can readily reconstruct any file $\mathbf{w} \in F_2^k$.

Case 2. $k = rl$ for some strictly positive integer $r < l$. Let $\mathbf{x}$ be the memory allocation of a file distribution protocol for (H_l, k) of memory size $\|\mathbf{x}\| = M(H_l, k)$. Again, we assume that $x_v = 0$ for $v \in \mathcal{W}_{2^l, l}$ and that the nodes in U_{2^l} are renamed to have $x_1 \leq x_2 \leq \cdots \leq x_{2^l}$. Defining $n \triangleq \lceil 2^l / l \rceil$ and $h \triangleq x_{n+1}$, we obtain

$$M(H_l, k) = \|\mathbf{x}\| \geq \sum_{u=n+1}^{2^l} x_u \geq (2^l - n)h > h \cdot 2^l \cdot \left(1 - \frac{1}{l} - \frac{1}{2^l}\right) \tag{29}$$

(compare with (28)).

To bound h from below, we regard the set

$$C \triangleq \{[\mathcal{E}_u(\mathbf{w})]_{u=1}^n \mid \mathbf{w} \in F_2^k\}$$

as an $(n, 2^k)$ code over an alphabet of $q \triangleq 2^h$ elements. Since C is separable with respect to any subset of $\langle n \rangle$ of size l, its minimum distance must be, by Lemma 1, at least $n - l + 1$. This, in turn, implies by Lemma 10 the inequality

$$\frac{1}{2^h} \leq 1 - \left(1 - \frac{l-1}{n}\right)\left(1 - \frac{1}{2^k}\right) \leq \frac{l-1}{n} + \frac{1}{2^k}. \tag{30}$$

Since $2^k \geq 2^l \geq n$, we thus have

$$\frac{1}{2^h} \leq \frac{l}{n} \leq \frac{l^2}{2^l}$$

or

$$h \geq l - 2\log_2 l.$$

Combining the last inequality with (29) yields

$$M(H_l, k) > 2^l \cdot (l - 2\log_2 l)\left(1 - \frac{1}{l} - \frac{1}{2^l}\right) = l \cdot 2^l \cdot (1 - o(1)), \tag{31}$$

where $o(1)$ stands for an expression, independent of k, which tends to zero as l goes to infinity. Recalling that $J(H_l, k) = r \cdot 2^l$, we thus obtain

$$\frac{M(H_l, k)}{J(H_l, k)} \geq \frac{l}{r} \cdot (1 - o(1)) = \frac{l^2}{k} \cdot (1 - o(1)). \tag{32}$$

The bounds (31) and (32) are definitive up to a multiplying factor of $1 - o(1)$: An upper bound $M(H_l, k) \leq l \cdot 2^l$ is obtained by assigning the coordinates of a $(2^l, 2^{rl})$ generalized Reed–Solomon code over $GF(2^l)$ to the nodes $u \in U_{2^l}$ of H_l; such a code is separable with respect to any subset of $\langle 2^l \rangle$ of size r and, therefore, with respect to any subset of size l.

Case 3. $k < l$. Let n and h be defined as in Case 2. Noting that (29) and (30) still apply, we have

$$\frac{1}{2^h} \leq \frac{l-1}{n} + \frac{1}{2^k} < 2\max\left\{\frac{l^2}{2^l}; \frac{1}{2^k}\right\},$$

i.e.,

$$h \geq \min\{l - \lceil 2\log_2 l\rceil; k\} \geq \left(1 - \frac{\lceil 2\log_2 l\rceil}{l}\right)\cdot k.$$

Combining the last inequality with (29) yields

$$M(H_l, k) \geq k \cdot 2^l \cdot (1 - o(1))\,. \tag{33}$$

Turning to $J(H_l, k)$, for $k < l$ we have $J(H_l, k) \geq 2^l - l + k$ (and by Remark 5 we have, in fact, equality): it is easy to verify that the integer vector $\mathbf{y} = [y_u]_{u\in V_{2^l,l}}$ which is defined by

$$y_u = \begin{cases} 1 & \text{if } u \in U_{2^l} \quad \text{and} \quad u \geq l - k + 1, \\ 0 & \text{otherwise,} \end{cases}$$

satisfies the inequality $A_{H_l}\mathbf{y} \geq k \cdot \mathbf{1}$. Hence, by (33) we obtain

$$\frac{M(H_l, k)}{J(H_l, k)} \geq k \cdot (1 - o(1))\,. \tag{34}$$

Again, the bounds (33) and (34) are definitive as we can simply replicate the file $\mathbf{w}$ into each node $u \in U_{2^l}$ of H_l, requiring a memory size of $k \cdot 2^l$. □

Appendix. The proofs of Propositions 1 and 2 make use of the following lemma.

LEMMA 11. *Let* $\mathbf{a} = [a_u]_{u\in V}$ *and* $\mathbf{p} = [p_u]_{u\in V}$ *be real vectors in* $[0, 1]^{|V|}$ *and let* $\mathbf{Y} = [Y_u]_{u\in V}$ *be a vector of independent random variables over* $\{0, 1\}$ *with* Prob $\{Y_u = 1\} = p_u$. *Then we have the following results*:

(a) *for every* $\delta \in [0, 1)$ *and* $\tau \leq \mathbf{a}\cdot\mathbf{p}$,

$$\text{Prob}\,\{\mathbf{a}\cdot\mathbf{Y} \leq (1-\delta)\tau\} \leq \left(\frac{e^{-\delta}}{(1-\delta)^{1-\delta}}\right)^{\tau};$$

(b) *for every* $\delta \geq 0$ *and* $\tau \geq \mathbf{a}\cdot\mathbf{p}$,

$$\text{Prob}\,\{\mathbf{a}\cdot\mathbf{Y} \geq (1+\delta)\tau\} \leq \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\tau}.$$

Proof. Lemma 11 is proved in [15] and [16]. Part (b) of the lemma appears as is in [15] and for the sake of completeness we include the proof of part (a) here.

For a real random variable Z and constants $\gamma \geq 0$ and b, we have

$$\text{Prob}\,\{Z \leq b\} \leq E(e^{\gamma(b-Z)}),$$

an inequality known as the Chernoff bound. Letting $Z = \mathbf{a}\cdot\mathbf{Y}$ and $b = (1-\delta)\tau$, we obtain, for every $\gamma \geq 0$,

$$\begin{aligned}
&\text{Prob}\,\{\mathbf{a}\cdot\mathbf{Y} \leq (1-\delta)\tau\} \\
&\leq E\left(e^{\gamma((1-\delta)r - \mathbf{a}\cdot\mathbf{Y})}\right) = e^{\gamma(1-\delta)\tau} E\left(\prod_{u\in V} e^{-\gamma a_u Y_u}\right) \\
&= e^{\gamma(1-\delta)\tau} \prod_{u\in V} E\left(e^{-\gamma a_u Y_u}\right) = e^{\gamma(1-\delta)\tau} \prod_{u\in V} \left(1 - p_u + p_u e^{-\gamma a_u}\right).
\end{aligned}$$

Substituting $t = e^{-\gamma}$ yields, for every $t \in (0, 1]$,

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{Y} \leq (1-\delta)\tau\} \leq \alpha(t), \tag{35}$$

where

$$\alpha(t) \triangleq t^{-(1-\delta)\tau} \prod_{u \in V}(1 - p_u(1 - t^{a_u})) \leq t^{-(1-\delta)\tau} \prod_{u \in V} \exp\{-p_u(1 - t^{a_u})\}$$

$$= t^{-(1-\delta)\tau} \exp\left\{-\sum_{u \in V} p_u(1 - t^{a_u})\right\}.$$

Now, for $a_u \in [0, 1]$ and $t \in (0, 1]$ we have $1 - t^{a_u} \geq a_u(1 - t) \geq 0$. Therefore,

$$\alpha(t) \leq t^{-(1-\delta)\tau} \exp\left\{-\sum_{u \in V} a_u p_u(1 - t)\right\} \leq (t^{-(1-\delta)} e^{t-1})^{\tau}$$

which, for $t = 1 - \delta$ becomes

$$\alpha(1 - \delta) \leq \left(\frac{e^{-\delta}}{(1-\delta)^{1-\delta}}\right)^{\tau}.$$

Part (a) is now obtained by substituting $t = 1 - \delta$ in (35). □

Proof of Proposition 1. Let r denote the difference $\ell - m$ and let

$$\tau \triangleq \ell - \ell \cdot \mathbf{a} \cdot \mathbf{z} + \mathbf{a} \cdot \mathbf{p}. \tag{36}$$

Note that $\mathbf{a} \cdot \mathbf{z} \geq 1$ implies $\tau \geq \mathbf{a} \cdot \mathbf{p}$ and that $\mathbf{a} \cdot \mathbf{p} \leq \ell \cdot \mathbf{a} \cdot \mathbf{z}$ implies $\tau \leq \ell$. Also, let $\mathbf{Y}$ be the random variable as in (7). Then,

$$\begin{aligned}\text{Prob}\{\mathbf{a} \cdot \mathbf{X} < m\} &= \text{Prob}\{\mathbf{a} \cdot \mathbf{Y} + \mathbf{a} \cdot \mathbf{s} < \ell - r\} \\ &= \text{Prob}\{\mathbf{a} \cdot \mathbf{Y} < \ell - \ell \cdot \mathbf{a} \cdot \mathbf{z} + \mathbf{a} \cdot \mathbf{p} - r\} \\ &= \text{Prob}\{\mathbf{a} \cdot \mathbf{Y} < \tau - r\},\end{aligned}$$

which readily proves the proposition for $r \geq \tau$. Hence, we assume from now on that $0 \leq r < \tau$.

Apply Lemma 11(a) with τ as in (36) and with $\delta = r/\tau$ (note that, indeed, $\tau \leq \mathbf{a} \cdot \mathbf{p}$). Defining $\sigma \triangleq \tau - r (> 0)$, we thus obtain,

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{Y} < \tau - r\} \leq \left(\frac{e^{-\delta}}{(1-\delta)^{(1-\delta)}}\right)^{\tau} = \left(1 + \frac{r}{\sigma}\right)^{\sigma} e^{-r}.$$

Therefore, to have $\text{Prob}\{\mathbf{a} \cdot \mathbf{X} < m\} \leq \frac{1}{\beta}$ it suffices to require that

$$r - \sigma \cdot \log_e\left(1 + \frac{r}{\sigma}\right) \geq \log_e \beta. \tag{37}$$

Case 1. $r \leq 2\sigma$. It is easy to verify that $\log_e(1 + t) \leq t - (t^2/6)$ whenever $0 \leq t \leq 2$. Hence, (37) is implied by

$$r - \sigma \cdot \left(\frac{r}{\sigma} - \frac{r^2}{6\sigma^2}\right) \geq \log_e \beta$$

which, in turn, is satisfied if $r \geq \sqrt{6\sigma \log_e \beta}$. Recalling that $\sigma = \tau - r \leq \ell - r = m$, inequality (37) is thus implied by

$$r \geq \sqrt{6m \log_e \beta}. \tag{38}$$

Case 2. $r > 2\sigma$. In this range,

$$\sigma \cdot \log_e \left(1 + \frac{r}{\sigma}\right) = r \cdot \log_e \left(\left(1 + \frac{r}{\sigma}\right)^{(\sigma/r)}\right) \leq r \cdot \log_e \sqrt{3}.$$

Hence, inequality (37) is satisfied if

$$r \geq \frac{\log_e \beta}{1 - \log_e \sqrt{3}}. \tag{39}$$

The existence of the constant c_1 is now implied by (38) and (39) (setting $c_1 = 2.5$ will do). □

Proof of Proposition 2. Let $\mathbf{Y}$ be the random variable as in (7) and let r be a positive number. Then

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{X} > E(\mathbf{a} \cdot \mathbf{X}) + r\} = \text{Prob}\{\mathbf{a} \cdot \mathbf{Y} > \mathbf{a} \cdot \mathbf{p} + r\}.$$

Now the proposition holds trivially when $\mathbf{a} \cdot \mathbf{p} = 0$, since, in this case, Prob $\{\mathbf{a} \cdot \mathbf{Y} = 0\} = 1$. Therefore, we assume from now on that $\mathbf{a} \cdot \mathbf{p} > 0$.

Apply Lemma 11(b) with $\tau = \mathbf{a} \cdot \mathbf{p}$ and $\delta = r/(\mathbf{a} \cdot \mathbf{p})$; we obtain

$$\text{Prob}\{\mathbf{a} \cdot \mathbf{Y} > \mathbf{a} \cdot \mathbf{p} + r\} \leq ((1+\delta)^{-(1+\delta)} e^{\delta})^{\tau}.$$

Therefore, to have Prob $\{\mathbf{a} \cdot \mathbf{X} > E(\mathbf{a} \cdot \mathbf{X}) + r\} \leq \frac{1}{\beta}$ it suffices to require that

$$\tau \cdot ((1+\delta)\log_e(1+\delta) - \delta) \geq \log_e \beta. \tag{40}$$

Case 1. $r/(\mathbf{a} \cdot \mathbf{p}) = \delta \leq \frac{3}{2}$. Noting that $(1+t)\log_e(1+t) \geq t + (t^2/4)$ for $0 \leq t \leq \frac{3}{2}$, inequality (40) is satisfied whenever

$$\frac{\delta^2 \tau}{4} = \frac{r^2}{4(\mathbf{a} \cdot \mathbf{p})} \geq \log_e \beta$$

which, with $E(\mathbf{a} \cdot \mathbf{X}) \geq \mathbf{a} \cdot \mathbf{p}$, is implied by

$$r \geq 2\sqrt{E(\mathbf{a} \cdot \mathbf{X}) \cdot \log_e \beta}. \tag{41}$$

Case 2. $r/(\mathbf{a} \cdot \mathbf{p}) = \delta > \frac{3}{2}$. Noting that $t \mapsto (1 + t^{-1})\log_e(1+t)$ is monotonously increasing for $t > 0$, we have

$$\begin{aligned} \tau \cdot ((1+\delta)\log_e(1+\delta) - \delta) &= r \cdot ((1+\delta^{-1})\log_e(1+\delta) - 1) \\ &\overset{\delta \geq \frac{3}{2}}{\geq} r \cdot \left(\left(\frac{5}{3}\log_e \frac{5}{2}\right) - 1\right) > \frac{r}{2}; \end{aligned}$$

i.e., inequality (40) is satisfied if

$$r \geq 2\log_e \beta. \tag{42}$$

The existence of the constant c_2 (such as $c_2 = 2$) is now implied by (41) and (42). □

Acknowledgment. We thank Noga Alon and Cynthia Dwork for the many helpful discussions. We also thank the anonymous referee for the useful comments and the suggestion that we consider other variations on the memory cost measure.

AN OPTIMAL ALGORITHM FOR COMPUTING VISIBILITY IN THE PLANE*

PAUL J. HEFFERNAN† AND JOSEPH S. B. MITCHELL‡

Abstract. The authors give an algorithm to compute the visibility polygon from a point among a set of h pairwise-disjoint polygonal obstacles with a total of n vertices. The algorithm uses $O(n)$ space and runs in optimal time $\Theta(n + h \log h)$, improving the previous upper bound of $O(n \log n)$. A direct consequence of the algorithm is an $O(n + h \log h)$ time algorithm for computing the convex hull of h disjoint simple polygons.

AMS subject classifications. 68U05, 68Q25

1. Introduction.

Let $\mathcal{D}$ be a planar polygonal domain with h holes and n vertices: $\mathcal{D}$ is a connected closed subset of the plane whose boundary consists of a set of n line segments. If $h = 0$, then $\mathcal{D}$ is simply connected and is called a *simple polygon*. If $h > 0$, then $\mathcal{D}$ is multiply connected, and its holes form a set $\mathcal{P} = \{P_1, P_2, \ldots, P_h\}$ of pairwise-disjoint simple polygons in the plane. The *visibility polygon* with respect to a point $s \in \mathcal{D}$ is the locus of all points $q \in \mathcal{D}$ such that $\overline{sq} \subset \mathcal{D}$. The problem of computing the visibility polygon with respect to a given point s is known as the "hidden line removal" problem and is fundamental in computational geometry.

Our Result. We provide an algorithm to compute a visibility polygon in optimal time $\Theta(n + h \log h)$ and space $O(n)$.

Relation to Previous Work. Algorithms to compute the visibility polygon have been known for some time; a clear summary of the many known visibility algorithms is given in Chapter 8 of O'Rourke's book [O'R]. For the case of a simple polygon P, optimal $O(n)$ algorithms have been given by [EA], [Le2], and [JS], who correct a minor error in [EA] and [Le2] while simplifying the algorithm of [Le2]. For the case of a polygon P with holes, straightforward $O(n \log n)$-time algorithms can be based on plane (rotational) sweep about s (as in [Le1] and [SO]) or based on divide-and-conquer (as in [AM]). In fact, by using the linear-time algorithms for simple polygons to compute the visible portion of the boundary of each hole, and then merging these "profiles," one can obtain a simple $O(n \log h)$ algorithm for computing the visibility polygon (see [AM] [AAGHI], and [As]).

There is an $\Omega(n + h \log h)$ lower bound (from sorting) for computing a visibility polygon [O'R], [SO]. Optimal algorithms that achieve this time bound were known for the special case in which the holes P_i are convex [AM], [As] or star-shaped [AM]. The question of whether or not an algorithm exists for the *general* case whose running time is *linear* in n has been a fundamental open problem. No algorithm was previously known with running time $O(n + f(h))$ for *any* function $f(h)$.

We resolve the open question by providing a few different methods, culminating in an optimal algorithm. We outline our approach below. We let $\tau(n)$ denote the time required to triangulate a simple polygon. By Chazelle's recent breakthrough [Ch], we know that

$\tau(n) = O(n)$, and that there are several fast deterministic and randomized algorithms giving bounds of $O(n \log\log n)$ [KKT], [TV] or $O(n \log^* n)$ [CTV], [Se].

(1) We give a very simple $O(n + h^2)$ algorithm that does not require triangulation.
(2) The algorithm of (1) can be transformed into a dynamic insertion procedure with time complexity $O(\tau(n) + h^2 \log \bar{n})$. Here, $\bar{n} \leq n$ is the number of sides of the most complex hole.
(3) We give an $O(\tau(n) + h \log^2 h)$ algorithm that is relatively simple but relies on triangulation.
(4) We give an $O(\tau(n) + h \log(\bar{n} + h))$ algorithm for the special case in which all of the holes are *stabbed* by a line.
(5) We give an $O(\tau(n) + h \log h + h \log\log h \log^2 \bar{n})$ algorithm based on applying the result (4) to $O(\log h)$ classes of obstacles, and then merging the resulting set of visibility polygons.
(6) Finally, we show how the algorithm of (5) can be modified to yield an optimal time bound of $\Theta(n + h \log h)$ for the general problem.
(7) A direct consequence of our algorithm is an $O(n + h \log h)$ time algorithm for computing the convex hull of h disjoint simple polygons.

Concurrent with our work, [BG] have given an $O(\tau(n) + h^{1+\epsilon})$ algorithm for "merging" the h holes (thereby permitting linear-time visibility computation). Most recently, [BC] have tightened the bound of [BG] to $O(\tau(n) + h \log^{1+\epsilon} h)$.

The remainder of this paper is organized as follows. In the next section we reduce the problem of computing a visibility polygon in a polygonal domain to an equivalent problem that we find easier to work with: computing the visibility profile of disjoint polygons. Section 3 establishes notation and basic properties. In §4, we give our $O(n + h^2)$ algorithm. In §5 we describe lid queries, a type of planar point location that is used in all of our subsequent algorithms. We give the dynamic insertion algorithm in §6, the $O(n + h \log^2 h)$ algorithm in §7, and the optimal $\Theta(n + h \log h)$ algorithm in §8. Section 9 is the conclusion.

2. Reduction to the visibility profile problem. Computing the visibility polygon is known to be equivalent to an alternate problem, that of computing the *visibility profile* from below of a collection of polygons, the so-called "lower envelope." Formally, the visibility profile of a collection of polygons can be described as a function $y = f(x)$ defined over the domain $\mathbb{R}$, where $f(x)$ is the minimum y coordinate of a point of the polygons with x coordinate x ($f(x) = \infty$ if no such point exists). For ease of exposition, we concentrate on the problem of computing visibility profiles. We justify this choice by giving a reduction of the visibility polygon problem to the visibility profile problem. Since the visibility polygon of the outer boundary of $\mathcal{D}$ can be computed in $O(n)$ time, and it can be merged with that of the holes in $O(n)$ time, we restrict our attention to the holes.

The basic idea of the reduction is to center a polar coordinate system, (θ, r), at s, and map the holes into an orthogonal coordinate system, (x, y), where, for a point p of a polygonal hole, $y(p) = r(p)$ and $x(p) = \theta(p) + 2\pi k$ (for some integer k). A line of sight in the polar system, a ray with terminus s, corresponds to a vertical line directed upward in the orthogonal system. If a hole does not intersect the ray $\theta = 0$, then we let the integer k equal 0 for all points on the hole. The situation becomes more complicated when a hole intersects $\theta = 0$; we will need to cut such a hole into two pieces. If P is such a hole, let t and t' be the points of $P \cap \{(\theta, r) | \theta = 0\}$ with minimum and maximum r coordinates, respectively. For a point $p \in P$, we define a value $x^*(p)$ to be the amount of winding (*not* taken mod 2π) on $P_{CW}(t, p)$, the clockwise subchain from t to p (note that $x^*(p) = \theta(p) + 2\pi k$, for some k). Lemma 2.1 (below) tells us that if we set $x(p) = x^*(p)$ for points $p \in P_{CW}(t, t')$, and $x(p) = x^*(p) + 2\pi$ for $p \in P_{CW}(t', t)$, then the visibility profile of P in the orthogonal system

over the x range $[0, 2\pi]$ corresponds to the visible portion of P around s. We have replaced P with two polygonal chains; these chains can be made into polygons if we "double" each vertex. While we have not mapped segments into straight-line segments, we have preserved the basic properties necessary to compute visibility. The visibility polygon problem in the polar system has now been reduced to computing the visibility profile from below and outputting the portion over the x range $[0, 2\pi]$.

LEMMA 2.1. *On subchain $P_{CW}(t, t')$, only points p with $x^*(p) \in [0, 2\pi)$ can be visible from s in the polar system, and on $P_{CW}(t', t)$, only points p with $x^*(p) \in (-2\pi, 0]$ can be visible.*

Proof. That no point $p \in P_{CW}(t, t')$ with $x^*(p) \geq 2\pi$ can be visible follows from the simplicity of $P_{CW}(t, t')$ and the fact that t is visible. To complete the proof, it suffices to show that no point $p \in P_{CW}(t', t)$ with $x^*(p) \geq 0$ can be visible. Consider that the sets $\{p \in P_{CW}(t, t') | x^*(p) \geq 0\}$ and $\{p \in P_{CW}(t', t) | x^*(p) \geq 0\}$ consist of collections of polygonal chains, with endpoints on the ray $\theta = 0$. Furthermore, any chain from $P_{CW}(t', t)$ must have its endpoints nested inside those of a chain from $P_{CW}(t, t')$, and therefore cannot see s. □

3. Notation and basic properties. Let $x(p)$ and $y(p)$ denote the x and y coordinates of a point p in the plane, and that $\rho_d(p)$ and $\rho_u(p)$ represent the rays with root p in the direction straight down and straight up, respectively. If a value x represents an x coordinate, then let x^- and x^+ denote the x coordinate values infinitesimally left and right of x, respectively.

We address the problem of computing the visibility profile from below of a collection of disjoint polygons, $\mathcal{P} = \{P_1, \ldots, P_h\}$. A polygon P_i contains two vertices, l_i and r_i, of a minimum and maximum x coordinate, respectively. Since we assume that the observer is at $y = -\infty$, the chain obtained by traversing P_i clockwise from l_i to r_i is completely blocked from the view of the observer by the counterclockwise chain of P_i from l_i to r_i. We therefore use only this lower chain of P_i when computing the visibility profile. In fact, in the remainder of this paper, we assume that $P_1, \ldots, P_h$ are polygonal chains joining their left endpoints (l_i) to their right endpoints (r_i).

For any set $S \subseteq \mathcal{P} = \{P_1, \ldots, P_h\}$, we let $VP(S)$ denote the visibility profile of the chains in S, and we let $VP(S; x)$ denote the point of $VP(S)$ with x coordinate x. We slightly abuse notation and write $VP(i, \ldots, j)$ and $VP(i, \ldots, j; x)$ instead of $VP(\{P_i, \ldots, P_j\})$ and $VP(\{P_i, \ldots, P_j\}; x)$. If $x \notin [x(l_{\min}), x(r_{\max})]$, where $x(l_{\min}) = \min_{i \in S} x(l_i)$ and $x(r_{\max}) = \max_{i \in S} x(r_i)$, then $VP(S; x)$ is the point (x, ∞).

We can think of the profile $VP(S)$ as a piecewise-continuous function over $\mathbb{R}$. The points x of discontinuity of $VP(S)$ are of two types:

- x is a *jump* if $VP(S)$ coincides with the same chain P_i at both x^- and x^+;
- x is a *leap* if $VP(S)$ coincides with distinct chains P_i and P_j ($i \neq j$) at x^- and x^+.

A maximal connected subdomain of $[x(l_{\min}), x(r_{\max})]$ that does not contain a leap in its interior is called a *piece* (the corresponding section of $VP(S)$ over this domain is also called a piece). Since a piece of $VP(S)$ corresponds to a section of a specific chain P_i, we say that P_i *appears* in $VP(S)$ with this piece. These definitions are illustrated in Fig. 1.

A special type of piece is a "piece at infinity"; that is, a maximal x interval over which no member of S appears. Pieces at infinity sometimes create special cases for our algorithms, but ones that can be handled easily.

While we have thought of $VP(S)$ as a function in order to define jumps and leaps, our algorithms will store a visibility profile $VP(S)$ as a polygonal chain. A vertical edge of the chain $VP(S)$ corresponds to a jump or leap. We call the vertical edge of a jump of a profile $VP(i)$ a *lid*, since its interior is disjoint from P_i. We will usually represent a lid by $\overline{ab}$, where $y(a) < y(b)$; therefore, if $\overline{ab}$ is a lid of $VP(i)$, then $VP(i; x(a)) = a$.

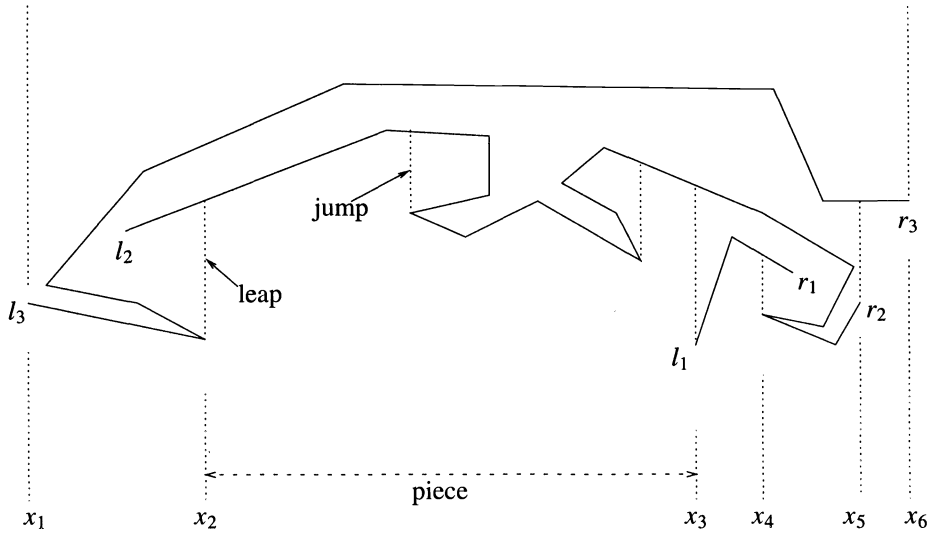

FIG. 1. *Definition of jumps, leaps, and pieces.*

A leap x between chains P_i and P_j can occur in one of two manners. The leap x may be caused by the left or right endpoint of one of the two chains, or it may occur where one profile intersects a lid of the other. These cases are illustrated in Fig. 1: Coordinates x_1 and x_3 correspond to leaps at a left endpoint, x_5 and x_6 correspond to leaps at a right endpoint, and x_2 and x_4 correspond to leaps at lids.

We will often use the expression "p is below q" to indicate that $y(p) < y(q)$. Similar use is made of the terms "above," "left," and "right." We say that profile $VP(S)$ is below profile $VP(S')$ at x coordinate x if $y(VP(S; x^-)) < y(VP(S'; x^-))$ *or* if $y(VP(S; x^+)) < y(VP(S'; x^+))$. It is possible for one but not both of these conditions to hold if one of the profiles has a jump, leap, or endpoint at x.

We will assume without loss of generality that all chains $P_1, \ldots, P_h$ lie completely above the x axis so that the point $p = (x, 0)$ is below $VP(i; x)$ for any x and any profile $VP(i)$.

LEMMA 3.1. *If $x(l_i) < x(l_j)$, then P_j appears at most once in $VP(i, j)$, that is, at most one piece of $VP(i, j)$ is contributed by $VP(j)$.*

Proof. Suppose that $VP(j)$ contributes two pieces to $VP(i, j)$. Let p and q be points of $VP(j)$ on each of the two pieces, with p on the left piece and q on the right piece. Let r be a point of $VP(i)$ that lies on a piece between the two pieces contributed by $VP(j)$, so that $x(p) < x(r) < x(q)$. Refer to Fig. 2.

Now consider the closed Jordan curve given by starting at point $(x(p), 0)$, going up to p, following chain P_j to q, going down to $(x(q), 0)$, and then returning to $(x(p), 0)$ along the x axis. Since point r is on the profile $VP(i, j)$, it must lie in the bounded component defined by this Jordan curve. On the other hand, the leftmost point l_i must lie in the unbounded component defined by the closed curve, since l_i is to the left of l_j. This implies that P_i must cross the Jordan curve, which is a contradiction, since p and q are on the profile, and P_i and P_j do not cross. □

LEMMA 3.2. *If $x(r_j) < x(r_i)$, then P_j appears at most once in $VP(i, j)$.*

Proof. Similar to Lemma 3.1. □

We can now give a full characterization of $VP(i, j)$, for chains P_i and P_j whose x coordinate domains overlap. Assume without loss of generality that $x(l_i) < x(l_j)$. Refer to Fig. 3.

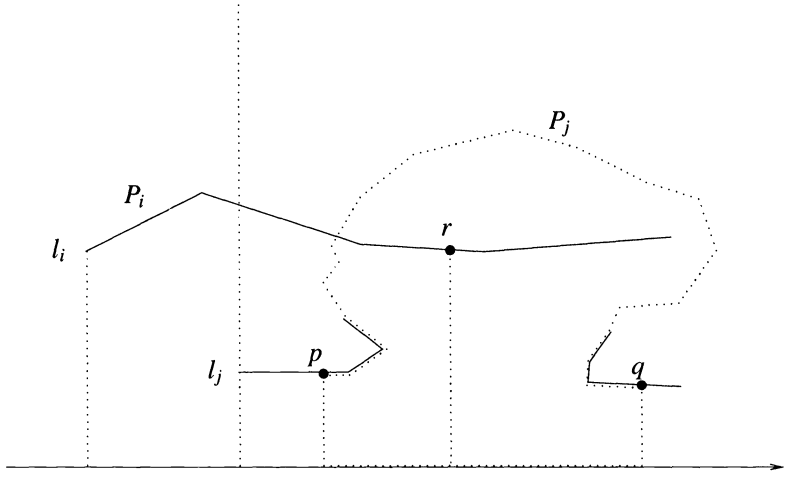

FIG. 2. *Proof of Lemma* 1.

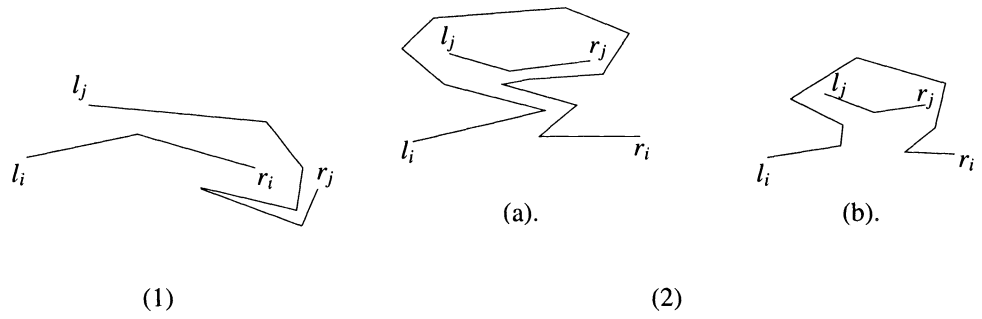

FIG. 3. *Structure of* $VP(i, j)$.

(1) If $x(r_i) < x(r_j)$, then clearly P_i and P_j each appear at least once in $VP(i, j)$, and by the previous two lemmas, each appears at most once. The profile $VP(i, j)$ therefore consists of a piece from $VP(i)$ lying left of a piece from $VP(j)$.

(2) If $x(r_j) < x(r_i)$, there are two possibilities:
   (a) Profile $VP(j)$ may lie completely above $VP(i)$, in which case $VP(i, j)$ is the single piece $VP(i)$.
   (b) If P_j appears once in $VP(i, j)$, then P_i must appear exactly twice, since pieces alternate, and the left- and rightmost pieces are from P_i.

We now state a combinatorial lemma of fundamental importance:

LEMMA 3.3. *The profile* $VP(S)$ *has* $O(|S|)$ *pieces.*

Proof. Consider the (ordered) sequence σ of indices of chains P_i that contribute pieces to $VP(S)$. There are $|S|$ different indices, and by the definition of pieces, no index i can appear twice consecutively in σ. By Lemma 3.1 (or Lemma 3.2), it is not possible to have a subsequence of the form $\ldots, i, \ldots, j, \ldots, i, \ldots, j, \ldots$. This implies that σ is a Davenport–Schinzel sequence of order 2, so its maximum length is given by $\lambda_2(|S|) = 2|S| - 1$. (See [Sh] for background on the theory of Davenport–Schinzel sequences.) □

4. An $O(n + h^2)$ algorithm. We describe now a simple $O(n + h^2)$-time algorithm for computing the visibility profile of a collection of disjoint polygons. Not only is the algorithm

relatively easy to implement, but it resolves the previously open theoretical question of whether or not an algorithm *linear* in n exists. And, even with the other results of this paper and the recent contributions of [BG] and [BC], it remains the only known algorithm linear in n that does not require linear-time triangulation.

Assume that we have indexed the chains $\mathcal{P} = \{P_1, \ldots, P_h\}$ so that their left endpoints $l_1, \ldots, l_h$ are sorted by decreasing x-coordinate. The algorithm simply considers the profiles one-by-one according to this order: step i consists of adding $VP(i)$ to $VP(1, \ldots, i-1)$ to obtain $VP(1, \ldots, i)$. The time to update the profile when we insert $VP(i)$ is linear in h and the size of P_i, implying the claimed overall time bound.

The algorithm maintains a sorted list of the leaps, $x_1, \ldots, x_K$, of the current profile $VP(1, \ldots, i-1)$. Each leap x_k in the list stores a pointer to the point $VP(1, \ldots, i-1; x_k)$. To add $VP(i)$ to the profile, we traverse $VP(i)$ to place pointers on the points $VP(i; x_1), \ldots, VP(i; x_K)$. Now for each leap x_k, we determine whether $VP(i)$ is below $VP(1, \ldots, i-1)$ at this x coordinate. (Recall that this means comparing $VP(i; x_k^-)$ to $VP(1, \ldots, i-1; x_k^-)$ and $VP(i; x_k^+)$ to $VP(1, \ldots, i-1; x_k^+)$.) If $VP(i)$ is below, we have identified a piece of $VP(i)$ in $VP(1, \ldots, i)$; we simultaneously traverse $VP(i)$ and $VP(1, \ldots, i-1)$ to the left, maintaining our pointers at the same approximate x coordinate, until we reach the x coordinate x_l, where $VP(i)$ is no longer below $VP(1, \ldots, i-1)$; x_l is the left endpoint of this piece of $VP(i)$, and consequently is a leap in $VP(1, \ldots, i)$. Similarly, we simultaneously traverse $VP(i)$ and $VP(1, \ldots, i-1)$ to the right to obtain the right endpoint, x_r. The portion of $VP(1, \ldots, i-1)$ between x_l and x_r is replaced by the corresponding portion of $VP(i)$, and the leaps at x_l and x_r are incorporated into the list, along with pointers to $VP(1, \ldots, i; x_l)$ and $VP(1, \ldots, i; x_r)$. Of course, the interval $[x_l, x_r]$ may contain leaps of $VP(1, \ldots, i-1)$ other than x_k, but this poses no difficulty to the algorithm. The special case of $x(r_i) < \min\{x(l_1), \ldots, x(l_{i-1})\}$ is handled without problem. The following lemma establishes that the new profile obtained in this manner is in fact $VP(1, \ldots, i)$, and that the updated list of leaps is the list for $VP(1, \ldots, i)$.

LEMMA 4.1. *Assume* $x(r_i) \geq \min\{x(l_1), \ldots, x(l_{i-1})\}$. *Each piece of* $VP(i)$ *in* $VP(1, \ldots, i)$ *must cover a leap of* $VP(1, \ldots, i-1)$, *that is, for each piece contributed by* $VP(i)$, *there exists a leap* x *of* $VP(1, \ldots, i-1)$ *such that* $VP(1, \ldots, i; x) \in VP(i)$.

Proof. Suppose we have a piece $[x_l, x_r]$ of $VP(i)$ in $VP(1, \ldots, i)$ that lies between consecutive leaps x_k and x_{k+1} of $VP(1, \ldots, i-1)$. Since $[x_k, x_{k+1}]$ is a single piece of $VP(1, \ldots, i-1)$, the points $VP(1, \ldots, i-1; x_k^+)$ and $VP(1, \ldots, i-1; x_{k+1}^-)$ lie on the same profile $VP(j)$. We have that $VP(j)$ lies below $VP(i)$ at x_k^+ and x_{k+1}^-, and that $VP(i)$ lies below $VP(j)$ at x_l^+, where $x_k < x_l < x_{k+1}$. But this contradicts Lemma 3.1, since $x(l_i) < x(l_j)$, by our ordering of the polygonal chains. □

We now analyze the time complexity of the algorithm. The initial indexing of the polygonal chains requires time $O(h \log h)$, to sort the left endpoints of the chains. Adding $VP(i)$ to $VP(1, \ldots, i-1)$ requires that we traverse $VP(i)$ twice—once to place pointers to $VP(i; x_1), \ldots, VP(i; x_K)$, and once during the simultaneous traversals of $VP(i)$ and $VP(1, \ldots, i-1)$. The time spent in all steps except the traversing of $VP(1, \ldots, i-1)$ is $O(|P_i| + h)$, implying a total of $O(n + h^2)$ over all steps. The simultaneous traversals of the updating step require that we traverse sections of $VP(1, \ldots, i-1)$, which consists of profiles that have already been processed. However, the portions we traverse are deleted from the current profile $VP(1, \ldots, i)$ and are never traversed again. Thus, the entire algorithm runs in time $O(n + h^2)$.

5. Lid queries. The algorithms that follow all make use of a logarithmic-time query that we call a *lid query*. A lid query is based on planar point location, a familiar notion in computational geometry. Basically, given a chain P_i and a point in the plane p, a lid query of

p on P_i asks where p is with respect to P_i. The result of such a query will give us important information about $VP(\{P_i, c\})$ for any chain c containing p such that $c \cap P_i = \emptyset$. We now describe lid queries in detail.

Consider a lid $\overline{ab}$ of $VP(i)$, the visibility profile of chain P_i. The lid $\overline{ab}$ and the subchain of P_i between a and b form a simple polygon, which we call a *pocket*, such that all points in the interior of the pocket are nonvisible from below. If a point p in the pocket lies on a chain c that does not intersect P_i, then c can be below $VP(i)$ only if it crosses $\overline{ab}$. Since $\overline{ab}$ is on $VP(i)$, crossing $\overline{ab}$ is also a sufficient condition for c to be below $VP(i)$ somewhere. We now state formally the information that we want from a *lid query*.

DEFINITION 5.1 (lid query). *For a point p not on P_i, exactly one of the following is true:*

1. *p is below $VP(i)$,*
2. *p is in a pocket of $VP(i)$,*
3. *p lies in the region above the simple, infinite chain $c = \rho_u(l_i) \cup P_i \cup \rho_u(r_i)$.*

If (1) *is true, a lid query of p on P_i returns $VP(i; x(p))$. (In Fig. 4, for example, a query on p_1 returns $VP(i; x(p_1))$.) If* 2 *is true, the lid query returns the lid $\overline{ab}$ that defines the pocket (e.g., a query on p_2 in the figure returns lid $\overline{a_2b_2}$). If* 3 *is true (as it is for p_3 in the figure), then the rays $\rho_u(l_i)$ and $\rho_u(r_i)$ together have the property that we desire in the lids, so the lid query returns them.*

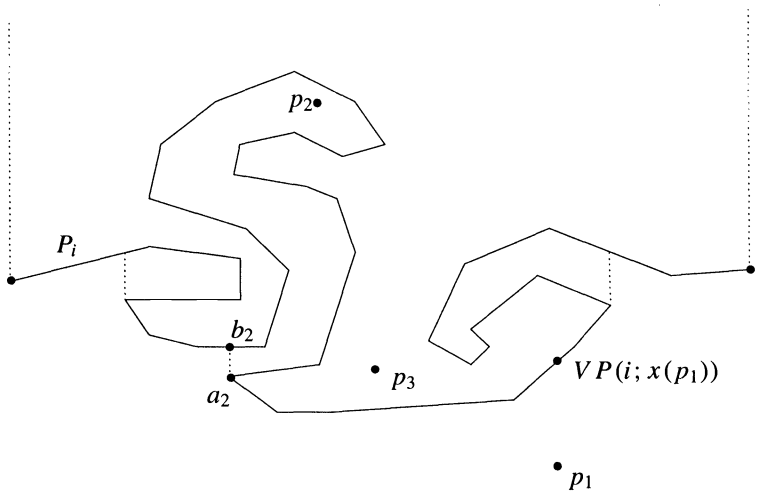

FIG. 4. *Examples of lid queries.*

Lid queries will be used often in our algorithm to determine quickly if and where a chain c containing a point p lies below the current profile $VP(S)$. Often, we will try to add a chain c to $VP(S)$ to form $VP(S \cup \{c\})$, knowing only that c contains a certain point p and that c and S are disjoint. We formalize this notion by defining the *lid property*.

DEFINITION 5.2 (lid property). *An x coordinate x has the lid property for point p and profile $VP(S)$ if, for any chain c that contains p and is disjoint from S, $VP(\{c\})$ is below $VP(S)$ somewhere only if $VP(\{c\})$ is below $VP(S)$ at x.*

When a lid query of a point p on a chain P_i returns a lid $\overline{ab}$, the x coordinate $x(a)$ satisfies the lid property for p and $VP(i)$. Our algorithm will produce, through the use of lid queries, x coordinates that satisfy the lid property for the current profile $VP(S)$; typically, these will be the x coordinates of either leaps or jumps of $VP(S)$.

Lid queries are basically planar point location. We first obtain the vertical visibility map of P_i (in $O(n)$ time for all chains, by [Ch]). Then P_i can be preprocessed to return the trapezoid of the map containing a query point in logarithmic time (by [Ki] or [EGSt], for example); this is sufficient to answer the query for case 1. For cases 2 and 3, we need to do some more work. Consider the dual graph of the trapezoidal decomposition, with the edge corresponding to the decomposition ray $\rho_u(r_i)$ deleted. This graph is a tree, and the trapezoids that comprise any given pocket correspond to a subtree. Each lid of $VP(i)$ corresponds to an edge in the tree that separates the subtree of the adjacent pocket from the rest of the tree. For each lid (including $\rho_u(l_i)$), we begin at the corresponding edge in the dual graph, and traverse through the subtree of the pocket, assigning to each node a pointer to the lid. Therefore, if the planar point location query encounters a trapezoid with a pointer to a lid, the lid query returns that lid. We see that the chains $P_1, \ldots, P_h$ can be preprocessed in $O(n)$ total time to handle lid queries in time $O(\log \bar{n})$, where $\bar{n}$ is the number of vertices on the largest of $P_1, \ldots, P_h$.

At this point we mention that our algorithms require a careful representation of a current profile $VP(S)$. We said earlier that $VP(S)$ is stored as a polygonal chain. It is important that this be done by adding pointers (along with necessary added vertices b at the top of leaps) to the original profiles $VP(i)$, $P_i \in S$. Therefore, to traverse a section of $VP(S)$, we begin by traversing a section of the appropriate profile $VP(i)$, and, upon encountering a leap at x coordinate x, leap to the new appropriate profile $VP(j)$ by means of a pointer from $VP(i; x)$ to $VP(j; x)$. We take care to mention the necessity of this representation of $VP(S)$, because our procedures will sometimes ask for a point $VP(S; x)$ by performing a lid query of $p = (x, 0)$ on the appropriate profile $VP(i)$. Since the lid query preprocessing is done on each original chain P_i, and we cannot afford to do preprocessing on an intermediate, composite profile like $VP(S)$, it is imperative that we can use a lid query on an individual chain P_i to find a point $VP(S; x)$.

6. A dynamic insertion algorithm. Through the use of lid queries, we can transform the $O(n + h^2)$ algorithm described in an earlier section into a dynamic insertion algorithm. That algorithm was not on-line, because it was necessary to order the chains in decreasing x coordinate order of their left endpoints. This ordering led to Lemma 4.1, which stated that when adding $VP(i)$ to $VP(1, \ldots, i-1)$, each piece of $VP(i)$ in $VP(1, \ldots, i)$ must cover a leap of $VP(1, \ldots, i-1)$. This meant that to construct $VP(1, \ldots, i)$, it was sufficient to compare $VP(i)$ and $VP(1, \ldots, i-1)$ only at the leaps of $VP(1, \ldots, i-1)$.

In the dynamic insertion version of the problem, we are given the chains in arbitrary order, and must compute the visibility profile of each intermediate collection of chains. Since the chains are not received in any particular order, it is possible that $VP(i)$ contributes a piece to $VP(1, \ldots, i)$ that covers no leap of $VP(1, \ldots, i-1)$. Such a piece is contained by a piece of $VP(1, \ldots, i-1)$. Therefore, the dynamic algorithm consists of checking, for each piece of $VP(1, \ldots, i-1)$, whether or not $VP(i)$ appears somewhere below it. This check can be made with the help of a lid query, as follows.

Suppose we have a piece of $VP(1, \ldots, i-1)$ that is contributed by $VP(j)$ and has left and right endpoints l and r. We first compare $VP(i)$ to $VP(j)$ at the endpoints of the piece; that is, we check if $VP(i; x(l))$ is below l or $VP(i; x(r))$ is below r. If $VP(i)$ is below at neither endpoint, then we use a lid query of the point $VP(i; x(l))$ on chain P_j. Recall that the lid $\overline{ab}$ returned by the query has the lid property, meaning that $VP(i)$ must be below $VP(j)$ at $x(a)$ if it is below anywhere. If the lid $\overline{ab}$ returned by the query has $x(l) \leq x(a) \leq x(r)$, then we compare $VP(i; x(a))$ with $\overline{ab}$. If $x(a) \notin [x(l), x(r)]$, then $VP(i)$ cannot be below $VP(j)$ anywhere in the interval $[x(l), x(r)]$, since it is not below at the endpoints of the interval, and $VP(i, j)$ has at most three pieces (Lemma 3.1). In this manner, we find a point of $VP(i)$ that is below $VP(j)$ over the interval $[x(l), x(r)]$, if one exists; we can traverse

$VP(i)$ and $VP(j)$ simultaneously to the left and to the right in order to update the profile over this interval.

We now analyze the time required to add a new chain to the current profile. The new chain P_i must be preprocessed for lid queries, in case it is queried in future steps. We must also traverse $VP(i)$ to find $VP(i; x)$ for every leap x of $VP(1, \ldots, i-1)$. There are $O(h)$ pieces of $VP(1, \ldots, i-1)$, and we may have to perform a lid query for each one. Our total time is

$$O(|P_i| + k_{i-1} + h \log \bar{n}),$$

where k_{i-1} is the number of vertices of $VP(1, \ldots, i-1)$ deleted from $VP(1, \ldots, i)$, and $\bar{n}$ is the size of the largest chain. Over h chains with n total vertices, with no chain having more than $\bar{n}$ vertices, the algorithm requires $O(n + h^2 \log \bar{n})$ time. This procedure is slightly more expensive than the $O(n + h^2)$ algorithm on which it is based, since, when we compare the new profile $VP(i)$ to a particular piece of $VP(1, \ldots, i-1)$, we must perform a lid query of $O(\log \bar{n})$ time, rather than a simple constant time check.

THEOREM 6.1. *There exists an on-line insertion algorithm for constructing the visibility profile of h chains with n vertices and $\bar{n}$ vertices on the largest chain, with time complexity $O(n + h^2 \log \bar{n})$. The insertion of an individual chain P can be performed in time $O(|P| + k + h \log \bar{n})$, where k is the size of the change.*

Our result compares favorably with the naive solution to this problem: one could perform on-line updates by simultaneously traversing $VP(i)$ and $VP(1, \ldots, i-1)$ between $x(l_i)$ and $x(r_i)$, but this approach requires $O(hn)$ time in the worst case. A slightly more sophisticated approach is to follow the algorithm that is outlined above, but, when the case of $VP(i)$ being above $VP(j)$ at both endpoints of a piece occurs, to use a simultaneous traversal instead of a lid query to update the piece. However, this approach, too, can experience worst-case performance of $O(nh)$.

7. An $O(n + h \log^2 h)$ algorithm. Using the notion of a lid query, we will describe our first $o(h^2)$ algorithm. This algorithm adds the chains one at a time to the current profile, basically by performing binary search on the profile. The algorithm is simple in all respects except the use of lid queries, and it introduces some ideas that will be used in the more sophisticated optimal algorithm.

We begin by indexing the chains $\mathcal{P} = \{P_1, \ldots, P_h\}$ so that their endpoints $l_1, \ldots, l_h$ are sorted by increasing x coordinate. (This is in contrast to the $O(n+h^2)$ algorithm, in which we wanted decreasing order.) By Lemma 3.1, a chain P_i can appear at most once in $VP(1, \ldots, i)$. In trying to add $VP(i)$ to $VP(1, \ldots, i-1)$, we will search for this solitary appearance.

The algorithm maintains the pieces of the current profile, $VP(1, \ldots, i-1)$, in a search tree. To add $VP(i)$, we perform a search. A search step at a node of the tree consists of comparing $VP(i)$ to the piece of $VP(1, \ldots, i-1)$ at that node; suppose this piece is contributed by $VP(j)$, and has endpoints l and r. If $VP(i; x(l))$ is below l, then we have found the solitary piece of $VP(i)$ in $VP(1, \ldots, i-1)$, and we can construct $VP(1, \ldots, i)$ by simultaneously traversing $VP(i)$ and $VP(1, \ldots, i-1)$ to the left and to the right. If $VP(i; x(l))$ is above l, we must determine if $VP(i)$'s contribution to $VP(1, \ldots, i)$ lies left or right of l. At this point, we perform a lid query of $VP(i; x(l))$ on P_j. If the query returns a lid $\overline{ab}$, we do the following: (1) if $x(a) < x(l)$, we continue our search on the left branch of the node, (2) if $x(r) < x(a)$, we continue on the right branch, (3) if $x(l) < x(a) < x(r)$, we simply check if $VP(i)$ is below a or crosses $\overline{ab}$. If the lid query tells us that $VP(i; x(l))$ lies in the region above $c = \rho_u(l_j) \cup P_j \cup \rho_u(r_j)$, we take the right branch, since we know that P_i does not extend as far left as $\rho_u(l_j)$. The fact that $VP(i)$ contributes at most one piece to

$VP(i, j)$ guarantees that the above search procedure will find a point of $VP(i)$ that is below $VP(1, \ldots, i-1)$, if one exists.

The procedure requires that at each step, we locate the point of $VP(i)$ with a given x coordinate. We must exhibit some care in doing this, since a naïve traversing scheme could result in some sections being covered many times, and therefore must be avoided. Instead of traversing $VP(i)$, we compute a point $VP(i, x)$ by performing a lid query of $(x, 0)$ on P_i.

To analyze the complexity of the rest of the procedure, we note that, since $VP(1, \ldots, i-1)$ has $O(h)$ pieces, the search consists of $O(\log h)$ steps. The search tree can be maintained in logarithmic time per insertion and deletion. Each search step requires a constant number of lid queries, which has time complexity $O(\log \bar{n})$, where $\bar{n}$ is the size of the largest chain of $\mathcal{P}$. Therefore the search to add $VP(i)$ requires time $O(\log h \log \bar{n})$. Of course, once we find a visible point of $VP(i)$, we must delete some of $VP(1, \ldots, i-1)$ in order to form $VP(1, \ldots, i)$, but this is $O(n)$ over all steps since no portion is deleted more than once.

By the above, the algorithm runs in time $O(n + h \log h \log \bar{n})$. We can rewrite this as $O(n + h \log^2 h)$ by the following argument. If $h = o(n/\log^2 n)$, then the entire time complexity becomes $O(n)$. If $h = \Omega(n/\log^2 n)$, then $\log h = \Omega(\log n)$, so $\log \bar{n} = O(\log h)$.

8. An optimal algorithm. We turn our attention now to a different algorithm, one which attains the optimal $\Theta(n + h \log h)$ time bound. We will describe first an algorithm that runs in time $O(n + h \log h + h \log \log h \log^2 \bar{n})$, and will then modify it to perform in optimal time.

We begin by sorting the x coordinates of the endpoints of $P_1, \ldots, P_h$, thereby obtaining a list $x_1, \ldots, x_{2h}$. If $\mathcal{P} = \{P_1, \ldots, P_h\}$, define S_1 to be the chains of $\mathcal{P}$ stabbed by the vertical line $x = x_h$. Define S_2 to be the chains of $\mathcal{P} \setminus S_1$ stabbed by $x = x_{\lfloor h/2 \rfloor}$ or $x = x_{\lfloor 3h/2 \rfloor}$. Continuing in this way, we obtain a partitioning of $\mathcal{P}$ into a class of subsets $S_1, \ldots, S_{\lceil \log 2h \rceil}$. Below, we will show that the visibility profile of a set S' of h' polygonal chains stabbed by a vertical line can be computed in time $O(n' + h' \log \bar{n}')$, where n' is the total number of vertices in S', and $\bar{n}'$ is the number of vertices on the largest chain in S'. Therefore $VP(S_1), \ldots, VP(S_{\lceil \log 2h \rceil})$ can be computed in time $O(n + h \log \bar{n})$, where $\bar{n}$ is the size of the largest chain in $\mathcal{P} = \{P_1, \ldots, P_h\}$. We will also show how to merge $VP(\mathcal{S}')$ with $VP(\mathcal{S}'')$ in $O(\bar{h} \log^2 \bar{n})$ time, for two subsets $\mathcal{S}'$ and $\mathcal{S}''$ of $\{S_1, \ldots, S_{\lceil \log 2h \rceil}\}$, with $\max\{i \mid S_i \in \mathcal{S}'\} < \min\{j \mid S_j \in \mathcal{S}''\}$, where $\bar{h}$ is the total number of polygonal chains in the sets comprising $\mathcal{S}'$ and $\mathcal{S}''$. This allows one to compute $VP(\mathcal{P})$ by recursively computing $VP(S_1 \cup \cdots \cup S_{\lceil (\log 2h)/2 \rceil})$ and $VP(S_{\lceil (\log 2h)/2 \rceil + 1} \cup \cdots \cup S_{\lceil \log 2h \rceil})$ and then merging them. Each step of the recursion requires time $O(h \log^2 \bar{n})$, and the recursion has depth $O(\log \log h)$, giving a total algorithm run-time of $O(n + h \log h + h \log \log h \log^2 \bar{n})$.

8.1. The profile for a set of stabbed polygons. We describe here the procedure for computing the visibility profile of a collection of polygonal chains $P_1, \ldots, P_h$, all of which are stabbed by a vertical line ℓ, which we take, without loss of generality, to be the y axis. We will describe a procedure for computing the portion of $VP(1, \ldots, h)$ lying to the left of ℓ; the portion lying to the right can be computed by a symmetric procedure. In this section, the notation $VP(S)$ denotes only the portion of the visibility profile of S lying to the left of ℓ, unless otherwise stated. We assume that, as a preprocessing step, we have computed $VP(i)$ and preprocessed P_i for lid queries for each chain P_i. For convenience, we will suppose that each chain P_i is oriented from its left endpoint l_i to its right endpoint r_i; we will refer to points as *preceding* or *succeeding* each other on P_i. For a chain P_i, let its *bottom point*, denoted b_i, be the point of $P \cap \ell$ with the least y coordinate; assume that we have sorted the bottom points by the y coordinate, and indexed the chains $P_1, \ldots, P_h$ so that the corresponding bottom points $b_1, \ldots, b_h$ are listed by increasing y coordinate. Note that no point of P_i succeeding b_i can lie on $VP(i)$, so it is sufficient to replace P_i by the subchain from l_i to b_i. Our procedure will inductively compute $VP(1, \ldots, k)$ by merging $VP(1, \ldots, k-1)$ with $VP(k)$. If the chains

$P_1, \ldots, P_h$ contain a total of n vertices, and no chain contains more than $\bar{n}$ vertices, then the procedure runs in time $O(n + h \log \bar{n} + h \log h)$.

The profile $VP(1, \ldots, k-1)$ consists of m pieces, which we denote, in left-to-right order, as $\pi_1, \ldots, \pi_m$. The function σ maps a piece to its chain, so that $VP(\sigma(j))$ contributes the piece π_j. Let $l(j)$ and $r(j)$ represent the left and right endpoints of the piece π_j; therefore π_j covers the x interval $[x(l(j)), x(r(j))]$.

The basic step is adding $VP(k)$ to $VP(1, \ldots, k-1)$. We will take advantage of the fact that $VP(k)$ can contribute at most one piece to $VP(1, \ldots, k)$.

LEMMA 8.1. *The chain $VP(k)$ contributes at most one piece to $VP(1, \ldots, k)$ (which is the portion of the profile lying left of the vertical stabber).*

Proof. If $k = 1$ the claim is trivial. For $k \geq 2$, it suffices to show that $VP(k)$ contributes at most one piece to the portion of $VP(j, k)$ lying left of ℓ, for all $j < k$. Because $VP(j; 0)$ is below $VP(k; 0)$, this is true by the proof of Lemma 3.3, which states that $VP(j, k)$ has at most three pieces. □

Since $VP(k)$ can contribute at most one piece, it suffices to find a single x coordinate x_k with the lid property for a point $q \in VP(k)$ and profile $VP(1, \ldots, k-1)$. The profile $VP(1, \ldots, k-1)$ consists of $O(h)$ pieces (by Lemma 3.3, since $k - 1 < h$). A natural approach would be to perform a binary search on the pieces of $VP(1, \ldots, k-1)$, asking at each step whether the desired value x_k lies left or right of the given piece. We must be able to determine efficiently whether x_k lies left or right. To do this, we must construct some structure on top of the input chains. We begin by defining, for a point $q \in VP(i)$, a *top point.*

DEFINITION 8.2. *Consider a point $q \in P_i$ on $VP(i)$. Define the* top point *of q, $t(q)$, as the first point of $P_i \cap \ell$ encountered when traversing P_i forwards from starting point q.*

As a preprocessing step, we assign to each vertex v of a profile $VP(i)$ a pointer to $t(v)$. This preprocessing can be done in linear time by traversing $VP(i)$ and P_i for each i.

We now develop a theory of *tunnels* for a chain P_i (refer to Fig. 5). Given P_i, we can construct a closed, simple curve by traversing P_i from l_i to b_i, going from b_i straight down to the origin, along the x axis, and then straight up to l_i. Denote by R_i the bounded region formed by this curve, and define R_i' to be the connected component of $R_i \cap \{(x, y) | x < 0\}$ that contains point l_i (on its boundary). We call a connected component of $R_i \setminus R_i'$ a *tunnel*, and the common boundary of R_i' with a tunnel is the *opening* of that tunnel; an opening is necessarily an interval of the y-axis. No point in the interior of a tunnel is visible from below, in the sense that a point in a tunnel of P_i is above $VP(i; x(p))$.

The intersection points of P_i with the y axis divide the y axis into a list of intervals, which we denote I_i, and can compute in linear time using Jordan sorting [HMRT]. For each interval that lies inside R_i, assign a pointer to the opening of the tunnel that contains it. For each interval outside R_i, assign a pointer to the "outside opening", namely, the interval from the highest point of $P_i \cap \ell$ to infinity. In Fig. 5, the pointers are shown as dotted lines. When we speak of the opening of a point $p = (0, y(p)) \notin P_i$ with respect to the chain P_i, we mean the opening assigned to the interval of I_i containing p. We now give the lemma that forms the basis of the binary search approach.

LEMMA 8.3. *Let π_i be a piece of $VP(1, \ldots, k-1)$, and let b_k be the bottom point of P_k. If the opening of b_k with respect to $P_{\sigma(i)}$ lies above (below) $t(l(i))$, then $VP(k)$ cannot appear in $VP(1, \ldots, k)$ to the right (left) of $x(l(i))$ unless it appears at $x(l(i))$.*

Proof. Construct a closed, simple curve c by tracing $P_{\sigma(i)}$ from $l(i)$ to $t(l(i))$, going straight down to the origin, along the x axis, and straight up to $l(i)$. Let B denote the bounded region of the plane formed by c.

Suppose the opening of b_k with respect to $P_{\sigma(i)}$ is below $t(l(i))$ (as in Fig. 6(a)). This means that p is inside $R_{\sigma(i)}$, and therefore in a tunnel (perhaps on the opening of the tunnel). The

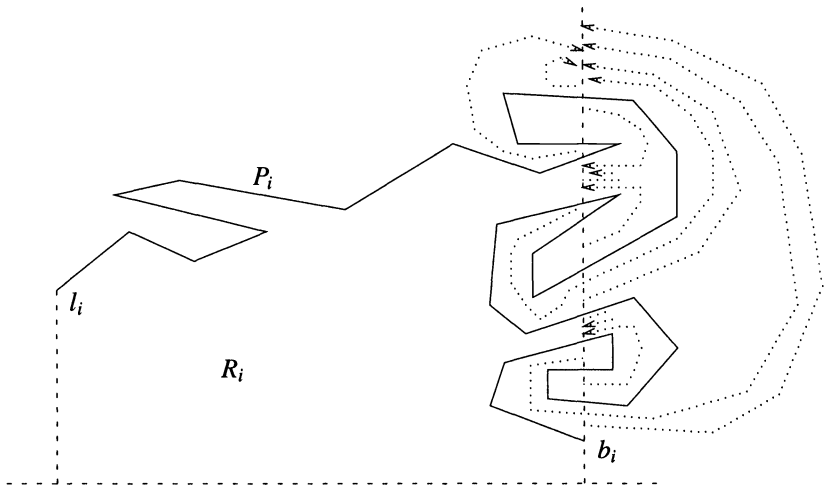

FIG. 5. *Examples of tunnels, and pointers to openings.*

chain P_k must have a point on the opening of the tunnel in order to be visible in $VP(\sigma(i), k)$, so assume we have such a point p. If P_k has a visible point of $VP(\sigma(i), k)$ lying left of $l(i)$, then it must leave the bounded region B. In order to leave B, starting at p and not intersecting $P_{\sigma(i)}$, the chain P_k must enter a tunnel with opening below $t(l(i))$, or cross $\rho_d(l(i))$. The portion of P_k in a tunnel is not visible, and P_k can exit a tunnel only through its opening, thereby re-entering B. If P_k crosses $\rho_d(l(i))$, then $VP(k)$ is below $VP(\sigma(i))$ at $x(l(i))$.

Suppose the opening is above $t(l(i))$. If b_k is outside of $R_{\sigma(i)}$, then P_k can be visible in $VP(\sigma(i), k)$ to the right of $x(l(i))$ only by crossing $\rho_d(l(i))$. If b_k is inside $R_{\sigma(i)}$ (as in Fig. 6(b)), then it is in a tunnel, and P_k can be visible only if it has point p on the opening of the tunnel. We assume P_k has a point p on this opening. To be visible in $VP(\sigma(i), k)$ to the right of $x(l(i))$, P_k must enter the bounded region B. To enter B from starting point p, P_k must enter a tunnel with opening above $t(l(i))$, or cross $\rho_d(l(i))$. While in such a tunnel, P_k is not visible, and it can exit the tunnel only through the opening above $t(l(i))$. If P_k crosses $\rho_d(l(i))$, then $VP(k)$ is below $VP(\sigma(i))$ at $x(l(i))$. □

We now describe the binary search on the pieces of $VP(1, \ldots, k-1)$ that finds x_k. At a step of the search, we have a piece π_i, and we determine the opening of b_k with respect to $P_{\sigma(i)}$; if it lies above (below) $t(l(i))$, we look for x_k to the left (right) of the piece. We compute the opening of b_k with respect to $P_{\sigma(i)}$ by maintaining, for $j = 1, \ldots, h$, the list of intervals I_j. We maintain a pointer to this list, initialized to the lowest interval, and updated after a query of b_k to the interval containing b_k. When given a new point $b_{k'}$ to query, we simply traverse through the list, starting from the pointer. In the example in Fig. 7, b' has an opening with respect to P below that of b, even though b' is above b; this is why each interval of I_j stores a pointer to its opening. Since $b_1, \ldots, b_h$ and the intervals of I_j each are ordered by increasing y coordinate, a single forwards traversal through I_j for $j = 1, \ldots, h$ allows us to perform all of these queries.

The binary search ends by isolating one piece π_i with the property that $VP(k)$ cannot appear left of $x(l(i))$ or right of $x(l(i+1)) = x(r(i))$ without appearing in the interval $[x(l(i)), x(r(i))]$. We look for a value x_k in this interval with the lid property, by performing a lid query of b_k on $P_{\sigma(i)}$. Since b_k is above $b_{\sigma(i)}$, the query will return a lid $\overline{ab}$. If the x coordinate of this lid, $x(a)$, lies in the interval $[x(l(i)), x(r(i))]$, then we set $x_k \leftarrow x(a)$, and if $x(a) <$

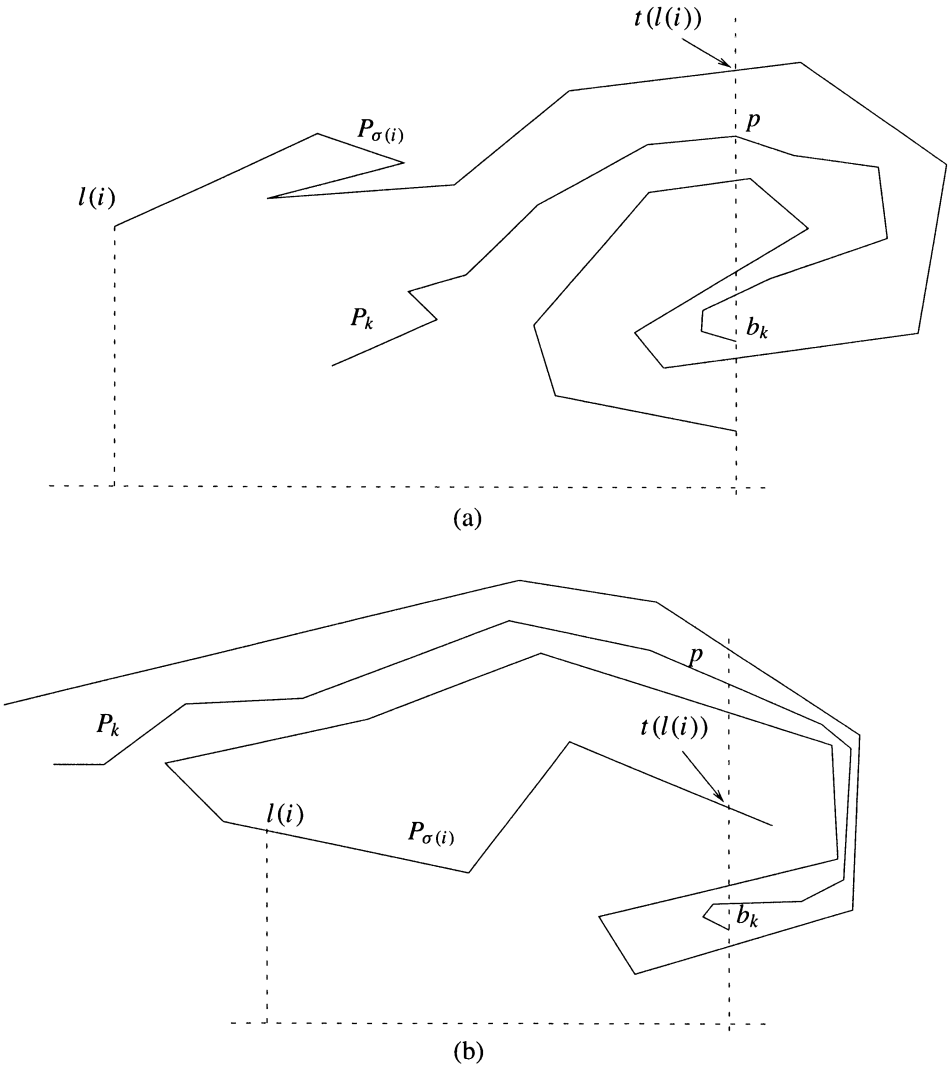

FIG. 6. *Proof of Lemma* 7.

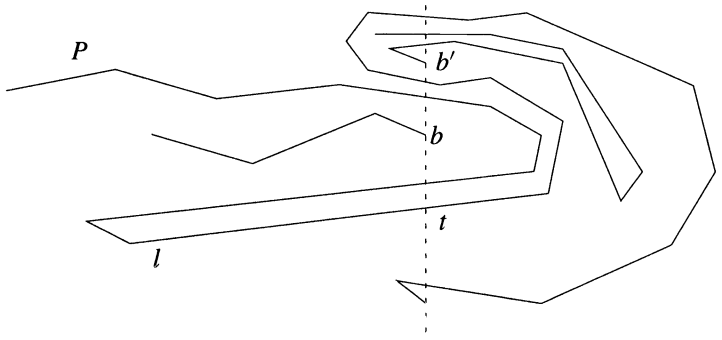

FIG. 7. *Binary search steps on a chain.*

$x(l(i))$ or $x(a) > x(r(i))$, then we set $x_k \leftarrow x(l(i))$ or $x_k \leftarrow x(r(i))$, respectively. We then compare $VP(k; x_k)$ and $VP(1, \ldots, k-1; x_k)$, and construct $VP(1, \ldots, k)$ by simultaneously traversing $VP(k)$ and $VP(1, \ldots, k-1)$. We now give the full algorithm.

Algorithm
Add P_1: We already have $VP(1)$, which consists of a single piece.
Add P_k, for $k \geq 2$:

We are given $VP(1, \ldots, k-1)$, with the pieces of $VP(1, \ldots, k-1)$ in a search tree. Perform the search described previously, using the lists I_j and the pointers to the these lists. There are two cases, which affect the way in which we construct $VP(1, \ldots, k)$:

Case 1: We find that the opening of b_k with respect to $P_{\sigma(1)}$ is above $t(l(1))$. We simply set $x_k \leftarrow x(l(1))$.

We now ask whether P_k is visible at x_k. This consists of asking whether $VP(k; x_k^-)$ is below $VP(1, \ldots, k-1; x_k^-)$, which is equivalent to asking whether P_k extends as far left as x_k^-.

If P_k is not visible at x_k, we set $VP(1, \ldots, k) \leftarrow VP(1, \ldots, k-1)$.

If P_k is visible at x_k, we compute $VP(k; x_k)$, and we traverse to the right from $VP(k; x_k)$ and $VP(1, \ldots, k-1; x_k)$ simultaneously, in order to construct the piece contributed by $VP(k)$—this gives us $VP(1, \ldots, k)$. We update the search tree of pieces of $VP(1, \ldots, k)$.

Case 2: The search returns the piece π_i.

Here we take advantage of lid queries. We query the point b_k to determine the lid $\overline{ab}$ of $VP(\sigma(i))$ that P_k must cross in order to be visible in $VP(\sigma(i), k)$. Note that since b_k is above $b_{\sigma(i)}$, the lid query will return a lid.

Subcase (a): $x(a) \in (x(l(i)), x(r(i)))$.
Set $x_k \leftarrow x(a)$.

Subcase (b): $x(a) > x(r(i))$.
Set $x_k \leftarrow x(r(i))$.

Subcase (c): $x(a) < x(l(i))$.
Set $x_k \leftarrow x(l(i))$.

We ask whether P_k is visible at x_k. This requires computing $VP(1, \ldots, k-1; x_k)$, which we already know from the lid query if $x_k \in (x(l(i)), x(r(i)))$. If x_k is $x(l(i))$ or $x(r(i))$, we can obtain $VP(1, \ldots, k-1; x_k)$ with an additional query of $P_{\sigma(i)}$ from the point $(x_k, 0)$. We are willing to spend n_k time to compute $VP(k; x_k)$, where n_k is the number of vertices of P_k, so it suffices to find $VP(k; x_k)$ by simply traversing $VP(k)$.

If $VP(k)$ is not visible at x_k, then we set $VP(1, \ldots, k) \leftarrow VP(1, \ldots, k-1)$.

If $VP(k)$ is visible at x_k, then we construct the piece contributed by $VP(k)$, by traversing simultaneously from $VP(k; x_k)$ and $VP(1, \ldots, k-1; x_k)$, both left and right—this gives $VP(1, \ldots, k)$. We update the search tree of pieces of $VP(1, \ldots, k)$.
End Algorithm

We now show that the value x_k produced by a step of the algorithm has the lid property.

LEMMA 8.4. *If $VP(k)$ appears in $VP(1, \ldots, k)$, then it appears in $VP(1, \ldots, k)$ at x_k.*

Proof. The claim follows directly from Lemma 8.3 for Case 1 of the algorithm.

For Case 2, it follows from Lemma 8.3 that if $VP(k)$ appears in $VP(1, \ldots, k)$, then it appears in the interval $[x(l(i)), x(r(i))]$.

Suppose the query returns a lid $\overline{ab}$ such that $x(a) \in (x(l(i)), x(r(i)))$. Then $VP(k)$ is somewhere below $VP(\sigma(i))$ only if P_k crosses $\overline{ab}$. Thus, $VP(k)$ appears in $VP(1, \ldots, k)$

only if $VP(k)$ is below $VP(1, \ldots, k-1)$ at $x(a)$, implying that $x_k = x(a)$ satisfies the lid property.

Suppose the query returns a lid $\overline{ab}$ such that $x(a) > x(r(i))$. We know that if $VP(k)$ appears in $VP(\sigma(i), k)$, then it appears at $x(a)$. Since $y(b_{\sigma(i)}) < y(b_k)$, $VP(k)$ can contribute at most one piece to the portion of $VP(\sigma(i), k)$ lying left of the y axis. Therefore, if $VP(k)$ is below $VP(\sigma(i))$ at $x(a)$ and at a value $x \in [x(l(i)), x(r(i))]$, then it is below at $x_k = x(r(i))$, which implies that x_k satisfies the lid property. A similar argument handles the case where $x(a) < x(l(i))$. □

The entire procedure for computing $VP(1, \ldots, h)$ requires time $O(n + h \log \bar{n} + h \log h)$, where n is the total number of vertices on $P_1, \ldots, P_h$ and $\bar{n}$ is the number of vertices on the largest chain. We established earlier that all preprocessing can be performed in $O(n)$ time. The bottom points are sorted by y coordinate in $O(h \log h)$ time.

The basic step of the procedure consists of merging $VP(k)$ with $VP(1, \ldots, k-1)$. We perform a binary search on the list of pieces of $VP(1, \ldots, k-1)$. The cost of each search step is a constant plus the number of intervals of the list $I_{\sigma(i)}$ that are traversed. The constant cost is charged to the search step, and the cost of each interval is charged to the interval itself, since no interval is traversed more than once. Since $VP(1, \ldots, k-1)$ has $O(h)$ pieces, all steps of all searches require $O(n + h \log h)$ time.

To merge $VP(k)$ with $VP(1, \ldots, k-1)$, we perform a constant number of lid queries, each in time $O(\log \bar{n})$, for a total of $O(h \log \bar{n})$ over all steps. Each step also traverses some portion of $VP(k)$, in time linear in the size of $VP(k)$, for a total of $O(n)$ time. Also, step k traverses the portion of $VP(1, \ldots, k-1)$ that is deleted from $VP(1, \ldots, k)$; all of these deletions require $O(n)$ time. This establishes the time bound of $O(n + h \log \bar{n} + h \log h)$ on the procedure.

8.2. Merging. We describe the merging of the visibility profiles of two subsets $\mathcal{S}'$ and $\mathcal{S}''$ of $\mathcal{S} = \{S_1, \ldots, S_{\lceil \log h \rceil}\}$, where $\max\{i \mid S_i \in \mathcal{S}'\} < \min\{j \mid S_j \in \mathcal{S}''\}$. We have a family of vertical lines such that every chain in $\mathcal{S}'$ is stabbed by at least one of the lines, but no chain of $\mathcal{S}''$ is stabbed by a line. Since the vertical lines separate the elements of $\mathcal{S}''$, we can individually consider the interval between each pair of consecutive lines. Therefore, we consider a vertical strip bordered by the lines π_l and π_r. All chains of $\mathcal{S}'$ that appear in $VP(\mathcal{S}')$ in the strip are stabbed by either π_l or π_r, and no chain of $\mathcal{S}''$ appearing in $VP(\mathcal{S}'')$ is stabbed by either line.

Inductively, we assume that we have, for $VP(\mathcal{S}')$ ($VP(\mathcal{S}'')$) over the strip, a sorted list of all leaps, and for each leap x of $VP(\mathcal{S}')$ ($VP(\mathcal{S}'')$), a pointer to $VP(\mathcal{S}'; x)$ ($VP(\mathcal{S}''; x)$). We merge the lists to form a single sorted list $x_1, \ldots, x_K$ of all leaps in $VP(\mathcal{S}')$ and $VP(\mathcal{S}'')$. For a leap x_k from $VP(\mathcal{S}')$ ($VP(\mathcal{S}'')$), we must compute a pointer to $VP(\mathcal{S}''; x_k)$ ($VP(\mathcal{S}'; x_k)$). We do this through lid queries, as follows. We can assume that in forming the list $x_1, \ldots, x_K$, every leap x_k from $VP(\mathcal{S}')$ knows which profile from $\mathcal{S}''$ contributes $VP(\mathcal{S}''; x_k)$. (This consists of knowing the leaps from $VP(\mathcal{S}'')$ that are nearest to x_k to the left and right.) Since we know the profile $VP(j)$ that contributes $VP(\mathcal{S}''; x_k)$, we can compute $VP(j; x_k) = VP(\mathcal{S}''; x_k)$ by querying the point $(x_i, 0)$ on P_j. Since $(x_k, 0)$ lies below $VP(j)$ (by our assumption that chains lie above the x axis), the query returns $VP(j; x_k)$.

We define a *subpiece* of $VP(\mathcal{S}')$ or $VP(\mathcal{S}'')$ as the portion of the profile between two consecutive leaps in the merged list $x_1, \ldots, x_K$. Note that a subpiece is a subset of some piece. A trivial special case occurs if one of the subpieces is at infinity. We will concentrate on the nontrivial situation, where the two subpieces are contributed by two profiles, $VP(i)$ and $VP(j)$. The following lemma motivates the merge procedure.

LEMMA 8.5. *Suppose we have a subpiece over the interval* $[x_k, x_{k+1}]$ *such that* $VP(i)$ *and* $VP(j)$ *contribute this subpiece to* $VP(\mathcal{S}')$ *and* $VP(\mathcal{S}'')$, *respectively. Then* $VP(\mathcal{S}')$ *is below* $VP(\mathcal{S}'')$ *somewhere in* $[x_k, x_{k+1}]$ *only if* $VP(i)$ *is below* $VP(j)$ *at* x_k *or* x_{k+1}.

Proof. We know that $VP(j)$, as an element of $VP(\mathcal{S}'')$, does not intersect π_l nor π_r, whereas $VP(i)$, as an element of $VP(\mathcal{S}')$, does intersect at least one of the two. This implies that either $x(l_i) < x(l_j)$ or $x(r_i) > x(r_j)$, which, by Lemma 3.1 or Lemma 3.2, means that $VP(j)$ appears at most once in $VP(i, j)$. This means it is impossible for $VP(j)$ to be below $VP(i)$ at both x_k and x_{k+1} when $VP(i)$ is below $VP(j)$ somewhere in between x_k and x_{k+1}. □

Now we combine the two profiles over the subpiece $[x_k, x_{k+1}]$. If $VP(j)$ is below $VP(i)$ at both x_k and x_{k+1}, then the entire subpiece is contributed by $VP(j)$. Below we describe a procedure for the case when $VP(i)$ is below at one of x_k and x_{k+1}, and $VP(j)$ is below at the other. We then show how this procedure can be modified to handle the case where $VP(i)$ is below at both x_k and x_{k+1}.

If $VP(i)$ is below at one of x_k and x_{k+1}, and $VP(j)$ is below at the other, then our task consists of finding the unique leap in $VP(i, j)$ between x_k and x_{k+1}, without traversing portions that are part of $VP(\mathcal{S}' \cup \mathcal{S}'')$. A naïve scheme could take time linear in the size of the portions of $VP(\mathcal{S}')$ and $VP(\mathcal{S}'')$ between x_k and x_{k+1}, but our approach requires only polylog time. Assume that the vertices of each original profile have been numbered in left-to-right order, and placed in a data structure so that if we are given a pointer to a vertex of the profile, we can in constant time return the numbering of the vertex. Our procedure maintains two pointers to $VP(i)$, denoted p_l^i and p_r^i, which are initialized to $VP(i; x_k)$ and $VP(i; x_{k+1})$, and pointers p_l^j and p_r^j to $VP(j)$, initialized to $VP(j; x_k)$ and $VP(j; x_{k+1})$. The pointers p_l^i and p_l^j will be maintained at the same x-coordinate, as will p_r^i and p_r^j. Initially we know that there is exactly one leap of $VP(i, j)$ between $x(p_l^i) = x(p_l^j)$ and $x(p_r^i) = x(p_r^j)$; the procedure maintains this property while moving $x(p_l^i) = x(p_l^j)$ and $x(p_r^i) = x(p_r^j)$ closer together, eventually sandwiching the leap. The procedure alternates steps on the pointer pairs (p_l^i, p_r^i) and (p_l^j, p_r^j). We describe a step on the pair (p_l^i, p_r^i):

1. Query the numbering of the vertices of $VP(i)$ nearest p_l^i and p_r^i, and assign these numberings to p_l^i and p_r^i.
2. Find q, the vertex of $VP(i)$ whose numbering is halfway between the numberings of p_l^i and p_r^i.
3. Compute $VP(j; x(q))$.
4. Compare the y coordinates of $VP(j; x(q))$ and $q = VP(i; x(q))$; this tells us whether the leap is left or right of $x(q)$; accordingly, update either p_l^i and p_l^j or p_r^i and p_r^j.

Upon completion of this step on the pair (p_l^i, p_r^i), perform a symmetric step on (p_l^j, p_r^j), and continue to alternate the steps. Eventually the total number of vertices on $VP(i)$ between p_l^i and p_r^i and on $VP(j)$ between p_l^j and p_r^j is less than a small, preset constant, so in constant time we find the leap and complete this subpiece of $VP(\mathcal{S}' \cup \mathcal{S}'')$.

A slight modification of the above procedure handles the case where $VP(i)$ is below $VP(j)$ at both x_k and x_{k+1}. Query $VP(j; x_k)$ on $VP(i)$, to find a lid $\overline{ab}$ which $VP(j)$ must cross in order to contribute a piece to $VP(i, j)$. If $x(a) \notin [x_k, x_{k+1}]$, then $VP(j)$ is not below $VP(i)$ anywhere in the interval $[x_k, x_{k+1}]$. If $x(a) \in [x_k, x_{k+1}]$, then perform a lid query on the point $(x(a), 0)$ to compute $VP(j; x(a))$. If $VP(i)$ is below $VP(j)$ at $x(a)$, then the subpiece between x_k and x_{k+1} is contributed totally by $VP(i)$; otherwise, we break the subpiece $[x_k, x_{k+1}]$ into two subpieces, $[x_k, x(a)]$ and $[x(a), x_{k+1}]$, and process each subpiece with the above procedure.

Consider the total time of merging $VP(\mathcal{S}')$ and $VP(\mathcal{S}'')$. Let $\bar{h}$ represent the total number of chains in $\mathcal{S}'$ and $\mathcal{S}''$, and $\bar{n}$ the number of vertices on the largest chain in the set $\mathcal{S}' \cup \mathcal{S}''$. Creating the combined sorted lists of leaps $x_1, \ldots, x_K$ for all strips takes time $O(\bar{h})$, because we already have the sorted lists of leaps for $\mathcal{S}'$ and $\mathcal{S}''$ separately. Computing $VP(i; x_k)$ and

$VP(j; x_k)$ for every leap x_k requires time $O(\bar{h} \log \bar{n})$, since it consists of performing one lid query per leap. We then process each of the $O(\bar{h})$ subpieces separately, perhaps breaking some subpieces into two subpieces with the help of a single lid query. Processing a subpiece consists of alternating steps on the pairs of pointers (p_l^i, p_r^i) and (p_l^j, p_r^j). Each step consists of one lid query plus some constant time work, and is therefore $O(\log \bar{n})$. Because every two steps eliminate at least half of the vertices of $VP(i)$ between p_l^i and p_r^i and of $VP(j)$ between p_l^j and p_r^j, the number of steps is $O(\log \bar{n})$. Therefore each subpiece requires $O(\log^2 \bar{n})$ time, for a total of $O(\bar{h} \log^2 \bar{n})$ time to merge $VP(\mathcal{S}')$ and $VP(\mathcal{S}'')$.

8.3. Putting it together: An optimal algorithm. The §§8.1 and 8.2 describe how to compute $VP(\mathcal{P})$ for $\mathcal{P} = \{P_1, \ldots, P_h\}$ in time $O(n + h \log h + h \log \log h \log^2 \bar{n})$, where n is the total number of vertices in $\mathcal{P}$, and $\bar{n}$ is the number of vertices on the largest chain of $\mathcal{P}$. A modification allows this algorithm to compute $VP(\mathcal{P})$ in optimal $\Theta(n + h \log h)$ time. The modification consists of breaking $\mathcal{P}$ into two groups, the "large" chains and the "small" ones, computing the visibility profile of each group separately, and then merging the profiles with a final linear-time merge.

The first observation to be made is that if $h = O(n/\log^3 n)$, then the algorithm's complexity is $O(n)$. Motivated by this observation, we break $\mathcal{P}$ into two groups as follows: all chains in $\mathcal{P}$ with more than $\log^3 n$ vertices are placed in the "large" group, and the rest in the "small" group. The large group can have no more than $n/\log^3 n$ members, so the algorithm can compute the visibility profile of this group in $O(n)$ time.

Assume that the small group has $h = \Omega(n/\log^3 n)$ members. (If not, the algorithm is $O(n)$ on this group.) No chain of the small group has more than $\log^3 n$ vertices, implying that $\bar{n} \leq \log^3 n$. The complexity of the algorithm is therefore $O(n + h \log h + h \log \log h \log^2(\log^3 n)) = O(n + h \log h + h \log \log h (\log \log n)^2)$. Since $h = \Omega(n/\log^3 n)$, we have that $\log \log n = O(\log \log h)$, which gives a complexity of $O(n + h \log h + h(\log \log h)^3) = O(n + h \log h)$. Therefore, the visibility profiles of both the small group and the large group can be computed in $O(n + h \log h)$, which gives $VP(\mathcal{P})$ in the same time bound.

9. Conclusion. In this paper, we have given a number of algorithms for computing visibility polygons in a polygonal domain, which culminated in a time-optimal $\Theta(n + h \log h)$ result. Another result was a simple $O(n + h^2)$-time algorithm, which is notable as the only known algorithm whose time-complexity is linear in n that does not require linear-time triangulation. We also gave a procedure that allows dynamic insertion of the polygonal holes.

Our visibility profile results immediately give new bounds on computing convex hulls of disjoint simple polygons, since the lower hull of a set of obstacles can be extracted in linear ($O(n)$) time from the lower envelope of the obstacles.

Several open problems present themselves:

- Can one develop a dynamic algorithm that allows both insertion and deletion of the holes?
- Does there exist an $O(n + f(n))$-time algorithm that does not require linear-time triangulation, where $f(h) = o(h^2)$?
- Can we extend our results to the case of (weak) visibility from a line segment?
- What can be done in the case that the h polygons are not necessarily disjoint, but have up to k intersection points?
- How quickly can one compute the visibility profile of h simple chains that are *not* assumed to be pairwise-disjoint? If, for example, there are k crossing points in the arrangement of chains, can we compute the visibility profile (lower envelope) in time $O(n + k + h \log h)$, or something close to this? (This problem is suggested to us by Reuven Bar Yehuda.)

A RANDOMIZED MAXIMUM-FLOW ALGORITHM*

JOSEPH CHERIYAN† AND TORBEN HAGERUP‡

Abstract. A randomized algorithm for computing a maximum flow is presented. For an n-vertex m-edge network, the running time is $O(nm + n^2(\log n)^2)$ with probability at least $1 - 2^{-\sqrt{nm}}$. The algorithm is always correct, and in the worst case runs in $O(nm \log n)$ time. The only use of randomization is to randomly permute the adjacency lists of the network vertices at the start of the execution.

The analysis introduces the notion of premature target relabeling (PTR) events and shows that each PTR event contributes $O(\log n)$ amortized time to the overall running time. The number of PTR events is always $O(nm)$; however, it is shown that when the adjacency lists are randomly permuted, then this quantity is $O(n^{3/2}m^{1/2} + n^2 \log n)$ with high probability.

1. Introduction.

A *network* is a graph together with one or more functions from the edges to the real numbers. Problems on networks arise often in theory and in practice. One of the central problems in this area is that of finding a *maximum flow* in a network. The input to the problem consists of a graph with two distinguished vertices, the *source* and the *sink*, and a nonnegative function on the edges called the *capacity*. Let n and m denote the number of vertices and edges, respectively, and let U denote the maximum capacity of any edge.

The first algorithm for the problem was presented by Ford and Fulkerson [FF57], [FF62]. Their algorithm does not run in polynomial time; moreover, when the capacities are irrational, it may not even terminate. More than a decade later, Edmonds and Karp [EK72] proposed a modification of the algorithm of [FF57] that runs in polynomial time. Independently, Dinic [D70] gave a faster polynomial-time algorithm.

The running times of the Dinic and Edmonds–Karp algorithms can be bounded by functions that depend only on n and m, but not on the actual edge capacities. This behavior is considered to be attractive and has been studied in the more general setting of combinatorial optimization. The input to a combinatorial optimization problem consists of a discrete structure (e.g., the graph in the maximum-flow problem), together with numeric parameters (e.g., the edge capacities in the maximum-flow problem). For an instance of the problem, let p denote the size of (a reasonable encoding of) the discrete structure, and let ℓ denote the maximum size of any numeric parameter (e.g., if the numeric parameters are integers with absolute values bounded by U, then one can take $\ell = 1 + \lceil \log(U+1) \rceil$; see Grötschel, Lovász, and Schrijver [GLS88]). An algorithm is said to be *strongly polynomial* if its running time in the arithmetic model (i.e., the total number of arithmetic operations, comparisons, and data transfers executed) is polynomial in p, and the maximum size of any number computed by the algorithm is polynomial in $p\ell$. The maximum-flow algorithms in [D70] and [EK72] are strongly polynomial.

*Received by the editors November 1, 1991; accepted for publication (in revised form) October 21, 1993. A preliminary and abridged version of this paper was presented at the 30th IEEE Symposium on Foundations of Computer Science in October 1989. Most of the research was carried out while both authors were at the Fachbereich Informatik of the Universität des Saarlandes, Saarbrücken, Germany.

The publication of [D70] and [EK72] led to further research on maximum-flow algorithms. Karzanov [K74] introduced the notion of a *preflow*, a generalization of a flow, and gave an algorithm that computes a maximum flow in $O(n^3)$ time by manipulating a preflow. Other improvements in the time complexity followed, and this line of research culminated in [ST83], where Sleator and Tarjan introduced a new data structure for dynamic trees and showed that by using this data structure, a maximum flow can be computed in $O(nm \log n)$ time. For graphs with $O(n^2/(\log n)^3)$ edges, this running time was the fastest then known. For networks with integer capacities, Gabow [Ga85] subsequently reported a simple algorithm based on the scaling technique with a running time of $O(nm \log U)$; under the so-called *similarity assumption*, i.e., $U = n^{O(1)}$, this algorithm is as fast as the one in [ST83].

A new approach for computing maximum flows was presented by Goldberg and Tarjan [GT88], based on earlier work by Goldberg [G85]. [GT88] introduced a generic algorithm for computing a maximum flow that works by manipulating a preflow, and gave a specific algorithm that uses the dynamic trees data structure and runs in time $O(nm \log(n^2/m))$. This improves on the algorithm in [ST83] for relatively dense graphs with $m = n^{2-o(1)}$. Cheriyan and Maheshwari [CM89] investigated several specific instances of the generic algorithm and showed that one of them runs in $\Theta(n^2\sqrt{m})$ time. For the special case of integer capacities, Ahuja and Orlin [AO89] devised an algorithm based on the scaling technique, called the *excess scaling algorithm*, that runs in $O(nm + n^2 \log U)$ time. Ahuja, Orlin, and Tarjan [AOT89] obtained several fast algorithms for this case by combining the dynamic trees data structure with the excess scaling algorithm.

At a somewhat general level, several aspects of the present paper were influenced by recent research on the *minimum-cost flow problem*. Edmonds and Karp [EK72], introducing the scaling technique, gave a polynomial minimum-cost flow algorithm for the special case of integer capacities. The algorithm, however, is not strongly polynomial. Edmonds and Karp left open the challenging question of whether a strongly polynomial algorithm exists. Although this question attracted research interest, no significant progress was reported for over a decade, until Tardos [T85] answered the question in the affirmative. There followed a number of other strongly polynomial algorithms: Fujishige [F86], Galil and Tardos [GaT88], Goldberg and Tarjan [GT89], [GT90], and Orlin [O88]. An idea common to these papers was the use of the scaling method for designing efficient strongly polynomial algorithms, and the most efficient realization of this idea was given in [O88], where the Edmonds–Karp capacity-scaling algorithm was "adapted" to real-valued capacities in order to achieve the fastest strongly polynomial running time known. The design of our algorithm was also motivated by this idea.

The focus of our work is on using randomization to improve on the Sleator–Tarjan time bound of $O(nm \log n)$ for finding a maximum flow. We show that by suitably incorporating the dynamic trees data structure into the excess scaling algorithm *and* randomly permuting the adjacency lists of the network vertices at the start of the execution, we can compute a maximum flow in $O(nm + n^2(\log n)^2)$ time with high probability, and in $O(nm \log n)$ time in the worst case.

The running time analysis introduces the notion of *premature target relabeling* (PTR) events and shows that each PTR event contributes $O(\log n)$ amortized time to the overall running time. The number of PTR events is always $O(nm)$; however, it is shown that when the adjacency lists are randomly permuted, then this quantity is $O(n^{3/2}m^{1/2} + n^2 \log n)$ with high probability.

Section 3 discusses a variant of the excess scaling algorithm, and in §4 an efficient strongly polynomial algorithm is designed, based on the algorithm in §3. The running time is analyzed in §§5–8. The critical component of the running time is identified in §5, and it is shown that the algorithm is strongly polynomial. Section 6 introduces PTR events and gives a probabilistic

bound on the number of these events, assuming that the adjacency lists are permuted randomly. The analysis is completed in §§7 and 8, first using simple arguments that lead to a somewhat loose time bound, and then using a more refined argument that gives the tightest bound known on the running time. Some conclusions are presented in §9.

2. Preliminaries. We use the traditional model for the study of problems on networks. Capacities and flow values are represented by real numbers, and all other quantities are represented by integers. For n-vertex input networks, we allow integers of absolute value $n^{O(1)}$, and we charge constant time for each arithmetic operation (i.e., addition, subtraction, comparison, or division by 2) on real numbers or integers, and for each data transfer. Further, we charge constant time for generating one random integer.

A *flow network* consists of a directed graph $G = (V, E)$, assumed to be symmetric (i.e., $(v, w) \in E \iff (w, v) \in E$), and a function $cap : E \to \mathbb{R}_+ \cup \{0\}$, the *capacity*, together with two distinguished vertices, the *source*, s, and the *sink*, t. Let $n = |V|$ and $m = |E|$, and let U denote the maximum capacity of any edge. We assume that $m \geq n \geq 3$ and that $U > 0$. For $v \in V$, let $\Gamma(v) = \{w \in V : (v, w) \in E\} = \{u \in V : (u, v) \in E\}$, and for every $(v, w) \in V \times V$, let $tail(v, w) = v$ and $head(v, w) = w$.

A *preflow* in G is a function $f : E \to \mathbb{R}$ with the following properties:

(1) $f(w, v) = -f(v, w)$ for all $(v, w) \in E$ (antisymmetry constraint);

(2) $f(v, w) \leq cap(v, w)$ for all $(v, w) \in E$ (capacity constraint);

(3) $\sum_{u \in \Gamma(v)} f(u, v) \geq 0$ for all $v \in V - \{s\}$ (nonnegativity constraint).

A preflow f in G is a *flow* if $\sum_{u \in \Gamma(v)} f(u, v) = 0$ for all $v \in V - \{s, t\}$ (flow conservation constraint). The *value* of f is $\sum_{u \in \Gamma(t)} f(u, t)$, and a *maximum flow* in G is a flow in G of maximum value.

For a fixed preflow f under consideration and for every vertex $v \in V$, the *flow excess* of v, $e(v)$, is defined as $\sum_{u \in \Gamma(v)} f(u, v)$, i.e., the net flow into v. A vertex v is called *active* if $v \in V - \{s, t\}$ and $e(v) > 0$.

An edge $(v, w) \in E$ is *residual* (with respect to f) if $f(v, w) < cap(v, w)$. The *residual capacity* of an edge (v, w), $rescap(v, w)$, is defined to be $cap(v, w) - f(v, w)$.

A *labeling* of G is a function $d : V \to \mathbb{N}_0 = \{0, 1, 2, \ldots\}$. The labeling is *valid* for G and a preflow f in G exactly if $d(t) = 0$, $d(s) = n$, and $d(v) \leq d(w) + 1$ for each residual edge (v, w). We call a residual edge (v, w) *eligible* if $d(v) = d(w) + 1$.

We now describe a generic algorithm that uses a preflow f in G and a labeling d of G. The basic procedure for manipulating f is as follows:

procedure *push*$((v, w) : edge; c : real)$;
  precondition: v is active, (v, w) is eligible and $0 < c \leq \min\{e(v), rescap(v, w)\}$.
    $f(v, w) := f(v, w) + c$; $f(w, v) := f(w, v) - c$;
    $e(v) := e(v) - c$; $e(w) := e(w) + c$;

By a *push* over (v, w) of *value* c we mean an execution of *push* with parameters (v, w) and c. v and w are called the *tail vertex* and the *head vertex* of the push, respectively. The push is called *saturating* if $f(v, w) = cap(v, w)$ afterwards; otherwise it is called *nonsaturating*. For a vertex v, a push *out of* v is a push over any edge of the form (v, w), and a push *into* v is a push over any edge of the form (u, v).

The basic procedure for manipulating the labeling d is as follows:

procedure *relabel*$(v : vertex)$;
  precondition: v is active, and no edge (v, w) emanating from v is eligible.
    $d(v) := d(v) + 1$;

An execution of *relabel*(v) is called a *relabeling* of v.

The generic algorithm starts by setting the flow on each edge that leaves the source equal to its capacity and the flow on each edge that is not incident with the source equal to zero. It also fixes some initial valid labeling. The algorithm then repeatedly executes *push* and *relabel* operations in any order. When no *push* or *relabel* operation has its precondition satisfied, i.e., when there are no more active vertices, the algorithm terminates. A formal description follows.

procedure *generic initialize*;
  for all $(v, w) \in E$ **do** $f(v, w) := 0$;
  for all $v \in V$ **do** $e(v) := 0$;
  for all $(s, v) \in E$ **do**
  begin
    $f(s, v) := cap(s, v)$;
    $f(v, s) := -f(s, v)$;
    $e(v) := cap(s, v)$;
  end;
  for all $v \in V - \{s\}$ **do** $d(v) := 0$;
  $d(s) := n$;

The generic maximum-flow algorithm:
  generic initialize;
  while there is an active vertex **do**
    execute some *push* or *relabel* operation whose precondition is satisfied.

There are some minor differences between the algorithm above and the generic maximum-flow algorithm of Goldberg and Tarjan [GT88]: the *push*(v, w) operation of [GT88] always sends $c = \min\{e(v), rescap(v, w)\}$ units of flow, and the *relabel*(v) operation of [GT88] sets $d(v)$ to $\min\{d(w) + 1 : w \in \Gamma(v) \text{ and } rescap(v, w) > 0\}$. Despite these differences, our algorithm shares the essential properties of the generic algorithm of Goldberg and Tarjan. In particular, the proofs given in [GT88] of the next two lemmas and of Theorem 2.4 carry over without modification.

LEMMA 2.1 [GT88]. *For all* $v \in V, 0 \leq d(v) \leq 2n - 1$ *throughout the execution. In particular, the total number of relabeling operations is* $\leq n(2n - 1) \leq 2n^2$.

LEMMA 2.2 [GT88]. *The total number of saturating pushes is* $O(nm)$.

Our analysis uses the notion of an *undirected edge* $\{v, w\}$, i.e., a pair of directed edges (v, w) and (w, v). Define the capacity of an undirected edge $\{v, w\}$ to be $ucap(v, w) = cap(v, w) + cap(w, v)$. For all $v \in V$, let $\deg(v)$ denote the number of undirected edges incident with v.

Each vertex $v \in V$ has an *adjacency list*, which consists of all edges $(v, w) \in E$. For each $v \in V$, the first eligible edge (if any) in v's adjacency list is called its *current edge* and is denoted by $ce(v)$ ($ce(v) = nil$, if there are no eligible edges (v, w)). We study implementations of the generic maximum-flow algorithm that maintain, for each vertex v, a pointer to $ce(v)$. Lemma 2.3, whose proof is similar to those of Lemma 4.1 and Theorem 4.2 in [GT88], shows that this contributes $O(nm)$ time to the total running time.

LEMMA 2.3. *Maintaining current edges for all vertices over the whole execution can be done in* $O(nm)$ *time.*

Proof. Maintain for each vertex $v \in V$ a pointer z_v into the adjacency list of v. At each relabeling of v, initialize z_v to point to $ce(v)$. Whenever the edge pointed to by z_v becomes ineligible, step z_v through v's adjacency list, starting from its previous position, until it either points to an eligible edge or reaches the end of the list. The fact that z_v always points to $ce(v)$, or to the end of v's adjacency list if $ce(v) = nil$, follows from the observation that once an

edge (v, w) becomes ineligible, it remains so until the next relabeling of v. For each relabeling of v, the total time spent in maintaining z_v is $O(\deg(v))$. Summing over all relabelings of all vertices gives a total time of $O(\sum_{v \in V}(2n-1)\deg(v)) = O(nm)$. □

THEOREM 2.4 [GT88]. *Suppose that the algorithm terminates. Then, at termination, the preflow f is a maximum flow.*

3. The excess scaling algorithm. In this section we consider networks with integer capacities. We give a variant of the excess scaling algorithm of Ahuja and Orlin [AO89] and show that although this algorithm is not strongly polynomial, the number of pushes executed by it is $O(n^2 m)$. In the next section, we make appropriate modifications to the algorithm to obtain a strongly polynomial algorithm.

The excess scaling algorithm that we are about to present is an instance of the generic algorithm of §2, and except for the minor differences noted there, it is also an instance of the generic maximum-flow algorithm of Goldberg and Tarjan [GT88]. The implementation of the generic algorithm in [GT88, p. 929] repeatedly selects an active vertex and applies a *push/relabel* step to it. Rather than selecting an arbitrary active vertex, it turns out to be advantageous to select an active vertex with relatively large flow excess. The excess scaling algorithm maintains a parameter Δ; initially $\Delta = 2^{\lfloor \log U \rfloor}$, and $\Delta = 0$ at termination. The execution of the algorithm is partitioned into *phases* such that Δ stays fixed during each phase and decreases by a factor of 2 between consecutive phases. We use "Δ" to denote both this parameter and its value at some step of the execution; the context will resolve any ambiguity. By a Δ-*phase*, where $\Delta \in \mathbb{R}$, we mean a phase in which the value of the parameter equals Δ.

Consider a particular phase. At the start of the phase the algorithm satisfies the invariant that $e(v) \leq 2\Delta$, for all $v \in V - \{s, t\}$. The algorithm selects an active vertex v only if $e(v) \geq \Delta$. Furthermore, among all such vertices it selects one with minimum $d(v)$. Another invariant for the Δ-phase is that every push has value $\leq 2\Delta$. It follows that for all $v \in V - \{s, t\}$, $e(v) < 3\Delta$ always (cf. Fact 3.4).

To satisfy the 2Δ bound on the value of every push, the value of every push out of a vertex $v \in V - \{s, t\}$ is computed using a modification $\tilde{e}(v)$ of $e(v)$ defined as follows:

$$\text{If } e(v) \leq 2\Delta, \text{ then } \tilde{e}(v) = e(v), \text{ otherwise } \tilde{e}(v) = \Delta.$$

This achieves two things: First, the amount of flow sent is always $\leq 2\Delta$, as claimed above. Second, if at some point $e(v) > 2\Delta$, then the algorithm attempts to make $e(v)$ equal to zero during the same phase by selecting v twice. (This would not be achieved, for example, by letting $\tilde{e}(v) = \min\{e(v), 2\Delta\}$.)

procedure $\tilde{e}(v : vertex) : real$;
  return (**if** $e(v) \leq 2\Delta$ **then** $e(v)$ **else** Δ);
procedure *select*: *vertex*;
  precondition: $\exists v \in V - \{s, t\} : e(v) \geq \Delta$.
    Return any vertex $v \in V - \{s, t\}$ with $e(v) \geq \Delta$ and
      $d(v) = \min\{d(u) : u \in V - \{s, t\} \text{ and } e(u) \geq \Delta\}$;

The excess scaling algorithm:
  generic initialize;
  $\Delta := 2^{\lfloor \log U \rfloor}$;
  while $\Delta \geq 1$ **do**
  begin
    while $\exists v \in V - \{s, t\} : e(v) \geq \Delta$ **do**
    begin
      $v :=$ *select*;

```
        while ce(v) ≠ nil and rescap(ce(v)) ≤ ẽ(v) do
            push (ce(v), rescap(ce(v)));    (* a saturating push *)
        if ce(v) = nil and ẽ(v) > 0 then
            relabel(v)
        else
            if e(v) ≥ Δ then
                push (ce(v), ẽ(v));         (* a nonsaturating push *)
    end;
    Δ := ⌊Δ/2⌋;
end.
```

To prove the correctness of the algorithm and to analyze its running time, we need the following facts. These facts are also used in subsequent sections.

Fact 3.1. For every vertex $w \in V - \{s, t\}$, $e(w)$ does not increase while $e(w) \geq \Delta$.

Proof. Any vertex v selected while $e(w) \geq \Delta$ has $d(v) \leq d(w)$, by definition. Since pushes are executed out of selected vertices only, it follows that the head vertex u of each push has $d(u) < d(w)$. In other words, no flow is sent into w while $e(w) \geq \Delta$. □

Fact 3.2. The value of every push is $\leq 2\Delta$.

Proof. This follows from the definition of $\tilde{e}$. □

Fact 3.3. The value of every nonsaturating push is $\geq \Delta$.

Fact 3.4. For every $v \in V - \{s, t\}$, $e(v) \leq 2\Delta$ at the start of each phase, $e(v) < \Delta$ at the end of each phase, and $e(v) < 3\Delta$ always.

Proof. Consider any $v \in V - \{s, t\}$. After initialization, $e(v) \leq 2\Delta$ clearly holds. At the termination of each phase, $e(v) < \Delta$, and hence $e(v) \leq 2\Delta$ at the start of the next phase. Facts 3.1 and 3.2 together imply that $e(v) < 3\Delta$ always. □

THEOREM 3.5 [AO89]. *The excess scaling algorithm is partially correct.*

Proof. The following claim shows that the termination condition for the generic algorithm is satisfied; the correctness then follows from Theorem 2.4.

Claim. When the last phase (with $\Delta = 1$) terminates, there are no active vertices.

To see this, use induction on the number of steps executed to show that the preflow f, and hence also the flow excess e, has integer values throughout. Therefore, when the last phase terminates, $e(v) = 0$ for all $v \in V - \{s, t\}$ (Fact 3.4). □

The next two results are not used later; however, they are of interest since the first one shows that the number of push steps can be bounded independently of U, while the second one uses this to give a new bound on the running time.

LEMMA 3.6. *The algorithm executes* $O(n^2 \min\{m, \log U\})$ *nonsaturating pushes.*

Proof. Ahuja and Orlin [AO89] gave an $O(n^2 \log U)$ bound on the number of nonsaturating pushes for their algorithm. Since the algorithmm here is a variant of the one in [AO89], a variant of their analysis applies here and gives the same $O(n^2 \log U)$ bound. We show the bound of $O(n^2 m)$ using a potential argument. First, for each $v \in V$, let

$$\phi(v) = \begin{cases} 0, & \text{if } e(v) = 0, \\ 1, & \text{if } 0 < e(v) \leq 2\Delta, \\ 2, & \text{if } e(v) > 2\Delta. \end{cases}$$

Intuitively, $\phi(v)$ is the number of times that v can be selected before $e(v)$ drops to zero (cf. the definition of $\tilde{e}$). Now take

$$\Phi = \sum_{v \in V - \{s,t\}} \phi(v) \cdot d(v).$$

A nonsaturating push over an edge (v, w) always lowers $\phi(v)$ by 1 and never increases $\phi(w)$ by more than 1 (Fact 3.2). Since $d(v) = d(w) + 1$, it follows that every nonsaturating push decreases Φ by at least 1. By Lemma 2.1, a saturating push increases Φ by at most $2n$, and a relabeling clearly increases Φ by at most 2. Furthermore, only saturating pushes and relabelings can increase Φ; in particular, note that going from one phase to the next leaves Φ unchanged. $\Phi = 0$ initially and $\Phi \geq 0$ always, so the total decrease in Φ (due to nonsaturating pushes) is bounded by the total increase in Φ (due to saturating pushes and relabelings). Since there are $O(nm)$ saturating pushes (Lemma 2.2) and $O(n^2)$ relabelings (Lemma 2.1), the number of nonsaturating pushes is $O(n \cdot nm + n^2) = O(n^2 m)$. □

THEOREM 3.7. *The excess scaling algorithm runs in time* $O(nm + n \log U + n^2 \min\{m, \log U\})$.

Proof. The initialization can be done in time $O(m)$. Each *relabel* or *push* step takes time $O(1)$. When the *select* procedure is implemented using appropriate data structures [AO89], [GTT90], it contributes an overall running time proportional to the number of pushes plus $O(n)$ per phase. The number of phases is $\lfloor \log U \rfloor + 1$. The theorem now follows from Lemmas 2.1–2.3 and 3.6. □

The next fact is very useful and has a straightforward proof. In the context of the minimum-cost flow problem, analogous results are crucial for designing and analyzing efficient strongly polynomial algorithms (cf. Lemma 4 of [F86] and Lemma 6 of [O88]). The proof technique used here resembles that of Lemma 6 in [O88].

Fact 3.8. For every fixed Δ-phase and every $(v, w) \in E$, the increase of $f(v, w)$ during the phase and all subsequent phases is at most $20n^2\Delta$.

Proof. Focus first on the Δ-phase and consider the potential

$$\Phi = \sum_{u \in V - \{s,t\}} e(u) \cdot d(u).$$

Whenever $f(v, w)$ increases by c (due to a push over (v, w) with value c), Φ decreases by at least c. The total increase of $f(v, w)$ during the phase is therefore bounded by the total decrease of Φ. $\Phi \geq 0$ always, and at the start of the phase $\Phi \leq 4n^2\Delta$ (by Lemma 2.1 and Fact 3.4). No *push* operation increases Φ, and a *relabel* operation increases Φ by at most 3Δ (by Fact 3.4). Consequently, the total increase of Φ is at most $6n^2\Delta$ (by Lemma 2.1). It follows that the total decrease of Φ is at most $10n^2\Delta$. Therefore, the total increase of $f(v, w)$ during the phase is at most $10n^2\Delta$.

The result now follows by summing over the remaining phases and using the fact that Δ decreases by a factor of 2 between consecutive phases. □

We call (v, w) a *forward huge edge* if $rescap(v, w) > 20n^2\Delta$. By Fact 3.8, a forward huge edge will never again be saturated. An undirected edge $\{v, w\}$ is called *huge* if $ucap(v, w) > 40n^2\Delta$. If $\{v, w\}$ is huge, clearly one of the directed edges (v, w) or (w, v), say, (v, w), is a forward huge edge. If the reverse edge (w, v) is not also a forward huge edge, we call it a *reverse huge edge*. Notice that an (undirected) huge edge continues to be huge until the end of the execution. We denote the total number of saturating pushes over (reverse) huge edges by $\sharp$*huge sat pushes*.

4. The strongly polynomial algorithm. The excess scaling algorithm has two bottlenecks that make it inefficient in comparison with previously known fast strongly polynomial algorithms. The first bottleneck is the large amount of time spent in executing nonsaturating pushes. The standard way of avoiding this bottleneck is to store for each vertex v the current edge $ce(v)$ together with $rescap(ce(v))$ in a suitable data structure that supports the operation of sending flow over a path of stored current edges. Such data structures make it possible to send flow over a path of l current edges in a running time that is substantially less than

proportional to l. The most efficient data structure known for this purpose is the *dynamic trees* data structure of Sleator and Tarjan [ST83].

From the point of view of achieving a running time of $O(nm)$, this data structure has one drawback. When used in the straightforward way, it contributes a running time of $O(\log n)$ per saturating push, i.e., of $O(nm \log n)$ overall, since the number of saturating pushes is $O(nm)$. In the context of the generic algorithm of Goldberg and Tarjan, a more efficient way of using the data structure is to insert an edge only if at least one nonsaturating push will be executed over the edge. In other words, the current edge of a vertex v is inserted into the data structure only when a push is to be applied to v while $rescap(ce(v)) > \tilde{e}(v)$, i.e., if the push operation will not saturate v's current edge.

We do not know whether this simple heuristic alone decreases the number of dynamic trees operations sufficiently. However, we obtain a remarkable decrease by combining it with another heuristic:

> At the start of the execution, randomly permute
> the adjacency list of each vertex.

The effectiveness of this heuristic comes from its interaction with scaling. As the execution progresses and the parameter Δ decreases, many edges eventually become huge. Roughly speaking, in a situation where there are many forward huge edges, the sum over all vertices v of the number of times v changes its current edge is significantly less than nm, unless the adjacency lists are maliciously ordered. A quantitative analysis of the efficiency of randomly permuting the adjacency lists needs the notion of PTR events, and we present such an analysis in §6 after developing the necessary machinery.

The second bottleneck of the excess scaling algorithm is that there are $\lfloor \log U \rfloor + 1$ phases, each of which incurs a running time overhead of $O(n)$ for initializing data structures. This bottleneck is easy to avoid. Rather than using the standard scaling method of decreasing the parameter Δ by a factor of 2 between phases, we use "tight scaling" and decrease Δ as much as possible between phases, i.e., at the end of each phase Δ is set to the minimum of $\Delta/2$ and $\max\{e(v) : v \in V - \{s, t\}\}$. We use a heap data structure to store all the vertices $v \in V - \{s, t\}$, with the key $e(v)$ used to maintain the heap order. Tight scaling with a running time overhead of $O(\log n)$ per phase is easy to implement in this way.

A *heap* is a data structure that maintains a set of *items*, each with a real-valued *key*, under the following operations [FT87]:

make heap:	Return a new empty heap.
is empty(h):	If the heap h has no items, then return *true*; otherwise return *false*.
insert(i, h):	Insert a new item i with predefined key into the heap h.
find max(h):	Return an item of maximum key in the heap h.
delete max(h):	Delete an item of maximum key from the heap h and return it.
delete(i, h):	Delete the item i from the heap h.
increase key(c, i, h):	Increase the key of the item i in the heap h by adding the nonnegative real number c.

The two last operations assume that the position of i in h is known. The *Fibonacci heaps* data structure [FT87] supports a sequence of k *delete* or *delete max* operations and l other heap operations, starting with no heaps, in time $O(l + k \log l)$.

The actual implementation of the strongly polynomial algorithm uses two heaps, rather than one, in order to execute the *select* step efficiently. The *d_heap* contains all vertices $v \in V - \{s, t\}$ with $e(v) \geq \Delta$. The heap order is maintained according to the key $-d(v)$. The *d_heap* is needed for efficiently selecting a vertex v with minimum $d(v)$ among those

with $e(v) \geq \Delta$. The *e_heap* is a Fibonacci heap containing all vertices $v \in V - \{s, t\}$ with $e(v) < \Delta$. The heap order is maintained according to the key $e(v)$. The *e_heap* is needed for efficient updating of Δ. A Fibonacci heap is used because only $O(1)$ amortized time can be allowed per *increase key* operation.

The *dynamic trees* data structure of Sleator and Tarjan [ST83], [ST85], [T83] maintains a set of vertex-disjoint rooted trees in which each tree edge has an associated real value and is considered to be directed toward the root, i.e., from child to parent. We shall need the following dynamic trees operations:

find root(v):	Find and return the root of the tree containing the vertex v.
find value(v):	Find and return the value of the edge from the vertex v to its parent. This operation assumes that v is not a tree root.
find min(v):	Return the nonroot ancestor w of v with minimum *find value*(w). In the case of ties, the ancestor furthest from v is returned. This operation assumes that v is not a tree root.
add value(v, c):	Add the real number c to the value of every edge on the path from the vertex v to *find root*(v).
link(v, w, c):	Combine the trees containing the vertices v and w by making w the parent of v and giving the value c to the new edge from v to w. This operation assumes that v and w are in different trees and that v is a tree root.
cut(v):	Break the tree containing the vertex v into two trees by deleting the edge from v to its parent. This operation assumes that v is not a tree root.

A sequence of k dynamic trees operations, starting with a collection of n single-vertex trees, can be executed in $O(k \log n)$ time.

We use the dynamic trees data structure to maintain a spanning forest F of G that contains a subset of the current edges, where the value associated with an edge in F is its residual capacity. The algorithm represents the preflow f in one of two different ways: For $(v, w) \in E$, if $(v, w) \notin F$ and $(w, v) \notin F$, then $f(v, w)$ is stored explicitly (using an array $f : E \to \mathbb{R}$). Otherwise, if $(v, w) \in F$, then $f(v, w)$ is given implicitly by $cap(v, w) - rescap(v, w)$ and $f(w, v)$ is given by $-f(v, w)$. Whenever a tree edge (v, w) is cut, we must find its associated value (i.e., $rescap(v, w)$) and then update the current values of $f(v, w)$ and $f(w, v)$. Also, when the algorithm terminates, $f(v, w)$ and $f(w, v)$ must be computed for all $(v, w) \in F$. The procedures *Link* and *Cut* given below execute a *link* and a *cut* and incorporate these conventions for representing f.

procedure *Link*$(v : vertex)$;
  (* Insert the edge $ce(v)$ into F *)
    Let $w = head(ce(v))$;
    link$(v, w,$ *rescap*$(v, w))$;

procedure *Cut*$(v : vertex)$;
  (* Cut the tree edge $ce(v) \in F$ and restore f values *)
    Let $w =$ *head*$(ce(v))$;
    $f(v, w) :=$ *cap*$(v, w) -$ *find value*(v); $f(w, v) := -f(v, w)$;
    cut(v).

The heart of the algorithm is the procedure *macropush*. The algorithm repeatedly selects a vertex $v \in V - \{s, t\}$ with $e(v) \geq \Delta$ that has minimum label $d(v)$ among the vertices with flow excess $\geq \Delta$, after which the *macropush* procedure is applied to v.

If v is a nonroot vertex in F, i.e., $v \neq$ *find root*(v), then *macropush* uses the dynamic trees data structure to send flow from v, over a path of current edges, to *find root*(v). If one or

more edges become saturated, then all saturated edges in F are deleted using *cut* operations. The algorithm may execute more than one nonsaturating push while sending flow over a path in F.

Now suppose that v is a root in F. Then *macropush* executes zero or more saturating pushes over edges emanating from v, without inserting these edges into the dynamic trees data structure. After this, provided that the remaining flow excess of v is at least $\Delta/2$ and that there is an eligible edge emanating from v, *macropush* executes a sequence consisting of a *Link*(v) operation and a nonsaturating push over $ce(v)$. The reason for executing a *Link*(v) only if $e(v) \geq \Delta/2$ is to ensure that only edges with sufficiently large capacities relative to Δ are ever inserted into the dynamic trees data structure (cf. Fact 5.2).

In the following outline of the algorithm, the operations on heaps are not mentioned explicitly. The procedure $\tilde{e}(v)$ is repeated from the previous section, and the procedures *relabel* and *select* are more elaborate versions of identically named procedures in previous sections.

```
procedure  ẽ(v : vertex) : real;
    return (if e(v) ≤ 2Δ then e(v) else Δ);

procedure  relabel(v : vertex);
    for all u ∈ V with ce(u) = (u, v) do
        if (u, v) ∈ F then Cut(u);
    d(v) := d(v) + 1;

procedure  select: vertex;
    (* Return an active vertex v with e(v) ≥ Δ and minimum d(v) among the vertices having
    flow excess ≥ Δ, or decrease Δ and then select v as before, or return with Δ = 0 *)
    if ∀v ∈ V − {s, t} : e(v) < Δ then
        Δ := min{Δ/2, max{e(v) : v ∈ V − {s, t}}};
    if Δ > 0 then
        let v be any active vertex with e(v) ≥ Δ and
            d(v) = min{d(u) : u ∈ V − {s, t} and e(u) ≥ Δ}
    else
        let v := t;    (* dummy value *)
    return (v);

procedure  macropush(v : vertex);
    (* Send flow from v until v is relabeled or until e(v) decreases to < Δ/2 due to saturating
    pushes out of v or until flow is sent from v over a path in F *)
    if v = find root(v) then
        begin
        while ce(v) ≠ nil and rescap(ce(v)) ≤ ẽ(v) do
            push(ce(v), rescap(ce(v)));    (* a saturating push *)
        if ce(v) = nil and ẽ(v) > 0 then
            begin relabel(v); return; end
        else
            if ẽ(v) < Δ/2 then return
            else
                Link(v);    (* insert ce(v) with rescap(ce(v)) > ẽ(v) ≥ Δ/2 *)
        end;
```

(* Send as much flow as possible from v to *find root*(v), and then cut the tree edges in F that get saturated *)
$c := \min\{$*find value*(*find min*$(v))$, $\tilde{e}(v)\}$;
change value$(v, -c)$;
$e(v) := e(v) - c$; $e($*find root*$(v)) := e($*find root*$(v)) + c$;
while $v \neq$ *find root*(v) and *find value*(*find min*$(v)) = 0$ **do** *Cut*(*find min*$(v))$;

The strongly polynomial algorithm:

generic initialize;
initialize the *d_heap*, the *e_heap* and the dynamic trees data structure;
for each $v \in V$, randomly permute the adjacency list of v;
$\Delta := \infty$;

loop
  $v :=$ *select*;
  if $\Delta = 0$ **then stop;** (* f is a maximum flow *)
  macropush(v);
forever.

THEOREM 4.1. *The strongly polynomial algorithm is partially correct.*

5. Preliminaries for the analysis. After presenting some elementary facts about the strongly polynomial algorithm, we give a lemma that identifies the critical component of its running time.

The algorithm is easily seen to satisfy Facts 3.1, 3.2, 3.4, and 3.8.

Fact 5.1. Between consecutive phases, Δ decreases by a factor of 2 or more.

Fact 5.2. When a *link* operation is executed on an edge (v, w), then *rescap*$(v, w) \geq \Delta/2$.

Fact 5.3. For all $v \in V$, any increase of $e(v)$ while $v \neq$ *find root*(v) is caused by saturating pushes into v.

Proof. Any flow sent into v by a nonsaturating push is sent further all the way to *find root*(v); hence a nonsaturating push causes $e(v)$ to increase only if $v =$ *find root*(v). □

Fact 5.4. For all $v \in V$, if an execution of *macropush*(v) starting with $v \neq$ *find root*(v) does not execute any *cut*, then either $e(v) = 0$ or $e(v) > \Delta$ when the procedure terminates.

Proof. Clearly the total amount of flow sent from v by the procedure is $c = \tilde{e}(v)$. The claim now follows from the definition of $\tilde{e}(v)$. □

By a *select step* we mean one iteration of the main loop (**loop** . . . **forever**) of the algorithm. A vertex v is said to be *processed* by a *select* step if the call of the *select* procedure in that iteration returns v. Let $\sharp$*selects* denote the total number of *select* steps over the whole execution, i.e., the number of iterations of the main loop of the algorithm.

LEMMA 5.5. *The running time of the strongly polynomial algorithm is* $O(nm + \sharp selects \cdot \log n)$.

Proof. The total time for operations on the *d_heap* is $O(\sharp selects \cdot \log n)$, because there are $O(\sharp selects)$ operations on the *d_heap*. Next, consider operations on the *e_heap* and observe that we need not insert the vertex processed by a *select* step into the *e_heap* (if it belongs there) until the end of the *select* step. A saturating push over an edge (v, w) therefore causes one *increase key* operation, and if $e(w)$ becomes $\geq \Delta$, then w must be deleted from the *e_heap* and inserted into the *d_heap*. The number of *e_heap* delete operations at most equals the number of *d_heap* insert operations, which is $O(\sharp selects)$. The number of *increase key* operations is bounded by $\sharp selects$ plus the number of saturating pushes, which is $O(nm)$. The total time needed for operations on the *e_heap* is therefore $O(nm + \sharp selects \cdot \log n)$.

Consider the remaining running time, excluding the time for heap operations. The initialization can be done in $O(m)$ time; in particular, note that random permutations can be computed in linear time (see, e.g., [S77]). Each iteration of the main loop runs in time $O(\log n)$, plus $O(\log n)$ times the number of *cut* operations executed, plus the time for executing saturating pushes over edges not in the dynamic trees data structure, plus the time for maintaining current edges. The total number of *cut* operations executed is $\leq \sharp selects$, because there is a distinct *link* operation corresponding to each *cut*, and the number of *link* operations is clearly $\leq \sharp selects$, since each iteration of the main loop executes at most one *link*. The overall time for maintaining the current edges is $O(nm)$, and the overall time for saturating pushes that are not associated with *cut* operations is $O(nm)$. Thus, the total running time is $O(nm + \sharp selects \cdot \log n)$. □

LEMMA 5.6. *$\sharp selects = O(nm)$, and the worst-case running time of the strongly polynomial algorithm is $O(nm \log n)$.*

Proof. It is easily seen that the total number of *cut* and *link* operations is $O(nm)$. It follows that the number of iterations of the main loop that execute either a *cut* or a *link* or a *relabel* or a saturating push is $O(nm + n^2) = O(nm)$.

To handle the remaining *select* steps, call each such step a *neat select* step and note that each neat *select* step moves flow from a nonroot in F to a root. Define Φ as the sum over all nonroot vertices v of $\phi(v)$, where ϕ is the function of the proof of Lemma 3.6, i.e.,

$$\phi(v) = \begin{cases} 0, & \text{if } e(v) = 0, \\ 1, & \text{if } 0 < e(v) \leq 2\Delta, \\ 2, & \text{if } e(v) > 2\Delta. \end{cases}$$

By the previous observation, each neat *select* step decreases Φ by at least 1. On the other hand, only saturating pushes and link operations can increase Φ, and each such operation increases Φ by at most 2. Since $\Phi = 0$ initially, the number of neat *select* steps is $O(nm)$, and the same bound applies to the total number of *select* steps.

The bound on the running time now follows from the previous lemma. □

The crucial part of the analysis is to show that for sufficiently dense graphs, randomly permuting the adjacency lists causes $\sharp selects$ to become significantly less than $\Theta(nm)$ with high probability. In the next section we analyze the efficiency of randomly permuting the adjacency lists, and based on this in §7 we give a simple analysis of $\sharp selects$.

6. PTR events. A *premature target relabeling* event (PTR event) is defined to be the relabeling of the head w of a current edge (v, w). In other words, a PTR event may be identified with a triple (v, w, k), where $0 \leq k \leq 2n - 2$ and $(v, w) \in E$ is the current edge of $v \in V$ when the vertex w, which currently has $d(w) = k$, gets relabeled. By definition, every *cut* executed by the *relabel* procedure corresponds to a PTR event; however, there may be other PTR events besides these, since the dynamic trees data structure may not contain all current edges. Denote by $\sharp$ptr the total number of PTR events.

The significance of PTR events is that a vertex changes its current edge if and only if either a saturating push occurs over the edge or a PTR event occurs on the edge. Since no forward huge edge is ever saturated (see §3), a vertex whose current edge is a forward huge edge changes its current edge exactly when a PTR event occurs on the edge.

LEMMA 6.1. *Over the whole execution, $\sharp huge\ sat\ pushes \leq m + \sharp$ptr.*

Proof. Between two consecutive saturating pushes over a reverse huge edge (w, v), there must be a push over the forward huge edge (v, w). When the push over (v, w) is executed, then $(v, w) \in F$. Consequently, between this step and the next saturating push over (w, v), a *cut* on (v, w) must be executed. Hence $\sharp huge\ sat\ pushes$ is at most m plus the number of cuts on forward huge edges, which is $\leq m + \sharp$ptr. □

It is easy to bound ♯ptr by $O(nm)$. However, for sufficiently dense graphs a much tighter bound can be obtained by making use of the fact that each vertex randomly and independently permutes its adjacency list at the start of the execution. Before delving into the analysis, we introduce some notation whose usefulness will become evident below.

For every finite set A, let $\mathrm{Perm}(A)$ be the set of all permutations of A, i.e., of all bijections from $\{1, \ldots, |A|\}$ to A. Given finite sets A and B and permutations $\mu \in \mathrm{Perm}(A)$ and $\sigma \in \mathrm{Perm}(B)$, let $\lambda(\mu, \sigma)$, called the *coascent* of μ and σ, be the length of a longest (not necessarily contiguous) common subsequence of the sequences $\mu(1), \ldots, \mu(|A|)$ and $\sigma(1), \ldots, \sigma(|B|)$. Given l permutations $\mu_1, \ldots, \mu_l$ of subsets of a finite set A, let $\Lambda(\mu_1, \ldots, \mu_l) = \max_{\sigma \in \mathrm{Perm}(A)} \sum_{i=1}^{l} \lambda(\mu_i, \sigma)$; note that this quantity does not depend on A. We call $\Lambda(\mu_1, \ldots, \mu_l)$ the *external coascent* of $\mu_1, \ldots, \mu_l$.

Example. This example is meant to familiarize the reader with the definitions of λ and Λ. For the duration of the example, we identify a permutation μ of a set B with the string $\mu(1) \ldots \mu(|B|)$ and use as our universe the set $A = \{a, b, c, d, e, f\}$ of six symbols.

Let $\mu = bead$ and $\sigma = fbadec$. Then $\lambda(\mu, \sigma) = 3$, since the sequence *bad* occurs in both μ and σ, whereas the only longer subsequence *bead* occurring in μ does not occur in σ.

Now take $\mu_1 = fade$, $\mu_2 = bead$ and $\mu_3 = dec$. Then $\Lambda(\mu_1, \mu_2, \mu_3) = 10$, since with $\sigma = fbadec$ we have $\sum_{i=1}^{3} \lambda(\mu_i, \sigma) = 10$, whereas it is not difficult to see that there is no permutation σ' of A with $\sum_{i=1}^{3} \lambda(\mu_i, \sigma') = 11$.

Identify V with the set $\{1, \ldots, n\}$ and let $\mu_v \in \mathrm{Perm}(\Gamma(v))$, for all $v \in V$. We shall say that the strongly polynomial algorithm is executed with the adjacency lists ordered according to $\mu_1, \ldots, \mu_n$ if the following holds after the initialization: For all $u \in V$ and all $v, w \in \Gamma(u)$, the edge (u, v) precedes (u, w) in u's adjacency list if and only if $\mu_u^{-1}(v) < \mu_u^{-1}(w)$. Furthermore, for $\sigma_0, \ldots, \sigma_{2n-2} \in \mathrm{Perm}(V)$, let us say that an execution of the algorithm relabels according to $\sigma_0, \ldots, \sigma_{2n-2}$ if the following holds for all k with $0 \le k \le 2n-2$ and all $v, w \in V$: If $d(v)$ is set to $k+1$ at some point of the execution and $d(w)$ is set to $k+1$ at some later point, then $\sigma_k^{-1}(v) < \sigma_k^{-1}(w)$. Except for the fact that some vertices may not be relabeled $k+1$ times, σ_k simply orders the vertices in V by the time of their $(k+1)$st relabeling.

Consider now an execution of the algorithm with the adjacency lists ordered according to $\mu_1, \ldots, \mu_n$ that relabels according to $\sigma_0, \ldots, \sigma_{2n-2}$. Fix $v \in V$ and k with $0 \le k \le 2n-2$ and suppose that for some vertices $w_1, \ldots, w_l \in V$, the execution incurs PTR events $(v, w_1, k), \ldots, (v, w_l, k)$, in that order. Then, clearly $\mu_v^{-1}(w_1) < \cdots < \mu_v^{-1}(w_l)$ and $\sigma_k^{-1}(w_1) < \cdots < \sigma_k^{-1}(w_l)$, i.e., the sequences $\mu_v(1), \ldots, \mu_v(|\Gamma(v)|)$ and $\sigma_k(1), \ldots, \sigma_k(n)$ have a (not necessarily contiguous) common subsequence of length l, namely $w_1, \ldots, w_l$. It follows that for all $v \in V$ and all k with $0 \le k \le 2n-2$, the total number of PTR events of the form (v, w, k), where $w \in V$, is bounded by $\lambda(\mu_v, \sigma_k)$. Summing over all $v \in V$ for fixed k with $0 \le k \le 2n-2$, we see that the total number of PTR events of the form (v, w, k), where $v, w \in V$, is bounded by

$$\sum_{v \in V} \lambda(\mu_v, \sigma_k) \le \Lambda(\mu_1, \ldots, \mu_n).$$

A final summation over all values of k yields the next lemma.

LEMMA 6.2. *For all $v \in V$, let $\mu_v \in \mathrm{Perm}(\Gamma(v))$. If the strongly polynomial algorithm is executed with the adjacency lists ordered according to $\mu_1, \ldots, \mu_n$, then* ♯ptr $\le 2n \cdot \Lambda(\mu_1, \ldots, \mu_n)$.

LEMMA 6.3. *Let A be a finite set with $|A| = N$, let $A_1, \ldots, A_N$ be subsets of A and take $M = \sum_{i=1}^{n} |A_i|$. Suppose that μ_i is drawn randomly from the uniform distribution over* $\mathrm{Perm}(A_i)$, *for $i = 1, \ldots, N$, and that $\mu_1, \ldots, \mu_N$ are independent. Then for all $r \ge \sqrt{NM} + N \log N$, $\Lambda(\mu_1, \ldots, \mu_N) = O(r)$ with probability at least $1 - 2^{-r}$.*

Proof. Recall that $\Lambda(\mu_1, \ldots, \mu_N) = \max_{\sigma \in \mathrm{Perm}(A)} \psi(\sigma)$, where $\psi(\sigma) = \sum_{i=1}^{n} \lambda(\mu_i, \sigma)$. We will show the probability that $\psi(\sigma)$ is large to be very small for each fixed $\sigma \in \mathrm{Perm}(A)$. Multiplying that probability by the number of choices for σ, i.e., by $N!$, we obtain an upper bound on the probability that $\Lambda(\mu_1, \ldots, \mu_N)$ is large.

Hence, let $\sigma \in \mathrm{Perm}(A)$ be arbitrary but fixed. For $i = 1, \ldots, N$, let $\Lambda_i = \lambda(\mu_i, \sigma)$ and take $S = \psi(\sigma) = \sum_{i=1}^{n} \Lambda_i$, the quantity of interest. For $i = 1, \ldots, N$, denote $|A_i|$ by a_i. Assume $N \geq 2$.

For arbitrary integers a and k with $0 \leq k \leq a \leq N$, the number of permutations μ of an arbitrary subset of A of cardinality a with $\lambda(\mu, \sigma) \geq k$ is at most $\binom{a}{k}^2 (a-k)!$. To see this, note that if $\lambda(\mu, \sigma) \geq k$, then the elements of a (not necessarily contiguous) subsequence of $\mu(1), \ldots, \mu(a)$ of length k appear in the same order in the sequence $\sigma(1), \ldots, \sigma(N)$. The elements of the subsequence can be chosen in $\binom{a}{k}$ ways, and the positions in which they appear in $\mu(1), \ldots, \mu(a)$ can also be chosen in $\binom{a}{k}$ ways, while the remainder of the sequence $\mu(1), \ldots, \mu(a)$ can be chosen in $(a-k)!$ ways. It follows that for $i = 1, \ldots, N$ and for all integers k with $1 \leq k \leq a_i$,

$$\Pr(\Lambda_i \geq k) \leq \frac{\binom{a_i}{k}^2 (a_i - k)!}{a_i!} \leq \frac{a_i^k}{(k!)^2} \leq \left(\frac{e^2 a_i}{k^2}\right)^k.$$

It can be seen that Λ_i is unlikely to exceed $\sqrt{a_i}$ by very much. By applying the Cauchy–Schwarz inequality $|u \cdot v| \leq |u|\,|v|$ to the vectors $u = (1, \ldots, 1)$ and $v = (\sqrt{a_1}, \ldots, \sqrt{a_N})$, we obtain

$$\sum_{i=1}^{N} \sqrt{a_i} \leq \sqrt{N} \cdot \sqrt{\sum_{i=1}^{N} a_i} = \sqrt{NM}.$$

Hence $S = \sum_{i=1}^{N} \Lambda_i$ is unlikely to exceed $\sqrt{NM}$ by very much. We now establish a precise bound.

First observe that for arbitrary $x \in \mathbb{R}$,

$$\Pr(S \geq x) = e^{-x} e^{x} \Pr(e^S \geq e^x) \leq e^{-x} E(e^S).$$

Second, since $\mu_1, \ldots, \mu_N$ and hence also $e^{\Lambda_1}, \ldots, e^{\Lambda_N}$ are independent,

$$E(e^S) = E\left(e^{\sum_{i=1}^{N} \Lambda_i}\right) = E\left(\prod_{i=1}^{N} e^{\Lambda_i}\right) = \prod_{i=1}^{N} E(e^{\Lambda_i}).$$

We next bound the quantities $E(e^{\Lambda_i})$. Let $i \in \{1, \ldots, N\}$ and let $b_i \geq 0$ be an arbitrary integer. Then

$$E(e^{\Lambda_i}) = \sum_{k=0}^{\infty} e^k \Pr(\Lambda_i = k) \leq \sum_{k=0}^{b_i} e^k \Pr(\Lambda_i = k) + \sum_{k=b_i+1}^{\infty} e^k \Pr(\Lambda_i \geq k)$$

$$\leq e^{b_i} \sum_{k=0}^{b_i} \Pr(\Lambda_i = k) + \sum_{k=b_i+1}^{\infty} e^k \left(\frac{e^2 a_i}{k^2}\right)^k \leq e^{b_i} + \sum_{k=b_i+1}^{\infty} \left(\frac{e^3 a_i}{k^2}\right)^k.$$

Choose b_i to make $\frac{e^3 a_i}{k^2} \leq \frac{1}{2}$ for $k \geq b_i + 1$, i.e., take $b_i = \lfloor \sqrt{2e^3 a_i} \rfloor$. Then

$$E(e^{\Lambda_i}) \leq e^{b_i} + \sum_{k=b_i+1}^{\infty} 2^{-k} = e^{b_i} + 2^{-b_i} \leq 2e^{\sqrt{2e^3 a_i}}.$$

Putting together everything yields

$$\Pr(S \geq x) \leq e^{-x} E(e^S) = e^{-x} \prod_{i=1}^{N} E(e^{\Lambda_i}) \leq e^{-x} \prod_{i=1}^{N} (2e^{\sqrt{2e^3 a_i}})$$

$$= e^{-x} \cdot 2^N e^{\sqrt{2e^3} \sum_{i=1}^{N} \sqrt{a_i}} \leq 2^N e^{\sqrt{2e^3}\sqrt{NM} - x}.$$

Recalling that σ can be chosen in $N!$ ways, we find

$$\Pr(\Lambda(\mu_1, \ldots, \mu_N) \geq x) \leq N! \cdot 2^N e^{\sqrt{2e^3}\sqrt{NM} - x}$$

$$\leq e^{2N \log N + \sqrt{2e^3}\sqrt{NM} - x}.$$

Given any $r \geq \sqrt{NM} + N \log N$, now choose

$$x = 2N \log N + \sqrt{2e^3}\sqrt{NM} + r = O(r)$$

and observe that

$$\Pr(\Lambda(\mu_1, \ldots, \mu_N) \geq x) \leq 2^{-r}. \qquad \square$$

LEMMA 6.4. *For every* $\alpha \geq 1$, $\sharp\text{ptr} = O(\alpha \cdot (n^{3/2} m^{1/2} + n^2 \log n))$ *with probability at least* $1 - 2^{-\alpha(\sqrt{nm} + n \log n)}$.

Proof. Combine Lemmas 6.2 and 6.3 $\square$

7. A simple analysis of operations on nonhuge edges and of the overall running time. In order to complete the analysis of the running time, i.e., to bound $\sharp$*selects*, we have to show good bounds for the total number of operations on nonhuge edges. In this section we derive somewhat loose bounds by using a simple argument, and in the next section we give better bounds by using a more refined argument.

Let β be a real number with $2 \leq \beta = n^{O(1)}$ (we fix $\beta = 2 + \sqrt{m/n}$ to get the main result). Define the *status* of an undirected edge $\{v, w\}$ as follows:

$\{v, w\}$ is said to be *small* if $ucap(v, w) < \Delta/\beta$, *medium* if $\Delta/\beta \leq ucap(v, w) \leq 40n^2\Delta$, and (as defined in §3) *huge* if $ucap(v, w) > 40n^2\Delta$. Note that the status of an edge may change during the execution, but at most twice.

A push is called *small*, *medium*, or *huge*, respectively, if it is executed over a small edge, a medium edge, or a huge edge. We denote the number of medium saturating pushes by $\sharp$*med sat pushes*.

There is an obvious bound of $O(nm)$ of $\sharp$*med sat pushes*. However, for sufficiently dense graphs $\sharp$*med sat pushes* can be shown to be significantly less than proportional to nm. Intuitively, the reason for the relatively small number of saturating pushes over medium edges is that an edge is medium for only $O(\log n)$ phases, i.e., medium edges are "short-lived."

In order to bound the number of medium saturating pushes, we partition these into three classes, (a), (b), and (c). To define the partition, consider a medium saturating push over an edge (v, w). If either $d(v)$ or $d(w)$ has the same value at the time of the push as at a "phase boundary," i.e., at the beginning or at the end of a phase, then the push is a class (a) push. Otherwise, if the number of medium (undirected) edges incident with w at the time of the push is $\leq \deg(w)/\beta$, it is a class (b) push. If neither of these cases applies, the push is a class (c) push. Note that if a push of class (b) or (c) is executed over an edge (v, w) during a particular period of eligibility of (v, w), then that period of eligibility of (v, w) lies entirely within one phase.

LEMMA 7.1. *Over the whole execution, the number of class* (a) *and class* (b) *medium saturating pushes is* $O(nm/\beta + m \log n)$.

Proof. The number of class (a) pushes is $O(m \log n)$ because each edge is medium for only $O(\log n)$ phases, and between two successive saturating pushes over an edge both its tail vertex and its head vertex have to be relabeled.

The number of class (b) pushes is $O(nm/\beta)$. To see this, note that between two consecutive relabelings of a vertex w there are $\leq \deg(w)/\beta$ medium saturating pushes of class (b) into w. Summing over all $w \in V$ and all relabelings of w gives $O(\sum_{w \in V}(2n - 1) \deg(w)/\beta) = O(nm/\beta)$. □

The medium saturating pushes of class (c) are more difficult to handle, and we need a few more results before we can tally them.

Define the *throughput* of a saturating push over an edge (v, w) while $d(v) = k$ to be equal to $rescap(v, w)$ when $d(v)$ is set to k. In other words, the throughput is the total amount of flow sent over (v, w) during a maximal period of eligibility of (v, w). Note that the value of the saturating push may be less than its throughput.

LEMMA 7.2. *Over the whole execution, the number of nonsmall saturating pushes with throughput* $< \Delta/\beta$ *is* $\leq m + \sharp ptr$.

Proof. Consider a nonsmall saturating push over an edge (v, w) while $d(v) = k$. Since $ucap(v, w) \geq \Delta/\beta$, it follows that when $d(v)$ is set to k, then $rescap(w, v) > 0$; also, obviously, $rescap(v, w) > 0$. Assume that either (v, w) or (w, v) has been used as a current edge before this use of (v, w) as a current edge. It can then be seen that the previous use of (v, w) or (w, v) as a current edge was terminated by a PTR event. The lemma follows. □

The medium saturating pushes of class (c) that have throughput $< \Delta/\beta$ are easily taken care of by the previous lemma, so we now turn our attention to the remaining class (c) pushes. Recall that all the pushes contributing to the throughput of a class (c) push are executed in the same phase.

Consider a vertex w that is the head vertex of a medium saturating push of class (c). By the definition of class (c), a fraction of more than $1/\beta$ of the undirected edges incident with w are medium. The next lemma enables us to focus on such vertices and to give a sufficiently good bound on the number of class (c) saturating pushes with throughput $\geq \Delta/\beta$ into these vertices. The lemma is a generalization of Lemma 6 of [AO89], whose proof, with a minor modification, shows that the number of pushes with value $\geq \Delta$ in any phase is $O(n^2)$.

LEMMA 7.3. *For every subset* V' *of* V *and in every fixed* Δ*-phase, the number of pushes with value* $\geq \Delta$ *into the vertices of* V' (*i.e., pushes over edges of the form* (v, w), *where* $w \in V'$) *is* $O(|V'| \cdot n + D)$, *where* D *denotes the number of relabel operations executed in the phase.*

Since our main objective at this point is to provide intuition, we prove the lemma only for the special case when all the edge capacities are integers; the proof trivially extends to the case of rational edge capacities. A direct but less intuitive proof of the general case of the lemma is given in the next section (Lemma 8.3).

Suppose that all the edge capacities are integers, and also assume that the algorithm uses integer division, i.e., the occurrence of $\Delta/2$ in the procedure *select* is replaced by $\lfloor \Delta/2 \rfloor$. (Note that the test $\tilde{e}(v) < \Delta/2$ in the procedure *macropush* can be carried out without division.) Induction on the number of steps executed shows the preflow f, and hence also the flow excess e, to have integer values throughout the execution, and it can be seen that this modification does not affect our analysis of the algorithm. Furthermore, each unit of flow remains an indivisible entity throughout the execution. Call each unit of flow a *flow atom*. Related notions of flow atoms were previously used to analyze maximum-flow algorithms by, for example, Shiloach and Vishkin [SV82], Goldberg [G85], Cheriyan and Maheshwari [CM89], and Tunçel [T90].

Proof. (Lemma 7.3, integer edge capacities). The lemma is a straightforward consequence of a property of the so-called moving sequence of a flow atom. Consider a flow atom q and define $d(q)$ to be $d(v)$, where v is the vertex at which q is currently located. Focus on the movement of q during the phase under consideration and note that each change of $d(q)$ is caused by either a push operation or a relabel operation applied to the vertex at which q is currently located.

The *moving sequence* of q, $ms(q)$, is a string over the alphabet $\{\langle u, i\rangle : u \in V' \text{ and } 0 \leq i \leq 2n - 1\} \cup \{\uparrow\}$ defined as follows: At the start of the phase, $ms(q)$ is empty. If q is pushed into a vertex $u \in V'$ (i.e., q is sent over an edge whose head vertex u is in V'), $\langle u, d(u)\rangle$ is appended to $ms(q)$, and if the vertex currently holding q undergoes a relabeling, then an $\uparrow$ is appended to $ms(q)$. Let $|ms(q)|_{\uparrow}$ denote the number of $\uparrow$ symbols in a moving sequence $ms(q)$, and let $|ms(q)|_{\downarrow}$ denote the number of remaining symbols in $ms(q)$, i.e., the number of symbols of the form $\langle u, i\rangle$. Finally let $n' = |V'|$.

The main property of moving sequences is

$$|ms(q)|_{\downarrow} \leq n' + |ms(q)|_{\uparrow}.$$

To show this relation, assume that $ms(q)$ contains at least one non-$\uparrow$ symbol, and let $\langle u, i\rangle$ be the first of these. Consider the prefix of $ms(q)$ up to and including the last symbol in $ms(q)$ with a first component of u and denote this prefix by $ms'(q)$. It is easy to show that $|ms'(q)|_{\downarrow} \leq 1 + |ms'(q)|_{\uparrow}$. To see this, note that each $\uparrow$ symbol corresponds to an increase of $d(q)$ by one, while each non-$\uparrow$ symbol corresponds to a decrease of $d(q)$ by one. Furthermore, by comparing the first non-$\uparrow$ symbol $\langle u, i\rangle$ in $ms'(q)$ with the symbol $\langle u, j\rangle$ at the end of $ms'(q)$ and noting that $d(u)$ is nondecreasing throughout the execution, we may conclude that $j \geq i$. Consequently, the number of non-$\uparrow$ symbols in $ms'(q)$ is at most one more than the number of $\uparrow$ symbols.

Now delete $ms'(q)$ from $ms(q)$. If the remaining string contains any non-$\uparrow$ symbols, let $\langle v, l\rangle$ be the first of these and consider the prefix $ms''(q)$ consisting of all symbols up to and including the last symbol with a first component of v. Using the same argument, it can be seen that $|ms''(q)|_{\downarrow} \leq 1 + |ms''(q)|_{\uparrow}$.

Repeating this argument a total of at most n' times shows that

$$|ms(q)|_{\downarrow} \leq n' + |ms(q)|_{\uparrow}.$$

Let Q denote the set of all flow atoms that are located at active vertices at the start of the phase (i.e., flow atoms located at s or t at the start of the phase are not in Q). Fact 3.4 clearly implies that $|Q| \leq 2n \cdot \Delta$. To count the number of pushes with value $\geq \Delta$ into the vertices of V', notice that each of these operations pushes $\geq \Delta$ flow atoms into some vertex $u \in V'$ and causes a symbol with a first component of u to be appended to the moving sequence of each of these flow atoms. Hence, the number of such pushes is

$$\begin{aligned}
&\leq (1/\Delta) \sum_{q \in Q} |ms(q)|_{\downarrow} \\
&\leq (1/\Delta) \sum_{q \in Q} (n' + |ms(q)|_{\uparrow}) \\
&\leq (1/\Delta)((2n \cdot \Delta \cdot n') + \sum_{q \in Q} |ms(q)|_{\uparrow}) \\
&\leq 2nn' + (1/\Delta)(3\Delta \cdot D) = 2nn' + 3D.
\end{aligned}$$

The last inequality follows because there are D *relabel* operations, and the total number of $\uparrow$ symbols appended by a single relabeling is at most 3Δ (Fact 3.4). □

We actually use a more technical but straightforward generalization of the previous lemma.

COROLLARY 7.4. *For every subset V' of V and in every fixed Δ-phase, the number of class* (c) *medium saturating pushes with throughput $\geq \Delta/\beta$ over edges of the form (v, w), where $w \in V'$, is $O(\beta(|V'| \cdot n + D))$, where D denotes the number of relabel operations executed in the phase.*

We need a technical definition. A Δ-phase is said to *hit* a vertex v if the number of medium (undirected) edges incident with v in the phase is $> \deg(v)/\beta$. Notice that each phase hits the head vertex of every class (c) medium saturating push executed in the phase. The following interpretation may be useful below: associate each undirected edge $\{v, w\}$ with the interval $[ucap(v, w)/(40n^2),\ \beta \cdot ucap(v, w)]$ on the x axis, and view "the phase" as a vertical line sweeping the x axis from ∞ to 0; the current value of Δ gives the current location of the sweep line, and an edge is medium exactly if its associated interval is currently intersected by the sweep line.

Fact 7.5. For all $v \in V$, the number of distinct phases that hit v is $O(\beta \log n)$. Therefore the sum over all phases of the number of vertices hit by the phase is $O(n\beta \log n)$.

Proof. Let the phases that hit v have parameters $\Delta_1, \Delta_2, \ldots$, and for $i = 1, 2, \ldots$, let $M_i(v)$ denote the set of medium (undirected) edges incident with v in the Δ_i-phase. The number of Δ_i- phases ($i \geq 2$) that hit v such that $M_1(v) \cap M_i(v) \neq \emptyset$ is $O(\log n)$, because in each such phase the parameter Δ_i is in the interval $[\Delta_1/(40n^2\beta), 40n^2\beta\Delta_1]$.

If v is hit by yet another phase (besides the $O(\log n)$ phases enumerated above) with parameter, say, $\Delta_j (j \geq 2)$, then $M_1(v) \cap M_j(v) = \emptyset$, and both $|M_1(v)|$ and $|M_j(v)|$ are $> \deg(v)/\beta$. Continuing the argument, it follows that v is hit by $O(\beta \log n)$ phases. □

LEMMA 7.6. *Over the whole execution, the number of class* (c) *medium saturating pushes is $O(n^2\beta^2 \log n + \sharp\text{ptr})$.*

Proof. By Lemma 7.2, the number of medium saturating pushes with throughput $< \Delta/\beta$ is $O(m + \sharp\text{ptr})$.

Consider a fixed Δ-phase and focus on the class (c) medium saturating pushes with throughput $\geq \Delta/\beta$ in that phase. Let V' denote the set of vertices hit by the phase, and let D denote the number of *relabel* operations in the phase. By applying Corollary 7.4, we can see that the number of class (c) medium saturating pushes with throughput $\geq \Delta/\beta$ is $O(\beta(|V'| \cdot n + D))$.

Finally, by summing over all phases and using Fact 7.5 and the fact that the total number of relabelings is $O(n^2)$, we find that the total number of class (c) medium saturating pushes with throughput $\geq \Delta/\beta$ is $O(n^2\beta^2 \log n)$. □

We are now ready to bound $\sharp$*selects* and thereby complete the simple analysis of the running time.

LEMMA 7.7. $\sharp selects = O(nm/\beta + n^2\beta^2 \log n + \sharp\text{ptr})$.

Proof. Every *cut* operation is associated with either a PTR event or a nonsmall saturating push, since no small edge is ever inserted into the dynamic trees data structure (Fact 5.2). Hence the number of *cut* operations is bounded by $\sharp$*med sat pushes* + $\sharp$*huge sat pushes* + $\sharp$ptr. The number of *link* operations clearly exceeds the number of *cut* operations by at most $n - 1$ because the forest F never contains more than $n - 1$ edges, and the number of *relabel* operations is $O(n^2)$. Therefore the number of *select* steps that execute either a *cut* or a *link* or a *relabel* is $O(n^2 + \sharp$*med sat pushes* + $\sharp$*huge sat pushes* + $\sharp$ptr).

The remaining *select* steps can be partitioned into two classes: those that execute one or more saturating pushes, and those that do not execute any saturating push.

The number of *select* steps that execute a saturating push and do not execute any *cut*, *link*, or *relabel* is $O(nm/\beta + \sharp$*med sat pushes* + $\sharp$*huge sat pushes*), because if a *select* step executes only small saturating pushes, then it executes at least $\beta/2$ saturating pushes, since

the flow excess of the processed vertex decreases from $\geq \Delta$ to $< \Delta/2$ and each small push has value $< \Delta/\beta$.

Now consider the *select* steps that do not execute any *cut*, *link*, *relabel*, or saturating push, and call each such step a *neat select* step. (The argument here is similar to that in the proof of Lemma 5.6.) The vertex processed by a neat *select* step is a nonroot in F throughout that step. Consider a fixed vertex v and focus on the part of the execution between two consecutive nonneat *select* steps that process v, or after the last such *select* step. Suppose that v is processed by one or more neat *select* steps in this part of the execution. When the first of these neat *select* steps is executed, then $\Delta \leq e(v) < 3\Delta$; hence it follows by Fact 5.4 that $e(v)$ decreases to zero after at most two neat *select* steps that process v, and over the whole execution, this gives a number of neat *select* steps that is at most twice the number of nonneat *select* steps. Before yet another neat *select* step that processes v, $e(v)$ has to increase from zero to $\geq \Delta$. Further, by Fact 5.3, any increase of $e(v)$ is caused by saturating pushes into v. Consider these saturating pushes and their associated edges (u, v), where $u \in V$. If each of these edges (u, v) has $ucap(u, v) < \Delta/\beta$ when v is processed by the neat *select* step, then clearly there are $\geq \beta$ saturating pushes into v, and over the whole execution this case gives $O(nm/\beta)$ neat *select* steps. Otherwise, either there is at least one nonsmall saturating push into v or the status of one of these edges changes (from small to medium or huge) between the earliest of these saturating pushes and the neat *select* step that processes v. Over the whole execution, the former case gives $O(\sharp \textit{med sat pushes} + \sharp \textit{huge sat pushes})$ neat *select* steps, and the latter case gives $O(m)$ neat *select* steps, because the total number of status changes of edges is $\leq 2m$.

Therefore, the total number of neat *select* steps is at most twice the total number of nonneat *select* steps, plus $O(m + nm/\beta + \sharp \textit{med sat pushes} + \sharp \textit{huge sat pushes})$. Hence

$$\begin{aligned} \sharp \textit{selects} &= O(nm/\beta + n^2 + \sharp \textit{med sat pushes} + \sharp \textit{huge sat pushes} + \sharp \text{ptr}) \\ &= O(nm/\beta + n^2\beta^2 \log n + \sharp \text{ptr}). \end{aligned}$$

For the second equation, we use the bound on $\sharp$*med sat pushes* given by Lemmas 7.1 and 7.6 and the bound on $\sharp$*huge sat pushes* given by Lemma 6.1. □

LEMMA 7.8. *For every $\alpha \geq 1$, the strongly polynomial maximum-flow algorithm runs in time $O(\alpha \cdot (nm + n^{4/3}m^{2/3}(\log n)^{4/3} + n^2(\log n)^2))$ with probability at least $1 - 2^{-\alpha(\sqrt{nm} + n \log n)}$.*

Proof. By taking $\beta = 2 + (m/(n \log n))^{1/3}$ and using the previous lemma and the bound on $\sharp$ptr given in Lemma 6.4, we see that $\sharp \textit{selects} = O(n^{4/3}m^{2/3}(\log n)^{1/3} + \alpha \cdot (n^{3/2}m^{1/2} + n^2 \log n))$ with probability at least $1 - 2^{-\alpha(\sqrt{nm} + n \log n)}$. The bound on the running time now follows from Lemma 5.5. □

For $m = \Omega(n(\log n)^4)$ the running time is $O(nm)$, with high probability.

8. A strengthened analysis of operations on medium edges and of the overall running time. An examination of the analysis in the previous section shows that the bottleneck in bounding $\sharp$*selects* is the contribution due to $\sharp$*med sat pushes*, since our bound for $\sharp$*med sat pushes* is $O(n^{4/3}m^{2/3}(\log n)^{1/3} + \sharp \text{ptr})$, whereas the bound for both $\sharp$*huge sat pushes* and $\sharp$ptr is $O(n^{3/2}m^{1/2} + n^2 \log n)$. In this section, a tighter analysis of the contribution of $\sharp$*med sat pushes* to $\sharp$*selects* is developed.

Recall that the medium saturating pushes are partitioned into three classes, (a), (b), and (c), and that the number of pushes in these classes are $O(m \log n)$, $O(nm/\beta)$, and $O(n^2\beta^2 \log n + \sharp \text{ptr})$, respectively, for any β with $2 \leq \beta = n^{O(1)}$. The bottleneck term in the bound for $\sharp$*med sat pushes* is due to the class (c) pushes.

In order to bound the contribution of the class (c) pushes to $\sharp$*selects*, we partition this class into two subclasses. A push over an edge (v, w) is called *terminal* if at the time of the push

$$|\{u : u \in V' \text{ and } d(u) = d(w)\}| < \beta,$$

where V' denotes the set of vertices hit by the current Δ-phase, i.e., if at the time of the push there are fewer than β "hit vertices" with labels equal to $d(w)$. Otherwise the push is *nonterminal*.

LEMMA 8.1. *Over the whole execution, the number of terminal pushes of class* (c) *is* $O(n^2\beta)$.

Proof. Fix $v \in V$ and $k \in \{1, \ldots, 2n-1\}$ and recall that if there are any class (c) pushes out of v at all while $d(v) = k$, then all pushes out of v while $d(v) = k$ occur in the same phase, i.e., the set V' does not change between the first and the last of these pushes. Since an edge out of v can become eligible only during a relabeling of v, while at the time of a terminal push out of v there are fewer than β eligible edges of the form (v, w), where $w \in V'$, it is now clear that the number of terminal class (c) pushes out of v while $d(v) = k$ is bounded by β. Summing over all $v \in V$ and all $k \in \{1, \ldots, 2n-1\}$ yields a total of $O(n^2\beta)$ terminal class (c) pushes. □

The next lemma is the key instrument for bounding the contribution of the nonterminal class (c) pushes to $\sharp$*selects*.

LEMMA 8.2. *The sum over all Δ-phases of the ratio of the total value of all nonterminal pushes in the Δ-phase to $\Delta/2$ is $O(n^2 \log n)$.*

To see the relevance of this lemma, notice that it directly gives an $O(n^2 \log n)$ bound on the number of nonterminal pushes with value $\geq \Delta/2$. To prove Lemma 8.2, we need a stronger version of Lemma 7.3. The following lemma may be used to bound the total value of nonterminal pushes in any Δ-phase by taking V' (in the lemma) to be the set of vertices hit by the phase and taking γ (in the lemma) to be equal to β.

LEMMA 8.3. *Let γ be a number ≥ 1. For every subset V' of V and in every fixed Δ-phase, the total value of pushes into vertices w such that when the push is executed*

$$|\{u : u \in V' \text{ and } d(u) = d(w)\}| \geq \gamma$$

is $O((|V'| \cdot n/\gamma + D)\Delta)$, where D denotes the number of relabel operations executed in the phase.

Proof. Let $h = |V'|$ and $V' = \{v_1, \ldots, v_h\}$ and for all $v \in V$, define the *fooling height* of v as

$$d'(v) = \max_{i_1 \geq d(v_1), \ldots, i_h \geq d(v_h)} |\{k \in \mathbb{N}_0 : 0 \leq k < d(v) \text{ and } |\{j : i_j = k\}| \geq \gamma\}|.$$

Intuitively, $d'(v)$ counts the maximum number of "dense virtual distance levels" between v and t, where a vertex $v_j \in V'$ is allowed to occupy any one virtual distance level numbered at least $d(v_j)$, and where a dense virtual distance level is one that contains at least γ vertices in V'.

d' has the following properties:

(1) $\forall v \in V : 0 \leq d'(v) \leq h/\gamma$;

(2) $\forall v, w \in V : d(v) > d(w) \Longrightarrow d'(v) \geq d'(w)$;

(3) $\forall v, w \in V : (d(v) > d(w) \text{ and } |\{u \in V' : d(u) = d(w)\}| \geq \gamma) \Longrightarrow d'(v) > d'(w)$;

(4) a relabeling of a vertex $v \in V$ increases $d'(v)$ by at most 1 and does not increase $d'(w)$ for any $w \in V \backslash \{v\}$.

Define the potential function

$$\Phi = \sum_{v \in V - \{s,t\}} e(v) \cdot d'(v).$$

At the start of the Δ-phase, $\Phi \leq 2n\Delta \cdot h/\gamma$ (by property (1) and Fact 3.4), and $\Phi \geq 0$ always. Φ does not increase due to push operations (by property (2)), and a relabeling increases Φ by at most 3Δ (by property (4) and Fact 3.4). It follows that the total increase in Φ during the Δ-phase is at most $3\Delta \cdot D$. Consequently, the total decrease in Φ during the Δ-phase is at most $2n\Delta \cdot h/\gamma + 3\Delta \cdot D$. Finally note that each push satisfying the condition of the lemma and of value c causes Φ to decrease by at least c (by property (3)). □

Proof (Lemma 8.2). Consider a fixed Δ-phase. Let V' denote the set of vertices hit by the phase, let D denote the number of relabelings executed in the phase, and take $\gamma = \beta$. Now apply Lemma 8.3, noting that every nonterminal push satisfies the condition of the lemma. Hence, the ratio of the total value of all nonterminal pushes in the phase to $\Delta/2$ is $O(|V'| \cdot n/\beta + D)$.

The lemma now follows by summing over all phases, using Fact 7.5 to bound the sum over all phases of the number of vertices hit by the phase and noting that the total number of *relabel* operations is $O(n^2)$. □

The proof of the next lemma follows the same outline as that of Lemma 7.7.

LEMMA 8.4. $\sharp selects = O(nm/\beta + n^2\beta + n^2 \log n + \sharp \text{ptr})$.

Proof. First we give an improved bound on the number of *select* steps that execute either a *cut* or a *link* or a *relabel*, by giving an improved bound on the number of *cut* operations. Notice that the throughput of any saturating push associated with a *cut* operation is $\geq \Delta/2$, because whenever an edge (v, w) is inserted into F (the procedure *macropush*), then $rescap(v, w) \geq \Delta/2$ (by Fact 5.2). We claim that the number of medium saturating pushes with throughput $\geq \Delta/2$ is $O(nm/\beta + n^2\beta + n^2 \log n)$. To see this, focus on the nonterminal class (c) pushes with throughput $\geq \Delta/2$, since the total number of class (a), class (b), and terminal class (c) pushes is $O(nm/\beta + m \log n + n^2\beta)$, by Lemmas 7.1 and 8.1. By applying Lemma 8.2 it can be seen that the number of nonterminal class (c) pushes with throughput $\geq \Delta/2$ is $O(n^2 \log n)$. The claim follows. Consequently, the number of *cut* operations is $O(nm/\beta + n^2\beta + n^2 \log n + \sharp \textit{huge sat pushes} + \sharp \text{ptr}) = O(nm/\beta + n^2\beta + n^2 \log n + \sharp \text{ptr})$, and the number of *select* steps that execute either a *cut* or a *link* or a *relabel* is also $O(nm/\beta + n^2\beta + n^2 \log n + \sharp \text{ptr})$.

The remaining *select* steps are partitioned into two classes: those that execute one or more saturating pushes, and those that do not execute any saturating push. (The argument here is a refined version of that used in the proof of Lemma 7.7.)

The number of *select* steps that execute a saturating push and do not execute any *cut*, *link*, or *relabel* is $O(nm/\beta + n^2\beta + n^2 \log n + \sharp \textit{huge sat pushes})$. To see this, first focus on such a *select* step that executes a nonterminal class (c) push. Notice that all of the saturating pushes executed by the *select* step are nonterminal and that the total value of these pushes is $\geq \Delta/2$. Now, by applying Lemma 8.2, we see that over the whole execution, this case gives $O(n^2 \log n)$ *select* steps. Over the whole execution, the number of *select* steps that execute either a class (a), a class (b), or a terminal class (c) push is $O(nm/\beta + m \log n + n^2\beta)$, and the number of *select* steps under consideration that execute only small saturating pushes is $O(nm/\beta)$, because any such step executes at least $\beta/2$ saturating pushes, since the flow excess of the processed vertex decreases from $\geq \Delta$ to $< \Delta/2$ and since each small push has value $< \Delta/\beta$.

Now consider the *select* steps that do not execute any *cut*, *link*, *relabel*, or saturating push, and call each such step a *neat select* step. As noted before, the vertex v processed by a neat *select* step is a nonroot in F throughout that step. Consider a fixed vertex v and focus on the part of the execution between two consecutive nonneat *select* steps that process v, or after the last such *select* step. Suppose that v is processed by one or more neat *select* steps in this part of the execution. When the first of these neat *select* steps is executed, then $\Delta \leq e(v) < 3\Delta$. Hence, it follows by Fact 5.4 that $e(v)$ decreases to zero after at most two neat *select* steps that process v, and over the whole execution, this gives a number of neat *select* steps that is at most

twice the number of nonneat *select* steps. Before yet another neat *select* step that processes v, $e(v)$ has to increase from zero to $\geq \Delta$. Furthermore, by Fact 5.3, any increase of $e(v)$ must be caused by saturating pushes into v. Consider these saturating pushes and their associated edges (u, v), where $u \in V$. If each of these edges (u, v) has $ucap(u, v) < \Delta/\beta$ when v is processed by the neat *select* step, then clearly there are $\geq \beta$ saturating pushes into v, and over the whole execution this case gives $O(nm/\beta)$ neat *select* steps. Otherwise, either the status of one of these edges changes (from small to medium or huge) between the earliest of these saturating pushes and the neat *select* step that processes v, or there is at least one nonsmall saturating push into v. Over the whole execution, the former case gives $O(m)$ neat *select* steps, because the total number of status changes of edges is $\leq 2m$. If there is an increase of $e(v)$ from zero to $\geq \Delta$ due to a nonsmall saturating push and zero or more small saturating pushes, followed by a neat *select* step that processes v, then we have two mutually exclusive cases. Either the increase of $e(v)$ is due to one or more nonterminal class (c) pushes whose values sum to $\geq \Delta/2$ together with zero or more small saturating pushes, or the increase of $e(v)$ is due to one or more of the following together with zero or more small saturating pushes: one or more nonterminal class (c) pushes whose values sum to $< \Delta/2$ together with $\geq \beta/2$ small saturating pushes, a class (a) push, a class (b) push, a terminal class (c) push, or a huge saturating push. Over the whole execution, the first case gives $O(n^2 \log n)$ neat *select* steps (by Lemma 8.2), and the second case gives $O(nm/\beta + m \log n + n^2\beta + \sharp$*huge sat pushes*$)$ neat *select* steps. Therefore the total number of neat *select* steps is at most twice the total number of nonneat *select* steps plus $O(nm/\beta + n^2\beta + n^2 \log n + \sharp$*huge sat pushes*$)$.

Finally, the number of *select* steps, $\sharp$*selects*, is $O(nm/\beta + n^2\beta + n^2 \log n + \sharp\text{ptr})$, using the bound on $\sharp$*huge sat pushes* given by Lemma 6.1. □

THEOREM 8.5. *For every* $\alpha \geq 1$, *a maximum flow can be computed in time* $O(\alpha \cdot (nm + n^2(\log n)^2))$ *with probability at least* $1 - 2^{-\alpha(\sqrt{nm}+n \log n)}$.

Proof. By taking $\beta = 2 + \sqrt{m/n}$ and using the previous lemma and the bound on $\sharp$ptr given in Lemma 6.4, we see that $\sharp$*selects* $= O(\alpha \cdot (n^{3/2}m^{1/2} + n^2 \log n))$ with probability at least $1 - 2^{-\alpha(\sqrt{nm}+n \log n)}$. The bound on the running time follows from Lemma 5.5. □

Notice that for $m = \Omega(n(\log n)^2)$ the running time is $O(nm)$, with high probability.

Remark. If, as in [CH89], a new random permutation μ_v of $\Gamma(v)$ is computed at each relabeling of v, then the failure probability of Theorem 8.5 can be reduced even further to $2^{-\alpha(n^{3/2}m^{1/2}+n^2 \log n)}$.

9. Conclusion. We have shown that by using randomization on nonsparse graphs (i.e., $m = \Omega(n(\log n)^2)$) we can compute a maximum flow in $O(nm)$ time with high probability. The crucial new idea in our analysis is the notion of PTR events.

The preliminary version of this work [CH89] stimulated new research that has resulted in further advances on computing maximum flows. The original analysis is slightly loose, giving an $O(nm + n^{3/2}m^{1/2}(\log n)^{3/2} + n^2(\log n)^2)$ running time and an $O(n^{3/2}m^{1/2}(\log n)^{1/2} + n^2 \log n)$ bound on $\sharp$*selects*, both with high probability. Tarjan [T89] improved the analysis to obtain a running time of $O(nm + n^2(\log n)^2)$, with high probability. The improved analysis presented in §8, which differs from the analysis of [T89], was discovered subsequently and reported briefly in [CHM90].

Alon [A90] presented a simple way of derandomizing the strongly polynomial algorithm without affecting the running time for sufficiently dense graphs (i.e., $m = \Omega(n^{5/3} \log n)$): at initialization, the adjacency lists of the network vertices are permuted according to "pseudo-random permutations" (i.e., a set $\{\xi_1, \ldots, \xi_n\}$ of permutations of V with $\Lambda(\xi, \ldots, \xi_n) \ll n^2$) that are generated deterministically in $O(n^2)$ time. The running time of the resulting deterministic algorithm is $O(nm + n^{8/3} \log n)$. Recently, faster deterministic algorithms were described in [KRT93] and [PW93].

Another paper based on the present one is [CHM90], which shows that a maximum flow can be computed in $O(n^3/\log n)$ time on a uniform-cost RAM, and that the number of operations executed on flow variables can be improved from $O(nm)$ for the strongly polynomial algorithm here to $O(n^{8/3}(\log n)^{4/3})$.

One avenue for further research suggested by this work is to investigate whether randomization is useful for solving related problems on networks such as the minimum-cost flow problem and the maximum-weight matching problem.

SPARSE APPROXIMATE SOLUTIONS TO LINEAR SYSTEMS*

B. K. NATARAJAN†

Abstract. The following problem is considered: given a matrix A in $\mathbf{R}^{m\times n}$, (m rows and n columns), a vector b in $\mathbf{R}^m$, and $\epsilon > 0$, compute a vector x satisfying $\|Ax - b\|_2 \leq \epsilon$ if such exists, such that x has the fewest number of non-zero entries over all such vectors. It is shown that the problem is NP-hard, but that the well-known greedy heuristic is good in that it computes a solution with at most $\lceil 18\ \mathrm{Opt}(\epsilon/2)\|\mathbf{A}^+\|_2^2 \ln(\|b\|_2/\epsilon)\rceil$ non-zero entries, where $\mathrm{Opt}(\epsilon/2)$ is the optimum number of nonzero entries at error $\epsilon/2$, $\mathbf{A}$ is the matrix obtained by normalizing each column of A with respect to the L_2 norm, and $\mathbf{A}^+$ is its pseudo-inverse.

1. Introduction.

The problem of computing a sparse approximate solution to a linear system is a fundamental problem in matrix computation. For matrices over the reals, the problem (variant thereof) has been studied under the name "subset selection" in statistical modeling by Golub and Van Loan (1983). For binary matrices, the problem has been studied as "minimum weight solution" in error corrective coding by Gallager (1968). The related "sparse null-space" problem is of interest in nonlinear optimization; see Coleman and Pothen (1986). Also, the "minimum set cover" problem can be viewed as computing a sparse solution to $Ax \geq b$, where all the entries are binary and the inequality is entry-wise; see Garey and Johnson (1979), Johnson (1974).

Our specific motivation for studying the problem is as follows. A widely used technique for the interpolation of irregularly spaced samples in higher dimensions is that of radial basis interpolation; see Hardy (1988). In brief, assign each of the given sample points a coefficient. The value of the interpolant at a new point is the weighted sum of these coefficients, where the weights are the distances of the respective samples from the new point. The coefficients themselves are the solution to the linear system of equations obtained by evaluating the interpolant at the each of the given points and equating them to the respective sample values; Michelli (1986) has shown that the linear system is always nonsingular.

In solving the above linear system, two issues are of interest. (1) The cost of evaluating the interpolant at a general point grows with the number of nonzero coefficients in the solution. Hence, it is desirable to have as few nonzeros as possible, while tolerating some error in the interpolation. (2) By the principle of Occam's Razor, the interpolant with the fewest nonzero coefficients is most likely to approximate the underlying function that generated the samples. Indeed, in the presence of noise in the data, it is desirable to pick a sparse but approximate interpolant. Recently, learning theoretic justifications of Occam's Razor in this setting have been established; see Natarajan (1993).

In light of the above, we are interested in obtaining a sparse approximate solution to the linear system specifying the coefficients of the interpolant. Similar arguments can also be made with respect to other interpolation methods, such as polynomial or trigonometric interpolation.

Previously, it was known that the problem is NP-hard if the solution is required to be over the integers; see Garey and Johnson (1979). For matrices over the reals, the heuristic of Golub, Klema, and Stewart (1976) is well known, as discussed in Golub and Van Loan (1983). In this paper, we show that the problem remains NP-hard over the reals. We then show that the obvious and well-known greedy heuristic (Golub and Van Loan (1983)) is provably good in that

the number of nonzeros reported is at most 18 $\text{Opt}(\epsilon/2)\|\mathbf{A}^+\|_2^2 \ln(\|b\|_2/\epsilon)$, where $\text{Opt}(\epsilon/2)$ is the optimum number of nonzero entries at error $\epsilon/2$, $\mathbf{A}$ is the matrix obtained by normalizing each column of A with respect to the L_2 norm, and $\mathbf{A}^+$ is its pseudo-inverse. The algorithm is essentially a marriage between the greedy set cover algorithm of Johnson (1974) and the QR algorithm for least squares solutions of linear systems of Golub and Van Loan (1983). It is important to note that minimizing the number of zeros is competitive with the stability of the algorithm, i.e., the norm of the computed solution. The heuristic of Golub, Klema, and Stewart (1976) offers stability, but not provably good sparseness, while our algorithm does the converse. An open problem is to obtain an algorithm that allows an explicit tradeoff.

The algorithm consumes $O(mn)$ time per entry reported. Since the entries of the solution are reported in order of their "significance," the proposed algorithm is a good candidate for the progressive solution of dense linear systems. Computational experiments on using the greedy algorithm for radial basis interpolation are discussed in Carlson and Natarajan (1994).

2. Hardness. Let SAS refer to the sparse approximate solution problem stated below.

Problem. Given a matrix A in $\mathbf{R}^{m\times n}$, (m rows and n columns), a vector b in $\mathbf{R}^m$, and $\epsilon > 0$, compute a vector x satisfying $\|Ax - b\|_2 \leq \epsilon$ if such exists, such that x has the fewest number of nonzero entries over all such vectors.

We first establish that SAS is NP-hard on the machine model of the infinite precision RAM; see Preparata and Shamos (1985), for instance.

THEOREM 1. SAS *is* NP-*hard.*

Proof. The proof is by reduction from the problem of "exact cover by 3 sets," as in the proof of hardness for the problem of "minimum weight solutions to linear systems." See Garey and Johnson (1979), pp. 221 and 246).

Exact Cover by 3-*sets.*

Instance. A set S, and a collection C of 3-element subsets of S.

Question. Does C contain an exact cover for S, i.e., a sub-collection $\hat{C}$ of C such that every element of S occurs exactly once in $\hat{C}$?

Let us use X3C to refer to the problem of exact cover by 3-sets, and show how to transform an instance of X3C to an instance of SAS. Given is an instance of X3C: $S = \{s_1, s_2, \ldots, s_m\}$, and $C = c_1, c_2, \ldots, c_n$. Without loss of generality we can assume that m is a multiple of 3, since otherwise there is trivially no exact cover. Let b be the vector $(1, 1, 1, \ldots, 1)$ of m ones. The matrix A will have n column vectors, one for each set in C. Specifically, for each set $c \in C$, the corresponding column vector will have entries $(z_1, z_2, \ldots, z_m)$ where $z_i = 1$ if $s_i \in c$ and $z_i = 0$ otherwise. Pick $\epsilon = \frac{1}{2}$.

We show that the constructed instance of SAS has a solution with $m/3$ or fewer entries if and only if the given instance of X3C has a solution. If the X3C instance has a solution, then consider the vector $x = (x_1, x_2, \ldots, x_n)$, where $x_i = 1$ if the ith set in C is included in the solution of the X3C instance, and $x_i = 0$ otherwise. Then, $Ax = b$ exactly and hence the SAS instance has a solution with exactly $m/3$ nonzero entries. Conversely, assume the SAS instance has a solution x with at most $m/3$ nonzero entries.

Since $\|Ax - b\|_2 \leq \frac{1}{2}$, each entry of Ax must be between $\frac{1}{2}$ and $\frac{3}{2}$. Since each column of A has only three nonzero entries, x must have at least $m/3$ entries. Thus x has exactly $m/3$ entries. Now consider the subcollection $\hat{C}$, consisting of those sets c_i such that the ith entry in x is nonzero. It is clear that $\hat{C}$ is an exact cover for S. □

3. The algorithm. The algorithm we consider is a merging of the greedy set cover algorithm of Johnson (1974) and the QR algorithm for the least-squares problem of Golub and Van Loan (1983). In essence, it is a QR algorithm where the column pivot is chosen greedily with respect to the right-hand side b of the linear system. Such a modification is well known; see

Golub and Van Loan (1983, p. 168, Exercise 6.4.8). In the interest of simplicity, we will not present the algorithm as a modification of the QR algorithm, but will present it as a two-phase algorithm with a subset selection phase, followed by an explicit solution phase.

In words, Algorithm Greedy below takes as input A, b, and ϵ. The algorithm first normalizes each column a_i of A. Then, at each iteration of the selection phase, the algorithm greedily picks that column of A that is closest in angle to the vector b. Then, b and the column vectors of A are projected onto the subspace orthogonal to the chosen column. This procedure is repeated until $\|b\|_2 \leq \epsilon$. In the solution phase, the algorithm solves the linear system problem $Bx = b^{(0)} - b^{(r)}$ where B is the matrix consisting of those columns of A that were chosen in the selection phase, $b^{(0)}$ is b at the start of the selection of phase, and $b^{(r)}$ is b at the end of the selection of phase.

Algorithm Greedy
input:
matrix A, column vector b, $\epsilon > 0$.
Subset Selection Phase:
Normalize each column of A to obtain $\mathbf{A}$.
$r \leftarrow 0$; $\tau \leftarrow \phi$;
$A^{(0)} \leftarrow \mathbf{A}$; $b^{(0)} \leftarrow b$;
while $\|b^{(r)}\|_2 > \epsilon$ **do**
  if $A^{(r)T} b^{(r)} = 0$ **then**
    no solution exists;
  else
    choose $k \in \{1, 2, \ldots, n\} - \tau$ such that column $a_k^{(r)}$ of $A^{(r)}$
    is closest to $b^{(r)}$, i.e., $|a_k^{(r)T} b^{(r)}|$ is maximum;
    project $b^{(r)}$ onto the subspace orthogonal to $a_k^{(r)}$, i.e.,
    $b^{(r+1)} \leftarrow b^{(r)} - \left(a_k^{(r)T} b^{(r)}\right) a_k^{(r)}$;
    $\tau \leftarrow \tau \cup \{k\}$;
    for $j \in \{1, 2, \ldots, n\} - \tau$ **do**
      project $a_j^{(r)}$ onto the subspace orthogonal to $a_k^{(r)}$, i.e.,
      $a_j^{(r+1)} \leftarrow a_j^{(r)} - \left(a_k^{(r)T} a_j^{(r)}\right) a_k^{(r)}$;
      normalize $a_j^{(r+1)}$, i.e.,
      $a_j^{(r+1)} \leftarrow a_j^{(r+1)} / \|a_j^{(r+1)}\|_2$;
    end
  end
  $r \leftarrow r + 1$;
end
Solution Phase:
Solve $Bx = b^{(0)} - b^{(r)}$ where B is the matrix
of columns of A with indices in τ.
end

THEOREM 2. *The number of vectors selected by Algorithm Greedy, and hence the number of nonzero entries in the computed solution, is at most*

$$\left\lceil 18 \, \mathrm{Opt}(\epsilon/2) \|\mathbf{A}^+\|_2^2 \ln\left(\frac{\|b\|_2}{\epsilon}\right)\right\rceil, \tag{1}$$

where $\mathrm{Opt}(\epsilon/2)$ *denotes the fewest number of nonzero entries over all solutions that satisfy* $\|Ax - b\|_2 \leq \epsilon/2$.

Our proof of Theorem 2 is a simplified and generalized variant of that of the greedy set cover algorithm given by Johnson (1974). For each value of r, at the start of the corresponding iteration of the algorithm, let $u^{(r)}$ be a vector with the minimum number of nonzero entries such that $\|A^{(r)}u^{(r)} - b^{(r)}\|_2 \leq \epsilon/2$. Also, we define $N^{(r)}$ as the number of nonzero entries in $u^{(r)}$ and $q^{(r)} = A^{(r)}u^{(r)}$. Let t be the number of iterations the algorithm runs in the selection phase. It is clear that the number of nonzero entries produced by the solution phase of the algorithm is at most t. Define

$$\rho = 4 \max_{0 \leq r < t} \frac{N^{(r)}\|u^{(r)}\|_2^2}{\|b^{(r)}\|_2^2}. \tag{2}$$

Our proof proceeds in a sequence of lemmas. In the first lemma, we bound t in terms of ρ. Lemmas 2 and 3 estimate the right-hand side of the above definition of ρ. Combining the three lemmas, we will obtain Theorem 2.

For $z \in \mathbf{R}$, let $\lceil \mathbf{z} \rceil$ denote the smallest integer greater than or equal to z.

LEMMA 1. *The number of iterations of the algorithm t is at most*

$$\left\lceil 2\rho \ln\left(\frac{\|b\|_2}{\epsilon}\right)\right\rceil. \tag{3}$$

Proof. Since $u^{(r)}$ only has $N^{(r)}$ nonzero entries, we will show that at least one of the columns of $A^{(r)}$ must be correspondingly close to $b^{(r)}$. Specifically, we establish a lower bound on $\|A^{(r)T}b^{(r)}\|_\infty$. Now,

$$b^{(r)} = \sum_{i=1}^{n} u_i^{(r)} a_i^{(r)} + \epsilon\vec{/}2, \tag{4}$$

where $\epsilon\vec{/}2$ stands for the generic error vector of L_2 norm at most $\epsilon/2$. Hence

$$b^{(r)T}b^{(r)} = \sum_{i=1}^{n} u_i^{(r)} b^{(r)T} a_i^{(r)} + b^{(r)T}\epsilon\vec{/}2. \tag{5}$$

$$\leq \left(\max_{i=1}^{n} |\, a_i^{(r)T} b^{(r)} \,|\right) \sum_{i=1}^{n} |u_i^{(r)}| + \|b^{(r)}\|_2 \epsilon/2. \tag{6}$$

Now,

$$b^{(r)T}b^{(r)} = \|b^{(r)}\|_2^2, \tag{7}$$

$$\max_{i=1}^{n} |\, a_i^{(r)T} b^{(r)} \,| = \|A^{(r)T}b^{(r)}\|_\infty, \tag{8}$$

and

$$\|b^{(r)}\|_2 \geq \epsilon. \tag{9}$$

Also, since $u^{(r)}$ has $N^{(r)}$ nonzero entries,

$$\sum_{i=1}^{n} |u_i^{(r)}| = \|u^{(r)}\|_1 \leq \sqrt{N^{(r)}}\|u^{(r)}\|_2. \tag{10}$$

Hence, we can write (6) as

$$\|b^{(r)}\|_2^2 \leq \|A^{(r)T}b^{(r)}\|_\infty \sqrt{N^{(r)}}\|u^{(r)}\|_2 + 1/2\|b^{(r)}\|_2^2. \tag{11}$$

Rearranging, we get

$$\|A^{(r)T}b^{(r)}\|_\infty \geq \frac{\|b^{(r)}\|_2^2}{2\sqrt{N^{(r)}}\|u^{(r)}\|_2}. \tag{12}$$

Using the above lower bound on $\|A^{(r)T}b^{(r)}\|_\infty$ we now estimate the rate at which $b^{(r)}$ diminishes at each iteration of the algorithm. Now,

$$b^{(r+1)} = b^{(r)} - \left(a_k^{(r)T}b^{(r)}\right)a_k^{(r)}, \tag{13}$$

where $a_k^{(r)}$ is the column chosen by the algorithm at the rth iteration. Since $|a_k^{(r)T}b^{(r)}|$ is a maximum, $|a_k^{(r)T}b^{(r)}| = \|A^{(r)T}b^{(r)}\|_\infty$ and we can rewrite the above as

$$b^{(r+1)} = b^{(r)} - \text{sign}\left(a_k^{(r)T}b^{(r)}\right)\|A^{(r)T}b^{(r)}\|_\infty a_k^{(r)}, \tag{14}$$

where sign( ) is the function that returns the sign of its argument. Since $b^{(r+1)}$ is orthogonal to $a_k^{(r)}$,

$$\|b^{(r+1)}\|_2^2 = \|b^{(r)}\|_2^2 - \|A^{(r)T}b^{(r)}\|_\infty^2. \tag{15}$$

Rearranging, we get

$$\|b^{(r+1)}\|_2^2 = \left(1 - \frac{\|A^{(r)T}b^{(r)}\|_\infty^2}{\|b^{(r)}\|_2^2}\right)\|b^{(r)}\|_2^2. \tag{16}$$

Substituting (12) in (16), we get

$$\|b^{(r+1)}\|_2^2 \leq \left(1 - \frac{\|b^{(r)}\|_2^2}{4N^{(r)}\|u^{(r)}\|_2^2}\right)\|b^{(r)}\|_2^2. \tag{17}$$

Using (2) in (17), we get

$$\|b^{(r+1)}\|_2^2 \leq (1 - 1/\rho)\|b^{(r)}\|_2^2. \tag{18}$$

Hence,

$$\|b^{(t)}\|_2^2 \leq (1 - 1/\rho)^t\|b^{(0)}\|_2^2. \tag{19}$$

The algorithm halts when $\|b^{(t)}\|_2^2 \leq \epsilon^2$. For this to happen, it suffices that t satisfy

$$(1 - 1/\rho)^t\|b^{(0)}\|_2^2 \leq \epsilon^2. \tag{20}$$

Rearranging and taking logarithms, we get

$$t\ln(1 - 1/\rho) \leq \ln\left(\frac{\epsilon^2}{\|b^{(0)}\|_2^2}\right). \tag{21}$$

Incorporating in (21) the following inequality, obtained from a Taylor expansion of the natural logarithm function,

$$\ln(1 - 1/\rho) \leq \frac{-1}{\rho}, \tag{22}$$

we get that it suffices if

$$t \geq \rho \ln\left(\frac{\|b^{(0)}\|_2^2}{\epsilon^2}\right) = 2\rho \ln\left(\frac{\|b\|_2}{\epsilon}\right). \tag{23}$$

This completes the proof of the lemma. □

We will now establish an upper bound on ρ, by first bounding $\|u^{(r)}\|_2$ and then incorporating a bound on $N^{(r)}$.

LEMMA 2. *For* $0 \leq r < t$, $\|u^{(r)}\|_2 \leq 3/2\|\mathbf{A}^+\|_2\|b^{(r)}\|_2$.

Proof. Let $\sigma = \{i \mid u_i^{(r)} \neq 0\}$ be the set of indices of the nonzero entries in $u^{(r)}$, and let $\tau = \{k_1, k_2, \ldots, k_r\}$ be the indices of the first r columns picked by the algorithm. For matrix A and set of indices μ, we use $\mu(A)$ to denote the set of column vectors $\{a_i \mid i \in \mu\}$.

We first show that $\sigma(A^{(0)}) \bigcup \tau(A^{(0)})$ is a linearly independent set. Assume the contrary, i.e., some linear combination of vectors from $\sigma(A^{(0)}) \bigcup \tau(A^{(0)})$ sum to zero. Not all of the vectors in this combination can be from $\tau(A^{(0)})$, since $\tau(A^{(0)})$ is a linearly independent set by the definition of the algorithm. So it must be that at least one of the vectors in this combination is from $\sigma(A^{(0)})$. It follows that this vector from $\sigma(A^{(0)})$ can be expressed as a linear combination of vectors from $\sigma(A^{(0)}) \bigcup \tau(A^{(0)})$. Since $\sigma(A^{(r)})$ is the projection of $\sigma(A^{(0)})$ on the subspace orthogonal to $\tau(A^{(0)})$, the above supposition implies that some vector in $\sigma(A^{(r)})$ can be expressed as a linear combination of vectors in $\sigma(A^{(r)})$. But this contradicts the assumption that $u^{(r)}$ has a minimum number of nonzero entries. Hence $\sigma(A^{(0)}) \bigcup \tau(A^{(0)})$ must be linearly independent.

We can now establish a bound on $\|u^{(r)}\|_2$. By definition,

$$q^{(r)} = \sum_{i \in \sigma} u_i^{(r)} a_i^{(r)}. \tag{24}$$

For $i \in \sigma$, we can write

$$a_i^{(r)} = \frac{a_i^{(r-1)} - v_i^{(r)}}{\sqrt{1 - \|v_i^{(r)}\|_2^2}}, \tag{25}$$

where $v_i^{(r)}$ is a vector in the span of $\tau(A^{(r-1)})$. Using this recurrence, we can express $a_i^{(r-1)}$ in terms of $a_i^{(r-2)}$ and so on down to $a_i^{(0)}$. Since $\tau(A^{(r)})$ is orthogonal to $\tau(A^{(r-1)})$, it follows that $v_i^{(r)}$ is orthogonal to $v_i^{(r-1)}$ and hence $\|v_i^{(r)} + v_i^{(r-1)}\|_2^2 = \|v_i^{(r)}\|_2^2 + \|v_i^{(r-1)}\|_2^2$. Using this, we can combine the recurrences (25) to obtain a single expression of the form

$$a_i^{(r)} = \frac{a_i^{(0)} - v_i}{\sqrt{1 - \|v_i\|_2^2}}, \tag{26}$$

where v_i is a vector in the span of $\tau(A^{(0)})$.

Substituting (26) in (24), we get

$$q^{(r)} = \sum_{i \in \sigma} u_i^{(r)} \frac{a_i^{(0)} - v_i}{\sqrt{1 - \|v_i\|_2^2}}. \tag{27}$$

Noting that v_i is a vector in the span of $\tau(A^{(0)})$ and hence can be expressed as a linear combination of the columns of $\tau(A^{(0)})$, we can rewrite (27) as

$$q^{(r)} = \sum_{i \in \sigma} \frac{u_i^{(r)}}{\sqrt{1 - \|v_i\|_2^2}} a_i^{(0)} + \sum_{i \in \tau} \delta_i a_i^{(0)}, \tag{28}$$

for some δ_i in $\mathbf{R}$. Let Z be the matrix with columns $\sigma(A^{(0)}) \bigcup \tau(A^{(0)})$, and Z^+ its pseudo-inverse. Also, let $w = Z^+ q^{(r)}$. As established above, the columns of Z are linearly independent, and hence the entries of w are uniquely determined as in (28) above. Specifically, for $i \in \sigma$,

$$w_i = \frac{u_i^{(r)}}{\sqrt{1 - \|v_i\|_2^2}}, \tag{29}$$

and for $i \in \tau$, $w_i = \delta_i$. Since $\sqrt{1 - \|v_i\|_2^2} < 1$, we have that for $i \in \sigma$, $|u_i^{(r)}| \leq |w_i|$. For $i \in \tau$, $w_i = \delta_i$, $u_i^{(r)} = 0$, and hence $|u_i^{(r)}| \leq |w_i|$. We therefore have

$$\|u^{(r)}\|_2 \leq \|w\|_2 \leq \|Z^+\|_2 \|q^{(r)}\|_2. \tag{30}$$

Noting that $q^{(r)} = b^{(r)} + \epsilon \vec{/} 2$, and that since $r < t$, $\|b^{(r)}\|_2 > \epsilon$, we can simplify the above as

$$\|u^{(r)}\|_2 \leq \|Z^+\|_2 \|b^{(r)} + \epsilon \vec{/} 2\|_2 \leq 3/2 \|Z^+\|_2 \|b^{(r)}\|_2. \tag{31}$$

Since the columns of Z are a linearly independent subset of the columns of $A^{(0)} = \mathbf{A}$, the smallest nonzero singular value of Z is greater than or equal to the smallest nonzero singular value of $\mathbf{A}$; see Golub and Van Loan (1983, p. 286). Recall that $\mathbf{A}^+$ is the pseudo-inverse of $\mathbf{A}$. Since $\|Z^+\|_2$ and $\|\mathbf{A}^+\|_2$ are the reciprocals of the smallest nonzero singular values of Z and $\mathbf{A}$, respectively, $\|Z^+\|_2 \leq \|\mathbf{A}^+\|_2$, and the proof of the lemma is complete. □

LEMMA 3. *The number of entries in the sparse solution is nonincreasing as the algorithm iterates, i.e.,* $N^{(r+1)} \leq N^{(r)} \leq N^{(0)}$.

Proof. As before let $\sigma = \{i \mid u_i^{(r)} \neq 0\}$ be the set of indices of the nonzero entries in $u^{(r)}$, By definition, $|\sigma| = N^{(r)}$. Suppose that the algorithm selects a vector from σ at the rth iteration. Then surely $u^{(r+1)}$ has one fewer nonzero entry than $u^{(r)}$, namely the entry corresponding to the selected vector. If the vector selected by the algorithm is not from σ, then σ remains the set of nonzero entries of $u^{(r+1)}$. In either case $N^{(r+1)} \leq N^{(r)}$ and the lemma follows. □

Noting that $N^{(0)} = \text{Opt}(\epsilon/2)$ we can use Lemma 3 to rewrite (2) as

$$\rho \leq 4 \max_{0 \leq r < t} \frac{N^{(0)} \|u^{(r)}\|_2^2}{\|b^{(r)}\|_2^2}. \tag{32}$$

Using Lemma 2 to substitute for $\|u^{(r)}\|_2$ in (32) gives us

$$\rho \leq 9 \max_{0 \leq r < t} N^{(0)} \|A^{(+)}\|_2^2. \tag{33}$$

Substituting (33) in the statement of Lemma 1, we get that the number of zeros in the computed solution is at most

$$\left\lceil 18 \, \text{Opt}(\epsilon/2) \|\mathbf{A}^+\|_2^2 \ln\left(\frac{\|b\|_2}{\epsilon}\right) \right\rceil. \tag{34}$$

This concludes the proof of Theorem 1.

A HEURISTIC SCHEDULING OF INDEPENDENT TASKS WITH BOTTLENECK RESOURCE CONSTRAINTS*

QINGZHOU WANG† AND ERNST L. LEISS†

Abstract. In this paper, the problem of scheduling independent tasks with bottleneck resource constraints is investigated. There is a set of independent tasks $\mathcal{T} = \{T_1, \ldots, T_n\}$ and a set of resources $\mathcal{R} = \{R_1, \ldots, R_m\}$. The available amount of resource R_j, for $j = 1, \ldots, m$, is (normalized to) 1. Each task T_i's execution requires at least $\lambda_{(i,j)} \leq 1$ units of resource $R_j \in \mathcal{R}$, and with these minimal resources, the execution time of T_i is τ_i. If there is a resource $R_{\beta(i)}$ so that T_i can use ξ units ($\xi \geq \lambda_{(i,\beta(j))}$) and reduce the execution time to $\frac{\lambda_{(i,\beta(i))}}{\xi}\tau_i$, we say that T_i can achieve *linear speed-up* with respect to $R_{\beta(i)}$. It is assumed that for each T_i, there is one, and only one, resource $R_{\beta(i)}$ that is T_i's *bottleneck* resource: T_i can use ξ units of $R_{(i,\beta(i))}$ and achieve linear speed-up, where ξ is between $\lambda_{(i,\beta(i))}$ and $\Lambda_{(i,\beta(i))} \leq 1$. The problem is to find a feasible schedule for all the tasks in $\mathcal{T}$ that has a shortest overall makespan.

This problem is a combination of two previously studied problems—scheduling tasks with resource constraints [*SIAM J. Comput.*, 4 (1975), pp. 187–200.] scheduling parallel tasks [*SIAM J. Comput.*, 21 (1992), pp. 281–294]. A variant of this problem was studied in [*J. Combin. Theory*, 21 (1976), pp. 257–298]. Because the problem is NP-hard, we propose the ECT (*earliest completion time*) algorithm as a heuristic solution and show that the performance ratio of the ECT makespan M_{ECT} to the optimal makespan M_{OPT} is bounded by $2l + m + 1$, where l is the number of the bottleneck resources in $\mathcal{R}$. When $l = 0$, this is exactly the performance bound shown by Garey and Graham in [*SIAM J. Comput.*, 4 (1975), pp. 187–200].

AMS subject classifications. 68Q20, 68Q25

1. Introduction.

In the problem of scheduling independent tasks with resource constraints, we have a set $\mathcal{R}$ of m resources, $R_1, \ldots, R_m$, and a set $\mathcal{T}$ of n independent tasks, $T_1, \ldots, T_n$. For each resource R_j, the total amount available is always (normalized to) 1. For each task T_i, there is a minimum resource requirement for its execution—T_i requires $\lambda_{(i,j)} \leq 1$ units of resource R_j, $j = 1, \ldots, m$. With these minimal resources, task T_i can be completed in τ_i time units. For each T_i, there is one, and only one, *bottleneck* resource $R_{\beta(i)}$. In other words, the function

$$\beta: \quad \{1, \ldots, n\} \to \{1, \ldots, m\}, \tag{1.1}$$

maps a task index to a resource index. A resource is said to be a bottleneck resource for T_i if T_i can use up to $\Lambda_{(i,\beta(i))} \leq 1$ units of resource $R_{\beta(i)}$ and achieve a linear speed-up; if T_i uses ξ units of resource $R_{\beta(i)}$, where $\lambda_{(i,\beta(i))} \leq \xi \leq \Lambda_{(i,\beta(i))}$, and $\lambda_{(i,j)}$ units of all other resources $R_j (j \neq \beta(i))$, the required time to complete T_i will be shortened to $(\lambda_{(i,\beta(i))}/\xi)\tau_i$. If a task T_i uses $\Lambda_{i,\beta(i))}$ units of its bottleneck resource during the execution, we call it *fully parallelized.*

If a resource R_j is a bottleneck resource of some task, we simply call it a *bottleneck resource*. Not all resources need to be bottleneck resources, so the number of bottleneck resources is denoted by l, with $0 \leq l \leq m$.

An execution schedule of n tasks in $\mathcal{T}$ is called *feasible*, if at any time during the schedule, the usage of each individual resource R_j, $j = 1, \ldots, m$ does not exceed the available amount, 1. Among all the feasible schedules, it is desirable to use the optimal schedule, i.e., that which completes all the tasks in the shortest possible time. The time to complete all the tasks is called *makespan*; the optimal (shortest possible) makespan is denoted by M_{OPT}. Finding the optimal schedule is NP-hard [3]. Therefore, we investigate heuristic algorithms that take polynomial time to implement but produce only suboptimal schedules. If S is a heuristic scheduling

*Received by the editors January 25, 1993; accepted for publication (in revised form) November 9, 1993.
†Department of Computer Science, University of Houston, Houston, Texas 77204-3475.

algorithm, we use M_S to denote its makespan. The closeness of how a heuristic algorithm S approximates the optimal scheduling is expressed by its performance bound: $\sup\{M_S/M_{\mathrm{OPT}}\}$.

In this paper, we investigate the performance of using the *earliest completion time* (ECT) algorithm [4] to schedule independent tasks with bottleneck constraints. We will show that in general the performance bound of the ECT algorithm is

$$\sup\left\{\frac{M_{\mathrm{ECT}}}{M_{\mathrm{OPT}}}\right\} = 3m + 1. \tag{1.2}$$

This can be refined to $2l + m + 1$ if there are only l bottleneck resources. In discussing the independent task scheduling with no bottleneck resources (i.e., $l = 0$), Garey and Graham [1] use a scheduling algorithm that is a special case of ECT and whose performance bound is $m + 1$. Furthermore, in a variant of this problem, where each task is assumed to always have unit execution time, Garey et al. [2] develop scheduling algorithms based on the first fit (FF) and the first fit decreasing (FFD) bin packing techniques. The FF and FFD scheduling algorithms have asymptotic performance bounds of $m + \frac{7}{10}$ and $m + \frac{1}{3}$, respectively.

The discussion in this paper will be as follows. The ECT algorithm and its graphical representation in the multiresource context will be presented first. Following the graphical representation, we will introduce the notion of *covering intervals*, which is based on those of *wide* and *narrow* tasks that were first defined in [4]. Then, we analyze the resource usage and derive our performance bound.

2. The ECT algorithm. The algorithm in the top half of Fig. 1 is a LIST algorithm in its simplest form, and without loss of generality, we can assume that the task index reflects the execution order according to the LIST scheduling. Because each task has its minimum resource requirements, the time t_N is the time when there are sufficient resources to execute at least one waiting task. Immediately starting the next task T_i, however, does not mean that we can give T_i its earliest completion time. For each task T_i ready to be executed,

```
input ( task set 𝒯 )
while 𝒯 ≠ ∅ do
    t_N ← time when there are sufficient resources for at least one T_i
    invoke Earliest_Completion(t_N, T_i)
    𝒯 ← 𝒯 − {T_i}
end_while
```

```
    procedure Earliest_Completion(t_N, T_i)
    for ξ ∈ [λ_(i,β(i))), Λ_(i,β(i))]{
        define t(ξ) = the earliest time ≥ t_N there are ξ units of R_β(i)
        define t̃(ξ) = t(ξ) + (λ_(i,β(i)) / ξ) τ_i
    }
(†) ξ_i ← min{t̃^{-1}(min{t̃(ξ) : ∀ξ})};
    schedule T_i with ξ_i units of R_β(i) at time t(ξ_i);
```

FIG. 1. *The ECT Algorithm for tasks with bottleneck resources.*

we further process it through the *Earliest_Completion* procedure as shown in the second half of Fig. 1. If more bottleneck resource $R_{\beta(i)}$ is becoming available soon, we are willing to delay the starting time of T_i to achieve its earliest completion.

LEMMA 2.1. *The $T()$ function defined in the Earliest_Completion procedure only assumes no more than n values.*

Proof. Let us assume that $T_{i_1}, \ldots, T_{i_k}$ are the running tasks at time t_N, and T_{i_l} completes before $T_{i_{l+1}}$. If T_{i_l} releases ξ_l units of $R_{\beta(i)}$ at its completion time, we can write the total

amount of $R_{\beta(i)}$ released by T_i and the tasks before it with the notation $\xi_l = \sum_0^l \zeta_j$. For all $\xi \in (\xi_l, \xi_{l+1}]$, $t(\xi)$ will equal the completion time of T_{i_l}.

When all T_{i_l}'s have completed, $\sum_0^k \zeta_j = 1$ and $R_{\beta(i)}$ is completely free. Since all T_{i_l}'s only form a subset of $\mathcal{T}$, i.e., $k+1 \leq n$, we have actually shown that $t()$ assumes no more than n values in $[\lambda_{(i,\beta(i))}, 1]$, so it can assume no more than n values in $[\lambda_{(i,\beta(i))}, \Lambda_{(i,\beta(i))}]$. □

LEMMA 2.2. *The value* $\min\{\tilde{t}(\xi) : \forall \xi \in [\lambda_{(i,\beta(i))}, \Lambda_{(i,\beta(i))}]\}$ *in the statement* (†) *in Fig.* 1 *can be calculated in no more than n steps.*

Proof. In the previous lemma, we have shown that $t()$ assumes no more than n values in the interval $(\xi_l, \xi_{l+1}]$. By the definition of $\tilde{t}$, within each such interval, $\tilde{t}()$ is a strictly descending function that attains the minimal value at ξ_{l+1}. Therefore the calculation of min value in (†) in Fig. 1 can be done in no more than n steps. □

LEMMA 2.3. *In the statement* (†) *in Fig.* 1, $\tilde{t}^{-1}(\min\{\tilde{t}(\xi) : \forall \xi \in [\lambda_{(i,\beta(i))}, \Lambda_{(i,\beta(i))}]\})$ *may not be a unique value, yet it will never assume more than n values.*

Proof. As shown in the proof of Lemma 2.2, $\tilde{t}()$ is strictly descending in the interval $(\xi_l, \xi_{l+1}]$. Since there are no more than $k+1$ such intervals, the inverse function in (†) in Fig. 1 has no more than $k+1 \leq n$ values. □

There are four time events associated with the scheduling of a task T_i:

(i) *preparation time*, $a_S(T_i) = t(\lambda_{i,\beta(i))})$;

(ii) *execution time*, $b_S(T_i) = t(\xi_i)$;

(iii) *completion time*, $c_S(T_i) = \tilde{t}(\xi_i)$; and

(iv) *full parallelization time*, $f_S(T_i) = \min\{t(\Lambda_{(i,\beta(i))}), c_S(T_i)\}$.

The following relationships should always hold:

$$(2.1) \qquad a_S(T_i) \leq b_S(T_i) < f_S(T_i) \leq c_S(T_i) \quad \text{and} \quad c_S(T_i) - b_S(T_i) = \frac{\lambda_{(i,\beta(i))}}{\xi_i}\tau_i,$$

where ξ_i is the actual number of units of $R_{\beta(i)}$ used by T_i.

3. The graphical representation. Each resource can be represented by a strip of height 1; before it is used by the tasks, the strip is white from time 0 to ∞. Without loss of generality, let us consider the graphic representation of a single resource R_j. R_j is a strip of height 1 with the following coloring patterns:

(i) R_j is the bottleneck resource of T_i, so in $[a_S(T_i), b_S(T_j))$, T_i's preparation introduces grey color (Fig. 2(a));

(ii) otherwise, R_j is colored *black*, completely or partially, representing the amount of resource being used (Fig. 2(b)).

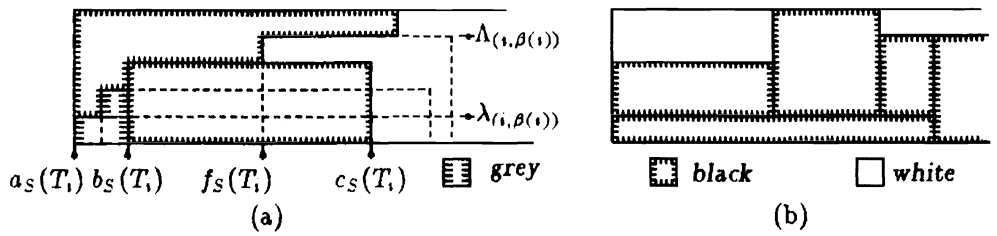

FIG. 2. *Two coloring patterns of a resource strip.*

LEMMA 3.1. *When it is colored in the first pattern, the strip* R_j *within the interval* $a_S(T_i), b_S(T_i))$ *is completely colored black or grey.*

Proof. This is really a direct result of the ECT scheduling. If there were any white space (free resource), it would have been consumed during the preparation of task T_i, and thus become grey. □

4. Wide and narrow tasks. Similar to [4], we put each task into one of two categories, $\mathcal{T} = \mathcal{T}_W \cup \mathcal{T}_N$:

(i) $T_i \in \mathcal{T}_W$, the set of *wide* tasks, if $\Lambda_{(i,\beta(i))} \geq \frac{1}{2}$;

(ii) otherwise, $T_i \in \mathcal{T}_N$, the set of *narrow* tasks.

We further define the *covering interval* $[X(T_i), Z(T_i))$ associated with each task T_i:

$$\begin{aligned} &X(T_i) = a_S(T_i), \qquad Z(T_i) = c_S(T_i), \quad \text{if } T_i \in \mathcal{T}_W; \\ &X(T_i) = a_S(T_i), \qquad Z(T_i) = f_S(T_i), \quad \text{if } T_i \in \mathcal{T}_N. \end{aligned} \tag{4.1}$$

If we eliminate from $\mathcal{T}$ the task $T_{i'}$ that satisfies

$$\exists i < i', \text{ such that } Z(T_{i'}) \leq Z(T_i), \tag{4.2}$$

we will have a subsequence of tasks

$$\mathcal{T}' = \{T_{i_1}, \ldots, T_{i_{n'}}\}. \tag{4.3}$$

The tasks in $\mathcal{T}'$ satisfy the following condition:

$$Z(T_{i_1}) < \cdots < Z(T_{i_k}) < \cdots < Z(T_{i_{n'}}). \tag{4.4}$$

This leads to a set of covering intervals that do not overlap:

$$[Y(T_{i_k}), Z(T_{i_k})) : \begin{cases} \text{if } k = 1, & Y(T_{i_k}) = X(T_{i_k}), \\ \text{otherwise}, & Y(T_{i_k}) = \max\{X(T_{i_k}), Z(T_{i_{k-1}})\}. \end{cases} \tag{4.5}$$

Associated with each such covering interval, there is a unique resource $R_{\beta(i_k)}$ that is the bottleneck resource of T_{i_k}. The next lemma estimates the resource usage of $R_{\beta(i_k)}$ in the interval $[Y(T_{i_k}), Z(T_{i_k}))$.

LEMMA 4.1. *Within the interval* $[y(T_{i_k}), Z(T_{i_k}))$, *the usage of the resource* $R_{\beta(i_k)}$ *is at least* $\frac{1}{2}(Z(T_{i_i}) - Y(T_{i_k}))$.

Proof. Let us consider the usage of $R_{\beta(i_k)}$ by all tasks $T_i \in \mathcal{T}$, with $i \leq i_k$. We distinguish the following two cases separately:

(i) the task T_{i_k} is a wide task;

(ii) the task T_{i_k} is a narrow task.

In the first case, we can directly use the analysis of wide tasks in [4, Lem. 6] after normalizing the unit of available resource to 1. It follows that the strip $R_{\beta(i_k)}$ in the interval is at least half colored black.

In the second case, T_{i_k} is a narrow task, and the right end of the interval is $Z(T_{i_k}) = f_S(T_{i_k}) \leq t(\Lambda_{i_k,\beta(i_k)}))$, which is no later than the time when task T_{i_k} could be fully parallelized If a narrow task cannot be fully parallelized, no more than half of the resource can be unused. Lemma 3.1 and Fig. 2(a) can help us to illustrate the argument. We can also conclude in the second case that the usage of $R_{\beta(i_k)}$ is no less than $\frac{1}{2}(z(T_{i_k}) - Y(T_{i_k}))$. □

In analyzing the usage of resources, there is a fundamental difference between the LIST scheduling of sequential tasks and the ECT scheduling of parallel tasks.

(i) In sequential task scheduling, for every task, the amount of resource it uses is always fixed, independent of the scheduling.

(ii) In ECT scheduling, the amount of bottleneck resource used by a task is always fixed as shown in the linear speed-up. The usage of nonbottleneck resource R_j by T_i can vary from $\lambda_{(i,j)}\tau_i$ to $\lambda_{(i,j)}\ \lambda_{(k,\beta(i))}/\Lambda_{(i,\beta(i))}\ \tau_i$, where the later is the minimal amount. The actual usage is scheduling dependent.

Because of this dependency, we must show how much $R_{\beta(i_k)}$ has been used by T_i, other than T_{i_k}, as a nonbottleneck resource.

LEMMA 4.2. *If $T_i, i < i_k$, uses $R_{\beta(i_k)}$ as a nonbottleneck resource, its usage within $[Y(T_{i_k}), Z(T_{i_k}))$ is minimal, not exceeding $\lambda_{(i,\beta(i_k))}\, \lambda_{(i,\beta(i))}/\Lambda_{(i,\beta(i))}\, \tau_i$.*

Proof. We are considering any $T_i \in \mathcal{T}$, where $\beta(i) \neq \beta(i_k)$ and $i < i_k$. However, we can immediately eliminate any wide task T_i, because $Z(T_i)$ equals its completion time, and this occurs before $Y(T_{i_k})$.

For a narrow task, because of the inequality of $Z(T_i) = \min\{c_S(T_i), t(\Lambda_{(i,\beta(i))})\} \leq Y(T_{i_k})$, whether $T_k \in \mathcal{T}'$ or $T_i \in \mathcal{T} - \mathcal{T}'$ we know that at time $Y(T_{i_k})$, T_i either has completed or could have been fully parallelized on its own bottleneck resource. Therefore, its usage of $R_{\beta(i_k)}$ is no greater than $\lambda_{(i,\beta(i_k))}\, \lambda_{i,\beta(i))}/\Lambda_{i,\beta(i))}\, \tau_i$, the minimal required amount. □

The following proposition reveals the relationship between the total length of $\cup[Y(T_{i_k}), Z(T_{i_k}))$ and M_{OPT}.

PROPOSITION 4.1. *If there are l bottleneck resources, $1 \leq l \leq m$, the combined length of all nonoverlapping intervals, $\sum(Z(T_{i_k}) - Y(T_{i_k}))$ will not exceed $2l \cdot M_{\mathrm{OPT}}$.*

Proof. After constructing the intervals (4.5), each interval is uniquely associated with a resource $R_{\beta(i_k)}$, which is at least half utilized by those tasks T_i starting before T_{i_k} and T_{i_k} itself (at least half colored black if it is considered as a strip). We have further shown that if a task T_i uses $R_{\beta(i_k)}$ as a nonbottleneck resource, its usage will not exceed the minimal amount. Therefore, the total length of intervals (4.5) associated with a single bottleneck resource will be no greater than $2M_{\mathrm{OPT}}$. Since there are only l bottleneck resources, the proposition follows. □

5. The overall analysis. After analyzing the intervals (4.5), we cannot claim that the complete makespan $[0, M_{\mathrm{ECT}})$ is covered by these intervals. Therefore, we must investigate the intervals of

$$[0, M_{\mathrm{ECT}}) - \bigcup_{k=1}^{n'} [Y(T_{i_k}), Z(T_{i_k})) = \bigcup_{i=1}^{\tau} [f_i, g_i). \tag{5.1}$$

At this point, we need a graph theory based result explained in [1]. There, the optimal makespan is normalized to 1 when compared with the suboptimal makespan to derive the performance bound. Without loss of generality, we also assume $M_{\mathrm{OPT}} = 1$. By using the same notation $r_j(t)$ to represent the utilization of resource R_j at time t, the following lemma, first appearing in [1], also holds for our ECT algorithm.

LEMMA 5.1. *If $t_0, t_1 \in \cup_{i=1}^{r}[f_i, g_i)$, and $t_1 - t_0 \geq 1$,*

$$\max_{j=1}^{m}\{r_j(t_0) + r_j(t_1)\} > M_{\mathrm{OPT}} = 1$$

will hold.

Proof. The ECT selection criteria is the same as that of the LIST algorithm, i.e, selecting any task that the available resources will satisfy. Since $t_1 - t_0 \leq M_{\mathrm{OPT}} = 1$, there is at least one task T_i that starts between $(t_0, t_1]$. If the statement is not true, the task T_i should have been scheduled by the ECT algorithm at t_0 or sooner. This is the same lemma as shown in [1], and the argument is also the same. □

Now we can apply the theorem based on graph theory from [1] and reach the conclusion that

$$\sum_{i=1}^{r}(g_i - f_i) \leq m + 1 = (m+1)M_{\mathrm{OPT}}. \tag{5.2}$$

Again, we encounter the fundamental difference between the LIST scheduling of sequential tasks and the ECT scheduling of parallel task, i.e., the usage of nonbottleneck resource is dependent on the ECT scheduling.

LEMMA 5.2. *If in* $[f_i, g_i)$, *a task* T_k *uses a nonbottleneck resource* R_j, *the total amount used will not exceed* $\lambda_{(k,j)}\ \lambda_{(k,\beta(k))}/\Lambda_{(k,\beta(k))}\ \tau_k$. *In other words, despite the difference mentioned earlier, the usage of nonbottleneck resources in* $\cup[f_i, g_i)$ *is always minimal.*

Proof. Based on the definition of intervals (4.5), only some narrow task could have part of their execution extended into intervals of $\cup[f_i, g_j)$. By the definition of $Z(T_{i_k})$, such tasks extending into $\cup[f_i, g_i)$ have passed the point of achieving full parallelization when entering $\cup[f_i, g_i)$. Using the same argument of Lemma 4.2, we can show the usage of nonbottleneck resources in $\cup[f_i, g_i)$ is also minimal. □

We have recognized the difference between the conventional LIST scheduling and the ECT scheduling. Despite this difference, in $\cup[f_i, g_i)$, the usage of nonbottleneck resources is always kept minimal as long as the ECT scheduling criterion is observed. This leads to the adaptation of the following proposition from the LIST scheduling analysis to our analysis.

PROPOSITION 5.1. *The total length of* $\cup[f_i, g_i)$ *will not exceed* $m + 1 = (m + 1)M_{\mathrm{OPT}}$, *i.e., the inequality of* (5.2) *will hold.*

Proof. The proof in [1] relies on two results, namely, Lemma 5.1 and the same resource usage in the proposed scheme as that in the optimal scheme. After getting the total usages in both the optimal and the proposed schemes, it can be shown that the total usage $\leq m$ in the optimal case implies that the total usage in the proposed case will not exceed m.

We have already proved our Lemma 5.1. As for the total usage, the usage of bottleneck resources does not change between the optimal schedule and the ECT schedule. The usage of nonbottleneck resources is minimal within $\cup[f_i, g_i)$; it could be even less than the usage in the optimal schedule within these intervals. We can conclude that within $\cup[f_i, g_i)$ the total usage will not exceed m, so the proposition follows. □

Combining Propositions 4.1 and 5.2, we can have the following theorem.

THEOREM 5.1. *The performance bound of the ECT algorithm for scheduling tasks with bottleneck resources satisfies the following inequality:*

$$\frac{M_{\mathrm{ECT}}}{M_{\mathrm{OPT}}} \leq 2l + m + 1, \tag{5.3}$$

where l *is the number of bottleneck resources.*

6. Conclusion. In this paper, we have discussed the earliest completion time scheduling of tasks requiring multiple resources and among which one is a bottleneck resource. There are two special cases of this problem that have been studied previously.

(i) There is no bottleneck resource, $l = 0$. Garey and Graham [1] have shown that $m + 1$ is a tight performance bound that is achieved by our algorithm.

(ii) There is only one resource, $m = 1$, and it is also the bottleneck resource, i.e., $l = 1$. In [4], we have shown that the ECT performance bound is at least 2.5. There is a gap of 1.5 between the performance bound 2.5 and the performance bound of $2l + m + 1 = 4$ shown in the present paper This gap is wider than the gap ($\approx \frac{1}{2}$) shown in [4], for the current analysis is relaxed to accommodate the requirement of multiple resources. As pointed out in [1], the constant term 1 in $2l + m + 1$ is needed only in some special instances, and this term accounts for the gap difference.

In the analysis of the FFD algorithm for scheduling tasks with unit execution time [2], it was shown that its asymptotic performance bound lies between $m + (m - 1)/m(m + 1)$ and $m + \frac{1}{3}$. In other words, the performance bound of this scheduling algorithms is dominated by the m term. In the ECT algorithm, the term $2l$ can assume a wide range of values between 0 and $2m$

depending on the number of bottleneck resources involved. It will be interesting to see how l, the number of bottleneck resources, can further influence the analysis and the tightness of the performance bound.

ON COMPUTING ALGEBRAIC FUNCTIONS USING LOGARITHMS AND EXPONENTIALS*

DIMA GRIGORIEV,† MICHAEL SINGER,‡ AND ANDREW YAO§

Abstract. Let ρ be a set of algebraic expressions constructed with radicals and arithmetic operations, and which generate the splitting field F of some polynomial. Let $N_\beta(\rho)$ be the minimum total number of root-takings and exponentiations used in any straightline program for computing the functions in ρ by taking roots, exponentials, logarithms, and performing arithmetic operations. In this paper it is proved that $N_\beta(\rho) = \nu(G)$, where $\nu(G)$ is the minimum length of any cyclic Jordan–Hölder tower for the Galois group G of F. This generalizes a result of Ja'Ja' [*Proceedings of the* 22nd *IEEE Symposium on Foundations of Computer Science*, 1981, pp. 95–100], and shows that the inclusion of certain new primitives, such as taking exponentials and logarithms, does not improve the cost of computing such expressions as compared with programs that use only root-takings.

Key words. algebraic expressions, complexity, differential algebra, exponentials, Galois group, Jordan–Hölder tower, logarithms

AMS subject classifications. 68Q25, 68Q40

1. Introduction.

The question of how efficiently one can evaluate expressions such as $(\Sigma_{1\le i<j\le n}\sqrt{(x_i-x_j)^2+(y_i-y_j)^2})/\binom{n}{2}$, the *mean distance* among n points in the plane, was raised in Shamos and Yuval [9]. A systematic study of this question was given in Pippenger [7], [8]. Let ρ be a family of algebraic expressions constructed from indeterminates using radicals and arithmetic operations. Define the cost of a program to be the number of root-takings used, with arithmetic operations given for free. Let $\mathbf{F}$ be the extension field generated by the members of ρ over the field of rational functions with complex coefficients. It was shown [7], [8] that, when the members of ρ are rational functions of the roots of rational functions, the minimum cost is equal to the number of the torsion orders for the Galois group of $\mathbf{F}$ (an Abelian group in this case). An extension was given[1] in Ja'Ja' [2], who showed that the minimum cost is equal to the minimum length of any cyclic Jordan–Hölder tower for the Galois group of $\mathbf{F}$, provided that $\mathbf{F}$ is a finite Galois extension over the field of rational functions. It is known [2], [8] that the former result is a special case of the latter.

These results can be used to determine the minimum cost for computing ρ in many cases. For example, for the mean distance problem, the Galois group can be shown [7] to be isomorphic to $(\mathbf{Z_2})^{\binom{n}{2}}$, which clearly has $\binom{n}{2}$ torsion orders.

As taking a root $y^{1/d}$ can be simulated by taking the logarithm $\log y$ followed by an exponentiation $\exp((\log y)/d)$, a natural question is whether the availability of the logarithm and exponential operations can substantially reduce the cost of evaluating algebraic expressions. In particular, can one evaluate the expression $\Sigma_{1\le i\le n}\sqrt{x_i}$ using $o(n)$ exponentiations and logarithm-takings? (Clearly, the expression can be evaluated with n root-takings.) The possible use of logarithms and exponentials, as well as other primitives, was mentioned in [9], but was not studied in later papers [2], [7], [8].

[1] Any finite Abelian group G can be uniquely decomposed into a direct sum of cyclic groups $\mathbf{Z_{d_1}} \oplus \mathbf{Z_{d_2}} \oplus \cdots \mathbf{Z_{d_t}}$, such that $d_t > 1$ and d_i is divisible by d_{i+1} for $1 \le i < t$. The integers d_i are called the *torsion orders* for G; t is the number of torsion orders for G.

In this paper, we show that under the same assumption as in [2] (i.e., $\mathbf{F}$ being a finite Galois extension), the availability of taking logarithms and exponentials does not reduce the cost. In particular, we prove that n or more operations are needed to evaluate $\Sigma_{1\le i\le n}\sqrt{x_i}$, with arithmetic operations given for free. In the next section, we give a precise statement of the main result (Theorem 1), after introducing the needed notation and background. The result is then proved in §3; some additional concepts and results from differential algebra (see [3]–[5]) are used in the proof.

We remark that the complexity question under other cost measures, in which the cost of taking a dth root may depend on d, was discussed in [2], [7], [8]. We will not pursue it here. We also would like to mention a related recent paper by Grigoriev and Karpinski [1], in which another complexity question involving root-takings was studied.

2. The main result. We use the standard terminology in algebra (as in Lang [6]). In what follows, let $\mathbf{Z}^+$ be the set of all positive integers.

An *α-program* A is a sequence of instructions of the form $z_1 \leftarrow I_1, z_2 \leftarrow I_2, \ldots, z_m \leftarrow I_m$, where I_i are of the form $(r_i(x_1, x_2, \ldots, x_n, z_1, \ldots, z_{i-1}))^{1/d_i}$ with r_i being any rational function in $x_1, \ldots, x_n, z_1, \ldots, z_{i-1}$ with complex coefficients and $d_i \in \mathbf{Z}^+$. We call m the *cost* of A. For $1 \le i \le m$, let $g_i(x_1, x_2, \ldots, x_n)$ be the functions defined inductively by $g_i(x_1, x_2, \ldots, x_n) = (r_i(x_1, x_2, \ldots, x_n, g_1(x_1, \ldots, x_n), \ldots, g_{i-1}(x_1, \ldots, x_n)))^{1/d_i}$. We always assume that the r_i have been chosen so that the denominators of these functions do not vanish identically. Informally, $g_i(x_1, x_2, \ldots, x_n)$ are the values assumed by the variables z_i for input $(x_1, x_2, \ldots, x_n)$. Let E_A denote the set of all functions of the form $r(x_1, x_2, \ldots, x_n, g_1(x_1, \ldots, x_n), \ldots, g_m(x_1, \ldots, x_n))$ where r is any rational function with complex coefficients whose denominator does not vanish identically when the substitution is made.

We note that each element of E_A defines a function algebraic over the field $\mathbf{F_0} = \mathbf{C}(x_1, \cdots, x_n)$ of rational functions in n variables with coefficients in the complex numbers $\mathbf{C}$.

A *solvable algebraic expression* is any element of E_A for any α-program A. Let $\rho = (f_1, f_2, \ldots, f_s)$ be a finite set of solvable algebraic expressions. We say that *ρ is computed by* A, if each $f_i \in E_A$. Let $N_\alpha(\rho)$ be the minimum cost of any α-program computing ρ. Clearly, $N_\alpha(\rho)$ is finite. For any such ρ, we can form the field $\mathbf{F_0}(\rho)$, which is the algebraic extension of $\mathbf{F_0}$ formed by adjoining the functions corresponding to the elements $f_1, \ldots, f_s$ of ρ.

Following [2], ρ is said to be *normal*, if $\mathbf{F_0}(\rho)$ is a finite Galois extension of $\mathbf{F_0}$. In other words, ρ is normal if ρ generates the splitting field of some polynomial over $\mathbf{F_0}$.

For any solvable group G, a *cyclic Jordan–Hölder tower* is a normal tower of groups

$$G = G_0 \triangleright G_1 \triangleright \cdots \triangleright G_{m-1} \triangleright G_m = 1,$$

where G_{i-1}/G_i is cyclic for each $1 \le i \le m$. Let $\nu(G)$ be the length m of the shortest cyclic Jordan-Hölder tower for G.

The next result is from Ja'Ja' [2], which we state as a lemma.

LEMMA 1 (See [2]). *If ρ is normal, then $N_\alpha(\rho) = \nu(G)$, where G is the Galois group for $\mathbf{F_0}(\rho)$ over $\mathbf{F_0}$.*

A *β-program* B is a sequence of instructions of the form $z_1 \leftarrow I_1, z_2 \leftarrow I_2, \ldots, z_m \leftarrow I_m$, where I_i are of the form a_i^{1/d_i}, $\exp(a_i)$, or $\log(a_i)$, where $a_i = r_i(x_1, x_2, \ldots, x_n, z_1, \ldots, z_{i-1})$ with r_i being any rational function in $x_1, \ldots, x_n, z_1, \ldots, z_{i-1}$ with complex coefficients and $d_i \in \mathbf{Z}^+$. We again always assume that the r_i have been chosen so that the denominators of these functions do not vanish identically. Let $\tau(B)$ be the number of instructions that either take roots or exponentials. Let $g_i(x_1, x_2, \ldots, x_n)$ be the functions associated with variables z_i, defined exactly as in the case for α-programs. Let E_B denote the set of all functions of the form $r(x_1, x_2, \ldots, x_n, g_1(x_1, \ldots, x_n), \ldots, g_m(x_1, \ldots, x_n))$ where r is any rational function

with complex coefficients whose denominators do not vanish identically when the substitution is made.

Let $\rho = (f_1, f_2, \cdots, f_s)$ be a finite set of solvable algebraic expression. We say that ρ *is computed by* B if each element f_i of ρ equals a function in E_B. Let $N_\beta(\rho)$ be the minimum $\tau(B)$ of any β-program B computing ρ.

Our main result is the following theorem.

THEOREM 1. *If ρ is normal, then $N_\beta(\rho) = \nu(G)$, where G is the Galois group for $\mathbf{F_0}(\rho)$ over $\mathbf{F_0}$.*

COROLLARY 1. *If ρ is normal, then $N_\beta(\rho) = N_\alpha(\rho)$.*

COROLLARY 2. *Let $\rho = \{f\}$, where $f = \Sigma_{1\le i\le n}\sqrt{x_i}$. Then $N_\beta(\rho) = n$.*

Remark. It is an interesting open question whether $N_\beta(\rho)$ is equal to $N_\alpha(\rho)$ when ρ is not required to be normal.

3. Proof of Theorem 1. Before proving the theorem, we introduce some terms in differential algebra (see [3]–[5]). A *differential field* is a field k together with a set $\Delta = \{\delta_i\}$ of mappings $\delta_i : k \to k$, called *derivations*, such that each δ_i satisfies the conditions $\delta_i(a + b) = \delta_i(a) + \delta_i(b)$, $\delta_i(ab) = \delta_i(a)b + a\delta_i(b)$, and $\delta_i(\delta_j(a)) = \delta_j(\delta_i(a))$ for all $\delta_i, \delta_j \in \Delta, a, b \in k$. For example, $\mathbf{F_0}$ can be considered a differential field when we use the derivations $\Delta = \{\delta_1, \ldots, \delta_n\}$ where $\delta_i(f) = \partial f/\partial x_i$. In this paper we are concerned only with differential fields that come from fields of differentiable functions a and that are extensions of this differential field. These extensions will be gotten by adjoining elements that can be interpreted as functions on some suitable region in complex n-space $\mathbf{C}^n$. We will use $\mathbf{K_0}$ to denote the differential field obtained from the field $\mathbf{F_0}$ equipped with these standard derivations Δ. Note that if $\mathbf{K}$ is a differential field containing $\mathbf{K_0}$ and if $a \in \mathbf{K}$, then the field obtained by adjoining $\exp(a)$ to $\mathbf{K}$ gives a differential field. The element $\exp(a)$ will satisfy the differential equations $\delta_i(\exp(a)) = \delta_i(a) \cdot \exp(a)$ for $i = 1, \ldots, n$. Similarly, the adjoining of $\log(a)$ gives a differential field and the element $\log(a)$ satisfies $\delta_i(\log(a)) = \delta_i(a)/a$ for $i = 1, \ldots, n$. We also note that if $\rho = (f_1, \ldots, f_s)$ is a set of solvable algebraic expressions (or, more generally, any set of algebraic functions), the derivations Δ can be extended uniquely to derivations on $\mathbf{F_0}(\rho)$ ([5, Lem. 1, p. 90]).

The classical Galois theory for field theory can be extended to a *differential Galois theory* for differential fields (See [4] and [5] for definitions and discussions of these concepts; [3] contains an excellent exposition of the theory in the case of only one derivation and the essential results extend, mutatis mutandi, to the case of several derivations). This Galois theory can be used to study the structure of the solutions of a system of partial linear differential equations, provided that the equations generate a differential ideal of finite linear dimension or, equivalently (see [5, Chap. IV.5]), the solution space is a finite-dimensional vector space (i.e., the system is holonomic). This is the case for the equations defining exponentials and logarithms (see [4] and [5]). To avoid possible confusion, we will reserve the term *Galois group* for the classical Galois group, and use the term *differential* Galois group when differential fields are being discussed. It should be noted, however, that if k_1 is an algebraic extension of k_0, a differential field of characteristic zero, then since all derivations on k_0 can be extended uniquely to derivations on k_1, we can identify the Galois group of k_1 over k_0 with the differential Galois group of k_1 over k_0 (with respect to these derivations). To see this note that any differential automorphism is by definition a usual automorphism. Conversely, for any automorphism σ of k_1 and k_0 and any derivation δ of k_1 that leaves k_0 invariant, we have that $\sigma^{-1} \circ \delta \circ \sigma$ is a derivation of k_1 agreeing with δ on k_0. Uniqueness implies that they must be equal on all of k_1 and so σ must be a differential automorphism. This remark allows us to apply results concerning differential Galois theory to the Galois theory of algebraic extensions of differential fields.

To prove Theorem 1, we first show that if $\mathbf{F_0}(\rho)$ is contained in a certain tower of differential fields, then there is a tower of algebraic extension fields of no greater length containing $\mathbf{F_0}(\rho)$. This result (Lemma 2) is at the heart of the proof for Theorem 1.

Let $\mathbf{K_0} \subset \mathbf{K_1} \subset \mathbf{K_2} \subset \cdots \subset \mathbf{K_m}$ be a tower of differential fields, where each $\mathbf{K_i}$ is obtained from $\mathbf{K_{i-1}}$ by adjoining an element u_i; u_i is either $\exp(a_i)$ or $\log(a_i)$ with $a_i \in \mathbf{K_{i-1}}$. Let I be the set of $1 \leq i \leq m$ such that u_i is $\exp(a_i)$. We recall from differential Galois theory that in this case each $\mathbf{K_i}$ is a Picard–Vessiot extension of $\mathbf{K_{i-1}}$. Furthermore, it is known (see [4, §4], or [5, Chap. VI.6]; [3, Lem. 3.9 and 3.10] contains similar results for the case of one derivation) that, if $i \in I$, the differential Galois group of $\mathbf{K_i}$ over $\mathbf{K_{i-1}}$ is an algebraic subgroup of $\mathbf{C}^*$, the multiplicative group of nonzero complex numbers, and if $i \notin I$, then the differential Galois group of $\mathbf{K_i}$ over $\mathbf{K_{i-1}}$ is an algebraic subgroup of $\mathbf{C}^+$, the additive group of complex numbers. Finally, we note that the proper algebraic subgroups of $\mathbf{C}^*$ are precisely the finite cyclic groups and the only proper algebraic subgroup of $\mathbf{C}^+$ is the trivial group. This can be seen by noting that a proper Zariski closed subset of either of these two groups must be finite and that in the first case, we will have a finite multiplicative subgroup of a field and in the second case we will have a finite subgroup of a torsion free group.

LEMMA 2. *If* $\mathbf{F_0}(\rho) \subset \mathbf{K_m}$ *then* $\nu(G) \leq |I|$.

Proof. Let $\mathbf{F_i} = \mathbf{F_0}(\rho) \cap \mathbf{K_i}$ for $1 \leq i \leq m$. Then $\mathbf{F_m} = \mathbf{F_0}(\rho)$. Note that $\mathbf{F_0} = \mathbf{F_0}(\rho) \cap \mathbf{K_0}$. Let H_i be the differential Galois group of $\mathbf{K_i}$ over $\mathbf{K_{i-1}}$. We claim that the following statement is true for $1 \leq i \leq m$.

FACT 1. $\mathbf{F_i}$ *is a Galois extension of* $\mathbf{F_{i-1}}$.

To prove this fact, let $\mathbf{E_i}$ be the subfield of elements of $\mathbf{K_i}$ algebraic over $\mathbf{K_{i-1}}$. $\mathbf{E_i}$ is a differential field and is left invariant by all elements of H_i. Therefore the differential Galois group of $\mathbf{K_i}$ over $\mathbf{E_i}$ is a normal subgroup of H_i and so $\mathbf{E_i}$ is a Galois extension of $\mathbf{K_{i-1}}$. Note that $\mathbf{F_i} = \mathbf{E_i} \cap \mathbf{F_0}(\rho)$. Let $p(x)$ be a polynomial with coefficients in $\mathbf{F_{i-1}}$. If $p(x) = 0$ has a root in $\mathbf{F_i}$, it must split in both $\mathbf{E_i}$ and $\mathbf{F_0}(\rho)$ (since $\mathbf{F_0}(\rho)$ is a fortiori normal over $\mathbf{F_{i-1}}$). Therefore $p(x) = 0$ splits in $\mathbf{F_i}$ and so $\mathbf{F_i}$ is a Galois extension of $\mathbf{F_{i-1}}$.

Now let J_i be the Galois group of $\mathbf{F_i}$ over $\mathbf{F_{i-1}}$. We claim that the following statement is true.

FACT 2. For $1 \leq i \leq m$, J_i *is the trivial group if* $i \notin I$, *and a cyclic group if* $i \in I$.

To prove this fact, consider the field $\mathbf{K_{i-1}} \cdot \mathbf{F_i}$. This is a subfield of $\mathbf{K_i}$. Since H_i is an abelian group, all of its subgroups are normal, so $\mathbf{K_{i-1}} \cdot \mathbf{F_i}$ is a normal extension of $\mathbf{K_{i-1}}$ whose differential Galois group L_i is the quotient of H_i by a closed subgroup of H_i. Furthermore, since $\mathbf{K_{i-1}} \cdot \mathbf{F_i}$ is a finite extension of $\mathbf{K_{i-1}}$, L_i is finite and thus coincides with the Galois group of this extension. If $i \notin I$, then H_i is either $\mathbf{C}^+$ or the trivial group. The only finite quotient of either of these groups by a closed subgroup is trivial. If $i \in I$, then H_i is either $\mathbf{C}^*$ or a finite cyclic group. The only possible finite quotients of these groups by closed subgroups are cyclic. To finish the proof of Fact 2, we note that $\mathbf{K_{i-1}} \cap \mathbf{F_i} = \mathbf{F_{i-1}}$ and so the Galois group J_i of $\mathbf{F_i}$ over $\mathbf{F_{i-1}}$ is isomorphic to L_i (see [6, Cor., p. 400] or [5, Chap. VII, Th. 1.12]; [3, Lem. 5.10] gives a related result but deals only with the case of one derivation).

We can now finish the proof of Lemma 2. Let G_i denote the group of automorphisms of $\mathbf{F_0}(\rho)$ leaving $\mathbf{F_i}$ fixed. By Facts 1 and 2, we conclude from the Galois theory that the series $G = G_0, G_1, G_2, \ldots, G_m = 1$ forms a cyclic Jordan–Hölder tower, with G_{i-1}/G_i being isomorphic to J_i. Deleting all $i \notin I$, we have a tower of length $|I|$. Hence $\nu(G) \leq |I|$. □

We now turn to the proof of Theorem 1. Observe that $N_\beta(\rho) \leq N_\alpha(\rho)$, which is not greater than $\nu(G)$ by Lemma 1. Thus, we only need to prove that $N_\beta(\rho) \geq \nu(G)$.

Let B be any β-program for computing ρ. Without loss of generality, we may assume that no root-taking operations are used in B, as we can replace any instruction $z \leftarrow r^{1/d}$ by two instructions $y \leftarrow (\log r)/d, z \leftarrow \exp(y)$ without changing the value of $\tau(B)$. Let the

instructions be $z_1 \leftarrow I_1, z_2 \leftarrow I_2, \ldots, z_m \leftarrow I_m$. Let $g_i(x_1, x_2, \ldots, x_n)$ be the functions associated with variables z_i.

For $1 \leq i \leq m$, let $\mathbf{K_i}$ be the differential field obtained by adjoining g_i to $\mathbf{K_{i-1}}$. By definition, the functions of E_B correspond to elements of $\mathbf{K_m}$ and $\mathbf{F_0}(\rho) \subset \mathbf{K_m}$. By Lemma 2, this implies $\nu(G) \leq \tau(B)$. This proves $\nu(G) \leq N_\beta(\rho)$ and completes the proof of Theorem 1. Corollary 1 follows immediately from the theorem and Lemma 1.

To prove Corollary 2, we note that ρ is normal and the Galois group G of $\mathbf{F_0}(\rho)$ over $\mathbf{F_0}$ is isomorphic to $\mathbf{Z_2}^n$. From the results in [2], [8] (see [8, Lem. 3.2, p. 399]), $\nu(G)$ is equal to the number of torsion orders of G, which is clearly n. Corollary 2 follows from the theorem immediately.

ALGORITHMS FOR ENUMERATING ALL SPANNING TREES OF UNDIRECTED AND WEIGHTED GRAPHS*

SANJIV KAPOOR† AND H. RAMESH‡

Abstract. In this paper, we present algorithms for enumeration of spanning trees in undirected graphs, with and without weights.

The algorithms use a search tree technique to construct a computation tree. The computation tree can be used to output all spanning trees by outputting only relative changes between spanning trees rather than the entire spanning trees themselves. Both the construction of the computation tree and the listing of the trees is shown to require $O(N + V + E)$ operations for the case of undirected graphs without weights. The basic algorithm is based on swapping edges in a fundamental cycle. For the case of weighted graphs (undirected), we show that the nodes of the computation tree of spanning trees can be sorted in increasing order of weight, in $O(N \log V + VE)$ time. The spanning trees themselves can be listed in $O(NV)$ time. Here N, V, and E refer, respectively, to the number of spanning trees, vertices, and edges of the graph.

Key words. spanning tree, undirected graph, weighted graph, enumeration

AMS subject classifications. 68Q25, 68R10

1. Introduction.

Spanning tree enumeration in undirected graphs is an important issue in many problems encountered in network and circuit analysis. Applications are given in [Ma72]. Weighted spanning tree enumeration in order would find application in a subroutine of a generate-and-test procedure for connecting together a set of points with the minimum amount of wire, where the connection satisfies some additional constraint, e.g., a minimum distance to be maintained between two wires.

Spanning tree enumeration has a long history (see references). Previous techniques employed for solving the problem include depth-first search [GM78], [TR75], selective generation and testing [Ch68], and edge exchanging [Ga77]. Of these, Gabow and Myers' algorithm [GM78] seems to be the fastest with a time complexity of $O(NV)$ on a graph with V vertices, E edges, and N spanning trees. Their algorithm requires $O(NV)$ time for generating the trees themselves and not merely for outputting them. Their algorithm is optimal, up to a constant factor, if all spanning trees of the graph need to be explicitly output. For many practical applications, the spanning trees need not be explicitly output and only a computation tree which gives relative changes between spanning trees is required. We note that from this computation tree, the spanning trees can be listed explicitly in $O(NV)$ operations, if required.

In this paper, we enumerate spanning trees by listing differences between them. Each node of the computation tree that describes this procedure represents a spanning tree of the graph. The spanning trees represented by a node and its parent in the computation tree differ in exactly one pair of edges, i.e., the spanning tree at any node is obtained by exchanging an edge in the spanning tree at its parent for an edge not present in that spanning tree. This exchange is obtained from the fundamental cycles of the graph. An edge external to a spanning tree can be exchanged with any edge in its fundamental cycle to give a spanning tree which differs from the original spanning tree in exactly one pair of edges. By repeating this for all external edges, all spanning trees which differ from the original spanning tree in one pair of edges

can be obtained. The computation tree is generated by repeatedly applying this procedure. Repetition of the same spanning tree is avoided by following a search tree inclusion–exclusion strategy. The algorithm presented here outputs, for each node of the computation tree, the difference between the spanning trees associated with that node and its predecessor in a preorder scan of the computation tree. This is done by traversing the computation tree in a depth-first manner. We describe two algorithms, each requiring $O(N + V + E)$ time. The first requires $O(V^2E)$ space and the second requires $O(VE)$ space. The first algorithm has a more general methodology and may be more useful in certain applications. It is used in the weighted case in this paper.

An $O(N \log V + VE)$ algorithm for sorting the nodes of the computation tree in increasing order of weight is also presented here and is based on the fact that there are a bounded number of exchanges that change one spanning tree into another. To output the spanning trees in sorted order, however, requires $O(NV)$ operations. The scheme presented betters the $O(N \log N)$ time heapsort used by Gabow [Ga77], which results in a total time complexity of $O(NE + N \log N)$.

In a companion paper [KR92], we use similar techniques to enumerate all spanning trees of a directed graph in $O(NV)$ time, improving upon the previous best known bound of $O(NE)$ time [GM78].

Section 2 describes the generation of spanning trees in undirected and unweighted graphs and §3 describes a way of ordering the spanning trees in the computation tree for weighted graphs. Each of the sections contains a description of the algorithms and proofs of their correctness and complexity.

2. Undirected spanning tree enumeration. Let G be an undirected graph with V vertices, E edges, and N spanning trees. $E(G)$ refers to the set of edges of the graph G.

2.1. Algorithm outline. In this section, we present an outline of the algorithm for generating all spanning trees of an undirected graph.

The algorithm starts off with a spanning tree T, and generates all other spanning trees from T by replacing edges in T by edges outside T. For undirected graphs, an edge in a fundamental cycle of the graph can be replaced by its corresponding nontree edge to result in a new spanning tree. Thus, a number of spanning trees can be generated from a single spanning tree by exchanging edges in a fundamental cycle with the corresponding nontree edge. This computation can be represented by a computation tree with spanning tree T at its root and the spanning trees resulting from these exchanges at its sons. To generate other spanning trees, these sons are expanded recursively in the same manner as the root. Thus each node in the computation tree is associated with a spanning tree of G.

We need to ensure that each spanning tree is generated exactly once. This is done by a search tree-type computation tree which uses the inclusion/exclusion principle. To aid the construction of the computation tree, at every node in the computation tree two sets with the following classification are maintained. For a node x in the computation tree, the set IN_x consists of edges which are always included in all spanning trees at x and its descendants in the computation tree. The set OUT_x contains edges which are not included in any spanning tree at x or at its descendants in the computation tree. We let S_x denote the spanning tree generated at x and G_x denote the current graph obtained by contracting edges in IN_x and removing edges in OUT_x. Note that G_x may be a multigraph. We define $CYCLE_x$ to be the set of fundamental cycles of nontree edges (with respect to S_x) which are in G_x. We now formally define the computation tree $C(G)$ with respect to the graph G. $C(G)$ has a spanning tree of G associated with every node. The computation tree starts with an arbitrary spanning tree at the root. Let A be a node in the computation tree and let S_A be the spanning tree associated with A. Let f be an edge not in OUT_A or S_A and let $c_f = (e_1, e_2, \ldots, e_k)$ be the fundamental cycle

in G_A formed by f with respect to S_A. Then A has as its sons B_i, $1 \leq i \leq k+1$. (See Fig. 1; each edge is labeled with the pair of edges exchanged.) For $1 \leq i \leq k$, B_i corresponds to the spanning tree obtained by the exchange (e_i, f). Note that e_i is not already in IN_A because edges in IN_A are contracted in G_A. B_{k+1} corresponds to a node in the computation tree such that no descendant of the node has f in the spanning trees generated. Note that the tree at B_{k+1} is the same as the one at its parent.

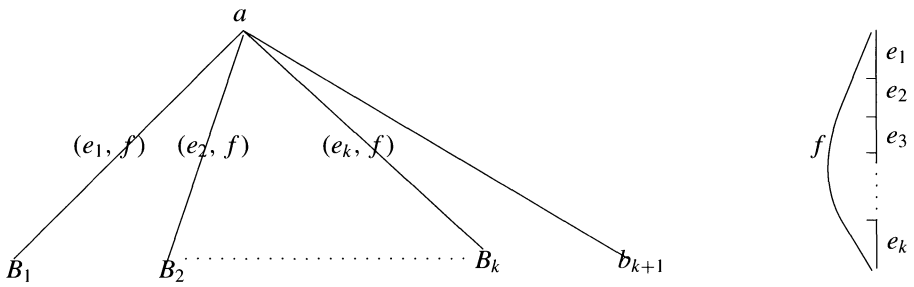

FIG. 1. $C(G)$.

The IN and OUT sets are formally defined as follows.

IN_{B_j} $= IN_A \cup \{e_1, e_2, \ldots, e_{j-1}\} \cup \{f\}$, for $1 \leq j \leq k$

OUT_{B_j} $= OUT_A \cup \{e_j\}$, for $1 \leq j \leq k$

$IN_{B_{k+1}}$ $= IN_A$

$OUT_{B_{k+1}}$ $= OUT_A \cup \{f\}$

S_{B_j} $= S_A - \{e_j\} \cup \{f\}$, for $1 \leq j \leq k$

$E(G_{B_j})$ $= E(G_A) - \{e_j\}$ *with edges* $e_1, e_2, \ldots, e_{j-1}$, f *contracted*, for $1 \leq j \leq k$

$CYCLE_{B_j}$ $= CYCLE_A$ **com** c_f *with edges* $e_1, e_2, \ldots, e_{j-1}$ *contracted in each resultant cycle* , for $1 \leq j \leq k$
{Here the **com** operation combines (see Fig. 3) all cycles in $CYCLE_A$ which contain edge e_j with c_f and leaves the other cycles intact}

$S_{B_{k+1}}$ $= S_A$

$E(G_{B_{k+1}})$ $= E(G_A) - \{f\}$

$CYCLE_{B_{k+1}}$ $= CYCLE_A - \{c_f\}$

The IN and OUT sets for the root x of the computation tree are both empty. S_x is any spanning tree, G_x is the original graph G, and $CYCLE_x$ is the set of fundamental cycles in G with respect to S. Before we show how to generate the computation tree, we show that $C(G)$ suffices to generate all the spanning trees of G.

LEMMA 2.1. *The computation tree has at its internal nodes and leaves all the spanning trees of* G.

Proof. The proof follows from induction and the inclusion/exclusion principle. The inclusion/exclusion is implemented in the computation tree as follows: Let A be the root node of the computation tree. The subtrees rooted at B_1 through B_k together form the computation tree of the spanning trees, which have the edge f in them. B_{k+1} is the root of the computation tree which computes all spanning trees not containing the edge f. Within the set of spanning trees which contain f, the subtree rooted at B_1 generates spanning trees without e_1, whereas

$B_2, \ldots B_k$ generate subtrees with e_1. A similar inclusion/exclusion process is repeated at each of the nodes $B_2, \ldots B_k$, i.e., the computation subtree rooted at B_j corresponds to the set of spanning trees which contain the edges $e_1, \ldots, e_{j-1}$ but not e_j. Moreover, the computation subtree corresponding to the inclusion of $e_1, \ldots, e_k$ and f need not be included in the computation tree since this choice of edges forms a cycle and will not lead to any spanning tree. □

In order to analyze the algorithms, it is convenient to define a compressed form $C'(G)$ of $C(G)$. Having generated node A with spanning tree S_A, we find the fundamental cycle corresponding to some nontree edge $f \in G_A$ and then the sons $B_1, \ldots, B_{k+1}$ according to the above description are generated. However, note that the sons of B_{k+1} will be obtained by using another nontree edge relative to S_A in a graph where f is absent. This is repeated along the entire rightmost branch of the computation tree. Since all these computations are with respect to S_A alone, we can obtain a compressed version of the computation tree called $C'(G)$ by considering all the fundamental cycles at node A and applying the inclusion/exclusion principle over the nontree edges. Figure 2 illustrates the compression. The compressed computation tree $C'(G)$ has the advantage that each node in the tree corresponds to a unique spanning tree. Since the compression does not eliminate nodes with distinct spanning trees in $C(G)$, $C'(G)$ generates all spanning trees of G. Each node of $C(G)$ is associated with exactly one node of $C'(G)$ and we refer to both nodes by the same name.

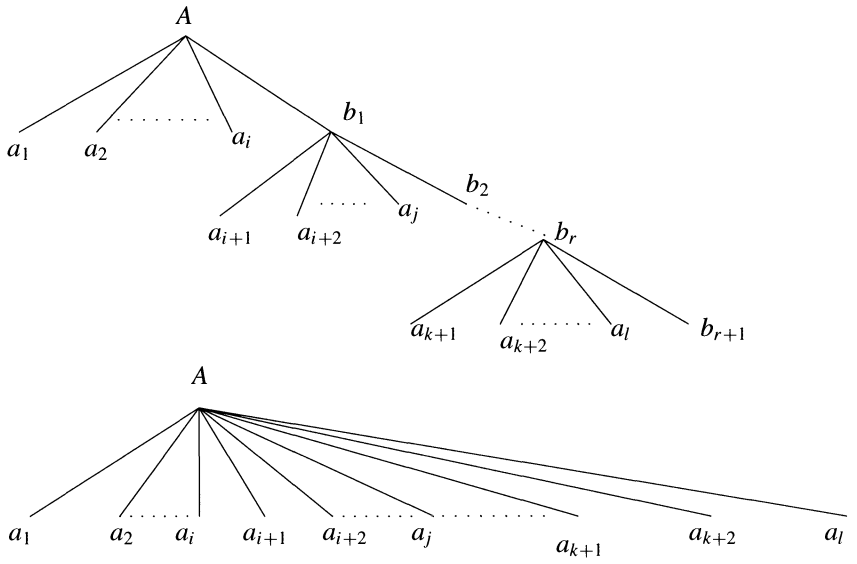

FIG. 2. $C'(G)$.

To achieve the construction of $C(G)$ in linear time, we outline schemes for finding the fundamental cycles and generating the sons of a node. An important issue in generating $C(G)$ is the computation of the set of fundamental cycles at each node of $C(G)$. Note that the current tree T has been obtained by replacing an edge e in the previous tree T' by a nontree edge f. This affects all the fundamental cycles containing the edge e. Each fundamental cycle containing edge e must now be *combined* with the fundamental cycle of f, i.e., a new cycle is obtained by removing edges common to both cycles (see Fig. 3).

In Algorithm 1, at each node A in $C(G)$, an arbitrary nontree edge f in G_A is chosen for exchanging. After each exchange is performed, each of the fundamental cycles affected

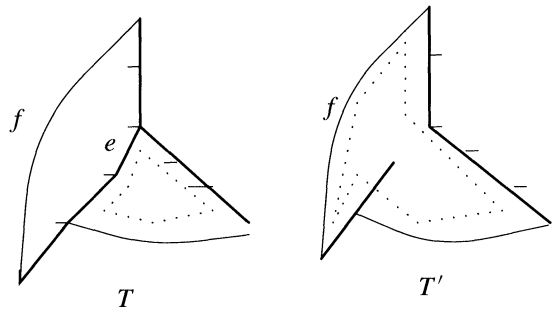

FIG. 3. *Cycle Combination*

by that exchange is combined with the fundamental cycle of f. This is done by scanning the affected cycles and changing them in time proportional to the sum of the lengths of the *resulting* cycles. Each fundamental cycle generates a number of spanning trees equal to the number of tree edges in it by exchanging with the corresponding nontree edge. This ensures that the computation tree is generated in linear time. This approach requires $O(V^2E)$ space and the data structure for maintaining the fundamental cycles is slightly elaborate. Furthermore, this involves repeated scanning of an edge which occurs in more than one cycle.

To reduce space and to simplify and speed up the data structures, we describe Algorithm 2. In this algorithm, the tree S_A is always a depth-first search tree (d.f.s tree) of G_A at each node A of $C(G)$. This is ensured in the following manner. We start at the root of $C(G)$ with the d.f.s tree of G. Further, at each node A of $C(G)$, the nontree edges in G_A are considered for exchanges in a particular order. The order is given by the increasing post-order number of the upper (i.e., closer to the root) endpoints of the nontree edges. Note that since S_A is a d.f.s tree of G_A, all the nontree edges are back edges with respect to S_A. Clearly, finding the fundamental cycle of a nontree edge f is now straightforward: it simply involves marching up S_A from the lower endpoint of f to its upper endpoint. As we shall describe later, combining fundamental cycles now becomes a matter of simply changing the endpoints of some edges. The total space used in this scheme is $O(VE)$.

We remark that while Algorithm 2 is more efficient, Algorithm 1 is more general. In particular, it can be used as the base scheme in generating the spanning trees of a weighted graph in order (§4) while Algorithm 2 fails in that application because of its depth-first restriction.

2.2. Algorithm 1 description. The main algorithm, *Main*, has as input a graph G. It generates a spanning tree T of G corresponding to the root of the computation tree and computes the fundamental cycles with respect to T. *Main* also initializes the data structures, which will be described shortly.

ALGO Main(G);
Find a spanning tree, T, of G;
Initialize data structures;
Gen(T);
End Main.

The heart of the algorithm is the generation scheme *Gen*, which generates the sons of a node in the computation tree and recursively generates the subtrees rooted at them. The entire computation tree is thus generated in an pre-order traversal of the tree. The following is an outline of the scheme.

Gen picks an edge f from F, the data structure which stores all nontree multiedges in the current graph. It then determines the fundamental cycle $c_f = (e_1, \ldots, e_k)$ of f with respect to T, the current spanning tree. Note that $e_1, \ldots, e_k$ are only the tree edges in c_f, with the actual fundamental cycle formed by these edges along with the edge f.

Each edge in c_f in chosen for exchange with f in turn. When a tree edge e_i is chosen for exchange, it is removed from the current graph (i.e., put in the OUT set). As a result, all fundamental cycles containing this edge are now modified, i.e., they now have to be combined with c_f. Note that by this point, the edges $e_1, \ldots, e_{i-1}$ are already added to the IN set and thus are already contracted in the graph and in c_f. Furthermore, the edge f must be contracted in the current graph as it is added to the IN set. These changes are made by procedure *Prepare–for–son*.

After the computation subtree rooted at the node corresponding to the exchange (e_i, f) is constructed recursively, the edge e_i must now be contracted in the current graph (i.e., added to the IN set). This is done in the procedure *Prepare–for–sons'–sibling–branch*.

Finally, the last branch of $C(G)$ involves removal of the edge f from the current graph; this is done in procedure *Prepare–for–final–son*. Note that before returning from *Gen*, the state of the data structures is restored to that at the time its invocation.

The output of *Gen* is derived from the variable $CHANGES$. $CHANGES$ accumulates the exchanges used to derive the current spanning tree from the previous spanning tree generated. $CHANGES$ is initialized to ϕ by $Main$ and reset whenever a spanning tree is output. It is modified whenever an edge of $C(G)$ is traversed in the downward direction and this modification is reversed while backtracking upwards along this edge.

ALGO Gen(T);
$mf \leftarrow$ A multiedge in F;
$f \leftarrow$ An edge in mf;
$F \leftarrow F - mf$;
$c_f \leftarrow$ the fundamental cycle of f w.r.t T in G;
/* $c_f \leftarrow (e_1, e_2, \ldots, e_k)$ in the order they occur in the cycle ; */
For $i = 1$ to k **do**
$T' \leftarrow T + f - e_i$;
$CHANGES \leftarrow CHANGES + \{(e_i, f)\}$;
Output $CHANGES$;
/*These are the difference from the last tree generated; */
$CHANGES \leftarrow \phi$;
Prepare–for–son(e_i);
If $F \neq \phi$ **then** *Gen(T)*;
$CHANGES \leftarrow CHANGES + \{(f, e_i)\}$;
If $i < k$ **then** *Prepare–for–sons'–sibling–branch*(e_i);
End For
Restore all changes made to the graph and the data
structures in the above *For* loop;
Restore multiedge $mf - f$ to F;
Prepare–for–final–son( );
If $F \neq \phi$ **then** *Gen*(T') ;
Restore changes made to the graph and the data
structures in *Prepare–for–final–son*;
Restore edge f to multiedge mf in F;
End Gen.

Next, we describe the subprocedures used by Gen. Their description and performance is linked to the data structures used. Clearly, the following data structures suffice.

1. The list F of nontree multiedges.
2. A data structure AG to maintain the current graph, which supports the operations of contracting and deleting edges. As described later, we store only nontree edges in AG. The tree edges are stored in the following cycle data structure.
3. A data structure C that stores all fundamental cycles of the current graph, which allows for determining the fundamental cycle of a particular nontree edge, determining all fundamental cycles which contain a particular tree edge, and combining all cycles containing a particular tree edge with a given cycle.

We describe the subprocedures used by *Gen* in terms of the operations performed upon the data structures mentioned above. Each operation will be described in detail later.

PROCEDURE Prepare–for–son(e_i);
    If $i = 1$ **then** contract nontree edge f in AG;
    Combine all cycles in C which contain tree edge
      e_i with cycle in C corresponding to edge f;
End Prepare–for–son.

PROCEDURE Prepare–for–sons'–sibling-branch(e_i);
    Contract e_i in all cycles in C containing e_i;
    Modify AG in order to reflect the contraction of e_i;
End Prepare–for–sons'–sibling-branch.

PROCEDURE Prepare–for–final–son;
    Delete nontree edge f from AG;
    Modify C to reflect the deletion of nontree edge f;
End Prepare–for–final–son.

Data structures. Next, we give a high level description of these data structures and the operations performed upon them by the subprocedures. As we will show later, the time spent in each of these operations can be amortized to nodes of $C'(G)$ and $C(G)$ in a manner such that each node gets charged a constant amount.

The graph data structure. The graph (which is a multigraph, in general) is maintained as an adjacency list structure AG of multiedges in the usual manner with just the following difference: edges that are not in the current spanning tree are maintained. Note that edges constituting a multiedge are clubbed together in this structure. The edges in the current spanning tree are maintained as part of the data structure storing the fundamental cycles.

Operations on the graph. Contraction and deletion of edges in AG is done as follows. Deleting a nontree edge from AG is straightforward and takes constant time, given a pointer to that edge. Next, consider the contraction of edges. Note that only tree edges are contracted in the algorithm. Contraction of a tree edge involves merging the adjacency lists of the two endpoints of the edge and takes time proportional to the number of multiedges in the two adjacency lists. While this merger is performed, one of the multiedges may become a self-loop; this multiedge is removed. This ensures that each nontree edge in AG has a fundamental cycle with at least one tree edge at all times.

LEMMA 2.2. *Data structure AG allows deletion and contraction of nontree edges in constant time and contraction of a tree edge in time proportional to the number of multiedges incident upon the two endpoints of that edge.*

The data structure *F*. The list F is maintained in the obvious way as a list of lists, with each list storing a nontree multiedge. These multiedges are linked to the correspond-

ing multiedges in AG, so changes in AG can be reflected in F in the same time bounds.

The cycle data structure. The data structure C for storing fundamental cycles is as follows. The tree edges in each fundamental cycle are stored in a circular doubly linked list in the order in which they appear. This list is accessible by the corresponding nontree multiedge. Note that all edges which constitute a multiedge share the same fundamental cycle. For each tree edge e which is not in the IN set, to find all fundamental cycles containing e, we maintain a list of fundamental cycles containing e. Furthermore, given a tree edge e which is not in the IN set, we need to be able to delete e from all cycles containing e in time proportional to the number of these cycles. Therefore, for each tree edge e, the list containing fundamental cycles also stores pointers to the location of e in each of the cycles.

Operations on the cycles. Consider deletion of nontree edge f first. If f is not part of a multiedge then its fundamental cycle must be removed from C and C must then be modified appropriately. This is easily accomplished in time proportional to the size of this fundamental cycle. If f is part of a multiedge, then no changes need be made to C. Next, consider contractions of tree edges. When a tree edge e_i is contracted, the change must be reflected in each of the cycles containing e_i. This takes time proportional to the number of such cycles.

It remains to describe the operation of combining cycles. Consider the generation of son B_i of A. All fundamental cycles containing e_i in the current graph must be combined with c'_f, the fundamental cycle of f with respect to S_A with the edges $e_1, \ldots, e_{i-1}$ contracted.

The cycle combination algorithm. We show how to combine cycles c and c_f in time proportional to the size of the resulting cycle. Note that the resulting cycle does not have any tree edges common to both c and c_f. Therefore, the main aim of the combining operation is to combine c and c_f while avoiding the chain of edges common to both c and c_f. This is done as follows. Let a_1 and a_2 be the endpoints of the nontree edge g associated with fundamental cycle c. Let a_3 and a_4 be the endpoints of the nontree edge f associated with fundamental cycle c_f. We show how to determine the endpoints of the chain D of tree edges, which constitutes the portion common to c and c_f in time proportional to $|c| + |c_f| - |D|$. Clearly, by knowing these two endpoints, the resulting cycle can easily be obtained in same time bound. Thus the time required to combine two cycles is proportional to the size of the resulting cycle.

We traverse c and c_f by using four pointers $p_1 \ldots p_4$, two per cycle, with p_i pointing to a_i initially. There are a number of rounds; in each round, each pointer traverses one edge of the cycle moving towards the other end of the cycle. Pointer p_i stops moving when either it reaches an edge which has been traversed previously (by some pointer) or it meets another pointer p_j. The latter conditions holds when either p_i and p_j point to the same vertex or they cross each other while traversing an edge. The procedure stops when all four pointers have stopped moving. The number of rounds is at most $\max\{|c|, |c_f|\} - |D|$ because as long as the above procedure continues, at least one of the four pointers must be outside D.

We show that the endpoints of D can be inferred from the final positions of the four pointers. Clearly, some two pointers must meet each other during the above procedure. There are three cases to consider depending upon which pointers meet. (See Fig. 4; pointers are shown in their final positions in each case.) First, suppose that the pointers which traverse c meet each other. Then the pointers which traverse c_f must be finally located at the two endpoints of D. The case where the two pointers which traverse c_f meet can be handled similarly. Second, suppose a pointer which traverses c meets a pointer which traverses c_f, but the remaining two pointers do not meet. These two remaining pointers must be finally located at the endpoints of D. Third, suppose each pointer which traverses c meets at least one pointer which traverses c_f. Then, it can easily be verified that each pointer which traverses c meets exactly one of the pointers traversing c_f. In this case, two of the pointers, one which traverses

c and one which traverses c_f, must be finally located at one endpoint of D while the other two pointers must be located at the other endpoint.

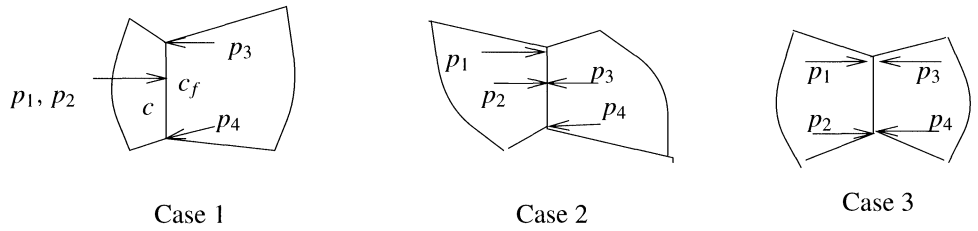

FIG. 4. *Three cases in the cycle combination algorithm.*

It follows that the cycle combination can be achieved in time proportional to the number of edges in the resulting cycle.

LEMMA 2.3. *The data structure C allows for the following items.*

1. *Deletion of nontree edge f in time proportional to the size of its fundamental cycle.*
2. *Contraction of tree edge e_i in time proportional to the number of cycle it is contained in.*
3. *Combining two cycles in time proportional to the size of the resulting cycle.*

This ends the description of the data structures.

2.2.1. Analysis. We start with the analysis of the time complexity of Algorithm 1. First, we show that the total output size of the algorithm is $O(N)$.

LEMMA 2.4. *The number of exchanges output by Gen is at most* $2N$.

Proof. Consider internal node x of $C(G)$. For each son y of x, except the last, one exchange is added to $CHANGES$ when y is generated and its opposite exchange ((e, f) is the exchange opposite to (f, e)) is added to $CHANGES$ after the sub-tree rooted at y has been generated. Therefore, the number of exchanges added to $CHANGES$ is at most $2N$. Furthermore, every time $CHANGES$ is output, it is reset to ϕ immediately. The lemma follows. □

The following lemma is the key one in obtaining the final complexity.

LEMMA 2.5. *The work done at each node A of $C(G)$ is $O(|s(A)|+|g(A)|+r(A))$, where $s(A)$ is the set of sons of A in $C(G)$, $g(A)$ is the set of sons in $C'(G)$ of nodes in $s(A)$, and $r(A)$ is the number of exchanges output at node A.*

Proof. The work done to output exchanges at A is at most $O(r(A))$. We consider the other operations performed at node A and show how to amortize the time spent in these operations to nodes in $s(A)$ and $g(A)$

Clearly, the operations performed in *Gen* (excluding those performed in the subprocedures) take time proportional to the number of sons of A. We look at the operations performed next in the subprocedures.

First, consider *Prepare–for–son*(e_i). Through Lemma 2.2, contracting f takes constant time. According to Lemma 2.3, the time to combine all cycles containing e_i with the fundamental cycle for f takes time proportional to the sum sizes of the resulting cycles. Each resulting cycle leads to a number of sons of B_i in $C'(G)$ equal to its size. Thus the time spent in combining cycles can be charged to the sons of node B_i in $C'(G)$. Consequently, each node in $g(A)$ gets charged once for cycle combinations over all calls to *Prepare–for–son*.

Next, consider *Prepare–for–sons'–sibling–branch*(e_i). First, consider contraction of the edge e_i in C. By Lemma 2.3, contracting e_i in C takes time proportional to the number of cycles it is contained in. Consider each of these cycles following the contraction of e_i.

At most one of these, c_j, say, will not contain a tree edge, as edges corresponding to a multiedge are clubbed together and self-loops are removed as they are formed. Therefore, each of these cycles except c_j and c'_f, the fundamental cycle of f with respect to S_A with the edges $e_1, \ldots, e_{i-1}, e_i$ contracted, will lead to at least one son of B_{i+1} in $C'(G)$. Next, consider the contraction of edge e_i in AG. By Lemma 2.2, this takes time proportional to the number of multiedges incident upon the two endpoints of e_i. Consider the set M of these multiedges, excluding the one multiedge which is converted to a self-loop upon contraction, if any. Following the contraction, we see that each multiedge $g \in M$ with tree edges other than the one contracted has a fundamental cycle containing at least one tree edge. (Recall that self-loops are removed as they are formed.) Therefore, every edge in each such multiedge g, with the possible exception of the multiedge having the same endpoints as f, gives rise to at least one son of B_{i+1} in $C'(G)$. Thus, the time spent in *Prepare–for–sons'–sibling–branch*(e_i) can be charged to the sons of node B_{i+1} in $C'(G)$. Therefore, each node in $g(A)$ gets charged at most twice over all calls to *Prepare–for–sons'–sibling–branch*.

Finally, consider *Prepare–for–final–son*. By Lemma 2.2, deletion of f from AG takes constant time. By Lemma 2.3, deletion of f from C takes time proportional to the size of its fundamental cycle, which, in turn, equals the number of sons of A in $C(G)$. The lemma follows. □

Next, we obtain the time complexity of *Gen* and *Main*.

THEOREM 2.6. *All spanning trees can be correctly generated in* $O(N + V + E)$ *time by Main.*

Proof. First, note that *Gen* correctly computes the spanning trees at sons of a node A of the computation tree. This follows from the fact that the cycles and the graph are correctly updated after the inclusion of edges into the IN and OUT sets. The correctness of the updates is evident from the operations on the data structures discussed in detail before. Also note that *Gen* correctly maintains $CHANGES$ which stores the difference between the current tree being output and the last spanning tree generated. Thus *Gen* correctly generates the computation tree and outputs the tree differences.

We next compute the time complexity. The preprocessing steps in *Main* before calling *Gen* is called require $O(V + E)$ time, in addition to the time required for setting up the cycle data structure. The latter can be charged to the sons of the root node of $C'(G)$. We show next that the time taken by the call to *Gen* in *Main* is $O(N)$.

The total time for outputting exchanges over all invocations of *Gen* is $O(N)$ by Lemma 2.4. Next, consider the time spent in a particular invocation of *Gen*, minus the time for outputting exchanges in that invocation. Let this invocation correspond to the creation of the sons of node x in $C(G)$. By Lemma 2.5, the time taken by this invocation of *Gen* is at most $O(|s(x)|+|g(x)|)$. Summing over all nodes of $C(G)$, it follows that the time taken by the call to *Gen* in *Main* is $O(N)$. The lemma follows. □

Next, we analyze the space complexity.

THEOREM 2.7. *The space required by the spanning tree enumeration algorithm, Main, is* $O(V^2E)$.

Proof. At each node of $C(G)$, changes to the data structures need to be stored to enable restoration later. These changes take $O(VE)$ space and this dominates the space requirement. The space taken to store changes when the last son of any node in $C(G)$ is generated is $O(1)$. (Only a nontree edge is deleted.) On any root-to-leaf path in $C(G)$, the number of nodes which are not the rightmost sons of their respective parents (note that this number is bounded by the height of $C'(G)$) is at most V. This is because any two spanning trees can differ in at most $V - 1$ pairs of edges. The theorem now follows from the fact that *Gen* generates $C(G)$ in a depth-first manner. □

2.3. Algorithm 2 description. We describe a second algorithm based on the use of depth-first search to construct $C(G)$.

As before, we generate the computation tree, $C(G)$ recursively: The details are as follows. At the root of the computation tree the spanning tree is constructed by a depth-first scan of the graph. In fact, we maintain the following invariant: At each node A of the computation tree, S_A is a d.f.s spanning tree of G_A. Consequently, all nontree edges in G_A are back edges with respect to S_A. This property makes the task of determining and combining fundamental cycles much easier. In particular, it is no longer necessary to maintain all the fundamental cycles in a separate data structure. Only the spanning tree S_A itself needs to be stored, with the edges in IN_A contracted. Given S_A, the fundamental cycle corresponding to a particular nontree edge $f \in G_A$ can now be found by marching along S_A from the endpoint farther from the root to the endpoint closer to the root. This is instrumental in reducing the space bound to $O(VE)$. The combination of cycles is also simplified, as we will describe below.

Moreover, in order to ensure efficiency we must ensure that all useless tree edges are not to be considered in the replacement process. Useless edges are those edges that do not give rise to an exchange and hence to a spanning tree. These are the edges that do not occur in any cycles; i.e., they are the bridges of the graph. We describe their removal below.

For convenience, let *up* and *down* denote the directions towards and away from the root, respectively. For each nontree edge, its *upper* endpoint is the one closer to the root.

2.3.1. Maintaining the d.f.s. invariant. We show how to maintain the invariant regarding the d.f.s nature of each spanning tree. Suppose node A of $C(G)$ has been generated and S_A is a d.f.s tree of G_A. Assume that the vertices of S_A are numbered by a post-order traversal of S_A. At node A, we select the nontree edge f, whose upper endpoint has the least post-order number among all the nontree edges in G_A. Edge f is used as the replacement edge. Furthermore, the tree edges in the fundamental cycle of f with respect to S_A are replaced in order, starting from the edge farthest from the root and proceeding upwards. Let $e_1, \ldots, e_k$ be these tree edges in that order, and let $e_i = (x_{i-1}, x_i)$. We claim that for each of the sons $B_1, \ldots, B_k$ of A, the spanning trees at these nodes are d.f.s trees of G_A. This is shown in Lemma 2.8. Before we prove this lemma, we describe the various operations that take place when these sons are generated. This is helpful in describing the proof of Lemma 2.8.

Let T be the data structure storing the spanning trees. T is implemented in the usual manner as a set of parent pointers and child pointers. Before any of the sons of A have been generated, T stores S_A. Consider the generation of son B_i of A. The edges $e_1, \ldots, e_{i-1}$, f are all in the IN set and therefore, must be contracted in T. As a result of this contraction, the sons of $x_0, \ldots, x_{i-1}$ in T now become sons of x_k. Furthermore, all nontree edges in G_A which have one of $x_0, \ldots, x_{i-1}$ as their lower endpoints must have their lower endpoint changed to x_k. Since edges $e_1, \ldots, e_{i-2}$, f would already have been contracted before son B_{i-1} is generated, only the sons of x_{i-1} need to be made sons of x_k, and only the lower endpoints of those nontree edges which currently have lower endpoint x_{i-1} need be set to x_k when son B_i is generated (see Fig. 5). Note that with this, we have effectively achieved the task of cycle combination.

LEMMA 2.8. *For each son B_i, $1 \leq i \leq k+1$ of A, all nontree edges in G_{B_i} are back edges with respect to S_{B_i}, assuming that all nontree edges in G_A are back edges with respect to S_A.*

Proof. For B_{k+1}, the lemma is easily seen to be true. Consider son B_i, $1 \leq i \leq k$. Consider any nontree edge g in G_{B_i}. Note that $g \in G_A$. The upper endpoint of g in S_A must be either x_k or an ancestor of x_k in S_A. From the previous paragraph, when S_{B_i} is obtained from S_A, the lower endpoint of g either remains unchanged or is changed to x_k. Furthermore, any descendant of x_k in S_A remains a descendant of x_k is S_{B_i}. Thus all nontree edges in G_{B_i} are back edges with respect to S_{B_i}. The lemma follows. □

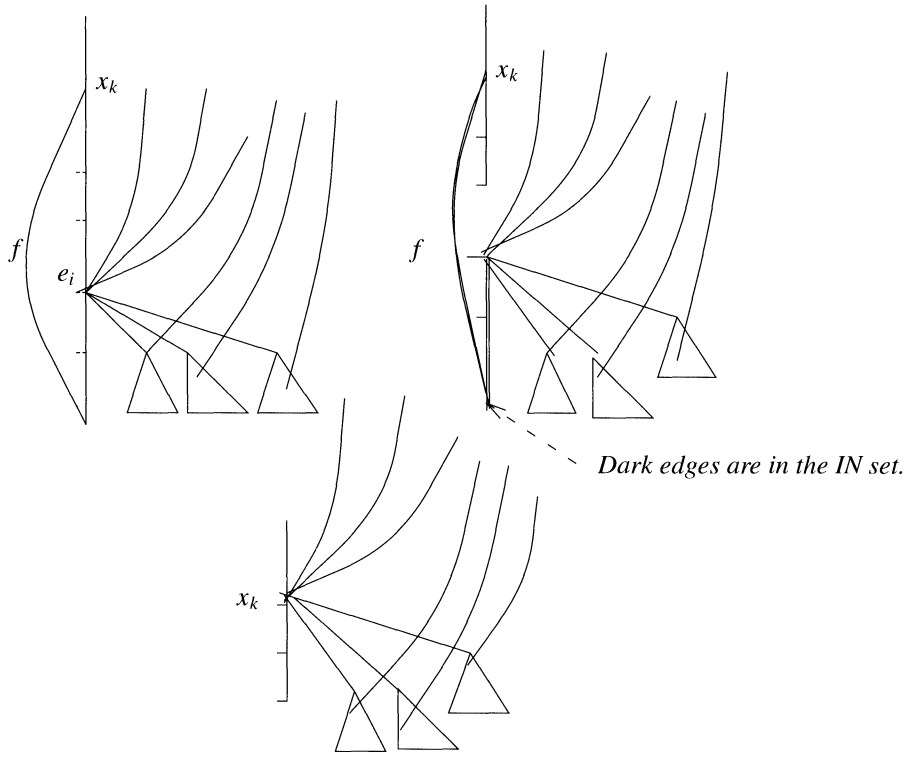

FIG. 5. *Generation of* B_i.

2.3.2. Detecting and removing bridge edges in T. Now we show how bridge edges in T are detected and removed as they are formed. This is initially accomplished by dividing the graph into its biconnected components and generating the spanning trees for each component separately. The spanning trees for the entire graph can be obtained easily from the spanning trees of its biconnected components.

Next, we show how bridges are detected at node A of $C(G)$ when its sons $B_1, \ldots, B_{k+1}$ are being generated, assuming that at A, T has no bridge edges. The following observations are key. Clearly, the only edges in T which can be converted to bridge edges are the edges $e_1, \ldots, e_k$. This can happen when either one of the e_i's is deleted or when f is deleted. The condition that characterizes the situation when e_i becomes a bridge edge is as follows. Let $j \geq i - 1$ be the smallest number such that x_j has either a branch (i.e., at least two sons) or an incident nontree edge. (Note that x_j would be the lower endpoint of such a nontree edge.) If $j \geq i$, then e_i is a bridge edge and so are the edges $e_{i+1}, \ldots, e_j$. But $e_{j+1}, \ldots, e_k$ remain nonbridge edges.

The bridge detection procedure which results from the above observations is as follows. First, consider the deletion of edge e_i. By this point, edges $e_1, \ldots, e_{i-1}$ are already contracted. Among the edges $e_{i+1}, \ldots, e_k$, those edges which are converted to bridge edges by this deletion are ascertained by traversing these edges in the above sequence until a vertex x_j, $j \geq i$, is found such that x_j has either a branch (i.e., at least two sons before the deletion of e_i) or a an incident nontree edge. The edges traversed are converted to bridge edges by the deletion of e_i. These edges are removed from T by simply removing the vertex x_{j-1} from T. Furthermore, note that when the edges $e_{i+1}, \ldots, e_j$ are deleted subsequently, bridge removal can be accomplished in

each case by the deletion of x_{j-1} from T. Later, when e_{j+1} is deleted, bridge detection will be done by traversing the edges $e_{j+2}, \ldots, e_k$ in that order. Next, consider the deletion of edge f. Bridge detection is done by traversing the edges $e_1, \ldots, e_k$ until a vertex x_j, $j \geq 0$, is found such that x_j has either a branch or an incident nontree edge. Bridge removal involves removing x_j from T.

LEMMA 2.9. *The total time taken for bridge detection over deletions of all of* $e_1, \ldots, e_k$ *is* $O(k)$. *The time taken for bridge detection when* f *is deleted is also* $O(k)$.

2.3.3. Data structures. Next, we describe details of the data structures used as well as the operations on them along with the time complexity of executing them. Later, we will show that a result similar to Lemma 2.5 holds for this algorithm too.

Storing tree edges. The data structure T stores the current spanning tree in the form of a parent pointer and a list of child pointers for each node, with only edges not currently in the IN set present. Determining the fundamental cycle of a particular nontree edge and deletion of a tree edge are trivial.

Consider edge contraction next. When edge $e_i = (x_{i-1}, x_i)$ is contracted, the sons of x_i are made sons of x_k. This takes time proportional to the number of sons of x_i. In order to account for this time, we use the invariant that each edge in T is a nonbridge edge in the current graph, i.e., it occurs in at least one fundamental cycle.

LEMMA 2.10. *Data structure* T *allows for*

1. *Determining the fundamental cycle of a nontree edge in time proportional to the length of the cycle.*
2. *Contracting tree edge* e_i *in time proportional to the number of sons of vertex* x_i *in* T.

Storing nontree edges. Recall that nontree edges have to be ordered by their upper endpoints. Furthermore, given a vertex v, we need to be able to determine all those nontree edges which have a lower endpoint v. These edges are required during the contraction of edges.

The following lemma is important for maintaining nontree edges in the requisite order. It shows that this order is independent of the particular node of $C(G)$ that is considered. Therefore, we can initially order nontree edges in an order given by a post-order traversal of the spanning tree at the root of $C(G)$; this order will hold throughout the algorithm.

LEMMA 2.11. *Suppose for edges* $e_a, e_b \in G_{B_i}$, *the upper endpoint of* e_a *appears before the upper endpoint of* e_b *in the post-order ordering of vertices in* S_{B_i}, $1 \leq i \leq k+1$. *Then the upper endpoint of* e_a *appears before the upper endpoint of* e_b *in the post-order ordering of vertices in* S_A.

Proof. This is clearly true for $i = k+1$. So suppose $i < k+1$. Edge $f = (x_0, x_k)$ has the least upper endpoint in the post-order ordering of all vertices in S_A. When B_i is generated, only the portion of S_A consisting of descendants of x_k is modified to give S_{B_i}. No descendants of x_k can have a greater post-order number than x_k. The lemma follows. □

As before, the data structure for storing nontree edges actually stores multiedges. This data structure has two components, *REP-LIST* and *ADJ-LIST*. Modifications to one of them can be reflected in the other without any extra time overhead by keeping pointers between the corresponding multiedges in the two structures.

REP-LIST is simply a list of nontree multiedges eligible for replacement, with the multiedges appearing in the requisite order. At each node A of $C(G)$, an edge f from the first multiedge in this list is picked for replacement and this edge is deleted from this list to generate the last son of A; selecting the replacement edge and deleting an edge thus takes constant time.

For each vertex v, *ADJ-LIST* stores a list of nontree multiedges which have v for their lower endpoint. Clearly, for vertex x_i, the lower endpoints of all edges which currently have

lower endpoint x_i can be changed to x_k by merging the multiedge list for x_i with that for x_k. Any self-loop formed is removed. (Note that since edges are organized into multiedges, at most one self-loop is formed per merger.) This can be done in time proportional to the number of multiedges in the two lists.

LEMMA 2.12. *Data structures* REP-LIST *and* ADJ-LIST *can be maintained such that*

1. *The replacement edge can be selected and deleted in constant time.*
2. *The lower endpoints of all nontree edges with lower endpoint x_i can be transferred to x_k in time proportional to the number of nontree multiedges incident upon the two vertices.*
3. *The ordering of nontree edges remains unchanged.*

2.3.4. Algorithm 2 pseudocode. For detail and clarity, we present the pseudocode of Algorithm 2. The main procedure *Main*2 sets up the initial data structures and then uses *Gen*2 to generate all spanning trees of G. The basic framework of *Main*2 and *Gen*2 is similar to that of *Main* and *Gen* but with one notable difference. *Main2* splits G into its biconnected components and generates all spanning trees of G by using *Gen*2 to generate all spanning trees of each biconnected component. *Gen*2 uses the procedures *Combine-Cycles*, *Remove-Bridges*1, and *Remove-Bridges*2. The first of these makes the changes required when edge edge e_{i-1} is contraction and edge e_i is deleted in order to generate son B_i of A. The last two perform the detection and removal of bridges from the graph resulting from deletion of edges $e_1, \ldots, e_k$ and the deletion of edge f, respectively. A stack *STACK* is used to store changes made to data structures before recursing so as to undo these changes after the recursion completes.

ALGO Main2(G)

Determine biconnected components of $G = (G_1, G_2, \ldots, G_k)$;
$T_i \leftarrow$ D.F.S tree of G_i, $1 \leq i \leq k$;
For each i, $1 \leq i \leq k$ do
    Compute *REP-LIST* and *ADJ-LIST*;
Use *Gen*2 to output all spanning trees of G in the
lexicographic ordering of the biconnected components.
End Main2.

ALGO Gen2(T)

If *REP-LIST*$= \phi$ **then** return;
$f = (u, v) \leftarrow$ First edge in *REP-LIST*;
    /* u represents the lower endpoint of the
    back edge in the DFS tree */
$c_f \leftarrow (x_1 = u, x_2, \ldots, x_{k+1} = v)$;
    /*the sequence of vertices in the fundamental cycle
    of f w.r.t T from bottom upwards */
REP-LIST $\leftarrow$ *REP-LIST* $- f$;
LAST $\leftarrow$ The first ancestor of x_1 whose
    father either has a branch or a back edge;
      /* Useful for bridge elimination, $LAST$ is local to *Gen*2 */
For $i = 1$ to k **do**
    $e \leftarrow (x_i, x_{i+1})$;
    $LAST \leftarrow$ *Remove-bridges*1$(LAST, x_i)$;
    $T \leftarrow T - e \cup f$;
    $IN \leftarrow IN + \{f\}$; /* Update the IN set*/

```
        OUT ← OUT + {e}; /* Update the OUT set*/
        CHANGES ← CHANGES +{(e, f)};
        Output CHANGES;
              /*Output differences from the last tree generated */
        CHANGES ← φ;
        If i < k Combine-cycles(i, x_k, f);
        Gen2(T);
        Restore LAST to T;
        CHANGES← CHANGES +{(f, e)};
        IN ← IN − {f};
        OUT ← OUT − {e};
        T ← T − f + e; /* restoring T */
        IN ← IN + {e}; /* adding edge removed to OUT set */
        inlist ← inlist ∪ e;
    End For;
    IN ← IN − inlist;
    OUT ← OUT + {f};
    Restore-changes;
        /* Undo all changes made by all calls to COMBINE-CYCLES
          in the above for loop using STACK to retrieve changes */
    ADJ-LIST[x1] ← ADJ-LIST[x1] − f;
        /* Prepares for last recursion associated with c_f */
    LAST ← Remove-bridges2( );
    Gen2(T);
    Restore vertex LAST to T;
    Restore f to the front of REP-LIST and to ADJ-LIST [x1];
    OUT ← OUT − {f};
End Gen2.

Procedure Combine-cycles(i, x_k, f);
    For each son y of x_i make father(y) ← x_k;
    Store the changes made above on STACK;
    For each sublist, l, of multiple back edges in ADJ-LIST(x_i) do
        If edges in l have upper endpoint v then
            Remove l from REP-LIST and ADJ − LIST[x_i];
                  /*Edges in l are now loops and hence removed */
            Store the changes made above on STACK;
        else
            Transfer l to ADJ-LIST(v);
            Store the changes made above on STACK;
End Combine-cycle;

Procedure Remove-bridges1(LAST, x_i);
    If x_i = father of vertex LAST in T then
        LAST ← The first (i.e., closest to x_i) ancestor of x_i in c_f
          whose father has a back edge or a branch;
            /* LAST is x_k if no such vertex exists */
    Remove vertex LAST from T;
    Return(LAST);
End Remove-bridges1.
```

Procedure Remove-bridges2( );

If $ADJ - LIST[x_1]$ is empty and x_1 has no son in T then

$LAST \leftarrow$The first (i.e., closest to x_1) ancestor of x_1 in c_f whose father has a back edge or a branch;

else

$LAST \leftarrow \phi$;

Remove vertex $LAST$ from T;

Return($LAST$);

End Remove-bridges2.

2.3.5. Time and space complexity. Lemma 2.4 holds for this algorithm too. Next, we show that Lemma 2.5 holds too.

LEMMA 2.13. *The work done at each node A of $C(G)$ is $O(|s(A)| + |g(A)| + r(A))$, where $s(A)$ is the set of sons of A in $C(G)$, $g(A)$ is the set of sons in $C'(G)$ of nodes in $s(A)$, and $r(A)$ is the number of exchanges output at node A.*

Proof. The work done to output exchanges at A is $O(r(A))$ We consider the other operations performed at node A and show how to amortize the time spent in these operations to nodes in $s(A)$ and $g(A)$.

Clearly, the operations performed in *Gen*2 (excluding those performed in the subprocedures) take time proportional to the number of sons of A. We look at the operations performed in the subprocedures next.

First, consider all invocations of procedure *Remove-Bridges*1 and *Remove-Bridges*2. By Lemma 2.9, the time spent in these procedures is proportional to the number of sons of A in $C(G)$.

Second, consider the call to *Combine-Cycle*(i, x_k, f). The two major operations done in this procedure are changing the parent pointers of sons of x_i to x_k and changing the lower endpoints of some nontree edges from x_i to x_k. We consider each of these in turn.

First, consider the operation of changing the parent pointers of the sons of x_i. By Lemma 2.10, this takes time proportional to the number of sons of x_i in T. Since bridges are removed from T as they are formed, for each son y of x_i in T (note that x_{i-1} is not in T currently as the edge (x_{i-1}, x_i) is in the IN set), there exists at least one nontree edge f' such that the edge (x_i, y) belongs to the fundamental cycle of f'. The exchange of f' for (x_i, y) leads to a son of B_{i+1} in $C'(G)$ to which the time for changing the parent pointer of y can be charged. Thus, over all calls to *Combine-Cycle*, each node in $g(A)$ gets charged at most once for changing parent pointers.

Second, consider the operation of changing the lower endpoints of some nontree edges from x_i to x_k. By Lemma 2.12, this takes time proportional to the number of nontree multiedges incident upon x_i and x_k. At most one of the multiedges incident upon x_i, i.e., the multiedge with upper endpoint x_k, is converted to a self-loop in the above process. All other multiedges which are incident upon any of the two vertices have a fundamental cycle containing at least one tree edge; each such fundamental cycle leads to at least one son of B_{i+1} in $C'(G)$. Therefore, the time spent in modifying lower endpoints in *Combine-Cycle*(i, x_k, f) can be charged to the grandsons of A through B_{i+1} in $C'(G)$. Thus, over all calls to *Combine-Cycle*, each node in $g(A)$ gets charged at most once for changing lower endpoints.

The lemma follows. □

THEOREM 2.14. *Algorithm* 2 *generates all spanning trees of T is $O(N + V + E)$ time correctly.*

Proof. First we consider correctness. From the discussions in the previous sections, it is easy to see that *Gen* generates the computation tree such that S_A is a d.f.s. tree of G_A. Thus the cycle and exchange generation process is correct. Note that *Gen* maintains G_A as a biconnected graph. Since *Main* calls *Gen* for each biconnected component all spanning trees can be generated by taking all possible combinations in the individual components.

Next we consider the time complexity. Without loss of generality assume that G is biconnected. If this is not the case, then for the ith biconnected component of G having N_i spanning trees, V_i vertices and E_i edges, the time taken will be $O(N_1 + V_1 + E_1)$ and the time to put the computation trees of the various components together in the obvious manner will be $O(\Pi_i N_i + \Sigma_i(V_i + E_i)) = O(N + V + E)$.

From Lemma 2.13, each node of $C(G)$ and $C'(G)$ is charged a constant amount for work done over all nodes of $C(G)$ and by Lemma 2.4, the total work done to output exchanges is $O(N)$. *Main* takes $O(V + E)$ time to construct the initial data structures. The theorem follows. □

THEOREM 2.15. *Algorithm* 2 *takes* $O(VE)$ *space.*

Proof. The space required for *REP-LIST* and *ADJ-LIST* and T is $O(V + E)$. Stack space for storing changes to be undone after returning from a recursive call is shown to be $O(VE + V^2)$ as follows. The parent vertex of any vertex is changed at most $O(V)$ times along any path of $C(G)$. The lower endpoint for any nontree edge is changed at most V times along any path in $C(G)$. An edge is deleted at most once along any path in $C(G)$. Consequently storing changes to *ADJ-LIST*, *REP-LIST* and T require $O(VE)$ space. So the total space is $O(VE)$. □

3. Generating the computation tree in increasing weight order. Next, assuming that the edges of G are weighted, we present an algorithm to generate the nodes of $C(G)$ in increasing order of weight.

The algorithm follows a branch and bound strategy on the computation tree. The root of the computation tree is now associated with the minimum spanning tree (MST) of the graph. The sons of the root are obtained as before by exchanging nontree edges with tree edges. The exchanges are made according to an order that ensures that the tree resulting from the exchange is the minimum spanning tree of the updated graph at the corresponding son. To ensure this, the nontree edges are considered for replacement in increasing order of weight. This is repeated at descendant nodes of the computation tree. The entire computation tree is generated in a branch and bound fashion. To ensure efficiency, we characterize each spanning tree generated by the exchange pair that generates it in the computation tree. The final algorithm is as follows: The generation algorithm first generates the tree at the root and the sons at the root are input to a queue indexed by the exchange pair. The actual sorted order is generated by selecting the minimum tree from among all queues. This is done by maintaining a priority queue containing the first element of each queue.

The algorithm that we describe is similar to *Gen*, but instead of traversing the nodes of the computation tree in a depth-first fashion, a branch and bound strategy is used where the node corresponding to the spanning tree that is to be output next is expanded.

ALGO Genwt
    Find min spanning tree, MST;
    Repeat
        Generate sons of node corresponding to MST
        by considering nontree edges in increasing weight order;
        Put each spanning tree generated into the
        queue indexed by the exchange using which it was
        obtained from its parent;
        Pick minimum weighted spanning trees, MST, from
        priority queue;
    Until all queues are empty.
END Genwt

3.1. Correctness and complexity.

LEMMA 3.1. *For node A in the computation tree, S_A is the Minimum Spanning Tree of G_A.*

Proof. The proof is by induction on the level of the tree. At the root, the claim is true by construction. Assume that the claim is true for a node A. The sons of the node are generated by considering nontree edges in increasing order of weight. Let the ordered set of nontree edges at A be $f_1, f_2, \ldots, f_m$. Let nontree edge f_i be used to generate sons $B_1, \ldots, B_k$ of A by exchanging with tree edges $e_1, \ldots, e_k$. Then edges $f_1, f_2, \ldots, f_{i-1}$ are absent from each of $G_{B_1}, G_{B_2}, \ldots, G_{B_k}$. Thus f_i is the smallest edge that is present in each of these graphs, but not in S_A. For each j from 1 to k, since e_j is absent from G_{B_j}, it follows that $S(G_{B_j})$ is the MST of G_{B_j}. □

LEMMA 3.2. *The number of exchanges is at most* $(V-1)(E-V+1)$.

Proof. The first entry in the exchange pair has $V-1$ values since the only edges allowed are those in the spanning tree associated with the root. This is true because the second entry in the exchange associated with any node is also in the IN set of that node and its descendants. The second entry in the exchange pair cannot be an edge in the spanning tree associated with the root, because first entry in the exchange associated with any node is in the OUT set of that node. The result follows. □

The next lemma follows from the branch and bound generation of the computation tree.

LEMMA 3.3. *The spanning trees enter the queue for each of the exchanges in sorted order.*

Thus we have the following theorem.

THEOREM 3.4. *Algorithm Genwt correctly sorts the nodes of the computation tree in* $O(N \log V + VE)$ *time.*

Proof. The correctness follows from Lemmas 3.1, 3.2 and 3.3. The time may be divided into generation of nodes in the computation tree and processing of the queues. Generation of the nodes in the computation tree requires $O(N+V+E)$ time. Processing the queues requires $O(N \log VE)$ steps since there are at most $O(VE)$ queues. An initial sorting of nontree edges may require $O(E \log E)$ steps resulting in the required time bound. □

THEOREM 3.5. *Genwt requires* $O(N+VE)$ *space.*

Proof. The proof follows from the space requirements of the computation tree and the queues. □

Output complexity. The output of the algorithm can be the computation tree itself in which the nodes are numbered according to the order in which they are sorted. Pointers to these nodes are maintained from a list whose indices give the index of the spanning tree. The space complexity is $O(N)$ words, where each word has $O(\log N)$ bits. The trees can also be explicitly listed out in $O(NV)$ time. Note that the output time thus exceeds the time for sorting.

4. Conclusions.

This paper presents a methodology for enumerating subgraphs of a given graph and illustrates this with the spanning tree problem. A companion paper [KKR94] describes enumeration of directed graphs. Efficient enumeration of cycles may also be possible using a similar scheme.

PERMUTING IN PLACE*

FAITH E. FICH†, J. IAN MUNRO‡, AND PATRICIO V. POBLETE§

Abstract. This paper addresses the fundamental problem of permuting the elements of an array of n elements according to some given permutation. It aims to perform the permutation quickly by using only a polylogarithmic number of bits of extra storage. The main result is an algorithm whose worst case running time is $O(n \log n)$ and uses $O(\log n)$ additional $\log n$-bit words of memory. A simpler method is presented for the case in which both the permutation and its inverse can be computed at (amortised) unit cost. This algorithm requires $O(n \log n)$ time and $O(1)$ words in the worst case. These results are extended to the situation in which a power of the permutation must be applied. A linear time, $O(1)$ word method is presented for the special case in which the data values are all distinct and are either initially in sorted order or will be when permuted.

Key words. permutation, reordering, space, in place

AMS subject classifications. 68P05, 68P10

1. Introduction.

Given an array $A[1..n]$ and a permutation $\pi : \{1, \ldots, n\} \to \{1, \ldots, n\}$, we wish to rearrange the elements of the array in place according to the permutation. More precisely, the rearrangement consists of performing the equivalent of the n *simultaneous* assignments

$$A[\pi(i)] \leftarrow A[i] \text{ for } i \in \{1, \ldots, n\}.$$

Thus if the array A originally contains the sequence of values $a_1, a_2, \ldots, a_n$, then, afterwards, it contains the sequence $a_{\pi^{-1}(1)}, a_{\pi^{-1}(2)}, \ldots, a_{\pi^{-1}(n)}$.

"In place" means that the algorithm performs the rearrangement by repeatedly interchanging pairs of elements. Hence, the set of values in the array and the number of times each occurs always remain the same. In particular, this definition precludes moving the elements into an auxiliary array and then putting each element, one at a time, into its correct location in the original array. It also means that the array cannot be padded with blanks (see, for example, [7]) to make it a more convenient size to work with.

The problem of rearranging data arises in a variety of situations. Some examples are transposing a rectangular matrix [12, Ex. 1.3.3–12], [7], rotating a bit map image, and exchanging two sections of an array [2, p. 134].

In sorting a list with very large records, it might be more efficient to manipulate pointers to the records rather than the records themselves and, afterwards, put each record into its appropriate location [13, p. 74]. Another way to sort [13, p. 76] is to first compare every pair of keys, then, for each record, count the number of other records that should precede it and rearrange the records accordingly.

In certain circumstances, searching is *not* most efficient when the elements of the array are in sorted order. If a large number of searches are going to be performed, it could be advantageous to rearrange a sorted array first. For example, one can simplify the index computation in a binary search by organizing the elements into a data structure that implicitly represents a complete binary search tree (via a breadth first, left to right, enumeration of its nodes) [1, Ex. 12–6, pp. 136, 183–184], [13, Ex. 6.2.1–24, pp. 422, 670], [12, p. 401]. heap, an element in location $i < n/2$ has its left and right children in locations $2i$ and $2i + 1$, respectively. When the data is stored on a disk with each block capable of holding b elements or in a virtual memory in which each page can contain b elements [13, pp. 472–473], the number of reads can be minimized by arranging the elements using a similar implicit representation of a complete $(b + 1)$-ary search tree [12, p. 401]. These three different arrangements are illustrated in Fig. 1. In the third case, $b = 3$.

FIG. 1. *Three arrangements of a list of length* 15.

We are interested in the amount of time and additional space needed to rearrange the elements of the array according to the input permutation. Previously known algorithms for this problem used either quadratic time or a linear amount of additional space in the worst case. In this paper, we present a concise algorithm that takes time $O(n \log n)$ and uses only $O(\log^2 n)$ bits of additional storage. We have a simpler method for the case in which both the permutation and its inverse are given; it takes the same amount of time and uses only $O(\log n)$ bits. Furthermore, we show how to use the fact that a permutation is known to rearrange the array either to or from sorted order to obtain an algorithm that takes time $O(n)$ and uses only $O(\log n)$ bits of additional storage.

Throughout the paper, we assume that the permutation π is given by means of an oracle. This models the situation where the value of $\pi(i)$ is computed from i (e.g., transposing a rectangular array) or the permutation cannot be changed (e.g., because it is being used by other processes). If the permutation is given by an array and its entries can be used to record information as the algorithm proceeds (perhaps destroying the permutation in the process), data rearrangement can be done efficiently by using $O(n)$ time and $O(\log n)$ additional bits of storage [13, Ex. 5.2–10, pp. 80, 595]. This is also the case when the permutation is given as a product of disjoint cycles.

2. Cycle leader algorithms. The cycle structure of the permutation can be exploited to obtain efficient algorithms for rearranging data. Permutations are composed of one or more disjoint cycles, as illustrated in Fig. 2. The arrows follow the direction $i \rightarrow \pi(i)$, indicating the direction in which the data should flow.

i	1	2	3	4	5	6	7	8	9	10
$\pi(i)$	3	9	4	2	1	6	8	7	5	10

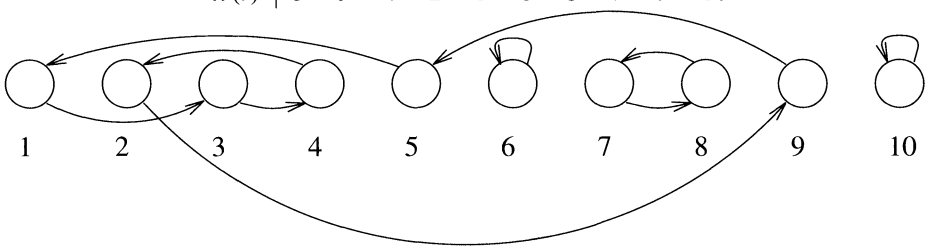

FIG. 2. *A graphical representation of a permutation.*

A basic operation is *ROTATE* (see Fig. 3) which, starting from some designated location in a cycle, moves the values from one location of the cycle to the next. We call this designated location the *cycle leader*. For example, the cycle leader could be the smallest location in the cycle. Once the cycle leader has been identified, *ROTATE* can be performed by proceeding through the cycle, starting with its cycle leader and exchanging the value located at the cycle leader with the values in the successive locations of the cycle. Each of these other values is involved in exactly one exchange (that takes it to its correct final location). Thus the time taken by such an algorithm is proportional to n, the length of the array, plus the amount of time it takes to find all the cycle leaders.

```
procedure ROTATE(leader)
i ← π(leader)
while i ≠ leader do
        interchange the values in A[leader] and A[i]
        i ← π(i)
```

FIG. 3. *Rotating the values in a cycle.*

If the permutation π is given as a product of disjoint cycles, identifying a leader for each cycle is very straightforward: merely take the first element in each cycle. The problem is more interesting when π is given as a mapping from the elements $1, \ldots, n$. One way to find all the cycle leaders in this case is to consider the locations $1, \ldots, n$ one at at time and, for each, determine whether it is a cycle leader.

If an additional, initially empty, bit vector of length n is available, it is easy to determine whether a location is the smallest element in its cycle in constant time. Specifically, when the value in an array location is moved, the bit corresponding to that location is set to 1. Since the locations are considered from smallest to largest, a location under consideration will have its corresponding bit equal to 0 exactly when it is a cycle leader [12, Ex. 1.3.3–12(b), pp. 180, 517–518]. Similarly, if π is given as an array whose elements can be modified, the same effect can be achieved by setting $\pi(i)$ to i when the value in array location i is moved.

Determining whether or not a location is the smallest element in its cycle can also be accomplished by using only a constant number of pointers into the array (each $\log_2 n$ bits long). Specifically, starting at the given location, proceed along the cycle until either the entire cycle has been traversed or a smaller location is encountered. In the first case, the given location is a cycle leader; otherwise it is not. The total amount of time to consider all n locations is $O(n^2)$. The worst case is achieved when $\pi = (1\ 2\ 3 \ldots n)$. For random permutations, an average of $O(n \log n)$ steps are performed [11], [13, p. 595].

These two ideas can be combined into the algorithm illustrated in Fig. 4.

THEOREM 2.1. *In the worst case, permuting an array of length n, given the permutation, can be done in* $O(n^2/b)$ *time and* $b + O(\log n)$ *bits of auxiliary space (consisting of a bit vector of length b plus a constant number of pointers) for* $b \leq n$.

The array A is conceptually divided into $\lceil n/b \rceil$ regions. Each region has size b, except for the last region, which might be smaller. The bit vector V is used to keep track of which locations in the region are encountered as the region is processed. If the location under consideration for being a cycle leader has a corresponding bit with value 0, its cycle is traversed until a smaller location is encountered. If no smaller location is encountered, then the location is a cycle leader and the cycle is rotated. Furthermore, if the location under consideration has a corresponding bit with value 1, then the location was previously encountered as part of a cycle containing some smaller location in the region and, hence, it is not a cycle leader. Theorem 2.1 follows from these observations.

```
for k ← 1 to ⌈n/b⌉ do
        s ← (k − 1)b
        if k ≤ ⌊n/b⌋ then l ← b
                     else l ← n − b⌊n/b⌋
        for i ← 1 to l do
            V[i] ← 0
        for i ← 1 to l do
            if V[i] = 0 then V[i] ← 1
                             j ← π(s + i)
                             while j > s + i do
                                 if j ≤ s + l then V[j − s] ← 1
                                 j ← π(j)
                             if j = s + i then ROTATE(s + i)
```

FIG. 4. *Rearranging an array using a bit vector V of length b.*

If both π and π^{-1} are available, then it is possible to get a more efficient algorithm. Determining whether or not a given location is the smallest element in its cycle can be done by starting at the location and proceeding alternatively forwards and backwards along the cycle until either the entire cycle has been traversed or a smaller location is encountered. (See Fig. 5.)

```
for i ∈ {1, ..., n} do
    j ← π(i)
    if j ≠ i then k ← π^{-1}(i)
                  while i < j and i < k do
                      if j = k then ROTATE(i)
                                    exit
                      j ← π(j)
                      if j = k then ROTATE(i)
                                    exit
                      k ← π^{-1}(k)
```

FIG. 5. *Rearranging an array using a permutation and its inverse.*

THEOREM 2.2. *In the worst case, permuting an array of length n, given the permutation and its inverse, can be done in $O(n \log n)$ time and $O(\log n)$ additional bits of storage.*

The analysis is similar to the bidirectional distributed algorithm for finding the smallest element in a ring of processors [8]. Specifically, the algorithm cannot determine whether i is a cycle leader after proceeding t steps forwards and t steps backwards along the cycle starting from i, only if the t elements following i and the t elements preceding i in its cycle are all larger than t. Furthermore, this will be the case for at most $1/t$ of the choices for i.

It is interesting to compare this algorithm to the $O(n^2)$ time $O(\log n)$ space algorithm mentioned above. Their expected behaviour on a random permutation is identical. However, the algorithm in Fig. 5 eliminates the bad cases.

It is not necessary that the cycle leader be the smallest (or largest) location in the cycle. One approach is to apply a hash function to the elements of the permutation and take as cycle leader the location in the cycle that hashes to the smallest value. Starting at a given location, the algorithm proceeds along the cycle until either the entire cycle has been traversed or another location that hashes to a smaller value is encountered. If the hash function is randomly chosen from among a set of 5-wise independent hash functions, then this results in a randomized algorithm using $O(\log n)$ space and expected time $O(n \log n)$ for every input permutation [9].

It was not clear to us whether or not it was possible to have a deterministic algorithm that used $n \log^{O(1)} n$ time and $\log^{O(1)} n$ space without having the inverse permutation available. However, using a rather different approach, we were able to devise such an algorithm.

THEOREM 2.3. *In the worst case, permuting an array of length n, given the permutation, can be done in $O(n \log n)$ time and $O(\log^2 n)$ additional bits of storage.*

First, consider the following characterization of the minimum locations in the cycles of the permutation π. Let $E_1 = \{1, \ldots, n\}$ and $\pi_1 = \pi$. For $r > 1$, we inductively define $E_r \subseteq E_{r-1}$ to be the set of *local minima* encountered following the permutation π_{r-1}, that is, $E_r = \{i \in E_{r-1} \mid \pi_{r-1}^{-1}(i) > i < \pi_{r-1}(i)\}$. We also define $\pi_r : E_r \to E_r$ to be the permutation that maps each element of E_r to the next element of E_r that is encountered following the permutation π_{r-1}. In other words, if $i \in E_r$, then $\pi_r(i) = \pi_{r-1}^m(i)$, where $m = \min\{m > 0 \mid \pi_{r-1}^m(i) \in E_r\}$, and $\pi_r(i) = \pi^M(i)$, where $M = \min\{M > 0 \mid \pi^M(i) \in E_r\}$. We call E_r the set of *order r elbows*.

For example, if $\pi = (1\ 5\ 3\ 6\ 10\ 4\ 2\ 9\ 8\ 7\ 11)$, as illustrated in Fig. 6, then

$E_1 = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11\}$, $\pi_1 = (1\ 5\ 3\ 6\ 10\ 4\ 2\ 9\ 8\ 7\ 11)$,
$E_2 = \{1, 2, 3, 7\}$, $\pi_2 = (1\ 3\ 2\ 7)$,
$E_3 = \{1, 2\}$, $\pi_3 = (1\ 2)$,
$E_4 = \{1\}$, and $\pi_4 = (1)$.

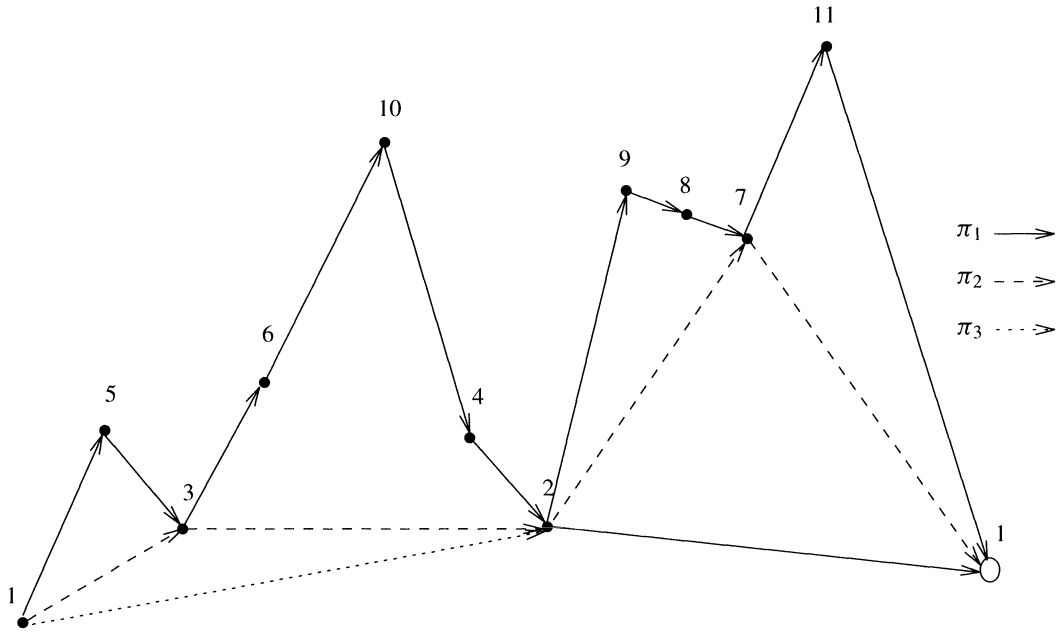

FIG. 6. *A cycle and its elbows.*

No more than half the elements in any cycle are local minima. Thus $|E_r| < |E_{r-1}|/2$. The minimum element of a cycle of π is always in E_r if the cycle contains more than one element of E_{r-1}. Hence the minimum element in a cycle is the unique elbow of maximum order in its cycle.

Computing the sets of elbows $E_1, E_2, \ldots$ and the corresponding permutations $\pi_1, \pi_2, \ldots$ can be done either in a top–down fashion, analogous to recursive descent parsing, or bottom–up, analogous to shift-reduce parsing. We explore both approaches in the two algorithms that follow.

The unidirectional nature of our oracle means that given $i \in E_r$, it is easy to compute $\pi_r(i)$ but difficult to compute $\pi_r^{-1}(i)$. Thus determining whether i is a local minimum of π_r (i.e., whether or not $i \in E_{r+1}$) is difficult starting from i, but easy starting from i's predecessor in π_r. For example, in Fig. 6, starting from 5 we can recognize that its successor, 3, is a local minimum in π_1. In turn, starting from 3 we can recognize that 2, its successor in π_2, is a local minimum in π_2.

For each cycle, the algorithm in Fig. 7 chooses the leader to be the unique element i in the cycle such that $\pi_{s-1} \ldots \pi_1(i) \in E_s$, where s is the maximum order of any element in the cycle. In other words, an element can be rejected as soon as it is seen not to be the element of maximum order. Dolev, Klawe, and Rodeh [4] and Peterson [14] independently discovered the usefulness of this choice of cycle leader for electing a leader in a unidirectional ring of processors using $O(n \log n)$ messages.

The procedure call $NEXT(r)$ is used to compute successive elements of π_r. It does this recursively, using successive elements of π_{r-1}.

For each $i \in \{1, \ldots, n\}$, the main program tests whether or not $\pi_1(i) \in E_2$ by comparing $\pi_1(i)$ with i and $\pi_1\pi_1(i)$; if so, it next tests whether or not $\pi_2\pi_1(i) \in E_3$ by comparing $\pi_2\pi_1(i)$ with $\pi_1(i)$ and $\pi_2\pi_2\pi_1(i)$, etc. One test is performed each iteration of the inner for loop. Eventually, a value of r is found such that $\pi_{r-1} \ldots \pi_1(i) \in E_r$ but $\pi_r\pi_{r-1} \ldots \pi_1(i) \notin E_{r+1}$. There are three possible ways this can occur. One is when $\pi_r\pi_{r-1} \ldots \pi_1(i) = \pi_{r-1} \ldots \pi_1(i)$. Then, since π_r is a permutation, this implies that the cycle of π_r that contains $\pi_{r-1} \ldots \pi_1(i)$ is trivial and thus $\pi_{r-1} \ldots \pi_1(i)$ is the minimum element in the cycle of π that contains it. In this case, i is a cycle leader. The other possible situations are when either $\pi_{r-1} \ldots \pi_1(i) < \pi_r\pi_{r-1} \ldots \pi_1(i)$ or $\pi_r\pi_{r-1} \ldots \pi_1(i) > \pi_r\pi_r\pi_{r-1} \ldots \pi_1(i)$. In both these cases, the algorithm detects that $\pi_r\pi_{r-1} \ldots \pi_1(i)$ is not the minimum element in its cycle and thus that i is not a cycle leader.

Using $O(\log^2 n)$ space, very little information about each permutation can be stored. We show that, essentially, only the most recently detected elbow of each order need be stored. The algorithm in Fig. 7 stores this information in the array $elbow$. For $r > 1$, $elbow[r]$ is used to store an element of E_r. Immediately prior to a call to $NEXT(r)$, the elements satisfy the condition

$$elbow[r] = elbow[r-1] \overset{\pi_{r-1}}{\rightarrow} \cdots \overset{\pi_1}{\rightarrow} elbow[0]$$

and immediately afterwards, they satisfy the condition

$$elbow[r] \overset{\pi_r}{\rightarrow} elbow[r-1] \overset{\pi_{r-1}}{\rightarrow} \cdots \overset{\pi_1}{\rightarrow} elbow[0].$$

The procedure $NEXT(r)$ computes $\pi_r(elbow[r])$. This leaves $elbow[r]$ unchanged and places the result in $elbow[r-1]$ (and, of course, updates the earlier elements in the array).

If $r > 1$, $NEXT(r)$ recursively computes successive elements along π_{r-1}, starting from $elbow[r]$, until a local minimum is detected. Since $elbow[r] \in E_r$, $elbow[r] < \pi_{r-1}(elbow[r])$. Initially, $elbow[r-1] = elbow[r]$ and $elbow[r-2] = \pi_{r-1}(elbow[r])$; thus $elbow[r-1] < elbow[r-2]$. The first while loop in $NEXT(r)$ advances $elbow[r-1]$ (and $elbow[r-2], \ldots, elbow[0]$, recursively) as long as π_{r-1} is strictly increasing. The cycle of π_{r-1} containing $elbow[r]$ is not trivial; thus, when the first while loop terminates, $elbow[r-1] > elbow[r-2] = \pi_{r-1}(elbow[r-1])$. The second while loop continues advancing $elbow[r-1]$ (and $elbow[r-2], \ldots, elbow[0]$, recursively) as long as π_{r-1} is strictly decreasing. At the end of the second while loop, $elbow[r-1] < elbow[r-2] = \pi_{r-1}(elbow[r-1])$. Hence $elbow[r-1]$ is the next local minimum of π_{r-1}. In other words, $elbow[r-1] = \pi_r(elbow[r])$.

Suppose $i' = \pi_r\pi_{r-1} \ldots \pi_1(i) \in E_r - E_{r+1}$. At the beginning of the rth iteration of the inner for loop of the main program, $elbow[r] = \pi_{r-1} \ldots \pi_1(i) = \pi_r^{-1}(i') \in E_r$. When the computation detects that $i' \notin E_{r+1}$, either $elbow[r] = \pi_r^{-1}(i')$ and $elbow[r-1] = i'$ or $elbow[r] = i'$ and $elbow[r-1] = \pi_r(i')$. Furthermore, $elbow[0] = \pi_1 \ldots \pi_{r-1}(elbow[r-1])$. It is easy to prove by induction on r that if $j \in E_r$ and M is the smallest positive integer such that $\pi_1 \ldots \pi_{r-1}(j) = \pi^M(j)$, then $\pi^L(j) \notin E_r$ for $1 \leq L \leq M$. Thus, starting from i' and proceeding along π, the element $\pi_1 \ldots \pi_{r-1}\pi_r(i')$ will be reached

```
procedure NEXT(r)
if r = 1 then elbow[0] ← π(elbow[1])
         else while elbow[r − 1] < elbow[r − 2] do
                    elbow[r − 1] ← elbow[r − 2]
                    NEXT(r − 1)
              while elbow[r − 1] > elbow[r − 2] do
                    elbow[r − 1] ← elbow[r − 2]
                    NEXT(r − 1)
return

for i ∈ {1, ..., n} do
      elbow[0] ← elbow[1] ← i
      for r ← 1, 2, ... do
            {loop invariant: elbow[r] = π_{r−1} ··· π_2 π_1(i) ∈ E_r}
            NEXT(r)
            if elbow[r] > elbow[r − 1]
            then elbow[r] ← elbow[r − 1]
                 NEXT(r)
                 if elbow[r] > elbow[r − 1] then exit
                 elbow[r + 1] ← elbow[r]
            else if elbow[r] = elbow[r − 1] then ROTATE(i)
                 exit
```

FIG. 7. *A recursive algorithm that rearranges an array using $O(n \log n)$ time and $O(\log^2 n)$ space.*

before $\pi_r^2(i')$. Similarly, starting from i' and proceeding backwards along π, the element $i = \pi_1^{-1} \ldots \pi_{r-1}^{-1} \pi_r^{-1}(i')$ will be reached before $\pi_r^{-2}(i')$. Therefore, testing whether or not i is a cycle leader involves proceeding along π in a subsegment of the region between $\pi_r^{-2}(i')$ and $\pi_r^2(i')$.

Considering all $i' \in E_r - E_{r+1}$, the permutation π is evaluated less than $4n$ times. (In fact, π is evaluated at most 4 times at each element.) Since E_r is empty for $r > \log_2 n$, the algorithm proceeds a total of $O(n \log n)$ steps along π.

Each call of $NEXT(1)$ proceeds one step along π. Each call of $NEXT(r)$, for $r > 1$, involves at least two recursive calls to $NEXT(r-1)$. The total amount of work performed by this call (excluding the work performed by the recursive calls) is proportional to the number of recursive calls it makes. For each i, every iteration of the inner for loop performs a constant amount of work (excluding the work performed by the subroutines it calls) and, except for possibly the last iteration, involves two calls to *NEXT*. Thus the total amount of work performed by the entire algorithm is proportional to the total number of steps the algorithm proceeds along π plus $O(n)$ steps to rotate all the cycles.

When π consists of a single cycle with the elements $\{0, \ldots, n-1\}$ ordered lexicographically with respect to the reverse of their $(\log n)$-bit binary representations (for example, $\pi = (0\ 4\ 2\ 6\ 1\ 5\ 3\ 7)$), the algorithm actually uses $\Omega(n \log n)$ steps. Hence the running time of the algorithm is in $\Theta(n \log n)$.

The algorithm uses $\Theta(\log n)$ variables, each capable of holding one element in $\{1, \ldots, n\}$. With care in implementation, only $O(\log n)$ bits are needed for representing the program stack. Thus a total of $\Theta(\log^2 n)$ bits of additional space are used by this algorithm.

An iterative, bottom–up version of the algorithm in Fig. 7 is given in Fig. 8. As $elbow[0]$ is advanced along the cycle of π containing i, $elbow[r]$, for $r > 1$, records the most recent element of E_r that has been detected. Each time a local minimum along π_{r-1} is detected, $elbow[r]$ is advanced to that location. The variable $state[r]$ encodes information about the portion of the cycle of π_r that is being examined.

The first time an element of E_r is detected, $state[r]$ is set to *GOT_ONE* and $elbow[r] = \pi_{r-1} \ldots \pi_1(i)$. When the next element of E_r (along π_r) is detected, the algorithm can determine

```
for i ∈ {1, ..., n} do
        elbow[1] ← i
        state[1] ← GOT_ONE
        repeat
                r ← 1
                elbow[0] ← π(elbow[1])
                while state[r] =DOWN and elbow[r] < elbow[r − 1] do
                        state[r] ←UP
                        elbow[r] ← elbow[r − 1]
                        r ← r + 1
                case state[r]

                GOT_ONE: if elbow[r] > elbow[r − 1]
                        then    state[r] ← GOT_TWO
                                elbow[r] ← elbow[r − 1]
                        else    if elbow[r] = elbow[r − 1] then ROTATE(i)
                                exit

                GOT_TWO: if elbow[r] > elbow[r − 1] then exit
                        state[r + 1] ← GOT_ONE
                        elbow[r + 1] ← elbow[r]
                        state[r] ← UP
                        elbow[r] ← elbow[r − 1]

                UP:     if elbow[r] > elbow[r − 1] then state[r] ← DOWN
                        elbow[r] ← elbow[r − 1]

                DOWN:   elbow[r] ← elbow[r − 1]
```

FIG. 8. *An iterative algorithm that rearranges an array using $O(n \log n)$ time and $O(\log^2 n)$ space.*

whether i's cycle contains only one element in E_r. If so, i is the leader of its cycle. Otherwise the algorithm sets $state[r]$ to GOT_TWO and tries to determine whether or not $\pi_r \pi_{r-1} \ldots \pi_1(i)$ is a local minimum of π_r (and hence an element of E_{r+1}).

If $state[r] = UP$, then $elbow[r]$ is known to be larger than $\pi_r^{-1}(elbow[r])$, which is its predecessor along π_r. Similarly, if $state[r] = DOWN$, then $elbow[r]$ is known to be smaller than $\pi_r^{-1}(elbow[r])$, which is its predecessor along π_r. This information is sufficient to detect successive local minima along π_r. Figure 9 illustrates the states that occur as the algorithm proceeds along a cycle.

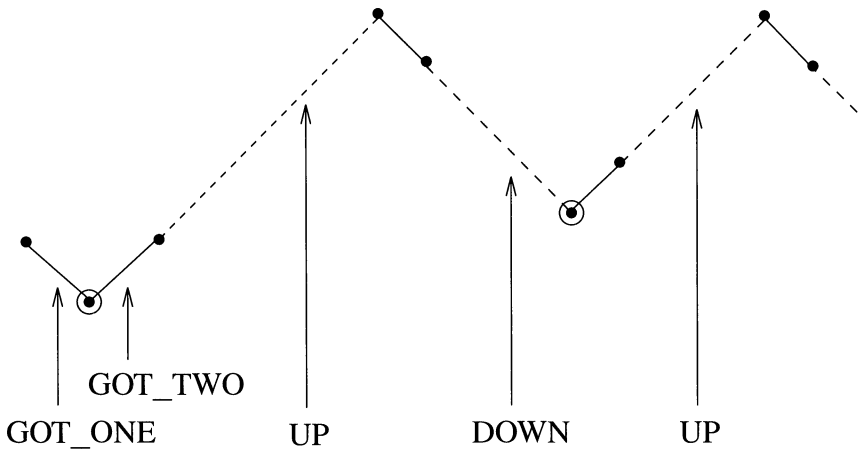

FIG. 9. *The states occurring in the iterative algorithm.*

```
procedure ROTATE_BACKWARDS(leader)
j ← leader
i ← π(leader)
while i ≠ leader do
        interchange the values in A[j] and A[i]
        j ← i
        i ← π(i)
```

repeat m times
        interchange the values in A[j] and A[i]
        i ← π(i)
        j ← π(j)

procedure ROTATE(q, leader, cyclelength)
irun ← q mod cyclelength
jrun ← cyclelength − irun
i ← leader
j ← leader
repeat irun times
        j ← π[j]
while irun ≠ jrun do
        if irun < jrun
        then temp ← i
                EXCHANGE(i, j, irun)
                i ← temp
                jrun ← jrun − irun
        else    temp ← i
                EXCHANGE(i, j, jrun)
                j ← temp
                irun ← irun − jrun
EXCHANGE(i, j, irun)
```

FIG. 11. *Rotating the values q steps in a cycle.*

A small but natural twist on our problem is that we are given π, but required to move the elements according to π^{-1}. The cycle leader technique of Theorem 2.3 is still applicable. It is only necessary to replace *ROTATE* by the procedure *ROTATE_BACKWARDS* given in Fig. 10.

Clearly this step requires time linear in the size of the cycle, and $O(\log n)$ bits of memory. The problem is easily generalized to being given π (and perhaps π^{-1}) and asked to apply π^q, where q may depend on the (length of the) cycle. Either one of the cycle leader methods is applicable. We need only define a modified procedure *ROTATE*$(q, leader, cyclelength)$. This is essentially the same problem as transposing an array. The following is a translation into our terms of the method discussed in [2, p. 134]. Suppose that the m elements along π starting at location i are distinct from the m elements along π starting at location j. Then the procedure *EXCHANGE*(i, j, m) exchanges these two sequences of elements. Both i and j are advanced m locations along the cycle as a result of an execution of the procedure *EXCHANGE* in Fig. 11.

We see that, including calls to π, the *ROTATE* algorithm requires time proportional to the length of the cycle in question; hence we can strengthen Theorems 2.2 and 2.3.

COROLLARY 2.4. *In the worst case, permuting an array of length n according to the permutation π^q, given π and its inverse, can be done in $O(n \log n)$ time and $O(\log n)$ additional bits of storage.*

COROLLARY 2.5. *In the worst case, permuting an array of length n according to the permutation π^q, given the permutation π, can be done in $O(n \log n)$ time and $O(\log^2 n)$ additional bits of storage.*

3. Permuting data in and out of order. In many situations, it is known that the array elements satisfy a fixed total order, i.e., when the data values are taken in a particular order, they form a sorted sequence. Suppose the array A has been rearranged according to the permutation π and let σ be a permutation such that

$$A[\sigma^{-1}(1)] \leq A[\sigma^{-1}(2)] \leq \cdots \leq A[\sigma^{-1}(n)].$$

Then element $A[i]$ has the $\sigma(i)$th smallest value, for $i = 1, \ldots, n$. In particular, if $\sigma(i) > \sigma(\pi(i))$ then $A[i] > A[\pi(i)]$. For example, if the permutation π rearranges the array A into sorted order, then σ is the identity permutation and if A was sorted before the rearrangement, then $\sigma = \pi^{-1}$.

Consider the rearrangement algorithm in Fig. 12. In particular, if the permutation π rearranges the array A into sorted order, then the algorithm is simply looking for places where the permutation wants to move an element to a lower numbered location and the element is smaller than the element that is currently there.

```
for i ∈ {1, ..., n} do
        if (σ(i) > σ(π(i))) and (A[i] < A[π(i)])
                then ROTATE(i)
```

FIG. 12. *Rearranging an array of distinct elements that satisfy a fixed total order.*

Notice that after the cycle containing location i has been rotated, $\sigma(i) > \sigma(\pi(i))$ implies $A[i] \geq A[\pi(i)]$. Thus each nontrivial cycle is rotated at most once.

Now suppose that no two consecutive elements along any nontrivial cycle have the same value, i.e., $i \neq \pi(i)$ implies $A[i] \neq A[\pi(i)]$ for all $i \in \{1, \ldots, n\}$. This condition is certainly true if the elements of the array A are distinct. We claim that before a given nontrivial cycle of the permutation π has been rotated, there is a location i in that cycle such that $\sigma(i) > \sigma(\pi(i))$ and $A[i] < A[\pi(i)]$. This implies that the cycle will be rotated at least once. Let i be any location in the cycle that satisfies $\sigma(i) > \sigma(\pi(i)) < \sigma(\pi^2(i))$. (This will be the case, for example, when $\pi(i)$ is the location containing the smallest value in the cycle.) The cycle leader will be the first such location encountered. After the cycle has been rotated, $A[\pi(i)] \leq A[\pi^2(i)]$, since $\sigma(\pi(i)) < \sigma(\pi^2(i))$. Also, the values in locations $\pi(i)$ and $\pi^2(i)$ were initially in locations i and $\pi(i)$, respectively. Hence, before the rotation, $A[i] \leq A[\pi(i)]$. However, $A[i] \neq A[\pi(i)]$, so $A[i] < A[\pi(i)]$, as required.

It is not necessary to rotate a cycle if all the elements it contains have the same value. However, there are other situations where a nontrivial cycle contains consecutive elements with the same value and the algorithm in Fig. 12 does not rotate the cycle. The example in Fig. 13 is constructed using two distinct values, α and β, where $\alpha < \beta$. It assumes the array is to be rearranged into sorted order. Except for the two middle elements, the array is already sorted, but since these two elements can be arbitrarily far apart in the cycle, no local test (such as the one in the algorithm in Fig. 12) can succeed in detecting them.

Notice that a cycle containing runs of equal-valued elements has the same effect as the cycle taking the beginning of each run to the beginning of the next run. Since no consecutive elements of this latter cycle have the same value, the technique used by the algorithm in Fig. 12 can be applied to identify a cycle leader.

If the functions π and $\sigma\pi$ can be evaluated in constant time (which is the case when π rearranges the array either into or out of sorted order), then the algorithm in Fig. 14 runs in

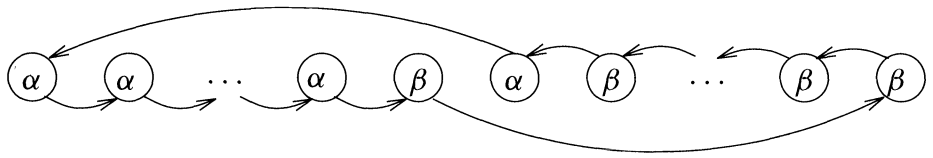

FIG. 13. *An example with runs of equal-valued elements.*

linear time. This is because the algorithm goes through the while loop at most once for each run of equal-valued elements in a cycle. In fact, the linear time bound holds also under a weaker assumption.

for $i \in \{1, \ldots, n\}$ **do**
  if $A[i] \neq A[\pi(i)]$ **then**
    $j \leftarrow \pi(i)$
    while $A[j] = A[\pi(j)]$ **do** $j \leftarrow \pi(j)$
    if $(\sigma(\pi(i)) > \sigma(\pi(j)))$ **and** $(A[\pi(i)] < A[\pi(j)])$ **then** *ROTATE*(i)

FIG. 14. *Rearranging any array of elements that satisfy a fixed total order.*

THEOREM 3.1. *Suppose that after the array A is permuted according to the permutation* π, *it satisfies* $A[\sigma^{-1}(1)] \leq A[\sigma^{-1}(2)] \leq \cdots \leq A[\sigma^{-1}(n)]$. *If all the elements* $\pi(1), \ldots, \pi(n)$, $\sigma\pi(1), \ldots, \sigma\pi(n)$ *can be computed in time* $O(n)$, *then A can be permuted according to* π *by using* $O(n)$ *time and* $O(\log n)$ *additional bits of storage, in the worst case.*

The proof follows from the observation that, for each element i, $\pi(i)$ and $\sigma\pi(i)$ are computed only a constant number of times during the course of the algorithm in Fig. 14. The running time of this algorithm is clearly dominated by the time spent performing these function evaluations.

The application that sparked our interest in the problem of rearranging data was building a data structure implicitly representing a complete binary search tree, given a sorted array of appropriate length n. Here the median is the root and is placed in location 1. Its children, the first and third quartiles, are in locations 2 and 3, respectively. In general, the left and right children of the element in location j are in locations $2j$ and $2j + 1$ (like a heap). Bentley [1] anticipates the result shown here in crediting Mahaney and Munro with a linear algorithm for this special case. In this case, the permutation π satisfies the property that if $x10^j$ is the $\lceil \log_2 n \rceil$-bit binary representation of i, then $0^j 1x$ is the $\lceil \log_2 n \rceil$-bit binary representation of $\pi(i)$.

When $n = 2^h - 1 + r$, where $1 \leq r < 2^h$, the sorted array can be rearranged to implicitly represent a binary search tree which is complete except for its last level and such that the nodes in the last level are as far left as possible. One method is to apply two permutations to the array. The first permutation π' moves the r values $1, 3, 5, \ldots, 2r - 1$ that belong in the last level of the tree to their correct locations at the end of the array, while keeping the other values in sorted order. Specifically,

$$\pi'(i) = \begin{cases} 2h + (i-1)/2 & \text{if } i \text{ is odd and } i < 2r, \\ i/2 & \text{if } i \text{ is even and } i < 2r, \\ i - r & \text{if } i > 2r. \end{cases}$$

The second permutation then rearranges the first $2^h - 1$ elements of the array into the implicit representation of a complete binary search tree, as above. Another method is to combine these two permutations into one, defining π as follows.

if i is odd **and** $i < 2r$
then $\pi(i) = 2^h + (i-1)/2$
else $\pi(i)$ is the number represented by $0^j 1x$,
where $x10^j$ is the h-bit binary representation of $\begin{cases} i/2, & \text{if } i \text{ is even and } i < 2r, \\ i - r, & \text{if } i \geq 2r. \end{cases}$

For most instruction sets, computing π once could take as much as $O(\log n)$ steps in the worst case. However, using only left and right shifts of distance one and single bit assignments and tests, $O(n)$ operations suffice to evaluate $\pi(i)$ for all $i \in \{1, \ldots, n\}$. As mentioned above, this is sufficient to obtain a linear time algorithm.

4. Conclusions. Since most permutations fix very few of their elements, any algorithm must take $\Omega(n)$ time on average and, hence, in the worst case. Also, $\Omega(\log n)$ additional bits of storage are needed to provide pointers to array elements that are being interchanged.

The open question that remains is whether there are better algorithms for rearranging an array given an arbitrary permutation π (and also possibly π^{-1}). Specifically, are there algorithms that use a small amount of additional space (e.g., $O(\log n)$ or $\log^{O(1)} n$) and only linear time? If not, are there deterministic algorithms that, given only π, run in $O(n \log n)$ time but use only $O(\log n)$ bits of additional storage?

When $b = n/\log\log n$, the algorithm in Fig. 4 uses $O(n \log\log n)$ time and $O(n/\log\log n)$ bits of additional storage. However, it is not even known whether there is an algorithm that uses $o(n \log n)$ time and $O(n^{1-\epsilon})$ space for some constant $\epsilon > 0$.

All of the algorithms presented in this paper are cycle leader algorithms. They proceed by identifying exactly one element in each cycle and rotating the cycle starting from that element. Performing all the rotations requires only linear time and two pointers. This leaves the problem of finding a leader for each cycle, or equivalently, finding the minimum element in each cycle. Cook and McKenzie [3] have shown that these problems and, more generally, computing the disjoint cycle representation of a permutation are NC^1-complete for deterministic logspace.

A previous version of the algorithm in Fig. 7 was interesting from the point of view that it did not operate by determining cycle leaders. Instead, it performed sweeps up and down the array, at each point deciding whether or not to interchange that element with another element and, if so, which one. It would be interesting to know if any algorithm for permuting an array can be transformed into a cycle leader algorithm. This would allow us to restrict attention to cycle leader algorithms when searching for new algorithms or trying to prove better tradeoffs.

The algorithms in Figs. 5, 7, and 8 and the $O(n^2)$ time, $O(\log n)$ space algorithm discussed before Fig. 4 can all be viewed as instances of a restricted type of cycle leader algorithm. Specifically, they separately test each element $i \in \{1, \ldots, n\}$ to see if it is a cycle leader by comparing elements forwards and/or backwards along the cycle. The tests depend only on the permutation π and the values of i. They do not depend on the order in which the elements are tested, as is the case for the algorithm in Fig. 4 (when $b > 1$) and the algorithm in Fig. 14, nor on the data values stored in the array, as is the case for the algorithm in Fig. 14.

Such algorithms are interesting because they immediately lead to distributed algorithms, using only comparisons of ID's, for electing a leader in a bidirectional ring of synchronous processors. Processor i tests whether element i is the leader of its cycle once it has learned the ID's of a sufficient number of its successors and predecessors. It requests these ID's by sending messages forwards and backwards around the ring for distances which are successive powers of 2. (See [8].) The total number of messages sent is proportional to the time taken by the cycle leader algorithm. Frederickson and Lynch [5] hava shown that any such distributed leader election algorithm sends $\Omega(n \log n)$ messages in the worst case. Thus these restricted types of cycle leader algorithms must use at least $\Omega(n \log n)$ time in the worst case. On the other hand, it is not clear how algorithms for electing a leader in a ring of processors can be

used to obtain cycle leader algorithms. The major problems seem to be how to deal with the timing of messages and how to represent the states of all the processors using less than a linear amount of space.

THE COMPLEXITY AND DISTRIBUTION OF HARD PROBLEMS*

DAVID W. JUEDES† AND JACK H. LUTZ‡

Abstract. Measure-theoretic aspects of the $\leq_m^P$-reducibility structure of the exponential time complexity classes E=DTIME(2^{linear}) and E_2 = DTIME($2^{polynomial}$) are investigated. Particular attention is given to the *complexity* (measured by the size of complexity cores) and *distribution* (abundance in the sense of measure) of languages that are $\leq_m^P$-hard for E and other complexity classes.

Tight upper and lower bounds on the size of complexity cores of hard languages are derived. The upper bound says that the $\leq_m^P$-hard languages for E are *unusually simple*, in the sense that they have smaller complexity cores than most languages in E. It follows that the $\leq_m^P$-complete languages for E form a measure 0 subset of E (and similarly in E_2).

This latter fact is seen to be a special case of a more general theorem, namely, that *every* $\leq_m^P$-degree (e.g., the degree of all $\leq_m^P$-complete languages for NP) has measure 0 in E and in E_2.

Key words. computational complexity, complexity classes, complete problems, complexity cores, polynomial reducibilities, resource-bounded measure

AMS subject classification. 68Q15

1. Introduction.

A decision problem (i.e., language) $A \subseteq \{0,1\}^*$ is said to be *hard* for a complexity class $\mathcal{C}$ if every language in $\mathcal{C}$ is efficiently reducible to A. If A is also an element of $\mathcal{C}$, then A is *complete* for $\mathcal{C}$. The most common interpretation of "efficiently reducible" here is "polynomial time many-one reducible," abbreviated "$\leq_m^P$-reducible." (See §2 for notation and terminology used in this introduction.) For example, in most usages, "NP-complete" means "$\leq_m^P$-complete for NP," the completeness notion introduced by Karp [15] and Levin [16].

In this paper, we investigate the *complexity* (measured by size of complexity cores) and *distribution* (i.e., abundance in the sense of measure) of languages that are $\leq_m^P$-hard for E (equivalently, E_2) and other complexity classes, including NP. (By "measure" here, we mean *resource-bounded measure* as developed by Lutz [17] and described in §3 of this paper.) We give a tight lower bound and, perhaps surprisingly, a tight *upper* bound on the sizes of complexity cores of hard languages. More generally, we analyze measure-theoretic aspects of the $\leq_m^P$-reducibility structure of exponential time complexity classes. We prove that $\leq_m^P$-hard problems are rare, in the sense that they form a p-measure 0 set. We also prove that every $\leq_m^P$-degree has measure 0 in exponential time.

Complexity cores, first introduced by Lynch [24] have been studied extensively [8]–[12], [14], [27]–[29]. Intuitively, a complexity core of a language A is a fixed set K of inputs such that *every* machine whose decisions are consistent with A fails to decide efficiently on all but finitely many elements of K. The meaning of "efficiently" is a parameter of the definition that varies according to the context. (See §4 for a precise definition.)

Orponen and Schöning [28] have established two lower bounds on the sizes of complexity cores of hard languages. First, every $\leq_m^P$-hard language for E has a dense P-complexity core. Second, if P $\neq$ NP, then every $\leq_m^P$-hard language for NP has a nonsparse polynomial complexity core.

‡Department of Computer Science, Iowa State University, Ames, Iowa 50011.

In §4 below, we extend the first of these results to languages that are weakly $\leq_m^P$-hard for E. (A language A is $\leq_m^P$-hard for E if every element of E is $\leq_m^P$-reducible to A. A language A is *weakly* $\leq_m^P$*-hard* for E if every element of some nonnegligible (i.e., nonmeasure 0) set of languages in E is reducible to A. Very recently, Lutz [19] has proven that "weakly $\leq_m^P$-hard" is more general than "$\leq_m^P$-hard.") Specifically, we prove that every language that is weakly $\leq_m^P$-hard for E or E_2 has a dense exponential complexity core. It follows that if NP does not have measure 0 in E or E_2, then every $\leq_m^P$-hard language for NP has a dense exponential complexity core. This conclusion is much stronger than Orponen and Schöning's conclusion that every such language has a nonsparse polynomial complexity core, although it is achieved at the cost of a stronger hypothesis. This hypothesis, originally proposed by Lutz, is discussed at some length in [18], [23], and [22].

In §5 we investigate the resource-bounded measure of the lower $\leq_m^P$-spans, the upper $\leq_m^P$-spans, and the $\leq_m^P$-degrees of languages in E and E_2. (The *lower* $\leq_m^P$*-span* of A is the set of all languages that are $\leq_m^P$-reducible to A. The *upper* $\leq_m^P$*-span* of A is the set of all languages to which A is $\leq_m^P$-reducible. The $\leq_m^P$*-degree* of A is the intersection of these two spans.) We prove the Small Span Theorem, which says that if A is in E or E_2, then at least one of the upper and lower spans must have resource-bounded measure 0. This implies that *every* $\leq_m^P$-degree (e.g., the degree of all $\leq_m^P$-complete languages for NP) has measure 0 in E and in E_2. It also implies that the $\leq_m^P$-hard languages for E form a set of p-measure 0. As noted in §7, a proof that this latter fact holds with $\leq_m^P$ replaced by $\leq_T^P$ would imply that $E \not\subseteq BPP$.

Languages that are $\leq_m^P$-hard for E are typically considered to be "at least as complex as" any element of E. Very early, Berman [6] established limits to this interpretation by proving that no $\leq_m^P$-complete language is P-immune, even though E contains P-immune languages. (In fact, Mayordomo [25] has recently shown that almost every language in E is P-bi-immune.) In §6 below we prove a very strong limitation on the complexity of $\leq_m^P$-hard languages for E. We prove that every $\leq_m^P$-hard language for E is decidable in $\leq 2^{4n}$ steps on a dense set of inputs which is also decidable in $\leq 2^{4n}$ steps. This implies that *every* DTIME(2^{4n})-complexity core of *every* $\leq_m^P$-hard language for E has a *dense complement*. Since almost every language in E has $\{0, 1\}^*$ as a DTIME(2^{4n})-complexity core (as proven in section 4), this says that $\leq_m^P$-hard languages for E are *unusually simple*, in that they have *unusually small* complexity cores. Intuitively, we interpret this to mean that the condition of being $\leq_m^P$-hard for E forces a language to have a high level of organization, thereby forcing it to be unusually simple in some respects.

2. Preliminaries. Here we present the notation and terminology that we use throughout the paper. To begin with, we write $\mathbf{N}$ for the set of natural numbers, $\mathbf{Z}$ for the set of integers, and $\mathbf{Z}^+$ for set of positive integers.

We deal primarily with *strings*, *languages*, *functions*, and *classes*. Strings are finite sequences of characters over the alphabet $\{0, 1\}$; we write $\{0, 1\}^*$ for the set of all strings. Languages are sets of strings. Functions usually map $\{0, 1\}^*$ into $\{0, 1\}^*$. A class is either a set of languages or a set of functions.

If $x \in \{0, 1\}^*$ is a string, we write $|x|$ for the *length* of x. If $A \subseteq \{0, 1\}^*$ is a language, then we write A^c, $A_{\leq n}$, and $A_{=n}$ for $\{0, 1\}^* - A$, $A \cap \{0, 1\}^{\leq n}$, and $A \cap \{0, 1\}^n$, respectively. The sequence of strings over $\{0, 1\}$, $s_0 = \lambda, s_1 = 0, s_2 = 1, s_3 = 00, \ldots$, is referred to as the *standard enumeration* of $\{0, 1\}^*$.

We use the string-pairing function $\langle x, y\rangle = bd(x)01y$, where $bd(x)$ is x with each bit doubled (e.g., $bd(1101) = 11110011$). For each $g : \{0, 1\}^* \to \{0, 1\}^*$ and $k \in \mathbf{N}$, we also define the function $g_k : \{0, 1\}^* \to \{0, 1\}^*$ by $g_k(x) = g(\langle 0^k, x\rangle)$ for all $x \in \{0, 1\}^*$.

We say that a property $\phi(n)$ of natural numbers holds *almost everywhere* (*a.e.*) if $\phi(n)$ is true for all but finitely many $n \in \mathbf{N}$. Similarly, $\phi(n)$ holds *infinitely often* (*i.o.*) if $\phi(n)$ is

true for infinitely many $n \in \mathbf{N}$. We write $[\![\phi]\!]$ for the Boolean value of a condition ϕ. That is, $[\![\phi]\!] = 1$ if ϕ is true, $[\![\phi]\!] = 0$ if ϕ is false.

If A is a finite set, we denote its cardinality by $|A|$. A language D is *dense* if there exists some constant $\epsilon > 0$ such that $|D_{\leq n}| > 2^{n^\epsilon}$ a.e. A language S is *sparse* if there exists a polynomial p such that $|S_{\leq n}| \leq p(n)$ a.e.. A language S is *cosparse* if S^c is sparse.

All *machines* here are deterministic Turing machines. The language accepted by a machine M is denoted by $L(M)$. The partial function computed by a machine M is denoted by $f_M : \{0,1\}^* \to \{0,1\}^*$. For a fixed machine M, the function $\text{time}_M(x)$ represents the number of steps that M uses on input x.

If $t(n)$ is a time bound, then we write

$$\text{DTIME}(t(n)) = \{L(M) \mid (\exists c)(\forall x)\text{time}_M(x) \leq c \cdot t(|x|) + c\}$$

for the set of languages decidable in $O(t(n))$ time. Similarly, we write

$$\text{DTIMEF}(t(n)) = \{f_M \mid (\exists c)(\forall x)\text{time}_M(x) \leq c \cdot t(|x|) + c\}$$

for the set of functions computable in $O(t(n))$-time. The classes of polynomial time decidable languages and polynomial time computable functions are then $\text{P} = \cup_{k=0}^{\infty}\text{DTIME}(n^k)$ and $\text{PF} = \cup_{k=0}^{\infty}\text{DTIMEF}(n^k)$, respectively. We are especially interested in classes of languages decidable in exponential time. We write

$$\text{E} = \bigcup_{c=1}^{\infty}\text{DTIME}(2^{cn})$$

and

$$\text{E}_2 = \bigcup_{c=1}^{\infty}\text{DTIME}(2^{n^c})$$

for the classes of languages decidable in 2^{linear} time and $2^{\text{polynomial}}$ time, respectively. Other complexity classes that we use here, such as NP, PH, PSPACE, etc., have completely standard definitions [2], [3].

If A and B are languages, then a *polynomial time, many-one reduction* (briefly, $\leq_{\text{m}}^{\text{P}}$-*reduction*) *of* A *to* B is a function $f \in \text{PF}$ such that $A = f^{-1}(B) = \{x \mid f(x) \in B\}$. A $\leq_{\text{m}}^{\text{P}}$-*reduction of* A is a function $f \in \text{PF}$ that is a $\leq_{\text{m}}^{\text{P}}$-reduction of A to some language B. Note that f is a $\leq_{\text{m}}^{\text{P}}$-reduction of A if and only if f is a $\leq_{\text{m}}^{\text{P}}$-reduction of A to $f(A) = \{f(x) \mid x \in A\}$. We say that A is *polynomial time, many-one reducible* (briefly, $\leq_{\text{m}}^{\text{P}}$-*reducible*) to B, and we write $A \leq_{\text{m}}^{\text{P}} B$, if there exists a $\leq_{\text{m}}^{\text{P}}$-reduction f of A to B. In this case, we also say that $A \leq_{\text{m}}^{\text{P}} B$ via f.

A language H is $\leq_{\text{m}}^{\text{P}}$-*hard* for a class $\mathcal{C}$ of languages if $A \leq_{\text{m}}^{\text{P}} H$ for all $A \in \mathcal{C}$. A language C is $\leq_{\text{m}}^{\text{P}}$-*complete* for $\mathcal{C}$ if $C \in \mathcal{C}$ and C is $\leq_{\text{m}}^{\text{P}}$-hard for $\mathcal{C}$. If $\mathcal{C} = \text{NP}$, this is the usual notion of NP-completeness [13]. In this paper we are especially concerned with languages that are $\leq_{\text{m}}^{\text{P}}$-hard or $\leq_{\text{m}}^{\text{P}}$-complete for E or E_2.

3. Resource-bounded measure. Resource-bounded measure [17], [21] is a very general theory whose special cases include classical Lebesgue measure, the measure structure of the class REC of all recursive languages, and measure in various complexity classes. In this paper, we are interested only in measure in E and E_2, so our discussion of measure is specific to these classes. The interested reader may consult §3 of [17] for more discussion and examples.

Throughout this section, we identify every language $A \subseteq \{0,1\}^*$ with its characteristic sequence $\chi_A \in \{0,1\}^\infty$, defined by $\chi_A[i] = [\![s_i \in A]\!]$ for all $i \in \mathbf{N}$. (Recall from §2 that

$s_0, s_1, s_2, \ldots$ is the standard enumeration of $\{0,1\}^*$.) We say that $x \in \{0,1\}^*$ is a *prefix*, or *partial specification*, of $A \subseteq \{0,1\}^*$ if x is a prefix of χ_A, i.e., if there exists $y \in \{0,1\}^\infty$ such that $\chi_A = xy$. In this case, we write $x \sqsubseteq A$. The set of all languages A for which x is a partial specification,

$$\mathbf{C}_x = \{A \subseteq \{0,1\}^* \mid x \sqsubseteq A\},$$

is the *cylinder specified by* the string $x \in \{0,1\}^*$. We say that the *measure* of the set $\mathbf{C}_x$ is $2^{-|x|}$. (Note that this is the probability that $A \in \mathbf{C}_x$ if $A \subseteq \{0,1\}^*$ is chosen probabilistically according to the random experiment in which an independent toss of a fair coin is used to decide membership of each string $x \in \{0,1\}^*$ in A.)

Notation. The classes $\mathrm{p}_1 = \mathrm{p}$ and p_2, both consisting of functions $f : \{0,1\}^* \to \{0,1\}^*$, are defined as follows.

$$\mathrm{p}_1 = \mathrm{p} = \{f \mid f \text{ is computable in polynomial time}\},$$
$$\mathrm{p}_2 = \{f \mid f \text{ is computable in } n^{(\log n)^{O(1)}} \text{ time}\}.$$

The measure structures of E and E_2 are developed in terms of the classes p_i, for $i = 1, 2$.

DEFINITION. A *density function* is a function $d : \{0,1\}^* \to [0, \infty)$ that satisfies

$$d(w) \geq \frac{d(w0) + d(w1)}{2} \tag{3.1}$$

for all $w \in \{0,1\}^*$. The *global value* of a density function d is $d(\lambda)$. The *set covered by* a density function d is

$$S[d] = \bigcup_{\substack{w \in \{0,1\}^* \\ d(w) \geq 1}} \mathbf{C}_w. \tag{3.2}$$

A density function d *covers* a set $X \subseteq \{0,1\}^\infty$ if $X \subseteq S[d]$.

For all density functions in this paper, equality actually holds in (3.1) above, but this is not required. Consider the random experiment in which a language $A \subseteq \{0,1\}^*$ is chosen by using an independent toss of a fair coin to decide whether each string $x \in \{0,1\}^*$ is in A. Taken together, parts (3.1) and (3.2) of the above definition imply that $\Pr[A \in S[d]] \leq d(\lambda)$ in this experiment. Intuitively, we regard a density function d as a "detailed verification" that $\Pr[A \in X] \leq d(\lambda)$ for all sets $X \subseteq S[d]$.

More generally, we are interested in "uniform systems" of density functions that are computable within some resource bound.

Since density functions are real-valued, their computations must employ finite approximations of real numbers. For this purpose, let

$$\mathbf{D} = \{m2^{-n} \mid m \in \mathbf{Z}, n \in \mathbf{N}\}$$

be the set of *dyadic rationals*. (These are rational numbers with finite binary expansions.) In order to have uniform criteria for computational complexity, we consider all functions of the form $f : X \to Y$, where each of the sets X, Y is $\mathbf{N}$, $\{0,1\}^*$, $\mathbf{D}$, or some Cartesian product of these sets, to really map $\{0,1\}^*$ into $\{0,1\}^*$. For example, a function $f : \mathbf{N}^2 \times \{0,1\}^* \to \mathbf{N} \times \mathbf{D}$ is formally interpreted as a function $\tilde{f} : \{0,1\}^* \to \{0,1\}^*$. Under this interpretation, $f(i, j, w) = (k, q)$ means that $\tilde{f}(\langle 0^i, \langle 0^j, w\rangle\rangle) = \langle 0^k, \langle u, v\rangle\rangle$, where u and v are the binary representations of the integer and fractional parts of q, respectively. Moreover, we only care about the values of $\tilde{f}$ for arguments of the form $\langle 0^i, \langle 0^j, w\rangle\rangle$, and we insist that these values have the form $\langle 0^k, \langle u, v\rangle\rangle$ for such arguments.

DEFINITION. An n-dimensional *density system* (n-*DS*) is a function

$$d : \mathbf{N}^n \times \{0,1\}^* \to [0,\infty)$$

such that $d_{\vec{k}}$ is a density function for every $\vec{k} \in \mathbf{N}^n$. It is sometimes convenient to regard a density function as a 0-DS.

DEFINITION. A *computation* of an n-DS d is a function $\hat{d} : \mathbf{N}^{n+1} \times \{0,1\}^* \to \mathbf{D}$ such that

$$|\hat{d}_{\vec{k},r}(w) - d_{\vec{k}}(w)| \leq 2^{-r}$$

for all $\vec{k} \in \mathbf{N}^n$, $r \in \mathbf{N}$, and $w \in \{0,1\}^*$. For $i = 1, 2$, a p_i-*computation* of an n-DS d is a computation $\hat{d}$ of d such that $\hat{d} \in \mathrm{p}_i$. An n-DS d is p_i-*computable* if there exists a p_i-computation $\hat{d}$ of d.

If d is an n-DS such that $d : \mathbf{N}^n \times \{0,1\}^* \to \mathbf{D}$ and $d \in \mathrm{p}_i$, then d is trivially p_i-computable. This fortunate circumstance, in which there is no need to compute approximations, frequently occurs in practice. (Such applications typically involve approximations, but these are "hidden" by invoking fundamental theorems whose proofs involve approximations).

We now come to the key idea of resource-bounded measure theory.

DEFINITION. A *null cover* of a set $X \subseteq \{0,1\}^\infty$ is a 1-DS d such that, for all $k \in \mathbf{N}$, d_k covers X with global value $d_k(\lambda) \leq 2^{-k}$. For $i = 1, 2$, a p_i-*null cover* of X is a null cover of X that is p_i-computable.

In other words, a null cover of X is a uniform system of density functions that cover X with rapidly vanishing global value. It is easy to show that a set $X \subseteq \{0,1\}^\infty$ has classical Lebesgue measure 0 (i.e., probability 0 in the above coin-tossing experiment) if and only if there exists a null cover of X.

DEFINITION. A set X has p_i-*measure* 0, and we write $\mu_{\mathrm{p}_i}(X) = 0$ if there exists a p_i-null cover of X. A set X has p_i-*measure* 1, and we write $\mu_{\mathrm{p}_i}(X) = 1$ if $\mu_{\mathrm{p}_i}(X^c) = 0$.

Thus a set X has p_i-measure 0 if p_i provides sufficient computational resources to compute uniformly good approximations to a system of density functions that cover X with rapidly vanishing global value.

We now turn to the internal measure structures of the classes $\mathrm{E} = \mathrm{E}_1 = \mathrm{DTIME}(2^{\mathrm{linear}})$ and $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{polynomial}})$.

DEFINITION. A set X has *measure* 0 *in* E_i, and we write $\mu(X \mid \mathrm{E}_i) = 0$, if $\mu_{\mathrm{p}_i}(X \cap \mathrm{E}_i) = 0$. A set X has *measure* 1 *in* E_i, and we write $\mu(X \mid \mathrm{E}_i) = 1$, if $\mu(X^c \mid \mathrm{E}_i) = 0$. If $\mu(X \mid \mathrm{E}_i) = 1$, we say that *almost every* language in E_i is in X.

We write $\mu(X|\mathrm{E}_i) \neq 0$ to indicate that X does *not* have measure 0 in E_i. Note that this does *not* assert that "$\mu(X|\mathrm{E}_i)$" has some nonzero value.

The following is obvious but useful.

FACT 3.1. *For every set* $X \subseteq \{0,1\}^\infty$,

$$\begin{array}{ccccc} \mu_{\mathrm{p}}(X) = 0 & \Longrightarrow & \mu_{\mathrm{p}_2}(X) = 0 & \Longrightarrow & \Pr[A \in X] = 0 \\ \Downarrow & & \Downarrow & & \\ \mu(X|\mathrm{E}) = 0 & & \mu(X|\mathrm{E}_2) = 0, & & \end{array}$$

where the probability $\Pr[A \in X]$ *is computed according to the random experiment in which a language* $A \subseteq \{0,1\}^*$ *is chosen probabilistically by using an independent toss of a fair coin to decide whether each string* $x \in \{0,1\}^*$ *is in* A.

It is shown in [17] that these definitions endow E and E_2 with internal measure structure. This structure justifies the intuition that if $\mu(X|\mathrm{E}) = 0$, then $X \cap \mathrm{E}$ is a *negligibly small* subset of E (and similarly for E_2). The next two results state aspects of this structure that are especially relevant to the present work.

THEOREM 3.2 [17]. *For all cylinders* $\mathbf{C}_w$, $\mu(\mathbf{C}_w|\mathrm{E}) \neq 0$ *and* $\mu(\mathbf{C}_w|\mathrm{E}_2) \neq 0$. *In particular,* $\mu(\mathrm{E}|\mathrm{E}) \neq 0$ *and* $\mu(\mathrm{E}_2|\mathrm{E}_2) \neq 0$.

The next lemma, which is used in proving Theorem 4.6 and Lemma 5.16, involves the following computational restriction of the notion of "countable union."

DEFINITION. Let $i \in \{1, 2\}$ and let $Z, Z_0, Z_1, Z_2, \cdots \subseteq \{0, 1\}^\infty$. Then Z is a p_i-*union of the* p_i-*measure* 0 *sets* $Z_0, Z_1, Z_2, \cdots$ if $Z = \cup_{j=0}^{\infty} Z_j$ and there exists a p_i-computable 2-DS d such that each d_j is a p_i-null cover of Z_j.

LEMMA 3.3 [17]. *Let* $i \in \{1, 2\}$ *and let* $Z, Z_0, Z_1, Z_2, \ldots \subseteq \{0, 1\}^\infty$. *If* Z *is a* p_i-*union of the* p_i-*measure* 0 *sets* $Z_0, Z_1, Z_2, \ldots$, *then* Z *has* p_i-*measure* 0. □

4. Complexity cores: Lower bounds. Orponen and Schöning [28] have shown that every $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard language for E has a dense polynomial complexity core. In this section we extend this result by proving that every weakly $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard language for E has a dense exponential complexity core. We begin by explaining our terminology.

Given a machine M and an input $x \in \{0, 1\}^*$, we write $M(x) = 1$ if M accepts x, $M(x) = 0$ if M rejects x, and $M(x) = \perp$ in any other case (i.e., if M fails to halt or M halts without deciding x). If $M(x) \in \{0, 1\}$, we write $\mathrm{time}_M(x)$ for the number of steps used in the computation of $M(x)$. If $M(x) = \perp$, we define $\mathrm{time}_M(x) = \infty$. We partially order the set $\{0, 1, \perp\}$ by $\perp < 0$ and $\perp < 1$, with 0 and 1 incomparable. A machine M is *consistent* with a language $A \subseteq \{0, 1\}^*$ if $M(x) \leq [\![x \in A]\!]$ for all $x \in \{0, 1\}^*$.

DEFINITION. Let $t : \mathbf{N} \to \mathbf{N}$ be a time bound and let $A, K \subseteq \{0, 1\}^*$. Then K is a DTIME($t(n)$)-*complexity core* of A if, for every $c \in \mathbf{N}$ and every machine M that is consistent with A, the "fast set"

$$F = \{x \,|\, \mathrm{time}_M(x) \leq c \cdot t(|x|) + c\}$$

satisfies $|F \cap K| < \infty$. (By our definition of $\mathrm{time}_M(x)$, $M(x) \in \{0, 1\}$ for all $x \in F$. Thus F is the set of all strings that M decides efficiently.)

Remark. The previous definition quantifies over all machines consistent with A, while the standard definition of complexity cores (cf. [3]) quantifies only over machines that *decide* A. For recursive languages A (and time-constructible bounds t), it is easy to see that the above definition is exactly equivalent to the standard definition. However, the above definition is stronger than the standard definition when A is not recursive. For example, consider *tally* languages (i.e., languages $A \subseteq \{0\}^*$). Under our definition, every DTIME(n)-complexity core K of every tally language must satisfy $|K - \{0\}^*| < \infty$. However, under the standard definition, complexity cores are only defined for recursive sets A (as in [3]), or else *every* set $K \subseteq \{0, 1\}^*$ is *vacuously* a complexity core for *every* nonrecursive language (tally or otherwise). Thus by quantifying over all machines consistent with A, our definition makes the notion of complexity core meaningful for nonrecursive languages A. This enables one to eliminate the extraneous hypothesis that A is recursive from several results. In some cases, this improvement is of little interest. However, in §6, we show that *every* $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard language H for E has unusually small complexity cores. This upper bound holds regardless of whether H is recursive.

Note that every subset of a DTIME($t(n)$)-complexity core of A is a DTIME($t(n)$)-complexity core of A. Note also that, if $s(n) = O(t(n))$, then every DTIME($t(n)$)-complexity core of A is a DTIME($s(n)$)-complexity core of A.

DEFINITION. Let $A, K \subseteq \{0, 1\}^*$.

1. K is a *polynomial complexity core* (or, briefly, a P-*complexity core*) of A if K is a DTIME(n^k)-complexity core of A for all $k \in \mathbf{N}$.

2. K is an *exponential complexity core* of A if there is a real number $\epsilon > 0$ such that K is a DTIME(2^{n^ϵ})-complexity core of A.

Much of our work here uses languages that are "incompressible by many-one reductions," an idea originally exploited by Meyer [26]. The following definitions develop this notion.

DEFINITION. The *collision set* of a function $f : \{0,1\}^* \to \{0,1\}^*$ is

$$C_f = \{x \in \{0,1\}^* \mid (\exists y < x) f(y) = f(x)\}.$$

Here, we are using the standard ordering $s_0 < s_1 < s_2 < \cdots$ of $\{0,1\}^*$.

Note that f is one-to-one if and only if $C_f = \emptyset$.

DEFINITION. A function $f : \{0,1\}^* \to \{0,1\}^*$ is *one-to-one almost everywhere* (or, briefly, *one-to-one a.e.*) if its collision set C_f is finite.

DEFINITION. Let $A, B \subseteq \{0,1\}^*$ and let $t : \mathbf{N} \to \mathbf{N}$. A $\leq_m^{\mathrm{DTIME}(t)}$*-reduction of* A *to* B is a function $f \in \mathrm{DTIMEF}(t)$ such that $A = f^{-1}(B)$, i.e., such that, for all $x \in \{0,1\}^*$, $x \in A$ iff $f(x) \in B$. A $\leq_m^{\mathrm{DTIME}(t)}$*-reduction of* A is a function f that is a $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A to $f(A)$.

It is easy to see that f is a $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A if and only if there exists a language B such that f is a $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A to B.

DEFINITION. Let $t : \mathbf{N} \to \mathbf{N}$. A language $A \subseteq \{0,1\}^*$ is *incompressible by* $\leq_m^{\mathrm{DTIME}(t)}$*-reductions* if every $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A is one-to-one a.e. A language $A \subseteq \{0,1\}^*$ is *incompressible by* $\leq_m^{\mathrm{P}}$*-reductions* if it is incompressible by $\leq_m^{\mathrm{DTIME}(q)}$-reductions for all polynomials q.

Intuitively, if f is a $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A to B and C_f is large, then f compresses many questions "$x \in A$?" to fewer questions "$f(x) \in B$?" If A is incompressible by $\leq_m^{\mathrm{P}}$-reductions, then very little such compression can occur.

Our first observation, an obvious generalization of a result of Balcázar and Schöning [4] (see Corollary 4.5), relates incompressibility to complexity cores.

LEMMA 4.4. *If* $t : \mathbf{N} \to \mathbf{N}$ *is time constructible, then every language that is incompressible by* $\leq_m^{\mathrm{DTIME}(t)}$*-reductions has* $\{0,1\}^*$ *as a DTIME*(t)*-complexity core.*

Proof. Let A be a language that does not have $\{0,1\}^*$ as a DTIME(t)-complexity core. It suffices to prove that A is not incompressible by $\leq_m^{\mathrm{DTIME}(t)}$-reductions. This is clear if $A = \emptyset$ or $A = \{0,1\}^*$, so assume that $\emptyset \neq A \neq \{0,1\}^*$. Fix $u \in A$ and $v \in A^c$. Since $\{0,1\}^*$ is not a DTIME(t)-complexity core of A, there exist $c \in \mathbf{N}$ and a machine M such that M is consistent with A and the fast set

$$F = \{x \mid \mathrm{time}_M(x) \leq c \cdot t(|x|) + c\}$$

is infinite. Define a function $f : \{0,1\}^* \to \{0,1\}^*$ by

$$f(x) = \begin{cases} u & \text{if } M(x) = 1 \text{ in} \leq c \cdot t(|x|) + c \text{ steps,} \\ v & \text{if } M(x) = 0 \text{ in} \leq c \cdot t(|x|) + c \text{ steps,} \\ x & \text{otherwise.} \end{cases}$$

Since t is time-constructible, $f \in \mathrm{DTIMEF}(t)$. Since M is consistent with A, f is a $\leq_m^{\mathrm{DTIME}(t)}$-reduction of A to A. Since F is infinite, at least one of the sets $f^{-1}(\{u\})$, $f^{-1}(\{v\})$ is infinite, so the collision set C_f is infinite. Thus A is not incompressible by $\leq_m^{\mathrm{DTIME}(t)}$-reductions. □

COROLLARY 4.5. *Let* $c \in \mathbf{N}$.

1 (*Balcazar and Schöning* [4]). *Every language that is incompressible by* $\leq_m^{\mathrm{P}}$*-reductions has* $\{0,1\}^*$ *as a P-complexity core.*

2. *Every language that is incompressible by* $\leq_m^{\mathrm{DTIME}(2^{cn})}$*-reductions has* $\{0,1\}^*$ *as a DTIME*(2^{cn})*-complexity core.*

3. *Every language that is incompressible by* $\leq_m^{\mathrm{DTIME}(2^{n^c})}$*-reductions has* $\{0,1\}^*$ *as a DTIME*(2^{n^c})*-complexity core.* □

We now prove that, in E and E_2, almost every language is incompressible by $\leq_m^{DTIME(t)}$-reductions, for exponential time bounds t.

THEOREM 4.6. *Let $c \in \mathbf{Z}^+$ and define the sets*

$$X = \{A \subseteq \{0,1\}^* | A \text{ is incompressible by } \leq_m^{DTIME(2^{cn})}\text{-reductions}\},$$

$$Y = \{A \subseteq \{0,1\}^* | A \text{ is incompressible by } \leq_m^{DTIME(2^{n^c})}\text{-reductions}\}.$$

Then $\mu_p(X) = \mu_{p_2}(Y) = 1$. Thus almost every language in E *is incompressible by $\leq_m^{DTIME(2^{cn})}$-reductions, and almost every language in* E_2 *is incompressible by $\leq_m^{DTIME(2^{n^c})}$-reductions.*

Proof. Let $c \in \mathbf{Z}^+$. We prove that $\mu_p(X) = 1$. The proof that $\mu_{p_2}(X) = 1$ is analogous.

Let $f \in DTIMEF(2^{(c+1)n})$ be a function that is universal for $DTIMEF(2^{cn})$, in the sense that

$$DTIMEF(2^{cn}) = \{f_i \mid i \in \mathbf{N}\}.$$

For each $i \in \mathbf{N}$, define a set Z_i of languages as follows: If the collision set C_{f_i} is finite, then $Z_i = \emptyset$. Otherwise, if C_{f_i} is infinite, then Z_i is the set of all languages A such that f_i is a $\leq_m^{DTIME(2^{cn})}$-reduction of A.

Define a function $d : \mathbf{N} \times \mathbf{N} \times \{0,1\}^* \to [0, \infty)$ as follows: Let $i, k \in \mathbf{N}$ be arbitrary, let $w \in \{0,1\}^*$, and let $b \in \{0,1\}$.

(i) $d_{i,k}(\lambda) = 2^{-k}$.

(ii) If $s_{|w|} \notin C_{f_i}$, then $d_{i,k}(wb) = d_{i,k}(w)$.

(iii) If $s_{|w|} \in C_{f_i}$, then fix the least $j \in \mathbf{N}$ such that $f_i(s_j) = f_i(s_{|w|})$ and set

$$d_{i,k}(wb) = 2 \cdot d_{i,k}(w) \cdot [\![b = w[j]]\!].$$

It is clear that d is a 2-DS. Since $f \in DTIMEF(2^{(c+1)n})$ and the computation of $d_{i,k}(w)$ only uses values $f_i(u)$ for strings u with $|u| = O(\log |w|)$, it is also clear that $d \in p$, so d is a p-computable 2-DS.

We now show that $Z_i \subseteq S[d_{i,k}]$ for all $i, k \in \mathbf{N}$. If C_{f_i} is finite, then this is clear (because $Z_i = \emptyset$), so assume that C_{f_i} is infinite and let $A \in Z_i$. Let w be a string consisting of the first l bits of the characteristic sequence of A, where s_{l-1} is the kth element of C_{f_i}. This choice of l ensures that clause (iii) of the definition of d is invoked exactly k times in the recursive computation of $d_{i,k}(w)$. Since f_i is a $\leq_m^{DTIME(2^{cn})}$-reduction of A (because $A \in Z_i$), we have $b = w[j]$ in each of these k invocations, so

$$d_{i,k}(w) = 2^k \cdot d_{i,k}(\lambda) = 1.$$

Thus $A \in \mathbf{C}_w \subseteq S[d_{i,k}]$. This confirms that $Z_i \subseteq S[d_{i,k}]$ for all $i, k \in \mathbf{N}$. It follows easily that for each $i \in \mathbf{N}$, d_i is a p-null cover of Z_i. This implies that

$$X^c = \bigcup_{k=0}^{\infty} Z_k$$

is a p-union of p-measure 0 sets, whence $\mu_p(X) = 1$ by Lemma 3.3. □

COROLLARY 4.7. *Almost every language in* E *and almost every language in* E_2 *is incompressible by $\leq_m^P$-reductions.* □

COROLLARY 4.8 (Meyer [26]). *There is a language $A \in$ E that is incompressible by $\leq_m^P$-reductions.* □

COROLLARY 4.9. *Let $c \in \mathbf{Z}^+$.*

1. *Almost every language in* E *has* $\{0, 1\}^*$ *as a DTIME*(2^{cn})*-complexity core.*

2. *Almost every language in* E_2 *has* $\{0, 1\}^*$ *as a DTIME*(2^{n^c})*-complexity core.* □

We now consider complexity cores of $\leq_m^P$-hard languages. Our starting point is the following two known facts.

FACT 4.10 (Orponen and Schöning [28]). *Every language that is* $\leq_m^P$*-hard for* E (*equivalently, for* E_2) *has a dense P-complexity core.*

FACT 4.11 (Orponen and Schöning [28]). *If* $P \neq NP$, *then every language that is* $\leq_m^P$*-hard for* NP *has a nonsparse P-complexity core.*

We first extend Fact 4.10. For this, we need a definition. The *lower* $\leq_m^P$*-span* of a language $A \subseteq \{0, 1\}^*$ is

$$P_m(A) = \{B \subseteq \{0, 1\}^* \mid B \leq_m^P A\},$$

i.e., the set of all languages lying at or below A in the $\leq_m^P$-reducibility structure of the set of all languages. Recall that a language A is $\leq_m^P$*-hard* for a complexity class $\mathcal{C}$ if $\mathcal{C} \subseteq P_m(A)$.

DEFINITION. A language $A \subseteq \{0, 1\}^*$ is *weakly* $\leq_m^P$*-hard* for E (respectively, for E_2) if $\mu(P_m(A) \mid E) \neq 0$ (respectively, $\mu(P_m(A) \mid E_2) \neq 0$). A language $A \subseteq \{0, 1\}^*$ is *weakly* $\leq_m^P$*-complete* for E (respectively, for E_2) if $A \in E$ (respectively, $A \in E_2$) and A is weakly $\leq_m^P$-hard for E (respectively, for E_2).

Thus a language A is weakly $\leq_m^P$-hard for E if a nonnegligible subset of the languages in E are $\leq_m^P$-reducible to A. Very recently, Lutz [19] has established the existence of languages that are weakly $\leq_m^P$-complete, but not $\leq_m^P$-complete, for E (and similarly for E_2). Although "$\leq_m^P$-hard for E" and "$\leq_m^P$-hard for E_2" are equivalent, we do not know the relationship between "weakly $\leq_m^P$-hard for E" and "weakly $\leq_m^P$-hard for E_2."

Recall that a language $D \subseteq \{0, 1\}^*$ is *dense* if there is a real number $\epsilon > 0$ such that $|D_{\leq n}| > 2^{n^\epsilon}$ a.e.

THEOREM 4.12. *Every language that is weakly* $\leq_m^P$*-hard for* E *or* E_2 *has a dense exponential complexity core.*

Proof. We prove this for E. The proof for E_2 is identical.

Let H be a language that is weakly $\leq_m^P$-hard for E. Then $P_m(H)$ does not have measure 0 in E, so by Theorem 4.6, there is a language $A \in P_m(H)$ that is incompressible by $\leq_m^{DTIME(2^n)}$-reductions. Let f be a $\leq_m^P$-reduction of A to H, let q be a strictly increasing polynomial bound on the time required to compute f, and let $\epsilon = \frac{1}{3 \cdot \deg(q)}$. Then the language $K = f(\{0, 1\}^*)$ is a dense DTIME(2^{n^ϵ})-complexity core of H. □

Lutz has proposed the investigation of the consequences of the strong hypotheses $\mu(NP \mid E) \neq 0$ and $\mu(NP \mid E_2) \neq 0$ [18], [23], [22]. In this regard, we have the following.

COROLLARY 4.13. *If* $\mu(NP \mid E) \neq 0$ *or* $\mu(NP \mid E_2) \neq 0$, *then every* $\leq_m^P$*-hard language for* NP *has a dense exponential complexity core.* □

Thus, for example, if NP is not small, then there is a dense set K of Boolean formulas in conjunctive normal form such that every machine that is consistent with SAT performs exponentially badly (either by running for more than $2^{|x|^\epsilon}$ steps or by failing to decide) on all but finitely many inputs $x \in K$.

Note that Theorem 4.12 extends Fact 4.10 and that Corollary 4.13 has a stronger hypothesis and stronger conclusion than Fact 4.11. Note also that Corollary 4.13 holds with NP replaced by PH, PP, PSPACE, or any class whatsoever.

The following result shows that the density bounds of Theorem 4.12 and Corollary 4.13 are tight.

THEOREM 4.14. *For every* $\epsilon > 0$, *each of the classes* NP, E, *and* E_2 *has a* $\leq_m^P$*-complete language, every P-complexity core* K *of which satisfies* $|K_{\leq n}| < 2^{n^\epsilon}$ *a.e.*

Proof. Let $\epsilon > 0$, let $\mathcal{C}$ be any one of the classes NP, E, E_2, and let A be a language that is $\leq_m^P$-complete for $\mathcal{C}$. Let $k = \lceil \frac{2}{\epsilon} \rceil$ and define the language

$$B = \{x10^{|x|^k} \mid x \in A\}.$$

Then B is $\leq_m^P$-complete for $\mathcal{C}$ and every P-complexity core K of B satisfies $|K_{\leq n}| < 2^{n^\epsilon}$ a.e. □

5. Measure of degrees. In this section we prove that all $\leq_m^P$-degrees have measure 0 in the complexity classes E and E_2. This fact and more follow from the Small Span Theorem, which we prove first.

Recall that the *lower* $\leq_m^P$*-span* of a language $A \subseteq \{0,1\}^*$ is

$$P_m(A) = \{B \subseteq \{0,1\}^* \mid B \leq_m^P A\}.$$

Similarly, define the *upper* $\leq_m^P$*-span* of A to be

$$P_m^{-1}(A) = \{B \subseteq \{0,1\}^* \mid A \leq_m^P B\}.$$

The $\leq_m^P$*-degree* of A is then

$$\deg_m^P(A) = P_m(A) \cap P_m^{-1}(A),$$

the intersection of the upper and lower spans.

The main result of this section is that, if A is in E or E_2, then at least one of the spans $P_m(A)$, $P_m^{-1}(A)$ is small.

THEOREM 5.15 (Small Span Theorem).

1. *For every* $A \in E$,

$$\mu(P_m(A) \mid E) = 0$$

or

$$\mu_p(P_m^{-1}(A)) = \mu(P_m^{-1}(A) \mid E) = 0.$$

2. *For every* $A \in E_2$,

$$\mu(P_m(A) \mid E_2) = 0$$

or

$$\mu_{p_2}(P_m^{-1}(A)) = \mu(P_m^{-1}(A) \mid E_2) = 0.$$

We first use the following lemma to prove Theorem 5.15. We then prove the lemma.

LEMMA 5.16. *Let A be a language that is incompressible by $\leq_m^P$-reductions.*

1. *If* $A \in E$, *then* $\mu_p(P_m^{-1}(A)) = \mu(P_m^{-1}(A)|E) = 0$.

2. *If* $A \in E_2$, *then* $\mu_{p_2}(P_m^{-1}(A)) = \mu(P_m^{-1}(A)|E_2) = 0$.

Proof of Theorem 5.15. To prove 1, let $A \in E$ and let X be the set of all languages that are incompressible by $\leq_m^P$-reductions. We have two cases.

Case I. If $P_m(A) \cap E \cap X = \emptyset$, then Corollary 4.7 tells us that $\mu(P_m(A) \mid E) = 0$.

Case II. If $P_m(A) \cap E \cap X \neq \emptyset$, then fix a language $B \in P_m(A) \cap E \cap X$. Since $B \in E \cap X$, Lemma 5.16 tells us that

$$\mu_p(P_m^{-1}(B)) = \mu(P_m^{-1}(B) \mid E) = 0.$$

Since $P_m^{-1}(A) \subseteq P_m^{-1}(B)$, it follows that

$$\mu_p(P_m^{-1}(A)) = \mu(P_m^{-1}(A) \mid E) = 0.$$

This proves 1. The proof of 2 is identical. □

Proof of Lemma 5.16. To prove 1, let $A \in E$ be incompressible by $\leq_m^P$-reductions. Let $f \in DTIMEF(2^n)$ be a function that is universal for PF, in the sense that

$$PF = \{f_i \mid i \in \mathbf{N}\}.$$

For each $i \in \mathbf{N}$, define the set Z_i of languages as follows. If the collision set C_{f_i} is infinite, then $Z_i = \emptyset$. Otherwise, if C_{f_i} is finite, then

$$Z_i = \{B \subseteq \{0,1\}^* \mid A \leq_m^P B \text{ via } f_i\}.$$

Note that

$$P_m^{-1}(A) = \bigcup_{i=0}^{\infty} Z_i,$$

because A is incompressible by $\leq_m^P$-reductions.

Define a function $d : \mathbf{N} \times \mathbf{N} \times \{0,1\}^* \to [0, \infty)$ as follows. Let $i, k \in \mathbf{N}$ be arbitrary, let $w \in \{0,1\}^*$, and let $b \in \{0,1\}$.

(i) $d_{i,k}(\lambda) = 2^{-k}$.

(ii) If there is no $j \leq 2|w|$ such that $f_i(s_j) = s_{|w|}$, then $d_{i,k}(wb) = d_{i,k}(w)$.

(iii) If there exists $j \leq 2|w|$ such that $f_i(s_j) = s_{|w|}$, then fix the least such j and set

$$d_{i,k}(wb) = 2 \cdot d_{i,k}(w) \cdot [\![b = [\![s_j \in A]\!]]\!].$$

It is clear that d is a 2-DS. Also, since $f \in DTIMEF(2^n)$ and $A \in E$, it is easy to see that $d \in p$, whence d is a p-computable 2-DS.

We now show that $Z_i \subseteq S[d_{i,k}]$ for all $i, k \in \mathbf{N}$. If C_{f_i} is infinite, then this is clear (because $Z_i = \emptyset$), so assume that $|C_{f_i}| = c < \infty$ and let $B \in Z_i$, i.e., $A \leq_m^P B$ via f_i. Let v be the string consisting of the first l bits of the characteristic sequence of B, where l is large enough that

$$f_i(\{s_0, \ldots, s_{2k+4c-1}\}) \subseteq \{s_0, \ldots, s_{l-1}\}.$$

Consider the computation of $d_{i,k}(v)$ by clauses (i), (ii), and (iii). Since $A \leq_m^P B$ via f_i, clause (iii) does not cause $d_{i,k}(w)$ to be 0 for any prefix w of v. Let

$$S = \{s_n \mid 0 \leq n < 2k + 4c \text{ and } f_i(s_n) \notin \{s_0, \ldots, s_{\lceil \frac{n}{2} \rceil - 1}\}\}$$

and

$$T = f_i(S),$$

then clause (iii) doubles the density whenever $s_{|w|} \in T$, so

$$d_{i,k}(v) \geq 2^{|T|} d_{i,k}(\lambda) = 2^{|T|-k} \geq 2^{|S|-k-c}.$$

Also, if

$$S' = \{s_n \mid 0 \leq n < 2k + 4c \text{ and } f_i(s_n) \notin \{s_0, \ldots, s_{k+2c-1}\}\},$$

then $S' \subseteq S$ and

$$|S'| \geq (2k + 4c) - (k + 2c) - c = k + c.$$

Putting this all together, we have

$$d_{i,k}(v) \geq 2^{|S|-k-c} \geq 2^{|S'|-k-c} \geq 1,$$

whence $B \in \mathbf{C}_v \subseteq S[d_{i,k}]$. This shows that $Z_i \subseteq S[d_{i,k}]$ for all $i, k \in \mathbf{N}$.

Since d is p-computable and $d_{i,k}(\lambda) = 2^{-k}$ for all $i, k \in \mathbf{N}$, it follows that, for all $i \in \mathbf{N}$, d_i is p-null cover of Z_i. This implies that $\mathrm{P}_{\mathrm{m}}^{-1}(A)$ is a p-union of the p-measure 0 sets Z_i. It follows by Lemma 3.3 that $\mu_{\mathrm{p}}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = \mu(\mathrm{P}_{\mathrm{m}}^{-1}(A) \mid \mathrm{E}) = 0$. This completes the proof of 1.

The proof of 2 is identical. One need only note that, if $A \in \mathrm{E}_2$, then $d \in \mathrm{p}_2$. □

Remark. Ambos-Spies [1] has shown that $\mathrm{P}_{\mathrm{m}}(A)$ has Lebesgue measure 0 whenever $A \notin \mathrm{P}$. Lemma 5.16 obtains a stronger conclusion (resource-bounded measure 0) from a stronger hypothesis on A.

It is now straightforward to derive consequences of these results for the structure of E and E_2. We first note that $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard languages for E are extremely rare.

THEOREM 5.17. *Let $\mathcal{H}_{\mathrm{E}}$ be the set of all languages that are $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard for* E. *Then* $\mu_{\mathrm{p}}(\mathcal{H}_{\mathrm{E}}) = 0$.

Proof. Let A be as in Corollary 4.8. Then $\mathcal{H}_{\mathrm{E}} \subseteq \mathrm{P}_{\mathrm{m}}^{-1}(A)$, so Lemma 5.16 tells us that

$$\mu_{\mathrm{p}}(\mathcal{H}_{\mathrm{E}}) = \mu_{\mathrm{p}}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = 0. \qquad \square$$

Theorem 5.17 immediately yields an alternate proof of the following result.

COROLLARY 5.18 (Mayordomo[25]). *Let $\mathcal{C}_{\mathrm{E}}$, $\mathcal{C}_{\mathrm{E}_2}$ be the sets of languages that are $\leq_{\mathrm{m}}^{\mathrm{P}}$-complete for* E, E_2, *respectively. Then* $\mu(\mathcal{C}_{\mathrm{E}} | \mathrm{E}) = \mu(\mathcal{C}_{\mathrm{E}_2} | \mathrm{E}_2) = 0$. □

(Mayordomo's proof of Corollary 5.18 used Berman's result [6], that no $\leq_{\mathrm{m}}^{\mathrm{P}}$-complete language for E is P-immune.)

As it turns out, Corollary 5.18 is only a special case of the following general result. *All* $\leq_{\mathrm{m}}^{\mathrm{P}}$-degrees have measure 0 in E and in E_2.

THEOREM 5.19. *For all* $A \subseteq \{0, 1\}^*$,

$$\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}) = \mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}_2) = 0.$$

Proof. Let $A \subseteq \{0, 1\}^*$. We prove that $\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}) = 0$. The proof that $\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}_2) = 0$ is identical (in fact simpler, because E_2 is closed under $\leq_{\mathrm{m}}^{\mathrm{P}}$).

If $\deg_{\mathrm{m}}^{\mathrm{P}}(A) \cap \mathrm{E} = \emptyset$, then $\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}) = 0$ holds trivially, so assume that $\deg_{\mathrm{m}}^{\mathrm{P}}(A) \cap \mathrm{E} \neq \emptyset$. Fix $B \in \deg_{\mathrm{m}}^{\mathrm{P}}(A) \cap \mathrm{E}$. Then, by Theorem 5.15,

$$\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(B) \mid \mathrm{E}) = \mu(\mathrm{P}_{\mathrm{m}}(B) \mid \mathrm{E}) = 0$$

or

$$\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(B) \mid \mathrm{E}) = \mu(\mathrm{P}_{\mathrm{m}}^{-1}(B) \mid \mathrm{E}) = 0.$$

Since $\deg_{\mathrm{m}}^{\mathrm{P}}(A) = \deg_{\mathrm{m}}^{\mathrm{P}}(B)$, it follows that $\mu(\deg_{\mathrm{m}}^{\mathrm{P}}(A) \mid \mathrm{E}) = 0$. □

We now have the following two corollaries for NP.

COROLLARY 5.20. *Let $\mathcal{H}_{\mathrm{NP}}$ be the set of languages that are $\leq_{\mathrm{m}}^{\mathrm{P}}$-hard for* NP.

1. *If* $\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0$, *then* $\mu(\mathcal{H}_{\mathrm{NP}} \mid \mathrm{E}) = 0$.
2. *If* $\mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0$, *then* $\mu(\mathcal{H}_{\mathrm{NP}} \mid \mathrm{E}_2) = 0$.

Proof. This follows immediately from Theorem 5.15, with $A = \mathrm{SAT}$. □

COROLLARY 5.21. *Let $\mathcal{C}_{\mathrm{NP}}$ be the set of languages that are $\leq_m^P$-complete for* NP. *Then* $\mu(\mathcal{C}_{\mathrm{NP}} \mid \mathrm{E}) = \mu(\mathcal{C}_{\mathrm{NP}} \mid \mathrm{E}_2) = 0$.

Proof. Since $\mathcal{C}_{\mathrm{NP}} = \deg_m^P(\mathrm{SAT})$, this follows immediately from Theorem 5.19. □

It is interesting to note that Corollary 5.21, unlike Corollary 5.20, is an absolute result, requiring no unproven hypothesis. The price we pay for this is that we do not know *why* it holds! For example, the Small Span Theorem tells us that $\mathcal{C}_{\mathrm{NP}} = \mathcal{H}_{\mathrm{NP}} \cap \mathrm{NP}$ has measure 0 in E because $\mu(\mathcal{H}_{\mathrm{NP}} \mid \mathrm{E}) = 0$ *or* $\mu(\mathrm{NP} \mid \mathrm{E}) = 0$, but it does *not* tell us which of these two very different situations occurs.

Note that Corollaries 5.20 and 5.21 also hold with NP replaced by *any other class whatsoever*.

We conclude this section by noting two respects in which the Small Span Theorem cannot be improved. First, the hypotheses $A \in \mathrm{E}$ and $A \in \mathrm{E}_2$ are essential for parts 1 and 2, respectively. For example, if A is p-random [20], then $\mu_p(\{A\}) \neq 0$, so none of $\deg_m^P(A)$, $P_m(A)$, $P_m^{-1}(A)$ can have p-measure 0.

The second respect in which the Small Span Theorem cannot be improved involves the variety of small-span configurations. In both E and E_2, either one or both of the upper and lower spans of a language can in fact be small. We give examples for E.

(a) It is well known [26] that there is a language $A \in \mathrm{E}$ that is both sparse and incompressible by $\leq_m^P$-reductions. Fix such a language A. By Lemma 5.16, $\mu_p(P_m^{-1}(A)) = 0$. Also, since A is sparse, the main result of [23] implies that $\mu_p(P_m(A)) = 0$.

(b) If $A \in \mathrm{P} - \{\emptyset, \{0,1\}^*\}$, then $\mu(P_m(A) \mid \mathrm{E}) = \mu_p(P_m(A)) = 0$, but $\mu_p(P_m^{-1}(A)) \neq 0$ and $\mu(P_m^{-1}(A) \mid \mathrm{E}) \neq 0$.

(c) If A is $\leq_m^P$-complete for E, then $\mu(P_m^{-1}(A) \mid \mathrm{E}) = \mu_p(P_m^{-1}(A)) = 0$ by Theorem 5.17, but $\mu(P_m(A) \mid \mathrm{E}) = \mu(\mathrm{E} \mid \mathrm{E}) \neq 0$.

Similar examples can be given for E_2.

6. Complexity cores: Upper bound. In this section we give an explicit *upper* bound on the sizes of complexity cores of languages that are $\leq_m^P$-hard for E. This bound implies that $\leq_m^P$-complete languages for E have *unusually small* complexity cores, for languages in E.

THEOREM 6.22. *For every $\leq_m^P$-hard language H for* E, *there exist $B, D \in \mathrm{DTIME}(2^{4n})$ such that D is dense and $B = H \cap D$.*

Proof. By Corollary 4.8, there is a language in E that is incompressible by $\leq_m^P$-reductions. In fact, Meyer's construction [26] shows that there is a language $A \in \mathrm{DTIME}(5^n)$ that is incompressible by $\leq_m^P$-reductions. As in Fact 4.10 and Theorem 4.12, this idea has often been used to establish *lower* bounds on the complexities of $\leq_m^P$-hard languages. Here we use it to establish an *upper* bound.

The following simple notation is useful here. The *nonreduced image* of a language $S \subseteq \{0,1\}^*$ under a function $f : \{0,1\}^* \to \{0,1\}^*$ is

$$f^{\geq}(S) = \{f(x) \mid x \in S \text{ and } |f(x)| \geq |x|\}.$$

Note that

$$f^{\geq}(f^{-1}(S)) = S \cap f^{\geq}(\{0,1\}^*)$$

for all f and S.

Let H be $\leq_m^P$-hard for E. Then there is a $\leq_m^P$-reduction f of A to H. Let $B = f^{\geq}(A)$, $D = f^{\geq}(\{0,1\}^*)$. Since $A \in \mathrm{DTIME}(5^n)$ and $f \in \mathrm{PF}$, it is clear that $B, D \in \mathrm{DTIME}(10^n) \subseteq \mathrm{DTIME}(2^{4n})$.

Fix a polynomial q and a real number $\epsilon > 0$ such that $|f(x)| \leq q(|x|)$ for all $x \in \{0,1\}^*$ and $q(n^{2\epsilon}) < n$ a.e. Let $W = \{x \mid |f(x)| < |x|\}$. Then, for all sufficiently large $n \in \mathbf{N}$,

writing $m = \lfloor n^{2\epsilon} \rfloor$, we have

$$\begin{aligned} f(\{0,1\}^{\leq m}) - \{0,1\}^{<m} &\subseteq f(\{0,1\}^{\leq m}) - f(W_{\leq m}) \\ &\subseteq f^{\geq}(\{0,1\}^{\leq m}) \\ &\subseteq D_{\leq q(m)} \\ &\subseteq D_{\leq n}, \end{aligned}$$

whence

$$\begin{aligned} |D_{\leq n}| &\geq |f(\{0,1\}^{\leq m})| - |\{0,1\}^{<m}| \\ &\geq |\{0,1\}^{\leq m}| - |C_f| - |\{0,1\}^{<m}| \\ &= 2^m - |C_f|. \end{aligned}$$

Since $|C_f| < \infty$, it follows that $|D_{\leq n}| > 2^{n^\epsilon}$ for all sufficiently large n. Thus D is dense.

Finally, note that $B = f^{\geq}(A) = f^{\geq}(f^{-1}(H)) = H \cap f^{\geq}(\{0,1\}^*) = H \cap D$. This completes the proof of Theorem 6.22. □

We now use Theorem 6.22 to prove our upper bound on the size of complexity cores for hard languages.

THEOREM 6.23. *Every DTIME(2^{4n})-complexity core of every $\leq_m^P$-hard language for* E *has a dense complement.*

Proof. Let H be $\leq_m^P$-hard for E and let K be a DTIME(2^{4n})-complexity core of H. Choose B, D for H as in Theorem 6.22. Fix machines M_B and M_D that decide B and D, respectively, with $\text{time}_{M_B}(x) = O(2^{4|x|})$ and $\text{time}_{M_D}(x) = O(2^{4|x|})$. Let M be a machine that implements the following algorithm.

begin
  input x;
  if $M_D(x)$ accepts
    then simulate $M_B(x)$
    else run forever
end M.

Then $x \in D \Rightarrow M(x) = [\![x \in B]\!] = [\![x \in H \cap D]\!] = [\![x \in H]\!]$ and $x \notin D \Rightarrow M(x) = \perp \leq [\![x \in H]\!]$, so M is consistent with H. Also, there is a constant $c \in \mathbf{N}$ such that for all $x \in D$,

$$\text{time}_M(x) \leq c \cdot 2^{4n} + c.$$

Since K is a DTIME(2^{4n})-complexity core of H, it follows that $K \cap D$ is finite. But D is dense, so this implies that $D - K$ is dense, whence K^c is dense. □

Note that Theorem 5.17 follows from Corollary 4.9 and Theorem 6.23, but that Theorem 6.23 tells us more.

The main construction of [19] shows that for every $c \in \mathbf{N}$, there is a language H that is weakly $\leq_m^P$-hard for E and has $\{0,1\}^*$ as a DTIME(2^{cn})-complexity core. Thus, in contrast with the lower bound given by Theorem 4.12, the upper bound given by Theorem 6.23 cannot be extended to weakly $\leq_m^P$-hard languages.

Finally, we note that the upper bound given by Theorem 6.23 is tight.

THEOREM 6.24. *Let $c \in \mathbf{N}$ and $0 < \epsilon \in \mathbf{R}$.*

1. E *has a $\leq_m^P$-complete language with a DTIME(2^{cn})-complexity core K that satisfies $|K_{\leq n}| > 2^{n+1} - 2^{n^\epsilon}$ a.e.*

2. E_2 *has a $\leq_m^P$-complete language with a DTIME(2^{n^c})-complexity core K that satisfies $|K_{\leq n}| > 2^{n+1} - 2^{n^\epsilon}$ a.e.*

Proof. We prove the result for E. The proof for E_2 is similar.

Let A be a language that is $\leq_m^P$-complete for E and let $k = \lceil \frac{2}{\epsilon} \rceil$. By Corollary 4.9, fix a language $B \in E$ that has $\{0, 1\}^*$ as a DTIME(2^{cn})-complexity core. Let

$$D = \{x10^{|x|^k} | x \in \{0, 1\}^*\}$$

and define the languages

$$C = (B - D) \cup \{x10^{|x|^k} \mid x \in A\}$$

and

$$K = D^c.$$

It is clear that C is $\leq_m^P$-complete for E. Also, for all sufficiently large n,

$$|D_{\leq n}| = \sum_{m=0}^{n} |D_{=m}| \leq \sum_{m=0}^{n} 2^{m^{\frac{1}{k}}} \leq (n+1)2^{n^{\frac{1}{k}}} \leq (n+1)2^{n^{\frac{\epsilon}{2}}} < 2^{n^\epsilon} - 1,$$

so

$$|K_{\leq n}| = 2^{n+1} - 1 - |D_{\leq n}| > 2^{n+1} - 2^{n^\epsilon} \text{ a.e.}$$

We complete the proof by showing that K is a DTIME(2^{cn})-complexity core for C. For this, let $s \in \mathbf{N}$, let M be a machine that is consistent with C, and define the fast set

$$F = \{x \mid \text{time}_M(x) \leq a \cdot 2^{c|x|} + a\}.$$

It suffices to prove that $|K \cap F| < \infty$.

Let $\hat{M}$ be a machine (designed in the obvious way) such that, for all $y \in \{0, 1\}^*$,

$$\hat{M}(y) = \begin{cases} M(y) & \text{if } y \notin D, \\ \perp & \text{if } y \in D. \end{cases}$$

Then $\hat{M}$ is consistent with B (because $B - D = C - D$ and M is consistent with C) and $\{0, 1\}^*$ is a DTIME(2^{cn})-complexity core for B, so the fast set

$$\hat{F} = \{x \mid \text{time}_{\hat{M}}(x) \leq (a+1)2^{c|x|} + a\}$$

is finite. Since $K \cap F = F - D$ and $(F - D) - \hat{F}$ is finite, it follows that $|K \cap F| < \infty$, completing the proof. □

7. Conclusion. In this paper we have investigated measure-theoretic aspects of the $\leq_m^P$-reducibility structure of the exponential time complexity classes E and E_2. Among other things, we have proven the following. (For simplicity we only consider the class E.)

(i) Every weakly $\leq_m^P$-hard language for E has a dense exponential complexity core (Theorem 4.12).

(ii) For every language $A \in E$, at least one of the spans $P_m(A)$, $P_m^{-1}(A)$ has resource-bounded measure 0 (Theorem 5.15, the Small Span Theorem). Thus the $\leq_m^P$-hard languages for E form a p-measure 0 set (Theorem 5.17), *every* $\leq_m^P$-degree has measure 0 in E (Theorem 5.19), and the $\leq_m^P$-complete languages for NP form a set of measure 0 in E (Corollary 5.21).

(iii) Every DTIME(2^{4n})-complexity core of every $\leq_m^P$-hard language for E has a dense complement (Theorem 6.23). Since almost every language in E has $\{0, 1\}^*$ as a DTIME(2^{4n})-complexity core (Corollary 4.9), this says that in E the $\leq_m^P$-complete languages are *unusually simple*, in the sense that they have *unusually small* complexity cores.

It is reasonable to conjecture that most of our results hold with $\leq_m^P$ replaced by $\leq_T^P$, but investigating this may be difficult. For example, consider Theorem 5.17. Bennett and Gill [5] have shown that $P_T^{-1}(A)$ has (classical) measure 1 for all $A \in$ BPP. Thus we cannot prove that the $\leq_T^P$-hard languages for E form a measure 0 set without also proving that E $\not\subseteq$ BPP.

A GENERAL APPROXIMATION TECHNIQUE FOR CONSTRAINED FOREST PROBLEMS*

MICHEL X. GOEMANS† AND DAVID P. WILLIAMSON‡

Abstract. We present a general approximation technique for a large class of graph problems. Our technique mostly applies to problems of covering, at minimum cost, the vertices of a graph with trees, cycles, or paths satisfying certain requirements. In particular, many basic combinatorial optimization problems fit in this framework, including the shortest path, minimum-cost spanning tree, minimum-weight perfect matching, traveling salesman, and Steiner tree problems.

Our technique produces approximation algorithms that run in $O(n^2 \log n)$ time and come within a factor of 2 of optimal for most of these problems. For instance, we obtain a 2-approximation algorithm for the minimum-weight perfect matching problem under the triangle inequality. Our running time of $O(n^2 \log n)$ time compares favorably with the best strongly polynomial exact algorithms running in $O(n^3)$ time for dense graphs. A similar result is obtained for the 2-matching problem and its variants. We also derive the first approximation algorithms for many NP-complete problems, including the nonfixed point-to-point connection problem, the exact path partitioning problem, and complex location-design problems. Moreover, for the prize-collecting traveling salesman or Steiner tree problems, we obtain 2-approximation algorithms, therefore improving the previously best-known performance guarantees of 2.5 and 3, respectively [*Math. Programming*, 59 (1993), pp. 413–420].

Key words. approximation algorithms, combinatorial optimization, matching, Steiner tree problem, T-joins, traveling salesman problem

1. Introduction.

Given a graph $G = (V, E)$, a function $f : 2^V \to \{0, 1\}$, and a nonnegative cost function $c : E \to \mathbb{Q}_+$, we consider the following integer program:

$$
\begin{aligned}
&\text{Min} && \sum_{e \in E} c_e x_e && \\
&\text{subject to:} && && \\
(IP) \qquad & && x(\delta(S)) \geq f(S) && \emptyset \neq S \subset V \\
& && x_e \in \{0, 1\} && e \in E
\end{aligned}
$$

where $\delta(S)$ denotes the set of edges having exactly one endpoint in S and $x(F) = \sum_{e \in F} x_e$. The integer program (IP) can be interpreted as a very special type of covering problem in which we need to find a minimum-cost set of edges that cover all cutsets $\delta(S)$ corresponding to sets S with $f(S) = 1$. The minimal solutions to (IP) are incidence vectors of forests. We therefore refer to the graph problem associated with (IP) as *a constrained forest problem*. Let (LP) denote the linear programming relaxation of (IP) obtained by relaxing the integrality restriction on the variables x_e to $x_e \geq 0$. For the most part we will consider constrained forest problems corresponding to *proper* functions; that is, a function $f : 2^V \to \{0, 1\}$ such that the following properties hold:

(i) [Symmetry] $f(S) = f(V - S)$ for all $S \subseteq V$; and
(ii) [Disjointness] If A and B are disjoint, then $f(A) = f(B) = 0$ implies $f(A \cup B) = 0$.

We also assume that $f(V) = 0$. Many interesting families of forests can be modelled by (IP) with proper functions. In Table 1, we have indicated some examples of proper functions along with the corresponding set of minimal forests. Thus the minimum-cost spanning tree, shortest path, Steiner tree, and T-join problems (see §3 for definitions) can be stated as *proper* constrained forest problems; that is, they can be modelled as (IP) with a proper function. Many more complex combinatorial optimization problems, such as the nonfixed point-to-point connection problem and the generalized Steiner tree problem, are also proper constrained forest problems.

TABLE 1
Examples of proper functions and proper constrained forest problems.

Input	$f(S)$	Minimal forests
	$f(S) = 1 \quad \forall S$	Spanning trees
$s, t \in V$	$f(S) = \begin{cases} 1 & \lvert S \cap \{s, t\}\rvert = 1 \\ 0 & \text{otherwise} \end{cases}$	s-t paths
$T \subseteq V$	$f(S) = \begin{cases} 1 & \emptyset \neq S \cap T \neq T \\ 0 & \text{otherwise} \end{cases}$	Steiner trees with terminals T
$T \subseteq V$	$f(S) = \begin{cases} 1 & \lvert S \cap T\rvert \text{ odd} \\ 0 & \text{otherwise} \end{cases}$	T-joins

Since many proper constrained forest problems are NP-complete, we focus our attention on heuristics. If a heuristic algorithm for an optimization problem delivers a solution guaranteed to be within a factor of α of optimal, it is said to have a *performance guarantee* of α. Furthermore, if it runs in polynomial time, it is called an α-approximation algorithm. In this paper, we present a $(2 - \frac{2}{|A|})$-approximation algorithm for proper constrained forest problems, where $A = \{v \in V : f(\{v\}) = 1\}$. Our algorithm runs in $O(\min(n^2 \log n, mn\alpha(m, n)))$ time, where $n = |V|$, $m = |E|$, and α is the inverse Ackermann function. For the sake of the analysis, we implicitly construct a feasible solution to the dual linear program to (LP), and we prove that the value of our approximate integral primal solution is within a factor of $2 - \frac{2}{|A|}$ of the value of this dual solution. Therefore, for all proper functions f, the ratio between the optimal values of (IP) and (LP) is upper bounded by $2 - \frac{2}{|A|}$. This result can be contrasted with the various logarithmic upper bounds on the ratio between the optimal values of general integer covering problems and their fractional counterparts (Johnson [19], Lovász [27], and Chvátal [5]).

Our algorithm can be characterized in several ways. It is an *adaptive greedy* algorithm in which, at every iteration, the edge with minimum *reduced* cost is selected. It is adaptive in the sense that the reduced costs are updated throughout the execution of the algorithm. It can also be seen as a primal-dual algorithm in which, alternately, primal and dual updates are performed.

Our approximation algorithm generalizes many classical exact and approximate algorithms. When applied to the spanning tree problem, it reduces to Kruskal's greedy algorithm [23]. For the s-t shortest path problem, our algorithm is reminiscent of the variant of Dijkstra's algorithm that uses bidirectional search (Nicholson [28]). The algorithm is exact in these two cases. For the Steiner tree problem, we obtain the minimum spanning tree heuristic whose many variants have been described in the literature (see [39]). In the case of the generalized Steiner tree problem, our algorithm simulates Agrawal, Klein, and Ravi's 2-approximation algorithm [1]. Their algorithm was instrumental in motivating our work. In particular, we generalize their use of duality from generalized Steiner trees to all proper constrained forest problems. In the process, we make their use of linear programming duality explicit and

provide some conceptual simplifications since neither our algorithm nor its analysis require contractions, recursive calls to construct the forest or subdivisions of edges, as is used in the presentation of Agrawal, Klein, and Ravi [1].

One important consequence of the algorithm is that it can be turned into a 2-approximation algorithm for the minimum-weight perfect matching problem given that the edge costs obey the triangle inequality. Our running time of $O(n^2 \log n)$ time is faster than the currently best-known algorithms that solve the problem exactly (due to Gabow [11] and Gabow and Tarjan [13]) on all but very sparse graphs. In addition, our algorithm improves upon all known approximation algorithms for this problem in either running time or performance guarantee.

Given the triangle inequality, the algorithm can also be turned into an approximation algorithm for related problems involving cycles or paths, instead of trees. This observation allows us to consider additional problems such as the traveling salesman problem, Hamiltonian location problems [25], and many other problems. Our algorithm can also be extended to handle some nonproper constrained forest problems. In general, our technique applies to many NP-complete problems arising in the design of communication networks, VLSI design, and vehicle routing. We have also been able to apply the technique to the prize-collecting traveling salesman problem (given the triangle inequality) and the prize-collecting Steiner tree problem, thereby deriving the first 2-approximation algorithms for these problems.

The rest of the paper is structured as follows. In §2, we describe our approximation algorithm for proper constrained forest problems. We also present its analysis and an efficient implementation. In §3, we describe how the algorithm can be applied to the various proper constrained forest problems mentioned above. In §4, we show how to extend the algorithm and proof techniques to other problems, including the prize-collecting traveling salesman problem. We discuss previous work for particular constrained forest problems in §§3 and 4. We conclude in §5 with a discussion of subsequent work.

2. The algorithm for proper constrained forest problems.

2.1. Description. The main algorithm is shown in Fig. 1. The algorithm takes as input an undirected graph $G = (V, E)$, edge costs $c_e \geq 0$ for all $e \in E$, and a proper function f. The algorithm produces as output a set of edges F' whose incidence vector of edges is feasible for (IP). The basic structure of the algorithm involves maintaining a forest F of edges, which is initially empty. The edges of F will be candidates for the set of edges to be output. The algorithm loops, in every iteration selecting an edge (i, j) between two distinct connected components of F, then merging these two components by adding (i, j) to F. The loop terminates when $f(C) = 0$ for all connected components C of F; since $f(V) = 0$, the loop will finish after at most $n - 1$ iterations. The set F' of edges that are output consists of only the edges of F needed to meet the covering requirements. More precisely, if an edge e can be removed from F such that $f(C) = 0$ for all components C of $F - e$, then e is omitted from F'.

The approximation properties of the algorithm will follow from the way we choose the edge each iteration. The decision is based on a greedy construction of an implicit solution to the dual of (LP). This dual is

$$
\begin{aligned}
& \text{Max} && \sum_{S \subset V} f(S) \cdot y_S && \\
& \text{subject to:} && && \\
(D) \qquad & && \sum_{S : e \in \delta(S)} y_S \leq c_e && e \in E, \\
& && y_S \geq 0 && \emptyset \neq S \subset V.
\end{aligned}
$$

Input: An undirected graph $G = (V, E)$, edge costs $c_e \geq 0$, and a proper function f
Output: A forest F' and a value LB

1 $F \leftarrow \emptyset$
2 *Comment: Implicitly set* $y_S \leftarrow 0$ *for all* $S \subset V$
3 $LB \leftarrow 0$
4 $\mathcal{C} \leftarrow \{\{v\} : v \in V\}$
5 For each $v \in V$
6 $d(v) \leftarrow 0$
7 While $\exists C \in \mathcal{C} : f(C) = 1$
8 Find edge $e = (i, j)$ with $i \in C_p \in \mathcal{C}$, $j \in C_q \in \mathcal{C}$, $C_p \neq C_q$ that minimizes $\epsilon = \frac{c_e - d(i) - d(j)}{f(C_p) + f(C_q)}$
9 $F \leftarrow F \cup \{e\}$
10 For all $v \in C_r \in \mathcal{C}$ do $d(v) \leftarrow d(v) + \epsilon \cdot f(C_r)$
11 *Comment: Implicitly set* $y_C \leftarrow y_C + \epsilon \cdot f(C)$ *for all* $C \in \mathcal{C}$.
12 $LB \leftarrow LB + \epsilon \sum_{C \in \mathcal{C}} f(C)$
13 $\mathcal{C} \leftarrow \mathcal{C} \cup \{C_p \cup C_q\} - \{C_p\} - \{C_q\}$
14 $F' \leftarrow \{e \in F :$ For some connected component N of $(V, F - \{e\})$, $f(N) = 1\}$

FIG. 1. *The main algorithm.*

Define an *active component* to be any component C of F for which $f(C) = 1$. In each iteration the algorithm tries to increase y_C uniformly for each active component C by a value ϵ that is as large as possible without violating the packing constraints $\sum y_S \leq c_e$. Finding such an ϵ will make a packing constraint tight for some edge (i, j) between two distinct components; the algorithm will then add (i, j) to F and merge these two components. An alternate view of this process is that the algorithm tries to find the edge (i, j) between distinct components with the minimum "reduced" cost ϵ.

We claim that the algorithm shown in Fig. 1 behaves in exactly this manner. To see that the dual solution generated in steps 2 and 11 is feasible for (D), note first that initially $\sum_{e \in \delta(S)} y_S = 0 \leq c_e$ for all $e \in E$. We show by induction that the packing constraints continue to hold. Note that it can be shown by induction that $d(i) = \sum_{S: i \in S} y_S$ for each vertex i; thus as long as vertices i and j are in different components, $\sum_{e \in \delta(S)} y_S = d(i) + d(j)$ for edge $e = (i, j)$. It follows that in a given iteration y_C can be increased by ϵ for each active component C without violating the packing constraints as long as

$$d(i) + d(j) + \epsilon \cdot f(C_p) + \epsilon \cdot f(C_q) \leq c_e,$$

for all $e = (i, j) \in E$, $i \in C_p$ and $j \in C_q$, C_p and C_q distinct. Thus the largest feasible increase in ϵ for a particular iteration is given by the formula in step 8. Once the endpoints i and j of an edge $e = (i, j)$ are in the same component, the sum $\sum_{S: e \in \delta(S)} y_S$ does not increase, so that these packing constraints will continue to hold. Hence when the algorithm terminates, the dual solution y constructed by the algorithm will be feasible for (D). By the preceding discussion, we also have that $c_e = \sum_{S: e \in \delta(S)} y_S$ for each $e \in F$. Note that the value LB computed in steps 3 and 12 corresponds to the value of the dual solution y. As the value of the dual solution is a lower bound on the optimal cost, LB provides a guarantee on the performance of the algorithm for any specific instance. Furthermore, LB will also be used in the analysis below to evaluate the worst-case performance guarantee of the algorithm.

To complete our claim that the algorithm in Fig. 1 behaves as described, we need to show that the edges removed in the final step of the algorithm are not necessary to meet the covering requirements; in other words, we need to show that F' is a feasible solution to (IP). We do this below.

Two snapshots of the algorithm for the proper function $f(S) \equiv |S| (\text{mod } 2)$ are shown in Figs. 2 and 3. The two snapshots are one iteration apart. In both figures, the cost of an edge is the Euclidean distance between its endpoints. The radius around each vertex v represents the value $d(v)$. Thick radii represent active components, thin radii inactive components. The region of the plane defined by these radii are the so-called moats of Jünger and Pulleyblank [20], [21]. The set of edges F at the end of the main loop is shown in Fig. 4, and the set of edges F' output by the algorithm is shown in Fig. 5.

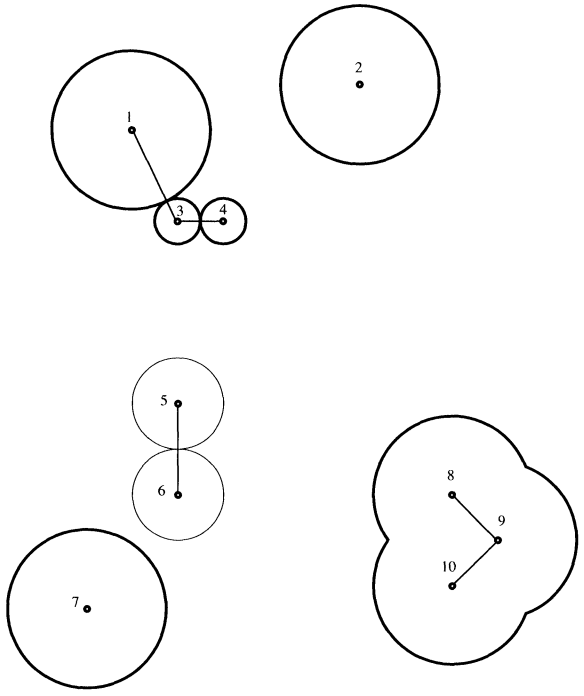

FIG. 2. *Snapshot of the algorithm.*

We can now see that the algorithm is a generalization of some classical graph algorithms. The shortest s-t path problem corresponds to the proper function $f(S) = 1$ if and only if $|S \cap \{s, t\}| = 1$. Our algorithm adds minimum-cost edges extending paths from both s and t in a manner reminiscent of Nicholson's bidirectional shortest path algorithm [28]. The main loop terminates when s and t are in the same component, and the final step of the algorithm removes all edges not on the path from s to t. Thus for this problem, whenever $y_S > 0$, $|F' \cap \delta(S)| = 1$, and whenever $e \in F'$, $\sum_{S:e \in \delta(S)} y_S = c_e$. In other words, the primal and dual feasible solutions F' and y obey the complementary slackness conditions; hence the solutions are optimal. Note that the edge removal step is necessary to obtain a good performance guarantee in this case; this statement is also true in general. The minimum-cost spanning tree problem corresponds to a proper function $f(S) = 1$ for $\emptyset \subset S \subset V$. For this function f, our algorithm reduces to Kruskal's algorithm: all components will always be active, and thus in each iteration the minimum-cost edge joining two components will be selected. Since Kruskal's algorithm produces the optimal minimum-cost spanning tree, our algorithm will also. The solutions produced do not obey the complementary slackness conditions for (LP), but induce optimal solutions for a stronger linear programming formulation of the spanning tree problem introduced by Jünger and Pulleyblank [20].

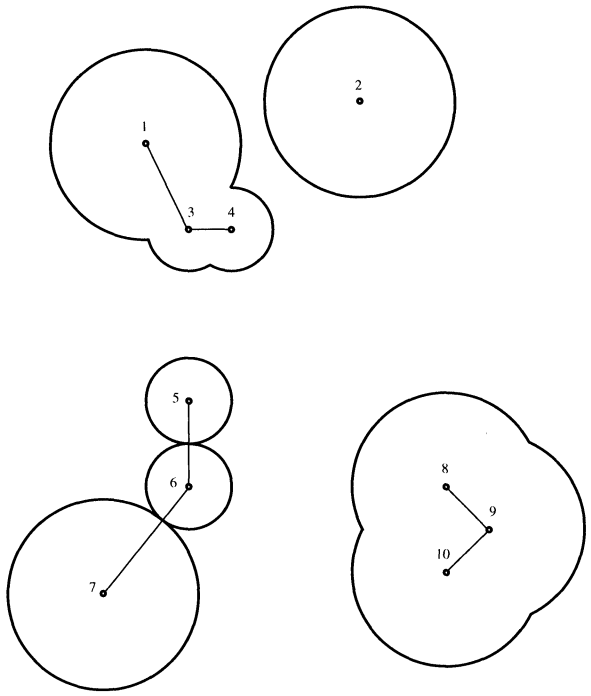

FIG. 3. *Snapshot of the algorithm one iteration later.*

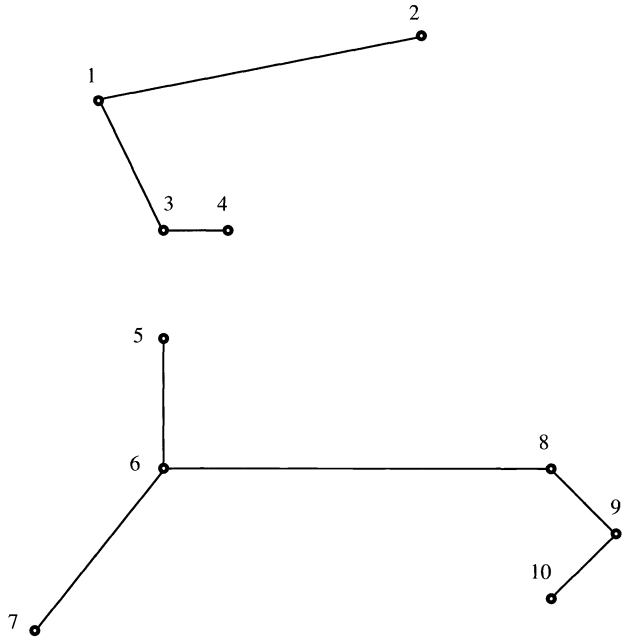

FIG. 4. *Set of edges after the main loop terminates.*

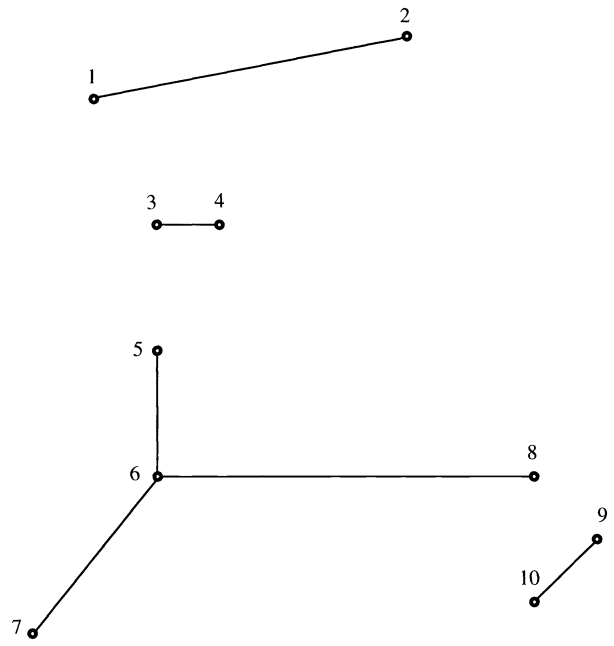

FIG. 5. *Final set of edges.*

2.2. Analysis. We now need to show that the algorithm has the properties we claim. We will begin by showing that the algorithm produces a feasible solution, and then we will turn to proving that the solution is within a factor of $(2 - \frac{2}{|A|})$ of the optimal solution. We assume throughout the ensuing discussion that F is the set of candidate edges selected by the algorithm, F' is the forest output by the algorithm, and that x' is the incidence vector of edges of F'.

OBSERVATION 2.1. *If* $f(S) = 0$ *and* $f(B) = 0$ *for some* $B \subseteq S$, *then* $f(S - B) = 0$.

Proof. By the symmetry property of f, $f(V - S) = f(S) = 0$. By disjointness, $f((V - S) \cup B) = 0$. By symmetry again, $f(S - B) = f((V - S) \cup B) = 0$. □

LEMMA 2.2. *For each connected component* N *of* F', $f(N) = 0$.

Proof. By the construction of F', $N \subseteq C$ for some component C of F. Now, let $e_1, \ldots, e_k$ be edges of F such that $e_i \in \delta(N)$ (possibly $k = 0$). Let N_i and $C - N_i$ be the two components created by removing e_i from the edges of component C, with $N \subseteq C - N_i$ (see Fig. 6). Note that since $e_i \notin F'$, it must be the case that $f(N_i) = 0$. Note also that the sets $N, N_1, N_2, \ldots, N_k$ form a partition of C. So then $f(C - N) = f(\cup_{i=1}^{k} N_i) = 0$ by disjointness. Because $f(C) = 0$, the observation above implies that $f(N) = 0$. □

THEOREM 2.3. *The incidence vector* x' *is a feasible solution to* (IP).

Proof. Suppose not, and assume that $x'(\delta(S)) = 0$ for some S such that $f(S) = 1$. Let $N_1, \ldots, N_p$ be the components of F'. In order for $x'(\delta(S)) = 0$, it must be the case that for all i, either $S \cap N_i = \emptyset$ or $S \cap N_i = N_i$. Thus $S = N_{i_1} \cup \cdots \cup N_{i_k}$ for some $i_1, \ldots, i_k$. By the lemma above, however, $f(N_i) = 0$ for all i, so $f(S) = 0$ by the disjointness of f. This contradicts our assumption that $f(S) = 1$. Therefore, x' must be a feasible solution. □

Now we will show that the algorithm has the approximation properties that we claim. For this purpose, we use the dual solution y implicitly constructed by the algorithm. Let Z_{LP}^* be the cost of the optimal solution to (LP), and let Z_{IP}^* be the cost of the optimal solution

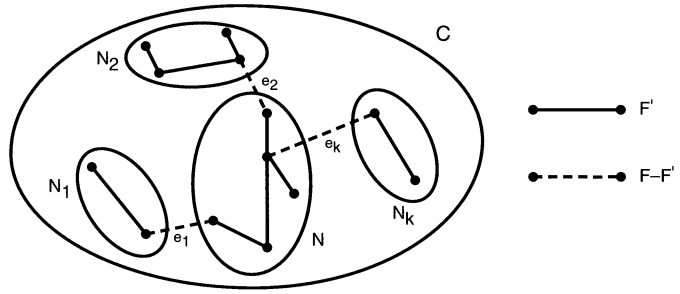

FIG. 6. *Illustration of Lemma* 2.2.

to (IP). Obviously $Z^*_{LP} \leq Z^*_{IP}$. Because y is a feasible dual solution and $y_S > 0$ only if $f(S) = 1$, it follows that $LB = \sum_{S \subset V} y_S \leq Z^*_{LP}$. We will now prove the following theorem.

THEOREM 2.4. *The algorithm in Fig.* 1 *produces a set of edges* F' *and a value* LB *such that*

$$\sum_{e \in F'} c_e \leq \left(2 - \frac{2}{|A|}\right) LB = \left(2 - \frac{2}{|A|}\right) \sum_{S \subset V} y_S \leq \left(2 - \frac{2}{|A|}\right) Z^*_{LP} \leq \left(2 - \frac{2}{|A|}\right) Z^*_{IP}.$$

Hence the algorithm is a $(2 - \frac{2}{|A|})$*-approximation algorithm for the constrained forest problem for any proper function* f.

Proof. Since we know that $\sum_{e \in F'} c_e = \sum_{e \in F'} \sum_{S : e \in \delta(S)} y_S$, by exchanging the summations we can rewrite $\sum_{e \in F'} c_e$ as $\sum_{S \subset V} y_S \cdot |F' \cap \delta(S)|$. To prove the theorem, we will show by induction on the main loop that

$$\sum_{S \subset V} y_S \cdot |F' \cap \delta(S)| \leq \left(2 - \frac{2}{|A|}\right) \sum_{S \subset V} y_S.$$

Certainly the inequality holds before the first iteration of the loop, since initially all $y_S = 0$. Consider the set $\mathcal{C}$ of components at the beginning of some iteration of the loop. The left-hand side of the inequality will increase by

$$\sum_{C \in \mathcal{C} : f(C) = 1} \epsilon \cdot |F' \cap \delta(C)|$$

in this iteration. If we can prove that this increase is bounded above by the increase of the right-hand side, namely

$$\left(2 - \frac{2}{|A|}\right) \epsilon \cdot |\mathcal{C}^1|,$$

where $\mathcal{C}^1 = \{C \in \mathcal{C} : f(C) = 1\}$, then we will be done.

The basic intuition behind the proof of this result is that the average degree of a vertex in a forest of at most $|A|$ vertices is at most $2 - \frac{2}{|A|}$. To begin, construct a graph H by considering the active and inactive components of this iteration as vertices of H, and the edges $e \in \delta(C) \cap F'$ for all $C \in \mathcal{C}$ as the edges of H. Remove all isolated vertices in H that correspond to inactive components. Note that H is a forest. We claim that no leaf in H corresponds to an inactive vertex. To see this, suppose otherwise, and let v be a leaf, C_v its associated inactive component, e the edge incident to v, and C the component of F that contains C_v. Let N and $C - N$ be the

two components formed by removing edge e from the edges of component C. Without loss of generality, say that $C_v \subseteq N$. The set $N - C_v$ is partitioned by some of the components of the current iteration; call these $C_1, \ldots, C_k$ (see Fig. 7). Since vertex v is a leaf, no edge in F' connects C_v to any C_i. Thus by the construction of F', $f(\cup C_i) = 0$. Since $f(C_v) = 0$ also, it follows that $f(N) = 0$. We know $f(C) = 0$, so by Observation 2.1 $f(C - N) = 0$ as well, and thus by the construction of F', $e \notin F'$, which is a contradiction.

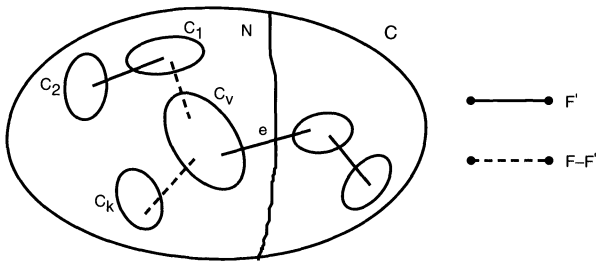

FIG. 7. *Illustration of claim that all leaves of H are active.*

In the graph H, the degree d_v of vertex v corresponding to component C must be $|\delta(C) \cap F'|$. Let N_a be the set of vertices in H corresponding to active components, so that $|N_a| = |\mathcal{C}^1|$. Let N_i be the set of vertices in H that correspond to inactive components. Then

$$\begin{aligned}\sum_{v \in N_a} d_v &= \sum_{v \in N_a \cup N_i} d_v - \sum_{v \in N_i} d_v \\ &\leq 2(|N_a| + |N_i| - 1) - 2|N_i| \\ &= 2|N_a| - 2.\end{aligned}$$

This inequality holds since H is a forest with at most $|N_a| + |N_i| - 1$ edges, and since each vertex corresponding to an inactive component has degree at least 2. Multiplying each side by ϵ, we obtain $\epsilon \sum_{v \in N_a} d_v \leq \epsilon(2|N_a| - 2)$, or

$$\epsilon \sum_{C \in \mathcal{C}^1} |F' \cap \delta(C)| \leq 2\epsilon(|\mathcal{C}^1| - 1) \leq \left(2 - \frac{2}{|A|}\right) \epsilon \cdot |\mathcal{C}^1|,$$

since the number of active components is always no more than $|A|$. Hence the theorem is proven. □

2.3. Implementing the algorithm. We now turn to the problem of implementing the algorithm efficiently and show how the algorithm can be made to run in $O(\min(n^2 \log n, mn\alpha(m, n)))$ time. We neglect the time taken to compute f from this discussion, since we can compute $f(C)$ in $O(n)$ time for all problems of interest, and since we need to perform this computation at most $O(n)$ times.

Some of the implementation details are obvious. For example, we can maintain the components C as a union-find structure of vertices. Then all merging will take at most $O(n\alpha(n, n))$ time overall, where α is the inverse Ackermann function [33]. The two main algorithmic problems arise from selecting the edge that minimizes ϵ at each iteration, and from finding the edges in F that belong in F'. We consider each of these problems separately.

As a naive approach to finding the minimum edge, we can simply use $O(m\alpha(m, n))$ time each iteration to compute the reduced cost $(c_e - d(i) - d(j))/(f(C_p) + f(C_q))$ for each edge $e = (i, j)$ and to check whether the edge spans two different components. Other loop

operations take $O(n)$ time, resulting in a running time of $O(mn\alpha(m, n))$ for the main loop, since there are at most $n - 1$ iterations.

By being somewhat more careful, we can reduce the time taken to find the minimum edge in dense graphs to $O(n \log n)$. We need three ideas for this reduced time bound. The first idea is to introduce a notion of time into the algorithm. We let the time T be 0 at the beginning of the algorithm and increment it by the value of ϵ each time through the main loop. The second idea is that instead of computing the reduced cost for an edge every time through the loop, we can maintain a priority queue of edges, where the key of an edge is the time T at which its reduced cost is expected to be zero. If we know whether the components of an edge's endpoints are active or inactive, and assume that the activity (or inactivity) will continue indefinitely, it is easy to compute this time T. Of course the activity of a component can change, but this occurs only when it is merged with another component, and only edges incident to the component are affected. In this case, we can recompute the key for each incident edge, delete the element with the old key, and reinsert it with the new key. The last idea we need for the lower time bound is that we only need to maintain a single edge between any two components. If there is more than one edge between any two components, one of the edges will always have a reduced cost no greater than that of the others; hence the others may be removed from consideration altogether.

Combining these ideas, we get the following algorithm for the main loop: first, we calculate the initial key value for each edge and insert each edge into the queue (in time $O(m \log n)$). Each time through the loop, we find the minimum edge (i, j) by extracting the minimum element from the queue. If $i \in C_p$ and $j \in C_q$, we delete all edges incident to C_p and C_q from the queue. For each component C_r different from C_p and C_q we update the keys of the two edges from C_p to C_r and C_q to C_r, select the one edge that has the minimum key value, then reinsert it into the queue. Since there are at most n components at any point in time, each iteration will have $O(n)$ queue insertions and deletions, yielding a time bound of $O(n \log n)$ per iteration, or $O(n^2 \log n)$ for the entire loop.

To compute F' from F, we iterate through the components C of F. Given a component C, we root the tree at some vertex, put each leaf of the tree in a separate list, and compute the f value for each of the leaves. An edge joining a vertex to its parent is discarded if the f value for the set of vertices in its subtree is 0. Whenever we have computed the f value for all the children of some vertex v, we concatenate the lists of all the children of v, add v to the list, and compute f of the vertices in the list. We continue this process until we have examined every edge in the tree. Since there are $O(n)$ edges, the process takes $O(n)$ time.

3. Applications of the algorithm. In this section, we list several problems to which the algorithm can be applied.

The generalized Steiner tree problem. The generalized Steiner tree problem is the problem of finding a minimum-cost forest that connects all vertices in T_i for $i = 1, \ldots, p$. The generalized Steiner tree problem is a proper constrained forest problem with $f(S) = 1$ if there exists $i \in \{1, \ldots, p\}$ with $\emptyset \neq S \cap T_i \neq T_i$ and 0 otherwise. In this case, our approximation algorithm has a performance guarantee of $2 - \frac{2}{k}$, where $k = \left|\bigcup_{i=1,\ldots,p} T_i\right|$, and simulates an algorithm of Agrawal, Klein, and Ravi [1]. Their algorithm was the first approximation algorithm for this problem.

When $p = 1$, the problem reduces to the classical Steiner tree problem. For a long time, the best approximation algorithm for this problem had a performance guarantee of $(2 - \frac{2}{k})$ (for a survey, see Winter [39]) but, very recently, Zelikovsky [40] obtained an $\frac{11}{6}$−approximation algorithm. An improved $\frac{16}{9}$-approximation algorithm based upon Zelikovsky's ideas was later proposed by Berman and Ramaiyer [3].

The performance guarantee of the algorithm can be shown to be tight for this problem. When $p = 1$, our algorithm reduces to the standard minimum-cost spanning tree heuristic (see Goemans and Bertsimas [15]). The heuristic can produce solutions which have cost $2 - \frac{2}{k}$ times the optimal cost, as is shown in [15].

The T-join problem. Given an even subset T of vertices, the T-join problem consists of finding a minimum-cost set of edges that has odd degree at vertices in T and even degree at vertices not in T. Edmonds and Johnson [9] have shown that the T-join problem can be solved in polynomial time and can be formulated by the linear program (LP) with the proper function $f(S) = 1$ if $|S \cap T|$ is odd and 0 otherwise. The edge-removing step of our algorithm guarantees that the solution produced is a T-join (see below). Using our algorithm, we obtain a $(2 - \frac{2}{|T|})$-approximation algorithm for the T-join problem.

The performance guarantee of the algorithm is tight for the T-join problem. Figure 8(a)-(c) shows an example on eight vertices in which the minimum-cost V-join has cost $4+3\epsilon$, while the solution produced by the algorithm has cost 7, yielding a worst-case ratio of approximately $\frac{7}{4} = 2 - \frac{2}{8}$. Clearly the example can be extended to larger numbers of vertices and to an arbitrary set T.

When $|T| = 2$, the T-join problem reduces to the shortest path problem. Our algorithm is exact in this case, since $2 - \frac{2}{|T|} = 1$.

The minimum-weight perfect matching problem. The minimum-weight perfect matching problem is the problem of finding a minimum-cost set of nonadjacent edges that cover all vertices. This problem can be solved in polynomial time by the original primal-dual algorithm discovered by Edmonds [7]. The fastest strongly polynomial time implementation of Edmonds' algorithm is due to Gabow [11]. Its running time is $O(n(m + n \log n))$. For integral costs bounded by C, the best weakly polynomial algorithm runs in $O(m\sqrt{n\alpha(m, n) \log n} \log nC)$ time and is due to Gabow and Tarjan [13].

These algorithms are fairly complicated and, in fact, too time-consuming for large instances that arise in practice. This motivated the search for faster approximation algorithms. Reingold and Tarjan [30] have shown that the greedy procedure has a tight performance guarantee of $\frac{4}{3}n^{0.585}$ for general nonnegative cost functions. Supowit, Plaisted, and Reingold [32] and Plaisted [29] have proposed an $O(\min(n^2 \log n, m \log^2 n))$ time approximation algorithm for instances that obey the triangle inequality. Their algorithm has a tight performance guarantee of $2 \log_3(1.5n)$. As shown by Gabow and Tarjan [13], an exact scaling algorithm for the maximum-weight matching problem can be used to obtain an $(1 + 1/n^a)$-approximation algorithm ($a \geq 0$) for the minimum-weight perfect matching problem. Moreover, if the original exact algorithm runs in $O(f(m, n) \log C)$ time, the resulting approximation algorithm runs in $O(m\sqrt{n \log n} + (1 + a) f(m, n) \log n)$. Vaidya [34] obtains a $(3 + 2\epsilon)$-approximation algorithm for minimum-weight perfect matching instances satisfying the triangle inequality. His algorithm runs in $O(n^2 \log^{2.5} n \log(1/\epsilon))$ time.

The algorithm for proper constrained forest problems can be used to approximate the minimum-weight perfect matching problem when the edge costs obey the triangle inequality. We use the algorithm with the proper function $f(S)$ being the parity of $|S|$, i.e., $f(S) = 1$ if $|S|$ is odd and 0 if $|S|$ is even. This function is the same as the one used for the V-join problem. The algorithm returns a forest whose components have even size. More precisely, the forest is a V-join, and each vertex has odd degree: if a vertex has even degree, then, by a parity argument, some edge adjacent to the vertex could have been deleted so that the resulting components have even size. Thus this edge would have been deleted in the final step of the algorithm. The forest can be transformed into a perfect matching with no increase of cost by repeatedly taking two edges (u, v) and (v, w) from a vertex v of degree three or more and replacing these edges with the edge (u, w). This procedure maintains the property

that the vertices have odd degree. After $O(n)$ iterations, each vertex has degree one. Since each iteration takes $O(1)$ time, the overall procedure gives an approximation algorithm for weighted perfect matching which runs in $O(n^2 \log n)$ time and has a performance guarantee of $2 - \frac{2}{n}$.

The performance guarantee of the algorithm is tight for this problem also, as in shown in Fig. 8(d).

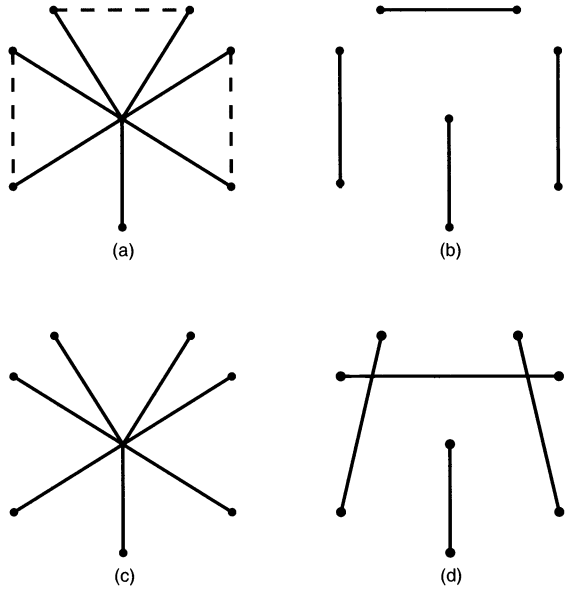

FIG. 8. *Worst-case example for V-join or matching. Graph* (a) *gives the instance: plain edges have cost* 1, *dotted edges have cost* $1 + \epsilon$, *and all other edges have cost* 2. *Graph* (b) *is the minimum-cost solution. Graph* (c) *is the set of edges found by the constrained forest algorithm, and graph* (d) *shows a bad (but possible) shortcutting of the edges to a matching.*

Point-to-point connection problems. In the point-to-point connection problem, we are given a set $C = \{c_1, \ldots, c_p\}$ of sources and a set $D = \{d_1, \ldots, d_p\}$ of destinations in a graph $G = (V, E)$ and we need to find a minimum-cost set F of edges such that each source-destination pair is connected in F [26]. This problem arises in the context of circuit switching and VLSI design. The fixed destination case in which c_i is required to be connected to d_i is a special case of the generalized Steiner tree problem where $T_i = \{c_i, d_i\}$. In the nonfixed destination case, each component of the forest F is only required to contain the same number of sources and destinations. This problem is NP-complete [26].

The nonfixed case is a proper constrained forest problem with $f(S) = 1$ if $|S \cap C| \neq |S \cap D|$ and 0 otherwise. For this problem, we obtain a $(2 - \frac{1}{p})$-approximation algorithm.

Exact partitioning problems. In the exact tree (cycle, path) partitioning problem, for a given k we must find a minimum-cost collection of vertex-disjoint trees (cycles, paths) of size k that cover all vertices. These problems and related NP-complete problems arise in the design of communication networks, vehicle routing, and cluster analysis. These problems generalize the minimum-weight perfect matching problem (in which each component must have size exactly 2), the traveling salesman problem, the Hamiltonian path problem, and the minimum-cost spanning tree problem.

We can approximate the exact tree, cycle, and path partitioning problems for instances that satisfy the triangle inequality. For this purpose, we consider the proper constrained forest

problem with the function $f(S) = 1$ if $|S| \not\equiv 0 \pmod{k}$ and 0 otherwise. Our algorithm finds a forest in which each component has a number of vertices that is a multiple of k, and such that the cost of the forest is within $2 - \frac{2}{n}$ of the optimal such forest. Obviously the cost of the optimal such forest is a lower bound on the optimal exact tree and path partitions. Given the forest, we duplicate each edge and find a tour of each component by shortcutting the resulting Eulerian graph on each component. If we remove every kth edge of the tour, starting at some edge, the tour is partitioned into paths of k nodes each. Some choice of edges to be removed (i.e., some choice of starting edge) accounts for at least $\frac{1}{k}$ of the cost of the tour, and so we remove these edges. Thus this algorithm is a $\left(4(1 - \frac{1}{k})(1 - \frac{1}{n})\right)$-approximation algorithm for the exact tree and path partitioning problems.

To produce a solution for the exact cycle partitioning problem, we add the edge joining the endpoints of each path; given the triangle inequality, this at most doubles the cost of the solution produced. We claim, however, that the algorithm is still a $\left(4(1 - \frac{1}{k})(1 - \frac{1}{n})\right)$-approximation algorithm for the cycle problem. To see that this claim is true, note that the following linear program is a linear programming relaxation of the exact cycle partitioning program, given the function f above:

$$\begin{aligned} \text{Min} \quad & \sum_{e \in E} c_e x_e & \\ \text{subject to:} & & \\ & x(\delta(S)) \geq 2f(S) & S \subset V \\ & x_e \geq 0 & e \in E. \end{aligned}$$

Its dual is

$$\begin{aligned} \text{Max} \quad & 2 \sum_{S \subset V} f(S) \cdot y_S & \\ \text{subject to:} & & \\ & \sum_{S : e \in \delta(S)} y_S \leq c_e & e \in E, \\ & y_S \geq 0 & \emptyset \neq S \subset V. \end{aligned}$$

We know the algorithm produces a solution y that is feasible for this dual such that $\sum_{e \in F'} c_e \leq (2 - \frac{2}{n}) \sum y_S$. The argument above shows how to take the set of edges F' and produce a set of edges T such that T is a solution to the exact cycle partitioning problem, and $\sum_{e \in T} c_e \leq 4(1 - \frac{1}{k}) \sum_{e \in F'} c_e$, so that

$$\sum_{e \in T} c_e \leq 8 \left(1 - \frac{1}{k}\right) \left(1 - \frac{1}{n}\right) \sum y_S.$$

Since $2 \sum y_S$ is the dual objective function, $2 \sum y_S$ is a lower bound on the cost of the optimal exact cycle partition, Z_C^*. Thus

$$\sum_{e \in T} c_e \leq 4 \left(1 - \frac{1}{k}\right) \left(1 - \frac{1}{n}\right) Z_C^*.$$

The proper functions corresponding to the nonfixed point-to-point connection problem, the T-join problem and the exact partitioning problems are all of the form $f(S) = 1$ if $\sum_{i \in S} a_i \not\equiv 0 \pmod{p}$ and 0 otherwise, for some integers a_i, $i \in V$, and some integer p.

4. Extensions. The main algorithm can be extended in a number of ways to handle nonproper functions f and even other somewhat different integer programming problems. We describe these extensions in this section.

4.1. More general functions f. We can weaken the conditions for a proper function f and obtain a modified $(2 - \frac{1}{n})$-approximation algorithm for the constrained forest problem. A number of new problems can be approximated under these weaker conditions; these problems are listed below. To solve these problems, the main algorithm must be modified to handle functions f that are not symmetric and cannot be made symmetric without violating disjointness. The central modifications that must be made involve maintaining a root vertex for each component, to cope with the asymmetry of f, and maintaining sets of vertices that must be connected in the final solution.

We omit discussion of the extended algorithm here because a recent algorithm of Williamson et al. [38] simplifies and subsumes our extended algorithm. Williamson et al. have shown how some of the results of this paper can be extended to *uncrossable* functions h. A function $h : 2^V \to \{0, 1\}$ is uncrossable if whenever $h(A) = h(B) = 1$ then either $h(A - B) = h(B - A) = 1$, or $h(A \cup B) = h(A \cap B) = 1$. Williamson et al. show that an algorithm somewhat similar to our algorithm finds solutions to (IP) for uncrossable functions that are within a factor of $2 - \frac{1}{n}$ of optimal. The algorithm can be implemented in polynomial time for many uncrossable functions, including those for which the function has the property that if $h(A) = 1$ then $h(B) = 1$ for $\emptyset \neq B \subset A$. The problems listed below fit in this category. See Williamson [36] and Goemans and Williamson [17] for a discussion of how the techniques of Williamson et al. apply to these problems.

Lower capacitated partitioning problems. The *lower capacitated partitioning problems* are like the exact partitioning problems except that each component is required to have at least k vertices rather than exactly k vertices. The lower capacitated *cycle* partitioning problem is a variant of the 2-matching problem. More precisely, the cases $k = 2$, 3, and 4 correspond to integer, binary, and triangle-free binary 2-matchings, respectively. The lower capacitated cycle partitioning problem is NP-complete for $k \geq 5$ (Papadimitriou (as reported in [6]) for $k \geq 6$ and Vornberger [35] for $k = 5$), polynomially solvable for $k = 2$ or 3 (Edmonds and Johnson [8]), while its complexity for $k = 4$ is open. Imielinska, Kalantari, and Khachiyan [18] have shown that the lower capacitated tree partitioning problem is NP-complete for $k \geq 4$.

The lower capacitated tree partitioning problem is the constrained forest problem corresponding to $f(S) = 1$ if $0 < |S| < k$ and 0 otherwise. The extended algorithm gives a $(2 - \frac{1}{n})$-approximation algorithm for this problem for any k. Furthermore, assuming the triangle inequality, this algorithm can be turned into a $(2 - \frac{1}{n})$-approximation algorithm for the lower capacitated cycle partitioning problem and a $(4 - \frac{2}{n})$-approximation algorithm for the lower capacitated path partitioning problem.

Location-design and location-routing problems. Many network design or vehicle routing problems require two levels of decisions. In the first level, the location of special vertices, such as concentrators or switches in the design of communication networks, or depots in the routing of vehicles, need to be decided. There is typically a set of possible locations and a fixed cost is associated with each of them. Once the locations of the depots are decided, the second level deals with the design or routing per se. These problems are called location-design or location-routing problems [24]. Several of these problems can be approximated using the extended algorithm. For example, we can provide a $(2 - \frac{1}{n})$-approximation algorithm for the problem in which we need to select depots among a subset D of vertices of a graph $G = (V, E)$ and cover all vertices in V with a set of cycles, each containing a selected depot [25], [24]. The goal is to minimize the sum of the fixed costs of opening our depots and the sum of the

costs of the edges of our cycles. The algorithm can also be extended to the case in which every cycle is required to have at least k vertices.

4.2. Nonnegative functions f. Using techniques from Goemans and Bertsimas [15], we can provide approximation algorithms for many functions $f : 2^V \to \mathbb{N}$, assuming that we can have multiple copies of an edge in the solution. Suppose f satisfies $f(S) = f(V - S)$ for all $S \subseteq V$, and, if A and B are disjoint, then $\max\{f(A), f(B)\} \geq f(A \cup B)$. Suppose also that f assumes at most p different nonzero values, $\rho_0 = 0 < \rho_1 < \cdots < \rho_p$. Let (IP') denote the integer program (IP) with the $x_e \in \{0, 1\}$ constraint replaced by the constraint $x_e \in \mathbb{N}$. Then we can show that there is an approximation algorithm for (IP') that comes within a factor of $2\sum_{k=1}^{p}(\rho_k - \rho_{k-1})/\rho_k$ of optimal. Note that at worst the values of f will be $0, 1, 2, 3, \ldots, f_{\max} = \max_S f(S)$, so that the performance guarantee will be at most $2\sum_{k=1}^{f_{\max}} \frac{1}{k} = O(\log f_{\max})$. The performance guarantee will also be no worse than $2p$. The algorithm for (IP') works by performing p iterations of our main algorithm. In iteration i, set $g(S) = 1$ if $f(S) \geq \rho_{p+1-i}$, $g(S) = 0$ otherwise, and call the main algorithm with function g. By the properties of f, g will be a proper function for the main algorithm. When the algorithm returns F', we make $(\rho_{p+1-i} - \rho_{p-i})$ copies of each edge, and add them to the set of edges to be output. The proof that constructing a set of edges in this way comes within a factor of $2\sum_{k=1}^{p}(\rho_k - \rho_{k-1})/\rho_k$ of optimal is essentially the same as the proof used by Goemans and Bertsimas. We can potentially reduce the number of calls to our main algorithm by using a "scaling" technique introduced by Agrawal, Klein, and Ravi [1], which requires $\lfloor \log f_{\max} \rfloor + 1$ iterations. In iteration i, we set $g(S) = 1$ if $f(S) \geq 2^{\lfloor \log f_{\max} \rfloor + 1 - i}$, $g(S) = 0$ otherwise, and call the main algorithm with the function g. We make $2^{\lfloor \log f_{\max} \rfloor + 1 - i}$ copies of the edges in the resulting F', and add them to the set of edges to be output. Using the Goemans and Bertsimas proof, it can be shown that this procedure results in a $(2\lfloor \log f_{\max} \rfloor + 2)$-approximation algorithm.

One application of allowing $f_{\max} > 1$ is the generalized Steiner network problem in which each pair of vertices i, j must be connected by r_{ij} edge-disjoint paths. In this case we want $f(S) = \max_{i \in S, j \notin S} r_{ij}$ For this particular problem, Agrawal, Klein, and Ravi [1] showed how to reduce this general case to the 0-1 case.

Williamson et al. [38] have recently shown how to approximate (IP) for functions of the type mentioned above when no edge replication is allowed.

4.3. The prize-collecting problems. The prize-collecting traveling salesman problem is a variation of the classical traveling salesman problem (TSP). In addition to the cost on the edges, we have also a penalty π_i on each vertex i. The goal is to find a tour on a subset of the vertices that minimizes the sum of the cost of the edges in the tour and the vertices not in the tour. We consider the version in which a prespecified root vertex r has to be in the tour; this is without loss of generality, since we can repeat the algorithm n times, setting each vertex to be the root. This version of the prize-collecting TSP is a special case of a more general problem introduced by Balas [2]. The prize-collecting Steiner tree problem is defined analogously. The standard Steiner tree problem can be seen to be a special case of the prize-collecting Steiner tree problem in which nonterminals have a penalty of zero, while terminals have a very large penalty (e.g., equal to the diameter of the graph).

Bienstock et al. [4] developed the first approximation algorithms for these problems. Their performance bounds are $5/2$ for the TSP version (assuming the triangle inequality) and 3 for the Steiner tree version. These approximation algorithms are not very efficient, however, since they are based upon the solution of a linear programming problem.

These problems do not fit in the framework of problems considered so far since they cannot be modelled by (IP). However, the main algorithm can be modified to give a $(2 - \frac{1}{n-1})$-

approximation algorithm for both the prize-collecting TSP (under the triangle inequality) and the prize-collecting Steiner tree problem. Moreover, these algorithms are purely combinatorial and do not require the solution of a linear programming problem as in [4]. We will focus our attention on the prize-collecting Steiner tree problem, and at the end of the section we will show how the algorithm for the tree problem can be easily modified to yield a prize-collecting TSP algorithm.

4.3.1. The prize-collecting Steiner tree. The prize-collecting Steiner tree can be formulated as the following integer program:

$$\text{Min} \quad \sum_{e \in E} c_e x_e + \sum_{T \subset V; r \notin T} z_T \left(\sum_{i \in T} \pi_i \right)$$

subject to:

$$\begin{aligned}
& x(\delta(S)) + \sum_{T \supseteq S} z_T \geq 1 && S \subset V; r \notin S \\
& \sum_{T \subset V; r \notin T} z_T \leq 1 && \\
& x_e \in \{0, 1\} && e \in E \\
& z_T \in \{0, 1\} && T \subset V; r \notin T.
\end{aligned} \tag{PC-IP}$$

Intuitively, z_T is set to 0 for all T except the set T of all vertices not spanned by the tree of selected edges. A linear programming relaxation $(PC\text{-}LP)$ of the integer program can be created by replacing the integrality constraints with the constraints $x_e \geq 0$ and $z_T \geq 0$ and dropping the constraint $\sum_T z_T \leq 1$ (in fact, including this constraint does not affect the optimal solution). The LP relaxation $(PC\text{-}LP)$ can be shown to be equivalent to the following, perhaps more natural, linear programming relaxation of the prize-collecting Steiner tree problem, which was used by the algorithm of Bienstock et al. [4]:

$$\text{Min} \quad \sum_{e \in E} c_e x_e + \sum_{i \neq r} (1 - s_i) \pi_i$$

subject to:

$$\begin{aligned}
& x(\delta(S)) \geq s_i && i \in S; r \notin S \\
& x_e \geq 0 && e \in E \\
& s_i \geq 0 && i \in V; i \neq r.
\end{aligned}$$

The dual of $(PC\text{-}LP)$ can be formulated as follows:

$$\text{Max} \quad \sum_{S: r \notin S} y_S$$

subject to:

$$\begin{aligned}
& \sum_{S: e \in \delta(S)} y_S \leq c_e && e \in E \\
& \sum_{S \subseteq T} y_S \leq \sum_{i \in T} \pi_i && T \subset V; r \notin T \\
& y_S \geq 0 && S \subset V; r \notin S.
\end{aligned} \tag{PC-D}$$

The algorithm for the prize-collecting Steiner tree problem is shown in Fig. 9. The basic structure of this algorithm is similar to that of the main algorithm. The algorithm maintains a forest F of edges, which is initially empty. Hence each vertex v is initially in its own connected

component. All components except the root r are considered active, and each vertex is initially unmarked. The algorithm loops, in each iteration doing one of two things. First, the algorithm may add an edge between two connected components of F. If the resulting component contains the root r, it becomes inactive; otherwise it is active. Second, the algorithm may decide to "deactivate" a component. Intuitively, a component is deactivated if the algorithm decides it is willing to pay the penalties for all vertices in the component. In this case, the algorithm labels each vertex in the component with the name of the component. The main loop terminates when all connected components of F are inactive. Since in each iteration the sum of the number of components and the number of active components decreases, the loop terminates after at most $2n - 1$ iterations. The final step of the algorithm removes as many edges from F as possible while maintaining two properties. First, all unmarked vertices must be connected to the root, since these vertices were never in any deactivated component and the algorithm was never willing to pay the penalty for these vertices. Second, if a vertex with label C is connected to the root, then so is every vertex with label $C' \supseteq C$.

Input: An undirected graph $G = (V, E)$, edge costs $c_{ij} \geq 0$, vertex penalties $\pi_i \geq 0$, and a root vertex r
Output: A tree F', which includes vertex r, and a set of unspanned vertices X

$F \leftarrow \emptyset$
Comment: Implicitly set $y_S \leftarrow 0$ *for all* $S \subset V$
$\mathcal{C} \leftarrow \{\{v\} : v \in V\}$
For each $v \in V$
  Unmark v
  $d(v) \leftarrow 0$
  $w(\{v\}) \leftarrow 0$
  If $v = r$ then $\lambda(\{v\}) \leftarrow 0$ else $\lambda(\{v\}) \leftarrow 1$
While $\exists C \in \mathcal{C} : \lambda(C) = 1$
  Find edge $e = (i, j)$ with $i \in C_p \in \mathcal{C}$, $j \in C_q \in \mathcal{C}$, $C_p \neq C_q$ that minimizes $\epsilon_1 = \frac{c_e - d(i) - d(j)}{\lambda(C_p) + \lambda(C_q)}$
  Find $\tilde{C} \in \mathcal{C}$ with $\lambda(\tilde{C}) = 1$ that minimizes $\epsilon_2 = \sum_{i \in \tilde{C}} \pi_i - w(\tilde{C})$
  $\epsilon = \min(\epsilon_1, \epsilon_2)$
  $w(C) \leftarrow w(C) + \epsilon \cdot \lambda(C)$ for all $C \in \mathcal{C}$
  Comment: Implicitly set $y_C \leftarrow y_C + \epsilon \cdot \lambda(C)$ *for all* $C \in \mathcal{C}$
  For all $v \in C_r \in \mathcal{C}$
    $d(v) \leftarrow d(v) + \epsilon \cdot \lambda(C_r)$
  If $\epsilon = \epsilon_2$
    $\lambda(\tilde{C}) \leftarrow 0$
    Mark all unlabelled vertices of $\tilde{C}$ with label $\tilde{C}$
  else
    $F \leftarrow F \cup \{e\}$
    $\mathcal{C} \leftarrow \mathcal{C} \cup \{C_i \cup C_j\} - \{C_i\} - \{C_j\}$
    $w(C_p \cup C_q) \leftarrow w(C_p) + w(C_q)$
    If $r \in C_p \cup C_q$ then $\lambda(C_p \cup C_q) \leftarrow 0$ else $\lambda(C_p \cup C_q) \leftarrow 1$
F' is derived from F by removing as many edges as possible but so that the following two properties hold: (1) every unlabelled vertex is connected to r; (2) if vertex v with label C is connected to r, then so is every vertex with label $C' \supseteq C$.
X is the set of all vertices not spanned by F'.

FIG. 9. *The algorithm for the prize-collecting Steiner tree problem.*

As with the main algorithm, the choices of the algorithm are motivated by the greedy construction of an implicit solution to the dual (PC-D). Initially all dual variables are set to

zero. In each iteration of the main loop, the algorithm increases y_C for all active C by a value ϵ that is as large as possible without violating the two types of packing constraints of $(PC\text{-}D)$: $\sum_{S:e\in\delta(S)} y_S \leq c_e$ for all $e \in E$, and $\sum_{S\subseteq T} y_S \leq \sum_{i\in T} \pi_i$ for all $T \subset V$. Increasing the y_C for active C by ϵ will cause one of the packing constraints to become tight. If one of the first kind of constraints becomes tight, then it becomes tight for some edge e between two connected components of the current forest F; hence we add this edge to F. If one of the second kind of constraints becomes tight, then it becomes tight for some active component C. In this case, the algorithm chooses to deactivate C.

We claim that the algorithm shown in Fig. 9 behaves exactly in the manner described above. The claim follows straightforwardly from the algorithm's construction of y and F, and from the fact that $d(i) = \sum_{S:i\in S} y_S$ and $w(C) = \sum_{S\subseteq C} y_S$ at the beginning of each iteration. Note that the algorithm keeps track of the activity of component C by setting $\lambda(C) = 1$ if and only if component C is active.

Let Z^*_{PCLP} and Z^*_{PCIP} be the optimal solutions to $(PC\text{-}LP)$ and $(PC\text{-}IP)$ respectively. Obviously $\sum_{S\subset V} y_S \leq Z^*_{PCLP} \leq Z^*_{PCIP}$. In a manner analogous to that of Theorem 2.4, we will show the following theorem.

THEOREM 4.1. *The algorithm in Fig. 9 produces a set of edges F' and a set of vertices X whose incidence vectors are feasible for $(PC\text{-}IP)$, and such that*

$$\sum_{e\in F'} c_e + \sum_{i\in X} \pi_i \leq (2 - \frac{1}{n-1}) \sum_{S\subset V} y_S \leq (2 - \frac{1}{n-1}) Z^*_{PCIP}.$$

Hence the algorithm is a $(2 - \frac{1}{n-1})$-approximation algorithm for the prize-collecting Steiner tree problem.

Proof. It is not hard to see that the algorithm produces a feasible solution to $(PC\text{-}IP)$, since F' has no nontrivial component not containing r and the component containing r is a tree.

By the construction of F', each vertex not spanned by F' (i.e., the vertices in X) lies in some component deactivated at some point during the algorithm. Furthermore, if the vertex was in some deactivated component C, then none of the vertices of C are spanned by F'. Using these observations, plus the manner in which components are formed by the algorithm, we can partition the vertices of X into disjoint deactivated components $C_1, \ldots, C_k$. These sets are the maximal labels of the vertices in X. Since each C_j is a deactivated component, it follows that $\sum_{S\subseteq C_j} y_S = \sum_{i\in C_j} \pi_i$, and thus that the inequality to be proven is implied by $\sum_{e\in F'} c_e + \sum_j \sum_{S\subseteq C_j} y_S \leq (2 - \frac{1}{n-1}) \sum_{S\subset V} y_S$. In addition, since $c_e = \sum_{S:e\in\delta(S)} y_S$ for each $e \in F'$ by construction of the algorithm, all we need to prove is that

$$\sum_{e\in F'} \sum_{S:e\in\delta(S)} y_S + \sum_j \sum_{S\subseteq C_j} y_S \leq (2 - \frac{1}{n-1}) \sum_{S\subset V} y_S,$$

or, rewriting terms as in Theorem 2.4,

$$\sum_S y_S |F' \cap \delta(S)| + \sum_j \sum_{S\subseteq C_j} y_S \leq (2 - \frac{1}{n-1}) \sum_{S\subset V} y_S.$$

As in Theorem 2.4, this theorem can be proven by induction on the main loop. Pick any particular iteration, and let $\mathcal{C}$ be the set of active components of the iteration. Let H be the graph formed by considering active and inactive components as vertices and the edges $e \in \delta(C) \cap F'$ for active C as the edges of H. Discard all isolated inactive vertices. Let N_a denote the set of active vertices in H, N_i the set of inactive vertices, N_d the set of active

vertices corresponding to active sets contained in some C_j, and d_v the degree of a vertex v in H. Note that $N_d = \{v \in N_a : d_v = 0\}$. In this iteration, the increase in the left-hand side of the inequality is $\epsilon(\sum_{v \in N_a} d_v + |N_d|)$ while the increase in the right-hand side of the inequality is $\epsilon(2 - \frac{1}{n-1})|N_a|$. Thus we would like to prove that $(\sum_{v \in N_a} d_v + |N_d|) \leq (2 - \frac{1}{n-1})|N_a|$. Note that the degree of any vertex corresponding to an active set in some C_j is zero. Hence if we can show that $\sum_{v \in N_a - N_d} d_v \leq (2 - \frac{1}{n-1})|N_a - N_d|$, then the proof will be complete.

To do this, we show that all but one of the leaves of H must be active vertices. Suppose that v is an inactive leaf of H, adjacent to edge e, and let C_v be the inactive component corresponding to v. Further suppose that C_v does not contain the root r. Since C_v is inactive and does not contain r, it must have been deactivated. Because C_v is deactivated, no vertex in C_v is unlabelled; furthermore, since v is a leaf, no vertex in C_v can lie on the path between the root and a vertex that must be connected to the root. By the construction of F', then, $e \notin F'$, which is a contradiction. Therefore, there can be at most one inactive leaf, which must correspond to the component containing r.

Then

$$\begin{aligned}
\sum_{v \in N_a - N_d} d_v &\leq \sum_{v \in (N_a - N_d) \cup N_i} d_v - \sum_{v \in N_i} d_v \\
&\leq 2(|(N_a - N_d) \cup N_i| - 1) - (2|N_i| - 1) \\
&= 2|N_a - N_d| - 1 \\
&\leq (2 - \frac{1}{n-1})|N_a - N_d|.
\end{aligned}$$

The inequality holds since all but one of the spanned inactive vertices has degree at least two, and since the number of active components is always at most $n - 1$. □

The algorithm can be implemented in $O(n^2 \log n)$ time, by using the same techniques as were given for the main algorithm. In this case, we must also keep track of the time at which we expect each component to deactivate, and put this time into the priority queue. The only other difference from the main algorithm is the final step in which edges are deleted. This step can be implemented in $O(n^2)$ time: first we perform a depth-first search from every unmarked vertex to the root, and "lock" all the edges and vertices on this path. We then look at all the deactivated components corresponding to the labels of "locked" vertices. If one of these contains an unlocked vertex, we perform a depth-first search from the vertex to the root and lock all the edges and vertices on the path. We continue this process until each locked vertex is in deactivated components that only contain locked vertices. We then eliminate all unlocked edges. This procedure requires at most n $O(n)$ time depth-first searches.

4.3.2. The prize-collecting traveling salesman problem. To solve the prize-collecting TSP given that edge costs obey the triangle inequality, we use the algorithm shown in Fig. 10. Note that the algorithm uses the above algorithm for the prize-collecting Steiner tree problem with penalties $\pi'_i = \pi_i/2$. To see that the algorithm is a $(2 - \frac{1}{n-1})$-approximation algorithm, we need to consider the following linear programming relaxation of the problem:

$$\text{Min} \quad \sum_{e \in E} c_e x_e + \sum_{T \subset V; r \notin T} z_T (\sum_{i \in T} \pi_i)$$

subject to:

$$\begin{aligned}
& x(\delta(S)) + 2 \sum_{T \supseteq S} z_T \geq 2 && r \notin S \\
& x_e \geq 0 && e \in E \\
& z_T \geq 0 && T \subset V; r \notin T.
\end{aligned}$$

This linear program is a relaxation of an integer program similar to $(PC\text{-}IP)$ in which $z_T = 1$ for the set of vertices T not visited by the tour, and $z_T = 0$ otherwise. We relax the constraint that each vertex in the tour be visited twice to the constraint that each vertex be visited at least twice. The dual of the linear programming relaxation is

$$\text{Max} \quad 2 \sum_{S: r \notin S} y_S$$

subject to:

$$\sum_{S: e \in \delta(S)} y_S \leq c_e \qquad e \in E$$

$$2 \sum_{S \subseteq T} y_S \leq \sum_{i \in T} \pi_i \qquad T \subset V, r \notin T$$

$$y_S \geq 0 \qquad S \subset V, r \notin S.$$

Note that this dual is very similar to $(PC\text{-}D)$. The dual solution generated by the algorithm for the prize-collecting Steiner tree for penalties π' will be feasible for the dual program above with penalties π. By duality, $2\sum_{S \subset V} y_S \leq Z^*_{PCTSP}$, where Z^*_{PCTSP} is the cost of the optimal solution to the prize-collecting TSP. Given a solution F' and X to the prize-collecting Steiner tree problem, the cost of our solution to the prize-collecting TSP is at most $2\sum_{e \in F'} c_e + \sum_{i \in X} \pi_i = 2(\sum_{e \in F'} c_e + \sum_{i \in X} \pi'_i)$. Theorem 4.1 shows that $\sum_{e \in F'} c_e + \sum_{i \in X} \pi'_i \leq (2 - \frac{1}{n-1}) \sum_{S \subset V} y_S$, so that

$$2(\sum_{e \in F'} c_e + \sum_{i \in X} \pi'_i) \leq 2(2 - \frac{1}{n-1}) \sum_{S \subset V} y_S \leq (2 - \frac{1}{n-1}) Z^*_{PCTSP}.$$

Thus the cost of the solution found by the algorithm is within $(2 - \frac{1}{n-1})$ of optimal.

Input: An undirected graph $G = (V, E)$, edge costs $c_{ij} \geq 0$, vertex penalties $\pi_i \geq 0$, and a root vertex r
Output: A tour T', which includes vertex r, and a set of unspanned vertices X

1 Apply the prize-collecting Steiner tree algorithm to the problem instance with graph G, edge costs c, root r, and penalties $\pi'_i = \pi_i/2$.
2 Duplicate the edges F' of the Steiner tree returned to form an Eulerian graph T.
3 Shortcut T to form a tour T'. Let X be all vertices not in the tour.

FIG. 10. *The algorithm for the prize-collecting traveling salesman problem.*

5. Concluding remarks. The approximation techniques described in the previous sections have been applied to a number of related problems since the appearance of a preliminary version of this paper [16]. Saran, Vazirani, and Young [31] showed how to use our techniques to derive an approximation algorithm for the minimum-cost 2-edge-connected graph problem. Their algorithm has a performance guarantee of 3, equal to the performance guarantee of an earlier algorithm of Frederickson and Ja'Ja' [10] for the same problem. Klein and Ravi [22] demonstrated a 3-approximation algorithm for solving (IP) for proper functions $f : 2^V \to \{0, 2\}$. Building on some ideas of Ravi and Klein, Williamson et al. [38] devised an approximation algorithm to solve (IP) for general proper functions $f : 2^V \to \mathbb{N}$ in which the disjointness condition is replaced by the more general condition $f(A \cup B) \leq \max(f(A), f(B))$ for disjoint A, B. The performance guarantee of the algorithm is at most $2k$, where $k = \max_S f(S)$, but can be lower depending on the values taken on by f. The algorithm depends on showing that the techniques of this paper can be extended to approximate uncrossable functions, as defined in §4. Goemans et al. [14] have shown how to improve the performance guarantee of this algorithm to $2(1 + \frac{1}{2} + \cdots + \frac{1}{k})$.

Gabow, Goemans, and Williamson [12] have shown how to efficiently implement the algorithm of Williamson et al. A consequence of the implementation of Gabow, Goemans, and Williamson is an $O(n^2 + n\sqrt{m \log \log n})$ implementation for our main algorithm. Finally, we have implemented the 2-approximation algorithm for Euclidean matching problems [37]. The performance of the algorithm in this case seems to be much better than the theoretical bounds given here: on 1,400 random and structured instances of up to 131,072 vertices, the algorithm was never more than 4% away from optimal.

Acknowledgments. The authors would like to thank David Shmoys for extensive comments on a draft of this paper.

D^{over}: AN OPTIMAL ON-LINE SCHEDULING ALGORITHM FOR OVERLOADED UNIPROCESSOR REAL-TIME SYSTEMS*

GILAD KOREN† AND DENNIS SHASHA‡

Abstract. Consider a real-time system in which every task has a value that it obtains only if it completes by its deadline. The problem is to design an on-line scheduling algorithm (i.e., the scheduler has no knowledge of a task until it is released) that maximizes the guaranteed value obtained by the system.

When such a system is underloaded (i.e., there exists a schedule for which all tasks meet their deadlines), Dertouzos [Proceedings IFIF Congress, 1974, pp. 807–813] showed that the earliest deadline first algorithm will achieve 100% of the possible value. Locke [Ph.D. thesis, Computer Science Dept., Carnegie-Mellon Univ., Pittsburgh, PA] showed that earliest deadline first performs very badly, however, when the system is overloaded, and he proposed heuristics to deal with overload.

This paper presents an optimal on-line scheduling algorithm for overloaded uniprocessor systems. It is optimal in the sense that it gives the best competitive ratio possible relative to an off-line scheduler.

Key words. competitive, worst-case guarantee, deadline

AMS subject classifications. 68M20, 68N25, 68Q20, 68Q25, 93C83

1. Introduction.

In real-time computing systems, correctness may depend on the completion time of tasks as much as their input/output behavior. Tasks in real-time systems have deadlines. If the deadline for a task is met, then the task is said to *succeed*. Otherwise it is said to have *failed*.

A system is *underloaded* if there exists a schedule that will meet the deadline of every task, and *overloaded* otherwise. Scheduling underloaded systems is a well-studied topic, and several on-line algorithms have been proposed for the optimal scheduling of these systems on a uniprocessor [5], [15]. Examples of such algorithms include *earliest-deadline-first* (D) and *smallest-slack-time*[1] (SL). However, none of these classical algorithms make performance guarantees during times when the system is overloaded. In fact, Locke has experimentally demonstrated that these algorithms perform quite poorly when the system is overloaded [14].

Practical systems are prone to intermittent overloading caused by a cascading of exceptional situations. A good on-line scheduling algorithm, therefore, should give a performance guarantee in overloaded as well as underloaded circumstances.

Researchers and designers of real-time systems have devised on-line heuristics to handle overloaded situations [2], [17]. Locke proposed several clever heuristics as part of the Carnegie-Mellon University Archons project [14]. Unfortunately, those heuristics offer no performance guarantee. This paper proposes an algorithm with strong performance guarantees for a large subset of the parameters considered by Locke's algorithm.

1.1. Background.

Real-time systems may be categorized by how they react when a task fails to meet its deadline. In a *hard real-time system*, a task failure is considered intolerable. The underlying assumption is that a task failure would result in a disaster, e.g., a fly-by-wire aircraft may crash if the altimeter is read a few milliseconds too late.

[1]The *slack time* of a task is the distance to its deadline minus its remaining computation time. Hence, the slack time of a task is a measure of its urgency—a task with small slack time would have to be scheduled soon in order to meet its deadline.

A less stringent class of systems is denoted as *soft real-time systems*. In such systems, each task has a positive value. The goal of the system is to obtain as much value as possible. If a task succeeds, then the system acquires its value. If a task fails, then the system gains less value from the task [15]. In a special case of soft real-time systems, called a *firm* real-time system [7], there is no value for a task that has missed its deadline, but there is no catastrophe either. (Other papers [1] denote such deadlines as *hard*. The reader should therefore be aware of the definitional variations.)

An *on-line* scheduling algorithm is one that is given no information about a task before its release time. Different tasks models can differ in the kind of information (and its accuracy) given upon release. We assume the following: when a task is released, its value and deadline are known precisely, its computation time may be known either precisely, or, more generally, within some range. Also, preemption is allowed and task switching takes no time.

The *value density* of a task is its value divided by its computation time. The *importance ratio* of a collection of tasks is the ratio of the largest value density to the smallest value density. When the importance ratio is 1, the collection is said to have *uniform value density*, i.e., a task's value equals its computation time. We will denote the importance ratio of a collection by k.

As in [4], [8], and [18] we quantify the performance guarantee of an on-line scheduler by comparing it with a *clairvoyant* [15, p. 39] scheduling algorithm (also called an off-line scheduler). A clairvoyant scheduler has complete a priori knowledge of all the parameters of all the tasks. A clairvoyant scheduler can choose a "scheduling sequence" that will obtain the maximum possible value achievable by any scheduler.[2]

As in [4], [8], and [18] we say that an on-line algorithm has a *competitive factor* r, $0 < r \leq 1$, *if and only if* it is guaranteed to achieve a cumulative value of at least r times the cumulative value achievable by a clairvoyant algorithm on *any* set of tasks. For convenience of notation, we use *competitive multiplier* as the figure of merit. The *competitive multiplier* is defined to be "one over the competitive factor." The smaller the competitive multiplier is, the better the guarantee. Our goal is to devise on-line algorithms whose guarantee is the best possible one.

Baruah et al. [3], [4] has demonstrated, by using an adversary argument, that in the uniform value density setting there can be *no* on-line scheduling algorithm with a competitive multiplier smaller than 4.

Koren and Shasha describe in a technical report [11] an algorithm called *DD-star* (DD*) that has a competitive multiplier of 4 in the *uniform* value density case and offers 100% of the possible value in the underloaded case. This showed that the bound of 4 is tight in the uniform value density case. Wang and Mao [20] independently report a similar guarantee.

On the complexity side, Baruah et. al [3], [4] showed, for environments with an importance ratio k, a lower bound of $(1 + \sqrt{k})^2$ on the best possible competitive multiplier of an on-line scheduler. This result and some pragmatic considerations reveal the following limitations of the competitive scheduling algorithms described above:

1. The algorithms all assume a uniform value density, yet some short tasks may be more important than some longer tasks.
2. The algorithms all assume that there is no value in finishing a task after its deadline. But a slightly late task may be useful in many applications.
3. The algorithms all assume that the computation time is known upon release. However, a task program that is not straight-line may take different times during different executions.

D^{over}, the on-line scheduling algorithm presented in this paper, addresses all these limitations.

[2]Finding the maximum achievable value for such a scheduler, even in the uniprocessor case, is reducible from the knapsack problem [6]; hence is NP-hard.

2. The main results. In this paper we present an on-line scheduling algorithm called D^{over} that has an optimal competitive multiplier of $(1+\sqrt{k})^2$ for environments with importance ratio k. Hence, we show that the bound in [3] and [4] is tight for all k. D^{over} also gives 100% of the value obtainable by a clairvoyant scheduler when the system is underloaded.

D^{over} can be implemented using balanced search trees, and runs at an *amortized* cost of $O(\log n)$ time per task, where n is the maximum over all time instants of the number of tasks in the system.

We also investigated two important extensions to the task model studied earlier.

- Gradual Descent:
  We relax the *firm deadline* assumption. Tasks that complete after their deadline can still have a positive value though less than their initial value. As in Locke [14], the task's value is given by a *value function* which depends on its completion time.
  We show that under a variety of value functions an appropriate version of D^{over} has a competitive multiplier of $(1+\sqrt{k})^2$ for environments with importance ratio k.
- Situations in which the exact computation time of a task is not known:
  Suppose the on-line scheduling algorithm does not know the exact computation time of a task upon its release. However, for every task T, an upper bound on its possible computation time denoted by $c_{\max}$ is given and the actual computation time of T denoted by c satisfies

$$(1-\epsilon)\cdot c_{\max} \le c \le c_{\max}$$

  for some $0 \le \epsilon < 1$.
  We show that in that case D^{over} has a competitive multiplier of

$$(1+\sqrt{k})^2 + (\epsilon \cdot k)(1+\sqrt{k}) + 1.$$

  We also show that no on-line scheduler can guarantee 100% of the value obtainable by a clairvoyant algorithm for underloaded systems in this setting.

To conserve space, we omit the details of the above two extensions in this paper. Full details can be found in [9] and [12].

The rest of the paper is organized as follows: Section 3 introduces some notation and definitions used in the paper. Section 4 describes D^{over}. Section 5 shows that D^{over} has the optimal competitive multiplier as mentioned previously. Section 6 presents the complete performance guarantee of D^{over} with respect to underloaded and overloaded periods. The paper ends with a brief conclusion section and a discussion of open problems.

3. Notation. Before we describe the full algorithm, we need some notation. We are given a collection of tasks $T_1, T_2 \cdots T_n \cdots$ denoted by Γ. For each task T_i, its value is denoted by v_i, its release time is denoted by r_i, its computation time by c_i and its deadline by d_i.

DEFINITION 3.1.

- *Underloaded and Overloaded Systems.* A system is *underloaded* if there exists a schedule that will meet the deadline of every task and *overloaded* otherwise.
- *Executable Period.* The *executable period*, Δ_i, of the task T_i is defined to be the following interval: $\Delta_i = [r_i, d_i]$.
  By definition, T_i may be scheduled only during its executable period.

Suppose a collection of tasks is being scheduled by some scheduler S.

- *Completed Task.* A task (successfully) *completes* if before its deadline, the scheduler S gives it an amount of execution time that is equal to its computation time.
- *Preempted Task.* A task is *preempted* when the processor stops executing it, but then the task might be scheduled again and possibly complete at some later point.

- *A Ready Task.* A task is said to be *ready* at time t if its release time is before t, its deadline is after t and it neither completed nor was abandoned before t (the current executing task, if any, is always a ready task).

The earliest deadline first algorithm (hereafter, D) is described in Fig. 1.

At any given moment, schedule the ready task with the earliest deadline.

FIG. 1. D, *the earliest deadline first scheduling algorithm.*

We shall make the following assumption:

ASSUMPTION 3.2.

- *Task Model.* Tasks may enter the system at any time; their computation times and deadlines are known exactly at their time of arrival. (We weaken this assumption of exact knowledge in [12].) Nothing is known about a task before it appears.
  We do assume, however, that an upper bound on the possible importance ratio is known a priori and can be used by the on-line scheduler. (This bound is denoted by k.) Other researchers have shown that this assumption can be relaxed [16].
- *Task Switching Takes No Time.* A task can be preempted and another one scheduled for execution instantly.

Suppose that a collection of tasks Γ with importance ratio k is given.

- *Normalized Importance.* Without loss of generality, assume that the smallest importance of a task in Γ is 1. Hence if Γ has *importance ratio* of k, the highest possible value density of a task in Γ is k.
- *No Overloaded Periods of Infinite Duration.* We assume that overloaded periods of infinite duration will not occur. This is a realistic assumption, since overload is normally the result of a temporary emergency or failure. Indeed, in the uniprocessor case, Baruah et. al [3] showed that there is no competitive on-line algorithm when overloaded periods of infinite duration are possible.[3] Note that the number of tasks in Γ may be infinite provided that no infinitely long overload period is generated.[4]

4. D^{over}. In the following algorithm, there are three kinds of *events* (each causing an associated interrupt) considered:

- Task Completion: Successful termination of a task. This event has the highest priority.
- Task Release: Arrival of a new task. This event has low priority.
- Latest-start-time Interrupt: The indication that a task must immediately be scheduled in order to complete by its deadline; that is, the task's remaining computation time is equal to the time remaining until its deadline. This event has also low priority (the same as task release).

If several interrupts happen simultaneously they are handled according to their priorities. A task completion interrupt is handled before the task release and latest-start-time interrupt interrupts, which are handled in random order. It may happen that a task completion event suppresses a lower priority interrupt, e.g., if the task completion handler schedules a task

[3]Intuitively, the adversary can generate a sequence of tasks with ever-growing values. This will force any competitive scheduler to abandon the current task in favor of the next one, and so on. If the competitive scheduler attempts to complete a task in favor of a new larger one, then the adversary completes the larger one. In either case, the on-line schedule will result in a small value compared with an arbitrarily large value for a clairvoyant scheduler.

[4]For the definition of overloaded periods, see §6.

that has just reached its *LST* (latest-start-time) then the task scheduling will obviate the need for the latest-start-time interrupt.

At any given moment, the set of ready tasks[5] is partitioned into two disjoint sets: *privileged* tasks and *waiting* tasks. Whenever a task is preempted it becomes a *privileged* task. However, whenever some task is scheduled as the result of a latest-start-time interrupt *all* the ready tasks (whether preempted or never scheduled) become *waiting* tasks.

D^{over} maintains a special quantity called availtime. Suppose a new task is released into the system and its deadline is the earliest among all ready tasks. The value of availtime is the maximum computation time that can be taken by such a task without causing the current task or any of the privileged tasks to miss their deadlines.

D^{over} requires three data structures, called Q_privileged, Q_waiting and Qlst. Each entry in these data structures corresponds to a task in the system. Q_privileged contains exactly the privileged tasks and Q_waiting contains the *waiting* tasks. These two structures are ordered by the tasks' deadlines. In addition, the third structure, Qlst, contains all tasks (again, not including the current task) ordered by their latest start times.

These data structures support Insert, Delete, Min, and Dequeue operations.

- The Min operation for Q_privileged or Q_waiting returns the entry corresponding to the task with the earliest deadline among all tasks in Q_privileged or Q_waiting. For Qlst the Min operation returns the entry corresponding to the task with the earliest *LST* among all tasks in the queue. The Min operation does not modify the queue.
- A Dequeue operation on Q_privileged (or Q_waiting) deletes from the queue the element returned by Min; in addition it deletes this element from Qlst. Likewise a Dequeue operation on Qlst will delete the corresponding element from either Q_privileged if it is a *privileged* task or from Q_waiting if it is a *waiting* task.

An entry of Q_waiting and Qlst consists of a single task, whereas an entry of Q_privileged is a 3-tuple (T, Previous-time, Previous-avail) where T is a task that was previously preempted at time Previous-time. Previous-avail is the value of the variable availtime at time Previous-time. All of these data structures are implemented as balanced trees (e.g. 2–3 trees).

D^{over}'s code is depicted in Figs. 2–4.

The following is an intuitive description of the algorithm: As long as no overload is detected (i.e., there is no *LST* interrupt), D^{over} schedules in the same way as D. Tasks that are preempted during this phase in favor of a task with an earlier deadline become privileged tasks. The task with the earliest deadline (either a newly released task or a *waiting* task) will be scheduled provided that it does not cause overload when added to the privileged tasks. This proviso is always met in situations of underload. During overload, when a *waiting* task reaches its *LST*, it will cause a latest-start-time interrupt. This means that some task must be abandoned: either the task that reached its *LST* or some of the privileged tasks. The latest-start-time interrupt routine compares the value of that task against the *sum* of the values of all the privileged tasks. If its value is greater than $(1 + \sqrt{k})$ times that sum, then this task will execute on the processor while all the privileged tasks will lose their privileged status to become *waiting* tasks (these tasks might later be successfully rescheduled). Otherwise, the task reaching its *LST* is abandoned. A task T that was scheduled by a latest-start-time interrupt can be abandoned in favor of another task T' that reaches its *LST* but only if T' has at least $(1 + \sqrt{k})$ times more value than T. D^{over} returns to schedule according to D when some task scheduled by its latest-start-time interrupt completes.

The reader may be curious to know why D^{over} compares *values* rather then *value densities* and why the values are compared using the magic factor of $(1 + \sqrt{k})$? The lower bound proof [3], [4] shows why value density cannot be a good criterion for choosing which task to

[5]Excluding the currently executing task.

In the following code, *Now()* is a function that returns the current time. *Schedule*(T) is a function that gives the processor to task T. *Laxity*(T) is a function that returns the amount of time the task has left until its deadline less its remaining computation time. That is, *laxity*(T) = *deadline*(T) − (*now*()+ *remaining_computation_time*(T)). ϕ denotes the empty set.
This code includes lines manipulating *intervals*. The notion of an interval is needed for purpose of analysis only, so these lines are commented.

```
1   recentval      := 0     (* This will be the running value of privileged tasks. *)
2   availtime      := ∞
                            (* Availtime will be the maximum computation time that
3                           can be taken by a new task without causing the current
                            task or the privileged tasks to miss their deadlines. *)
4   Qlst           := φ     (* All ready tasks, ordered according to their latest
                            start time. *)
5   Q_privileged   := φ     (* The privileged tasks ordered by deadline order. *)
6   Q_waiting      := φ     (* All the waiting tasks ordered by their deadlines. *)
7   idle           := true  (* In the beginning the processor is idle. *)

8   loop
9    task completion :
10     if (both Q_privileged and Q_waiting are not empty) then
                    (* Both queues are not empty and contain together all the ready tasks.
11                  The ready task with the earliest deadline will be scheduled unless it is a
                    task of Q_waiting and it cannot be scheduled with all the privileged tasks.
                    The first element in each queue is probed by the Min operation. *)
12
13                  (T Q_privileged, t_prev, avail_prev) := Min(Q_privileged);
14
```

FIG. 2. *D^{over}—a competitive optimal on-line scheduling algorithm.*

abandon.[6] The factor of $(1 + \sqrt{k})$ happened to be the one that gave the desired result since it yields the correct ratio between the minimal value gained by D^{over} and the maximal value that might have been missed.

5. Analysis of D^{over}. In order to facilitate the analysis of D^{over} it is convenient to introduce the notation of intervals.

DEFINITION 5.1.

- *Intervals.* The intervals are created (opened) and closed according to the scheduling decisions of D^{over} and this process is depicted in the code of D^{over} in §4.
  When an interval is created (comments 37 and 59 of D^{over}) it is considered *open*, meaning that it may be extended, it is closed when a task completes while Q_privileged is empty (comments 33 and 48). A new interval would be opened when the next task is scheduled. Initially, there is no open interval. Hence, the first interval is opened when the processor first becomes nonidle.

[6] In that proof, going after high value density tasks (the short *teasers*) will give the on-line scheduler minuscule value compared to the clairvoyant scheduler that will schedule a low-value density task that has long computation time and hence big value.

```
        (* Next, compute the current value of availtime. This is the correct value
        because T Q_privileged is the task last inserted of those tasks currently in
15      Q_privileged; t_prev is the time when T Q_privileged was preempted; and
        the available computation time has decreased by the time elapsed since
        this element was inserted to the queue. *)
16
17      availtime := avail_prev − (now() − t_prev);
18      (* Probe the first element of Q_waiting and check which of the two tasks
        should be scheduled. *)
19      T_Q_waiting := Min(Q_waiting);
20      if d_Q_waiting < d Q_privileged and
        availtime≥ remaining_computation_time(T_Q_waiting) then
21        (* Schedule the task from Q_waiting. *)
22        Dequeue(Q_waiting);
23        availtime:= availtime − remaining_computation_time(T_Q_waiting) ;
24        availtime:= min(availtime, laxity(T_Q_waiting));
25        Schedule T_Q_waiting;
26      else
27        (* Schedule the task from Q_privileged. *)
28        Dequeue(Q_privileged);
29        recentval := recentval − value(T Q_privileged);
30        Schedule T Q_privileged;
31      endif   (*which task to schedule. *)
32    else if (Q_waiting is not empty) then
33      (* Q_privileged is empty. The current interval is closed here, t_close =
        now(). The first task in Q_waiting is scheduled *)
34
35      T_current := Dequeue(Q_waiting);
36      availtime:= laxity(T_current);
37      (* A new interval is created with t_begin = now().*)
38
39      Schedule T_current;
40    else if (Q_privileged is not empty)
41      (* Q_waiting is empty. The first task in Q_privileged is scheduled *)
42
43      (T_current, t_prev, avail_prev) := Dequeue(Q_privileged);
44      recentval := recentval − value(T_current);
45      availtime := avail_prev − (now() − t_prev);
46      Schedule T_current;
47    else
48      (* Both queues are empty. The interval is closed here, t_close = now(). *)
49
50      idle := true;
51      availtime:= ∞;
52    endif
53  end (*task completion *)
```

FIG. 3. D^{over} (*continued*).

```
54  task release : (* T_arrival is released. *)
55      if (idle ) then
56          Schedule T_arrival;
57          availtime := laxity(T_arrival);
58          idle  := false;
59          (* A new interval is created with t_begin = now().*)
60      else  (*T_current is executing  *)
61          if  d_arrival < d_current and
            availtime ≥ computation_time(T_arrival) then
62            (* No overload is detected, so the running task is preempted. *)
63            Insert T_current into Qlst;
64            Insert (T_current, now(), availtime) into Q_privileged;
65            (* The inserted task will be, by construction, the task with the earliest
              deadline in Q_privileged*)
66            availtime:= availtime − remaining_computation_time(T_arrival);
67            availtime:= min(availtime, laxity(T_arrival))
68            recentval := recentval + value(T_current);
69            Schedule T_arrival;
70          else  (* T_arrival has later deadline or availtime is not big enough.*)
71            (* T_arrival is to wait in Q_waiting  *)
72            Insert T_arrival into Qlst and Q_waiting;
73          endif
74      endif  (*idle  *)
75  end  (*release  *)

76  latest-start-time interrupt :
77      (* The processor is not idle and the current time is the latest start time of
        the first task in Qlst. *)
78
79      T_next = Dequeue(Qlst);
80      if (v_next >  (1 + √k) (v_current + recentval)) then
81          (*v_next is big enough; it is scheduled.  *)
82          Insert T_current into Qlst and Q_waiting;
83          Remove all privileged tasks from
            Q_privileged and insert them into Qlst and Q_waiting;
84          (* Q_privileged = φ  *)
85          recentval := 0;
86          availtime:= 0
87          Schedule T_next;
88      else  (*v_next is not big enough; it is abandoned.  *)
89          Abandon T_next;
90      endif
91  end (*LST  *)
92  end{loop }
```

FIG. 4. D^{over} (*continued*).

The interval consists of the time between the point it was opened and the point it was closed. We will denote by $I = [t_{begin}, t_{close}]$ an interval I that was opened at t_{begin} and closed at t_{close}.

Note: Two intervals may overlap only at their endpoints.

- *BUSY:* Suppose D^{over} schedules a collection of tasks. Let $BUSY$ denote the time where the processor is not idle during the execution of these tasks. For simplicity, the length of $BUSY$ will also be denoted by $BUSY$.
  Note that $BUSY$ equals the union of all intervals created by D^{over}.

Suppose that a collection of tasks Γ with importance ratio k is given, and D^{over} schedules this collection. When a task is scheduled, it can have zero or positive slack time. A task may be preempted and then rescheduled several times. We will be concerned mainly with the last time a task was scheduled. For the purposes of analyzing D^{over}, we will partition the collection of tasks according to the question of whether the task had completed exactly at its deadline or before its deadline or failed.

- Let F (for fail) denote the set of tasks that were abandoned.
- Let S^p (for successful with positive time before the deadline) denote the set of tasks that completed successfully and that ended some positive time before their deadlines.
- Let S^0 (for successful with 0 time before the deadline) denote the set of tasks that completed successfully but ended exactly at their deadlines.

Call a task *order-scheduled* if it was scheduled by the task completion or task release handlers. Call a task *lst-scheduled* if it was scheduled as a result of a latest-start-time interrupt. (As mentioned previously, a latest-start-time interrupt is raised on a waiting task when it reaches its latest start time (*LST*), i.e. the last time when it can start executing and still complete by its deadline).

The first task in each interval is order-scheduled. The subsequent tasks (if any) in this interval may be order-scheduled or lst-scheduled. Proposition 5.2 shows that once a task is lst-scheduled, all subsequent tasks of this interval must be lst-scheduled. During an interval, several order-scheduled tasks may complete but only one lst-scheduled task can complete. (This task will also be the last task that executes in the interval.)

PROPOSITION 5.2. *According to the scheduling of D^{over}, once a task is lst-scheduled, then all subsequent tasks, in the current interval, are lst-scheduled.*

Proof. Suppose the current task, $T_{current}$, is lst-scheduled and a task, $T_{arrival}$, is released. $T_{arrival}$ will not be scheduled by the task release handler because when the current task is lst-scheduled availtime equals zero (see statement 86 of D^{over}) hence no task can be scheduled by the task release handler (see statement 61 of D^{over}). □

Let recentval(t) denote[7] recentval at time t and achievedvalue(t) denote the value achieved during the current interval before t by D^{over}. For an interval I, achievedvalue(I) is the total value obtained during I.

We partition the value obtained during I in two different ways:

- ordervalue vs. lstvalue: ordervalue(I) is the total value obtained by order-scheduled tasks that completed during I. The value obtained by lst-scheduled tasks is denoted by lstvalue(I). (There is at most one such task in any interval I.)
- zerolaxval vs. poslaxval: zerolaxval(I) denotes the total value obtained by tasks that completed at their deadlines during I (tasks in S^0). The value obtained by tasks that completed before their deadlines is denoted by poslaxval(I).

Hence, for every interval

$$\text{achievedvalue}(I) = \text{ordervalue}(I) + \text{lstvalue}(I) = \text{zerolaxval}(I) + \text{poslaxval}(I).$$

When the index (I) is omitted we refer to the entire execution. For example, ordervalue denotes the total value obtained by order-scheduled tasks summing over all intervals.

[7] In the following only recentval is a variable explicitly manipulated by D^{over}. All the others, zerolaxval, poslaxval, ordervalue and lstvalue, are introduced here to facilitate the analysis. This is why they do not reference algorithm statements.

EXAMPLE 5.3. Before the detailed analysis, let us first study an example of D^{over}'s scheduling. Consider the overloaded collection of six tasks depicted in Table 1. For notational convenience we will denote the tasks by their deadlines, hence for example T_{20} is a task with deadline at time 20. In this example we assume uniform value density (i.e., $k = 1$). D^{over} schedules the above collection as follows: In the beginning availtime is ∞ and Q_privileged is empty. First, D^{over} schedules T_{20} to run at time 0. Availtime is set to 14 since this is T_{20}'s laxity.

TABLE 1
The tasks for Example 5.3.

Task	*Release-Time*	*Computation-Time*	*Deadline*	Δ_i
T_{20}	0	6	20	[0, 20]
T_{34}	1	26	34	[1, 34]
T_{24}	1	20	24	[1, 24]
T_{18}	2	5	18	[2, 18]
T_{17}	3	2	17	[3, 17]
T_5	4	1	5	[4, 5]

At time 1, T_{34} is released into the system. Since T_{34}'s deadline is not earlier than the current task's (T_{20}), T_{34} is inserted into Q_waiting (and Qlst with *LST* equal to 8). Also at time 1, T_{24} is released. Again, since its deadline is after 20, this task is inserted into Q_waiting and Qlst with *LST* equal to 4.

At time 2, T_{18} is released. This time the current task is preempted. T_{20} is inserted into Q_privileged and Qlst with *LST* equals 16. Availtime is decremented by the computation time of T_{18}. Its new value is 9. The value of recentval is set to the value of T_{20} (6).

T_{18} executes for one time unit until time 3, when T_{17} is released. T_{17} is scheduled since its computation time (2) is smaller then availtime (9). Availtime is decremented by the computation time of T_{17}. Its new value is 7. The value of T_{18} (5) is added to recentval , which becomes 11.

At time 4, two events occur: T_{24} reaches its *LST* and T_5 is released. These events can be handled in any order and we choose to handle the latest-start-time interrupt first. T_{24} reaches its *LST* but its value is smaller than twice ($1 + \sqrt{k} = 2$) the value of the current task plus recentval ($2 + 11$). Hence, T_{24} is abandoned. T_5 is released and its deadline is earlier than the current task's (T_{17}). T_5 is scheduled since its computation time is smaller then availtime($1 < 7$). T_5 has laxity of zero which is smaller than the current availtime minus the computation time of T_5 (6). Hence, availtime is now set to 0 and recentval becomes $11 + 2 = 13$.

For reason of space we cannot describe here the rest of the execution. (Table 2 summarizes the entire execution.) In this example $S^0 = [T_5, T_{34}]$, $S^p = [T_{17}]$ and $F = [T_{18}, T_{20}, T_{24}]$. Only three tasks complete their execution and the total value obtained by D^{over} is 29. A clairvoyant scheduler can achieve a value of 34 by scheduling T_{17}, T_{20}, and T_{34}. Also notice that the system is already overloaded at time 1, but the first time an overload is "detected" by D^{over} is at time 4 because of the *LST* interrupt.

5.1. Proof strategy. Our goal is to show that D^{over} has a competitive multiplier of $(1 + \sqrt{k})^2$ for every collection of tasks with importance ratio of k. We will start by proving some lemmas about the behavior of D^{over}. Then we will try to estimate the best possible behavior of a clairvoyant algorithm by comparison to D^{over}. Our basic strategy is to bound from below what D^{over} achieves during each interval. This will lead to a global lower bound over the entire execution. Then, we bound from above what a clairvoyant scheduler can achieve during the entire execution.

TABLE 2

D^{over}'s scheduling for Example 5.3. *A new interval is opened at time* 0. T_{24} *reaches its LSTat time* 4 *and then abandoned.* T_{34} *reaches its LSTat time* 8 *and then scheduled.* T_{20} *and* T_{18} *reach their LSTs at times* 15 *and* 16 *respectively both are abandoned. The interval is closed with the completion of* T_{34} *at time* 34.

5.2. Some lemmas about D^{over}'s scheduling. In this section we present some technical lemmas about the behavior of D^{over}. These lemmas will be used in the next section when comparing D^{over}'s performance with that of a clairvoyant scheduler. These lemmas concern the relationship between the interval length and the value achieved by D^{over} in that interval (Lemma 5.5), as well as the relationship between the computation time and value of tasks abandoned in an interval with respect to the value achieved in the interval (Lemmas 5.6 and 5.7). Recall that BUSY is the union of all intervals (Definition 5.1).

LEMMA 5.4.

1. *For any task* T_i *in* S^0, $\Delta_i = [r_i, d_i] \subseteq BUSY$.
2. *For any task* T_i *in* F. *Suppose* T_i *was abandoned at time* t_{aban}, *then* $[r_i, t_{aban}] \subseteq BUSY$.

Proof. A processor is idle under D^{over} scheduling only if there is no *ready* task.

- A task T_i of S^0 does not complete before its deadline, hence it is a *ready* task during all its executable period. This implies that there is no idle time during the executable period of T_i.
- Similarly, a task of F is a ready task from its release time to the point at which it is abandoned. Therefore there is no idle time between its release point and its abandonment point. □

LEMMA 5.5. *For any interval* $I = [t_{begin}, t_{close}]$, *the length of* I, $t_{close} - t_{begin}$ *will satisfy*

$$t_{close} - t_{begin} \leq \mathsf{ordervalue}(I) + \left(1 + \frac{1}{\sqrt{k}}\right) \cdot \mathsf{lstvalue}(I)$$

$$= \mathsf{achievedvalue}(I) + \frac{1}{\sqrt{k}} \cdot \mathsf{lstvalue}(I).$$

Recall that ordervalue(I) *and* lstvalue(I) *are the values obtained by* D^{over} *from the order-scheduled and the lst-scheduled tasks, respectively, during* I.

Proof. An interval $I = [t_{begin}, t_{close}]$ has the following two subportions, the second of which may be empty:

1. $[t_{begin}, t_{first\_lst}]$
   From the beginning of I to the point in time, t_{first_lst}, in which the first lst-scheduled task is scheduled. During this period all tasks are order-scheduled and some may complete their execution.
   If no task is lst-scheduled in I then define t_{first_lst} to be t_{close}. In this case the second subportion is empty.
2. $[t_{first\_lst}, t_{close}]$
   During this period, all tasks are scheduled and preempted by latest-start-time interrupt. Only the last task to be scheduled completes.

If there are no lst-scheduled tasks in I then all tasks that executed from t_{begin} to t_{close} completed successfully. The value achieved is $\mathsf{ordervalue}(I)$ and is at least as big as the duration of execution.[8] Hence, the lemma is proved in this case.

Otherwise, suppose that $T_1, T_2, \cdots, T_m$ ($m \geq 1$) are the tasks that were lst-scheduled in I. Hence, T_1 was scheduled at t_{first_lst}, later it was preempted (and abandoned) by T_2 and so forth. Eventually T_m preempts T_{m-1} and completes at t_{close}, its value v_m is $\mathsf{lstvalue}(I)$.

Denote by l_i the length of the execution of T_i during the process above. T_m preempted T_{m-1} hence $v_m > (1+\sqrt{k})v_{m-1}$. Which yields[9]

$$l_{m-1} < v_{m-1} < \frac{v_m}{(1+\sqrt{k})} = \frac{\mathsf{lstvalue}(I)}{(1+\sqrt{k})}.$$

Going backward along the chain of preemptions we get

$$l_i < v_i < \frac{v_{i-1}}{(1+\sqrt{k})} < \frac{\mathsf{lstvalue}(I)}{(1+\sqrt{k})^{m-i}} \quad \text{for all } 1 \leq i \leq m-1. \tag{1}$$

T_1 preempted the last order-scheduled task hence (see statement 80 of D^{over})

$$v_1 > (1+\sqrt{k})\{\,\mathsf{recentval}(t_{first\_lst}) + \text{ value(current task at time } t_{first\_lst})\}. \tag{2}$$

Also,

$$t_{first\_lst} - t_{begin} \leq \mathsf{ordervalue}(I) + \mathsf{recentval}(t_{first\_lst}) + \text{value(current task at time } t_{first\_lst}). \tag{3}$$

This holds because the processor is not idle between t_{begin} and t_{first_lst} (as part of $BUSY$) and the right-hand side above represents the sum of the values of all the tasks that were scheduled between t_{begin} and t_{first_lst}. This sum must be greater than or equal to their period of execution by the normalized importance assumption (Assumption 3.2). Inequalities (1)–(3) imply

$$t_{first\_lst} - t_{begin} < \mathsf{ordervalue}(I) + \frac{v_1}{(1+\sqrt{k})} < \mathsf{ordervalue}(I) + \frac{\mathsf{lstvalue}(I)}{(1+\sqrt{k})^m}.$$

We have produced the following bound on the distance between t_{begin} and t_{close}:

[8] Recall that the value density of every task is equal to or greater than 1, by Assumption 3.2 above.

[9] Note that always $l_i \leq v_i$. However, for a task that was abandoned a strict inequality $l_i < v_i$ holds.

$$
\begin{aligned}
t_{close} - t_{begin} &= (t_{first\_lst} - t_{begin}) + (t_{close} - t_{first\_lst}) \\
&= (t_{first\_lst} - t_{begin}) + (l_1 + l_2 + \cdots + l_m) \\
&\leq \mathsf{ordervalue}(I) \\
&\quad + \mathsf{lstvalue}(I) \cdot \left(1 + \frac{1}{(1+\sqrt{k})} + \frac{1}{(1+\sqrt{k})^2} + \cdots + \frac{1}{(1+\sqrt{k})^m}\right) \\
&\leq \mathsf{ordervalue}(I) + \mathsf{lstvalue}(I) \cdot \sum_{i=0}^{\infty} \frac{1}{(1+\sqrt{k})^i} \\
&= \mathsf{ordervalue}(I) + \mathsf{lstvalue}(I) \cdot \left(1 + \frac{1}{\sqrt{k}}\right) \\
&= \mathsf{achievedvalue}(I) + \frac{1}{\sqrt{k}} \cdot \mathsf{lstvalue}(I).
\end{aligned}
$$

The last equality follows from the fact that achievedvalue(I) = ordervalue(I) + lstvalue(I) by definition. □

LEMMA 5.6. *Suppose T_i was abandoned during the interval I. Then*

$$v_i \leq (1+\sqrt{k}) \cdot \mathsf{achievedvalue}(I).$$

Recall that achievedvalue*(I) is the total value obtained during I.*

Proof. Let $I = [t_{begin}, t_{close}]$ be an interval. Define the *Prospective Value* map of I, PV_I, as follows:

$$PV_I(t) = \mathsf{ordervalue}(t) + \mathsf{recentval}(t) + \text{value(current task at time } t) \quad \text{where } t_{begin} \leq t \leq t_{close}.$$

Claim For every interval, $I = [t_{begin}, t_{close}]$,

1. PV_I is monotone nondecreasing.
2. PV_I reaches, at the end of the interval, the total value obtained in I, i.e.,

$$PV_I(t_{close}) = \mathsf{achievedvalue}(I).$$

Note. PV is not a function because it might have several values for one time instance since D^{over} can make several scheduling decisions at one time instance (Assumption 3.2). However, as a map with the ordered sequence of scheduling decisions as its domain, PV_I is a function.

Proof of Claim. There are two cases. The first applies when there are no lst-scheduled tasks in I, the other applies when such tasks exist.

Case 1. Suppose that there are no lst-scheduled tasks in I. Then every task that was scheduled does complete. Let $S(t)$ be the set of tasks that were scheduled (not necessary completed) up to t. One can verify by induction that

$$PV_I(t) = \sum_{T_i \in S(t)} v_i.$$

The reason is that no scheduled task is abandoned hence at each moment a task is either the current task or in Q_privileged or has already completed. At the closing of I all tasks have completed. Hence,

$$PV_I(t_{close}) = \sum_{T_i \in S(t_{close})} v_i = \mathsf{achievedvalue}(I).$$

PV_I is monotone (when there are no lst-scheduled tasks) because $S(t)$ is a monotone increasing set of tasks.

Case 2. Suppose there were lst-scheduled tasks. Assume that the first lst-scheduled task, T_1, was scheduled at time t_{first_lst}. Let t be a time instance just before the scheduling of T_1, then by definition:

$$PV_I(t) = \text{ordervalue}(t) + \text{recentval}(t) + \text{value(current task at time } t)$$

T_1 is scheduled only if

$$v_1 > (1 + \sqrt{k}) \cdot (\text{recentval}(t) + \text{value(current task at time } t))$$

When T_1 is scheduled recentval is set to zero hence we can conclude that

$$\begin{aligned} PV_I(t_{first\_lst}) &= \text{ordervalue}(t_{first\_lst}) + \text{recentval}(t_{first\_lst}) + value(T_1) \\ &= \text{ordervalue}(t) + 0 + value(T_1) \\ &> \text{ordervalue}(t) + (\text{recentval}(t) + \text{value(current task at time } t)) \\ &= PV_I(t) \end{aligned}$$

Thus, PV_I is monotone from t_{begin} to t_{first_lst} (as in the case when there are no lst-scheduled tasks). It is left to show that PV_I continues to be monotone. After t_{first_lst}, PV_I equals to

$$\text{ordervalue}(I) + \text{value(current task at time } t)$$

because recentval remains equal to zero. This is a monotone increasing value since ordervalue(I) is fixed and a task T will preempt the current task only if it has a larger value than the current task's value. In particular if T_i is the last task to be scheduled in I then

$$\begin{aligned} PV_I &= \text{ordervalue}(I) + v_i \\ &= \text{ordervalue}(I) + \text{lstvalue}(I) = \text{achievedvalue}(I). \end{aligned}$$

So, the claim is proved.

End of proof of claim. We return to the proof of Lemma 5.6. There is only one way a task, T_i, can be abandoned at time t:

- T_i reaches its *LST* at t. A latest-start-time interrupt is generated. However, T_i has insufficient value to preempt the task executing at time t.

Hence if T_i was abandoned then

$$\begin{aligned} v_i &< (1 + \sqrt{k}) \cdot \{\text{recentval}(t) + \text{value(current task at time } t)\} \\ &\leq (1 + \sqrt{k}) \cdot PV_I(t), \text{ by definition of } PV, \\ &\leq (1 + \sqrt{k}) \cdot \text{achievedvalue}(I), \text{ by the claim.} \quad \square \end{aligned}$$

LEMMA 5.7. *Suppose T_i was abandoned at time t in $I = [t_{begin}, t_{close}]$. Then*

$$c_i \geq d_i - t_{close}.$$

Proof. A task T_i, can be abandoned at time t only when

- It reaches its *LST* at t. A latest-start-time interrupt is generated. However, the current task is not preempted.

T_i reached its *LST* hence its remaining computation time is $d_i - t$. Also, $t \leq t_{close}$ by assumption. Hence the (initial) computation time of T_i is at least $d_i - t_{close}$. $\square$

5.3. How well can a clairvoyant scheduler do. Given a collection of tasks Γ, our goal is to bound the maximum value that a clairvoyant algorithm can obtain from scheduling Γ. We do it by observing the way D^{over} schedules Γ. From D^{over}'s scheduling we get the partitioning of the tasks to S^0, S^p, and F. We also take notice of the time periods in which the processor was not idle in this scheduling. As defined earlier, the union of these periods is called $BUSY$.

In order to bound the value that can be achieved from scheduling Γ, we will offer the clairvoyant algorithm two gifts that can only improve the value it can obtain. We will show an upper bound on the value the clairvoyant algorithm can get with these gifts hence bounding the value it can achieve from the original collection.

- As a first gift, we will give the clairvoyant algorithm the sum of the values of all tasks in S^p at no cost to it (i.e. it will devote no time to these tasks). Then we will see what the clairvoyant algorithm can achieve on $F \cup S^0$.
- As a second gift, suppose that in addition to the value achieved from scheduling the tasks $F \cup S^0$ the clairvoyant scheduler can get an additional value called *granted value*. The amount of granted value depends on the schedule chosen by the the clairvoyant scheduler: A value density of k will be granted for every period of $BUSY$ that is not used for executing a task. (This is reminscent of farm subsidies for not growing grain.)

The clairvoyant scheduler must consider that scheduling a task might reduce the granted value (since time in $BUSY$ is used). Of course, when this reduction is bigger than the value of a task then the task should not be scheduled. Suppose the clairvoyant algorithm had chosen a scheduling for $F \cup S^0$. We can assume that no task was scheduled entirely during $BUSY$ because the granted value lost would be greater or equal to the value gained from scheduling the task. We have shown that tasks of S^0 can execute only during $BUSY$ hence this leaves only tasks of F that were scheduled partially outside $BUSY$. Executing T results in a gain of $value(T)$, but entails a loss of the granted value for the time that T executed in $BUSY$.

The clairvoyant scheduler has now two options. It can schedule no task during the entire $BUSY$ period and get only (the whole) granted value or it can use some of $BUSY$ in order to schedule some of F tasks. We will show that the maximal possible gain from choosing the second option over the first is bounded by $(1 + \sqrt{k}) \cdot$ achievedvalue. Putting this together will give the desired result (Theorem 5.14).

In the aforementioned scenario the clairvoyant scheduler can achieve (using the gifts) the maximal value of the sum in equation (4) ranging over all possible schedulings[10] of F.

$$\begin{matrix}\text{value obtained from those tasks of } F \\ \text{that were scheduled}\end{matrix} + k \cdot \begin{matrix}\text{length of time in } BUSY \text{ not utilized} \\ \text{to schedule the tasks of } F.\end{matrix} \tag{4}$$

Denote by $C(\cdot)$ the value that a clairvoyant algorithm can achieve from a collection of tasks. We would like to show that $C(F \cup S^0)$ cannot be greater then this maximal value. This will then give us an upper bound on what a clairvoyant algorithm can achieve.

LEMMA 5.8.

$$C(F \cup S^0) \leq \max_{\substack{\text{possible} \\ \text{scheduling of} \\ F}} \left\{ \begin{matrix}\text{value obtained by} \\ \text{scheduling tasks of } F\end{matrix} + k \cdot \begin{matrix}\text{length of time in} \\ BUSY \text{ not utilized by} \\ \text{tasks of } F\end{matrix} \right\}.$$

[10] Suppose a *clairvoyant scheduler* has to schedule a collection of tasks A. We can assume that it schedules a task only if that task eventually completes. Hence the work of a clairvoyant scheduler is first to choose the set of tasks $A' \subseteq A$ that will be scheduled and then to work out the details of the processor allocation among the tasks of A'. We will call all possible selections of A' and processor allocation *a scheduling* of A.

Proof.

$$C(F \cup S^0) = \max \left\{ \begin{array}{c} \textit{value obtained from} \\ \textit{scheduling tasks of } F \end{array} + \begin{array}{c} \textit{value obtained from scheduling tasks of} \\ S^0 \textit{ during the time not used by tasks of } F \end{array} \right\}.$$

S^0 tasks can be scheduled only during $BUSY$ (Lemma 5.4), hence

$$\begin{array}{c} \textit{value obtained from scheduling} \\ \textit{tasks of } F \end{array} + \begin{array}{c} \textit{value obtained from scheduling tasks of } S^0 \\ \textit{during the time not used by tasks of } F \end{array}$$

$$\leq \begin{array}{c} \textit{value obtained by scheduling} \\ F \end{array} + k \cdot \begin{array}{c} \textit{length of time in } BUSY \textit{ not utilized by tasks} \\ \textit{of } F. \end{array}$$

The lemma is proved. □

Suppose a task $T_f \in F$ is scheduled to completion by the clairvoyant algorithm. If T_f executes entirely during $BUSY$ then the left-hand factor of the sum is increased only by v_i which is smaller than or equal to $k \cdot c_i$ while the right-hand factor is decreased by $k \cdot c_i$ giving zero or negative net change. Thus we assume that T_f executes (at least partially) outside $BUSY$.

LEMMA 5.9. *Suppose T_f is abandoned (by D^{over}) at time t_{aban} and that $I = [t_{begin}, t_{close}]$ is the interval in which T_f is abandoned. Then, if T_f is to be executed (by the clairvoyant algorithm) anywhere outside $BUSY$ it must be after t_{close}.*

Proof. $\Delta_f = [r_f, t_{aban}] \cup [t_{aban}, d_f]$. The first portion of Δ_f is contained in $BUSY$ (Lemma 5.4). $[t_{aban}, t_{close}] \subseteq I \subseteq BUSY$, hence if T_i is to be scheduled anywhere outside $BUSY$ it must be after t_{close}.[11] □

Now we are ready to give an upper bound on how much additional value can the clairvoyant algorithm achieve by scheduling tasks of F compared with collecting only the granted value without scheduling any tasks. We make strong use of the fact that when a task T is abandoned during I, T's value cannot be too large with respect to achievedvalue(I).

LEMMA 5.10. *With the above gifts, the total* net *gain obtained by the clairvoyant algorithm from scheduling the tasks abandoned during I is not greater than*

$$(1 + \sqrt{k}) \cdot \text{achievedvalue}(I).$$

Proof. Assume that a clairvoyant scheduler selected a scheduling for the tasks of F, considering the value that can be gained from leaving $BUSY$ periods idle. We can assume that a clairvoyant algorithm executes a task only if this task eventually completes. If the clairvoyant algorithm does not schedule any of the tasks abandoned during I, the lemma is proved. Hence, assume that of all the tasks abandoned in $I = [t_{begin}, t_{close}]$, the clairvoyant scheduler schedules $T_1, T_2, \ldots, T_m$ (in order of completion). These tasks execute for $l_1, l_2, \ldots, l_m$ time *after* t_{close} (hence, maybe outside $BUSY$). We know that all the l_i's are greater than zero (otherwise there is no net gain).

Lemma 5.6 ensures that the biggest possible value of a task to be abandoned during I is $(1 + \sqrt{k}) \cdot \text{achievedvalue}(I)$. If such a task has value density k its execution time is $\frac{(1+\sqrt{k}) \cdot \text{achievedvalue}(I)}{k}$. Denote by L the maximal value of this execution time and the length of l_1

$$L = \max \left\{ \frac{(1 + \sqrt{k}) \cdot \text{achievedvalue}(I)}{k}, l_1 \right\}. \tag{5}$$

[11] Note that parts of $[t_{close}, d_f]$ might be included in $BUSY$ as a new interval may be opened before d_f.

Let j be the index less than to m such that

$$\sum_{i \le j} l_i \le L < \sum_{i \le j} l_i + l_{j+1}.$$

If no such j exists, define j to be m.

First, assume that we have an equality, $\sum_{i \le j} l_i = L$. The $\sum_{i \le j} l_i < L$ case is a little more complicated and will be treated later.

We will show that the net gain from scheduling tasks within a period of L after the end of the interval cannot be greater than $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I)$.

- Suppose that in (5), the maximum is the first term. Then the total net gain from $T_1, T_2, \ldots, T_j$ is not greater than

$$k \cdot \sum_{i \le j} l_i = k \cdot L = (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I). \tag{6}$$

- If on the other hand the second term is maximal in (5) then the value obtained by scheduling T_1 is at most $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I)$ (Lemma 5.6).

Now we will show that the net gain from scheduling tasks "after" L is never positive.

Every task T_i that executed at a time of at least L after the end of the interval, where $j < i \le m$, has an execution time c_i of at least $d_i - t_{close}$ (see Lemma 5.7).

$$\begin{aligned} c_i &\ge d_i - t_{close} \\ &\ge \text{"the point at which } T_i \text{ completes (according to the clairvoyant)"} - t_{close} \\ &\ge (t_{close} + \sum_{g \le i} l_g) - t_{close} = \sum_{g \le i} l_g \\ &\ge l_i + \sum_{g \le j} l_g = l_i + L. \end{aligned}$$

For $i > j$, T_i was scheduled by the clairvoyant scheduler but used only l_i time after t_{close}. Hence, T_i executed at least L time before t_{close} that is to say in $BUSY$ by lemma 5.9. The "loss" from scheduling T_i during $BUSY$ is at least $k \cdot L$. The value obtained by scheduling T_i is at most $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I)$ (Lemma 5.6). Hence the net gain is less than or equal to

$$\begin{aligned} & (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I) - k \cdot L \\ \le\ & (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I) - (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I) = 0. \end{aligned}$$

We conclude that the clairvoyant algorithm is better off not scheduling any task T_i, $j < i \le m$. Hence, the lemma is proved for the case that $\sum_{i \le j} l_i = L$.

What if L does not equal any of the partial sums? That is, what if $\sum_{i \le j} l_i < L < \sum_{i \le j+1} l_i$? We will augment the total value given to the clairvoyant by some non-negative amount. Then we will show that even with this addition the net gain achieved by the clairvoyant algorithm is bounded by $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I)$, hence proving the lemma.

First we will take the value density of T_j to be k. This move can only increase the overall value achieved by the clairvoyant algorithm. We will also "transfer" some execution time (and hence also value) from T_{j+1} to T_j. We will transfer exactly $L - \sum_{i \le j} l_i$ execution time. There will be a nonnegative net increase of $(k - \text{value density}(T_{j+1})) \cdot (L - \sum_{i \le j} l_i)$ in the overall achieved value of the clairvoyant algorithm and we are back in the case of $L = \sum_{i \le j} l_i$. The total net gain from $T_1, \ldots, T_j$ is bounded by $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}(I)$ while the net gain from all other tasks is zero or negative. □

Our strategy thus far has entailed partitioning the problem into what the clairvoyant can obtain with respect to a given interval. We now compute an upper bound for what the clairvoyant algorithm can obtain over all intervals. Note that this may overestimate what the clairvoyant algorithm obtains, because the time periods that the clairvoyant algorithm uses on the tasks of two neighboring intervals may overlap.

COROLLARY 5.11. *With the previous gifts, the total net gain (over the entire execution) obtained by the clairvoyant algorithm from scheduling the tasks of F is not greater than*

$$(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}.$$

Proof. Lemma 5.10 measured the maximum net gain per interval. By construction, each task is accounted for in exactly one interval. Therefore, summing over all intervals we conclude that the total net gain during the entire execution is less than or equals to $(1 + \sqrt{k}) \cdot \mathsf{achievedvalue}$. □

The previous corollary bounds the value that the clairvoyant algorithm could obtain beyond the granted value, which equals $k \cdot BUSY$. Now, we will estimate the granted value (by bounding the length of $BUSY$) to get an upper bound on $C(S^0 \cup F)$.

LEMMA 5.12.

$$C(F \cup S^0) \leq k \cdot (\mathsf{achievedvalue} + \frac{1}{\sqrt{k}} \cdot \mathsf{zerolaxval}) + (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}$$

$$= (k + 1 + \sqrt{k}) \cdot \mathsf{achievedvalue} + \sqrt{k} \cdot \mathsf{zerolaxval}.$$

Proof. Lemma 5.8 shows that $C(S^0 \cup F)$ is bounded by the maximum, ranging over all possible schedulings of the tasks of F, of the following sum:

(value obtained by scheduling F) +

$k \cdot$ (length of time in $BUSY$ not utilized by F tasks).

Corollary 5.11 shows that this sum is less than or equal to

$$(1 + \sqrt{k}) \cdot \mathsf{achievedvalue} + k \cdot BUSY.$$

Lemma 5.5, summed over all intervals, yields

$$BUSY \leq \mathsf{achievedvalue} + \frac{1}{\sqrt{k}} \cdot \mathsf{lstvalue}.$$

$\mathsf{lstvalue}(I) \leq \mathsf{zerolaxval}(I)$ always holds because every task that is lst-scheduled must have completed at its deadline. This implies that

$$BUSY \leq \mathsf{achievedvalue} + \frac{1}{\sqrt{k}} \cdot \mathsf{zerolaxval}.$$

Hence,

$$C(S^0 \cup F) \leq k \cdot \left(\mathsf{achievedvalue} + \frac{1}{\sqrt{k}} \cdot \mathsf{zerolaxval}\right) + (1 + \sqrt{k}) \cdot \mathsf{achievedvalue}$$

$$= (k + 1 + \sqrt{k}) \cdot \mathsf{achievedvalue} + \sqrt{k} \cdot \mathsf{zerolaxval},$$

which proves the lemma. □

We gave the clairvoyant algorithm the value of all tasks in S^p. We also got a bound on $C(S^0 \cup F)$. The following lemma shows that the sum of these two values bounds the value the clairvoyant can get from the entire collection.

LEMMA 5.13.

$$C(F \cup S^0 \cup S^p) \leq C(F \cup S^0) + C(S^p) = C(F \cup S^0) + \sum_{T_i \in S^p} v_i.$$

Proof. The first inequality is due to the fact that $C(\cdot)$ is a sublinear function. The reason is that executing tasks of S^p might interfere with tasks of $F \cup S^0$ and vice versa. Therefore, the value of the union may be less than the sum of the values of the individual sets. D^{over} schedules to completion all the tasks of S^p, hence $C(S^p)$ equals the sum of the values of all these tasks. This yields the desired result. □

Given a collection of tasks Γ, Lemmas 5.12 and 5.13 give an upper bound on the value that the clairvoyant algorithm can obtain from Γ in terms of the value obtained by D^{over} (achievedvalue, zerolaxval, and poslaxval). The next theorem puts these results together.

THEOREM 5.14. *D^{over} has a competitive multiplier of $(1 + \sqrt{k})^2$. That is, D^{over} obtains at least $\frac{1}{(1+\sqrt{k})^2}$ times the value of a clairvoyant algorithm given any task collection Γ.*

Proof. In the notation of the lemmas, we derive from Lemma 5.12 that

$$C(S^0 \cup F) \leq (k + 1 + \sqrt{k}) \cdot \text{achievedvalue} + \sqrt{k} \cdot \text{zerolaxval}.$$

We will bound $\sqrt{k} \cdot$ zerolaxval in the previous equation.

$$\begin{aligned} \sqrt{k} \cdot \text{achievedvalue} &= \sqrt{k} \cdot \text{zerolaxval} + \sqrt{k} \cdot \text{poslaxval} \geq \sqrt{k} \cdot \text{zerolaxval} + \text{poslaxval} \\ &\Rightarrow \sqrt{k} \cdot \text{zerolaxval} \leq \sqrt{k} \cdot \text{achievedvalue} - \text{poslaxval}. \end{aligned}$$

Hence, replacing ($\sqrt{k} \cdot$ zerolaxval) by ($\sqrt{k} \cdot$ achievedvalue $-$ poslaxval) yields

$$\begin{aligned} C(S^0 \cup F) &\leq (k + 1 + \sqrt{k}) \cdot \text{achievedvalue} + \sqrt{k} \cdot \text{achievedvalue} - \text{poslaxval} \\ &= (1 + \sqrt{k})^2 \cdot \text{achievedvalue} - \text{poslaxval}. \end{aligned}$$

By using Lemma 5.13 we get

$$\begin{aligned} C(F \cup S^0 \cup S^p) &\leq C(F \cup S^0) + C(S^p) \\ &= C(F \cup S^0) + \text{poslaxval} \\ &\leq ((1 + \sqrt{k})^2 \cdot \text{achievedvalue} - \text{poslaxval}) + \text{poslaxval} \\ &= (1 + \sqrt{k})^2 \cdot \text{achievedvalue}. \end{aligned}$$

□

5.4. The running complexity of D^{over}. In the previous section, we analyzed the performance of D^{over} in the sense of what value it will achieve from scheduling tasks to completion. In this section we study the cost of executing the scheduling algorithm itself.

THEOREM 5.15. *If n bounds the number of unscheduled tasks in the system at any instant, then each task incurs an $O(\log n)$ amortized cost.*

Proof. D^{over} requires three data structures called Q_privileged, Q_waiting, and Qlst, all of them priority queues, implemented as balanced search trees, e.g., 2–3 trees. They support Insert, Delete, Min, and Dequeue operations, each taking $O(\log n)$ time for a queue with n tasks. The structures share their leaf nodes which represent tasks.

D^{over} consists of a main loop with three "interrupt handlers" within it. The total number of operations is dominated by the number of times each of these handler clauses is executed and the number of data structure operations in each clause.

Suppose a history of m tasks is given. First, let us estimate the number of times each handler clause can be executed. A task during its lifetime causes exactly one task release event and at most one task completion event as well as at most one latest-start-time interrupt event. Hence, while scheduling m tasks the total number of events is bounded by $3m$.

Now we will bound the number of queue operations in each handler clause.

- In the handler for the task release event (statement 54), there is a constant number of queue operations. Hence, this contributes a total of $O(m)$ queue operations during the entire history.
- In the handler for the task completion event (statement 9) there is a constant number of queue operations. Hence, this contributes a total of $O(m)$ queue operations during the entire history.
- In the handler for latest-start-time interrupt event (see statement 76), the number of queue operations is proportional to the number of tasks in Q_privileged plus a constant. (Because the privileged tasks are all inserted into Q_waiting, statement 83.) How many tasks can be in Q_privileged throughout the history? A task can enter Q_privileged only as a result of task release event (statement 64); there are at most m such events. Hence, the total number of tasks in Q_privileged is at most m, which means that the total number of queue operations is $O(m)$ during the entire history.

We conclude that the total number of operations for the entire history is $O(m \log n)$ and the theorem is proved. □

6. Underloaded periods: Conflicting tasks. Intuitively, D^{over} is an optimal scheduler during underloaded periods, because it mimics the *earliest-deadline-first* algorithm during those periods. It gives its nontrivial competitive guarantee during overloaded periods.

To make these statements precise, we must define what underloaded and overloaded mean. Informally, underload means a situation in which all tasks can be scheduled to completion by their deadlines. Such tasks are designated as *conflict-free*. The following algorithm (Fig. 5) gives a precise definition of conflict-free and their antithesis—*conflicting tasks*.[12]

D^{over} schedules to completion all conflict-free tasks (thus, all tasks in an underloaded system) and also obtains at least $\frac{1}{(1+\sqrt{k})^2}$ times the value a clairvoyant algorithm can get from the conflicting tasks. The proof rests on the proof of the competitive guarantee given in this paper and can be found in [9] and [12].

7. Conclusions. This paper has presented an optimal on-line scheduling algorithm for overloaded uniprocessor systems. It is optimal in the sense that it gives the best competitive multiplier possible relative to an off-line scheduler. In fact, the performance guarantee of D^{over} is even stronger: D^{over} schedules to completion all tasks in underloaded periods and achieves at least $\frac{1}{(1+\sqrt{k})^2}$ of the value a clairvoyant algorithm can get during overloaded periods. The model accounts for different value densities and generalizes to soft deadlines [9], [12].

This work leaves many problems open. Here is a small sample.

- This paper assumes that k is given and known in advance. It is interesting to know if this assumption can be relaxed. Recently, in an unpublished result, Schieber [16] devised a variant of D^{over} that gives the optimal guarantee even when k is not known in advance.
- What guarantees can be given for parallel scheduling algorithms? Recently we have found some results in this area, but much remains to be done, because those results are not tight in all cases [9], [10], [13].

[12] Note that the purpose of this algorithm is to define conflicting and conflict-free tasks. No scheduler need ever execute it.

21  return(Γ) (*In case that no conflict was found *)
```

FIG. 5. *The remove conflicts algorithm.*

- What guarantees can be given when tasks are not independent, e.g., for systems with locks or precedence constraints?
- In practice, real-time systems have some periodic critical tasks and other less critical tasks which may be aperiodic. A typical solution (as taken in the Spring Kernel, for example, in [19]) is to devote certain intervals to the critical tasks and to allow the less critical tasks to run during the rest of the time. D^{over} gives its usual guarantee with respect to the less critical tasks in this situation. (The accounting is a little more difficult since useful time has "holes" in it which correspond to subintervals allocated to critical tasks.) An unanswered question follows: What is a good competitive algorithm that can take advantage of the cases when a given critical task executes in less time than is allocated for it? We suspect the competitive guarantee may be worse, since the clairvoyant algorithm might then execute a task that D^{over} had prematurely abandoned.
- In general, the question of proof tools for such systems is open. We believe that the techniques in §5.3 will prove to be very useful.

Acknowledgments. The authors thank Marc Donner, Bud Mishra, and Doug Locke for many inspiring discussions.

ORDERED AND UNORDERED TREE INCLUSION*

PEKKA KILPELÄINEN† AND HEIKKI MANNILA†

Abstract. The following tree-matching problem is considered: Given labeled trees P and T, can P be obtained from T by deleting nodes? Deleting a node u entails removing all edges incident to u and, if u has a parent v, replacing the edge from v to u by edges from v to the children of u. The problem is motivated by the study of query languages for structured text databases. Simple solutions to this problem require exponential time. For ordered trees an algorithm is presented that requires $O(|P||T|)$ time and space. The corresponding problem for unordered trees is also considered and a proof of its NP-completeness is given. An algorithm is presented for the unordered problem. This algorithm works in $O(|P||T|)$ time if the out-degrees of the nodes in P are bounded by a constant, and in polynomial time if they are $O(\log |T|)$.

1. Introduction and motivation.

Let T be a tree and u be a node in T with parent node v. Denote by $delete(T, u)$ the tree obtained from T by removing the node u. The children of u become children of v. (See Fig. 1.)

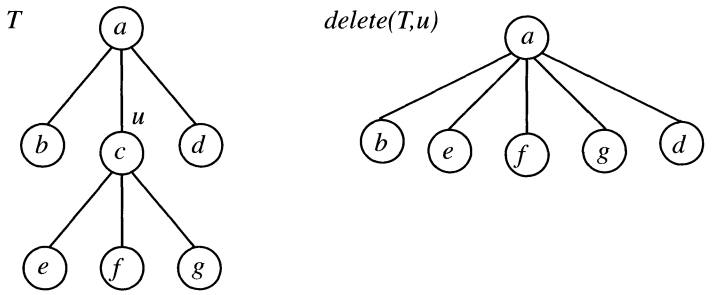

FIG. 1. *The effect of removing the node u from the tree T.*

We consider the following problem: Given two trees P and T, called the *pattern* and the *target*, can we obtain pattern P by deleting some nodes from target T? That is, is there a sequence $u_1, \ldots, u_k$ of nodes such that for

$$\begin{aligned} T_0 &= T \text{ and} \\ T_{i+1} &= delete(T_i, u_{i+1}) \text{ for } i = 0, \ldots, k-1 , \end{aligned}$$

we have $T_k = P$. If this is the case, what are the nodes in T that are (not) deleted by the sequence? We call this problem the *tree inclusion problem.*

Our specific interest in the tree inclusion problem comes from its applicability in structured text databases. A structured text database can be considered as a collection of parse trees that represent the structure of the stored documents [6], [11], [24]. Tree inclusion has been suggested as a primitive for expressing queries on structured documents [17] and as a means of retrieving information from structured documents [13].

A preliminary version of this article has appeared in *Proceedings of the International Joint Conference on the Theory and Practice of Software Development*, Vol. 1, Springer-Verlag, New York, 1991, pp. 202–214.

†Department of Computer Science, University of Helsinki, P.O. Box 26 (Teollisuuskatu 23), SF-00014 University of Helsinki, Finland (kilpelai@cs.helsinki.fi and mannila@cs.helsinki.fi).

As an example, consider querying grammatical structures. Figure 2 shows the parse tree of a natural language sentence. One might want to locate, say, those sentences that include a verb phrase containing the verb "holds" and the noun "cat" and any adverb, in this order. These are exactly the sentences whose parse tree can be transformed to the tree in Fig. 3 by deleting nodes.

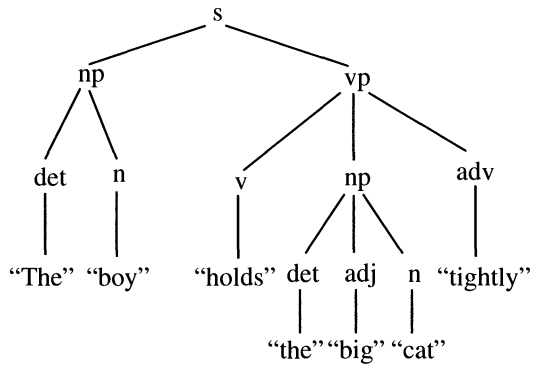

FIG. 2. *The parse tree of a sentence.*

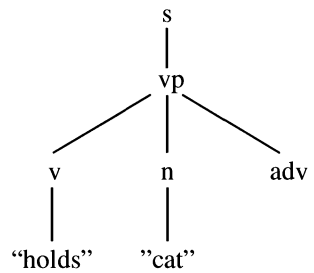

FIG. 3. *An included tree of the parse tree.*

The tree inclusion problem resembles *tree pattern matching* [8], [16], [4], [19], which has several applications. In that problem one wants to find out whether one can obtain a tree that has P as a subtree by removing complete sets of descendant nodes from T. The resemblance of the problems apparently does not extend to the algorithms. For tree pattern matching, the trivial algorithm works in time $O(|P||T|)$, where $|P|$ is the number of nodes in tree P, and $|T|$ is the number of nodes in tree T. The reason why tree pattern matching is a fairly simple problem is that there are only $|T|$ possible places where P can be matched in T. Hence the trivial algorithm can simply test all the possibilities. The $O(|P||T|)$ bound was not broken unitl recently [16], [4].

For the tree inclusion problem, there are exponentially many ways to obtain the included tree. Thus it is not feasible to check all the possibilities.

In this paper, we analyze the computational complexity of the tree inclusion problem. We give a polynomial time algorithm for solving the tree inclusion problem for ordered trees, i.e., when the ordering of siblings has significance. The algorithm is based on dynamic programming and it works in time $O(|P||T|)$.

The ordering among siblings is crucial for solving the tree inclusion problem efficiently. In the case of unordered trees, the problem is NP-complete. This result follows from the known NP-completeness of MINOR CONTAINMENT [9], [21]. To our knowledge, the

proof has not been published. We present a proof that is based on a direct reduction from SATISFIABILITY.

We also present an algorithm for solving the tree inclusion problem on unordered trees. The algorithm may require time that is exponential, but only in the width of the pattern. This means that if the out-degrees of the pattern nodes are $O(\log |T|)$, the unordered tree inclusion problem is solvable in polynomial time. This would usually be the case if we think P as a query and T as a large database [13].

The rest of this paper is organized as follows. We start by giving definitions and some properties of tree inclusion in §2. In §3 we relate the tree inclusion problem and our results to previous research, then we concentrate on solving the ordered tree inclusion problem. In §4 we develop the idea of *left embeddings*, which is the basis of our algorithms. Section 5 presents the basic algorithm. This algorithm may repeat the same computations many times, which leads to an exponential behavior. In §6 we develop the algorithm further. The use of a table for storing the results of subcomputations leads to an algorithm requiring $O(|P||T|)$ running time and storage. In §7 we consider the tree inclusion problem with unordered trees and give a proof of its NP-completeness. In §8 we present and analyze an algorithm for solving the unordered tree inclusion problem. Section 9 is a short conclusion.

2. Forest inclusion. We concentrate on labeled trees that are *ordered*, i.e., the order between siblings is significant. Ordered labeled trees appear in various fields, including programming language implementation, natural language processing, and molecular biology.

Technically, it is convenient to consider a slight generalization of trees, namely forests. A *forest* is a finite ordered sequence of disjoint finite trees. A *tree* T consists of a specially designated node $root(T)$ called the *root* of the tree, and a forest $\langle T_1, \ldots, T_k \rangle$, where $k \geq 0$. The trees $T_1, \ldots, T_k$ are the *subtrees* of the root of T or the *immediate subtrees* of tree T, and k is the *out-degree* of the root of T. The roots of the trees $T_1, \ldots, T_k$ are the *children* of the root of T and *siblings* of each other. The root is an *ancestor* of all the nodes in its subtrees, and the nodes in the subtrees are *descendants* of the root. The set of descendants of a node u is denoted by $desc(u)$. A *leaf* is a node with an empty set of descendants.

Sometimes we treat a tree T as the forest $\langle T \rangle$. We may also denote the set of nodes in a forest F by F. For example, if we speak of functions from a forest F to a forest G, we mean functions mapping *nodes* of F onto *nodes* of G. The *size* of a forest F, denoted by $|F|$, is the number of nodes in F.

The restriction of a forest F to a node u with its descendants is called the *subtree of F rooted by u*, and it is denoted by $F[u]$.

Let $F = \langle T_1, \ldots, T_k \rangle$ be a forest. The *preorder of a forest* F is the order of the nodes visited during a preorder traversal. A *preorder traversal of a forest* $\langle T_1, \ldots, T_k \rangle$ is as follows: Traverse the trees $T_1, \ldots, T_k$ in ascending order of the indices in preorder. To traverse a tree in preorder, first visit the root and then traverse the forest of its subtrees in preorder. The *postorder* is defined similarly, except that in a postorder traversal the root is visited *after* traversing the forest of its subtrees in postorder. The preorder and postorder numbers of a node u are denoted by $pre(u)$ and $post(u)$.

The following lemma binds together the ancestorship and the preorder and postorder.

LEMMA 2.1. *Let u and v be nodes in a forest F. Then u is an ancestor of v if and only if $pre(u) < pre(v)$ and $post(v) < post(u)$.*

Proof. See Exercise 2.3.2-20 in [15]. □

Let N be a set of nodes. A *labeling* for N is a function from N to some alphabet.

DEFINITION 2.2. *Let F and F' be forests, N and N' be the sets of their nodes, and let* label *be a labeling for $N \cup N'$. An injective function $f : N \to N'$ is an* embedding of F in F', *if for all nodes $u, v \in N$*

1. f preserves labels, *i.e.*, $label(f(u)) = label(u)$,
2. f preserves ancestors, *i.e.*, $f(u) \in desc(f(v))$ *if and only if* $u \in desc(v)$, *and*
3. f preserves the left-to-right order *of nodes.*

If there is an embedding of F *in* F', *we say that* F' includes F, *denoted* $F \sqsubseteq F'$, *and that* F *is an* included forest (or tree) *of* F'. *Forests* F *and* F' *are* isomorphic *if there is a bijective embedding of* F *in* F'.

If the second condition in the above definition is satisfied, the condition on the left-to-right order can be stated as

$$pre(u) < pre(v) \text{ if and only if } pre(f(u)) < pre(f(v)) ,$$

or, by Lemma 2.1, equivalently as

$$post(u) < post(v) \text{ if and only if } post(f(u)) < post(f(v)) .$$

EXAMPLE 2.3. *The included forests of the forest* $\langle a(b, c)\rangle$ *are* $\langle\rangle$, $\langle a\rangle$, $\langle b\rangle$, $\langle c\rangle$, $\langle b, c\rangle$, $\langle a(b)\rangle$, $\langle a(c)\rangle$, *and* $\langle a(b, c)\rangle$.

LEMMA 2.4. *The relation* $\sqsubseteq$ *is a partial ordering* (*up to isomorphism*), *i.e., it is reflexive, transitive, and antisymmetric.*

The next lemma justifies the formulation of the tree inclusion problem given in the introduction.

LEMMA 2.5. *A forest* G *includes a forest* F *if and only if a forest isomorphic to* F *can be obtained from* G *by deleting nodes.* (*The deletion of a node* v *from* G *replaces the tree* $G[v]$ *by the subtrees of* v.)

Proof. If u and v are nodes of G, the removal of a third node does not change the relative ordering of u and v. □

A forest may have exponentially many included forests, as shown in the next lemma.

LEMMA 2.6. *A forest* F *may have* $\binom{|F|}{m}$ *nonisomorphic included forests of size* m.

Proof. If every node in F has a different label, we get a nonisomorphic included forest of size m for every possible selection of $|F| - m$ nodes to be deleted. The number of such selections is $\binom{|F|}{m}$. □

EXAMPLE 2.7. *The forest* $\langle a(x, b(y(d, e), f), c)\rangle$ *has* 8 *nodes with different labels. Therefore it has* 256 *nonisomorphic included forests. If the labels are similar, the number of nonisomorphic included forests is smaller. For example, the forest* $\langle a(a, a(a(a, a), a), a)\rangle$ *has same size and form as the previous one, but it has only* 68 *nonisomorphic included forests.*

3. Related research. The ordered tree inclusion problem can be found in Exercise 2.3.2-22 of [15]. Knuth gives a sufficient condition for the existence of an embedding.

Tree inclusion can be considered to be a special case of the editing distance problem for trees [25], [27]. In [27], Zhang and Shasha give an algorithm for computing the edit distance. It can also be used for solving the ordered tree-inclusion problem. Their algorithm requires time

$$O(|P| \cdot |T| \cdot min(depth(P), leaves(P)) \cdot min(depth(T), leaves(T))) .$$

Thus their solution is slower than ours by a factor of

$$min(depth(P), leaves(P)) \cdot min(depth(T), leaves(T)) .$$

Shasha and Zhang have recently presented new sequential and parallel algorithms for the editing distance problem with unit cost edit operations [22].

The tree inclusion problem is a generalization of the *subsequence problem* for strings. ("Can the string x be obtained from the string y by deleting characters?") The subsequence problem can be solved in linear time by a straightforward scan. On the other hand, tree inclusion problem is a special case of the MINOR CONTAINMENT problem for graphs [21], [9]. In that problem, given two graphs $G = (V, E)$ and $H = (U, F)$, one has to decide whether G contains H as a *minor*, i.e., is there a subgraph of G that can be converted to H by a sequence of "contractions." In a contraction, two adjacent vertices and an edge between them are replaced by a single new vertex. All the other edges previously incident on either contracted vertex are then viewed incident to the new vertex.

MINOR CONTAINMENT is known to be NP-complete even for free trees, when both H and G are given as inputs.[1] This implies that MINOR CONTAINMENT is NP-complete also for rooted trees or, using our terminology, that tree inclusion is NP-complete for unordered trees. Recently Matoušek and Thomas [18] have independently published a proof of NP-completeness of unordered tree inclusion.

This classification suggests some further problems. It is possible to compute a maximal common subsequence for two strings in quadratic time and in linear space [7]. The corresponding problem of finding a maximal common included tree of two trees can be solved by Zhang and Shasha's editing distance algorithm [27]. Our algorithm specialized for the tree embedding problem is simpler and more efficient than Zhang and Shasha's algorithm. It is not clear yet if the algorithm also can be extended to solve the largest common included tree problem.

A related problem is the *tree pattern matching problem.* (See, e.g., [8], [19].) In tree pattern matching one is given a pattern tree (of m nodes), possibly with variables standing for arbitrary subtrees, and a subject tree (of n nodes). The problem is to locate the subtrees of the subject tree that are isomorphic to some tree presented by the pattern. The $O(mn)$ time bound of the naive algorithm has been difficult to improve for the general case. A recent paper of Kosaraju [16] presents an $O(nm^{0.75}\ polylog(m))$ algorithm. Dubiner, Galil, and Magen improve this result in their paper [4] by presenting an $O(n\sqrt{m}\ polylog(m))$ algorithm.

Checking whether an unordered tree is a subgraph of another one can be done in time $O(m^{3/2}n)$ by using bipartite matching [20], [26].

A unified treatment of related tree matching problems with some further variations is presented in [14].

4. Left embeddings. In this section, we develop concepts that help us efficiently solve the ordered tree inclusion problem. Throughout the rest of the paper, let *label* be a labeling for the nodes of the trees.

We concentrate on searching *root-preserving embeddings.*

DEFINITION 4.1. *Let P and T be trees. A* root-preserving embedding of P in T *is an embedding f of P in T such that $f(root(P)) = root(T)$. If there is a root-preserving embedding of P in T, we say that the root node of T is an* occurrence *of P.*

The following simple lemma states that we do not lose generality by restricting to root-preserving embeddings.

LEMMA 4.2. *Let F and G be forests, and let P and T be two trees whose roots are labeled by the same symbol, such that the immediate subtrees of P form forest F and the immediate subtrees of T form forest G. Then $F \sqsubseteq G$ if and only if there is a root-preserving embedding of P in T.*

[1] For every *fixed* planar graph (and therefore for every fixed tree and forest) H there is a polynomial time algorithm for testing whether H is a minor of a given graph G [21], [9].

There may be exponentially many ways to embed the subtrees of a tree P in the subtrees of a tree T. In order to limit the search among these embeddings, we develop algorithms that search for a root-preserving embedding of P in T by processing the subtrees of P from left to right and trying to embed them as deep and as left as possible in T.

In order to discuss the relationship between images of sibling nodes in an embedding, we define the sets of *right and left relatives* of a node.

DEFINITION 4.3. *Let F be a forest, N be the set of its nodes, and v be a node in F. The set of* right relatives *of v is defined by*

$$rr(v) = \{x \in N \mid pre(v) < pre(x) \wedge post(v) < post(x)\} ,$$

i.e., the right relatives of v are those nodes that follow v both in preorder and in postorder. The set of left relatives *of node v, denoted by $lr(v)$, is the set of nodes that precede v both in preorder and in postorder. (See Fig. 4.)*

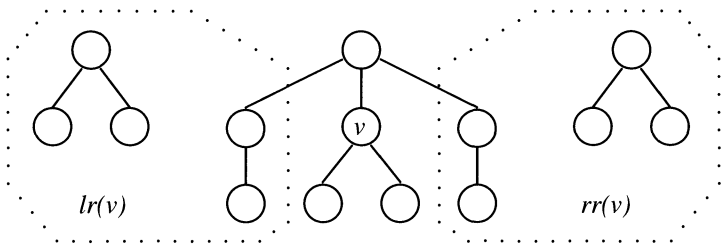

FIG. 4. *The left and right relatives of node v.*

The crucial observation is that an embedding that maps a node u to a node v can map right siblings of u to the right relatives of v only.

The next lemma can be used as a tool with Lemma 2.1 to derive the two lemmas following it.

LEMMA 4.4. *Let u, v, and x be three nodes in a forest. Then it is not possible that both*

$$\begin{array}{ccccc} pre(u) & < & pre(v) & < & pre(x) \quad \text{and} \\ post(x) & < & post(u) & < & post(v) \end{array}$$

hold.

Proof. The above conditions imply by Lemma 2.1 that u and v are ancestors of x but neither of them is an ancestor of the other, which is not possible in a forest. □

The next simple lemma states that the descendants of a right relative are also right relatives.

LEMMA 4.5. *Let v and x be nodes, and assume $x \in rr(v)$. Then $desc(x) \subset rr(v)$.*

The next lemma states that the right relatives of a node v are contained in the right relatives of the nodes that precede v in postorder. This fact is the justification for the strategy of embedding the trees as early as possible in postorder, when searching for an embedding of a forest.

LEMMA 4.6. *Let v and x be nodes in a forest. If $post(v) \leq post(x)$, then $rr(x) \subseteq rr(v)$.*

The next definition gives a name for the embeddings that are searched for by our algorithms.

DEFINITION 4.7. *Let $F = \langle T_1, \ldots, T_k \rangle$ and G be forests, and let $\mathcal{E}$ be a collection of embeddings of F in G. An embedding $f \in \mathcal{E}$ is a* left embedding *of $\mathcal{E}$ if for every $g \in \mathcal{E}$*

$$post(f(root(T_k))) \leq post(g(root(T_k))) .$$

A left embedding of the set of all embeddings of F in G is a left embedding *of F in G.*

It is obvious that every finite nonempty set of embeddings has at least one left embedding. Therefore the following theorem holds, allowing us to restrict to left embeddings when testing for the existence of an embedding.

THEOREM 4.8. *Let F and G be forests. There is an embedding of F in G if and only if there is a left embedding of F in G.*

The next theorem presents a method to build left embeddings by proceeding from left to right. The method is applied in Algorithms 5.1 and 6.1.

THEOREM 4.9. *Let $F = \langle P_1, \ldots, P_k \rangle$, where $k \geq 2$, and G be forests, and let f be a left embedding of $F_1 = \langle P_1, \ldots, P_i \rangle$ in G, where $1 \leq i < k$. Let F_2 be the forest $\langle P_{i+1}, \ldots, P_k \rangle$ and let $\mathcal{E}$ be the set of such embeddings g of F_2 in G that $g(root(P_{i+1})) \in rr(f(root(P_i)))$. Then the following items hold:*

1. *If $\mathcal{E}$ is empty, there is no embedding of F in G.*
2. *If $\mathcal{E}$ is nonempty and g is a left embedding of $\mathcal{E}$, then $f \cup g$ is a left embedding of F in G.*

Proof.

1. Assume contrapositively that g is an embedding of F in G. Let g_1 and g_2 be the restrictions of g in F_1 and F_2, respectively. Then $g_2(root(P_{i+1})) \in rr(g_1(root(P_i)))$, and $post(f(root(P_i))) \leq post(g_1(root(P_i)))$, since f is a left embedding of F_1 in G. Therefore

$$g_2(root(P_{i+1})) \in rr(f(root(P_i)))$$

by Lemma 4.6, which means that $g_2 \in \mathcal{E}$.

2. First we show that $f \cup g$ is an embedding of F in G. It is sufficient to show that $f \cup g$ preserves the relative order of any two nodes x of F_1 and y of F_2. Now $root(P_i)$ is the last node of forest F_1 in postorder. Therefore we have by Lemma 4.6 that $root(P_j) \in rr(x)$ for all $i < j \leq k$, and Lemma 4.5 states that $y \in rr(x)$ also when y is not the root of any of the trees $P_{i+1}, \ldots, P_k$. Next we can see that $g(y) \in rr(f(x))$ by applying the same argument to the images of the above nodes.

Next we show that $f \cup g$ is a left embedding of F in G. For this, let h be any embedding of F in G, and let h_1 and h_2 be the restrictions of h to F_1 and F_2, respectively. Now we have that $h_2 \in \mathcal{E}$, and therefore $post(g(root(P_k))) \leq post(h_2(root(P_k)))$. This entails the claim since $g(root(P_k)) = (f \cup g)(root(P_k))$ and $h_2(root(P_k)) = h(root(P_k))$. □

5. The basic algorithm. Now we are ready to give an algorithm for testing whether there is a root-preserving embedding of a pattern tree P in a target tree T. Let $P_1, \ldots, P_k$ be the immediate subtrees of P. First, our algorithm searches the image $f(root(P_1))$ of $root(P_1)$ under a left embedding f of $\langle P_1 \rangle$ in the immediate subtrees of tree T, if such an embedding exists. The algorithm uses a pointer p for traversing the descendants of $root(T)$. After finding a left embedding f for the forest $\langle P_1, \ldots, P_i \rangle$, p points at node $f(root(P_i))$. In order to extend f to a left embedding of $\langle P_1, \ldots, P_{i+1} \rangle$ in the subtrees of $root(T)$, we try to find the closest right relative x of p in postorder, such that x is an occurrence of P_{i+1} and a descendant of $root(T)$.

The algorithm refers to nodes by their postorder numbers. The minimum of a set of nodes is the first node of the set in postorder. The algorithm also refers to an auxiliary target node 0, which precedes every other node of tree T in both preorder and postorder. This means that all other target nodes are right relatives of node 0. We denote the size of T by n. The root of T being the last target node in postorder is then n.

ALGORITHM 5.1. *Testing whether a tree T includes a tree P.*
Input: *Trees P and T.*
Output: **true** *if and only if there is a root preserving embedding of P in T.*
Method: *Call emb(root(P), root(T));*

```
1.  function emb(u, v);
2.      if label(u) ≠ label(v) then return false;
3.      else
4.          let u_1, ..., u_k be the children of u; (if u is a leaf, k = 0)
5.          p := min(desc(v) ∪ {n + 1}) − 1;
6.          comment: p is the predecessor of desc(v), or n if v is a leaf;
7.          i := 0;
8.          while i < k and p < v do
9.              p := min({x ∈ rr(p) | emb(u_{i+1}, x)} ∪ {n + 1});

20. end.
```

The loop on lines 8–15 tests whether there is a left embedding of the forest $\langle P[u_1], \ldots, P[u_k]\rangle$ in the forest of subtrees of v. This is, by Theorem 4.8 and Lemma 4.2, equivalent to testing whether there is a root-preserving ordered embedding of $P[u]$ in $T[v]$, because on these lines $label(u) = label(v)$. The test is successful if and only if all the subtrees of u can be embedded in the loop, i.e., if and only if $i = k$ on line 16.

The test is obviously correct if the pattern node u is a leaf. Let node u have children. If the target node v is a leaf, p gets value n on line 5 of the algorithm, which prevents the execution of lines 8–16. This is consistent with the fact that in this case $P[u]$ cannot be embedded in $T[v]$. Otherwise, if target node v has descendants, p gets the value $min(desc(v)) - 1$, which is the closest left relative of v. The postorder numbers of the descendants of v then, are $\{p + 1, p + 2, \ldots, v - 1\}$. By Lemma 4.5, $desc(v) \subset rr(p)$. Then, if $P[u_1]$ has occurrences in $desc(v)$, the first execution of line 9 finds in p the first of them in postorder. The correctness of the remaining executions of the loop follows from Theorem 4.9.

The primitive operations of moving to the first descendant node or to the next or previous node in postorder can be performed in constant time, after a linear time preprocessing of tree T. Note that the tests $p \in desc(v)$ and $x \in rr(p)$ can be realized as simple comparisons of preorder and postorder numbers. (See Lemma 2.1 and Definition 4.3.)

The algorithm above may still need exponential time in the size of the trees. Consider trees $P_n = r(a(a(\ldots a(a(b))\ldots)))$ (a b-leaf with n a-ancestors below root r) and $T_n = r(a(a(\ldots a(\ldots a(a)\ldots), b)\ldots)))$ (a chain of $2n$ a-nodes below root r; the nth a has also a b-leaf as a child). The algorithm would try in the recursive calls on line 9 a total of $\binom{2n}{n}$ embeddings before finding the right images for the a-nodes and an embedding for the whole tree P_n.

6. A dynamic programming solution. The previous algorithm may repeat the same computations an exponential number of times in the worst case. To avoid this, we use an $m \times n$ table ($m = |P|, n = |T|$) to store results of subcomputations. As before, we test for the existence of a root-preserving embedding of $P[u]$ in $T[v]$ by trying to find a left embedding of u's subtrees in v's subtrees. The key is to organize the evaluation so that the step that extends the left embedding of $\langle P_1, \ldots, P_i \rangle$ into an embedding of $\langle P_1, \ldots, P_{i+1} \rangle$ can either find the correct occurrence of P_{i+1} or decide that there is none in *constant time*.

Let us define a table e having rows $1, \ldots, m$ and columns $0, \ldots, n-1$. As before, we refer to the nodes of P and T by their postorder numbers; the numbers of P are used as row indices of the table, and the numbers of T are used as column indices and contents of the table. Denote by $R(P, T)$ the collection of root-preserving embeddings of a tree P in a tree T. We compute into table e values ($u \in P$, $v \in \{0, \ldots, n-1\}$)

$$e(u, v) = min(\{x \in rr(v) \mid \exists f \in R(P[u], T[x])\} \cup \{n+1\}) . \tag{1}$$

That is, $e(u, v)$ contains the closest right relative of target node v that is an occurrence of $P[u]$, or $n+1$ meaning that $P[u]$ has no occurrences among the right relatives of v. The result of the computation can be found on row m (i.e., *root*(P)) of the table. Pattern P can be embedded in T if and only if $e(m, 0) \leq n$, and every $v \in T$ that appears on row m of table e is an occurrence of P.

The new algorithm uses pointer p in the same way as Algorithm 5.1 did. When a root-preserving embedding of $P[u]$ in $T[v]$ is found, another pointer q is used for writing value v into $e(u, q)$ for those nodes q for which v is the appropriate value along (1). Since those nodes q are left relatives of node v, columns $0 \ldots n-1$ suffice for the table because node n, i.e., the root of the target, has no right relatives.

ALGORITHM 6.1. *Testing whether a tree T includes a tree P, dynamic programming version.*
Input: *Trees P and T ($|P| = m$, $|T| = n$).*
Output: *Table e filled so that for all $u \in P$ and $v = 0, \ldots, n-1$*

$$e(u, v) = \min(\{x \in rr(v) \mid \exists f \in R(P[u], T[x])\} \cup \{n+1\}) .$$

Method:

```
1.  for u := 1, ..., m do
2.      comment: Initialize row u of e;
3.      for v := 0, ..., n - 1 do e(u, v) := n + 1; od;
4.      Let u_1, ..., u_k be the children of u; (if u is a leaf, k = 0)
5.      q := 0;
6.      for v := 1, ..., n do
7.          if label(v) = label(u) then
8.              p := min(desc(v) ∪ {n + 1}) - 1;
9.              i := 0;
10.             while i < k and p < v do
11.                 p := e(u_{i+1}, p);
12.                 if p ∈ desc(v) then i := i + 1; fi;
13.             od;
14.             if i = k then
15.                 while q ∈ lr(v) do
16.                     e(u, q) := v;
17.                     q := q + 1;
18.                 od;
```

19. **fi**;
20. **fi**;
21. **od**;
22. **od**.

As an example, consider how Algorithm 6.1 finds the embedding of a tree $P = a(c, e)$ in a tree $T = a(b(c), a(b(d), a(b(e))))$. The trees and the result of the computation can be seen in Fig. 5. Each column of table e is shown to the right of the corresponding target node.

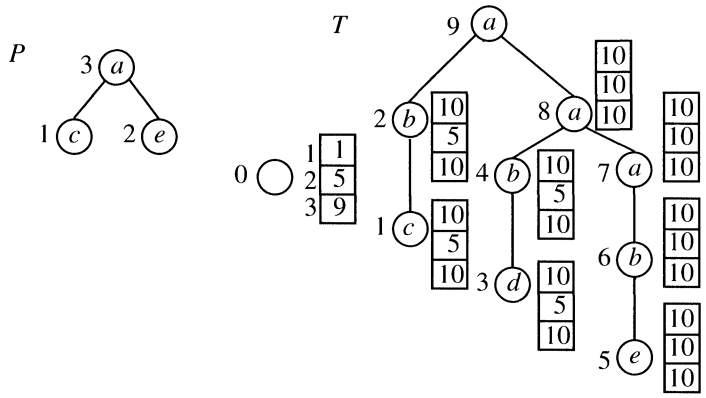

FIG. 5. *The result of applying the algorithm to trees P and T.*

First, $u = 1$, the leaf of P labeled by c, and $v = 1$, the similar leaf of T. Since the labels match and u has no children ($i = k = 0$), we have an embedding. The value of $v = 1$ is written into $e(1, 0)$ only, since 0 is the only left relative of v. After that, no more matching labels are found for $u = 1$ in nodes $v = 2, \ldots, 9$ of T.

Next $u = 2$, the second leaf of P. The first node v of T such that $label(v) = label(u) = e$ is node 5. As above, we have an embedding, and the value of $v = 5$ is written into $e(2, q)$ for the left relatives $q = 0, \ldots, 4$ of v. Again the remaining nodes $v = 6, \ldots, 9$ are scanned without encountering any matching labels.

Finally, $u = 3 = root(P)$. Node $v = 7$ is the first node of T with $label(v) = label(u) = a$. The node p preceding $desc(v)$ in postorder is node 4. The first child of u is node number 1. Its image in $rr(p) \supset desc(v)$ is looked up from $e(1, 4)$; value $n + 1 = 10$ means that there is no embedding of the child in $desc(v)$. Next, a similar failure occurs with $v = 8$ and $p = 2$. Finally $v = 9 = root(T)$, $label(v) = label(u) = a$, which leads to testing the embedding of the subtrees of u by executing $p := 0$, $p := e(1, 0) = 1$, and $p := e(2, 1) = 5$. The algorithm has found a root-preserving embedding of P in T. The value of $v = 9$ is written as the final result into $e(3, 0)$. Since 0 is the only left relative of 9, the computation ends.

THEOREM 6.2. *Algorithm* 6.1 *fills table e correctly.*

Proof. Consider a fixed pattern node u. We outline a proof that all columns of row u get correct values in the **while**-loop on lines 15–18 of the algorithm. First, the precondition that all columns up to q have got the right values is initially true when $q = 0$. We show that the following invariant holds on line 16:

$$\exists f \in R(P[u], P[v]) \quad \wedge \quad v \in rr(q) \tag{2}$$

$$\wedge\, \forall 1 \leq x < v : (\exists g \in R(P[u], T[x]) \quad \Rightarrow \quad x \notin rr(q)) \,. \tag{3}$$

The invariant shows that the loop writes correct values into $e(u, q)$. Since q increases only in the loop, the truth of the invariant maintains the precondition for the subsequent executions of the loop.

Assume that u is a leaf; then $e(u, q)$ should be assigned the number of the first node v in $rr(q)$ such that $label(v) = label(u)$. It is clear that (2) holds when we are on line 16. (Note that $q \in lr(v)$ and $v \in rr(q)$ are equivalent.) When line 16 is executed for the first time, (3) is vacuously true. By Lemma 4.6 we can strengthen (3) into

$$\forall\, 1 \le x < v, \forall\, y \ge q : (\exists\, g \in R(P[u], T[x]) \Rightarrow x \notin rr(y)) \,. \tag{4}$$

At the exit from the loop, $v \notin rr(q)$ allows us to deduce from (4) that

$$\forall\, 1 \le x \le v, \forall\, y \ge q : (\exists\, g \in R(P[u], T[x]) \Rightarrow x \notin rr(y)) \,. \tag{5}$$

This postcondition makes (3) true on the subsequent executions of the loop. It also shows that the writing is complete, i.e., value v must not be written into $e(u, y)$ for any column $y \ge q$.

Next, assume that u is a nonleaf node, and the rows of the table e corresponding to the children of u have been correctly computed. Then, as in Algorithm 5.1, the **while**-loop on lines 10–13 finds a left embedding of the subtrees of u in the subtrees of v, if there is any. The correctness of the **while**-loop on lines 13–16 is verified as in the base case. □

THEOREM 6.3. *Algorithm* 6.1 *requires* $O(mn)$ *time and space.*

Proof. Space: Table e requires $O(mn)$ space.

Time: During every execution of the outermost loop q may increase in steps of one from 0 to n. Therefore, the **while**-loop that increments q requires $O(n)$ steps per one outermost loop. One execution of the **while**-loop on lines 10–13 requires time $O(1 + |u|)$, where $|u|$ is the out-degree of node u. We get total time

$$O\left(\sum_{u=1}^{m}(n + \sum_{v=1}^{n}(1 + |u|))\right) = O\left(n \sum_{u=1}^{m}(2 + |u|)\right) \,.$$

The sum $\sum_{u=1}^{m} |u|$ equals the number of edges in tree P, which is $m - 1$. Therefore the total time is $O(n(3m - 1)) = O(mn)$. □

7. Unordered tree inclusion. So far we have presented an efficient algorithm for the tree inclusion problem in the case of ordered trees. Now we turn to the unordered version of the problem, which appears to be essentially harder.

A tree P is an *unordered included tree* of a tree T if the nodes of P can be injectively mapped onto the nodes of T preserving the labels and the ancestorship relation between nodes. Such a mapping is called an *unordered embedding*. We do not require the left-to-right order of the nodes to be preserved in an unordered embedding.

As before, the tree inclusion can be characterized also operationally.

LEMMA 7.1. *A tree P is an unordered included tree of a tree T if and only if P can be obtained from T by deleting nodes and permuting subtrees.*

The existence of an efficient algorithm for unordered tree inclusion is unlikely, since the problem appears to be NP-complete. We prove the NP-completeness of unordered tree inclusion by a reduction from the basic NP-complete problem SATISFIABILITY [3], [5]. For proving the NP-completeness of unordered tree inclusion we use the following lemma stating that a slight restriction of SATISFIABILITY is still NP-complete.

LEMMA 7.2. *Let $U = \{u_1, \ldots, u_n\}$ be a set of Boolean variables and $C = \{c_1, \ldots, c_m\}$ be a collection of clauses over U. Now C can be transformed in polynomial time into such a collection of clauses $C' = \{c'_1, \ldots, c'_{m'}\}$ that*

1. *C is satisfiable if and only if C' is satisfiable, and*
2. *no negated variable occurs in two clauses of C'.*

Proof. Let $D = \{\{u, y_u\}, \{\bar{u}, \bar{y}_u\} \mid u \in U\}$, where y_u is a new variable, for each $u \in U$. Clauses $\{u, y_u\}$ and $\{\bar{u}, \bar{y}_u\}$ express exclusive or of u and y_u, i.e., a truth assignment can satisfy

them only if it assigns opposite values to u and y_u. Let E be the set of clauses obtained from C by replacing each negated occurrence $\bar{u}$ of a variable by y_u, and let $C' = D \cup E$. Now C' is satisfiable if and only if C is satisfiable. The transformation obviously can be done in polynomial time. □

THEOREM 7.3. *The unordered tree inclusion problem is NP-complete.*

Proof. It is easy to see that the problem is in NP: An algorithm can guess the mapping of the pattern nodes onto the target nodes and check in polynomial time that it is indeed an embedding.

The completeness for NP is shown by a reduction from SATISFIABILITY. Let an instance of SATISFIABILITY be given by a collection of variables $U = \{u_1, \ldots, u_n\}$ and a collection of clauses $C = \{c_1, \ldots, c_m\}$ over U. By Lemma 7.2 we can assume that no negated variable appears in two clauses of C.

Form a pattern tree P and a target tree T of unordered tree inclusion problem as follows. Let $P = (N_P, E_P)$ be a tree given by nodes $N_P = \{0, \ldots, m\}$ and by parent-child edges

$$E_P = \{(0, x) \mid x \in N_P, x \neq 0\} .$$

Let $label(x) = x$ for all $x \in N_P$. The intuition is that the nodes of tree P, excluding the root, represent clauses of C and each of them is labeled by the index of the corresponding clause. Let $T = (N_T, E_T)$ be the tree whose nodes consist of pairs

$$\begin{aligned} N_T \quad = \quad & \{(0, 0)\} \cup \\ & \{(u, j) \mid u \in c_j \in C\} \cup \\ & \{(\bar{u}, j) \mid \bar{u} \in c_j \in C\} , \end{aligned}$$

and whose parent-child edges are

$$\begin{aligned} E_T \quad = \quad & \{((0, 0), (u, j)) \mid u \in c_j \in C, \bar{u} \notin \cup C\} \cup \\ & \{((0, 0), (\bar{u}, j)) \mid \bar{u} \in c_j \in C\} \cup \\ & \{((\bar{u}, j), (u, k)) \mid \bar{u} \in c_j \in C, u \in c_k \in C\} . \end{aligned}$$

So, tree T has one node corresponding to each occurrence of a literal in a clause of C, and an additional root node $(0, 0)$. The nodes for the positive occurrences of variables that do not occur negated in C are children of the root of T. A node $(\bar{u}, j)$ corresponding to a negated occurrence of variable u is a child of the root of T and the parent of the nodes corresponding to the positive occurrences of u. The assumption of unique occurrences of negative literals implies that each node except the root has a unique parent, and thus T is indeed a tree. Let $label((x, j)) = j$ for all nodes $(x, j) \in N_T$, i.e., the nodes corresponding to the literal occurrences in a clause c_j are labeled by j. An example of the construction is shown in Fig. 6.

Obviously, the trees can be formed in polynomial time.

Now we claim that there is a satisfying truth assignment for C if and only if P is an unordered included tree of T. First, assume that t is a satisfying truth assignment for C. Define a mapping h from the nodes of P onto the nodes of T as follows: For the root of P set $h(0) = (0, 0)$ and for other nodes j of P set $h(j) = (l, j)$, where $(l, j) \in N_T$ is some node such that literal l is true under truth assignment t; such a node can be selected because t satisfies at least one literal of every clause $c_j \in C$. Now h is an unordered embedding, since it is obviously injective and label preserving, and it cannot map two sibling nodes from P to an ancestor and its descendant in T. Otherwise, by the construction of T, truth assignment t would satisfy both a positive and a negative occurrence of the same variable, which is impossible.

Next assume that h is an unordered embedding of P in T. Set $t(x) =$ false if the range of h contains a node $(\bar{x}, j)$ corresponding to a negative occurrence of variable x, and $t(x) =$ true

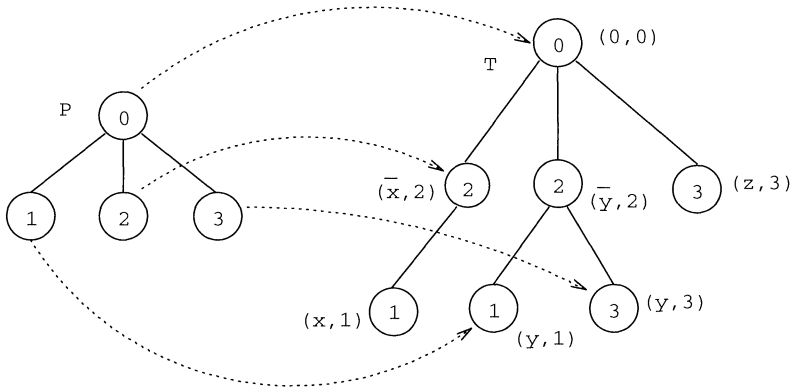

FIG. 6. *Trees for clauses* $c_1 = \{x, y\}$, $c_2 = \{\bar{x}, \bar{y}\}$, *and* $c_3 = \{y, z\}$. *The embedding shown by arrows corresponds to satisfying truth assignments that set* x *to false and* y *to true.*

if the range of h contains a node (x, j) corresponding to a positive occurrence of variable x. It is easy to see that t is a well-defined truth assignment for a subset of variables in C, and that t satisfies at least one literal in each clause of C. □

8. An algorithm for unordered tree inclusion. In this section we present an algorithm for solving the unordered tree-inclusion problem. The algorithm requires exponential time in the worst case. In the light of the NP-completeness of the problem, it is unlikely that we can do any better. We will see that the difficulty of solving the problem lies in permuting the left-to-right order of the pattern nodes. If the size or the branching of the pattern is limited, the problem becomes feasible to our algorithm.

Let P be the pattern tree and T the target tree. The next algorithm is based on manipulating match systems consisting of subsets of pattern nodes. The *match system* $S(v)$ for a target node v consists of all the subsets $\{u_1, \ldots, u_k\}$ of pattern nodes such that the forest $\langle P[u_1], \ldots, P[u_k]\rangle$ has an unordered embedding in $T[v]$. The algorithm computes the match systems for each target node while going through the target in a bottom-up order. Note that if v' is an ancestor of a target node v, then $T[v] \sqsubseteq T[v']$ and therefore $S(v) \subseteq S(v')$. Also, for each pattern node u we have that $\{u\} \in S(v)$ only if $children(u) \in S(v)$.

ALGORITHM 8.1. *Unordered tree inclusion algorithm.*
Input: *Trees* P *and* T ($|P| = m$, $|T| = n$).
Output: *The nodes* v *of* T *such that there is a root-preserving unordered embedding of* P *in* $T[v]$.
Method:

```
1.    for v := 1, ..., n do
2.    comment: Go through the target nodes in postorder;
3.        S := {∅};
4.        Let v_1, ..., v_l, l ≥ 0, be the children of v;
5.        for i := 1, ..., l do
6.            S := {A ∪ B | A ∈ S, B ∈ S(v_i)};
7.        od;
8.        SΔ := ∅;
9.        for all u ∈ P such that label(u) = label(v) do
10.           if children(u) ∈ S then
11.               SΔ := SΔ ∪ {{u}};
```

```
12.              fi;
13.          od;
14.          if {root(P)} ∈ SΔ then
15.          comment: An occurrence found;
16.              output v;
17.          fi;
18.          S(v) := S ∪ SΔ;
19.      od.
```

The algorithm computes the match system $S(v)$ for a target node v with children $v_1, \ldots, v_l$ as follows. First the loop on lines 5–7 computes from the match systems of the children of v a set S. The invariant for the loop says that the set S consists of the subsets $\{u_1, \ldots, u_k\}$ of such pattern nodes that the forest $\langle P[u_1], \ldots, P[u_k]\rangle$ has an unordered embedding in the forest $\langle T[v_1], \ldots, T[v_i]\rangle$. For $i = 0$ this is clearly true, since $S = \{\emptyset\}$. Next, assume inductively that the invariant holds for $i - 1$ when $0 < i \leq l$, and that $S(v_i)$ is the correct match system for the child v_i of target node v. Now it is rather easy to see that the forest $\langle P[u_1], \ldots, P[u_k]\rangle$ has an unordered embedding in $\langle T[v_1], \ldots, T[v_i]\rangle$ if and only if $\{u_1, \ldots, u_k\} = A \cup B$ for some $A \in S$ and $B \in S(v_i)$.

Next the algorithm computes in a set $S\Delta$ the singleton sets $\{u\}$ of the pattern nodes u for which there is a root-preserving embedding of $P[u]$ in $T[v]$; these are exactly those nodes u whose label matches the label of v and whose set of children belongs to S. After this process, $S \cup S\Delta$ is the the match system of v.

We will restrict match systems to consist of sets of sibling nodes only. (Note that they only affect the insertion of new pattern nodes to the match systems on line 10 of Algorithm 8.1.) This can be done by restricting, on line 6, to uniting only sets A and B of nodes that have a common parent.

The size of the match systems depends on P only. If P is fixed, executing line 6 and the loop on lines 9–13 takes constant time. The algorithm examines every target node at most twice; once as v and at most once as a child of v. Therefore we have the following result.

THEOREM 8.2. *For a fixed pattern P, an instance (P, T) of the unordered tree inclusion problem can be solved in time $O(|T|)$.*

If we are to solve the problem repeatedly with the same pattern P, we can solve it in two phases. The first phase is to perform a preprocessing on P, which may take a long time as a function of $|P|$. After the preprocessing a modified version of Algorithm 8.1 needs time that is only linear in $|T|$ and not a function of $|P|$. The preprocessing would be based on enumerating the collection $\mathcal{S}(P)$ of possible values of variable S, and using this enumeration to index arrays storing the possible assignments performed on lines 6, 9–13 and 18. A similar approach can be found in the bottom-up tree pattern matching algorithm of [8].

The preprocessing is reasonable only when the size of $\mathcal{S}(P)$ is not too large. The size of collection $\mathcal{S}(P)$ depends strongly on the form of the pattern P. If P consists of m nodes that form a path from the root to a single leaf, $\mathcal{S}(P)$ consists of $m + 1$ systems that are $\{\emptyset\}$, $\{\emptyset, \{1\}\}, \ldots,$ and $\{\emptyset, \{1\}, \ldots, \{m\}\}$. At the other extreme, the size of $\mathcal{S}(P)$ can be doubly exponential in m. To see this, consider a pattern P consisting of a root node and $m - 1$ leaves. Let $\mathcal{A}$ be the system consisting of the sets of $\lfloor (m-1)/2 \rfloor$ leaves of P. Obviously $|\mathcal{A}| = \binom{m-1}{\lfloor (m-1)/2 \rfloor}$, and every subset of $\mathcal{A}$ belongs to $\mathcal{S}(P)$. Therefore

$$|\mathcal{S}(P)| > 2^{\binom{m-1}{\lfloor (m-1)/2 \rfloor}}.$$

Each match system S is *monotone decreasing*, i.e., if $A \in S$, then $B \in S$ for each $B \subseteq A$. Thus we can represent the match systems as *Sperner systems* by maintaining their maximal

elements only. The following results give an upper bound for the number of Sperner systems on m nodes.

PROPOSITION 8.3 [23], [1]. *The size of a Sperner system on an m-element set is at most* $\binom{m}{\lfloor m/2 \rfloor}$.

PROPOSITION 8.4 [2]. *The number of set systems $\mathcal{A}$ on an m-element set, satisfying*

$$|\mathcal{A}| \leq c\binom{m}{\lfloor m/2 \rfloor}, \tag{6}$$

is at most

$$2^{\frac{c}{2}\binom{m}{\lfloor m/2 \rfloor}\log m(1+o(1))}.$$

Putting together these propositions gives the following upper bound for the number of Sperner systems on an m-element set, denoted by $\alpha(m)$:

$$\alpha(m) \leq 2^{\frac{1}{2}\binom{m}{\lfloor m/2 \rfloor}\log m(1+o(1))}$$

When the systems in $\mathcal{S}(P)$ are Sperner systems this is also an upper bound for the size of $\mathcal{S}(P)$. As discussed above, a pattern consisting of a root node and $m-1$ leaves brings $\mathcal{S}(P)$ fairly close to this bound.

Let us next analyze how Algorithm 8.1 performs with patterns whose branching is limited. The executions of line 6 will dominate the execution time of the algorithm. Let k be the largest out-degree of any node in P. Any set of sibling nodes of P has at most 2^k subsets. On line 6 we need to unite only subsets A and B that consist of children of a common parent at a time. For each of the $|P|$ parents in the pattern there will be at most $O(2^k 2^k)$ pairs of such sets. Each union $A \cup B$ can be formed in $O(k)$ time and the union can be checked for not being a duplicate of any other member of the resulting system S in $O(k2^k)$ time.

The rest of the algorithm can be executed in $O(|P|)$ time per one target node by choosing a reasonable data structure for S and $S\Delta$. We have derived the following upper bound for the time complexity of the unordered tree-inclusion problem.

THEOREM 8.5. *If the out-degrees of the nodes of P are bounded by k, the unordered tree-inclusion problem is solvable in time $O(|P|k2^{2k}|T|)$. Specifically, if k is a constant, the problem is solvable in $O(|P||T|)$ time, and if k is $O(\log|T|)$, the problem is solvable in time $O(|P|\log|T||T|^3)$.*

A similar but less precise result could also be obtained by using the dynamic programming approach.

9. Conclusions. We have considered the tree-inclusion problem, which arises from database query processing. We have given a dynamic processing solution requiring $O(mn)$ time, where m and n are the sizes of the trees. The algorithm is faster than the previous ones. The corresponding problem for unordered trees is considerably more difficult. We have given a proof of its NP-completeness. For the unordered problem we have presented an algorithm that works in $O(mn)$ time if the out-degrees of the pattern nodes are bounded by a constant, and in polynomial time if they are $O(\log n)$.

There are several open problems. One is improving the running time of the algorithm for the ordered problem. Breaking the mn-barrier seems rather hard, however. Another promising area is trying to reduce some matching problems to the tree-inclusion problem; this could give upper or lower bounds for the complexity of this problem.

In an application where the target tree is very large, the $\Theta(mn)$ space and time requirements of Algorithm 6.1 may be unacceptable. Another algorithm that solves the ordered tree-inclusion problem in $O(m\,depth(T))$ space has been presented in [10]. The idea of this

algorithm is similar to Algorithm 8.1, with the difference that in the ordered case the match systems have a more economical representation. The complexity of the new algorithm is sensitive to the instances of the problem: it runs in time $O(c_P(T)\,n)$, where $c_P(T)$ is the number of the subtrees of P that are included in T. If no part of the pattern appears in the target, the algorithm runs in time $O(n)$.

Acknowledgments. We wish to thank Kari-Jouko Räihä and an anonymous referee for useful comments on previous versions of the article.

RANDOMIZED INTERPOLATION AND APPROXIMATION OF SPARSE POLYNOMIALS*

YISHAY MANSOUR†

Abstract. We present a randomized algorithm that interpolates a sparse polynomial in polynomial time in the bit complexity model. The algorithm can be also applied to approximate polynomials that can be approximated by sparse polynomials (the approximation is in the L_2 norm).

Key words. polynomial interpolation, randomized algorithms, approximation, harmonic analysis

AMS subject classifications. 65D05, 65T99, 41A10

1. Introduction.

We consider the problem of interpolating a sparse polynomial with integer coefficients. The interpolation model is the following. The algorithm can query the polynomial P on any input x, and receives the value $P(x)$ with some finite accuracy. The accuracy parameter determines the number of significant bits that are given from the value of $P(x)$, which helps truncate $P(x)$ after that number of significant bits. The running time of the algorithm is the number of bit operations performed.

The parameters of the sparse polynomial are n—the number of variables, t—an upper bound on the number of nonzero coefficients, d—an upper bound on the degree of a single variable, and L—an upper bound on the absolute value of the largest coefficient. A t-sparse polynomial is a polynomial with at most t nonzero coefficients. The number of bits required to express a t-sparse polynomial is $O(t(\log L + n \log d)) = \text{poly}(n, t, \log d, \log L)$.[1]

Our main result is a randomized algorithm that interpolates a t-sparse polynomial in time $\text{poly}(n, t, \log d, \log L)$. In the analysis of the algorithm, we count the number of operations performed, but since the accuracy that our algorithm requires is very small (logarithmic in the above parameters), the running time remains $\text{poly}(n, t, \log d, \log L)$ in the bit complexity model.

An interesting application of our algorithm is finding an *approximation* by a sparse polynomial. The approximation is in the L_2 norm, i.e., the expected error squared is small. The main result is that if a polynomial P can be approximated by a t-sparse polynomial Q such that the power of $P - Q$ is bounded by ϵ, then our algorithm can find a t-sparse polynomial Q' such that the power of $P - Q'$ is bounded by $O(\epsilon)$. (The *power* of a polynomial is the sum of the squares of its coefficients.) Our algorithm achieves this by finding only the "large" coefficients of P, rather than finding all of the coefficients of P. This notion of approximation is especially interesting when the values of the variables have approximately unit magnitude. We believe that this notion of approximation is especially interesting in our framework, since if we allow the value of the variable to be, for example, 2, then the output of the polynomial may have already d bits.

Interpolation of a univariate polynomial can be performed in time $O(d \log d)$, using the Fast Fourier Transform (FFT). The FFT does not use the information about the sparsity of the polynomial, therefore, its running time is polynomial in d, rather than t and $\log d$. Since the FFT algorithm does not consider the sparsity of the polynomial, for multivariate polynomials where the number of possible coefficients is exponential, its running time is exponential.

[1] We denote by poly(a) a function which is bounded by a polynomial in a, i.e., $a^{O(1)}$.

Previous works on sparse multivariate polynomial interpolation were mainly in the algebraic model, where each operation requires one unit of time. When considering those works in the bit complexity model, one has to take into account the number of bits which were given to the polynomial, and also the size of the result of the polynomial and the required accuracy on the result. Zippel [Zip79] gave a probabilistic algorithm that runs in time $\text{poly}(n, t, d)$. His algorithm evaluates the polynomial at points of size $\Theta(\log ntd)$ bits and requires $\Theta(d \log ntd + \log L)$ bits, which implies that the running time in the bit complexity model is $\text{poly}(n, t, d, \log L)$.

Grigoriev and Karpinski [GK87] showed a deterministic NC algorithm to compute a matching, in the case that the permanent is sparse. (The permanent can be viewed as a generic multivariate polynomial.) Ben-Or and Tiwari [BOT88] gave a deterministic algorithm to compute a sparse multivariate polynomial that runs in time $\text{poly}(n, t, \log d)$. The algorithm evaluates the polynomial at points of size $O(t \log n)$ bits and requires accuracy of $O(td \log n + \log L)$ bits. Therefore, the running time of their algorithm in the bit complexity model requires time $\text{poly}(n, t, d, \log L)$. Grigoriev, Karpinski, and Singer [GKS90b] showed how to interpolate a rational function with $O(nt^t)$ points, which is independent of the degree d ! However, in the bit complexity model the running time is $\text{poly}(n, t^t, d, \log L)$. Algorithms for interpolation of sparse polynomials over finite field appears in [GKS90a] and [Kar89].

The work here extends the technique developed in [GL89] and [KM91] for the Fourier transform over the hypercube. The extension handles a ring of integers modulo an integer (i.e., Z_d). After we show how to handle Z_d, we use the previous techniques and extend the result to handle Z_d^n.

Remark. In this work, we are interested in the bit complexity model. In the analysis, we use the algebraic model and count the number of operations. By guaranteeing that the precision that our algorithm requires is small, we make sure that its running time in both models is similar.

The paper is organized as follows. Section 2 mentions a few known facts about the Chernoff bounds, discrete Fourier transform, and defines the black box model. Section 3 has the interpolation to univariate sparse polynomials with small coefficients, which is extended in §4 to handle arbitrary coefficients. The precision accuracy that the algorithm requires is discussed in §5. Section 6 deals with the approximation of a real valued function by sparse polynomials. Section 7 extends the case of univariate polynomials to multivariate polynomials.

2. Preliminaries. Chernoff bounds. In the analysis of our randomized algorithms, we use Chernoff bounds. The following theorem formalizes the bounds in a way which would be most useful for us. (See [HR89].)

THEOREM 2.1 (Chernoff bound). *Let $X_1, \ldots, X_m$ be i.i.d with $E[X_i] = p$, $|X_i| \leq H$ and let $S_m = X_1 + \cdots + X_m$. If $m \geq \frac{2H^2}{\epsilon^2} \ln \frac{2}{\delta}$, then*

$$Pr\left[\left|\frac{S_m}{m} - p\right| > \epsilon\right] \leq \delta.$$

Complex numbers. The magnitude of a complex number $z = a + ib$ is $\|z\| = \sqrt{a^2 + b^2}$. Let $\omega_d = e^{\frac{2\pi}{d} i}$ be a dth root of unity. Recall that $\|\omega_d^k\| = 1$ for any d and k.

Discrete Fourier transform. We list here a few known facts about the discrete Fourier transform. Consider a polynomial $P(x) = \sum_{j=0}^{d-1} a_j x^j$. Each coefficient of the polynomial satisfies

$$a_j = \frac{1}{d} \sum_{k=0}^{d-1} P(\omega_d^k) \omega_d^{-kj}.$$

Parseval identity relates the sum of the squares of the coefficients to the values of the polynomial as follows:

$$\sum_{j=0}^{d-1} a_j^2 = \frac{1}{d}\sum_{k=0}^{d-1} P(\omega_d^k)P(\omega_d^{-k}) = \frac{1}{d}\sum_{k=0}^{d-1} \|P(\omega_d^k)\|^2.$$

For any integer k not divisible by d,

$$\sum_{m=0}^{d-1} (\omega_d^k)^m = 0.$$

The black box model. Our algorithm assumes that it has a black box that evaluates the polynomial P. The algorithm evaluates the polynomial at roots of unity of the form ω_d^k. The interaction between the algorithm and the black box is the following.

To evaluate the polynomial P at ω_d^k, the algorithm gives the black box the pair (d, k). Denote by $\rho(k, d)$ the output of the black box on input (d, k).

The black box has *precision accuracy* ϵ if for any input (d, k), the absolute error is at most ϵ, i.e.,

$$\|P(\omega_d^k) - \rho(d, k)\| \leq \epsilon.$$

Let $H = \max_k\{\|P(\omega_d^k)\|\}$. The number of bits required for precision accuracy ϵ is $O(\log H + \log \frac{1}{\epsilon})$.

3. Univariate polynomials. In this section we discuss interpolation of t-sparse polynomials with integer coefficients. The result is based on a searching technique that we develop to search in the space of the possible coefficients. The search technique is similar to the one in [GL89] and [KM91].

Given a polynomial $P(x)$, we split it into two polynomials: one that includes the coefficients of odd degrees (denoted by $P_{1,1}$), and the other which includes the coefficients of even degrees (denoted by $P_{0,1}$). Note that $P_{0,1}(x) = (P(x) + P(-x))/2$ and $P_{1,1}(x) = (P(x) - P(-x))/2$. In a similar way we define $P_{\alpha,\ell}(x)$, where $0 \leq \alpha \leq 2^\ell - 1$ and $0 \leq \ell \leq \log d$, as follows:

$$P_{\alpha,\ell}(x) = \sum_{j:\, e_j \bmod 2^\ell = \alpha} a_{e_j} x^{e_j}.$$

The algorithm works as follows. It keeps a list of the current candidates polynomials, $P_{\alpha,\ell}$. The algorithm takes a polynomial $P_{\alpha,\ell}$ off the list and tests if it is identically zero. If the polynomial is identically zero no action is taken. (This implies that we terminate the search for coefficients of exponents e, $e = \alpha \bmod 2^\ell$, since all those coefficients are zero.) Otherwise, we continue recursively searching, i.e., we add to the list of candidates polynomials the polynomials $P_{\alpha+2^\ell,\ell+1}$ and $P_{\alpha,\ell+1}$. When $\ell = \log d$, then we have reached a nonzero coefficient. (Namely, the polynomial $P_{\alpha,\log d}(x) = a_\alpha x^\alpha$.)

Since there are at most t nonzero coefficients and for each coefficient we perform $\log d$ recursive calls, the total number of recursive calls is bounded by $O(t \log d)$.

We are not able to compute the values of the polynomials that we create *exactly*, but rather we are able to approximate them very well. One way to overcome this is to approximate the value of a polynomial at randomly selected points, and if at some point it is more than $1/2$ then we assume that it is a nonzero polynomial. Here we choose an alternative way to test for zero polynomials that is based on approximating the power of the polynomial. Since the polynomial has integer coefficients, if it is a nonzero polynomial then it has power at least one. We approximate the power of the polynomial and if the approximation is more than $1/2$, we assume that the polynomial is nonzero. We prefer the method that is based on approximating the power since it extends more naturally to the case of large coefficients and to the case of approximation by sparse polynomials.

3.1. The main procedure. In this subsection, we outline the main idea of how to recover the coefficients of a t-sparse polynomial $P(x) = \sum_{j=1}^{t} a_{e_j} x^{e_j}$, whose coefficients are integers. The basic strategy is to recover the exponents e_j bit after bit, starting from the least significant bit.

Allow d to be the smallest power of two greater than $\max_j\{e_j\}$, i.e., $d = 2^{\lceil \log(1+\max_j\{e_j\})\rceil}$. Consider the sets $S_\ell = \{e_j \bmod 2^\ell : 1 \le j \le t\}$ for $0 \le \ell \le \log d$. The set S_ℓ includes the ℓ least significant bits of the exponents e_j. Clearly, the size of a set S_ℓ is bounded by t, and the set S_0 includes only zero. We show how to compute the set $S_{\ell+1}$ given the set S_ℓ.

From the definition of S_ℓ it follows that if $\alpha \notin S_\ell$ then $P_{\alpha,\ell}(x) \equiv 0$, while if $\alpha \in S_\ell$ then $P_{\alpha,\ell}(x) \not\equiv 0$. One step in the construction is testing if a polynomial is identically zero. Assume that we are given such a procedure $ZERO(P_{\alpha,\ell})$ that returns $TRUE$ if and only if $P_{\alpha,\ell} \equiv 0$ (later we will show how to implement it).

Given the set S_ℓ we construct the set $S_{\ell+1}$ as follows. For each $\alpha \in S_\ell$ we create two integers: $\alpha_0 = \alpha$ and $\alpha_1 = \alpha + 2^\ell$. For each α_σ, $\sigma \in \{0, 1\}$, we test $ZERO(P_{\alpha_\sigma,\ell})$. If $ZERO(P_{\alpha_\sigma,\ell})$ is $FALSE$ we add α_σ to $S_{\ell+1}$. Since the set $S_{\log d}$ includes all the exponents of P, when we recover $S_{\log d}$ we have found all the exponents of P.

CLAIM 3.1. *The algorithm constructs each S_ℓ correctly.*

Proof. The proof is by induction on ℓ. Initially S_0 includes only zero, so it is correct. Assume that we constructed S_ℓ correctly. We have to show two properties of $S_{\ell+1}$: that any element added should have been added and that every element of $S_{\ell+1}$ was added at some point.

An element $\beta = \alpha_\sigma$, $\sigma \in \{0, 1\}$, is added to $S_{\ell+1}$ only if $ZERO(P_{\beta,\ell+1})$ is $FALSE$. This implies that $\sum_{j:e_j \bmod 2^{\ell+1}=\beta} a_{e_j}^2 \neq 0$. Therefore, there exists some coefficient a_{e_j} such that $e_j \bmod 2^{\ell+1} = \beta$, which is not zero.

For the second part assume that $\beta \in S_{\ell+1}$. Let $\beta \bmod 2^\ell = \alpha$. By the induction hypothesis $\alpha \in S_\ell$. When we handle α, in one of the two cases we test $\alpha_\sigma = \beta$. Since $\beta \in S_{\ell+1}$, $ZERO(P_{\beta,\ell+1}) = ZERO(P_{\alpha_\sigma,\ell+1})$ is $FALSE$. Hence β was added to $S_{\ell+1}$. □

LEMMA 3.2. *The number of calls to the procedure $ZERO$ is bounded by $O(t \log d)$.*

Proof. There are $\log d$ sets S_ℓ. The size of each set S_ℓ is bounded by t. For each element $\alpha \in S_\ell$ we perform two calls, $ZERO(\alpha_0, \ell)$ and $ZERO(\alpha_1, \ell)$. □

So far we have an algorithm that requires an oracle for computing $P_{\alpha,\ell}(x)$ and the procedure $ZERO$. In the next subsection we show how to approximate $P_{\alpha,\ell}$, and in the subsection after that we show how to approximate $ZERO$.

3.2. Approximating $P_{\alpha,\ell}(x)$. In this subsection we show how to approximate $P_{\alpha,\ell}(x)$. The main tool in the approximation is the following lemma.

LEMMA 3.3. *For any polynomial $P(x)$, α and ℓ, such that $0 \le \alpha \le 2^\ell$, then*

$$P_{\alpha,\ell}(\omega_d^k) = \frac{1}{2^\ell} \sum_{m=0}^{2^\ell-1} P\left(\omega_d^{k+m\frac{d}{2^\ell}}\right) \omega_d^{-\alpha m \frac{d}{2^\ell}}.$$

Proof. The proof is somewhat technical. We basically transform the right-hand side to the left-hand side. We start by substituting for $P(x)$ the expression $\sum_{j=0}^{d} a_j x^j$. This means that the right-hand side is

$$\frac{1}{2^\ell} \sum_{m=0}^{2^\ell-1} \sum_{j=0}^{d-1} a_j \omega_d^{j(k+m\frac{d}{2^\ell})} \omega_d^{-\alpha m \frac{d}{2^\ell}}.$$

We can change the order of summation and rewrite it as

$$\sum_{j=0}^{d-1} a_j \omega_d^{jk} \left[\frac{1}{2^\ell} \sum_{m=0}^{2^\ell-1} \left(\omega_d^{(j-\alpha)\frac{d}{2^\ell}}\right)^m\right].$$

Consider the expression between the brackets. If $j = \alpha \bmod 2^\ell$, then the expression is one, and otherwise it is equal to zero. Therefore we can rewrite it as

$$\sum_{j:\ j \bmod 2^\ell = \alpha} a_j \omega_d^{jk} = P_{\alpha,\ell}(\omega_d^k). \qquad \square$$

We can use Lemma 3.3 to approximate $P_{\alpha,\ell}$. Define the following random variable:

$$A_m(\alpha, \ell, k) = \frac{1}{m} \sum_{i=1}^{m} P\left(\omega_d^{k+\beta_i \frac{d}{2^\ell}}\right) \omega_d^{-\alpha\beta_i \frac{d}{2^\ell}},$$

where β_i is chosen uniformly in the set $\{0, \ldots, 2^\ell - 1\}$. The random variable $A_m(\alpha, \ell, k)$ is an approximation for $P_{\alpha,\ell}(\omega_d^k)$ that uses m sample points. The following lemma, which is an application of Chernoff bounds, states how "good" the approximation is.

LEMMA 3.4. *Let $P(x)$ be a polynomial such that $\max_j\{\|P(w_d^j)\|\} \le H$. There exists a constant c, such that for $m \ge cH^4 \log \frac{2}{\delta}$. Then, for any k,*

$$\text{Prob}\left[\|A_m(\alpha, \ell, k) - P_{\alpha,\ell}(\omega_d^k)\| \ge \frac{1}{16H}\right] \le \delta.$$

Proof. The proof is an application of the Chernoff bounds and the fact that $\|A_m(\alpha, \ell, k) - P_{\alpha,\ell}(\omega_d^k)\| \le 2H$. $\square$

The main use of Lemma 3.4 would be through the following claim.

CLAIM 3.5. *Let a and b be complex numbers such that $\|a\| \le H$. If $\|a - b\| \le \frac{1}{16H}$, then*

$$\left|\|a\|^2 - \|b\|^2\right| \le \frac{1}{4}.$$

3.3. Testing for zero polynomials. Our aim is to show that with high probability we can approximate each $ZERO(\alpha, \ell)$ correctly. This would imply that we can run the entire algorithm using the approximation, rather than testing $ZERO(\alpha, \ell)$. The approximating function is named $APPROX\_ZERO$. The main idea would be to approximate the power of the function. If the polynomial is the zero polynomial, then the power is zero, otherwise the power is at least one (since we assumed that the coefficients are integers).

For a polynomial $P(x) = \sum a_j x^j$, let $\text{power}(P) = \sum_j a_j^2$. In order to approximate the power of a polynomial, we define the following random variable:

$$B_{m_1,m_2}(\alpha, \ell) = \frac{1}{m_1} \sum_{i=1}^{m_1} \|A_{m_2}(\alpha, \ell, k_i)\|^2,$$

where k_i is chosen uniformly in the set $\{0, \ldots, d-1\}$. The random variable $B_{m_1,m_2}(\alpha, \ell)$ is an approximation of $\text{power}(P_{\alpha,\ell})$. The following lemma states how "good" the approximation is.

LEMMA 3.6. *Let $P(x)$ be a polynomial such that $H = \max_k\{\|P(w_d^k)\|\}$. There exists a constant c, such that for $m_1 \ge cH^4 \log \frac{1}{\delta}$ and $m_2 \ge cH^4 \log \frac{m_1}{\delta}$, then*

$$\text{Prob}\left[|B_{m_1,m_2}(\alpha, \ell) - \text{power}(P_{\alpha,\ell})| \ge \frac{1}{2}\right] \le \delta.$$

Proof. Lemma 3.3 shows how to compute $P_{\alpha,\ell}(\omega_d^k)$ from the values of $P(w_d^j)$. One can observe that the value of $P_{\alpha,\ell}(\omega_d^k)$ is a weighted average of the values of $P(w_d^j)$. From this we can deduce that $\max_k\{\|P_{\alpha,\ell}(\omega_d^k)\|\} \le H$.

The proof of the lemma uses Chernoff bounds. Since $\|P_{\alpha,\ell}(\omega_d^k)\|^2 \le H^2$, by choosing m_1 values of k_i's at random, such that $m_1 \ge cH^4 \log \frac{1}{\delta}$, Theorem 2.1 guarantees that with probability $1 - \delta/2$,

$$\left|\text{power}(P_{\alpha,\ell}) - \frac{1}{m_1} \sum_{i=1}^{m_1} \|P_{\alpha,\ell}(\omega_d^{k_i})\|^2\right| \le \frac{1}{4}.$$

Based on Lemma 3.4 for every k_i with probability $1 - \delta/(2m_1)$, the random variable $A_{m_2}(\alpha, \ell, k_i)$ approximates $P_{\alpha,\ell}(\omega_d^{k_i})$ with error less than $1/16H$. By Claim 3.5 this implies that the difference between $\|A_{m_2}(\alpha, \ell, k_i)\|^2$ and $\|P_{\alpha,\ell}(\omega_d^{k_i})\|^2$ is at most $1/4$, which completes the proof of the lemma. □

Now we are ready to define the function $APPROX\_ZERO(\alpha, \ell)$. In order to compute $APPROX\_ZERO(\alpha, \ell)$, we first compute $B_{m_1,m_2}(\alpha, \ell) = b$, where m_1 and m_2 are chosen according to Lemma 3.6, then if b is smaller than $1/2$ we return $TRUE$, otherwise we return $FALSE$. The following theorem states that with high probability, this is a good approximation.

THEOREM 3.7. *For any ℓ and α, $0 \leq \alpha \leq 2^{\ell}$,*

$$\text{Prob}[APPROX\_ZERO(\alpha, \ell) \neq ZERO(\alpha, \ell)] \leq \delta.$$

Proof. It is easy to show that if $APPROX\_ZERO(\alpha, \ell) \neq ZERO(\alpha, \ell)$, then

$$|B_{m_1,m_2}(\alpha, \ell) - \text{power}(P_{\alpha,\ell})| \geq \frac{1}{2};$$

the theorem follows from Lemma 3.6. □

3.4. Approximating a single coefficient. We need to approximate each coefficient that we found at the end of the algorithm with an error of at most ϵ. Given an exponent e, we show how to approximate its coefficients, a_e.

Define the random variable $COEF_m(e)$ to be

$$COEF_m(e) = \left\lfloor \frac{1}{2} + \frac{1}{m} \sum_{i=1}^{m} P(\omega_d^{\beta_i}) \omega_d^{-\beta_i e} \right\rfloor,$$

where β_i is chosen uniformly from $\{0, \ldots, d-1\}$. The random variable $COEF_m(e)$ is an approximation of the coefficient a_e using m sample points. The following lemma states how close the random variable $COEF_m(e)$ is to the coefficient a_e.

LEMMA 3.8. *Let P be a polynomial and $H = \max_j\{\|P(\omega_d^j)\|\}$, then for $m \geq 32H^2 \log \frac{2}{\delta}$*

$$\text{Prob}\,[COEF_m(e) \neq a_e] \leq \delta.$$

Proof. If $COEF_m(e) \neq a_e$ then $|COEF_m(e) - a_e| \geq 1$, since they are both integers. In such a case, $|\frac{1}{2} + \frac{1}{m}\sum_{i=1}^{m} P(\omega_d^{\beta_i})\omega_d^{-\beta_i e} - a_e| \geq 1/2$ The claim of the lemma follows from Chernoff bounds. □

3.5. Univariate interpolation algorithm: Small coefficients. We can now use the building blocks in this section to show the following result.

THEOREM 3.9. *Let P be a nonzero univariate polynomial with at most t integer coefficients, each of magnitude at most L, and $H = \max_k\{\|P(w_d^k)\|\}$. The running time of the algorithm is $O(H^8 t \log d \log^2 \frac{1}{\delta'} + tH^2 \log \frac{1}{\delta}) = \text{poly}(n, t, \log d, \log L)$, where $\delta' = O(\frac{1}{H^8 t \log d \log^2 \frac{1}{\delta}})$.*

Proof. There are $O(t \log d)$ recursive calls. Each time in $APPROX\_ZERO$ we test $O(H^4 \ln \frac{1}{\delta})$ different k_i's. For each k_i we use $O(H^4 \log \frac{1}{\delta})$ points to approximate it. At the end, for each of the t coefficients we call the procedure $COEF$ and use $O(H^2 \log \frac{1}{\delta})$ points. □

The main drawback of the above result is that the running time depends on H, which could be proportional to the largest coefficient, i.e., L, and not polynomial in the bit representation of the coefficients, i.e., $\log L$. In the next subsection we show how to overcome this deficiency.

4. Handling large coefficients. The aim of this section is to modify the algorithm of the previous section so that its running time would be polynomial in $\log L$. The technique

we use in handling large coefficients is similar in spirit to the scaling techniques in graph algorithms. We first find the exponents whose coefficients are "very" large. We approximate the coefficients of those exponents and subtract them from the polynomial. Since we only approximate the coefficients, the new polynomial may still have nonzero coefficients for those exponents. The main advantage is that the new polynomial has, in the worst case, the same number of nonzero coefficients, while the maximum value of a coefficient is smaller.

Consider a t-sparse polynomial $P(x)$, i.e.,

$$P(x) = \sum_{j=1}^{t} a_{e_j} x^{e_j}.$$

As before, let the parameter d be the smallest power of two larger than the degree, i.e., $d = 2^{\lceil \log(1+\max_j\{e_j\})\rceil}$. Similarly, let L be the smallest power of two that is larger than the maximum coefficient in absolute value, i.e., $L = 2^{\lceil \log(\max_j\{|a_{e_j}|\})\rceil}$.

Our aim is to perform the interpolation in time that is polynomial in t, $\log d$ and $\log L$. The following is the basic idea of the algorithm. Given L, the bound on the largest coefficient, we consider the sets $Z_1 = \{e_j \ : \ L/2 \leq |a_{e_j}| \leq L\}$ and $Z_2 = \{e_j \ : \ \frac{L}{8\sqrt{t}} \leq |a_{e_j}| \leq L\}$. We find a set Y such that $Z_1 \subset Y \subset Z_2$. Once we found the set Y (in time polynomial in t, $\log d$ and $\log L$), we approximate each of the coefficients of the exponents in Y with an absolute error of less than a $L/4$. This implies that, with high probability, the difference between the real coefficient and the approximated coefficient is less than $L/4$. For each $e_j \in Y$, denote by γ_{e_j} the approximated value of the coefficient a_{e_j} and in order to ensure that the new polynomial is integral, enforce γ_{e_j} to be integral. More formally, let Q be the polynomial we created,

$$Q(x) = \sum_{e_j \in Y} \gamma_{e_j} x^{e_j}.$$

Consider the polynomial $P'(x) = P(x) - Q(x)$. Assume that $Z_1 \subset Y \subset Z_2$ and $|\gamma_{e_j} - a_{e_j}| \leq L/4$, the polynomial P' is t-sparse, and has integer coefficients of size at most $L/2$. This implies that in polynomial time we reduced the problem of recovering the coefficients of a polynomial with maximum coefficient L (i.e., $P(x)$), to the problem of recovering the coefficients whose maximum coefficient is $L/2$ (i.e., $P'(x)$). Therefore after $O(\log L)$ such iterations the maximum coefficient is $O(\sqrt{t})$. Once the coefficients are of size $O(\sqrt{t})$ the algorithm of Theorem 3.9 would recover all the coefficients.

4.1. Approximating the power. The main idea is that with a sample size that depends on t and is independent of L, we can approximate power$(P_{\alpha,\ell})$. We start by modifying the approximation of $P_{\alpha,\ell}$.

LEMMA 4.1. *Let P be a t-sparse polynomial each of whose coefficient is bounded in magnitude by L. There exists a constant c, such that if $m \geq ct^4 \log \frac{2}{\delta}$, then for any k,*

$$\text{Prob}\left[\|A_m(\alpha, \ell, k) - P_{\alpha,\ell}(\omega_d^k)\| \geq \frac{L}{64t}\right] \leq \delta.$$

As before, this implies the following about the difference in the magnitude.

CLAIM 4.2. *Let a and b be complex numbers such that $\|a\| \leq tL$. If $\|a - b\| \leq \frac{L}{64t}$, then*

$$\left|\|a\|^2 - \|b\|^2\right| \leq \frac{L^2}{16}.$$

We can now claim the result about approximating the power.

LEMMA 4.3. *Let P be a t-sparse polynomial each of whose coefficient is bounded in magnitude by L. There exists a constant c such that if $m_1 \geq ct^4 \log \frac{1}{\delta}$ and $m_2 \geq ct^4 \log \frac{m_1}{\delta}$, then*

$$\text{Prob}\left[|B_{m_1,m_2}(\alpha, \ell) - \text{power}(P_{\alpha,\ell})| \leq \frac{3L^2}{32}\right] \leq \delta.$$

Proof. The polynomial P is t-sparse. Furthermore, each coefficient is bounded by L. Therefore, the magnitude of $P(w_d^k)$ is bounded by tL, and the magnitude of $P_{\alpha,\ell}(w_d^k)$ is bounded by tL. Once we bounded the magnitude of $P_{\alpha,\ell}$ we can use the Chernoff bounds to claim that with probability $1 - \delta/2$ the difference between $\text{power}(P_{\alpha,\ell})$ and $\frac{1}{m_1}\sum_{1\leq j\leq m_1} \|P_{\alpha,\ell}(\omega_d^{k_j})\|^2$ is less than $L^2/32$.

Based on Lemma 4.1, for every k_i with probability $1 - \delta/(2m_1)$ the random variable $A_{m_2}(\alpha, \ell, k_i)$ approximates $P_{\alpha,\ell}(\omega_d^{k_i})$ with error less than $L/(64t)$. By Claim 4.2 this implies that the difference between $\|A_{m_2}(\alpha, \ell, k_i)\|^2$ and $\|P_{\alpha,\ell}(\omega_d^{k_i})\|^2$ is at most $L^2/16$. □

Now we define the equivalent of the $ZERO$ and $APPROX\_ZERO$ procedures. Let $LARGE(P, L)$, where P is a polynomial and L an integer, be $TRUE$ if and only if P has some coefficient a_j such that $|a_j| \geq L/2$. As before, we cannot compute $LARGE(P, L)$ directly, but we can approximate it. We approximate the value of $LARGE(P_{\alpha,\ell}, L)$ by $APPROX\_LARGE(\alpha, \ell, L)$ which is defined as follows: Compute $B_{m_1,m_2}(\alpha, \ell) = b$ and if $b \geq \frac{5L^2}{32}$ return $TRUE$, otherwise return $FALSE$.

LEMMA 4.4. *Let P be a t-sparse polynomial, each of whose coefficient is bounded in magnitude by L. For any α and ℓ, $0 \leq \alpha \leq 2^\ell$, then*

$$\text{Prob}[APPROX\_LARGE(\alpha, \ell, L) = FALSE \text{ and } LARGE(P_{\alpha,\ell}, L) = TRUE] \leq \delta.$$

Proof. Assume that $LARGE(P_{\alpha,\ell}, L)$ is $TRUE$. This implies that $\text{power}(P_{\alpha,\ell}) \geq L^2/4$, since some coefficient is larger than $L/2$. With probability $1 - \delta$,

$$|B_{m_1,m_2}(\alpha, \ell) - \text{power}(P_{\alpha,\ell})| \geq \frac{3L^2}{32}.$$

This implies that with probability $1 - \delta$ we have $B_{m_1,m_2}(\alpha, \ell) \geq \frac{5L^2}{32}$, which is equivalent to $APPROX\_LARGE(\alpha, \ell, L)$ being $TRUE$. □

LEMMA 4.5. *Let P be a t-sparse polynomial each of whose coefficient is bounded in magnitude by L. For any α and ℓ, $0 \leq \alpha \leq 2^\ell$, then*

$$\text{Prob}\left[APPROX\_LARGE(\alpha, \ell, L) = TRUE \text{ and } LARGE\left(P_{\alpha,\ell}, \frac{L}{4\sqrt{t}}\right) = FALSE\right] \leq \delta.$$

Proof. Assume that $LARGE(P_{\alpha,\ell}, \frac{L}{4\sqrt{t}})$ is $FALSE$. This implies that $\text{power}(P_{\alpha,\ell}) \leq L^2/64$, since no coefficient is larger than $\frac{L}{8\sqrt{t}}$. With probability $1 - \delta$,

$$|B_{m_1,m_2}(\alpha, \ell) - \text{power}(P_{\alpha,\ell})| \geq \frac{3L^2}{32}.$$

This implies that with probability at most δ, we have $B_{m_1,m_2}(\alpha, \ell) \geq \frac{5L^2}{32}$, which is equivalent to $APPROX\_LARGE(\alpha, \ell, L) = TRUE$. □

The above two lemmas show that if $APPROX\_LARGE(\alpha, \ell, L)$ is $TRUE$, then with high probability $P_{\alpha,\ell}$ is a nonzero polynomial (and even has a coefficient larger than $\frac{L}{8\sqrt{t}}$), and if

$P_{\alpha,\ell}$ has a coefficient larger than $L/2$, then with high probability $APPROX\_LARGE(\alpha, \ell, L)$ is $TRUE$.

Note that the number of recursive calls when we use the procedure $LARGE$ is bounded, as before, by $t \log d$, since every time $LARGE$ is $TRUE$, we are focusing on at least one of the t coefficients.

4.2. Approximating a single coefficient. The approximation of a single coefficient is done as in the case of small coefficients, in §3.4. The only difference is that we need to approximate each coefficient that we found with absolute error less than $L/4$.

LEMMA 4.6. *There is a constant c such that for $m \geq ct^2 \log \frac{1}{\delta}$,*

$$\text{Prob}\,[|COEF_m(e) - a_e| \geq L/4] \leq \delta.$$

4.3. Putting it all together. The basic building block would be a procedure $FIND(P, L)$ that receives a polynomial P with coefficients of magnitude at most L and returns a list of exponents and their respective coefficients such that with high probability this list includes all the coefficients larger than $L/2$ and no coefficient smaller than $\frac{L}{8\sqrt{t}}$.

The procedure $FIND(P, L)$ works as the algorithm in §3, but uses the subroutine $APPROX\_LARGE$ instead of $APPROX\_ZERO$. At the beginning we start with a set Y_0 that has only 0. At phase ℓ, for each element $\alpha \in Y_\ell$, we create $\alpha_0 = \alpha$ and $\alpha_1 = \alpha + 2^\ell$. We add α_σ to $Y_{\ell+1}$ only if $APPROX\_LARGE(\alpha_\sigma, \ell + 1, L)$ is $TRUE$.

Since we are modifying the original polynomial, we describe how to compute the output that the black box returns to the algorithm. We have a polynomial $R(x)$, which is initially identically zero. (This polynomial would be used to "change" the original polynomial P that the algorithm is approximating.) Each time the algorithm queries the black box on a point ω_d^k, we query the original black box on input (d, k) and get a reply $\rho(d, k)$ (which is simply $P(\omega_d^k)$ with finite accuracy), we reply to the algorithm with $\rho(d, k) - R(\omega_d^k)$.

The main algorithm runs in phases. We maintain that after the ith phase, with high probability, $P(x) - R(x)$ is a polynomial with at most t nonzero coefficients and its maximum coefficient is at most $L/2^i$. The ith phase consists from the following steps: (1) We call $FIND(P - R, L/2^{i-1})$ that returns a set Y_i. With high probability the set Y_i includes all the coefficients in the range $L/2^i$ to $L/2^{i-1}$. (2) For each exponent in $e \in Y_i$ we approximate its coefficient a_e by γ_e, such that the difference is at most $L/2^{i+1}$. Let $Q_i(x) = \sum_{e \in Y_i} \gamma_e x^e$. (3) We add the polynomial $Q_i(x)$ to the polynomial $R(x)$.

Once the size of the coefficients is $O(\sqrt{t})$, the algorithm uses the algorithm for small coefficients (see Theorem 3.9) to completely recover the coefficients and adds this polynomial to R. At this point, with high probability, the polynomial $R(x)$ at is identical to the polynomial $P(x)$.

We have established the following theorem.

THEOREM 4.7. *There exists a randomized algorithm that interpolates a t-sparse polynomial, whose coefficients are integers less than L. The algorithm runs in time polynomial in t,* $\log d$, *and* $\log L$.

5. Precision accuracy. Our algorithms use complex numbers. When we measure the bit complexity, we need to specify the accuracy to which we require the complex numbers to be. This in turn also determines the bit complexity of the algorithm, since it determines the size of the numbers that the algorithm operates on. Since most of our operations are simply averaging over a set of random inputs, the algorithm requires only a low accuracy. The following claim shows how we can bound the precision accuracy.

CLAIM 5.1. *Adding m numbers with precision accuracy ϵ/m results in an output that has an absolute error of at most ϵ. Furthermore, if each of the m numbers is bounded in*

absolute value by H, then their description requires only $O(\log H + \log \frac{m}{\epsilon})$ bits to guarantee a precision accuracy of ϵ in the result.

The values used in $COEF_m(e)$ and $A_m(\alpha, \ell, k)$ are bounded by tL. This implies that by using $O(\log tL + \log \frac{m}{\epsilon})$ bits (and precision accuracy ϵ/m) in their computation, we introduce an additive error of at most $O(\epsilon)$. Since those random variables are used only as an approximation, the additional error could be absorbed in the error margins that we assumed before. (Recall that $B_{m_1,m_2}(\alpha, \ell)$ is define through A_m, and therefore the precision accuracy of B_{m_1,m_2} is determined by the precision accuracy of A_m.)

6. Approximation by polynomials. Assume that rather than recovering all the coefficients of the polynomial we are interested in recovering all the "large" coefficients of the polynomial. This is a very interesting case, since in many cases we may regard the other coefficients as "noise" that is not interesting.

The formal scenario is the following. As before, we are given a polynomial P as a black box, however, we are not guaranteed that it is either t-sparse or has integer coefficients. We assume that there is some polynomial Q, with t integer coefficients, such that the power of $P - Q$ is at most ν.

Our algorithm will recover a polynomial Q' such that the power of $P - Q'$ is bounded by $\nu + O(\epsilon)$. The number of recursive calls done by the algorithm is bounded by $O((t + \nu) \log d)$. The correctness is argued as before (each coefficient larger than one would be reached, with high probability). The running time can be bounded by observing that the difference between P and Q can cause the algorithm, for each specific value of ℓ, to search at most $O(\nu)$ values that would not lead to a coefficient of size at least one. The time to perform a single $APPROX\_ZERO$ or $APPROX\_LARGE$ remains the same.

We made a restriction that the approximating polynomial Q has integer coefficients. This restriction can be easily removed in the following way. Assume that there is a polynomial R that has real coefficients, and the power of $P - R$ is at most ν. Consider the polynomial R' that is achieved by multiplying the coefficients of R by t/ϵ, and rounding them to the nearest integer. The difference between $R(x)$ and $R'(x) * (\epsilon/t)$ is bounded by ϵ. This implies that the polynomial $P(x) * (t/\epsilon)$ has a good approximation by an integer polynomial R'.

7. Multivariate polynomials. The technique that we developed for univariate polynomials extends to multivariate polynomials and uses ideas similar to [GL89], [KM91], and [Zip79]. In this section we give a sketch of the ideas of the extension.

The idea for multivariate polynomials is the following. As before, we first recover all the "large coefficients." We proceed variable by variable, and find the exponents of the "large coefficients." Then we approximate the coefficients, and subtract them from the original polynomial. The main difference is that we recover the exponents of the interesting coefficients sequentially.

In the rest of this subsection we set the required definitions for the algorithm, and the test function that is used. Consider the polynomial

$$P(x_1, \ldots, x_n) = \sum_{j=1}^{t} a_{e_{1,j},\ldots,e_{n,j}} x_1^{e_{1,j}} x_2^{e_{2,j}} \cdots x_n^{e_{n,j}}.$$

As in the case of a single variable, we can compute a single coefficient as follows:

$$a_{e_1,\ldots,e_n} = \frac{1}{d^n} \sum_{k_1=0}^{d-1} \cdots \sum_{k_n=0}^{d-1} P(\omega_d^{k_1}, \omega_d^{k_2}, \ldots, \omega_d^{k_n}) \omega_d^{-k_1 e_1} \cdots \omega_d^{-k_n e_n}.$$

Also, the Parseval identity holds:

$$\sum_{j=1}^{t} a_{e_{1,j},\ldots,e_{n,j}}^2 = \frac{1}{d^n} \sum_{k_1=0}^{d-1} \cdots \sum_{k_n=0}^{d-1} \|P(\omega_d^{k_1}, \omega_d^{k_2}, \ldots, \omega_d^{k_n})\|^2.$$

The polynomial $P_{\alpha,\ell}$ is replaced by $P_{<e_1,\ldots,e_{j-1}>,\alpha,\ell}$, which is the polynomial that includes only the coefficients in which the exponents of $x_1, \ldots, x_{j-1}$ are $e_1, \ldots e_{j-1}$, respectively, the power of x_j equals to α modulus 2^ℓ, and the exponents of the variables $x_{j+1}, \ldots, x_n$ are unrestricted. The idea is that we are executing the univariate polynomial algorithm on the jth input. The input $x_1, \ldots x_{j-1}$ can appear with only a specific power, while there is no restriction on the exponents of $x_{j+1}, \ldots, x_n$. Formally,

$$P_{<e_1,\ldots,e_{j-1}>,\alpha,\ell}(x_1, \cdots, x_n) = x_1^{e_1} \cdots x_{j-1}^{e_{j-1}} \sum_{e_j \bmod 2^\ell = \alpha} x_j^{e_j} \sum_{e_{j+1}=0}^{d-1} \cdots \sum_{e_n=0}^{d-1} a_{e_1,\ldots,e_n} x_{j+1}^{e_{j+1}} \cdots x_n^{e_n}.$$

We define POWER as follows:

$$POWER[e_1, \ldots, e_{j-1}, \alpha, \ell] = E_{\vec{k}}[\| P_{<e_1,\ldots,e_{j-1}>,\alpha,\ell}(\vec{\omega_d^k})\|^2].$$

Where $\vec{k} = k_1, \ldots, k_n$ and $k_j \in \{0, \ldots, d-1\}$, and $\vec{\omega_d^k}$ is the input $x_1 = \omega_d^{k_1}, \ldots, x_n = \omega_d^{k_n}$. The expectation is uniform over all $\vec{k}$. As before, $POWER[e_1, \ldots, e_{j-1}, \alpha, \ell]$ equals the sum of the squares of coefficients in the polynomial $P_{<e_1,\ldots,e_{j-1}>,\alpha,\ell}(x_1, \ldots, x_n)$.

We search the jth variable before we continue to the $j+1$ variable. We find all the exponents to be prefixes of all the nonzero coefficients, up to the jth component (there are at most t). With each such prefix we continue to search for the $j+1$th component. The argument for correctness is similar to the argument for the univariate polynomials.

Consider the following example: $P(x_1, x_2) = q_1(x_1) + q_2(x_1)x_2$, where q_1 and q_2 are polynomials. Consider the expression

$$\begin{aligned} E_{k_2}\left[\left(q_1(\omega_d^k) + q_2(\omega_d^k)\omega_d^{k_2}\right)\left(q_1(\omega_d^{-k}) + q_2(\omega_d^{-k})\omega_d^{-k_2}\right)\right] &= E_{k_2}[q_1(\omega_d^k)q_1(\omega_d^{-k})] \\ &+ E_{k_2}[q_2(\omega_d^k)q_2(\omega_d^{-k})] \\ &+ E_{k_2}[q_1(\omega_d^k)q_2(\omega_d^{-k})\omega_d^{-k_2}] \\ &+ E_{k_2}[q_2(\omega_d^k)q_1(\omega_d^{-k})\omega_d^{k_2}]. \end{aligned}$$

Note that the first two terms do not depend on x_2 while the last two terms evaluate to zero, due to the averaging over x_2. In general, the averaging over all possible values of a certain variable causes the cross terms in the expression of the power to cancel out, therefore it has the effect of essentially "ignoring" this variable.

Acknowledgments. I would like to thank László Babai, Persi Diaconis, Marek Karpinski, Eyal Kushilevitz, Michael Rabin, and Prasoon Tiwari, for the discussions that I had with each of them.

AN $\mathcal{NC}$ ALGORITHM FOR EVALUATING MONOTONE PLANAR CIRCUITS*

A. L. DELCHER† AND S. RAO KOSARAJU‡

Abstract. Goldschlager first established that a special case of the monotone planar circuit problem can be solved by a Turing machine in $O(\log^2 n)$ space. Subsequently, Dymond and Cook refined the argument and proved that the same class can be evaluated in $O(\log^2 n)$ time with a polynomial number of processors. In this paper, we prove that the general monotone planar circuit value problem can be evaluated in $O(\log^4 n)$ time with a polynomial number of processors, settling an open problem posed by Goldschlager and Parberry.

Key words. parallel algorithms, planar circuits, monotone circuits

AMS subject classification. 68Q22

1. Introduction. The complexity of computing the output values of a boolean combinational circuit has been a much-studied problem in theoretical computer science. Ladner [12] showed that the general circuit value problem is $\mathcal{P}$-complete, and Goldschlager [4] showed that even if the circuit is restricted to be planar, or if it is restricted to be monotone, the problem remains $\mathcal{P}$-complete.

Goldschlager also established that a special case of the monotone planar circuit value problem can be solved by a Turing machine in $O(\log^2 n)$ space [5]. Subsequently, Dymond and Cook refined the argument and proved that the same class is in $\mathcal{NC}$ by showing that it can be evaluated in $O(\log^2 n)$ time with a polynomial number of processors [2]. In this paper, we prove that on a CREW PRAM the general monotone planar circuit value problem can be evaluated in $O(\log^4 n)$ time with a polynomial number of processors, which settles an open problem posed in [6].

In the next section we define the problem precisely. In §§3 and 4 we describe solutions to restricted versions of the problem. Finally, in §5 we show how the general problem can be reduced to these restricted versions.

2. Preliminaries. The input to our problem is a monotone combinational circuit, with a given embedding in the two-dimensional plane. Each node in the circuit is one of the following:

1. A boolean AND gate.
2. A boolean OR gate.
3. A NO-OP gate which has fan-in one and computes the identity function.
4. A constant gate with value 0 or 1. Such a node may have nonzero fan-in; however, the output is the specified constant, independent of the inputs.

Our problem will be to compute the truth value of every node in the circuit.

In a natural way, we view the circuit as a directed acyclic graph. We shall refer to nodes with zero fan-in (which must be constant nodes) as *source nodes*. Similarly we shall refer to nodes in the circuit with zero fan-out as *sink nodes*.

Without loss of generality, we can assume the following.

1. No gate has fan-in greater than two. Otherwise, we can easily replace higher fan-in gates with a planar arrangement of fan-in-2 gates.

2. The sink nodes of the circuit all lie on a single face of the planar embedding. Otherwise, in parallel for each separate sink independently, we can solve the circuit value problem consisting of exactly those nodes from each of which there is a path to the given sink. This results in a single sink, and the value of each node is the same as its value in the original circuit. In what follows we consistently arrange the circuits so that the sinks lie on the outermost face of the embedding. Our algorithms, however, do not depend on this fact.

Note that all these assumptions can be realized from an arbitrary instance of the problem by an $\mathcal{NC}$ computation. For example, testing a graph for planarity and constructing its embedding can be done in $O(\log^2 n)$ time with $O(n)$ processors [10]. Reachability for general graphs can be computed by simple transitive closure in $O(\log^2 n)$ time with $O(n^3)$ processors, and for planar directed graphs in $O(\log^4 n)$ time with only $O(n)$ processors [8]. Further references may be found in [1], [3], [7], [9], and [14].

We shall describe the algorithm for the general problem by presenting algorithms for a sequence of special cases to which the general problem can be reduced. Throughout this paper, unless otherwise specified, the term "circuit" should be interpreted to mean a monotone circuit with a given planar embedding. This embedding will remain fixed throughout all the computations.

3. Stratified circuits. We begin with a special class of circuits in which all nodes are arranged into levels such that all interconnections occur in a regular fashion between adjacent levels.

Let $C = (V, E)$ be a circuit. We use $|C|$ to denote the number of nodes in C. By the *level* of any node v in C we mean the length of its longest path to a sink node. We assume that level numbers are calculated for each node based on the initial circuit C, and that these same level numbers are used in all recursive procedures on subcircuits of C. Thus, the level of each sink node in C is 0, but in subcircuits of C, sink nodes may have other level numbers. We use L_C to denote the highest-numbered level in C. We shall refer to nodes at level L_C of the circuit as *primary source nodes*. (Note that all nodes at level L_C must be source nodes, since otherwise there would be a level number higher than L_C.) Finally, let $C_{i..j}$ denote the subcircuit of C that comprises all nodes at levels i through j.

DEFINITION 3.1. *A* stratified circuit *is a circuit $C = (V, E)$ in which we have the following items.*

1. *Every arc connects nodes at consecutive level numbers, i.e., for each arc $u \to v$ in E, $\mathit{level}(u) = 1 + \mathit{level}(v)$.*

2 (*Nested level property*). *For $0 \le i \le L_C$, all level-i nodes in $C_{0..i}$ lie on a single face. (Recall that the planar embedding for $C_{0..i}$ is fixed by the given embedding of C.)*

3. *Every source node is a primary source node.*

A restricted stratified circuit *is a stratified circuit in which all constant gates have fan-in zero.*

Dymond and Cook showed that a restricted stratified circuit with left and right boundaries for each level could be solved in $O(\log^2 n)$ time with a polynomial number of processors [2]. Their algorithm computes truth values at each level of the circuit as alternating intervals of 0/1 values. By determining where the alternations occur, the truth values of all remaining nodes are implicitly computed. The algorithms in [5] and [2] rely crucially on the fact that in a monotone planar circuit, no alternation at level i of the circuit can result in more than one alternation at level $i - 1$.

We note that the Dymond–Cook algorithm does not require that all sinks of the circuit be on the same face, or that level numbers be defined in terms of distance to sink nodes. In particular, if u is an AND- or OR-node in a restricted stratified circuit, the result of converting u to a NO-OP-node and deleting one of its input connections remains a restricted stratified circuit, although a new sink node may have been created.

The algorithm of Dymond and Cook [2] can be modified in a straightforward fashion to handle any restricted stratified circuit. The only difference is that whereas each level of the circuit in the Dymond–Cook case has distinct left and right boundaries, in the general restricted stratified circuit each level is a "ring." These rings have the same properties with regard to alternations, however, and the alternations can be computed in the same fashion, simply by allowing for the wraparound. The modifications needed to the algorithm of Dymond and Cook are minor and obvious.

Thus, we have the next proposition.

PROPOSITION 3.2. *The value at each node in a restricted stratified circuit can be computed in* $O(\log^2 n)$ *time with a polynomial number of processors.*

Following the approach in [11], we generalize slightly our notion of stratified circuits as follows in Definition 3.3.

DEFINITION 3.3. *A* stratified circuit with variables *is a stratified circuit in which primary source nodes, in addition to being labelled* 0 *or* 1, *may be labelled by a third possibility,* $\boxed{?}$, *indicating that the value of the node is not known.*

A restricted stratified circuit with variables *is a stratified circuit with variables in which all constant gates have fan-in zero.*

We shall refer to source nodes labelled with $\boxed{?}$ as *variables*. The value to be computed at each node v in circuit with variables now also has three possibilities: 0 or 1 if the value of v is independent of any variable inputs, or $\boxed{?}$ if v does depend on variable nodes, i.e., if there is at least one assignment of 0/1 values to variables that makes v be 0, and at least one assignment that makes v be 1. Note that our initial problem is the special case of this generalized problem in which there are no input variables, so that the value of no node in the circuit is $\boxed{?}$.

PROPOSITION 3.4. *The value at each node in a restricted stratified circuit with variables can be computed in* $O(\log^2 n)$ *time with a polynomial number of processors.*

Proof. The version with variables can be reduced to the version without variables as follows.

Step 1. Set the value of all source variables to 0 and compute the value of each node in the resulting restricted stratified circuit. Any node whose value is 1 will be 1 for any assignment of values to the input variables.

Step 2. Set the value of all source variables to 1 and compute the value of each node in the resulting restricted stratified circuit. Any node whose value is 0 will be 0 for any assignment of values to the input variables.

Step 3. All other nodes depend on the input variables and should be labelled $\boxed{?}$.

The correctness of this procedure follows from the fact that the circuit is monotone, containing only AND and OR operations. By Proposition 3.2, each step can be performed in $O(\log^2 n)$ time with a polynomial number of processors. □

We now consider the entire class of stratified circuits with variables. Our strategy in evaluating such a circuit is to split the circuit into two subcircuits, C_1 and C_2, where the outputs of C_2 are the inputs to C_1. We change the inputs of C_1 to be variables and then recursively solve the two subcircuits. Finally, we convert C_1 into a restricted stratified circuit and resolve it by using the correct outputs of C_2.

More specifically, let $C = (V, E)$ be a stratified circuit with $|C| = n$. We determine the value at each node in C as follows.

Step 1. Find a level i such that $n/4 \leq |C_{0..i}| < 3n/4$ and $n/4 \leq |C_{i..L_C}| < 3n/4$. Such an i exists since the fan-in of each node in C is at most 2, if we assume that C is connected.[1] If C is not connected, we can compute its connected components and process each separately.

[1] When we say C is connected we mean that the graph obtained by making all arcs in C undirected is connected.

Step 2. Relabel all level-i AND, OR, and NO-OP nodes in $C_{0..i}$ to $\boxed{?}$, and denote the resulting circuit C_1. Let C_2 denote $C_{i..L_C}$.

Step 3. Recursively solve C_1 and C_2 in parallel. The values of the C_2 nodes are the correct values for that part of the original circuit C.

Step 4. Remove from C_1 all nodes whose labels have been determined to be 0 or 1, together with all out edges from these nodes. Note that the other end of such an edge is now either labelled 0 or 1 (and hence is removed), or else is labelled $\boxed{?}$ and has exactly one input also labelled $\boxed{?}$. Also convert AND and OR nodes labelled $\boxed{?}$ and having exactly one input labelled $\boxed{?}$ to a NO-OP node. Call the resulting circuit C_1'. Note that all in-degree-0 nodes of C_1' are at level i, i.e., C_1' is a restricted stratified circuit with variables.

Step 5. Assign the labels computed for the sink nodes of C_2 to the corresponding C_1' sources, and call the resulting circuit C_1''. Since C_1'' is a restricted, stratified circuit with variables, its values can be computed as described in Proposition 3.4.

Steps 1, 2, and 4 are easily accomplished in $O(\log n)$ time with a polynomial number of processors, and by Proposition 3.4, Step 5 can be computed in $O(\log^2 n)$ time with a polynomial number of processors. In Step 3, since there are two parallel recursive calls on circuits of size at most $3n/4$, the entire algorithm runs in $O(\log^3 n)$ time with a polynomial number of processors.

PROPOSITION 3.5. *The value at each node of a stratified circuit C (with or without variables) can be computed in $O(\log^3 n)$ time with a polynomial number of processors.*

4. Focused circuits. In this section we show how another class of circuits can be converted to stratified circuits, and therefore can be solved in $\mathcal{NC}$.

DEFINITION 4.1. *A* focused circuit *is a circuit $C = (V, E)$ in which there is a subset of the sources $\{s_1, \ldots, s_k\}$ lying on a single face of C such that every non-source node in C can be reached by a (directed) path from some s_i.*

Note that in a focused circuit, any node that cannot be reached from $\{s_1, \ldots, s_k\}$ must be a source node. Recall that we are assuming all circuits are given with a planar embedding that has all sinks on a single face.

We now describe a procedure that converts any given focused circuit C into an equivalent stratified circuit C'. By equivalent we mean that every node of C has a corresponding node in C' that computes the same value.

Procedure Convert

Step 1. For each node v, determine the length ℓ_v of the longest path from any s_i to v. Let $\ell_{\max}$ be the maximum value of ℓ_v in C.

Step 2. Set the level number of all sink nodes to 0, and set the level number of every other node v to $\ell_{\max} - \ell_v$.

Step 3. For each arc $u \to v$ of the circuit with $\mathit{level}(u) > \mathit{level}(v) + 1$, replace $u \to v$ with a path of length $\mathit{level}(u) - \mathit{level}(v)$ composed entirely of NO-OP nodes. Assign appropriate level numbers for these new nodes. (Note that $\mathit{level}(u)$ cannot be less than $\mathit{level}(v)$.)

Step 4. Remove every source node v that is not reachable from any s_i by making an appropriate change to the labels of nodes adjacent to v. For example, if the value of v is 1 and there is an arc $v \to u$, then make u a NO-OP node if it were an AND gate, make u a constant-1 node if it were an OR gate, and leave u unchanged if it is a constant gate. Note that u cannot be a NO-OP gate since such gates have fan-in of one and u is reachable from some s_i and is adjacent to source node v. A similar set of changes applies if the value of v is 0.

PROPOSITION 4.2. *The above procedure converts a focused circuit C into an equivalent stratified circuit C'.*

Proof. Clearly, C' is a planar circuit equivalent to C since the only changes made are the replacement of arcs by paths of NO-OP nodes and the partial evaluation of nodes with constant inputs. To show that C' is a stratified circuit, it is easy to verify that the procedure correctly determines level numbers, that every arc in C' connects nodes at successive levels, and that the only source nodes are $\{s_1, \ldots, s_k\}$, which are primary source nodes. It only remains to verify that C' satisfies the nested level property.

Suppose C' did not satisfy the nested level property. Then let i be a level number such that in $C'_{0..i}$ there are two level-i nodes, a and b, that do not lie on the same face. But a and b are both reachable from the face containing $s_1, \ldots, s_k$ by edges not contained in $C'_{0..i}$, which contradicts the planarity of C'. Thus, C' must satisfy the nested level property. □

Steps 2–4 in Procedure Convert are accomplished easily in $O(\log n)$ time with a polynomial number of processors. Step 1, finding the longest paths in a directed acyclic graph, can be accomplished by matrix multiplications by using addition and MAX operations in $O(\log^2 n)$ time with a polynomial number of processors [1], [3]. Thus, from Propositions 3.5 and 4.2 we have the next proposition.

PROPOSITION 4.3. *The value at each node of a focused monotone planar circuit C can be computed in $O(\log^3 n)$ time with a polynomial number of processors.*

5. General circuits. In this section we show how the procedures from the previous sections can be used to construct an $\mathcal{NC}$ algorithm to compute the value at each node in any monotone planar circuit C.

In $C = (V, E)$, with $|V| = n$, and for any set of nodes S, let ***reach***(S) denote the subgraph of C by comprising the union of all (directed) paths that begin at a node in S. By an abuse of notation we denote ***reach***$(\{s_i, \ldots, s_j\})$ as simply ***reach***$(s_i, \ldots, s_j)$. By a *connected component* of $C \setminus$ ***reach***(S), we mean a subcircuit of C, which is a connected component in the underlying undirected graph of C with ***reach***(S) having been removed. Let $s_1, s_2, \ldots, s_k$ be the source nodes of C.

We consider two cases.

Case 1. Some s_i, $1 \leq i \leq k$, has the property that no connected component of $C \setminus$ ***reach***(s_i) contains more than $n/2$ nodes.

In this case, we can first, in parallel, recursively solve the subcircuits corresponding to each connected component in $C \setminus$ ***reach***(s_i), and then use the results to solve the subcircuit corresponding to ***reach***(s_i), which is now a focused circuit.

Case 2. For each s_i, $1 \leq i \leq k$, some connected component of $C \setminus$ ***reach***(s_i) contains more than $n/2$ nodes.

Fix an arbitrary order for $s_1, s_2, \ldots, s_k$. We first find the smallest index i_0 such that $C \setminus$ ***reach***$(s_1, \ldots, s_{i_0})$ has a connected component with more than $n/2$ nodes, but that no connected component of $C \setminus$ ***reach***$(s_1, \ldots, s_{i_0}, s_{i_0+1})$ has more than $n/2$ nodes. Clearly such an i_0 exists, since every node in C is contained in ***reach***$(s_1, \ldots, s_k)$, and can be found within $O(\log^3 n)$ time by an $\mathcal{NC}$ algorithm.

Let P be the connected component of $C \setminus$ ***reach***$(s_1, \ldots, s_{i_0})$ that contains more than $n/2$ nodes. (See Fig. 1.) By our choice of i_0, s_{i_0+1} must lie within P. In addition, observe that there is no arc in C from a node u outside P to a node v in P, since otherwise ***reach***$(s_1, \ldots, s_{i_0})$ would include v. Note also that no connected component of $P \setminus$ ***reach***(s_{i_0+1}) contains more than $n/2$ nodes, since $C \setminus$ ***reach***$(s_1, \ldots, s_{i_0}, s_{i_0+1})$ has no connected component with more than $n/2$ nodes.

To solve the original circuit C, we first find index i_0 and connected component P as above. We then compute $C_1 =$ ***reach***(P) and $C_2 =$ ***reach***(s_{i_0+1}). Now recursively, in parallel, we

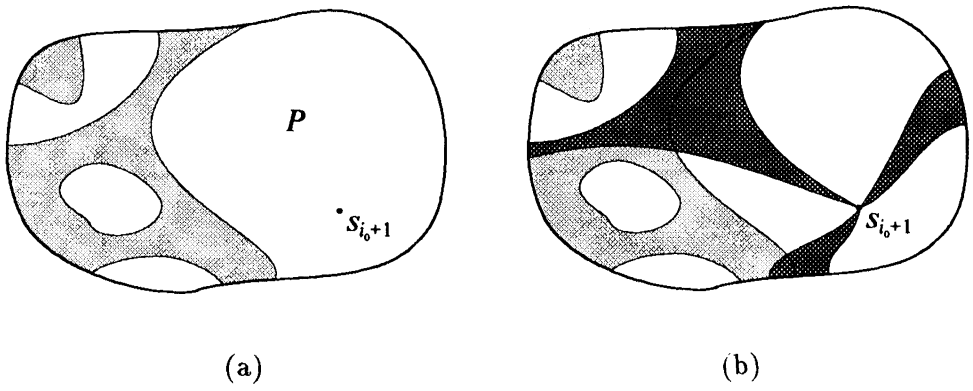

FIG. 1. *Abstract Representation of a Case* 2 *Circuit. Recall that all sinks lie on the outer face.* (a) *The shaded region represents* reach$(s_1, \ldots, s_{i_0})$. (b) *Nodes in* $C_2 =$ reach(s_{i_0+1}) *are now also shaded.*

solve all the subcircuits corresponding to connected components of both $C \setminus C_1$ and $P \setminus C_2$. Note that each of these subcircuits contains fewer than $n/2$ nodes. After all these subcircuits have been solved, what remains of the original circuit is $C_2 \cap P$ within P and $C_1 \setminus P$ outside of P. Now $C_2 \cap P$ can be solved as a focused circuit, since by definition every node in C_2 is reachable from s_{i_0+1}. Note that all inputs needed to solve $C_2 \cap P$ are now available as a result of solving $P \setminus C_2$. Finally, $C_1 \setminus P$ can be solved as a focused circuit, since all its nodes can be reached from source nodes on the face representing P, and the values of these source nodes have been computed. In addition, the previous solution of the connected components of $C \setminus C_1$ provides the other necessary inputs to $C_1 \setminus P$.

In both cases, by performing a series of $\mathcal{NC}$ computations in $O(\log^3 n)$ time, we reduce the problem to parallel recursive calls on subcircuits of size at most $n/2$, where the combined size of all these subcircuits is less than n.

Thus we show our main result in the following proposition.

PROPOSITION 5.1. *The value at each node of a monotone, planar circuit C can be computed in* $O(\log^4 n)$ *time with a polynomial number of processors.*

Recently, Yang [15] has developed an $O(\log^3 n)$-time $\mathcal{NC}$ algorithm for solving monotone planar circuits using the straight-line-code parallel evaluation technique of Miller, Ramachandran, and Kaltofen [13].

PRIVATE COMPUTATIONS OVER THE INTEGERS*

BENNY CHOR†, MIHÁLY GERÉB-GRAUS‡, AND EYAL KUSHILEVITZ§

Abstract. The subject of this work is the possibility of private distributed computations of n-argument functions defined over the integers. A function f is t-private if there exists a protocol for computing f, so that no coalition of at most t participants can infer any additional information from the execution of the protocol. It is known that over *finite* domains every function can be computed $\lfloor (n-1)/2 \rfloor$-privately. Some functions, like addition, are even n-private.

We prove that this result cannot be extended to infinite domains. The possibility of privately computing f is shown to be closely related to the *communication complexity* of f. By using this relation, we show, for example, that n-argument addition is $\lfloor (n-1)/2 \rfloor$-private over the nonnegative integers, but not even 1-private over all the integers.

Finally, a complete characterization of t-private *Boolean* functions over countable domains is given. A Boolean function is 1-private if and only if its communication complexity is *bounded*. This characterization enables us to prove that every Boolean function falls into one of the following three categories: It is either n-private, $\lfloor (n-1)/2 \rfloor$-private but not $\lceil n/2 \rceil$-private, or not 1-private.

Key words. private distributed computations, communication complexity

AMS subject classifications. 94A15, 94A60, 68R05

1. Introduction.

A set of $n \geq 3$ computationally unbounded parties, each holding an input x_i taken from a domain D, wishes to cooperate in distributively computing the value $f(x_1, x_2, \ldots, x_n)$ of a predetermined function f. These parties are honest, namely, they all follow their prescribed protocol. They communicate over a complete point-to-point communication network, where eavesdropping is not possible. A function f is called *t-private* if there is a communication protocol for computing f so that no coalition of at most t participants gets any additional information from the execution of the protocol. Ben-Or, Goldwasser, and Wigderson [5] and Chaum, Crépeau, and Dåmgard [8] have shown that if the domain D of f is *finite*, then f is $\lfloor (n-1)/2 \rfloor$-private. Specific functions, like addition, are even n-private over finite domains [6], while certain functions, like Boolean OR, are not $\lceil n/2 \rceil$-private [5].[1] However, functions of interest are typically defined not over finite domains, but over all strings, over the integers, or more generally over some countable domain. To apply the protocol of [5] and [8], one has to (implicitly or explicitly) assume an upper bound on the input size. If the bound does not hold, then the protocol, which depends not only on f but also on the size of the domain, has to be adjusted. This adjustment amounts to revealing additional information on the magnitude of the inputs.

The question we deal with in this work is private computations of functions defined over countable domains. In other words, is there a private protocol for computing f which can be applied to all inputs, regardless of their sizes? Before going any further, we remark that the $\lfloor (n-1)/2 \rfloor$-private protocol of [5] and [8] cannot be used in the infinite domain. Its first step is to apply a secret sharing scheme to every input. Secret sharing schemes strongly rely on the finiteness of the domain, and indeed do not exist over countable domains [7], [11].

[1] The study of private distributed computing was initiated in [18] and [13]. The model used there is different – the communication lines are not secure against eavesdropping, and on the other hand the participants are computationally bounded, so cryptographic techniques can be employed.

We show that the privacy of f is closely related to the *communication complexity* of f as defined by Yao [17]; namely, to the number of bits that need to be communicated among n parties in order to compute f (using any protocol, not necessarily a private one). The connection between these two notions enables us to show that a wide class of functions are $\lfloor (n-1)/2 \rfloor$-private. This class includes, among others, maximum and minimum, addition over the nonnegative integers, and multiplication over all integers. The relations to communication complexity are further used in our impossibility results. For example, we show that over the (negative and nonnegative) integers, addition is not even 1-private. That is, there is no protocol which computes the sum of n integers and preserves privacy even with respect to single participants. This contrasts with the $\lfloor (n-1)/2 \rfloor$-privacy of addition over the nonnegative integers, and the n-privacy of addition over any finite domain.

We give a complete characterization of private Boolean functions: A Boolean function is 1-private if and only if its communication complexity is *bounded*. Since many Boolean functions have unbounded communication complexity, this proves that there are Boolean functions which are not even 1-private. Furthermore, we show that if a Boolean f is 1-private, then it is also $\lfloor (n-1)/2 \rfloor$-private. In [10] it was shown that if a Boolean f is $\lceil n/2 \rceil$-private, then it is also n-private. Hence there is a three-level privacy hierarchy for Boolean functions: Every Boolean function (defined over a countable domain) is either n-private, $\lfloor (n-1)/2 \rfloor$-private but not $\lceil n/2 \rceil$-private, or not 1-private.

The remainder of this paper is organized as follows: In §2 we describe the model and give the needed definitions. In §3 we apply communication complexity arguments to produce private protocols for various functions. Section 4 contains the impossibility results for the functions addition and integer gcd. In §5 we prove our characterization for the Boolean case, and its implications. Section 6 introduces a model of nonterminating protocols which compute f "in the limit," and demonstrate some intriguing private protocols in this model. Finally, §7 contains concluding remarks and open problems.

2. Model and definitions. The system consists of a synchronous network of n computationally unbounded parties, $P_1, P_2, \ldots, P_n$. Each pair of parties is connected by a secure (no eavesdropping) and reliable communication channel. At the beginning of an execution, each party P_i has an input $x_i \in \{0,1\}^*$. (No probability space is associated with the inputs.) In addition, each party has a random input r_i taken from a source of randomness R_i (the random inputs are independent). The parties wish to compute the value of a function $f(x_1, x_2, \ldots, x_n)$. To this end, they exchange messages as prescribed by a protocol $\mathcal{F}$. The parties are honest, that is, they follow the protocol $\mathcal{F}$, and there are no failures of any kind. Messages are sent in rounds, where in each round every processor sends a (nonempty) message to every other processor. The protocol specifies n functions, one per party, which determine the messages sent by each party. The arguments to the messages producing function of each processor are its input, its random input, the round number, the messages it received so far, and the identity of the receiver.

The communication S sent in an execution of the protocol is the concatenation of all messages sent in the execution, parsed according to sender, receiver, and round number. For a subset $T \subseteq \{1, 2, \ldots, n\}$, we denote by S_T the communication S with the exception of messages sent between parties in $\bar{T}$. The communication length of the protocol $\mathcal{F}$ on inputs $x_1, \ldots, x_n$ is the maximum length of all communications S, sent in $\mathcal{F}$ on these inputs, over all random inputs. We say that a communication string S, parsed as above, is *consistent* with the protocol $\mathcal{F}$, party P_i, and input x_i if the following holds: There is a positive probability that if P_i has input x_i and receives the messages in the string S that are destined to P_i, then P_i will send messages identical to those messages in S that emanate from P_i. (Notice that to be consistent with just one party, the communication string need not be an actual string sent in some execution.)

We say that a protocol $\mathcal{F}$ computes the function f with *ε-advantage* ($0 < \varepsilon \leq \frac{1}{2}$) if for every input $\vec{x} = (x_1, \ldots, x_n)$ the last message in the protocol, is an identical message sent by party P_1 to all parties, indicating that this is the last message in the execution, and containing a value $\mathcal{F}(\vec{x}, \vec{r})$ which satisfies

$$Pr_{\vec{r}}(\mathcal{F}(\vec{x}, \vec{r}) = f(\vec{x})) \geq \frac{1}{2} + \varepsilon .$$

Denote by $p_k(\vec{x})$ the probability that more than k bits are exchanged between the parties during the execution of the protocol $\mathcal{F}$ with input $\vec{x}$, (the probability space is over the random inputs of all parties). The protocol is *terminating* if for every input $\vec{x}$,

$$\lim_{k \to \infty} p_k(\vec{x}) = 0 .$$

We say that a coalition (i.e., a set of parties) T *does not learn any additional information* (other than what follows from its input and the function value) from the execution of a randomized protocol $\mathcal{F}$, which computes f, if the following holds: For every two inputs $\vec{x}, \vec{y} \in (\{0,1\}^*)^n$ that agree in their T entries (i.e., $\forall i \in T : x_i = y_i$) and satisfy $f(\vec{x}) = f(\vec{y})$, the messages passed between T and $\bar{T}$ are identically distributed. That is, for every communication S,

$$Pr_{\vec{r}}(S_T | \vec{x}) = Pr_{\vec{r}}(S_T | \vec{y}) ,$$

where the probability space is over the random inputs of all parties.

We say that a protocol $\mathcal{F}$ for computing f is *t-private* if any coalition T of at most t parties does not learn any additional information from the execution of the protocol. We say that a function f is *t-private* if there exists a t-private terminating protocol that computes it with ε-advantage, for some $0 < \varepsilon \leq \frac{1}{2}$.

We end this section with some standard communication complexity definitions. Let $\{0,1\}^{\leq m}$ denote the collection of binary strings whose length is at most m. The ε-advantage *communication complexity* of f, when restricted to $\{0,1\}^{\leq m}$ denoted $C_\varepsilon(f_m)$, is the minimum over all n-party protocols which compute f with ε-advantage over $\{0,1\}^{\leq m}$, of the worst case communication length of the protocol, over all n-tuples of inputs that are all at most m-bit long. (Notice that party P_i has input x_i. This is the "regular" definition, as in [17] and [16], and should not be confused with the one of Chandra, Furst and Lipton [9].) The ε-advantage *communication complexity* of a function f, denoted $C_\varepsilon(f)(m)$, is defined as $C_\varepsilon(f_m)$. For *deterministic* protocols, $C_{\det}(f)(m)$ is defined similarly. We say that f has *bounded* communication complexity if there is some positive ε ($0 < \varepsilon \leq 1/2$) and an integer d such that for all m, $C_\varepsilon(f)(m) \leq d$.

3. Functions that can be privately computed. In this section we present a sufficient condition, based on $C_\varepsilon(f)$, for $\lfloor (n-1)/2 \rfloor$-privacy of f. This enables us to derive $\lfloor (n-1)/2 \rfloor$-private error-free protocols for a wide family of "natural" functions. We start with a lemma.

LEMMA 3.1. *Let $B \subseteq \{0,1\}^*$ and let $f : (\{0,1\}^*)^n \to B$. If for every $b \in B$ the function*

$$f_b(\vec{x}) = \begin{cases} 1 & \text{if } f(\vec{x}) = b, \\ 0 & \text{otherwise,} \end{cases}$$

can be computed t-privately, using an error-free protocol, then f is t-private.

Proof. The value of $f_b(\vec{x})$ for every $b \in B$ is determined by the value of $f(\vec{x})$. Thus, to compute $f(\vec{x})$, the parties can go over every $b \in B$ (say, in lexicographic order) and compute $f_b(\vec{x})$ by using the given t-private protocol for f_b without revealing any additional

information. The protocol terminates when for some $b \in B$ the value of $f_b(\vec{x})$ is 1. From the definition of f_b, this implies that $f(\vec{x}) = b$. Since every function f_b is computed by an error-free, t-private protocol, it is not hard to verify that the resulting protocol is error-free and is t-private. □

THEOREM 3.2. *Let* $f : (\{0,1\}^*)^n \to B$ *and* $0 < \varepsilon \leq \frac{1}{2}$. *If for every* $b \in B$ *the communication complexity* $C_\varepsilon(f_b)$ *is bounded, then* f *is* $\lfloor (n-1)/2 \rfloor$*-private.*

Proof. Using Lemma 3.1, it is enough to prove that for every $b \in B$, the function f_b is $\lfloor (n-1)/2 \rfloor$-private. Fix $b \in B$. By the assumption, $C_\varepsilon(f_b)$ is bounded. Extending a theorem of Yao [17] from the two-party to the n-party case, it follows that $C_{\det}(f_b)(m)$ is at most exponential in $C_\varepsilon(f_b)(m)$. In particular, if $C_\varepsilon(f_b)$ is bounded, then so is $C_{\det}(f_b)$. If for all m, $C_{\det}(f)(m) \leq d$, this means that for every m, there is a d-bit protocol for f on $\left(\{0,1\}^{\leq m}\right)^n$. Using König's lemma, this implies the existence of one deterministic protocol, $\mathcal{F}$, defined over $(\{0,1\}^*)^n$, which computes f and for every input exchanges at most d bits. (To prove this, consider the following tree: The nodes in level m of the tree are the protocols that compute f on $\left(\{0,1\}^{\leq m}\right)^n$ that use at most d bits of communication. A protocol in level $m+1$ is the son of a protocol in level m if they have the same communication on all inputs in $\left(\{0,1\}^{\leq m}\right)^n$. Since for every m there exists such a protocol, the tree is infinite. In addition, each protocol in level m has finitely many sons—at most the number of possibilities to map the strings of length $m+1$ into the set of d-bit communications. This implies, through the use of König's lemma, the existence of an infinite branch in the tree. This branch defines a protocol that computes f over $(\{0,1\}^*)^n$, and uses at most d bits of communication.)

Let $\{S_1, S_2, \ldots, S_k\}$ $(k \leq 2^d)$ be the set of all possible communications (in this deterministic protocol) with last message (the output) consisting of "1." We describe an $\lfloor (n-1)/2 \rfloor$-private protocol, $\mathcal{F}'$, which computes f_b. In the first step of $\mathcal{F}'$, each party P_i locally computes the set y_i as follows:

$$y_i = \{j \mid 1 \leq j \leq k, \text{ the communication } S_j \text{ is consistent with } x_i\}.$$

Let

$$f_b^*(y_1, \ldots, y_n) = \begin{cases} 1 & \text{if } \cap y_i \neq \emptyset, \\ 0 & \text{otherwise,} \end{cases}$$

that is, $f_b^*(\vec{y}) = 1$ if and only if there is a communication S_j with "output" 1, which is consistent with the inputs of all n participants. One can verify that $f_b^*(\vec{y}) = f_b(\vec{x})$ and that f_b^*'s domain is finite (every y_i is a subset of $\{1, 2, \ldots k\}$). Thus, using the protocols of [5] and [8] the value of $f_b^*(\vec{y})$ can be computed $\lfloor (n-1)/2 \rfloor$-privately, which implies that the value of $f_b(\vec{x})$ can be computed $\lfloor (n-1)/2 \rfloor$-privately. Through Lemma 3.1, the proof of the theorem is completed. □

COROLLARY 3.3. *Let* $f : (\{0,1\}^*)^n \to B$ *and* $0 < \varepsilon \leq \frac{1}{2}$. *If* $C_\varepsilon(f)$ *is bounded, then* f *is* $\lfloor (n-1)/2 \rfloor$*-private.*

COROLLARY 3.4. *Let* $f : (\{0,1\}^*)^n \to B$. *If for every* $b \in B$ *the set* $f^{-1}(b)$ *is finite, then* f *is* $\lfloor (n-1)/2 \rfloor$*-private.*

These results imply that many "natural" functions can be computed $\lfloor (n-1)/2 \rfloor$-privately. This includes functions as addition over the positive integers, maximum and minimum, and multiplication over the integers. Note that for the minimum and maximum, $f^{-1}(b)$ is infinite for every b. However, these two functions satisfy the condition of Theorem 3.2 and thus are $\lfloor (n-1)/2 \rfloor$-private.

Finally, we remark that the above protocols satisfy a stronger definition of privacy, as defined in [10].

4. Impossibility results. In this section we apply communication complexity arguments to prove the existence of functions that are not even 1-private. Specifically, we show that addition over $\mathcal{Z}$, the ring of integers, is not 1-private. The same result holds for integer gcd.

THEOREM 4.1. *Let* $0 < \varepsilon \leq \frac{1}{2}$ *and* $n \geq 3$. *Let* $SUM_n : \mathcal{Z}^n \to \mathcal{Z}$ *be defined as* $SUM_n(\vec{x}) = \sum_{i=1}^{n} x_i$. *There is no* ε*-advantage protocol which computes* SUM_n 1*-privately.*

The high-level structure of the proof is as following: Assume, towards a contradiction, that there exists an ε-advantage, 1-private protocol $\mathcal{F}$ which computes SUM_n. Privacy arguments imply that, with high probability, the number of bits communicated by $\mathcal{F}$ on all inputs $\vec{x}$ which satisfy $SUM_n(\vec{x}) = 0$ is bounded. We then show how to transform $\mathcal{F}$ into a two-argument protocol which computes the predicate "identity" using bounded communication. This contradicts a known lower bound.

LEMMA 4.2. *Let* $0 < \varepsilon \leq \frac{1}{2}$ *and* $0 < \delta \leq 1$ *be two constants. Suppose there is an* ε*-advantage,* 1*-private protocol* $\mathcal{F}$ *for computing* SUM_n. *Then there exists a constant* d *such that for every input vector* $\vec{x}$ *with* $SUM_n(\vec{x}) = 0$, *the probability that fewer than* d *bits are transmitted during the execution of* $\mathcal{F}$ *is at least* $1 - \delta$.

Proof. We first show that for every $\vec{x}$ with $SUM_n(\vec{x}) = 0$, the distribution of messages on every link (P_i, P_j) $(i < j)$ of the network, when the input is $\vec{x}$, is the same as the distribution of messages on this link, when the input is $(0, 0, \ldots, 0)$. Then, we prove the existence of a constant d as above for the input vector $(0, 0, \ldots, 0)$. Combining these two claims we get the proof of the lemma.

Let $\vec{x}$ be an input vector satisfying $SUM_n(\vec{x}) = 0$. To simplify the notation, we restrict attention to the link (P_1, P_2). Consider the following three input vectors:

$$\begin{array}{lllllll} \vec{x} & = & (x_1, & x_2, & x_3, & x_4, \ldots, & x_n), \\ \vec{x'} & = & (x_1, & 0, & x_2 + x_3, & x_4, \ldots, & x_n), \\ \vec{0} & = & (0, & 0, & 0, & 0, \ldots, & 0). \end{array}$$

By the assumptions, SUM_n is 0 for all three vectors. By 1-privacy, the distribution of messages on the link (P_1, P_2) must be the same for the two vectors $\vec{x}$ and $\vec{x'}$. Otherwise P_1 will be able to distinguish between the two. Similarly, the distribution of messages on the link (P_1, P_2) must be equal for the two vectors $\vec{x'}$ and $\vec{0}$, as otherwise P_2 will be able to distinguish between them. Thus, the distribution of messages on the link (P_1, P_2) is equal for $\vec{x}$ and $\vec{0}$.

In the second part of the proof, we use the termination condition for the input vector $\vec{0}$. It implies that for each link (P_i, P_j) there exists a constant $d_{i,j}$ such that the probability that more then $d_{i,j}$ bits are exchanged over (P_i, P_j) during the execution of the protocol on $\vec{0}$ is at most $\delta / \binom{n}{2}$.

Let $\vec{x}$ be any input vector that satisfies $SUM_n(\vec{x}) = 0$. By the first part of the proof, the probability that more than $d_{i,j}$ bits are exchanged over (P_i, P_j) during the execution of the protocol on $\vec{x}$ is also bounded by $\delta / \binom{n}{2}$. Thus, the probability that more than $d = \sum_{i<j} d_{i,j}$ bits are exchanged (over all $\binom{n}{2}$ communication lines) during the execution of $\mathcal{F}$ on $\vec{x}$ is at most δ. This completes the proof of the lemma. □

The next lemma is a known result in communication complexity. Let $ID : \{0, 1\}^m \times \{0, 1\}^m \to \{0, 1\}$ be the following function:

$$ID(a, b) = \begin{cases} 1 & \text{if } a = b, \\ 0 & \text{otherwise.} \end{cases}$$

LEMMA 4.3 (Yao [17]). *For every constant* $0 < \varepsilon \leq \frac{1}{2}$, $C_\varepsilon(ID)(m) = \Theta(\log m)$.

Proof of Theorem 4.1. Assume, towards a contradiction, that there exists a protocol $\mathcal{F}$ which computes SUM_n 1-privately with ε-advantage. Let $\delta = \frac{\varepsilon}{2}$. By using Lemma 4.2 we

see that there exists a constant d such that for every input vector $\vec{x}$ that satisfies $SUM_n(\vec{x}) = 0$, the probability that more than d bits are transmitted during the execution of $\mathcal{F}$ is bounded by δ. We use this property of $\mathcal{F}$ to construct a randomized protocol $\mathcal{A}$ to compute the ID function over $\{0,1\}^m \times \{0,1\}^m$, with $\varepsilon/2$ - advantage, which uses only a constant $(d+1)$ number of bits. This will be a contradiction to Lemma 4.3.

The protocol $\mathcal{A}$ works as following: On input $(a,b) \in \{0,1\}^m \times \{0,1\}^m$, the two parties (denoted by P_1^* and P_2^*) will simulate the protocol $\mathcal{F}$:

- P_1^* will simulate P_1 with $x_1 = a$ (the integer in the range $[0, 2^m - 1]$ whose binary representation is the string a).
- P_2^* will simulate $P_2, P_3, \ldots, P_n$ with $x_2 = -b$ and $x_3 = x_4 = \ldots = x_n = 0$.

The parties P_1^* and P_2^* will simulate $\mathcal{F}$ until it either terminates, or d bits are transmitted. If $\mathcal{F}$ terminates with final value 0, the parties output $ID(a,b) = 1$ (specifically, they claim that $a = b$). If $\mathcal{F}$ terminates with value $\neq 0$, or does not terminate after exchanging d bits, then the parties output $ID(a,b) = 0$ (that is, they claim that $a \neq b$).

Clearly, the protocol $\mathcal{A}$ transmits at most $d+1$ bits. What we now show is that $\mathcal{A}$ computes the value of the ID function over $\{0,1\}^m \times \{0,1\}^m$ with probability $\geq \frac{1}{2} + \frac{\varepsilon}{2}$. If $a = b$, then the constructed $\vec{x}$ satisfies $SUM_n(\vec{x}) = 0$. Through Lemma 4.2, the probability that more than d bits are exchanged on such input is at most δ. The other possible source of error is an incorrect output of $\mathcal{F}$. The probability that this happens is no greater than $\frac{1}{2} - \varepsilon$. Thus, the overall error probability of $\mathcal{A}$ on (a,b) is no greater than $\frac{1}{2} - \varepsilon + \delta$. By the choice of δ this is equal to $\frac{1}{2} - \frac{\varepsilon}{2}$. If $a \neq b$ then $\vec{x}$ satisfies $SUM_n(\vec{x}) \neq 0$. If more than d bits are transmitted, then $\mathcal{A}$ outputs 0, which is the correct value of ID in this case. As the probability of error in $\mathcal{F}$ is bounded by $\frac{1}{2} - \varepsilon$, then clearly this is so in case that the execution terminates with at most d communicated bits. Thus, on such (a,b) the protocol $\mathcal{A}$ computes the correct value of $ID(a,b)$ with probability at least $\frac{1}{2} + \varepsilon$. This completes the proof. □

COROLLARY 4.4. *Multiplication over the rationales is not* 1*-private.*

Proof. Addition over the integers can be reduced to multiplication in the cyclic group $\{2^i \mid i \in \mathcal{Z}\}$ by mapping the integer i to the rational number 2^i. Thus a 1-private protocol for multiplication over the rationales would translate into a 1-private protocol for addition over the integers, which contradicts Theorem 4.1. □

The technique relating communication complexity and privacy is applicable for various other functions. For example, we have the following theorem.

THEOREM 4.5. *Let* $0 < \varepsilon \leq \frac{1}{2}$ *and* $n \geq 2$. *Let* $\mathcal{N}$ *denote the set of natural numbers* $\{1, 2, \ldots\}$, *and* $GCD_n : \mathcal{N}^n \to \mathcal{N}$ *be defined as the greatest common divisor of the* n *arguments. There is no* ε*-advantage protocol which computes* GCD_n 1*-privately.*

Proof. The proof of this theorem is very similar to the proof for Theorem 4.1. We sketch the differences: the analogue of Lemma 4.2 will be proved for input vectors satisfying $GCD_n(\vec{x}) = 1$. In the proof of the analogous lemma we use the following triples of n-tuples:

$$\begin{array}{rcl} \vec{x} & = & (\ x_1,\ x_2,\ x_3,\ x_4, \ldots,\ x_n\ ), \\ \vec{x'} & = & (\ x_1,\ 1,\ x_3,\ x_4, \ldots,\ x_n\ ), \\ \vec{1} & = & (\ 1,\ 1,\ 1,\ 1, \ldots,\ 1\ ). \end{array}$$

Now, let $PRIMES = \{q_1, q_2, q_3, \ldots\}$ denote the sequence of prime numbers. In the proof of the theorem we will construct a protocol for ID as follows: On input (a,b) (two natural numbers ≥ 1)

- P_1^* will simulate P_1 with $x_1 = q_a$.
- P_2^* will simulate $P_2, P_3, \ldots, P_n$ with $x_2 = x_3 = \ldots = x_n = q_b$.

Clearly, $GCD_n(\vec{x}) = 1$ if and only if $a \neq b$. Thus the original argument holds here as well. □

5. Characterization for Boolean functions. In this section we characterize the privacy of any Boolean function f in terms of its communication complexity. Corollary 3.3 implies that any Boolean function f with bounded communication complexity is $\lfloor (n-1)/2 \rfloor$-private. The main theorem in this section states the reverse implication. More precisely, a Boolean function whose communication complexity is unbounded is not even 1-private. We set the stage for the theorem by introducing some definitions and claims.

Let $A \subseteq \{0,1\}^* \times \{0,1\}^*$. Define a relation $\sim_A$ on $A \times A$ by $(x_1, y_1) \sim_A (x_2, y_2)$ if $x_1 = x_2$ or $y_1 = y_2$. The equivalence relation $\equiv_A$ is defined as the transitive closure of $\sim_A$. $Class(A)$ denotes the number of equivalence classes of $\equiv_A$ (it can be infinite). For any set $S \subseteq \{0,1\}^* \times \{0,1\}^*$, define S_1 and S_2 as the projections of S on the first and second coordinates, respectively. We now present two simple properties of the equivalence classes of the relation previously defined.

CLAIM 1. Let $A \subseteq \{0,1\}^* \times \{0,1\}^*$, and let K and L be two disjoint (nonempty) equivalence classes of $\equiv_A$. Then $K_1 \cap L_1 = K_2 \cap L_2 = \emptyset$.

Proof. The proof follows directly from the definition of the equivalence relation $\equiv_A$. □

CLAIM 2. Let $A \subseteq \{0,1\}^* \times \{0,1\}^*$, and let K and L be two disjoint (nonempty) equivalence classes of $\equiv_A$. If $(x, y) \in (K_1 \times L_2) \cup (L_1 \times K_2)$, then $(x, y) \notin A$.

Proof. Assume, without loss of generality, that $(x, y) \in (K_1 \times L_2)$. This implies that there exist y' such that $(x, y') \in K$ and x' such that $(x', y) \in L$. Suppose that $(x, y) \in A$. By the definition of $\sim_A$ these pairs satisfy $(x, y') \sim_A (x, y) \sim_A (x', y)$, contradicting the disjointness of the two $\equiv_A$ equivalence classes K and L. □

The next lemma states that if A and B cover $\{0,1\}^* \times \{0,1\}^*$ (A and B need not be disjoint), then either $Class(A) \leq 2$ or $Class(B) \leq 2$. Furthermore, if $Class(B) \geq 3$ then $Class(A) = 1$. Notice that it is possible to have $Class(A) = Class(B) = 2$, e.g., by taking $A = \{(x, y) | x \equiv y \pmod 2\}$ and $B = \{(x, y) | x \not\equiv y \pmod 2\}$.

LEMMA 5.1. *Suppose that* $\{0,1\}^* \times \{0,1\}^* \subseteq A \cup B$. *If* $Class(B) \geq 3$, *then* $Class(A) = 1$.

Proof.[2] Let C, D, E be three distinct equivalence classes of $\equiv_B$. Let (x_1, y_1), (x_2, y_2), and (x_3, y_3) be arbitrary elements of C, D and E, respectively (see Fig. 1). By Claim 1, $x_i \neq x_j$ and $y_i \neq y_j$ for every $i \neq j$ $(1 \leq i, j \leq 3)$. Consider the element (x_1, y_2). By Claim 2, $(x_1, y_2) \in A$. Similarly, $(x_i, y_j) \in A$ for every $i \neq j$ $(1 \leq i, j \leq 3)$. Furthermore, by Claim 1, they all belong to the same equivalence class of $\equiv_A$. Denote this class by F.

	y_1	y_2	y_3	y_4
x_1	C	F	F	-
x_2	F	D	F	-
x_3	F	F	E	-
x_4	?	?	-	G

FIG. 1

Assume, towards a contradiction, that $\equiv_A$ has another equivalence class G and let $(x_4, y_4) \in G$. By Claim 1, $x_4 \neq x_j$ and $y_4 \neq y_j$ for every $1 \leq j \leq 3$. Consider the element (x_4, y_1). By Claim 2, $(x_4, y_1) \notin A$. Therefore, $(x_4, y_1) \in B$ and by Claim 1 it must belong to C. By a similar argument, (x_4, y_2) must belong to D. This implies that $C_1 \cap D_1 \neq \emptyset$, which contradicts Claim 1. □

[2]This proof simplifies our original proof, which appeared in the early version of this paper. It is due to Freddy Bruckstein and Alon Orlitsky, and it appears here with their kind permission.

THEOREM 5.2. *Let* $f : (\{0,1\}^*)^n \to \{0,1\}$ *be* 1*-private. Then the communication complexity of* f *is bounded.*

Proof. Let $f : (\{0,1\}^*)^n \to \{0,1\}$, and $\mathcal{F}$ be a 1-private protocol which computes f with ε-advantage. We show that $\mathcal{F}$ can be modified to a communication protocol which computes f with $\frac{\varepsilon}{2}$-advantage while exchanging only a bounded number of bits between every pair of parties (where the bound does not depend on the input).

In order to carry out this transformation, it would be desirable to be in a situation similar to that occurring in SUM_n, where every $\vec{z} \in f^{-1}(0)$ has message distribution similar to some *fixed* input ($\vec{0}$ for SUM_n). While this desired situation may not occur, something weaker, but sufficient for our purposes, does. For every link (P_i, P_j), there is a value $v \in \{0,1\}$ and there are at most two *fixed* inputs $\vec{x}(i,j), \vec{w}(i,j) \in (\{0,1\}^*)^n$ so that for every $\vec{z} \in f^{-1}(v)$, the distribution of messages exchanged on the link (P_i, P_j), given input $\vec{z}$, is *identical* to the same distribution either given input $\vec{x}(i,j)$ or given input $\vec{w}(i,j)$.

Let $1 \le i < j \le n$. Define the set $A_{i,j}$ (resp., $B_{i,j}$) by $(x_i, x_j) \in A_{i,j}$ if there exists an n-tuple $\vec{x} = (x_1, x_2, \ldots, x_n)$ extending (x_i, x_j) such that $f(\vec{x}) = 0$ (resp., $f(\vec{x}) = 1$). Notice that $A_{i,j} \cup B_{i,j}$ covers $\{0,1\}^* \times \{0,1\}^*$. We now relate the 1-privacy of f to the sets $A_{i,j}$, $B_{i,j}$.

Suppose $f(\vec{x}) = f(\vec{w}) = 0$ and $(x_i, x_j) \equiv_{A_{i,j}} (w_i, w_j)$. Any 1-private protocol which computes f induces identical distribution of messages exchanged between P_i and P_j, given the input $\vec{x}$ and the input $\vec{w}$. (Similarly for $f(\vec{x}) = f(\vec{w}) = 1$ and $(x_i, x_j) \equiv_{B_{i,j}} (w_i, w_j)$.) The proof of this claim is immediate from the definitions of the sets $A_{i,j}$, $B_{i,j}$, the relations $\sim_{A_{i,j}}$, $\sim_{B_{i,j}}$, $\equiv_{A_{i,j}}$ and $\equiv_{B_{i,j}}$, and 1-privacy.

By Lemma 5.1, for each (i,j), at least one of the sets $A_{i,j}$, $B_{i,j}$ has no more than two equivalence classes in the corresponding $\equiv$ equivalence relation. Without loss of generality, $A_{i,j}$ has at most two equivalence classes, and let (x_i, x_j) and (w_i, w_j) be fixed representatives of the two classes. (Notice that for a different pair i', j', the set $B_{i',j'}$ can be the set with $Class(\cdot) \le 2$.) Let $\vec{x}(i,j)$ and $\vec{w}(i,j)$ denote two inputs in $f^{-1}(0)$ whose projections on the i and j coordinates yield the above representatives (take $\vec{x}(i,j) = \vec{w}(i,j)$ if there is only one equivalence class).

Let $\mathcal{F}$ be a 1-private protocol which computes f with ε-advantage ($0 < \varepsilon \le \frac{1}{2}$). Consider runs of $\mathcal{F}$ on the $2 \cdot \binom{n}{2}$ inputs $\vec{x}(1,2), \vec{w}(1,2), \ldots, \vec{x}(n-1,n), \vec{w}(n-1,n)$. Let d be the minimal integer such that the probability that P_i and P_j exchange more than d bits, given that the input is either $\vec{x}(i,j)$ or $\vec{w}(i,j)$, is less than ε/n^2 (for all (i,j) pairs).

We modify the protocol $\mathcal{F}$ as follows: All parties run $\mathcal{F}$ until it either terminates, or some pair attempts to exchange more than d bits. Suppose, without loss of generality, that the first such pair is $(1,2)$, and further that $\vec{x}(1,2), \vec{w}(1,2) \in A_{1,2}$. In this case, the pair aborts the execution of $\mathcal{F}$, and announces that the value of f is 1. (In case of conflicting announcements in the same round, the one resulting from the minimal pair in lexicographical order is adopted by all parties.)

The modified protocol exchanges at most $d \cdot \binom{n}{2}$ bits on all inputs. We argue that it computes the correct answer with probability at least $\frac{1}{2} + \frac{\varepsilon}{2}$. Suppose, without loss of generality, that $f(\vec{z}) = 0$. For all pairs i, j with representatives $\vec{x}(i,j), \vec{w}(i,j) \in A_{i,j}$, the messages exchanged between P_i and P_j on input $\vec{z}$ are distributed identically to one of the two representatives, and thus the probability that more than d bits will be exchanged in $\mathcal{F}$ is bounded above by ε/n^2. Thus the probability that some i, j with representatives in $A_{i,j}$ will abort the execution of $\mathcal{F}$ and announce "1" as the final outcome is smaller then $\varepsilon/2$. Any pair i, j with $\vec{x}(i,j), \vec{w}(i,j) \in B_{i,j}$ cannot announce "1" as the final outcome by aborting $\mathcal{F}$'s execution. The other source of errors stems from errors in $\mathcal{F}$'s final outcome. The probability that this occurs is smaller than $\frac{1}{2} - \varepsilon$. Thus the overall probability of error in the modified protocol is smaller than $\frac{1}{2} - \frac{\varepsilon}{2}$. □

By combining Theorem 5.2 and Corollary 3.3, we get the next corollary.

COROLLARY 5.3. *A Boolean function* $f : (\{0,1\}^*)^n \to \{0,1\}$ *is* 1*-private if and only if it has bounded communication complexity. If* f *is* 1*-private, then it is* $\lfloor (n-1)/2 \rfloor$*-private.*

Together with the characterization of $\lceil n/2 \rceil$-private Boolean functions of [10], we conclude with the following theorem.

THEOREM 5.4. *Any Boolean function* $f : (\{0,1\}^*)^n \to \{0,1\}$ *is either*

- n*-private.*
- $\lfloor (n-1)/2 \rfloor$*-private private but not* $\lceil n/2 \rceil$*-private.*
- *not* 1*-private.*

6. Nonterminating protocols. So far, we considered protocols that are private, compute the correct value (with probability at least $\frac{1}{2} + \varepsilon$), and terminate (with probability 1). In this section we show that if we abandon the termination condition (and the requirement that a distinguished "last message" is sent), and require instead only "correctness in the limit," then private computations which were not possible before become possible. We exemplify the model via two examples. Consider the following nonterminating protocol for computing SUM_n:

For $k = 1, 2, 3, \ldots,$

- each party P_i locally computes $y_i \in [-k, k]$ such that $y_i \equiv x_i \pmod{2k+1}$.
- The parties compute n-privately, using the protocol of [6], s_k such that $s_k \equiv \sum_{i=1}^{n} y_i \pmod{2k+1}$ and $s_k \in [-k, k]$. The value s_k is the outcome of the kth round.

It is easy to see that no coalition (of any size $t \leq n$) gets any additional information from the execution of this protocol. After a *finite* number of iterations (which depends on the input vector) the output s_k stabilizes on the correct value. Thus, SUM_n is n-private in the nonterminating model.

The next example shows that we can demand even more. Consider the following nonterminating protocol for computing GCD_n:

For $k = 1, 2, 3, \ldots,$

- each party P_i computes $y_i = 1$ if $k \mid x_i$ and $y_i = 0$ otherwise.
- The parties compute, $\lfloor (n-1)/2 \rfloor$-privately, the AND of the y_i's. This bit indicates whether k divides all the x_i's or not. The output of the kth round is the maximal $g \leq k$ that divides all the x_i's.

The protocol computes the function GCD_n, and it is $\lfloor (n-1)/2 \rfloor$-private in the nonterminating model. In the protocol for SUM_n, no participant knows when the result stabilizes. Here, however, the gcd can never exceed x_i. Thus after x_i many iterations, party P_i knows that he knows the final outcome. After $\max_{i=1}^{n} x_i$ iterations, all the parties know that they know the final outcome. However, the protocol must continue, since the parties do not know whether the other parties know that the result is already final. In other words, the privacy requirements prevent the parties from achieving *common knowledge* [14] on the fact that the result is already final, and an infinite execution is enforced.

7. Concluding remarks. In case that a function f is not 1-private, it can still be computed by first revealing the lengths $|x_i|$ of all participants inputs, and then by using the protocols for the finite case of [8] and [5]. However, $f(\vec{x})$ can always be computed while revealing only smaller amount of additional information (for a formal definition see [3] and [4])—the *maximal* input length, i.e., $\max_{i=1}^{n} |x_i|$—in the following two steps:

- Compute $\lfloor (n-1)/2 \rfloor$-privately the value $m = \max_{i=1}^{n} |x_i|$.
- Compute $\lfloor (n-1)/2 \rfloor$-privately the value of f over the *finite* domain of strings with length at most m.

For functions with low circuit complexity, the second step can be performed efficiently using the protocols described in [5], [8], and [1]. The first step can be performed by using the protocol described in the proof of Theorem 3.2 (§3): In the ℓth round, party P_i sets $y_i = 1$ if $|x_i| \leq \ell$ and $y_i = 0$ otherwise. Then, the parties compute $\lfloor (n-1)/2 \rfloor$-privately the AND of the y_i's and stop with output ℓ if the AND is 1. This step is therefore polynomial time in the length of the input $\vec{x}$. It is possible to substantially reduce the number of iterations in this part while preserving the polynomial complexity, by checking in the ℓth round whether $\max_{i=1}^{n} |x_i| \leq 2^{\ell}$. Thus if the maximum is m, this fact is found in $O(\log m)$ rounds (instead of $O(m)$ rounds).

A possible direction for extending Theorem 5.2 to functions with non-Boolean range might be to generalize Lemma 5.1 to the coloring of the two-dimensional plane by more than two colors. However, such generalizations of the lemma are not true: There are three colorings of the plane (say by colors 0,1,2), where $Class(0) = Class(1) = Class(2) = \infty$. Such example was constructed by Nati Linial, and is included, with his kind permission, in the Appendix. It remains open whether the corresponding generalization of Theorem 5.2 is true.

One of the interesting questions in the area of private computations has been to investigate the structure of the *privacy hierarchy*. Recently, we have resolved this question [12] for n-argument functions which are defined over finite domains. We have shown that for finite domains, the privacy hierarchy has exactly $\lfloor n/2 \rfloor$ levels. For any $\lceil n/2 \rceil \leq t \leq n-2$, an n–argument function which is t-private but not $t+1$-private was constructed. The major tool used in this proof was to partition the n inputs into two sets of appropriate sizes and apply the criteria for privacy of two argument functions. This approach is not useful in determining t-privacy for t which is at most $\lfloor (n-1)/2 \rfloor$, because one of the two sizes will be larger than t. Indeed, the results in [12] leave open the structure of the privacy hierarchy for functions defined over countable domains.

The communication complexity techniques used in the present work are of a very different nature than the partition techniques which we have just mentioned. They enable us to show that the privacy hierarchy contains a new, additional level (0-privacy). We believe that these techniques will also play an important role in future research towards resolving the exact structure of the privacy hierarchy over countable domains.

Appendix. In this appendix we describe an example, due to Nati Linial, of a function $f : \mathcal{N} \times \mathcal{N} \to \{0, 1, 2\}$ with the property that $Class(0) = Class(1) = Class(2) = \infty$. This example implies that Lemma 5.1 cannot be extended to non-Boolean functions. The function f is defined as follows (see Fig. 2):

$$f(x, y) = \begin{cases} x \bmod 3 & \text{if } x = y, \\ x + 1 \bmod 3 & \text{if } x \neq y \wedge (x \equiv y) \bmod 3, \\ 2(x + y) \bmod 3 & \text{otherwise.} \end{cases}$$

It can be verified that every diagonal point (x, x) forms a singleton equivalence class. Since for each value in $\{0, 1, 2\}$ there are infinitely many preimages of the form (x, x), it follows that $Class(0) = Class(1) = Class(2) = \infty$.

Acknowledgments. We are grateful to Shai Ben-David, Josh Benaloh, and Charlie Rackoff for very helpful discussions and contributions to this work. Thanks to Freddy Bruckstein and Alon Orlitsky for simplifying the proof of Lemma 5.1 and to Nati Linial for his three-coloring example. We would also like to thank Oded Goldreich, who has the good quality of commenting quickly on early drafts.

SPARSE POLYNOMIAL INTERPOLATION IN NONSTANDARD BASES*

Y. N. LAKSHMAN† AND B. DAVID SAUNDERS‡

Abstract. In this paper, we consider the problem of interpolating univariate polynomials over a field of characteristic zeros that are sparse in (a) the Pochhammer basis, or (b) the Chebyshev basis. The polynomials are assumed to be given by black boxes, i.e., one can obtain the value of a polynomial at any point by querying its black box. We describe efficient new algorithms for these problems. Our algorithms may be regarded as generalizations of Ben-Or and Tiwari's (1988) algorithm (based on the BCH decoding algorithm) for interpolating polynomials that are sparse in the standard basis. The arithmetic complexity of the algorithms is $O(t^2 + t \log d)$, which is also the complexity of the univariate version of the Ben-Or and Tiwari algorithm. That algorithm and those presented here also share the requirement of $2t$ evaluation points.

AMS subject classifications. 68Q40, 12Y05, 41A05

Introduction. In this paper, we consider the problem of efficiently interpolating polynomials given by black boxes that have sparse representations in various bases. Usually, one considers a polynomial $f(x) = \sum_{i=0}^{n} a_i x^i$ as t-sparse if at most t of the coefficients a_i are non-zero. The problem of interpolating a sparse polynomial from a list of values at specific points, or from values given by a black box that evaluates the polynomial is of great importance in computational algebra. Sparse interpolation has received significant attention in several recent papers. (Ben-Or and Tiwari (1988), Clausen, Dress, Grabmeier, and Karpinski (1988), Kaltofen and Lakshman (1988), Grigoriev and Karpinski (1987), Grigoriev, Karpinski, and Singer (1990), (1991a), (1994), Borodin and Tiwari (1990), Zippel (1990).) In particular, the problem of interpolating a t-sparse univariate polynomial given a black box for evaluating the polynomial can be efficiently solved using Ben-Or and Tiwari's adaptation of the BCH decoding algorithm.

Sparse interpolation is well recognized as a very useful tool for controlling intermediate expression swell in computer algebra (Zippel (1990), Kaltofen and Trager (1990)). Sparse polynomials and rational functions can be evaluated quickly and that makes them attractive to several applications and an interesting line of research is to try to infer properties of sparse polynomials (such as divisibility, existence of nontrivial greatest common divisor, the existence of real roots, etc.) from their values at a small number points (see Grigoriev, Karpinski, and Odlyzko (1992)). Traditionally, "sparse polynomial (or rational function)" is taken to mean a polynomial (or rational function) with a "few terms" where the "terms" are power products of the variables involved. One can reasonably ask for sparse representations for polynomials in other bases such as the Chebyshev polynomials or the shifted power basis $1, x - \alpha, (x - \alpha)^2, \ldots$. In this paper, we consider two classes of polynomials—those which are sparse in the Chebyshev basis and those which are sparse in the Pochhammer basis. A polynomial $f(x) = \sum_{i=0}^{n} a_i T_i(x)$ is t-sparse in the Chebyshev basis if at most t of the coefficients a_i are nonzero, where $T_i(x)$ is the ith Chebyshev polynomial. Sparse Pochhammer polynomials are defined similarly. We provide algorithms for interpolating such polynomials efficiently, given a black box that evaluates the polynomial. The algorithms require as input an upper bound t on the number of nonzero terms in the interpolating polynomial. The arithmetic complexity of the algorithms is $O(t^2 + t \log d)$, which is also the complexity of the

univariate version of the Ben-Or and Tiwari algorithm. That algorithm and those presented here also share the requirement of $2t$ evaluation points. However, when one considers the bit complexity (when the ground field is $\mathbf{Q}$), the Ben-Or and Tiwari algorithm and our sparse Chebyshev algorithm involve intermediate values of bit size $O(td)$, whereas in the sparse Pochhammer algorithm intermediate values grow to a bit length of $O(d \log(t))$.

Several recent results concerning sparse interpolation are similar in spirit to the BCH-decoding algorithm. In Dress and Grabmeier (1991), it is shown that many of the sparse interpolation algorithms can be formulated and proven correct in the context of t-sparse sums of abelian monoids. A somewhat different framework in Grigoriev, Karpinski, and Singer (1991a) in terms of t-sparse sums of eigenfunctions of operators is shown to provide several generalizations of the sparse interpolation algorithm of Ben-Or and Tiwari. In fact, an efficient algorithm for interpolating polynomials sparse in the Pochhammer basis follows from an observation in Grigoriev, Karpinski, and Singer (1991a) which points out that t-sparse sums of eigenfunctions of the operator $x\Delta(f) = x(f(x) - f(x-1))$ correspond to polynomials that are t-sparse in the Pochhammer basis. We use the Pochhammer case as a motivating example for our discussion of the Chebyshev case.

The problem of efficiently interpolating polynomials that are sparse in the Chebyshev basis was stated as an open problem in Borodin and Tiwari (1990). Our algorithm provides a solution and it is another generalization of the algorithm of Ben-Or and Tiwari. It uses properties shared by the standard power basis and the Chebyshev polynomials and appears to be different from the generalizations presented in Dress and Grabmeier (1991), Grigoriev, Karpinski, and Singer (1991a). While the general structure of our algorithm appears similar to the algorithms falling into the Dress–Grabmeier framework, the details are quite different. In particular, the centerpiece of the algorithms in the Dress–Grabmeier framework is a certain Toeplitz matrix where, as in our algorithm, a similar role is played by a matrix that is *the sum of a Toeplitz matrix and a Hankel matrix*. It would be interesting to reconcile our algorithm with the Dress–Grabmeier or the Grigoriev–Karpinski–Singer framework.

The rest of the paper is organized as follows. In §1, we motivate our discussion by briefly stating the algorithm for interpolating polynomials that are sparse in the Pochhammer basis. In §2, we describe our algorithm for interpolating polynomials sparse in the Chebyshev basis. Section 3 provides an analysis of the complexity of the algorithm, which is followed by some additional remarks in the last section.

1. Sparse interpolation in the Pochhammer basis. The Pochhammer symbol $x^{\overline{n}}$ denotes the rising factorial power

$$x(x+1)\dots(x+n-1)$$

for any integer $n \geq 0$. It is easily shown that $x^{\overline{i}}$, $i = 0, 1, 2, \dots$ is a $\mathbf{Q}$ basis for the polynomial ring $\mathbf{Q}[x]$. A polynomial $f(x)$ is t-sparse in the Pochhammer basis (of rising powers) if and only if $\exists f_i \in \mathbf{Q}$, $e_i \in \mathcal{Z}_+$, $i = 1, \dots, t$, such that

$$f(x) = \sum_{k=1}^{t} f_k x^{\overline{e_k}}.$$

We assume that $e_1 > e_2 > \cdots > e_t$. Suppose we are given a black box that returns the value of $f(x)$ at any $x \in \mathbf{Q}$ and a bound t on the number of nonzero terms in the representation of $f(x)$ in the Pochhammer basis. Then, we can interpolate $f(x)$ from its values at $x = 1, 2, \dots, 2t$. The algorithm follows from an observation in Grigoriev, Karpinski, and Singer (1991a) which places this problem in the framework of Dress and Grabmeier. It is an elementary fact that the finite difference operator behaves like the derivative on the Pochhammer symbol. More

precisely, let

$$\Delta(f(x)) = f(x+1) - f(x).$$

We have

$$\begin{aligned}\Delta(x^{\overline{n}}) &= (x+1)^{\overline{n}} - x^{\overline{n}} \\ &= n(x+1)^{\overline{n-1}}.\end{aligned}$$

Let

$$f^{(i)}(x) = \sum_{k=1}^{t} e_k^i f_k x^{\overline{e_k}} \text{ for } i = 0, 1, \ldots.$$

Note that

$$x\Delta(f^{(i)}(x)) = f^{(i+1)}(x).$$

We can compute $f^{(i)}(a)$ for $i = 0, 1, \ldots, 2t-1$ by repeated applications of the above recurrence from the values $f(a+i)$, $i = 0, 1, \ldots, 2t-1$.

Consider the polynomial $\Psi(z)$ of degree t whose roots are the e_i, $i = 1, \ldots, t$, i.e.,

$$\Psi(z) = \prod_{i=1}^{t}(z - e_i).$$

Let

$$\Psi(z) = z^t + \psi_{t-1}z^{t-1} + \cdots + \psi_1 z + \psi_0.$$

The $f^{(i)}$ and ψ_i satisfy the following linear relations. Assume that $\psi_t = 1$.

LEMMA 1. *For* $j = 0, \ldots, t-1$, $\sum_{i=0}^{t} \psi_i f^{(i+j)}(a) = 0$.

Proof. This is a special case of Theorem 1 in Dress and Grabmeier (1991). (See page 62 in that paper.) □

Furthermore, Theorem 1 in Dress and Grabmeier (1991) shows that if t is the number of nonzero terms in the representation of $f(x)$ in the Pochhammer basis, then the $t \times t$ matrix $\mathcal{F}$ with $\mathcal{F}_{i,j} = f^{(i+j-2)}(a)$ is nonsingular for any $a > 0$. By using this, one can compute the polynomial $\Psi(z)$ from $f(a), f(a+1), \ldots, f(a+2t-1)$. The roots of $\Psi(z)$ are the "Pochhammer exponents" of $f(x)$. Knowing these one can easily compute the coefficients f_k. We omit details to avoid repetition but state the algorithm for the sake of completeness.

Algorithm Sparse-Pochhammer-Interpolation

Input: A black box for evaluating a polynomial $f(x)$. $f(x)$ is known to be t-sparse in the Pochhammer basis.

Output: A list of pairs (f_i, e_i), $i = 1, \ldots, t$ such that $f(x) = \sum_{i=1}^{t} f_i x^{\overline{e_i}}$.

1. *Query the black box to obtain the values of* $f(x)$ *at* $x = a, a+1, \ldots, a+2t-1$ *for some* $a \neq 0$. *Compute* $f^{(i)}(a)$ *for* $i = 0, 1, \ldots, 2t-1$ *from* $f(a+i)$, $i = 0, 1, \ldots, 2t-1$.
2. *Solve the system of linear equations* $\mathcal{F}\vec{\psi} = -\vec{\mathsf{f}}$. *If*

$$\vec{\psi} = (\ \psi_0 \quad \psi_1 \quad \ldots \quad \psi_{t-1}\ )^T,$$

then the auxiliary polynomial $\Psi(z)$ *is given by*

$$\Psi(z) = z^t + \psi_{t-1}z^{t-1} + \cdots + \psi_1 z + \phi_0.$$

3. *Find the integer roots of* $\Psi(z)$. *The roots are the exponents of* $f(x)$, *i.e.,* $e_1, e_2, \ldots, e_t$.
4. *Solve the linear system of equations* $\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{F}}$ *to obtain* $f_1 a^{\overline{e_1}}, \ldots, f_t a^{\overline{e_t}}$. *Since we know the* e_i *and* a, *the coefficients* f_i *are easily determined. Output the list of pairs* $[(f_1, e_1), \ldots, (f_t, e_t)]$.

Analysis of the Sparse-Pochhammer-Interpolation algorithm. While the sparse Pochhammer interpolation algorithm and the algorithm of Ben-Or and Tiwari for interpolating polynomials sparse in the standard power basis both illustrate the Dress–Grabmeier framework, the details are quite different. The sparse Pochhammer algorithm differs in a fundamental way from the algorithm of Ben-Or and Tiwari. The counterpart of the auxiliary polynomial $\Psi(z)$ in Ben-Or and Tiwari's algorithm has as roots a^{e_i}, whereas here the auxiliary polynomial $\Psi(z)$ has as roots the *degrees* e_i of the nonzero terms in the interpolating polynomial. This has implications on how we actually compute the roots of the auxiliary polynomial. Also, this algorithm uses a completely different set of evaluation points (importantly, the evaluation points are smaller).

The analysis will be brief, pointing out the effect of the differences just mentioned. We assume unit cost for a black box query. The $f^{(i)}(a)$ for $i = 0, 1, \ldots, 2t-1$ can be computed from $f(a+i)$, $i = 0, 1, \ldots, 2t-1$ by using $O(t^2)$ field operations. The Toeplitz system of equations $\mathcal{F}\vec{\psi} = -\vec{f}$ can be solved using $O(t^2)$ field operations using the Berlekamp–Massey algorithm (Kaltofen and Lakshman (1988)) to find the coefficients of the auxiliary polynomial $\Psi(z)$. We can use the Cantor–Zassenhaus algorithm to factor $\Psi(z)$ modulo a suitable prime p and the Hensel lifting to recover the integer roots. The cost is $O(t^2 + t \log d)$, where d is the degree of the interpolating polynomial (see, for instance, Loos (1983)). The final step of solving a transposed Vandermonde system of equations can be done using the algorithm of Zippel (1990) in $O(t^2)$ field operations. We can now add up the costs of the four steps and we have the following theorem.

THEOREM 2. *The sparse Pochhammer interpolation algorithm performs $O(t^2 + t \log d)$ field operations to interpolate a t-Pochhammer-sparse polynomial given by a black box. Here, d is the degree of the polynomial being interpolated (not part of the input). The algorithm makes $2t$ queries to the black box evaluating the polynomial. The numerator and denominator of the rational numbers that arise during the algorithm have $O(d \log(t))$ bits.* □

2. Sparse interpolation in the Chebyshev basis. In this section, we describe an efficient algorithm for interpolating polynomials in $\mathbf{Q}[x]$ that are sparse in the Chebyshev basis, where $\mathbf{Q}$ is the field of rational numbers. The algorithm is entirely rational, so it applies over any field of characteristic zero. The analysis in §3 in terms of arithmetic operations would apply in the general characteristic zero case as well, provided the evaluation point a is rational and $a \geq 2$. The bit complexity analysis, of course, is specific to the base field $\mathbf{Q}$. Let $T_n(x)$ denote the nth Chebyshev polynomial of the first kind:

$$T_0(x) = 1, \quad T_1(x) = x, \quad T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x) \text{ for } n \geq 2.$$

It is well known that $T_i(x)$, $i = 0, 1, 2, \ldots$ is a $\mathbf{Q}$-basis for the polynomial ring $\mathbf{Q}[x]$.

Let $f(x) = \sum_{i=0}^{m} f_i T_i(x)$ be a polynomial in the ring $\mathbf{Q}[x]$. As usual, we say that $f(x)$ is t-sparse (in the Chebyshev basis) if and only if at most t of the f_i's are nonzero.

Suppose we are given a black box that returns the value of $f(a)$ for any $a \in \mathbf{Q}$. We present an algorithm that interpolates $f(x)$ from its values at specially chosen $2t$ points. Our algorithm may be regarded as a generalization of the Ben-Or and Tiwari algorithm (Ben-Or and Tiwari (1988)). We identify two crucial properties that are required for the generalization to work. In the context of Chebyshev polynomials, they are the following items:

- For $m, n \geq 0$, $T_n(T_m(x)) = T_{mn}(x) = T_m(T_n(x))$, i.e., Chebyshev polynomials commute with respect to composition.
- For $m, n \geq 0$, $T_m(x)T_n(x) = 1/2(T_{m+n}(x) + T_{|m-n|}(x))$, i.e., the product of two Chebyshev polynomials is a *fixed* linear form in two others.

These properties are easy consequences of well-known properties of the Chebyshev polynomials. Before describing our interpolation algorithm, we need a statement of uniqueness of a sparse interpolating polynomial.

LEMMA 3. *Let $f(x)$ be a t-sparse polynomial (in the Chebyshev basis). If for some $a > 1$, $f(T_i(a)) = 0$ for $i = 0, 1, 2, \ldots, t-1$, then $f(x)$ is identically zero.*

Proof. Since $f(x)$ is t-sparse, there exist $f_i \in \mathbf{Q}$ and $\delta_i \in \mathcal{Z}_+$, for $i = 1, \ldots, t$ such that

$$f(x) = f_1 T_{\delta_1}(x) + f_2 T_{\delta_2}(x) + \cdots + f_t T_{\delta_t}(x).$$

Now, we can rewrite the fact that $f(T_i(a)) = 0$ for $i = 0, 1, 2, \ldots, t-1$ as $\mathcal{V}\vec{\mathrm{f}} = \vec{\mathbf{0}}$, where

$$\mathcal{V} = \begin{pmatrix} T_{\delta_1}(T_0(a)) & T_{\delta_2}(T_0(a)) & \ldots & T_{\delta_t}(T_0(a)) \\ T_{\delta_1}(T_1(a)) & T_{\delta_2}(T_1(a)) & \ldots & T_{\delta_t}(T_1(a)) \\ \vdots & \vdots & \ddots & \vdots \\ T_{\delta_1}(T_{t-1}(a)) & T_{\delta_2}(T_{t-1}(a)) & \ldots & T_{\delta_t}(T_{t-1}(a)) \end{pmatrix}, \qquad \vec{\mathrm{f}} = \begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_t \end{pmatrix}$$

If f is not identically zero, then $\mathcal{V}$ is singular. Let $\vec{c} = (c_0, c_1, \ldots, c_{t-1})^T$ be such that $\vec{c}^T\mathcal{V} = 0$. Consider the polynomial

$$C(x) = c_0 T_0(x) + c_1 T_1(x) + \cdots + c_{t-1} T_{t-1}(x)$$

of degree at most $t-1$. Use the fact that $T_{\delta_j}(T_i(a)) = T_i(T_{\delta_j}(a))$ and rewrite $\mathcal{V}$ as

$$\mathcal{V} = \begin{pmatrix} T_0(T_{\delta_1}(a)) & T_0(T_{\delta_2}(a)) & \ldots & T_0(T_{\delta_t}(a)) \\ T_1(T_{\delta_1}(a)) & T_1(T_{\delta_2}(a)) & \ldots & T_1(T_{\delta_t}(a)) \\ \vdots & \vdots & \ddots & \vdots \\ T_{t-1}(T_{\delta_1}(a)) & T_{t-1}(T_{\delta_2}(a)) & \ldots & T_{t-1}(T_{\delta_t}(a)) \end{pmatrix}.$$

Now, $\vec{c}^T\mathcal{V} = 0$ implies that $T_{\delta_1}(a), T_{\delta_2}(a), \ldots, T_{\delta_t}(a)$ are all roots of $C(x)$. These t values are distinct. (In fact, the values $T_i(a)$ are strictly monotonic increasing if $a > 1$, which is straightforward to check from the defining recurrence.) But $C(x)$ is of degree $t-1$ and cannot have t roots. Hence, $\mathcal{V}$ cannot be singular, and f must be identically zero. □

As a consequence, we have the next corollary.

COROLLARY 4. *If $f(x)$ and $g(x)$ are two distinct t-sparse polynomials, then for each $a > 1$ there is an i, $0 \le i \le 2t-1$ such that $f(T_i(a)) \neq g(T_i(a))$.*

Proof. Consider $h(x) = f(x) - g(x)$. The polynomial $h(x)$ is $2t$-sparse and if the corollary is not true, then $h(T_i(a)) = 0$ for $i = 0, \ldots, 2t-1$. Apply the previous lemma. □

We can now describe the sparse interpolation algorithm. As before, $f(x) = \sum_{i=1}^{t} f_i T_{\delta_i}(x)$. The algorithm determines the δ_i first. Once the δ_i are known, it is a simple task to compute the coefficients f_i. Let $a_i = f(T_i(a))$, $i = 0, 1, \ldots, 2t-1$ for some $a > 1$. Consider the polynomial of degree t whose roots are $T_{\delta_i}(a)$ represented in the Chebyshev basis, normalized to have a leading coefficient of 1, i.e.,

$$\Phi(z) = T_t(z) + \phi_{t-1} T_{t-1}(z) + \cdots + \phi_0 T_0(z)$$

and

$$\Phi(T_{\delta_i}(a)) = 0 \text{ for } i = 1, \ldots, t.$$

Our strategy is to compute $\Phi(z)$ and then find its integer roots. First, we show that the coefficients of $\Phi(z)$ satisfy the following linear relations:

LEMMA 5.

$$\sum_{j=0}^{t-1} \phi_j \times (a_{i+j} + a_{|j-i|}) = -(a_{i+t} + a_{|t-i|})$$

for $i = 0, 1, 2, \ldots$.

Proof. Assume $\phi_t = 1$.

$$\begin{aligned}
\left(\sum_{j=0}^{t-1} \phi_j a_{j+i}\right) + a_{t+i} &= \sum_{j=0}^{t} \phi_j \left(\sum_{l=1}^{t} f_l T_{\delta_l}(T_{j+i}(a))\right) \\
&= \sum_{l=1}^{t} f_l \left(\sum_{j=0}^{t} \phi_j T_{\delta_l}(T_{j+i}(a))\right) = \sum_{l=1}^{t} f_l \left(\sum_{j=0}^{t} \phi_j T_{j+i}(T_{\delta_l}(a))\right) \\
&= \sum_{l=1}^{t} f_l \left(\sum_{j=0}^{t} \phi_j (2T_j(T_{\delta_l}(a))T_i(T_{\delta_l}(a)) - T_{|j-i|}(T_{\delta_l}(a)))\right) \\
&= \sum_{l=1}^{t} f_l \left[\Phi(T_{\delta_l}(a)) \times 2T_i(T_{\delta_l}(a)) - \left(\sum_{j=0}^{t} \phi_j T_{|j-i|}(T_{\delta_l}(a))\right)\right] \\
&= -\sum_{l=1}^{t} f_l \left(\sum_{j=0}^{t} \phi_j T_{\delta_l}(T_{|j-i|}(a))\right) \\
&= -\phi_j \left(\sum_{l=1}^{t} f_l T_{\delta_l}(T_{|j-i|}(a))\right) = -\sum_{j=0}^{t} \phi_j a_{|j-i|} \\
&= -\left(\sum_{j=0}^{t-1} \phi_j a_{|j-i|}\right) - a_{|t-i|}.
\end{aligned}$$

Hence, $\sum_{j=0}^{t-1} \phi_j (a_{i+j} + a_{|j-i|}) = -(a_{i+t} + a_{|t-i|})$. □

The above lemma says that the coefficients of $\Phi(z)$ satisfy the system of equations

$$\mathcal{A}\vec{\phi} = -\vec{\alpha},$$

where

$$\mathcal{A} = \begin{pmatrix} 2a_0 & 2a_1 & \dots & 2a_{t-1} \\ 2a_1 & a_2 + a_0 & \dots & a_t + a_{t-2} \\ \vdots & \vdots & \ddots & \vdots \\ 2a_{t-1} & a_t + a_{t-2} & \dots & a_{2t-2} + a_0 \end{pmatrix}, \quad \vec{\phi} = \begin{pmatrix} \phi_0 \\ \phi_1 \\ \vdots \\ \phi_{t-1} \end{pmatrix},$$

$$\vec{\alpha} = \begin{pmatrix} 2a_t \\ a_{t+1} + a_{t-1} \\ \vdots \\ a_{2t-1} + a_1 \end{pmatrix}.$$

Notice that $\mathcal{A}_{i,j} = a_{i+j} + a_{|i-j|}$ is the sum of a Toeplitz matrix and a symmetric Hankel matrix. Next, we show that $\mathcal{A}$ is nonsingular.

LEMMA 6. *$\mathcal{A}$ is nonsingular.*

Proof. Consider the (transposed) *Vandermonde-like* matrix $\mathcal{V}$ and diagonal matrix $\mathcal{B}$.

$$\mathcal{V} = \begin{pmatrix} T_{\delta_1}(T_0(a)) & T_{\delta_2}(T_0(a)) & \dots & T_{\delta_t}(T_0(a)) \\ T_{\delta_1}(T_1(a)) & T_{\delta_2}(T_1(a)) & \dots & T_{\delta_t}(T_1(a)) \\ \vdots & \vdots & \ddots & \vdots \\ T_{\delta_1}(T_{t-1}(a)) & T_{\delta_2}(T_{t-1}(a)) & \dots & T_{\delta_t}(T_{t-1}(a)) \end{pmatrix},$$

$$\mathcal{B} = \begin{pmatrix} 2f_1 & 0 & \dots & 0 \\ 0 & 2f_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 2f_t \end{pmatrix}.$$

According to arguments similar to those in Lemma 1, $\mathcal{V}$ is nonsingular. Since f has exactly t terms, no f_i is zero, hence $\mathcal{B}$ is nonsingular. We claim that $\mathcal{A} = \mathcal{V}\mathcal{B}\mathcal{V}^T$, thereby proving that $\mathcal{A}$ is nonsingular. The (i, j)th element of the product $\mathcal{V}\mathcal{B}\mathcal{V}^{tr}$ is

$$\sum_{l=1}^{t} 2f_l T_{\delta_l}(T_i(a))T_{\delta_l}(T_j(a)) = \sum_{l=1}^{t} 2f_l T_i(T_{\delta_l}(a))T_j(T_{\delta_l}(a))$$

$$= \sum_{l=1}^{t} f_l(T_{i+j}(T_{\delta_l}(a)) + T_{|i-j|}(T_{\delta_l}(a))) = \sum_{l=1}^{t} f_l(T_{\delta_l}(T_{i+j}(a)) + T_{\delta_l}(T_{|i-j|}(a)))$$

$$= a_{i+j} + a_{|i-j|} = \mathcal{A}_{i,j}. \qquad \square$$

From the above lemmas we see that we can compute the coefficients of $\Phi(z)$ by solving the linear system of equations given by $\mathcal{A}\vec{\phi} = -\vec{\alpha}$. The roots of $\Phi(z)$ are integers with special properties and they can be determined without using numerical root finding algorithms. The roots of $\Phi(z)$ are $T_{\delta_i(a)}$ and we can determine the "Chebyshev exponents" δ_i from $T_{\delta_i}(a)$. The coefficients f_i of f can be determined by solving the linear system of equations given by

$$\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{a}},$$

where $\mathcal{V}$ is the matrix in the previous lemma and

$$\vec{\mathsf{f}} = (\ f_1 \quad f_2 \quad \ldots \quad f_t\ )^T, \qquad \vec{\mathsf{a}} = (\ a_0 \quad a_1 \quad \ldots \quad a_{t-1}\ )^T.$$

To summarize, we now collect all the steps of our interpolation algorithm.

Algorithm Sparse-Chebyshev-Interpolation

Input: A black box for evaluating a polynomial $f(x)$ known to be t-sparse in the Chebyshev basis.

Output: A list of pairs $(f_i, \delta_i), i = 1, \ldots, t$ such that $f(x) = \sum_{i=1}^{t} f_i T_{\delta_i}(x)$.

1. *Query the black box to obtain the values of* $f(x)$ *at the* $2t$ *points* $x = T_i(a)$, $i = 0, 1, \ldots, 2t-1$ *for some* $a > 1$. *Let* $a_i = f(T_i(a))$.
2. *Solve the system of linear equations* $\mathcal{A}\vec{\phi} = -\vec{\alpha}$. *If*

$$\vec{\phi} = (\ \phi_0 \quad \phi_1 \quad \ldots \quad \phi_{t-1}\ )^T,$$

then the auxiliary polynomial $\Phi(z)$ *is given by*

$$\Phi(z) = z^t + \phi_{t-1}z^{t-1} + \cdots + \phi_1 z + \phi_0.$$

3. *Find the integer roots of* $\Phi(z)$. *The roots are* $T_{\delta_1}(a), T_{\delta_2}(a), \ldots, T_{\delta_t}(a)$. *Find the "Chebyshev powers"* $\delta_1, \delta_2, \ldots, \delta_t$ *from* $T_{\delta_1}(a), T_{\delta_2}(a), \ldots, T_{\delta_t}(a)$.
4. *Solve the linear system of equations* $\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{a}}$ *to obtain the coefficients* $f_1, \ldots, f_t$ *of* f. *Output the list of pairs* $[(f_1, \delta_1), \ldots, (f_t, \delta_t)]$.

3. Analysis of the Chebyshev Interpolation Algorithm. In our analysis, we first count the number of field operations ($+, -, \times, /$ involving rational numbers) performed by the algorithm in the worst case. We then bound the bit sizes of the rational numbers that might arise during the computation, thus giving upper bounds on the number of bit operations performed by the algorithm. We also assume that querying the black box for the value of $f(x)$ is a unit cost operation.

Solving $\mathcal{A}\vec{\phi} = -\vec{\alpha}$. The matrix $\mathcal{A}$ is the sum of a Hankel and a Toeplitz matrix of size $t \times t$. Such systems can be solved by well-known techniques using $O(t^2)$ field operations (see, for example, Merchant and Parks (1982)).

Finding the integer roots of $\Phi(z)$. The special nature of the roots of $\Phi(z)$ (all are integers of the type $T_{\delta_j}(a)$) allows us to compute them without using regular root finders. Since $\Phi(z)$ is expressed in the Chebyshev basis with leading coefficient 1, ϕ_{t-1}, the coefficient of $T_{t-1}(z)$, is given by

$$\phi_{t-1} = \begin{cases} -T_{\delta_1}(a) & \text{if } t = 1, \\ -2\sum_{j=1}^{t} T_{\delta_j}(a) & \text{if } t > 1. \end{cases}$$

Let $s = -\phi_{t-1}/2$. It is easily shown from the defining recurrence that $T_n(a) = 1/2(\beta^n + \bar{\beta}^n)$, where $\beta = a + \sqrt{a^2 - 1}$ and $\bar{\beta} = a - \sqrt{a^2 - 1}$ for $n = 0, 1, 2, \ldots$. Suppose that for convenience we choose $a = 2$. Then $\beta = 2 + \sqrt{3}$ and $\bar{\beta} = 2 - \sqrt{3}$. Without any loss of generality, assume that $\delta_1 > \delta_2 > \cdots > \delta_t$. Clearly, δ_1 is the unique integer k such that

$$1/2(\beta^k + \bar{\beta}^k) \leq s < 1/2(\beta^{k+1} + \bar{\beta}^{k+1}).$$

We can find such a k by an algorithm analogous to the binary powering algorithm as follows:

Choose $D = 2\lceil \log_2(s) \rceil$; $(1/2(\beta^D + \bar{\beta}^D) > s)$
Compute integer arrays p, q such that
  $p_i + q_i\sqrt{3} = \beta^{2^i}$ for $i = 0, 1, \ldots$ to at most D.
$i := 0$; $p_0 := 1$; $q_0 := 0$;
loop
  $increment(i)$;
  $p_i := p_{i-1}^2 + 3q_{i-1}^2$; $q_i := 2p_{i-1}q_{i-1}$;
until $p_i > s$;
$decrement(i)$;
$k := 2^i$; $j := i - 1$; $\widehat{p} := p_i$; $\widehat{q} := q_i$;
loop
  $tmp := \widehat{p} \times p_i + 3\widehat{q} \times q_i$;
  if $(tmp \leq s)$ **then**
    $\widehat{q} := p_i \times \widehat{q} + q_i \times \widehat{p}$; $\widehat{p} := tmp$; $k := k + 2^j$; **fi;**
  $decrement(j)$;
until $j = 0$;
return $k, \widehat{p}$; $\{\widehat{p} = T_k(2)\}$

Once we know k, i.e., δ_1, we can set $s := s - T_k(2)$ and repeat the process to get δ_2 and so on. The number of field operations performed by the above algorithm is $O(\log_2 D)$ and we need to run it t times to compute all the δ_i. Therefore, the Chebyshev exponents can be computed by performing $O(t \log_2 D)$ field operations. D is chosen to be $2\lceil \log_2(s) \rceil$ and

$$s = -\phi_{t-1}/2 = \sum_{j=1}^{t} T_{\delta_j}(a) < 1/2(\beta^{\delta_1+1} + \bar{\beta}^{\delta_1+1}) < 4^{\delta_1}.$$

Therefore, the number of bits in the integers involved in the root finding step is no more than $2\delta_1$.

Solving $\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{a}}$. $\mathcal{V}$ is the transpose of a Vandermonde-like matrix. An $n \times n$ non-singular Vandermonde matrix can be inverted by using $O(n^2)$ field operations and $O(n)$ space (Zippel (1990)). More efficient algorithms ($O(n \log^2 n \log(\log n))$ time) that use fast polynomial multiplication are also known (Canny, Kaltofen, and Lakshman (1989)). In the following discussion, we adapt Zippel's algorithm for solving the system of equations $\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{a}}$. Consider the product

$$\mathcal{V}^T\mathcal{A} = \begin{pmatrix} T_0(T_{\delta_1}(a)) & T_1(T_{\delta_1}(a)) & \dots & T_{t-1}(T_{\delta_1}(a)) \\ T_0(T_{\delta_2}(a)) & T_1(T_{\delta_2}(a)) & \dots & T_{t-1}(T_{\delta_2}(a)) \\ \vdots & \vdots & \ddots & \vdots \\ T_0(T_{\delta_t}(a)) & T_1(T_{\delta_t}(a)) & \dots & T_{t-1}(T_{\delta_t}(a)) \end{pmatrix} \begin{pmatrix} c_{11} & c_{12} & \dots & c_{1t} \\ c_{21} & c_{22} & \dots & c_{2t} \\ \vdots & \vdots & \ddots & \vdots \\ c_{t1} & c_{t2} & \dots & c_{tt} \end{pmatrix}.$$

This product is the matrix

$$\begin{pmatrix} P_1(T_{\delta_1}) & P_2(T_{\delta_1}) & \dots & P_t(T_{\delta_1}) \\ P_1(T_{\delta_2}) & P_2(T_{\delta_2}) & \dots & P_t(T_{\delta_2}) \\ \vdots & \vdots & \ddots & \vdots \\ P_1(T_{\delta_t}) & P_2(T_{\delta_t}) & \dots & P_t(T_{\delta_t}) \end{pmatrix},$$

where $P_j(z)$ is the polynomial

$$P_j(z) = c_{1j}T_0(z) + c_{2j}T_1(z) + c_{3j}T_2(z) + \cdots + c_{tj}T_{t-1}(z).$$

Notice that by choosing

$$P_j(z) = \prod_{i \neq j} \frac{z - T_{\delta_i}(a)}{T_{\delta_j}(a) - T_{\delta_i}(a)},$$

the product becomes the identity matrix. In other words, the jth column of the inverse of $\mathcal{V}^T$ is made up of the coefficients of $P_j(z)$ *expressed in the Chebyshev basis.* Let $P_{j,i}$ denote the coefficient of $T_i(z)$ in $P_j(z)$. Since the inverse of the transpose is the transpose of the inverse, the system of equations $\mathcal{V}\vec{\mathsf{f}} = \vec{\mathsf{a}}$, i.e.,

$$\begin{pmatrix} T_{\delta_1}(T_0(a)) & T_{\delta_2}(T_0(a)) & \dots & T_{\delta_t}(T_0(a)) \\ T_{\delta_1}(T_1(a)) & T_{\delta_2}(T_1(a)) & \dots & T_{\delta_t}(T_1(a)) \\ \vdots & \vdots & \ddots & \vdots \\ T_{\delta_1}(T_{t-1}(a)) & T_{\delta_2}(T_{t-1}(a)) & \dots & T_{\delta_t}(T_{t-1}(a)) \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_t \end{pmatrix} = \begin{pmatrix} a_0 \\ a_1 \\ \vdots \\ a_{t-1} \end{pmatrix},$$

has the solution

$$f_j = a_0P_{j,0} + a_1P_{j,1} + \cdots + a_{t-1}P_{j,t-1} \quad \text{for} \quad j = 1, \dots, t.$$

The coefficients $P_{j,i}$ can be computed as follows. Let

$$P(z) = \prod_{k=1}^{t}(z - T_{\delta_k}(a)).$$

($P(z)$ is actually $\Phi(z)/2^{t-1}$, $\Phi(z)$ being the auxiliary polynomial computed in step 2 of the interpolation algorithm.) Let

$$\widehat{P}_j(z) = P(z)/(z - T_{\delta_j}(a)),$$

be expressed in the Chebyshev basis. We can compute $\widehat{P}_j(z)$ from $P(z)$ by "synthetic Chebyshev division"—use the identity

$$T_k(z) = (z - T_{\delta_j}(a)) \times 2T_{k-1}(z) + 2T_{\delta_j}(a)T_{k-1}(z) + T_{k-2}(z) \quad \text{for } k > 1$$

$t - 1$ times on $P(z)$. This division can be performed by using $O(t)$ field operations. Let $D_j = \widehat{P}_j(T_{\delta_j}(a))$. Clearly,

$$P_j(z) = \widehat{P}_j(z)/D_j.$$

D_j can be computed by using $O(t)$ field operations (evaluate $\widehat{P}_j(z)$ at $T_{\delta_j}(a)$). Therefore, we can compute all the Chebyshev coefficients of $P_j(z)$ in $O(t)$ field operations, and from them we can compute f_j by using $O(t)$ field operations. Since each f_j needs $O(t)$ field operations in this scheme, we need $O(t^2)$ field operations to compute all the f_j, $j = 1, \ldots, t$. Notice that we need $O(t)$ space to hold the coefficients of each $P_j(z)$. However, we can reuse the same space for all the $P_j(z)$. Hence, we only need $O(t)$ storage units. Also, notice that the rational numbers encountered in this scheme have numerators and denominators with $O(t \log(T_{\delta_1}(a)))$ bits. Notice that $\log(T_{\delta_1}(a) = O(d))$, where d is the degree of the interpolating polynomial. We can now add up the costs of the four steps and we have the next theorem.

THEOREM 7. *The sparse Chebyshev interpolation algorithm performs $O(t^2 + t \log d)$ field operations to interpolate a t-Chebyshev-sparse polynomial given by a black box. Here d is the degree of the polynomial being interpolated (not part of the input). The algorithm makes $2t$ queries to the black box evaluating the polynomial. The numerator and denominator of the rational numbers that arise during the algorithm have $O(td)$ bits.* □

Remark 1. We may not know the exact number of terms in the polynomial, just only an upper bound $\tau \geq t$. In such a case, we can still use the algorithm, except that the matrix $\mathcal{A}$ will be singular (for $\tau > t$). The solution is to use the largest nonsingular leading principle minor of $\mathcal{A}$ in place of $\mathcal{A}$. Its rank gives the exact number of terms in the interpolating polynomial. The details are worked out for the Ben-Or and Tiwari algorithm in Kaltofen and Lakshman (1988) and are essentially the same for this case.

Remark 2. We have used classical algorithms for solving the various subproblems in the interpolation algorithm. One can use asymptotically faster algorithms to improve the overall complexity of the interpolation algorithm to $O(t(\log^2 t \log(\log t) + \log d))$ field operations. See Kaltofen and Lakshman (1988) and Canny et al. (1989).

Remark 3. The algorithm that we have discussed can be viewed as a generalization of the Ben-Or and Tiwari algorithm which in turn is based on the BCH decoding algorithm. The generalization uses a crucial property of the Chebyshev polynomials, namely, that they commute with respect to composition, i.e., $T_n(T_m(z)) = T_m(T_n(z))$. It turns out that this property is rather special and the only *families* of polynomials that exhibit this property are the Chebyshev polynomials and the standard powers $\{1, z, z^2, \ldots\}$. More precisely, it is known that if in a family of polynomials $f_0(z), f_1(z), f_2(z), \ldots$ with $\deg(f_i(z)) = i$, it is true that $f_i(f_j(z)) = f_j(f_i(z))$ for any $i, j \geq 0$, then either $f_i(z) = \lambda((\lambda^{-1}(z))^i)$ for all i or $f_i(z) = \lambda(T_i(\lambda^{-1}(z)))$ for all i, where $\lambda(z) = az + b$ and $\lambda^{-1}(z) = (z - a)/b$ for some constants a, b. (See, for instance, Rivlin (1974).)[1] The algorithm can be adapted easily to interpolate polynomials that are sparse in such "generalized" power bases or Chebyshev bases.

One can consider several possible "natural" bases and polynomials that are sparse in those bases. For example, suppose we know that the polynomial given by a black box is t-sparse in the basis $1, x - \alpha, (x - \alpha)^2, (x - \alpha)^3, \ldots$ for some unknown α. Two recent papers discuss algorithms for solving this problem (Grigoriev and Karpinski (1992) and Lakshman and Saunders (1994)).

Sparsity in the standard basis is related to the number of real roots of the polynomial (sparsity limits the number of variations in sign), which is not the case when we consider polynomials that are sparse in the Chebyshev or Pochhammer bases. What are the corresponding observations about sparsity in these bases?

Acknowledgments. We thank our colleagues Prof. Bobby Caviness, Prof. David Wood, and Prof. Jeremy Johnson for several helpful discussions. Our thanks also to Prof. Michael Singer of North Carolina State University for detailed comments on an earlier draft.

[1] We are grateful to Dr. Jeremy Johnson of Drexel University for bringing this to our attention.

A NEW APPROACH TO FORMAL LANGUAGE THEORY BY KOLMOGOROV COMPLEXITY*

MING LI† AND PAUL VITÁNYI‡

Abstract. We present a new approach to formal language theory by using Kolmogorov complexity. The main results presented here are an alternative for pumping lemma(s), a new characterization for regular languages, and a new method to separate deterministic context-free languages and nondeterministic context-free languages. The use of the "incompressibility arguments" is illustrated by many examples. The approach is also successful at the high end of the Chomsky hierarchy since one can quantify nonrecursiveness in terms of Kolmogorov complexity.

Key words. formal language theory, Kolmogorov complexity, pumping lemmas, regular languages, finite automata, deterministic context-free languages

AMS subject classifications. 68Q30, 68Q45, 68Q68, 68Q50

1. Introduction.

It is feasible to reconstruct parts of formal language theory by using algorithmic information theory (Kolmogorov complexity). We provide theorems on how to use Kolmogorov complexity as a concrete and powerful tool. We do not just want to introduce fancy mathematics; our goal is to help our readers do a large part of formal language theory in the most essential, easiest, and sometimes even obvious ways. In this paper, it is only important to us to demonstrate that the application of Kolmogorov complexity in the targeted area is not restricted to trivialities. The proofs of the theorems in this paper may not be easy. However, the theorems are the type that are used as a tool. Once derived, our theorems are easy to apply.

1.1. Prelude.

The first application of Kolmogorov complexity in the theory of computation was in [18] and [19]. By redoing proofs of known results, it was shown that static, descriptional (program size) complexity of a *single* random string can be used to obtain lower bounds on dynamic, computational (running time) complexity. None of the inventors of Kolmogorov complexity originally had these applications in mind. Recently, Kolmogorov complexity has been applied extensively to solve classic open problems of sometimes two decades standing [15], [11], [8], [9]. For more examples, see the textbook [12].

The secret of Kolmogorov complexity's success in dynamic, computational lower bound proofs rests on a simple fact: the overwhelming majority of strings has hardly any computable regularities. We call such a string "Kolmogorov random" or "incompressible." A Kolmogorov random string cannot be (effectively) compressed. Incompressibility is a noneffective property: no individual string, except finitely many, can be proved incompressible.

Recall that a traditional lower bound proof by counting usually involves *all* inputs of certain length. One shows that a certain lower bound has to hold for *some* "*typical*" input. Since an individual typical input is *hard* (sometimes impossible) to find, the proof must involve all the inputs. Now we understand that a typical input of each length can be constructed via

an incompressible string. However, only finitely many individual strings can be effectively proved to be incompressible. No wonder the old counting arguments had to involve all inputs. In a proof using the "incompressibility method," one uses an individual incompressible string that is known to *exist* even though it cannot be constructed. Then one shows that if the assumed lower time bound would not hold, then this string could be compressed, and hence it would not be incompressible.

1.2. Outline of the paper. The incompressibility argument also works for formal languages and automata theory. Assume the basic notions treated in a textbook such as [6].

The first result is a powerful alternative to pumping lemmas for regular languages. It is well known that not all nonregular languages can be shown to be nonregular by the usual uvw-pumping lemma. There is a plethora of pumping lemmas to show nonregularity, like the "marked pumping lemma," and so on. In fact, it seems that many example nonregular languages require their own special purpose pumping lemmas. Recently, [7], [21], [3], exhaustive pumping lemmas that characterize the regular languages have been obtained.

These pumping lemmas are complicated and complicated to use. The last reference uses Ramsey theory. In contrast, by using Kolmogorov complexity we give a new characterization of the regular languages that simply makes our intuition of the "finite stateness" of these languages rigorous and easy to apply. Since it is a characterization, it works for all nonregular languages. We give several examples of its application, some of which were quite difficult using pumping lemmas.

To prove that a certain context-free language (cfl) is not deterministic context-free (dcfl) has required laborious ad-hoc proofs [6], or cumbersome and difficult pumping lemmas or iteration theorems [4], [24]. We give necessary (Kolmogorov complexity) conditions for dcfl, that are very easy to apply. We test the new method on several examples in cfl–dcfl, which were hard to handle before. In certain respects the KC-DCFL lemma may be more powerful than the related lemmas and theorems mentioned above. On the high end of the Chomsky hierarchy we present, for completeness, a known characterization of recursive languages, and a necessary condition for recursively enumerable languages.

2. Kolmogorov complexity. From now on, let x denote both the natural number and the xth binary string in the sequence 0, 1, 00, 01, 10, 11, 000, ... That is, the representation "3" corresponds both to the natural number 3 and to the binary string 00. This way we obtain a natural bijection between the nonnegative integers $\mathcal{N}$ and the finite binary strings $\{0, 1\}^*$. Numerically, the binary string $x_{n-1} \ldots x_0$ corresponds to the integer

$$2^n - 1 + \sum_{i=0}^{n-1} x_i 2^i. \tag{1}$$

We use notation $l(x)$ to denote the *length* (number of bits) of a binary string x. If x is not a finite binary string but another finite object like a finite automaton, a recursive function, or a natural number, then we use $l(x)$ to denote the length of its standard binary description. Let $\langle \cdot, \cdot \rangle : \mathcal{N} \times \mathcal{N} \to \mathcal{N}$ be a standard recursive, invertible, one-one encoding of pairs of natural numbers in natural numbers. This idea can be iterated to obtain a pairing from triples of natural numbers with natural numbers $\langle x, y, z \rangle = \langle x, \langle y, z \rangle \rangle$, and so on.

Any of the usual definitions of Kolmogorov complexity in [10], [19], and [12] will do for the sequel. We are interested in the shortest effective description of a finite object x. To fix thoughts, consider the problem of describing a string x over 0's and 1's. Let $T_1, T_2, \ldots$ be the standard enumeration of Turing machines. Since T_i computes a partial recursive function $\phi_i : \mathcal{N} \to \mathcal{N}$, we obtain the standard enumeration $\phi_1, \phi_2, \ldots$ of partial recursive functions.

We denote $\phi(\langle x, y\rangle)$ as $\phi(x, y)$. Any partial recursive function ϕ from strings over 0's and 1's to such strings, together with a string p, the *program* for ϕ to compute x, such that $\phi(p) = x$, is a description of x. It is useful to generalize this idea to the conditional version: $\phi(p, y) = x$ such that p is a program for ϕ to compute x, given a binary string y for free. Then the *descriptional* complexity C_ϕ of x, *relative* to ϕ and y, is defined by

$$C_\phi(x|y) = \min\{l(p) : p \in \{0, 1\}^*, \phi(p, y) = x\},$$

or ∞ if no such p exists.

For a *universal* partial recursive function ϕ_0, computed by the universal Turing machine U, we know that, for each partial recursive function $\phi = Q_i$ there is a constant c_ϕ such that for all strings x, y, we have $\phi_0(i, x, y) = \phi(x, y)$. Hence, $C_{\phi_0}(x|y) \leq C_\phi(x|y) + c_\phi$. We fix a reference universal function ϕ_0 and define the *conditional Kolmogorov complexity* of x given y as $C(x|y) = C_{\phi_0}(x|y)$.[1]

The *unconditional Kolmogorov complexity* of x is $C(x) = C(x|\epsilon)$, where ϵ denotes the empty string ($l(\epsilon) = 0$).

Since there is a Turing machine that just copies its input to its output we have $C(x|y) \leq l(x) + O(1)$, for each x and y. Since there are 2^n binary strings of length n, but only $2^n - 1$ possible shorter descriptions, it follows that $C(x) \geq l(x)$ for some binary string x of each length. We call such strings *incompressible* or *random* [16], [17]. It also follows that for each length n and each binary string y, there is a binary string x of length n such that $C(x|y) \geq l(x)$. Considering C as an integer function, using the obvious one-one correspondence between finite binary words and nonnegative integers, it can be shown that $C(x) \to \infty$ for $x \to \infty$. Finally, $C(x, y)$ denotes $C(\langle x, y\rangle)$.

EXAMPLE 1 (self-delimiting strings). A *prefix code* is a mapping from finite binary code words to source words such that no code word is a proper prefix of any other code word. We define a particular prefix code.

For each binary source word $x = x_1 \ldots x_n$, define the code word $\bar{x}$ by

$$\bar{x} = 1^{l(x)}0x.$$

Define

$$x' = \overline{l(x)}x.$$

The string x' is called the *self-delimiting* code of x.

Set $x = 01011$. Then $l(x) = 5$, which corresponds to binary string "10," and $\overline{l(x)} = 11010$. Therefore, $x' = 1101001011$ is the self-delimiting code of "01011."

The self-delimiting code of a positive integer x requires $l(x) + 2\log l(x) + 1$ bits. It is easy to verify that $l(x) = \lfloor \log(x + 1) \rfloor$. All logarithms are base 2 unless otherwise noted. For convenience, we simply replace the length $l(x)$ of a natural number x by "$\log x$."

EXAMPLE 2 (substrings of incompressible strings). Is a substring of an incompressible string also incompressible? A string $x = uvw$ can be specified by a short description for v of length $C(v)$, a description of $l(u)$, and the literal description of uw. Moreover, we need information to tell these three items apart. Such information can be provided by prefixing each item with a self-delimiting description of its length. Together this takes $C(v) + l(uw) + O(\log l(x))$ bits. Hence,

$$C(x) \leq C(v) + O(\log l(x)) + l(uw).$$

[1] Similarly, we define the complexity of the xth partial recursive function ϕ conditional to the yth partial recursive function ψ by $C(\phi|\psi) = C(x|y)$.

Thus, if we choose x incompressible, $C(x) \geq l(x)$, then we obtain

$$C(v) \geq l(v) - O(\log l(x)).$$

It can be shown that this is optimal—some substring of an incompressible string of length n may be compressible by an $\Omega(\log n)$ additional term. This conforms to a fact we know from probability theory: every random string of length n is expected to contain a run of about $\log n$ consecutive zeros (or ones). Such a substring has complexity $O(\log \log n)$.

3. Regular sets and finite automata.

DEFINITION 3.1. *Let Σ be a finite nonempty alphabet, and let Q be a (possibly infinite) nonempty set of states. A* transition function *is a function $\delta : \Sigma \times Q \to Q$. We extend δ to δ' on Σ^* by $\delta'(\epsilon, q) = q$ and*

$$\delta'(a_1 \ldots a_n, q) = \delta(a_n, \delta'(a_1 \ldots a_{n-1}, q)).$$

Clearly, if δ' is not $1-1$, then the automaton "forgets" because some x and y from Σ^* drive δ' into the same memory state. An automaton *A is a quintuple $(\Sigma, Q, \delta, q_0, q_f)$, where everything is as above and $q_0, q_f \in Q$ are distinguished as* initial state *and* final state, *respectively. We call A a* finite automaton *(fa) if Q is finite.*

We denote "indistinguishability" of a pair of histories $x, y \in \Sigma^*$ by $x \sim y$, defined by $\delta'(x, q_0) = \delta'(y, q_0)$. "Indistinguishability" of strings is reflexive, symmetric, transitive, and right-invariant ($\delta'(xz, q_0) = \delta'(yz, q_0)$ for all z). Thus, "indistinguishability" is a right-invariant equivalence relation on Σ^*. It is a simple matter to ascertain this formally.

DEFINITION 3.2. *The language accepted by automaton A as above is the set $L = \{x : \delta'(x, q_0) = q_f\}$. A* regular language *is a language accepted by a finite automaton.*

It is a straightforward exercise to verify from the definitions the following fact (which will be used later).

THEOREM 3.3 (Myhill and Nerode). *The following statements about $L \subseteq \Sigma^*$ are equivalent.*

(i) *$L \subseteq \Sigma^*$ is accepted by some finite automaton.*

(ii) *L is the union of equivalence classes of a right-invariant equivalence relation of finite index on Σ^*.*

(iii) *For all $x, y \in \Sigma^*$ define right-invariant equivalence $x \sim y$ by the following item: for all $z \in \Sigma^*$ we have $xz \in L$ iff $yz \in L$. Then the number of $\sim$-equivalence classes is finite.*

Subsequently, closure of finite automaton languages under complement, union, and intersection follow by simple construction of the appropriate δ functions from given ones. Details can be found in any textbook on the subject such as [6]. The clumsy pumping lemma approach can now be replaced by the Kolmogorov formulation below.

3.1. Kolmogorov complexity replacement for the pumping lemma. An important part of formal language theory is deriving a hierarchy of language families. The main division is the Chomsky hierarchy, with regular languages, context-free languages, context-sensitive languages and recursively enumerable languages. The common way to prove that certain languages are not regular is by using "pumping" lemmas, for instance, the uvw lemma. However, these lemmas are quite difficult to state and cumbersome to prove or use. In contrast, we show below how to replace such arguments by simple and intuitive, yet rigorous, Kolmogorov complexity arguments.

Regular languages coincide with the languages accepted by finite automata. This invites a straightforward application of Kolmogorov complexity. Let us give an example. We prove that $\{0^k 1^k : k \geq 1\}$ is not regular. If it were, then the state q of a particular accepting fa A after processing 0^k, together with A, is, up to a constant, a description of k. Namely, by running A

initialized in state q on input consisting of only 1's, the first time A enters an accepting state is after precisely k consecutive 1's. The size of the description of A and q is bounded by a constant, say c, which is independent of k. Altogether, it follows that $C(k) \leq c + O(1)$. But choosing k with $C(k) \geq \log k$ we obtain a contradiction for all large enough k. Hence, since A has a fixed finite number of states, there is a fixed finite number that bounds the Kolmogorov complexity of each natural number: contradiction. We generalize this observation as follows.

DEFINITION 3.4. *Let Σ be a finite nonempty alphabet and $\phi : \mathcal{N} \to \Sigma^*$ be a total recursive function. Then ϕ enumerates (possibly a proper subset of) Σ^* in order $\phi(1), \phi(2), \ldots$. We call such an order* effective *and ϕ an* enumerator. *The* lexicographical order *is the effective order such that all words in Σ^* are ordered first according to length, and then lexicographically within the group of each length. Another example is ϕ such that $\phi(i) = p_i$, the standard binary representation of the ith prime, is an effective order in $\{0, 1\}^*$. In this case ϕ does not enumerate all of Σ^*. Let $L \subseteq \Sigma^*$. Define $L_x = \{y : xy \in L\}$.*

LEMMA 3.5 (KC regularity). *Let $L \subseteq \Sigma^*$ be regular and let ϕ be an enumerator in Σ^*. Then there exists a constant c that depends only on L and ϕ such that for each x, if y is the nth string enumerated in (or in the complement of) L_x, then $C(y) \leq C(n) + c$.*

Proof. Let L be a regular language. The nth string y such that $xy \in L$ for some x can be described by

- this discussion and a description of the fa that accepts L,
- a description of ϕ, and
- the state of the fa after processing x, and the number n.

The statement "or in the complement of" follows, since regular languages are closed under complementation. □

As an application of the KC Regularity lemma we prove that $\{1^p : p \text{ is prime}\}$ is not regular. Consider the string $xy = 1^p$ with p the $(k+1)$th prime. Set $x = 1^{p'}$, with p' the kth prime. Then $y = 1^{p-p'}$, and y is the lexicographical first element in L_x. Hence, by Lemma 3.5, $C(p - p') = O(1)$. But the difference between two consecutive primes grows unbounded. Since there are only $O(1)$ descriptions of length $O(1)$, we have a contradiction. We give some more examples from the well-known textbook of Hopcroft and Ullman [6].

EXAMPLE 3 (Exercise 3.1(h)* in [6]). Show that $L = \{xx^R w : x, w \in \{0, 1\}^* - \{\epsilon\}\}$ is not regular. Set $x = (01)^m$, where $C(m) \geq \log m$. Then, the lexicographically first word in L_x is y with $y = (10)^m 0$. But $C(y) = \Omega(\log m)$, which contradicts the KC Regularity lemma.

EXAMPLE 4. Prove that $L = \{0^i 1^j : i \neq j\}$ is not regular. Set $x = 0^m$, where $C(m) \geq \log m$. Then the lexicographically first word *not* in $L_x \bigcap \{1\}^*$ is $y = 1^m$. But $C(y) = \Omega(\log m)$, which contradicts the KC Regularity lemma.

EXAMPLE 5 (Exercise 3.6* in [6]). Prove that $L = \{0^i 1^j : \gcd(i, j) = 1\}$ is not regular. Set $x = 0^{(p-1)!}1$, where $p > 3$ is a prime, $l(p) = n$, and $C(p) \geq n - \log n$. Then the lexicographically first word in L_x is 1^{p-1}, which contradicts the KC Regularity lemma.

EXAMPLE 6 (§2.2, Exercises 11–15 in [4]). Prove that $\{p : p$ is the standard binary representation of a prime $\}$ is not regular. Suppose the contrary, and p_i denotes the ith prime, $i \geq 1$. Consider the least binary $p_m = uv$ $(= u2^{l(v)} + v)$, with $u = \Pi_{i<k} p_i$ and v not in $\{0\}^*\{1\}$. Such a prime p_m exists since each interval $[n, n + n^{11/20}]$ of the natural numbers contains a prime [5].

Consider p_m now as an integer, $p_m = 2^{l(v)}\Pi_{i<k} p_i + v$. Since integer $v > 1$ and v is not divided by any prime less than p_k (because p_m is prime), the binary length $l(v) \geq l(p_k)$. Because p_k goes to infinity with k, the value $C(v) \geq C(l(v))$ also goes to infinity with k. But since v is the lexicographical first suffix, with integer $v > 1$ such that $uv \in L$, we have $C(v) = O(1)$ by the KC Regularity lemma, which is a contradiction.

3.2. Kolmogorov complexity characterization of regular languages. While the pumping lemmas are not precise enough (except for the difficult construction in [3]) to characterize the regular languages, this is easy with Kolmogorov complexity. In fact, the KC Regularity lemma is a direct corollary of the characterization below. The theorem is not only a device to show that some nonregular languages are nonregular, as are the common pumping lemmas, but it is a *characterization* of the regular sets. Consequently, it determines whether or not a given language is regular, just like the Myhill–Nerode theorem. The usual characterizations of regular languages seem to be practically useful only to prove regularity. The need for pumping lemmas stems from the fact that characterizations tend to be very hard to use in showing nonregularity. In contrast, the KC characterization is practicable for both purposes, as shown in the examples.

DEFINITION 3.6. *Let Σ be a nonempty finite alphabet, and let y_i be the ith element of Σ^* in lexicographic order, $i \geq 1$. For $L \subseteq \Sigma^*$ and $x \in \Sigma^*$, let $\chi = \chi_1\chi_2 \ldots$ be the* characteristic sequence *of $L_x = \{y : xy \in L\}$, defined by $\chi_i = 1$ if $xy_i \in L$,* and *$\chi_i = 0$* otherwise. We denote $\chi_1 \ldots \chi_n$ by $\chi_{1:n}$.

THEOREM 3.7 (Regular KC characterization). *Let $L \subseteq \Sigma^*$, and assume the notation above. The following statements are equivalent.*

(i) *L is regular.*

(ii) *There is a constant c_L that depends only on L, such that for all $x \in \Sigma^*$ and for all n, $C(\chi_{1:n}|n) \leq c_L$.*

(iii) *There is a constant c_L that depends only on L, such that for all $x \in \Sigma^*$ and for all n, $C(\chi_{1:n}) \leq C(n) + c_L$.*

(iv) *There is a constant c_L that depends only on L, such that for all $x \in \Sigma^*$ and for all n, $C(\chi_{1:n}) \leq \log n + c_L$.*

Proof. (i) $\rightarrow$ (ii): By similar proof as the KC Regularity lemma.

(ii) $\rightarrow$ (iii): obvious.

(iii) $\rightarrow$ (iv): obvious.

(iv) $\rightarrow$ (i): shown in the following claim.

CLAIM 3.8. For each constant c there are only finitely many one-way infinite binary strings ω such that for all n, $C(\omega_{1:n}) \leq \log n + c$.

Proof. The claim is a weaker version of Theorem 6 in [2]. It turns out that the weaker version admits a simpler proof. To make the treatment self-contained, we present this new proof in the Appendix. □

By (iv) and the claim, there are only finitely many distinct χ's associated with the x's in Σ^*. Define the right-invariant equivalence relation $\sim$ by $x \sim x'$ if $\chi = \chi'$. This relation induces a partition of Σ^* in equivalence classes $[x] = \{y : y \sim x\}$. Since there is a one-one correspondence between the $[x]$'s and the χ's, and there are only finitely many distinct χ's, there are also only finitely many $[x]$'s, which implies that L is regular by the Myhill–Nerode theorem. □

REMARK 1. The KC Regularity lemma may be viewed as a corollary of the theorem. If L is regular, then clearly L_x is regular, and it follows immediately that there are only finitely many associated χ's, and each can be specified in at most c bits, where c is a constant depending only on L (and enumerator ϕ). If y is, say, the nth string in L_x, then we can specify y as the string corresponding to the nth '1' in χ, using only $C(n) + O(1)$ bits to specify y. Hence $C(y) \leq C(n) + O(1)$. Without loss of generality, we need to assume that the nth string enumerated in L_x in the KC-regularity Lemma is the string corresponding to the nth '1' in χ by the enumeration in the Theorem, or that there is a recursive mapping between the two.

REMARK 2. If L is nonregular, then there are infinitely many $x \in \Sigma^*$ with distinct equivalence classes $[x]$, each of which has its own distinct associated characteristic sequence χ. It is easy to see, for each automaton (finite or infinite) and for each χ associated with an equivalence class $[x]$, we have

$$C(\chi_{1:n}|n) \to \inf\{C(y) : y \in [x]\} + O(1),$$

for $n \to \infty$. The difference between finite and infinite automata is precisely expressed in the fact that only in the first case does there exist an a priori constant which bounds the left-hand term for all χ.

We show how to prove positive results with the KC characterization theorem. (Examples of negative results were given in the preceding section.)

EXAMPLE 7. Prove that $L = \Sigma^*$ is regular. There exists a constant c such that for each x the associated characteristic sequence is $\chi = 1, 1, \ldots$, with $C(\chi_{1:n}|n) \leq c$. Therefore, L is regular by the KC characterization theorem.

EXAMPLE 8. Prove that $L = \{x : x$ is accepted by a 2-way dfa$\}$ is regular. There exists a constant c such that for each x we have $C(\chi_{1:n}|n) \leq c$. Therefore, L is regular by the KC Characterization theorem.

4. Deterministic context-free languages. We present a Kolmogorov complexity based criterion to show that certain languages are not dcfl. In particular, it can be used to demonstrate the existence of witness languages in the difference of the family of context-free languages (cfls) and deterministic context-free languages (dcfls). Languages in this difference are the most difficult to identify; other non-dcfl are also non-cfl and in those cases we can often use the pumping lemma for context-free languages. The new method compares favorably with other known related techniques (mentioned in the Introduction) by being simpler, easier to apply, and apparently more powerful (because it works on a superset of examples). Yet our primary goal is to demonstrate the usefulness of Kolmogorov complexity in this matter.

A language is a dcfl iff it is accepted by a deterministic pushdown automaton (dpda).

Intuitively, Lemma 4.2 tries to capture the following. Suppose a dpda accepts $L = \{0^n 1^n 2^n : n \geq 1\}$. Then the dpda needs to first store a representation of the all 0 part, and then retrieve it to check against the all 1 part. But after that check, it seems inevitable that it has discarded the relevant information about n, and cannot use this information again to check against the all 2 part. That is, the complexity of the all 2 part should be $C(n) = O(1)$, which yields a contradiction for large n.

DEFINITION 4.1. *A one-way infinite string $\omega = \omega_1\omega_2 \ldots$ over Σ is* recursive *if there is a total recursive function $f : \mathcal{N} \to \Sigma$ such that $\omega_i = f(i)$ for all $i \geq 1$.*

LEMMA 4.2 (KC-DCFL). *Let $L \subseteq \Sigma^*$ be recognized by a deterministic pushdown machine M and let c be a constant. Let $\omega = \omega_1\omega_2 \ldots$ be a recursive sequence over Σ which can be described in c bits. Let $x, y \in \Sigma^*$ with $C(x, y) < c$ and let $\zeta = \ldots\zeta_2\zeta_1$ be a (reversed) recursive sequence over Σ of the form $\ldots yyx$. Let $n, m \in \mathcal{N}$ and $w \in \Sigma^*$ be such that items* (i)–(iii) *below are satisfied.*

(i) *For each i $(1 \leq i \leq n)$, given M's state and pushdown store contents after processing input $\zeta_m \ldots \zeta_1\omega_1 \ldots \omega_i$, a description of ω, and an additional description of at most c bits, we can reconstruct n by running M and observing only acceptance or rejection.*

(ii) *Given pushdown store contents after processing input $\zeta_m \ldots \zeta_1\omega_1 \ldots \omega_n$ and M's state, we can reconstruct w from an additional description of at most c bits.*

(iii) $C(\omega_1 \ldots \omega_n) \geq 2 \log\log m$.

Then there is a constant c' depending only on L and c such that $C(w) \leq c'$.

Proof. Let L be accepted by M with input head h_r. Assume that m, n, w satisfy the conditions in the statement of the lemma. For convenience we write

$$u = \zeta_m \ldots \zeta_1, \qquad v = \omega_1 \ldots \omega_n.$$

For each input $z \in \Sigma^*$, we denote with $c(z)$ the pushdown store contents at the time h_r has read all of z, and moves to the right adjacent input symbol. Consider the computation of M on input uv from the time when h_r reaches the end of u. There are two cases, which follow.

Case 1. There is a constant c_1 such that for infinitely many pairs m, n that satisfy the statement of the lemma, if h_r continues and reaches the end of v, then all of the original $c(u)$ has been popped except at most the bottom c_1 bits.

That is, machine M decreases its pushdown store from size $l(c(u))$ to size c_1 during the processing of v. The first time this occurs, let v' be the processed initial segment of v, and v'' the unprocessed suffix (so that $v = v'v''$) and let M be in state q. We can describe w by the following items:[2]

- A self-delimiting description of M (including Σ) and this discussion in $O(1)$ bits.
- A self-delimiting description of ω in $(1 + \epsilon)c$ bits.
- A description of $c(uv')$ and q in $c_1 \log |\Sigma| + O(1)$ bits.
- The "additional description" mentioned in item (i) of the statement of the lemma in self-delimiting format, using at most $(1 + \epsilon)c$ bits. Denote it by p.
- The "additional" description mentioned in item (ii) of the statement of the lemma in self-delimiting format, using at most $(1 + \epsilon)c$ bits. Denote it by r.

By item (i) in the statement of the lemma we can reconstruct v'' from M in state q and with pushdown store contents $c(uv')$, and ω, using description p. Subsequently, by starting M in state q with pushdown store contents $c(uv')$, we process v''. At the end of the computation we have obtained M's state and pushdown store contents after processing uv. According to item (ii) in the statement of the lemma, together with description r, we can now reconstruct w. Since $C(w)$ is at most the length of this description,

$$C(w) \leq 4c + c_1 \log |\Sigma| + O(1).$$

Setting $c' := 4c + c_1 \log |\Sigma| + O(1)$ satisfies the lemma.

Case 2. By way of contradiction, assume that Case 1 does not hold. That is, for each constant c_1 all but finitely many pairs m, n that satisfy the conditions in the lemma cause M not to decrease its stack height below c_1 during the processing of the v part of input uv.

Fix some constant c_1. Set m, n so that they satisfy the statement of the lemma, and to be as long as required to validate the argument below. Choose u' as a suffix of $yy \ldots yx$ with $l(u') > 2^m$ and

$$C(l(u')) < \log \log m. \tag{2}$$

That is, $l(u')$ is much larger than $l(u)$ $(= m)$ and much more regular. A moment's reflection learns that we can always choose such a u'.

CLAIM 4.3. For large enough m there exists a u' as above, such that M starts in the same state and accesses the same top $l(c(u)) - c_1$ elements of its stack during the processing of the v parts of both inputs uv and $u'v$.

Proof. By assumption, M does not read below the bottom c_1 symbols of $c(u)$ while processing the v part of input uv.

We argue that one can choose u' such that the top segment of $c(u')$ is precisely the same as the top segment of $c(u)$ above the bottom c_1 symbol for large enough $l(u), l(u')$.

To see this we examine the initial computation of M on u. Since M is deterministic, it must either cycle through a sequence of pushdown store contents, or increase its pushdown store with repetitions on long enough u (and u'). Namely, let a triple (q, i, s) mean that M is in state q, has top pushdown store symbol s, and h_r is at ith bit of some y. Consider only the triples (q, i, s) at the steps where M will never go below the current top pushdown store level

[2]Since we need to glue together different binary items in the encoding, and in a way so that we can effectively separate them again, like $\langle x, y \rangle = x'y$, we count $C(x) + 2 \log C(x) + 1$ bits for a self-delimited encoding $x' = 1^{l(l(x))}0l(x)x$ of x. We only need to give self-delimiting forms for all but one constituent description item.

again while reading u. (That is, s will not be popped before going into v.) There are precisely $l(c(u))$ such triples. Because the input is repetitious and M is deterministic, some triple must start to repeat within a constant number of steps and with a constant interval (in height of M's pushdown store) after M starts reading y's. It is easy to show that within a repeating interval only a constant number of y's are read.

The pushdown store does not cycle through an a priori bounded set of pushdown store contents, since this would mean that there is a constant c_1 such that the processing by M of any suffix of $yy \ldots yx$ does not increase the stack height above c_1. This situation reduces to Case 1 with $v = \epsilon$.

Therefore, the pushdown store contents grow repetitiously and unboundedly. Since the repeating cycle starts in the pushdown store after a constant number of symbols, and its size is constant in number of y's, we can adjust u' so that M starts in the same state and reads the same top segments of $c(u)$ and $c(u')$ in the v parts of its computations on uv and $u'v$. This proves the claim. □

The following items form a description from which we can reconstruct v.

- This discussion and a description of M in $O(1)$ bits.
- A self-delimiting description of the recursive sequence ω of which v is an initial segment in $(1 + \epsilon)c$ bits.
- A self-delimiting description of the pair $\langle x, y \rangle$ in $(1 + \epsilon)c$ bits.
- A self-delimiting description of $l(u')$ in $(1 + \epsilon)C(l(u'))$ bits.
- A program p to reconstruct v given ω and M's state and pushdown store contents after processing u. By item (i) of the statement of the lemma, $l(p) \leq c$. Therefore, a self-delimiting description of p takes at most $(1 + \epsilon)c$ bits.

The following procedure reconstructs v from this information. By using the description of M and u' we construct the state $q_{u'}$ and pushdown store contents $c(u')$ of M after processing u'. By Claim 4.3, the state q_u of M after processing u satisfies $q_u = q_{u'}$ and the top $l(c(u)) - c_1$ elements of $c(u)$ and $c(u')$ are the same. Run M on input ω starting in state $q_{u'}$ and with stack contents $c(u')$. By assumption, no more than $l(c(u)) - c_1$ elements of $c(u')$ get popped before we have processed $\omega_1 \ldots \omega_n$. By just looking at the consecutive states of M in this computation, and using program p, we can find n according to item (i) in the statement of the lemma. To reconstruct v requires by definition at least $C(v)$ bits. Therefore,

$$\begin{aligned} C(v) &\leq (1 + \epsilon)C(l(u')) + 4c + O(1) \\ &\leq (1 + \epsilon) \log \log m + 4c + O(1), \end{aligned}$$

where the last inequality follows by equation (2). But this contradicts item (iii) in the statement of the lemma for large enough m. □

Items (i)–(iii) in the KC-DCFL lemma can be considerably weakened, but the presented version gives the essential idea and power: it suffices for many examples. A more restricted, but easier, version is the following.

COROLLARY 4.4. *Let $L \subseteq \Sigma^*$ be a dcfl and let c be a constant. Let x and y be fixed finite words over Σ and let ω be a recursive sequence over Σ. Let u be a suffix of $yy \ldots yx$, let v be a prefix of ω, and let $w \in \Sigma^*$ such that*

(i) *v can be described in c bits given L_u in lexicographical order;*

(ii) *w can be described in c bits given L_{uv} in lexicographical order; and*

(iii) $C(v) \geq 2 \log \log l(u)$.

Then there is a constant c' depending only on L, c, x, y, ω such that $C(w) \leq c'$.

All the following context-free languages were proved to be not dcfl only with great effort before [6], [4], [24]. Our new proofs are more direct and intuitive. Basically, if v is the first word in L_u, then processing the v part of input uv must have already used up the information

of u. But if there is not much information left on the pushdown store, then the first word w in L_{uv} cannot have high Kolmogorov complexity.

EXAMPLE 9 (Exercise 10.5 (a)** in [6]). Prove $L = \{x : x = x^R, x \in \{0, 1\}^*\}$ is not dcfl. Suppose the contrary. Set $u = 0^n1$ and $v = 0^n$, $C(n) \geq \log n$, which satisfies item (iii) of the lemma. Since v is lexicographically the first word in L_u, item (i) of the lemma is satisfied. The lexicographically first nonempty word in L_{uv} is 10^n, and so we can set $w = 10^n$ which satisfies item (ii) of the lemma. But now we have $C(w) = \Omega(\log n)$, which contradicts the KC-DCFL lemma and its corollary.

Approximately the same proof shows that the context-free language $\{xx^R : x \in \Sigma^*\}$ and the context-sensitive language $\{xx : x \in \Sigma^*\}$ are not deterministic context-free languages.

EXAMPLE 10 (Exercise 10.5 (b)** in [6] and Example 1 in [24]). Prove $\{0^n1^m : m = n, 2n\}$ is not dcfl. Suppose the contrary. Let $u = 0^n$ and $v = 1^n$, where $C(n) \geq \log n$. Then v is the lexicographically first word in L_u. The lexicographically first nonempty word in L_{uv} is 1^n. Set $w = 1^n$, and $C(w) = \Omega(\log n)$, contradicting the KC-DCFL lemma and its corollary.

EXAMPLE 11 (Example 2 in [24]). Prove $L = \{xy : l(x) = l(y), y$ contains a "1," $x, y \in \{0, 1\}^*\}$ is not dcfl. Suppose the contrary. Set $u = 0^n1$ where $l(u)$ is even. Then $v = 0^{n+1}$ is lexicographically the first even length word not in L_u. With $C(n) \geq \log n$, this satisfies items (i) and (iii) of the lemma. Choosing $w = 10^{2n+3}$, the lexicographically first even length word not in L_{uv} starting with a "1", satisfies item (ii). But $C(w) = \Omega(\log n)$, which contradicts the KC-DCFL lemma and its corollary.

EXAMPLE 12. Prove $L = \{0^i1^j2^k : i, j, k \geq 0, i = j$ or $j = k\}$ is not dcfl. Suppose the contrary. Let $u = 0^n$ and $v = 1^n$, where $C(n) \geq \log n$, satisfying item (iii) of the lemma. Then, v is lexicographically the first word in L_u, satisfying item (i). The lexicographic first word in $L_{uv} \cap \{1\}\{2\}^*$ is 12^{n+1}. Therefore, we can set $w = 12^{n+1}$ and satisfy item (ii). Then $C(w) = \Omega(\log n)$, contradicting the KC-DCFL lemma and its corollary.

EXAMPLE 13 (pattern-matching). The KC-DCFL lemma and its corollary can be used in a tricky manner. We prove $\{x\#yx^Rz : x, y, z \in \{0, 1\}^*\}$ is not dcfl. Suppose the contrary. Let $u = 1^n\#$ and $v = 1^{n-1}0$, where $C(n) \geq \log n$, which satisfies item (iii) of the lemma. Since $v' = 1^n$ is the lexicographically first word in L_u, the choice of v satisfies item (i) of the lemma. (We can reconstruct v from v' by flipping the last bit of v' from 1 to 0.) Then $w = 1^n$ is lexicographically the first word in L_{uv}, to satisfy item (ii). Since $C(w) = \Omega(\log n)$, this contradicts the KC-DCFL lemma and its corollary.

5. Recursive, recursively enumerable, and beyond. It is immediately obvious how to characterize recursive languages in terms of Kolmogorov complexity. If $L \subseteq \Sigma^*$, and $\Sigma^* = \{v_1, v_2, \ldots\}$ is effectively ordered, then we define the characteristic sequence $\lambda = \lambda_1, \lambda_2, \ldots$ of L by $\lambda_i = 1$ if $v_i \in L$ and $\lambda_i = 0$ otherwise. In terms of the earlier developed terminology, if A is the automaton accepting L, then λ is the characteristic sequence associated with the equivalence class $[\epsilon]$. Recall Definition 4.1 of a recursive sequence. A set $L \in \Sigma^*$ is recursive iff its characteristic sequence λ is a recursive sequence. The next theorem then follows from the definitions and the first paragraph of the Appendix.

THEOREM 5.1 (recursive KC characterization). *A set $L \in \Sigma^*$ is recursive iff there exists a constant c_L (depending only on L) such that, for all n, $C(\lambda_{1:n}|n) < c_L$.*

L is r.e. (recursively enumerable) if the set $\{n : \lambda_n = 1\}$ is r.e. In terms of Kolmogorov complexity, the following theorem gives not only a qualitative but even a quantitative difference between recursive and r.e. languages. The following theorem is due to Barzdin' [1], [13].

THEOREM 5.2 (KC r.e.). (i) *If L is r.e., then there is a constant c_L (depending only on L), such that for all n, $C(\lambda_{1:n}|n) \leq \log n + c_L$.*

(ii) *There exists an r.e. set L such that $C(\lambda_{1:n}) \geq \log n$, for all n.*

Note that, with L as in item (ii), the set $\Sigma^* - L$ (which is possibly non-r.e.) also satisfies item (i). Therefore, item (i) is not a Kolmogorov complexity characterization of the r.e. sets.

EXAMPLE 14. Consider the standard enumeration of Turing machines. Define $k = k_1 k_2 \ldots$ by $k_i = 1$ if the ith Turing machine started on its ith program halts ($\phi_i(i) < \infty$), and $k_i = 0$ otherwise. Let A be the language such that k is its characteristic sequence. Clearly, A is an r.e. set. In [1] it is shown that $C(k_{1:n}) \geq \log n$ for all n.

EXAMPLE 15. Let k be as in the previous example. Define a one-way infinite binary sequence h by

$$h = k_1 0^2 k_2 0^{2^2} \ldots k_i 0^{2^i} k_{i+1} \ldots .$$

Then, $C(h_{1:n}) = O(C(n)) + \Theta(\log \log n)$. Therefore, if h is the characteristic sequence of a set B, then B is not recursive, but more "sparsely" nonrecursive than A is.

EXAMPLE 16. The probability that the optimal universal Turing machine U halts on self-delimiting binary input p, randomly supplied by tosses of a fair coin, is Ω, $0 < \Omega < 1$. Let the binary representation of Ω be $0.\Omega_1\Omega_2 \ldots$ Let Σ be a finite nonempty alphabet, and $v_1, v_2, \ldots$ an effective enumeration without repetitions of Σ^*. Define $L \subseteq \Sigma^*$ such that $v_i \in L$ iff $\Omega_i = 1$. It can be shown (see, for example, [12]) that the sequence $\Omega_1, \Omega_2, \ldots$ satisfies

$$C(\Omega_{1:n}|n) \geq n - \log n - 2 \log \log n - O(1),$$

for all but finitely many n.

Hence neither L nor $\Sigma^* - L$ is r.e. It is not difficult to see that $L \in \Delta_2 - (\Sigma_1 \cup \Pi_1)$, in the arithmetic hierarchy (that is, L is not recursively enumerable) [22], [23].

6. Questions for future research. (a) It is not difficult to give a direct KC analogue of the $uvwxy$ pumping lemma (as Tao Jiang pointed out to us). Just like the pumping lemma, this will show that $\{a^n b^n c^n : n \geq 1\}$, $\{xx : x \in \Sigma^*\}$, $\{a^p : p \text{ is prime}\}$, and so on, are not cfl. Clearly, this hasn't yet captured the Kolmogorov complexity heart of cfl. In general, can we find a CFL-KC characterization?

(b) What about ambiguous context-free languages?

(c) What about context-sensitive languages and deterministic context-sensitive languages?

Appendix: Proof of Claim 3.8. A *recursive real* is a real number whose binary expansion is recursive in the sense of Definition 4.1. The following result is demonstrated in [14] and attributed to A.R. Meyer. For each constant c there are only finitely many $\omega \in \{0, 1\}^\infty$ with $C(\omega_{1:n}|n) \leq c$ for all n. Moreover, each such ω is a recursive real.

In [2] this is strengthened to a version with $C(\omega_{1:n}) \leq C(n) + c$, and strengthened again to a version with $C(\omega_{1:n}) \leq \log n + c$. Claim 3.8 is weaker than the latter version by not requiring the ω's to be recursive reals. For completeness sake, we present a new direct proof of Claim 3.8 avoiding the notion of recursive reals.

Recall our convention of identifying integer x with the xth binary sequence in lexicographical order of $\{0, 1\}^*$ as in (1).

Proof of Claim 3.8. Let c be a positive constant, and let

$$\begin{aligned} A_n &= \{x \in \{0, 1\}^n : C(x) \leq \log n + c\}, \\ A &= \{\omega \in \{0, 1\}^\infty : \forall_{n \in \mathcal{N}}[C(\omega_{1:n}) \leq \log n + c]\} . \end{aligned} \tag{3}$$

If the cardinality $d(A_n)$ of A_n dips below a fixed constant c', for infinitely many n, then c' is an upper bound on $d(A)$. This is because it is an upper bound on the cardinality of the set of prefixes of length n of the elements in A, for *all* n.

Fix any $l \in \mathcal{N}$. Choose a binary string y of length $2l + c + 1$ that satisfies

$$C(y) \geq 2l + c + 1. \tag{4}$$

Choose i maximum such that for division of y in $y = mn$ with $l(m) = i$ we have

$$m \leq d(A_n). \tag{5}$$

(This holds at least for $i = 0 = m$.) Define similarly a division $y = sr$ with $l(s) = i + 1$. By maximality of i, we have $s > d(A_r)$. From the easily proven $s \leq 2m + 1$, it then follows that

$$d(A_r) \leq 2m. \tag{6}$$

We prove $l(r) \geq l$. Since by (5) and (3) we have

$$m \leq d(A_n) \leq 2^c n,$$

it follows that $l(m) \leq l(n) + c$. Therefore,

$$2l + c + 1 = l(y) = l(n) + l(m) \leq 2l(n) + c,$$

which implies that $l(n) > l$. Consequently, $l(r) = l(n) - 1 \geq l$.

We prove $d(A_r) = O(1)$. By dovetailing the computations of the reference universal Turing machine U for all programs p with $l(p) \leq \log n + c$, we can enumerate all elements of A_n. We can reconstruct y from the mth element, say y_0, of this enumeration. Namely, from y_0 we reconstruct n since $l(y_0) = n$, and we obtain m by enumerating A_n until y_0 is generated. By concatenation we obtain $y = mn$. Therefore,

$$C(y) \leq C(y_0) + O(1) \leq \log n + c + O(1). \tag{7}$$

From (4), we have

$$C(y) \geq \log n + \log m. \tag{8}$$

Combining (7) and (8), it follows that $\log m \leq c + O(1)$. Therefore, by (6),

$$d(A_r) \leq 2^{c+O(1)}.$$

Here, c is a fixed constant independent of n and m. Since $l(r) \geq l$ and we choose l arbitrarily, $d(A_r) \leq c_0$ for a fixed constant c_0 and infinitely many r, which implies $d(A) \leq c_0$, and hence the claim. □

We avoided establishing, as in the cited references, that the elements of A defined in (3) are recursive reals. The resulting proof is simpler, and sufficient for our purpose, since we only need to establish the finiteness of A.

REMARK 3. The difficult part of the Regular KC Characterization theorem above consists in proving that the KC Regularity lemma is exhaustive, i.e., can be used to prove the nonregularity of all nonregular languages. Let us look a little more closely at the set of sequences defined in item (iii) of the KC Characterization theorem. The set of sequences A of (3) is a superset of the set of characteristic sequences associated with L. According to the proof in the cited references, this set A contains finitely many *recursive* sequences (computable by Turing machines). The subset of A consisting of the characteristic sequences associated with L, satisfies much more stringent computational requirements, since it can be computed using only the finite automaton recognizing L. If we replace the plain Kolmogorov complexity in the statement of the theorem by the so-called "prefix complexity" variant K, then the equivalent set of A in (3) is

$$\{\omega \in \{0, 1\}^\infty : \forall_{n \in \mathcal{N}}[K(\omega_{1:n}) \leq K(n) + c]\},$$

which is finite [12, Exercise 3.24] and contains nonrecursive sequences by a result of Solovay [20].

Acknowledgments. We thank Peter van Emde Boas, Theo Jansen, Tao Jiang for reading the manuscript and commenting on it, and the anonymous referees for extensive comments and suggestions for improvements. John Tromp improved the proof of Claim 3.8.

$O(M \cdot N)$ ALGORITHMS FOR THE RECOGNITION AND ISOMORPHISM PROBLEMS ON CIRCULAR-ARC GRAPHS*

WEN-LIAN HSU†

Abstract. Circular-arc graphs have a rich combinatorial structure. The circular endpoint sequence of arcs in a model for a circular-arc graph is usually far from unique. We present a natural restriction on these models to make it meaningful to define the unique representations for circular-arc graphs. We characterize those circular-arc graphs which have unique restricted models and give an $O(m \cdot n)$ algorithm for recognizing circular-arc graphs. We think a more careful implementation could reduce the complexity to $O(n^2)$. Our approach is to reduce the recognition problem of circular-arc graphs to that of circle graphs. This approach has the following advantages: it is conceptually simpler than Tucker's $O(n^3)$ recognition algorithm; it exploits the similarity between circle graphs and circular-arc graphs in a natural fashion; it yields an isomorphism algorithm. A main contribution of this result is an illustration of the transformed decomposition technique. The decomposition tree developed for circular-arc graphs generalizes the concept of the PQ-tree, which is a data structure that keeps track of all possible interval representations of a given interval graph. As a consequence, our approach also yields an $O(m \cdot n)$ isomorphism algorithm for circle graphs.

AMS subject classifications. 68Q25, 68R05, 68R10

1. Introduction.

Intersection graphs have recently received much attention in the study of algorithmic graph theory and their applications (see e.g., [1], [8], [9], [12], [15], [20]). Well-known special classes of intersection graphs include interval graphs, chordal graphs, circular-arc graphs, permutation graphs, circle graphs, and so on. Various optimization problems (e.g., maximum clique, maximum independent set, and minimum coloring problems) on these graphs have also been studied extensively [6], [7], [10], [11], [13], [14], [21]. We shall denote a graph G by a pair (V, E), where V denotes the finite vertex set of G and E denotes a set of edges connecting vertices of G. Let $n = |V|$ and $m = |E|$.

Circular-arc graphs have applications in genetic research [18], traffic control [19], and computer compiler design [21]. Tucker [22] has given an $O(n^3)$ algorithm for recognizing circular-arc graphs. However, the algorithm and its proof are involved. Based on Tucker's algorithm, Wu [23] wrote a dissertation on the isomorphism problem of circular-arc graphs (but it never appeared in journal form). Spinrad [17] simplified Tucker's algorithm for the case that the given graph can be covered by two cliques.

In this paper we present $O(m \cdot n)$ algorithms for both the recognition and isomorphism problems on circular-arc graphs. We think a more careful implementation could reduce the complexity to $O(n^2)$. Our approach is to reduce the circular-arc graph recognition problem to the circle graph recognition problem. We believe this approach has the following advantages: (1) it is conceptually simple, (2) it exploits the similarity between circle graphs and circular-arc graphs in a natural fashion, and (3) it yields an isomorphism algorithm for circular-arc graphs as a by-product.

A main contribution of our result is an illustration of the "transformed decomposition" technique. A common drawback of ordinary decomposition techniques is that they do not seem to yield useful reduction for the specific class of graphs of interest. Our example illustrates how one might be able to modify the given class to another one for which decomposition produces fruitful reduction. In the study of interval graphs (a subclass of circular-arc graphs), a new data structure, PQ-trees [1], was created to keep track of all possible interval representations of a given interval graph. The decomposition tree discovered in this paper generalizes the

concept of PQ-trees and keeps track of all possible representations of a given circular-arc graph. We also give characterizations of the class of uniquely representable interval graphs as well as circular-arc graphs. Finally, for the two widely used techniques, substitution and join decomposition, our result illustrates a case where they can be blended together harmoniously to complement each other.

The difficulty in dealing with circular-arc graphs lies largely in the fact that even a simple circular-arc graph (or interval graph) can have an exponential number of arc representations. We propose a notion of *normalized representations* with the property that the relative endpoint positions of any two arcs in such representations are prescribed by the adjacency relationships of their corresponding vertices in G. By restricting ourselves to these special representations, we can eliminate trivial variations. Through graph decomposition, we provide a characterization of those circular-arc graphs that possess "unique" normalized representations.

We now define some notations used in the paper. Let F be a family of nonempty sets. The *intersection graph* of F is obtained by representing each set in F by a vertex and connecting two vertices by an edge if and only if their corresponding sets have a nonempty intersection. When F is a family of intervals on the real line, the intersection graph is called an *interval graph*. When F is a family of arcs (resp., chords) on a circle, the intersection graph is called a *circular-arc graph* (resp., *circle graph*). A permutation graph is a circle graph in which the circle can be divided into two halves, say part A and part B, and each chord has one end in A and the other end in B. Each of these representations using intervals, arcs, or chords is called a *model* for the corresponding graph.

Let R be an arc model of a circular-arc graph G. Without loss of generality, assume all arc endpoints in R are distinct. Each point on the circle has a coordinate, denoted by p. Let the arcs of F be denoted as $1, 2, \ldots, n$. Since it is the relative positions (not the actual coordinates) of these endpoints that concern us in this paper, we shall label the endpoints as follows. For each arc i, traversing from a point of the circle not in i along the clockwise direction, the first endpoint of i encountered is called the *head* of i (labeled by $h(i)$), and the second endpoint of i encountered is called the *tail* of i (labeled by $t(i)$). Denote arc i by $(h(i), t(i))$. Associate with R a *circular label sequence* obtained from a clockwise traversal (see Fig. 1.1) of the circle starting with any endpoint label. In the special case of an interval graph, we associate with its interval model a *left–right label sequence*. Denote the coordinate of a label m by $p(m)$. For two points c and d on the circle, define *segment* (c, d) to be the part of the circle obtained by traversing from c along the clockwise direction to d. For convenience, an arc $(h(i), t(i))$ is also used to denote the segment $(p(h(i)), p(t(i)))$. From now on, we shall only consider the label of an endpoint rather than its actual coordinate.

Two models for a circular-arc graph (resp., interval) are said to be *equivalent* if a circular (resp., left–right) label sequence of one model can be obtained from that of the other through rotation or reflection (resp., through reflection). A circular-arc (resp., interval) graph G is said to have a *unique* circular-arc (resp., interval) model if all circular-arc (resp., interval) models for G are equivalent. It is easy to see that a given circular-arc graph can have an exponential number of nonequivalent models. For example, by permuting the head labels and the tail labels of n mutually overlapping intervals, one can obtain $(n!)^2/2$ different models. In the next section, we introduce the notion of normalized models that eliminates a large number of trivial model variations. Note that equivalent chord models for a circle graph have been defined analogously in [5].

The main technique used in our recognition algorithm is graph decomposition. This is a useful divide-and-conquer scheme for attacking many optimization and recognition problems. Gabor, Hsu, and Supowit [5] and, independently, Bouchet [2] used the join decomposition to

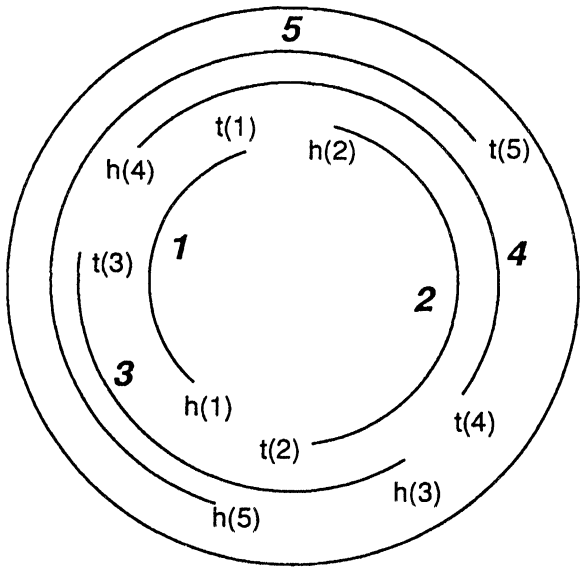

FIG. 1.1. *The circular label sequence of a circular-arc graph.*

efficiently recognize circle graphs. We shall adopt the same decomposition here in recognizing circular-arc graphs.

The idea behind these decompositions is discussed in greater detail in §3. In the next section we introduce the notion of normalized models for a circular-arc graph, which is used throughout the remainder of this paper. Section 4 describes uniquely representable interval graphs. Section 5 is devoted to the transformation of circular-arc graphs to circle graphs. The decomposition of circular-arc graphs is discussed in §§6 and 7. Section 8 discusses the time complexity of our algorithm. Finally, we show that our approach yields an isomorphism algorithm on circular-arc graphs in §9.

2. Normalized models for circular-arc graphs. We are interested in those circular-arc models in which the overlapping relationships (described below) of any two arcs are strictly dictated by their corresponding neighborhood structures in the graph (and therefore remain the same in all these representing models).

DEFINITION. *Given a circular-arc model R, there are four possible overlapping relationships on a pair of arcs* u_2 *and* u_2 *in D defined as follows (an example is shown in Fig.* 2.1):

(1) u_1 *is independent of* u_2 *if they do not overlap.*

(2) u_1 *is contained in (resp., contains)* u_2 *if segment* $(h(u_1), t(u_1))$ *is contained in (resp., contains) segment* $(h(u_2), t(u_2))$.

(3) u_1 *and* u_2 *strictly overlap if their four endpoints appear alternately on the circle.*

(4) u_1 *and* u_2 *cover the circle if the two segments* $(h(u_1), t(u_1))$ *and* $(h(u_2), t(u_2))$ *together cover the whole circle.*

For the special class of interval graphs, only the first three relationships are applicable when considering their interval representations.

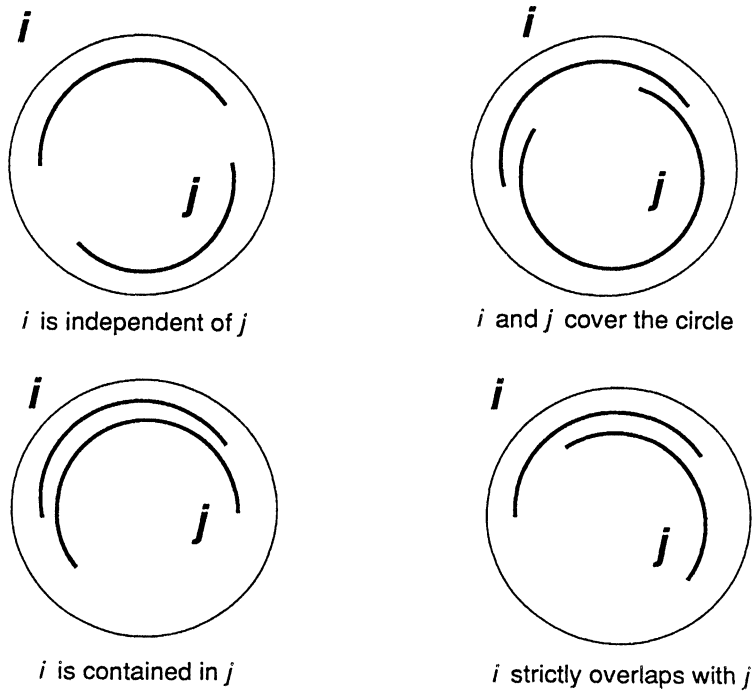

FIG. 2.1. *Four possible overlapping relationships on arcs u_1 and u_2.*

Denote by $N(v)$ (or $N_G(v)$) the set consisting of v and all vertices adjacent to v in G.

DEFINITION. *Two vertices v_1 and v_2 in a graph G are said to be*

(1) *independent if v_1 is not adjacent to v_2.*

(2) *strictly adjacent if v_1 is adjacent to v_2 but neither $N(v_1)$ nor $N(v_2)$ is contained in the other.*

(3) *strongly adjacent if v_1 and v_2 are strictly adjacent but every w in $V(G)\backslash N(v_1)$ satisfies that $N(w) \subsetneq N(v_2)$ and every w' in $V(G)\backslash N(v_2)$ satisfied that $N(w') \subseteq N(v_1)$.*

(4) *similar if $N(v_1)\backslash\{v_1\} = N(v_2)\backslash\{v_2\}$ (v_1, v_2 are said to form a similar pair).*

These relationships can be determined by finding the partial order (based on $\supseteq$) on the containment relationships of the $N(v)$'s for all v (details in §8). A vertex v in G is said to be a *D-vertex* (short for "dominating") if $N(v) = V(G)$. To avoid ambiguity, normalized models are defined only for those circular-arc graphs that contain neither similar pairs nor D-vertices.

DEFINITION. *Let G be a circular-arc graph containing neither similar pairs nor D-vertices. A circular-arc model R for G is said to be a normalized model (N-model) if every pair of arcs u_2 and u_2 in R and their corresponding vertices v_1 and v_2 in G satisfy the following conditions*:

(1) *u_1 is independent of $u_2 \Leftrightarrow v_1$ is not adjacent to v_2.*

(2) *u_1 is contained in $u_2 \Leftrightarrow N(v_1) \subseteq N(v_2)$.*

(3) *u_1 strictly overlaps with $u_2 \Leftrightarrow v_1$ and v_2 are strictly but not strongly adjacent.*

(4) *u_1 and u_2 cover the circle $\Leftrightarrow v_1$ and v_2 are strongly adjacent.*

For interval graphs, an interval N-model is defined with (3) *and* (4) *combined into*

(3′) *u_1 strictly overlaps with $u_2 \Leftrightarrow v_1$ and v_2 are strictly adjacent.*

Since the conditions on the vertex pair are mutually disjoint and collectively exhaustive, the notion "normalized model" is well defined. The overlapping relationships of all pairs of arcs in an N-model are completely determined by their corresponding vertex adjacency relationships.

Next, we describe an algorithm that transforms any circular-arc model of G into an N-model provided there are no similar pairs or D-vertices in G. Let R be a circular-arc model for G. It suffices to find a model R^* in which two arcs cross exactly when their corresponding vertices are strictly but not strongly adjacent, since this condition will force R^* to be an N-model.

DEFINITION. *A pair of arcs u_1 and u_2 are said to form a* "violation" *if they strictly overlap with each other in R but either their corresponding vertices v_1 and v_2 are strongly adjacent* (type I violation) *or they are not strictly adjacent* (type II violation).

We divide our algorithm into two parts. Define a *head* (or *tail*) *block* of a model R to be a set of maximal contiguous subsequence of head (or tail) labels in the circular label sequence of R. The term "block" refers to either a head block or a tail block. Given a block B, $NEXT(B)$ (resp., $PREV(B)$) refers to the neighboring block of B in the clockwise (resp., counterclockwise) direction. By inserting an endpoint into a block B, we mean inserting its label into the subsequence of B in arbitrary order. It is easy to check that, in both algorithms, reordering within a block does not change the arc overlapping relationships.

ALGORITHM I (ELIMINATING TYPE I PAIRS)

1. For each head $h(i)$, let $T(h(i))$ be the first tail block (encountered in a counterclockwise traversal from $h(i)$) that contains the tail of some arc not overlapping with arc i. Partition $T(h(i))$ into two blocks $T_1 = \{t(i_1), \ldots, t(i_r)\}$ and $T_2 = \{t(j_1), \ldots, t(j_s)\}$ where T_1 contains those tails whose corresponding arcs are not overlapping with i and $T_2 = T(h(i))\backslash T_1$. If $T_2 = \emptyset$, then insert $h(i)$ into $NEXT(T(h(i)))$. If $T_2 \neq \emptyset$, then insert a new head block $B' = \{h(i)\}$ in between T_1 and T_2.
2. Repeat the above procedure symmetrically for each tail $t(i)$ in the clockwise direction.

LEMMA 2.1. *Let R_1 be the model obtained at the end of Algorithm* I. *Then, R_1 does not contain any type* I *pair.*

Proof. Suppose otherwise. Let i_1, i_2 be a pair crossing in R_1 with their corresponding vertices v_1 and v_2 strongly adjacent in G. Without loss of generality, assume the circular label sequence for R_1 is $h(i_1)h(i_2)t(i_1)t(i_2)$. Let H_1 be the block containing $h(i_1)$ and T_2 the block containing $t(i_2)$.

By Algorithm I, there exists an arc j not overlapping with i_1 such that $t(j)$ is in $PREV(H_1)$ and another arc j' not overlapping with i_2 such that $h(j')$ is in $NEXT(T_2)$. Let the corresponding vertices of j and j' be w and w', respectively. Then, $w \notin N(v_1)$ and $w' \notin N(v_2)$. Since v_1 is strongly adjacent to v_2, we must have that $w \in N(v_2)$, $w' \in N(v_1)$. Then, $t(j)$ must be in arc j' and w is adjacent to w'. But then, we have $N(w) \not\subseteq N(v_2)$, contradictory to the strong adjacency of v_1 and v_2. □

ALGORITHM II (ELIMINATING TYPE II PAIRS)

1. For each head block $H = \{h(i_1), \ldots, h(i_r)\}$ in R_1, let the clockwise tail order of arcs $i_1, \ldots, i_r$ in R_1 be $i'_1, \ldots, i'_r$ (transversing from $h(i_r)$). Then order the head labels in H in the reverse order as $h(i'_r), \ldots, h(i'_1)$.
2. Reorder the tails in each tail block in reverse to the clockwise order of their heads.

Note that all arcs with their heads in the same block must have their corresponding tail labels in distinct tail blocks; otherwise, we would have similar pairs. Hence, the relative order of their tails remains the same throughout the algorithm and there is no need to reorder the same head block. The same holds for the tail blocks.

LEMMA 2.2. *Let R be the arc model obtained from R_1 at the end of Algorithm* II. *Then R is an N-model.*

Proof. Since we do not move any arc label out of its current block and R_1 does not contain any type I pair, R cannot contain any type I pair. Next, we show that R does not contain any

type II pair. Suppose otherwise. Let i_1, i_2 be a pair crossing in R_1 such that their corresponding vertices v_1 and v_2 satisfy $N(v_1) \subseteq N(v_2)$.

Without loss of generality, assume the circular label sequence for R is $h(i_1)h(i_2)t(i_1)t(i_2)$. $h(i_1)$ and $h(i_2)$ cannot belong to the same head block, otherwise their relative order would be $h(i_2)h(i_1)t(i_1)t(i_2)$ by Algorithm II. Hence, there must exist a tail $t(j)$ in segment $(h(i_1), h(i_2))$ such that arc j does not overlap with arc i_2, contradictory to the fact that $N(v_1) \subseteq N(v_2)$. □

COROLLARY 2.3. *Let G be a circular-arc graph containing neither similar pairs nor D-vertices. Then there exists an N-model for G. If, in particular, G is an interval graph, then there also exists an interval N-model for G.*

From here on, we assume the given graph does not contain similar pairs or D-vertices and consider only normalized models. To characterize graphs having unique N-models, we need to apply certain graph decompositions, which are discussed in the next section.

3. The substitution decomposition and the join decomposition. We shall consider two important graph decompositions in this section. The first such operation is substitution decomposition, also known as *modular decomposition.* We shall follow closely the notations of Spinrad [16], in which an $O(n^2)$ decomposition algorithm is given. Let V' be a subset of V. Denote by $G[V']$ the subgraph of G induced on V'.

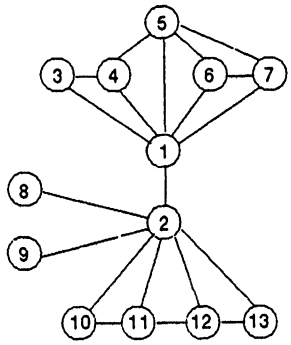
DEFINITION. *A graph G* contains a substitution *if there exists a partition of $V(G)$ into V_0, V_1, and V_2 with $|V_0| \geq 2$ and $|V_1 \cup V_2| \geq 1$ such that every vertex in V_0 is adjacent to every one in V_1 and no vertex in V_0 is adjacent to any one in V_2. Then, G is decomposable into $G[V_0]$ and the graph $G[V_1 \cup V_2]$ with an additional vertex v_0 connected to every vertex in V_1. Such a decomposition is called the* substitution decomposition *or* modular decomposition.

DEFINITION. *A* module *M is a subset of $V(G)$ such that between M and each vertex v in $V \setminus M$ there are either no edges or all possible edges. M is a* connected *module iff $G[M]$ is connected. M is* complement connected *iff the complement of $G[M]$ is connected. An unconnected module is called a* parallel *module. A connected module whose complement is unconnected is called a* series *module. A module that is both connected and complement connected is called a* neighborhood *module. A module M of size greater than 1 is nontrivial if $M \neq V(G)$. A graph G is s-inseparable if it does not contain any nontrivial module.*

By definition, every module is exactly one of these three types. A series or parallel module M can be decomposed into the connected components of $G[M]$ or $\overline{G}[M]$. A module M ($\neq N$) is a *maximal submodule* of a neighborhood module N if no other proper submodule of N contains M. A neighborhood module can be uniquely decomposed into its maximal submodules as its components. The modular decomposition starts with the module $V(G)$ and creates a corresponding root node in the decomposition tree labeled with S, P, or N, depending on the type of the module. Then it decomposes this module into components M_1, $M_2, \ldots, M_k$ using one of the above three rules. For each M_i, find its modular decomposition tree and make its root node a son of the root node representing $V(G)$. The resulting tree is called a *modular decomposition tree* of G. In [15], it was shown that there exists a unique modular decomposition tree for a graph G, namely, all modular decomposition trees for G are isomorphic. Fig. 3.1 gives a sample graph with its modular decomposition tree.

The *representative graph* of a module M in the decomposition tree is a graph induced by a subset consisting of a single vertex from each component submodule of M. We denote the representative graph of each module by G_i and attach it to the root of this module. The representative graph of a series module is a clique. The representative graph of a parallel module is an independent set. The representative graph of a neighborhood module is s-inseparable by our definition.

SUBSTITUTION DECOMPOSITION



The graph G

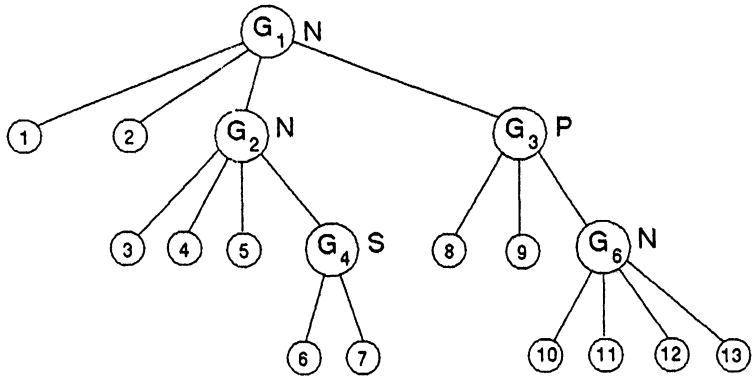


FIG. 3.1. *The substitution decomposition tree of a graph.*

DEFINITION. *The* s-inseparable components *of a graph G are defined to be either*

(1) *a single vertex if there is no neighborhood module in T, or*

(2) *the representative graphs of neighborhood modules in the decomposition tree T of G.*

The example in Fig. 3.1 has three neighborhood modules and each of their representative graphs is an induced path with four vertices.

Another decomposition is the *join decomposition* of Cunningham [3].

DEFINITION. *A graph G is said to have a* join *if* $V(G)$ *can be partitioned into* V_0, V_1, V_2, *and* V_3 *with* $|V_0 \cup V_1| \geq 2$ *and* $|V_2 \cup V_3| \geq 2$ *such that every possible edge exists between* V_1, V_2 *and no edge exists between* V_0, $V_2 \cup V_3$, *or between* $V_0 \cup V_1$, V_3. *In this case, we say G is decomposable into* H_1 *and* H_2 *where* H_1 *is the induced subgraph of* $G[V_0 \cup V_1]$ *with an extra vertex* v_1 *adjacent to every vertex in* V_1 *and* H_2 *is the induced subgraph* $G[V_2 \cup V_3]$ *with an extra vertex* v_2 *adjacent to every vertex in* V_2. *A graph G is said to be* j-inseparable *if it does not contain any join.*

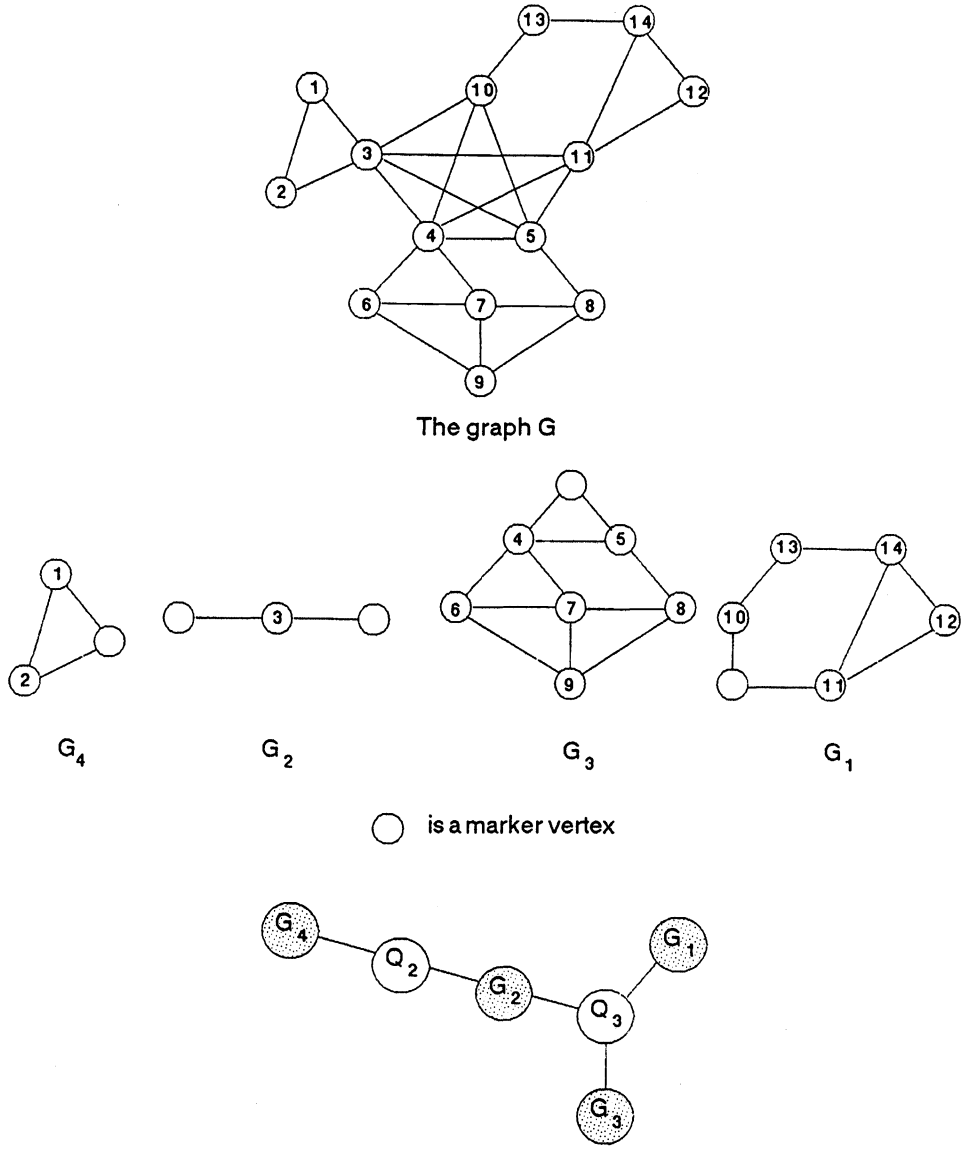

FIG. 3.2. *The join decomposition tree of a graph G.*

A j-inseparable graph with at least four vertices must be connected. Cunningham [3] gave an $O(n^3)$ algorithm to decompose a graph completely into j-inseparable components and showed that there is a unique join decomposition tree. (There is no complete description on how such a tree is formed; however, the reader familiar with the decomposition of a graph into 3-connected components should be able to figure out the construction.) Gabor, Hsu, and Supowit [5] later improved it to $O(m \cdot n)$ time (faster than [3] on sparse graphs). An example is shown in Fig. 3.2.

Our decomposition scheme on circular-arc graphs can be briefly described as follows. For the special class of interval graphs, we show that their s-inseparable components have

unique interval N-models in §4. We transform a general circular-arc graph G into a circle graph G_c and separate this circle graph into s-inseparable components. We then show that the corresponding induced subgraphs in G of these components in G_c have unique N-models. These N-models can be used to compose an N-model for the original circular-arc graph G.

4. A characterization of uniquely representable interval graphs. In this section, we present a proof that s-inseparable interval graphs have unique interval N-models. This analysis is of interest in its own right since it does not involve those powerful arguments borrowed from circle graphs [5]. The characterization of circular-arc graphs that have unique circular-arc N-models is given in §6.

Given an interval N-model R of an interval graph, the head of an interval is its left endpoint and the tail is its right endpoint. We shall not be concerned about the notion of "strongly adjacent" vertices for interval graphs since there is no corresponding geometric meaning on intervals.

THEOREM 4.1. *If an interval graph G does not contain any substitution, then it has a unique interval N-model.*

Proof. Associate with G the following graph G_c, whose vertex set is $V(G)$ and whose edge set consists of those strictly adjacent pairs of vertices in G. Since G does not contain any substitution, G must be connected. An interval is said to be *minimal* in G if it does not contain any other interval in G. An interval is said to be *simplicial* if it is minimal and is contained in all intervals that overlap with it. Let V_1 be the set of all simplicial intervals in G. Note that intervals in V_1 must be independent.

We first show that $G_c\backslash V_1$ is connected. Suppose otherwise. Let i be a minimal arc in $G\backslash V_1$. Let C_1 be a connected component in $G_c\backslash V_1$ containing i. Let j be any interval in $G\backslash(V_1 \cup C_1)$ that overlaps with some interval, say w, in C_1 (such a j must exist; otherwise, G is disconnected). Since j does not strictly overlap with w, we must have j contains w. Then all vertices of C_1 that overlap with w must also overlap with j and, hence, are contained in j. Through breadth-first search, we can argue that all vertices in C_1 must be contained in j. Let V_1' be the subset of simplicial intervals in V_1 that overlap with some vertices in C_1. Then, all intervals in V_1' are also contained in j. Now, if $|C_1| = |\{i\}| = 1$, then since i is not simplicial in G, there must exist an interval i' in V_1' contained in i. Therefore, $|C_1 \cup V_1'| \geq 2$ and $C_1 \cup V_1'$ is a nontrivial module in G, a contradiction.

We now show that there is a unique endpoint ordering for intervals in $G\backslash V_1$ in any N-model for G. This would imply that there is a unique N-model for G, since there is a unique way to insert intervals of V_1 once a model for $G\backslash V_1$ is formed. Let T be a spanning tree for the graph $G_c\backslash V_1$. Pick an arbitrary node of T as the root and perform a breadth-first search on T. Let $\pi = i_1, \ldots, i_k$ be the resulting vertex ordering of $G_c\backslash V_1$. Then π satisfies that each i_s strictly overlaps with some interval in $\{i_1, \ldots, i_{s-1}\}$. Since i_2 strictly overlaps with i_1, one may assume the endpoint order of i_1, i_2 is $h(i_2)h(i_1)t(i_2)t(i_1)$.

We now prove inductively that for each i_s, $s = 3, \ldots, k$, there is a unique way to insert the endpoints of i_s into the unique label sequence for $H_{s-1} = \{i_1, \ldots, i_{s-1}\}$. It suffices to show that, for any interval j in H_{s-1}, there is a unique left–right order between $\{h(i_s), t(i_s)\}$ and $\{h(j), t(j)\}$. If j contains i_s, then the order for i_s and j is $h(j)h(i_s)t(i_s)t(j)$; if j is contained in i_s, then the order is $h(i_s)h(j)t(j)t(i_s)$. Hence, consider the case that j strictly overlaps with i_s. Let j' be another interval of H_s that strictly overlaps with j. Without loss of generality, assume the endpoint order of j, j' is $h(j')h(j)t(j')t(j)$. If i_s does not overlap with j', then the order is $h(j)h(i_s)t(j)t(i_s)$. If i_s contains j' or is contained in j', the order is $h(i_s)h(j)t(i_s)t(j)$. Hence, assume i_s strictly overlaps with j'. If $N(i_s)\backslash[N(j) \cup N(j')] \neq \emptyset$, then the order is $h(j)h(i_s)t(j)t(i_s)$; otherwise, we have $N(j)\backslash[N(i_s) \cup N(j')] \neq \emptyset$, and the order is $h(i_s)h(j)t(i_s)t(j)$. □

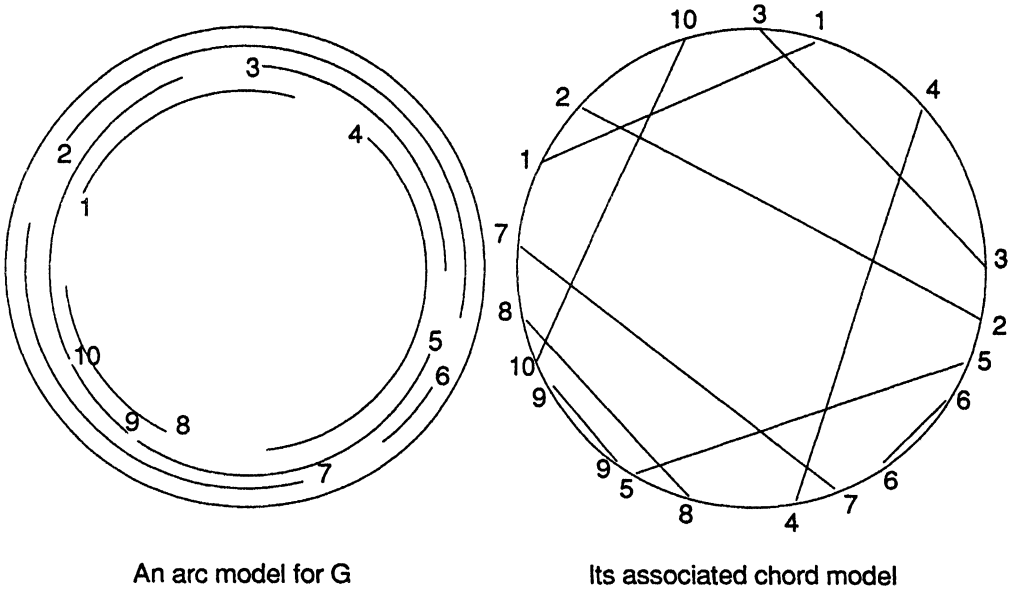

FIG. 5.1. *The chord model associated with a circular-arc model.*

5. The circle graph G_c associated with a circular-arc graph G. Graph decomposition has been successfully adopted to tackle the recognition problems for special classes of intersection graphs (see [7]). Gabor, Hsu, and Supowit [5] recently gave an $O(m \cdot n)$ decomposition algorithm for recognizing circle graphs. They made use of the following properties.

THEOREM 5.1 [5]. (1) *A graph G is a circle graph iff every j-inseparable component of G is a circle graph.*

(2) *Each j-inseparable circle graph has a unique chord model.*

We shall apply similar decomposition approaches to circular-arc graphs to obtain components that have unique N-models. In our approach, we first transform the proposed circular-arc graph to a circle graph and then make use of Theorem 5.1.

DEFINITION. *Associate with each graph G the graph G_c that has the same vertex set as G such that two vertices in G_c are adjacent iff they are strictly but not strongly adjacent in G.*

Consider a circular-arc graph G with an N-model R. Associate with each arc in R a chord that connects its two endpoints The resulting chord model D is called an *associated chord model* for G. Since two arcs cross in R exactly when their corresponding chords in D cross, this chord model gives rise to the circle graph G_c. An example is shown in Fig. 5.1. Although there can be many associated chord models for G, they all give rise to the unique circle graph G_c defined above.

Our decomposition approach is motivated by the analysis below. Given a circular-arc graph G and an N-model R for G, the following two types of structures in R can create multiple chord models by reversing the order of arc endpoints in a subset of $V(G)$. Let A be a subset of vertices in G. For convenience, we shall refer to "an arc in A" instead of "an arc in R corresponding to a vertex in A." (The notions "vertex," "arc," and "chord" will be used interchangeably whenever no confusion arises.)

Type I. There exist a segment (a, b) and a partition of $V(G)$ into two sets A and B such that all endpoints of arcs in A are contained in (a, b) and all endpoints of arcs in B are contained in (b, a) and $|A| \geq 2$, $|B| \geq 2$ (see Fig. 5.2).

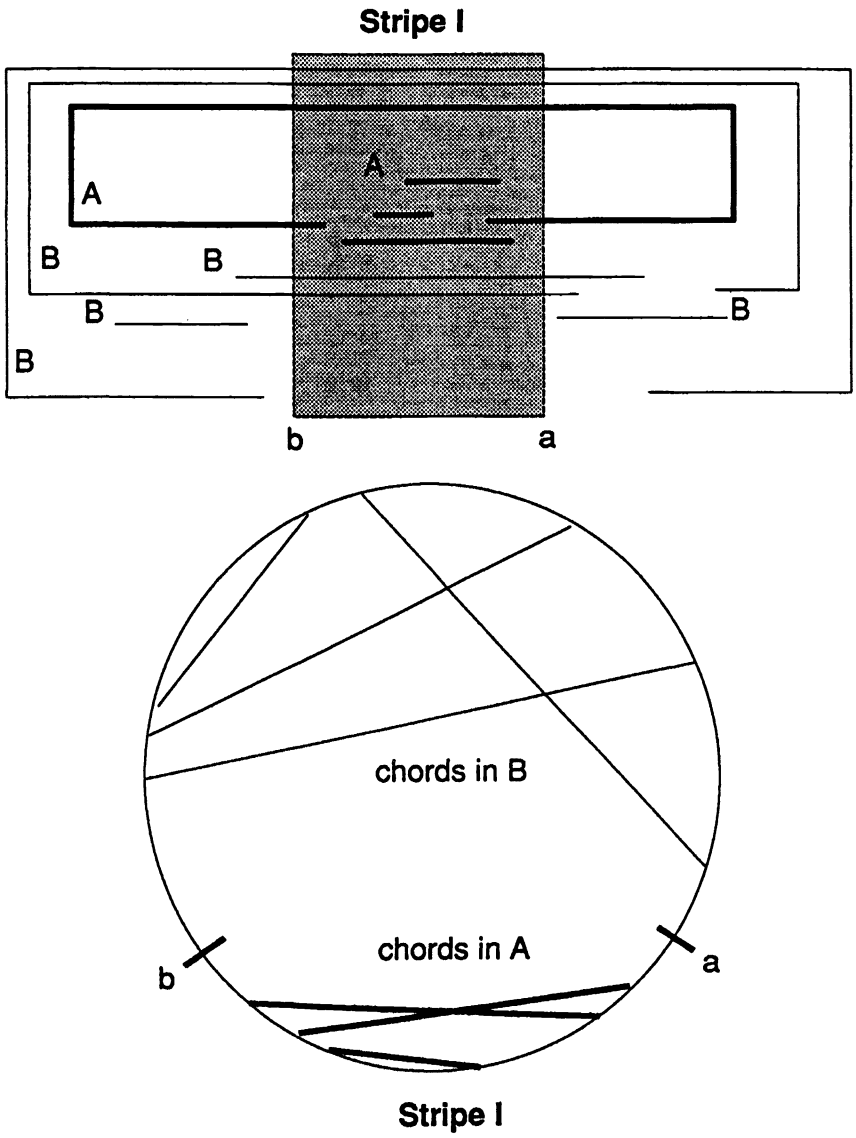

FIG. 5.2. *A circular-arc graph containing a type* I *structure.*

Type II. There exist two disjoint segments (a_1, b_1), (a_2, b_2) and a partition of $V(G)$ into A and B such that each arc in A has one endpoint in (a_1, b_1) and the other endpoint in (a_2, b_2) but none of the endpoints of arcs in B are in $(a_1, b_1) \cup (a_2, b_2)$ and $|A| \geq 2$, $|B| \geq 1$ (see Fig. 5.3).

Note that, in both cases, if G is an interval graph, then it must contain a substitution.

As one can see in Figs. 5.3 and 5.4, type I structures give rise to disconnected G_c and type II structures give rise to nontrivial modules in G_c. These two types of structures can be eliminated by applying the modular decomposition on the transformed graph G_c. The corresponding induced subgraph in G of the s-inseparable components in G_c can be shown to have unique N-models. The above discussion of type I and type II structures is there to give

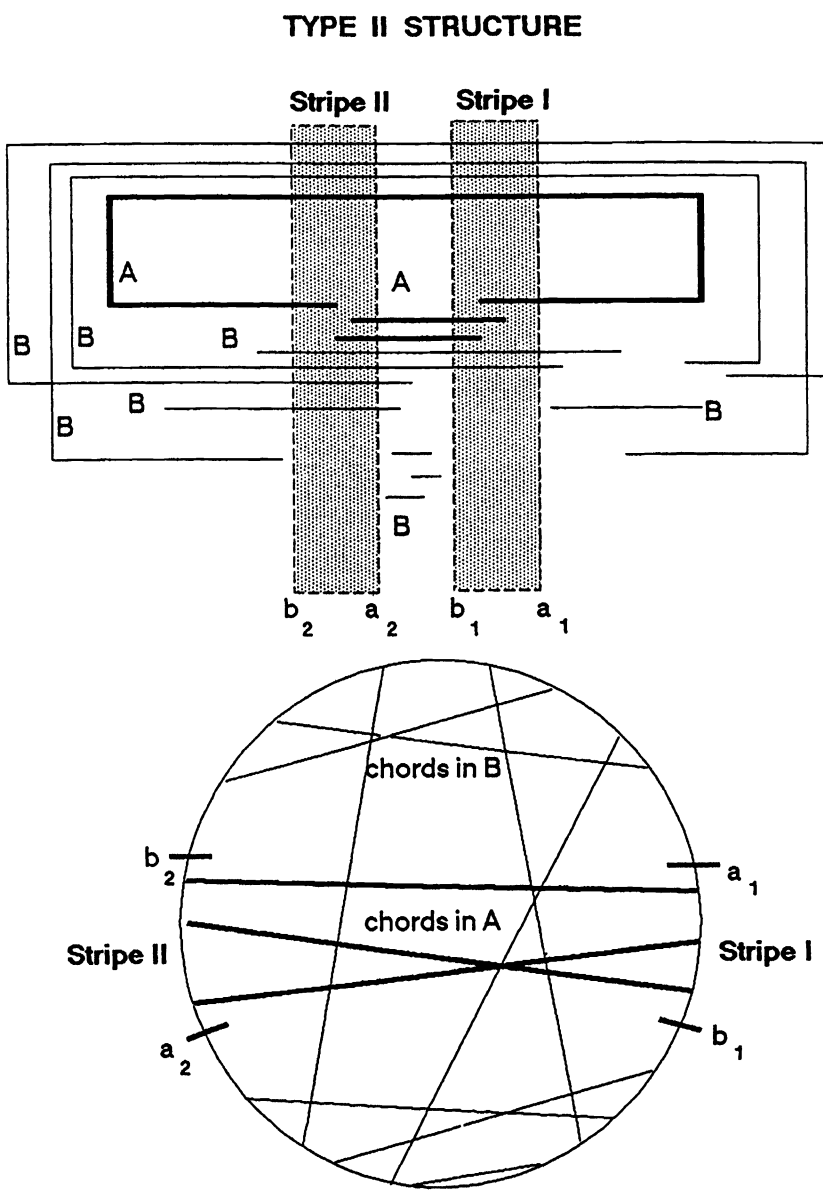

FIG. 5.3. *A circular-arc graph containing a type* II *structure.*

the reader guidance and is not necessary for the remainder of the proof. The following lemma states that, without loss of generality, we can assume the complement of G_c is connected.

LEMMA 5.2. *Let G be a graph with a disconnected $\overline{G}_c$. Let $C_1, C_2, \ldots, C_k$ be the components of $\overline{G}_c$. Let H_c^i and H^i, $i = 1, \ldots, k$, be their corresponding induced subgraphs in G_c and G, respectively. Then G is a circular-arc graph iff each of the H^i, $i = 1, \ldots, k$, is a circular-arc graph.*

Proof. The "only if" part is trivial. Consider the "if" part. Each H_c^i, $i = 1, \ldots, k$, is a permutation graph since there is a chord intersecting all of its chords in any model of G_c. Let the circular endpoint sequence H^i be $S^i(A)S^i(B)$, where every arc has exactly one endpoint

in $S^i(A)$ and the other one in $S^i(B)$. Then $S^1(A)S^2(A), \ldots, S^k(A)S^1(B)S^2(B), \ldots S^k(B)$ is a valid circular label sequence of an arc model for G. □

The transformation from an associated chord model of G_c back to an N-model for G involves the decision as to on which side of the chord the corresponding arc should be placed. This can be uniquely determined as shown in the following lemma.

LEMMA 5.3. *Let G be a circular-arc graph with a connected $\overline{G}_c$. Let D be an associated chord model of G_c. Then D determines a unique N-model R of G.*

Proof. Fix the placement of any arc u in the circle first. Let U_1 be the set of all vertices adjacent to u in $\overline{G}_c$. Then every arc in U_1 can now be placed on the side of their corresponding chord opposite u (if it is independent of u or covers the circle with u) or on the same side as u (if it contains u or is contained in u). Since the complement of G_c is connected, one can argue through a breadth-first search in $\overline{G}_c$ from u that every arc in G can be placed on a unique side of its corresponding chord in D. □

Conversely, however, not every chord model of G_c is an associated chord model for G since the model could violate other adjacency relationships in G that are missing in G_c.

5.1. The series and parallel relationships among nonadjacent vertices in G_c. The missing adjacency relationships in G caused by the transformation can be completely captured by the "series and parallel" relationships in G_c.

DEFINITION. *Three chords $d_1 = (a_1, b_1)$, $d_2 = (a_2, b_2)$, and $d_3 = (a_3, b_3)$ in a circle are said to be* in parallel with d_2 between d_1 and d_3 (*denoted by $d_1|d_2|d_3$) if the clockwise order of their endpoints is $a_1a_2a_3b_3b_2b_1$. They are said to be* in series (*denoted by $d_1 - d_2 - d_3$) if the clockwise order is $a_1b_1a_2b_2a_3b_3$.*

The following lemma is easy to justify.

LEMMA 5.4. *Let D be any chord model associated with an N-model for G. Let v_i, v_j, and v_k be three vertices in G and d_i, d_j, d_k their corresponding chords in D. Then these three chords satisfy $d_i|d_j|d_k$ iff one of the following conditions holds:*

(1) *v_k contains v_j; v_j contains v_i.*
(2) *v_k contains v_j; v_j and v_i cover the circle.*
(3) *v_k is contained in v_j; v_i contains v_j.*
(4) *v_k is contained in v_j; v_i is independent of v_j.*
(5) *v_k is independent of v_j; v_j contains v_i.*
(6) *v_k is independent of v_j; v_j and v_i cover the circle.*
(7) *v_k and v_j cover the circle; v_j is independent of v_i.*
(8) *v_k and v_j cover the circle; v_i contains v_j.*

DEFINITION. *Three pairwise nonadjacent vertices v_i, v_j, and v_k in G_c are said to be* in parallel with v_j between v_i and v_k (*denoted by $v_i|v_j|v_k$) if their relationships in G satisfy one of the eight (mutually exclusive) conditions in Lemma* 5.4. *Three vertices v_i, v_j, and v_k are said to be* in parallel *if they are in parallel with one of them "between" the other two. Three pairwise nonadjacent vertices v_i, v_j, and v_k of G_c that are not in parallel are said to be* in series (*denoted by $v_i - v_j - v_k$). A set of more than three vertices are said to be in parallel (resp., in series) if every three vertices in the set are in parallel (resp., in series).*

Note that when $v_i - v_j - v_k$, there is nothing special about j rather than i or k. Consider any vertex u of G_c. Let I_u be the set of vertices not adjacent to u in G_c. Partition I_u into two subsets L_u and R_u such that L_u consists of all vertices in I_u that are either contained in u or strongly adjacent to u in G and R_u consists of those in I_u that are either not adjacent to u or containing u in G. These two sets L_u and R_u are referred to as the "two sides" of u. Note that when $v_i - v_j - v_k$, then any two of them are on the same side of the third one. It is easy to see that if $v_1 \in L_u$ and $v_2 \in R_u$, then $v_1|u|v_2$. The converse is also true as shown in the following lemma.

LEMMA 5.5. *If $v_i|v_j|v_k$ in G_c then* (i) *v_i and v_k are on different sides of v_j*; (ii) *v_j and v_k are on the same side of v_i. If $v_i - v_j - v_k$, then v_i and v_k are on the same side of v_j.*

Proof. Without loss of generality, assume v_i is in L_{v_j}. Consider their relationships in G.

First, assume $v_i|v_j|v_k$. If v_i is contained in v_j in G, then $v_i|v_j|v_k$ implies that either v_k contains v_j (condition (1) of Lemma 5.4) or v_k is independent of v_j (condition (5) of Lemma 5.4). In either case, v_k must be in R_{v_j} and R_{v_i}. Hence, (i) holds. Since v_i is in R_{v_j}, (ii) also holds. If, on the other hand, v_i is strongly adjacent to v_j, then either v_k contains v_j (condition (2) of Lemma 5.4) or v_k is independent of v_j (condition (6) of Lemma 5.4) and we arrive at the same conclusion.

Now, assume $v_i - v_j - v_k$. This implies that none of the eight conditions in the definition of parallel vertices given in Lemma 5.4 apply to v_i, v_j, and v_k. If v_i is contained in v_j, then because conditions (1) and (5) do not hold, we have that v_k is either contained in v_j or strongly adjacent to v_j. Hence, $v_k \in L_{v_j}$ and v_i, v_k are on the same side of v_j. If v_i is strongly adjacent to v_j, then because conditions (2) and (6) do not hold, we also have that v_k is either contained in v_j or strongly adjacent to v_j and thus, derive the same conclusion. □

5.2. Conformal models. We shall now characterize those models of G_c that can be transformed into N-models for G.

DEFINITION. *A model D of G_c is said to be* conformal to G (*in short*, conformal), *if for every vertex u of G the chords associated with vertices in L_u are on one side of d_u (the chord for u) and those in R_u are on the other side of d_u.*

Equivalently, by Lemma 5.5, a model D is conformal if it satisfies (5.1) in G_c,

(5.1) for any three pairwise nonadjacent vertices v_i, v_j, and v_k,
$v_i|v_j|v_k$ iff their corresponding chords in D satisfy $D_i|d_j|d_k$.

DEFINITION. *An arc model $R(H)$ for an induced subgraph H of G is an* induced N-model *for H if the arc overlapping relationships in $R(H)$ conform to the vertex adjacency relationships in G (rather than those in H). A chord model $D(H_c)$ for an induced subgraph H_c of G_c is* conformal *if it satisfies* (5.1) *in G_c. $D(H_c)$ is said to be* conformal to a vertex *u not in H_c if there exists a placement for the chord of u into $D(H_c)$ such that the resulting chord model satisfies* (5.1).

THEOREM 5.6. *Let G be a circular-arc graph with a connected $\overline{G}_c$. Then a model for G_c is conformal iff it is a chord model associated with an N-model for G.*

Proof. The "if" part is trivial by the definition of parallel vertices. Hence, consider the "only if" part. Let D be a conformal chord model for G_c. Let u be any vertex of G_c. Fix the arc placement of u in the circle first. Then start placing the remaining arcs one by one according to the breadth-first search procedure described in the proof of Lemma 5.3. Similar to Lemma 5.3, the arc placement is uniquely determined.

We show that the resulting model R is an arc model for G (such an arc model is necessarily an N-model for G). If every new arc placed satisfies its adjacency relationships with all arcs previously placed, then we are done. Hence, assume there are violations of the adjacency relationships. Since two adjacent vertices of G_c must have their chords cross in model D, they cannot create any violation. Therefore, assume the first violation is found between two nonadjacent vertices v_i and v_j of G_c when we try to place v_j (whereas the arc for v_i has already been placed). We shall derive a contradiction. Let S be the set of arcs successfully placed so far (immediately before v_j). Let $v_i P v_j$ be a shortest path in $\overline{G}_c$ connecting v_i and v_j through vertices in S. The path $v_i P v_j$ can be viewed as a series of "forced" placements starting with some vertex (the one first encountered in a breadth-first search from u) in P and ending with v_i, v_j.

If $|P| \geq 2$, then the subgraph H_c of G_c is induced on vertices of the path is j-inseparable. By Theorem 5.1, there is a unique chord model for H_c. By Lemma 5.3, this results in a unique arc model for H_c, which must be the same as the one induced by D. But the violation on v_i and v_j implies that such a placement produces a violation. Hence, G is not a circular-arc graph.

If $P = \{v_k\}$, then v_i, v_j, and v_k are pairwise nonadjacent in G_c. Hence, either (i) v_i, v_j, and v_k are in parallel or (ii) they are in series. In either case, it is easy to verify that once the two pairs of arcs $\{v_i, v_k\}$ and $\{v_j, v_k\}$ are correctly placed, it forces the placement of $\{v_i, v_j\}$ to be correct. A similar argument can be used for case (ii).

Hence, such a violation does not exist and our placement strategy successfully produces an N-model for G. □

By Theorem 5.7, the problem of testing whether G is a circular-arc graph is equivalent to that of checking if G_c has a conformal model. In the next section, we first consider the special case that G_c is s-inseparable. The general case is discussed in §§6 and 7.

5.3. S-inseparable components of G_c.

THEOREM 5.7. *Let G be a circular-arc graph. If G_c is s-inseparable, then G has a unique N-model.*

Proof. We show that G_c has a unique conformal model. First, decompose G_c into j-inseparable component graphs. Each of these components has a unique chord model by Theorem 5.1, which must be conformal (otherwise, G is not a circular-arc graph). Next, we show by induction on $|V(G_c)|$ that there is a unique way to compose a conformal model for G_c from those individual conformal models of the j-inseparable components of G_c. This is trivially true for graphs with no more than four vertices. Suppose this holds for all graphs whose cardinality is less than $|V(G_c)|(\geq 5)$. If G_c is j-inseparable, we are done. Otherwise, there exists a partition of $V(G_c)$ into V_0, V_1, V_2, and V_3 with $|V_0 \cup V_1| \geq 2$ and $|V_2 \cup V_3| \geq 2$ such that every possible edge exists between V_1, V_2 and no edge exists between V_0, $V_2 \cup V_3$, or between $V_0 \cup V_1$, V_3 in G_c. Because G_c is s-inseparable, none of these four sets can be empty. If $|V_1| > 1$ and there exists a vertex s in V_1 that is adjacent to all other vertices in $V_1 \cup V_2$, then it is easy to verify that $G_c \backslash \{s\}$ is s-inseparable. We can proceed with the construction below to show that $G_c \backslash \{s\}$ has a unique conformal model, and, furthermore, there is a unique way to insert the chord of s into this model. The argument is symmetric if such a vertex s belongs to V_2. Therefore, assume no such vertex s exists. Then it is easy to verify that the corresponding two component graphs, H_1 and H_2 of G_c (the existence of a substitution in either H_1 or H_2 would imply the existence of one in G_c), are s-inseparable.

By induction, both H_1 and H_2 have unique conformal chord models D_1 and D_2, respectively. First, assume $|V_0 \cup V_1| \geq 3$ and $|V_2 \cup V_3| \geq 3$. Now, there must exist a chord d_0 from V_0 and a chord d_1 from V_1 that do not intersect each other (otherwise, either V_0 or V_1 has size ≥ 2 and creates a substitution). Similarly, there exist a chord d_2 from V_2 and a chord d_3 from V_3 that do not intersect each other. There are four possible placements in composing chords in D_1 and D_2 to form a model for G_c. Each of these placements creates different series or parallel relationships among $\{d_0, d_1, d_3\}$ and $\{d_0, d_2, d_3\}$. Hence, the vertex adjacency relationships of G dictates that there is a unique way to compose D_1 and D_2 (the fact that G is a circular-arc graph guarantees that there is at least one feasible placement from these two models).

Now consider the degenerate case where either $|V_0| = |V_1| = 1$ or $|V_2| = |V_3| = 1$. Suppose there are two noncrossing chords d_2 and d_3 in D_2. The two placements of d_0 create different $\{d_0, d_2, d_3\}$ relations, so they cannot both be N-models. If no such noncrossing pair exists, then either V_2 or V_3 is a module or (if both have just one vertex) G is a P_4. □

COROLLARY 5.8. *Let G be a circular-arc graph with a connected G_c. Then each induced subgraph H of G corresponding to the representative graph H_c of a parallel or neighborhood module M in G_c has a unique induced N-model.*

Proof. Note that since G_c is connected, each proper submodule of G_c must correspond to a permutation graph. If M is a neighborhood module, then H_c is s-inseparable. Hence, the corollary is true by Theorem 5.8. If M is a parallel module (M cannot be $V(G_c)$), then H_c consists of a set of parallel vertices. Since the chords in any conformal model for H_c must follow the unique linear order dictated by the parallel relationships of vertices in H, there is a unique conformal model $D(H)$ for H_c. Since the complement of H_c is connected, $D(H)$ gives rise to a unique N-model for H by Lemma 5.3. □

This corollary will be used at the end of §6 to compose a conformal model for G_c. The general scheme of our transformed decomposition can be summarized as follows. Take a proposed circular-arc graph G, transform it into the graph G_c, and perform a decomposition on G_c to obtain components that correspond to uniquely representable induced subgraphs for G. If G is indeed a circular-arc graph, then we find a conformal model of G_c and transform it back to an arc model for G. Otherwise we could either detect a contradiction at an intermediate step or, at the end, construct an arc model for G that violates its vertex adjacency relationships. The transformation enables us to use well-known techniques for decomposing circle graphs.

We shall first illustrate our decomposition approach in §6 on those circular-arc graphs whose associated circle graphs are connected and then describe the reduction from general circular-arc graphs to the above subclass in §7.

6. Consistent decomposition of a connected G_c. Throughout this section we assume the graph G satisfies the following:

(6.1) Both $\overline{G}_c$ and G_c are connected.

The general case is discussed in §7. We shall describe a decomposition scheme on G_c that serves the following purposes: (a) yields components that are s-inseparable, (b) provides enough information on constructing a conformal model for G_c when G is a circular-arc graph, and (c) gives rise to a unique decomposition tree.

The example in Fig. 6.1 points out a major drawback of the ordinary modular decomposition when applied to G_c. Although the set $\{1, 2, 3\}$ is a maximal submodule in the neighborhood module $V(G_c)$, their placements are quite different due to the additional "conformity" constraint. A closer look at the type II structures reveals that they give rise to modules of a very special kind—those modules whose endpoint labels consists of two consecutive subsequences in any N-model (such modules will be called consistent modules in the next section). Therefore, we need to devise a decomposition scheme that accommodates this requirement.

6.1. Consistent modules of G_c. Let M be any subset of $V(G_c)$. Let $I(M)$ denote the set of vertices in $V(G_c)\backslash M$ that are not adjacent to all vertices of M in G_c. Note that M is a module iff no vertex in $I(M)$ is adjacent to any vertex of M.

DEFINITION. *A subset M of $V(G_c)$ is* consistent with *a subset $M' \subseteq I(M)$ if the following three conditions hold*:

(6.2) All vertices of M are on the same side of every vertex v in M' (in particular, M is a module).

(6.3) If $v_1 - u - v_2$ (resp., $v_1|u|v_2$ or $u|v_1|v_2$) for some u in M and v_1, v_2 in M', then $v_1 - u_1 - v_2$ (resp., $v_1|u_1|v_2$ or $u_1|v_1|v_2$) for every u_1 in M.

(6.4) There exist no u_1, u_2 in M and v in M' such that $v - u_1 - u_2$.

M is consistent *in G_c if it is consistent with $I(M)$.*

Note that any module (other than the whole graph) in a connected circle graph must be a permutation graph. Since it is possible to draw a chord that crosses all chords in a permutation model, a permutation graph does not contain three vertices in series.

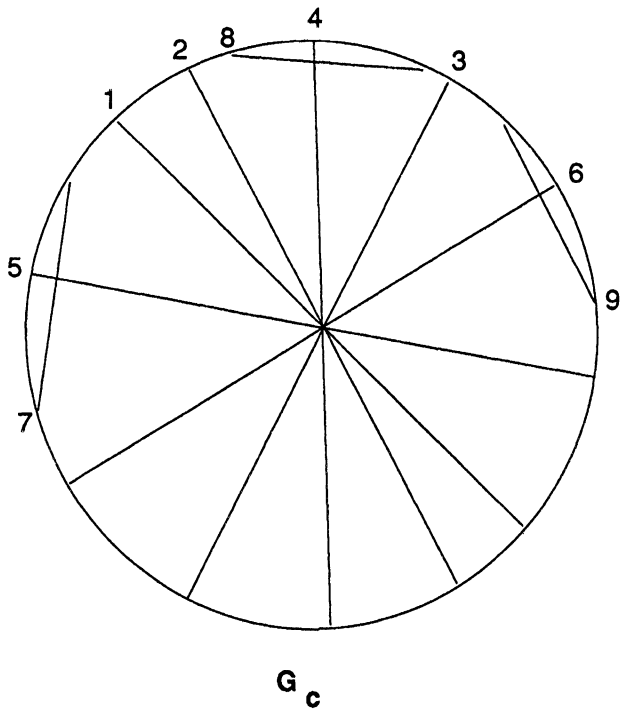

FIG. 6.1. *A maximal submodule that is not consistent. The partition of $V(G_c)$ into maximal submodules is* {1, 2, 3}, {4}, {5}, {6}, {7}, {8}, {9}. *The partition of $V(G_c)$ into maximal consistent submodules is* {1, 2}, {3}, {4}, {5}, {6}, {7}, {8}, {9}. *Hence the submodule* {1, 2, 3} *is not consistent.*

LEMMA 6.1. *Let M be a consistent submodule of $V(G_c)$ that gives rise to a permutation graph, then all submodules resulting from the ordinary substitution decomposition of M are consistent.*

Proof. Let $M_1, \ldots, M_k$ be the children submodules of M. Then each M_i is consistent with $I(M)$. We shall show that each M_i is consistent with $I(M_i)$. Since M gives rise to a permutation graph, there do not exist three vertices in series in M. Hence (6.4) holds for each M_i. To show that (6.2), (6.3) hold for M_i, we consider the following three cases:

(1) M is a parallel module. Then each M_i is a connected component of M. The parallel relationships dictate that there is a unique linear order for vertices from different M_i's in any conformal model. Hence, (6.2) and (6.3) hold.

(2) M is a series module. Then each M_i is a connected component in the complement of $G_c[M]$ and $I(M_i) = I(M)$. Since M is consistent, each M_i is consistent with $I(M)$, the same as $I(M_i)$.

(3) M is a neighborhood module. Then $M_1, \ldots, M_k$ are the maximal submodules of M. Suppose one of them, say M_i, is not consistent.

If M_i violates (6.2) then there exist a vertex v in $I(M_i)\backslash I(M)$ and two vertices u, u' in M_i such that $u|v|u'$. Let U be the set of all vertices in $I(M_i)$ between u and u' (and in parallel with u, u'). Since M is consistent, $U \subseteq M$. Let t be any vertex in $M\backslash M_i$ adjacent to u in G_c. Because M_i is a module, t is also adjacent to u'. By considering any chord model D for G_c, it is easy to argue that t must be adjacent to every vertex in U. Now, let v' be any vertex in $I(M_i)\backslash U$. Then, u and u' must be on the same side of v' and we have either $v'|u|u'$ or $u|u'|v'$. In any case v' cannot be adjacent to any vertex in U. Furthermore,

$M\backslash(M_i \cup U) \neq \emptyset$; otherwise, M is not connected. Hence, we conclude that $M_i \cup U$ is a module in M, contradictory to the fact that M_i is a maximal submodule of M.

If M_i violates (6.3), then a similar contradiction can be obtained. □

COROLLARY 6.2. *If G_c is a permutation graph, then all submodules in the substitution decomposition tree are consistent (note that this holds even if G_c is disconnected).*

6.2. Consistent partition of the neighborhood module $V(G_c)$. By assuming (6.1), $V(G_c)$ must be a neighborhood module. Let $M_1, \ldots, M_k$ be the maximal submodules that partition $V(G_c)$ in the "ordinary" neighborhood decomposition that are not necessarily consistent. Then each of them gives rise to a permutation graph. Note that k must be at least 3. The following lemma shows that it suffices for us to refine the series modules of $V(G_c)$.

LEMMA 6.3. *If a maximal submodule M_i of $V(G_c)$ is not consistent, then it is a series module.*

Proof. Consider any chord model D of G_c. Since M_i gives rise to a permutation graph, chords in M_i have one endpoint in a segment s_1 and the other endpoint in a disjoint segment s_2 of the circle. If those endpoints of M_i in s_1 as well as those in s_2 are consecutive in D, then one can easily verify that M_i is consistent.

Hence, without loss of generality, assume there is a chord $t = [a, b]$ in $V(G_c)\backslash M_i$ such that endpoint a is between two endpoints i, i' of M_i in segment s_1. If t crosses all chords of M_i, then endpoint b must fall in segment s_2. From model D, one can see that M_i is a series module. Now consider the case that $t \in I(M_i)$. Let $P = t \ldots t'u$ be a shortest path from t to M_i with $t' \notin M_i$, $u \in M_i$. Then one endpoint of t' falls between i, i' in segment s_1 and t' crosses all chords of M_i. Hence, the other endpoint of t' is in segment s_2. Since all chords of M_i crosses t', M_i must be a series module. □

THEOREM 6.4. *Let M_i be a maximal series submodule of the neighborhood module $V(G_c)$. Then there is a unique partition of M_i into maximal subsets $M^1, M^2, \ldots, M^r$, each of which is consistent in G_c.*

Proof. Consider the following relation "$\approx$" on M_i: $u \approx v$ iff (a) u, v are on the same side of every t in $I(M_i)$; (b) for any two t_1, t_2 in $I(M_i)$, $t_1|u|t_2$ iff $t_1|v|t_2$; $t_1 - u - t_2$ iff $t_1 - v - t_2$; and (c) there is no t in $I(M_i)$ such that $t - u - v$. It is not difficult to show that this is an equivalence relation. Let $M^1, \ldots, M^r$ be the unique partition of M_i into equivalence classes. By the definition of "$\approx$," these M^j's must be maximal subsets of M_i consistent with $I(M_i)$. Since M_i is a series module, $I(M^j) = I(M_i)$ for $j = 1, \ldots, r$. Hence, each M^j is consistent with $I(M^j)$. □

DEFINITION. *The* consistent partition *of $V(G_c)$ is the unique refinement of maximal submodules of $V(G_c)$ into their maximal consistent submodules as described in Theorem* 6.8. *A maximal submodule in the neighborhood partition of $V(G_c)$ is said to be* split *if it is refined in the consistent partition (an example is shown in Fig.* 6.1).

DEFINITION. *The* consistent decomposition tree *T has $V(G_c)$ as its root module, the maximal consistent submodules of $V(G_c)$ as the children submodules of $V(G_c)$, and the substitution decomposition tree of each children submodule M_i as the subtree of T with root module M_i. Every submodule associated with an internal node of the decomposition tree T is referred to as a* T-submodule.

Because the decomposition at each node is unique, the tree T is unique up to isomorphism. Since all children T-submodules of $V(G_c)$ are consistent and give rise to permutation graphs, by Lemma 6.5, all T-submodules of the tree T are consistent. We shall show that the representative graph of $V(G_c)$ has a unique conformal model. An important property of T-submodules is the following.

LEMMA 6.5. *Let M be a T-submodule that gives rise to a permutation graph. Let D be any conformal model for G_c. Then the endpoints of chords of M can be partitioned into two*

sets A_1, A_2 such that each chord of M has one endpoint in A_1 and the other in A_2 and those endpoints in A_1 (resp., A_2) are consecutive in D.

Proof. We first show that the lemma holds for each children T-submodule M^j of $V(G)$.

CLAIM. *Let $v = [w, x]$ be a chord in $V(G)\backslash M^j$ crossing all chords in M^j. Let (a_1, b_1) (resp., (a_2, b_2)) be the shortest segment containing w (resp., x) with endpoints from chords in M^j. Then, there must exist a chord in $I(M^j)$ whose two endpoints are contained either in (a_1, b_1) or in (a_2, b_2).*

Proof of Claim. Suppose otherwise. Let U_1 (resp., U_2) be the set of chords in D such that at least one of their endpoints falls in (a_1, b_1) (resp., (a_2, b_2)). Since we assume no chord of U_1 (resp., U_2) have both endpoints in (a_1, b_1) (resp., (a_2, b_2)), each chord of U must cross all chords in M^j. Therefore, all of their other endpoints must fall in (a_2, b_2) (resp., (a_1, b_1)). Hence, $U_1 = U_2$. From model D, it is easy to check that $M^j \cup U_1$ is consistent. Since $V(G_c)\backslash(M^j \cup U_1) \supseteq I(M^j) \neq \emptyset$, we have that $M^j \cup U_1$ is a nontrivial consistent submodule of $V(G_c)$, a contradiction. □

Let v' be a chord in $I(M)$ with its endpoints either in (a_1, b_1) or in (a_2, b_2). We shall find another chord t' in $I(M)$ whose endpoints are either in (b_1, a_2) or in (b_2, a_1). If none of the segments (b_1, a_2) and (b_2, a_1) contain endpoints of chords not in M^j, the lemma holds. Hence, assume to the contrary, there is a chord $t = (p, q)$ in $V(G)\backslash M^j$ such that one of its endpoints, say p, falls in (b_2, a_1). Let (c_1, d_1) be the shortest segment containing p with endpoints in M^j. If $q \in (c_1, d_1)$, let $t' = t$. Otherwise, t crosses M^j and q must fall in (b_1, a_2). Let (c_2, d_2) be the shortest segment containing q with endpoints in M^j (see Fig. 6.2). By the claim, the existence of t implies that there exists a chord t' in $I(M)$ whose endpoints are contained in either (c_1, d_1) or (c_2, d_2). In either case, one can easily verify that t' and v' are in series with some chord in M^j, and they are in parallel with some other chord in M^j, contradictory to the consistency of M^j.

Next, we show that Lemma 6.5 holds for each T-submodule of M^j. By induction, we need only show this for every children T-submodule of M^j. By Lemma 6.1, these T-submodules are all consistent. If M^j is a parallel module, then the lemma is implied by the unique parallel linear order of the T-submodules of M^j. If M^j is a neighborhood module, then the above argument on M^j itself can be applied here. Hence, consider the case that M^j is a series module. If any child T-submodule M' of M^j does not satisfy the lemma, then M' must be a series module. But then, M' should not have been a component in the series decomposition of M^j (each component of a series module must have a connected complement). □

THEOREM 6.6. *Consider a neighborhood module $V(G_c)$. Let $V' = \{v_1, \ldots, v_r\}$ be a set of representatives from the maximal consistent submodules $M^1, \ldots, M^p$ in the consistent partition of $V(G_c)$. Then there is a unique conformal model for V'. Furthermore, this model is independent of the v_i's selected (we shall refer to the subgraph induced on V' as the* representative graph for $V(G_c)$).

Proof. By Lemma 6.5, the consecutive endpoint property of the M^j's implies that such a model is independent of the v_i's selected. The endpoints of any subset V_1 of V' divide the circle into a collection of segments. Chords not in V_1 can be inserted into a chord model for V_1 by specifying the pair of segments that contain its two endpoints.

CLAIM 1. *There do not exist four chords u_1, u_2, u_3, and u_4 with endpoints a_i, b_i, $i = 1, 2, 3, 4$ arranged as $a_1a_3a_2a_4b_1b_3b_2b_4$ in D such that u_1, u_2 belong to a maximal submodule M_i; u_3, u_4 belong to another maximal submodule M_j.*

Proof of Claim 1. If these chords exist, then any chord in $V(G_c)\backslash(M_i \cup M_j)$ that crosses M_i must also cross M_j and vice versa. This would make $M_i \cup M_j$ a module of $V(G_c)$ (note that the number of maximal consistent submodules of $V(G_c)$ is at least three). □

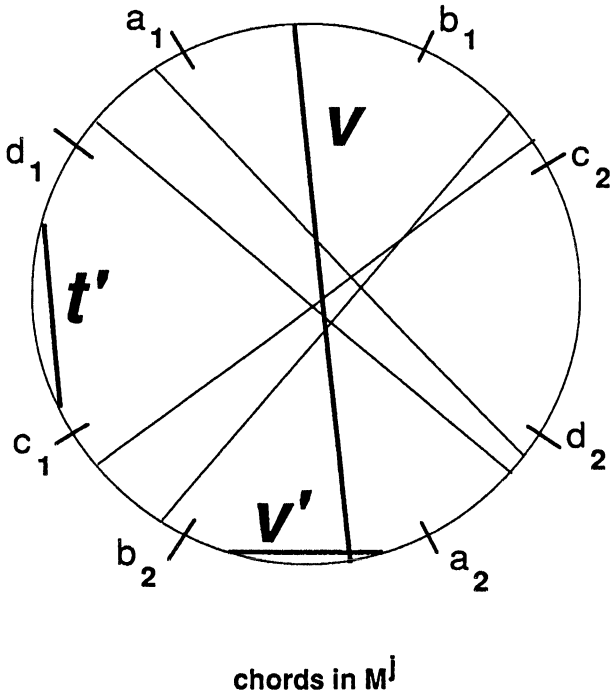

FIG. 6.2. *The four segments and* M^j.

Let M_i be any maximal submodule in the neighborhood partition (as opposed to the consistent partition) of $V(G_c)$. Let $v_{i_1}, \ldots, v_{i_r}$ be the representatives in V' from the maximal consistent submodules $M^{i_1}, \ldots, M^{i_r}$ of M_i.

CLAIM 2. *For any subset* V'' *of* V' *that constitutes a set of representatives for all maximal submodules except* M_i *in the neighborhood partition of* $V(G_c)$, *there is a unique conformal model for* $\{v_{i_1}, \ldots, v_{i_k}\} \cup V''$.

Proof of Claim 2. By Theorem 5.7, there is a unique conformal model for each $\{v_{i_m}\} \cup V''$, $m = 1, \ldots, k$. Since there is a conformal model for $\{v_{i_1}, \ldots, v_{i_k}\} \cup V''$, the endpoint order for chords in V'' in each model $\{v_{i_m}\} \cup V''$, $m = 1, \ldots, k$ must be the same. The endpoints of chords in V'' divide the circle into a collection C of segments. Therefore, there is a unique pair of segments in C for the chord of each v_{i_m}, $m = 1, \ldots, k$. It remains to show that no two representative chords form M_i can have one of their endpoints sharing the same segment in C (since M_i is a module, these two chords would have to share the same pair of segments in C).

Suppose there are two chords, say v_{i_1}, v_{i_2}, sharing the same pair of segments of C. By Lemma 6.3, M_i is a series module. Hence, v_{i_1} must cross v_{i_2}. If there exists a chord v in $I(M_i)$ such that one of its endpoints separates those of v_{i_1} and v_{i_2} in one of the segment pair, say s, then following the proof of Lemma 6.3, one can argue that there exist a chord v' in $V(G)\backslash M$ with an endpoint in s that crosses both v_{i_1} and v_{i_2}. Let v_s be the representative in V'' of the module containing v' (since the endpoints of v_s are used in defining the segments in C, v_s cannot be the same as v'). Then v_{i_1}, v_{i_2}, v', and v_s form a forbidden configuration described in Claim 1. □

By Claim 2, there will be no ambiguity in placing the representative chords $v_{i_1}, v_{i_2}, \ldots, v_{i_k}$ of any maximal submodule M into the unique model for any subset V'' of V' described in the beginning of the proof. Hence, we can construct a unique model for V' as follows. Start by choosing an arbitrary V'' and construct the unique conformal model for V''. Let $M_1, \ldots, M_s$

be the maximal submodules of $V(G_c)$ in the neighborhood partition. Place the chords in $V' \cap M_i$, $i = 1, \ldots, s$ into the current conformal model one by one. This concludes the proof of Theorem 6.6. □

Suppose G_c has a conformal model. To ensure that a model $D(M)$ for a T-submodule M is consistent with respect to chords not in M, it may appear that we need to check the consistency of $D(M)$ with respect to each vertex in $I(M)$. Since each T-submodule M other than $V(G_c)$ is consistent and gives rise to a permutation graph, it can be easily shown that $D(M)$ is consistent in G_c iff $D(M)$ is consistent with respect to an arbitrary vertex in $I(M)$. Hence, we can construct a conformal model for G_c as follows.

For each T-submodule M, let $V(M)$ be a set of representatives in a representative graph for M. Choose a vertex $u(M)$ in $I(M)$ and construct a conformal model for the subgraph induced on $V(M) \cup \{u(M)\}$. By Lemma 6.5, a model for G_c can be composed in a bottom-up fashion along the tree T by recursively replacing the representative chord with its corresponding permutation chord model as follows: (a) when M is a parallel module, we place the chord models of its children T-submodules according to the unique linear order dictated by the parallel relationships; (b) when M is a neighborhood module, we place them according to the unique N-model described in Corollary 5.8; and (c) when M is a series module, its children chord models are made to intersect each other's.

THEOREM 6.7. *Let G be a graph satisfying* (6.1). *Let T be the unique decomposition tree for G_c. Then G is a circular-arc graph iff for every T-submodule M there is a conformal model for the subgraph induced on $V(M) \cup \{u(M)\}$.*

7. Decomposition of a circular-arc graph G with a disconnected G_c. In §6 we assume G_c is connected and apply the consistent decomposition to eliminate type II structures in G. In case G_c is not connected (type I structure exists), one needs to arrange the relative positions of its components according to the series and parallel relationships in G, which makes the model construction for each component of G_c more involved. We shall adopt the following approach:

(a) Represent the series and parallel relationships among the components by a tree.

(b) Construct a unique conformal model for each component node of the tree in (1).

(c) Combine the individual component models together based on the tree in (1) to form a conformal model for G_c.

Figure 7.1 illustrates the importance of keeping track of such relationships by showing an example of a noncircular-arc graph G with disconnected G_c. In this example, we have two conflicting series relationships 6-2-4 and 6-3-5.

7.1. The unique tree T_{NS} representing the series and parallel relationships among components in G_c. Consider a circular-arc graph G with a disconnected G_c. Let $C_1, \ldots, C_k$ be the connected components of G_c.

DEFINITION. *Three components C_i, C_j, and C_k are said to be* in parallel (*denoted by $C_i|C_j|C_k$*) *if there exist three vertices v_i, v_j, and v_k from C_i, C_j, and C_k, respectively, satisfying $v_i|v_j|v_k$. Three components that are not in parallel are said to be* in series (*denoted by $C_i - C_j - C_k$*) (*if $C_i - C_j - C_k$, then any three vertices v_i, v_j, and v_k from C_i, C_j, and C_k, respectively, must also be in series*). *A collection of components are in series if every three of them are.*

DEFINITION. *A component C_i is said to be* near *another component C_j if there exists no component C_k such that $C_i|C_k|C_j$. Define a collection Q of components to be an NS-*collection *if the components in Q are in series and every two components are near each other.*

Let $N_1, N_2, \ldots, N_r$ be the maximal NS-collections of G_c. It is easy to check that the number of maximal NS-collection of G_c is no greater than the number of connected components in G_c. An example is given in Fig. 7.2.

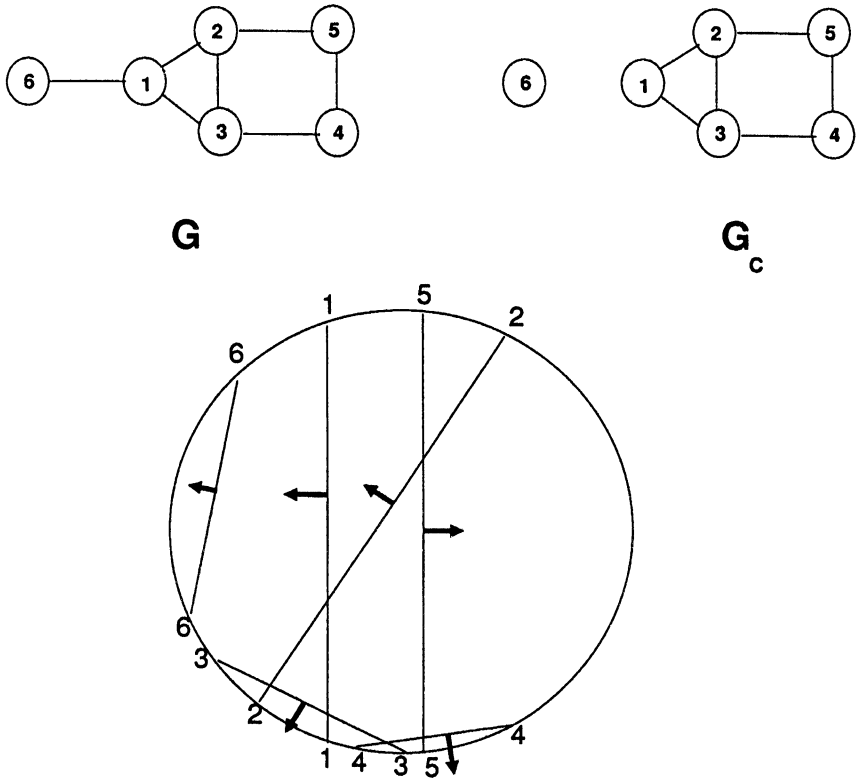

FIG. 7.1. *A noncircular-arc graph G with a disconnected G_c. The five vertices component of G_c gives a uniquely representable circular-arc graph. Because* 6 *and* 1 *are adjacent in G. we have to place arc* 6 *to the left of its chord. But then* 6 *and* 2 *have to be adjacent, a contradiction.*

The following relationships on the components can be easily justified.

LEMMA 7.1. *Let C_i be any component of G_c. Let N_j, N_j' be two maximal NS-collection containing C_i. Then, for any two components C, C′ of $N_j \backslash \{C_i\}$ and $N_j' \backslash \{C_i\}$, respectively, we have $C|C_i|C'$.*

Now, construct a bipartite graph T_{NS} with vertex set on the components C_i's of G_c and the maximal NS-collections N_i's by connecting each N_i to every component in N_i by an edge. An example is given in Fig. 7.3.

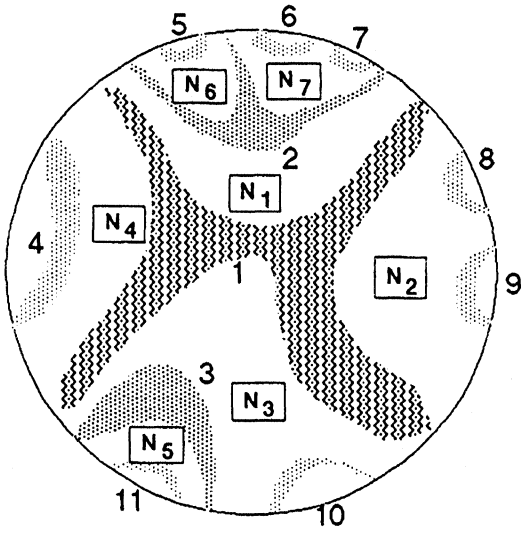
THEOREM 7.2. *The graph T_{NS} is a tree (called the* series-parallel tree, *or SP-tree, of G_c).*

Proof. Suppose there exists a cycle $C_1, N_1, C_2, N_2, \ldots, C_m, N_m, C_1$. By Lemma 7.1, we have (a) $C_1|C_2|C_3, C_2|C_3|C_4, \ldots, C_{m-1}|C_m|C_1$ and (b) $C_m|C_1|C_2$. However, (a) implies that C_2 and C_m are on the same side of C_1, which contradicts (b). □

7.2. C-inseparable graphs. In this section, we show that the problem of constructing a conformal model for G_c can be reduced to that of constructing a conformal model for each of its c-inseparable components defined below.

DEFINITION. *For each component C_i, define a* c-inseparable component *G_i of G_c to be the union of C_i together with any vertex from N_j for each maximal NS-collection N_j containing C_i (as shown in Fig.* 7.4). *G_c is c-inseparable if there exists a component C_i such that $G_c = G_i$.*

As far as the conformal model S of G_i is concerned, any vertex from any component of N_j will result in the same model. Therefore, the selection is immaterial. If G_c is connected, then it



G_c

$N_1 = \{ C_1, C_2 \}$

$N_2 = \{ C_1, C_8, C_9 \}$

$N_3 = \{ C_1, C_3, C_{10} \}$

$N_4 = \{ C_1, C_4 \}$

$N_5 = \{ C_3, C_{11} \}$

$N_6 = \{ C_2, C_5 \}$

$N_7 = \{ C_2, C_6, C_7 \}$

FIG. 7.2. *The maximal NS-collection of* G_c.

is clearly c-inseparable by this definition. The following two lemmas provide characterizations of c-inseparable graphs. The first one can be easily justified.

LEMMA 7.3. *The* T_{NS} *tree for a c-inseparable graph* $G_c (= G_i)$ *satisfies that*

(1) *every component of* G_c, *except possibly* C_i, *is a leaf in* T_{NS} *containing exactly one vertex of* G_c.

(2) *every maximal NS-collection of* G_c *consists of* C_i *and a leaf component.*

THEOREM 7.4. *Consider a circular-arc graph G. Suppose* G_c *is c-inseparable and disconnected. Let* C_i *be the component such that* $G_i = G_c$. *Let K be the set of vertices of* G_c *not in* C_i. *Then any conformal model for* G_c *satisfies that*

(1) *between any two chords u, v in K there is a chord d in* C_i *such that* $u|d|v$.

(2) *those chords in K are in series following a unique (up to rotation and reversal) circular order around the circle.*

Proof. Each vertex in K forms a single vertex component of G_c. Let u, v be two vertices in K. By Lemmas 7.1 and 7.3, $u|C_i|v$. Hence, condition (1) holds.

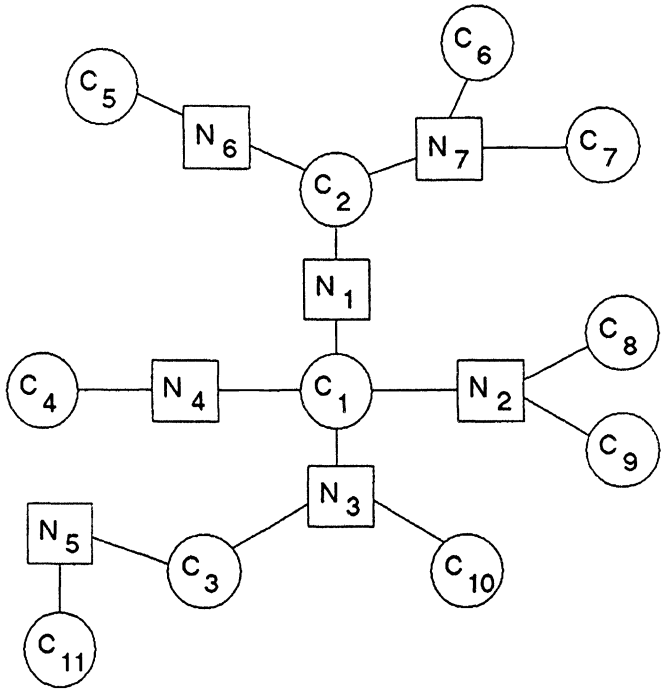


FIG. 7.3. *The series parallel tree T_{NS} of a graph G_c.*

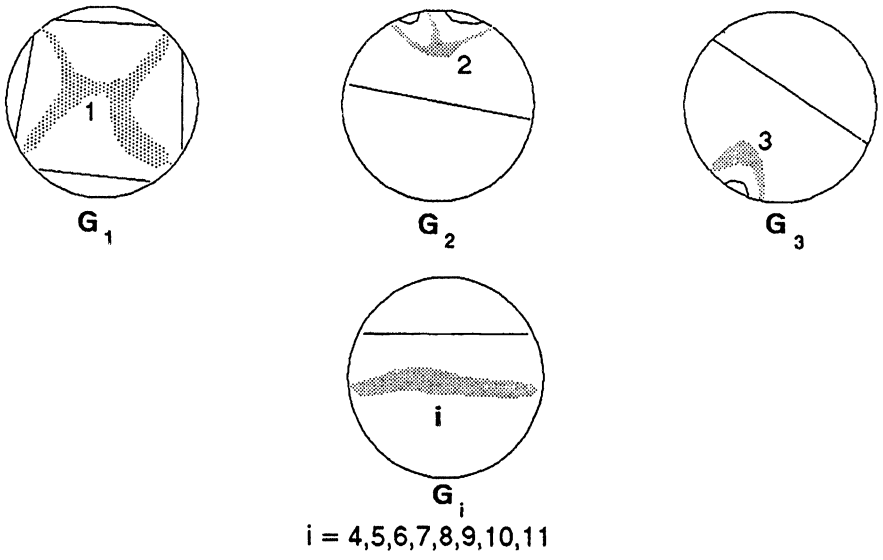

FIG. 7.4. *The c-inseparable components of a graph G_c.*

Condition (2) can be proved by the following set partitioning argument. Each vertex u in C_i partitions K into two sets, L_u and R_u. By considering vertices of C_i one by one and refining the partition on K, we can eventually conclude that, in the final partition of K, every set is a singleton by (1). □

THEOREM 7.5. *Assume $\overline{G}_c$ is connected. Then, G_c has a conformal model iff each of its c-inseparable component G_i has a conformal model.*

Proof. The "only if" part is trivial since each G_i is an induced subgraph of G_c. Hence, consider the "if" part.

We prove this by induction on $|V(G_c)|$. Assume G_c is not c-inseparable; otherwise, the theorem is trivially true. By Lemma 7.3, we have the following cases.

Case 1. T_{NS} contains a leaf component C whose size is greater than 1. Let u_1 be any vertex in C and u_2 be any vertex not in C. Let H_1 be the subgraph of G_c induced on $[V(G_c)\backslash C]\cup\{u_1\}$ and H_2 be the subgraph of G_c induced on $C\cup\{u_2\}$.

Case 2. T_{NS} contains a maximal NS-collection N that contains more than two components and at least one of them, say C, is not a leaf. Now, deleting the edge between N and C will result in two trees T_1 (the one containing N) and T_2 (the one containing C). Let u_1 be any vertex in C and u_2 be any vertex contained in a component in T_1. Let H_1 be the subgraph of G_c induced on the union of $\{u_1\}$ and those components in T_1. Let H_2 be the subgraph of G_c induced on the union of $\{u_2\}$ and those components in T_2.

By Lemma 7.1, all vertices of $V(H_j)\backslash\{u_j\}$ are on the same side of u_j in G_c for $j=1,2$. By induction, each of H_1 and H_2 has a conformal model D_1, D_2 with endpoint sequences, S_1ab and S_1cd, respectively, where $[a,b]$ is the chord for u_1, $[c,d]$ is the chord for u_2. The reason that a, b are consecutive in D_1 is because all other chords are on the same side of $[a,b]$ by the conformity of D_1. The same argument goes for c, d.

Let D be the chord model with endpoint sequence S_1S_2. D satisfies that any two chords of A are on the same side of every chord in B and vice versa. It also satisfies the intersection relationships of G_c. Hence, it is easy to check that D satisfies (5.1). □

7.3. Constructing a conformal model for a c-inseparable G_c. In this section, assume G_c has a conformal model and is c-inseparable. Let C be the component of G_c of size greater than 1 (if no such component exists, then $|V(G_c)|\leq 3$ and the problem is trivial). Let K be the set of remaining vertices $u_1,\ldots,u_k$, each of which constitutes a single-vertex component of G_c and is indexed according to the unique circular order prescribed in Theorem 7.4. We shall first construct a consistent decomposition tree T for the subgraph $G_c[C]$ and then insert the vertices of K into conformal models of appropriate T-submodules. For any T-submodule M in C, let $I(M)$ be the set of vertices of C not adjacent to M. A module M is said to be *split* by a vertex $u\notin M$ if there exist vertices v, v' in M such that either (a) $u-v-v'$ or (b) there exists a $u'\notin M$ such that $u|v|u'$ and $u-v'-u'$.

LEMMA 7.6. *Let u be a vertex in K. Let M be a T-submodule and $M_1,\ldots,M_r$ be the children T-submodules of M. If M is split by u, then at most one of the M_i's is split by u.*

Proof. Suppose M_1 and M_2 are both split by u. Let D be a conformal model for G_c. Suppressing the endpoints on u, the endpoints of M_1 (resp., M_2) should be divided into two consecutive sequences A_1 and B_1 (resp., A_2 and B_2) because M_1 and M_2 are consistent in C (Lemma 6.5). Since all chords of C are on the same side of u, $h(u)$ and $t(u)$ should also be consecutive. The chord of u can be split M_1 only if either A_1 or B_1 is separated by $h(u), t(u)$. Since $h(u), t(u)$ can only separate one of the four sequences A_1, B_1, A_2, and B_2, at most one of M_1 and M_2 can be split by u. □

Following this lemma, we can find a unique path P from the root of T to a node representing a module, denoted by $M(u)$, which is split by u, but none of the children of $M(u)$ is split. If $M(u)$ is a series module, let $u(M)$ be a vertex outside $M\cup\{u\}$. Then divide those representative chords of M uniquely into two sets: those that are in between u, $u(M)$ and those that are in series with u and $u(M)$. Hence, consider the case that $M(u)$ is a parallel or a neighborhood module. Let D^* be the unique conformal models for the representative graph of $M(u)$. Then the series and parallel relationships of G dictate that there is a unique way to insert the chord of u into D^*. Therefore, we can insert each u of K uniquely into its corresponding T-submodule $M(u)$ in T. We call these adjusted modules *augmented T-submodules* (note that several u's

could be inserted into the same T-submodule, but no two of them can share the same segment). The resulting tree T' with vertices of K added is called the *consistent decomposition tree* of G_c.

8. Complexity analysis of the recognition algorithm. Our algorithm consists of the following five major steps. Each step can be shown to take at most $O(m \cdot n)$ time. Steps (4) and (5) are used for disconnected G_c. Described below is not the flow chart, but the main steps of the algorithm. After a model of G_c is constructed, we need to test if its corresponding arc model faithfully represents G.

(1) Transform G to G_c, determine L_v and R_v for each vertex v in G_c.

(2) Given a graph G satisfying (6.1), determine its consistent decomposition tree T.

(3) Determine a unique conformal chord model for the representative graph of each T-submodule by applying the join decomposition. Compose a conformal model for G_c in (4) from those of its T-submodules or declare that such a model does not exist.

(4) Given a graph G with a disconnected G_c, determine its series parallel tree T_{NS}.

(5) For each inseparable component G_i of G_c such that $G_c[C_i] = G_i$, construct the consistent decomposition tree T_i for $G_c[C_i]$. Determine the unique path for each vertex of K along T_i and construct the corresponding augmented T-submodule. Construct a conformal model for G_i. Finally, compose a model for G_c from those of its c-inseparable components.

To carry out step (1), we first construct the *containment graph* G^* of G, which is the directed graph with the same vertex set as G whose edges satisfy that $(u, v) \in G^*$ (directed from u to v) iff $N_G(u) \supseteq N_G(v)$ (u contains v in G). For each vertex u, it takes $O(m)$ time to determine all $N_G(v)s$ that contain $N_G(u)$. Hence, the construction of G^* takes $O(m \cdot n)$ time. Now, two vertices u and v are strictly adjacent iff $(u, v) \in G$ but there is no edge from one to the other in G^*; they are strongly adjacent iff $N_G(u) \cup N_G(v) = V$, $V \backslash N_G(v) = N_{G^*}(u)$ and $V \backslash N_G(u) = N_{G^*}(v)$. The partition of vertices in G_c not adjacent to a vertex v into L_v and R_v can be obtained from the graph G and its containment graph G^*.

If we assume that G satisfies (6.1), $V(G_c)$ must be a neighborhood module. Hence, in step (2), we first partition $V(G_c)$ into its maximal submodules using the substitution decomposition. Then refine each maximal series submodule M_i of $V(G_c)$ into its maximal consistent subsets $M^1, \ldots, M^r$ based on the following partitioning argument. Pick a vertex u in G_c, partition each maximal module M_i not containing u into $M_i \cap L_u$ and $M_i \cap R_u$ by scanning each vertex of L_u once. Now, iteratively refine the current partition based on the remaining vertices of G_c. Then the final partition of each M_i will be the collection of its maximal consistent subsets. This operation would take $O(m)$ time. Now, find the substitution decomposition tree of each M^j and combine them to form our consistent decomposition tree T. Hence, the total time spent in step (2) is $O(n^2)$ due to the substitution decomposition.

For step (3), the conformal models for series and parallel T-submodules can be easily composed from those of their children. To determine a conformal model for the representative graph G_M of each neighborhood T-submodule M (other than $V(G_c)$), we apply the join decomposition to G_M and combine the unique models of the j-inseparable components of G_M according to the algorithm described in the proof of Theorem 5.7. The conformal model for the representative graph of $V(G_c)$ is obtained using the above partitioning argument. These conformal models can then be used to compose a conformal model for T. In summary, the operations involved in step (3) are the substitution decomposition, the join decomposition, and the chord model construction in [5], each of which takes at most $O(m \cdot n)$ time.

The operations involved in the construction of T_{NS} in step (4) are very similar to the refinement procedure used in step (2). Pick a component C of G_c and a vertex u in C. Partition the remaining components into two clusters according to L_u and R_u. Iteratively refine the clusters based on every other vertex of C. At the end, each cluster consists of

components whose series-parallel relationships with respect to every vertex of C are identical. Furthermore, each cluster corresponds to a maximal NS-collection N_j containing C. This procedure can be recursively applied to the connected components within each cluster and we can eventually determine the series-parallel relationships of all components of G_c and construct the SP-tree T_{NS}. The total time complexity is $O(m+n)$.

Now consider step (5). Let G_i be a c-inseparable component graph of G_c. We shall follow the notations in §7.3 to construct a conformal model for G_i. Let C_i be the connected component of G_i with more than one vertices. Let K_i be the set of remaining vertices. The unique T-submodule $M(u)$ for each u in K_i can be determined in a bottom-up fashion. For each T-submodule M in the bottom level, we test which u in K_i splits M by keeping a vertex $u(M) \in C_i \backslash M$ and partition K with respect to each v in M according to L_v and R_v. Hence, all the augmented T-submodules and the consistent decomposition tree of G_c can be constructed in $O(m)$ time. Once the chord model for each c-inseparable component is available, composing a conformal model of G_c according to T_{NS} takes only $O(m)$ time.

9. The isomorphism problem on circular-arc graphs. We first consider the isomorphism problem for circular-arc graphs satisfying (6.1). To test the isomorphism between two such circular-arc graphs G and G', it suffices to test whether there exist isomorphic conformal models for G_c and G'_c. We shall make use of the unique consistent decomposition trees T and T' for G and G', respectively. A by-product of our algorithm is an isomorphism algorithm for circle graphs, which involves only the join decomposition. The unique consistent decomposition tree T of G_c satisfies the following properties. Its leaves are the vertices of G_c. It has a unique root and every interior node (except the root, which uses the consistent partition) is associated with N, P, or S, indicating three types of decompositions. The representative graph of an S-node is a clique. The representative graph of a P-node is an independent set (consisting of parallel vertices). The representative graph of an N-node is an s-inseparable component that is neither a clique nor an independent set. Each s-inseparable component of G_c corresponds to a uniquely representable induced subgraph of G. Since each internal node has at least two children, the total number of internal nodes (and therefore, the total number of nodes) of T is $O(n)$.

Define the *level* $\ell(v)$ of a node v in T to be the length of the unique path from v to the root. For each internal node v of T, denote the subtree with root v by T_v. Our isomorphism algorithm assigns integer labels to the nodes of T and T' such that a node v of T and another node v' of T' receive the same label iff there exists isomorphic conformal models for T_v and T'_v.

ISOMORPHISM ALGORITHM

(1) Determine the respective consistent decomposition trees T and T'. Assign the label 1 to each leaf of T and T'.

(2) Assign labels to the internal nodes of T and T' level iteratively with decreasing ℓ. Assume all nodes at level ℓ (denoted by S_ℓ, S'_ℓ, respectively) of T and T' have been assigned labels. Let v and v' be nodes in $S_{\ell-1}$ and $S'_{\ell-1}$, respectively.

(2.1) If v and v' correspond to series modules in T and T' and their children have the same collections of labels, then assign the same new label to them.

(2.2) If v and v' correspond to parallel modules in T and T' and the labels of their children follow the same unique parallel sequence, then they receive the same new label.

(2.3) If v and v' correspond to neighborhood modules (or, consistent partitions) in T and T', then there exist unique conformal models D and D', respectively, for their representative graphs H and H'. The isomorphism testing of v and v' can be reduced

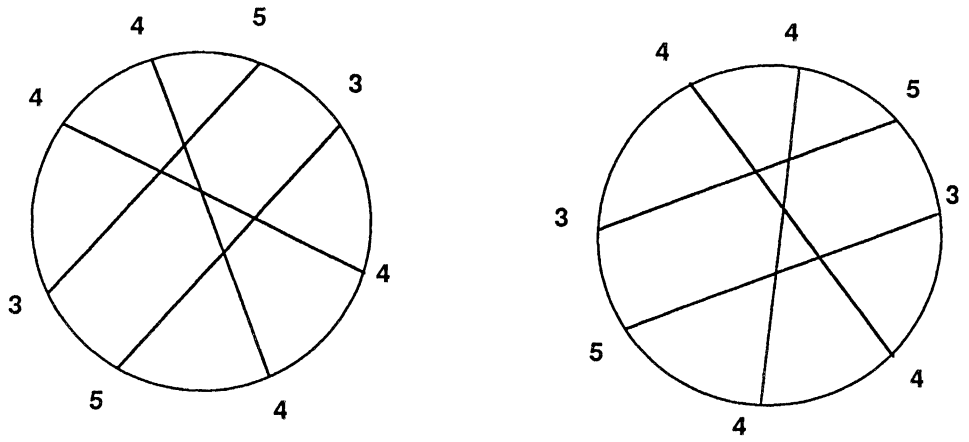

FIG. 9.1. *Testing the isomorphism of two unique chord models. If the chords are not labeled, then index each end the clockwise distance to its opposite end. Then, the isomorphism testing can be reduced to test if* 44534453 *is a substring of* 3445344534453445$3544354435443544. *If the chords are labeled, then in the above indexing scheme attach the label of the chord immediately after its index and apply string matching.*

to a string matching problem by using origin-free circular indexing of the endpoints of D and D' as shown in Fig. 9.1.

The time complexity for step (1) is $O(m \cdot n)$. Next, we claim the complexity for step (2) is $O(n^2)$ provided all the conformal models of the representative graphs are available. The labels assigned at each level starts from 0. Using bucket sort, we can obtain the sorted children label sequence of each node in level $\ell - 1$ in $|S_\ell|$ time. Step (2.1) can be done by comparing the sorted children label sequence. Step (2.2) can be carried out by comparing the unique label sequence. The complexity for (2.3) can be analyzed as follows. Testing the isomorphism between two unique conformal models D and D' as illustrated in Fig. 9.1 takes $O(|D|+|D'|)$ time. Hence, the time it takes to label all nodes in $S_{\ell-1}$ and $S'_{\ell-1}$ is $O(|S_\ell|^2)$. Let ℓ^* be the largest level number. Given the decomposition trees and conformal models for their representative graphs, the overall time complexity is bounded by $\sum_{\ell=1}^{\ell^*} O(|S_\ell|^2) = O(n^2)$, since $\sum_{\ell=1}^{\ell^*} |S_\ell| = O(|T|) = O(n)$.

Next, consider the isomorphism problem for circular-arc graphs whose associated G_c is not connected. Assume the SP-tree and all c-completion graphs have been computed. We divide our algorithm into two parts. First, we test their c-inseparable components for isomorphism. This can be carried out by testing the isomorphism of their corresponding (augmented) consistent decomposition tree using the algorithm in Fig. 9.1. Next, assign the same label to all components in the SP-trees T_{NS} and T'_{NS} of G_c and G'_c, respectively, if their c-inseparable components are isomorphic. Assign another distinct label to all nodes representing maximal NS-collections. Then the isomorphism testing of G_c and G'_c is reduced to that of two labeled trees T_{NS} and T'_{NS}.

Testing the isomorphism of two c-inseparable components, say H_c and H'_c, of G_c and G'_c takes $O(|V(H_c)|)$ time according to the previous analysis. Now, assigning labels to the components of the SP-trees can be done by testing for each component H_c of T_{NS} whose isomorphic components in T'_{NS} in $O(|V(H_c)| \cdot n)$ time. Hence, the total time for the label assignment of nodes in the SP-trees is $O(n^2)$. Finally, testing the isomorphism of two labeled trees takes time proportional to the number of vertices in the trees. Therefore, the total time spent in step (2) is $O(n^2)$.

Acknowledgments. We would like to thank the referees for their detailed comments that greatly enhanced the readability of this paper. We think a more careful implementation of the algorithm of this paper could reduce the complexity to $O(n^2)$. For example, a crucial step constructing the containment graph of circular-arc graphs in step (1) of §8 can be reduced to $O(n^2)$ time using a result of [4]. Since this result was submitted four years ago, some improvement has been obtained in the interim (notably, the result of [4]). However, we believe this paper has provided a useful framework for dealing with the structures of interval graphs and circular-arc graphs; in particular, the characterizations of prime components. Perhaps more efficient algorithms can be discovered along this line of thought.

WHEN TREES COLLIDE: AN APPROXIMATION ALGORITHM FOR THE GENERALIZED STEINER PROBLEM ON NETWORKS*

AJIT AGRAWAL†, PHILIP KLEIN‡, AND R. RAVI§

Abstract. We give the first approximation algorithm for the *generalized network Steiner problem*, a problem in network design. An instance consists of a network with link-costs and, for each pair $\{i, j\}$ of nodes, an edge-connectivity requirement r_{ij}. The goal is to find a minimum-cost network using the available links and satisfying the requirements. Our algorithm outputs a solution whose cost is within $2\lceil \log_2(r+1) \rceil$ of optimal, where r is the highest requirement value. In the course of proving the performance guarantee, we prove a combinatorial min-max approximate equality relating minimum-cost networks to maximum packings of certain kinds of cuts. As a consequence of the proof of this theorem, we obtain an approximation algorithm for optimally packing these cuts; we show that this algorithm has application to estimating the reliability of a probabilistic network.

Key words. approximation algorithm, network design, Steiner tree problem

AMS subject classifications. 68R10, 68Q25

1. Introduction.

Consider the following scenario. Client industries of a telephone company have requested commercial telephone connections between pairs of their offices in different cities. The telephone company must then install a network of fiberoptic telephone links that accommodates all the clients' requirements. That is, the network must contain a path using these links between every pair of cities specified by the clients. Given the cost of installing links between different cities, the company must now decide which links to install so as to minimize its cost. (See Fig. 1.)

We formalize the problem as follows. Let G be a graph with nonnegative edge-costs, and let R be a set of node-pairs (s_i, t_i). We call these pairs *site-pairs*, and we say the nodes s_i, t_i are *sites*. We call a subgraph H of G a *requirement join* if H contains a path between s_i and t_i for every requirement (s_i, t_i). We call the node-pairs *requirements* because they represent connectivity constraints that must be satisfied by the output subgraph. We abbreviate *requirement join* by *R-join* when we want to emphasize the set R of requirements. The problem we consider in this paper is to find a minimum-cost R-join.

The problem faced by the telephone company can be directly formulated as a minimum-cost R-join problem. In this formulation, it is assumed that a link can be used simultaneously by many clients. This assumption is reasonable in light of the very high bandwidth of fiberoptic links.

Consider the special case of this problem in which there is a set T of *terminals*, and every pair of nodes in T needs to be connected. This special case is known in the literature as the *Steiner tree problem in networks*. This problem was one of the first seven problems shown to be NP-complete by Karp [19]. Given the range of its applications, it is not surprising that this problem has been well-studied. Many enumeration algorithms, heuristics [33], [44], [18], and approximation algorithms [6], [38], [25], [11], [31], [37], [29], [45] are known for the problem. Polynomial-time solutions for restricted classes of graphs are also known (see [42]).

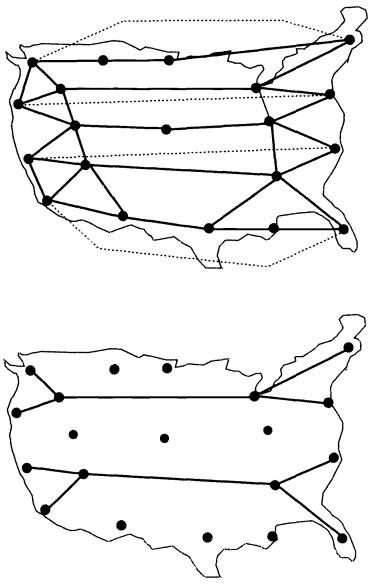

FIG. 1. *An instance of the unweighted network design problem and its solution. Solid edges correspond to unit-cost links; dotted edges connect site pairs.*

However, none of the algorithms addresses the more general case in which each client can specify an arbitrary pair of cities. Note that in this general case the solution network need not be connected. Moreover, a minimum-cost Steiner tree solution can be arbitrarily costlier than a minimum-cost solution to this more general problem.

In this paper, we give the first approximation algorithm for the minimum-cost R-join problem.

THEOREM 1.1. *There is a polynomial-time algorithm for finding an R-join of cost at most $2 - 2/k$ times minimum, where k is the number of sites.*

1.1. The generalized Steiner problem in networks. The algorithm of Theorem 1.1 is useful when the network to be constructed need not be connected. However, the algorithm is also useful, as a subroutine, even in designing connected networks. Namely, we consider a generalization of the minimum-cost R-join problem involving certain redundancy requirements.

Consider the scenario described above but where each client can specify that her pair of cities must be connected by some number of edge-disjoint paths so that the connection is less vulnerable to link failure. The goal is to design a network satisfying these specifications. The network is allowed to contain multiple links between the same pair of nodes; all such links have the same cost.

To model this situation, we allow more general requirements. The set R of requirements consists of triples (s_i, t_i, r_i), where r_i, the requirement value, is a positive integer. An *R-multijoin* is a multiset of the edges of G that contains r_i edge-disjoint paths from s_i to t_i, for every requirement (s_i, t_i, r_i). The cost of an R-multijoin is the sum of the costs of the edges in the multiset, counting multiplicities. Using our approximation algorithm for minimum-cost R-join, we obtain an approximation algorithm for minimum-cost R-multijoin.

THEOREM 1.2. *There is a polynomial-time algorithm for finding an R-multijoin of cost at most $(2 - 2/k)\lceil \log_2(r_{\max} + 1)\rceil$ times minimum, where $r_{\max}$ is the largest requirement value and k is the number of sites.*

This problem is called *multiterminal network synthesis* by Chien [7] and Gomory and Hu [13]. Gomory and Hu and later Sridhar and Chandrasekaran [35] address the synthesis problem for the special case where the input graph is the complete graph with all costs identical.

The problem is also essentially identical to the *generalized Steiner problem* as formulated by Krarup ([26], as cited in [41]). The problem is referred to as the design of minimum-cost *survivable networks* in the work of Steiglitz, Weiner, and Kleitman [36]. These researchers pose the problem of finding a subgraph of minimum cost satisfying given connectivity requirements. The problem we address differs in that we allow the solution to contain multiple copies of links appearing only once in the input graph G.

In this paper we will use the term *R-multijoin* whenever the requirements R include requirement values exceeding one, and will reserve the term *R-join* for the case when the requirement values are all one. The former case is addressed only in §3.3, where we show how to reduce the problem to the latter case. The remainder of the paper addresses only the latter case.

1.2. Packing cuts, with application to network reliability. Our results also have application to evaluating network reliability. Suppose the telephone company has an existing network and the same list of clients, each specifying a pair of cities. The company needs to determine how likely it is that random failure of communication links renders some of its clients' requirements unsatisfiable.[1] Assuming link failures are independent, determining the probability that the surviving links can serve all clients' requirements is a generalization of the #P-complete problem [39] called network reliability. No approximation algorithms are known.

However, one powerful and useful heuristic for estimating two-terminal and k-terminal reliability [8], [9] can be directly generalized to handle the case of arbitrary pairs. The (generalized) heuristic consists in finding a large collection of edge-disjoint cuts in the network such that each cut separates at least one client's pair of cities. For a surviving network to be able to serve all clients' requirements, at least one edge in each cut must survive; thus such a cut-packing can be used to obtain a lower bound on the probability of catastrophic failure. Experience [9] with this heuristic in the cases of two-terminal and k-terminal reliability indicates that it is one of the best available.

One of the results of this paper is an algorithm for finding a nearly maximum collection of such cuts in an auxiliary network whose reliability is the same as that of the original network. We give more details in §3.

1.3. The combinatorial basis for our algorithms: A new approximate min-max equality. At the heart of our proofs of near-optimality is a combinatorial theorem that relates the R-join problem to the cut-packing problem in the case of unit edge-weights.

THEOREM 1.3. *The minimum size of an R-join is approximately equal to one-half the maximum size of a collection of cuts, where each cut separates some site-pair, and no edge is in more than two cuts. By "approximately," we mean within a factor of* $2 - 2/k$, *where* k *is the number of sites.*

The proof of Theorem 1.3 is algorithmic and is given in §5. We can formulate the two combinatorial quantities as the values of integer linear programs that are dual to one another. It follows from Theorem 1.3 that the fractional relaxations of these programs provide good approximations to both combinatorial quantities. Moreover, the factor of $2 - 2/k$ is

[1] A related problem—finding the minimum number of communication links that would need to fail for *all* requirements to be unsatisfiable—can be solved approximately, using techniques we presented in an earlier paper [22].

existentially tight, as shown by the example of a k-cycle given by Goemans and Bertsimas [14].

2. Related work.

2.1. The Steiner tree problem in networks. There have been volumes of work done on the Steiner tree problem in networks, including proposed solution methods, computational experiments, heuristics, probabilistic and worst-case analyses, and algorithms for special classes of graphs. Winter [41] and more recently Hwang and Richards [17] surveyed this body of work.

Karp [19] showed that the problem is NP-complete. Takahashi and Matsuyama [38], Kou, Markowsky and Berman [25], El-Arbi [11], Rayward-Smith [33], Aneja [2], and Wong [44] are among those who proposed heuristics. Among these, the heuristics that have been analyzed have a worst-case performance ratio of $2 - 2/k$, where k is the number of terminals that need to be connected (called Z-vertices in [41]). One algorithm, proposed by Plesnik [31] and by Sullivan [37], performs somewhat better. Recently Zelikovsky gave an approximation algorithm with a performance ratio of 11/6 [45]. Berman and Ramaiyer [6] have improved this to 16/9.

In computational experiments, these heuristics generally perform considerably better than the worst-case bounds. Jain [18] proposed an integer-program formulation of the Steiner tree problem in networks, and showed that for two random distributions of costs, the value of this integer program differed drastically from the value of its fractional relaxation.

2.2. The generalized Steiner problem in networks. The *generalized Steiner problem in networks*, as originally formulated by Krarup (see [42]), is as follows. The input consists of a graph with edge-costs, a subset Z of the vertices, and, for each pair of vertices $i, j \in Z$, a required edge-connectivity r_{ij}. The goal is to output a minimum-cost subnetwork satisfying the connectivity requirements. When the r_{ij}'s are allowed to be zero, we can clearly assume without loss of generality that Z consists of all the vertices of the graph.

Previous to our work, no approximation algorithms for the generalized Steiner problem were known. There have been papers on finding exact solutions and on algorithms for special classes of graphs [41], [42].

In the work of Goemans and Bertsimas, described below, and in our work, the edge-connectivity requirement is allowed to be satisfied in part by duplicating edges of the input graph. This corresponds to "buying" multiple communication links of the same cost and with the same endpoints.

2.3. Survivable networks. In recent work, Goemans and Bertsimas [14] considered a special case of the generalized Steiner problem in networks. Instead of arbitrary requirement values, the input includes an assignment of integers r_i to nodes. The goal is to find a minimum-cost network satisfying requirements $r_{ij} = \min(r_i, r_j)$. They propose a simple but powerful approach which involves solving a series of ordinary Steiner tree problems using a standard heuristic. They show that this approach yields solutions that are within a factor of $2\min(\log R, p)$ of optimal, where R is the maximum r_i and p is the number of distinct nonzero values r_i in the input. Moreover, they show that their analysis is tight in the worst case.

Goemans and Bertsimas restricted their attention to edge-connectivity requirements of the special form $r_{ij} = \min(r_i, r_j)$ so that each subproblem has essentially the form of an (ungeneralized) Steiner tree problem. That enabled them to solve each subproblem approximately, using one of the known approximation algorithms for the Steiner tree. By providing an approximation algorithm for the case of $r_{ij} \in \{0, 1\}$, we make it possible to handle requirements r_{ij} not of that special form.

2.4. Subsequent work. Building on our result, Goemans and Williamson [16] simplified and generalized our algorithm. They describe a framework in which to formulate and find approximately optimal solutions for many *constrained forest problems*, of which the minimum-cost R-join problem is an example. Their approximation algorithm uses an approach similar to ours and achieves the same performance guarantee. Goemans and Williamson describe an implementation of their algorithm that runs in $O(n^2 \log n)$ time on graphs with n nodes.

In work building on that of Goemans and Williamson, we showed [32] how to obtain approximately optimal solutions to 2-edge-connected versions of the problems addressed in [16]. In these problems, one needs to achieve 2-connectivity without duplicating links. Finally, several subsequent papers [15], [23], [40] extended these methods to give approximation algorithms for the generalized Steiner problem without link duplication.

3. Background. An instance of the generalized Steiner problem consists of a graph G with edge-costs c, together with a collection $\{R_1, \ldots, R_b\}$ of *requirements*: each requirement R_i consists of a *site pair* $\{s_i, t_i\}$, a pair of nodes of G, and a *requirement value* r_i, a positive integer. A feasible network is a multiset N consisting of edges of G, such that for every requirement $R_i = (\{s_i, t_i\}, r_i)$, there are at least r_i edge-disjoint paths between s_i to t_i in the multigraph with edges N.

3.1. The unweighted case. To prove performance guarantees for our algorithm, we exploit an approximate duality between feasible networks and packings of cuts. Fix some instance of the generalized Steiner problem, where all costs and requirement values are 1. Thus the instance consists of a graph G and a collection of site pairs $\{s_i, t_i\}$. Let k denote the cardinality of the set of sites, i.e., the set of nodes appearing in site pairs. Note that the number of sites may be significantly smaller than the total number of nodes. A *feasible network* is a subgraph in which, for every site pair $\{s_i, t_i\}$, there is a path between s_i and t_i.

Let N be any feasible solution for this instance. Observe that if N is minimal, then it is just a forest. Let S be any subset of nodes of G such that for some site pair $\{s_i, t_i\}$, one of the sites is in S and one is not. In this case, the set of edges A with exactly one endpoint in S is called a *requirement cut*. There must be a path between s_i and t_i in N, so N intersects A in at least one edge. Thus we have the following lemma.

LEMMA 3.1. *Every feasible network and every requirement cut have at least one edge in common.*

Suppose $A_1, \ldots, A_\beta$ are (not necessarily distinct) requirement cuts such that each edge of G occurs in at most two cuts. We call such a collection of cuts a 2-packing. Then we have the following easy lower bound on the minimum size of a network design.

LEMMA 3.2. *The minimum size of a feasible network is at least one-half the maximum size of a 2-packing of requirement cuts.*

Proof. Let N be a feasible network and let $A_1, \ldots, A_\beta$ be a 2-packing consisting of β requirement cuts. We have

$$|N| \geq \sum_{e \in N} \frac{1}{2} |\{i : e \in A_i\}| = \frac{1}{2} \sum_{i=1}^{\beta} |A_i \cap N| \geq \frac{1}{2}\beta \tag{1}$$

because each $|A_i \cap N|$ is at least one. □

For comparison, Edmonds and Johnson [10] show that T-joins and T-cuts satisfy an analogous inequality, and, more importantly, they satisfy it with equality.

Instead of showing equality, we show approximate equality, to within a factor of $2(1 - 1/k)$. This is the content of Theorem 1.3.

Our proof of Theorem 1.3 is algorithmic. We give an algorithm that constructs a feasible network and a 2-packing, such that the first has size at most $(1 - 1/k)$ times the second. It fol-

lows that the feasible network is approximately minimum and the 2-packing is approximately maximum, to within a factor of $2(1 - 1/k)$.

The first step is to transform the original graph G_0 into a bipartite graph G by replacing each edge uv of G_0 with two edges ux and xv in series, where x is a new node. The resulting graph G has the following properties:

- Any minimal feasible network in G corresponds to a feasible network in G_0 of half the size.
- Any packing of edge-disjoint requirement cuts in G corresponds to a 2-packing of requirement cuts in G_0 of the same size.

Consequently, in order to prove Theorem 1.3 for G_0, it is sufficient to show the following for G:

(2) we can find a feasible network N and a packing of edge-disjoint requirement cuts $A_1, \ldots, A_\beta$ such that $N \leq 2(1 - 1/k)\beta$, where k is the total number of sites.

We show (2) in §§4 and 5.

3.2. The weighted case. Now we consider the case in which the costs of edges may vary, but the requirement values are still all one. It turns out that, like Edmonds and Johnson's theorem, Lemma 3.2 and Theorem 1.3 are self-refining. For nonnegative integer edge-costs c, we simply replace each edge e by a path of length $c(e)$. We say a collection of requirement cuts is a $2c$-packing if each edge e appears at most $2c(e)$ times. Using this transformation, we obtain the following theorem from Theorem 1.3.

THEOREM 3.3. *The minimum-cost of a feasible network is at least one-half the size of a $2c$-packing of requirement cuts, and at most $(1 - 1/k)$ times this size.*

To actually compute an approximately minimum feasible network, we use a more direct approach, which we describe in §4.2.1.

3.3. Arbitrary integral requirements. So far we have dealt with the case in which each site pair need only be connected in the final feasible network. As discussed in the introduction and §2, a client may also require that there be at least r_{ij} edge-disjoint paths between her pair of sites.[2] Thus the case dealt with up to now requires each r_{ij} to be either 0 or 1.

In order to obtain an approximation algorithm for this generalized problem from our algorithm for the case of 0–1 requirements, we make use of a heuristic technique due to Goemans and Bertsimas [14]. They propose a technique they call the *tree heuristic*, which consists essentially of decomposing a problem with many different requirement values into a series of simpler problems in which only two requirement values appear. As we mentioned in §2, they use the technique for solving only a special case of the generalized Steiner problem. In conjunction with our new algorithms for the 0–1 case, however, the technique can be easily adapted to apply to the general case.

Let the different values of r_{ij} be $0 = p_0 < p_1 < p_2 < \cdots < p_s$. For each $0 < d \leq s$, consider the transformed problem

$$r_{ij}^d = \begin{cases} p_d - p_{d-1} & \text{if } r_{ij} \geq p_d, \\ 0 & \text{otherwise,} \end{cases}$$

which is essentially $p_d - p_{d-1}$ copies of a 0–1 problem. Use a standard heuristic to find an approximately optimal solution, and combine the solutions to the s transformed problems to

[2] In this case, the feasbile network is allowed to use multiple copies of edges of the input graph; each copy of a given edge costs the same.

get a solution to the original problem. The resulting performance guarantee is $\Theta(s)$.[3] By using a similar approach, if each r_i is an integer b bits long, then the original problem can be decomposed into b problems, and the resulting performance bound is $2(1 - 1/k)b$. This is how we get the performance bound stated in Theorem 1.2.

The obvious question is whether one can do better than this. Goemans and Bertsimas can show that their analysis is tight, so another approach is needed, one that can deal simultaneously with widely varying requirement values.

3.4. Reliability estimation. In the introduction, we described a heuristic for estimation of network reliability in a probabilistic network. In order to use this heuristic effectively, we want to find a maximum collection of edge-disjoint requirement cuts. This problem is NP-complete for general graphs. Moreover, an approximation algorithm for this cut-packing problem would yield an approximation algorithm for maximum independent set [9], an unlikely outcome in view of recent results [3], [4], [12]. We instead show how to make use of a cut-packing in bipartite graphs. We apply the transformation described in §3.1 to turn an arbitrary graph into a bipartite graph with all sites on one side of the bipartition: replace an edge having failure probability $1 - p$ with two series edges each having failure probability $1 - \sqrt{p}$. We do not change the probability of reliability in carrying out this transformation, and we can apply the algorithm of §4 to find an approximately maximum set of edge-disjoint cuts in the resulting graph.

Thus we propose a four-step recipe for estimating network reliability. Transform the network into a bipartite network, find an approximately maximum cut-packing, compute for each cut the probability that at least one edge survives, and multiply these probabilities to get an upper bound on the probability that all clients can continue to communicate.

4. The algorithm. In this section, we describe an algorithm for finding a cut-packing and an R-join. In §4.2, we describe how to find a cut-packing in the case of unit edge-weights. In §4.2.1 we describe the modification needed to handle arbitrary edge-weights. The algorithm for finding an R-join is the same in the two cases.

4.1. Overview. We start by providing an overview of the algorithm for the case of unit edge-weights. The algorithm grows breadth-first search trees from the sites, accumulating cuts as it proceeds. The algorithm employs a notion of timesteps. At each timestep, each of the breadth-first trees grows by an additional level. Each tree grows until all the sites it contains have found their mates. When trees collide, they are merged. As the algorithm grows trees, it builds networks spanning the sites in each of these trees. Using a charging scheme, we show that the size of each network in a tree is about twice the number of cuts accumulated while growing the tree.

4.2. Finding a cut-packing. Assume the input graph has unit edge-weights; we briefly address the more general case at the end of this subsection. Let G be a bipartite graph with all sites on the same side of the bipartition. (We can obtain such a graph from an arbitrary graph as described in §3.1. All subsequent references to the "original graph" refer to G.) We are given a collection of site pairs $\{s_1, t_1\}, \{s_2, t_2\}, \ldots, \{s_b, t_b\}$. We refer to the nodes s_i, t_i as *sites*. We say that two sites in the same site pair are *mates* of each other.

The algorithm for constructing the cut-packing is quite intuitive. (A summary is given at the end of this subsection.) We grow disjoint breadth-first search trees from all sites s simultaneously. We call the edges connecting one level to the next in a breadth-first search tree a *level cut*. Each level cut in a breadth-first search tree rooted at s is a requirement

[3] More specifically, Goemans and Bertsimas show the performance bound is $2(1 - 1/k)(\sum_{d=1}^{s}(p_d - p_{d-1})/p_d)$.

cut because its edges separate s from its mate. Thus at each timestep, we accumulate one additional requirement cut for each tree being grown.

When multiple trees collide, we merge them into a single tree and continue growing from its boundary. Thus in general a tree may contain many sites. As soon as every site in a tree has its mate in the same tree, we can no longer guarantee that subsequent level cuts of the tree are requirement cuts, so we call the tree *inactive*, and we contract all its nodes into a single *supernode*. A tree that is still in the process of being grown is said to be *active*. The algorithm terminates when there are no active trees. At this point, every site pair's two nodes are contained in the same tree. More precisely, since each tree has become inactive, and has hence been contracted to a supernode, there are no sites remaining in the graph.

Because of contractions, the graph on which we are working evolves during the course of the algorithm. We use G_t to denote the graph after t timesteps. When we refer to a graph, unless we explicitly call it the "original graph," we will mean the contracted graph G_t at a certain point t in the algorithm.

It is important to the analysis that all active trees grow at the same rate. The algorithm takes place over a series of timesteps. In each timestep, each active tree grows by one level. Thus after t timesteps, active trees that have not participated in any collisions all have radius t (as measured in the contracted graph G_t). More generally, let the *boundary* of a tree be the set of nodes at the most recent level of the tree. We have the following proposition.

PROPOSITION 4.1. *After t timesteps, each node in the boundary of an active tree is distance t from some site internal to the tree.*

In the initial bipartite graph, all the sites are on the same side of the bipartition. We show that this property continues to hold throughout the algorithm.

LEMMA 4.2. *After t timesteps, the graph is still bipartite, with all sites on the same side of the bipartition.*

Proof. The proof is by induction on t. The basis $t = 0$ is trivial. We must show that the bipartition property described in the lemma is preserved by contractions. Suppose that G_{t-1} obeys the property, and that after t timesteps, some tree T has just become inactive and is about to be contracted. By Proposition 4.1, all the nodes in the boundary of T have distance t from some site. Hence they all belong in the same side of G_{t-1}'s bipartition. It follows that after the nodes of T are contracted to a single node, the bipartition property still holds. □

We can use Lemma 4.2 to show that all the cuts found by the algorithm are edge-disjoint.

COROLLARY 4.3. *No edge belongs to a level cut of more than one tree.*

Proof. By Proposition 4.1 and Lemma 4.2, all the nodes in boundaries of all active trees are in the same side of the bipartition of the graph. Hence no edge is incident to two active trees. □

Thus trees collide by reaching the same node in a given step. Below we summarize the cut-packing algorithm. In anticipation of the analysis of the algorithm, we "assign" cuts found to particular trees.

1 Initialize each site to be an active tree. Repeat the following steps until every tree is inactive.
2 Grow each tree by one level. Assign the corresponding level cut to the tree.
3 Contract each tree that has just become inactive.
4 Repeat
5 Take two distinct trees sharing a boundary node, and merge them into a single tree. (For the cut-packing algorithm, merging trees consists merely of taking the union of their nodes and of the cuts assigned to them.)
6 Until no more trees can be merged.

Because trees are merged immediately after they collide, we can claim the following. Just before the trees are grown, they are node-disjoint. Just after the trees are grown, they are *internally* node-disjoint: only their boundaries can share nodes. We make use of this property in the next subsection.

4.2.1. The cut-packing algorithm for weighted edges. The cut-packing algorithm in the case of weighted edges is only slightly more elaborate. We describe it in this subsection. The algorithm to find a feasible network based on the cut-packing, described in the next section, remains unchanged.

The key is to carry out many timesteps in a single iteration. It is useful to imagine that in each iteration, the growing trees continuously "consume" all their incident edges at the same rate until some edge is completely consumed, at which time things must be updated. We assume for simplicity that the edge-weights are integral. For each edge, we maintain a variable indicating how much of that edge remains to be consumed. To determine the amount λ by which to grow active trees in an iteration, we compute two minima:

$$\lambda_1 = \min_e \text{ amount of } e \text{ yet to be consumed,} \tag{3}$$

where the min is over edges e that have one endpoint in an active tree, and

$$\lambda_2 = \min_e \text{ amount of } e \text{ yet to be consumed,} \tag{4}$$

where the min is over edges e that have both endpoints in distinct active tree.

Finally, we let $\lambda = \min\{\lambda_1, \frac{1}{2}\lambda_2\}$.

To grow the trees by λ, we update the variables associated with edges: each edge having one endpoint in an active tree has its variable decreased by λ, and each edge having its endpoints in distinct active trees has its variable decreased by 2λ (because each such edge is being consumed from both sides). Then we execute steps 3 through 6 of the unweighted algorithm. It follows by the definition of λ that at least one edge is wholly consumed in an iteration, hence at least one tree grows by at least one node. For a tree T, let t_T be the number of nodes in T. It follows that the potential function $\sum_T t_T$ − (number of trees) goes up by at least one in each iteration, and hence that the number of iterations is at most the number of nodes in the graph. Thus the cut-packing algorithm requires only polynomial time.[4]

4.3. The network-design algorithm. The basic approach to building a feasible network is also quite intuitive. For each tree, we maintain a connected network connecting together all sites in the tree. This is easy: start with each site being a network in itself, and, whenever trees merge, use simple paths to join up their two networks.

It is possible to show that for each tree, the size of a network for that tree is no more than twice the number of cuts assigned to the tree. Such an analysis, however, is insufficient: the networks formed in this way are not connected in the original graph, because of the contractions we have performed along the way. A path that contains a supernode is not in general a path in the original graph. Therefore, we must be more careful in joining networks, and must not forget to include edges between nodes within inactive trees. Note that such edges do not even appear in the contracted graph G_t.

We introduce some terminology to help us relate various contracted graphs to each other and to the original graph. We call a node a *real node* if it appears in the original graph, in

[4]Using a heap to organize the edges incident to each tree, one can implement the algorithm to run in $O(n^2 \log n)$ time [1]. Using a more sophisticated two-level heap structure, one can implement it in $O(n\sqrt{m} \log n)$ time [21].

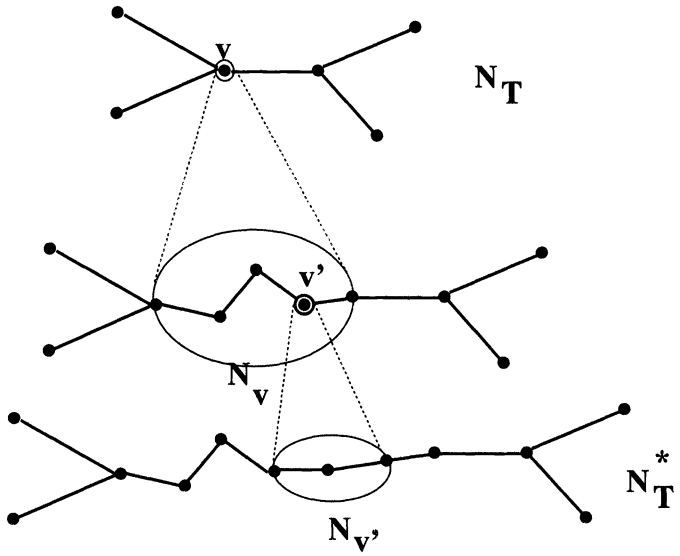

FIG. 2. *The network N_T corresponds in a natural way to a subgraph N_T^* of the original graph. To obtain N_T^* from N_T, replace each supernode v in N_T with the subgraph N_v and recurse on the supernodes in N_v, like v' above.*

order to distinguish such nodes from supernodes. If the tree T was contracted to form the supernode v, we say T *corresponds* to v, and vice versa. We say v *immediately encloses* v' if v is a supernode corresponding to a tree T containing v'. Note that each node is immediately enclosed by at most one node. A node enclosed by another node does not appear in the current graph, but we cannot simply forget about it since it continues to play a role in the algorithm.

We define the relation *encloses* to be the reflexive and transitive closure of the relation *immediately encloses*. That is, v encloses v' if by some series of contractions, v' was identified with other nodes to form v.

For an edge e incident to a node v in a contracted graph, there is a real node v' enclosed in v such that e is incident to v' in the original graph. We say that v' is the real node *by which e is incident to v*.

For each tree T, we maintain a *network* N_T, a subgraph of T. We maintain the following *site-inclusion invariant*:

- For each T, the network N_T includes all sites that are nodes of T.

We specifically mean to exclude those sites strictly enclosed by supernodes belonging to T. The site-inclusion invariant speaks only of those sites that are themselves nodes of T. If v is a supernode corresponding to an (inactive) tree T, we use T_v to denote T, and we use N_v to denote N_T. We say a node is *free* if it is not contained in any network N_T.

Each network N_T corresponds in a natural way to a subgraph N_T^* of the original graph. Namely, to get N_T^* from N_T, replace each supernode v in N_T with the subgraph N_v, and recurse on the supernodes in N_v (see Fig. 2).

We want each network N_T to correspond to a connected subgraph in the original graph. We therefore maintain the following *connectivity invariant*:

- Each subgraph N_T^* is connected.

At any stage in the algorithm, the networks N_T induce a subgraph of the original graph, namely the subgraph induced by the edges in $\bigcup_T N_T$ where the union is over all trees active and inactive. Let us call this subgraph N. Note that each induced subgraph N_T^* is a subgraph of N.

We now observe that when the algorithm terminates, the invariants imply that N is indeed a feasible network—for each site pair $\{s_1, s_2\}$, there is a path in N between s_1 and s_2. Let T be the tree containing s_1. Once the algorithm terminates, T must be inactive, and hence contains s_1's mate s_2 as well. By the site-inclusion invariant, s_1 and s_2 are nodes of N_T. Since they are original nodes, they are also nodes of the induced subgraph N_T^*, which is a subgraph of N. Finally, by the connectivity invariant, N_T^* is connected, so the required path exists.

Now we give the algorithm for network design. We run the cut-packing algorithm of the last subsection and, whenever a "merge" of trees occurs, we update the N_T's in order to maintain the invariants. Initially, when every active tree T consists of a single site, N_T consists also of this site. For each tree T not yet formed, N_T is empty. Thus trivially the invariants hold initially.

In step 5 of the cut-packing algorithm, we merge a pair of distinct trees T_1 and T_2 sharing a common boundary node v. By simply taking the union of their networks N_{T_i}, we get a network that obeys the site-inclusion invariant. However, this network does not obey the connectivity invariant. We must therefore connect up these networks. To do this, we add paths from the common node v to each of the networks N_{T_i}. This involves some care when v is a supernode. However, in this description of the algorithm, we postpone discussion of this case until §4.4. Assume therefore that v is a real node. We call a procedure CONNECTTONETWORK (v, T_i) for $i = 1, 2$.

The goal of CONNECTTONETWORK (v, T) is to augment various networks $N_{T'}$ until v is connected to N_T^*. To do this, the procedure first finds a shortest path P_0 in T from v to a site in T, identifies the shortest initial subpath P of P_0 that ends on a node of N_T, and adds the edges of P to N_T. We are not done yet; P does not necessarily correspond to a connected subgraph of the original graph because it may contain supernodes. Moreover, we have just added such supernodes u to N_T, so the networks N_u corresponding to these supernodes belong to N_T^*. In order to maintain the connectivity invariant, therefore, we must connect the networks N_u to N_T^*. We make these connections recursively using a procedure EXPANDPATH (u, P). This procedure expands P into a real path (i.e. a path in the original graph) by replacing each supernode u in the path with a subpath within T_u that connects a boundary node of T_u to u's network, goes through that network, and comes out again to the boundary of T_u. For technical reasons, EXPANDPATH does not replace the last node of P, so if this last node is a supernode, we use a recursive call to CONNECTTONETWORK to make this part of the path real. Making a path real using EXPANDPATH and CONNECTTONETWORK is illustrated in Fig. 3.

Now we give the procedure for CONNECTTONETWORK (v, T). Once again, the basic idea is to find a short path P in T from v to the network N_T, then introduce additional edges to make P correspond to a real path, i.e., a path among the real nodes.

CONNECTTONETWORK(v, T)

Assumption: The node v is a real node enclosed by some node v_0 in the boundary of T.

C1 Let v_0 be the node in T that encloses v.

C2 Let P_0 be a shortest path in T from v_0 to a site s. Let v_r be the first node of P_0 belonging to N_T, and let P be the subpath of P_0 from v_0 to v_r.

C3 Add P to N_T.

C4 Call EXPANDPATH(v, P) to make a real path out of P, except possibly for the last connection.

C5 If the last node v_r in P is a real node, then stop.

C6 Else,

C7 Let T' be the (inactive) tree corresponding to the supernode v_r.

C8 Let v' be the real node by which the last edge of P is incident to v_r.

C9 Recursively call CONNECTTONETWORK(v', T').

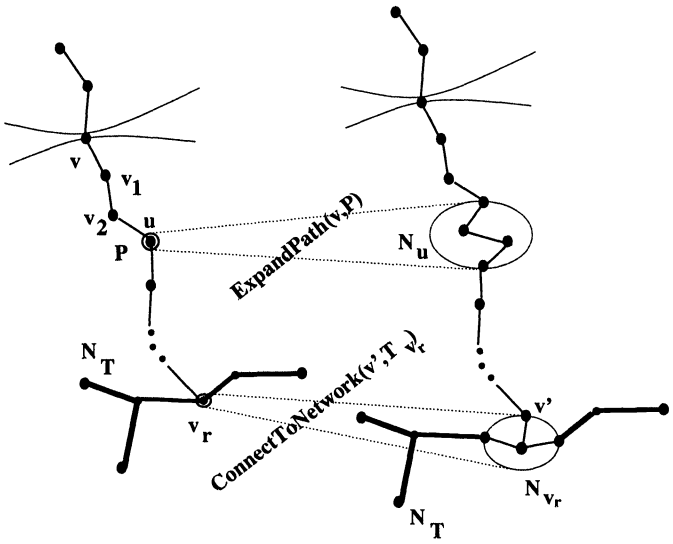

FIG. 3. *After identifying a path P of $v_1, \ldots, v_r$ to connect v to T, any supernode u in P is expanded by* EXPANDPATH(v, P) *into a connection via the network tree of u, N_u. If the last node in P, v_r is a supernode, it is recursively expanded to a path in the original graph by identifying a vertex v' on its boundary and calling* CONNECTTONETWORK(v', T_{v_r}) *recursively to connect v' to the network N_{v_r}.*

The procedure CONNECTTONETWORK uses a subprocedure EXPANDPATH(v, P) to make a real path out of P. For each node v of P except the last, if v is a supernode, we may have to add edges to N_v.

EXPANDPATH(v, P)
Assumption: P is a path in some tree T, whose first node encloses v, which is assumed to be a real node.

```
E1    Write P = v0 e0 v1 e1 ... e_{r-1} v_r.
E2    For i := 0 to r - 1 do
E3      Let v' be the real node by which e_i is incident to v_i.
E4      Comment: We must make a real path in N from v to v'.
E5      If v_i is a supernode then
E6        Let T be the tree corresponding to v_i.
E7        Call CONNECTTONETWORK(v, T).
E8        Call CONNECTTONETWORK(v', T).
E9        Comment: Now there is a real path from v to T's network to v'.
E10     Let v be the real node by which e_i is incident to v_{i+1}.
```

To prove that by using these procedures in the merge we maintain the connectivity invariant, we would use induction to show the following two statements. The call CONNECTTONETWORK(v, T) introduces edges in N_T^* to connect the real node v to N_T^*. The call EXPANDPATH(v, P) introduces edges in the networks N_{v_i} (for each supernode $v_i \in P$ except the last) so that the edges of P are connected up in N.

4.4. Merging trees whose common node is a supernode. To complete the description of the algorithm, we consider the case in which the node at which trees collide is a supernode rather than a real node. Let v be a supernode and suppose trees $T_1, \ldots, T_k$ collide at v at time t. We describe how to merge these trees.

To initialize, let $T = T_1$. For $i = 2$ to k, we merge T_i into T as follows. Since v is on the boundary of T_i, Proposition 4.1 ensures a path of length t from v to a site of T_i. Let e be the first edge on this path and let v_i be the real node by which e is incident to v. We then call CONNECTTONETWORK(v_i, T) and CONNECTTONETWORK(v_i, T_i). These calls establish a path going through v_i between the network of T and the network of T_i. We then let T be the resulting merged tree, i.e., $T := T \cup T_i$. This completes the merge of T_i into T.

The second invocation, CONNECTTONETWORK(v_i, T_i), needs some elaboration. As we shall see in the next section, the analysis of the algorithm requires that steps E7 and E8 of EXPANDPATH be executed at most once for a given tree T during the course of the algorithm. The first invocation of CONNECTTONETWORK(v_i, T) executes these two steps for the tree T_v corresponding to the supernode v. We must therefore avoid executing these steps in subsequent invocations of CONNECTTONETWORK. Fortunately, the choice of v_i enables us to avoid executing these steps, as we now explain.

Step C2 of CONNECTTONETWORK selects a path P_0 from the supernode v to a site in T_i. By choice of v_i, we can select the path P_0 so that its first edge is incident to the real node v_i in G. P is an initial subpath of P_0. Therefore, when we call EXPANDPATH(v_i, P) in step C4, we omit the iteration $i = 0$ in EXPANDPATH in which P's connection to v_i is made a real connection. This omission avoids reexecution of steps E7 and E8 of EXPANDPATH on the tree T_v.

5. Proving the performance guarantee of the R-join algorithm. To prove (2) of §3.1, we shall show that the cost of the feasible network produced by the algorithm is small relative to the number of cuts produced.

At any point in the execution of the algorithm, the *age* of a tree is the number of timesteps the tree grew. Thus the age of an active tree is the current number of elapsed timesteps, while the age of an inactive tree is the number of timesteps that had elapsed when the tree became inactive. We denote the age of a tree T by $age(T)$. We define the *connect-cost* of a call to the subroutine CONNECTTONETWORK as the number of edges added to the network by the routine not including any calls to the routine EXPANDPATH. That is, the cost for a call is the number of edges added in step C3, plus the cost of the recursive call in C9. We recursively define the *height* of a node to be 0 if it is a real node and one more than the maximum height of any node it encloses if it is a supernode.

LEMMA 5.1. *Steps* E7 *and* E8 *of* EXPANDPATH *are executed at most once for a given tree T through the course of the algorithm.*

Proof. Suppose we are about to begin the merging process for a given timestep. Through a series of calls to CONNECTTONETWORK, we build paths P that connect up some trees' networks. The key observation is that for every such path P, constructed in step C2 of CONNECTTONETWORK, every node of P except the last was previously free. (Recall that a *free* node is one that is not contained in any network N_T.) Moreover, since the edges of P are added to the network in step C3, such nodes are subsequently not free. Consequently, each node appears as a nonfinal node of a path P at most once during the course of the algorithm.

To complete the proof of the lemma, we need only add that a tree T for which steps E7 and E8 of EXPANDPATH(v, P) are executed corresponds to a nonfinal node v_i of the path P. □

LEMMA 5.2. *The connect-cost of a tree T is at most $age(T)$.*

Proof. We prove it by induction on the height of the nodes on the path from v to N_T. The statement trivially holds if all nodes have height 0, because by Proposition 4.1, v is at distance $age(T)$ from N_T.

Assume that the statement is true for nodes of height at most l. Let P be the path added in step C3, and let v_r be P's final node. By Proposition 4.1, P has at most $age(T)$ edges.

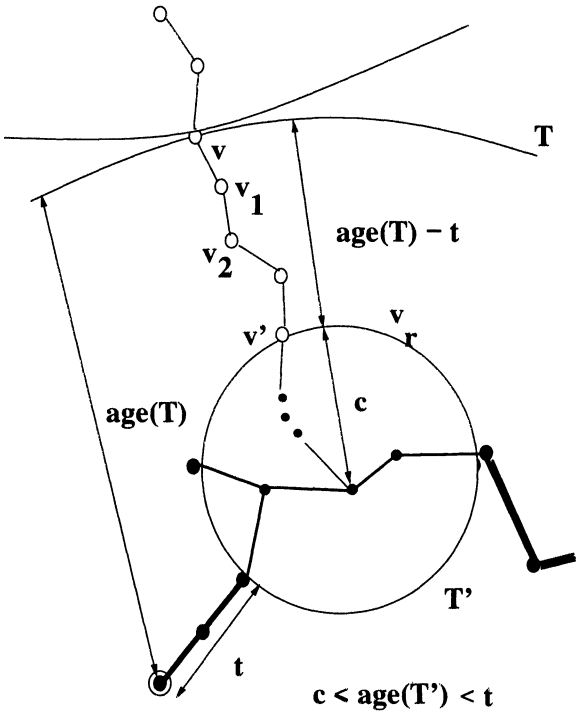

FIG. 4. *Proof of Lemma* 5.2 *that the cost of a call to* CONNECTTONETWORK *in the construction of the solution for the tree T is at most age(T).*

Therefore, if v_r is a real node, we are through. Otherwise, v_r corresponds to an inactive tree T'. The proof for this case is illustrated in Fig. 4. Let c be the cost of the recursive call CONNECTTONETWORK(v', T') in step C9. By the inductive hypothesis, c is at most $age(T')$, since no node in T' has height more than l. Suppose v_r was added to T after t timesteps. It follows that the number of edges in P is $age(T) - t$. Moreover, $age(T')$ is at most t, since T' was already inactive when v_r was added to T. Hence the total cost of the call to CONNECTTONETWORK which is $|P| + c$, is at most $age(T) - t + age(T')$, which in turn is at most $age(T)$. □

Define the *expand-cost* of a tree T as the cost of the calls CONNECTTO-NETWORK(v, T) and CONNECTTONETWORK(v', T) in steps E7 and E8. By Lemmas 5.1 and 5.2, the expand-cost of T is at most $2 \cdot age(T)$. Moreover, by the proof of Lemma 5.1, if the node v corresponding to T remains forever free, then these calls are never made, so the expand-cost of T is zero. We use $ExpandCost(T)$ to denote the expand-cost of T.

When trees $T_1, \ldots, T_r$ merge, the network N_T for the resulting tree T is constructed by taking the union of the networks for the T_i's, and then making some calls to CONNECTTONETWORK. We recursively define the cost of T as the sum of the costs of the trees merged to form T, plus the costs of the calls to CONNECTTONETWORK. Thus the cost of a tree T is the number of edges added to create N_T^*, not including edges added in steps E7 and E8 of EXPANDPATH. We denote the cost of T by $Cost(T)$.

We will charge the cost of a tree against the number of cuts assigned to the tree. Recall from the cut-packing algorithm that in each timestep we grow each tree, and assign the corresponding level cut to the tree. Moreover, when trees are merged, their cuts are assigned to the resulting tree. We denote the number of cuts assigned to a tree by $CP(T)$.

LEMMA 5.3. *After t timesteps have elapsed, the cost of a tree T is at most $2 \cdot CP(T) - 2 \cdot age(T)$.*

Proof. We shall prove this statement by induction on the number t of elapsed timesteps. When t is 0, the lemma holds trivially. Assume that the statement holds for t. During the $t+1$st timestep, each active tree T, is grown by one level, so $CP(T)$ goes up by one, while its age also increases by one. So far, so good. Next, trees are merged. The additional cost incurred in merging $T_1, \ldots, T_r$ to form a tree T is the cost of $2(r-1)$ calls to CONNECTTONETWORK, each at cost at most $age(T)$ by Lemma 5.2. Hence the total cost of T is

$$2(r-1)age(T) + \sum_{i=1}^{r} Cost(T_i)$$

which, by the inductive hypothesis, is at at most $2(CP(T) - age(T))$. □

Now we can bound the size of the feasible network output by our algorithm. The size is the sum, over all inactive trees T of the cost of T plus the expand-cost of T. For any tree T whose node remains free, the expand-cost is zero. Let us call a tree free if its corresponding supernode is free. Thus we have

$$\begin{aligned} &\text{size of feasible network} \\ &\leq \sum_{T} Cost(T) + ExpandCost(T) \\ &\leq \sum_{\text{free } T} Cost(T) + \sum_{\text{unfree } T} (Cost(T) + ExpandCost(T)) \\ &\leq 2(\sum_{T} CP(T) - \sum_{\text{free } T} age(T)), \end{aligned} \tag{5}$$

where the last inequality follows from Lemma 5.3 and our remarks about expand-cost.

Since $\sum_T CP(T)$ is the total number of cuts assigned by the cut-packing algorithm, we have proved a version of (2) with a factor of 2 instead of $2(1-1/k)$. To get the smaller factor, we prove a lower bound on the second sum in (5).

For a tree T, let k_T denote the number of sites that are nodes of T. Define $k_T^* = \sum\{k_{T'} : T \text{ encloses } T'\}$. Similarly, let $CP^*(T) = \sum\{CP(T') : T \text{ encloses } T'\}$.

LEMMA 5.4. *For any tree T, $age(T)$ is at least $CP^*(T)/k_T^*$.*

Proof. The key observation is that for any tree T', $CP(T')$ is at most $k_{T'}$ times $age(T')$, since each of the $k(T')$ sites is assigned a maximum of one cut per timestep until $age(T')$ timesteps. If T' is enclosed by T, then $age(T')$ is at most $age(T)$, so we have

$$\begin{aligned} CP^*(T) &= \sum\{CP(T') : T \text{ encloses } T'\} \\ &\leq \sum\{k_{T'} : T \text{ encloses } T'\} age(T) = k_T^* age(T). \end{aligned}$$ □

We use Lemma 5.4 to get our lower bound on $\sum\{age(T) : T \text{ free}\}$. Let $k^* = \max\{k_T^* : T \text{ free}\}$. Then by Lemma 5.4, for each free tree T, $age(T) \geq CP^*(T)/k^*$. Since each tree is enclosed by some free tree, $\sum\{CP^*(T) : T \text{ free}\}$ is the total number CP of cuts assigned. Hence

$$\sum\{age(T) : T \text{ free}\} \geq CP/k^*. \tag{6}$$

Substituting into (5) and replacing k^* by k, the total number of sites, gives (2) and completes the proof of Theorem 1.3.

6. Further directions for research. Two important variants of the basic Steiner tree problem in networks are the node Steiner problem [34], in which nodes are assigned costs, and the directed Steiner tree problem, in which the input graph is directed and one seeks a directed tree as the solution. It is an open problem to find good approximation algorithms for either problem. It was observed by Berman [5] that the set cover problem is reducible to the node Steiner problem via an approximation-preserving transformation. Khuller [20] made an analogous observation concerning the directed Steiner tree problem. In fact, Segev [34] gave an approximation-preserving reduction from the node Steiner problem to the directed Steiner problem. In view of Lund and Yannakakis' recent result showing that the set cover problem cannot be approximated by a factor smaller than logarithmic [28], it is natural to ask whether there are logarithmic-factor approximation algorithms for the node and directed Steiner problems. We have recently discovered such an algorithm for the former problem [24].

RECTILINEAR PATH PROBLEMS AMONG RECTILINEAR OBSTACLES REVISITED*

CHUNG-DO YANG†, D. T. LEE‡, AND C. K. WONG§

Abstract. Efficient algorithms are presented for finding rectilinear collision-free paths between two given points among a set of rectilinear obstacles. The results improve the time complexity of previous results for finding the shortest rectilinear path the minimum-bend shortest rectilinear path, the shortest minimum-bend rectilinear path and the minimum-cost rectilinear path. For finding the shortest rectilinear path, a graph-theoretic approach is used and an algorithm is obtained with $O(m \log t + t \log^{3/2} t)$ running time, where t is the number of extreme edges of given obstacles and m is the number of obstacle edges. Based on this result an $O(N \log N + (m+N) \log t + (t+N) \log^2(t+N))$ running time algorithm for computing the L_1 minimum spanning tree of given N terminals among rectilinear obstacles is obtained. For finding the minimum-bend shortest path, the shortest minimum-bend rectilinear path, and the minimum-cost rectilinear path, we devise a new dynamic-searching approach and derive algorithms that run in $O(m \log^2 m)$ time using $O(m \log m)$ space or run in $O(m \log^{3/2} m)$ time and space.

Key words. rectilinear shortest path, minimum-bend path, path preserving graph, computational geometry, rectilinear obstacles

1. Introduction.

The problem of finding paths among obstacles has been extensively studied in the past. As the integrated circuits draw more research interest, finding rectilinear paths using different criteria has become an important variation of the traditional shortest path problem in automated circuit design. Both measures, the *number of bends* and the *length* of a rectilinear path, are two important factors while routing between two points among a set of rectilinear obstacles. Many efficient algorithms about finding rectilinear paths with respect to these two factors separately or jointly have been obtained [3], [4], [8], [10]–[14], [16], [18]. There are two particularly good results for finding shortest path (SP). The first, due to Clarkson, Kapoor, and Vaidya [3], runs in $O(m \log^{3/2} m)$ time, where m is the number of obstacle edges. The second, due to Wu et al. [16], runs in $O(m \log t + t^2 \log t)$ time, where t is the number of extreme edges of given obstacles. Mitchell [11] proposed a wave-front approach to find the shortest rectilinear path in $O(m \log^2 m)$ time, which is later reported to run in $\theta(m \log m)$ time after some modifications [12]. An edge on the boundary of an obstacle is an *extreme* edge if its two adjacent edges lie on the same side of the line containing the edge. Results from [3], [11], [12] are also applicable to any polygonal obstacles. Here we only focus on rectilinear paths. In this paper we shall present an $O(m \log t + t \log^{3/2} t)$-time algorithm that combines features of both results to find a shortest path. Finding the minimum spanning tree (MST) among N terminals can also be solved in $O(N \log N + (m+N) \log t + (t+N) \log^2(t+N))$ time based on the same method, which improves the $O(N \log N + (m+t^2) \log t)$-time algorithm due to Wu et al. [16].

With regard to the number of bends, Ohtsuki [13] proposed an $O(m \log^2 m)$-time and $O(m)$-space algorithm for finding a minimum-bend path (MBP). By combining their algorithms with the data structure from Imai and Asano [6], finding a minimum-bend path can be solved in $\theta(m \log m)$ time and space.

When both measures are considered jointly one may define problems by assigning different optimization priorities to length and bends. Recently, Yang, Lee, and Wong [17] presented algorithms to find a minimum-bend shortest path (MBSP), a shortest minimum-bend path (SMBP) and also a minimum-cost path (MCP) in $O(mt + m \log m)$ time, where t is the number of the extreme edges. We shall show below that this class of problems can be solved in $O(m \log^{3/2} m)$ time by applying a *hybrid* approach, called *dynamic-searching*, which is a combination of the graph-theoretic approach and the continuous-search (e.g., wave-front) approach. We first generate a graph just for guidance purposes and then by traversing the graph construct the corresponding rectilinear paths on the fly, thereby obtaining our goal path.

In the following, we first define our problems and give some preliminaries in §2. In §3, we show the faster algorithm for SP and MST. In §4, we focus on solving MBSP, SMBP, and MCP. We introduce the dynamic-searching approach and the guidance graph and then present our algorithms. The conclusion follows in the last section.

2. Preliminaries. A *rectilinear path* Π_{pq} is a path connecting two points p and q, which consists of only horizontal and vertical line segments.

Given two terminals s and d and a set of rectilinear obstacles, we define the following problems.

Problem SP is to find a path with the shortest distance. Such a path is called the shortest path, denoted *sp*.

Problem MBSP is to find a path with a minimum number of bends among all the shortest paths from s to d. Such a path is called the minimum-bend shortest path, denoted *mbsp*.

Problem SMBP is to find the shortest one among all the minimum-bend paths from s to d. Such a path is called the shortest minimum-bend path, denoted *smbp*.

Problem MCP is to find the minimum-cost path from s to d where the cost is a nondecreasing function f of the number of bends and the length of a path. Denote such a path *mcp*.

Each of the input obstacles is specified by a sequence of edges in clockwise order. An *extreme edge* is an obstacle edge with both of its adjacent edges lying on the same side of the line containing it. An *extreme point* is an endpoint of an extreme edge. Let m be the number of obstacle edges and t be the number of extreme edges. Let *EXTM* be the set of extreme points and let V be the set of obstacle vertices. Note that for a convex rectilinear polygon, there are only four extreme edges and eight extreme points. Much of the following discussion will be on a point set, $\{s, d\} \bigcup EXTM$, which will be denoted as *EXTMSD*.

We now define a basic graph generated by Clarkson, Kapoor, and Vaidya [3], which will be used in both of our algorithms for SP and for MBSP, SMBP and MCP.

DEFINITION 1. *Let R_{pq} denote the closed rectangle with segment $\overline{pq}$ as its diagonal. Given a set of points S, a point $q \in S$ is a* staircase point *of a point $p \in S$ if and only if R_{pq} does not contain any point in S other than p and q. Let $SC(p)$ denote the set of staircase points of point p.*

We recall an important property employed by Clarkson, Kapoor, and Vaidya [3] and refer to their algorithm as Algorithm C in what follows. That is, a shortest path from one point p to some other point q can always be replaced by subpaths going from p to one of its staircase points and the same holds for subsequent subpaths. With this property, Algorithm C obtains a graph on the vertex set, $V \bigcup \{s, d\}$, by adding all the edges between points and their staircase points. Such a graph, which preserves shortest paths, may contain $O(m^2)$ edges and $O(m)$ vertices, which yields a basic $O(m^2)$-time path-finding algorithm. Then by introducing *Steiner points* to the graph, they reduce the graph to have $O(m \log m)$ vertices and edges, referred to as Algorithm C1. Algorithm C1 constructs the graph in a recursive manner. A

cutting line that divides the vertices in two halves is introduced first. Then all the vertices are projected onto this line, creating *Steiner points*. Edges are added between vertices and their corresponding Steiner points, and between consecutive Steiner points. Recursively perform the cutting, projecting and adding edges on the subsets of vertices that lie on both sides of the cutting line. Since each vertex can create at most $O(\log m)$ Steiner points, the number of vertices of the graph is $O(m \log m)$. The edges, which are either horizontal or vertical, are also added during the creation of Steiner points. Therefore, it is not difficult to see that there are $O(m \log m)$ edges. The time complexity to search this graph for a shortest path is thus $O(m \log^2 m)$.

To further improve the time complexity, they use a *grouping* technique to generate more edges but fewer vertices, i.e., $O(m \log^{3/2} m)$ edges and $O(m \log^{1/2} m)$ vertices, for the graph and are able to reduce the time complexity of the searching to $O(m \log^{3/2} m)$. This algorithm is referred to as Algorithm C2. The grouping technique is to virtually cut the space into strips before they generate Steiner points such that each strip contains only $O(\sqrt{\log m})$ points. In each strip, only two Steiner points are created (the highest and the lowest) to provide connections across strips. Inside a strip, an edge is created for each pair of vertices that lie on different sides of the cutting line. It can be proved that such a graph still preserves the shortest path. Note that this refined graph contains some *oblique* edges due to the direct connections inside each strip. This property makes this graph different from the previous one when we use it in our algorithm later. We refer the reader to [3] or [10] for details of these algorithms.

By applying Fredman and Tarjan's $O(|E| + |V| \log |V|)$ shortest path algorithm [5] on the final graph, they obtain the shortest path in $O(m \log^{3/2} m)$ time.

On the other hand, the algorithm of Wu et al. [16], referred to as Algorithm W, finds the rectilinear shortest path among rectilinear obstacles by first constructing a so-called "*track graph*" based on the extreme edges. Horizontal and vertical tracks, which are projected from extreme edges, are the edges and the intersections of these tracks are the vertices of the track graph. The graph plus the graph representing the obstacle vertices and edges, is of size $O(m + t^2)$, hence yielding an $O(m \log t + t^2 \log t)$ time algorithm.

Depending on the values of t and m, Algorithm W may be asymptotically more efficient than Algorithm C2 and vice versa.

Before we present our algorithm, which is better than both, let us give some preliminary results.

DEFINITION 2. *A* U-shaped *subpath* (*or* U-subpath *for short*) *consists of three segments, s_1, s_2, and s_3 such that s_1 and s_3 lie on the same side of the line containing s_2; segment s_2 is referred to as the* U-segment *of the* U-*subpath. A* staircase *path is a path containing no* U-*subpath.*

LEMMA 2.1 (see Fig. 1). *Any sp, mbsp, smbp, or mcp, $\Pi_{s,d}$, from s to d can be divided into a sequence of subpaths $\pi_i, i = 1, \ldots, m$, such that all π_i's are staircase paths and the start and endpoints of all π_i are points in EXTMSD.*

Proof. If the U-segments of all the U-subpaths of $\Pi_{s,d}$ contain extreme points, then each U-subpath can be cut into subpaths at these extreme points and each subpath will satisfy the property as claimed. Consider now a U-subpath of $\Pi_{s,d}$ denoted as s_1, s_2, and s_3, such that its U-segment does not contain any extreme point (as in Fig. 1). We can always *shorten* the U-subpath by shrinking s_1 and s_3 and moving s_2 accordingly without incurring any bends. A strictly better *sp*, *smbp*, *mbsp*, or *mcp* can therefore be obtained, which yields a contradiction. That is, any *sp*, *mbsp*, *smbp*, or *mcp* can be represented by a sequence of staircase subpaths starting and ending at points in *EXTMSD*. □

The above lemma implies that it is sufficient to just consider staircase paths while deriving efficient algorithms.

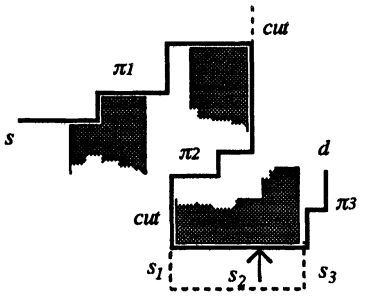

FIG. 1. *Divide a path into staircase subpaths.*

3. A faster algorithm for SP.

3.1. A smaller path-preserving graph. Our algorithm is based on the following observation that it is sufficient to generate a shortest-path-preserving graph by just considering the extreme points and their projection points when using Algorithm C1 or C2.

DEFINITION 3. *Given a set of obstacles, define* the projection point set $\mathcal{P}(p)$ *of a point* p *to be* $\{q | q$ *is on some obstacle boundary and* $\overline{qp}$ *is a horizontal or vertical collision-free segment*$\}$.

Let $PJ = \{q | q \in \mathcal{P}(p), p \in EXTMSD\}$ and $I = EXTMSD \bigcup PJ$ denote the set of *essential points*, which are used in the construction of the backbone of the shortest-path-preserving graph. They are not, however, the only vertices in the final graph.

DEFINITION 4. *Define the graph* $SPG0$ *to be a graph with vertex set equal to* I *and edge set equal to* $\{(a, b) | a, b \in I, a \in SC(b)\}$. *The cost of edge* (a, b) *is the rectilinear distance between points* a *and* b.

The graph $SPG0$ is the backbone of the graphs that we generate later. $SPG0$ contains in the worst case $O(|I|)$ (or $O(t)$) vertices and $O(|I|^2)$ (or $O(t^2)$) edges. We adopt the graph reduction method used in Algorithm C1 by introducing Steiner points. Let SPG_r denote the reduced graph we generate. Let SPG_{rr} denote the refined, reduced graph when the method of Algorithm C2 is used. We have the following lemma whose proof is similar to that given in [3], [10], [14].

LEMMA 3.1. SPG_r *has* $O(|I| \log |I|)$ *vertices and edges, and can be computed in* $O(m \log |I| + |I| \log |I|)$ *time.* SPG_{rr} *has* $O(|I| \log^{1/2} |I|)$ *vertices and* $O(|I| \log^{3/2} |I|)$ *edges, and can be computed in* $O(m \log |I| + |I| \log^{3/2} |I|)$ *time.*

DEFINITION 5. *Define the boundary graph* BG *to be a graph with vertex set equal to* $EXTM \bigcup PJ$ *and edge set equal to the set of edges connecting* p *and* q *in the vertex set that lie consecutively on the boundary of an obstacle. The cost of the edge* (p, q) *is defined to be the shorter rectilinear path length along the boundary of the obstacle connecting points* p *and* q.

Let SPG be the union of SPG_{rr} and BG. The following lemma is easily established.

LEMMA 3.2. SPG *contains* $O(t \log^{1/2} t)$ *vertices and* $O(t \log^{3/2} t)$ *edges.*

We now prove that SPG is a shortest-path-preserving graph. Since the extreme points are in SPG, from Lemma 2.1 it is sufficient to show that for any shortest path all its subpaths connecting points in $EXTMSD$ are embedded in SPG.

LEMMA 3.3. *If there exists a shortest staircase path* RP *connecting two points* $p, q \in EXTMSD$, *then there is a path* P *in* SPG *connecting* p *and* q *with the same length as* RP.

Proof. Denote the abscissa and ordinate of a point p as $p.x$ and $p.y$, respectively. Without loss of generality, let $p.x \leq q.x$ and $p.y \leq q.y$, as shown in Fig. 2(a). Let the sequence of adjacent segments in RP be denoted as $h_1, v_1, h_2, v_2, \ldots, h_g, v_g$, where h_i's are horizontal

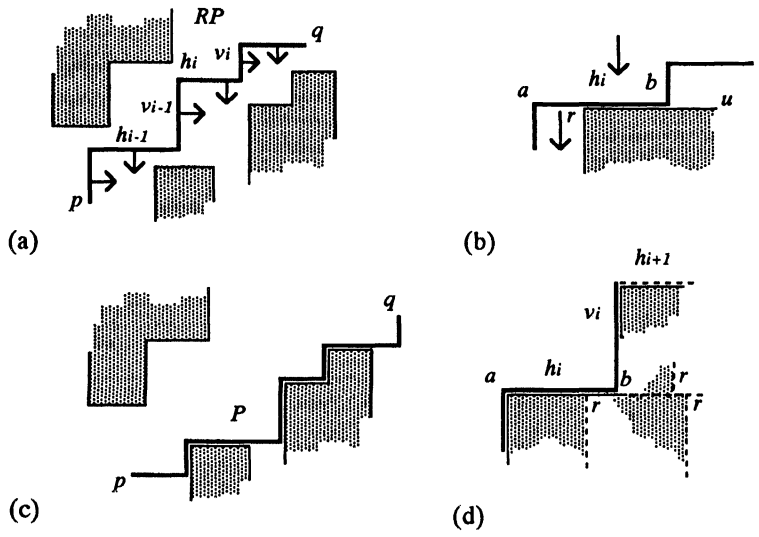

FIG. 2. *Situations while dragging paths.*

segments and v_i's are vertical segments. h_1 and v_g can be empty, respectively. Apparently, the path is in R_{pq}. If there is no obstacle intersecting R_{pq}, then p and q are staircase points of each other, and P is an edge in SPG. Suppose that there are obstacles in R_{pq}. We perform the following dragging operations to h_i from $i = 1$ to $i = g$:

(1) Drag h_i downward until it either is as low as p, hits some obstacle, or is as low as h_{i-1}. In the last case, merge h_i and h_{i-1} to be one horizontal edge.

(2) If $h_i = (a, b)$, $a.x < b.x$, hits some obstacle on edge (r, u) but $r \neq a$, then break h_i into two segments, (a, r) and (r, b) and perform dragging operations on (a, r) (Fig. 2(b)).

(3) At each dragging, the adjacent vertical segments are adjusted accordingly.

We then perform the same dragging operations to the vertical segments on RP except that we drag them rightward and adjust horizontal segments accordingly.

Denote as P the resultant path (Fig. 2(c)) after performing these operations. It is not hard to see that P has the following properties: first, it has the same length as RP; second, it is a staircase path; third, all the turning points between h_i and v_{i-1} (after re-ordering segments on P as $\{h_1, v_1, \ldots, h_{g'}, v_{g'}\}$) will be an *upper-left* corner of an obstacle. Since we focus only on paths between points in *EXTMSD*, we may assume that there is no extreme point on P. Otherwise, those subpaths formed by cutting P at those extreme points can be considered respectively.

Consider a horizontal edge $h_i = (a, b)$, $1 < i \leq m'$ (treat all the other horizontal segments similarly and all vertical ones symmetrically). As in Fig. 2(d), point a is either p or a corner vertex of an obstacle as shown before. Let (a, r) be the edge of obstacle o containing a.

(1) If the boundary of o turns downward at r and $r.x \leq b.x$, then r is an extreme point on (a, b), which violates our assumption.

(2) If it turns upward at r, $r = b$ is a vertex of o.

(3) If it turns upward or downward at r where $r.x > b.x$ and h_{i+1} exists, then v_i must align with an *extreme* edge γ (due to the rightward dragging we performed on v_i) of a possibly different obstacle and b is its projection on o. If h_{i+1} does not exist in this case, then v_i must connect q, which also makes b a projection point. Thus, b is a projection point on o. Therefore h_i is part of an edge in the boundary graph.

All edges in P satisfying (2)–(3) are either connecting extreme points to the projections or connecting points in $EXTM \bigcup PJ$ along the boundary of obstacles. The first kind of edges are all in SPG_{rr}, and the second kind of edges are in BG and thus also included in SPG. Note that the dragging operations may be performed symmetrically by shifting horizontal segments upwards and vertical segments leftward. Since all the edges or subpaths of P are embedded by SPG, the lemma is proved. □

We conclude with the following theorem.

THEOREM 3.4. *SPG is a shortest-path-preserving graph.*

Now we summarize the algorithm to construct SPG and find the shortest rectilinear path.

Algorithm FindSRP.

1. Sort all the obstacle edges on their X and Y coordinates.
2. By plane-sweeping horizontally and vertically, find the projection set PJ. Projection points are recorded in order in lists associated with every obstacle edge. Each such list can be implemented as a balanced binary search tree [1].
3. Find the boundary graph BG along all obstacle boundaries by using $EXTM$ and PJ as its vertex set. This is done by traversing the obstacle boundary and linking up all the extreme points and the projection points in lists associated with obstacle edges.
4. Find SPG_{rr} as in Algorithm C2 using $EXTMSD \bigcup PJ$ as the vertex set.
5. Merge SPG_{rr} and BG to obtain SPG.
6. Find the shortest path from s to d on the graph SPG using Fredman and Tarjan's algorithm [5].

THEOREM 3.5. *The Algorithm FindSRP finds the shortest rectilinear path from s to d among rectilinear obstacles in $O(m \log t + t \log^{3/2} t)$ time using $O(m + t \log^{3/2} t)$ space.*

Proof. Steps 1 and 2 take $O(m \log t)$ time. For step 3, computing BG can be done in $O(m)$ time by traversing along the obstacle boundaries. For step 4, construction of SPG_{rr} can be computed in $O(m \log t + t \log^{3/2} t)$ time. The reader is referred to [3], [10], [14]. Since SPG_{rr} contains $O(t \log^{3/2} t)$ edges and $O(t \log^{1/2} t)$ vertices, and BG contains $O(t)$ edges and vertices, the combined SPG can be computed in time linear in the size of SPG. Finally, in step 6, applying Fredman and Tarjan's shortest path algorithm on SPG that runs in $O(|E|+|V| \log |V|)$ time, we are able to find the shortest rectilinear path in $O(t \log^{3/2} t)$ time. Overall, the time needed is of $O(m \log t + t \log^{3/2} t)$. The space needed is $O(m + t \log^{3/2} t)$. The correctness of the algorithm follows immediately. □

3.2. Finding MST among obstacles. With the same approach, one can handle multiple input points and generate a similar graph where the minimum spanning tree (MST) is preserved. Given N terminals, Wu et al. [16] obtained the MST in $O(N \log N + (m+t^2) \log t)$ time based on the *track graph*. Here we simply let the essential point set be the same as we used before with all the N input terminals included. As mentioned earlier, based on Algorithm C1, we can generate SPG_r containing only $O(|I| \log |I|)$ edges and vertices for the essential point set I. Combining this graph with the boundary graph we have a different shortest-path-preserving graph, denoted SPG_m, with $O((t + N) \log(t + N))$ edges and vertices.

Since the pairwise shortest paths are all retained in SPG_m, the MST is also retained. We then adopt the algorithm presented by Wu et al. [15], [16] that runs in $O(|E_G| \log |V_G|)$ time for finding an MST among a set of points S on a graph $G = (V_G, E_G)$ with $S \subseteq V_G$.

THEOREM 3.6. *The minimum spanning tree of N terminals among obstacles can be computed in $O(N \log N + (m + N) \log t + (t + N) \log^2(t + N))$ time, where m is the number of obstacle edges and t is the number of the extreme edges of obstacles.*

4. Faster algorithms for MBSP, SMBP, and MCP. We now deal with problems, MBSP, SMBP, and MCP. We shall refer to any of *mbsp*, *smbp*, or *mcp* as an *optimal path*.

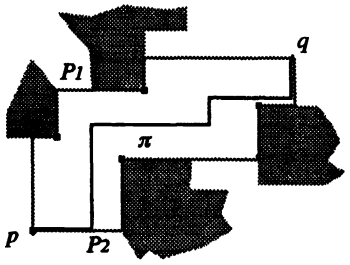

FIG. 3. *The corridor of a path.*

DEFINITION 6. *A point p is said to* 1-dominate *a point q if the X- and Y-coordinates of p and q satisfy the condition* $p.x \geq q.x$ *and* $p.y \geq q.y$. *In other words, point p lies in the first quadrant when point q is placed at the origin.* 2,3,4-dominating *relations are defined symmetrically.*

Redefining the *essential point set* in Definition 3.1 to be $V \bigcup \{s, d\}$, and using Algorithm C1, we obtain a graph, referred to as *guidance graph*, and denoted as GG. The guidance graph will be used to *guide* our path finding algorithm. The graph was also exploited by Lee, Yang, and Chen [10] to solve shortest path problems when the obstacles are *weighted.* We summarize some properties of GG as follows.

LEMMA 4.1 ([3], [10], [14]). *GG has the following properties:*

(1) It has $O(m \log m)$ edges and vertices.

(2) V is a subset of the vertex set of GG.

(3) All edges in GG are horizontal or vertical.

(4) For any two points p and q in V, if R_{pq} is empty, then there is a shortest path between p and q in GG.

(5) It can be constructed in $O(m \log m)$ time using $O(m \log m)$ space.

We show below that the guidance graph contains at least a path that is homotopic to an optimal path.[1] Lemma 2.1 implies that if for any staircase subpath π of an optimal path between two points p and q in V, we can find a path in GG between p and q that is homotopic to π, then there is always a path in GG that is homotopic to the optimal path. We introduce the *corridor* of a staircase path between two points p and q in V. We consider only the staircase (first type) where point q 1-dominates point p. The corridor of a staircase (second type) where q 2-dominates p is defined similarly. Without loss of generality, a staircase in the following discussions refers to the first type. The second type of staircase can be treated similarly. Let π_{pq} denote the staircase path in R_{pq} for $p, q \in V$ and q 1-dominates p. Let $D(\pi_{pq})$ and $U(\pi_{pq})$ denote the sets of vertices in V that lie in R_{pq} and below and above π_{pq}, respectively.

DEFINITION 7 (see Fig. 3). *Given two points* $p, q \in V$, *with q* 1*-dominating p, and a staircase path* π *from p to q, define* corridor(p, q, π) *to be the* open *rectilinear region enclosed by two staircase paths from p to q, denoted* P_1 *and* P_2, *where* P_1 *and* P_2 *satisfy the following:* P_1 *passes through and makes upward turns at points in* $U(\pi_{pq})$ *that are not* 4*-dominated by any other point in* $U(\pi_{pq})$ *and* P_2 *passes through and makes rightward turns at points in* $D(\pi_{pq})$ *that are not* 2*-dominated by any other point in* $D(\pi_{pq})$.

One can see that the *corridor*(p, q, π) does not contain any points of V and all staircase paths between p and q in *corridor*(p, q, π) are homotopic to each other.

LEMMA 4.2. *There exists a path* π *from s to d in GG such that* π *is homotopic to an optimal path from s to d.*

[1] Two paths are homotopic to each other if one can be continuously dragged to become the other without crossing any points in V.

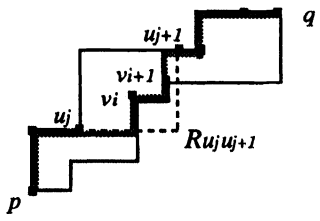

FIG. 4. *A path in the corridor and GG.*

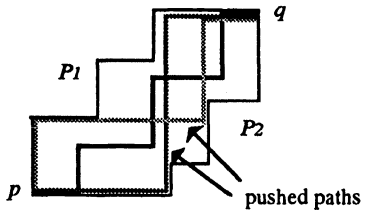

FIG. 5. *Two pushed paths from p in a corridor.*

Proof. From Lemma 2.1, we can focus on a staircase subpath between two points p and q in V. Let π^*_{pq} denote a staircase subpath from p to q of an optimal path. Let $u_{i,i=1,\ldots,k}$ and $v_{i,i=1,\ldots,t}$ represent the points in V on P_1 and P_2 that define *corridor*(p, q, π^*_{pq}), respectively (Fig. 4). v_i 1-dominates v_j if $i > j$ and u_k 1-dominates u_l if $k > l$. Now let $z_{i,i=1,\ldots,r}$ be any *maximal* sequence such that z_i is in $u_{i,i=1,\ldots,k}$ or in $v_{i,i=1,\ldots,t}$, and z_i 1-dominates z_j if $i > j$. Apparently, all z_i's are in V and for every two consecutive elements z_i and z_{i+1}, there is no other point in $R_{z_i z_{i+1}}$. According to the definition of GG, GG provides the connection between z_i and z_{i+1} and thus there is a path in GG connecting p and q through $z_{i,i=1,\ldots,r}$. We therefore conclude that there is a path from s to d embedded in GG that is homotopic to any optimal path from s to d. □

DEFINITION 8 (see Fig. 5). *Define a pushed staircase path from p to q in corridor*(p, q, π) *to be a staircase path from p to q, such that the path only makes turns alternately at points on* P_1 *and* P_2. *Any two-segment subpath, connecting a horizontal and a vertical segment, is called an* L-subpath. *A* canonical path *from s to d is a concatenation of pushed staircase paths connecting two points p and q with the last segment of each staircase path overlapping the leading segment of the next pushed staircase path.*

LEMMA 4.3. *There are at most four different kinds of pushed staircase paths from p to q in the corridor between p and q for any* $p, q \in V$.

Proof. (see Fig. 5) Starting from either p or q, there are at most two pushed staircase paths, one starting horizontally and the other starting vertically. Once we decide on the first segment of the pushed path from either p or q, the rest of it is unique. □

LEMMA 4.4. *There exists an optimal path from s to d such that any of its staircase subpaths between two consecutive points* $p, q \in EXTMSD$ *is a pushed path.*

Proof. Consider a subpath between p and q of an assumed optimal path. Let it be Π^*_{pq}. Without loss of generality, let q 1-dominate p. Consider *corridor*(p, q, Π^*_{pq}) as a polygon containing Π^*_{pq}. Since there are no points in V inside the corridor, we can, starting from p, drag all the horizontal segments of Π^*_{pq} upward and vertical segments rightward until they hit the boundary of the corridor without increasing the length or the number of bends. Consequently we obtain a pushed path from p to q with the same length and number of bends as Π^*_{pq}. This applies to all such subpaths in an optimal path. The lemma is proved. □

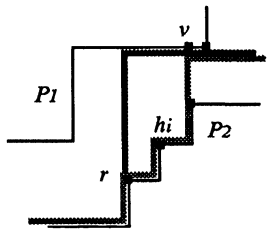

FIG. 6. *An L-subpath.*

This lemma implies that there exists an optimal path which is a canonical path.

LEMMA 4.5. *For a pushed staircase path* Π *from* p *to* q, *there is a path* P_{GG} *in* GG *from* p *to* q *passing through all the essential points on* Π.

Proof. According to the definition of pushed path, Π is a sequence of horizontal or vertical segments or L-subpaths connecting points in V. Since every horizontal or vertical segment between two points, u and v in V on path Π, is obviously an edge in GG, we can focus on proving that each L-subpath is also supported in GG.

Without loss of generality (Fig. 6), consider an L-subpath that goes from $r \in D(\Pi_{pq})$ upward and then turns rightward to $v \in U(\Pi_{pq})$ without containing any other points in V. If R_{rv} is empty, then we are sure that the connection between r and v is supported in GG. Otherwise, there are some essential points on P_2 falling in R_{rv}. Order them as $h_i, \{i = 1, \ldots, k\}$ such that R_{r,h_1}, $R_{h_i,h_{i+1}}$ and $R_{h_k,v}$ are all empty. Based on the properties of GG, between every two consecutive points of $\{r, h_1, h_2, \ldots, h_k, w\}$ there exists a path in GG. Therefore, the L-subpath between r and v is also supported. This completes the proof. □

We call the path P_{GG} described in Lemma 4.5 a *target path*. We intend to search on GG a target path and convert it to a canonical path by some *dragging* operations. Since GG contains only vertical or horizontal edges, we always append a vertical or horizontal segment to the end of the computed pushed path when we advance in the graph searching process. The last segment of a pushed path may be subject to dragging operation. When we reach d, we have a pushed path, which will be an optimal path. By focusing only on dragging the target path, we define the *dragging* operations applied to segments of a path.

DEFINITION 9. *Let* $last(\pi)$ *be the last staircase subpath of* π *from* p *to* v, *where* p, $v \in V_{GG}$. *A segment* w *of* $last(\pi)$ *is fixed if either*

(1) w *is horizontal (respectively, vertical) and cannot be dragged any further vertically (respectively, horizontally) without crossing any point in* V, *or*

(2) *it is the first segment of* $last(\pi)$.

It is floating *otherwise.*

When we advance along a target path on GG, the fixed portion of the path remains fixed thereafter and need not be considered again. Only the floating segment of the path needs to be considered for possible dragging, as defined below.

DEFINITION 10. *Let* π_{sp} *be a pushed path from* s *to* p, *and let* π'_{sq} *be the path formed by concatenating to* π_{sp} *an edge* $e \in E_{GG}$ *from* p *to* q, *where* e *is either horizontal or vertical (Fig. 7). Let* π_{sq} *be the pushed path dragged from* π'_{sq} *by the following dragging operations. Let* w *and* w_{new} *be the last segments of* π_{sp} *and* π_{sq}, *respectively, and assume they are horizontal. The vertical case can be defined similarly. Define the dragging operations on* π'_{sq} *as follows*:

(1) q *is to the right of* p (e *is horizontal*) (*Fig.* 7(a)): $w_{new} = w||e$ *is of the same type (fixed or floating) as* w, *where "||" denotes path concatenation. Note that* w *is fixed if it borders an obstacle above.*

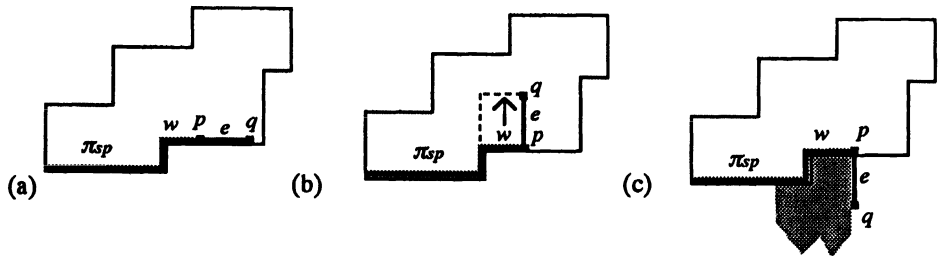

FIG. 7. *Dragging operations while advancing on e.*

(2) *q is to the left of p: Since w is horizontal, this is not possible.*

(3) *q is above p (e is vertical):*

(3.1) *w is fixed: Let w_{new} be e. w_{new} is fixed if it borders an obstacle to the right.*

(3.2) *w is floating: (Fig. 7(b)) Drag w upward and adjust π accordingly:*

(3.2.1) *If w can be dragged to q without hitting a point in V, then w_{new} is the dragged w.*

(3.2.2) *Otherwise, we ignore this advancing step.*

(4) *q is below p (e is vertical): (Fig. 7(c))*

(4.1) *If w borders an obstacle below it, we have a U-subpath here. We now have a new staircase subpath (of the second type) with w being the leading segment, which is fixed, and last$(\pi_{sq}) = w||e$.*

(4.2) *Otherwise, we ignore it.*

LEMMA 4.6. *A target path in GG can be successfully transformed by the dragging operations defined above to be a canonical path which is an optimal path.*

Proof. We can follow Lemma 4.5 and just focus on an L-subpath of an optimal path between two points in V. If each L-subpath from u to v can be formed by dragging a corresponding subpath on the target path from u to v, then the lemma is proved. According to Lemma 4.5 the corresponding subpath on the target path consists of horizontal and vertical edges which form a staircase path from u to v. There is no point of V in the area between this subpath and our L-shaped optimal subpath from u to v. Clearly, we will not hit any point in V when we do the dragging. Operations (1) and (3) are sufficient to drag edges in such a staircase path to form the L-subpath. Operation (3.2.2) ignores the case when we hit some point during dragging. Step (4.1) is just for making turns around a boundary edge and forming a U-subpath. Step (4.2) ignores the cases not belonging to the target path. □

4.1. The Algorithm and Its Complexity. Now we are ready to describe our algorithm: we apply Dijkstra's shortest path searching algorithm [1] on the graph GG to find the optimal path. While searching on GG and computing the pushed path, more than one pushed path may be generated when we reach a vertex from different edges. The information of the pushed paths leading to a vertex will be computed, and compared. Only the *best path(s)* obtained thus far will be retained at each vertex. We discuss below only the algorithm for MBSP. Modifications to the algorithms for solving SMBP or MCP are straightforward.

Algorithm MBSP.

1. Construct the guidance graph GG, and preprocess V for the dragging operations. This can be done using method in [2], which supports $O(\log m)$ query time using $O(m \log m)$ preprocessing time and linear space.
2. Apply Dijkstra's algorithm to find the optimal path according to metric vector $v = (d(\pi), b(\pi))$, where $d(\pi)$ and $b(\pi)$ denote the length and the number of bends of π, respectively. Let π_u be a pushed path obtained so far from s to a vertex u on GG.

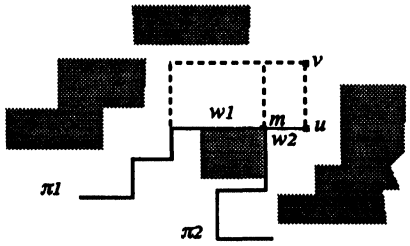

FIG. 8. *One path subsumes the other.*

There may be other pushed paths computed while reaching u from other edges and have been stored in u. We thus store at u the *type* of staircase of the last staircase subpath. Do the following:

2.1. If π_u is strictly worse than any other stored in u, discard π_u.

2.2. If π_u is strictly better (with lexicographically smaller metric) than some of the pushed paths stored in u, we discard the worse ones and store π_u at u.

2.3. If two have the same metric and the same type, compare their last segments. If their last segments overlap, then discard the one with the longer last segment. Otherwise (If they are not of the same type), keep both of them in u.

2.4. Calculate the metric vector of a pushed path advancing to each neighbor v of u via edge (u, v) in GG and put that into the queue used by the Dijkstra's algorithm. Note that there are at most eight pushed paths stored at each vertex u. That is, for each type of path there are two pushed paths, with the last segment leading to u either horizontally or vertically.

When we reach a vertex u, we ignore a pushed path if there exists one with smaller metric. When two pushed paths have the same metric, yet reaching u in different directions, we simply keep them all in u and proceed with the next advancing. We are able to compare and ignore some of those pushed paths that are of the same type and reach u in the same direction. See Lemma 4.7 below. The number of pushed paths that need to be stored in each vertex u is therefore at most eight, i.e., four pushed paths from vertex v that i-dominates u, $i = 1, 2, 3, 4$, and the last segment to u can be either vertical or horizontal.

LEMMA 4.7. *Consider two pushed staircase paths π_1 and π_2 with the same metric vector from s to some vertex u in GG. If the last segment, w_1, of π_1 is longer than the last segment, w_2, of π_2 and w_1 contains w_2 (Fig. 8), then any pushed path generated using π_1 will not be better than the pushed path generated using π_2. The same holds for other types of paths.*

Proof. Without loss of generality, let w_1 and w_2 be horizontal. Let the other endpoint of w_2 be m (u is the other endpoint). If w_1 is fixed, then obviously π_2 can replace π_1 in any further case. If w_1 is floating, then we may obtain a pushed path from π_1 by dragging w_1 upward. Wherever w_1 goes, the area swept over by it is empty. Since w_2 is shorter, it can also be dragged to the same position as w_1 with the same vertical distance offset. The dragging adds the same vertical distance offset to both paths and yet incurs no extra bend to either path. That is, any pushed path π_1 can grow to is no better than the best pushed path grown from π_2. The lemma is proved. □

THEOREM 4.8. *The problems MBSP, SMBP, and MCP can be solved in $O(m \log^2 m)$ time, using $O(m \log m)$ space.*

Proof. According to Lemma 4.6, while traversing the target path and applying the dragging operations on the way, we can get an optimal path from s to d. Lemma 4.7 guarantees that when a path is discarded, there must be some other path that subsumes it. This ensures that the final path is an optimal path. As to the running time, according to Lemma 4.1, the time

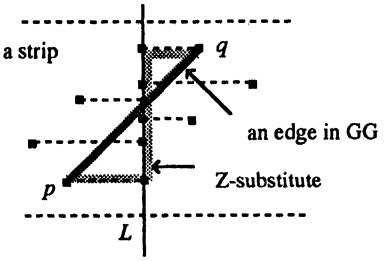

FIG. 9. *The Z-substitute.*

needed to generate the graph GG is $O(m \log m)$. The time used for searching on GG from s to d follows the complexity of Dijkstra's algorithm which is $O(|E| \log |E|)$ on a graph $G(V, E)$. The time for searching on GG is therefore $O(m \log^2 m)$. When we advance on GG through an edge, we perform dragging operations on at most eight pushed paths. Since each dragging operation can be done in $O(\log m)$ time [2] with $O(m \log m)$ time and $O(m)$ space preprocessing, the time complexity of the algorithm is $O(m \log^2 m)$. We need space for storing the guidance graph ($O(m \log m)$) and the pushed paths. Each pushed path has size less than that of its corresponding target path on GG and an edge of GG can be traversed (appended and dragged) by at most eight pushed paths from one of its end points. Therefore, the size of all the pushed paths kept while searching will be $O(E_{GG})$ or $O(m \log m)$. □

4.2. Solving MBSP, SMBP and MCP in $O(m \log^{3/2} m)$ time. The algorithm can be modified to run in $O(m \log^{3/2} m)$ time as follows. First, we find a more suitable guidance graph and a more efficient searching algorithm. Algorithm C2, as mentioned, can construct a refined, reduced graph, SPG_{rr}, providing the same connections as GG, with $O(m \log^{3/2} m)$ edges and $O(m \log^{1/2} m)$ vertices in $O(m \log^{3/2} m)$ time. We adopt this graph as the new *guidance graph*, denoted GG', and use the shortest path searching algorithm of Fredman and Tarjan [5], which runs in time $O(|E| + |V| \log |V|)$. The algorithm thus spends only $O(m \log^{3/2} m)$ time on graph searching. However, one of the properties in Lemma 4.1 does not hold any more, that is, the edges in GG' are not necessarily horizontal and vertical. This has effects on our dragging operations since we can only deal with horizontal and vertical segments in our dragging. We thus do some adjustments to the graph and compute substitutes for all such oblique edges.

From [3], each oblique edge in GG' is constructed from a set of horizontal and vertical edges in GG, which forms a *Z-shaped subpath* consisting of three segments where the first and the third lie on the different sides of the line containing the second one (Fig. 9). We call these three segments the *Z-substitute* of the original oblique edge. We can perform dragging similarly on these three segments when we encounter an oblique edge while searching on the new guidance graph and transform the target path to a pushed path.

To handle oblique edges, we add one dragging operation to the previous definition.

DEFINITION 11. *Define dragging operations as follows (assume last(π) is a staircase path):*

(1)–(4) *The same as operations* (1)–(4) *in Definition* 10.

(5) *For an oblique edge, replace it by the three segments of the corresponding Z-substitute. Apply the same operations as* (1)–(4) *to each of them in sequence.*

Besides reducing searching time on the guidance graph GG', we must devise a better way to perform dragging, since spending $O(\log m)$ time for each dragging consumes overall $O(|E_{GG'}| \log m)$ time, which becomes $O(m \log^{5/2} m)$.

In the following, we compute the *hit vertices* for each edge (at most one in each direction) when we generate the the graph GG' in $O(m \log^{3/2} m)$ time. Thereafter, while searching and computing the path, we are able to obtain in $O(1)$ time the hit vertex for each dragging operation, thus realizing a total of $O(m \log^{3/2} m)$ time. Note that the dragging operations are applied to the last segment of a pushed path (i.e., the w_{new} in the dragging definition) which may consist of several edges of the graph GG'. For example, consider that we form w_{new} by concatenating a horizontal last segment w with a horizontal edge e on GG. We simply let the hit vertex of w_{new} be the lower one of the hit vertices of w and e when we drag w_{new} upward. Dragging horizontal segments downward or dragging vertical segments can be done similarly.

DEFINITION 12. *An* upward (respectively, downward) hit vertex *h of a horizontal edge e in GG is the farthest of all the obstacle vertices that e can be dragged upward (respectively, downward) to hit without crossing the* interior *of any obstacle. A leftward or rightward hit vertex of a vertical edge in GG is defined symmetrically. The hit vertex of an edge e in GG′ is defined as follows.*

(1) *If e is also in GG then e inherits all its hit vertices in GG.*

(2) *If e is not in GG, then it is an oblique edge. The hit vertices of e are defined to be the hit vertices of the three segments of the* Z-*substitute of e. For each vertical segment g the hit vertex in each direction is the nearest hit vertex of all the edges in GG that compose g.*

Note that a hit vertex of an edge can be undefined if the edge cannot be dragged to hit any vertex or can only be dragged to hit a portion of the obstacle boundary that does not contain any vertex. We attempt to store the Z-substitute for each oblique edge in GG' and compute its hit vertices when we construct GG'. We will embed the computation of the hit vertices of all the edges on GG' in the recursive steps where the edges of GG' are constructed. Following is the algorithm for constructing GG' including the computation of hit vertices. Graph GG and the hit vertices of its edges are generated as intermediate products. The reader is referred to [3], [14] for details of the original algorithm. Here we only put emphasis on how we compute the hit vertices.

Algorithm FindGG′.

1. Sort all vertices in $V' = V \bigcup \{s, d\}$ vertically and horizontally.
2. Find the median vertical cut line L that divides V' in halves.
3. Find the projection points, if visible, from all the vertices to the cut line L. Call those projection points the *potential Steiner points*. Call the edges connecting vertices to their projections the *potential horizontal edges*. An obstacle edge that is cut by L is marked as a potential horizontal edge with a distinction as to whether it borders the obstacle below or above. For two vertices on the same side of L and with the same ordinate, we only generate one potential Steiner point and one potential horizontal edge from the one nearer to L, if it exists. (Note that these potential points and edges are in GG. They are called *potential* since not all of them will be inserted into GG'.)
4. (Find the hit vertices of the potential horizontal edges.)
   Initialize an empty stack for storing those potential horizontal edges that are to the left of L. Scanning these edges from top to bottom, we compute the downward hit vertices. Let the edge we encounter be e and let ve be the vertex that produces e (Fig. 10(a)). Let the edge at the top of the stack be te.
   (a) e is longer than te:
      (a.1) If e borders an obstacle boundary below it, then pop all the edges off from the stack leaving the hit vertices of them undefined, and let ve be the downward hit vertex of e.
      (a.2) Otherwise, push e onto the stack.

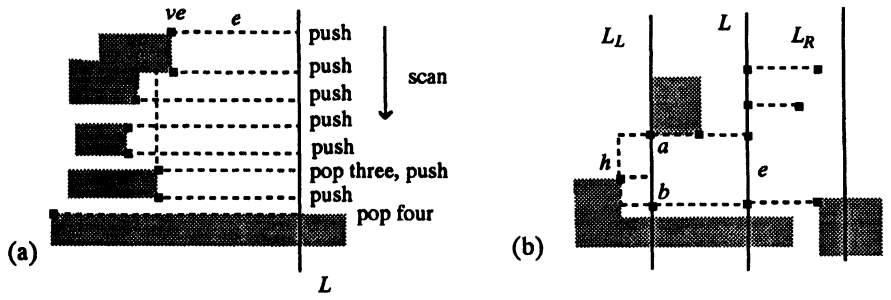

FIG. 10. *Finding the hit vertices for the potential edges.*

(b) e is not longer than te:

(b.1) If e borders an obstacle boundary below it, then keep popping an edge te off from the stack until the stack is empty. Let ve be the downward hit vertex of te if te is not shorter than e and let the hit vertex of te be undefined, otherwise. Let the downward hit vertex of e be ve.

(b.2) Otherwise, keep popping an edge te off from the stack as long as te is longer than e, and let the hit vertex of te be ve. Push e onto the stack.

Find the upward hit vertices in a similar way. Do the same for the potential horizontal edges on the right of L. Call the edges connecting those consecutive potential Steiner points on L the *potential vertical edges*.

5. (Find the hit vertices of the potential vertical edges.)

At each recursive step, we compute the hit vertices of all the potential vertical edges generated on the cut lines. Let L be the cut line under consideration. We look at the two nearest existing cut lines on each side of L, which were generated in previous recursive steps. Let them be L_L and L_R which are on the left side and right side of L, respectively (Fig. 10(b)).

(a) If there is no previous cut line on either side, i.e., the first cut line and those leftmost and rightmost cut lines during the recursive cutting process, then we simply scan over all the points on that side and find the leftward or rightward hit vertices directly. Otherwise, do the following.

(b) The leftward hit vertices of the edges on L are obtained either from vertices between L and L_L, if it exists, or from the leftward hit vertices on the potential vertical edges on L_L, if there is no vertex between L and L_L. The rightward hit vertices of all the potential vertical edges on L can be found in a similar way (from the vertices between L and L_R and those rightward hit vertices on L_R.)

6. (Find the hit vertices of the edges in GG'.)

Cut the plane into horizontal strips of size $O(\sqrt{\log m})$ each and decide which potential Steiner points and which potential edges are added to GG' (see [3], [14]). For those potential edges that are added to GG', let them have the same hit vertices. Some oblique edges which connect pairs of points on different sides of L are generated in each recursive step. We record with each oblique edge, its Z-substitute which consists of three segments: two potential horizontal edges from its end points to L and one vertical segment which is composed of all consecutive potential vertical edges between the potential Steiner points on L of the two end points. We regard the three segments in a Z-substitute as three edges while dragging and thus we need to compute the hit vertices of them respectively. The hit vertices of the two horizontal edges are those computed in step 4. The hit vertex of the vertical segment is obtained by comparing the hit vertex of each individual potential vertical edge obtained in step 5 and selecting the nearest.

7. Do steps 2–6 recursively to the vertex sets on the left side and the right side of L, respectively.

Algorithm FindGG' generates the same graph structure as in [3]. In addition, the hit vertices of all the horizontal and vertical edges on GG' and of the Z-substitutes of all the oblique edges are computed.

LEMMA 4.9. *Algorithm FindGG' runs in $O(m \log^{3/2} m)$ time and space and the hit vertices of all the edges in GG' are correctly computed.*

Proof. The complexity is the same as Algorithm C2 since in each recursive step we compute the hit vertices in time linear in the number of points processed. The only step we need to address is the computation of Z-substitutes and their hit vertices for each pair of vertices inside a strip. Inside each strip, as the accumulated distances are computed [3], [14], [10], we construct a hit vertex table recording the nearest hit vertex in each direction between every pair (not necessarily consecutive) of potential Steiner vertices on L in the strip. This information can later be used for computing the hit vertices of a vertical segment in a Z-substitute. The time complexity therefore is still kept within the same bound. For the correctness of computing the hit vertices, we distinguish two cases as follows:

(1) When a vertex h is the downward hit vertex of a potential horizontal edge e:
If there is any other potential horizontal edge e' between h and e, it must not be shorter than e. If e' is as long as e then it must not border an obstacle below. According to the algorithm, for these cases, e' will be pushed onto a stack. When h is scanned, we pop all edges on top of the stack before we meet an edge shorter than the edge from h to L, which certainly includes e. The case when h is the upward hit vertex of e is proved similarly.

(2) When a vertex h is the leftward hit vertex of a potential vertical edge e:
Let e be on a cut line L. If h falls between L and L_L, then we can certainly find it during the scan. If h falls to the left of L_L, then h must be a hit vertex of some potential vertical edge on L_L. We can assume that h has been recorded as the leftward hit vertex of this potential vertical edge. The reason is that since e can be dragged over L_L to hit h, the two vertices that have projections on the endpoints of e must have projections on L_L as well. These two projections are two potential Steiner points on L_L (denoted as a and b in Fig. 10(b)). Therefore, there must be one or more potential vertical edges on L_L between a and b, and one of them will hit h when dragged leftward. Hence by scanning all the hit vertices on L_L and vertices between L_L and L, we can correctly compute the hit vertices of edges on L. The proof for computing the rightward hit vertices is similar. □

After we have computed all the hit vertices of all the edges of the new guidance graph, the dragging operations can be redefined as follows.

DEFINITION 13. *The dragging operations are defined to be those specified in Definitions* 10 *and* 11 *and the following corresponding operations*:

(1) *The upward hit vertex of w_{new} is the lower one of the upward hit vertices of w and e.*

(2) *The same as in Definition* 10.

(3.1) *The upward hit vertex of w_{new} is the upward hit vertex of e.*

(3.2.1) *If the upward hit vertex of h is higher than q then we drag w to q and let it be w_{new}. The upward hit vertex of w_{new} is that of w.*

(3.2.2) *The same as in Definition* 10.

(4) *and* (5) *are the same as in Definition* 11.

One can see that such dragging operations have the same effects as do the previously defined ones. However, we do not perform segment dragging queries any more. The algorithm is the same except the dragging operations are modified. The space needed is $O(|E_{GG'}|)$ for storing GG'.

THEOREM 4.10. *Problems MBSP, SMBP, and MCP can be solved in* $O(m \log^{3/2} m)$ *time and space.*

5. Conclusion. In this paper, we have presented two results improving on previous ones on finding rectilinear paths among obstacles. We have shown that a *smaller* shortest-path-preserving graph for shortest rectilinear paths among rectilinear obstacles is sufficient and thus obtained a more efficient algorithm for problem *sp*. As a by-product, a faster algorithm for finding the minimum spanning tree of a set of terminals among obstacles is also obtained. Furthermore we have presented a dynamic-searching approach which computes optimal paths dynamically while searching on a guidance graph. Problems MBSP, SMBP, and MCP can be solved efficiently using this approach. It is not clear whether a *better* guidance graph can be obtained to yield a more efficient algorithm for these problems. The problems of how one can improve the time complexities of these algorithms remain open. The results of this paper cannot be extended to non-rectilinear cases in an obvious way.

Acknowledgment. The authors thank the anonymous referee for the comments that greatly helped improve the presentation of the paper.

EVALUATION OF POLYNOMIALS USING THE STRUCTURE OF THE COEFFICIENTS*

JÜRG GANZ†

Abstract. A new algorithm to evaluate polynomials that exploits the structure of their coefficients is proposed. This algorithm is an extension of one due to Savage with the advantage that it is not restricted to coefficients from a set whose cardinality is small compared to the degree of the polynomial. The new algorithm is shown to be asymptotically optimum for evaluating arbitrary functions in finite fields and for evaluating polynomials with real coefficients in a binary fixed-point representation. To illustrate that it is nonasymptotically useful as well, the new algorithm is shown to reduce the time for syndrome calculation for binary Bose–Chaudhuri–Hocquenghem (BCH) codes of practical interest.

Key words. polynomial evaluation, straight-line algorithm, finite fields, binary fixed-point representations, decoding BCH codes

1. Introduction.

This paper is concerned with the evaluation of polynomials

$$p(X) = c_n \cdot X^n + \cdots + c_1 \cdot X + c_0$$

whose coefficients c_i belong to a field $\mathcal{F}$ when the argument X assumes a value x in a field $\mathcal{E}$, which in general is an extension of $\mathcal{F}$. Three different problems can be distinguished, namely,

1. Evaluate $p(X)$ with specified coefficients $c_0, \ldots, c_n$ at an arbitrary argument x.
2. Evaluate $p(X)$ with arbitrary coefficients $c_0, \ldots, c_n$ at a specified argument x.
3. Evaluate $p(X)$ with arbitrary coefficients $c_0, \ldots, c_n$ at an arbitrary argument x.

The "specified" items are those known in advance and can be used to design an appropriate algorithm, whereas the "arbitrary" items are the actual input to the algorithm. The well-known Horner's rule (cf. [3, p. 467])

$$p(X) = (\cdots (c_n \cdot X + c_{n-1}) \cdot X + \cdots + c_1) \cdot X + c_0$$

suggests an algorithm that solves the third problem with $2n$ operations. Of course this algorithm solves the first and second problem as well when the "specified" items are included within the algorithm rather than given as inputs. Horner's rule is easy to implement and needs no storage beyond an accumulator.

In many applications some specified polynomial has to be evaluated many times, which corresponds to the first problem. Here it may be worthwhile to do some precomputation to devise an algorithm suited for that polynomial. The concept of a straight-line algorithm (SLA) has been introduced to study this problem (see also [4] or [3, p. 475] where an SLA is called a polynomial chain). An SLA is defined as follows:

> The input x, which can be any element of $\mathcal{E}$, is assigned as the "result" of step 0 of the algorithm. At each step i, for $i = 1, 2, \ldots, k$, the algorithm performs one operation on two operands. The operation must be either addition or multiplication. One of the two operands at step i must be the result of the operation at step j for some $0 \leq j < i$. The other operand at step i must be either a fixed specified element of $\mathcal{F}$ (and these specified elements will be called the *constants* of the SLA) or the result of the operation at step h for some $0 \leq h \leq j$.

*Received by the editors February 3, 1992; accepted for publication (in revised form) November 11, 1993.

†Signal and Information Processing Laboratory, Swiss Federal Institute of Technology, CH-8092 Zürich, Switzerland.

Note that the choice of operands at each step in an SLA is independent of the *values* of the input and of the *values* computed in previous steps. An SLA *evaluates* a polynomial $p(X)$ if for some i, $0 \leq i \leq k$, and for every input $x \in \mathcal{E}$, the result of step i is $p(x)$. Note that the same SLA can evaluate many different polynomials.

There have been several suggestions for devising SLAs to evaluate polynomials with no restrictions on the coefficients. But the resultant SLAs do not significantly improve on Horner's rule. In fact, it has been shown that there are polynomials such that every SLA that evaluates them needs at least about n additions and $\frac{n}{2}$ multiplications; cf. [3, pp. 475–479] for more details.

In applications where the field $\mathcal{E}$ is a proper extension of $\mathcal{F}$, i.e., $\mathcal{E} \neq \mathcal{F}$, a *nonscalar multiplication*, i.e., a multiplication with both operands in $\mathcal{E}$, is typically more complex than a *scalar multiplication*, i.e., a multiplication with one operand in $\mathcal{F}$ and one operand in $\mathcal{E}$. Thus, SLAs that minimize the number of nonscalar multiplications are of interest. Some SLAs have been proposed that need only about $\sqrt{n}$ nonscalar multiplications, but the total number of operations is still about $2n$ (cf. [6]).

A quite different approach has been taken by Savage [7], who gave an SLA that outperforms previous SLAs when the number $\mathbf{s}$ of different coefficients is much smaller than the degree of the polynomial n. Under this condition, Savage showed that the number of nonscalar multiplications needed is not larger than $2\sqrt{n+1}-2$ and that this can be achieved with a total of only $(n/\log_{\mathbf{s}} n) \cdot (2 + o(1))$ operations, where $o(1)$ denotes a function that is negligible compared to 1 for n large. It is possible to choose the parameters of Savage's algorithm differently so as to minimize the total number of operations. This minimization leads to a version of Savage's algorithm that needs only a total of $(n/\log_{\mathbf{s}} n) \cdot (1 + o(1))$ operations if $\mathbf{s}$ is much smaller than n.

In this paper we extend Savage's result by allowing coefficients c_i from a subset of $\mathcal{F}$, which can be much larger than in the original approach. These coefficients c_i are constrained to be a linear combination of some specified generators $\beta_1, \ldots, \beta_m \in \mathcal{F}$, where all scalars of the linear combination are in a specified set $\mathcal{A} \subseteq \mathcal{F}$ with cardinality $|\mathcal{A}| = a$. Equivalently, the coefficients c_i are constrained to lie in the set

$$\mathcal{S} = \{\beta_1 \cdot a_1 + \cdots + \beta_m \cdot a_m \mid a_j \in \mathcal{A}\} \subseteq \mathcal{F}.$$

Such coefficient sets occur frequently in practical applications. We will also assume with no real loss of generality that $\mathcal{A}$ contains at least the two neutral elements 0 and 1 of the field $\mathcal{F}$. There are at most $s \triangleq a^m \geq |\mathcal{S}|$ different coefficients of the above form. The new SLA given in §2 will evaluate polynomials of degree n with such coefficients using a total of $(n/\log_s n) \cdot (1 + o(1))$ operations under only the restriction that $a = |\mathcal{A}|$ is much smaller than mn. Alternatively, the number of nonscalar multiplications can be upper-bounded by $2\sqrt{n+1}-2$ together with a total of $(n/\log_s n) \cdot (2 + o(1))$ operations under the restriction that a is much smaller than $m^2 n$. These are the same asymptotic forms as for Savage's algorithm except that the upper bound $s = a^m$ on the number of different coefficients has replaced the number $\mathbf{s}$ of different coefficients in Savage's formulas and, more importantly, that the range of validity of the result is now determined by a instead of by $\mathbf{s}$. It follows that the new SLA algorithm outperforms all previous SLAs for all $s \leq n + 1$ and n sufficiently large compared to a. Note that the case $s = n + 1$ is that of polynomials whose coefficients are all different. Further, note that although we demanded that the coefficients must be chosen from a finite set $\mathcal{S}$, we did not restrict the field $\mathcal{E}$ itself to be finite.

In §3, we use counting arguments to show that there are polynomials of degree n with coefficients from any set $\mathcal{S}$ of size $s \leq n+1$ that cannot be evaluated with $(n/\log_s n)\cdot(1-o(1))$ operations by an SLA using at most s constants. This shows the optimality of the new algorithm

in certain circumstances. For evaluating arbitrary functions in a finite field GF(p^m) (with p prime), the new algorithm is shown to be asymptotically optimum as m gets large. Furthermore, the new algorithm is shown to be well suited for evaluating polynomials with real coefficients restricted to a binary fixed-point representation, which is a case of considerable practical interest.

In §4, the new algorithm is applied to the third polynomial-evaluation problem in which both the argument and the coefficients are inputs. It has been shown that Horner's rule is optimum among SLAs with $n+2$ inputs for solving this third problem, cf. [3, p. 479]. Nevertheless, it is shown that the new algorithm can be "extended" by allowing *indirect addressing of operands by inputs* and will then outperform Horner's rule when the coefficients are from the set $\mathcal{S}$ defined above. With a simple adaptation, the new extended algorithm also solves the second polynomial-evaluation problem. This has interesting practical consequences because the computation of a single component of the discrete Fourier transform (DFT) at a fixed frequency x for an arbitrary time sequence of the form $c_0, \ldots, c_n$ corresponds exactly to this second problem. Finally, an application in decoding binary Bose–Chaudhuri–Hocquenghem (BCH) codes is given that shows that the new extended algorithm improves upon known methods of syndrome calculation for parameters far away from asymptotics (e.g., for the 7-error-correcting binary BCH code with block length 127).

In the last section, the similarities and differences between the new algorithm and the one due to Savage are discussed. Some possible generalizations of the new algorithm are also given.

2. The new algorithm. In this section, we propose a new SLA to solve the first polynomial-evaluation problem. Assume with no real loss of generality that $n = q \cdot p \cdot l - 1$, so that the polynomial $p(X)$ of degree n with coefficients in $\mathcal{S}$ can be written as

$$p(X) = g_0(X) + g_1(X) \cdot X^{pl} + \cdots + g_{q-1}(X) \cdot X^{(q-1)pl}, \tag{1}$$

where $g_k(X)$ is a polynomial of degree less than pl with coefficients in $\mathcal{S}$. Let the equation

$$g_k(X) = \beta_1 \cdot h_{k,1}(X) + \cdots + \beta_m \cdot h_{k,m}(X) \tag{2}$$

define the polynomials $h_{k,1}(X), \ldots, h_{k,m}(X)$, which are polynomials of degree less than pl with coefficients in $\mathcal{A}$, and similarly let

$$h_{k,j}(X) = t_{k,j,0}(X) + t_{k,j,1}(X) \cdot X^l + \cdots + t_{k,j,p-1}(X) \cdot X^{(p-1)l} \tag{3}$$

define the polynomials $t_{k,j,0}(X), \ldots, t_{k,j,p-1}(X)$ with coefficients in $\mathcal{A}$ and degree less than l.

Given the input $x \in \mathcal{E}$, the algorithm comprises the following four steps:

Step 1. Form p lists containing all possible $t_{k,j,i}(x) \cdot x^{il}$ and compute x^{pl}:

a) Form list 0 of the values of all a^l polynomials of degree less than l with coefficients in $\mathcal{A}$ evaluated at x. (This requires $l-2$ nonscalar multiplications to form $x^2, x^3, \ldots, x^{l-1}$, together with $(l-1)(a-2)$ scalar multiplications to evaluate the monomials with coefficients not 1, together with $a^l - (a-1)l - 1$ additions to evaluate the binomials, trinomials, etc., by summing values already computed, since each addition can be designed to evaluate a new polynomial in the manner that the value of a trinomial is the sum of the value of a monomial and a binomial, etc.)

b) For $i = 1, 2, \ldots, p-1$, form list i consisting of the values in list 0 each multiplied with x^{il}. (This requires, for each value of i, l nonscalar multiplications starting from $x^{il-1} = x^{(i-1)l+l-1}$ to form $x^{il}, x^{il+1}, \ldots, x^{il+l-1}$,

together with $l(a-2)$ scalar multiplications to evaluate the monomials, together with $a^l-(a-1)l-1$ additions to evaluate the binomials, trinomials, etc., by summing values already computed in a way similar to that in Step 1a.)

c) Compute the value of x^{pl}. (This requires only one nonscalar multiplication because $x^{pl-1}=x^{(p-1)l+l-1}$ is already available in list $p-1$.)

(The whole of Step 1 requires a total of less then $p\cdot a^l$ operations, of which $pl-1$ are nonscalar multiplications.)

Step 2. Compute $h_{k,j}(x)$ for $0\le k<q$ and $1\le j\le m$ by adding according to (3) the values $t_{k,j,i}(x)\cdot x^{il}$ from list i for $i=0,1,\dots,p-1$. (This takes at most $p-1$ additions for each of the qm values of k and j.)

Step 3. Compute $g_k(x)$ for $0\le k<q$ by first multiplying $h_{k,j}(x)$ by the scalar β_j and then summing for $j=1,2,\dots,m$ according to (2). (This takes m scalar multiplications and $m-1$ additions for each of the q values of k.)

Step 4. Compute $p(x)$ according to (1) in the manner (reminiscent of Horner's rule)

$$p(x)=(\cdots(g_{q-1}(x)\cdot x^{pl}+g_{q-2}(x))\cdot x^{pl}+\cdots+g_0(x).$$

(This takes $q-1$ nonscalar multiplications and $q-1$ additions.)

The entire algorithm requires

$$\begin{aligned}C_{tot}&<p\cdot a^l+q\cdot m\cdot(p-1)+q\cdot(2m-1)+2\cdot(q-1)\\&=p\cdot a^l+q\cdot m\cdot p+q\cdot m+q-2\end{aligned}$$

operations, of which

$$C_{ns}=p\cdot l+q-2$$

are nonscalar multiplications. We optimize these numbers by the following choices of the parameters:

1. The bound on the total number of operations C_{tot} is approximately minimized by choosing

$$q=\frac{n+1}{pl},\quad l=\lceil\log_a(mn)-3\cdot\log_a\log_a(mn)\rceil,\quad p=\lceil\log_a(mn)\rceil.$$

When a is much smaller than mn, this gives

$$C_{tot}\le\frac{mn}{\log_a(mn)}\cdot(1+o(1))\le\frac{n}{\log_s n}\cdot(1+o(1)),$$

where $o(1)$ is negligible compared to 1 for n large. This total computation is less than that of Horner's algorithm if the set $\mathcal{S}$ of allowed coefficients satisfies

$$|\mathcal{S}|\le s=a^m\le n+1.$$

Note that this restriction still permits all $n+1$ coefficients of the polynomial to be different. This removes the severe restriction that the number of different coefficients must be much smaller than the degree n of the polynomial, which is needed to make Savage's algorithm [7] superior to Horner's.

2. The number of nonscalar multiplications C_{ns} is minimized by choosing

$$q=pl=\sqrt{n+1}.$$

Independently of a and m, this gives

$$C_{ns} = 2\sqrt{n+1} - 2.$$

Fixing this choice of q, the bound on the total number of operations is then approximately minimized by the choice

$$l = \lceil \tfrac{1}{2} \log_a(m^2 n) - \log_a \log_a(m^2 n) \rceil.$$

For a small compared to $m^2 n$, this yields

$$C_{tot} \leq \frac{mn}{\log_a(m^2 n)} \cdot (2 + o(1)) \leq \frac{n}{\log_s n} \cdot (2 + o(1)),$$

which again is superior to other SLAs when $|\mathcal{S}| \leq s \leq n + 1$.

For software implementations of the algorithm, we consider briefly the amount of storage needed when the total number of operations is optimized. The necessary storage is determined by Step 1 and, for the optimizing choice of parameters, equals storage for

$$p \cdot a^l \approx \frac{mn}{(\log_a(mn))^2} \leq \frac{n}{m \cdot (\log_s n)^2}$$

elements of $\mathcal{E}$. On the average, each of these elements is used

$$\frac{qm}{a^l} \approx \log_a(mn) \approx m \cdot \log_s n$$

times in Step 2.

Note that Steps 3 and 4 can essentially be executed in reverse order as follows:

Step 3′. Compute $g'_j(x)$ for $1 \leq j \leq m$ in the manner

$$g'_j(x) = (\cdots (h_{q-1,j}(x) \cdot x^{pl} + h_{q-2,j}(x)) \cdot x^{pl} + \cdots + h_{0,j}(x).$$

(These are polynomials with coefficients in $\mathcal{A}$ and degree at most n. The computation takes $q - 1$ nonscalar multiplications and $q - 1$ additions for each of the m values of j.)

Step 4′. Compute $p(x)$ by first multiplying $g'_j(x)$ by the scalar β_j and then summing for $j = 1, 2, \ldots, m$. (This takes m scalar multiplications and $m - 1$ additions.)

This exchange reduces the total number of operations by q, but has no effect on the asymptotics and significantly increases the number of nonscalar multiplications.

Finally, we want to stress that we designed an SLA that uses as constants the elements $\beta_1, \ldots, \beta_m$ and the elements of $\mathcal{A}$. The specific coefficients of the polynomial determine the exact structure of the algorithm.

3. Optimality of the new algorithm. In this section, it is shown for $|\mathcal{S}| = s$ that the new algorithm is asymptotically optimum among all SLAs that use constants from a set of size $s = |\mathcal{S}|$ (which need not be the set $\mathcal{S}$ itself). First, we count the number of different polynomials that can be evaluated by SLAs of length k that use constants from a set of size s. For this purpose, consider a gate network having as input signals x and the constants $\gamma_1, \ldots, \gamma_s$ and containing k gates, each of which performs the operation of addition or multiplication, cf. Fig. 1.

We now specify that the first input to each gate is either the input signal x or the output of another gate and that the second input to each gate is either an input signal (i.e., x or a constant γ_i) or the output of another gate. For each gate there are 2 choices for its type, k

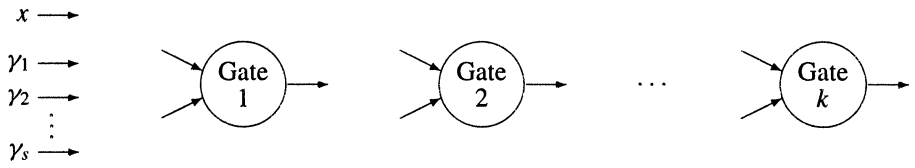

FIG. 1. *The components of the gate networks used to bound the length of SLAs.*

choices for its first input, and $k+s$ choices for its second input. This gives exactly $(2\cdot k\cdot(k+s))^k$ gate networks as defined here.

We will call a gate network irredundant if it does not contain two gates of the same type with identical inputs. We will say that two gate networks are essentially the same if they differ only by a permutation of the gate labels. There are exactly $k!$ gate networks that are essentially the same as a given irredundant gate network. Thus the number of essentially different irredundant gate networks is upper-bounded by the total number of gate networks divided by $k!$, i.e., there are at most $(2\cdot k\cdot(k+s))^k/k!$ essentially different irredundant gate networks. A gate network performs a well-defined computation only if its connections are loop free, but we do not need to exploit this fact.

Every SLA corresponds to a unique gate network in the manner that gate i implements step i of the SLA. We will call an SLA irredundant if its corresponding gate network is irredundant, i.e., if it contains no step that merely repeats the computation of a previous step. Similarly, we will call two SLAs essentially different if their corresponding gate networks are essentially different. It follows that there are at most $(2\cdot k\cdot(k+s))^k/k!$ essentially different irredundant SLAs of length k. (It is important to note that the $k!$ irredundant gate networks that are essentially the same as the gate network corresponding to some irredundant SLA do not all correspond to SLAs because some permutations of the gate labels may require that a gate with label i operates on the output of a gate with label j where $j > i$, so that the corresponding "algorithm" would not be an SLA. Thus, in general there are fewer than $k!$ irredundant SLAs of length k that are essentially the same.)

Every SLA of length k evaluates at most k different polynomials, one at each step. Moreover, every polynomial that can be evaluated by an SLA of length k can trivially also be evaluated by an irredundant SLA of length k. Because SLAs that are essentially the same evaluate the same set of polynomials, it now follows that the number P_k of polynomials that can be evaluated by SLAs of length k satisfies

$$\begin{aligned} P_k &\le k\cdot(2\cdot k\cdot(k+s))^k/k! \\ &\le (k+s)^k\cdot(2e)^k\cdot\sqrt{k}, \end{aligned} \tag{4}$$

where we have used Stirling's bound on the factorial [2, pp. 52–54].

For all of the s^{n+1} polynomials of degree $n \ge s-1$ with coefficients in a set of size s to be evaluated by SLAs of length k would require that

$$P_k \ge s^{n+1}$$

or, equivalently, that

$$\log_s P_k \ge n+1. \tag{5}$$

Suppose that k satisfies

$$k \le \frac{n}{\log_s n}\cdot\left(1-\frac{\log_s 4e}{\log_s n}\right) < n, \tag{6}$$

where we note that there exists an n_0 such that the middle member in these inequalities is greater than 1 for all $n \geq n_0$ and any s satisfying $2 \leq s \leq n+1$. Taking the logarithm of both sides in (4), upperbounding $k+s$ by $2n$, and then replacing k by its tighter upperbound in (6) gives

$$\begin{aligned} \log_s P_k &\leq k(\log_s n + \log_s 4e) + \tfrac{1}{2}\log_s k \\ &\leq n\left(1 - \left(\frac{\log_s 4e}{\log_s n}\right)^2\right) + \tfrac{1}{2}\log_s n \\ &< n \end{aligned}$$

for $n \geq n_0$, which contradicts (5). We conclude that, for large enough n and any set of size s with $2 \leq s \leq n+1$, there are polynomials of degree n and coefficients in this set that cannot be evaluated by an SLA with constants from a set of size s that uses

$$k = \frac{n}{\log_s n} \cdot (1 - o(1))$$

or fewer operations (where o(1) is negligible compared to 1 for n large). It follows that the new algorithm—designed for certain sets of coefficients of size s—is asymptotically optimum.

Counting arguments similar to those above were used for similar applications by Savage [8, pp. 114–115] and Wegener [10, pp. 87–90]. These authors did not introduce the concept of irredundant gate networks but simply claimed that the number of essentially different gate networks is upper-bounded by the total number of gate networks divided by $k!$, which is in fact not true. The counting argument given here shows, however, that the bounds in [8, pp. 114–115] and [10, pp. 87–90] on the required number of gates are nonetheless correct.

Application 1: Finite fields. Consider the finite field GF(p^m) with p prime. It is well known that every function f : GF(p^m) $\longrightarrow$ GF(p^m) may be represented by a polynomial of degree n less than p^m with coefficients in GF(p^m). Therefore, the number of operations needed to evaluate any function can be upper-bounded by that needed for the evaluation of polynomials with degree $n = p^m - 1$. The new algorithm can be applied with $\mathcal{A} = \text{GF}(p)$ and $\beta_1, \ldots, \beta_m$ forming a basis for GF(p^m) over GF(p); thus $\mathcal{S} = \mathcal{F} = \mathcal{E} = \text{GF}(p^m)$. The condition that $|\mathcal{A}| = p$ is much smaller than $mn = m(p^m - 1)$ is certainly fulfilled for large enough m. It follows that, for large m, every such function f may be evaluated with at most

$$C_{tot} \leq p^m \cdot (1 + o(1))$$

operations in GF(p^m), where $o(1)$ is negligible compared to 1.

On the other hand, because $s = |\mathcal{S}| = p^m$, the previous arguments showed that there are functions (i.e., polynomials of degree less than p^m) that require more than

$$p^m \cdot (1 - o(1))$$

operations to be evaluated in GF(p^m) (see also [4] where this same bound is shown to apply when subtraction and division are also allowed as operations). We conclude that the new algorithm is asymptotically optimum for evaluating arbitrary functions in GF(p^m) when m is large.

Application 2: Binary fixed-point representation. Many practical computations use a binary fixed-point representation of real numbers. This representation can be described in our notation by

$$\mathcal{A} = \{0, 1\} \text{ and } \beta_i = 2^{i+offset}$$

for $i = 1, \ldots, m$, where m gives the precision and *offset* determines the binary point of the representation. This defines the set of coefficients that are allowed. The operations may be realized with greater precision, or even in floating point, in order to achieve the desired precision of the result. Considering the results of §2, we see that the new algorithm may be preferable for polynomials of degree 2^m with coefficients in this representation, and it certainly outperforms other known SLAs for large degrees. In fact, for the total number of operations, the new algorithm is asymptotically optimum among all SLAs using constants in this representation.

4. Adaptation to variable coefficients. The new SLA of §2 evaluates a polynomial $p(X)$ with the argument x as input. We now adapt this algorithm to the case where the values of the coefficients $c_0, \ldots, c_n$ are additional inputs. The new algorithm can be adapted to solve this third polynomial-evaluation problem when the following conditions are fulfilled:

1. The coefficients $c_0, \ldots, c_n$ lie in a set $\mathcal{S}$ for which $\beta_1, \ldots, \beta_m$ and the elements of $\mathcal{A}$ are known in advance. (This allows one to perform the calculations of Steps 1 and 3 in exactly the same way as before.)
2. Given a coefficient $c_i = \beta_1 \cdot a_{i,1} + \cdots + \beta_m \cdot a_{i,m}$, it must be easy to compute its components $a_{i,1}, \ldots, a_{i,m}$ (or, as would generally be the case in practice, these components are the actual inputs to the algorithm).
3. The components $a_{i,j}$ of the coefficients c_i, which are the inputs to the algorithm, are allowed to determine the operands in Step 2 of the previous algorithm. (This means that the new algorithm is not in fact an SLA, but is rather the result of extending the notion of an SLA to allow *indirect addressing of operands by inputs*.)

The third condition prevents a hard-wired implementation of the new extended algorithm. Nevertheless, this extension is well suited for a software implementation of the algorithm because indirect addressing is easy to realize. In fact, most software implementations of the SLA of §2, in which the components $a_{i,j}$ are constants, would probably also use indirect addressing for convenience. Therefore it makes no great difference in a software implementation whether the components $a_{i,j}$ are constants or inputs. If the implementation is on a general-purpose single-processor computer, then the number of field operations needed essentially determines the performance of the algorithm. In this case, all the counting and optimizing of the number of operations for the SLA of §2 are still valid for the extension. This also includes the computation of the amount of storage needed, which was determined at the end of §2. It follows that the extended new algorithm can outperform Horner's rule even for the third polynomial-evaluation problem.

There are also applications where the argument x is fixed and only the coefficients c_i are inputs. To adapt our algorithm to this case, which is the second polynomial-evaluation problem, all the above conditions still must be observed, but there is now the possibility to precompute all the lists of Step 1 because both x and the elements of $\mathcal{A}$ are known in advance. Adapting the new algorithm, we find that the performance strongly depends on the storage D available for the lists of Step 1. With the same parameters as in §2, we find that

$$D = p \cdot a^l$$

storage locations are needed together with

$$C_{tot} = q(pm + m + 1) - 2$$

operations to perform Steps 2, 3, and 4. Again assuming without real loss of generality that $n = l \cdot p \cdot q - 1$, we see that the number of operations can be well approximated even for

moderate n as

$$C_{tot} \approx \frac{m\,n}{l} \cdot \left(1 + \frac{1}{p}\right).$$

Choosing now $p \approx \log_a D$, the storage requirement is equivalent to $l \approx \log_a D - \log_a \log_a D$ and the number of operations becomes

$$C_{tot} \approx \frac{m\,n}{\log_a D} = \frac{n}{\log_s D}$$

for D large compared to a. This shows that the adaptation of the new algorithm to the second polynomial-evaluation problem yields an algorithm that outperforms Horner's rule if storage on the order of the number of possibly different coefficients s is available. Note that at the same time the number of operations needed for the precomputation (which is less than D) and the number of nonscalar multiplications needed in Step 4 ($C_{ns} = q - 1$) are quite small. But the minimizing of C_{ns} is preferably done with a simple algorithm that first precomputes the powers of the argument x. As an example, if $D = n$ storage locations are available, then all needed powers of x can be precomputed and, with n scalar multiplications and n additions, every polynomial can be computed.

Application 3: Decoding binary BCH codes. Binary BCH codes are widely used for error correction or detection; a detailed treatment can be found in [1, Chap. 7]. For a primitive binary BCH code of block length $N = 2^M - 1$ and design distance $d = 2t+1$, the received block $[c_{N-1}, \cdots, c_1, c_0]$ can be identified with the polynomial $p(X) = c_{N-1}X^{N-1} + \cdots + c_1 X + c_0$ with binary coefficients c_i. There exists a decoding algorithm that computes which coefficients are incorrect, provided that at most t errors occurred in transmission. The most commonly used algorithm consists of computing syndromes, finding the error locator polynomial, and calculating its zeros (see [1, pp. 183–193] for all details). In this application we focus on the first part of this decoding algorithm, namely, computing the syndromes $S_j = p(\alpha^j)$ for $j = 1, 3, \ldots, 2t - 1$, where α is a primitive element in GF(2^M).

Consider now an implementation of such a decoding algorithm on a general-purpose single-processor computer. Assume that procedures for executing field operations in GF(2^M) are available. Obviously, the number of field operations required determines the running time of the decoding algorithm. The syndrome calculation consists of evaluating the polynomial $p(X)$ for t values of its argument. This can be done by Horner's rule with $2t(N-1)$ operations. The additions in Horner's rule call for adding a coefficient that is either 0 or 1, and hence these additions can be skipped or easily implemented. In general, however, the $C_s \triangleq t(N-1)$ multiplications in Horner's rule must be performed. Indeed, this is a substantial part of the whole decoding computation.

We propose an algorithm to reduce the number of field operations needed to calculate the syndromes. The syndrome calculation requires the evaluation of a polynomial $p(X)$ of degree $N - 1$ with binary coefficients c_i for t values x of X. This corresponds exactly to the second polynomial-evaluation problem. Because the coefficients are binary, we have $m = 1$ in the definition of the set $\mathcal{S}$ of coefficients. Thus, Step 3 of the algorithm in §2 can be omitted. Therefore, it suffices to perform the following calculations for $j = 1, 3, \ldots, 2t - 1$:

Step 1. Precompute the lists $T_0, T_1, \ldots, T_{p-1}$ containing the values

$$T_i[\underline{a}] = \left(a_{l-1} \cdot (\alpha^j)^{l-1} + \cdots + a_1 \cdot \alpha^j + a_0\right) \cdot (\alpha^j)^{il}$$

for all $\underline{a} = [a_{l-1}, \ldots, a_0] \in \{0, 1\}^l$. Additionally compute $\alpha^{jpl} = \alpha^j \cdot T_{p-1}[[1, 0, \ldots, 0]] = \alpha^j \cdot (\alpha^j)^{(p-1)l+l-1}$. (This can be done in the manner of Step 1 in §2 with less than $p \cdot 2^l$ operations, of which $pl - 1$ are multiplications. The storage needed is equal to the total number of operations.)

Step 2. For the binary inputs $c_0, \ldots, c_{N-1}$, compute

$$h_k(\alpha^j) = T_{p-1}[\underline{c}_{k,p-1}] + \cdots + T_0[\underline{c}_{k,0}],$$

where $\underline{c}_{k,i} = [c_{kpl+il+l-1}, \ldots, c_{kpl+il+1}, c_{kpl+il}]$ for $k = 0, \ldots, q-1$. (This can be done with $q(p-1)$ additions.)

Step 3. Finally, compute

$$p(\alpha^j) = (\cdots (h_{q-1}(\alpha^j) \cdot \alpha^{jpl} + h_{q-2}(\alpha^j)) \cdot \alpha^{jpl} + \cdots + h_0(\alpha^j)$$

by Horner's rule. (This requires $2(q-1)$ operations (half of which are multiplications) where $q = \lceil N/pl \rceil$.)

There is no additional storage needed for the computation in Steps 2 and 3 if the h_k are computed as they are used in Step 3. Table 1 lists the operations required for calculating syndromes for the binary BCH code ($N = 127$, $t = 7$) by this new method. For the chosen values, which are of practical interest, using Horner's rule to compute the syndromes requires $C_s = t(N-1) = 882$ multiplications and 882 trivial additions; the new method requires only 98 multiplications and 308 (nontrivial) additions. The improvement is especially great for the usual implementation of field operations in which multiplication is much more time-consuming than addition. This shows that the use of a small amount of storage can significantly simplify syndrome calculation for practical applications.

The optimum choice of the parameters is highly dependent on the actual implementation of the field operations and on the trade-off between storage and time that is suited to the application. The new algorithm gives an efficient way to use a certain amount of storage to minimize the number of field operations required to calculate the syndromes. If only a very small amount of storage is available, then there is the possibility of doing the precomputation with every computation. For this case, it is sufficient to store the lists $T_0, \ldots, T_{p-1}$ for one j, which amounts to $p2^l$ storage locations. The number of field operations is then the sum of those in the precomputation and the computation, which is still small. For the above parameters, 24 storage locations together with 546 field operations (154 multiplications) suffice.

5. Generalizations and remarks. The new polynomial-evaluation algorithm of §2 uses some ideas from an algorithm of Lupanov [5] (see also [10, pp. 91–92]) for evaluating Boolean functions in many variables. Strassen [9] extended Lupanov's ideas to an algorithm evaluating a multivariable polynomial $p(X_1, \ldots, X_r) \in \mathcal{F}[X_1, \ldots X_r]$, having degree less than n in each variable, at a value $[x_1, \ldots, x_r] \in \mathcal{E}^r$. Strassen showed that if $|\mathcal{F}|$ is much smaller than n^r, then at most $(n^r / \log_{|\mathcal{F}|}(n^r)) \cdot (1 + o(1))$ operations in $\mathcal{E}$ are needed. For $r = 1$, this result is very similar to Savage's [7]; both results hold if the number of different coefficients is much smaller than the degree of the polynomial. But Strassen's result is stated with only a small finite field as the coefficient set, whereas Savage's result holds for any small set. The crucial new idea exploited in this paper is to extend the set of allowed coefficients to the set of restricted linear combinations of specified generators, the restriction being that the scalars

TABLE 1

Computation count for calculating syndromes for the binary BCH code ($N = 127$, $t = 7$) by the new method. (The precomputation requires $t(pl-1) = 56$ multiplications and $t(p(2^l - l - 1)) = 84$ additions.)

Parameters			Precomputation and storage	Computation		
				#Additions	#Mult.	#Operations
p	l	$q = \lceil \frac{N}{pl} \rceil$	$tp2^l$	$t(qp-1)$	$t(q-1)$	$t(qp+q-2)$
3	3	15	168	308	98	406

come from a small set. This makes it possible to improve on Horner's algorithm even in cases where all the coefficients of the polynomial are distinct. This extension can be applied to polynomials in many variables as well.

The specific similarities and differences between the new algorithm and the one due to Savage [7] are the following. Steps 1 and 2 correspond to Savage's "computation of linear forms" and are only slightly refined compared to the steps used in the polynomial-evaluation application of his algorithm. Step 3 exploits our assumed structure of the coefficients, while Step 4 is exactly the same as Savage's final step. For the case where $m = 1$ (i.e., $\mathcal{A} = \mathcal{S}$), Step 3 is not required and the new algorithm virtually reduces to Savage's because our refinements in Step 1 and 2 are asymptotically negligible.

In all of the above, we have never actually used the fact that $\mathcal{F}$ or $\mathcal{E}$ are fields so that division by nonzero elements is well defined. In fact, we have not even used the commutativity of multiplication. Therefore our proposed algorithm works even if $\mathcal{F}$ and $\mathcal{E}$ are distinct noncommutative rings related by a ring-homomorphism $\phi : \mathcal{F} \longrightarrow \mathcal{E}$ with $\phi(1) = 1$, where the 1's are the neutral elements of the multiplication operations in the respective rings. As an example $\mathcal{F}$ could be the ring of 2×2 real matrices, $\mathcal{E}$ the ring of 4×4 real matrices, and ϕ the ring-homomorphism

$$\phi(M) = \begin{bmatrix} M & 0 \\ 0 & M \end{bmatrix},$$

where $M \in \mathcal{F}$ and 0 is the neutral element for addition in $\mathcal{F}$.

Finally, our new algorithm can be easily generalized to handle polynomials with coefficients from a set

$$\mathcal{S} = \{\beta_1 \cdot a_{i,1} + \cdots + \beta_m \cdot a_{i,m} \mid a_{i,j} \in \mathcal{A}_j\},$$

where the finite sets $\mathcal{A}_1, \ldots, \mathcal{A}_m$ are all different. It is possible to show the same asymptotics as before if the cardinalities of the sets are bounded by $|\mathcal{A}_j| \leq a$. We do not carry out this generalization in detail because we do not see a practical application for it at the moment.

Acknowledgments. The author is grateful to J. L. Massey, who significantly improved the presentation of this paper, and to A. Hiltgen for many constructive discussions.

WHEN IS THE ASSIGNMENT BOUND TIGHT FOR THE ASYMMETRIC TRAVELING-SALESMAN PROBLEM?*

ALAN FRIEZE†, RICHARD M. KARP‡, AND BRUCE REED§

Abstract. We consider the probabilistic relationship between the value of a random asymmetric traveling salesman problem $ATSP(M)$ and the value of its assignment relaxation $AP(M)$. We assume here that the costs are given by an $n \times n$ matrix M whose entries are independently and identically distributed. We focus on the relationship between $Pr(ATSP(M) = AP(M))$ and the probability p_n that any particular entry is zero. If $np_n \to \infty$ with n then we prove that $ATSP(M) = AP(M)$ with probability 1-o(1). This is shown to be best possible in the sense that if $np(n) \to c$, $c > 0$ and constant, then $Pr(ATSP(M) = AP(M)) < 1 - \phi(c)$ for some positive function ϕ. Finally, if $np_n \to 0$ then $Pr(ATSP(M) = AP(M)) \to 0$.

1. Introduction.

The *assignment problem* (AP) is the problem of finding a minimum-weight perfect matching in an edge-weighted bipartite graph. An instance of the AP can be specified by an $n \times n$ matrix $M = (m_{ij})$; here m_{ij} represents the weight of the edge between x_i and y_j, where $X = \{x_1, x_2, \ldots, x_n\}$ is the set of "left vertices" in the bipartite graph and $Y = \{y_1, y_2, \ldots, y_n\}$ is the set of "right vertices." The AP can be stated in terms of the matrix M as follows: find a permutation σ of $\{1, 2, \ldots, n\}$ that minimizes $\sum_{i=1}^{n} m_{i,\sigma(i)}$. Let $AP(M)$ be the optimal value of the instance of the AP specified by M.

The *asymmetric traveling-salesman problem* (ATSP) is the problem of finding a Hamiltonian circuit of minimum weight in an edge-weighted directed graph. An instance of the ATSP can be specified by an $n \times n$ matrix $M = (m_{ij})$ in which m_{ij} denotes the weight of edge $< i, j >$. The ATSP can be stated in terms of the matrix M as follows: find a cyclic permutation π of $\{1, 2, \ldots, n\}$ that minimizes $\sum_{i=1}^{n} m_{i,\pi(i)}$; here a cyclic permutation is one whose cycle structure consists of a single cycle. Let $ATSP(M)$ be the optimal value of the instance of the ATSP specified by M.

It is evident from the parallelism between the above two definitions that $AP(M) \leq ATSP(M)$. The ATSP is NP hard, whereas the AP is solvable in time $O(n^3)$. Several authors (for a recent survey see [BaTo]) have investigated whether the AP can be used effectively in a branch-and-bound method to solve the ATSP.

The most striking evidence of the power of this approach is given by the recent work of Miller and Pekny [MiPe]. Among many other computational results, they obtained optimal solutions to random instances with up to 500,000 cities, in which the m_{ij} were drawn independently from the integers in the range $[0, n]$. Miller and Pekny noticed that $AP(M)$ was often equal to $ATSP(M)$, and they exploited this observation by developing a special method to search for a cyclic permutation among the optimal solutions to the AP.

Motivated by the computational experience of Miller and Pekny, we have investigated the following question: when the m_{ij} are drawn independently from a common distribution (over, say, the nonnegative reals), what is the probability that $AP(M) = ATSP(M)$? The answer depends on the probability that an entry is zero. We show that, if the expected number of zeros in a row of M tends to infinity as $n \to \infty$ then the probability that $AP(M) =$

$ATSP(M)$ tends to 1, and we give an $O(n^3)$-time algorithm for finding an optimal solution to the ATSP with high probability. Conversely, if the underlying distribution is uniform over the range of integers $[0..\lfloor c_n n \rfloor]$, where c_n tends to infinity with n, then the probability that $AP(M) = ATSP(M)$ tends to 0. Finally, we show that if the underlying distribution is uniform over the range of integers $[0..\lfloor cn \rfloor]$ where c is a positive constant, then the probability that $AP(M) = ATSP(M)$ does not tend to 1. We conjecture that for distributions of this type, the probability that $AP(M) = ATSP(M)$ tends to some positive constant less than 1 which depends on c.

The results of this paper are closely related to some earlier results of Karp [K], Karp and Steele [KS], and Dyer and Frieze [DF]. Here the $m_{i,j}$ are drawn independently from the uniform distribution over [0,1]. Karp showed that $ATSP(M)/AP(M) = 1 - o(1)$ (whp) (we use the notation (whp) as shorthand for "with probability tending to 1 as n tends to infinity"). Later, Karp and Steele and then Dyer and Frieze strengthened this result in several ways. For example, the latter paper shows that the error term is $o((\log n)^4/n)$.

2. The theorems.

THEOREM 2.1. *Let $\{X_n\}$ be a sequence of random variables over the nonnegative reals. Let $p_n = Pr[X_n = 0]$ and let $w(n) = np_n$. Let $M = M(n)$ be an $n \times n$ matrix whose entries are drawn independently from the same distribution as X_n. If $w(n) \to \infty$ as $n \to \infty$ then $AP(M) = ATSP(M)$ (whp).*

(Examination of the proof of Theorem 2.1 reveals that the distribution of nonzeros can be more complicated than actually stated. Indeed one can allow the costs to be generated as follows: start with an *arbitrary* real nonnegative $n \times n$ matrix M. Randomly permute its rows and columns. Then for each $i, j \in [n]$ replace $M_{i,j}$ with zero, with probability p_n. There is also the proviso that the probability of two identical columns should tend to zero with n.)

Frieze [Fr] has shown that, if $w(n) = \ln n + t(n)$, where $t(n)$ tends to infinity, then $ATSP(M) = 0$ (whp), and so $AP(M) = ATSP(M)$ (whp). Thus, we restrict attention to the case where $w(n) = O(\ln n)$. The case where X_n has the uniform distribution over the range of integers $[0..N(n)]$ is particularly relevant to the Miller–Pekny computations. In this case, Theorem 2.1 tells us that $AP(M) = ATSP(M)$ (whp) provided that $N(n) = o(n)$.

THEOREM 2.2. *Let $M = M(n)$ be an $n \times n$ matrix whose entries are drawn independently from the uniform distribution over $\{0, 1, \ldots, \lfloor cn \rfloor\}$, where c is a positive constant. Then the probabilty that $AP(M) \neq ATSP(M)$ does not tend to zero as n tends to infinity.*

THEOREM 2.3. *Let $M = M(n)$ be an $n \times n$ matrix whose entries are drawn independently from the uniform distribution over $\{0, 1, \ldots, \lfloor c_n n \rfloor\}$, where c_n tends to infinity with n. Then the probability that $AP(M) \neq ATSP(M)$ tends to 1 as n tends to infinity.*

3. Proof of Theorem 2.1. We begin with some conventions and definitions.When n is understood from context we abbreviate p_n by p, $w(n)$ by w and $M(n)$ by M; also, "permutation" will mean "permutation of $\{1, 2, \ldots, n\}$."

Let H be the weighted bipartite graph with vertex set $X \cup Y$, where $X = \{x_1, x_2, \ldots, x_n\}$ and $Y = \{y_1, y_2, \ldots, y_n\}$, and with an edge of weight m_{ij} between x_i and y_j. Let G be the complete digraph on vertex set $\{1, 2, \ldots, n\}$, in which each edge $< i, j >$ has weight m_{ij}. A *cycle cover* is a subgraph of G in which each of the n vertices has in-degree 1 and out-degree 1. The AP can be stated in any of the following equivalent forms:

- find a perfect matching of minimum weight in H;
- find a cycle cover of minimum weight in G;
- find a permutation σ to minimize $\sum_{i=1}^{n} m_{i,\sigma(i)}$.

Let the indicator variable z_{ij} be 1 if $m_{ij} = 0$ and 0 otherwise. Then the z_{ij} are independent, and each z_{ij} is equal to 1 with probability p. Emulating a useful trick due to Walkup [Wal1], we

view the z_{ij} as being generated in the following way. Let h be defined by the equation $1-p=(1-h)^5$ and let z_{ij}^k, for $i=1,2,\ldots,n$, $j=1,2,\ldots,n$ and $k=1,2,3,4,5$, be independent indicator variables, each of which is equal to 1 with probability h. Let $z_{ij}=\max_{k=1}^5 z_{ij}^k$. Then the z_{ij} are independent and each is equal to 1 with probability p. For $k=1,2$, let H_k be the bipartite graph with vertex set $X\cup Y$ and an edge between x_i and y_j if and only if $z_{ij}^k=1$. For $k=3,4,5$, let G_k be the digraph with vertex set $\{1,2,\ldots,n\}$ and an edge from i to j if and only if $z_{ij}^k=1$. The edges of G_3, G_4, and G_5, respectively, will be called *out-edges*, *in-edges*, and *patch edges*. Each type of edge will play a special role in the construction of a Hamiltonian circuit of weight $AP(M)$. It will be important that the random graphs H_1 and H_2 and the random digraphs G_3, G_4, and G_5 are completely independent. Also, let $s(n)=nh(n)$; $s(n)$ is the expected degree of a vertex in H_1 or H_2, and the expected out-degree of a vertex in G_3, G_4 or G_5. Clearly, $s(n)\geq\frac{w(n)}{5}$, and thus $s(n)$ tends to infinity if $w(n)$ does.

The construction of the desired Hamiltonian circuit proceeds in the following stages:

- (Identification of "troublesome vertices.") By considering the edges of $H_1\cup H_2$ identify a set $A\subset X$ and a set $B\subset Y$. The cardinality of $A\cup B$ is small (whp). The set $A\cup B$ contains the vertices of exceptionally small degree plus certain other vertices that are likely to be incident with edges of nonzero weight in an optimal assignment. At the same time construct a matching in H which is of minimum weight, subject to the condition that it covers the vertices in $A\cup B$ and no other vertices.
- Consider the subgraph of $H_1\cup H_2$ induced by $(X\setminus A)\cup(Y\setminus B)$. This bipartite graph has a perfect matching (whp). Combining that perfect matching with the matching constructed in the previous step, obtain an optimal assignment for H in which every nonzero-weight edge is incident with a vertex in $A\cup B$.
- The optimal assignment just constructed has the properties of a random permutation.
- Using the out-edges and in-edges, attempt to convert the original optimal assignment into a permutation with no short cycles. This process succeeds (whp).
- Using the patch edges, patch the long cycles together into a single cycle, thus solving the $ATSP$. The patching process succeeds (whp).

The overall strategy of the proof is to construct an optimal assignment while keeping the in-edges, out-edges, and patch edges (except those incident with $A\cup B$) in reserve for use in converting the optimal assignment to a tour. In the following sections we describe the algorithm in greater detail and give the proofs of the main assertions.

4. Identification of the sets A and B. Consider the directed bipartite graph D with vertex set $X\cup Y$. The edges of D are those of H_1 directed from X to Y plus those of H_2 directed from Y to X. The expected out-degree of a vertex in D is $s(n)$, which we abbreviate by s. Let $d(v)$ be the out-degree of vertex v, let $N(v)$ be the set of out-neighbors of v, and, for any set of vertices S, let $N(S)$ be the set of vertices adjacent from vertices in S.

We give an iterative construction for identifying a small set $A\cup B$ of vertices that are likely to be incident with edges of nonzero weight in an optimal assignment.

Let $W_{-1}=\{x\in X\cup Y|d(x)\leq s/2\}$. Let F_0 be a minimum weight matching in H which covers the vertices of W_{-1}. Let W_0 denote the set of vertices covered by F_0. Define a maximal sequence $(W_0,F_0),(W_1,F_1),\ldots,(W_r,F_r)=(W,F)$ where (W_i,F_i) is obtained from (W_{i-1},F_{i-1}) as follows: suppose there exists $x\notin W_{i-1}$ such that $|N(x)\cap W_{i-1}|\geq s/4$. F_i is then a minimum weight matching in H which covers W_{i-1} and x and, necessarily, one other vertex y. We then take $W_i=W_{i-1}\cup\{x,y\}$. (F_i is obtained by constructing a least cost augmenting path from x w.r.t. F_{i-1}.)

LEMMA 4.1. $|W|<3ne^{-\frac{s}{5}}$ *(whp)*.

Proof. The proof follows from two simple claims. They can easily be justified by the first moment method; the calculations are omitted.

CLAIM 1. $|W_{-1}| \leq ne^{-s/5}$ *(whp).*

CLAIM 2. $S \subseteq X \cup Y$, $|S| \leq 3ne^{-s/5}$ *implies that (whp), in* $H_1 \cup H_2$, S *contains fewer than* $2|S|$ *edges.*

Assume the conditions of the above two claims. Then $|W_0| \leq 2|W_{-1}| \leq 2ne^{-s/5}$. Now $|W_i| = |W_0| + 2i$ and W_i contains at least $is/4$ edges. If $|W| \geq 3ne^{-s/5}$ then r, the number of pairs of vertices adjoined to W_0 in constructing the set W, is greater than or equal to $r_0 = \lfloor ne^{-s/5}/2 \rfloor$. But then W_{r_0} has at most $3ne^{-s/5}$ vertices and contains at least $r_0 s/4$ edges, contradicting Claim 2. □

We then take $A = W \cap X$ and $B = W \cap Y$. The subprocess of constructing A involves counting the edges directed into $Y \setminus B$ from each vertex $x \in X \setminus A$, but does not depend at all on which particular vertices in $Y \setminus B$ are adjacent to x. Thus, $N(x) \cap (Y \setminus B)$ is of cardinality at least $s/4$ and it is a random set in the sense that the probability that it is equal to a given subset of $Y \setminus B$ depends only on the cardinality of that subset; moreover, there is no dependency among the distinct sets $N(x) \cap (Y \setminus B)$ as x ranges over $X \setminus A$. Similar statements can be made about the sets $N(y) \cap (X \setminus A)$, for $y \in Y \setminus B$. There are also no dependencies between these two collections of sets. Furthermore, in constructing W using the augmenting path approach, we did not need to consider the cost of any edge with both its endpoints in $H - W$. Thus, each such edge is still an in, out, or patch edge with probability h.

5. Construction of an optimal assignment.

LEMMA 5.1. *The subgraph of* $H_1 \cup H_2$ *induced by* $(X \setminus A) \cup (Y \setminus B)$ *has a perfect matching (whp).*

Proof. Recall that a random k-out bipartite graph on the vertex set $X \cup Y$, where X and Y are disjoint n-element sets, is constructed by having each vertex in X choose k random neighbors in Y and each vertex in Y choose k random neighbors in X. The proof follows immediately from Walkup's result [Wal2] that a random k-out bipartite graph has a perfect matching (whp) for any $k \geq 2$. □

Thus, we can obtain an optimal assignment (whp) by combining an optimal matching covering $A \cup B$ with a perfect matching in the subgraph of $H_1 \cup H_2$ induced by $(X \setminus A) \cup (Y \setminus B)$.

6. Structure of the optimal assignment. In this section we show that, if M is a random instance of the AP, then, with suitable implementation, the construction of an optimal assignment based on Lemma 5.1 yields a random permutation. Define the *equivalence class* of a matrix M as the set of all matrices obtained by permuting the columns of M. A typical member of this equivalence class, corresponding to the permutation π, is the matrix M^π defined by $m^\pi_{i,\pi(j)} = m_{ij}$. Except for a negligible fraction of the matrices in U_n^N (namely, those with two equal columns), the equivalence class of M consists of $n!$ distinct and equiprobable matrices. Let σ be the optimal assignment for M obtained by the algorithm described above. Then $\pi\sigma$ is an optimal assignment for M^π. Moreover, the algorithm for constructing the optimal assignment can be implemented so that the following hold:

- If σ is the optimal assignment constructed for M, then $\pi\sigma$ is the optimal assignment constructed for M^π;
- A, the set of troublesome rows for M, is also the set of troublesome rows for M^π.

One way to ensure this is to permute the columns of M into lexicographic order, find the set of troublesome rows and an optimal assignment in the resulting matrix, and then permute the columns back. For any fixed σ, as π ranges over all permutations of $\{1, 2, \ldots, n\}$, $\pi\sigma$ also ranges over all permutations of $\{1, 2, \ldots, n\}$. Since all the matrices in $[M]$ are equally likely, we have established that the permutation produced by the optimal assignment algorithm described above is equally likely to be any permutation.

We note some facts about random permutations. Let σ be drawn at random from the set of permutations of $\{1, 2, \ldots, n\}$. Then the following are true:

- σ has at most $2 \ln n$ cycles (whp);
- For all k,there are fewer than $w(n)^k$ cycles of length k (whp);
- There are at most $\frac{n}{w^{1/3}}$ vertices on cycles of length at most $\frac{n}{\sqrt{w}}$ (whp).

Now let σ be the optimal assignment selected by our algorithm. Then we have the following lemma.

LEMMA 6.1. *No cycle of σ has more than one-tenth of its vertices in W (whp).*

Proof. Conditioning on the event that M lies in a particular equivalence class, σ is equally likely to be any permutation, while A is a fixed set of very small cardinality (whp). A straightforward calculation shows that no cycle has more than one-twentieth of its vertices in A (whp). Indeed, given $|A| = a \leq 3ne^{-s/5}$, the expected number of cycles containing so many members of A is at most

$$\sum_{k=1}^{n} \binom{n-a}{k-\lceil k/20 \rceil} \binom{a}{\lceil k/20 \rceil} (k-1)! n^{-k} \leq \sum_{k=1}^{n} 2^k \left(\frac{a}{n}\right)^{k/20} = o(1).$$

A similar argument applies to B. □

7. Elimination of small cycles. Call a cycle in a permutation *small* if it contains fewer than $\frac{n}{\sqrt{w}}$ vertices. We now show how the out-edges and in-edges are used to convert the original optimal assignment into an optimal assignment in which no cycle is small. Our procedure is to take each small cycle of the original optimal assignment σ in turn and try to remove it without creating any new small cycles. During its execution our algorithm will designate a vertex as *dirty* when its out-edges or in-edges have been observed, so that they may no longer be considered random. The initial set of dirty vertices is the set W defined above. A vertex that is not dirty will be called *clean*. If i is clean then, independently for each j, $< i, j >$ is an out-edge with probability $\frac{s}{n}$ and $< j, i >$ is an in-edge with probability $\frac{s}{n}$. Throughout the computation, we will maintain the property that at least nine-tenths of the vertices in any remaining short cycle are clean.

We now describe the *rotation-closure algorithm* that is used to eliminate one small cycle. Let C be a small cycle of length k in the current optimal assignment. Let $\hat{k} = \min(\lceil \frac{9k}{10} \rceil, \lfloor \ln \ln n \rfloor)$. Choose $\hat{k}$ clean vertices on C. We make up to $\hat{k}$ separate attempts to remove C. The ith attempt consists of an out phase and an in phase. Let v_i be the ith of the $\hat{k}$ clean vertices selected from C, and let u_i be the predecessor of v_i on C.

7.1. The out phase. Define a *near-cycle-cover* as a digraph θ consisting of a directed path P_θ ending at a clean vertex plus a set of vertex-disjoint directed cycles covering the vertices not in P_θ. We obtain an initial near-cycle-cover by deleting edge $< u_i, v_i >$ from the current optimal assignment, thus converting the small cycle C into a path from v_i to u_i. We then attempt to obtain many near-cycle-covers by a rotation process. The state of this process is described by a rooted tree whose nodes are near-cycle-covers, with the original near-cycle-cover at the root. Consider a typical node θ consisting of a path P_θ directed from a_θ to b_θ plus a cycle cover of the remaining vertices. We obtain descendants of θ by looking at out-edges directed from b_θ. Consider an edge that is directed from b_θ to a vertex y whose predecessor x is clean. Such an edge is *successful* if either y lies on a large cycle or y lies on P_θ and the subpaths of P_θ from a_θ to x and from y to b_θ are both of length at least $\frac{n}{\sqrt{w}}$. In such cases a descendant of θ is created by deleting $< x, y >$ and inserting $< b_\theta, y >$. Once node θ has been examined, b_θ is permanently marked dirty. The tree of near-cycle-covers is grown in a breadth-first manner until the number of leaves reaches $m = \sqrt{n \ln n}$.

We shall show later that the number of vertices marked dirty throughout the entire algorithm is $o(n)$ (whp). Assuming this, noting that each path P_θ ends in a clean vertex

b_θ, and assuming that the number of vertices on short cycles is less than $\frac{n}{w^{1/3}}$ (this is true (whp)) the number of descendants of node θ is a random variable whose distribution is $BINOMIAL(n - o(n), s/n)$, and the random variables associated with distinct nodes are independent. Suppose that level t of the rooted tree describing the out phase has a vertices. Then, applying a Chernoff bound on the tails of the binomial distribution, the number of nodes at level $t+1$ lies between $\frac{as}{2}$ and $2as$, with probability greater than or equal to $1 - e^{-\frac{as}{10}}$. Hence the probability that the out phase fails to produce m leaves is (quite conservatively) at most

$$\sum_{k=1}^{\infty} e^{-ks/10} \leq e^{-s/20}.$$

7.2. The in phase. The tree produced by an out phase has m terminal nodes. Each of these is a near-cycle-cover in which the directed path begins at v_i. Let the jth terminal node be denoted G_j, and let the directed path in G_j run from v_i to x_j. During the in phase we grow rooted trees independently from all the G_j, $j = 1, 2, \ldots, m$. The process is like the out phase except that, in computing the descendants of a node θ, we fan backward along in-edges rather than forward along out-edges. For example, if a node θ with a path P_θ from a_θ to x_j is encountered, then we look for in-edges of the form $< x, a_\theta >$ such that x does not lie on a short cycle and y, the successor of x in G_θ, is clean. We then create a descendant by deleting $< x, y >$ and inserting $< x, a_\theta >$, provided that this substitution does not create a path or cycle of length less than $\frac{n}{\sqrt{w}}$. Once the descendants of θ have been computed, the node a_θ is permanently marked dirty.

Suppose that $S_1, S_2, \ldots, S_m$ are the near-cycle-covers produced by the out phase. We describe a two-stage process for producing the near-cycle-covers of the in phase which is equivalent to that described in the previous paragraph. In the first stage, imagine that we grow the trees ensuring only that edges from clean vertices are used and that y is not on a small cycle. Thus we allow new small cycles to be produced. Each tree is grown to a depth ℓ where $(w/2)^\ell \approx m$. The following is true (whp): for each tree, and each depth $t < \ell$, the ratio between the number of nodes of depth $t+1$ and the number of nodes of depth t lies between $w/2$ and $2w$. The parameter ℓ is chosen so that even if each nonleaf has only $w/2$ descendants, the tree will still have at least m leaves. Let Σ_j denote the set of initial vertices of the paths of the near-cycle-covers created from S_j in this way. We show that $\Sigma_1 = \Sigma_2 = \cdots = \Sigma_m$. In fact let $\Sigma_j^{(t)}$ denote the set of start vertices of the paths at level t in the jth tree. Clearly $\Sigma_j^{(0)} = \{v_i\}$ for all j and so assume inductively that we have $\Sigma_j^{(t)} = \Sigma_1^{(t)}$ for some $t \geq 0$. But then the clean vertices $\Sigma_j^{(t+1)}$ whose in-edges are directed into $\Sigma_j^{(t)}$ are the same as the clean vertices $\Sigma_1^{(t+1)}$ whose in-edges are directed into $\Sigma_1^{(t)}$. This completes the inductive step. We see also that from this construction the number of vertices marked dirty by this stage is at most $(2w)^\ell$ and then it is easy to see that the total number of dirty vertices produced is $O(n^{.5+o(1)})$. It follows from our analysis of the out phase that if $\mathcal{E}$ denotes the event "we fail to produce m trees in the first stage," then

$$Pr(\mathcal{E}) \leq e^{-w/20}. \tag{1}$$

We do not have to multiply the right-hand side of (1) by m because the construction above succeeds for all S_j if and only if it succeeds for S_1. In the second stage we prune the m trees we have produced by deleting any edge which involved the construction of a small cycle. For $j = 1, 2, \ldots, m$, let T_j be the pruned tree grown from root G_j during the two stages. Thus T_j is what we would get from G_j if we had followed the procedure described in the second paragraph of this section.

Let us call T_j *good* if it has m leaves and *bad* otherwise. Since the number of vertices marked dirty during the entire computation is $o(n)$, by the same analysis that was applied to the out phase, the probability that an individual T_j is bad is less than or equal to $e^{-\frac{w}{20}}$. Thus the expected number of bad trees is at most $me^{-\frac{w}{20}}$ and, by Markov's inequality, the probability that the number of bad trees is at least $m/2$ is bounded above by $2e^{-\frac{w}{20}}$. Thus,

$$Pr\left(\exists \geq \frac{m}{2} \text{ good trees}\right) \geq Pr(\mathcal{E}) - Pr\left(\exists \geq \frac{m}{2} \text{ bad trees}\right)$$
$$\geq 1 - 3e^{-w/20}.$$

Assuming that the out phase succeeds in creating a rooted tree with m leaves, and that at least half of the m trees T_j created during the in phase are good, we now have at least $m/2$ sets, each consisting of m near-cycle-covers. In the set associated with T_j, each near-cycle-cover consists of a path ending at x_j, together with a cycle cover of the remaining vertices. The m paths have distinct starting points. Since the out-edges from x_j are unconditioned, the probability that none of the $\frac{m^2}{2}$ paths is closed by an out-edge is bounded above by $(1-\frac{s}{n})^{m^2/2} \leq n^{-\frac{s}{2}}$. Thus, with probability at least $1 - n^{-\frac{s}{2}}$, one of these paths can be closed with an out-edge, and doing so creates an optimal assignment with one short cycle less than the optimal assignment that existed at the beginning of the out phase.

Thus the probability that the tth attempt at removing C fails given that the first $t-1$ attempts have also failed can be bounded by, say, e^{-Aw} for some absolute constant $A > 0$. Since we make $\hat{k}$ attempts, the probability that we fail to remove all short cycles is at most

$$\sum_{k=1}^{\lfloor \ln \ln n \rfloor} w^k e^{-\hat{k}Aw} + 2 \ln n e^{-Aw \ln \ln n} = o(1).$$

8. The patching process. At the start of the patching process we have an optimal assignment without small cycles, and the patch edges are unobserved, and thus unconditioned, except for those incident with the set of vertices $W = \{i | x_i \in A\} \cup \{j | y_j \in B\}$. Suppose we start with cycles $C_1, C_2, \ldots, C_r$, each of which contains at least $\frac{n}{\sqrt{w}}$ vertices. We describe a procedure that attempts to patch these cycles together to form a tour. The basic operation of patching together two cycles C and C' is as follows. Suppose cycle C contains an edge $< a_1, a_2 >$ and cycle C' contains an edge $< b_1, b_2 >$. If $< a_1, b_2 >$ and $< b_1, a_2 >$ are both patch edges then we can combine C and C' into a single cycle by deleting $< a_1, a_2 >$ and $< b_1, b_2 >$ and inserting $< a_1, b_2 >$ and $< b_1, a_2 >$.

We attempt to create a tour by repeatedly patching cycles together in this way. We describe a generic step in which, having patched $C_1, C_2, \ldots, C_{s-1}$ together to form a cycle C, we try to patch C_s and C together. There are at most $3ne^{-\frac{s}{5}}$ vertices in W on $C_s \cup C$. Independently, for each pair consisting of an unconditioned vertex on C_s and an unconditioned vertex on C, a patch edge is present with probability s/n. Thus, the probability that there is no pair of edges that will patch C_s and C together is bounded above by $(1 - (\frac{s(n)}{n})^2)^{(|C|-3ne^{-s/5})(|C_s|-3ne^{-s/5})}$. This is less than or equal to $e^{-w+o(1)}$. Hence the probability that the patching process fails is bounded above by $\sqrt{w}e^{-w+o(1)} = o(1)$.

We have now completed the entire proof of Theorem 2.1.

9. The proofs of Theorems 2.2 and 2.3. In proving Theorems 2.2 and 2.3, we shall describe the generation of our matrix M, the corresponding bipartite graph H, and the directed graph G in a slightly different manner.

We first generate a random $n \times n$ matrix N where each entry is drawn uniformly from $\{0, 1, \ldots, \lfloor c_n n \rfloor\}$ and these choices are independent (note that in order to combine

Theorems 2.2 and 2.3 we insist only that c_n is either constant or goes to infinity with n). We then randomly choose a permutation Π of $\{1, \ldots, n\}$ with each permutation equally likely. We obtain M by setting $m_{i\pi(j)} = n_{ij}$ (where n_{ij} is the entry in the ith row and jth column of N). Proceeding in this fashion rather than choosing the elements of M directly makes certain assertions about the independence of events obvious. We let H' be the bipartite graph which corresponds to N in the same way that H corresponds to M. We note that if we choose some optimal matching in H' then the corresponding matching in M will have the cycle cover of a random permutation.

We now need some definitions. So, consider an arbitrary matrix N and corresponding bipartite subgraph H'. By a *forced edge* of H' we mean an edge which is in every optimal matching in H'. By an *active edge* we mean an edge which is in some optimal matching of H' and has weight at least one. The first step in proving Theorems 2.2 and 2.3 is to note that if a particular weighting has a lot of forced edges then probably it will not satisfy $AP(M) = ATSP(M)$. In particular if all the edges are forced then the probability that $ATSP(M) = AP(M)$ is $\frac{1}{n}$.

The precise result we will need is that if for some weighting the corresponding H' has s forced edges then the probability that the corresponding cycle cover has a non-Hamiltonian cycle made up only of forced edges — a *forced cycle* — is the same as it would be if we took a random cycle cover and then chose s edges at random and called them forced. This follows from the manner in which we generate M. It is convenient now to give a lower bound for the probability $\pi_{t,n}$ that a random cycle cover has a cycle of length at most t (more precise esitmates are available, see for example Bollobás [B]). We will use $\pi_{t,n} \geq 1 - \frac{1}{t+1}$. To see this use induction on

$$\pi_{t,n} = \left(2t - 1 + \sum_{i=t+1}^{n-t-1} \pi_{t,i}\right)/n,$$

which is a consequence of the fact that the size of the cycle containing 1 is uniformly distributed. The following lemma then follows easily.

LEMMA 9.1. *For any weighting of N such that H' has s forced edges, the probability that the corresponding weighting of M has a forced cycle of size at most $n-1$ and hence $AP(M) \neq ATSP(M)$ is at least*

$$\max\left\{\left(1 - \frac{1}{t+1}\right)\left(\frac{s(s-1)\ldots(s-t+1)}{n(n-1)\ldots(n-t+1)}\right) \mid t = 1, 2, \ldots, n-1\right\}.$$

The second step in the proof is to note that most weightings will have many active edges because many vertices of G will not be the tail of any arc of cost zero. In fact since the probability that x is such a vertex is $(1 - \frac{1}{\lfloor c_n n \rfloor})^n$, we obtain the following lemma.

LEMMA 9.2. *The expected number of active edges for a random weighting is at least*

$$(1 + o(1))ne^{-1/c_n}.$$

The key to the proof is the following lemma which links these two results.

LEMMA 9.3. *The expected number of forced edges in a random weighting is at least the expected number of active edges.*

Combining Lemmas 9.2 and 9.3, we obtain that the expected number of forced edges is at least $(1 + o(1))ne^{-1/c_n}$. Theorem 2.2 then follows immediately from Lemma 9.1, on taking $t = 2$, i.e.,

$$\begin{aligned} Pr(AP(M) \neq ATSP(M)) &\geq Pr \text{ (forced cycle of length at most 2)} \\ &\geq E\left(\frac{2s(s-1)}{3n(n-1)}\right) \\ &\geq \frac{2E(s)(E(s)-1)}{3n(n-1)} \qquad \text{by Jensen's inequality} \\ &= (1-o(1))\frac{2e^{-2/c}}{3}. \end{aligned}$$

Again combining Lemmas 9.1, 9.2, and 9.3 we see that if c_n tends to infinity with n then Theorem 2.3 follows from

$$\begin{aligned} Pr(AP(M) \neq ATSP(M)) &\geq Pr \text{ (forced cycle of length at most } t) \\ &\geq \left(1-\frac{1}{t+1}\right)\left(1-\frac{2}{c_n}\right)^t\left(1-O\left(\frac{t^2}{n}\right)\right) \\ &= 1-o(1) \end{aligned}$$

if $t \to \infty, t = o(c_n + \sqrt{n})$.

One can tighten Theorem 2.2 slightly by insisting that the solution to $AP(M)$ contains no 1-cycles. Thus let $D(M)$ denote problem $AP(M)$ with the added constraint that the permutation should contain no 1-cycles, i.e., be a *derangement*. If the solution to $AP(M)$ is a derangement then it also solves $D(M)$ and the probability of this tends to e^{-1}. Since forced edges occur independently of the cycle structure we can see that

$$Pr(D(M) \neq ATSP(M)) \geq (1-o(1))\left(\frac{2}{3}-(1-e^{-1})\right)e^{-2/c}.$$

The question of whether or not Theorem 2.3 can be similarly strengthened remains open. The answer is almost certainly yes, but how do we prove it?

It remains only to prove Lemma 9.3.

To prove Lemma 9.3, we give an injective mapping from the (weighting, active-edge) pairs to the (weighting, forced-edge) pairs. This implies the result. Indeed, let $m = \lfloor c_n \rfloor + 1$ and Ω_e (respectively, Ω'_e) denote the set of weightings in which e is an active (respectively, forced) edge. Then

$$\begin{aligned} E(s) &= m^{-n}\sum_e |\Omega_e| \\ &\geq m^{-n}\sum_e |\Omega'_e| \qquad \text{as will be shown} \\ &= E \text{ (number of active edges)}. \end{aligned}$$

It only remains to show that $|\Omega_e| \geq |\Omega'_e|$ for all edges e. Now, given an active edge e in a weighting W, we obtain a new weighting W' by reducing the weight on e by 1 and leaving all other weights the same. We note that the cost of an optimal matching with respect to W' is one less than the cost of an optimal matching with respect to W and any optimal matching with respect to W' must use e. In our mapping, we map (W, e) to (W', e). Clearly, this gives the desired injection. This completes the proof of Lemma 9.3 and the two theorems. We note that our injection is almost a bijection because adding one to a forced edge yields an active edge in a new matching unless the forced edge has weight $\lfloor c_n n \rfloor$, which is a rare occurrence.

SCALING ALGORITHMS FOR THE SHORTEST PATHS PROBLEM*

ANDREW V. GOLDBERG†

Abstract. We describe a new method for designing scaling algorithms for the single-source shortest paths problem and use this method to obtain an $O(\sqrt{n}m \log N)$ algorithm for the problem. (Here n and m are the number of nodes and arcs in the input network and N is essentially the absolute value of the most negative arc length; arc lengths are assumed to be integral.) This improves previous bounds for the problem. The method extends to related problems.

Key words. shortest paths problem, graph theory, networks, scaling

AMS subject classifications. 68Q20, 68Q25, 68R10, 05C70

1. Introduction. In this paper we study the shortest paths problem where arc lengths can be both positive and negative. This is a fundamental combinatorial optimization problem that often comes up in applications and as a subproblem in algorithms for many network problems. We assume that the length function is integral, as is the case in most applications.

We describe a framework for designing scaling algorithms for the shortest paths problem and derive several algorithms within this framework. Our fastest algorithm runs in $O(\sqrt{n}m \log N)$ time, where n and m are the number of nodes and arcs of the input network, respectively, and the arc costs are at least $-N$.[1] Our approach is related to the cost-scaling approach to the minimum-cost flow problem [2], [14], [18], [21].

Previously known algorithms for the problem are as follows. The classical Bellman–Ford algorithm [1], [8] runs in $O(nm)$ time. Our bound is better than this bound for $N = o(2^{\sqrt{n}})$. Scaling algorithms of Gabow [12] and Gabow and Tarjan [13] are dominated by an assignment subroutine. The former algorithm runs in $O(n^{3/4}m \log N)$ time; the latter algorithm runs in $O(\sqrt{n}m \log(nN))$ time.[2] Our bound dominates these bounds. The fastest shortest paths algorithm currently known for planar graphs [9], [19] runs in $O(n^{1.5})$ time. Our algorithm runs in $O(n^{1.5} \log N)$ time on planar graphs and is competitive for small values of N.

Our framework is very flexible. In §§8 and 9 we describe two variations of the $O(\sqrt{n}m \log N)$ algorithm. The first variation seems more practical and the second variation shows the relationship between our method and Dijkstra's shortest path algorithm [6]. The flexibility of our method may lead to better running time bounds.

The shortest paths problem is closely related to other problems, such as the minimum-cost flow, assignment, and minimum-mean length cycle problems. Our method for the shortest paths problem extends to these problems. In §10 we sketch extensions to the minimum-cost flow and assignment problems. McCormick [20] shows an extension to the minimum-mean cycle problem. The resulting algorithms achieve bounds that are competitive with those of the fastest known algorithms, but are somewhat simpler.

2. Preliminaries. The input to the single-source shortest paths problem is (G, s, l), where $G = (V, E)$ is a directed graph, $l : E \to \mathbf{R}$ is a length function, and $s \in V$ is the

[1]We assume that $N \geq 2$ so that $\log N > 0$.

[2]In [12], [13] these bounds are stated in terms of C, the maximum absolute value of arc costs. As noted by an anonymous referee, it is easy to see that C can be replaced by N.

source node (see, e.g., [4], [23]). The goal is to find shortest paths distances from s to all other nodes of G or to find a negative length cycle in G. If G has a negative length cycle, we say that the problem is *infeasible*. We assume that the length function is integral. We also assume, without loss of generality, that all nodes are reachable from s in G and that G has no multiple arcs. The latter assumption allows us to refer to an arc by its endpoints without ambiguity.

We denote $|V|$ by n and $|E|$ by m. Let M be the smallest arc length. Define $N = -M$ if $M < -1$ and $N = 2$ otherwise. Note that $N \geq 2$ and $l(a) \geq -N$ for all $a \in E$.

A *price function* is a real-valued function on nodes. Given a price function p, we define a *reduced cost function* $l_p : E \to \mathbf{R}$ by

$$l_p(v, w) = l(v, w) + p(v) - p(w).$$

We say that a price function p is *feasible* if

$$l_p(a) \geq 0 \quad \forall a \in E. \tag{1}$$

For an $\epsilon \geq 0$, we say that a price function is *ϵ-feasible* if

$$l_p(a) > -\epsilon \quad \forall a \in E. \tag{2}$$

Given a price function p, we say that an arc a is *admissible* if $l_p(a) \leq 0$, and denote the set of admissible arcs by E_p. The *admissible graph* is defined by $G_p = (V, E_p)$.

If the length function is nonnegative, the shortest paths problem can be solved in $O(m + n \log n)$ time [10], or in $O(m + n \log n / \log\log n)$ time [11] in a random access machine computation model that allows certain word operations. We call such a problem *Dijkstra's shortest paths problem* [6]. Given a feasible price function p, the shortest paths problem can be solved as follows. Let d be a solution to the Dijkstra's shortest paths problem (G, s, l_p). Then the distance function d' defined by $d'(v) = d(v) + p(v) - p(s)$ is the solution to the input problem.

We restrict our attention to the problem of computing a feasible price function or finding a negative length cycle in G.

3. Successive approximation and bit scaling frameworks. Our method computes a sequence of ϵ-feasible price functions with ϵ decreasing by a factor of two at each iteration. Initially, all the prices are zero and ϵ is the smallest power of two that is greater than N. The method maintains integral prices. At each iteration, the method halves ϵ and applies the REFINE subroutine, which takes as input a (2ϵ)-feasible price function and returns an ϵ-feasible price function or discovers a negative length cycle. In the latter case, the computation halts.

LEMMA 3.1. *Suppose a price function p is integral and 1-feasible. Then for every $a \in E$, $l_p(a) \geq 0$.*

Proof. The lemma follows from the fact that $l_p(a)$ is integral and $l_p(a) > -1$. □

Bit scaling, first applied to the shortest paths problem by Gabow [12], can be used instead of successive approximation in all algorithms described in this paper. The bit scaling version of our method rounds lengths *up* to a certain precision, initially the smallest power of two that is greater than N. The lengths and prices are expressed in the units determined by the precision. Note that since the lengths are rounded up, a negative cycle with respect to the rounded lengths is also negative with respect to the input lengths.

Each iteration of the algorithm starts with a price function that is feasible with respect to the current (rounded) lengths. Note that this is true initially because of the choice of the initial unit. At the beginning of an iteration, the lengths and prices are multiplied by two, and one is subtracted from the arc lengths as appropriate to obtain the higher precision. The resulting price function is 1-feasible with respect to the current length function; the feasibility

is restored using REFINE. The method terminates when the precision unit becomes 1, which happens in $O(\log N)$ iterations. Note that the basic problem solved at each iteration of the bit scaling method is a special version of the shortest paths problem where the arc lengths are integers greater or equal to -1.

The following lemma is obvious.

LEMMA 3.2. *Both the successive approximation and the bit scaling methods terminate in* $O(\log N)$ *iterations.*

Note that if the current unit in the bit scaling method is U and the current price function is feasible with respect to the rounded length function, then the price function is U-feasible with respect to the input length function. Thus bit scaling can be viewed as a special case of successive approximation. The work on the minimum-cost flow problem [18] shows that successive approximation is more general than bit scaling; in particular, the former can be easily used to obtain strongly polynomial algorithms.

We describe bit scaling version in the algorithms. This allows us to avoid certain technical details and slightly simplifies the presentation. However, all algorithms can be restated in the successive approximation framework in a straightforward way.

When describing bit scaling implementations of REFINE, we denote the current rounded length function by l. We also use the following definitions. We call an arc (v, w) *improvable* if $l_p(v, w) = -1$, and we call a node w *improvable* if there is an improvable arc entering w.

4. Dealing with admissible cycles. Suppose that G_p has a cycle Γ. Since the reduced cost of a cycle is equal to the length of the cycle, $l(\Gamma) \leq 0$.

If $l(\Gamma) < 0$, or $l(\Gamma) = 0$ and there is an arc (v, w) such that $l_p(v, w) < 0$ and both v and w are on Γ, then the input problem is infeasible and the method terminates. Otherwise, we contract Γ and remove self-loops adjacent to the contracted node. A feasible price function on the contracted graph extends to a feasible price function on the original graph in a straightforward way.

Our algorithm uses an $O(m)$-time subroutine DECYCLE(G_p) that works as follows. Find strongly connected components of G_p (see, e.g., [22]); if a component contains a negative reduced cost arc, G has a negative length cycle; otherwise contract each component. (Note that the prices of nodes in each contracted component change by the same amount, so the reduced costs of arcs with both ends in the same component do not change.)

Suppose G_p is acyclic. Then G_p defines a partial order on V and on the subset of improvable nodes. This motivates the following definitions. A set of nodes S is *closed* if every node reachable in G_p from a node in S belongs to S. A set of nodes (arcs) S is a *chain* if there is a path in G_p containing every element of S.

5. Cut-relabel operation. In this section we study the CUT-RELABEL operation which is used by our method to transform a 1-feasible price function into a feasible one. The CUT-RELABEL operation takes a closed set S and decreases prices of all nodes in S by 1.[3] Note that the operation preserves integrality of the prices (and therefore integrality of the reduced costs).

LEMMA 5.1. *The* CUT-RELABEL *operation does not create any improvable arcs.*

Proof. The only arcs whose reduced cost is decreased by CUT-RELABEL are the arcs leaving S. Let a be such an arc. The relabeling decreases $l_p(a)$ by 1. Before the relabeling, S is closed and therefore $l_p(a) > 0$. By integrality, $l_p(a) \geq 1$. After the relabeling, $l_p(a) \geq 0$. □

The above lemma implies that CUT-RELABEL does not create improvable nodes. The next lemma shows how to use this operation to reduce the number of improvable nodes.

[3] Alternatively, the operation can decrease prices of all nodes of S by the maximum amount ϵ' such that Lemma 5.1 holds.

LEMMA 5.2. *Let p be a 1-feasible price function. Let S be a closed set of nodes, and let $X \subseteq S$ be a set of improvable nodes such that every improvable arc entering a node of X crosses the cut defined by S. After the set S is relabeled, nodes in X are no longer improvable.*

Proof. Let p' be the price function after the relabeling. Let $w \in X$ and let (v, w) be an improvable arc with respect to p. By the statement of the lemma, $v \notin S$. Thus the relabeling increases l_p by 1, and, by 1-feasibility of p, $l_{p'}(v, x) \geq 0$. □

A simple algorithm based on CUT-RELABEL applies the following procedure to every improvable node v.

1. DECYCLE(G_p).
2. $S \leftarrow$ set of nodes reachable from $\{v\}$ in G_p.
3. CUT-RELABEL(S).

It is easy to see that given a 1-feasible price function, this algorithm computes a feasible one in $O(nm)$ time.

6. Faster algorithm. In this section we introduce an $O(\sqrt{n}m \log N)$ algorithm for finding a feasible price function. Let k denote the number of improvable nodes. At each iteration, the algorithm either finds a closed set S such that applying CUT-RELABEL to S reduces the number of improvable nodes by at least $\sqrt{k}$, or a chain S such that applying ELIMINATE-CHAIN to S reduces the number of improvable nodes by at least $\sqrt{k}$. (The ELIMINATE-CHAIN operation is described in the next section.) An iteration takes linear time and is based on the results of §§5 and 7 and the following lemma, which is related to Dilworth's theorem (see, e.g., [7]).

LEMMA 6.1. *Suppose G_p is acyclic. Then there exists a chain $S \subseteq E$ such that S contains at least $\sqrt{k}$ improvable arcs or a closed set $S \subseteq V$ such that relabeling S reduces the number of improvable nodes by at least $\sqrt{k}$. Furthermore, such an S can be found in $O(m)$ time.*

Proof. Construct a graph G' by adding a source node r to G_p and arcs from r to all nodes in V. Note that G' is acyclic. Define $l'(a) = l_p(a)$ for all $a \in E_p$ and $l'(a) = 0$ for the newly added arcs a. The absolute value of the path length with respect to l' is equal to the number of improvable arcs on the path. Let $d' : V \rightarrow \mathbf{R}$ give the shortest paths distances from r with respect to l' in G'. Since G' is acyclic, d' can be computed in linear time. Define $D = \max_V |d'|$.

If $D \geq \sqrt{k}$, then a shortest path from r to a node v with $d'(v) = -D$ contains a chain with at least $\sqrt{k}$ improvable arcs.

If $D < \sqrt{k}$, then the partitioning of the set of improvable nodes according to the value of d' on these nodes contains at most $\sqrt{k}$ nonempty subsets. Let X be a subset containing the maximum number of improvable nodes and let i be the value of d' on X. Observe that X contains at least $\sqrt{k}$ improvable nodes. Define $S = \{v \in V | d'(v) \leq i\}$.

Clearly $X \subseteq S$. Also, S is closed. This is because if $v \in S$ and there is a path from v to w in G_p, then the length of this path with respect to l' is nonpositive, so $d'(w) \leq d'(v) \leq i$ and therefore $w \in S$.

We show that after CUT-RELABEL is applied to S, nodes in X are no longer improvable. Let $x \in X$ and let (v, x) be an improvable arc. Then $l'(v, x) = -1$ and therefore $d'(v) > d'(x) = i$. Thus $v \notin S$ and (v, w) is not improvable after relabeling of S. □

The efficient implementation of REFINE is described in Fig. 1. The implementation reduces the number of improvable nodes k by at least $\sqrt{k}$ at each iteration by eliminating cycles in G_p, finding S as in Lemma 6.1, and eliminating at least $\sqrt{k}$ improvable nodes in S using techniques of §§4, 5, and 7. In §7 below we describe a linear time implementation of ELIMINATE-CHAIN. This implies that an iteration REFINE runs in linear time.

LEMMA 6.2. *The implementation of* REFINE *described in this section runs in $O(\sqrt{n}m)$ time.*

```
procedure REFINE(p);
    k ← the number of improvable nodes;
    repeat
        DECYCLE(G_p);
        S ← a chain or a set as in Lemma 6.1;
        if S is a chain then
          ELIMINATE-CHAIN(S);
        else
          CUT-RELABEL(S);
        k ← the number of improvable nodes;
    until k = 0;
    return(p);
end.
```

FIG. 1. *An efficient implementation of* REFINE.

Proof. We need to bound the number of iterations of REFINE. Each iteration reduces k by at least $\sqrt{k}$, and $O(\sqrt{k})$ iterations reduce k by at least a factor of two. The total number of iterations is bounded by

$$\sum_{i=0}^{\infty} \sqrt{\frac{n}{2^i}} = O(\sqrt{n}). \qquad \square$$

Lemmas 3.2 and 6.2 imply the following result.

THEOREM 6.3. *The shortest paths algorithm with* REFINE *implemented as described in this section runs in* $O(\sqrt{nm} \log N)$ *time.*

7. Eliminate-chain subroutine. Suppose that G_p is acyclic and let Γ be a path in G_p. Let $(v_1, w_1), \ldots, (v_t, w_t)$ be the collection of all improvable arcs on Γ such that for $1 \leq i < j \leq t$, the path visits v_j before v_i (i.e., v_1 is visited last). By definition, nodes $w_1, \ldots, w_t$ are improvable. In this section we describe a subroutine ELIMINATE-CHAIN that modifies p so that the nodes $w_1, \ldots, w_t$ are no longer improvable and no new improvable nodes are created, or finds a negative length cycle in G. The subroutine runs in $O(m)$ time.

At iteration i, ELIMINATE-CHAIN finds the set S_i of all nodes reachable from w_i in the admissible graph and applies CUT-RELABEL to S_i. If w_i is improvable after the relabeling, the algorithm concludes that the problem is infeasible.

LEMMA 7.1. *The path* Γ *is always admissible. If* w_i *is improvable after iteration* i*, then the problem is infeasible.*

Proof. The price function is modified only by CUT-RELABEL. At iteration i, S_i contains w_i, all its successors on Γ, and no other nodes of Γ (by induction on i). Therefore $l_p(v_i, w_i)$ changes exactly once during iteration i, when it increases by 1. The arc (v_i, w_i) is improvable before the change, and admissible after the change. Reduced costs of other arcs on Γ do not change during the execution of ELIMINATE-CHAIN.

Suppose w_i is improvable immediately after iteration i. Then there must be a node v such that (v, w_i) is improvable and $v \in S_i$. By construction of S_i, there must be an admissible path from w_i to v. This path together with the arc (v, w_i) forms a negative length cycle. $\square$

Lemmas 5.1 and 7.1 imply that the implementation of ELIMINATE-CHAIN is correct. Next we show how to refine this implementation to achieve $O(m)$ running time. The key fact that allows such an implementation is that the sets S_i are nested.

First, we contract the set of nodes S_i at every iteration. The reason for contracting is to allow us to change the prices of nodes in S_i efficiently (these prices change by the same

amount). The CONTRACT(S_i) operation collapses all nodes of S_i into one node s_i and assigns the price of the new node to be zero. (The price of s_i is actually an increment to the prices of the nodes in S_i.) Reduced costs of the arcs adjacent to the new node remain the same as immediately before CONTRACT. Note that we have at most one contracted node at any point during ELIMINATE-CHAIN, but contracted nodes can be nested.

The UNCONTRACT(s_i) operation, applied to a contracted node s_i, restores the graph as it was just before the corresponding CONTRACT operation and adds $p(s_i)$ to prices of all nodes in S_i. At the end of the chain elimination process, we apply UNCONTRACT until the original graph is restored.

Contraction is used for efficiency only and does not change the price function computed by ELIMINATE-CHAIN, because by Lemma 7.1 $S_i \subseteq S_j$ for $1 \leq i < j \leq t$.

Second, we implement the search for the nodes reachable from w_i's in the admissible graph in a way similar to Dial's implementation [5] of Dijkstra's algorithm.[4] Our implementation uses a priority queue that holds items with integer key values in the range $[0, \ldots, 2n]$; the amortized cost of the priority queue operations is constant. We assume the following queue operations.

- enqueue(v, Q): add a node v to a priority queue Q.
- min(Q): return the minimum key value of elements on Q.
- extract-min(Q): remove a node with the minimum key value from Q.
- decrease-key(v, x): decrease the value of key(v) to x.
- shift(Q, δ): add δ to the key values of all elements of Q.

All of these operations except shift are standard; a constant time implementation of shift is trivial.

Note that if p is 1-feasible and $l_p(a) \geq 2n$, then a can be deleted from the graph. This is because in the current iteration, the reduced cost of an arc can decrease by at most n; at the next iteration, by at most $n/2$ (measured in the current units), and so on. Thus the reduced cost of a will remain nonnegative from now on. We assume that such arcs are deleted as soon as their reduced costs become large enough.

We define the key assignment function h that maps reduced costs into integers as follows.

$$h(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ x & \text{otherwise.} \end{cases}$$

During the chain elimination computation, each node is *unlabeled*, *labeled*, or *scanned*. Unlabeled nodes have infinite keys; other nodes have finite keys. The priority queue Q contains labeled nodes. Initially all nodes are unlabeled. At the beginning of iteration i, key(w_i) is set to zero and w_i is added to Q. While Q is not empty and the minimum key value of the queue nodes is zero, a node with the minimum key value is extracted from the queue and scanned as in Dijkstra's algorithm except that $h(l_p(a))$ is used instead of $l_p(a)$ (see Fig. 2). When this process stops, the scanned nodes are contracted, the new node is marked as scanned, and its key is set to zero. Then the price of the new node is decreased by 1 and shift(Q, -1) is executed. This concludes iteration i.

Next we prove correctness of the implementation.

LEMMA 7.2. *The sets S_i are computed correctly for every $i = 1, \ldots, t$.*

Proof. For convenience we define $S_0 = \emptyset$. Consider an iteration i. It is enough to show that S_i is correct if $1 \leq i \leq t$ and S_{i-1} is correct.

Let v be a node on Q with the zero key value. We claim that v is reachable from w_i in the current admissible graph. To see this, consider two cases. If v was a node on Q with zero key

[4] In §9 we show that Dial's implementation can be used directly. The implementation described in this section, however, gives a better insight into the method.

```
procedure SCAN(v);
    for all (v, w) do
        if key(w) = ∞ then
            mark w as labeled;
            key(w) ← l_p(v, w);
            insert(w, Q);
        else if w is labeled and key(w) < h(l_p(v, w)) then
            decrease-key(w, l_p(v, w));
    mark v as scanned;
end.
```

FIG. 2. *The scan operation.*

value at the beginning of the iteration, then v is reachable from w_i by Lemma 7.1. Otherwise, key of v became zero when an arc (u, v) was scanned. We can make an inductive assumption that u is reachable from w_i. By definition of h, $h(u, v) = 0$ implies that $l_p(u, v) \leq 0$, and therefore v is reachable from w_i.

Let Γ be an admissible path originating at w_i. It is easy to see by induction on the number of arcs on Γ that all nodes on Γ are scanned and added to S_i.

It follows that at the end of iteration i, S_i contains all nodes reachable from w_i in the admissible graph. □

LEMMA 7.3. ELIMINATE-CHAIN *runs in* $O(m)$ *time.*

Proof. Each node is scanned at most once because a scanned node is marked as such and never added to Q. A contracted node is never scanned. The time to scan a (noncontracted) node is proportional to degree of the node, so the total scan time is $O(m)$.

The time of a CONTRACT operation is $O(1 + n')$, where n' is the number of nodes being contracted. The number of CONTRACT operations is at most n and the sum of n' values over all CONTRACT operations is at most $2n$. Thus the total cost of contract operations is $O(n)$.

The cost of an UNCONTRACT operation is $O(1 + n')$, where n' is the same as in the corresponding CONTRACT operation. Thus the total time for these operations is $O(2n)$. □

8. Alternative chain elimination. In this section we describe an algorithm based on an alternative implementation of REFINE. We call this implementation REFINE-P. The algorithm runs in $O(\sqrt{nm} \log N)$ time.

REFINE-P works in iterations, which we call *passes*. At the beginning of every pass we check for negative cycles and eliminate zero length admissible cycles using DECYCLE. Then we compute distances d' defined in the proof of Lemma 6.1. Given a nonnegative integer M, we define the *key function*

$$\delta(v) = \min(-d'(v), M) \quad \forall v \in V.$$

(We discuss the choice of initial value of M later.) Sometimes we refer to $\delta(v)$ as the *key* of v. Let V_M denote the set of nodes with key value M. At each iteration of a pass, CUT-RELABEL is applied to V_M. Then keys of nodes in V_M and all nodes reachable from V_M in the admissible graph are changed to $M - 1$ and M is decreased by one. This process is repeated until M reaches zero; at this point the pass terminates. A pass can be implemented to run in linear time; the implementation is similar to that of ELIMINATE-CHAIN. We leave the details to the reader.

The next lemma implies that CUT-RELABEL in used correctly in a pass.

LEMMA 8.1. *Immediately before a* CUT-RELABEL *operation is applied by a pass,* V_M *is closed with respect to the current admissible graph.*

Proof. Before the first CUT-RELABEL operation, V_M is closed by of the definition of δ. The admissible graph is changed only by the CUT-RELABEL operations, and after every such operation a search is done to enforce the closeness of V_M. □

Note that the function d' is well defined if the admissible graph does not have negative cycles.

LEMMA 8.2. *If at the beginning of an iteration of a pass the admissible graph is acyclic, then*

$$\delta(v) = \min(-d'(v), M) \quad \forall v \in V.$$

Proof. The proof is by induction on the number of iterations. Keys are initialized so that the statement of the lemma holds before the first iteration. Suppose that the statement is true immediately before iteration i, and show that it holds immediately after the iteration.

The d' value of nodes in V_M increases by one, and the keys of these nodes are decreased by one at the end of the iteration. The d' values of a node outside V_M changes only if this node becomes reachable from V_M in the admissible graph, in which case the new d' value of this node is $-(M-1)$ or less. The keys of the nodes that become reachable are correctly set to $M-1$. □

Recall that $D = \max_V |d'|$.

LEMMA 8.3. *Suppose that the value of M at the beginning of a pass is equal to t such that $0 < t \leq D$, and the admissible graph does not contain negative cycles throughout the pass. Then the pass decreases the number of improvable nodes by at least t.*

Proof. Given $v, w \in V$, we say that $v \succ w$ if there is a negative reduced cost path from v to w in the admissible graph. If the admissible graph does not contain negative cycles, then "$\succ$" defines a partial order on V.

Consider the beginning of an iteration of a pass, Let v be a maximum element (with respect to "$\succ$") of the set of nodes with key value M. By the previous lemma, v is an improvable node. By the choice of v, if (u, v) is an improvable arc then $u \notin V_M$. Therefore v is no longer improvable at the end of the iteration.

Each iteration of the pass reduces the number of improvable nodes, and the number of iterations is t. □

Next we discuss the choice of initial value of M. Define d_i to be the number of improvable nodes with d' value of $-i$ (in the beginning of a pass). If the initial value of M is i, $0 < i \leq D$, and there are no negative cycles, the number of improvable nodes is reduced by at least d_i by the first application of CUT-RELABEL. Combining this observation with the above lemma, we conclude that the pass reduces the number of improvable nodes by $\max(i, d_i)$. A more careful analysis shows that the improvement is at least $i + d_i - 1$, since all improvable nodes with an initial d' value of i and at least one improvable node for each value of j, $0 < j < i$, are no longer improvable after a pass. Define $k_i = i + d_i - 1$, and set M to the index that maximizes k_i. By an argument of Lemma 6.1, $k_M = \Omega(\sqrt{n})$. This implies the following theorem.

THEOREM 8.4. *With the above choice of the initial value of M, the alternative implementation of* REFINE *runs in $O(\sqrt{n}m)$ time.*

We would like to note that in practice, a pass is likely to reduce the number of improvable nodes by more then k_i, and it may be more advantageous to chose higer initial values for M. The algorithm performance is likely to be better than the above worst-case bound suggests.

9. Chain elimination using Dijkstra's algorithm. In this section we show yet another implementation of ELIMINATE-CHAIN. This implementation uses Dial's implementation of Dijkstra's algorithm [5], and does not use the CUT-RELABEL operation explicitly.

Let Γ be a path in G_p. An auxiliary network A is defined as follows.

- Let d' be the distance function on Γ with respect to l_p from the beginning of Γ to all nodes on Γ.

- Define $l'(a) = \max(0, l_p(a))$.
- Define $d'(v) = 0$ for v not on Γ.
- Add a source node t, connect t to all $v \in V$ and define $l'(t, v) = n + d'(v)$.

ELIMINATE-CHAIN works as follows.

1. Construct the auxiliary network A.
2. Compute shortest paths distances d in A with respect to l'.
3. $\forall v \in V$, $p'(v) \leftarrow p(v) + d(v) - n$.
4. Replace p by p'.

LEMMA 9.1. *The above version of* ELIMINATE-CHAIN *can be implemented to run in linear time.*

Proof. The fact that all steps of ELIMINATE-CHAIN except for the shortest paths computation take linear time is obvious. The shortest paths computation takes linear time if Dial's implementation [5] of Dijkstra's algorithm is used. This is because l' is nonnegative and the source is connected to the other nodes by arcs of length at most n. □

LEMMA 9.2.

1. *p' is integral.*
2. $\forall a \in E$, $l_{p'} \geq -1$.
3. ELIMINATE-CHAIN *does not create improvable arcs.*

Proof. The first claim follows from the fact that l' is integral. The last two claims follow from the observation that l'_d is nonnegative and, for $a \in E$, $l'_d(a) - l_{p'}(a) = 1$ if a is improvable and 0 otherwise. □

LEMMA 9.3. *If the problem is feasible, then $\forall v$ on Γ $p'(v) = p(v) + d'(v)$.*

Proof. Clearly $p'(v) \leq p(v) + d'(v)$. Assume for contradiction that for some node v on Γ, $p'(v) < p(v) + d'(v)$. For the shortest path P in A from t to v, we have $l'(P) < n + d'(v)$ and therefore $l_p(P) < n + d'(v)$. Let (t, w) be the first arc of P, and let Q be P with (t, w) deleted. We have

$$l_p(Q) = l_p(P) - n - d'(w) < d'(v) - d'(w).$$

Note that since l' is nonnegative, w must be a successor of v on Γ. Let R be the part of Γ between v and w. By the definition of d',

$$l_p(R) = d'(w) - d'(v).$$

Thus $l_p(Q) + l_p(R) < 0$. This is a contradiction because the paths Q and R form a cycle. □

LEMMA 9.4. *If the problem is feasible and v is an improvable node on Γ with respect to p, then v is not improvable with respect to p'.*

Proof. Assume for contradiction $\exists (u, v) \in E : l_{p'}(u, v) < 0$. Let P be the shortest path in A from t to u, let (t, w) be the first arc on P, and let Q be P with (t, w) deleted. Note that $d(u) \leq d(v)$, because otherwise $l_{p'}(u, v)$ cannot be negative. Therefore w must be a successor of v on Γ. Let R be the portion of Γ between v and w.

Since Q is a shortest path, we have $l'_d(Q) = 0$. This implies $l_{p'}(Q) \leq 0$. By the previous lemma $l_{p'}(R) = 0$. Therefore the cycle formed by R, Q, and (u, v) has a negative reduced cost with respect to p'. This is a contradiction. □

Remark. Implications of Lemma 9.4 are stronger than those of Lemma 7.1: if the problem is feasible, the former lemma guarantees that all improvable nodes on Γ are "fixed," and the latter guarantees only that the nodes that are heads of the improvable arcs on Γ are "fixed."

10. Extensions to the minimum-cost circulation and assignment problems. Our shortest path method extends to the minimum-cost circulation problem. The intuitive difference is that when a shortest path algorithm finds a negative cycle, it terminates; when the corresponding minimum-cost circulation algorithm finds a negative cycle, it increases the flow around the

cycle so that an arc on the cycle becomes saturated, and continues. In our discussion below, we assume that the reader is familiar with [17], [18]. We denote the reduced costs by c_p and the residual graph by G_f.

We define admissible arcs to be residual arcs with negative reduced costs, as in [17], [18]. Without loss of generality, we assume that a feasible initial circulation is available. A simple algorithm based on the CUT-RELABEL operation does the following at each iteration. First, it cancels admissible cycles; this can be done in $O(m \log n)$ time (see, e.g., [17]). Next, the algorithm picks an improvable node v, finds the set S of nodes reachable from v in the admissible graph, and executes CUT-RELABEL(S). The resulting algorithm runs in $O(nm \log n \log(nC))$ time (note that the initial flow may have residual arcs with reduced cost of $-C$ with respect to the zero price function). We can also use the TIGHTEN operation to obtain a minimum-cost flow algorithm with the same running time. These algorithms are variations of the tighten-and-cancel algorithms of [17].

In the above minimum-cost flow algorithms, the admissible graph changes due to flow augmentations in addition to price changes. Because of this fact, our analysis of the improved algorithms for the shortest paths problem does not seem to extend to the minimum-cost flow problem. In the special case of the assignment problem, the analysis of the improved shortest path algorithm can be extended to obtain an $O(\sqrt{n}m \log(nC))$ time algorithm. This bound matches the fastest known scaling bound [13], but the algorithm is different. The idea is to define the admissible graph and improvable arcs so that an improvable node has exactly one improvable arc going into it and the residual capacity of this arc is one. This is possible because of the special structure of the assignment problem. When an admissible cycle is canceled, all improvable arcs on this cycle are saturated and there are no improvable nodes on the cycle after the cancellation.

11. Concluding remarks. We described a framework for designing scaling algorithms. The CUT-RELABEL operation can be used to design algorithms within this framework. The framework is very flexible and can be used to design numerous algorithms for the problem. Using these results, we improved the time bound for the problem. We believe that further investigation of this framework is a promising research direction.

One can apply the version of ELIMINATE-CHAIN described in §9 without using scaling. It can be shown that in this case if the problem is feasible, all negative reduced costs of arcs on Γ are changed to nonnegative ones, and reduced costs of other arcs do not become more negative. This suggests a possibility of solving the general shortest paths problem in $O(\sqrt{m})$ Dijkstra shortest paths computations. The problem, however, is that our way of dealing with the first case of Lemma 6.1 does not work without scaling.

Our definition of ϵ-feasibility corresponds to that of ϵ-optimality for minimum cost flows [14], [18]. If one follows [14], [18] faithfully, however, one would define ϵ-feasibility using $l_p(a) \geq -\epsilon$ instead of (2) and not consider arcs with zero reduced costs admissible. Under these definitions, the admissible graph cannot have zero length cycles, so there is no need for DECYCLE. However, these definitions seem to lead to an $O(\log(nN))$ bound on the number of iterations of the scaling loop of the method. The *tighten* operation described in [17] also leads to an implementation of the method that runs in $O(\log(nN))$ iterations of the scaling loop.

The techniques introduced in this paper have a practical impact. In particular, the techniques of §8 proved to be crucial in our implementation of price update computation in a minimum-cost flow algorithm [15], which resulted in a significant improvement of performance.

Preliminary experiments with the algorithm of this paper, conducted as a part of the experimental study described in [3], suggest that the algorithm is not the best one to use in

practice. Although on some problem families the algorithm significantly outperformed the classical methods, it was dominated by the algorithm of [16] on all problem classes studied.

The algorithms we discussed scale ϵ by a factor of two. Any factor greater than one can be used instead without affecting the asymptotic time bounds. The method can be modified to maintain a tentative shortest path tree. When the algorithm terminates, this tree is the shortest path tree. This eliminates the need for the Dijkstra computation at the end of the algorithm.

Acknowledgments. I am grateful to Tomasz Radzik for suggesting an important idea for the proof of Lemma 6.2 and the stronger statement of Lemma 9.4, and to Bob Tarjan for suggesting a clean implementation of DECYCLE. I would also like to thank Serge Plotkin, Éva Tardos, and David Shmoys for useful discussions and comments on a draft of this paper.

COUNTEREXAMPLES FOR DIRECTED AND NODE CAPACITATED CUT-TREES*

ANDRÁS A. BENCZÚR†

Abstract. We show that there is no cut-tree for various connectivity concepts, hence pointing out errors in the papers of Schnorr [*SIAM J. Comput.*, 8 (1979), pp. 265–275] and Gusfield and Naor [*Networks*, 21 (1991), pp. 505–520]. Gomory and Hu [*SIAM J. Appl. Math.*, 9 (1961), pp. 551–560] constructed a cut-tree for undirected graphs which compactly represents a minimum cut for each pair of vertices. This has a straightforward generalization to directed Eulerian graphs, cf. Gupta [*SIAM J. Appl. Math.*, 15 (1967), pp. 168–171]. A generalization for arbitrary directed graphs was given by Schnorr. There is a well-known transformation of vertex connectivity to directed edge connectivity; directed edge cuts correspond to vertex cuts in some weak sense. The result of Schnorr was later applied by Gusfield and Naor for such a cut-tree construction. In this paper counterexamples are described to show that for directed graphs there is no cut-tree and therefore the cut-tree results of Schnorr and Gusfield and Naor are incorrect. Our final example shows that, without weakening the notion of vertex connectivity, it is impossible to construct vertex cut-trees for undirected graphs in general.

Key words. Gomory–Hu trees, minimum cuts, graph connectivity

AMS subject classifications. 05C40, 90B10

1. Introduction.

A theorem of Gomory and Hu [5] states that the minimum edge cuts between all pairs of vertices in an undirected edge capacitated graph G can be represented by a tree as follows. First, the value of a minimum cut between $s, t \in G$ is equal to the smallest of the capacities of the edges on the unique s–t path in the tree. Second, the removal of any edge of capacity c from the tree separates the vertices of the tree into two classes, in which the cut in G given by this partition has capacity c as well.

Trees satisfying both conditions are called *cut-equivalent trees* or, in short, *cut-trees*; when only the first condition is satisfied we call them *flow-equivalent trees*. Note that both flow-equivalent and cut-trees can be computed by $n - 1$ max-flow computations [5] and they encode all the $\binom{n}{2}$ minimum cut values. By looking at a cut-tree we can also find one such minimum cut for any pair of nodes.

It is important to note that while a cut-equivalent tree is always flow equivalent by definition, the converse does not hold. In general, the number of different flow-equivalent trees corresponding to a graph is considerably more than that of the cut-trees; for example, it is true that each graph has a flow-equivalent tree which is a path (see [4]).

As a generalization of the Gomory–Hu theorem, Cheng and Hu [2] proved the existence of flow (*but not cut*) equivalent trees for the case when an *arbitrary* value is assigned to the (undirected) cuts of the graph. The resulting tree represents all the minimum cuts of pairs of vertices with respect to this weight.

A natural question arises: can we construct equivalent trees for directed graphs? As a simple instance, the problem for directed Euler graphs easily reduces to undirected graphs and hence a cut-tree exists (cf. Gupta [7]). In general, however, we cannot ask for a compact representation of all the $n(n-1)$ directed cuts, since there can be $(n+2)(n-1)/2$ different values among them; see [3].

Not everything is lost, however. For a given pair of vertices, there are two different maximum flow values depending on which direction we choose. Let us consider the smaller

one only. For each cut, the smaller of the capacities of the cut itself and the cut directed the other way are assigned. Then this assignment is symmetric, i.e., the values correspond to the *undirected* cuts of the graph. Hence the result of Cheng and Hu [2] can be applied to this symmetric directed case to construct flow-equivalent trees.

What about the existence of cut-trees for the above symmetric directed case? Schnorr presented an algorithm for generating such cut-trees in [10]. One aim of this paper is to show that Schnorr's result was *incorrect*, since there is no cut-tree for this case in general. (We note here that Schnorr also presented a flow-equivalent tree algorithm for this case and that is correct, but it is less efficient than the Cheng–Hu algorithm.)

Another possible task is to find a compact representation of minimum vertex cuts or cut values. One possible way to deal with vertex cuts is to transform the original graph to a directed graph (see §3). There a pair of vertices corresponds to each vertex of the original graph. Note that the connectivity properties of the transformed graph are different from the original vertex connectivities. The two inconvenient differences are the following. First, it is possible that the minimum u–v cut is u itself; this means that in the original graph u and v are separated by removing u. Second, we can get no information about vertex connectivity between vertices connected by an edge. Furthermore, while a vertex cut can have an arbitrary large number of disconnected components, a corresponding edge cut has always two components. (Consequently there may be several corresponding edge cuts.) To emphasize the difference of this notion from that of the vertex cuts, we call the former *separations* (for precise definition see §3).

The result of Cheng and Hu can be applied then to construct a flow-equivalent tree for *separations* in the transformed directed graphs (as noted in [8]). Following this approach, we may ask if cut-trees for these directed graphs exist. Applying the incorrect result of Schnorr [10], Gusfield and Naor [8] immediately got a cut-tree construction for minimum separations (on the duplicated vertex set). The existence of such a cut-tree will also be disproved in this paper.

Even for separations, it is probably more natural to construct equivalent trees with vertices from the original (and not the duplicated) vertex set of the graph. Granot and Hassin [6] have such a construction for (in our terms) undirected flow-equivalent trees and Benczúr [1] has one for cut-trees. There, as for the Gomory–Hu trees, the minimum separation value is the least of the capacities among edges of the tree on the path connecting the vertices investigated.

In contrast to separations, let us consider vertex cuts. Using the Cheng–Hu [2] result we can construct flow-equivalent trees by transforming the vertex-capacitated graph to a directed edge-capacitated one and assigning infinite cut-values to the trivial single-point cuts. Conversely, we show an example in which we cannot represent minimum vertex cuts by a cut-tree. (There are a lot of hard minimum vertex cut structures; for example, two K_n-s joined by n edges forming a matching is n-connected and has 2^n minimum capacity cuts.)

Finally, we note that the paper of Benczúr [1] is a counterpart to this paper; it proposes a graph connectivity model (separations in mixed edge- and vertex-capacitated graphs) where cut-trees exist. This model contains both undirected edge cuts and vertex separations where one may construct cut-trees.

2. Directed edge cuts. First we give some notation and the definitions of crossing edge cuts and laminar set systems. The latter is necessary only as background, since the counterexamples can be verified without knowledge of these simple facts.

2.1. Edge cuts. Let $G = (V, E)$ be a graph. For $U \subset V$ let $\delta(U)$ and $\rho(U)$ denote the set of edges leaving (respectively, entering) U. For $V_1 \subset V$, $\delta(V_1)$ is a directed edge cut separating V_1 and $V_2 = V - V_1$. We denote this cut by $(V_1|V_2)$. Two cuts $(V_1|V_2)$ and $(W_1|W_2)$ are *crossing* if the four sets of form $V_i \cap W_j$ are all nonempty.

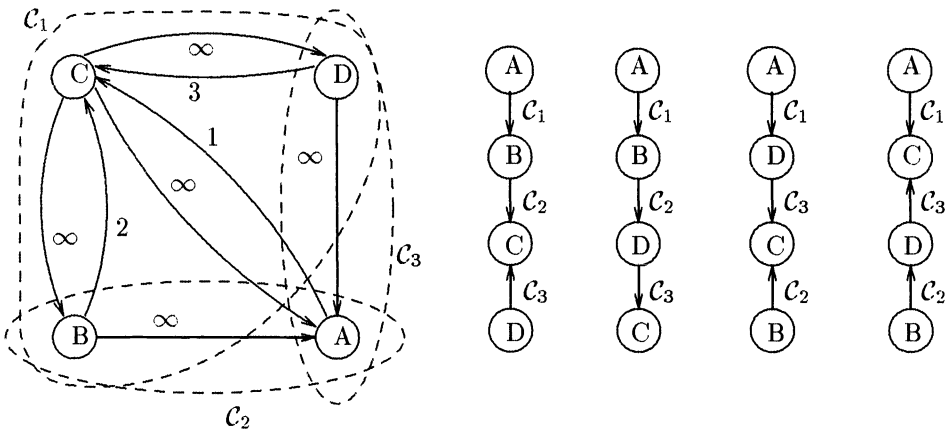

FIG. 1. *Left: directed graph with no cut-equivalent tree. Right: the four flow-equivalent trees of the graph, neither of which is cut equivalent.*

2.2. Set systems. We call a set system *laminar* if for any two nondisjoint members, V_1 and V_2, either $V_1 \subseteq V_2$ or $V_1 \supseteq V_2$. We need two well-known and simple facts. First, for a system of cuts $\{(V_1^{(i)}|V_2^{(i)}) : i \leq n\}$ we can build a laminar system by selecting either $V_1^{(i)}$ or $V_2^{(i)}$ for all $i \leq n$ if and only if it contains no crossing pairs. Second, the laminar systems are those which can be represented as labels of a rooted tree such that the label of a descendant is a subset of that of its ancestor. (This is exactly the case for the Gomory–Hu trees of undirected edge cuts, cf. [9].)

2.3. Counterexamples. Now we give the counterexamples for the erroneous theorems. C.P. Schnorr in [10] claims that it is possible to construct a *cut-tree* in the directed case. We give the counterexample for this theorem in Fig. 1. The graph contains four vertices, hence seven possible cuts. It is easy to find that among them the unique minimum cuts for vertex pairs are $C_1 = (A|BCD)$, $C_2 = (AB|CD)$, and $C_3 = (AD|BC)$ of Fig. 1. Since C_2 and C_3 are crossing, there cannot be a cut-tree for this graph.

Let us discuss the error in Schnorr's paper. His Theorem 3.4 [10, p. 272] is stated as follows. ($F_{u,v}$ is the max-flow value from u *to* v, $\tilde{N}$ is the tree constructed by the algorithm.)

THEOREM 3.4 OF [10]. $\min\{F_{u,v}, F_{v,u}\}$ *equals the minimum capacity of the edges on the path that connects* $\{u\}$ *and* $\{v\}$ *in* $\tilde{N}$. *If among the minimum capacity edges on the undirected path connecting* u *and* v *in* $\tilde{N}$ *some edge* e *is directed from* $\{u\}$ *to* $\{v\}$, *then* $F_{u,v} = \min\{F_{u,v}, F_{v,u}\}$ *and the weak components of* $\tilde{N} - \{e\}$ *yield a minimum* (u, v)*-cut.*

His algorithm does the following. It picks the minimum possible value cut of the graph, on Fig. 1 C_1. Then, as Lemma 3.1 [10, p. 270] states, we can always select minimum value cuts in both components of the previous cut so that they do not cross each other. This is true *inside* $\{B, C, D\}$ since then $C_2 = (B|CD)$ and $C_3 = (D|BC)$ do not cross. However, they do cross in the *entire* graph, which is not recognized in the rest of [10].

Gusfield and Naor have incorrect theorems in [8] because they use the above result of [10]. Their cut-tree construction for the same case as in [10] certainly cannot work. Their other directed cut-tree construction deals with cuts directed *into a fixed vertex*. Adding edges of infinite capacity directed from this fixed vertex to each other vertex makes this equivalent to the original directed problem. Figure 1 with "root" C is a counterexample, because the minimum cuts separating C from the other vertices directed into C are exactly the minimum cuts C_1, C_2, and C_3, where C_2 and C_3 cross each other.

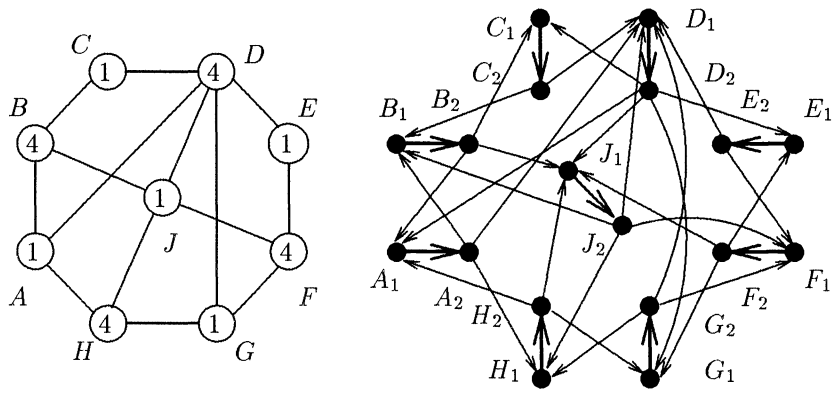

FIG. 2. *Left: vertex-capacitated graph. Right: its transformed digraph.*

3. Undirected vertex cuts. Another application for directed connectivity is to find a compact representation of minimum vertex cuts or cut values: one possible way to deal with vertex cuts is to transform the original graph to a directed graph. In [8] a vertex cut-tree (which is in our terms a cut-tree for separations) algorithm is also presented by transforming the graph to a directed one. Before giving a counterexample to this algorithm, we discuss the method of transforming vertex connectivity in a more general form for mixed cuts as well. Let us start with definitions. Let $G = (V, E)$ be a graph with a positive vertex capacity function c.

DEFINITION OF CUTS. *A* vertex cut *is a minimal $C \subset V(G)$ such that $G - C$ is disconnected. (The number of components can be arbitrarily large.) For a given $T \subset V(G)$, a* mixed cut *(C, D) is a minimal set of vertices $C \subset T$ and edges $D \subset E(G)$ such that erasing them from the graph makes it disconnected. (This is a generalization of vertex cuts, where simply $T = V(G)$ and the edge capacities are infinite.)*

DEFINITION OF SEPARATIONS. *A* separation *denoted by $C = (H_1|C|H_2)$ is a partition of the vertex set $V(G)$ into three (possibly empty) subsets H_1, H_2, and C. C is called the* cutset; *the edges connecting H_1 and H_2 are the* cut edges. *In* vertex *separations there are no edges connecting H_1 and H_2. The capacity of the separation is just $c(C)$.*

We introduce the standard technique (which can be found in [4]) to transform mixed (or vertex) connectivity to directed edge connectivity in another graph $G'(V', E')$ with edge-capacity function e'. Let G' consist of vertices v_1, v_2 for all $v \in V$. We shall denote an edge directed from s to t by (s, t). Then let $(t_1, t_2) \in E'$ with $e'(t_1, t_2) = c(t)$ if $t_1 \neq t_2$. And for all edges (u, v) of G, let (u_2, v_1) and (v_2, u_1) be edges of E' with the same capacity as (u, v) in G. (An example is given in Fig. 2.)

The correspondence of separations and edge cuts is the following. Assume a separation $(H_1|C|H_2)$ is given. Then $H'_j = \{t_j : t \in C\} \cup \{v_1, v_2 : v \in H_j\}$ for $j = 1, 2$ is a partition of V' where the cut directed from H'_1 to H'_2 has the capacity of the separation. Note that we may choose an arbitrary component of the cut for H_1 and let $H_2 = V(G) - C - H_1$. Thus there are always at least two different edge cuts corresponding to the original cut. And conversely, for $s \neq t$ let $(H'_1|H'_2)$ be an s_1–t_2 cut of G'. By defining $H_i = \{v : v_1, v_2 \in H'_i\}$ $(i = 1, 2)$ and $C = V(G) - (H_1 \cup H_2)$, $(H_1|C|H_2)$ is a separation with the same capacity as $(H'_1|H'_2)$.

Note that in the transformed directed graph there are cuts with a single vertex on one side. If we transform them back to the vertex-capacitated graph, a one-vertex "cut" corresponds to these cuts, which "cuts" itself from the rest of the vertices. For vertex pairs connected by an edge, obviously this is the only possibility for a minimum cut. This is why we need the weaker notion of separations: the transformed graph contains information on separations, not

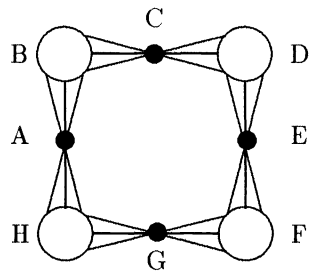

FIG. 3. *Two-vertex-connected graph with two crossing minimum cuts AE and CG.*

cuts. Note that both the (incorrect) result of Gusfield and Naor [8] and the flow-equivalent result of Granot and Hassin [6] deal with separations and not cuts.

Now we discuss a counterexample for the existence of cut-trees for separations in transformed vertex-capacitated graphs. Gusfield and Naor [8] simply use the incorrect result of Schnorr [10] to construct such a tree. Although we have presented a counterexample for Schnorr's result, it is not a transformed graph. Hence we give a special counterexample for this case. Also, it can happen that there is no cut-tree containing a minimum cut for *all* pairs of vertices of the *directed* graph, but if we restrict our attention to a set of edge cuts corresponding to a set of minimum vertex separations for all pairs of vertices, we can build a cut-tree consisting of these cuts. This can happen, since in general there are at least two edge cuts corresponding to vertex cuts and one of them is always redundant. Thus we have an aim which is even stronger than showing that the result of [8] is incorrect: we shall give an example where we cannot select a set of minimum vertex separations for all pairs of nodes and corresponding edge cuts in the transformed graph such that this set of edge cuts bears with a cut-tree representation.

Let us consider the example of Fig. 2. The three cuts of this graph AJC, AJG, and EJG should all be listed to separate vertices B, D, F, and H. Let us see if this is possible on the transformed graph. The two possibilities to select the cut corresponding to the separation ACJ on the transformed graph are $\delta(A_1B_1B_2C_1J_1)$ and $\rho(A_2B_1B_2C_2J_2)$. Let us consider the case when we pick the first one; the analysis of the second case is similar. Then from the two–two possibilities of the cuts corresponding to AJG and EJG, those not crossing the selected one are $\rho(A_2G_2H_1H_2J_2)$ and $\rho(E_2F_1F_2G_2J_2)$, respectively. But these cuts cross each other. So the necessary directed cuts cannot be represented by a tree, contradicting the claim of [8].

Finally, we give an example to show that it is impossible to construct cut-trees for (original) vertex cuts. Let the graph of Fig. 3 have four vertices A, C, E, and G of capacity one; the other vertices are either of large capacity or, if we want unit capacities, they represent large cliques. A cut-tree must contain the two minimum cuts AE and CG to separate C from G (respectively, A from E). If we forget about the four vertices of capacity one, the above two cuts can be considered as edge cuts $(BH|DF)$ and $(BD|HF)$. Since these cuts are crossing each other, there is no cut-tree representing them, i.e., there is no tree which has edges corresponding to both of these two vertex cuts and contains B, D, F, and H as required.

TREE RECONSTRUCTION FROM PARTIAL ORDERS*

SAMPATH K. KANNAN† AND TANDY J. WARNOW‡

Abstract. The problem of constructing trees given a matrix of interleaf distances is motivated by applications in computational evolutionary biology and linguistics. The general problem is to find an edge-weighted tree which most closely approximates (under some norm) the distance matrix. Although the construction problem is easy when the tree exactly fits the distance matrix, optimization problems under all popular criteria are either known or conjectured to be *NP*-complete. In this paper we consider the related problem where we are given a partial order on the pairwise distances and wish to construct (if possible) an edge-weighted tree realizing the partial order. We are particularly interested in partial orders which arise from *experiments* on triples of species. We will show that the consistency problem is *NP-hard* in general, but that for certain special cases the construction problem can be solved in polynomial time.

Key words. algorithms, graphs, evolutionary trees, evolution

AMS subject classifications. 05C05, 05C85, 06A06, 06A07, 68Q25, 92-08, 92B05, 92D15, 92D20

1. Introduction.

Constructing edge-weighted trees from distance data is a classical problem motivated by applications in molecular biology, computational linguistics, and other areas. Here we are given an n-by-n distance matrix M and asked to find a tree T with leaves $1, 2, \ldots, n$ such that the path distance d_{ij}^T in the tree closely approximates the matrix M. When $d_{ij}^T = M_{ij}$ the matrix is said to be *additive* and efficient algorithms exist for constructing trees from additive distance data (see [8], [5], [1], and others). Various optimization criteria for the problem were proposed and many *NP*-hardness results were published ([2], [3], and others). In fact, in [3] it is shown that for one of the standard optimization criteria (finding a minimum sized tree T such that $d_{ij}^T \geq M_{ij}$, where the size of the tree is the sum of the edge weights in the tree), there is a constant $\epsilon > 0$ such that no polynomial time algorithm can approximate the optimal solution within a ratio of n^ϵ unless *P=NP*. Thus, constructing trees from distance data is a hard problem and the usual heuristic approaches are unlikely to lead to reasonable solutions.

However, for many applications, the actual numeric data is quite unreliable (see [3], [4] for discussions of how interspecies distances are derived in computational molecular biology and why the data is unreliable). One way of handling this unreliability is to assume that distances are given with error bars. This approach was taken by Farach, Kannan, and Warnow in [3]. In this paper, we will take a different approach and assume that we have confidence only in relative information, so that our input will be given in the form of a partial order on the pairwise distances. We are particularly interested in the problem where the partial order is constructed from *experiments* on triples of species, where these experiments are of one of the following two types.

Total order model (TOM). A *TOM* experiment on i, j, k determines the total order of the three pairwise distances $d(i, j), d(j, k), d(i, k)$, with equality or strict inequality indicated.

Partial order model (POM). A *POM* experiment on i, j, k determines the minimum elements of $d(i, j), d(j, k), d(i, k)$.

This author's research was supported by National Science Foundation grant DMS 90-05833 and Department of Energy grants DE-FG03-90ER60999 and DE-AC04-76DP00789. This work began when this author was visiting the Center for Discrete Mathematics and Theoretical Computer Science.

These models are inspired by the model of Kannan, Lawler, and Warnow [6], in which rooted trees are constructed using experiments which determine the *rooted* topology for any three species.

We study the following problems under these models.

Consistency. Given a partial order on a set of distances, does there exist an edge-weighted tree which realizes this partial order?

Construction. Given the ability to perform an experiment, how quickly can we construct an edge-weighted tree realizing the experiments (here we assume the experiments *are* consistent)?

The essential difference between the consistency problem and the construction problem is that we are *not* allowed to perform additional experiments to determine the consistency of a given set of experiments. This makes a substantial difference in complexity, with the consequence that determining consistency is NP-complete for some of the models below where construction can be done efficiently.

We present the following results:

1. The problem of determining whether a set of POM or TOM experiments is consistent with some tree is *NP*-complete, whether the tree is constrained to be unweighted and without degree-two nodes, or can be arbitrary. This result is described in §2.
2. We can construct unweighted binary trees in $O(n^3)$ time from TOM experiments and in $O(n^4)$ time from POM experiments. These results are described in §§3 and 4, respectively.

Constructing unweighted binary trees is motivated by the work of Winkler [9], who considered the related *discrete metric realization* problem, in which one is given an n-by-n distance matrix M and an integer k and the task is to create a graph G with n distinguished vertices and at most k edges such that the shortest path in the graph G between x_i and x_j is exactly equal to M_{ij}. Winkler showed that this problem is *strongly* NP-complete for general graphs and for unweighted graphs without nodes of degree two.

2. Consistency of TOM or POM experiments. In this section we show that determining whether a set of either TOM or POM experiments is consistent with a tree is *NP*-complete for weighted trees as well as for unweighted trees without nodes of degree two. We begin by considering a related problem of constructing trees using unrooted *quartets*, where a quartet is an unrooted tree on four leaves, i, j, k, l. Each quartet q is constrained to contain an edge e so that $q - \{e\}$ describes a partition of the four leaves into two sets of two leaves each. We indicate this by writing $q = (ij, kl)$. Thus, q indicates that the topology on leaves i, j, k, l is as shown in Fig. 1.

The unrooted quartet consistency (UQC) problem is as follows.

Problem: Unrooted quartet consistency.

Input: A set Q of quartets on the species set $S = \{s_1, s_2, \ldots, s_n\}$.

Question: Does there exist a tree T with leaves labeled by the species of S such that if $q = (ij, kl) \in Q$, then there is an edge e in T such that i, j are on one side of e and k, l are on the other side.

The UQC problem was shown *NP-complete* by Steel in [7].

We can now prove that determining consistency of TOM experiments is *NP*-complete.

THEOREM 2.1. *TOM consistency is NP-complete.*

Proof. The reduction is from the UQC problem. Let I be an instance of the UQC problem and let (ab, cd) be one of the topology constraints.

We create two new leaves x and y and write down total order constraints for the triples (x, y, a), (x, y, b), (x, y, c) and (x, y, d) as follows:

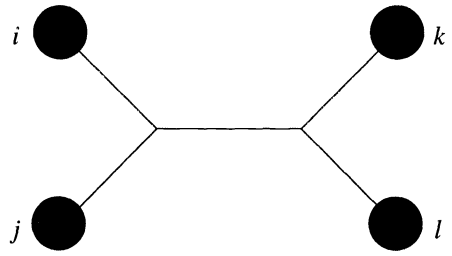

FIG. 1.

$$d(x,a) < d(y,a) < d(x,y),$$
$$d(x,b) < d(y,b) < d(x,y),$$
$$d(y,c) < d(x,c) < d(x,y),$$
$$d(y,d) < d(x,d) < d(x,y).$$

It is not hard to see that any edge-weighted tree satisfying each of the four constraints above also satisfies the topology constraint imposed by the quartet. Thus any tree that is consistent with the constraints of the TOM problem is consistent with the constraints of the UQC problem.

Conversely, suppose there is a tree that is consistent with the constraints of the UQC problem. We augment this tree with the addition of the newly defined leaves such as x and y as follows. For each quartet (ab, cd), let $e = (u, v)$ be an edge in the tree separating ab from cd, with u on the a, b side, and v on the c, d side. In the TOM problem we introduced dummy species x and y such that a, b are closer to x than to y, and c, d are closer to y than to x. Attach these leaves x and y to u and v, respectively and set $w(x,u) = w(y,v) = n^2$. All edges in the original tree are left at unit weight. It is then clear that the augmented tree satisfies all the constraints of the derived instance. Hence we have a valid reduction showing the NP-completeness of the consistency problem for TOM experiments. □

It is easy to see that this proof implies that the consistency of POM experiments is also an *NP*-complete problem, and for both cases the weights on the edges are integers between 1 and n^2. What is not quite as obvious is that consistency of TOM and POM experiments is still *NP*-complete when we restrict ourselves to trees of unit weight and without degree-two nodes. We now prove this for TOM experiments, since the proof for POM experiments follows along the same lines.

THEOREM 2.2. *Determining consistency of TOM experiments with unit weight trees is* NP*-complete.*

Proof. That the problem is in *NP* is trivial; thus we need only show that it is *NP*-hard. By the above proof, determining whether a set of TOM experiments is consistent with a tree in which every edge has integer weight bounded by n^2 is *NP*-complete. We will show that this problem (bounded integer weight TOM experiment consistency) reduces to unit weight TOM experiment consistency.

Let $S = \{s_1, s_2, \ldots, s_n\}$ be a set of leaves and $\mathcal{E}$ a set of k TOM experiments. Let $S' = S \cup \{x_1, x_2, \ldots, x_{2n^3}\}$ be another set of leaves. We will show that $S, \mathcal{E}$ is consistent with a weighted tree T if and only if $S', \mathcal{E}$ is consistent with an unweighted tree T' without degree-two nodes. It is clear that we can assume that T contains no nodes of degree two. So suppose T realizes the TOM experiments. By our construction, we can assume that T has only integer weights on the edges and that these integer weights are bounded by n^2. For each edge e in T with weight $w(e) > 1$, we introduce $w(e) - 1$ additional internal nodes to that edge and $w(e) - 1$ new leaves hanging off those new internal nodes. We then set the weight

of the newly created edges to be 1. It is clear that this new tree T' still satisfies the original set of experiments $\mathcal{E}$ and that it contains at most $2n^3$ additional leaves. Setting $S' = \text{leaves}(T')$, we note that $S', \mathcal{E}$ is realized by T'.

For the converse, if the experiments in E can be realized by a unit-weighted tree T on leaf set S and at most $2n^2$ additional leaves, since E does not contain any constraints involving the additional leaves, E is realized by the tree T with the additional leaves stripped off. □

As a consequence, we have the following corollary.

COROLLARY 2.3. *Let $\leq_P$ be a partial order defined on the set of pairwise distances, d_{ij}. Then determining whether $\leq_P$ is compatible with an edge-weighted (or unweighted) tree is NP-complete.*

3. An $O(n^3)$ algorithm for constructing unweighted trees from TOM experiments. We examine the problem of constructing a tree T with unweighted edges (equivalently, $w(e) = 1$ for all edges $e \in E(T)$) and no nodes of degree two. We will assume here the ability to perform an experiment on any triple of species i, j, k, where the output of the experiment on the triple i, j, k will be a linear ordering on the three pairwise distances, with either equality or strict inequality indicated.

3.1. Sibling sets. The general structure of the algorithm is to discover a pair of sibling supernodes and connect them, making a new supernode. A *supernode* represents a subtree induced by an edge-deletion of T. Note that any tree where each internal node has degree three must have at least two pairs of sibling nodes. Once we locate a sibling pair i_1, i_2 we "collapse" the nodes representing i_1, i_2 into a supernode. We therefore need to show how to determine siblinghood of pairs of supernodes.

We will always maintain the following invariants: we will always know the exact tree that any particular supernode represents and each supernode will represent a portion of the overall tree which is connected to the rest of the tree by exactly one edge. We will abuse the notation slightly and use "supernode" to represent not only a collection of the original vertices, but also the tree structure that we have computed on them. The root of a supernode V is defined to be the node $r(V)$ in V at which the rest of the tree is attached to V. For each supernode V we choose a "representative" v which is a leaf of the original tree that is contained in V and is nearest to the root of V. We denote the representative of a supernode V by $\text{rep}(V)$. We define $d(V) = d(\text{rep}(V), r(V))$. Initially, the supernodes are singleton sets and $d(V) = 0$ for all supernodes V. We will also say that V_1 and V_2 are siblings if $d(r(V_1), r(V_2)) = 2$.

We will clarify each step of the algorithm in what follows. It is particularly important to note that a "collapse" of a set of nodes does not mean throwing away any of the individual nodes; in fact, even after we collapse a set of nodes we will need to refer to experiments involving individual nodes in the set that has been collapsed. Also note that the recursive application of the algorithm is not straightforward since after a single collapse we are not allowed to perform experiments on the new leaf that is created.

3.2. Determining sibling pairs. We have three techniques for determining whether V_1 and V_2 are siblings, depending on how large $|d(V_1) - d(V_2)|$ is.

Given two supernodes V_1 and V_2 with representatives i_1 and i_2, and given any leaf $j \notin V_1 \cup V_2$, we can determine whether j is closer to i_1 or i_2 and use this information to determine whether V_1 and V_2 are siblings. We therefore make the following definitions:

LT: $(V_1, V_2) \in LT$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $d(j, i_1) < d(j, i_2)$.

GT: $(V_1, V_2) \in GT$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $d(i_2, j) < d(j, i_1)$.

EQ ("equals"): $(V_1, V_2) \in EQ$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $d(i_1, j) = d(i_2, j)$.

We now describe the details of how we determine whether two supernodes are siblings. We begin with the case where $d(V_1) = d(V_2)$.

Suppose that $d(V_1) = d(V_2)$ and i_1 and i_2 are the representatives of V_1 and V_2, respectively. If V_1 and V_2 are siblings, then for all $j \notin V_1 \cup V_2$, $d(i_1, j) = d(i_2, j)$. Thus, we will find that $(V_1, V_2) \in EQ$ and $(V_1, V_2) \notin LT \cup GT$. On the other hand, if V_1 and V_2 are not siblings, then there is an internal node v closer to the root of V_1 than to V_2, and if j is a leaf in the subtree rooted at v on the path from V_1 to V_2, then $d(i_1, j) < d(i_2, j)$. Thus, $(V_1, V_2) \in LT$. We therefore can characterize the pairs of supernodes V_1, V_2 such that $d(V_1) = d(V_2)$, which *must* be siblings as explained in the following lemma.

LEMMA 3.1. *Let V_1 and V_2 be supernodes with $d(V_1) = d(V_2)$. Then V_1 and V_2 are siblings* if and only if $(V_1, V_2) \notin LT \cup GT$. *This can be determined in $O(n)$ time.*

Equally simple is the case where $d(V_1) = d(V_2) + 1$. For this case we have the following lemma, the proof of which is omitted.

LEMMA 3.2. *Let V_1 and V_2 be supernodes such that $d(V_1) = d(V_2) + 1$. Then V_1 and V_2 are siblings* if and only if $(V_1, V_2) \notin EQ \cup LT$. *This can be determined in $O(n)$ time.*

In the case where $d(V_1) \geq d(V_2) + 2$, once again let i_1 and i_2 be the representatives of V_1 and V_2, respectively. If $(V_1, V_2) \in EQ \cup LT$ we can conclude immediately that V_1 and V_2 are not sibling supernodes. However, the converse does not hold since if the roots of V_1 and V_2 are connected by a path of length three we would still have $(V_1, V_2) \notin EQ \cup LT$. We need a different technique to handle this case.

We assume that V_1 and V_2 are siblings and derive either a contradiction or confirmation of this assumption. Since we know the entire structure of V_1 and V_2 under our assumption above, we know the length of the path P from i_1 to i_2. We have two cases. If P is of even length, let x be the midpoint of P. Because of our assumption, we can identify the above node x which lies within V_1. Since x has degree greater than two we can find a leaf y which lies in a branch of x other than the ones containing i_1 or i_2 (y lies within V_1 as well and we can identify such a y quickly). Then V_1 and V_2 are siblings if and only if $d(i_1, y) = d(i_2, y)$. If P is of odd length, the proof is similar — we identify the two middle nodes w and x in P and check that for leaves y_1 and y_2 hanging off third branches of w and x, respectively, $d(y_1, i_1) < d(y_1, i_2)$ and $d(y_2, i_1) > d(y_2, i_2)$. Again these conditions will hold if and only if V_1 and V_2 are actually siblings. We summarize the above in the following lemma.

LEMMA 3.3. *Let V_1 and V_2 be supernodes with $d(V_1) \geq d(V_2) + 2$. We can determine whether V_1 and V_2 are siblings in $O(n)$ time.*

Remark 1. It is possible using clever data structures for maintaining the structure of supernodes to reduce the time to check siblinghood in this case to sublinear. However, we don't do this, since in the other cases we do need linear time to check siblinghood.

3.3. Implementation and running time. It is clear that the invariants will be maintained after the detection of sibling pairs and the merger of the constituent supernodes into a bigger supernode. When we have only three supernodes left we stop and construct the tree. We then have to check that this tree is in fact consistent with all of the experiments that have been performed.

In order to see that the running time is $O(n^3)$, note that we perform $O(n^2)$ tests of siblinghood initially (between every pair of given species). Since each test of siblinghood takes $O(n)$ time, this initial step costs $O(n^3)$. Now suppose we determine that two supernodes I and J are siblings. We then need to look at the remaining supernodes to see if any of these are also siblings to I (and hence to J). Hence, to determine the sibling set containing I will cost us $O(n)$ sibling tests, for a total cost of $O(n^2)$. This cost is only incurred by a new sibling pair, and since there are at most $O(n)$ sibling pairs, this only occurs $O(n)$ times. Hence, the overall cost is $O(n^3)$.

Note that the algorithm above is optimal since we have to check that the tree is correct with respect to $\Omega(n^3)$ experiments. However, we might consider a related promise problem where the task is to construct a tree under the promise that such a tree exists. In this case, the lower bound does not hold and the problem of whether there is a more efficient algorithm is open.

4. An $O(n^4)$ algorithm for constructing unweighted binary trees from POM experiments. The algorithm we use for constructing unweighted binary trees from POM experiments uses some of the same techniques as in the previous section. Here, an experiment on i, j, k only returns pair(s) which have minimum distance, and does not totally order that set. We indicate this experimental outcome by $O(i, j, k)$, and understand this to be a set of pairs.

As in the previous algorithm, we work with supernodes and determine siblinghood pairs.

4.1. Determining sibling pairs. We again have techniques for determining siblinghood of supernodes V_1 and V_2, which depend on $|d(V_1) - d(V_2)|$. Since we do not obtain a total order on distances, we use different definitions of the sets *EQ, LT,* and *GT,* in which we may combine information from different experiments in order to infer the existence of internal nodes v for which we can determine the relative proximity of v to the leaves i_1 and i_2, where $i_1 \in V_1$ and $i_2 \in V_2$.

LT: $(V_1, V_2) \in LT$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $(i_1, j) \in O(i_1, i_2, j)$ but $(i_2, j) \notin O(i_1, i_2, j)$, *or* there exist leaves j, k in $T - (V_1 \cup V_2)$ such that $(i_1, j) \in O(i_1, j, k)$ and $(i_2, j) \notin O(i_2, j, k)$. *Membership in this set indicates the existence of an internal node v so that $d(i_1, v) < d(i_2, v)$.*

GT: $(V_1, V_2) \in GT$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $(i_2, j) \in O(i_1, i_2, j)$ but $(i_1, j) \notin O(i_1, i_2, j)$, *or* there exist leaves j, k in $T - (V_1 \cup V_2)$ such that $(i_2, j) \in O(i_2, j, k)$ and $(i_1, j) \notin O(i_1, j, k)$. *Membership in this set indicates the existence of an internal node v so that $d(i_1, v) > d(i_2, v)$.*

EQ ("equals"): $(V_1, V_2) \in EQ$ if and only if there exists leaf $j \in T - (V_1 \cup V_2)$ such that $\{(i_1, j), (i_2, j)\} \subset O(i_1, i_2, j)$. *Membership in this set indicates the existence of an internal node v so that $d(i_1, v) = d(i_2, v)$.*

In order to be able to use membership or nonmembership in these sets EQ, GT, and LT, we need two more lemmas. First we make the following definition.

DEFINITION 1. *Let i be a leaf, v an internal node and c be a variable or a constant whose value is a positive integer. Suppose it is known that $d(i, v) \geq c$. An experiment on i, r, s is said to be* (c, i, v) critical *if from the outcome of the experiment on (i, r, s) and previous experiments, it is possible to deduce whether $d(i, v) = c$. In other words, an experiment i, r, s is* (c, i, v) critical *if its outcome can be predicted from the assumption that $d(i, v) = c$ and if the predicted outcome will equal the true outcome if and only if $d(i, v) = c$.*

We can now prove the following lemma.

LEMMA 4.1. *Let v be an internal node separating T into three subtrees, T_1, T_2, and T_3. Let i be a node in T_1 with $d(i, v) \geq k$ where k is a constant or a variable whose value is a positive integer and $\min_{x \in \mathcal{L}(T_2)} d(x, v) = t \geq k + 2$. Then there exist leaves $r, s \in T_2$ such that i, r, s is a (k, i, v)-critical experiment.*

Proof. Define the distance function $d^*(i, r) = d(v, r) + k$. Trivially, $d(i, r) \geq d^*(i, r)$ for all $r \in T_2$ with equality if and only if $d(i, v) = k$. Let x be the leaf in T_2 of shortest d^*-distance from i, and let $d^*(i, x) = L$. By construction, $L \geq 2k + 2$. In the path from i to x let c be the node which is at d^*-distance $\lfloor \frac{L}{2} \rfloor$ from i. Since $L \geq 2k + 2$, $c \in T_2$. As before, the removal of c from the tree splits the leaves into three sets, $S_1(c)$, $S_2(c)$, and $S_3(c)$. Let $i \in S_1(c)$ and $x \in S_2(c)$, and let y be the node closest to i in $S_3(c)$. The d^*-distance from y to c is at least equal to $\lceil \frac{L}{2} \rceil$ because of the way that x was chosen. If the d^*-distance from y to

c is less than or equal to $\lceil \frac{L+1}{2} \rceil$, then the experiment i, x, y is a (k, i, v)-critical experiment. Suppose on the other hand that the d^*-distance from y to c is greater than $\lceil \frac{L+1}{2} \rceil$. Then let the path from i to y be of length L' and let c' be the node along this path of d^*-distance $\lfloor \frac{L'}{2} \rfloor$ from i. Then c lies strictly between i and c' and we can repeat the argument by considering i and y and the third branch out of c'. Ultimately this procedure has to terminate since the tree is finite. At this point we will have found suitable x and y so that (i, x, y) is a (k, i, v)-critical experiment. □

Note that in general it is not possible to make the above proof constructive in the obvious manner since we do not know the structure of the overall tree. Thus finding suitable x and y could take $O(n^2)$ time in the worst case.

If V_1 and V_2 were siblings, since we already know the structure of V_1 and V_2 we can predict the outcome of every experiment involving leaves only in $V_1 \cup V_2$. It is thus clear that a necessary condition for V_1 and V_2 to be siblings is that the *predicted* outcome $\mathcal{PO}(i, j, k)$ must equal the actual outcome of the experiment, $O(i, j, k)$, for every $\{i, j, k\} \subset V_1 \cup V_2$.

We also need the following lemma.

LEMMA 4.2. *Let V_1 and V_2 be supernodes with representatives i_1 and i_2, and let $v \notin V_1 \cup V_2$ be a node on the path between i_1 and i_2. Let v separate T into the subtrees $S_t(v)$, $t = 1, 2, 3$ with $i_1 \in S_1(v)$, $i_2 \in S_2(v)$, and let j be the leaf in $S_3(v)$ closest to v. Then there exist leaves $k, l \in T - (V_1 \cup V_2)$ such that the experiments on i_1, i_2, k and l indicate that*

$$(V_1, V_2) \in LT \text{ if } d(i_1, v) < d(i_2, v),$$
$$(V_1, V_2) \in GT \text{ if } d(i_1, v) > d(i_2, v).$$

Proof. If $d(i_1, v) < d(i_2, v)$, then $O(i_1, i_2, j) = \{(i_1, i_2\}$ or else $(i_1, j) \in O(i_1, i_2, j)$. If $(i_1, j) \in O(i_1, i_2, j)$ then $(i_2, j) \notin O(i_1, i_2, j)$ so that $(V_1, V_2) \in LT$. On the other hand, if $(i_1, j) \notin O(i_1, i_2, j)$ then we can deduce that $d(j, v) > d(i_2, v) > d(i_1, v)$ so that $d(j, v) \geq d(i_1, v) + 2$. We can therefore apply Lemma 4.1 and deduce the existence of leaves r, s in $T - (V_1 \cup V_2)$ so that the experiment on (i_1, r, s) is $(d(i_1, v), i_1, v)$-critical. It is then easy to see that the experiments on i_1, i_2, r, and s determine that $d(i_2, v) > d(i_1, v)$ so that $(V_1, V_2) \in LT$. A similar analysis shows that $(V_1, V_2) \in GT$ if $d(i_1, v) > d(i_2, v)$. □

Determining siblinghood when $d(V_1) = d(V_2)$. We can now prove the following lemma.

LEMMA 4.3. *Let V_1 and V_2 be supernodes with $d(V_1) = d(V_2)$. Then V_1 and V_2 are siblings if and only if the ordered pair $(V_1, V_2) \notin GT \cup LT$.*

Proof. The necessity is obvious. For the sufficiency, apply Lemma 4.2. □

Determining siblinghood when $|d(V_1) - d(V_2)| = 1$.

LEMMA 4.4. *Let V_1 and V_2 be supernodes with $d(V_1) = d(V_2) + 1$, with representatives i_1 and i_2, respectively, and assume that the path P between the roots of the supernodes has length at least four. Then there exist experiments indicating that $(V_1, V_2) \in LT$.*

Proof. Let v be the node on P adjacent to the root of V_1. Then $d(v, i_1) = d(V_1) + 1 = d(V_2) + 2 < d(i_2, v)$. By Lemma 4.2, there exist leaves $a, b \in T - (V_1 \cup V_2)$ such that the experiments on a, b, i_1, i_2 indicate that $(V_1, V_2) \in LT$. □

However, we still need to be able to determine that V_1 and V_2 are not siblings when the distance between their roots is exactly three. For this case we have a different technique.

As noted before, if V_1 and V_2 are siblings, then $d(v, i_1) = d(v, i_2) + 1$ for all nodes $v \in T - (V_1 \cup V_2)$. In particular, the parity of the distances $d(v, i_1)$ and $d(v, i_2)$ will be different for every node $v \in T - (V_1 \cup V_2)$. Let P be the path from the root r_1 of V_1 to the root r_2 of V_2. Suppose that P has length exactly three. Let v be the node adjacent to r_1 in P and let x be a leaf in the subtree below v. Then $d(x, i_1) = d(x, i_2)$, so that the parities of $d(x, i_1)$ and $d(x, i_2)$ are identical. We will show that we can determine the existence of a leaf x so that $d(x, i_1)$ and $d(x, i_2)$ have the same parity, when V_1 and V_2 have distance exactly three apart.

LEMMA 4.5. *Let V_1 and V_2 be supernodes of distance three apart and with $d(V_1) = d(V_2) + 1$. Then there exists an experiment indicating that $(V_1, V_2) \in EQ$ or there exist experiments indicating that $parity(i_1, x) = parity(i_2, x)$ for a leaf $x \in T - (V_1 \cup V_2)$.*

Proof. Let v be the node closest to r_1 in the path from V_1 to V_2. As indicated before, every leaf x in the subtree Q rooted at v is equidistant to i_1 and i_2. Suppose for some $x \in Q$, $(i_1, x) \in O(i_1, i_2, x)$. Then $\{(i_1, x), (i_2, x)\} \subset O(i_1, i_2, x)$ so that $(V_1, V_2) \in EQ$. Otherwise, for all $x \in Q$, $(i_1, i_2) = O(i_1, i_2, x)$, so that $d(i_1, i_2) < d(i_1, x) = d(i_2, x)$. Let y be the node of longest distance from i_1 within Q. We will show that we can determine the parity of the distance from i_1 to y.

If the distance $d(i_1, y)$ is even, then the node z halfway along the path from i_1 to y is an element of Q. For any leaf t in the subtree Q' rooted at z not containing either i_1 or y, $O(i_1, y, t) = \{(i_1, t), (y, t)\}$. This indicates that $d(i_1, y)$ is even. On the other hand, if the distance $d(i_1, y)$ is odd, then for all t, $\{(i_1, t), (y, t)\} \not\subset O(i_1, y, t)$. Thus, we can determine the parity of $d(i_1, y)$ for y the leaf furthest from i_1 in Q. However, by construction, y is also the leaf of longest distance to i_2 in Q, so that the parity of $d(i_2, y)$ can also be determined. By our construction, $d(i_2, y) = d(i_1, y)$, so that the parity is the same. □

We summarize our findings in the following theorem.

THEOREM 4.6. *Let V_1, V_2 be supernodes with $d(V_1) = d(V_2) + 1$. Then we can determine in $O(n^2)$ time whether V_1 and V_2 are siblings.*

Proof. We first check whether $(V_1, V_2) \in LT \cup EQ$ by examining $O(n^2)$ experiments involving at least one of i_1 and i_2. If $(V_1, V_2) \in LT \cup EQ$ then we know immediately that V_1 and V_2 cannot be siblings. However, if $(V_1, V_2) \notin LT \cup EQ$, it is still possible that they are not siblings but have a path of distance exactly three between them. By the previous lemma, if the distance between V_1 and V_2 were exactly three, we would be able to determine that $(V_1, V_2) \in EQ$ or else that $d(x, i_1)$ and $d(x, i_2)$ have the same parity, for some $x \in T - (V_1 \cup V_2)$, by examining $O(n^2)$ experiments. Should we find such an x we know that V_1 and V_2 are not siblings. Otherwise the only possibility is that they are in fact siblings. □

Determining siblinghood when $|d(V_1) - d(V_2)| \geq 2$. Determining siblinghood in this case is a straightforward application of Lemma 4.1. More precisely, suppose, without loss of generality that $d(V_1) \geq d(V_2) + 2$. Then we know that $d(r(V_1), i_2) \geq d(V_2) + 2$ with equality if and only if V_1 and V_2 are siblings. Thus we can find x and y (within V_1 in this case) which confirm or refute the assumption of siblinghood of V_1 and V_2.

THEOREM 4.7. *Let V_1 and V_2 be supernodes such that $d(V_2) - d(V_1) \geq 2$, and let $i_1 = \text{rep}(V_1)$. Then V_1 and V_2 are siblings if and only if for all leaves $j, k \in V_2$, $\mathcal{PO}(i_1, j, k) = O(i_1, j, k)$. Furthermore, we can determine whether $\mathcal{PO}(i_1, j, k) = O(i_1, j, k)$ for all $j, k \in V_2$ in $O(|V_2|)$ time, only knowing the structures of V_1 and V_2.* The proof follows that for the case where the experiments are TOM experiments.

4.2. Implementation and running time. At the top level the construction algorithm for the POM model is identical to the algorithm for the TOM model. The difference is only in the procedure for testing siblinghood of two supernodes. In the POM model this takes $O(n^2)$ time leading to an overall running time of $O(n^4)$.

5. Conclusions and open problems. The models presented in this paper strictly generalize any distance-based models of tree reconstruction since we can infer order information given actual distances. It may even be possible to incorporate some tolerance in the distance values by considering $d(i, j)$ to be less than $d(k, l)$ only if $d(k, l) - d(i, j) > B$ for some tolerance parameter B.

There are obvious optimization questions related to the construction questions we have considered; for example, for a given set $\mathcal{E}$ of experiments (TOM or POM), what is the maximum cardinality subset of $\mathcal{E}$ which is consistent with a tree? Since consistency of TOM and POM experiments is an *NP*-complete problem, whether the tree is weighted or unweighted, these problems are *NP*-hard.

The major open question is whether there are polynomial time algorithms to reconstruct *weighted* trees in the TOM and POM models.

A GENERALIZATION OF THE SUFFIX TREE TO SQUARE MATRICES, WITH APPLICATIONS*

RAFFAELE GIANCARLO†

Abstract. We describe a new data structure, the *Lsuffix tree*, which generalizes McCreight's suffix tree for a string [*J. Assoc. Comput. Mach.*, 23 (1976), pp. 262–272] to a square matrix. All matrices have entries from a totally ordered alphabet Σ. Based on the Lsuffix tree, we give efficient algorithms for the static versions of the following dual problems that arise in low-level image processing and visual databases.

Two-dimensional pattern retrieval. We have a library of texts $S = \{TEXT^1, \ldots, TEXT^r\}$, where $TEXT^i$ is an $n_i \times n_i$ matrix, $1 \leq i \leq r$. We may preprocess the library. Then, given an $m \times m$, $m \leq n_i$, $1 \leq i \leq r$, pattern matrix PAT, we want to find all occurrences of PAT in $TEXT$, for all $TEXT \in S$. Let $t(S) = \Sigma_{i=1}^{r} n_i^2$ be the size of the library. The preprocessing step builds the Lsuffix tree for the matrices in S and then transforms it into an index (a trie defined over Σ). It takes $O(t(S)(\log|\Sigma| + \log t(S)))$ time and $O(t(S))$ space. The index can be queried directly in $O(m^2 \log|\Sigma| + totocc)$ time, where $totocc$ is the total number of occurrences of PAT in $TEXT$, for all $TEXT \in S$.

Two-dimensional dictionary matching. We have a dictionary of patterns $DC = \{PAT_1, \ldots, PAT_s\}$, where PAT_i is of dimension $m_i \times m_i$, $1 \leq i \leq s$. We may preprocess the dictionary. Then, given an $n \times n$ text matrix $TEXT$, we want to search for all occurrences of patterns in the dictionary in the text. Let $t(DC) = \Sigma_{i=1}^{s} m_i^2$ be the size of the dictionary and let $\bar{t}(DC)$ be the sum of the m_i's. The preprocessing consists of building the Lsuffix tree for the matrices in DC. It takes $O(t(DC) \log|\Sigma| + \bar{t}(DC) \log \bar{t}(DC)))$ time and $O(t(DC))$ space. The search step takes $O(n^2(\log|\Sigma| + \log \bar{t}(DC)) + totocc)$ time, where $totocc$ is the total number of occurrences of patterns in the text.

Both problems have a dynamic version in which the library and the dictionary, respectively, can be updated by insertion or deletion of square matrices in them. In a companion paper we will provide algorithms for the dynamic version.

1. Introduction.

String matching is one of the most widely studied areas in computer science, since it is interesting from a combinatorial point of view and has applications as well. It consists of finding all occurrences of a length m string pat in a length n string $text$, $m \leq n$, where both strings are defined over an alphabet Σ. Aho gives an excellent survey of pattern matching algorithms [1]. Such algorithms are in roughly two complementary classes, with each class satisfying complementary performance criteria and requirements arising in applications.

Dictionary matching algorithms. These algorithms preprocess a dictionary $D = \{pat_1, \ldots, pat_r\}$ of string patterns, each of length m_i; then one can look for the occurrences of patterns of the dictionary into the text. They are appropriate in applications where the dictionary does not change much over time and one can afford slow search times. Aho and Corasick [2] designed the most general algorithms for this class: the dictionary D is preprocessed in $O((\Sigma_{i=1}^{r} m_i) \log|\Sigma|)$ time and then one can search for all the occurrences of patterns of D into a text in $O(n \log|\Sigma| + totocc)$ time, where $totocc$ is the number of such occurrences and n is the length of the text.

Pattern retrieval algorithms. These algorithms preprocess the text to build an index data structure that represents all substrings of the text. The index supports a wide variety of queries. The most basic one is $occurrence(pat)$: report all occurrences of string pat in the text. One can also define more sophisticated queries that ask for statistical information about the structure

of the text, e.g., find the longest repeated substring of the text. Such indices are appropriate in applications where we have time to preprocess the text, but we need fast response times to our queries. The best known representative of this class is the suffix tree by McCreight [22] (see also [26] and [10]). It can be built in $O(n \log |\Sigma|)$ time and in $O(n)$ space. The query $occurrence(pat)$ takes $O(m \log |\Sigma| + totocc)$ time. Moreover, it also supports fast answers to statistical queries about the text.

In recent years, there has been growing interest in pattern matching in higher dimensions, due to its relevance to low-level image processing [23] and to the advent of visual databases in multimedia systems [19]. We need the following notation. All matrices have entries defined from a totally ordered alphabet Σ. An $n \times m$ matrix A has height n and width m.

1.1. Two-dimensional pattern matching: State of the art.

Dictionary matching algorithms. The model is similar to that used for strings except that all patterns in the dictionary and the text are matrices. We discuss first the case in which the dictionary is composed of one pattern PAT of dimension $m_1 \times h_1$. Let the text be an $n \times w$ matrix. The first such algorithms, independently discovered by Baker [8] and Bird [9], need $O((m_1 \times h_1 + n \times w) \log |\Sigma|)$ time. Amir, Benson, and Farach [3] made the first substantial step toward alphabet independence for this problem by devising an $O((m_1 \times h_1) \log |\Sigma| + n \times w)$ time algorithm. Recently, Galil and Park [12] closed the gap by improving the time bound to $O(m_1 \times h_1 + n \times w)$. All of these algorithms have the drawback that they can preprocess only one pattern at a time or a dictionary of patterns that can have different widths but the same height. Algorithms for the special case in which the patterns in the dictionary are squares, each of arbitrary height=width, are given by Amir et al. [4], [6] and in this paper (see also [15]). The results have been obtained independently and with different approaches (see §1.2 for technical discussion). Finally, Idury and Schaffer [18] have recently devised data structures and algorithms that preprocess a dictionary of pattern matrices $D = \{PAT_1, \ldots, PAT_r\}$, each of dimension $m_i \times h_i$, $1 \leq i \leq r$; the patterns can be searched for in a text of dimension $n \times w$. The preprocessing step takes $O((\Sigma_{i=1}^{r} m_i \times h_i)\text{polylog}(\Sigma_{i=1}^{r} m_i \times h_i))$ time and the search step takes $O((n \times w)\text{polylog}(\Sigma_{i=1}^{r} m_i \times h_i))$ time.

Pattern retrieval algorithms. The model is similar to that used for strings, but the text is a matrix $TEXT$. Therefore, we want an index that represents all submatrices of $TEXT$ and that at least supports the query $occurrence(PAT)$, i.e., report all occurrences of the pattern matrix PAT in the text matrix. For a long time only straightforward data structures and algorithms were known. Indeed, using a spiral representation of square matrices, Gonnet [16] claims that, for the special case of square matrices, it is possible to build a patricia tree (referred to as PAT-Tree [16]) representing all submatrices of an $n \times n$ $TEXT$ matrix in $O(n^2 \log n)$ *expected time*. However, in the worst case, that data structure can be built in $O(n^4)$ time. Then, using the PAT-Tree, Gonnet [16] claims that one can find all occurrences of a square matrix PAT, of height m, in $O(\log n)$ *expected time* independent of the number of occurrences. Again, in the worst case, the time bound to find all such occurrences is $O(m \log |\Sigma| + occ)$. Here we are interested in the design of data structures that can be efficiently built according to the worst case time analysis. As it will be clear from the results of the next subsection, our data structure guarantees nearly two orders of magnitude speed-up with respect to the solution proposed in [16]. This paper provides the first data structure, the Lsuffix tree, that can be efficiently built and that represents all square submatrices of an $n \times n$ $TEXT$ [15]. Therefore, here we provide a two-dimensional analog of the suffix tree for the special case of square matrices. For completeness, we report that the author has also devised an index data structure that represents all submatrices of a general matrix $TEXT$ [14]. However, it is also shown that the problem of building an index data structure that represents all square submatrices of a square matrix is computationally easier than building an index data structure that represents

all submatrices of a general matrix [14]. Thus the special case we are dealing with here is interesting. Moreover, the algorithmic techniques needed here seem to be interesting in their own right (see §1.2 for technical discussion).

From now on we restrict attention to square matrices.

1.2. Our results. As implied by the above discussion, there was no efficient algorithm known that builds a two-dimensional analog of the suffix tree for square text matrices. The main contribution of this paper is to provide efficient algorithms that build and query such a two-dimensional suffix tree for square matrices, which we call the Lsuffix tree (the name Lsuffix will become clear later). Based on such a data structure, we obtain efficient algorithms for the static version of the following problems that arise in low-level image processing [23] and visual databases [19]. In a companion paper [13], we will provide algorithms for the dynamic version. We show the dependence of the time bound on the alphabet size.

Two-dimensional pattern retrieval. We have a library of texts $S=\{TEXT^1, \ldots, TEXT^r\}$, where $TEXT^i$ is an $n_i \times n_i$ matrix, $1 \leq i \leq r$. We may preprocess the library. Then, given an $m \times m$, $m \leq n_i$, $1 \leq i \leq r$, pattern matrix PAT, we want to find all occurrences of PAT in $TEXT$ (query), for all $TEXT \in S$. Let $t(S) = \Sigma_{i=1}^{r} n_i^2$ be the size of the library.

(i) The preprocessing step builds the Lsuffix tree for the matrices in S and then transforms it into an index (a trie defined over Σ). It takes $O(t(S)(\log|\Sigma| + \log t(S)))$ time and $O(t(S))$ space. Based on the index and in the same time bound, we can precompute three tables which are a space-economical representation of the index taking only a total of $5t(S)$ memory locations.

(ii) The index can be queried directly in $O(m^2 \log|\Sigma| + totocc)$ time, where $totocc$ is the total number of occurrences of PAT in $TEXT$, for all $TEXT \in S$. The query procedure is simple and likely to perform well in practice.

(iii) The tables support a query procedure, with an $O(m^2 + \log t(S) + totocc)$ time bound, which is similar to the one devised by Manber and Myers for suffix arrays [21]. This procedure is also simple and likely to perform well in practice. It beats the one in (ii) when it is costly to store the index or when $|\Sigma|$ is large compared to $t(S)$.

Two-dimensional dictionary matching. We are given a dictionary of patterns $DC = \{PAT_1, \ldots, PAT_s\}$, where PAT_i is of dimension $m_i \times m_i$, $1 \leq i \leq s$. We may preprocess the dictionary. Then, given an $n \times n$ text matrix $TEXT$, we want to search for all occurrences of patterns in the dictionary in the text (search step). Let $t(DC) = \Sigma_{i=1}^{s} m_i^2$ be the size of the dictionary and let $\bar{t}(DC)$ be the sum of the m_i's.

(iv) The preprocessing consists of building the Lsuffix tree for the matrices in DC. It takes $O(t(DC) \log|\Sigma| + \bar{t}(DC) \log \bar{t}(DC)))$ time and $O(t(DC))$ space. Based on it, the search step simulates a finite state automaton in $O(n^2(\log|\Sigma| + \log \bar{t}(DC)) + totocc)$ time, where $totocc$ is the total number of occurrences of patterns in the text. Such a simulation is different from the query procedures in (ii) and (iii).

Amir et al. [4], [6] have independently obtained data structures and algorithms for the two-dimensional dictionary matching problem. In the static version, we have the same time bounds as the ones reported in [6], but the dynamic version of their algorithms is better (see [6], [15]). The algorithms reported in [4] seem to be efficient for the static case only and their time bound is slightly better than the ones obtained here. The algorithmic techniques used in [4], [6] and the data structures they build are different from ours. They build what can be considered the two-dimensional analog of the Aho–Corasick one-dimensional pattern matching machine [2] while we build the two-dimensional analog of the suffix tree [22]. It is an interesting open problem to establish whether their techniques and data structures extend to the efficient construction and query of the Lsuffix tree, so that we can obtain alternative solutions to the two-dimensional pattern retrieval problem.

For the construction of the Lsuffix tree, we introduce Lstrings, a linear representation of square matrices (thus, L stands for linear). Using a different formalism, Amir and Farach [4] introduced such a linearization. We define suffix and prefix relations for Lstrings that are generalizations of the usual ones for strings and that seem to capture the intuitive idea of what a suffix and prefix of a square matrix should be.

The Lsuffix tree is for an Lstring what the suffix tree is for a string. However, because of the new suffix relation, the algorithm that builds the Lsuffix tree is a nonobvious generalization of McCreight's suffix tree algorithm (MC for short) for a string [22]. Indeed, the *rescanning phase*, the key component of MC, breaks down for Lstrings due to the fact that a key property that holds for strings does not hold for Lstrings. Using terminology introduced by Baker [7], we refer to this property as the distinct right context property and we will discuss it in §5. Thus we need new ideas for the design of an efficient algorithm that builds a suffix tree for Lstrings. Another problem is how to label the Lsuffix tree so that it concisely represents all the suffixes of an Lstring (essential to keep the size of the data structures in the pattern retrieval problem bounded by $t(S)$) and how to extract information from those labels (essential to get a fast query algorithm for the pattern retrieval problem). For strings and suffix trees, the problem is easy to solve: a label (i, j) represents the string from position i to j [22]. For Lstrings and their suffixes, it is more complicated since it turns out that it is not convenient to represent Lstrings explicitly as strings in Σ^*.

The algorithmic techniques presented in this paper have already proved useful in other contexts and seem to be able to deal with a general problem that might have other applications as well. Indeed, in a study on the design of tools to detect code duplication in large software systems, Baker [7] has developed a theory for *p-strings*, a generalization of ordinary strings, and she has defined a *p-suffix* tree, a generalization of the suffix tree to *p-strings*. Although far apart in terms of both application areas and definitions, p-strings and Lstrings share the lack of the distinct right context property. Thus the construction of the p-suffix tree uses some of the techniques devised here for the construction of the Lsuffix tree. In general, the techniques presented here are useful when we need to build a suffix-tree-like data structure for objects that are similar to strings except for the fact that the distinct right context property does not hold for them.

We anticipate that the technical presentation of our results will be confined to one matrix. The definitions and algorithms generalize easily to a set of matrices. The remainder of this paper is organized as follows. Section 2 contains some preliminary notation needed in the rest of the paper. In §3 we define Lstrings and point out their relation to matrices. We also define compacted tries for Lstrings and finally the suffix tree for a square matrix A. We briefly discuss the use of such a data structure for pattern matching. In §§5 and 6 we give the algorithm that builds the Lsuffix tree for one Lstring and discuss why the algorithm by McCreight [22] will not work for Lstrings. Then in §7 we generalize the construction to a set of Lstrings and from it we obtain an algorithm to build the suffix tree of a square matrix. In §8 we show how to transform compacted tries for Lstrings into compacted tries for strings, which is needed to obtain fast response times for the pattern retrieval problem. The last three sections deal with applications, concluding remarks, and open problems.

2. Preliminaries. In this section we introduce some notation and the basic data structures needed in the rest of the paper. Given an $n \times n$ matrix A, we denote by $A[i : k, j : l]$ the submatrix of A with corners in $(i, j), (k, j), (i, l), (k, l)$. When $i = k$ or $j = l$, we omit one of the repeated indices. Let Σ be an alphabet and assume that there is a total order $<$ defined on it. Let \$ be a special symbol not part of the alphabet Σ and let us make the convention that it does not match itself, i.e., each instance of \$ is different from the others.

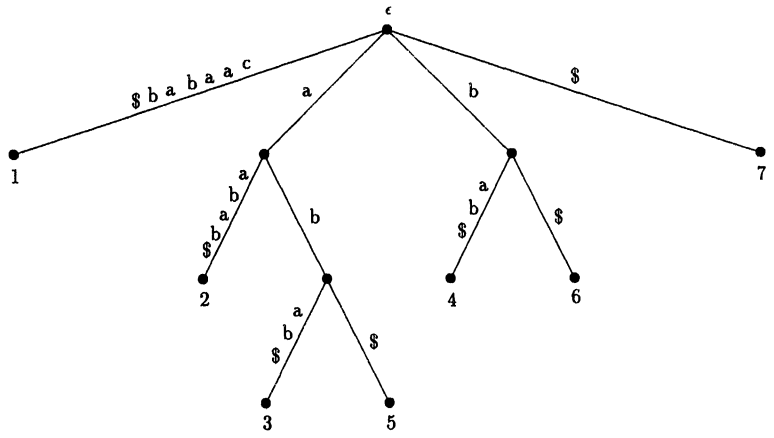

FIG. 1. *Suffix tree for string* caabab$.

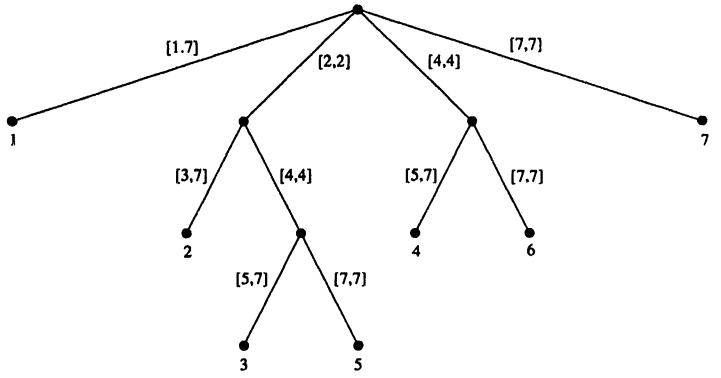

FIG. 2. *Labeled version of suffix tree in Fig.* 1.

Let $x\$$ be a string. The suffix tree T_x for the string $x\$$ [22] is a compacted patricia tree (see [20] for a definition of patricia trees) that satisfies the following conditions. Each edge from parent to offspring is labeled with a substring of $x\$$ and, for each suffix $x[i, |x|]\$$, there is a path from the root to a leaf whose concatenation of labels gives $x[i, |x|]\$$. Because the $\$$ does not match any character of Σ, all suffixes of $x\$$ are distinct. So, there is a one-to-one correspondence between the leaves of T_x and the suffixes of x. We remark that each substring on each edge of the suffix tree can be represented in constant space (see Figs. 1 and 2).

The suffix tree was proposed by McCreight [22] as a space-efficient alternative to Weiner's position tree [26]. It can be built in $O(|x| \log |\Sigma|)$ time and it has $O(|x|)$ nodes. The algorithm by McCreight can also be extended to build the suffix tree for a set of strings $x_1, \ldots, x_k$ by building the suffix tree for $X = x_1\$x_2\$ \ldots \$x_k\$$, where now $\$$ is a separator. The time complexity is $O(|X| \log |\Sigma|)$.

Let F be a forest of rooted directed trees. We are interested in performing the following operations on nodes and edges of F:

- $newnode(v)$: create a new node v, which is also root of a new tree.
- $link(w, v)$: Combine the trees containing v and w by adding the edge (w, v). This operation assumes that v and w are in different trees and that v is a tree root.
- $cut(v)$: Divide the tree containing v into two trees by deleting the edge $(parent(v), v)$. This operation assumes that v is not a tree root.

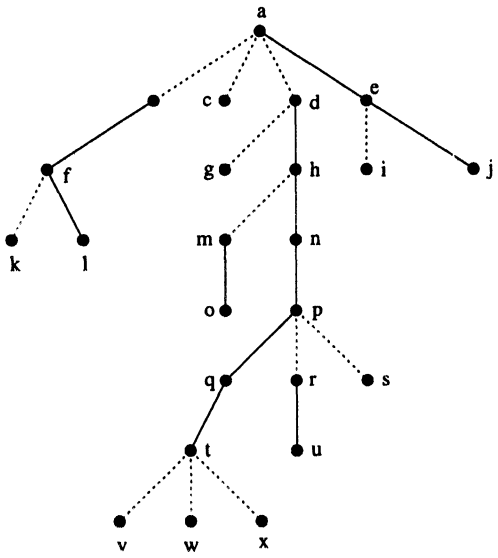

FIG. 3. *A tree partitioned into solid paths. Path t, q, p, n, h, d has head t and tail d.*

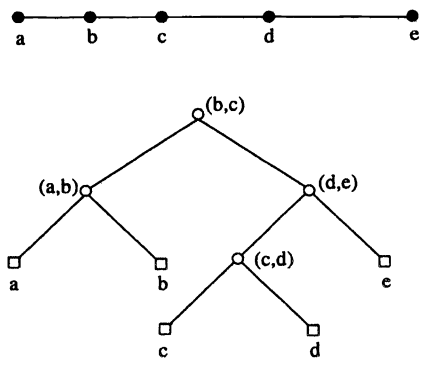

FIG. 4. *A path and a binary tree representing it. Path with head a and tail e. Leaves are labeled with corresponding vertices, internal nodes with corresponding edges.*

Sleator and Tarjan [25] designed a data structure that supports the three operations just defined, among others. Each operation can be implemented to take $O(\log g)$ time in the worst case, where g is the number of nodes in the tree involved in the operation. A tree $\hat{T}$ in the forest is represented as a collection of disjoint solid paths connected by dashed edges (see Fig. 3). Each solid path has a tail and a head, the node further away and closest to the root of $\hat{T}$, respectively (see Fig. 3). What is important for our purposes is that each solid path is represented as a binary search tree such that its leaves, from left to right, give the nodes on the solid path from tail to head. Moreover, the internal nodes represent the edges on the path in such a way that a symmetric order traversal gives the edges on the path from tail to head and, therefore, the nodes in decreasing order of distance from the root of $\hat{T}$ (see Fig. 4). Sleator and Tarjan [25] define the operation $expose(v)$ that returns the path from v to the root of its tree $\hat{T}$ in the forest represented as a solid path. That operation takes $O(\log g)$ time, where g is the number of nodes of $\hat{T}$. For further details, the reader is referred to [25].

We also need the data structures and algorithms of Harel and Tarjan [17] (see also [24]) to compute the lowest common ancestor (LCA for short) of two nodes in a static tree. They

preprocess the tree in time linear in its size. Then, each LCA query can be answered in constant time.

3. From the suffix tree to the Lsuffix tree. In this section we give the definition of Lsuffix tree. We proceed as follows. In §3.1 we discuss at an informal level what such a data structure should represent and how it should represent it. We provide the definition of Lstring and discuss the correspondence between Lstrings and matrices. In §3.2 we formalize the requirements of §3.1. There we first introduce the notion of compacted trie for Lstrings, then give a formal definition of Lsuffix tree for one Lstring. Then we generalize it to a set of Lstrings so that it will represent all square submatrices of a given matrix A and briefly discuss its use for pattern matching.

3.1. Requirements. Let us start with an obvious observation about T_x, the suffix tree of a string $x\$$. As a trie, it represents the set of all suffixes of x in such a way that suffixes with common prefixes share a path in T_x. Since each substring of x is prefix of some suffix of x, for each substring of x there is a path in T_x that corresponds to that substring. That is the reason why T_x is useful for string matching purposes.

Informally, given a square matrix $A[1 : n, 1 : n]$, we want a tree data structure such that for each square submatrix of A there is a path in our tree that "corresponds" to that submatrix, so that we can use it for pattern matching purposes (patterns are square matrices). The tree shape of our data structure seems to impose the constraint that square submatrices of A that have common "prefixes" (whatever the definition of "prefix" is) must share the same path on the tree. Informally, we call it the *common prefix constraint*. If we want a data structure analog to T_x, each submatrix of A must be a "prefix" of some "suffix" of A (whatever the definition of "suffix" is), so that we can build the "correspondence" between all submatrices of A and the paths of our tree by considering only the "suffixes" of A. Informally, we call such correspondence the *completeness* constraint. Our data structure must satisfy both constraints simultaneously.

Keeping those two constraints in mind, let us consider the following definitions of prefix and suffix of a square matrix. For $1 \leq j \leq n$, $A[j : n, j : n]$ is the *jth suffix* of A and $A[1 : j, 1 : j]$ is the *jth prefix* of A (see Fig. 5). Note that any square submatrix of A whose upper left corner lies on the main diagonal of A can be described as a prefix of a suffix of A (see Fig. 5). Let us number each diagonal (not necessarily the main one) of A by d if its elements are $A[i, j]$ with $i - j = d$, $0 \leq |d| \leq n - 1$. Let A_d be the square submatrix of A whose main diagonal is the dth diagonal of A. Since every element of A is on a diagonal of A, it is easy to see that each square submatrix of A is described as the prefix of a suffix of A_d for some d, $0 \leq |d| \leq n - 1$ (see Fig. 5). Thus the completeness constraint can be satisfied provided that our data structure represents all suffixes of A_d, $0 \leq |d| \leq n - 1$.

To satisfy the common prefix constraint, we adopt a linear representation of a matrix A, which we call Lstring. The same representation, with a different formalism, has been introduced by Amir and Farach [4]. We discuss it informally first. Given $A[1 : n, 1 : n]$ and with reference to Fig. 6, notice that we can divide it into n "L-shaped characters", the ith being composed of row $A[i, 1 : i - 1]$ and column $A[1 : i, i]$. Let us "write down" those L-shaped characters in one dimension and in the order given by their top-down appearence in A (see Fig. 6). We get a representation of A in terms of a string of L-shaped characters which we call Lstring. We also need the notion of a chunk, which is the analog of the notion of substring for strings. Informally, we obtain a chunk if we write down the L-shaped characters of A in one dimension, in the order given by their top-down appearence in A and starting at row k and ending at row j (see Fig. 6). As it should be clear from the figure, Lstrings are intended to represent matrices while chunks are intended to represent pieces of matrices centered along the main diagonal.

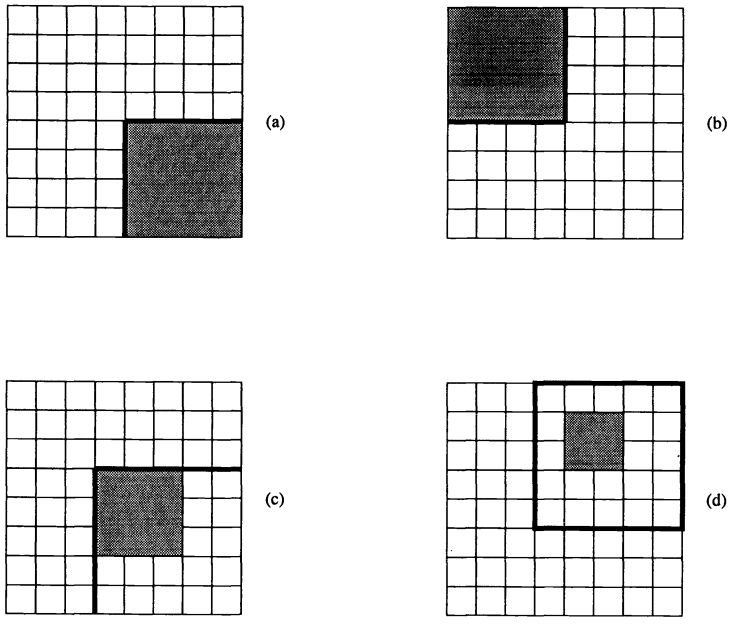

FIG. 5. (a) *The shaded region is the fifth suffix of A.* (b) *The shaded region is the fourth prefix of A.* (c) *The shaded submatrix of A, with upper left corner on the main diagonal of A, is the third prefix of the fourth suffix of A (the one with bold boundaries).* (d) A_{-3} *is shown in bold boundaries. The shaded submatrix of A is the second prefix of the second suffix of* A_{-3}.

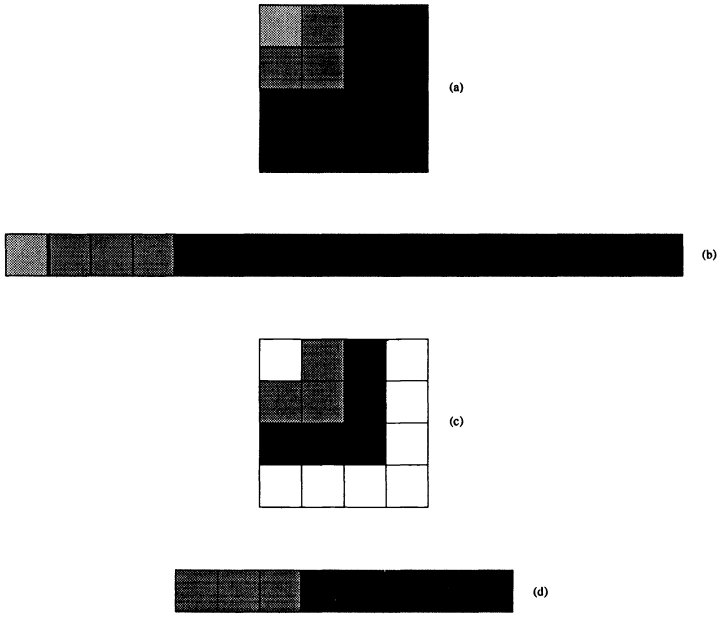

FIG. 6. (a) *A matrix divided into "L-shaped characters." Entries with the same shading are part of the same "character."* (b) *A linear representation of the matrix in* (a) *in terms of "L-shaped characters."* (c) *A chunk composed of two "L-shaped characters," and* (d) *its linear representation.*

More formally, let $L\Sigma = \cup_{i=1}^{\infty} \Sigma^{2i-1}$. We refer to the strings of $L\Sigma$ as *Lcharacters* and we consider each of them as an "atomic" item (composed of "subatomic" parts, which are the

characters of Σ). We refer to $L\Sigma$ as the *alphabet of Lcharacters*. Two Lcharacters are *equal* if and only if they are equal as strings over Σ. Moreover, given two Lcharacters Lw and Lu of equal length as strings of Σ^*, $Lw \leq Lu$ if and only if Lw as a string is lexicographically smaller than or equal to Lu as a string. Two Lcharacters can be *concatenated* by concatenating the strings corresponding to them; however, we have the following restriction: an Lcharacter in Σ^{2i-1} can *precede* only an Lcharacter in $\Sigma^{2(i+1)-1}$ and *succeed* only one in $\Sigma^{2(i-1)-1}$. Any number of Lcharacters whose concatenation satisfies the above restriction is a *chunk*. An *Lstring* is a chunk such that the first Lcharacter is in Σ. However, the definition of Lstring is most easily understood in terms of their natural correspondence to matrices.

For any matrix $A[1:n, 1:n]$, consider the concatenation of strings $a_1, \ldots, a_n$ such that a_i is a string of length $2i-1$ equal to $A[i, 1:i-1]A[1:i, i]$ (see Fig. 7). Since $a_i \in \Sigma^{2i-1}$, it can be seen as an Lcharacter and, since $a_1 \in \Sigma$, the concatenation of strings $a_1, \ldots, a_n$ is an Lstring La naturally corresponding to A. We denote the ith Lcharacter of La as $La[i]$. The length of La is n, i.e., the number of Lcharacters in the Lstring.

Throughout this paper, when we write down a matrix as an Lstring Lb, the first $i-1$ characters in row i will always correspond to the first $i-1$ characters of $Lb[i]$ and the first i characters of column i will always correspond to the last i characters of $Lb[i]$. Conversely, the first $i-1$ characters of $Lb[i]$ will always correspond to the first $i-1$ characters of row i and the last i characters of $Lb[i]$ will always correspond to the first i characters of column i of a matrix. With such convention, Lb uniquely identifies a square matrix B

and vice versa. A chunk starting at the ith Lcharacter and ending at the jth Lcharacter of Lb is denoted L$b[i, j]$. Through the correspondence between Lstrings and matrices, it is easy to see that L$b[i, j]$ corresponds to a piece of matrix B centered on the main diagonal of B (see Fig. 6).

The jth *Lprefix* of La, denoted L$pref_j(La)$, is the Lstring corresponding to $A[1 : j, 1 : j]$, the jth prefix of A. Given A, L$pref_j(La)$ is easy to obtain since we can take $A[1 : j, 1 : j]$ and write it down as an Lstring. Notice that Lb is an Lprefix of La if and only if the matrix B corresponding to Lb is equal to a prefix of A (see Fig. 7). The jth Lsuffix of La, denoted L$suf_j(La)$, is the Lstring corresponding to $A[j : n, j : n]$, the jth suffix of A. Given A, L$suf_j(La)$ is easy to obtain since we can take $A[j : n, j : n]$ and write it down as an Lstring. Notice that Lb is Lsuffix of La if and only if the matrix B corresponding to Lb is equal to a suffix of A (see Fig. 7).

Let La_d be the Lstring corresponding to A_d. By definition of the prefix and suffix of a matrix, every square submatrix of A is a prefix of some suffix of A_d for some $d, 0 \leq |d| \leq n-1$. Thus, using the correspondence between La_d and A_d and, in general, the correspondence between matrices and Lstrings, we have the following fact.

FACT 1. *Let B be a square matrix and Lb be the Lstring corresponding to it. B is a submatrix of A if and only if Lb is Lprefix of some Lsuffix of La_d, for $0 \leq |d| \leq n-1$.*

Intuitively and drawing an analogy from strings, our data structure needs to be a compacted trie over the alphabet LΣ (whatever such a trie is) that "represents" all Lsuffixes of La_d for all d, $|d| \leq n-1$. That is, for each Lsuffix of La_d, $0 \leq |d| \leq n-1$, there is a path from the root to a leaf "spelling out" that Lsuffix. Using Fact 1 and the fact that matrices with common prefixes are represented by Lstrings with common Lprefixes, that data structure can satisfy both the completeness and the common prefix constraint.

3.2. Definition. We now give a formal definition of our data structure, the Lsuffix tree, and show that it satisfies what we have informally called the completeness and common prefix constraint in the previous section. In §3.2.1 we introduce the notion of trie over the alphabet LΣ. In §3.2.2 we define the Lsuffix tree for one Lstring La and discuss some technical issues related to its representation. Then, in §3.2.3 we generalize it to the set of Lstrings corresponding to A_d, $0 \leq |d| < n$. That data structure will be *the Lsuffix tree* of matrix A.

3.2.1. Tries over the alphabet LΣ. We start with an example. Consider three matrices X, Y, and Z and their corresponding Lstrings Lx, Ly, and Lz (see Fig. 8). We can represent such Lstrings (and therefore the matrices) with a tree by letting Lstrings that have Lprefixes in common share the same path in the tree (see Fig. 8). We can label the edges of such tree with Lcharacters and require that the Lcharacters on two edges, one incoming and the other outgoing the same node, be compatible for concatenation since each of Lx, Ly and Lz must be obtained as the concatenation of the labels on the path from the root to a leaf.

In general, a trie over the alphabet LΣ, representing a set of Lstrings C, is defined in a way analogous to a trie for strings. That is, it is a tree with each edge labeled with an Lcharacter and that satisfies the following:

1. For each Lstring Lx in C there is a leaf v such that the concatenation (according to the rule for Lcharacters) of the labels on the path from the root to v gives Lx.
2. For each node u and w, u is ancestor of w if and only if Lz is the Lprefix of Ly. where Lz and Ly are the Lstrings obtained by concatenating the labels of the edges on the paths from the root to u and w, respectively.
3. All edges outgoing the same node are labeled with a different Lcharacter.

Tries for Lstrings can have nodes of outdegree one, just like tries for strings can have nodes of outdegree one (see Fig. 8). We compact tries for Lstrings by compacting chains of

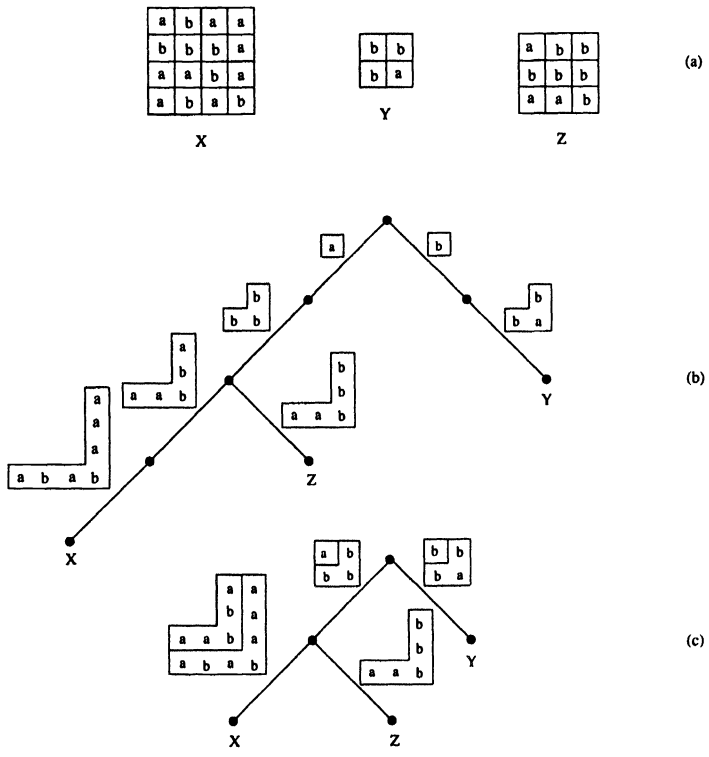

FIG. 8. (b) *The tree over the alphabet* $L\Sigma$ *representing the Lstrings corresponding to matrices in* (a). (c) *The compacted version of the tree in* (b). *Notice chunks on the edges.*

nodes with outdegree one into a single edge. The label on that new edge is the concatenation of the Lcharacters on the edges of the chain, i.e., it is a chunk. So, we can define a compacted trie representing a set of Lstrings as a trie representing the same set of Lstrings in which chains of nodes of outdegree one are compressed into one edge and the edges of the compacted trie are labeled with chunks (see Fig. 8). Notice that there is no loss of information in going from a trie representing a set of Lstrings to a compacted trie representing the same set. Moreover, sibling edges in the compacted trie are labeled with chunks that start with different Lcharacters. We need the following fact.

FACT 2. *Let* C *be a set of Lstrings represented by a compacted trie* LT_C. *Let* Lz *be the Lstring of length* b *obtained by concatenating the chunks on the edges from the root of* LT_C *to some node* v *in* LT_C. *The first Lcharacter on the label of each edge outgoing* v *is a string in* Σ^{2b-1}.

Proof. Notice that in the uncompacted version LT of LT_C, the Lcharacter on the incoming edge of a node $u' \in LT$ at depth i must be in Σ^{2i-1} (see Fig. 8). This follows from the fact that the path from the root of LT to $u' \in LT$ gives an Lstring of length i and the concatenation rule for Lcharacters. Now Fact 2 follows because in LT_C the depth of the nonunary nodes of LT changes but the length of the Lstring they represent is the same. □

We need the following notation. Given a compacted trie LT over the alphabet $L\Sigma$, a node u is the *locus* of an Lstring $L\alpha$ if and only if the concatenation of the labels on the path from the root of LT to u is equal to $L\alpha$. The *extension* of $L\alpha$ is any Lstring of which $L\alpha$ is an Lprefix. The *extended locus* of $L\alpha$ is the locus of the shortest extension of $L\alpha$ whose locus is defined in LT. The *contracted locus* of $L\alpha$ is the locus of the longest Lprefix of $L\alpha$ whose

locus is defined in LT. Using the definitions just given and the definition of a compacted trie over the alphabet $L\Sigma$, the locus, extended locus, and contracted locus of an Lstring are unique nodes in LT. Moreover, when an Lstring has a locus defined in LT then its contracted and extended locuses are the same as its locus. Similar definitions of locus, extended locus, and contracted locus can be defined for a string and a compacted trie over the alphabet Σ.

FACT 3. *Let C be a set of Lstrings and let LT_C be the compacted trie representing the Lstrings in the set. Lstring Ly has an extended locus in LT_C if and only if it is Lprefix of some Lstring in the set C.*

Proof. Assume that Ly has an extended locus u in LT_C. Thus Ly is Lprefix of Lz, the Lstring of which u is a locus. But Lz is the Lprefix of some Lstring in C by definition of trie over the alphabet $L\Sigma$ and the way we compact it. So, Ly is the Lprefix of some Lstring in C.

Assume that Lx is the Lstring in C of which Ly is the Lprefix and let i be the length of Ly, i.e., it is composed of i Lcharacters. Consider the node v on the path from the root to the leaf associated to Lx that is closest to the root and such that the concatenation of the labels on the path p from the root to v gives an Lprefix Lz of Lx of length at least i. Notice that there is no other node $w \neq v$ that is the locus of Lz (otherwise two edges outgoing the same node have labels that start with equal Lcharacters). Therefore v is the extended locus of Ly because Lz is the shortest extension of Ly having a locus defined in LT_C. □

3.2.2. The Lsuffix tree of one Lstring. Intuitively, the Lsuffix tree for one Lstring is like the suffix tree for a string. That is, the Lsuffix tree for an Lstring La is a compacted trie over the alphabet $L\Sigma$ representing the set of all Lsuffixes of La (suffixes of A). Just like the last character of a string is required to be unique for ordinary suffix trees, we require that the last Lcharacter of an Lstring be unique for Lsuffix trees. Given a matrix A, we augment it with a bottom row and rightmost column of \$'s (see Fig. 7a for a matrix so augmented). That bottom row and rightmost column corresponds naturally to an Lcharacter that we denote $\hat{\$}$. The Lstring that corresponds to $A\hat{\$}$ is $La\hat{\$}$. Since \$ does not match anything, no Lsuffix of a given Lstring with $\hat{\$}$ endmarker is an Lprefix of any other Lsuffix of any other Lstring. Formally, the Lsuffix tree LT_a for La is a compacted trie over the alphabet $L\Sigma$, satisfying the following constraints (see Fig. 9 for an example):

1. There is no internal node of outdegree one.
2. Each edge is labeled with a chunk.
3. Chunks assigned to sibling edges start with different Lcharacters, which are of the same length as strings in Σ^*.
4. The concatenation of the chunks labeling the edges on the path from the root to a leaf gives exactly one Lsuffix of $La\hat{\$}$, say $Lsuf_l(La\hat{\$})$ (the Lstring corresponding to $A[l:n, l:n]\hat{\$}$). That leaf is labeled with l.

What is important to note is that there is a one-to-one correspondence between the leaves of LT_a and the Lsuffixes of $La\hat{\$}$ (which are all distinct because $\hat{\$}$ does not match anything).

FACT 4. *Given an $n \times n$ matrix A and its corresponding Lstring La, the Lsuffix tree for La has $O(n)$ nodes.*

Proof. It has exactly $n + 1$ leaves (one per Lsuffix, including $\hat{\$}$) and each internal node has outdegree at least two. □

Notice that each chunk on the edges of LT_a can be a long sequence of Lcharacters and the sum of the lengths of such chunks might exceed $O(n)$, the number of nodes of LT_a. We solve this potential problem by representing each chunk in constant space, independent of its length. The idea is similar to the one used by McCreight in the suffix tree T_x for a string $x\$$ [22], where the substring y on a given edge is represented by a pair (i, j) such that $x[i, j] = y$.

Consider an edge (u, v) in LT_a and let α be the chunk labeling that edge. Let f be any arbitrary leaf in the subtree rooted at v and let l be the label of that leaf. Recall from the

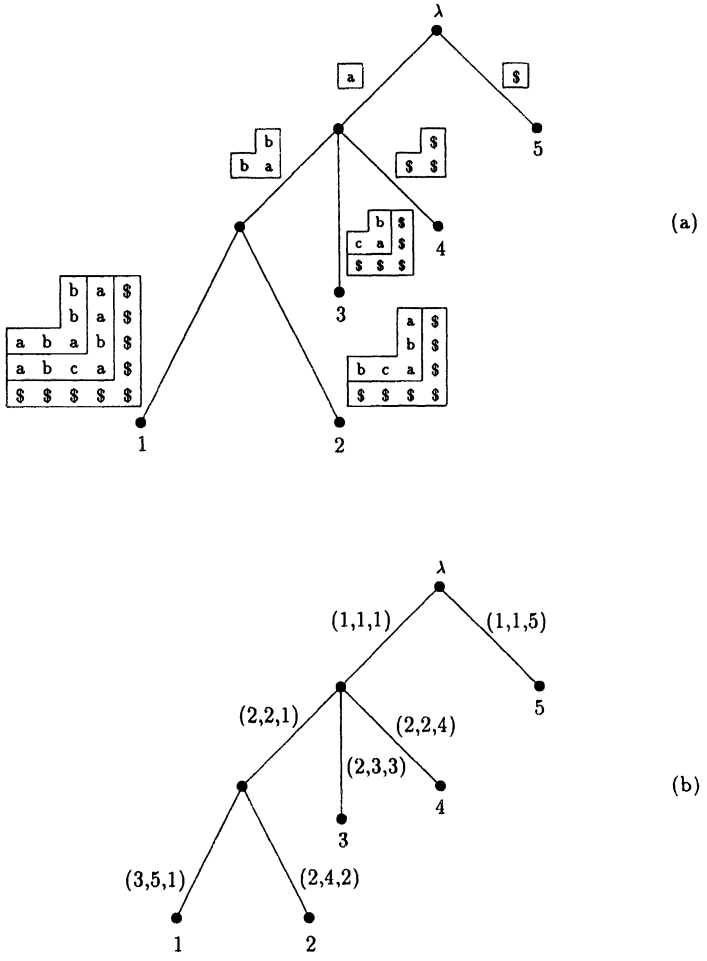

FIG. 9. (a) *The Lsuffix tree corresponding to the Lstring in Fig.* 7b. (b) *The same tree in* (a) *with chunks substituted by triples.*

definition of Lsuffix tree for La that the concatenation of the labels on the path from the root to f must give $Lsuf_l(La\hat{\$})$ (the Lstring corresponding to $A[l : n, l : n]\hat{\$}$). Since (u, v) is on that path, its label α must "appear" somewhere in $Lsuf_l(La\hat{\$})$, i.e., there exist p and q, $p \leq q$, such that the chunk $Lsuf_l(La\hat{\$})[p, q]$ corresponds to α. So, α can be represented in constant space by the triple (p, q, l). In the next paragraph we will discuss how to recover $Lsuf_l(La\hat{\$})[p, q]$ from the triple. We will address the issue on how to compute such triples in §§5 and 6, where we show how to build the Lsuffix tree for one Lstring. For the time being, we assume that each chunk on the edges of LT_a has been substituted by an appropriate triple. See Fig. 9 for an example of an Lsuffix tree for one Lstring in which chunks are represented by triples. From now on, we will make no distinction between chunks and their representation as triples.

One last issue we have to address is how to explictly recover, in constant time, an occurrence in the matrix A of any Lcharacter of the chunk α, when that chunk is represented by the triple (p, q, l). Recall that an Lcharacter is obtained as the concatenation of a subrow and subcolumn of A. What we mean by occurrence of Lcharacter in A is the starting points of a

subrow and subcolumn of A whose concatenation gives the Lcharacter. So, based on the triple, we need to compute the coordinates of two entries of A. Rather than give explicit formulas, we provide a high level description. The triple (p, q, l) corresponds to $\mathrm{L}suf_l(La\hat{\$})[p, q]$. We know that La represents A. Now, $\mathrm{L}suf_l(La\hat{\$})$ =Lc represents a matrix $C = A[l : n, l : n]\hat{\$}$ and so α is $\mathrm{L}suf_l(La\hat{\$})[p, q]$ =Lc$[p, q]$. Thus we can compute in constant time where C starts in A. Because of the correspondence between Lstrings and matrices and the definition of chunk, we know that Lc$[g]$, $p \leq g \leq q$, is equal to $C[g, 1 : g - 1]C[1 : g, g]$. But since we know where C starts in A, we also know where $C[g, 1 : g - 1]$ and $C[1 : g, g]$ start in A and therefore where an occurrence of Lc$[g]$ starts in A. Thus we can access, in constant time, the starting point(s) in A of any Lcharacter in the chunk α based only on the triple (p, q, l). As a side effect of our representation of chunks, we do not need to know explicitly the Lstring La or its Lsuffixes, since we can recover from the matrix A any chunk or Lcharacter in those Lstrings. We obtain the following theorem.

THEOREM 1. *Given an $n \times n$ matrix A, let La be the Lstring corresponding to A. When chunks on the edges of LT_a are represented by triples, the total size of LT_a, i.e., number of nodes, edges, and triples, is $O(n)$. Moreover, given a triple, we can recover in constant time the starting point(s) of an occurrence in A of any of the Lcharacters in the chunk corresponding to the triple.*

Proof. The first part of the theorem comes from Fact 4 and the fact that each edge has only one triple. The second part comes from the discussion preceding the theorem on how to recover chunks from triples. □

3.2.3. The Lsuffix tree for a matrix. Since we need to represent all submatrices of A, we have to define the Lsuffix tree for a set of Lstrings. For notational convenience, we introduce $2n - 1$ special symbols $\$_d$, $0 \leq |d| < n$. Each special symbol is unique and has the same properties of \$. $\hat{\$}_d$, $0 \leq |d| < n$, is analogous to $\hat{\$}$. Let D be the set of Lstrings $La_d\hat{\$}_d$ corresponding to $A_d\hat{\$}_d$, $0 \leq |d| < n$. Formally, the Lsuffix tree LT_D for matrix A and set of Lstrings D is a compacted trie defined on the alphabet $\mathrm{L}\Sigma$ satisfying constraints (1), (2) and (3), of the definition of Lsuffix tree, except that (4) now becomes

4. The concatenation of the chunks labeling the edges on the path from the root to a leaf gives exactly one Lsuffix of the Lstrings in the set, say $\mathrm{L}suf_l(La_i\hat{\$}_i)$. That leaf is labeled with (l, i).

See Fig. 10 for an example. Notice that the length of La_d, i.e., the number of Lcharacters in La_d, is $k_d = n - |d|$ since La_d represents the matrix A_d whose main diagonal is of length $n - |d|$, $0 \leq |d| < n$. Consider the last Lsuffix of $La_d\hat{\$}_d$, i.e., $\mathrm{L}suf_{k_d+1}(La_d\hat{\$}_d)$. It is $\$_d$ because $\$_d$ is the last entry on the main diagonal of $A_d\hat{\$}_d$. By our conventions about $\$_d$ and definition of equality of Lcharacters, the last Lsuffix of $La_d\hat{\$}_d$ is not equal to the last Lsuffix of $La_j\hat{\$}_j$, for any j. So, $2n - 1$ of the leaves of LT_D correspond to $\$_d$, for $1 \leq |d| < n$. Notice also that there is a one-to-one correspondence between the Lsuffixes of $La_d\hat{\$}_d$ and the leaves of LT_D. Let $t(D) = \Sigma_{d=1-n}^{n-1}(k_d + 1)$.

FACT 5. *LT_D has $O(n^2)$ nodes.*

Proof. It has exactly $t(D)$ leaves (one per Lsuffix including $\$_d$'s) and each internal node has outdegree at least two. Moreover $t(D) = O(n^2)$. □

We now prove formally that LT_D satisfies what, in §3.1, we informally called the completeness and common prefix constraint for matrix A.

THEOREM 2. *Let B be a square matrix and let Lb be the corresponding Lstring. B is a submatrix of A if and only if Lb has an extended locus u in LT_D. Moreover, let F be any square submatrix of A having B as a prefix and let Lf be the Lstring corresponding to F. The extended locus of Lf in LT_D is a descendant of u.*

(a)

x	o	o	$
o	x	o	$
x	o	x	$
$	$	$	$

(b)

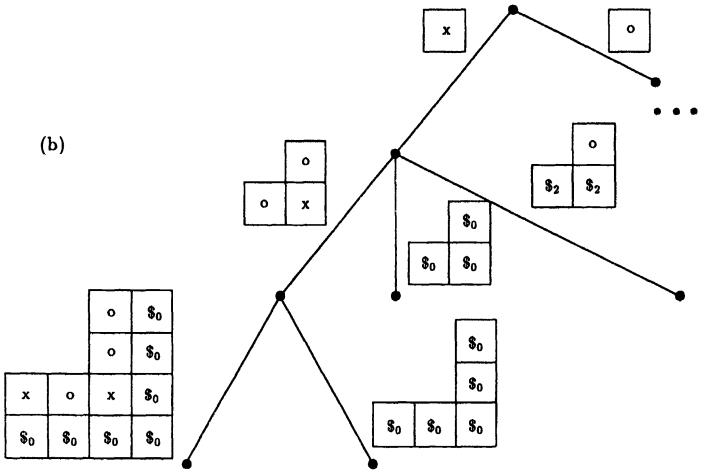

FIG. 10. (b) *The Lsuffix tree of the matrix A in* (a). *Only the suffixes of* A_0 *and* A_2 *are shown in full.*

Proof. By Fact 1, B is a submatrix of A if and only if Lb is an Lprefix of some Lsuffix of La_d, for $0 \leq |d| \leq n-1$. By definition, LT_D is a compacted trie representing the set C of all Lsuffixes of Lstrings in D. So, by Fact 3 (applied to Lb and LT_D) Lb has an extended locus u in LT_D if and only if Lb is an Lprefix of some Lsuffix of La_d, for $0 \leq |d| \leq n-1$. This proves the first part of the theorem.

For the second part, let Lz be the Lstring of which u is the locus. Let us assume that the extended locus v of Lf is not in the subtree of LT_D rooted at u. Since B is the prefix of F, Lb is the Lprefix of Lf. Thus, on the path from the root of LT_D to v, there is a node w that satisfies the definition of extended locus of Lb. $w \neq u$ because v is not a descendant of u. Therefore Lb has two extended locuses, which is a contradiction, since the extended locus of an Lstring is unique. □

Notice that each chunk on the edges of LT_D can be a long sequence of Lcharacters and the sum of the lengths of such chunks might exceed $O(n^2)$, the number of nodes of the Lsuffix tree for the chosen set D and matrix A. We represent each chunk in constant space, independent of its length. The idea is similar to the one used in the case of one Lstring in §3.2.2. Indeed, consider an edge (u, v) in LT_D and let β be the chunk labeling that edge. Let f be any arbitrary leaf in the subtree rooted at v and let (l, i) be the label of that leaf. We can show that β is part of L$suf_l(La_i\hat{\$}_i)$ by reasoning analogous to that used in §3.2.2 to show that α is part of L$suf_l(La\hat{\$})$. Thus the quadruple (p, q, l, i) can represent β, for some $p \leq q$. We will address the issue on how to compute such quadruples in §7, where we show how to build LT_D. For

the time being, we assume that each chunk on the edges of LT_D has been substituted by an appropriate quadruple. From now on, we will make no distinction between chunks and their representation as quadruples (or triples when we are dealing with one Lstring).

Now we show how to explicitly recover, in constant time, the starting point of an occurrence in the matrix A of any Lcharacter of the chunk β, when that chunk is represented by the quadruple (p, q, l, i). The meaning of an occurrence of an Lcharacter in A is the same as the one used for triples. Rather than giving explicit formulas, we provide a high-level description. The quadruple (p, q, l, i) corresponds to $Lsuf_l(La_i\hat{\$}_i)[p, q]$. We know that La_i represents A_i, the square submatrix of A whose main diagonal is the ith of A and we know where A_i occurs in A. The remainder of the proof is analogous to the one used in §3.2.2 to show that we can recover Lcharacters from triples. As a side effect of our representation of chunks, we do not need to know explicitly the Lstrings La_d and their Lsuffixes, $0 \leq |d| < n$, since we can recover from the matrix A any chunk or Lcharacter in them. We obtain the following theorem.

THEOREM 3. *Given an $n \times n$ matrix A, let D be the set of Lstrings corresponding to $A_d\hat{\$}_d$, $0 \leq |d| < n$. When chunks on the edges of LT_D are represented by quadruples, the total size of LT_D, i.e., number of nodes, edges, and quadruples, is $O(n^2)$. Moreover, given a quadruple, we can recover in constant time the starting point(s) of an occurrence in A of any of the Lcharacters in the chunk corresponding to the quadruple.*

Proof. The first part of the theorem comes from Fact 5 and the fact that each edge has only one quadruple. The second part comes from the discussion preceding the theorem on how to recover chunks from quadruples. □

Theorems 2 and 3 can be generalized to hold for a set of matrices $\{A^1, A^2, \ldots, A^s\}$, each of dimension $n_i \times n_i$, $1 \leq i \leq s$. Indeed, D can now be the set of Lstrings corresponding to $A^j_{d_j}\hat{\$}^j_{d_j}$, $1 \leq j \leq s$ and $0 \leq |d_j| < n_j$ ($\$^j_{d_j}$ are special symbols as is \$). Quadruples on each of the edges of LT_D can be trivially substituted by quintuples by adding an entry that keeps track of in which matrix the chunk on that edge occurs (however, we can still use quadruples by suitably renaming the Lstrings in D). The total space is $O(\Sigma_{i=1}^s n_i^2)$.

We now outline how "in principle" LT_D can be used for pattern matching. Assume that we want to find all occurrences of a matrix PAT in A. We write down PAT in terms of the corresponding Lstring $Lpat$. Then, we search for the occurrence of $Lpat$ in LT_D in a way analogous to how we search for the occurrence of a string y in T_x, the suffix tree of a string $x\$$. That is, we find the shortest path starting at the root of LT_D such that the concatenation of the labels on that path gives an Lstring having $Lpat$ as Lprefix. Let v be the last node on that path, i.e., v is the extended locus of $Lpat$ in LT_D. By Theorem 2, PAT occurs in A. Moreover, again by Theorem 2, PAT is the prefix of all suffixes of A_d, $0 \leq |d| < n$, corresponding to the leaves in the subtree of LT_D rooted at v.

To make such approach work in time that is proportional to the size of PAT, we need to reduce the outdegree of the nodes of LT_D. (Given a node $u \in LT_D$, selecting an edge (u, v) whose label starts with a given Lcharacter takes $O(\log n)$ time, since the alphabet $L\Sigma$ is infinite.) In §8 we define the refinement of an Lsuffix tree, the RLsuffix tree, which is a compacted trie defined over Σ and therefore has outdegree at most Σ. Then, in §9 we will show how, based on the search strategy outlined here, we can use the RLsuffix tree for pattern matching.

4. Comparing Lcharacters efficiently. In order to get efficient algorithms for the construction of the Lsuffix tree for a matrix A, we need to be able to compare efficiently two Lcharacters (of equal length as strings in Σ^*). We obtain that by a suitable preprocessing of the matrix A, which we now describe.

Let *rows* (*cols*, respectively) be the string obtained by concatenating the rows (columns, respectively) of A, in row (column, respectively) major order and separated by \$. We build the

suffix trees T_{rows} and T_{cols} for strings $rows$ and $cols$, respectively. That takes $O(n^2 \log |\Sigma|)$ time [22]. Each leaf of T_{rows} (T_{cols}, respectively) is labeled with an entry (i, j) indicating that the path from the root to that leaf spells out $A[i, j : n]\$$ ($A[i : n, j]\$$, respectively). We augment both trees with LCA data structures. That takes $O(n^2)$ time and each LCA query can be answered in constant time [17], [24].

Let us define the operation *compare* as follows. It takes in input the quadruples (p, q, l, i) and (p, q', g, j) and an integer e, $p \leq e \leq \min(q, q')$. It returns the result of the comparison $\mathrm{L}suf_l(a_i\hat{\$}_i)[e] \leq \mathrm{L}suf_g(a_j\hat{\$}_j)[e]$ and the length of the longest prefix common to those two Lcharacters when seen as strings over Σ. We remark that we can define a version of *compare* that takes in input triples rather than quadruples. Its implementation is the same as the one using quadruples. Given the preprocessing of matrix A described above, *compare* can be implemented to take constant time. Let (r_1, c_1) and (r_2, c_2) be the starting points of the subrow and subcolumn of A giving $\mathrm{L}suf_l(a_i\hat{\$}_i)[e]$, i.e., that Lcharacter is equal to $A[r_1, c_1 : c_1 + e - 2]A[r_2 : r_2 + e - 1, c_2]$. Let (r_1', c_1') and (r_2', c_2') be the same points for $\mathrm{L}suf_g(a_j\hat{\$}_j)[e]$, i.e., that Lcharacter is equal to $A[r_1', c_1' : c_1' + e - 2]A[r_2' : r_2' + e - 1, c_2']$. Such starting points can be computed in constant time, as pointed out in §3.2.3. Let f_1 and f_1' (g_1 and g_1', respectively) be the leaves of T_{rows} (T_{cols}, respectively) that have label (r_1, c_1) and (r_1', c_1') ((r_2, c_2) and (r_2', c_2'), respectively), respectively. We use the query $LCA(f_1, f_1')$ (on T_{rows}) to compute the longest prefix common to $A[r_1, c_1 : c_1 + e - 2]$ and $A[r_1', c_1' : c_1' + e - 2]$ and the query $LCA(g_1, g_1')$ (on T_{cols}) to compute the longest prefix common to $A[r_2 : r_2 + e - 1, c_2]$ and $A[r_2' : r_2' + e - 1, c_2']$. That also takes constant time. Given such information, it is easy to compute the output of *compare*. We obtain the following lemma.

LEMMA 1. *We can preprocess the matrix A in $O(n^2 \log |\Sigma|)$ time, so that each compare operation takes constant time.*

Throughout the remainder of this paper, we assume that *compare* takes constant time. We will charge the time complexity of the preprocessing only once to the algorithm of §7.

5. Construction of the Lsuffix tree for one Lstring: High-level description. We give a high-level description of our algorithm for the construction of the Lsuffix tree for $\mathrm{L}a\hat{\$}$, an Lstring of length $n+1$ that corresponds to matrix $A\$$. We do so by drawing an analogy between MC and our algorithm pointing out the differences and presenting the general structure of the latter.

5.1. MC algorithm: High-level description. Let y be a string of length n. MC inserts the suffixes of $y\$$, from longest to shortest, into a tree initially of one node. Let T_i be the suffix tree after the ith insertion (iteration of MC) and let $head_i$ denote the longest prefix of $y[i, n + 1] = y[i, n]\$$ that is also a prefix of $y[j, n + 1]$, for some $j < i$. Since there is a $j < i$ such that $y[j, j + |head_i| - 1] = head_i = y[i, i + |head_i| - 1]$ and $y[j + |head_i|] \neq y[i + |head_i|]$ and T_i is a compacted trie that represents the first i suffixes of $y\$$, $head_i$ has a locus in T_i. Notice that $head_i$ may not have a locus defined in T_{i-1}.

When we insert $y[i, n + 1]$ into T_{i-1} (to transform it into T_i), we can "make it share" for as long as possible a path in T_{i-1} with the suffixes that T_{i-1} represents. Since $head_i$ is the longest prefix that $y[i, n + 1]$ has in common with $y[j, n + 1]$, $1 \leq j < i$, we can proceed as follows.

MC*—High-level description, iteration *i

- Given T_{i-1}, create a locus for $head_i$ in T_{i-1}, if it does not exist, and make a new leaf representing $y[i, n + 1]$ offspring of that locus. (The resulting tree is T_i.)

Unfortunately, at the time of the insertion of $y[i, n + 1]$ into T_{i-1}, $head_i$ is not known and it is not known whether it has already a locus in T_{i-1}. MC cleverly computes where to

possibly create a locus for $head_i$ in T_{i-1} based on $head_{i-1}$ and some additional information computed during previous iterations. We outline the essential parts of such algorithm. For a detailed description, proof of correctness, and time analysis the reader is referred to [22].

Essential to the whole construction is the notion of suffix links with which the suffix tree is augmented and that are incrementally computed by MC. For each internal node p of T_{i-1}, there is a *suffix link* pointing to a node z if and only if p is the locus of a string $a\alpha$, $a \in \Sigma$ and $\alpha \in \Sigma^*$, and $z \in T_{i-1}$ is the locus of α. We now show that, with the exception of the locus of $head_{i-1}$, for each internal node p of T_{i-1} the node where the suffix link of p must point exists in that tree. That will bring to light that the definition of suffix links implicitly uses the distinct right context property for strings defined as follows.

- *Distinct right context property for strings* [7]. In a string x of length n, if the longest prefix that the suffixes $x[i, n]$ and $x[j, n]$ have in common is of length $k+1$, i.e., $x[i, i+k] = x[j, j+k]$ and $x[i, i+k+1] \neq x[j, j+k+1]$, then the longest prefix that the suffixes $x[i+1, n]$ and $x[j+1, n]$ have in common is of length $k \geq 1$, i.e., $x[i+1, i+k] = x[j+1, j+k]$ and $x[i+1, i+k+1] \neq x[j+1, j+k+1]$.

As we will see, such a property does not extend to matrices and Lstrings and therefore we will not be able to define suffix links for the Lsuffix tree. Here is an outline of the proof that the node where the suffix link of p must point exists in T_{i-1}, $p \neq$ locus of $head_{i-1}$. Since $a\alpha$ has a locus p in T_{i-1} and $p \neq$ locus of $head_{i-1}$, it occurs as prefix of at least two of the first $i-2$ suffixes of $y\$$ and in at least two of such occurrences it is followed by distinct letters (recall the definition of T_{i-1}). So $a\alpha$ is the longest prefix that two such suffixes have in common. Applying the distinct right context property to such suffixes (which are among the first $i-2$ of $y\$$), we get that there exist at least two suffixes (now among the first $i-1$ of $y\$$) that have α as the longest prefix. Thus, α must have a locus defined in T_{i-1}, i.e, z exists in T_{i-1}.

Notice that the high-level design of iteration i requires creation of a locus for $head_i$ in T_{i-1} when that locus does not exist. We can proceed in two ways. One consists of finding $head_i$ by starting at the root of T_{i-1} and traversing a path on that tree guided by the characters of $y[i, n+1]$. The other is to use the relationship between $head_{i-1}$, $head_i$ and the nodes of T_{i-1} to skip as much as possible of a prefix of $y[i, n+1]$ and then look for the remainder of $head_i$ by traversing a path of T_{i-1} that starts at a descendant of the root. The second approach will turn out to be more efficient and it is the one followed by MC. To this end, we need to know where to create the locus of $head_i$ in T_{i-1}, when needed.

LEMMA 2 [22]. *Assume that $head_i$ does not have a locus defined in T_{i-1}. The right place in T_{i-1} to create that node is as an offspring of the contracted locus of $head_i$ in that tree.*

When $head_i$ has a locus defined in T_{i-1}, we need to find it because we need to create a leaf offspring of that locus. Otherwise, by Lemma 2, we need to find the contracted locus of $head_i$ in T_{i-1}, create a locus for that string, and then create a leaf as offspring of the new node. Since we do not know whether $head_i$ has a locus in T_{i-1}, we find the contracted locus of that string. By definition of contracted locus and locus of a string, they will be the same node when $head_i$ has a locus defined in T_{i-1}. Again, we want to find such contracted locus by skipping as much as possible of a prefix of $y[i, n+1]$ through the use of the relationship between $head_{i-1}$, $head_i$, and the nodes of T_{i-1}. (As it turns out, all the information needed is already in the tree.) We need the following fact, which can be used to prove the lemma following it. In turn, the lemma tells us the "general neighborhood" in T_{i-1} where the contracted locus of $head_i$ is.

FACT 6 [22]. *Let β be the second suffix of $head_{i-1}$. That is, it is the empty string when $head_{i-1}$ is the empty string and otherwise $head_{i-1} = a\beta$, $a \in \Sigma$ and $\beta \in \Sigma^*$. β is a prefix of $head_i$.*

LEMMA 3 [22]. *The contracted locus of $head_i$ in T_{i-1} is in the subtree rooted at u, where u is the contracted locus of β in T_{i-1} and β is the second suffix of $head_{i-1}$, as defined in Fact 6.*

MC searches for the contracted locus of $head_i$ in T_{i-1} using the strategy suggested by Lemma 3. That is, it locates u and starts the search from u (that amounts to "skipping" a prefix of length $|\beta|$ of $head_i$, during the search for the contracted locus of $head_i$). Then, it modifies T_{i-1} according to the high level design of iteration i. It proceeds as follows.

MC*—Skeleton iteration *i

- If $head_{i-1}$ is the empty string, $u := root(T_{i-1})$; skip *rescanning*.
- *Rescanning phase*: find the locus u in T_{i-1} of β, where $head_{i-1} = a\beta$, $a \in \Sigma$. This is done as follows. Given the parent node v of the locus of $head_{i-1}$ (known to the algorithm at the end of iteration $i-1$), we get to the node w pointed to by the suffix link of v. It can be shown that u is in the subtree of T_{i-1} rooted at w and can be found in amortized constant time by a downward path traversal starting at w. (Thus the suffix link is a shortcut used to find the locus of β quickly. We cannot use the suffix link of the locus of $head_{i-1}$ because it may not be defined in T_{i-1}.)
- *Scanning*: since β is a prefix of $head_i$, find the rest of $head_i$ by traversing the downward path from u in T_{i-1} that "spells out" a prefix of $y[i+|\beta|, n+1]$. (Now, $head_i$ is known and so is its contracted locus in T_{i-1}.) We can create the locus for $head_i$ in T_{i-1} and make a new leaf representing $y[i, n+1]$ offspring of that locus. (Thus T_{i-1} is transformed in T_i.)

5.2. Our algorithm: High-level description. Analogous to MC, our algorithm also inserts the suffixes of $A[1 : n+1, 1 : n+1] = A\hat{\$}$, from longest to shortest, into a tree of initially one node. Recall that such suffixes are $A[j : n+1, j : n+1]$, $1 \le j \le n+1$. More precisely, it inserts the Lsuffixes of $La\hat{\$}$, from longest to shortest, into a tree initially of one node. Let LT_i be the tree at the end of the ith insertion (iteration). That is, LT_i is a compacted trie over the alphabet $L\Sigma$ that represents the suffixes $A[j : n+1, j : n+1]$, $1 \le j \le i$, of $A\hat{\$}$ as Lstrings, i.e., it represents the set of Lsuffixes $Lsuf_j(La\hat{\$})$, $1 \le j \le i$.

Let $Lhead_i$ be the Lstring corresponding to the longest prefix of $A[i : n+1, i : n+1]$ that is also prefix of $A[j : n+1, j : n+1]$, for some $1 \le j < i$, i.e., it is the longest Lprefix of $Lsuf_i(La\hat{\$})$ that is also an Lprefix of $Lsuf_j(La\hat{\$})$, for some $j < i$ (see Fig. 11). In the remainder of this paper, let l_i be the length, i.e., number of Lcharacters, of $Lhead_i$, $1 \le i \le n+1$. Notice that $Lhead_i$ is an Lstring corresponding to a matrix equal to $A[i : i+l_i-1, i : i+l_i-1]$. It is the empty Lstring if and only if $l_i = 0$. Notice also the analogy between $Lhead_i$ and $head_i$.

FACT 7. *$Lhead_i$ has a locus in LT_i.*

Proof. By definition, LT_i is a compacted trie over the alphabet $L\Sigma$ that represents all suffixes $A[k : n+1, k : n+1]$, $1 \le k \le i$, of $A\hat{\$}$ as Lstrings, i.e., all $Lsuf_k(La\hat{\$})$, $1 \le k \le i$. By definition, $Lhead_i$ is the Lstring corresponding to the longest prefix of $A[i : n+1, i : n+1]$ that is also prefix of $A[j : n+1, j : n+1]$, for some $j < i$, i.e., it is the longest Lprefix of $Lsuf_i(La\hat{\$})$ that is also an Lprefix of $Lsuf_j(La\hat{\$})$, for some $j < i$. So, $Lhead_i$ occurs at least twice as an Lprefix of $Lsuf_k(La\hat{\$})$, $1 \le k \le i$, followed by distinct Lcharacters. Therefore, it must have a locus defined in LT_i. □

Note that $Lhead_i$ may not have a locus defined in LT_{i-1}. When we insert the Lstring corresponding to $A[i : n+1, i : n+1]$, i.e., $Lsuf_i(La\hat{\$})$, into LT_{i-1} (to transform it into LT_i), we can "make it share" for as long as possible a path in LT_{i-1} with the Lsuffixes LT_{i-1}. Since $Lhead_i$ is by definition the longest Lprefix that $Lsuf_i(La\hat{\$})$ has in common with the other Lsuffixes represented by LT_{i-1}, we can proceed as follows (notice the analogy with ***MC*—High-level description**):

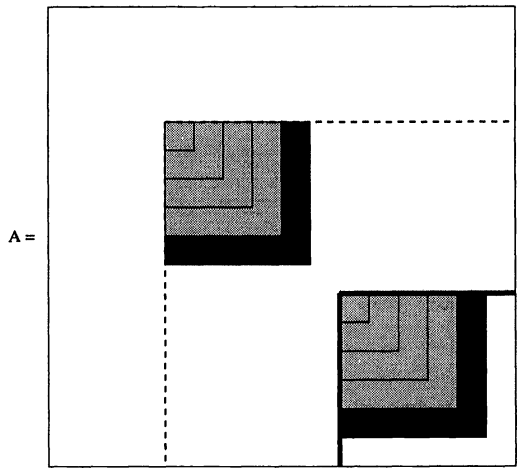

FIG. 11. *$Lsuf_i(La\$)$ corresponds to the suffix of A with bold boundaries. $Lsuf_i(La\$)$ corresponds to the one with dashed boundaries. $Lhead_i$ corresponds to the gray areas. The Lcharacters succeeding the two occurrences of $Lhead_i$ are different.*

Lsuffix tree algorithm—High-level description, iteration *i*

- Given LT_{i-1}, create a locus for $Lhead_i$ in LT_{i-1}, if it does not already exist, and make a new leaf representing $Lsuf_i(La\hat{\$})$, i.e, the suffix $A[i : n+1, i : n+1]$, offspring of that locus. (The resulting tree is LT_i.)

As in ***MC*—High-level description**, at the time of insertion of $Lsuf_i(La\hat{\$})$ into LT_{i-1}, $Lhead_i$ is not known and may not even have a locus defined in that tree. We can try to push the analogy with MC and define suffix links for the nodes of LT_{i-1}. However, the distinct right context property does not extend to matrices and Lstrings. Indeed, it would be as follows. (We state it for matrices but it can be immediately translated into an equivalent form for Lstrings.)

- *Distinct right context property for square matrices.* In a square matrix $A[1 : n, 1 : n]$, if the longest prefix that the suffixes $A[i : n, i : n]$ and $A[j : n, j : n]$ have in common is of length $k+1$, i.e., $A[i : i+k, i : i+k] = A[j : j+k, j : j+k]$ and $A[i : i+k+1, i : i+k+1] \neq A[j : j+k+1, j : j+k+1]$, then the longest prefix that the suffixes $A[i+1 : n, i+1 : n]$ and $A[j+1 : n, j+1 : n]$ have in common is of length $k \geq 1$, i.e., $A[i+1 : i+k, i+1 : i+k] = A[j+1 : j+k, j+1 : j+k]$ and $A[i+1 : i+k+1, i+1 : i+k+1] \neq A[j+1 : j+k+1, j+1 : j+k+1]$.

Figure 12 provides a counterexample. The reader should convince himself or herself that what the lack of such property implies is that if we try to define a suffix link for any node of LT_{i-1} in analogy with the definition by MC, we are not granted the existence in LT_{i-1} of the node where that suffix link should point to. Since suffix links are essential for an efficient rescanning "á la McCreight," we need to come up with a new rescanning technique. For the remainder of this section and for the next one, let $v \in LT_{i-1}$ denote the locus of $Lhead_{i-1}$. Intuitively, our rescanning technique works as follows. We start from v, carefully pick a leaf q in the subtree of LT_{i-1} rooted at v and, from there, "move" to a leaf q' that has the property that the contracted locus of $Lhead_i$ in LT_{i-1} is on the path from the root of LT_{i-1} to q'. Lemmas 4, 5, and 6 prove that such approach works.

Let the leaf $g \in LT_{i-1}$ be the locus of the Lstring corresponding to matrix $A[i-1 : n+1, i-1 : n+1]$, i.e., the locus of $Lsuf_{i-1}(La\hat{\$})$. We define suffix links for all the leaves of LT_{i-1}, except g, as follows.

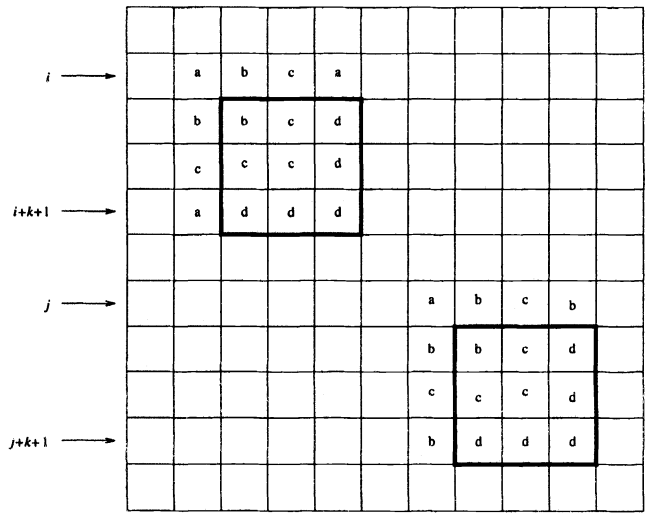

FIG. 12. *A counterexample to the distinct right context property for square matrices. The two submatrices in bold boundaries are equal, whereas they would be different if the property were true.*

DEFINITION 1. *For each leaf* $q \in LT_{i-1}$ *and* $q \neq g$, *locus of the Lstring corresponding to* $A[j : n+1, j : n+1]$, *i.e.,* $Lsuf_j(La\hat{\$})$, $j < i-1$, *there is a suffix link pointing to leaf* w, *where* w *is the locus of the Lstring corresponding to* $A[j+1 : n+1, j+1 : n+1]$, *i.e.,* $Lsuf_{j+1}(La\hat{\$})$. *We denote such suffix link as* $SL(q) = w$.

Note that the high-level design of iteration i requires creation of a locus for $Lhead_i$ in LT_{i-1} when that locus does not exist. As for strings, we can proceed in two ways. One consists of finding $Lhead_i$ by starting at the root of LT_{i-1} and traversing a path on that tree guided by the Lcharacters of $Lsuf_i(La\hat{\$})$. The other is to use the relationship between $Lhead_{i-1}$, $Lhead_i$, and the nodes of LT_{i-1} to skip as much as possible of an Lprefix of $Lsuf_i(La\hat{\$})$ and then look for the remainder of $Lhead_i$ by traversing a path of LT_{i-1} that starts at a descendant of the root. The second approach will turn out to be more efficient and it is the one our algorithm will follow. To this end, we need to know where to create the locus of $Lhead_i$ in LT_{i-1}, when needed.

LEMMA 4. *Assume that* $Lhead_i$ *does not have a locus defined in* LT_{i-1}. *The correct place in* LT_{i-1} *to create that node is as an offspring of the contracted locus of* $Lhead_i$ *in that tree. The extended locus of* $Lhead_i$ *in* LT_{i-1} *exists and it is an offspring of the contracted locus of* $Lhead_i$ *in that tree.*

Proof. Since $Lhead_i$ does not have a locus defined in LT_{i-1}, it cannot be the empty Lstring (otherwise $root(LT_{i-1})$ would be its locus). Thus, the matrix $E = A[i : i+l_i-1, i : i+l_i-1]$ corresponding to it cannot be empty. By definition of $Lhead_i$, the correspondence between Lstrings and matrices and the fact that \$ does not match any character (including itself), there exists a $j < i$ such that E is a proper prefix of $W = A[j : n+1, j : n+1]$. Thus $Lhead_i$ is a proper Lprefix of $Lsuf_j(La\hat{\$})$, $j < i$, the Lstring corresponding to a matrix equal to W. By Fact 3 (applied to LT_{i-1} and $Lhead_i$), $Lhead_i$ has an extended locus $\hat{v}$ in LT_{i-1}. Since $Lhead_i$ does not have a locus defined in LT_{i-1}, the contracted locus v' of $Lhead_i$ in LT_{i-1} must be the parent of $\hat{v}$ (by the definition of contracted and extended locuses of an Lstring). Thus the locus of $Lhead_i$ must be an offspring of v' since the Lstring of which v' is locus is the longest Lprefix of $Lhead_i$ that has a locus defined in LT_{i-1}. We create such locus by "splitting" the edge $(v', \hat{v})$. □

When $L head_i$ has a locus defined in LT_{i-1}, we need to find it because we need to create a leaf offspring of that locus. Otherwise, by Lemma 4, we need to find the contracted locus of $L head_i$ in LT_{i-1}, create a locus for that Lstring, and then create a leaf as an offspring of the new internal node. Since we do not know whether $L head_i$ has a locus in LT_{i-1}, we find the contracted locus of that Lstring. When $L head_i$ has a locus defined in LT_{i-1}, they will be the same node by the definition of contracted locus and locus of an Lstring. Again in analogy with MC, we want to find such a contracted locus by skipping as much as possible of an Lprefix of $L suf_i(La\hat{\$})$ through the use of the relationship between $L head_{i-1}$, $L head_i$, and the nodes of LT_{i-1} (as it turns out, all the information needed is already in LT_{i-1}). In this section and the next one, let $h = \min(0, l_{i-1} - 1)$. Notice that the matrix $A[i : i + h - 1, i : i + h - 1]$ corresponds to $L suf_2(L head_{i-1})$. It is empty if and only if $L suf_2(L head_{i-1})$ is the empty Lstring, i.e., $0 \leq l_{i-1} \leq 1$. In the remainder of this paper, let $L\alpha$ denote $L suf_2(L head_{i-1})$. We need the following lemma, which states some properties of $L\alpha$.

LEMMA 5. *$L\alpha$, the Lstring corresponding to $A[i : i + h - 1, i : i + h - 1]$, is such that* (a) *it is an Lprefix of $L head_i$, the Lstring corresponding to $A[i : i + l_i - 1, i : i + l_i - 1]$;* (b) *it has an extended locus r' in LT_{i-1};* (c) *r' is an ancestor of any leaf $\hat{u} = SL(q)$, where $q \neq g$ is any leaf descendant of v; and* (d) *the contracted locus u of $L\alpha$ in LT_{i-1} is the parent of r', when $L\alpha$ does not have a locus defined in LT_{i-1}.*

Proof. By the definition of $L head_{i-1}$, there is a suffix $A[j : n+1, j : n+1]$, $j < i-1$, of $A\hat{\$}$ such that the longest prefix common to $A[j : n+1, j : n+1]$ and $A[i-1 : n+1, i-1 : n+1]$ is $A[i - 1 : i + l_{i-1} - 2, i - 1 : i + l_{i-1} - 2]$ (it may be empty). Let q be the leaf locus of $L suf_j(La\hat{\$})$. Since $L head_{i-1}$ is an Lprefix of $L suf_j(La\hat{\$})$, q is in the subtree of LT_{i-1} rooted at v. Moreover, it cannot be equal to g because that leaf is locus of $L suf_{i-1}(La\hat{\$})$ and $j < i - 1$. Let $\hat{u} = SL(q)$. By definition of a suffix link, $\hat{u}$ is the locus of $L suf_{j+1}(La\hat{\$})$.

Since $h = \min(0, l_{i-1}-1)$, $A[j+1 : n+1, j+1 : n+1]$ has $A[i : i+h-1, i : i+h-1]$ as a prefix (it may be empty). So $L\alpha$, the Lstring that corresponds to $A[i : i+h-1, i : i+h-1]$, is an Lprefix of $L head_i$ by definition of $L head_i$. That proves (a).

As for (b), (c), and (d), note that $L\alpha$ is the Lprefix of $L suf_{j+1}(La\hat{\$})$ ($A[j+1 : n+1, j+1 : n+1]$ has $A[i : i + h - 1, i : i + h - 1]$ as a prefix). So, by Fact 3 (applied to $L\alpha$ and LT_{i-1}), $L\alpha$ has an extended locus r' in that tree. Moreover, r' must be the locus of an Lstring Lprefix of $L suf_{j+1}(La\hat{\$})$ (otherwise it cannot be the extended locus of $L\alpha$). Therefore, r' is an ancestor of $\hat{u}$. The contracted locus u of $L\alpha$ is either r' or the parent of r' in LT_{i-1}, by definition of the contracted locus, extended locus, and locus of an Lstring. □

Note that the contracted locus of an Lstring always exists in a compacted trie over the alphabet $L\Sigma$ since the root is the locus of the empty Lstring. In the remainder of this section and in the next one, let u denote the contracted locus of $L\alpha$ in LT_{i-1}, Lb denote the string of which u is locus, and r' denote the extended locus of $L\alpha$ in LT_{i-1}. The following lemma tells us the "general neighborhood" in LT_{i-1} where the contracted locus of $L head_i$ is as given in the following lemma.

LEMMA 6. *The contracted locus of $L head_i$, the Lstring corresponding to $A[i : i+l_i-1, i : i + l_i - 1]$, in LT_{i-1} is in the subtree rooted at u.*

Proof. Lb is the Lstring obtained by concatenating the labels of the path from $root(LT_{i-1})$ to u. By definition of a contracted locus, Lb is an Lprefix of $L\alpha$ and therefore an Lprefix of $L head_i$. (By Lemma 5, $L\alpha$ is Lprefix of $L head_i$.) But only the nodes in the subtree rooted at u have Lb as Lprefix (by definition of compacted trie over the alphabet $L\Sigma$). Therefore the contracted locus of $L head_i$ must be in that subtree. □

In analogy with MC, we search for the contracted locus of $L head_i$ in LT_{i-1} using the strategy suggested by Lemma 6. That is, we locate u and start the search from u. We will

show that, in such a way, we can "manage to skip" Lα, an Lprefix of L$head_i$, when searching for the contracted locus of L$head_i$ in LT_{i-1}. Then we modify LT_{i-1} according to the high-level design of iteration i. We also have a rescanning and scanning phase. As with MC, our rescanning phase finds u. However, it is implemented differently than the one in MC because we have suffix links defined at the leaves of LT_{i-1} whereas MC has suffix links defined for the internal nodes of T_{i-1}. In addition, we need to be careful with the management of the labels on the edges of the Lsuffix tree, the comparisons of Lcharacters, and the update of our auxiliary data structures. (We will deal with such issues in §6.)

We anticipate that our procedure will not do rescanning when L$head_{i-1}$ is the empty Lstring because in that case L$suf_2(Lhead_{i-1}) =$ Lα is the empty Lstring and its contracted locus (and locus) is $root(LT_{i-1})$, so it is already known. The skeleton of the ith iteration of **STI**, the procedure that inserts Lsuffixes into the Lsuffix tree, is given below. We assume, and justify later, that it knows the locuses v and g in LT_{i-1} of the Lstrings corresponding to $A[i-1 : i+l_{i-1}-2, i-1 : i+l_{i-1}-2]$ and $A[i-1 : n+1, i-1 : n+1]$, i.e., L$head_{i-1}$ and L$suf_{i-1}(La\hat{\$})$. For the first iteration, those two nodes are the same (the root of LT_0).

Procedure STI—Skeleton iteration i

1. If $v = root(LT_{i-1})$ then $u := root(LT_{i-1})$ and skip *rescanning*.
2. *Rescanning*: find the contracted locus u of Lα, given the locus $v \neq root(LT_{i-1})$ of L$head_{i-1}$ and SL for all leaves in LT_{i-1}, except g.
3. *Scanning*: starting from u and skipping Lα, find the contracted locus of L$head_i$. If needed, create a locus for L$head_i$ and make a new leaf representing the $Lsuf_i(La\hat{\$})$ offspring of that locus. Compute SL for g.

6. Construction of the Lsuffix tree for one Lstring: Detailed description. In this section we show how we proceed for the rescanning and scanning phase of the ith iteration of our algorithm. We do so by assuming the following invariant, which will be maintained by the algorithm and tells us which information we have available at the beginning of iteration i to perform the computation prescribed by the skeleton of **STI**. Before we state the invariant, we recall that the leaf $g \in LT_{i-1}$, the locus of the Lstring corresponding to matrix $A[i-1 : n+1, i-1 : n+1]$, does not have a value of SL defined.

INVARIANT 1. *At the beginning of iteration i,* **STI** *knows the locus v of L$head_{i-1}$ and the leaf g locus of $Lsuf_{i-1}(La\hat{\$})$ in LT_{i-1}. The values of SL are known to* **STI** *for all leaves in LT_{i-1}, except g. For all nodes z of LT_{i-1}, the length $l(z)$ of the Lstring of which z is locus is known to* **STI**. *Each internal node $c \in LT_{i-1}$ has a pointer to a leaf (arbitrarily chosen) in the subtree of LT_{i-1} rooted at c. Moreover, all edges outgoing any internal node of LT_{i-1} are sorted according to the first Lcharacter on the chunk labeling that edges (we keep them in a binary search tree).*

Based on the information granted by Invariant 1 we have to show the following:

1. How to find the contracted locus u of Lα, when $v \neq root(LT_{i-1})$. (This corresponds to rescanning.)
2. How to find, starting from u, the contracted locus of L$head_i$. (This is part of scanning.)
3. How to change LT_{i-1} into LT_i, computing, for the new nodes the length of the Lstrings of which they are locuses and, for the new edges, their labels. How to compute $SL(g)$. (This is part of scanning.)

6.1. Point one. We refer to the operation that finds the contracted locus u of Lα in LT_{i-1} as $findclocus$. It takes in input $v \neq root(LT_{i-1})$, the locus of L$head_{i-1}$ in LT_{i-1}. We first prove its correctness (Lemma 7) and then we discuss its implementation (Lemma 8).

Procedure *findclocus*

- Select any offspring c of v not equal to the leaf g locus of $\mathrm{L}suf_{i-1}(La\hat{\$})$. Let q be the leaf of $\mathrm{L}T_{i-1}$ pointed to by c. On the path from the root of $\mathrm{L}T_{i-1}$ to $SL(q)$, u is the deepest node such that $l(u) \leq h$.

LEMMA 7. *Assume that $v \neq root(LT_{i-1})$ and that Invariant 1 holds at the beginning of iteration i. findclocus correctly computes the contracted locus u of $L\alpha$ in LT_{i-1}.*

Proof. Notice that by the definition of $\mathrm{L}head_{i-1}$ and the fact that g is the locus of $\mathrm{L}suf_{i-1}(La\hat{\$})$, g is an offspring of v, so the node c selected by *findpath* is not an ancestor of g. By the invariant, c points to a leaf q in the subtree of $\mathrm{L}T_{i-1}$ rooted at c. Since c is not an ancestor of g, $q \neq g$. Therefore, $\hat{u} = SL(q)$ is defined by the invariant and can be computed by *findclocus*.

Since $q \neq g$ is any arbitrary leaf in the subtree of $\mathrm{L}T_{i-1}$ rooted at v, we have that the extended locus r' of $\mathrm{L}\alpha$ is an ancestor of $\hat{u}$ (by Lemma 5). By Lemma 5, u is an ancestor of r' and therefore an ancestor of $\hat{u}$. Thus, by the definition of contracted locus, we have that u must be the deepest node on the path from $root(LT_{i-1})$ to $\hat{u}$ such that $l(u) \leq h$. □

In order to efficiently perform *findclocus*, we represent $\mathrm{L}T_{i-1}$ as a dynamic tree [25]. That is, as a set of edge-disjoint solid paths. *Expose* is the dynamic tree operation of interest to us for the implementation of *findclocus*. It has been described in §2. We implement *findclocus* as follows. Let $\hat{u} = SL(q)$. Since Invariant 1 holds, we can get from v to $\hat{u}$ in constant time. We do $expose(\hat{u})$: it returns the path $\hat{p}$ from $\hat{u}$ to the root of $\mathrm{L}T_{i-1}$ in a search tree. As pointed out in §2, a symmetric order traversal of that search tree gives the nodes of $\hat{p}$ in decreasing order of distance from $root(LT_{i-1})$. Note that $l(w) < l(y)$, when node w is closer than y to the root. Moreover, by the invariant, for each node of $\hat{p}$, the length of the Lstrings of which it is locus is known to **STI**. Thus we can use that binary search tree to find, by binary search, the node u further away from $root(LT_{i-1})$ such that $l(u) \leq h$.

Since LT_{i-1} has at most $O(n)$ nodes (at most as many as the final Lsuffix tree for $La\hat{\$}$), *expose* takes $O(\log n)$ time on a dynamic tree of size at most $O(n)$ [25]. Moreover, the binary search is performed on a balanced search tree of at most $O(n)$ nodes, so *findclocus* takes $O(\log n)$ time. For later reference, we summarize the above discussion in the following lemma.

LEMMA 8. *Assume that the invariant holds at the beginning of iteration i. findclocus can be implemented to take $O(\log n)$ time.*

6.2. Point two. In what follows, let B denote the matrix corresponding to the Lstring $\mathrm{L}b$ whose locus is u, the contracted locus of $\mathrm{L}\alpha$. B is of dimension $l(u) \times l(u)$ because $\mathrm{L}b$ is an Lstring of that length. Before we discuss the second point, we need the following facts.

FACT 8. *Assume that $h = l(u)$, i.e., Lb and $L\alpha$ are Lstrings of the same length. Then u is the locus of $L\alpha$ implying that $Lb = L\alpha$, i.e., $A[i : i + h - 1, i : i + h - 1] = B$.*

Proof. The fact is proven by the definition of a contracted locus and locus of an Lstring. □

FACT 9. *Assume that u is not the locus of $L\alpha$, i.e., Lb is shorter than $L\alpha$, the Lstring corresponding to $A[i : i + h - 1, i : i + h - 1]$. $L\alpha$ is equal to the concatenation of Lb with the first $h - l(u)$ Lcharacters of the chunk on the edge (u, r'), i.e., $A[i : i + h - 1, i : i + h - 1]$ has B as a proper prefix and its remaining rows and columns correspond to the first $h - l(u)$ Lcharacters of the chunk on the edge (u, r').*

Proof. Since u is not the locus of $\mathrm{L}\alpha$, its extended locus r' is an offspring of u (by Lemma 5). Let $\mathrm{L}x$ be the Lstring of which r' is locus. $\mathrm{L}x$ is obtained by appending the chunk on the edge (u, r') to $\mathrm{L}b$. But $\mathrm{L}b$ is a proper Lprefix of $\mathrm{L}\alpha$, which is a proper Lprefix of $\mathrm{L}x$. Thus, $\mathrm{L}\alpha$ can be obtained from $\mathrm{L}b$ by appending to it the first $h - l(u)$ Lcharacters of the

chunk on the edge (u, r'), i.e., $A[i : i+h-1, i : i+h-1]$ has B as a proper prefix and its remaining rows and columns correspond to the first $h - l(u)$ Lcharacters of the chunk on the edge (u, r'). □

FACT 10. *Assume that there is no offspring r of u such that the first Lcharacter of the chunk on the edge (u, r) is $A[i+l(u), 1 : i+l(u)-1]A[1 : i+l(u), i+l(u)]$, i.e., the Lcharacter corresponding to $Lsuf_i(La\hat{\$})[l(u)+1]$. Then $Lb = Lhead_i$, i.e., $A[i : i+l_i-1, i : i+l_i-1] = B$.*

Proof. u is the contracted locus of $L\alpha$, an Lstring whose corresponding matrix is equal to $A[i : i+h-1, i : i+h-1]$. Thus the Lstring of which u is locus corresponds to a matrix equal to $A[i : i+l(u)-1, i : i+l(u)-1]$, which is a prefix of $A[i : n+1, i : n+1]$. So, Lb is an Lprefix of $Lsuf_i(La\hat{\$})$. Since none of the chunks on the edges outgoing u starts with $Lsuf_i(La\hat{\$})[l(u)+1]$, i.e., $A[i+l(u), 1 : i+l(u)-1]A[1 : i+l(u), i+l(u)]$, we have that Lb is the longest Lprefix that $Lsuf_i(La\hat{\$})$ has in common with $Lsuf_j(La\hat{\$})$, for $1 \leq j < n$ (by definition of LT_{i-1} and of trie over the alphabet $L\Sigma$). By definition of $Lhead_i$, we have that $Lb = Lhead_i$. □

For the sake of presentation on how we proceed for the second point, let us assume that f is the extended locus of $Lhead_i$ in LT_{i-1}. We anticipate that we will find the contracted locus of $Lhead_i$ by finding f and that we will establish the correctness of our approach while we present it. We also remark that in such a discussion we make critical use of Lemmas 4 and 6, as will be pointed out.

f must exist and it is in the subtree of LT_{i-1} rooted at u. Indeed, if $Lhead_i$ has a locus in LT_{i-1} then f is that locus (by definition of a locus and extended locus of an Lstring). In such a case, f is the node we are looking for and, by Lemma 6, it is in the subtree of LT_{i-1} rooted at u. If $Lhead_i$ does not have a locus in LT_{i-1}, its contracted locus is an internal node and f is one of its offsprings (by Lemma 4). In such a case, $parent(f)$ is the node we are looking for and, again by Lemma 6, f is in the subtree of LT_{i-1} rooted at u.

So, by finding f, we also find the contracted locus of $Lhead_i$ in LT_{i-1}. We start the search from u. We refer to $findpath(u, Lsuf_i(La\hat{\$}))$ as the operation that, starting from u, locates f in LT_{i-1}. It returns $parent(f)$ when f is not the locus of $Lhead_i$ in LT_{i-1}. Otherwise, it returns f. It can be described as follows.

Procedure *findpath*

- Select the only offspring r of u such that the first Lcharacter of the chunk on the edge (u, r) is $A[i+l(u), 1 : i+l(u)-1]A[1 : i+l(u), i+l(u)]$, i.e., the Lcharacter equal to $Lsuf_i(La\hat{\$})[l(u)+1]$. There are two cases to consider.
- **Case a.** No such offspring exists. By Fact 10, u is the locus of $Lhead_i$ and must be equal to f by definition of the extended locus of an Lstring. Exit.
- **Case b.** r exists. Rather than trying to be formal, we explain how we find f using Fig. 13. We need some preliminary observations. Fig. 13b gives the matrix $A[i : n+1, i : n+1]$ divided up into a prefix equal to B (by Facts 8 and 9, B is a prefix of $A[i : i+h-1, i : i+h-1]$) and chunks $\beta_1, \beta_2, \ldots, \beta_s, \ldots, \beta_q$. Such chunks correspond, in an obvious way, to the chunks $\beta'_1, \beta'_2, \ldots, \beta'_s, \ldots, \beta'_q$ on the edges of the path from u to f (shown in Fig. 13a). Note that β_e and β'_e, $1 \leq e \leq q$, have the same number of Lcharacters. Using such an observation and Fact 2 (applied to LT_{i-1}), one can easily prove that β_e and β'_e, $1 \leq e \leq q$, start with Lcharacters of the same length as strings in Σ^*. Therefore, by the concatenation rule for Lcharacters, the lth Lcharacter of β_e is, as a string of Σ^*, the same length as the lth Lcharacter of β'_e. Since β_e and β'_e can both be expressed as triples, we can use *compare* to compare their lth Lcharacters (recall its definition from §4). *findpath* skips the first $h - l(u)$ Lcharacters of the chunk on the edge (u, r), i.e., they are

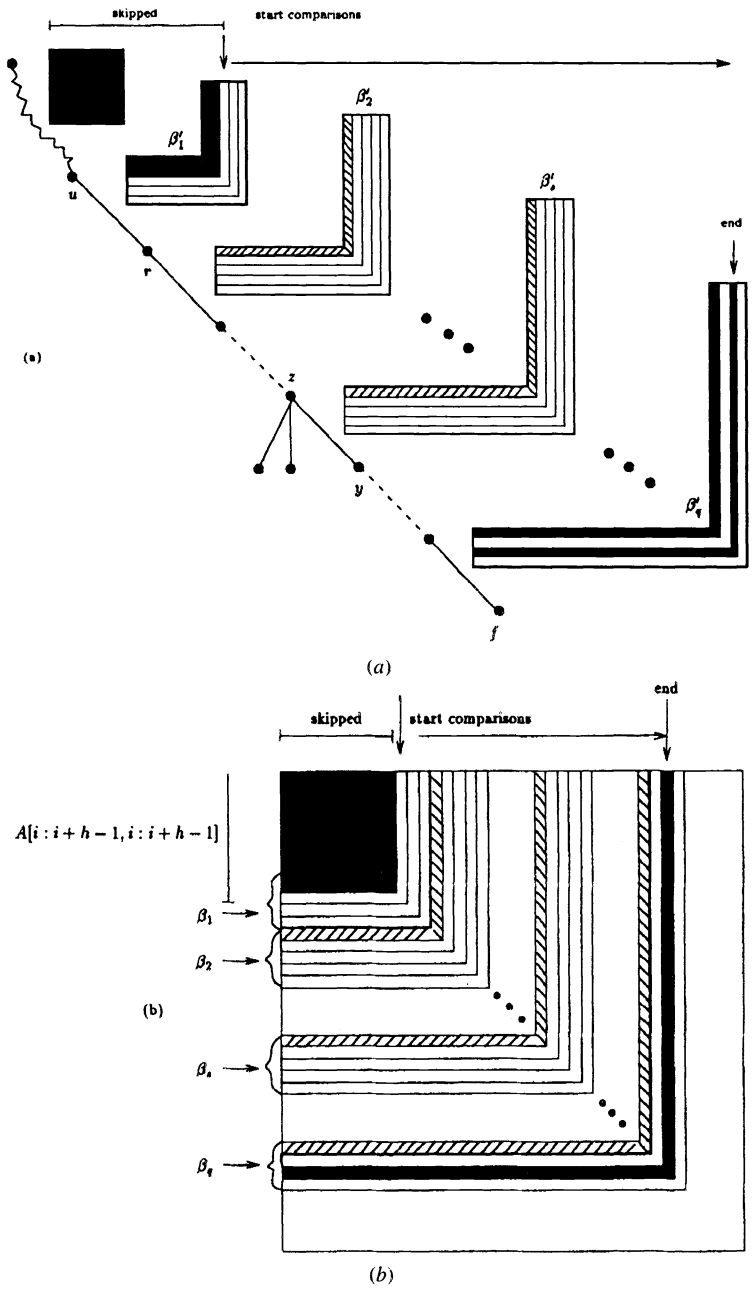

FIG. 13. (a) *The path from root* (LT_{i-1}) *to* f. (b) *The matrix* $A[i : n+1, i : n+1]$ *divided up into the matrix on the path from root* (LT_{i-1}) *to* u *and chunks corresponding to the ones on the edges of the path from* u *to* f.

not compared against the corresponding Lcharacters of the Lstring obtained from $A[i : n+1, i : n+1]$. By Facts 8 (case $h = l(u)$) and 9 (case $h > l(u)$), this amounts to skipping $A[i : i+h-1, i : i+h-1]$, the matrix corresponding to $L\alpha$. That is correct because by Lemma 5 such an Lstring is an Lprefix of $Lhead_i$. Starting with the Lcharacter of $A[i : n+1, i : n+1]$ pointed to by the arrow *start*, *findpath*

compares, one by one and from left to right, the Lcharacters of $A[i : n+1, i : n+1]$ with the corresponding ones on the edges of the path from u to f. A mismatch must eventually be found because the last Lcharacter of $A[i : n+1, i : n+1]$ is $\hat{\$}$ and it does not match any other Lcharacter. In Fig. 13, such a mismatch is between the Lcharacters pointed to by the arrow *end*. Notice that we perform $end - start + 1 = l_i - h + 1$ comparisons of Lcharacters in the chunks $\beta_1, \beta_2, \ldots, \beta_s, \ldots, \beta_q$ and $\beta'_1, \beta'_2, \ldots, \beta'_s, \ldots, \beta'_q$. *findpath* interleaves such comparisons with the "selection of the node to visit next" (recall that the path from u to f is not known to *findpath*). To this end, the Lcharacters in $A[i : n+1, i : n+1]$ between *start* and *end* with bars in them are special: they are the first Lcharacters of $\beta_2, \ldots, \beta_s, \ldots, \beta_q$ and are used by *findpath* to go from u to f. Indeed, assume that *findpath* has reached node z of the path from u to f. It selects the edge (z, y) whose label starts with an Lcharacter that is equal to the first Lcharacter of the chunk β_s of $A[i : n+1, i : n+1]$. The number of nodes visited is bounded by $l_i - h + 1$. Notice that, once we get to f, it is a simple matter to decide whether to return $parent(f)$ or f. We omit the details.

By Invariant 1, the edges outgoing each node of LT_{i-1} are sorted according to the first Lcharacter of the chunk outgoing each edge. So, the "selection of the node to visit next" can be done in $O(\log n)$ comparisons of Lcharacters. Therefore, the total time spent by *findpath* in comparisons of Lcharacters is bounded by $O((l_i - h + 1)\log n))$ (*findpath* visits at most $l_i - h + 1$ nodes and performs $l_i - h + 1$ comparisons of Lcharacters in the chunks $\beta_1, \beta_2, \ldots, \beta_s, \ldots, \beta_q$ and $\beta'_1, \beta'_2, \ldots, \beta'_s, \ldots, \beta'_q$). The remainder of the procedure takes $O((l_i - h + 1)\log n)$ additional time.

Recall that $h = \min(0, l_{i-1} - 1)$ and that *compare* takes constant time. For later reference, we summarize the above discussion in the following lemma.

LEMMA 9. *Starting from the contracted locus u of Lα, the procedure findpath correctly returns the contracted locus of Lhead$_i$ in LT$_{i-1}$. It takes* $O((l_i - h + 1)\log n) = O((l_i - \min(0, l_{i-1} - 1) + 1)\log n)$ *time.*

6.2.1. Point three. Recall the following facts. *findpath* returns a node $\hat{w}$ such that it is the locus of L*head*$_i$, if it exists in LT$_{i-1}$. Otherwise, $\hat{w}$ is its contracted locus. Moreover, $l(v)$ is known to **STI** by the invariant and Lα is of length $l(v) - 1$. Thus the length of L*head*$_i$ is easily computed knowing the length $l(v) - 1$ of Lα and the number of Lcharacter comparisons performed by *findpath*.

We refer to the procedure that actually transforms LT$_{i-1}$ into LT$_i$ as *updatetree*. It takes in input $\hat{w}$.

Procedure *updatetree*

- **Case a.** $\hat{w}$ is the locus of L*head*$_i$ in LT$_{i-1}$. A leaf g' is created as offspring of $\hat{w}$. It is labeled with i, since that leaf is the locus of the Lstring corresponding to $A[i : n+1, i : n+1]$, i.e., L*suf*$_i(La\hat{\$})$. The edge $(\hat{w}, g')$ is labeled with the triple $(l(\hat{w}) + 1, n + 1, i)$ that corresponds to the chunk obtained by deleting L*head*$_i$ from L*suf*$_i(La\hat{\$})$ ($l(\hat{w})$ is known by the invariant because $\hat{w}$ is a node of LT$_{i-1}$). The labeling is correct because $\hat{w}$ is locus of L*head*$_i$, g' is locus of L*suf*$_i(La\hat{\$})$, and the path from the root of LT$_i$ to g' must give that latter Lstring. $\hat{w}$ is made point to g'. Moreover, $SL(g)$ is set to g'. That is correct by the definition of a suffix link and the fact that g and g' are the locuses of L*suf*$_{i-1}(La\hat{\$})$ and L*suf*$_i(La\hat{\$})$, respectively.
- **Case b.** $\hat{w}$ is the contracted locus of L*head*$_i$ in LT$_{i-1}$, but that Lstring does not have a locus defined. Let f be its extended locus (it must exist by Lemma 4 and it is

known to $findpath$). Let (p_1, p_2, j) be the label on the edge $(\hat{w}, f) \in LT_{i-1}$. A new node w' is created as a locus of $Lhead_i$ by splitting the edge $(\hat{w}, f)$ (w' is made offspring of $\hat{w}$). The label on the edge $(\hat{w}, w')$ is set to $(p_1, p_1 + l_i - l(\hat{w}) - 1, j)$ and the one on the edge (w', f) to $(p_1 + l_i - l(\hat{w}), p_2, j)$. The labeling is correct. Indeed, the concatenation of the Lstring of which $\hat{w}$ is locus with the first $l_i - l(\hat{w})$ Lcharacters of the chunk on the former edge $(\hat{w}, f)$ is equal to $Lhead_i$. But the concatenation of the chunks on the edges $(\hat{w}, w')$ and (w', f) gives the chunk on the former edge $(\hat{w}, f)$. Thus the way $updatetree$ handles the split of the edge $(\hat{w}, f)$ does not change the set of Lstrings given by the paths of the Lsuffix tree before the split. $l(w')$ is correctly set to l_i since w' is the locus of $Lhead_i$. Then we proceed as in Case a, with $\hat{w}$ replaced by w'.

Note that the insertion of the new nodes in LT_{i-1} to transform it in LT_i can be done by a constant number of $link$ and cut operations (LT_{i-1} is a dynamic tree). Each such operation costs $O(\log n)$ time [25]. Moreover, the insertion of the new edges can be done in the same amount of time and in such a way that, for each node where they are inserted, the list of edges outgoing that node is still sorted according to the first Lcharacter of the chunk outgoing each edge. Using this fact and the invariant, we have that the edges outgoing each node of LT_i are still sorted according to the first Lcharacter of the chunk outgoing each edge. The remainder of the procedure takes constant time. For later reference, we summarize the above discussion into the following lemma.

LEMMA 10. *Assume that the invariant holds at the beginning of iteration i. Let w and g' be the locuses of $Lhead_i$ and $Lsuf_i(La\hat{\$})$ in LT_i. $updatetree$ correctly transforms LT_{i-1} into LT_i, computing, for w and g', the length of the Lstrings of which they are locuses and, for the new edges, their labels. It correctly sets $SL(g)$ to g' and w to point to g', a leaf in the subtree of LT_i rooted at w. It takes $O(\log n)$ time. Moreover, the edges outgoing each node of LT_i are sorted according to the first Lcharacter of the chunk outgoing each edge.*

6.3. Pseudocode, correctness, and time analysis. We now provide the pseudocode of **STI**, expressed in terms of the procedures given in the previous subsections. Then we prove its correctness and we analyze it.

Procedure STI—Pseudocode iteration i

1. If $v = root(LT_{i-1})$ then $u := root(LT_{i-1})$ and skip *rescanning*.
2. *rescanning*: $u := findclocus(v)$.
3. *scanning*: $\hat{w} := findpath(u, Lsuf_i(La\hat{\$}))$; $updatetree(\hat{w})$.

THEOREM 4. *Given an Lstring $La\hat{\$}$, corresponding to matrix $A[1 : n, 1 : n]\hat{\$}$, and an initial Lsuffix tree LT_0 of one node,* **STI** *correctly builds the Lsuffix tree for $La\hat{\$}$ by inserting, from longest to shortest, the Lsuffixes of $La\hat{\$}$ into LT_0. It takes $O(n \log n)$ time.*

Proof. The proof of correctness is by induction. During iteration i, **STI** inserts $Lsuf_i(La\hat{\$})$, the Lstring corresponding to $A[i : n + 1, i : n + 1]$, into LT_{i-1}, the Lsuffix tree containing the Lstrings corresponding to the first $i - 1$ suffixes of A. Our inductive hypothesis is that at the beginning of the ith iteration, LT_{i-1} is known and that Invariant 1 holds. We show that during the ith iteration, procedure **STI** correctly transforms LT_{i-1} into LT_i and maintains the invariant. Therefore, our inductive hypothesis will be satisfied at the beginning of iteration $i + 1$. That will prove that **STI** correctly builds LT_n, the Lsuffix tree for $La\hat{\$}$.

Note that for $i = 1$, $LT_{i-1} = LT_0$ is known. It consists of one node v (the root) which is the locus of $Lhead_0$, the empty Lstring. v is also a leaf locus of $Lsuf_0(La\hat{\$})$, because that Lstring is empty. $l(v) = 0$ and there are no internal nodes. So, the invariant is satisfied for $i = 1$. Let us assume that it holds for $i > 1$; we show that it holds for $i + 1$. Recall that $L\alpha$ is

$\mathrm{L}suf_2(\mathrm{L}head_{i-1})$. Let w and g' be the locuses of $\mathrm{L}head_i$ and $\mathrm{L}suf_i(\mathrm{L}a\hat{\$})$ in $\mathrm{L}T_i$, respectively. We consider two cases corresponding to whether or not rescanning is performed.

When the contracted locus u of $\mathrm{L}\alpha$ is $root(LT_{i-1})$, **STI** skips *rescanning*. By Lemma 9, $findpath$ correctly finds the contracted locus $\hat{w} \in LT_{i-1}$ of $\mathrm{L}head_i$. By Lemma 10, $updatetree$ correctly transforms $\mathrm{L}T_{i-1}$ into $\mathrm{L}T_i$, computing, for w and g', the length of the Lstrings of which such nodes are locuses. Since the length of the Lstrings of which the nodes of $\mathrm{L}T_{i-1}$ are locuses is known by the invariant, we know $l(z)$, for all $z \in LT_i$. $findpath$ also correctly computes $SL(g)$, where g is the only leaf in $\mathrm{L}T_{i-1}$ that did not have a value of SL defined (by the invariant). Therefore, g' is the only leaf in $\mathrm{L}T_i$ that does not have a value of SL defined. w is made to point to g', a leaf in the subtree of $\mathrm{L}T_i$ rooted at w. Since w is possibly the only internal node of $\mathrm{L}T_i$ not in $\mathrm{L}T_{i-1}$ and the invariant holds, we have that each internal node $c \in LT_i$ has a pointer to a leaf (arbitrarily chosen) in the subtree of $\mathrm{L}T_i$ rooted at c. Finally, w and g', the locuses of $\mathrm{L}head_i$ and $\mathrm{L}suf_i(\mathrm{L}a\hat{\$})$ in $\mathrm{L}T_i$ are known to the algorithm. Thus the invariant is satisfied.

When the contracted locus u of $\mathrm{L}\alpha$ is not $root(LT_{i-1})$, **STI** finds that node by calling $findclocus$, which correctly returns u by Lemma 7. The proof that our inductive hypothesis holds for $i+1$ also in this case is now as in the preceding case.

As for the time analysis, note that there can be at most n calls to the procedures $findclocus$, $findpath$, and $updatetree$. The cost of the ith iteration is given by adding the bounds in Lemmas 8, 9, and 10. Thus it is bounded by $O((l_i - \min(0, l_{i-1} - 1) + 1) \log n)$ time. Adding over all iterations, we get the claimed bounds because $l_1 \leq n+1$ and $l_{n+1} = 0$ ($\hat{\$}$ does not match anything). □

7. Construction of the Lsuffix tree for matrix A. Given an $n \times n$ matrix A, recall from §3.2 that the Lsuffix tree for A is the Lsuffix tree for the set of Lstrings corresponding to $A_d\hat{\$}_d$, $0 \leq |d| < n$, i.e., $D = \{\mathrm{L}a_d\hat{\$}_d,\ 0 \leq |d| < n\}$. We build such a data structure by "reducing" the problem to the one of building the Lsuffix tree of a single Lstring (which we know how to do with the algorithm of the previous section). Indeed, let B be the matrix obtained from $A_d\hat{\$}_d$, $0 \leq |d| < n$, as shown in Fig. 14. Let $\hat{n} = n^2 + 2n - 1$ and $\mathrm{L}T_b$ be the Lsuffix tree for $\mathrm{L}b\hat{\$}$. In the remainder of this section, let q be the leaf of LT_b that is the locus of the Lstring corresponding to $B[\hat{n}+1, \hat{n}+1] = \$$, i.e., the leaf that is the locus of the Lstring corresponding to the last suffix of $B\hat{\$}$. We need the following lemma.

LEMMA 11. *The Lsuffix tree LT_D for the Lstrings in $D = \{\mathrm{L}a_d\hat{\$}_d,\ 0 \leq |d| < n\}$ is isomorphic to $LT_b - \{q\}$, where LT_b is the Lsuffix tree for Lstring $\mathrm{L}b\hat{\$}$ (the Lstring corresponding to matrix $B\hat{\$}$).*

Proof. We establish a one-to-one correspondence between the nodes of $\mathrm{L}T_D$ and the ones of $\mathrm{L}T_b - \{q\}$.

We first establish a one-to-one correspondence between the leaves of $\mathrm{L}T_D$ and the ones of $\mathrm{L}T_b - \{q\}$. By definition of an Lsuffix tree of an Lstring (set of Lstrings, respectively), there is a one-to-one correspondence between the leaves of LT_b (LT_D, respectively) and the suffixes of $B\hat{\$}$ ($A_d\hat{\$}_d$, $0 \leq |d| < n$, respectively). But there is a one-to-one correspondence between the suffixes of B and the ones of $A_d\hat{\$}_d$ (as shown in Fig. 14), which proves our claim.

We now show that there is a one-to-one correspondence between the internal nodes of LT_D and the ones of LT_b. Let C be a square submatrix of B along its main diagonal and such that C has no rows and columns of special characters $\$_d$. Given the correspondence between suffixes of B and suffixes of A_d, $0 \leq |d| < n$, any such submatrix C of B is a prefix of some suffix of B if and only if C is a prefix of some suffix of A_d, $0 \leq |d| < n$. Using this fact, the fact that $\hat{\$}_d$, $0 \leq |d| < n$, does not match anything, and the correspondence between square matrices and Lstrings, it is straightforward to prove that an Lstring has an internal node as a

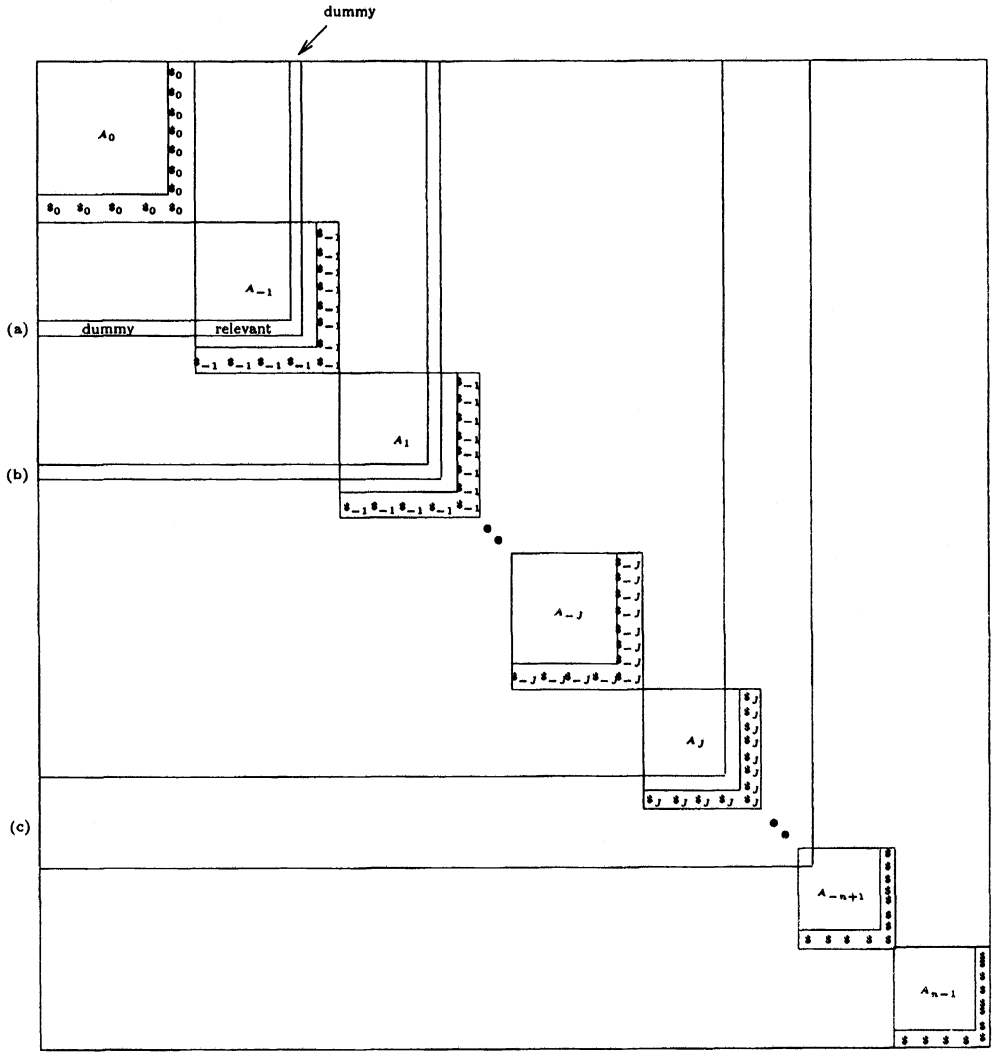

FIG. 14. *Matrix B corresponding to* $A_d\hat{\$}_d$, $0 \leq |d| < n$. *Entries of B outside* $A_d\hat{\$}_d$, $0 \leq |d| < n$, *have dummy symbols (not shown).*

locus in LT_b if and only if it has an internal node as a locus in LT_D. Since the internal nodes of both trees are locuses of Lstrings, we have a one-to-one correspondence between the internal nodes of LT_D and the ones of LT_b. □

Before we describe how to obtain LT_D from LT_b, we need a few preliminary observations. Note that B is an $\hat{n} \times \hat{n}$ matrix such that each row (column, respectively) is obtained from a given subrow (subcolumn, respectively) of A by adding dummy symbols to the beginning and end of it. Thus, there is no need to build B explicitly. Moreover, we point out that each chunk (and in particular Lcharacters) of $Lb\hat{\$}$ and its Lsuffixes is made up of a *dummy part* covering subrows and subcolumns of B with dummy characters in them and a *relevant part* covering subrows and subcolumns of B that correspond to subrows and subcolumns of matrices $A_d\hat{\$}$, $0 \leq |d| < n$ (for an example, see chunk (a) in Fig. 14).

We can compare Lcharacters from Lb and any of its Lsuffixes as follows. We preprocess the matrix A as in §4. By Lemma 1, that takes $O(n^2 \log |\Sigma|)$ time. Then, given two Lcharacters from triples of chunks of Lb or of its Lsuffixes, we take only the starting points in B of an occurrence of the relevant parts of those Lcharacters. Using the correspondence (shown in Fig. 14) between the matrices $A_d\hat{\$}$, $0 \leq |d| < n$, and the suffixes of B, such starting points can be translated, in constant time, into the starting points in A of an occurrence of two Lcharacters of $La_d\hat{\$}_d$, $0 \leq |d| < n$, or one of its Lsuffixes. Then we can use *compare* as described in §4. The bounds in Lemma 1 still hold.

We can build the Lsuffix tree LT_D of matrix A by building the Lsuffix tree LT_b for the Lstring $Lb\hat{\$}$ (corresponding to matrix $B\hat{\$}$). By Lemma 11, LT_D is isomorphic to $LT_b - \{q\}$. Then we have to transform $LT_b - \{q\}$ into LT_D by a suitable transformation of labels (which will be outlined shortly). We proceed as follows. We use the procedure of §§5 and 6 to build LT_b with the following changes. Any time we need an Lcharacter from Lb or one of its Lsuffixes, we recover its relevant part in matrix A through the correspondence (shown in Fig. 14) between the matrices $A_d\hat{\$}$, $0 \leq |d| < n$, and the suffixes of B. Such a translation takes constant time. Moreover, when we need to compare Lcharacters from $Lb\hat{\$}$ or any of its Lsuffixes, we use *compare* as described above. Notice that it still takes constant time. Using the fact that $\hat{n} = O(n^2)$ and Theorem 4, we can build LT_b in $O(n^2 \log n)$ time.

Once we have LT_b, we delete leaf q and translate the triples representing chunks of Lb and its Lsuffixes into quadruples representing chunks of Lstrings $La_d\hat{\$}_d$ and their Lsuffixes, $0 \leq |d| < n$. Let (p, q, l) be a triple on an edge (u, v) of $LT_b - \{q\}$. It represents chunk $Lsuf_l(Lb\hat{\$})$. There are two cases to consider: one in which the relevant part of (p, q, l) is fully within a suffix of some A_d (see chunk (b) in Fig. 14) and the other in which it is not (see chunk (c) in Fig. 14). For the case depicted in Fig. 14b, we translate the triple (p, q, l) into a quadruple that represents only the relevant part of $Lsuf_l(Lb\hat{\$})$ and therefore corresponds to the correct chunk of Lstrings $La_d\hat{\$}_d$ and their Lsuffixes, $0 \leq |d| < n$, that is to be placed on the edge (u, v) of LT_D. In the other case, $v \in LT_b$ is a leaf since $\$_j$ occurs only once in B and $\$_j$ is in the relevant part of (p, q, l) (see Fig. 14c). We translate such a triple into the correct quadruple to be placed on the edge $(u, v) \in LT_D$ by keeping only the relevant part of (p, q, l) (which is above the subrow and to the right of the subcolumn of $\$_j$'s in B). In both cases, this transformation takes constant time. Since the size of LT_b is $O(\hat{n})$ (by Fact 4) and since $\hat{n} = O(n^2)$, we get that we can transform $LT_b - \{q\}$ into LT_D in $O(n^2)$ time. Moreover, the transformation is such that the edges outgoing each node of LT_D are sorted according to the first Lcharacter on the chunk of each edge. Recalling that preprocessing of the matrix A takes $O(n^2 \log |\Sigma|)$ time and that LT_b can be built in $O(n^2 \log n)$ time, we get the following theorem.

THEOREM 5. *Given an $n \times n$ matrix A, we can build the Lsuffix tree for matrix A in $O(n^2(\log n + \log |\Sigma|))$ time. Moreover, the edges outgoing each node of LT_D are sorted according to the first Lcharacter on the chunk of each edge.*

8. Refining the Lsuffix tree for matrix A. As pointed out at the end of §3.2.3, the Lsuffix tree LT_D for matrix A can be used to find all occurrences of a matrix PAT into A. However, the outdegree of nodes in LT_D may be large, resulting in a slow-down in the search time. We can avoid such a slow-down by reducing the outdegree of the nodes in LT_D, i.e., by refining it. Indeed, the *refinement* of the Lsuffix tree for A, referred to as the RLsuffix tree for A and denoted RLT_D, is a compacted trie defined over Σ. Thus the outdegree of each node of the Lsuffix tree is at most Σ and we can "jump" from one node to another in $O(\log |\Sigma|)$ time. Intuitively, it represents the same information as LT_D but in a different format. Indeed, LT_D represents Lstrings, which are "strings" defined over an alphabet of Lcharacters. Since

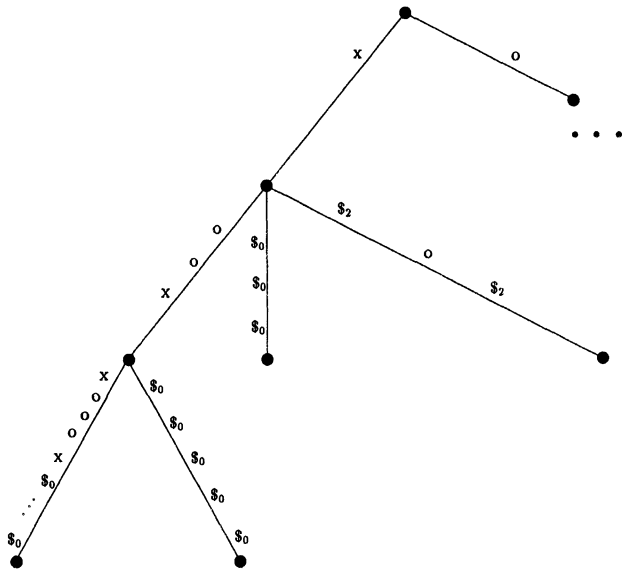

FIG. 15. *The refinement of the Lsuffix tree of Fig.* 10. *Only the part corresponding to the suffixes of* A_0 *and* A_2 *are shown.*

Lcharacters are strings over Σ, we can represent Lstrings as strings in Σ^*. In fact, RLT_D represents the same Lstrings as LT_D but as strings in Σ^*. (See Fig. 15 for an example.) Let $\leq$ denote the lexicographic order relation for strings of Σ^*.

8.1. Construction of RLT_D: High-level description. We give a constructive definition of RLT_D by describing, at a high level, how it is obtained from LT_D. In what follows, for a given internal node $v \in LT_D$, let $off(v)$ be the number of offsprings of v in LT_D and let $w_1 < \cdots < w_{off(v)}$ be the list of its offsprings sorted according to the first Lcharacter of the chunks on the corresponding edges. Such a list can be easily obtained from LT_D in $O(off(v))$ time, since we keep the edges outgoing v in the order $w_1 < \cdots < w_{off(v)}$ (see Theorem 5). Let β_i denote the string that corresponds to the chunk on the edge (v, w_i), $1 \leq i \leq off(v)$, when we write it down as a string in Σ^*. For each internal node $v \in LT_D$, we build a compacted trie $PT(v)$ defined over Σ. It represents, as strings in Σ^*, the chunks on the edges outgoing v, i.e., it represents $\beta_1, \ldots, \beta_{off(v)}$. So, each edge of $PT(v)$ has a string assigned to it, which is a substring of some β_i. Since each chunk on the edges outgoing v starts with a different Lcharacter (by definition of Lsuffix tree), no β_i can be a prefix of any other β_j. Thus there is a one-to-one correspondence between the leaves of $PT(v)$ and the offsprings of v. We make the root of $PT(v)$ correspond to v. Once the $PT(v)$'s have been computed for each internal node $v \in LT_D$, we glue them together according to the parent–offspring relation in LT_D. That is, for each edge $(v, f') \in LT_D$, the root of $PT(f')$ is coalesced with the leaf corresponding to it in $PT(v)$. The resulting tree is RLT_D.

Note that with such a construction there is no loss of information. That is, RLT_D represents the same information as LT_D, but in a different format. Moreover, there is a one-to-one correspondence between the leaves of LT_D and the ones of RLT_D. Indeed, the leaf $f' \in LT_D$ labeled (l, i) and such that the path from the root of LT_D to f' spells out the Lstring $Lsuf_l(La_i\hat{\$}_i)$ corresponds to the leaf $f \in RLT_D$ such that the path from the root of RLT_D to f spells out $Lsuf_l(La_i\hat{\$}_i)$ as a string of Σ^*. The converse is also true. We assign the label (l, i) to f. Note that RLT_D has $O(n^2)$ leaves.

In what follows we bound the size of RLT_D. We start by describing how the strings on its edges are represented. This involves discussing the representation of strings on the edges of a single $PT(v)$. Given a string γ on an edge of $PT(v)$, we represent it in constant space with a sixtuple (p, q, l, i, bgn, end) which means the following. Let β be the string obtained by writing down the chunk $\mathrm{L}suf_l(La_i\hat{\$}_i)[p, q]$ represented by quadruple (p, q, l, i) (which is on some edge $(v, w_j) \in LT_D$). Then $\gamma = \beta[bgn, end]$. We need the following fact, which will be useful in the next section.

FACT 11. *Given the sixtuple (p, q, l, i, bgn, end), let γ be the string it represents. A prefix $\hat{\gamma}$ of γ can be recovered from the sixtuple in $O(|\hat{\gamma}|)$ time.*

Proof. (p, q, l, i, bgn, end) encodes $\gamma = \beta[bgn, end]$, where β corresponds to the chunk $\mathrm{L}suf_l(La_i\hat{\$}_i)[p, q]$ as a string of Σ^*. Using the definition of chunk, we know that the tth, $p \leq t \leq q$, Lcharacter of that chunk has length $2t - 1$ as a string of Σ^*. Let k be the maximal integer such that $\Sigma_{i=0}^{k}(2(p + i) - 1) = k^2 + 2p(k + 1) - 1 < bgn$. It can be found in constant time. In order to get to the starting point of γ and $\hat{\gamma}$ in β, we need to skip the first $k + 1$ Lcharacters of $\mathrm{L}suf_l(La_i\hat{\$}_i)[p, q]$. Skipping the first $bgn - 1$ characters, we take the subsequent $end - bgn + 1$ characters out of the ones that compose the Lcharacters in the chunk $\mathrm{L}suf_l(La_i\hat{\$}_i)[p + k + 1, q]$. They correspond to $\hat{\gamma}$. By Theorem 3, we can access the starting points of an occurrence of any of those Lcharacters in A in constant time. So, using the correspondence between Lcharacter and subrows and subcolumns of A, we can get $\hat{\gamma}$ in time linear in its size. □

FACT 12. *The size of $PT(v)$, i.e., number of nodes, edges, and labels, is $O(off(v))$.*

Proof. $PT(v)$ is a compacted trie over the alphabet Σ that has $O(off(v))$ leaves. By the definition of a compacted trie [20], each internal node of $PT(v)$, except possibly the root, has outdegree at least two. Thus the number of nodes, edges, and labels (one per edge) is bounded by $O(off(v))$. □

LEMMA 12. *Given a node g in RLT_D, let lf be the number of leaves in the subtree T_g of RLT_D rooted at g. The number of nodes in T_g is $O(lf)$.*

Proof. Since each $PT(v)$, $v \in LT_D$ and internal node, is a compacted trie, only its root can have outdegree one. Moreover, since $PT(v)$ represents at least two different strings (no β_i is prefix of any other β_j and $off(v) \geq 2$), each leaf of $PT(v)$ must descend from a parent of outdegree at least two. Since RLT_D is obtained by gluing all the $PT(v)$'s together, for each internal node $v \in LT_D$, the above properties of $PT(v)$ imply the following properties for RLT_D: (a) the nodes of outdegree one in RLT_D must be offsprings of nodes of outdegree at least two; (b) all leaves of RLT_D must be offsprings of internal nodes of outdegree at least two.

Consider a tree T'_g obtained from T_g by "contracting" the internal nodes of outdegree one into their offsprings. Note that because of property (b) of RLT_D, T'_g has the same number of leaves of T_g and, because of property (a) of RLT_D, it is at least half the size of T_g. Since each node in T'_g has outdegree at least two, its size is $O(lf)$, which proves the claimed bound on the size of T_g. □

LEMMA 13. *The size of RLT_D, i.e., number of nodes, edges, and labels, is $O(n^2)$.*

Proof. The lemma follows from Lemma 12 (applied to the root of RLT_D) and the fact that RLT_D has $O(n^2)$ leaves. □

THEOREM 6. *Let B be a square matrix and let Lb be the corresponding Lstring. B is submatrix of A if and only if the string corresponding to Lb has an extended locus w in RLT_D. Moreover, let F be any square submatrix of A having B as a prefix and let Lf be the Lstring corresponding to F. The extended locus of the string corresponding to Lf in RLT_D is a descendant of w.*

Proof. Given the way in which we obtain RLT_D from LT_D, the theorem is a simple variation of Theorem 2. The proof is omitted. □

8.2. Construction of RLT_D: Low-level description. Let us assume that LT_D has been built and let us assume that the matrix A has been preprocessed so that *compare* takes constant time. The main point in the construction of RLT_D is the computation of $PT(v)$, $v \in LT_D$, which we now present.

Recall that $w_1 < \cdots < w_{off(v)}$ is the list of offsprings of v in LT_D sorted according to the first Lcharacter of the chunks on the corresponding edges and that β_i denotes the string that corresponds to the chunk on the edge (v, w_i), $1 \le i \le off(v)$, when we write it down as a string in Σ^*. Note that, for $i < j$, $\beta_i < \beta_j$ because $w_i < w_j$. Moreover, the longest prefix that β_i and β_j have in common is "confined" to the first Lcharacter of the chunks on the edges (v, w_i) and (v, w_j) (no two such chunks can start with the same Lcharacter, by definition of an Lsuffix tree). Since we have pointers to such Lcharacters (the quadruples representing the chunks), we can compute the length of such a prefix by using *compare* (recall its definition from §4). Note also that given a quadruple representing a chunk, we can compute the length of the string corresponding to the chunk in constant time. Thus, we can assume that the lengths of $\beta_1, \ldots, \beta_{off(v)}$ are known.

We build $PT(v)$ incrementally by inserting into it the path representing β_i, once the path representing β_r is already there, for $1 \le r < i$. Assume that we have $PT_{i-1}(v)$, the compacted trie that represents $\beta_1 < \cdots < \beta_{i-1}$, and assume that the following invariant holds.

INVARIANT 2. *The edges outgoing any node of $PT_{i-1}(v)$ are sorted according to the first character of the string on each edge. The array $PATH$ stores the nodes of $\hat{p}$, where $\hat{p}$ is the path representing β_{i-1} in $PT_{i-1}(v)$. Moreover, the nodes in $PATH$ are sorted in increasing order of the length of the strings of which they are locuses. For each node $c \in \hat{p}$, the length $len(c)$ of the string of which c is a locus is known.*

Note that for $i = 2$, $PT_1(v)$ is an edge representing β_1 and $\hat{p}$ is that edge (it can be stored in $PATH$ in constant time). Moreover, since we know the length of β_1 and $root(PT_{i-1}(v))$ is the locus of the empty string, we also know the length of the strings of which the nodes in $\hat{p}$ are locuses. Since $PT_1(v)$ has only one edge, all edges outgoing the same internal node are sorted according to the first character of the strings on those edges. Thus Invariant 2 is satisfied for $i = 2$. Now we show how to transform $PT_{i-1}(v)$ into $PT_i(v)$ and how to maintain Invariant 2 for $i \ge 2$. We do not actually provide all details, since many of them are quite standard operations in manipulating tries.

Transformation of $PT_{i-1}(v)$ into $PT_i(v)$. Let len be the length of the longest prefix common to β_{i-1} and β_i. We can compute it in constant time using *compare*, as already discussed. Since $\beta_r < \beta_{i-1}$, for $r < i - 1$, no β_r can have a prefix in common with β_i of length longer than len. This implies that we can create the path p representing β_i by making it "share" $\beta_i[1, len]$ with $\hat{p}$. Thus p is obtained from $\hat{p}$ by creating, if needed, a locus u for $\beta_i[1, len]$ on $\hat{p}$ and then, as an offspring of u, a leaf f representing $\beta_i[len + 1, |\beta_i|]$. This is done as follows. We have the nodes of $\hat{p}$ in $PATH$, sorted in increasing order of the length of the strings of which they are locuses. We find where to create u on $\hat{p}$ by finding, through a binary search on $PATH$, the maximal node c for which $len(c) \le len$. If $len(c) = len$ then $u = c$. Otherwise u is created by splitting the edge $(c, c') \in PT_{i-1}(v)$ whose label starts with $\beta_i[len(c) + 1]$ (u becomes an offspring of c and the parent of c' in $PT_i(v)$). Moreover, $len(u) = len$ and $len(f) = |\beta_i|$. Note that the split of the edge $(c, c') \in PT_{i-1}$ causes the split of the label on that edge into two. That can be done in constant time. We omit the details. Moreover, the sixtuple that has to label the edge $(u, f) \in PT_i(v)$ can be obtained in constant time from the quadruple labeling the edge $(v, w_i) \in LT_D$ and len. Again, we omit the details. We also remark that the edge (u, f) and possibly the edges (c, u) and (u, c') can be placed

in such a way that all edges outgoing the same internal node of $PT_i(v)$ are sorted according to the first character of the strings on those edges. Again, we omit the details. The above discussion proves that part of Invariant 2 will hold for $PT_i(v)$.

Update of $PATH$. We update $PATH$ to contain p by throwing out all descendants of c (which follow it in $PATH$) and appending to it u and the new leaf f. The descendants of c can be deleted in constant time by moving the right boundary of $PATH$ so that c is the last element of $PATH$. The update of $PATH$ establishes that the remainder of Invariant 2 will hold for $PT_i(v)$.

LEMMA 14. *$PT(v)$ can be correctly built in $O(off(v)(\log|\Sigma| + \log n))$ time and in such a way that edges outgoing any node of $PT(v)$ are sorted according to the first character of the string on each edge.*

Proof. The proof of correctness is by induction. It is given by the discussion preceding the lemma. The most expensive step in the transformation of $PT_{i-1}(v)$ into $PT_i(v)$ is a binary search on $PATH$. The rest of the work requires constant time (including the update of $PATH$ and calls to *compare*) or $O(\log|\Sigma|)$ time (to insert the new edges so that the list of edges outgoing any node of $PT_i(v)$ is sorted according to the first character on those edges). Since the size of $PT(v)$ is bounded by $O(off(v))$ (by Fact 12) and $|PT_j(v)| \leq |PT(v)|$, $j = 1 \ldots off(v)$, $PATH$ has at most $off(v) \leq n^2$ nodes in it. Thus a binary search takes $O(off(v)\log n)$ time. Summing the work for $i = 2, \ldots, off(v)$, we obtain the claimed bound. □

THEOREM 7. *RLT_D can be built in $O(n^2(\log|\Sigma| + \log n))$ time and in such a way that the edges outgoing any node of RLT_D are sorted according to the first character of the string on each edge.*

Proof. For each internal node $v \in LT_D$, the edges outgoing any node of $PT(v)$ are sorted according to the first character of the string on each edge (by Lemma 14). RLT_D is obtained by gluing those trees together, so it has the same property. The work required to build $PT(v)$ for each internal node $v \in LT_D$ is bounded in Lemma 14. Since the sum of the $off(v)$'s over all internal nodes v of LT_D is bounded by $O(n^2)$, we get that the total work to build the $PT(v)$'s is bounded by $O(n^2)$ calls to *compare* and $O(n^2(\log|\Sigma| + \log n))$ additional time. The bound of the theorem follows by noting that *compare* takes a constant time per call and that gluing the $PT(v)$'s together can be done in $O(n^2)$ time. □

9. Application one: Pattern retrieval. In this section we apply the Lsuffix tree and its refinement to derive efficient algorithms for the pattern retrieval problem. In order to simplify the presentation, we limit our discussion to the case in which the library S has only one text, an $n \times n$ matrix $TEXT$. The results generalize easily to a set of texts.

9.1. Pattern retrieval through an index. We are interested in building an index representing all square submatrices of $TEXT$ (preprocessing step). Then, given an $m \times m$ matrix PAT, we want to use the index to find all occurrences of PAT in $TEXT$. Let $TEXT_d$ be the square submatrix of $TEXT$ whose main diagonal is the dth diagonal of $TEXT$, $0 \leq |d| \leq n-1$, and let Lt_d denote the Lstring corresponding to $TEXT_d$, $0 \leq |d| \leq n-1$. Moreover, let $D = \{Lt_d\hat{\$}_d, 0 \leq |d| < n\}$.

The preprocessing step consists of building the Lsuffix tree LT_D for matrix $TEXT$ and then refining it. By Theorems 5 and 7 that will take $O(n^2(\log|\Sigma| + \log n))$ time.

Let $Lpat$ be the Lstring corresponding to matrix PAT and let pat be $Lpat$, when we write it down as a string of Σ^*.

THEOREM 8. *PAT occurs in $TEXT$ if and only if pat has an extended locus u in RLT_D. Moreover, all such occurrences are prefixes of suffixes of $TEXT_d$, $0 \leq |d| < n$, corresponding to the leaves of the subtree of RLT_D rooted at u.*

Proof. PAT occurs in $TEXT$ if and only if it is a square submatrix of $TEXT$ and, by Theorem 6, if and only if *pat* has an extended locus u in RLT_D. That proves the first part of the theorem. For the second part, note that PAT occurs in $TEXT$ if and only if it is the prefix of some suffix of $TEXT_d$. Let C be one of these suffixes, Lc be the Lstring corresponding to it, and c be the string obtained from Lc when we consider Lcharacters as strings. By Theorem 6, c has an extended locus in RLT_D. That extended locus must be a leaf f (it follows from the way we build RLT_D from LT_D and the fact that the extended locus of Lc in LT_D is a leaf). Again by Theorem 6, f must be in the subtree of RLT_D rooted at u (PAT is a prefix of C). □

Given PAT, we can construct *pat* in $O(m^2)$ time using the correspondence between matrices and Lstrings. Then the search for the extended locus of *pat* in RLT_D is a nearly standard search for the extended locus of a string in a compacted trie defined over Σ. However, we have to be careful with the fact that there are sixtuples on the edges of RLT_D, rather than actual strings. We give details only on how to traverse one edge of RLT_D guided by *pat*.

Assume that we have reached a node $g \in RLT_D$, locus of $pat[1, s]$. We select the edge to traverse the next by finding the edge (g, h) whose label starts with $pat[s+1]$. That can be done in $O(\log|\Sigma|)$ time because, by Theorem 7, the edges outgoing any node of RLT_D are sorted according to the first character of the string on each edge. Let (p, q, l, i, bgn, end) be the label on the edge (g, h) and let γ be the string it represents. Let $l = \min(m^2 - s, end - bgn + 1)$. We extract from the sixtuple a prefix $\hat{\gamma}$ of γ of length l. By Fact 11, this can be done in $O(l)$ time. Then we compare $\hat{\gamma}$ with $pat[s+1, s+l]$. This takes $O(l)$ time. If they are equal, we go on with the edge traversal starting from h and guided by $pat[s+l+1, m^2]$. Otherwise, there is no extended locus of *pat* in RLT_D.

Such an edge traversal costs $O(l + \log|\Sigma|)$ time. Since we never back up in reading the input, the whole time bound for the search procedure is bounded by $O(m^2 \log|\Sigma|)$ time.

Once we have reached the extended locus u of *pat* in RLT_D, we know, by Theorem 8, that the *occ* occurrences of PAT in $TEXT$ are given by the labels on the *occ* leaves of the subtree T_u of RLT_D rooted at u. By Lemma 12, the size of T_u is $O(occ)$, so we can visit its leaves, starting from u, in $O(occ)$ time. We summarize the above discussion in the following theorem.

THEOREM 9. *Finding all occurrences of matrix PAT in TEXT takes* $O(m^2 \log|\Sigma| + occ)$ *time, where occ is the number of occurrences of PAT in TEXT.*

9.2. Pattern retrieval through a set of table. Here we outline how to convert the refined Lsuffix tree RLT_D for matrix $TEXT$ into a set of tables, which can then be used to perform pattern matching. We assume that the reader is throughly familiar with the notation and approach of Manber and Myers to build suffix arrays for strings [21], which we briefly summarize.

Given a text string, Manber and Myers define three tables that contain lexicographic information about all suffixes of the text string and show how to compute such tables using a doubling technique. Using the tables, they devise a simple binary search procedure that finds all occurrences of a given pattern string in the text string. Such a procedure finds the set of suffixes of text that have the pattern as a prefix. The time performance of the search procedure depends on the size N of the tables and the length m of the pattern string: it is $O(m + \log N + occ)$, where *occ* is the number of occurrences of the pattern in the text.

Let $\alpha_{l,d}$ be the string corresponding to $Lsuf_l(Lt_d)$, $0 \le |d| < n$ and $1 \le l \le n - |d|$. Recall from §8 that the concatenation of the labels on the path from the root of RLT_D to a leaf labeled (l, d) gives $\alpha_{l,d}$. Here we also define three tables, which are the same as the ones of Manber and Myers, except that they contain lexicographic information about the n^2 strings $\alpha_{l,d}$. However, we do not use the doubling technique of Manber and Myers since we obtain

such tables directly from RLT_D. Then the procedure that searches for matrix PAT in $TEXT$ is the one of Manber and Myers, where the pattern string is pat. Thus such a procedure will find the set of $\alpha_{l,d}$, $0 \leq |d| < n$ and $1 \leq l \leq n - |d|$ that has pat as prefix. Because of the one-to-one correspondence between the α's, the Lsuffixes of Lt_d and the suffixes of $TEXT_d$, this is equivalent to finding all suffixes of $TEXT_d$, $0 \leq |d| < n$, that have PAT as a prefix (a proof of this fact is implicit in Theorem 8). In what follows, we give only an outline of our construction since the rationale behind it is as in [21].

Let us assume that RLT_D has been computed. By Theorem 7, it can be built in $O(n^2(\log|\Sigma| + \log n))$ time. As in [21], let us define an array $POS[0, n^2 - 1]$ of pairs such that $\alpha_{POS[k]} \leq \alpha_{POS[j]}$ for $k \leq j$. We use RLT_D to compute POS. We can compute POS by traversing RLT_D alphabetically since such visit will give us the α's sorted lexicographically. By Theorem 7, the edges outgoing any node of RLT_D are sorted according to the first character of the string on each edge, so such alphabetic visit can be done in $O(n^2)$ time.

Given two strings β and γ, let $lcp(\beta, \gamma)$ be the length of the longest prefix common to β and γ. Again as in [21], consider all the possible triples (L, M, R) that can arise in a binary search on the interval $[0, n^2 - 1]$ (here L, M, and R denote the left point, middle point, and right point of the interval that remains to be searched). There are exactly $n^2 - 2$ such triples, each with a unique midpoint $M \in [1, n^2 - 2]$ and for each triple $0 \leq L < M < R \leq n^2 - 1$. Let (L_M, M, R_M) be the unique triple containing midpoint M. Let $Llcp$ be an array of size $n^2 - 2$ such that $Llcp[M] = lcp(\alpha_{POS[L_M]}, \alpha_{POS[M]})$. Moreover, let $Rlcp$ be an array of size $n^2 - 2$ such that $Rlcp[M] = lcp(\alpha_{POS[R_M]}, \alpha_{POS[M]})$. These two arrays can be computed in $O(n^2)$ time as follows. We augment RLT_D with LCA data structures [17], [24] in $O(n^2)$ time. Now each entry of $Llcp$ and $Rlcp$ can be computed in constant time by an LCA query, for a total of $O(n^2)$ time. We have the following theorem.

THEOREM 10. *The tables POS, $Llcp$, and $Rlcp$ can be built in $O(n^2(\log|\Sigma| + \log n))$ time.*

Given a matrix PAT, we use the same search procedure of Manber and Myers [21] to find the subset of the $\alpha_{l,d}$, $0 \leq |d| < n$ and $1 \leq l \leq n - |d|$, that has pat as a prefix. As already pointed out, that is equivalent to finding all suffixes of $TEXT_d$, $0 \leq |d| < n$, that have pat as prefix. As in [21], such a procedure needs to compare characters of the $\alpha_{l,d}$ with characters of pat. pat can be explicitly built from PAT in $O(m^2)$ time. However, we do not construct the $\alpha_{l,d}$ explicitly. (It would be too costly.) Instead, we recover, when needed and in constant time, each character $\alpha_{l,d}[i]$ through the correspondence between $\alpha_{l,d}$, $\mathrm{L}suf_l(Lt_d)$, and the entries of $TEXT$. Thus, the time complexity of the procedure of Manber and Myers is unchanged and will depend on the size n^2 of our tables and the length m^2 of pat.

THEOREM 11. *Given that the arrays POS, $Llcp$, and $Rlcp$ have been computed for the matrix $TEXT$, finding all occurrences of PAT in $TEXT$ takes $O(m^2 + \log n + occ)$ time, where occ is the number of such occurrences.*

10. Application two: Dictionary matching. We are given a dictionary of s distinct square matrices $PAT_1, \ldots, PAT_s$, which we call patterns, where PAT_i is of dimension $m_i \times m_i$, $1 \leq i \leq s$. We are allowed to preprocess the dictionary (preprocessing step). Then we are given a square matrix $TEXT$ of dimension $n \times n$, which we call text. We must report all occurrences of patterns of the dictionary in the text (search step). The search step may be repeated with different texts.

10.1. Preprocessing step. Our preprocessing step consists of building a compacted trie LT over the alphabet $\mathrm{L}\Sigma$ that represents, as Lstrings, all suffixes of $PAT_1\hat{\$}_1, \ldots, PAT_s\hat{\$}_s$. Let $\mathrm{L}pat_1\hat{\$}_1, \ldots, \mathrm{L}pat_s\hat{\$}_s$ be the Lstrings corresponding to those matrices. Assume that an edge of LT is labeled by chunk $\mathrm{L}suf_i(\mathrm{L}pat_j\hat{\$}_j)[p, q]$. We represent such chunk in constant

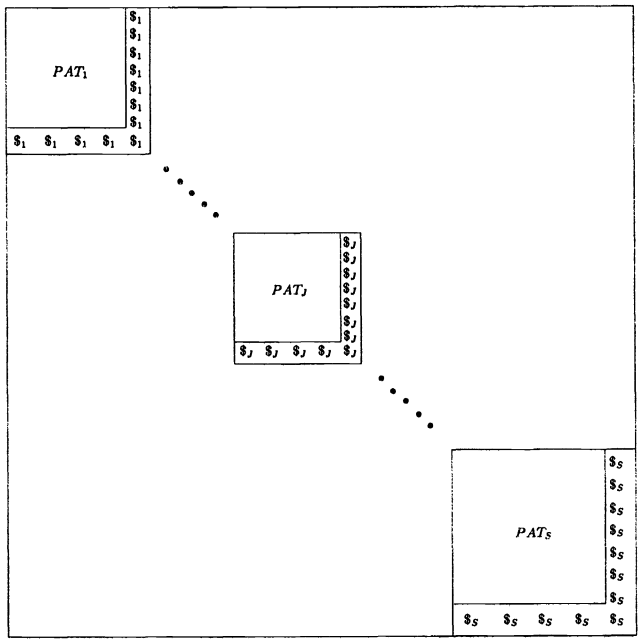

FIG. 16.

space with a quadruple (p, q, i, j). Using the quadruple, we can recover the starting points in $PAT_j\hat{\$}_j$ of each Lcharacter in the chunk. (The approach is the same as the one in §3.2.3, where we have shown how, from quadruples, we can recover starting points in A of each Lcharacter of chunks coming from the Lstrings corresponding to A_d, $0 \leq |d| < n$, and its suffixes.)

In order to build LT, we use the same approach of as in §7, where we have shown how to build the compacted trie LT_D representing, as Lstrings, all suffixes of matrices A_d, $1 \leq |d| < n$. Indeed, we think of $PAT_1\hat{\$}_1, \ldots, PAT_s\hat{\$}_s$ as being aligned, in that order, on the main diagonal of a matrix B (see Fig. 16). B is of dimension $\hat{n} = \Sigma_{i=1}^{s}(m_i + 1)$ and it has dummy symbols in its entries not covered by any $PAT_j\hat{\$}_j$. Note that we do not actually need to build B explicitly since we can recover its entries from the pattern matrices. In what follows, we omit the details and proofs since the analogy with the construction of §7 is obvious. (The role played here by PAT_j, $1 \leq j \leq s$, is the same as the role played by A_d, $0 \leq |d| < n$, in §7.)

Let LT_b be the Lsuffix tree for Lstring $Lb\hat{\$}$ and let $\hat{q}$ be the leaf of LT_b that is the locus of the Lstring corresponding to $B[\hat{n} + 1, \hat{n} + 1] = \$$, i.e., the leaf that is the locus of the Lstring corresponding to the last suffix of $B\hat{\$}$. Using exactly the same arguments as in Lemma 11, we can show that LT is isomorphic to $\mathrm{L}T_b - \{\hat{q}\}$. Thus we can obtain LT by building $\mathrm{L}T_b - \{\hat{q}\}$ and then transforming the triples on its edges into quadruples representing chunks of $\mathrm{L}pat_j$, $1 \leq j \leq s$, or of its Lsuffixes. This latter step is similar to the transformation of $\mathrm{L}T_b - \{q\}$ into LT_D described in §7 and we omit the details. We point out that in transforming $\mathrm{L}T_b$ into LT, we keep all the auxiliary data structures that are used in §§5 and 6 to build $\mathrm{L}T_b$. In particular, for each leaf $q \in LT$, $SL(q)$ is a suffix link defined exactly as for $\mathrm{L}T_b$ and its value is known at the end of the computation (because $\mathrm{L}T_b$ satisfies Invariant 1). Moreover, LT is a dynamic tree and each node of LT points to some arbitrary leaf in its subtree. Note also that the size of LT is $O(\hat{n})$, since LT_b is the Lsuffix tree of an Lstring of length $O(\hat{n})$ and, by Theorem 1, LT_b has size $O(\hat{n})$.

As for the efficient construction of LT_b, recall that we need to be able to compare, in constant time, two Lcharacters of equal length as strings of Σ^* and each coming from $Lb\hat{\$}$ or one of its Lsuffixes. Note that the chunks (and in particular the Lcharacters) of $Lb\hat{\$}$ and of its Lsuffixes have a relevant part and a dummy part, which are defined as in §7 except that the matrices A_d's are replaced by the matrices PAT_j's. Again as in §7, we consider only the relevant parts of Lcharacters coming from Lb or one of its Lsuffixes. Thus the problem of comparing two Lcharacters of equal length as strings of Σ^* with each coming from $Lb\hat{\$}$ or one of its Lsuffixes boils down to the efficient comparison of two Lcharacters of equal length as strings of Σ^* and each coming from $Lpat_j$, $1 \leq j \leq s$, or one of its Lsuffixes. In order to compare two such Lcharacters in constant time, we proceed as in §4. However, the suffix tree T_{rows} (T_{cols}, respectively) is the suffix tree of the string obtained by concatenating (separated by \$'s) all rows (columns, respectively) of matrices PAT_j, $1 \leq j \leq s$. Notice that there is a unique leaf such that the concatenation of the labels on the path from $root(T_{rows})$ ($root(T_{cols})$, respectively) to that leaf gives $PAT_{j_1}[i_1, g_1 : m_{j_1}]$ ($PAT_{j_1}[i_1 : m_{j_1}, g_1]$, respectively). Such construction takes $O(\hat{n} \log |\Sigma|)$ time because $rows$ and $cols$ are strings of length $O(\hat{n})$ [22]. We augment both T_{rows} and T_{cols} with LCA data structures [17], [24]. As in §4, the comparison of two Lcharacters, each coming from $Lpat_j$, $1 \leq j \leq s$, or one of its Lsuffixes, reduces to a constant number of LCA queries and therefore takes constant time. Thus the comparison of two Lcharacters, each coming from $Lb\hat{\$}$ or one of its Lsuffixes, also takes constant time. Now, by Theorem 4, we can build LT_b in $O(\hat{n} \log \hat{n})$ time.

We need to augment LT with additional data structures that will be useful during the search step. We mark each node of LT that is a locus of some Lstring corresponding to some PAT_g, $1 \leq g \leq s$. For each node $w \in LT$, we set a *prefix link* to its lowest marked proper ancestor. Such data structures can be computed in $O(\hat{n})$ time by a bottom up visit of LT. We finally note that since LT is a compacted trie for the Lsuffixes of $Lpat_j\hat{\$}_j$, $Lpat_j$ may not have a locus defined in LT. That happens only when PAT_j is not a prefix of any other PAT_i because $\hat{\$}_j$ does not match $\hat{\$}_i$, $i \neq j$. In that case $Lpat_j$ has an extended locus, which corresponds to the leaf u, locus of $Lpat_j\hat{\$}_j$. We assume that, in such a case, the length of $Lpat_j$ is stored at u and that u is marked. The computation of this information can be easily done during the computation of LT, leaving the time bounds unchanged. The above discussion outlines the proof of the following theorem.

THEOREM 12. *Given a set of matrices $PAT_1, \ldots, PAT_s$, each of dimension $m_i \times m_i$, $1 \leq i \leq s$, the preprocessing step for the dictionary matching problem takes $O(\hat{n}(\log \hat{n} + \log |\Sigma|))$ time, where $\hat{n} = \Sigma_{i=1}^{s}(m_i + 1)$.*

10.2. Search step. Given an $n \times n$ matrix $TEXT$, we want to use LT to find all occurrences of the patterns of the dictionary in the text. Let $TEXT_d$ and Lt_d, $0 \leq |d| < n$, be defined as in §9.1.

For a fixed d, $1 \leq i \leq n - |d|$, let $k = \max(d + 1, 1)$, $l = \max(1, -d + 1)$, $k' = \min(n, n + d)$, and $l' = \min(n, n - d)$. For $i = 1 \ldots n - |d|$, let $Lh_{i,d}$ be the longest Lprefix of $Lsuf_i(Lt_d)$ that has an extended locus w in LT. That is, $Lh_{i,d}$ corresponds to the longest prefix of $TEXT[k + i - 1 : k', l + i - 1 : l']$ that is also a prefix of some matrix represented in LT as Lstring. Such matrices are all suffixes of patterns in the dictionary. In what follows, let $l_{i,d}$ be the length of $Lh_{i,d}$.

We first show how to find all occurrences of patterns of the dictionary in position $(k + i - 1, l + i - 1)$ of the text, given $Lh_{i,d}$. Then we address the problem of computing $Lh_{i,d}$ for a fixed d and for $i = 1 \ldots n - |d|$. Finally, we put all the pieces together.

10.3. Finding occurrences in one position of *TEXT*. Fix i and d, $0 \leq |d| < n$ and $1 \leq i \leq n - |d|$, and let k, k', l, and l' be defined as above. We show how to compute all

occurrences of patterns of the dictionary in position $(k+i-1, l+i-1)$ of $TEXT$, assuming that we know $Lh_{i,d}$ and its extended locus w in LT. The following procedure takes in input i, d, the length of $Lh_{i,d}$ and w. Its correctness and time analysis are addressed in Lemma 15. (Since its proof is analogous to the one-dimensional case reported in [5], we omit it.)

Procedure *occurrence*

1 If w is a marked internal node and it is the locus of $Lh_{i,d}$, or it is a marked leaf and the length stored at that leaf is equal to the length of $Lh_{i,d}$, then report an occurrence at (k, l).
2 Starting from w and following the prefix links, visit all marked internal nodes on the path from $root(LT)$ to w. For each of them, report an occurrence at (k, l).

LEMMA 15. *Given i, d, the length of $Lh_{i,d}$, and w, procedure occurrence correctly finds in $O(occ_{i,d}+1)$ time, the $occ_{i,d}$ occurrences of patterns of the dictionary that start at position $(k+i-1, l+i-1)$ of $TEXT$.*

10.4. Computing $Lh_{i,d}$, d fixed and $i = 1 \ldots n-|d|$. The approach that we use in computing $Lh_{i,d}$, for $i = 1 \ldots n-|d|$, is essentially the same that we used in §§5 and 6 to compute $Lhead_i$. Recalling the notation and definitions used in §5, the analogy is the following. LT_{i-1} can be seen as a compacted trie representing (as Lstrings) the first $i-1$ suffixes of $A[1 : n+1, 1 : n+1]$. Thus $Lhead_i$ corresponds to the longest prefix of $A[i : n+1, i : n+1]$ that is also prefix of some matrix represented by LT_{i-1} as Lstrings. LT can be seen as a compacted trie representing (as Lstrings) all suffixes of patterns in the dictionary. But $Lh_{i,d}$ is the longest Lprefix of $Lsuf_i(Lt_d)$ that has an extended locus in LT. Thus $Lh_{i,d}$ corresponds to the longest prefix of $TEXT[k+i-1 : k', l+i-1 : l']$ that is also prefix of some matrix represented in LT as Lstring.

Recall that the computation of $Lhead_i$ is done in order of increasing i. Moreover, it is based on the relationship between $Lhead_i$, $Lhead_{i-1}$, and the information stored in LT_{i-1}. Indeed, starting from the contracted locus of $Lhead_{i-1}$ in LT_{i-1}, we first find the contracted locus of $L\alpha$, which is the second suffix of $Lhead_{i-1}$ and a prefix of $Lhead_i$. We do rescanning only when the contracted locus of $Lhead_{i-1}$ is not $root(LT_{i-1})$. Then, starting from the contracted locus of $L\alpha$, we find the rest of $Lhead_i$. (This is scanning.)

Analogous to that, the computation of $Lh_{i,d}$ is also done in order of increasing i, $i = 1 \ldots n-|d|$. Moreover, it is based on the relationship between $Lh_{i,d}$, $Lh_{i-1,d}$, and the information stored in LT. Indeed, let $h = \min(0, l_{i-1,d}-1)$ and let $L\gamma$ be the second Lsuffix of $Lh_{i-1,d}$. Since $Lh_{i-1,d}$ corresponds to $TEXT[k+i-2 : k+i+l_{i-1,d}-3, l+i-2 : l+i+l_{i-1,d}-3]$, $L\gamma$ corresponds to $TEXT[k+i-1 : k+i+h-2, l+i-1 : l+i+h-2]$ and it is the analog of $L\alpha$ above. Starting from the extended locus of $Lh_{i-1,d}$ in LT, we first find the contracted locus of $L\gamma$. Here there is also a rescanning phase (similar to the one of §§5 and 6) which is done only when the extended locus of $Lh_{i-1,d}$ is not $root(LT)$, i.e., when both $Lh_{i-1,d}$ and $L\gamma$ are not empty. Then, from the contracted locus of $L\gamma$, we find the rest of $Lh_{i,d}$. This is the scanning phase and it will be much simpler than the one in §§5 and 6 since there is no need to update either LT or any auxiliary data structure.

The procedure that we use to find $Lh_{i,d}$ is a stripped down version of **STI**. It takes in input v, the extended locus of $Lh_{i-1,d}$. For $i = 1$, it takes in input $root(LT)$, which is the extended locus of the empty Lstring $Lh_{0,d}$. Scanning and rescanning are implemented as in **STI**. Therefore, we omit here a detailed discussion of such implementations.

Procedure DSTI—Skeleton iteration *i*

1. If $v = root(LT)$ then $u := root(LT)$ and skip *rescanning*.
2. *Rescanning:* find the contracted locus u of $L\gamma$, given the extended locus $v \neq root(LT)$ of $Lh_{i-1,d}$ and SL for all leaves in LT.
3. *Scanning:* starting from u and skipping $L\gamma$, find the extended locus of $Lh_{i,d}$.

LEMMA 16. *Fix d, $1 \leq |d| < n$. Given the Lstring Lt_d, corresponding to matrix $TEXT[k : k', l : l']$, and LT, the compacted trie over the alphabet $L\Sigma$ representing (as Lstrings) all suffixes of matrices in the dictionary,* **DSTI** *correctly computes $Lh_{i,d}$, for $i = 1 \ldots n - |d|$. It takes $O((n - |d|) \log \hat{n})$ time.*

Proof. The proof of correctness is by induction. It is similar to the proof of correctness reported in Theorem 4 and it is omitted. As for the time analysis, using the techniques of §6, the cost of the ith iteration is bounded by $O((l_i - \min(0, l_{i-1} - 1) + 1) \log \hat{n})$ time. Adding over all iterations, we get the claimed bounds because $l_{1,d} \leq n - |d|$ and $l_{n-|d|,d} \leq 1$. □

10.5. Putting the pieces together. In this subsection we first address the issue on how to compare, in constant time, Lcharacters coming from Lstrings representing suffixes of patterns in the dictionary with Lcharacters coming from Lstrings representing suffixes of $TEXT_d$, $0 \leq |d| < n$. Then we derive the time complexity of the whole search procedure.

Again, we use quadruples to represent chunks coming from Lt_d, $0 \leq |d| < n$. The quadruple (p, q, i, d) represents the chunk $Lsuf_i(Lt_d)[p, q]$. We can recover, in constant time, the starting points in $TEXT$ of an occurrence of any of the Lcharacters from such a chunk. We use the same approach as in §3.2.3, where we have shown how, given a quadruple, we can recover in constant time the starting points in A of an occurrence of any of the Lcharacters from the chunk represented by the quadruple.

In order to achieve the desired time bound to compare two Lcharacters, one coming from Lstrings representing patterns and the other coming from Lstrings representing submatrices of $TEXT$, we need to express the rows (columns, respectively) of $TEXT$ in function of the rows (columns, respectively) of the patterns. Indeed, consider $TEXT[g, f : n]$ ($TEXT[g : n, f]$, respectively). Among the rows (columns, respectively) of the pattern matrices, we compute the subrow (subcolumn, respectively) that has a prefix of maximum length in common with $TEXT[g, f : n]$ ($TEXT[g : n, f]$, respectively). In formulae, we compute a quadruple $(e, \hat{v}, r, j)$ such that $PAT_j[e, \hat{v} : \hat{v} + r - 1]$ ($PAT_j[e : e + r - 1, \hat{v}]$, respectively) is the longest subrow (subcolumn, respectively) of patterns that is a prefix of $TEXT[g, f : n]$ ($TEXT[g : n, f]$, respectively). For each entry (g, f) of $TEXT$, we store such quadruple in an array $WHERER$ ($WHEREC$, respectively). Given that during the preprocessing step we have computed T_{rows} (T_{cols}, respectively), the computation of $WHERER$ ($WHEREC$, respectively) is a standard string matching task [11] and it can be done in $O(n^2 \log |\Sigma|)$ time.

Let us assume that we want to compare the Lcharacter $Lsuf_{i_1}(Lpat_{j_1})[q] = \delta$ with the Lcharacter $Lsuf_i(Lt_d)[q] = \epsilon$. Note that $\delta = \delta_1\delta_2$, where $\delta_1 = PAT_{j_1}[i_1+q-1, i_1 : i_1+q-2]$ and $\delta_2 = PAT_{j_1}[i_1 : i_1 + q - 1, i_1 + q - 1]$. Moreover, $\epsilon = \epsilon_1\epsilon_2$, where $\epsilon_1 = TEXT[k+i+q-2, l+i-1 : l+i+q-3]$ and $\epsilon_2 = TEXT[k+i-1 : k+i+q-2, l+i+q-2]$. Using the table $WHERER$ ($WHEREC$, respectively), we know where the longest prefix ω_1 (ω_2, respectively) of $TEXT[k + i + q - 2 : l + i - 1 : n]$ ($TEXT[k + i - 1 : n, l + i + q - 2]$, respectively) occurs as a subrow (subcolumn, respectively) of some pattern matrix. Say it occurs in position (c_1, c_2) of PAT_r. Using an LCA query involving the leaves of T_{rows} (T_{cols}, respectively) associated with $PAT_r[c_1, c_2 : m_r]$ ($PAT_r[c_1 : m_r, c_2]$, respectively) and $PAT_{j_1}[i_1 + q - 1, i_1 : m_{j_1}]$ ($PAT_{j_1}[i_1 : m_{i_1}, i_1 + q - 1]$, respectively), we can compute in constant time the longest prefix common to ω_1 (ω_2, respectively) and δ_1 (δ_2, respectively). Using such information, we can compute in constant time whether δ_1 (δ_2, respectively) is equal to ϵ_1 (ϵ_2, respectively), therefore establishing, in constant time, whether the two Lcharacters are equal.

In order to find all occurrences of patterns of the dictionary in the text, we first compute the arrays $WHERER$ and $WHEREC$ defined above. This will cost a total of $O(n^2 \log |\Sigma|)$ time. Then we use the algorithm of §10.4 to compute $Lh_{i,d}$, for $i = 1 \ldots n - |d|$ and $0 \leq |d| < n$. Summing the bound of Lemma 16 over all d's, this will cost a total of $O(n^2 \log \hat{n})$ time.

For each $Lh_{i,d}$, we report all occurrences in the corresponding position of $TEXT$ using the procedure of §10.3. Summing the bound of Lemma 15, for $i = 1 \cdots n - |d|$ and $0 \leq |d| < n$, this will cost a total of $O(occ + n^2)$ time, where occ is the number of occurrences of patterns in the text. We obtain the following theorem.

THEOREM 13. *Given LT, the compacted trie representing (as Lstrings) all suffixes of matrices in the dictionary, it takes $O(n^2 \log \hat{n} + occ)$ time to find the occ occurrences of pattern matrices of the dictionary in an $n \times n$ matrix $TEXT$.*

11. Concluding remarks and open problems. We have shown how to efficiently build the Lsuffix tree and its refinement for an $n \times n$ matrix A. We have then discussed applications of this new data structure to the pattern retrieval problem and to dictionary matching. It would be interesting to obtain algorithms for the construction of the Lsuffix tree and of the RLsuffix tree with time complexity linear in the input size. That would provide solutions to the pattern retrieval and dictionary matching problems with time complexities analogous to the ones known for the one-dimensional problems.

Acknowledgments. I would like to thank Brenda Baker for many helpful discussions and comments related to this paper.

EFFICIENT ALGORITHMS FOR THE HITCHCOCK TRANSPORTATION PROBLEM*

TAKESHI TOKUYAMA† AND JUN NAKANO†

Abstract. We consider the Hitchcock transportation problem on n supply points and k demand points when n is much greater than k. The problem can be solved in $O(kn^2 \log n + n^2 \log^2 n)$ time if an efficient minimum-cost flow algorithm is directly applied. Applying a geometric method named *splitter finding* and a randomization technique, we can improve the time complexity when the ratio c of the maximum supply to the minimum supply is sufficiently small. The expected running time of our randomized algorithm is $O(\frac{kn \log cn}{\log(n/k^4 \log^2 k)})$ if $n > k^4 \log^2 k$, and $O(k^5 \log^2 n \log cn)$ if $n \leq k^4 \log^2 k$. If $n = \Omega(k^{4+\epsilon})$ $(\epsilon > 0)$ and $c = \text{poly}(n)$, the problem is solved in $O(kn)$ time, which is optimal.

1. Introduction.

Consider a complete directed bipartite graph $\mathcal{G} = K(n, k)$ with n source nodes $s_1, \ldots, s_n$ and k demand nodes $t_1, \ldots, t_k$. The node s_i has a supply of size ω_i for $i = 1, 2, \ldots, n$, and t_j has a demand of size λ_j for $j = 1, 2, \ldots, k$. Each directed edge (s_i, t_j) has a cost $\alpha_{i,j}$, which is charged for each unit of flow on it. The problem of finding the minimum cost flow from supply points to demand points is called the Hitchcock transportation problem [4]–[6] (Fig. 1.1).

For an intuitive example, imagine a distributed data system with k storage devices D_1, D_2, ..., D_k and n data $z_1, z_2, \ldots, z_n$. The sizes of D_j and z_i are λ_j and ω_i, respectively. Each data is called by processors, and if data z_i is placed in D_j, the (expected) communication time for calling a unit of data z_i is known to be $\alpha_{i,j}$. The problem of finding the allocation of data that minimizes the communication cost is formulated into the Hitchcock transportation problem. The Hitchcock transportation problem can be formulated as an instance of linear programming. Its standard form is as follows:

$$\text{Minimize} \quad \sum_{i=1}^{n} \sum_{j=1}^{k} \alpha_{i,j} y_{i,j} \tag{1.1}$$

subject to

$$\sum_{i=1}^{n} y_{i,j} = \lambda_j \quad (j = 1, 2, \ldots, k), \tag{1.2}$$

$$\sum_{j=1}^{k} y_{i,j} = \omega_i \quad (i = 1, 2, \ldots, n), \tag{1.3}$$

$$y_{i,j} \geq 0 \quad (i = 1, 2, \ldots, n;\ j = 1, 2, \ldots, k). \tag{1.4}$$

Because of the symmetry of the problem, we can assume that $n \geq k$ without loss of generality. The problem is feasible if and only if $\sum_{j=1}^{k} \lambda_j = \sum_{i=1}^{n} \omega_i$. However, we can relax this feasibility condition to $\sum_{j=1}^{k} \lambda_j \leq \sum_{i=1}^{n} \omega_i$ and replace (1.2) with the inequalities

$$\sum_{j=1}^{k} y_{i,j} \leq \omega_i \quad (i = 1, 2, \ldots, n),$$

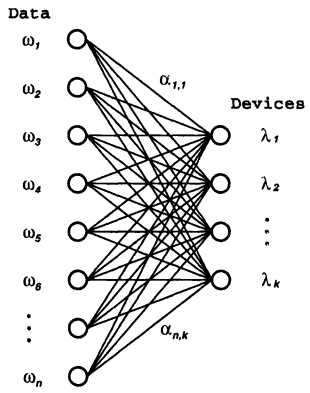

FIG. 1.1. *The Hitchcock transportation problem.*

since the relaxed problem is transformed into the standard form by defining a virtual demand point t_{k+1} such that $\lambda_{k+1} = \sum_{i=1}^{n} \omega_i - \sum_{j=1}^{k} \lambda_j$ and $\alpha_{i,k+1} = 0$ for $i = 1, 2, \ldots, n$.

The Hitchcock transportation problem is a kind of capacitated minimum-cost flow problem, which is known to be soluble in strongly polynomial time [10], [11], [16], [18]. Indeed, the problem is the minimum-cost flow problem on a network with $N = n + k$ nodes and $M = kn$ edges. The best existing algorithm [16] for solving the uncapacitated minimum-cost flow problem is $O(N \log N(M + N \log N))$, which solves the Hitchcock transportation problem in $O(kn^2 \log n + n^2 \log^2 n)$ time if $n \geq k$. This complexity is more than the square of n even if k is very small.

In many applications, the number of supply points (n) is often much greater than that of demand points (k), or vice versa. Indeed, in the example shown above, the number of data is usually much greater than that of devices. Matsui [13] gives a linear-time algorithm for solving the Hitchcock transportation problem with respect to n if k can be considered as a constant. However, the time complexity of his algorithm is $O(n(k!)^2)$ if k is not a constant; thus it is too expensive unless k is extremely small. Recently, Ahuja et al. [1] studied network flow problems in unbalanced bipartite graphs (where $k \ll n$), and obtained an $O(k^2 n \log(nC))$ time algorithm for the Hitchcock transportation problem (where $C = \max\{|\alpha_{i,j}|\}$ is the maximum edge cost of the associated bipartite graph).

If $\omega_i = 1$ for all $i = 1, 2, \ldots, n$, the problem is named the λ-assignment problem. Tokuyama and Nakano [20] gave a geometric approach called *splitter finding* to the λ-assignment problem and solved it in $O(nk + n^{0.5}k^{3.5})$ expected time, which they have recently improved to $O(nk + k^{2.5}n^{0.5} \log^{1.5} n)$ expected time [19].

In this paper, we first give a geometric interpretation of the problem and show that Orlin's algorithm can solve the Hitchcock transportation problem in $O(k^2 n \log^2 n)$ time if it is efficiently implemented. The main result is that if there is a constant c such that $1 \leq \omega_i \leq c$ for $1 \leq i \leq n$, we can design an efficient randomized algorithm with a new pruning technique, whose running time is

$$\begin{cases} O\left(\dfrac{kn \log cn}{\log(n/k^4 \log^2 k)}\right), & \text{when } n > k^4 \log^2 k, \\ O(k^5 \log^2 n \log cn). & \text{when } n \leq k^4 \log^2 k, \end{cases}$$

with a probability larger than $1 - n^{-\gamma}$ for any positive constant γ. If $n = \Omega(k^{4+\epsilon})$ ($\epsilon > 0$) and c is polynomial in n, this algorithm runs in $O(kn)$ time, which is optimal.

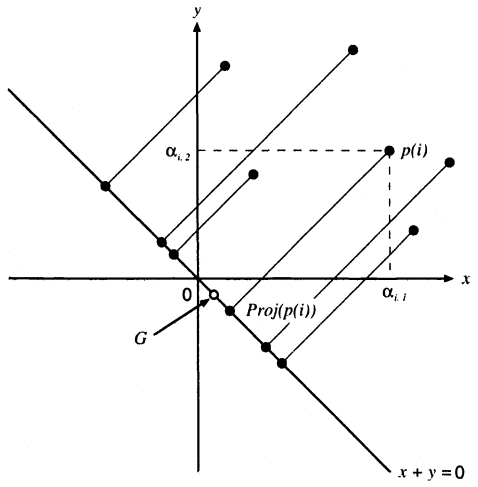

FIG. 2.1. *Geometric transformation in two-dimensional space.*

2. Geometric interpretation. Given a Hitchcock transportation problem defined by (1.1), ..., (1.4), we consider the following geometric model. For each index i ($i = 1, 2, \ldots, n$), we define a point $p(i) = (\alpha_{i,1}, \ldots, \alpha_{i,k})$ in k-dimensional real space $\mathbf{R}^k$. Let $S = \{p(1), p(2), \ldots, p(n)\}$. We call ω_i the *weight* of $p(i)$ (it is often called the *supply* of $p(i)$ in the literature).

In the bipartite graph $\mathcal{G}$, if an amount of ξ out of the weight of the supply node s_i flows on the edge (i, j), we say that a ξ portion of the point $p(i)$ is *assigned* to the jth demand point t_j.

Before dealing with general cases, we first consider the very easy case where $k = 2$ and give an intuition of our idea. If $k = 2$, S is a set of n points on a plane. If a ξ portion of $p(i)$ is assigned to t_1 and $\omega_i - \xi$ portion is assigned to t_2, the cost for the point $p(i)$, which is the sum of the costs on the edges $(i, 1)$ and $(i, 2)$ on $\mathcal{G}$, is $\xi\alpha_{i,1} + (\omega_i - \xi)\alpha_{i,2}$. Therefore, if we increase ξ by a unit size, the cost increases by $\alpha_{i,1} - \alpha_{i,2}$, which we call the *reduced cost* of the edge $(i, 1)$. Hence, the problem is solved by the following way: first we compute the reduced costs of the edge $(i, 1)$ for $i = 1, 2, \ldots, n$. Then, we assign the points to t_1 in smallest-first fashion with respect to the reduced cost until the weight sum becomes λ_1. Then, we assign the other points to t_2. Notice that there is at most one supply node that has positive flows to both t_1 and t_2.

Geometrically, if we project the point $p(i)$ orthogonally on the line $x + y = 0$, we get a point $\text{Proj}(p(i)) = ((\alpha_{i,1} - \alpha_{i,2})/2, (\alpha_{i,2} - \alpha_{i,1})/2)$ (Fig. 2.1). The reduced cost is proportional to the x-coordinate value of $\text{Proj}(p(i))$. We choose a point G on the line $x + y = 0$ such that satisfying the total weight of the points on the left of G is at most λ_1, and that on the right of it is at most λ_2. We call this point the λ-splitter. Hence, the Hitchcock transportation problem is equivalent to the problem of computing the splitter if $k = 2$, which can be solved by the randomized selection algorithm [17].

We generalize the idea to the higher-dimensional case. We project each point $p(i) = (\alpha_{i,1}, \ldots, \alpha_{i,k})$ orthogonally onto the hyperplane L defined by the equation $x_1 + x_2 + \cdots + x_k = 0$ (Fig. 2.2) and let $G = (g_1, g_2, \ldots, g_k)$ be a point on L. For each j ($j = 1, \ldots, k$), a closed region satisfying $x_j - g_j \leq x_h - g_h$ for all $h \neq j$ is called the jth region split by G, which is denoted by $T(G; j)$. The space subdivision of $\mathbf{R}^k$ into $T(G; j)$ ($j = 1, 2, \ldots, k$) is called a *splitting* and G a *splitter* (Fig. 2.3). We project points of S onto L to obtain a point set that is

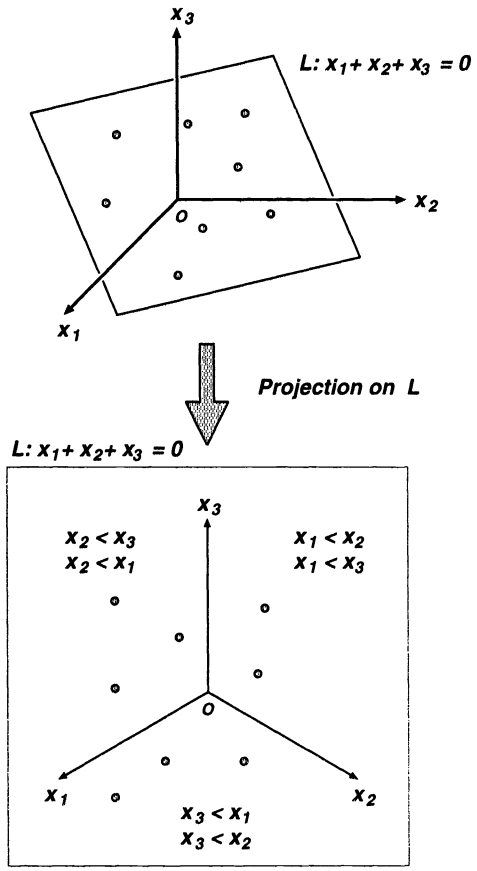

FIG. 2.2. *Geometric transformation in three-dimensional space.*

also denoted by S, but it is clear from the context, otherwise stated. The following theorem was originally proved by Numata and Tokuyama [15].

THEOREM 2.1 (existence of λ-splitter). *There exists a splitter G such that the sum of the weights of the points of S in $\bigcup_{j\in J} T(G; j)$ is greater than or equal to $\sum_{j\in J} \lambda_j$ for any $J \subset \{1, 2, \ldots, k\}$.*

Note that each $T(G; j)$ is a closed region containing its boundary. The splitter G defined in the theorem is called a *λ-splitter* of the point set S. The corresponding splitting is called a λ-splitting, which is a generalization of that given by the authors [20]. In the next section we show how to construct a λ-splitter incrementally.

THEOREM 2.2. *For a λ-splitter $G(g_1, \ldots, g_k)$, the Hitchcock transportation problem has a solution satisfying $y_{i,j} = \omega_i$ if $p(i)$ is in the interior of $T(G; j)$, $y_{i,j} = 0$ if $p(i)$ is outside $T(G; j)$, and $y_{i,j_1} + y_{i,j_2} = \omega_i$ if $p(i)$ is on the boundary between $T(G; j_1)$ and $T(G; j_2)$ (if $p(i)$ is contained in more than two closed regions $T(G; j_t)$ $(t = 1, \ldots, m)$, $\sum_{t=1}^{m} y_{i,j_t} = \omega_i$). Conversely, any solution of the Hitchcock transportation problem satisfies the above condition for a λ-splitter.*

Proof. It is easy to see that if we suitably divide the weights of boundary elements between regions, we can find a solution of (1.2), (1.3), and (1.4) that satisfies the conditions of the theorem. We will show that this solution minimizes the total cost. We define $\beta_{i,j} = \alpha_{i,j} - g_j$ for $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, k$. Since $\sum_{i,j} \beta_{i,j} y_{i,j} = \sum_{i,j} \alpha_{i,j} y_{i,j} - \sum_j \lambda_j g_j$, the

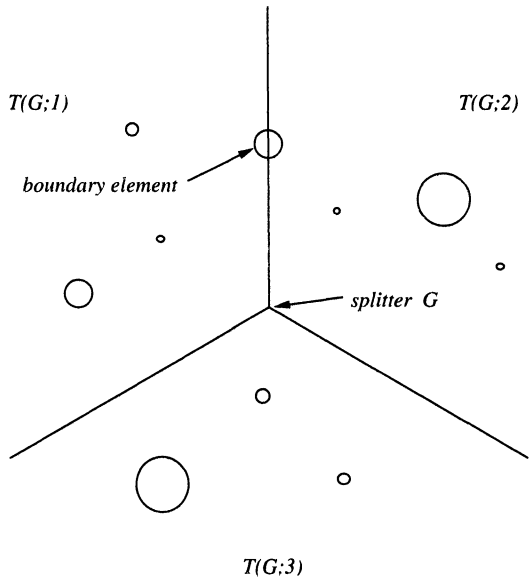

FIG. 2.3. *Splitter and splitting of point set projected onto the plane L ($k = 3$ and the area of each circle pictorially represents the weight of the corresponding point).*

optimal solution does not change if we replace $\alpha_{i,j}$ with $\beta_{i,j}$ for all i and j. In the new problem, the splitter coincides with the origin O. Since the region $T(O; j)$ is defined by $x_j \leq x_h$ for all $h \neq j$, it is clear that the above solution minimizes the total cost. The converse statement is obvious from the above argument. □

For the readers familiar with the linear programming, we note that the splitter can be defined by using the duality of LP and Theorem 2.2 is proved by using the *dual complementary slackness* condition [3], [12], [14]. Indeed, if we introduce variables u_i $(i = 1, 2, \ldots, n)$ and v_j $(j = 1, 2, \ldots, k)$ and define $\tilde{\omega}_{i,j} = \omega_{i,j} - u_i - v_j$, it is easy to see that the solution of the Hitchcock transportation problem is stable if we replace $\omega_{i,j}$ by $\tilde{\omega}_{i,j}$ for all i and j. The dual-complementary slackness condition says that we can choose u_i and v_j suitably so that

$$\tilde{\omega}_{i,j} = \min_{l=1,2,\ldots,k} \{\tilde{\omega}_{i,l}\}, \tag{2.1}$$

if the flow on the edge (i, j) of $\mathcal{G}$ is nonzero. (We omit the proof.) Since equation (2.1) is independent of u_i, we can set $u_i = (1/k) \sum_{j=1}^{k} \omega(i, j)$. Also, we can choose a solution of equation (2.1) satisfying $\sum_{j=1}^{k} v_j = 0$. Then, a solution $(v_1, \ldots, v_k)$ is a splitter, and vice versa. Note that the above fact has been used in the classical method for solving the Hitchcock transportation problem using *transportation tableau* [3], [14], where u_i is chosen as $\min_{j=1,\ldots,k}\{\omega_{i,j} - v_j\}$.

Theorem 2.2 implies that if we find a splitter, we can solve the Hitchcock transportation problem by finding a transportation of the points on the boundaries between regions. We call a λ-splitting a λ-*transportation* if we correctly assign the weights of the boundary elements.

Each region of a splitting has $k - 1$ boundary facets and there are $k(k - 1)/2$ facets in total. We say that S is simple if the number of incidence relations between the boundary facets and points is at most $k - 1$ for any splitter. Since the degree of freedom of G is $k - 1$, we can always make S simple by applying a small perturbation. For example, we may use the SOS system of Edelsbrunner [7]. Furthermore, the algorithm in this paper can be easily applied to

a nonsimple case almost directly without loss of time complexity. Thus, we assume from now on that S is simple.

Although the splitter is not unique, we may make the following observation.

PROPOSITION 2.3. *The solution of the Hitchcock transportation problem is unique if S is simple.*

3. Scaling algorithm. In this section, we give an efficient algorithm based on Orlin's minimum-cost flow algorithm [16]. Ours is an incremental algorithm that uses the scaling method. The main theorem in this section is as follows.

THEOREM 3.1. *The Hitchcock transportation problem is solvable in $O(k^2 n \log^2 n)$ time.*

In the rest of this section, which is devoted to proving the theorem, we assume that the weights are integers. Let the maximum weight be U and define $l = \lfloor \log_2 U \rfloor$. First, we design an $O(k^2 nl \log n)$ time algorithm, which resembles the Edmonds–Karp algorithm [8].

We decompose a point p into at most $l + 1$ points according to the 2-adic (binary) decomposition of its weight ω_p. The newly-created point with a weight 2^h is denoted by $p^{(h)}$ if its origin is the point p. Thus, we have a set $\tilde{S}$ of at most $n(l+1)$ points, each of which has a weight that is a power of 2. For a number a and an integer h, we define $a^{(h)} = 2^h \lfloor a/2^h \rfloor$, and extend this notation to vectors: $\lambda^{(h)} = (\lambda_1^{(h)}, \ldots, \lambda_k^{(h)})$. We thus obtain an incremental algorithm consisting of $l + 1$ stages.

```
HITCHCOCK
1.  G = origin;
2.  W = 0; {W is the total weight of the points inserted so far}
3.  for h = 0 to l;
    begin
3.1.    SPLIT(h, G, W);
    end;
end;
```

```
SPLIT(h, G, W)
1.  L = list of all the points of weight 2^(l-h);
2.  while L is not empty, and W < Σ_{j=1}^{k} λ_j^{(l-h)};
    begin
2.1.    choose a point p from L;
2.2.    add p in the region (say, T(G; s)) containing p in the current splitting;
2.3.    if the total weight assigned to T(G; s) exceeds λ_s^{(l-h)} then
2.3.1       UPDATE(G);
        end if;
2.4.    W = W + 2^(l-h);
    end while;
3.  split each remaining point in L into two points of weight 2^(l-h-1);
4.  return;
end;
```

The subroutine UPDATE(G) updates the current transportation so that no region overflows. Let the current splitter be $G = (g_1, g_2, \ldots, g_k)$. Let γ_j be the total weight currently assigned to $T(G; j)$; that is, G is a γ-splitter of the set of points added so far. Suppose that we are at the hth stage (i.e., executing SPLIT(h, G, W)); a new point is inserted into $T(G; s)$ and UPDATE is called. We say that an element of $T(G; j)$ is a *proper* element if some portion of its weight is assigned to $T(G; j)$ in the current transportation. Clearly, an interior element is a proper element.

We first assume the following two properties and show later that these properties hold throughout the algorithm.

PROPERTY 1. *There exists a region $T(G; t)$ such that $\gamma_t \leq \lambda_t^{(l-h)} - 2^{l-h}$.*

PROPERTY 2. *For each proper element of each region, the portion of its weight assigned to the region is an integer multiple of 2^{l-h}.*

For each ordered pair of two regions $T(G; a)$ and $T(G; b)$, we compute a point $q(a, b)$, which is the nearest proper element in $T(G; a)$ to the boundary between the two regions. Note that $q(a, b)$ may be a boundary element. We construct a complete directed graph $\mathcal{D}$ on the node set $\{v_1, v_2, \ldots, v_k\}$. For each directed edge (v_a, v_b), we give a (nonnegative) length $q(a, b)_b - q(a, b)_a - (g_b - g_a)$, where $q(a, b)_j$ is the jth coordinate value of $q(a, b)$.

Next, if the newly inserted point falls in the region $T(G; s)$, we compute the shortest path tree $\mathcal{T}$ of $\mathcal{D}$ rooted at v_s. Then, a new splitter $G' = (g'_1, \ldots, g'_k)$, which by definition satisfies $\sum_{j=1}^{k} g'_j = 0$, is defined by

$$g'_a - g'_b = q(a, b)_a - q(a, b)_b \tag{3.1}$$

for all pairs (a, b) such that (v_a, v_b) is a directed edge in the shortest path tree $\mathcal{T}$.

Since there are $k - 1$ adjacent relations in the tree, G' is uniquely determined. The following is a key lemma.

LEMMA 3.2. *A proper element of $T(G; j)$ is in $T(G'; j)$.*

Proof. Consider a point $x = (x_1, \ldots, x_k)$ located in the region $T(G; a)$. What we have to prove is that $x_a - x_b \leq q(a, b)_a - q(a, b)_b$ (for $b \neq a$) implies $x_a - x_b \leq g'_a - g'_b$, or $g'_a - g'_b \geq q(a, b)_a - q(a, b)_b$. If the edge (v_a, v_b) is in the shortest path tree $\mathcal{T}$, the claim is obvious from (3.1). If $(v_a, v_b) \notin \mathcal{T}$, we have $\text{dist}(s, b) \leq \text{dist}(s, a) + \text{length}(a, b)$, where $\text{dist}(s, a)$ denotes the distance from the root v_s to the node v_a in $\mathcal{T}$. Since for an edge $(v_i, v_j) \in \mathcal{T}$, $\text{length}(i, j) = q(i, j)_j - q(i, j)_i - (g_j - g_i) = g'_j - g'_i - (g_j - g_i)$, we obtain $\text{length}(a, b) \geq \text{dist}(s, b) - \text{dist}(s, a) = g'_b - g'_a - (g_b - g_a)$, that is, $g'_a - g'_b \geq q(a, b)_a - q(a, b)_b$. □

From this lemma, we are assured that we can find G' by translating the boundary facets without moving across any points in the current splitting as in Fig. 3.1.

COROLLARY 3.3. *G' is a γ-splitter of the point set before insertion.*

We will show that there is such a transportation after the insertion that the weight assigned to $T(G; t)$ is $\gamma_t + 2^{l-h}$ for some region satisfying Property 1 and that the weight assigned to $T(G; j)$ is γ_j for $j \neq t$.

We consider the shortest path from v_s to v_t, and push a flow of size 2^{l-h} along it. From the definition of G', if the flow is pushed from v_a to the adjacent node v_b, there exists a proper boundary element of $T(G'; a)$ on the boundary between $T(G'; a)$ and $T(G'; b)$. From Property 2, we can move 2^{l-h} of the weight of the boundary element from $T(G'; a)$ to $T(G'; b)$. Thus, we can push the weight successively according to the shortest path so that the weight of $T(G; s)$ is diminished by 2^{l-h} and that of $T(G; t)$ is increased by 2^{l-h}.

Hence, we can update the transportation so that no region overflows if Properties 1 and 2 hold throughout the algorithm.

CLAIM 3.4. *Property 1 and Property 2 hold throughout the algorithm.*

Proof. Obviously, these properties hold initially. If Property 2 holds in one stage of HITCHCOCK (i.e., for some h in step 3), then it clearly holds in the next stage. Thus, it suffices to show that update procedure UPDATE(G) preserves Property 2. Since the weight of a point assigned to a region is changed by 2^{l-h}, UPDATE(G) preserves Property 2.

Because of the weight check in step 2 of SPLIT(h, G, W), the total weight assigned so far is less than $\sum_{j=1}^{k} \lambda_j^{(l-h)}$, and thus less than or equal to $(\sum_{j=1}^{k} \lambda_j^{(l-h)}) - 2^{l-h}$. Thus, Property 1 follows Property 2. □

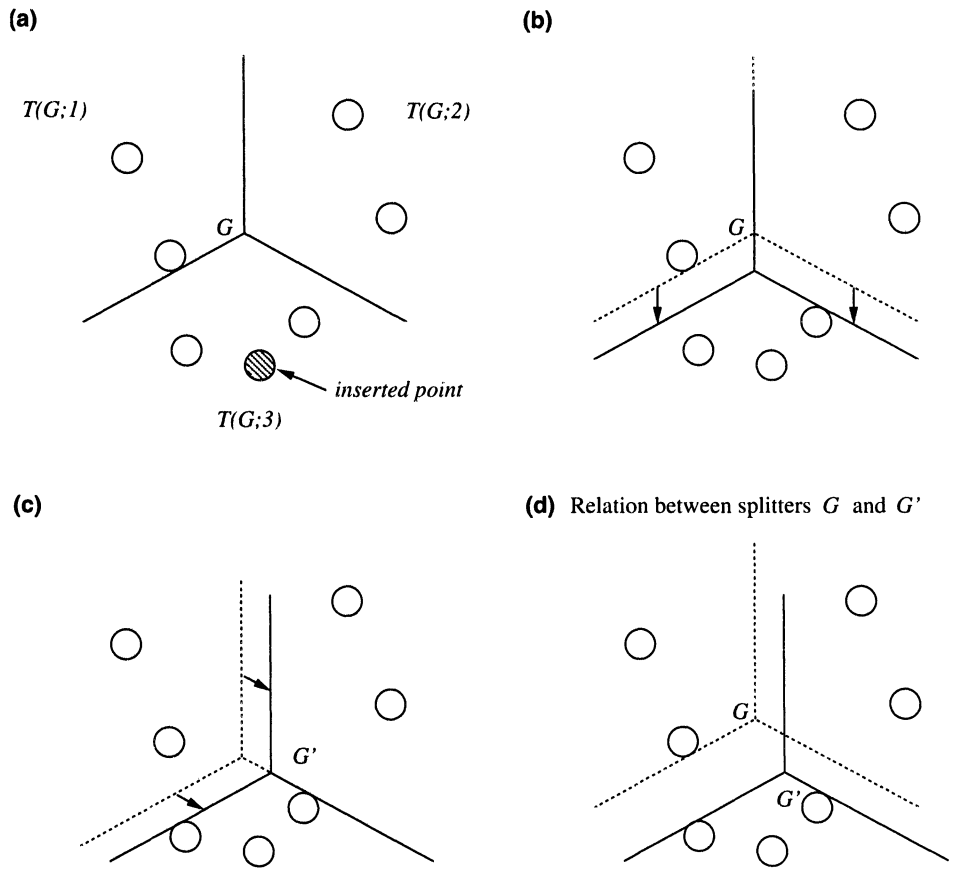

FIG. 3.1. *Update of the splitter.*

Therefore, the algorithm correctly solves the transportation problem.

PROPOSITION 3.5. *The scaling algorithm solves the Hitchcock transportation problem in* $O(k^2 nl \log n)$ *time and* $O(kn)$ *space.*

Proof. Let $G = (g_1, g_2, \ldots, g_k)$ be the current splitter. When a point $p = (p_1, p_2, \ldots, p_k)$ is inserted, we find an index s such that $p_s - g_s = \min_j\{p_j - g_j\}$. Then, it is easy to see that p is contained in $T(G; s)$. This operation requires $O(k)$ time. When UPDATE is called, we must find $k(k-1)$ points $\{q(a, b) \mid a, b = 1, 2, \ldots, k;\ a \neq b\}$. If we provide $k(k-1)$ priority queues, these points can be found in $O(k^2 \log n)$ time. The storage needed for these priority queues is $O(kn)$, and thus is asymptotically not more than the input size. The time complexity for computing the shortest path tree of $\mathcal{D}$ is $O(k^2)$. Thus, the overall complexity for an insertion is $O(k^2 \log n)$. During each stage, at most k points are split. In consequence, the total number of insertions is not more than $n(l+1) + kl$. Thus, the proposition is proven. □

The above algorithm is not strongly polynomial. To make it strongly polynomial, we apply Orlin's contraction technique [16]. We consider a point p in S with a weight ω. Suppose that p is decomposed into $\mathcal{P} = \{p^{(h)} \mid h \subset \{0, 1, \ldots, l\}\}$ of $\tilde{S}$. Instead of adding all portions of p in the procedure HITCHCOCK, we only take the first $\lceil \log_2 8nk \rceil$ largest portions of $\mathcal{P}$ for the input. We contract the other small portions to a point $\mathrm{cont}(p)$.

Suppose we have just inserted all portions of p except $\mathrm{cont}(p)$. The size of each point which is or will be inserted during the current stage is at most $\omega/8nk$. Thus, the total weight

of the remaining points of $\tilde{S}$ is at most $n(1 + 1/2 + 1/4 + \cdots)\omega/8nk < \omega/4k$ after this stage has been completed.

Since at least $(1 - \frac{1}{4nk})\omega$ of the weight of p has been inserted at the end of the current stage, there exists a region (which we denote as the $f(p)$th region) to which at least $\omega/2k$ of the weight of p is assigned. Thus, the portion of p assigned to the $f(p)$th region is greater than twice of the total weight of the remaining points and we obtain the following claim.

CLAIM 3.6. *In the final splitting, at least $\omega/4k$ of the weight of p is assigned to the $f(p)$th region.*

Using the above claim, we modify the algorithm as follows. When the first $\lceil \log 8nk \rceil$ portions of a point p have been inserted (we denote the current grain size by 2^{l-h}), we assign $\mathrm{cont}(p)$ to the $f(p)$th region just after the insertion. Let $w(\mathrm{cont}(p))$ be the weight of the contracted portion. Apparently, $w(\mathrm{cont}(p)) < 2^{l-h}$. The assignment of $\mathrm{cont}(p)$ to $f(p)$ is algorithmically done by simply replacing $\lambda_{f(p)}$ by $\lambda_{f(p)} - w(\mathrm{cont}(p))$. Since the 2-adic expansion of $\lambda_{f(p)}$ is changed, it may happen that the $f(p)$th region overflows by 2^{l-h} after this replacement. In this case, we remove a 2^{l-h} portion of an arbitrary point in the $f(p)$th region, put it in L, and go to step 2 of SPLIT(j, G, W).

Although we have modified the algorithm as above, Properties 1 and 2 both hold. The modified algorithm outputs a splitter of the points, each of which has a weight smaller than the original weight by the weight of the contracted portion. The demands λ_j ($j = 1, 2, \ldots, k$) are also modified during the algorithm. The contracted portion $\mathrm{cont}(p)$ is assigned to $f(p)$ for each point p. It remains to show that the assignment of $\mathrm{cont}(p)$ to $f(p)$ does not contradict to the splitter output by the algorithm, which follows immediately from Claim 3.6. Hence, the algorithm correctly computes the transportation.

We have reduced the number of insertions from $O(nl)$ to $O(n \log nk)$. Note that although we use the 2-adic expansions of ω_i and λ_j, it is easy to see that it suffices to compute their first $O(\log n)$ terms. Hence, we obtain Theorem 3.1.

We remark that the expected performance of the algorithm is much better than its worst case complexity, since the number of updates of the splitter is usually much smaller than that of insertions. An insertion without updating of the splitter is done in $O(k)$ amortized time if we use Fibonacci heaps [9] as priority queues in the algorithm.

4. Randomized algorithms for the c-grained case.

4.1. Simple randomized algorithm for small c. The scaling algorithm solves the Hitchcock transportation problem in $O(k^2 n \log^2 n)$ time. However, in the special case where $\omega_i = 1$ for $i = 1, 2, \ldots, n$, the problem is known to be solvable in $O(kn + k^{2.5} n^{0.5} \log^{1.5} n)$ time by a randomized algorithm [20], [19].

Let us try to use a randomization technique under more relaxed conditions.

DEFINITION 4.1. *A Hitchcock transportation problem is called c-grained for a constant $c \geq 1$ if $1 \leq \omega_i \leq c$ for all $1 \leq i \leq n$. Here, ω_i $(1 \leq i \leq n)$ are real numbers.*

In this section, we show that if $n > c^2 k^4 \log ck$, we can improve the performance of the algorithm by pruning points using random sampling for a c-grained transportation problem.

THEOREM 4.2. *The c-grained Hitchcock transportation problem is solvable in $O(nk + c^{2/3} n^{2/3} k^{10/3} \log^{7/3} n)$ time with a probability larger than $1 - n^{-\gamma}$ for any constant γ.*

In particular, if $n > c^2 k^7 \log^7 ck$, the problem can be solved in the optimal $O(nk)$ time. Note that we can often decompose some heavily weighted points into lighter weighted ones to reduce c. Furthermore, we will see in the next section that it does not matter if there are a small number of points whose weights are less than 1.

Let S_0 be a subset of S consisting of m points chosen uniformly at random from S. Let G be the λ-splitter that we want to find.

LEMMA 4.3. *The total weight of the points of S_0 located in $T(G; j)$ is less than $\frac{m\lambda_j}{n} + \sqrt{rcm\lambda_j/n}$ with a probability larger than $1 - e^{-r/4}$.*

Proof. A random variable X denotes the sum of the weight of points of S_0 located in $T(G; j)$. We define a random variable $X(p)$ as follows. If the point p is in $T(G; j)$, then $X(p) = \omega(p)$ (the weight of the point), otherwise $X(p) = 0$. Thus, the expected value of X is

$$\mathrm{E}[X] = \sum_{p \in S_0} \mathrm{E}[X(p)] = m\left(\frac{1}{n} \sum_{p \in T(G;j)} \omega(p)\right) = \frac{m\lambda_j}{n}.$$

Here, for a c-grained case, the following Chernoff-like bounds hold (see the appendix for proof):

$$(4.1) \quad \begin{cases} \Pr\bigl(X > (1+\delta)\mathrm{E}[X]\bigr) < \exp\{-\mathrm{E}[X]\delta^2/4c\} & (0 < \delta \leq 4.1)\,, \\ \Pr\bigl(X < (1-\delta)\mathrm{E}[X]\bigr) < \exp\{-\mathrm{E}[X]\delta^2/2c\} & (0 < \delta < 1)\,. \end{cases}$$

The lemma is easily derived from them. □

Let $\Lambda = \sum_{j=1}^{k} \lambda_j$ and let W be the total weight of points in S_0. Then, the following corollary holds.

COROLLARY 4.4. *With a probability larger than $1 - e^{-m\Lambda\delta^2/4cn}$,*

$$W > (1-\delta)\frac{m\Lambda}{n}.$$

Here, we choose $\delta = \sqrt{rcn/m\Lambda}$, which gives a probability of $1 - e^{-r/4}$ in the above corollary, and hereafter we consider only the case where $\delta < 1$.

We define a vector $\mu(1) = (\mu(1)_1, \ldots, \mu(1)_k)$ as follows:

$$(4.2) \quad \mu(1)_j = \begin{cases} \dfrac{\lambda_j W}{\Lambda} + \sqrt{\dfrac{rcm\lambda_j}{n}} & \text{for } j \neq 1\,, \\ \dfrac{\lambda_1 W}{\Lambda} - \displaystyle\sum_{i=2}^{k} \sqrt{\dfrac{rcm\lambda_i}{n}} & \text{for } j = 1\,. \end{cases}$$

We calculate the $\mu(1)$-splitter $G(1)$ of S_0, which satisfies the following lemma.

LEMMA 4.5. *The probability that $G(1)$ is located in $T(G; 1)$ is greater than $1-(k-1)e^{-r/4}$.*

Proof. If $G(1)$ is located in the interior of $T(G; j)$ for $j \neq 1$, then all the points in $T(G(1); j)$ are also in $T(G; j)$. Thus, there are more than $\mu(1)_j$ points in $T(G; j)$ in this case, which can occur with a probability less than $e^{-r/4}$, as the previous lemma shows. □

COROLLARY 4.6. *The probability that all the points of S in the interior of $T(G(1); 1)$ lie in the interior of $T(G; 1)$ is greater than $1 - (k-1)e^{-r/4}$.*

For i $(i = 2, 3, \ldots, k)$, we have a slightly different definition of vectors $\mu(i)$:

$$(4.3) \quad \mu(i)_j = \begin{cases} \dfrac{\lambda_j W}{\Lambda} + \Delta_j & \text{for } j \neq i\,. \\ \dfrac{\lambda_i W}{\Lambda} - \displaystyle\sum_{1 \leq \ell \leq k, \ell \neq i} \Delta_\ell & \text{for } j = i\,, \end{cases}$$

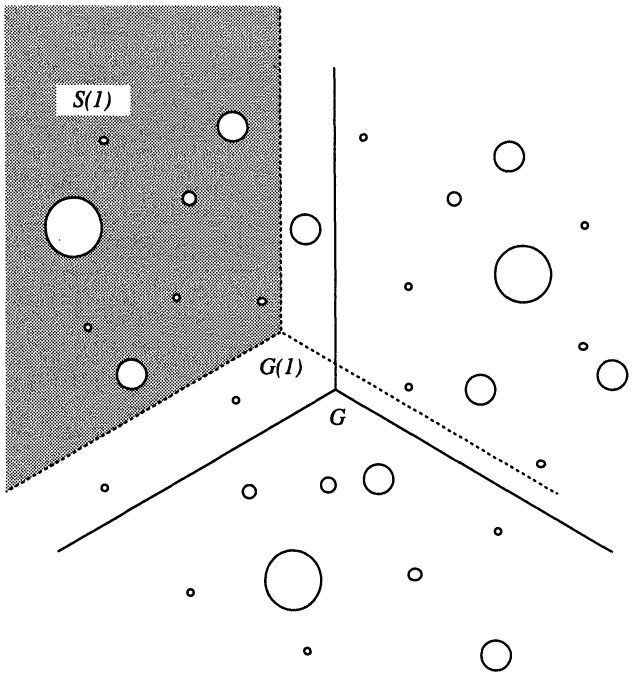

FIG. 4.1. *The set* $S(1)$.

where $\Delta_j = \sqrt{rcm\lambda_j/n} + \epsilon$. Let $G(i)$ be the associated splitter of S_0 with $\mu(i)$. Here, we introduce an arbitrary small real number $\epsilon > 0$ to obtain the following lemma.

LEMMA 4.7. *For all* i $(i = 2, 3, \ldots, k)$, *the splitter* $G(i)$ *is contained in* $T(G(1); i)$.

Proof. Suppose that $G(i) \subset T(G(1); j)$ for some i $(2 \leq i \leq k)$ and $j \neq i$. Obviously, $j \neq 1$ (that is, $T(G(i); 1) \not\subset T(G(1); 1)$), because $\mu(i)_1 > \frac{\lambda_1 W}{\Lambda} > \mu(1)_1$. For $j \neq 1$, since $\mu(i)_j = \mu(1)_j + \epsilon$, the property that $T(G(i); j) \subset T(G(1); j)$ leads to a contradiction. Thus, $G(i) \subset T(G(1); i)$. □

Now, let $S(i)$ $(i = 1, 2, \ldots, k)$ be the set of points of S located in $T(G(i); i)$ (Fig. 4.1) and let ν_i be the total weight of points of $S(i)$. The expected value of ν_1 is

$$\mathrm{E}[\nu_1] = \frac{n}{m}\left(\frac{\lambda_1}{\Lambda}\mathrm{E}[W] - \sum_{i=2}^{k}\sqrt{\frac{rcm\lambda_i}{n}}\right) = \lambda_1 - \frac{n}{m}\sum_{i=2}^{k}\sqrt{\frac{rcm\lambda_i}{n}},$$

and ν_1 is more than

$$\mathrm{E}[\nu_1] - \frac{n}{m}\left(\frac{\lambda_1}{\Lambda}\frac{m\Lambda}{n}\delta + \sqrt{\frac{crm\lambda_1}{n}}\right) \geq \lambda_1 - cn\sqrt{\frac{rk}{m}}, \tag{4.4}$$

with a probability greater than $1 - ke^{-r/4}$ (see Corollaries 4.4 and 4.6). Similarly, we can estimate ν_i for $i = 2, \ldots, k$.

Let us describe a simple randomized algorithm. Choose a sample of size m, set $r = \log k + \gamma \log n$ for a constant γ, and calculate $G(1), \ldots, G(k)$ using the scaling algorithm. For each point p of S, we find a region containing p in the splitting with respect to $G(1)$. If it happens to be in $T(G(1); 1)$, p is a point of $S(1)$. If it is in $T(G(1); i)$ and $i \neq 1$, we check whether it is contained in $T(G(i); i)$. This operation needs $O(k)$ time for each point (from Lemma 4.7).

Now we define a set $\bar{S} = S - \cup_{i=1}^{k} S(i)$ and let $\xi = \lambda - \nu$.

PROPOSITION 4.8. *A ξ-splitter of $\bar{S}$ is a λ-splitter of S with a probability larger than $1 - ke^{-r}$.*

Thus, we can find the λ-splitter of S using the scaling algorithm to compute the ξ-splitter of $\bar{S}$.

Let us analyze the complexity of the algorithm. The probability $1-ke^{-r}$ becomes $1-n^{-\gamma}$, since we choose $r = \log k + \gamma \log n$. Since the weight of points in $\bar{S}$ is $O(ckn\sqrt{rk/m})$, the number of points in $\bar{S}$ is also bounded by $O(ckn\sqrt{rk/m})$. Thus, it takes $O(k^2 \log^2 n(ckn\sqrt{kr/m}))$ time to compute the splitter of $\bar{S}$. On the other hand, it takes $O(k^3 m \log^2 m)$ time for the scaling algorithm to compute k splitters of the sample points. If we set $m = c^{2/3} r^{1/3} k^{4/3} n^{2/3}$, we obtain Theorem 4.2, and for this choice of m, the constraint $\delta < 1$ becomes $c < k^4 \Lambda^3 / n \log^2 n$, which is always satisfied in the c-grained case.
