ASYMPTOTIC CONDITIONAL PROBABILITIES: THE UNARY CASE*

ADAM J. GROVE[†], JOSEPH Y. HALPERN[‡], AND DAPHNE KOLLER[§]

Abstract. Motivated by problems that arise in computing *degrees of belief*, we consider the problem of computing asymptotic conditional probabilities for first-order sentences. Given first-order sentences φ and θ, we consider the structures with domain $\{1, \ldots, N\}$ that satisfy θ, and compute the fraction of them in which φ is true. We then consider what happens to this fraction as N gets large. This extends the work on 0-1 laws that considers the limiting probability of first-order sentences, by considering asymptotic *conditional* probabilities. As shown by Līogon'kīĭ [*Math. Notes Acad. USSR*, 6 (1969), pp. 856–861] and by Grove, Halpern, and Koller [*Res. Rep.* RJ 9564, IBM Almaden Research Center, San Jose, CA, 1993], in the general case, asymptotic conditional probabilities do not always exist, and most questions relating to this issue are highly undecidable. These results, however, all depend on the assumption that θ can use a nonunary predicate symbol. Līogon'kīĭ [*Math. Notes Acad. USSR*, 6 (1969), pp. 856–861] shows that if we condition on formulas θ involving unary predicate symbols only (but no equality or constant symbols), then the asymptotic conditional probability does exist and can be effectively computed. This is the case even if we place no corresponding restrictions on φ. We extend this result here to the case where θ involves equality and constants. We show that the complexity of computing the limit depends on various factors, such as the depth of quantifier nesting, or whether the vocabulary is finite or infinite. We completely characterize the complexity of the problem in the different cases, and show related results for the associated approximation problem.

1. Introduction.

Suppose we have a sentence θ expressing facts that are known to be true, and another sentence φ whose truth is uncertain. Our knowledge θ is often insufficient to determine the truth of φ: both φ and its negation may be consistent with θ. In such cases, it can be useful to assign a *probability* to φ given θ. In a companion paper [23], we described our motivation for investigating this idea, and presented our general approach. We repeat some of this material below, to provide the setting for the results of this paper.

One important application of assigning probabilities to sentences—indeed, the one that has provided most of our motivation—is in the domain of decision theory and artificial intelligence. Consider an agent (or expert system) whose knowledge consists of some facts θ, who would like to assign a *degree of belief* to a particular statement φ. For example, a doctor may want to assign a degree of belief to the hypothesis that a patient has a particular illness, based on the symptoms exhibited by the patient together with general information about symptoms and diseases. Since the actions the agent takes may depend crucially on this value, we would like techniques for computing degrees of belief in a principled manner.

The difficulty of defining a principled technique for computing the probability of φ given θ, and then actually computing that probability, depends in part on the language and logic being considered. In decision theory, applications often demand the ability to express statistical knowledge (for instance, correlations between symptoms and diseases) as well as first-order

knowledge. Work in the field of 0-1 *laws* (which, as discussed below, is closely related to our own) has examined some higher-order logics as well as first-order logic. Nevertheless, the pure first-order case is still difficult, and is important because it provides a foundation for all extensions. In this paper and in [23] we address the problem of computing conditional probabilities in the first-order case. In a related paper [22], we consider the case of a first-order logic augmented with statistical knowledge.

The general problem of assigning probabilities to first-order sentences has been well studied (cf. [15] and [16]). In this paper, we investigate two specific formalisms for computing probabilities, based on the same basic approach. Our approach is itself an instance of a much older idea, known as *the principle of insufficient reason* [28] or *the principle of indifference* [26]. This states that all possibilities should be given equal probability, and was once regarded as one of the most basic principles of probability theory. (See [24] for a discussion of the history of the principle.) We use this idea to assign equal degrees of belief to all basic "situations" consistent with the known facts. The two formalisms we consider differ only in how they interpret "situation." We discuss this in more detail below.

In many applications, including the one of most interest to us, it makes sense to consider finite domains only. In fact, the case of most interest to us is the behavior of the formulas φ and θ over large finite domains. Similar questions also arise in the area of 0-1 *laws*. Our approach essentially generalizes the methods used in the work on 0-1 laws for first-order logic to the case of conditional probabilities. (See Compton's overview [8] for an introduction to this work.) Assume, without loss of generality, that the domain is $\{1, \ldots, N\}$ for some natural number N. As we said above, we consider two notions of "situation." In the *random-worlds method*, the possible situations are all the worlds, or first-order models, with domain $\{1, \ldots, N\}$ that satisfy the constraints θ. Based on the principle of indifference, we assume that all worlds are equally likely. To assign a probability to φ, we therefore simply compute the fraction of them in which the sentence φ is true. The random-worlds approach views each individual in $\{1, \ldots, N\}$ as having a distinct name (even though the name may not correspond to any constant in the vocabulary). Thus, two worlds that are isomorphic with respect to the symbols in the vocabulary are still treated as distinct situations. In some cases, however, we may believe that all relevant distinctions are captured by our vocabulary, and that isomorphic worlds are not truly distinct. The *random-structures method* attempts to capture this intuition by considering a situation to be a *structure*—an *isomorphism class* of worlds. This corresponds to assuming that individuals are distinguishable only if they differ with respect to properties definable by the language. As before, we assign a probability to φ by computing the fraction of the structures that satisfy φ among those structures that satisfy θ.[1]

Since we are computing probabilities over finite models, we have assumed that the domain is $\{1, \ldots, N\}$ for some N. However, we often do not know the precise domain size N. In many cases, we know only that N is large. We therefore estimate the probability of φ given θ by the asymptotic limit, as N grows to infinity, of this probability over models of size N.

Precisely the same definitions of asymptotic probability are used in the context of 0-1 laws for first-order logic, but without allowing prior information θ. The original 0-1 law, proved independently by Glebskiĭ et al. [18] and Fagin [13], states that the asymptotic probability of any first-order sentence φ with no constant or function symbols is either 0 or 1. This means that such a sentence is true in almost all finite structures, or in almost none.

[1] The random-worlds method considers what has been called in the literature *labeled* structures, while the random-structures method considers *unlabeled* structures [8]. We choose to use our own terminology for the random-worlds and random-structures methods, rather than the terminology of labeled and unlabeled. This is partly because we feel it is more descriptive, and partly because there are other variants of the approach that are useful for our intended application, and that do not fit into the standard labeled/unlabeled structures dichotomy (see [2]).

Our work differs from the original work on 0-1 laws in two respects. The first is relatively minor: we need to allow the use of constant symbols in φ, as they are necessary when discussing individuals (such as patients). Although this is a minor change, it is worth observing that it has a significant impact. It is easy to see that once we allow constant symbols, the asymptotic probability of a sentence φ is no longer either 0 or 1; for example, the asymptotic probability of $P(c)$ is $\frac{1}{2}$. Moreover, once we allow constant symbols, the asymptotic probability under random worlds and under random structures need not be the same. The more significant difference, however, is that we are interested in the asymptotic *conditional* probability of φ, given some prior knowledge θ. That is, we want the probability of φ over the class of finite structures defined by θ.

Some work has already been done on aspects of this question. Līogon'kiĭ [31], and independently Fagin [13], showed that asymptotic conditional probabilities do not necessarily converge to any limit. Subsequently, 0-1 laws were proved for special classes of first-order structures (such as graphs, tournaments, partial orders, etc.; see the overview paper [8] for details and further references). In many cases, the classes considered could be defined in terms of first-order constraints. Thus, these results can be viewed as special cases of the problem that we are interested in: computing asymptotic *conditional* probabilities relative to structures satisfying the constraints of a database. Lynch [32] showed that, for the random-worlds method, asymptotic probabilities exist for first-order sentences involving unary functions, although there is no 0-1 law. (Recall that the original 0-1 result is specifically for first-order logic *without* function symbols.) This can also be viewed as a special case of an asymptotic conditional probability for first-order logic without functions, since we can replace the unary functions by binary predicates, and condition on the fact that they are functions.

The most comprehensive work on this problem is the work of Līogon'kiĭ [31].[2] In addition to pointing out that asymptotic conditional probabilities do not exist in general, he shows that it is undecidable whether such a probability exists. (We generalize Līogon'kiĭ's results for this case in [23].) He then investigates the special case of conditioning on formulas involving unary predicates only (but no constants or equality). In this case, he proves that the asymptotic conditional probability does exist and can be effectively computed, even if the left side of the conditional, φ, has predicates of arbitrary arity and equality. This gap between unary predicates and binary predicates is somewhat reminiscent of the fact that first-order logic over a vocabulary with only unary predicates (and constant symbols) is decidable, while if we allow even a single binary predicate symbol, then it becomes undecidable [11], [29]. This similarity is not coincidental; some of the techniques used to show that first-order logic over a vocabulary with unary predicate symbols is decidable are used by us to show that asymptotic conditional probabilities exist.

In this paper, we extend the results of Līogon'kiĭ [31] for the unary case. We first prove (in §3) that, if we condition on a formula involving only unary predicates, constants, and equality that is satisfiable in arbitrarily large models, the asymptotic conditional probability exists. We also present an algorithm for computing this limit. The main idea we use is the following: to compute the asymptotic conditional probability of φ given θ, we examine the behavior of φ in finite models of θ. It turns out that we can partition the models of θ into a finite collection of classes, such that φ behaves *uniformly* in any individual class. By this we mean that almost all worlds in the class satisfy φ or almost none do; i.e., there is a 0-1 law for the asymptotic probability of φ when we restrict attention to models in a single class. In §3 we define these classes and prove the existence of a 0-1 law within each class. We also

[2] In an earlier version of this paper [21], we stated that, to our knowledge, no work had been done on the general problem of asymptotic conditional probabilities. We thank Moshe Vardi for pointing out to us the work of Līogon'kiĭ [31].

TABLE 1
Complexity of asymptotic conditional probabilities.

Existence	NP-complete	NEXPTIME-complete	NEXPTIME-complete
Compute	#P/PSPACE	#EXP-complete	#TA(EXP,LIN)-complete
Approximate	(co-)NP-hard	(co-)NEXPTIME-hard	TA(EXP,LIN)-hard

show how the asymptotic conditional probability of φ given θ can be computed using these 0-1 probabilities.

In §4 we turn our attention to the complexity of computing the asymptotic probability in this case. Our results, which are the same for random worlds and random structures, depend on several factors: whether the vocabulary is finite or infinite, whether there is a bound on the depth of quantifier nesting, whether equality is used in θ, whether nonunary predicates are used, and whether there is a bound on predicate arities. For a fixed and finite vocabulary, there are just two cases: if there is no bound on the depth of quantifier nesting then computing asymptotic conditional probabilities is PSPACE-complete, otherwise the computation can be done in linear time. The case in which the vocabulary is not fixed (which is the case more typically considered in complexity theory) is more complex. The results for this case are summarized in Table 1. Perhaps the most interesting aspect of this table is the factors that cause the difference in complexity between #EXP and #TA(EXP,LIN) (where #TA(EXP,LIN) is the counting class corresponding to alternating Turing machines that take exponential time and make only a linear number of alternations; a formal definition is provided in §4.5). If we allow the use of equality in θ, then we need to restrict both φ and θ to using only unary predicates to get the #EXP upper bound. On the other hand, if θ does not mention equality, then the #EXP upper bound is attained as long as there is some fixed bound on the arity of the predicates appearing in φ. If we have no bound on the arity of the predicates that appear in φ, or if we allow equality in θ and predicates of arity 2 in φ, then the #EXP upper bound no longer holds, and we move to #TA(EXP,LIN).

Our results showing that computing the asymptotic probability is hard can be extended to show that finding a nontrivial estimate of the probability (i.e., deciding if it lies in a nontrivial interval) is almost as difficult. The lower bounds for the arity-bounded case and the general case require formulas of quantification depth 2 or more. For unquantified sentences or depth-1 quantification, things seem to become an exponential factor easier. We do not have tight bounds for the complexity of computing the degree of belief in this case; we have a #P lower bound and a PSPACE upper bound. The results for depth 1 are not proved in this paper; see [27] for details.

We observe that apart from our precise classification of the complexity of these problems, our analysis provides an effective algorithm for computing the asymptotic conditional probability. The complexity of this algorithm is, in general, double-exponential in the number of unary predicates used and in the maximum arity of any predicate symbol used; it is exponential in the overall size of the vocabulary and in the lengths of φ and θ.

Our results are of more than purely technical interest. The random-worlds method is of considerable theoretical and practical importance. We have already mentioned its relevance to computing degrees of belief. There are well-known results from physics that show the close connection between the random-worlds method and *maximum entropy* [25]. These results say that in certain cases the asymptotic probability can be computed using maximum entropy methods. Some formalization of similar results, but in a framework that is close to that of the current paper, can be found in [33] and [22]. (These results are of far more interest when there are statistical assertions in the language, so we do not discuss them here.)

As we observe in [23] and [22], this connection relies on the fact that we are conditioning on a unary formula. In fact, in almost all applications where maximum entropy has been used (and where its application can be best justified in terms of the random-worlds method) the knowledge base is described in terms of unary predicates (or, equivalently, unary functions with a finite range). For example, in physics applications we are interested in such predicates as quantum state (see [10]). Similarly, AI applications and expert systems typically use only unary predicates [7] such as symptoms and diseases. In general, many properties of interest can be expressed using unary predicates, since they express properties of individuals. Indeed, a good case can be made that statisticians tend to reformulate all problems in terms of unary predicates, since an event in a sample space can be identified with a unary predicate [36]. Indeed, in most cases where statistics are used, we have a basic unit in mind (an individual, a family, a household, etc.), and the properties (predicates) we consider are typically relative to a single unit (i.e., unary predicates). Thus, results concerning computing the asymptotic conditional probability if we condition on unary formulas are significant in practice.

2. Definitions. Let Φ be a set of predicate and function symbols, and let $\mathcal{L}(\Phi)$ (resp., $\mathcal{L}^-(\Phi)$) denote the set of first-order sentences over Φ with equality (resp., without equality). To simplify the presentation, we begin by assuming that Φ is finite; the case of an infinite vocabulary is deferred to §2.3. Much of the material in §§2.1 and 2.2 is taken from [23].

2.1. The random-worlds method. We begin by defining the random-worlds, or labeled, method. Given a sentence $\xi \in \mathcal{L}(\Phi)$, let $\#world_N^{\Phi}(\xi)$ be the number of worlds, or first-order models, of ξ over Φ with domain $\{1, \ldots, N\}$. Note that the assumption that Φ is finite is necessary for $\#world_N^{\Phi}(\xi)$ to be well defined. Define

$$\Pr_N^{w,\Phi}(\varphi \mid \theta) = \frac{\#world_N^{\Phi}(\varphi \wedge \theta)}{\#world_N^{\Phi}(\theta)} .$$

In [23], we proved the following proposition.

PROPOSITION 2.1. *Let Φ, Φ' be finite vocabularies, and let φ, θ be sentences in both $\mathcal{L}(\Phi)$ and $\mathcal{L}(\Phi')$. Then $\Pr_N^{w,\Phi}(\varphi \mid \theta) = \Pr_N^{w,\Phi'}(\varphi \mid \theta)$.*

Thus, the value of $\Pr_N^{w,\Phi}(\varphi \mid \theta)$ does not depend on the choice of Φ. We therefore omit reference to Φ in $\Pr_N^{w,\Phi}(\varphi \mid \theta)$, writing $\Pr_N^{w}(\varphi \mid \theta)$ instead.

We would like to define $\Pr_\infty^{w}(\varphi \mid \theta)$ as the limit $\lim_{N\to\infty} \Pr_N^{w}(\varphi \mid \theta)$. There is a small technical problem we have to deal with in this definition: we must decide what to do if $\#world_N^{\Phi}(\theta) = 0$, so that $\Pr_N^{w}(\varphi \mid \theta)$ is not well defined. In [23], we differentiate between the case where $\Pr_N^{w}(\varphi \mid \theta)$ is well defined for all but finitely many N's, and the case where it is well defined for infinitely many N's. As we shall show (see Lemma 3.30) this distinction need not be made when θ is a unary formula. Thus, for the purposes of this paper, we use the following definition of well-definedness, which is simpler than that of [23].

DEFINITION 2.2. The asymptotic conditional probability according to the random-worlds method, denoted $\Pr_\infty^{w}(\varphi \mid \theta)$, is *well defined* if $\#world_N^{\Phi}(\theta) \neq 0$ for all but finitely many N. If $\Pr_\infty^{w}(\varphi \mid \theta)$ is well defined, then we take $\Pr_\infty^{w}(\varphi \mid \theta)$ to denote $\lim_{N\to\infty} \Pr_N^{w}(\varphi \mid \theta)$. □

Note that for any formula φ, the issue of whether $\Pr_\infty^{w}(\varphi \mid \theta)$ is well defined is completely determined by θ. Therefore, when investigating the question of how to decide whether such a probability is well defined, it is often useful to ignore φ. We therefore say that $\Pr_\infty^{w}(* \mid \theta)$ *is well defined* if $\Pr_\infty^{w}(\varphi \mid \theta)$ is well defined for every formula φ (which is true iff $\Pr_\infty^{w}(\mathit{true} \mid \theta)$ is well defined).

2.2. The random-structures method. As we explained in the introduction, the random-structures method is motivated by the intuition that worlds that are indistinguishable within the language should only be counted once. Thus, the random-structures method counts the number of (*unlabeled*) *structures*, or isomorphism classes of worlds.

Formally, we proceed as follows. Given a sentence $\xi \in \mathcal{L}(\Phi)$, let $\#\mathit{struct}_N^{\Phi}(\xi)$ be the number of isomorphism classes of worlds with domain $\{1, \ldots, N\}$ over the vocabulary Φ satisfying ξ. Note that since all the worlds that make up a structure agree on the truth value they assign to ξ, it makes sense to talk about a structure satisfying or not satisfying ξ. We can then proceed, as before, to define $\Pr_N^{s,\Phi}(\varphi \mid \theta)$ as $\frac{\#\mathit{struct}_N^{\Phi}(\varphi\wedge\theta)}{\#\mathit{struct}_N^{\Phi}(\theta)}$. We define asymptotic conditional probability, denoted $\Pr_\infty^{s,\Phi}(\varphi \mid \theta)$ in terms of $\Pr_N^{s,\Phi}(\varphi \mid \theta)$, in analogy to the earlier definition for random worlds. It is clear that $\#\mathit{world}_N^{\Phi}(\theta) = 0$ iff $\#\mathit{struct}_N^{\Phi}(\theta) = 0$, so that well-definedness is equivalent for the two methods, for any φ, θ.

PROPOSITION 2.3. *For any* $\theta \in \mathcal{L}(\Phi)$, $\Pr_\infty^{w}(* \mid \theta)$ *is well defined iff* $\Pr_\infty^{s,\Phi}(* \mid \theta)$ *is well defined.*

As the following example, taken from [23], shows, for the random-structures method the analogue to Proposition 2.1 does not hold; the value of $\Pr_N^{s,\Phi}(\varphi \mid \theta)$, and even the value of the limit, depends on the choice of Φ. This example, together with Proposition 2.1, also demonstrates that the values of conditional probabilities generally differ between the random-worlds method and the random-structures method. By way of contrast, Fagin [14] showed that the random-worlds and random-structures methods give the same answers for unconditional probabilities, if we do not have constant or function symbols in the language.

Example 2.4. Suppose $\Phi = \{P\}$, where P is a unary predicate symbol. Let θ be $\exists! x\, P(x) \vee \neg\exists x\, P(x)$ (where, as usual, "$\exists!$" means "exists a unique"), and let φ be $\exists x\, P(x)$. For any domain size N, $\#\mathit{struct}_N^{\Phi}(\theta) = 2$. In one structure, there is exactly one element satisfying P and $N - 1$ satisfying $\neg P$; in the other, all elements satisfy $\neg P$. Therefore, $\Pr_\infty^{s,\Phi}(\varphi \mid \theta) = \frac{1}{2}$.

Now, consider $\Phi' = \{P, Q\}$, for a new unary predicate Q. There are $2N$ structures where there exists an element satisfying P: the element satisfying P may or may not satisfy Q, and of the $N - 1$ elements satisfying $\neg P$, any number between 0 and $N - 1$ may also satisfy Q. On the other hand, there are $N + 1$ structures where all elements satisfy $\neg P$: any number of elements between 0 and N may satisfy Q. Therefore, $\Pr_N^{s,\Phi'}(\varphi \mid \theta) = \frac{2N}{3N+1}$, and $\Pr_\infty^{s,\Phi'}(\varphi \mid \theta) = \frac{2}{3}$.

We know that the asymptotic limit for the random-worlds method will be the same, whether we use Φ or Φ'. Using Φ, notice that the single structure where $\exists! x\, P(x)$ is true contains N worlds (corresponding to the choice of element satisfying P), whereas the other possible structure contains only one world. Therefore, $\Pr_\infty^{w}(\varphi \mid \theta) = 1$. □

Although the two methods give different answers in general, we shall see in the next section that there are important circumstances under which they agree.

2.3. Infinite vocabularies. Up to now we have assumed that the vocabulary Φ is finite. As we observed, this assumption is crucial in our definitions of $\#\mathit{world}_N^{\Phi}(\xi)$ and $\#\mathit{struct}_N^{\Phi}(\xi)$. Nevertheless, in many standard complexity arguments it is important that the vocabulary be infinite. For example, satisfiability for propositional logic formulas is decidable in linear time if we consider a single finite vocabulary; we need to consider the class of formulas definable over some infinite vocabulary of propositional symbols to get NP-completeness.

How can we modify the random-worlds and random-structures methods to deal with an infinite vocabulary Ω? The issue is surprisingly subtle. One plausible choice depends on the observation that even if Ω is infinite, the set of symbols appearing in a given sentence is always finite. We can thus do our computations relative to this set. More formally, if $\Omega_{\varphi\wedge\theta}$ denotes the set of symbols in Ω that actually appear in $\varphi \wedge \theta$, we could define $\Pr_N^{w,\Omega}(\varphi \mid \theta) = \Pr_N^{w,\Omega_{\varphi\wedge\theta}}(\varphi \mid \theta)$. Similarly, for the random-structures method, we could define $\Pr_N^{s,\Omega}(\varphi \mid \theta) = \Pr_N^{s,\Omega_{\varphi\wedge\theta}}(\varphi \mid \theta)$. The problem with this approach is that the values given by the random-structures approach depend on the vocabulary, and it is easy to find two equivalent sentences φ and φ' such that $\Omega_\varphi \neq \Omega_{\varphi'}$ and $\Pr_\infty^{s,\Omega_{\varphi\wedge\theta}}(\varphi \mid \theta) \neq \Pr_\infty^{s,\Omega_{\varphi'\wedge\theta}}(\varphi' \mid \theta)$. (A simple example of this phenomenon can be obtained by modifying Example 2.4 slightly.) Thus, under this approach, the value of asymptotic conditional probabilities can depend on the precise syntax of the sentences involved. We view this as undesirable, and so we focus on the following two interpretations of infinite vocabularies.[3]

The first of these two alternative approaches treats an infinite vocabulary as a limit of finite subvocabularies. Assume for ease of exposition that Ω is countable. Let Ω_m consist of the first m symbols in Ω (using some arbitrary fixed ordering). We can then define $\Pr_N^{w,\Omega}(\varphi \mid \theta) = \lim_{m\to\infty} \Pr_N^{w,\Omega_m}(\varphi \mid \theta)$ (where we take $\Pr_N^{w,\Omega_m}(\varphi \mid \theta)$ to be undefined if $\varphi, \theta \notin \mathcal{L}(\Omega_m)$).[4] Similarly, we can define $\Pr_N^{s,\Omega}(\varphi \mid \theta) = \lim_{m\to\infty} \Pr_N^{s,\Omega_m}(\varphi \mid \theta)$. It follows from the results we prove below that these limits are independent of the ordering of the symbols in the vocabulary.

The second interpretation is quite different. In it, although there may be an infinite vocabulary Ω in the background, we assume that each problem instance comes along with a finite vocabulary Φ as part of the input. Thus, in our infinite vocabulary Ω, we may have predicates that are relevant to medical diagnosis, physics experiments, automobile insurance, etc. When thinking about medical applications, we use that finite portion Φ of the infinite vocabulary that is appropriate. In this approach, we always deal with finite vocabularies, but ones whose size is potentially unbounded because we do not fix the relevant vocabulary in advance.

In essence, the first approach can be viewed as saying that there really is an infinite vocabulary, while the second approach considers there to be an infinite collection of finite vocabularies (with no bound on the size of the vocabularies in the collection). The distinction between these possibilities is not usually examined as closely as we have done here. This is because the difference is rarely important. For example, propositional satisfiability is NP-complete over an infinite vocabulary, no matter how we interpret "infinite." In our context, the difference turns out to be moderately significant. For random worlds, an argument based on Proposition 2.1 shows the two approaches lead to the same answers (as does the approach that we rejected where, when computing $\Pr_N^{w,\Omega}(\varphi \mid \theta)$, we restrict the vocabulary to $\Omega_{\varphi\wedge\theta}$). On the other hand, the two approaches can lead to quite different answers in the case of the random-structures approach. It is important to point out, however, that the complexity of all problems we consider turns out to be the same no matter which interpretation of "infinite" we use.

In fact, as we now show, according to the first approach the random-structures method and the random-worlds method agree whenever we have an infinite vocabulary (and thus we have an analogue to Fagin's result [14] for the case of unconditional probabilities). A structure of size N is an equivalence class of at most $N!$ worlds, since there are at most $N!$ worlds isomorphic to a given world. We say that such a structure is *rigid* if it consists of exactly $N!$ worlds. It is easy to see that a structure is rigid just if every (nontrivial) permutation of the domain elements in a world that makes up the structure produces a *different* world in that structure. We say a world is rigid if the corresponding structure is.

Example 2.5. Let Φ consist of a single unary predicate P, and consider the worlds over the domain $\{1, 2, 3\}$. All worlds where the denotation of P contains exactly two elements are isomorphic. Therefore, these worlds form a single structure $\mathcal{S}$. There are three worlds in

[3] We note, however, that all our later complexity results concerning infinite vocabularies can be easily shown to hold for the definition just discussed.

[4] Here, we chose to take the limit on the vocabulary, and only then to take the limit on the domain size. We could, however, have chosen to reverse the order of the limits, or to consider arbitrary joint limits of these two parameters. The approach taken here seems to be the most well motivated in this framework.

$\mathcal{S}$, corresponding to the possible denotations of P: $\{1, 2\}$, $\{1, 3\}$, $\{2, 3\}$. Therefore, $\mathcal{S}$ is not rigid. In fact, it is easy to see that no structure over Φ is rigid. Now, consider structures over $\Phi' = \{P, Q\}$, where Q is a new unary predicate. The set of all worlds where the denotation of P contains two elements no longer forms a structure over Φ'. For example, one structure $\mathcal{S}'$ over Φ' is the set of worlds where the denotations of $P \wedge Q$, $P \wedge \neg Q$, and $\neg P \wedge Q$ each contain one element. There are six worlds in $\mathcal{S}'$, corresponding to the possible permutations of the three domain elements. Therefore, $\mathcal{S}'$ is rigid. □

This example demonstrates that increasing the vocabulary tends to cause rigidity. We now formalize this intuition, and show its importance. Note that in the following definition (and throughout the paper) all logarithms are taken to the base 2.

DEFINITION 2.6. We say that a vocabulary Φ is *sufficiently rich* with respect to N if

(a) Φ contains at least κ_N constant symbols and $\kappa_N \geq N^2 \log N$, or

(b) Φ contains at least π_N unary predicate symbols and $\pi_N \geq 3 \log N$, or

(c) Φ contains at least one nonunary predicate symbol. □

Fagin showed that if Φ contains at least one nonunary predicate symbol, then the number of worlds over Φ of size N is asymptotically $N!$ times the number of structures [14]. That is, almost all structures are rigid in this case. We now generalize this result. Let *rigid* be an assertion that is true only in rigid structures or rigid worlds; note that *rigid* cannot be expressed in first-order logic. If $F(N)$ and $G(N)$ are two functions of N, we write $F(N) \sim G(N)$ if $\lim_{N\to\infty} F(N)/G(N) = 1$.

THEOREM 2.7. *Suppose that for every N, Φ and Ω_N are disjoint finite vocabularies such that Ω_N is sufficiently rich with respect to N. Then for any $\xi \in \mathcal{L}(\Phi)$,*

$$\lim_{N\to\infty} \Pr_N^{s,\Phi\cup\Omega_N}(\mathit{rigid} \mid \xi) = 1,$$

provided that ξ is satisfiable for all sufficiently large domains. Hence, $\#\mathit{world}_N^{\Phi\cup\Omega_N}(\xi) \sim N!\#\mathit{struct}_N^{\Phi\cup\Omega_N}(\xi)$.

Proof. We first prove the result under the additional assumptions that $\xi = \mathit{true}$ and $\Phi = \emptyset$. We consider each of the three possibilities for sufficient richness separately, and for each case we show that almost all structures are rigid. As we said above, the case where Ω_N contains at least one nonunary predicate and $\xi = \mathit{true}$ is Fagin's result, so we need only consider the remaining two cases.

Suppose $\xi = \mathit{true}$, $\Phi = \emptyset$, and Ω_N contains κ_N constant symbols. Without loss of generality, we can assume that these constants are the only symbols in Ω_N, because any expansion of a rigid structure over Ω_N to a richer vocabulary will also be rigid. Consider a structure $\mathcal{S}$. All the worlds that make up $\mathcal{S}$ must agree on the equality relations between the interpretations of the constants. That is, for any pair of constant symbols c and c', either they are equal in all worlds that make up the structure or not equal in all of them. Thus, a lower bound on the number of distinct structures over Ω_N is given by the number of ways of partitioning κ_N objects into N or fewer equivalence classes. There is no closed form expression for this number, but a simple lower bound is obtained by counting structures where the first N constants denote distinct objects. There are $N^{(\kappa_N - N)}$ such structures, because we must choose, for each of the other constants, to which of the first N constants it is equal. It is easy to see that if all or all but one of the elements in a structure (that is, in any of the worlds in that structure) are denoted by some constant, then this structure is rigid. Hence, if a structure is nonrigid, then two or more elements are not denoted by any constant. Thus, an upper bound on the number of nonrigid structures is $(N-2)^{\kappa_N}$. Therefore,

$$\Pr_N^{s,\Omega_N}(\neg\mathit{rigid} \mid \mathit{true}) \leq \frac{(N-2)^{\kappa_N}}{N^{\kappa_N - N}} = N^N \left(1 - \frac{2}{N}\right)^{\kappa_N} < N^N e^{-2\frac{\kappa_N}{N}}.$$

This will tend to 0 if $\kappa_N \geq N^2 \log N$.

Next, suppose that $\xi = \mathit{true}$, $\Phi = \emptyset$, and Ω_N contains π_N unary predicate symbols. As before, we can assume that these predicates comprise all of Ω_N. Consider a structure $\mathcal{S}$ and a world $\mathcal{W}$ in the isomorphism class making up that structure. These π_N unary predicates partition the domain of $\mathcal{W}$ into 2^{π_N} cells, according to the subset of predicates satisfied by each of the domain elements. Notice that the predicates actually partition each of the isomorphic worlds in s in the same way (in that corresponding elements of the partition have the same size). Thus, a lower bound on the number of distinct structures over Φ is the number of ways of allocating N indistinguishable elements into 2^{π_N} distinguishable cells, which is $\binom{2^{\pi_N}+N-1}{N}$. Clearly, a structure is nonrigid if and only if some element of the partition contains more than one domain element. Thus, an upper bound on the number of nonrigid structures can be obtained by counting the number of structures over $N-1$ elements, then choosing one of the these elements to be a "double" element, representing two elements. This can be done in $(N-1)\binom{2^{\pi_N}+N-2}{N-1}$ ways. Therefore,

$$\Pr_N^{s,\Omega_N}(\neg \mathit{rigid} \mid \mathit{true}) \le \frac{(N-1)\binom{2^{\pi_N}+N-2}{N-1}}{\binom{2^{\pi_N}+N-1}{N}} = \frac{N^2-N}{2^{\pi_N}+N-1}.$$

This tends to zero if $2^{\pi_N}/N^2 \to \infty$ as N grows, which is ensured by the assumption $\pi_N \ge 3\log N$.

Finally, we drop the assumptions that $\xi = \mathit{true}$ and $\Phi = \emptyset$. Given a structure over Ω_N, we can choose the denotation for the predicates in Φ in any way that satisfies ξ. It is easy to verify that if the original structure is rigid, all such choices lead to distinct structures. Therefore,

$$\#\mathit{struct}_N^{\Phi\cup\Omega_N}(\mathit{rigid} \wedge \xi) \ge \#\mathit{struct}_N^{\Omega_N}(\mathit{rigid}) \cdot \#\mathit{world}_N^{\Phi}(\xi)\ .$$

On the other hand, clearly

$$\#\mathit{struct}_N^{\Phi\cup\Omega_N}(\neg\mathit{rigid} \wedge \xi) \le \#\mathit{struct}_N^{\Omega_N}(\neg\mathit{rigid}) \cdot \#\mathit{world}_N^{\Phi}(\xi)\ .$$

The second factor is the same in both these bounds, and therefore

$$\Pr_N^{s,\Phi\cup\Omega_N}(\mathit{rigid} \mid \xi) \ge \Pr_N^{s,\Omega_N}(\mathit{rigid} \mid \mathit{true})\ .$$

From our results for $\xi = \mathit{true}$ and $\Phi = \emptyset$ we conclude that $\lim_{N\to\infty} \Pr_N^{s,\Phi\cup\Omega_N}(\mathit{rigid} \mid \xi) = 1$. □

We also need to prove an analogous result for the random-worlds method. Note that while, if we restrict to formulas in $\mathcal{L}(\Phi)$, the answers given by the random-worlds method are independent of the vocabulary, the predicate *rigid* has a special definition in terms of the random-structures method, and so rigidity may well depend on the vocabulary. Thus, in the next result, we are careful to mention the vocabulary being used.

COROLLARY 2.8. *Suppose that for every N, Φ and Ω_N are disjoint finite vocabularies such that Ω_N is sufficiently rich with respect to N. Then for any $\xi \in \mathcal{L}(\Phi)$,*

$$\lim_{N\to\infty} \Pr_N^{w,\Phi\cup\Omega_N}(\mathit{rigid} \mid \xi) = 1,$$

provided that ξ is satisfiable in all sufficiently large domains.

Proof. Any rigid structure with domain size N that satisfies ξ corresponds to $N!$ worlds. On the other hand, nonrigid structures correspond to fewer than $N!$ worlds. It follows that the proportion of worlds satisfying ξ that are rigid is at least as great as the proportion of structures satisfying ξ that are rigid. Since the latter proportion is asymptotically 1, so is the former. □

Our main use of this theorem is in the following two corollaries. The first shows that when the vocabulary is infinite (and therefore sufficiently rich) the random-worlds and random-structures methods coincide. The second corollary shows that the same thing happens when the vocabulary is sufficiently rich because of a high-arity predicate, as long as this predicate does not appear in the formula we are conditioning on.

COROLLARY 2.9. *Suppose that Ω is infinite and $\varphi, \theta \in \mathcal{L}(\Omega)$. Then*

(a) $\Pr_N^{w,\Omega}(\varphi \mid \theta) \sim \Pr_N^{s,\Omega}(\varphi \mid \theta)$,

(b) $\Pr_\infty^{w,\Omega}(\varphi \mid \theta) = \Pr_\infty^{s,\Omega}(\varphi \mid \theta)$.

Proof. Fix N, and let Ω_m be the first m symbols in some enumeration of Ω. We will be interested in the limit as $m \longrightarrow \infty$, so without loss of generality assume that $m > N^2 \log N + |\Omega_{\varphi\wedge\theta}|$. Clearly $\Omega_m - \Omega_{\varphi\wedge\theta}$ is sufficiently rich with respect to N, so by Theorem 2.7, almost all structures are rigid. Since a rigid structure over a domain of size N consists of $N!$ worlds, we get:

$$\Pr_N^{w,\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\varphi \mid \theta) = \frac{\#world_N^{\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\varphi \wedge \theta)}{\#world_N^{\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\theta)} \sim \frac{\#struct_N^{\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\varphi \wedge \theta)}{\#struct_N^{\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\theta)}$$
$$= \Pr_N^{s,\Omega_{\varphi\wedge\theta}\cup\Omega_m}(\varphi \mid \theta).$$

Since this holds for any sufficiently large m, it certainly holds at the limit. This proves part (a). Part (b) follows easily. □

We can easily strengthen part (a) and prove that we actually have $\Pr_N^{w,\Omega}(\varphi \mid \theta) = \Pr_N^{s,\Omega}(\varphi \mid \theta)$, for all N. Since we do not need this result in this paper, we omit the proof here. We remark that this result also holds for much richer languages; we did not use the fact that we were dealing with first-order logic anywhere in the proof.

COROLLARY 2.10. *Suppose that $\varphi, \theta \in \mathcal{L}(\Phi)$ where Φ contains some nonunary predicate symbol that does not appear in θ. Then* $\Pr_\infty^{w}(\varphi \mid \theta) = \Pr_\infty^{s,\Phi}(\varphi \mid \theta)$.

Proof. Using the rules of probability theory, we know that

$$\Pr_\infty^{s,\Phi}(\varphi \mid \theta) = \Pr_\infty^{s,\Phi}(\varphi \mid \theta\wedge rigid)\cdot\Pr_\infty^{s,\Phi}(rigid \mid \theta) + \Pr_\infty^{s,\Phi}(\varphi \mid \theta\wedge\neg rigid)\cdot\Pr_\infty^{s,\Phi}(\neg rigid \mid \theta),$$

if all limits exist. Because of the high-arity predicate, $\Phi - \Phi_\theta$ is sufficiently rich with respect to any N. Therefore, by Theorem 2.7, we deduce that $\Pr_\infty^{s,\Phi}(rigid \mid \theta) = 1$ and $\Pr_\infty^{s,\Phi}(\neg rigid \mid \theta) = 0$. Thus

$$\Pr_\infty^{s,\Phi}(\varphi \mid \theta) = \Pr_\infty^{s,\Phi}(\varphi \mid \theta \wedge rigid) .$$

Using Corollary 2.8 instead of Theorem 2.7, we can similarly show

$$\Pr_\infty^{w,\Phi}(\varphi \mid \theta) = \Pr_\infty^{w,\Phi}(\varphi \mid \theta \wedge rigid) .$$

Because of rigidity,

$$\Pr_\infty^{s,\Phi}(\varphi \mid \theta \wedge rigid) = \Pr_\infty^{w,\Phi}(\varphi \mid \theta \wedge rigid).$$

The result now follows immediately. □

3. Asymptotic probabilities. We begin by defining some notation that will be used consistently throughout the rest of the paper. We use Φ to denote a finite vocabulary, which may include nonunary as well as unary predicate symbols and constant symbols. We take $\mathcal{P}$ to be the set of all unary predicates in Φ, $\mathcal{C}$ to be the set of all constant symbols in Φ, and define $\Psi = \mathcal{P} \cup \mathcal{C}$. Finally, if φ is a formula, we use Φ_φ to denote those symbols in Φ that appear in φ; we can similarly define $\mathcal{C}_\varphi$, $\mathcal{P}_\varphi$, and Ψ_φ.

Our goal is to show how to compute asymptotic conditional probabilities. As we explained in the introduction, the main idea is the following. To compute $\Pr^w_\infty(\varphi \mid \theta)$, we partition the models of θ into a finite collection of classes, such that φ behaves *uniformly* in any individual class, that is, there is a 0-1 law for the asymptotic probability of φ when we restrict attention to models in a single class. Computing $\Pr^w_\infty(\varphi \mid \theta)$ reduces to first identifying the classes, computing the relative weight of each class (which is required because the classes are not necessarily of equal relative size), and then deciding, for each class, whether the asymptotic probability of φ is zero or one. In this section we deal with the logical aspects of this process; namely, showing how to construct an appropriate partition into classes. In the next section, we use results from this section to construct algorithms that compute asymptotic probabilities, and examine the complexity of these algorithms.

For most of this section, we will concentrate on the asymptotic probability according to random worlds. In §3.5 we discuss the modifications needed to deal with random structures, which are relatively minor.

3.1. Unary vocabularies and atomic descriptions. The success of the approach outlined above depends on the lack of expressivity of unary languages. In this section we show that sentences in $\mathcal{L}(\Psi)$ can only assert a fairly limited class of constraints. For instance, one corollary of our general result will be the well-known theorem that, if $\theta \in \mathcal{L}(\Psi)$ is satisfiable at all, it is satisfiable in a "small" model, one of size at most exponential in the size of the θ. (See [1] for a proof of this result and further historical references.)

We start with some definitions.

DEFINITION 3.1. Given a vocabulary Φ and a finite set of variables $\mathcal{X}$, a *complete description D* over Φ and $\mathcal{X}$ is an unquantified conjunction of formulas such that

- for every predicate $R \in \Phi \cup \{=\}$ of arity m, and for every $z_1, \ldots, z_m \in \mathcal{C} \cup \mathcal{X}$, D contains exactly one of $R(z_1, \ldots, z_m)$ or $\neg R(z_1, \ldots, z_m)$ as a conjunct;
- D is consistent.[5] □

We can think of a complete description as being a formula that describes as fully as possible the behavior of the predicate symbols in Φ over the constant symbols in Φ and the variables in $\mathcal{X}$.

We can also consider complete descriptions over subsets of Φ. The case when we look just at the unary predicates and a single variable x will be extremely important.

DEFINITION 3.2. Let $\mathcal{P}$ be $\{P_1, \ldots, P_k\}$. An *atom* over $\mathcal{P}$ is a complete description over $\mathcal{P}$ and some variable $\{x\}$. More precisely, it is a conjunction of the form $P'_1(x) \wedge \ldots \wedge P'_k(x)$, where each P'_i is either P_i or $\neg P_i$. Since the variable x is irrelevant to our concerns, we typically suppress it and describe an atom as a conjunction of the form $P'_1 \wedge \ldots \wedge P'_k$. □

Note that there are $2^k = 2^{|\mathcal{P}|}$ atoms over $\mathcal{P}$, and that they are mutually exclusive and exhaustive. We use $A_1, \ldots, A_{2^{|\mathcal{P}|}}$ to denote the atoms over $\mathcal{P}$, listed in some fixed order. For example, there are four atoms over $\mathcal{P} = \{P_1, P_2\}$: $A_1 = P_1 \wedge P_2$, $A_2 = P_1 \wedge \neg P_2$, $A_3 = \neg P_1 \wedge P_2$, $A_4 = \neg P_1 \wedge \neg P_2$.

We now want to define the notion of *atomic description* which is, roughly speaking, a maximally expressive formula in the unary vocabulary Ψ. Fix a natural number M. A size M atomic description consists of two parts. The first part, the *size description with bound M*, specifies exactly how many elements in the domain should satisfy each atom A_i, except that if there are M or more elements satisfying the atom it only expresses that fact, rather than giving the exact count. More formally, given a formula $\xi(x)$ with a free variable x, we take $\exists^m x\, \xi(x)$ to be the sentence that says there are precisely m domain elements satisfying ξ:

[5] Inconsistency is possible because of the use of equality. For example, if D includes $z_1 = z_2$ as well as both $R(z_1, z_3)$ and $\neg R(z_2, z_3)$, it is inconsistent.

$$\exists^m x\, \xi(x) =_{\text{def}} \exists x_1 \ldots x_m \left(\bigwedge_i \left(\xi(x_i) \wedge \bigwedge_{j \neq i} (x_j \neq x_i) \right) \wedge \forall y (\xi(y) \Rightarrow \vee_i (y = x_i)) \right).$$

Similarly, we define $\exists^{\geq m} x\, \xi(x)$ to be the formula that says that there are at least m domain elements satisfying ξ:

$$\exists^{\geq m} x\, \xi(x) =_{\text{def}} \exists x_1 \ldots x_m \left(\bigwedge_i \left(\xi(x_i) \wedge \bigwedge_{j \neq i} (x_j \neq x_i) \right) \right).$$

DEFINITION 3.3. A *size description with bound M (over $\mathcal{P}$)* is a conjunction of $2^{|\mathcal{P}|}$ formulas: for each atom A_i over $\mathcal{P}$, it includes either $\exists^{\geq M} x\, A_i(x)$ or a formula of the form $\exists^m x\, A_i(x)$ for some $m < M$. □

The second part of an atomic description is a complete description that specifies the properties of constants and free variables.

DEFINITION 3.4. A *size M atomic description* (over Ψ and $\mathcal{X}$) is a conjunction of:

- a size description with bound M over $\mathcal{P}$, and
- a complete description over Ψ and $\mathcal{X}$. □

Note that an atomic description is a finite formula, and there are only finitely many size M atomic descriptions over Ψ and $\mathcal{X}$ (for fixed M). For the purposes of counting atomic descriptions (as we do in §3.4), we assume some arbitrary but fixed ordering of the conjuncts in an atomic description. Under this assumption, we cannot have two distinct atomic descriptions that differ only in the ordering of conjuncts. Given this, it is easy to see that atomic descriptions are mutually exclusive. Moreover, atomic descriptions are exhaustive—the disjunction of all consistent atomic descriptions of size M is valid.

Example 3.5. Consider the following size description σ with bound 4 over $\mathcal{P} = \{P_1, P_2\}$:

$$\exists^1 x\, A_1(x) \wedge \exists^3 x\, A_2(x) \wedge \exists^{\geq 4} x\, A_3(x) \wedge \exists^{\geq 4} x\, A_4(x).$$

Let $\Psi = \{P_1, P_2, c_1, c_2, c_3\}$. It is possible to augment σ into an atomic description in many ways. For example, one consistent atomic description ψ_* of size 4 over Ψ and $\emptyset$ (no free variables) is:[6]

$$\sigma \wedge A_2(c_1) \wedge A_3(c_2) \wedge A_3(c_3) \wedge c_1 \neq c_2 \wedge c_1 \neq c_3 \wedge c_2 = c_3.$$

On the other hand, the atomic description

$$\sigma \wedge A_1(c_1) \wedge A_1(c_2) \wedge A_3(c_3) \wedge c_1 \neq c_2 \wedge c_1 \neq c_3 \wedge c_2 \neq c_3$$

is an inconsistent atomic description, since σ dictates that there is precisely one element in the atom A_1, whereas the second part of the atomic description implies that there are two distinct domain elements in that atom. □

As we explained, an atomic description is, intuitively, a maximally descriptive sentence over a unary vocabulary. The following theorem formalizes this idea by showing that each unary formula is equivalent to a disjunction of atomic descriptions. For a given M and set $\mathcal{X}$ of variables, let $\mathcal{A}^{\Psi}_{M,\mathcal{X}}$ be the set of consistent atomic descriptions of size M over Ψ and $\mathcal{X}$.

DEFINITION 3.6. Let $d(\xi)$ denote the *depth of quantifier nesting* in ξ. We define $d(\xi)$ by induction on the structure of ξ as follows:

[6] In our examples, we use the commutativity of equality in order to avoid writing down certain superfluous disjuncts. In this example, for instance, we do not write down both $c_1 \neq c_2$ and $c_2 \neq c_1$.

- $d(\xi) = 0$ for any atomic formula ξ,
- $d(\neg\xi) = d(\xi)$,
- $d(\xi_1 \wedge \xi_2) = d(\xi_1 \vee \xi_2) = \max(d(\xi_1), d(\xi_2))$,
- $d(\forall y\, \xi) = d(\exists y\, \xi) = d(\xi) + 1$. □

THEOREM 3.7. *If ξ is a formula in $\mathcal{L}(\Psi)$ whose free variables are contained in $\mathcal{X}$, and $M \geq d(\xi) + |\mathcal{C}| + |\mathcal{X}|$, then there exists a set of atomic descriptions $\mathcal{A}^{\Psi}_{\xi} \subseteq \mathcal{A}^{\Psi}_{M,\mathcal{X}}$ such that ξ is equivalent to $\bigvee_{\psi \in \mathcal{A}^{\Psi}_{\xi}} \psi$.*

Proof. We proceed by a straightforward induction on the structure of ξ. We assume without loss of generality that ξ is constructed from atomic formulas using only the operators $\wedge$, $\neg$, and $\exists$.

First suppose that ξ is an atomic formula. That is, ξ is either of the form $P(z)$ or of the form $z = z'$, for $z, z' \in \mathcal{C} \cup \mathcal{X}$. In this case, either the formula ξ or its negation appears as a conjunct in each atomic description $\psi \in \mathcal{A}^{\Psi}_{M,\xi}$. Let $\mathcal{A}^{\Psi}_{\xi}$ be those atomic descriptions in which ξ appears as a conjunct. Clearly, ξ is inconsistent with the remaining atomic descriptions. Since the disjunction of the atomic descriptions in $\mathcal{A}^{\Psi}_{M,\mathcal{X}}$ is valid, we obtain that ξ is equivalent to $\bigvee_{\psi \in \mathcal{A}^{\Psi}_{\xi}} \psi$.

If ξ is of the form $\xi_1 \wedge \xi_2$, then by the induction hypothesis, ξ_i is equivalent to the disjunction of a set $\mathcal{A}^{\Psi}_{\xi_i} \subseteq \mathcal{A}^{\Psi}_{M,\mathcal{X}}$, for $i = 1, 2$. Clearly ξ is equivalent to the disjunction of the atomic descriptions in $\mathcal{A}^{\Psi}_{\xi_1} \cap \mathcal{A}^{\Psi}_{\xi_2}$. (Recall that the empty disjunction is equivalent to the formula *false*.)

If ξ is of the form $\neg\xi'$ then, by the induction hypothesis, ξ' is equivalent to the disjunction of the atomic descriptions in $\mathcal{A}^{\Psi}_{\xi'}$. It is easy to see that ξ is the disjunction of the atomic descriptions in $\mathcal{A}^{\Psi}_{\neg\xi'} = \mathcal{A}^{\Psi}_{M,\mathcal{X}} - \mathcal{A}^{\Psi}_{\xi'}$.

Finally, we consider the case that ξ is of the form $\exists y\, \xi'$. Recall that $M \geq d(\xi) + |\mathcal{C}| + |\mathcal{X}|$. Since $d(\xi') = d(\xi) - 1$, it is also the case that $M \geq d(\xi') + |\mathcal{C}| + |\mathcal{X} \cup \{y\}|$. By the induction hypothesis, ξ' is therefore equivalent to the disjunction of the atomic descriptions in $\mathcal{A}^{\Psi}_{\xi'}$. Clearly ξ is equivalent to $\exists y \vee_{\psi \in \mathcal{A}^{\Psi}_{\xi'}} \psi$, and standard first-order reasoning shows that $\exists y \vee_{\psi \in \mathcal{A}^{\Psi}_{\xi'}} \psi$ is equivalent to $\vee_{\psi \in \mathcal{A}^{\Psi}_{\xi'}} \exists y\, \psi$. Since $\mathcal{A}^{\Psi}_{\xi'} \subseteq \mathcal{A}^{\Psi}_{M,\mathcal{X} \cup \{y\}}$, it suffices to show that for each atomic description $\psi \in \mathcal{A}^{\Psi}_{M,\mathcal{X} \cup \{y\}}$, $\exists y\, \psi$ is equivalent to an atomic description in $\mathcal{A}^{\Psi}_{M,\mathcal{X}}$.

Consider some $\psi \in \mathcal{A}^{\Psi}_{M,\mathcal{X} \cup \{y\}}$; we can clearly pull out of the scope of $\exists y$ all the conjuncts in ψ that do not involve y. It follows that $\exists y\, \psi$ is equivalent to $\psi' \wedge \exists y\, \psi''$, where ψ'' is a conjunction of $A(y)$, where A is an atom over $\mathcal{P}$, and formulas of the form $y = z$ and $y \neq z$. It is easy to see that ψ' is a consistent atomic description over Ψ and $\mathcal{X}$ of size M. To complete the proof, we now show that $\psi' \wedge \exists y\, \psi''$ is equivalent to ψ'. There are two cases to consider. First suppose that ψ'' contains a conjunct of the form $y = z$. Let $\psi''[y/z]$ be the result of replacing all free occurrences of y in ψ'' by z. Standard first-order reasoning (using the fact that $\psi''[y/z]$ has no free occurrences of y) shows that $\psi''[y/z]$ is equivalent to $\exists y\, \psi''[y/z]$, which is equivalent to $\exists y\, \psi''$. Since ψ is a complete atomic description which is consistent with ψ'', it follows that each conjunct of $\psi''[y/z]$ (except $z = z$) must be a conjunct of ψ', so ψ' implies $\psi''[y/z]$. It immediately follows that ψ' is equivalent to $\psi' \wedge \exists y\, \psi''$ in this case. Now suppose that there is no conjunct of the form $y = z$ in ψ''. In this case, $\exists y\, \psi''$ is certainly true if there exists a domain element satisfying atom A different from the denotations of all the symbols in $\mathcal{X} \cup \mathcal{C}$. Notice that ψ implies that there exists such an element, namely, the denotation of y. However, ψ' must already imply the existence of such an element since ψ' must force there to be enough elements satisfying A to guarantee the existence of such an element. (We remark that it is crucial for this last part of the argument that $M \geq |\mathcal{X}| + 1 + |\mathcal{C}|$.) Thus, we again have that ψ' is equivalent to $\psi' \wedge \exists y\, \psi''$. It follows that $\exists y\, \psi$ is equivalent to a consistent atomic description in $\mathcal{A}^{\Psi}_{M,\mathcal{X}}$, namely ψ', as required. □

For the remainder of this paper we will be interested in sentences. Thus, we restrict attention to atomic descriptions over Ψ and the empty set of variables. Moreover, we assume that all formulas mentioned are in fact sentences, and have no free variables.

DEFINITION 3.8. For $\Psi = \mathcal{P} \cup \mathcal{C}$, and a sentence $\xi \in \mathcal{L}(\Psi)$, we define $\mathcal{A}_\xi^\Psi$ to be the set of consistent atomic descriptions of size $d(\xi) + |\mathcal{C}|$ over Ψ such that ξ is equivalent to the disjunction of the atomic descriptions in $\mathcal{A}_\xi^\Psi$. □

It will be useful for our later results to prove a simpler analogue of Theorem 3.7 for the case where the sentence ξ does not use equality or constant symbols. A *simplified atomic description over $\mathcal{P}$* is simply a size description with bound 1. Thus, it consists of a conjunction of $2^{|\mathcal{P}|}$ formulas of the form $\exists^{\geq 1} x\, A_i(x)$ or $\exists^0 x\, A_i(x)$, one for each atom over $\mathcal{P}$. Using the same techniques as those of Theorem 3.7, we can prove the following theorem.

THEOREM 3.9. *If $\xi \in \mathcal{L}^-(\mathcal{P})$, then ξ is equivalent to a disjunction of simplified atomic descriptions over $\mathcal{P}$.*

Proof. The proof is left to the reader. □

3.2. Named elements and model descriptions. Recall that we are attempting to divide the worlds satisfying θ into classes such that:

- φ is uniform in each class, and
- the relative weight of the classes is easily computed.

In the previous section, we defined the concept of atomic description, and showed that a sentence $\theta \in \mathcal{L}(\Psi)$ is equivalent to some disjunction of atomic descriptions. This suggests that atomic descriptions might be used to classify models of θ. Līogon'kīĭ [31] has shown that this is indeed a successful approach, as long as we consider languages without constants and condition only on sentences that do not use equality. In Theorem 3.9 we showed that, for such languages, each sentence is equivalent to the disjunction of simplified atomic descriptions. The following theorem, due to Līogon'kīĭ, says that classifying models according to which simplified atomic description they satisfy leads to the desired uniformity property. This result will be a corollary of a more general theorem that we prove later.

PROPOSITION 3.10. [31] *Suppose that $\mathcal{C} = \emptyset$. If $\varphi \in \mathcal{L}(\Phi)$ and ψ is a consistent simplified atomic description over $\mathcal{P}$, then $\Pr_\infty^w(\varphi \mid \psi)$ is either 0 or 1.*

If $\mathcal{C} \neq \emptyset$, then we do not get an analogue to Proposition 3.10 if we simply partition the worlds according to the atomic description they satisfy. For example, consider the atomic description ψ_* from Example 3.5, and the sentence $\varphi = R(c_1, c_1)$ for some binary predicate R. Clearly, by symmetry, $\Pr_\infty^w(\varphi \mid \psi_*) = 1/2$, and therefore φ is not uniform over the worlds satisfying ψ_*. We do not even need to use constant symbols, such as c_1, to construct such counterexamples. Recall that the size description in ψ_* included the conjunct $\exists^1 x\, A_1(x)$. So if $\varphi' = \exists x\, (A_1(x) \wedge R(x, x))$ then we also get $\Pr_\infty^w(\varphi' \mid \psi_*) = 1/2$.

The general problem is that, given ψ_*, φ can refer "by name" to certain domain elements and thus its truth can depend on their properties. In particular, φ can refer to domain elements that are denotations of constants in $\mathcal{C}$ as well as to domain elements that are the denotations of the "fixed-size" atoms—those atoms whose size is fixed by the atomic description. In the example above, we can view "the x such that $A_1(x)$" as a name for the unique domain element satisfying atom A_1. In any model of ψ_*, we call the denotations of the constants and elements of the fixed-size atoms the *named elements* of that model. The discussion above indicates that there is no uniformity theorem if we condition only on atomic descriptions, because an atomic expression does not fix the denotations of the nonunary predicates with respect to the named elements. This analysis suggests that we should augment an atomic description with complete information about the named elements. This leads to a finer classification of models which does have the uniformity property. To define this classification formally, we need the following definitions.

DEFINITION 3.11. The *characteristic* of an atomic description ψ of size M is a tuple C_ψ of the form $\langle (f_1, g_1), \ldots, (f_{2^{|\mathcal{P}|}}, g_{2^{|\mathcal{P}|}}) \rangle$, where

- $f_i = m$ if exactly $m < M$ domain elements satisfy A_i according to ψ,
- $f_i = *$ if at least M domain elements satisfy A_i according to ψ,
- g_i is the number of distinct domain elements which are interpretations of elements in $\mathcal{C}$ that satisfy A_i according to ψ. □

Note that we can compute the characteristic of ψ immediately from the syntactic form of ψ.

DEFINITION 3.12. Suppose $C_\psi = \langle (f_1, g_1), \ldots, (f_{2^{|\mathcal{P}|}}, g_{2^{|\mathcal{P}|}}) \rangle$ is the characteristic of ψ. We say that an atom A_i is *active* in ψ if $f_i = *$; otherwise A_i is *passive*. Let $A(\psi)$ be the set $\{i \ : \ A_i \text{ is active in } \psi\}$. □

We can now define named elements.

DEFINITION 3.13. Given an atomic description ψ and a model $\mathcal{W}$ of ψ, the *named elements* in $\mathcal{W}$ are the elements satisfying the passive atoms and the elements that are denotations of constants.

The number of named elements in any model of ψ is

$$\nu(\psi) = \sum_{i \in A(\psi)} g_i + \sum_{i \notin A(\psi)} f_i,$$

where $C_\psi = \langle (f_1, g_1), \ldots, (f_{2^{|\mathcal{P}|}}, g_{2^{|\mathcal{P}|}}) \rangle$, as before. □

As we have discussed, we wish to augment ψ with information about the named elements. We accomplish this using the following notion of *model fragment* which is, roughly speaking, the projection of a model onto the named elements.

DEFINITION 3.14. Let $\psi = \sigma \wedge D$ for a size description σ and a complete description D over Ψ. A *model fragment* $\mathcal{V}$ for ψ is a model over the vocabulary Φ with domain $\{1, \ldots, \nu(\psi)\}$ such that:

- $\mathcal{V}$ satisfies D, and
- $\mathcal{V}$ satisfies the conjuncts in σ defining the sizes of the passive atoms. □

We can now define what it means for a model $\mathcal{W}$ to satisfy a model fragment $\mathcal{V}$.

DEFINITION 3.15. Let $\mathcal{W}$ be a model of ψ, and let $i_1, \ldots, i_{\nu(\psi)} \in \{1, \ldots, N\}$ be the named elements in $\mathcal{W}$, where $i_1 < i_2 < \cdots < i_{\nu(\psi)}$. The model $\mathcal{W}$ is said to *satisfy* the model fragment $\mathcal{V}$ if the function $F(j) = i_j$ from the domain of $\mathcal{V}$ to the domain of $\mathcal{W}$ is an isomorphism between $\mathcal{V}$ and the submodel of $\mathcal{W}$ formed by restricting to the named elements. □

Example 3.16. Consider the atomic description ψ_* from Example 3.5. Its characteristic C_{ψ_*} is $\langle (1, 0), (3, 1), (*, 1), (*, 0) \rangle$. The active atoms are thus A_3 and A_4. Note that $g_3 = 1$ because c_2 and c_3 are constrained to denote the same element. Thus, the number of named elements $\nu(\psi_*)$ in a model of ψ_* is $1 + 3 + 1 = 5$. Therefore each model fragment for ψ_* will have domain $\{1, 2, 3, 4, 5\}$. The elements in the domain will be the named elements; these correspond to the single element in A_1, the three elements in A_2, and the unique element denoting both c_2 and c_3 in A_3.

Let Φ be $\{P_1, P_2, c_1, c_2, c_3, R\}$ where R is a binary predicate symbol. One possible model fragment $\mathcal{V}_*$ for ψ_* over Φ gives the symbols in Φ the following interpretation:

$$\begin{array}{lll} c_1^{\mathcal{V}_*} = 4, & c_2^{\mathcal{V}_*} = 3, & c_3^{\mathcal{V}_*} = 3, \\ P_1^{\mathcal{V}_*} = \{1, 2, 4, 5\}, & P_2^{\mathcal{V}_*} = \{1, 3\}, & R^{\mathcal{V}_*} = \{(1, 3), (3, 4)\}. \end{array}$$

It is easy to verify that $\mathcal{V}_*$ satisfies the properties of the constants as prescribed by the description D in ψ_* as well as the two conjuncts $\exists^1 x\, A_1(x)$ and $\exists^3 x\, A_2(x)$ in the size description in ψ_*.

Now, let $\mathcal{W}$ be a world satisfying ψ_*, and assume that the named elements in $\mathcal{W}$ are $3, 8, 9, 14, 17$. Then $\mathcal{W}$ satisfies $\mathcal{V}_*$ if this 5-tuple of elements has precisely the same properties in $\mathcal{W}$ as the 5-tuple $1, 2, 3, 4, 5$ does in $\mathcal{V}_*$. □

Although a model fragment is a semantic structure, the definition of satisfaction just given also allows us to regard it as a logical assertion that is true or false in any model over Φ whose domain is a subset of the natural numbers. In the following, we use this view of a model description as an assertion frequently. In particular, we freely use assertions which are the conjunction of an ordinary first-order ψ and a model fragment $\mathcal{V}$, even though the result is not a first-order formula. Under this viewpoint it makes perfect sense to use an expression such as $\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V})$.

DEFINITION 3.17. A *model description* augmenting ψ over the vocabulary Φ is a conjunction of ψ and a model fragment $\mathcal{V}$ for ψ over Φ. Let $\mathcal{M}^\Phi(\psi)$ be the set of model descriptions augmenting ψ. (If Φ is clear from context, we omit the subscript and write $\mathcal{M}(\psi)$ rather than $\mathcal{M}^\Phi(\psi)$.) □

It should be clear that model descriptions are mutually exclusive and exhaustive. Moreover, as for atomic descriptions, each unary sentence θ is equivalent to some disjunction of model descriptions. From this, and elementary probability theory, we conclude the following fact, which forms the basis of our techniques for computing asymptotic conditional probabilities.

PROPOSITION 3.18. *For any $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}(\Psi)$*

$$\Pr_\infty^w(\varphi \mid \theta) = \sum_{\psi \in \mathcal{A}_\theta^\Psi} \sum_{(\psi \wedge \mathcal{V}) \in \mathcal{M}(\psi)} \Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V}) \cdot \Pr_\infty^w(\psi \wedge \mathcal{V} \mid \theta),$$

if all limits exist.

As we show in the next section, model descriptions have the uniformity property so the first term in the product will always be either 0 or 1.

It might seem that the use of model fragments is a needless complication and that any model fragment, in its role as a logical assertion, will be equivalent to some first-order sentence. Consider the following definition.

DEFINITION 3.19. Let $n = \nu(\psi)$. The *complete description capturing* $\mathcal{V}$, denoted $D_\mathcal{V}$, is a formula that satisfies the following:[7]

- $D_\mathcal{V}$ is a complete description over Φ and the variables $\{x_1, \ldots, x_n\}$ (see Definition 3.1),
- for each $i \neq j$, $D_\mathcal{V}$ contains a conjunct $x_i \neq x_j$, and
- $\mathcal{V}$ satisfies $D_\mathcal{V}$ when i is assigned to x_i for each $i = 1, \ldots, n$. □

Example 3.20. The complete description $D_{\mathcal{V}_*}$ capturing the model fragment $\mathcal{V}_*$ from the previous example has conjuncts such as $P_1(x_1)$, $\neg P_1(x_3)$, $R(x_1, x_3)$, $\neg R(x_1, x_2)$, and $x_4 = c_1$. □

The distinction between a model fragment and the complete description capturing it is subtle. Clearly if a model satisfies $\mathcal{V}$, then it also satisfies $\exists x_1, \ldots, x_n\, D_\mathcal{V}$. The converse is not necessarily true. A model fragment places additional constraints on which domain elements are denotations of the constants and passive atoms. For example, a model fragment might entail that, in any model over the domain $\{1, \ldots, N\}$, the denotation of constant c_1 is less than that of c_2. Clearly, no first-order sentence can assert this. The main implication of this difference is combinatorial; it turns out that counting model fragments (rather than the complete descriptions that capture them) simplifies many computations considerably. Although we typically use model fragments, there are occasions where it is important to remain within

[7] Note that there will, in general, be more than one complete description capturing $\mathcal{V}$. We choose one of them arbitrarily for $D_\mathcal{V}$.

first-order logic and use the corresponding complete descriptions instead. For instance, this is the case in the next subsection. Whenever we do this we will appeal to the following result, which is easy to prove.

PROPOSITION 3.21. *For any $\varphi \in \mathcal{L}(\Phi)$ and model description $\psi \wedge \mathcal{V}$ over Φ, we have*

$$\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V}) = \Pr_\infty^w(\varphi \mid \psi \wedge \exists x_1, \ldots, x_{\nu(\psi)}\, D_{\mathcal{V}}).$$

Proof. The proof is left to the reader. □

3.3. A conditional 0-1 law. In the previous section, we showed how to partition θ into model descriptions. We now show that φ is uniform over each model description. That is, for any sentence $\varphi \in \mathcal{L}(\Phi)$ and any model description $\psi \wedge \mathcal{V}$, the probability $\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V})$ is either 0 or 1. The technique we use to prove this is a generalization of Fagin's proof of the 0-1 law for first-order logic without constant or function symbols [13]. This result states that if φ is a first-order sentence in a vocabulary without constant or function symbols, then $\Pr_\infty^w(\varphi)$ is either 0 or 1.[8] It is well known that we can get asymptotic probabilities that are neither 0 nor 1 if we use constant symbols, or if we look at general conditional probabilities. However, in the special case where we condition on a model description there is still a 0-1 law. Throughout this section let $\psi \wedge \mathcal{V}$ be a fixed model description with at least one active atom, and let $n = \nu(\psi)$ be the number of named elements according to ψ.

As we said earlier, the proof of our 0-1 law is based on Fagin's proof. Like Fagin, our strategy involves constructing a theory T which, roughly speaking, states that any finite fragment of a model can be extended to a larger fragment in all possible ways. We then prove two propositions.

1. T is complete; that is, for each $\varphi \in \mathcal{L}(\Phi)$, either $T \models \varphi$ or $T \models \neg\varphi$. This result, in the case of the original 0-1 law, is due to Gaifman [16].
2. For any $\varphi \in \mathcal{L}(\Phi)$, if $T \models \varphi$ then $\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V}) = 1$.

Using the first proposition, for any sentence φ, either $T \models \varphi$ or $T \models \neg\varphi$. Therefore, using the second proposition, either $\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V}) = 1$ or $\Pr_\infty^w(\neg\varphi \mid \psi \wedge \mathcal{V}) = 1$. The latter case immediately implies that $\Pr_\infty^w(\varphi \mid \psi \wedge \mathcal{V}) = 0$. Thus, these two propositions suffice to prove the conditional 0-1 law.

We begin by defining several concepts which will be useful in defining the theory T.

DEFINITION 3.22. Let $\mathcal{X}' \supseteq \mathcal{X}$, let D be a complete description over Φ and $\mathcal{X}$, and let D' be a complete description over Φ and $\mathcal{X}'$. We say that D' *extends* D if every conjunct of D is a conjunct of D'. □

The core of the definition of T is the concept of an *extension axiom*, which asserts that any finite substructure can be extended to a larger structure containing one more element.

DEFINITION 3.23. Let $\mathcal{X} = \{x_1, \ldots, x_j\}$ for some k, let D be a complete description over Φ and $\mathcal{X}$, and let D' be any complete description over Φ and $\mathcal{X} \cup \{x_{j+1}\}$ that extends D. The sentence

$$\forall x_1, x_2, \ldots, x_j\ (D \Rightarrow \exists x_{j+1} D')$$

is an *extension axiom.* □

In the original 0-1 law, Fagin considered the theory consisting of all the extension axioms. In our case, we must consider only those extension axioms whose components are consistent with ψ, and which extend $D_{\mathcal{V}}$.

[8] As we noted in the introduction, the 0-1 law was first proved by Glebskĭi et al. [18]. However, it is Fagin's proof technique that we are using here.

DEFINITION 3.24. Given $\psi \wedge \mathcal{V}$, we define T to consist of $\psi \wedge \exists x_1, \ldots, x_n\, D_{\mathcal{V}}$ together with all extension axioms

$$\forall x_1, x_2, \ldots, x_j\ (D \Rightarrow \exists x_{j+1} D')$$

in which D (and hence D') extends $D_{\mathcal{V}}$ and in which D' (and hence D) is consistent with ψ. □

We have used $D_{\mathcal{V}}$ rather than $\mathcal{V}$ in this definition so that T is a first-order theory. Note that the consistency condition above is not redundant, even given that the components of an extension axiom extend $D_{\mathcal{V}}$. However, inconsistency can arise only if D' asserts the existence of a new element in some passive atom (because this would contradict the size description in ψ).

We now prove the two propositions that imply the 0-1 law.

PROPOSITION 3.25. *The theory T is complete.*

Proof. The proof is based on a result of Loś and Vaught [40] which says that any first-order theory with no finite models, such that all of its countable models are isomorphic, is complete. The theory T obviously has no finite models. The fact that all of its countable models are isomorphic follows by a standard "back and forth" argument. That is, let $\mathcal{U}$ and $\mathcal{U}'$ be countable models of T. Without loss of generality, assume that both models have the same domain $\mathcal{D} = \{1, 2, 3, \ldots\}$. We must find a mapping $F : \mathcal{D} \rightarrow \mathcal{D}$ which is an isomorphism between $\mathcal{U}$ and $\mathcal{U}'$ with respect to Φ.

We first map the named elements in both models to each other, in the appropriate way. Recall that T contains the assertion $\exists x_1, \ldots, x_n\, D_{\mathcal{V}}$. Since $\mathcal{U} \models T$, there must exist domain elements $d_1, \ldots, d_n \in \mathcal{D}$ that satisfy $D_{\mathcal{V}}$ under the model $\mathcal{U}$. Similarly, there must exist corresponding elements $d'_1, \ldots, d'_n \in \mathcal{D}$ that satisfy $D_{\mathcal{V}}$ under the model $\mathcal{U}'$. We define the mapping F so that $F(d_i) = d'_i$ for $i = 1, \ldots, n$. Since $D_{\mathcal{V}}$ is a complete description over these elements, and the two substructures both satisfy $D_{\mathcal{V}}$, they are necessarily isomorphic.

In the general case, assume we have already defined F over some j elements $\{d_1, d_2, \ldots, d_j\} \in \mathcal{D}$ so that the substructure of $\mathcal{U}$ over $\{d_1, \ldots, d_j\}$ is isomorphic to the substructure of $\mathcal{U}'$ over $\{d'_1, \ldots, d'_j\}$, where $d'_i = F(d_i)$ for $i = 1, \ldots, j$. Because both substructures are isomorphic there must be a description D that is satisfied by both. Since we began by creating a mapping between the named elements, we can assume that D extends $D_{\mathcal{V}}$. We would like to extend the mapping F so that it eventually exhausts both domains. We accomplish this by using the even rounds of the construction (the rounds where j is even) to ensure that $\mathcal{U}$ is covered, and the odd rounds to ensure that $\mathcal{U}'$ is covered. More precisely, if j is even, let d be the first element in $\mathcal{D}$ which is not in $\{d_1, \ldots, d_j\}$. There is a model description D' extending D that is satisfied by $d_1, \ldots, d_j, d$ in $\mathcal{U}$. Consider the extension axiom in T asserting that any j elements satisfying D can be extended to $j+1$ elements satisfying D'. Since $\mathcal{U}'$ satisfies this axiom, there exists an element d' in $\mathcal{U}'$ such that $d'_1, \ldots, d'_j, d'$ satisfy D'. We define $F(d) = d'$. It is clear that the substructure of $\mathcal{U}$ over $\{d_1, \ldots, d_j, d\}$ is isomorphic to the substructure of $\mathcal{U}'$ over $\{d'_1, \ldots, d'_j, d'\}$. If j is odd, we follow the same procedure, except that we find a counterpart to the first domain element (in $\mathcal{U}'$) which does not yet have a pre-image in $\mathcal{U}$. It is easy to see that the final mapping F is an isomorphism between $\mathcal{U}$ and $\mathcal{U}'$. □

PROPOSITION 3.26. *For any $\varphi \in \mathcal{L}(\Phi)$, if $T \models \varphi$ then $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V}) = 1$.*

Proof. We begin by proving the claim for a sentence $\xi \in T$. By the construction of T, ξ is either $\psi \wedge \exists x_1, \ldots, x_n\, D_{\mathcal{V}}$ or an extension axiom. In the first case, Proposition 3.21 trivially implies that $\Pr^w_\infty(\xi \mid \psi \wedge \mathcal{V}) = 1$. The proof for the case that ξ is an extension axiom is based on a straightforward combinatorial argument, which we briefly sketch. Recall that one of the conjuncts of ψ is a size description σ. The sentence σ includes two types of conjuncts: those of the form $\exists^m x\, A(x)$ and those of the form $\exists^{\geq M} x\, A(x)$. Let σ' be σ with the conjuncts of the second type removed. Let ψ' be the same as ψ except that σ' replaces σ. It is easy to show that $\Pr^w_\infty(\exists^{\geq M} x\, A(x) \mid \psi' \wedge \mathcal{V}) = 1$ for any active atom A, and so $\Pr^w_\infty(\psi \mid \psi' \wedge \mathcal{V}) = 1$. Since $\psi \Rightarrow \psi'$, by straightforward probabilistic arguments, it suffices to show that $\Pr^w_\infty(\xi \mid \psi' \wedge \mathcal{V}) = 1$.

Suppose ξ is an extension axiom involving D and D', where D is a complete description over $\mathcal{X} = \{x_1, \ldots, x_j\}$ and D' is a description over $\mathcal{X} \cup \{x_{j+1}\}$ that extends D. Fix a domain size N, and some particular j domain elements $d_1, \ldots, d_j$ that satisfy D. Observe that, since D extends $D_{\mathcal{V}}$, all the named elements are among $d_1, \ldots, d_j$. For a given $d \notin \{d_1, \ldots, d_j\}$, let $B(d)$ denote the event that $d_1, \ldots, d_j, d$ satisfies D', conditioned on $\psi' \wedge \mathcal{V}$. The probability of $B(d)$, given that $d_1, \ldots, d_j$ satisfies D, is typically very small but is bounded away from 0 by some β independent of N. To see this, note that D' is consistent with $\psi \wedge \mathcal{V}$ (because D' is part of an extension axiom) and so there is a consistent way of choosing how d is related to $d_1, \ldots, d_j$ so as to satisfy D'. Then observe that the total number of possible ways to choose d's properties (as they relate to $d_1, \ldots, d_j$) is independent of N. Since D extends $D_{\mathcal{V}}$, the model fragment defined over the elements $d_1, \ldots, d_j$ satisfies $\psi' \wedge \mathcal{V}$. (Note that it does not necessarily satisfy ψ, which is why we replaced ψ with ψ'.) Since the properties of an element d and its relation to $d_1, \ldots, d_j$ can be chosen independently of the properties of a different element d', the different events $B(d)$, $B(d'), \ldots$ are all independent. Therefore, the probability that there is no domain element at all that, together with $d_1, \ldots, d_j$, satisfies D' is at most $(1-\beta)^{N-j}$. This bounds the probability of the extension axiom being false, relative to fixed $d_1, \ldots, d_j$. There are exactly $\binom{N}{j}$ ways of choosing j elements, so the probability of the axiom being false anywhere in a model is at most $\binom{N}{j}(1-\beta)^{N-j}$. However, this tends to 0 as N goes to infinity. Therefore, the axiom $\forall x_1, \ldots, x_j\, (D \Rightarrow \exists x_{j+1}\, D')$ has asymptotic probability 1 given $\psi' \wedge \mathcal{V}$, and therefore also given $\psi \wedge \mathcal{V}$.

It remains to deal only with the case of a general formula $\varphi \in \mathcal{L}(\Phi)$ such that $T \models \varphi$. By the compactness theorem for first-order logic, if $T \models \varphi$ then there is some finite conjunction of assertions $\xi_1, \ldots, \xi_m \in T$ such that $\wedge_{i=1}^m \xi_i \models \varphi$. By the previous case, each such ξ_i has asymptotic probability 1, and therefore so does this finite conjunction. Hence, the asymptotic probability $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ is also 1. □

As outlined above, this concludes the proof of the main theorem of this section, which we now state.

THEOREM 3.27. *For any sentence* $\varphi \in \mathcal{L}(\Phi)$ *and model description* $\psi \wedge \mathcal{V}$, $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ *is either* 0 *or* 1.

Note that if ψ is a simplified atomic description, then there are no named elements in any model of ψ. Therefore, the only model description augmenting ψ is simply ψ itself. Thus Proposition 3.10, which is Līogon'kīĭ's result, is a corollary of the above theorem.

3.4. Computing the relative weights of model descriptions. We now want to compute the relative weights of model descriptions. It will turn out that certain model descriptions are dominated by others, so that their relative weight is 0, while all the dominating model descriptions have equal weight. Thus, the problem of computing the relative weights of model descriptions reduces to identifying the dominating model descriptions. There are two factors that determine which model descriptions dominate. The first, and more significant, is the number of active atoms; the second is the number of named elements. Let $\alpha(\psi)$ denote the number of active atoms according to ψ.

To compute these relative weights of the model descriptions, we must evaluate $\#world^{\Phi}_N(\psi \wedge \mathcal{V})$. The following lemma gives a precise expression for the asymptotic behavior of this function as N grows large.

LEMMA 3.28. *Let ψ be a consistent atomic description of size $M \geq |\mathcal{C}|$ over Ψ, and let $(\psi \wedge \mathcal{V}) \in \mathcal{M}^{\Phi}(\psi)$.*

(a) *If $\alpha(\psi) = 0$ and $N > \nu(\psi)$, then $\#world_N^{\Psi}(\psi) = 0$. In particular, this holds for all $N > 2^{|\mathcal{P}|}M$.*

(b) *If $\alpha(\psi) > 0$, then*

$$\#world_N^{\Phi}(\psi \wedge \mathcal{V}) \sim \binom{N}{n} a^{N-n} 2^{\sum_{i \geq 2} b_i (N^i - n^i)},$$

where $a = \alpha(\psi)$, $n = \nu(\psi)$, and b_i is the number of predicates of arity i in Φ.

Proof. Suppose that $C_\psi = \langle (f_1, g_1), \ldots, (f_{2^{|\mathcal{P}|}}, g_{2^{|\mathcal{P}|}}) \rangle$ is the characteristic of ψ. Let $\mathcal{W}$ be a model of cardinality N, and let N_i be the number of domain elements in $\mathcal{W}$ satisfying atom A_i. In this case, we say that the *profile of* $\mathcal{W}$ is $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}} \rangle$. Clearly we must have $N_1 + \cdots + N_{2^{|\mathcal{P}|}} = N$. We say that the profile $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}} \rangle$ is *consistent* with C_ψ if $f_i \neq *$ implies that $N_i = f_i$, while $f_i = *$ implies that $N_i \geq M$. Notice that if $\mathcal{W}$ is a model of ψ, then the profile of $\mathcal{W}$ must be consistent with C_ψ.

For part (a), observe that if $\alpha(\psi) = 0$ and $N > \sum_i f_i$, then there can be no models of cardinality N whose profile is consistent with C_ψ. However, if $\alpha(\psi) = 0$, then $\sum_i f_i$ is precisely $\nu(\psi)$. Hence there can be no models of ψ of cardinality N if $N > \nu(\psi)$. Moreover, since $\nu(\psi) \leq 2^{|\mathcal{P}|}M$, the result holds for any $N > 2^{|\mathcal{P}|}$. This proves part (a).

For part (b), let us first consider how many ways there are of choosing a world satisfying $\psi \wedge \mathcal{V}$ with cardinality N and profile $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}} \rangle$. To do the count, we first choose which elements are to be the named elements in the domain. Clearly, there are $\binom{N}{n}$ ways in which this can be done. Once we choose the named elements, their properties are completely determined by $\mathcal{V}$.

It remains to specify the rest of the properties of the world. Let R be a nonunary predicate of arity $i \geq 2$. To completely describe the behavior of R in a world, we need to specify which of the N^i i-tuples over the domain are in the denotation of R. We have already specified this for those i-tuples all of whose components are named elements. There are n^i such i-tuples. Therefore, we have $N^i - n^i$ i-tuples left to specify. Since each subset is a possible denotation, we have $2^{N^i - n^i}$ possibilities for the denotation of R. The overall number of choices for the denotations of all nonunary predicates in the vocabulary is therefore $2^{\sum_{i \geq 2} b_i (N^i - n^i)}$.

It remains only to choose the denotations of the unary predicates for the $N' = N - n$ domain elements that are not named. Let $i_1, \ldots, i_a$ be the active atoms in ψ, and let $h_j = N_{i_j} - g_{i_j}$ for $j = 1, \ldots, a$. Thus, we need to compute all the ways of partitioning the remaining N' elements so that there are h_j elements satisfying atom A_{i_j}; there are $\binom{N'}{h_1\ h_2\ \ldots\ h_a}$ ways of doing this.

We now need to sum over all possible profiles, i.e., those consistent with $\psi \wedge \mathcal{V}$. If $i_j \in A(\psi)$, then there must be at least M domain elements satisfying A_{i_j}. Therefore $N_{i_j} \geq M$, and $h_j = N_{i_j} - g_{i_j} \geq M - g_{i_j}$. This is the only constraint on h_j. Thus, it follows that

$$\#world_N^{\Phi}(\psi \wedge \mathcal{V}) \sim \sum_{\{h_1, \ldots, h_a:\ h_1 + \cdots + h_a = N',\ \forall j\ h_j \geq M - g_{i_j}\}} \binom{N}{n} 2^{\sum_{i \geq 2} b_i (N^i - n^i)} \binom{N'}{h_1\ \ldots\ h_a}.$$

This is equal to

$$\binom{N}{n} 2^{\sum_{i \geq 2} b_i (N^i - n^i)} S$$

for

$$S = \sum_{\{h_1, \ldots, h_a:\ h_1 + \cdots + h_a = N',\ \forall j\ h_j \geq M - g_{i_j}\}} \binom{N'}{h_1\ \ldots\ h_a}.$$

It remains to get a good asymptotic estimate for S. Notice that

$$\sum_{\{h_1,\ldots,h_a:\ h_1+\cdots+h_a=N'\}} \binom{N'}{h_1\ \ldots\ h_a} = a^{N'},$$

since the sum can be viewed as describing all possible ways to assign one of a possible atoms to each of N' elements. Our goal is to show that $a^{N'}$ is actually a good approximation for S as well. Clearly $S < a^{N'}$. Let

$$S_j = \sum_{\{h_1,\ldots,h_a:\ h_j<M,\, h_1+\cdots+h_a=N'\}} \binom{N'}{h_1\ \ldots\ h_a}.$$

Straightforward computation shows that

$$\begin{aligned} S_1 &= \sum_{\{h_1,\ldots,h_a:\ h_1<M,\ h_1+\cdots+h_a=N'\}} \binom{N'}{h_1\ \ldots\ h_a} \\ &= \sum_{h_1=0}^{M-1} \sum_{\{h_2,\ldots,h_a:\ h_2+\cdots+h_a=N'-h_1\}} \binom{N'}{h_1}\binom{N'-h_1}{h_2\ \ldots\ h_a} \\ &\le \sum_{h_1=0}^{M-1} \frac{(N')^{h_1}}{h_1!}(a-1)^{N'-h_1} \\ &< MN^M(a-1)^{N'}. \end{aligned}$$

Similar arguments show that $S_j < MN^M(a-1)^{N'}$ for all j. It follows that

$$\begin{aligned} S &> \sum_{\{h_1,\ldots,h_a:h_1+\cdots+h_a=N'\}} \binom{N'}{h_1\ \ldots\ h_a} - (S_1+\cdots+S_a) \\ &> a^{N'} - aMN^M(a-1)^{N'}. \end{aligned}$$

Therefore,

$$S \sim a^{N'} = a^{N-n},$$

thus concluding the proof. □

The asymptotic behavior described in this lemma motivates the following definition.

DEFINITION 3.29. Given an atomic description ψ over Ψ, let the *degree* of ψ, written $\Delta(\psi)$, be the pair $(\alpha(\psi), \nu(\psi))$, and let degrees be ordered lexicographically. We extend this definition to sentences as follows. For $\theta \in \mathcal{L}(\Psi)$, we define the *degree of* θ *over* Ψ, written $\Delta^{\Psi}(\theta)$, to be $\max_{\psi\in\mathcal{A}_\theta^\Psi} \Delta(\psi)$, and the *activity count* of θ to be $\alpha^{\Psi}(\theta)$ (i.e., the first component of $\Delta^{\Psi}(\theta)$). □

One important conclusion of this lemma justifies our treatment of well-definedness (Definition 2.2) when conditioning on unary formulas. It shows that if θ is satisfied in some "sufficiently large" model, then it is satisfiable over all "sufficiently large" domains.

LEMMA 3.30. *Suppose that* $\theta \in \mathcal{L}(\Psi)$, *and* $M = d(\theta) + |\mathcal{C}_\theta|$. *Then the following conditions are equivalent:*

(a) *θ is satisfied in some model of cardinality greater than* $2^{|\mathcal{P}|}M$,

(b) $\alpha^{\Psi}(\theta) > 0$,

(c) *for all* $N > 2^{|\mathcal{P}|}M$, *θ is satisfiable in some model of cardinality* N,

(d) $\Pr_\infty^w(* \mid \theta)$ *is well defined.*

Proof. By definition, θ is satisfiable in some model of cardinality N iff $\#world_N^{\Psi}(\theta) > 0$. We first show that (a) implies (b). If θ is satisfied in some model of cardinality N greater than $2^{|\mathcal{P}|}M$, then there is some atomic description $\psi \in \mathcal{A}_\theta^{\Psi}$ such that ψ is satisfied in some model of cardinality N. Using part (a) of Lemma 3.28, we deduce that $\alpha(\psi) > 0$ and therefore that $\alpha^{\Psi}(\theta) > 0$. That (b) entails (c) can be verified by examining the proof of Lemma 3.28. That (c) implies (d) and (d) implies (a) is immediate from the definition of well-definedness. □

For the case of sentences in the languages without equality or constants, the condition for well-definedness simplifies considerably.

COROLLARY 3.31. *If* $\theta \in \mathcal{L}^{-}(\mathcal{P})$, *then* $\Pr_\infty^w(* \mid \theta)$ *is well defined iff* θ *is satisfiable.*

Proof. The only if direction is obvious. For the other, if θ is consistent, then it is equivalent to a nonempty disjunction of consistent simplified atomic descriptions. Any consistent simplified atomic description has arbitrarily large models. □

We remark that we can extend our proof techniques to show that Corollary 3.31 holds even if $\mathcal{C} \neq \emptyset$, although we must still require that θ does not mention equality. We omit details here.

For the remainder of this paper, we will consider only sentences θ such that $\alpha^{\Psi}(\theta) > 0$.

Lemma 3.28 shows that, asymptotically, the number of worlds satisfying $\psi \wedge \mathcal{V}$ is completely determined by the degree of ψ. Model descriptions of higher degree have many more worlds, and therefore dominate. On the other hand, model descriptions with the same degree have the same number of worlds at the limit, and are therefore equally likely. This observation allows us to compute the relative weights of different model descriptions.

DEFINITION 3.32. For any degree $\delta = (a, n)$, let $\mathcal{A}_\theta^{\Psi,\delta}$ be the set of atomic descriptions $\psi \in \mathcal{A}_\theta^{\Psi}$ such that $\Delta(\psi) = \delta$. For any set of atomic descriptions $\mathcal{A}'$, we use $\mathcal{M}(\mathcal{A}')$ to denote $\cup_{\psi \in \mathcal{A}'} \mathcal{M}(\psi)$. □

THEOREM 3.33. *Let* $\theta \in \mathcal{L}(\Psi)$ *and* $\Delta^{\Psi}(\theta) = \delta \geq (1, 0)$. *Let* ψ *be an atomic description in* $\mathcal{A}_\theta^{\Psi}$, *and let* $\psi \wedge \mathcal{V} \in \mathcal{M}^{\Phi}(\psi)$.

(a) *If* $\Delta(\psi) < \delta$ *then* $\Pr_\infty^w(\psi \wedge \mathcal{V} \mid \theta) = 0$.

(b) *If* $\Delta(\psi) = \delta$ *then* $\Pr_\infty^w(\psi \wedge \mathcal{V} \mid \theta) = 1/|\mathcal{M}^{\Phi}(\mathcal{A}_\theta^{\Psi,\delta})|$.

Proof. We begin with part (a). Since $\Delta^{\Psi}(\theta) = \delta = (a, n)$, there must exist some atomic description $\psi' \in \mathcal{A}_\theta^{\Psi}$ with $\Delta(\psi') = \delta$. Let $\psi' \wedge \mathcal{V}'$ be some model description in $\mathcal{M}(\psi')$.

$$\begin{aligned}
\Pr_N^w(\psi \wedge \mathcal{V} \mid \theta) &= \frac{\#world_N^{\Phi}(\psi \wedge \mathcal{V})}{\#world_N^{\Phi}(\theta)} \\
&\leq \frac{\#world_N^{\Phi}(\psi \wedge \mathcal{V})}{\#world_N^{\Phi}(\psi' \wedge \mathcal{V}')} \\
&\sim \frac{\binom{N}{\nu(\psi)}(\alpha(\psi))^{N-\nu(\psi)} 2^{\sum_{i \geq 2} b_i (N^i - \nu(\psi)^i)}}{\binom{N}{n} a^{N-n} 2^{\sum_{i \geq 2} b_i (N^i - n^i)}} \\
&= O(N^{\nu(\psi)-n}(\alpha(\psi)/a)^N).
\end{aligned}$$

The last step uses the fact that n and $\nu(\psi)$ can be considered to be constant, and that for any constant k, $\binom{N}{k} \sim N^k/k!$. Since $\Delta(\psi) < \delta = (a, n)$, either $\alpha(\psi) < a$ or $\alpha(\psi) = a$ and $\nu(\psi) < n$. In either case, it is easy to see that $N^{\nu(\psi)-n}(\alpha(\psi)/a)^N$ tends to 0 as $N \rightarrow \infty$, giving us our result.

To prove part (b), we first observe that, due to part (a), we can essentially ignore all model descriptions of low degree. That is:

$$\#world_N^{\Phi}(\theta) \sim \sum_{(\psi' \wedge \mathcal{V}') \in \mathcal{M}(\mathcal{A}_\theta^{\Psi,\delta})} \#world_N^{\Phi}(\psi' \wedge \mathcal{V}').$$

Therefore,

$$\begin{aligned}\Pr^w_N(\psi \wedge \mathcal{V} \mid \theta) &= \frac{\#world^\Phi_N(\psi \wedge \mathcal{V})}{\sum_{(\psi' \wedge \mathcal{V}') \in \mathcal{M}(\mathcal{A}^{\Psi,\delta}_\theta)} \#world^\Phi_N(\psi' \wedge \mathcal{V}')} \\ &\sim \frac{\binom{N}{n} a^{N-n} 2^{\sum_{i\geq 2} b_i(N^i - n^i)}}{\sum_{(\psi' \wedge \mathcal{V}') \in \mathcal{M}(\mathcal{A}^{\Psi,\delta}_\theta)} \binom{N}{n} a^{N-n} 2^{\sum_{i\geq 2} b_i(N^i - n^i)}} \\ &= \frac{1}{|\mathcal{M}(\mathcal{A}^{\Psi,\delta}_\theta)|},\end{aligned}$$

as desired. □

Combining this result with Proposition 3.18, we deduce the following.

THEOREM 3.34. *For any $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}(\Psi)$ such that $\Delta^\Psi(\theta) = \delta \geq (1, 0)$,*

$$\Pr^w_\infty(\varphi \mid \theta) = \sum_{(\psi \wedge \mathcal{V}) \in \mathcal{M}(\mathcal{A}^{\Psi,\delta}_\theta)} \Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V}) / |\mathcal{M}(\mathcal{A}^{\Psi,\delta}_\theta)|.$$

This result, together with the techniques of the next section, will allow us to compute asymptotic conditional probabilities.

The results of Līogon'kīĭ are a simple corollary of the above theorem. For an activity count a, let $\mathcal{A}^{\Psi,a}_\theta$ denote the set of atomic descriptions $\psi \in \mathcal{A}^\Psi_\theta$ such that $\alpha(\psi) = a$.

THEOREM 3.35. [31] *Assume that $\mathcal{C} = \emptyset$, $\varphi \in \mathcal{L}(\Phi)$, $\theta \in \mathcal{L}^-(\mathcal{P})$, and $\alpha^\mathcal{P}(\theta) = a > 0$. Then* $\Pr^w_\infty(\varphi \mid \theta) = \sum_{\psi \in \mathcal{A}^{\mathcal{P},a}_\theta} \Pr^w_\infty(\varphi \mid \psi) / |\mathcal{A}^{\mathcal{P},a}_\theta|$.

Proof. By Theorem 3.9, a sentence $\theta \in \mathcal{L}^-(\mathcal{P})$ is the disjunction of the simplified atomic descriptions in $\mathcal{A}^\mathcal{P}_\theta$. A simplified atomic description ψ has no named elements, and therefore $\Delta(\psi) = (\alpha(\psi), 0)$. Moreover, $\mathcal{M}(\psi) = \{\psi\}$ for any $\psi \in \mathcal{A}^\mathcal{P}_\theta$. The result now follows trivially from the previous theorem. □

This calculation simplifies somewhat if φ and θ are both monadic. In this case, we assume without loss of generality that $d(\varphi) = d(\theta)$. (If not, we can replace φ with $\varphi \wedge \theta$ and θ with $\theta \wedge (\varphi \vee \neg\varphi)$.) This allows us to assume that $\mathcal{A}^\Psi_{\varphi\wedge\theta} \subseteq \mathcal{A}^\Psi_\theta$, thus simplifying the presentation.

COROLLARY 3.36. *Assume that $\varphi, \theta \in \mathcal{L}^-(\mathcal{P})$, and $\alpha^\mathcal{P}(\theta) = a > 0$. Then*

$$\Pr^w_\infty(\varphi \mid \theta) = \frac{|\mathcal{A}^{\mathcal{P},a}_{\varphi\wedge\theta}|}{|\mathcal{A}^{\mathcal{P},a}_\theta|}.$$

Proof. Since φ is monadic, $\varphi \wedge \theta$ is equivalent to a disjunction of the atomic descriptions $\mathcal{A}^\mathcal{P}_{\varphi\wedge\theta} \subseteq \mathcal{A}^\mathcal{P}_\theta$. Atomic descriptions are mutually exclusive; thus, for $\psi \in \mathcal{A}^\Psi_\theta$, $\Pr^w_\infty(\varphi \mid \psi) = 1$ if $\psi \in \mathcal{A}^\Psi_{\varphi\wedge\theta}$ and $\Pr^w_\infty(\varphi \mid \psi) = 0$ otherwise. The result then follows immediately from Theorem 3.35. □

3.5. Asymptotic probabilities for random structures. We now turn our attention to computing asymptotic conditional probabilities using the random-structures method. There are two cases. In the first, there is at least one nonunary predicate in the vocabulary. In this case, random structures is equivalent to random worlds, so that the results in the previous section apply without change.

THEOREM 3.37. *If $\Phi \neq \Psi$ then for any $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}(\Psi)$,* $\Pr^{s,\Phi}_\infty(\varphi \mid \theta) = \Pr^w_\infty(\varphi \mid \theta)$.

Proof. Since $\Phi \neq \Psi$, there is at least one nonunary predicate in Φ that does not appear in θ. We can therefore apply Corollary 2.10, and conclude the desired result. □

Random worlds and random structures differ in the second case, when all predicates are unary, but the absence of high-arity predicates makes this a much simpler problem. For the rest of this section, we investigate the asymptotic probability of φ given θ using random structures, for $\varphi, \theta \in \mathcal{L}(\Psi)$. As discussed earlier, we can assume without loss of generality that $\mathcal{A}^{\Psi}_{\varphi\wedge\theta} \subseteq \mathcal{A}^{\Psi}_{\theta}$.

We will use the same basic technique of dividing the structures satisfying θ into classes, and computing the probability of φ on each part. In the case of random structures, however, we partition structures according to the atomic description they satisfy. That is, our computation makes use of the equation

$$\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta) = \sum_{\psi \in \mathcal{A}^{\Psi}_{\theta}} \Pr^{s,\Psi}_{\infty}(\varphi \mid \psi)\Pr^{s,\Psi}_{\infty}(\psi \mid \theta).$$

As for the case of random worlds, we assign weights to atomic descriptions by counting structures. The following lemma computes $\#struct^{\Psi}_{N}(\psi)$ for an atomic description ψ. In the case of random worlds, we saw in Lemma 3.28 that certain model descriptions $\psi \wedge \mathcal{V}$ dominate others, based on the activity count $\alpha(\psi)$ and the number of named elements $\nu(\psi)$ of the atomic description. The following analogue of Lemma 3.28 shows that, for the random-structures method, atomic descriptions of higher activity count $\alpha(\psi)$ dominate regardless of the number of named elements.

LEMMA 3.38. *Let ψ be a consistent atomic description of size $M \geq |\mathcal{C}|$ over Ψ.*

(a) *If $\alpha(\psi) = 0$ and $N > \nu(\psi)$, then $\#struct^{\Psi}_{N}(\psi) = 0$. In particular, this holds for $N > 2^{|\mathcal{P}|}M$.*

(b) *If $\alpha(\psi) > 0$ then $\#struct^{\Psi}_{N}(\psi) \sim \frac{N^{\alpha(\psi)-1}}{(\alpha(\psi)-1)!}$.*

Proof. Part (a) follows immediately from Lemma 3.28(a), since $\#struct^{\Psi}_{N}(\psi) = 0$ iff $\#world^{\Psi}_{N}(\psi) = 0$.

We now proceed to show part (b). Suppose that $C_{\psi} = \langle (f_1, g_1), \ldots, (f_{2^{|\mathcal{P}|}}, g_{2^{|\mathcal{P}|}})\rangle$ is the characteristic of ψ. Let $\mathcal{S}$ be a structure of cardinality N. For any of the models in $\mathcal{S}$, let N_i be the number of domain elements satisfying atom A_i (because $\mathcal{S}$ is an isomorphism class, N_i must be the same for all worlds in the class). As before, we say that the *profile of $\mathcal{S}$* is $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}}\rangle$. Clearly we must have $N_1 + \cdots + N_{2^{|\mathcal{P}|}} = N$. Recall that the profile $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}}\rangle$ is consistent with C_{ψ} if $f_i \neq *$ implies that $N_i = f_i$, while $f_i = *$ implies that $N_i \geq M$. Notice that if $\mathcal{S}$ is a structure of ψ, then the profile of $\mathcal{S}$ must be consistent with C_{ψ}. In fact, there is a unique structure consistent with ψ with cardinality N and profile $\langle N_1, \ldots, N_{2^{|\mathcal{P}|}}\rangle$. This is because a structure is determined by the number of elements in each atom, the assignment of constants to atoms, and the equality relations between the constants. The first part is determined by the profile, while the second and third are determined by ψ. It therefore remains to count only the number of profiles consistent with C_{ψ}. Let $N' = N - \sum_{i \notin A(\psi)} f_i$, and let $i_1, \ldots, i_a$, $a = \alpha(\psi)$, be the active components of C_{ψ}. We want to compute

$$S = |\{\langle N_{i_1}, \ldots, N_{i_a}\rangle : N_{i_1} + \cdots + N_{i_a} = N',\ \forall j\ N_{i_j} \geq M\}| .$$

Notice that, since $\sum_{i \notin A(\psi)} f_i$ and a are constants,

$$|\{\langle N_{i_1}, \ldots, N_{i_a}\rangle : N_{i_1} + \cdots + N_{i_a} = N'\}| = \binom{N'+a-1}{a-1} \sim \frac{(N')^{a-1}}{(a-1)!} \sim \frac{N^{a-1}}{(a-1)!} .$$

As in the proof of Lemma 3.28, let $S_j = |\{\langle N_{i_1}, \ldots, N_{i_a}\rangle : N_{i_1} + \cdots + N_{i_a} = N',\ N_{i_j} < M\}|$. It is easy to see that

$$\begin{aligned} S_1 &= \sum_{N_{i_1}=0}^{M-1} |\{\langle N_{i_2}, \ldots, N_{i_a}\rangle : N_{i_2} + \cdots + N_{i_a} = N' - N_{i_1}\}| \\ &< M(N')^{a-2} , \end{aligned}$$

and similarly for all other S_j. Therefore,

$$\begin{aligned} S &\geq \binom{N'+a-1}{a-1} - (S_1 + \cdots + S_a) \\ &> \binom{N'+a-1}{a-1} - aM(N')^{a-2} \\ &\sim \frac{(N')^{a-1}}{(a-1)!} - aM(N')^{a-2} \\ &\sim \frac{N^{a-1}}{(a-1)!} . \end{aligned}$$

It follows that $S \sim \frac{N^{a-1}}{(a-1)!}$, as desired. □

COROLLARY 3.39. *If $\theta \in \mathcal{L}(\Psi)$, $\alpha^{\Psi}(\theta) = a > 0$, and $\psi \in \mathcal{A}_{\theta}^{\Psi}$, then*

(a) *if $\alpha(\psi) < a$ then $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta) = 0$,*

(b) *if $\alpha(\psi) = a$ then $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta) = 1/|\mathcal{A}_{\theta}^{\Psi,a}|$.*

Proof. Using Lemma 3.38, we can deduce that

$$\Pr_N^{s,\Psi}(\psi \mid \theta) \sim \frac{N^{\alpha(\psi)-1}/(\alpha(\psi)-1)!}{\sum_{\psi' \in \mathcal{A}_{\theta}^{\Psi}} N^{\alpha(\psi')-1}/(\alpha(\psi')-1)!} .$$

As in the proof of Theorem 3.33, we can deduce that if $\alpha(\psi) < a = \alpha^{\Psi}(\theta)$, then $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta) = 0$. Therefore

$$\#struct_N^{\Psi}(\theta) \sim \sum_{\psi' \in \mathcal{A}_{\theta}^{\Psi,a}} \#struct_N^{\Psi}(\psi').$$

Since $\#struct_N^{\Phi}(\psi')$ is asymptotically the same for all ψ' with the same activity count $\alpha(\psi')$, we deduce that if $\alpha(\psi) = a$, then $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta) = 1/|\mathcal{A}_{\theta}^{\Psi,a}|$. □

We can now complete the computation of the value of $\Pr_{\infty}^{s,\Psi}(\varphi \mid \theta)$ for the case of unary φ, θ.

THEOREM 3.40. *If $\varphi, \theta \in \mathcal{L}(\Psi)$ and $a = \alpha^{\Psi}(\theta) > 0$, then*

$$\Pr_{\infty}^{s,\Psi}(\varphi \mid \theta) = \frac{|\mathcal{A}_{\varphi\wedge\theta}^{\Psi,a}|}{|\mathcal{A}_{\theta}^{\Psi,a}|} .$$

Proof. Recall that

$$\Pr_{\infty}^{s,\Psi}(\varphi \mid \theta) = \sum_{\psi \in \mathcal{A}_{\theta}^{\Psi}} \Pr_{\infty}^{s,\Psi}(\varphi \mid \psi) \Pr_{\infty}^{s,\Psi}(\psi \mid \theta).$$

We have already computed $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta)$. It remains to compute $\Pr_{\infty}^{s,\Psi}(\varphi \mid \psi)$ for an atomic description ψ. Recall that $\varphi \wedge \theta$ is equivalent to a disjunction of the atomic descriptions $\mathcal{A}_{\varphi\wedge\theta}^{\Psi} \subseteq \mathcal{A}_{\theta}^{\Psi}$, and that atomic descriptions are mutually exclusive. Therefore, for $\psi \in \mathcal{A}_{\theta}^{\Psi}$, it is easy to see that $\Pr_{\infty}^{s,\Psi}(\varphi \mid \psi) = 1$ if $\psi \in \mathcal{A}_{\varphi\wedge\theta}^{\Psi}$ and $\Pr_{\infty}^{s,\Psi}(\varphi \mid \psi) = 0$ otherwise. Since $\Pr_{\infty}^{s,\Psi}(\psi \mid \theta)$ is 0 except if $\psi \in \mathcal{A}_{\theta}^{\Psi,a}$, it follows from Corollary 3.39 that

$$\Pr_{\infty}^{s,\Psi}(\varphi \mid \theta) = \frac{|\mathcal{A}_{\varphi\wedge\theta}^{\Psi,a}|}{|\mathcal{A}_{\theta}^{\Psi,a}|},$$

as desired. □

Recall that if $\xi \in \mathcal{L}^{-}(\mathcal{P})$, then $\Delta^{\mathcal{P}}(\xi) = (\alpha^{\mathcal{P}}(\xi), 0)$. Thus, comparing Corollary 3.36 with Theorem 3.40 shows that, for formulas in $\mathcal{L}^{-}(\mathcal{P})$, random worlds and random structures are the same.

COROLLARY 3.41. *If $\varphi, \theta \in \mathcal{L}^{-}(\mathcal{P})$, then for any $\Psi \supseteq \mathcal{P}$, $\Pr^{w}_{\infty}(\varphi \mid \theta) = \Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$.*

Note that, although in general the asymptotic conditional probability in the case of random structures may depend on the vocabulary, for formulas without constant symbols or equality, it does not.

COROLLARY 3.42. *If $\varphi, \theta \in \mathcal{L}^{-}(\mathcal{P})$, and $\mathcal{P}_{\varphi\wedge\theta} \subseteq \Psi \cap \Psi'$ then $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta) = \Pr^{s,\Psi'}_{\infty}(\varphi \mid \theta) = \Pr^{w}_{\infty}(\varphi \mid \theta)$.*

4. Complexity analysis. In this section we investigate the computational complexity of problems associated with asymptotic conditional probabilities. In fact, we consider three problems: deciding whether the asymptotic probability is well defined, computing it, and approximating it. As we did in the previous section, we begin with the case of random worlds. As we shall see, the same complexity results also hold for the random-structures case (even though, as we have seen, the actual values being computed can differ between random structures and random worlds). The analysis for the unary case of random structures is given in §4.6.

Our computational approach is based on Theorem 3.34, which tells us that

$$\Pr^{w}_{\infty}(\varphi \mid \theta) = \frac{1}{|\mathcal{M}(\mathcal{A}^{\Psi,\delta}_{\theta})|} \cdot \sum_{(\hat{\psi}\wedge\mathcal{V}) \in \mathcal{M}(\mathcal{A}^{\Psi,\delta}_{\theta})} \Pr^{w}_{\infty}(\varphi \mid \hat{\psi} \wedge \mathcal{V}).$$

The basic structure of the algorithms we give for computing $\Pr^{w}_{\infty}(\varphi \mid \theta)$ is simply to enumerate model descriptions $\hat{\psi} \wedge \mathcal{V}$ and, for those of the maximum degree, compute the conditional probability $\Pr^{w}_{\infty}(\varphi \mid \hat{\psi} \wedge \mathcal{V})$. In §4.1 we show how to compute this latter probability.

The complexity of computing asymptotic probabilities depends on several factors: whether the vocabulary is finite, whether there is a bound on the depth of quantifier nesting, whether equality is used in θ, whether nonunary predicates are used, and whether there is a bound on predicate arities. If we consider a fixed and finite vocabulary there are just two cases: if there is no bound on the depth of quantifier nesting then computing probabilities is PSPACE-complete; otherwise the computation can be done in linear time. The case in which the vocabulary is not fixed, which is the case more typically considered in complexity theory, is more complicated. The problem of computing probabilities is complete for the class #EXP (defined below) if either (a) equality is not used in θ and there is some fixed bound on the arity of predicates that can appear in φ, or (b) all predicates in φ are unary. Weakening these conditions in any way—allowing equality while maintaining any arity bound greater than one, or allowing unbounded arity even without using equality in θ—gives the same complexity as the general case (which is complete for a class we call #TA(EXP, LIN), defined later). All these results for the case of an unbounded vocabulary use formulas with quantifier depth 2. As suggested in the introduction, the complexity of the problem drops in the case of formulas of depth 1. A detailed analysis for this case can be found in [27].

4.1. Computing the 0-1 probabilities. The method we give for computing $\Pr^{w}_{\infty}(\varphi \mid \hat{\psi} \wedge \mathcal{V})$ is an extension of Grandjean's algorithm [20] for computing asymptotic probabilities in the unconditional case. For the purposes of this section, fix a model description $\hat{\psi} \wedge \mathcal{V}$ over Φ. In our proof of the conditional 0-1 law (§3.3), we defined a theory T corresponding to $\psi \wedge \mathcal{V}$. We showed that T is a complete and consistent theory, and that $\varphi \in \mathcal{L}(\Phi)$ has asymptotic probability 1 iff $T \models \varphi$. We therefore need an algorithm that decides whether $T \models \varphi$.

Grandjean's original algorithm decides whether $\Pr^w_\infty(\varphi)$ is 0 or 1 for a sentence φ with no constant symbols. For this case, the theory T consists of all possible extension axioms, rather than just the ones involving model descriptions extending $D_\mathcal{V}$ and consistent with ψ (see Definition 3.24). The algorithm has a recursive structure, which at each stage attempts to decide something more general than whether $T \models \varphi$. It decides whether $T \models D \Rightarrow \xi$, where

- D is a complete description over Φ and the set $\mathcal{X}_j = \{x_1, \dots, x_j\}$ of variables, and
- $\xi \in \mathcal{L}(\Phi)$ is a formula whose only free variables (if any) are in $\mathcal{X}_j$.

The algorithm begins with $j = 0$. In this case, D is a complete description over $\mathcal{X}_0$ and Φ. Since Φ contains no constants and $\mathcal{X}_0$ is the empty set, D must in fact be the empty conjunction, which is equivalent to the formula *true*. Thus, for $j = 0$, $T \models D \Rightarrow \varphi$ iff $T \models \varphi$. While $j = 0$ is the case of real interest, the recursive construction Grandjean uses forces us to deal with the case $j > 0$ as well. In this case, the formula $D \Rightarrow \varphi$ contains free variables; these variables are treated as being universally quantified for purposes of determining if $T \models D \Rightarrow \varphi$.

Our algorithm is the natural extension to Grandjean's algorithm for the case of conditional probabilities and for a language with constants. The chief difference is that we begin by considering $T \models D_\mathcal{V} \Rightarrow \varphi$ (where $\mathcal{V}$ is the model fragment on which we are conditioning). Suppose $D_\mathcal{V}$ uses the variables $x_1, \dots, x_n$, where $n = \nu(\psi)$. We have said that $T \models D_\mathcal{V} \Rightarrow \varphi$ is interpreted as $T \models \forall x_1, \dots, x_n\ (D_\mathcal{V} \Rightarrow \varphi)$, and this is equivalent to $T \models (\exists x_1, \dots, x_n\ D_\mathcal{V}) \Rightarrow \varphi$ because φ is closed. Because $\exists x_1, \dots, x_n\ D_\mathcal{V}$ is in T by definition, this latter assertion is equivalent to $T \models \varphi$, which is what we are really interested in.

Starting from the initial step just outlined, the algorithm then recursively examines smaller and smaller subformulas of φ, while maintaining a description D which keeps track of any new free variables that appear in the current subformula. Of course, D will also extend $D_\mathcal{V}$ and will be consistent with ψ.

We now describe the algorithm in more detail. Without loss of generality, we assume that all negations in φ are pushed in as far as possible, so that only atomic formulas are negated. We also assume that φ does not use the variables $x_1, x_2, x_3, \dots$. The algorithm proceeds by induction on the structure of the formula, until the base case—an atomic formula or its negation—is reached. The following equivalences form the basis for the recursive procedure:

1. If ξ is of the form ξ' or $\neg\xi'$ for an atomic formula ξ', then $T \models D \Rightarrow \xi$ iff ξ is a conjunct of D.
2. If ξ is of the form $\xi_1 \wedge \xi_2$, then $T \models D \Rightarrow \xi$ iff $T \models D \Rightarrow \xi_1$ and $T \models D \Rightarrow \xi_2$.
3. If ξ is of the form $\xi_1 \vee \xi_2$ then $T \models D \Rightarrow \xi$ iff $T \models D \Rightarrow \xi_1$ or $T \models D \Rightarrow \xi_2$.
4. If ξ is of the form $\exists y\, \xi'$ and D is a complete description over Φ and $\{x_1, \dots, x_j\}$, then $T \models D \Rightarrow \xi$ iff $T \models D' \Rightarrow \xi'[y/x_{j+1}]$ for some complete description D' over Φ and $\{x_1, \dots, x_{j+1}\}$ that extends D and is consistent with ψ.
5. If ξ is of the form $\forall y\, \xi'$ and D is a complete description over Φ and $\{x_1, \dots, x_j\}$, then $T \models D \Rightarrow \xi$ iff $T \models D' \Rightarrow \xi'[y/x_{j+1}]$ for all complete descriptions D' over Φ and $\{x_1, \dots, x_{j+1}\}$ that extend D and are consistent with ψ.

The proof that this procedure is correct is based on the following proposition, which can easily be proved using the same techniques as for Proposition 3.25.

PROPOSITION 4.1. *If D is a complete description over Φ and $\mathcal{X}$ and $\xi \in \mathcal{L}(\Phi)$ is a formula all of whose free variables are in $\mathcal{X}$, then either $T \models D \Rightarrow \xi$ or $T \models D \Rightarrow \neg\xi$.*

Proof. We know that T has no finite models. By the Löwenheim–Skolem Theorem [12, p. 141], we can, without loss of generality, restrict attention to countably infinite models of T.

Suppose $\mathcal{X} = \{x_1, x_2, \ldots, x_j\}$ and that $T \not\models D \Rightarrow \xi$. Then there is some countable model $\mathcal{U}$ of T, and j domain elements $\{d_1, \ldots, d_j\}$ in the domain of $\mathcal{U}$, which satisfy $D \wedge \neg\xi$. Consider another model $\mathcal{U}'$ of T, and any $\{d'_1, \ldots, d'_j\}$ in the domain of U' that satisfy D. Because D is a complete description, the substructures over $\{d_1, \ldots, d_j\}$ and $\{d'_1, \ldots, d'_j\}$ are isomorphic. We can use the back and forth construction of Proposition 3.25 to extend this to an isomorphism between $\mathcal{U}$ and $\mathcal{U}'$. But then it follows that $\{d'_1, \ldots, d'_j\}$ must also satisfy $\neg\xi$. Since $\mathcal{U}$ was arbitrary, $T \models D \Rightarrow \neg\xi$. The result follows. □

The following result shows that the algorithm above gives a sound and complete procedure for determining whether $T \models D_{\mathcal{V}} \Rightarrow \varphi$.

THEOREM 4.2. *Each of the equivalences in steps* (1)–(5) *above is true.*

Proof. The equivalences for steps (1)–(3) are easy to show, using Proposition 4.1. To prove (4), consider some formula $D \Rightarrow \exists y\, \xi'$, where D is a complete description over $x_1, \ldots, x_j$ and the free variables of ξ are contained in $\{x_1, \ldots, x_j\}$. Let $\mathcal{U}$ be some countable model of T, and let $d_1, \ldots, d_j$ be elements in $\mathcal{U}$ that satisfy D. If $\mathcal{U}$ satisfies $D \Rightarrow \exists y\, \xi'$ then there must exist some other element d_{j+1} that, together with $d_1, \ldots, d_j$, satisfies ξ. Consider the description D' over $x_1, \ldots, x_{j+1}$ that extends D and is satisfied by $d_1, \ldots, d_{j+1}$. Clearly $T \not\models D' \Rightarrow \neg\xi'[y/x_{j+1}]$ because this is false in $\mathcal{U}$. So, by Proposition 4.1, $T \models D' \Rightarrow \xi'[y/x_{j+1}]$ as required.

For the other direction, suppose that $T \models D' \Rightarrow \xi'[y/x_{j+1}]$ for some D' extending D. It follows that $T \models \exists x_{j+1} D' \Rightarrow \exists x_{j+1}\xi'[y/x_{j+1}]$. The result follows from the observation that T contains the extension axiom $\forall x_1, \ldots, x_j(D \Rightarrow \exists x_{j+1} D')$.

The proof for case (5) is similar to that for case (4), and is omitted. □

We analyze the complexity of this algorithm in terms of alternating Turing machines (ATMs) [5]. Recall that in an ATM, the nonterminal states are classified into two kinds: universal and existential. Just as with a nondeterministic TM, a nonterminal state may have one or more successors. The terminal states are classified into two kinds: accepting and rejecting. The computation of an ATM forms a tree, where the nodes are instantaneous descriptions (IDs) of the machine's state at various points in the computation, and the children of a node are the possible successor IDs. We recursively define what it means for a node in a computation tree to be an *accepting* node. Leaves are terminal states, and a leaf is accepting just if the machine is in an accepting state in the corresponding ID. A node whose ID is in an existential state is accepting iff at least one of its children is accepting. A node whose ID is in a universal state is accepting iff all of its children are accepting. The entire computation is accepting if the root is an accepting node.

We use several different measures for the complexity of an ATM computation. The time of the computation is the number of steps taken by its longest computation branch. The number of *alternations* of a computation of an ATM is the maximum number of times, over all branches, that the type of state switched (from universal to existential or vice versa). The number of *branches* is simply the number of distinct computation paths. The number of branches is always bounded by an exponential in the computation time, but sometimes we can find tighter bounds.

Grandjean's algorithm, and our variant of it, is easily implemented on an ATM. Each inductive step corresponding to a disjunction or an existential quantifier can be implemented using a sequence of existential guesses. Similarly, each step corresponding to a conjunction or a universal quantifier can be implemented using a sequence of universal guesses. Note that the number of alternations is at most $|\varphi|$. We must analyze the time and branching complexity of this ATM. Given $\psi \wedge \mathcal{V}$, each computation branch of this ATM can be regarded as doing the following. It

(a) constructs a complete description D over the variables $x_1, \ldots, x_{n+k}$ that extends $D_{\mathcal{V}}$ and is consistent with ψ, where $n = \nu(\psi)$ and $k \leq |\varphi|/2$ is the number of variables appearing in φ,

(b) chooses a formula ξ or $\neg\xi$, where ξ is an atomic subformula of φ (with free variables renamed appropriately so that they are included in $\{x_1, \ldots, x_{n+k}\}$), and

(c) checks whether $T \models D \Rightarrow \xi$.

Generating a complete description D requires time $|D|$, and if we construct D by adding conjuncts to $D_{\mathcal{V}}$ then it is necessarily the case that D extends $D_{\mathcal{V}}$. To check whether D is consistent with ψ, we must verify that D does not assert the existence of any new element in any finite atom. Under an appropriate representation of ψ (outlined after Corollary 4.4 below), this check can be done in time $O(|D|2^{|\mathcal{P}|})$. Choosing an atomic subformula ξ of φ can take time $O(|\varphi|)$. Finally, checking whether $T \models D \Rightarrow \xi$ can be accomplished by simply scanning $|D|$. It is easy to see that we can do this without backtracking over $|D|$. Since $|D| > |\xi|$, it can be done in time $O(|D|)$. Combining all these estimates, we conclude that the length of each branch is $O(|D|2^{|\mathcal{P}|} + |\varphi|)$.

Let D be any complete description over Φ and $\mathcal{X}$. Without loss of generality, we assume that each constant in Φ is equal to (at least) one of the variables in $\mathcal{X}$. To fully describe D we must specify, for each predicate R of arity i, which of the i-tuples of variables used in D satisfy R. Thus, the number of choices needed to specify the denotation of R is bounded by $|\mathcal{X}|^{\rho}$ where ρ is the maximum arity of a predicate in Φ. Therefore, $|D|$ is $O(|\Phi||\mathcal{X}|^{\rho})$. In the case of the description D generated by the algorithm, $\mathcal{X}$ is $\{x_1, \ldots, x_n, x_{n+1}, \ldots, x_{n+k}\}$, and $n + k$ is less than $n + |\varphi|$. Thus, the length of such a description D is $O(|\Phi|(n + |\varphi|)^{\rho})$.

Using this expression, and our analysis above, we see that the computation time is certainly $O(|\Phi|2^{|\mathcal{P}|}(n + |\varphi|)^{\rho})$. In general, the number of branches of the ATM is at most the number of complete descriptions multiplied by the number of atomic formulas in φ. The first of these terms can be exponential in the length of each description. Therefore the number of branches is $O(|\varphi|2^{|\Phi|(n+|\varphi|)^{\rho}}) = 2^{O(|\Phi|(n+|\varphi|)^{\rho})}$. We can, however, get a better bound on the number of branches if all predicates in Φ are unary (i.e., if $\rho = 1$). In this case, ψ already specifies all the properties of the named elements. Therefore, a complete description D is determined when we decide, for each of the at most k variables in D not corresponding to named elements, whether it is equal to a named element and, if not, which atom it satisfies. It follows that there are at most $(2^{|\Phi|} + n)^k$ complete descriptions in this case, and so at most $|\varphi|(2^{|\Phi|} + n)^k$ branches. Since $k \leq |\varphi|/2$, the number of branches is certainly $O((2^{|\Phi|} + n)^{|\varphi|})$ if $\rho = 1$. We summarize this analysis in the following theorem, which forms the basis for almost all of our upper bounds in this section.

THEOREM 4.3. *There exists an alternating Turing machine that takes as input a finite vocabulary Φ, a model description $\psi \wedge \mathcal{V}$ over Φ, and a formula $\varphi \in \mathcal{L}(\Phi)$, and decides whether* $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ *is* 0 *or* 1. *The machine uses time $O(|\Phi|2^{|\mathcal{P}|}(\nu(\psi) + |\varphi|)^{\rho})$ and $O(|\varphi|)$ alternations, where ρ is the maximum arity of predicates in Φ. If $\rho > 1$, the number of branches is $2^{O(|\Phi|(\nu(\psi)+|\varphi|)^{\rho})}$. If $\rho = 1$, the number of branches is $O((2^{|\Phi|} + \nu(\psi))^{|\varphi|})$.*

An alternating Turing machine can be simulated by a deterministic Turing machine which traverses all possible branches of the ATM, while keeping track of the intermediate results necessary to determine whether the ATM accepts or rejects. The time taken by the deterministic simulation is linear in the product of the number of branches of the ATM and the time taken by each branch. The space required is the logarithm of the number of branches plus the space required for each branch. In this case, both these terms are $O(|D| + |\varphi|)$, where D is the description generated by the machine. This allows us to prove the following important corollary.

```
Procedure $Compute\text{-}Pr_\infty(\varphi \mid \theta)$
    $\delta \leftarrow (0, 0)$
    For each model description $\psi \wedge \mathcal{V}$ do:
        Compute $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ using our variant of Grandjean's algorithm
        If $\Delta(\psi) = \delta$ and $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V}) = 1$ then
            $count(\theta) \leftarrow count(\theta) + 1$
            Compute $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ using our variant of Grandjean's algorithm
            $count(\varphi) \leftarrow count(\varphi) + \Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$
        If $\Delta(\psi) > \delta$ and $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V}) = 1$ then
            $\delta \leftarrow \Delta(\psi)$
            $count(\theta) \leftarrow 1$
            Compute $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ using our variant of Grandjean's algorithm
            $count(\varphi) \leftarrow \Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$
    If $\delta = (0, 0)$ then output "$\Pr^w_\infty(\varphi \mid \theta)$ not well defined"
        otherwise output "$\Pr^w_\infty(\varphi \mid \theta) = count(\varphi)/count(\theta)$".
```

FIG. 1. Compute-$\Pr_\infty$ *for computing asymptotic conditional probabilities.*

COROLLARY 4.4. *There exists a deterministic Turing machine that takes as input a finite vocabulary Φ, a model description $\psi \wedge \mathcal{V}$ over Φ, and a formula $\varphi \in \mathcal{L}(\Phi)$, and decides whether $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ is 0 or 1. If $\rho > 1$ the machine uses time $2^{O(|\Phi|(\nu(\psi)+|\varphi|)^\rho)}$ and space $O(|\Phi|(\nu(\psi) + |\varphi|)^\rho)$. If $\rho = 1$ the machine uses time $2^{O(|\varphi||\Phi|\log(\nu(\psi)+1))}$ and space $O(|\varphi||\Phi|\log(\nu(\psi) + 1))$.*

4.2. Computing asymptotic conditional probabilities. Our overall goal is to compute $\Pr^w_\infty(\varphi \mid \theta)$ for some $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}(\Psi)$. To do this, we enumerate model descriptions over Φ of size $d(\theta) + |\mathcal{C}|$, and check which are consistent with θ. Among those model descriptions that are of maximal degree, we compute the fraction of model descriptions $\psi \wedge \mathcal{V}$ for which $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$ is 1.

More precisely, let $\delta_\theta = \Delta^\Psi(\theta)$. Theorem 3.34 tells us that

$$\Pr^w_\infty(\varphi \mid \theta) = \frac{1}{|\mathcal{M}(\mathcal{A}_\theta^{\Psi,\delta_\theta})|} \sum_{(\psi \wedge \mathcal{V}) \in \mathcal{M}(\mathcal{A}_\theta^{\Psi,\delta_\theta})} \Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V}).$$

The procedure *Compute-Pr_∞*, described in Fig. 1, generates one by one all model descriptions of size $d(\theta) + |\mathcal{C}|$ over Φ. The algorithm keeps track of three things, among the model descriptions considered thus far: (1) the highest degree δ of a model description consistent with θ, (2) the number $count(\theta)$ of model descriptions of degree δ consistent with θ, and (3) among the model descriptions of degree δ consistent with θ, the number $count(\varphi)$ of descriptions such that $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V}) = 1$. Thus, for each model description $\psi \wedge \mathcal{V}$ generated, the algorithm computes $\Delta(\psi)$. If $\Delta(\psi) < \delta$ or $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ is 0, then the model description is ignored. Otherwise, if $\Delta(\psi) > \delta$, then the count for lower degrees is irrelevant. In this case, the algorithm erases the previous counts by setting $\delta \leftarrow \Delta(\psi)$, $count(\theta) \leftarrow 1$, and $count(\varphi) \leftarrow \Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$. If $\Delta(\psi) = \delta$, then the algorithm updates $count(\theta)$ and $count(\varphi)$ appropriately.

Examining *Compute-Pr_∞*, we see that its complexity is dominated by two major quantities: the time required to generate all model descriptions, and the time required to compute each 0-1 probability using our variant of Grandjean's algorithm. The complexity of the latter was given in Theorem 4.3 and Corollary 4.4. The following proposition states the length of a model description; the time required to generate all model descriptions is exponential in this length.

PROPOSITION 4.5. *If $M > |\mathcal{C}|$ then the length of a model description of size M over Φ is*

$$O(|\Phi|(2^{|\mathcal{P}|}M)^{\rho}).$$

Proof. Consider a model description over Φ of size $M = d(\theta) + |\mathcal{C}|$. Such a model description consists of two parts: an atomic description ψ over Ψ and a model fragment $\mathcal{V}$ over Φ which is in $\mathcal{M}(\psi)$. To specify an atomic description ψ, we need to specify the unary properties of the named elements; furthermore, for each atom, we need to say whether it has any elements beyond the named elements (i.e., whether it is active). Using this representation, the size of an atomic description ψ is $O(|\Psi|\nu(\psi) + 2^{|\mathcal{P}|})$. As we have already observed, the length of a complete description D over Φ and $\mathcal{X}$ is $O(|\Phi||\mathcal{X}|^{\rho})$. In the case of a description $D_{\mathcal{V}}$ for $\mathcal{V} \in \mathcal{M}(\psi)$, this is $O(|\Phi|\nu(\psi)^{\rho})$. Using $\nu(\psi) \leq 2^{|\mathcal{P}|}M$, we obtain the desired result. □

Different variants of this algorithm are the basis for most of the upper bounds in the remainder of this section.

4.3. Finite vocabulary. We now consider the complexity of various problems related to $\Pr_{\infty}^{w}(\varphi \mid \theta)$ for a fixed finite vocabulary Φ. The input for such problems is simply φ and θ, and so the input length is the sum of the lengths of φ and θ. Since, for the purposes of this section, we view the vocabulary Φ as fixed (independent of the input), its size and maximum arity can be treated as constants.

We first consider the issue of well-definedness.

THEOREM 4.6. *Fix a finite vocabulary Φ with at least one unary predicate symbol. For $\theta \in \mathcal{L}(\Psi)$, the problem of deciding whether $\Pr_{\infty}^{w}(* \mid \theta)$ is well defined is PSPACE-complete. The lower bound holds even if $\theta \in \mathcal{L}^{-}(\{P\})$.*

Proof. It follows from Lemma 3.30 that $\Pr_{\infty}^{w}(* \mid \theta)$ is well defined iff $\alpha^{\Psi}(\theta) > 0$. This is true iff there is some atomic description $\psi \in \mathcal{A}_{\theta}^{\Psi}$ such that $\alpha(\psi) > 0$. This holds iff there exists an atomic description ψ of size $M = d(\theta) + |\mathcal{C}|$ over Ψ and some model fragment $\mathcal{V} \in \mathcal{M}^{\Psi}(\psi)$ such that $\alpha(\psi) > 0$ and $\Pr_{\infty}^{w}(\theta \mid \psi \wedge \mathcal{V}) = 1$. Since we are working within Ψ, we can take $\rho = 1$ and $|\mathcal{P}|$ to be a constant, independent of θ. Thus, the length of a model description $\psi \wedge \mathcal{V}$ as given in Proposition 4.5 is polynomial in $|\theta|$. It is therefore possible to generate model descriptions in PSPACE. Using Corollary 4.4, we can check, in polynomial space, for a model description $\psi \wedge \mathcal{V}$ whether $\Pr_{\infty}^{w}(\theta \mid \psi \wedge \mathcal{V})$ is 1. Therefore, the entire procedure can be done in polynomial space.

For the lower bound, we use a reduction from the problem of checking the truth of quantified Boolean formulas (QBF), a problem well known to be PSPACE-complete [37]. The reduction is similar to that used to show that checking whether a first-order sentence is true in a given finite structure is PSPACE-hard [6]. Given a quantified Boolean formula β, we define a first-order sentence $\xi_{\beta} \in \mathcal{L}^{-}(\{P\})$ as follows. The structure of ξ_{β} is identical to that of β, except that any reference to a propositional variable x, except in the quantifier, is replaced by $P(x)$. For example, if β is $\forall x \exists y\, (x \wedge y)$, ξ_{β} will be $\forall x \exists y\, (P(x) \wedge P(y))$. Let θ be $\xi_{\beta} \wedge \exists x\, P(x) \wedge \exists x\, \neg P(x)$. Clearly, $\Pr_{\infty}^{w}(* \mid \theta)$ is well defined exactly if β is true. □

In order to compute asymptotic conditional probabilities in this case, we simply use *Compute-Pr*$_{\infty}$. In fact, since *Compute-Pr*$_{\infty}$ can also be used to determine well-definedness, we could also have used it to prove the previous theorem.

THEOREM 4.7. *Fix a finite vocabulary Φ. For $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}(\Psi)$, the problem of computing $\Pr_{\infty}^{w}(\varphi \mid \theta)$ is PSPACE-complete. Indeed, deciding if $\Pr_{\infty}^{w}(\varphi \mid true) = 1$ is PSPACE-hard even if $\varphi \in \mathcal{L}^{-}(\{P\})$ for some unary predicate symbol P.*

Proof. The upper bound is obtained directly from *Compute-Pr*$_{\infty}$ in Fig. 1. The algorithm generates model descriptions one by one. Using the assumption that Φ is fixed and finite, each model description has polynomial length, so that this can be done in PSPACE. Corollary 4.4 implies that, for a fixed finite vocabulary, the 0-1 probabilities for each model description can also be computed in polynomial space. While *count*(θ) and *count*(φ) can be exponential (as large as the number of model descriptions), only polynomial space is required for their binary representation. Thus, *Compute-Pr*$_\infty$ works in PSPACE under the assumption of a fixed finite vocabulary.

For the lower bound, we provide a reduction from QBF much like that used in Theorem 4.6. Given a quantified Boolean formula ξ and a unary predicate symbol P, we construct a sentence $\xi_\beta \in \mathcal{L}^-(\{P\})$ just as in the proof of Theorem 4.6. It is easy to see that $\Pr^w_\infty(\xi_\beta \mid \mathit{true}) = 1$ iff β is true. (By the unconditional 0-1 law, $\Pr^w_\infty(\xi_\beta \mid \mathit{true})$ is necessarily either 0 or 1.) □

It follows immediately from Theorem 4.7 that we cannot approximate the limit. Indeed, if we fix ϵ with $0 < \epsilon < 1$, the problem of deciding whether $\Pr^w_\infty(\varphi \mid \theta) \in [0, 1-\epsilon]$ is PSPACE-hard even for $\varphi, \theta \in \mathcal{L}^-(\{P\})$. We might hope to prove that for any nontrivial interval $[r_1, r_2]$, it is PSPACE-hard to decide if $\Pr^w_\infty(\varphi \mid \theta) \in [r_1, r_2]$. This stronger lower bound does not hold for the language $\mathcal{L}^-(\{P\})$. Indeed, it follows from Theorem 3.35 that if Φ is any fixed vocabulary then, for $\varphi \in \mathcal{L}(\Phi)$ and $\theta \in \mathcal{L}^-(\Psi)$, $\Pr^w_\infty(\varphi \mid \theta)$ must take one of a finite number of values (the possible values being determined entirely by Φ). So the approximation problem is frequently trivial; in particular, this is the case for any $[r_1, r_2]$ that does not contain one of the possible values. To see that there are only a finite number of values, first note that there is a fixed collection of atoms over Φ. If θ does not use equality, an atomic description can only say, for each atom A over Φ, whether $\exists x\, A(x)$ or $\neg\exists x\, A(x)$ holds. There is also a fixed set of constant symbols to describe. Therefore, there is a fixed set of possible atomic descriptions. Finally, note that the only named elements are the constants, and so there is also a fixed (and finite) set of model fragments. This shows that the set of model descriptions is finite, from which it follows that $\Pr^w_\infty(\varphi \mid \theta)$ takes one of finitely many values fixed by Φ. Thus, in order to have $\Pr^w_\infty(\varphi \mid \theta)$ assume infinitely many values, we must allow equality in the language. Moreover, even with equality in the language, one unary predicate does not suffice. Using Theorem 3.34, it can be shown that two unary predicates are necessary to allow the asymptotic conditional probability to assume infinitely many possible values. As the following result shows, this condition also suffices.

THEOREM 4.8. *Fix a finite vocabulary Φ that contains at least two unary predicates and rational numbers $0 \le r_1 \le r_2 \le 1$ such that $[r_1, r_2] \ne [0, 1]$. For $\varphi, \theta \in \mathcal{L}(\mathcal{P})$, the problem of deciding whether $\Pr^w_\infty(\varphi \mid \theta) \in [r_1, r_2]$ is PSPACE-hard, even given an oracle that tells us whether the limit is well defined.*

Proof. We first show that, for any rational number r with $0 < r < 1$, we can construct φ_r, θ_r such that $\Pr^w_\infty(\varphi_r \mid \theta_r) = r$. Suppose $r = q/p$. We assume, without loss of generality, that $\Phi = \{P, Q\}$. Let θ_r be the sentence

$$\exists^{p-1}x\, P(x) \wedge \big(\exists^{q-1}x\,(P(x) \wedge Q(x)) \vee \exists^{q}x\,(P(x) \wedge Q(x))\big) \wedge \exists^{0}x\,(\neg P(x) \wedge \neg Q(x)).$$

That is, no elements satisfy the atom $\neg P \wedge \neg Q$, either q or $q-1$ elements satisfy the atom $P \wedge Q$, and $p-1$ elements satisfy P. Thus, there are exactly two atomic descriptions consistent with θ_r. In one of them, ψ_1, there are $q-1$ elements satisfying $P \wedge Q$ and $p-q$ elements satisfying $P \wedge \neg Q$ (all the remaining elements satisfy $\neg P \wedge Q$). In the other, ψ_2, there are q elements satisfying $P \wedge Q$ and $p-q-1$ elements satisfying $P \wedge \neg Q$. Clearly, the degree of ψ_1 is the same as that of ψ_2, so that neither one dominates. In particular, both define $p-1$ named elements. The number of model fragments for ψ_1 is $\binom{p-1}{q-1} = \frac{(p-1)!}{(q-1)!(p-q)!}$. The number of model fragments for ψ_2 is $\binom{p-1}{q} = \frac{(p-1)!}{q!(p-q-1)!}$. Let φ_r be ψ_1. Clearly

$$\begin{aligned}\Pr^w_\infty(\varphi_r \mid \theta_r) &= \frac{|\mathcal{M}(\psi_1)|}{|\mathcal{M}(\psi_1)| + |\mathcal{M}(\psi_2)|} \\ &= \frac{(p-1)!/((q-1)!(p-q)!)}{(p-1)!/((q-1)!(p-q)!) + (p-1)!/(q!(p-q-1)!)} \\ &= \frac{q}{q+(p-q)} = \frac{q}{p} = r\,.\end{aligned}$$

Now, assume we are given $r_1 \leq r_2$. We prove the result by reduction from QBF, as in the proof of Theorem 4.6. If $r_1 = 0$ then the result follows immediately from Theorem 4.7. If $0 < r_1 = q/p$, let β be a QBF, and consider $\Pr^w_\infty(\xi_\beta \wedge \varphi_{r_1} \mid \theta_{r_1} \wedge \exists x\, \neg P(x))$. Note that, since $p \geq 2$, θ_{r_1} implies $\exists x\, P(x)$. It is therefore easy to see that this probability is 0 if β is false and $\Pr^w_\infty(\varphi_{r_1} \mid \theta_{r_1}) = r_1$ otherwise. Thus, we can check if β is true by deciding whether $\Pr^w_\infty(\xi_\beta \wedge \varphi_{r_1} \mid \theta_{r_1} \wedge \exists x\, \neg P(x)) \in [r_1, r_2]$. This proves PSPACE-hardness.[9] □

These results show that simply assuming that the vocabulary is fixed and finite is not by itself enough to lead to computationally easy problems. Nevertheless, there is some good news. We observed in a companion paper [23] that if Φ is fixed and finite, and we bound the depth of quantifier nesting, then there exists a linear time algorithm for computing asymptotic probabilities. In general, as we observed in [23], we cannot effectively construct this algorithm, although we know that it exists. As we now show, for the case of conditioning on a unary formula, we can effectively construct this algorithm.

THEOREM 4.9. *Fix $d \geq 0$. For $\varphi \in \mathcal{L}(\Phi)$, $\theta \in \mathcal{L}(\Psi)$ such that $d(\varphi), d(\theta) \leq d$, we can effectively construct a linear time algorithm that decides if $\Pr^w_\infty(\varphi \mid \theta)$ is well defined and computes it if it is.*

Proof. The proof of the general theorem in [23] shows that if there is a bound d on the quantification depth of formulas and a finite vocabulary, then there is a finite set Σ_d of formulas such that every formula ξ of depth at most d is equivalent to a formula in Σ_d. Moreover, we can construct an algorithm that, given such a formula ξ, will in linear time find some formula equivalent to ξ in Σ_d. (We say "some" rather than "the," because it is necessary for the algorithm's constructibility that there will generally be several formulas equivalent to ξ in Σ_d.) Given this, the problem reduces to constructing a lookup table for the asymptotic conditional probabilities for all formulas in Σ_d. In general, there is no effective technique for constructing this table. However, if we allow conditioning only on unary formulas, it follows from Theorem 4.7 that there is. The result now follows. □

4.4. Infinite vocabulary—restricted cases.

In the next two sections we consider an infinite vocabulary Ω. As discussed in §2.3, there are at least two distinct interpretations for asymptotic conditional probabilities in the case of an infinite vocabulary. One interpretation of "infinite vocabulary" views Ω as a potential or background vocabulary, so that every problem instance includes as part of its input the actual finite subvocabulary that is of interest. So, although this subvocabulary is finite, there is no bound on its possible size. The alternative is to interpret infinite vocabularies more literally, using the limit process explained in §2.3. In the case of the random-worlds method, Proposition 2.1 shows that both interpretations give the same result. Thus, it is immediate that all complexity results we prove with respect to one interpretation immediately hold for the other. As we are postponing the discussion of random structures to §4.6, we present the earlier results with respect to the second, less cumbersome, interpretation.

[9] In this construction, it is important to note that although φ_{r_1} and θ_{r_1} can be long sentences, their length depends only on r_1, which is treated as being fixed. Therefore, the constructed asymptotic probability expression does have length polynomial in $|\beta|$. This is also the case in similar constructions later in the paper.

As before, we are interested in computing the complexity of the same three problems: deciding whether the asymptotic probability is well defined, computing it, and approximating it. As we mentioned earlier, the complexity is quite sensitive to a number of factors. One factor, already observed in the unconditional case [4], [20], is whether there is a bound on the arity of the predicates in Ω. Without such a bound, the problem is complete for the class #TA(EXP,LIN). Unlike the unconditional case, however, simply putting a bound on the arity of the predicates in Ω is not enough to improve the complexity (unless the bound is 1); we also need to restrict the use of equality, so that it cannot appear in the right-hand side of the conditional. Roughly speaking, with equality, we can use the named elements to play the same role as the predicates of unbounded arity. In this section, we consider what happens if we in fact restrict the language so that either (1) Ω has no predicate of arity ≥ 2, or (2) there is a bound (which may be greater than 1) on the arity of the predicates in Ω, but we never condition on formulas that use equality. As we now show, these two cases turn out to be quite similar. In particular, the same complexity results hold.

Throughout this section, we take Ω to be a fixed infinite vocabulary such that all predicate symbols in Ω have arity less than some fixed bound ρ. Let $\mathcal{Q}$ be the set of all unary predicate symbols in Ω, let $\mathcal{D}$ be the set of all constant symbols in Ω, and let $\Upsilon = \mathcal{Q} \cup \mathcal{D}$.

We start with the problem of deciding whether the asymptotic probability is well defined. Since well-definedness depends only on the right-hand side of the conditional, which we already assume is restricted to mentioning only unary predicates, its complexity is independent of the bound ρ.

The following theorem, due to Lewis [30], is the key to proving the lower bound for well-definedness (and for some of the other results in this section as well).

THEOREM 4.10. [30] *The problem of deciding whether a sentence $\xi \in \mathcal{L}^{-}(\mathcal{Q})$ is satisfiable is NEXPTIME-complete. Moreover, the lower bound holds even for formulas ξ of depth* 2.

Lewis proves this as follows: for any nondeterministic Turing machine **M** that runs in exponential time and any input w, he constructs a sentence $\xi \in \mathcal{L}^{-}(\mathcal{Q})$ of quantifier depth 2 and whose length is polynomial in the size of **M** and w, such that ξ is satisfiable iff there is an accepting computation of **M** on w.

Our first use of Lewis's result is to show that determining well-definedness is NEXPTIME-complete; this result does not require the assumptions that we are making throughout the rest of this section.

THEOREM 4.11. *For $\theta \in \mathcal{L}(\Upsilon)$, the problem of deciding if* $\Pr^{w}_{\infty}(* \mid \theta)$ *is well defined is NEXPTIME-complete. The NEXPTIME lower bound holds even for $\theta \in \mathcal{L}^{-}(\mathcal{Q})$ where $d(\theta) \leq 2$.*

Proof. For the upper bound, we proceed much as in Theorem 4.6. Let $\Psi = \Upsilon_\theta$ and let $\mathcal{C} = \mathcal{D}_\theta$. We know that $\Pr^{w}_{\infty}(* \mid \theta)$ is well defined iff there exists an atomic description ψ of size $M = d(\theta) + |\mathcal{C}|$ over Ψ and some model fragment $\mathcal{V} \in \mathcal{M}^{\Psi}(\psi)$ such that $\alpha(\psi) > 0$ and $\Pr^{w}_{\infty}(\theta \mid \psi \wedge \mathcal{V}) = 1$. Since all the predicates in Ψ have arity 1, it follows from Proposition 4.5 that the size of a model description $\psi \wedge \mathcal{V}$ over Ψ is $O(|\Psi| 2^{|\mathcal{P}|} M)$. Since $|\Psi| < |\theta|$, this implies that model descriptions have exponential length, and can be generated by a nondeterministic exponential time Turing machine. Because we can assume that $\rho = 1$ here when applying Corollary 4.4, we can also deduce that we can check whether $\Pr^{w}_{\infty}(\theta \mid \psi \wedge \mathcal{V})$ is 0 or 1 using a deterministic Turing machine in time $2^{O(|\theta||\Psi| \log(\nu(\psi)+1))}$. Since $|\Psi| \leq |\theta|$, and $\nu(\psi)$ is at most exponential in $|\theta|$, it follows that we can decide if $\Pr^{w}_{\infty}(\theta \mid \psi \wedge \mathcal{V}) = 1$ in deterministic time exponential in $|\theta|$. Thus, to check if $\Pr^{w}_{\infty}(* \mid \theta)$ is well defined we nondeterministically guess a model description $\psi \wedge \mathcal{V}$ of the right type, and check that $\alpha(\psi) > 0$ and that $\Pr^{w}_{\infty}(\theta \mid \psi \wedge \mathcal{V}) = 1$. The entire procedure can be executed in nondeterministic exponential time.

For the lower bound, observe that if a formula ξ in $\mathcal{L}^-(\Phi)$ is satisfied in some model with domain $\{1, \dots, N\}$ then it is satisfiable in some model of every domain size larger than N. Therefore, $\xi \in \mathcal{L}^-(\mathcal{Q})$ is satisfiable if and only if the limit $\Pr^w_\infty(* \mid \xi)$ is well defined. The result now follows from Theorem 4.10. □

We next consider the problem of computing the asymptotic probability $\Pr^w_\infty(\varphi \mid \theta)$, given that it is well defined. We show that this problem is #EXP-complete. Recall that #P (see [38]) is the class of integer functions computable as the number of accepting computations of a nondeterministic polynomial-time Turing machine. More precisely, a function $f : \{0, 1\}^* \rightarrow \mathbb{N}$ is said to be in #P if there is a nondeterministic Turing machine $\mathbf{M}$ such that for any w, the number of accepting paths of $\mathbf{M}$ on input w is $f(w)$. The class #EXP is the exponential time analogue.

The function we are interested in is $\Pr^w_\infty(\varphi \mid \theta)$, which is not integer valued. Nevertheless, we want to show that it is in #EXP. In the spirit of similar definitions for #P (see, for example, [39] and [34]) and NP (e.g., [17]) we extend the definition of #EXP to apply also to non-integer-valued functions.

DEFINITION 4.12. An arbitrary function f is said to be *#EXP-easy* if there exists an integer-valued function g in #EXP and a polynomial-time-computable function h such that for all x, $f(x) = h(g(x))$. (In particular, we allow h to involve divisions, so that $f(x)$ may be a rational function.) A function f is *#EXP-hard* if, for every #EXP-easy function g, there exist polynomial-time functions h_1 and h_2 such that, for all x, $g(x) = h_2(f(h_1(x)))$.[10] A function f is *#EXP-complete* if it is #EXP-easy and #EXP-hard. □

We can similarly define analogues of these definitions for the class #P.

We now show that for an infinite arity-bounded vocabulary in which equality is not used, or for any unary vocabulary, the problem of computing the asymptotic conditional probability is #EXP-complete. We start with the upper bound.

THEOREM 4.13. *If either* (a) $\varphi, \theta \in \mathcal{L}(\Upsilon)$ *or* (b) $\varphi \in \mathcal{L}(\Omega)$ *and* $\theta \in \mathcal{L}^-(\Upsilon)$, *then computing* $\Pr^w_\infty(\varphi \mid \theta)$ *is #EXP-easy.*

Proof. Let $\Phi = \Omega_{\varphi\wedge\theta}$, let $\Psi = \Upsilon_{\varphi\wedge\theta}$, and let $\mathcal{P}$ and $\mathcal{C}$ be the appropriate subsets of Ψ. Let $\delta_\theta = \Delta^\Psi(\theta)$. Recall from the proof of Theorem 4.7 that we would like to generate the model descriptions $\psi \wedge \mathcal{V}$ of degree δ_θ, consider the ones for which $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V}) = 1$, and compute the fraction of those for which $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$. More precisely, consider the set of model descriptions of size $M = d(\varphi \wedge \theta) + |\mathcal{C}|$. For a degree δ, let $count^\delta(\theta)$ denote the number of those model descriptions for which $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V}) = 1$. Similarly, let $count^\delta(\varphi)$ denote the number for which $\Pr^w_\infty(\varphi \wedge \theta \mid \psi \wedge \mathcal{V}) = 1$. We are interested in the value of the fraction $count^{\delta_\theta}(\varphi)/count^{\delta_\theta}(\theta)$.

We want to show that we can nondeterministically generate model descriptions $\psi \wedge \mathcal{V}$, and check in deterministic exponential time whether $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ (or, similarly, $\Pr^w_\infty(\varphi \wedge \theta \mid \psi \wedge \mathcal{V})$) is 0 or 1. We begin by showing the second part: that the 0-1 probabilities can be computed in deterministic exponential time. There are two cases to consider. In case (a), φ and θ are both unary, allowing us to assume that $\rho = 1$ for the purposes of Corollary 4.4. In this case, the 0-1 computations can be done in time $2^{O(|\varphi\wedge\theta||\Psi|\log(\nu(\psi)+1))}$, where $\Psi = \Upsilon_{\varphi\wedge\theta}$. As in Theorem 4.11, $|\Psi| \leq |\varphi \wedge \theta|$ and $\nu(\psi)$ is at most exponential in $|\theta|$, allowing us to carry out the computation in deterministic exponential time. In case (b), $\theta \in \mathcal{L}^-(\Upsilon)$, and therefore the only named elements are the constants. In this case, the 0-1 probabilities can be computed in deterministic time $2^{O(|\Phi|(\nu(\psi)+|\varphi\wedge\theta|)^\rho)}$, where $\Phi = \Omega_{\varphi\wedge\theta}$. However, as we have just discussed, $\nu(\psi) < |\varphi \wedge \theta|$, implying that the computation can be completed in exponential time.

[10] Notice that we need the function h_2 as well as h_1. For example, if g is an integer-valued function and f always returns a rational value between 0 and 1, as is the case for us, then there is no function h_1 such that $g(x) = f(h_1(x))$.

Having shown how the 0-1 probabilities can be computed, it remains only to generate model descriptions in the appropriate way. However, we do not want to consider all model descriptions, because we must count only those model descriptions of degree δ_θ. The problem is that we do not know δ_θ in advance. We will therefore construct a nondeterministic exponential time Turing machine $\mathbf{M}$ such that the number of accepting paths of $\mathbf{M}$ encodes, for each degree δ, both $\mathit{count}^{\delta}(\varphi)$ and $\mathit{count}^{\delta}(\theta)$. We need to do the encoding in such a way as to be able to isolate the counts for δ_θ when we finally know its value. This is done as follows.

Let ψ be an atomic description ψ over Ψ of size M. Recall that the degree $\Delta(\psi)$ is a pair $(\alpha(\psi), \nu(\psi))$ such that $\alpha(\psi) \leq 2^{|\mathcal{P}|}$ and $\nu(\psi) \leq 2^{|\mathcal{P}|}M$. Thus, there are at most $E = 2^{2|\mathcal{P}|}M$ possible degrees. Number the degrees in increasing order: $\delta_1, \ldots, \delta_E$. We want it to be the case that the number of accepting paths of $\mathbf{M}$ written in binary has the form

$$p_{10} \cdots p_{1m} q_{10} \cdots q_{1m} \cdots p_{E0} \cdots p_{Em} q_{E0} \cdots q_{Em},$$

where $p_{i0} \ldots p_{im}$ is the binary representation of $\mathit{count}^{\delta_i}(\varphi)$ and $q_{i0} \ldots q_{im}$ is the binary representation of $\mathit{count}^{\delta_i}(\theta)$. We choose m to be sufficiently large so that there is no overlap between the different sections of the output. The largest possible value of an expression of the form $\mathit{count}^{\delta_i}(\theta)$ is the maximum number of model descriptions of degree δ_i over Φ. This is clearly less than the overall number of model descriptions, which we computed in §4.2.

The machine $\mathbf{M}$ proceeds as follows. Let m be the smallest integer such that 2^m is more than the number of possible model descriptions, which, by Proposition 4.5, is $2^{O(|\Phi|(2^{|\mathcal{P}|}M)^{\rho})}$. Note that m is exponential and that $\mathbf{M}$ can easily compute m from Φ. $\mathbf{M}$ then nondeterministically chooses a degree δ_i, for $i = 1, \ldots, E$. It then executes $E - i$ phases, in each of which it nondeterministically branches $2m$ times. This has the effect of giving this branch a weight of $2^{2m(E-i)}$. It then nondeterministically chooses whether to compute $p_{i0} \ldots p_{im}$ or $q_{i0} \ldots q_{im}$. If the former, it again branches m times, separating the results for $\mathit{count}^{\delta_i}(\varphi)$ from those for $\mathit{count}^{\delta_i}(\theta)$. In either case, it now nondeterministically generates all model descriptions $\psi \wedge \mathcal{V}$ over Φ. It ignores those for which $\Delta(\psi) \neq \delta_i$. For the remaining model descriptions $\psi \wedge \mathcal{V}$, it computes $\Pr^w_\infty(\varphi \wedge \theta \mid \psi \wedge \mathcal{V})$ in the first case, and $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ in the latter. This is done in exponential time, using the same technique as in Theorem 4.11. The machine accepts precisely when this probability is 1.

This procedure is executable in nondeterministic exponential time, and results in the appropriate number of accepting paths. It is now easy to compute $\Pr^w_\infty(\varphi \mid \theta)$ by finding the largest degree δ for which $\mathit{count}^{\delta}(\theta) > 0$, and dividing $\mathit{count}^{\delta}(\varphi)$ by $\mathit{count}^{\delta}(\theta)$. □

We now want to prove the matching lower bound. As in Theorem 4.11, we make use of Lewis's NEXPTIME-completeness result. As there, this allows us to prove the result even for $\varphi, \theta \in \mathcal{L}^-(\mathcal{Q})$ of quantifier depth 2. A straightforward modification of Lewis's proof shows that, given w and a nondeterministic exponential time Turing machine $\mathbf{M}$, we can construct a depth-2 formula $\xi \in \mathcal{L}^-(\mathcal{Q})$ such that the number of simplified atomic descriptions over $\mathcal{P}_\xi$ consistent with ξ is exactly the number of accepting computations of $\mathbf{M}$ on w. This allows us to prove the following theorem.

THEOREM 4.14. *Given $\xi \in \mathcal{L}^-(\mathcal{Q})$, counting the number of simplified atomic descriptions over $\mathcal{P}_\xi$ consistent with ξ is #EXP-complete. The lower bound holds even for formulas ξ of depth* 2.

This theorem forms the basis for our own hardness result.

THEOREM 4.15. *Given $\varphi, \theta \in \mathcal{L}^-(\mathcal{Q})$ of depth at least* 2, *the problem of computing* $\Pr^w_\infty(\varphi \mid \theta)$ *is #EXP-hard, even given an oracle for deciding whether the limit exists.*

Proof. Given $\varphi \in \mathcal{L}^-(\mathcal{Q})$, we reduce the problem of counting the number of simplified atomic descriptions over $\mathcal{P}_\varphi$ consistent with φ to that of computing an appropriate asymptotic probability. Recall that, for the language $\mathcal{L}^-(\mathcal{Q})$, model descriptions are equivalent to sim-

FIG. 3. *Two maximal atomic descriptions.*

plified atomic descriptions. Therefore, computing an asymptotic conditional probability for this language reduces to counting simplified atomic descriptions of maximal degree. Thus, the major difficulty we need to overcome here is the converse of the difficulty that arose in the upper bound. We now want to count *all* simplified atomic descriptions consistent with φ, while using the asymptotic conditional probability in the most obvious way would only let us count those of maximum degree. For example, the two atomic descriptions whose characteristics are represented in Fig. 2 have different degrees; the first one will thus be ignored by a computation of asymptotic conditional probabilities.

Let $\mathcal{P}$ be $\mathcal{P}_\varphi = \{P_1, \ldots, P_k\}$, and let Q be a new unary predicate not in $\mathcal{P}$. We let $A_1, \ldots, A_K$ for $K = 2^k$ be all the atoms over $\mathcal{P}$, and let $A'_1, \ldots, A'_{2K}$ be all the atoms over $\mathcal{P}' = \mathcal{P} \cup \{Q\}$, such that $A'_i = A_i \wedge Q$ and $A'_{K+i} = A_i \wedge \neg Q$ for $i = 1, \ldots, K$.

We define θ' as follows:

$$\theta' =_{\text{def}} \forall x, y \left(\left(Q(x) \wedge \bigwedge_{i=1}^{k} (P_i(x) \Leftrightarrow P_i(y)) \right) \Rightarrow Q(y) \right).$$

The sentence θ' guarantees that the predicate Q is "constant" on the atoms defined by $\mathcal{P}$. That is, if A_i is an atom over $\mathcal{P}$, it is not possible to have $\exists x\,(A_i(x) \wedge Q(x))$ as well as $\exists x\,(A_i(x) \wedge \neg Q(x))$. Therefore, if ψ is a simplified atomic description over $\mathcal{P}'$ which is consistent with θ', then, for each $i \leq K$, at most one of the atoms A'_i and A'_{K+i} can be active, while the other is necessarily empty. It follows that $\alpha(\psi) \leq K$. Since there are clearly atomic descriptions of activity count K consistent with θ', the atomic descriptions of maximal degree are precisely those for which $\alpha(\psi) = K$. Moreover, if $\alpha(\psi) = K$, then A'_i is active iff A'_{K+i} is not. Two atomic descriptions of maximal degree are represented in Fig. 3. Thus, for each set $I \subseteq \{1, \ldots, K\}$, there is precisely one simplified atomic description ψ consistent with θ' of activity count K where A'_i is active in ψ iff $i \in I$. Therefore, there are exactly 2^K simplified atomic descriptions ψ over $\mathcal{P}'$ consistent with θ' for which $\alpha(\psi) = K$.

Let $\theta = \theta' \wedge \exists x\, Q(x)$. Notice that all simplified atomic descriptions ψ with $\alpha(\psi) = K$ that are consistent with θ' are also consistent with θ, except for the one where no atom in $A'_1, \ldots, A'_K$ is active. Thus, $|\mathcal{A}_\theta^{\mathcal{P}',K}| = 2^K - 1$. For the purposes of this proof, we call a simplified atomic description ψ over $\mathcal{P}'$ consistent with θ for which $\alpha(\psi) = K$ a *maximal atomic description.* Notice that there is an obvious one-to-one correspondence between consistent simplified atomic descriptions over $\mathcal{P}$ and maximal atomic descriptions over $\mathcal{P}'$. A maximal atomic description where A'_i is active iff $i \in I$ (and A'_{K+i} is active for $i \notin I$) corresponds to the simplified atomic description over $\mathcal{P}$ where A_i is active iff $i \in I$. (For example, the two consistent simplified atomic descriptions over $\{P_1, P_2\}$ in Fig. 2 correspond to the two maximal atomic descriptions over $\{P_1, P_2, Q\}$ in Fig. 3.) In fact, the reason we consider θ rather than θ' is precisely because there is no consistent simplified atomic description over $\mathcal{P}$ which corresponds to the maximal atomic description where no atom in $A'_1, \ldots, A'_K$ is active (since there is no consistent atomic description over $\mathcal{P}$ where none of $A_1, \ldots, A_K$ are active). Thus, we have overcome the hurdle discussed above.

We now define φ_Q; intuitively, φ_Q is φ restricted to elements that satisfy Q. Formally, we define ξ_Q for any formula ξ by induction on the structure of the formula:

- $\xi_Q = \xi$ for any atomic formula ξ,
- $(\neg\xi)_Q = \neg\xi_Q$,
- $(\xi \wedge \xi')_Q = \xi_Q \wedge \xi'_Q$,
- $(\forall y\, \xi(y))_Q = \forall y\, (Q(y) \Rightarrow \xi_Q(y))$.

Note that the size of φ_Q is linear in the size of φ. The one-to-one mapping discussed above from simplified atomic descriptions to maximal atomic descriptions gives us a one-to-one mapping from simplified atomic descriptions over $\mathcal{P}$ consistent with φ to maximal atomic descriptions consistent with $\varphi_Q \wedge \exists x\, Q(x)$. This is true because a model satisfies φ_Q iff the same model restricted to elements satisfying Q satisfies φ. Thus, the number of model descriptions over $\mathcal{P}$ consistent with φ is precisely $|\mathcal{A}^{\mathcal{P}',K}_{\varphi_Q \wedge \theta}|$.

From Corollary 3.36, it follows that

$$\Pr{}^w_\infty(\varphi_Q \mid \theta) = \frac{|\mathcal{A}^{\mathcal{P}',K}_{\varphi_Q \wedge \theta}|}{|\mathcal{A}^{\mathcal{P}',K}_{\theta}|} = \frac{|\mathcal{A}^{\mathcal{P}}_{\varphi}|}{2^K - 1}.$$

Thus, the number of simplified atomic descriptions over $\mathcal{P}$ consistent with φ is $(2^K - 1)\Pr^w_\infty(\varphi_Q \mid \theta)$. This proves the lower bound. □

As in Theorem 4.8, we can also show that any nontrivial approximation of the asymptotic probability is hard, even if we restrict to sentences of depth 2.

THEOREM 4.16. *Fix rational numbers* $0 \leq r_1 \leq r_2 \leq 1$ *such that* $[r_1, r_2] \neq [0, 1]$. *For* $\varphi, \theta \in \mathcal{L}^-(\mathcal{Q})$ *of depth at least* 2, *the problem of deciding whether* $\Pr^w_\infty(\varphi \mid \theta) \in [r_1, r_2]$ *is both NEXPTIME-hard and co-NEXPTIME-hard, even given an oracle for deciding whether the limit exists.*

Proof. Let us begin with the case where $r_1 = 0$ and $r_2 < 1$. Consider any $\varphi \in \mathcal{L}^-(\mathcal{Q})$ of depth at least 2, and assume without loss of generality that $\mathcal{P} = \mathcal{P}_\varphi = \{P_1, \ldots, P_k\}$. Choose $Q \notin \mathcal{P}$, let $\mathcal{P}' = \mathcal{P} \cup \{Q\}$, and let ξ be $\forall x(P_1(x) \wedge \ldots \wedge P_k(x) \wedge Q(x))$. We consider $\Pr^w_\infty(\varphi \mid \varphi \vee \xi)$. Clearly $\varphi \vee \xi$ is satisfiable, so that this asymptotic probability is well defined. If φ is unsatisfiable, then $\Pr^w_\infty(\varphi \mid \varphi \vee \xi) = 0$. On the other hand, if φ is satisfiable, then $\alpha^{\mathcal{P}}(\varphi) = j > 0$ for some j. It is easy to see that $\alpha^{\mathcal{P}'}(\varphi) = \alpha^{\mathcal{P}'}(\varphi \vee \xi) = 2j$. Moreover, φ and $\varphi \vee \xi$ are consistent with precisely the same simplified atomic descriptions with $2j$ active atoms. This is true since $\alpha^{\mathcal{P}'}(\xi) = 1 < 2j$. It follows that if φ is satisfiable, then $\Pr^w_\infty(\varphi \mid \varphi \vee \xi) = 1$.

Thus, we have that $\Pr^w_\infty(\varphi \mid \varphi \vee \xi)$ is either 0 or 1, depending on whether or not φ is satisfiable. Thus, $\Pr^w_\infty(\neg\varphi \mid \varphi \vee \xi)$ is in $[r_1, r_2]$ iff φ is satisfiable; similarly, $\Pr^w_\infty(\neg\varphi \mid \neg\varphi \vee \xi)$ is in $[r_1, r_2]$ iff φ is valid. By Theorem 4.10, it follows that this approximation problem is both NEXPTIME-hard and co-NEXPTIME-hard.

If $r_1 = q/p > 0$, we construct sentences φ_{r_1} and θ_{r_1} of depth 2 in $\mathcal{L}^-(\mathcal{Q})$ such that $\Pr^w_\infty(\varphi_{r_1} \mid \theta_{r_1}) = r_1$.[11] Choose $\ell = \lceil \log p \rceil$, and let $\mathcal{P}'' = \{Q_1, \ldots, Q_\ell\}$ be a set of predicates

[11] The sentences constructed in Theorem 4.8 for the same purpose will not serve our purpose in this theorem, since they used unbounded quantifier depth.

such that $\mathcal{P}'' \cap \mathcal{P}' = \emptyset$. Let $A_1, \ldots, A_{2^\ell}$ be the set of atoms over $\mathcal{P}''$. We define θ_{r_1} to be

$$\exists^1 x\,(A_1(x) \vee A_2(x) \vee \ldots \vee A_p(x)).$$

Similarly, φ_{r_1} is defined as

$$\exists^1 x\,(A_1(x) \vee A_2(x) \vee \ldots \vee A_q(x)).$$

Recall from §3.1 that the construct "$\exists^1 x$" can be defined in terms of a formula of quantifier depth 2. There are exactly p atomic descriptions of size 2 of maximal degree consistent with θ_{r_1}; each has one element in one of the atoms $A_1, \ldots, A_p$ and no elements in the rest of the atoms among $A_1, \ldots, A_p$, with all the remaining atoms (those among $A_{p+1}, \ldots, A_{2^\ell}$) being active. Among these atomic descriptions, q are also consistent with φ_{r_1}. Therefore, $\Pr^w_\infty(\varphi_{r_1} \mid \theta_{r_1}) = q/p$. Since the predicates occurring in $\varphi_{r_1}, \theta_{r_1}$ are disjoint from $\mathcal{P}'$, it follows that

$$\Pr^w_\infty(\varphi \wedge \varphi_{r_1} \mid (\varphi \vee \xi) \wedge \theta_{r_1}) = \Pr^w_\infty(\varphi \mid \varphi \vee \xi) \cdot \Pr^w_\infty(\varphi_{r_1} \mid \theta_{r_1}) = \Pr^w_\infty(\varphi \mid \varphi \vee \xi) \cdot r_1.$$

This is equal to r_1 (and hence is in $[r_1, r_2]$) if and only if φ is satisfiable, and is 0 otherwise. □

The lower bounds in this section all hold provided we consider formulas whose quantification depth is at least 2. Can we do better if we restrict to formulas of quantification depth at most 1? As is suggested by Table 1, we can. The complexities typically drop by an exponential factor. For example, checking well-definedness becomes NP-complete rather than NEXPTIME-complete. For the problem of computing probabilities for formulas with quantification depth 1, we know that the problem is in PSPACE, and is (at least) #P-hard. Finally, the problem of approximating probabilities is hard for both NP and co-NP. A detailed analysis of these results can be found in [27]; some related work for a propositional language has been done by Roth [35].

4.5. Infinite vocabulary—the general case. In §4.4 we investigated the complexity of asymptotic conditional probabilities when the (infinite) vocabulary satisfies certain restrictions. As we now show, the results there were tight in the sense that the restrictions cannot be weakened. We examine the complexity of the general case, in which the vocabulary is infinite with no bound on predicates' arities and/or in which equality can be used.

The problem of checking if $\Pr^w_\infty(\varphi \mid \theta)$ is well defined is still NEXPTIME-complete. Theorem 4.11 (which had no restrictions) still applies. However, the complexity of the other problems we consider does increase. It can be best described in terms of the complexity class TA(EXP,LIN)—the class of problems that can be solved by an exponential time ATM with a linear number of alternations. The class TA(EXP,LIN) also arises in the study of unconditional probabilities where there is no bound on the arity of the predicates. Grandjean [20] proved a TA(EXP,LIN) upper bound for computing whether the unconditional probability is 0 or 1 in this case, and Immerman [4] proved a matching lower bound. Of course, Grandjean's result can be viewed as a corollary of Theorem 4.3. Immerman's result, which has not, to the best of our knowledge, appeared in print, is a corollary of Theorem 4.18 which we prove in this section.

To capture the complexity of computing the asymptotic probability in the general case, we use a counting class #TA(EXP,LIN) that corresponds to TA(EXP,LIN). To define this class, we restrict attention to the class of ATMs whose initial states are existential. Given such an ATM **M**, we define an *initial existential path* in the computation tree of **M** on input w to be a path in this tree, starting at the initial state, such that every node on the path corresponds to an existential state except for the last node, which corresponds to a universal or an accepting state. That is, an initial existential path is a maximal path that starts at the root of the tree and contains only existential nodes except for the last node in the path. We say that an integer-valued function $f : \{0, 1\}^* \to I\!N$ is in #TA(EXP,LIN) if there is a machine **M** in the class TA(EXP,LIN) such that, for all w, $f(w)$ is the number of existential paths in the computation tree of **M** on input w whose last node is accepting (recall that we defined a notion of "accepting" for any node in the tree in §4.1). We extend the definition of #TA(EXP,LIN) to apply to non-integer-valued functions and define *#TA(EXP,LIN)-easy* just as we did before with #P and #EXP in §4.4.

We start with the upper bound.

THEOREM 4.17. *For* $\varphi \in \mathcal{L}(\Omega)$ *and* $\theta \in \mathcal{L}(\Upsilon)$*, the function* $\Pr^w_\infty(\varphi \mid \theta)$ *is in #TA(EXP,LIN).*

Proof. Let $\Phi = \Omega_{\varphi\wedge\theta}$, let $\Psi = \Upsilon_{\varphi\wedge\theta}$, and let ρ be the maximum arity of a predicate in Φ. The proof proceeds precisely as in Theorem 4.13. We compute, for each degree δ, the values $count^\delta(\theta)$ and $count^\delta(\varphi)$. This is done by nondeterministically generating model descriptions $\psi \wedge \mathcal{V}$ over Φ, branching according to the degree of ψ, and computing $\Pr^w_\infty(\varphi \wedge \theta \mid \psi \wedge \mathcal{V})$ and $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ using a TA(EXP,LIN) Turing machine.

To see that this is possible, recall from Proposition 4.5 that the length of a model description over Φ is $O(|\Phi|(2^{|\mathcal{P}|}M)^\rho)$. This is exponential in $|\Phi|$ and ρ, both of which are at most $|\varphi \wedge \theta|$. Therefore, it is possible to guess a model description in exponential time. Similarly, as we saw in the proof of Theorem 4.13, only exponentially many nondeterministic guesses are required to separate the output so that counts corresponding to different degrees do not overlap. These guesses form the initial nondeterministic stage of our TA(EXP,LIN) Turing machine. Note that it is necessary to construct the rest of the Turing machine so that a universal state always follows this initial stage, so that each guess corresponds exactly to one initial existential path; however, this is easy to arrange.

For each model description $\psi \wedge \mathcal{V}$ so generated, we compute $\Pr^w_\infty(\theta \mid \psi \wedge \mathcal{V})$ or $\Pr^w_\infty(\varphi \wedge \theta \mid \psi \wedge \mathcal{V})$ as appropriate, accepting if the conditional probability is 1. It follows immediately from Theorem 4.3 and the fact that there can only be exponentially many named elements in any model description we generate that this computation is in TA(EXP,LIN). Thus, the problem of computing $\Pr^w_\infty(\varphi \mid \theta)$ is in #TA(EXP,LIN). □

We now want to prove the matching lower bound. Moreover, we would like to show that the restrictions from §4.4 cannot be weakened. Recall from Theorem 4.13 that the #EXP upper bound held under one of two conditions: either (a) φ and θ are both unary, or (b) the vocabulary is arity-bounded and θ does not use equality. To show that (a) is tight, we show that the #TA(EXP,LIN) lower bound holds even if we allow φ and θ to use only binary predicates and equality. (The use of equality is necessary, since without it we know from (b) that the problem is #EXP-easy.) To show that (b) is tight, we show that the lower bound holds for a non-arity-bounded vocabulary, but without allowing equality in θ. Neither lower bound requires the use of constants.

The proof of the lower bounds is lengthy, but can be simplified somewhat by some assumptions about the construction of the TA(EXP,LIN) machines we consider. The main idea is that the existential "guesses" being made in the initial phase should be clearly distinguished from the rest of the computation. To achieve this, we assume that the Turing machine has an additional *guess tape*, and the initial phase of every computation consists of nondeterministically generating a *guess string* γ which is written on the new tape. The machine then proceeds with a standard alternating computation, but with the possibility of reading the bits on the guess tape.

More precisely, from now on we make the following assumptions about an ATM **M**. Consider any increasing functions $T(n)$ and $A(n)$ (in essence, these correspond to the time complexity and number of alternations), and let w be an input of size n. We assume:

- **M** has two tapes and two heads (one for each tape). Both tapes are one-way infinite to the right.
- The first tape is a work tape, which initially contains only the string w.
- **M** has an initial nondeterministic phase, during which its only action is to nondeterministically generate a string γ of zeros and ones, and write this string on the second tape (the guess tape). The string γ is always of length $T(n)$. Moreover, at the end of this phase, the work tape is as in the initial configuration, the guess tape contains only γ, the heads are at the beginning of their respective tapes, and the machine is in a distinguished universal state s_0.
- After the initial phase, the guess tape is never changed.
- After the initial phase, **M** takes at most $T(n)$ steps on each branch of its computation tree, and makes exactly $A(n) - 1$ alternations before entering a terminal (accepting or rejecting) state.
- The state before entering a terminal state is always an existential state (i.e., $A(n)$ is odd).

Let **M**$'$ be any (unrestricted) TA(T,A) machine that "computes" an integer function f. It is easy to construct some **M** satisfying the restrictions above that also computes f. The machine **M** first generates the guess string γ, and then simulates **M**$'$. At each nondeterministic branching point in the initial existential phase of **M**$'$, **M** uses the next bit of the string γ to dictate which choice to take. Observe that this phase is deterministic (given γ), and can thus be folded into the following universal phase. (Deterministic steps can be viewed as universal steps with a single successor.) If not all the bits in γ are used, **M** continues the execution of **M**$'$, but checks in parallel that the unused bits of γ are all 0's. If not, **M** rejects. It is easy to see that on any input w, **M** has the same number of accepting paths as **M**$'$, and therefore accepts the same function f. Moreover, **M** has the same number of alternations as **M**$'$, and at most a constant factor blowup in the running time.[12] This shows that it will be sufficient to prove our hardness results for the class #TA(EXP,LIN) by considering only those machines that satisfy these restrictions. For the remainder of this section we will therefore assume that all ATMs are of this type.

Let **M** be such an ATM and let w be an input of size n. We would like to encode the computation of **M** on w using a pair of formulas φ_w, θ_w. (Of course, these formulas depend on **M** as well, but we suppress this dependence.) Our first theorem shows how to encode part of this computation: given some appropriate string γ of length $T(n)$, we construct formulas that encode the computation of **M** immediately following the initial phase of guessing γ. More precisely, we say that **M** *accepts* w *given* γ if, on input w, the initial existential path during which **M** writes γ on the guess tape leads to an accepting node. We construct formulas $\varphi_{w,\gamma}$ and $\theta_{w,\gamma}$ such that $\Pr_\infty^w(\varphi_{w,\gamma} \mid \theta_{w,\gamma})$ is either 0 or 1, and is equal to 1 iff **M** accepts w given γ.

We do not immediately want to specify the process of guessing γ, so our initial construction will not commit to this. For a predicate R, let $\varphi[R]$ be a formula that uses the predicate R. Let ξ be another formula that has the same number of free variables as the arity of R. Then $\varphi[\xi]$ is the formula where every occurrence of R is replaced with the formula ξ, with an appropriate substitution of the arguments of R for the free variables in ξ.

THEOREM 4.18. *Let* **M** *be a TA(T,A) machine as above, where $T(n) = 2^{t(n)}$ for some polynomial $t(n)$ and $A(n) = O(n)$. Let w be an input string of length n, and $\gamma \in \{0,1\}^{T(n)}$ be a guess string.*

[12] For ease of presentation, we can and will (somewhat inaccurately, but harmlessly) ignore this constant factor and say that the time complexity of **M** is, in fact, $T(n)$.

(a) *For a unary predicate R, there exist formulas $\varphi_w[R]$, $\xi_\gamma \in \mathcal{L}(\Omega)$ and $\theta_w \in \mathcal{L}(\Upsilon)$ such that* $\Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w) = 1$ *iff* $\mathbf{M}$ *accepts w given γ and is* 0 *otherwise. Moreover, φ_w uses only predicates with arity* 2 *or less.*

(b) *For a binary predicate R, there exist formulas $\varphi'_w[R]$, $\xi'_\gamma \in \mathcal{L}(\Omega)$ such that* $\Pr^w_\infty(\varphi'_w[\xi'_\gamma] \mid$ *true*$) = 1$ *iff* $\mathbf{M}$ *accepts w given γ and is* 0 *otherwise.*

The formulas $\varphi_w[R]$, θ_w, and $\varphi'_w[R]$ are independent of γ, and their length is polynomial in the representation of $\mathbf{M}$ *and w. Moreover, none of the formulas constructed use any constant symbols.*

Proof. Let Γ be the tape alphabet of $\mathbf{M}$ and let S be the set of states of $\mathbf{M}$. We will identify an instantaneous description (ID) of length ℓ of $\mathbf{M}$ with a string Σ^ℓ for $\Sigma = \Sigma_W \times \Sigma_G$, where Σ_W is $\Gamma \cup (\Gamma \times S)$ and Σ_G is $(\{0, 1\} \cup (\{0, 1\} \times \{h\}))$. We think of the Σ_W component of the ith element in a string as describing the contents of the ith location in the work tape and also, if the tape head is at location i, the state of the Turing machine. The Σ_G component describes the contents of the ith location in the guess tape (whose alphabet is $\{0, 1\}$) and whether the guess tape's head is positioned there. Of course, we consider only strings in which exactly one element in $\Gamma \times S$ appears in the first component and exactly one element in $\{0, 1\} \times \{h\}$ appears in the second component. Since $\mathbf{M}$ halts within $T(n)$ steps (not counting the guessing process, which we treat separately), we need only deal with IDs of length at most $T(n)$. Without loss of generality, assume all IDs have length exactly $T(n)$. (If necessary, we can pad shorter IDs with blanks.)

In both parts of the theorem, IDs are encoded using the properties of domain elements. In both cases, the vocabulary contains predicates whose truth value with respect to certain combinations of domain elements represent IDs. The only difference between parts (a) and (b) is in the precise encoding used. We begin by showing the encoding for part (a).

In part (a), we use the sentence θ_w to define $T(n)$ named elements. This is possible since θ_w is allowed to use equality. Each ID of the machine will be represented using a single domain element. The properties of the ID will be encoded using the relations between the domain element representing it and the named elements. More precisely, assume that the vocabulary has $t(n)$ unary predicates $P_1, \ldots, P_{t(n)}$, and one additional unary predicate P^*. The domain is divided into two parts: the elements satisfying P^* are the named elements used in the process of encoding IDs, while the elements satisfying $\neg P^*$ are used to actually represent IDs. The formula θ_w asserts (using equality) that each of the atoms A over $\{P^*, P_1, \ldots, P_{t(n)}\}$ in which P^* (as opposed to $\neg P^*$) is one of the conjuncts contains precisely one element:

$$\forall x, y \left(\left(P^*(x) \land P^*(y) \land \bigwedge_{i=1}^{t(n)} (P_i(x) \Leftrightarrow P_i(y)) \right) \Rightarrow x = y \right).$$

Note that θ_w has polynomial length and is independent of γ.

We can view an atom A over $\{P^*, P_1, \ldots, P_{t(n)}\}$ in which P^* is one of the conjuncts as encoding a number between 0 and $T(n) - 1$, written in binary: if A contains P_j rather than $\neg P_j$, then the jth bit of the encoded number is 1; otherwise it is 0. (Recall that $T(n)$, the running time of $\mathbf{M}$, is $2^{t(n)}$.) In the following, we let A_i, for $i = 0, \ldots, T(n) - 1$, denote the atom corresponding to the number i according to this scheme. Let e_i be the unique element in the atom A_i for $i = 0, \ldots, T(n) - 1$. When representing an ID using a domain element d (where $\neg P^*(d)$), the relation between d and e_i is used to represent the ith coordinate in the ID represented by d. Assume that the vocabulary has a binary predicate R_σ for each $\sigma \in \Sigma$. Roughly speaking, we say that the domain element d represents the ID $\sigma_0 \ldots \sigma_{T(n)-1}$ if $R_{\sigma_i}(d, e_i)$ holds for $i = 0, \ldots, T(n) - 1$. More precisely, we say that d

represents $\sigma_0 \ldots \sigma_{T(n)-1}$ if

$$\neg P^*(d) \wedge \bigwedge_{i=0}^{T(n)-1} \forall y \left(A_i(y) \Rightarrow \left(R_{\sigma_i}(d, y) \wedge \bigwedge_{\sigma' \in \Sigma - \{\sigma_i\}} \neg R_{\sigma'}(d, y) \right) \right).$$

Note that not every domain element d such that $\neg P^*(d)$ holds encodes a valid ID. However, the question of which ID, if any, is encoded by a domain element d depends only on the relations between d and the finite set of elements $e_0, \ldots, e_{T(n)-1}$. This implies that, with asymptotic probability 1, every ID will be encoded by some domain element. More precisely, let $ID(x) = \sigma_0 \ldots \sigma_{T(n)-1}$ be a formula which is true if x denotes an element that represents $\sigma_0 \ldots \sigma_{T(n)-1}$. (It should be clear that such a formula is indeed expressible in our language.) Then for each ID $\sigma_0 \ldots \sigma_{T(n)-1}$ we have

$$\Pr_\infty^w(\exists x\, (ID(x) = \sigma_0 \ldots \sigma_{T(n)-1}) \mid \theta_w) = 1.$$

For part (b) of the theorem, we must represent IDs in a different way because we are not allowed to condition on formulas that use equality. Therefore, we cannot create an exponential number of named elements using a polynomial-sized formula. The encoding we use in this case uses two domain elements per ID rather than one. We now assume that the vocabulary Ω contains a $t(n)$-ary predicate R_σ for each symbol $\sigma \in \Sigma$. Note that this uses the assumption that there is no bound on the arity of predicates in Ω. For $i = 0, \ldots, T(n) - 1$, let $b^i_{t(n)} \cdots b^i_1$ be the binary encoding of i. We say that the pair (d_0, d_1) of domain elements *represents the ID* $\sigma_0 \ldots \sigma_{T(n)-1}$ if

$$d_0 \neq d_1 \wedge \bigwedge_{i=0}^{T(n)-1} \left(R_{\sigma_i}(d_{b^i_1}, \ldots, d_{b^i_{t(n)}}) \wedge \bigwedge_{\sigma' \in \Sigma - \{\sigma_i\}} \neg R_{\sigma'}(d_{b^i_1}, \ldots, d_{b^i_{t(n)}}) \right).$$

Again, we can define a formula in our language $ID(x_0, x_1) = \sigma_0 \ldots \sigma_{T(n)-1}$ which is true if x_0, x_1 denote a pair of elements that represent $\sigma_0 \ldots \sigma_{T(n)-1}$. As before, observe that for each ID $\sigma_0 \ldots \sigma_{T(n)-1}$ we have

$$\Pr_\infty^w(\exists x_0, x_1\, (ID(x_0, x_1) = \sigma_0 \ldots \sigma_{T(n)-1}) \mid \mathit{true}) = 1.$$

In both case (a) and case (b), we can construct formulas polynomial in the size of $\mathbf{M}$ and w that assert certain properties. For example, in case (a), *Rep*(x) is true of a domain element d if and only if d encodes an ID. In this case, *Rep*(x) is the formula

$$\neg P^*(x) \wedge \forall y \left(P^*(y) \Rightarrow \dot{\bigvee}_{\sigma \in \Sigma} R_\sigma(x, y) \right) \wedge$$
$$\exists! y\, (P^*(y) \wedge \bigvee_{\sigma \in ((\Gamma \times S) \times \Sigma_G)} R_\sigma(x, y)) \wedge \exists! y\, (P^*(y) \wedge \bigvee_{\sigma \in (\Sigma_W \times (\{0,1\} \times \{h\}))} R_\sigma(x, y))$$

where $\dot{\bigvee}$ is an abbreviation whose meaning is that precisely one of its disjuncts is true.

In case (b), *Rep*(x_0, x_1) is true of a pair (d_0, d_1) if and only if it encodes an ID. The construction is similar. For instance, the conjunct of *Rep*(x_0, x_1) asserting that each tape position has a uniquely defined content is

$$x_0 \neq x_1 \wedge \forall z_1, \ldots, z_{t(n)} \left(\left(\bigwedge_{i=1}^{t(n)} (z_i = x_0 \vee z_i = x_1) \right) \Rightarrow_{\sigma \in \Sigma} a \dot{\bigvee_{\sigma \in \Sigma}} R_\sigma(z_1, \ldots, z_{t(n)}) \right).$$

Except for this assertion, the construction for the two cases is completely parallel given the encoding of IDs. We will therefore restrict the remainder of the discussion to case (a). Other relevant properties of an ID that we can formulate are:

- $Acc(x)$ (resp., $Univ(x)$, $Exis(x)$) is true of a domain element d if and only if d encodes an ID and the state in $ID(d)$ is an accepting state (resp., a universal state, an existential state).
- $Step(x, x')$ is true of elements d and d' if and only if both d and d' encode IDs and $ID(d')$ can follow from $ID(d)$ in one step of **M**.
- $Comp(x, x')$ is true of elements d and d' if and only if both d and d' encode IDs, and $ID(d')$ is the final ID in a maximal nonalternating path starting at $ID(d)$ in the computation tree of **M**, and the length of this path is at most $T(n)$. A maximal nonalternating path is either a path all of whose states are existential except for the last one (which must be universal or accepting), or a path all of whose states are universal except for the last one. We can construct *Comp* using a divide and conquer argument, so that its length is polynomial in $t(n)$.

We remark that *Acc*, *Step*, etc. are not new predicate symbols in the language. Rather, they are complex formulas described in terms of the basic predicates R_σ. We omit details of their construction here; these can be found in [20].

It remains only to describe the formula that encodes the initial configuration of **M** on input w. Since we are interested in the behavior of **M** given a particular guess string γ, we begin by encoding the computation of **M** after the initial nondeterministic phase; that is, after the string γ is already written on the guess tape and the rest of the machine is back in its original state. We now construct the formula $Init[R](x)$ that describes the initial configuration. This formula takes R as a parameter, and has the form $Init'(x) \wedge R(x)$. The formulas substituted for $R(x)$ will correspond (in a way discussed below) to possible guesses γ.

We begin by considering case (a). We assume the existence of an additional binary predicate B_0. It is easy to write a polynomial-length formula $Init'(x)$ which is true of a domain element d if and only if d represents an ID where: (a) the state is the distinguished state s_0 entered after the nondeterministic guessing phase, (b) the work tape contains only w, (c) the heads are at the beginning of their respective tapes, and (d) for all i, the ith location of the guess tape contains 0 iff $B_0(d, e_i)$. Here e_i is, as before, the unique element in atom A_i. Note that the last constraint can be represented polynomially using the formula

$$\forall y \left(P^*(y) \Rightarrow \left(B_0(x, y) \Leftrightarrow \bigvee_{\sigma \in \Sigma_W \times \{0,(0,h)\}} R_\sigma(x, y) \right) \right).$$

We also want to find a formula ξ_γ that can constrain B_0 to reflect the guess γ. This formula, which serves as a possible instantiation for R, does not have to be of polynomial size. We define it as follows, where for convenience, we use B_1 as an abbreviation for $\neg B_0$:

$$(1) \qquad \xi_\gamma(x) =_{\text{def}} \bigwedge_{i=0}^{T(n)-1} \forall y \left(A_i(y) \Rightarrow B_{\gamma_i}(x, y) \right) .$$

Note that this is of exponential length.

In case (b), the relation of the guess string γ to the initial configuration is essentially the same modulo the modifications necessary due to the different representation of IDs. We only sketch the construction. As in case (a), we add a predicate B'_0, but in this case of arity $t(n)$. Again, the predicate B'_0 represents the locations of the 0's in the guess tape following the initial nondeterministic phase. The specification of the denotation of this predicate is done using an exponential-sized formula ξ'_γ, as follows (again taking B'_1 to be an abbreviation for $\neg B'_0$):

$$\xi'_\gamma(x_0, x_1) =_{\text{def}} B'_{\gamma_0}(x_0, \ldots, x_0, x_0) \wedge B'_{\gamma_1}(x_0, \ldots, x_0, x_1) \wedge \ldots \wedge B'_{\gamma_{T(n)-1}}(x_1, \ldots, x_1, x_1).$$

Using these formulas, we can now write a formula expressing the assertion that **M** accepts w given γ. In writing these formulas, we make use of the assumptions made about **M** (that it is initially in the state immediately following the initial guessing phase, that all computation paths make exactly $A(n)$ alternations, and so on). The formula $\varphi_w[R]$ has the following form:

$$\exists x_1\,(\mathit{Init}[R](x_1) \wedge \forall x_2\,(\mathit{Comp}(x_1,x_2) \Rightarrow \exists x_3\,(\mathit{Comp}(x_2,x_3) \wedge \forall x_4\,(\mathit{Comp}(x_3,x_4) \Rightarrow \dots \\ \exists x_{A(n)}\,(\mathit{Comp}(x_{A(n)-1},x_{A(n)}) \wedge \mathit{Acc}(x_{A(n)}))\dots)))).$$

It is clear from the construction that $\varphi_w[R]$ does not depend on γ and that its length is polynomial in the representations of **M** and w.

Now suppose $\mathcal{W}$ is a world satisfying θ_w in which every possible ID is represented by at least one domain element. (As we remarked above, a random world has this property with asymptotic probability 1.) Then it is straightforward to verify that $\varphi_w[\xi_\gamma]$ is true in $\mathcal{W}$ iff **M** accepts w. Therefore $\Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w) = 1$ iff **M** accepts w given γ and 0 otherwise. Similarly, in case (b), we have shown the construction of analogous formulas $\varphi'_w[R]$, for a binary predicate R, and ξ'_γ such that $\Pr^w_\infty(\varphi'_w[\xi'_\gamma] \mid \mathit{true}) = 1$ iff **M** accepts w given γ, and is 0 otherwise. □

We can now use the above theorem in order to prove the #TA(EXP,LIN) lower bound.

THEOREM 4.19. *For* $\varphi \in \mathcal{L}(\Omega)$ *and* $\theta \in \mathcal{L}(\Upsilon)$, *computing* $\Pr^w_\infty(\varphi \mid \theta)$ *is #TA(EXP,LIN)-hard. The lower bound holds even if* φ, θ *do not mention constant symbols and either* (a) φ *uses no predicate of arity* > 2, *or* (b) θ *uses no equality.*

Proof. Let **M** be a TA(EXP,LIN) Turing machine of the restricted type discussed earlier, and let w be an input of size n. We would like to construct formulas φ, θ such that from $\Pr^w_\infty(\varphi \mid \theta)$ we can derive the number of accepting computations of **M** on w. The number of accepting initial existential paths of such a Turing machine is precisely the number of guess strings γ such that **M** accepts w given γ. In Theorem 4.18, we showed how to encode the computation of such a machine **M** on input w given a nondeterministic guess γ. We now show how to force an asymptotic conditional probability to count guess strings appropriately.

As in Theorem 4.18, let $T(n) = 2^{t(n)}$, and let $\mathcal{P}' = \{P'_1, \dots, P'_{t(n)}\}$ be new unary predicates not used in the construction of Theorem 4.18. As before, we can view an atom A' over $\mathcal{P}'$ as representing a number in the range $0, \dots, T(n) - 1$: if A contains P'_j, then the jth bit of the encoded number is 1; otherwise it is 0. Again, let A'_i, for $i = 0, \dots, T(n) - 1$, denote the atom corresponding to the number i according to this scheme. We can view a simplified atomic description ψ over $\mathcal{P}'$ as representing the string $\gamma = \gamma_0 \dots \gamma_{T(n)-1}$ such that γ_i is 1 if ψ contains the conjunct $\exists z\, A'_i(z)$, and 0 if ψ contains its negation. Under this representation, for every string γ of length $T(n)$, there is a unique simplified atomic description over $\mathcal{P}'$ that represents it; we denote this atomic description ψ_γ. Note that ψ_γ is not necessarily a consistent atomic description, since the atomic description where all atoms are empty also denotes a legal string—that string where all bits are 0.

While it is possible to reduce the problem of counting accepting guess strings to that of counting simplified atomic descriptions, this is not enough. After all, we have already seen that computing asymptotic conditional probabilities ignores all atomic descriptions that are not of maximal degree. We deal with this problem as in Theorem 4.15. Let Q be a new unary predicate, and let θ' be, as in Theorem 4.15, the sentence

$$\forall x, y \left(\left(Q(x) \wedge \bigwedge_{j=1}^{t(n)} (P'_j(x) \Leftrightarrow P'_j(y)) \right) \Rightarrow Q(y) \right).$$

Observe that here we use θ' rather than the formula θ of Theorem 4.15, since we also want to count the "inconsistent" atomic description where all atoms are empty. Recall that, assuming θ', each simplified atomic description ψ_γ over $\mathcal{P}'$ corresponds precisely to a single maximal atomic description ψ'_γ over $\mathcal{P}' \cup \{Q\}$. We reduce the problem of counting accepting guess strings to that of counting maximal atomic descriptions over $P' \cup \{Q\}$.

We now consider cases (a) and (b) separately, beginning with the former. Fix a guess string γ. In Theorem 4.18, we constructed formulas $\varphi_w[R], \xi_\gamma \in \mathcal{L}(\Omega)$ and $\theta_w \in \mathcal{L}(\Upsilon)$ such that $\Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w) = 1$ iff **M** accepts w given γ, and is 0 otherwise. Recall that the formula $\xi_\gamma(x)$ (see equation (1)) sets the ith guess bit to be γ_i by forcing the appropriate one of $B_0(x, e_i)$ and $B_1(x, e_i)$ to hold, where e_i is the unique element in the atom A_i. In Theorem 4.18, this was done directly by reference to the bits γ_i. Now, we want to derive the correct bit values from ψ_γ, which tells us that the ith bit is 1 iff $\exists z\, A'_i(z)$. The following formula ξ has precisely the desired property:

$$\xi(x) =_{\text{def}} \forall y \left(P^*(y) \Rightarrow \left(B_1(x, y) \Leftrightarrow \exists z \left(Q(z) \wedge \bigwedge_{j=1}^{t(n)} (P_j(y) \Leftrightarrow P'_j(z)) \right)\right)\right).$$

Clearly, $\psi'_\gamma \models \xi \Leftrightarrow \xi_\gamma$.

Similarly, for case (b), the formula ξ' is:

$$\xi'(x_0, x_1) =_{\text{def}} \forall y_1, \ldots, y_{t(n)} \left(\left(\bigwedge_{j=1}^{t(n)} (y_j = x_0 \vee y_j = x_1) \right) \Rightarrow \right.$$
$$\left. \left(B'_1(y_1, \ldots, y_{t(n)}) \Leftrightarrow \exists z \left(Q(z) \wedge \bigwedge_{j=1}^{t(n)} (y_j = x_1 \Leftrightarrow P'_j(z)) \right)\right)\right).$$

As in part (a), $\psi'_\gamma \models \xi' \Leftrightarrow \xi'_\gamma$.

Now, for case (a), we want to compute the asymptotic conditional probability $\Pr^w_\infty(\varphi[\xi] \mid \theta_w \wedge \theta')$. In doing this computation, we will use the observation (whose straightforward proof we leave to the reader) that if the symbols that appear in θ_2 are disjoint from those that appear in φ_1 and θ_1, then $\Pr^w_\infty(\varphi_1 \mid \theta_1 \wedge \theta_2) = \Pr^w_\infty(\varphi_1 \mid \theta_1)$. Using this observation and the fact that all maximal atomic descriptions over $\mathcal{P}' \cup \{Q\}$ are equally likely given $\theta_w \wedge \theta'$, by straightforward probabilistic reasoning we obtain:

$$\begin{aligned}\Pr^w_\infty(\varphi_w[\xi] \mid \theta_w \wedge \theta') &= \sum_{\psi'_\gamma} \Pr^w_\infty(\varphi_w[\xi] \mid \theta_w \wedge \theta' \wedge \psi'_\gamma) \cdot \Pr^w_\infty(\psi'_\gamma \mid \theta_w \wedge \theta') \\ &= \frac{1}{2^{T(n)}} \sum_{\psi'_\gamma} \Pr^w_\infty(\varphi_w[\xi] \mid \theta_w \wedge \theta' \wedge \psi'_\gamma).\end{aligned}$$

We observed before that ξ is equivalent to ξ_γ in worlds satisfying ψ'_γ, and therefore

$$\Pr^w_\infty(\varphi_w[\xi] \mid \theta_w \wedge \theta' \wedge \psi'_\gamma) = \Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w \wedge \theta' \wedge \psi'_\gamma) = \Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w),$$

where the second equality follows from the observation that none of the vocabulary symbols in ψ'_γ or θ' appear anywhere in $\varphi_w[\xi_\gamma]$ or in θ_w. In Theorem 4.18, we proved that $\Pr^w_\infty(\varphi_w[\xi_\gamma] \mid \theta_w)$ is equal to 1 if the ATM accepts w given γ and 0 if not. We therefore obtain that

$$\Pr^w_\infty(\varphi_w[\xi] \mid \theta_w \wedge \theta') = \frac{f(w)}{2^{T(n)}}.$$

Since both $\varphi_w[\xi]$ and $\theta_w \wedge \theta'$ are polynomial in the size of the representation of **M** and in $n = |w|$, this concludes the proof for part (a). The completion of the proof for part (b) is essentially identical. □

It remains only to investigate the problem of approximating $\Pr^w_\infty(\varphi \mid \theta)$ for this language.

THEOREM 4.20. *Fix rational numbers $0 \le r_1 \le r_2 \le 1$ such that $[r_1, r_2] \ne [0, 1]$. For $\varphi, \theta \in \mathcal{L}(\Omega)$, the problem of deciding whether $\Pr^w_\infty(\varphi \mid \theta) \in [r_1, r_2]$ is TA(EXP,LIN)-hard, even given an oracle for deciding whether the limit exists.*

Proof. For the case of $r_1 = 0$ and $r_2 < 1$, the result is an easy corollary of Theorem 4.18. We can generalize this to the case of $r_1 > 0$, using precisely the same technique as in Theorem 4.16. □

4.6. Complexity for random structures. So far in this section, we have investigated the complexity of various problems relating to the asymptotic conditional probability using the random-worlds method. We now deal with the same issues for the case of random structures. It turns out that most of our results for random worlds carry through to random structures for trivial reasons.

First, consider the issue of well-definedness. By Proposition 2.3, well-definedness is equivalent for random worlds and random structures. Therefore, all of the results obtained for random worlds carry through unchanged for random structures.

For computing or approximating the limit, Theorem 3.37 allows us to restrict attention to unary vocabularies and unary sentences φ and θ. In particular, there is no need to duplicate the results in §4.5. For the remainder of this section, we analyze the complexity of computing $\Pr^{s,\Psi}_\infty(\varphi \mid \theta)$ for $\varphi, \theta \in \mathcal{L}(\Psi)$. As before, we can assume that $\mathcal{A}^\Psi_{\varphi\wedge\theta} \subseteq \mathcal{A}^\Psi_\theta$.

The computational approach is essentially the same as that for random worlds. However, as we showed in §3.5, rather than partitioning θ into model descriptions, we can make use of the assumption that the vocabulary is unary and instead partition it into atomic descriptions ψ. That is, for $a = \alpha^\Psi(\theta)$,

$$\Pr^{s,\Psi}_\infty(\varphi \mid \theta) = \frac{1}{|\mathcal{A}^{\Psi,a}_\theta|} \cdot \sum_{\psi \in \mathcal{A}^{\Psi,a}} \Pr^w_\infty(\varphi \mid \psi) \left(= \frac{|\mathcal{A}^{\Psi,a}_{\varphi\wedge\theta}|}{|\mathcal{A}^{\Psi,a}_\theta|} \right).$$

As for random worlds, we begin with the problem of computing 0-1 probabilities. In §4.1, we showed how to extend Grandjean's algorithm to compute $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$. Fix a unary vocabulary Ψ, and suppose that $\psi \wedge \mathcal{V}$ is a model description over Ψ, with $n = \nu(\psi)$. Recall from Proposition 3.21 that $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V}) = \Pr^w_\infty(\varphi \mid \psi \wedge \exists x_1, \dots, x_n\, D_\mathcal{V})$. However, in the unary case it is easy to see that $\psi \wedge \exists x_1, \dots, x_n\, D_\mathcal{V}$ is equivalent to ψ. This is because the only nontrivial properties of the named elements given by $\mathcal{V}$ is which atom each of them satisfies and the equality relations between the constants, and this information is already present in the atomic description ψ.

Therefore, we conclude that $\Pr^w_\infty(\varphi \mid \psi)$ is either 0 or 1, because this is so for $\Pr^w_\infty(\varphi \mid \psi \wedge \mathcal{V})$. Now recall that if $\psi \in \mathcal{A}^\Psi_\varphi$ then ψ implies φ. In this case, clearly $\Pr^w_\infty(\varphi \mid \psi) = \Pr^{s,\Psi}_\infty(\varphi \mid \psi) = 1$. Similarly, if $\psi \notin \mathcal{A}^\Psi_\varphi$, then ψ is inconsistent with φ and $\Pr^w_\infty(\varphi \mid \psi) = \Pr^{s,\Psi}_\infty(\varphi \mid \psi) = 0$. So it follows that we can continue to use Grandjean's algorithm, as described in §4.1, to compute $\Pr^{s,\Psi}_\infty(\varphi \mid \psi)$.

THEOREM 4.21. *There exists an alternating Turing machine that takes as input a finite unary vocabulary Ψ, an atomic description ψ over Ψ, and a formula $\varphi \in \mathcal{L}(\Psi)$, and decides whether $\Pr^{s,\Psi}_\infty(\varphi \mid \psi)$ is 0 or 1. The machine uses time $O(|\Psi| 2^{|\mathcal{P}|}(\nu(\psi) + |\varphi|))$ and has at most $O((2^{|\Psi|} + \nu(\psi))^{|\varphi|})$ branches and $O(|\varphi|)$ alternations.*

As before, we can simulate the ATM deterministically.

COROLLARY 4.22. *There exists a deterministic Turing machine that takes as input a finite unary vocabulary Ψ, an atomic description ψ over Ψ, and a formula $\varphi \in \mathcal{L}(\Psi)$, and decides whether $\Pr^{w,\Psi}_\infty(\varphi \mid \psi)$ is 0 or 1. The machine uses time $2^{O(|\varphi||\Psi| \log(\nu(\psi)+1))}$ and space $O(|\varphi||\Psi| \log(\nu(\psi) + 1))$.*

We now analyze the complexity of computing $\Pr^{s,\Psi}_\infty(\varphi \mid \theta)$. We begin with the case of a fixed finite vocabulary Ψ.

THEOREM 4.23. *Fix a finite unary vocabulary Ψ with at least one predicate symbol. For $\varphi, \theta \in \mathcal{L}(\Psi)$, the problem of computing $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$ is PSPACE-complete. Moreover, deciding if $\Pr^{w}_{\infty}(\varphi \mid true) = 1$ is PSPACE-hard, even if $\varphi \in \mathcal{L}^{-}(\{P\})$.*

Proof. By Corollaries 3.41 and 3.42, if $\varphi, \theta \in \mathcal{L}^{-}(\{P\})$ and $P \in \Psi$, then $\Pr^{w}_{\infty}(\varphi \mid \theta) = \Pr^{s,\{P\}}_{\infty}(\varphi \mid \theta) = \Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$. Thus, the lower bound follows immediately from Theorem 4.7.

For the upper bound, we follow the same general procedure of *Compute-Pr*$_{\infty}$: generating all atomic descriptions of size $d(\theta) + |\mathcal{C}|$, and computing $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$. The only difference is that, rather than counting only model descriptions of the highest degree $\Delta(\psi) = (\alpha(\psi), \nu(\psi))$, we count all atomic descriptions of the highest activity count $\alpha(\psi)$. Clearly, since there are fewer atomic descriptions than model descriptions, and an atomic description has a shorter description length than a model description, the complexity of the resulting algorithm can only be lower than the corresponding complexity for random worlds. The algorithm for random structures is therefore also in PSPACE. □

Just as Theorem 4.7, Theorem 4.23 shows that even approximating the limit is hard. That is, for a fixed ϵ with $0 < \epsilon < 1$, the problem of deciding whether $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta) \in [0, 1-\epsilon]$ is PSPACE-hard even for $\varphi, \theta \in \mathcal{L}^{-}(\{P\})$. As for the case of random worlds, this lower bound cannot be generalized to arbitrary intervals $[r_1, r_2]$ unless we allow equality. In particular, for any fixed finite language, there is a fixed number of atomic descriptions of size 1, where this number depends only on the language. Therefore, there are only finitely many values that the probability $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$ can take for $\varphi, \theta \in \mathcal{L}^{-}(\Psi)$. However, and unlike the case for random worlds, for random structures once we have equality in the language, a single unary predicate suffices in order to have this probability assume infinitely many values.

THEOREM 4.24. *Fix a finite unary vocabulary Ψ that contains at least one unary predicate and rational numbers $0 \le r_1 \le r_2 \le 1$ such that $[r_1, r_2] \ne [0, 1]$. For $\varphi, \theta \in \mathcal{L}(\Psi)$, the problem of deciding whether $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta) \in [r_1, r_2]$ is PSPACE-hard, even given an oracle that tells us whether the limit is well defined.*

Proof. We first prove the result under the assumption that $\Psi = \{P\}$.

For the case of $r_1 = 0$ and $r_2 < 1$, the result follows trivially from Theorem 4.23. Let $r_1 = q/p > 0$. As for random worlds, we construct formulas $\varphi_{r_1}, \theta_{r_1}$ such that $\Pr^{s,\{P\}}_{\infty}(\varphi_{r_1} \mid \theta_{r_1}) = r_1$. The formula θ_{r_1} is $\exists x\, P(x) \wedge \exists^{\le p} x\, P(x)$. The formula φ_{r_1} is $\exists x\, P(x) \wedge \exists^{\le q} x\, P(x)$. Clearly, there are p atomic descriptions consistent with θ_{r_1}, among which q are also consistent with φ_{r_1}. Thus, $\Pr^{s,\{P\}}_{\infty}(\varphi_{r_1} \mid \theta_{r_1}) = q/p = r_1$.

Now, as in Theorem 4.8, let β be a QBF, and define ξ_β as in that proof. As there, $\Pr^{s,\{P\}}_{\infty}(\xi_\beta \wedge \varphi_{r_1} \mid \theta_{r_1} \wedge \exists x\, \neg P(x))$ is 0 if β is false and r_1 if it is true. Thus, by computing this probability, we can decide the truth of β, proving PSPACE-hardness in this case.

The result in the case that $\Psi \ne \{P\}$ is not immediate as it is for random worlds, since the asymptotic probability in the case of random structures may depend on the vocabulary. We define a formula θ' to be the following conjunction: for each predicate P' in $\Psi - \{P\}$, θ' contains the conjunct $\forall x P'(x)$. If Ψ contains constant symbols, let c be a fixed constant symbol in Ψ. Then θ' also contains the conjunct $\bigwedge_{P' \in \Psi} P'(c)$, and conjuncts $c = c'$ for each constant c' in Ψ. We leave it to the reader to check that for any formulas $\varphi, \theta \in \mathcal{L}(\{P\})$, $\Pr^{s,\{P\}}_{\infty}(\varphi \mid \theta) = \Pr^{s,\Psi}_{\infty}(\varphi \mid \theta \wedge \theta')$. □

For the case of a finite vocabulary and a bound on the quantifier depth, precisely the same argument as that given for Theorem 4.9 allows us to show the following.

THEOREM 4.25. *Fix $d \ge 0$. For $\varphi, \theta \in \mathcal{L}(\Psi)$ such that $d(\varphi), d(\theta) \le d$, we can effectively construct a linear time algorithm that decides if $\Pr^{s,\Psi}_{\infty}(\varphi \mid \theta)$ is well defined and computes it if it is.*

We now drop the assumption that we have a fixed finite vocabulary. As we previously discussed, there are at least two distinct interpretations for asymptotic conditional probabilities in this case. One interpretation of "infinite vocabulary" views Ω as a potential or background vocabulary, so that every problem instance includes as part of its input the actual finite subvocabulary that is of interest. So although this subvocabulary is finite, there is no bound on its possible size. The alternative is to interpret infinite vocabularies more literally, using the limit process explained in §2.3. As we mentioned, for random worlds the two interpretations are equivalent. However, this is not the case for random structures, where the two interpretations may give different answers. In fact, from Corollary 2.9, it follows that the random-structures method reduces to the random-worlds method under the second interpretation. Thus, the complexity results are the same for random worlds and random structures under this interpretation. As we already observed, even under the first interpretation, the random-structures method reduces to the random-worlds method if there is a binary predicate in the language. It therefore remains to prove the complexity results for random structures only for the first interpretation, where the vocabulary is considered to be part of the input, under the assumption that the language is unary. As Example 2.4 shows, in this case, the random-worlds method may give answers different from those given by the random-structures method. Nevertheless, as we now show, the same complexity bounds hold for both random worlds and random structures.

As for the case of the finite vocabulary, the lower bounds for computing the probability (Theorem 4.15) and for approximating it (Theorem 4.16) only use formulas in $\mathcal{L}^-(\mathcal{P})$ for some $\mathcal{P} \subset \mathcal{Q}$. Therefore, by Corollaries 3.41 and 3.42, the lower bounds hold unchanged for random structures.

THEOREM 4.26. *For $\Psi \subset \Upsilon$ and $\varphi, \theta \in \mathcal{L}^-(\mathcal{P})$ of depth at least 2, the problem of computing $\Pr_\infty^{s,\Psi}(\varphi \mid \theta)$ is #EXP-hard, even given an oracle for deciding whether the limit exists.*

THEOREM 4.27. *Fix rational numbers $0 \leq r_1 \leq r_2 \leq 1$ such that $[r_1, r_2] \neq [0, 1]$. For $\Psi \subseteq \Omega$ and $\varphi, \theta \in \mathcal{L}^-(\mathcal{P})$ of depth 2, the problem of deciding whether $\Pr_\infty^{s,\Psi}(\varphi \mid \theta) \in [r_1, r_2]$ is both NEXPTIME-hard and co-NEXPTIME-hard, even given an oracle for deciding whether the limit exists.*

It remains only to prove the #EXP upper bound for computing the asymptotic probability.

THEOREM 4.28. *For $\Psi \subseteq \Omega$ and $\varphi, \theta \in \mathcal{L}(\Psi)$, the problem of computing $\Pr_\infty^{s,\Psi}(\varphi \mid \theta)$ is #EXP-easy.*

Proof. We again follow the outline of the proof for the case of random worlds. Recall that in the proof of Theorem 4.13 we construct a Turing machine such that the number of accepting paths of **M** encodes, for each degree δ, $count^\delta(\varphi)$ and $count^\delta(\theta)$. From this encoding we could deduce the maximum degree, and calculate the asymptotic conditional probability. This was accomplished by guessing a model description $\psi \wedge \mathcal{V}$, and branching sufficiently often, according to $\Delta(\psi)$, so that the different counts in the output are guaranteed to be separated. The construction for random structures is identical, except that we guess atomic descriptions ψ rather than model descriptions, and branch according to $\alpha(\psi)$ rather than according to $\Delta(\psi)$. Again, since there are fewer atomic descriptions than model descriptions, and the representation of atomic descriptions is shorter, the resulting Turing machine is less complex, and therefore also in #EXP. □

5. Conclusions. In this paper and [23], we have carried out a rather exhaustive study of complexity issues for two principled methods for computing degrees of belief: the random-worlds method and the random-structures method. These are clearly not the only methods that one can imagine for this purpose. However, as discussed in [2] and [22], both methods are often successful at giving answers that are intuitively plausible and which agree with well-known desiderata. We believe this success justifies a careful examination of complexity issues.

Here we have focused on the case where the formula we are conditioning on is a unary first-order formula. As we mentioned in the introduction, in many applications we want to move beyond first order and also allow for statistical knowledge. Both methods continue to make sense in this case. Furthermore, as shown in [33], [3], and [27], for a unary language we can often calculate asymptotic probabilities in the random-worlds method, using a combination of the techniques in this paper and the principle of maximum entropy. Since a lot is already known about computing maximum entropy (for example, [7], [9], [19]), this combination may lead to efficient algorithms for some practical problems.

Acknowledgments. We would like to thank Fahiem Bacchus, with whom we started working on this general area of research. We would also like to thank Ron Fagin and Moshe Vardi for useful comments on a previous draft of this paper. Ron's comments encouraged us to discuss both the random-structures and the random-worlds methods in this paper. We would also like to thank Moshe for pointing out the reference [31]. Finally, we would like to thank Andrew Granville for help with some of the details of Theorem 4.8.

A FAST DERANDOMIZATION SCHEME AND ITS APPLICATIONS*

YIJIE HAN†

Abstract. This paper presents a fast derandomization scheme for the PROFIT/COST problem. Through the applications of this scheme the time complexity of $O(\log^2 n \log\log n)$ for the $\Delta + 1$ vertex-coloring problem using $O((m+n)/\log\log n)$ processors on the concurrent read exclusive write parallel random-access machine (CREW PRAM), the time complexity of $O(\log^{2.5} n)$ for the maximal independent set problem using $O((m+n)/\log^{1.5} n)$ processors on the CREW PRAM and the time complexity of $O(\log^{2.5} n)$ for the maximal matching problem using $O((m+n)/\log^{0.5} n)$ processors on the exclusive read exclusive write (EREW) PRAM are shown.

Key words. derandomization, parallel algorithms, graph algorithms, graph coloring, maximal independent set, maximal matching

1. Introduction.

Recent progress in derandomization has resulted in several efficient sequential and parallel algorithms [ABI], [BR], [BRS], [H], [HI], [KW], [L1], [L2], [L3], [MNN], [PSZ], [Rag], [Sp]. The essence of the technique of derandomization lies in the design of a sample space that is easy to search, in the probabilistic analysis showing that the expectation of a desired random variable is no less than demanded, and in the search technique which ultimately returns a good sample point. Raghavan [Rag] and Spencer [Sp] showed how to search an exponential-size sample space to obtain polynomial-time sequential algorithms. Their technique cannot be applied directly to obtain efficient parallel algorithms through derandomization. Alon et al. [ABI], Karp and Wigderson [KW], and Luby [L1], [L2], [L3] developed schemes using $O(n)$ random variables with limited independence on a small sample space and thus obtained efficient parallel algorithms through derandomization. Berger and Rompel [BR] and Motwani et al. [MNN] presented novel designs in which $(\log^c n)$-wise independent random variables are used in randomized algorithms and then $\mathcal{NC}$ [Co] algorithms are obtained through the derandomization of these randomized algorithms.

To obtain efficient parallel algorithms, i.e., algorithms using no more than a linear number of processors and running in polylog time, Luby [L2], [L3] outlined an elegant framework in which pairwise independent random variables are designed on a sample space that facilitates binary search. His framework [L2], [L3] consists of a derandomization scheme for the bit-pairs PROFIT/COST problem and the general-pairs PROFIT/COST problem, and applications of the scheme to three problems: the $\Delta + 1$ vertex-coloring problem, the maximal independent set problem, and the maximal matching problem. By applying his derandomization scheme, he obtained a linear processor concurrent read exclusive write (CREW) algorithm for the $\Delta + 1$ vertex-coloring problem with time complexity $O(\log^3 n \log\log n)$. Although he put the three problems in a very nice setting, his derandomization scheme is not efficient enough to improve on parallel algorithms for the maximal independent set problem and the maximal matching problem obtained through ad hoc designs [GS2], [IS]. To illustrate his ideas, Luby gave linear processor algorithms for the maximal independent set problem and the maximal matching problem with time complexity $O(\log^5 n)$ through derandomization [L3].

Recently, Han and Igarashi [HI] gave a fast derandomization scheme for the bit-pairs PROFIT/COST problem. Their scheme yields a fast CREW parallel algorithm for

the bit-pairs PROFIT/COST problem with time complexity $O(\log n)$ using a linear number of processors. Han then showed [H] how to obtain an exclusive read exclusive write (EREW) algorithm with the same time and processor complexities. Their result improves the time complexity of Luby's $\Delta + 1$ vertex-coloring algorithm to $O(\log^3 n)$. The most interesting feature in Han and Igarashi's scheme [H], [HI] is the design of a sample space which allows redundancy and mutual independence to be exploited.

In this paper, we give a new scheme to speed up the derandomization process of the general-pairs PROFIT/COST problem. This scheme allows several bit-pairs PROFIT/COST problems in one general-pairs PROFIT/COST problem to be solved in one pass. We note that our scheme cannot be constructed efficiently under the setting of previous derandomization schemes [L2], [L3] because it would require more than a linear number of processors. The power of our derandomization scheme allows us to improve the time complexity for the $\Delta + 1$ vertex-coloring problem and to obtain new efficient parallel algorithms for the maximal independent set problem and the maximal matching problem.

A substantial amount of effort has been put into the search for efficient parallel algorithms for these three problems. There are important special cases where optimal parallel algorithms are known. Hagerup et al. [HCD] have an optimal parallel algorithm for the 5-coloring of planar graphs which implies an optimal parallel algorithm for the maximal independent set problem for planar graphs. Significant progress has also been made on the three problems for graphs [ABI], [GS1], [GS2], [HI], [IS], [KW], [L1], [L2], [L3]. In this paper, we only study these three problems on graphs.

Luby obtained through derandomization a CREW algorithm for the $\Delta + 1$ vertex-coloring problem with time complexity $O(\log^3 n \log\log n)$ using a linear number of processors. Han and Igarashi's work [HI] improves the time complexity for the $\Delta + 1$ vertex-coloring problem to $O(\log^3 n)$. In this paper, we improve the time complexity for the $\Delta + 1$ vertex-coloring problem to $O(\log^2 n \log\log n)$ using $O((m+n)/\log\log n)$ processors on the CREW parallel random-access machine (PRAM) [FW]. For the maximal independent set problem, the first $\mathcal{NC}$ algorithm, which was obtained by Karp and Wigderson [KW], has time complexity $O(\log^4 n)$ using $O(n^3/\log^3 n)$ processors on the EREW PRAM. Their result has since been improved to time $O(\log^2 n)$ using $O(mn^2)$ processors on the EREW PRAM by Luby [L1] and to time $O(\log^3 n)$ using $O((m+n)/\log n)$ processors on the EREW PRAM by Goldberg and Spencer [GS1], [GS2]. In this paper, we obtain an EREW algorithm with time complexity $O(\log^{2.5} n)$ using $O((m+n)/\log^{0.5} n)$ processors. We are able to achieve the same time complexity using $O((m+n)/\log^{1.5} n)$ processors on the CREW PRAM. We also obtain a CREW algorithm with time complexity $O(\log^2 n)$ using $O(n^{2.376})$ processors. For the maximal matching problem, Israeli and Shiloach's concurrent read concurrent write (CRCW) algorithm [IS] has time complexity $O(\log^3 n)$ using $O(m+n)$ processors. In this paper, we give an EREW algorithm with time complexity $O(\log^{2.5} n)$ using $O((m+n)/\log^{0.5} n)$ processors.

Since our algorithms are obtained through derandomization, they are derived at a loss of efficiency from the original randomized algorithms.

Our approach to the three problems follows that of Luby's [L2], [L3]. Our results are obtained through the novel design of sample spaces which follows Han and Igarashi's work [H], [HI], the formulation of our fast derandomization process, and the adaptive applications of the fast derandomization techniques to the three problems.

We have outlined here only the main results achieved. There are ramifications of our results which we will mention in the remaining sections of the paper.

2. Preliminaries. The *bit-pairs PROFIT/COST* (BPC) and the *general-pairs PROFIT/COST* (GPC) problems as formulated by Luby [L2] can be described as follows.

Let $\vec{x} =< x_i \in \{0, 1\}^q : i = 0, \ldots, n-1 >$. Each point $\vec{x}$ out of the 2^{nq} points is assigned probability $1/2^{nq}$. Given function $B(\vec{x}) = \sum_{i,j} f_{i,j}(x_i, x_j)$, where $f_{i,j}$ is defined as a function $\{0, 1\}^q \times \{0, 1\}^q \rightarrow \mathcal{R}$. The GPC problem is to find a good point $\vec{y}$ such that $B(\vec{y}) \geq E[B(\vec{x})]$. B is called the general-pairs BENEFIT function and the $f_{i,j}$'s are called the GPC functions. When $q = 1$, the GPC problem is called a BPC problem and the $f_{i,j}$'s are called the BPC functions.

The size m of the problem is the number of nontrivial PROFIT/COST functions present in the input.

Let $G = (V, E)$ be a graph with $|V| = n$ and $|E| = m$. The degree of $v \in V$ is denoted by $d(v)$. Let $\Delta = \max\{d(v) | v \in V\}$. The output of the $\Delta + 1$ vertex coloring is $color(v) \in \{1, \ldots, \Delta + 1\}$ for all $v \in V$ such that if $(i, j) \in E$, then $color(i) \neq color(j)$. $I \subseteq V$ is an independent set if for $v, w \in I, v \neq w$, $(v, w) \notin E$. I is a maximal independent set if I is not a proper subset of any other independent set. $M \subseteq E$ is a matching set if no two edges in M have a common vertex. M is maximal if it is not a proper subset of any other matching set.

Han and Igarashi [HI] have formulated the BPC problem as a tree-contraction problem [MR]. Without loss of generality, assume that n is a power of 2. n 0/1-valued uniformly distributed mutually independent random variables r_i, $0 \leq i < n$, are used. A *random-variable tree* T is built for $\vec{x}$. T is a complete binary tree with n leaves plus a node which is the parent of the root of the complete binary tree (thus there are n interior nodes in T and the root of T has only one child). The n variables x_i, $0 \leq i < n$, are associated with n leaves of T, and the n random variables r_i, $0 \leq i < n$, are associated with the interior nodes of T. The n leaves of T are numbered from 0 to $n - 1$. Variable x_i is associated with leaf i.

Variables x_i, $0 \leq i < n$, are chosen randomly as follows. Let $\vec{r} =< r_i : i = 0, \ldots, n - 1 >$ and let $r_{i_0}, r_{i_1}, \ldots, r_{i_{\log n}}$ be the random variables on the path from leaf i to the root of T. Random variable x_i is defined to be $x_i(\vec{r}) = (\sum_{j=0}^{\log n - 1} i_j \cdot r_{i_j} + r_{i_{\log n}}) \bmod 2$, where i_j is the jth bit of i starting with the least significant bit. It can be verified [H] that random variables x_i, $0 \leq i < n$, are uniformly distributed mutually independent random variables.

Due to the linearity of expectation and pairwise independence of random variables in $\vec{x}$, $E[B(\vec{x})] = \sum_{i,j} E[f_{i,j}(x_i, x_j)] = \sum_{i,j} E[f_{i,j}(x_i(\vec{r}), x_j(\vec{r}))] = E[B(\vec{x}\ (\vec{r}))]$. The problem now is to find a sample point $\vec{r}$ such that $B(\vec{r}) \geq E[B] = \frac{1}{4} \sum_{i,j} (f_{i,j}(0, 0) + f_{i,j}(0, 1) + f_{i,j}(1, 0) + f_{i,j}(1, 1))$.

Han and Igarashi's algorithm [HI] fixes random variables r_i (setting their values to 0's and 1's) one level in a step starting from the level next to the leaves (level 0) and going upward on the tree T until level $\log n$. Since there are $\log n + 1$ interior levels in T, all random variables will be fixed in $\log n + 1$ steps.

Let random variable r_i at level 0 be the parent of the random variables x_i and $x_{i\#0}$ in the random variable tree, where $i\#j$ is a number obtained by complementing the jth bit of i. r_i will be fixed as follows. Compute $f_0 = E[f_{i,i\#0} + f_{i\#0,i} | r_i = 0] = (f_{i,i\#0}(0, 0) + f_{i,i\#0}(1, 1) + f_{i\#0,i}(0, 0) + f_{i\#0,i}(1, 1))/2$ and $f_1 = E[f_{i,i\#0} + f_{i\#0,i} | r_i = 1] = (f_{i,i\#0}(0, 1) + f_{i,i\#0}(1, 0) + f_{i\#0,i}(0, 1) + f_{i\#0,i}(1, 0))/2$. If $f_0 \geq f_1$, then set r_i to 0 else set r_i to 1. All random variables at level 0 will be fixed in parallel in constant time using n processors. This results in a smaller space with higher expectation for B. Therefore, this smaller space contains a good point.

If r_i is set to 0, then $x_i = x_{i\#0}$; if r_i is set to 1, then $x_i = 1 - x_{i\#0}$. Therefore, after r_i is fixed, x_i and $x_{i\#0}$ can be combined. The n random variables x_i, $0 \leq i < n$, can be reduced to $n/2$ random variables. PROFIT/COST functions $f_{i,j}$, $f_{i\#0,j}$, $f_{i,j\#0}$, and $f_{i\#0,j\#0}$ can also be combined into one function. It can be checked that the combining can be done in constant time using a linear number of processors.

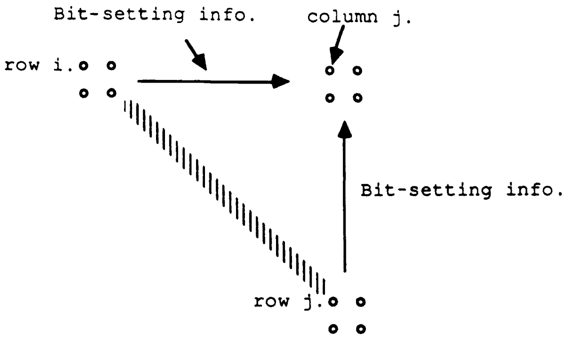

FIG. 1.

During the combining process, variables x_i and $x_{i\#0}$ are combined into a new variable $x^{(1)}_{\lfloor i/2 \rfloor}$, and functions $f_{i,j}$, $f_{i\#0,j}$, $f_{i,j\#0}$, and $f_{i\#0,j\#0}$ are combined into a new function $f^{(1)}_{\lfloor i/2 \rfloor, \lfloor j/2 \rfloor}$. After combining, a new function $B^{(1)}$ is formed which has the same form as B but has only $n/2$ variables. As we stated above, $E[B^{(1)}] \geq E[B]$.

What we have explained above is the first step of the algorithm in [HI]. This step takes constant time using a linear number of processors. After k steps, the random variables at levels 0 to $k-1$ in the random-variable tree are fixed, the n random variables $\{x_0, x_1, \ldots, x_{n-1}\}$ are reduced to $n/2^k$ random variables $\{x^{(k)}_0, x^{(k)}_1, \ldots, x^{(k)}_{n/2^k-1}\}$, and functions $f_{i,j}, i, j \in \{0, 1, \ldots, n-1\}$, have been combined into $f^{(k)}_{i,j}, i, j \in \{0, 1, \ldots, n/2^k - 1\}$.

After $\log n$ steps, $B^{(\log n)} = f^{(\log n)}_{0,0}(x^{(\log n)}_0, x^{(\log n)}_0)$. The bit at the root of the random-variable tree is now set to 0 if $f^{(\log n)}_{0,0}(0, 0) \geq f^{(\log n)}_{0,0}(1, 1)$, and 1 otherwise. Thus Han and Igarashi's algorithm [HI] solves the BPC problem in $O(\log n)$ time with a linear number of processors.

Let $n = 2^k$ and A be an $n \times n$ array. Elements $A[i, j]$, $A[i, j\#0]$, $A[i\#0, j]$, and $A[i\#0, j\#0]$ form a *gang*, which is denoted by $g_A[\lfloor i/2 \rfloor, \lfloor j/2 \rfloor]$. All gangs in A form array g_A.

When visualized on a two-dimensional array A (as shown in Fig. 1), a stage of Han and Igarashi's algorithm can be interpreted as follows. Let function $f_{i,j}$ be stored at $A[i, j]$. Setting the random variables at level 0 of the random-variable tree is done by examining the PROFIT/COST functions in the diagonal gang of A. Function $f_{i,j}$ then gets the bit-setting information from $g_A[\lfloor i/2 \rfloor, \lfloor i/2 \rfloor]$ and $g_A[\lfloor j/2 \rfloor, \lfloor j/2 \rfloor]$ to determine how it is to be combined with other functions in $g_A[\lfloor i/2 \rfloor, \lfloor j/2 \rfloor]$.

A *derandomization tree D* can be built which reflects the way the BPC functions are combined. D is of the following form. The input BPC functions are stored at the leaves, $f_{i,j}$ is stored in $A_0[i, j]$. A node $A_l[i, j]$ at level $l > 0$ is defined if there exist input functions in the range $A_0[u, v]$, $i * 2^l \leq u < (i+1) * 2^l$, $j * 2^l \leq v < (j+1) * 2^l$. A derandomization tree is shown in Fig. 2.

Tree D can be constructed [H], [HI] by first sorting the input into the file-major indexing and then building the tree bottom-up. The derandomization tree helps to reduce the space requirement for the BPC problem. Han and Igarashi's algorithm [HI] has time complexity $O(\log n)$ using a linear number of processors.

The algorithm given by Han and Igarashi [HI] is a CREW algorithm. Recently, Han [H] has given an EREW algorithm for the BPC problem with time complexity $O(\log n)$ using a linear number of processors.

We now discuss some variations of the above algorithm to be used in §§5 and 6.

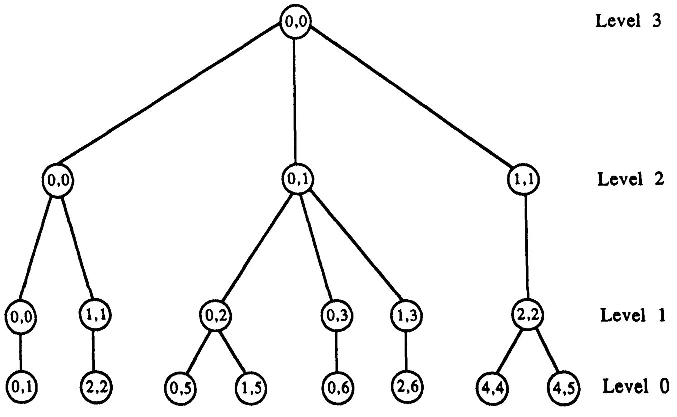

FIG. 2. *A derandomization tree. Pairs in the circles and the subscripts of PROFIT/COST problems.*

In some applications, the BPC functions cannot be combined in order to obtain an efficient algorithm. If the functions are not combined, then there could be several BPC functions $f_1(x_{i_1}, x_{j_1})$, $f_2(x_{i_2}, x_{j_2}), \ldots, f_l(x_{i_k}, x_{j_k})$ associated with an interior node r in the random-variable tree, where x_{i_t}, x_{j_t} are leaves in the subtree rooted at r. If r is not the root of the whole random-variable tree, then one of x_{i_t}, x_{j_t} is in the left subtree of r and the other in the right subtree of r, $1 \leq t \leq k$.

Let x_i be a leaf of a random-variable subtree T. Let the random variables on the path from x_i to the root r of T be set to $a_0, a_1, \ldots, a_l$. We define $\Psi(x_i, r) = \sum_{j=0}^{l}(a_j \cdot i_j) \bmod 2$. This function resembles the Ψ function defined by Luby [L2], [L3].

In fixing r, we tentatively set r to 0 and 1, respectively, and evaluate $f_t(\Psi(x_{i_t}, r)$, $\Psi(x_{j_t}, r)) + f_t(\Psi(x_{i_t}, r) \oplus 1, \Psi(x_{j_t}, r) \oplus 1)$, $1 \leq t \leq k$, where $\oplus$ is the exclusive-or function. We then get the sum of these functions and compare the sum for $r = 0$ with the sum for $r = 1$ to decide whether r should be set to 0 or 1. It takes $O(\log n)$ time to get the sum because there are at most $O(n^2)$ functions.

We note that $\Psi(x_i, r)$ can be evaluated progressively as the derandomization process proceeds, i.e., $\Psi(x_i, r) = (\Psi(x_i, r') + tr) \bmod 2$, where r is the parent of r' and t is the bit of i corresponding to r.

Thus if the functions are not combined in the derandomization process, a BPC problem requires $O(\log^2 n)$ time to solve.

In our applications we also use a combination of Luby's technique [L2] and Han and Igarashi's technique [H], [HI] for solving a BPC problem. The random-variable tree used in Luby's algorithm degenerates to a chain of length $\log n + 1$ plus n leaves. Therefore there are $\log n + 1$ random variables $r_0, r_1, \ldots, r_{\log n}$ associated with the interior nodes in the tree. x_i is chosen randomly by the formula $x_i = (\sum_{j=0}^{\log n - 1} i_j \cdot r_j + r_{\log n}) \bmod 2$. It can be shown [L2] that x_i's are pairwise independent random variables. In Luby's algorithm, the random variables in the random-variable tree are also fixed one level at a time. His algorithm takes $O(\log n)$ time to fix one level resulting in time complexity $O(\log^2 n)$. We stress that the random-variable tree used in Luby's algorithm has only $\log n + 1$ random variables. Thus the sample space contains only $2n$ sample points, while the sample space used in Han and Igarashi's algorithm [H], [HI] has 2^n sample points.

Combining Luby's technique and Han and Igarashi's technique [H], [HI], we could solve a BPC problem by using a random-variable tree T as shown in Fig. 3(c). T has $S = \lceil(\log n + 1)/a\rceil$ blocks, where a is a parameter. Block s contains levels as to $a(s+1) - 1$ of T. Block 0 has $C_0 = \lceil n/2^a \rceil$ chains. Block s has $C_s = \lceil C_{s-1}/2^a \rceil$ chains. Each chain

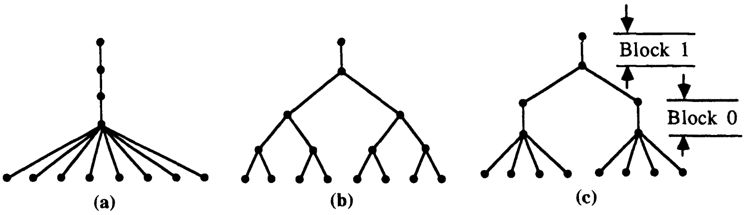

FIG. 3. (a) *Luby's tree.* (b) *Han and Igarashi's tree.* (c) *A tree of combination.*

in block s has length a running from level as to level $a(s+1)-1$. A node at level as in a chain (except the one in the last chain) has 2^a children at level $as-1$. Block $S-1$ has only one chain of length $\log n+1-a(S-1)$. There is a random bit r at each interior node of T and random variable x_i is associated with the ith leaf of T. x_i is chosen randomly as $x_i(\vec{r}) = (\sum_{j=0}^{\log n-1} i_j \cdot r_{i_j} + r_{i_{\log n}}) \bmod 2$, where $r_{i_0}, r_{i_1}, \ldots, r_{i_{\log n}}$ are the random variables on the path from leaf i to the root of T. It is straightforward to show that the x_i's are uniformly distributed pairwise independent random variables.

Different random variable trees are shown in Fig. 3.

3. A scheme for the GPC problem. In this section, we present a scheme to speed up the derandomization process for the GPC problem.

In [L2] and [L3], Luby presented the following derandomization scheme for solving the GPC problem.

Let $\vec{y} = \langle y_i \in \{0,1\}^p : i = 0, 1, \ldots, n-1\rangle$. Let $\vec{x_u}$, $p \le u < q$, be totally independent random bit strings, each of length n. Let $\vec{z}$ be a vector of n bits. We write the BENEFIT function $B(x_0, x_1, \ldots, x_{n-1})$, where each x_i is a variable containing q bits, as $B(\vec{x_{q-1}} \cdots \vec{x_{p+1}}\vec{x_p}\vec{y})$, where $\vec{y}$ contains the least significant p bits of all variables and $\vec{x_i}$ contains the ith bits of all variables. Define $TB(\vec{y}) = E[B(\vec{x_{q-1}} \cdots \vec{x_{p+1}}\vec{x_p}\vec{y})]$.Then $E[TB(\vec{x_p}\vec{y})] = E[E[B(\vec{x_{q-1}} \cdots \vec{x_{p+1}}\vec{z}\vec{y})| \vec{z} = \vec{x_p}]] = E[B(\vec{x_{q-1}} \cdots \vec{x_p}\vec{y})] = TB(\vec{y})$. That is, $TB(\vec{y})$ can also be obtained by first computing $TB(\vec{x_p}\vec{y})$, and $TB(\vec{y}) = E[TB(\vec{x_p}\vec{y})]$ $= \sum_{\vec{z}} TB(\vec{z}\vec{y})Pr(\vec{x_p} = \vec{z} \mid \vec{x_{p-1}} \cdots \vec{x_0} = \vec{y})$. Thus there exists a $\vec{z}$ such that $TB(\vec{z}\vec{y}) \ge TB(\vec{y})$. After $TB(\vec{x_p}\vec{y})$ are evaluated for all values of $\vec{x_p}$, the problem of finding such a $\vec{z}$ is a BPC problem. Because in the GPC problem function B is the sum of GPC functions, each depending on at most two variables, pairwise independent random variables can be used for bits in each $\vec{x_u}$, $p+1 \le u < q$. Luby's algorithm for the GPC problem then uses his algorithm for the BPC problem to find a $\vec{z}$ satisfying $TB(\vec{z}\vec{y}) \ge E[TB(\vec{x_p}\vec{y})] = TB(\vec{y})$, thus fixing the random bits in $\vec{x_p}$.

Luby's solution [L2], [L3] to the GPC problem can be interpreted as follows: it solves the GPC problem by solving q BPC problems, one for each $\vec{x_u}$. These BPC problems are solved sequentially. After the BPC problems for $\vec{x_u}$, $0 \le u < v$, are solved, BPC functions $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ are evaluated based on the setting of bits x_{i_u}, x_{j_u}, $0 \le u < v$. Suppose x_{i_u} is set to y_{i_u} and x_{j_u} is set to y_{j_u}, $0 \le u < v$. $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ is evaluated as $f_{i_v,j_v}(y_{i_v}, y_{j_v}) = E[f_{i,j}(x_i, x_j)|x_{i_0} = y_{i_0}, x_{j_0} = y_{j_0}, \ldots, x_{i_{v-1}} = y_{i_{v-1}}, x_{j_{v-1}} = y_{j_{v-1}}, x_{i_v} = y_{i_v}, x_{j_v} = y_{j_v}]$, $y_{i_v}, y_{j_v} = 0, 1$. After BPC functions $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ have been obtained and stored in a table, the BPC algorithm is invoked to fix $\vec{x_v}$.

If we are to solve several BPC problems in a GPC problem simultaneously, we must have BPC functions $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ before the setting of the bits x_{i_u} and x_{j_u}, $0 \le u < v$. Since there are a total of $2v$ bits, we could try out all possible 4^v bit patterns. For each bit pattern we have a distinct function $f_{i_v,j_v}(x_{i_v}, x_{j_v})$. If $q = O(\log n)$, we need only a polynomial number of processors to work on all these functions.

If we use Luby's random-variable tree for each BPC problem, then there are $\log n + 1$ random variables and $2n$ sample points for each BPC problem. Thus if we try to solve for $\vec{x_v}$ before $\vec{x_u}$, $0 \leq u < v$, are solved, we have to take care of $(2n)^v$ possible situations. Apparently more than a polynomial number of processors are needed if v is not a constant. So how about using Han and Igarashi's random-variable tree [H], [HI]? There are now n random variables and 2^n sample points for each BPC problem. The situation seems to be even more difficult to deal with. However, by close examination, we find out that instead we could reduce the number of processors by using Han and Igarashi's random-variable tree.

We now present a scheme which allows several $\vec{x_u}$'s to be fixed in one pass using Han and Igarashi's random-variable tree for each BPC problem.

First we give a sketch of our approach. The incompleteness of the description in this paragraph will be elaborated on in the rest of this section. Let P be the GPC problem we are to solve. P can be decomposed into q BPC problems to be solved sequentially. Let P_u be the uth BPC problem. Imagine that we are to solve P_u, $0 \leq u < k$, in one pass, i.e., we are to fix $\vec{x_0}, \vec{x_1}, \ldots, \vec{x_{k-1}}$ in one pass, with the help of enough processors. For the moment, we can have a random-variable tree T_u and a derandomization tree D_u for P_u, $0 \leq u < k$. In Step j, our algorithm will work on fixing the bits at level $j - u$ in T_u, $0 \leq u \leq \min\{k - 1, j\}$. The computation in each tree D_u proceeds as we have described in the last section. Note that BPC functions $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ depend on the setting of bits x_{i_u}, x_{j_u}, $0 \leq u < v$. The main difficulty with our scheme is that when we are working on fixing $\vec{x_v}$, the $\vec{x_u}$, $0 \leq u < v$, have not been fixed yet. The only information we can use when we are fixing the random variables at level l of T_u is that random variables at levels 0 to $l + c - 1$ are fixed in T_{u-c}, $0 \leq c \leq u$. This information can be accumulated in the pipeline of our algorithm and transmitted on the *bit-pipeline trees*. Fortunately, this information is sufficient for us to speed up the derandomization process without resorting to too many processors. For the sake of a clear exposition, we first describe a CREW derandomization algorithm. We then show how to convert the CREW algorithm to an EREW algorithm.

Suppose we have $c\sum_{i=0}^{k}(m * 4^i)$ processors available, where c is a constant. Assign $cm * 4^u$ processors to work on P_u for $\vec{x_u}$. We shall work on $\vec{x_u}$, $0 \leq u \leq k$, simultaneously in a pipeline. The random-variable tree for P_u (except that for P_0) is not constructed before the derandomization process begins; rather, it is constructed from a forest as the derandomization process proceeds. A forest containing 2^u random-variable trees corresponds to each variable x_{i_u} in P_u because there are 2^u bit patterns for x_{i_j}, $0 \leq j < u$. We use F_u to denote the random-variable forest for P_u. We fix the random bits on the lth level of F_v (for $\vec{x_v}$) under the condition that random bits from level 0 to level $l+c-1$, $0 \leq c \leq v$, in F_{v-c} have already been fixed. We perform this fixing in constant time. The 2^u random-variable trees corresponding to each random variable x_{i_u} are built bottom-up as the derandomization process proceeds. Immediately before the step in which we fix the random bits on the lth level of F_u, the 2^u random-variable trees corresponding to x_{i_u} are constructed up to the lth level. The details of the algorithm for constructing the random-variable trees will be given later in this section.

Consider a GPC function $f_{i,j}(x_i, x_j)$ under the condition stated in the last paragraph. When we start working on $\vec{x_v}$, we should have the BPC functions $f_{i_v,j_v}(x_{i_v}, x_{j_v})$ evaluated and the function values stored in a table. However, because $\vec{x_u}$, $0 \leq u < v$, have not been fixed yet, we have to try out all possible cases. There are a total of 4^v patterns for bits x_{i_u}, x_{j_u}, $0 \leq u < v$. We use 4^v BPC functions for each pair (i, j). We use

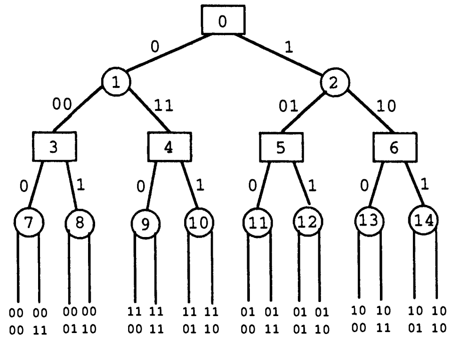

FIG. 4.

$f_{i_v,j_v}(x_{i_v}, x_{j_v})(y_{v-1}y_{v-2}\cdots y_0, z_{v-1}z_{v-2}\cdots z_0)$ to denote the function $f_{i_v,j_v}(x_{i_v}, x_{j_v})$, obtained under the condition that $(x_{i_{v-1}}x_{i_{v-2}}\cdots x_{i_0}, x_{j_{v-1}}x_{j_{v-2}}\cdots x_{j_0})$ is set to $(y_{v-1}y_{v-2}\cdots y_0, z_{v-1}z_{v-2}\cdots z_0)$.

For each pair $(w, w\#0)$ at each level l (this is the level in the random-variable forest), $0 \leq l \leq \log n$, a *bit-pipeline tree* is built (Fig. 4) which is a complete binary tree of height $2k$. Nodes at even depth from the root in a bit-pipeline tree are selectors, and nodes at odd depth are fanout gates. A signal *true* is initially input into the root of the tree and propagates downward toward the leaves. The selectors at depth $2d$ select the output by the decision of the random bits which are the parents of random variables x_{w_d}, $x_{w\#0_d}$ in F_d. One random variable corresponds to each selector. Let random variable r correspond to the selector s. If r is set to 0 then s selects the left child and propagates the true signal to its left child, while no signal is sent to its right child. If r is set to 1 then the true signal will be sent to the right child and no signal will be sent to the left child. If s does not receive any signal from its parent then no signal will be propagated to s's children no matter how r is set. The gates at odd depth in the bit pipeline tree are fanout gates, and pointers from them to their children are labeled with bits which are conditionally set. Refer to Fig. 4, which shows a bit-pipeline tree of height 4. If the selector at the root (node 0) selects 0 (which means that the random variable which is the parent of x_{w_0} and $x_{w\#0_0}$ in the random-variable forest is set to 0), then $x_{w_0} = x_{w\#0_0}$, and therefore the two random variables can only assume the patterns 00 or 11 which are labeled on the pointers from node 1. If, on the other hand, node 0 selects 1 then $x_{w_0} = 1 - x_{w\#0_0}$, the two random variables can only assume the patterns 01 or 10 which are labeled on the pointers of node 2. Let us take node 4 as another example. If node 4 selects 0 then $x_{w_1} = x_{w\#0_1}$; thus the pointers of node 9 are labeled with $\begin{smallmatrix}1&1\\0&0\end{smallmatrix}$ and $\begin{smallmatrix}1&1\\1&1\end{smallmatrix}$. This indicates that the bits for $(w_1w_0, w\#0_1w\#0_0)$ can have two patterns, $(01, 01)$ or $(11, 11)$.

The bit-pipeline tree built for level $\log n$ has height k. No fanout gates will be used. This is a special and simpler case compared to the bit-pipeline trees for other levels. In the following discussion we only consider bit pipeline tree for levels other than $\log n$.

LEMMA 1. *In a bit-pipeline tree there are exactly 2^d nodes at depth $2d$ which will receive the true signal from the root.*

Proof. Each selector selects only one path. Each fanout gate sends the true signal to both children. Therefore, exactly 2^d nodes at depth $2d$ will receive the true signal from the root. □

For each node i at even depth, we shall also say that it has the *conditional-bit pattern* (or *conditional bits*, *bit pattern*), which is the pattern labeled on the pointer from $p(i)$. The root of the bit-pipeline tree has an empty string as its bit pattern.

Define Step 0 as the step when the true signal is input to node 0. The function of a bit-pipeline tree can be described as follows.

Step t: Selectors at depth $2t$ which have received true signals select 0 or 1 for $(w_t, w\#0_t)$. Pass the true signal and the bit-setting information to nodes at depth $2t+2$.

Now consider the selectors at depth $2d$. By Lemma 1, a set of 2^d selectors at depth $2d$ receive the true signal. We call this set the *surviving set* $S^l_{w,d}$. We also denote by $S^l_{w,d}$ the set of bit patterns the 2^d surviving selectors have, where w in the subscript is for $(w, w\#0)$ and l is the level for which the pipeline tree is built. Let selector $s \in S^l_{w,d}$ have bit pattern $(y_{d-1}y_{d-2}\cdots y_0, z_{d-1}z_{d-2}\cdots z_0)$. s compares

$$\begin{aligned} & f^{(l)}_{w_d,w\#0_d}(0,0)(y_{d-1}y_{d-2}\cdots y_0, z_{d-1}z_{d-2}\cdots z_0) \\ & \quad + f^{(l)}_{w_d,w\#0_d}(1,1)(y_{d-1}y_{d-2}\cdots y_0, z_{d-1}z_{d-2}\cdots z_0) \\ & \quad + f^{(l)}_{w\#0_d,w_d}(0,0)(z_{d-1}z_{d-2}\cdots z_0, y_{d-1}y_{d-2}\cdots y_0) \\ & \quad + f^{(l)}_{w\#0_d,w_d}(1,1)(z_{d-1}z_{d-2}\cdots z_0, y_{d-1}y_{d-2}\cdots y_0) \end{aligned}$$

with

$$\begin{aligned} & f^{(l)}_{w_d,w\#0_d}(0,1)(y_{d-1}y_{d-2}\cdots y_0, z_{d-1}z_{d-2}\cdots z_0) \\ & \quad + f^{(l)}_{w_d,w\#0_d}(1,0)(y_{d-1}y_{d-2}\cdots y_0, z_{d-1}z_{d-2}\cdots z_0) \\ & \quad + f^{(l)}_{w\#0_d,w_d}(0,1)(z_{d-1}z_{d-2}\cdots z_0, y_{d-1}y_{d-2}\cdots y_0) \\ & \quad + f^{(l)}_{w\#0_d,w_d}(1,0)(z_{d-1}z_{d-2}\cdots z_0, y_{d-1}y_{d-2}\cdots y_0) \end{aligned}$$

and selects 0 if the former is no less than the latter and 1 otherwise. Note that the selectors which do not receive the true signal (there are $4^d - 2^d$ of them) have bit patterns which are eliminated.

Let $LS^l_{w,d} = \{\alpha | (\alpha, \beta) \in S^l_{w,d}\}$ and $RS^l_{w,d} = \{\beta | (\alpha, \beta) \in S^l_{w,d}\}$.

LEMMA 2. $LS^l_{w,d} = RS^l_{w,d} = \{0, 1\}^d$.

Proof. Lemma 2 is proved by induction. Assume that the lemma is true for bit-pipeline trees of height $2d-2$. A bit-pipeline tree of height $2d$ can be constructed by using a new selector as the root, two new fanout gates at depth 1, and four copies of the bit-pipeline tree of height $2d-2$ at depth 2. If the root selects 0, then patterns 00 and 11 are concatenated with patterns in $S^l_{w,d-1}$; therefore, both $LS^l_{w,d-1}$ and $RS^l_{w,d-1}$ are concatenated with $\{0, 1\}$. The situation when the root selects 1 is similar. □

Now let us consider how functions $f^{(l)}_{i_d,j_d}(x_{i_d}, x_{j_d})(\alpha, \beta)$ are combined. Take the difficult case where both i and j are odd. By Lemma 2, there is only one pattern $p_1 = (\alpha', \alpha) \in S^l_{i\#0,d}$ and there is only one pattern $p_2 = (\beta', \beta) \in S^l_{j\#0,d}$. If the selector having bit pattern p_1 selects 0, then $x_{i_d} = x_{i\#0_d}$ else $x_{i_d} = 1 - x_{i\#0_d}$. If the selector having bit pattern p_2 selects 0, then $x_{j_d} = x_{j\#0_d}$ else $x_{j_d} = 1 - x_{j\#0_d}$. In any case, the conditional-bit pattern is changed to (α', β'), i.e., $f^{(l)}_{i_d,j_d}(x_{i_d}, x_{j_d})(\alpha, \beta)$ will be combined into $f^{(l+1)}_{\lfloor i/2\rfloor_d,\lfloor j/2\rfloor_d}(x_{\lfloor i/2\rfloor_d}, x_{\lfloor j/2\rfloor_d})(\alpha', \beta')$. Note that $x_{\lfloor i/2\rfloor_d}$ and $x_{\lfloor j/2\rfloor_d}$ are new random variables, and here we are not using a superscript to denote this fact. The following lemma ensures that at most four functions will be combined into $f^{(l+1)}_{\lfloor i/2\rfloor_d,\lfloor j/2\rfloor_d}(x_{\lfloor i/2\rfloor_d}, x_{\lfloor j/2\rfloor_d})(\alpha', \beta')$.

Let $S = \{(\alpha', \beta') | (\alpha', \alpha) \in S^l_{i,d}, (\beta', \beta) \in S^l_{j,d}, \alpha, \beta \in \{0, 1\}^d\}$.

LEMMA 3. $|S| = 4^d$.

Proof. The definition of S can be viewed as a linear transformation. Represent $x \in \{0, 1\}^d$ by a vector of 2^d bits with the xth bit set to 1 and the rest of the bits set to 0. The transformation $\alpha \mapsto \alpha'$ can be represented by a permutation matrix of order 2^d. The transformation $(\alpha, \beta) \mapsto (\alpha', \beta')$ can be represented by a permutation matrix of order 2^{d+1}. □

Lemma 3 tells us that the functions to be combined are permuted; therefore, no more than four functions will be combined under any conditional-bit pattern.

We call this scheme of combining *combining functions with respect to the surviving set.*

We have completed a preliminary description of our derandomization scheme for the GPC problem. The algorithm for processors working on $\vec{x}_d$, $0 \leq d < k$, can be summarized as follows.

Step t $(0 \leq t < d)$: Wait for the pipeline to be filled.

Step $d + t$ $(0 \leq t < \log n)$: Fix random variables at level t for all conditional-bit patterns in the surviving set. (*There are 2^d such patterns in the surviving set.*) Combine functions with respect to the surviving set. (*At the same time the bit-setting information is transmitted to the nodes at depth $2d + 2$ on the bit-pipeline tree.*)

Step $d + \log n$: Fix the only remaining random variable at level $\log n$ for the only bit pattern in the surviving set. Output the good point for $\vec{x}_d$. (*At the same time, the bit-setting information is transmitted to the node at depth $d + 1$ on the bit-pipeline tree.*)

THEOREM 1. *The GPC problem can be solved on the CREW PRAM in time $O((q/k + 1)(\log n + k + \tau))$ with $O(4^k m)$ processors, where τ is the time for a single processor to evaluate a BPC function $f_{i_d, j_d}(x_{i_d}, x_{j_d})(\alpha, \beta)$.*

Proof. The correctness of the scheme comes from the fact that as random bits are fixed, a smaller space with higher expectation is obtained, and thus when all random bits are fixed, a good point is found. To solve the uth BPC problem is to evaluate $P_u(\vec{z}) = E[B(\vec{x}_{q-1} \cdots \vec{x}_{u+1} \vec{z} \vec{y})]$, $\vec{z} \in \{0, 1\}^n$, where $\vec{y} = < y_i \in \{0, 1\}^u : i = 0, 1, \ldots, n-1 >$ is fixed. We then view $\vec{z}$ as a random variable uniformly distributed on $\{0, 1\}^n$ and find $\vec{z}'$ such that $P_u(\vec{z}') \geq E[P_u(\vec{z})]$. If we have a huge number of processors, we could solve all BPC problems in parallel by solving each P_u with all possible $\vec{y}$'s. Such an algorithm is apparently correct. In our scheme, $P_u(\vec{z})$ is evaluated by evaluating $E[f_{i,j}(\alpha\beta, \alpha'\beta')]$, $\alpha, \alpha' \in \{0, 1\}$, $\beta, \beta' \in \{0, 1\}^u$. This is guaranteed to be correct by linearity of expectation. We use a pipeline to solve the P_u's. Thus our algorithm is still correct while the number of processors needed is drastically reduced.

With $O(4^k m)$ processors, k $\vec{x}_u$'s are fixed in one pass. Each pass takes $O(\log n + k + \tau)$ time, τ for evaluating BPC functions (i.e., setting up the function tables for the BPC problems) and $O(\log n + k)$ time for fixing all random bits on the random-variable trees. The time complexity for solving the GPC problem is $O((q/k + 1)(\log n + k + \tau))$. □

We have not yet discussed explicitly the way the random-variable trees are constructed. The construction is implied in the surviving set we computed. We now give the algorithm for constructing the random variable trees. This algorithm will help better understand the whole scheme.

The ith node under conditional-bit pattern j at the lth level of the random-variable trees for P_u is stored in $T_u^{(l)}[i][j]$. The leaves are stored in $T_u^{(-1)}$. Initially, bit-pipeline trees for level -1 are built such that $T_u^{(-1)}[i][j]$ has two children $T_{u+1}^{(-1)}[i][j0]$, $T_{u+1}^{(-1)}[i][j1]$, where $j0$ and $j1$ are the concatenations of j with 0 and 1, respectively. Note that the bit-pipeline tree constructed here is different from the one we built before, but in principle they are the same tree and perform the same function in our scheme. The algorithm for constructing the random-variable trees for P_u is below.

```
PROCEDURE RV-TREE
  begin
    Step $t$ $(0 \leq t < u)$: Wait for the pipeline to be filled.

    Step $u + t$ $(0 \leq t < \log n)$:
      (*In this step, we will build $T_u^{(t)}[i][j]$, $0 \leq i < n/2^{t+1}$, $0 \leq j < 2^u$. At the
      beginning of this step, $T_{u-1}^{(t)}[i][j]$ has already been constructed. Let $T_{u-1}^{(t-1)}[i0][j]$
      and $T_{u-1}^{(t-1)}[i1][j']$ be the two children of $T_{u-1}^{(t)}[i][j]$ in the random-variable tree.
      $T_u^{(t-1)}[i0][j0]$ and $T_u^{(t-1)}[i0][j1]$ are the children of $T_{u-1}^{(t-1)}[i0][j]$, and $T_u^{(t-1)}[i1][j'0]$
      and $T_u^{(t-1)}[i1][j'1]$ are the children of $T_{u-1}^{(t-1)}[i1][j']$ in the bit-pipeline tree for level
      $t-1$. The setting of the random variable $r$ for the pair $(i0, i1)$ at level $t$ for $P_{u-1}$,
      i.e., the random variable in $T_{u-1}^{(t)}[i][j]$, is known.*)

      make $T_u^{(t-1)}[i0][j0]$ and $T_u^{(t-1)}[i1][j'r]$ the children of $T_u^{(t)}[i][j0]$ in the random-
      variable forest for $P_u$; (*$jr$ is the concatenation of $j$ and $r$.*)

      make $T_u^{(t-1)}[i0][j1]$ and $T_u^{(t-1)}[i1][j'\bar{r}]$ the children of $T_u^{(t)}[i][j1]$ in the random-
      variable forest for $P_u$; (*$\bar{r}$ is the complement of $r$.*)

      make $T_u^{(t)}[i][j0]$ and $T_u^{(t)}[i][j1]$ the children of $T_{u-1}^{(t)}[i][j]$ in the bit-pipeline tree
      for level $t$;

      fix the random variables in $T_u^{(t)}[i][j0]$ and $T_u^{(t)}[i][j1]$;

    Step $u + \log n$:
      (*At the beginning of this step, the random-variable trees have been built for $T_i$,
      $0 \leq i < u$. Let $T_{u-1}^{(\log n)}[0][j]$ be the root of $T_{u-1}$. The random variable $r$ in
      $T_{u-1}^{(\log n)}[0][j]$ has been fixed. In this step, we will choose one of the two children of
      $T_{u-1}^{(\log n)}[0][j]$ in the bit-pipeline tree for level $\log n$ as the root of $T_u$.*)

      make $T_u^{(\log n-1)}[0][jr]$ the child of $T_u^{(\log n)}[0][jr]$ in the random-variable tree;

      make $T_u^{(\log n)}[0][jr]$ the child of $T_{u-1}^{(\log n)}[0][j]$ in the bit-pipeline tree for level $\log n$;

      fix the random variable in $T_u^{(\log n)}[0][jr]$;

      output $T_u^{(\log n)}[0][jr]$ as the root of $T_u$;
  end
```

Procedure RV-Tree uses the pipelining technique as well as a dynamic-programming technique. These are some of the essential elements of our scheme.

An example of the execution of Procedure RV-Tree is shown in Fig. 5.

We now show how to remove the concurrent-read feature from the scheme. The difficulty here is in the step of combining functions with respect to the surviving set. The size of the surviving set $S_{u,k}^l$ is 2^k while there are 4^k conditional-bit patterns. There are 4^k functions $f_{u_k,v_k}^{(l)}(x_{u_k}, x_{v_k})$, one for each bit pattern (α, β). All 4^k functions will consult the surviving set

FIG. 5. (*Cont.*)

in order for them to be combined into new functions. The problem is how to do it in constant time without resorting to concurrent read.

We show how to let $f^{(l)}_{u_k,u\#0_k}(x_{u_k}, x_{u\#0_k})(\alpha, \beta)$ to acquire the bit pattern α' which satisfies $(\alpha', \beta) \in S^l_{u,k}$. Function $f^{(l)}_{u_k,v_k}(x_{u_k}, x_{v_k})(\alpha, \beta)$ can then obtain the bit pattern α' from $f^{(l)}_{u_k,u\#0_k}(x_{u_k}, x_{u\#0_k})(\alpha, \beta)$ by the pipeline scheme described in [H].

Suppose we are to solve P_u, $0 \leq u \leq k$, in one pass. We solve 4^k copies of P_{k-1}; one copy corresponds to one conditional-bit pattern in P_k. $f^{(l)}_{u_k,v_k}(x_{u_k}, x_{v_k})(\alpha, \beta)$ in P_k can obtain α' by following the computation in the copy of P_{k-1} which corresponds to (α, β). This can be done without concurrent read. Now for each of the 4^k copies of P_{k-1}, we solved 4^{k-1} copies of P_{k-2}; one copy corresponds to one conditional-bit pattern in P_{k-1}, and so on. Thus to remove concurrent read we need $c^{k^2}(m+n)$ processors for solving P_u, $0 \leq u \leq k$, in one pass, where c is a suitable constant. Note also that it takes $O(k^2)$ time to make needed copies.

THEOREM 2. *The GPC problem can be solved on the EREW PRAM in time $O((q/\sqrt{k} + 1)(\log n + k + \tau))$ with $O(c^k m)$ processors, where c is a suitable constant and τ is the time for a single processor to evaluate a BPC function $f_{u_d,v_d}(x_{u_d}, x_{v_d})(\alpha, \beta)$.*

4. Δ + 1 vertex coloring.

We apply our scheme to Luby's formulation of the $\Delta + 1$ vertex-coloring problem [L2], [L3]. First we adapt his formulation and then apply our fast derandomization scheme to obtain a faster algorithm. Luby showed [L2], [L3] that after solving a GPC problem a constant fraction of the vertices can be deleted. The main change now is to show that after solving a GPC problem a constant fraction of the edges can be deleted. We follow the notations and definitions as given by Luby [L2], [L3].

Let $G = (V, E)$ be the graph we are to color. Let $adj(i)$ be the set of vertices which are adjacent to vertex i, and let $d(i)$ be the degree of vertex i. Let $avail_i$ be the set of colors which can be used to color vertex i, and let $Navail_i = |avail_i|$. Let k_i be such that $2^{k_i-1} < 4Navail_i \leq 2^{k_i}$ and let $Nlist_i = 2^{k_i}$. Let $list_i[0, \ldots, Nlist_i - 1]$ be an array such that the first $Navail_i$ entries in $list_i$ are the elements of $avail_i$ in sorted order and the remaining entries in $list_i$ have value Λ. Let $q = \max\{k_i | i \in V\}$. Let $\vec{x} = < x_i \in \{0, 1\}^q, i \in V >$. For $i \in V$, let $list_i(x_i)$ be the entry in $list_i$ indexed by the first k_i bits of x_i. Also define the following functions.

For all $i \in V$, let

$$Y_i(x_i) = \begin{cases} 1 \text{ if } list_i(x_i) \in avail_i, \\ 0 \text{ if } list_i(x_i) = \Lambda. \end{cases}$$

For all $(i, j) \in E$, let

$$Y_{i,j}(x_i, x_j) = \begin{cases} -1 \text{ if } list_i(x_i) = list_j(x_j) \neq \Lambda, \\ 0 \text{ otherwise.} \end{cases}$$

The BENEFIT function B is defined as

$$B(\vec{x}) = \sum_{i \in V} \frac{d(i)}{2} \left(Y_i(x_i) + \sum_{j \in adj(i)} Y_{i,j}(x_i, x_j) \right).$$

Function B sets a lower bound on the number of edges deleted [L2], [L3] should the vertex i be tentatively assigned color $list_i(x_i)$. We will not repeat the definitions of the auxiliary functions TY_i and $TY_{i,j}(x_i, x_j)$, since their definitions can be found in [L2] and [L3]. The auxiliary function TB is now defined as

$$TB\,(\vec{x}) = \sum_{i \in V} \frac{d(i)}{2} \left(TY_i\,(x_i) + \sum_{j \in adj(i)} TY_{i,j}\,(x_i, x_j) \right).$$

Following Luby's proof [L2], [L3], we have $TY_i(\Lambda) \geq 1/8$, $TY_{i,j}(\Lambda, \Lambda) \geq -1/16$, and therefore we have the following lemma.

LEMMA 4. $TB\ (\overrightarrow{\Lambda}) \geq |E|/16$.

Thus by solving a GPC problem,[1] we are guaranteed to eliminate a constant fraction of the edges.

Let $c^k m$ be the number of processors needed to compute k BPC problems in a GPC problem in one pass. There will be $O(\log n)$ stages in the modified algorithm. Each stage contains a constant number of GPC problems and reduces the number of edges so that there will be no more than a $1/c$ fraction of the edges left. Therefore, during stage i there will be e edges in the remaining graph and $c^i e$ processors available. Because each stage has $O(\log n)$ BPC problems, the time complexity for stage i is $O(\log^2 n/i)$. Thus the time complexity of the whole algorithm becomes $O(\sum_{i=1}^{O(\log n)} \log^2 n/i) = O(\log^2 n \log\log n)$.

The number of processors used in the algorithm can be reduced to $O((m+n)/\log\log n)$. We examine the first $O(\log\log\log n)$ stages. In stage i, we can have $c^i/\log\log n$ processors for each edge under each conditional-bit pattern. Therefore, the tables for the BPC functions in stage i can be computed in time $O(\log^2 n \log\log n/c^i)$, and the overall time for table construction for the whole algorithm is $O(\log^2 n \log\log n)$. The calculation for the time for constructing the derandomization trees is similar and can be shown to be $O(\log^2 n \log\log n)$ with $O((m+n)/\log\log n)$ processors. In the first $O(\log\log\log n)$ stages, our GPC algorithm will be invoked with $k = 1$. The time complexity for these stages is

$$O\left(\sum_{i=0}^{O(\log\log\log n)} \frac{\log^2 n \log\log n}{c^i}\right) = O(\log^2 n \log\log n).$$

The remaining stages take $O(\log^2 n \log\log n)$ time by the analysis in the last paragraph.

THEOREM 3. *There is a CREW PRAM algorithm for the* $\Delta + 1$ *vertex-coloring problem with time complexity* $O(\log^2 n \log\log n)$ *using* $O((m+n)/\log\log n)$ *processors.*

We also have, the following theorem.

THEOREM 4. $O(mn^\epsilon)$ *processors are sufficient to solve the* $\Delta + 1$ *vertex-coloring problem in time* $O(\log^2 n)$ *on the CREW PRAM, where* $\epsilon > 0$ *is an arbitrary constant.*

Proof. This is because one GPC problem can now be solved in $O(\log n)$ time. □

5. Maximal independent set. Let $G = (V, E)$ be an undirected graph. For $W \subseteq V$, let $N(W) = \{i \in V \mid \exists\ j \in W, (i, j) \in E\}$. Known parallel algorithms [ABI], [KW], [GS1], [GS2], [L1], [L3] for computing a maximal independent set have the following form.

```
PROCEDURE GENERAL-INDEPENDENT
begin
      $I := \phi$;
      $V' := V$;
      while $V' \neq \phi$ do
         begin
            Find an independent set $I' \subseteq V'$;
            $I := I \cup I'$;
            $V' := V' - (I' \cup N(I'))$;
         end
end
```

[1] The problem formulated [L2], [L3] resembles a GPC problem. It is not a GPC problem in the strict sense. For our purpose, we may view it as a GPC problem because our GPC algorithm applies.

Luby's work [L3] formulated each iteration of the while loop in General-Independent as a GPC problem. We now adapt Luby's formulation [L1], [L3].

Let k_i be such that $2^{k_i-1} < 4d(i) \leq 2^{k_i}$. Let $q = \max\{k_i | i \in V\}$. Let $\vec{x} =< x_i \in \{0,1\}^q, i \in V\}$. The length $|x_i|$ of x_i is defined to be k_i. Define[2]

$$Y_i(x_i) \quad = \begin{cases} 1 & \text{if } x_i(|x_i|-1)\cdots x_i(0) = 0^{|x_i|}, \\ 0 & \text{otherwise,} \end{cases}$$

$$Y_{i,j}(x_i, x_j) = -Y_i(x_i)Y_j(x_j),$$

$$B(\vec{x}) \quad = \sum_{i \in V} \frac{d(i)}{2}$$

$$\sum_{j \in adj(i)} \left(Y_j(x_j) + \sum_{k \in adj(j), d(k) \geq d(j)} Y_{j,k}(x_j, x_k) + \sum_{k \in adj(i)-\{j\}} Y_{j,k}(x_j, x_k) \right),$$

where $x_i(p)$ is the pth bit of x_i.

Function B sets a lower bound on the number of edges deleted from the graph [L1], [L3] should vertex i be tentatively labeled as an independent vertex if $x_i = (0 \cup 1)^{q-|x_i|}0^{|x_i|}$. The following lemma was proven in [L1, Thm. 1].

LEMMA 5 [L1]. *$E[B] \geq |E|/c$ for a constant $c > 0$.*

Function B can be written as

$$B(\vec{x}) = \sum_{j \in V} \left(\sum_{i \in adj(j)} \frac{d(i)}{2} \right) Y(x_j) + \sum_{(j,k) \in E, d(k) \geq d(j)} \left(\sum_{i \in adj(j)} \frac{d(i)}{2} \right) Y_{j,k}(x_j, x_k)$$

$$+ \sum_{i \in V} \frac{d(i)}{2} \sum_{j,k \in adj(i), j \neq k} Y_{j,k}(x_j, x_k)$$

$$= \sum_i f_i(x_i) + \sum_{(i,j)} f_{i,j}(x_i, x_j),$$

where

$$f_i(x_i) = \left(\sum_{j \in adj(i)} \frac{d(j)}{2} \right) Y(x_i)$$

and

$$f_{i,j}(x_i, x_j) = \delta(i,j) \left(\sum_{k \in adj(i)} \frac{d(k)}{2} \right) Y_{i,j}(x_i, x_j) + \left(\sum_{k \in V \text{ and } i,j \in adj(k)} \frac{d(k)}{2} \right) Y_{i,j}(x_i, x_j),$$

$$\delta(i,j) \quad = \begin{cases} 1 & \text{if } (i,j) \in E \text{ and } d(j) \geq d(i), \\ 0 & \text{otherwise.} \end{cases}$$

Thus each execution of a GPC procedure eliminates a constant fraction of the edges from the graph. It takes $O(M(n))$ (which is currently $O(n^{2.376})$ [CW]) processors to compute a

[2] In Luby's formulation [L3], $Y_i(x_i)$ is zero unless the first $|x_i|$ bits of x_i are 1's. In order to be consistent with the notations in our algorithm, we let $Y_i(x_i)$ be zero unless the first $|x_i|$ bits of x_i are 0's.

matrix multiplication in time $O(\log n)$ to arrive at the GPC functions f_i's and $f_{i,j}$'s because of the term $\sum_{i \in V} \frac{d(i)}{2} \sum_{j,k \in adj(i), j \neq k} Y_{j,k}(x_j, x_k)$ in function B. We organize our algorithm for the maximal independent set problem into $O(\log n)$ stages such that in stage i, the graph has no more than $|E|/c^i$ vertices and a constant number of GPC problems will be solved in stage i. By Theorem 1, we achieve time complexity $O(\log^2 n)$.

THEOREM 5. *There is a CREW PRAM algorithm for the maximal independent set problem with time complexity $O(\log^2 n)$ using $O(M(n))$ processors.*

Proof. The time and processor complexities for computing matrix multiplication dominate. □

We will give a second algorithm for the maximal independent set problem. We take advantage of the special properties of the GPC functions to reduce the number of processors to $O(m + n)$. We cannot use the derandomization scheme in §3 directly because it would involve a matrix multiplication, as we have seen in the design of our first maximal independent set algorithm. The structure of our second algorithm is complicated. We first give an overview of the algorithm.

5.1. Overview of the second algorithm. Because we can reduce the number of edges by a constant fraction after solving a GPC problem, a maximal independent set will be computed after $O(\log n)$ GPC problems are solved. Our algorithm has two stages, the initial stage and the speedup stage. The initial stage consists of the first $O(\log^{0.5} n)$ GPC problems. Each GPC problem is solved in $O(\log^2 n)$ time. The time complexity for the initial stage is thus $O(\log^{2.5} n)$. When the first stage finishes, the remaining graph has size $O((m + n)/2^{\sqrt{\log n}})$. There are $O(\log n)$ GPC problems in the speedup stage. A GPC problem of size s in the speedup stage is solved in time $O(\log^2 n/\sqrt{k})$ with $O(c^k s \log n)$ processors. Therefore the time complexity of the speedup stage is $O(\sum_{i=O(\sqrt{\log n})}^{O(\log n)} (\log^2 n/\sqrt{i})) = O(\log^{2.5} n)$. The initial stage is mainly to reduce the processor complexity while the speedup stage is mainly to reduce the time complexity.

We used matrix multiplication in our first algorithm because of the term $\sum_{i \in V} \frac{d(i)}{2} \cdot \sum_{j,k \in adj(i), j \neq k} Y_{j,k}(x_j, x_k)$ in function B. We shall call this term the vertex-cluster term. There is a cluster $C(v) = \{x_w | (v, w) \in E\}$ for each vertex v. Alternatively we may use $O(\sum_{v \in V} d^2(v))$ processors, $d^2(v)$ processors for cluster $C(v)$, to evaluate all GPC functions and to apply our derandomization scheme given in §3. However, to reduce the number of processors to $O(m + n)$ we have to use a modified version of our derandomization scheme in §3.

Consider the problem of fixing a random-variable r in the random-variable tree. We did this in constant time in §3 (Theorem 1). We now outline how r is fixed in the initial stage. We cannot do it in constant time because the GPC function $f(x, y)$, where x and y are the leaves in the subtree rooted at r, is in fact the sum of several functions scattered in the second term of function B and in several clusters. We will not combine BPC functions in the derandomization process. As we have explained in §2, setting r requires $O(\log n)$ time because of the summation of function values. (Note that the summation of n items can be done in time $O(n/p + \log n)$ time with p processors.) A BPC problem takes $O(\log^2 n)$ time to solve. We pipeline all BPC problems in a GPC problem and get time complexity $O(\log^2 n)$ for solving a GPC problem.

The functions in B have a special property which we will exploit in our algorithm. Each variable x_i has a length $|x_i| \leq q = O(\log n)$. $Y_{i,j}(x_i, x_j)$ is 0 unless the first $|x_i|$ bits of x_i are 0's and the first $|x_j|$ bits of x_j are 0's. When we apply our scheme, there is no need to keep BPC functions $Y_{i_u,j_u}(x_{i_u}, x_{j_u})$ for all conditional-bit patterns because many of these patterns will yield zero BPC functions. In our algorithm, we keep one copy of $Y_{i_u,j_u}(x_{i_u}, x_{j_u})$ with conditional bits set to 0's. This of course helps reduce the number of processors. In particular, the random-variable tree for each P_u now requires at most $O(n)$ processors, instead of $O(c^u n)$ processors as we have used in §3 on the CREW PRAM.

There are $d^2(i)$ BPC functions in cluster $C(i)$, while we can allocate at most $d(i)$ processors in the very first GPC problem because we have at most $O(m+n)$ processors for the GPC problem. What we do is use an *evaluation tree* for each cluster. The evaluation tree $TC(i)$ for cluster $C(i)$ is a "subtree" of the random-variable tree. The leaves of $TC(i)$ are the variables in $C(i)$. An interior node of the random-variable tree is not present in $TC(i)$ if none of the leaves of the subtree rooted at the interior node is in $C(i)$. When we are fixing r, if r is not in $TC(i)$ then cluster $C(i)$ does not contribute anything. If r is in $TC(i)$ then the contribution of $C(i)$ can be obtained by evaluating the function $f(x, y)$, where x and y are leaves in the evaluation subtree rooted at r and x and y are in different subtrees of r. If r has a leaves in the left subtree and b leaves in the right subtree then the contribution from $TC(i)$ for fixing r is the sum of ab function values. We will give the details of evaluating this sum using a constant number of operations.

Let us summarize the main ideas. We do not combine functions and achieve time $O(\log^2 n)$ for solving a BPC problem. We put all BPC problem in a GPC problem as one batch into a pipeline to get $O(\log^2 n)$ time for solving a GPC problem. We use a special property of functions in B to maintain one copy for each BPC function for only conditional bits of all 0's. We use evaluation trees to take care of the vertex cluster term.

We now sketch the speedup stage. Since we have to solve $O(\log n)$ GPC problems in this stage, we have to reduce the time complexity for a GPC problem to $o(\log^2 n)$ in order to obtain $o(\log^3 n)$ time. We use a modified random-variable tree as shown in Fig. 3(c) in §2. Such a random-variable tree has $S = \lceil(\log n + 1)/a\rceil$ blocks. Each block contains a levels. We fix a block in a step instead of fixing a level in a step. Each step takes $O(\log n)$ time and a BPC problem takes $O(S \log n)$ time. If we have as many processors as we want, we could solve all BPC problems in a GPC problem by enumerating all possible cases instead of putting them through a pipeline; i.e., in solving P_u, we could guess all possible settings of random variables for P_v, $0 \leq v < u$. We have explained this approach in the proof of Theorem 1 in §2. In doing so we would achieve time $O(S \log n)$ for solving a GPC problem. In reality, we have extra processors, but they are not enough for us to enumerate all possible situations. We therefore put a BPC problems of a GPC problem in a team. All BPC problems in a team are solved by enumeration. Thus they are solved in time $O(S \log n)$. Let b be the number of teams we have. We put all these teams into a pipeline and solve them in time $O((S+b)\log n)$. The approach of the speedup stage can be viewed as that of the initial stage with added parallelism which comes with the help of extra processors.

5.2. The initial stage. We first show how to solve a GPC problem for function B in time $O(\log^2 n)$ using $O((m+n)\log n)$ processors.

$O(m+n)$ processors will be allocated to each BPC problem. The algorithm for processors working on F_u has the following form.

Step t $(0 \leq t < u)$: Wait for the pipeline to be filled.

Step $u + t$ $(0 \leq t < \log n)$: Fix random variables at level t.

Step $u + \log n$: Fix the only remaining random variable at level $\log n$. Output the good point for $\vec{x}_u$.

We will allow $O(\log n)$ time for each step and $O(\log^2 n)$ time for the whole algorithm. Note that we do not combine functions with respect to the surviving set and therefore use $O(\log n)$ time for a step.

The way T_u is constructed can be described by algorithm MRV-Tree, a modified version of algorithm RV-Tree in §3. In MRV-Tree we do not enumerate all possible conditional-bit patterns. Only the bit pattern of all 0's is kept. Thus a node on a bit-pipeline tree may not have both children. A variable x_i only appears in F_u as x_{i_u} with $u < |x_i|$ because the setting of random variables in F_u, $u \geq |x_i|$, is not affected by x_{i_u}.

```
PROCEDURE MRV-TREE
  begin
    Step $t$ $(0 \leq t < u)$: Wait for the pipeline to be filled.

    Step $u$:
      (*In this step, we will build $T_u^{(0)}[i][j]$. $0 \leq i < n/2$ and $j$ are indices for which
      $T_u^{(0)}[i][j]$ is not empty. At the beginning of this step, $T_{u-1}^{(0)}[i][j]$ has already been
      constructed if it is not empty. Random variables $x_i$ have been transmitted to depth
      $u$ of the bit pipeline tree for level 0.*)

    for each node $T_u^{(0)}[i][j]$
      if $T_u^{(0)}[i][j]$ has received either $x_{2i}$ or $x_{2i+1}$ from $T_{u-1}^{(0)}[i][j/2]$
        (*$x_{2i}$ and $x_{2i+1}$ becomes $x_{2i_u}$ and $x_{2i+1_u}$ in $T_u$.*) then
        begin
          if $T_u^{(0)}[i][j]$ has received $x_{2i}$ then
            make it the left child of $T_u^{(0)}[i][j]$ in the random-variable forest for $P_u$;

          if $T_u^{(0)}[i][j]$ has received $x_{2i+1}$ then
            make it the right child of $T_u^{(0)}[i][j]$ in the random-variable forest for $P_u$;

          fix random variable $r$ in $T_u^{(0)}[i][j]$;

          make $T_u^{(0)}[i][j]$ a child of $T_{u-1}^{(0)}[i][j/2]$ in the bit-pipeline tree;

          if $T_u^{(0)}[i][j]$ has received $x_{2i}$ and $|x_{2i}| \geq u$ then
            transmit $x_{2i}$ to $T_{u+1}^{(0)}[i][j0]$;

          if $T_u^{(0)}[i][j]$ has received $x_{2i+1}$ and $|x_{2i+1}| \geq u$ then
            transmit $x_{i\#0}$ to $T_{u+1}^{(0)}[i][jr]$;
        end
      else (*$T_u^{(0)}[i][j]$ is empty.*);

    Step $u+t$ $(1 \leq t < \log n)$:
      (*In this step, we will build $T_u^{(t)}[i][j]$, $0 \leq i < n/2^{t+1}$ and $j$ are indices for
      which $T_u^{(t)}[i][j]$ is not empty. At the beginning of this step, $T_{u-1}^{(t)}[i][j]$ has already
      been constructed. Let $T_{u-1}^{(t-1)}[i0][j]$ and $T_{u-1}^{(t-1)}[i1][j']$ (they may be empty) be the
      two children in the random-variable subtree rooted at $T_{u-1}^{(t)}[i][j]$. $T_u^{(t-1)}[i0][j0]$
      and $T_u^{(t-1)}[i0][j1]$ (they may be empty) are the children of $T_{u-1}^{(t-1)}[i0][j]$, and
      $T_u^{(t-1)}[i1][j'0]$ and $T_u^{(t-1)}[i1][j'1]$ (they may be empty) are the children of
      $T_{u-1}^{(t-1)}[i1][j']$ in the bit pipeline tree for level $t-1$. The setting of the random
      variable $r$ for the pair $(i0, i1)$ at level $t$ for $P_{u-1}$, i.e., the random variable in
      $T_{u-1}^{(t)}[i][j]$, is known.*)
```

```
if $T_u^{(t-1)}[i0][j0]$ is not empty then
    make it the left child of $T_u^{(t)}[i][j0]$ in the random-variable forest for $P_u$;

if $T_u^{(t-1)}[i1][j'r]$ is not empty then
    make it the right child of $T_u^{(t)}[i][j0]$ in the random-variable forest for $P_u$;

if $T_u^{(t-1)}[i0][j1]$ is not empty then
    make it the left child of $T_u^{(t)}[i][j1]$ in the random-variable forest for $P_u$;

if $T_u^{(t-1)}[i1][j'\bar{r}]$ is not empty then
    make it the right child of $T_u^{(t)}[i][j1]$ in the random-variable forest for $P_u$;

if $T_u^{(t)}[i][j0]$ is not empty then
    make it the left child of $T_{u-1}^{(t)}[i][j]$ in the bit-pipeline tree for level $t$;

if $T_u^{(t)}[i][j1]$ is not empty then
    make it the right child of $T_{u-1}^{(t)}[i][j]$ in the bit-pipeline tree for level $t$;

fix the random variables in $T_u^{(t)}[i][j0]$ and $T_u^{(t)}[i][j1]$;

Step $u + \log n$:
    (*At the beginning of this step, the random-variable trees have been built for $T_i$, $0 \le i < u$. Let $T_{u-1}^{(\log n)}[0][j]$ be the root of $T_{u-1}$. The random variable $r$ in $T_{u-1}^{(\log n)}[0][j]$ has been set. In this step, we will choose one of the two children of $T_{u-1}^{(\log n)}[0][j]$ in the bit-pipeline tree for level $\log n$ as the root of $T_u$.*)

    if $T_u^{(\log n-1)}[0][jr]$ is not empty then
        begin
            make $T_u^{(\log n-1)}[0][jr]$ the child of $T_u^{(\log n)}[0][jr]$ in the random-variable tree;

            make $T_u^{(\log n)}[0][jr]$ the child of $T_{u-1}^{(\log n)}[0][j]$ in the bit-pipeline tree for level $\log n$;

            fix the random variable in $T_u^{(\log n)}[0][jr]$;

            output $T_u^{(\log n)}[0][jr]$ as the root of $T_u$;
        end
end
```

Note that i and j in $T_u^{(t)}[i][j]$ are parameters and $T_u^{(t)}$ is not a two dimensional array here. We can view algorithm MRV-Tree as one which distributes random variables x_i into different sets. Each set is indexed by (u, t, i, j). We call these sets BD sets because they are obtained on the bit-pipeline trees and the derandomization trees. x is in $BD(u, t, i, j)$ if x is a leaf in $T_u^{(t)}[i][j]$. When u and t are fixed, $BD(u, t, i, j)$ sets are disjoint. Because we allow $O(\log n)$ time for each step in MRV-Tree, the time complexity for constructing the random-variable trees is $O(\log^2 n)$.

See Fig. 6 for an execution of MRV-Tree.

FIG. 6. (*Cont.*)

Example. Variables are distributed into the BD sets as shown below.

Step 0:
$x_0, x_1 \in BD(0,0,0,\epsilon)$;
$x_2, x_3 \in BD(0,0,1,\epsilon)$;
$x_4, x_5 \in BD(0,0,2,\epsilon)$;
$x_6, x_7 \in BD(0,0,3,\epsilon)$.

Step 1:
$x_0, x_1, x_2, x_3 \in BD(0,1,0,\epsilon)$;
$x_4, x_5, x_6, x_7 \in BD(0,1,1,\epsilon)$;
$x_0, x_1 \in BD(1,0,0,0)$;
$x_2, x_3 \in BD(1,0,1,0)$;
$x_4 \in BD(1,0,2,0)$;
$x_5 \in BD(1,0,2,1)$;
$x_6, x_7 \in BD(1,0,3,0)$.

Step 2:
$x_0, x_1, x_2, x_3,$
$x_4, x_5, x_6, x_7 \in BD(0,2,0,\epsilon)$;
$x_0, x_1 \in BD(1,1,0,0)$;
$x_2, x_3 \in BD(1,1,0,1)$;
$x_4 \in BD(1,1,1,0)$;
$x_5, x_6, x_7 \in BD(1,1,1,1)$;
$x_0, x_1 \in BD(2,0,0,00)$;
$x_2, x_3 \in BD(2,0,1,00)$;
$x_4 \in BD(2,0,2,00)$;
$x_5 \in BD(2,0,2,10)$;
$x_6 \in BD(2,0,3,00)$;
$x_7 \in BD(2,0,3,01)$.

Step 3:
$x_0, x_1, x_2, x_3,$
$x_4, x_5, x_6, x_7 \in BD(0,3,0,\epsilon)$;
$x_0, x_1, x_5, x_6, x_7 \in BD(1,2,0,0)$;
$x_2, x_3, x_4 \in BD(1,2,0,1)$;
$x_0, x_1 \in BD(2,1,0,00)$;
$x_5, x_7 \in BD(2,1,0,10)$;
$x_6 \in BD(2,1,0,11)$;
$x_2, x_3 \in BD(2,1,1,00)$;
$x_4 \in BD(2,1,1,10)$.

Step 4:
$x_2, x_3, x_4 \in BD(1,3,0,0)$;
$x_2, x_3 \in BD(2,2,0,00)$;
$x_4 \in BD(2,2,0,01)$.

Step 5:
$x_2, x_3 \in BD(2,3,0,00)$.

Now consider GPC functions of the form $Y_i(x_i)$ and $Y_{i,j}(x_i, x_j)$ except the functions in the vertex-cluster term. Our algorithm will distribute these functions into sets $BDF(u,t,i',j')$ by the execution of MRV-Tree, where $BDF(u,t,i',j')$ is essentially the BD set except it is for functions. $Y_{i,j}$ is in $BDF(u,t,i',j')$ iff both x_i and x_j are in $BD(u,t,i',j')$, $\max\{k|$ (the kth bit of $i\ XOR\ j) = 1\} = t$, $|x_i| > u$, and $|x_j| > u$, where XOR is the bitwise exclusive-or operation, with the exception that all functions belong to $BDF(u, \log n, 0, j')$ for some j'. The condition $\max\{k|$ (the kth bit of $i\ XOR\ j) = 1\} = t$ ensures that x_i and x_j are in different subtree of the tree rooted at $T_u^{(t)}[i'][j']$. The conditions $|x_i| > u$ and $|x_j| > u$ ensure that x_i and x_j are still valid. The algorithm for the GPC functions for P_u is shown below.

```
PROCEDURE FUNCTIONS
  begin
    Step $t$ ($0 \le t < u$):
      (*Functions in $BDF(0, t, i', \Lambda)$ reach depth 0 of the bit-pipeline tree for level $t$.*)
      Wait for the pipeline to be filled;
    Step $u + t$ ($0 \le t < \log n$):
      (*Let $S = BDF(u, t, i', j')$.*)
      if $S$ is not empty then
        begin
        for each GPC function $Y_{i,j}(x_i, x_j) \in S$
            compute the BPC function $Y_{i_u,j_u}(x_{i_u}, x_{j_u})$ with conditional bits set to all 0's;

        (*To fix the random bit in $T_u^{(t)}[i'][j']$,*)
        $T_u^{(t)}[i'][j'] := 0$;
        $F_0 := \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(t)}[i'][j']), \Psi(x_j, T_u^{(t)}[i'][j']))$
            $+ \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(t)}[i'][j']) \oplus 1, \Psi(x_j, T_u^{(t)}[i'][j']) \oplus 1) + VC$;
        (*$VC$ is the function value obtained for functions in the vertex-cluster term. We shall explain how to compute it later. $\oplus$ is the exclusive-or operation.*)

        $T_u^{(t)}[i'][j'] := 1$;
        $F_1 := \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(t)}[i'][j']), \Psi(x_j, T_u^{(t)}[i'][j']))$
            $+ \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(t)}[i'][j']) \oplus 1, \Psi(x_j, T_u^{(t)}[i'][j']) \oplus 1) + VC$;

        if $F_0 \geq F_1$ then $T_u^{(t)}[i'][j'] := 0$
        else $T_u^{(t)}[i'][j'] := 1$;
        (*The random bit is fixed.*)

        (*To decide whether $Y_{i,j}$ should remain in the pipeline,*)
        for each $Y_{i,j} \in S$
            begin
              if $\Psi(x_i, T_u^{(t)}[i'][j']) \neq \Psi(x_j, T_u^{(t)}[i'][j'])$ then remove $Y_{i,j}$;
              (*$Y_{i,j}$ is a zero function in the remaining computation of $P_u$ and also a zero function in $P_v$, $v > u$.*)

              if$(\Psi(x_i, T_u^{(t)}[i'][j']) = \Psi(x_j, T_u^{(t)}[i'][j'])) \wedge (|x_i| \geq u+1) \wedge (|x_j| \geq u+1)$ then
                  (*Let $b = \Psi(x_i, T_u^{(t)}[i'][j'])$.*)
                  put $Y_{i,j}$ into $BDF(u+1, t, i', j'b)$; (*$Y_{i,j}$ is to be processed in $Y_{u+1}$.*)

            end
    end
Step $u + \log n$:
  if $S = BDF(u, \log n, 0, j')$ is not empty then
  (*$S$ is the only set left for this step.*)
    begin
        for each GPC function $Y_{i,j}(x_i, x_j)$ $(Y_i(x_i)) \in S$
            compute the BPC function $Y_{i_u,j_u}(x_{i_u}, x_{j_u})$ $(Y_{i_u}(x_{i_u}))$ with conditional bits set to all 0's;

        (*To fix the random bit in $T_u^{(\log n)}[0][j']$,*)
        $T_u^{(\log n)}[0][j'] := 0$;
        $F_0 := \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(\log n)}[0][j']), \Psi(x_j, T_u^{(\log n)}[0][j']))$
            $+ \sum_{Y_i \in S} Y_{i_u}(\Psi(x_i, T_u^{(\log n)}[0][j'])) + VC$;

        $T_u^{(\log n)}[0][j'] := 1$;
        $F_1 := \sum_{Y_{i,j} \in S} Y_{i_u,j_u}(\Psi(x_i, T_u^{(\log n)}[0][j']), \Psi(x_j, T_u^{(\log n)}[0][j']))$
```

```
            $+ \sum_{Y_i \in S} Y_{i_u}(\Psi(x_i, T_u^{(\log n)}[0][j'])) + VC$;

        if $F_0 \geq F_1$ then $T_u^{(\log n)}[0][j'] := 0$
        else $T_u^{(\log n)}[0][j'] := 1$;
        (*The random bit is fixed.*)

        (*To decide whether $T_{i,j}$ should remain in the pipeline,*)
        for each $Y_{i,j} \in S$
            begin
                (*Let $b = T_u^{(\log n)}[0][j']$). $\Psi(x_i, T_u^{(\log n)}[0][j'])$ and $\Psi(x_j, T_u^{(\log n)}[0][j'])$ must be equal here.*)
                if $(\Psi(x_i, T_u^{(\log n)}[0][j']) = \Psi(x_j, T_u^{(\log n)}[0][j']) = 0) \wedge ((|x_i| \geq u + 1) \vee (|x_j| \geq u + 1))$
                then
                    put $Y_{i,j}$ into $BDF(u + 1, \log n, 0, j'b)$;
                else remove $Y_{i,j}$;
            end

        (*To decide whether $Y_i$ should remain in the pipeline,*)
        for each $Y_i \in S$
            begin
                (*Let $b = T_u^{(\log n)}[0][j']$). *)
                if $(\Psi(x_i, T_u^{(\log n)}[0][j']) = 0) \wedge (|x_i| \geq u + 1)$ then
                    put $Y_i$ into $BDF(u + 1, \log n, 0, j'b)$;
                else remove $Y_i$;
            end
    end
end
```

The functions being evaluated can also be viewed as being pipelined through the derandomization trees.

There are $O(\log n)$ steps in MRV-Tree and FUNCTIONS, each step takes $O(\log n)$ time and $O((m + n)\log n)$ processors.

Now we describe how the functions in the vertex-cluster term are evaluated. Each function $Y_{i,j}(x_i, x_j)$ in the vertex-cluster term is defined as $Y_{i,j}(x_i, x_j) = -1$ if the first $|x_i|$ bits of x_i are 0's and the first $|x_j|$ bits of x_j are 0's, and otherwise as $Y_{i,j}(x_i, x_j) = 0$. Let $l(i) = |x_i| - u$. Then $Y_{i_u, j_u}(\Lambda, \Lambda)(0^u, 0^u) = -1/2^{l(i)+l(j)}$ and $Y_{i_u, j_u}(0, 0)(0^u, 0^u) = -1/2^{l(i)+l(j)-2}$ if $|x_i| > u$ and $|x_j| > u$. Procedure MRV-Tree is executed in parallel for each cluster $C(v)$ to build an *evaluation tree* $TC(v)$ for $C(v)$. An evaluation tree is similar to the random-variable tree. The difference between the random-variable tree and $TC(v)$ is that the leaves of $TC(v)$ consist of variables from $C(v)$. Let $r = T_{u,v}^{(t)}[i'][j']$ be the root of a subtree T' in $TC(v)$ which is to be constructed in the current step. Let L and R be the left and right subtrees of T', respectively. Let r_L and r_R be the roots of L and R, respectively. At the beginning of the current step, L and R have already been constructed. Random variables in the interior nodes of L and R have been fixed. Define $M(x, b) = \sum_{\Psi(i,x)=b} \frac{1}{2^{l(i)}}$, where i's are leaves in the subtree rooted at x. At the beginning of the current step, $M(r_L, b)$ and $M(r_R, b)$, $b = 0, 1$, have already been computed and associated with r_L and r_R, respectively. During the current step, r_L is made the left child of r and r_R is made the right child of r. Now r is tentatively set to 0 and 1 to obtain the value VC for fixing r in procedure FUNCTIONS. We first compute $VC(v, r)$ for each

v. $VC(v, r) = 2\sum_{b=0}^{1} M(r_L, b)M(r_R, b \oplus r)$, where $\oplus$ is the exclusive-or operation. The VC value used in procedure FUNCTIONS is $-\sum_{\{v \mid T_{u,v}^{(t)}[i'][j'] \text{ is not empty}\}} \frac{d(i)}{2} VC(v, T_{u,v}^{(t)}[i'][j'])$. After setting r, we obtain an updated value for $M(r, b)$ as $M(r, b) = M(r_L, b) + M(r_R, b \oplus r)$. If T' has only one subtree, then $VC(v, r) = 0$ and $M(r, b)$ need to be computed after r is set.

The above paragraph shows that we need only spend $O(T_{VC})$ operations for evaluating VC for all vertex clusters in a BPC problem, where T_{VC} is the total number of tree nodes of all evaluation trees. T_{VC} is $O(m \log n)$ because there are a total of $O(m)$ leaves and some nodes in the evaluation trees have one child.

We briefly describe the data structure for the algorithm. We build the random-variable tree and evaluation trees for P_0. Nodes $T_0^{(t)}[i][\Lambda]$ in the random-variable tree and nodes $T_{0,v}^{(t)}[i][\Lambda]$ in the evaluation trees and functions in $BDF(0, t, i, \Lambda)$ are sorted by the pair (t, i). This is done only once and takes $O(\log n)$ time with $O(m + n)$ processors [AKS], [C]. As the computation proceeds, the random-variable tree and each evaluation tree will split into several trees; each BDF set will split into several sets, one for each distinct conditional bit pattern. A BDF set in P_u can split into at most two in P_{u+1}. Since we allow $O(\log n)$ time for each step, we can allocate memory for the new level to be built in the evaluation trees. We use pointers to keep track of the bit-pipeline trees and the evaluation trees. The nodes and functions in the same BD and BDF sets (indexed by the same (u, t, i', j')) should be arranged to occupy consecutive memory cells to facilitate the computation of F_0 and F_1 in FUNCTIONS. These operations can be done in $O(\log n)$ time using $O((m + n)/\log n)$ processors.

It is now straightforward to verify that our algorithm for solving a GPC problem takes $O(\log^2 n)$ time, $O(\log n)$ time for each of the $O(\log n)$ steps. We note that in each step for each BPC problem we have used $O(m + n)$ processors. This can be reduced to $O((m + n)/\log n)$ processors because in each step, $O(m + n)$ operations are performed for each BPC problem. They can be done in $O(\log n)$ time using $O((m + n)/\log n)$ processors. Since we have $O(\log n)$ BPC problems, we need only $O(m + n)$ processors to achieve time complexity $O(\log^2 n)$ for solving one GPC problem.

We use $O((m + n)/\log^{0.5} n)$ processors to solve the first $O(\log^{0.5} n)$ GPC problems in the maximal independent set problem. Recall that the execution of a GPC algorithm will reduce the size of the graph by a constant fraction. For the first $O(\log \log n)$ GPC problems, the time complexity is $O(\sum_{i=1}^{O(\log \log n)} \log^{2.5} n/c^i) = O(\log^{2.5} n)$, where $c > 1$ is a constant. In the ith GPC problem, we solve $O(c^i \log^{0.5} n)$ BPC problems in a batch, incurring $O(\log^2 n)$ time for one batch and $O(\log^{2.5} n/c^i)$ time for the $O(\log^{0.5} n/c^i)$ batches. The time complexity for the remaining GPC problems is $O(\sum_{i=O(\log \log n)}^{\log^{0.5} n} \log^2 n) = O(\log^{2.5} n)$.

5.3. The speedup stage. The input graph here is the output graph from the initial stage. The speedup stage consists of the rest of the GPC problems.

We have to reduce the time complexity for solving one GPC problem to under $O(\log^2 n)$ in order to obtain an $o(\log^3 n)$ algorithm for the maximal independent set problem. After the initial stage, we have a small-size problem and we have extra processor power to help us speed up the algorithm.

We redesign the random-variable tree T for a BPC problem. We use the design as shown in Fig. 3(c) in §2. There are $S = \lceil(\log n + 1)/a\rceil$ blocks in T, where a is a parameter.

We note that the design of T incorporates design techniques from both [H], [HI] and [L2], [L3]. The advantage of Han and Igarashi's design [H], [HI] is that random bits can be fixed independently if these bits are at the same level of T. The advantage of Luby's design is that there are fewer random bits in T, which is desirable in the speedup stage of our algorithm for the maximal independent set problem.

LEMMA 6. *If all random variables in the interior nodes of a proper subtree T' of T are fixed, the random variables x_j at the leaves of T' can only assume two different patterns.*

Proof. This is because the random variables from the root of T to the parent of the root of T' are common to all x_j's at the leaves of T'. □

In fact, we have implicitly used this lemma in constructing the bit-pipeline tree in the design of our GPC algorithm and in procedure RV-Tree.

The q BPC problems in a GPC problem are divided into $b = q/a$ teams (without loss of generality, assuming it is an integer). Team i, $0 \leq i < b$, has a BPC problems. Let J_w be the wth team. The algorithm for fixing the random variables for J_w can be expressed as follows.

Step t $(0 \leq t < w)$: Wait for the pipeline to be filled.
Step $t + w$ $(0 \leq t < S)$: Fix random variables in block t in random-variable forests for J_w.

Each step will be executed in $O(\log n)$ time. Since there are $O(b + S)$ steps, the time complexity is $O(\log^2 n/a)$ for the above algorithm since $q = O(\log n)$.

For a graph with m edges and n vertices, to fix random bits in block 0 for P_0, we need $2^a(m + n)$ processors to enumerate all possible 2^a bit patterns for the a bits in block 0. To fix the bits in block 0 for P_v, $v < a$, we need $2^{a(v+1)}$ patterns to enumerate all possible $a(v + 1)$ bits in block 0 for P_u, $u \leq v$. For each of the $2^{a(v+1)}$ patterns, there are 2^v conditional-bit patterns. Thus we need $c^{a^2}(m + n)$ processors for team 0 for a suitable constant c. Although the input to each team may have many conditional-bit patterns, it contains at most $O(m + n)$ random-variable trees (in the input random-variable forest). We need keep working for only those conditional-bit patterns which are not associated with empty trees. Thus the number of processors needed for each team is the same because when team J_w is working on block i, the bits in block i have already been fixed for teams J_u, $u < w$, and because we keep only nonzero functions. The situation here is similar to the situation in the initial stage. Thus the total number of processors we need for solving one GPC problem in time $O(\log^2 n/a)$ is $c^{a^2}(m+n)\log n/a = O(c^{a^2}(m+n)\log n)$. We conclude that one GPC problem can be solved in time $O(\log^2 n/\sqrt{k})$ with $O(c^k(m + n)\log n)$ processors. Therefore, the time complexity for the speedup stage is $O(\sum_{k=1}^{\log n}(\log^2 n/\sqrt{k})) = O(\log^{2.5} n)$.

THEOREM 6. *There is an EREW PRAM algorithm for the maximal independent set problem with time complexity $O(\log^{2.5} n)$ using $O((m + n)/\log^{0.5} n)$ processors.*

We shall call this algorithm MAX.

5.4. Further improvement. To reduce the processor complexity by another factor of $\log n$ on the CREW model, we need only work on the first $O(\log\log n)$ GPC problems. These GPC problems belong to the initial stage.

Consider the first GPC problem. At the beginning of the GPC algorithm, all GPC functions (in $BDF(0, t, i, \Lambda)$), nodes in the random-variable tree (in $T_0^{(t)}[i][\Lambda]$) and nodes in the evaluation trees (in $T_{0,v}^{(t)}[i][\Lambda]$) will be sorted by the parameter (t, i). This takes $O(m\log n/p+\log n)$ time with p processors. A GPC function f will be passed down the bit-pipeline tree in the procedure FUNCTIONS. At each depth of the bit-pipeline tree, f is involved in a constant number of operations. Thus each GPC function will account for $O(\log n)$ operations, giving a total of $O(m\log n)$ operations. This can be done in time $O(m\log n/p + \log^2 n)$ with p processors. The nodes in the random-variable tree and the nodes in an evaluation tree, as they pass down the bit-pipeline tree, can be decomposed into several random-variable trees and evaluation trees, one for each conditional-bit pattern. Each leaf in these trees can be involved in $O(\log n)$ operations in a BPC problem and therefore $O(\log^2 n)$ operations in the GPC problem. This gives time $O(m\log^2 n/p + \log^2 n)$. On the CREW PRAM, we can avoid evaluating nodes in a evaluation tree which has only one child. As long as we only evaluate nodes in the evaluation trees which have two children, the number of operations for evaluating the nodes in an evaluation tree is proportional to the number of leaves in the tree. This helps to cut the time for evaluating the evaluation trees to $O(m/p + \log^2 n)$ for a BPC problem and to $O(m \log n/p + \log^2 n)$ for the GPC problem. However, a node v at level l in an evaluation tree could have its parent $p(v)$ at level $l + c$ with $c > 1$, because now we require that $p(v)$ have two children. When $p(v)$ is evaluated, we need the value $\Psi(v, p(v))$. In order to obtain this value, we keep updated $\Psi(v, w)$ for all leaves v in a random-variable tree and the current node w. The $\Psi(v, w)$ value for the n leaves in the random-variable forest for a BPC problem will be updated immediately after the random variables at each level are fixed. This takes $O(n \log n/p)$ time for a BPC problem and $O(n \log^2 n/p)$ time for the GPC problem. In summary, the first GPC problem can be solved in time $O(m \log n/p + n \log^2 n/p + \log^2 n)$ with p processors. If $m > n \log n$, the time will become $O(m \log n/p + \log^2 n)$.

One might argue that since the evaluation trees are built bottom-up, if a node is not checked one cannot know whether that node has one or two children. The answer is that we cannot avoid checking whether a node r in an evaluation tree of P_u has one or two children. But if we know r has one child, we can avoid checking r's descendants in the bit-pipeline tree, i.e., those nodes in P_v, $v > u$, which are descendants of r in the bit-pipeline tree.

Our modified algorithm for the GPC problem will first check whether $m > n \log n$. If $m \leq n \log n$ we first construct G' induced by vertices in V with degree no greater than $\log n$. We then solve the maximal independent set problem for G' in time $O(m \log n/p + \log^2 n)$, using an algorithm to be described later. Now the remaining graph can be viewed as satisfying $m > n \log n$, and the rest of the computation takes $O(m \log n/p + \log^2 n)$ time as explained above. We therefore achieve time $O(m \log n/p + \log^2 n \log\log n)$ for the first $O(\log\log n)$ GPC problems. The remaining graph can now be solved by MAX.

We now describe an algorithm for finding a maximal independent set for a graph satisfying $\Delta = O(\log n)$. This algorithm is obtained by using a modified version of our $\Delta + 1$ vertex-coloring algorithm. We first color the graph with $\Delta + 1$ colors and then find a maximal independent set by sequencing through these colors.

LEMMA 7 [HI]. *A BPC problem can be solved by first sorting the input BPC functions into the file-major indexing, which takes $O(m \log n/p + \log n)$ time, and then building the derandomization tree and derandomizing the random variables, which takes $O(m/p + \log n)$ time, where p is the number of processors used.*

The reason that the computation for a BPC problem except the sorting step takes $O(m/p + \log n)$ time is that the derandomization process can be formulated [HI] as a tree-contraction process [MR]. Note that in order to establish Lemma 7, the derandomization tree D should take the form such that each interior node of D must have at least two children [HI].

LEMMA 8. *The $\Delta + 1$ vertex-coloring problem can be solved in time $O(m \log n/p + \log n(\log\log n)^2)$ using p processors on the CREW PRAM if $\Delta = O(\log n)$.*

Proof. Since $\Delta = O(\log n)$, one GPC problem now contains only $O(\log\log n)$ BPC problems. Since the derandomization trees for all the BPC problems in a GPC problem are the same, we need only build one derandomization tree and then make $O(\log\log n)$ copies of the tree. The time complexity for building the derandomization trees in the GPC algorithm is $O(m \log n/p + \log n)$. The time complexity for building the tables is $O(m \log\log n/p + \log n)$ for a BPC problem, because $\Delta = O(\log n)$, and $O(m(\log\log n)^2/p + \log n \log\log n)$ for the GPC problem. The time complexity for the rest of the computation in the GPC algorithm is $O(m \log\log n/p + \log n \log\log n)$ using p processors because the BPC problems are solved sequentially. Thus the first $O(\log\log n)$ GPC problems can be solved in time

$$O\left(\left(\sum_{i=1}^{O(\log\log n)} \frac{m \log n}{c^i p}\right) + \log n(\log\log n)^2\right) = O(m \log n/p + \log n(\log\log n)^2)$$

using p processors. Now the graph has size $O(m/\log^2 n)$. It can be colored using the algorithm in §4. Note again that each GPC problem has only $O(\log\log n)$ BPC problems. □

THEOREM 7. *There is a CREW PRAM algorithm for the maximal independent set problem with time complexity $O(\log^{2.5} n)$ using $O((m+n)/\log^{1.5} n)$ processors.*

The dominating operations in each step of our maximal independent set algorithm are memory allocation and summation. These operations can be done in time $O(\log n/\log\log n)$ on the CRCW PRAM [P], [Re], [CV]. Therefore, we have the following corollary.

COROLLARY. *There is a CRCW PRAM algorithm for the maximal independent set problem with time complexity $O(\log^{2.5} n/\log\log n)$ using $O((m+n)\log\log n/\log^{1.5} n)$ processors.*

6. Maximal matching. Let $N(M) = \{(i,k) \in E,\ (k,j) \in E \mid \exists (i,j) \in M\}$. A maximal matching can be found by repeatedly finding a matching M and removing $M \cup N(M)$ from the graph.

We adapt Luby's work [L3] to show that after an execution of the GPC procedure a constant fraction of the edges will be reduced.

Let k_i be such that $2^{k_i-1} < 4d(i) \leq 2^{k_i}$. Let $q = \max\{k_i | i \in V\}$. Let $\vec{x} =< x_{ij} \in \{0,1\}^q, (i,j) \in E\}$. The length $|x_{ij}|$ of x_{ij} is defined to be $\max\{k_i, k_j\}$. Define

$$Y_{ij}(x_{ij}) = \begin{cases} 1 & \text{if } x_{ij}(|x_{ij}|-1)\cdots x_{ij}(0) = 0^{|x_{ij}|}, \\ 0 & \text{otherwise.} \end{cases}$$

$$Y_{ij,i'j'}(x_{ij}, x_{i'j'}) = -Y_{ij}(x_{ij})Y_{i'j'}(x_{i'j'}),$$

$$B(\vec{x}) = \sum_{i\in V} \frac{d(i)}{2} \left(\sum_{j\in adj(i)} \left(Y_{ij}(x_{ij}) + \sum_{k\in adj(j), k\neq i} Y_{ij,jk}(x_{ij}, x_{jk}) \right) + \sum_{j,k\in adj(i), j\neq k} Y_{ij,ik}(x_{ij}, x_{ik}) \right),$$

where $x_{ij}(p)$ is the pth bit of x_{ij}.

Function B sets a lower bound on the number of edges deleted from the graph [L3] should edge (i,j) be tentatively labeled as an edge in the matching set if $x_{ij} = (0 \cup 1)^{q-|x_{ij}|}0^{|x_{ij}|}$. The following lemma can be proven by following Luby's proof for Theorem 1 in [L1].

LEMMA 9. *$E[B] \geq |E|/c$ for a constant $c > 0$.*

Function B can be written as

$$B(\vec{x}) = \sum_{(i,j)\in E} \frac{d(i)+d(j)}{2} Y_{ij}(x_{ij}) + \sum_{j\in V} \sum_{i,k\in adj(j), i\neq k} \frac{d(i)}{2} Y_{ij,jk}(x_{ij}, x_{jk})$$

$$+ \sum_{i\in V} \frac{d(i)}{2} \sum_{j,k\in adj(i), j\neq k} Y_{ij,ik}(x_{ij}, x_{ik})$$

By using the same technique as in §5, we can obtain a CREW algorithm for the maximal-matching problem with time complexity $O(\log^2 n)$ using $O(M(n))$ processors. The details of this algorithm are omitted here.

There are two cluster terms in function B. We only need explain how to evaluate the cluster term $\sum_{j\in V} \sum_{i,k\in adj(j), i\neq k} \frac{d(i)}{2} Y_{ij,jk}(x_{ij}, x_{jk})$. The rest of the functions can be computed as we have done for the maximal independent set problem in §5.

Again we build an evaluation tree $TC(v)$ for each cluster $C(v)$ in the cluster term. Let $l(ij) = |x_{ij}| - u$. Let $r = T^{(t)}_{u,v}[i'][j']$ be the root of a subtree T' in $TC(v)$ which is to be constructed in the current step. Let L and R be the left and right subtrees of T', respectively. Let r_L and r_R be the roots of L and R, respectively. At the beginning of the current step, L and R have already been constructed. Random variables in the interior nodes of L and R have been fixed. Define $M(x,b) = \sum_{\Psi(ij,x)=b} \frac{1}{2^{l(ij)}}$. Define $N(x,b) = \sum_{\Psi(ij,x)=b} \frac{d(i)}{2} \frac{1}{2^{l(ij)}}$. At the beginning of the current step, $M(r_L, b)$, $M(r_R, b)$, $N(r_L, b)$, and $N(r_R, b)$, $b = 0, 1$, have already been computed and associated with r_L and r_R, respectively. During the current step, r_L is made the left child of r and r_R is made the right child of r. Now r is tentatively set to 0 and 1 to obtain value VC for fixing r. We first compute $VC(v, r)$ for each v. $VC(v,r) = \sum_{b=0}^{1}(N(r_L, b)M(r_R, b \oplus r) + M(r_L, b)N(r_R, b \oplus r))$. The VC value is $-\sum_{\{v | T^{(t)}_{u,v}[i'][j'] \text{ is not empty}\}} VC(v, T^{(t)}_{u,v}[i'][j'])$. After setting r, we obtain updated values $M(r,b)$ and $N(r,b)$ as $M(r,b) = M(r_L, b) + M(r_R, b \oplus r), N(r,b) = N(r_L, b) + N(r_R, b \oplus r)$.

Since this computation does not require more processors, we have the following theorem.

THEOREM 8. *There is an EREW PRAM algorithm for the maximal matching problem with time complexity $O(\log^{2.5} n)$ using $O((m+n)/\log^{0.5} n)$ processors.*

For the maximal-matching problem, we cannot remove another factor of $\log n$ from the processor complexity as we did for the maximal independent set problem because there are $O(m)$ leaves in the random-variable trees of a BPC problem, while there are only $O(n)$ leaves in the maximal independent set problem.

Again in the CRCW PRAM algorithm a factor of $\log \log n$ can be taken out from the time complexity and put into the processor complexity.

Acknowledgments. The author wishes to thank the anonymous referees for their careful reviewing and helpful comments on the manuscript. The author also thanks Professor Richard Cole for making several good suggestions about the paper.

WEIGHTED MULTIDIMENSIONAL SEARCH AND ITS APPLICATION TO CONVEX OPTIMIZATION*

RICHA AGARWALA† AND DAVID FERNÁNDEZ-BACA‡

Abstract. We present a weighted version of Megiddo's multidimensional search technique and use it to obtain faster algorithms for certain convex optimization problems in $\mathbf{R}^d$, for fixed d. This leads to speed-ups by a factor of $\log^d n$ for applications such as solving the Lagrangian duals of matroidal knapsack problems and of constrained optimum subgraph problems on graphs of bounded tree-width.

Key words. computational geometry, convex optimization, Lagrangian relaxation, multidimensional search

1. Introduction.

This paper has three main parts. In the first (§2), we present a weighted version of the multidimensional search technique of Megiddo [27], [17], [10]. The second part (§3) discusses the application of our result to a class of convex optimization problems in fixed dimension which were studied earlier by Cohen and Megiddo [14], [15] and in a different context by Aneja and Kabadi [4]. In rough terms, the results in [14], [15], and [4] can be summarized as follows. Suppose that g is a concave function whose domain $\mathcal{Q}$ is a convex subset of $\mathbf{R}^d$ and that g is computable in $O(T)$ time by an algorithm $\mathcal{A}$ that only performs additions, multiplications by constants, copies, and comparisons on intermediate values that depend on the input numbers. Then g can be maximized in $O(T^{d+1})$ time. Cohen and Megiddo go on to show that substantial speed-ups are possible by exploiting whatever parallelism is inherent to algorithm $\mathcal{A}$. Thus, if $\mathcal{A}$ carries out D parallel steps, each of which does at most M comparisons, the running time will be $O((D \log M)^d T)$. By applying weighted multidimensional search and a generalization of Cole's circuit-simulation technique [16], we are able to reduce this to $O((D^d + \log^d M)T)$ in some cases.

Lagrangian relaxation is a source of several problems that fall into the framework described above [4]. This widely used approach is based on the observation that many hard optimization problems are actually easy problems that are complicated by a relatively small set of side constraints. By "pricing out" the bad side constraints into the objective function, one obtains a simpler convex optimization problem whose optimum solution provides good bounds on the optimum value of the original problem. The third part of this paper (§4) explains the application of our results to Lagrangian relaxation problems where the number of bad constraints is fixed. We give two examples of problems where the methods described in §3 give faster algorithms than those of [4], [14]: solving the Lagrangian duals of *matroidal knapsack problems* [11] and of certain constrained optimum subgraph problems on graphs of bounded tree-width.

2. Weighted multidimensional search.

Let us first introduce some notation. Suppose $\Lambda \subseteq \mathbf{R}^d$ is convex and that $h : \mathbf{R}^d \to \mathbf{R}$ is an affine function. Define $\text{sign}_\Lambda(h)$ as

$$\text{sign}_\Lambda(h) = \begin{cases} 0 & \text{if } h(\lambda) = 0 \text{ for some } \lambda \in \Lambda, \\ +1 & \text{if } h(\lambda) > 0 \text{ for all } \lambda \in \Lambda, \\ -1 & \text{if } h(\lambda) < 0 \text{ for all } \lambda \in \Lambda. \end{cases}$$

We will write sign for sign_Λ when no confusion can arise. A function h is *resolved* if $\text{sign}_\Lambda(h)$ has been computed. Obviously, if $h(\lambda) = a_0$, $\text{sign}(h)$ can be immediately determined from the sign of a_0.

Suppose we have a set $\mathcal{H}$ of d-dimensional affine functions and an oracle $\mathcal{B}^d$ that can compute $\text{sign}_\Lambda(h)$ for any $h \in \mathcal{H}$. The problem is to resolve every $h \in \mathcal{H}$ using as few oracle calls as possible. The following result is proved in [27], [17], [10].

THEOREM 2.1. *For each fixed $d \geq 0$ there exist positive constants $\beta(d)$ and $\alpha(d)$, $\alpha(d) \leq 1/2$, and an algorithm* SEARCH *such that, given a set $\mathcal{H}$ of affine functions,* SEARCH *either returns an affine function h such that* $\text{sign}_\Lambda(h) = 0$ *or resolves every $h \in \mathcal{H}' \subseteq \mathcal{H}$, where $|\mathcal{H}'| \geq \alpha(d) \cdot |\mathcal{H}|$, by making at most $\beta(d)$ calls to $\mathcal{B}^d$. Furthermore, the work done by* SEARCH *in addition to the oracle calls is $O(|\mathcal{H}|)$.*

In reality, the above references have proofs of this result for the case where Λ is a single point, but the proof extends easily to the case where Λ is a convex set. By repeatedly applying algorithm SEARCH, we can resolve all functions in $\mathcal{H}$ with $O(\log|\mathcal{H}|)$ oracle calls. In this section, we shall prove a weighted version of Theorem 2.1. Let S be a set on which a weight function $w : S \to \mathbf{R}^+$ has been defined. For $S' \subseteq S$, we write $w(S')$ to denote $\sum_{s \in S'} w(s)$. We have the following result.

THEOREM 2.2. *For each $d \geq 0$, there exist constants $\beta(d)$ and $\alpha(d)$, $\alpha \leq 1/2$, and an algorithm* WEIGHTED-SEARCH *with the following property. Given a set $\mathcal{H}$ of affine functions and a weight function $w : \mathcal{H} \to \mathbf{R}^+$,* WEIGHTED-SEARCH *either returns an affine function h such that* $\text{sign}_\Lambda(h) = 0$ *or finds a subset $\mathcal{H}' \subseteq \mathcal{H}$ with $w(\mathcal{H}') \geq \alpha(d) \cdot w(\mathcal{H})$ and resolves every $h \in \mathcal{H}'$ by making at most $\beta(d)$ calls to $\mathcal{B}^d$. Furthermore, the work done by* WEIGHTED-SEARCH *in addition to the oracle calls is $O(|\mathcal{H}|)$.*

The proof of this theorem will require some preliminary results, which are discussed next.

2.1. Preliminaries. Procedure WEIGHTED-SEARCH uses two simple algorithms. The first is MATCH, which, given two sets A and B, attempts to match disjoint subsets of B with elements of A in a "greedy" manner.

```
ALGORITHM MATCH
Input: Sets $A = \{a_1, \ldots, a_{|A|}\}$ and $B = \{b_1, \ldots, b_{|B|}\}$ and a weight function $w$ :
    $A \cup B \to \mathbf{R}^+$.
Output: Either FAILURE or disjoint sets $S_1, \ldots, S_{|A|}$ such that, for each $i$, $S_i = \{a_i\} \cup D_i$
    where $D_i \subseteq B$ and $w(D_i) \geq w(a_i)$.
begin
    $j \leftarrow 1$
    for $i = 1$ to $|A|$ do begin
        $D_i \leftarrow \emptyset$
        while $w(D_i) < w(a_i)$ do begin
            if $j > |B|$ then return FAILURE
            $D_i \leftarrow D_i \cup b_j$
            $j \leftarrow j + 1$
        end
        $S_i \leftarrow \{a_i\} \cup D_i$
    end;
    return $S_1, \ldots, S_{|A|}$
end
```

The running time of this algorithm is clearly $O(|B|)$. We shall say that MATCH *succeeds* if it does not return FAILURE. If MATCH succeeds, then the solution returned obviously satisfies its output conditions. The next lemma gives one scenario in which MATCH always succeeds.

LEMMA 2.3. *If* $\min_{x\in A} w(x) \geq \max_{y\in B} w(y)$ *and* $w(B) \geq 2w(A)$, *then* MATCH *succeeds. Furthermore, each set* $S_i = \{a_i\} \cup D_i$ *returned by* MATCH *satisfies* $w(D_i) < 2w(a_i)$.

Proof. (This is a proof by contradiction.) Suppose the conditions of the lemma hold and that MATCH returns FAILURE. Then there exists a k, $1 \leq k \leq |A|$, such that, at the kth iteration of the **for** loop, MATCH runs out of elements of B to match up with a_k; i.e., $w(D_k) < w(a_k)$ and $B = \cup_{i=1}^{k} D_i$, where $D_1, \ldots, D_k$ are the subsets of B constructed by MATCH up to this point. Thus, $\sum_{j=1}^{k} w(D_j) = w(B)$. For $j = 1, \ldots, k$, let $D_j = \{d_{j1}, d_{j2}, \ldots, d_{jl_j}\}$. By construction, for $1 \leq j \leq k-1$, $w(D_j) - w(d_{jl_j}) < w(a_j)$. Thus, for $1 \leq j \leq k-1$, $w(D_j) < w(a_j) + w(d_{jl_j}) \leq 2w(a_j)$, as $\min_{x\in A} w(x) \geq \max_{y\in B} w(y)$. Together with the above-mentioned fact that $w(D_k) < w(a_k)$, we get that

$$w(B) = \sum_{j=1}^{k} w(D_j) < \sum_{j=1}^{k} 2w(a_j) \leq 2w(A),$$

which is a contradiction. Therefore, MATCH succeeds, and for each set $S_i = \{a_i\} \cup D_i$, $w(D_i) < 2w(a_i)$. □

MATCH is invoked by the following algorithm.

ALGORITHM PAIRING

Input: Sets A, B, a weight function $w : A \cup B \to \mathbf{R}^+$, and a number m such that $W/2 \geq w(B) \geq w(A) \geq (W/2 - m)$, where $W = w(A \cup B) + m$.

Output: $k \geq 0$ disjoint sets $S_1, \ldots, S_k$, and an element e satisfying the following conditions:

(P1) Each S_i has the form $S_i = \{c_i\} \cup D_i$, where $e \neq c_i$, and either
(1) for all i, $e, c_i \in A$ and $D_i \subseteq B$, or
(2) for all i, $e, c_i \in B$ and $D_i \subseteq A$.
(P2) for all i, $2w(c_i) > w(D_i) \geq w(c_i)$.
(P3) $\sum_{i=1}^{k} w(c_i) + w(e) + m \geq W/6$.

Note: In order to break ties between items with equal weights, we assume an arbitrary but fixed ordering among the elements in A and in B. Given any two elements x and y, where either both are in A or both are in B, we will say that x precedes y if $(w(x), x)$ is lexicographically smaller than $(w(y), y)$.

Step 1. Find $a \in A$ and $b \in B$ such that $w(A_1), w(B_1) \leq w(A)/3$ and $w(A_1 \cup \{a\}), w(B_1 \cup \{b\}) \geq w(A)/3$, where $A_1 = \{x \in A : x \text{ precedes } a\}$ and $B_1 = \{x \in B : x \text{ precedes } b\}$. Let $A_2 = A - A_1$ and $B_2 = B - B_1$.

Step 2. If $w(a) \geq w(b)$, do the following steps.

Step 2(a). If $w(a) + m \geq W/6$, then return $k = 0$ and $e = a$.

Step 2(b). Call MATCH with inputs A_1 and B_2. Let $S_1, \ldots, S_{|A_1|}$ be the sets returned by this call. Return $S_1, \ldots, S_{|A_1|}$, and $e = a$.

Step 3. If $w(a) < w(b)$, do the following steps.

Step 3(a). If $w(b) + m \geq W/6$, then return $k = 0$ and $e = b$.

Step 3(b). Call MATCH with inputs B_1 and A_2. Let $S_1, \ldots, S_{|B_1|}$ be the sets returned by this call. Return $S_1, \ldots, S_{|B_1|}$ and $e = b$.

LEMMA 2.4. PAIRING *correctly computes output satisfying conditions* (P1)–(P3).

Proof. If the output is returned in Step 2(a) or Step 3(a), the conditions are trivially satisfied. We now consider Step 2(b); the analysis for Step 3(b) is similar. By construction, $\min_{x\in A_1} w(x) \geq \max_{y\in B_2} w(y)$ and $w(B_2) \geq 2w(A)/3 \geq 2w(A_1)$. Since the conditions of Lemma 2.3 are satisfied, MATCH succeeds and conditions (P1) and (P2) are satisfied. Since MATCH works correctly, we have $\sum_{i=1}^{|A_1|} w(c_i) = w(A_1)$. Therefore, $\sum_{i=1}^{k} w(c_i) + w(e) + m =$

$w(A_1) + w(a) + m$. Because $w(A_1) + w(a) \geq w(A)/3$,

$$\sum_{i=1}^{k} w(c_i) + w(e) + m \geq w(A)/3 + m \geq (w(A) + m)/3.$$

Since $w(A) + m \geq W/2$, we obtain

$$\sum_{i=1}^{k} w(c_i) + w(e) + m \geq W/6$$

as desired. □

PAIRING can be implemented to run in $O(n)$ time, where $n = |A| + |B|$. Step 1 takes $O(n)$ time as elements a and b can be found by repeated median finding [12]. Steps 2 and 3 also take linear time, since MATCH takes linear time.

2.2. The search algorithm. We shall now prove Theorem 2.2. The implementation of WEIGHTED-SEARCH that we propose is an extension of Megiddo's [27] and Dyer's [17] algorithms for unweighted multidimensional search (see Theorem 2.1). Suppose $\mathcal{H} = \{h_1, \ldots, h_n\}$, where $h_i(\lambda) = a_i^T \lambda + d_i$. If $a_i = 0$, sign(h_i) is simply the sign of d_i, and no oracle calls are needed. Thus, the presence of h_i's with $a_i = 0$ can only help. We shall henceforth assume that $a_i \neq 0$, for $i = 1, \ldots, n$. In this case, each affine function h_i corresponds to a hyperplane $H_i \in \mathbf{R}^d$, where $H_i = \{\lambda : h_i(\lambda) = 0\}$. Computing sign$(h_i)$ is thus equivalent to determining whether H_i intersects Λ and, if not, which side of H_i contains Λ. We shall find it convenient to deal interchangeably with hyperplanes and affine functions and to extend the weight function w to these hyperplanes by making $w(H_i) = w(h_i)$.

The numbers $\beta(d)$ and $\alpha(d)$ are derived recursively with respect to the dimension. For $d = 1$, the hyperplanes are n real numbers $\lambda_1, \ldots, \lambda_n$. In this case, WEIGHTED-SEARCH finds the weighted median λ_m, inquires about its position relative to λ^*, and resolves either $\{\lambda_i : \lambda_i \leq \lambda_m\}$ or $\{\lambda_i : \lambda_i \geq \lambda_m\}$. Thus, $\beta(1) = 1$ and $\alpha(1) = 1/2$. For $d \geq 2$ we proceed as follows.

Form a set $\mathcal{H}_\infty = \{H_i : a_{i2} = 0\}$. Each $H_i \in \mathcal{H} - \mathcal{H}_\infty$ intersects the λ_1–λ_2 plane (i.e., the plane where $\lambda_i = 0$ for $i \notin \{1, 2\}$) in a straight line $a_{i1}\lambda_1 + a_{i2}\lambda_2 = b_i$. Since for every scalar $l \neq 0$, sign$(h(\lambda)) =$ sign$(l) \cdot$ sign$(h(\lambda)/l)$, we can rewrite the equations of these hyperplanes so that $a_{i1} \geq 0$. Let the *slope* α_i of H_i be the same as that of $a_{i1}\lambda_1 + a_{i2}\lambda_2 = b_i$ with respect to $\lambda_2 = 0$; i.e., let $\alpha_i = (-a_{i1}/a_{i2})$. Let α^* be the weighted median of the set $\{\alpha_i\}$ where the weight of α_i is $w(H_i)$. Now we make the slopes of roughly weighted half of the hyperplanes nonnegative and weighted half nonpositive by using the change of variables $\lambda_2 = \lambda_2' + \alpha^*\lambda_1$ and $a_{i1} = a_{i1}' - \alpha^* a_{i2}$. This change of variables is only done to simplify the exposition and, indeed, needs to be reversed before making an oracle call. For convenience, we now drop the primes on λ_2' and a_{i1}'. Recalculate the slopes of the hyperplanes after making this change in variables. All hyperplanes that originally had a slope of α^* will have 0 slope. Let $\mathcal{H}_0 = \{H_i : \alpha_i = 0\}$, $\mathcal{H}_- = \{H_i : \alpha_i < 0\}$, and $\mathcal{H}_+ = \{H_i : \alpha_i > 0\}$.

Let $m = w(\mathcal{H}_\infty) + w(\mathcal{H}_0)$ and $W = w(\mathcal{H})$. Since 0 is our new weighted median slope, $w(\mathcal{H}_-) \leq (W - w(\mathcal{H}_\infty))/2 \leq W/2$ and $w(\mathcal{H}_-) + w(\mathcal{H}_0) \geq (W - w(\mathcal{H}_\infty))/2$. Therefore, $w(\mathcal{H}_-) \geq W/2 - w(\mathcal{H}_\infty)/2 - w(\mathcal{H}_0) \geq W/2 - m$. Similarly, $W/2 \geq w(\mathcal{H}_+) \geq (W/2 - m)$. Thus, sets $\mathcal{H}_-$, $\mathcal{H}_+$ and the number m satisfy the preconditions of PAIRING—assuming, without loss of generality, that $w(\mathcal{H}_-) \leq w(\mathcal{H}_+)$. WEIGHTED-SEARCH calls PAIRING$(\mathcal{H}_-, \mathcal{H}_+, m)$. Let $S_1, \ldots, S_l$, e be the sets and the element returned, where $S_i = \{c_i\} \cup D_i$. By output condition (P3) of PAIRING,

$$\sum_{i=1}^{l} w(c_i) + w(e) + m \geq W/6. \tag{1}$$

Next, we resolve the hyperplane associated with e, denoted by H_e, by calling the oracle directly. If H_e intersects Λ, we return H_e; otherwise, for the hyperplanes corresponding to elements in $S_1, \ldots, S_l$, we do the following.

Suppose that for each set $S_i = \{c_i\} \cup D_i$, c_i corresponds to a hyperplane $H_i \in \mathcal{H}_-$ and that D_i has a corresponding set of hyperplanes $\{H_{i1}, H_{i2}, \ldots, H_{iq_i}\} \subseteq \mathcal{H}_+$. (The analysis for the case where c_i is associated with a hyperplane in $\mathcal{H}_+$ is completely analogous.) For each i, form pairs $(H_i, H_{i1}), (H_i, H_{i2}), \ldots, (H_i, H_{iq_i})$. By Lemma 2.3, for each i and j,

$$w(H_{ij}) \leq w(H_i). \tag{2}$$

Consider a typical pair (H_i, H_{ij}). Since H_i and H_{ij} have strictly negative and strictly positive slopes, respectively, their intersection is a $(d-1)$-dimensional hyperplane. Through this intersection, we can draw hyperplanes $H_{ij}^{(1)}$ and $H_{ij}^{(2)}$ whose slopes are $+\infty$ and 0 respectively. Mathematically,

$$H_{ij}^{(1)}: \quad (a_{i2}a_{ij1} - a_{i1}a_{ij2})\lambda_1 = (a_{i2}b_{ij} - a_{ij2}b_i) - \sum_{r=3}^{d}(a_{i2}a_{ijr} - a_{ij2}a_{ir})\lambda_r,$$

$$H_{ij}^{(2)}: \quad (a_{i2}a_{ij1} - a_{i1}a_{ij2})\lambda_2 = (a_{ij1}b_i - a_{i1}b_{ij}) - \sum_{r=3}^{d}(a_{ij1}a_{ir} - a_{i1}a_{ijr})\lambda_r.$$

Note that $H_{ij}^{(1)}$ and $H_{ij}^{(2)}$ are $(d-1)$-dimensional hyperplanes. Now, assign a weight of $\min(w(H_i), w(H_{ij}))$ to each of $H_{ij}^{(1)}$ and $H_{ij}^{(2)}$. From equation (2), we get that $\min(w(H_i), w(H_{ij})) = w(H_{ij})$. This along with condition (P2) of PAIRING gives us

$$\sum_{r=1}^{q_i} w(H_{ir}^{(1)}) = \sum_{r=1}^{q_i} w(H_{ir}^{(2)}) = \sum_{r=1}^{q_i} w(H_{ir}) \geq w(c_i) = w(H_i). \tag{3}$$

Recursively apply WEIGHTED-SEARCH to the set of $(d-1)$-dimensional hyperplanes $\{H_{ij}^{(1)}\} \cup \mathcal{H}_\infty$. This requires $\beta(d-1)$ oracle calls. If an oracle call finds a hyperplane that intersects Λ, we return that hyperplane. Otherwise, let W_∞ and W_1 denote the weights of the hyperplanes resolved from sets $\mathcal{H}_\infty$ and $\{H_{ij}^{(1)}\}$, respectively, and let $w(\{H_{ij}^{(1)}\}) = \sum_{i=1}^{l}\sum_{r=1}^{q_i} w(H_{ir})$. Then,

$$W_\infty + W_1 \geq \alpha(d-1)\Big(w(\mathcal{H}_\infty) + w(\{H_{ij}^{(1)}\})\Big). \tag{4}$$

Let $\mathcal{H}^{(2)}$ be the set of hyperplanes in $\{H_{ij}^{(2)}\}$ for which the corresponding $H_{ij}^{(1)}$'s have been resolved in the previous step. Recursively apply WEIGHTED-SEARCH to the set of $(d-1)$-dimensional hyperplanes in $\mathcal{H}^{(2)} \cup \mathcal{H}_0$. This requires at most $\beta(d-1)$ oracle calls. As before, if we find a hyperplane which intersects Λ, we return that hyperplane; otherwise, we proceed as follows. Letting W_0 and W_{12} denote the weights of the hyperplanes resolved from sets $\mathcal{H}_0$ and $\mathcal{H}^{(2)}$, respectively, we have

$$W_0 + W_{12} \geq \alpha(d-1)(w(\mathcal{H}_0) + W_1). \tag{5}$$

To summarize the algorithm up to this point, observe that we have either found a hyperplane which intersects Λ or, from the original set $\mathcal{H}$, we have resolved an element e of weight $w(e)$, a subset of weight W_∞ of the planes in $\mathcal{H}_\infty$, and a subset of weight W_0 of the planes in $\mathcal{H}_0$. In addition to this, we have resolved a subset of weight W_1 of the hyperplanes in set $\{H_{ij}^{(1)}\}$ and a subset of weight W_{12} of the hyperplanes in set $\mathcal{H}^{(2)}$. For each hyperplane contributing to W_{12}, we have also resolved its pair in the set $\{H_{ij}^{(1)}\}$. However, W_1 and W_{12} represent the total weights of sets of auxiliary hyperplanes, rather than elements of $\mathcal{H}$. We shall now show that by resolving such auxiliary hyperplanes, we are guaranteeing the resolution of sufficiently many hyperplanes from $(\mathcal{H}_- \cup \mathcal{H}_+) - \{H_e\}$.

LEMMA 2.5. *Let W_a be the total weight of the hyperplanes resolved in $(\mathcal{H}_- \cup \mathcal{H}_+) - \{H_e\}$. Then, $W_a \geq W_{12}/2$.*

Proof. Consider a particular set $S_i = \{H_i\} \cup \{H_{i1}, H_{i2}, \ldots, H_{iq_i}\}$. The auxiliary hyperplanes formed by the intersection of hyperplanes in S_i are

$$(H_{i1}^{(1)}, H_{i1}^{(2)}), \ldots, (H_{iq_i}^{(1)}, H_{iq_i}^{(2)}).$$

Suppose $H_{i1}^{(2)}, H_{i2}^{(2)}, \ldots, H_{ip}^{(2)}$ were resolved in the second recursive call. Then these hyperplanes contributed to W_{12}. Hence, the contribution, C_i, of the auxiliary hyperplanes resulting from S_i to W_{12} is $C_i = \sum_{j=1}^{p} w(H_{ij}^{(2)})$, and W_{12} can be written as

$$W_{12} = \sum_{i=1}^{l} C_i. \tag{6}$$

For each $H_{ij}^{(2)}$ that gets resolved, its corresponding $H_{ij}^{(1)}$ has already been resolved in the first recursive call. We now rely on an observation of Megiddo [27], who noted that if we know the position of Λ relative to both $H_{ij}^{(1)}$ and $H_{ij}^{(2)}$, we can determine the position of Λ relative to at least one of H_i and H_{ij}. Let R_i be the sum of the weights of the hyperplanes resolved from S_i. Since $\cup_{i=1}^{l} S_i \subseteq (\mathcal{H}_- \cup \mathcal{H}_+) - \{H_e\}$ and the S_i's are disjoint,

$$W_a \geq \sum_{i=1}^{l} R_i. \tag{7}$$

We have two cases to consider:

Case I. In each pair, H_{ij} is resolved. Then due to equation (3), we have

$$R_i = \sum_{j=1}^{p} w(H_{ij}) = \sum_{j=1}^{p} w(H_{ij}^{(2)}) = C_i.$$

Case II. H_i is resolved in at least one pair. Then equation (3) along with condition (P2) of PAIRING implies that

$$R_i \geq w(H_i) = w(c_i) > \sum_{j=1}^{l} w(H_{ij})/2 \geq \sum_{j=1}^{p} w(H_{ij}^{(2)})/2 = C_i/2.$$

Therefore, in either case $R_i \geq C_i/2$. This along with equations (6) and (7) gives us the following:

$$W_a \geq \sum_{i=1}^{l} R_i \geq \sum_{i=1}^{l} C_i/2 = W_{12}/2.$$

Therefore, $W_a \geq W_{12}/2$. □

Let W_T be the total weight of the hyperplanes from $\mathcal{H}$ that are resolved by our algorithm; i.e., $W_T = w(e) + W_\infty + W_0 + W_a$. Using Lemmas 2.4 and 2.5 and equations (3)–(5), we have

$$\begin{aligned}
W_T &\geq w(e) + W_\infty + W_0 + W_{12}/2 \\
&\geq w(e) + W_\infty + \alpha(d-1) \cdot (w(\mathcal{H}_0) + W_1)/2 \\
&\geq w(e) + \alpha(d-1) \cdot \left(w(\mathcal{H}_0) + \alpha(d-1) \cdot (w(\mathcal{H}_\infty) + w(\{H_{ij}^{(1)}\})) \right)/2 \\
&\geq \alpha(d-1)^2 \cdot \left(w(e) + w(\mathcal{H}_0) + w(\mathcal{H}_\infty) + \sum_{i=1}^{l} w(c_i) \right)/2 \\
&\geq \alpha(d-1)^2 \cdot W/12.
\end{aligned}$$

From the preceding discussion, we conclude that the number of oracle calls satisfies $\beta(d) = 2\beta(d-1) + 1$, with $\beta(1) = 1$, and that the fraction of the total weight satisfies $\alpha(d) \geq \alpha(d-1)^2/12$, with $\alpha(1) = 1/2$. Hence, $\beta(d) = 2^d - 1$ and $\alpha(d) = 12/24^{2^{d-1}}$.

The same arguments as in [17] can be used to show that the total work done by WEIGHTED-SEARCH is $O(n)$. We omit the details.

2.3. Improving the efficiency of the search. Following Dyer [17], the *efficiency* of a search scheme is the ratio $e = \alpha(d)/\beta(d)$. As for unweighted search, the efficiency of a weighted search scheme will affect the running time of the algorithms that use the scheme as a subroutine. The search scheme we have just presented has e that is doubly exponentially small in d. Borrowing ideas from [17], we shall sketch how to make the efficiency singly exponentially small.

Let us write $\mathcal{S}(d, \beta, \alpha)$ to denote a weighted search scheme that, given a set of weighted affine functions in $\mathbf{R}^d$ of total weight W, resolves a fraction of total weight $\alpha \cdot W$ using β oracle calls. Thus, the algorithm that we have developed can be denoted by $\mathcal{S}(d, 2^d - 1, 12/24^{2^{d-1}})$. Suppose that we have an $\mathcal{S}(d-1, \beta(d-1), \alpha(d-1))$ scheme S_{d-1}. To obtain a search procedure for $\mathbf{R}^d$, proceed as follows. First, construct a $\mathcal{S}(d-1, \beta', \alpha')$ procedure with

$$\alpha' = 1 - (1 - \alpha(d-1))^r \quad \text{and} \quad \beta' = r \cdot \beta(d-1)$$

by carrying out r iterations, each of which consists of applying S_{d-1} and removing the hyperplanes that are resolved. Next, use $\mathcal{S}(d-1, \beta', \alpha')$ and the pairing scheme described earlier to obtain a procedure $\mathcal{S}(d, \beta'', \alpha'')$, where

$$\alpha'' = [1 - (1 - \alpha(d-1))^r]^2/12 \quad \text{and} \quad \beta'' = 2 \cdot r \cdot \beta(d-1) + 1.$$

Applying this procedure l times gives us a procedure $\mathcal{S}(d, \beta(d), \alpha(d))$ that solves d-dimensional hyperplanes with

$$\beta(d) = l \cdot \beta'' = l(2r \cdot \beta(d-1) + 1)$$

and

$$\alpha(d) = 1 - (1 - \alpha'')^l = 1 - \left\{ 1 - \frac{1}{12}[1 - (1 - \alpha(d-1))^r]^2 \right\}^l.$$

We can use this framework to obtain a scheme $\mathcal{S}(d, \beta(d), \alpha(d))$, where $\alpha(d) \geq 1/12$ for all d. For $d = 1$, we can easily obtain a scheme $\mathcal{S}(1, 1, 1/2)$. Suppose $\alpha(d-1) \geq 1/12$. If we choose $l = 2$ and $r = 15$, we get

$$\alpha(d) = 1 - \left\{ 1 - \frac{1}{12}[1 - (1 - 1/12)^{15}]^2 \right\}^2 \geq 1/12$$

as desired. Now

$$\beta(d) = 2 \cdot (2 \cdot 15 \cdot \beta(d-1) + 1) \leq 2(60^{d-1}),$$

and we have a procedure $\mathcal{S}(d, 2(60^{d-1}), 1/12)$ whose efficiency is singly exponentially small.

3. Convex optimization in fixed dimension. An algorithm is *piecewise affine* if the only operations it performs on intermediate values that depend on the input numbers are additions, multiplications by constants, copies, and comparisons [14], [15]. Several well-known algorithms fall into this category, including many network-optimization algorithms [13], [33]. Suppose $\mathcal{Q} \subseteq \mathbf{R}^d$ is a (possibly empty) convex set defined by a set of at most l linear inequalities, where l is some fixed integer. Let $g : \mathcal{Q} \to \mathbf{R}$ be a concave function. Our goal is to compute

$$g^* = \max\{g(\lambda) : \lambda \in \mathcal{Q}\} \tag{8}$$

or, if $\mathcal{Q} = \emptyset$, to return a message that this problem is infeasible. Cohen and Megiddo [14], [15] showed that, if g is computable by a piecewise affine algorithm that runs in time T and makes D sets of at most M comparisons, then problem (8) can be solved in $O((D \log M)^d T)$ time. Closely related results were obtained by Norton, Plotkin, and Tardos [29] and Aneja and Kabadi [4]. Toledo has extended this work to problems involving piecewise polynomial functions [34]. The main result of this section is to show that weighted multidimensional search in conjunction with Cole's circuit-simulation technique [16] can sometimes be used to solve (8) in $O((D^d + \log^d M)T)$ time.

To streamline the presentation, for the most part we shall omit any mention of constants that depend on d. The magnitude of these values is discussed in §3.3.

3.1. The basic scheme. We now review the solution scheme of Megiddo and Cohen [14], [15] and Aneja and Kabadi [4] as it forms the basis for our algorithm. Our presentation is somewhat simpler, among other reasons because it avoids the notion of "minimal weak approximation" used in [14]. We shall assume that problem (8) is bounded. This is done without loss of generality, since unbounded problems can be handled by Seidel's technique of adding "constraints at infinity" [32]. Note also that if g is computable by a piecewise affine algorithm, it is the lower envelope of a finite set of linear functions [14]. We say that a linear function $f : \mathbf{R}^d \to \mathbf{R}$ is *active* at $\lambda^{(0)} \in \mathcal{Q}$ if $g(\lambda^{(0)}) = f(\lambda^{(0)})$ and $g(\lambda) \leq f(\lambda)$ for all $\lambda \in \mathcal{Q}$ and we shall write Λ to denote the set of maximizers of g.

Let us refer to the algorithm that solves a d-dimensional problem of the form (8) as algorithm $\mathcal{C}^d$. Let H be a hyperplane in $\mathbf{R}^d$, and let g_H^* denote the maximum of g on H; i.e.,

$$g_H^* = \max\{g(\lambda) : \lambda \in H \cap \mathcal{Q}\}.$$

Suppose we have an oracle $\mathcal{B}^d$ that, as in §2, returns $\text{sign}_\Lambda(h)$ for any given affine function h. Moreover, if h defines a hyperplane H, $\mathcal{B}^d$ returns g_H^*, assuming $H \cap \mathcal{Q} \neq \emptyset$.

Obviously, $\mathcal{A}$ can play the role of $\mathcal{C}^0$. For $d \geq 1$, $\mathcal{C}^d$ proceeds as follows. First, it determines whether $\mathcal{Q}$ is empty and, if so, returns a message saying that (8) is infeasible. Since $\mathcal{Q}$ is defined by a fixed number of linear inequalities, this takes $O(1)$ time. If $\mathcal{Q} \neq \emptyset$, $\mathcal{C}^d$ uses Megiddo's algorithm simulation technique [25], [26] to do one of two things. The first option is to find a hyperplane H defined by $h(\lambda) = 0$ such that $\text{sign}_\Lambda(h) = 0$. Then, clearly, $g^* = g_H^*$. The second option is to find a linear function f and a set of linear inequalities $\mathcal{L}$ defining a nonempty convex set $\mathcal{Q}^* \subseteq \mathcal{Q}$ such that

(C1) $\mathcal{Q}^* \subseteq \Lambda$ and

(C2) f is active at every $\lambda \in \mathcal{Q}^*$.

In this case, solving (8) reduces to solving the linear programming problem

$$\max\{f(\lambda) : \lambda \in \mathcal{Q}^*\},$$

which can be done in time linear in $\mathcal{L}$, since d is fixed [27]. Algorithm $\mathcal{C}^d$ relies on the observation that, because $\mathcal{A}$ is piecewise affine and its inputs are linear functions of λ, all the intermediate values of its real variables can be represented implicitly as linear forms in λ. Using this representation, a single computation path of $\mathcal{A}$, may correspond to the evaluation of $g(\lambda)$ for a *set* of distinct λ-values.

Suppose that for $s \leq r$, we know how to find a set $\mathcal{Q}' \subset \mathbf{R}^d$ defined by a set of linear inequalities $\mathcal{L}$ such that $\mathcal{Q}' \cap \Lambda \neq \emptyset$ and such that the outcomes of the first r steps of any computation path of $\mathcal{A}$ for every $\lambda^* \in \mathcal{Q}'$ are exactly the same (when values are represented implicitly). We wish to find such a set for $s = r + 1$. Before proceeding, note that finding $\mathcal{Q}'$ when $s = 0$ is trivial, since we can choose $\mathcal{Q}' = \mathcal{Q}$. For $s = r + 1$, observe that knowing the outcomes of the first r steps tells us what the $(r + 1)$st step of $\mathcal{A}$ will be; we now need to determine the outcome of this step. If the $(r+1)$st step is an addition of two or more numbers, a multiplication by a constant, or an assignment, $\mathcal{C}^d$ does the corresponding operations with linear forms and proceeds to the next step of $\mathcal{A}$.

If the $(r+1)$st step is a comparison between two variables, $\mathcal{C}^d$ compares the corresponding linear forms $f_1(\lambda)$ and $f_2(\lambda)$ using $\mathcal{B}^d$ to resolve the function $h(\lambda) = f_1(\lambda) - f_2(\lambda)$. Suppose $h(\lambda) = 0$ defines a hyperplane H. If $\text{sign}_\Lambda(h) = 0$, then g^* is the value of g^*_H returned by the oracle, and $\mathcal{C}^d$ halts. Otherwise, $\mathcal{C}^d$ updates $\mathcal{L}$ by adding the inequality $h(\lambda) > 0$ if $\text{sign}(h) = +1$ or the inequality $h(\lambda) < 0$ if $\text{sign}(h) = -1$. The next step to be simulated from $\mathcal{A}$ will be the action corresponding to $f_1(\lambda) > f_2(\lambda)$ or $f_1(\lambda) < f_2(\lambda)$ depending on whether $\text{sign}(h)$ is $+1$ or -1. If h is a constant function, the oracle's job is trivial, since the outcome of the comparison is independent of λ and the simulation proceeds accordingly.

If $\mathcal{C}^d$ simulates $\mathcal{A}$ to completion, $\mathcal{Q}'$ will satisfy condition (C1). Furthermore, the output of $\mathcal{A}$ will be a linear function f satisfying condition (C2). Since $\mathcal{A}$ does $O(T)$ comparisons, $|\mathcal{L}| = O(T)$ and the resulting linear program in d variables can be solved in $O(T)$ time [27]. The total time for algorithm $\mathcal{C}^d$ is therefore $O(T \cdot b(d))$, where $b(d)$ is the running time of $\mathcal{B}^d$. We now turn our attention to the implementation of $\mathcal{B}^d$.

Implementing the oracle. Let $h(\lambda) = \sum_{i=1}^{d} a_i\lambda_i + b$ be the function to be resolved. If $a_i = 0$ for $i = 1, \ldots, n$, $\text{sign}(h)$ depends simply on the sign of b. Otherwise, $H = \{\lambda : h(\lambda) = 0\}$ is a hyperplane in $\mathbf{R}^d$. To resolve h, $\mathcal{B}^d$ first determines if $H \cap \mathcal{Q} = \emptyset$. If this is so, then, since $\Lambda \subseteq \mathcal{Q}$, we simply need to find a point $\lambda^{(0)} \in \mathcal{Q}$ and evaluate $\text{sign}_{\{\lambda^{(0)}\}}(h)$. Determining if the intersection of H and $\mathcal{Q}$ is nonempty and finding a point inside $\mathcal{Q}$ take $O(1)$ time, since $\mathcal{Q}$ is defined by a set of $O(l)$ linear inequalities and l is fixed.

From now on, assume $H \cap \mathcal{Q} \neq \emptyset$. Now, if $\Lambda \cap H = \emptyset$, due to concavity of g, the set of all points λ' such that $g(\lambda') > g^*_H$ is contained in only one side of H. This observation leads to the following result, which is the basis for the implementation of $\mathcal{B}^d$.

LEMMA 3.1. *Let $H = \{\lambda : h(\lambda) = 0\}$ be a hyperplane in $\mathbf{R}^d$, and for every real number a, let $H(a)$ denote the hyperplane given by $H(a) = \{\lambda : h(\lambda) = a\}$. Then,*

$$sign_\Lambda(h) = \begin{cases} +1 & \textit{if } (\exists\epsilon > 0)[g^*_{H(\epsilon)} > g^*_H], \\ -1 & \textit{if } (\exists\epsilon > 0)[g^*_{H(-\epsilon)} > g^*_H], \\ 0 & \textit{otherwise}. \end{cases}$$

Furthermore, if $sign_\Lambda(h) = +1$ $[sign_\Lambda(h) = -1]$, then $g^*_{H(\gamma)} > g^*_H$ $[g^*_{H(-\gamma)} > g^*_H]$ for all $\gamma \in (0, \epsilon]$, where $\epsilon > 0$ is sufficiently small.

The lemma tacitly assumes that $H(\epsilon) \cap \mathcal{Q} \neq \emptyset$ $[H(-\epsilon) \cap \mathcal{Q} \neq \emptyset]$ for some $\epsilon > 0$. If $H(\epsilon) \cap \mathcal{Q} = \emptyset$ $[H(-\epsilon) \cap \mathcal{Q} = \emptyset]$ for every $\epsilon > 0$, we can immediately conclude that

$\text{sign}(h) \neq +1$ [$\text{sign}(h) \neq -1$]. Thus, we shall continue assuming that $H(\epsilon) \cap \mathcal{Q} \neq \emptyset$ and $H(-\epsilon) \cap \mathcal{Q} \neq \emptyset$ for some $\epsilon > 0$.

Lemma 3.1 implies that we can implement $\mathcal{B}^d$ by computing g_H^*, $g_{H(\epsilon)}^*$ and $g_{H(-\epsilon)}^*$ for sufficiently small $\epsilon > 0$. Computing g_H^* is a $(d-1)$-dimensional problem of the same form as that of computing g^*; hence, g_H^* can be calculated by recursively calling $\mathcal{C}^{d-1}$. We can also compute $g_{H(\epsilon)}^*$ using $\mathcal{C}^{d-1}$, provided $\mathcal{C}^{d-1}$ treats ϵ as a symbolic constant whose only known attribute is being arbitrarily small and positive. (The details of computing $g_{H(-\epsilon)}^*$ are analogous and therefore omitted.) The output $g_{H(\epsilon)}^*$ of this execution of $\mathcal{C}^{d-1}$ will depend linearly on ϵ; i.e., $g_{H(\epsilon)}^* = g_0 + g_1\epsilon$. The values of $g_{H(\epsilon)}^*$ and g_H^* are compared by computing $y = \text{sign}(g_H^* - g_{H(\epsilon)}^*) = \text{sign}((g_H^* - g_0) - g_1\epsilon)$. If $|g_H^* - g_0| > 0, d = \text{sign}(g_H^* - g_0)$, since ϵ is arbitrarily small. Otherwise, $d = \text{sign}(-g_1)$, since ϵ is positive. Of course, $\mathcal{C}^{d-1}$ will itself call $\mathcal{B}^{d-1}$, which will introduce a perturbation of its own. In order to deal effectively with the various symbolic perturbations, we shall establish a certain ordering among them.

The state of the execution of $\mathcal{C}^d$ is partially described by sequence of currently active procedure calls (i.e., calls that have not yet been completed). Let us follow one sequence of procedure calls $\mathcal{C}^d \to \mathcal{B}^d \to \mathcal{C}^{d-1} \to \mathcal{B}^{d-1} \to \cdots \to \mathcal{B}^{d-r+1} \to \mathcal{C}^{d-r}$. Within this sequence, for $0 \leq j \leq r-1$, $\mathcal{B}^{d-j} \to \mathcal{C}^{d-j-1}$ corresponds to one of the three calls to $\mathcal{C}^{d-j-1}$ done by $\mathcal{B}^{d-j}$; we refer to this part of the sequence as *level* j. Each level reduces the dimension of the problem by one. Also, depending on which of the three calls the level corresponds to, the call may or may not introduce a perturbation. If it does, we shall refer to the perturbation as ϵ_j. Let $\mathcal{J} = \{i_1, \ldots, i_s\} \subseteq \mathcal{I} = \{0, \ldots, r\}$ consist of all j's such that a perturbation is introduced up to level j. We assume that $0 \leq i_1 \leq r$ and, for $0 \leq j \leq s-1$, $0 \leq i_j < i_{j+1} \leq r$. The set $\mathcal{J}$ indicates which perturbations are "active" at the current stage of the execution of $\mathcal{C}^d$. The problem to be solved at level r can thus be expressed as

$$g_r^* = \max\{g(\lambda) : \lambda \in \mathcal{Q}'(\epsilon_{i_1}, \ldots, \epsilon_{i_s})\},$$

where $\mathcal{Q}'(\epsilon_{i_1}, \ldots, \epsilon_{i_s})$ is a $(d-r)$-dimensional subset of $\mathbf{R}^d$ defined by the intersection of $O(d)$ linear inequalities in $\{\lambda_i\}$ and $\epsilon_{i_1}, \ldots, \epsilon_{i_s}$.

Now, suppose $\mathcal{C}^{d-r}$ invokes $\mathcal{B}^{d-r}$ to resolve a hyperplane

$$H(\epsilon_{i_1}, \ldots, \epsilon_{i_s}) = \{\lambda : h(\lambda, \epsilon_{i_1}, \ldots, \epsilon_{i_s}) = 0\}.$$

For every real number a, let $H'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}, a) = \{\lambda : h(\lambda, \epsilon_{i_1}, \ldots, \epsilon_{i_s}) = a\}$. Then, applying Lemma 3.1, $\mathcal{B}^d$ solves three problems:

$$\begin{aligned}
g_{r+1}^*(0) &= \max\{g(\lambda) : \lambda \in \mathcal{Q}'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}) \cap H'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}, 0)\},\\
g_{r+1}^*(\epsilon_{r+1}) &= \max\{g(\lambda) : \lambda \in \mathcal{Q}'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}) \cap H'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}, \epsilon_{r+1})\},\\
g_{r+1}^*(-\epsilon_{r+1}) &= \max\{g(\lambda) : \lambda \in \mathcal{Q}'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}) \cap H'(\epsilon_{i_1}, \ldots, \epsilon_{i_s}, -\epsilon_{r+1})\},
\end{aligned}$$

where $\epsilon_{r+1} > 0$. By Lemma 3.1, if there exists an $\epsilon_{r+1} > 0$ such that $g_{r+1}^*(\epsilon_{r+1}) > g_{r+1}^*(0)$, then $g_{r+1}^*(\gamma) > g_{r+1}^*$ for *any* $\gamma \in (0, \epsilon_{r+1}]$. Thus, when dealing symbolically with ϵ_{r+1}, we can assume that it is arbitrarily smaller than any one of $\epsilon_{i_1}, \ldots, \epsilon_{i_s}$. By the same reasoning, when dealing with perturbations $\epsilon_{i_1}, \ldots, \epsilon_{i_s}$, we can always act under the assumption that

$$0 < \epsilon_{i_s} \ll \epsilon_{i_{s-1}} \ll \cdots \ll \epsilon_{i_2} \ll \epsilon_{i_1} \ll 1. \tag{9}$$

Since $\mathcal{A}$ is piecewise affine, all numbers manipulated at any level of the execution of $\mathcal{C}^d$ are linear forms in the λ_i's and the ϵ_i's. Suppose the execution of $\mathcal{C}^d$ produces a sequence of procedure calls that eventually triggers a comparison between two values. If the values involve λ (and, possibly, some ϵ_i's), the comparison will be handled by an oracle call. Otherwise, we will be comparing linear forms in the $\epsilon_i's$. For a correct implementation of $\mathcal{C}^d$, it suffices to deal properly with the second kind of comparison. Suppose the two numbers have the form $u = u_0 + \sum_{j=1}^{s} u_j \epsilon_{i_j}$ and $v = v_0 + \sum_{j=1}^{s} v_j \epsilon_{i_j}$. We must compute sign$(t)$, where $t = t_0 + \sum_{j=1}^{s} t_j \epsilon_{i_j}$ and $t_j = u_j - v_j$, $j = 1, \dots, s$. Obviously, if $t_j = 0$ for $j = 0, 1, \dots, s$, sign$(t) = 0$. Otherwise, there is a smallest subscript d, $0 \leq d \leq s$, such that $|t_d| > 0$. By (9), $\epsilon_{i_{d+1}}, \dots, \epsilon_{i_s}$ can be assumed to be arbitrarily smaller than ϵ_{i_d}. Thus sign$(t) =$ sign(t_d). We should note that the use of perturbation techniques is common in mathematical programming [13], [31], one example being the *lexicographic rule* applied in the simplex algorithm. These methods have also found applications in computational geometry [18]. An earlier application of perturbation methods to parametric computing was given by Megiddo [28].

Let $c(d)$ be the running time of $\mathcal{C}^d$. Since at any level, the number of perturbations that $\mathcal{C}^j$ will have to deal with is d, and d is fixed, the running time of $\mathcal{C}^j$ will be the same, asymptotically, whether it deals with a perturbed or an unperturbed problem. As we have seen, $c(d)$ is $O(T \cdot b(d))$, where $b(d)$ is the running time of $\mathcal{B}^d$, and $b(d)$ is $O(c(d-1))$ because $\mathcal{B}^d$ is implemented via three recursive calls to $\mathcal{C}^{d-1}$. Since $c(0) = O(T)$, we conclude that $c(d)$ is $O(T^{d+1})$.

3.2. Speeding up the search. The main bottleneck in algorithm $\mathcal{C}^d$ is the need to apply oracle $\mathcal{B}^d$ to each affine function generated during the simulation of algorithm $\mathcal{A}$. One way to reduce this problem is to arrange things so that by using a small number of oracle calls, we are able to resolve a large number of functions. Megiddo [26] proposed a way to do this in the context of one-dimensional problems, an idea that has subsequently been used in multidimensional optimization [14], [29]. Megiddo's approach is to simulate the execution of a *parallel* algorithm $\mathcal{A}$ for computing $g(\lambda)$ rather than a sequential one. Suppose $\mathcal{A}$ uses M processors and carries out at most D parallel steps. In each step of the simulation, a *batch* of at most M comparisons is carried out. In $\mathcal{C}^d$'s simulation of $\mathcal{A}$, each such comparison has an associated affine function h which can be resolved using $\mathcal{B}^d$. Every parallel step produces a set of $O(M)$ hyperplanes. By using Theorem 2.1, we either resolve these $O(M)$ hyperplanes with $O(\log M)$ oracle calls or find a hyperplane H which intersects Λ. In the latter case, we reduce the original problem to the $(d-1)$-dimensional problem of computing the maximum g_H^* on $H \cap \Lambda$, because this maximum will also be a global maximum. Since $\mathcal{B}^d$ is implemented by making at most three recursive calls to $\mathcal{C}^{d-1}$, the running time of $\mathcal{C}^d$ is $O(c(d-1) \cdot D \cdot \log M + T)$, where $c(d)$ denotes the running time of $\mathcal{C}^d$. Since $c(0) = O(T)$, the running time of $\mathcal{C}^d$ will be $O((D \log M)^d T)$.

Cole [16] showed that one can improve on Megiddo's results for certain important special cases. Like Megiddo's method, Cole's technique applies to one-dimensional parametric search problems, but we shall show that it can be extended to higher dimensions. What follows shall require some elementary knowledge of *combinational circuits* as described, say, in [12]. A *combinational circuit* $\mathcal{G}$ is a directed acyclic graph whose nodes are *combinational elements* (e.g., adders, min gates, etc.) and where an edge from element e_1 to element e_2 implies that the output of e_1 is an input to e_2. Elements of zero fan-in are *inputs*; elements of zero fan-out are *outputs*. An element is said to be *active* if all its inputs are known, but the associated operation has not been carried out yet. An element is said to have been *resolved* when the associated operation has been carried out.

Now, suppose that the algorithm $\mathcal{A}$ simulated by $\mathcal{C}^d$ is implemented as a combinational circuit $\mathcal{G}$ (which is given to us explicitly) of width M and depth D, whose elements are multiplier gates where one of the two inputs is a constant, min gates, adders, and subtractors. Megiddo's approach would simulate $\mathcal{G}$ level by level, in D steps, where each step would carry out the operations of the gates at a given level. The operations within a level would be carried out using Theorem 2.1, with $O(\log M)$) calls to the oracle $\mathcal{B}^d$. In Cole's approach, each step only resolves a fixed fraction of of the active nodes, using only a constant number of oracle calls. The choice of which nodes to resolve is guided by a weight function $w : V(\mathcal{G}) \to \mathbf{R}$. To describe the strategy precisely, we will need some notation. The *active weight*, W, of the circuit is the sum of the weights of its active elements. Let $\alpha \leq 1/2$ be a positive number. An *α-oracle with respect to w* — or simply an α-oracle — is a procedure that is guaranteed to resolve a set of active elements whose total weight is at least $\alpha W/2$. The following is a restatement and an extension of a result in [16].

LEMMA 3.2. *Let $\mathcal{G}$ be a combinatorial circuit of width M and depth D. Let $d_{\min} = \min\{d_I, d_O\}$, where d_I (d_O) denotes the maximum fan-in (fan-out) of an element of $\mathcal{G}$. Then, there exists a weight function w such that $\mathcal{G}$ can be evaluated with $O(D \log d_{\min} + \log M)$ calls to an α-oracle with respect to w.*

Proof. Let the weight function w be defined as follows. The weight of each output element is 1, and the weight of each internal element is twice the sum of weights of its immediate descendants. Then scale the weights to make the total weight of input elements equal to M.

LEMMA 3.3. *At the start of the $(k+1)$st iteration, $k \geq 0$, the active weight is at most $(1-\alpha/2)^k \cdot M$.*

Proof. By induction on k. The result holds for $k = 0$ since, at the start of the first iteration, only the input elements are active and their total weight is M. To prove the inductive step, it suffices to show that at each iteration the active weight is reduced by a factor of at least $\alpha/2$.

Suppose element e is resolved. Then e ceases to be active, but all its descendants may become active. Hence, the resolution of e reduces the active weight by at least $w(e)/2$. Let the active weight of the network be W. In one step, the α-oracle resolves a set of elements whose total weight is at least $\alpha \cdot W$. Thus, in one step, the active weight is reduced from W to $(1-\alpha/2)W$. □

LEMMA 3.4. *The weight of any circuit element is at least $(2d_{\min})^{-D}$.*

Proof. After the initial weight assignment, but prior to scaling, the total weight of the elements at depth j is at most $M(2d_{\min})^{D-j}$. Thus, the total weight of the input nodes is at most $M(2d_{\min})^D$. Hence the scaling factor is at most $(2d_{\min})^D$. Since, prior to scaling, every element has a weight of at least 1, after scaling the weight of any circuit element will be at least $(2d_{\min})^{-D}$. □

LEMMA 3.5. *Let $\gamma = c(D \log 2d_{\min} + \log M)$, where $c = \lfloor 1 - 1/\log_2(1-\alpha/2) \rfloor$. Then, there will be no active elements after $k \geq \gamma$ iterations.*

Proof. First, observe that

$$\begin{aligned} \gamma &> -(D \log 2d_{\min} + \log M) / \log_2(1-\alpha/2) \\ &= -\left(\log M \cdot (2d_{\min})^D\right) / \log_2(1-\alpha/2) \\ &= \log_{(1-\alpha/2)} (M \cdot (2d_{\min})^D)^{-1}. \end{aligned} \tag{10}$$

By Lemma 3.3, the active weight at the start of the $(k+1)$st iteration is at most $(1-\alpha/2)^k \cdot M$. Using (10) and the fact that $(1-\alpha/2)$ is less than 1, we have

$$\begin{aligned} (1-\alpha/2)^k \cdot M &\leq (1-\alpha/2)^\gamma \cdot M \\ &< (1-\alpha/2)^{\log_{(1-\alpha/2)}(M \cdot (2d_{\min})^D)^{-1}} \cdot M \\ &= (2d_{\min})^{-D}. \end{aligned}$$

As the weight of any element in the circuit is at least $(2d_{\min})^{-D}$ and the active weight is strictly less than this weight, there are no active elements after the kth iteration. □

By Lemma 3.5, there will be no active elements after $c(D \log 2d_{\min} + \log M)$ steps, where c depends only on α. Thus, $\mathcal{G}$ can be evaluated with $O(D \log d_{\min} + \log M)$ calls to an α-oracle. □

In order to use Lemma 3.2, we need to give an efficient implementation of the α-oracle. We will actually implement a slight variant of the α-oracle, which will allow for early termination of the simulation in case the optimum if found at some intermediate step. Let A be the set of active elements of $\mathcal{G}$ and let $A_1 \subseteq A$ be the set of adders, subtractors, and constant multipliers. Each $e \in T_1$ can be resolved immediately by simply doing the corresponding operation on the input linear forms. The remaining active elements are comparators, every one of which has an associated affine function. Let the set of all such functions be $\mathcal{H} = \{h_1, \ldots, h_n\}$, where h_i is the function associated with $e_i \in A - A_1$, and assign a weight of $w(e_i)$ to h_i. We either resolve a fixed fraction of the functions with $O(1)$ oracle calls using algorithm WEIGHTED-SEARCH of §2 or, if at any point during its execution, WEIGHTED-SEARCH encounters a hyperplane H (even an auxiliary one) such that $H \cap \Lambda \neq \emptyset$, we return g^*_H. In either case, the running time of the α-oracle is $O(c(d-1))$, since each oracle call requires $O(1)$ calls to $\mathcal{C}^{d-1}$. Thus, Lemma 3.2 leads to an implementation of $\mathcal{C}^d$ whose running time is $O(c(d-1)(D + \log M) + D \cdot M)$. Since $c(0) = O(T)$, we can deduce that the running time of $\mathcal{C}^d$ is $O((D^d + \log^d M)T)$ (note that the weight function required for the application of Lemma 3.2 can be computed within this time bound).

3.3. Some remarks on constant factors. The use of schemes involving multidimensional search seems to lead invariably to large constants that depend on d [17]. Using standard techniques [10], [17], it can be shown that the algorithms described in this section have hidden constants of the form $2^{O(d^2)}$, provided the search algorithm with singly exponentially small efficiency is used. Some improvements are possible. For the case where all the weights are powers of 1/4, as would occur if the circuit to be simulated is a comparator-based sorter, we can obtain a search scheme with $\alpha(d) = 1/3$ and $\beta(d) = 2(20^{d-1})$; the details are technical and hence omitted. Using this improved scheme, the running time of the optimization algorithm will still have a constant of the form $2^{O(d^2)}$, but the constant inside the O will be smaller.

4. Solving the Lagrangian dual when the number of constraints is fixed. The method of Lagrangian relaxation, originally developed by Held and Karp [21], [22], is motivated by the observation that many combinatorial problems that are known to be NP-hard can be viewed as easy problems complicated by a relatively small set of side constraints. More formally, we consider optimization problems of the following sort:

$$Z_P = \min\{c^T x : Ax \leq 0, x \in X\}, \tag{11}$$

where c is a $n \times 1$ vector, A is a $d \times n$ matrix, x is a $n \times 1$ vector, and X is a polyhedral subset of $\mathbf{R}^d$. The set of inequalities $Ax \leq 0$ constitutes the complicating set of constraints in the sense that, in its absence, the problem is polynomially solvable.

The *Lagrangian relaxation* of (11) is obtained by pricing out the constraints $Ax \leq 0$ into the objective function by introducing a vector $\lambda = (\lambda_1, \ldots, \lambda_d)$ of Lagrange multipliers as follows:

$$Z_D(\lambda) = \min\{c^T x + \lambda^T Ax : x \in X\}. \tag{12}$$

It is well known that $Z_D(\lambda) \leq Z_P$ for all $\lambda \geq 0$ [20]. Thus, if there is a polynomial-time algorithm to compute $Z_D(\lambda)$ for any fixed $\lambda \geq 0$, problem (12) will provide an efficient way to obtain a lower bound on the solution to (11). Such a bound can be of great utility in branch-and-bound methods. The best lower bound on Z_P attainable via (12) is given by

$$Z^*_D = \max\{Z_D(\lambda) : \lambda \geq 0\}. \tag{13}$$

Problem (13) is the *Lagrangian dual* of (11) with respect to the set of constraints $Ax \leq 0$, and Z_D^* is the *value* of the Lagrangian dual.

Computational experiments have repeatedly shown that Z_D^* provides excellent lower bounds on the optimum solution of Z_P [20], thus motivating the search for efficient algorithms to solve the Lagrangian dual. One widely used method is *subgradient optimization*, first proposed in [22]. Despite its success in practice, this technique is not known to be a polynomial-time algorithm even if (12) can be solved in polynomial time.

It is well known that if $Z_D(\lambda)$ can be computed in polynomial time for each fixed $\lambda \geq 0$, then the Lagrangian dual can be solved in polynomial time [31]. Recently, Bertsimas and Orlin [6] have presented faster polynomial-time algorithms for certain special cases. An issue that has received some attention [4] is whether there exist *strongly polynomial* algorithms to solve the Lagrangian dual. (An algorithm is said to be strongly polynomial if the number of arithmetic operations it carries out is polynomially bounded independently of the magnitudes of the input numbers.) The algorithms discussed above are not strongly polynomial even if $Z_D(\lambda)$ can be computed in strongly polynomial time.

We shall be interested here only in the case where the number d of complicating constraints is fixed. Since Z_D is a concave function [31], if $Z_D(\lambda)$ is computable in strongly polynomial time by a piecewise affine algorithm, the results of Megiddo and Cohen described in §3 imply the existence of strongly polynomial-time algorithms to solve the Lagrangian dual. We focus our attention on two broad families of problems where weighted multidimensional search allows us to obtain faster algorithms than the Megiddo–Cohen approach: matroidal knapsack problems and a class of constrained optimum subgraph problems on graphs of bounded treewidth.

4.1. Matroidal knapsack problems. What follows presupposes some familiarity with matroid theory (see, e.g., [23]). Consider a matroid $\mathcal{M} = (E, \mathcal{G})$ where E, the *ground set*, is a finite set and $\mathcal{G}$ is a collection of certain subsets of E called *independent sets*. We assume that $\mathcal{G}$ is given in a *concise* form; i.e., there is an algorithm with running time $c(n)$, polynomial in $n = |E|$, for finding whether a given subset of E is independent. Suppose each element $e \in E$ has a *value* $v(e)$. In ordinary matroid optimization problems, one must find an optimum *base* (maximal independent set) of maximum total value. The standard algorithm for doing so is the *greedy method*, which first sorts the elements according to value and then considers the elements in nonincreasing order. An element e is added to the current set A if $A \cup \{e\}$ is independent. The greedy algorithm takes time $O(n \log n + nc(n))$.

In *multiconstrained matroidal knapsack* (MMK) problems, in addition to a value, each $e \in E$ has a d-dimensional *size* vector $s(e)$, and there is a d-dimensional *capacity* vector C. The problem is to find a base G^* such that

$$Z^* = \sum_{e \in G^*} v(e) = \max_{G \in \mathcal{G}} \left\{ \sum_{e \in G} v(e) : \sum_{e \in G} s(e) \leq C \right\}.$$

We refer the reader to Camerini et al. [11] for a discussion of the various applications of these problems, as well as for references. MMK problems are in general NP-hard. We can bound Z^* by solving its Lagrangian dual. Let

$$Z_D(\lambda) = \max_{G \in \mathcal{G}} \left\{ \sum_{e \in G} v(e) - \lambda^T \left(\sum_{e \in G} s(e) - C \right) \right\}.$$

The Lagrangian dual is

$$Z_D^* = \min\{Z_D(\lambda) : \lambda \geq 0\}. \tag{14}$$

In [11], Camerini et al. outline an algorithm for (14) whose running time is not guaranteed to be polynomial. Noting that the crucial first stage of the greedy method (where all comparisons are done) can be carried out in parallel using an $O(\log n)$-depth, $O(n)$-width sorting circuit [2], we can use the Cohen–Megiddo technique to obtain an $O((n\log n+n\cdot c(n))\cdot\log^{2d} n)$ algorithm using the approach outlined in §3, with the greedy algorithm playing the role of algorithm $\mathcal{A}$. Using Lemma 3.2, and the weighted multidimensional search algorithm, we obtain a $O((n\log n + n\cdot c(n))\cdot \log^d n)$ algorithm. We note that if the underlying matroidal problem has a more specialized structure (e.g., if it is the spanning tree problem), even faster algorithms are possible.

4.2. Constrained optimum subgraph problems. Optimum subgraph problems have the following form. Given a graph G with real-valued vertex and edge weight functions $w_V : V(G) \to \mathbf{R}$ and $w_E : E(G) \to \mathbf{R}$, respectively, find an optimum (i.e., minimum- or maximum-weight) subgraph H satisfying a property P. Well-known examples of such problems are minimum-weight dominating set, minimum-weight vertex cover, and the traveling salesman problem. Let us write $\mathsf{val}_G(H)$ to denote $\sum_{v\in V(H)} w_V(v) + \sum_{e\in E(H)} w_E(e)$, where H is a subgraph of G. We can express all optimum subgraph problems as

$$(15)\qquad z_G^P = \operatorname{opt}\{\mathsf{val}_G(H) : H \text{ a subgraph of } G \text{ satisfying } P\},$$

where "opt" is either "min" or "max," depending on the problem.

Even though many optimum subgraph problems are known to be NP-complete, several researchers have developed methodologies for devising linear-time algorithms for graphs of *bounded tree-width* [3], [5], [8], [9], [7], [35] (for a definition of tree-width, see [30]). While their approaches differ from each other in several respects, in essence they all deal with subgraph problems that have certain "regularity" properties that make them amenable to dynamic programming solutions. The class of regular problems is broad, and includes the subgraph problems mentioned above, as well as many others, such as the maximum cut problem and the Steiner tree problem (see, e.g., [3], [9], [7]).

Suppose that, in addition to a weight function, every $v \in V(G)$ ($e \in E(G)$) has a d-dimensional size vector $s_V(v)$ ($s_E(e)$). The problem is to solve (15) subject to the knapsack-like constraint

$$\sum_{v\in V(H)} s_V(v) + \sum_{e\in E(H)} s_E(e) \le t,$$

where t is a d-dimensional capacity vector. Even if the unconstrained problem is solvable in polynomial time, the constrained one may be NP-hard. Such is the case, for example, for the dominating set problem on trees (which are graphs of tree-width 1) even if $d = 1$ [24].

For every $v \in V(G)$, let $W_V(v,\lambda) = w_V(v) + \lambda^T s_V(v)$ and for every $e \in E(G)$, let $W_E(e,\lambda) = w_E(e) + \lambda^T s_E(e)$. Let us write $\mathsf{Val}_G(H,\lambda)$ to denote $\sum_{v\in V(H)} W_V(v,\lambda) + \sum_{e\in E(H)} W_E(e,\lambda)$, where H is a subgraph of G. The Lagrangian relaxation of problem (15) is

$$(16)\qquad Z_G^P(\lambda) = \operatorname{opt}\{\mathsf{Val}_G(H,\lambda) : H \text{ a subgraph of } G \text{ satisfying } P\}.$$

If property P is regular, there exists an $O(n)$-time algorithm to compute $Z_G^P(\lambda)$ for any fixed λ. Also, as proved in [19], there exists an $O(n)$-size, $O(\log n)$-depth combinational circuit that computes $Z_G^P(\lambda)$ for any fixed λ. Thus, the results of Cohen and Megiddo summarized in §3 imply that the Lagrangian dual can be solved in $O(n\log^{2d} n)$ time. Using weighted multidimensional search and Lemma 3.2, we can improve this to $O(n\log^d n)$.

Acknowledgment. We thank the referee for several useful comments.

RAY SHOOTING AMIDST CONVEX POLYHEDRA AND POLYHEDRAL TERRAINS IN THREE DIMENSIONS*

PANKAJ K. AGARWAL† AND MICHA SHARIR‡

Abstract. We consider the problem of ray shooting in a three-dimensional scene consisting of m (possibly intersecting) convex polyhedra or polyhedral terrains with a total of n faces, i.e., we want to preprocess them into a data structure, so that the first intersection point of a query ray and the given polyhedra can be determined quickly. We present a technique that requires $O((mn)^{2+\varepsilon})$ preprocessing time and storage, and can answer ray-shooting queries in $O(\log^2 n)$ time. This is a significant improvement over previously known techniques (which require $O(n^{4+\varepsilon})$ space and preprocessing) if m is much smaller than n, which is often the case in practice. Next, we present a variant of the technique that requires $O(n^{1+\varepsilon})$ space and preprocessing, and answers queries in time $O(m^{1/4}n^{1/2+\varepsilon})$, again a significant improvement over previous techniques when $m \ll n$.

1. Introduction.

The *ray-shooting* problem can be defined as follows:

> *Given a collection Γ of n objects in $\mathbb{R}^d$, preprocess Γ into a data structure so that one can quickly determine the first object of Γ intersected by a query ray.*

The ray-shooting problem has received much attention in the last few years because of its applications in computer graphics and other geometric problems [1], [3], [4], [5], [6], [9], [10], [14], [17], [21], [28]. Most of the work to date studies the planar case, where Γ is a collection of line segments in $\mathbb{R}^2$. Chazelle and Guibas proposed an optimal algorithm for the special case where Γ is the boundary of a simple polygon [17]. Their algorithm answers a ray-shooting query in $O(\log n)$ time using $O(n)$ space; simpler algorithms, with the same asymptotic performance bounds, were recently developed in [14] and [22]. If Γ is a collection of arbitrary segments in the plane, the best-known algorithm answers a ray-shooting query in time $O(\frac{n}{\sqrt{s}} \log^{O(1)} n)$ using $O(s^{1+\varepsilon})$ space and preprocessing[1] [1], [6], [9], where s is a parameter that varies between n and n^2. Although no lower bound is known for this case, it is conjectured that this bound is close to optimal. In spite of some recent developments, the three-dimensional ray-shooting problem seems much harder and it is still far from being fully solved. The general three-dimensional ray-shooting problem is to preprocess a collection of n triangles, so that the first triangle hit by a query ray can be computed efficiently. If the triangles are the faces of a convex polyhedron, then an optimal algorithm, with $O(\log n)$ query time and linear space, can be obtained using the hierarchical decomposition scheme of Dobkin and Kirkpatrick [20]. If the triangles form a *polyhedral terrain* (a piecewise-linear surface intersecting every vertical line in ex-

[1] Throughout this paper, bounds of this kind mean that, given any arbitrarily small positive constant ε, the algorithm can be fine-tuned so that its performance satisfies the bound; the multiplicative constants in such bounds usually depend on ε and tend to ∞ as $\varepsilon \downarrow 0$.

actly one point), then the technique of Chazelle et al. [15] yields an algorithm that requires $O(n^{2+\varepsilon})$ space and answers ray-shooting queries in $O(\log n)$ time. Nontrivial solutions to the general problem were obtained only recently; see [4], [6], and [10] for some of these results. The best-known algorithm for ray shooting among triangles in three dimensions is due to Agarwal and Matoušek [5]; it answers a ray-shooting query in time $O(\frac{n^{1+\varepsilon}}{s^{1/4}})$ after $O(s^{1+\varepsilon})$ space and preprocessing. The parameter s can range between n and n^4. If s assumes its maximum value, queries can be answered in $O(\log n)$ time; see [5], [6], and [28] for more details. We remark that no nontrivial lower bounds are known for the three-dimensional problem as well, although such bounds are known for the related *simplex range-searching* problem [12], which is used as a subprocedure in the solutions just mentioned.

The performance of these algorithms is rather inefficient when n is large, so a natural objective is to find special cases where this performance can be improved. The case that we consider here is where the three-dimensional scene is formed by m convex polyhedra or polyhedral terrains with a total of n faces (general nonconvex polyhedra can be decomposed into convex pieces and be replaced by these pieces). In many typical instances of the problem m is much smaller than n; for example, curved objects, like balls, cylinders, cones, etc., are usually approximated by a polyhedron with a large number of faces. Our goal is to develop an algorithm whose performance depends on both m and n, and is much better than that of the general technique when $m \ll n$.

In this paper we achieve this goal, presenting a technique that uses $O((mn)^{2+\varepsilon})$ storage and answers ray-shooting queries in $O(\log^2 n)$ time. Our algorithm is the first algorithm for ray shooting among convex polyhedra (or polyhedral terrains) whose performance depends on both m and n and matches the performance of [5] when $m \approx n$. We also present another algorithm that answers a query in time $O(m^{1/4}n^{1/2+\varepsilon})$ using $O(n^{1+\varepsilon})$ space and preprocessing, so it matches the bound of [5] when $m \approx n$, but is considerably faster when $m \ll n$.

In [7] we have presented an algorithm to preprocess a collection of m convex polygons in the plane, with a total of n vertices, into a data structure of size $O(mn \log m)$, so that a ray-shooting query can be answered in $O(\log^2 n \log^2 m)$ time. If the polygons are disjoint, or the starting point of the ray always lies in the common exterior of the polygons, then the space and preprocessing can be improved to $O((m^2 + n) \log m)$. The algorithm works even for a collection of disjoint simple polygons.

A problem related to ray shooting among a collection of convex polyhedra in three dimensions is the so-called *stabbing problem*, where one wants to determine whether a query line intersects all polyhedra. This problem seems to be easier than the ray-shooting problem: Pellegrini and Shor [29] have described a data structure of size $O(n^{2+\varepsilon})$ that can answer a stabbing query in $O(\log n)$ time.

We will first describe, in §2, the overall structure of the algorithm. We next present, in §3, an algorithm for detecting an intersection between a query segment and a collection of convex polyhedra or polyhedral terrains, which is the main subroutine used in our algorithm. For the sake of convenience, we describe the algorithm only for a collection of convex polyhedra, but the same technique works for polyhedral terrains as well. Next, in §4, we develop a variant of the technique for answering a query efficiently if only close-to-linear space is allowed. In §5, we give an application of our results to translational motion planning in $\mathbb{R}^3$: given m convex polyhedral obstacles, with a total of n faces, and a polyhedral object B, with k vertices, free to translate amidst them, we show how to preprocess them in time and space $O((kmn)^{2+\varepsilon})$, so that, given any free placement z of B and direction $\mathbf{u}$, we can compute in time $O(\log^2 kn)$ the first obstacle to be hit as B is translated from z in direction $\mathbf{u}$. Again, this is a substantial improvement over previous results when $m \ll kn$. We conclude in §6 with a discussion of our results and a few open problems.

2. The overall algorithm. Let $\mathcal{P} = \{P_1, \ldots, P_m\}$ be a set of m convex polyhedra, let n_i be the number of edges in P_i, and put $n = \sum_{i=1}^{m} n_i$ (we prefer to have n denote the total number of edges, rather than the number of faces, of the P_i's; by Euler's relation, these two quantities differ only by a small multiplicative factor). Without loss of generality assume that each face of P_i is triangulated; otherwise we can triangulate all faces of P_i by adding $O(n_i)$ additional edges. For the sake of convenience, we split the boundary of each P_i into its top portion (visible from $z = +\infty$) and its bottom portion (visible from $z = -\infty$). We construct separate data structures for the top portions and for the bottom portions, and answer a ray-shooting query by searching in both structures and by selecting the output point nearest to the ray origin. In what follows we describe only the data structure for the top portions of the given polyhedra; with a slight abuse of notation, we will refer to these top portions also as "polyhedra." We note that this step is not required if the P_i's are polyhedral terrains.

Our general ray-shooting scheme is based on the parametric searching technique of Agarwal and Matoušek [4]. In this technique we build a data structure for solving *segment-intersection detection* queries, each asking whether a query segment e intersects any of the (top portions of the) given polyhedra. Given a query ray ρ, we replace it by the segment aw, where a is the origin of ρ and w is the first point of intersection between ρ and the given polyhedra. We query the data structure with the segment aw. Of course, we do not know w (our goal is to find it!), so we feed our data structure with a generic, unspecified input w. As we will see below, each step of the algorithm asks a question of the following form: given a query point p and a hyperplane h, determine whether p lies above, below, or on h; here p is either the origin a of ρ, the Plücker point of the line containing ρ, or the generic point w. In the first two cases, we can answer the question in $O(1)$ time. To determine the position of w with respect to a plane h, it is sufficient to determine whether a and w lie on the same side of h. We compute the intersection point σ of ρ and h. If ρ does not intersect h, we can immediately conclude that a and w lie on the same side of h. Otherwise, we invoke the segment-intersection detection procedure with the segment $a\sigma$. If $a\sigma$ intersects any of the polyhedra in $\mathcal{P}$, then a and w lie on the same side of h; otherwise they lie on the opposite sides of h. This also restricts the allowed range of w. When the algorithm terminates, we obtain the exact location of w, thereby answering the original ray-shooting query. It is shown in [4] that the performance of this parametric searching technique is only slightly worse (by a logarithmic factor) than the cost of a single (explicit) segment-intersection detection query; see [4] for more details.

3. Segment-intersection detection. We now present an algorithm for the segment-intersection detection problem, i.e., preprocess $\mathcal{P}$ into a data structure, so that one can quickly determine whether a query segment intersects any of the polyhedra in $\mathcal{P}$. In this section we aim to achieve fast (polylogarithmic) query time, at the expense of storage and preprocessing. The opposite case, that of using only close-to-linear storage at the expense of query time, will be studied in §4. We will construct two data structures. The first one, denoted as $\Psi_1(\mathcal{P})$, determines whether e intersects a face of some P_i whose xy-projection does not contain any of the endpoints of the xy-projection of e. The second data structure, denoted as $\Psi_2(\mathcal{P})$, determines whether e intersects a face of some P_i whose xy-projection contains one of the endpoints of the xy-projection of e. Throughout this section we will use γ^* to denote the xy-projection of an object γ in $\mathbb{R}^3$, and A^* to denote $\{\gamma^* \mid \gamma \in A\}$ for a set A of such objects.

3.1. First data structure. In this subsection we describe a data structure $\Psi_1(\mathcal{P})$ that determines whether the query segment intersects a face of some P_i whose projection does not contain any endpoint of e^*. Let E_i denote the set of edges of P_i. We project them onto the xy-plane, and let E_i^* denote the set of resulting projected segments. Let $E^* = \bigcup_{i=1}^{m} E_i^*$. We

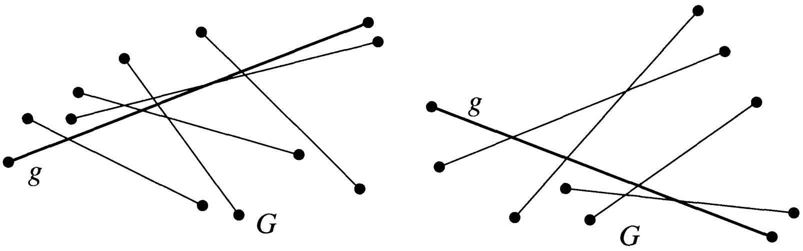

FIG. 1. *A canonical subset G of the output for a query segment g*; (i) *g intersects all segments of G from below*; (ii) *g intersects all segments of G from above.*

preprocess E^* into a data structure of size $O(n^{2+\varepsilon})$, using a variant of the technique described in Agarwal and Sharir [6], so that the set of all segments of E^* intersected by a query segment in the xy-plane can be represented as $O(\log n)$ pairwise disjoint precomputed subsets. The algorithm of [6] constructs a multilevel partition tree on E^*. Roughly speaking, it stores a family of subsets of E^*, called *canonical subsets*, into a tree-like data structure. There are at most $O((n/2^j)^{2+\varepsilon})$ canonical subsets of size between 2^{j-1} and 2^j. For a given query segment g, the canonical subsets that form the query output can be computed in $O(\log n)$ time, and there is a constant number of output subsets of size between 2^{j-1} and 2^j for each $j = 0, 1, \ldots$. Furthermore, for each canonical subset G of the query output, either the left endpoints of all segments in G lie above the line containing the query segment g, or all of them lie below that line. In the first case g, considered as a rightward-directed segment, intersects all of these segments from below, and in the second case it intersects all of them from above. (In the xy-plane, a rightward-directed segment g is said to intersect another segment e from "below" if they intersect and the left endpoint of e lies above the line containing g; intersection from "above" is defined symmetrically; see Fig. 1.) See [4] and [6] for details. In what follows we only consider the case where g intersects all segments of G from below.

Let Γ^* be a canonical subset of E^*, and let Γ be the set of corresponding pohyhedra edges, and put $\nu = |\Gamma^*|$. Let $\Gamma_i^* = \Gamma^* \cap E_i^*$, and let $\mu \leq \nu$ denote the number of nonempty Γ_i^*'s. Set $s = \lceil \nu/\mu \rceil$. We orient the edges of Γ^* from left to right. We preprocess Γ so that, for a (directed) query line ℓ in $\mathbb{R}^3$ whose xy-projection intersects all segments of Γ^*, one can quickly determine whether ℓ passes above or below the edges in Γ. The way in which we have oriented the xy-projections of the edges in Γ and of ℓ ensures that the above/below relationships between ℓ and these edges are determined solely by the sign of the *relative orientations* between ℓ and the lines containing these edges. This will enable us to determine whether a query segment intersects any of the given polyhedra, as will be described in more detail below. The relative orientation of two oriented lines ℓ, λ in $\mathbb{R}^3$ is defined to be the orientation of any simplex $abcd$, where $a, b \in \ell$, $c, d \in \lambda$, so that ℓ is oriented from a to b and λ is oriented from c to d. Equivalently, it is also the sign of the inner product between the two vectors in projective 5-space representing the *Plücker coordinates* of the two lines. (For the sake of convenience, we will not distinguish between the projective 5-space and the affine 5-space $\mathbb{R}^5$.) To be more precise, ℓ can be mapped to a point $\pi(\ell)$, called a *Plücker point*, and λ can be mapped to a hyperplane $\varpi(\lambda)$, called a *Plücker hyperplane*, in $\mathbb{R}^5$, so that ℓ has positive orientation with respect to λ if and only if $\pi(\ell)$ lies above the hyperplane $\varpi(\lambda)$. The Plücker points of all lines in $\mathbb{R}^3$ lie on a quadric surface, known as the *Plücker surface*, in $\mathbb{R}^5$. More details concerning Plücker's coordinates and relative orientations can be found in [15] and [31].

Recall that we are only preprocessing the upper portions of the polyhedra, which implies that the (relative) interiors of edges of Γ_i^* are pairwise disjoint. We define a linear ordering for a set G of t nonintersecting segments in the xy-plane: let e, e' be two segments in G; $e \prec e'$ if the x-projections of e and e' overlap and e' lies above e along a vertical line (parallel to the y-axis), if the x-projections of e and e' are disjoint and e lies to the left of e'. This is indeed a linear ordering, and it can be computed in $O(t \log t)$ time, as shown by Guibas, Overmars, and Sharir [21]. They have also shown that, for any $e, e' \in G$, if $e \prec e'$ and a rightward-directed line intersects both of them from below, then it intersects e before e'.

We sort each Γ_i^* according to this ordering and, abusing the notation slightly, we denote the resulting sequence also by Γ_i^*. Suppose $\Gamma_i^* = (e_0^*, e_1^*, \ldots, e_{t_i}^*)$. We mark the first, the last, and every sth edge of Γ_i^*, i.e., we mark e_0^*, e_s^*, $e_{2s}^*, \ldots, e_{t_i}^*$. For each marked edge e_{sj}^*, let $\Gamma(e_{sj}) = \{e_{sj+1}, e_{sj+2}, \ldots, e_u\}$, where $u = \min\{t_i, (s+1)j\}$, be the set of edges of P_i whose xy-projections form the block of edges of Γ_i^* following e_{sj}^* and ending at the next marked edge. Let G be the set of edges of polyhedra in $\mathcal{P}$ corresponding to the marked segments of Γ^*, each oriented so that its xy-projection is rightward directed; note that

$$|G| \le \sum_i \left(\left\lceil \frac{t_i}{s} \right\rceil + 1 \right) \le \sum_i \left(\frac{t_i}{s} + 2 \right) \le \frac{\mu}{\nu} (\sum_i t_i) + 2\mu \le 3\mu .$$

We will construct on G a data structure based on a partitioning scheme due to Chazelle, Sharir, and Welzl [18]. For a segment $\gamma \in \mathbb{R}^3$, this structure decomposes G further into canonical subsets, so that, for each canonical subset of G, either all the corresponding original polyhedra edges lie above γ or all of them lie below γ. Next, for each canonical subset Q in the output, we determine whether there is an edge in some $\Gamma(e)$, for $e \in Q$, that passes on the other side of γ, thereby implying that γ intersects the polyhedron P_i containing e. In more detail, this is done as follows.

Map the (directed) line containing each segment of G to its Plücker hyperplane in $\mathbb{R}^5$; let H denote the set of resulting hyperplanes, and put $t = |H| \le 3\mu$. Set r to be some sufficiently large constant. We compute a $(1/r)$-*net* R of H of size $O(r \log r)$. (We call a subset $R \subseteq H$ a $(1/r)$-net if every (relatively open) simplex intersecting more than $|H|/r$ hyperplanes of H intersects a hyperplane of R; it is well known that there exists such an R with the prescribed size.) R can be computed in $O(t)$ time if r is constant [11], [23]. We triangulate the arrangement $\mathcal{A}(R)$. Let Ξ denote the simplices of the triangulation that intersect the Plücker surface. By a result of Aronov, Pellegrini, and Sharir [8], the number of simplices in Ξ is $O(r^4 \log^5 r)$. By construction, each simplex in Ξ intersects at most t/r hyperplanes of H.

For each $\Delta \in \Xi$, let $H_\Delta \subseteq H$ denote the set of hyperplanes that intersect the interior of Δ. We also associate with Δ two other subsets U_Δ and L_Δ of H; U_Δ is the set of hyperplanes that lie fully above Δ, and L_Δ is the set of hyperplanes that lie fully below Δ.

We construct two auxiliary data structures on U_Δ and L_Δ. Let

$$\overline{U}_\Delta = \bigcup \{\Gamma(e) \mid e \text{ is an edge corresponding to a hyperplane in } U_\Delta\},$$
$$\overline{L}_\Delta = \bigcup \{\Gamma(e) \mid e \text{ is an edge corresponding to a hyperplane in } L_\Delta\}.$$

Note that $|\overline{U}_\Delta|, |\overline{L}_\Delta| \le st$. We map the lines containing the edges of $\overline{U}_\Delta$ to their Plücker hyperplanes in $\mathbb{R}^5$ and preprocess their lower envelope for point-location queries, using an algorithm of Clarkson [19]. That is, we preprocess the hyperplanes into a data structure, so that we can quickly determine whether a query point lies below all hyperplanes. Similarly, we map the edges of $\overline{L}_\Delta$ to their Plücker hyperplanes and preprocess their upper envelope for similar point location queries. Each point location structure requires $O((st)^{2+\delta})$ space and preprocessing time, for any $\delta > 0$, and answers a query in $O(\log st)$ time; see [19] for details.

Our data structure needs one more ingredient: for each simplex $\Delta \in \Xi$ and for each polyhedron P_i we consider the first (marked) edge, if any, of Γ_i that contributes a hyperplane to $U_\Delta \cup L_\Delta$. For each such edge e, let f_1, f_2 be the two faces of P_i incident to e (if e is the first or the last edge of Γ_i, it is possible that only one of these faces is defined). Let F_Δ be the collection of at most $2t$ resulting faces. We preprocess F_Δ for segment-intersection detection queries using the techniques described in [5] and [6]. It requires $O(t^{4+\delta})$ space and preprocessing time, for any $\delta > 0$, and can determine in $O(\log t)$ time whether a query segment intersects any triangle in F_Δ.

Finally, we recursively preprocess H_Δ, for each simplex $\Delta \in \Xi$. The recursion stops when $|H_\Delta|$ falls below some specified constant n_0. The resulting structure is a tree $T = T(\Gamma)$ of depth $O(\log n)$, each of whose nodes has degree at most $O(r^4 \log^5 r)$. We repeat the same procedure for all canonical subsets Γ of E. This completes the description of the data structure.

Let us analyze the space and preprocessing time of the above structure. First let us analyze the space required by the tree structure $T(\Gamma)$ constructed on a canonical subset Γ. Let $S(u)$ denote the space required by the subtree of T constructed on a set H_Δ consisting of u hyperplanes. Since the degree of each node in T is $O(r^4 \log^5 r)$, and the auxiliary structure stored at each child requires $O(s^{2+\delta}u^{2+\delta} + u^{4+\delta})$ space, we get the following recurrence:

$$S(u) \le \begin{cases} O(1) & \text{if } u \le n_0, \\ c_1 r^4 \log^5 r \cdot S\left(\frac{u}{r}\right) + c_2(s^{2+\delta}u^{2+\delta} + u^{4+\delta}) & \text{if } u > n_0, \end{cases}$$

where c_1, c_2, and n_0 are some appropriate absolute constants. The solution of this recurrence is

$$S(u) \le A s^{2+\delta'} u^{4+\delta'}, \tag{1}$$

for another $\delta' > 0$ that tends to 0 with δ and for some sufficiently large constant $A = A(\delta')$. Indeed, arguing inductively, (1) obviously holds for $u \le n_0$, and for $u > n_0$ we have

$$\begin{aligned} S(u) &\le c_1 r^4 \log^5 r \cdot S\left(\frac{u}{r}\right) + c_2(s^{2+\delta}u^{2+\delta} + u^{4+\delta}) \\ &\le c_1 r^4 \log^5 r A s^{2+\delta'} \left(\frac{u}{r}\right)^{4+\delta'} + c_2(s^{2+\delta}u^{2+\delta} + u^{4+\delta}) \\ &= A s^{2+\delta'} u^{4+\delta'} \left(\frac{c_1 \log^5 r}{r^{\delta'}} + \frac{c_2}{A}\left(\frac{(su)^{\delta-\delta'}}{u^2} + \frac{u^{\delta-\delta'}}{s^{2+\delta'}}\right)\right) \\ &\le A s^{2+\delta'} u^{4+\delta'}, \end{aligned}$$

provided that $\delta' > \delta$ and r, A are sufficiently large. Hence, the total space required by T is

$$S(t) = O(s^{2+\delta'} t^{4+\delta'}) = O(\lceil \nu/\mu \rceil^{2+\delta'} \mu^{4+\delta'}) = O(\nu^{2+\delta'} \mu^{2+\delta'}),$$

because $\mu \le \nu$. We calibrate δ so that δ' is equal to the original ε. Since there are $O\left((n/2^j)^{2+\varepsilon}\right)$ canonical subsets of E^* of size between 2^{j-1} and 2^j, the overall space required by the data structure is

$$\sum_{j=1}^{\lceil \log n \rceil} O\left(\left(\frac{n}{2^j}\right)^{2+\varepsilon}\right) \cdot O(2^{j(2+\varepsilon)} m^{2+\varepsilon}) = O((mn)^{2+\varepsilon'}),$$

for another $\varepsilon' > 0$ that tends to 0 with ε. Hence the total storage required by the data structure is $O((mn)^{2+\varepsilon})$ for any $\varepsilon > 0$. Following a similar analysis, one can show that the preprocessing time is also $O((mn)^{2+\varepsilon})$.

3.2. Second data structure. Next, we describe the second data structure $\Psi_2(\mathcal{P})$, which, given a query segment γ, determines whether there is a face f of some polyhedron P_i such that γ intersects f and that f^* contains one of the endpoints of γ^*. The data structure is again based on the partitioning scheme due to Chazelle et al. [18]. As in the preceding subsection, we consider here only the top portions of the given polyhedra. Choosing a sufficiently large constant parameter r, we partition the plane, in $O(n)$ time, into a collection Δ of $O(r^2)$ triangles, so that each triangle intersects at most n/r edges of E^* [23]. With each triangle $\Delta \in \Delta$, we associate a subset $E^*_\Delta \subseteq E^*$, and a subset F_Δ of faces of polyhedra in $\mathcal{P}$. An edge e^* belongs to E^*_Δ if the boundary of one of the triangles incident to e^* (i.e., the projected polyhedra faces) intersects Δ. A face f belongs to F_Δ if $\Delta \subset f^*$. It is easily seen that $|E^*_\Delta| \le 5n/r$ and $|F_\Delta| \le m$. We preprocess the triangles of F_Δ for segment-intersection detection queries, as in the first data structure [5], [6]. This structure requires $O(m^{4+\delta})$ space and preprocessing time, for any $\delta > 0$, and answers a query in $O(\log m) = O(\log n)$ time. We recursively preprocess each E^*_Δ and its associated collection of incident faces, and thereby obtain the entire structure. Note that each recursive processing of a set E^*_Δ involves $n_\Delta = O(n/r)$ edges, at most $2n_\Delta$ incident faces, and $m_\Delta \le n_\Delta$ polyhedra to which these edges and faces belong. $\Psi_2(\mathcal{P})$ is thus a tree of height $O(\log n)$.

If we denote by $S'(m,n)$ the maximum space required by $\Psi_2(\mathcal{P})$ for a collection of m polyhedra with n edges, then $S'(m,n)$ satisfies the following recurrence:

$$S'(m,n) \le \begin{cases} O(1) & \text{if } n \le n_0, \\ \sum_{j=1}^{c_1 r^2} S'(m_{\Delta_j}, n_{\Delta_j}) + c_2 m^{4+\delta} & \text{if } n > n_0, \end{cases}$$

where $m_{\Delta_j} \le n_{\Delta_j} \le \frac{5n}{r}$, for each j, and n_0, c_1, c_2 are appropriate constants. The solution of this recurrence is

$$S'(m,n) \le B(mn)^{2+\varepsilon}, \tag{2}$$

for some constant B and another $\varepsilon > 0$ that tends to 0 with δ. Indeed,

$$\begin{aligned} S'(m,n) &\le \sum_{j=1}^{c_1 r^2} S'(m_{\Delta_j}, n_{\Delta_j}) + c_2 m^{4+\delta} \\ &\le c_1 r^2 B \left(\frac{5mn}{r}\right)^{2+\varepsilon} + c_2 m^{4+\delta} \\ &\le B(mn)^{2+\varepsilon} \left(\frac{5^{2+\varepsilon} c_1}{r^\varepsilon} + \frac{c_2}{B} \cdot \frac{m^{\delta-\varepsilon}}{n^\varepsilon} \cdot \left(\frac{m}{n}\right)^2\right) \\ &\le B(mn)^{2+\varepsilon}, \end{aligned}$$

provided that $\varepsilon > \delta$ and r, B are chosen sufficiently large. The last inequality follows from the fact that $m \le n$. A similar analysis yields the same bound on the preprocessing time needed to construct the structure.

3.3. Answering a query. We now describe how to answer a query. Let γ be a query segment in $\mathbb{R}^3$, oriented so that its xy-projection is rightward directed, and let ℓ be the directed line containing γ. We want to determine whether γ intersects any P_i.

DEFINITION 3.1. *A segment γ lies* above *another segment e in $\mathbb{R}^3$ if their xy-projections intersect and the vertical line through this intersection meets γ at a point higher than the point at which it meets e.*

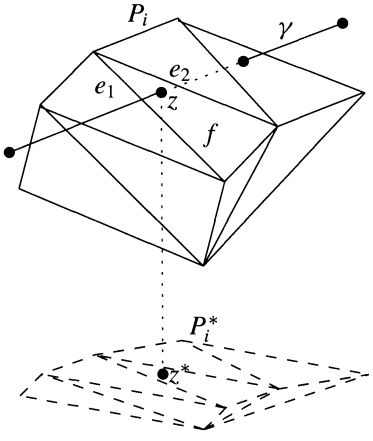

FIG. 2. *Illustration of Lemma* 3.2.

The query answering procedure is based on the following simple lemma.

LEMMA 3.2. *A segment $\gamma = pq$ in $\mathbb{R}^3$ intersects a polyhedron $P_i \in \mathcal{P}$ if and only if at least one of the following two conditions holds:*

(i) *A face of P_i, whose xy-projection contains an endpoint of γ^*, intersects γ.*

(ii) *There is a face f of P_i such that γ lies below (resp., above) one of the edges e_1 of f and lies above (resp., below) another edge e_2 of f. Moreover, assume that γ^* intersects e_2^* after e_1^*; then, for any canonical subset Γ^* of E^* that contains e_2, either e_2^* is the first edge in Γ_i^*, or there is a marked edge e^* in Γ_i^* such that $e_2 \in \Gamma(e)$, and γ lies below (resp., above) e and above (resp., below) e_2.*

Proof. The "if" part is obvious. For the "only if" part, assume that γ intersects P_i but does not intersect the faces of P_i whose projections contain the endpoints of γ^*. Let z be the leftmost intersection point of P_i and γ, and let f be the face of P_i containing z. Since the endpoints of γ^* do not lie in f^*, γ^* completely crosses f^* (see Fig. 2). Let e_1^* and e_2^* be the edges of f^* intersected by γ^* in this order. Since z is the only intersection point of γ and f, either e_1 lies below γ and e_2 lies above γ, or vice-versa.

Assume that e_2 lies above γ. Let Γ^* be a canonical subset of E^* containing e_2^*. If e_2^* is not the first edge in Γ_i^*, then let e^* be the last marked edge in Γ_i^* immediately preceding e_2^*, i.e., $e_2 \in \Gamma(e)$. Recall that the first edge of Γ_i^* is marked, so e^* is always properly defined. Since z is the leftmost intersection point of γ and P_i, and e_2 lies above γ, it is easily seen that e lies below γ. This completes the proof of the lemma. □

In view of the above lemma we can answer a query as follows. First of all, we determine, using $\Psi_2(\mathcal{P})$, whether there is a face f of some polyhedron P_i such that γ intersects f and an endpoint of γ^* lies in f^*. If we find such a face, we stop right away. In more detail, we query the structure with the left endpoint p^* of γ^*. We follow a path in $\Psi_2(\mathcal{P})$ starting from the root. At each node we do the following. If v is a leaf, we determine explicitly whether γ intersects any of the faces associated with v. Otherwise, let Δ be the set of triangles associated with v. We determine (say, by brute force) the triangle $\Delta \in \Delta$ that contains p^*. We query the auxiliary structure to determine whether any face of F_Δ intersects γ. If the answer is yes, we stop. Otherwise we descend to the child of v corresponding to the triangle Δ and recursively search within E_Δ^*. We apply the same procedure to the right endpoint of γ. The correctness of this procedure is easy to verify.

Next, we query $\Psi_1(\mathcal{P})$ with γ. First, we find all segments of E^* intersected by γ^*. Let Γ^* be a canonical subset in the query output. Without loss of generality assume that the left endpoints of all segments in Γ^* lie above γ^*, and all their right endpoints lie below γ^*, so that γ^* intersects all segments of Γ^* from below. In this case γ lies above (resp., below) a segment e of Γ (with both γ^* and e^* being rightward directed) if and only if the relative orientation of γ with respect to e is positive (resp., negative); see [15]. By Lemma 3.2, it suffices to determine whether there is a Γ_i such that either γ intersects a face incident to the first marked edge of Γ_i, or Γ_i contains a marked edge e that lies below (resp., above) γ but an edge of $\Gamma(e)$ lies above (resp., below) γ. We map the (directed) line ℓ containing γ to its Plücker point $\pi(\ell)$ in $\mathbb{R}^5$. We determine the simplex $\Delta \in \Xi$ that contains $\pi(\ell)$ (since $\pi(\ell)$ lies on the Plücker surface, Ξ contains such a simplex). First, we determine in $O(\log n)$ time whether γ intersects any triangle of F_Δ. If the answer is "yes," we stop right away. Otherwise, we continue as follows.

By construction, $\pi(\ell)$ lies above all hyperplanes of L_Δ and below all hyperplanes of U_Δ, and therefore γ lies above (resp., below) all edges e corresponding to the hyperplanes of L_Δ (resp., U_Δ). We now have to determine whether γ lies below (resp., above) any edge in $\overline{L}_\Delta$ (resp., $\overline{U}_\Delta$). To do so, we locate $\pi(\ell)$ in the upper envelope of $\overline{L}_\Delta$ (resp., in the lower envelope of $\overline{U}_\Delta$). If $\pi(\ell)$ does not lie above the upper envelope of $\overline{L}_\Delta$, then $\pi(\ell)$ lies below some hyperplane of $\overline{L}_\Delta$, which implies that γ passes below the corresponding edge, and therefore intersects one of the polyhedra. We handle $\overline{U}_\Delta$ symmetrically. This completes the description of the query answering procedure. The correctness of the procedure is easy to verify, in view of Lemma 3.2.

Let $Q(u)$ be the maximum query time spent at a subtree of T consisting of u hyperplanes. Since we spend $O(\log n)$ time in querying the auxiliary structure stored at u, we get the following recurrence:

$$Q(u) \le Q(u/r) + O(\log u). \tag{3}$$

The solution of (3) is easily seen to be $O(\log^2 u)$ if $r > 1$ is constant, so the total time spent in querying the first data structure, for a fixed canonical set Γ^* of size ν, is $O(\log^2 \nu)$. The solution of (3) can be improved to $O(\log \nu)$ by choosing $r = n^\varepsilon$. However, if $r = \nu^\varepsilon$, we cannot use a brute-force method to find the simplex of the partitioning Ξ in Plücker 5-space, which contains the query point. Instead, we preprocess the hyperplanes containing the facets of simplices in Ξ for answering point location queries using the algorithm of Chazelle and Friedman [16]. Their algorithm preprocesses a collection of n hyperplanes in $\mathbb{R}^d$ into a data structure of size $O(n^{d+\delta})$, so that a point location query can be answered in time $O(\log n)$. Thus, the simplex containing a query point can be computed in time $O(\log \nu)$ using $O((r^4 \log^5 r)^{5+\delta}) = O(r^{10+\delta}) = O(\nu^{\varepsilon(10+\delta)})$ space, for an arbitrarily small constant $\delta > 0$. It is easily seen that this additional structure does not affect the asymptotic bound on the total storage required by T. One can similarly modify the algorithm of Agarwal and Sharir [6], so that the overall query time of the first data structure, summed over all canonical subsets of E^*, also reduces to $O(\log n)$; see [10] and [27] for details. A similar analysis shows that the time spent in querying $\Psi_2(\mathcal{P})$ is $O(\log^2 n)$ if r is chosen to be a constant, and that it can be improved to $O(\log n)$ by choosing $r = n^\varepsilon$, modifying the structure as above.

Hence, we obtain the following theorem.

THEOREM 3.3. *Let $\mathcal{P} = \{P_1, \dots, P_m\}$ be a collection of m (possibly intersecting) convex polyhedra in $\mathbb{R}^3$ with a total of n edges. Given any $\varepsilon > 0$, we can preprocess $\mathcal{P}$ in time $O((mn)^{2+\varepsilon})$ into a data structure of size $O((mn)^{2+\varepsilon})$, so that an intersection between $\mathcal{P}$ and a query segment in $\mathbb{R}^3$ can be detected in $O(\log n)$ time.*

Remark 3.4. Notice that we never used the fact that the P_i's are convex polyhedra. The only property we needed was that the xy-projections of edges in each E_i were pairwise disjoint (and that the projected faces enclosed by the edges of E_i^* formed a simply connected planar region). Hence, the above algorithm also works for polyhedral terrains. We need the nonintersecting property of E_i^* to order the segments of a canonical subset Γ using the algorithm of Guibas, Overmars, and Sharir [21]. This is the only step that does not extend to arbitrary nonconvex polyhedra. We leave it to the reader to verify that our technique does indeed carry over to the case of polyhedral terrains.

We can now plug the above procedure into the general parametric searching procedure of Agarwal and Matoušek [4]. We have explained in §2 how this is done. To complete the description, one has to check that the operations that are performed by the above segment-intersection detection procedure conform to the set-up of §2. In particular, we have to ensure that we can simulate the segment-intersection detection algorithm on the segment $o\sigma$, where o is the starting point of the ray and σ is the (unknown) first intersection point of the query ray and $\mathcal{P}$, as described in §2. First of all, observe that the coordinates of the Plücker point of the line ℓ containing a query segment depend only on ℓ and not on the endpoints of γ, so the data structures constructed on Plücker hyperplanes or Plücker points can be searched explicitly, without having to generate any generic comparison, so no oracle calls are required at all. All the other data structures, constructed in two or three dimensions, are searched either with the endpoints of the query segment, or with their xy-projections, or with the point dual to the line supporting γ^*. For example, the first level of $\Psi_2(\mathcal{P})$ is searched with an endpoint of γ^*, and the first level of the two-dimensional segment-intersection structure is searched with the line supporting γ^* (actually with the point dual to that line). We leave it to the reader to verify, based on the techniques described in [6] and [5], that each comparison generated by both data structures arises in one of the following tests.

(i) Does a tetrahedron contain an endpoint of γ?

(ii) Does a triangle in the xy-plane contain an endpoint of γ^*?

(iii) Does the point dual to the line supporting γ^* lie in a given triangle in the xy-plane?

Since all of the above questions can be reduced to determining whether a given half-space contains σ, we can indeed use the general parametric search technique, as described in §2. We thus obtain the main result of the paper.

THEOREM 3.5. *Let $\mathcal{P} = \{P_1, \dots, P_m\}$ be a collection of m (possibly intersecting) convex polyhedra or polyhedral terrains in $\mathbb{R}^3$ with a total of n edges. Given any $\varepsilon > 0$, we can preprocess $\mathcal{P}$ in time $O((mn)^{2+\varepsilon})$ into a data structure of size $O((mn)^{2+\varepsilon})$, so that the first intersection point of $\mathcal{P}$ and a query ray can be computed in $O(\log^2 n)$ time.*

4. Data structures with almost linear size. In this section we consider the problem of preprocessing $\mathcal{P}$ into a data structure of size $O(n^{1+\varepsilon})$, so that a ray-shooting query can be answered in time $O(m^{1/4}n^{1/2+\varepsilon})$. We will use a similar approach to that in the preceding sections, except that we will replace each of the data structures used above by an alternative structure that uses only close-to-linear storage. As above, the structures that we will obtain are multilevel partition trees, composed of rather standard components, but, for the sake of completeness, we will provide a brief description of them. The overall structure of the algorithm is the same as in §3, that is, the algorithm uses parametric searching to replace ray-shooting queries by segment-intersection detection queries. These queries are handled, on a conceptual level, exactly as above. For the new data structures, we need the following notation.

DEFINITION 4.1. *Let S be a set of n points in $\mathbb{R}^d$ and let $r < n$ be some parameter. A* simplicial r-partition *for S is a collection $\Pi = \{(S_1, \Delta_1), \dots, (S_t, \Delta_t)\}$, where $S_1, \dots, S_t$ form a partition of S, $t \le 2r$, $|S_i| \le \lceil n/r \rceil$, and Δ_i is a simplex containing S_i. The maximum number of simplices intersected by a hyperplane is called the* crossing number *of Π.*

Matoušek has shown that there exists a simplicial r-partition with crossing number $O(r^{1-1/d})$ [25], [26]. Agarwal and Matoušek [5] proved that if S lies on an algebraic surface of some fixed degree, then the crossing number can be improved to $O(r^{1-1/(d-1)}\log^{d/(d-1)} r)$. Moreover, if $r = O(1)$, such a simplicial partition can be computed in linear time.

4.1. First data structure. We begin by describing the modified version of the first data structure, denoted as $\overline{\Psi}_1(\mathcal{P})$. Using the technique of Agarwal and Sharir [6], one can preprocess the set E of polyhedron edges into a data structure of size $O(n^{1+\varepsilon})$, consisting of $O((n/2^j)^{1+\varepsilon})$ canonical subsets of size between 2^{j-1} and 2^j, for each $j = 0, 1, \ldots$, so that all segments of E^* intersected by a query segment in the xy-plane can be reported as a collection of $O(n^{1/2+\varepsilon})$ pairwise disjoint canonical subsets; moreover, for each j there are $O((n/2^j)^{1/2+\varepsilon})$ canonical subsets of size between 2^{j-1} and 2^j in the query output. For each canonical subset in the query output, the query segment meets all its edges from below, or meets all of them from above. Let Γ be a canonical subset of this level of the data structure. We construct a secondary data structure $T(\Gamma)$ on Γ, similar to the one in the previous section. Put $\nu = |\Gamma|$ and define μ and s as in §3.1. Let G be the set of marked edges of Γ as defined in the previous section. We map the lines containing the segments of G (oriented from left to right) to their Plücker points (rather than hyperplanes as in the previous section) in $\mathbb{R}^5$. Let S be the set of resulting points; put $t = |S|$. Let r be some appropriate constant. Since all points of S lie on the (quadratic) Plücker surface, we can construct, as remarked above, a simplicial r-partition $\Pi = \{(S_1, \Delta_1), \ldots, (S_u, \Delta_u)\}$ of S with crossing number $O(r^{3/4}\log^{5/4} r)$. Let $t_i = |S_i|$, for $i = 1, \ldots, u$. We construct a secondary structure for each S_i, of the form described below, and then preprocess each pair (S_i, Δ_i) recursively. The resulting structure is a two-level partition tree of depth $O(\log n)$. Let $E(S_i)$ denote the edges of E corresponding to the points in S_i, and let

$$\overline{U}_i = \bigcup\{\,\Gamma(e) \mid e \in E(S_i)\,\}.$$

Put $\overline{u}_i = |\overline{U}_i| \leq st_i$. We map each line containing an edge of $\overline{U}_i$ to its Plücker point in $\mathbb{R}^5$ and preprocess the set of resulting points into a linear-size data structure that answers empty half-space queries (given a query half-space g in $\mathbb{R}^5$, it determines whether g contains any point of $\overline{U}_i$) in time $O(\overline{u}_i^{1/2+\delta})$, for some $0 < \delta < \varepsilon$; see [24]. We also preprocess the triangles incident to the edges in $E(S_i)$ for segment-intersection detection queries, using the algorithm of Agarwal and Matoušek [5]; it requires $O(t_i^{1+\delta})$ space and answers a query in time $O(t_i^{3/4+\delta})$. This completes the description of the first data structure. Since a secondary structure constructed on u points requires $O(u^{1+\delta})$ space, the total space required by the first data structure for a fixed canonical subset Γ with ν edges is $O(\nu^{1+\delta})$. Summing it over all canonical subsets of Γ^*, we obtain

$$\sum_{j=1}^{\lceil\log n\rceil}\left(\frac{n}{2^j}\right)^{1+\varepsilon}\cdot O(2^{j(1+\delta)}) = O(n^{1+\varepsilon})\sum_{j=1}^{\lceil\log n\rceil}2^{j(\delta-\varepsilon)} = O(n^{1+\varepsilon}),$$

since $\delta < \varepsilon$. The preprocessing time is also $O(n^{1+\varepsilon})$.

4.2. Second data structure. Next, we describe the modified version of the second data structure, denoted as $\overline{\Psi}_2(\mathcal{P})$. We will construct a four-level partition tree. The first three levels of $\overline{\Psi}_2(\mathcal{P})$ will filter out the faces of polyhedra in $\mathcal{P}$ whose xy-projections contain an endpoint of γ, and the fourth level will determine whether any of these faces intersect the query segment.

In more detail, let F be the set of faces of polyhedra in $\mathcal{P}$, and let F^* denote the set of the xy-projections of these faces. By our assumption, each face in F^* is a triangle. We split each face $f \in F$ into two subtriangles by drawing a plane parallel to the yz-plane through the "middle" vertex of f, as shown in Fig. 3. We will continue to denote the new set of faces by

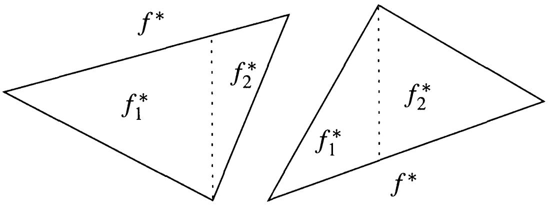

FIG. 3. *Splitting each triangle into two triangles.*

F and the set of their xy-projections by F^*. Each triangle in F^* has one vertical edge (i.e., parallel to the y-axis) and two nonvertical edges. Let I denote the set of the x-projections of triangles in F^*. We construct a segment tree B on I; see [30] for details on segment trees. Every node v of B is associated with an interval δ_v and stores a "canonical" subset $I(v)$ of I, where each interval in $I(v)$ contains δ_v (but does not contain $\delta_{p(v)}$, where $p(v)$ is the parent of v). Moreover, $\sum_{v\in B}|I(v)| = O(n\log n)$. We preprocess each canonical subset separately.

Let $F^*(v)$ denote the set of triangles corresponding to the intervals in $I(v)$; put $t = |F^*(v)|$. We construct a partition tree $\mathcal{T} = \mathcal{T}(v)$ on $F^*(v)$. For each triangle $\triangle \in F^*(v)$, pick one of its nonvertical edges. Let V denote the set of points in the xy-plane, dual to the lines supporting these edges. Each node w of $\mathcal{T}$ will be associated with a subset of V and a triangle. The root u is associated with V and the entire xy-plane. Let r be some appropriate constant. We construct, in linear time, a simplicial r-partition $\Pi = \{(V_1, \tau_1), \ldots, (V_u, \tau_u)\}$ for V with crossing number $O(\sqrt{r})$ [25], [26]. We create a child w_i of u corresponding to each pair (V_i, τ_i) and store a two-level auxiliary structure at w_i, as detailed below. We recursively preprocess V_i and attach the resulting tree of auxiliary substructures to w_i. The recursion stops when the number of points in V_i falls below some prespecified constant.

The auxiliary structure at w_i is constructed as follows. For each point $p \in V_i$, we pick the other nonvertical edge of the triangle corresponding to p. Let W_i denote the set of points dual to lines supporting these edges; $|W_i| \le \lceil t/r \rceil$. We construct a partition tree on W_i as above. The root of the partition tree is associated with W_i and the entire xy-plane. We compute a simplicial r-partition $\Pi_i = \{(W_{i1}, \tau_{i1}), \ldots, (W_{iu_i}, \tau_{iu_i})\}$ for W_i, create a child w_i of the root for each pair (W_{ij}, τ_{ij}), and recursively preprocess W_{ij}. Let F_{ij} denote the set of faces in $F(v)$ corresponding to points in W_{ij}. If F_{ij} contains two faces of the same polyhedron, we do not store any structure at w_i (because, for any projected endpoint p of a query segment, any set F_{ij} that will be picked up by the query will have the property that all its projected triangles contain p, so an F_{ij} of the above kind will never have to be processed by any query). Otherwise we preprocess F_{ij} for segment-intersection detection queries in 3-space, using the algorithm of Agarwal and Matoušek [5], and store it at the node corresponding to (W_{ij}, τ_{ij}) as its auxiliary structure. This completes the description of the second data structure. Following the same analysis as for $\overline{\Psi}_1(\mathcal{P})$, one can show that the total space and preprocessing time required are $O(n^{1+\varepsilon})$.

4.3. Answering a query. A segment-intersection detection query is answered exactly the same way as in §3.3. That is, we first query $\overline{\Psi}_2(\mathcal{P})$ and determine whether any of the faces, whose xy-projections contain an endpoint of γ, intersects γ. If γ does not intersect any such face, then we determine, using $\overline{\Psi}_1(\mathcal{P})$, whether e intersects any other face of the polyhedra in $\mathcal{P}$.

Let p be the left endpoint of γ^*. We want to determine whether any face whose xy-projection contains p intersects γ. A triangle $f^* \in F^*$ contains p if and only if the following three conditions are satisfied:

(i) the x-projection of f^* contains the x-coordinate of p,
(ii) one of the nonvertical edges of f^* lies above p, and
(iii) the other nonvertical edge of f^* lies below p (in the xy-plane).

To filter out the faces whose xy-projections satisfy these three conditions, we query the segment tree B (the first-level structure of $\overline{\Psi}_2(\mathcal{P})$) with p and compute the $O(\log n)$ nodes of B whose associated intervals contain the x-coordinate of p. Let v be such a node of B, and let ℓ denote the line dual to p. We query the (second-level) partition tree $\mathcal{T} = \mathcal{T}(v)$ with ℓ. We start at the root and at each node w, visited by the algorithm, we do the following. Let (V, τ) be the pair associated with w. If w is a leaf, we directly determine whether γ intersects any of the triangles of F corresponding to points in V. So assume that w is an internal node. If τ intersects ℓ, we visit all the children of w. Otherwise, we visit the auxiliary structure stored at w. Without loss of generality assume that τ lies fully above ℓ; the other case can be handled symmetrically. We search the (third-level) auxiliary partition tree stored at w with ℓ in the same way as we searched $\mathcal{T}(v)$. That is, at each node ξ of this third-level structure, we do the following. Let (W', τ') be the pair associated with ξ. If ℓ intersects the triangle τ', we recursively search at each child of ξ. If τ' lies fully above ℓ, then both nonvertical edges of triangles in $F^*_{\tau'}$, the set of triangles of $F^*(v)$ corresponding to the points in W', lie above the left endpoint of γ^*, which implies that p lies below all triangles in $F^*_{\tau'}$. Consequently, we do not search the subtree rooted at ξ any further. Finally, if τ' lies fully below ℓ, we can conclude that p lies in the triangles of $F^*_{\tau'}$. Let $F_{\tau'} \subseteq F(v)$ denote the set of faces of polyhedra corresponding to triangles in $F^*_{\tau'}$. Using the fourth-level auxiliary structure stored at ξ, we test whether γ intersects any of the triangles in $F_{\tau'}$. If γ intersects a triangle of $F_{\tau'}$, we stop right away, otherwise we continue with the overall search. If no face of $F(v)$, whose xy-projection contains p, intersects γ, we repeat the above step with the right endpoint of γ.

If the above procedure does not detect an intersection between $\mathcal{P}$ and γ, we query $\overline{\Psi}_1(\mathcal{P})$ as follows. We determine the segments of E^* intersected by the xy-projection γ^* of the query segment γ. Let Γ be a canonical subset of the output to this subquery. We map the line containing γ to its Plücker hyperplane h, and query the secondary structure (partition tree) constructed on the marked edges of Γ with h. The root of the partition tree stores a simplicial r-partition $\Pi = \{(S_1, \Delta_1), \ldots, (S_\alpha, \Delta_\alpha)\}$. For each simplex Δ_i in Π, we test whether h intersects Δ_i. If h intersects Δ_i, we recursively search the substructure constructed on S_i. On the other hand, if h does not intersect Δ_i, all points in S_i lie either above h or below h, say above h. Then, as is easily checked, we know that all edges $e \in E(S_i)$ lie above γ, so it suffices to determine whether γ intersects any of the faces incident to any edge in $E(S_i)$, or whether any edge of $\overline{U}_i$ lies below γ. Both of these conditions can be tested, by querying the third-level substructures stored with $E(S_i)$, in time $O(u^{3/4+\delta} + s\overline{u}^{1/2+\delta})$ (where $u = |S_i|$ and $su \geq |\overline{U}_i|$). This completes the description of the algorithm for answering a query.

We now analyze the total time spent in answering a query. First let us consider the time spent in querying $\overline{\Psi}_2(\mathcal{P})$. For $1 \leq i \leq 4$, let $Q^{(i)}(m, n)$ denote the maximum query time at an ith level structure (including the time spent at its auxiliary structures), storing n triangles which belong to m different polyhedra. Since the above procedure visits only $O(\log n)$ nodes of the segment tree,

$$Q^{(1)}(m, n) = O(\log n) \cdot Q^{(2)}(m, n). \tag{4}$$

The fourth-level structure of $\overline{\Psi}_2(\mathcal{P})$ has at most one triangle from each polyhedron, so $m = n$ and, by [5], $Q^{(4)}(m, n) = O(m^{3/4+\delta})$, for any $\delta > 0$. Finally, for $i = 2, 3$ (i.e., for partition trees constructed on sets of nonvertical edges of triangles), a line intersects only $O(\sqrt{r})$ triangles of the r-partition constructed on the set of points associated with any tree node. Therefore the query line recursively searches only $O(\sqrt{r})$ children of any interior node, which yields the following recurrence:

$$Q^{(i)}(m,n) \le \begin{cases} \sum_{i=1}^{c_1\sqrt{r}} Q^{(i)}(m_i,n_i) + Q^{(i+1)}(m,n) & \text{if } n \ge n_0, \\ O(1) & \text{if } n < n_0, \end{cases} \tag{5}$$

where n_0, c_1 are appropriate constants, and $n_i \le n/r$, $m_i \le m$ for each i. We claim that the solution of the above recurrence is

$$Q^{(i)}(m,n) \le Am^{1/4}n^{1/2+\varepsilon}, \tag{6}$$

for any $\varepsilon > 0$. We will prove the recurrence for $i = 3$; a similar proof works for $i = 2$. Equation (6) is obviously true for $n \le n_0$ (provided A is chosen sufficiently large); and for $n > n_0$, we have, for an appropriate constant $c_2 > 0$,

$$\begin{aligned} Q^{(3)}(m,n) &\le \sum_{i=1}^{c_1\sqrt{r}} Q^{(3)}(m_i,n_i) + c_2m^{3/4+\delta} \\ &\le \sum_{i=1}^{c_1\sqrt{r}} Am_i^{1/4}\left(\frac{n}{r}\right)^{1/2+\varepsilon} + c_2m^{3/4+\delta} \\ &\le Am^{1/4}n^{1/2+\varepsilon}\frac{c_1}{r^{\varepsilon}} + c_2m^{3/4+\delta} \\ &\le Am^{1/4}n^{1/2+\varepsilon}, \end{aligned}$$

provided that $\varepsilon \ge \delta$ and that the constants r, A are chosen sufficiently large (we also use here the obvious fact that $m \le n$).

Similarly, we can show that $Q^{(2)}(m,n) = O(m^{1/4}n^{1/2+\varepsilon})$. Plugging (6) into (4), we can conclude that the maximum query of $\Psi_2(\mathcal{P})$ is $O(m^{1/4}n^{1/2+\varepsilon})$.

Next, we analyze the query time of $\Psi_1(\mathcal{P})$. Recall that we spend $O(u^{3/4+\delta} + (su)^{1/2+\delta})$ time at a third-level substructure of size u. Let $Q^{(2)}(u)$ denote the maximum query time of the second-level partition constructed on a subset of u marked edges of Γ. Since the crossing number of the simplicial r-partition stored at each node of the (second-level) partition tree is $O(r^{3/4}\log^{5/4} r)$, we obtain the following recurrence:

$$Q^{(2)}(u) \le c_1r^{3/4}\log^{5/4} r \cdot Q^{(2)}\left(\frac{u}{r}\right) + c_2(u^{3/4+\delta} + (su)^{1/2+\delta}), \tag{7}$$

where c_1, c_2 are appropriate constants. The solution of the above recurrence is easily checked to be

$$Q^{(2)}(u) = O(s^{1/2+\delta}u^{3/4+\delta}) .$$

Hence, the total time spent in querying a single first-level canonical subset Γ is

$$O(s^{1/2+\delta}\mu^{3/4+\delta}) = O\left(\left\lceil\frac{\nu}{\mu}\right\rceil^{1/2+\delta}\mu^{3/4+\delta}\right) = O(\mu^{1/4}\nu^{1/2+\delta}).$$

Recall that there are $O((n/2^j)^{1+\varepsilon})$ first-level canonical subsets of size between 2^{j-1} and 2^j, so the overall query time of the first data structure is at most

$$\sum_{j=1}^{\lceil\log n\rceil} O\left(\left(\frac{n}{2^j}\right)^{1+\varepsilon}\right) \cdot O\left(m^{1/4}2^{j(1/2+\delta)}\right) = O(m^{1/4}n^{1/2+\varepsilon'}),$$

where $\varepsilon' \geq \varepsilon + \delta$ is another arbitrarily small constant. Putting everything together, we obtain the following theorem.

THEOREM 4.2. *Let $\mathcal{P} = \{P_1, \ldots, P_m\}$ be a collection of m (possibly intersecting) convex polyhedra or polyhedral terrains in $\mathbb{R}^3$ with a total of n edges. Given any $\varepsilon > 0$, we can preprocess $\mathcal{P}$ in time $O(n^{1+\varepsilon})$ into a data structure of size $O(n^{1+\varepsilon})$, so that one can determine in time $O(m^{1/4}n^{1/2+\varepsilon})$ whether a query segment intersects any polyhedron (or polyhedral terrain) in $\mathcal{P}$.*

Again, we plug this procedure into the parametric search technique to answer a ray-shooting query. We leave it to the reader to verify that each comparison can be reduced to determining whether the first intersection of the ray and $\mathcal{P}$ lies in a query half-space. Hence, we can conclude with the following theorem.

THEOREM 4.3. *Let $\mathcal{P} = \{P_1, \ldots, P_m\}$ be a collection of m (possibly intersecting) convex polyhedra or polyhedral terrains in $\mathbb{R}^3$ with a total of n edges. Given any $\varepsilon > 0$, we can preprocess $\mathcal{P}$ in time $O(n^{1+\varepsilon})$ into a data structure of size $O(n^{1+\varepsilon})$, so that the first intersection point, if any, of a query ray with the polyhedra of $\mathcal{P}$ can be computed in $O(m^{1/4}n^{1/2+\varepsilon})$ time.*

5. Application to motion planning. An interesting application of our algorithm for ray shooting amidst convex polyhedra is the following motion-planning problem in $\mathbb{R}^3$. Suppose we have a convex polyhedral object B bounded by k faces, which is free to translate amidst a collection of m convex polyhedral obstacles, $A_1, \ldots, A_m$, with a total of n faces. Preprocess them into a data structure so that, given any free placement Z of B and a direction $\mathbf{u}$, we can efficiently find the first obstacle, if any, to be hit as we translate B from Z in direction $\mathbf{u}$.

This problem can be easily reduced to the ray-shooting problem amidst a collection of *intersecting* convex polyhedral objects. We simply compute the Minkowski differences (also known as *expanded obstacles*)

$$A_i^* = A_i - B_0 = \{x - y \mid x \in A_i,\ y \in B_0\},$$

for $i = 1, \ldots, m$; here B_0 denotes some standard placement of the object B. If A_i has n_i faces, then A_i^* is a convex polyhedron consisting of at most $O(kn_i)$ faces, so the total number of faces of the expanded obstacles is $O(kn)$.

Now, given a free placement Z of B and a direction $\mathbf{u}$, we can find the first obstacle to be hit by B when it is translated from Z in direction $\mathbf{u}$ by performing a ray-shooting query with the ray $(z, \mathbf{u})$ amidst the expanded obstacles A_i^*, where z is the displacement of B from its standard placement B_0 to the placement Z. The first expanded obstacle that the ray hits corresponds to the first obstacle that B hits. Applying the results in the previous sections, we thus obtain the following corollary.

COROLLARY 5.1. *Given a collection of m convex polyhedral obstacles with a total of n faces and a convex polyhedral object B with k faces, we can preprocess them, in time $O((kmn)^{2+\varepsilon})$, into a data structure of size $O((kmn)^{2+\varepsilon})$, so that, given any placement Z of B and direction $\mathbf{u}$, we can determine, in $O(\log^2 kn)$ time, the first obstacle, if any, that B hits when translated from Z in direction $\mathbf{u}$.*

6. Conclusion. In this paper we presented two data structures for answering ray-shooting queries among a collection of m convex polyhedra or polyhedral terrains with a total of n faces. The first method answers a query in $O(\log^2 n)$ time using $O((mn)^{2+\varepsilon})$ space and preprocessing time, while the second method achieves $O(m^{1/4}n^{1/2+\varepsilon})$ query time, using $O(n^{1+\varepsilon})$ space and preprocessing time. When $m \ll n$, both methods are significantly better than previous techniques, which either require $O(n^{4+\varepsilon})$ space and preprocessing for a polylogarithmic query time, or require $O(n^{3/4+\varepsilon})$ query time for almost-linear storage and preprocessing. Of course, when $m \approx n$, our algorithms perform as well as the previous ones. For $m = 1$, the performance of our algorithms matches that of the best known algorithm for ray shooting in a polyhedral terrain [4], [15], but is not as good as the best known technique for a single convex polyhedron.

We conclude by mentioning some open problems:

1. If $m = 1$, neither of our structures achieves close-to-optimal performance for the case of a single convex polyhedron. For example, the space and preprocessing time of our first technique are $O(n^{2+\varepsilon})$, in contrast with the technique of [20], which can answer a ray-shooting query in $O(\log n)$ time, using $O(n)$ space and $O(n \log n)$ preprocessing. It is clear from this that we are not fully exploiting the fact that the given polyhedra are convex. It would be interesting to improve our techniques further so that their performance approaches that of [20] for the case of a single convex polyhedron. (We are also not exploiting at all the pairwise disjointness of the given polyhedra.) A plausible goal to shoot for might be to improve our first technique so that it yields a data structure that requires only $O(m^{4+\varepsilon} + n)$ or $O(m^{3+\varepsilon} n)$ space and preprocessing.
2. How far can our techniques be extended? It seems unlikely that any improvement over the general previous techniques can be obtained for ray shooting among arbitrary nonconvex polyhedra, but perhaps there are useful special cases, beyond the case of terrains, for which faster techniques exist.
3. One application of our algorithms is for the case of a small number of curved surfaces, each approximated by a polyhedral surface with a large number of faces. An alternative attack on this case would be to drop the polyhedral representation altogether and to develop special techniques for ray shooting amidst curved objects. This is a more difficult problem for general surfaces, although some progress has recently been done for the case of ray shooting amidst spheres (see [2] and [5]).
4. Finally, as mentioned in the introduction, no nontrivial lower bounds are known for any of the ray-shooting problems.

Acknowledgments. The authors thank Mark de Berg and other attendants of the 2nd Utrecht Workshop on Computational Geometry and Its Application for raising the problem studied here.

A NEW CHARACTERIZATION OF TYPE-2 FEASIBILITY*

B. M. KAPRON† AND S. A. COOK‡

Abstract. K. Mehlhorn introduced a class of polynomial-time-computable operators in order to study poly-time reducibilities between functions. This class is defined using a generalization of A. Cobham's definition of feasibility for type-1 functions to type-2 functionals. Cobham's feasible functions are equivalent to the familiar poly-time functions. We generalize this equivalence to type-2 functionals. This requires a definition of the notion "poly time in the length of type-1 inputs." The proof of this equivalence is not a simple generalization of the proof for type-1 functions; it depends on the fact that Mehlhorn's class is closed under a strong form of simultaneous limited recursion on notation and requires an analysis of the structure of oracle queries in time-bounded computations.

Key words. type-2 computability, polynomial time, notational recursion, oracle Turing machine

AMS subject classifications. 68Q05, 68Q15, 03D65, 03D20

1. Introduction. A *type*-1 *function* is a mapping from $\mathbb{N}$ to $\mathbb{N}$. We will denote the set of all functions by ${}^{\mathbb{N}}\mathbb{N}$. A *type*-2 *functional* is a mapping from $({}^{\mathbb{N}}\mathbb{N})^k \times \mathbb{N}^l$ to $\mathbb{N}$, for some k and l. More specifically, we will call a mapping of this sort a *functional with rank* (k, l).

For type-1 functions, there is a well-established notion of computational feasibility. Namely, a function is feasible if it is computable in polynomial time on a Turing machine. More specifically, a function f is poly time if there is a Turing machine (TM) M and a polynomial p such that for all x, M with input x computes $f(x)$ and runs in time $p(n)$, where $n = |x|$, and for $x \in \mathbb{N}$, $|x|$ denotes the length of the binary notation of x, that is $\lceil \log(x+1) \rceil$. This notion of feasibility is robust in the sense that it is independent of the computational model used, assuming that the model is "reasonable." In [1], Cobham presented a machine-independent characterization of computational feasibility, via an inductive definition. Cobham's definition, while important, lacks the intuitive appeal of the machine-based characterization because, intuitively, feasibility depends on a notion of bounding computational resources (in this case running time) in a general computational model in some natural way.

Questions about feasibility arise when dealing with type-2 functionals as well, for example, in the study of reducibilities [9], computable analysis [5], and descriptive set theory [10]. Mehlhorn's study [9] of feasible reducibilities appears to be one of the first to consider the notion of feasibility for type-2 functionals. Here, a class of *poly-time operators* is defined, using a generalization of Cobham's definition. Subsequent studies, such as [10] and [4], take Mehlhorn's approach. The work done to date in this area does not address the question of whether there is a natural machine-based definition of Mehlhorn's class. In this paper, we provide an affirmative answer to the question.

2. A computational model for functionals. Our model for type-2 computability is a generalization of the familiar multitape oracle Turing machine (OTM). However, we allow arbitrary type-1 functions as oracles, rather than subsets of $\mathbb{N}$. Note that we also use the term oracle Turing machine to refer to this modified model. In addition to the normal work tapes, there is an *oracle-query tape* and an *oracle-answer tape* for each function input. These tapes are infinite in one direction. In order to query a function oracle at an input x, we write x (in binary) on the corresponding query tape, move the read head on the oracle tape to the

†Department of Computer Science, University of Victoria, Victoria, BC V8W 3P6, Canada (bmkapron@csr.uvic.ca). The work of this author was completed while at the University of Toronto as part of his Ph.D. thesis [6].

‡Department of Computer Science, University of Toronto, Toronto, ON M5S 1A4, Canada (sacook@theory.toronto.edu).

beginning, and enter a query state for that oracle. In the next step, the value of the function at the specified input is written (in binary) at the beginning of the corresponding answer tape, and the head of the answer tape is returned to the leftmost position. The rest of the answer tape is overwritten with blanks. There is also a special, read-only *input tape*. One work tape is specified as the *output tape*.

An OTM M computes a functional F_M of rank (k, l) if it has k oracle-query states, and for all $f_1, \ldots, f_k$ and $x_1, \ldots, x_l$, whenever M is started with $x_1, \ldots, x_l$ written in binary (and separated by blanks) on its input tape, and when f_i is the function associated with query state i, M halts with $F_M(\vec{f}, \vec{x})$ written at the beginning of its output tape, followed by blanks and with the read head of the work tape in the leftmost position. In this case we say that M has *function inputs* $f_1, \ldots, f_k$ and *number inputs* $x_1, \ldots, x_l$ and that M is a *rank-*(k, l) *OTM*.

The running time of a Turing machine is normally just the number steps that it executes before halting. This is also the case for OTMs with set oracles. With function oracles, on the other hand, there are two possible conventions for the cost of an oracle call. The first is to charge one time step, reflecting our intuition that oracles are like subroutines with unlimited power. However, it is also reasonable to charge the length of the value returned by the oracle, reflecting the fact that the answer returned by the oracle must still be written down on the output tape. More formally, if we query oracle f at input $\vec{x}$, the associated cost is $\max\{1, |f(\vec{x})|\}$. Thus we have an I/O cost associated with an oracle call. We choose the latter convention.[1]

DEFINITION 2.1. *The* running time *of an OTM with a given input is the sum of the costs of the steps it executes. We denote by* $T_M(\vec{f}, \vec{x})$ *the running time of* M *on inputs* $\vec{f}$ *and* $\vec{x}$.

Because of the way we charge for oracle calls, the number of steps in a computation is not equal to its running time, as oracle calls are atomic steps with nonunit cost. We denote by $\text{Steps}(M, \vec{f}, \vec{x}, t)$ the least number of steps that M must execute on inputs $\vec{f}, \vec{x}$ so that the sum of the costs of those steps is at least t. In the case that $t > T_M(\vec{f}, \vec{x})$, we adopt the convention that $\text{Steps}(M, \vec{f}, \vec{x}, t)$ denotes $\text{Steps}(M, \vec{f}, \vec{x}, T_M(\vec{f}, \vec{x})) + 1$. We will write $\text{Steps}(t)$ when $M, \vec{f}$, and $\vec{x}$ are understood. We will also denote by $S_M(\vec{f}, \vec{x})$ the value $\text{Steps}(T_M(\vec{f}, \vec{x}))$, that is, the total number of steps taken by M on inputs $\vec{f}$ and $\vec{x}$ before halting. It is important to note that the computation of an OTM for a given function input depends only on the values of the function at those points which are actually queried during the computation. This is formalized as follows (we will restrict our attention to rank-$(1, 1)$ functionals for the sake of simplicity.)

DEFINITION 2.2. *For any function* f, *any rank-*$(1, 1)$ *OTM* M, *and any* $t, x \in \mathbb{N}$, *let* $Q(M, f, x, t)$ *denote the* query set *consisting of all* y *such that* M *with inputs* f *and* x *queries* f *at* y *within* $\text{Steps}(t)$ *steps of its execution. For any set* $Q \subseteq \mathbb{N}$ *and any function* f, *let* f_Q, *the* query restriction of f, *be the function such that* $f_Q(y) = f(y)$ *for all* $y \in Q$, *and* $f_Q(y) = 0$ *otherwise.*

PROPOSITION 2.3. *If* $Q = Q(M, f, x, t)$, *then the first* $\text{Steps}(t)$ *steps of the execution of* M *on inputs* f *and* x *are identical to its first* $\text{Steps}(t)$ *steps on inputs* f_Q *and* x.

3. Basic feasible functionals. Cobham [1] gave an inductive definition of type-1 feasible functions in terms of certain initial functions and closure conditions. The most important aspect of this definition is closure under *limited recursion on notation*. Cobham's feasible functions coincide exactly with the familiar poly-time functions. Mehlhorn [9] generalized Cobham's definition to type-2 functionals to define the class of *polynomial-time operators*. We will consider a functional version of this generalization based on that given by Townsend [10]. We differ somewhat from Townsend, who considers functionals over $\{0, 1\}^*$. Also, we include all

[1] Recently, A. Ignjatovič [6] showed that the main result of this paper also holds in the unit cost model. His techniques differ significantly from ours.

type-1 poly-time functions as initial functionals. This simplifies the closure schemes needed for argument manipulation. Note that we will refer to functionals in this class as *basic feasible functionals* (BFFs) rather than poly-time functionals. An explanation of this terminology is given in [4]. We first introduce some schemes for defining functionals.

DEFINITION 3.1. *F is defined from $H, G_1, \ldots, G_l$ by* functional composition *if for all $\vec{f}$ and $\vec{x}$,*

$$F(\vec{f}, \vec{x}) = H(\vec{f}, G_1(\vec{f}, \vec{x}), \ldots, G_l(\vec{f}, \vec{x})).$$

F is defined from G by expansion *if for all $\vec{f}$, $\vec{g}$, $\vec{x}$, and $\vec{y}$,*

$$F(\vec{f}, \vec{g}, \vec{x}, \vec{y}) = G(\vec{f}, \vec{x}).$$

F is defined from G, H, and K by limited recursion on notation (LRN) *if for all $\vec{f}$, $\vec{x}$, and y,*

$$\begin{aligned} F(\vec{f}, \vec{x}, 0) &= G(\vec{f}, \vec{x}), \\ F(\vec{f}, \vec{x}, y) &= H(\vec{f}, \vec{x}, y, F(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor)), \qquad y > 0, \\ |F(\vec{f}, \vec{x}, y)| &\le |K(\vec{f}, \vec{x}, y)|. \end{aligned}$$

DEFINITION 3.2. *Let X be a set of type-2 functionals. The class of* basic feasible functionals defined from X (BFF(X)) *is the smallest class of functionals containing X, all type-1 poly-time functions and the application functional* Ap, *defined by* Ap$(f, x) = f(x)$, *and which is closed under functional composition, expansion, and limited recursion on notation. If $F \in BFF(X)$, we say that F is* basic feasible in X. *The* basic feasible functionals (BFFs) *are just $BFF(\emptyset)$.*[2] *If a functional F is in $BFF(\{F_1, \ldots, F_n\})$, we say that F is* feasible in $F_1, \ldots, F_n$.

The BFFs have a strong closure property with respect to computation by OTMs. We now define this property.

DEFINITION 3.3. *A class X of functionals has the* Ritchie–Cobham property *if for all F, $F \in X$ iff there is an OTM M and some $G \in X$ so that M computes F and for all inputs $\vec{f}$ and $\vec{x}$, the running time of M is bounded by $|G(\vec{f}, \vec{x})|$.*

The following result is due to Mehlhorn [9].

THEOREM 3.4. *The BFFs have the Ritchie–Cobham property.*

Mehlhorn proved this result for the model in which oracle calls have unit cost. It is not hard to adapt Mehlhorn's proof to prove the forward direction for our model. Note that simulating the application functional Ap requires more running time in our model because of the extra cost associated with an oracle call. However, this overhead can easily be incorporated into the time bound.

Sufficiency in our model follows from Mehlhorn's result. However, we need a somewhat stronger result in §5, which we now outline. We will show that for any OTM M, there is a BFF Run$_M$ such that the value of Run$_M(\vec{f}, \vec{x}, T)$, where $T \in \mathbb{N}$, is an encoding of a sequence of instantaneous descriptions (IDs) which give the history of the first Steps$(M, \vec{f}, \vec{x}, |T|)$ steps of M's execution with inputs $\vec{f}$ and $\vec{x}$. Below, we give an outline of how Run$_M$ is defined by limited recursion on notation (LRN) on T. Also, it is not hard to define a BFF Output so that if x codes a sequence of IDs, then Output(x) is the contents of the output tape of the last ID in the sequence. So if F is computed by an OTM M for which there is a BFF

[2] In [8], the definition of BFF(X) also includes closure under *functional substitution.* Results of Townsend [10] show that this definition is equivalent to the one given here.

G so that for all inputs $\vec{f}$ and $\vec{x}$, the running time of M is bounded by $|G(\vec{f}, \vec{x})|$, we have $F(\vec{f}, \vec{x}) = \text{Output}(\text{Run}_M(\vec{f}, \vec{x}, G(\vec{f}, \vec{x})))$, and so F is a BFF.

In order to define Run_M, we first use standard low-level encoding techniques, similar to those of [9], to define a BFF Next_M such that $\text{Next}_M(\vec{f}, \vec{x}, i)$ returns the ID which follows from ID i of M on inputs $\vec{f}$ and $\vec{x}$, assuming that i is a valid ID for M. In the case where the state associated with i is an oracle-query state, we use the Ap functional to obtain the resulting value. Now, to compute $\text{Run}_M(\vec{f}, \vec{x}, T)$, we use LRN on T to iterate Next_M $|T|$ times, starting with M's initial configuration. However, during each iteration, we also check that the overall running time (including the cost incurred for oracles calls) does not exceed $|T|$. If this is not the case, we "exit" from the iteration at this point. Finally, note that $|\text{Run}_M(\vec{f}, \vec{x}, T)|$ is $O(|T|(|\vec{x}| + |T|))$, independently of $\vec{f}$. Full details of this construction can be found in [7].

This result provides some evidence of the naturalness of the BFFs. However, it does not provide a purely machine-based characterization of type-2 feasibility. We will now introduce such a characterization.

4. Basic poly-time functionals. Recall that a type-1 function f is poly time if there is a TM M and a polynomial p such that M computes f and, for all inputs x, the running time of M with input x is bounded by $p(|x|)$. Hence a function is feasible if it is computable in time polynomial in the size of its input. A naive generalization of this characterization to type-2 functionals would lead us to propose that a functional is feasible if it is computable in time polynomial in the lengths of its inputs, where now its inputs include functions as well as numbers. In order to formalize this proposal, we need to answer two questions. The first is, what is the "length" of a function input f? Since f is an infinite object, there can be no single $n \in \mathbb{N}$ which measures the length of f. However, for each x there is an associated length $|f(x)|$, which is also the cost of querying f at x. Viewing f as a subroutine, there is a worst-case complexity for calling f, given this query cost. It is this complexity which we define to be the length of f.

DEFINITION 4.1. *For any $f \in^{\mathbb{N}} \mathbb{N}$, the* length *of f, denoted $|f|$, is the function defined by*

$$|f|(n) = \max_{|y| \leq n} |f(y)|.$$

Given this definition for the length of a function, we are presented with a second question: when is a functional "polynomial in" the length of a function? We answer this question by generalizing polynomials to allow function variables.

DEFINITION 4.2. First-order variables *are elements of the set* $\{n_1, n_2, \dots\}$. Second-order variables *are elements of the set* $\{L_1, L_2, \dots\}$. Second-order polynomials *are defined inductively: any $c \in \mathbb{N}$ is a second-order polynomial*; *first-order variables are second-order polynomials*; *and if P and Q are second-order polynomials and L is a second-order variable, then $P + Q$, $P \cdot Q$, and $L(P)$ are second-order polynomials.*

We will refer to second-order polynomials as polynomials when the context makes this distinction clear. Suppose P is a polynomial, all of whose first-order variables are among $n_1, \dots, n_s$ and all of whose second-order variables are among $L_1, \dots, L_t$. Then for any sequence $f_1, \dots, f_t$ of functions and any sequence $x_1, \dots, x_s$ of numbers, $P(\vec{f}, \vec{x})$, *P evaluated at $\vec{f}, \vec{x}$* denotes some natural number. For example, if

$$P_0 = L_1(L_1(n_1 \cdot n_1)) + L_1(L_1(n_1) \cdot L_1(n_1)) + L_1(n_1) + 4 \tag{1}$$

and $f(x) = x^2$, then

$$\begin{aligned} P_0(f,2) &= f(f(2\cdot 2)) + f(f(2)\cdot f(2)) + f(2) + 4 \\ &= (4^2)^2 + (2^2\cdot 2^2)^2 + 2^2 + 4 \\ &= 520. \end{aligned}$$

We are now ready to introduce a type-2 analogue for the poly-time functions, based on our generalizations of polynomials and lengths for functions.

DEFINITION 4.3. *A functional F is* basic poly time *if there is an OTM M and a second-order polynomial P such that M computes F, and for all $\vec{f}$ and $\vec{x}$, $T_M(\vec{f},\vec{x})$ is bounded by $P(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|)$.*

Note that if M and P are as in the preceding definition, we will say that P *bounds the running time of M.*

5. Equivalence of basic feasible and basic poly-time functionals. We have proposed a new definition for type-2 feasibility, namely basic poly-time computability. In this section, we will show that our new definition coincides with Mehlhorn's. We begin with the following theorem.

THEOREM 5.1. *Every BFF is basic poly time.*

In order to prove the theorem, we require the following easily demonstrated facts.

LEMMA 5.2. *Suppose P and Q are polynomials with first-order variables $n_1,\ldots,n_l$ and second-order variables $L_1,\ldots,L_{k+1}$. Then for all i, $1\le i\le l$, there is a polynomial P' so that for all $\vec{g}$, $\vec{x}$,*

$$P'(\vec{g},\vec{x}) = P(\vec{g},x_1,\ldots,x_{i-1},Q(\vec{g},\vec{x}),x_{i+1},\ldots,x_l).$$

LEMMA 5.3. *Suppose P is a polynomial with first-order variables $n_1,\ldots,n_l$ and second-order variables $L_1,\ldots,L_k$. Then for all monotone nondecreasing $g_1,\ldots,g_k$ and all $x_1,\ldots,x_l$, and for all i, $1\le i\le l$, and all y, if $y\ge x_i$, then*

$$P(\vec{g},x_1,\ldots,x_{i-1},y,x_{i+1},\ldots,x_l)\ge P(\vec{g},\vec{x}).$$

Proof of Theorem 5.1. By Theorem 3.4, it suffices to show that if F is a BFF, then there is a polynomial P so that for all $\vec{f}$, $\vec{x}$, $|F(\vec{f},\vec{x})|\le P(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|)$. We proceed by induction on the definition of F. The result is clear when F is an initial function. We now consider each definition scheme. In each case, we assume that F is defined from functionals for which the theorem holds. The case of expansion is straightforward. If F is defined from F, G, and K by LRN and P is a bounding polynomial for K, then it is also a bounding polynomial for F (since $|F(\vec{f},\vec{x})|\le|K(\vec{f},\vec{x})|$). Now suppose that F is defined from $H,G_1,\ldots,G_l$ by functional composition, and suppose that P is a bounding polynomial for H and P_i is a bounding polynomial for G_i, $1\le i\le l$. By Lemma 5.2, there is a polynomial P' such that for all $\vec{f}$ and $\vec{x}$,

$$\begin{aligned} &P'(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|) \\ &= P(|f_1|,\ldots,|f_k|,P_1(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|),\ldots, \\ &\quad P_l(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|)), \end{aligned}$$

so by Lemma 5.3, $|G(\vec{f},\vec{x})|\le P'(|f_1|,\ldots,|f_k|,|x_1|,\ldots,|x_l|)$. □

Surprisingly, the converse of 5.1 is also true, so that the BFFs and the basic poly-time functionals coincide. We begin by considering an example which illustrates some of the problems associated with proving the converse.

Let F_1 be defined as follows:

$$F_1(f,x) = \begin{cases} (\mu k < x)(\max_{i \le k} |f(i)| = k) & \text{if such a } k \text{ exists,} \\ x & \text{otherwise.} \end{cases}$$

It is easy to see that this functional is basic poly time. For inputs f and x we can compute F_1 in time bounded by $c_1[|f|(|x|)]^2 + c_2$ for constants c_1 and c_2 as follows: just evaluate f at successive inputs, starting with 0, until we find a point k such that $F_1(f,x) = k$ or reach x. Now we will make at most $F_1(f,x) + 1$ such evaluations, and each evaluation returns a value with length bounded by $|f|(|x|)$. The approximate run-time bound is then obtained by noting that $F_1(f,x) \le |f|(|x|)$. This approach to computing F_1 does not allow us to conclude that F_1 is a BFF. In particular, it appears that with such an approach, computing F_1 for certain inputs f and x would require a recursion with an exponential number of iterations. However, this problem can be avoided with a nested recursion, as we will now show. In order to do so, we need to consider the auxiliary function F_2:

$$F_2(f,x) = \begin{cases} (\mu k \le F_1(f,x))(f(k) = \max_{0 \le i \le F_1(f,x)} f(i)) & \text{if such a } k \text{ exists,} \\ x & \text{otherwise.} \end{cases}$$

$F_2(f,x)$ returns the smallest point y, $0 \le y \le F_1(f,x)$, such that y maximizes f over $\{0, \ldots, F_1(f,x)\}$. So if $F_1(f,x) < x$, $|f(F_2(f,x))| = F_1(f,x)$. Otherwise, $|f(F_2(f,x))| \ge x$. Let

$$F(f,x) = \langle F_1(f,x), F_2(f,x) \rangle$$

and let

$$G(f,x,y) = \langle F_1(f, \min(|x|, y)), F_2(f, \min(|x|, y)) \rangle,$$

where $\langle \cdot, \cdot \rangle$ is a poly-time pairing function. Clearly G is basic feasible (we can use LRN on x to do a "brute-force" search). Let # be the rank (0, 2) BFF defined by $x\#y = 2^{|x|\cdot|y|}$. We define F using LRN, as follows:

$$\begin{cases} F(f,0) = \langle 0,0 \rangle, \\ F(f,x) = \textbf{if } \Pi_1(F(f, \lfloor \frac{x}{2} \rfloor)) < \lfloor \frac{x}{2} \rfloor \textbf{ then } F(f, \lfloor \frac{x}{2} \rfloor), \\ \qquad\qquad \textbf{else } G(f, f(\Pi_2(F(f, \lfloor \frac{x}{2} \rfloor)))\#2, x), \\ |F(f,x)| \le |\langle x,x \rangle|, \end{cases}$$

where Π_1 and Π_2 are poly-time projection functions. So $F_1(f,x) = \Pi_1(F(f,x))$.

To simplify the presentation of our result, we will restrict our attention to functionals of rank (1, 1). Basically, we want to show that if F is computed by an OTM M with running time bounded by P, then there is a BFF G so that for all f and x, the running time of M is bounded by $|G(f,x)|$. More formally, our goal is to find a BFF G so that $F(f,x) = \text{Output}(\text{Run}_M(f,x,G(f,x)))$. Now if there were a BFF H such that $|H(f,x)| \ge |f|(|x|)$, our task would be trivial, since we could then obtain the BFF G from H. It is not hard to show that there is no BFF H with the required property.

LEMMA 5.4. *For any BFF F, if f is a* 0–1*-valued function, then there is a polynomial p such that for all x, $|F(f,x)| \le p(|x|)$.*

Proof. Use a straightforward induction on the definition of F. □

THEOREM 5.5. *If H is a functional such that for all f and x, $|H(f, x)| \geq |f|(|x|)$, then H is not basic feasible.*

Proof. Assume that H is a BFF, and let f be a 0–1-valued function. By Theorem 3.4 and Lemma 5.4, there is an OTM M and a polynomial p such that for all x, $H(f, x)$ is computable by M in time $p(|x|)$. So in computing $H(f, x)$, M can query f at no more that $p(|x|)$ different inputs, and thus for some x_0 there is a y, $|y| \leq |x_0|$, so that M, on input f and x_0, does not query f at y. Let f' be defined by

$$f'(x) = \begin{cases} 2 \cdot H(f, x) + 1 & \text{if } x = y, \\ f(x) & \text{otherwise.} \end{cases}$$

Now by Proposition 2.3, M behaves identically with inputs f, x_0 and f', x_0, so that

$$|H(f, x_0)| = |H(f', x_0)| \geq |f'|(|x_0|) = |H(f, x_0)| + 1,$$

and we have derived a contradiction. □

Our goal now is to try to simplify P in such a way that the value of $P(|f|, |x|)$ can be feasibly computed without using a functional such as H. We begin by noting the following facts regarding running times.

LEMMA 5.6. *Suppose M is an OTM and P is a polynomial which bounds the running time of M. For any f, x, and t, if $Q = Q(M, f, x, t)$ and $t > P(|f_Q|, |x|)$, then $S_M(f_Q, x) <$ Steps(t).*

Proof. Suppose this is not the case for some t, and let $Q = Q(M, f, x, t)$. Since $S_M(f_Q, x) = \text{Steps}(T_M(f_Q, x))$ and Steps is monotone increasing, $T_M(f_Q, x) \geq t$. So $T_M(f_Q, x) > P(|f_Q|, |x|)$, contrary to Proposition 2.3. □

LEMMA 5.7. *Suppose M is an OTM and P is a polynomial which bounds the running time of M. For any f, x, t, and t', if $Q = Q(M, f, x, t)$, $Q' = Q(M, f, x, t')$, and $t' > P(|f_Q|, |x|)$, then either $|Q'| > |Q|$ or $S_M(f_{Q'}, x) <$ Steps(t').*

Proof. Suppose $|Q'| = |Q|$. Then $Q' = Q$, so $P(|f_{Q'}|, |x|) = P(|f_Q|, |x|)$. But then $t' > P(|f_{Q'}|, |x|)$, and so by Lemma 5.6, $S_M(f_{Q'}, x) < \text{Steps}(t')$. □

We denote by $t(M, f, x, r)$ the least value t such that $\text{Steps}(t) = S_M(f, x)$ or $|Q(M, f, x, t)| = r$. We will abbreviate this by $t(r)$ in appropriate contexts.

LEMMA 5.8. *Suppose $t = t(M, f, x, r)$ and $Q = Q(M, f, x, t)$ for $r \in \mathbb{N}$. If* Steps$(t) <$ *$S_M(f, x)$, then* Steps$(t) \leq$ *$S_M(f_Q, x)$.*

Proof. Given that $\text{Steps}(t) < S_M(f, x)$, M with input f and x must query f at r distinct inputs before halting. But then by Proposition 2.3, the same is true of M with inputs f_Q, x. The result follows by the minimality of t. □

We now want to show that for our bounding polynomial P, there is a $d \in \mathbb{N}$ and a first-order polynomial $\hat{P}$ so that for any query set Q, there are points $q_1, \ldots, q_d$ in Q such that

$$P(|f_Q|, |x|) \leq \hat{P}(|f(q_1)|, \ldots, |f(q_d)|, |x|).$$

This will reduce our problem of finding a basic feasible bounding function for M to the problem of finding BFFs which gives us such $q_1, \ldots, q_d$ in $Q(M, f, x, P(|f|, |x|))$. We now describe the method for obtaining the first-order polynomial $\hat{P}$.

DEFINITION 5.9. *Let P be a polynomial. We define $d(P)$, the* depth *of P, by induction on P: $d(c) = d(n_i) = 0$; $d(P+Q) = d(P \cdot Q) = \max\{d(P), d(Q)\}$; and $d(L(P)) = 1+d(P)$.*

Let P be a polynomial with depth d. For $1 \leq c \leq d$, let $P^c_1, \ldots, P^c_{k_c}$ be an enumeration of the depth-c subpolynomials of P which have the form $L(Q)$, where L is a second-order variable and $d(Q) = c - 1$. If $P_j^c = L(Q)$, let $Q_j^c = Q$. Clearly, for any Q_j^c there is a first-order polynomial $\hat{Q}_j^c$, $1 \leq i < c$, $1 \leq l \leq k_c$, such that for all $\vec{g}$ and $\vec{x}$,

$$Q_j^c(\vec{g}, \vec{x}) = \hat{Q}_j^c(P_1^1(\vec{g}, \vec{x}), \ldots, P_{k_1}^1(\vec{g}, \vec{x}), \ldots, P_{k_{c-1}}^{c-1}(\vec{g}, \vec{x}), \vec{x})).$$

Now suppose that M is an OTM and that P is a depth-d polynomial bounding the running time of M. For any inputs f and x and any t, there are $q_1, \ldots, q_d \in \mathcal{Q}(M, f, x, t)$ so that for $1 \leq c \leq d$ and $1 \leq j \leq k_c$,

$$|q_c| \leq \max_{1 \leq j \leq k_c} Q_j^c(|f_{\mathcal{Q}}|, |x|) \tag{2}$$

and

$$|f(q_c)| \geq \max_{1 \leq j \leq k_c} P_j^c(|f_{\mathcal{Q}}|, |x|). \tag{3}$$

But then there are first-order polynomials $\hat{Q}_c$, $1 \leq c \leq d$ such that for $1 \leq j \leq k_c$,

$$Q_j^c(|f_{\mathcal{Q}}|, |x|) \leq \hat{Q}_c(|f(q_1)|, \ldots, |f(q_{c-1})|, |x|). \tag{4}$$

Similarly, there is a first-order polynomial $\hat{P}$ such that

$$P(|f_{\mathcal{Q}}|, |x|) \leq \hat{P}(|f(q_1)|, \ldots, |f(q_d)|, |x|).$$

As an example, for the polynomial P_0 given in (1), we have

$$\begin{aligned} P_0(|f_{\mathcal{Q}}|, |x|) &\leq |f_{\mathcal{Q}}|(|f_{\mathcal{Q}}|(|x|^2)) + |f_{\mathcal{Q}}|([|f_{\mathcal{Q}}|(|x|)]^2) + |f_{\mathcal{Q}}|(|x|) + 4 \\ &\leq |f_{\mathcal{Q}}|(|f(q_1)|) + |f_{\mathcal{Q}}|(|f(q_1)|^2) + |f(q_1)| + 4 \\ &\leq |f(q_2)| + |f(q_2)| + |f(q_1)| + 4, \end{aligned}$$

where $|q_1| \leq |x|^2$ and $|q_2| \leq |f(q_1)|^2$. So we have $\hat{Q}_1 = n_1^2$, $\hat{Q}_2 = n_1^2$, and $\hat{P} = 2 \cdot n_2 + n_1 + 4$.

DEFINITION 5.10. *Let M be an OTM whose running time is bounded by the depth-d polynomial P. For* $1 \leq c \leq d$, *the cth* maximizing argument *for M, f, x, and t is the least-value q_c satisfying* (2) *and* (3) *for $\mathcal{Q} = \mathcal{Q}(M, f, x, t)$. The cth maximizing argument for M, f, x, and t is denoted $q_c(M, f, x, t)$, or just $q_c(t)$ when M, f, and x are understood.*

Recall that for any first-order polynomial $p(n_1, \ldots, n_k)$ with positive coefficients, there is a poly-time function f_p so that $|f_p(x_1, \ldots, x_k)| = p(|x_1|, \ldots, |x_k|)$, for all $x_1, \ldots, x_k$. Since the application functional is a BFF, for $\hat{Q}_1, \ldots, \hat{Q}_d, \hat{P}$, there are BFFs $G_{\hat{Q}_1}, \ldots, G_{\hat{Q}_d}, G_{\hat{P}}$ so that for all $f, x, q_1, \ldots, q_d$,

$$|G_{\hat{Q}_c}(f, q_1, \ldots, q_{c-1}, x)| = \hat{Q}_c(|f(q_1)|, \ldots, |f(q_{c-1})|, |x|), \quad 1 \leq c \leq d,$$

and

$$|G_{\hat{P}}(f, q_1, \ldots, q_d, x)| = \hat{P}(|f(q_1)|, \ldots, |f(q_d)|, |x|).$$

Now suppose that there are BFFs $G_1, \ldots, G_d$ such that for $1 \leq c \leq d$,

$$|f(G_c(f, x))| \geq |f(q_c(M, f, x, P(|f|, |x|))|.$$

We could then define a basic feasible bounding functional G by

$$G(f, x) = G_{\hat{P}}(f, G_1(f, x), \ldots, G_d(f, x), x).$$

As a first step toward finding such functionals, we will introduce a parameter r, which bounds the number of inputs at we allow M to query f. Formally, if $d(P) = d$, let $\mathrm{Max\_Arg}^c_M$, $1 \le c \le d$, be the functional of rank $(1, 2)$ defined by

$$\mathrm{Max\_Arg}^c_M(f, x, r) = \begin{cases} 0 & \text{if } r = 0, \\ q_c(M, f, x, t) + 1 & \text{otherwise,} \end{cases}$$

where t is the smallest value such that $S_M(f, x) \le \mathrm{Steps}(t)$ or $|Q(M, f, x, t)| \ge r$. In general, we will denote such a t by $t(M, f, x, r)$, or just $t(r)$ in the appropriate context.

CLAIM 5.11. *For any OTM M with running time bounded by a polynomial P with depth d,* $\mathrm{Max\_Arg}^c_M$ *is a BFF for* $1 \le c \le d$.

Given this claim, we only need to show that we can feasibly eliminate the use of the parameter r. If we could show that there is a BFF R such that for all f and x, $R(f, x) = |Q(M, f, x, P(|f|, |x|))|$, we would be finished, because we would then have

$$\mathrm{Max\_Arg}^c_M(f, x, R(f, x)) - 1 = q_c(M, f, x, P(|f|, |x|)).$$

What we will actually show is that there is a constant d and a sequence $r_1, \ldots, r_d$ of "approximations" to $R(f, x)$ such that r_1 is basic feasible in f, x and r_{c+1} is basic feasible in r_c, f, and x, and such that a basic feasible bounding functional G can be obtained from the r_c's. Intuitively, r_c is an upper bound on $R(f, x)$, assuming that M queries f only at points y such that $|y| \le |q_c|$. Given r, let

$$(5) \qquad T = G_{\hat{P}}(f, \mathrm{Max\_Arg}^1_M(f, x, r) - 1, \ldots, \mathrm{Max\_Arg}^d_M(f, x, r) - 1, x),$$

and $Q = Q(M, f, x, t)$, where $t = t(r)$. If $S_M(f, x) \le \mathrm{Steps}(t)$, $|T| \ge P(|f|, |x|)$, and so $F(f, x) = \mathrm{Output}(\mathrm{Run}_M(f, x, T))$. Otherwise, $S_M(f_Q, x) \ge \mathrm{Steps}(t)$ by Lemma 5.8, and so, by Lemma 5.6, $P(|f_Q|, |x|) \ge t$. By the definition of T, $|T| \ge P(|f_Q|, |x|)$. Finally, since each query made by M has at least unit cost, $t \ge r$. Combining these inequalities gives $|T| \ge r$. Now there is a BFF A which satisfies

$$|f(A(f, x))| = \max_{y \le |x|} |f(y)|.$$

Since $|T| \ge r$, $|f(A(f, 2\#T))| \ge |f|(|r|)$. In other words, if M on inputs f and x runs for long enough to query f at r inputs, then we can feasibly compute an upper bound of $|f|(|r|)$ from f, x, and r.

We will now give an example to show how we take advantage of the approach described above. Recall the polynomial P_0 given in (1).

$$P_0(|f|, |x|) = |f|(|f|(|x|^2)) + |f|([|f|(|x|)]^2) + |f|(|x|) + 4.$$

Suppose P_0 bounds the running time of M which computes the functional F. For inputs f and x, we will begin by trying to find q_1. For any Q, $|q_1| \le |x|^2 \le |x\#x|$. So we begin by setting $r_1 = x\#x$. Let T_1 be T as defined in (5), for $r = r_1$. Now if M halts before making r_1 queries, it halts in $\mathrm{Steps}(|T_1|)$ steps, so we do not need to go any further, since $|T_1|$ will bound the running time of M. Otherwise, we have a value $l_1 = A(f, 2\#T_1)$ so that $|f(l_1)| \ge |f(q_1)|$. Since $|q_2| \le |f(q_1)|^2$, we now try $r_2 = f(l_1)\#f(l_1)$, and let T_2 be T as defined by (5) for $r = r_2$. Again, if M halts in $\mathrm{Steps}(|T_2|)$ steps, we are done. Otherwise, we have a value $l_2 = A(f, 2\#T_2)$ so that $|f(l_2)| \ge |f(q_2)|$. Under the assumption that for inputs f and x, M does not halt in $\mathrm{Steps}(|T_1|)$ or $\mathrm{Steps}(|T_2|)$ steps, the running time of M must be bounded by $2 \cdot |f(l_2)| + |f(l_1)| + 4$. So if Pad is the rank $(0, 2)$ BFF defined by $\mathrm{Pad}(x, y) = x \cdot 2^{|y|}$ and

$$G(f, x) = \max\{T_1, T_2, \mathrm{Pad}(\mathrm{Pad}(2\#\mathrm{Ap}(f, l_2), \mathrm{Ap}(f, l_1)), 16)\},$$

then

$$F(f, x) = \text{Output}(\text{Run}_M(f, x, G(f, x))).$$

Formalizing this argument for arbitrary bounding polynomials, we obtain our main result.

THEOREM 5.12. *If F is a rank-$(1, 1)$ basic poly-time functional, then F is basic feasible.*

Proof. Suppose that F is a computed by an OTM M such that for all f and x, the running time of M with inputs f, x is bounded by $P(|f|, |x|)$, where $d(P) = d$. Let

$$\begin{aligned}
r_1 &= G_{\hat{Q}_1}(f, x), \\
T_c &= G_{\hat{P}}(f, \text{Max\_Arg}^1_M(f, x, r_c) - 1, \ldots, \text{Max\_Arg}^d_M(f, x, r_c) - 1, x), && 1 \le c \le d, \\
l_c &= A(f, 2\#T_c), && 1 \le c \le d, \\
r_c &= G_{\hat{Q}_c}(f, l_1, \ldots, l_{c-1}, x), && 2 \le c \le d,
\end{aligned}$$

and define G by

$$G(f, x) = \max\{G_{\hat{P}}(f, l_1, \ldots, l_d, x), T_1, \ldots, T_d\}.$$

An argument similar to that given in the example shows that for all f and x,

$$F(f, x) = \text{Output}(\text{Run}_M(f, x, G(f, x))). \qquad \square$$

It remains to demonstrate Claim 5.11. We want to show that Max_Arg^c_M is a BFF for $1 \le c \le d$. To do so, we also consider for $1 \le c \le d$, the functional Max_Arg_Unary^c_M of rank $(1, 2)$ such that for all f, x, r, and R, if $|R| = r$ then

$$\text{Max\_Arg}^c_M(f, x, r) = \text{Max\_Arg\_Unary}^c_M(f, x, R).$$

We begin by showing that Max_Arg_Unary^c_M is feasible for case where $d = 1$.

LEMMA 5.13. *For any OTM M with running time bounded by a depth-1 polynomial P, Max_Arg_Unary^1_M is basic feasible.*

Proof. Max_Arg_Unary^1_M is defined by LRN on R. $\text{Max\_Arg\_Unary}^1_M(f, x, 0) = 0$. Now suppose that we have defined $\text{Max\_Arg\_Unary}^1_M(f, x, \lfloor \frac{R}{2} \rfloor)$. Let $t = t(|\lfloor \frac{R}{2} \rfloor|)$, $Q = Q(t)$, and

$$T = 2 \cdot G_{\hat{P}}(f, \text{Max\_Arg\_Unary}^1_M(f, x, \lfloor \tfrac{R}{2} \rfloor) - 1, x) + 1.$$

Finally, let $h = \text{Run}_M(f, x, T)$. We claim that h encodes enough of the computation of M so that $\text{Max\_Arg\_Unary}(f, x, R)$ can be feasibly computed from h. If $S_M(f, x) \le \text{Steps}(t)$, then $|T| \ge P(|f|, |x|)$, so the claim holds. Otherwise, by Lemma 5.8, $S_M(f_Q, x) \ge \text{Steps}(t)$. Since T is defined so that $|T| > P(|f_Q|, |x|)$, we have, by Lemma 5.7, that $|Q(M, f, x, |T|)| > |Q(M, f, x, t)|$. Since $t = t(|\lfloor \frac{R}{2} \rfloor|)$, it follows that $|Q(M, f, x, |T|)| > |R|$, and again the claim holds. Since $|\text{Max\_Arg\_Unary}^1_M(f, x, R)|$ is bounded by $|G_{\hat{Q}_1}(f, x)|$, we conclude that Max_Arg_Unary^1_M is basic feasible. $\square$

LEMMA 5.14. *For any M with running time bounded by a depth-1 polynomial P, Max_Arg^1_M is basic feasible.*

Proof. Max_Arg^1_M is defined by LRN on r. We set $\text{Max\_Arg}^1_M(f, x, 0) = 0$. Now suppose that we have defined $\text{Max\_Arg}^1_M(f, x, \lfloor \frac{r}{2} \rfloor)$. Let Let $t = t(\lfloor \frac{r}{2} \rfloor)$, $Q = Q(t)$, and

$$T = 2 \cdot G_{\hat{P}}(f, \text{Max\_Arg}^1_M(f, x, \lfloor \tfrac{r}{2} \rfloor) - 1, x) + 1.$$

Finally, let $h = \text{Run}_M(f, x, T)$. If $S_M(f, x) \leq \text{Steps}(t)$, $|T| > P(|f|, |x|)$, and so h encodes the whole history of M's execution on inputs f, x and we can obtain $\text{Max\_Arg}^1_M(f, x, r)$ via a feasible computation on this history.

Otherwise, $S_M(f_Q, x) \geq \text{Steps}(t)$ by Lemma 5.8, so by Lemma 5.6, $P(|f_Q|, |x|) \geq t$. Now T is defined so that $|T| > P(|f_Q|, |x|)$, so $|T| > t$. Since every query has at least unit cost, $t \geq \lfloor \frac{r}{2} \rfloor$, and so we have $|T| \geq r$. It is easy to show that there is a poly-time function $s(x, y)$ so that if $|x| > y$, then $|s(x, y)| = y$. So

$$\text{Max\_Arg}^1_M(f, x, r) = \text{Max\_Arg\_Unary}^1_M(f, x, s(T, r)).$$

Since

$$|\text{Max\_Arg}^1_M(f, x, R)| \leq |G_{\hat{Q}_1}(f, x)|,$$

we conclude that Max_Arg^1_M is basic feasible. □

It is not hard to see that this argument can be extended to give a simultaneous definition of $\text{Max\_Arg\_Unary}^c_M(f, x, r)$ and $\text{Max\_Arg}^c_M(f, x, y)$, $1 \leq c \leq d$, assuming that the running time of M is bounded by a depth-d polynomial. So before we can conclude that these functions are BFFs as in Claim 5.11, we must extend LRN to allow simultaneous definitions. We begin by considering a simple extension of LRN.

Definition 5.15. *$F_1, \ldots, F_k$ are defined from $\vec{G}$, $\vec{H}$, and $\vec{K}$ by* simultaneous limited recursion on notation (SLRN) *iff for all $\vec{f}$, $\vec{x}$, and y,*

$$F_i(\vec{f}, \vec{x}, 0) = G_i(\vec{f}, \vec{x}), \quad 1 \leq i \leq k,$$

$$F_i(\vec{f}, \vec{x}, y) = H_i(\vec{f}, \vec{x}, y, \vec{F}(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor)), \quad y > 0, 1 \leq i \leq k,$$

$$|F_i(\vec{f}, \vec{x}, y)| \leq |K_i(\vec{f}, \vec{x}, y)|, \quad 1 \leq i \leq k.$$

Lemma 5.16. *If $F_1, \ldots, F_k$ are defined from $\vec{G}$, $\vec{H}$, and $\vec{K}$ by SLRN, then F_i is basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, $1 \leq i \leq k$.*

Proof. Recall that for $k \in \mathbb{N}$, there are poly-time functions $\lambda x_1 \ldots \lambda x_k . \langle x_1, \ldots, x_k \rangle$ and Π^k_i, $1 \leq i \leq k$, such that $\Pi^k_i(\langle x_1, \ldots, x_k \rangle) = x_i$. Now it is not hard to see that we can define, using LRN, a functional F, basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, such that $F_i(\vec{f}, \vec{x}, y) = \Pi^k_i(F(\vec{f}, \vec{x}, y))$. □

It would appear that SLRN is too weak to allow the simultaneous definition of the functionals Max_Arg^c_M, $1 \leq c \leq d$. The problem arises in attempting to provide bounds for these functionals. By (2) and (4), we know that

$$|\text{Max\_Arg}^c_M(\vec{f}, \vec{x}, y)| \leq |G_{\hat{Q}_c}(f, \text{Max\_Arg}^1_M(\vec{f}, \vec{x}, y) - 1, \ldots, \text{Max\_Arg}^{c-1}_M(\vec{f}, \vec{x}, y) - 1, x)|$$

and $\text{Max\_Arg\_Unary}^c_M(\vec{f}, \vec{x}, r)$ is similarly bounded. However, the bounding conditions for SLRN do not allow such a general form of bounding. We now introduce a form of simultaneous recursion which does.

Definition 5.17. *$F_1, \ldots, F_k$ are defined from $\vec{G}$, $\vec{H}$, and $\vec{K}$ by* multiple limited recursion on notation (MLRN) *iff for all $\vec{f}$, $\vec{x}$, and y,*

$$F_i(\vec{f}, \vec{x}, 0) = G_i(\vec{f}, \vec{x}), \quad 1 \leq i \leq k,$$

$$F_i(\vec{f}, \vec{x}, y) = H_i(\vec{f}, \vec{x}, y, \vec{F}(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor)), \quad y > 0, 1 \leq i \leq k,$$

$$|F_1(\vec{f}, \vec{x}, y)| \leq |K_1(\vec{f}, \vec{x}, y)|,$$

$$|F_i(\vec{f}, \vec{x}, y)| \leq |K_i(\vec{f}, \vec{x}, y, F_1(\vec{f}, \vec{x}, y), \ldots, F_{i-1}(\vec{f}, \vec{x}, y))|, \quad 2 \leq i \leq k.$$

MLRN is a generalization of a scheme introduced by Cook in [2]. The apparent power of this scheme compared to SLRN arises from the use of weaker bounds for $|F_i(\vec{f}, \vec{x}, y)|$, which require bounding only in terms of $F_1, \ldots, F_{i-1}$. Otherwise, MLRN is identical to SLRN. Surprisingly, it is no more powerful than SLRN.

THEOREM 5.18. *If $F_1, \ldots, F_k$ are defined by MLRN from $\vec{G}$, $\vec{H}$, and $\vec{K}$, then F_i is basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, $1 \leq i \leq k$.*

This is a result which is interesting in its own right. We postpone its proof to the following section, and continue now with the thread of our main result.

Proof of Claim 5.11. We extend the proof of Lemma 5.14, to allow a simultaneous definition of Max_Arg_Unary^c_M, $1 \leq c \leq d$, using MLRN. We then use these functionals to give a simultaneous definition of Max_Arg^c_M, $1 \leq c \leq d$, again using MLRN. □

6. Feasibility of MLRN. This section is devoted to the proof of Theorem 5.18. Our first step is to consider an apparently weaker version of MLRN.

DEFINITION 6.1. *$F_1, \ldots, F_k$ are defined from $\vec{G}$, $\vec{H}$, and $\vec{K}$ by* weak multiple limited recursion on notation (WMLRN) *iff for all $\vec{f}$, $\vec{x}$, and y,*

$$F_i(\vec{f}, \vec{x}, 0) = G_i(\vec{f}, \vec{x}), \quad 1 \leq i \leq k,$$

$$F_i(\vec{f}, \vec{x}, y) = H_i(\vec{f}, \vec{x}, y, F_1(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor), \ldots, F_k(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor)), \quad y > 0, 1 \leq i \leq k,$$

$$|F_1(\vec{f}, \vec{x}, y)| \leq |K_1(\vec{f}, \vec{x}, y)|,$$

$$|F_i(\vec{f}, \vec{x}, y)| \leq |K_i(\vec{f}, \vec{x}, y, F_{i-1}(\vec{f}, \vec{x}, y))|, \quad 2 \leq i \leq k.$$

Once we show that the BFFs are closed under WMLRN, we obtain a proof of Theorem 5.18, as follows.

Proof of Theorem 5.18. We show that there are functionals $F'_1, \ldots, F'_k$, basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, so that for $1 \leq i \leq k$,

$$F'_i(\vec{f}, \vec{x}, y) = \langle F_1(\vec{f}, \vec{x}, y), \ldots, F_i(\vec{f}, \vec{x}, y) \rangle.$$

$F'_i, \ldots, F'_k$ are defined by WMRLN, as follows:

$$F'_i(\vec{f}, \vec{x}, 0) = \langle G_1(\vec{f}, \vec{x}), \ldots, G_i(\vec{f}, \vec{x}) \rangle,$$

$$F'_i(\vec{f}, \vec{x}, y) = \langle H_1(\vec{f}, \vec{x}, y, \Pi^k_1((F'_1(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor))), \ldots, \Pi^k_k((F'_k(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor)))), \ldots,$$

$$H_i(\vec{f}, \vec{x}, y, \Pi^k_1((F'_1(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor))), \ldots, \Pi^k_k((F'_k(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor))))) \rangle, \quad y > 0,$$

$$|F'_1(\vec{f}, \vec{x}, y)| \leq |K_1(\vec{f}, \vec{x}, y)|,$$

$$|F'_i(\vec{f}, \vec{x}, y)| \leq |\langle K_1(\vec{f}, \vec{x}, y), K_2(\vec{f}, \vec{x}, y, \Pi^{i-1}_1(F'_{i-1}(\vec{f}, \vec{x}, y))), \ldots,$$

$$K_i(\vec{f}, \vec{x}, y, \Pi^{i-1}_1(F'_{i-1}(\vec{f}, \vec{x}, y)), \ldots, \Pi^{i-1}_{i-1}(F'_{i-1}(\vec{f}, \vec{x}, y))) \rangle| \qquad \square$$

It remains to show that the BFFs are closed under WMLRN. Suppose $F_1, \ldots, F_k$ are defined by WMLRN. By introducing extra parameters $z_1, \ldots, z_k$ so that F_i is bounded in terms of z_{i-1} rather than F_{i-1}, it is possible to define by SLRN functionals $E_1, \ldots, E_k$ so that E_i agrees with F_i when supplied with appropriate values for $z_1, \ldots, z_{k-1}$. This is formalized in Lemma 6.2 below. It then remains to define $z_1, \ldots, z_{k-1}$ with the required property. In fact, functionals giving appropriate values for $z_1, \ldots, z_{k-1}$ can be defined by WMLRN. Then, by induction on k, we can conclude that the F_i's are definable using SLRN. This is formalized in Lemma 6.3 below. We will write $x \subseteq y$ if for some i, $x = \lfloor y/2^i \rfloor$.

LEMMA 6.2. *Suppose that $F_1, \ldots, F_k$ are defined from $\vec{G}$, $\vec{H}$, and $\vec{K}$ by WMLRN. Then there are functionals $E_1, \ldots, E_k$, basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, so that for all $z_1, \ldots, z_{k-1}$, $y'_1, \ldots, y'_{k-1}$ and all y, if*

$$(6) \qquad |F_i(\vec{f}, \vec{x}, v)| \leq |K_i(\vec{f}, \vec{x}, y'_{i-1}, z_{i-1})|, \quad 2 \leq i \leq k,$$

for all $v \subseteq y$, then

$$E_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) = F_i(\vec{f}, \vec{x}, y), \quad 1 \leq i \leq k.$$

Proof. Let $L_1, \ldots, L_k$ be defined as follows:

$$L_1(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) = K_1(\vec{f}, \vec{x}, y),$$

$$L_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) = K_i(\vec{f}, \vec{x}, y'_{i-1}, z_{i-1}), \quad 2 \leq i \leq k.$$

Let $H'_1, \ldots, H'_k$ be defined as follows:

$$H'_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y, \vec{t}) = \begin{cases} H_i(\vec{f}, \vec{x}, y, \vec{t}) & \text{if } |H_i(\vec{f}, \vec{x}, y, \vec{t})| \leq |L_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y))|, \\ L_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) & \text{otherwise.} \end{cases}$$

Finally, let $G'_1, \ldots, G'_k$ be defined as follows:

$$G'_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}) = G_i(\vec{f}, \vec{x}).$$

$E_1, \ldots, E_k$ are defined by SLRN from $\vec{G'}$, $\vec{H'}$, and $\vec{L}$. Clearly, E_i is bounded by L_i, $1 \leq i \leq k$. We now show by induction on y that if (6) holds for all $v \subseteq y$, then

$$E_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) = F_i(\vec{f}, \vec{x}, y), \quad 1 \leq i \leq k.$$

This follows directly when $y = 0$. Now suppose it is the case for $\lfloor \frac{y}{2} \rfloor$. Assume that (6) holds for all $v \subseteq y$. Then it holds for all $v \subseteq \lfloor \frac{y}{2} \rfloor$, and by the induction hypothesis we have

$$E_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, \lfloor \tfrac{y}{2} \rfloor) = F_i(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor), \quad 1 \leq i \leq k,$$

and so

$$H_i(\vec{f}, \vec{x}, y, E_1(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, \lfloor \tfrac{y}{2} \rfloor), \ldots, E_k(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, \lfloor \tfrac{y}{2} \rfloor)) = F_i(\vec{f}, \vec{x}, y), \quad 1 \leq i \leq k.$$

Now $|F_1(\vec{f}, \vec{x}, y)| \leq |K_1(\vec{f}, \vec{x}, y)|$ and by our assumption that (6) holds for all $v \subseteq y$, for $2 \leq i \leq k$ we have

$$|F_i(\vec{f}, \vec{x}, y)| \leq |L_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y)|.$$

We then conclude, referring to (6), that $E_i(\vec{f}, \vec{x}, \vec{y'}, \vec{z}, y) = F_i(\vec{f}, \vec{x}, y)$. □

LEMMA 6.3. *If $F_1, \dots, F_k$ are defined by WMLRN from $\vec{G}$, $\vec{H}$, and $\vec{K}$, then F_i is basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, $1 \leq i \leq k$.*

Proof. We proceed by induction on $k \geq 2$. When $k = 2$, we show that there is a functional P, basic feasible in $\vec{G}$, $\vec{H}$, $\vec{K}$ so that for all y and all $v \subseteq y$,

$$(7) \qquad |F_2(\vec{f}, \vec{x}, v)| \leq |K_2(\vec{f}, \vec{x}, \Pi_1(P(\vec{f}, \vec{x}, y)), \Pi_2(P(\vec{f}, \vec{x}, y)))|.$$

Having defined such a P, we can conclude from the preceding lemma that

$$F_i(\vec{f}, \vec{x}, y) = E_i(\vec{f}, \vec{x}, \Pi_1(P(\vec{f}, \vec{x}, y)), \Pi_2(P(\vec{f}, \vec{x}, y)), y), \quad i = 1, 2,$$

so that F_i is basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, $i = 1, 2$. It is easy to see that if P satisfies

$$(8) \qquad P(\vec{f}, \vec{x}, y) = \langle v, F_1(\vec{f}, \vec{x}, v)\rangle,$$

where $v \subseteq y$ maximizes $|K_2(\vec{f}, \vec{x}, v, F_1(\vec{f}, \vec{x}, v))|$, then P will satisfy (7) for all $v \subseteq y$. So it suffices to find a BFF P which satisfies (8) for all y. Now define P as follows:

$$P(\vec{f}, \vec{x}, 0) = \langle 0, G_1(\vec{f}, \vec{x})\rangle,$$

$$P(\vec{f}, \vec{x}, y) = \begin{cases} \langle y, z_1\rangle & \text{if } |K_2(\vec{f}, \vec{x}, y, z_1)| \geq |K_2(\vec{f}, \vec{x}, \Pi_1(t_1), \Pi_2(t_1)))|, \\ t_1 & \text{otherwise,} \end{cases} \qquad y > 0,$$

where

$$z_1 = H_1(\vec{f}, \vec{x}, y, E_1(\vec{f}, \vec{x}, \Pi_1(t_1), \Pi_2(t_1), \lfloor \tfrac{y}{2} \rfloor), E_2(\vec{f}, \vec{x}, \Pi_1(t_1), \Pi_2(t_1), \lfloor \tfrac{y}{2} \rfloor))$$

and

$$t_1 = P(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor).$$

We will show that P satisfies (8) for all y, by induction on the notation of y. This follows directly when $y = 0$. Now assume that P satisfies (8) for $\lfloor \frac{y}{2} \rfloor$. Then P satisfies (7) for all $v \subseteq \lfloor \frac{y}{2} \rfloor$, so that by the preceding lemma, $z_1 = F_1(\vec{f}, \vec{x}, y)$. But then, by the induction hypothesis and the definition of P,

$$P(\vec{f}, \vec{x}, y) = \begin{cases} \langle y, F_1(\vec{f}, \vec{x}, y)\rangle & \text{if } |K_2(\vec{f}, \vec{x}, y, F_1(\vec{f}, \vec{x}, y))| \geq |K_2(\vec{f}, \vec{x}, v, F_1(\vec{f}, \vec{x}, v))|, \\ \langle v, F_1(\vec{f}, \vec{x}, v)\rangle & \text{otherwise,} \end{cases}$$

where $v \subseteq \lfloor \frac{y}{2} \rfloor$ maximizes $|K_2(\vec{f}, \vec{x}, v, F_1(\vec{f}, \vec{x}, v))|$. It is then clear that P satisfies (8) for y, as required. Finally, since P satisfies (8) for all y,

$$|P(\vec{f}, \vec{x}, y)| \leq |\langle y, \max_{v \subseteq y} K_1(\vec{f}, \vec{x}, v)\rangle|,$$

so that, in fact, P is definable by LRN from functionals basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$.

Now assume that the result holds for $k - 1$. We show validity for k as follows: we will show that there are $P_1, \dots, P_{k-1}$, basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$ so that for $2 \leq i \leq k$,

$$(9) \qquad |F_i(\vec{f}, \vec{x}, v)| \leq |K_i(\vec{f}, \vec{x}, \Pi_1(P_{i-1}(\vec{f}, \vec{x}, y)), \Pi_2(P_{i-1}(\vec{f}, \vec{x}, y)))|$$

for all y and all $v \subseteq y$. By the preceding lemma, we will then have

$$F_i(\vec{f}, \vec{x}, y) = E_i(\vec{f}, \vec{x}, \Pi_1(P_1(\vec{f}, \vec{x}, y)), \dots, \Pi_1(P_{i-1}(\vec{f}, \vec{x}, y)), \Pi_2(P_1(\vec{f}, \vec{x}, y)), \dots,$$
$$\Pi_2(P_{i-1}(\vec{f}, \vec{x}, y), y)),$$

so that F_i is basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$, $1 \leq i \leq k$. We will attempt to define $P_1, \ldots, P_{k-1}$ by WMLRN. By the induction hypothesis, we can then conclude that $P_1, \ldots, P_{k-1}$ are basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$. It is easy to see that for $1 \leq i \leq k-1$, if P_i satisfies

$$(10) \qquad P_i(\vec{f}, \vec{x}, y) = \langle v_i, F_i(\vec{f}, \vec{x}, v_i)\rangle,$$

where $v_i \subseteq y$ maximizes $|K_{i+1}(\vec{f}, \vec{x}, v_i, F_i(\vec{f}, \vec{x}, v_i))|$, then P_i will satisfy (9) for all $v \subseteq y$. So it suffices to find BFFs $P_1, \ldots, P_{k-1}$ which satisfy (10) for all y. Define $P_1, \ldots, P_{k-1}$ as follows:

$$P_i(\vec{f}, \vec{x}, 0) = \langle 0, G_i(\vec{f}, \vec{x})\rangle,$$

$$P_i(\vec{f}, \vec{x}, y) = \begin{cases} \langle y, z_i\rangle & \text{if } |K_{i+1}(\vec{f}, \vec{x}, y, z_i)| \geq |K_{i+1}(\vec{f}, \vec{x}, \Pi_1(t_i), \Pi_2(t_i))|, \\ t_i & \text{otherwise}, \end{cases} \qquad y > 0,$$

where

$$z_i = H_i(\vec{f}, \vec{x}, y, E_1(\vec{f}, \vec{x}, \Pi_1(t_1), \ldots, \Pi_1(t_{k-1}), \Pi_2(t_1), \ldots, \Pi_2(t_{k-1})), \ldots,$$
$$E_k(\vec{f}, \vec{x}, \Pi_1(t_1), \ldots, \Pi_1(t_{k-1}), \Pi_2(t_1), \ldots, \Pi_2(t_{k-1})))$$

and

$$t_i = P_i(\vec{f}, \vec{x}, \lfloor \tfrac{y}{2} \rfloor).$$

We now show, by induction on the notation of y, that the P_i's satisfy (10) for all y. This is clear when $y = 0$. Assume that for $1 \leq i \leq k-1$, P_i satisfies (10) for $\lfloor \frac{y}{2} \rfloor$. Then for $1 \leq i \leq k-1$, P_i satisfies (9) for all $v \subseteq \lfloor \frac{y}{2} \rfloor$, so that by the preceding lemma, $z_i = F_i(\vec{f}, \vec{x}, y)$. But then, by the induction hypothesis and the definition of P_i, for $1 \leq i \leq k-1$ we have

$$P_i(\vec{f}, \vec{x}, y)$$
$$= \begin{cases} \langle y, F_i(\vec{f}, \vec{x}, y)\rangle & \text{if } |K_{i+1}(\vec{f}, \vec{x}, y, F_i(\vec{f}, \vec{x}, y))| \geq |K_{i+1}(\vec{f}, \vec{x}, v_i, F_i(\vec{f}, \vec{x}, v_i))|, \\ \langle v_i, F_i(\vec{f}, \vec{x}, v_i)\rangle & \text{otherwise}, \end{cases}$$

where $v_i \subseteq y$ maximizes $|K_{i+1}(\vec{f}, \vec{x}, v_i, F_i(\vec{f}, \vec{x}, v_i))|$. It is then clear that for $1 \leq i \leq k-1$, P_i satisfies (10) for y, as required.

It remains to show that $P_1, \ldots, P_{k-1}$ are bounded in such a way so that they are definable by WMLRN. The bound for P_1 is obtained as in the base case. Now for $2 \leq i \leq k-1$, we conclude from the definition of P_i that

$$|\Pi_2(P_i(\vec{f}, \vec{x}, y))| \leq \max_{v \subseteq y} |F_i(\vec{f}, \vec{x}, v))|.$$

We also conclude from the definition of F that

$$|F_i(\vec{f}, \vec{x}, v)| \leq |K_i(\vec{f}, \vec{x}, v, F_{i-1}(\vec{f}, \vec{x}, v))|$$

Combining these equalities with the fact that for $1 \leq i \leq k-1$, P_i satisfies (10) for all y, we see that

$$|\Pi_2(P_i(\vec{f}, \vec{x}, y))| \leq |K_i(\vec{f}, \vec{x}, \Pi_1(P_{i-1}(\vec{f}, \vec{x}, y)), \Pi_2(P_{i-1}(\vec{f}, \vec{x}, y))).$$

Finally, since $|\Pi_1(P_i(\vec{f}, \vec{x}, y))| \leq |y|$, $P_1, \ldots, P_{k-1}$ are definable by WMLRN from functionals basic feasible in $\vec{G}$, $\vec{H}$, and $\vec{K}$. □

LINEAR TIME AND MEMORY-EFFICIENT COMPUTATION*

KENNETH W. REGAN†

Abstract. A realistic model of computation called the *block-move* (BM) model is developed. The BM regards computation as a sequence of finite transductions in memory, and operations are timed according to a memory cost parameter μ. Unlike previous memory-cost models, the BM provides a rich theory of linear time, and in contrast to what is known for Turing machines (TMs), the BM is proved to be highly *robust* for linear time. Under a wide range of μ parameters, many forms of the BM model, ranging from a fixed-wordsize random-access machine (RAM) down to a single finite automaton iterating itself on a single tape, are shown to simulate each other up to constant factors in running time. The BM is proved to enjoy efficient universal simulation, and to have a tight deterministic time hierarchy. Relationships among BM and TM time complexity classes are studied.

Key words. computational complexity, theory of computation, machine models, Turing machines, random-access machines, simulation, memory hierarchies, finite automata, linear time, caching

1. Introduction.

This paper develops a new theory of linear-time computation. The *block-move* (BM) model introduced here extends ideas and formalism from the *block-transfer* (BT) model of Aggarwal, Chandra, and Snir [2]. The BT is a random-access machine (RAM) with a special *block-transfer* operation, together with a parameter $\mu : \mathbf{N} \to \mathbf{N}$ called a *memory-access cost function*. The RAM's registers are indexed 0,1,2,..., and $\mu(a)$ denotes the cost of accessing register a. A block transfer has the form

$$copy\ [a_1 \ldots b_1]\ into\ [a_2 \ldots b_2],$$

and is *valid* if these intervals have the same size m and do not overlap. With regard to a particular μ, the charge for the block transfer is $m + \mu(c)$ time units, where $c = \max\{a_1, b_1, a_2, b_2\}$. The idea is that after the initial charge of $\mu(a)$ for accessing the two blocks, a line of consecutive registers can be read or written at unit time per item. This is a reasonable reflection of how pipelining can hide memory latency, and accords with the behavior of physical memory devices (see [3], p. 1117, or [34], p. 214). An earlier paper [1] studied a model called HMM which lacked the block-transfer construct. The main memory-cost functions treated in these papers are $\mu_{\log}(a) := \lceil \log_2(a+1) \rceil$, which reflects the time required to write down the memory address a, and the functions $\mu_d(a) := \lceil a^{1/d} \rceil$ with $d = 1, 2, 3, \ldots$, which model the asymptotic increase in communication time for memory laid out on a d-dimensional grid. (The cited papers write f in place of μ and α for $1/d$.) The two-level *input/output* (*I/O*) *complexity* model of Aggarwal and Vitter [3] has fixed block size and a fixed cost for accessing the outer level, while the *uniform memory hierarchy* (UMH) model of Alpern, Carter, and Feig [5] scales block size and memory access cost upward in steps at higher levels.

The BM makes the following changes to the BT. First, the BM fixes the wordsize of the underlying machine, so that registers are essentially the same as cells on a Turing tape. Second, the BM provides native means of shuffling and reversing blocks. Third and most important, the BM allows other finite transductions S besides *copy* to be applied to the data in a block operation. A *block move* has the form

$$S\ [a_1 \ldots b_1]\ into\ [a_2 \ldots b_2].$$

*Received by the editors June 17, 1993; accepted for publication (in revised form) July 28, 1994. This research was supported in part by NSF Research Initiation Award CCR-9011248.

If x is the string formed by the symbols in cells a_1 through b_1, this means that $S(x)$ is written to the tape beginning at cell a_2 in the direction of b_2, with the proviso that a blank B appearing in the output $S(x)$ leaves the previous content of the target cell unchanged. This proviso implements *shuffle*, while *reverse* is handled by allowing $b_1 < a_1$ and/or $b_2 < a_2$. The block move is *valid* if the two intervals are disjoint and meets the *strict boundary condition* if $S(x)$ neither overflows nor underflows $[a_2 \dots b_2]$. The *work* performed in the block move is defined to be the number $|x|$ of bits read, while the *memory-access charge* is again $\mu(c)$, $c = \max\{a_1, b_1, a_2, b_2\}$. The μ*-time* is the sum of these two numbers. Adopting terms from [5], we call a BM M *memory efficient* if the total memory-access charges stay within a constant factor (depending only on M) of the work performed, and *parsimonious* if the ratio of access charges to work approaches 0 as the input length n increases.

In the BT model, Aggarwal, Chandra, and Snir [2] proved tight nonlinear lower bounds of $\Theta[n \log n]$ with $\mu = \mu_1$, $\Theta[n \log\log n]$ with $\mu = \mu_d, d > 1$, and $\Theta[n \log^* n]$ with $\mu = \mu_{\log}$, for the so-called "touch problem" of executing a sequence of operations during which every value in registers $R_1 \dots R_n$ is copied at least once to R_0. Since any access to R_a is charged the same as copying R_a to R_0, this gives lower bounds on the time for any BT computation that involves all of the input. In the BM model, however, the other finite transductions can glean information about the input in a way that *copy* cannot. Even under the highest cost function μ_1 that we consider, many interesting nonregular languages and functions are computable in linear time.

1.1. Previous models. It has long been realized that the standard unit-cost RAM model [21], [31], [18] is too powerful for many practical purposes. Feldman and Shapiro [22] contend that realistic models $\mathcal{M}$, both sequential and parallel, should have a property they call "polynomial vicinity," which we state as follows: let C be a data configuration, and let H_C stand for the finite set of memory locations (or data items) designated as "scanned" in C. For all $t > 0$, let I_t denote the set of locations (or items) i such that there exists an $\mathcal{M}$-program that, when started in configuration C, scans i within t time units. Then the model $\mathcal{M}$ has *vicinity* $v(t)$ if for all C and t, $|I_t|/|H_C| \leq v(t)$. In three-dimensional space, real machines "should have" at most cubic vicinity. The RAM model, however, has exponential vicinity even under the *log-cost criterion* advocated by Cook and Reckhow [18]. So do the random-access Turing machine (RAM-TM) forms described in [30], [26], [7], [14], [64], and so do TMs with tree-structured tapes (see [57], [63], [51], [52]). Turing machines with d-dimensional tapes (see [31], [60], [50]) have vicinity $O(t^d)$, regardless of the number of such tapes or number of heads on each tape, even with head-to-head jumps allowed. The standard TM model, with $d = 1$, has linear vicinity. The "RAM with polynomially compact memory" of Grandjean and Robson [29] limits integers i that can be stored and registers a that can be used to a polynomial in the running time T. This is not quite the same as polynomial vicinity—if $t \ll T$, the machine within t steps could still address a number of registers that is exponential in t. The BM has polynomial vicinity under μ_d (though not under $\mu_{\log}$), because any access outside the first t^d cells costs more than t time units. The theorem of [56] that deterministic linear time on the standard TM (DLIN) is properly contained in nondeterministic TM linear time (NLIN) is not known to carry over to any model of superlinear vicinity.

1.2. Practical motivations. The BM attempts to capture, with a minimum of added notation, several important properties of computations on real machines that the previous models neglect or treat too coarsely. The motivations are largely the same as those for the BT and UMH. As calibrated by μ, memory falls into a *hierarchy* ranging from relatively small amounts of low-indexed fast memory up through to large amounts of slow external storage. An algorithm that enjoys good *temporal locality of reference*, meaning that long stretches of its operation use relatively few different data items, can be implemented as a BM program that first copies the needed items to low memory (figuratively, to a cache) and is rewarded by a lower sum of memory-access charges. Good *spatial locality of reference*, meaning that needed data items are stored in neighboring locations in approximately the order of their need, is rewarded by the possibility of batching or pipelining a sequence of operations in the same block move. However, the BM appears to emphasize the sequencing of data items within a block more than the BT and UMH do, and we speak more specifically of *good serial access* rather than spatial locality of reference. The BM breaks sequential computation into phases in which access is serial and the operation is a finite transduction, and allows "random" access only between phases. Both μ*-time*(n) and the count $R(n)$ of block moves provide ways to quantify random access as a resource. The latter also serves as a measure of parallel time, since finite transductions can be computed by parallel prefix sum. Indeed, the BM is similar to the Pratt–Stockmeyer vector machine [61], and can also be regarded as a fixed-wordsize analogue of Blelloch's "scan" model [11].

1.3. Results. The first main theorem is that the BM is a very *robust* model. Many diverse forms of the machine simulate each other up to constant factors in μ-time, under a wide range of cost functions μ. Allowing multiple tapes or heads, expanding or limiting the means of tape access, allowing invalid block moves, making block boundaries preset or datadependent in a block move, and even reducing the model down to a single finite automaton that iterates itself on a single tape make no or little difference. We claim that this is the first sweeping *linear-time* robustness result for a natural model of computation. A "linear speed-up" theorem, similar to the familiar one for Turing machines, makes the constant factors on these simulations as small as desired. All of this gives the complexity measure μ*-time* a good degree of machine independence. Some of the simulations preserve the work (w) and memory-access charges (μ*-acc*) separately, while others trade w off against μ*-acc* to preserve their sum.

Section 2 defines the basic BM model and also the reduced form. Section 3 defines all the richer forms, and §4 proves their equivalence. The linear speed-up theorem and some results on memory efficiency are in §5. The second main result of this paper, in §6, shows that like the RAM but unlike what is known for the standard multitape Turing machine model (see [36], [24]), the BM carries only a constant factor overhead for universal simulation. The universal BM given is efficient under any μ_d, while separate constructions work for $\mu_{\log}$. In consequence, for any fixed $\mu = \mu_d$ or $\mu_{\log}$, the BM complexity classes DμTIME$[t]$ form a *tight deterministic time hierarchy* as the order of the time function t increases. Whether there is any hierarchy at all when μ rather than t varies is shown in §7 to tie back to older questions of determinism versus nondeterminism. This section also compares the BM to standard TM and RAM models and studies BM complexity classes. Section 8 describes open problems, and §9 presents conclusions.

2. The block-move model. We use λ for the empty string and B for the *blank* character. $\mathbf{N}$ stands for $\{0, 1, 2, 3, \dots\}$. Characters in a string x of length m are numbered $x_0x_1 \cdots x_{m-1}$. We modify the *generalized sequential machine* (GSM) of [36] so that it can exit without reading all of its input.

DEFINITION 2.1. *A* generalized sequential transducer (GST) *is a machine S with components $(Q, \Gamma, \delta, \rho, s, F)$, where $F \subseteq Q$ is the set of* terminal states, $s \in Q \setminus F$ *is the* start state, $\delta : (Q \setminus F) \times \Gamma \rightarrow Q$ *is the* transition function, *and* $\rho : (Q \setminus F) \times \Gamma \rightarrow \Gamma^*$ *is the* output function. *The* I/O alphabet Γ *may contain the blank B.*

A sequence $(q_0, x_0, q_1, x_1, \dots, q_{m-1}, x_{m-1}, q_m)$ is a halting trajectory *of S on input x if $q_0 = s$, $q_m \in F$, $x_0x_1 \dots x_{m-1}$ is an initial substring of x, and for $0 \leq i \leq m-1$, $\delta(q_i, x_i) = q_{i+1}$. The* output $S(x)$ *is defined to be $\rho(q_0, x_0) \cdot \rho(q_1, x_1) \cdots \rho(q_{m-1}, x_{m-1})$.*

By common abuse of notation we also write $S(\cdot)$ for the partial function computed by S. Except briefly in §8, all finite-state machines we consider are deterministic. A symbol c is an

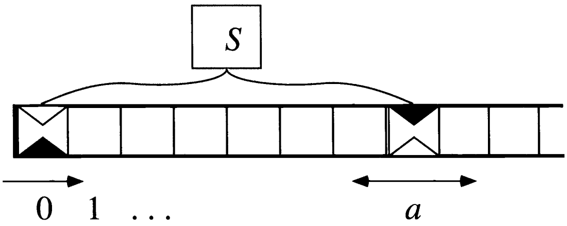

FIG. 1. *BM with allowed head motions in a pass.*

endmarker for a GST S if every transition on c sends S to a terminal state. Without loss of generality, B is an endmarker for all GSTs.

The intuitive picture of our model is a "circuit board" with GST "chips," each of which can process streams of data drawn from a single tape. The formalism is fairly close to that for Turing machines in [36].

DEFINITION 2.2. *A* block machine (BM) *is denoted by* $M = (Q, \Sigma, \Gamma, \delta, B, S_0, F)$, *where*

- Q *is a finite set consisting of* GSTs, move states, *and* halt states;
- F *is the set of halt states*;
- *every GST has one of the four labels* Ra, La, $0R$, *or* $0L$;
- move states *are labeled either* $\lfloor a/2 \rfloor$, $2a$, *or* $2a+1$;
- Σ *is the I/O alphabet of* M, *while the work alphabet* Γ *is used by all GSTs*;
- *the* start state S_0 *is a GST with label* Ra; *and*
- *the* transition function δ *is a mapping from* $(Q \setminus F) \times \Gamma$ *to* Q.

We find it useful to regard GSTs as "states" in a BM machine diagram, reading the machine in terms of the specific functions they perform, and submerging the individual states of the GSTs onto a lower level. M has two tape heads, called the "cell-0 head" and the "cell-a head," which work as follows in a GST pass (Fig. 1). Let $\sigma[i]$ stand for the symbol in tape cell i, and for $i, j \in \mathbf{N}$ with $j < i$ allowed, let $\sigma[i \dots j]$ denote the string formed by the symbols from cell i to cell j.

DEFINITION 2.3. *A* pass *by a GST S in a BM works as follows, with reference to the* current address a *and each of the four* modes Ra, La, $0R$, $0L$:

(Ra) *S reads the tape moving rightward from cell* a. *Since B is an endmarker for S, there is a cell* $b \geq a$ *in which S exits. Let* $x := \sigma[a \dots b]$ *and* $y := S(x)$. *If* $y = \lambda$, *the pass ends with no change in the tape. For* $y \neq \lambda$, *let* $c := |y| - 1$. *Then y is written into cells* $[0 \dots c]$, *except that if* $y_i = B$, *cell i is left unchanged. This completes the pass.*

(La) *S reads the tape moving leftward from cell* a. *Unless S runs off the left end of the tape (causing a "crash"), let* $b \leq a$ *be the cell in which S exits. As before let* $x := \sigma[a \dots b]$, $y := S(x)$, *and if* $y \neq \lambda$, $c := |y| - 1$. *Then formally, for* $0 \leq i \leq c$, *if* $y_i \neq B$ *then* $\sigma[i] := y_i$, *while if* $y_i = B$ *then* $\sigma[i]$ *is unchanged.*

($0R$) *S reads from cell* 0, *necessarily moving right. Let c be the cell in which S halts. Let* $x := \sigma[0 \dots c]$, $y := S(x)$, *and* $b := a + |y| - 1$. *Then y is written rightward from a into cells* $[a \dots b]$, *with the same convention about B as above.*

($0L$) *This is the same as* $0R$, *except that* $b := a - |y| + 1$, *and y is written leftward from a into* $[a \dots b]$.

Here a, b, and c are the access points *of the pass. Each of the four kinds of passes is* valid *if either* (i) $y = \lambda$, (ii) $a, b, c \leq 1$, *or* (iii) $c < \min\{a, b\}$. *The case* $y = \lambda$ *is called an* empty pass, *while if* $|x| = 1$, *then it is called a* unit pass.

In terms of §1, Ra and La execute the block move $S[a \dots b]$ *into* $[0 \dots c]$, except that the boundaries b and c are not set in advance and can depend on the data x. Similarly $0R$ and

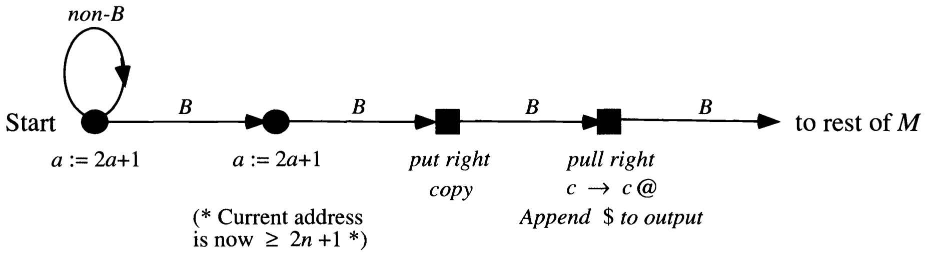

FIG. 2. *A BM that makes a fresh track.*

$0L$ execute $S\,[0\ldots c]$ *into* $[a\ldots b]$. We make the distinction that in a *pass*, the read and write boundaries may depend on the data, while in a *block move* (formalized in the next section), they are set beforehand. The tape is regarded as linear for passes or block moves but as a binary tree for addressing. The root of the tree is cell 1, while cell 0 is an extra cell above the root. The validity condition says that the intervals $[a\ldots b]$ and $[0\ldots c]$ must not overlap, with a technically convenient exception in case the whole pass is done in cells 0 and 1. If a pass is invalid, M is considered to "crash." A pass of type Ra or La figuratively "pulls" data to the left end of the tape, and we refer to it as a *pull*; similarly, we call a pass of type $0R$ or $0L$ a *put*. Furthering the analogy to internal memory or to a processor cache, these pass types might be called a *fetch* and *writeback*, respectively. An La or $0L$ pass can reverse a string on the tape.

DEFINITION 2.4. *A valid computation $\vec{c}$ by a BM $M = (Q, \Sigma, \Gamma, \delta, B, S_0, F)$ is defined as follows. Initially $a = 0$, the tape contains x in cells $0\ldots|x|-1$ with all other cells blank, and S_0 makes the first pass. When a pass by a GST S ends, let c be the character read on the transition in which S exited. Then control passes to $\delta(S, c)$. In a move state q, the new current address a' equals $\lfloor a/2\rfloor$, $2a$, or $2a+1$ according to the label of q, and letting d be the character in cell a', control passes to state $\delta(q, d)$. All passes must be valid, and a valid computation ends when control passes to a halting state. Then the* output, *denoted by $M(x)$, is defined to be $\sigma[0\ldots m-1]$, where $\sigma[m]$ is the leftmost non-Σ character on the tape. If M is regarded as an acceptor, then the language of strings accepted by M is denoted by $L(M) := \{x \in \Sigma^* | M(x)$ halts and outputs 1 $\}$.*

The convention on output is needed since a BM cannot erase, i.e., write B. Alternatively, for an acceptor, F could be partitioned into states labeled ACCEPT and REJECT.

DEFINITION 2.5. *A* memory-cost function *is any function $\mu : \mathbf{N} \rightarrow \mathbf{N}$ with the properties* (a) $\mu(0) = 0$, (b) $(\forall a)\mu(a) \le a$, *and* (c) $(\forall N \ge 1)(\forall a)\mu(Na) \le N\mu(a)$.

Our results will only require the property (c′): $(\forall N \ge 1)(\exists N' \ge 1)$ $(\forall^\infty a)$ $\mu(Na) \le N'\mu(a)$. While property (c) can be named by saying that μ is "sublinear," we do not know a standard mathematical name for (c′), and we prefer to call either (c) or (c′) the *tracking property* for the following reason.

EXAMPLE 2.1. Tracking. *Figure 2 diagrams a multichip BM routine that changes the input $x = x_0x_1\cdots x_{n-1}$ to $x_0@x_1@\cdots x_{n-2}@x_{n-1}$ @ \$, where @ acts as a "surrogate blank," and only @ or B appears to the right of the \$. This divides the tape into two* tracks *of odd and even cells. A BM can write a string y to the second track by pulling it as $By_0By_1\cdots By_{m-1}By_m$, since the blanks B leave the contents of the first track undisturbed. Two strings can also be* shuffled *this way. Since $\mu(2a) \le 2\mu(a)$, the tracking no more than doubles the memory-access charges.*

The principal memory cost functions we consider in this paper are the *log-cost function* $\mu_{\log}(a) := \lceil\log_2(a+1)\rceil$, and for all $d \ge 1$, the *d-dimensional layout function* $\mu_d(a) := \lceil a^{1/d}\rceil$. These have the tracking property.

DEFINITION 2.6. *For any memory-cost function μ, the μ-time of a valid pass that reads x and operates the cell-a head in the interval $[a \dots b]$ is given by $\mu(a) + |x| + \mu(b)$. The* work *of the pass is $|x|$, and the* memory-access charge *is $\mu(a) + \mu(b)$. A move state that changes a to a' performs 1 unit of work and has a memory-access charge of $\mu(a) + \mu(a')$. The sum of the work over all passes in a valid computation $\vec{c}$ is denoted by $w(\vec{c})$, the total memory-access charges by μ-acc$(\vec{c})$, and the total μ-time by $\mu(\vec{c}) := w(\vec{c}) + \mu\text{-}acc(\vec{c})$.*

Intuitively, the charge for a pass is $\mu(a)$ time units to access cell a, plus $|x|$ time units for reading or writing the block, plus $\mu(b)$ to communicate to the central processing unit (CPU) that the pass has ended and to reset the heads. We did not write $\max\{\mu(a), \mu(b)\}$ because b is not known until after the time to access a has already been spent; this makes no difference up to a factor of two. Replacing $|x|$ by $|x| + |S(x)|$ or by $\max\{|x|, |S(x)|\}$, or adding $\mu(c)$ to $\mu(a) + \mu(b)$, also make no difference in defining w or μ-*acc*, this time up to a constant factor that may depend on M.

DEFINITION 2.7. *For any input x on which a BM M has halting computation $\vec{c}$, we define the following complexity measures.*

Work: $w(M, x) := w(\vec{c})$.
Memory access: $\mu\text{-}acc(M, x) := \mu\text{-}acc(\vec{c})$.
μ-time: $\mu\text{-}time(M, x) := w(M, x) + \mu\text{-}acc(M, x)$.
Space: $s(M, x) :=$ *the maximum of a for all access points a in* $\vec{c}$.
Pass count: $R(M, x) :=$ *the total number of passes in* $\vec{c}$.

M is dropped when it is understood, and the above are extended in the usual manner to functions $w(n)$, μ-*acc*(n), μ-*time*(n), $s(n)$, and $R(n)$ by taking the maximum over all inputs x of length n. A measure of space closer to the standard TM space measure could be defined in the extended BM models of the next section by placing the input x on a separate read-only input tape, but we do not pursue space complexity further in this paper. The pass count appears to be sandwiched between two measures of *reversals* for multitape TMs, namely the now-standard one of [59], [35], [16] and the stricter notion of [43], which essentially counts keeping a TM head stationary as a reversal.

DEFINITION 2.8. *For any memory-cost function μ and recursive function $t : \mathbf{N} \rightarrow \mathbf{N}$,* D$\mu$TIME$[t]$ *stands for the class of languages accepted by BMs M that run in time $t(n)$, i.e., such that for all x, $\mu\text{-}time(M, x) \leq t(|x|)$.* TLIN *stands for* D$\mu_1$TIME$[O(n)]$.

We also write DμTIME$[t]$ and TLIN for the corresponding function classes. Section 7 shows that TLIN is contained in the TM linear-time class DLIN. We argue that languages and functions in TLIN have true linear-time behavior even under the most constrained implementations.

We do not separate out the work performed from the total memory-access charges in defining BM complexity classes, but do so in adapting the following notions and terms from [5] to the BM model.

DEFINITION 2.9. (a) *A BM M is* memory efficient, *under a given memory-cost function μ, if there is a constant K such that for all x, $\mu\text{-}time(M, x) \leq K \cdot w(M, x)$.*

(b) *M is* parsimonious *under μ if $\mu\text{-}time(M, x)/w(M, x) \rightarrow 1$ as $|x| \rightarrow \infty$.*

Equivalently, M is memory efficient under μ if $\mu\text{-}acc(M, x) = O(w)$ and parsimonious under μ if $\mu\text{-}acc(M, x) = o(w)$, where the asymptotics are as $|x| \rightarrow \infty$. The intuition, also expressed in [5], is that efficient or parsimonious programs make good use of a memory cache.

Definition 2.9 does not imply that the given BM M is optimal for the function f it computes. Indeed, from *Blum's speed-up theorem* [12] and the fact that μ-*time* is a complexity measure, there exist computable functions with no μ-*time*-optimal programs at all. To apply the concepts of memory efficiency and parsimony to languages and functions, we use the following relative criterion.

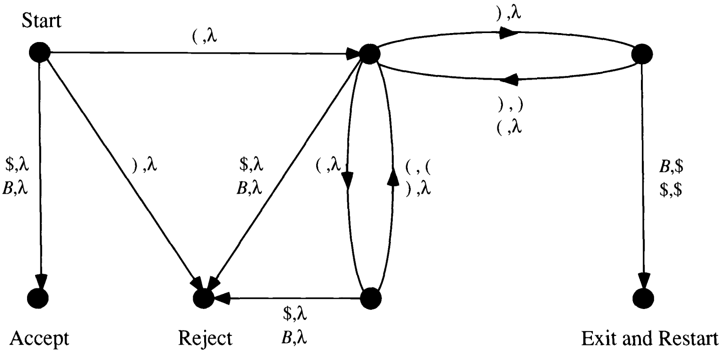

FIG. 3. *Reduced-form BM for the language of balanced parentheses.*

DEFINITION 2.10. (a) *A function f is* inherently μ-efficient *if for every BM M_0 that computes f, there is a BM M_1 that computes f and a constant $K > 0$ such that for all x, μ-time$(M_1, x) \leq K \cdot w(M_0, x)$.*

(b) *f is* inherently μ-parsimonious *if for every BM M_0 computing f there is a BM M_1 computing f such that* $\limsup_{|x| \to \infty}$ *μ-time$(M_1, x)/w(M_0, x) \leq 1$.*

By definition, μ-parsimony $\Longrightarrow$ μ-efficiency, and if f is inherently efficient (resp., parsimonious) under μ_1, then f is inherently efficient (resp., parsimonious) under every memory-cost function $\mu \leq \mu_1$.

Just for the next three examples, we drop the validity condition on rightward pulls; that is, we allow the tape intervals $[a \ldots b]$ and $[0 \ldots c]$ to overlap in an Ra move. This is intuitively reasonable so long as the cell-0 head does not overtake the cell-a head and write over a cell that the latter has not read yet. Theorem 4.1 will allow us to drop the validity condition with impunity, but the proof of Theorem 2.1 below requires that it be in force.

EXAMPLE 2.2. Balanced parentheses. *Let D_1 stand for the language of balanced parenthesis strings over $\Sigma := \{\,(,)\,\}$. Let the GST S work as follows on any $x \in \Sigma^*$: If $x = \lambda$, S goes to a terminal state marked* ACCEPT; *if x begins with "$)$", S goes to* REJECT. *Else S erases the leading "$)$" and thereafter takes bits in twos, translating*

$$(1) \qquad ((\mapsto (\qquad)) \mapsto) \qquad () \mapsto \lambda \qquad)(\mapsto \lambda.$$

If x ends in "$)$" or $|x|$ is odd, S also signals REJECT. *Then S has the property that for any $x \neq \lambda$ that it does not immediately reject, $x \in D_1 \iff S(x) \in D_1$. Furthermore, $|S(x)| < |x|/2$. We can think of D_1 as being self-reducible in a particularly sharp sense.*

Figure 3 shows the corresponding BM in the "reduced form" defined below. The "\$" endmarker is written on the first pass and prevents leftover "garbage" on the tape from interfering with later passes. We take this for granted in some later descriptions of BMs. For any memory-cost function μ, the running time of M is bounded by

$$(2) \qquad \sum_{i=0}^{\log_2 n} \mu(0) + 2^i + \mu(2^i),$$

which is $O(n)$ even for $\mu = \mu_1$. Hence the language D_1 belongs to TLIN.

EXAMPLE 2.3. Counting. *Let $\Sigma := \{\mathrm{a}, \mathrm{b}\}$. We can build a GST S with alphabet $\Gamma = \{\mathrm{a}, \mathrm{b}, 0, 1, \$, B\}$ that runs as follows on inputs of the form $x' = xu\$$ with $x \in \{\mathrm{a}, \mathrm{b}\}^*$ and $u \in \{0, 1\}^*$: S erases bits $x_0, x_2, x_4, \ldots$ of x and remembers $|x|$* modulo 2. *S then copies u, and on reading the final \$ (or on the first pass, B), S outputs $0\$$ if $|x|$ was even, $1\$$ if $|x|$*

was odd. S is also coded so that if $x = \lambda$, S goes to HALT. *Let M be the BM which iterates S on input x. Then $M(x)$ halts with $|x|$ in binary notation on its tape (followed by "\$" and "garbage"). The μ-time for this iteration is likewise $O(n)$ even for $\mu = \mu_1$.*

EXAMPLE 2.4. Simulating a TM. *Let $T := (Q, \Sigma, \Gamma, \delta, B, q_0, F)$ be a single-tape TM in the notation of* [36]. *Define the* ID alphabet *of T to be $\Gamma_I := (Q \times \Gamma) \cup \Gamma \cup \{\wedge, \$\}$, where $\wedge, \$ \notin \Gamma$. The simulating BM M on an input $x = x_0 \cdots x_{n-1}$ makes a rightward pull that lays down the delimited initial ID $\wedge(q_0, x_0)x_1x_2 \cdots x_{n-1}\$$ of $T(x)$. The finite control of T is turned into a single GST S with alphabet Γ_I that produces successive IDs in the computation with each pass. Whenever T writes a blank, M writes @. Let T be programmed to move its head to cell* 0 *before halting. Then the final pass by M removes the $\wedge$ and \$ and leaves exactly the output $y := T(x)$ on the tape. Actually, because a BM cannot erase tape cells, y would be followed by some number of symbols @, but Definition* 2.4 *still makes y the output of M. Hence the BM is a universal model of computation.*

The machines in Examples 2.2–2.4 only make rightward pulls from cell 0. Each is really a GST that iterates on its own output, a form generally known as a "cascading finite automaton" (CFA). Up to small technical differences, CFAs are comparable to the one-way "sweeping automata" studied by Ibarra et al. [37]–[41], [15]. These papers characterize both one-way and two-way arrays of identical finite-state machines in terms of these and other automata and language classes. The following shows that the BM can be regarded as a generalization of these arrays, insofar as a BM can dynamically change its origin point a and direction of operation.

DEFINITION 2.11. *The* reduced form *of the BM model consists of a single GST S whose terminal states q have labels $l_1(q) \in \{a, \lfloor a/2 \rfloor, 2a, 2a{+}1,$ HALT$\}$ and $l_2(q) \in \{Ra, La, 0R, 0L\}$. The initial pass has mode Ra with $a = 0$. Whenever a pass by S exits in some state q with $l_1(q) \neq$ HALT, the labels $l_1(q)$ and $l_2(q)$ determine the address and mode for the next pass. Computations and complexity measures are defined as before.*

THEOREM 2.1. *Every BM M is equivalent to a BM M′ in reduced form, up to constant factors in all five measures of Definition* 2.7.

Proof. The idea is to combine all the GSTs of M into a single GST S and save the current state of M in cells 0 and 1. Each pass of M is simulated by at most six passes of M', except for a "staircase" of $O(\log n)$ moves at the end which is amortized into the constant factors. This simulation expands the alphabet but does not make any new tracks. The details are somewhat delicate, owing to the lack of internal memory when a pass by M' ends, and require the validity condition on passes. The full proof is in the appendix. □

In both directions, the tape cells used by M and M' are almost exactly the same, i.e., M is simulated "in place." Hence we consider the BM and the reduced form to be essentially identical. The idea of gathering all GSTs into one works with even less technical difficulty for the extended models in the next section.

3. Extensions of the BM.

We consider five natural ways of varying the BM model: (1) Remove or circumvent the validity restriction on passes. (2) Provide "random addressing" rather than "tree access" in move states. (3) Provide delimiters a_1, b_1, a_2, b_2 for block moves $S\,[a_1 \dots b_1]$ *into* $[a_2 \dots b_2]$, where the cell b_1 in which S exits is determined or calculated in advance. (4) Require that for every such block move, b_2 is such that $S(x)$ exactly fills $[a_2 \dots b_2]$. (5) Provide multiple main tapes and GSTs that can read from and write to k-many tapes at once. These extensions can be combined. We define them in greater detail, and in the next section, prove equivalences among them and the basic model.

DEFINITION 3.1. *A* BM with buffer mechanism *has a new tape called the* buffer tape *and GST chips S with the following six labels and functions:*

(*RaB*) *The GST S reads x from the main tape beginning in cell a and writes $S(x)$ to the buffer tape. The output $S(x)$ must have no blanks in it, and it completely replaces any* *previous content of the buffer. Taking b to be the cell in which S exits, the μ-time is $\mu(a) + |x| + \mu(b)$ as before.*

(LaB) *This is defined as for RaB, but reading leftward from cell a.*

(BaR) *Here S draws its input x from the buffer, and $S(x)$ is written on the main tape starting in cell a. Blanks in $S(x)$ are allowed and treated as before. When S exits, even if it has not read all of the buffer tape, the buffer is flushed. With b the destination of the last output bit (or $b = a$ if none), the μ-time is likewise $\mu(a) + |x| + \mu(b)$.*

(BaL) *This is defined as for BaR, but writing $S(x)$ leftward from cell a.*

($0B$) *This is defined as for RaB, but using the cell-0 head to read the input, and μ-time $|x| + \mu(c)$.*

($B0$) *This is defined as for BaR, but using the cell-0 head to write the output; likewise, μ-time $|x| + \mu(c)$.*

All six types of passes are automatically valid. Further details of computations and complexity measures are the same as before. A BM with limited buffer mechanism *has no GSTs with labels $B0$ or $0B$ and consequently has no cell-0 head.*

The original BM's moves of type Ra or La can now be simulated directly by RaB or LaB followed by $B0$, while $0R$ or $0L$ is simulated by $0B$ followed by BaR or BaL. For the limited buffer mechanism, the simulation is trickier, but for $\mu = \mu_d$ we will show that it can be done efficiently. The next extension allows "random access."

DEFINITION 3.2. *The* address mechanism *adds an* address tape *and new* load *moves labeled RaA, LaA, and $0A$. These behave and are timed like the buffer moves RaB, LaB, and $0B$, respectively, but direct their output to the address tape instead. As with the buffer, the output completely replaces the previous content of the address tape. Addresses are written in binary notation with the least significant bit leftmost on the tape. The output a' of a load becomes the new current address. Move states may be discarded without loss of generality.*

EXAMPLE 3.1. Palindromes. *Let* Pal *denote the language of palindromes over a given alphabet Σ. We sketch a BM M with address mechanism that accepts* Pal. *On input x, M makes a fresh track on its tape via Example* 2.1 *and runs the procedure of Example* 2.3 *to leave $n := |x|$ in binary notation on this track. In running this procedure, we either exempt rightward pulls from the validity condition or give M the buffer mechanism as well. The fresh-track cell which divides the right half of x from the left half has address $n' := 2\lfloor n/2 \rfloor + 1$. A single $0A$ move can read n but copy the first bit as* 1 *to load the address n'. M then pokes a* \$ *into cell n'. Another load prepends a "0" so as to address cell $2n$, and M then executes a leftward pull that interleaves the left half of x with the right half. A bit-by-bit compare from cell* 0 *finishes the job. M also runs in linear μ_1-time.*

The address mechanism provides for indirect addressing via a succession of loads and makes it easy to implement pointers, linked lists, trees, and other data structures and common features of memory management on a BM, subject to charges for the number and size of the references.

Thus far, all models have allowed data-dependent block boundaries. We call any of the above kinds of BM M *self-delimiting* if there is a subalphabet Γ_e of *endmarkers* such that all GSTs in M terminate precisely on reading an endmarker. (If we weaken this property slightly to allow a GST S to exit on a nonendmarker on its second transition, then it is preserved in the proof of Theorem 2.1.) The remaining extensions preset the read block $[a_1 \dots b_1]$ and the write block $[a_2 \dots b_2]$, and this is when we speak of a *block move* rather than a *pass*. Having b_1 fixed would let us use the original GSM model from [36]. However, the machines that follow are always able to drop an endmarker into cell b_1 and force a GST S to read all of $[a_1 \dots b_1]$. Hence we may ignore the distinction and retain "GST" for consistency.

DEFINITION 3.3. *A* block move *is denoted by $S[a_1 \dots b_1]$ into $[a_2 \dots b_2]$ and has this effect on the tape: Let $x := \sigma[a_1 \dots b_1]$. Then $S(x)$ is written to the tape beginning at a_2*

and proceeding in the direction of b_2, with the proviso that each blank in $S(x)$ leaves the target cell unchanged, as in Definition 2.3. *The block move is* valid *so long as the intervals* $[a_1 \ldots b_1]$ *and* $[a_2 \ldots b_2]$ *are disjoint. It* underflows *if* $|S(x)| < |b_2 - a_2| + 1$ *and* overflows *if* $|S(x)| > |b_2 - a_2| + 1$.

By default we tolerate underflows and overflows in block moves. We draw an analogy between the next form of the BM and a text editor in which the user may mark a source and destination block and perform an operation on them. One important point is that the BM does not allow insertions and deletions of the familiar "cut-and-paste" kind; instead, the output flows over the destination block and overwrites or lets stand according to the use of B in Definition 2.3. Willard [69] describes a model of a file system that lacks insertion and deletion and gives fairly efficient algorithms for simulating them. Many text processors allow the user to define and move *markers* for points of immediate access in a file. Usually the maximum number of markers allowed is fixed to some number m. Adopting a term from data structures, we give the machine four *fingers*, with labels a_1, b_1, a_2, b_2, which can be assigned among the m markers and which delimit the source and destination blocks in any block move. Finger a_1 may be thought of as the "cursor." The dual use of "a_1" as the fixed label of a finger and as the number of the cell its assigned marker currently occupies may cause some confusion, but we try to keep the meanings clear below. The same applies to a_2, b_1, and b_2, and to later usage of these labels to name four special "address tapes."

DEFINITION 3.4. *A* finger BM *has four* fingers, *labeled* a_1, b_1, a_2, b_2, *and some number* $m \geq 4$ *of* markers. *Initially, one marker is on the last bit of the input, while all other markers and all four fingers are on the first bit in cell* 0. *An invocation of a GST S executes the block move* $S[a_1 \ldots b_1]$ *into* $[a_2 \ldots b_2]$. *The* work *performed by the block move is* $|b_1 - a_1| + 1$, *while the* memory-access charge *is* $\mu(c)$, *where* $c = \max\{a_1, b_1, a_2, b_2\}$. *In a move state,* each *marker on some cell a may be moved to cell* $\lfloor a/2 \rfloor$, $2a$, *or* $2a+1$ *(or kept where it is), and the four fingers may be redistributed arbitrarily among the markers. The cost of a move state is the maximum of* $\mu(a)$ *over all addresses a involved in finger or marker* movements; *those remaining stationary are not charged.*

One classical difference between "fingers" and "pointers" is that there is no fixed limit on the number of pointers a program can create. Rather than define a form of the BM analogous to the *pointer machines* of Schönhage and others [45], [66], [67], [49], [10], we move straight to a model that uses "random-access addressing," a mechanism usually considered stronger than pointers (for in-depth comparisons, see [9], [10] and also [68]). The following BM form is based on a random-access TM (RAM-TM; cf. "RTM" in [30] and "indexing TM" in [14], [64], [8]), and is closest to the BT.

DEFINITION 3.5. *A* RAM-BM *has one* main tape, *four* address tapes, *which are labeled* a_1, b_1, a_2, *and* b_2 *and given their own heads, and a finite control comprised of* RAM-TM states *and* GST states. *In a RAM-TM state, the current main-tape address a is given by the content of tape* a_1. *The machine may read and change both the character in cell a and those scanned on the address tapes and move each address tape head one cell left or right. In a GST state S, the address tapes give the block boundaries for the block move* $S\,[a_1 \ldots b_1]$ into $[a_2 \ldots b_2]$ *as described above, and control passes to some RAM-TM state. A RAM-TM step performs work* 1 *and incurs a memory-access charge of* $\max\{\,\mu(a), \mu(b)\,\}$, *where b is the rightmost extent of an address tape head. Block moves are timed as above. Both a RAM-TM step and a block move add* 1 *to the pass count* $R(n)$. *Other details of computations are the same as for the basic BM model.*

A fixed-wordsize analogue of the original BT model of [2] can now be had by making *copy* the only GST allowed in block moves. A RAM-BM *with address loading* can use block moves rather than RAM-TM steps to write addresses.

DEFINITION 3.6. *A finger BM or a RAM-BM obeys the* strict boundary condition *if in every block move* $S[a_1 \dots b_1]$ into $[a_2 \dots b_2]$, $|S(x)| = |b_2 - a_2| + 1$.

This constraint is notable when S is such that $|S(x)|$ varies widely for different x of the same length. The next is a catch-all for further extensions.

DEFINITION 3.7. *For* $k \geq 2$, *a* k-input GST *has* k*-many input tapes and one output tape, with* $\delta : (Q \setminus F) \times \Gamma^k \to Q$ *and* $\rho : (Q \setminus F) \times \Gamma^k \to \Gamma^*$. *Each input head advances one cell at each step.*

DEFINITION 3.8. *A* multitape BM *has some number* $k \geq 2$ *of main tapes, each possibly equipped with its own address and/or buffer tapes, and uses* k*-input GSTs in passes or block moves.*

Further details of computations and complexity measures for multitape BMs can be inferred from foregoing definitions, and various validity and boundary conditions can be formulated. The proofs in the next section will make the workings of these machines clear.

Finally, given two machines M and M' of any kind and a cost function μ, we say M' *simulates* M *linearly in* μ if μ*-time*$(M', x) = O(\mu\text{-}time(M, x)) + O(|x|)$. The extra "$O(n)$" is stated because like the RAM-TM, several BM variants give a sensible notion of computing in *sub*linear time, while all the simulations to come involve an $O(n)$-time preprocessing phase to set up tracks on the main tape. Now we can state the following theorem.

THEOREM 3.1 (main robustness theorem). *For any rational* $d \geq 1$, *all forms of the BM defined above simulate each other linearly in* μ_d*-time.*

If we adapted a standard convention for TMs to state that every BM on a given input x takes time at least $|x| + 1$ (cf. [36]), then we could say that all the simulations have constant-factor overheads in μ_d*-time*.

4. Proof of the main robustness theorem. The main problems solved in the proof are: (1) how to avoid overlaps in reading and writing by "tape-folding" (Theorem 4.1), (2) how to simulate random access with one read head whose movements are limited (Lemma 4.6), and (3) how to precompute block boundaries without losing efficiency (Lemma 4.11 through Theorem 4.15). Analogues of these problems are known in other areas of computation, but solving them with only a constant-factor overhead in μ*-time* requires some care. Some of the simulations give constant-factor overheads in both w and μ*-acc*, but others trade off the work against the memory-access charges. We also state bounds on w' and μ*-acc*$'$ for the simulating machine M' individually, and on the number R' of passes M' requires, in or after proofs. The space $s'(n)$ is always $O(s(n))$.

4.1. Simulations for data-dependent block boundaries. The first simulation uses the tracking property $\mu(Na) \leq N\mu(a)$ from Definition 2.5 and does not give constant-factor overheads in all measures. We give full details in this proof, in order to take reasonable shortcuts later.

THEOREM 4.1. *For every BM* M *with buffer, there is a BM* M' *such that for every* μ, M' *simulates* M *linearly in* μ*-time.*

Proof. Let M have the buffer mechanism. Let C be the largest number of symbols output in any transition of any GST in M. Let $K := \lceil \log_2(2C + 6) \rceil$ and $N := 2^K$. The BM M' first makes N-many tracks by iterating the procedure of Example 2.1. The track comprising cells $0, N, 2N, 3N, \dots$ represents the main tape of M, while the two tracks flanking it are "marker tracks." The track through cells $2, N + 2, \dots$ represents the buffer tape. The other tracks are an "extension track," a "holding track," C-many "pull bays," and C-many "put bays." M' uses the symbol @ to reserve free space in tracks and uses $\wedge$ and \$ to mark places in the tape. A \$ also delimits the buffer track so that leftover "garbage" does not interfere. Two invariants are that before every simulated pass by M with current address a, the current address a' of M' equals Na, and the tracks apart from the main and buffer tracks contain only blanks and @ symbols.

The move $a := 2a$ by M is simulated directly by $a' := 2a'$ in M'. The move $a := 2a+1$ is simulated by effecting $a' := \lfloor a'/2 \rfloor$ K-many times, then $a' := 2a'+1$, and then $a' := 2a'$ K-many times. The move $a := \lfloor a/2 \rfloor$ is simulated by effecting $a' := \lfloor a'/2 \rfloor$ $(K+1)$-many times, and then $a' := 2a$ K-many times. Since K is a constant, the overhead in μ-*acc* for each move is constant. Henceforth we refer to "cell a on the main track" in place of a'.

We need only describe how M' simulates each of the six kinds of pass by M. Since M has the $0B$ and $B0$ instructions, we may assume that the current address a for the other four kinds is always ≥ 1. For each state q of a GST S of M, M' has a GST S'_q which simulates S starting in state q, and which exits only on the endmarker \$. We write just S' when $q = s$ or q is understood.

(a) *RaB*. M' chooses $a_1 := 2a$, pokes $\wedge$ to the left of cell a, and pokes \$ to the left of cell a_1. M' then pulls $y_1 := S'[a \ldots a_1 - 1]$ to the C-many pull bays. By the choice of C, $|y_1| \leq Ca$, and so the pull is valid.

If the cell b in which S exits falls in the interval $[a \ldots a_1 - 1]$, then S' likewise exits in cell b. Since the exit character has no \$, the transition out of S' communicates that S has exited. M' then makes $(K+1)$-many moves $a := 2a$ so that M' now addresses cell Na_1 on the main track, which is cell $N^2 a_1$ overall. M' puts $y := y_1$ onto the extension track and then pulls y onto the buffer track. One more put then overwrites the used portion of the extension track with @ symbols. M' then effects $a := \lfloor a/2 \rfloor$ $(K+1)$-many times so that it addresses the original cell a again, and re-simulates S in order to overwrite the copy of y on the pull bays by @ symbols. All of these passes are valid. M' finally removes the $\wedge$ and \$ markers at cells a and a_1. The original time charge to M was $\mu(a) + m + (b)$, where $m = b - a + 1$. The time charged to M' in this case is bounded by

$$\begin{aligned}
\mu(Na) &+ 2 + \mu(Na-1) + \mu(Na_1) + 2 + \mu(Na_1 - 1) && \text{(poke $\wedge$ and \$)}\\
&+ \mu(Na) + Nm + \mu(Nb) && \text{(simulate S)}\\
&+ 2K\mu(N^2 a_1) && \text{(move to cell Na_1)}\\
&+ 3\mu(N^2 a_1) + 3N^2 m + 3\mu(N^2 a_1 + N^2(m-1)) && \text{(put and pull y)}\\
&+ 2K\mu(N^2 a_1) + \mu(Na) + Nm + \mu(Nb) + 2\mu(Na) + 4 + 2\mu(Na_1) && \text{(clean up)}\\
&\leq (14N + 8N^2K + 12N^2)\mu(a) + (3N^2 + 2N)m + 2N\mu(b) + 4. && (m-1 \leq a).
\end{aligned}$$

So far, both the work w' and the memory-access charges μ-*acc'* to M' are within a constant factor of the corresponding charges to M.

If S does not exit in $[a \ldots a_1 - 1]$, S' exits on the \$ marker. This tells M' to do a dummy pull to save the state q that S was in when S' hit the \$, and then to execute a put that copies y_1 from the pull bays to the put bays rightward from cell a. M' then effects $a := 2a$ so now $a = a_1$, lets $a_2 := 2a_1$, pokes another \$ to the left of cell a_2, pulls $y_2 := S'_q[a_1 \ldots a_2 - 1]$ to the pull bays, and then puts y_2 into the put bays rightward of cell a_1. Since the \$ endmarker is in cell $Na_1 - 1$, this move is valid; nor does y_2 overlap y_1. If S didn't halt in $[a_1 \ldots a_2 - 1]$, M' saves the state q' that S was in when S' hit cell a_2, setting things up for the next stage with $a_3 := 2a_2$. The process is iterated until S finally exits in some cell b in some interval $[a_{j-1} \ldots a_j - 1]$. Then $y := y_1 y_2 \cdots y_j$ equals $S[a \ldots b]$. M' moves to cell Na_j, puts y onto the extension track rightward of cell Na_j, pulls y to the buffer track, and "cleans up" the extension track as before. M' then takes $(K+1)$-many steps backward to cell a_{j-1} and cleans up the pull and put bays with a pull and a put. Finally, M' effects $a := \lfloor a/2 \rfloor$ until it finds the $\wedge$ originally placed at cell a, meanwhile removing all of the \$ markers, and then removes the $\wedge$. This completes the simulated pull by S.

Let j be such that $a_j \leq b < a_{j+1}$. Then the number m of symbols read by S is at least $a_j - a$. An induction on j shows that the running totals of both w' and μ-acc' stay bounded by Dm, where D is a constant that depends only on M, not on a or j. Hence the μ-time for the simulation by M' is within $2D$ times the μ-time charged to M for the pass. (However, when $j > 0$, μ-acc'/μ-acc may no longer be bounded by a constant.)

(b) $0B$. M' first runs S on cell 0 only and stores the output y_0 on the first cells of the C-many put bays. M' then follows the procedure for *RaB* with $a = 1$. The analysis is essentially the same.

(c) *LaB*. M' first pokes a $\wedge$ to the left of cell a and \$ to the left of cell $\lfloor a/2 \rfloor$. The $\wedge$ allows M' to detect whether a is even or odd; i.e., whether it needs to simulate $a := 2a$ or $a := 2a{+}1$ to recover cell a. M' then pulls $y_1 := S'[a \ldots \lfloor a/2 \rfloor]$ to the pull bays. Note that cell $\lfloor a/2 \rfloor$ is included; M' avoids a crash by remembering the first $2C$-many symbols of y_1 in its finite control. If S didn't exit in $[a \ldots \lfloor a/2 \rfloor]$, M' remembers the state q that S would have gone to after processing cell $\lfloor a/2 \rfloor$. M' then copies cells $[0 \ldots \lfloor a/2 \rfloor - 1]$ of the main track into cells $[\lfloor a/2 \rfloor + 1 \ldots a]$ of the holding track, and does a leftward pull by S'_q to finish the work by S, stashing its output y_2 on the put bays. If S'_q does not exit before hitting the \$, then S ran off the left end of the tape and M crashed. Let $y := y_1 y_2$. Since $|y| \leq Ca$, M' can copy y to the buffer via cell Na of the extension track by means similar to before, and "clean up" the pull and put bays and holding and extension tracks before returning control to cell a. Here both w' and μ-acc' stay within a fixed constant factor of the corresponding charges to M for the pass.

(d) *BaR*. M' marks cell a on the left with a \$, and does a dummy simulation of S on cells $[0 \ldots a - 1]$ of the buffer track. If S exits in that interval, M' puts $S[0 \ldots a - 1]$ directly onto the main track, and this completes the simulated pass. If not, M' puts $y_0 := S[0 \ldots a - 1]$ onto the holding track rightward of cell a, and remembers the state q in which S' hits the \$. M' then follows the procedure for simulating *RaB* beginning with S'_q, except that it copies $@^a y_0 y_1 \cdots y_j$ to the extension track via cell Na_j. The final pull then goes to the main track but translates @ by B so that the output written by M lines up with cell a of the main track. There is no need to "clean up" the read portion of the buffer tape since all writes to it are delimited. A calculation similar to that for *RaB* yields a constant bound on the μ-*time* and work for the simulated pass, though possibly not on the μ-*access* charges.

(e) $B0$. Under the simulation, this is the same as $0B$ with the roles of the main track and buffer track reversed and @ translated to B.

(f) *BaL*. M' marks cell a on the left with \$ and puts $y_1 := S[0 \ldots a - 1]$ *rightward* from cell a of the holding track. If S exits in that interval of the buffer tape, M' then pulls y_1 to the left end of the holding track. Note that if $|y_1| > a{+}1$, then M was about to crash. M' remembers the first symbol c' of y_1 in its finite control to keep this last pull valid just in case $|y_1| = a{+}1$. Then M' puts c' into cell a, pokes a \$ to the left of cell $\lfloor a/2 \rfloor$, and executes a "delay-1 copy" of the holding track up to the \$ into the main track leftward from cell a. If a B or @ is found on the holding track before the \$, meaning that $|y_1| \leq \lfloor a/2 \rfloor$, the copy stops there and the simulated *BaL* move is finished. If not, i.e., if $|y_1| > \lfloor a/2 \rfloor$, then the delay allows the character c'' in cell $\lfloor a/2 \rfloor - 1$ of the holding track to be suppressed when the \$ is hit, so that the copy is valid. Since $|y_1| > \lfloor a/2 \rfloor$, M' can now afford to do the following: poke a \$ to the *right* of cell a, effect $a := 2a$, and do a *leftward pull* of cells $[2a \ldots a{+}1]$ of the holding track into cells $[0 \ldots a{-}1]$ of the main track, translating @ as well as B by B to leave previous contents of the main track undisturbed. This stitches the rest of y_1 beginning with c'' correctly into place. M' also cleans up cells $[0 \ldots 2a]$ of the holding track by methods seen before, and removes the \$ signs.

If S does not exit in $[0 \ldots a - 1]$, M' executes a single Ra move starting S' from cell a, once again holding back the first character of this output y_2 just in case y_1 was empty and

$|y_2| = a+1$. If this pull is invalid, then likewise $|y_2| > a+1$ and M crashed anyway. M' then concatenates y_2 to the string y_1 kept on the holding track to form y, and does the above with y. As in *LaB*, the overhead in both w and μ-*acc* is constant. This completes the proof. □

The converse simulation of a BM by a BM with buffer is clear and has constant-factor overheads in all measures, by remarks following Definition 3.1. It is interesting to ask whether the above can be extended to a linear simulation of a *concatenable* buffer (cf. [46]), but this appears to run into problems related to the nonlinear lower bounds for the touch problem in [2]. The proof gives $w'(n) = O(w(n) + n)$ and $R'(n) = O(R(n) \log s(n))$. For μ-*acc'*, the charges in the rightward moves are bounded by a constant times $\sum_{j=0}^{\log b} \mu(b/2^j)$. For $\mu = \mu_d$ this sum is bounded by $2d\mu_d(b)$, and this gives a constant-factor overhead on μ_d-*acc*. However, for $\mu = \mu_{\log}$ there is an extra factor of $\log b$.

COROLLARY 4.2. *A BM that violates the validity conditions on passes can be simulated linearly by a BM that observes the restrictions.*

We digress briefly to show that allowing simultaneous read and overwrite on the main tape does not alter the power of the model, and that the convention on B gives no power other than *shuffle*. A *two-input Mealy machine* (2MM) is essentially the same as a 2-input GST with $\rho : (Q \setminus F) \times \Gamma^2 \to \Gamma^*$.

PROPOSITION 4.3. *Let M be a BM with the following extension to the buffer mechanism: in a put step, M may invoke any 2MM S that takes one input from the buffer and the other from the main tape, writes to the main tape, and halts when the buffer is exhausted. Then M can be simulated by a BM M' with buffer at a constant-factor overhead in all measures, for all μ.*

Proof. To simulate the put by a 2MM S, M' copies the buffer to a separate track so as to interleave characters with the segment of the main tape of M concerned. Then M' invokes a GST S' that takes input symbols in twos and simulates S. Finally M' copies the output of S' from its own buffer over the main tape segment of M. □

PROPOSITION 4.4. *At a constant-factor overhead in all measures, for all μ, a BM M can be simulated by a BM M' that lacks B but has the following implementation of shuffle: M' has the above buffer extension, but restricted to the fixed 2MM which interleaves the symbols of its two input strings.*

Proof. Let Γ' consist of Γ together with all ordered pairs of characters from Γ; then the fixed 2MM can be regarded as mapping $\Gamma^* \times \Gamma^*$ onto Γ'^*. Now consider any GST S of M that can output blanks. Let S' write a dummy character @ in place of B, and let M' shuffle the output of S' with the content of the target block of the main tape. Finally M' executes a pass which, for all $c_1, c_2 \in \Gamma$ with $c_1 \neq @$, translates $(c_1, @)$ to c_1 and (c_1, c_2) to c_2. □

Besides the tracking property, our further simulations require something which, again for want of a standard mathematical name, we call the following.

DEFINITION 4.1. *A memory-access cost function μ has the* tape-compression property *if* $(\forall \epsilon > 0)(\exists \delta > 0)(\forall^\infty a)\, \mu(\lceil \delta a \rceil) < \epsilon\, \mu(a)$.

LEMMA 4.5. *For any $d \geq 1$, the memory-cost function μ_d has the tape compression property. In consequence, $\sum_{i=0}^{\log_2 b} \mu_d(\lceil b/2^i \rceil) = O(\mu_d(b))$.*

Proof. Take $\delta < \epsilon^d$. If δ of the form $1/2^k$ satisfies (a) for $\epsilon := 1/2$, then by elementary calculation, for all but finitely many b, $\sum_{i=0}^{\log_2 b} \mu(\lceil b/2^i \rceil) \leq 2k\mu(b)$. □

Lemma 4.5 promises a constant-factor overhead on the memory-access charges for "staircases" under μ_d, whereas an extra log factor can arise under $\mu_{\log}$. The simulation of random access by tree access in the next lemma is the lone obstacle to extending the results that follow to $\mu_{\log}$. Since any function $\mu(m)$ with the tape-compression property must be $\Omega[m^\epsilon]$ for some $\epsilon > 0$, this pretty much narrows the field to the functions μ_d. To picture the tree we write UP, DOWN LEFT, and DOWN RIGHT in place of the moves $\lfloor a/2 \rfloor$, $2a$, and $2a+1$ by M'.

LEMMA 4.6. *For every BM M with address mechanism, there is a basic BM M' such that for all $d \geq 1$, M' simulates M linearly under μ_d.*

Proof. We need to show how M' simulates a load step of M that loads an address a_1 from cells $[a_0 \ldots b_0]$ of the main tape. Let $m := |a_0 - b_0| + 1$. M' makes one spare track for operations on addresses. M' first pulls a_1 in binary to the left end of this track. By Theorem 4.1 we may suppose that this pull is valid. The cost is proportional to the charge of $\mu(a_0) + m + \mu(b_0)$ to M for the load. By our convention on addresses, the least significant bit of a_1 is leftmost. In this pull, M' replaces the most significant "1" bit of a_1 by a "\$" endmarker. M' then moves UP until its cell-a head reaches cell 1. With $k := \lceil \log_2 a_0 \rceil$, the total memory-access charges so far are proportional to $\sum_{i=0}^{k} \mu(2^i)$, which is bounded by a fixed constant times $\mu(a_0)$ by Lemma 4.5. Since the number of bits in a_1 is bounded by Cm, where C depends only on M, the work done by M' is bounded by $2Cm + k$. Since $k < \mu(a_0)$, we can ignore k. Hence the μ*-time* charged so far to M' is bounded by a fixed constant of that charged to M for the load.

M' now executes a rightward pull that copies all but the bit b before the \$ endmarker, b being the second most significant bit of a_1. This pull is not valid owing to an overlap on the fresh track, but by Corollary 4.2 we may suppose that it is valid. If $b = 0$ M' moves DOWN LEFT, while if $b = 1$, M' moves DOWN RIGHT. M' then executes a put that copies the remainder of a_1 (plus the \$) rightward from the new location a. M' iterates this process until all bits of a_1 are exhausted. At the end, $a = a_1$. Because of the tracking, M' moves DOWN LEFT once more so that it scans cell $2a$, which is cell a of the main track. This completes the simulated load. Recalling $|a_1| \leq Cm$, and taking $l := \lceil \log_2(a_1) \rceil$, the μ*-time* for this second part is bounded by a constant times

$$\sum_{i=0}^{l} \mu(2^i) + 2(m - i) + \mu(2^i + 2(m - i)). \tag{3}$$

By Lemma 4.5, the total memory-access charges in this sum are bounded by a fixed constant times $\mu(a_1)$. The work to simulate the load is proportional to $m \cdot l$, that is, to $(\log a_1)^2$, which causes an extra log factor over the work by M in the load. The key point, however, is that since M loaded the address a_1, M will be charged $\mu_d(a_1)$ on the next pass, which is asymptotically greater than $(\log a_1)^2$. Hence the μ_d*-time* of M' stays proportional to the μ_d*-time* of M. □

COROLLARY 4.7. *For every BM M with both the address and buffer mechanism, we can find a basic BM M', and a BM M'' with the limited buffer mechanism, such that for any $d \geq 1$, M' and M'' simulate M linearly under μ_d.*

Proof. The constructions of Lemma 4.6 and Theorem 4.1 yield M'. For M'', we may first suppose that M is modified so that whenever M loads an address a, it first stores a spare copy of a at the left end of a special track. Now consider a pass of type $B0$ or $0B$ made by M. M'' invokes a GST that remembers cell 0 and writes 1 to the address tape. Then with $a' = 1$, M'' simulates the pass by a $Ba'R$ or $Ra'B$ move. M'' then recovers the original address a by loading it from the track. Thus far M'' is a BM with address and buffer that doesn't use its cell 0 head. The method of Lemma 4.6 then removes the address mechanism in a way unaffected by the presence of the buffer. □

We remark that Lemma 4.6 and Theorem 4.1 apply to different kinds of pass by M, with two exceptions. First, pulling 1 to the left end of the track in the proof of Lemma 4.6 may require simulating a buffer. However, this can be accounted against the cost to M for the load. Second, the buffer is needed for overlaps in the further processing of a_1. However, this is needed for at most $O(\log\log(a_1))$-many passes, each of which involves $O(\log a_1)$ work, and these costs are dominated by the time to process a_1 itself. Hence in Corollary 4.7, the bounds from Lemma 4.6 and Theorem 4.1 are additive rather than compounded, and with $\mu = \mu_d$ we obtain for M' μ_d-$acc'(n) = O(\mu_d\text{-}acc(n))$, $\mu_{\log}$-$acc'(n) = O(\mu_{\log}\text{-}acc(n) \log s(n))$, $w'(n) = O(w(n) + n + R(n) \log s(n))$, and $R'(n) = O(R(n) \log s(n))$.

LEMMA 4.8. *For every RAM-BM M, we can find a BM M' with the address and buffer mechanisms, such that for any memory-cost function μ that is $\Omega(\log n)$, M' simulates M linearly under μ.*

Proof. First, M' makes separate tracks for the address tapes and worktapes of M, and also for storing the locations of the heads on these tapes of M. Whenever M begins a block move $S[a_1 \ldots b_1]$ *into* $[a_2 \ldots b_2]$, M' first computes the signs of $b_1 - a_1$ and $b_2 - a_2$, and remembers them in its finite control. M' then loads the true address of cell a_1 on the main tape, and pulls the data through a copy of S labeled *RaB* or *LaB*—depending on sign—to the buffer. Then M' loads 0 to access a_2, loads a_2 itself, and finally copies the buffer right or left from cell a_2. Since μ is $\Omega(\log n)$, the μ-*time* charged to M' is bounded by a fixed constant times the charge of $1 + |b_1 - a_1| + \max\{\, \mu(a_1), \mu(a_2), \mu(b_1), \mu(b_2) \,\}$ incurred by M. Similarly the μ-*acc* charge to M' has the same order as that to M, though if $|b_1 - a_1| < \log(b_1)$, this may not be true of the work.

If M executes a standard RAM-TM transition, the cost to M is $1 + \mu(a_1) + \mu(c)$, where a_1 is the cell addressed on the main tape and c is the greatest extent of an address tape or worktape head of M. M' first loads a_1 and writes the symbol written by M into location a_1 with a unit put. Then M' loads each of the addresses for the other tapes of M in turn, updates each one with a unit pull and a unit put, remembers the head movement on that tape, and increments or decrements the corresponding address accordingly. The time charge for updating the other tapes stays within a fixed constant factor of $\mu(c)$. □

Remark. It would be nice to have the last simulation work when the charge to M for a RAM-TM transition is just $1 + \mu(a_1)$. The difficulty is that even though $|a_1| < a_1$, it need not hold that $c < a_1$, since M might be using a lot of space on its worktapes. The issue appears to come down to whether a multitape TM running in time t can be simulated by a BM in μ-*time* $O(t)$. We discuss related open problems in §8.

LEMMA 4.9. *A finger BM can be simulated by a BM with address and buffer mechanisms, with the same bounds as in Lemma* 4.8.

Proof. M' stores and updates the finitely many markers on separate tracks in a similar manner to the last proof. The extra work per block move simulated to write or load these addresses is $O(\log s(n))$ as before. Both here and in Lemma 4.8, $R'(n) = O(R(n))$. □

THEOREM 4.10. *Let M be a RAM-BM, a finger BM, or a BM with the address and/or buffer mechanisms. Then we can find a BM M' that simulates M linearly under any μ_d.*

Proof. This follows by concatenating the constructions of the last two lemmas with that of Corollary 4.7. Since $R'(n) = O(R(n))$ in the former, the bounds on work and pass count remain $w'(n) = O(w(n) + n + R(n) \log s(n))$ and $R'(n) = O(R(n) \log s(n))$. □

This completes the simulation of most of the richer forms of the model by the basic BM, with a constant factor overhead in μ_d-*time*. By similar means, one can reduce the number of markers in a finger BM all the way to four. In going up to the richer forms, we encounter the problem that the finger BM and RAM-BM have preset block boundaries for input, and if the strict boundary condition is enforced, also for output.

4.2. Simulations for preset block boundaries. The simulation in Theorem 4.1 does not make M' self-delimiting because it does not predetermine the cell $b \in [a_0 \ldots a_1]$ in which its own simulating GST S' will exit. We could try forcing S' to read all of $[a_0 \ldots a_1]$, but part (a) of the proof of Theorem 4.1 had $a_1 := 2a_0$, and if, e.g., $\mu(a_0) = \sqrt{a_0}$ and $b - a$ is small, M' would do much more work than it should. However, if one chooses the initial increment e to be too small in trying $a_1 := a_0 + e$, $a_2 := a_0 + 2e$, $a_3 := a_0 + 4e, \ldots$, the sum of the

μ-access charges may outstrip the work. To balance the charges we take $e := \mu(a_0)$. This requires M' to *calculate* $\mu(a)$ dynamically during its computation and involves a concept of "time-constructible function" similar to that defined for Turing machines in [36].

DEFINITION 4.2. *Let* μ *be a memory-cost function, and let* $t : \mathbf{N} \to \mathbf{N}$ *be any function. Then* t *is* μ*-time* constructible *if* $t(n)$ *is computable in binary notation by a BM* M *in* μ*-time* $O(t(n))$.

Note that the time is in terms of n, not the length of n. We use this definition for $t = \mu$ itself, in saying that μ is μ-time constructible. The following takes d to be rational because there are real numbers $d \geq 1$ such that no computable function whatever gives $\lceil m^{1/d} \rceil$ to within a factor of 2 for all m. In this section it would suffice to estimate $\lceil m^{1/d} \rceil$ by some binary number of bit length $|m|/d$, but we need the proof idea of incrementing fingers and the exact calculation of $\mu_d(m)$ for later reference.

LEMMA 4.11. *For any rational* $d \geq 1$*, the memory cost function* μ_d *is* μ_d*-time constructible by a finger BM that observes the strict boundary condition.*

Proof. For any rational $d \geq 1$, the function $\lceil m^{1/d} \rceil$ is computable in polynomial time, hence in time $(\log m)^{O(1)}$ by a single-tape TM T. The finger BM M simulates the tape of T beginning in cell 2, and tracks the head of T with its "main marker" m_1. M also uses a character @ which is combined into others like so: if T scans some character c in cell a, M scans $(c, @)$. M then uses two unit block moves $S[a \ldots a]$ *into* $[0 \ldots 0]$ and $S[0 \ldots 0]$ *into* $[a \ldots a]$ to read and write what T does. It remains to simulate the head moves by T.

To picture a tree, we again say UP, DOWN LEFT, and DOWN RIGHT in place of moves from a to $\lfloor a/2 \rfloor$, $2a$, or $2a+1$. M can test whether a is a left or right child by moving UP and DOWN LEFT and seeing whether the character scanned contains the @. If T moves right and a is a left child, M then intersperses moves UP and DOWN RIGHT with unit block moves to and from cell 0 to change $(c, @)$ back to c and place @ into cell $a+1$. If instead a is a right child, M introduces a new marker m_5 into cell 1 and writes $\wedge$ there. M moves m_5 DOWN LEFT to count how far UP m_1 has to go until it reaches either a left child or the root (i.e., cell 1). By unit block moves, M carries @ along with m_1, and by assigning a finger to marker m_5, can test whether m_5 is on cell 1. If m_1 reaches a left child, M moves it UP, DOWN RIGHT, and then DOWN LEFT until m_5 comes back to the $\wedge$. Then m_1 is in cell $a+1$. If m_1 hits the root marked by $\wedge$, then a had the form $2^k - 1$, and so M moves m_1 DOWN LEFT k times. The procedure for decrementing m_1 when T moves left is similar, with RIGHT and LEFT reversed.

For each step by T, the work by M is proportional to $\log a$. By Lemma 4.5 for μ_d, the total memory-access charge for incrementing or decrementing a finger in cell a is $O(\mu_d(a))$. Since $a \leq (\log m)^{O(1)}$, the total μ_d*-time* for the simulation is still a polynomial in $\log m$, and hence is $o(\mu_d(m))$. □

This procedure can also be carried out on one of 2^K-many tracks in a larger machine, computing $a \pm 2^K$ instead of $a \pm 1$ to follow head moves by T. The counting idea of the next lemma resembles the linear-size circuits constructed for 0–1 sorting in [55].

LEMMA 4.12. *The function* #a(x)*, which gives the number of occurrences of* "a" *in a string* $x \in \{\text{a}, \text{b}\}^*$*, is computable in linear* μ_1*-time by a BM that observes the strict boundary condition.*

Proof. The BM M operates two GSTs S_1 and S_2 that read bits of x in pairs. Each records the parity p of the number of pairs "ab" or "ba" it has seen thus far, and if $|x|$ is odd, each behaves as though the input were xb. S_1 outputs the final value of p to a second track. S_2 makes the following translations

$$\text{aa} \mapsto \text{a}, \qquad \text{bb} \mapsto \text{b}, \qquad \text{ab,ba} \mapsto \begin{cases} \text{b} & \text{if } p = 0, \\ \text{a} & \text{if } p = 1 \end{cases}$$

to form a string x' such that $|x'| = \lceil |x|/2 \rceil$. Then $\#\text{a}(x) = 2\#\text{a}(x') + p$. This is iterated until no a's are left in x, at which point the bits p combine to form #a(x) in binary notation with the least significant bit first.

M begins with one marker m_1 in cell $n-1$. We first note that even setting up the two tracks requires a trick to get two more markers to cell $n-1$. M starts a marker m_5 in cell 1 and moves it DOWN LEFT or DOWN RIGHT according to whether m_1 is on a left or right child. When m_1 reaches cell 1, m_5 records $n-1$ in reverse binary notation. Then M starts moving m_5 back up while ferrying m_2 and m_3 along with m_1. Then M places m_2 and m_3 into cells $2n$ and $4n-1$, and with reference to Example 2.1, executes $(c \mapsto c@)[0 \dots n-1]$ *into* $[2n \dots 4n-1]$ and *copy*$[2n \dots 4n-1]$ *into* $[0 \dots 2n-1]$. This also uses one increment and decrement of a marker as in the proof of Lemma 4.11.

M uses a new marker m_6 to locate where the next bit p will go, incrementing m_6 after running S_1. In running S_2, always $|S_2(x')| = \lceil |x'|/2 \rceil$, and by appropriate parity tests using its markers m_1, m_2, and m_3, M can place its fingers so that all these moves are valid and meet the strict boundary condition. For the kth iteration by S_2, these three markers are all on cells with addresses lower than $n/2^{k-2}$, and even if each needs to be incremented by 1 with the help of m_5, the μ_1 charges for simulating the iteration still total less than a fixed constant times $n/2^{k-2}$. This also subsumes the $O(\log^2 n)$ charge for updating m_6. Hence the sum over all iterations is still $O(n)$. □

THEOREM 4.13. *For every BM M and rational $d \geq 1$, we can find a finger BM M' that simulates M linearly under μ_d and observes the strict boundary condition.*

Proof. As in the proof of Theorem 4.1, let C be the maximum number of characters output in any GST transition of M, and let $K := \log_2(2C + 6)$. M' first makes $N := 2^K$ tracks, by using the last proof's modification of the procedure of Example 2.1. Besides $2C$-many tracks for handling the output of passes and one track for the main tape of M, M' uses one track to record the current address a of M with the least significant bit *rightmost*, one to compute and store $e := \mu_d(a)$ via Lemma 4.11, one to store addresses a_j below, two for Lemma 4.12, and one for other arithmetic on addresses. M' uses eight markers. Marker m_1 occupies cell Na to record the current address a of M. A move to $\lfloor a/2 \rfloor$ by M is handled by moving m_1 UP $K+1$ times and DOWN LEFT K times, and other moves are handled similarly. Meanwhile, marker m_6 stays on the last bit of the stored address a, and updating a requires only one marker increment or decrement and $O(\log \log a)$ work overall. From here on we suppress the distinction between a and Na and other details that are the same as in Theorem 4.1.

First consider a rightward pull by M that starts a GST S from cell a_0 on its main tape. M' has already stored a_0 in binary, and computes $e := \mu_d(a_0)$. Since $\mu_d(a_0) \leq a_0$, e fits to the left of marker m_6 in cell $|a|$. M' then places m_3 into cell $|a|+1$ and m_4 into cell $2|a|+1$ and executes two block moves from $[|a| \dots 0]$ and $[0 \dots |a|]$ into $[|a|+1 \dots 2|a|+1]$ that shuffle a_0 and e on their respective tracks with the least significant bits aligned and leftmost. M' then executes *add*$[|a|+1 \dots 2|a|+1]$ *into* $[|a| \dots 0]$ to produce a_1. A final carry that would make $|a_1| > |a_0|$ and cause a crash can be caught and remembered in the finite control of M' by running a "dummy addition" first and then marking cell $2|a|+1$ to suppress its output by the GST *add*. Then M' "walks" marker m_2 out to cell a_1 by using m_3 to read the value of a_1 and m_5 to increment m_3.

Next M' walks m_4 out to cell e (i.e., Ne), and keeps m_3 in cell 0. Let S' be a copy of S which pads the output of each transition out to length exactly C, and which sends its output z to the C-many tracks used as "pull bays." S' is also coded so that if S exits, S' records that fact and writes $@^C$ in each transition thereafter. Then M' can execute $S'[a_1 \dots a_2]$ *into* $[0 \dots e]$ in compliance with the strict boundary condition. Now M' can calculate the number i of non-@ symbols in z by the method of Lemma 4.12. To write the true output $y_1 = S[a_0 \dots a_1]$ and ensure the block move is valid, M' must still use the pull bays to hold y_1, so M' calculates

$i' := \lceil i/C \rceil$ (actually, $i' = N\lceil i/C \rceil$). Next M walks m_4 out to cell i' and can finally simulate the first segment of the pass by S by executing $S[a_1 \dots a_2]$ *into* $[0 \dots i']$.

If S exited in $[a_0 \dots a_1]$, M' need only transfer the output y_1 of the last pass onto the left end of the main track. This can be done in two block moves after locating markers into cells i', Ci', and $2Ci'$. Else, M' transfers y_1 instead to the put bays and assigns a new marker m_7 to the "stitch point" in the put bays for the next segment of y. The final marker m_8 goes to cell a_1 and is used for the left end of the read block in all succeeding segments. In three block moves, M' can both double e to $2e$ and compute $a_2 := a_0 + 2e$ using *add* as before. If and when the current value of e has length greater than $|a_0|$, M' reassigns marker m_6 to the end of e rather than a_0, incrementing it each time e is doubled. Then M' walks m_2 out to cell a_2 and, remembering the state q of S where the previous segment left off, produces $y_2 := S_q[a_1{+}1 \dots a_2]$ by the same counting method as before. To stitch y_2 into place on the put bays, M' converts the current location of m_7 into a numeric value k, adds it to $i := |y_2|$, and finds cells $i + k$ and $2i + k$ for two block copies. In case S did not exit in $[a_1 \dots a_2]$, m_7 is moved to cell $i + k$, m_8 to a_2, m_2 to $a_3 := a_0 + 4e$, and the process is repeated.

Let b be the actual cell in which S exits, and let $j \geq 0$ be such that $a_j < b \leq a_{j+1}$. Then the μ_d*-time* charged to M for the pull is at least

$$t_j := \mu_d(a_0) + \mu_d(a_0 + 2^{j-1}e) + 2^{j-1}e \geq 2e + 2^{j-1}e. \tag{4}$$

(For $j = 0$, read "2^{j-1}" as 0.) By Lemma 4.5, the memory access charge for walking a marker out to cell a_j is bounded by a constant (depending only on d) times $\mu_d(a_j)$. The charges for the marker arithmetic come to a polynomial in $\log a_j$, and the charges for stitching segments y_j into place stay bounded by the work performed by M'. Hence the μ_d*-time* charged to M' is bounded by a constant times

$$u_j := \mu_d(a_0) + \sum_{i=0}^{j} \mu_d(a_0 + 2^i e) + e + \sum_{i=0}^{j-1} 2^i e. \tag{5}$$

Then $u_j \leq e + \sum_{i=0}^{j} \mu_d(2^{i+1}a_0) + 2^j e \leq 2^{j+2}e + 2^j e \leq 10t_j$.

For a leftward pull step by M, M' uses the same choice of $e := \mu_d(a_0)$. If $e > a_0/2$, then M' just splits $[0 \dots a_0]$ into halves as in the (*LaB*) part of the proof of Theorem 4.1. Else, M' proceeds as before with $a_{j+1} := a_0 - 2^j e$ and checks at each stage whether $a_{j+1} \geq a_0/2$ so that the next simulated pull will be valid. If not, then the amount of work done by M thus far, namely $2^{j-1}e$, is at least $a_0/4$. Thus M' can copy all of $[a_j \dots 0]$ to another part of the tape and finish it off while remaining within a constant factor of the charge to M. The remaining bounds are much the same as those for a rightward pull above.

For a rightward or leftward put, marker m_1 is kept at the current address a, cell 0 is remembered in the finite control, and the procedure for a rightward pull is begun with $a_0 = 1$ and m_8 assigned there. Here $e = 1$, and the rest is a combination of the (*BaR*) or (*BaL*) parts of the proof of Theorem 4.1 to ensure validity, and the above ways to meet the strict boundary condition in all block moves. □

Remarks. This simulation can be made uniform by providing d as a separate input. It can also be done using 8 tracks rather than $2C + 6$, though even taking $e := \mu_d(a_0)/C$ does not guarantee that the *third* stage of a rightward pull, which reads $[a_0 + 2e, a_0 + 4e]$, will be valid. The fix is first to write the strings y_j further rightward on the tape, then assemble them at the left end. Theorem 4.13 preserves $w(n) + \mu_d\text{-}acc(n)$ up to constant factors, but does not do so for either $w(n)$ or $\mu_d\text{-}acc(n)$ separately. When $d < 1$, the case $b = a$ gives a worst-case extra work of $a^{1/d}$, while the case of $b = 2a$ gives a total memory-access charge of roughly $2(\log a)(d - 1)/d$ times $\mu_d(a)$. This translates into $w'(n) = O(w(n) + n + R(n)s(n)^{1/d})$

and μ_d-$acc'(n) = O(\mu_d\text{-}acc(n) \log s(n))$. However, when $d = 1$, *both* w and μ_1-*acc* are preserved up to a factor of $10N$. Allowing that $\mu_d(a_0)$ can be estimated to within a constant factor in $O(\log a_0)$ block moves, the pass count still carries $R'(n) = O(R(n)\log^2 s(n))$ because each movement in walking a marker to a_j adds 1 to R'. The following shows some technical improvements of having addressing instead of tree access.

THEOREM 4.14. *Let $\mu = \mu_{\log}$ or $\mu = \mu_d$ with d rational. Then every BM M can be simulated linearly under μ by a RAM-BM M' with address loading that observes the strict boundary condition.*

Proof. For μ_d the simulation of the finger BM M' from the last proof by a RAM-BM is clear—the RAM-BM can even use RAM-TM steps for the address arithmetic. For $\mu_{\log}$, the point is that M' can take $e := |a_0|$, and we may presume e is already stored. The calculated quantities a_j can be loaded in one block move. (Using RAM-TM steps to write them would incur $\mu_{\log}$ access charges proportional to $\log a_0 \log\log a_0$.) The tradeoff argument of the proof of Theorem 4.13 works even for $\mu_{\log}$, and the above takes care of a constant-factor bound on the other steps in the simulation. This also gives $R'(n) = O(R(n)\log s(n))$. □

The tradeoff method of Theorem 4.13 seems also to be needed for the following "tape-reduction theorem."

THEOREM 4.15. *For every rational $d \geq 1$, a multitape BM M can be simulated linearly in μ_d-time by a one-tape BM M'.*

Proof. Suppose that M uses k tapes, each with its own buffer, and GSTs S that produce k output strings as well as read k inputs. We first modify M to a machine M' that has k main tracks, k address tracks, one "input track," and one "buffer track." For any pass by M with S, M' will interleave the k inputs on the input track, do one separate pull for each of the k outputs of S, and interleave the outputs on its buffer track. When M subsequently invokes a k-input GST T to empty its buffers, M' uses a one-tape GST that simulates T on the buffer track, invoking it k times to write each of the k outputs of T to their destinations on the main tracks.

It remains only to show how M' marks the portions of the inputs to interleave. As in the proof of Theorem 4.13, there is the difficulty of not knowing in advance how long S will run on its k inputs. The solution is the same. M' first calculates the maximum a_j of the addresses $a_1, \ldots, a_k$ on its address tracks and then calculates $e := \mu_d(a_j)$. For each i, $1 \leq i \leq k$, M' drops an endmarker into cell $a_i \pm e$ according to the direction on main track i. Then M' copies only the marked-off portions of the tracks, putting those on its input track, and simulates the one-tape version S_1 of S. If S_1 exits within that portion, then M' continues as M' does. If S_1 does not exit within that portion, M' tries again with $a_i \pm 2e$, $a_i \pm 4e, \ldots$ until it does. The same calculation as in Theorem 4.13, plus the observation that if the direction on track j is leftward then no track uses an address greater than $2a_j$, completes the proof. □

Finally, we may restate Theorem 3.1 in a somewhat stronger form.

THEOREM 4.16. *For any rational $d \geq 1$, all of the models defined in* §3 *are equivalent, linearly in μ_d-time, to a BM in reduced form that is self-delimiting with* "$" *as its only endmarker.*

Proof. This is accomplished by Theorems 2.1 through 4.15. The procedures of Lemmas 4.13 and 4.6 and Theorem 4.1 are self-delimiting and need only one endmarker $. The trick of writing $ on special tracks into the cell immediately left or right of the addressed cell a allows $ to survive the proof of Theorem 2.1 without being "tupled" into the characters c_0, c_1, or c_a. □

With all this said and verified, we feel justified in claiming that there is one salient Block Machine model, and that the formulations given here are natural. The basic BM is the tightest for investigating the structure of computations, and helps the lower bound technique we suggest in Section 8. The richer forms make it easier to show that certain functions do belong to Dμ_dTIME[$t(n)$].

5. Linear speed-up and efficiency. The following "linear speed-up" theorem shrinks the constants in all the above simulations, at the usual penalty in alphabet size. First, we give a precise definition.

DEFINITION 5.1. *The* linear speed-up property *for a model of computation and measure of time complexity states that for every machine M with running time $t(n)$, and every $\epsilon > 0$, there is a machine M' that simulates M and runs in time $\epsilon \cdot t(n) + O(n)$.*

In the corresponding definition for TMs in [36], the additive $O(n)$ term is $n+1$ and is used to read the input. For the DTM, time $O(n)$ properly contains time $n+1$, while for the NTM these are equal [13]. For the BM under cost function μ, the $O(n)$ term is $n + \mu(n)$.

THEOREM 5.1. *With respect to any unbounded memory cost function μ that has the tape compression property, all of the BM variants described in* §§2 *and* 3 *have the linear speed-up property.*

Proof. Let the BM M and $\epsilon > 0$ be given. The BM M' uses two tracks to simulate the main tape of M. Let δ in the tape-compression property be such that for almost all n, $\mu(\delta n) \leq (\epsilon/12C) \cdot \mu(n)$. Here C is a constant that depends only on M. Let $k := \lceil 1/2\delta \rceil$, let "@" stand for the blank in Γ, and let $\Gamma' := \Gamma^k \cup \{ B \}$. M' uses B only to handle its own two tracks. We describe M' as though it has a buffer; the constant C absorbs the overhead for simulating one if M' lacks the buffer mechanism. On any input x of length n, M' first spends $O(n)$ time units on a pull step that writes x into $\lceil n/k \rceil$-many characters over the compressed alphabet Γ' on the main track. Thereafter, M' simulates M with compressed tapes. In any pass by M that writes output to the main tape, M' writes the compressed output to the alternate track. M' then uses the pattern of @ symbols in each compressed output character to mask the elements of each main track character that should not be overwritten, sending the combined output to the buffer. One more pass writes the result back to the main tape. If the cost to M for the pass was $\mu(a) + |b-a| + \mu(b)$, the cost to M', allowing for the tracking, is no more than

$$\begin{aligned} &3\,[\,\mu(2\lceil a/k \rceil) + (2/d)|b-a| + 2 + \mu(2\lceil b/k \rceil)] \\ &\quad \leq (\epsilon/2)\mu(a) + (\epsilon/2)|b-a| + 6 + (\epsilon/2)\mu(b). \end{aligned}$$

The "+2" and "+6" allow for an extra cell at either end of the compressed block. Since μ is unbounded, we have $\mu(a) \cdot (\epsilon/2) + 6 \leq \epsilon \cdot \mu(a)$ for all but finitely many a. The main technical difficulty of the standard proof for TMs is averted because μ absorbs any time that M might spend moving back and forth across block boundaries. The compression by a factor of ϵ holds everywhere except for cells $1, \ldots, m$ on the main tape, where m is least such that $\mu(m) \geq 12/\epsilon$, but M' can keep the content of these cells in its finite control. The remaining details are left to the reader. For BMs with address tapes, we may suppose that the addresses are written in a machine-dependent radix rather than in binary. □

COROLLARY 5.2. *For all of the simulations in Theorems* 2.1–4.15, *and all* $\epsilon > 0$,

(a) *if M runs in μ_d-time $t(n) = \omega(n)$, then M' can be constructed to run in μ_d-time $\epsilon t(n)$ for all but finitely many n.*

(b) *if M runs in μ_d-time $O(n)$, then M' can be made to run in μ_d-time $(1+\epsilon)n$.*

Mostly because of Lemma 4.6 and Theorem 4.13, the above simulations do not guarantee constant factor overheads in either w or μ-*acc*. They do, however, preserve μ-efficiency.

PROPOSITION 5.3. *For all of the simulations of a machine M by a machine M' in Theorems* 2.1–4.15, *and memory cost functions μ they hold for, if M is μ-efficient then M' is also μ-efficient.*

Proof. Let K_1 be the constant from the simulation of M by M', and let K_2 come from Definition 2.9(a) for M. Then for all but finitely many inputs x, we have

$$\mu\text{-}time(M', x) \leq K_1(\mu\text{-}time(M, x) + |x|) \leq K_1(K_2(w(M, x) + |x|) \leq 2K_1K_2w(M', x).$$

The last inequality follows because every simulation has $w(M', x) \geq w(M, x)$ and $w(M', x) \geq |x|$. Hence M' is μ-efficient. □

So long as we adopt the convention that every function takes work at least n+1 to compute, we can state the following corollary.

COROLLARY 5.4. *For any memory-cost function μ_d, with $d \geq 1$ and rational, the notion of a language or function being memory efficient under μ_d does not depend on the choice among the above variants of the BM model.* □

We do not have analogous results for parsimony. However, the above allows us to conclude that for $d = 1, 2, 3, \ldots$, memory efficiency under μ_d is a fundamental property of languages or functions. Likewise we have a robust notion of the class $\mathrm{D}\mu_d\mathrm{TIME}[t(n)]$ of functions computable in *μ_d-time* $t(n)$, for any time bound $t(n) \geq n$. The next section shows that for any fixed d, the classes $\mathrm{D}\mu_d\mathrm{TIME}[t(n)]$ form a tight hierarchy as the time function t varies.

6. Word problems and universal simulation. We use a simple representation of a list $\vec{x} := (x_1, \ldots, x_m)$ of nonempty strings in Σ^* by the string $x_1\#\ldots\#x_m\#$, where $\# \notin \Sigma$. More precisely, we make the last symbol c of each element a pair $(c, \#)$ so as to separate elements without adding space, and also use pair characters $(c, @)$ or $(c, \$)$ to mark selected elements. The *size* of the list is m, while the *bit length* of the list is $n := \sum_{i=1}^{m} |x_i|$. We let r stand for $\max\{\, |x_i| : 1 \leq i \leq m \,\}$. Following [16] we call the list *normal* if the strings x_i all have length r. We number lists beginning with x_1 to emphasize that the x_i are not characters.

LEMMA 6.1. (a) *The function mark($\vec{x}$, y), which marks all occurrences of the string y in the normal list $\vec{x}$, belongs to* TLIN.

(b) *The function shuffle, which is defined for normal lists $\vec{x} := (x_1, \ldots, x_m)$ and $\vec{y} := (y_1, \ldots, y_m)$ of the same length and element size r by shuffle($\vec{x}$, $\vec{y}$) $= (x_1, y_1, x_2, y_2, \ldots, x_m, y_m)$, belongs to* TLIN. *Here r as well as m may vary.*

Remark. Even if the lists $\vec{x}$ and $\vec{y}$ are not normal, *mark* and *shuffle* can be computed in linear *μ_1-time* so long as they are *balanced* in the sense that $(\exists k)(\forall i)2^{k-1} < |x_i| \leq 2^k$. This is because a balanced list can be padded out to a normal list in linear *μ_1-time* (we do not give the details here), and then the padding can be removed. To normalize an unbalanced list may expand the bit length quadratically, and we do not know how to compute *shuffle* in linear *μ_1-time* for general lists.

Proof. (a) Let r be the element size of the normal list $\vec{x}$. If $|y| \neq r$, then there is nothing to do. Else, the BM M uses the idea of "recursive doubling" (cf. the section on vector machines in [6]) to produce y^k, where $k = \lceil \log_2 m \rceil$. This time is linear as a function of $n = rm$. Then M interleaves $\vec{x}$ and y^k on a separate track, and a single pass that checks for matches between # signs marks all the occurrences of y in $\vec{x}$ (if any).

(b) Suppose m is even. M first uses two passes to divide $\vec{x}$ into the "odd list" $x_1@^r x_3 @^r \cdots x_{m-1}@^r$ and the "even list" $@^r x_2 @^r x_4 @^r \cdots @^r x_m$. Single passes then convert these to $x_1 @^{3r} x_3 @^{3r} \cdots x_{m-1} @^{3r}$ and $@^{2r} x_2 @^{3r} x_4 @^{3r} \cdots @^{3r} x_m$. A pull step that writes the second over the first but translates @ to B then produces $\vec{x}\,' := x_1 @^r x_2 @^r x_3 @^r \cdots @^r x_m$. If m is odd then the "odd list" is $x_1 @^r x_3 @^r \cdots @^r x_m$ and the "even list" is $@^r x_2 @^r x_4 @^r \cdots @^r x_{m-1} @^r$, but the final result $\vec{x}\,'$ is the same. By a similar process, M converts $\vec{y}$ to $\vec{y}\,' := @^r y_1 @^r y_2 \cdots @^r y_m @^r$. Writing $\vec{y}\,'$ on top of $\vec{x}\,'$ and translating @ to B then yields *shuffle*($\vec{x}$, $\vec{y}$). This requires only a constant number of passes. □

A *monoid* is a set H together with a binary operation $\circ$ defined on H, such that $\circ$ is associative and H has an element that is both a right and a left identity for $\circ$. We fix attention on the following representation of the *monoid of transformations* $\mathcal{M}_S$ of a finite-state machine S. $\mathcal{M}_S$ *acts* on the state set Q of S and is *generated* by the functions $\{ g_c : c \in \Sigma \}$, defined by $g_c(q) = \delta(q, c)$ for all $q \in Q$, by letting $\circ$ be composition of maps on Q, and closing out the g_c under $\circ$. Here we ignore the output function ρ of S, intending to use it once the *trajectory* of states S enters on an argument z is computed. We also remark that $\mathcal{M}_S$ need not contain the identity mapping on Q, though it does no harm for us to adjoin it. By using known decomposition theorems for finite transducers [47], [32], [48], we could restrict attention to the cases where each g_c either is the identity on Q or identifies two states (a "reset machine") or each g_c is a permutation of Q and $\mathcal{M}_S$ is a group (a "permutation machine"; cf. [17]). These points do not matter here. We encode each state in Q as a binary string of some fixed length k, and encode each element g of $\mathcal{M}_S$ by the list $q\#g(q)\#\cdots$ over all $q \in Q$. Without loss of generality, we extend Q to $Q' := \{ 0, \ldots, 2^k-1 \}$ and make g the identity on elements $q \geq n$.

The *word problem* for monoids is as follows: given a list $\vec{g} := g_n g_{n-1} \cdots g_2 g_1$ of elements of the monoid, not necessarily distinct, compute the representation of $g_n \circ g_{n-1} \circ \cdots \circ g_2 \circ g_1$. Let us call the following the *trajectory problem*: given $\vec{g}$ and some $w \in \{ 0, 1 \}^k$, compute the n-tuple $(g_1(w), g_2(g_1(w)), \ldots, \vec{g}\,(w))$. The basic idea of the following is that "parallel prefix sum" is μ_1-efficient on a BM.

LEMMA 6.2. *There is a fixed BM M that, for any size parameter k, solves the word and trajectory problems for monoids acting on* $\{ 0, 1 \}^k$ *in* μ_1*-time* $O(n \cdot k2^k)$. *In particular, these problems for any fixed finite monoid belong to* TLIN.

Proof. Let T be a TM which, for any k, composes two mappings $h_1, h_2 : \{ 0, 1 \}^k \to \{ 0, 1 \}^k$ using the above representation. For ease of visualization, we make T a single-tape TM which on any input of the form $h_2\#h_1\#$ uses only the $2k \cdot 2^k$ cells occupied by the input as workspace, and which outputs $h_2 \circ h_1\#$ shuffled with "@" symbols so that the output has the same length as the input. We also program T so that on input $h\#$, T leaves h unchanged. The running time $t(k)$ of T depends only on k and is $O(k2^k)^2$. As in Example 2.4, we can create a GST S whose input alphabet is the ID alphabet of T, such that for any nonhalting ID I of T, $S(I)$ is the unique ID J such that $I \vdash_T J$.

The BM M operates as follows on input $\vec{g} := g_n\#g_{n-1}\#\cdots\#g_2\#g_1\#$. It first saves $\vec{g}$ in cells $[(nk \cdot 2^k + 1) \ldots (2nk \cdot 2^k)]$ of a separate storage track. We may suppose that n is even; if n is odd, g_n is left untouched by the current phase of the recursion. M first sets up the initial ID of T on successive pairs of maps, viz. $\wedge q_0 g_n\#g_{n-1}\# \wedge q_0 g_{n-2}\#g_{n-3}\# \cdots \wedge q_0 g_2\#g_1\#$. Then M invokes S in repeated left-to-right pulls, until all simulated computations by T have halted. Then M erases all the @'s, leaving $(g_n \circ g_{n-1})\#(g_{n-2} \circ g_{n-3})\# \cdots (g_2 \circ g_1)\#$ on the tape. The number of sweeps is just $t(k)$, and hence the total μ_1*-time* of this phase is $\leq 2t(k) \cdot n = O(n)$.

M copies this output to cells $[((n/2)k \cdot 2^k + 1) \ldots (nk \cdot 2^k)]$ of the storage track, and then repeats the process, until the last phase leaves $h := g_n \circ g_{n-1} \circ \cdots \circ g_2 \circ g_1$ on the tape. Since the length of the input halves after each phase, the total μ_1*-time* is still $O(n)$. This finishes the word problem.

To solve the trajectory problem, M uses the stored intermediate results to recover the path $(w, g_1(w), g_2(g_1(w)), \ldots, h(w)) =: (w, w_1, w_2, \ldots, w_n)$ of the given $w \in \{ 0, 1 \}^k$. Arguing inductively from the base case $(w, h(w))$, we may suppose that M has just finished computing the path $(w, w_2, w_4, \ldots, w_{n-2}, w_n)$. M shuffles this with the string $g_1\#g_3\#g_5\#\ldots\#g_{n-1}$ and then simulates in the above manner a TM T' that given a g and a w computes $g(w)$. All this takes μ_1*-time* $O(n)$. □

The following presupposes that all BMs M are described in such a way that the alphabet Γ_M of M can be represented by a uniform *code* over $\{ 0, 1 \}^*$. This *code* is extended to represent monoids $\mathcal{M}$ as described above.

THEOREM 6.3. *There is a BM M_U and a computable function code such that for any BM M and rational $d \geq 1$, there is a constant K such that for all inputs x to M, M_U on input $(code(M), code(x), d)$ simulates $M(x)$ within μ_d-time $K \cdot \mu_d$-time(M, x).*

Proof. M_U uses the alphabet $\Gamma_U := \{0, 1, @, \$, (0, \#), (1, \#), (@, \#), \Delta, B\}$. By Theorem 2.1, we may suppose that M has a single GST $S = (Q, \Gamma_M, \Gamma_M, \delta, \rho, s_0)$. Let $k := \lceil \log_2 |\Gamma_M| \rceil$, and let l be the least integer above $\log_2 |Q|$ that is a multiple of k. The *code* function on strings codes each $c \in \Gamma_M$ by a 0–1 string of length k, except that the last bit of $code(c)$ is combined with # and B is coded by $@^{k-1}(@, \#)$.

The monoid $\mathcal{M}$ of transformations of S is encoded by a k-tuple of elements of the form $code(c)code(g_c)$ over all $c \in \Gamma_M$. Here $code(g_c)$ is as described before Lemma 6.2. Dummy states are added to Q so that $code(g_c)$ has length exactly $2l \cdot 2^l$; then $code(\mathcal{M})$ has length exactly $2^k(k + 2l \cdot 2^l)$. Let C be the maximum number of symbols written in any transition of M. The code of S includes a string $code(\rho)$ that gives the output for each transition in δ, padded out with @ symbols to length exactly C (i.e., length Ck under *code*). The rest of the code of M lists the mode-change information for each terminal state of S. Finally, the input x to M is represented by the string $code(x)$ of length $|x|2^k$.

M_U has four tracks: one for the main tape of M, one for the code of M, one for simulating passes by M, and one for scratchwork. M_U uses d to compute $e := \mu_d(a)$, and follows just the part of the proof of Theorem 4.13 that locates the cells $a_j := a \pm 2^{j-1}e$, in order to drop \$ characters there. This allows M_U to pull off from its main track in cells $[a \ldots a_j]$ the *code* of the first $m := 2^{j-1}e/4k$ characters of the string x that M reads in the pass being simulated. (If this pass is a put rather than a pull, then $e = 1$ and x is in cells $[1 \ldots 2^{j-1}]$.) Then M_U changes $code(z)$ to

$$z' := (code(z_0))^j \cdot (code(z_1))^j \cdots (code(z_{m-1}))^j,$$

where $m := |z|$ and $j := 2^k(1 + 2(l/k)2^l)$. This can be done in linear μ_1-*time* by iterating the procedure for *shuffle* in Lemma 6.1(b). Now for each $i, 0 \leq i \leq m-1$, the ith segment of z' has the same length as $code(\mathcal{M})$. Next, M uses "recursive doubling" to change $code(\mathcal{M})$ to $(code(\mathcal{M}))^m$. This also takes only $O(m)$ time. Then the strings z' and $(code(\mathcal{M}))^m$ are interlaced on the scratchwork track. A single pass that matches the labels $code(c)$ to segments of z' then pulls out the word $g_z := g_{z_0} \cdot g_{z_1} \cdots g_{z_{m-1}}$.

M evaluates this word by the procedure of Lemma 6.2, yielding the encoded trajectory $s' := (s_0, s_1, \ldots, s_m)$ of S on input z. By a process similar to that of the last paragraph, M_U then aligns s' with $(code(\rho))^m$ and interleaves them, so that a single pass pulls out the output y of the trajectory. Then $code(y)$ is written to the main tape, erasing the symbols Δ used for padding and translating @ to B. The terminal state s_m of the trajectory is matched against the list that gives the mode information for the next pass of M (Lemma 6.1(a)), and M_U changes its mode and/or current address accordingly.

If the original pass by M cost μ-*time* $\mu(a) + m + \mu(b)$, then the simulation takes μ-*time* $\mu(4a) + O(m) + \mu(4b)$. The constant in the "$O(m)$" depends only on M. We have described M_U as though there were no validity restrictions on passes, but Theorems 4.1 and 2.1 convert M_U to a basic BM while keeping the constant overhead on μ_d-*time*. □

Remarks. This result implies that there is a fixed, finite collection of GSTs that form an efficient "universal chipset." It might be interesting to explore this set in greater detail. The constant on the "$O(m)$" is on the order of $2^{2(l+k)}(l + k)$. We inquire whether there are other representations of finite automata or their monoids that yield notably more efficient off-line simulations than the standard one used here. The universal simulation in Theorem 6.3 does not preserve w or μ_d-*acc* individually because it uses the method of Theorem 4.13 to compensate for its lack of "foreknowledge" about where a given block move by M will exit. The simulation does preserve memory efficiency, on account of Proposition 5.3. If, however, we suppose that M is already self-delimiting in a way made transparent by *code*, then we obtain constant overheads in both w and μ-*acc*, and the simulation itself becomes independent of μ.

THEOREM 6.4. *There is a BM M_U and a computable function code such that for any memory-cost function μ and any self-delimiting BM M, there is a constant K such that for all inputs x to M, M_U on input $x' = (code(M), code(x))$ simulates $M(x)$ with $w(U, x') \leq Kw(M, x)$ and $\mu\text{-}acc(U, x') \leq K\mu\text{-}acc(M, x)$.*

Proof. The function *code* is changed so that it encodes the endmarkers of M by strings that begin with "\$." Then M_U pulls off the portion x of its main track up to \$. The rest of the operation of M_U is the same, and the bounds now require only the tracking property of μ. (If the notion of "self-delimiting" is weakened as discussed before Definition 3.3, then we can have M_U first test whether a GST S exits on the second symbol of x.) □

To use these results for diagonalization, we need two preliminary lemmas. Recall that a function t is μ-*time constructible* if $t(n)$ is computable in binary notation in μ-time $O(t(n))$. Since all of n must be read, t must be $\Omega(\log n)$.

LEMMA 6.5. *If a BM M is started on an input of length n, then any pass by M either takes μ_1-time $O(n)$ or else no more than doubles the accumulated μ-time before the pass.*

Proof. Any portion of the tape other than the input that is read in the pass must have been previously written in some other pass or passes. (Technically, this uses our stipulation that B is an endmarker for GSTs.) Thus the conclusion follows. □

LEMMA 6.6. *For any memory-cost function μ that is μ-time constructible, a BM M can maintain a running total of its own μ-time with only a constant-factor slowdown.*

Proof. To count the number $m = |b - a| + 1$ of transitions made by one of its GST chips S in a given pass, a BM M can invoke a "dummy copy" of S that copies the content x of the cells up to where S exits to a fresh track, and then count $|x|$ on that track by the $O(m)$-time procedure of Example 2.3. Then M invokes S itself and continues operation as normal. Since μ is $\Omega(\log n)$, the current address a can be copied and updated on a separate track in μ-*time* $O(\mu(a))$. Also in a single pass, M can add a and m in μ-*time* $O(\mu(a) + m)$, and thus obtain b itself. M then calculates $\mu(b)$ in μ-*time* $O(\mu(b))$, and finally adds $k := \mu(a) + m + \mu(b)$ to its running total t of μ-*time*. In case t is much longer than k, we want the work to be proportional to $|k|$, not to $|t|$. Standard "carry–save" techniques, or alternatively an argument that long carries cannot occur too often, suffice for this. □

THEOREM 6.7. *Let $d \geq 1$ be rational, and let t_1 and t_2 be functions such that t_2 is μ_d-time constructible, and t_1 is $o(t_2)$. Then* DμTIME$[t_1]$ *is properly contained in* DμTIME$[t_2]$.

Proof. The proof of Theorem 6.3 encoded BMs M over the alphabet Γ_U, but let *code*$'$ recode M over $(00 \cup 11)^*$. We build a BM M_D that accepts a language $D \in$ DμTIME$[t_2] \setminus$ DμTIME$[t_1]$ as follows. M_D has two extra tracks on which it logs its own μ-*time*, as in Lemma 6.6. On any input x, M_D first calculates $n := |x|$, and then calculates $t_2(n)$ on its "clock track." Next, M_D lets w be the maximal initial segment of doubled bits of x. Since the set $\{\, code(M) : M \text{ is a BM} \,\}$ is recursive, M_D can decide whether w is the *code*$'$ of a BM M in some time $U(n)$. The device of using w ensures that there are ∞-many inputs in which any given BM M is presented to M_D. If w is not a valid code, M_D halts and rejects.

If so, M_D runs M_U on input $code(M) \cdot code(x)$, except that after every pass by M_U, M_D calculates the μ-*time* of the pass and subtracts it from the total on its clock tape. If the total ever falls below $t_2(n)/2$, M_D halts and rejects. Otherwise, if the simulation of $M(x)$ finishes before the clock "rings," M_D rejects if M accepts, and accepts if M rejects. By Lemma 6.5, the total μ-*time* of M_D never exceeds $t_2(n)$.

Now let L be accepted by a BM M_L that runs in μ-*time* $t_1(n)$. Let K_1 be the constant overhead for M_U to simulate M_L in Theorem 6.3, and let K_2 be the overhead in Lemma 6.6.

Since t_1 is $o(t_2)$, there exists an x such that $t_2(|x|)/t_1(|x|) > 4K_1K_2$, the maximal initial segment $w \in (00 \cup 11)^*$ of x is $code'(M_L)$, and $U(|w|) < |x|$. Then the simulation of $M_L(x)$ by M_D finishes within μ-*time* $(1/2)t_2(|x|)$, and $M_D(x) \neq M_L(x)$. □

It is natural to ask whether the classes Dμ_dTIME$[t(n)]$ also form a tight hierarchy when t is held constant and d varies. The next section relates this to questions of determinism versus nondeterminism.

We observe finally that the BM in its original, reduced, and buffer forms all give the same definition of D$\mu_{\log}$TIME$[t(n)]$, and we have the following theorem.

THEOREM 6.8. *For any time functions* t_1, t_2 *such that* $t_1(n) \geq n$, $t_1 = o(t_2)$, *and* t_2 *is* $\mu_{\log}$-*time constructible,* D$\mu_{\log}$TIME$[t_1]$ *is properly contained in* D$\mu_{\log}$TIME$[t_2]$.

Proof. Here the strict boundary condition is not an issue, but the efficient universal simulation still requires delimiting the read block in advance. The idea is to locate cells $a_1, a_2, a_3, \ldots$, in the proof of Theorem 4.13 without addressing by the following trick. As in Theorem 4.14, the current address a_0 is already stored and $e = |a_0|$. In a rightward pull, rather than add $a_0 \dotplus e$, M' puts a_0 itself in binary rightward from cell a_0 on a separate track, appending an endmarker \$. By "recursively doubling" the string a_0, M' can likewise delimit the cells $a_2, a_3, \ldots$ Leftward pull steps are handled similarly, and put steps do not need $\mu_{\log}(a_0)$ at all. This is all that is needed for the efficient universal simulation. The remainder follows as above, since $\mu_{\log}$ is $\mu_{\log}$-*time* constructible—in fact, $\mu_{\log}(a) = |a|$ is computable in μ_1-*time* $O(|a|)$. □

A similar statement holds for the perhaps-larger $\mu_{\log}$-*time* classes for the BM variants that do use addressing.

7. Complexity theory and the BM model.

Our first result shows that the construction in the *Hennie–Stearns theorem* [33], which states that any multitape TM that runs in time $t(n)$ can be simulated by a two-tape TM in time $t(n)\log t(n)$, is memory efficient on the BM under μ_1. It has been observed in general that this construction is an efficient caching strategy. DTIME$[t(n)]$ refers to TM time, and DLIN stands for DTIME$[O(n)]$.

THEOREM 7.1. *For any function* t, DTIME$[t(n)] \subseteq$ Dμ_1TIME$[t(n)\log t(n)]$.

Proof. With reference to the treatment in [36], let M_1 be a multitape TM with alphabet Γ that runs in time $t(n)$, and let M_2 be the two-tape TM in the proof. The k-many tapes of M_1 are simulated on $2k$-many tracks of the first tape of M_2 so that all tape heads of M_1 are maintained on cell 0 of each track. M_2 uses its second tape only to transport blocks of the form $[2^{j-1} \ldots 2^j{-}1]$ from one part of the first tape to another. The functions used in these moves are homomorphisms between the alphabets Γ^{2k} and Γ^k that pack and unpack characters in blocks. Thus a BM M_3 simulating M_2 can compute each move in a single GST pass. By the structure of the blocks, any pass that incurs a memory-access charge of $\mu_1(2^j) = 2^j$ simulates at least 2^{j-1} moves of M_2. Hence the work and the μ_1 charges to M_3 are both $O(t(n)\log t(n))$. □

We do not know whether the random-access capability of a BM can be exploited to give an $O(t \log t)$ simulation that holds the work to $O(t)$, even for $\mu = \mu_{\log}$. Indeed, $O(t \log t)$ is the best bound we know for all memory-cost functions μ between $\mu_{\log}$ and μ_1. One consequence of this proposition is that sets in DLIN can be padded out to sets in TLIN.

COROLLARY 7.2. (a) *For every* $L \in$ DLIN, *the language* $\{\, x\#0^{|x|\log|x|} : x \in L \,\}$ *belongs to* TLIN.

(b) TLIN *contains* P-*complete languages, so* TLIN $\subseteq$ NC $\Longleftrightarrow$ P = NC.

Hence it is unlikely that all TLIN functions can be computed in polylog-many passes like the examples in this paper. If a BM quickly compresses the amount of information remaining to be processed into cells $[0 \ldots \sqrt{n}\,]$, it can then spend $O(\sqrt{n})$ time accessing these cells in any order desired and still run in linear μ_1-*time*.

THEOREM 7.3. *Let* M *be a BM that runs in* μ-*time* $t(n)$ *and space* $s(n)$. *Then we can find a DTM* T *that simulates* M *in time* $O[t(n)s(n)/\mu(s(n))]$.

Proof. T has two tapes, one for the main tape of M and one used as temporary storage for the output in passes. (If M has the buffer mechanism, then the second tape of T simulates the buffer.) Let s stand for $s(n)$. Consider a move by M that changes the current address a to $\lfloor a/2 \rfloor$. T can find this cell in at most $3a/2$ steps by keeping count with its second tape. Since $s/a \geq 1$, the tracking property $\mu(Na) \leq N\mu(a)$ with $N := s/a$ gives $a/\mu(a) \leq s/\mu(s)$. Hence the ratio of the time used by T to the μ-time charged to M stays $O[s/\mu(s)]$. The same holds for the moves $a := 2a$ and $a := 2a+1$. T has every GST S of M in its finite control, and simulates a pull by writing $S[a \dots b]$ to its second tape, moving to cell 0, copying $S[a \dots b]$ over the first tape, and moving back to cell a. Both this and the analogous simulation of a put by T take time $O(a + b)$, and even the ratio of this to the memory-access charges $\mu(a) + \mu(b)$, not even counting the number of bits processed by M, keeps the running total of the time logged by T below $t(n)s/\mu(s)$. □

COROLLARY 7.4. *For any time bound* $t(n) \geq n$, $\mathrm{D}\mu_1\mathrm{TIME}[t(n)] \subseteq \mathrm{DTIME}[t(n)]$. *In particular,* TLIN $\subseteq$ DLIN.

More generally, for any $d \geq 1$, $\mathrm{D}\mu_d\mathrm{TIME}[t(n)] \subseteq \mathrm{DTIME}[t^{2-(1/d)}(n)]$. Allowing TMs to have d-dimensional tapes brings this back to a linear-time simulation.

LEMMA 7.5. *For any integer* $d \geq 1$ *and time bound* $t(n) \geq n$, *a BM* M *that runs in* μ_d*-time* $t(n)$ *can be simulated in time* $O(t(n))$ *by a* d*-dimensional TM* T.

Proof. T has one d-dimensional tape on which it winds the main tape of M in a spiral about the origin, and one linear tape on which it buffers outputs by the GST S of M. In any pass that incurs a μ_d charge of $a^{1/d}$, T can walk between cell a and the origin within $a^{1/d}$ steps and complete the move. □

Let us say that a language or function in $\mathrm{D}\mu_d\mathrm{TIME}[O(n)]$ *has dimension* d. For a problem above linear time, we could say that its *dimensionality* is the least d, if any, for which the problem has relatively optimal BM programs that are μ_d-efficient (see Definition 2.10). The main robustness theorem is our justification for this concept of dimensionality. Lemma 7.5 says that it is no less restrictive than the older concept given by d-dimensional Turing machines. For $d > 1$ we suspect that it is noticeably more restrictive. The d-dimensional tape reduction theorem of Paul, Seiferas, and Simon [58] gives $t'(n)$ roughly equal to $t(n)^{1+1/d}$, and when ported to a BM, incurs memory access charges close to $t(n)^{1+2/d}$. Intuitively, the problem is that a d-dimensional TM can change the direction of motion of its tape head(s) at any step, whereas this would be considered a break in pipelining for the simulating BM, and thus subject to a memory-access charge.

We write $\mathrm{RAM\text{-}TIME}^{\log}$ for time on the log-cost RAM. A log-cost RAM can be simulated with constant-factor overhead by a TM with one binary tree-structured tape and one standard worktape [57], and the latter is simulated in real time by a RAM-TM.

PROPOSITION 7.6. *For any time function* t,

(a) $\mathrm{RAM\text{-}TIME}^{\log}[t(n)] \subseteq \mathrm{D}\mu_{\log}\mathrm{TIME}[t(n)\log t(n)]$.

(b) $\mathrm{D}\mu_{\log}\mathrm{TIME}[t(n)] \subseteq \mathrm{RAM\text{-}TIME}^{\log}[t(n)\log t(n)]$.

Proof. Straightforward simulations give these bounds. (The extra $\log t(n)$ factor in (b) dominates a factor of $\log\log n$ that was observed by [44] for the simulation of a TM (or RAM-TM) by a log-cost RAM.) □

For *quasilinear time*, i.e., time $qlin = n(\log n)^{O(1)}$, the extra $\log n$ factors in Theorem 7.1 and Proposition 7.6 do not matter. Following Schnorr [65], we write DQL and NQL for the TM time classes DTIME[$qlin$] and NTIME[$qlin$]. Gurevich and Shelah [30] proved that $\mathrm{RAM\text{-}TIME}^{\log}[qlin]$ is the same as deterministic nearly linear time on the RAM-TM and several other RAM-like models, and perhaps more surprisingly, that the nondeterministic counterparts of these classes are all equal to NQL.

COROLLARY 7.7. (a) $\mathrm{D}\mu_1\mathrm{TIME}[qlin] = \mathrm{DQL}$.

(b) $\mathrm{D}\mu_{\log}\mathrm{TIME}[qlin] = \mathrm{RAM\text{-}TIME}^{\log}[qlin] \subseteq \mathrm{NQL}$.

Hence the objective of separating the classes DμTIME[$O(n)$], as μ varies from μ_1 through μ_d to $\mu_{\log}$, by anything more than factors of $O(\log n)$, runs into the problem of whether DQL $\neq$ NQL, which seems as hard as showing P $\neq$ NP. Whether they can be separated by even one $\log n$ factor is discussed in the next section.

8. Open problems and further research. The following languages have been much studied in connection with linear-time algorithms and nonlinear lower bounds. We suppose that the lists in L_{dup} and L_{int} are all normal.

(a) Pattern matching: $L_{pat} = \{\, p\#t : (\exists u, v \in \{0,1\}^*)\, t = upv \,\}$.

(b) Element (non)distinctness: $L_{dup} = \{\, x_1\#\cdots\#x_m : (\exists i, j)\, i < j \wedge x_i = x_j \,\}$.

(c) List intersection: $L_{int} = \{\, x_1\#\cdots\#x_m, y_1\#\cdots\#y_m : (\exists i, j)\, x_i = y_j \,\}$.

(d) Triangle: $L_{\Delta} = \{A : A$ is the adjacency matrix of an undirected graph that contains a triangle$\}$.

L_{pat} belongs to DLIN (see [25], [23]), and was recently shown not to be solvable by a one-way non-sensing multihead DFA [42]. L_{dup} and L_{int} can be solved in linear time by a RAM or RAM-TM that treats list elements as cell addresses. L_{Δ} is not believed to be solvable in linear time on a RAM at all. The best method known involves computing $A^2 + A$, and squaring $n \times n$ integer matrices takes time approximately $N^{1.188}$, where $N = n^2$, by the methods of [19]. (For directed triangles, cubing A is the best way known.)

OPEN PROBLEM 1. *Do any of the above languages belong to* TLIN? *If not, prove nonlinear lower bounds.*

A BM can be made nondeterministic (NBM) by letting $\delta(q, c)$ be multiply valued and, more strongly, by using nondeterministic GSTs or GSM mappings in block moves. Define NTLIN to be linear time for NBMs of the *weaker* kind. Then all four of the above languages belong to NTLIN. Moreover, they require only $O(\log n)$ bits of nondeterminism.

OPEN PROBLEM 2. *Is* NTLIN $\neq$ TLIN? *For reasonable μ and time bounds t, is there a general separation of* NμTIME[$t(n)$] *from* DμTIME[$t(n)$]?

Grandjean [27], [28] shows that a few NP-complete languages are also hard for NLIN under TM linear time reductions, and hence by the theorem of [56] lie outside DLIN, not to mention TLIN. However, these languages seem not to belong to NTLIN, nor even to linear time for NBMs of the stronger kind. The main robustness theorem and subsequent simulations hold for the weaker kind of nondeterminism, but our proofs do not work for the stronger because they rerun the GST S used in a pass. We suspect that different proofs will give similar results. A separation of the two kinds can be shown with regard to the pass-count measure $R(n)$, which serves as a measure of parallel time (e.g., $R(n) = \text{polylog}(n)$ and polynomial work $w(n)$ by deterministic BMs characterizes NC [62]). P. van Emde Boas [personal communication, 1994] has observed that while deterministic BMs and NBMs of the weaker kind belong to the *second machine class* of [68] with $R(n)$ as time measure, NBMs of the stronger kind have properties shown there to place models beyond the second machine class. Related to Open Problem 2 is whether the classes Dμ_dTIME[$O(n)$] differ as d varies. It is also natural to study *memory-efficient* reductions among problems.

The following idea for obtaining such separations and proving nonlinear lower bounds in *μ-time* on a deterministic BM M suggests itself: let $\Gamma_{M,x}$ stand for the set of access points used in the computation of the BM M on input x. In order for M to run in linear *μ-time*, $\Gamma_{M,x}$ must thin out at the high end of memory. In particular for $\mu = \mu_1$, there are long segments between access points that can be visited only a constant number of times. The technical difficulty is that block moves can still transport information processed in low memory to these segments, and the proof of Theorem 7.1 suggests that a lower bound of $\Omega[n \log n]$ may be the best achievable in this manner. In general, we advance the BM as a logical next step in the longstanding program of proving nonlinear lower bounds for natural models of computation.

In particular, we ask whether the techniques used by Dietzfelbinger, Maass, and Schnitger [20] to obtain lower bounds for Boolean matrix transpose and several sorting-related functions on a certain restricted two-tape TM can be applied to the differently restricted kind of two-tape TM in Theorems 7.1 and 7.3. The latter kind is equivalent to a TM with one worktape and one pushdown store with the restriction that after any POP, the entire store must be emptied before the next PUSH.

We have found two variants to the BM model that seem to depart from the cluster of robustness results shown in this paper. They relate to generally known issues of *delay* in computations. The first definition is the special case for GSTs of Manacher's notion of a "fractional on-line RAM algorithm with steady-paced output" [53].

DEFINITION 8.1. *Let $d \geq 0$ and $e \geq 1$ be integers. A GST S runs in* fixed output delay d/e *if for every terminal trajectory $(q_0, x_0, q_1, \ldots, x_{m-1}, q_m)$, and each $i \leq m-2$, $|\rho(q_i, x_i)| = d$ if e divides $i+1$, $= 0$ otherwise. For the exiting transition, $|\rho(q_{m-1}, x_{m-1})|$ depends only on $(m \bmod e)$. The quantity $C := d/e$ is called the* expansion factor *of S.*

Note that the case $d = 0$ is allowed. Every GST function g can be written as $e \circ f$, where f is fixed delay and e is an erasing homomorphism: pad each output of the GST for g to the same length with "@" symbols, and let e erase them. A k-input GST *with stationary moves allowed* may keep any of its input heads stationary in a transition. Such a machine can be converted to an equivalent form coded like an ordinary GST in which every state q has a label $j \in \{1, \ldots, k\}$ such that q reads and advances only the head on tape j.

DEFINITION 8.2. (a) *A BM* runs in fixed output delay *if every GST chip in M runs in fixed output delay.*

(b) *A* pause buffer BM *is a BM with buffer whose put steps may use 2-input GSTs with variable input delay (cf. Proposition* 4.3*).*

Put another way, the BM model presented in this paper requires fixed delay in reading input but not in writing output, while (a) requires both and (b) requires neither. We did not adopt (b) because we feel that stationary moves by a 2-GST in the course of a pass require communication between the heads, insofar as further movements depend on the current input symbols, and hence should incur memory-access charges. We defend our choice against a similar criticism that would require (a) by contending that in a single-tape GST pass, the motion of the read head is not affected by the write head, and the motion of the write head depends only on local factors as bits come in to it. Also, every BM has a limit C on the number of output bits per input bit read by a GST. The main robustness theorem (Theorem 3.1), in particular the ability to forecast the length of the output of a pass by fixed-delay means shown in Theorem 4.13, satisfies our doubts about this.

The robustness results in this paper do carry over to the case of fixed output delay.

THEOREM 8.1. *For any rational $d \geq 1$, the fixed-delay restrictions of the BM and all the variants defined in* §3 *simulate each other up to constant factors in μ_d-time.*

Proof. All auxiliary operations in the simulations in §4 use GSTs that run in fixed output delay, except for the second, unpadded run of the GST S in Theorem 4.13. However, if S already runs in fixed output delay, so does this run. □

Under the proof of Theorem 2.1, the corresponding notion for the reduced form of the model is "fixed delay after the initial transition." Our proof of efficient universal simulation does not quite carry over for fixed output delay because the quantities k and l in the proof of Theorem 6.3 may differ for different M. The operations that pull off the word g_z and the padded output *code*(y) run in "stride" a function of k and l, but this is not fixed. We believe that the proof can be modified to do so under a different representation scheme for monoids.

Whether a similar robustness theorem holds for the pause-buffer BM leads to an open problem of independent interest: can every k-input GST be simulated by a composition tree of two-input GSTs when stationary moves are allowed? The questions of the power of both variants versus the basic BM can be put in concrete terms.

OPEN PROBLEM 3. *Can the homomorphism $Er_2 : \{0, 1, 2\}^* \to \{0, 1\}^*$, which erases all 2's in its argument, be computed in linear μ_1-time by a BM that runs in fixed output delay?*

OPEN PROBLEM 4. *For every two-input GST S with stationary moves allowed, does the function $S'(x\#y) := S(x, y)$ belong to* TLIN?

THEOREM 8.2. (a) *The answer to Open Problem* 3 *is "yes" iff for every memory-cost function μ and BM M, there is a BM M' that runs in fixed output delay and simulates M linearly under μ.*

(b) *The answer to Open Problem* 4 *is "yes" iff for every memory-cost function μ and pause-buffer BM M, there is a BM M' that simulates M linearly under μ.*

Proof. For the forward implication of (a), M' pads every output by M with @ symbols, coding the rest over $\{0, 1\}^*$, and runs $Er_@$ on a separate track to remove the padding. That of (b) is proved along the lines of Proposition 4.3. The reverse implications are immediate, and all this needs only the tracking property of μ. □

Alon and Maass [4] prove substantial time–space tradeoffs for the related "sequence-equality" problem SE[n]: given $x, y \in \{0, 1, 2\}^n$, does $Er_2(x) = Er_2(y)$? We inquire whether their techniques, or those of [54], can be adapted to the BM. The BM in Theorem 7.1 runs in output delay 1/2, 1, or 2 for all passes, so the two kinds of BM can be separated by no more than a log factor. A related question is whether every language in TLIN, with or without fixed output delay, has linear-sized circuits.

Further avenues for research include analyzing implementations of certain important algorithms on the BM, as done for the BT and UMH in [2], [5]. Here the BM is helped by its proximity to the Pratt–Stockmeyer vector machine, since conserving memory-access charges and parallel time often lead to similar methods. One can also study storage that is expressly laid out on a two-dimensional grid or in three-dimensional space, where a *pass* might be defined to follow either a one-dimensional line or a two-dimensional plane. We expect the former not to be much different from the BM model with its one-dimensional tape, and we also note that CD-ROM and several current two-dimensional drive technologies use long one-dimensional tracks. The important issue may not be so much the topology of the memory itself, but whether "locality is one-dimensional" for purposes of pipelining.

Last, we ask about meaningful technical improvements to the simulations in this paper. The lone obstacle to extending the main robustness theorem for $\mu = \mu_{\log}$ is the simulation of random access by tree access in Lemma 4.6. The constants on our universal simulation are fairly large, and we seek a more efficient way of representing monoids and computing the products. Two more questions are whether the BM loses power if the move option $a := 2a+1$ is eliminated, and whether the number m of markers in a finger BM can be reduced to $m-1$ or to 4 without multiplying the number of block moves by a factor of $\log t(n)$.

9. Conclusion. In common with motivations expressed in [2] and [5], the BM model fosters a finer analysis of many theoretical algorithms in terms of how they use memory and how they really behave in running time when certain practicalities of implementation are taken into account. We have shown that the BM model is quite robust and that the concept of functions and languages being computable in a memory-efficient manner does not depend on technical details of setting up the model. The richer forms of the model are fairly natural to program, providing random access and the convenience of regarding finite transductions such as addition and vector Booleans as basic operations. The tightest form of the model is syntactically simple, retains the bit-string concreteness of the TM, and seems to be a tractable object of study for lower bound arguments. The robustness is evidence that our abstraction is "right."

In contrast to the extensive study of polynomial-time computation, very little is known about linear-time computation. Owing to an apparent lack of linear-time robustness among various kinds of TMs, RAMs, and other machines, several authorities have queried their suitability as a model for computation in $O(n)$ time. Since we have μ as a parameter we have admittedly not given a single answer to the question, "What is linear time?", and leave TLIN, Dμ_2TIME[$O(n)$], and Dμ_3TIME[$O(n)$] as leading candidates. However, the BM model does supply a robust yardstick for assessing the complexity of many natural combinatorial problems and for investigating the structure of several other linear-time complexity classes. It has a tight deterministic time hierarchy right down to linear time. The efficient universal simulator which we have constructed to show this result uses the word problem for finite monoids in an interesting manner. The longstanding program of showing nonlinear lower bounds in reasonable models of computation has progressed up to machines apparently just below the BM (under μ_1) in power, so that attacking the problems given here seems a logical next step. The authors of [3] refer to the "challenging open problem" of extending their results when bit manipulations for dissecting records are available. The bit operations given to the BM seem to be an appropriate setting for this problem. A true measure of the usefulness of the BM model will be whether it provides good ground for developing and connecting methods that solve older problems not framed with the term "BM." We offer the technical content of this paper as appropriately diligent spadework.

Appendix: Proof of Theorem 2.1. For every move state q in M we add a new GST S_q that performs a 1-bit empty pull just to read the currently scanned character d, and then sends control to $\delta(q, d)$. This modification no more than doubles the μ access charges, and gives M the following property: for any pass by a GST S_i, the next GST S_k to be invoked (or HALT) is a function only of i and the character c that caused S_i to exit, and there is at most one intervening move. Henceforth we assume that M has this form, and number its GST chips by $S_0, \ldots, S_r$, with S_0 as start chip.

M' uses an alphabet Γ' which includes the alphabet Γ of M, a surrogate blank @, tokens $\{ s_0, \ldots, s_r \}$ for the chips of M, markers $\{ m_U, m_L, m_R, m_{no}, m_H \}$ for the three kinds of move, "no move," and HALT, special *instruction markers* $\{ I_0, \ldots, I_{12} \}$, *plus* certain tuples of length up to 7 of the foregoing characters. We also use @ to indicate that the symbol written to cell 0 is immaterial.

During the simulation, the first component of every tuple in a cell i is the character $c_i \in \Gamma$ in that cell of the tape of M. Except initially, cell 1 holds both c_0 and c_1, so that cell 0 can be overwritten by other characters. This also allows M' to simulate all moves by M without ever moving its own cell-a head back to cell 0. The markers I_0 and I_1 tell M' when the cell-a head of M is in cell 0 or 1. For $a \geq 2$, the heads of M and M' coincide. The other main invariant of the simulation is that the only cell besides cells 0 and 1 to contain multiple symbols is cell a. The two initial moves of M' set up these invariants.

Character(s) read	Action (Initial mode is Ra, $a = 0$.)
c_0, c_1	Pull $[c_0, c_1]$ to cell 0, $a := a$, *mode* $:= 0R$.
$[c_0, c_1], c_1$	Put @ into cell 0 and $[c_1, c_0, s_0, I_0]$ into cell 1, $a := 2a + 1$, *mode* $:= Ra$.

The first move must automatically be executed every time M' moves its tape head to a new cell a, $a \geq 2$, since this cell and cell $a + 1$ will always contain single characters over Γ. However, the second move is unique to the initialization because cell 1 will never again hold a single character. The cell-a head of M' is now on cell 1, but the I_0 enables M to record that the cell-a head of M is still on cell 0.

The lone GST S of M' includes two copies of each GST S_i of M. The first is a "dummy copy" which simulates S_i but suppresses output until it picks up the character c that causes S_i to exit. On this exiting transition, the dummy outputs a token s_k for the next GST S_k and a token m for the intervening move, or m_{no} for none, or m_H for HALT. The other copy simulates the actual pass by S_i. It has special states that distinguish whether S_i has written zero, one, or at least two output symbols in the pass, since the first one or two symbols of the output y are altered. If S_i performs a pull and $|y| \geq 2$, we define $c'_0 := y_0$ if $y_0 \neq B$, but $c'_0 := c_0$ if $y_0 = B$. Similarly $c'_1 := y_1$ if $y_1 \neq B$, but $c'_1 := c_1$ if $y_1 = B$. On the tape of M', the output y looks like $[c'_0, c'_1, \ldots][c'_1, c'_0, \ldots]y_2 \cdots y_l$, where $l = |y|$. For $|y| \leq 1$, treat the missing y_1 and/or y_0 as B. Besides these functional conventions on s_k, m, c'_0, and c'_1, we omit reference to the address a if it is not changed and omit the second character read by S when it does not affect control at the large initial branch. Let S_i be the current GST of M.

Character(s) read	Action (Current mode is Ra, $a = 1$.)
$[c_1, c_0, s_i, I_0]$	By the validity conditions (Definition 2.3), the output y by S_i has length at most 2. Hence the next-move token m and next-GST token s_k can be picked up and the output y written in one pass, without needing the dummy copy of S_i. If $m = m_H$, S pulls @ to cell 0 and $[c'_1, c'_0, I_{12}]$ to cell 1. If $m = m_R$, pulls $@[c'_1, c'_0, s_k, I_1]$ to signify that the cell-a head of M is now on cell 1. Else S pulls $@[c'_1, c'_0, s_k, I_0]$, and this step repeats. In each case, *mode* $:= Ra$.
$[c_1, c_0, I_{12}]$	Pull c_0 into cell 0, c_1 into cell 1, and HALT.
$[c_1, c_0, s_i, I_1]$	Simulate S_i as for $[c_1, c_0, s_i, I_0]$ to get m, s_k, and y, but treat c_1 as the first input character to S_i. If $m = m_H$ pull $@[c'_1, c'_0, I_{12}]$, if $m = m_U$ pull $@[c'_1, c'_0, s_k, I_0]$, and if $m = m_{no}$, pull $@[c'_1, c'_0, s_k, I_1]$. In these three cases, the address of M' stays at 1. If $m = m_L$, then pull $@[c'_1, c'_0, s_k]$ and effect $a := 2a$. If $m = m_R$, pull $@[c'_1, c'_0, s_k]$ and effect $a := 2a + 1$. In every case, the mode stays Ra.

The last two cases give $a \geq 2$. When $a \geq 2$, the next pass by S encounters a single character $c_a \in \Gamma$ on its start transition (possibly $c_a = B$), and S must perform the first operation above. This overwrites the @ in cell 0. However, the new character $[c'_1, c'_0, s_k]$ in cell 1 prevents the initial sequence from recurring, viz. the following:

Character(s) read	Action (Current mode is Ra, $a \geq 2$.)
c_a, c_{a+1}	Pull $[c_a, c_{a+1}]$ to cell 0, $a := a$, *mode* $:= 0R$.
B	Pull $[@, @, I_0]$ to cell 0, $a := a$, *mode* $:= 0R$.
$[c_a, c_{a+1}]$, $[c_1, c_0, s_i]$	Put $[c_a, c_0, c_1, s_i, I_2]$ into cell a. If the label of S_i is La then *mode* $:= La$, else *mode* $:= Ra$.
$[c_a, c_0, c_1, s_i, I_2]$	If S_i is labeled $0L$ or $0R$, then pull $[c_0, c_1, c_a, s_i, I_6]$ into cell 0, and *mode* $:=$ the mode of S_i. Else S simulates the dummy copy of S_i to find m and s_k, treating c_a as the first input character to S_i, and pulls $[c_0, c_1, c_a, m, s_k, s_i, I_3]$ to cell 0 with *mode* $:= 0R$.
$[c_0, c_1, c_a, m, s_k, s_i, I_3]$	Put $[c_a, c_0, c_1, m, s_k, s_i, I_4]$ into cell a, *mode* $:=$ the mode of S_i.
$[c_a, c_0, c_1, m, s_k, s_i, I_4]$	Simulate the pull move by S_i, translating its output y to $[c'_0, c'_1, c_a, m, I_5][c'_1, c'_0, s_k]y_2 \cdots y_l$, and change *mode* to $0R$. *Remark:* For c_a to be correct, it is vital that cell a not be overwritten in this pull.

$[c_0, c_1, c_a, m, I_5]$ Put c_a into cell a. On exit, if $m = m_{no}$ then leave a unchanged, if $m = m_U$ effect $a := \lfloor a/2 \rfloor$, if $m = m_L$ effect $a := 2a$, and if $m = m_R$ effect $a := 2a + 1$. In each of these four cases, *mode* $:= Ra$. For $m = m_H$, see below.

If the last move was *up*, i.e., a to $\lfloor a/2 \rfloor$, we may now have $a = 1$ again. Since the "sentinel" in cell 1 is always correctly updated to the next GST S_i, this is handled by the following:

$[c_1, c_0, s_i]$ Same as for $[c_1, c_0, s_i, I_1]$.

If still $a \geq 2$, then S once again senses single characters in cells a and $a + 1$, and the cycle repeats. The other branch with instruction 6 goes as follows:

$[c_0, c_1, c_a, s_i, I_6]$ Here S_i is labeled $0L$ or $0R$, and this is the current mode. S treats c_0, c_1 as the first two input characters in simulating the dummy copy of S_i, and puts $[c_a, c_0, c_1, m, s_k, s_i, I_7]$ into cell a with *mode* $:= Ra$.

$[c_a, c_0, c_1, m, s_k, s_i, I_7]$ Pull $[c_0, c_1, c_a, m, s_k, s_i, I_8]$ into cell 0, *mode* := the mode of S_i.

$[c_0, c_1, c_a, m, s_k, s_i, I_8]$ Simulate the put by S_i. If the output y is empty or begins with B, let $c'_a := c_a$. Else let $c'_a := y_0$. Copy y as $[c'_a, c_0, c_1, m, s_k, I_9]$, and set *mode* $:= 0R$.

$[c_a, c_0, c_1, m, s_k, I_9]$ Pull $[c_0, c_1, c_a, m, I_5]$ to cell 0 and $[c_1, c_0, s_k]$ to cell 1, *mode* $:= Ra$.

The validity conditions prevent cell a from being overwritten in a pull. It is possible for cell 1 to be overwritten by a leftward put that exits after just one input bit, but this can only happen if $a \leq C$, where C is the maximum number of bits a leftward pull chip of M can write in its first transition. The problem can be solved either by exploiting the ability of M itself to remember C-many characters in its finite control, or by reprogramming M so that no leftward pull chip outputs more than one symbol on its first step. Details are left to the reader.

The final halting routine involves a "staircase" to leave the tape exactly the same as that of M at the end of the computation. It picks up in the case $[c_0, c_1, c_a, m, I_5]$ with $m = m_H$.

$[c_0, c_1, c_a, m_H, I_5]$ Put $[c_a, c_0, c_1, I_{10}]$ into cell a, *mode* $:= Ra$.

$[c_a, c_0, c_1, I_{10}]$ Pull $[c_0, c_1, c_a, I_{11}]$ to cell 0 and $[c_1, c_0, I_{12}]$ to cell 1, with *mode* $:= 0R$.

$[c_0, c_1, c_a, I_{11}]$ Put c_a into cell a, effect $a := \lfloor a/2 \rfloor$, *mode* $:= Ra$.

c_a, c_{a+1} Pull $[c_a, c_{a+1}]$ to cell 0, *mode* $:= 0R$.

$[c_a, c_{a+1}], [c_1, c_0, I_{12}]$ Put c_a into cell a, effect $a := \lfloor a/2 \rfloor$, *mode* $:= Ra$.

$[c_1, c_0, I_{12}]$ As above, pull c_0 into cell 0, c_1 into cell 1, and HALT.

M' uses exactly the same tape cells as M, making at most eight passes of equal or less cost for each pass by M. The final "staircase" down from cell a is accounted against the μ-charges for M to have moved out to cell a. Hence both the number of bits processed by M' and the μ-*acc* charges to M' are within a constant factor of their counterparts in M.

For the converse simulation of the reduced form S by a BM M, the only technical difficulty is that S may have different exiting transitions on the same character c. The solution is to run a dummy copy of S that outputs a token t for the state in which S exits. Then t is used to send control to the move state of M' that corresponds to the label $l_1(t)$, and thence to a copy of S with the pass-type label $l_2(t)$. The details of running the dummy copy are the same as above. □

By using more "instruction markers" one can make the mode of M' always follow the cycle $Ra, 0R, La, 0L$. Hence the only decision that need depend on the terminal state of the lone GST S is the next origin cell a.

Acknowledgments. I would like to thank Professor Michael C. Loui for comments on preliminary drafts of this work and for bringing [2] and [5] to my attention. Professors Pierre McKenzie and Gilles Brassard gave me a helpful early opportunity to test these ideas at an open forum in a University of Montreal seminar. Special thanks are due to Professors Klaus Ambos-Spies, Steven Homer, Uwe Schöning, and other organizers of the 1992 Schloss Dagstuhl Workshop on Structural Complexity for inviting me to give a presentation out of which the present work grew. Last, I thank an anonymous referee and several colleagues for helpful suggestions on nomenclature and presentation.

ON THE COMPOSITION OF ZERO-KNOWLEDGE PROOF SYSTEMS*

ODED GOLDREICH† AND HUGO KRAWCZYK‡

Abstract. The wide applicability of zero-knowledge interactive proofs comes from the possibility of using these proofs as subroutines in cryptographic protocols. A basic question concerning this use is whether the (sequential and/or parallel) composition of zero-knowledge protocols is zero-knowledge too. We demonstrate the limitations of the composition of zero-knowledge protocols by proving that the original definition of zero-knowledge is not closed under sequential composition; and that even the strong formulations of zero-knowledge (e.g., black-box simulation) are not closed under parallel execution.

We present lower bounds on the round complexity of zero-knowledge proofs, with significant implications for the parallelization of zero-knowledge protocols. We prove that three-round interactive proofs and constant-round Arthur–Merlin proofs that are black-box simulation zero-knowledge exist only for languages in BPP. In particular, it follows that the "parallel versions" of the first interactive proofs systems presented for quadratic residuosity, graph isomorphism, and any language in NP, are not black-box simulation zero-knowledge, unless the corresponding languages are in BPP. Whether these parallel versions constitute zero-knowledge proofs was an intriguing open questions arising from the early works on zero-knowledge. Other consequences are a proof of optimality for the round complexity of various known zero-knowledge protocols and the necessity of using secret coins in the design of "parallelizable" constant-round zero-knowledge proofs.

Key words. zero-knowledge, cryptographic protocols, interactive proofs

AMS subject classifications. 68Q99, 94A60

1. Introduction.

In this paper we investigate the problem of composing zero-knowledge proof systems. Zero-knowledge proof systems, introduced in the seminal paper of Goldwasser, Micali, and Rackoff [GMR1], are efficient interactive proofs which have the remarkable property of yielding nothing but the validity of the assertion. Namely, whatever can be efficiently computed after interacting with a zero-knowledge prover, can be efficiently computed on input of a valid assertion. Thus, a zero-knowledge proof is computationally equivalent to an answer of a trusted oracle.

A basic question regarding zero-knowledge interactive proofs is whether their composition remains zero-knowledge. This question is not only of theoretical importance, but is also crucial to the utilization of zero-knowledge proof systems as subprotocols inside cryptographic protocols. Of particular interest are sequential and parallel composition. Candidate "theorems" (whose correctness we investigate) are listed here.

Sequential Composition. Let Π_1 and Π_2 be zero-knowledge proof systems for languages L_1 and L_2, respectively. Then, on input $x_1 \circ x_2$, first executing Π_1 on x_1 and afterwards executing Π_2 on x_2 constitutes a zero-knowledge interactive proof system for $L_1 \circ L_2$.

Parallel Composition. Let Π_1 and Π_2 be as above. Then, on input $x_1 \circ x_2$, concurrently executing Π_1 on input x_1 and Π_2 on x_2 constitutes a zero-knowledge interactive proof system for $L_1 \circ L_2$. (Concurrent execution means that the ith message of the composed protocol consists of the concatenation of the ith messages in Π_1 and Π_2, respectively.)

Sequential composition. Soon after the publication of [GMR1], several researchers noticed that the formulation of zero-knowledge proposed therein (hereafter referred as the *original* formulation) is probably not closed under sequential composition. In particular, Feige

and Shamir [Fei] proposed a protocol conjectured to be a counterexample to the Sequential Composition "Theorem." In this paper we use the ideas of [Fei] and new results on pseudorandom distributions [GK] to prove that, indeed, the *original formulation of zero-knowledge is not closed under sequential composition.* Our proof is independent of any intractability assumption. It applies to the notion of *computational* zero-knowledge (see §2), and uses computationally unbounded provers. (So far no proof exists for the same result with provers limited to polynomial time, or for statistical or perfect zero-knowledge.)

The reader should be aware that the Sequential Composition Theorem was proven (by Goldreich and Oren [GO], [Ore]) for a stronger ("nonuniform") formulation of zero-knowledge suggested by several authors (cf. [Fei], [GMR2], [GO], [Ore], and [TW]). The Sequential Composition Theorem is crucial to the utilization of zero-knowledge interactive proofs in cryptographic applications and in particular to the construction of cryptographic protocols for playing any computable game [Yao], [GMW2].

Parallel composition. Parallel composition of interactive proofs is widely used as a means of decreasing the error probability of proof systems, while maintaining the number of rounds. Of course, one would be interested in applying these advantages of parallelism to zero-knowledge protocols as well. Parallelism is also used in multiparty protocols in which parties wish to prove (the same and/or different) statements to various parties concurrently. Unfortunately, we show in this paper a counterexample to the Parallel Composition Theorem. Namely, we introduce a pair of protocols which are (computational) zero-knowledge with respect to the strongest known definitions (including the nonuniform formulation discussed above and the "black-box simulation" formulation discussed below) yet their parallel composition is not zero-knowledge (not even in the "weak" sense of the original [GMR1] formulation). Also in this case, our proof does not rely on any unproven hypotheses; on the other hand, it uses in an essential way the unbounded computational power of the prover and the computational notion of zero-knowledge. Based on intractability assumptions, Feige and Shamir [FS2] show a perfect zero-knowledge protocol with a polynomial-time prover which fails parallel composition. Our results below on three-round zero-knowledge proofs imply a similar result, but our case requires a superlogarithmic number of repetitions, while in [FS2] two repetitions suffice.

By the above result we have ruled out the possibility of proving that particular interactive proofs are zero-knowledge by merely arguing that they are the result of parallel composition of various zero-knowledge protocols. But this does not resolve the question of whether concrete cases of composed interactive proofs are zero-knowledge. In particular, since the first presentation of the results in [GMR1] and [GMW1], it was repeatedly asked whether the "parallel versions" of the interactive proofs presented for quadratic residuosity, graph isomorphism, and any language in NP are zero-knowledge.

Round complexity of zero-knowledge proofs. In this paper we prove a general result concerning the round complexity of zero-knowledge interactive proofs which, in particular, resolves the question of parallelization of the above-mentioned protocols. This general result states that *only BPP languages have three-round interactive proofs which are black-box simulation zero-knowledge.*[1] Since the parallel versions of the above examples are three-round interactive proofs (with negligible cheating probability for the prover) it follows that these interactive proofs cannot be proven zero-knowledge using black-box simulation zero-knowledge, unless the corresponding languages are in BPP. This (negative) result is proven for computa-

[1] This result applies to interactive proofs in which the prover can convince the verifier of accepting a false assertion with only negligible probability. The above-mentioned languages have three-round zero-knowledge interactive proofs in which the prover has a significant (e.g., constant) probability of cheating.

tional zero-knowledge proofs and therefore applies to statistical and perfect zero-knowledge as well.

Loosely speaking, we say that an interactive proof for a language L *is black-box simulation zero-knowledge* if there exists a (probabilistic polynomial-time) universal simulator which, using any (even nonuniform) verifier V^* as a black box, produces a probability distribution which is polynomially indistinguishable from the distribution of conversations of (the same) V^* with the prover, on inputs in L. This definition of zero-knowledge is more restrictive than the original one, which allows each verifier V^* to have a specific simulator S_{V^*}. Nevertheless, all *known* zero-knowledge protocols are also black-box simulation zero-knowledge. This fact cannot come as a surprise since it is hard to conceive of a way of taking advantage of the full power of the more liberal definition.

It is not plausible that our result could be extended to four-round interactive proofs since such proofs are known for languages believed to be outside BPP. The protocols for quadratic nonresiduosity [GMR1] and graph nonisomorphism [GMW1] are such examples. In addition, zero-knowledge interactive proofs of five rounds are known for quadratic residuosity and graph isomorphism [BMO1], and, assuming the existence of claw-free permutations, there exist five-round zero-knowledge interactive proofs for any language in NP [GKa]. Moreover, our results extend to zero-knowledge *arguments*[2], for which Feige and Shamir [FS1] presented (assuming the existence of one-way functions) a four-round protocol for any language in NP. Our result implies that the round complexity of this protocol is optimal (as long as BPP $\neq$ NP).

Constant-round Arthur–Merlin proofs. When restricting ourselves to Arthur–Merlin interactive proofs, we can extend the above result to any constant number of rounds. We show that *only BPP languages have constant-round Arthur–Merlin proofs which are also black-box simulation zero-knowledge.*

Arthur–Merlin interactive proofs, introduced by Babai [Bab], are interactive proofs in which all the messages sent by the verifier are the outcome of his coin tosses. In other words, the verifier "keeps no secrets from the prover." Our result is a good reason to believe that the only feasible way of constructing constant-round zero-knowledge interactive proofs is to let the verifier use "secret coins." Indeed, the above-mentioned constant-round zero-knowledge proofs, as well as the constant-round statistical zero-knowledge proofs of [BMO2], use secret coins. Thus, secret coins do help in the zero-knowledge setting. This should be contrasted with the result of Goldwasser and Sipser [GS], which states that Arthur–Merlin interactive proofs are *equivalent* to general interactive proofs (as far as language recognition is concerned). They show that any language having a general interactive proof (IP) of k rounds also has an Arthur–Merlin (or AM) proof of k rounds. Using our result we see that in the zero-knowledge setting such a preservation of rounds (when transforming IP into AM) is not plausible (e.g., graph nonisomophism).

Our result concerning Arthur–Merlin proofs is tight in the sense that the languages considered above (e.g., graph nonisomorphism, every language in NP) have unbounded (i.e., $\omega(n)$-round, for every unbounded function $\omega : N \to N$) Arthur–Merlin proof systems which are black-box simulation zero-knowledge. In particular, we get that bounded-round Arthur–Merlin proofs which are black-box zero-knowledge exist only for BPP, while unbounded round proofs of the same type exist for all PSPACE (if one-way functions exist [IY], [B*], [Sha]). That is, while the *finite hierarchy* of languages having black-box zero-knowledge Arthur–

[2] Interactive *arguments* (also known as "computationally sound proofs" and "computationally convincing protocols") differ from an interactive proof system in that the soundness condition of the system is formulated with respect to *probabilistic polynomial-time* provers, possibly with auxiliary input (see [BCC]). Namely, *efficient* provers cannot fool the verifier into accepting an input not in the language, except with negligible probability.

Merlin proofs collapses to BPP (= AM(0)), the corresponding *infinite hierarchy* contains all of PSPACE. This implies (assuming the existence of one-way functions) a separation between the two hierarchies.

Organization. In §2 we outline the definitions of interactive proofs and zero-knowledge, and introduce some terminology and notation used throughout the paper. Section 3 presents the definitions and results concerning pseudorandom distributions that are used for disproving the composition theorems. In §§4 and 5 we present these disproofs for the case of sequential and parallel composition, respectively. Finally, in §6 we present the lower bounds on the round complexity of black-box simulation zero-knowledge proofs. We stress that this last section is technically independent from §§3, 4, and 5 and can be read without going through these sections.

2. Preliminaries. The notions of interactive proofs and zero-knowledge were introduced by Goldwasser, Micali, and Rackoff [GMR1]. Here, we give an informal outline of these notions. For formal and complete definitions, as well as the basic results concerning these concepts, the reader is referred to [GMR1], [GMW1], and [GMR2].

An *interactive proof* is a two-party protocol in which a computationally unrestricted *prover*, P, interacts with a probabilistic polynomial-time *verifier*, V, by exchanging messages. Both parties share a common input x. At the end of the interaction the verifier computes a predicate depending on this input and the exchanged messages in order to *accept* or *reject* the input x. Such a protocol, denoted $\langle P, V\rangle$, is called an *interactive proof for a language L* if the following two conditions hold.

Completeness property. For any positive constant c and sufficiently long $x \in L$, Prob(V accepts x) $> 1 - |x|^{-c}$.

Soundness property. For any positive constant c and sufficiently long $x \notin L$, Prob(V accepts x) $< |x|^{-c}$, no matter how the prover behaves during the protocol.

(The above probabilities are taken over the coin tosses of both the prover and the verifier.) In other words, we require that on inputs belonging to L the probability that the prover P "convinces" V to accept the common input is almost 1, while on inputs outside L there is no prover that can fool V into accepting, except with negligible probability.

Note. Notice that we define an interactive proof to have a negligible probability of error. Some authors define this probability to be just a constant (e.g., $\frac{1}{3}$). The latter is motivated by the fact that constant-error interactive proofs can be converted into negligible-error proofs by parallel repetition. However, in the setting of zero-knowledge interactive proofs, our results show that such parallel repetition may sacrifice the zero-knowledge property.

An interactive proof in which the *honest* verifier chooses all its messages at random (i.e., with uniform probability over the set of all strings of the same length as the message) is called an *Arthur–Merlin* interactive proof [Bab]. That is, in an Arthur–Merlin proof system the only nontrivial computation carried out by the honest verifier is the evaluation of a polynomial-time predicate at the end of the interaction, in order to decide the acceptance or rejection of the input to the protocol. We say that such a verifier uses *public coins.* (Notice that there is no "public coin" restriction on the cheating verifiers.)

We say that an interactive proof has k rounds if there are a total of k messages (alternately) exchanged between the prover and verifier during the protocol (i.e., we count messages from both parties). In general, the number k can be a function $k(|x|)$ of the input length. The notation IP(k) stands for the class of languages having k-round interactive proofs, and AM(k) stands for languages having k-round Arthur–Merlin interactive proofs.

An interactive proof is called *zero-knowledge* if on input $x \in L$ no probabilistic polynomial-time verifier (i.e., one that may arbitrarily deviate from the predetermined program) gains information from the execution of the protocol except the knowledge that x belongs to L.

This means that any polynomial-time computation based on the conversation with the prover can be simulated, without interacting with the real prover, by a probabilistic polynomial-time machine ("the simulator") that gets x as its only input. More precisely, let $\langle P, V^*\rangle(x)$ denote the probability distribution generated by the interactive machine (verifier) V^*, which interacts with the prover P on input $x \in L$. We say that an interactive proof is *zero-knowledge* if for all probabilistic polynomial-time machines V^*, there exists a probabilistic expected polynomial-time algorithm M_{V^*} (called the *simulator*) that on inputs $x \in L$ produces probability distributions $M_{V^*}(x)$ that are polynomially indistinguishable from the distributions $\langle P, V^*\rangle(x)$. (This notion of zero-knowledge is also called *computational zero-knowledge*.)[3]

The above formalization of the notion of zero-knowledge is taken from the original paper by Goldwasser, Micali, and Rackoff [GMR1]. Later, stronger formulations of zero-knowledge were introduced in which the simulation requirement is extended to deal with stronger verifiers [Fei], [GMR2], [GO], [Ore], [TW], namely, verifiers with nonuniform properties (e.g., probabilistic polynomial-time verifiers that get an additional *auxiliary-input* tape), or verifiers modeled by polynomial-size circuits.

One further formulation of zero-knowledge is called *black-box simulation zero-knowledge* [GO], [Ore]. This formulation differs from the former by requiring the existence of a ("universal") simulator that, using any (nonuniform) verifier V^* as a black box, succeeds in simulating the $\langle P, V^*\rangle$ interaction. In other words, there exists a probabilistic expected polynomial-time oracle machine M such that for any polynomial-size verifier V^* and for $x \in L$, the distributions $\langle P, V^*\rangle(x)$ and $M^{V^*}(x)$ are polynomially indistinguishable.

Remark. A complete formalization of the notion of black-box simulation zero-knowledge requires dealing with the following technical problem. The simulator uses V^* as a black box. This means that the simulator is responsible, during the simulation process, for feeding into the black box the external parameters that determine the behavior of V^*. These parameters are the string representing the input to the protocol, the contents of the random tape of V^*, and the messages of the prover. A problem arises when feeding the random coins used by V^*. Although the number of coin tosses used by a particular verifier V^* is bounded by a polynomial, there is no *single* polynomial that bounds this number for *all* possible verifiers. On the other hand, the simulator M runs (expected) time that is bounded by a specific polynomial. So, how can this simulator manage to feed a verifier requiring more coin tosses than this bound? In [BMO2] this problem is overcome by stating the existence of two random tapes for M. The first is used in the regular way for M's computations. The second can be entirely fed by M into V^* in a single step. That is, M can feed the random coins for the black box in an "intelligent way" as long as the number of coins does not exceed the time capability of M; beyond this number it can only feed truly random bits. We stress that this formalization is general enough to include all *known* zero-knowledge proofs.

An alternative solution to the above problem is to have, *for each* polynomial p, a simulator M_p which simulates all verifiers V^* that use at most $p(|x|)$ random coins on any input x. Clearly, the running time of the simulator M_p may depend on the polynomial p, and then the above difficulty is overcome. This second formulation is weaker than the one proposed in [BMO2], but it suffices for the results proved in our paper and is therefore adopted here. (In fact, our results in §6 only require the existence of a simulator that simulates deterministic verifiers, i.e., M_p with $p \equiv 0$.)

Based on the above remark we give our definition of black-box simulation zero-knowledge.

[3] Other definitions were proposed in which it is required that the distribution generated by the simulator be *identical* to the distribution of conversations between the verifier and the prover (*perfect* zero-knowledge), or at least statistically close (*statistical* zero-knowledge). See [GMR2] for further details.

DEFINITION. *An interactive proof $\langle P, V \rangle$ is called* black-box simulation zero-knowledge *if for every polynomial p, there exists a probabilistic expected polynomial-time oracle machine M_p such that for any polynomial-size verifier V^* that uses at most $p(n)$ random coins on inputs of length n, and for $x \in L$, the distributions $\langle P, V^* \rangle(x)$ and $M_p^{V^*}(x)$ are polynomially indistinguishable.*

Note. The notion of polynomial indistinguishability in the above definition can be formalized based on nonuniform polynomial-size distinguishers or uniform polynomial-time distinguishers which have black-box access to the corresponding V^*. Our results apply to both formalizations.

Terminology. Throughout this paper we use the term *negligible* to denote functions that are (asymptotically) smaller than 1 over any polynomial, and the term *nonnegligible* to denote functions that are greater than 1 over some fixed polynomial. More precisely, a function f from nonnegative integers to reals is called *negligible* if for all constants c and sufficiently large n, $f(n) < n^{-c}$. The function f is called *nonnegligible* if there exists a constant c such that for all (sufficiently large) n, $f(n) > n^{-c}$. (Observe that nonnegligible is not the complement of negligible.)

Notation. We use the notation $e \in_R S$ for "the element e is chosen with uniform probability from the set S."

3. On evasive and pseudorandom sets. In the demonstration of counterexamples for the "composition theorems" we make use of pseudorandom distributions which have some interesting "evasiveness" properties. These properties and the corresponding proofs are given in [GK] and cited here without proof.

Roughly speaking, a distribution on a set of strings of length k is *pseudorandom* if this distribution cannot be efficiently (i.e., in time polynomial in k) distinguished from the uniform distribution on the set of all strings of length k. In order to formalize this notion one has to define it in asymptotical terms and refer to collections of distributions (called *pseudorandom ensembles*), rather than single distributions. The notion of a "pseudorandom set" is made precise in the following definition.

DEFINITION 3.1. *A set $S \subseteq \{0,1\}^k$ is called $(\tau(k), \varepsilon(k))$-*pseudorandom *if for any (probabilistic) circuit C of size $\tau(k)$ with k inputs and a single output*

$$|p_C(S) - p_C(\{0,1\}^k)| \le \varepsilon(k),$$

where $p_C(S)$ (resp., $p_C(\{0,1\}^k)$) denotes the probability that C outputs 1 when given elements of S (resp., $\{0,1\}^k$), chosen with uniform probability.

Note that a collection of uniform distributions on a sequence of sets $S_1, S_2, \ldots,$ where each S_k is a $(\tau(k), \varepsilon(k))$-pseudorandom set, constitutes a pseudorandom ensemble, provided that both functions $\tau(n)$ and $\varepsilon^{-1}(n)$ grow faster than any polynomial. Therefore, we shall refer to such a sequence of sets as a *pseudorandom ensemble.*

We now present the concept of "evasive sets." Informally, evasiveness means that it is hard, for efficient algorithms, to find strings which belong to these sets.

DEFINITION 3.2. *Let $S_1, S_2, \ldots$ be a sequence of (nonempty) sets such that for every n, $S_n \subseteq \{0,1\}^{Q(n)}$, for a fixed polynomial Q. Such a sequence is called a* polynomially evasive *(denoted* P-evasive*) ensemble if for any probabilistic polynomial-time algorithm A, any constant c, any sufficiently large n, and any $x \in \{O, 1\}^n$,*

$$\text{Prob}(A(x) \in S_n) < n^{-c},$$

where the probability is taken over the random coins of algorithm A.

The following theorem states the existence of a P-evasive ensemble which is also pseudorandom.

THEOREM 3.1 [GK]. *There exists a* P*-evasive pseudorandom ensemble* $S_1, S_2, \ldots$ *with* $Q(n) = 4n$*. Furthermore, there exists a Turing machine which on input* 1^n *outputs the set* S_n*.*

For disproving the parallel composition theorem we shall need a stronger notion of evasiveness. Namely, one which also resists nonuniform algorithms. This definition of evasiveness involves a collection of sets for each length, rather than a single set per length as in the uniform case.

DEFINITION 3.3. *Let* $Q(\cdot)$ *be a polynomial, and for* $n = 1, 2, \ldots$ *let* $\mathcal{S}^{(n)}$ *be a collection of* 2^n *sets* $\{S_1^{(n)}, \ldots, S_{2^n}^{(n)}\}$*, where each* $S_i^{(n)} \subseteq \{0, 1\}^{Q(n)}$*. The sequence* $\mathcal{S}^{(1)}, \mathcal{S}^{(2)}, \ldots$ *is called a* nonuniform polynomially evasive (*denoted* P/poly-evasive) *ensemble if for any* $c > 0$*, sufficiently large* n*, and any (probabilistic) circuit* C *of size* n^c *(with* n *inputs and* $Q(n)$ *outputs)*

$$\text{Prob}(C(i) \in S_i) < \frac{1}{n^c},$$

where the probability is taken over the random coins of C *and* $i \in \{1, \ldots, 2^n\}$*, both with uniform probability.*

That is, a sequence $\mathcal{S}^{(1)}, \mathcal{S}^{(2)}, \ldots$ is a P/poly-evasive ensemble if any circuit of size polynomial in n, which gets a randomly selected index of one of the sets in $\mathcal{S}^{(n)}$, cannot succeed in outputting an element in that set, except for a negligible probability.

Remark. Notice that in the definition of P-evasive ensembles the (uniform) algorithm trying to hit an element in the evasive set S_n gets as input a string x of length n, which can be seen as an auxiliary input. The crucial difference between this "uniform" definition and the definition of P/poly-evasiveness is that in the latter the auxiliary input is allowed to be of any length polynomial in the length of the target strings, while in the former the auxiliary input is properly shorter than the target strings in the set S_n.

The following theorem states the existence of a P/poly-evasive ensemble which is composed of pseudorandom sets.

THEOREM 3.2. *There exists a* P*/poly-evasive ensemble* $\mathcal{S}^{(1)}, \mathcal{S}^{(2)}, \ldots$ *with* $Q(n) = 4n$*, such that for every* n*, each* $S_i^{(n)}$ *is a* $(2^{n/4}, 2^{-n/4})$*-pseudorandom set of cardinality* 2^n*. Furthermore, there exists a Turing machine which on input* 1^n *outputs the collection* $\mathcal{S}^{(n)}$*.*

The proof of this theorem is given in the appendix.

4. Sequential composition of zero-knowledge protocols.

A natural requirement from the notion of zero-knowledge proofs is that the information obtained by the verifier during the execution of a zero-knowledge protocol will not enable him to extract any additional knowledge from subsequent executions of the same protocol. That is, it would be desirable for the *sequential composition* of zero-knowledge protocols to yield a protocol which is itself zero-knowledge. Such a property is crucial for applications of zero-knowledge protocols in cryptography (for details and further motivation, see [GO] and [Ore]).

We prove that the original definition of (computational) zero-knowledge introduced by Goldwasser, Micali, and Rackoff in [GMR1], *is not closed* under sequential composition. Several authors have previously observed that this definition *probably* does not guarantee the robustness of zero-knowledge under sequential composition, and hence have introduced more robust formulations of zero-knowledge [Fei], [GMR2], [GO], [Ore], [TW]. But so far, no proof has been given for the claim that computational zero-knowledge (with uniform verifiers) fails under sequential composition.

Intuitively, the reason that a zero-knowledge protocol could not be closed under sequential composition is that the definition of zero-knowledge requires that the information transmitted in the execution of the protocol is "useless" for any *polynomial-time computation*; it does not rule out the possibility that a cheating verifier could take advantage of this "knowledge" in a subsequent interaction with the (*nonpolynomial time*) prover for obtaining valuable information. This intuition (presented in [Fei]) is the basis of our example of a protocol which is zero-knowledge in a single execution but reveals significant information when composed twice in a sequence. This protocol, presented in the proof of the following theorem, uses a P-evasive ensemble as defined in Definition 3.2 and whose existence is stated in Theorem 3.1.

THEOREM 4.1. *Computational zero-knowledge* ([GMR1]*formulation*) *is not closed under sequential composition.*

Proof. Let $S_1, S_2, \ldots$ be a P-evasive pseudorandom ensemble as described in Theorem 3.1. Also, let K be an (arbitrary) hard Boolean function, in the sense that the language $L_K = \{x : K(x) = 1\}$ is not in BPP (we use this function as a "knowledge" function).

We present the following interactive-proof protocol $\langle P, V \rangle$ for the language $L = \{0, 1\}^*$. (Obviously, this language has a trivial zero-knowledge proof in which the verifier accepts every input without carrying out any interaction. We intentionally modify this trivial protocol in order to demonstrate a zero-knowledge protocol which fails sequential composition.)

Let x be the common input for P and V, and let n denote the length of x. The verifier V begins by sending to the prover a random string s of length $4n$. The prover P checks whether $s \in S_n$ (the nth set in the P-evasive ensemble defined above). If this is the case (i.e., $s \in S_n$), then P sends to V the value of $K(x)$. Otherwise (i.e., $s \notin S_n$), P sends to V a string s_0 randomly selected from S_n. In any case the verifier accepts the input x (as belonging to L).

We stress that the same P-evasive ensemble is used in all the executions of the protocol. Thus, the set S_n does not depend on the specific input to the protocol, but only on its length. Therefore, the string s_0, obtained by the verifier in the first execution of the protocol, enables him to deviate from the protocol during a second execution in order to obtain the value of $K(x')$, for any x' of length n (and in particular for $x' = x$). Indeed, consider a second execution of the protocol, this time on input x'. A "cheating" verifier, which sends the string $s = s_0$ instead of choosing it at random, will get the value of $K(x')$ from the prover. Observe that this cheating verifier obtains information that it could not compute by itself. There is no way to simulate in probabilistic polynomial time the interaction in which the prover sends the value of $K(x')$; otherwise the language L_K would be in BPP (indeed, such a simulator could be used as a probabilistic polynomial-time algorithm for computing the function K with negligible error probability. To see that, notice that the real prover in an interaction with the above cheater verifier on inputs (x, x') will output $k(x')$ with probability 1. Therefore, the simulator must output the correct value of $k(x')$ with probability almost 1, or otherwise, its output is polynomially distinguishable from the real conversations). Thus, the protocol is not zero-knowledge when composed twice.

On the other hand, the protocol is zero-knowledge (when executed once). To show this, we present for any verifier V^*, a polynomial-time simulator M_{V^*} that can simulate the conversations between V^* and the prover P. There is only one message sent by the prover during the protocol. It sends the value of $K(x)$ when the string s sent by the verifier belongs to the set S_n, and a randomly selected element of S_n otherwise. By the evasivity condition of the set S_n, there is only a negligible probability that the first case holds. Indeed, no probabilistic polynomial-time machine (in our case, the verifier) can find such a string $s \in S_n$, except with negligible probability (no matter what the input x to the protocol is). Thus, the simulator can succeed by always simulating the second possibility, i.e., the sending of a random element s_0 from S_n. This step is simulated by randomly choosing s_0 from $\{0, 1\}^{4n}$ rather than from S_n. The indistinguishability of this choice from the original one follows from the fact that each S_n is a pseudorandom subset of $\{0, 1\}^{4n}$, and that the prover chooses s_0 from S_n with uniform probability. □

Remark. The argument presented in the above proof generalizes to any language L having a zero-knowledge interactive proof. Simply modify the zero-knowledge proof for L as in the proof of Theorem 4.1.

Remark. Another example of a zero-knowledge protocol which is not closed under sequential composition was independently found by D. Simon [Sim]. His construction assumes the existence of secure encryption systems.

5. Parallel composition of zero-knowledge protocols. In this section we address the question of whether zero-knowledge interactive proofs are robust under parallel composition.

Clearly, we cannot expect the original Goldwasser–Micali–Rackoff (GMR) definition to satisfy this condition: it is easy to see that a zero-knowledge protocol which is not closed under sequential composition can be transformed into another zero-knowledge protocol which fails parallel composition.

In light of the fact that *auxiliary-input* zero-knowledge is robust under sequential composition [GO], [Ore], it is an interesting open question whether this formulation of zero-knowledge is also robust under parallel composition. The main result of this section is that this is *not* the case. We prove the existence of protocols which are zero-knowledge even against nonuniform verifiers (e.g., auxiliary-input zero-knowledge), but which do not remain zero-knowledge when executed twice in parallel. As in the case of sequential composition our results concern only computational zero-knowledge.

The ideas used for the design of a protocol which fails parallel composition are similar to those used for the sequential case. There, we have used the pseudorandomness and evasiveness of some sets to construct the intended protocol. We also use this method here. The main difficulty of extending these properties to the present case is that now we need an evasive collection which resists even nonuniform verifiers. Clearly, a P-evasive ensemble will not satisfy this condition, since for any set of strings there exist nonuniform verifiers which can output elements in this set (e.g., by getting such a string as auxiliary input). Instead, we use the notion of P/poly-evasive ensembles as defined in Definition 3.3. Based on Theorem 3.2, which states the existence of such ensembles, we prove the main result of this section.

THEOREM 5.1. *Computational zero-knowledge* (*even with nonuniform verifiers*) *is not closed under parallel composition.*

Proof. We present a pair of protocols $\langle P_1, V_1\rangle$ and $\langle P_2, V_2\rangle$ which are zero-knowledge when executed independently, but whose parallel composition is provably not zero-knowledge.

We use some dummy steps in the protocols in order to achieve synchronization between them. Of course, one can modify the protocol, substituting these extra steps by significant ones. The version we give here prefers simplicity over naturality. Both protocols consist of five steps and are described below (see also Fig. 1).

The first protocol is denoted $\langle P_1, V_2\rangle$. Let x be the input to the protocol and let n denote its length. The protocol uses (for all its executions) a P/poly-evasive ensemble $S^{(1)}, S^{(2)}, \ldots$ with the properties described in Theorem 3.2. It also involves a hard Boolean function K as in the proof of Theorem 4.1. The prover P_1 begins by sending to V_1 an index $i \in_R \{1, \ldots, 2^n\}$. After two dummy steps the verifier V_1 sends to P_1 a string $s \in_R \{0, 1\}^{4n}$. The prover P_1 checks whether $s \in S_i^{(n)}$. If this is the case then it sends to V_1 the value of $K(x)$, (otherwise an empty message). This concludes the protocol.

The second protocol $\langle P_2, V_2\rangle$ uses the *same* P/poly-evasive ensemble $S^{(1)}, S^{(2)}, \ldots$ as protocol $\langle P_1, V_1\rangle$ does. The first step of the protocol is a dummy one. In the second step the verifier V_2 sends to P_2 an index $j \in_R \{1, \ldots, 2^n\}$. The prover P_2 responds with a string $r \in_R S_j^{(n)}$. After two more dummy steps the protocol stops.

We show that each of the above protocols is indeed zero-knowledge (even for nonuniform verifiers). For the first protocol, there are two steps of the prover to be simulated. In the

P_1	V_1	step	P_2	V_2
$i \in_R \{1, \cdots, 2^n\} \rightarrow$		1	dummy step	
	dummy step	2		$\leftarrow j \in_R \{1, \cdots, 2^n\}$
dummy step		3	$r \in_R S_j^{(n)} \rightarrow$	
	$\leftarrow s \in_R \{0,1\}^{4n}$	4		dummy step
if $s \in S_i^{(n)}$: $K(x) \rightarrow$		5	dummy step	

FIG. 1. *Protocols $\langle P_1, V_1\rangle$ and $\langle P_2, V_2\rangle$ with input x.*

first step P_1 sends an index $i \in_R \{1, \dots, 2^n\}$. The simulator does the same. In the second step, the prover sends the value of $K(x)$ *only* if the verifier succeeds in presenting him with a string which belongs to the set $S_i^{(n)}$. By the evasivity condition of the sequence $S^{(1)}, S^{(2)}, \dots$, this will happen with negligible probability and therefore the simulator can always simulate this step as for the case where the verifier sends a string $s \notin S_i^{(n)}$. (Observe that the circuits in the definition of P/poly-evasive ensembles only get as input the index of the set to be hit. Nevertheless, in our case the circuits also have an additional input x. Clearly, this cannot help them find an element in $S_i^{(n)}$; otherwise, circuits which have such a string incorporated will contradict the evasiveness condition.)

In the second protocol, $\langle P_2, V_2\rangle$, the only significant step of the prover P_2 is when it sends an element $r \in_R S_j^{(n)}$ in response to the index j sent by the verifier. In this case the simulator will send a string $r' \in_R \{0, 1\}^{4n}$. Using the pseudorandomness property of the set $S_j^{(n)}$ we get that the simulator's choice is polynomially indistinguishable from the prover's one.

Finally, we show that the parallel composition of the above protocols into a single protocol $\langle P, V\rangle$ is not zero-knowledge. Let V^* be a "cheating" verifier which behaves as follows. Instead of sending a randomly selected index j (corresponding to the second step of the subprotocol $\langle P_2, V_2\rangle$) it sends the index i received from P as part of P_1's first step. Thus, $j = i$, and the prover P will respond with a string $r \in S_i^{(n)}$. In the next step this V^* will send string r to P instead of the "random" string s that V_1 should send to P_1. The prover P will verify that $r \in S_i^{(n)}$ and then will send the information $K(x)$. By the hardness of the function K this step cannot be simulated by a probabilistic polynomial-time machine. Therefore, the composed protocol $\langle P, V\rangle$ is not zero-knowledge. □

Remark. The two protocols $\langle P_1, V_1\rangle$ and $\langle P_2, V_2\rangle$ can be merged into a single zero-knowledge protocol which is not robust under parallel composition. In this merged protocol, the verifier chooses (at random) an index $i \in \{1, 2\}$, sends it to the prover, and then both parties execute the protocol $\langle P_i, V_i\rangle$. When executing two copies of this protocol in parallel, the verifiers may choose $i = 1$ and $i = 2$, respectively, thus forcing a parallel execution of $\langle P_1, V_1\rangle$ and $\langle P_2, V_2\rangle$, which we have shown not to be zero-knowledge.

6. On the round complexity of zero-knowledge proofs. In this section we present lower bounds on the round complexity of black-box simulation zero-knowledge interactive proofs. We show that only languages in BPP have constant-round Arthur–Merlin interactive proofs which are *black-box simulation zero-knowledge.* (For a definition of black-box simulation zero-knowledge and Arthur–Merlin interactive proofs, see §2.) We have the following theorem.

THEOREM 6.1. *A language L has a constant-round Arthur–Merlin interactive proof which is black-box simulation zero-knowledge if and only if $L \in BPP$.*

In §6.1 we present a proof for a special case of this theorem, namely, for the case of a three-round Arthur–Merlin protocol. The general case is proved in §6.2 using careful extensions of the ideas presented for this special case.

The three-round case can also be extended to general interactive proof systems. That is, we also have the following theorem, proved in §6.3.

THEOREM 6.2. *A language L has a three-round interactive proof which is black-box simulation zero-knowledge if and only if $L \in BPP$.*

(We remark that [GO] and [Ore] show that two-round (auxiliary-input) zero-knowledge proofs—not necessarily black-box simulation—exist only for BPP languages.)

Our results are optimal in the sense that there exist Arthur–Merlin interactive proofs, for languages believed to be outside BPP, with unbounded number of rounds and which are black-box simulation zero-knowledge. Similarly, there exist four-round interactive proof protocols (using private coins) which are also black-box simulation zero-knowledge. For further details about these protocols, and some consequences concerning the hierarchy of languages having zero-knowledge Arthur–Merlin proofs, see §1.

It is interesting to note that our results hold also for a weaker notion of black-box simulation zero-knowledge, namely, one which only requires the existence of a black-box simulator that succeeds in simulating conversations with *deterministic* (nonuniform) verifiers. The sufficiency of this condition follows from the proofs below. Also, the formulation of the completeness condition of an interactive proof (see §2) can be relaxed in the following way. We have defined the completeness condition by requiring that the prover convince the verifier of accepting an input in the language with probability almost 1 (i.e., 1 minus a negligible fraction). For the correctness of our results it suffices to require just a nonnegligible probability. (In this section we use this weaker formulation of the completeness condition.) On the other hand, the requirement of a negligible probability of convincing the verifier to accept an input not in the language (the soundness condition) is essential. (For example, three-round zero-knowledge protocols exist for all languages in NP if the soundness condition is formulated with probability $\frac{1}{2}$ [GMW1].) Finally, our results hold also in the setting of *interactive arguments* [BCC], i.e., "interactive proofs" in which the prover is limited to probabilistic polynomial-time computations, possibly getting an auxiliary input.

6.1. The case AM(3).

The protocol $\langle \mathbf{P}, \mathbf{V} \rangle$. Consider an Arthur–Merlin protocol $\langle P, V \rangle$ for a language L, consisting of three rounds. We use the following notation. Denote by x the input for the protocol, and by n the length of this input. The first message in the interaction is sent by the prover. We denote it by α. The second round is the V, which sends a string β. The third (and last) message is from P, and we denote it by γ. The predicate computed by the verifier V in order to accept or reject the input x is denoted by ρ_V, and we consider it, for convenience, as a deterministic function $\rho_V(x, \alpha, \beta, \gamma)$. (For the general case, see Remark 6.2.) We will also assume, without loss of generality, the existence of a polynomial $l(n)$ such that $|\alpha| = |\beta| = l(n)$.

The simulation process. Let this three-round Arthur–Merlin protocol $\langle P, V \rangle$ be black-box simulation zero-knowledge. Denote by M the guaranteed probabilistic expected polynomial-time black-box simulator which, given access to the black-box V^*, simulates $\langle P, V^* \rangle$. The process of simulation consists of several "tries" or calls to the interacting verifier V^* ("the black box"). In each such call the simulator M feeds the arguments for V^*. These arguments are the input y (which may be different from the "true" input x), the random coins for V^*, and a string α representing the message sent by the prover P. In our case, it suffices for our results to consider a simulator that is just able to simulate conversations with *deterministic* (*nonuniform*) *verifiers*. In particular, this simulator does not care about feeding the black-box V^* with random coins. This simplifies our proof by avoiding any reference to these random coins for V^*, and strengthen our result (since it holds even under the sole existence of this weak kind of simulator).

After completing its tries the simulator outputs a conversation $(y, \alpha, \beta, \gamma)$.

We shall make some further simplifying assumptions on the behavior of the simulator M, which will not restrict the generality. In particular, we assume that some cases, which may arise with only negligible probability, do not happen at all. This cannot significantly effect the success probability of the simulator. In other words, any black-box simulator which successfully simulates $\langle P, V^* \rangle$ conversations of deterministic verifiers V^* can be changed into another simulator for which the following conventions hold and which has the same success probability as the original simulator, except for a possibly negligible difference. We assume the following:

- The conversations output by M always have the form $(x, \alpha, \beta, \gamma)$ (i.e., $y = x$), and that the string β equals the message output by V^* when fed with inputs x and α. Note that these conditions always hold for the real conversations generated by the prover P and the (deterministic) verifier V^*. Therefore, the simulator must almost always do the same. (Otherwise, a distinguisher which has access to V^* would distinguish between the simulator's output and the original conversations.)
- The simulator M explicitly tries, in one of its calls to V^*, the arguments x and α appearing in the output conversation. (For example, once the simulator decides on the output conversation with a specific parameter α, it explicitly feeds V^* with x and this value of α, regardless of whether it asked α before or not. In any case, the answer of the deterministic V^* to the pair (x, α), will be always the same.)
- The simulator runs in (strictly) polynomial time. (In Remark 6.1 below we show how to handle the general case in which the simulator runs in *expected* polynomial time.) We denote by $t(n)$ a polynomial bounding the number of calls tried by M before outputting a conversation.

The simulator as a subroutine. Our goal is to present a BPP algorithm for the language L. The idea is to use the simulator M in order to distinguish between inputs in and outside L. For that, we use the simulator itself as a subroutine of the BPP algorithm. We do not make any assumption on the internal behavior of this simulator, but just use the following observation. *The behavior of the simulator M, interacting with a verifier V^*, is completely determined by the input x, the random tape R_M used by M, and the strings output by V^** (*in response to the arguments fed by the simulator during its tries*). Therefore, in order to operate M, we just need to feed it with an input x, a tape of random coins, and a sequence of responses to its messages α. Below we formally describe a computation process that uses M as a subroutine. (We stress that in this process there is no *explicit* verifier present.)

Fix an input x of length n, a string R_M (of length $q(n)$, where $q(\cdot)$ is a polynomial bounding the number of random coins used by M on inputs of length n), and $t = t(n)$ (arbitrary) strings $\beta^{(1)}, \beta^{(2)}, \ldots, \beta^{(t)}$, each of length $l(n)$. Activate M on input x with its random tape containing R_M. For each y and α tried by M, respond with a message β from the above list $\beta^{(1)}, \beta^{(2)}, \ldots, \beta^{(t)}$ according to the following rule. (This rule depends on the strings α but not on y.) To the first α presented by M respond with $\beta^{(1)}$. For subsequent α's check whether the same string α was presented by M. If so, respond with the same β as in that case; if it is the first time this α is presented then respond with the first unused $\beta^{(i)}$ in the list. That is, if α is the ith *different* string presented by M then we respond with $\beta^{(i)}$. We denote the ith different α by $\alpha^{(i)}$. Clearly, $\alpha^{(i)}$ is uniquely determined by x, R_M, and the $i-1$ strings $\beta^{(1)}, \ldots, \beta^{(i-1)}$, i.e., there exists a deterministic function α_M such that $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \ldots \beta^{(i-1)})$. We denote by $\text{conv}_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)}) = (x, \alpha, \beta, \gamma)$ the conversation output by the simulator M when activated with these parameters (notice that t strings $\beta^{(i)}$ always suffice for answering all tries of M). By our convention on the simulator M, there exists i, $1 \leq i \leq t$, such that $\alpha = \alpha^{(i)}$ and $\beta = \beta^{(i)}$.

DEFINITION. *We say that a vector* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is M-good if* $\text{conv}_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is an accepting conversation for the (honest) verifier V, namely, if* $\text{conv}M(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)}) = (x, \alpha, \beta, \gamma)$ *and* $\rho_V(x, \alpha, \beta, \gamma) = ACCEPT$. *We say that* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is (M, i)-good (or i-good for short) if it is M-good and* $\alpha = \alpha^{(i)}$, $\beta = \beta^{(i)}$.

The main property of M-good strings is stated in the following lemma.

LEMMA 6.3. *Let* $\langle P, V\rangle$ *be a three-round Arthur–Merlin protocol for a language L. Suppose* $\langle P, V\rangle$ *is black-box simulation zero-knowledge, and let M be a black-box simulator as above. Then,*

1. *for strings x outside L, only a negligible portion of the vectors* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *are M-good*;
2. *for strings x in L there exists a nonnegligible portion of the vectors* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *that are M-good. (This nonnegligible portion is at least one half of the completeness probability of the protocol* $\langle P, V\rangle$*, i.e., at least half the probability that P convinces V to accept x.)*

Before proving this key lemma, we use it to prove Theorem 6.1 for the case of the three-round Arthur–Merlin interactive proof.

Proof of Theorem 6.1 (*for the case* AM(3)). By Lemma 6.3 we get the following BPP algorithm for the language L. On input x:

*select at random a vector $(R_M, \beta^{(1)}, \ldots, \beta^{(t)})$;

*accept x if and only if $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ is M-good.

The complexity of this algorithm is like the complexity of testing for M-goodness. The latter is polynomial-time since it involves running the simulator M which is polynomial-time, and evaluating the predicate ρ_V, which is also polynomial-time computable. The success probability of the algorithm is given by Lemma 6.3. □

Proof of Lemma 6.3. (1) Assume that the portion of M-good vectors $(x, R, \beta^{(1)}, \ldots, \beta^{(t)})$ for x's not in L is not negligible. This means that there exist infinitely many $x \notin L$ for which the portion of M-good vectors is nonnegligible. For each such x, there exists an index i_0, $1 \leq i_0 \leq t$, for which a nonnegligible fraction of the vectors $(x, R, \beta^{(1)}, \ldots, \beta^{(t)})$ are i_0-good (since there are only polynomially many possible values for i_0). Thus, there exists a nonnegligible number of prefixes $(x, R, \beta^{(1)}, \ldots, \beta^{(i_0-1)})$, each with a nonnegligible number of i_0-good continuations $(\beta^{(i_0)}, \ldots, \beta^{(t)})$ (i.e., such that $(x, R, \beta^{(1)}, \ldots, \beta^{(i_0-1)}, \beta^{(i_0)}, \ldots, \beta^{(t)})$ are i_0-good). Let $(x, R, \beta^{(1)}, \ldots, \beta^{(i_0-1)})$ be such a prefix, and let $\alpha^{(i_0)} = \alpha_M(x, R, \beta^{(1)}, \ldots, \beta^{(i_0-1)})$. For each i_0-good continuation $(\beta^{(i_0)}, \ldots, \beta^{(t)})$ machine M outputs a conversation $(x, \alpha^{(i_0)}, \beta^{(i_0)}, \gamma)$ for which $\rho_V(x, \alpha^{(i_0)}, \beta^{(i_0)}, \gamma) = ACCEPT$. In particular, there exists a nonnegligible number of $\beta^{(i_0)}$ for which this happens.

In other words, for each x as above, there exists a string $\alpha_x (= \alpha^{(i_0)})$ for which the set $B(x, \alpha_x) = \{\beta : \exists\gamma, \rho_V(x, \alpha_x, \beta, \gamma) = ACCEPT\}$ is of nonnegligible size among all possible strings β. Consider now a ("cheating") prover that sends this α_x as its first message. If V responds with $\beta \in B(x, \alpha_x)$, the prover sends the corresponding γ, which convinces V to accept. Since V selects its messages β at random, then the probability of being convinced by the above prover is (at least) as big as the relative size of $B(x, \alpha_x)$, i.e., nonnegligible. Concluding, we have shown the existence of a prover that for infinitely many x's outside L convinces V to accept with nonnegligible probability. This contradicts the soundness condition of the protocol $\langle P, V\rangle$, and this part of the lemma follows.

(2) We show that for strings x in L a nonnegligible portion of the vectors $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ are M-good. We do it by considering the behavior of the simulator M when receiving "random-like" responses from the verifier. This behavior is analyzed by introducing a particular family of "cheating" verifiers, each of them associated to a different hash function from a family of *$t(n)$-wise independent hash functions*. The $t(n)$-wise independence (where $t(n)$ is the bound on the number of simulator's tries) achieves the necessary randomness from the verifiers' responses.

Let $x \in L$ and let n denote its length. Consider a family of hash functions H_n which map $l(n)$-bit strings into $l(n)$-bit strings, such that the locations assigned to the strings by a randomly selected hash function are uniformly distributed and $t(n)$-wise independent. (Recall that $l(n)$ is the length of messages α and β in the Arthur–Merlin protocol $\langle P, V\rangle$ for L, while $t(n)$ is the bound on the number of M's tries.) For properties and implementation of such functions, see, e.g., [Jof], [WC], and [CG]; in particular, we observe that such functions can be described by a string of length $t(n) \cdot l(n)$, i.e., polynomial in n.

For each hash function $h \in H_n$ we associate a (deterministic nonuniform) verifier V_h^*, which responds to the prover's message α with the string $\beta = h(\alpha)$ (V_h^* has wired in the description of h). Consider the simulation of $\langle P, V_h^*\rangle$ conversations by the simulator M. Fixing an input x, a random tape R_M for M, and a function $h \in H_n$, the whole simulation is determined. In particular, this (uniquely) defines a sequence of α's tried by the simulator, and the corresponding responses β of V_h^*. We denote by $\alpha^{(1)}, \alpha^{(2)}, \ldots, \alpha^{(s)}$, the *different* values of α in these tries. When $s < t$, we complete this sequence to $\alpha^{(1)}, \ldots, \alpha^{(s)}, \alpha^{(s+1)}, \ldots, \alpha^{(t)}$, by adding $t - s$ strings α in some canonical way, such that the resultant $\alpha^{(1)}, \ldots, \alpha^{(t)}$ are all different. Let $\beta^{(i)} = h(\alpha^{(i)})$, $1 \le i \le t$, and define $v(x, R_M, h) = (x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$. Part (2) of the lemma follows from the following two claims.

CLAIM 1. For $x \in L$, there is a nonnegligible portion of the pairs (R_M, h) for which the vector $v(x, R_M, h)$ is M-good.

Proof. For any input x to the protocol $\langle P, V\rangle$, let p_x denote the probability that the prover P convinces V (the honest verifier) to accept x. In other words, p_x is the probability, over the coin sequences R_P of the prover P, and (random) choices β of V, that the resultant conversation $(x, \alpha(x, R_P), \beta, \gamma(x, R_P, \beta))$ is accepting. By the completeness property of the protocol $\langle P, V\rangle$, we get that for x's in L the probabilities p_x are nonnegligible.

Let $x \in L$ and consider the interaction between the real prover P and the verifiers V_h^* on the input x. Each coin sequence R_P determines the message α and the corresponding response $h(\alpha)$ by V_h^*. By the uniformity property of the family H_n we get that for every α, all β's are equiprobable as the result of $h(\alpha)$. Therefore, the probability that P and V_h^* (for h uniformly chosen from H_n) output an accepting conversation is exactly the same as the probability, p_x, that P and V output such a conservation.

Finally, since the simulator M succeeds in simulating $\langle P, V_h^*\rangle$ conversations for all functions $h \in H_n$, we get that for each h the probability that M outputs an accepting conversation when interacting with V_h^* is almost the same (up to negligible difference) as the probability that P and V_h^* output an accepting conversation. This last probability, for $h \in_R H_n$, is p_x. We conclude that the probability, over random R_M and h, that $v(x, R_M, h)$ is M-good is almost p_x and thus nonnegligible. The claim follows. □

CLAIM 2. For all strings x and R_M, and for h chosen with uniform probability from H_n, the vector $v(x, R_M, h)$ is uniformly distributed over the set $\{(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)}) : \beta^{(i)} \in \{0, 1\}^{l(n)}\}$.

Proof. Recall the function α_M introduced above. Observe that

$$v(x, R_M, h) = (x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$$

if and only if for every i, $1 \le i \le t$,

$$h(\alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i-1)})) = \beta^{(i)}.$$

On the other hand, by the uniformity and $t(n)$-independence property of the family H_n, we have that for any t *different* elements $a_1, \ldots, a_t$ in the domain of the functions $h \in H_n$, the sequence $h(a_1), \ldots, h(a_t)$ is uniformly distributed over all the possible sequences $b_1, \ldots, b_t$ for b_i in the range of the functions H_n.

Thus, for all strings x and R_M, and for fixed $\beta^{(1)}, \ldots, \beta^{(t)}$, the probability (for $h \in_R H_n$) that $v(x, R_M, h) = (x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ equals the probability that for every i, $1 \leq i \leq t$, h maps $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i-1)})$ into $\beta^{(i)}$. Since, by definition, all $\alpha^{(i)}$'s are different, then we can use the above property of the family H_n to get that the latter probability is the same for every sequence $\beta^{(1)}, \ldots, \beta^{(t)}$ (i.e., we put $a_i = \alpha^{(i)}$ and $b_i = \beta^{(i)}$). The claim follows. □

Claim 2 states that for any R_M, the value of $v(x, R_M, h)$ is uniformly distributed over all possible vectors $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$. On the other hand, by Claim 1, a nonnegligible portion of $v(x, R_M, h)$ are M-good, and then we get that a nonnegligible portion of the vectors $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ are M-good.

The lemma follows. □

Remark 6.1 (*expected polynomial-time simulator*). For simplicity we have assumed that the given simulator, M, for the protocol $\langle P, V\rangle$ runs in (strictly) polynomial time. Nevertheless, in the definition of zero-knowledge we allow this simulator to run in *expected* polynomial time. We show that our results also hold in this general case by transforming a given expected polynomial-time simulator M into a strictly polynomial-time simulator M', and showing that Lemma 6.3 holds for this new simulator. Then, we can use the modified simulator M' in the BPP algorithm for the language L.

The simulator M' behaves like M, but its running time is truncated after some (fixed) polynomial number of steps, denoted $s(n)$. We show how to choose this polynomial $s(n)$. Let $T(n)$ be a polynomial bounding the *expected* running time of M, and let $p(n)$ be a (lower) bound on the probability that the prover P convinces the (honest) verifier V to accept an input in L of length n. We define $s(n)$ to be $2 \cdot T(n)/p(n)$. Since $1/p(n)$ is polynomially bounded (by the completeness condition of the protocol $\langle P, V\rangle$), then $s(n)$ is polynomially bounded. With this modification of M the proof of Lemma 6.3 remains valid, except for a more delicate argument in the proof of Claim 1. The required changes follow.

In that proof we claimed that "for each h the probability that M outputs an accepting conversation when interacting with V_h^* is almost the same (up to a negligible difference) as the probability that P and V_h^* output an accepting conversation." This is true for the original simulator M, but not necessarily for M'. Since we cut the running of M after $s(n)$ steps, then there exist cases in which M' does not complete the original behavior of M. Nevertheless, by the choice of $s(n)$, the probability (over the coin tosses of M') that this happens (i.e., the running time of M exceeds $s(n)$) is at most $p(n)/2$. Thus, for any h, the probability that the truncated simulator, M', outputs an accepting conversation when interacting with V_h^* differs from the probability that P and V_h^* output an accepting conversation by at most $p(n)/2$. For $h \in_R H_n$, this last probability was shown (in the original proof of Claim 1) to be at least $p(n)$, and then we get that the probability, over random $R_{M'}$ and h, that $v(x, R_{M'}, h)$ is M'-good is (up to a negligible difference) larger than $p(n)/2$, and then nonnegligible. Therefore, Claim 1 follows in this case also. □

Remark 6.2 (*randomized* ρ_V). We have assumed that the only coin tosses of the (honest) verifier V during the Arthur–Merlin protocol $\langle P, V\rangle$ are the bits corresponding to the string β sent to the prover, and that no additional coin tosses are used in order to compute the accepting/rejecting predicate ρ_V. This restriction can be removed from the above proof by using finer arguments, as done in our treatment of the general IP(3) case (of §6.3).

More generally, any AM(k) protocol in which the predicate ρ_V depends on the whole conversation and some additional random string can be transformed into an AM($k + 1$) protocol in which no such additional string is used: simply let the verifier send this random string as its last message. Hence, since we prove our result for any constant-round AM protocol, we can assume that ρ_V is deterministic. □

Remark 6.3 (*interactive arguments*). We now show how to generalize the above proof of the case AM(3) in order to prove the same result in the setting of interactive arguments, i.e., "interactive proofs" in which the soundness condition is required only with respect to provers limited to probabilistic polynomial-time computations, possibly getting an auxiliary input. We have to prove Lemma 6.3 in this setting. Notice that part (2) of the lemma relies on the completeness and zero-knowledge properties of the interactive proof, but these properties are not influenced by the soundness condition. Therefore, this part of the proof automatically holds for interactive arguments. The other part, part (1), relies on the soundness of the interactive proof, thus a modification is required in the proof to deal with provers having just polynomial power.

In that proof we showed, by contradiction, the existence of infinitely many x's not in L for which a cheating prover can convince the verifier to accept x with nonnegligible probability. The success of this prover was shown by proving, for each such x, the *existence* of a message α_x that for nonnegligibly many β's a string γ exists such that $\rho_V(x, \alpha_x, \beta, \gamma) = ACCEPT$. In the interactive arguments, setting the sole existence of such an α_x is not sufficient. The limited prover should find in probabilistic polynomial time this string and the corresponding response γ to the message β sent by V. We describe such a prover P^*, which uses the simulator M in order to find the required strings. It begins by choosing $i \in_R \{1, \dots, t\}$ and random strings R_M, $\beta^{(1)}, \dots, \beta^{(i-1)}$. Then it computes $\alpha = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})$ and sends this α to V. Once V responds with β, the prover P^* chooses $t-i$ random strings $\beta^{(i+1)}, \dots, \beta^{(t)}$, computes (using the simulator M) the conversation $\mathrm{conv}_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)}, \beta, \beta^{(i+1)}, \dots, \beta^{(t)})$, and sends to V the message γ appearing in this conversation. If the chosen vector is i-good then this γ convinces V to accept the conversation. We analyze the probability of such an event.

There exists a nonnegligible probability that P^* chooses i, $1 \leq i \leq t$, for which the number of i-good vectors is nonnegligible (we saw that such an i exists). On the other hand, the whole vector $(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)}, \dots, \beta^{(t)})$ is chosen at random (except for x): the β component by the verifier (the protocol is Arthur–Merlin!) and the other components by P^*. Therefore, there is a nonnegligible probability that the resultant vector is i-good, in which case V accepts x. This way P^* works in polynomial time and has a nonnegligible probability of convincing V to accept x, from which we derive the required contradiction. □

6.2. The case AM(k): Secret coins help zero-knowledge. In this section we consider constant-round Arthur–Merlin interactive proofs. We show that a language having such an interactive proof which is also black-box simulation zero-knowledge belongs to BPP, thus proving Theorem 6.1. We present this proof based on the proof for the particular case of AM(3) as given in §6.1. The basic ideas are similar, but their implementation is technically more involved in this general case. We highly recommend familiarity with §6.1 before going through the present section.

The protocol ⟨P, V⟩. Let $\langle P, V\rangle$ be a k-round Arthur–Merlin protocol for a language L. For simplicity of the exposition we make some assumptions on the form of the protocol without restricting the generality of the proof. We consider protocols in which both the first and last messages are sent by the prover. By adding dummy messages any protocol can be converted into one of this form. Notice that in such a protocol, the number of rounds is always an odd number $k = 2 \cdot m + 1$. The prover P sends $m + 1$ messages which we denote by $\alpha_1, \dots, \alpha_m$ and γ, respectively. The m messages by V are denoted $\beta_1, \dots, \beta_m$. The input to the protocol is denoted by x, and its length by n. The predicate computed by the verifier V in order to accept or reject the input x is denoted by ρ_V, and we assume it to be a deterministic function of the conversation $\rho_V(x, \alpha_1, \beta_1, \ldots, \alpha_m, \beta_m, \gamma)$. (Our results hold also for interactive proofs in which ρ_V depends on an additional random string. See Remark 6.2.) We need the following technical convention. We assume that all prover messages in the protocol have a form that allows them, by only seeing the ith message α_i, to uniquely reconstruct all previous messages sent by the prover during the conversation. This is easily achieved by simple concatenation of previous messages (using a delimiter or some length convention). We also assume the existence of a polynomial $l(n)$ such that all prover's and verifier's messages on an n-length input have length $l(n)$ (e.g., using dummy padding). Finally, we let the verifier V check whether the received messages conform to the above conventions, and reject the conversation if not.

The simulation process. We denote by M the black-box simulator for the protocol $\langle P, V \rangle$. The simulation process consists of several tries by the simulator M. Each try involves feeding the verifier V^* (i.e., the black box representing it) with a value y as the input to the protocol, and the messages α_i, $1 \leq i \leq m$, that simulate the messages sent by P. (Again, we do not care about random coins for V^*; we just need a simulator that is able to simulate conversations with deterministic verifiers.) The simulator M chooses these arguments, in the successive tries, depending on the random tape R_M and the responses β_i output by the black box V^* during the current and previous tries. After each try the simulator may decide to output a conversation of the form $(y, \alpha_1, \beta_1, \ldots, \alpha_m, \beta_m, \gamma)$ or to perform a new try. We assume that the output conversation has $y = x$ (i.e., the input component in the conversation corresponds to the actual input being simulated), that the α messages appearing in the output conversation fit our convention on the form of the prover's messages, and that the simulator explicitly tries the output conversation. Namely, it operates (in one of the tries) the black box V^* on input x and $\alpha_1, \ldots, \alpha_m$ as appearing in the output conversation, and, respectively, gets as responses to V^* the strings $\beta_1, \ldots, \beta_m$, also appearing in this conversation. These assumptions are apparently restricting ones, since the simulator is allowed to output conversations that are not "legal conversations" between the prover P and the simulated verifier V^*. Nevertheless, a simulator that succeeds simulating the $\langle P, V^* \rangle$ conversations will output such illegal conversations with only negligible probability (otherwise the simulated conversations can be easily distinguished from the true ones). Finally, we consider, for the sake of simplicity, only simulators that run in (strictly) polynomial time. The necessary changes in the proof for handling the general case in which the simulator runs in expected polynomial time are analogous to the ones described in Remark 6.1 for the case AM(3). We denote by $\hat{t}(n)$ a polynomial bounding the number of calls to V^* tried by M before outputting a conversation, and put $t(n) = m \cdot \hat{t}(n)$ (notice that $t(n)$ constitutes an upper bound on the total number of messages α tried by M during the whole simulation).

The simulator as a subroutine. Our goal is to present a BPP algorithm for the language L, and we use the simulator M to achieve it. The way M is used is similar to the way we used the simulator in the AM(3) case (see §6.1). In the present case, the behavior of the simulator M when "interacting" with a verifier V^* is determined by the input x to the protocol, the random tape R_M, and the strings β output by V^* as responses to the strings fed by M during the different tries. Also, here we define a computational process that uses M as a subroutine.

Fix an input x of length n, a string R_M, and $t = t(n)$ strings $\beta^{(1)}, \beta^{(2)}, \ldots, \beta^{(t)}$, each of length $l(n)$. Activate M on input x with its random tape containing R_M. For each message α presented by M, respond in the following way. (The responses will depend on the strings α, but not on y.) If α is "illegal," then respond with a special "reject-message." By illegal we mean a message α that does not fit our above conventions on the form of the prover's messages. For legal α's we respond (impersonating a black-box verifier) with one of the β's from the above list $\beta^{(1)}, \ldots, \beta^{(t)}$ according to the following rule. If the same α was previously presented by M (i.e., during a previous try), respond with the same β as in that case. If α is the ith *different* (legal) string presented by M since the beginning of the simulation, then respond with $\beta^{(i)}$. We denote the ith different α by $\alpha^{(i)}$. Clearly, $\alpha^{(i)}$ is uniquely determined by x, R_M, and the $i-1$ strings $\beta^{(1)}, \ldots, \beta^{(i-1)}$. That is, there exists a deterministic function α_M such that $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i-1)})$. We denote by $\mathrm{conv}_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)}) = (y, \alpha_1, \beta_1, \ldots, \alpha_m, \beta_m, \gamma)$ the conversation output by the simulator M when activated with these parameters (notice that t strings $\beta^{(i)}$ always suffice for answering all tries of M). By our convention on the simulator M and on the form of the prover's messages it follows that there exists a sequence of indices $1 \leq i_1 < i_2 < \cdots < i_m \leq t$ such that for each α_j, β_j, $j = 1, \ldots, m$, appearing in the output conversation, $\alpha_j = \alpha^{(i_j)}$ and $\beta_j = \beta^{(i_j)}$. This is true since the simulator always outputs a conversation which was explicitly generated in one of its tries. The increasing property of the sequence of indices i_j is enforced by the special form of the "legal" messages α, namely, by the fact that we respond to message α_j only if we had previously responded to the messages $\alpha_1, \ldots, \alpha_{j-1}$. In the present setting we use the following definition of M-good vectors.

DEFINITION. *We say that a vector* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is M-good if* $\mathrm{conv}_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is an accepting conversationfor the (honest) verifier V. We say that* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *is* $(i_1, i_2, \ldots, i_m)$*-good if it is M-good and the corresponding conversation has* $\alpha_j = \alpha^{(i_j)}$ *and* $\beta_1 = \beta^{(i_j)}$*, for* $j = 1, \ldots, m$.

The following lemma is analogous to Lemma 6.3.

LEMMA 6.4. *Let* $k = 2 \cdot m + 1$ *be a constant, and let* $\langle P, V\rangle$ *be a k-round Arthur–Merlin protocol for a language L. Suppose* $\langle P, V\rangle$ *is black-box simulation zero-knowledge, and let M be a black-box simulator as above. Then*

1. *for strings x outside L, only a negligible portion of the vectors* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *are M-good*;
2. *for strings x in L there exists a nonnegligible portion of the vectors* $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ *that are M-good. (This nonnegligible portion is at least one half of the completeness probability of the protocol* $\langle P, V\rangle$*, i.e., half the probability that P convinces V to accept x).*

Proof of Theorem 6.1. Using Lemma 6.4 we get that the algorithm described in the proof of Theorem 6.1 for the special case of AM(3) (see §6.1) is a BPP algorithm for the language L. □

Proof of Lemma 6.4. This proof is essentially analogous to the proof of Lemma 6.3, although some delicate modifications are required.

(1) Assume that the portion of M-good vectors $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ for x's not in L is not negligible. This means that there exist infinitely many $x \notin L$ for which the portion of M-good vectors is nonnegligible. Observe that there are only polynomially many different sequences $1 \leq i_1 < i_2 < \cdots < i_m \leq t$ (i.e., $\binom{t(n)}{m}$, and m is a constant), and then note that for each x, as above, there exists a sequence $(i_1, i_2, \ldots, i_m)$ for which nonnegligibly many vectors $(x, R_M, \beta^{(1)}, \ldots, \beta^{(t)})$ are $(i_1, i_2, \ldots, i_m)$-good. Next, we describe a prover P^* which convinces the (honest) verifier V to accept any of the above inputs $x \notin L$ with nonnegligible probability, thus contradicting the soundness condition of the protocol $\langle P, V\rangle$.

The prover P^* begins by choosing a sequence $(i_1, i_2, \ldots, i_m)$ at random. Then, it chooses random strings $R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)}$ and uses them to compute $\alpha_1 = \alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)})$. It sends α_1 to V and receives back the response β_1. Now P^* chooses random $\beta^{(i_1-1)}, \ldots, \beta^{(i_2-1)}$ and computes $\alpha_2 = \alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \ldots, \beta^{(i_2-1)})$. After receiving the response β_2 from the verifier, P^* selects new random strings $\beta^{(i_2+1)}, \ldots, \beta^{(i_3-1)})$ and computes $\alpha_3 = \alpha_M(x, R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \ldots, \beta^{(i_2-1)}, \beta_2, \beta^{(i_2+1)}, \ldots, \beta^{(i_3-1)})$. This process continues until all messages α_i, β_i, $1 \leq i \leq m$, are computed and exchanged. When the resultant vector $(x, R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \ldots,$

$\beta^{(i_2-1)}, \beta_2, \ldots, \beta^{(t)})$ is $(i_1, i_2, \ldots, i_m)$-good, then computing the function conv_M on this vector results in an accepting (for V) conversation $(x, \alpha_1, \beta_1, \ldots, \alpha_m, \beta_m, \gamma)$ (with α_i, β_i, as defined above). But then, by sending this γ, the prover P^* convinces V to accept. The probability that this happens equals the probability that the above vector $(x, R_M, \beta^{(1)}, \ldots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \ldots, \beta^{(i_2-1)}, \beta_2, \ldots, \beta^{(t)})$ is $(i_1, i_2, \ldots, i_m)$-good. Since this sequence of indices and all the vector components (excluding x) are chosen at random (recall that V chooses its messages, $\beta_1, \ldots, \beta_m$, at random!) then this probability is nonnegligible.

(2) The proof of this part is analogous to the corresponding proof in Lemma 6.3. We use a set H_n of $t(n)$-independent hash functions ($t(n)$ as defined in this section) to define a family of verifiers V_h^*. For all $h \in H_n$, the verifier V_h^* responds to a legal message α sent by the prover with $h(\alpha)$, and with a rejection message if α is illegal. The statements for Claims 1 and 2 remain the same, as does the proof of Claim 2. The proof of Claim 1 needs a more delicate argument, as follows. As in the AM(3) case we consider the interaction between the prover P and a verifier V_h^*, but now this interaction generates a conversation of the form $(x, \alpha_1, \beta_1, \ldots, \alpha_m, \beta_m, \gamma)$. In particular, for each h and random tape R_P for P a unique sequence of messages $\beta_1, \ldots, \beta_m$ (the responses of V_h^*) is determined. We have to show that for every tape R_P all sequences $\beta_1, \ldots, \beta_m$ are equiprobable for $h \in_R H_n$. The proof of this property uses a similar argument as in the proof of Claim 2: observe that the pair R_P and h generates the responses $\beta_1, \ldots, \beta_m$ if and only if, for every i, $1 \le i \le m, h(\alpha_P(x, R_P, \beta_1, \ldots, \beta_{i-1})) = \beta_i$. (Here α_P stands for the function computed by P in order to determine its next message α.) Thus, the probability (for $h \in_R H_n$) that a given sequence $\beta_1, \ldots, \beta_m$ is generated is like the probability that for every i, $1 \le i \le m, h$ maps $\alpha_P(x, R_P, \beta_1, \ldots, \beta_{i-1})$ into β_i. Since the functions H_n are m-independent (by definition they are $t(n)$-independent, but $m \le t(n)$), and the messages $\alpha_1, \ldots \alpha_m$ output by P are all different by convention, we get that the latter probability is the same for every sequence $\beta_1, \ldots, \beta_m$.

From this property of the pairs R_P and h we conclude that the probability that P and V_h^* (for $h \in_R H_n$) output an accepting conversation is exactly the same as the probability that P and the honest V output such a conversation.

The rest of the proof follows as in Claim 1 of Lemma 6.3 □

Remark 6.4. Notice that the prover P^* described in the proof of part (1) of Lemma 6.4 is a polynomial-time prover. The other parts of the proof of Theorem 6.1 also hold for such provers, and then we get that our result remains valid also in the setting of interactive arguments.

6.3. The case IP(3). In the setting of general interactive proofs the (honest) verifier is not restricted to choosing all its messages at random, but can compute them based on the input x, a random ("secret") string r, and the previous messages of the prover. In the case of three rounds this means that the only message sent by V during the protocol is computed by means of a (deterministic) function $\beta_V(x, r, \alpha)$, where α is the first message sent by P. Also, in this case V accepts or rejects a conversation based on a predicate $\rho_V(x, r, \alpha, \gamma)$ (γ is the last message sent by P).

Here we outline the proof of Theorem 6.2, based on the proof presented in §6.1 for the AM(3) case.

Proof of Theorem 6.2 (*outline*). Let L be a language having a three-round interactive proof which is black-box simulation zero-knowledge. Let $\langle P, V\rangle$ be such a protocol and let M be the corresponding black-box simulator. The simulation process consists of several tries; in each of them the simulator feeds the black box V^* with arguments y (the input) and α (the prover's message), and gets an answer β from V^*. (Again, it suffices to consider a simulator just able to simulate conversations with deterministic verifiers, so this simulator does not feed V^* with a random tape.) We assume the same conventions on the simulator as the ones described in §6.1 for the proof of the AM(3) case.

- The simulator always outputs a conversation of the form $(x, \alpha, \beta, \gamma)$, where x and α are fed into the black-box V^* in one of the simulator tries, and β is the response of V^* to these arguments.
- The simulator runs in strictly polynomial time. In particular, $t(n)$ stands for the polynomial bound on the number of tries made by M on inputs of length n during the simulation process (the case of expected polynomial-time simulators is handled exactly as in Remark 6.1).

The main modification with respect to the proof of the AM(3) case is in the way we use the simulator M as a subroutine for constructing the BPP algorithm for the language L. Recall that the whole simulator process is completely determined by the input to the protocol, x, the contents of M's random tape, R_M, and the responses by the verifier. This was true for the AM(3) case and remains true here. In the former case we used M as a subroutine by feeding it with x and a randomly chosen string R_M. Then, we used $t = t(n)$ random strings $\beta^{(1)}, \ldots, \beta^{(t)}$ as the response of the virtual verifier. In the present case we choose a string R_M, as before, and t random strings denoted $r^{(1)}, \ldots, r^{(t)}$, each of length $l(n)$, where $l(n)$ is a (polynomial) bound on the number of random bits used by the (honest) verifier in the IP(3) protocol $\langle P, V\rangle$. The idea is to use these strings as the random coins of the virtual verifier for responding to M's tries. More precisely, for each try by the simulator, consisting of an input y to the protocol and a message α, we compute $\beta = \beta_V(y, r^{(i)}, \alpha)$, and feed it into M as the verifier's response to α. For each new try we use a new $r^{(i)}$ (in increasing order of i), except in the case in which the present α was also presented in a previous try. If so, we use the same $r^{(i)}$ as in that case.

Note that a unique conversation is determined by x, R_M, and the t strings $r^{(1)}, \ldots, r^{(t)}$. Thus, as in the case AM(3), we can define $\mathrm{conv}_M(x, R_M, r^{(1)}, \ldots, r^{(t)})$ to be the conversation output by M when the described process is finished. Also, we denote by $\alpha^{(i)}$ the ith *different* α output by M during the simulation. Clearly, $\alpha^{(i)}$ is uniquely determined by x, R_M, and the strings $r^{(1)}, \ldots, r^{(i-1)}$; thus we denote $\alpha^{(i)} = \alpha_M(x, R_M, r^{(1)}, \ldots, r^{(i-1)})$.

By our convention on M, if $\mathrm{conv}(x, R_M, r^{(1)}, \ldots, r^{(t)}) = (x, \alpha, \beta, \gamma)$, then M explicitly tried the arguments x and α during the simulation, and got as response the string β. This means that there exists (at least one) i, $1 \leq i \leq t$, such that $\beta = \beta_V(x, r^{(i)}, \alpha)$. This fact is used in the following definition.

DEFINITION. *We say that a vector* $(x, R_M, r^{(1)}, \ldots, r^{(t)})$ *is M-good if* $\mathrm{conv}(x, R_M, r^{(1)}, \ldots, r^{(t)}) = (x, \alpha, \beta, \gamma)$ *and* $\rho_V(x, r^{(i)}, \alpha, \gamma) =$ *ACCEPT, where i is the minimal value for which* $\beta = \beta_V(x, r^{(i)}, \alpha)$. *According to this value of i, we call the conversation (M, i)-good (or i-good for short).*

Using this re-definition of the notion of M-goodness, Lemma 6.3 of §6.1 also holds in the present (IP(3)) case, by just changing the $\beta^{(i)}$ notation by $r^{(i)}$ in the formulation of the lemma. Theorem 6.2 then follows by using the BPP algorithm as described in the proof of the AM(3) case. For the proof of Lemma 6.3 in the present case we note the following simple modifications. In the proof of part (1) we use the same reasoning as in the corresponding proof in §6.1 but applied to the strings $r^{(i)}$ instead of $\beta^{(i)}$. We note that the soundness probability of the protocol is now defined over the random coins used by V, i.e., over the choices $r^{(i)}$. For the proof of the other part of the lemma we slightly modify the definition of the verifiers V_h^*. We still use the same family of hash functions, but the verifier V_h^* works as follows: on message α sent by the prover, V_h^* responds with $\beta = \beta_V(x, h(\alpha), \alpha)$, i.e., it computes β as the honest verifier does, but using $h(\alpha)$ as the random coins of V. The rest of the proof (including Claims 1 and 2) remains essentially unchanged (up to the replacement of "responses $\beta^{(i)}$" by "random coins $r^{(i)}$"). □

Remark 6.5. As in the previous cases also, the IP(3) case extends to the setting of interactive arguments. The modifications in the proof are analogous to the ones described in Remark 6.3.

7. Concluding remarks. Although the results presented in this paper are negative in nature, we believe that they have played a positive role in the development of the field.

We believe that sequential composition is a fundamental requirement of zero-knowledge protocols. It is analogous to requiring that adding two algebraic expressions, each evaluating to zero, yields an expression which evaluates to zero. Furthermore, sequential composition is required when using zero-knowledge proofs as tools in the design of cryptographic protocols (an application which is the primary motivation of zero-knowledge). *The fact that the original formulation of zero-knowledge is not closed under sequential composition establishes the importance of augmenting this formulation by an auxiliary input* (cf. [GO], [Ore], [TW], and [Gol]). It should be stressed, of course, that all known zero-knowledge proofs also satisfy the augmented formulation.

Parallel composition is the key to improving the efficiency (in terms of number of rounds) of zero-knowledge protocols, but we do not believe that it is a fundamental requirement. Carrying the analogy of the previous paragraph, one cannot require that "interleaving" two expressions (each evaluating to zero) yields an expression which evaluates to zero. *The fact that all known formulations of (computational) zero-knowledge are not closed under parallel composition motivates the introduction of weaker notions such as* witness indistinguishability [FS2] *which suffice for many applications.* Namely, instead of strengthening the hypothesis of the alleged Parallel Composition Theorem (as was done in the case of Sequential Composition), one relaxes the conclusion of the Parallel Composition Theorem (and this weaker conclusion turns to suffice in many applications).

The fact that ("nontrivial") black-box zero-knowledge proofs cannot be both of AM type and of constant number of rounds establishes the importance of "private coins" in the design of constant-round zero-knowledge proofs. In other words, in the process of such proofs, the verifier must "commit" (and later "decommit") to some pieces of information. In fact, such commitments are the core of the constant-round zero-knowledge proofs (and arguments) for any language in NP presented in [BCY], [FS1], and [GKa] (relying on various reasonable intractability assumptions) and in the (unconditional) zero-knowledge proof for graph isomorphism presented in [BMO1].

Appendix: Proof of existence of P/poly-evasive pseudorandom ensembles. In this appendix we present the proof of Theorem 3.2. We first restate the theorem.

THEOREM 3.2. *There exists a* P/poly*-evasive ensemble* $\boldsymbol{S}^{(1)}, \boldsymbol{S}^{(2)}, \ldots$ *with* $Q(n) = 4n$, *such that for every* n, *each* $S_i^{(n)}$ *is a* $(2^{n/4}, 2^{-n/4})$*-pseudorandom set of cardinality* 2^n. *Furthermore, there exists a Turing machine which on input* 1^n *outputs the collection* $\boldsymbol{S}^{(n)}$.

Proof. For any integer n, we denote by $\boldsymbol{R}^{(n)}$ the collection of sets $S \subseteq \{0, 1\}^{4n}$ of cardinality 2^n which are $(2^{n/4}, 2^{-n/4})$-pseudorandom, and by $\boldsymbol{C}^{(n)}$ the set of (deterministic) circuits of size $2^{n/4}$ having n inputs and $4n$ outputs.

We prove the theorem by showing, for any large enough n, the existence of 2^n sets $S_1, \ldots, S_{2^n}$ from $\boldsymbol{R}^{(n)}$ such that for any circuit $C \in \boldsymbol{C}^{(n)}$, and $i \in_R \{1, \ldots, 2^n\}$, $\text{Prob}(C(i) \in S_i) < 2^{-n/4}$. Denoting this collection of 2^n sets by $\boldsymbol{S}^{(n)}$, we get that the resultant sequence $\boldsymbol{S}^{(1)}$, $\boldsymbol{S}^{(2)}, \ldots$ by a P/poly-evasive ensemble that satisfies the conditions of Theorem 3.2. We stress that considering only deterministic circuits does not restrict the generality, since we can wire in such a circuit a sequence of "random coins" that maximizes the probability $\text{Prob}(C(i) \in S_i)$.

We turn to show the existence of a collection of sets as described above. We do it by proving that there exists a positive probability to randomly choose 2^n sets $S_1, \ldots, S_{2^n}$ from $\boldsymbol{R}^{(n)}$ with the above evasivity property.

For a fixed $C \in \boldsymbol{C}^{(n)}$ and a fixed $i, 1 \leq i \leq 2^n$, consider the probability, denoted $\mathrm{Prob}_S(C(i) \in S)$, that the element $C(i)$ belongs to the set S, for S uniformly chosen over all subsets of $\{0,1\}^{4n}$ of size 2^n. Clearly,

$$\mathrm{Prob}(C(i) \in S) = 1 - \frac{\binom{2^{4n}-1}{2^n}}{\binom{2^{4n}}{2^n}} = \frac{2^n}{2^{4n}} < \frac{1}{2^{2n}}.$$

We call a set $S \subseteq \{0,1\}^{4n}$, $|S| = 2^n$, *C-bad* if there exists some $i, 1 \leq i \leq 2^n$, such that $C(i) \in S$. Fixing a circuit C, we have that for S uniformly chosen over all subsets of $\{0,1\}^{4n}$ of size 2^n,

$$\mathrm{Prob}_S(S \text{ is } C\text{-bad}) \leq \sum_{i=1}^{2^n} \mathrm{Prob}_S(C(i) \in S) < 2^n 2^{-2n} = 2^{-n}.$$

In [GK] it is proven that the measure of $\boldsymbol{R}^{(n)}$ (i.e., the proportion of sets S which are $(2^{n/4}, 2^{-n/4})$-pseudorandom) is at least $1 - 2^{-2^{n/4}}$. Therefore, for each circuit $C \in \boldsymbol{C}^{(n)}$ the probability, hereafter denoted as p_C, to uniformly choose from $\boldsymbol{R}^{(n)}$ a set S which is C-bad is

$$p_C = \mathrm{Prob}_S(S \text{ is } C\text{-bad} \mid S \in \boldsymbol{R}^{(n)}) < \frac{2^{-n}}{1 - 2^{-2^{n/4}}}.$$

We now proceed to compute the probability that for a fixed circuit $C \in \boldsymbol{C}^{(n)}$, a collection of 2^n randomly chosen sets from $\boldsymbol{R}^{(n)}$ contains a significant portion of C-bad sets. We define as "significant" a fraction $p_C + \delta_n$. (The quantity δ_n will be determined later.) Let ρ be a random variable assuming as its value the fraction of C-bad sets on a random sample of 2^n sets from $\boldsymbol{R}^{(n)}$. Clearly, the expected value of ρ is p_C. Using Hoeffding's inequality [Hoe] (see also [GK]) we get that

$$\mathrm{Prob}(\rho \geq p_C + \delta_n) \leq e^{-22^n \delta_n^2},$$

i.e., this quantity bounds the probability of choosing at random 2^n sets from $\boldsymbol{R}^{(n)}$ among which the fraction of C-bad sets is larger than $p_C + \delta_n$.

Recall that we are interested in choosing 2^n sets that are evasive for *all* circuits $C \in \boldsymbol{C}^{(n)}$. That is, we require that for *any* C, the number of C-bad sets among the 2^n sets we choose is negligible. In order to bound the probability that 2^n randomly selected sets *do not* satisfy this condition, we multiply the above probability, computed for a single circuit, by the total number of circuits in $\boldsymbol{C}^{(n)}$ which is at most $2^{(2^{n/4})^2} = 2^{2^{n/2}}$. Putting $\delta_n = 2^{-n/4}/\sqrt{2}$ we get

$$2^{2^{n/2}} \cdot e^{-22^n \delta_n^2} = 2^{2^{n/2}} \cdot e^{-22^n 2^{-\frac{n}{2}-1}} = 2^{2^{n/2}} \cdot e^{-2^{n/2}} < 1.$$

We conclude that there exists a positive probability that 2^n sets $S_1, \ldots, S_{2^n}$ chosen at random from $\boldsymbol{R}^{(n)}$ have the property that for any circuit $C \in \boldsymbol{C}^{(n)}$ the fraction of C-bad sets among $S_1, \ldots, S_{2^n}$ is less than $p_C + \delta_n$. Therefore, such a collection of sets does exist.

Finally, we bound, for this fixed collection $S_1, \ldots, S_{2^n}$, and for any circuit $C \in \boldsymbol{C}^{(n)}$, the probability $\mathrm{Prob}_i(C(i) \in S)i)$, for i randomly chosen from $\{1, \ldots, 2^n\}$. We have

$$\begin{aligned}\mathrm{Prob}_i(C(i) \in S_i) &= \mathrm{Prob}_i(C(i) \in S_i \mid S_i \text{ is } C\text{-bad}) \cdot \mathrm{Prob}_i(S_i \text{ is } C\text{-bad}) \\ &\quad + \mathrm{Prob}_i(C(i) \in S_i \mid S_i \text{ is not } C\text{-bad}) \cdot \mathrm{Prob}_i(S_i \text{ is not } C\text{-bad}) \\ &\leq 1 \cdot (p_C + \delta_n) + 0 < \frac{2^{-n}}{1 - 2^{-2^{n/4}}} + \frac{2^{-n/4}}{\sqrt{2}} < 2^{-n/4}.\end{aligned}$$

Therefore, we have shown for every circuit C of size $2^{n/4}$ that $\text{Prob}_i(C(i) \in S_i) < 2^{-n/4}$, thus proving the required properties of the sets $S_1, \ldots, S_{2^n}$.

Such a collection can be generated by a Turing machine by considering all possible collections $\{S_1, \ldots, S_{2^n}\}$ and checking whether they evade all the circuits in the set $\mathcal{C}^{(n)}$. □

Acknowledgments. Silvio Micali was one of the only researchers to strongly object to the "intuition" that the parallel versions of the interactive proof systems for quadratic residuosity, graph isomophism, and all languages in NP, are zero-knowledge. The results in this paper are rooted in this clear vision of Silvio. We are grateful to him for that.

THE ISOMORPHISM CONJECTURE HOLDS RELATIVE TO AN ORACLE*

STEPHEN FENNER[†], LANCE FORTNOW[‡], AND STUART A. KURTZ[§]

Abstract. The authors introduce symmetric perfect generic sets. These sets vary from the usual generic sets by allowing limited infinite encoding into the oracle. We then show that the Berman–Hartmanis isomorphism conjecture holds relative to any sp-generic oracle, i.e., for any symmetric perfect generic set A, all $\mathbf{NP}^A$-complete sets are polynomial-time isomorphic relative to A. Prior to this work, there were no known oracles relative to which the isomorphism conjecture held.

As part of the proof that the isomorphism conjecture holds relative to symmetric perfect generic sets, it is also shown that $\mathbf{P}^A = \mathbf{FewP}^A$ for any symmetric perfect generic A.

Key words. computational complexity, relativization, isomorphism conjecture

AMS subject classification. 68Q15

1. Introduction.

Is it possible to define a notion of genericity such that all **NP***-complete sets are p-isomorphic?*
Judy Goldsmith and Deborah Joseph [6]

We construct an oracle relative to which the Berman–Hartmanis isomorphism conjecture [1], [2] is true. This conjecture holds that any two **NP**-complete sets are isomorphic to one another by a polynomial-time computable and invertible one–one reduction. The isomorphism conjecture has been the subject of considerable research. We recommend the surveys by Joseph and Young [11] and Kurtz, Mahaney, and Royer [15].

The attempt to construct oracles relative to which the isomorphism conjecture either succeeded or failed began soon after the conjecture was made in 1976.

Success was first obtained in finding oracles relative to which the conjecture fails. In 1983, Kurtz (in an unpublished manuscript) constructed an oracle relative to which the conjecture failed. Hartmanis and Hemachandra [8] later combined Kurtz's construction with Rackoff's construction [18] of an oracle relative to which $\mathbf{P} = \mathbf{UP}$ (and thus no one-way functions exist [7]). In 1989, Kurtz, Mahaney, and Royer [16] showed that the conjecture fails relative to a random oracle; and Kurtz [12] gave an improved version of his original construction that showed that the conjecture fails relative to a Cohen generic oracle.

The attempt to construct an oracle relative to which the conjecture succeeds has proven much more difficult. Even partial successes have been viewed as important advances. In 1986, Goldsmith and Joseph [6] constructed an oracle relative to which a partially relativized version of the isomorphism conjecture holds. Namely, they constructed an oracle A such that all of the p-complete sets for $\mathbf{NP}^A$ are p^A-isomorphic.

An *m-degree* is an equivalence class of sets all many–one reducible to each other. In 1987, Kurtz, Mahaney, and Royer [13] gave a relativized version of their collapsing degree construction [14] and showed that there is an oracle A relative to which *some* m-degree in $\mathbf{NP}^A$ collapses. Finally, in 1989, Homer and Selman [9], [10] gave an oracle relative to which the complete degree for Σ_2^{P} collapsed.

We introduce a new notion of genericity, define the *symmetric perfect generic sets* (a.k.a. the *sp-generic sets*), and present the following theorem.

THEOREM 1.1. *Relative to any symmetric perfect generic set A, all* **NP***-complete sets are polynomial-time isomorphic.*

We improve upon the work of Goldsmith and Joseph [6] by allowing **NP**-complete sets via relativized reductions.

After describing the mathematical background needed for this paper, in §3 we will describe sp-generic sets and give some of their properties. In §4 we show that $\mathbf{P}^A = \mathbf{FewP}^A$ for any sp-generic A, which will form a necessary part of our proof that the isomorphism conjecture holds relative to any sp-generic oracle. In §5 we will give some intuition for the proof of the isomorphism conjecture, followed by the detailed proof.

2. Mathematical preliminaries. The natural numbers are denoted by $\mathbf{N}$. The cardinality of a set X is denoted by $\|X\|$. Let $\Sigma = \{0, 1\}$.

We will use lower case Greek letters for partial functions from $\Sigma^* \to \{0, 1\}$. We say τ *extends* σ to mean that τ is equal to σ everywhere that σ is defined. We often identify a language $A \subseteq \Sigma^*$ as its characteristic function, for instance, in saying A extends σ. The everywhere-undefined function is denoted by $\emptyset$. Two functions are *compatible* if they agree everywhere both are defined. For compatible σ and τ, the smallest partial function extending both is denoted $\sigma \cup \tau$. We use $\mathrm{dom}(\tau)$ and $\mathrm{range}(\tau)$ to represent the domain and range of τ, respectively.

We say a computation path of an oracle Turing machine using τ is *defined* if $\tau(x)$ is defined for all queries x along that path. If M is an oracle nondeterministic Turing machine, we say that $M^\tau(x)$ accepts on a path p if all queries to the oracle made along p are in the domain of τ and are answered according to τ, and p ends in an accepting state.

We will sometimes need a machine to know the domain of τ as well as the values of τ on its domain. For these machines, we will define the total function $\overline{\tau} : \Sigma^* \times \{0, 1\} \to \{0, 1\}$ as follows:

$$\overline{\tau}(x, i) = \begin{cases} 1 & \text{if } x \in \mathrm{dom}(\tau) \text{ and } \tau(x) = i, \\ 0 & \text{otherwise.} \end{cases}$$

By abuse of terminology we will on occasion use the expression "$f^A(x)$" to refer to one of (i) the value $f^A(x)$, (ii) the function $x \mapsto f^A(x)$, or (iii) the computation of a particular machine computing f on input x using oracle A. We will try to make clear which interpretation of "$f^A(x)$" we mean when it cannot easily be inferred from context.

A one–one polynomial-time function f^A is *invertible relative to* A if there exists a polynomial-time function g^A such that for all $x \in \Sigma^*$, $g^A(f^A(x)) = x$. Note that g^A does not have to recognize the range of f^A.

For a function f and an oracle A, let $f^{A(-1)}(z)$ be the set of strings x such that $f^A(x) = z$.

Let $\mathbf{CNF}^A$ be a relativized version of **CNF** formulae (see [6]). We will also consider the formulae in a closed form, e.g., instead of a formula looking like $(x \vee y)$, it will look like $\exists x \exists y (x \vee y)$. This will allow us to talk about "true" and "false" formulae and make it easier to combine formulae with other expressions. Because we only talk about $\mathbf{NP}^A$-completeness, we only allow "$\exists$" as a quantifier. $\mathbf{SAT}^A$ consists of the true formulae relative to the oracle A.

Using standard encoding tricks and simple modifications of the theorems of Cook [4] and Berman and Hartmanis [2], we get that the following properties of $\mathbf{CNF}^A$ and $\mathbf{SAT}^A$ hold for all oracles A:

1. For every nondeterministic oracle Turing machine M that runs in time $O(n^i)$, there exists a polynomial-time unrelativized function f such that
   (a) f reduces $L(M^A)$ to $\mathbf{SAT}^A$, and
   (b) for all x, $|f(x)| = O(|x|^{2i})$.

2. Every formula $\varphi \in \mathbf{CNF}^A$ has a representation as a binary string. Every binary string represents a formula in $\mathbf{CNF}^A$.
3. Every formula represented by a binary string of n bits can only depend on A on strings of length shorter than n.
4. There is an unrelativized polynomial-time padding function P such that for all formulae φ and strings z,
   (a) $P(\varphi, z)$ is true if and only if φ is true,
   (b) $|P(\varphi, z)| > \max(|\varphi|, |z|)$, and
   (c) from $P(\varphi, z)$ we can in unrelativized polynomial time recover φ and z.

Berman and Hartmanis [2] observed that for any languages B and L such that B is $\mathbf{NP}^A$-complete and has such a padding function and L in $\mathbf{NP}^A$, there is a one-to-one length-increasing invertible reduction from L to B.

Let $i = \langle i_0, i_1 \rangle$ using the standard pairing function. Let $f_0, \dots,$ be an enumeration of functions where f_i simulates the deterministic oracle Turing machine with code i_0 running in time n^i. Let $M_0, \dots$ be an enumeration of nondeterministic oracle machines where M_i simulates the Turing machine with code i_1 running in time n^i.

We use **FP** to represent the class of polynomial-time computable functions.

3. Symmetric perfect generic sets. In this section, we define the specific type of generic set that we use in this paper. We will later show that the isomorphism conjecture holds to all such generics.

DEFINITION 3.1. *A sequence $\langle a_i \rangle_{i \in \mathbf{N}}$ of integers forms an* iterated-polynomial *sequence if there exists a polynomial p such that $p(n) \geq n^2$ for all n, $a_0 \geq 2$, and $a_{i+1} = p(a_i)$ for all i.*

DEFINITION 3.2. *A partial characteristic function $\tau : \Sigma^* \to \{0, 1\}$ is a* symmetric perfect forcing condition *if there is an iterated-polynomial sequence $\langle a_i \rangle_{i \in \mathbf{N}}$ such that*

$$\left(\bigcup_{i \in \mathbf{N}} \Sigma^{a_i} \right) \cap \operatorname{dom}(\tau) = \emptyset.$$

In other words, $\tau(x)$ is undefined for all x such that $|x| = a_i$ for some $i \in \mathbf{N}$. Note that $\tau(x)$ may be undefined on other x as well.

We generally refer to symmetric perfect forcing conditions as *sp-conditions*. As opposed to most types of forcing conditions, sp-conditions cannot necessarily be coded into finite objects.

The name *symmetric perfect* is intended to describe the topological structure of the conditions and to honor our intellectual debts. Topologically, we can view a symmetric perfect condition τ as a complete binary tree, the branchings of which correspond to points x at which $\tau(x)$ is undefined. The paths of a complete binary tree form a closed set without isolated points in their natural topology, i.e., they are *perfect*.

From a scholarly point of view, our *symmetric perfect* conditions are special cases of Gerald Sacks's *pointed perfect* conditions [20]. The unique contribution of Sacks was to recognize that forcing conditions need not be recursive (as they are in the standard finite extension arguments or in the recursion theoretic minimal degree construction). Rather, it is sufficient that τ be recursive in each of its members. This is his notion of *pointedness*. Our conditions are pointed because they can be conceived of as a complete binary tree which has been pruned at a coinfinite recursive set of points. This pruning is *symmetric* in that we remove either all of the left branchings at x (by setting $\tau(x) = 1$) or all of the right branchings at x (by setting $\tau(x) = 0$).

DEFINITION 3.3. *A set S of symmetric perfect forcing conditions is* dense *if for every sp-condition τ, there exists an sp-condition σ in S such that σ extends τ.*

DEFINITION 3.4. *A language A is* symmetric perfect generic (*sp-generic*) *if for every definable dense set S of sp-conditions, there is a $\sigma \in S$ extended by A.*

By *definable* we mean the set $\{\overline{\sigma} \mid \sigma \in S\}$ is a Π^1_1 class (see [19]).

The following theorem is a simple adaptation of the Baire category theorem.

THEOREM 3.1. *Every sp-condition τ is extended by an sp-generic language A.*

Proof. Let $D_1, \ldots$ be an enumeration of the definable dense sets. Let $\sigma_0 = \tau$. For every $i > 0$, let $\sigma_i = \sigma$ for some $\sigma \in D_i$ such that σ extends σ_{i-1}. For all $x \in \Sigma^*$, let $A(x) = \lim_{i \to \infty} \overline{\sigma}_i(x, 1)$. □

DEFINITION 3.5. *A proposition $P(A)$ is said to be* forced *by an sp-condition τ if $P(A)$ is true for all oracles A extending τ.*

Note that this definition is simpler but different from the usual definition of forcing on generic sets.

If $P(A)$ is a first-order proposition in A, then the set S of conditions that force $P(A)$ is definable since $\sigma \in S$ if and only if for all A extending σ, $P(A)$ holds.

We can already see the power of sp-generic sets by the following lemma.

LEMMA 3.2. *Given any sp-condition τ and any language X, there is an sp-condition σ extending τ such that σ forces $X \in \mathrm{P}^A$.*

Proof. Let $\langle a_i \rangle_{i \in \mathrm{N}}$ be the iterated-polynomial sequence such that τ is undefined on strings of length $\langle a_i \rangle_{i \in \mathrm{N}}$. For each i, let $b_i = a_{2i}$ and $d_i = a_{2i+1}$. Let $f(x) = x01^j$, where j is the smallest value such that $|x01^j| = d_i$ for some i. Clearly j is bounded by a polynomial in $|x|$, f is one–one and range$(f) \cap \mathrm{dom}(\tau) = \emptyset$. Define $\sigma(y)$ as

$$\sigma(y) = \begin{cases} \tau(y) & \text{if } y \in \mathrm{dom}(\tau), \\ 1 & \text{if } y = f(x) \text{ and } x \in X, \\ 0 & \text{if } y = f(x) \text{ and } x \notin X, \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Thus for any A extending σ, $x \in X$ if and only if $f(x) \in A$. The partial function σ is undefined on strings of length $\langle b_i \rangle_{i \in \mathrm{N}}$, so σ is an sp-condition. □

Of course, Lemma 3.2 does not imply that there is an sp-generic set G such that for every set X, X is polynomial-time Turing reducible to G. Lemma 3.2 only implies that all X such that the predicate "$X \in \mathrm{P}^A$" is first-order definable are encoded into all sp-generics.

4. P = FewP relative to sp-generics.

In this section, we will show that, relative to sp-generics, acceptance of nondeterministic machines with a small number of accepting paths can be decided in polynomial time.

THEOREM 4.1. *If A is an sp-generic oracle, then* $\mathbf{P}^A = \mathbf{FewP}^A$.

This proof will build on ideas from Blum and Impagliazzo [3], Hartmanis and Hemachandra [8], and Rackoff [18].

An immediate corollary follows.

COROLLARY 4.2. *For any sp-generic oracle A,* $\mathbf{P}^A = \mathbf{UP}^A$.

Let R_i be the requirement "Either there is some input x such that $M_i^A(x)$ has more than n^i accepting paths, or $L(M_i^A) \in \mathbf{P}^A$."

By our enumeration of Turing machines at the end of §2, if A satisfies R_i for all i, then $\mathbf{P}^A = \mathbf{FewP}^A$.

Fix i. The set of sp-conditions that force R_i is definable since R_i is a first-order proposition in A. We will show that the set of sp-conditions that force R_i is dense. Then any sp-generic A will extend a τ such that τ forces R_i. We will show that these sets are dense by showing how to extend any sp-condition τ to another condition σ such that σ forces R_i.

Let $M = M_i$ and let τ be an sp-condition. Suppose τ does not force "For all x, $M^A(x)$ has at most $|x|^i$ accepting paths." For some A extending τ and some x, we will have that

$M^A(x)$ has more than $|x|^i$ accepting paths. Let $\sigma = \tau \cup (A$ restricted to strings of length at most $|x|^i)$. Clearly σ extends τ and forces "For some x, $M^A(x)$ has more than $|x|^i$ accepting paths." To see that σ is an sp-condition, pick a c such that $a_c > |x|^i$ and let $b_j = a_{c+j}$ for all $j \in \mathbf{N}$.

For the rest of this section, we will assume τ forces "For all x, $M^A(x)$ has at most $|x|^i$ accepting paths."

By Lemma 3.2, there is an sp-condition σ extending τ such that σ forces $\mathbf{SAT}^{\overline{\tau}} \in \mathbf{P}^A$.

Suppose A extends σ. We will show that $L(M^A) \in \mathbf{P}^A$.

Consider the following algorithm for computing $M^A(x)$ using A as an oracle. The idea is the same as that used in [3]. We repeatedly look for *some* extension α of the partial oracle (not necessarily compatible with A) which makes M have the maximum possible number of accepting paths. To ensure consistency with A, we then answer all queries in the domain of α according to A.

In the algorithm below, we maintain the following invariants for all j:

- A extends γ_j,
- γ_{j+1} extends γ_j,
- $|\gamma_{j+1}| \leq |\gamma_j| + n^{i+1}$, and
- $\mathrm{dom}(\gamma_j) \cap \mathrm{dom}(\tau) = \emptyset$ (this fact is not crucial for the proof).

```
BEGIN ALGORITHM
  $\gamma_0 \leftarrow \emptyset$.
  FOR $j \leftarrow 0$ TO $|x|^{2i} - 1$ DO
     Let $n$ be the largest number for which there is an $\alpha$ extending $\gamma_j$ such that
        • $\alpha$ is compatible with $\tau$, and
        • $M^{\alpha\cup\tau}(x)$ has at least $n$ distinct accepting paths.
     Choose some $\alpha$ that satisfies these two conditions with minimal domain, meaning that
        dom($\alpha$) contains only those queries made along $n$ distinct accepting paths which are
        not in dom($\tau$). If $n = 0$, then $\alpha = \emptyset$.
     $\gamma_{j+1} \leftarrow$ ($A$ restricted to dom($\alpha$)).
     /* This trick is borrowed from [3]. It will be explained later. */
  ENDFOR
  $\gamma \leftarrow \gamma_{|x|^{2i}}$.        /* Note that A extends $\gamma$. */
  IF $M^{\gamma\cup\tau}(x)$ has an accepting path
     THEN accept
     ELSE reject.
END ALGORITHM.
```

Theorem 4.1 now follows from the following two lemmas.

LEMMA 4.3. *The above algorithm runs in polynomial time relative to* $\mathbf{SAT}^{\overline{\tau}}$ *and thus relative to* A.

Proof. We show that there is a fixed polynomial bound on both the size of γ_j and the running time of the jth iteration of the FOR loop for all $j < |x|^{2i}$. Assume, inside the jth iteration of the FOR loop, that γ_j has polynomial size. By our assumptions about the behavior of machine M on oracles extending τ, we have $0 \leq n \leq |x|^i$. For any such n, the question—given γ_j—of whether there exists an α extending γ_j compatible with τ such that $M^{\alpha\cup\tau}(x)$ has at least n accepting paths is an $\mathbf{NP}^{\overline{\tau}}$ question and hence can be answered by a single query to $\mathbf{SAT}^{\overline{\tau}}$ (such an α can always be chosen to have polynomial size: only include oracle queries not already in dom(τ) made along n distinct accepting paths). Thus n can be determined using polynomially many queries to $\mathbf{SAT}^{\overline{\tau}}$. Once n is found, a polynomial-size α causing $M^{\alpha\cup\tau}(x)$ to accept on n distinct paths can be constructed bit by bit in a straightforward way by making

$\mathbf{NP}^{\overline{\tau}}$ queries of the form "Given a sequence $\vec{v}$ of k bits, is there such an α whose first $k+1$ bits are $\vec{v}0$?" Similarly, we can construct the n paths. Once such an α is found, $\mathrm{dom}(\alpha)$ can be made to be minimal simply by eliminating any queries in $\mathrm{dom}(\alpha) - \mathrm{dom}(\gamma_i)$ not made along any accepting path of $M^{\alpha\cup\tau}(x)$; thus we can find a minimal α with at most polynomially many additional $\mathbf{NP}^{\overline{\tau}}$ queries. The size of $\mathrm{dom}(\alpha) - \mathrm{dom}(\gamma_j)$ is at most a polynomial in $|x|$ independent of j, so we can compute γ_{j+1} by asking polynomially many queries to A, and its size is the same as that of α. We thus have that for *all* $j \leq |x|^{2i}$, the size of γ_j and the running time of the jth iteration of the FOR loop are both bounded by a fixed polynomial in $|x|$, and thus the entire FOR loop runs in polynomial time, and $\gamma_{|x|^{2i}}$ has size polynomial in $|x|$.

Since after the FOR loop, γ has polynomial size, we can determine whether $M^{\gamma\cup\tau}(x)$ has an accepting path by asking one additional $\mathbf{NP}^{\overline{\tau}}$ question. Thus, the entire algorithm runs in polynomial time relative to A, which proves Lemma 4.3. □

LEMMA 4.4. *The above algorithm correctly decides $M^A(x)$.*

Proof. Suppose $M^A(x)$ has exactly k accepting paths. Let β be the partial function of minimal domain such that

- A extends β, and
- $M^{\beta\cup\tau}(x)$ has k distinct accepting paths.

Since $k \leq |x|^i$ and each path of $M^A(x)$ can make only $|x|^i$ queries, the size of $\mathrm{dom}(\beta)$ is at most $|x|^{2i}$ (if $k = 0$, then $\beta = \emptyset$).

CLAIM 4.5. *After the FOR loop, $\gamma_{|x|^{2i}} = \gamma$ extends β.*

Lemma 4.4 immediately follows from Claim 4.5 and the fact that A extends γ. Indeed, since $M^{\beta\cup\tau}(x)$ and $M^A(x)$ have the same number of accepting paths, we know that $M^{\gamma\cup\tau}(x)$ and $M^A(x)$ have the same number of accepting paths because extending a partial oracle can never decrease the number of accepting paths. Thus we accept if and only if $M^A(x)$ has at least one accepting path.

It remains only to prove Claim 4.5. This is similar to the incompatibility argument in [3]. It suffices to show that $\mathrm{dom}(\beta) \subseteq \mathrm{dom}(\gamma)$, since both β and γ are compatible with A. Suppose that for some $j < |x|^{2i}$ we have $\|\mathrm{dom}(\beta) - \mathrm{dom}(\gamma_j)\| = \ell > 0$. If the α chosen in the jth iteration of the FOR loop does not extend β, then it must be incompatible with β, otherwise the union $\beta \cup \alpha$ would cause $M^{\beta\cup\alpha\cup\tau}(x)$ to have at least one more accepting path than $M^{\alpha\cup\tau}(x)$ (the extra path is "contributed" by β). This contradicts the fact that α was chosen to allow the maximum possible number of accepting paths of $M^{\alpha\cup\tau}(x)$. Hence β and γ_{j+1} share at least one additional point in their domains, so $\|\mathrm{dom}(\beta) - \mathrm{dom}(\gamma_{j+1})\| \leq \ell - 1$. Since $\|\mathrm{dom}(\beta) - \mathrm{dom}(\gamma_0)\| \leq |x|^{2i}$, we must have $\|\mathrm{dom}(\beta) - \mathrm{dom}(\gamma)\| = 0$, which proves the claim. □

5. The isomorphism conjecture.

5.1. Intuition. In this section, we give some of the ideas of the proof that the isomorphism conjecture holds relative to sp-generic oracles. A full and complete proof is presented beginning in §5.2.

We first consider how researchers created oracles for which the isomorphism conjecture fails. Typically, they would create a hard function f^A and an oracle A such that $f^A(\mathbf{SAT}^A)$ is $\mathbf{NP}$-complete but not isomorphic to $\mathbf{SAT}^A$. One approach is to have f^A scramble $\mathbf{SAT}$ in a way that no reduction to $f^A(\mathbf{SAT}^A)$ could be invertible. Kurtz, Mahaney, and Royer used this approach to show that the isomorphism conjecture fails to a random oracle [16]. However, since we know that $\mathbf{P}^A = \mathbf{UP}^A$ for sp-generic oracles A (Corollary 4.2), any such scrambling function can be unscrambled.

When Kurtz showed that the isomorphism conjecture fails for regular generic oracles [12] and Hartmanis and Hemachandra created an oracle A relative to which the isomorphism conjecture fails while $\mathbf{P}^A = \mathbf{UP}^A \neq \mathbf{NP}^A$ [8], they had to use a different approach. They created functions f^A that work as follows: For φ a boolean formula represented as a string, define $\xi^A(\varphi)$ by

$$\xi^A(\varphi) = A(\varphi 01)A(\varphi 011)\ldots A(\varphi 01^n),$$

where n is the number of variables in φ. Let θ be a small true instance of $\mathbf{SAT}^A$ and define f^A by

$$f^A(\varphi) = \begin{cases} \theta & \text{if } \xi^A(\varphi) \text{ is a satisfying assignment of } \varphi, \\ \varphi & \text{otherwise.} \end{cases}$$

Note that for any oracle A and this kind of f^A, $f^A(\mathbf{SAT}^A)$ is $\mathbf{NP}^A$-complete. Using an A that encodes solutions to $\mathbf{SAT}^A$, Kurtz and Hartmanis and Hemachandra show that $f^A(\mathbf{SAT}^A)$ contains large gaps and, for reasons of density alone, cannot be isomorphic to $\mathbf{SAT}^A$.

In order to hint at how we prove our main result, we will describe how for sp-generic sets A, $f^A(\mathbf{SAT}^A)$ must be isomorphic to $\mathbf{SAT}^A$.

The oracles designed by Kurtz and Hartmanis and Hemachandra that prevent isomorphisms to $\mathbf{SAT}^A$ work by having $\xi^A(\varphi)$ be a satisfying assignment to φ. Since we are trying to create an oracle A such that the isomorphism conjecture holds, we will call the computation $f^A(\varphi)$ *bad* if $\xi^A(\varphi)$ is a satisfying assignment to φ, and all other computations $f^A(\varphi)$ we will call *good*. Note that if $f^A(\varphi)$ is good, then $f^A(\varphi) = \varphi$. Whether $f^A(\varphi)$ is good will, of course, depend on A.

Berman and Hartmanis [2] show that in order to have $\mathbf{SAT}^A$ isomorphic to $f^A(\mathbf{SAT}^A)$ we need only find a polynomial-time one–one length-increasing invertible function g^A that reduces $\mathbf{SAT}^A$ to $f^A(\mathbf{SAT}^A)$. Our $g^A(\varphi)$ will work as follows: Find a formula ψ such that

1. $|\psi| > |\varphi|$,
2. ψ is true relative to A iff φ is true relative to A,
3. $f^A(\psi)$ is good.

Then $g^A(\varphi) = f^A(\psi) = \psi$ is our reduction. The trick is for $g^A(\varphi)$ to find such a ψ.

We use a straightforward combinatorial argument to show that there exists an invertible polynomial-time function $h(\varphi, w)$ such that the following hold:

1. For all w, $|h(\varphi, w)| > |\varphi|$.
2. For all w and sp-generic A, $h(\varphi, w)$ is true relative to A if and only if φ is true relative to A.
3. For all sp-generic A, there exists a w such that $f^A(h(\varphi, w))$ is good.

Now all g^A has to do is find a w such that $f^A(h(\varphi, w))$ is good. We will use f^A to help g^A in this task.

Let $s(\varphi)$ be the formula that encodes the **NP** statement "φ is true and there exists a w such that $f^A(h(\varphi, w))$ is good." Clearly, for A, $|s(\varphi)| > |\varphi|$ and $s(\varphi)$ is true if and only if φ is true because there always is a w such that $f^A(h(\varphi, w))$ is good.

We now create $g^A(\varphi)$ as follows: Look at the computation of $f^A(s(\varphi))$. If $f^A(s(\varphi))$ is good, then output $f^A(s(\varphi)) = s(\varphi)$. Otherwise, $\xi^A(s(\varphi))$ is a satisfying assignment to $s(\varphi)$, and thus from $\xi^A(s(\varphi))$, we can obtain a w such that $f^A(h(\varphi, w))$ is good. The function g^A then outputs $f^A(h(\varphi, w)) = h(\varphi, w)$ for that w. Notice that g^A is not only length-increasing but also one–one and invertible.

Of course there is no a priori reason that a general reduction has to act like f^A. We will, however, force a general f^A to look similar to the f^A described above or not be a reduction.

Suppose f^A reduces $\mathbf{SAT}^A$ to $L(M^A)$, where f^A is an arbitrary deterministic function running in time n^i and M^A is a nondeterministic Turing machine also running in time n^i. Let us define $h(\varphi, w)$ to be a formula that encodes the following:

$$(\varphi \wedge \exists y \langle \varphi, w, y, 1\rangle \in A) \vee \exists y \langle \varphi, y, 0\rangle \in A,$$

where the y's are quantified over strings of length exactly $|\varphi|^i$. If we put at least one string of the form $\langle \varphi, w, y, 1\rangle$ into A and no strings of the form $\langle \varphi, y, 0\rangle$ into A, then φ is true if and only if $h(\varphi, w)$ is true.

We now need a notion of goodness for $f^A(h(\varphi, w))$ for arbitrary f^A. We would like to call $f^A(h(\varphi, w))$ good if $f^A(h(\varphi, w))$ fails to find a satisfying assignment to $h(\varphi, w)$. However such a thing could be hard to verify. We could, however, determine which queries to A are made by $f^A(h(\varphi, w))$. Thus we call $f^A(h(\varphi, w))$ good if $f^A(h(\varphi, w))$ does not query any string $\langle \varphi, w, y, 1\rangle$ such that $\langle \varphi, w, y, 1\rangle \in A$, i.e., $f^A(h(\varphi, w))$ does not find this part of a satisfying assignment to $h(\varphi, w)$. If $f^A(h(\varphi, w))$ is good, then we can alter the truth value of $h(\varphi, w)$ without affecting the value $f^A(h(\varphi, w))$.

Suppose $f^A(h(\varphi, w))$ is good and $q = |f^A(h(\varphi, w))| \leq |\varphi|$. Then $M^A(q)$ cannot ask questions of the form $\langle \varphi, w, y, 1\rangle$ or $\langle \varphi, y, 0\rangle$ because they are too long. We can prevent f^A from being a reduction by setting $h(\varphi, w)$ to true if $M^A(q)$ rejects or setting $h(\varphi, w)$ to false if $M^A(q)$ accepts.

Suppose $f^A(h(\psi, w_1)) = f^A(h(\theta, w_2))$ and neither of these computations ask questions about whether $\langle \psi, w_1, y, 1\rangle$, $\langle \psi, y, 0\rangle$, $\langle \theta, w_2, y, 1\rangle$, or $\langle \theta, y, 0\rangle$ are in A. Then we can prevent f^A from being a reduction by setting $h(\psi, w_1)$ to true and $h(\theta, w_2)$ to false.

We can combine the above techniques under the auspices of sp-generics to produce a reduction g that is length-increasing and almost one–one. Using the fact that $\mathbf{P}^A = \mathbf{FewP}^A$ for sp-generic A and applying this construction twice we can produce a one–one length-increasing reduction g. Grollmann and Selman [7] show that we get g invertible for free since $\mathbf{P}^A = \mathbf{UP}^A$ for sp-generic A.

5.2. Proof of the relativized isomorphism conjecture. In order to formally prove Theorem 1.1, we need the following technical lemma, whose proof we defer to §5.3.

LEMMA 5.1. *Let A be an sp-generic set, M^A a relativized nondeterministic polynomial-time Turing machine, and f^A a relativized polynomial-time reduction from* $\mathbf{SAT}^A$ *to $L(M^A)$. There is a polynomial-time function g^A and a polynomial $p(n)$ such that the following hold*:

1. *g^A reduces* $\mathbf{SAT}^A$ *to $L(M^A)$*;
2. *g^A is length increasing*;
3. *for all $q \in \Sigma^*$, if $\|g^{A(-1)}(q)\| > 1$, then*
   (a) $\|f^{A(-1)}(q)\| > 1$,
   (b) *q is in $L(M^A)$*,
   (c) $\|g^{A(-1)}(q)\| \leq p(|q|)$.

Proof of Theorem 1.1 (*assuming Lemma* 5.1). Let L be $\mathbf{NP}^A$-complete. There must exist a nondeterministic polynomial-time machine M and a polynomial-time function f such that $L = L(M^A)$ and f^A reduces $\mathbf{SAT}^A$ to L. Apply Lemma 5.1 and let g^A be the function that fulfills the properties of this lemma.

Let $T = \{q \mid \|g^{A(-1)}(q)\| > 1\}$. Note that T is in $\mathbf{FewP}^A$ because of 2 and 3(c), and thus T is in $\mathbf{P}^A$ since $\mathbf{P}^A = \mathbf{FewP}^A$ relative to sp-generic oracles (Theorem 4.1).

Let θ be a fixed member of $\mathbf{SAT}^A$ such as $(\exists x)x \vee \overline{x}$. Define $\hat{f}^A(\varphi)$ as follows:

$$\hat{f}^A(\varphi) = \begin{cases} g^A(\theta) & \text{if } g^A(\varphi) \in T, \\ g^A(\varphi) & \text{otherwise.} \end{cases}$$

Note that $\hat{f}^A$ is a reduction from $\mathbf{SAT}^A$ to L because of 3(b).

Apply Lemma 5.1, this time to $\hat{f}^A$, and let $\hat{g}^A$ be the resulting function. Note that the only possible q such that $\|\hat{g}^{A(-1)}(q)\| > 1$ is $q = g^A(\theta)$ because of 3(a).

Let $G^A(\varphi) = \hat{g}^A(P(\varphi, q))$, where P is the padding function for $\mathbf{SAT}^A$. Berman and Hartmanis [2] show that the claim below immediately implies that $\mathbf{SAT}^A$ is p^A-isomorphic to L. □

CLAIM 5.2. *The function G^A is a one–one length-increasing reduction from* $\mathbf{SAT}^A$ *to L whose inverse is computable in* $\mathbf{FP}^A$.

Clearly G^A is a reduction. Since $\hat{g}^A$ and P are length increasing, then G^A is length increasing. Also, G^A is one–one. Suppose $G^A(\varphi) = G^A(\psi)$; then $\hat{g}^A(P(\varphi, q)) = \hat{g}^A(P(\psi, q)) = q$, but this contradicts the fact that $\hat{g}^A$ is length increasing.

By Corollary 4.2, we know that $\mathbf{P}^A = \mathbf{UP}^A$. Grollmann and Selman [7] show that $\mathbf{P}^A = \mathbf{UP}^A$ implies that all one–one length-increasing polynomial-time functions relative to A are invertible relative to A. This proves the claim. □

5.3. Proof of Lemma 5.1. We define requirement R_i as follows: "Lemma 5.1 holds for $f^A = f_i^A$ and $M^A = M_i^A$." Note that by the definitions of f_i and M_i in §2, all pairs of reductions and machines will be covered by some R_i.

Fix i. Let S_i be the set of sp-conditions that force R_i. Since the statement of Lemma 5.1 is first-order definable in A, we have that S_i is a definable set of conditions. We need now show that S_i is dense. Then any sp-generic A will extend a τ such that τ forces R_i. We will show S_i is dense by showing how to extend any sp-condition τ to another condition σ such that σ forces R_i.

Fix i and let τ be an sp-condition and $\langle a_j \rangle_{j \in \mathbf{N}}$ be the corresponding iterated-polynomial sequence. We will create an sp-condition σ with corresponding sequence $\langle b_j \rangle_{j \in \mathbf{N}}$ that forces R_i. Let $f = f_i$ and $M = M_i$.

Suppose τ does not force "f^A reduces $\mathbf{SAT}^A$ to $L(M^A)$." For some A extending τ and some φ, we will have that either φ is true and $f^A(\varphi) \notin L(M^A)$ or φ is false and $f^A(\varphi) \in L(M^A)$. Let $m = \max(|\varphi|^i, |f^A(\varphi)|^i)$. Let $\sigma = \tau \cup$ (A restricted to strings of length at most m). Clearly, σ extends τ and forces "f^A does not reduce $\mathbf{SAT}^A$ to $L(M^A)$" and thus forces R_i. To see that σ is an sp-condition, pick a c such that $a_c > m$ and let $b_j = a_{c+j}$ for all $j \in \mathbf{N}$.

For the remainder of this proof we will assume that τ forces "f^A reduces $\mathbf{SAT}^A$ to $L(M^A)$."

Pick an e such that $a_{j+e} > a_j^{3i}$ for all j. Since $p(n) \geq n^2$ for all n by Definition 3.1, any $e > \log_2(3i)$ will suffice. Pick a c such that a_c is sufficiently large to avoid all the degenerate cases in this proof. For all j, let $b_j = a_{c+2ej}$ and $d_j = a_{c+2ej+e}$. This proof will never do any encoding on strings of length b_j, guaranteeing that σ is an sp-condition. In fact, all of the interesting coding for σ will occur for strings of length d_j. Initially, set $\sigma = \tau$ and also define $\sigma(x) = 0$ for every $x \notin \mathrm{dom}(\tau)$ such that x does not have length b_j or d_j for some j.

Let φ be an arbitrary $\mathbf{CNF}^A$ formula. Pick the smallest j such that $d_j > 4|\varphi|^i$. We define special tupling functions $\langle \varphi, y, 0 \rangle$, $\langle \varphi, w, y, 1 \rangle$, and $\langle \varphi, w, y, 2 \rangle$ where we are only interested in w and y as they range over strings of length $\lfloor d_j/4 \rfloor$. We design these tupling functions so that they have disjoint ranges over strings of length exactly d_j. Since $|\varphi|$, $|y|$, and $|w|$ are all bounded by $d_j/4$, such an encoding is not hard to achieve.

Let $h(\varphi, w)$ be the formula that encodes

$$(\varphi \wedge \exists y \langle \varphi, w, y, 1 \rangle \in A) \vee \exists y \langle \varphi, y, 0 \rangle \in A.$$

In other words, create a nondeterministic oracle Turing machine M such that M^A accepts if this expression is true and apply the relativized version of Cook's theorem, mentioned in §2. We will have $|h(\varphi, w)| = O(d_j^2)$.

Define $\mathbf{f}^A(h(\varphi, w))$ as follows: Simulate $f^A(h(\varphi, w))$. Whenever $f^A(h(\varphi, w))$ queries a string of the form $\langle \varphi', w', z, 1 \rangle$, $\mathbf{f}^A$ will query $\langle \varphi', w', z, 2 \rangle$.

We say the computation $\mathbf{f}^A(h(\varphi, w))$ is *good* if, for all z, $\mathbf{f}^A(h(\varphi, w))$ queries $\langle \varphi, w, z, 2 \rangle$ then $\langle \varphi, w, z, 2 \rangle \notin A$. Note that whether $\mathbf{f}^A(h(\varphi, w))$ is good does not depend on whether any string of the form $\langle \varphi', w', z, 1 \rangle$ is in A.

Let $r(\varphi)$ be the formula that encodes

$$\exists w[(\exists y \langle \varphi, w, y, 1 \rangle \in A) \text{ and } \mathbf{f}^A(h(\varphi, w)) \text{ is good}].$$

Let $s(\varphi)$ be the formula that encodes

$$(\varphi \wedge r(\varphi)) \vee \exists y \langle \varphi, y, 0\rangle \in A.$$

By suitable padding in Cook's theorem [4], we can construct s and h such that each is one–one and range$(h) \cap$ range$(s) = \emptyset$. Note that h, r, and s can be computed in unrelativized polynomial time.

LEMMA 5.3. *There is a way to set σ on the strings of length $\langle d_j \rangle_{j\in\mathrm{N}}$ such that the following hold:*

1. *σ forces "For every formula φ, $r(\varphi)$ is true."*
2. *For every φ and w, there is exactly one y such that $\sigma(\langle \varphi, w, y, 1\rangle) = 1$.*
3. *For all φ and y, $\sigma(\langle \varphi, y, 0\rangle) = 0$.*
4. *For all φ, y, and w, $\sigma(\langle \varphi, w, y, 1\rangle) = \sigma(\langle \varphi, w, y, 2\rangle)$.*

This is a combinatorial lemma that follows mainly because there are many more ways to set σ than there are extensions to σ that $\mathbf{f}^A(h(\varphi, w))$ could query. We will give a complete proof of Lemma 5.3 in §5.4.

Note that $\mathbf{f}^A(h(\varphi, w)) = f^A(h(\varphi, w))$ for all w and A where A extends σ. Also note that σ forces "For every φ and w, φ is true if and only if $h(\varphi, w)$ is true if and only if $s(\varphi)$ is true."

We now describe the algorithm for $g^A(\varphi)$.

```
BEGIN ALGORITHM
 (1) Simulate $f^A(s(\varphi))$ and let $S$ be the set of $w$ such that $f^A(s(\varphi))$ queried a string of the
     form $\langle \varphi, w, y, 1\rangle$.
 (2) If for some $w \in S$, $\mathbf{f}^A(h(\varphi, w))$ is good, then output $\mathbf{f}^A(h(\varphi, w))$ for the first such $w$.
 (3) Otherwise output $f^A(s(\varphi))$.
END ALGORITHM.
```

CLAIM 5.4. *For any A extending σ, the function g^A is a reduction from* $\mathbf{SAT}^A$ *to $L(M^A)$.*

Proof. The fact that g^A is a reduction now follows from the construction of g^A and the fact that τ forces f^A to be a reduction. □

We now show that σ forces g^A to fulfill conclusions (2) and (3)(a–c) of Lemma 5.1. We will show that if there exists an oracle A extending σ such that g^A fails to fulfill these conditions, then there exists an oracle B extending τ such that f^B does not reduce $\mathbf{SAT}^B$ to $L(M^B)$. This contradicts the assumption that τ forces f^B to be such a reduction.

We will create a B that disagrees with A only on strings longer than formulas involved in the assumed failure of some part of (2) or (3)(a–c) for g^A. This will guarantee that the truth values of these formulas will remain unchanged.

First, we show that the sp-condition σ forces that g^A is length-increasing, thus fulfilling condition (2) of Lemma 5.1.

Suppose by way of contradiction that $|g^A(\varphi)| \leq |\varphi|$. Let $q = g^A(\varphi)$. Note that $M^A(q)$ cannot look at any string of the form $\langle \varphi, y, 0\rangle$, $\langle \varphi, w, y, 1\rangle$, or $\langle \varphi, w, y, 2\rangle$ because they are too long.

We have two cases each with two subcases.

1. $q = \mathbf{f}^A(h(\varphi, w))$ output by the algorithm for $g^A(\varphi)$ in step (2):
   (a) $M^A(q)$ rejects. There must be some y such that $f^A(h(\varphi, w))$ did not query $\langle \varphi, y, 0\rangle$. Then with $B = A \cup \{\langle \varphi, y, 0\rangle\}$, f^B would not be a reduction.
   (b) $M^A(q)$ accepts. By the definition of the functions g^A and $\mathbf{f}^A$ and by parts (3) and (4) of Lemma 5.3, we have that $f^A(h(\varphi, w))$ queries $\langle \varphi, w, z, 1\rangle$ only if $\langle \varphi, w, z, 1\rangle \notin A$. Then with B equal to A minus all strings of the form $\langle \varphi, w, z, 1\rangle$, f^B would not be a reduction.
2. $q = f^A(s(\varphi))$ output by the algorithm for $g^A(\varphi)$ in step (3):
   (a) $M^A(q)$ rejects. There must be some y such that $f^A(s(\varphi))$ did not query $\langle \varphi, y, 0\rangle$. Then with $B = A \cup \{\langle \varphi, y, 0\rangle\}$, f^B would not be a reduction.

(b) $M^A(q)$ accepts. Let S be the set from the definition of g^A. Let B equal A minus all strings of the form $\langle\varphi, w, z, 1\rangle$ for $w \notin S$. If $r(\varphi)$ is false relative to B, then f^B is no longer a reduction since $f^B(s(\varphi)) = f^A(s(\varphi)) = q$, $s(\varphi)$ is false relative to B, and $q \in L(M^B)$.
Suppose $r(\varphi)$ is true relative to B. By the definition of $r(\varphi)$, we have that for some $w \in S$, $\mathbf{f}^B(h(\varphi, w))$ is good. Note that the computation of $\mathbf{f}^B(h(\varphi, w))$ is identical to the computation of $\mathbf{f}^A(h(\varphi, w))$. Since $\mathbf{f}^B(h(\varphi, w))$ is good, then $\mathbf{f}^A(h(\varphi, w))$ is also good, and so the algorithm for g^A would have output $\mathbf{f}^A(h(\varphi, w))$ in step (2).

Thus g^A is length increasing.

Suppose for some A extending σ and some q, $\|g^{A(-1)}(q)\| > 1$. Clearly, by the definition of g^A and the fact that h and s are both one–one with range$(h) \cap$ range$(s) = \emptyset$, $\|f^{A(-1)}(q)\| > 1$. Thus we have fulfilled condition (3)(a) of Lemma 5.1. We need to show how to fulfill conditions (3)(b) and (3)(c).

Suppose $q \notin L(M^A)$. Let ψ and η be such that $g^A(\psi) = g^A(\eta) = q$. We can assume without loss of generality that $|\psi| \le |\eta| < |q|$. There must be some y such that neither $g^A(\psi)$ nor $g^A(\eta)$ queries $\langle\eta, y, 0\rangle$. Let $B = A \cup \{\langle\eta, y, 0\rangle\}$. Suppose $g^A(\psi) = f^A(\nu)$ and $g^A(\eta) = f^A(\mu)$ for some formulas μ and ν. Then $f^B(\nu) = f^B(\mu) = q$ but ν is false and μ is true relative to B, and thus f^B is not a reduction. Thus we have fulfilled condition (3)(b) of Lemma 5.1.

We will now show how to fulfill condition (3)(c) with $p = t+2$ where t is the running time of g^A. Suppose $q \in L(M^A)$ and $\|g^{A(-1)}(q)\| \ge p(|q|) = t(|q|) + 2$. Let ψ be a minimum-length formula such that $g^A(\psi) = q$. By the pigeonhole principle, there is some formula $\eta \ne \psi$ such that $g^A(\eta) = q$ and $g^A(\psi)$ does not ask any queries of the form $\langle\eta, w, z, 1\rangle$ or $\langle\eta, w, z, 2\rangle$. Suppose $g^A(\psi) = f^A(\nu)$ for some formula ν.

Note that the value $f^A(\nu)$ and the truth value of ν cannot depend on whether strings of the form $\langle\eta, w, z, 1\rangle$ are in A. Since $g^A(\psi)$ simulates $f^A(\nu)$ and $g^A(\psi)$ does not ask any queries of the form $\langle\eta, w, z, 1\rangle$, then $f^A(\nu)$ does not ask any queries of the form $\langle\eta, w, z, 1\rangle$. The truth value of ν can only depend on whether strings of the form $\langle\psi, y, 0\rangle$, $\langle\psi, w, y, 1\rangle$, and $\langle\psi, w, y, 2\rangle$ are in A and the truth value of ψ and whether $\mathbf{f}^A(h(\psi, w))$ is good for some w. None of these depend on whether strings of the form $\langle\eta, w, z, 1\rangle$ are in A.

We have two cases.

1. $q = g^A(\eta) = \mathbf{f}^A(h(\eta, w))$ output by the algorithm for $g^A(\eta)$ in step (2). By the definition of g^A and $\mathbf{f}^A$ and by Lemma 5.3, we have that $f^A(h(\eta, w))$ queries $\langle\eta, w, z, 1\rangle$ only if $\langle\eta, w, z, 1\rangle \notin A$. Thus if we let B equal A minus all strings of the form $\langle\eta, w, z, 1\rangle$, the following four properties hold:
   (a) $h(\eta, w)$ is false relative to B,
   (b) ν is true,
   (c) $f^B(h(\eta, w)) = f^A(h(\eta, w)) = \mathbf{f}^A(h(\eta, w)) = g^A(\eta) = q$, and
   (d) $q = g^A(\psi) = f^A(\nu) = f^B(\nu)$.
   Thus f^B will not be a reduction.
2. $q = f^A(s(\eta))$ output in step (3) of the algorithm. Let S be the set from the definition of g^A. Let B equal A minus all strings of the form $\langle\eta, w, z, 1\rangle$ for $w \notin S$. Note that $f^B(s(\eta)) = f^A(s(\eta))$. Also, $r(\eta)$ is false relative to B for the same reasons as in case (2)(b) of the proof of condition (2) above, and thus $s(\eta)$ is also false relative to B. Thus
$$f^B(s(\eta)) = f^A(s(\eta)) = g^A(\eta) = q = g^A(\psi) = f^A(\nu) = f^B(\nu)$$
and ν is true relative to B, and thus f^B is not a reduction.

Thus we have fulfilled condition (3c). We have now fulfilled all of the conditions of Lemma 5.1. □

5.4. Proof of Lemma 5.3. We will use relativized Kolmogorov complexity for this proof. For an excellent background in Kolmogorov complexity, see the book by Li and Vitányi [17].

We need to find a σ extending τ that fulfills the conditions of Lemma 5.3. Note that by our construction of the d_j sequence, we have that $d_j > d_{j-1}^{9i^2}$. Fix j and let ℓ be the least integer such that $d_{j-1} \leq 4\ell^i$ and u be the greatest integer such that $d_j > 4u^i$. For $j = 0$, let $\ell = 0$. The values ℓ and u bound the lengths of formulae φ such that $\langle \varphi, y, 0\rangle$, $\langle \varphi, w, y, 1\rangle$, and $\langle \varphi, w, y, 2\rangle$ all have length d_j.

Let $z = |w| = |y| = \lfloor d_j/4 \rfloor$. Let $m = z2^z \sum_{\ell \leq e \leq u} 2^e$. Let x be a string of length m such that $K^{\overline{\tau}}(x) \geq m$, i.e., x is Kolmogorov random with respect to $\overline{\tau}$.

View x as a concatenation of strings $x_{\varphi,w}$ of length z, where φ ranges over all formulae of length between ℓ and u and w ranges over all strings of length z. Set $\sigma(\langle \varphi, w, x_{\varphi,w}, 1\rangle) = \sigma(\langle \varphi, w, x_{\varphi,w}, 2\rangle) = 1$ for all φ and w, and set σ to zero for all other strings of length d_j.

Clearly, this σ fulfills conditions (2)–(4) of Lemma 5.3. We still need to show that σ forces "For all formula φ, $r(\varphi)$ is true."

Suppose there is some oracle A extending σ such that for some formula φ, $r(\varphi)$ is false relative to A. We will show how to describe x with a string of length much shorter than x, contradicting the fact that x is Kolmogorov random.

Recall that $h(\varphi, w)$ has length $O(d_j^2)$. Thus $\mathbf{f}^A(h(\varphi, w))$ has running time at most $O(d_j^{2i})$. Thus $\mathbf{f}^A$ can only depend on the strings in $A' = A^{<b_{j+1}}$.

Initialize B to be A' with all the strings of the form $\langle \varphi, w, y, 2\rangle$ removed.

Create a string v as follows:

```
1. Initially set $v = \epsilon$.
2. For $w$ ranging over strings of length $z$ do the following:
   (a) For $j = 1$ to $|h(\varphi, w)|^i$,
           if the $j$th query of $\mathbf{f}^A(h(\varphi, w))$ exists and is a string $\langle \varphi, w', y, 2\rangle \in A' - B$,
           then mark $j$ and add $\langle \varphi, w', y, 2\rangle$ to $B$.
   (b) Concatenate to $v$ the number of marked $j$ followed by a list of marked $j$. Write
       these numbers with leading zeros if necessary to keep the lengths consistent in
       order to make the encoding simpler.
```

The orders in which w and j are chosen in this procedure play an important role in allowing us to keep the description of A' small.

Since $r(\varphi)$ is false relative to A then for every w, $\mathbf{f}^A(h(\varphi, w))$ queries the unique string of the form $\langle \varphi, w, y, 2\rangle$ in A (and thus in A'). Thus every such string will be added to B in step w of the above procedure if not before. At the end of this procedure, we will have $B = A'$.

The length of v is bounded by $O(2^z \log d_j)$ because there are 2^z strings in $A' - B$ initially. Note that each $\langle \varphi, w, y, 2\rangle \in A'$ can only contribute to one marking.

Now we claim that we can construct A' and thus x using an oracle for $\overline{\tau}$ and the tuple $\langle A^{\leq b_j}, v, \varphi, x'\rangle$, where x' is the concatenation of $x_{\psi,w}$ for all formulae $\psi \neq \varphi$ of length between ℓ and u, and w ranging over all strings of length z. We can reconstruct A' by repeating the procedure above using v to tell us which queries of the form $\langle \varphi, w, y, 2\rangle$ are in A'.

We can encode the tuple $\langle A^{\leq b_j}, v, \varphi, x'\rangle$ as a string of length $|A^{\leq b_j}| + |v| + |\varphi| + |x'|$ plus an additional $O(d_j)$ bits to encode the length of each piece.

The total length is bounded by $O(d_j) + 2^{b_j+1} + O(2^z \log d_j) + d_j + m - z2^z < m - O(1)$. There might exist a finite number of j such that this inequality fails. We can eliminate this possibility by an appropriate choice of a_c in the beginning of §5.3.

We have created a fixed Turing machine that outputs x with oracle $\overline{\tau}$ and input $\langle A^{\leq b_j}, v, \varphi, x'\rangle$, a tuple whose length is strictly less than $|x|$. This contradicts the fact that x was Kolmogorov random relative to $\overline{\tau}$. □

6. Conclusions and open questions. Later work by Fenner, Fortnow, Kurtz, and Li [5] show that relative to sp-generics, $\mathbf{P} = \mathbf{BPP} = \mathbf{NP} \cap \text{co-}\mathbf{NP} = \mathbf{SPP}$ but the polynomial-time hierarchy is proper. They also look at notions of genericity in a broader sense and show several interesting oracle results based on these ideas.

We have shown that relative to sp-generic oracles the isomorphism conjecture holds. Several obvious open questions remain:

- Does the isomorphism conjecture hold in the unrelativized world? Despite Theorem 1.1, the authors believe the evidence supports the position that the conjecture does not hold. Theorem 1.1 shows that a proof of this result will require nonrelatizing techniques.
- How complicated must an oracle A be such that the isomorphism conjecture holds relative to A? By Lemma 3.2 we can easily see that there are no sp-generic oracles in the arithmetic hierarchy. However, we can fulfill just the requirements necessary for the isomorphism conjecture with a set recursive in the halting problem.
- Is there a recursive oracle A? One could wonder whether we could recursively fulfill all the necessary requirements. We could use time-bounded Kolmogorov complexity in §5.4, but determining whether τ forces f to be a reduction is not decidable. However, we believe that a careful finite-injury argument could lead to a recursive oracle.
- Is there an oracle relative to which the isomorphism conjecture is true and the polynomial-time hierarchy collapses? A related question is whether there exists an oracle A such that $\mathbf{P}^A = \mathbf{UP}^A$ and $\mathbf{NP}^A = \mathbf{EXP}^A$. This oracle A also would imply that the isomorphism conjecture holds (see [10]).

Acknowledgments. This paper grew from discussions at the Dagstuhl workshop on structural complexity theory with many people, especially Ted Slaman, Bill Gasarch, Steve Homer, and Alan Selman.

We would like to thank other people for helpful discussions on the isomorphism conjecture over time: Steve Mahaney, Jim Royer, and Mike Sipser.

We also thank Richard Beigel, Bill Gasarch, Steve Homer, and Jim Royer for their comments on earlier drafts of this paper. We would also like to thank the anonymous referee for his or her extensive comments.

And, of course, we would like to acknowledge Juris Hartmanis for bringing this challenging problem to the world.

Note added in proof. John Rogers [21], extending the ideas in this paper, has created a relativized world where the isomorphism conjecture holds and $\mathbf{P} \neq \mathbf{UP}$, i.e., one-way functions exist.

A UNIFIED APPROACH TO DYNAMIC POINT LOCATION, RAY SHOOTING, AND SHORTEST PATHS IN PLANAR MAPS*

YI-JEN CHIANG†, FRANCO P. PREPARATA†, AND ROBERTO TAMASSIA†

Abstract. We describe a new technique for dynamically maintaining the trapezoidal decomposition of a connected planar map $\mathcal{M}$ with n vertices and apply it to the development of a unified dynamic data structure that supports point-location, ray-shooting, and shortest-path queries in $\mathcal{M}$. The space requirement is $O(n \log n)$. Point-location queries take time $O(\log n)$. Ray-shooting and shortest-path queries take time $O(\log^3 n)$ (plus $O(k)$ time if the k edges of the shortest path are reported in addition to its length). Updates consist of insertions and deletions of vertices and edges, and take $O(\log^3 n)$ time (amortized for vertex updates). This is the first polylog-time dynamic data structure for shortest-path and ray-shooting queries. It is also the first dynamic point-location data structure for connected planar maps that achieves optimal query time.

Key words. point location, ray shooting, shortest path, computational geometry, dynamic algorithm

AMS subject classifications. 68U05, 68Q25, 68P05, 68P10

1. Introduction.

A number of operations within the context of planar maps (or subdivisions, as determined by a planar graph embedded in the plane) have long been regarded as important primitives in computational geometry. First and foremost among these operations is planar point location, i.e., the identification of the map region containing a given query point; shortest-path and ray-shooting queries have also been considered very prominently.

Starting with the pioneering work in planar point location of the 1970s [10], [18], over the years several techniques have been developed, culminating in asymptotically time- and space-optimal methods [12], [17], [29] that are also of sufficiently practical flavor. Such methods, however, refer to the *static* case where no alteration of the map is allowed during its use. Due to the obvious importance of the *dynamic* setting, in recent years considerable attention has been devoted to the development of dynamic point-location algorithms [2], [6], [8], [14], [15], [21], [25], [26], [31].

All the known dynamic point-location results are for connected maps, since maintaining region names in a disconnected map would require solving half-planar range searching in a dynamic environment, for which no polylog-time algorithm is known. The best results to date for dynamic point location in an n-vertex connected map are due to Cheng and Janardan [6] and Baumgarten, Jung, and Mehlhorn [2]. The technique of [6] achieves $O(\log^2 n)$ query time, $O(\log n)$ update time, and $O(n)$ space. The data structure of [2] has query and insertion time $O(\log n \log\log n)$ and deletion time $O(\log^2 n)$, using $O(n)$ space, where the time bounds are amortized for the updates. In many real-time applications, point-location queries are executed more frequently than updates, so that it is often desirable to achieve optimal $O(\log n)$ query time in a dynamic setting. The only previous technique that supports $O(\log n)$-time queries in a dynamic environment is restricted to monotone maps [8]. For a survey of dynamic point-location techniques and other dynamic algorithms in computational geometry, see Chiang and Tamassia [9].

Algorithmic research on shortest-path and ray-shooting queries has also experienced steady progress, resulting in time-optimal techniques for the static setting [1], [5], [7], [16],

[19]. In particular, the linear-space data structures of Chazelle and Guibas [5] and of Guibas and Hershberger [16] support in $O(\log n)$ time ray-shooting and shortest-path queries, respectively, in a simple polygon with n vertices. No polylog-time method was previously known in a dynamic setting, although a polylog-time ray-shooting technique by Reif and Sen [28], designed for monotone polygons, may be extensible to the general case. Sublinear-time techniques are known only for ray-shooting queries [1], [7], with $O(\sqrt{n}\,\text{polylog}(n))$ query/update time; they support ray shooting in a set of possibly intersecting segments without taking advantage of the structure of planar maps.

A property that appears to greatly facilitate the development of dynamic point-location techniques is *monotonicity* [8], [15], [25]. Whereas the restriction to monotone maps is quite adequate for many important applications, the exclusion of more general maps is a severe shortcoming. In the static case, a connected map can be reduced to monotone (or, as we say in this paper, *normalized*) by the straightforward insertion of (auxiliary) diagonals. The same approach, when attempted for the dynamic setting, could lead to onerous updates, such as when the insertion of an edge causes the removal of a very large number of normalizing diagonals. A rather complicated and only partially documented technique due to Fries [13] is reported to assure that only a logarithmic number of normalizing diagonals be involved in any update.

In this paper we combine the feature just stated with the underpinnings of the trapezoid method, whose search efficiency both in theory [4], [23] and practice [11] is well established. This leads to the adoption of horizontal normalizing diagonals, called *lids*. The method rests on three major components:

1. a *normalization structure* that transforms a connected map into a monotone one by the addition of horizontal diagonals, while guaranteeing that no more than a logarithmic number of such diagonals are affected by insertions/deletions of edges/vertices,
2. a *hull structure* that stores the convex hulls of the chains and subchains of the monotone subregions, so that ray-shooting and shortest-path queries can be efficiently performed,
3. a *location structure* that represents a recursive decomposition of the normalized map into trapezoidal regions, and supports point-location queries in optimal time.

It is important to underscore that a single tree structure—the normalization structure—provides the unifying framework for the three applications considered. In fact, this structure, while ensuring efficient updates by controlling the size of the modifications, can be naturally augmented with node-appended secondary structures to support shortest-path and ray-shooting queries. It can also be supplemented with a distinct, but tightly coupled, location structure designed for efficient point location. The main normalization structure and its two auxiliary components act in a tightly integrated fashion. Point location is crucially used in shortest-path and ray-shooting queries and in the update of the normalization structure.

The fundamental constituents of our data structures are monotone chains and trapezoids determined by edges and horizontal lines through vertices. This provides the unifying framework for the three applications mentioned earlier. Indeed, a simple augmentation of the normalization structure provides the right environment for all three queries, as we shall illustrate. It should be underscored that, although their linkings are obviously elaborate, the elementary data structures employed are particularly simple, so that not only asymptotic efficiency is established, but also practical potential is apparent.

Our main results are outlined in the following theorem.

THEOREM 1.1. *There exists a fully dynamic data structure that supports point-location, ray-shooting, and shortest-path queries in a connected planar map $\mathcal{M}$ with n vertices. The space requirement is $O(n \log n)$. Point-location queries take time $O(\log n)$. Ray-shooting and shortest-path queries take time $O(\log^3 n)$ (plus $O(k)$ time if the k edges of a shortest path* *are reported in addition to its length*). *Updates take* $O(\log^3 n)$ *time* (*amortized for vertex updates*).

As a corollary, we can also perform stabbing queries, i.e., determine the k edges of map $\mathcal{M}$ intersected by a query segment, in $O((k+1)\log^3 n)$ time.

The contributions of this work can be summarized in the following points:

- We present the first polylog-time dynamic data structure for shortest-path queries in connected planar maps. All previous data structures for shortest paths are static and take linear time for either queries or updates when used in a dynamic environment.
- We provide the first polylog-time dynamic data structure for ray-shooting queries in connected planar maps. The previous best result is $O(\sqrt{n}\,\text{polylog}(n))$ query time.
- We present the first dynamic data structure for point-location queries in connected planar maps with optimal $O(\log n)$ query time and polylog update time. The previous best result is $O(\log n \log\log n)$ query time.
- We provide the first dynamic point-location data structure that checks the validity of an edge insertion, i.e., whether the new edge does not intersect the current edges of the map. Previous dynamic point-location data structures did not have such a capability due to the lack of an efficient dynamic ray-shooting technique.

In §2 we briefly review the terminology of planar maps and the basic data structures used by our method. The mechanics of the dynamic maintenance of a normalized map are described in §3, while §§4, 5, and 6 are respectively devoted to shortest-path, point-location, and ray-shooting queries.

2. Review of background. For the geometric terminology used in this paper, see [24]. A *connected planar map* $\mathcal{M}$ is a subdivision of the plane into polygonal regions whose underlying planar graph is connected. The map is augmented with two vertical rays, one directed toward $y = +\infty$ and the other toward $y = -\infty$, respectively issuing from the vertices of $\mathcal{M}$ with maximum and minimum y-coordinates. Thus, all but two regions of $\mathcal{M}$ are bounded simple polygons. In the following, n denotes the number of vertices of the planar map $\mathcal{M}$ currently being considered. Also, we assume that no two vertices of $\mathcal{M}$ have the same y-coordinate; the degenerate cases can be handled by standard techniques and will not be discussed in this paper.

In the plane we have an orthogonal frame of reference (x, y). A polygonal chain γ is *monotone* if any horizontal line intersects it in a single point or in a single interval or not at all. A simple polygon r is *monotone* if its boundary consists of two monotone chains. A *cusp* of a polygon is a vertex v whose internal angle is greater than π and whose adjacent vertices are both strictly above (lower cusp) or strictly below (upper cusp) v. A polygon is monotone if and only if it has no cusps. A map is monotone if all its regions are monotone.

The *trapezoidal decomposition* of a connected map $\mathcal{M}$ is obtained by drawing from each vertex v of $\mathcal{M}$ two horizontal rays that either remain unbounded or terminate when they first meet edges of $\mathcal{M}$. The resulting segments are called *splitters*. It is easily verified that a region of $\mathcal{M}$ with s vertices is partitioned by the splitters into $s-1$ trapezoids (see Fig. 1). The trapezoidal decomposition of $\mathcal{M}$ is geometrically dualized by mapping each of the obtained trapezoids τ to an arbitrary point $\delta(\tau)$ in the interior of τ. Each of the splitters is mapped to an edge between images of trapezoids in the usual way. We let $\delta(\mathcal{M})$ denote the resulting dual graph, which is a forest of trees since the trapezoids of a single region $r \in \mathcal{M}$ dualize to a tree $\delta(r)$ (because r has no holes). Note that each node of $\delta(r)$ has degree at most four. Let s_i, $i = 1, 2$, denote either a splitter or an extreme vertex of region r. Then $\text{SLEEVE}(s_1, s_2)$ denotes the union of the trapezoids traversed by the shortest path within r between any point of s_1 and any point of s_2. (Note the duality between "sleeves" in region r and paths in tree $\delta(r)$.) In a notationally consistent manner, $\delta(s)$ denotes the edge of $\delta(r)$ that is the dual of splitter s.

Our data structures are based on a variety of balanced search trees. We observe that all the standard operations on balanced search trees (insertion, deletion, split, and join) can be performed by means of a logarithmic number of more basic primitives, which we call "elementary joins and splits," defined as follows:

- An *elementary join* of two binary trees T_1 and T_2 forms a new tree T by making T_1 and T_2 the left and right subtrees of a new root node.
- An *elementary split* yields the left and right subtrees T_1 and T_2 of T by removing its root.

In particular, a simple rotation can be viewed as a sequence of four elementary splits and joins.

Three special types of data structures will be used in this paper: biased binary trees [3], $BB[\alpha]$-trees [20], and dynamic trees [30].

A *biased binary tree* [3] is a binary search tree whose leaves store weighted items. Let w be the sum of all weights. We have that the depth of a leaf with weight w_i is at most $\log(w/w_i) + 2$, and each of the following update operations can be done in $O(\log w)$ time: change of the weight of an item, insertion/deletion of an item, and split/splice of two biased trees [3].

A $BB[\alpha]$-tree [20] (where α is a fixed real, with $\frac{1}{4} < \alpha \leq 1 - \frac{\sqrt{2}}{2}$) is a binary search tree and has the following important properties (among others):

- A $BB[\alpha]$-tree with n nodes has height $O(\log n)$.
- Assume that we augment a $BB[\alpha]$-tree with secondary structures stored at its nodes. Let the subtree with root μ have ℓ leaves, and let the time for updating the secondary structures after a rotation at node μ be $O(\ell \log \ell)$. Then the amortized time of an update operation in a sequence of n insertions and deletions starting from an initially empty $BB[\alpha]$-tree is $O(\log^2 n)$.

Dynamic trees [30] are designed to represent a forest of rooted trees, with each edge directed toward the root of its tree (and called an *arc*). Some important operations (among others) supported by dynamic trees include the following:

link(μ, ν). Add an arc from μ to ν, thereby making μ a child of ν in the forest. This operation assumes that μ is the root of one tree and ν is a node of another tree.

cut(μ). Delete the arc from μ to its parent, thereby dividing the tree containing μ into two trees.

evert(μ). Make μ the root of its tree by reversing the path from μ to the original root.

Each arc of the trees is classified as *solid* or *dashed*, so that each tree is partitioned into a collection of *solid paths*, connected by dashed arcs. A solid path is maintained by a data structure called a *path tree*. Using biased binary trees [3] as the standard implementation of path trees, each of the above operations takes $O(\log n)$ time, where n is the size of the tree(s) in the forest involved.

3. The dynamics of trapezoidal decompositions. Given a connected map $\mathcal{M}$, our objective is first to systematically transform (*normalize*) it into a monotone map, and then to illustrate how to efficiently maintain it under a dynamic regimen of edge and vertex insertions/deletions.

3.1. Normalization. We first address the problem of normalization. Each region r of $\mathcal{M}$ is handled individually. We refer to a region r, bounded or unbounded. In the following, we denote by m the current number of vertices in r.

We imagine representing $\delta(r)$ as a dynamic tree $\Delta(r)$ [30] (see Fig. 1). We choose an arbitrary node of $\delta(r)$ as the *root*, which immediately forces a direction on each edge, referred to hereafter as an *arc* and directed toward the root. Since we have chosen to dualize each

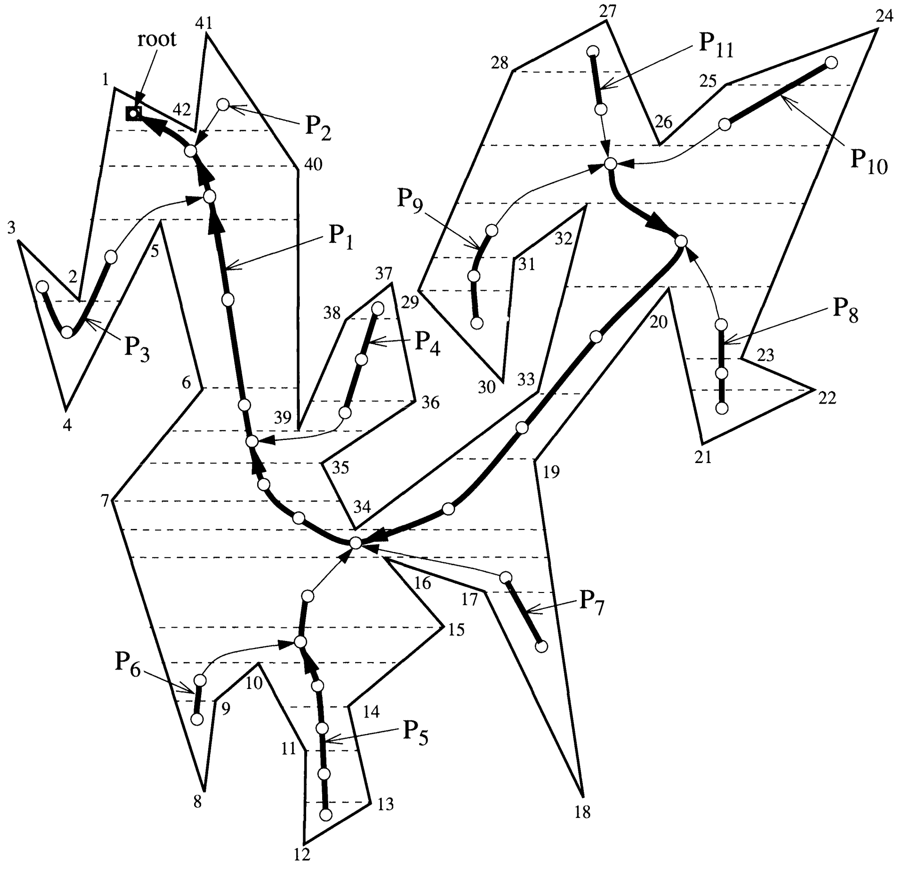

FIG. 1. *Example of a region r and its dynamic tree* $\Delta(r)$ ($P_1,\ldots,P_{11}$ *are solid paths*).

trapezoid to a point in its interior, the y-component of each arc has a well-defined sign. An arc is usually denoted either by a single letter or by an ordered pair (origin, destination). The arcs are classified as follows: letting $w(\mu)$, *weight* of μ, denote the number of nodes in the subtree rooted at node μ, an arc (μ, ν) is classified *heavy* if $w(\mu) \geq \frac{1}{2}w(\nu)$ and *light* otherwise. Consequently, at most one heavy arc enters a node of $\Delta(r)$. Note that the attributes {light, heavy} pertain uniquely to the weight structure of the dynamic tree $\Delta(r)$.

Arcs are also classified as *solid* or *dashed* to enforce the property that *at most one solid arc enters a node* of $\Delta(r)$. The maximal paths of consecutive solid arcs (possibly consisting of a single node) are called *solid paths*, and each corresponds to a sleeve of r. Note that the attributes {dashed, solid} pertain to a given, but otherwise arbitrary, decomposition of r into sleeves.

The weight structure and the sleeve decomposition are tied by the following *weight invariant*, which holds before and after the execution of data structure operations (queries or updates): heavy arcs are solid and light arcs are dashed. However, during the execution of operations, we may change heavy arcs to dashed and light arcs to solid, and thus loose the original correspondence. The weight invariant is restored at the completion of each operation.

Region r contains a set of splitters, called *lids*, which are the duals of the following arcs:

Rule 1. All dashed arcs.

Rule 2. Any two consecutive solid arcs whose y-components have opposite signs.

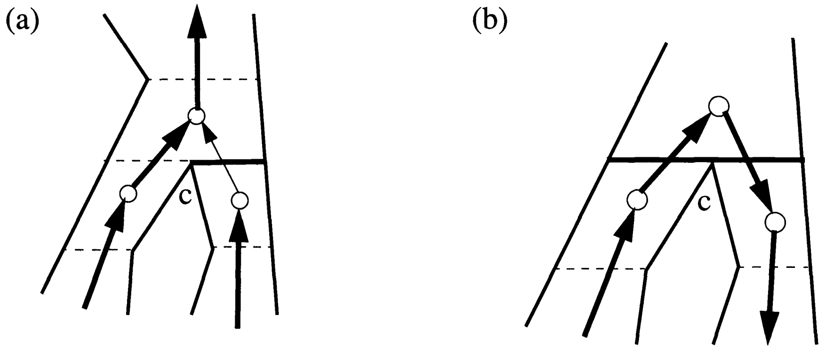

FIG. 2. *Proof of Lemma* 3.1.

Note that each lid is generated by a vertex of r. The set of lids *normalizes* r. Namely, we have the following lemma.

LEMMA 3.1. *The set of lids partitions r into a collection of monotone polygons.*

Proof. Let c be a cusp of polygon r. We consider the two arcs of $\Delta(r)$ which are the duals of the two splitters issuing from c. If at least one of them is dashed (see Fig. 2(a)), then there is at least one lid issuing from cusp c corresponding to the dashed arc (Rule 1). If on the other hand both arcs are solid, then one must have a positive y-component and the other a negative one, or otherwise they would enter the same node of $\Delta(r)$ and thus would violate the property that at most one solid arc enters a node (see Fig. 2(b)). Then these two arcs are consecutive solid arcs with y-components of opposite signs, and there are two lids from c corresponding to these arcs (Rule 2). Hence there is always at least one horizontal lid issuing from each cusp c of r, thereby achieving a decomposition of r into monotone polygons. □

LEMMA 3.2. *Each directed path of the dynamic tree* $\Delta(r)$ *contains at most* $\log_2 m$ *light arcs.*

Proof. Moving away from the root, each light arc traversed reduces the size of the current subtree by at least one half, since $w(child) < \frac{1}{2}w(parent)$. □

COROLLARY 3.3. *Any straight line drawn in region r crosses* $O(\log m)$ *lids.*

Proof. The weight invariant is always preserved before and after the execution of data structure operations. Each lid then corresponds to either (i) a light arc (Rule 1, since dashed arcs are light) or (ii) a solid arc at which the solid path containing this arc changes monotonicity with respect to the y-axis (Rule 2). By Lemma 3.2, any straight line l drawn in r crosses $O(\log m)$ lids of type (i). Now consider the lids of type (ii). Lemma 3.2 also implies that l goes through $O(\log m)$ solid paths. Observe that each solid path P can be partitioned into maximal monotone subpaths, and l can go through at most one such monotone subpath, thus crossing at most two lids of solid arcs of P. It follows that the number of lids of type (ii) crossed by l is also $O(\log m)$. □

3.2. The double-thread data structure. It is intuitively clear that insertion or deletion of an edge may substantially modify the set of trapezoids, whereas it alters only slightly the structure of region boundaries. For this reason, we adopt a data structure that represents a solid path of $\Delta(r)$ by two "threads"; these two threads respectively correspond to two chains whose union is the boundary of the sleeve associated with the solid path. The proposed structure is referred to as *double-thread data structure* for region r, denoted by $DT(r)$.

Each arc α of $\Delta(r)$ can be drawn to intersect its dual splitter issuing from some vertex v of r. Therefore we associate α with v. Notice that each vertex v in $\mathcal{M}$ is associated with two arcs: if v is a cusp of some region r, then the two splitters issuing from v both lie in r and thus cross two arcs of $\Delta(r)$; otherwise, v belongs to two regions r_1 and r_2 and the two splitters issuing from v cross respectively an arc of $\Delta(r_1)$ and an arc of $\Delta(r_2)$. Instead of maintaining the nodes of $\Delta(r)$, we choose to maintain the arcs of $\Delta(r)$ using the vertices of r as their representatives, by associating each node of $\Delta(r)$ to the arc issuing from it. As a consequence, each solid path P is represented by two binary trees *lthread*(P) and *rthread*(P), referred to as *thread trees*, whose implementation is described below. Recall that each solid path is directed toward the root. Each vertex v associated with an arc on solid path P is classified as follows: walking along P toward the root, vertex v is classified *left* if it lies to the left of P and *right* otherwise. Notice that if P is followed by a dashed arc α (every solid path except the one terminating at the root of $\Delta(r)$ has this property), then we also include α as an arc on solid path P in our representation.

The arcs of a solid path P can be partitioned into maximal monotone (on the basis of the signs of their y-components) subpaths $Q_1, Q_2, \ldots, Q_k$. Our thread trees *lthread*(P) and *rthread*(P) are each implemented as a two-level (called lower and upper) balanced binary tree (i.e., the roots of lower-level trees are leaves of the upper-level tree). Referring to *lthread*(P), in the lower level, we have a balanced binary tree *ltree*(Q_i) for each Q_i, where the leaves of *ltree*(Q_i) store the left vertices of Q_i in their path order. Thread tree *rthread*(P) is analogously organized, with *rtree*(Q_i) storing the right vertices. The roots of *ltree*(Q_i) and *rtree*(Q_i) are bidirectionally linked. In the upper level, *lthread*(P) (and analogously *rthread*(P)) has the roots of *ltree*(Q_1), *ltree*$(Q_2), \ldots,$ *ltree*(Q_k) as leaves in their path order. A bidirectional link also exists between the roots of *lthread*(P) and *rthread*(P). An example is shown in Fig. 5(a).

Any node on P might be pointed to (via dashed arcs) by some other solid paths in the dynamic tree $\Delta(r)$. Suppose that P' points to P via an arc α' associated with vertex v'. Two situations may now occur: (i) vertex v' is also associated with an arc of P (e.g., see paths P_2, P_3, and P_4 in Fig. 1 with $P = P_1$). Then v' is a left or right vertex of P (thus stored as a lower-level leaf of *lthread*(P) or *rthread*(P)). We establish a pointer from each root of *lthread*(P') and *rthread*(P') to that lower-level leaf v' (see Fig. 5(b)). The possible instances of this situation are illustrated in Fig. 3(b and d). (ii) vertex v' is not associated with an arc of P (e.g., see paths P_5 and P_7 in Fig. 1 with $P = P_1$). This occurs if P changes monotonicity (by crossing both splitters of a cusp c) at the node reached by arc α'. In this case, in order to provide a destination for the pointers from the roots of *lthread*(P') and *rthread*(P'), we introduce an auxiliary leaf, called a *coupler* (usually denoted by letter H), inserted between the two consecutive subtrees (both either *ltree*s or *rtree*s) of the thread tree not containing cusp c (see Fig. 5(b)). The possible instances of this situation are illustrated in Fig. 3(c and e).

Note that a pointer destination may be needed when a solid path P begins (Fig. 4(b and c) and Fig. 1 for $P = P_1$). In this case, we adopt the convention to insert a coupler preceding either *ltree*(Q_1) or *rtree*(Q_1), where Q_1 is the initial monotone subpath of P (see Fig. 5(b)). The overall data structure $DT(r)$ consists therefore of two rooted trees of in degree at most 4 (see Fig. 5(b)).

We now define a new parameter of nodes of $DT(r)$ (*DT-nodes*), called *charge*, which will be used to maintain the weights of the nodes of the dynamic tree $\Delta(r)$. Each DT-node corresponding to a vertex of r (a leaf of a lower-level tree) is labeled *distinguished*; the charge of a DT-node is the number of the distinguished nodes in the subtree of which it is the root.

According to its definition, the weight $w(\mu)$ of a node μ of $\Delta(r)$ is the number of the nodes in the subtree of which it is the root, or, equivalently, the number of the arcs in this subtree plus the arc α issuing from μ. It is immediate that, denoting by v the vertex associated with arc α and by Q_i the monotone subpath containing α, this number is obtained as the sum of two items: (1) the sum of the charges of all lower-level leaves (actually leaves or couplers) up to and including v in the thread tree containing v, and (2) in the other thread tree, the sum of the charges of all lower-level leaves *preceding* v^*, where v^* is the first vertex on monotone subpath Q_i whose splitter follows the splitter issuing from v, or if v^* does not exist (because

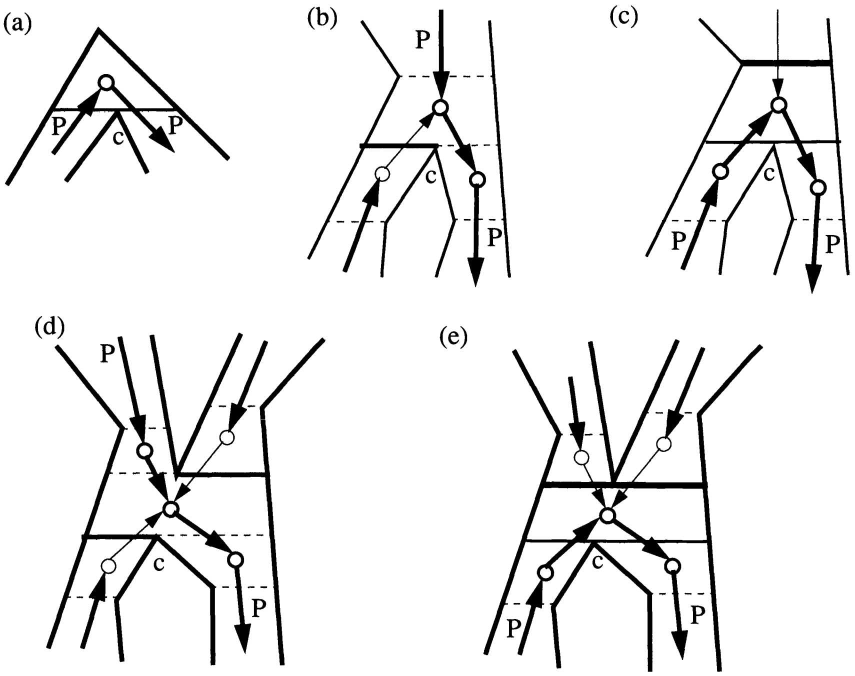

FIG. 3. *All possible cases in which a solid path P crosses a splitter issuing from a cusp c. Note that P does not change monotonicity* (*i.e., crosses only one splitter issuing from c*) *in* (b) *and* (d), *and P changes monotonicity* (*i.e., crosses both splitters issuing from c*) *in* (a), (c), *and* (e).

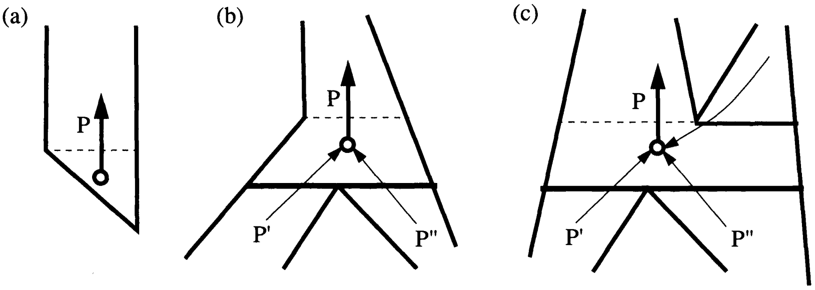

FIG. 4. *All possible cases in which a solid path P starts. Note that a coupler of P is needed to provide a destination of P' and P'' in* (b) *and* (c).

Q_i terminates at v), the sum of the charges of all lower-level leaves up to and including the last leaf of the appropriate subtree of Q_i (either $ltree(Q_i)$ or $rtree(Q_i)$). For example, let us look at $w(\mu_1)$ and $w(\mu_2)$ in Fig. 6. For $w(\mu_2)$, $v^* = s$, thus $w(\mu_2)$ is the sum of the charges of all lower-level leaves of *rthread*(P) from left up to and including v which corresponds to μ_2, and the charges of all lower-level leaves of *lthread*(P) up to and including coupler H; for $w(\mu_1)$, v^* does not exist, and thus $w(\mu_1)$ is the sum of the charges of all lower-level leaves of *rthread*(P) up to and including v which corresponds to μ_1, and the charges of all lower-level leaves of *lthread*(P) up to and including u. Clearly, we can locate v^* or decide its nonexistence in logarithmic time, using the y-coordinate of v to perform a binary search on either $ltree(Q_i)$ or $rtree(Q_i)$ of the thread tree that does not contain v.

The preceding discussion establishes the following lemma.

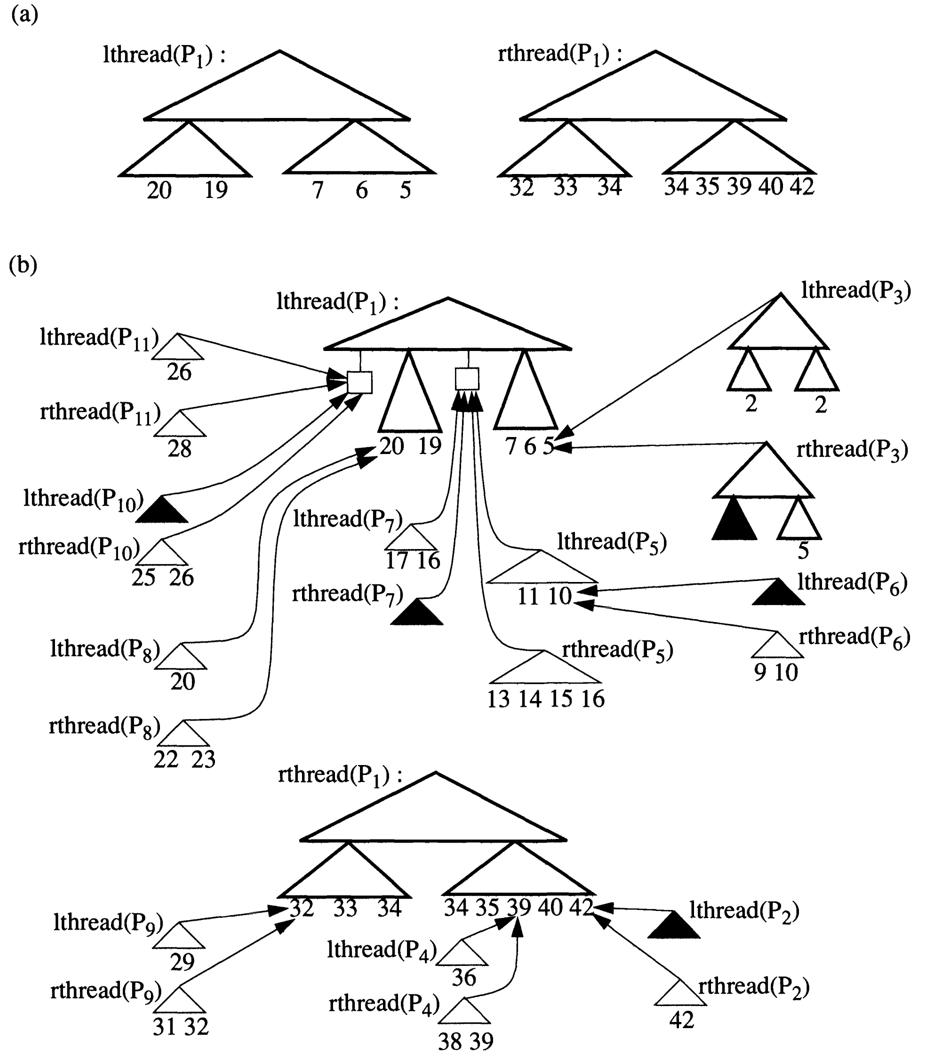

FIG. 5. *Double-thread data structure $DT(r)$ for region r in Fig.* 1: (a) *basic thread trees for* P_1; (b) *complete structure of* $DT(r)$. *The bidirectional pointers linking pairs of corresponding thread trees and thread subtrees are omitted.*

LEMMA 3.4. *The space complexity of the normalization structure for an n-vertex map is* $O(n)$.

Our data structure has an auxiliary component, called *dictionary*. The *dictionary* stores the names of vertices, edges, and regions, so that their representatives occurring in various places in the normalization structure, hull structure, location structure (see §§ 4 and 5), etc., can be efficiently accessed. The edges of a region r are also maintained in the dictionary by a balanced binary tree according to their circular order, with the root of the tree storing the name of r. We store with each edge e two pointers respectively to its left and right representatives in such trees, so that given e, the region r to its left (respectively, right) can be found by accessing its left (respectively, right) representative and walking up to the root of the tree of r. It is easy to see that accessing and updating the dictionary can be performed in logarithmic time, and

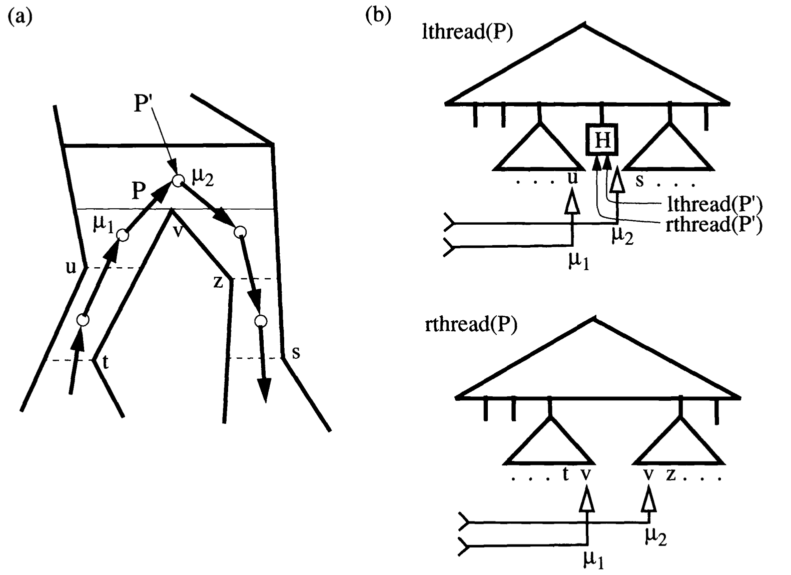

FIG. 6. *Weights $w(\mu_1)$, $w(\mu_2)$ of nodes μ_1, μ_2 of the dynamic tree $\Delta(r)$: $w(\mu_2)$ is the sum of the charges of all lower-level leaves of rthread(P) from left up to and including the occurrence of v which corresponds to μ_2, and the charges of all lower-level leaves of lthread(P) up to and including coupler H; $w(\mu_1)$ is the sum of the charges of all lower-level leaves of rthread(P) up to and including the occurrence of v which corresponds to μ_1, and the charges of all lower-level leaves of lthread(P) up to and including u.*

that the dictionary does not affect the space complexity of our data structure. Therefore we omit any further discussion of the dictionary in the rest of the paper.

3.3. Update operations. We define the following update operations on a connected map $\mathcal{M}$:

INSERTEDGE$(e, v_1, v_2, r; r_1, r_2)$. Insert edge $e = (v_1, v_2)$ into region r such that r is partitioned into two regions r_1 and r_2.

REMOVEEDGE$(e, v_1, v_2, r_1, r_2; r)$. Remove edge $e = (v_1, v_2)$ and merge the regions r_1 and r_2 formerly on the two sides of e into a new region r.

INSERTVERTEX$(v, e; e_1, e_2)$. Split the edge $e = (u, w)$ into two edges $e_1 = (u, v)$ and $e_2 = (v, w)$ by inserting vertex v along e.

REMOVEVERTEX$(v, e_1, e_2; e)$. Let v be a vertex with degree two such that its incident edges $e_1 = (u, v)$ and $e_2 = (v, w)$, are on the same straight line. Remove v and merge e_1 and e_2 into a single edge $e = (u, w)$.

ATTACHVERTEX$(v_1, e; v_2)$. Insert edge $e = (v_1, v_2)$ and degree-one vertex v_2 inside some region r, where v_1 is a vertex of r.

DETACHVERTEX(v, e). Remove a degree-one vertex v and edge e incident on v.

With the above repertory, the following theorem is immediate.

THEOREM 3.5. *An arbitrary connected map $\mathcal{M}$ with n vertices can be assembled from the empty map, and disassembled to obtain the empty map, by a sequence of $O(n)$ operations drawn from the set {point-location query,* INSERTVERTEX, REMOVEVERTEX, INSERTEDGE, REMOVEEDGE, ATTACHVERTEX, DETACHVERTEX}.

Now we show that ATTACHVERTEX and DETACHVERTEX can be simulated by a sequence of $O(1)$ operations taken among the first four of the repertory and point-location query. Referring for simplicity to ATTACHVERTEX$(v_1, e; v_2)$, we have the following emulation routine: perform

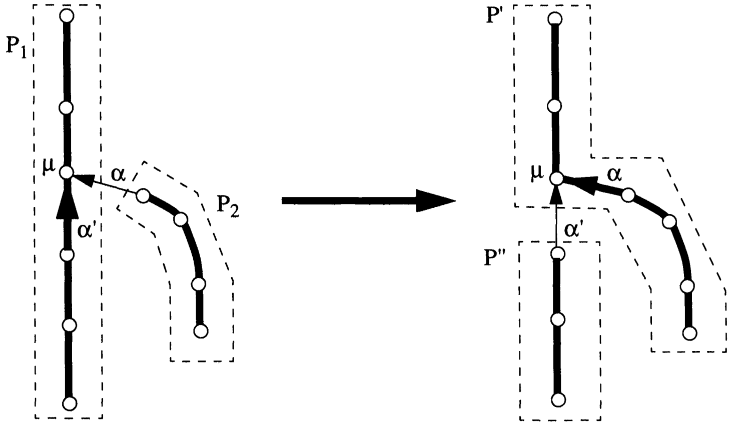

FIG. 7. *Example of splice*$(P_1, P_2; P', P'')$.

a point-location query of v_2 to obtain the region r containing it (which also provides the trapezoid containing v_2), compute the two horizontal projection points v' and v'' of v_2 on the boundary of r, insert vertices v' and v'', insert edge (v', v''), insert vertex v_2 on (v', v''), insert edge e, remove edges (v', v_2) and (v_2, v''), and finally remove vertices v' and v''.

In the rest of this section, we describe how to implement the first four operations of the above repertory on the dynamic tree $\Delta(r)$ of an arbitrary region r (a simple polygon), represented by the double-thread data structure described above.

3.3.1. Primitive dynamic-tree operations. We begin by considering some elementary dynamic-tree operations *expose*, *conceal*, and *evert* introduced in [30], in terms of which the operations of the above repertory can be immediately expressed. In the course of some updates, we may change a solid arc to dashed and vice versa and thus violate the weight invariant; thus we need the capability to restore such weight invariant. Such actions are effected by the operations *expose* and *conceal* introduced in [30]. Operation *expose*(μ), for some node μ of $\Delta(r)$, transforms the unique path P from node μ to the root of $\Delta(r)$ into a solid path, by changing the dashed arcs in P to solid and the solid arcs incident to P to dashed. Since this transformation may violate the weight invariant of dynamic trees, the inverse operation *conceal*(P) is used to remove the violation, by identifying all the light arcs in P and making them dashed, and also identifying all heavy arcs (if any) among the arcs incident to P and making them solid.

The primitive operation used in *expose* and *conceal* is *splice*$(P_1, P_2; P', P'')$, acting on two given paths P_1 and P_2 to produce two new paths P' and P'' (see Fig. 7). Originally, solid path P_2 points to node μ of solid path P_1 via a dashed arc α. Denoting by α' the (solid) arc of P_1 terminating at μ (if any), *splice* exchanges the roles of α and α', i.e., it creates two new solid paths P' and P'' with P'' pointing to P' via dashed arc α' (again, P'' and α' might be empty).

Operation *splice*$(P_1, P_2; P', P'')$ essentially involves splitting and concatenating both threads of the paths concerned. Specifically, *lthread*(P_1) is split into *lthread*(P''') and *lthread*(P''), and then *lthread*(P_2) is concatenated with *lthread*(P''') to form *lthread*(P'); this happens analogously for *rthread*. Operation *slice* may require either the insertion or the deletion of a coupler (see, for example, splicing P_4 to P_1 (insertion) and P_5 to P_1 (deletion) in Fig. 1). Since a constant number of splits/concatenations have to be performed, we have the following lemma.

LEMMA 3.6. *Operation slice can be executed in $O(\log m)$ time on the double-thread data structure.*

Since each directed path in $\Delta(r)$ contains at most $\log_2 m$ light arcs by Lemma 3.2 (each accessible by climbing to the root of an $O(\log m)$-depth thread tree), *expose* uses at most $\log_2 m$ *slice* operations and therefore is executed in $O(\log^2 m)$ time.

Given a solid path P, operation *conceal*(P) identifies the light arcs of P which have to be made dashed and the heavy arcs (if any) incident to P which have to be made solid in order to comply with the weight invariant of dynamic trees. It can be carried out by finding the topmost (i.e., closest to the root of $\Delta(r)$) light arc α, splitting P at α, removing the subpath from the root up to and including α, and then repeating the process for the remaining solid path, until no light arc is found. The heavy arcs incident to P can then be identified (and made solid) in a straightforward way: each time a light arc (μ, ν) is found, we check all (up to three) arcs incident to ν to see if any one of them is heavy; finally, we also apply this checking process to the arcs incident to the bottommost node of P. So the main issue for performing *conceal*(P) is how to find the topmost light arc.

Before describing its adaptation to the double-thread data structure, we briefly review the standard implementation of operation *conceal* as proposed by Sleator and Tarjan [30]. Let the dynamic-tree nodes of solid path P be stored left to right as the leaves of a balanced binary tree $T(P)$, called in [30] a *path tree*. Each leaf ζ of $T(P)$ stores *local_weight*(ζ), defined as the sum of the local weights of all dashed-arc children (which are the roots of some other path trees) of ζ, if any, plus 1 (to account for ζ itself). For each internal node η, *local_weight*(η) is defined as the sum of the local weights of its children. Note the similarlity between the *local weights* of nodes in path tree $T(P)$ and *charges* of nodes in thread trees *lthread*(P) and *rthread*(P) defined in §3.2. Actually, parameters *local_weight* and *charge* are identical except for their usages in computing $w(\mu)$—the weight of a dynamic-tree node μ. In $T(P)$, $w(\mu)$ is the left-to-right prefix sum of the local weights of the leaves, whereas in thread trees, $w(\mu)$ is contributed by the prefix sums of the charges of the leaves in *both* *lthread*(P) and *rthread*(P) (see §3.2). Let T_η be the subtree of $T(P)$ rooted at internal node η. Denoting by λ the rightmost leaf in T_η, and by ξ the leaf adjacent to λ on the left, variable *lefttilt*(η) is defined by *lefttilt*$(\eta) \overset{\Delta}{=} w(\xi) -$ *local_weight*(λ). We recall that arc (ξ, λ) of P is light if and only if $w(\xi) < \frac{1}{2}w(\lambda)$, i.e., $w(\xi) < \frac{1}{2}(w(\xi) +$ *local_weight*$(\lambda))$, which yields *lefttilt*$(\eta) < 0$.

Moreover, define *leftmin*$(\eta) \overset{\Delta}{=}$ *min*$\{$*lefttilt*$(\theta) : \theta$ is an internal node of $T_\eta\}$. It follows that if *leftmin*$(\eta) \geq 0$, then there is no light arc between any two adjacent leaves of T_η. Also, variable *netleft*(η) is defined as *leftmin*(η) if η is the root of $T(P)$ and *leftmin*$(\eta) -$ *leftmin*$($*parent*$(\eta))$ otherwise. Correspondingly, variables *netright*(η), *rightmin*(η), and *righttilt*(η) are defined symmetrically in a straightforward manner by summing the local weights from right to left for the purpose of reversing the path direction. In summary, each internal node η of $T(P)$ stores three values: *local_weight*(η), *netleft*(η), and *netright*(η).

To find the topmost light arc in P, we traverse a path from the root of $T(P)$ with the following advancing mechanism. Assume inductively that, for the current node η, parameter *leftmin*(η) (< 0) is known. Let η' and η'' be the left and right children of η, respectively, and ξ be the leftmost leaf of $T_{\eta''}$. From the definition

$$\textit{netleft}(\eta'') = \textit{leftmin}(\eta'') - \textit{leftmin}(\eta),$$

we obtain *leftmin*(η''). If *leftmin*$(\eta'') < 0$, then we proceed to η''. Otherwise, we compare *local_weight*(η') and *local_weight*(ξ). If *local_weight*$(\eta') <$ *local_weight*(ξ), then the arc leading to ξ is the sought light arc; else, we compute *leftmin*$(\eta') =$ *leftmin*$(\eta) +$ *netleft*(η') (which is necessarily < 0) and proceed to η' (this establishs the inductive step). By this process, akin to binary search, the topmost light arc can be found in $O(\log m)$ time. Recall that by Lemma 3.2, there are at most $\log_2 m$ light arcs in $T(P)$.

We are now ready to consider the implementation of *conceal* for the double-thread data structure. We treat thread trees *lthread*(P) and *rthread*(P) independently as two path trees, with parameter *charge* playing the role of *local weight*. By the method just illustrated, we identify at most $\log_2 m$ light arcs from each of *lthread*(P) and *rthread*(P). Note that a light arc (ξ, λ) in P assures the existence of a light arc (ξ', λ) in either *lthread*(P) or *rthread*(P) that contains leaf λ, where ξ' is the left-neighboring leaf of λ. Indeed, in $T(P)$, the sum $w(\xi)$ of the local weights up to and including ξ satisfies $w(\xi) < \mathit{local\_weight}(\lambda)$. But in the appropriate thread tree (i.e., either *lthread*(P) or *rthread*(P) that contains λ), the sum w' of the charges up to and including ξ' is only a fraction of $w(\xi)$ ($w(\xi)$ is contributed by *both* *lthread*(P) and *rthread*(P)), so that $w' \leq w(\xi) < \mathit{local\_weight}(\lambda) = \mathit{charge}(\lambda)$, and (ξ', λ) is light. Hence $2\log_2 m$ light arcs from *lthread*(P) and *rthread*(P) give all possible candidates for light arcs in P. For each such candidate (ξ', λ), we perform a binary search in the paired thread tree to locate the point just before λ, at the same time accumulate the total charge w'' up to and including this point in that tree, then compute $w(\xi)$ by adding w'' to w', and check if $w(\xi) < \mathit{charge}(\lambda)$ $(= \mathit{local\_weight}(\lambda))$. Therefore, we find $2\log_2 m$ candidates, perform $2\log_2 m$ binary searches for checking, identify at most $\log_2 m$ light arcs in P (and also at most $\log_2 m + 1$ heavy arcs incident to P), and then split and join P accordingly—each of these operations within $O(\log m)$ time. This leads to the following lemma.

LEMMA 3.7. *The update of the double-thread data structure as required by the operation conceal can be performed in* $O(\log^2 m)$ *time.*

Operation *evert*(μ), for an arbitray node μ of $\Delta(r)$, moves the root of $\Delta(r)$ to μ while preserving the weight invariant. If we can reverse the direction of a solid path, then *evert*(μ) can be carried out as follows: we perform *expose*(μ) to obtain a solid path P from μ to the original root, reverse the direction of P (which effectively moves the root to μ), and then perform *conceal*(P) to comply with the weight invariant. We add a "direction" bit to each node of the thread trees, so that when we reverse the direction of a solid path P, the direction bit of the root of *lthread*(P) is complemented, indicating that the meanings of left and right subtrees of *lthread*(P) are interchanged; this is done similarly for the direction bit of the root of *rthread*(P). Also, these two complemented bits indicate that *lthread*(P) means *rthread*(P) and vice versa. Given the direction bits and operations *expose* and *conceal*, we can perform *evert* in the double-thread data structure in $O(\log^2 m)$ time.

In the following, if μ is a node of $\Delta(r)$ and a an incoming arc of μ, the notations *expose*(a) and *expose*(μ) are equivalent, and similarly for *evert*.

LEMMA 3.8. *Given splitters* s_1 *and* s_2 *of region* r *with* m *vertices,* SLEEVE(s_1, s_2) *and the corresponding solid path between* $\delta(s_1)$ *and* $\delta(s_2)$ *can be constructed in* $O(\log^2 m)$ *time, by means of* $O(\log^2 m)$ *elementary splits/joins of thread trees.*

Proof. We obtain a solid path between $\delta(s_1)$ and $\delta(s_2)$ by *evert*$(\delta(s_1))$ and *expose*$(\delta(s_2))$. Each of operations *evert* and *expose* uses $O(\log^2 m)$ elementary splits/joins and takes $O(\log^2 m)$ time. □

The double-thread structure adds two new primitive operations to the original repertory of dynamic trees. Operation *part*$(P, e;\ P_1, P_2)$ on a solid monotone path P separates *lthread*(P) and *rthread*(P), and creates two new solid paths P_1 and P_2 by adjoining *lthread*(P) and *rthread*(P) to a new edge e. Namely, *lthread*(P_1) = *lthread*(P), *rthread*$(P_1) = e$, *lthread*$(P_2) = e$, and *rthread*(P_2) = *rthread*(P). The operation *pair*$(P_1, P_2;\ P, e)$ is the inverse operation of *part*$(P, e;\ P_1, P_2)$ and is implemented similarly.

LEMMA 3.9. *Operations part and pair have time complexity* $O(1)$.

As we shall see in the next section, operations *part* and *pair* are crucial in the efficient execution of INSERTEDGE and REMOVEEDGE.

3.3.2. Insertion and deletion of edges and vertices. Operation INSERTEDGE(e, v_1, v_2, r; r_1, r_2) is carried out as follows:

1. For $i = 1, 2$, if v_i is an extreme vertex of r, let $s_i = v_i$, else let s_i be a splitter of r induced by v_i. If v_i is a cusp of r, then there are two such splitters; by viewing edge $e = (v_1, v_2)$ as issuing from v_i, s_i is taken as the left splitter of v_i if e goes toward left (and as the right splitter otherwise), so that SLEEVE(s_1, s_2) is the smallest monotone sleeve that contains e.
2. Construct SLEEVE(s_1, s_2) and the corresponding solid path P by performing $evert(\delta(s_1))$ and then $expose(\delta(s_2))$.
3. Insert edge e by performing $part(P, e; P_1, P_2)$, so that there are new solid paths P_1 and P_2 respectively in new regions r_1 and r_2.
4. For each of the (up to three) solid paths previously pointing to the head of P, make it point to the head of P_1 if it lies in r_1, and to the head of P_2 if it lies in r_2; do this similarly for the solid paths previously pointing to the tail of P. Note that P_1 and P_2 have the same orientation as P.
5. Create a new dynamic tree $\Delta(r_1)$ for r_1, by putting the root at the end of P_1 that is closer to v_1 (which does not change the direction of P_1), then performing operation $conceal(P_1)$; similarly create a new dynamic tree $\Delta(r_2)$. Note that the *conceal* operations readily splice the solid paths pointing to the heads and tails of P_1 and of P_2 if necessary.

We analyze the time complexity of the above operation. Steps 1, 3, and 4 take $O(1)$ time, and the other steps globally involve a fixed number of *evert*, *expose*, and *conceal* operations, so that the total time required for updating the double-thread data structure is $O(\log^2 m)$.

Operation REMOVEEDGE(e, v_1, v_2, r_1, r_2; r) is the inverse operation of INSERTEDGE. We first evert v_1 and then expose v_2 in both $\Delta(r_1)$ and $\Delta(r_2)$, pair the two solid paths into one, and conceal it. This can also be done in $O(\log^2 m)$ time.

Operation INSERTVERTEX(v, e; e_1, e_2) is performed as follows. We insert v with $charge(v) = 1$ into $lthread(P)$ and $rthread(P')$ for some solid paths P and P' of different regions r and r', where both $lthread(P)$ and $rthread(P')$ contain two endpoints v_1 and v_2 of e. In dynamic tree $\Delta(r)$, we perform *expose* on the one of v_1 and v_2 that is farther from the root to obtain a solid path, and then perform *conceal* on this path; in $\Delta(r')$ we perform exactly the same operations. It is easy to see that operation INSERTVERTEX is executed in $O(\log^2 m)$ time. Operation REMOVEVERTEX is the inverse operation of INSERTVERTEX and can be completed within the same time bound.

4. Shortest-path queries. In this section, we illustrate how the normalization data structure can be modified, by appending secondary data structures collectively called *hull structure*, to answer the following queries:

PATHLENGTH(q_1, q_2, r). Return the length of a shortest path inside region r between query points q_1 and q_2.

PATH(q_1, q_2, r). Return the shortest path inside region r between query points q_1 and q_2 as a chain of segments.

First, by point location (see §5) we can check whether q_1 and q_2 belong to r. Note that we need to specify within which region the shortest path is sought to avoid ambiguities when both q_1 and q_2 belong to edges of the subdivision. We now show that the above queries can be supported in worst-case time $O(\log^3 n)$ and $O(\log^3 n + k)$, respectively, where k is the number of segments in the shortest path reported by PATH.

The notion of *hourglass* is central to our current problem. We adopt the terminology proposed by Guibas and Hershberger [16].

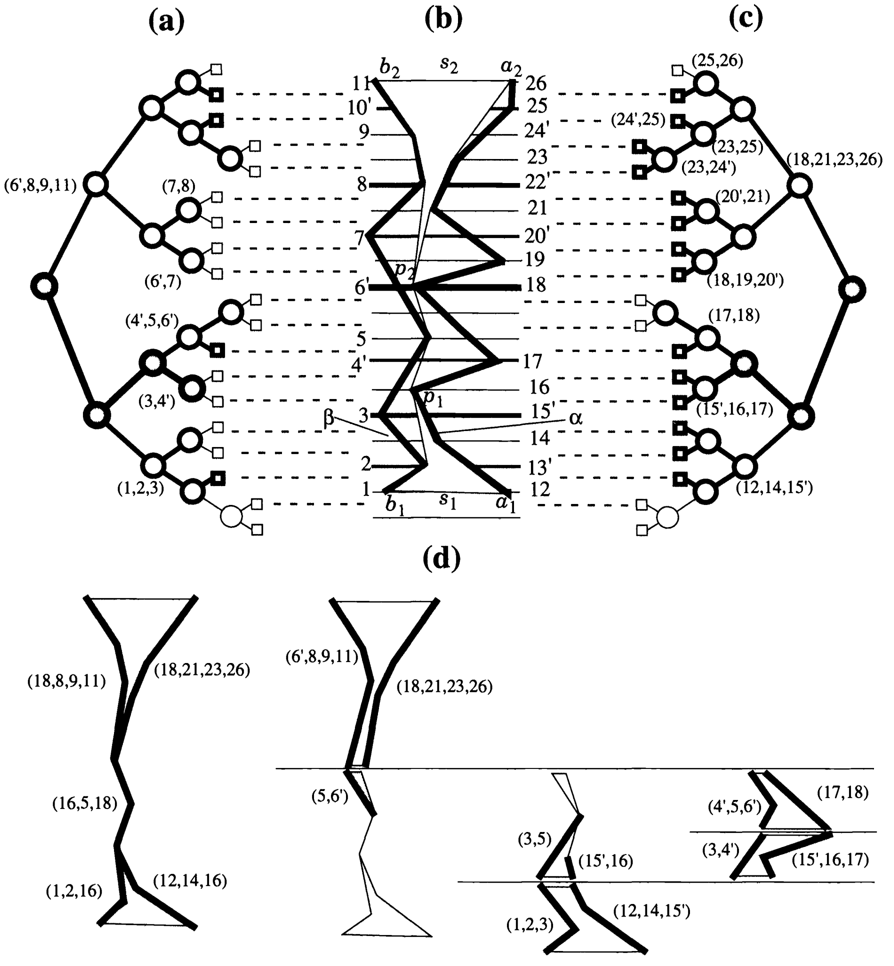

FIG. 8. *Example of representation of hourglasses in the nodes of ltree*(Q) *and rtree*(Q) *of a monotone path* Q. (b) *The sleeve of* Q (*directed from left to right*)*: the parallel lines drawn on it represent set* Y; *the points on the sleeve with labels of the type* i' *delimit fragments of the same edge*; *the hourglass between the extreme splitters of the sleeve is shown grey filled.* (a) *Pruned tree ltree*(Q)*: the nodes of ltree*(Q) *are those drawn with thick lines, while the nodes drawn with thin lines denote the subtrees of* $\mathcal{Y}$ *pruned away to construct ltree*(Q); *the grey-filled nodes are associated with closed sleeves, and the white-filled nodes are associated with open sleeves. Next to each white-filled node* μ *we show the subchain of* HOURGLASS(μ) *stored at* μ. (c) *Pruned tree rtree*(Q) (*similar comments as in* (a) *apply*). (d) *Hourglasses of the grey-filled nodes and of their children. The subchains stored at each node are labeled and shown with thick lines.*

Consider two nonintersecting diagonals $s_1 = (a_1, b_1)$ and $s_2 = (a_2, b_2)$ of r, where the endpoints have been named so that the counterclockwise cyclic sequence of points in the boundary of r includes the subsequence (a_1, a_2, b_2, b_1). The *hourglass* of s_1 and s_2, denoted HOURGLASS(s_1, s_2), is the subregion of r formed by the union of all the shortest paths PATH(q_1, q_2, r) with $q_1 \in s_1$ and $q_2 \in s_2$ (see Fig. 8(b)). It is known that the boundary of HOURGLASS(s_1, s_2) is the concatenation of s_1, PATH(a_1, a_2, r), s_2, and PATH(b_2, b_1, r). Let α be the subchain of r counterclockwise from a_1 to a_2, and define β similarly for b_2 and b_1. The hourglass has one of the following special structures (as analyzed in [16]):

Open hourglass. If the convex hulls inside r of α and β do not intersect, then PATH(a_1, a_2, r) is the convex hull of the subchain of α clockwise from a_1 to a_2, and similarly for PATH(b_2, b_1, r).

Closed hourglass. If the convex hulls of α and β intersect, then there exist vertices p_1 and p_2 of $\alpha \cup \beta$ such that $\text{PATH}(a_1, a_2, r) \cap \text{PATH}(b_1, b_2, r) = \text{PATH}(p_1, p_2, r)$. Without loss of generality, assume that p_1 is in α. Then $\text{PATH}(a_1, p_1, r)$ is the convex hull inside r of the subchain of α from a_1 to p_1, while $\text{PATH}(b_1, p_1, r)$ is the union of segment (p_1, p_1') and the convex hull inside r of the subchain of β from b_1 to p_1', where p_1' is the vertex of β closer to b_1 on the two tangents from p_1 to β. Similar arguments apply to p_2. The union of $\text{PATH}(a_i, p_i, r)$ and $\text{PATH}(b_i, p_i, r)$ $(i = 1 \text{ or } 2)$ is called a *funnel* [19]. Vertices p_1 and p_2 are called the *apices* of the hourglass, and the path between them the *string* of the hourglass (see Fig. 8(b)).

If we represent an hourglass by its string and the (two to four) convex chains forming the rest of its boundary, and for each polygonal chain represented, we also store its length, then given $\text{HOURGLASS}(s_1, s_2)$, it is possible to compute $\text{PATHLENGTH}(q_1, q_2, r)$ in $O(\log n)$ time for any two points $q_1 \in s_1$ and $q_2 \in s_2$ by means of $O(1)$ common-tangent computations. Also, given $\text{HOURGLASS}(s_1, s_2)$ and $\text{HOURGLASS}(s_2, s_3)$ in r, with s_1 and s_3 on opposite sides of the line containing s_2, it is possible to compute $\text{HOURGLASS}(s_1, s_3)$ in time $O(\log n)$ by means of $O(1)$ common-tangent computations and $O(1)$ split and join operations on the chains forming the two hourglasses.

We now consider the modifications of the normalization data structure that enable the support of the given path queries. As we shall see, only three items are needed, i.e.,

(i) the choice of an appropriate implementation of the trees *ltree* and *rtree* introduced in §3.2;

(ii) the appending of secondary data structures (collectively called "hull structure") to the nodes of *ltree*s and *rtree*s. The *hull structure* stores at the nodes of *ltree*s and *rtree*s the hourglasses of the corresponding sleeves; it establishes an implicit correspondence between the two chains of a monotone sleeve, allowing both efficient access to the hourglass of the sleeve and fast pairing or parting of the two chains as required by edge insertion or deletion;

(iii) a separate BB[α]-tree $\mathcal{Y}$ (called *Y-tree*) that determines a hierarchical partition of the plane into horizontal strips, according to which *ltree*s and *rtree*s are implemented.

We first describe the adopted representation of polygonal chains. A concatenable queue, called *chain tree*, will be used to represent a polygonal chain γ. The chain tree T for γ is a balanced tree and has in-order thread pointers. Each node μ of T corresponds to a subchain γ_μ of γ and stores the endpoints of γ_μ, the common point of the subchains of the children of γ_μ, and the length of γ_μ. It should be clear that this information can be updated in $O(1)$ time per elementary join or split, so that splitting or splicing two chain trees takes logarithmic time. With this representation, it is possible to find the two tangents from a point to a convex chain and the four common tangents between two convex chains in logarithmic time [24].

We now give the details of our representation of hourglasses. An open hourglass is represented by storing its two convex chains into chain trees. A closed hourglass is represented by storing into separate substructures the four convex chains forming the funnels, and the string between the apices. The convex chains of the funnels and the string are each stored into a chain tree.

Without loss of generality, we assume that the degree of each vertex of $\mathcal{M}$ is at most 3. This is not restrictive since we can expand a vertex v with degree $d > 3$ into a chain of degree-3 vertices connected by edges of infinitesimal length. Since the sum of the degrees of all vertices of $\mathcal{M}$ is $O(n)$, the total number of vertices after the expansion is still $O(n)$. Every update operation in the original map $\mathcal{M}$ can be simulated with $O(1)$ operations in the modified map with bounded-degree vertices.

We consider the ordered sequence Y of the y-coordinates of the vertices of $\mathcal{M}$ and establish a one-to-one correspondence between Y and the leaves of a BB[α]-tree $\mathcal{Y}$, called *Y-tree*, which is added as a separate tree into the data structure. Tree $\mathcal{Y}$ determines a hierarchical partition of the plane into horizontal strips according to the well-known segment-tree scheme. Each node of $\mathcal{Y}$ corresponds to a *canonical interval* of y-coordinates. A vertical interval (y', y'') with $y', y'' \in Y$ is uniquely partitioned into $O(\log n)$ canonical intervals, called the *fragments* of (y', y''), and their associated nodes in $\mathcal{Y}$ are called the *allocation nodes* of (y', y''). We extend this terminology to any geometric entity that is uniquely associated with a vertical interval, such as an edge, a monotone chain, or a monotone sleeve.

We now introduce the useful notion of the "pruned tree." A *pruned tree* of a rooted tree T is a tree S that can be obtained from T by removing from it the subtrees rooted at a selected subset of its nodes. Pruned trees of a balanced tree T support the full repertory of concatenable queue operations. Each operation takes $O(\log n)$ time and is performed by means of $O(\log n)$ elementary joins and splits between pruned trees whose roots are associated with sibling nodes in T. A sequence I of k consecutive intervals with endpoints in Y will be stored in a pruned subtree of $\mathcal{Y}$, whose leaves are the allocation nodes of the intervals of I and whose internal nodes are the ancestors of such leaves. It is easy to verify that the pruned tree associated with I has $O(k \log n)$ nodes and $O(\log n)$ height.

Now, we show how to modify the normalization structure so that hourglasses can be dynamically maintained (see Fig. 8). We denote with Q a maximal monotone subpath of a solid path P and specify the implementation of *ltree*(Q) and *rtree*(Q). We use pruned trees augmented with chain trees as secondary structures. Our scheme uses ideas from [22] and [16].

- Trees *ltree*(Q) and *rtree*(Q) are implemented by means of pruned trees with respect to $\mathcal{Y}$.
- Let μ be a node of *ltree*(Q) (nodes of *rtree*(Q) are handled identically) and ν the parent of μ. Node μ has a pointer to the corresponding node y of $\mathcal{Y}$. Also, if μ is not a leaf, then we establish a back pointer from y to μ. We do not set up back pointers from y to leaves of *ltree*(Q) (or of *rtree*(Q)) in order to obtain efficient updates, as we shall see later. Consider the subpath Q' of Q associated with the subtree of *ltree*(Q) rooted at μ. We denote with SLEEVE(μ) the sleeve of Q', with s_1 and s_2 the splitters that delimit SLEEVE(μ), with HOURGLASS(μ) the hourglass of s_1 and s_2 (namely, HOURGLASS(s_1, s_2)), and with CHAIN(μ) the "left chain" of SLEEVE(μ), i.e., the chain formed by the edge fragments stored at the leaves of the subtree of *ltree*(Q) rooted at μ.

  We distinguish several subcases:
  - If μ is a leaf of *ltree*(Q), then μ stores the corresponding edge fragment.
  - If HOURGLASS(μ) is open and HOURGLASS(ν) is closed, then μ stores in a secondary data structure the right convex hull of CHAIN(μ).
  - If both HOURGLASS(μ) and HOURGLASS(ν) are open, then μ stores in a secondary data structure only the endpoints of CHAIN(μ) and the portion of the right hull of CHAIN(μ) that is not stored at an ancestor of μ.
  - If HOURGLASS(μ) is closed and μ is the root of *ltree*(Q), then μ stores in secondary data structure the (up to five) components of HOURGLASS(μ).
  - If HOURGLASS(μ) is closed and μ is not the root, then μ stores the apices and the length of the string of HOURGLASS(μ), plus the subchains of the funnels of HOURGLASS(μ) that are not stored at the ancestors of μ.
- The upper levels (see §3.2) of thread trees *lthread*(P) and *rthread*(P) are essentially identical (except for the couplers). Also, an internal node μ in the upper level of *lthread*(P) stores the length and the endpoints of the string of HOURGLASS(μ). The corresponding node of *rthread*(P) stores exactly the same information.

LEMMA 4.1. *The space requirement of the hull structure is* $O(n \log n)$.

Proof. We only need to determine the space used by the secondary structures (the chain trees) that augment the *ltree*s and *rtree*s. Consider the set S of all segments s such that s is either an edge fragment or the tangent segment in the hourglass of a node in *ltree* or *rtree*. We claim that the size of S is $O(n \log n)$. By standard segment-tree arguments, the number of edge fragments in S is $O(n \log n)$. For the tangent segments, consider the hourglasses HOURGLASS(μ), HOURGLASS(μ'), and HOURGLASS(μ'') of a node μ and its children μ' and μ''. Note that SLEEVE(μ') and SLEEVE(μ'') share a common splitter, say s_2, and the other splitters s_1 of SLEEVE(μ') and s_3 of SLEEVE(μ'') lie on opposite sides of s_2. It follows that HOURGLASS(μ) = HOURGLASS(s_1, s_3) is obtained from HOURGLASS(μ') = HOURGLASS(s_1, s_2) and HOURGLASS(μ'') = HOURGLASS(s_2, s_3) by $O(1)$ common-tangent computations, and thus each node μ contains $O(1)$ tangent segments. Again, by segment-tree arguments, the total number of nodes in *ltree*s and *rtree*s is $O(n \log n)$, hence the total number of tangent segments in S is $O(n \log n)$. Also, each segment of S is stored $O(1)$ times in the data structure, since it can have representatives in an allocation node (for an edge fragment), in the highest open hourglass, and in the highest monotone hourglass, and there may be two such nodes for each segment (recall that edges have two "sides," and the corresponding nodes in the paired *ltree* and *rtree* may have duplicate information). We conclude that the secondary structures are a collection of balanced trees with a total of $O(n \log n)$ nodes, and hence use total space $O(n \log n)$. □

Query operations PATHLENGTH(q_1, q_2, r) and PATH(q_1, q_2, r) are performed as follows:

1. Find the trapezoids τ_1 and τ_2 of the trapezoidal decomposition of r containing q_1 and q_2, using the point-location machinery of §5. Let s_1 and s_2 be the splitters on the boundary of τ_1 and τ_2, such that q_1 and q_2 are on opposite sides of SLEEVE(s_1, s_2).
2. Create the solid path P for SLEEVE(s_1, s_2) (P is the path between edges $\delta(s_1)$ and $\delta(s_2)$ of $\delta(r)$), by means of *evert*($\delta(s_1)$) and *expose*($\delta(s_2)$). The secondary structure stored at the root of *lthread*(P) (or *rthread*(P)) yields a representation of HOURGLASS(s_1, s_2).

Given the representation of HOURGLASS(s_1, s_2), after computing in time $O(\log n)$ the tangents from q_1 and q_2 to the appropriate funnels, we can answer PATHLENGTH(q_1, q_2, r) and PATH(q_1, q_2, r) in time $O(1)$ and $O(k)$, respectively (where k is the number of edges of the shortest path reported). Finally, we conceal the path exposed in step 2 to satisfy the weight invariant.

Regarding updates, we have the following lemma (see the example in Fig. 9).

LEMMA 4.2. *An elementary split or join of two thread trees in the normalization structure augmented with the hull structure takes time* $O(\log n)$.

Proof. After an elementary split or join of two solid thread trees, we need to update only the secondary data structures of their roots. Since such data structures represent the hourglasses of the corresponding sleeves, they can be updated in $O(\log n)$ time (see Fig. 9). Note that for a nonmonotone solid path the updates are limited to its leftmost or rightmost monotone subpath. For this reason it is sufficient to store only the length of the string in the nodes of the upper levels of the *lthread* and *rthread* trees. □

As a consequence, splitting a solid path or joining two solid paths takes time $O(\log^2 n)$. Note that parting or pairing *ltree*(Q) and *rtree*(Q) of a monotone path Q (because of an edge insertion or deletion in the corresponding sleeve) takes $O(1)$ time. The lemma below follows from Lemmas 3.8 and 4.2.

LEMMA 4.3. *Queries* PATHLENGTH(q_1, q_2, r) *and* PATH(q_1, q_2, r) *are performed in time* $O(\log^3 n)$ *and* $O(\log^3 n + k)$, *respectively, where k is the number of edges of the shortest path reported.*

Now, we discuss how operation INSERTVERTEX(v, e; e_1, e_2) affects the new data structure. First, we insert a new node $y(v)$ into $\mathcal{Y}$. Let μ be one of the two nodes in the *ltree* and *rtree*

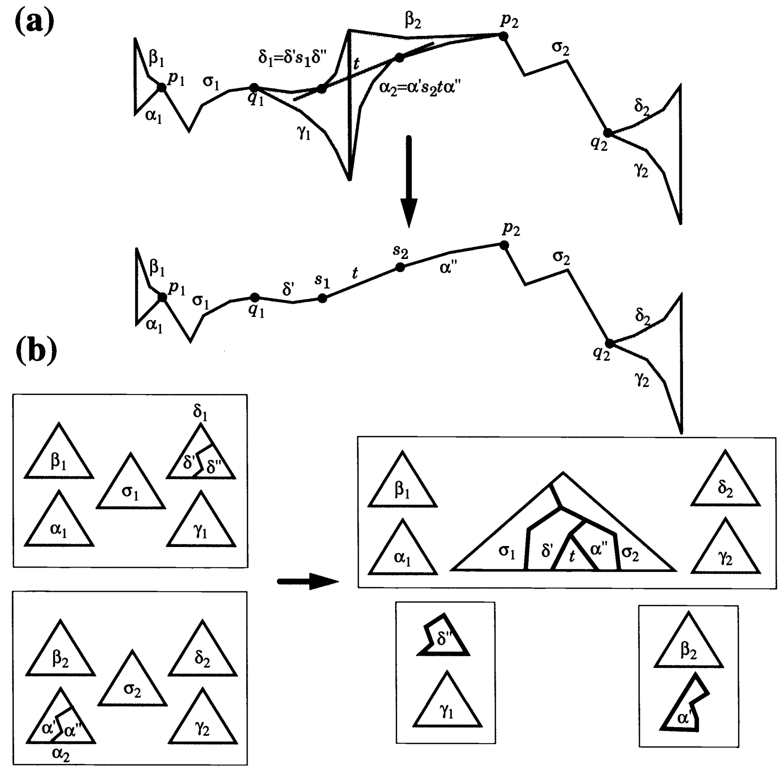

FIG. 9. *Example of update of the secondary structures in an elementary join of two solid paths.* (a) *Geometric construction of the hourglass.* (b) *Construction of the representation of the root hourglass by means of split and join operations on the chain trees in the repr·esentation of the hourglasses of the children nodes.*

that stores the fragment of edge e where v is inserted, and let y be the corresponding node of $\mathcal{Y}$. Before the insertion of v, there is a pointer from μ to y but no back pointer from y to μ, since μ is a leaf of a pruned tree. After the insertion of v, the fragment of e stored in μ is further partitioned into $O(\log n)$ fragments (but the total number of fragments of e is still $O(\log n)$) according to the subtree of $\mathcal{Y}$ rooted at y ($y(v)$ has already been inserted into this subtree); we allocate these edge fragments into a new tree T_μ, expand leaf μ to T_μ, establish a pointer from y to μ, and rename all fragments of e to e_1 or e_2 appropriately.

The insertion of $y(v)$ into $\mathcal{Y}$ may cause rebalancing operations in $\mathcal{Y}$ carried out by means of rotations. A rotation between a node y' and its child y'' implies that horizontal cuts at y'' now take priority over horizontal cuts at y'. It is easy to see that the rotation only affects the subtrees of the *ltree*s and *rtree*s rooted at the nodes pointed to by y'. We rebuild such subtrees from scratch, which can be done in time proportional to their size. Note that prior to the rotation, a leaf μ of *ltree* or *rtree* corresponding to y' stores an edge fragment that spans the canonical vertical interval I of y', and thus μ is not affected by the rotation (except that after the rotation we have to redirect the original pointer of μ to y' so that it now points to y'', since y'' now corresponds to I). Since there may be a large number of such leaves μ that do not require rebuilding, we do not establish a back pointer from y' to leaf μ in our data structure (as we have already seen), so that inefficient checking for the necessity of rebuilding is avoided. Also, the redirection of all pointers of leaves μ from y' to y'' can be done efficiently when we rotate y' with y'': we switch the contents of the *physical* nodes y' and y'' to interchange the roles of the physical nodes y' and y'' (and then carry out the rotation appropriately by $O(1)$ elementary splits and joins), so that all these pointers are effectively redirected, though no actual changes are made to the pointers. Now we show that the rebuilding of the subtrees of *ltree*s and *rtree*s caused by a rotation in $\mathcal{Y}$ can be performed efficiently.

LEMMA 4.4. *Let y be a node of $\mathcal{Y}$ whose subtree has ℓ leaves. The subtrees of ltrees and rtrees with the hull structure appended whose roots are pointed to by node y have total size $O(\ell \log \ell)$ and can be built in time $O(\ell \log \ell)$.*

Proof. The subtree of $\mathcal{Y}$ rooted at y has exactly $2\ell - 1$ nodes. Thus there are $O(\ell)$ vertices inside the canonical vertical interval I of node y. The leaves of the subtree rooted at a node pointed by y store the edge fragments that are inside I but do not span I. Hence, the edges contributing to such fragments must be incident on some vertex inside I. Since each vertex has bounded degree, there are $O(\ell)$ such edges. Also, since the subtree of $\mathcal{Y}$ has height $O(\log \ell)$, each such edge has $O(\log \ell)$ fragments inside I. We conclude that the total number of leaves in the subtrees rooted at node pointed by y is $O(\ell \log \ell)$, and hence their total size is also $O(\ell \log \ell)$. □

By the properties of BB[α]-trees, we derive the following lemma.

LEMMA 4.5. *The amortized rebalancing time of the Y-tree $\mathcal{Y}$ in a sequence of update operations is $O(\log^2 n)$.*

We conclude the following.

THEOREM 4.6. *Shortest-path queries* PATHLENGTH(q_1, q_2, r) *and* PATH(q_1, q_2, r) *in an n-vertex connected planar map can be performed in worst-case time $O(\log^3 n)$ and $O(\log^3 n+k)$, respectively (where k is the number of edges of the shortest path reported), using a fully dynamic data structure that uses space $O(n \log n)$ and supports updates of the map in time $O(\log^3 n)$ (amortized for vertex updates).*

Remark. In a concrete situation where vertices are a priori restricted to a fixed set of ordinates, tree $\mathcal{Y}$ is static; if we then implement the trees *ltree* and *rtree* by means of *contracted binary trees* [27] of depth $< \log |Y|$ (whose maintenance requires no rotation), then the update times become $O(\log^2 n \log |Y|)$, in the worst case.

The following arc two additional types of queries that can be supported by the described data structure without any modification.

TRAILLENGTH$(q_1, q_2 | e_1, \ldots, e_\ell)$. Allowing edges $e_1, \ldots, e_\ell$ to be deleted, are points q_1 and q_2 reachable to each other? If so, then return the length of the shortest path.

TRAIL$(q_1, q_2 | e_1, \ldots, e_\ell)$. Allowing edges $e_1, \ldots, e_\ell$ to be deleted, are points q_1 and q_2 reachable to each other? If so, then return the shortest path.

An immediate application is that viewing the edges of the map as walls, we are allowed to put doors on edges $e_1, \ldots, e_\ell$. Can a pointlike robot at position q_1 reach position q_2? If so, then report the shortest path or its length.

Clearly, by using REMOVEEDGE, point-location query (see §5), PATHLENGTH or PATH, and INSERTEDGE operations, queries TRAILLENGTH and TRAIL can be answered in worst-case time $O((\ell + 1) \log^3 n)$ and $O((\ell + 1) \log^3 n + k)$, respectively, where k is the number of edges of the shortest path reported.

5. Point location. In this section, we consider the problem of answering point-location queries.

LOCATE(q). Find the region containing query point q. If q is on an vertex or edge, then return that vertex or edge.

Our dynamic point-location data structure is inspired by the static trapezoid method [23] and its dynamic version for monotone maps [8]. It uses the normalization and hull structures as the underpinning of update operations. Queries are instead performed in a location structure, a binary tree called *trapezoid tree*.

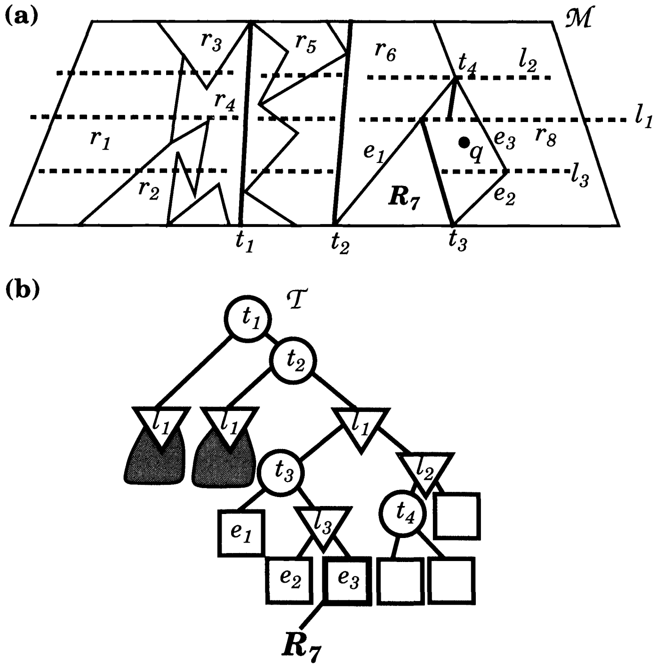

FIG. 10. *Example of the construction of trapezoid tree $\mathcal{T}$ for map $\mathcal{M}$.* (a) *Recursive decomposition of $\mathcal{M}$ by vertical and horizontal cuts.* (b) *Trapezoid tree $\mathcal{T}$ associated with the decomposition in part* (a).

The trapezoid tree defines a binary partition of the plane obtained by means of vertical and horizontal cuts. It differs in many substantial aspects from the trapezoid trees used in [8], [23], the most striking difference being that it is not balanced.

The trapezoid tree $\mathcal{T}$ for map $\mathcal{M}$ is based on the *Y-tree* $\mathcal{Y}$ (see §4) and on the normalization of $\mathcal{M}$ as reflected by the normalization structure (see §3). We view the unnormalized map $\mathcal{M}$ as a trapezoid with its sides at infinity. If a trapezoid τ contains more than a single edge fragment in its interior, we recursively decompose it into trapezoids whose vertical spans are canonical vertical intervals, according to the following rules (see Fig. 10):

Vertical cut. If τ is a coupler or is vertically spanned by a monotone subpath Q and the hourglass H of SLEEVE(Q) is open, we decompose τ by one of the supporting tangents t of H.

Horizontal cut. If no vertical cut is possible, then we decompose τ by cutting it along the horizontal line at the y-coordinate associated with the (unique) allocation node of τ in $\mathcal{Y}$.

Note that a vertical cut always takes priority over a horizontal cut. If more vertical cuts are possible, their order is arbitrary. We represent the above decomposition of $\mathcal{M}$ by means of a binary tree $\mathcal{T}$ (see Fig. 10). Each node of $\mathcal{T}$ is associated with a trapezoid τ of the decomposition and the partitioning object (a tangent or a horizontal line) of τ, and stores the representation of such object. Nodes of $\mathcal{T}$ are classified into three categories (and the association): a ○-*node* (a vertical cut), a ∇-*node* (a horizontal cut), and a □-*node* (a terminal trapezoid of the decomposition and its edge fragment).

The above decomposition process is closely related to the one induced by the segment tree. In particular, the leaves of $\mathcal{T}$ are in one-to-one correspondence with the fragments of the edges of $\mathcal{M}$, so that tree $\mathcal{T}$ has $O(n \log n)$ leaves. Since each node stores a constant amount of information, we have that the space requirement of the trapezoid tree $\mathcal{T}$ is $O(n \log n)$.

It is clear that a point-location query LOCATE(q) can be performed by traversing a root-to-leaf path in $\mathcal{T}$, where at each internal node μ we branch left or right depending on the discrimination of the query point q with respect to the partitioning object stored at μ. Indeed, the leaf reached identifies an edge that is first hit by a horizontal ray through q. Since we did not impose any balance requirement on $\mathcal{T}$, the query time could be linear in the worst case.

To speed up queries, we implement $\mathcal{T}$ as a dynamic tree [30], i.e., $\mathcal{T}$ is decomposed into solid paths (which should not be confused with the solid paths in the normalization structure), connected by dashed arcs (see Fig. 11). Each solid path is associated with a path tree, implemented as a biased search tree [3]. Note that the sequence of nodes of a solid path of $\mathcal{T}$ identifies a sequence of nested trapezoids. For example, in path tree $T(P_1)$ of Fig. 11(c), leaf t_1 identifies the trapezoid of the entire map $\mathcal{M}$, and leaf t_4 identifies the trapezoid whose right side is at infinity and whose other sides are t_2, l_1, and l_2. A point-location query starts at the root of the path tree of the topmost solid path of $\mathcal{T}$ (e.g., the root of $T(P_1)$ in Fig. 11(c)). At a given internal node η of a path tree, we consider the rightmost node ζ in the left subtree of η (readily available given thread pointers). We discriminate q against the trapezoid τ of ζ and go to the left or right child of η according to whether q is inside or outside τ (recall that a solid path is stored bottom-to-top in the left-to-right leaves of its path tree). When we reach a leaf of a path tree (which represents a node μ of $\mathcal{T}$), we always exit on a dashed arc, and we always know the exit except for the case of the last node of the solid path, in which case we go to its left or right child by discriminating q against the partitioning object of μ. For example, in Fig. 11(c), when we reach leaf l_1 of $T(P_1)$, we know that the next node to visit is the root of $T(P_2)$, since that is the only exit; when we reach leaf l_3 of $T(P_2)$, we discriminate q with l_3 and move down right to $T(P_5)$ by the fact that q is above l_3. By this process, we will finally reach a leaf of a path tree with no exit (representing a leaf of $\mathcal{T}$), which identifies an edge of the region containing q.

Using biased search trees [3] as the standard implementation of path trees, we have the following lemma.

LEMMA 5.1. *The time complexity for a point-location query is* $O(\log n)$.

Proof. Let $(\nu_1, \mu_1), \ldots, (\nu_\ell, \mu_\ell)$ be the sequence of dashed arcs traversed by the query algorithm, with ν_i the parent of μ_i. (Note that μ_ℓ is the leaf reached by the query algorithm.) Also, let μ_0 be the root of $\mathcal{T}$. Since the path trees are implemented as biased search trees, we have that the number of nodes visited in the solid path of ν_i is at most $\log(\mathit{weight}(\mu_{i-1})/\mathit{weight}(\nu_i)) + 2$. Hence, the time complexity of a point-location query is $O(\sum_{i=1}^{\ell} \log(\mathit{weight}(\mu_{i-1})/\mathit{weight}(\nu_i)))$. Since $\mathit{weight}(\mu_i) < \mathit{weight}(\nu_i)$, the above sum telescopes, and we have that a point-location query takes time $O(\log n)$. □

To perform update operations, we establish bidirectional links between the trapezoid tree and the normalization structure. Let μ be a node of $\mathcal{T}$. We have the following:

- If μ is a $\bigcirc$-node, let Q' be the subpath of a monotone path Q associated with the vertical cut at μ (i.e., the sleeve of Q' spans the trapezoid of μ and has an open hourglass). We establish pointers between μ and the nodes of $\mathit{ltree}(Q)$ and $\mathit{rtree}(Q)$ associated with Q'.
- If μ is a ∇-node, let Q' and R' be subpaths of monotone paths Q and R such that Q' and R' span the leftmost and rightmost regions in the trapezoid of μ. We establish pointers between μ and the nodes of $\mathit{ltree}(R)$ and $\mathit{rtree}(Q)$ associated with R' and Q', respectively. Also, we establish a back pointer from the allocation node y of μ in $\mathcal{Y}$ to μ.
- If μ is a $\Box$-node, we establish pointers between μ and the two nodes in the normalization structure associated with the same edge fragment.

Note that every node of a thread tree associated with an open hourglass is pointed to by exactly two nodes of $\mathcal{T}$.

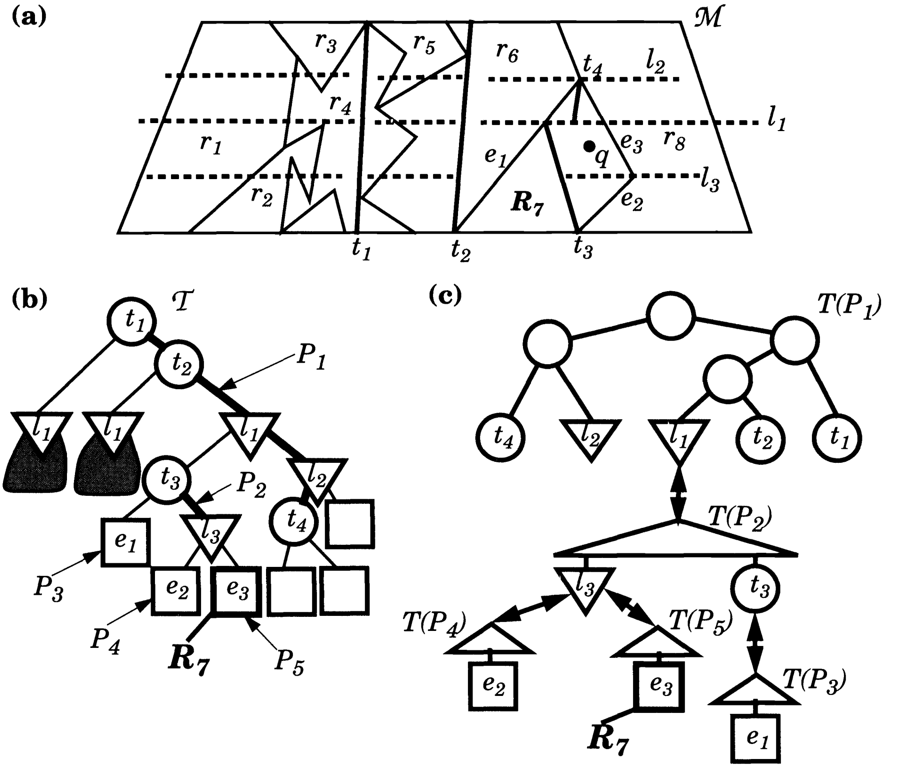

FIG. 11. *Representing trapezoid tree $\mathcal{T}$ by a dynamic tree.* (a) *The same decomposition of $\mathcal{M}$ as in Fig.* 10(a). (b) *Decomposing trapezoid tree $\mathcal{T}$ of Fig.* 10(b) *into solid paths P_1, P_2, ...* (c) *Actual data structure representing $\mathcal{T}$, where $T(P_i)$ is the path tree for solid path P_i in $\mathcal{T}$. The left-to-right leaves of $T(P_i)$ represent bottom-to-top nodes of P_i, which in turn correspond to smaller-to-bigger nested trapezoids.*

Now, we discuss how update operations affect the trapezoid tree. Since the decomposition described by $\mathcal{T}$ is determined by the monotone paths, we update the trapezoid tree whenever monotone paths are changed in the normalization structure. We only need to consider the effects on the trapezoid tree of elementary splits, joins, partings, and pairings of monotone paths. Each such elementary operation in the normalization structure corresponds to performing $O(1)$ link and cut operations in the trapezoid tree. Details are shown in Figs. 12 and 13. Link and cut operations are performed in $O(\log n)$ time by standard dynamic tree algorithms. Regarding vertex insertions, a rotation at a node y in the *Y-tree* $\mathcal{Y}$ caused by a vertex update is handled by rebuilding the subtrees of $\mathcal{T}$ whose roots are ∇-nodes pointed by y. With an argument analogous to the one of Lemma 4.4, we can prove the following lemma.

LEMMA 5.2. *Let y be a node of $\mathcal{Y}$ whose subtree has ℓ leaves. Then the subtrees of $\mathcal{T}$ whose roots are pointed to by y have total size $O(\ell \log \ell)$ and can be built in time $O(\ell \log \ell)$.*

Hence the amortized cost of rebalancing $\mathcal{Y}$ in a sequence of updates is $O(\log^2 n)$. We conclude the following.

THEOREM 5.3. *Point-location queries* LOCATE(q) *in an n-vertex connected planar map can be performed in worst-case time $O(\log n)$ using a fully dynamic data structure that uses space $O(n \log n)$ and supports updates of the map in time $O(\log^3 n)$ (amortized for vertex updates).*

Note that query LOCATE(q) is used in the update of the hull structure.

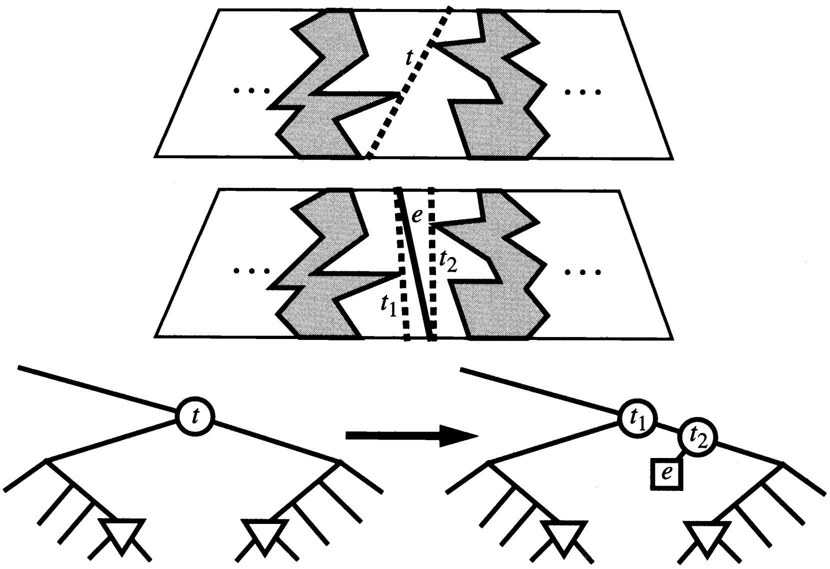

FIG. 13. *Update of the trapezoid tree caused by parting a monotone path in the normalization structure because of an edge insertion.*

6. Ray shooting. In this section, we consider the problem of performing ray-shooting queries of the following type:

SHOOT(q, d). Find the first vertex or edge hit by a query ray (q, d) in direction d originating at point q.

We show that the dynamic point-location data structure in the previous section also supports ray-shooting queries in worst-case time $O(\log^3 n)$. Without loss of generality, assume that (q, d) is oriented upwards. The ray-shooting algorithm is as follows.

First, we perform LOCATE(q) to determine the region r containing q. If q lies on a vertex or edge, an infinitesimal perturbation of q in direction d enables us to find the first region r entered by the ray. Query LOCATE(q) also identifies the monotone sleeve SLEEVE(Q) of r containing q and the splitter s_1 of SLEEVE(Q) immediately below q. We find the first intersection q' of (q, d) with the boundary of SLEEVE(Q). If q' is on a vertex or edge of r, then we report q' and stop; else (q' is on a lid of SLEEVE(Q)) we apply the algorithm recursively to the new ray (q', d).

We find the first intersection q' of (q, d) with the boundary of SLEEVE(Q) by the process below:

1. Find the topmost splitter s_2 in SLEEVE(Q) such that HOURGLASS(s_1, s_2) is open, by means of $O(\log n)$ elementary splits and joins of subpaths of Q that yield a new monotone path R such that SLEEVE(s_1, s_2) = SLEEVE(R). Note that the boundary of SLEEVE(R) is part of the boundary of SLEEVE(Q) except for possibly s_1 and s_2, where s_2 is part of the boundary of SLEEVE(Q) if and only if s_2 is the top lid of SLEEVE(Q).
2. Find the first intersection p of (q, d) with the boundary of SLEEVE(R).
3. If p is not on s_2, or if p is on s_2 but s_2 is the top lid of SLEEVE(Q), then p is on the boundary of SLEEVE(Q) and thus the desired intersection q'. Return p and stop.
4. Else (p is on s_2 and s_2 is not the top lid of SLEEVE(Q)), set $s_1 := s_2$, $q := p$, and go to step 1. Note that this situation can occur at most twice, since s_2 is the topmost splitter above s_1 such that HOURGLASS(s_1, s_2) is open, and any straight line can completely go through at most one such hourglass, with the bottom and top portions of the line possibly in the two (below and above) adjacent hourglasses (see Fig. 14).

In step 2, the first intersection p of (q, d) with the boundary of SLEEVE(R) can be found by a binary search in the trees *ltree*(R) and *rtree*(R) as follows: at a current node μ with children μ' and μ'', where CHAIN(μ') is below CHAIN(μ''), we determine the intersection of (q, d) with the convex hull of CHAIN(μ). If the intersection is on a real edge or on a lid, then we are done. Else it is on a (fictitious) convex hull edge; we then compute the complete convex hulls of CHAIN(μ') and CHAIN(μ''), and repeat the process on μ' or on μ'' depending on whether or not (q, d) intersects with the convex hull of CHAIN(μ'), respectively.

The computation of point q' can be done in $O(\log^2 n)$ time: step 1 performs $O(\log n)$ elementary joins and splits of solid subpaths of Q, each in $O(\log n)$ time by Lemma 4.2; step 2 takes $O(\log^2 n)$ time, with $O(\log n)$ time on each node visited during the binary search; finally, the steps are executed at most three times by step 4. The number of recursive calls to compute a sequence of such points q' is $O(\log n)$, since the query ray intersects $O(\log n)$ lids by Corollary 3.3. At the end, we conceal the path of $\Delta(r)$ traversed by the query ray to restore the weight invariant. We conclude with the following theorem.

THEOREM 6.1. *Ray-shooting queries* SHOOT(q, d) *in an n-vertex connected planar map can be performed in worst-case time $O(\log^3 n)$ using a fully dynamic data structure that uses space $O(n \log n)$ and supports updates of the map in time $O(\log^3 n)$ (amortized for vertex updates).*

Theorem 6.1 also provides the capability of checking the validity of an edge insertion, i.e., whether the new edge does not intersect the current edges of the map. Moreover, as a corollary, we can perform stabbing queries, namely, determine the k edges of the map intersected by a query segment, in time $O((k + 1) \log^3 n)$.

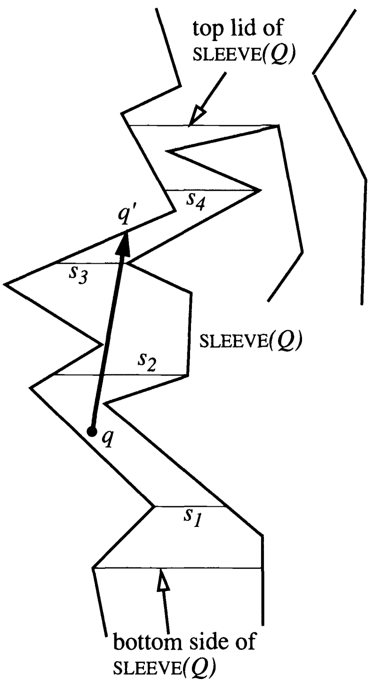

FIG. 14. *The situation in step* 4 *of the process for computing* q' *can occur at most twice. For* $i = 1, 2, 3$, s_{i+1} *is the topmost splitter above* s_i *such that* HOURGLASS(s_i, s_{i+1}) *is open. As shown, the situation of step* 4 *occurrs twice when* (q, d) *hits* s_2 *and* s_3, *respectively. Note that* (q, d) *cannot reach* s_4, *or otherwise* HOURGLASS(s_2, s_4) *would be open and* s_3 *would not be the topmost splitter above* s_2 *such that* HOURGLASS(s_2, s_3) *is open.*

APPROXIMATE MAX-FLOW MIN-(MULTI)CUT THEOREMS AND THEIR APPLICATIONS*

NAVEEN GARG[†], VIJAY V. VAZIRANI[†], AND MIHALIS YANNAKAKIS[‡]

Abstract. Consider the multicommodity flow problem in which the object is to maximize the sum of commodities routed. We prove the following approximate max-flow min-multicut theorem:

$$\frac{\text{min multicut}}{O(\log k)} \leq \text{ max flow } \leq \text{ min multicut},$$

where k is the number of commodities. Our proof is constructive; it enables us to find a multicut within $O(\log k)$ of the max flow (and hence also the optimal multicut). In addition, the proof technique provides a unified framework in which one can also analyse the case of flows with specified demands of Leighton and Rao and Klein et al. and thereby obtain an improved bound for the latter problem.

Key words. approximation algorithm, multicommodity flow, minimum multicut

AMS subject classifications. 68Q25, 90B10

1. Introduction.

Much of flow theory, and the theory of cuts in graphs, is built around a single theorem—the celebrated max-flow min-cut theorem of Fort and Fulkerson [FF] and Elias, Feinstein, and Shannon [EFS]. The power of this theorem lies in that it relates two fundamental graph-theoretic entities via the potent mechanism of a min-max relation.

The importance of this theorem has led researchers to seek its generalization to the case of *multicommodity flow*. In this setting, each commodity has its own source and sink, and the object is to maximize the sum of the flows subject to capacity and flow conservation requirements. The notion of a *multicut* generalizes that of a cut and is defined as a set of edges whose removal disconnects each source from its corresponding sink. Clearly, maximum multicommodity flow is bounded by minimum multicut; the question is whether equality holds. This can be established for some special cases, e.g., if there are only two commodities [Hu]; however, one can construct very simple examples to show that equality does not hold in general. Consider a tree of height one with three leaves. Each pair of leaf vertices form the source–sink pair for a commodity. All edges have unit capacities. The max flow in this graph is $\frac{3}{2}$, whereas the minimum multicut is 2.

Why does the theorem hold for a single commodity, and why does the generalization fail? For an explanation, consider the LP formulation of the maximum multicommodity flow problem. As shown in §5, the dual of this is the LP relaxation of the minimum multicut problem, i.e., the optimal *integral* solution to the dual is the minimum multicut. In general, the vertices of the dual polyhedron are not integral. However, for the case of a single commodity, they are integral (see [GV] for an exact characterization), and the max-flow min-cut theorem is simply a consequence of the LP-duality theorem. For the multicommodity case, the LP-duality theorem shows only that maximum flow is equal to the minimum fractional (i.e., relaxed) multicut.

In this situation, the best one can hope for is an approximate max-flow min-cut theorem. In ground-breaking work, Leighton and Rao [LR] gave the first such

theorem. Let us consider a second formulation of the multicommodity flow problem that has also been widely studied in the past. In this formulation, a demand, D_i, is specified for each commodity, i. The object is to determine the maximum number, f, called *throughput*, such that fD_i amount of each commodity i can be routed simultaneously, subject to capacity and conservation constraints. (Equivalently, the object is to determine the minimum number, u, such that if the capacity of each edge is multiplied by u, then all the demands can be simultaneously satisfied. Clearly, at optimality $f = \frac{1}{u}$.) The analogue of a minimum cut in this case is a sparsest cut into two parts, one that minimizes the ratio of capacity of the cut to the demand across the cut. Let α be this minimum. Clearly, $f \leq \alpha$, and once again equality does not generally hold.

Leighton and Rao considered a special case of the above-stated formulation, called uniform multicommodity flow, in which there is a commodity corresponding to each pair of vertices and all the demands are unity. They proved the following approximate max-flow min-cut theorem:

$$\frac{\alpha}{O(\log n)} \leq f \leq \alpha,$$

where n is the number of vertices in the graph. Subsequently, Klein et al. [KARR] managed to attack the arbitrary demands problem, and proved that

$$\frac{\alpha}{O(\log C \log D)} \leq f \leq \alpha,$$

where C is the sum of capacities of all edges and D is the sum of all demands. However, one restriction they impose is that all capacities and demands be integral. The lower bound was later improved to $\alpha/O(\log n \log D)$ by Tragoudas [Trag]. [LR], [KARR], and [Trag] also give polynomial-time algorithms for finding an approximation to the sparsest cut, the factors being $O(\log n)$ and $O(\log C \log D)$ (or $O(\log n \log D)$), respectively.

We address the first version of the multicommodity flow problem, henceforth referred to as the *maximum multicommodity flow* problem, and prove the following approximate max-flow min-multicut theorem:

$$\frac{M}{O(\log k)} \leq f \leq M,$$

where f is the max flow, M is the minimum multicut, and k is the number of commodities. We also show that our theorem is tight up to a constant factor, and we give a polynomial-time algorithm for finding a multicut within $O(\log k)$ of the optimal fractional, and therefore also of the integral multicut.

Our general approach is similar to that of Leighton and Rao [LR] and Klein et al. [KARR]. We consider the LP-relaxation of the minimum multicut problem and use its optimal solution to define a graph with distance labels on the edges. Starting from a source or a sink, we grow a region in this graph until we find a cut of small enough capacity separating the root from its mate. The region is removed and the process is repeated. Our method differs in several respects from previous methods. It dispenses with the discretization of the edge distances and employs a technique that leads to quicker termination of the region growth process and thus produces a better bound on the capacity of the cut. These techniques are encapsulated in the two region-growing lemmas of §4, which use the idea of packing cuts to grow regions.

Our analysis is also useful in the demands version of the multicommodity flow problem. It establishes a unified framework in which simpler proofs of the theorems of Leighton and Rao and Klein et al. can be given by dispensing with tokenizing distances. We also avoid the dynamic resetting of the parameters for region growing and restarting the procedure. In both cases we use heavily ideas from the original papers. Using our lemmas, we improve the [KARR] and [Trag] results to

$$\frac{\alpha}{O(\log k \log D)} \leq f \leq \alpha.$$

We also dispense with the restriction that capacities be integral. Furthermore, Plotkin and Tardos [PT] give a method of scaling demands so that the log D factor in these results can be replaced by $\log k$, thus yielding an improved bound of $O(\log^2 k)$ on the gap between f and α.

The following problem is a generalization of the uniform multicommodity flow problem considered by Leighton and Rao and by Tragoudas. It was called the *product multicommodity flow problem* in [LR] and the *complete concurrent flow problem* in [Trag]. In this problem, each vertex has a nonnegative weight $w(v)$ (assumed to be positive integer in [LR] and [Trag] but this is not essential), and there is a commodity for each unordered pair u, v of vertices, with a demand of $w(u)w(v)$. The object again is to maximize the throughput subject to capacity and conservation constraints. Let

$$\alpha = \min_{S \subseteq V} \frac{C_{\nabla(S)}}{w(S)w(\bar{S})},$$

where $w(S)$ in the sum of weights of vertices in S.

Let W be the sum of weights of all vertices, and C be the sum of all edge capacities. Then, Leighton and Rao prove $\alpha/O(\log\min(\frac{W}{w_{\min}}, \frac{C}{c_{\min}})) \leq f \leq \alpha$, where $w_{\min}$ is the weight of the lightest vertex, and $c_{\min}$ is the minimum over all vertices of the sum of capacities of edges incident at the vertex. Tragoudas improves the lower bound to $\alpha/O(\log n)$ [Trag]. Using our techniques, we improve this result to

$$\frac{\alpha}{O(\log k)} \leq f \leq \alpha,$$

where k is the number of vertices having nonzero weight.

The multicut problem finds numerous applications, e.g., in circuit partitioning problems. It was first stated by Hu in 1963 [Hu]. For $k = 1$, the problem coincides with the ordinary min cut problem. For $k = 2$, it can also be solved in polynomial time by two applications of a max-flow algorithm [YKCP]. The problem was proven NP-hard and MAX SNP-hard for any $k \geq 3$ by Dalhaus et al. [DJPSY]. Because of the MAX SNP-hardness, there is no polynomial-time approximation scheme for multicut for $k \geq 3$ (assuming $P \neq NP$) [ALMSS]. Note that, in the demands case, the sparsest cut problem can be solved in polynomial time for fixed k (or $k = O(\log n)$) because in this case we are concerned only with cuts into two parts, and thus we can try all possible partitions of the sources and sinks into two parts and compute the minimum cut for each partition.

Dahlhaus et al. [DJPSY] studied the *multiway cut* (or *multiterminal cut*) problem: given a set of "terminal" vertices T, find a minimum weight set of edges that disconnects every terminal from every other terminal. This is the special case of the multicut problem where there is one commodity for every pair of vertices from the subset T. [DJPSY] gave a factor-of-2 approximation algorithm for this case and showed that it can be used to approximate the general multicut problem within a factor of 2 with a running time that has k in the exponent. Thus the running time is polynomial only for fixed k.

Klein et al. [KARR] used their approximation algorithm for the sparsest cut to give an $O(\log^3 n)$ approximation algorithm for multicut. They also gave some applications of the multicut problem obtaining approximation algorithms with ratio $O(\log^3 n)$ for the following problems: deleting the minimum number of clauses to make a 2CNF $\equiv$ formula satisfiable, deleting the minimum number of edges from a graph to make it bipartite, and a via minimization problem in VLSI. Our improvement for multicut gives us an $O(\log n)$ approximation algorithm for these problems.

2. LP formulations for max multicommodity flow. Given an undirected graph $G = (V, E)$, a capacity function $c : E \rightarrow \Re^+$, and k pairs of vertices (not necessarily distinct) $\{s_i, t_i\}$ $1 \leq i \leq k$, we associate a commodity, i, with the pair $\{s_i, t_i\}$ and designate s_i as the source and t_i as the sink for commodity i. A *multicommodity flow* is a way of simultaneously routing commodities from their sources to sinks, subject to capacity and conservation constraints.

The assumption that each commodity has a single source and a single sink can be made without loss of generality. The more general case where a commodity i may have a set S_i of sources and a set T_i of sinks can be easily reduced to this one by adding a new source s_i with edges to the vertices in S_i and a new sink t_i with edges to T_i.

A multicommodity flow in which the sum of the flows over all the commodities is maximized will be called a *max* (*multicommodity*) *flow*. A *multicut* is defined as a set of edges whose removal disconnects each $\{s_i, t_i\}$ pair. The weight of the multicut is the sum of the capacities of the edges in it. The MULTICUT problem is to find a multicut of minimum weight.

We say that two vertices *share index* i if they form the source–sink pair for commodity i.

Assume that there exist edges (t_i, s_i) in $G, 1 \leq i \leq k$. These edges are special; the only flow allowable on edge (t_i, s_i) is commodity i flowing from t_i to s_i. There are no capacity restrictions on these edges. This allows us to view max flow as a circulation in which the sum of the flows in the edges $(t_i, s_i), 1 \leq i \leq k$, is to be maximized. Let f^l_{ij} denote the flow of commodity l in edge (i, j). The LP formulation of the problem is as follows:

$$\begin{array}{llll}
\text{maximize} & \displaystyle\sum_{i=1}^{k} f^i_{t_i s_i} & & \\
\text{subject to} & \displaystyle\sum_{(j,i)\in E} f^l_{ji} - \sum_{(i,j)\in E} f^l_{ij} \leq 0 & \forall i \in V & \forall l \in [l, \ldots, k], \\
& \displaystyle\sum_{l=1}^{k} f^l_{ij} + \sum_{l=1}^{k} f^l_{ji} \leq c_{ij} & \forall (i,j) \in E - \bigcup_{i=1}^{k}\{(t_i, s_i)\}, & \\
& f^l_{ij} \geq 0 & \forall (i,j) \in E & \forall l \in [1, \ldots, k].
\end{array}$$

The first set of inequalities says that the total flow of each commodity into vertex i is at most the total flow out of it. Note that, if these inequalities hold for each vertex $i \in V$, then in fact they must all hold with equality, thereby implying flow conservation at each node. This is because a deficit in the flow balance at one node must imply a surplus at some other. The second set of inequalities are capacity constraints on the edges; the total flow over all commodities summed in both directions is at most the capacity of the edge.

The dual of this LP is

$$\begin{array}{llll}\text{minimize} & \displaystyle\sum_{(i,j)\in E} d_{ij}c_{ij} & & \\ \text{subject to} & d_{ij} \geq p_i^l - p_j^l & \forall (i,j) \in E - \displaystyle\bigcup_{i=1}^{k}\{(t_i,s_i)\} & \forall l \in [1,\dots,k], \\ & p_{s_i}^i - p_{t_i}^i \geq 1 & \forall l \in [1..k], & \\ & p_i^l \geq 0 & \forall i \in V & \forall l \in [1,\dots,k], \\ & d_{ij} \geq 0 & \forall (i,j) \in E - \displaystyle\bigcup_{i=1}^{k}\{(t_i,s_i)\}. & \end{array}$$

The variable d_{ij} can be viewed as a distance label on the edge (i,j) and p_i^l as the potential corresponding to commodity l on vertex i. Thus the dual problem is an assignment of potentials to vertices and distance labels to edges so that the potential difference (for each commodity) across each edge is no more than the distance label of that edge. Furthermore, the potential difference between the source and the sink for each commodity should be at least 1. These two conditions imply that the distance between each s_i, t_i under the distance label assignment d_{ij} is at least 1. The following LP (with, however, exponentially many constraints) expresses this much more simply.

$$\begin{array}{lll}\text{minimize} & \displaystyle\sum_{e\in E} d_e c_e & \\ \text{subject to} & \displaystyle\sum_{e\in E} d_e q_i^j(e) \geq 1 & \forall q_i^j \\ & d_e \geq 0 & \forall e \in E,\end{array}$$

where q_i^j denotes the jth path in G (under some arbitrary numbering) from s_i to t_i and $q_i^j(e)$ is the characteristic function of this path, i.e., $q_i^j(e) = 1$ if $e \in q_i^j, 0$ otherwise.

Clearly the distance labels of a feasible solution to the first LP give a feasible solution to the second LP with the same objective function. Conversely, given a feasible solution to the second LP compute potentials on the vertices for each commodity as follows:

p_i^l = length of the shortest path from vertex i to the sink for commodity l, under distance labels d_e.

It can be shown that these potentials, together with the distance labels d_e, are a feasible solution to the first LP with the same objective function. Hence the two formulations of the dual are equivalent.

The dual program can now be viewed as an assignment of nonnegative distance labels d_e to edges $e \in E$, so as to minimize $\sum_{e\in E} d_e c_e$, subject to the constraint that each $\{s_i, t_i\}$ pair be at least a unit distance apart. An integral solution to the dual problem corresponds to a multicut; the edges with $d_e = 1$ form a multicut. Hence, the dual is the LP relaxation of the MULTICUT problem.

3. Overview of the algorithm. In this section we will give a high-level description of our algorithm, justifying the steps taken on intuitive grounds.

Our goal is to pick a set of edges of small capacity whose removal separates all s_i, t_i pairs; the total capacity of edges picked should be within a small factor of the max flow (our factor is $O(\log k)$). Clearly, such edges will be bottlenecks for the max flow, so one possibility is to find a max flow using an LP subroutine and start with the set of saturated edges. A better possibility is to find an optimal solution to the dual LP and consider the set of edges having positive distance labels. Notice that, by complementary slackness, $d_e > 0 \Rightarrow \sum_{l=1}^{k} f_{ij}^l + \sum_{l=1}^{k} f_{ji}^l = c_e$, where $e = (i, j)$, i.e., e must be saturated in every max flow. Moreover, the edges $D = \{e | d_e > 0\}$ constitute a multicut.

The entire set D may have a very large capacity; we wish to pick a small capacity subset that is still a multicut. The optimal dual solution is the most cost effective way of picking a fractional multicut. This provides the clue that, for our purpose, edges with large distance labels should be more important than edges with small distance labels. Our algorithm indirectly gives preference to edges having large distance labels. We start by defining the length of edge e in G as d_e. We then find disjoint sets, called regions, such that for each set S, $C_{\nabla(S)} \leq \epsilon. wt(S)$, where $C_{\nabla(S)}$ is the capacity of the cut $(S, \overline{S})$, ϵ is an appropriately chosen parameter, and $wt(S)$ is roughly $\sum c_e d_e$, where the sum is over all edges having at least one endpoint in S. No region contains both source and sink of any pair, and for each commodity either the source or the sink is in some region. Under these conditions, the union of the cuts of the regions is a multicut and has capacity bounded by $2\epsilon F$, where F is the value of the maximum flow.

The overall approach of finding the optimal fractional solution to the dual LP and then growing regions was introduced by Leighton and Rao [LR] for the uniform multicommodity flow problem. The procedure for growing regions is similar to a graph clustering technique first proposed by Awerbuch in [Aw] (for graphs without capacities or lengths on the edges), and is also similar to that used by Leighton and Rao [LR] and Klein et al. [KARR] (for graphs with capacities and lengths) in the context of multicommodity flows. Each region is formed by growing out radially, with respect to the edge lengths d_e, from one of the sources, as in the usual shortest path computation; the region is grown as long as it accumulates weight fast enough. The reason for adopting radial growth is that this maximizes the weight of the region for a given bound on the pairwise distance between vertices in the region. The region-growing process is formally described in the next section. The main differences from [LR] and [KARR] are in the initialization of the process (assignment of initial weights wt for the roots of the regions), the elimination of the discretization of the lengths of the edges, and the use of auxiliary variables associated with the layers of the radial growth. The idea of packing cuts is used for growing the regions and for accounting. This yields simpler proofs, as well as a more precise bound on ϵ.

4. Two crucial lemmas. In this section we shall prove two region-growing lemmas that will be central to our multicut algorithm. We shall prove these in sufficient generality so that they can be applied to the other versions of the multicommodity flow problem as well.

Given a graph $G = (V, E)$, a capacity function $c : E \rightarrow \Re^+$ and distance labels $d : E \rightarrow \Re^+$ on the edges, define $B = \sum_{e \in E} d_e c_e$. A subset of vertices $V' \subseteq V$ is provided to the region-growing algorithm as the set of candidate roots from which regions will be grown. In our case, V' is the set of sources and sinks. We associate a variable y_S with each subset $S \subset V$; initially $y_S = 0$ for all S. The cut associated with a set S, denoted by $\nabla(S)$, is the set of edges with exactly one end point in S. The capacity of the cut, $C_{\nabla(S)}$, is $\sum_{e \in \nabla(S)} c_e$.

4.1. Growing a region. A region is grown in a radial manner starting from a root vertex, r. The order in which vertices are included in the region is the same as the order in which Dijkstra's algorithm finds shortest paths to vertices from r. We begin by picking a vertex, $r \in V'$, and assign it a weight $wt(r) = B/q$, where $q = |V'|$.

At any point in the algorithm we identify a set, A, as the active set and raise its variable y_A. Initially, the active set is $\{r\}$. Define the weight enclosed by the set A as

$$wt(A) = \sum_{S \subseteq A} y_S C_{\nabla(S)} + wt(r).$$

It is important that the y_S's must form a packing, i.e., $\forall e \in E$: $\sum_{S: e \in \nabla(S)} y_S \leq d_e$. Thus, if while raising y_A we find that $\sum_{e \in \nabla(S)} y_S = d_e$ for some edge $e = (u, v) \in \nabla(A)$, $u \in A$, we make the set $A \cup \{v\}$ active, i.e., $A \leftarrow A \cup \{v\}$, and start increasing the variable corresponding to it. We keep growing the active set in this manner, one vertex at a time, until

$$C_{\nabla(A)} \leq \epsilon \cdot wt(A) \tag{1}$$

is satisfied, where ϵ is a constant that will be set appropriately while applying the lemma. Let $\mathcal{R}$ denote the active set for which condition 1 is satisfied.

Define the *radius* of A, $rad(A) = \sum_{S \subseteq A} y_S$.

LEMMA 4.1. $rad(\mathcal{R}) < \ln(q + 1)/\epsilon$.

Proof. The claim is trivial if $rad(\mathcal{R}) = 0$, so assume $rad(\mathcal{R}) > 0$. Let $S_1, S_2, \ldots, S_l$ denote the successive sets for which the variable $y_S > 0$. It is easy to check that these sets are nested, i.e., if $i < j$ then $S_i \subset S_j$. In what follows we denote the value of the variable y_{S_i} by y_i and $C_{\nabla(S_i)}$ by C_i.

Since, while raising the variable y_{S_i} from 0 to y_i, condition 1 was not satisfied

$$C_i \geq \epsilon \cdot wt(S_i).$$

From our definition of the weight enclosed by a set, it follows that

$$\begin{aligned} wt(S_i) &= wt(S_{i-1}) + y_i C_i \\ &\geq wt(S_{i-1}) + \epsilon y_i wt(S_i), \end{aligned} \tag{2}$$

where for $i = 1$ we let $wt(S_0) = wt(r)$ in the above equation. Note that $wt(S_{i-1}) > 0$ for all i and hence $0 < \epsilon y_i < 1$. Thus,

$$wt(S_i) \geq \frac{wt(S_{i-1})}{(1 - \epsilon y_i)}.$$

Hence,

$$wt(S_l) \geq \frac{wt(r)}{(1-\epsilon y_1)(1-\epsilon y_2)\cdots(1-\epsilon y_l)}$$

$$= \frac{B}{q(1-\epsilon y_1)(1-\epsilon y_2)\cdots(1-\epsilon y_l)}.$$

Since the y_S's form a packing ($\forall e \in E : \sum_{S:e\in\nabla(S)} y_S \leq d_e$), it follows that

$$\sum_{i=1}^{l} y_i C_i = \sum_{i=1}^{l}\left(y_i \sum_{e\in\nabla(S_i)} c_e\right) = \sum_{e\in E}\left(c_e \sum_{S:e\in\nabla(S)} y_S\right) \leq \sum_{e\in E} c_e d_e = B,$$

and hence,

$$wt(S_l) = \sum_{i=1}^{l} y_i C_i + wt(r) \leq B + \frac{B}{q} = B\left(1+\frac{1}{q}\right).$$

Therefore,

$$\frac{B}{q(1-\epsilon y_1)(1-\epsilon y_2)\cdots(1-\epsilon y_l)} \leq wt(S_l) \leq B\left(1+\frac{1}{q}\right),$$

which implies that

$$\frac{1}{(1-\epsilon y_1)(1-\epsilon y_2)\cdots(1-\epsilon y_l)} \leq q+1.$$

Taking natural logs we get

$$\sum_{i=1}^{l} \ln(1-\epsilon y_i)^{-1} \leq \ln(q+1).$$

From (2) it follows that $0 < \epsilon y_i < 1$, $1 \leq i \leq l$. Since $\ln(1-x)^{-1} > x$ for $0 < x < 1$,

$$\epsilon \sum_{i=1}^{l} y_i < \ln(q+1).$$

Thus, $rad(\mathcal{R}) = \sum_{i=1}^{l} y_i < \ln(q+1)/\epsilon$. □

Let $dist_d(u,v)$ denote the shortest path distance between u and v under the distance label assignment d. Consider vertex $v \in \mathcal{R}$. Let S_i be the first set containing v, i.e., $v \in S_i - S_{i-1}$. Then from the manner in which we grow the region it follows that

$$dist_d(r,v) = rad(S_{i-1}). \tag{3}$$

COROLLARY 4.2. *For all $u,v \in \mathcal{R}$, $dist_d(r,u) \leq rad(\mathcal{R})$ and $dist_d(u,v) \leq 2rad(\mathcal{R})$.*

4.2. Growing disjoint regions. Having grown a region rooted at an arbitrary vertex in V', remove all vertices contained in the region and grow another region starting from a new root picked from V'. Continue in this manner until the residual graph contains no vertex of V'. Let $\mathcal{R}_1, \mathcal{R}_2 \dots, \mathcal{R}_p$ denote the regions formed. It is easy to see that these are disjoint. Clearly, $p \leq |V'| = q$.

Let $M = \nabla(\mathcal{R}_1) \cup \nabla(\mathcal{R}_2) \cup \cdots \cup \nabla(\mathcal{R}_p)$.

LEMMA 4.3. $\sum_{e \in M} c_e \leq 2\epsilon B$.

Proof. Let $G_i = (V_i, E_i)$ be the graph obtained by deleting vertices contained in $\cup_{j=1}^{i-1} \mathcal{R}_j$ ($G_1 = G$). Furthermore, let $C^i_{\nabla(S)}$ denote the capacity of the cut $\nabla(S)$ in G_i. Note that $\sum_{e \in M} c_e = \sum_{i=1}^p C^i_{\nabla(\mathcal{R}_i)}$.

Each region $\mathcal{R}_i$ satisfies condition 1. Therefore, $C^i_{\nabla(\mathcal{R}_i)} \leq \epsilon . wt(\mathcal{R}_i)$, $1 \leq i \leq p$. Hence,

$$\sum_{i=1}^p C^i_{\nabla(\mathcal{R}_i)} \leq \epsilon \sum_{i=1}^p wt(\mathcal{R}_i)$$
$$= \epsilon \left(\sum_{i=1}^p \sum_{S \subseteq \mathcal{R}_i} y_S C^i_{\nabla(S)} + \sum_{i=1}^p wt(r_i) \right),$$

where r_i is the root of region $\mathcal{R}_i$. Since the y_S's form a packing,

$$\sum_{i=1}^p \sum_{S \subseteq \mathcal{R}_i} y_S C^i_{\nabla(S)} \leq \sum_{e \in E} d_e c_e = B.$$

Also,

$$\sum_{i=1}^p wt(r_i) = \frac{B}{q} p \leq B.$$

Thus, $\sum_{i=1}^p C^i_{\nabla(\mathcal{R}_i)} \leq 2\epsilon B$, and hence $\sum_{e \in M} c_e \leq 2\epsilon B$. □

When growing region $\mathcal{R}_j$ in the graph G_j, we have that $\sum_{e \in E_j} d_e c_e \leq \sum_{e \in E} d_e c_e = B$. However, the proof of Lemma 4.1 goes through without any modifications. Regarding (3), note that $rad(S_{i-1})$ is now the shortest path distance between r and v in the graph G_j; the shortest distance between these vertices in G might be even smaller. Hence Corollary 4.2 still holds.

COROLLARY 4.4. $\sum_{i=1}^p C_{\nabla(\mathcal{R}_i)} \leq 4\epsilon B$.

Proof. An edge in M occurs in at most two cuts $\nabla(\mathcal{R}_i)$, $1 \leq i \leq p$. Thus,

$$\sum_{i=1}^p C_{\nabla(\mathcal{R}_i)} \leq 2 \sum_{e \in M} c_e \leq 4\epsilon B. \qquad \square$$

The time complexity of growing disjoint regions is $O(m + n \log n)$ as our algorithm is essentially the same as Dijkstra's algorithm for shortest paths.

5. Approximate max-flow min-multicut theorem. Clearly, the max flow, F, is less than the weight of the minimum multicut, M, i.e., $F \leq M$.

The main result of this section is an algorithm that finds a multicut of weight at most $F \cdot O(\log k)$. We state this as a theorem for later reference.

THEOREM 5.1 (approximating the minimum multicut). *Consider an instance of the* MULTICUT *problem specified by a graph* $G = (V, E)$*, a capacity function* $c : E \rightarrow \Re^+$*, and* k *pairs of vertices. One can, in polynomial time, find a multicut separating the specified pairs of vertices having weight within a factor* $O(\log k)$ *of the maximum flow over these pairs.*

Since M is the minimum multicut, $M \leq F \cdot O(\log k)$. Thus the ratio of the optimal integral solution to the optimal fractional solution of the dual program is at most $O(\log k)$.

COROLLARY 5.2 (approximate max-flow min-multicut theorem). $F \leq M \leq F \cdot O(\log k)$.

Furthermore, this bound on the ratio of the minimum multicut and maxflow is tight, as shown in Theorem 5.4.

For planar graphs, Tardos and Vazirani [TV] obtain a constant factor approximation for the minimum multicut. Garg, Vazirani, and Yannakakis [GVY] approximate the minimum multicut on trees to within twice the optimal. They also give a factor-$\frac{1}{2}$ approximation algorithm for maximum integral multicommodity flow on trees, and they show that even for planar graphs the integrality gap for flow is unbounded, thereby ruling out LP duality based methods for approximating maximum integral multicommodity flow. Both these results also establish approximate max-flow min-multicut theorems.

5.1. Finding the multicut. First, solve the dual LP to obtain a set of distance labels, d_e, $e \in E$. Next, grow regions as in §4. The constant ϵ and the set V' are chosen to ensure that $\nabla(\mathcal{R}_1) \cup \nabla(\mathcal{R}_2) \cup \cdots \cup \nabla(\mathcal{R}_p)$ is a multicut.

The vertices of V that are the source for some commodity form the set V', i.e., $V' = \cup_{i=1}^{k}\{s_i\}$. Thus, $s_i \in \cup_{j=1}^{p}\mathcal{R}_j$, $1 \leq i \leq k$. Now if we can choose ϵ so that no two vertices in $\mathcal{R}_i$, $1 \leq i \leq p$, share an index, we shall be finished.

LEMMA 5.3. *If* $\epsilon = 2\ln(k+1)$*, then no two vertices in* $\mathcal{R}_i$ *share an index.*

Proof. Note that $q = |V'| \leq k$. Therefore, if $\epsilon = 2\ln(k+1)$, then, by Lemma 4.1, $rad(\mathcal{R}_i) < \frac{1}{2}$. Hence, by Corollary 4.2, the distance between any two vertices in $\mathcal{R}_i$ is less than 1. Since the assignment of distance labels to edges is such that the distance between any two vertices sharing an index is at least 1, no two vertices in $\mathcal{R}_i$ share an index. □

Substituting this choice of ϵ into Lemma 4.3, we find that the multicut obtained has weight at most $4B\ln(k+1)$. Since $B = \sum_{e \in E} d_e c_e = F$, the max flow, the weight of the multicut is within a factor $4\ln(k+1)$ of the max flow.

5.2. A tight example.

THEOREM 5.4. *For all* $k, n, k \leq n$*, there exists an* n *vertex graph,* G*, and* $\Omega(k^2)$ *pairs of vertices in* G *such that the ratio between the minimum multicut and the max flow is* $\Omega(\log k)$.

Proof. As in [LR], we use an expander graph and similar arguments, but here we need to choose an appropriate set of source–sink pairs and consider cuts into many parts. Let $G = (V, E)$ be a k-vertex, bounded degree expander graph (each vertex has degree at most d, for an appropriate constant d). Every vertex has at most $\frac{k}{2}$ vertices within distance $\log_d\left(\frac{k}{2}\right)$. Thus, G has $\Omega(k^2)$ pairs of vertices that are a distance $\log_d\left(\frac{k}{2}\right)$ or more apart. Let these be the pairs for the MULTICUT instance. All edges of the graph have unit capacity, and hence the total capacity of the edges is $O(k)$. Since each flow path is $\Omega(\log k)$ long, the maximum flow is $O(k/\log k)$.

The optimum multicut induces a partition of the vertex set of G. Since G is an expander, any set S in the partition has $\Omega(|S|)$ edges running across it, provided $|S| \leq \frac{k}{2}$. Any subgraph with more than $\frac{k}{2}$ vertices has pairs that are $\log_d\left(\frac{k}{2}\right)$ apart, and hence contains a pair of vertices that share an index. Thus, no set in the partition induced by the multicut has more than $\frac{k}{2}$ vertices, and so each set S in the partition has $\Omega(|S|)$ edges running across it. Hence the number of edges in the multicut is $\Omega(k)$. This yields a ratio of $\Omega(\log k)$ between the weight of the minimum multicut and the maxflow.

Note that splitting an edge by adding vertices on the edge does not change the max flow or the minimum multicut. We modify G into an n-vertex graph by adding an appropriate number of vertices on the edges of G. □

We remark that, in the case of the multiway cut problem [DJPSY] (i.e., the special case of the multicut problem where the given set of source–sink pairs for the commodities consists of all pairs of vertices from a given subset S of terminals), the gap between min cut and max flow is much smaller; it is at most $2 - \frac{2}{k}$ [Cu]. Of course, if S is the whole set of vertices (i.e., there is one commodity for every pair of vertices), the problem is trivial and there is no gap: max flow = min cut = total capacity of the graph.

6. Multicommodity flow with specified demands. We next consider the case when along with the source and sink for commodity i, $1 \leq i \leq k$, we are also specified a demand, dem(i), for the commodity. A multicommodity flow is *feasible* if it meets the demand for each commodity.

As in §4 we define the cut associated with S, denoted by $\nabla(S)$, as the set of edges with exactly one end point in S. The capacity of the cut, $C_{\nabla(S)}$, is $\sum_{e\in\nabla(S)} c_e$. The set S separates commodity i if and only if exactly one of $\{s_i, t_i\}$ is in S. The demand across the cut, $D_{\nabla(S)}$, is the sum of the demands of all commodities separated by set S. Clearly, the following condition is necessary for the existence of a feasible multicommodity flow.

Cut condition. For all $S \subseteq V$, $C_{\nabla(S)} \geq D_{\nabla(S)}$.

However, this condition is not sufficient. Extensive work has been done on characterizing graphs with distinguished sources and sinks for which the cut condition is both necessary and sufficient. Again, no complete characterization is known.

Klein et al. view this problem as follows: they wish to find the minimum factor, u, by which the capacity of the edges should be raised to ensure a feasible flow. Equivalently, they wish to find the maximum factor, f, such that it is possible to route simultaneously an amount $f \cdot$ dem(i) of each commodity while satisfying the capacity constraints. At optimality $f = \frac{1}{u}$.

Let q_i^j denote a path in G from s_i to t_i and $q_i^j(e)$ be the characteristic function of this path, i.e., $q_i^j(e) = 1$ if $e \in q_i^j$, 0 otherwise. Then an LP formulation for this problem is

$$\begin{array}{lll} \text{maximize} & f & \\ \text{subject to} & \sum_{i,j} f_i^j q_i^j(e) \leq c_e & \forall e \in E, \\ & \sum_j f_i^j \geq f.dem(i), & 1 \leq i \leq k, \\ & f_i^j \geq 0 & \forall q_i^j, \end{array}$$

where f_i^j is the flow along the path q_i^j. Thus, multicommodity flow is feasible if and only if f is at least 1.

We can formulate the dual LP which now calls for an assignment of nonnegative distance labels, d_e, to edges $e \in E$ so as to minimize $\sum_{e \in E} d_e c_e$, subject to the constraint $\sum_{l=1}^{k} dist_d(s_l, t_l) dem(l) \geq 1$, where $dist_d(u,v)$ is the shortest path distance between u and v under this assignment of distance labels. At optimality, we have $\sum_{e \in E} d_e c_e = f$.

How does f relate to the structure of the graph? The cut condition motivates the following definition. Define the *sparsest cut* as the cut that minimizes the ratio $C_{\nabla(S)}/D_{\nabla(S)}$. Let

$$\alpha = \min_{S \subseteq V} \frac{C_{\nabla(S)}}{D_{\nabla(S)}}.$$

Clearly, $f \leq \alpha$. Klein et al. show that the "throughput" f is at least $\alpha / O(\log C \log D)$, where C is the sum of all capacities and D is the total demand. This was later improved to $\alpha / O(\log n \log D)$ by Tragoudas [Trag].

We improve this result by providing a tighter bound on f.

THEOREM 6.1.

$$\frac{\alpha}{O(\log k \log D)} \leq f \leq \alpha.$$

Thus, for a multicommodity flow to be feasible it is necessary that the sparsest cut ratio, α, be at least 1 *and sufficient that it be* $O(\log k \log D)$.

Plotkin and Tardos [PT] give a method of scaling demands so that the log D factor in Theorem 6.1 can be replaced by log k. Hence, they improve the bound in Theorem 6.1 to $O(\log^2 k)$.

For uniform multicommodity flow on bounded degree expanders, the ratio between f and α is $O(\log n)$ (n is the number of vertices) [LR]. We can, as in Theorem 5.4, modify this by adding new vertices on edges to get a graph on n vertices and k commodities ($k \leq \frac{n(n-1)}{2}$) for which $f = \alpha / O(\log k)$. It is an open problem to bridge the gap between the $O(\log^2 k)$ bound of [PT] and this $O(\log k)$ example.

For planar graphs, Klein, Plotkin, and Rao [KPR] show that multicommodity flow is feasible if the sparsest cut ratio, α, is logarithmic.

6.1. Proof of Theorem 6.1. First solve the dual LP to obtain a set of distance labels, d_e, $e \in E$. By LP duality we have that the optimal "throughput" f is equal to $B = \sum_{e \in E} d_e c_e$. We will find a cut whose ratio of capacity to demand is within a factor $\rho = 16 \ln(k+1) \log D$ of f (and hence also of the optimal ratio α).

As in Klein et al., the algorithm proceeds in phases. Each phase involves growing regions as in §4. If the source s_j and sink t_j of a commodity belong to the same region in a phase we will say that commodity j is routed during that phase. In each phase we only consider the commodities that have not been routed so far, i.e., the set V' of candidate roots consists of the vertices that are sources for some unrouted commodity. Thus, $q = |V'| \leq k$. Let the *residual demand* at phase i, D_i, be the total demand over commodities which have not been routed in phases 1 to $i-1$. We set the rate of expansion for phase i to $\epsilon_i = \rho D_i / 8$. The purpose is to route a significant fraction of the demand while keeping the cut small. (Contrast this with Lemma 5.3 where ϵ was chosen so that no commodity had its endpoints in the same region.)

We claim that at least one of the regions $\mathcal{R}_j$ in one of the phases has ratio of capacity to demand at most ρf. Suppose that this is not the case, i.e., $C_{\nabla(\mathcal{R}_j)}/D_{\nabla(\mathcal{R}_j)} > \rho f$

for all regions. We will derive a contradiction to the constraint $\sum_{l=1}^{k} dist_d(s_l, t_l)dem(l) \geq 1$.

Consider phase i. The residual demand after phase i is

$$D_{i+1} \leq \sum_{j=1}^{p} D_{\nabla(\mathcal{R}_j)} \leq \frac{1}{\rho f} \sum_{j=1}^{p} C_{\nabla(\mathcal{R}_j)}.$$

From Corollary 4.4 we get

$$D_{i+1} \leq \frac{4\epsilon_i B}{\rho f} = \frac{4\epsilon_i f}{\rho f} = \frac{D_i}{2}.$$

Since $q \leq k$ it follows from Lemma 4.1 and Corollary 4.2 that any two vertices in the same region are less than $2\ln(k+1)/\epsilon_i$ apart. Thus for any commodity l that is routed in phase i we have

$$dist_d(s_l, t_l) < \frac{2\ln(k+1)}{\epsilon_i} = \frac{16\ln(k+1)}{\rho D_i}.$$

Therefore, the sum of the quantities $dist_d(s_l, t_l)dem(l)$ over the commodities routed in phase i is less than $16\ln(k+1)/\rho$. Since the residual demand is halved in each phase, all the commodities are routed after at most $\log D$ phases. Therefore, the sum over all commodities is

$$\sum_{l=1}^{k} dist_d(s_l, t_l)dem(l) < \frac{16\ln(k+1)\log D}{\rho} = 1,$$

a contradiction.

7. Product multicommodity flow. In this section, we will use our region-growing lemmas to establish an improved bound for the product multicommodity flow problem (defined in the introduction). If all the vertex weights are unity, this also gives a cleaner proof for the uniform multicommodity flow problem by dispensing with discretization (the rest of the ideas remain essentially the same). Another case of special interest is when a subset of the vertices (say k in number) have unit weights and the rest have weights zero. We call this the *k-terminal uniform multicommodity flow problem.* It can be viewed as the analogue of the multiway cut problem in the demands case. For this case, the gap between the maximum throughput and the minimum ratio of a cut is $O(\log k)$.

As stated in the previous section, the example of Leighton and Rao can be easily adapted to show that the $O(\log k)$ gap is essentially tight for the k-terminal uniform multicommodity flow problem (up to a constant factor). It is interesting to note that, in both the minimum multicut problem and the sparsest cut problem, there is a $\log k$ discrepancy between the uniform case (where we have all pairs among a given set of terminals) and the general case (arbitrary set of pairs): in the multicut problem the integrality gap is $2 - \frac{1}{k}$ in the uniform case versus $O(\log k)$ in the nonuniform case. In the sparsest cut problem it is $O(\log k)$ versus $O(\log^2 k)$. The first three of these bounds are essentially tight. Only the last gap is not known to be tight; we do not have an example for the sparsest cut problem that takes advantage of nonuniformity.

In the product multicommodity flow problem each vertex v has a (nonnegative) weight $w(v)$, and there is a commodity for each unordered pair u, v of vertices with demand $w(u)w(v)$. Let

$$\alpha = \min_{S\subseteq V} \frac{C_{\nabla(S)}}{w(S)w(\overline{S})}.$$

The throughput f is clearly bounded from above by α.

The dual program again calls for an assignment of nonnegative distance labels, d_e, to the edges $e \in E$, so that $\sum_{e\in E} d_e c_e$ is minimized subject to the constraint that $\sum_{u,v\in V} w(u)w(v)\,dist_d(u,v) \geq 1$, where the sum extends over all unordered pairs of vertices. At optimality we have

$$\sum_{e\in E} d_e c_e = f.$$

THEOREM 7.1. *For the product multicommodity flow problem, the maximum throughput f and the minimum ratio α of a cut satisfy the inequalities*

$$\frac{\alpha}{O(\log k)} \leq f \leq \alpha,$$

where k is the number of vertices having nonzero weight. We can find in polynomial time a cut whose ratio is within a factor $O(\log k)$ of the minimum ratio.

A closely related quantity to the ratio of a cut $\nabla(S)$ is its *flux*:

$$\frac{C_{\nabla(S)}}{\min(w(S), w(\overline{S}))}.$$

Let

$$\beta = \min_{S\subseteq V} \frac{C_{\nabla(S)}}{\min(w(S), w(\overline{S}))}.$$

Recall that W denotes the sum of the weights of all the vertices. Since $\frac{W}{2} \leq \max(w(S),\, w(\overline{S})) \leq W$, it follows that $\frac{\alpha W}{2} \leq \beta \leq \alpha W$. Therefore, Theorem 7.1 implies that the minimum flux β lies between $\frac{fW}{2}$ and $fW \cdot O(\log k)$. Also, a cut approximates the minimum ratio α within a factor $O(\log k)$ if and only if it approximates the minimum flux β within a factor $O(\log k)$.

7.1. Proof of Theorem 7.1. We follow the structure of the Leighton–Rao proof for the uniform multicommodity flow problem, except that we shall use the lemmas of §4. Also, it is not necessary to readjust adaptively the expansion rate ϵ of the regions and restart the procedure. First solve the dual LP to obtain a set of distance labels d_e. By LP duality, we have that f is equal to $B = \sum_{e\in E} d_e c_e$. We shall find a cut whose flux is at most $\hat{\beta} = fW(4\ln(k+1)+1)$; thus its ratio of capacity to demand is within a factor $2(4\ln(k+1)+1)$ of the throughput f and hence also of the optimal ratio α.

We find a good cut in two stages. In the first stage we grow regions as in §4 with V' as the set of vertices with nonzero weight; $|V'| = k$. We choose $\epsilon = \hat{\beta}W/4f$. If one of the regions has flux at most $\hat{\beta}$ we are finished. Suppose this is not the case. We show then that one of the regions contains vertices of weight at least $\frac{W}{2}$. If every region $\mathcal{R}_i$ contains vertices of weight less than $\frac{W}{2}$, then its flux is

$$\frac{C_{\nabla(\mathcal{R}_i)}}{\min(w(\mathcal{R}_i), w(\overline{\mathcal{R}_i}))} = \frac{C_{\nabla(\mathcal{R}_i)}}{w(\mathcal{R}_i)} > \hat{\beta}.$$

Therefore,

$$\sum_{i=1}^{p} C_{\nabla(\mathcal{R}_i)} > \hat{\beta} \sum_{i=1}^{p} w(\mathcal{R}_i) = \hat{\beta} W.$$

However, by Corollary 4.4 we have

$$\sum_{i=1}^{p} C_{\nabla(\mathcal{R}_i)} \leq 4\epsilon B = 4\epsilon f = \hat{\beta} W.$$

We conclude that one of the regions, say $\mathcal{R}*$, has weight at least $\frac{W}{2}$. Let r be the root of region $\mathcal{R}*$.

In the second stage we reset all the variables y_S to zero and grow a region from root r as in §4. However, now we do not check for condition 1 and stop only when all vertices are included in the region. Let $\{r\} = S_1 \subset S_2 \subset \cdots \subset S_t$ denote the sets with $y_S > 0$. We will argue that one of these sets has flux at most $\hat{\beta}$. Assume that this is not the case; we shall derive a contradiction to the constraint $\sum_{u,v \in V} w(u)w(v)\mathit{dist}_d(u,v) \geq 1$.

First observe that $\mathit{dist}_d(u,v) \leq \mathit{dist}_d(r,u) + \mathit{dist}_d(r,v)$. Therefore,

$$\sum_{u,v \in V} w(u)w(v)\mathit{dist}_d(u,v) \leq W \sum_{v \in V} w(v)\mathit{dist}_d(r,v).$$

If S_i is the smallest set containing vertex v then $\mathit{dist}_d(r,v) = \sum_{S \subset S_i} y_S$. Let $S_l = \mathcal{R}$ be the first set in the chain that contains all the vertices of $\mathcal{R}*$. The set $\mathcal{R}$ may be a proper superset of $\mathcal{R}*$, because some nodes may have been deleted from the graph in the previous stage by the time we grew the region around r. In any case, however, $\mathit{rad}(\mathcal{R}) \leq \mathit{rad}(\mathcal{R}*)$. Since $|V'| = k$, by Lemma 4.1

$$\mathit{rad}(\mathcal{R}) < \frac{\ln(k+1)}{\epsilon} = \frac{4f\ln(k+1)}{W\hat{\beta}}.$$

The total weighted distance of all the vertices from r is

$$\sum_{v \in V} w(v)\mathit{dist}_d(r,v) = \sum_{S} y_S(W - w(S)) = \sum_{S \subset \mathcal{R}} y_S(W - w(S)) + \sum_{S \supseteq \mathcal{R}} y_S(W - w(S)).$$

Now,

$$\sum_{S \subset \mathcal{R}} y_S(W - w(S)) \leq W \sum_{S \subset \mathcal{R}} y_S \leq W \cdot \mathit{rad}(\mathcal{R}) < \frac{4f\ln(k+1)}{\hat{\beta}}.$$

Since $w(\mathcal{R}) \geq \frac{W}{2}$, all supersets of $\mathcal{R}$ have weight at least $\frac{W}{2}$. Hence, the flux for these sets if $C_{\nabla(S)}/(W - w(S)) \geq \hat{\beta}$ and thus

$$\sum_{S \supseteq \mathcal{R}} y_S(W - w(S)) \leq \frac{1}{\hat{\beta}} \sum_{S \supseteq \mathcal{R}} y_S C_{\nabla(S)} \leq \frac{1}{\hat{\beta}} \sum_{e \in E} d_e c_e = \frac{f}{\hat{\beta}}.$$

Therefore, $\sum_{v \in V} w(v)\mathit{dist}_d(r,v) < \frac{f}{\hat{\beta}}(4\ln(k+1) + 1) < \frac{1}{W}$, and hence

$$\sum_{u,v \in V} w(u)w(v)\mathit{dist}_d(u,v) < 1,$$

a contradiction.

8. Applications. Several graph problems can be viewed as edge deletion problems. We wish to find a minimum weight set of edges whose removal yields a graph with a desired structure π [Ya]. Klein et al. [KARR] propose a method for approximating such a problem when the property π can be specified as a 2CNF $\equiv$ formula so that deleting edges from the graph corresponds to deleting clauses in the formula. In particular, they show how to model the minimum edge deletion graph bipartization problem, i.e., deleting a minimum weight set of edges so that the resulting graph is bipartite. The 2CNF $\equiv$ deletion problem is defined as follows.

> A 2 CNF $\equiv$ formula, F, is a weighted set of clauses of the form $P \equiv Q$ where P, Q are literals. Find a minimum weight set of clauses the deletion of which makes the formula satisfiable.

Klein et al. showed that this problem can be reduced to the minimum multicut problem. Construct a graph $G(F)$ whose vertex set is the set of literals in F. For each clause of the kind $P \equiv Q$ include two edges (P, Q) and $(\overline{P}, \overline{Q})$ of capacity equal to the weight of the clause $P \equiv Q$.

LEMMA 8.1. *A 2CNF $\equiv$ formula, F, is satisfiable if and only if no connected component of the graph $G(F)$ contains both a literal and its complement.*

Proof. An edge (P, Q) in $G(F)$ implies that the literals P and Q take the same truth value. Thus, if a literal and its complement occur in the same connected component then the 2CNF $\equiv$ formula is not satisfiable.

Conversely, note that if two literals P, Q are in the same connected component then their complementary literals $\overline{P}$, $\overline{Q}$ are also in the same connected component. Thus, the components can be paired, so that in each pair one component contains a set of literals and the other contains the complementary literals. We can now obtain a satisfying assignment by setting, for each pair of components, the literals of one component to true (and the other's to false). □

Let M be a minimum weight set of edges whose removal separates the pairs of complementary literals in $G(F)$ and let W be the minimum weight set of clauses whose deletion makes F satisfiable. Then we have the following lemma.

LEMMA 8.2. $wt(W) \leq wt(M) \leq 2wt(W)$.

Proof. The minimum multicut, M, in $G(F)$ corresponds to a set of clauses (of weight at most $wt(M)$) whose deletion makes the formula satisfiable. Hence, $wt(W) \leq wt(M)$.

Each clause of F corresponds to two edges in $G(F)$. Thus the set W corresponds to a multicut in $G(F)$ of weight at most $2wt(W)$. Therefore, $wt(M) \leq 2wt(W)$. □

Finding the set of edges, M, is exactly the MULTICUT problem on the graph $G(F)$ with every pair of complementary literals forming a source–sink pair. Thus, the number of pairs, k, is equal to the number of variables in the formula, n, and hence by Theorem 5.1 we can approximate M to within a factor $O(\log n)$. Using Lemma 8.2 we get the following theorem.

THEOREM 8.3. *Given a 2CNF $\equiv$ formula, one can in polynomial time find a set of clauses of weight at most a factor $O(\log n)$ of the minimum weight set of clauses whose deletion makes the formula satisfiable.*

COROLLARY 8.4. *The edge-deletion graph bipartization problem can be approximated within a factor $O(\log n)$ in polynomial time.*

We leave open the question of whether these problems can be approximated within some constant factor. We know they are both MAX SNP-hard [PY] and hence do not have a polynomial-time approximation scheme unless $P = NP$ [ALMSS].

Acknowledgment. We wish to thank Phil Klein for simplifying the formulation in §6, which made the presentation more uniform.

ROBUST CHARACTERIZATIONS OF POLYNOMIALS WITH APPLICATIONS TO PROGRAM TESTING*

RONITT RUBINFELD[†] AND MADHU SUDAN[‡]

Abstract. The study of self-testing and self-correcting programs leads to the search for robust characterizations of functions. Here the authors make this notion precise and show such a characterization for polynomials. From this characterization, the authors get the following applications. Simple and efficient self-testers for polynomial functions are constructed. The characterizations provide results in the area of coding theory by giving extremely fast and efficient error-detecting schemes for some well-known codes. This error-detection scheme plays a crucial role in subsequent results on the hardness of approximating some NP-optimization problems.

Key words. coding theory, program correctness, low-degree polynomial testing

1. Introduction.

The study of program checkers [Blu88], [BK89], self-testing programs [BLR90], and self-correcting programs [BLR90], [Lip91] was introduced in order to allow one to use a program P to compute a function without trusting that P works correctly. A *program checker* checks that the program gives the correct answer on a particular input, a *self-testing program* for f tests that program P is correct on most inputs, and a *self-correcting program* for f takes a program P that is correct on most inputs and uses it to compute f correctly on every input with high probability. The program checker, self-tester, and self-corrector may call the program as a black box, are required to do something other than to actually compute the function, and should be much simpler and at least different from any program for the function f in the precise sense defined by [BK89]. It is straightforward to show that checkers, self-testers, and self-correctors for functions are related in the following way: If f has a self-tester and a self-corrector, then it can be shown that f has a program result checker. Conversely, if f has a checker, then it has a self-tester (though not necessarily a self-corrector). It is argued in [BK89] and [BLR90] that this provides an attractive alternative method for attacking the problem of program correctness.

One of the main goals of the research in the area of self-testing/correcting programs and program checking is to find general techniques for finding very simple and efficient self-testers, self-correctors, and checkers for large classes of problems. In fact, some success towards this goal has been achieved. For example, in [BK89], it is shown how to use techniques from the area of interactive proof systems in order to write checkers. Using these and other techniques, checkers (and hence self-testers) have been found for a variety of problems [AHK], [BK89], [Rub90], [Kan90], [BFLS91], [BF91]. If a function is random self-reducible, i.e., the value of the function at any

input can be inferred from its value at randomly chosen inputs, then it has a self-corrector [BLR90], [Lip91]. This provides self-correctors for a surprising range of functions, including the class of linear functions (homomorphisms between groups) and polynomials.

In the direction of characterizing functions that have self-testers, some success has been achieved in [BLR90]. They give a number of methods of constructing self-testers for functions, some of which we mention here. They observe that any checker for a function can be used to construct a self-tester for the function. They present a particular method of constructing self-testers for a variety of functions based on a method of bootstrapping from tests over smaller domains. They also show another method of constructing self-testers for all linear functions, i.e., functions that act as homomorphisms between groups, in other words satisfy $f(x) + f(y) = f(x + y)$ for a group operation $+$.

The main focus of this paper is to study and understand the functions which have self-testers and to broaden the class of functions that are known to have self-testers. The linearity tester of [BLR90] is the starting point for this paper. A particularly interesting feature of this linearity tester is that it breaks the task of self-testing a function into the two tasks of (1) testing it for certain "structural properties" and (2) using the structural property to then identify the function precisely. In this paper, we introduce a new notion—a function-family tester—which helps delineate these two tasks more clearly. We first introduce some terminology.

We work with functions defined over some finite domain $\mathcal{D}$. The *distance* between two functions f and g over the domain $\mathcal{D}$ is the fraction of points $x \in \mathcal{D}$ where the two functions disagree:

$$d(f,g) \equiv \frac{|\{x \in \mathcal{D} | f(x) \neq g(x)\}|}{|\mathcal{D}|}.$$

We say that two functions are *ϵ-close* if $d(f,g) \leq \epsilon$. In some of the informal discussions that follow, we drop the ϵ and just describe two functions as being close. In such cases, it is implied that we are talking of some small enough ϵ. In terms of this notion, a self-tester for a function f may be defined as follows.

An ϵ-self-tester T for a function f over a domain $\mathcal{D}$ is a (randomized) oracle program that takes as input a program P and behaves as follows:

- It accepts P if $d(P,f) = 0$.
- It rejects P (with high probability) if P and f are not ϵ-close.
- It behaves arbitrarily otherwise.

1.1. Testers for function families using robust characterizations. Let $\mathcal{F}$ be a family of functions. An *ϵ-function-family tester* T for the family $\mathcal{F}$ takes as input a program P and tests if there exists a function $f \in \mathcal{F}$ such that P is ϵ-close to f.

The notion of a function-family tester captures the notion of verifying properties of a function as follows: Let $\mathcal{P}$ be a property we wish to test for. Let $\mathcal{F}$ be the family of all functions that have the property $\mathcal{P}$. Then a function-family tester for $\mathcal{F}$ can be used to test if a program P "essentially" has the property $\mathcal{P}$ (i.e., there exists a function with property $\mathcal{P}$ that is close to P). To make some of these abstract definitions concrete, let us work with the simple example of the property of linearity among functions from $\mathcal{Z}_p$ to $\mathcal{Z}_p$. For this example, the family of functions we work with is $\mathcal{F}_{\text{linear}} \equiv \{f_a | a \in \mathcal{Z}_p, f_a(x) = a \cdot x\}$. Thus a tester for the family of linear functions verifies that the computation of a program P is essentially linear.

The existence of a function-family tester for any class of functions implies a powerful characterization of the family. In particular, consider any program that is rejected by the tester. In order to reject the program, the tester will have found some evidence in the small set of sampled points which "proves" that P can not be a member of $\mathcal{F}$. In other words, all members of $\mathcal{F}$ must satisfy some property on the set of inputs that are examined by the family tester. Thus all members of $\mathcal{F}$ satisfy a "local" property (by local we mean a property on a set of small size—we define this notion more formally in §2). Moreover, if all such local properties are satisfied, then the tester accepts the function, implying that these local constraints form a characterization of the family. Thus in order for a function family to have a tester, it needs to have a local characterization. In our example, such a local characterization of linear functions is the property that $\forall x, y \in \mathcal{Z}_p$, $f(x) + f(y) = f(x+y)$. If a function is not linear then there exists a counterexample of size three that proves that it is not linear.

However, local characterizations do not form a sufficient condition for the construction of testers. Typically an exact local characterization of a family of functions involves a universal quantification, which is not feasible to verify. In our example, the characterization of linear functions by the property $\forall x, y \in \mathcal{Z}_p$, $f(x)+f(y) = f(x+y)$ is not useful to test a purported linear function, since we cannot hope to efficiently test that this holds for all possible pairs x and y. Thus for a characterization to be useful for testing, it needs to be "robust," involving the words "for most" rather than "for all." Specifically, let $\mathcal{F}$ be the function family that satisfies the properties at all inputs and let f be any function that satisfies the properties at most inputs. Then f must be close to some $g \in \mathcal{F}$ (see §2 for a more formal definition). In our example, if $f(x) + f(y) = f(x + y)$ is satisfied by f for most x, y, then $f(x) = c \cdot x$ for most x and some constant c.

1.2. Our results on function family testing. One of the main emphases of this paper is to find robust characterizations for the family of low-degree univariate and multivariate polynomials. In §3, we start by describing some (well-known) local characterizations of univariate and multivariate polynomials and then prove that some of these characterizations are actually robust characterizations. As an immediate consequence, we get function-family testers for all low-degree polynomials over finite fields. For the case of polynomials over Z_p, our testers are very simple and do not even need to multiply elements of the field. Our testers are the first testers that directly attempt to test the total degree of a polynomial (as opposed to the testers of [BFLS91], [FGLSS91], and [AS92], all of which test that the degree in each variable is not too large). The proof of correctness of our tester also is different from the proofs of correctness of the other testers in that it does not rely on an inductive argument based on the number of variables. This allows for its "efficiency" to be independent of the number of variables and provides the hope for the existence of a tester with nearly optimal efficiency.

A second emphasis of this paper is the notion of test sets that allows us to use the results on function-family testing to obtain self-testers for specific functions. Informally, a *test set* is a set of points from the domain such that no two functions from the family $\mathcal{F}$ agree with each other on all the points from the test set. Our self-tester for a specific function f would require, as a description of f, its value on all points in a test set. The complexity (running time) of the self-tester will depend on the size of the test set.

1.3. Other implications of low-degree testing. The task of constructing family testers for the family of low-degree polynomials is closely related to the task of error detection in Reed–Solomon codes. In fact, a low-degree test can be described as a "randomized" error detector that determines whether the number of errors in a received word is small or not. In this sense, the error detectors we construct have the feature that they are highly efficient and can be used to get estimates on the distance of a received word from a valid codeword. This perspective can similarly be applied to the results of [BLR90] to get randomized error-detecting and correcting schemes for the Hadamard codes that probe the received word in only a constant number of bits to detect an error or find any bit of the codeword closest to the received word. In fact, it has been observed by M. Naor [Nao92] that these results can be used to construct codes for which error-detection/correction can be performed by uniform quasipolynomial-sized circuits of constant depth. In §7, we define the notion of a "locally testable code"—a notion that precisely describes the relationship between testing and error-correcting codes. We also provide applications of our testers to the construction of "locally testable codes" in the section.

A different perspective on the construction of family testers is to view it as the following approximation problem:

> Given a family of functions $\mathcal{F}$ and a function P, estimate the distance $d(P, \mathcal{F})$ between P and $\mathcal{F}$ to within a small multiplicative error.

A tester for a function family $\mathcal{F}$ essentially yields such an approximator (provided $d(P, \mathcal{F})$ is smaller than half) by defining some new quantities $\delta(P, \mathcal{F})$ that are easy to estimate by random sampling and then showing that some approximate relations hold between $\delta(P, \mathcal{F})$ and $d(P, \mathcal{F})$. For example, the linearity test of [BLR90] may be viewed as trying to approximate the distance $d(f, \mathcal{F}_{\text{linear}})$. To approximate this distance, they define the quantity $\delta(f, \mathcal{F}_{\text{linear}}) \equiv \Pr[f(x) + f(y) \neq f(x+y)]$ which is easy to approximate. Then they show that $\delta(f, \mathcal{F}_{\text{linear}})/3 \leq d(f, \mathcal{F}_{\text{linear}}) \leq 9/2\delta(f, \mathcal{F}_{\text{linear}})$. The testers given here define similar quantities related to low-degree polynomials and show similar approximate relationships. Such inequalities may be of independent interest.

The task of low-degree testing forms a central ingredient in the proof of MIP = NEXPTIME due to [BFL91]. The tester given here provides an alternate mechanism that works in their setting. The efficiency of low-degree testing also becomes very important to the ensuing results on hardness of approximations [FGLSS91], [ALMSS92], and therefore a lot of attention has been paid to this problem [BFL91], [BFLS91], [FGLSS91], [AS92]. However, all these results focus on tests that are close variants of the test given in [BFL91]. The low-degree test given here is fundamentally different from the ones mentioned above and originated from independent considerations in the work of [GLRSW91]. The efficiency of the tester shown here may also be found in [RS92]. It turns out that this tester is particularly well-suited to such multiple prover applications and provides a one round, constant prover proof that a function is a low degree polynomial over finite fields. This is observed in subsequent work of [ALMSS92] (see also [Sud92]) and follows by using an improved analysis for Lemma 5.3 from [AS92]. This turns out to play a crucial role in the NP = PCP$(\log n, O(1))$ result of [ALMSS92], which in turn provides hardness results for a wide variety of approximation problems. An exact description of the relevance of the various testers and the chronology of contributions maybe found in §8.

1.4. Organization of the paper. The rest of this paper is organized as follows. In §2 we formally define the notions of local characterizations—exact and robust. Section 3 lists some (well-known) exact characterizations of low-degree polynomials. Sections 4 and 5 show that two of these exact characterizations are robust. In §6, we describe the applications of these characterizations to self-testing of programs. In §7, we define a notion of locally testable codes (based on the notion of probabilistically checkable proofs) and show applications of our testers to such codes. Section 8 contains some concluding remarks.

2. Local characterizations: Exact and robust. In this section, we make precise the notion of a local characterization and what we mean by exact and robust characterizations. We will also isolate a parameter associated with the robust characterizations that captures the efficiency of the tester suggested by the characterization.

We will use $\mathcal{D}$ to represent a finite domain. We will consider here families of functions $\mathcal{F}$ where $f \in \mathcal{F}$ maps elements from $\mathcal{D}$ to a range $\mathcal{R}$. We illustrate these definitions using the example of linear functions. Here the domain and range are $\mathcal{Z}_p$ and the family of functions is $\{f_a | a \in \mathcal{Z}_p$ where $f_a(x) = a \cdot x\}$.

DEFINITION 2.1 (neighborhoods). *A* k-local neighborhood N *is an ordered tuple of (not necessarily distinct) k points from $\mathcal{D}$. A* k-local collection of neighborhoods $\mathcal{N}$ *is a set of k-local neighborhoods.*

DEFINITION 2.2 (properties). *A* k-local property $\mathcal{P}$ *is a function from* $(\mathcal{D} \times \mathcal{R})^k$ *to* $\{0, 1\}$. *We say that a function f satisfies a property $\mathcal{P}$ over a neighborhood N if* $\mathcal{P}(\{(x, f(x))\}_{x \in N}) = 1$.

DEFINITION 2.3 (exact characterizations). *A property $\mathcal{P}$ over a collection of neighborhoods $\mathcal{N}$ is an* exact characterization *of a family of functions $\mathcal{F}$ if a function f satisfies $\mathcal{P}$ over all neighborhoods $N \in \mathcal{N}$ exactly when $f \in \mathcal{F}$. The characterization is k-local if the property $\mathcal{P}$ (and the collection $\mathcal{N}$) is k-local.*

In our example, the collection of neighborhoods $\mathcal{N} = \{(x, y, x+y) | x, y \in \mathcal{Z}_p\}$. The property $\mathcal{P}$ is 3-local and is satisfied by f on the triple (x_1, x_2, x_3) if $f(x_1) + f(x_2) = f(x_3)$. Thus over the collection of neighborhoods $\mathcal{N}$, $\mathcal{P}$ gives a 3-local characterization of the family of linear functions.

DEFINITION 2.4 (robust characterizations). *A property $\mathcal{P}$ over a collection of neighborhoods $\mathcal{N}$ is said to be an* (ϵ, δ)-robust characterization *of $\mathcal{F}$, if whenever a function f satisfies $\mathcal{P}$ on all but a δ fraction of the neighborhoods in $\mathcal{N}$, it is ϵ-close to some function $g \in \mathcal{F}$. Moreover, all members of $\mathcal{F}$ satisfy $\mathcal{P}$ on all neighborhoods in $\mathcal{N}$.*

To continue with the example of linear functions, the theorem of [BLR90] can be used to say that $\mathcal{P}$ over the neighborhood $\mathcal{N}$ is a $(\frac{9}{2}(\frac{2}{9} - \alpha), \frac{2}{9} - \alpha)$-robust characterization of linear functions for any constant α.

The exact constant ϵ determining closeness is not very important for the family of multivariate polynomials. For most of the characterizations we consider here, it can be shown that any function f is $((1 + o(1))\delta)$-close to some member g of $\mathcal{F}$ if f is $\frac{1}{4}$-close to g and violates only a δ fraction of the neighborhood constraints. Thus for the purposes of this paper, we fix the value of ϵ to be $\frac{1}{4}$.

In order to test if f is close to some member of $\mathcal{F}$, one would need to sample at least $\frac{1}{\delta}$ of the neighborhoods in $\mathcal{N}$ and test if $\mathcal{P}$ holds on these neighborhoods. Hence, the parameter $\frac{1}{\delta}$ is referred to as the *efficiency* of the characterization.

3. Exact characterizations of polynomials. In this section, we start by describing some (well-known) exact local characterizations of polynomial functions. In later sections, we will show that some of these characterizations can be made robust.

The family of degree-d polynomials can be characterized in a number of ways. The different characterizations arise from looking at different collections of neighborhoods $\mathcal{N}$. The property P has to remain invariant in the following sense: P will be satisfied by f on a neighborhood N if there exists a polynomial that agrees with f on all points in N. The complexity of a neighborhood test, i.e., testing whether a constraint is being satisfied by a neighborhood, is also influenced by the choice of the neighborhood. Thus by choosing the characterizations appropriately, we might be able to tradeoff the simplicity of the neighborhood test against the number of times the test needs to be repeated. The different characterizations also have to be qualified by different restrictions on the underlying ring. For instance, some characterizations hold only for finite fields while others hold only for rings of the form $\mathcal{Z}_m$. We will take care to point out the restrictions on the characterizations. We give examples of possible neighborhoods and their corresponding tests.

1. *Univariate polynomials.* The following characterization of univariate polynomials holds for a function f mapping a ring R to itself.
   (a) *Characterization.* $f : R \mapsto R$ is a polynomial of degree at most d if and only if $\forall x_0, \ldots, x_{d+1} \in R$, there exists a polynomial $g_{x_0,\ldots,x_{d+1}}$ of degree at most d such that $f(x_i) = g_{x_0,\ldots,x_{d+1}}(x_i)$.
   (b) *Neighborhood structure.* $\mathcal{N} = R^{d+2}$, i.e., all possible (multi)subsets of R of size $d+2$.
   (c) *Complexity of neighborhood test.* A test of the above nature involves finding the (unique) degree d polynomial g that agrees with f at the points $x_0, \ldots, x_d$ and then evaluating $g(x_{d+1})$ and verifying that this equals $f(x_{d+1})$. Standard interpolation techniques (see, for instance, [dW70]) imply that this is equivalent to computing coefficients $\alpha_0, \ldots, \alpha_{d+1}$, where the $\{\alpha_i\}$'s depend only on the $\{x_i\}$'s, and verifying that $\sum_{i=0}^{d+1} \alpha_i \cdot f(x_i) = 0$. The α_i's can be computed using elementary algorithms with $O(d^2)$ additions, subtractions, and multiplications over R.
2. *Univariate polynomials using evenly spaced points.* This characterization works over the ring $\mathcal{Z}_m$. Let $\alpha_i = \binom{d+1}{i}(-1)^{i+1}$. The interpolation identity for degree d polynomials on evenly spaced points, $x, x+h, \ldots, x+(d+1)\cdot h$, reduces to $\sum_{i=0}^{d+1} \alpha_i f(x + i \cdot h) = 0$. We refer to x as the *starting point* and h as the *offset.*
   (a) *Characterization.* $f : \mathcal{Z}_m \mapsto \mathcal{Z}_m$ is a polynomial of degree at most d if and only if $\forall x, h \in \mathcal{Z}_m$, $\sum_{i=0}^{d+1} \alpha_i f(x + i \cdot h) = 0$.
   (b) *Neighborhood structure.* Define the neighborhood sets $N_{x,h} \equiv \{x + i \cdot h\}_{i=0}^{d+1}$. Then the neighborhood collection is $\mathcal{N} = \bigcup_{x,h \in \mathcal{Z}_m} N_{x,h}$.
   (c) *Complexity of neighborhood test.* Notice that the constants α_i are now independent of x and h and can be precomputed once and for all. In fact, due to the special relationship between the α_i's, given the value of f at the points $x + i \cdot h$, we can compute the above summation with $O(d^2)$ additions and subtractions and *no multiplications* (see appendix).
3. *Multivariate polynomials using lines.* This characterization applies to m-variate functions over a finite field F. Define the notion of a *line* through the space F^m as follows: For $\hat{x}, \hat{h} \in F^m$, the line $l_{\hat{x},\hat{h}}$ through $\hat{x}$ with offset $\hat{h}$ is the set of points $\{\hat{x} + i \cdot \hat{h} | i \in F\}$. We will often refer to the line in its parametric form $l_{\hat{x},\hat{h}}(i)$. Observe that a polynomial f of total degree d, restricted to a line $l_{\hat{x},\hat{h}}(i)$ becomes a univariate polynomial of degree at most d in the parameter i. This gives us the following characterization of degree d polynomials over sufficiently large finite fields ($|F| \geq 2d+1$).[1]
   (a) *Characterization.* The function $f : F^m \mapsto F$ is a polynomial of degree at most d if and only if $\forall \hat{x}, \hat{h} \in F^m$, f restricted to $l_{\hat{x},\hat{h}}(i)$ is a univariate polynomial in i of degree at most d (see appendix for a proof).
   (b) *Neighborhood structure.* Let the neighborhoods be lines. Then $\mathcal{N} \equiv$

[1] The above characterization is not the tightest possible in its requirement of the parameter $|F|$. Indeed, for the case of fields of prime order this can be improved to the optimal case $|F| \geq d+2$ and this has been shown recently in [FS94]. For arbitrary finite fields, it turns out that $|F| \geq d+2$ is not a sufficient condition for this characterization to hold. A counterexample to this effect is also shown in [FS94].

$\{N_{\hat{x},\hat{h}} = l_{\hat{x},\hat{h}} | \hat{x}, \hat{h} \in F^m\}$.

   (c) *Complexity of neighborhood test.* In this form the characterization is not very local since the counterexamples are lines, i.e., collections of $|F|$ points. But this characterization is interesting to us because it says that the characterization of multivariate polynomials can be reduced to the characterization of univariate polynomials (on these lines). Thus we find that we can now use, for instance, characterization 1 to find counterexamples of size at most $d+2$. The complexity of a neighborhood test here is no more than the complexity of the neighborhood test in characterization 1.

4. *Multivariate polynomials using axis parallel lines.* This characterization is a specialization of the characterization above, in terms of special lines—*axis-parallel lines.* We say that a line is *axis parallel* if the offset $\hat{h}$ contains only one nonzero coordinate.
   (a) *Characterization.* $f : F^m \mapsto F$ is a polynomial of degree at most d in each variable if and only if $\forall$ axis-parallel lines, f restricted to the line is a univariate polynomial of degree at most d. Notice that here we characterize polynomials differently, i.e., in terms of individual degree in each variable rather than total degree.
   (b) *Neighborhood structure.* The neighborhoods here are sets of the form $N_{i,\hat{\beta}} \equiv \{(\beta_1, \ldots, \beta_{i-1}, t, \beta_i, \ldots, \beta_{m-1}) | t \in F\}$, for every choice of $\hat{\beta} \in F^{m-1}$ and every choice of $i \in \{1, \ldots, m\}$. Then

$$\mathcal{N} = \bigcup_{i \in \{1,\ldots,m\}, \hat{\beta} \in F^{m-1}} N_{i,\hat{\beta}}.$$

   (c) *Complexity of neighborhood test.* The complexity of a neighborhood test is the same as the complexity of characterization 1.

5. *Multivariate polynomials*: *Evenly spaced points.* A combination of characterizations 2 and 3 gives the following characterization of polynomials over $\mathcal{Z}_p$, provided p is large enough for characterization 3 to hold.
   (a) *Characterization.* $f : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ is a polynomial of degree at most d if and only if $\forall \hat{x}, \hat{h} \in \mathcal{Z}_p^m$, $\sum_{i=0}^{d+1} \alpha_i f(\hat{x}+i\hat{h}) = 0$, where $\alpha_i = (-1)^{i+1}\binom{d+1}{i}$.
   (b) *Neighborhood structure.* The neighborhoods here are of the form $N_{\hat{x},\hat{h}} \equiv \{\hat{x} + i\hat{h} | i \in \{0, \ldots, d+1\}\}$. Then $\mathcal{N} \equiv \bigcup_{\hat{x},\hat{h} \in \mathcal{Z}_p^m} N_{\hat{x},\hat{h}}$.
   (c) *Complexity of neighborhood test.* The complexity of this neighborhood test is the same as the complexity in characterization 2.

6. *Multivariate polynomials*: *Evenly spaced points* 2. This characterization is a trivial consequence of the characterization above and seems weaker since its neighborhood structure is larger than those of the ones above. But it turns out that this characterization is much more useful due to the kind of robustness it yields. This characterization holds for polynomials over $\mathcal{Z}_p$, for $p > 10d$.
   (a) *Characterization.* $f : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ is a polynomial of degree at most d if and only if $\forall \hat{x}, \hat{h} \in \mathcal{Z}_p^m$, the values of f at the points $\{\hat{x}+i\hat{h} | i \in \{0, \ldots, 10d\}\}$ agree with some univariate polynomial g of degree at most d in t.
   (b) *Neighborhood structure.* The neighborhoods here are sets of the form $N_{\hat{x},\hat{h}} \equiv \{\hat{x} + i\hat{h} | i \in \{0, \ldots, 10d\}\}$. Then $\mathcal{N} \equiv \bigcup_{\hat{x},\hat{h} \in \mathcal{Z}_p^m} N_{\hat{x},\hat{h}}$.
   (c) *Complexity of the neighborhood test.* Once again it turns out that the complexity of this test is within a constant factor of the complexity of

the test in characterization 2, i.e., $O(d^2)$ additions and subtractions and no multiplications (see appendix).

All characterizations above turn out to be robust. The robustness of characterization 1 is straightforward and omitted here (see, for instance, [Sud92]). The robustness of 4 follows from the work of [BFL91] (see also [BFLS91], [FGLSS91], [AS92], [Lun92]). The robustness of characterizations 2, 3, 5, and 6 are presented in §§4 and 5.

A typical robust characterization theorem for degree d polynomials in m variables over a finite field F would go as follows:

> There exists a δ_0 (which may be a function of d, m, and $|F|$) such that for $\delta \leq \delta_0$, if the fraction of neighborhoods where P satisfies the local constraints is at least $1 - \delta$, then P is ϵ-close to some degree-d polynomial (where ϵ is some function of δ).

An important parameter in determining the efficiency of a tester is the relationship between δ_0 and m, d, and $|F|$. For instance, if $\delta_0 = \frac{1}{dm \log |F|}$, then this implies that we will have to test that the local property holds for at least $dm \log |F|$ randomly chosen neighborhoods before we can satisfy ourselves that P is close to some polynomial. Our main thrust will be to get a theorem that holds for as high a δ_0 as possible.[2]

In what follows, we show first that characterization 5 above is robust with $\delta_0 = \Theta(\frac{1}{d^2})$. This proof gives a simple and efficient tester for the family of multivariate polynomials that works with $O(d^3)$ probes into f. Robustness of the characterizations in 2 and 3 follow as special cases. This bound on δ_0 is in contrast to the robustness of 4 that has an inherent dependency on m.

Next we show the robustness of characterization 6. The efficiency of this test is analyzed modulo the efficiency of a certain test for bivariate polynomials and is shown to be within a constant factor of the bivariate test. We also show that the efficiency of the bivariate test is $O(d)$, giving a test for multivariate polynomials that works with $O(d^2)$ probes into f.

4. A robust characterization of polynomial functions.

In this section, we prove the robustness of characterization 5. We consider a function (program) P mapping m variables from $\mathcal{Z}_p$ to $\mathcal{Z}_p$ and prove the following theorem.

THEOREM 4.1. *For $\delta_0 = \frac{1}{2(d+2)^2}$, if $P : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ satisfies*

$$\delta \equiv \Pr_{x,h \in_R \mathcal{Z}_p^m} \left[P(x) \neq \sum_{i=1}^{d+1} \alpha_i P(x + i \cdot h) \right] \leq \delta_0,$$

then there exists a degree-d polynomial $g : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ that is 2δ-close to P.

This theorem makes very minimal requirements on the field size required for its validity. The theorem is valid whenever characterization 5 holds, and Friedl and Sudan [FS94] have shown that this holds for $p \geq d + 2$—the smallest conceivable field size for which the test could be defined. We do not know of other testers that work with such a minimal requirement on the field size.

We define $g(x)$ to be $\text{maj}_{h \in \mathcal{Z}_p^m}\{\sum_{i=1}^{d+1} \alpha_i P(x + ih)\}$, where maj of a set is the function that picks the element occurring most often (choosing arbitrarily in the case of ties). First we show that g is 2δ-close to P. Later in this section, we show that g is a low-degree polynomial.

[2] A secondary parameter of interest is the relationship between ϵ and δ. In all the proofs that follow, we will only show that $\epsilon = 2\delta$. Actually, once such a result is shown, it can be shown again that any $\epsilon > \delta$ works.

LEMMA 4.2. *g and P agree on more than a $1-2\delta$ fraction of the inputs from Z_p^m.*

Proof. Consider the set of elements x such that $\Pr_h[P(x) = \sum_{i=1}^{d+1} \alpha_i P(x + i * h)] < \frac{1}{2}$. If the fraction of such elements is more than 2δ, then it contradicts the condition that $\Pr_{x,h}[\sum_{i=0}^{d+1} \alpha_i P(x+i*h) = 0] = \delta$. For all remaining elements, $P(x) = g(x)$. □

In the following lemmas, we show that the function g satisfies the interpolation formula for all x and h and is therefore a degree-d polynomial. We do this by first showing that for all x, $g(x)$ is equal to the interpolation of P at x by most offsets t. We then use this to show that the interpolation formula is satisfied by g for all x, h.

LEMMA 4.3. *For all $x \in Z_p^m$, $\Pr_h\left[g(x) = \sum_{i=1}^{d+1} \alpha_i P(x + i * h)\right] \geq 1 - 2(d+1)\delta$.*

Proof. Observe that $h_1, h_2 \in_R Z_p^m$ implies that when i and j do not equal 0,

$$x + i * h_1 \in_R Z_p^m \text{ and } x + j * h_2 \in_R Z_p^m$$

$$\Rightarrow \Pr_{h_1,h_2}\left[P(x + i * h_1) = \sum_{j=1}^{d+1} \alpha_j P(x + i * h_1 + j * h_2)\right] \geq 1 - \delta$$

$$\Rightarrow \Pr_{h_1,h_2}\left[P(x + j * h_2) = \sum_{i=1}^{d+1} \alpha_i P(x + i * h_1 + j * h_2)\right] \geq 1 - \delta.$$

Combining the two, we get

$$\begin{aligned} \Pr_{h_1,h_2}\left[\sum_{i=1}^{d+1} \alpha_i P(x + i * h_1)\right. &= \sum_{i=1}^{d+1}\sum_{j=1}^{d+1} \alpha_i\alpha_j P(x + i * h_1 + j * h_2) \\ &= \left.\sum_{j=1}^{d+1} \alpha_j P(x + j * h_2)\right] \\ &\geq 1 - 2(d+1)\delta. \end{aligned}$$

The lemma now follows from the observation that the probability that the same object is drawn twice from a set in two independent trials lower bounds the probability of drawing the most likely object in one trial. Suppose the objects are ordered so that p_i is the probability of drawing object i, and $p_1 \geq p_2 \geq \cdots$. Then the probability of drawing the same object twice is $\sum_i p_i^2 \leq \sum_i p_1 p_i = p_1$. □

LEMMA 4.4. *For all $x, h \in Z_p^m$, if $\delta \leq \frac{1}{2(d+2)^2}$, then $\sum_{i=0}^{d+1} \alpha_i g(x + i * h) = 0$ (and thus g is a degree-d polynomial* [dW70]).

Proof. Observe that, since $h_1 + ih_2 \in_R Z_p^m$, we have for all $0 \leq i \leq d+1$,

$$\Pr_{h_1,h_2}\left[g(x + i * h) = \sum_{j=1}^{d+1} \alpha_j P((x + i * h) + j * (h_1 + ih_2))\right] \geq 1 - 2(d+1)\delta.$$

Furthermore, we have for all $1 \leq j \leq d+1$

$$\Pr_{h_1,h_2}\left[\sum_{i=0}^{d+1} \alpha_i P((x + j * h_1) + i * (h + j * h_2)) = 0\right] \geq 1 - \delta.$$

Putting these two together, we get

$$\Pr_{h_1,h_2}\left[\sum_{i=0}^{d+1} \alpha_i g(x + i * h) = \sum_{j=1}^{d+1} \alpha_j \sum_{i=0}^{d+1} \alpha_i P((x + j * h_1) + i * (h + j * h_2)) = 0\right] > 0.$$

The lemma follows since the statement "$\sum_{i=0}^{d+1} \alpha_i g(x+i*h) = 0$" is independent of h_1 and h_2, and therefore if its probability is positive, it must be 1. □

Proof of Theorem 4.1. Theorem 4.1 follows from Lemmas 4.2 and 4.4. □

5. Efficient tester for polynomials. In this section, we prove the robustness of characterization 6. Recall that this characterization uses the collection of neighborhoods $\mathcal{N} = \{N_{x,h} | x, h \in \mathcal{Z}_p^m\}$, where $N_{x,h} = (x, x+h, \ldots, x+10dh)$. The following theorem shows that the efficiency of this characterization is $O(d)$, i.e., if a function satisfies the consistency test on all but a $O(\frac{1}{d})$ fraction of the neighborhoods, then it is close to a polynomial.

THEOREM 5.1. *There exists a constant c such that for* $0 \leq \delta \leq \frac{1}{cd}$, *if f is a function from* $\mathcal{Z}_p^m$ *to* $\mathcal{Z}_p$ *that satisfies the neighborhood consistency test on all but a* δ *fraction of the collection of neighborhoods* $\mathcal{N} = \{N_{x,h} | x, h \in \mathcal{Z}_p^m\}$ *(where* $N_{x,h} = \{x, x+h, \ldots, x+10dh\}$*), then there exists a polynomial* $g : \mathcal{Z}_p^m \to \mathcal{Z}_p$ *of total degree at most d such that* $d(f, g) \leq (1+o(1))\delta$ *(provided* $p > 10d$.*)*

In the rest of this section, we prove this theorem for the case $d \geq 1$. (The case $d = 0$ amounts to proving that f is a constant and is omitted as a straightforward exercise.)

Fix a function f that satisfies the neighborhood constraints on all but a δ fraction of the neighborhoods.

The proof follows the same basic outline as the one in §4, but in order to achieve the better efficiency, we use ideas that can be thought of in terms of error correction. Thus many of the steps that were quite simple in §4 require more work here. In §4, the function g was defined to be the value that occurs most often (for most h) when one looks at the evaluation at x of the unique polynomial that agrees with the values of f at $x+h, \ldots, x+(d+1)h$. Here we view the values of a polynomial at $x+h, \ldots, x+10dh$ as a codeword. Intuitively, the values of f at $x+h, \ldots, x+10dh$ will often have enough good information in it to allow us to get back to a correct codeword. The function g defined below can be thought of as the value that occurs most often (for most h) when one looks at the polynomial defined by the *error correction* of the values of f at $x, x+h, \ldots, x+10dh$ evaluated at x. We then show that g has the following properties:

1. $g(x) = f(x)$ with probability at least $1 - \delta - o(\delta)$ if x is picked randomly from $\mathcal{Z}_p^m$.
2. On every neighborhood $N_{x,h}$, g is described by a univariate polynomial of degree d.

Notice that characterization 6 now implies that g is a degree d polynomial.

Notation. For $x, h \in \mathcal{Z}_p^m$, we let $P_{x,h}(i)$ be (the unique) polynomial in i that satisfies $P_{x,h}(i) = f(x+ih)$ for at least $6d$ values of $i \in \{0, \ldots, 10d\}$. If no such polynomial exists, then $P_{x,h}$ is defined to be `error`.

$$\text{Let } g : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p \text{ be } g(x) \equiv \text{plurality}_h\{P_{x,h}(0)\}$$

where the plurality is taken over P's that are not `error`.

In §4, it is shown that if one computes the value of a polynomial function at x by interpolating from the values of the function along offset h_1 that are in turn computed by interpolating from the values of the function along offset h_2, then one would get the same answer as if one had computed the value of the function at x by interpolating from the values of the function along offset h_2 that are in turn computed by interpolating from the values of the function along offset h_1. This is not hard to see because it turns out that an interpolation is a weighted summation and obtaining the identity amounts to changing the order of a double summation (see, for instance, Lemma 4.3). Here g is actually an interpolation of the *error correction* of the values of the function, which is no longer a simple algebraic function of the observed values. We repair the situation by constructing a bivariate polynomial $Q(i,j)$ that agrees with $f(x+i\cdot h_1+j\cdot h_2)$ for most values of i and j. This allows us to get back to simple interpolation where we work with the function $Q(i,j)$ rather than f. Lemma 5.2 shows when such a bivariate polynomial can be set up to agree with a matrix of values m_{ij}. Lemma 5.3 shows how to use this polynomial to simulate the effect of the interchange in the order of the summation.

The following lemma follows directly from the axis parallel characterization of polynomials.

LEMMA 5.2. *For $X, Y \subset \mathcal{Z}_p$ with $|X|, |Y| > d+2$, if $\{r_i\}_{i\in X}$ and $\{c_j\}_{j\in Y}$ are univariate (degree-d) polynomials such that for all $i \in X$ and $j \in Y$, $r_i(j) = c_j(i)$, then there exists a polynomial $Q(.,.)$ such that for all i,j $Q(i,j) = r_i(j) = c_j(i)$.*

LEMMA 5.3 (matrix polynomial lemma). *Given families of univariate degree-d polynomials $\{r_i\}_{i=0}^{10d}$ and $\{c_j\}_{j=0}^{10d}$ and a matrix $\{m_{ij}\}_{i=0,j=0}^{10d,10d}$ that satisfy the following:*

- *For 90% of the i's in $\{0,\dots,10d\}$, $r_i(j) = m_{ij}$ for all $j \in \{0,\dots,10d\}$.*
- *For 90% of the j's in $\{0,\dots,10d\}$, $c_j(i) = m_{ij}$ for all $i \in \{0,\dots,10d\}$.*

Then there exists a bivariate polynomial $Q(\cdot,\cdot)$ of degree d in each variable such that $\forall i_0, j_0 \in \{0,\dots,10d\}$ the following holds:

- *For at least 90% of the i's in $\{0,\dots,10d\}$, $Q(i,j_0) = m_{ij_0}$.*
- *For at least 90% of the j's in $\{0,\dots,10d\}$, $Q(i_0,j) = m_{i_0j}$.*

Proof. Let X be the set of good rows of M, i.e., those with the property that $r_i(j)$ equals $c_j(i)$ for all values of $j \in \{0,\dots,10d\}$. Similarly, let Y be the set of good columns. It can now be seen that the conditions of Lemma 5.2 are applicable, implying that there exists a polynomial $Q(i,j)$ such that $Q(i,j) = r_i(j) = c_j(i)$ for all $(i,j) \in X \times Y$, where $|X|$ and $|Y|$ are both at least $9d$. But for any $i \in X$, there exists a unique polynomial describing all the elements in its row and Q agrees with it on 90% of its elements. Thus, for $i \in X$, $Q(i,j) = m_{ij}$ for all $j \in \{0,\dots,10d\}$. In particular this holds for $j = j_0$, i.e., for all $i \in X$, $Q(i,j_0) = m_{ij_0}$. Similarly, by using the columns indexed by Y, one can show that $Q(i_0,j) = m_{i_0j}$ for all $j \in Y$. The lemma follows, since the cardinalities of X and Y are at least $9d$. □

The following lemmas are analogous to Lemmas 4.2–4.4 of §4. Lemma 5.4 and Corollary 5.5 roughly correspond to Lemma 4.3. Lemma 5.4 essentially states that the plurality in the definition of g is actually an overwhelming majority. This may be obtained by setting $i_0 = 0$ in the statement of the lemma. The slightly stronger statement used here is needed later. Lemma 5.6 is similar to Lemma 4.2 and shows that g and f agree at all but a $\delta + o(\delta)$ fraction of the places. Lemma 5.7 shows that g is a multivariate polynomial of degree d.

LEMMA 5.4. *There exists a constant c_1 such that for $\delta_1 = c_1\delta$, the following holds:*

$$\forall x \in F^m, i_0 \in \{0,\dots,10d\}, \quad \Pr_{h_1,h_2}[P_{x,h_1}(i_0) = P_{x+i_0h_1,h_2}(0)] \geq 1-\delta_1.$$

Proof. Pick $h_1, h_2 \in_R \mathcal{Z}_p^m$ and define $M = \{m_{ij}\}$ to be the matrix given by $m_{ij} = f(x+ih_1+jh_2)$. We show that M satisfies the conditions required by Lemma 5.3 (with $j_0 = 0$), with probability at least $1-\delta_1$. This suffices to prove the lemma, since this implies that the polynomial P_{x,h_1} is the polynomial $Q(i,j)$ restricted to $j = 0$ and that $P_{x+i_0h_1,h_2}$ is $Q(i_0,j)$. Thus $P_{x,h_1}(i_0) = P_{x+i_0h_1,h_2}(0) = Q(i_0,0)$.

Any row of the matrix, other than the 0th row, represents a random neighborhood (independent of x) and satisfies the neighborhood constraint with probability $1-\delta$. Thus with probability at least $1-10\delta$, we have that the fraction of rows that do not have a degree-d polynomial describing them is at most 0.1. An analogous argument can be made for the columns. Thus M satisfies the conditions required by Lemma 5.3 with probability at least $1 - 20\delta$. The lemma is satisfied with the choice of $c_1 = 20$. □

COROLLARY 5.5. *For $x \in \mathcal{Z}_p^m, i \in \{0, \ldots, 10d\}$, $\Pr_h[g(x+ih) = P_{x,h}(i)] \geq 1 - 2\delta_1$.*

Proof. Let B be the set of h's that violate $P_{x,h}(i) = \text{majority}_{h_1}\{P_{x+ih,h_1}(0)\}$. For all $h \notin B$, notice that $g(x+ih) = P_{x,h}(i)$. Also for h in B, the probability, for a randomly chosen h_1, that $P_{x+ih,h_1}(0) \neq P_{x,h}(i)$ is at least $\frac{1}{2}$. Thus with probability at least $\frac{|B|}{2p^m}$, we find that a randomly chosen pair (h, h_1) violates the condition $P_{x+ih,h_1}(0) = P_{x,h}(i)$. Applying Lemma 5.4, we get that $\frac{|B|}{p^m}$ is at most $2\delta_1$. □

We next show that g and f agree in most places.

LEMMA 5.6. *$d(f,g) \leq \delta(1+o(1))$.*

Proof. Let B' be the set of x's that satisfy $f(x) \neq P_{x,h}(0)$ for at least $1 - 2\delta_1$ fraction of the h's in $\mathcal{Z}_p^m$. Observe that due to Corollary 5.5, for all $x \notin B'$, $f(x)$ is the same as $g(x)$ ($g(x)$ can disagree with $P_{x,h}(0)$ on at most a $2\delta_1$ fraction of the h's). The size of B' as a fraction of $\mathcal{Z}_p^m$ can be at most $\frac{\delta}{1-2\delta_1}$. Thus we find that $d(f,g) \leq \frac{\delta}{1-2\delta_1} = \delta(1+o(1))$. □

Notation. For $x, h \in \mathcal{Z}_p^m$, we define $P_{x,h}^{(g)}(i)$ to be (the unique) polynomial in i that satisfies $P_{x,h}^{(g)}(i) = g(x+ih)$ for at least $9d$ values of $i \in \{0, \ldots, 10d\}$. If no such polynomial exists, then $P_{x,h}^{(g)}$ is defined to be `error`.

LEMMA 5.7. *There exists a constant γ such that if $\delta \leq \frac{1}{\gamma d}$ then $\forall x, h \quad g(x) = P_{x,h}^{(g)}(0)$.*

Proof. As in the proof of Lemma 5.4, we will pick a convenient matrix on which we will apply Lemma 5.3. This time the matrix of choice is obtained by picking $h_1, h_2 \in_R \mathcal{Z}_p^m$ and letting $m_{ij} = g(x + ih + j(h_1 + ih_2))$.

We will now show that Lemma 5.3 can be applied to this matrix with high probability (for $i_0 = j_0 = 0$). Observe that every row $\{m_{ij}\}_{j=0}^{10d}$ represents a random neighborhood containing the fixed point $x + ih$, and hence Corollary 5.5 implies that $P_{x+ih,h_1+ih_2}(j)$ agrees with m_{ij} for any choice of j with probability $1 - 2\delta_1$. Thus, for every i, with probability at least $1 - 2cd\delta_1$, $P_{x+ih,h_1+ih_2}(j)$ agrees with m_{ij} for all but $\frac{1}{cd}$ fraction of the j's. Thus with probability at least $1 - 22cd\delta_1$, this holds for at least 90% of the rows, including the row $i = 0$. By picking $c > 10$, we satisfy the conditions required of the rows in Lemma 5.3. A similar argument based on the columns shows that the conditions required of the columns are also true with probability $1 - 20cd\delta_1 - o(1)$ (all columns except for the 0th one represent random neighborhoods). Thus the conditions required for Lemma 5.3 are satisfied with probability at least $1 - 42cd\delta_1 - o(1)$.

Applying Lemma 5.3, we find that there exists a bivariate polynomial $Q(i,j)$ such that it agrees with m_{i0} for 90% of the i's. Thus $P_{x,h}^{(g)}(i) = Q(i,0)$. We now argue that $m_{00} = Q(0,0)$, and this will complete the proof, since $m_{00} = g(x)$.

By Lemma 5.3, we find that $m_{0j} = Q(0,j)$ for 90% of the j's, implying $P_{x,h_1}^{(g)}(j) = Q(0,j)$. By Corollary 5.5, we also find that $m_{00} = P_{x,h_1}(0)$ with probability at least $1 - 2\delta_1$. In order to show that this equals $Q(0,0)$, it now suffices to show that $P_{x,h_1}^{(g)}(\cdot) = P_{x,h_1}(\cdot)$.

This last part follows from the following observation: For $j \neq 0$, $x + jh_1$ is distributed uniformly over F^m, and thus with probability $1 - (1+o(1))\delta$, we have $g(x+jh_1) = f(x+jh_1)$ (by Corollary 5.5). Hence with probability at least $1 - 10\delta - o(1)$, $g(x+jh_1) = f(x+jh_1)$ for 90% of the j's. But both the polynomials $P_{x,h_1}(j)$

and $P^{(g)}_{x,h_1}(j)$ agree with $f(x+jh_1)$ and $g(x+jh_1)$ for 90% of the j's, respectively. Thus $P^{(g)}_{x,h_1}(\cdot)$ must agree with $P_{x,h_1}(\cdot)$ on at least 80% of the inputs, implying $P^{(g)}_{x,h_1}(\cdot) = P_{x,h_1}(\cdot)$.

Thus with probability at least $1-(42cd\delta_1+2\delta_1+10\delta+o(1))$ (over random choices of h_1 and h_2), the identity $g(x) = P^{(g)}_{x,h}(0)$ holds. But this event is deterministic (independent of h_1 and h_2) and hence if its probability is positive then it must always hold. If $\delta < 1/((20)(541)d)$, then $\delta_1 < 1/(541d)$ and thus the above probability is positive. □

Proof (*of Theorem* 5.1). Lemma 5.7 implies that along each line $l_{x,h}$, g can be described by a univariate polynomial of degree at most d. Characterization 6 can now be applied to infer that g is a polynomial of total degree at most d. From Lemma 5.6, we now know that f and g differ in at most $\delta(1+o(1))$ fraction of the places. This completes the proof. □

6. Self-testing polynomials. In this section, we complement the results of [BF90] and [Lip91] by showing how to construct a self-tester for any polynomial function. The results can also be generalized to give self-testers and self-correctors for functions in finite dimensional function spaces that are closed under shifting and scaling.

Previously, program testing was thought of as the following: *Pick a random input x and verify that $P(x) = f(x)$ by computing f via another program.* This method has two problems: first, it relies on believing the other program to be correct, and second, since testing is often done at runtime [BLR90], it negates the benefits of designing faster programs, since the computation time will be dominated by the computation time of the old program.

As in [BLR90], our testers are of a nontraditional form and use the robust characterization of the function being tested. The tester is given a short specification of the function in the form of properties that the function must have and verifies that these properties "usually" hold. We show that these properties are such that if the program "usually" satisfies these properties, then it is essentially computing the correct function.

6.1. Test sets. Given that a function computes a polynomial, we want a way of specifying that it is the correct polynomial. We do this by specifying the function value of the polynomial at a number of inputs. It is easy to see that the number of inputs required is exactly the number of inputs necessary to determine whether two degree-d polynomials are distinct. Since any two degree-d univariate polynomial functions can only agree on d points, it suffices to check whether or not the polynomial functions agree at *any* $d+1$ points to determine whether or not they are distinct. On the other hand, distinct multivariate polynomials can agree at an unbounded number of points. However, it is well known that there *exists* a set of $(d+1)^m$ points such that no two degree-d, m-variate polynomials can agree at all points in the set. We make the following definition.

DEFINITION 6.1. *We say that $\mathcal{T} = \{(x_1, y_1), \ldots, (x_t, y_t)\}$ is a (d,m)-*polynomial test set *if there is only one degree-d, m-variable polynomial f such that for all $i \in [1, \ldots, t]$, $f(x_i) = y_i$. A (d,m)-test set need only be of size $(d+1)^m$.*

When the number of variables is small, the provision that the value of the function is known on at least $(d+1)^m$ points is not very restrictive, since the degree is assumed to be small with respect to the size of the field. Suppose one has a program for the RSA function $x^3 \bmod q$. Traditional testing requires that the tester know the value of $f(x)$ for random values of x. Here one only needs to know the following simple and easy to generate specification: f is a degree-3 polynomial in one variable, and

$f(0) = 0, f(1) = 1, f(-1) = -1, f(2) = 8$. These function values are the same over any ring Z_q of size at least 9.

6.2. Testing algorithm. Our self-tester for a polynomial of degree d with m variables assumes that the specification of the polynomial is given by the value of the function on a (d, m)-polynomial test set.

THEOREM 6.2. *If f is a degree-d polynomial in m variables over $\mathcal{Z}_p$, and the value of f is given on a (d, m)-polynomial test set, then for $\epsilon \leq O(1/d^2)$, f has an $(\frac{\epsilon}{2(d+2)}, 4\epsilon)$-self-tester on $\mathcal{Z}_p$ with $O((d+1)^m/\epsilon + d \cdot \max(d^2, \frac{1}{\epsilon}))$ calls to P.*

The self-testing is done in two phases, one verifying that the program is essentially computing some degree-d polynomial function g and the other verifying that the g is the correct polynomial function by verifying that g (rather than P) is correct on the polynomial test set.

We now give the self-testing program that is used to prove Theorem 6.2.

For simplicity, in the description of our self-testing program, we assume that whenever the self-tester makes a call to P, it verifies that the answer returned by P is in the proper range, and if the answer is not in the proper range, then the program notes that there is an error.

We use $x \in_R Z_p^m$ to denote that x is chosen uniformly at random in Z_p^m.

```
PROGRAM POLYNOMIAL-SELF-TEST ($P, \epsilon, \beta, \mathcal{T} = ((x_1, f(x_1)), \ldots, (x_t, f(x_t)))$)

Degree Test
    Repeat $\Theta(\frac{1}{\epsilon} \log(1/\beta))$ times
        Pick $x, h \in_R Z_p^m$ and test that $\sum_{i=0}^{d+1} \alpha_i P(x + i * h) = 0$
    Reject $P$ if the test fails more than an $\epsilon$ fraction of the time.

Equality Test
    For $j$ going from 1 to $t$ do
        Repeat $\Theta(\log(d/\beta))$ times
            Pick $h \in_R Z_p^m$ and test that $f(x_j) = \sum_{i=1}^{d+1} \alpha_i P(x_j + i * h)$.
        Reject $P$ if the test fails more than 1/4th of the time.
```

6.3. Correctness of algorithm: Notation. Let $\delta \equiv \Pr_{x,h}[\sum_{i=0}^{d+1} \alpha_i P(x + i * h) \neq 0]$. We say program P is ϵ-good if $\delta \leq \frac{\epsilon}{2}$ and $\forall j \in \{1, \ldots, t\}$, $\Pr_h[f(x_j) = \sum_{i=1}^{d+1} \alpha_i P(x_j + i * h)] \geq \frac{3}{4}$. We say P is ϵ-bad if either $\delta > 2\epsilon$ or if $\exists j$ such that $\Pr_h[f(x_j) = \sum_{i=1}^{d+1} \alpha_i P(x_j + i * h)] < \frac{1}{2}$. (Note that there are programs that are neither ϵ-good or ϵ-bad.)

The following lemma is easy to prove.

LEMMA 6.3. *With probability at least $1 - \beta$, an ϵ-good program is passed by Polynomial-Self-Test. With probability at least $1 - \beta$, an ϵ-bad program is rejected by Polynomial-Self-Test.*

It is easy to see that if a program P $\frac{\epsilon}{2(d+2)}$-computes f, then it is ϵ-good. On the other hand, we need to show that if P does not 4ϵ-compute f, then it is ϵ-bad. We show the contrapositive, i.e., that if P is not ϵ-bad, then it 4ϵ-computes f.

If P is not ϵ-bad, then $\delta \leq 2\epsilon$. Under this assumption, we show that there exists a function g with the following properties:

1. $g(x) = P(x)$ for most x.
2. $\forall x, t, \sum_{i=0}^{d+1} \alpha_i g(x + it) = 0$, and thus g is a degree-d polynomial.
3. $g(x_j) = f(x_j)$ for $j \in \{0, 1, \ldots, d\}$.

The function g is as defined in the previous section on robust characterizations, and properties 1 and 2 follow from the lemmas proved there. In order to show property 3, we also have the following lemma.

LEMMA 6.4. *$g(x_j) = f(x_j)$.*

Proof. The proof follows from the definition of g and the fact that P is not ϵ-bad. □

THEOREM 6.5. *The program Polynomial-Self-Test is an $(\frac{\epsilon}{2(d+2)}, 4\epsilon)$-self-testing program for any degree-d polynomial function over Z_p^m specified by its values at any (d,m)-polynomial test set $\mathcal{T}$, if $\epsilon \leq \frac{1}{4(d+2)^2}$.*

Proof. The proof follows from Lemmas 6.3, 4.4, and 6.4. □

7. Locally testable codes.

In this section, we introduce some definitions related to coding and show the implications of low-degree testing to generating codes with nice properties.[3] We start by describing some standard parameters associated with error-correcting codes.

An n-letter string over the alphabet Σ is an element of Σ^n. Given a string $w \in \Sigma^n$, the ith character of w is denoted w_i. Given strings $w, w' \in \Sigma$, the relative distance between w and w', denoted $d(w, w')$ is the fraction of indices $i \in \{1, \ldots, n\}$ where $w_i \neq w'_i$. (Here onwards we will drop the term relative from the description of this parameter.)

DEFINITION 7.1 (error-correcting code). *A (k, n, Δ, a)-code consists of an alphabet Σ such that $\log|\Sigma| = a$ and a function $C : \Sigma^k \to \Sigma^n$, such that for any two strings $m, m' \in \Sigma^k$, the distance between $C(m)$ and $C(m')$ is at least Δ.*

For the purposes of this section, we will restrict our attention to error-correcting codes within a small range of the above parameters which are interesting for the applications to probabilistically checkable proofs. We call these the *good* codes. Such codes need to have constant relative distance. The encoded message is allowed to be much larger than the original message size, as long as the final length is polynomially bounded. Perhaps the most interesting aspect is the alphabet size. While the ultimate goal would be to get codes which work over a constant-sized alphabet, getting an alphabet size which is significantly smaller than the message size (smaller than any nonconstant polynomial) turns out to be an important intermediate goal. Here we choose this parameter to be polylogarithmic in the message size.

DEFINITION 7.2 (good code). *A family of codes $\{C_i\}$ with parameters $(k_i, n_i, \Delta_i, a_i)$ is* good *if $k_i \to \infty$, n_i is upper bounded by some polynomial in k_i, $\Delta_i > 0$, and a_i is upper bounded by some function growing as* polylog(k_i).

A wide variety of codes described in practice satisfy the properties required of a good code. In particular we describe the polynomial codes.

DEFINITION 7.3 (polynomial codes). *Fix some $\epsilon > 0$. The* polynomial codes *$\{P_m\}$ are chosen by letting $d = \lceil m^{1+\epsilon} \rceil$ and picking a finite field F of size between $10d$ and $20d$. The code achieves $k_m = \binom{m+d}{m}$ and $n_m = |F|^m$ over the alphabet F and works as follows: The message is viewed as specifying the coefficients of a degree-d polynomial in m variables and the encoding consists of the value of this polynomial at all inputs.*

It may be verified that $\{P_m\}$ forms a good code with distance at least 0.9. In what follows, we will describe how this family of codes and a related code have extremely "good" local checkability properties. The following definition formalizes the notion of local checkability. Informally, the definition expects that by probing a string in just

[3] These definitions are motivated by subsequent work in the area of proof checking where our tester has found applications, most notably that of [ALMSS92].

p (randomly chosen) letters, the verifier can test if it close to a valid codeword and if not rejects it with probability at least δ.

DEFINITION 7.4 (locally testable code). *For a positive integer p and a positive real number δ, an (n,k,Δ,a)-code C over the alphabet Σ is* (p,δ)-locally testable *if the following exist:*

- *a probability space Ω which can be* efficiently *sampled,*
- *functions $q_1, q_2, \dots, q_p : \Omega \to \{1,\dots,n\}$, and*
- *a boolean function $V : \Omega \times \Sigma^p \to \{0,1\}$,*

with the property that for all $w \in \Sigma^n$, if

$$\Pr_{r\in\Omega}\left[V(r, w_{q_1(r)}, \dots, w_{q_p(r)}) = 0\right] < \delta$$

then there exists a (unique) string $m \in \Sigma^k$ such that $d(w, C(m)) < \Delta/2$. Conversely, if $w = C(m)$ for some m, then $V(r, w_{q_1(r)}, \dots, w_{q_p(r)}) = 1$ for all $r \in \Omega$.

Before we describe the kind of locally checkable codes that our testers provide, we attempt to motivate the definition above by showing that (seemingly minor) modifications of the above definitions yield important concepts in proof checking—namely, probabilistically checkable proofs. We consider especially probabilistically checkable proofs over a large alphabet in which the number of alphabets that a verifier is allowed to probe is a parameter. This concept is an important ingredient in the recursive construction of probabilistically checkable proofs [AS92], [ALMSS92], [BGLR93] and is also of independent interest in complexity theory [LS91], [FL92a]. The original definition of probabilistically checkable proofs is due to [AS92] based on an implicit notion in [FGLSS91]. A very closely related notion—that of holographic proofs—appears in the work of [BFLS91]. The particular choice of parameters made in the following definition is due to [BGLR93].

DEFINITION 7.5 (PCP). *Given functions $r, p, a, \delta : \mathcal{Z}^+ \to \mathcal{Z}^+$, a language $L \subset \{0,1\}^*$ is said to be in PCP$[r,p,a,\delta]$ if there exists a polynomially growing function $n(l)$ and an alphabet Σ of size $a(l)$ such that for all integers $l > 0$ the following exist:*

- *a probability space Ω which can be sampled using $r(l)$ bits,*
- *functions $q_1, q_2, \dots, q_{p(k)} : \Omega \to \{1,\dots,n(l)\}$,*
- *a boolean function $V : \{0,1\}^l \times \Omega \times \Sigma^p \to \{0,1\}$,*

with the property that for all $x \in \{0,1\}^l$, if $w \in \Sigma^{n(l)}$ satisfies

$$\Pr_{r\in\Omega}\left[V(x, r, w_{q_1(r)}, \dots, w_{q_p(r)}) = 0\right] < \delta,$$

then $x \in L$. Conversely, if $x \in L$, then there exists $w \in \Sigma^n(l)$ such that for all $r \in \Omega$, $V(x, r, w_{q_1(r)}, \dots, w_{q_p(r)}) = 1$.

It turns out that there is strong correlation between PCP$[\log, p, \text{polylog}, \delta]$ and good codes which are (p,δ)-locally checkable. In particular, the codes we describe next translate into such probabilistically checkable proofs.

The robust characterization of polynomials described in Theorem 5.1 shows that the polynomial codes are $(d+2, \Omega(1/d))$-locally testable. Observe further that for the polynomial codes, the growth of d is polylogarithmic in k. It seems that the approach above cannot hope to give codes which are testable using fewer than $\Omega(d)$ probes. However, this is not the case. We describe next a simple way of modifying the codes so as to give codes with appreciably better local testability. These codes are obtained by observing that the codes we have constructed so far use a much smaller alphabet size than necessary for "goodness."

DEFINITION 7.6 (polynomial-line codes). *Fix some $\epsilon > 0$. The* polynomial-line codes *$\{L_m\}$ are chosen by letting $t = \lceil m^{1+\epsilon} \rceil$ and picking a finite field F of size* *between 10d and 20d. The code achieves* $k_m = \binom{m+d}{m}/(d+1)$ *and* $n_m = |F|^{2m}$ *over the alphabet* F^{d+1}. *As in the polynomial codes, the message again consists of* $\binom{m+d}{d}$ *field elements and is viewed as a degree-d polynomial specified by its coefficients. Given a message polynomial p, the codeword is constructed as follows: For every pair of field elements* $\hat{x}, \hat{h} \in F^m$, *let* $l_{\hat{x},\hat{h}}$ *be the line through* $\hat{x}$ *with offset* $\hat{h}$ *as in characterization 3. p restricted to* $l_{\hat{x},\hat{h}}$ *is a univariate polynomial of degree d. Let* $C_{\hat{x},\hat{h}} \in F^{d+1}$ *be the vector of coefficients of this univariate polynomial. The codeword consists of* $\{C_{\hat{x},\hat{h}}\}_{\hat{x},\hat{h}\in F^m}$.

It is easy to see that the polynomial-line codes are also good codes. The proof of Theorem 5.1 can be transformed to show that the polynomial-line codes are locally testable with a constant number of probes. More specifically, the following can be shown.

PROPOSITION 7.7. *The polynomial-line codes are* $(2, \Omega(1/d))$*-locally testable.*

Better analysis of some portions of our proof yields even better statements about the polynomial-line codes. This is described in the next section.

8. Conclusions.

There has been a spate of results about low-degree tests in the last few years. A brief listing includes the low-degree test of [BFL91] and [Lun92], which was the first test for multivariate polynomials, the results of [BFLS91] and [FGLSS91], obtained independently from and concurrently with ours (from [GLRSW91] and [RS92]), and subsequent works [AS92], [ALMSS92], [FHS94], [PS94], and [FS94]. Here we summarize some of their achievements along with a comparison with our results. We start by distinguishing the merits of our tester from those of [BFL91] and [BFLS91].

8.1. Program checking.

The test of [BFL91] and [Lun92] in the program-checking setting allows the self-tester to be convinced that the program is computing a multivariate polynomial function of low degree in polynomial time. However, the tests are somewhat complicated to perform, because they involve the reconstruction of a univariate polynomial, given its values at a number of points (which in turn requires multiplications and matrix inversions), and later the evaluation of the reconstructed polynomial at random points. If the given function is a function of a single variable, then the tester of [BFL91] and [Lun92] is no simpler than a program evaluating the polynomial. Therefore it does not have the "little-oh" property defined in [BK89] nor is it *different* from the program evaluating the polynomial, in the sense defined by [BLR90], and it does not give a self-tester or checker. Our test in contrast is *different*, since it requires no multiplications to perform the test.

8.2. Relationship with proof checking.

The low-degree tester forms a crucial ingredient in the recent results on proof checking. Our result from §4 gives a very simple proof of one of the relatively hard parts of the proof of MIP=NEXPTIME shown by [BFL91]. The hardness of the analysis of the tester of [BFL91] (and its simplifications; see, for instance, [FGLSS91]) is in their need to rely on the isoperimetric properties of the m-dimensional grid. Our proof, on the other hand, does not seem to require any combinatorics and is instead based on elementary algebraic/probabilistic techniques. This difference may be explained as follows: The success of the test does indeed depend on the isoperimetric properties of a graph related to the neighborhood structure. In the case of the test of [BFL91], this graph turns out to be in the m-dimensional grid. In our case, the underlying graph turns out to be a complete graph. This graph is obviously much easier to analyze because its properties and hence the proof are devoid of any combinatorial statements.

We now describe some of the subsequent results and the role of our tester in these results. The contrast is described in terms of locally testable codes.

8.3. Locally testable codes. The low-degree test described in [BFL91] and [BFLS91] gives rise to good codes which also have nice local checkability property. A sequence of improvements [BFL91], [BFLS91], [FGLSS91] culminated in the work of [AS92], which achieves asymptotically optimal bounds for such codes by showing that they are $(2, \Omega(1/m))$-locally testable. The highlight of [AS92] is that the locality bounds are independent of the degree of the polynomial that they work with. However, the dependence of δ on m is inherent for such codes and $\delta \to 0$ as $m \to \infty$. The polynomial-line codes described in §7 seem to have no inherent reason why δ should go to zero. This turns out to be indeed the case. In [ALMSS92], it is observed that a combination of the analysis of [AS92] and that of §5 implies that there exists a constant $\delta > 0$ such that the polynomial-line codes are $(2, \delta)$-locally testable, provided that the field F is of cardinaltity at least d^2. As mentioned in §7, this translates into a proof of NP $\subset$ PCP[log, $O(1)$, polylog, $\Omega(1)$] in [ALMSS92]. By employing the technique of recursive proof checking, due to [AS92], on such proof systems [ALMSS92] go on to prove that NP $\subset$ PCP[log, $O(1)$, $O(1)$, $\Omega(1)$]. The local testability of the polynomial-line codes has been further improved in two ways recently. [PS94] have shown that the polynomial-line codes are $(2, \delta)$-locally checkable over linear-sized fields as well, for some $\delta > 0$. In a different direction, it is shown in [FS94] that the polynomial-line codes are $(2, \delta)$-locally checkable for all $\delta < \frac{1}{8}$.

Appendix.

A.1. Evenly spaced points. The following algorithm may be used to test if a function $f^{(0)}$ on m evenly spaced points—$x, x+h, \ldots, x+(m-1)h$—(where $m > d+1$) agrees with a degree-d polynomial.

```
for $i = 1$ to $d + 1$ do
    for $j = 1$ to $m - i$
        $f^{(i)}(x + jh) = f^{(i-1)}(x + (j + 1)h) - f^{(i-1)}(x + jh)$
    endfor
endfor
verify $f^{(d+1)}(x + jh) = 0$, for all $j \in \{0, \ldots, m - d - 2\}$.
```

The correctness of this algorithm follows from the following well-known fact:

FACT A.1. *$f^{(i)}(x)$ is a degree-$(d-i)$ polynomial if and only if $f^{(i-1)}$ is a degree-$(d-i+1)$ polynomial.*

(Follows from the fact that $f^{(i)}$ acts as the discrete derivative of $f^{(i-1)}$.)

This implies that $f^{(d)}$ is a constant if and only if $f^{(0)}$ is a degree-d polynomial, implying in turn that $f^{(d+1)}$ is identically zero if and only if $f^{(0)}$ is a degree-d polynomial. Observe further that the algorithm performs $O(md)$ additions and subtractions and no multiplications. Finally, it can also be checked that in case $m = d + 2$, then algorithm simply verifies that $\sum_{i=0}^{d+1} \alpha_i f^{(0)}(x + ih) = 0$, where $\alpha_i = (-1)^{i+1}\binom{d+1}{i}$.

A.2. Characterizations.

LEMMA A.2 (axis-parallel lines). *$f : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ is a polynomial in m variables of degree at most d in each variable if and only if for all $i \in \{1, \ldots, m\}$, $\beta_j \in \mathcal{Z}_p$ $(j \neq i)$, $f(\beta_1, \ldots, \beta_{i-1}, x_i, \beta_{iH}, \ldots, \beta_m)$ is a polynomial in x_i of degree at most d.*

Proof [*Sketch*]. It is clear that every polynomial of degree d in each variable restricted to axis-parallel lines behaves as a univariate polynomial of degree d. The other direction can be proved by induction on m. The base case $m = 1$ is obvious. For general $m > 1$, let $f_i(x_1, \ldots, x_{m-1})$ be the function $f(x_1, \ldots, x_{m-1}, i)$. By induction f_i is a polynomial of degree d in $m - 1$ variables. Now consider the function $h(x_1, \ldots, x_m) \equiv \sum_{i=0}^{d} \delta_i^{(d)}(x_m) f_i(x_1, \ldots, x_{m-1})$ (where $\delta_i^{(d)}$ is the unique polynomial of degree d in one variable that is 1 at $x_m = i$ and 0 for other values of $x_m \in \{0, \ldots, d\}$).

It is clear by construction that h is a polynomial of degree at most d in each variable. We now argue that f and h are identical. Fix $x_1 = \beta_1, \ldots, x_{m-1} = \beta_{m-1}$. It is clear that $h(x_1, \ldots, x_m) = f(x_1, \ldots, x_m)$ for $x_m \in \{0, \ldots, d\}$. Moreover, both h and f are degree-d polynomials in x_m which agree at $d + 1$ places. Hence f and h must agree at all values of x_m. Since this held for any choice of β_i's, f and h agree everywhere. □

LEMMA A.3 (general lines). *For $p \geq 2d + 1$, $f : \mathcal{Z}_p^m \mapsto \mathcal{Z}_p$ is a polynomial in m variables of total degree at most d if and only if $\forall \hat{x}, \hat{h} \in \mathcal{Z}_p^m$, $f(\hat{x} + t \cdot \hat{h})$ is a univariate polynomial in t of degree at most d.*

Proof. It is clear that every polynomial restricted to lines must become a degree-d polynomial in the parameter describing the line. Here we prove the other direction of the characterization. We first observe that since the set of all lines includes the axis parallel lines, we can use Lemma A.2 to show that f is a polynomial in m variables with degree at most d in each variable. Having got this weak characterization, we will now strengthen this to a tighter one. By induction on the number of variables, we can assume that f restricted to any value of the last variable x_m is a polynomial of total degree at most d in the variables $x_1, \ldots, x_{m-1}$. Thus f becomes a function in x_1 through x_m of total degree $d' \leq 2d$.

Assume for contradiction that $d' > d$. Now consider the function $f(t \cdot \hat{h})$ for $\hat{h} \in_R \mathcal{Z}_p^m$. The coefficient of $t^{d'}$ is a polynomial in $\hat{h}$ of degree d' which with probability at least $1 - \frac{d'}{p}$ should be nonzero. (Note that to make this probability positive, we need $2d < p$.) Thus f restricted to this line is a polynomial of degree $d' > d$, which violates the given condition on f. □

Acknowledgments. We are very grateful to Avi Wigderson for suggesting that our tester in §4 can be made more efficient, as well as his technical help in proving the theorems of §5. We are also very grateful to Sasha Shen for pointing out that the tester given in [GLRSW91] works for multivariate polynomials. In particular, characterization 3 and its relevance to our test are due to him. We are grateful to Dick Lipton for illuminating conversations on the use of the testers presented here, and to Mike Luby, Shafi Goldwasser, and Umesh Vazirani for technical suggestions. We would also like to thank Dieter van Melkebeek and the anonymous referees for pointing out numerous errors in earlier versions.

GENOME REARRANGEMENTS AND SORTING BY REVERSALS*

VINEET BAFNA† AND PAVEL A. PEVZNER‡

Abstract. Sequence comparison in molecular biology is in the beginning of a major paradigm shift—a shift from *gene* comparison based on local mutations (i.e., insertions, deletions, and substitutions of nucleotides) to *chromosome* comparison based on global rearrangements (i.e., inversions and transpositions of fragments). The classical methods of sequence comparison do not work for global rearrangements, and little is known in computer science about the edit distance between sequences if global rearrangements are allowed. In the simplest form, the problem of gene rearrangements corresponds to *sorting by reversals*, i.e., sorting of an array using reversals of arbitrary fragments. Recently, Kececioglu and Sankoff gave the first approximation algorithm for sorting by reversals with guaranteed error bound 2 and identified open problems related to chromosome rearrangements. One of these problems is Gollan's conjecture on the reversal diameter of the symmetric group. This paper proves the conjecture. Further, the problem of expected reversal distance between two random permutations is investigated. The reversal distance between two random permutations is shown to be very close to the reversal diameter, thereby indicating that reversal distance provides a good separation between related and nonrelated sequences in molecular evolution studies. The gene rearrangement problem forces us to consider reversals of *signed permutations*, as the genes in DNA could be positively or negatively oriented. An approximation algorithm for signed permutation is presented, which provides a performance guarantee of $\frac{3}{2}$. Finally, using the signed permutations approach, an approximation algorithm for sorting by reversals is described which achieves a performance guarantee of $\frac{7}{4}$.

Key words. computational molecular biology, sorting by reversals, genome rearrangements

AMS subject classifications. 68Q25, 68Q05

1. Introduction.

Genus *Lobelia* comprises over 350 species that range from small, slender herbs to woody, giant-rosette plants. Figure 1 presents the order of genes in *Tobacco* and *Lobelia fervens* chloroplast genomes with a hypothetical sequence of rearrangement events (Knox et al. [KDP93]) during evolution of *Lobelia fervens* from a tobacco-like ancestral genome.

It is not so easy to verify that the evolutionary events shown in Fig. 1 represent the *shortest* series of reversals transforming the *Tobacco* permutation into the *Lobelia fervens* permutation. In fact, Theorem 2 of this paper indicates that the shortest sequence of rearrangement events contains just 4 reversals, shown in Fig. 2 (however, for the case of *signed* permutations (see below) the evolutionary events presented in Fig. 1 do represent the shortest series of reversals).

With the advent of large-scale DNA mapping and sequencing, the number of *genome comparison* problems similar to the one presented in Fig. 1 is rapidly growing in different areas, including evolution of plant cpDNA (Raubeson and Jansen [RJ92], Hoot and Palmer [HP94]) and mtDNA (Palmer and Herbon [PH88], Fauron and Havlik [FH89]), animal mtDNA (Hoffman et al. [HBB92], Sankoff et al. [SLA92]), virology (Koonin and Dolya [K93], Hannenhalli et al. [HCKP95]), *Drosophila* genetics (Whiting et al. [WPFJ89]), and comparative physical mapping (Lyon [L88]). Genome comparison has certain merits and demerits as compared to classical *gene* comparison.

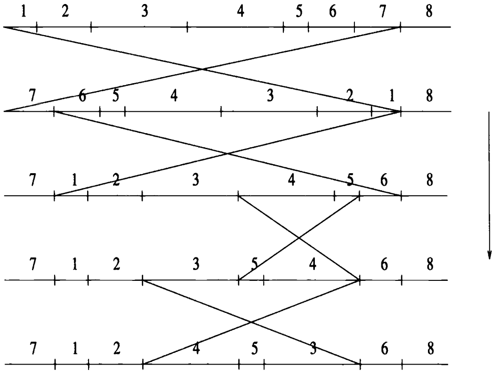

FIG. 2. *An optimal reversal sequence for* $\pi = 71245368$.

Genome comparison ignores actual DNA sequences of genes, while gene comparison ignores gene order. The ultimate goal would be to combine merits of both genome and gene comparison in a single algorithm. However, until recently, studies of genome rearrangements were based on heuristic methods, and there were no algorithms to analyze gene orders in molecular evolution. Kececioglu and Sankoff found an algorithm for reversal distance with guaranteed error bound 2 and raised a spectrum of open problems motivated by genome rearrangements [KS93]. The present paper solves some of them.

In the problem we consider, the order of genes in two organisms is represented by permutations $\pi = (\pi_1\pi_2\dots\pi_n)$ and $\sigma = (\sigma_1\sigma_2\dots\sigma_n)$. A *reversal* $\rho(i,j)$ of an interval$[i,j]$ is the permutation

$$\begin{pmatrix} 1 & 2 & \dots & i-1 & \mathbf{i} & \mathbf{i+1} & \dots & \mathbf{j-1} & \mathbf{j} & j+1 & \dots & n \\ 1 & 2 & \dots & i-1 & \mathbf{j} & \mathbf{j-1} & \dots & \mathbf{i+1} & \mathbf{i} & j+1 & \dots & n \end{pmatrix}.$$

Clearly $\pi \cdot \rho$ has the effect of reversing genes $\pi_i, \pi_{i+1}, \dots, \pi_j$.

Given permutations π and σ, the *reversal distance problem* is to find a series of reversals $\rho_1, \rho_2, \ldots, \rho_t$ such that $\pi \cdot \rho_1 \cdot \rho_2 \cdots \rho_t = \sigma$ and t is minimum. We call t the *reversal distance* between π and σ. Note that reversal distance between π and σ equals the reversal distance between $\sigma^{-1}\pi$ and the *identity* permutation $\imath$. *Sorting* π *by reversals* is the problem of finding reversal distance $d(\pi)$, between π and $\imath$.

Reversals generate the *symmetric group* S_n. Given an arbitrary permutation π from S_n, we seek a shortest product of *generators* $\rho_1 \cdot \rho_2 \cdots \rho_t$ that equals π. Even and Goldreich [EG81] show that given a set of generators of a permutation group and a permutation π, determining the shortest product of generators that equals π is NP-hard. Jerrum [J85] proves that the problem is PSPACE-complete, and remains so, when restricted to two generators. In our problem, the generator set is fixed. However, Kececioglu and Sankoff [KS93] conjecture that sorting by reversals is NP-complete.

Gates and Papadimitriou [GP79] studied a similar *sorting by prefix reversals* problem (also known as *pancake-flipping problem*): given an arbitrary permutation π, find $d_{pref}(\pi)$, which is the minimum number of reversals of the form $\rho(1,i)$ that sort π. Their concern is with bounds on the *prefix reversal diameter* of the symmetric group, $d_{pref}(n) = \max_{\pi \in S_n} d_{pref}(\pi)$. They show that $d_{pref}(n) \leq \frac{5}{3}n + \frac{5}{3}$ (see also [GT78]) and that for infinitely many n, $d_{pref}(n) \geq \frac{17}{16}n$ [GP79]. Aigner and West [AW87] consider the diameter of sorting when the operation is reinsertion of the first element, and Amato et al. [ABSR89] consider a variation inspired by reversing trains. Kececioglu and Sankoff [KS93] found an approximation algorithm for sorting by reversals with performance guarantee 2. They also devised efficient bounds, allowing them to solve the reversal distance problem optimally or almost optimally for n ranging from 30 to 50. This range covers the biologically important case of mitochondrial genomes.

Define $d(n) = \max_{\pi \in S_n} d(\pi)$ to be the *reversal diameter* of the symmetric group of order n. Gollan conjectured that $d(n) = n - 1$ and that only one permutation γ_n, and its inverse, γ_n^{-1}, require $n - 1$ reversals to be sorted (see Kececioglu and Sankoff [KS93] for details). The *Gollan* permutation, in one-line notation, is defined as follows:

$$\gamma_n = \begin{cases} (3,1,5,2,7,4,\ldots,n-3,n-5,n-1,n-4,n,n-2), & n \text{ even}, \\ (3,1,5,2,7,4,\ldots,n-6,n-2,n-5,n,n-3,n-1), & n \text{ odd}. \end{cases}$$

For $n \leq 11$, Gollan verified this conjecture using extensive computations. Kececioglu and Sankoff [KS93] developed lower bounds for reversal distance, allowing them to verify Gollan's conjecture for $n \leq 200$ for $n \equiv 1 \pmod 3$. In the present paper, we introduce the notion of the *breakpoint graph* of a permutation and establish the links between reversal distance and *maximum cycle decomposition* of this graph. This construction allows us to prove Gollan's conjecture. Further, we study the problem of expected reversal distance between two random permutations. We demonstrate that reversal distance between two random permutations is very close to the reversal diameter of the symmetric group, thereby indicating that reversal distance provides a good separation between related and nonrelated sequences in molecular evolution studies.

Afterwards, we study reversals of *signed* permutations. The *Lobelia fervens* permutation (Fig. 1) corresponds to the signed permutation $(-7, +1, +2, +4, +5, +3, -6, +8)$. In the biologically more relevant signed case, every reversal of fragment $[i, j]$ changes the signs of the elements within that fragment. We are interested in the minimum number of reversals required to transform the signed permutation π into the identity signed permutation $(+1, +2, \ldots, +n)$. We devise an approximation algorithm

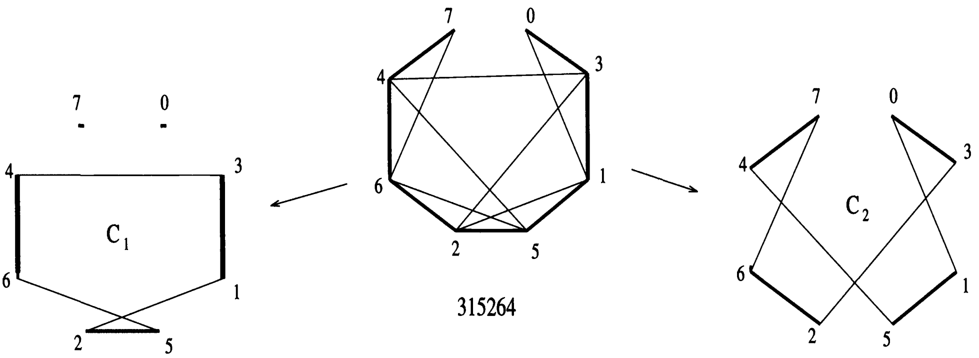

FIG. 3. *Breakpoint graph for* $\gamma_6 = 315264$ *and its maximum cycle decomposition.*

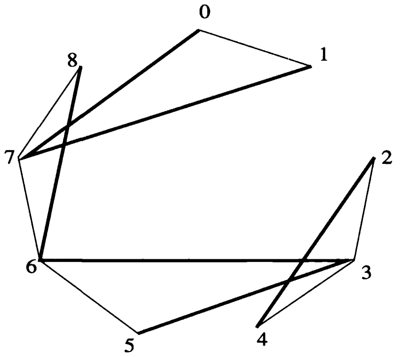

FIG. 4. *Breakpoint graph for the* Lobelia fervens *permutation.*

for sorting signed permutations by reversals with guaranteed error bound $\frac{3}{2}$. Finally, we use signed permutations to get a performance guarantee of $\frac{7}{4}$ for sorting unsigned permutations by reversals, thereby improving on the factor of 2 due to Kececioglu and Sankoff [KS93].

2. Breakpoint graph and reversal distance. Let $i \sim j$ if $|i-j| = 1$. Extend a permutation $\pi = \pi_1\pi_2\dots\pi_n$ by adding $\pi_0 = 0$ and $\pi_{n+1} = n+1$. We call a pair of consecutive elements π_i and π_{i+1}, $0 \leq i \leq n$, of π an *adjacency* if $\pi_i \sim \pi_{i+1}$, and a *breakpoint* if $\pi_i \not\sim \pi_{i+1}$. Define an edge-colored graph $G(\pi)$ with $n+2$ vertices $0, 1, \dots, n, n+1$. We join vertices i and j by a *black* edge if (i, j) is a *breakpoint* of π. We join vertices i and j by a *gray* edge if $i \sim j$ and i and j are not consecutive in π. The graph $G(\gamma_6)$, corresponding to the Gollan permutation $\gamma_6 = 315264$, is shown in Fig. 3.

A sequence of vertices $x_1x_2\dots x_m = x_1$ is called a *cycle* in a graph $G(V, E)$ if $(x_i, x_{i+1}) \epsilon E$ for $1 \leq i \leq m-1$. A cycle in an edge-colored graph G is called *alternating* if the colors of every two consecutive edges of this cycle are distinct. In the following, we consider *cycle decompositions* of $G(\pi)$ into the maximum number $c(\pi)$ of edge-disjoint alternating cycles. A maximum cycle decomposition of $G(\gamma_6)$ into 2 cycles is shown in Fig. 3. Figure 4 displays the breakpoint graph for the *Lobelia fervens* permutation, $\pi = 7124536$, with $c(\pi) = 2$. (Black edges are shown by thick lines, while gray edges are shown by thin ones.) Note that cycles can be vertex self-intersecting.

A vertex v in the graph G is called *balanced* if the number of black edges incident to v equals the number of gray edges incident to v. A *balanced graph* is a graph in which every vertex is balanced. It is easy to see that $G(\pi)$ is a balanced graph for every π; therefore, it contains an alternating Eulerian cycle in every connected component. For characterization of alternating Eulerian cycles in edge-colored graphs, see Kotzig [K68] and Pevzner [P94].

Cycle decompositions play an important role in estimating the reversal distance. When we apply a reversal to a permutation, there might be a change in the number of breakpoints, as well as in the number of cycles in a maximum decomposition. In Theorem 1, we show that there is a strong correlation between these two changes. This idea allows us to bound the reversal distance in terms of the size of the maximum cycle decomposition.

Denote the number of black edges in $G(\pi)$ (breakpoints in π) as $b = b(\pi)$ and the number of adjacencies in π as $a(\pi)$. Let $c(\pi)$ be the number of cycles in a maximum cycle decomposition of $G(\pi)$. Given an arbitrary reversal ρ, denote $\Delta b = \Delta b(\pi, \rho) = b(\pi\rho) - b(\pi)$ (increase in breakpoints), $\Delta a = \Delta a(\pi, \rho) = a(\pi\rho) - a(\pi)$ (increase in adjacencies), and $\Delta c = \Delta c(\pi, \rho) = c(\pi\rho) - c(\pi)$ (increase in the number of cycles in a maximum decomposition).

THEOREM 1. *For every permutation π and reversal ρ, $\Delta c(\pi, \rho) - \Delta b(\pi, \rho) \leq 1$.*

Proof. We augment $G(\pi)$ to get $G'(\pi)$ as follows: For every adjacency (π_i, π_{i+1}) in π, add a cycle of length 2 with one black and one gray edge connecting π_i and π_{i+1}. Every decomposition of $G(\pi)$ into $c(\pi)$ cycles corresponds to a decomposition of $G'(\pi)$ into $c(\pi) + a(\pi)$ cycles and, conversely, any decomposition of $G'(\pi)$ into $c'(\pi)$ cycles corresponds to a decomposition of $G(\pi)$ into at least $c'(\pi) - a(\pi)$ cycles.

We will prove that the number of cycles in $G'(\pi)$ changes by no more than one in a single reversal. An arbitrary reversal $\rho(i, j)$ involves 4 vertices of $G'(\pi)$ and leads to replacing two black edges *DEL*$= \{(\pi_{i-1}, \pi_i), (\pi_j, \pi_{j+1})\}$ by the black edges *ADD* $= \{(\pi_{i-1}, \pi_j), (\pi_i, \pi_{j+1})\}$.

If these two black edges in *ADD* belong to the same cycle in a maximum cycle decomposition of $G'(\pi\rho)$, then a deletion of that cycle gives a cycle decomposition of $G'(\pi)$ with at least $c'(\pi\rho) - 1$ cycles. Therefore, $c'(\pi) \geq c'(\pi\rho) - 1$ and $\Delta c' = \Delta c + \Delta a \leq 1$.

On the other hand, if the black edges in *ADD* belong to different cycles C_1 and C_2 in a maximum cycle decomposition of $G'(\pi\rho)$, then deleting $C_1 \cup C_2$ gives a set of edge-disjoint cycles of size $c'(\pi\rho) - 2$ in the graph $G(\pi\rho) \setminus (C_1 \cup C_2)$. Clearly, the set of edges $(C_1 \cup C_2 \cup DEL) \setminus ADD$ forms a balanced graph and must contain at least one cycle. Combining this cycle with the previously obtained $c'(\pi\rho) - 2$ cycles, we obtain a cycle decomposition of $G(\pi) = (G(\pi\rho) \setminus (C_1 \cup C_2)) \cup (C_1 \cup C_2 \cup DEL \setminus ADD)$ into at least $c'(\pi\rho) - 1$ cycles. Therefore, $\Delta c' = \Delta c + \Delta a \leq 1$.

Finally, observing that $a(\pi) + b(\pi) = n + 1$ implies $\Delta b + \Delta a = 0$, we prove the theorem. □

Theorem 1 immediately gives us a new lower bound for the reversal distance in terms of the number of breakpoints and the size of a maximum cycle decomposition of the breakpoint graph.

THEOREM 2. *For every permutation π, $d(\pi) \geq b(\pi) - c(\pi)$.*

Proof. Let $\rho_t, \ldots, \rho_1$ be a shortest series of reversals transforming $\pi = \pi_t$ into the identity permutation π_0. Denote $\pi_{i-1} = \pi_i \rho_i$ for $i = 1, \ldots, t$, and apply Theorem 1 for a permutation π_i and reversal ρ_i.

$$d(\pi_i) = d(\pi_{i-1}) + 1 \geq d(\pi_{i-1}) - \Delta b(\pi_i, \rho_i) + \Delta c(\pi_i, \rho_i)$$

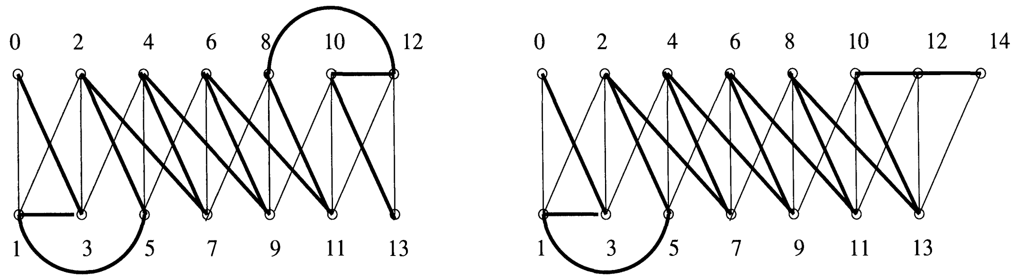

FIG. 5. $G(\gamma_{12})$ *and* $G(\gamma_{13})$.

$$= d(\pi_{i-1}) + (b(\pi_i) - b(\pi_{i-1})) + (c(\pi_{i-1}) - c(\pi_i)).$$

Recalling that $d(\pi_0) = b(\pi_0) = c(\pi_0) = 0$, we get

$$d(\pi_i)-(b(\pi_i)-c(\pi_i)) \geq d(\pi_{i-1})-(b(\pi_{i-1})-c(\pi_{i-1})) \geq \cdots \geq d(\pi_0)-(b(\pi_0)-c(\pi_0)) = 0.$$

Substituting $i = t$, we prove the theorem. □

3. Reversal diameter of the symmetric group. Now we have a characterization of the reversal distance of a permutation in terms of the maximum cycle decomposition of the breakpoint graph. Next we show that the graph corresponding to the Gollan permutation, γ_n, has at most two disjoint alternating cycles.

LEMMA 1. *Every alternating cycle in* $G(\gamma_n)$ *contains the vertex* 1 *or* 3.

Proof. Let us recall the Gollan permutation:

$$\gamma_n = \begin{cases} (3,1,5,2,7,4,\ldots,n-3,n-5,n-1,n-4,n,n-2), & n \text{ even}, \\ (3,1,5,2,7,4,\ldots,n-6,n-2,n-5,n,n-3,n-1), & n \text{ odd}. \end{cases}$$

Let i be the minimal odd vertex of an alternating cycle X in $G(\gamma_n)$. Consider the sequence i, j, k of consecutive vertices in X, where (i,j) is black, and (j,k) is gray.

If $i > 5$, then $j = i-3$ or $j = i-5$ and $k = j+1$ or $k = j-1$ (see the structure of the Gollan permutation and Fig. 5), implying that k is odd and $k < i$, a contradiction. If $i = 5$, then $j = 2$ and k is either 1 or 3, a contradiction. Therefore, i is either 1 or 3. □

THEOREM 3 (Gollan conjecture). *For every* n, $d(\gamma_n) = d(\gamma_n^{-1}) = n-1$.

Proof. For $n \leq 2$, the claim is trivial. For $n > 2$, partition the vertex set of $G(\gamma_n)$ into $V_l = \{0,1,3\}$ and V_r. From Lemma 1 and the fact that there is no cycle contained in V_l, we see that every alternating cycle must contain at least 2 edges from the cut (V_l, V_r). Because the cut (V_l, V_r) consists of 4 edges $((1,2),(1,5),(3,2),(3,4))$, the maximum number of edge-disjoint alternating cycles in a cycle decomposition of $G(\gamma_n)$ is at most $\frac{4}{2} = 2$.

From Theorem 2, $d(\gamma_n) \geq b(\gamma_n) - c(\gamma_n) \geq n+1-2 = n-1$. On the other hand, $d(\gamma_n) \leq n-1$ [WEHM82]. Finally, note that $d(\gamma_n^{-1}) = d(\gamma_n)$. □

Before we prove that γ_n and γ_n^{-1} are the only permutations in S_n with a reversal distance of $n-1$ (*strong Gollan conjecture*), we need to extend the concept of sorting permutations by reversals as follows: For any permutation of $\{1,\ldots,n\}$, $\pi = \pi_1\pi_2\ldots\pi_n$, let $\hat{\pi} = \hat{\pi}_1\hat{\pi}_2\ldots\hat{\pi}_n$, with $\hat{\pi}_i = \pi_i+1$, be a permutation of $\{2,3,\ldots,n\}$. Define $d(\hat{\pi})$ as the minimum number of reversals required to transform $\hat{\pi}$ to $234\ldots n+1$. Clearly, $d(\hat{\pi}) = d(\pi)$.

THEOREM 4 (strong Gollan conjecture). *For every n, γ_n and γ_n^{-1} are the only permutations that require $n-1$ reversals to be sorted.*

Proof. Define $\mathcal{P}_n \equiv \{\pi | \pi \in S_n \text{ and } d(\pi) = n-1\}$. We have seen that $\mathcal{P}_n \supseteq \{\gamma_n, \gamma_n^{-1}\}$. In what follows, we inductively prove that $\mathcal{P}_n \subseteq \{\gamma_n, \gamma_n^{-1}\}$.

For $n \leq 2$, the claim is trivial. Assume that the claim is true up to $n-1$. Consider $\pi \in \mathcal{P}_n$. Let ρ_π be the unique reversal that brings n to the right end, that is, $\pi \cdot \rho_\pi = \pi' n$, where π' is a permutation of $\{1, \ldots, n-1\}$.

It follows that $d(\pi) \leq 1 + d(\pi')$. Then, $d(\pi') \geq d(\pi) - 1 = n-2$. By induction, π' is either γ_{n-1} or γ_{n-1}^{-1}. Define $\mathcal{A} = \{\pi | \pi \cdot \rho_\pi = \gamma_{n-1} n\}$ and $\mathcal{B} = \{\pi | \pi \cdot \rho_\pi = \gamma_{n-1}^{-1} n\}$, where γn denotes the concatenation of a permutation γ with element n. Obviously, $\mathcal{P}_n \subseteq \mathcal{A} \cup \mathcal{B}$.

Likewise, define ρ'_π as the unique reversal that brings 1 to the left end, that is, $\pi \rho'_\pi = 1\pi'$, where π' is a permutation of $\{2, 3, \ldots, n\}$. As before, $d(\pi') \geq n-2$, which implies that π is $\hat{\gamma}_{n-1}$ or $\hat{\gamma}_{n-1}^{-1}$. Define $\mathcal{C} = \{\pi | \pi \cdot \rho'_\pi = 1\hat{\gamma}_{n-1}\}$ and $\mathcal{D} = \{\pi | \pi \cdot \rho'_\pi = 1\hat{\gamma}_{n-1}^{-1}\}$. Then, $\mathcal{P}_n \subseteq \mathcal{C} \cup \mathcal{D}$.

Therefore, $\mathcal{P}_n \subseteq \{\mathcal{A} \cup \mathcal{B}\} \cap \{\mathcal{C} \cup \mathcal{D}\}$. We state the following without proof:

1. $\mathcal{A} \cap \mathcal{C} = \phi$,
2. $\mathcal{A} \cap \mathcal{D} = \{\gamma_n\}$,
3. $\mathcal{B} \cap \mathcal{C} = \{\gamma_n^{-1}\}$,
4. $\mathcal{B} \cap \mathcal{D} = \phi$.

It follows that $\mathcal{P}_n \subseteq \{\gamma_n, \gamma_n^{-1}\}$. □

4. Expected reversal distance. For any permutation $\pi \in S_n$, consider a set of cycles that form a maximum decomposition and partition them by size. Let $c_i(\pi)$ denote the number of alternating cycles of length i in a maximum decomposition, which do not include either vertex 0 or $n+1$. There are at most two edge disjoint cycles, which contain the vertex 0 or $n+1$. Then

$$c(\pi) \leq \sum_{i=4}^{2(n+1)} c_i(\pi) + 2. \tag{1}$$

For $k \leq 2(n+1)$, let us consider cycles in the decomposition whose size is at least k. The number of such cycles is $c(\pi) - \sum_{i=4}^{k-1} c_i(\pi) - 2$. Now, the breakpoint graph of π has exactly $2b(\pi)$ edges. From this and the fact that the cycles are edge disjoint, we have

$$\forall k \leq 2(n+1), \qquad c(\pi) - \sum_{i=4}^{k-1} c_i(\pi) - 2 \leq \frac{1}{k}\left(2b(\pi) - \sum_{i=4}^{k-1} i c_i(\pi)\right). \tag{2}$$

From (1) and (2), we get

$$\forall k \leq 2(n+1), \qquad c(\pi) \leq \frac{1}{k}\left(2b(\pi) + \sum_{i=4}^{k-1}(k-i)c_i(\pi)\right) + 2. \tag{3}$$

Theorem 2 and inequality (3) imply that for all $k \leq 2(n+1)$, we can bound $d(\pi)$ as

$$d(\pi) \geq \left(1 - \frac{2}{k}\right) b(\pi) - \frac{1}{k}\left(\sum_{i=4}^{k-1}(k-i)c_i(\pi)\right) - 2 \tag{4}$$

$$\geq \left(1 - \frac{2}{k}\right) b(\pi) - \left(\sum_{i=4}^{k-1} c_i(\pi)\right) - 2. \tag{5}$$

Consider a permutation π chosen uniformly at random. As a cycle imposes a restriction on the permutation, it is intuitively clear that π does not have too many cycles. Denote the expected number of cycles of length i in a maximum cycle decomposition of $G(\pi)$ by $E(c_i(\pi)) = \frac{1}{n!}\sum_{\pi \in S_n} c_i(\pi)$. If we can bound $E(c_i(\pi))$, we can use (5) above to get a lower bound on the expected reversal distance. Lemma 2 provides such a bound which is, somewhat surprisingly, independent of n. Note that there is a slight ambiguity in the definition of $E(c_i(\pi))$, which depends on the choice of a maximum cycle decomposition for each $\pi \in S_n$. This does not affect Lemma 2, however, which holds for an arbitrary cycle decomposition.

LEMMA 2. $E(c_i(\pi)) \leq \frac{2^i}{i}$.

Proof. A cycle of length $i = 2t$ is a set of t breakpoints (unordered pairs of vertices) of the form

$$\{(x'_t, x_1), (x'_1, x_2), (x'_2, x_3), \ldots, (x'_{t-1}, x_t)\}, \text{ with } x_j \sim x'_j.$$

Consider the set $x_1, x_2, \ldots, x_t$. First, we claim that in every maximum cycle decomposition, $x_1, x_2, \ldots, x_t$ are all distinct. To see this, consider the case $x_k = x_l$, for some $1 \leq k < l \leq t$. Then $(x'_k, x_{k+1}), (x'_{k+1}, x_{k+2}), \ldots, (x'_{l-1}, x_l = x_k)$ form an alternating cycle, which can be detached to give a larger decomposition.

We have $\frac{n!}{(n-t)!}$ ways of selecting the ordered set, $x_1, x_2, \ldots, x_t$. Once this is fixed we have a choice of at most 2 elements for each of the x'_j, giving a bound of $2^t\frac{n!}{(n-t)!}$ on the number of cycles of length $2t$. Note, however, that we count each $(2t)$-cycle $2t$ times, so a tighter bound for the number of cycles of length $2t$ is $\frac{2^t}{2t}\frac{n!}{(n-t)!}$.

Choose an arbitrary $(2t)$-cycle. The number of permutations in which this cycle can occur is no more than the number of ways of permuting the remaining $n - 2t$ elements plus the t pairs that form the cycle. Additionally, each pair can be flipped to give a different order, which gives at most $2^t(n-t)!$ permutations. Let p be the probability that an arbitrary $(2t)$-cycle is present in a random permutation. Then $p \leq \frac{2^t(n-t)!}{n!}$ and

$$E(c_i(\pi) = E(c_{2t}(\pi)) \leq \sum_{\{\text{all } (2t)\text{-cycles}\}} p \leq \frac{2^{2t}}{2t} = \frac{2^i}{i}. \qquad \square$$

There are a total of $2n$ ordered adjacencies. Any such pair occurs in exactly $(n-1)!$ permutations, so the probability that it occurs in a random permutation is $\frac{1}{n}$. Then the expected number of adjacencies $E(a) = \frac{2n}{n} = 2$ and the expected number of breakpoints $E(b) = n + 1 - E(a) = n - 1$.

We use Lemma 2 and $E(b) = n - 1$ to get a bound on the expected diameter.

THEOREM 5. $E(d) \geq (1 - \frac{4.5}{\log n})n$.

Proof. From inequality (5), for all $k \leq 2(n+1)$,

$$\begin{aligned} E(d) &\geq \left(1 - \frac{2}{k}\right)E(b) - \sum_{i=4}^{k-1} E(c_i) \geq \left(1 - \frac{2}{k}\right)(n-1) - \sum_{i=4}^{k-1} 2^i/i \\ &\geq \left(1 - \frac{2}{k}\right)(n-1) - \sum_{i=4}^{k-1} 2^i \geq n - \frac{2n}{k} - \left(1 - \frac{2}{k}\right) - 2^k + 1 \\ &\geq n - \frac{2n}{k} - 2^k. \end{aligned}$$

TABLE 1
Comparison of theoretical and experimental lower bounds on expected diameter.

n	20	30	40	50	60	70	80	90	100
Theoretical	8.00	15.08	22.58	30.08	37.58	45.08	52.58	60.08	67.58
Experimental (matching)	12.60	19.92	27.34	34.05	41.09	48.73	55.80	63.33	70.49
Experimental (linear program)	12.6	20.8	28.5	35.9	43.6	51.7	58.9	67.6	74.2

Choose $k = \log \frac{n}{\log n}$. Then $2^k \leq \frac{n}{k}$ and

$$E(d) \geq \left(1 - \frac{3}{\log \frac{n}{\log n}}\right) n \geq \left(1 - \frac{4.5}{\log n}\right) n \qquad \text{for } n \geq 2^{16}.$$

Lemma 2 and inequality (4) for $k = 10$ imply that $E(d) \geq (1 - \frac{4.5}{\log n})n$ for $19 < n < 2^{16}$. For $1 \leq n \leq 19$, $(1 - \frac{4.5}{\log n})n < 1$. □

Although the bound provided by Theorem 5 is good asymptotically, it is weak for small values of n. However, the bound given by inequality (3) is tight if we select a k that gives the minimum value. We first give an example for $n = 100$ and then compare theoretical and experimental values for lower bounds on the expected diameter.

From Lemma 2 we have $E(c_4) \leq \frac{16}{4}$, $E(c_6) \leq \frac{64}{6}$, and $E(c_8) \leq \frac{128}{8}$. Consider a random permutation with $n = 100$ and $E(b) = n - 1 = 99$. Applying inequality (3) for $k = 8$, we derive $E(c) \leq \frac{1}{8}\left(198 + (8-4)4 + (8-6)\frac{64}{6}\right) + 2 \simeq 31.42$. This gives a lower bound for expected diameter with $n = 100$ as 67.58, which is close to experimental bounds based on maximum matching and linear programming [KS93]. Table 1 compares theoretical and experimental bounds over a range of n.

Kececioglu and Sankoff [KS93] use the lower bounds to prune the branch and bound tree, in order to solve the reversal distance problem. In the case of signed reversals (see below), the cycle decomposition is unique, and we can use Theorem 2 to get comparable bounds, at a significant reduction in running time.

5. Short cycles and approximation of reversal distance. Starting from this section we discuss approximation algorithms for sorting by reversals. Define a *strip* of π as an interval $[i, j]$ such that $(i-1, i)$ and $(j, j+1)$ are breakpoints and no breakpoint lies between them. A strip is *increasing* if $\pi_i < \pi_j$; otherwise it is *decreasing*. A strip of one element is both increasing and decreasing, except for π_0 and π_{n+1}, which are always increasing.

A reversal can add or remove no more than two breakpoints. Define an i-reversal, $i \in \{0, 1, 2\}$, as one that removes i breakpoints. Our task is to remove breakpoints by reversals and merge strips into one increasing strip. Clearly, we need at least $\frac{b(\pi)}{2}$ reversals. For an upper bound on the number of reversals, Kececioglu and Sankoff [KS93] give a greedy algorithm (Fig. 6) and prove the following assertions.

LEMMA 3. ([KS93]) *Let π be a permutation with a decreasing strip. Then* (i) *π has a* 1- *or* 2-*reversal, and* (ii) *if every reversal that removes a breakpoint of π leaves a permutation with no decreasing strips, then π has a* 2-*reversal.*

Partition a sequence of reversals into *rounds*, so that each round (except, perhaps, the first one) begins with a 0-reversal and has no other 0-reversals. Lemma 3 implies that in procedure *KS*, each round ends in a 2-reversal, thereby proving that every 0-reversal can be amortized against a 2-reversal and, *on the average*, we need at

```
**Procedure** $KS(\pi)$
**while** $\pi$ contains a breakpoint **do**
    $\rho = \text{Greedy}(\pi)$
    $\pi = \pi \cdot \rho$
**endwhile**

**Procedure** $Greedy(\pi)$
**begin**
    Return a reversal that removes the most breakpoints of $\pi$,
    resolving ties in favor of reversals that leave a decreasing strip.
**end**
```

FIG. 6. *The greedy algorithm.*

most one reversal to remove a breakpoint. Comparison of the upper bound of $b(\pi)$ reversals against the lower bound $\frac{b(\pi)}{2}$ provides a performance guarantee of 2. Can we do better?

Theorem 2 gives a stronger lower bound of $d(\pi) \geq b(\pi) - c(\pi)$, where $c(\pi)$ is the number of cycles in a maximum cycle decomposition of the breakpoint graph. Note that breakpoints correspond to black edges in this graph and every alternating cycle has at least 2 black edges. Therefore, the lower bound of $d(\pi) \geq \frac{b(\pi)}{2}$ is a simple corollary of Theorem 2.

Also, using inequality (2), we derive

$$d(\pi) \geq b(\pi) - c_4(\pi) - (c(\pi) - c_4(\pi)) \geq b(\pi) - c_4(\pi) - \frac{b(\pi) - 2c_4(\pi)}{3} = \frac{2}{3}b(\pi) - \frac{1}{3}c_4(\pi).$$

In the following sections we devise algorithms that sort π in at most $b(\pi) - \epsilon c_4(\pi)$ steps, for some $\epsilon > 0$. Then, the performance ratio of our algorithms is

$$(6) \qquad \mathcal{A} = \max_{0 \leq c_4(\pi) \leq \frac{b(\pi)}{2}} \left\{ \frac{b(\pi) - \epsilon c_4(\pi)}{\frac{2}{3}b(\pi) - \frac{1}{3}c_4(\pi)} \right\} \leq \begin{cases} 2 - \epsilon, & \epsilon \leq \frac{1}{2}, \\ \frac{3}{2} & \text{otherwise.} \end{cases}$$

6. Approximation algorithm for signed permutations. It is interesting to note that while the problem of sorting signed permutations is easier to handle, it is more relevant from a biological point of view. This is because genes are *directed* fragments of DNA sequences (Fig. 1).

We note that the concept of breakpoint graph as well as strips extends naturally to signed permutations. Define a transformation from a signed permutation π of order n to an unsigned permutation $\pi' \in S_{2n}$ as follows: replace $+i$ by $2i-1, 2i$ and $-i$ by $2i, 2i-1$. We observe that the identity signed permutation maps to the identity (unsigned) permutation, and the effect of a reversal on π can be mimicked by a reversal on π'. Therefore, any lower bound on π' is a lower bound on π. In particular, Theorem 2 holds.

For the upper bound, we shall perform reversals only across breakpoints so that any reversal on the unsigned permutation can be mimicked by a reversal on the signed permutation. It follows that, for our purpose, the two permutations are equivalent and in the following discussion, whenever we refer to the breakpoint graph or strips of a signed permutation, it is implied that we refer to the breakpoint graph or strips, respectively, of the transformed unsigned permutation.

Observe that in a breakpoint graph of signed permutations, every vertex has degree at most 2. Therefore the cycle decomposition is unique, thus making the case

```
Procedure SignedSort($\pi$)
 1. while $\pi$ contains a breakpoint do
 2.     if $\pi$ has no decreasing strips
 3.         if any 4-cycle $C$ remains in $G(\pi)$
 4.             Find a cycle $C'$ which crosses $C$.
 5.             Do a 0-reversal on $C'$ so that the 4-cycle $C$ is oriented.
 6.             Do a 2-reversal on the 4-cycle $C$.
 7.         else
 8.             Do a 0-reversal on an arbitrary cycle.
 9.     else
10.         $\rho = Greedy(\pi)$
11.         $\pi = \pi \cdot \rho$
12. endwhile
```

FIG. 7. *Algorithm for sorting signed permutations.*

of signed permutations easier to handle. Below, we devise an algorithm that sorts signed permutations in $b(\pi) - \frac{1}{2}c_4(\pi)$ steps, thereby achieving a performance ratio of $\frac{3}{2}$. Later, we will use signed permutations to improve the performance guarantee for (unsigned) sorting by reversals.

In order to be able to sort a signed permutation π in less than $b(\pi)$ steps, we need 2-reversals that *do not have to be amortized* against 0-reversals. In the breakpoint graph of a signed permutation, 2-reversals correspond to elimination of 4-cycles, while 1-reversals correspond to shortening of longer cycles. However, the breakpoints might be oriented in such a way that 1- and 2-reversals are infeasible.

We call $\rho(i,j)$ a *reversal on a cycle* if the breakpoints (π_{i-1}, π_i) and (π_j, π_{j+1}) belong to the *same* cycle. A cycle is *oriented* if there exists a 1- or 2-reversal on it. Two cycles are *crossing* if some of the breakpoints corresponding to their black edges are *interleaved* in the permutation. For example, for γ_6, $\rho : 315264 \rightarrow 315624$ is a reversal on the cycle $C = 134652$ (Fig. 3), since the breakpoints $(5,2)$ and $(6,4)$ belong to C. C is oriented since ρ is a 1-reversal. Cycles C_1 and C_2 in Fig. 3 are crossing as their breakpoints ($(3,1)$ and $(6,4)$ in C_1, $(1,5)$ and $(4,7)$ in C_2) are interleaved in the permutation 315264.

Note that a reversal on a cycle can orient an unoriented crossing cycle. The following lemma shows that we can use reversals on a cycle to orient 4-cycles, for signed permutations.

LEMMA 4. *Any 4-cycle C that is not oriented has a crossing cycle C'. Also, there exists a reversal on C' which will orient C.*

Proof. A 4-cycle that is not oriented is of the form $\ldots i, j \ldots j', i' \ldots$, with $i \sim i'$ and $j \sim j'$. Since (j, j') is a gray edge in the breakpoint graph, the set of elements strictly between j and j' in the permutation, $\mathcal{S}$, is nonempty. Consider the largest and the smallest (not necessarily distinct) elements in $\mathcal{S}$. For at least one of these two elements, say k, there exists $k' \sim k$ such that $k' \notin \mathcal{S}$, and $k' \neq j, j'$. Consequently, there exist breakpoints (k,l) and (k',m) which are interleaved with (i,j) and (j',i'). Also, since all cycles in signed permutations are vertex-disjoint, $k' \neq i, i'$. Then, the cycle which contains the black edges (k,l) and (k',m) and the gray edge (k,k') is a crossing cycle for the 4-cycle C, and a reversal along the edges (k,l) and (k',m) will orient C. □

Lemma 4 motivates the algorithm *SignedSort* for sorting signed permutations (Fig. 7). It uses the procedure *Greedy*, which was described earlier (Fig. 6).

LEMMA 5. *After step (6) in SignedSort, some decreasing strips remain.*

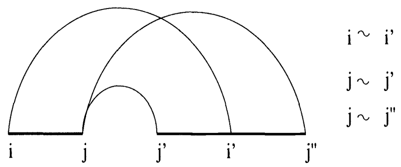

FIG. 8. *A 2-overlapping pair of cycles* (i, j, j', i') *and* (j, i, i', j'').

Proof. Step (4) is executed when all strips in π are increasing. The 0-reversal of Step (5), which is on an increasing strip, creates a decreasing strip. To remove the decreasing strip, the reversal of Step 6 would need to be on the same interval, which it is not. □

LEMMA 6. *If there is a* 4*-cycle in* $G(\pi)$ *at the beginning of any round of SignedSort (except, perhaps, the first one), then there are at least two* 2*-reversals in that round.*

Proof. If there is a 4-cycle in $G(\pi)$ at the beginning of any round (except, perhaps, the first one), that round begins with a 0-reversal followed by a 2-reversal. (Note that this cycle is nonoriented since all cycles in a permutation with no decreasing strips are nonoriented.) Also, from Lemma 5, some decreasing strips remain after this 2-reversal. At the point, as the permutation has decreasing strips we call *Greedy.* Then Lemma 3 implies that every round of *Greedy* ends in a 2-reversal, thus proving that as long as there are 4-cycles at the beginning of a round in *SignedSort*, there are at least two 2-reversals in that round. □

THEOREM 6. *SignedSort sorts a signed permutation* π *in at most* $b(\pi) - \frac{1}{2}c_4(\pi)$ *reversals and provides an approximation ratio of* $\frac{3}{2}$.

Proof. Let d_i be the number of i-reversals in *SignedSort.* Observing that $b(\pi) = d_1 + 2d_2$, *SignedSort* sorts π in $d_0 + d_1 + d_2 = b(\pi) + d_0 - d_2$ steps.

Each round of *SignedSort* has exactly one 0-reversal (except, perhaps, the first one) and at least one 2-reversal, implying $d_2 \geq d_0$. In addition, by Lemma 6, if there is a 4-cycle in π at the beginning of a round, then there are at least two 2-reversals in that round. Therefore, if there are r such rounds, then $d_2 \geq d_0 + r$. On the other hand, each of the 4-cycles in $c_4(\pi)$ must be removed in a 2-reversal in one of these r rounds (4-cycles in signed permutations are unaffected by the other reversals). These $c_4(\pi)$ 2-reversals in r rounds together with 2-reversals in each of the remaining $d_0 - r$ rounds imply that $d_2 \geq d_0 + c_4(\pi) - r$.

From these two inequalities, we have $d_2 \geq d_0 + \frac{1}{2}c_4(\pi)$, which implies that *SignedSort* sorts π in $b(\pi) + d_0 - d_2 \leq b(\pi) - \frac{1}{2}c_4(\pi)$ steps. The bound on performance follows from equation (6). □

7. Approximation algorithm for sorting by reversals.

In general, finding a maximum cycle decomposition is not straightforward. In this section, we concentrate only on finding a cycle decomposition (not necessarily maximum) with a large number of 4-cycles, since such a decomposition will provide an improved performance ratio for sorting by reversals.

Any two 4-cycles can share at most two edges. Two 4-cycles are 2*-overlapping* if they share two edges.

LEMMA 7. *If two* 4*-cycles of* $G(\pi)$ *are* 2*-overlapping, then one of them is oriented (i.e., a* 2*-reversal is possible on it).*

Proof. The only way a pair of alternating 4-cycles can 2-overlap is shown in Fig. 8. It can be verified that in any permutation of i, j, j', i', j'' that preserves such a structure, one of the 4-cycles is oriented. □

The 4*-cycle graph* $H(\pi)$ of a permutation π is defined as a graph in which each node corresponds to a 4-cycle of $G(\pi)$, and two nodes are connected by an edge if the corresponding 4-cycles share an edge in $G(\pi)$. An *independent set* in $H(\pi)$ corresponds to a set of edge disjoint 4-cycles. Furthermore, this graph has bounded degree, and there are efficient algorithms to find good approximations to a maximum independent set in bounded degree graphs.

We call a graph *strongly d-bounded* if the degree of every vertex in the graph is bounded by d and the degree of at least one vertex in every connected component of the graph is less than d.

LEMMA 8. *If $G(\pi)$ has no 2-overlapping cycles, then the 4-cycle graph $H(\pi)$ is strongly 4-bounded.*

Proof. It is easy to see that in a graph $G(\pi)$ without 2-overlapping cycles, a 4-cycle can have at most four other alternating cycles sharing edges with it. Consider a 4-cycle C containing the maximal element i of π among all 4-cycles in a given connected component of $H(\pi)$. Since $i+1$ does not belong to any 4-cycle in this component, at most one of the neighboring cycles of C contains the vertex of $G(\pi)$ corresponding to that maximal element. It follows that C has at most three neighbors in $H(\pi)$. □

LEMMA 9. *In a strongly d-bounded graph $G(V,E)$, an independent set of size at least $\frac{|V|}{d}$ can be computed in $O(E)$ time.*

Proof. Pick a vertex of degree less than d, add it to the independent set, and remove the neighbors. Clearly, the remaining graph is strongly d-bounded. Repeat this step until no vertices are left. As no more than d vertices are removed in each step, the size of the independent set is at least $\frac{|V|}{d}$. □

LEMMA 10. *In a strongly d-bounded graph $G(V,E)$, a $\frac{2}{(d+1)}$ approximation to a maximum independent set can be computed in $O(E)$ time.*

Proof. Let the size of the maximum independent set be $a \cdot n$, for some a, where $|V| = n$. Consequently, the minimum vertex cover for G has a size $= (1-a)\cdot n$. We can find a vertex cover V' of size at most $\min\{2(1-a)\cdot n, n\}$ in $O(E)$ time [CLR90]. Then $I_1 = V \backslash V'$ is an independent set for G, of size at least $\max\{(2a-1)\cdot n, 0\}$. Another independent set I_2 is given by Lemma 9 and is of size $\frac{n}{d}$. Obviously, we select the larger of the two sets.

There are two cases in analyzing the performance of our approximation:

$\max\{(2a-1)n, 0\} = 0$:

This implies that $a \leq \frac{1}{2}$. In this case we select I_2. Performance is $\frac{1}{ad} \geq \frac{2}{d}$.

$\max\{(2a-1)n, 0\} = (2a-1)n$:

In this case we select the larger of the two sets, I_1 and I_2. The performance is $\max\{\frac{1}{da}, \frac{(2a-1)}{a}\}$, with $a > \frac{1}{2}$. In the worst case, $\frac{1}{ad} = \frac{(2a-1)}{a}$, which implies that $a = \frac{(d+1)}{2d}$, and performance is $\frac{2}{(d+1)}$. □

Lemmas 7, 8, and 10 motivate the algorithm *ReversalSort* (Fig. 9). Theorem 7 provides a performance guarantee for this algorithm.

THEOREM 7. *The algorithm ReversalSort achieves an approximation ratio of $\frac{9}{5}$.*

Proof. Note that every reversal on the signed permutation σ' in step (4) of *ReversalSort* can be simulated on the unsigned permutation σ. Therefore, an upper bound on the number of reversals in *SignedSort*(σ') is an upper bound on the number of reversals in step (4) of *ReversalSort.* If the number of 4-cycles found in the cycle decomposition in step (2) is $c_4'(\sigma)$, then from Theorem 6, we have the bound $d(\sigma) \leq b(\sigma) - \frac{1}{2}c_4'(\sigma)$ for the number of reversals in step (4) of *ReversalSort.* Let $\rho_1\rho_2\ldots\rho_x$ be 2-reversals chosen in step (1) of the algorithm, so that $\pi\rho_1\rho_2\ldots\rho_x = \sigma$. Clearly, $b(\pi) - b(\sigma) = 2x$. Therefore, *ReversalSort* requires no more than $x + b(\sigma) - \frac{1}{2}c_4'(\sigma) = b(\pi) - x - \frac{1}{2}c_4'(\sigma)$ reversals to sort π.

```
Algorithm ReversalSort(π)
  1. Starting with the permutation $\pi$, perform 2-reversals on $G(\pi)$ until no 2-overlapping
     cycles remain (Lemma 7). Let $\sigma$ denote the resulting permutation.
  2. Use the Independent Set approximation in $H(\sigma)$ to find a set of nonoverlapping
     4-cycles of size at least $\frac{2}{5}c_4(\sigma)$ in the breakpoint graph $G(\sigma)$ (Lemmas 8 and 10).
     Find an arbitrary cycle decomposition of the remaining edges.
  3. Split vertices of degree 4 in $G(\sigma)$ according to the cycle decomposition found in step
     (2), so that the cycles are vertex disjoint. In terms of strips, replace single elements
     by strips, oriented appropriately, resulting in a signed permutation $\sigma'$.
  4. Call SignedSort($\sigma'$) to sort $\sigma'$. Sorting of $\sigma'$ mimics sorting of $\sigma$.
```

FIG. 9. *Algorithm for sorting by reversals.*

Let $i(\delta)$ be the size of the maximum independent set in a 4-cycle graph $H(\delta)$. Lemmas 8 and 10 guarantee that $c'_4(\sigma) \geq \frac{2}{5}i(\sigma)$. On the other hand, $i(\pi) - i(\sigma) \leq 4x$, since every reversal in step (1) "destroys" at most four of the $i(\pi)$ vertices of the maximum independent set in $H(\pi)$ (there are at most 4 nonoverlapping cycles sharing edges with a 4-cycle). Therefore,

$$\begin{aligned} d(\pi) &\leq b(\pi) - x - \tfrac{1}{5}i(\sigma) &&\leq b(\pi) - x - \tfrac{1}{5}(i(\pi) - 4x) \\ &\leq b(\pi) - \tfrac{1}{5}x - \tfrac{1}{5}c_4(\pi) &&\leq b(\pi) - \tfrac{1}{5}c_4(\pi). \end{aligned}$$

The bound on performance follows from equation (6). □

8. Improved approximation for sorting by reversals. In this section, we modify *ReversalSort* to improve the performance ratio. Recall that in step (1) of *ReversalSort*(π), we perform 2-reversals to transform π into a permutation σ, which has the property that $H(\sigma)$ is strongly 4-bounded. This allows us to find a set of 4-cycles of size at least $\frac{2}{5}c_4(\sigma)$. In this section, we transform π using 2-reversals into a permutation σ, so that $H(\sigma)$ is *bipartite*. Consequently, we can find a maximum set of nonoverlapping 4-cycles in σ, which leads to improved performance.

The problem of transforming π into ν is equivalent to sorting $\nu^{-1}\pi$, and, for convenience, we shall switch between the two notations. Denote $G(\pi, \nu) \equiv G(\nu^{-1}\pi)$, $b(\pi, \nu) \equiv b(\nu^{-1}\pi)$, $i(\pi, \nu) \equiv i(\nu^{-1}\pi)$. Observe that $G(\pi, \nu)$ and $G(\nu, \pi)$ coincide, but have reversed colors, i.e., black (gray) edges in $G(\pi, \nu)$ are gray (black) in $G(\nu, \pi)$. It follows that $b(\pi, \nu) = b(\nu, \pi)$ and $i(\pi, \nu) = i(\nu, \pi)$.

Figure 10 describes the procedure *Transform* that transforms π into a permutation σ with the following properties.

LEMMA 11. *$H(\sigma)$ is bipartite.*

Proof. Consider a 4-cycle in $G(\sigma)$ formed by the vertices $\sigma_i, \sigma_{i+1}, \sigma_j, \sigma_{j+1}$, with $i + 1 < j$. Because no 2-reversals are possible on $\sigma = Transform(\pi)$, every 4-cycle in $G(\sigma)$ must be nonoriented. Therefore, we must have $\sigma_i \sim \sigma_{j+1}$ and $\sigma_j \sim \sigma_{i+1}$. Now, observe that these vertices form a 4-cycle in $G(\sigma^{-1})$ also, with the color on the edges reversed. If $\sigma_j - \sigma_{i+1} = \sigma_{j+1} - \sigma_i$, then the 4-cycle in $G(\sigma^{-1})$ is oriented. Therefore, $\sigma_j - \sigma_{i+1} = -(\sigma_{j+1} - \sigma_i)$.

To interpret this graphically, direct black edges of $G(\sigma)$ from π_k to π_{k+1} and gray edges from k to $k + 1$. We call edges of a cycle *coordinated* if they are directed the same way along this cycle. Note that if black edges of a 4-cycle are not coordinated, then this cycle is oriented. Since there is no oriented cycles in $G(\sigma)$, black edges in every 4-cycle of $G(\sigma)$ are coordinated. Also, since there is no oriented cycles in $G(\sigma^{-1})$, black edges in every 4-cycle of $G(\sigma^{-1})$ are coordinated. An observation that

```
Procedure Transform($\pi$)
begin
    $\bar{\pi} = \pi$
    $\bar{\nu} = \imath$        /* $\imath$ is the identity permutation*/
    while $\bar{\nu}^{-1} \cdot \bar{\pi}$ or $\bar{\pi}^{-1} \cdot \bar{\nu}$ has a 2-reversal, $\rho$
        if $\rho$ is a 2-reversal on $\bar{\nu}^{-1} \cdot \bar{\pi}$
            $\bar{\pi} = \bar{\pi} \cdot \rho$
        else $\bar{\nu} = \bar{\nu} \cdot \rho$
    endwhile
    return $\bar{\nu}^{-1} \cdot \bar{\pi}$
end
```

FIG. 10. *Algorithm for preprocessing permutation π using 2-reversals.*

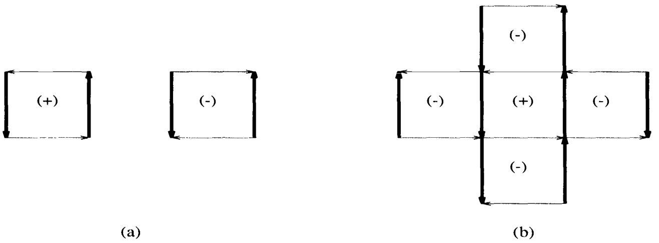

FIG. 11. (+) *and* (−) *cycles in $G(\pi)$.*

the edges of $G(\sigma)$ and $G(\sigma^{-1})$ have the same directions but reverse colors implies that gray edges in every 4-cycle of $G(\sigma)$ are coordinated. Only two such 4-cycles (denoted (+) and (−)) are possible (Fig. 11a). Further, observe that all cycles that share an edge with a cycle of type (+), must be of type (−), and vice-versa (Fig. 11b). This implies that $H(\sigma)$ is bipartite. □

LEMMA 12. *σ can be sorted in $b(\sigma) - \frac{1}{2}i(\sigma)$ reversals.*

Proof. Because $H(\sigma)$ is a bipartite graph (Lemma 11), we can reduce maximum independent set problem in $H(\sigma)$ to the maximum matching problem [CLR90]. Moreover, since $H(\sigma)$ is a graph of bounded degree, we can find a maximum independent set in $H(\sigma)$ in $O(n^{\frac{3}{2}})$ time by the maximum matching algorithm [HK73]. This implies that we can find a cycle decomposition of G(σ) in which the number of 4-cycles is $i(\sigma)$. The lemma then follows from Theorem 6. □

Let $\rho_1\rho_2\ldots\rho_x$ be the sequence of reversals in *Transform* that transforms π into $\bar{\pi}$ ($\pi\rho_1\rho_2\ldots\rho_x = \bar{\pi}$) and $\varrho_1\varrho_2\ldots\varrho_y$ be the sequence of reversals that transforms $\imath$ into $\bar{\nu}$ ($\imath\varrho_1\varrho_2\ldots\varrho_y = \bar{\nu}$).

LEMMA 13. *Let $\sigma =$ Transform(π). Then, $b(\pi) - b(\sigma) = 2(x+y)$, and $i(\pi) - i(\sigma) \leq 4(x+y)$.*

Proof. In each iteration of the **while** loop in *Transform*, $(\bar{\pi}, \bar{\nu})$ is transformed into $(\bar{\pi}', \bar{\nu}')$, in one of two ways. Either (i) $\bar{\pi}' = \bar{\pi} \cdot \rho$, $\bar{\nu}' = \bar{\nu}$, or (ii) $\bar{\pi}' = \bar{\pi}$, $\bar{\nu}' = \bar{\nu} \cdot \rho$. In case (ii), ρ is a 2-reversal on $\bar{\pi}^{-1}\bar{\nu}$, which implies that $2 = b(\bar{\pi}^{-1}\bar{\nu}) - b((\bar{\pi}')^{-1}\bar{\nu}') = b(\bar{\nu}, \bar{\pi}) - b(\bar{\nu}', \bar{\pi}') = b(\bar{\pi}, \bar{\nu}) - b(\bar{\pi}', \bar{\nu}')$. A similar argument holds for case (i), implying that $b(\bar{\pi}, \bar{\nu}) - b(\bar{\pi}', \bar{\nu}') = 2$. $i(\bar{\pi}, \bar{\nu}) - i(\bar{\pi}', \bar{\nu}') \leq 4$ follows from the fact that every 2-reversal can destroy at most four nonoverlapping 4-cycles in the breakpoint graph.

The lemma follows from the fact that each reversal in *Transform* belongs to either the sequence $\rho_1\rho_2\ldots\rho_x$ or the sequence $\varrho_1\varrho_2\ldots\varrho_y$, implying a total of $x+y$ reversals. □

ImprovedSort (Fig. 12) exploits the structure of the permutation $\sigma =$ *Trans-*

```
Algorithm ImprovedSort($\pi$)
  1. Call Transform($\pi$) to find a sequence of reversals $\rho_1\rho_2\dots\rho_x$ and $\varrho_1\varrho_2\dots\varrho_y$ such that $\pi\rho_1\rho_2\dots\rho_x = \bar{\pi}$ and $\iota\varrho_1\varrho_2\dots\varrho_y = \bar{\nu}$. Let $\sigma = \bar{\nu}^{-1}\bar{\pi}$.
  2. Find a maximum set of nonoverlapping 4-cycles in $G(\sigma)$ by solving the maximum independent set problem in the bipartite graph $H(\sigma)$ (Lemma 11). Find an arbitrary cycle decomposition of the remaining edges.
  3. Split vertices of degree 4 in $G(\sigma)$ according to the cycle decomposition found in step (2), so that the cycles are vertex disjoint. In terms of strips, replace single elements by strips, oriented appropriately, resulting in a signed permutation $\sigma'$.
  4. Call SignedSort($\sigma'$) to find a sequence of reversals that sort $\sigma'$. Note that this sequence is mimicked by a sequence of reversals $\varphi_1\varphi_2\dots\varphi_z$ that sorts $\sigma$.
  5. Apply the sequence of reversals $\rho_1\rho_2\dots\rho_x\varphi_1\varphi_2\dots\varphi_z\varrho_y\dots\varrho_2\varrho_1$ to sort $\pi$.
```

FIG. 12. *Improved algorithm for sorting by reversals.*

form(π) to sort π more efficiently. Theorem 8 analyzes the performance of this improved algorithm.

THEOREM 8. *ImprovedSort sorts π in $b(\pi) - \frac{1}{4}c_4(\pi)$ steps.*

Proof. From step (5) of *ImprovedSort*, $d(\pi) \leq x + y + z$. Lemmas 12 and 1 3 and the inequality $i(\pi) \geq c_4(\pi)$ provide an upper bound

$$\begin{aligned} x + y + z &\leq x + y + b(\sigma) - \tfrac{1}{2}i(\sigma) \\ &= b(\pi) - (x + y) - \tfrac{1}{2}i(\sigma) \\ &\leq b(\pi) - \tfrac{(i(\pi) - i(\sigma))}{4} - \tfrac{1}{2}i(\sigma) \\ &\leq b(\pi) - \tfrac{1}{4}i(\pi) \\ &\leq b(\pi) - \tfrac{1}{4}c_4(\pi). \qquad \square \end{aligned}$$

Theorem 8 and equation (6) imply Corollary 1.

COROLLARY 1. *The algorithm ImprovedSort achieves an approximation ratio of* $\frac{7}{4}$.

9. Running time. We show that all our algorithms have complexity of $O(n^2)$. Consider lines 4–6 of *SignedSort*. If we maintain both π and π^{-1}, it takes $O(n)$ time to find a 4-cycle, as well as a crossing cycle. Kececioglu and Sankoff [KS93] give an $O(n)$ implementation of *Greedy*. Finally, no more than $n - 1$ reversals are required to sort a permutation π, which gives an upper bound of $O(n^2)$ for *SignedSort*. For *ReversalSort* and *ImprovedSort*, the most expensive preprocessing step is that of finding the maximum independent set in a bipartite graph, which takes $O(n^{\frac{3}{2}})$ time. Therefore, the time bounds do not change for the improved sorting algorithms.

10. Genome rearrangements. Sequence alignment is often the first step in molecular evolution studies. However, in many cases sequence alignment is very unreliable, thus making further evolutionary tree reconstruction almost impossible. For example, the similarity between many genes in herpes viruses is so low that it is frequently indistinguishable from the background noise. As a result, the classical methods of *sequence comparison* frequently lead to ambiguous conclusions for such highly diverged genomes, and alternative methods are sought (Karlin et al. [KMS94]). Since it is often found that the order of genes is much more conserved than the DNA sequence, an approach based on comparison of *gene orders* (Sankoff [S93]) versus traditional comparison of *DNA sequences* seems to be a method of choice for many "hard-to-analyze" genomes.

Surprisingly enough, genome comparison might also outperform gene comparison for such highly conserved genomes as plant mitochondrial DNA(mtDNA). The point mutation rate in plant mtDNA is estimated to be 100 times slower than in animal mtDNA, and many genes are 99%–99.9% identical in related species (Palmer and Herbon [PH88]). However, although there is little change in the DNA sequence of the plant mitochondrial genes from one species to another, there is rapid and extensive change in gene arrangements. This implies that the traditional methods for comparing sequences are not very conclusive in this case either.

The described algorithms for sorting by reversals were implemented and applied for analysis of genome rearrangements in herpes viruses, plant organelles, and mammalian X chromosomes. For plant organelles, Bafna and Pevzner [BP95] corrected previously postulated scenarios for genome rearrangements in the *Brassica* family. For herpes viruses, Hannenhalli et al. [HCKP95] were able to come out with three alternative gene orders in common herpesvirus ancestor. Surprisingly enough, in all biological examples we analyzed, $d(\pi) = b(\pi) - c(\pi)$, thus indicating that the bound provided by Theorem 2 might be rather tight. A similar observation has been made by Kececiougli and Sankoff [KS94]: $b(\pi) - c(\pi)$ approximated $d(\pi)$ with accuracy 1 for each of 100 randomly chosen permutations on 10,000 elements. It indicates that the bound provided by the Theorem 2 is extremely tight and raises the problem of finding an exact estimate for reversal distance in terms of cycle decompositions.

Acknowledgments. We would like to thank John Kececioglu and David Sankoff for sending us the manuscript of their paper and for useful discussions. We are grateful to Piotr Berman for useful comments on approximating maximum independent sets of bounded degree graphs, and to Sing-Hoi Sze for carefully reading the manuscript and pointing out errors. We also thank both referees for many valuable comments.

NOTE ON "A LINEAR-TIME ALGORITHM FOR COMPUTING *K*-TERMINAL RELIABILITY IN A SERIES-PARALLEL NETWORK"*

A. SATYANARAYANA†, R. K. WOOD‡, L. CAMARINOPOULOS§, AND G. PAMPOUKIS§

In an original and very interesting paper (Satyanarayana and Wood [1]) concerning polygon-to-chain reductions in a stochastic network, a small inconsistency occurs in the proof of Theorem 1. In particular, this happens in cases where the whole set of $\boldsymbol{K}$-vertices lies in the remaining polygon. Such an example is the case of polygon type 5, where the appropriate note has been made by the authors for $|\boldsymbol{K}| = 2$. Analogous notes must also be made for polygon types 4, 6, and 7, when $\boldsymbol{K}= 2$, 3, and 4, respectively. The correct transformations are given in Table 1 (note that dark vertices are $\boldsymbol{K}$-vertices).

UPWARD PLANAR DRAWING OF SINGLE-SOURCE ACYCLIC DIGRAPHS*

MICHAEL D. HUTTON[†] AND ANNA LUBIW[‡]

Abstract. An upward plane drawing of a directed acyclic graph is a plane drawing of the digraph in which each directed edge is represented as a curve monotone increasing in the vertical direction. Thomassen has given a nonalgorithmic, graph-theoretic characterization of those directed graphs with a single source that admit an upward plane drawing. This paper presents an efficient algorithm to test whether a given single-source acyclic digraph has an upward plane drawing and, if so, to find a representation of one such drawing. This result is made more significant in light of the recent proof by Garg and Tamassia that the problem is NP-complete for general digraphs.

The algorithm decomposes the digraph into biconnected and triconnected components and defines conditions for merging the components into an upward plane drawing of the original digraph. To handle the triconnected components, we provide a linear algorithm to test whether a given plane drawing of a single-source digraph admits an upward plane drawing with the same faces and outer face, which also gives a simpler, algorithmic proof of Thomassen's result. The entire testing algorithm (for general single-source directed acyclic graphs) operates in $O(n^2)$ time and $O(n)$ space (n being the number of vertices in the input digraph) and represents the first polynomial-time solution to the problem.

1. Introduction.

There is a wide range of results dealing with drawing, representing, or testing planarity of graphs [5]. Steinitz and Rademacher [22], Fáry [10], Stein [21], and Wagner [26] independently showed that every planar graph can be drawn in the plane using only straight line segments for the edges. Tutte [25] showed that every 3-connected planar graph admits a convex straight-line drawing, where the facial cycles other than the unbounded face are all convex polygons. The first linear-time algorithm for testing planarity of a graph was given by Hopcroft and Tarjan [14].

Planar graph layout has many interesting applications and has been widely studied as a method to visualize structures commonly modeled as graphs [5]. Combinational boolean circuits, subroutine call-charts, PERT graphs, isa-hierarchies in artificial intelligence, and many other objects are naturally described with directed acyclic graphs and are best understood visually when all edges are drawn in the same direction. Planarity is of obvious benefit in graph drawing, so it is a natural problem to consider upward drawings in combination with planarity.

An *upward plane drawing* of a digraph is a plane drawing such that each directed arc is represented as a curve monotone increasing in the y-direction. In particular, the digraph must be acyclic (a DAG). A digraph is *upward planar* if it has an upward plane drawing. Consider the digraphs in Fig. 1. By convention, the edges in the diagrams in this paper are directed upward unless specifically stated otherwise, and direction

Upward planar

Non-upward-planar

FIG. 1. *Upward planar and non-upward-planar digraphs.*

arrows are omitted unless necessary. The digraph on the left is upward planar: an upward plane drawing is given. The digraph on the right is not upward planar—although it is planar, since placing v inside the face f would eliminate crossings, at the cost of producing a downward edge. Kelly [17], Kelly and Rival [18], and Di Battista and Tamassia [7] have shown that for every upward plane drawing, there exists a *straight-line* upward plane drawing with the same faces and outer face, in which every edge is represented as a straight line segment. This is an analogue of the previously mentioned straight-line drawing result for undirected planar graphs. The general problem of recognizing upward planar digraphs has recently been shown to be NP-complete [12]. For the case of single-source single-sink digraphs there is a polynomial-time recognition algorithm provided by Platt's result [19] that such a digraph is upward planar iff the digraph with a source-to-sink edge added is planar. An algorithm to find an upward plane drawing of such a digraph was given by Di Battista and Tamassia [7]. For the special case of bipartite digraphs, upward planarity is equivalent to planarity [6].

In this paper, we will give an efficient algorithm to test upward planarity for single-source digraphs, eliminating the single-sink restriction. For the most part, we will be concerned only with constructing an upward planar *representation*—enough combinatorial information to specify an upward plane drawing without giving actual numerical coordinates for the vertices. This notion will be made precise in §3. We will remark on the extension to a drawing algorithm in §7. Our main result is an $O(n^2)$ algorithm to test whether a given single-source, n-vertex digraph is upward planar, and if so, to give a representation for it which leads to a drawing with known methods. This result is partly based on a graph-theoretic result of Thomassen [24, Them. 5.1].

THEOREM 1.1 (Thomassen). *Let Γ be a plane drawing of a single-source digraph G. Then there exists an upward plane drawing Γ' strongly equivalent to (i.e., having the same faces and outer face as) Γ iff the source α of G is on the outer face of Γ, and for every cycle Σ in Γ, Σ has a vertex β which is not the tail of any directed edge inside or on Σ.*

The necessity of Thomassen's condition is clear: for a digraph G with upward plane drawing Γ', and for any cycle Σ of Γ', the vertex of Σ with highest y-coordinate cannot be the tail of an edge of Σ nor the tail of an edge whose head is inside Σ.

Since a 3-connected graph has a unique planar embedding (up to the choice of the outer face) by Whitney's theorem (cf. [2]), Thomassen concludes that his theorem provides a “good characterization” of 3-connected upward planar digraphs—i.e., puts the class of 3-connected upward planar digraphs in NP intersect co-NP. An efficient algorithm is not given, however (there are potentially an exponential number of possible cycles to check), nor does Thomassen address the issue of non-3-connected digraphs (which could have an exponential number of different planar embeddings).

The problem thus decomposes into two main issues. The first is to describe Thomassen's result algorithmically; we do this in §4 with a linear-time algorithm, which provides an alternative proof of his theorem. The second issue is to isolate the triconnected components of the input digraph and determine how to put the “pieces” back together after the embedding of each is complete. This more complex issue is treated in §6, after a discussion of decomposition properties in §5.

The algorithm for splitting the input into triconnected components and merging the embeddings of each operates in $O(n^2)$ time. Since a triconnected graph is uniquely embeddable in the plane up to the choice of the outer face, and the number of possible external faces of a planar graph is linear by Euler's formula, the overall time to test a given triconnected component is also $O(n^2)$, so the entire algorithm is quadratic.

2. Preliminaries.

In addition to the definitions below, we will use standard terminology and notation of Bondy and Murty [2].

All digraphs in this paper are acyclic unless otherwise stated, and n always denotes the number of vertices in the current digraph. We will use the term *cycle* and the various notions of connectivity with respect to the *underlying undirected graph*, so a digraph G is *connected* if there exists an undirected path between any two vertices in G. For S a set of vertices, $G\backslash S$ denotes G with the vertices in S and all edges incident to vertices in S removed. If S contains a single vertex v, we will use the notation $G\backslash v$ rather than $G\backslash\{v\}$. G is k-connected if it has at least $k+1$ vertices and the removal of at least k vertices is required to *disconnect* the graph. By Menger's theorem [2], G is k-connected iff there exist k vertex-disjoint undirected paths between any two vertices. A set of vertices whose removal disconnects the graph is a *cut-set*. The terms *cut vertex* and *separation pair* apply to cut-sets of size one and two, respectively. A graph which has no cut vertex is *biconnected* (2-connected). A graph with no separation pair is *triconnected* (3-connected). For G with cut vertex v, a *component* of G with respect to v is formed from a connected component H of $G\backslash v$ by adding to H the vertex v and all edges between v and H. For G with separation pair $\{u,v\}$, a *component* of G with respect to $\{u,v\}$ is formed from a connected component H of $G\backslash\{u,v\}$ by adding to H the vertices u and v and all edges between u and v and vertices of H. The edge (u,v), if it exists, forms a component by itself. An algorithm for finding triconnected components[1] in linear time is given in Hopcroft and Tarjan [13] (and also [3]). A related concept is that of *graph/digraph union*: we define $G_1 \cup G_2$ for components with “shared” vertices to be the *inclusive* union of all vertices and edges. That is, for v in both G_1 and G_2, the vertex v in $G_1 \cup G_2$ is adjacent to edges in each of the subgraphs G_1 and G_2.

Contracting an edge $e = (u,v)$ in a graph G results in a graph, denoted G/e, with the edge e removed and vertices u and v *identified*. Inserting new vertices within edges of G generates a *subdivision* of G. A *directed subdivision* of a digraph G results from repeatedly adding a new vertex w to divide an edge (u,v) into (u,w) and (w,v). (Directed) graphs G_1 and G_2 are *homeomorphic* if both are (directed) subdivisions of some other (directed) graph. G is planar iff every subdivision of G is planar [2].

[1] Note that Hopcroft and Tarjan's “components” include an extra (u,v) edge.

In a directed graph, the *in-degree* of a vertex v is the number of edges directed toward v, denoted deg^-v. Analogously, the *out-degree* (deg^+v) of v is the number of edges directed away from v. A vertex of in-degree 0 is a *source* in G, and a vertex of out-degree 0 is a *sink*.

Adopting some poset notation, we will write $u \leq v$ if there is a directed path $u \overset{*}{\rightarrow} v$ of length 0 or more, and $u < v$ ($u \overset{+}{\rightarrow} v$) to emphasize that u and v are distinct. Vertices u and v are *comparable* if $u \leq v$ or $v \leq u$, and *incomparable* otherwise. If (u, v) is an edge of a digraph, then u *dominates* v, u is *incident to* v, and v is *incident from* u.

3. A combinatorial view of upward planarity. As discussed by Edmonds and others (see [11]), a connected graph G is planar iff it has a *planar representation*: a cyclic ordering of edges around each vertex such that the resulting set of *faces* F satisfies $2 = |F| - |E| + |V|$ (Euler's formula). A *face* is a cyclically ordered sequence of edges and vertices $v_0, e_0, v_1, e_1, \ldots, v_{k-1}, e_{k-1}$, where $k \geq 3$, such that for any $i = 0, \ldots, k-1$, the edges e_{i-1} (subscript addition modulo k) and e_i are incident with the vertex v_i and consecutive in the cyclic edge ordering for v_i.

We will say that two plane drawings are *equivalent* if they have the same representation—i.e., the same set of faces. Two plane drawings are *strongly equivalent* if they have the same representation and the same outer face.

One method of combinatorially specifying an upward planar drawing is provided by the following result of (independently) Di Battista and Tamassia [7] and Kelly [17]. They use the concept of a planar *s-t digraph*, defined to be a planar DAG which has a single source s and a single sink t and contains the edge (s, t)—exactly the upward planarity condition of Platt [19] for single-source single-sink digraphs.

THEOREM 3.1 (Di Battista and Tamassia, Kelly). *Let G be a directed acyclic graph. If G is upward planar then edges can be added to it to obtain a planar s-t digraph (i.e., G is a (spanning) subgraph of a planar s-t digraph). Conversely, if edges can be added to G to obtain a planar s-t digraph G', then G is upward planar. Furthermore, for any planar embedding Γ of G' with (s, t) on the outer face, there is an upward plane drawing of G strongly equivalent to Γ with the extra edges removed.*

The final statement was not explicitly given. However, to prove their result, Di Battista and Tamassia give an algorithm which takes a planar *s-t* digraph, finds an *arbitrary* planar representation of it, and outputs an upward plane drawing which respects this embedding, so the statement follows. Their algorithm, which we will require later in the paper, runs in $O(n)$ arithmetic[2] steps ($O(n \log n)$ arithmetic steps for a straight-line drawing).

The disadvantage of this NP characterization in terms of planar *s-t* digraphs is the difficulty of testing it. Thomassen's co-NP condition on single-source digraphs suffers from the same problem. For the case of single-source digraphs, we will give a testable (algorithmic) characterization in the next section.

To provide some motivation for this algorithm, we give another characterization of single-source upward planar digraphs, equivalent to Thomassen's.

First, we define $P(v)$, the *predecessor set of* v, to be the set $\{u : u \leq v \text{ in } G\}$. Notice the set $P(v)$ includes v. Define G_v to be the induced subgraph of G on $P(v)$. For a planar representation Γ of G, define Γ_v to be the planar representation induced by Γ on G_v.

[2] It is important to specify the time in arithmetic steps, because the algorithm is necessarily output sensitive: coordinates can require $\Omega(n)$ bits each [8].

PROPOSITION 3.2. *Given a single source DAG G and a planar representation Γ of G with a specified outer face and source s on the outer face, G has an upward plane drawing strongly equivalent to Γ iff the following condition holds.*

CONDITION 3.3. *For each vertex $v \in V$, v is a sink on the outer face of the planar embedding Γ_v induced by $P(v)$.*

We will often refer to a planar representation Γ satisfying Condition 3.3 as an *upward planar representation* of G.

Since a strongly equivalent upward plane drawing provides the same planar representation Γ and predecessors of v have smaller y-coordinates in the drawing, v must be on the outer face of Γ'_v. Thus the necessity holds. We will complete the proof of this in §5; it is not necessary for the algorithm in the next section.

4. Strongly equivalent upward planarity. Consider the following question: given a single-source acyclic digraph G and a planar representation Γ for G, with s on the outer face of Γ, does G admit an upward planar drawing strongly equivalent to Γ?

Define a *violating cycle* of G with respect to Γ to be a cycle Σ such that every vertex of Σ is the tail of an edge inside or on Σ. This is the condition arising from Thomassen's theorem (1.1). As observed in the introduction, a violating cycle in Γ precludes the existence of an strongly equivalent upward drawing.

We present a linear-time algorithm to test whether G has an upward planar embedding strongly equivalent to Γ with a designated outer face. The algorithm will return the edges necessary to augment G so that sinks occur only on the outer face in the positive case or a violating cycle in the negative case. Since any planar representation of a single-source DAG with the source and all sinks on the outer face is a subgraph of a planar s-t digraph—simply designate one sink as t and add an edge from the source and all other sinks to it—the algorithm provides a new proof of Thomassen's theorem.

The algorithm is recursive, and the proof that it works is by induction. If there is a sink v on the outer face of Γ, then recursively (trivial if G has one node) determine a violating cycle for $G \backslash v$ (in which case we are done) or a set of edges X required to augment $\Gamma \backslash v$ ($G \backslash v$) to a planar representation Γ' with all sinks on the outer face. Now add v and edges incident to v to the outer face of Γ'. To determine the additional required edges to resolve the internal sinks in the new faces, consider all vertices w which are sinks on the outer face of Γ' but are not sinks on the outer face of Γ. Adding the edges (w, v) (where they do not already exist in G) to X retains planarity, single-sourcedness, and acyclicity in $G \cup X$ and does not change the outer face.

It remains to deal with the case when the outer face of Γ has no sink. We claim that in this case G has a violating cycle: If the outer face of Γ is a cycle, then it is a violating cycle. If the outer face is a walk, then follow it starting at s, and let v be the first vertex which repeats. Vertex v must be a cut vertex. Consider the segment of the walk from v to v. If this segment contains only one other vertex, say u, then u is a sink, which is a contradiction. Otherwise, we obtain a cycle C from v to v. The two edges incident with v must be directed away from v, and no other vertex is a sink on C, so C must be a violating cycle.

The above algorithm can be implemented in linear time (so that each vertex is involved in no more than a constant number of operations) using data structures no more complicated than a linked list. We then have Theorem 4.1.

THEOREM 4.1. *Given an n-vertex single-source acyclic digraph G and a plane representation Γ, the above algorithm tests, in linear time, whether G admits an*

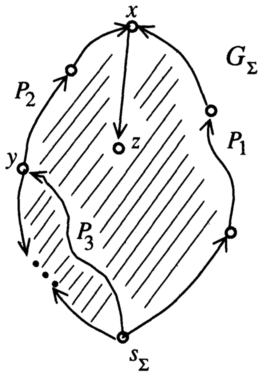

FIG. 2. *Violating cycle precludes Condition* 3.1.

upward planar drawing strongly equivalent to Γ.

5. Decomposition properties of upward planar graphs. This section completes the discussion of upward planar representations and introduces various decomposition properties of upward planar digraphs. The purpose is twofold: first, the properties are necessary for the proofs in the next section; second, they provide an intuitive look at the structure of upward planar digraphs and hence motivate the decomposition approach we take in the recognition algorithm.

We begin by completing the proof of Proposition 3.2 from §3.

Proof of Proposition 3.2: *Sufficiency.* We need that for any planar representation Γ of G satisfying Condition 3.3, G admits an upward plane drawing strongly equivalent to Γ—equivalently, that the existence of a violating cycle precludes Condition 3.3 from holding for some vertex v.

Suppose a violating cycle Σ exists in G with respect to Γ. Let G_Σ be the subgraph of G formed by edges and vertices inside or on Σ.

Without loss of generality, G_Σ has one source s_Σ, which must lie on Σ. If G_Σ had two sources s_1 and s_2, then both would be on Σ. Since G has a single source s, there exist directed paths P_1 from s to s_1 and P_2 from s to s_2. The last edge of each path is not in G_Σ. If either path has a vertex other than its terminal vertex on Σ, then adding to Σ the portion of the path from the last such vertex to the terminal produces another violating cycle enclosing a larger subgraph with one fewer sources. Otherwise, P_1 and P_2 contain a last common vertex, and adding the portions of the paths from that vertex to the terminals s_1 and s_2 produces another violating cycle enclosing a larger subgraph with one fewer sources. Thus we can assume that G_Σ has a single source s_Σ. The remainder of the proof references Fig. 2.

Starting from s_Σ, walk counterclockwise around Σ. Let x be the first encountered vertex with both edges of Σ directed toward x. Let y be the first encountered vertex after x with both edges of Σ directed away from y. Note that both exist, although y may be s_Σ. Let P_1 be the directed path from s_Σ to x, counterclockwise on Σ, and let P_2 be the directed path from y to x clockwise on Σ.

Since s_Σ is the single source of G_Σ, there is a directed path P_3 in G_Σ from s_Σ to y. (If $y = s_\Sigma$, then P_3 is this single vertex.) P_3 cannot contain a vertex of P_2 other than y; otherwise we would get a directed cycle using portions of P_2 and P_3. Let u be the last vertex of P_1 on P_3. Let Π be the simple undirected cycle consisting of the portion of P_3 from u to y, the portion of P_2 from y to x, and the portion of P_1 from

u to x. Let G_Π be the subgraph of G formed by edges and vertices inside or on Π.

Since Σ is a violating cycle, x is not a sink in G_Σ, so there is an edge (x, z) inside Σ and thus inside Π. We will show that vertex z violates condition 3.1. Vertex z cannot be on Π; otherwise, a directed cycle is formed. Thus z is strictly inside Π. But all the vertices of Π are predecessors of z. Thus z violates condition 3.1. □

Note that the results of the preceding two sections, combined with the characterization of Di Battista and Tamassia and the single-source characterization of Thomassen, give the following theorem.

THEOREM 5.1. *The following conditions are equivalent for a single-source DAG G with planar representation Γ having a designated outer face and single source s which is on the outer face:*

(i) *G has an upward plane drawing strongly equivalent to Γ.*

(ii) *G is a (spanning) subgraph of some planar s-t digraph which has an upward plane drawing strongly equivalent to Γ (after removal of the extra edges).*

(iii) *For all $v \in G$, v is a sink on the outer face of Γ_v.*

(iv) *Γ does not contain a violating cycle.*

We note that condition (iii) is the only one which can obviously be tested in polynomial time.

In the remainder of this section, we give some operations which preserve upward planarity. The first operation contracts an edge connected to a vertex of in- (out-) degree 1. The second attaches one upward planar digraph to another at a single vertex. The third attaches an upward planar digraph in place of an edge of another upward planar digraph. The last splits a vertex into two vertices.

First, we will prove a useful preliminary result.

PROPOSITION 5.2. *Let G be a connected upward planar digraph. Then G is a subgraph of some single-source upward planar G^* such that all nonsource $v \in V(G)$ have the same in-degree in G as in G^*.*

Proof. We illustrate how to add the edges required to "resolve the extra sources" without affecting the in-degree of nonsource vertices.

Let Γ be a drawing of G in the plane bounded by $x_{\min}$, $x_{\max}$, $y_{\min}$ and $y_{\max}$, with height h and width w and centred at $(0,0)$. Without loss of generality, we assume Γ is a straight-line drawing. Add new vertices s, t, l, and r at $(0,-2h), (0,2h), (-2w,0)$, and $(2w,0)$, respectively. Add lines (edges) $(s,l), (s,r), (r,t)$, and (l,t). Add further edges (s,w) for all vertices w drawn with y-coordinate of $y_{\min}$ and (w,t) for all vertices w drawn with y-coordinate of $y_{\max}$.

The construction so far has merely added a specified outer face on the drawing, with a unique maximum sink and minimum source, so clearly the resulting drawing Γ^{**} (digraph G^{**}) is an upward plane drawing (upward planar digraph). We now wish, for each source x, to "resolve" the source by adding a new edge incident to it; the resulting digraph will prove our proposition. Let Γ be an upward plane drawing of G, and perform the following operation for each source x, except the one just added in the outer face. Extend a line L vertically down from x to the first line or vertex in the drawing. If L first intersects a vertex w, add the (w,x) edge to both G and the drawing Γ—the result is clearly upward planar. If L first intersects an edge, rotate it along the edge until L hits some vertex w of Γ and add the edge (w,x) as before; for one of the two directions, a vertex will be found before the line becomes horizontal. Neither operation added in-degree to a nonsource vertex, so the claim is satisfied. □

Note that the above is of no particular *algorithmic* significance, since the drawing

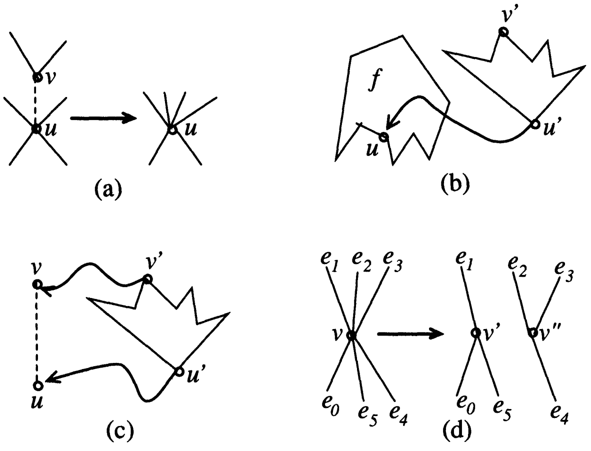

FIG. 3. *Properties of upward planar representation.*

of G (or existence thereof) is the goal rather than the input. However, it allows us to prove the following lemmas in the more general context of upward planar digraphs, i.e., without the single-source assumption.

LEMMA 5.3. *Let G be a DAG and v, dominated by u, be a vertex of G with in-degree* 1. *Then $G/(u,v)$ is upward planar if G is upward planar.* (*See Fig.* 3(a).)

Note that the same result holds for G and edge (u,v) with $deg^+u = 1$ by symmetry. Lemma 5.3 is a generalization of a previously known fact—that G is upward planar iff any directed subdivision of G is (cf. [24]).

Proof. Let Γ be an upward plane drawing of G. Applying Proposition 5.2, there is a single-source digraph G^* containing G as a subgraph in which the in-degree of v is still 1. Clearly if the result holds for $G^*/(u,v)$, it holds for any subgraph, namely $G/(u,v)$, so it will be sufficient to assume G is a single-source digraph for the remainder of the proof and show Condition 3.3 holds.

Let Γ be a planar representation for G, with a designated outer face, satisfying Condition 3.3. Let Γ_w for $w \in V$ be as defined for Condition 3.3. Then Γ', formed by contracting (u,v) in Γ, is a planar representation for $G' = G/(u,v)$ with a designated outer face. Clearly if some $w \neq v$ is on the outer face of Γ_w, it is on the other face of $\Gamma_w/(u,v)$. This, with the fact that G is acyclic, implying $G_w/(u,v) = G'_w$ for all $w \in V - \{v\}$ (i.e., P(w) doesn't change as a result of contracting (u,v)), gives that w is a sink on the outer face of Γ'_w—Condition 3.3. □

Topologically, this construction can be viewed as "pulling" v and all edges incident from v down a corridor of width ϵ around (u,v) until u and v meet.

LEMMA 5.4. *Let G be an upward planar digraph with a vertex u, and let H be an upward planar digraph with a single source u'. Let G' be the digraph formed by identifying u and u' in $G \cup H$. Then G' is upward planar.* (*See Fig.* 3(b).)

Proof. As above, there is an upward planar single-source digraph G^* containing G by Proposition 5.2, and G' is a subgraph of $G^* \cup H$ with u and u' identified, so it is sufficient to prove the result for a single-source upward planar G.

Suppose Γ^G and Γ^H are the given planar representations, with designated outer faces, both satisfying Condition 3.3. Let Γ^G_v and Γ^H_v be as defined for Condition 3.3 for G and H, respectively. We show how to construct a planar representation Γ' for $G \cup H$ (identifying u and u'), with a given outer face, which satisfies Condition 3.3.

If u is on the outer face of Γ^G, then place Γ^H in the outer face, identifying u and u'. Otherwise, there are (possibly) $k+1$ faces of Γ^G corresponding to the outer face of Γ^G_u (for k the out-degree of u); insert Γ^H in any one of these faces. It is easy to show that, under this construction, w is a sink on the outer face of Γ'_w if it was a sink on the outer face of Γ^G_w (respectively, Γ^H_w) previously. □

This construction can be viewed as "inserting" the drawing for H into some face "above" u in the drawing of G.

LEMMA 5.5. *Let G be an upward planar digraph with an edge (u,v), and let H be an upward planar digraph with a single source u' and a sink v' both on the outer face. Let G' be the digraph formed by removing the (u,v) edge of G and adding H, identifying vertex u with u' and vertex v with v'. Then G' is upward planar.*

Proof. This has the same flavour as the previous proof, so we can be more brief. Again, by Proposition 5.2 it is sufficient to assume that G has a single source. Let Γ^G and Γ^H be planar representations, with designated outer faces, satisfying Condition 3.3.

Form a planar representation Γ' of G' by replacing (u,v) by Γ^H in Γ^G. The result is planar and has a well-defined outer face. We need that Γ' satisfies Condition 3.3. As in the previous proof, it is easy to show that w is a sink on the outer face of Γ'_w whenever it is a sink on the outer face of Γ^G_w (respectively, Γ^H_w). □

This construction can be viewed as replacing a directed edge in an upward plane drawing of G with another upward plane drawing of H which is, in some sense, "topologically equivalent" to an edge within the drawing of G.

LEMMA 5.6. *Let G be a DAG which has an upward planar representation where the cyclic edge order about vertex v is $e_0,\ldots,e_{k-1}$ (vertices $v_0,\ldots v_{k-1}$). Let G' be the DAG formed by splitting v into two vertices: v' incident with edges $e_i,\ldots,e_j$, and v'' incident with edges $e_{j+1},\ldots,e_{i-1}$ ($i \neq j$, arithmetic* mod *k). Then G' is upward planar. If G has a single source, and i and j are such that each of v' and v'' retains at least one incoming edge, then the resulting G' is also a single-source digraph.* (*See Fig.* 3(d).)

Proof. The last statement is clearly true; no new sources can be added by the construction if each new vertex has an incoming edge. Again, it is sufficient to show the first part for single-source G, since the resulting digraph is otherwise a subgraph of the construction applied to G^* (of Proposition 5.2). Let Γ be a planar representation for G satisfying Condition 3.3.

Without loss of generality, assume that the construction does not make v' a source unless v was itself a source. We prove the result for $G'' = G' + (v', v'')$—it is easy to augment Γ' (the planar representation formed by separating v into v' and v'' in Γ) to Γ'' with the edge (v', v'') because v' and v'' share a face. The construction of Γ'' from Γ preserves planarity and cannot introduce a dicycle; it remains to show Condition 3.3 holds for G'' and Γ''. The set of faces in Γ'' is identical to that of Γ, save for the two new faces sharing (v', v''), so Condition 3.3 is satisfied for all w not incident from either v' or v''. Any v_i incident from v' or v'' (via edge e_i) is clearly on the outer face of Γ''_{v_i} whenever it is on the outer face of Γ_{v_i}, since the construction can only add vertices to an outer face, never remove them. □

6. Separation into triconnected components. The algorithm of §4 tests for upward planarity of a single-source DAG G starting from a given planar representation and an outer face of G. In principle, we could apply this test to all planar representations of G, but this would take exponential time. In order to avoid this, we will decompose the digraph into biconnected and then into triconnected components.

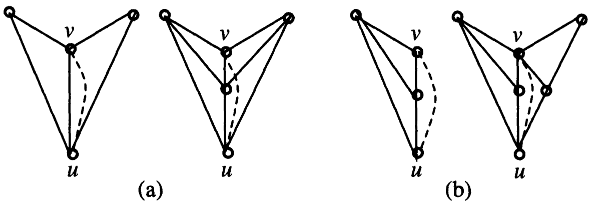

FIG. 4. *Added complication of two-vertex cut-sets.*

Each triconnected component has a unique planar representation (see [2]) and only a linear number of possible outer faces. We can thus test upward planarity of the triconnected components in quadratic time using the algorithm of §4. Since we will perform the splitting and merging of triconnected components in quadratic time, the total time will then be quadratic.

To decompose G into biconnected components we use the following lemma.

LEMMA 6.1. *A DAG G with a single source s and a cut vertex v is upward planar iff each of the k components H_i of G (with respect to v) is upward planar.*

Proof. If G is upward planar, then so are its subgraphs, the H_i's. For the converse, note that if $v \neq s$, then v is the unique source in all but one of the H_i's; and if $v = s$, then v is the unique source in each H_i. Apply Lemma 5.4. □

Dividing G into triconnected components is more complicated, because the cut-set vertices impose restrictive structure on the merged digraph. In the biconnected case, it is sufficient to simply test each component separately, since biconnected components do not interact in the combined drawing. The analogous approach for triconnected components would be to add a new edge between the vertices of the cut-set in each component, then perform the test recursively. This, however, does not suffice for upward planarity, as illustrated by the two examples in Fig. 4. (Recall our convention that direction arrowheads are assumed to be "upward" unless otherwise specified.) In (a), the union of the digraphs is upward planar, but adding the edge (u, v) to each makes the second component non-upward-planar. In (b), the digraph is non-upward-planar, but each of the components is upward planar with (u, v) added.

We will find it convenient to split the digraph G into exactly two pieces at a separation pair $\{u, v\}$, where one of these pieces, E, is a component with respect to the separation pair, and the other piece, F, is the union of the remaining components. This forces each piece to fit into one face of the embedding of the other piece.

LEMMA 6.2. *For G, E, and F as above, let Γ be a plane embedding of G, and let Γ_E and Γ_F be the embeddings induced on E and F, respectively. Then in Γ, all of E lies in a single face of Γ_F and all of F lies in a single face of Γ_E. Furthermore, at least one of E, F must lie in the outer face of Γ_F, Γ_E, respectively.*

Proof. Any distinct vertices x and y in E, neither being u or v, must share a path in E which avoids both u and v (lies entirely within E). Hence, for Γ, a plane embedding of G, and Γ_E and Γ_F, the respective subembeddings of E and F, if vertices x and y of E are in different faces of Γ_F, they could not share a path which avoids both u and v without violating planarity. Clearly, also, one of E, F must have two vertices on the outer face of the total drawing Γ (which has at least three vertices) and hence must lie entirely in the outer face of the other subdrawing. □

We will test the upward planarity of a biconnected digraph G by breaking it at a cut-set into pieces E and F, as above, and looking for upward planar embeddings Γ_E and Γ_F that fit together as in Lemma 6.2.

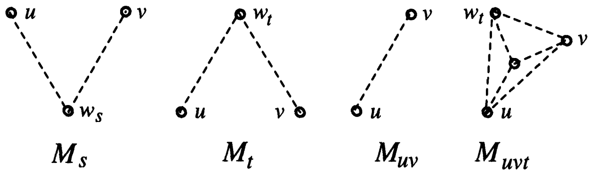

FIG. 5. *Marker graphs.*

We need a face in Γ_E that contains u and v and is the right "shape" to accommodate the "shape" of Γ_F; and we need a face in Γ_F that contains u and v and is the right "shape" to accommodate the "shape" of Γ_E. (Figure 4(b) showed an example where these conditions fail.) These conditions will be enforced by adding a "marker" connecting u and v to E (F, respectively) that captures the "shape" of Γ_F (Γ_E, respectively) and forces u and v to lie in a common face. For example, the simplest case is when u is the source and v is the sink of F; then the marker representing Γ_F in E is a single (u, v) edge.

Besides playing the primary role described above, the markers will also be used to make the two components 3-connected and single source, thus allowing us to recurse on smaller subproblems. The markers we are interested in are shown in Fig. 5.

We need one other main idea. The last statement of Lemma 6.2 is that one of E, F, must lie in the outer face of Γ_F, Γ_E, respectively. For undirected digraphs, this causes no problem, since any face can be made the outer one. However, for upward planarity, this condition complicates things. The situation is simplified when $s \neq u, v$. In this case, we will take E to be the $\{u, v\}$ component containing s, and so Γ_E must lie in the outer face of Γ_F. When $s \in \{u, v\}$, we must do extra work to decide the "outer" component.

Having determined or decided that Γ_E must lie in the outer face of Γ_F, we know that u and v must be on the outer face of Γ_F. Thus our algorithm will solve the more general problem of testing upward planarity under the condition that some specified set X of vertices, called the "outer" set, must lie on the outer face.

To summarize, given a biconnected digraph G and an "outer" set of vertices X, we break G at a cut-set $\{u, v\}$ into one component E, containing s, and the union of the remaining components F. We add appropriate markers to E and F, specify their "outer" sets, and recurse. We must prove that G has an upward planar embedding with its "outer" set on the outer face iff the smaller digraphs do.

The details and proofs of this plan make up the remainder of this section. We will consider three cases separately: when u and v are incomparable, when u and v are comparable with $s < u < v$, and when u and v are comparable with $u = s$.

An important note to make at this time is that the markers, except for M_{uv}, are subgraphs attached at only two vertices, which means that $\{u, v\}$ will still constitute a cut-set. For the purposes of determining cut-sets and making recursive calls, the markers should be treated as distinguished edges—a single edge labelled to indicate its role. As long as the type of marker is identified, the algorithm can continue to treat the vertices of attachment as source, sink, or neither, as appropriate for the particular operation.

6.1. Cut-set u, v; u and v are incomparable. Here we consider vertex cut-sets $\{u, v\}$ which are incomparable (then neither is s). We divide the digraph G at $\{u, v\}$ into two subgraphs—the *source component* E (the one component which contains the source s) and the union of the remaining components F.

First, we need some preliminary results.

PROPOSITION 6.3. *If G is a connected DAG with exactly two sources u and v, then there exists some w_t such that two vertex-disjoint (except at w_t) directed paths $u \overset{+}{\rightarrow} w_t$ and $v \overset{+}{\rightarrow} w_t$ exist in G.*

Proof. Let G be such a DAG and let P be an undirected path from u to v. Note that every x in P is comparable with either u or v, otherwise G has more than two sources. Follow P from u to the first node x (following y on P) incomparable with u (in G). Then x is comparable with v and (x, y) is an edge in G (otherwise $u < x$), so y is also comparable with v. Taking the first common vertex in the paths $u \overset{+}{\rightarrow} y$ and $v \overset{+}{\rightarrow} y$ gives w_t. □

The following result shows the existence of lower bounds and upper bounds (in the partial order corresponding to G) under certain conditions. This allows us to prove the necessity conditions in Theorem 6.5 (to come).

LEMMA 6.4. *If G is a biconnected DAG with a single source s, and if u and v are incomparable vertices in G, then there exists some w_s such that two vertex-disjoint (except at w_s) directed paths $w_s \overset{+}{\rightarrow} u$ and $w_s \overset{+}{\rightarrow} v$ exist in G. If $\{u, v\}$ is a cut-set in G, then there also exists some w_t such that two vertex-disjoint (except at w_t) directed paths $u \overset{+}{\rightarrow} w_t$ and $v \overset{+}{\rightarrow} w_t$ exist in G.*

Proof. Since G is a single-source digraph, there exist directed paths from s to u and s to v in G. Taking the last common vertex in these paths gives w_s.

For the existence of w_t, let u and v be an incomparable separation pair of G. Since $\{u, v\}$ cuts G into at least two connected components, any nonsource component H has u and v as its (exactly) two sources, and the result follows from Proposition 6.3. □

We are now ready to proceed with the statement of the first main result of the decomposition.

THEOREM 6.5. *Let G be a biconnected directed acyclic digraph with a single source s, and let $X = \{x_i\} \subseteq V(G)$ be a set of vertices. Let $\{u, v\}$ be a separation pair of G, with u and v incomparable. Let E be the connected component of G with respect to $\{u, v\}$ containing s, and let F be the union of all other components. Then G admits an upward plane drawing with all vertices of X on the outer face iff*

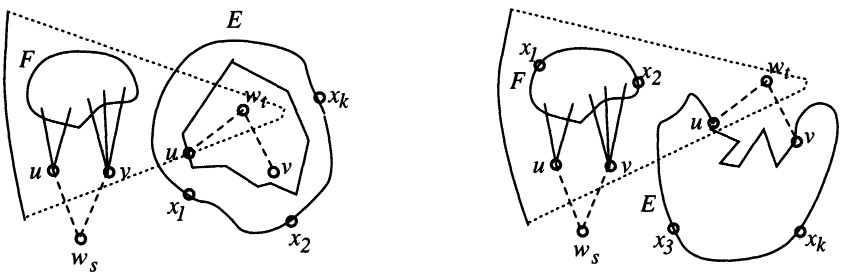
(i) *$E' = E \cup M_t$ admits an upward plane drawing with all vertices of X in E on the outer face and with w_t on the outer face if some $x \in X$ is contained in F, and*

(ii) *$F' = F \cup M_s$ admits an upward plane drawing with all vertices of X in F on the outer face.*

Here, as in the remaining cases, the proof will have the same basic flavour. The necessity of the marker conditions will follow from the existence of the corresponding marker "within" (i.e., homeomorphic to a subgraph of) the companion component. The sufficiency will be shown by applying the properties of an upward planar representation from §4 to combine upward planar representations for the two subproblems into a single upward planar representation.

Proof. Necessity. Suppose G admits an upward planar drawing (representation) Γ with all $x_i \in X$ on the outer face. Follow Fig. 6.

Since u and v are incomparable, there exists a w_s and vertex-disjoint directed paths $w_s \overset{+}{\rightarrow} u$ and $w_s \overset{+}{\rightarrow} v$ in G by Lemma 6.4; specifically, these must be in E if G has a single source. Then $F' = F \cup \{(w_s, u), (w_s, v)\}$ is homeomorphic to a subgraph



(a) No x_i's in F

(b) x_i's in F

FIG. 6. *Merging E and F; cut-set $\{u, v\}$ is incomparable.*

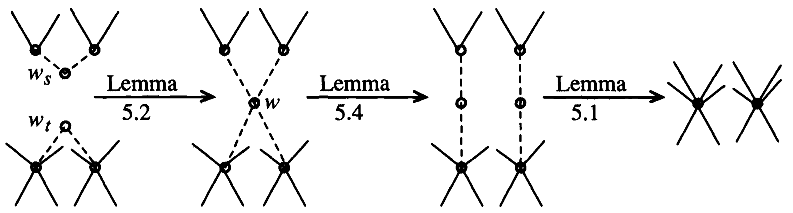


FIG. 7. *Merge construction; $\{u, v\}$ is incomparable.*

of G and hence upward planar itself. F' can be obtained from G by deleting and contracting E to its marker—this will not decrease the set of vertices on the outer face. Thus, since Γ has all the x_i's of F on its outer face, F' has an upward planar drawing with all vertices of X in F on the outer face. We have (ii).

Similarly, there exists some w_t in F such that $E \cup \{(u, w_t), (v, w_t)\}$ is homeomorphic to a subgraph of G, so E' is upward planar. As above, any x_i in E and also on the outer face of Γ will be on the outer face of the subdrawing formed by Γ_E and the $u \overset{+}{\rightarrow} w_t, v \overset{+}{\rightarrow} w_t$ paths. By Lemma 6.2, Γ_F must lie entirely within one face of Γ_E, so if some x_i in F is on the outer face of the drawing Γ, then the portion of the drawing formed by the $u \overset{+}{\rightarrow} w_t$ and $v \overset{+}{\rightarrow} w_t$ paths (hence w_t itself) must be in the outer face of the subdrawing Γ_E, giving (i).

Sufficiency. Suppose E' and F' admit upward planar representations satisfying (i) and (ii). Identifying the single source w_s of F' and w_t in E' (call the new vertex w) per Lemma 5.4, the result G' is upward planar. Splitting w into w_l with the leftmost two vertices and w_r with the rightmost two vertices (Lemma 5.6) and contracting the (w_l, u) and (w_l, v) edges (Lemma 5.3) gives exactly G, which is hence upward planar. The construction is illustrated in Fig. 7.

For the sufficiency of the x_i conditions, we notice that all nonmarker vertices of X on the outer face of the E' drawing are also on the outer face of the constructed drawing. If F contains no x_i, this is sufficient; otherwise, w_t being on the outer face of E' guarantees that the nonmarker vertices of X in F' are also on the outer face of the result. □

6.2. Cut-set u, v, where $u < v$, $u \neq s$. Here we consider any other vertex cut-sets not involving the source s. We again divide G into the *source component* E and the union of the remaining components F. Note that v can be a source in E as long as there is a u to v path in F.

An additional preliminary result will be useful.

LEMMA 6.6. *If G is a biconnected DAG with a single source s and cut-set $\{u,v\}$, where $u < v$ in G and $u \neq s$, then in any nonsource component H of G with respect to $\{u,v\}$, where $deg^+v > 0$, there exists some w_t such that $u \xrightarrow{+} w_t$ and $v \xrightarrow{+} w_t$ are vertex-disjoint directed paths in H.*

Proof. No vertex other than u and v can be a source in H, otherwise G has more than one source; and u is always a source in H. If v is also a source, then we are done by Proposition 6.3.

If v is not a source, let $w \in H$ be a vertex dominated by v. G is biconnected, so there are two vertex-disjoint $u \xrightarrow{+} w$ undirected paths in G. But u and v are cut vertices in G, so at least one of the paths P lies completely within H and does not contain v (since w is in H and the only exit points from H are u and v). Every x on P is comparable with either u or v, or else G has more than one source. Find the last vertex y on P which has a $u \xrightarrow{+} y$ path (in G) without v. If $y = w$, then we are done. Otherwise, the vertex x following y on P has any $u \xrightarrow{+} x$ path necessarily going through v. Then there exist directed paths $v \xrightarrow{+} x$ and $u \xrightarrow{+} x$ with the latter not containing v, so the first common vertex on these paths provides a w_t. □

We can now continue with the second main result of the decomposition.

THEOREM 6.7. *Let G be a biconnected directed acyclic digraph with a single source s, and let $X = \{x_i\} \subseteq V(G)$ be a set of vertices. Let $\{u,v\}$ be a separation pair of G with $u < v$ in G and $u \neq s$. Let E be the source component of G with respect to $\{u,v\}$ and F be the union of all other components. Then G admits an upward plane drawing with all vertices of X on the outer face iff*

(i) *$E' = (E \cup F$-marker) admits an upward plane drawing with all vertices of X in E on the outer face and w_t (if it exists; otherwise the edge (u,v)) on the outer face if some $x \in X$ is contained in F, and*

(ii) *$F' = (F \cup E$-marker) admits an upward plane drawing with w_t (if it exists; otherwise the edge (u,v)) and all vertices of X in F on the outer face,*

where

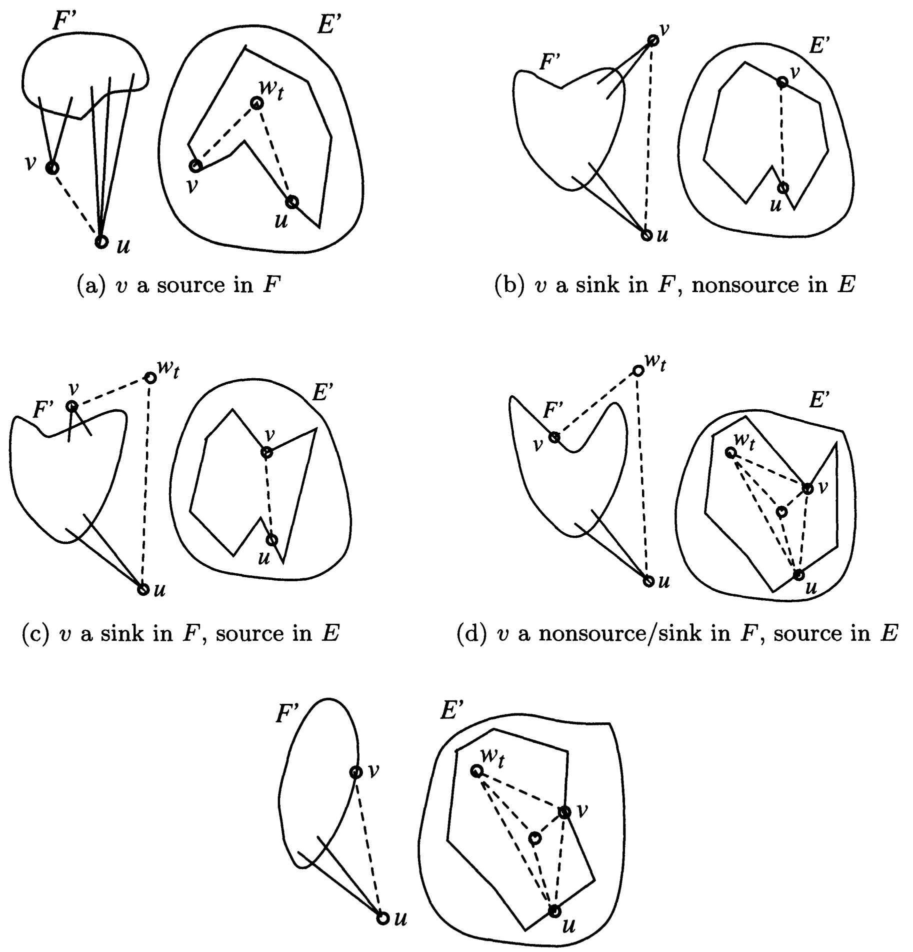
$$F\text{-}marker = \begin{cases} M_t & \text{if } v \text{ is a source in } F, \\ M_{uv} & \text{if } v \text{ is a sink in } F, \\ M_{uvt} & \text{otherwise,} \end{cases}$$

and

$$E\text{-}marker = \begin{cases} M_t & \text{if } v \text{ is a source in } E, \\ M_{uv} & \text{otherwise.} \end{cases}$$

Proof. Necessity. Suppose G admits an upward plane drawing with all $x_i \in X$ on the outer face. Follow Fig. 8.

Necessity of condition (i). If v is a source in F, then there exists some w_t in F and vertex-disjoint paths $u \xrightarrow{+} w_t$ and $v \xrightarrow{+} w_t$ by Proposition 6.3; so $E' = E \cup M_t$ is homeomorphic to a subgraph of G and is upward planar. If v is a sink in F, then u is the single source of F, since only u and v are possible sources. Thus, in F, there is a path $u \xrightarrow{+} v$, so $E' = E \cup M_{uv}$ is homeomorphic to a subgraph of G and is upward planar. If v is neither a source nor a sink in F, then, by Lemma 6.6, there is also some $w_t > v$ and disjoint directed paths $u \xrightarrow{+} w_t$ and $v \xrightarrow{+} w_t$ in G. Since v is a nonsource in F, there is also a $u \xrightarrow{+} v$ path in F. This path crosses the $u \xrightarrow{+} w_t$ path at some latest



(a) v a source in F

(b) v a sink in F, nonsource in E

(c) v a sink in F, source in E

(d) v a nonsource/sink in F, source in E

(e) v a nonsource/sink in F, nonsource in E

FIG. 8. *Merging E and F; cut-set $\{u, v\}$ and $u < v$.*

vertex z on that path, so $E \cup (u \xrightarrow{*} z) \cup (z \xrightarrow{+} v) \cup (z \xrightarrow{+} w_t) \cup (v \xrightarrow{+} w_t)$ is a subgraph of G and hence upward planar. Note that these four paths are disjoint. Since z has in-degree 1, we can contract the $u \xrightarrow{*} z$ path to u without destroying upward planarity, by Lemma 5.3, so $E \cup \{(u, v), (u, w_t), (v, w_t)\}$ has an upward planar subdivision and is upward planar itself. By Lemma 6.2, F lies in a single face of Γ_E, so no other vertices lie inside the u, v, w_t triangle, and the extra edges and vertex for M_{uvt} can be added without destroying planarity.[3] If some x_i is in F, then by the same argument as Theorem 6.5, all of F must be in the outer face of Γ_E. The marker, hence w_t or the (u, v) edge as appropriate, is therefore in the outer face of the drawing induced by E on Γ.

Necessity of condition (ii). If v is a source in E, then by Proposition 6.3, there are vertex-disjoint paths $s \xrightarrow{+} w_t$ and $v \xrightarrow{+} w_t$ in E. There must be an $s \xrightarrow{+} u$ path in E, otherwise there is either a second source (u is a source in F, so it cannot

[3] The point of adding these edges is to fix the face in E for the sufficiency conditions.

also be a source in E) or a cycle in G ($u < v$ in G, so there can be no $v \overset{+}{\rightarrow} u$ directed path in E). Let z be the last vertex common to paths $s \overset{+}{\rightarrow} u$ and $s \overset{+}{\rightarrow} w_t$. Then $F \cup \{(z, u), (z, w_t), (v, w_t)\}$ is homeomorphic to a subgraph of G and is upward planar. Since $deg^- u = 1$ (in this digraph), the edge (z, u) can be contracted without destroying upward planarity, by Lemma 5.3, and $F' = F \cup M_t$ is upward planar.

Otherwise (v a nonsource), if $u < v$ in E, then $F' = F \cup M_{uv}$ is homeomorphic to a subgraph of G and hence is upward planar. If u and v are incomparable in E, then they share a greatest lower bound w_s, by Lemma 6.4, and $F \cup \{(w_s, u), (w_s, v)\}$ is upward planar. Again, $deg^- u = 1$ in F, so the (w_s, u) edge can be contracted to give $F' = F \cup M_{uv}$.

The requirement for the E-marker to be on the outer face of Γ induced by F follows as before. Γ_E lies entirely within one face of Γ_F, and this is necessarily the outer face since E contains the source s.

Sufficiency. Suppose E' and F' admit upward plane drawings meeting the requirements (i) and (ii).

Case 1: *v is a source in F.* (See Fig. 8(a).) If v is a source in F, it cannot at the same time be a source in E, since $u < v$ in either E or F. Thus $F' = F \cup (u, v)$ is upward planar with single source u. Using Lemma 5.4, add F' (with u and v renamed as u' and v') to E', identifying u' with w_t. We can do this so that edges (v, w_t) and (w_t, v') are consecutive in the cyclic order about w_t. Using Lemma 5.6, split w_t by making these two edges incident with a new vertex u_1 and the remaining edges incident with a new vertex u_2. Now v' and u_1 have in-degree 1, so use Lemma 5.3 to contract their in-edges, thus identifying v and v'. Vertex u_2 has in-degree 1, so contract (u, u_2). The result is the digraph G, and thus G is upward planar.

Case 2: *v is a sink in F.* (The two possibilities are illustrated in Fig. 8(b) and (c).) If v is a nonsource in E, then $F' = F \cup (u, v)$ is upward planar with u and v on the outer face by assumption. If v is a source in E, then $F' = F \cup M_t$ is upward planar with w_t on the outer face. In either case, F is upward planar with single source u and sink v on the outer face. By Lemma 5.5, we can add F to E' in place of the (u, v) edge in E', and the result, G, is upward planar.

Case 3: *v is a nonsource/sink in F.* (See Fig. 8(d).) Suppose v is a source in E. Then $F' = F \cup M_t$ is upward planar with the sink w_t on the outer face. Using Lemma 5.5, add F' (renaming u and v to u' and v' respectively) to E' in place of the edge (u, v), identifying u' with u and w_t with v. Throw away the edge (u, w_t) and the remaining marker edges of E'. Vertex v now has in-degree 1, so the edge (v', v) can be contracted by Lemma 5.3, and the result, G, is upward planar. Note that the M_{uvt} marker attached to E' is stronger than we actually require here (M_{uv} would do), but it necessarily does exist (as previously proven) and is needed for the next part of this case.

Suppose then that v is a nonsource in E. Consider the upward planar representation of E' and throw away the marker edges, save for $(u, w_t), (v, w_t)$, and (u, v), which then form a face. $F' = F \cup (u, v)$ is upward planar with u and v on the outer face. Let z be some sink on the outer face, and add the edge (v, z) to obtain F'', upward planar with u, v, and z on the outer face. Using Lemma 5.5, add F'' (with u and v renamed to u' and v') to E' in place of the edge (u, w_t), identifying u' with u and z with w_t. Do this so that v' and v share the face of edges $(u, v'), (v', z), (u, v)$, and (v, z). Clearly, we can now identify the vertices v and v'. We obtain an upward planar digraph containing G as a subgraph. See Fig. 8(e).

As in the proof of Theorem 6.5, we notice that all vertices on the outer face of E' are necessarily on the outer face of the combined drawing, and if some x_i exists in F, then it is on the outer face of F' and is forced to the outer face of the combined drawing by the second part of condition (i). □

6.3. Cut-set *s*, *v*. As mentioned in the introduction to §6 (see also Lemma 6.2), it is important to be able to distinguish the "inner" and "outer" components. The inner component will be embedded in a face of the outer one, and thus the inner component will have to have the marker on its outer face since this marker is a proxy for the outer component. If we have to check each component as a potential inner component, we must recursively solve two subproblems for each component, and an exponential-time blowup results.

Until now, the outer component has been uniquely identified as the *source component*, since that component cannot lie within an internal face of any other component. If we have a cut-set of the form $\{s, v\}$, where s is the source, then we lose this restriction, so we handle it instead by requiring one of the components, E, to be 3-connected, so that deciding if it can be the inner face does not require recursive calls. To decide if E can be the inner face, we need to test if it satisfies the role of E in the previous theorem—i.e., has an upward planar representation with the marker on its outer face. This can be done in linear time using the algorithm of §4. If G has only cut-sets of the form $\{s, v\}$, then for at least one such cut-set, one of the components will be triconnected. Given the list of cut-sets, we can find such a cut-set and such a component in linear time using a depth-first search.

We capture these ideas in terms of two theorems. One is applicable if the triconnected component, E, can be the inner component, and one if it cannot. E "can be" the inner component iff it satisfies the same conditions that the inner component F satisfied in the previous Theorem 6.7. The similarity of both of these theorems to Theorem 6.7 should be clear. Note that in the statement of these theorems, we continue to use u (redundant since $u = s$) for consistency with previous usage.

THEOREM 6.8. *Let G be a biconnected DAG with a single source s, and let $X = \{x_i\} \subseteq V(G)$ be a set of vertices. Let $\{u, v\}$ be a separation pair of G where $u = s$, E be a 3-connected component of G with respect to $\{u, v\}$, and F be the union of all other components of G with respect to $\{u, v\}$. If*

$E' = (E \cup F$-marker$)$ admits an upward plane drawing with w_t (if it exists; otherwise the edge (u, v)) and all vertices of X in E on the outer face,

then G admits an upward plane drawing with all vertices of X on the outer face iff

(i) *$F' = (F \cup E$-marker$)$ admits an upward plane drawing with all vertices of X in F on the outer face, and w_t (if it exists; otherwise the edge (u, v)) also on the outer face if some $x \in X$ contained in E,*

where

$$E\text{-marker} = \begin{cases} M_t & \text{if } v \text{ is a source in } E, \\ M_{uv} & \text{if } v \text{ is a sink in } E, \\ M_{uvt} & \text{otherwise,} \end{cases}$$

and

$$F\text{-marker} = \begin{cases} M_t & \text{if } v \text{ is a source in } F, \\ M_{uv} & \text{otherwise.} \end{cases}$$

Proof. The proof is similar to the necessity of Theorem 6.7 with some (simplifying) modifications. We will be more brief except where differences exist.

Necessity. Suppose G has an upward planar representation Γ with all x_i's on the outer face, and that some upward planar representation $\Gamma_{E'}$ satisfies the precondition for E'. We need to show that the condition (i) holds.

If v is a source in E, then there exist vertex disjoint paths $u \overset{+}{\to} w_t$ and $v \overset{+}{\to} w_t$ in E by Proposition 6.3, so $F' = F \cup M_t$ is homeomorphic to a subgraph of G and hence upward planar. If v is a sink in E, then u is the only source, so $u \overset{+}{\to} v$ exists in E and $F' = F \cup M_{uv}$ is upward planar. Otherwise, v is neither and there exist vertex-disjoint $u \overset{+}{\to} v$, $v \overset{+}{\to} w_t$, and $u \overset{+}{\to} w_t$ paths in E by Lemma 6.6 and the fact that $u = s$ is the single source in E, so $F' = F \cup \{(u,v),(u,w_t),(v,w_t)\}$ is upward planar. Since these three edges are a face in the representation of this digraph, the required extra edges and vertices can be added and the result is upward planar. The necessity of the x_i conditions follows as before, since if some vertex of E is required on the outer face, then all of E is.

Sufficiency. The sufficiency proof is exactly that of Theorem 6.7. This is because the various constructions are not dependent on u differing from s. □

THEOREM 6.9. *Let G be a biconnected DAG with a single source s and let $X = \{x_i\} \subseteq V(G)$ be a set of vertices. Let $\{u,v\}$ be a separation pair of G where $u = s$, E be a 3-connected component of G with respect to $\{u,v\}$, and F be the union of all other components of G with respect to $\{u,v\}$. If it is not true that*

$E^* = (E \cup F^*$-marker) admits an upward plane drawing with w_t (if it exists; otherwise the edge (u,v)) and all vertices of X in E on the outer face,

where

$$F^*\text{-}marker = \begin{cases} M_t & \text{if } v \text{ is a source in } F, \\ M_{uv} & \text{otherwise,} \end{cases}$$

then G admits an upward plane drawing with all vertices of X on the outer face iff

(i) *there is no $x \in X$ contained in F,*

(ii) *$F' = (F \cup E$-marker) admits an upward plane drawing with w_t (if it exists; otherwise the edge (u,v)) on the outer face, and*

(iii) *$E' = (E \cup F$-marker) admits an upward plane drawing with all $x \in X$ on the outer face,*

where

$$E\text{-}marker = \begin{cases} M_t & \text{if } v \text{ is a source in } E, \\ M_{uv} & \text{otherwise,} \end{cases}$$

and

$$F\text{-}marker = \begin{cases} M_t & \text{if } v \text{ is a source in } F, \\ M_{uv} & \text{if } v \text{ is a sink in } F, \\ M_{uvt} & \text{otherwise.} \end{cases}$$

Proof (*outline*). Since E has no upward plane drawing with u and v both appropriately on the outer face, by Lemma 6.2, the only way G could be upward planar is if F can be embedded within an internal (hence the new condition (i)) face of E. Thus the outer face of G is fixed as being some face of the drawing of E' not containing v. It remains to ensure that there is some embedding of F which will fit the structural constraints of the shape of a face shared by s and v in the drawing of E. These are exactly the conditions previously required by E for embedding within the drawing of F. The remainder of the proof does not rely on the triconnectedness of either component, and it is similar to the proof of Theorem 6.8 with the roles of E and F reversed. □

6.4. The algorithm. Here we briefly summarize our algorithm and discuss its complexity.

Given DAG G, we first isolate biconnected components using the algorithm discussed in [23]. By Lemma 6.1, these can be tested independently. This step requires $\Theta(n)$ time, plus the time to test each piece independently.

For a biconnected DAG G, we use the triconnected components algorithm of [13] to find a list of separation pairs which breaks G into triconnected components ($\Theta(n)$ time). This list can be rearranged in linear time so that separation pairs involving the source appear last.

For each cut-set $\{u, v\}$ where $u \neq s$, isolate the source component using depth-first search ($\Theta(n)$ time), apply the appropriate theorem (6.5 or 6.7) to add markers and partition X, then recurse. The required time is given by

$$T(n) = T(k) + T(n-k) + O(n) \quad (k \geq 1),$$

which is $O(n^2)$, assuming we can do the base case on the smaller triconnected digraphs in $O(n^2)$ time.

Given a biconnected G with cut-set $\{s, v\}$, isolate a triconnected component (again with DFS) as E, and test, using the algorithm of §4, to see if has an upward plane embedding as specified in Theorem 6.8; this requires only $O(n)$ time, since a triconnected digraph has at most two embeddings with two specified vertices on the outer face. If E passes, continue with testing F as per Theorem 6.8. Otherwise, the operation is absorbed into the $O(n)$ term in the recurrence above, and we apply Theorem 6.9, forcing F to have u and v on the outer face. The previous recurrence and bound apply to this step.

Given a triconnected G, simply apply the algorithm of §4 to all possible outer faces and test for upward planarity in $O(n^2)$ time.

If we wish to output our G embedded into a planar s-t digraph (for drawing), we must find the necessary set of augmenting edges. This can be done by simply running the final upward planar representation through the algorithm of §4.

The entire algorithm operates in $O(n^2)$ time, and correctness follows from the cited results. We have the following theorem.

THEOREM 6.10. *Testing a single-source acyclic digraph for upward planarity, and outputting an upward planar representation when it exists, can be done in* $O(n^2)$ *time.*

7. Conclusions and further work. We have given a linear-time algorithm to test whether a given single-source digraph has an upward plane drawing strongly equivalent to a given plane drawing and to give a representation for this drawing if it exists. This provides, in combination with the decomposition results of §§5 and 6, an efficient $O(n^2)$ algorithm to test upward planarity of an arbitrary single-source digraph. We have also given a combinatorial characterization of single-source upward planar digraphs which provides new insights into their structure.

A lower bound for the single-source upward planarity problem is not known, although we believe that it may be possible to perform the entire test in subquadratic (perhaps linear) time. An obvious extension of this work would be to find such an algorithm or prove a lower bound.

This paper has concentrated on the issues of efficiently testing for an upward plane drawing. However, with the planar representation which results, we can augment the digraph to a planar s-t digraph with our algorithm of §4, then apply the algorithm of Di Battista and Tamassia to generate an actual drawing in $O(n)$ arithmetic steps, or $O(n \log n)$ arithmetic steps for a straight-line drawing [7]. Since an actual drawing must specify physical coordinates for the vertices, it becomes relevant to ask how big the integer grid must be or, equivalently, how much real precision is required. If bends are allowed, an $O(n)$-by-$O(n)$ grid suffices [7], similar to the case of undirected planar graphs [4], [20]. There is no upper bound known on the worst-case size requirement for straight-line upward plane drawings, but Di Battista, Tamassia, and Tollis [8] have exhibited a class of upward planar digraphs requiring an $\Omega(2^n)$-sized integer grid. Thus, any straight-line drawing algorithm is output sensitive—individual coordinates could require $\Omega(n)$ bits, causing the output size to dominate the arithmetic time. Without an upper bound on the required area, it is not known if the drawing algorithm remains polynomial time—any digraph requiring doubly exponential coordinate size would then need exponential time. It would be interesting to characterize some classes of digraphs which permit straight-line upward plane drawings on a polynomially sized grid. Guaranteeing minimum area in all cases is, however, NP-hard [9].

The more general problem, testing upward planarity of an arbitrary acyclic digraph, has recently been shown to be NP-complete [12]. Another recent development by Bertolazzi and Di Battista [1] shows how to efficiently test a triconnected (multisource, multisink) DAG for upward planarity, a more general analogue of the result in §4.

AN EFFICIENT PARALLEL ALGORITHM FOR THE GENERAL PLANAR MONOTONE CIRCUIT VALUE PROBLEM*

VIJAYA RAMACHANDRAN† AND HONGHUA YANG†

Abstract. A planar monotone circuit (PMC) is a Boolean circuit that can be embedded in the plane and that contains only AND and OR gates. Goldschlager, Dymond, Cook, and others have developed NC^2 algorithms to evaluate a special layered form of a PMC. These algorithms require a large number of processors ($\Omega(n^6)$, where n is the size of the input circuit). Yang and, more recently, Delcher and Kosaraju have given NC algorithms for the general planar monotone circuit value problem. These algorithms use at least as many processors as the algorithms for the layered case.

This paper gives an efficient parallel algorithm that evaluates a general PMC of size n in polylog time using only a linear number of processors on an exclusive read exclusive write parameter random-access machine (EREW PRAM). This parallel algorithm is the best possible to within a polylog factor and is a substantial improvement over the earlier algorithms for the problem. The algorithm uses several novel techniques to perform the evaluation, including the use of the dual of the plane embedding of the circuit to determine the propagation of values within the circuit.

Key words. circuit value problem, planar monotone circuit, plane graph, dual graph, parallel algorithm, EREW PRAM

1. Introduction.

A *Boolean circuit* is a directed network of AND, OR, and NOT gates whose wires do not form directed cycles. The problem of evaluating a Boolean circuit, given the values of its inputs, is called the *circuit value problem* (CVP). This is a central problem in the area of algorithms and complexity. Ladner [16] has shown that CVP is P-complete under log space reductions. Some special cases of CVP have been studied, among which the *monotone circuit value problem*, where the Boolean circuit has only AND and OR gates, and the *planar circuit value problem*, where the Boolean circuit has a plane embedding, have been shown to be P-complete by Goldschlager [9].

A *planar monotone circuit* (PMC) is a Boolean circuit that is both planar and monotone. One interesting special case of CVP is the *planar monotone circuit value problem* (PMCVP), which is the problem of evaluating a PMC. In this paper, we give an efficient parallel algorithm for the PMCVP that runs in polylog time using a linear number of processors. The parallel computation model we use here is the exclusive read exclusive write parameter random-access machine (EREW PRAM) model [14].

Here is a summary of earlier results for the PMCVP. Goldschlager [7], [8], Dymond and Cook [4], and Mayr [17] have shown that the problem of evaluating a special layered form of PMC is in NC^2. The first NC algorithm for the general PMCVP was given by Yang [24]; this algorithm runs in $O(\log^3 n)$ time on an EREW PRAM and uses the straight-line code parallel evaluation technique of Miller, Ramachandran, and Kaltofen [18]. Recently, Delcher and Kosaraju [3] have given another NC algorithm for the general PMCVP that runs in $O(\log^4 n)$ time using a polynomial number of processors on a concurrent read exclusive write (CREW) PRAM. All of the algorithms

listed above use a large number of processors (at least $\Omega(n^6)$, where n is the size of the input circuit).

In earlier work (Ramachandran and Yang [20]), we gave an $O(\log^2 n)$-time EREW PRAM algorithm using a linear number of processors to evaluate a layered PMC. The algorithm we present in this paper, when restricted to evaluate a layered PMC, works with the same processor-time bounds as the one in [20]. However, it is substantially different in that it works on a plane embedding of the PMC and its dual graph instead of exploiting a nice layered structure as in [20]. In one sense, our algorithm can be considered to be simpler than the one in [20], since our new approach allows us to eliminate some tedious case analysis used in [20]. Our algorithm uses some ideas from [20] as well as from [24] and [3]. In the highest level of our algorithm, we use an approach similar to that used in [3] to transform a general PMC into "face f induced subcircuits" (using the terminology of [24]—these circuits are called "focused circuits" in [3]). These subcircuits are then evaluated using an algorithm to evaluate a "one-input-face PMC." The major contribution of our paper is our efficient parallel algorithm to evaluate a one-input-face PMC, which is a PMC, not necessarily layered, all of whose input nodes are on the boundary of one face.

The rest of this paper is organized as follows. In §3, we present our algorithm to evaluate a one-input-face PMC. The treatment in §3 is self-contained and does not depend on any result in [20]. In §4, we give an algorithm that runs in polylog time using n processors on an EREW PRAM for evaluating a face f induced subcircuit given a special type of an input assignment. This algorithm works by recursively applying the algorithm for evaluating a one-input-face PMC. Finally, in §5, we give an algorithm that runs in polylog time using n processors on an EREW PRAM for solving the general PMCVP by recursively applying the algorithm for evaluating a face induced subcircuit.

Our results are of interest for several reasons. In designing our efficient parallel algorithm for the PMCVP, we have developed a variety of efficient parallel algorithms for processing planar directed acyclic graphs (DAGs), especially the technique of working on the dual of a planar DAG. (Other examples of algorithmic techniques based on the dual of a plane embedding can be found in [22], [13].) These tools are likely to be of use in algorithms for other problems on planar directed graphs. Our results are of interest in the context of parallel complexity, since all of the earlier algorithms for the PMCVP used indirect methods, such as the relationship between sequential space and parallel time [1] or the parallel evaluation of straight-line code [18], to place the problem in NC. By using direct techniques, we are not only able to place the problem in NC but are also able to obtain a very efficient algorithm for its solution. Finally, the evaluation of circuits is a basic and important problem in computer science. Planar circuits occur very naturally in the design of integrated circuits, and the requirement that the circuit be monotone is not a restriction if the inputs are available together with their complements. Thus our efficient parallel algorithm for the evaluation of planar monotone circuits could be of practical importance.

2. Preliminaries.

DEFINITION 2.1. *A* face *of a plane graph $C = (V, E)$ is a maximal portion of the plane for which any two points may be joined by a curve such that each point of the curve neither corresponds to a vertex of C nor lies on any curve corresponding to an edge of C. The* boundary *of a face f in C consists of all those points x corresponding to vertices and edges of C having the property that x can be joined to a point of f by* *a curve, all of whose points different from x belong to f. (By this definition, a single edge in f belongs to the boundary of f.)*

DEFINITION 2.2. *An embedded* planar monotone circuit (PMC) *is a plane DAG $C = (V, E)$, where*

(i) *V is the set of gates (or vertices) in the PMC consisting of input nodes, AND gates, and OR gates,*

(ii) *E is the set of directed wires (or edges) in the PMC,*

(iii) *the fan-in (or in-degree) of an input node is* 0 *and of an AND or OR gate is either* 1 *or* 2, *and C may have input nodes that are in different faces,*

(iv) *the fan-out (or out-degree) of an output gate is* 0, *and of other gates is nonzero, and C may have more than one output gate, but all output gates of C are in the same face.*

In the rest of the paper, whenever we use the term PMC, we should assume that the PMC is given with an embedding. In case an embedding is not given, we can use the algorithm in Ramachandran and Reif [19] to obtain one. We assume that the plane embedding of a PMC C is given by its combinatorial definition: a clockwise cyclic ordering of edges incident on each vertex in C, and a counterclockwise cyclic ordered sequence of vertices and edges $g_0, e_0, g_1, e_1, \ldots, g_{k-1}, e_{k-1}$ on the boundary of a face in C such that for any i, $0 \leq i \leq k-1$, the edges e_{i-1} and e_i are incident on vertex g_i and e_{i-1} appears immediately before e_i in the cyclic ordering of the edges incident on g_i.

DEFINITION 2.3. *A* complete input assignment *to a PMC is an assignment of values* 0 *or* 1 *to all input nodes in the PMC. A* partial input assignment *to a PMC is an assignment of values* 0 *or* 1 *to a subset of the input nodes in the PMC. An input node that is not assigned a value in a partial input assignment has an* unknown *value. (A complete input assignment is a special case of a partial input assignment.)*

DEFINITION 2.4. *The* partial evaluation problem of a PMC *is the problem of evaluating the value of every gate in the PMC that can be evaluated, given a partial input assignment to the PMC. The gates in a PMC that cannot be evaluated under a partial input assignment have* unknown *values. A PMC is* completely evaluated *if the value of every gate in it is either* 0 *or* 1, *and it is* partially evaluated *otherwise. The* PMCVP *is the problem of completely evaluating a PMC, given a complete input assignment to the PMC.*

A one-input-face PMC we define below is a PMC with the following differences: (i) It is a restriction of a PMC in that all of its input nodes are on the boundary of a single face. (ii) It is a generalization of a PMC in that it may contain *pseudowires*, which are wires that carry no value. Our algorithm may need to add pseudowires in a PMC during the computation in §3.2.

DEFINITION 2.5. *A* one-input-face PMC *C is a variant of a PMC with the following properties.*

1. *C is a plane DAG consisting of input nodes, AND gates, and OR gates.*

2. *All input nodes of C are on the boundary of a single face f_I. The in-degree of an input node is* 0 *and of an AND or OR gate is either* 1 *or* 2.

3. *A gate in C with out-degree* 0 *is called an* output gate. *The out-degree of other gates or input nodes is nonzero. C may have more than one output gate, but all output gates of C are on the boundary of a single face f_O.*

4. *If f_I and f_O are identical, then the input nodes and the output gates of C may not interlace, i.e. there exists a part of the boundary of f_I which contains all*

input nodes but no output gates.

5. *Some of the gates in C may contain a single output wire that does not carry any value and that goes into a two-input gate* (*note that such a gate with a single output wire that does not carry any value is* not *an output gate*). *We call a wire that does not carry any value a* pseudowire. *Further, a two-input gate g may receive at most one input from a pseudowire, and the value of g only depends on its nonpseudo input wire*(*s*).

We will give a recursive algorithm in §3 that evaluates a one-input-face PMC of size n in $O(\log^2 n)$ time using n processors on an EREW PRAM, where properties (4) and (5) in Definition 2.5 are needed after the first level of recursion.

DEFINITION 2.6. *Reach*$(i_1, \ldots, i_k)$ *for some input nodes* $i_1, \ldots, i_k$ *in a PMC is the part of the PMC that is reachable from* $i_1, \ldots, i_k$. *Given a subcircuit P of a PMC, Reach*(P) *is defined to be the part of the circuit reachable from the input nodes in P. Induced*$(i_1, \ldots, i_k)$ *for some input nodes* $i_1, \ldots, i_k$ *that are on the boundary of a single face f* (*where* $i_1, \ldots, i_k$ *need not be all the input nodes of f*) *in a PMC C is Reach*$(i_1, \ldots, i_k)$ *augmented with a new input node set V_{IN} and a wire set E_{IN}, which are formed as follows: if a gate* $x \in C \setminus$ *Reach*$(i_1, \ldots, i_k)$ *has some output wires* $(x, y_1), (x, y_2), \ldots, (x, y_l)$, $(l \geq 1)$, *pointing to gates* $y_1, y_2, \ldots, y_l$ *in Reach*$(i_1, \ldots, i_k)$, *then we add a new input node i_x to V_{IN} and wires* $(i_x, y_1), (i_x, y_2), \ldots, (i_x, y_l)$ *to E_{IN}. We call such Induced*$(i_1, \ldots, i_k)$ *a face f* induced (sub)circuit.

It is easy to see that a face f induced circuit is still a PMC. A face f induced circuit C_f is not necessarily a one-input-face PMC, since the newly added input nodes can appear in faces other than f in C_f. But C_f is still simpler than a general PMC in the sense that all gates in C_f except the newly added input nodes are reachable from some input nodes on the boundary of face f, and once the values of the new input nodes are known, C_f can be transformed into a logically equivalent one-input-face PMC. We give an algorithm in §4 that partially evaluates a face induced circuit of size n given a special input assignment, in polylog(n) time using n processors on an EREW PRAM, by recursively calling the algorithm for evaluating a one-input-face PMC. In §5, we give an algorithm that completely evaluates a general PMC of size n in polylog(n) time using n processors on an EREW PRAM, by recursively calling the algorithm for partially evaluating a face induced circuit, given a special input assignment.

3. The one-input-face PMC. We first consider the problem of completely evaluating a one-input-face PMC C given a complete input assignment. This treatment appears in §§3.1–3.3. We then solve the problem of partially evaluating a one-input-face PMC in §3.4. Our approach is to first find a set of gates in C that are guaranteed to have value 1 and then recursively evaluate the remaining smaller unevaluated subcircuits of C. In an earlier paper [20], we had considered a special case of a one-input-face PMC, namely, a layered PMC (as mentioned in the introduction). In a layered PMC, a sequence of gates with value 1 at one layer guarantees that a sequence of gates at the next layer will have value 1. The left and the right boundaries of the gates with value 1 are defined by the starting gate and the ending gate of the sequence at each layer, respectively. In a one-input-face PMC C that does not have the layered property, we do not have such a simple correspondence. In the treatment below, we work with the dual of a plane embedding of C and define the left and right boundaries of the gates with value 1 in a manner that allows us to determine the propagation of the 1 values through the circuit.

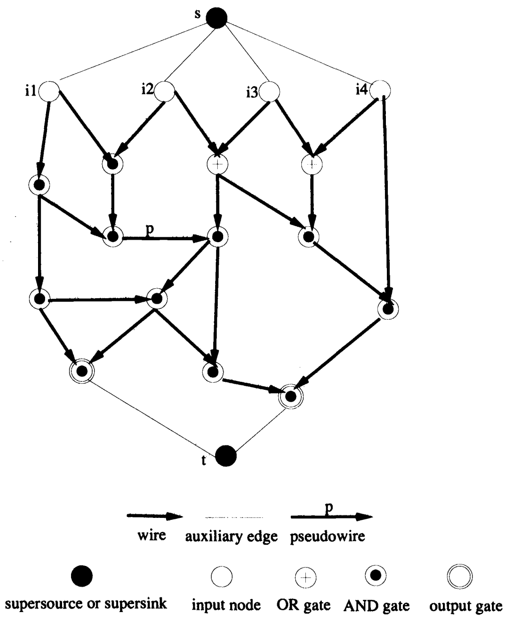

FIG. 1. *C_{aug}: a one-input-face PMC C augmented with a supersource s and a supersink t. Here $f_I = f_O$.*

In §3.1, we will give some definitions and lemmas. In §3.2, we will present our techniques for finding the left and right boundaries of the gates with value 1 and for simplifying the remaining circuit of C. In §3.3, we will give the complete algorithm for evaluating a one-input-face PMC given a complete input assignment and its complexity analysis. In §3.4, we will extend the algorithm to evaluate a one-input-face PMC given a partial input assignment.

Throughout §3, we use C to refer to a one-input-face PMC unless otherwise stated.

3.1. Definitions.

DEFINITION 3.1. *A gate is a* source *of a face f in C if it has two output wires that are on the boundary of f. A gate is a* sink *of a face f in C if it has exactly two input wires and both are on the boundary of f. Let f_I be the face of C whose boundary contains all the input nodes and let f_O be the face of C whose boundary contains all the output gates. C_{aug} is a DAG obtained from C by adding a super source s in f_I and auxiliary wires connecting s to every input node in C and a super sink t in f_O and auxiliary wires connecting every output gate to t (see Fig. 1).*

By Definition 2.5, if f_I and f_O are identical, then the input nodes and the output gates may not interlace in C. Hence C_{aug} is still a plane graph. In the rest of the paper, we assume that C has at least two input nodes. If C has only one input node, then by Definition 2.2, all gates in C have the same value as the only input node, which is a trivial case. The reason that we augment C to C_{aug} is that there is a single source and a single sink in every face of C_{aug} as shown in the following lemma. This property is crucial to many definitions given in this subsection.

Note that not every one-input-face PMC has a downward plane drawing [11] as in Fig. 1 if f_I and f_O are different faces.

LEMMA 3.1. *Every face in C_{aug} has exactly one source and one sink.*

Proof. Every gate in C_{aug} is reachable from s and reachable to t. Since C_{aug} is a DAG, there is at least one source and one sink on the boundary of a face in C_{aug}. Suppose a face f has two sources s_1 and s_2 and therefore two sinks t_1 and t_2. Then we consider the following four directed paths in C_{aug}: the path P_1 from s to s_1, the path P_2 from s to s_2, the path P_3 from t_1 to t, and the path P_4 from t_2 to t. The path P consisting of P_1 and P_2 joins the face f' at s_1 and s_2. The path Q consisting of P_3 and P_4 joins the face f' at t_1 and t_2. But s_1 and s_2 interlace with t_1 and t_2 on the boundary of f. But the two paths P and Q have to be embedded in one side of the boundary of f. This is a contradiction. Hence every face in C_{aug} has exactly one source and exactly one sink. □

The following lemma is needed for Definition 3.3.

LEMMA 3.2. *The output wires of a gate g in C_{aug} are placed consecutively in the cyclic ordering of the wires around g.*

Proof. Let g be a gate in C_{aug} with two input wires i_1 and i_2 and two output wires o_1 and o_2, such that o_1 and o_2 interlace with i_1 and i_2 in the cyclic ordering of the wires around g. Since every gate in C_{aug} is reachable to t, there are two directed paths P_1 and P_2 in C_{aug} from g to t, where P_1 goes through o_1 and P_2 goes through o_2. Let x be the first gate (except g) on P_1 that is also on P_2. Since C_{aug} is acyclic, x must be the first gate (except g) on P_2 that is also on P_1. The subpath of P_1 from g to x and the subpath of P_2 from g to x form an undirected cycle which divides the plane into two parts C_{inside} and $C_{outside}$, where C_{inside} is the part of the plane that is inside the cycle and $C_{outside}$ is the part of the plane that is outside the cycle. Without loss of generality, assume that the supersource s and the input wire i_2 are in $C_{outside}$. Let $i_1 = (g_1, g)$. Then g_1 and i_1 are in C_{inside} and g_1 is not reachable from s since otherwise there would be a directed cycle in C_{aug}. Hence g_1 is reachable from some input nodes in C_{inside} that cannot be reached from s in $C_{outside}$. This is a contradiction. □

DEFINITION 3.2. *The* left (right) input wire *of a two-input gate g is the input wire of g that appears immediately after (before) an output wire of g in the clockwise cyclic ordering of the wires around g.*

Note that the source and the sink of a face f in C_{aug} partition the boundary of f into two disjoint (except at the source and the sink) directed paths.

DEFINITION 3.3. *The path from the source to the sink going through the left input wire of the sink is the* counterclockwise boundary *of the face, and the path from the source to the sink going through the right input wire of the sink is the* clockwise boundary *of the face.*

DEFINITION 3.4. *The* dual digraph $C^*_{aug} = <V^*, E^*>$ *of the plane directed* primal graph $C_{aug} = <V, E>$ *is defined as follows.*

(i) *For each* primal face f *in* C_{aug}, *define a* dual vertex f^* *in* V^*.

(ii) *For each* primal edge e *in* C_{aug} *such that e is on the clockwise boundary of a primal face f_1 and the counterclockwise boundary of another primal face f_2, define a* counterclockwise dual edge $e^{*+} = (f_1^*, f_2^*)$ *in* E^* *and a* clockwise dual edge $e^{*-} = (f_2^*, f_1^*)$ *in* E^*.

Note that in the dual graph C^*_{aug}, we introduce dual edges of both directions, clockwise and counterclockwise, for each edge in the primal graph. The dual graph C^*_{aug} can also be viewed as the result of forming the undirected dual graph of C_{aug} and replacing the dual edges by dual arcs of both directions.

For convenience, for a primal face f, and a primal edge e, we will use f^*, e^{*+},

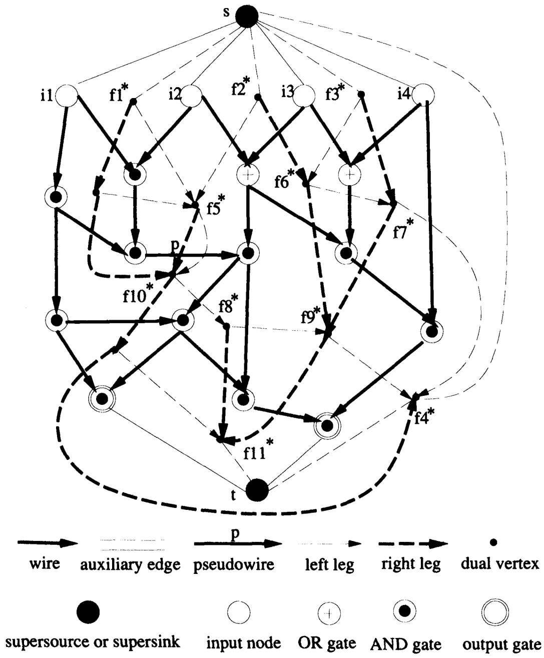

FIG. 2. *C_{aug} and A_{aug}, the auxiliary dual graph. C_{aug} consists of the solid edges. A_{aug} consists of the dashed edges. The two graphs overlap at s and t.*

and e^{*-} to indicate the dual vertex of f, the counterclockwise dual edge of e, and the clockwise dual edge of e, respectively.

In the following definition, we define an auxiliary graph (which can be viewed as a subgraph of C^*_{aug} augmented with s and t) that contains some edges called *left legs* and *right legs.* These edges aid us in defining regions of C_{aug} where value 1 propagates from input nodes. Thus, their definitions are dependent on whether a gate is an AND gate or an OR gate and whether a wire is a pseudowire, since an AND gate has value 1 if both of its inputs have value 1, an OR gate has value 1 if one of its inputs has value 1, and a pseudowire does not pass any value.

DEFINITION 3.5. *The* auxiliary dual graph $A_{aug} = <V_1^*, E_1^*>$ *is defined as follows (see Fig.* 2).

(i) *V_1^* contains the dual vertices of all the primal faces in C_{aug}, together with the supersource s and the supersink t.*

(ii) *E_1^* contains all the dual edges called the* left legs *and the* right legs *defined as follows.*

Let f be a primal face in C_{aug} whose boundary does not contain t, and let g be the sink of f with left input wire w_l and right input wire w_r.

(i) *If g is an OR gate with no pseudo input wire, then the* left leg *and the* right leg *of f^* are w_l^{*-} (i.e., the clockwise dual edge of w_l) and w_r^{*+} (i.e., the counterclockwise dual edge of w_r), respectively.*

(ii) *If g is an AND gate with no pseudo input wire, then the* left leg *and the* right leg *of f^* are w_r^{*+} and w_l^{*-}, respectively.*

(iii) *If w_l is a pseudowire, then both the* left leg *and the* right leg *of f^* are w_l^{*-}.*

(iv) *If w_r is a pseudowire, then both the* left leg *and the* right leg *of f^* are w_r^{*+}.*

Let f be a primal face whose boundary contains t or s in C_{aug}. Then we add an auxiliary edge (f^*, t) or (s, f^*) to E_1^*, respectively.

$A_{aug} \setminus \{s, t\}$ is a subgraph of C_{aug}^* that contains some dual edges of the input wires to the sinks of the faces in C_{aug}. It is easy to see that after being augmented with s and t, A_{aug} is still a plane graph, since the input nodes and the output gates of C do not interlace.

LEMMA 3.3. *If there is an edge $e^* = (f_1^*, f_2^*)$ in A_{aug} which is either a left leg or a right leg, then there is a directed path of length at least* 1 *from the sink s_1 of f_1 to the sink s_2 of f_2 in C_{aug}.*

Proof. By Definition 3.5, s_1 must be on either the clockwise boundary or the counterclockwise boundary of f_2 in C_{aug}. Since a gate (except t) has at most two input wires and therefore can be the sink of at most one face, s_1 cannot be the sink of f_2. Hence there is a directed path of length at least 1 from s_1 to s_2. □

COROLLARY 3.3.1. *A_{aug} is a plane DAG whose only vertex with out-degree* 0 *is t.*

Proof. By Lemma 3.3, A_{aug} is acyclic and hence a DAG. It is obvious that the only vertex in A_{aug} with out-degree 0 is t. □

DEFINITION 3.6. *Two input nodes i_1 and i_2 in C_{aug} are* adjacent *if the wire (s, i_1) and the wire (s, i_2) are adjacent in the cyclic ordering of the wires around s in C_{aug}. Given a complete input assignment to the input nodes of C_{aug}, a* valid base B *is a maximal sequence of adjacent input nodes with value* 1. *The* left (right) bounding face *of a valid base B is the face in C_{aug} whose clockwise (counterclockwise) boundary contains an input node in B, but whose counterclockwise (clockwise) boundary does not (see Fig.* 5*).*

If all input nodes in C_{aug} have value 1, then the left bounding face and the right bounding face are not defined. But this is a trivial case, since we know that all gates of C_{aug} must have value 1.

DEFINITION 3.7. *For a valid base B in C_{aug}, let f_l and f_r be the left and right bounding faces of B, respectively. The* left boundary *and the* right boundary *of B are the two directed paths P_l^* and P_r^*, respectively, in A_{aug}, such that* (1) *P_l^* and P_r^* start from s,* (2) *P_l^* consists of left legs and auxiliary edges and goes through (s, f_l^*),* (3) *P_r^* consists of right legs and auxiliary edges and goes through (s, f_r^*), and* (4) *P_l and P_r end at their first common vertex g^* (g^* could be t) after s (see Figs.* 5 *and* 6*).*

DEFINITION 3.8. *Given a valid base B, the left boundary P_l^* of B and the right boundary P_r^* of B divide the plane into two regions. The region whose counterclockwise boundary is P_l^* and whose clockwise boundary is P_r^* is called the* internal region *of B, and the other region is called the* external region *of B (see Figs.* 5 *and* 6*).*

LEMMA 3.4. *Given a complete input assignment to C_{aug} where there is only one valid base B (all other input nodes have value* 0*), a gate g in C_{aug} evaluates to* 1 *iff g is in the internal region of B.*

Proof. Let us embed A_{aug} and C_{aug} in the plane simultaneously with the same supersource s and the same supersink t (as in Fig. 2) such that the only primal edges in C_{aug} that cross the left and right boundaries P_l^* and P_r^* of B are the input wires to the sinks of some of the primal faces in C_{aug}. (This is provable by Definitions 3.5 and 3.7.) A sink in C_{aug} with a pseudo input wire can have only its pseudo input wire (but not the other input wire) crossing P_l^* or P_r^*. Further, a sink of a primal face f in C_{aug} cannot have its two input wires crossing an edge w_l^* in P_l^* and an edge w_r^* in P_r^*, respectively, since otherwise f^* would be the common starting vertex of both w_l^* and w_r^* and therefore would be a common vertex of P_l^* and P_r^*. However, P_l^* and P_r^*

do not end at f^* since w_l^* is in P_l^* and w_r^* is in P_r^*. This is a contradiction.

Therefore, if we remove all wires that cross P_l^* and P_r^* from C_{aug} and call the resulting graph C'_{aug}, then every gate (except the input nodes) in C'_{aug} still has at least one nonpseudo input wire (by the previous paragraph) and hence can still be reached from some input nodes without going through pseudowires. Further, the gates in the internal (external) region of B in C'_{aug} can be reached only by the input nodes in the internal (external) region. Therefore, if we remove all wires crossing P_l^* and P_r^* from C_{aug}, the gates in the internal region of B will have value 1 and the gates in the external region of B will have value 0. We now show that this is still the case even if we do not remove the wires crossing P_l^* and P_r^* from C_{aug}. By Definition 3.5, a wire in C_{aug} outgoing from a gate in the external region of B and incoming to a gate in the internal region of B is either an input wire to a two-input OR gate or a pseudo input wire to a two-input gate. Hence the gates in the internal region of B in C_{aug} will still have value 1. A primal edge in C_{aug} outgoing from the internal region of B to the external region of B is either an input wire to a two-input AND gate that is in the external region of B or a pseudowire to a two-input gate that is in the external region of B. Hence the gates in the external region of B in C_{aug} will still have value 0. Hence the lemma holds. □

COROLLARY 3.4.1. *Given a complete input assignment to C_{aug}, if a gate g is in the internal region of a valid base in C_{aug}, then g evaluates to* 1.

Proof. The corollary is proved by Lemma 3.4 and the monotonicity of C_{aug}. □

Note that the reverse of Corollary 3.4.1 need not be true if there is more than one valid base in C_{aug}, i.e., some gates outside the internal regions of the valid bases of C_{aug} might also be evaluated to 1. Hence our approach to evaluate a one-input-face PMC C_{aug} is to first find some of the gates that evaluate to 1 based on the internal regions of the valid bases of C_{aug}, remove them from C_{aug}, and repeatedly evaluate the resulting C_{aug}.

3.2. Complete evaluation of a one-input-face PMC. In this subsection, we give an efficient method for computing the left and the right boundaries for all valid bases in C_{aug} simultaneously, given a complete input assignment to C_{aug}. The main idea is to identify for each dual vertex f^* in A_{aug} whether it is on the left (right) boundary of some valid base in C_{aug} (i.e., whether $BOUN_l(f^*)$ or $BOUN_r(f^*)$ defined in Definition 3.10 below is nonempty). Based on this approach, we present a technique to transform the part of C_{aug} that has not been evaluated to 1 into several subcircuits that are one-input-face PMCs with smaller sizes and, more importantly, with geometrically decreasing number of valid bases.

We first define two tree structures that consist of left legs and right legs.

DEFINITION 3.9. *Let V_l (V_r) be the set of vertices of A_{aug} (except s) that are reachable through left (right) legs and auxiliary edges incoming to t from the dual vertex of the left (right) bounding face of some valid base in C. We define T_l^* (T_r^*) to be the subgraph of A_{aug} induced by V_l (V_r).*

For example, Fig. 3 gives T_l^* and T_r^* for the circuit in Fig. 1 with an input assignment $(0, 1, 0, 1)$ to the input nodes i_1, i_2, i_3, i_4.

LEMMA 3.5. *Both T_l^* and T_r^* are convergent trees.*

Proof. By Corollary 3.1.1, A_{aug} is a DAG. By Definition 3.5, there is exactly one left leg and one right leg or one auxiliary edge outgoing from each vertex (except s) in A_{aug}. Hence the lemma holds. □

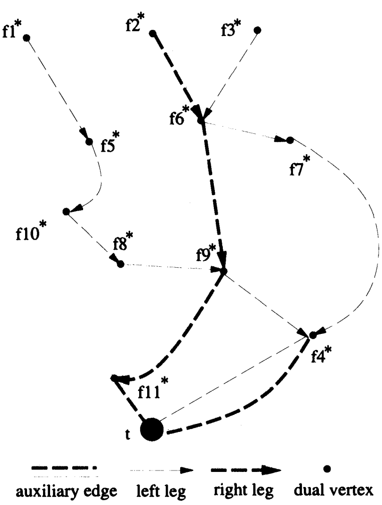

FIG. 3. T_l^* *and* T_r^* *for the circuit in Fig.* 1, *given an input assignment* $(0,1,0,1)$ *to the input nodes* i_1, i_2, i_3, i_4. T_l^* *consists of the light dashed edges.* T_r^* *consists of the dark dashed edges.*

In the following definitions and lemmas, we define $BOUN_l(f^*)$ $(BOUN_r(f^*))$ and related concepts and describe our approach to compute $BOUN_l(f^*)$ $(BOUN_r(f^*))$. Among the sets defined below are two related and similar concepts, $BOUN_l(f^*)$ $(BOUN_r(f^*))$ and $BASE_l(f^*)$ $(BASE_r(f^*))$. These sets are different in that the latter is a superset of the former and is defined to aid the computation of the former.

DEFINITION 3.10. *$PRED_l(f^*)$ $(PRED_r(f^*))$ is the set of the* proper predecessors *of f^* in T_l^* (T_r^*), i.e., the set of dual vertices that can reach f^* through directed paths of length at least* 1 *in T_l^* (T_r^*).*

We associate with each dual vertex f^* in T_l^* (T_r^*) the following sets of valid bases of C_{aug}:

(i) $BASE_l(f^*)$ $(BASE_r(f^*))$ is the set of valid bases B such that the dual vertex of the left (right) bounding face of B is either f^* or in $PRED_l(f^*)$ $(PRED_r(f^*))$. (Informally, $BASE_l(f^*)$ $(BASE_r(f^*))$ is the set of the valid bases in C_{aug} whose left (right) boundaries either contain f^* or a predecessor of f^* in T_l^* (T_r^*).)

(ii) $BOUN_l(f^*)$ $(BOUN_r(f^*))$ is the set of valid bases B whose left (right) boundary contains f^*.

(iii) $JOIN(f^*) = BASE_l(f^*) \cap BASE_r(f^*)$. (Informally, $JOIN(f^*)$ is the set of valid bases whose left and right boundaries either terminate at f^*, or terminate at a predecessor of f^* and the extension of the left and right boundaries rejoin at f^*.)

(iv) $TERM(f^*)$ is the set of valid bases whose left and right boundaries terminate exactly at f^*.

For convenience, if a set for a dual vertex in A_{aug} cannot be defined through Definition 3.10 (e.g., if a dual vertex is not in T_l^*), we assume that it is empty.

Figure 4 illustrates the above definitions. For valid base $B_2 = \{i_4\}$ with left bounding face f_3 and right bounding face f_4 in Fig. 1, the left boundary of B_2 is a subpath of the path from f_3^* to t in T_l^* and the right boundary of B_2 is a subpath of the path from f_4^* to t in T_r^* (in this case, the subpath is the single vertex f_4^*). Notice the difference between $BASE_l(f_4^*) = \{B_1, B_2\}$ and $BOUN_l(f_4^*) = \{B_2\}$, between $BASE_r(t) = \{B_1, B_2\}$ and $BOUN_r(t) = \phi$, and between $JOIN(t) = \{B_1, B_2\}$ and

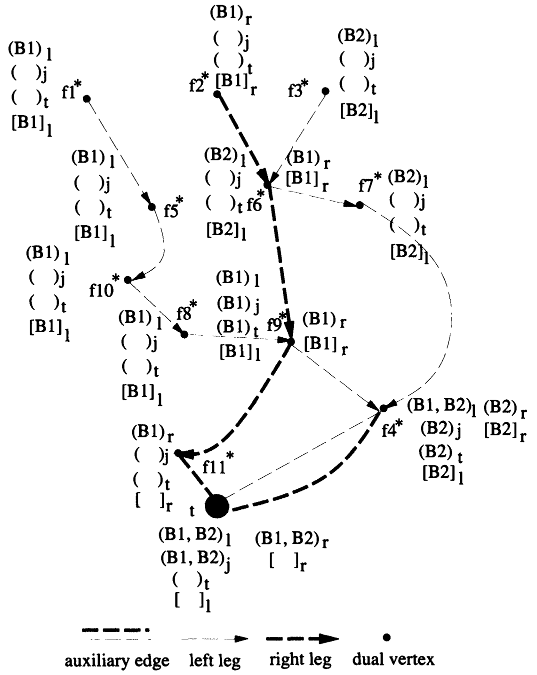

FIG. 4. *Illustrations for the sets $BASE_l$, $BASE_r$, $BOUN_l$, $BOUN_r$, $JOIN$, and $TERM$ on T_l^* and T_r^*. For each node f^* in T_l^*, the contents of $()_l$ denote $BASE_l(f^*)$, the contents of $[]_l$ denote $BOUN_l(f^*)$, the contents of $()_j$ denote $JOIN(f^*)$, and the contents of $()_t$ denote $TERM(f^*)$. For each node f^* in T_r^*, the contents of $()_r$ denote $BASE_r(f^*)$ and the contents of $[]_r$ denote $BOUN_r(f^*)$.*

$TERM(t) = \phi$.

The relations among these sets are summarized in the following lemma. For convenience, we will focus on the sets with index l. The relations among the sets with index r are symmetric.

LEMMA 3.6. *Let f^* be a dual vertex in A_{aug}. Then the following hold:*

1. *$BASE_l(f_p^*) \subseteq BASE_l(f^*)$ for any $f_p^* \in PRED_l(f^*)$.*
2. *$BOUN_l(f^*) \cap BOUN_l(f_1^*) = \phi$ and $BASE_l(f^*) \cap BASE_l(f_1^*) = \phi$ for any f_1^* that does not have predecessor–successor relation with f^* in T_l^*.*
3. *$TERM(f^*) \cap TERM(f_1^*) = \phi$ for any $f_1^* \neq f^*$.*
4. *$TERM(f^*) = JOIN(f^*) \setminus \cup_{f_p^* \in PRED_l(f^*)} JOIN(f_p^*)$.*
5. *$BOUN_l(f^*) = BASE_l(f^*) \setminus \cup_{f_p^* \in PRED_l(f^*)} TERM(f_p^*)$, and $|BOUN_l(f^*)| = |BASE_l(f^*)| - \sum_{f_p^* \in PRED_l(f^*)} |TERM(f_p^*)|$.*

Proof. The correctness of (1)–(3) follows directly from Definition 3.10. The correctness of (4) follows from Definition 3.7, Definition 3.10, (1), and (2). The correctness of (5) follows from Definition 3.10 and (1)–(3). □

Our goal is to identify the gates that are on the left and right boundaries of some valid base. Since a left leg (f_1^*, f_2^*) is on the left boundary of some valid base iff $|BOUN_l(f_1^*)| > 0$ and $|BOUN_l(f_2^*)| > 0$, it suffices to compute $|BOUN_l(f^*)|$ for every f^* in T_l^*. $BASE_l(f^*)$ (and hence $|BASE_l(f^*)|$) can be easily computed using the Euler-tour technique [23] on T_l^* (see Procedure 2 in §3.3 for details). Since

$BASE_l(f^*)$ ($BASE_r(f^*)$) contains valid bases with consecutive labels (modulo the total number of bases) in the total order of the valid bases, it can be described succinctly by a range $[x, y]$, where x and y are the numbers of the first and the last valid bases in $BASE_l(f^*)$ ($BASE_r(f^*)$), respectively. If we can compute $|TERM(f^*)|$ for every f^* that is in both T_l^* and T_r^*, then we can compute $|BOUN_l(f^*)|$ using (5) in Lemma 3.6 and the Euler-tour technique. It remains to compute $|TERM(f^*)|$ for every f^* that is in both T_l^* and T_r^*.

We can try to compute $|TERM(f^*)|$ directly from (4) in Lemma 3.6. However, note that the sets $JOIN(f^*) = BASE_l(f^*) \cap BASE_r(f^*)$ are not necessarily disjoint for different f^* in T_l^* if they have predecessor–successor relation. Instead, we show in the following lemma that they satisfy some important properties, and then in Lemma 3.8, we give a formula to compute $TERM(f^*)$ with disjoint $JOIN(f^*)$ sets.

LEMMA 3.7. (1) *If f_p^* is a predecessor of f^* in both T_l^* and T_r^*, then $JOIN(f_p^*) \subseteq JOIN(f^*)$.*

(2) *Otherwise, $JOIN(f^*) \cap JOIN(f_p^*) = \phi$.*

Proof. (1) By (1) in Lemma 3.6, we have both $BASE_l(f_p^*) \subseteq BASE_l(f^*)$ and $BASE_r(f_p^*) \subseteq BASE_r(f^*)$. Therefore, $JOIN(f_p^*) \subseteq JOIN(f^*)$.

(2) Without lose of generality, assume f^* and f_p^* do not have predecessor–successor relation in T_l^*. Then by (2) in Lemma 3.6, $BASE_l(f^*) \cap BASE_l(f_p^*) = \phi$. Therefore, $JOIN(f_p^*) \cap JOIN(f^*) = \phi$. □

Based on Lemma 3.7, we give the following definition.

DEFINITION 3.11. *For a dual vertex f^* and one of its predecessors f_p^* in T_l^* with $JOIN(f^*) \neq \phi$ and $JOIN(f_p^*) \neq \phi$, $JOIN(f_p^*)$ is* immediately enclosed *by $JOIN(f^*)$, denoted by $JOIN(f_p^*) \subseteq_I JOIN(f^*)$, iff $JOIN(f_p^*) \subseteq JOIN(f^*)$ and there is no dual vertex f_q^* on the directed path from f_p^* to f^* in T_l^* such that $JOIN(f_q^*) \subseteq JOIN(f^*)$.*

LEMMA 3.8. *For a dual vertex f^* that is in both T_l^* and T_r^*,*

1. $TERM(f^*) = JOIN(f^*) \setminus \cup_{f_p^* \in PRED_l(f^*) \wedge JOIN(f_p^*) \subseteq_I JOIN(f^*)} JOIN(f_p^*)$,
2. $|TERM(f^*)| = |JOIN(f^*)| - \sum_{f_p^* \in PRED_l(f^*) \wedge JOIN(f_p^*) \subseteq_I JOIN(f^*)} |JOIN(f_p^*)|$.

Proof. By (4) in Lemma 3.6 and Lemma 3.7, (1) holds immediately. By Definition 3.11, none of the f_p^* in the summation in (2) has predecessor–successor relation. By Lemma 3.7, the sets $JOIN(f_p^*)$ in (2) are disjoint. Hence (2) holds. □

The above lemmas give us the necessary tools to compute $|BOUN_l(f^*)|$ efficiently in parallel. The algorithms that implement the computations in Lemmas 3.6 and 3.8 are given in Procedures 2 and 3 and in the proof of Lemma 3.16 in §3.3. Having computed the left and right boundaries of the valid bases of C_{aug}, our next step is to identify the regions of C_{aug} that consist of gates with value 1. In the following definition, we define a *separating graph* A_{sep}, which is a subgraph of A_{aug} that consists of the left and right boundaries of all the valid bases of C_{aug} and which is used to find the regions of C_{aug} that consists of gates with value 1.

DEFINITION 3.12. (1) *A* separating graph *A_{sep} contains s and the vertices f^* in A_{aug} for which either $BOUN_l(f^*) \neq \phi$ or $BOUN_r(f^*) \neq \phi$. A_{sep} contains t if $BOUN_l(t) \neq \phi$ or $BOUN_r(t) \neq \phi$.*

(2) *An edge (f_1^*, f_2^*) of A_{aug} is an edge in A_{sep} if one of the following three conditions holds*: (a) *$f_1^* = s$ and f_2 is the left or right bounding face of a valid base,* (b) *$BOUN_l(f_1^*) \neq \phi$, $BOUN_l(f_2^*) \neq \phi$ and $BOUN_l(f_1^*) \neq TERM(f_1^*)$, or* (c) *$BOUN_r(f_1^*) \neq \phi$, $BOUN_r(f_2^*) \neq \phi$ and $BOUN_r(f_1^*) \neq TERM(f_1^*)$.*

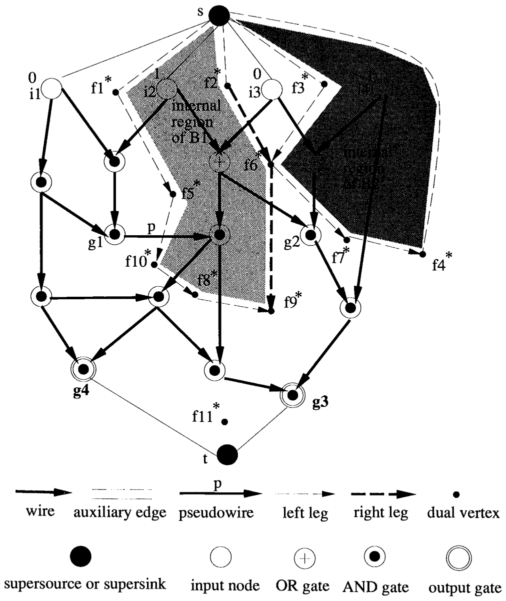

FIG. 5. *C_{aug} and A_{sep} to show the left and right boundaries of B_1 and B_2. C_{aug} consists of the solid edges. The complete input assignment to the input nodes i_1, i_2, i_3, i_4 is $(0,1,0,1)$. $B_1 = \{i_2\}$ and $B_2 = \{i_4\}$ are two valid bases. The left bounding face and the right bounding face of B_1 are f_1 and f_2, respectively. The left boundary of B_1 is the directed path $(s, f_1^*, f_5^*, f_{10}^*, f_8^*, f_9^*)$ and the right boundary of B_1 is the directed path (s, f_2^*, f_6^*, f_9^*). The part of the plane inside the two boundaries is the internal region of B_1 and the part of the plane outside the two boundaries is the external region of B_1. The left bounding face and the right bounding face of B_2 are f_3 and f_4, respectively. The left boundary of B_2 is the directed path $(s, f_3^*, f_6^*, f_7^*, f_4^*)$ and the right boundary of B_2 is the directed path (s, f_4^*). A_{sep} consists of all dashed edges.*

A_{sep} is a subgraph of A_{aug}, which is a subgraph of C^*_{aug} (the dual graph of C_{aug}) augmented with s and t (see Figs. 5 and 6). Hence A_{sep} is a plane graph. Each face in A_{sep} is called a *separating region* of the primal graph C_{aug}. Note that a separating region of C_{aug} either is in the internal region of a valid base or in the external region of every valid base. In the latter case, we call it an *external separating region.*

In the example in Fig. 5, A_{sep} consists of the left and right boundaries of B_1 and B_2. The separating regions of C_{aug} in Fig. 5 are the face in A_{sep} with boundary $(s, f_1^*, f_5^*, f_{10}^*, f_8^*, f_9^*, f_6^*, f_2^*, s)$ (i.e., the internal region of B_1), the face in A_{sep} with boundary $(s, f_3^*, f_6^*, f_7^*, f_4^*, s)$ (i.e., the internal region of B_2), the face in A_{sep} with boundary $(s, f_2^*, f_6^*, f_3^*, s)$, and the face in A_{sep} with boundary $(s, f_1^*, f_5^*, f_{10}^*, f_8^*, f_9^*, f_6^*, f_7^*, f_4^*, s)$.

DEFINITION 3.13. *A wire w is* incoming to (outgoing from) *a subcircuit C' if the head* (*tail*) *of w is a gate in C' but the tail* (*head*) *of w is not.*

LEMMA 3.9. *All incoming wires to an external separating region R in C_{aug} are either wires with value* 1 *or pseudowires.* (*Any input node in R will have value* 0.)

Proof. The wires incoming to R must come from the internal regions of some valid bases, since a wire crosses a boundary of a valid base B either from the internal region to the external region of B, or from the external region to the internal region of B. Since R is not in the internal region of any valid base of C_{aug}, all the wires incoming to R are wires outgoing from the internal regions of some valid bases. By

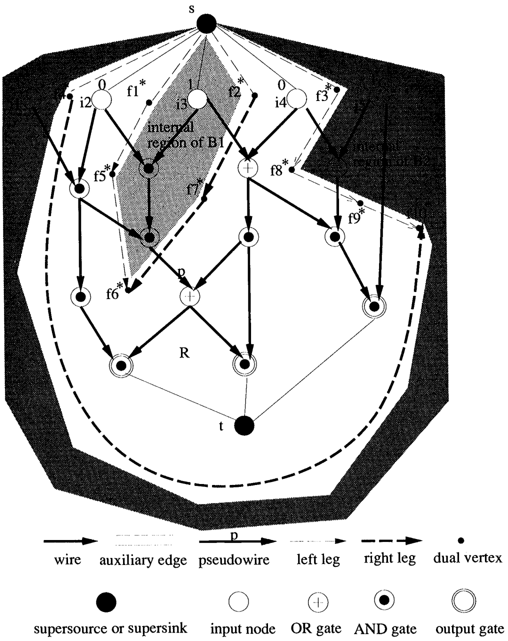

FIG. 6. *C_{aug} and A_{sep} to show the left and right boundaries of B_1 and B_2. C_{aug} consists of the solid edges. A_{sep} consists of the dashed edges. The complete input assignment to the input nodes i_1, i_2, i_3, i_4, i_5 is $(1, 0, 1, 0, 1)$. $B_1 = \{i_3\}$ and $B_2 = \{i_5, i_1\}$ are two valid bases. The left boundary of B_1 is the directed path (s, f_1^*, f_5^*, f_6^*) and the right boundary of B_1 is the directed path (s, f_2^*, f_7^*, f_6^*). The left boundary of B_2 is the directed path $(s, f_3^*, f_8^*, f_9^*, f_{10}^*)$ and the right boundary of B_2 is the directed path (s, f_4^*, f_{10}^*).*

Corollary 3.4.1, the gates in the internal region of any valid base of C_{aug} have value 1. Hence all incoming wires to R are either wires with value 1 or pseudowires. □

Recall that Corollary 3.4.1 states that the gates in the internal region of every valid base of C_{aug} have value 1. Hence the gates in the separating regions that are in the internal region of a valid base have value 1. In the following corollary, we will extend Corollary 3.4.1 to show that in fact the gates in any separating region (including the external separating region) that does not contain an input node with value 0 will have value 1.

COROLLARY 3.9.1. *If a separating region R of C_{aug} does not contain an input node with value* 0, *then all the gates of C_{aug} in R have value* 1.

Proof. If R is in the internal region of a valid base, then by Corollary 3.4.1, the lemma holds. Now we consider an external separating region R that is not in the internal region of any valid base of C. By Lemma 3.9, all incoming wires to R are either wires with value 1 or pseudowires. Since R does not contain an input node with value 0, all the gates in R will have value 1. □

By Corollary 3.9.1, the problem of evaluating the one-input-face PMC C is now reduced to the problem of evaluating each subcircuit of C_{aug} in an external separating region that contains input nodes with value 0, since the gates in other separating regions are known to have value 1. Our next step is to transform these subcircuits into one-input-face PMCs so that we can evaluate these subcircuits recursively. One nontrivial problem with a subcircuit of C_{aug} in a separating region is that the output

```
PROCEDURE 1. Subcircuit transformation
Input: $C_R$, the subcircuit of $C_{aug}$ in an external separating region $R$ containing at least
        one input node with value 0.
Output: $C'_R$, a one-input-face PMC logically equivalent to $C_R$.
0. Initialize $C'_R$ to $C_R$;
1. for each wire $w_i$ in $C_{aug}$ incoming to $C_R$ in parallel do
        let $g$ be the gate in $C_R$ receiving $w_i$ as an input;
        {{note that $g$ must be a two-input AND gate and the sink of a face}}
        (a) if the other input wire of $g$ is in $R$ then remove $w_i$ from $C'_R$;
        (b) else (i.e., the other input wire of $g$ is a wire incoming to $C_R$)
                make $g$ a new input node with value 1 in $C'_R$;
            end {if};
   end {for};
2. for each wire $w_o$ in $C_{aug}$ outgoing from $C_R$ in parallel do
        insert a one-input AND gate $g_{w_o}$ in $w_o$ with $g_{w_o}$ lying inside $R$,
        and remove the part of $w_o$ outgoing from $g_{w_o}$;
        let $w_o^* = (f_1^*, f^*)$ be the dual edge on the boundary of $R$ that crosses $w_o$;
        assume $w_o$ is on the counterclockwise (clockwise) boundary of the face $f$ in $C_{aug}$;
        let $s_f$ be the sink of $f$ in $C_{aug}$;
        let $w^*$ be the other edge connected to $f^*$ on the boundary of $R$ in $A_{sep}$;
        (a) if $w^*$ is an outgoing edge of $f^*$
            then {{$w^*$ crosses either the left input wire $w_l$ or the right input wire $w_r$ of $s_f$}}
                attach an output wire to $g_{w_o}$ in $C'_R$ by adding a pseudowire as follows:
                {{so that $g_{w_o}$ would not be an output gate in $C'_R$, and $C'_R$ is a plane graph}}
                (i) if $w^*$ crosses $w_l$ ($w_r$)
                    then {{$s_f$ must be a two-input AND gate}}
                        connect $g_{w_o}$ and $s_f$ through a pseudowire to replace $w_l$ ($w_r$) in $C'_R$;
                    end {if};
                (ii) if $w^*$ crosses $w_r$ ($w_l$)
                    then make $g_{w_r}$ (i.e., the one-input AND gate inserted in $w_r$ at
                        at the beginning of step 2) a two-input AND gate
                        and connect $g_{w_o}$ to $g_{w_r}$ through a pseudowire in $C'_R$;
                    end {if};
            end {if};
        (b) if $w^*$ is an incoming edge of $f^*$ {{$f^*$ is called a bottom of $R$ in this case}}
            then make $g_{w_o}$ a new output gate in $C'_R$;
            end {if};
   end {for};
end.
```

gates of the subcircuit may interlace with the input nodes of the subcircuit, which makes it impossible to add a supersink to the subcircuit without violating the planarity property. For example, in Fig. 5, after removing the gates in the internal region of B_1 and the internal region of B_2, g_1 will be a new output gate and g_2 will be a new input gate, and the input nodes and the output gates i_1, g_1, g_2, g_3, and g_4 are interlaced with each other in the resulting subcircuit. The following definition and procedure give a method we will apply to solve this problem. This construction uses pseudo wires (defined in part (5) of Definition 2.5).

DEFINITION 3.14. *A circuit C' is* logically equivalent *to a circuit C, if from a partially evaluated C we construct C' (possibly with additional gates) such that for each unevaluated gate g in C, there is a gate in C' with the same value as g.*

The algorithm given in Procedure 1 transforms a subcircuit of C_{aug} in an external separating region that contains at least one input node with value 0 into a logically equivalent one-input-face PMC. Some examples of this transformation are given in Fig. 7. We now show that C'_R constructed by Procedure 1 is a one-input-face PMC that is logically equivalent to C_R.

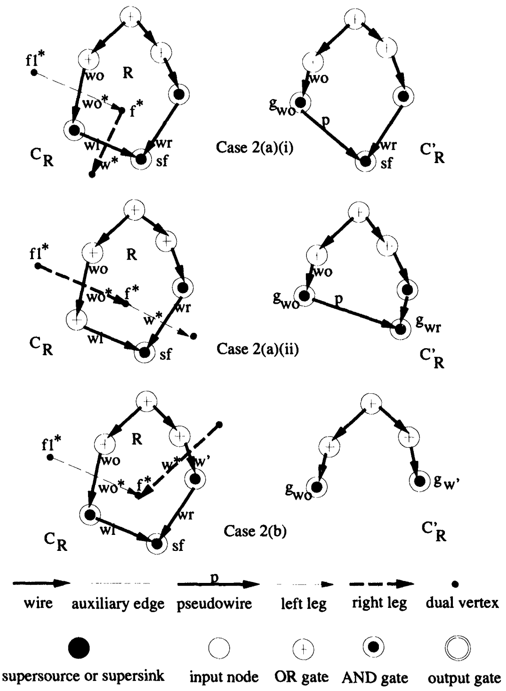

FIG. 7. *The circuit transformation of C_R to C'_R.*

LEMMA 3.10. *C'_R is logically equivalent to C_R.*

Proof. We first show that step 1 in Procedure 1 does not change the value of the gates in C'_R that were originally in C_R. Since C_R is in the external region of every valid base, by Definition 3.5, a wire outgoing from the internal region of some valid base and incoming to R must be either a pseudowire or an input wire to a two-input AND gate whose other input wire is not a pseudowire. By Lemma 3.9, all the incoming wires to R are either wires with value 1 or pseudowires. Hence removing a pseudo input wire or an input wire with value 1 to a two-input AND gate g (whose other input wire is not a pseudowire) in step 1(a) will not change the value of g in C'_R, and the two-input AND gate g in step 1(b) indeed has value 1.

Step 2 in Procedure 1 reduces the number of new output gates in C'_R by adding pseudowires. Steps 2(a)(ii) and 2(b) do not change any input to the gates of C'_R that were originally in C_R. Step 2(a)(i) changes an input to s_f by replacing w_l (w_r) with a pseudowire. However, since w_l (w_r) is an incoming wire to the external separating region R, by the arguments given in the previous paragraph, w_l (w_r) is either a pseudo input wire or an input wire with value 1, s_f is a two-input AND gate, and w_r (w_l) is not a pseudowire. Hence the value of s_f depends only on the value of w_r (w_l) and is the same in both C_R and C'_R. □

LEMMA 3.11. *C'_R is a plane DAG.*

Proof. It is easy to see that C'_R is still a plane graph since the pseudowires introduced in Procedure 1 will not cross any existing wires in C_R.

Suppose there is a directed cycle in C'_R. Then we map a gate g on the cycle to a gate in C_{aug} by the following function f: $f(g) = g$ if g is a gate in C_{aug}; $f(g) = g_2$ if g is not gate in C_{aug} but is a new gate inserted in wire (g_1, g_2) of C_{aug} in step 2

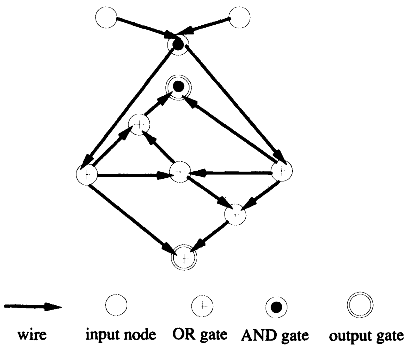

FIG. 8. *An example of a PMC with all input nodes in a single face but output gates in different faces. This PMC cannot be converted into a one-input-face PMC by adding pseudowires to the output gates, since any pseudowire added to an output gate will create a directed cycle in this example.*

of Procedure 1. For each edge (g_1, g_2) on the cycle in C'_R, if (g_1, g_2) is not an edge in C_{aug}, then we add a new edge $(f(g_1), f(g_2))$ to C_{aug} and call the augmented graph C'_{aug}. Hence there is a cycle in C'_{aug} containing new edges. We now prove that for each new edge $(f(g_1), f(g_2))$ in C'_{aug}, there is a directed path in C_{aug} from $f(g_1)$ to $f(g_2)$. We consider the following three cases:

(i) *Case* 1. Both g_1 and g_2 are gates in C_{aug}. Then $(f(g_1), f(g_2)) = (g_1, g_2)$, which is a wire in C_{aug}.

(ii) *Case* 2. g_1 is a newly added gate in C'_R, but g_2 is a gate in C_{aug}. Suppose g_1 is inserted in the wire (g_3, g_4) of C_{aug}. Then (g_1, g_2) is a pseudowire added in step 2(a)(i) of Procedure 1 and g_2 is the sink of the face whose boundary contains g_4. Hence there is a directed path from $f(g_1) = g_4$ to $f(g_2) = g_2$ in C_{aug}.

(iii) *Case* 3. g_2 is a newly added gate in C'_R, but g_1 is a gate in C_{aug}. Then g_2 is inserted in the wire $(g_1, f(g_2))$ of C_{aug} in step 2 of Procedure 1. Hence there is a directed path from $f(g_1) = g_1$ to $f(g_2)$ in C_{aug}.

(iv) *Case* 4. Both g_1 and g_2 are newly added gates in C'_R. Then (g_1, g_2) is a pseudo wire added in step 2(a)(ii) of Procedure 1. Suppose g_1 is inserted in the wire (g_3, g_4) of C_{aug} and g_2 is inserted in the wire (g_5, g_6) of C_{aug}. Then (g_5, g_6) is an outgoing edge from C_R, and g_6 is the sink of the face whose boundary contains g_4. Hence there is a directed path from $f(g_1) = g_4$ to $f(g_2) = g_6$ in C_{aug}.

Hence there is a directed cycle in C_{aug}, which contradicts the fact that C_{aug} is a DAG. Hence C'_R is acyclic. □

At this point, one might wonder if it is the case that any PMC whose input nodes are on the boundary of a single face can be converted to a one-input-face PMC by adding pseudowires to the output gates. The example in Fig. 8 shows that this is not always possible when the output gates are on the boundaries of multiple faces. The construction of C'_R exploited some special properties of a one-input-face PMC and its separating regions to guarantee that the result is a DAG, and this is not always the case when the input circuit is not a one-input-face PMC.

We now show that a subcircuit C'_R output by Procedure 1 must have all inputs in one face, all outputs in one face, and no interlacing of inputs and outputs. This will establish that C'_R is a one-input-face PMC.

A dual vertex f^* is a *bottom* of a separating region R if it is the head of two edges (which are dual edges of C_{aug}) on the boundary of R. (See step 2(b) of Procedure 1

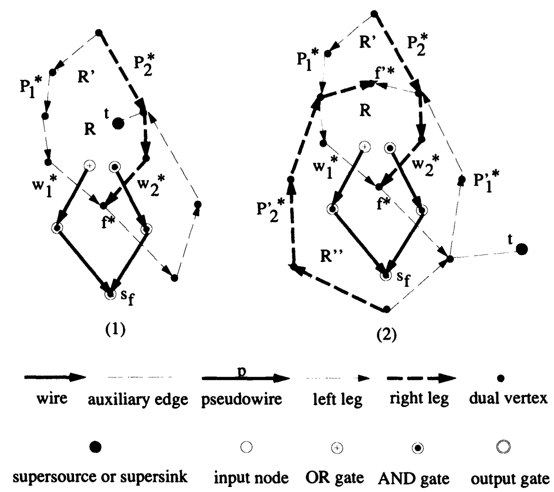

FIG. 9. *Figures for the proof of Lemma* 3.12.

and case 2(b) in Fig. 7.)

LEMMA 3.12. *A separating region R has at most one bottom, and if R has a bottom, then R does not contain the supersink t.*

Proof. Let f^* be a bottom of R and let w_1^* and w_2^* be the two edges incoming to f^*. We find two paths P_1^* and P_2^* in A_{sep} such that (a) P_1^* goes to f^* through w_1^* and P_2^* goes to f^* through w_2^* and (b) P_1^* and P_2^* intersect with each other only at their starting vertices and their ending vertices. Let R' be the region whose counterclockwise boundary is P_1^* and whose clockwise boundary is P_2^*. Then R is inside R', since R is a face in A_{sep}.

We first prove that t is not in R', which implies that t is not in R (see (1) in Fig. 9). Let s_f be the sink of the primal face f. If s_f is t, then we have proved that t is not in R'. Otherwise, since the primal edges of w_1^* and w_2^* are outgoing from R', s_f and its two input wires must be outside of R' (note that the two input wires of s_f cannot be the primal edges of w_1^* and w_2^*, since only the dual edges outgoing from f^* can cross the input wires of s_f). Hence any outgoing edges from f^* in A_{aug} must be outside of R', since they cross the two input wires of s_f. Hence if t were in R', then A_{aug} would have contained a directed cycle, since there is a directed path from f^* to t in A_{aug}. This is a contradiction.

We now prove that R has at most one bottom (see (2) in Fig. 9). Suppose R has another bottom f'^*. Let $w_1'^*$ and $w_2'^*$ be the two edges incoming to f'^*. We find two paths $P_1'^*$ and $P_2'^*$ in A_{sep} such that (a) $P_1'^*$ goes to f'^* through $w_1'^*$ and $P_2'^*$ goes to f'^* through $w_2'^*$ and (b) $P_1'^*$ and $P_2'^*$ intersect with each other only at their starting vertices and their ending vertices. Let R'' be the region whose counterclockwise boundary is $P_1'^*$ and whose clockwise boundary is $P_2'^*$. Then by the proof in the previous paragraph, t is neither in R' nor in R''. But at least one path from f^* or f'^* to t will create a directed cycle in A_{aug}. This is a contradiction. □

COROLLARY 3.12.1. *If C_R contains a bottom, then C'_R does not contain an original output gate of C_{aug}, and C'_R contains at most two newly created output gates, and the two output gates are adjacent to each other on the boundary of a face; if C_R does not contain a bottom, then C'_R does not contain any newly created output gates (C'_R may contain some original output gates of C_{aug}).*

Proof. If C_R contains a bottom, then t is not in C'_R and hence C'_R does not contain an original output gate of C_{aug} (since the auxiliary wires connecting output gates to t do not cross the boundary of R). Further, since C'_R has at most one bottom, at most two new output gates are created in C'_R and they are adjacent to each other on the boundary of a face (see case 2(b) in Fig. 7). If C_R does not contain a bottom, then no new output gates are created in C'_R by the construction in Procedure 1. □

LEMMA 3.13. *All newly created input nodes in C'_R are on the boundary of a single face.*

Proof. After removing all the gates not in R and the wires crossing the boundary of R, all the input nodes in C'_R are on the boundary of a single face, which is the external face of C'_R. Further, the new faces created by the new pseudowires added in step 2 of Procedure 1 do not contain input nodes on their boundaries. □

LEMMA 3.14. *Procedure* 1 *constructs a one-input-face PMC C'_R that is logically equivalent to C_R and runs in $O(1)$ time using a linear number of processors on an EREW PRAM.*

Proof. Lemma 3.13 and Corollary 3.12.1 ensure that the output gates and the input nodes in C'_R do not interlace. By Lemmas 3.10, 3.11, and 3.13 and Corollary 3.12.1, C'_R is a one-input-face PMC that is logically equivalent to C_R.

It is straightforward to see that all steps in Procedure 1 can be implemented in constant time using a linear number of processors. □

We conclude this subsection by showing that a subcircuit C'_R output by Procedure 1 contains at most half the number of valid bases in C_{aug}.

DEFINITION 3.15. *We say two valid bases B and B'* meet *if the right boundary of B and the left boundary of B' have a common vertex. The transitive closure of the meet relation partitions the set of the valid bases in C_{aug} into equivalence classes.*

LEMMA 3.15. *The number of the valid bases in C'_R is at most half of the number of valid bases in C_{aug}.*

Proof. Let g be a newly created input node in C'_R. We say g is a *descendant of* a valid base B of C_{aug} if an original input of g is in the internal region of B. This lemma follows from the following two claims.

CLAIM 1. *Every newly created input node in C'_R is a descendant of at least two distinct valid bases of C_{aug}, and the two valid bases are in the same equivalence class of C_{aug}.*

CLAIM 2. *The newly created input nodes in C'_R that are descendants of the valid bases in the same equivalence class of C_{aug} are in the same valid base in C'_R.*

By Claim 1, a singleton equivalence class of C_{aug} does not generate a new input node with value 1 in C'_R. By Claim 2, an equivalence class of C_{aug} containing at least two valid bases generates at most one valid base in C'_R. Hence the lemma holds.

We first prove Claim 1. Since only the sink of a face can have its input wires crossed by the dual edges in A_{sep}, a newly created input node g must be the sink of a face f in C_{aug}. The two original input wires w_1 and w_2 of g must cross a dual edge w_1^* (which is a left leg) on the left boundary of a valid base and a dual edge w_2^* (which is a right leg) on the right boundary of a valid base, respectively. Since w_1^* and w_2^* are outgoing from the same vertex f^*, they cannot be on the left and right boundaries of the same valid base (since the left and right boundaries end at their first common vertex after s). Therefore, the input wires of g are outgoing from the internal regions of at least two different valid bases (the internal regions of several valid bases may overlap). Further, the two valid bases are in the same equivalence class, since f^* is a

```
ALGORITHM 1. Complete evaluation of a one-input-face PMC
Input: An embedded one-input-face PMC $C$ and a complete input assignment to $C$.
Output: Each gate in $C$ is assigned a value 0 or 1.
1.  if all input nodes in $C$ have value 1
2.  then assign value 1 to all gates in $C$; return;
    else if all input nodes in $C$ have value 0
3.       then assign value 0 to all gates in $C$; return;
         end {if};
    end {if};
4.  Augment $C$ to $C_{aug}$, and construct the auxiliary dual graph $A_{aug}$;
5.  Find the edges in $A_{aug}$ that are on the boundaries of valid bases of $C_{aug}$ (see Procedure 2);
6.  Construct the separating graph $A_{sep}$;
7.  Remove the wires in $C_{aug}$ that cross the boundary edges of $A_{sep}$;
8.  Find the (undirected) connected components in the remaining $C_{aug}$;
9.  for each connected component $C_R$ found in step 8 in parallel do
10.     if $C_R$ does not contain input nodes with value 0
11.     then assign value 1 to all gates in $C_R$;
12.     else transform $C_R$ to $C'_R$ using Procedure 1;
13.          Recursively evaluate $C'_R$;
        end {if};
    end {for};
end.
```

common vertex of the left boundary of one valid base and the right boundary of the other valid base.

We now prove Claim 2. Since the external separating region R contains at least one input node with value 0, the boundary of R must contain the supersource s. Further, s may appear on the boundary of R more than once (see Fig. 6; s appears twice on the boundary of the external separating region R which consists of the part of the plane between the internal region of B_1 and the internal region of B_2). Since multiple appearances of s are possible, if we remove s from the boundary of R, the boundary will be divided into several connected portions, each enclosing a disjoint part of C_{aug} (in Fig. 6, the two disjoint parts are the internal region of B_1 and the internal region of B_2). The valid bases in one part cannot be in the same equivalence class as a valid base in a different part. Let P be a connected portion of the boundary of R after removing S. Let I be the set of all newly created input nodes that are descendants of the valid bases in the equivalence classes enclosed in P. Then the original input wires of the input nodes in I must cross the dual edges in P. Hence the input nodes in I are adjacent on the boundary of a face in C'_R and therefore are in the same valid base in C'_R. □

3.3. An efficient algorithm for the one-input-face PMCVP. Based on the approach we presented in the previous subsection, we give an efficient EREW PRAM algorithm, called Algorithm 1, for evaluating a one-input-face PMC.

The correctness and complexity analysis of Algorithm 1 will be given in Theorem 3.1. All steps in Algorithm 1 are quite straightforward to implement except step 5, which is implemented by Procedure 2. Step 2.5 in Procedure 2 is implemented by Procedure 3, which is similar to a procedure used for the layered PMC in [20].

LEMMA 3.16. *Procedure* 2 (*i.e.*, *step* 5 *in Algorithm* 1) *correctly finds the edges in* A_{aug} *that are on the boundaries of valid bases of* C_{aug} *and runs in* $O(\log n)$ *time using a linear number of processors on an EREW PRAM.*

Proof. The correctness of all steps (except step 2.5) of Procedure 2, which imple-

```
PROCEDURE 2. Finding the edges in $A_{aug}$ that are on the boundaries of valid bases
Input: $C_{aug}$, $A_{aug}$, and a complete input assignment to $C_{aug}$.
Output: The edges of $A_{aug}$ that are on the boundaries of valid bases of $C_{aug}$ are marked.
2.1. Find all the valid bases in $C_{aug}$ and label them in the order of the sequence in which
     they appear on the boundary of the input face of $C_{aug}$;
2.2. Construct $T_l^*$ and $T_r^*$ from $A_{aug}$;
2.3. Compute $BASE_l(f^*)$ and $BASE_r(f^*)$ for each dual vertex $f^*$ in $A_{aug}$;
2.4. Compute $JOIN(f^*) = BASE_l(f^*) \cap BASE_r(f^*)$ for each dual vertex $f^*$ in $A_{aug}$;
2.5. Find the enclosure relation $\subseteq_I$ among the $JOIN(f^*)$ (see Procedure 3);
2.6. Compute $|TERM_l(f^*)|$ and $|TERM_r(f^*)|$ for each dual vertex $f^*$ in $A_{aug}$ using Lemma 3.8;
2.7. Compute $|BOUN_l(f^*)|$ and $|BOUN_r(f^*)|$ for each dual vertex $f^*$ in $A_{aug}$ using Lemma 3.6;
2.8. Mark all dual edges $(f^*, g^*)$ in $A_{aug}$
     with $|BOUN_l(f^*)| > 0$ and $|BOUN_l(f^*)| > |TERM(f^*)|$
     or with $|BOUN_r(f^*)| > 0$ and $|BOUN_r(f^*)| > |TERM(f^*)|$;
end.
```

```
PROCEDURE 3. Finding the enclosure relation $\subseteq_I$ for the $JOIN(f^*)$
Input: $T_l^*$ and $JOIN(f^*)$ for each dual vertex $f^*$ on $T_l^*$.
Output: The enclosure forest $EF^*$ such that a dual vertex $f_p^*$ is the immediate predecessor of
        a vertex $f^*$ in $EF^*$ iff $JOIN(f_p^*) \subseteq_I JOIN(f^*)$.
3.1. for each vertex $f^*$ with nonempty $JOIN(f^*)$ and with the length of the longest path from
         a leaf to $f^*$ in $T_l^*$ being $k$ in parallel do
3.2.     Assign two triples $(x,\ -k,\ f^*)$, $(y,\ k,\ f^*)$ for each range $[x, y]$ in $JOIN(f^*)$;
     end {for};
3.3. Sort all triples into nondecreasing order according to the first two elements in a triple;
3.4. for each triple $(x,\ -k,\ f^*)$, where $k \geq 0$ in parallel do
3.5.     Find its previous triple $(n',\ k',\ f'^*)$ in the sorted list;
3.6.     if $(k' < 0)$ and $(f^* \neq f'^*)$ then $f'^*$ is the parent of $f^*$ in $EF^*$;
3.7.     else if $(k' > 0)$ and $(f^* \neq f'^*)$ then $f'^*$ is the left sibling of $f^*$ in $EF^*$; end {if};
         end {if};
     end {for};
3.8. Construct the $EF^*$ from the parent and sibling relations;
end.
```

ments step 5 of Algorithm 1, has been proved in Lemmas 3.6 and 3.8. We now show the correctness of Procedure 3, which implements step 2.5 of Procedure 2. Let f_1^* and f_2^* be two vertices in T_l^* such that the longest paths from a leaf to f_1^* and from a leaf to f_2^* are of length k_1 and k_2, respectively. By Lemma 3.7, f_1^* is a successor of f_2^* in T_l^* and $JOIN(f_1^*) \supseteq JOIN(f_2^*)$ iff $k_1 > k_2$, and for each range $[x_2, y_2]$ of $JOIN(f_2^*)$, there exists a range $[x_1, y_1]$ of $JOIN(f_1^*)$, such that $x_1 \leq x_2 \leq y_2 \leq y_1$ in the cyclic order. $JOIN(f_1^*) \cap JOIN(f_2^*) = \phi$ iff for each range $[x_2, y_2]$ of $JOIN(f_2^*)$ and each range $[x_1, y_1]$ of $JOIN(f_1^*)$, $x_1 \leq y_1 < x_2 \leq y_2$ in the cyclic order. Therefore, if (n', k', f'^*) and $(x, -k, f^*)$ are two consecutive triples in the sorted list, we have the following: (1) if $k' < 0$ and $f^* \neq f'^*$, then $JOIN(f^*) \subseteq_I JOIN(f'^*)$ and f'^* must be the immediate successor of f^* in the EF^*; (2) if $k' > 0$ and $f^* \neq f'^*$, then f^* and f'^* share the common immediate successor in EF^*.

Next, we analyze the time complexity of Procedure 2.

In step 2.2, T_l^* (T_r^*) can be computed using Euler-tour technique as follows. We first remove s and all right (left) legs from A_{aug}. Then the resulting graph A'_{aug} is a tree rooted at t by the uniqueness of left (right) legs. We then mark the leaf nodes of A'_{aug} that are the dual vertices of the left (right) bounding faces of valid bases of C. Finally, we apply the Euler-tour technique to find all the successors of the marked leaf nodes, and the resulting subtree of A'_{aug} is T_l^* (T_r^*).

In step 2.3, since $BASE_l(f^*)$ $(BASE_r(f^*))$ contains valid bases with consecutive labels (modulo the total number of bases) in the total order of the valid bases, it

```
ALGORITHM 2. Partial evaluation of a one-input-face PMC
Input: A one-input-face PMC $C$ and a partial input assignment to $C$.
Output: Each gate in $C$ that can be evaluated is assigned a value 0 or 1.
1. Assign value 1 to all input nodes with unknown value in $C$ and apply Algorithm 1;
2. Let $A$ be the set of the gates assigned value 0 in this solution of step 1;
3. Assign value 0 to all input nodes with unknown value in $C$ and apply Algorithm 1;
4. Let $B$ be the set of the gates assigned value 1 in this solution of step 3;
5. Assign value 0 to all gates in $A$, assign value 1 to all gates in $B$, and assign unknown value
   to the gates of $C$ that are neither in $A$ nor in $B$;
end.
```

can be described succinctly by a range $[l, h]$ where l and h are the numbers of the first and the last valid bases in $BASE_l(f^*)$ $(BASE_r(f^*))$, respectively. $BASE_l(f^*)$ $(BASE_r(f^*))$ can be computed using Euler-tour technique on T_l^* (T_r^*) as follows. We first label each leaf node of T_l^* (T_r^*) with the label of its corresponding valid base. Then for each vertex f^* in T_l^* (T_r^*), we apply the Euler-tour technique to find the smallest label and the largest label among the leaf predecessors of f^* in T_l^* (T_r^*) and assign them to l and h, respectively.

In step 2.4, $JOIN(f^*)$ can be computed from $BASE_l(f^*)$ and $BASE_r(f^*)$ in constant time and be represented by at most two ranges.

Based on the above analysis, we conclude that steps 2.2–2.4 can be implemented in $O(\log n)$ time using a linear number of processors.

Procedure 3 (which implements step 2.5 in Procedure 2) can be implemented in $O(\log n)$ time with a linear number of processors using the parallel merge sort of [2] and the Euler-tour technique.

It is easy to see that all other steps of Procedure 2 can be implemented in $O(\log n)$ time using a linear number of processors by computing prefix sums and applying Euler-tour and tree-evaluation techniques in [6] and [15]. □

THEOREM 3.1. *Algorithm* 1 *correctly solves the complete evaluation problem of a one-input-face PMC, given a complete input assignment, and runs in* $O(\log^2 n)$ *time using n processors on an EREW PRAM, where n is the size of the circuit.*

Proof. Steps 1–4 are quite straightforward. The correctness of step 5 is proved by Lemma 3.16. The correctness of steps 6–13 is proved by Corollary 3.9.1 and Lemma 3.14.

It is straightforward to see that all steps except steps 5, 8, and 13 in Algorithm 1 can be implemented in $O(\log n)$ time using a linear number of processors. Lemma 3.16 shows that step 5 can be implemented in the same time complexity. Step 8 can be implemented in $O(\log n)$ time optimally by applying the algorithm in [5] for finding connected components in a planar undirected graph.

By Lemma 3.15, the number of the recursive levels needed to complete the evaluation is $O(\log n)$. Therefore, the overall time needed by Algorithm 1 is bounded by $O(\log^2 n)$. Further, the total number of gates in all remaining subcircuits C_R in step 12 in Algorithm 1 is less than the number of gates in the original C_{aug}, since for each newly inserted gate in C_R, there is a unique gate in the internal region of a valid base being removed. Therefore, the processor bound holds. □

3.4. Partial evaluation of a one-input-face PMC. We extend Algorithm 1 to solve the partial evaluation problem of a one-input-face PMC in Algorithm 2.

THEOREM 3.2. *Algorithm* 2 *correctly solves the partial evaluation problem of a one-input-face PMC, given a partial input assignment, and runs in* $O(\log^2 n)$ *time* *using n processors on an EREW PRAM, where n is the size of the circuit.*

Proof. By the monotonicity of the circuit, A is a subset of the gates that should be evaluated to 0 in the partial evaluation of C, and B is a subset of the gates that should be evaluated to 1 in the partial evaluation of C. Further, we now show that a gate g of C that is neither in A nor in B should have unknown values in the partial evaluation of C. Suppose that this is not the case. Let g be a gate that should be evaluated to 0 (1) in the partial evaluation of C, and let g be in neither A nor B. Then g evaluates to 0 (1) under every possible input assignment to the input nodes with unknown values in C. In particular, g has value 0 (1) when all input nodes with unknown values are assigned value 1 (0), which means g is in A (B). This is a contradiction. Therefore, Algorithm 2 is correct.

It is easy to see that the time complexity of Algorithm 2 is the same as that of Algorithm 1, since it is dominated by the two calls on Algorithm 1. □

4. The face induced PMC. In this section, we consider a face f induced circuit C_f, which is defined in §2. For convenience, we assume that C_f is embedded with f being the external face. An *f-partial input assignment* to C_f is a partial input assignment where only input nodes in f can have unknown values and the input nodes in faces other than f must have values 0 or 1. The problem of partially evaluating C_f given an f-partial input assignment is called the *f-partial evaluation* of C_f. Algorithm 3 gives our method to perform an f-partial evaluation of C_f. Algorithm 3 is similar to an algorithm in [3] which first layers a face induced circuit (which squares the size of the circuit) and then recursively partitions the circuit at an appropriate layer. Our algorithm performs a more efficient evaluation by working on a face induced circuit directly and partitioning the circuit according to its topological ordering. It then partially evaluates each subcircuit either recursively or using Algorithm 2.

Recall that a *topological ordering* of a digraph is a linear ordering of its vertices such that every edge in the graph points from a lower-numbered vertex to a higher-numbered vertex. It is well known that a digraph has a topological ordering iff it is a DAG. We now prove the correctness of Algorithm 3 and analyze its complexity.

LEMMA 4.1. *Immediately before step 8, every connected subcircuit in P_l and P_h is a face f' induced circuit for some face f' with an f'-partial input assignment.*

Proof. Let us add to C_f a supersource s in face f and a supersink t in the output face of C_f for the purpose of the proof. We connect s to each input node in f with an edge and connect each output gate to t with an edge. The resulting C_f is still a plane graph.

Only input nodes in f can have unknown values in each connected subcircuit in P_l, since no new input nodes are created in P_l. We now show that the output gates in P_l are in the same face. By step 5, every directed path from a gate in P_h to t consists only of gates in P_h. Hence the gates in P_h can be coalesced to t and the resulting C_f is still a plane graph. The wires outgoing from gates in P_l to gates in P_h are now incoming to t. Hence after we cut the wires outgoing from gates in P_l to t and remove t, the output gates of the connected subcircuits in P_l are in a single face, which we call f_1. Hence every connected subcircuit in P_l is still a face f induced circuit with an f-partial input assignment.

P_h is $C \setminus P_l$ plus some new input nodes with unknown values generated in step 6. The output gates in P_h are not changed and hence are still in the same face. The new input nodes with unknown values are in the same face f_1, since all gates in P_l can be coalesced to s. If there are original input nodes in f remaining in P_h (which

ALGORITHM 3. *f-partial evaluation of a face f induced circuit C_f*

```
Input: A face $f$ induced circuit $C_f$ with an $f$-partial input assignment.
Output: The solution of the $f$-partial evaluation problem of $C_f$.
1. if $C_f$ contains only one gate then return the value of the gate end {if};
2. Obtain a topological ordering of the gates in $C_f$;
3. Let $m$ be the total number of the noninput gates in $C_f$;
4. Find $g_1$ such that there are $\lfloor m/2 \rfloor$ noninput gates before $g_1$ in the topological ordering;
5. Partition the gates in $C_f$ into two parts $P_l$ and $P_h$, such that $P_l$ contains $g_1$ and the gates
   before $g_1$ in the ordering and $P_h$ contains the gates after $g_1$ in the ordering, and remove
   the wires of $C_f$ pointing from gates in $P_l$ to gates in $P_h$;
6. for each gate $g$ in $P_h$ in parallel do
       if all input wire(s) of $g$ are removed
       then replace $g$ by an input node with unknown value in $P_h$;
       else if $g$ is a two-input gate and only one input wire of $g$ is removed
               then add an input node $i$ with unknown value and a wire from $i$ to $g$ in $P_h$;
               end {if};
       end {if};
   end {for};
7. Find the (undirected) connected subcircuits in $P_l$ and $P_h$;
8. $f'$-partially evaluate every connected subcircuit in $P_l$ and $P_h$ recursively in parallel, where $f'$
   is the external input face of the subcircuit;
   {{it will be shown below that each such subcircuit is a face $f'$ induced circuit with an
   $f'$-partial assignment}}
9. Remove all gates that are assigned 0 or 1 in step 8 in $P_h$;
10. Assign the output values of $P_l$ to the input nodes of $P_h$;
11. Partially evaluate every connected subcircuit in $P_h$ using Algorithm 2 in parallel;
   {{it will be shown below that each such subcircuit is a one-input-face PMCs}}
end.
```

are the only input nodes in C_f that possibly carry unknown value), then f_1 must be identical to f. Hence every connected subcircuit in P_h is still a face f_1 induced circuit with an f_1-partial input assignment. □

LEMMA 4.2. *Immediately before step* 11, *every connected subcircuit in P_h is a one-input-face PMC.*

Proof. We show that after removing all gates assigned 0 or 1 in P_h in step 9, no new input nodes are generated, i.e., no gate with in-degree 1 or 2 in P_h becomes a gate with in-degree 0. Let g be a gate with in-degree at least 1 in P_h just before step 9. If all gate(s) that provide inputs to g have known values, then the value of g should be evaluated in step 8 and g should be removed in step 9. If all gate(s) that provide inputs to g have unknown values, then the in-degree of g is not changed. If one input of a two-input gate g has unknown value and the other has known value, then the in-degree of g is 1 after step 9. Hence no new input nodes are generated in P_h in step 9. By Lemma 4.1, every connected subcircuit in P_h and P_l in step 8 is a face f' induced circuit for some input face f' with an f' partial input assignment. Therefore, immediately before step 11, the only input nodes left in each connected subcircuit in P_h are the input nodes in f' that carry unknown value. Hence every connected subcircuit in P_h is a one-input-face PMC. □

THEOREM 4.1. *Algorithm* 3 *correctly solves the f-partial evaluation problem of a face f induced circuit C_f and runs in $O(\log^4 n)$ time using n processors on an EREW PRAM, where n is the size of C_f.*

Proof. The correctness of steps 8 and 11 are shown by Lemmas 4.1 and 4.2. It is straightforward to see that other steps in Algorithm 3 are correct.

Step 1 takes constant time. Step 2 can be implemented in $O(\log^3 n)$ time using n processors on an EREW by Theorem 4.1 in Kao and Klein [12]. The connectivity of a

```
ALGORITHM 4. Complete evaluation of a general PMC
Input: A general PMC $C$ with input nodes $i_1, \ldots, i_m$ and a complete input assignment.
Output: Each gate in $C$ is assigned a value 0 or 1.
0. if $C$ contains only one gate then return the value of the gate end {if};
1. Find the smallest $k$, $0 \leq k \leq m$, such that every connected subcircuit in
   $C \setminus \mathit{Reach}(i_1, i_2, \ldots, i_{(k+1)})$ is of size $\leq n/2$ (see Fig. 10);
   Let $P$ be a connected subcircuit of size $> n/2$ in $C \setminus \mathit{Reach}(i_1, i_2, \ldots, i_k)$ when $k \geq 1$;
2. if $k \geq 1$
3. then Recursively solve the complete evaluation problem for the connected subcircuits in
          $C \setminus \mathit{Reach}(P)$ and in $P \setminus \mathit{Reach}(i_{(k+1)})$ (whose sizes are all $\leq n/2$) in parallel
          (see Fig. 10 and Lemmas 5.1 and 5.2 for steps 3–8);
          {{it will be shown that each such subcircuit is a general PMC with a complete input
          assignment}}
4.        Completely evaluate $\mathit{Induced}(i_{(k+1)}) \cap P$ using Algorithm 3;
          {{it will be shown that each such subcircuit is a face induced circuit with a complete
          input assignment}}
          {{now all gates in $P$ and $C \setminus \mathit{Reach}(P)$ are completely evaluated}}
5.        Remove $P$ from $C$, let $o_1, \ldots, o_{m'}$ be the gates of $P$ with wires outgoing to $\mathit{reach}(P)$;
          {{$o_1, \ldots, o_{m'}$ are on the boundary of a single face in $\mathit{reach}(P)$}}
6.        Completely evaluate $\mathit{Induced}(o_1, \ldots, o_{m'})$ (i.e., $\mathit{Reach}(P) \setminus P$) using Algorithm 3;
          {{it will be shown that each such subcircuit is a face induced circuit with a complete
          input assignment}}
7. else Recursively solve the complete evaluation problem for the connected subcircuits in
        $C \setminus \mathit{Reach}(i_1)$ (whose sizes are all $\leq n/2$) in parallel;
8.      Evaluate $\mathit{Induced}(i_1)$ using Algorithm 3;
   end {if};
end.
```

plane undirected graph in steps 8 and 11 can be solved in $O(\log n)$ time using $n/\log n$ processors on an EREW by the algorithm in Gazit [5]. Steps 3–6 and 9–10 can be implemented in $O(\log n)$ time using $n/\log n$ processors. Step 11 takes $O(\log^2 n)$ time using n processors by Theorem 3.2. Let n' be the number of noninput gates in the original C_f. Since the in-degree of each gate in C_f is ≤ 2, we have $n' < n \leq 3n'$. Each of P_h and P_l contains at most $\lceil n'/2 \rceil$ noninput gates and therefore at most $3\lceil n'/2 \rceil$ total gates (including the new input nodes). Let $T(n)$ be the time needed for Algorithm 3 to partially evaluate a circuit with n gates. We have

$$T(3n') \leq T(3\lceil n'/2 \rceil) + O(\log^3 n).$$

Solving the above recurrence equation, we have $T(3n') = O(\log^4 n)$. Hence $T(n) \leq T(3n') = O(\log^4 n)$. □

5. The general PMCVP. In this section, we give in Algorithm 4 our overall algorithm for evaluating a general PMC. This algorithm evaluates a general PMC recursively by decomposing it into smaller PMCs and disjoint face induced subcircuits. The smaller PMCs are evaluated recursively, while each face induced subcircuit is evaluated by Algorithm 3. We then show the correctness and complexity of Algorithm 4 in Lemma 5.1 and Theorem 5.1. A sketch of an algorithm similar to Algorithm 4 is given in [3].

LEMMA 5.1. *Each connected subcircuit in steps* 3 *and* 7 *is a general PMC with a complete input assignment.*

Proof. Since the gates in $\mathit{Reach}(P)$ can be coalesced into a single gate, the output gates in $C \setminus \mathit{Reach}(P)$ are in the same face. Similarly, the output gates in P and $P \setminus \mathit{Reach}(i_{(k+1)})$ are in the same face. The input nodes in $C \setminus \mathit{Reach}(P)$ are

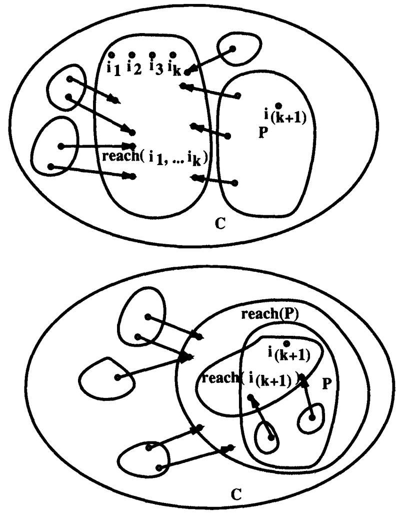

FIG. 10. *A general PMC C of size n, where P is a connected subcircuit of size $> n/2$ in $C \setminus reach(i_1, i_2, \ldots, i_k)$ but $C \setminus reach(i_1, i_2, \ldots, i_{(k+1)})$ does not contain any connected subcircuit of size $> n/2$.*

original input nodes in C. Since there is no wire in C outgoing from a gate in $C \setminus P$ to P, the input nodes in $P \setminus Reach(i_{(k+1)})$ are also original input nodes in C. Hence each connected subcircuit in $C \setminus Reach(P)$ and $P \setminus Reach(i_{(k+1)})$ is a general PMC with a complete input assignment, and can be completely evaluated recursively in step 3. A similar proof holds for step 7. □

LEMMA 5.2. *Each connected subcircuit in steps* 4, 6, *and* 8 *is a face induced circuit with a complete input assignment.*

Proof. The output gates in $Induced(i_{(k+1)}) \cap P$ are in the same face since they are a subset of the output gates in P. $Induced(i_{(k+1)}) \cap P$ are reachable from the original input $i_{(k+1)}$. The other new input nodes in $Induced(i_{(k+1)}) \cap P$ get their value from $P \setminus Reach(i_{(k+1)})$, which is completely evaluated in step 3. Hence $Induced(i_{(k+1)}) \cap P$ is a face f (that contains $i_{(k+1)}$) induced circuit with a complete input assignment and can be completely evaluated using Algorithm 3 in step 4.

The output gates in $Induced(o_1, \ldots, o_{m'})$ (i.e., $Reach(P) \setminus P$) are the output gates in $Reach(P)$, and the output gates in $Reach(P)$ are a subset of the output gates in C and are in the same face. The input nodes $o_1, \ldots, o_{m'}$ in $Reach(P) \setminus P$ are the output gates in P and are in the same face, which we call f_1, and are completely evaluated in steps 3 and 4. All gates in $Reach(P) \setminus P$ are reachable from the input nodes $o_1, \ldots, o_{m'}$ in f_1. The other input gates in $Reach(P) \setminus P$ get values from gates in $C \setminus Reach(P)$, which is completely evaluated in step 3. Hence $Induced(o_1, \ldots, o_{m'})$ (i.e., $Reach(P) \setminus P$) is a face f_1 induced circuit with a complete input assignment and can be completely evaluated using Algorithm 3 in step 6.

A similar proof holds for step 8. □

THEOREM 5.1. *Algorithm* 4 *correctly solves the PMCVP for a general PMC C and runs in $O(\log^6 n)$ time using n processors on an EREW PRAM, where n is the size of the circuit.*

Proof. The correctness of Algorithm 4 has been shown in Lemmas 5.1 and 5.2.

The reachability in steps 1, 3, and 7 can be implemented in $O(\log^4 n)$ time using

n processors on an EREW by the multiple-source reachability algorithm for planar digraphs in Guattery and Miller [10]. The k in step 1 can be found by a binary search. Hence the total time needed in step 1 is $O(\log^5 n)$. The connectivity of a plane undirected graph in steps 1, 3, and 7 can be solved in $O(\log n)$ time using n processors on an EREW by the algorithm in Gazit [5]. By Theorem 4.1, steps 4–6 and 8 can be implemented in $O(\log^4 n)$ time using n processors on an EREW. It is easy to see that the connected subcircuits in steps 3 and 7 are of size $\leq n/2$ and the subcircuits obtained in each step are disjoint. Let $T(n)$ be the time needed for Algorithm 4 to evaluate a PMC with n gates. We have

$$T(n) = T(n/2) + O(log^5 n).$$

Solving the above recurrence equation, we have $T(n) = O(\log^6 n)$. □

Note that the high power in the logarithm for the running time is mainly due to the running time of the reachability algorithms in [10] and [12]. An improvement in the running time of the parallel algorithms for reachability in a plane DAG would imply an improvement in the running time of our algorithm.

THE BOOLEAN HIERARCHY AND THE POLYNOMIAL HIERARCHY: A CLOSER CONNECTION*

RICHARD CHANG† AND JIM KADIN‡

Abstract. We show that if the Boolean hierarchy collapses to level k, then the polynomial hierarchy collapses to $\mathrm{BH}_3(k)$, where $\mathrm{BH}_3(k)$ is the kth level of the Boolean hierarchy over Σ_2^{P}. This is an improvement over the known results, which show that the polynomial hierarchy would collapse to $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[O(\log n)]}$. This result is significant in two ways. First, the theorem says that a deeper collapse of the Boolean hierarchy implies a deeper collapse of the polynomial hierarchy. Also, this result points to some previously unexplored connections between the Boolean and query hierarchies of Δ_2^{P} and Δ_3^{P}. Namely,

$$\mathrm{BH}(k) = \text{co-BH}(k) \Longrightarrow \mathrm{BH}_3(k) = \text{co-BH}_3(k),$$

$$\mathrm{P}^{\mathrm{NP}\|[k]} = \mathrm{P}^{\mathrm{NP}\|[k+1]} \Longrightarrow \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+1]} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+2]}.$$

1. Introduction.

The Boolean hierarchy (BH) was defined as the closure of NP under Boolean operations and is identical to the difference hierarchy of NP sets [1, 2, 7]. Kadin [3] showed that if the BH collapses at any level, the polynomial-time hierarchy (PH) collapses to $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[O(\log n)]}$, the class of languages in $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ that are recognized by deterministic polynomial-time machines that make $O(\log n)$ queries to an $\mathrm{NP}^{\mathrm{NP}}$ oracle. Since the BH is contained in P^{NP}, this result showed that the structure of classes above NP but within P^{NP} is related to the structure of the PH as a whole.

In this paper we extend Kadin's result by showing that if the BH collapses to its kth level (if $\mathrm{BH}(k) = \text{co-BH}(k)$), then the PH collapses to the kth level of the BH within Δ_3^{P} (the difference hierarchy of $\mathrm{NP}^{\mathrm{NP}}$ languages). That is,

$$\text{if } \mathrm{BH}(k) = \text{co-BH}(k), \text{ then } \mathrm{PH} \subseteq \mathrm{BH}_3(k)$$

(see §2 for precise definitions). The kth level of the Δ_3^{P} Boolean hierarchy ($\mathrm{BH}_3(k)$) is contained within $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[\log k+1]}$, the class of languages in $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ recognized by machines that make at most $\lceil \log k + 1 \rceil$ queries for all inputs. Therefore, the collapse of the BH implies that the languages within the PH can be recognized by deterministic polynomial-time machines that make a constant number of queries to an $\mathrm{NP}^{\mathrm{NP}}$ oracle, and the deeper the collapse of the BH, the smaller this constant is.

This result also yields two unexpected corollaries:

1. If $\mathrm{BH}(k) = \text{co-BH}(k)$, then $\mathrm{BH}_3(k) = \text{co-BH}_3(k)$.
2. If $\mathrm{P}^{\mathrm{NP}\|[k]} = \mathrm{P}^{\mathrm{NP}\|[k+1]}$, then $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+1]} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+2]}$.

The first corollary says that the collapse of the BH in Δ_2^{P} implies an identical collapse of the BH in Δ_3^{P}. The second corollary says that the bounded query hierarchies within Δ_2^{P} and Δ_3^{P} are linked. $\mathrm{P}^{\mathrm{NP}\|[k]}$ is the class of languages recognizable by deterministic polynomial-time machines that are allowed to ask k questions in parallel to an oracle from NP (all k queries must be asked at once, so no query can depend on the answers to other queries). $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k]}$ is the class of languages recognizable by deterministic polynomial-time machines that are allowed to ask k questions in parallel to an oracle from $\mathrm{NP}^{\mathrm{NP}}$. If the query hierarchy in Δ_2^{P} collapses, then the query hierarchy in Δ_3^{P} collapses to almost the same level. At first glance, one would think that these corollaries could be proven directly by a straightforward oracle replacement proof. However, the only proof that we know uses a refined version of Kadin's "hard/easy" formulas argument.

The "hard/easy" formulas argument [3, 5], which showed that the collapse of the BH implies the collapse of the PH, went as follows:

- If the BH collapses to its kth level, then the unsatisfiable Boolean formulas of each length n can be partitioned into "easy" and "hard" formulas. The easy formulas can be recognized as unsatisfiable by a particular NP algorithm, and the hard formulas cannot be recognized by this algorithm.
- The hard formulas are key strings, because sequences of at most $k-1$ hard formulas of length n contain enough information to allow an NP machine to recognize all the unsatisfiable formulas of length n.
- A sparse set S was constructed by taking one sequence of hard formulas for each length.
- Since co-NP $\subseteq \mathrm{NP}^S$, the results of Yap [8] imply that PH $\subseteq \Sigma_3^{\mathrm{P}}$.
- By arguing further that $S \in \mathrm{NP}^{\mathrm{NP}}$, it was shown that PH $\subseteq \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[O(\log n)]}$.[1]

In this paper we present a deeper analysis of the hard sequences. We show that it is not necessary to choose a particular hard sequence to put into S. In fact, a smaller amount of information, contained in a sparse set T, is enough to allow a Σ_2^{P} machine to recognize Σ_3^{P} languages, i.e.,

$$\mathrm{NP}^{\mathrm{NP}^{\mathrm{NP}}} \subseteq \mathrm{NP}^{T \oplus \mathrm{SAT}}.$$

Since $T \in \mathrm{NP}^{\mathrm{NP}}$ and is almost a tally set (T is a subset of a P-printable set), we are able to show that $\mathrm{NP}^{\mathrm{NP}^{\mathrm{NP}}}$ is contained in the $\mathrm{BH}_3(k)$.

2. Definitions and notation. We assume that the reader is familiar with the classes NPand co-NP, PH, and the NP-complete set SAT.

Notation. For any language L, $L^{\leq n}$ is the set of strings in L of length less than or equal to n. $L^{=n}$ is the set of strings in L of length n.

Notation. We will write π_j for the jth projection function, and $\pi_{(i,j)}$ for the function that selects the ith through jth elements of a k-tuple. For example,

$$\pi_j(\langle x_1, \ldots, x_k\rangle) = x_j,$$
$$\pi_{(1,j)}(\langle x_1, \ldots, x_k\rangle) = \langle x_1, \ldots, x_j\rangle.$$

Notation. We will assume a canonical encoding of the polynomial-time nondeterministic oracle Turing machines, $N_1, N_2, N_3, \ldots$, with effective composition, etc.

[1] Mahaney [6] has found an error in the proof presented in [3] and [5] that the set S is in $\mathrm{NP}^{\mathrm{NP}}$. See [4]. The argument presented in this paper does not use the erroneous reasoning and actually proves a stronger result.

Also, we will assume that all polynomials and running times used in this paper are at least $O(n)$ and are monotone increasing.

DEFINITION. *We write* BH(k) *and* co-BH(k) *for the kth levels of the* BH, *defined as follows:*

$$\mathrm{BH}(1) \overset{\mathrm{def}}{=} \mathrm{NP},$$

$$\mathrm{BH}(k+1) \overset{\mathrm{def}}{=} \{L_1 - L_2 \mid L_1 \in \mathrm{NP} \textit{ and } L_2 \in \mathrm{BH}(k)\},$$

$$\text{co-BH}(k) \overset{\mathrm{def}}{=} \{L \mid \overline{L} \in \mathrm{BH}(k)\}.$$

DEFINITION. *We write* BH$_3$(k) *and* co-BH$_3$(k) *for the kth levels of the* BH *in* Δ_3^{P}*, defined as follows:*

$$\mathrm{BH}_3(1) \overset{\mathrm{def}}{=} \mathrm{NP}^{\mathrm{NP}},$$

$$\mathrm{BH}_3(k+1) \overset{\mathrm{def}}{=} \{L_1 - L_2 \mid L_1 \in \mathrm{NP}^{\mathrm{NP}} \textit{ and } L_2 \in \mathrm{BH}_3(k)\},$$

$$\text{co-BH}_3(k) \overset{\mathrm{def}}{=} \{L \mid \overline{L} \in \mathrm{BH}_3(k)\}.$$

An equivalent way to define the BH *is as follows* [1]:

$$\mathrm{BH}(1) \overset{\mathrm{def}}{=} \mathrm{NP},$$

$$\mathrm{BH}(2k) \overset{\mathrm{def}}{=} \{L \mid L = L' \cap \overline{L_2}, \textit{where } L' \in \mathrm{BH}(2k-1) \textit{and } L_2 \in \mathrm{NP}\},$$

$$\mathrm{BH}(2k+1) \overset{\mathrm{def}}{=} \{L \mid L = L' \cup L_2, \textit{where } L' \in \mathrm{BH}(2k) \textit{and } L_2 \in \mathrm{NP}\},$$

$$\text{co-BH}(k) \overset{\mathrm{def}}{=} \{L \mid \overline{L} \in \mathrm{BH}(k)\}.$$

From this definition, it is not hard to prove that the following languages are complete for the respective levels of the BH under polynomial-time many–one reductions [1].

DEFINITION. *We write* $\mathrm{L}_{\mathrm{BH}(k)}$ *for the canonical complete language for* BH(k) *and* $\mathrm{L}_{\text{co-BH}(k)}$ *for the complete language for* co-BH(k):

$$\mathrm{L}_{\mathrm{BH}(1)} \overset{\mathrm{def}}{=} \mathrm{SAT},$$

$$\mathrm{L}_{\mathrm{BH}(2k)} \overset{\mathrm{def}}{=} \{\langle x_1, \ldots, x_{2k}\rangle \mid \langle x_1, \ldots, x_{2k-1}\rangle \in \mathrm{L}_{\mathrm{BH}(2k-1)} \textit{ and } x_{2k} \in \overline{\mathrm{SAT}}\},$$

$$\mathrm{L}_{\mathrm{BH}(2k+1)} \overset{\mathrm{def}}{=} \{\langle x_1, \ldots, x_{2k+1}\rangle \mid \langle x_1, \ldots, x_{2k}\rangle \in \mathrm{L}_{\mathrm{BH}(2k)} \textit{ or } x_{2k+1} \in \mathrm{SAT}\},$$

$$\mathrm{L}_{\text{co-BH}(1)} \overset{\mathrm{def}}{=} \overline{\mathrm{SAT}},$$

$$\mathrm{L}_{\text{co-BH}(2k)} \overset{\mathrm{def}}{=} \{\langle x_1, \ldots, x_{2k}\rangle \mid \langle x_1, \ldots, x_{2k-1}\rangle \in \mathrm{L}_{\text{co-BH}(2k-1)} \textit{ or } x_{2k} \in \mathrm{SAT}\},$$

$$\mathrm{L}_{\text{co-BH}(2k+1)} \overset{\mathrm{def}}{=} \{\langle x_1, \ldots, x_{2k+1}\rangle \mid \langle x_1, \ldots, x_{2k}\rangle \in \mathrm{L}_{\text{co-BH}(2k)} \textit{ and } x_{2k+1} \in \overline{\mathrm{SAT}}\}.$$

DEFINITION. L_{u_2} *and* L_{u_3} *are the canonical* $\leq_{\mathrm{m}}^{\mathrm{P}}$*-complete languages for* Σ_2^{P} *and* Σ_3^{P}*, respectively:*

$$L_{u_2} \overset{\mathrm{def}}{=} \{(N_j, x, 1^i) \mid N_j^{\mathrm{SAT}}(x) \textit{accepts in } \leq |x| + i \textit{ steps}\},$$

$$L_{u_3} \overset{\mathrm{def}}{=} \{(N_j, x, 1^i) \mid N_j^{L_{u_2}}(x) \textit{accepts in } \leq |x| + i \textit{ steps}\}.$$

3. An example for BH(2) = co-BH(2). In this section we outline the proof of the main theorem for the case $k = 2$. We want to show that if BH(2) = co-BH(2), then $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{BH}_3(2)$. This case contains the spirit of the proof of the main theorem and allows us to illustrate the proof without worrying about even and odd cases or messy indices.

If BH(2) = co-BH(2), then there is a reduction from $\mathrm{L}_{\mathrm{BH}(2)}$ to $\mathrm{L}_{\text{co-BH}(2)}$ via some polynomial-time function h. So, if $h(F_1, F_2) = (G_1, G_2)$, then

$$F_1 \in \mathrm{SAT} \text{ and } F_2 \in \overline{\mathrm{SAT}} \iff G_1 \in \overline{\mathrm{SAT}} \text{ or } G_2 \in \mathrm{SAT}.$$

The key is that h maps a conjunction to a disjunction. Both conditions of the conjunction are met if just one of the disjuncts is met. In the easy case, if G_2 is satisfiable, then F_1 is satisfiable and F_2 *is not satisfiable.* This gives rise to an NP algorithm for recognizing some of $\overline{\mathrm{SAT}}$: Given any formula F_2, guess a formula F_1 with $|F_1| \leq |F_2|$ and accept if $\pi_2 \circ h(F_1, F_2) \in \mathrm{SAT}$.

Formulas that can be recognized as unsatisfiable by this NP algorithm are said to be *easy.* Formally, a Boolean formula F is easy if $\exists F_1$ with $|F_1| \leq |F|$ and $\pi_2 \circ h(F_1, F) \in \mathrm{SAT}$. If all unsatisfiable formulas are easy, then co-NP = NP. So it is likely that there are *hard* unsatisfiable formulas. We say a formula F is *hard* if

1. $F \in \overline{\mathrm{SAT}}$,
2. $\forall F_1$ with $|F_1| \leq |F|$, $\pi_2 \circ h(F_1, F) \in \overline{\mathrm{SAT}}$.

While the set of hard strings is probably not in NP (note that it is in co-NP), an individual hard formula of length m encodes enough information to allow an NP machine to recognize all of $\overline{\mathrm{SAT}}^{\leq m}$. Let F be a hard formula of length m. Suppose F_1 is any formula of length $\leq m$ and $h(F_1, F) = (G_1, G)$. Since F is hard, we know that $F \in \overline{\mathrm{SAT}}$ and $G \in \overline{\mathrm{SAT}}$. Recall that

$$F_1 \in \mathrm{SAT} \text{ and } F \in \overline{\mathrm{SAT}} \iff G_1 \in \overline{\mathrm{SAT}} \text{ or } G \in \mathrm{SAT}.$$

Replacing $F \in \overline{\mathrm{SAT}}$ with "true" and $G \in \mathrm{SAT}$ with "false," we get

$$F_1 \in \mathrm{SAT} \iff G_1 \in \overline{\mathrm{SAT}},$$

or (by negating both sides of the iff)

$$F_1 \in \overline{\mathrm{SAT}} \iff G_1 \in \mathrm{SAT}.$$

So, given the hard string F, an NP machine can recognize if $F_1 \in \overline{\mathrm{SAT}}^{\leq m}$ by computing $G_1 = \pi_1 \circ h(F_1, F)$ and verifying that $G_1 \in \mathrm{SAT}$. In other words, a hard formula of length m and the reduction from BH(2) to co-BH(2) induce a reduction from $\overline{\mathrm{SAT}}^{\leq m}$ to SAT.

The approach taken by Kadin [3] was to encode enough information into a sparse set S so that an NP^S machine could get hold of a hard string of a given length or determine that there was none. Then the NP^S machine could recognize $\overline{\mathrm{SAT}}$, implying that co-NP $\subseteq \mathrm{NP}^S$ and that the PH collapses [8].

In this paper we take a slightly different approach to show that the collapse of the BH implies a deeper collapse of the PH. Rather than constructing a sparse oracle that allows an NP machine to recognize $\overline{\mathrm{SAT}}$, we show that there is a smaller amount of information, essentially a tally set, that allows an $\mathrm{NP}^{\mathrm{NP}}$ machine to recognize the complete language for Σ_3^{P}. For the case where BH(2) = co-BH(2), this information is the tally set

$$T \stackrel{\mathrm{def}}{=} \{1^m \mid \exists \text{ a hard formula of length } m\}.$$

First we show that $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{NP}^{T \oplus \mathrm{NP}}$. Since the set of hard formulas is in co-NP, if we tell an $\mathrm{NP}^{\mathrm{NP}}$ machine that there is a hard formula of length m, it can guess a hard formula and verify with one query that it is hard. With that formula, the $\mathrm{NP}^{\mathrm{NP}}$ machine can produce an NP algorithm that recognizes $\overline{\mathrm{SAT}}^{=m}$. If we tell an $\mathrm{NP}^{\mathrm{NP}}$ machine that there are no hard formulas of length m, then it knows that the "easy" NP algorithm recognizes all of $\overline{\mathrm{SAT}}^{=m}$. In either case, the $\mathrm{NP}^{\mathrm{NP}}$ machine can use an NP algorithm for $\overline{\mathrm{SAT}}^{=m}$ to remove one level of oracle querying from a Σ_3^{P} machine and therefore recognize any Σ_3^{P} language.

Now we show that $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[2]}$. Since an $\mathrm{NP}^{\mathrm{NP}}$ machine can guess and verify hard formulas, $T \in \mathrm{NP}^{\mathrm{NP}}$. This implies that a $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine can tell with one query if there are any hard formulas of a given length. Since this is exactly what an $\mathrm{NP}^{\mathrm{NP}}$ machine needs to recognize a Σ_3^{P} language, the $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine can pass the information in one more $\mathrm{NP}^{\mathrm{NP}}$ query and therefore recognize a Σ_3^{P} language with only two queries. Hence $\mathrm{BH}(2) = \text{co-BH}(2)$ implies $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[2]}$, the class of languages recognizable in deterministic polynomial-time with two queries to $\mathrm{NP}^{\mathrm{NP}}$.

With more work, we can show that Σ_3^{P} is actually contained in the second level of the Δ_3^{P} BH.

4. Main result. We can generalize the analysis of the previous section to higher levels of the BH by replacing the concept of hard formulas with the concept of *hard sequences* of formulas. Just as an individual hard formula could be used with the reduction from BH(2) to co-BH(2) to induce a reduction from $\overline{\mathrm{SAT}}$ to SAT, a hard sequence is a j-tuple that can be used with a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from BH($k$) to co-BH($k$) to define a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from BH($k-j$) to co-BH($k-j$).

DEFINITION. *Suppose* $L_{\mathrm{BH}(k)} \leq_{\mathrm{m}}^{\mathrm{P}} L_{\text{co-BH}(k)}$ *via some polynomial-time function* h. *Then we call* $\langle 1^m, x_1, \ldots, x_j \rangle$ *a* hard sequence *with respect to* h *if* $j = 0$ *or if all of the following hold:*

1. $1 \leq j \leq k-1$.
2. $|x_j| \leq m$.
3. $x_j \in \overline{\mathrm{SAT}}$.
4. $\langle 1^m, x_1, \ldots, x_{j-1} \rangle$ *is a hard sequence with respect to* h.
5. *For all* $y_1, \ldots, y_\ell \in \Sigma^{\leq m}$ *(where* $\ell = k - j$*),*

$$\pi_{\ell+1} \circ h(\langle y_1, \ldots, y_\ell, x_j, \ldots, x_1 \rangle) \in \overline{\mathrm{SAT}}.$$

If $\langle 1^m, x_1, \ldots, x_j \rangle$ is a hard sequence, then we refer to j as the *order* of the sequence and say that it is a hard sequence for length m. Also, we will call a hard sequence *maximal* if it cannot be extended to a hard sequence of higher order. We say that j is the maximum order for length m if there is a hard sequence of order j for length m and there is no hard sequence of order $j+1$ for length m. Finally, when the individual strings $x_1, \ldots, x_j$ are of no importance, we use the shortened notation $\langle 1^m, \vec{x} \rangle$ instead of $\langle 1^m, x_1, \ldots, x_j \rangle$.

Our proof that $\mathrm{BH} \subseteq \mathrm{BH}(k)$ implies $\mathrm{PH} \subseteq \mathrm{BH}_3(k)$ is rather involved. All of our lemmas and theorems start with the assumption that $\mathrm{BH}(k) = \text{co-BH}(k)$ or, in other words, that there exists a function h that is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $L_{\mathrm{BH}(k)}$ to $L_{\text{co-BH}(k)}$. First we show that a hard sequence of order j for length m does indeed induce a reduction from $L_{\mathrm{BH}(k-j)}$ to $L_{\text{co-BH}(k-j)}$ (Lemma 4.1). Then we show that a maximal hard sequence for length m induces a polynomial-time reduction from $\overline{\mathrm{SAT}}^{\leq m}$ to SAT (Lemma 4.2). In Lemma 4.3 we argue that given a maximal hard sequence, an NP machine can recognize an initial segment of L_{u_2}, the canonical complete language for

Σ_2^{P}. Lemma 4.4 takes this a step further by showing that given the maximum order of hard sequences for a length, an $\mathrm{NP}^{\mathrm{NP}}$ machine can recognize an initial segment of L_{u_3}, the canonical complete language for Σ_3^{P}. We then define the set T which encodes the orders of hard sequences for each length, and we show that $T \in \mathrm{NP}^{\mathrm{NP}}$ (Lemma 4.5). We put all this analysis together in Theorem 4.6 and show that $\mathrm{BH}(k) = \text{co-BH}(k)$ implies $\mathrm{PH} \subseteq \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[k]}$.

Moving toward the Δ_3^{P} BH, we prove that an NP machine can recognize if there is a hard sequence of order j for length m if it is given a hard sequence for a polynomially longer length (Lemma 4.7). In Lemma 4.8 we show that the maximum order of hard sequences for a length is enough information to permit an $\mathrm{NP}^{\mathrm{NP}}$ machine to recognize when a string *is not in* L_{u_3}; that is, the $\mathrm{NP}^{\mathrm{NP}}$ machine can recognize an initial segment of a complete language for Π_3^{P}. Finally, this gives us the machinery to prove our main theorem.

We start by showing that a hard sequence of order j for length m induces a reduction from $\mathrm{L}_{\mathrm{BH}(k-j)}$ to $\mathrm{L}_{\text{co-BH}(k-j)}$ for tuples of strings up to length m.

LEMMA 4.1. *Suppose* $\mathrm{L}_{\mathrm{BH}(k)} \leq_{\mathrm{m}}^{\mathrm{P}} \mathrm{L}_{\text{co-BH}(k)}$ *via some function* h *and* $\langle 1^m, x_1, \ldots, x_j\rangle$ *is a hard sequence with respect to* h. *Then for all* $y_1, \ldots, y_\ell \in \Sigma^{\leq m}$ *(where* $\ell = k - j$*),*

$$\langle y_1, \ldots, y_\ell\rangle \in \mathrm{L}_{\mathrm{BH}(\ell)} \iff \pi_{(1,\ell)} \circ h(\langle y_1, \ldots, y_\ell, x_j, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell)}.$$

Proof (by induction on j).

Induction hypothesis $P(j)$. For all $y_1, \ldots, y_{k-j} \in \Sigma^{\leq m}$

$$\langle y_1, \ldots, y_{k-j}\rangle \in \mathrm{L}_{\mathrm{BH}(k-j)} \iff \pi_{(1,k-j)} \circ h(\langle y_1, \ldots, y_{k-j}, x_j, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(k-j)}.$$

Base case $P(0)$. By the hypothesis of the lemma, h reduces $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$, so

$$\langle y_1, \ldots, y_k\rangle \in \mathrm{L}_{\mathrm{BH}(k)} \iff h(\langle y_1, \ldots, y_k\rangle) \in \mathrm{L}_{\text{co-BH}(k)}.$$

However, $\pi_{(1,k)} \circ h(\langle y_1, \ldots, y_k\rangle) = h(\langle y_1, \ldots, y_k\rangle)$, so

$$\langle y_1, \ldots, y_k\rangle \in \mathrm{L}_{\mathrm{BH}(k)} \iff \pi_{(1,k)} \circ h(\langle y_1, \ldots, y_k\rangle) \in \mathrm{L}_{\text{co-BH}(k)}.$$

Induction case $P(j+1)$. Suppose $P(j)$ holds. Let $\ell = k - j$. Let $\langle 1^m, x_1, \ldots, x_{j+1}\rangle$ be a hard sequence. By the induction hypothesis, for all $y_1, \ldots, y_{\ell-1} \in \Sigma^{\leq m}$,

$$\langle y_1, \ldots, y_{\ell-1}, x_{j+1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell)} \iff \pi_{(1,\ell)} \circ h(\langle y_1, \ldots, y_{\ell-1}, x_{j+1}, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell)}.$$

If ℓ is even, then by the definitions of $\mathrm{L}_{\mathrm{BH}(\ell)}$ and $\mathrm{L}_{\text{co-BH}(\ell)}$,

(1)
$$\begin{array}{lcl} \langle y_1, \ldots, y_{\ell-1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)} \circ h(\langle y_1, \ldots, y_{\ell-1}, x_{j+1}, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \quad \text{and } x_{j+1} \in \overline{\mathrm{SAT}} & \iff & \text{or } \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, x_{j+1}, \ldots, x_1\rangle) \in \mathrm{SAT}. \end{array}$$

If ℓ is odd, then by the definitions of $\mathrm{L}_{\mathrm{BH}(\ell)}$ and $\mathrm{L}_{\text{co-BH}(\ell)}$,

(2)
$$\begin{array}{lcl} \langle y_1, \ldots, y_{\ell-1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)} \circ h(\langle y_1, \ldots, y_{\ell-1}, x_{j+1}, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \quad \text{or } x_{j+1} \in \mathrm{SAT} & \iff & \text{and } \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, x_{j+1}, \ldots, x_1\rangle) \in \overline{\mathrm{SAT}} \end{array}$$

or (by negating both sides of the iff)

(3)

$$\begin{array}{ccc} \langle y_1,\dots,y_{\ell-1}\rangle \notin \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)}{\circ}h(\langle y_1,\dots,y_{\ell-1},x_{j+1},\dots,x_1\rangle) \notin \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \text{and } x_{j+1}\in\overline{\mathrm{SAT}} & \iff & \text{or } \pi_\ell{\circ}h(\langle y_1,\dots,y_{\ell-1},x_{j+1},\dots,x_1\rangle)\in \mathrm{SAT}. \end{array}$$

Since $\langle 1^m, x_1,\dots,x_{j+1}\rangle$ is a hard sequence, we know from parts 3 and 5 of the definition of a hard sequence that $x_{j+1}\in\overline{\mathrm{SAT}}$ and

$$\pi_\ell{\circ}h(\langle y_1,\dots,y_{\ell-1},x_{j+1},\dots,x_1\rangle)\in\overline{\mathrm{SAT}}.$$

Therefore, in equations (1) and (3), the second conjunct on the left side is true and the second disjunct on the right side is false. Hence

$$\langle y_1,\dots,y_{\ell-1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell-1)} \iff \pi_{(1,\ell-1)}{\circ}h(\langle y_1,\dots,y_{\ell-1},x_{j+1},\dots,x_1\rangle)\in \mathrm{L}_{\text{co-BH}(\ell-1)}.$$

Then, replacing $k-j$ for ℓ, we have

$$\begin{gathered} \langle y_1,\dots,y_{k-(j+1)}\rangle \in \mathrm{L}_{\mathrm{BH}(k-(j+1))} \\ \iff \\ \pi_{(1,k-(j+1))}{\circ}h(\langle y_1,\dots,y_{k-(j+1)},x_{j+1},\dots,x_1\rangle)\in \mathrm{L}_{\text{co-BH}(k-(j+1))}. \end{gathered}$$

So, we have established the induction hypothesis $P(j+1)$. □

Lemma 4.2 shows that a maximal hard sequence for length m induces a polynomial-time reduction from $\overline{\mathrm{SAT}}^{\le m}$ to SAT or, in other words, given a maximal hard sequence for length m, an NP machine can recognize $\overline{\mathrm{SAT}}^{\le m}$.

LEMMA 4.2. *Suppose* $\mathrm{L}_{\mathrm{BH}(k)} \le^{\mathrm{P}}_{\mathrm{m}} \mathrm{L}_{\text{co-BH}(k)}$ *via some function h and* $\langle 1^m, x_1,\dots,x_j\rangle$ *is a maximal hard sequence with respect to h. Then for all* $y\in\Sigma^{\le m}$

$$\begin{gathered} y\in\overline{\mathrm{SAT}} \\ \iff \\ \exists\, y_1,\dots,y_{\ell-1}\in\Sigma^{\le m}\quad \pi_\ell{\circ}h(\langle y_1,\dots,y_{\ell-1},y,x_j,\dots,x_1\rangle)\in\mathrm{SAT} \end{gathered}$$

(where $\ell = k-j$*).*

Proof. If $j=k-1$ ($\langle y_1,\dots,y_{\ell-1}\rangle$ is the empty sequence), then by Lemma 4.1, for all $y\in\Sigma^{\le m}$,

$$y\in\mathrm{BH}(1) \iff \pi_1{\circ}h(\langle y,x_j,\dots,x_1\rangle)\in\text{co-BH}(1).$$

However, BH(1) = SAT and co-BH(1) = $\overline{\mathrm{SAT}}$. So, we have

$$y\in\mathrm{SAT} \iff \pi_1{\circ}h(\langle y,x_j,\dots,x_1\rangle)\in\overline{\mathrm{SAT}}$$

or (by negating both sides of the iff)

$$y\in\overline{\mathrm{SAT}} \iff \pi_1{\circ}h(\langle y,x_j,\dots,x_1\rangle)\in\mathrm{SAT}.$$

Thus, the lemma holds when $j=k-1$ (i.e., when $y_1,\dots,y_{\ell-1}$ is the empty sequence).

Consider the case when $j<k-1$.

($\Rightarrow$) Suppose $y\in\overline{\mathrm{SAT}}$. Since $\langle 1^m,x_1,\dots,x_j\rangle$ is maximal, $\langle 1^m,x_1,\dots,x_j,y\rangle$ is not a hard sequence. However, $j+1\le k-1$, $|y|\le m$, $y\in\overline{\mathrm{SAT}}$, and $\langle 1^m,x_1,\dots,x_j\rangle$

is a hard sequence. So, $\langle 1^m, x_1, \ldots, x_j, y\rangle$ must fail to be a hard sequence by failing to satisfy condition 5 of the definition of hard sequences. Thus

$$\exists\, y_1, \ldots, y_{\ell-1} \in \Sigma^{\leq m} \quad \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{SAT}.$$

($\Leftarrow$) Suppose that for some $y_1, \ldots, y_{\ell-1} \in \Sigma^{\leq m}$,

$$\pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{SAT}.$$

Since $\langle x_1, \ldots, x_j\rangle$ is a hard sequence for length m, by Lemma 4.1

$$\langle y_1, \ldots, y_{\ell-1}, y\rangle \in \mathrm{L}_{\mathrm{BH}(\ell)} \iff \pi_{(1,\ell)} \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell)}.$$

If ℓ is even, then by the definitions of $\mathrm{L}_{\mathrm{BH}(\ell)}$ and $\mathrm{L}_{\text{co-BH}(\ell)}$,

(4)

$$\begin{array}{lcl} \langle y_1, \ldots, y_{\ell-1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)} \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \quad \text{and } \ y \in \overline{\mathrm{SAT}} & \iff & \text{or } \ \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{SAT}. \end{array}$$

If ℓ is odd, then by the definitions of $\mathrm{L}_{\mathrm{BH}(\ell)}$ and $\mathrm{L}_{\text{co-BH}(\ell)}$,

(5)

$$\begin{array}{lcl} \langle y_1, \ldots, y_{\ell-1}\rangle \in \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)} \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \quad \text{or } \ y \in \mathrm{SAT} & \iff & \text{and } \ \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \overline{\mathrm{SAT}} \end{array}$$

or (by negating both sides of the iff)

(6)

$$\begin{array}{lcl} \langle y_1, \ldots, y_{\ell-1}\rangle \notin \mathrm{L}_{\mathrm{BH}(\ell-1)} & & \pi_{(1,\ell-1)} \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \notin \mathrm{L}_{\text{co-BH}(\ell-1)} \\ \quad \text{and } \ y \in \overline{\mathrm{SAT}} & \iff & \text{or } \ \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{SAT}. \end{array}$$

In either case, we already know by hypothesis that

$$\pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1\rangle) \in \mathrm{SAT},$$

so the right sides of the iff in equations (4) and (6) are satisfied. Therefore, the left sides of equations (4) and (6) must also be satisfied, and we have $y \in \overline{\mathrm{SAT}}$. □

Lemma 4.2 essentially states that a maximal hard sequence produces a way to witness that a formula is unsatisfiable. Hence, given a maximal hard sequence, an NP machine can guess these witnesses and verify that formulas up to a certain length are unsatisfiable. But if an NP machine can verify that formulas are unsatisfiable, it can simulate an $\mathrm{NP}^{\mathrm{NP}}$ computation by guessing the answer to each NP query and verifying that its answer is correct. We use this idea to prove Lemma 4.3, which states that given a maximal hard sequence, an NP machine can recognize an initial segment of L_{u_2}, the canonical complete language for Σ_2^{P}.

LEMMA 4.3. *Suppose h is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$. Then there exist an* NP *machine N_{σ_2} and a polynomial p_{σ_2} such that if $m \geq p_{\sigma_2}(|w|)$ and $\langle 1^m, x_1, \ldots, x_j\rangle$ is a maximal hard sequence w.r.t. h, then*

$$w \in L_{u_2} \iff N_{\sigma_2}(w, \langle 1^m, x_1, \ldots, x_j\rangle) \ \textit{accepts}.$$

Proof. Let $L_{u_2} = L(N_{u_2}^{\mathrm{SAT}})$. Define $p_{\sigma_2}(n)$ to be the upper bound on the running time of N_{u_2} on inputs of length n. Obviously, $N_{u_2}(w)$ queries only strings of length $\leq m$, since $m \geq p_{\sigma_2}(|w|)$. On input $(w, \langle 1^m, x_1, \ldots, x_j\rangle)$, N_{σ_2} does the following:

1. Simulate N_{u_2} step by step until N_{u_2} makes an oracle query to SAT.
2. When N_{u_2} queries "$y \in \text{SAT}$?", branch into two computations. One guesses that $y \in \text{SAT}$; the other guesses that $y \in \overline{\text{SAT}}$.
3. The branch that guesses $y \in \text{SAT}$ will guess a satisfying assignment for y. If none are found, all computations along this branch terminate. If a satisfying assignment is found, then the guess that $y \in \text{SAT}$ is correct and the simulation continues.
4. The branch that guesses $y \in \overline{\text{SAT}}$ will use the maximal hard sequence to find a witness for $y \in \overline{\text{SAT}}$, i.e., it guesses $\ell - 1$ strings $y_1, \ldots, y_{\ell-1} \in \Sigma^{\leq m}$, computes

$$F = \pi_\ell \circ h(\langle y_1, \ldots, y_{\ell-1}, y, x_j, \ldots, x_1 \rangle),$$

and guesses a satisfying assignment for F. If none are found, all computations along this branch terminate. Otherwise, the guess that $y \in \overline{\text{SAT}}$ is correct and the simulation continues.

By Lemma 4.2, if $\langle 1^m, x_1, \ldots, x_j \rangle$ is a maximal hard sequence, then for each query y, $y \in \overline{\text{SAT}}$ iff some computation in step 4 finds a satisfiable F. So, in the simulation of the oracle query, all the computations along one branch will terminate and some computations in the other branch will continue. Thus the simulation continues iff the guesses for the oracle answers (either $y \in \text{SAT}$ or $y \in \overline{\text{SAT}}$) are verified, and hence

$$w \in L(N_{u_2}^{\text{SAT}}) \iff N_{\sigma_2}(w, \langle 1^m, x_1, \ldots, x_j \rangle) \text{ accepts.} \qquad \square$$

Taking the spirit of Lemma 4.3 one step further, we show that with the help of a maximal hard sequence, an NP^{NP} machine can simulate a Σ_3^{P} machine. In addition, an NP^{NP} machine can guess and verify hard sequences, so it does not need to be given a maximal hard sequence; all it really needs is the *maximum order.* Therefore, there exists an NP^{NP} machine which, given the maximum order of hard sequences for a length, can recognize initial segments of L_{u_3}, the complete language for Σ_3^{P}.

LEMMA 4.4. *Suppose h is a $\leq_{\text{m}}^{\text{P}}$-reduction from $\text{L}_{\text{BH}(k)}$ to $\text{L}_{\text{co-BH}(k)}$. There exist an NP^{SAT} machine N_{σ_3} and a polynomial p_{σ_3} such that for any $m \geq p_{\sigma_3}(|w|)$, if j is the maximum order for length m w.r.t. h, then*

$$w \in L_{u_3} \iff N_{\sigma_3}^{\text{SAT}}(w, j, 1^m) \text{ accepts.}$$

Furthermore, if j is greater than the maximum order for length m w.r.t. h,

$$\forall w \;\; N_{\sigma_3}^{\text{SAT}}(w, j, 1^m) \text{ rejects.}$$

Proof. Let $L_{u_3} = L(N_{u_3}^{L_{u_2}})$, where $L_{u_2} = L(N_{u_2}^{\text{SAT}})$ is the canonical complete language for Σ_2^{P}. Let $r(n)$ be a polynomial upper bound on the running time of N_{u_3} on inputs of length n. Clearly, $N_{u_3}(w)$ will query only strings of length $\leq r(n)$, where $n = |w|$. Apply Lemma 4.3 to obtain N_{σ_2} and the polynomial p_{σ_2}. Let $p_{\sigma_3}(n) \overset{\text{def}}{=} p_{\sigma_2}(r(n))$.

The critical observation to make here is that the set of hard sequences is in co-NP. (This is obvious from the definition of hard sequences.) So, given j, the maximum order for length $m \geq p_{\sigma_3}(n)$, an NP^{NP} machine can guess j strings $x_1, \ldots, x_j \in \Sigma^{\leq m}$ and ask the NP oracle if $\langle 1^m, x_1, \ldots, x_j \rangle$ forms a hard sequence. If $\langle 1^m, x_1, \ldots, x_j \rangle$ does form a hard sequence, then it must also be a maximal sequence since it is of maximum order. Now, $N_{\sigma_3}^{\text{SAT}}(w, j, 1^m)$ can simulate $N_{u_3}^{L_{u_2}}(w)$ step by step, and when

N_{u_3} queries "$y \in L_{u_2}$?", N_{σ_3} will ask "$(y, \langle 1^m, x_1, \ldots, x_j\rangle) \in L(N_{\sigma_2})$." By Lemma 4.3 the two queries will return with the same answers, so

$$w \in L(N_{u_3}^{L_{u_2}}) \iff N_{\sigma_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts.}$$

Note that when N_{σ_3} guesses the hard sequence $\langle 1^m, x_1, \ldots, x_j\rangle$, several computation paths of the NP machine may survive because there may be many hard sequences of maximum order. However, uniqueness is not important here because any maximal hard sequence will work for N_{σ_2}. So, all the computation branches that manage to guess a hard sequence of maximum order will have the same acceptance behavior. Furthermore, if j is greater than the maximum order, then none of the computation paths survive because there are no hard sequences of order j for length m. Thus, in this case, $N_{\sigma_3}(w, j, 1^m)$ will reject. □

We have shown that maximal hard sequences and maximum orders expand the computational power of nondeterministic machines. We define the set T to be the set of strings encoding the orders of hard sequences for each length.

DEFINITION. *Suppose h is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$. We define an associated set T by*

$$T \stackrel{\text{def}}{=} \{(1^m, j) \mid \exists x_1, \ldots, x_j \in \Sigma^{\leq m}, \text{s.t. } \langle 1^m, x_1, \ldots, x_j\rangle \textit{ is a hard sequence.}\}$$

Note that since the set of hard sequences is in co-NP, T itself is in $\mathrm{NP}^{\mathrm{NP}}$. This gives us the following lemma.

LEMMA 4.5. *Suppose h is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$. Then the set T defined above is in* $\mathrm{NP}^{\mathrm{NP}}$. □

Since $T \in \mathrm{NP}^{\mathrm{NP}}$, a $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine can compute the order of the maximum hard sequence for length m with $k-1$ queries. The $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine can then pass this number to the $\mathrm{NP}^{\mathrm{NP}}$ machine $N_{\sigma_3}^{\mathrm{SAT}}$ of Lemma 4.4 to recognize L_{u_3}, the complete language for Σ_3^{P}. Therefore, if the BH collapses to its kth level, Lemmas 4.4 and 4.5 imply that the PH collapses to $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[k]}$. This collapse of the PH implied by the collapse of the BH is lower than previously known.

THEOREM 4.6. *Suppose h is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$. Then there exists a $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine which accepts L_{u_3} with only k queries to the $\mathrm{NP}^{\mathrm{NP}}$ oracle. That is, the PH collapses to $\mathrm{P}^{(\mathrm{NP}^{\mathrm{NP}})[k]}$.*

Proof. By Lemma 4.4, there exists N_{σ_3} and p_{σ_3} such that if j is the maximum order for length m and $m \geq p_{\sigma_3}(|w|)$, then

$$w \in L_{u_3} \iff N_{\sigma_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts.}$$

Using the fact that T is in $\mathrm{NP}^{\mathrm{NP}}$ (Lemma 4.5), a $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine can determine if $(1^m, \ell)$ is in T by asking the oracle. Doing this for all values of ℓ between 1 and $k-1$, it can determine the maximum ℓ such that $(1^m, \ell)$ is in T. This maximum ℓ—call it j—is, of course, the maximum order for length m. Then with one final query, the $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ machine asks if

$$N_{\sigma_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts.}$$

If the oracle answers "yes," the machine accepts. Otherwise, it rejects. □

Note that we could make Theorem 4.6 stronger by using binary search instead of linear search to find the maximum order. However, we will push the collapse even further in Theorem 4.9, so our inquiry will follow a new direction.

The following lemma states that an NP machine can recognize if there is a hard sequence of order j for length m if it is given a maximal hard sequence for a longer length.

LEMMA 4.7. *Suppose h is a $\leq_{\rm m}^{\rm P}$-reduction from $\rm L_{BH(k)}$ to $\rm L_{co\text{-}BH(k)}$. There exist an* NP *machine N_t and a polynomial p_t such that if $\langle 1^{m_2}, \vec{x}\,\rangle$ is a maximal hard sequence w.r.t. h and $m_2 \geq p_t(m_1 + k)$, then*

$$(1^{m_1}, j_1) \in T \iff N_t((1^{m_1}, j_1), \langle 1^{m_2}, \vec{x}\,\rangle) \text{ accepts.}$$

Proof. Use Lemmas 4.3 and 4.5. □

In Lemma 4.4 we showed that, with the help of the maximum order, an $\rm NP^{NP}$ machine can recognize a complete language for $\Sigma_3^{\rm P}$. In the next lemma we show that with the help of the maximum order, an $\rm NP^{NP}$ machine can also recognize a complete language for $\Pi_3^{\rm P}$ (i.e., recognize when a string is *not* in L_{u_3}).

LEMMA 4.8. *Suppose h is a $\leq_{\rm m}^{\rm P}$-reduction from $\rm L_{BH(k)}$ to $\rm L_{co\text{-}BH(k)}$. Let L_{u_3} be the canonical complete language for $\Sigma_3^{\rm P}$. There exist an $\rm NP^{SAT}$ machine N_{π_3} and a polynomial p_{π_3} such that for any $m \geq p_{\pi_3}(|w|)$, if j is the maximum order for length m w.r.t. h, then*

$$w \in \overline{L_{u_3}} \iff N_{\pi_3}^{\rm SAT}(w, j, 1^m) \text{ accepts.}$$

Furthermore, if j is greater than the maximum order for length m w.r.t. h,

$$\forall w \quad N_{\pi_3}^{\rm SAT}(w, j, 1^m) \text{ rejects.}$$

Proof. Let $L_{u_3} = L(N_{u_3}^{L_{u_2}})$ where L_{u_2} is the canonical complete language for $\Sigma_2^{\rm P}$. By Lemma 4.4, there exist N_{σ_3} and p_{σ_3} such that if j_1 is the maximum order for length m_1 and $m_1 \geq p_{\sigma_3}(|w|)$, then

$$w \in L_{u_3} \iff N_{\sigma_3}^{\rm SAT}(w, j_1, 1^{m_1}) \text{ accepts.}$$

The language accepted by $N_{\sigma_3}^{\rm SAT}$ is in $\Sigma_2^{\rm P}$, so we can reduce it to L_{u_2} via some polynomial-time function g. Let $r(n)$ be an upper bound on the running time of g. Using Lemma 4.3, we see that there exist N_{σ_2} and p_{σ_2} such that if $\langle 1^{m_2}, \vec{y}\,\rangle$ is a maximal hard sequence and $m_2 \geq p_{\sigma_2}(r(|w| + k + m_1))$, then

$$N_{\sigma_3}^{\rm SAT}(w, j_1, 1^{m_1}) \text{ accepts} \iff N_{\sigma_2}(g(w, j_1, 1^{m_1}), \langle 1^{m_2}, \vec{y}\,\rangle) \text{ accepts.}$$

Let N_s be the NP machine that runs the reduction g and then simulates N_{σ_2}, i.e.,

$$N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\,\rangle) \text{ accepts} \iff N_{\sigma_2}(g(w, j_1, 1^{m_1}), \langle 1^{m_2}, \vec{y}\,\rangle) \text{ accepts.}$$

Let $p_s \stackrel{\rm def}{=} p_{\sigma_2} \circ r$. Now, if $m_1 \geq p_{\sigma_3}(|w|)$, $m_2 \geq p_s(|w| + k + m_1)$, j_1 is the maximum order for length m_1 and $\langle 1^{m_2}, \vec{y}\,\rangle$ is a maximal hard sequence, then

$$(7)\ w \in L_{u_3} \iff N_{\sigma_3}^{\rm SAT}(w, j_1, 1^{m_1}) \text{ accepts} \iff N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\,\rangle) \text{ accepts.}$$

We are trying to prove that there exists a machine $N_{\pi_3}^{\rm SAT}$ that accepts $(w, j, 1^m)$ if $w \notin L_{u_3}$ when m is big enough in relation to $|w|$ and j is the maximum order of the hard sequences for length m. The $N_{\pi_3}^{\rm SAT}$ that we have in mind will map

$$(w, j, 1^m) \longrightarrow (w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\,\rangle)$$

and accept iff $N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\rangle)$ rejects (iff $w \notin L_{u_3}$). $N_{\pi_3}^{\mathrm{SAT}}$ can tell if $N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\rangle)$ rejects with one query to SAT.

The difficulty in mapping $(w, j, 1^m) \longrightarrow (w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\rangle)$ lies in the fact that $N_{\pi_3}^{\mathrm{SAT}}$ is given j, the maximum order of hard sequences for one length m, and it must compute the maximum orders of two other lengths, m_1 and m_2. We will define p_{π_3} so that if $m \geq p_{\pi_3}(|w|)$, then m will be bigger enough than both m_1 and m_2 so that we can apply Lemma 4.7 to compute j_1 and j_2.

Let $p_{\pi_3}(n) \overset{\mathrm{def}}{=} p_t(p_s(n + k + p_{\sigma_3}(n)) + k)$, i.e., $p_{\pi_3}(n) = p_t(m_2 + k)$ where $m_2 = p_s(n+k+m_1)$ and $m_1 = p_{\sigma_3}(n)$ (recall p_t is the polynomial bound from Lemma 4.7).

$N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m)$ will do the following. (We will annotate the program with a description of what $N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m)$ accomplishes when j is the maximum order.)

1. Reject if $m < p_{\pi_3}(|w|)$.
2. Guess j strings $x_1, \ldots, x_j \in \Sigma^{\leq m}$ and confirm that $\langle 1^m, x_1, \ldots, x_j\rangle = \langle 1^m, \vec{x}\rangle$ is a hard sequence by asking the SAT oracle. (Recall that checking if a given tuple forms a hard sequence is a co-NP question.) If j is the maximum order and $\langle 1^m, \vec{x}\rangle$ is a hard sequence, then $\langle 1^m, \vec{x}\rangle$ is a maximal hard sequence, too.
3. Let $n = |w|$. Compute $m_1 = p_{\sigma_3}(n)$ and $m_2 = p_s(n + k + m_1)$.
4. For $\ell = 0$ to $k - 1$, ask SAT if $N_t((1^{m_1}, \ell), \langle 1^m, \vec{x}\rangle)$ accepts. Let j_1 be the maximum ℓ where $N_t((1^{m_1}, \ell), \langle 1^m, \vec{x}\rangle)$ does accept. Note that $m = p_t(m_2 + k) \geq p_t(m_1 + k)$, so j_1 is the maximum order for length m_1 (by Lemma 4.7) if j is the maximum order for length m.
5. For $\ell = 0$ to $k - 1$, ask SAT if $N_t((1^{m_2}, \ell), \langle 1^m, \vec{x}\rangle)$ accepts. Let j_2 be the maximum ℓ where $N_t((1^{m_2}, \ell), \langle 1^m, \vec{x}\rangle)$ does accept. As in step 4, j_2 is the maximum order for length m_2 if j is the maximum order for length m.
6. Guess j_2 strings $y_1, \ldots, y_{j_2} \in \Sigma^{\leq m_2}$ and confirm that $\langle 1^{m_2}, y_1, \ldots, y_{j_2}\rangle = \langle 1^{m_2}, \vec{y}\rangle$ is a hard sequence (with one query to SAT). Note that if $\langle 1^{m_2}, \vec{y}\rangle$ is a hard sequence and j_2 is the maximum order, then $\langle 1^{m_2}, \vec{y}\rangle$ is also a maximal hard sequence.
7. Ask SAT if $N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\rangle)$ accepts. If SAT returns "no," then $N_{\pi_3}^{\mathrm{SAT}}$ accepts. Note that by the preceding discussion, if j is the maximum order for length m, then j_1 is the maximum order for length m_1 and $\langle 1^{m_2}, \vec{y}\rangle$ is a maximal hard sequence. Also, $m_1 = p_{\sigma_3}(|w|)$ and $m_2 = p_s(|w| + k + m_1)$, so by equation (7)

$$w \in L_{u_3} \iff N_s(w, j_1, 1^{m_1}, \langle 1^{m_2}, \vec{y}\rangle) \text{ accepts.}$$

Now, we argue that if j is the maximum order for length m and $m \geq p_{\pi_3}(|w|)$, then

$$w \in \overline{L_{u_3}} \iff N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts.}$$

First of all, $N_{\pi_3}^{\mathrm{SAT}}$ accepts in step 7 only. So, if $w \in L_{u_3}$, all computation paths of $N_{\pi_3}^{\mathrm{SAT}}$ reject—even those that reach step 7, because SAT would answer "yes" in step 7. On the other hand, if $w \in \overline{L_{u_3}}$, then some computation path will reach step 7, get "no" from the SAT oracle, and accept.

Finally, we note that if j is greater than the maximum order for length m, then no computation path will survive step 2. Thus, in this case $N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m)$ rejects. □

Now we are ready to prove our main theorem. This theorem demonstrates a close linkage between the collapse of the BH and the PH.

THEOREM 4.9. *Suppose h is a $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduction from $\mathrm{L}_{\mathrm{BH}(k)}$ to $\mathrm{L}_{\text{co-BH}(k)}$. Let L_{u_3} be the canonical complete language for Σ_3^{P}. Then there exist languages $B_1, \ldots, B_k \in \mathrm{NP}^{\mathrm{NP}}$ such that*

$$L_{u_3} = B_1 - (B_2 - (B_3 - (\cdots - B_k))).$$

That is, $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{BH}_3(k)$, and therefore $\mathrm{PH} \subseteq \mathrm{BH}_3(k)$.

Proof. First, recall that in Lemmas 4.4 and 4.8 it was shown that $N_{\sigma_3}^{\mathrm{SAT}}$ and $N_{\pi_3}^{\mathrm{SAT}}$ accepted L_{u_3} and $\overline{L_{u_3}}$ (respectively) with the help of the maximum order for a large enough length (and they reject if the number given for the maximum order is too large). Let w be any string. Let $m = \max(p_{\sigma_3}(|w|), p_{\pi_3}(|w|))$; then m is large enough so that if j is the maximum order for length m,

$$N_{\sigma_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts } \iff w \in L_{u_3},$$

$$N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ accepts } \iff w \notin L_{u_3}.$$

We will define the $\mathrm{NP}^{\mathrm{NP}}$ languages $B_1, \ldots, B_k$ to be the strings accepted by $\mathrm{NP}^{\mathrm{NP}}$ machines that try to guess j, the maximum order for length m, and then run N_{σ_3} and N_{π_3}. These $\mathrm{NP}^{\mathrm{NP}}$ machines cannot verify when they have guessed the true maximum order; instead, they will base their acceptance behavior on whether they can determine that an earlier machine in the sequence may have been fooled by an incorrect guess for j. This successive approximation scheme converges to the language L_{u_3} within k steps.

DEFINITION. *For $1 \leq \ell \leq k$, the language B_ℓ is the set of strings w with the property that there exist $j_1, \ldots, j_\ell$ such that*

1. $0 \leq j_1 < j_2 < \cdots < j_\ell \leq k-1$,
2. *for all odd d, $1 \leq d \leq \ell$, $N_{\sigma_3}^{\mathrm{SAT}}(w, j_d, 1^m)$ accepts,*
3. *for all even d, $1 \leq d \leq \ell$, $N_{\pi_3}^{\mathrm{SAT}}(w, j_d, 1^m)$ accepts.*

Clearly, B_ℓ is in $\mathrm{NP}^{\mathrm{NP}}$ since an $\mathrm{NP}^{\mathrm{NP}}$ machine can guess $j_1, \ldots, j_\ell$, verify the first property, and then simulate $N_{\sigma_3}^{\mathrm{SAT}}$ and $N_{\pi_3}^{\mathrm{SAT}}$ for the different values of j_d. Also, observe that the B_ℓ's form a nested sequence

$$B_k \subseteq B_{k-1} \subseteq \cdots \subseteq B_2 \subseteq B_1.$$

Finally, note that if $r = \max\{\ell \mid w \in B_\ell\}$, then

$$w \in B_1 - (B_2 - (B_3 - (\cdots - B_k))) \iff r \text{ is odd}.$$

Example. Here we give an example which demonstrates that

$$w \in L_{u_3} \iff r = \max\{\ell \mid w \in B_\ell\} \text{ is odd}.$$

Let $k = 8$, the maximum order for length m be 5, and $N_{\sigma_3}^{\mathrm{SAT}}$ and $N_{\pi_3}^{\mathrm{SAT}}$ behave as shown in Table 1 below for the different values of s plugged in as the guess for the maximum order.

Note that since the maximum order is 5, both $N_{\sigma_3}^{\mathrm{SAT}}$ and $N_{\pi_3}^{\mathrm{SAT}}$ reject for $s = 6, 7$. Also, one of $N_{\sigma_3}^{\mathrm{SAT}}(w, 5, 1^m)$ and $N_{\pi_3}^{\mathrm{SAT}}(w, 5, 1^m)$ must accept and the other reject. For smaller s, both may accept or reject, since their behavior is unpredictable. Finally, $w \in L_{u_3}$, so we want show that r is odd.

To determine if $w \in B_\ell$, look for an alternating (between the top and bottom row) sequence of accepts starting from the top row moving left to right. If there is such a sequence of ℓ acceptances, then $w \in B_\ell$. In this example, $r = 3$.

TABLE 1

$s =$	0	1	2	3	4	5	6	7
$N_{\sigma_3}^{\mathrm{SAT}}(w, s, 1^m)$	rej	acc	acc	rej	rej	acc	rej	rej
$N_{\pi_3}^{\mathrm{SAT}}(w, s, 1^m)$	acc	rej	acc	rej	acc	rej	rej	rej

- $w \in B_1$, because j_1 can be 1, 2, or 5.
- $w \in B_2$, because both $N_{\sigma_3}^{\mathrm{SAT}}(w, 1, 1^m)$ and $N_{\pi_3}^{\mathrm{SAT}}(w, 4, 1^m)$ accept.
- $w \in B_3$ with $j_1 = 1, j_2 = 2, j_3 = 5$.
- $w \notin B_4, B_5, \ldots, B_8$, because there is no alternating sequence longer than 3. The sequence $j_1 = 0, j_2 = 1, j_3 = 2, j_4 = 5$ does not count because the sequence must start from the top row.

CLAIM 4.10. *If $w \in L_{u_3}$, then $r = \max\{\ell \mid w \in B_\ell\}$ is odd.*

Proof. Let j be the maximum order for length m. Now suppose r is even and $w \in B_r$. Then, there exist $j_1, \ldots, j_r$ so that properties 1–3 in the definition above hold. Therefore,

$$N_{\pi_3}^{\mathrm{SAT}}(w, j_r, 1^m) \text{ accepts}$$

(since r is even and $w \in B_r$). Since $w \in L_{u_3}$, for the true maximum order j,

$$N_{\pi_3}^{\mathrm{SAT}}(w, j, 1^m) \text{ rejects.}$$

Therefore $j_r \neq j$. Observe that j_r cannot be greater than j either since for all $s > j$,

$$N_{\pi_3}^{\mathrm{SAT}}(w, s, 1^m) \text{ rejects.}$$

Hence $j_r < j$.

Since we are given that $w \in L_{u_3}$, we know that $N_{\sigma_3}^{\mathrm{SAT}}(w, j, 1^m)$ must accept (Lemma 4.4). Now consider the sequence $j_1, \ldots, j_{r+1}$, where $j_{r+1} = j$. $N_{\sigma_3}^{\mathrm{SAT}}(w, j_{r+1}, 1^m)$ accepts and $r + 1$ is odd, which implies that $j_1, \ldots, j_{r+1}$ satisfies conditions 1–3, and therefore $w \in B_{r+1}$. Thus if r is even, $r \neq \max\{\ell \mid w \in B_\ell\}$. Therefore, r must be odd.

CLAIM 4.11. *If $w \notin L_{u_3}$ then $r = \max\{\ell \mid w \in B_\ell\}$ is even.*

Proof. This is similar to the proof of Claim 4.10.

Combining Claims 4.10 and 4.11 with the observation that if $r = \max\{\ell \mid w \in B_\ell\}$, then

$$w \in B_1 - (B_2 - (B_3 - (\cdots - B_k))) \iff r \text{ is odd},$$

we have

$$w \in L_{u_3} \iff w \in B_1 - (B_2 - (B_3 - (\cdots - B_k))). \qquad \square$$

Theorem 4.9 also shows some unexpected connections between the Boolean and query hierarchies within Δ_2^{P} and Δ_3^{P}.

COROLLARY 4.12. $\mathrm{BH}(k) = \text{co-BH}(k) \Longrightarrow \mathrm{BH}_3(k) = \text{co-BH}_3(k)$.

COROLLARY 4.13. $\mathrm{P}^{\mathrm{NP}\|[k]} = \mathrm{P}^{\mathrm{NP}\|[k+1]} \Longrightarrow \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+1]} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+2]}$.

Proof. We use the fact that the Boolean and query hierarchies are intertwined:

$$\mathrm{P}^{\mathrm{NP}\|[k]} \subseteq \mathrm{BH}(k+1) \subseteq \mathrm{P}^{\mathrm{NP}\|[k+1]} \quad \text{and} \quad \mathrm{BH}_3(k+1) \subseteq \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+1]}.$$

If $\mathrm{P}^{\mathrm{NP}\|[k]} = \mathrm{P}^{\mathrm{NP}\|[k+1]}$, then $\mathrm{BH}(k+1)$ is closed under complementation. Moreover, Corollary 4.12 implies that $\mathrm{BH}_3(k+1)$ is closed under complementation as well. Thus, the Boolean and query hierarchies in Δ_3^{P} collapse to $\mathrm{BH}_3(k+1)$. These simple containments give a result that is off by one. However, we believe that with more effort we should be able to show that $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k]} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}\|[k+1]}$. □

5. Conclusion. We have demonstrated a closer connection between the BH and the PH—a deeper collapse of the BH implies a deeper collapse of the PH. We would like to think that this relationship is a consequence of some underlying structure connecting $\mathrm{BH}(k)$ and $\mathrm{BH}_3(k)$. However, attempts to simplify the proof along these lines have failed. Is there some straightforward argument which would show that $\mathrm{BH}(k) = \text{co-}\mathrm{BH}(k)$ implies $\mathrm{BH}_3(k)$ is closed under complementation? Could such an argument be extended to show that $\Sigma_3^{\mathrm{P}} \subseteq \mathrm{BH}_3(k)$? Finally, we ask, is this collapse optimal (for $k \geq 2$) or can it be shown that $\mathrm{BH}(k) = \text{co-}\mathrm{BH}(k)$ implies $\mathrm{PH} \subseteq \mathrm{BH}(k)$?

Acknowledgments. We are grateful to Juris Hartmanis for his support and guidance. We would also like to thank Stephen Mahaney for starting us on this endeavor and Georges Lauri for reading a draft of this paper.

LOW-DEGREE SPANNING TREES OF SMALL WEIGHT*

SAMIR KHULLER[†], BALAJI RAGHAVACHARI[‡], AND NEAL YOUNG[§]

Abstract. Given n points in the plane, the degree-K spanning-tree problem asks for a spanning tree of minimum weight in which the degree of each vertex is at most K. This paper addresses the problem of computing low-weight degree-K spanning trees for $K > 2$. It is shown that for an arbitrary collection of n points in the plane, there exists a spanning tree of degree 3 whose weight is at most 1.5 times the weight of a minimum spanning tree. It is shown that there exists a spanning tree of degree 4 whose weight is at most 1.25 times the weight of a minimum spanning tree. These results solve open problems posed by Papadimitriou and Vazirani. Moreover, if a minimum spanning tree is given as part of the input, the trees can be computed in $O(n)$ time.

The results are generalized to points in higher dimensions. It is shown that for any $d \geq 3$, an arbitrary collection of points in $\Re^d$ contains a spanning tree of degree 3 whose weight is at most 5/3 times the weight of a minimum spanning tree. This is the first paper that achieves factors better than 2 for these problems.

1. Introduction.

Given n points in the plane, how do we find a spanning tree of minimum weight among those in which each vertex has degree at most K? Here the weight of an edge between two points is defined to be the Euclidean distance between them. This problem is referred to as the *Euclidean degree-K spanning tree problem* and is a generalization of the Hamilton path problem, which is known to be NP-hard [10, 12]. When $K = 3$, it was shown to be NP-hard by Papadimitriou and Vazirani [15], who conjectured that it is NP-hard for $K = 4$ as well. When $K = 5$, the problem can be solved in polynomial time [14].

This paper addresses the problem of computing low-weight degree-K spanning trees for $K > 2$. In any metric space, it is known that there always exists a spanning tree of degree 2 whose cost is at most twice the cost of a minimum spanning tree (MST). This is shown by taking a Euler tour of an MST (in which each edge is taken twice) and producing a Hamilton tour by short-cutting the Euler tour. In the case of general metric spaces, it is easy to generate examples in which the ratio of a shortest Hamilton path to the weight of an MST is arbitrarily close to 2. But such examples do not translate to points in $\Re^d$. In view of this, Papadimitriou and Vazirani [15] posed the problem of obtaining factors better than 2 for the Euclidean degree-K spanning-tree problem. It should be noted that in the special case of $K = 2$, Christofides [3] gave a simple and elegant polynomial-time approximation algorithm with an approximation ratio of 1.5 for computing a traveling salesperson tour for points satisfying the triangle inequality (points in a metric space).

1.1. Our contributions. In this paper, we show that for an arbitrary collection of n points in the plane, there exists a degree-3 spanning tree whose weight is at most 1.5 times the weight of an MST. We also show that there exists a degree-4 spanning tree whose weight is at most 1.25 times the weight of an MST. This solves an open problem posed by Papadimitriou and Vazirani [15].

Moreover, if an MST is given as part of the input, the trees can be computed in $O(n)$ time. Note that our bound of 1.5 for the degree-3 spanning-tree problem is an "absolute" guarantee (based on the weight of an MST) as opposed to a "relative" guarantee for the degree-2 spanning tree obtained by Christofides [3] (based on the weight of an optimal solution).

We also generalize our results to points in higher dimensions. We show that for any $d \geq 2$, an arbitrary collection of points in $\Re^d$ contains a degree-3 spanning tree whose weight is at most 5/3 times the weight of an MST. This is the first paper that achieves factors better than 2 for these problems.

1.2. Significance of our results. Many approximation algorithms make use of the triangle inequality to obtain approximate solutions to NP-hard problems. These algorithms typically involve a "short-cutting" step where the triangle inequality is used to bound the cost of the obtained solution. Examples include Christofides's heuristic for the traveling salesperson problem [3], biconnectivity augmentation [8], approximate weighted matching [11], prize-collecting traveling salesperson [2], and bounded-degree subgraphs which have low weight and small bottleneck cost [16].

A question of general interest is how to obtain improved approximation algorithms for such problems when the points come from a Euclidean, as opposed to arbitrary, metric space. This requires making use of more than just the triangle inequality. Surprisingly, for most problems, improved algorithms are not known. (A notable exception is the famous Euclidean Steiner tree problem [5, 6].) We use rudimentary geometric techniques to obtain an improved algorithm for the Euclidean degree-K spanning-tree problem.

The key to our method is to give short-cutting steps that are provably better than implied by the triangle inequality alone. Lemma 3.3, which bounds the perimeter of an arbitrary triangle in terms of distances to its vertices from any point, is typical of the techniques that we use to get better bounds.

1.3. Related work. Papadimitriou and Vazirani showed that any MST whose vertices have integer coordinates has maximum degree at most 5 [15]. Monma and Suri [14] showed that for *every* set of points in the plane, there exists a degree-5 MST.

Many recent works have given algorithms to find subgraphs of bounded degree that simultaneously satisfy other given constraints. A polynomial-time algorithm to find a spanning tree or a Steiner tree of a given subset of vertices in a graph with degree at most one more than minimum was given by Fürer and Raghavachari [9]. This was extended to weighted graphs by Fischer [7]. He showed how to find MSTs whose degree is within a constant multiplicative factor plus an additive $O(\log n)$ of the optimal degree. The degree bound is improved further in the case when the number of different edge weights is bounded by a constant. Ravi et al. [16] consider the problem of computing bounded-degree subgraphs satisfying given connectivity properties in a graph whose edge weights satisfy the triangle inequality. They give efficient algorithms for computing subgraphs which have low weight and small bottleneck cost. Salowe [18] and Das and Heffernan [4] consider the problem of computing bounded-degree graph spanners and provide algorithms for computing them. Robins and Salowe [17] study the maximum degrees of MSTs under various metrics.

2. Preliminaries. Let $V = \{v_1, \ldots, v_n\}$ be a set of n points in the plane. Let G be the complete graph induced by V, where the weight of an edge is the Euclidean distance between its endpoints. We use the terms points and vertices interchangeably. Let $\overline{uv}$ be the Euclidean distance between vertices u and v. Let $T_{\min}$ be an MST of the points in V. Let $w(T)$ denote the total weight of a spanning tree T. Let T_k denote a spanning tree in which every vertex has degree at most k. Let $\deg_T(v)$ be the degree of a vertex v in the tree T. Let ΔABC denote the triangle formed by points A, B, and C. Let $\angle ABC$ denote the angle formed at B between line segments AB and BC. Let $\overline{ABC}$ denote the perimeter of ΔABC; and more generally, let $\overline{v_1 v_2 \ldots v_k}$ denote the perimeter of the polygon formed by the line segments $v_i v_{i+1}$ for $1 \leq i \leq k$, where $v_{k+1} = v_1$.

In this paper, we prove the following: for an arbitrary set of points in $\Re^2$,

$$\exists T_3 : \quad w(T_3) \leq 1.5 \times w(T_{\min}), \tag{1}$$

$$\exists T_4 : \quad w(T_4) \leq 1.25 \times w(T_{\min}). \tag{2}$$

For an arbitrary set of points in $\Re^d$ $(d > 2)$,

$$\exists T_3 : \quad w(T_3) \leq \frac{5}{3} \times w(T_{\min}). \tag{3}$$

3. Points in the plane. We first consider the case of $\Re^2$—points in the plane. We first note some useful properties of MSTs in $\Re^d$.

PROPOSITION 3.1 ([15]). *Let AB and BC be two edges incident to a point B in an MST of a set of points in $\Re^d$. Then $\angle ABC$ is a largest angle in ΔABC.*

COROLLARY 3.2. *Let AB and BC be two edges incident to a point B in an MST of a set of points in $\Re^d$. Then*

- *$\angle ABC \geq 60°$,*
- *$\angle BAC, \angle BCA \leq 90°$.*

3.1. An upper bound on the perimeter of a triangle. We now prove an upper bound on the perimeter of an arbitrary triangle in terms of distances to its vertices from an arbitrary point. This lemma is useful in proving the performances of our algorithms. The lemma is also interesting in its own right, and we believe that it and the associated techniques will be useful in other geometrical problems.

LEMMA 3.3. *Let X, A, B, and C be points in $\Re^d$ with $\overline{XA} \leq \overline{XB}, \overline{XC}$. Then*

$$\overline{ABC} \leq (3\sqrt{3} - 4)\overline{XA} + 2(\overline{XB} + \overline{XC}). \tag{4}$$

Note that $3\sqrt{3} - 4 \approx 1.2$. Recall that $\overline{ABC}$ is the perimeter of the triangle and $\overline{XY}$ is the distance from X to Y.

Proof. Let B' and C' be points on XB and XC, respectively, such that $\overline{XA} = \overline{XB'} = \overline{XC'}$ (see Fig. 1). First we observe that the lemma is true if it is true for the points X, A, B', and C'. This follows because by the triangle inequality,

$$\overline{ABC} \leq \overline{AB'C'} + 2\overline{BB'} + 2\overline{CC'}.$$

By our assumption,

$$\overline{AB'C'} \leq (3\sqrt{3} - 4)\overline{XA} + 2(\overline{XB'} + \overline{XC'}).$$

Combining the two inequalities yields the desired result. Therefore, in the rest of the proof, we show that the lemma is true when the "arms" $\overline{XA}$, $\overline{XB'}$, and $\overline{XC'}$ are equal.

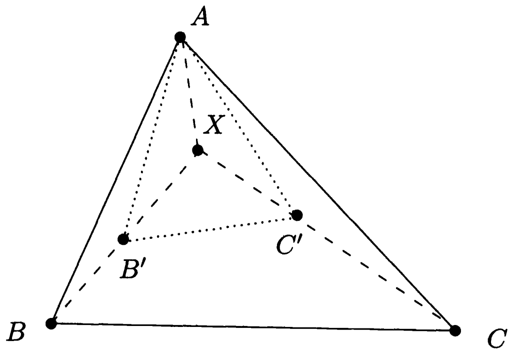

FIG. 1. *Shrinking to obtain canonical form.*

It is not very difficult to see that to maximize the perimeter of the triangle, X will be in the plane defined by A, B', and C', and thus X is at the center of a circle passing through A, B', and C'.

By scaling, it suffices to consider the case when the circle has unit radius. In this case, the right-hand side (r.h.s.) of (4) is exactly $3\sqrt{3}$. Thus, it suffices to show that the maximum perimeter achieved by any triangle whose vertices lie on a unit circle is $3\sqrt{3}$. This is easily proved [13]. □

Note that in an arbitrary metric space it is possible to have an (equilateral) triangle of perimeter six and a point X at distance one from each vertex.

3.2. Spanning trees of degree 3. We now assume that we are given a Euclidean MST T of degree at most 5. We show how to convert T into a tree of degree at most 3. The weight of the resulting tree is at most 1.5 times the weight of T.

High level description. The tree T is rooted at an arbitrary leaf vertex. Since T is a degree-5 tree, once it is rooted at a leaf, each vertex has at most four children. For each vertex v, the shortest path P_v starting at v and visiting every child of v is computed. The final tree T_3 consists of the union of the paths $\{P_v\}$. Figure 2 gives the above algorithm. In analyzing the algorithm, we think of each vertex v as replacing its edges from its children with the path P_v. The above technique of "short-cutting" the children of a vertex by "stringing" them together has been known before, especially in the context of computing degree-3 trees in metric spaces (see [16, 18]).

```
TREE-3($V,T$) — Find a degree-3 tree of $V$.
Root the MST $T$ at a leaf vertex $r$.
For each vertex $v \in V$ do
    Compute $P_v$, the shortest path starting at $v$ and visiting all the children of $v$.
Return $T_3$, the tree formed by the union of the paths $\{P_v\}$.
```

FIG. 2. *Algorithm to find a degree-3 tree.*

Note. Typically, the initial MST has very few nodes with degree greater than 3 [1]. In practice, it is worth modifying the algorithm to scan the vertices in preorder, maintaining the partial tree T_3 of edges added so far, and to add paths to T_3 as follows. When considering a vertex v, if the degree of v in the partial T_3 is 2, add the path P_v as described in the algorithm. Otherwise, its degree is 1, so, in this case, relax the requirement that the added path must start at v. That is, add the shortest path that visits v and all of v's children to T_3 (see §3.3). This modification will never increase the cost of the resulting tree but may offer substantially lighter trees in practice.

LEMMA 3.4. *The algorithm in Fig.* 2 *outputs a spanning tree of degree* 3.

Proof. An easy proof by induction shows that the union of the paths forms a tree. Each vertex v is on at most two paths and is an interior vertex of at most one path. □

LEMMA 3.5. *Let v be a vertex in an MST T of a set of points in $\Re^2$. Let P_v be a shortest path visiting $\{v\} \cup child_T(v)$ with v as one of its endpoints.*

$$w(P_v) \leq 1.5 \times \sum_{v_i \in child_T(v)} \overline{vv_i}.$$

By the above lemma, each path P_v has weight at most 1.5 times the weight of the edges it replaces. Thus we have the following theorem.

THEOREM 3.6. *Let T be an MST of a set of points in $\Re^2$. Let T_3 be the spanning tree output by the algorithm in Fig.* 2.

$$w(T_3) \leq 1.5 \times w(T).$$

Proof of Lemma 3.5. We consider the various cases that arise depending on the number of children of v. The cases when v has no children or exactly one child are trivial.

Case 1. *v has* 2 *children, v_1, v_2.* There are two possible paths for P_v, namely $P_1 = [v, v_1, v_2]$ and $P_2 = [v, v_2, v_1]$. Clearly,

$$w(P_v) = \min(w(P_1), w(P_2)) \leq \frac{w(P_1) + w(P_2)}{2} = \frac{\overline{vv_1}}{2} + \frac{\overline{vv_2}}{2} + \overline{v_1v_2} \leq 1.5\ (\overline{vv_1} + \overline{vv_2}).$$

Case 2. *v has* 3 *children, v_1, v_2, v_3.* Let v_1 be the child that is nearest to v. Consider the following four paths (see Fig. 3): $P_1 = [v, v_1, v_2, v_3], P_2 = [v, v_1, v_3, v_2], P_3 = [v, v_2, v_1, v_3]$, and $P_4 = [v, v_3, v_1, v_2]$.

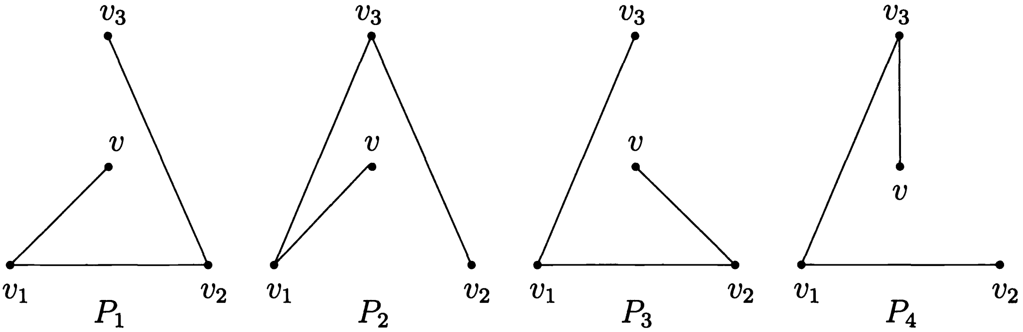

FIG. 3. *T_3, three children.*

The path P_v is at most as heavy as the lightest of $\{P_1, P_2, P_3, P_4\}$. The weight of the lightest of these paths is at most any convex combination of the weights of the paths. Specifically,

$$w(P_v) \leq \min(w(P_1), w(P_2), w(P_3), w(P_4)) \leq \frac{w(P_1)}{3} + \frac{w(P_2)}{3} + \frac{w(P_3)}{6} + \frac{w(P_4)}{6}.$$

We will now prove that

$$\frac{w(P_1)}{3} + \frac{w(P_2)}{3} + \frac{w(P_3)}{6} + \frac{w(P_4)}{6} \leq 1.5\ (\overline{vv_1} + \overline{vv_2} + \overline{vv_3}).$$

This simplifies to

$$\overline{v_1v_2} + \overline{v_2v_3} + \overline{v_3v_1} \leq 1.25\ \overline{vv_1} + 2(\overline{vv_2} + \overline{vv_3}),$$

which follows from Lemma 3.3.

Case 3. *v has 4 children, v_1, v_2, v_3, v_4, ordered clockwise around v.* Let v' be the point of intersection of the diagonals $\overline{v_1v_3}$ and $\overline{v_2v_4}$. Note that the diagonals do intersect because the polygon $v_1v_2v_3v_4$ is convex (follows from Corollary 3.2).

Let v_3 be the point that is furthest from v', among $\{v_1, v_2, v_3, v_4\}$. Consider the following two paths (see Fig. 4): $P_1 = [v, v_4, v_1, v_2, v_3], P_2 = [v, v_2, v_1, v_4, v_3]$.

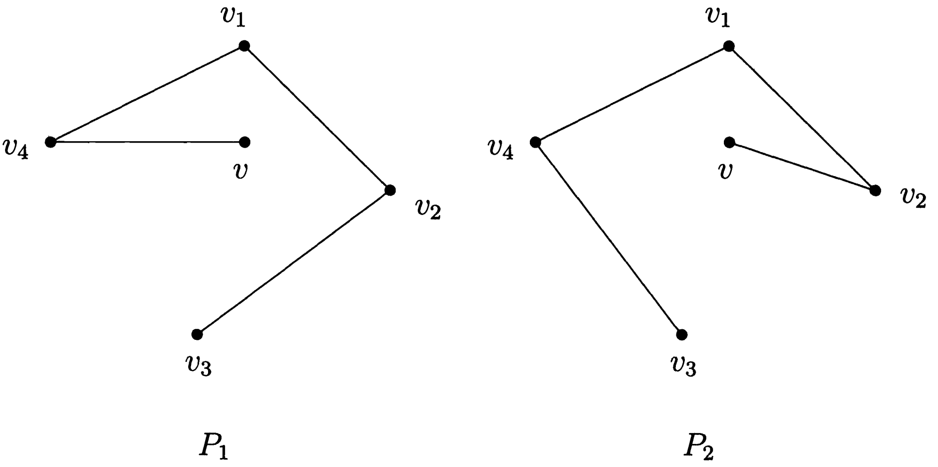

FIG. 4. T_3, *four children.*

Clearly,

$$w(P_v) \leq \min(w(P_1), w(P_2)) \leq \frac{w(P_1)}{2} + \frac{w(P_2)}{2}.$$

We will show that

$$\frac{1}{2}(w(P_1) + w(P_2)) \leq 1.5(\overline{vv_1} + \overline{vv_2} + \overline{vv_3} + \overline{vv_4}).$$

This simplifies to

$$\overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) \leq 3(\overline{vv_1} + \overline{vv_3}) + 2(\overline{vv_2} + \overline{vv_4}). \tag{5}$$

We will first prove that

$$\overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) \leq 3(\overline{v'v_1} + \overline{v'v_3}) + 2(\overline{v'v_2} + \overline{v'v_4}). \tag{6}$$

Once we prove (6), by the triangle inequality, we can conclude that (5) is true, since $\overline{vv_1} + \overline{vv_3} \geq \overline{v_1v_3} = \overline{v'v_1} + \overline{v'v_3}$ and $\overline{vv_2} + \overline{vv_4} \geq \overline{v_2v_4} = \overline{v'v_2} + \overline{v'v_4}$.

We prove (6) by contradiction. Suppose there exists a set of points which does not satisfy (6). Suppose we shrink $v'v_3$ by δ. The left side of the above inequality decreases by at most 2δ, whereas the right side of the inequality decreases by exactly 3δ. Therefore, as we shrink $v'v_3$, the inequality stays violated. Suppose $v'v_3$ shrinks and becomes equal to another edge $v'v_i$ for some $i \in \{1, 2, 4\}$. We now shrink both $v'v_3$ and $v'v_i$ simultaneously at the same rate. Again, it is easy to show that the inequality continues to be violated as $v'v_3$ and $v'v_i$ shrink. Hence we reach a configuration where three of the edges are equal.

Without loss of generality, the length of the three edges is 1 and the length of the fourth edge is some $\epsilon \leq 1$.

There are two subcases to consider. The first is when $v'v_1 = \epsilon$ and the second is when $v'v_2 = \epsilon$. (The case when $v'v_4 = \epsilon$ is the same as the second case.)

Case 3a. $v'v_1 = \epsilon$. We wish to prove that

$$\overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) \leq 7 + 3\epsilon.$$

We want to show that the function $F(\epsilon) = \overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) - 7 - 3\epsilon$ is nonpositive in the domain $0 \leq \epsilon \leq 1$. Simplifying, we get

$$F(\epsilon) = 2\overline{v_1v_2} + \overline{v_2v_3} + \overline{v_3v_4} + 2\overline{v_1v_4} - 7 - 3\epsilon.$$

Each of $\overline{v_iv_j}$ in the definition of F is a convex function of ϵ due to the following reason. Let p be the point closest to v_j on the line connecting v_i and v'. Observe that as v_i moves towards v', $\overline{v_iv_j}$ decreases if v_i is moving towards p and increases otherwise. Since F is a sum of convex functions minus a linear function, it is a convex function of ϵ. Therefore, it is maximized at either $\epsilon = 0$ or $\epsilon = 1$.

When $\epsilon = 1$, all four points are at the same distance from v'. If angle $\angle v_4v'v_1 = \alpha$ then F can be written as a function of a single variable α and it can be verified that F reaches a maximum value of $10\sqrt{0.8} - 10$, which is nonpositive.

When $\epsilon = 0$, $\overline{v_1v_2} = \overline{v_1v_4} = 1$. Simplifying we get $F = \overline{v_2v_3} + \overline{v_3v_4} - 3$, and it reaches a maximum value of $2\sqrt{2} - 3$, which is nonpositive (when $\epsilon = 0$, note that v_1 is the midpoint of the line segment v_2v_4).

Case 3b. $v'v_2 = \epsilon$. We wish to prove that

$$\overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) \leq 8 + 2\epsilon.$$

We want to show that the function $F'(\epsilon) = \overline{v_1v_2v_3v_4} + (\overline{v_1v_2} + \overline{v_1v_4}) - 8 - 2\epsilon$ is nonpositive in the domain $0 \leq \epsilon \leq 1$.

As a function of ϵ, function F' is a sum of convex functions minus a linear function and thus is convex. Therefore, it is maximized at either $\epsilon = 0$ or $\epsilon = 1$.

The case $\epsilon = 1$ leads to the same configuration as in Case 3a.

When $\epsilon = 0$, $\overline{v_1v_2} = \overline{v_2v_3} = 1$. Here $F' = 2\overline{v_1v_4} + \overline{v_3v_4} - 5$. If angle $\angle v_4v'v_1 = \alpha$, then F' can be written as a function of a single variable α and it can be verified that F' reaches a maximum value of $5\sqrt{0.8} - 5$, which is nonpositive.

This concludes the proof of Lemma 3.5. □

The example in Fig. 5 shows that the 1.5 factor is tight for the algorithm in Fig. 2, modified according to the note following its description. The same example also shows that the 1.5 factor is tight for the unmodified algorithm since the unmodified algorithm never outputs a lighter tree than the modified algorithm. Each curved arc shown in Fig. 5 is actually a straight line and has been drawn curved for convenience. The vertex that is the child of the root has three children and is forced to drop one child. In doing so, the degree of its child goes to 4, and it in turn drops one of its children. The algorithm could make choices in such a way that the changes propagate through the tree and the tree T_3 output by the algorithm may be as shown in the figure. The ratio of the cost of the final solution to the cost of the MST can be made arbitrarily close to 1.5. See §5 for a discussion on the worst-case ratio between degree-3 trees and MSTs.

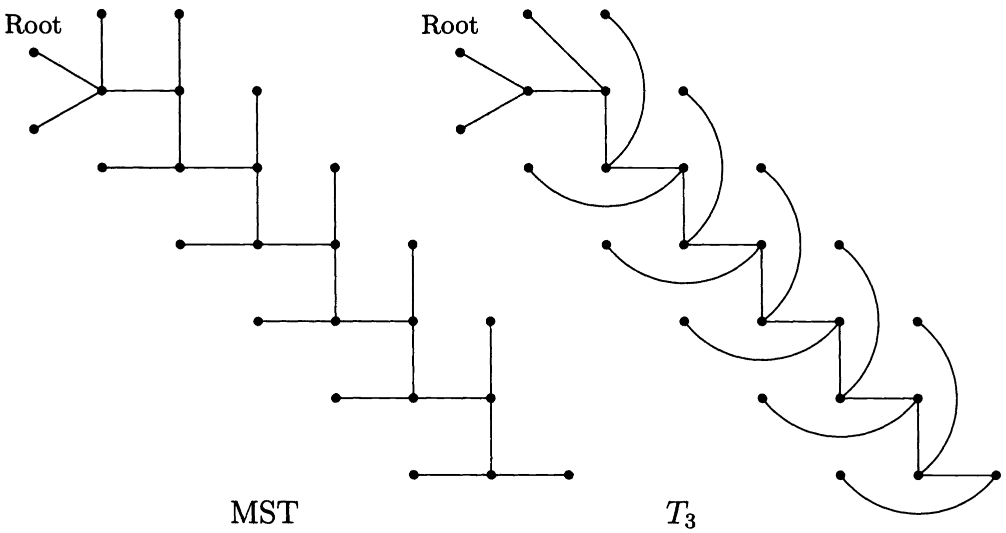

FIG. 5. *Bad example for algorithm in Fig.* 2.

3.3. Spanning trees of degree 4. We now assume that we are given a Euclidean minimum-spanning tree in which every vertex has degree at most 5. We show how to convert this tree to a tree in which every vertex has degree at most 4.

High level description. The basic idea is the same as in the previous algorithm. The difference is that we don't insist that each path P_v start at v. The tree is rooted at an arbitrary leaf. For each vertex v, the minimum-weight path P_v visiting v and all of v's children (not necessarily starting at v) is computed. The final tree T_4 consists of the union of the paths $\{P_v\}$. Again, for the analysis we think of each path P_v replacing the edges between v and its children in T.

```
TREE-4($V, T$) — Find a degree-4 tree of $V$.
Root the MST $T$ at a leaf vertex $r$.
For each vertex $v \in V$ do
    Compute the shortest path $P_v$ visiting $v$ and all its children.
Return $T_4$, the tree formed by the union of the paths $\{P_v\}$.
```

FIG. 6. *Algorithm to find a degree-*4 *tree.*

LEMMA 3.7. *The algorithm in Fig.* 6 *returns a degree-*4 *spanning tree of the given set of points* V.

Proof. A proof by induction shows that T_4 is a tree. Each vertex v occurs in at most two paths and thus has degree at most 4. □

LEMMA 3.8. *Let* v *be a vertex in an MST* T *for a set of points in* $\Re^2$. *Let* P_v *be the shortest path visiting* $\{v\} \cup \mathit{child}_T(v)$.

$$w(P_v) \leq 1.25 \times \sum_{v_i \in \mathit{child}_T(v)} \overline{vv_i}.$$

From the above lemma, each path P_v weighs at most 1.25 times the net weight of the edges it replaces. Thus we have the following theorem.

THEOREM 3.9. *Let T be an MST of a set of points in $\Re^2$. Let T_4 be the spanning tree output by the algorithm in Fig.* 6.

$$w(T_4) \leq 1.25 \times w(T).$$

Proof of Lemma 3.8. The proof is similar to the proof of Lemma 3.5. As before, we consider cases depending on the number of children of v. The cases when v has no children, one child, or two children are trivial.

Case 1. *v has 3 children, v_1, v_2, v_3.* Let v_1 be the point that is closest to v, among its children. Consider the following four paths (see Fig. 7): $P_1 = [v_2, v_1, v, v_3], P_2 = [v_2, v, v_1, v_3], P_3 = [v_1, v, v_2, v_3]$, and $P_4 = [v_1, v, v_3, v_2]$.

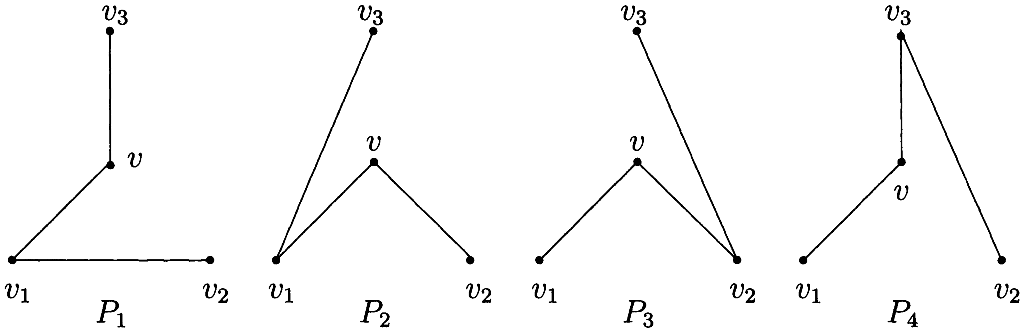

FIG. 7. *T_4, three children.*

Clearly,

$$w(P_v) \leq \frac{w(P_1)}{3} + \frac{w(P_2)}{3} + \frac{w(P_3)}{6} + \frac{w(P_4)}{6}.$$

We will show that

$$\frac{w(P_1)}{3} + \frac{w(P_2)}{3} + \frac{w(P_3)}{6} + \frac{w(P_4)}{6} \leq \frac{2+\sqrt{3}}{3}(\overline{vv_1} + \overline{vv_2} + \overline{vv_3}).$$

This proves the three-child case because $\frac{2+\sqrt{3}}{3}$ approximately equals 1.244 and is less than 1.25. This simplifies to

$$\frac{\overline{v_1v_2} + \overline{v_1v_3} + \overline{v_2v_3}}{3} + \overline{vv_1} + \frac{\overline{vv_2} + \overline{vv_3}}{2} \leq \frac{2+\sqrt{3}}{3}(\overline{vv_1} + \overline{vv_2} + \overline{vv_3}),$$

which further simplifies to

$$\overline{v_1v_2v_3} \leq (\sqrt{3}-1)\overline{vv_1} + \left(\sqrt{3} + \frac{1}{2}\right)(\overline{vv_2} + \overline{vv_3}). \tag{7}$$

Since v_1 is the closest point to v, applying Lemma 3.3, we get

$$\overline{v_1v_2v_3} \leq (3\sqrt{3}-4)\overline{vv_1} + 2(\overline{vv_2} + \overline{vv_3}),$$

and hence

$$\begin{aligned}\overline{v_1v_2v_3} &\le (\sqrt{3}-1)\overline{vv_1} + (2\sqrt{3}-3)\overline{vv_1} + 2(\overline{vv_2} + \overline{vv_3})\\ &\le (\sqrt{3}-1)\overline{vv_1} + (\sqrt{3}+\frac{1}{2})(\overline{vv_2}+\overline{vv_3}).\end{aligned}$$

This proves (7).

Case 2. *v has* 4 *children,* v_1, v_2, v_3, v_4. Assume that v_1 is the point that is closest to v among v's children. Let the order of the points be v_1, v_2, v_3, v_4 when we scan the plane clockwise from v starting from an arbitrary direction.

There are two cases, depending on whether v_4 or v_3 is the point that is furthest from v among its children. We first address the case when v_4 is the furthest point. (The proof for the case when v_2 is the point furthest from v is symmetric to the case when v_4 is the furthest point.)

Consider the following paths: $P_1 = [v_4, v_1, v, v_2, v_3]$ and $P_2 = [v_4, v_3, v, v_1, v_2]$ (see Fig. 8).

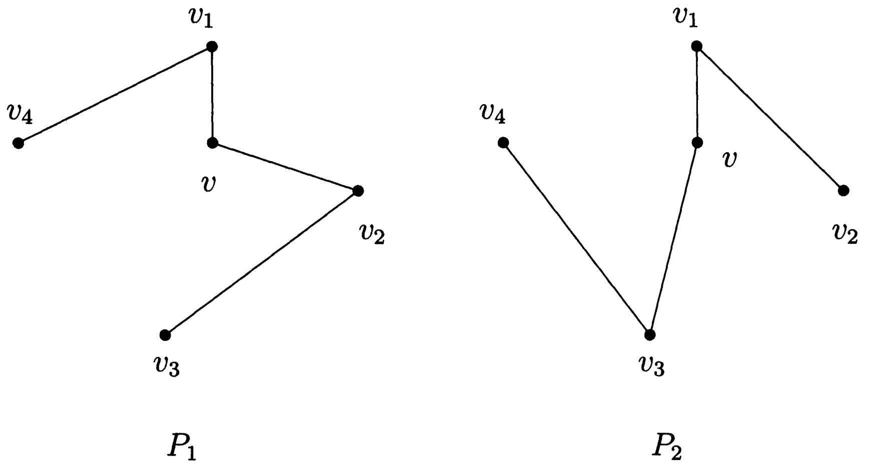

FIG. 8. T_4, *four children.*

The path P_v added by the algorithm is at most as heavy as the lighter of the paths P_1 and P_2. Hence

$$w(P_v) \le \min(P_1, P_2) \le \frac{w(P_1)+w(P_2)}{2}.$$

We will show that

$$\frac{w(P_1)+w(P_2)}{2} \le 1.25(\overline{vv_1} + \overline{vv_2} + \overline{vv_3} + \overline{vv_4}).$$

Simplifying, we need to show that

$$\frac{1}{2}(\overline{v_4v_1} + \overline{v_1v} + \overline{vv_2} + \overline{v_2v_3} + \overline{v_4v_3} + \overline{v_3v} + \overline{vv_1} + \overline{v_1v_2}) \le \frac{5}{4}(\overline{vv_1} + \overline{vv_2} + \overline{vv_3} + \overline{vv_4}).$$

Further simplifying, we get

$$\overline{v_1v_2v_3v_4} \le \frac{1}{2}\overline{vv_1} + \frac{5}{2}\overline{vv_4} + \frac{3}{2}(\overline{vv_2} + \overline{vv_3}).$$

Note that if it happens that v_3 was the farthest point from v among v's children, we get a similar equation with v_3 and v_4 being exchanged in the r.h.s of the equation. By symmetry, the case when v_2 is furthest is similar to v_4 being farthest.

Without loss of generality, $\overline{vv_3} \geq \overline{vv_2}$. The proof now proceeds in a manner similar to the proof of Lemma 3.3. If there is a configuration of points for which this equation is not true (the l.h.s exceeds the r.h.s) then we can move v_4, v_3 closer to v until $\overline{vv_2} = \overline{vv_3} = \overline{vv_4}$. In doing this, we decrease the l.h.s by at most $2(\overline{vv_4} - \overline{vv_2}) + 2(\overline{vv_3} - \overline{vv_2})$. Clearly, the r.h.s decreases by exactly $4(\overline{vv_4} - \overline{vv_2}) + 4(\overline{vv_3} - \overline{vv_2})$. This ensures that the l.h.s is still greater than the r.h.s. Hence without loss of generality, if there is a configuration for which our equation is not true, then there is a configuration with the property that $\overline{vv_4} = \overline{vv_3} = \overline{vv_2}$. We now show that when this property is true there is no counterexample.

By scaling, we may assume that $\overline{vv_4} = \overline{vv_3} = \overline{vv_2} = 1$ and $\overline{vv_1} = \epsilon$, where $\epsilon \leq 1$.

Note that (by Corollary 3.2) v was originally within the convex hull of its four children. Also (by Corollary 3.2), every child is on the convex hull. These properties are both maintained by the above shrinking steps.

We now wish to prove that

$$\overline{v_1v_2v_3v_4} \leq \frac{11}{2} + \frac{1}{2}\epsilon.$$

It is easily shown using elementary calculus that for any ϵ such that v_1 is on the convex hull of the points $\{v_1, \ldots, v_4\}$, rotating v_1 and v_3 around v until $\angle v_1vv_2 = \angle v_1vv_4$ (see Fig. 9) and $\angle v_2vv_3 = \angle v_4vv_3$ does not decrease the perimeter. Also, it maintains that v_1 is on the convex hull. Assume the two pairs of angles are equal, and define $F(\epsilon) = \overline{v_1v_2v_3v_4} - \epsilon/2 - 11/2$. We will show that F is nonpositive over the domain of possible ϵ's.

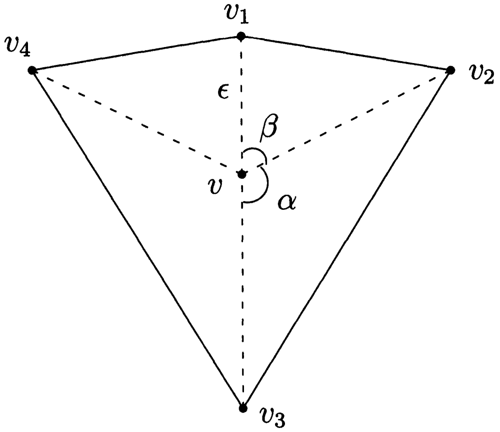

FIG. 9. *Figure to illustrate degree-4 case.*

As a function of ϵ, function F is a sum of convex functions minus a linear function and thus is convex. Therefore, F is maximized either when $\overline{vv_1} = 1$ or when v_1 is the midpoint of edge $\overline{v_2v_4}$ (since v_1 is on the convex hull, v_1 cannot cross the edge; hence this interval contains all possible values for ϵ).

In the first case, all four points lie on a unit circle with center at v. For any four such points, it is easily proven using calculus that $\overline{v_1v_2v_3v_4}$ is maximized when the four points are the vertices of a square at $4\sqrt{2} \approx 5.66$. Thus, $F(1) < 0$.

In the second case, $\overline{v_1v_2v_3v_4} = \overline{v_2v_3v_4}$. As noted previously, this is at most $3\sqrt{3} \approx 5.2$. Thus, $F(\epsilon) < 0$.

We now deal with the case when v_3 is the furthest point. In this case, we take the paths $P_1 = [v_4, v_1, v, v_2, v_3]$ and $P_2 = [v_3, v_4, v, v_1, v_2]$. The path P added by the algorithm is at most as heavy as the lighter of the paths P_1 and P_2. Hence,

$$w(P) \leq \min(P_1, P_2) \leq \frac{w(P_1) + w(P_2)}{2}.$$

Simplifying, we get

$$\overline{v_1v_2v_3v_4} \leq \frac{1}{2}\overline{vv_1} + \frac{5}{2}\overline{vv_3} + \frac{3}{2}(\overline{vv_2} + \overline{vv_4}).$$

The proof of this is identical to the proof of the previous case. □

4. Points in higher dimensions. We show how to compute a degree-3 tree (T_3) when the points are in arbitrary dimension $d \geq 3$. The algorithm for computing the tree is similar to the algorithm for computing degree-3 trees in the plane—the tree T_3 is formed by rooting the MST and taking the union of the paths $\{P_v\}$, where each P_v is the shortest path starting at v and visiting all of the children of v in the rooted MST. It is known that any Euclidean MST has constant degree [17] (for any fixed dimension), so that the algorithm still requires only linear time. The bound on the weight of T_3 is similar, except that v may have more children. We prove that regardless of the number of children that v has, the weight of P_v is at most 5/3 the weight of the edges that it replaces:

LEMMA 4.1. *Let $\{v, v_1, v_2, \ldots, v_k\}$ be a set of arbitrary points in $\Re^d$. There is a path P, starting at v, that visits all the points $v_1, v_2, \ldots, v_k$ such that*

$$w(P) \leq \frac{5}{3}\sum_{i=1}^{k}\overline{vv_i}.$$

Proof. We prove this by induction on the degree of v. Sort the points in increasing distance from v as $v_1, \ldots, v_k$. Let $v = v_0$. The lemma is trivially true when $k = 0, 1, 2$. Let us assume that the lemma is true for all values of k up to some $\ell \geq 2$. Consider $k = \ell + 1$. By the induction hypothesis, the claim is true when v has $k - 3$ children; hence we can find a path P' that starts at v and visits all vertices v_i ($i = 1, \ldots, k-3$) (not necessarily in that order) such that $w(P') \leq (5/3)\sum_{i=1}^{k-3}\overline{vv_i}$. Let v_j be the last vertex on the path P'. We add the cheapest path P'' that starts at v_j and visits v_{k-2}, v_{k-1}, and v_k (again, not necessarily in that order). This path together with P' will form a path that starts at v and visits all vertices adjacent to v. We now show that

$$w(P'') \leq \frac{5}{3}(\overline{vv_{k-2}} + \overline{vv_{k-1}} + \overline{vv_k}). \tag{8}$$

This suffices to prove the lemma. Let $P_1, \ldots, P_6$ be the six possibilities for P''. Clearly,

$$w(P'') \leq \frac{1}{6}\sum_{i=1}^{6} w(P_i).$$

We will prove that

$$\frac{1}{6}\sum_{i=1}^{6} w(P_i) \leq \frac{5}{3}(\overline{vv_{k-2}} + \overline{vv_{k-1}} + \overline{vv_k}).$$

This simplifies to

$$(9) \qquad 2\,\overline{v_{k-2}v_{k-1}v_k} + \sum_{i=k-2}^{k} \overline{v_j v_i} \leq 5(\overline{vv_{k-2}} + \overline{vv_{k-1}} + \overline{vv_k}).$$

Notice that if the above equation is not true, we can "shrink" all the v_i $(i = k-2, k-1, k)$ until $\overline{vv_j} = \overline{vv_{k-2}} = \overline{vv_{k-1}} = \overline{vv_k}$. Assume that $\delta = (\overline{vv_{k-2}} - \overline{vv_j}) + (\overline{vv_{k-1}} - \overline{vv_j}) + (\overline{vv_k} - \overline{vv_j})$. This can be done because the r.h.s decreases by 5δ and the l.h.s decreases by at most 5δ. If the above equation is not true, then it is also not true when the distance from v to all the points is the same. By scaling, we can assume that the distance of the points from v is 1. We call this a canonical configuration. The following proposition is implied by Lillington's work [13] and helps in completing the proof.

PROPOSITION 4.2. *Let $A, B, C,$ and D be points on a unit sphere in d dimensions, $d \geq 3$. The function $F = \overline{AB} + \overline{AC} + \overline{AD} + \overline{BC} + \overline{CD} + \overline{BD}$ reaches a maximum value of $4\sqrt{6}$ when the points $A, B, C,$ and D form a regular tetrahedron.*

We will now show that (9) is satisfied by the canonical configuration. The left side of (9) can be written as the sum of the sides of the tetrahedron formed by the points $\{v_k, v_{k-1}, v_{k-2}, v_j\}$ and the sum of the sides of the triangle formed by the points $\{v_k, v_{k-1}, v_{k-2}\}$. These points lie on a sphere whose center is v. By Lemma 4.2, the first sum is bounded by $4\sqrt{6}$. The second sum is bounded by $3\sqrt{3}$. Hence the left side of (9) is bounded by $4\sqrt{6} + 3\sqrt{3}$, which is about 14.994. The right side of (9) is 15. Hence (9) is satisfied by the canonical configuration and therefore all configurations. This concludes the proof of Lemma 4.1. □

Remark. The algorithm outlined earlier runs in linear time only when d, the number of dimensions, is a constant. The algorithm can be modified to run in linear time for all d as follows. Observe that in the proof of Lemma 4.1, we considered the neighbors of v only three at a time. Therefore, the algorithm could also group vertices into sets of three each, based on the distance from v, and inductively construct the path as in the proof of the lemma. This algorithm would have the same performance guarantee (5/3) as the earlier algorithm for constructing a degree-3 tree and in addition have the added advantage of running in linear time for all dimensions.

5. Conclusions. We have given a simple algorithm for computing a degree-3 (degree-4) tree for points in the plane that is within 1.5 (1.25) of an MST of the points. An extension of the algorithm finds a degree-3 tree of an arbitrary set of points in d dimensions within 5/3 of an MST. If an MST of the points is given as part of the input, our algorithms run in linear time. All our proofs are based on elementary geometric techniques.

Though our algorithms improve greatly the best-known ratios for each of the respective problems, there are still large gaps between the ratios that we obtain and the best bounds that we think are achievable. For example, in the case of points in the plane, consider the ratio of the weight of a minimum weight degree-3 tree to the weight of an MST. The worst example that we can obtain for this ratio is $\frac{\sqrt{2}+3}{4} \approx 1.104$ (with five points, where four of the points are at the corners of a square and the fifth point is in the middle). There is a large gap between this and the ratio of 1.5 obtained by our algorithm. Is 1.104 the worst-case ratio? Are there polynomial time algorithms which obtain factors better than 1.5? Notice that the performance ratio obtained by our algorithm on the example in Fig. 5 is highly sensitive to the vertex chosen as the root. One potential algorithm is to simply try all possible vertices as the root, and to pick the tree of minimum weight. Does such an algorithm have a better performance guarantee?

For the problem of finding degree-4 trees, our algorithm obtains a ratio of 1.25. Unlike degree-3 trees, we are unable to show that this ratio is tight for the algorithm. Can the factor of 1.25 for the algorithm be improved? The worst example for the ratio between a minimum-weight degree-4 tree and an MST that we can obtain is about 1.035 (five points on the vertices of a regular pentagon with a sixth point in their centroid). Are there examples with worse ratios?

Problems of approximating degree-k trees in higher dimensions and in general metric spaces within factors better than 2 are still open.

Acknowledgments. We thank Andras Bezdek for telling us about [13]. We thank Karoly Bezdek and Bob Connelly for useful discussions and the committee members of the 1994 Syposium on the Theory of Computing for simplifying the proof of Lemma 3.3 and for pointing out [14].

OPTIMAL CLOCK SYNCHRONIZATION UNDER DIFFERENT DELAY ASSUMPTIONS*

HAGIT ATTIYA[†], AMIR HERZBERG[‡], AND SERGIO RAJSBAUM[§]

Abstract. The problem of achieving optimal clock synchronization in a communication network with arbitrary topology and perfect clocks (that do not drift) is studied. Clock synchronization algorithms are presented for a large family of delay assumptions. Our algorithms are modular and consist of three major components. The first component holds for any type of delay assumptions; the second component holds for a large, natural family of local delay assumptions; the third component must be tailored for each specific delay assumption.

Optimal clock synchronization algorithms are derived for several types of delay assumptions by appropriately tuning the third component. The delay assumptions include lower and upper delay bounds, no bounds at all, and bounds on the difference of the delay in opposite directions. In addition, our model handles systems where some processors are connected by broadcast networks in which every message arrives at all the processors at approximately the same time. A composition theorem allows combinations of different assumptions for different links or even for the same link; such mixtures are common in practice.

Our results achieve the best possible precision in each execution. This notion of optimality is stronger than the more common notion of worst-case optimality. The new notion of optimality applies to systems where the worst-case behavior of any clock synchronization algorithm is inherently unbounded.

1. Introduction.

In most large-scale distributed systems, processors communicate by message transmission and do not have access to a central clock. Nonetheless it is useful, and sometimes even necessary, for the processors to obtain some common notion of time. The technique used to attain this notion of time is known as *clock synchronization.* Synchronized clocks are useful for various applications such as control of real-time processes, transaction processing in database systems, and communication protocols. Recently, several software protocols that support clock synchronization in communication networks have been proposed [1, 7, 13, 15, 16]; system designers have been advocating the use of synchronized clocks [10].

The quality of synchronization is measured by its *precision*, i.e., how close together it brings the clocks at different processors.[1] The precision influences the correctness and the efficiency of applications using the synchronized clocks.

The best precision that can be achieved is determined by the timing uncertainty that is inherent in the system. There are two main sources of timing uncertainty in a distributed system. First, local clocks at different processors are independent: they do not start together and may run at different speeds. Second, messages sent between processors incur uncertain delays.

A relatively simple case is when local clocks are accurate, i.e., run at the same speed, and there are upper and lower bounds for the delay on each link. Clock synchronization algorithms under this assumption, whose precision is optimal in the worst case, are described in [4, 11]. Subsequent work concentrated on clocks that may drift and on fault tolerance (e.g., [2, 7, 20, 21]; see the survey in [19]). To achieve high precision, these algorithms require the existence of tight lower and upper bounds on message delay.

However, in real systems it is often the uncertainty of message delay, rather than clock drift, that causes most of the difficulty in synchronizing clocks [13, 7]. Almost every processor in a distributed system has access to a high-quality, very accurate hardware clock; it is not unrealistic to assume that local clocks are accurate and have no drift.[2] On the other hand, often there do not exist tight upper and lower bounds on message delay, while there is other relevant information about the delays. For example, in some systems, a bound on the difference between delays in opposite directions is known. This motivated us to revisit the case in which local clocks run at the same speed and have no drift, thus focusing on the impact of message delay uncertainty on clock synchronization.

Our main contribution is a methodology for designing optimal clock synchronization algorithms under a variety of assumptions on message delay uncertainty. The strongest results are obtained for a natural family of local delay assumptions; this family includes all the assumptions studied in previous theoretical work. A delay assumption is *local* if it is specified for a pair of processors, e.g., processors connected by a link. We show that in this case, a clock synchronization algorithm can be obtained by considering each pair separately. This simplifies the analysis substantially and allows different pairs of processors to satisfy different assumptions. Furthermore, we prove a composition theorem that allows us to combine several local delay assumptions. For example, it is possible that for some pair of processors there will be upper and lower bounds on the message delay in each direction as well as a bound on the difference between message delays in opposite directions.

The basic difficulty of clock synchronization stems from the existence of two different system executions in which all processors have the same views. The tightness of the achievable synchronization depends on how "far away" in real time such executions can be. We capture this notion quantitatively as the *maximal shift* between processors in a given execution. Using this notion, we partition the design of a clock synchronization algorithm into three stages.

[1] This does not ensure that clocks are close to real time. It is easy to adapt our results to reach this goal if a perfect real-time clock is available. Synchronization to real time is often useful and is achieved by practical protocols that usually also deal with multiple, imperfect real-time clocks, e.g., the Internet NTP [13].

[2] To deal with the small drift that does exist, the clock synchronization mechanism is invoked periodically; see, e.g., Kopetz and Ochsenreiter [7].

1. Computing corrections to the local clocks from the maximal shifts. This stage is valid for any kind of message delay assumptions.
2. Computation of maximal shifts from *maximal local shifts*, which depend only on the views of pairs of processors. This stage is valid for message delay assumptions that are local.
3. Computation of the maximal local shifts from the local views. This depends on the specific message delay assumptions.

The computations in stages 1 and 2 are performed by a centralized, off-line algorithm.

Our methodology yields optimal clock synchronization algorithms for a variety of delay assumptions by adapting the third stage. In particular, we show how to compute maximal local shifts for the following message delay assumptions:

1. upper and lower bounds on delays are known (including the degenerated cases of zero lower bound and/or infinite upper bound);
2. there is a bound on the difference on the delay in opposite directions; and
3. there is a bound on the difference in the times when different processors receive a multicast message.

Most previous formal work on deterministic clock synchronization addressed only a restricted version of the first assumption where the delay upper bounds are finite. However, an observation of [1] shows that in many actual links, there is some minimal delay (e.g., due to the actual transmission rate and processing time), while there is no known upper bound. The second assumption follows experimental results (cf. [13]), showing that message delays in opposite directions of a bidirectional link are usually very close. The last assumption is useful for broadcast networks that are used in many local area networks; this is the assumption used in [5, 18].

Our composition theorem implies that our algorithms apply to systems where the same pair of processors satisfies several different delay assumptions. Such mixtures are quite common in practical, heterogeneous systems. For example, there are systems in which several local area (broadcast) networks are connected by bridges or (long-distance) links.

Our work extends the results of Halpern, Megiddo, and Munshi [4], who use linear programming techniques that do not illuminate the inherent difficulties of synchronizing clocks. We believe that our work gives a more precise understanding of the problem, explicitly showing the requirements of each step and thereby facilitating adaptation to other delay assumptions. Their results are a special case of the general methodology developed here, in which exactly one message is sent on each link, and upper and lower bounds on delays are known. In fact, the algorithm we obtain for this specific setting is essentially the one in [4].

Previous definitions of optimal clock synchronization were based on the worst (largest) difference between clocks of two processors in any execution. For some of the assumptions that we study in this paper, e.g., when no upper bounds on the delays are known, this worst case is inherently unbounded. Moreover, as already stated in [4], we would like to award algorithms that exploit favorable conditions and achieve the best possible precision in each specific instance. We give a precise definition of optimality for each specific execution and show that it is achieved by our algorithms (and hence also by the algorithm of [4]).

When trying to crystallize these ideas, it turned out that the decision of which messages to send should be separated from the method for adjusting the clocks based on the local message histories. Our framework shows how to adjust the clocks optimally, given any set of local message histories. The decision of which messages to send, to whom, when, etc., can therefore take other considerations into account, e.g., message traffic optimization, and is left outside of the scope of this paper.

The rest of this paper is organized as follows. In §2 the model and the clock synchronization problem are defined. Section 3 presents the general clock synchronization algorithm and proves that it achieves optimal precision; the algorithm is independent of the message delay assumptions. In §4 we show how to compute the inputs needed for the general clock synchronization algorithm, when some local information about the views of the processors is given; the computation is valid for local systems. In §5 we show how to compute the required information on the views for several specific delay assumptions. Conclusions and open questions appear in §6.

2. Definitions.

2.1. Defining optimal precision. We would like a clock synchronization algorithm to obtain the best possible precision, that is, to bring the logical clocks as close to each other as possible. However, it is not obvious how to compare the precision achieved by different algorithms and how to define optimality.

An elegant solution is to evaluate a clock synchronization algorithm by the worst (largest) precision achieved in any of its executions. This worst-case interpretation follows the tradition of worst-case complexity analysis of algorithms.

This definition has two drawbacks. First, like any definition that concentrates on the worst case, it does not award algorithms that behave well in other cases. An algorithm that is optimal under this definition can be very inefficient in executions where the delays are favorable. Second, worst-case analysis is meaningful only if the worst-case precision is bounded. However, in many important cases, the worst-case precision can easily be shown to be unbounded, e.g., when there are no upper bounds on message delay.

We believe a more refined notion of optimality is warranted. Intuitively, an optimal algorithm is one whose precision, in every execution, is not larger than the precision of any other algorithm in an execution where the message delivery system "acts the same."

Formalizing this idea is not so simple. The major difficulty is finding a satisfying definition for executions where the message delivery system acts the same. The problem is that the properties of the execution are determined by the interaction between the message delivery system and the algorithm. The algorithm controls the execution by deciding when to send messages, while the message delivery system controls the execution by determining their delay.[3] It is difficult to isolate the effect on the execution determined by the message delivery system. Such isolation is necessary in order to compare executions of a given algorithm to executions of other algorithms where the message delivery system is equally adversarial. A definition is too strong if it compares an execution of one algorithm with an execution of another algorithm in which message delays are unfairly favorable. Conversely, a definition is too weak if executions with the same message delivery policy are not compared. We sidestep this problem by noticing that the construction of a clock synchronization algorithm has two aspects: first, the design of the interactive part where the processors send messages; and second, calculating corrections using the views of the processors that were obtained during the interactive part. In this paper, we do not address the first

[3] This is not merely a formal issue: from a practical point of view, if an algorithm sends too many messages in a short period of time, the network becomes congested and delays are long and highly variant.

aspect. We assume that we have a set of views, one for each processor, and we ask how to compare optimal corrections for this set of views.

2.2. Model of computation. Here we formalize the behavior of the interactive part of a clock synchronization algorithm, which is a distributed algorithm running on a network. The distributed algorithm decides when to send messages, while the network decides when to deliver the messages. The interplay between the distributed algorithm and the network generates a set of executions. The result of this execution is the input to the clock synchronization function.

We consider a set $P = \{p_1, \ldots, p_n\}$ of *processors.* With each processor $p \in P$ we associate a (local) clock. The clock cannot be modified by the processor. Processors do not have access to real time; each processor obtains its only information about time from its clock and from messages sent by other processors. The clock is represented by a local time component, which is a real number. In the sequel, the term *clock time* refers to the local time component of the processor, while the term *real time* refers to the absolute time as measured by an outside observer. In this work we assume that clocks do not drift, i.e., that they run at the same rate as real time, but they are not necessarily synchronized with each other.

We list the *events* that can occur at processor p, together with an informal explanation.

Message-receive events—receive(p, m, q) for all messages m and processors q: processor p receives message m from processor q.

Message-send events—send$(p,\ m,\ q)$ for all messages m and processors q: processor p sends message m to processor q.

Timer-set events—timer-set$(p,\ T)$ for all clock times T: processor p sets a timer to go off when its clock reads T.

Timer events—timer$(p,\ T)$ for all clock times T: a timer that was set for time T on p's clock goes off.

Start events—start$(p,\ 0)$: p starts executing the algorithm, with the initial value of its clock being 0.

The message-receive, timer, and start events are *interrupt events.*

Each processor is modeled as an automation with a (possibly infinite) set of states, including an initial state, and a transition function. Each interrupt event causes an application of the transition function, which runs from states, clock times, and interrupt events to states, sets of message-send events, and sets of timer-set events (for subsequent clock times). That is, the transition function takes as input the current state, clock time, and interrupt event (which is the receipt of a message from another processor or a timer going off) and produces a new state, a set of messages to be sent, and a set of timers to be set for the future.

A *step* of p is a tuple (s, T, i, s', M, TS), where s and s' are states; T is a clock time; i is an interrupt event; M is a set of message-send events; TS is a set of timer-set events; and s', M, and TS are the results of p's transition function acting on s, T, and i. A *history* π of a processor p is a mapping associating to each number from $\Re$ (real time) a finite sequence (possibly empty) of steps such that the following hold.

1. For each real time t, there is only a finite number of times $t' < t$ such that the corresponding sequence of steps is nonempty (thus the concatenation of all the sequences in real-time order is a sequence).
2. The interrupt event in the first step of the history is a start event, and the old state in the first step is p's initial state; furthermore, there are no other

start events; let S_π be the real time of the start event.

3. The old state of each subsequent step is the new state of the previous step.
4. For each real time t, the clock-time component T of each step in the corresponding sequence is equal to $t - S_\pi$ (thus, the clock time of the start event of p is 0).
5. For each real time t, in the corresponding sequence there is at most one timer event and it is ordered after all other events.
6. A timer is received by p at clock time T if and only if p has previously set a timer for T.

An *execution* is a set of histories, one for each processor p in P, such that there is a one-to-one correspondence between the messages received by q from p and the messages sent by p to q for any processors p and q. (To simplify our discussion, we assume that messages are unique, so this correspondence is uniquely defined.) Note that this definition allows messages to be lost and delivered in non-FIFO (first in–first out) order; however, it assumes messages are not corrupted or duplicated. We use the message correspondence to define the *delay* of a message m received in execution α, denoted $\mathrm{d}_\alpha(m)$, to be the real time of receipt minus the real time of sending. When α is clear from the context, we simply write $\mathrm{d}(m)$.

Let $S_{\alpha,p} = S_\pi$ where π is p's history in α; that is, $S_{\alpha,p}$ is the real time of the start event of the processor p in α.

Note that the message delivery system is not explicitly modeled. The requirements from an execution state are that messages are delivered without duplication and that the system does not generate messages; the system can reorder or lose messages.

A system $(P, \mathcal{A})$ is a set of processors P and a set of executions $\mathcal{A}$, called *admissible executions.* For example, $\mathcal{A}$ may allow communication only between specific pairs of processors connected by a link.

The cornerstone of our definitions and proofs is the notion of equivalent executions. Informally, two executions are equivalent if they are indistinguishable to the processors; only an outside observer who has access to the real time can tell them apart.

To formalize this notion, define the *view* of processor p in history π to be the concatenation of the sequences of steps in π in real-time order. (Note that the view includes the clock times.) The real times of occurrence are not represented in the view. Let α be an execution, and let π be p's history in α. The view of p in α is the view of p in π and is denoted $\alpha|p$. Two executions α and α' are *equivalent*, denoted $\alpha \equiv \alpha'$, if for every processor $p \in P, \alpha|p = \alpha'|p$.

2.3. The clock synchronization problem. The goal of a clock synchronization algorithm is to bring the clocks of the processors as close to each other as possible, while keeping the clocks' values with the progress of real time. Intuitively, each processor maintains a *logical clock*, which "corrects" the value of the local clock. Since the logical clock is required not to drift from the progress of real time, it is straightforward to see that the logical clock must be the local clock plus some correction factor. Thus, the goal of a clock synchronization algorithm is to compute a correction for each processor such that, for any two processors, the values of the local clocks (at the same real time) plus the respective corrections are close.

Specifically, a *clock synchronization algorithm* is a function from a set of n views to a vector of n real numbers, called *corrections.* Given a clock synchronization algorithm f and an execution α, we abuse notation and denote by $f(\alpha)$ the vector obtained by applying f to the n views in α; we denote by $f(\alpha, p)$ the component of

$f(\alpha)$ that corresponds to p. Since a clock synchronization algorithm depends only on the views, we have the following claim.

CLAIM 2.1. *If $\alpha \equiv \alpha'$, then $f(\alpha) = f(\alpha')$.*

Recall that at any real time t, the clock value of p is $t - S_{\alpha,p}$. Given a clock synchronization function f, the corrected local time of p in α is $t - S_{\alpha,p} + f(\alpha, p)$. Therefore, $|(S_{\alpha,p} - f(\alpha,p)) - (S_{\alpha,q} - f(\alpha,q))|$ is the difference between the corrected local times of p and q in α.

To capture the precision achieved by some vector of corrections $\vec{x} = \langle x_1, \ldots, x_n \rangle$ denote $\rho(\alpha, \vec{x}) = \max_{p,q \in P} |(S_{\alpha,p} - x_p) - (S_{\alpha,q} - x_q)|$. That is, $\rho(\alpha, \vec{x})$ is the largest discrepancy between two clocks of different processors after they are corrected.

Because the computation of the corrections does not distinguish between equivalent executions, we measure the precision for a specific execution α by considering the worst discrepancy achieved for all the executions equivalent to α. Let $\mathcal{A}$ be the set of admissible executions. Formally, for any execution $\alpha \in \mathcal{A}$, the inherent precision achieved by a vector of corrections $\vec{x}$ is

$$\bar{\rho}(\alpha, \vec{x}) = \sup\{\rho(\alpha', \vec{x}) : \alpha' \equiv \alpha \text{ and } \alpha' \in \mathcal{A}\}.$$

DEFINITION 2.1. *A clock synchronization algorithm f* computes optimal corrections *if for every admissible execution α and every vector of corrections $\vec{x}$, $\bar{\rho}(\alpha, f(\alpha)) \leq \bar{\rho}(\alpha, \vec{x})$.*

We call $\bar{\rho}(\alpha, f(\alpha))$ the *precision* of f on α and use the shorthand $\bar{\rho}(\alpha, f)$.

3. A general clock synchronization algorithm. As mentioned before, the basic difficulty of computing corrections is the fact that there may be two admissible executions α and α' in which all processors have the same views. Clearly, the tightness of the achievable synchronization depends on how "far away" in real time α' can be from α. We formally quantify this idea by defining the maximal shift between processors in a given execution. We show that if estimates of the maximal shifts are available, then there exists a function that computes optimal corrections. This is done by showing a lower bound for the precision that depends only on the maximal shifts. Then we show that this bound is tight by presenting a method for computing corrections that achieves this value as its precision. In subsequent sections we show how to estimate the maximal shifts for specific systems.

3.1. Maximal shifts. Consider two equivalent executions α and α'. It follows that for any $p \in P$, the sequence of steps in α' is equal to the sequence of steps in α, except that p executes its steps at different real times. Since the clocks have no drift, it follows that the difference between the real times of occurrence of a step in α and the corresponding step in α' is *fixed*, independently of the step. This implies that α' can be obtained by "shifting" the steps of the processors in α.

In the rest of this section, we formalize this notion of *shifting* and study its properties. This technique was originally introduced by Lundelius and Lynch [11] to prove lower bounds on the precision achieved by clock synchronization algorithms in complete graphs.

Formally, given a history π of processor p and a real number s, a new history $\pi' = \text{shift}(\pi, s)$ is defined by $\pi'(t) = \pi(t + s)$ for all t. That is, all tuples are shifted earlier in π' by s if s is positive and later by $-s$ if s is negative. Clearly, the views do not change with shifting. Furthermore, we have the following result.

LEMMA 3.1 (Lundelius and Lynch [11]). *Let π be a history of processor p, and let s be a real number. Then $\pi' = \text{shift}(\pi, s)$ is a history of p and $S_{\pi'} = S_\pi - s$.*

Let α and α' be two equivalent executions such that each processor $p \in P$ is shifted in α' with respect to (w.r.t.) α by s_p; the *vector of shifts* of α' w.r.t. α is the vector $\vec{s} = \langle s_1, \ldots, s_n \rangle$. That is, execution α' was obtained by replacing p's history in α, π, with $\text{shift}(\pi, s_p)$, for each $p \in P$, and by retaining the same correspondence between message-send and message-receive events. (Technically, the correspondence is redefined so that a pairing in α that involves the event for p at time t, in α' involves the event for p at time $t - s_p$.) We denote α' by $\text{shift}(\alpha, \vec{s})$. Clearly, we have the following claim.

CLAIM 3.2. *Let* $\alpha' = \text{shift}(\alpha, \langle s_1, \ldots, s_n \rangle)$. *For every message* m *received by processor* p *from* q *in* α, $\mathrm{d}_{\alpha'}(m) = \mathrm{d}_\alpha(m) + (s_q - s_p)$.

The following claim follows from the definitions.

CLAIM 3.3. *For any pair of executions* α *and* α', $\alpha \equiv \alpha'$ *if and only if there exists a vector of shifts* $\vec{s}$ *such that* $\alpha' = \text{shift}(\alpha, \vec{s})$.

We now formalize the notion of how "far away" a processor can be shifted w.r.t. another processor. Fix a system $(P, \mathcal{A})$, and let $\alpha \in \mathcal{A}$. We say that s is an *admissible shift of* q *w.r.t.* p *in* α if there exists a vector of shifts $\vec{s} = \langle s_1, \ldots, s_n \rangle$ with $s_q - s_p = s$ such that $\alpha' = \text{shift}(\alpha, \vec{s})$ is in $\mathcal{A}$. Define

$$\mathrm{ms}_\alpha(p, q) = \sup\{s : s \text{ is an admissible shift of } q \text{ w.r.t. } p \text{ in } \alpha\}.$$

This is the *maximal shift* of q w.r.t. p in α; that is, how far away can q be shifted from p while retaining the admissibility of the execution. Since 0 is obviously an admissible shift of q w.r.t. p in α, it follows that $\mathrm{ms}_\alpha(p, q) \geq 0$. Note that in certain cases, e.g., when no message was sent, the maximal shift can be infinite.

CLAIM 3.4. *Let* $\alpha \in \mathcal{A}$ *and let* $\alpha' \equiv \alpha$. *If* $\alpha' \in \mathcal{A}$, *then* $S_{\alpha',p} - S_{\alpha',q} \leq S_{\alpha,p} - S_{\alpha,q} + \mathrm{ms}_\alpha(p, q)$ *for any two processors* p *and* q.

Proof. By Claim 3.3, $\alpha' = \text{shift}(\alpha, \vec{s})$ for some vector of shifts $\vec{s} = \langle s_1, \ldots, s_n \rangle$. Fix a pair of processors p and q. Since $\alpha' \in \mathcal{A}$, it follows that $s_q - s_p \leq \mathrm{ms}_\alpha(p, q)$. The claim follows since $S_{\alpha',p} = S_{\alpha,p} - s_p$ and $S_{\alpha',q} = S_{\alpha,q} - s_q$. □

3.2. The lower bound. Fix a system $(P, \mathcal{A})$, an admissible execution α, and a clock synchronization algorithm f. The following lemma relates the maximal shift and the attainable precision.

LEMMA 3.5. *For any pair of processors* p *and* q, $\bar{\rho}(\alpha, f) \geq S_{\alpha,p} - f(\alpha, p) - S_{\alpha,q} + f(\alpha, q) + \mathrm{ms}_\alpha(p, q)$.

Proof. Let s be an arbitrary admissible shift of q w.r.t. p in α. Let $\alpha' \in \mathcal{A}$ be an execution such that $\alpha' \equiv \alpha$ and q is shifted w.r.t. p by s. Then

$$\begin{aligned}\bar{\rho}(\alpha, f) \geq \rho(\alpha', f(\alpha')) &\geq S_{\alpha',p} - f(\alpha', p) - S_{\alpha',q} + f(\alpha', q) \\ &= S_{\alpha,p} - f(\alpha', p) - S_{\alpha,q} + f(\alpha', q) + s \\ &= S_{\alpha,p} - f(\alpha, p) - S_{\alpha,q} + f(\alpha, q) + s \quad \text{(by Claim 2.1)}.\end{aligned}$$

Since s was chosen arbitrarily,

$$\bar{\rho}(\alpha, f) \geq S_{\alpha,p} - f(\alpha, p) - S_{\alpha,q} + f(\alpha, q) + \mathrm{ms}_\alpha(p, q). \qquad \square$$

The previous lemma implies that if $\mathrm{ms}_\alpha(p, q)$ is infinite for a pair of processors p, q then no clock synchronization algorithm can achieve a finite precision $\bar{\rho}(\alpha, f)$. The expression defined next will turn out to be a lower bound on the precision that can be achieved in α. Let θ be a cyclic sequence of processors, that is, $\theta = p_0, p_1, \ldots, p_{k-1}, p_k$, where $p_k = p_0$; processors p_i and p_{i+1} are not necessarily adjacent in the graph.

Denote $|\theta| = k$ and $\text{ms}_\alpha(\theta) = \sum_{i=0}^{k-1} \text{ms}_\alpha(p_i, p_{i+1})$. Let $A_\alpha(\theta) = \text{ms}_\alpha(\theta)/|\theta|$, and define

$$A_\alpha^{\max} = \max\{A_\alpha(\theta) : \theta \text{ is a cyclic sequence of processors}\}.$$

THEOREM 3.6. *For any clock synchronization algorithm $f, \bar{\rho}(\alpha, f) \geq A_\alpha^{\max}$.*

Proof. Let $\theta = p_0, \ldots, p_k$ be an arbitrary cyclic sequence of processors (where $p_k = p_0$). By Lemma 3.5,

$$\bar{\rho}(\alpha, f) \geq S_{\alpha,p_i} - f(\alpha, p_i) - S_{\alpha,p_{i+1}} + f(\alpha, p_{i+1}) + \text{ms}_\alpha(p_i, p_{i+1})$$

for every $i, 0 \leq i \leq k-1$. Summing over all the consecutive processors in θ, we have

$$k \cdot \bar{\rho}(\alpha, f) \geq \sum_{i=0}^{k-1} [S_{\alpha,p_i} - f(\alpha, p_i) - S_{\alpha,p_{i+1}} + f(\alpha, p_{i+1}) + \text{ms}_\alpha(p_i, p_{i+1})].$$

Clearly,

$$\sum_{i=0}^{k-1} [S_{\alpha,p_i} - f(\alpha, p_i) - S_{\alpha,p_{i+1}} + f(\alpha, p_{i+1})] = 0,$$

and hence,

$$\bar{\rho}(\alpha, f) \geq \frac{1}{k} \sum_{i=0}^{k-1} \text{ms}_\alpha(p_i, p_{i+1}) = A_\alpha(\theta),$$

as needed. □

3.3. The upper bound. Now we show the converse direction, i.e., that there exists a clock synchronization algorithm f with $\bar{\rho}(\alpha, f) = A_\alpha^{\max}$, for every α, provided certain estimates can be computed from the views. By Theorem 3.6, no other clock synchronization algorithm can achieve better precision. Hence our clock synchronization algorithm computes optimal corrections in the sense of Definition 2.1.

Clearly, if the values of $\text{ms}_\alpha(p, q)$ are known, then it is possible to calculate $A_\alpha^{\max}$. As we shall see, computing $A_\alpha^{\max}$ is the crux of computing optimal corrections. However, since the views do not include the actual message delays, it is not clear what the set of equivalent executions is; hence, in general, it is impossible to compute the values of $\text{ms}_\alpha(p, q)$ from the views. Below we show that it suffices to have only estimates on $\text{ms}_\alpha(p, q)$. In the next sections, we show how to obtain these estimates for specific systems.

Define the *estimated maximal global shift* to be $\widetilde{\text{ms}}_\alpha(p, q) = \text{ms}_\alpha(p, q) + S_{\alpha,p} - S_{\alpha,q}$. The next lemma is the key to replacing ms_α with the estimates $\widetilde{\text{ms}}_\alpha$ in the calculation of $A_\alpha^{\max}$. The lemma shows that the maximum average cycle weight with respect to the actual maximal shifts is equal to the maximum average cycle weight with respect to the estimates. Specifically, for any cyclic sequence of processors $\theta = p_0, \ldots, p_k$ (where $p_k = p_0$), let $\widetilde{\text{ms}}_\alpha(\theta) = \sum_{i=0}^{k-1} \widetilde{\text{ms}}_\alpha(p_i, p_{i+1})$. Also, let $\tilde{A}_\alpha(\theta) = \widetilde{\text{ms}}_\alpha(\theta)/|\theta|$, and define

$$\tilde{A}_\alpha^{\max} = \max\{\tilde{A}_\alpha(\theta) : \theta \text{ is a cyclic sequence of processors}\}.$$

LEMMA 3.7. $A_\alpha^{\max} = \tilde{A}_\alpha^{\max}$.

Proof. Consider any cyclic sequence of processors $\theta = p_0, \ldots, p_k$ (where $p_k = p_0$), and sum the estimates around the cycle as follows:

$$\sum_{i=0}^{k-1} \tilde{\mathrm{ms}}_\alpha(p_i, p_{i+1}) = \sum_{i=0}^{k-1} [\mathrm{ms}_\alpha(p_i, p_{i+1}) + S_{\alpha,p_i} - S_{\alpha,p_{i+1}}].$$

However, the values for S_{α,p_i} cancel each other and we get $\sum_{i=0}^{k-1} \mathrm{ms}_\alpha(p_i, p_{i+1})$, which is $\mathrm{ms}_\alpha(\theta)$. Since this holds for every cyclic sequence of processors, it also holds for any sequence θ where A_α is maximized, i.e., where $A_\alpha(\theta) = A_\alpha^{\max}$. □

Thus, we have the following function for computing corrections.

FUNCTION SHIFTS

Given inputs $\tilde{\mathrm{ms}}_\alpha(p,q) = \mathrm{ms}_\alpha(p,q) + S_{\alpha,p} - S_{\alpha,q}$ for every pair of processors p and q.

1. Compute $A_\alpha^{\max}$ (by computing $\tilde{A}_\alpha^{\max}$).
2. Select an arbitrary root processor r. The correction for each processor $p \in P$ is $\mathrm{dist}_w(r,p)$—the distance in the (complete) directed graph relative to the weights $w(p,q) = A_\alpha^{\max} - \tilde{\mathrm{ms}}_\alpha(p,q)$.

The value of $\tilde{A}_\alpha^{\max}$ can be computed in step 1 by using an algorithm of Karp [6] that runs in $O(n^3)$ time. By Lemma 3.7, this is equivalent to computing $A_\alpha^{\max}$. By definition, $A_\alpha^{\max} \geq A_\alpha(\theta) = \mathrm{ms}_\alpha(\theta)/|\theta|$ for any cycle θ. Therefore,

$$\sum_{\langle p,q\rangle \in \theta} (A_\alpha^{\max} = \tilde{\mathrm{ms}}_\alpha(p,q)) = |\theta| A_\alpha^{\max} - \tilde{\mathrm{ms}}_\alpha(\theta) \geq 0.$$

This implies that there are no negative weight cycles in the complete graph with the weights $w(p,q) = A_\alpha^{\max} - \tilde{\mathrm{ms}}_\alpha(p,q)$. Thus, the distances can be computed as in step 2.

THEOREM 3.8. *The function* SHIFTS *computes optimal corrections with precision* $A_\alpha^{\max}$ *in each execution* α.

Proof. Denote by $f(\alpha)$ the vector of corrections computed by SHIFTS given $\tilde{\mathrm{ms}}_\alpha(p,q)$. We will show that $\bar{\rho}(\alpha, f) \leq A_\alpha^{\max}$; it follows from Theorem 3.6 that these are optimal corrections.

To prove that $\bar{\rho}(\alpha, f) \leq A_\alpha^{\max}$ we need to show that $\rho(\alpha', f(\alpha')) \leq A_\alpha^{\max}$ for any admissible execution $\alpha' \equiv \alpha$. It suffices to show that for every pair of processors p and q,

$$S_{\alpha',p} - f(\alpha',p) - S_{\alpha',q} + f(\alpha',q) \leq A_\alpha^{\max}.$$

Fix some pair of processors p and q. By the definition of the function SHIFTS, $f(\alpha,q) = \mathrm{dist}_w(r,q)$ and $f(\alpha,p) = \mathrm{dist}_w(r,p)$, relative to the weights $w(p,q) = A_\alpha^{\max} - \tilde{\mathrm{ms}}_\alpha(p,q)$. Thus

$$f(\alpha,q) - f(\alpha,p) = \mathrm{dist}_w(r,q) - \mathrm{dist}_w(r,p) \leq w(p,q) = A_\alpha^{\max} - \tilde{\mathrm{ms}}_\alpha(p,q).$$

Adding $\tilde{\mathrm{ms}}_\alpha(p,q) - \mathrm{ms}_\alpha(p,q)$ to both sides, we get

$$\tilde{\mathrm{ms}}_\alpha(p,q) - \mathrm{ms}_\alpha(p,q) + f(\alpha,q) - f(\alpha,p) \leq A_\alpha^{\max} - \mathrm{ms}_\alpha(p,q).$$

By the definition of estimated maximal shifts, $\tilde{\mathrm{ms}}_\alpha(p,q) - \mathrm{ms}_\alpha(p,q) = S_{\alpha,p} - S_{\alpha,q}$. Hence

$$S_{\alpha,p} - S_{\alpha,q} + f(\alpha,q) - f(\alpha,p) + \mathrm{ms}_\alpha(p,q) \leq A_\alpha^{\max}.$$

Since $\alpha \equiv \alpha'$, Claim 2.1 implies that $f(\alpha) = f(\alpha')$, and thus

$$S_{\alpha,p} - S_{\alpha,q} + f(\alpha',q) - f(\alpha',p) + \mathrm{ms}_\alpha(p,q) \leq A_\alpha^{\max}.$$

By Claim 3.4, $S_{\alpha',p} - S_{\alpha',q} \leq S_{\alpha,p} - S_{\alpha,q} + \mathrm{ms}_\alpha(p,q)$, and thus,

$$S_{\alpha',p} - f(\alpha',p) - S_{\alpha',q} + f(\alpha',q) \leq A_\alpha^{\max},$$

as needed. □

This theorem implies that given estimates $\tilde{\mathrm{ms}}_\alpha$ of the maximal shifts, we can compute optimal corrections.

4. Calculating estimates in local systems. In the previous section, we reduced the problem of designing an optimal clock synchronization algorithm to the problem of finding the estimates $\tilde{\mathrm{ms}}_\alpha(p,q)$ of maximal shifts for each pair of processors p and q. Given such estimates, the clock synchronization problem can be solved by computing the function SHIFTS. Next we show how to calculate $\tilde{\mathrm{ms}}_\alpha$. In this section, we show how to compute these estimates in the natural class of local systems. Intuitively, in local systems the delays of messages sent to a pair of processors, e.g., along edges connecting them, do not depend on the delays of messages sent to other processors.

For local systems, estimates $\tilde{\mathrm{ms}}(p,q)$ can be computed in two steps. In the first step, local (pairwise) estimates $\tilde{\mathrm{mls}}(p,q)$ are computed. In the second step, the desired global estimates $\tilde{\mathrm{ms}}(p,q)$ are produced by combining the local estimates. In this section we deal only with the second step; i.e., we show how to compute global estimates from local estimates. In the next section, we compute the local estimates based on the views for several specific systems.

To design a clock synchronization algorithm for a specific local system, only the calculation of local estimates must be modified. As illustrated by the particular systems discussed in the next section, this calculation handles each pair of processors separately. This significantly simplifies reasoning and allows us to deal with combinations of several assumptions on the same or on different edges, as we show at the end of this section.

4.1. Local systems. Informally, a system is local if its admissible executions can be expressed as the intersection of sets of executions, each set restricting only the views of a specific pair of processors.

DEFINITION 4.1. *A set of executions $\mathcal{A}_{p,q}$ is* local *to p and q provided that for every execution $\alpha \in \mathcal{A}_{p,q}$, if there exists an execution α' such that $\alpha'|q = \alpha|q$ and $\alpha'|p = \alpha|p$, then $\alpha' \in \mathcal{A}_{p,q}$.*

Note that this implies that $\mathcal{A}_{p,q}$ allows arbitrary shifts as long as both p and q are shifted by the same amount, which is reworded as follows.

CLAIM 4.1. *Assume $\mathcal{A}_{p,q}$ is local to p and q. Let $\alpha \in \mathcal{A}_{p,q}$, and let $\vec{s} = \langle s_1, \ldots, s_n \rangle$ be a vector of shifts such that $s_p = s_q$. Then* $\mathrm{shift}(\alpha, \vec{s}) \in \mathcal{A}_{p,q}$.

Let $\alpha \in \mathcal{A}_{p,q}$. We say that s is a *locally admissible shift* of q w.r.t. p in α if there exists a vector of shifts $\vec{s} = \langle s_1, \ldots, s_n \rangle$ such that $s_q - s_p = s$ and $\mathrm{shift}(\alpha, \vec{s}) \in \mathcal{A}_{p,q}$. We have the following claim.

CLAIM 4.2. *Assume $\mathcal{A}_{p,q}$ is local to p and q, and consider an execution $\alpha \in \mathcal{A}_{p,q}$. A value s is a locally admissible shift of q w.r.t. p in α if and only if for every vector of shifts $\vec{s} = \langle s_1, \ldots, s_n \rangle$ with $s_q - s_p = s$,* $\mathrm{shift}(\alpha, \vec{s}) \in \mathcal{A}_{p,q}$.

Define the *maximal local shift of q w.r.t. p in α* to be

$$\mathrm{mls}_\alpha(p,q) = \sup\{s : s \text{ is a locally admissible shift of } q \text{ w.r.t. } p \text{ in } \alpha\}.$$

Intuitively, $\text{mls}_\alpha(p,q)$ is the maximal possible shift of q w.r.t. p in α, when the admissibility of processors other than p and q need not be preserved.

We usually leave the sets $\mathcal{A}_{p,q}$ unspecified when they are clear from the context. Later, when we want to specify different assumptions on the same pair of processors, we consider more than one local set of executions for this pair. In this case, to distinguish between different local sets for processors p and q we will use $\mathcal{A}_{p,q}, \mathcal{A}'_{p,q}, \mathcal{A}''_{p,q}$, etc.

DEFINITION 4.2. *A set of admissible executions $\mathcal{A}$ is* local *if there exist local sets $\mathcal{A}_{p,q}$ such that $\mathcal{A} = \bigcap_{p,q \in P} \mathcal{A}_{p,q}$, and for every p and q, $\mathcal{A}_{p,q}$ is local to p and q.*

Claim 4.2 implies the following.

CLAIM 4.3. *Assume $\mathcal{A}$ is local. Let $\vec{s} = \langle s_1, \ldots, s_n \rangle$ be a vector of shifts and let $\alpha \in \mathcal{A}$. Then* $\text{shift}(\alpha, \vec{s}) \in \mathcal{A}$ *if and only if $s_q - s_p$ is a locally admissible shift of q w.r.t. p in α, for every pair of processors p and q.*

Notice that $\text{mls}_\alpha(p,q) \geq \text{ms}_\alpha(p,q)$ and $\text{mls}_\alpha(p,q) \geq 0$. We say that $\text{mls}_\alpha(p,q)$ is a *local shift*, while $\text{ms}_\alpha(p,q)$ is a *global shift.*

Note that $\text{mls}_\alpha(p,q)$ may differ from $\text{mls}_\alpha(q,p)$. However, if $\text{shift}(\alpha, \langle s_1, \ldots, s_n \rangle)$ is in $\mathcal{A}_{p,q}$, then $s_q - s_p$ is a locally admissible shift of q w.r.t. p and $s_p - s_q$ is a locally admissible shift of p w.r.t. q. Thus, if s is a locally admissible shift of q w.r.t. p in α, then $-s$ is a locally admissible shift of p w.r.t. q in α.

Throughout the rest of the section, we assume that $\mathcal{A}$ is local with respect to some local sets of executions. Hence, the locally admissible shifts are defined. Furthermore, we assume that the locally admissible shifts have the following property.

ASSUMPTION 1. *Let x and y be two numbers such that $x < y$. For every two processors p, q and every $\alpha \in \mathcal{A}$, if x and y are locally admissible shifts of q w.r.t. p in α, then every value $z \in [y, x]$ is a locally admissible shift of q w.r.t. p in α.*

Intuitively, this assumption implies that the possible shifts constitute a continuous interval without any singularity points, and therefore, it holds in most natural applications.

4.2. From local shifts to global shifts. Our goal is to compute global estimates $\widetilde{\text{ms}}_\alpha(p,q)$ from local estimates $\widetilde{\text{mls}}_\alpha(p,q)$. In this section, as a first step in this direction, we show how to obtain maximal global shifts $\text{ms}_\alpha(p,q)$ from maximal local shifts $\text{mls}_\alpha(p,q)$. This also shows how to derive a lower bound on the precision of clock synchronization from a lower bound on the precision of each edge independently.

Let α be an admissible execution. Denote by $\text{dist}_{w'}(p,q)$ the distance from p to q in the graph G relative to the weights $w'(p,q) = \text{mls}_\alpha(p,q)$. We assume that all the distances $\text{dist}_{w'}$ are finite; it is not difficult to generalize the result for the case of infinite distances.

LEMMA 4.4. *For any pair of processors p and q,* $\text{dist}_{w'}(p,q) \leq \text{ms}_\alpha(p,q)$.

Proof. Assume, by way of contradiction, that for some pair of processors p and q, $\text{dist}_{w'}(p,q) > \text{ms}_\alpha(p,q)$. Thus there exists some value s, $\text{ms}_\alpha(p,q) < s < \text{dist}_{w'}(p,q)$. We show that s is a (globally) admissible shift of q w.r.t. p in α, which contradicts the definition of $\text{ms}_\alpha(p,q)$.

Since $s > \text{ms}_\alpha(p,q)$, it follows that $s > 0$. Thus we can write $s = c \cdot \text{dist}_{w'}(p,q)$, for some real number c, $0 < c < 1$. Fix some pair of processors j and k. By Assumption 1, $c \cdot \text{mls}_\alpha(k,j)$ is a locally admissible shift of j w.r.t. k in α. In addition, $c \cdot \text{mls}_\alpha(j,k)$ is a locally admissible shift of k w.r.t. j in α, and thus $-c \cdot \text{mls}_\alpha(j,k)$ is a locally admissible shift of j w.r.t. k in α.

For every processor i define $s_i = c \cdot \text{dist}_{w'}(p,i)$; note that $s_p = 0$ and $s_q = s$. We now show that $s_j - s_k$ is a locally admissible shift of j w.r.t. k in α. By the triangle inequality

$$\mathrm{dist}_{w'}(p,j) \leq \mathrm{dist}_{w'}(p,k) + w'(k,j),$$

and since $w'(k,j) = \mathrm{mls}_\alpha(k,j)$, we have (by changing sides)

$$\mathrm{dist}_{w'}(p,j) - \mathrm{dist}_{w'}(p,k) \leq \mathrm{mls}_\alpha(k,j).$$

Since $c > 0$, by multiplying by c and substituting s_j and s_k, we get

$$s_j - s_k \leq c \cdot \mathrm{mls}_\alpha(k,j).$$

By similar reasoning.

$$s_k - s_j \leq c \cdot \mathrm{mls}_\alpha(j,k).$$

This implies

$$-c \cdot \mathrm{mls}_\alpha(j,k) \leq s_j - s_k \leq c \cdot \mathrm{mls}_\alpha(k,j).$$

Since $-c \cdot \mathrm{mls}_\alpha(j,k)$ and $c \cdot \mathrm{mls}_\alpha(k,j)$ are locally admissible shifts of j w.r.t. k in α, Assumption 1 implies that $s_j - s_k$ is a locally admissible shift of j w.r.t. k in α.

Since this holds for any j and k, Claim 4.3 implies that $\mathrm{shift}(\alpha, \langle s_1, \ldots, s_n\rangle)$ is in $\mathcal{A}$. Therefore, $s = s_q - s_p$ is a (globally) admissible shift of q w.r.t. p in α. Since $s > \mathrm{ms}_\alpha(p,q)$, this contradicts the definition of $\mathrm{ms}_\alpha(p,q)$. □

We now show that $\mathrm{ms}_\alpha(p,q) = \mathrm{dist}_{w'}(p,q)$, by proving the converse inequality.

LEMMA 4.5. *For any two processors p and q,* $\mathrm{ms}_\alpha(p,q) \leq \mathrm{dist}_{w'}(p,q)$.

Proof. Let s be an arbitrary admissible shift of q w.r.t. p in α. Then there exists a vector of shifts $\vec{s} = \langle s_1, \ldots, s_n\rangle$ with $s = s_q - s_p$, such that shift $(\alpha, \vec{s}) \in \mathcal{A}$. Consider a shortest path $p_0, \ldots, p_k$ from $p = p_0$ to $q = p_k$ w.r.t. the weights w'. Summing over the path we get

$$(1) \qquad \sum_{i=1}^{k}(s_{p_i} - s_{p_{i-1}}) = s_{p_k} - s_{p_0} = s_q - s_p = s.$$

Since $\mathrm{shift}(\alpha, \vec{s}) \in \mathcal{A}$, Claim 4.3 implies that $s_{p_i} - s_{p_{i-1}}$ is a locally admissible shift of p_i w.r.t. p_{i-1} in α. Hence,

$$(2) \qquad s_{p_i} - s_{p_{i-1}} \leq \mathrm{mls}_\alpha(p_{i-1}, p_i) = w'(p_{i-1}, p_i)$$

for each $i - 1, \ldots, k$. By combining (1) and (2) we get

$$s = \sum_{i=1}^{k}(s_{p_i} - s_{p_{i-1}}) \leq \sum_{i=1}^{k} w'(p_{i-1}, p_i) = \mathrm{dist}_{w'}(p,q).$$

Therefore, $s \leq \mathrm{dist}_{w'}(p,q)$. Since this holds for any admissible shift, it follows that $\mathrm{ms}_\alpha(p,q) \leq \mathrm{dist}_{w'}(p,q)$. □

THEOREM 4.6. *For any admissible execution α and any two processors p and q, $\mathrm{ms}_\alpha(p,q)$ can be computed from* $\mathrm{mls}_\alpha(p,q)$.

Proof. For any admissible execution α and any two processors p and q, Lemma 4.4 implies that $\mathrm{ms}_\alpha(p,q) \geq \mathrm{dist}_{w'}(p,q)$, where $w'(p,q) = \mathrm{mls}_\alpha(p,q)$. Lemma 4.5 implies that $\mathrm{ms}_\alpha(p,q) = \mathrm{dist}_{w'}(p,q)$. The claim follows since $\mathrm{dist}_{w'}(p,q)$ depends only on $\mathrm{mls}_\alpha(p,q)$. □

4.3. Using estimates for local shifts. Now the issue is how to compute the values $\tilde{\mathrm{ms}}_\alpha(p,q)$ that are needed as inputs to the function SHIFTS. We assume that the function is provided with estimates of the local shifts. Under this assumption the computation can be accomplished by the following function.

FUNCTION GLOBAL ESTIMATES

Given inputs $\tilde{\mathrm{mls}}_\alpha(p,q) = \mathrm{mls}_\alpha(p,q) + S_{\alpha,p} - S_{\alpha,q}$ for every pair of processors p and q.

1. Compute $\tilde{\mathrm{ms}}_\alpha(p,q)$ by a shortest path computation in G with weights $\tilde{\mathrm{mls}}_\alpha(p,q)$.

THEOREM 4.7. *The function* GLOBAL ESTIMATES *computes* $\tilde{\mathrm{ms}}_\alpha(p,q)$, *for every pair of processors* p *and* q.

Proof. Observe that the weight of any cycle w.r.t. the weights $\tilde{\mathrm{mls}}_\alpha$ is equal to the weight of the cycle w.r.t. the weights mls_α because the S components cancel. It follows that there are no negative weight cycles in G w.r.t. the weights $\tilde{\mathrm{mls}}_\alpha$. Also, the weight of any path from p to q w.r.t. weights $\tilde{\mathrm{mls}}_\alpha$ is equal to the weight of the path w.r.t. mls_α plus $S_{\alpha,p} - S_{\alpha,q}$. The claim follows from Theorem 4.6. □

By composing functions GLOBAL ESTIMATES and SHIFTS, we can compute the optimal corrections and their precision given only the estimates to the maximal local shifts $\tilde{\mathrm{mls}}_\alpha$. This follows immediately from Theorem 4.7 together with Theorem 3.8.

4.4. A composition theorem. In many systems, several constraints are imposed on the delay of messages. For example, it is possible that there is a bound on the delay in each direction of the link as well as a bound on the difference in message delay in opposite directions. In these cases, the system is local w.r.t. several sets of executions, each of which is local to the same pair of processors p and q. We now show how to combine several sets of executions local to p and q into a single complex set of executions local to p and q. This allows us to deal with local systems by regarding each pair of processors and each assumption separately; this will be useful in the next section.

We remark that the theory developed so far already allows us to deal with local systems where different pairs of processors obey different types of constraints.

Note that the notion of an admissible shift (and the derived notion of maximal shift) is defined in the context of a specific set of admissible executions. To develop the results in this section it is convenient to state this fact explicitly by saying that a value is an admissible shift (or maximal shift) *under* $\mathcal{A}$, where $\mathcal{A}$ is some set of executions.

For some pair of processors p and q, let $\mathcal{A}'_{p,q}$ be a set of executions local to p and q, and let $\mathcal{A}''_{p,q}$ be another set of executions local to p and q. Denote $\mathcal{A}_{p,q} = \mathcal{A}'_{p,q} \cap \mathcal{A}''_{p,q}$. It is easy to see that $\mathcal{A}_{p,q}$ is local to p and q. For any execution $\alpha \in \mathcal{A}$, let $\mathrm{mls}'_\alpha(p,q)$ be the maximal local shift of q w.r.t. p in α under $\mathcal{A}'_{p,q}$. Similarly, define $\mathrm{mls}_\alpha(p,q)$ and $\mathrm{mls}''_\alpha(p,q)$. We have the following theorem.

THEOREM 4.8. $\mathrm{mls}_\alpha(p,q) = \min\{\mathrm{mls}'_\alpha(p,q), \mathrm{mls}''_\alpha(p,q)\}$.

Proof. The fact that $\mathrm{mls}_\alpha(p,q) \le \mathrm{mls}'_\alpha(p,q)$ follows immediately since every execution in $\mathcal{A}_{p,q}$ is an execution in $\mathcal{A}'_{p,q}$. Thus if s is a locally admissible shift of q w.r.t. p in α under $\mathcal{A}_{p,q}$, then it is a locally admissible shift of q w.r.t. p in α under $\mathcal{A}'_{p,q}$. Similarly $\mathrm{mls}_\alpha(p,q) \le \mathrm{mls}''_\alpha(p,q)$. Therefore, $\mathrm{mls}_\alpha(p,q) \le \min\{\mathrm{mls}'_\alpha(p,q), \mathrm{mls}''_\alpha(p,q)\}$.

Assume for contradiction that s is a value such that $\mathrm{mls}_\alpha(p,q) < s < \min\{\mathrm{mls}'_\alpha(p,q), \mathrm{mls}''_\alpha(p,q)\}$. Since $\mathrm{mls}_\alpha(p,q) < s < \mathrm{mls}'_\alpha(p,q)$, Assumption 1 implies that s is a locally admissible shift of q w.r.t. p in α under $\mathcal{A}'_{p,q}$. Similarly, s

is also a locally admissible shift of q w.r.t. p in α under $\mathcal{A}''_{p,q}$. By Claim 4.2, for every vector of shifts $\vec{s} = \langle s_1, \ldots, s_n \rangle$, such that $s = s_q - s_p$, $\text{shift}(\alpha, \vec{s})$ is in both $\mathcal{A}'_{p,q}$ and $\mathcal{A}''_{p,q}$. Therefore, $\text{shift}(\alpha, \vec{s})$ is in $\mathcal{A}_{p,q}$. Thus, s is a locally admissible shift of q w.r.t. p in α under $\mathcal{A}_{p,q}$, a contradiction since $\text{mls}_\alpha(p,q) < s$. Therefore $\text{mls}_\alpha(p,q) = \min\{\text{mls}'_\alpha(p,q), \text{mls}''_\alpha(p,q)\}$. □

5. Clock synchronization for specific delay assumptions. We now show how to compute estimated maximal local shifts for specific sets of executions $\mathcal{A}_{p,q}$ local to p and q, given the views. By Theorems 4.7 and 4.8, this implies a clock synchronization algorithm that computes optimal corrections for any system whose set of admissible executions is the intersection of any collection of sets of these types. By Theorem 4.7, all we must show is how to compute the estimates of the maximal local shifts $\widetilde{\text{mls}}_\alpha(p,q)$. This calculation is based on estimates for the delays (defined below), which can easily be computed from the views of the processors.

The *estimated delay* $\tilde{\text{d}}(m)$ of a message m sent from p to q is the actual (real-time) delay plus the difference in (real-time) start times of the processors; that is, $\tilde{\text{d}}(m) = \text{d}(m) + S_{\alpha,p} - S_{\alpha,q}$. This is similar to the definitions of estimated maximal global shifts and estimated maximal local shifts. The next lemma shows that the estimated delay can be computed from the views.

LEMMA 5.1. *Given the views of processors p and q in an execution α, it is possible to compute the estimated delay $\tilde{\text{d}}(m)$ of any message m sent from p to q.*

Proof. Let $t_p(m)$ denote the local (p's) clock time when p sent the message m according to p's view; similarly, $t_q(m)$ denotes the local (q's) clock time when q received the message m according to q's view. By property 4 of histories as defined in §2.2, m was sent at real time $t_p(m) + S_{\alpha,p}$; similarly, m was received at real time $t_q(m) + S_{\alpha,q}$. It follows that the delay of m is $\text{d}(m) = (t_q(m) + S_{\alpha,q}) - (t_p(m) + S_{\alpha,p})$. Hence, $\tilde{\text{d}}(m) = \text{d}(m) + S_{\alpha,p} - S_{\alpha,q} = t_q(m) - t_p(m)$. Since messages are unique, $t_p(m)$ and $t_q(m)$ can be computed from the views of p and q. □

5.1. Bounds on the delay. In the systems considered in [4, 11], there is an upper and a lower bound on the transmission delay for any edge. We extend this assumption by allowing edges without upper bounds, in which case we say that the upper bound is ∞. In particular, this gives optimal clock synchronization for completely asynchronous networks where there are no bounds on the delay.

Consider a set $\mathcal{A}_{p,q}[l,u]$ where l and u give bounds (real numbers) for each ordered pair of processors p and q, such that $0 \le l(p,q) \le u(p,q) \le \infty$. Execution α is in $\mathcal{A}_{p,q}[l,u]$ if the delay of every message sent from p to q is in the range $[l(p,q), u(p,q)]$ and the delay of every message from q to p is in the range $[l(q,p), u(q,p)]$. Clearly, $\mathcal{A}_{p,q}[l,u]$ is local to p and q.

The maximal delay of a message received by q from p in execution α is denoted $\text{d}^{\max}_\alpha(p,q)$. Similarly, the minimal delay of a message received by q from p in α is denoted $\text{d}^{\max}_\alpha(p,q)$. If no message was received by q from p in α, then $\text{d}^{\max}_\alpha(p,q) = -\infty$ and $\text{d}^{\min}_\alpha(p,q) = \infty$. We first observe that in such systems, $\text{mls}_\alpha(p,q)$ depends only on the maximal and minimal delays between p and q.

LEMMA 5.2. *Let α be an execution of $(P, \mathcal{A}_{p,q}[l,u])$. Then*

$$\text{mls}_\alpha(p,q) = \min\{(u(q,p) - \text{d}^{\max}_\alpha(q,p)), (\text{d}^{\min}_\alpha(p,q) - l(p,q))\}.$$

Proof. We can partition the constraints on the communication between p and q in two: the conditions on the delay of messages from p to q, and the conditions on the delay of messages from q to p. This is done by expressing the set $\mathcal{A}_{p,q}[l,u]$ as the intersection of $\mathcal{A}_{\langle q,p\rangle}[l,u]$, which constrains the messages from q to p, and $\mathcal{A}_{\langle p,q\rangle}[l,u]$, which constrains the messages from p to q. Let $\mathrm{mls}'_\alpha(p,q)$ be the maximal local shift of q w.r.t. p in α under $\mathcal{A}_{\langle q,p\rangle}[l,u]$; $\mathrm{mls}''_\alpha(p,q)$ is defined similarly under $\mathcal{A}_{\langle p,q\rangle}[l,u]$.

We first show that $\mathrm{mls}'_\alpha(p,q) = u(q,p) - \mathrm{d}^{\max}_\alpha(q,p)$. It is obvious that $\mathrm{mls}'_\alpha(p,q) \leq u(q,p) - \mathrm{d}^{\max}_\alpha(q,p)$. Assume, by way of contradiction, that $s > u(q,p) - \mathrm{d}^{\max}_\alpha(q,p)$ is a locally admissible shift of q w.r.t. p in α. This immediately implies that $\mathrm{d}^{\max}_\alpha(q,p) > -\infty$; i.e., at least one message was received by p from q.

Denote $\alpha' = \mathrm{shift}(\alpha, \langle s_1, \ldots, s_n\rangle)$, where $s_q = s$ and $s_i = 0$ for all $i \neq q$. By Claim 4.2, α' is in $\mathcal{A}_{\langle q,p\rangle}$. By Claim 3.2, if a message m from q to p has delay d in α, then m has delay $\mathrm{d}+s$ in α'. Thus, $\mathrm{d}^{\max}_{\alpha'}(q,p) = \mathrm{d}^{\max}_\alpha(q,p) - s$. Since $s > u(q,p) - \mathrm{d}^{\max}_\alpha(q,p)$ and $\mathrm{d}^{\max}_\alpha(q,p) > -\infty$, it follows that the maximal delay of a message from q to p in α' is strictly greater than $u(q,p)$, which is a contradiction.

In a similar manner, we show that $\mathrm{mls}''_\alpha(p,q) = \mathrm{d}^{\min}_\alpha(p,q) - l(p,q)$. It is obvious that $\mathrm{mls}''_\alpha(p,q) \leq \mathrm{d}^{\min}_\alpha(p,q) - l(p,q)$. Assume, by way of contradiction, that $s > \mathrm{d}^{\min}_\alpha(p,q) - l(p,q)$ is a locally admissible shift of q w.r.t. p in α. This immediately implies that $\mathrm{d}^{\min}_\alpha(p,q) < \infty$; i.e., at least one message was received by q from p.

Let α' be as defined above. By Claim 4.2, α' is in $\mathcal{A}_{\langle p,q\rangle}$. By Claim 3.2, if a message m from p to q has delay d in α, then m has delay $\mathrm{d} - s$ in α'. Thus, $\mathrm{d}^{\min}_{\alpha'}(p,q) = \mathrm{d}^{\min}_\alpha(p,q) - s$. Since $s > \mathrm{d}^{\min}_\alpha(p,q) - l(p,q)$ and $\mathrm{d}^{\min}_\alpha(p,q) < \infty$, it follows that the minimal delay of a message from p to q in α' is less than $l(p,q)$, which is a contradiction.

The claim now follows from Theorem 4.8. □

Lemma 5.2 gives the maximal local shifts as a function of the actual maximal and minimal delays. However, the views of the processors give only estimates of the delays, not the delays themselves. Yet, the estimates of the delays give an estimate for the maximal local shift $\widetilde{\mathrm{mls}}_\alpha(p,q)$. Formally, the *estimated maximal delay* is defined as

$$\tilde{\mathrm{d}}^{\max}_\alpha(p,q) = \mathrm{d}^{\max}_\alpha(p,q) + S_{\alpha,p} - S_{\alpha,q},$$

while the *estimated minimal delay* is defined as

$$\tilde{\mathrm{d}}^{\min}_\alpha(p,q) = \mathrm{d}^{\min}_\alpha(p,q) + S_{\alpha,p} - S_{\alpha,q}.$$

We have the following result.

COROLLARY 5.3. *Let α be an admissible execution of $(P, \mathcal{A}_{p,q}[l,u])$. Then*

$$\widetilde{\mathrm{mls}}_\alpha(p,q) = \min\{(u(q,p) - \tilde{\mathrm{d}}^{\max}_\alpha(q,p)), (\tilde{\mathrm{d}}^{\min}_\alpha(p,q) - l(p,q))\}.$$

Note that $\tilde{\mathrm{d}}^{\max}$ and $\tilde{\mathrm{d}}^{\min}$ can be computed from the views of p and q, since $\tilde{\mathrm{d}}^{\min}_\alpha(p,q)$ is the minimum of $\tilde{\mathrm{d}}(m)$ for all messages m received by q from p in α and $\tilde{\mathrm{d}}^{\max}_\alpha(p,q)$ is the maximum of $\tilde{\mathrm{d}}(m)$ for all messages m received by q from p in α.

If we make the natural assumption that all delays are nonnegative, we get a general bound on mls and $\widetilde{\mathrm{mls}}$ (without any other bounds on the delay).

COROLLARY 5.4. *Let α be an admissible execution of a system $(P, \mathcal{A}_{p,q})$ local to p, q. Then $\mathrm{mls}_\alpha(p,q) \leq \mathrm{d}^{\min}_\alpha(p,q)$ and $\widetilde{\mathrm{mls}}_\alpha(p,q) \leq \tilde{\mathrm{d}}^{\min}_\alpha(p,q)$.*

5.2. Links with bounds on the round-trip delay bias. In many communication links there are no tight bounds on the transmission delays. However, whenever the traffic load in one direction of a link is high, the load in the opposite direction of the link is also high. Thus, it is possible to give a bound on the difference, or bias, between the delay in one direction and the delay in the opposite direction. For the purpose of illustrating our techniques, we simplify the assumption and require that the difference between the delay of any pair of messages in opposite direction be bounded. We now show how to calculate maximal local shifts for links in this case. It is possible to generalize our results to the more realistic scenario in which this assumption holds only for messages that were sent "around the same time."

Specifically, we associate a nonnegative number $b(p,q)$ with processors p,q. An execution α is in $\mathcal{A}_{p,q}[b]$ if for any message m received by p from q and any message m' received by q from p, $|\mathrm{d}_\alpha(m) - \mathrm{d}_\alpha(m')| \leq b(p,q)$. We also restrict $\mathcal{A}_{p,q}[b]$ to nonnegative delays; i.e., for every message m, $\mathrm{d}(m) \geq 0$. The next lemma shows that $\mathrm{mls}_\alpha(p,q)$ depends only on the maximal and minimal delays between p and q.

LEMMA 5.5. *Let α be an admissible execution of $(P, \mathcal{A}_{p,q}[b])$. Then*

$$\mathrm{mls}_\alpha(p,q) = \min\left\{\mathrm{d}_\alpha^{\min}(p,q), \frac{1}{2}[b(p,q) + \mathrm{d}_\alpha^{\min}(p,q) - \mathrm{d}_\alpha^{\max}(q,p)]\right\}.$$

Proof. Consider the following two sets of admissible executions local to p and q. The first set $\mathcal{A}'_{p,q}$ contains every execution α such that the delay of every message in α is nonnegative; denote the maximal local shifts under $\mathcal{A}'_{p,q}$ by mls'_α. The second set $\mathcal{A}''_{p,q}$ is like $\mathcal{A}_{p,q}[b]$ except that the delays are allowed to be negative; denote the maximal local shifts under $\mathcal{A}''_{p,q}$ by mls''_α. Clearly $\mathcal{A}_{p,q}[b]$ is the intersection of $\mathcal{A}'_{p,q}$ and $\mathcal{A}''_{p,q}$. By Theorem 4.8, $\mathrm{mls}_\alpha(p,q) = \min\{\mathrm{mls}'_\alpha(p,q), \mathrm{mls}''_\alpha(p,q)\}$. By Lemma 5.2, $\mathrm{mls}'_\alpha(p,q) = \mathrm{d}_\alpha^{\min}(p,q)$. Therefore, it suffices to prove that $\mathrm{mls}''_\alpha(p,q) = \frac{1}{2}[b(p,q) + \mathrm{d}_\alpha^{\min}(p,q) - \mathrm{d}_\alpha^{\max}(q,p)]$.

Fix a value s and denote $\alpha' = \mathrm{shift}(\alpha, \langle s_1, \ldots, s_n\rangle)$, where $s_q = s$ and $s_i = 0$ for all $i \neq q$. By Claim 4.2, s is a locally admissible shift of q w.r.t. p in α if and only if $\alpha' \in \mathcal{A}_{p,q}(\epsilon)$.

By Claim 3.2, for any message m received by p from q, $\mathrm{d}_{\alpha'}(m) = \mathrm{d}_\alpha(m) + s$. Similarly, for any message m' received by q from p, $\mathrm{d}_{\alpha'}(m') = \mathrm{d}_\alpha(m') - s$. Therefore,

$$\mathrm{d}_{\alpha'}(m') - \mathrm{d}_{\alpha'}(m) = \mathrm{d}_\alpha(m') - \mathrm{d}_\alpha(m) - 2s,$$

$$\mathrm{d}_{\alpha'}(m) - \mathrm{d}_{\alpha'}(m') = \mathrm{d}_\alpha(m) - \mathrm{d}_\alpha(m') + 2s.$$

The round-trip delay bias of an arbitrary pair of messages m and m' in α' is at most $b(p,q)$ if and only if

$$\mathrm{d}_\alpha(m') - \mathrm{d}_\alpha(m) - 2s \leq b(p,q),$$

$$\mathrm{d}_\alpha(m) - \mathrm{d}_\alpha(m') + 2s \leq b(p,q).$$

Since α is admissible and $s \geq 0$, the first inequality trivially holds. Hence, s is a locally admissible shift of q w.r.t. p if and only if

$$s \leq \frac{1}{2}[b(p,q) + \mathrm{d}_\alpha(m') - \mathrm{d}_\alpha(m)].$$

Namely,

$$s \leq \frac{1}{2}[b(p,q) + \mathrm{d}_\alpha^{\min}(p,q) - \mathrm{d}_\alpha^{\max}(q,p)].$$

Thus $\text{mls}''_\alpha(p,q) = \frac{1}{2}[b(p,q) + \text{d}^{\min}_\alpha(p,q) - \text{d}^{\max}_\alpha(q,p)]$. □

COROLLARY 5.6. *Let α be an admissible execution of $(P, \mathcal{A}[b])$. Then*

$$\widetilde{\text{mls}}_\alpha(p,q) = \min\left\{\tilde{\text{d}}^{\min}_\alpha(p,q), \frac{1}{2}[b(p,q) + \tilde{\text{d}}^{\min}_\alpha(p,q) - \tilde{\text{d}}^{\max}_\alpha(q,p)]\right\}.$$

5.3. Multicast networks. Communication in many networks is performed through broadcast media where a message is transmitted simultaneously to a subset of the processors. Multicast transmission may often have useful timing properties for clock synchronization. In this subsection we investigate a simple timing property: there exists a bound ε on the difference between the arrival times of a message at different processors. We do not assume that there is any bound on the delay of any individual message.

Optimal clock synchronization algorithms for multicast networks that have a bound on the differences in delay for different processors are presented in [5, 18]. Our solution demonstrates the usefulness of the reductions of the preceding sections. To provide optimal clock synchronization under the multicast assumption we need only to find a way of defining local shifts. This, somewhat surprisingly, turns out to be an easy task. Furthermore, the broadcast model can be limited to specific subsets corresponding to subnetworks of an internet and combined with the other assumptions using the composition theorem.

To define this assumption, we allow events of the form $\text{send}(p, m, Q)$ for all messages m and sets of processors Q; this event represents a multicast of m to the processors in Q. The definition of an execution is modified so that there is a one-to-one correspondence between the messages received by p from k to messages sent by k to p or multicast by k to a set Q that includes p for any processors p and k. Let $\text{d}(p,m)$ denote the difference between the time the message m is multicast by some processor k and the time processor p receives it; this is the *delay of the message m to p*. The *estimated delay of the message m to p* in α is $\tilde{\text{d}}(p,m) = \text{d}(p,m) + S_{\alpha,k} - S_{\alpha,p}$. As before, the estimated delay of a message from k to p can be computed from the views of p and k.

The system is the pair $(P, \mathcal{A}(\varepsilon))$, where $\mathcal{A}(\varepsilon)$ is the intersection of local sets $\mathcal{A}_{p,q}(\varepsilon)$ for every unordered pair of processors p and q. An execution α is in $\mathcal{A}_{p,q}(\varepsilon)$ if for every message m multicast to both p and q, $|\text{d}(p,m) - \text{d}(q,m)| \leq \varepsilon$. That is, m reaches p at most ε time units after it reaches q, and vice versa.

Note that $\mathcal{A}_{p,q}(\varepsilon)$ is local to p and q. This is because any shift applied to both p and q does not change the difference $\text{d}(p,m) - \text{d}(q,m)$. The next lemma shows how to calculate $\text{mls}_\alpha(p,q)$.

LEMMA 5.7. *Let α be an admissible execution of $(P, \mathcal{A}_{p,q}(\varepsilon))$. Then*

$$\text{mls}_\alpha(p,q) = \varepsilon + \min_m\{\text{d}(q,m) - \text{d}(p,m)\}.$$

Proof. Fix a value s and denote $\alpha' = \text{shift}(\alpha, \langle s_1, \ldots, s_n\rangle)$, where $s_q = s$ and $s_i = 0$ for all $i \neq q$. By Claim 4.2, s is a locally admissible shift of q w.r.t. p in α if and only if $\alpha' \in \mathcal{A}_{p,q}(\varepsilon)$.

For every message m multicast to both p and q, let $\text{d}'(q,m)$ and $\text{d}'(p,m)$ denote the delay of m in α' for processors p and q, respectively. The value s is a locally admissible shift of q w.r.t. p in α if and only if

$$|\text{d}'(p,m) - \text{d}'(q,m)| \leq \varepsilon$$

for every message m multicast to both p and q. If q is not the sender of m, then $\mathrm{d}'(p,m) = \mathrm{d}(p,m)$ and $\mathrm{d}'(q,m) = \mathrm{d}(q,m) - s$; if q is the sender of m, then $\mathrm{d}'(q,m) = \mathrm{d}(q,m)$ and $\mathrm{d}'(p,m) = \mathrm{d}(p,m) + s$. In both cases, s is a locally admissible shift of q w.r.t. p in α if and only if

$$|\mathrm{d}(p,m) - \mathrm{d}(q,m) + s| \leq \varepsilon$$

for every message m multicast to both p and q.

Hence, s is a locally admissible shift of q w.r.t. p in α if and only if

$$|s| \leq \varepsilon + |\mathrm{d}(p,m) - \mathrm{d}(q,m)|$$

for every message m multicast to both p and q. Since $\mathrm{mls}_\alpha(p,q) \geq 0$, this implies that

$$\mathrm{mls}_\alpha(p,q) = \varepsilon + \min_m\{\mathrm{d}(p,m) - \mathrm{d}(q,m)\},$$

as needed. □

As before, this result also applies to the estimated delays that can be computed from the views.

COROLLARY 5.8. *Let α be an admissible execution of $(P, \mathcal{A}_{p,q}(\varepsilon))$. Then*

$$\widetilde{\mathrm{mls}}_\alpha(p,q) = \varepsilon + \min_m\{\tilde{\mathrm{d}}(p,m) - \tilde{\mathrm{d}}(p,m)\}.$$

Proof. Fix a message m and let k be the sender of m. We have

$$\begin{aligned}\widetilde{\mathrm{mls}}_\alpha(p,q) &= \mathrm{mls}_\alpha(p,q) + S_{\alpha,p} - S_{\alpha,q} \quad \text{(by definition)}\\ &= \varepsilon + \min_m\{\mathrm{d}(q,m) - \mathrm{d}(p,m)\} + S_{\alpha,p} - S_{\alpha,q} \quad \text{(by Lemma 5.7)}\\ &= \varepsilon + \min_m\{(\mathrm{d}(q,m) + S_{\alpha,k} - S_{\alpha,q}) - (\mathrm{d}(p,m) + S_{\alpha,k} - S_{\alpha,p})\}\\ &= \varepsilon + \min_m\{\tilde{\mathrm{d}}(q,m) - \tilde{\mathrm{d}}(p,m)\} \quad \text{(by definition),}\end{aligned}$$

as needed. □

6. Discussion. We have presented a framework for designing optimal clock synchronization algorithms under a variety of assumptions on message delay uncertainty. The general result yields optimal clock synchronization algorithms under the following assumptions: upper and lower bounds on delays are known (including degenerated cases); only a bound on the difference of the round-trip delays is known; and a multicast assumption that bounds the difference in delay in reaching different processors is known. Moreover, the results apply to cases where different links satisfy different assumptions or where the same link satisfies several assumptions. This work extends results of Halpern, Megiddo, and Munshi [4] and introduces a new notion of optimality on any specific instance.

The specific delay assumptions analyzed here are typical of realistic systems, and it seems relatively easy to perform similar analysis for additional delay assumptions. It is our belief that this will lead to the design of optimal clock synchronization algorithms for other message delay assumptions.

In this paper, we only address the issue of computing optimal corrections, given the views of the processors. An interesting open question is to compute the optimal corrections in a distributed manner. To understand the difficulty involved in the distributed implementation of this computation, consider the following straightforward approach. Each pair of neighboring processors p and q compute $\widetilde{\mathrm{mls}}_\alpha(p,q)$ and $\widetilde{\mathrm{mls}}_\alpha(q,p)$ using the estimated delays (which can be deduced from their views). All processors send the estimated maximum local shifts to a distinguished processor (leader). The leader computes the estimated maximum global shifts using function GLOBAL ESTIMATES and a correction value for each processor according to function SHIFTS. Finally, the leader sends the corrections to the processors. Note, however, that the precision obtained by this centralized clock synchronization algorithm is optimal only with respect to the part of the execution that does not include the messages to and from the leader. That is, any additional communication, required for exchanging the views, is bound to change the views themselves. A solution may require the definition of optimality to be relaxed.

Extensions of our work to the truly distributed case appear in [17]. This work also generalizes some of our results to clocks that drift. Other follow-up work includes an investigation of the problem from the knowledge theoretic point of view [14]. Some techniques for developing clock synchronization algorithms for broadcast networks appeared in [3].

Another important open question is to achieve optimal clock synchronization in systems where the probabilistic properties of the message delay distribution are known. This assumption is at the heart of most practical algorithms for clock synchronization [1, 13]. We believe the setting developed here allows one to address this assumption and that this will lead to improvements to these important algorithms.

Finally, an obvious open problem is to make our results to be fault tolerant, following the many works addressing fault-tolerant clock synchronization.

Acknowledgments. We thank Joe Halpern, Marios Mavronicolas, Boaz Patt-Shamir, and the anonymous referees for helpful comments.

LINEAR-TIME REPRESENTATION ALGORITHMS FOR PROPER CIRCULAR-ARC GRAPHS AND PROPER INTERVAL GRAPHS*

XIAOTIE DENG†, PAVOL HELL‡, AND JING HUANG§

Abstract. Our main result is a linear-time (that is, time $O(m+n)$) algorithm to recognize and represent proper circular-arc graphs. The best previous algorithm, due to A. Tucker, has time complexity $O(n^2)$. We take advantage of the fact that (among connected graphs) proper circular-arc graphs are precisely the graphs orientable as local tournaments, and we use a new characterization of local tournaments. The algorithm depends on repeated representation of portions of the input graph as proper interval graphs. Thus we also find it useful to give a new linear-time algorithm to represent proper interval graphs. This latter algorithm also depends on an orientation characterization of proper interval graphs. It is conceptually simple and does not use complex data structures. As a byproduct of the correctness proof of the algorithm, we also obtain a new proof of a characterization of proper interval graphs by forbidden subgraphs.

Key words. proper circular-arc graphs, proper interval graphs, local tournaments, representation algorithms

1. Introduction.

An *interval graph* is the intersection graph of a family of linear intervals; a *proper interval graph* is the intersection graph of an inclusion-free family of linear intervals. A *circular-arc graph* is the intersection graph of a family of circular arcs; as above, it is called *proper* if the family can be chosen to be inclusion free. The families of intervals or of circular arcs are called *representations* of the corresponding graphs.

Algorithmic aspects of interval graphs have been extensively studied; cf. [7]. In particular, there are linear-time (i.e., time $O(m+n)$, where m and n are, respectively, the numbers of edges and of vertices of the input graph) algorithms to find a representation of a given input graph by a family of intervals if one exists [5, 14]. It is a long-standing open problem to find a linear-time algorithm for the representation of circular-arc graphs. Here we give a linear-time algorithm for the representation of *proper* circular-arc graphs. Tucker [18] gave a matrix characterization of proper circular-arc graphs and an associated representation algorithm, which runs in time $O(n^2)$ (cf. [15]).

Our algorithm depends on a linear-time method to represent proper interval graphs. Such a method can be extracted from existing algorithms for interval graphs [7, p. 195]. However, we also include in this paper a new linear-time algorithm for the representation of proper interval graphs. This is a simple incremental algorithm which does not use special data structures such as PQ-trees [5, 14]. Moreover, it is formulated in a way that makes it convenient to use as a subroutine for our main algorithm for proper circular-arc graphs. (It should be remarked that W. L. Hsu has recently announced a linear-time algorithm for the representation of general interval graphs, which does not use PQ-trees; cf. [10].)

We have given an earlier algorithm for the representation of proper circular-arc graphs with time complexity $O(\Delta m)$ in [9]; cf. also [2, 8, 13]. (Here Δ denotes the

maximum degree of the input graph.) Thus the present algorithm is more efficient; nevertheless, for graphs of bounded degree both algorithms are linear, and we believe the algorithm in [9] (which is conceptually much simpler) remains interesting.

Our algorithm for the representation of proper circular-arc graphs has immediate applications in situations where existing algorithms for optimization problems on proper circular-arc graphs assume that a representation by circular-arcs is given. For instance, there are $O(n)$ algorithms for solving the maximum clique problem, the maximum independent set problem, and the q-colouring problem in proper circular-arc graphs, provided a representation by circular arcs is given; cf. [4, 11, 17]. In view of our $O(m + n)$ representation algorithm, we may now conclude that all these problems for proper circular-arc graphs are solvable in time $O(m+n)$ with no further restriction.

The correctness proof of our algorithms depends on the progress we made on another problem—the understanding of the structure of local tournaments. A *local tournament* (cf. [1, 8, 13]), is an oriented graph in which the inset as well as the outset of every vertex is a tournament. Local tournaments turn out to be a useful generalization of tournaments and many interesting algorithmic problems can be efficiently solved for this class of oriented graphs (cf. [1, 8, 13]). Local tournaments are relevant to our purposes because of the fact that (among connected graphs) proper circular-arc graphs are precisely the graphs orientable as local tournaments and proper interval graphs are precisely the graphs orientable as nonstrong local tournaments. These results are essentially due to Skrien [16] (cf. also [9, 12, 13]), and they allow us to deal with orientations of the input graph instead of having to deal with representations of it. We have developed new characterizations of local tournaments and of nonstrong local tournaments, and we shall use them below to prove the correctness of our algorithms.

To capture the situations where some edges of the input graph have already been oriented and others are still undirected, we employ the notion of a *mixed graph*: it is a graph H with some directed edges (arcs) and some undirected edges such that if H contains the directed edge xy, then it contains neither the directed edge yx nor the undirected edge xy. The *inset*, respectively the *outset*, of a vertex v in a mixed graph H is the set of all vertices u in H for which uv, respectively vu, is a directed edge of H. A directed path in a mixed graph contains only directed edges (all oriented in the same direction). Note that the class of mixed graphs without directed edges is precisely the class of undirected graphs and the class of mixed graphs without undirected edges is precisely the class of oriented graphs.

Let D be a mixed graph. If xy is a directed edge of D, then we say that x dominates y and write $x \rightarrow y$; otherwise, we say that x does not dominate y and write $x \not\rightarrow y$. We say that D is *strong* if, for any two vertices x and y, D contains a directed path from x to y (and a directed path from y to x); otherwise, it is called *nonstrong.*

Let G be an undirected graph. For any vertex v, let $N(v)$ be the neighbourhood of v, i.e., the set of vertices which are adjacent to v. The *closed neighbourhood* of v is the set $N[v] = N(v) \cup \{v\}$. We define an equivalence relation on $V(G)$ in which a and b are equivalent just if $N[a] = N[b]$. The classes of this equivalence are called the *blocks* of G. It follows from the definition that two blocks are either completely adjacent (every vertex of one is adjacent to every vertex of the other) or completely nonadjacent (no vertex of one is adjacent to any vertex of the other). We shall use the terms adjacent blocks and nonadjacent blocks to describe these respective situations. If the vertices a and b of an edge ab are equivalent, we call the edge ab *balanced*; otherwise, ab is an *unbalanced* edge. We say that G is *reduced* if there are no balanced edges, i.e., if distinct vertices have distinct closed neighbourhoods.

The *underlying graph* of a mixed graph D is the undirected graph $G(D)$ with the vertex set $V(D)$ in which xy is an edge of $G(D)$ only if it is a directed or undirected edge of D. We say that D is *connected* if $G(D)$ is connected. We say that D is *reduced* if $G(D)$ is reduced. We call an arc ab of D balanced if the edge ab is balanced in $G(D)$.

2. Local tournaments. First we discuss the structure of local tournaments. A detailed treatment appears in [12] (cf. also [13]); we summarize here only the main points relevant to our algorithm. We begin with nonstrong local tournaments.

A *straight enumeration* of an oriented graph D is a linear ordering $v_1, v_2, \dots, v_n$ of its vertices such that for each i there exist nonnegative integers k and l such that the vertex v_i has inset $\{v_{i-1}, v_{i-2}, \dots, v_{i-k}\}$ and outset $\{v_{i+1}, v_{i+2}, \dots, v_{i+l}\}$. Note that any arc v_iv_j has $i < j$ and the subgraph induced by $v_i, v_{i+1}, \dots, v_j$ is a transitive tournament. An oriented graph which admits a straight enumeration is called *straight.* An undirected graph is said to have a *straight orientation* if it admits an orientation which is a straight oriented graph.

PROPOSITION 2.1. *The following properties are equivalent for an oriented graph D:*

1. *D is straight*;

2. *there exists an inclusion-free family of intervals associated with the vertices of D such that u dominates v in D if and only if the interval associated with u contains the left endpoint of the interval associated with v (the interval of u intersects the interval of v "on the left").*

Proof. 1 *implies* 2: Given a straight enumeration $v_1, v_2, \dots v_n$ of D, we associate with v_i the interval from i to $i + d_i + 1 - \frac{1}{i}$, where d_i denotes the outdegree of v_i.

2 *implies* 1: Given an inclusion-free family of intervals, we order the vertices as $v_1, v_2, \dots, v_n$ in such a way that the left endpoints of the corresponding intervals form an increasing sequence. □

COROLLARY 2.2. *A graph is a proper interval graph if and only if it has a straight orientation.* □

We see from the above that we can construct the intervals of a representation of G in time $O(m + n)$ provided that we have a straight enumeration of an orientation D of G. Thus our algorithm for representing a proper interval graph needs only to find a straight enumeration of an orientation of G.

Note that a straight oriented graph is a nonstrong local tournament. (In fact, it is an acyclic local tournament.) Moreover, *all* nonstrong local tournaments arise in a simple fashion from straight oriented graphs. Let S be an oriented graph and let T_v be a family of disjoint tournaments indexed by the vertices v of S. The *substitution operation* on S with respect to T_v, $v \in V(S)$ results in an oriented graph D obtained from S by replacing each v by the corresponding T_v and with each vertex of T_v dominating each vertex of T_u in D just if $v \rightarrow u$ in S. Note that each edge of each T_v is balanced and, if S is reduced, there are no other balanced edges in D. The *full reversal* of an oriented graph D is the operation of reversing the directions of all oriented edges (arcs) of D.

The following theorem describes a method to generate all possible nonstrong local tournaments (other than tournaments) as well as all possible nonstrong local-tournament orientations of a fixed undirected graph.

THEOREM 2.3 ([12, 13]). *Let D be a connected oriented graph which is not a tournament. Then D is a nonstrong local tournament if and only if it is obtained from* *a reduced straight oriented graph S (with $|V(S)| > 1$) by the substitution operation with respect to some family of tournaments $T_v, v \in V(S)$.*

Moreover, if D is a nonstrong local tournament, then for every nonstrong local-tournament orientation D' of $G(D)$, either D' or the full reversal of D' is obtained from the same S by the substitution operation with respect to a family $T'_v, v \in V(S)$, where $|T'_v| = |T_v|$ for each $v \in V(S)$. □

COROLLARY 2.4. *Let G be a connected proper interval graph and D and D' two arbitrary nonstrong local tournament orientations of G. Then D' can be obtained from D by changing the directions of some balanced arcs and then possibly performing a full reversal.* □

In order to concisely describe all possible nonstrong local tournament orientations of a fixed connected proper interval graph, we introduce a modified substitution operation in which we replace each vertex v by a complete undirected graph T_v, again with each vertex of T_v dominating each vertex of T_u if and only if $v \rightarrow u$. A *straight mixed graph H* is a mixed graph obtained from a reduced straight oriented graph S by such a substitution operation with respect to a family T_v of complete graphs. Note that the blocks of the resulting mixed graph are precisely the vertex sets of the complete graphs T_v. (In other words, each undirected edge is balanced and each directed edge is unbalanced.) Let H be a straight mixed graph. *A straight enumeration* $V_1, V_2, \ldots, V_p$ of the blocks of H is an ordering of the blocks of H in the order of the straight enumeration of the corresponding vertices of S. In the following, we shall often define a straight mixed graph by describing a straight enumeration of its blocks. Given a sequence of blocks $V_1, V_2, \ldots, V_p$ of an undirected graph G, consider the mixed graph H obtained by leaving all edges xy of G with x and y from the same V_j undirected and orienting each edge xy with $x \in V_i$, $y \in V_j$, and $i < j$ from x to y. Then this is a straight mixed graph provided that for any i and j such that V_i is adjacent to V_j, the subgraph induced by the intermediate blocks $V_i \cup V_{i+1} \cup \cdots \cup V_j$ is complete.

If we orient the undirected edges so that each T_v becomes a transitive tournament, we obtain a straight oriented graph. Conversely, starting from a straight oriented graph, we obtain a straight mixed graph by replacing all balanced arcs by the corresponding undirected edges. Therefore we may extract from Corollaries 2.2 and 2.4 the following useful result.

COROLLARY 2.5. *Each connected proper interval graph is uniquely orientable as a straight mixed graph up to full reversal.* □

A similar discussion applies to general (possibly strong) local tournaments. A *round enumeration* of an oriented graph D is a circular ordering $v_1, v_2, \ldots, v_n$ of its vertices such that for each i there exist nonnegative integers k and l such that the vertex v_i has inset $\{v_{i-1}, v_{i-2}, \ldots, v_{i-k}\}$ and outset $\{v_{i+1}, v_{i+2}, \ldots, v_{i+l}\}$; here additions and subtractions are modulo n. Note that in this case there can be arcs v_iv_j with both $i < j$ and $i > j$; however, it is still true that if v_iv_j is an arc (regardless of whether $i < j$ or $j < i$), the subgraph induced by $v_i, v_{i+1}, \ldots, v_j$ is a transitive tournament. (The subscripts are again computed modulo n.) An oriented graph which admits a round enumeration is called *round*. An undirected graph is said to have a *round orientation* if it admits an orientation which is a round oriented graph. Clearly a round oriented graph is a local tournament. It is easy to see that an induced subgraph of a round oriented graph is a round oriented graph and a straight subgraph of a straight oriented graph is a straight oriented graph. Moreover, it is clear that a straight enumeration is a special case of a round enumeration and that, in fact, a round oriented graph is straight if and only if it is nonstrong.

PROPOSITION 2.6. *The following properties are equivalent for a connected ori-*

ented graph D:

1. *D is round;*

2. *there exists an inclusion-free family of circular arcs associated with the vertices of D such that $u \rightarrow v$ in D if and only if the circular arc associated with u contains the counterclockwise endpoint of the circular arc associated with v.* □

COROLLARY 2.7. *A connected graph is a proper circular-arc graph if and only if it has a round orientation.* □

The proof of Proposition 2.6 is analogous to that of Proposition 2.1, and it also yields an $O(m+n)$ method to find a representation of a given graph G by circular arcs, provided that a round enumeration of an orientation of G is given. In fact, we may modify the interval representation given in the proof of Proposition 2.1 by identifying two vertices x and y of the real line whenever $|x-y| = n+1$. This makes the real line into a circle and the intervals into circular arcs. Thus it will be sufficient to specify a linear-time algorithm to provide a round enumeration of an oriented graph D with $G(D) = G$ if one exists and to report that one does not exist otherwise.

Just as nonstrong local tournaments are related to straight oriented graphs in Theorem 2.3, general local tournaments are related to round oriented graphs. However, the relationship is more complicated. The next theorem describes a method to generate all possible local tournaments as well as all possible local-tournament orientations of a fixed undirected graph. A *special reversal* of a round oriented graph D is defined as follows: Consider the complement $\overline{G}$ of $G(D)$. If $\overline{G}$ has an odd cycle or if $\overline{G}$ is connected, then no special reversal is possible. Otherwise ($\overline{G}$ is disconnected and bipartite), we let A be either the set of all unbalanced arcs within a fixed component of $\overline{G}$ or the set of all unbalanced arcs between two fixed components of $\overline{G}$. The special reversal corresponding to A is the operation that reverses the directions of all arcs in the set A.

THEOREM 2.8 ([12, 13]). *Let D be a connected oriented graph. Then D is a local tournament if and only if it is obtained from some reduced round oriented graph R by the substitution operation with respect to some family $T_v, v \in V(R)$, possibly followed by special reversals.*

Moreover, if D is a local tournament, then every local-tournament orientation of $G(D)$ is obtained from the same R by the substitution operation with respect to a family $T'_v, v \in V(R)$, where $|T'_v| = |T_v|$ for each $v \in V(R)$, possibly followed by special reversals and/or a full reversal. □

COROLLARY 2.8. *Let G be a connected proper circular-arc graph and D and D' be two arbitrary local-tournament orientations of G. Then D' can be obtained from D by changing the directions of some balanced arcs and then possibly performing special reversals and/or a full reversal.* □

A *round mixed graph H* is a mixed graph obtained from a reduced round oriented graph R by such a substitution operation with respect to a family T_v ($v \in V(R)$) of complete graphs. Note that if we orient the undirected edges of a round mixed graph in an arbitrary way, we obtain a local tournament, and if we do it in such a way that each T_v is a transitive tournament, then we get a round oriented graph. Conversely, if we erase the directions of all balanced arcs in a round oriented graph, we obtain a round mixed graph. Thus we obtain the following result from Corollaries 2.7 and 2.9 (using the fact that no special reversals are possible if the complement of G is connected or nonbipartite).

COROLLARY 2.9. *Let G be a connected proper circular-arc graph. If the complement of G is connected or nonbipartite, then it is uniquely orientable as a round mixed graph up to full reversal.* □

3. Proper circular-arc graphs. We now give our linear-time algorithm for the representation of proper circular arc graphs. Recall that Tucker [18] gives an $O(n^2)$ algorithm; thus we only need to deal with the case when the number of edges is small relative to n^2. Let x be a vertex of minimum degree in G. Let A be the graph induced by $N[x]$ and let $B = G - A$. We may assume that B is not a complete graph. Indeed, if B is complete, we can find a representation of G by Tucker's algorithm; since x is a vertex of minimum degree, we conclude that the number of edges of G is $m \geq \frac{n^2-2n}{4}$ and so $n^2 = O(m+n)$, i.e., Tucker's algorithm is in fact linear in this case. We may also assume that G is not a proper interval graph—this can be tested in linear time by the algorithm presented in the next section. Note that a proper circular-arc graph which is not a proper interval graph must be connected.

Thus let G be a proper circular-arc graph which is not a proper interval graph. Note that this implies that G is connected and can be oriented as a strong round oriented graph $\vec{G}$. As mentioned above, we wish to find some round orientation of G. We assume from now on that B is not complete.

PROPOSITION 3.1. *Both A and B are connected proper interval graphs.*

Proof. Let $v_1, v_2, \ldots, v_n$ be a round enumeration of $\vec{G}$ and let $x = v_1$. Let f be the least integer such that v_f dominates x in $\vec{G}$ and let g be the largest integer such that x dominates v_g in $\vec{G}$. Then $f > g$ and both the subgraph of $\vec{G}$ induced by $\{v_f, v_{f+1}, \ldots, v_1\}$ and the subgraph of $\vec{G}$ induced by $\{v_1, v_2, \ldots, v_g\}$ are transitive tournaments; hence $A = \{v_f, v_{f+1}, \ldots, v_n, v_1, v_2, \ldots, v_g\}$ and $B = \{v_{g+1}, \ldots, v_{f-1}\}$. It follows that A and B are connected graphs. Let $\vec{A}$ be the subgraph of $\vec{G}$ induced by the vertices of A and let $\vec{B}$ be defined similarly. Then both $\vec{A}$ and $\vec{B}$ are round oriented graphs. We shall argue that they are, in fact, straight oriented graphs, and hence A and B are proper interval graphs. We shall show that, in fact, both A and B are acyclic oriented graphs. The subgraphs of A induced by $\{v_f, v_{f+1}, \ldots, v_1\}$ and by $\{v_1, v_2, \ldots, v_g\}$ are transitive tournaments oriented from v_f to v_1 and from v_1 to v_g. Thus for A it only remains to verify that there is no arc $v_i v_j$ with $2 \leq i \leq g$ and $f \leq j \leq n$. Any such arc would imply that $v_i, v_{i+1}, \ldots, v_j$ is a transitive tournament, contradicting the assumption that B is not complete. This proves that $\vec{A}$ is an acyclic round oriented graph and thus a straight oriented graph. For $\vec{B}$ the proof is similar, as any arc $v_i v_j$ with $g < j < i < f$ in $\vec{B}$ would imply that v_i dominates $v_1 = x$, contradicting the definition of B. □

According to the above proposition, we may construct a straight mixed orientation B' of B. For this, we may use the technique of the next section, which will also produce a straight enumeration $B_1, \ldots, B_q$ of the blocks of B'. Let L be the set of all vertices of A which are adjacent (in G) to a vertex of B_q and R the set of all vertices of A which are adjacent to a vertex of B_1. Let $C = G - L$ and $D = G - R$. Finally, let E be the subgraph of G induced by the vertices of $A \cup B_q$. Note that C and D both contain B as an induced subgraph and that E contains A as an induced subgraph.

PROPOSITION 3.2. *All three graphs C, D, and E are connected proper interval graphs.*

Proof. Consider again the round enumeration $v_1, v_2, \ldots, v_n$ of $\vec{G}$, where $x = v_1, A = \{v_f, v_{f+1}, \ldots, v_n, v_1, v_2, \ldots, v_g\}$, and $B = \{v_{g+1}, \ldots, v_{f-1}\}$. We claim that

$$C = \{v_{h+1}, v_{h+2}, \ldots, v_n, v_1, \ldots, v_{f-1}\}$$

for some $h, f \leq h \leq n$. Consider first the straight enumeration $v_{g+1}, \ldots, v_{f-1}$ of $\vec{B}$. Clearly, any block of $\vec{B}$ consists of consecutive vertices in this enumeration. Thus we obtain a straight mixed orientation of B by keeping the directions of all unbalanced edges of B according to their direction in $\vec{B}$. Since the B' is unique, up to a full reversal, we may assume, by considering a full reversal of $\vec{G}$ if necessary, that $B_q = \{v_s, v_{s+1}, \dots, v_{f-1}\}$ for some $s, g+1 < s < f$. Now we prove that $L = \{v_f, v_{f+1}, \dots, v_h\}$, where h is the largest integer such that v_{f-1} dominates v_h (thus $f \le h \le n$). Indeed, it follows from the definition of round enumeration that each $v_i, f \le i \le h$ is adjacent to a vertex (namely v_{f-1}) of B_q. On the other hand, if some v_j is dominated by a vertex in B_q, then it is also dominated by v_{f-1}; hence $f \le j \le h$ by the definition of h. Also, no v_j in A can dominate a vertex in B_q because then B would be a complete graph (recall that all vertices in B_q have the same closed neighbourhood in B). Having found L, we now know that $C = \{v_{h+1}, v_{h+2}, \dots, v_n, v_1, \dots, v_{f-1}\}$. In the order $v_{h+1}, v_{h+2}, \dots, v_n, v_1, \dots, v_{f-1}$ of vertices, there are no arcs from a later vertex to an earlier vertex because $v_{h+1}, v_{h+2}, \dots, v_n, v_1, \dots, v_g$ is part of the straight enumeration of $\vec{A}$, $v_{g+1}, v_{g+2}, \dots v_{f-1}$ is our straight enumeration of $\vec{B}$, and any arc $v_i v_j$ with $v_i \in B$ and $v_j \in A, j \notin \{f, f+1, \dots, h\}$ would imply that $v_i, v_{i+1}, \dots, v_j$ is a transitive tournament, contradicting the definition of h. Let $\vec{C}$ be the subgraph of $\vec{G}$ induced by the vertices of C. Then $v_{h+1}, v_{h+2}, \dots, v_n, v_1, \dots, v_{f-1}$ is a straight enumeration of $\vec{C}$. Hence C is a proper interval graph.

The argument for D is symmetric and it also yields the fact that $R = \{v_k, v_{k+1}, \dots, v_g\}$, where $1 < k \le g$. In particular, we note for future reference that the sets L and R are disjoint.

Let $\vec{E}$ be the subgraph of $\vec{G}$ induced by the vertices of E. Recall that $B_q = \{v_s, v_{s+1}, \dots, v_{f-1}\}$. We claim that $v_s, v_{s+1}, \dots, v_n, v_1, \dots, v_g$ is a straight enumeration of $\vec{E}$. This follows easily from the fact that $v_f, v_{f+1}, \dots, v_n, v_1, \dots, v_g$ is a straight enumeration of $\vec{A}$, $v_s, v_{s+1}, \dots, v_{f-1}$ a part of our straight enumeration of $\vec{B}$, and there is no arc $v_i v_j$ with $v_i \in A$ and $v_j \in B_q$ because B is not complete. The connectivity of C, D, E is clear from the above arguments. □

Now we may compute, again using techniques of the next section, straight mixed orientations C', D', E' of C, D, E, respectively. Recall that these orientations are unique up to full reversal. Our algorithm consists of combining the straight mixed graphs C', D', E' to form a round mixed orientation of G. To do this, we may have to replace some of C', D', E' by their full reversals. It must be possible to do this *consistently*, i.e., in such a way that all edges of G which are oriented in more than one of the mixed graphs C', D', E' are oriented there in the same way. To see this, consider the straight mixed graphs C'', D'', E'' obtained from $\vec{C}, \vec{D}, \vec{E}$ by replacing all balanced arcs by the corresponding undirected edges. They clearly have the property that all edges of G are oriented consistently (because they all arise from $\vec{G}$); however, according to Proposition 3.2 and Corollary 2.5, each of C', D', E' is equal to the corresponding C'', D'', E'' or its full reversal. To explicitly find the right orientations C', D', E', we may proceed as follows. Arbitrarily fix C' to be either of the two possible straight mixed orientations of C. This determines D', since C and D both contain B, which is not complete and hence contains an unbalanced arc. (In other words, fixing an orientation of C determined the direction of at least one edge of D and hence determined D'.) In turn, this determines the orientation of E since the edge $v_{f-1}v_f$ of G is an unbalanced edge of both D and E (recall that x is not adjacent to v_{f-1} but is adjacent to v_f). It is clear that these operations can be performed in time $O(m+n)$ once any straight mixed orientations of C, D, E are known. Thus assume that C', D', E' are oriented consistently and let H be the mixed orientation of G in which an edge is oriented only if it is oriented in any of the graphs C', D', E' and is oriented according to the orientation it has there; clearly, this can also be done in time $O(m+n)$.

PROPOSITION 3.3. *The mixed graph H is a round mixed graph.*

Proof. We first prove that each unbalanced edge of G is unbalanced in one of the mixed straight graphs C', D', E' (and hence it is oriented in that graph). Consider an unbalanced edge uv of G. If both u and v are vertices of B and if uv is balanced in B, then there exists a vertex $z \in A$ such that, say, z is adjacent to u but not to v. Since $L \cap R = \emptyset$ (see the last sentence of the proof of Proposition 3.2), $z \in C$ or $z \in D$. Thus u, v, z are vertices of C or D and hence the edge uv is an unbalanced edge in C or D. If uv is unbalanced in B, then it is also unbalanced in C (and D) since B is an induced subgraph of C. If both u and v are vertices of A and if uv is balanced in A, then there exists a vertex $z \in B$ such that, say, z is adjacent to u but not to v. Suppose first that z dominates u. If any vertex of B dominates u, then a vertex z' of B_q dominates u (consider the round enumeration $\dots, z, \dots, v_{f-2}, v_{f-1}, \dots, u, \dots$ of $\vec{G}$); thus $u \in L$. If z' is adjacent to v, then u, v, z are vertices of D and uv is an unbalanced edge of D; if z' is not adjacent to v, then u, v, z' are vertices of E and uv is an unbalanced edge of E. If uv is unbalanced in A, then it is also unbalanced in E. If (say) u is a vertex of A and v a vertex of B, then x is adjacent to u but not v and $u \notin L$ or $u \notin R$; thus u, v, x are vertices of C or D and uv is an unbalanced edge of C or D. From the way A', B', C', D', E' were chosen, we see that they all agree with $\vec{G}$ or the full reversal of $\vec{G}$. Therefore, H is obtained from $\vec{G}$ (or its reversal) by ignoring the directions on the balanced arcs. Therefore, H is a round mixed graph. □

We now summarize the algorithm.

ALGORITHM 3.4. *Let G be a graph with n vertices and m edges.*

[Step 1.] *Test if G is a proper interval graph by Algorithm* 4.4. *If it is, then represent it by linear intervals viewed as a special case of circular arcs.*

[Step 2.] *Choose a vertex x of minimum degree in G. Let A be the graph induced by $N[x]$ and let $B = G - A$. If B is a clique, then find a representation of G by Tucker's algorithm. Otherwise, proceed as follows.*

[Step 3.] *If B is not a proper interval graph, then report that G is not a proper circular-arc graph. Otherwise, orient B as a straight mixed graph B' by Algorithm* 4.4, *which also produces a straight enumeration $B_1, B_2, \dots, B_q$ of the blocks of B'.*

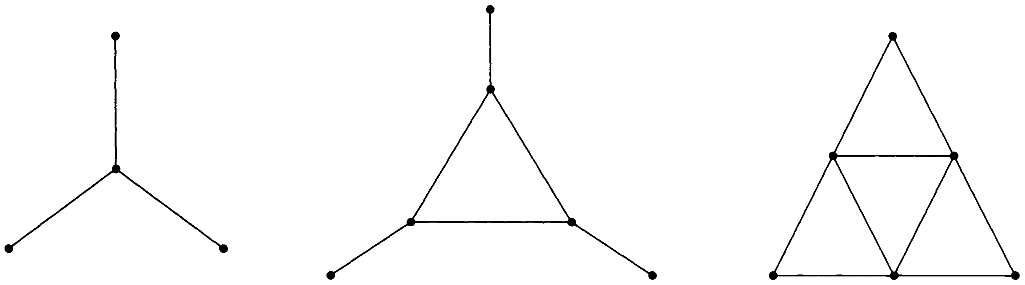
[Step 4.] *Let L be the set of vertices of A adjacent to a vertex of B_q and let R be the set of vertices of A adjacent to a vertex of B_1. Let $C = G - L$ and $D = G - R$, and let E be the subgraph of G induced by $A \cup B_q$. If any of C, D, E is not a proper interval graph, then report that G is not a proper circular-arc graph. Otherwise, orient C, D, E as straight mixed graphs C', D', E' by Algorithm* 4.4.

[Step 5.] *If it is not possible to perform full reversals on C', D', E' so that all edges are oriented consistently, then report that G is not a proper circular-arc graph. Otherwise find consistent orientations C', D', E' and construct H from G by orienting any edge uv so that $u \rightarrow v$ provided that $u \rightarrow v$ in any of the mixed graphs C', D', E'.*

[Step 6.] *Orient all remaining undirected edges of H so that each block of H becomes a transitive tournament. Let D be the resulting oriented graph.*

[Step 7.] *Transform D into a circular-arc representation of G by the method of Proposition* 2.6.

The correctness of the algorithm is implicit in our propositions. When we report that G is not a proper circular-arc graph in Step 3, then Proposition 3.1 implies that this is true. When we report this in Step 4, then Proposition 3.2 implies that this is true. When we report the same conclusion in Step 5, then this is true by the remarks following the proof of Proposition 3.2. The mixed graph H constructed in Step 5



the claw the net the tent

FIG. 1. *The claw, the net, and the tent.*

is round by Proposition 3.3. The oriented graph D constructed in Step 6 is round according to the remark following Corollary 2.8.

Steps 1, 3, and 4 are done in linear-time by Algorithm 4.4. (In Step 4, we also need to identify L and R, but this can clearly be done in time $O(m+n)$.) Step 2 also takes only linear-time according to the comments at the beginning of this section. We have already explained how the test for consistency can be done in time $O(m+n)$. The remainder of Step 5 and Step 6 are clearly linear. Step 7 can also be carried out in linear-time, as explained after Proposition 2.6.

4. Proper interval graphs.

In this section, we give an $O(m+n)$-time algorithm to represent proper interval graphs. As mentioned above, such algorithms already exist. However, our algorithm is simpler than the existing algorithms, avoids difficult data structures, and directly produces the straight mixed graph orientation of the input graph that is required by Algorithm 3.4. Furthermore, the proof of correctness of our algorithm implies as a byproduct a new proof of a theorem of Wegner [19]; cf. Corollary 4.3.

Assume that G is a connected graph, as otherwise we can work separately on each component of G. Our algorithm will insert vertices of G one at a time into an already formed straight mixed graph to form a new straight mixed graph. If G is a proper interval graph, then this process continues successfully until a straight mixed graph orientation of G is obtained. This is what is needed in Algorithm 3.4. If a concrete representation by intervals is desired, then we can again orient the remaining undirected edges so that each block is a transitive tournament and then represent the resulting straight oriented graph as explained in the proof of Proposition 2.1. (All this can still be done in time $O(m+n)$.) It is easy to see that any chordless cycle of length greater than three and any of the three graphs (the claw, the net, or the tent) in Fig. 1 is not orientable as nonstrong local tournament and hence is not a proper interval graph. (This is also well known [7].) Therefore, no graph which contains a chordless cycle of length greater than three, a copy of the claw, the net, or the tent, as an induced subgraph can be a proper interval graph.

We emphasize that by Corollary 2.5 the straight mixed graph orientation of a connected proper interval graph is unique up to a full reversal. Therefore, the corresponding straight enumeration of blocks is also unique up to reversing the order of the blocks. This is crucial in what follows, even though it is not always explicitly mentioned. In particular, if we have two connected straight mixed graphs H and H' with straight enumerations $V_1, V_2, \dots, V_p$ and $V_1', V_2', \dots, V_{p'}'$ and if H is an induced subgraph of H', then we may assume (by performing a full reversal on H' if necessary) that each edge oriented both in H and H' is oriented in the same directions in both. Moreover, it is clear that two vertices equivalent in H' are also equivalent in H. Therefore, any edge unbalanced in H remains unbalanced in H'; this also means that any edge oriented in H remains oriented in H'. Suppose that H' has just one more vertex than H, say vertex v. Then each V_i breaks into two blocks $V_i \cap N(v)$ and $V_i - N(v)$ of H' (if v has both some neighbours and some nonneighbours in V_i), combines with v to form a block $V_i \cup \{v\}$ of H' (if v has exactly the same closed neighbourhood as V_i in H'), or remains a block of H' (otherwise).

Now we suppose that G is a connected proper interval graph and H is a straight mixed orientation of a connected subgraph of G. Let $V_1, V_2, \ldots, V_p$ be a fixed straight enumeration of the blocks of H. Let v be a vertex of G which is not in H but is adjacent to a vertex of H. We wish to find a straight mixed orientation H' of the subgraph of G induced by v together with the vertices of H. According to the above observations on the form of the blocks of H', it remains only to describe which edges of G not oriented in H are oriented in H'. We can do this by describing the straight enumeration of the blocks of H', because the direction of all unbalanced edges is determined by this order, to go from the earlier block towards the later block.

Before we can describe the straight enumeration of the blocks of H', we need to analyze the possible connections of v in H. In fact, these are rather restricted as far as the blocks of H are concerned.

PROPOSITION 4.1. *Let* $1 \leq a < b < c \leq p$.

1. *If* v *is adjacent to a vertex in* V_a *and to a vertex in* V_c*, then* v *is completely adjacent to* V_b *(i.e.,* v *is adjacent to every vertex of* V_b*).*

2. *If* v *is adjacent to a vertex in* V_b *and nonadjacent to a vertex in* V_a *and a vertex in* V_c*, then* V_a *is nonadjacent to* V_c.

3. *If* $V_a \rightarrow V_b \rightarrow V_c$ *and if* v *is adjacent to a vertex in* V_b*, then* v *is completely adjacent to* V_a *or to* V_c.

Proof. Assume that v is adjacent to $x \in V_a$ and $z \in V_c$ but not to $y \in V_b$. We may assume without loss of generality that a, b, and c are chosen so that $c - a$ is minimal. Then $c - a \geq 2$ and v is not adjacent to at least one vertex in each V_d with $a < d < c$. Moreover, V_a and V_c are adjacent blocks, for otherwise any shortest path from V_a to V_c in $V_a \cup V_{a+1} \cup \cdots \cup V_c$ together with v would induce chordless cycle of length greater than three, a contradiction. (The subgraph induced by $V_a \cup V_{a+1} \cup \cdots \cup V_b$ is connected because the connectivity of H implies that each V_i is adjacent to V_{i+1}.) Since $V_1, V_2, \cdots, V_p$ is a straight enumeration of H, the vertices in $V_a \cup V_{a+1} \cup \cdots \cup V_b$ induce a complete subgraph of G. Consider the three blocks V_a, V_b, V_c; any two distinct blocks have distinct neighbourhoods in H. Thus there exists a block V_i which is adjacent to exactly one of the blocks V_a, V_b, and there exists a block V_j which is adjacent to exactly one of the blocks V_b, V_c. If V_i is adjacent to V_a but not to V_b and V_j is adjacent to V_c but not to V_b, then clearly $i < a < c < j$, and v must be completely adjacent to both V_i and V_j, as otherwise G would contain a copy of the claw centered at x or z. Now the vertices x, y, z, v together with any vertex of V_i and any of vertex of V_j induce a copy of the tent, contradicting the fact that G is a proper interval graph. Thus we may assume without loss of generality that V_i is adjacent to V_b but not to V_a. Then clearly $i > c$ and v must be completely nonadjacent to V_i, as otherwise G would contain a four-cycle induced by v, x, z and a vertex of V_i. If, additionally, V_j is adjacent to V_b but not to V_c, then we would similarly have $j < a$ and v completely adjacent to V_j. In this case G would contain a copy of the tent induced by x, y, z, v, any vertex of V_i, and any vertex of V_j. If, on the other hand, V_j is adjacent to V_c but not to V_b, then clearly $c < i < j$ and, moreover, v must be completely adjacent to V_j, as otherwise G would contain a copy of the claw centered at z. Now we conclude that G contains a chordless five-cycle induced by v, x, y, any vertex of V_i, and any vertex of V_j.

For the second statement, suppose that v is adjacent to $y \in V_b$ and is nonadjacent to $x \in V_a$ and $z \in V_c$. Assume that V_a is adjacent to V_c. The blocks V_a and V_b have distinct closed neighbourhoods in H. If there is a block V_d which is adjacent to V_b but not adjacent to V_a, then $d > c$ because V_a is adjacent to V_c. Note that v is not adjacent to any vertex in V_d according to the first statement. Hence for any $w \in V_d$, $\{x, y, w, v\}$ induces a claw in G, contradicting the fact that G is a proper interval graph. Thus there must be a block V_e which is adjacent to V_a but nonadjacent to V_b. Similarly, there is a block V_f which is adjacent to V_c but nonadjacent to V_b. Note that $e < a$ and $f > c$. Hence v is adjacent to no vertex in V_e or V_f. Choose any $u \in V_e$ and any $w \in V_f$ and note that the subgraph induced by $\{x, y, z, u, w, v\}$ is a copy of the net, again contradicting the fact that G is a proper interval graph.

For the last statement, suppose that there are three vertices $x \in V_a$, $y \in V_b$, and $z \in V_c$ such that v is adjacent to y but not to x or z. By the second statement, x is not adjacent to z. Then G contains a claw induced by $\{x, y, z, v\}$. □

Remark. We note that the proof of Proposition 4.1 applies even if we replace the assumption that G is a connected proper interval graph by the assumption that G is a connected chordal graph which contains no induced claw, net, or tent. (A graph is called *chordal* if it contains no chordless cycle of length greater than three [7].) □

Under the above assumptions that G is a connected proper interval graph (or indeed that G is a connected chordal graph which contains no induced claw, net, or tent), H a straight mixed orientation of a connected subgraph of G, and v a vertex of G but not of H, we also have the following.

PROPOSITION 4.2. *The subgraph of G induced by v and the vertices of H is a proper interval graph.*

Proof. According to part 1 of Proposition 4.1, the blocks of H that are completely adjacent to v form a (possibly empty) sequence of consecutive blocks, say, $V_l, V_{l+1}, \ldots, V_r$, for some l and r. We first assume that $1 < l < r < p$. Let $a = l - 1$ and $c = r + 1$; thus $a \geq 1$ and $c \leq p$. Note that (again by part 1 of Proposition 4.1), v is nonadjacent to all V_j with $j < a$ and $j > c$. It further follows from part 2 of Proposition 4.1 that V_a and V_c are nonadjacent. Let b be the largest integer greater than a such that V_b is adjacent to V_a, and let d be the smallest integer less than c such that V_d is adjacent to V_c. Then both $a < b < c$ and $a < d < c$. We claim that $b < d$. Suppose $b \geq d$ and let x and y be two vertices in V_a and V_c, respectively, which are nonadjacent to v; such vertices exist by the definition of l and r. Let z be any vertex of V_d. Then H has a claw induced by $\{x, y, z, v\}$.

We are now ready to describe the straight mixed graph H' in the case when $1 < l < r < p$. If the set $N(v)$ intersects V_a, then (cf. above) V_a breaks into $V_a - N(v)$ and $V_a \cap N(v)$ and we modify the straight enumeration of the blocks of H by replacing V_a with $V_a - N(v), V_a \cap N(v)$, in this order. Similarly, if the set $N(v)$ intersects V_c, then we modify the straight enumeration by replacing V_a with $V_c \cap N(v), V_c - N(v)$, in this order. Note that these operations imply that some of the previously undirected edges have become oriented, e.g., the edges oriented from $V_c - N(v)$ to $V_c \cap N(v)$. It remains to describe where the vertex v goes in the straight enumeration of H'. Recall that it can form its own block or it can be added to an existing block V_j.

If $N(v)$ intersects V_a, then we put $\{v\}$ as a separate block just after V_b. If $N(v)$ intersects V_c, then we put $\{v\}$ as a separate block just before V_d. We note that if $N(v)$ intersects both V_a and V_c, then these two instructions coincide because in this case we necessarily have $d = b + 1$. Suppose $d > b + 1$, and let x and y be vertices of $N(v) \cap V_a$ and $N(v) \cap V_c$, respectively. Let z be any vertex of V_{b+1}. Then $\{x, y, z, v\}$ forms a claw of G, a contradiction. (The vertices x, y are nonadjacent because z and y are nonadjacent and V_a precedes V_{b+1} in the straight enumeration of H_{i+1}.) It is not difficult to verify that what we have defined is indeed a straight enumeration of H'. For instance, suppose that both $N(v) \cap V_a$ and $N(v) \cap V_c$ are nonempty and consider two adjacent blocks from the straight enumeration

$$V_1, \ldots, V_{a-1}, V_a - N(v), V_a \cap N(v), \ldots, V_b, \{v\}, V_d, \ldots, V_c \cap N(v), V_c - N(v), V_{c+1}, \ldots, V_p$$

described above. If two blocks V_i and V_j with $i < j < a$ are adjacent, then the intermediate blocks are $V_i, V_{i+1}, \ldots, V_j$ and they induce a complete graph since this was the case in H; a similar argument applies if $i > j > c$. If $a < i < c$, then the intermediate blocks may additionally contain also the block $\{v\}$, which was not included in H. However, $\{v\}$ is adjacent to all blocks $V_i, V_{i+1}, \ldots V_j$ and the graph induced by the intermediate blocks is still complete. If the block $V_a - N(v)$ or the block $V_a \cap N(v)$ is adjacent to V_j, then $j \leq b$ by the definition of b and again the graph induced by the intermediate blocks is complete. If the block v is adjacent to a block V_j with, say, $j \leq b$, then it is adjacent to all blocks V_i with $j \leq i \leq b$ and once more the graph induced by the intermediate blocks is complete. A similar argument applies in the case of the adjacent blocks $\{v\}$ and $V_a \cap N(v)$. In what follows, we shall omit these simple verifications. They are all similar to the above.

If $N(v)$ intersects neither V_a nor V_c, then $N(v) = V_l \cup \cdots \cup V_r$. There may be a block V_j with $b < j < d$ adjacent to both V_l and V_r. Since by the definition of b and d we know that V_j is not adjacent to $V_{l-1} = V_a$ or $V_{r+1} = V_c$, the closed neighbourhood in H_i of any vertex of V_j is $V_l \cup \cdots \cup V_r$. Thus there can be at most one such block V_j, as distinct blocks have distinct closed neighbourhoods. Moreover, the closed neighbourhood of V_j in H' is the same as that of v. Thus we obtain a straight enumeration of H' by replacing V_j with $V_j \cup \{v\}$. On the other hand, each block V_j with $b < j < d$ is adjacent to at least one of V_l, V_r because otherwise we would have a claw formed by v and any vertices from V_l, V_j, V_r. Let u be the least integer greater than b such that V_u is adjacent to V_r and w be the largest integer smaller that d such that V_w is adjacent to V_l. Note that $b < u \leq d$ and $b \leq w < d$. We may assume that $u > w$ because otherwise there would be a block V_j with $b < j < d$ adjacent to both V_l and V_r. This means that $u = w + 1$ because each V_j with $b < j < d$ is adjacent to at least one of V_l, V_r. To obtain the desired straight enumeration of H' from $V_1, \ldots, V_p$, we insert a new block $\{v\}$ just before V_u.

The case $1 = l < r < p$ is very similar to the above arguments. We let $b = l = 1$ and $c = r + 1$ and define d as above to be the smallest integer less than c such that V_d is adjacent to V_c. Then the above discussion applies almost verbatim, except that we may have $d = b = 1$. In this case we insert the block $\{v\}$ before V_1.

Because of symmetry, it only remains to consider the following cases:

When $1 = l = r = p$, then H has only one block, V_1, and v is completely adjacent to it. Then $V_1 \cup \{v\}$ is the unique block of H'.

When $1 = l = r < p$, then $\{v\}, V_1, V_2 \cap N(v), V_2 - N(v), \ldots, V_p$ is a straight enumeration of the blocks of H'.

When $1 = l < r = p$, then v is completely adjacent to all blocks of H. We define $b = 1$ and $d = p$ and proceed as above, letting w be the largest integer greater than 1 such that V_w is adjacent to V_1 and u be the least integer smaller than p such that V_u is adjacent to V_p. Thus if $u = w$, we have the enumeration $V_1, \ldots, V_u \cup \{v\}, \ldots, V_p$ and if $u > w$, i.e., $u = w+1$ (cf. above), we have the enumeration $V_1, \ldots, V_w, \{v\}, V_u, \ldots, V_p$.

(Clearly, $u < w$ is not possible.)

The case $1 < l = r < p$ is impossible by part 3 of Proposition 4.1.

Finally, there is the trivial case when $l > r$, i.e., when v is not completely adjacent to any block of H. In the ordering the vertices of G as $v_1, \ldots, v_n$, we made sure that $v = v_{i+1}$ is adjacent to some vertex of H, say in block V_u. By part 3 of Proposition 4.1, $u = 1$ or $u = p$. Without loss of generality, we may assume that $u = 1$. If $p = 1$, i.e., if H has only one block V_1, then $\{v\}, V_1 \cap N(v), V_1 - N(v)$ is a straight enumeration of the blocks of H'. The case $p = 2$ is impossible since distinct blocks of H have distinct closed neighbourhoods, and when $p \geq 3$ then part 3 of Proposition 4.1 implies that v is nonadjacent to all V_j with $j > 1$. Then $\{v\}, V_1 \cap N(v), V_1 - N(v), V_2, \ldots, V_p$ is a straight enumeration of the blocks of H'. Now we have described the straight mixed graph H' in all cases. □

It is interesting to note that the proposition implies the following well-known result [7] (see also [3] for a refinement).

COROLLARY 4.3 ([19]). *Let G be an undirected graph. Then G is a proper interval graph if and only if it is chordal and does not contain the claw, the net, or the tent as an induced subgraph.*

Proof. We have already observed that the condition is necessary. Therefore, suppose that there is a chordal graph which does not contain an induced claw, net, or tent and which is not a proper interval graph, and let G be such a graph which has the smallest possible number of vertices. Then G must be connected; let v be a vertex of G such that $G - v$ is also connected. By the minimality of G, we know that $G - v$ can be oriented as a straight mixed graph H. Since Proposition 4.2 is valid for the graph G (cf. the sentence just before Proposition 4.2), we see that G itself is orientable as a straight mixed graph, contradicting the fact that G is not a proper interval graph. □

The proof of the above proposition is, in fact, an algorithm for inserting v into H. We summarize our algorithm for the representation of proper interval graphs as follows.

ALGORITHM 4.4. *Let G be a connected graph.*

[Step 1.] *Order the vertices of G as $v_1, v_2, \ldots, v_n$ in such a way that the subgraph induced by $\{v_1, v_2, \ldots, v_i\}$ is connected, for each $i = 1, 2, \ldots, n$. Let $v = v_1$ and $H = \{v\}$.*

[Step 2.] *Perform the following operation as long as possible: If the vertices of H are $\{v_1, v_2, \ldots, v_i\}$, then let $v = v_{i+1}$ and insert v into H as described above.*

[Step 3.] *If H does not contain all vertices, then report that G is not a proper interval graph.*

[Step 4.] *If desired, transform H into an interval representation of G by first orienting each block to be a transitive tournament and then using the method of Proposition* 2.1.

The correctness of the algorithm is assured by Proposition 4.2. Indeed, if the algorithm halts before H contains all the vertices, then some v could not be inserted and hence G is not a proper interval graph.

Our Algorithm 4.4 can be implemented in time $O(m + n)$. Since the first version of this manuscript, Corneil, Kim, Natarajan, and Olariu have published an even simpler linear-time recognition algorithm for proper interval graphs ("Simple linear time recognition of unit interval graphs," *Inform. Process. Lett.*, 55 (1995), pp. 99–104). It is possible to use their algorithm instead of ours for the purposes of Algorithm 3.4. One only has to notice that their algorithm can produce a straight mixed graph orientation of the input graph because our blocks B_i consist precisely of vertices v with equal value of their function $NextD(v)-PrevD(v)$. (Our Algorithm 4.4 remains interesting because it is incremental, and its correctness proof implies Wegner's theorem.)

Finally, we remark that we believe there is an incremental linear-time algorithm to directly compute a round mixed orientation of a given undirected graph along the lines of Algorithm 4.4. We hope to return to this idea in the future.

Acknowledgment. The authors wish to thank R. Shamir for his interest and for helpful comments.

AN $O(N+M)$-TIME ALGORITHM FOR FINDING A MINIMUM-WEIGHT DOMINATING SET IN A PERMUTATION GRAPH*

C. RHEE[†], Y. D. LIANG[‡], S. K. DHALL[§], AND S. LAKSHMIVARAHAN[§]

Abstract. Farber and Keil [*Algorithmica*, 4 (1989), pp. 221–236] presented an $O(n^3)$-time algorithm for finding a minimum-weight dominating set in permutation graphs. This result was improved to $O(n^2 \log^2 n)$ by Tsai and Hsu [*SIGAL '90 Algorithms, Lecture Notes in Computer Science*, Springer-Verlag, New York, 1990, pp. 109–117] and to $O(n(n+m))$ by the authors of this paper [*Inform. Process. Lett.*, 37 (1991), pp. 219–224], respectively. In this paper, we introduce a new faster algorithm that takes only $O(n+m)$ time to solve the same problem, where m is the number of edges in a graph of n vertices.

1. Introduction.

Let $\pi = (\pi[1], \pi[2], \ldots, \pi[n])$ be a permutation on the set $V_n = \{1, 2, \ldots, n\}$. For example, if $\pi = (2, 1, 5, 4, 6, 3)$, then $\pi[3] = 5, \pi[5] = 6, \pi^{-1}[5] = 3$, and $\pi^{-1}[6] = 5$, where $\pi^{-1}[i]$ denotes the *position* of the number i in the sequence $(\pi[1], \pi[2], \ldots, \pi[n])$. Let $G(\pi) = (V, E)$ be an undirected graph such that $V = V_n$ and $(i, j) \in E$ if and only if $(i-j)(\pi^{-1}[i] - \pi^{-1}[j]) < 0$. Then an undirected graph G is called a *permutation graph* if there is a permutation π such that G is isomorphic to $G(\pi)$[5].

For an undirected graph $G = (V, E)$, a subset D of V is called a *dominating set* for G if for every $u \in V - D$ there exists $v \in D$ such that $(u, v) \in E$, where $V - D$ denotes the set-theoretic difference of V and D. A graph G is called a *weighted graph* if there is a weight function $w : V \longrightarrow R$ (the set of reals), where $w[i]$ is called the weight of node i. Manacher and Mankus [7] showed that any algorithm for finding a minimum-weight dominating set for nonnegative weights can be extended to incorporate negative-weight vertices without loss of efficiency. Hence, for simplicity, we assume that $w[i]$ is nonnegative. For any subset $D \subseteq V$, let $W(D) = \sum_{i \in D} w[i]$ denote the *weight of D*. A subset $D \subseteq V$ is called a *minimum-weight dominating set* for G if $W(D)$ is a minimum over all dominating sets for G.

Permutation graphs are known to have a variety of practical applications [5], and for this reason, many algorithms have been developed in the literature. Pnueli, Lempel, and Even [8] described an $O(n^3)$ algorithm for testing if a given undirected graph G is a permutation graph. Spinrad [10] improved the above result by deriving an $O(n^2)$ algorithm for orienting comparability graphs. A proper subset of the permutation graphs called cographs has been studied by Corneil, Perl, and Stewart [3]. Bipartite permutation graphs were analyzed by Spinrad, Brandstädt, and Stewart [11]. Farber and Keil [4] developed $O(n^3)$ algorithms for finding a minimum-weight dominating set and a minimum-weight independent dominating set in permu-

tation graphs. In addition, they also described an $O(n^2)$ algorithm for the minimum cardinality dominating set problem. Atallah, Manacher, and Urrutia [2] presented an $O(n \log^2 n)$ algorithm for finding a minimum independent dominating set in a permutation graph. Later Atallah and Kosaraju [1] presented an $O(n \log n)$ time algorithm for the *maxdominance problem* to which the minimum-weight independent dominating set problem for permutation graphs can be reduced in linear time. Rhee, Dhall, and Lakshmivarahan [9] gave the first NC algorithm for minimum-weight domination in permutation graphs. Recently Tsai and Hsu [12] and the authors of this paper [6] improved one of Farber and Keil's results for the minimum-weight dominating set problem to $O(n^2 \log^2 n)$ time and $O(n(n+m))$ time, respectively. In this paper we propose an $O(n+m)$ time algorithm for finding a minimum-weight dominating set in a permutation graph G, where n and m indicate the number of vertices and edges in G, respectively.

In §2 we provide some preliminary definitions and state some theorems from [6] that lay out an essential dynamic computation structure of our algorithm. In §3 we present the algorithm and some data structures that support an efficient implementation of the algorithm. In §4 we derive time bounds of various subroutines used in the algorithm. Section 5 is devoted to describing an efficient scheme for computing a major component of the algorithm. A summary and time-complexity analysis of the algorithm is given in §6. Finally, some concluding remarks are made in §7.

2. Preliminaries. For a better illustration of our approach, we introduce a visualization of the permutation graph, called the *permutation diagram.* The permutation diagram consists of two horizontal parallel channels, named the top channel and the bottom channel. We put the numbers $1, 2, \ldots, n$ on the top channel, in this order, from left to right, and put the numbers $\pi[1], \pi[2], \ldots, \pi[n]$ on the bottom channel in the same way; then, for each $i \in V_n$, we draw a straight line joining two i's, one on the top channel and the other on the bottom channel. We label each such line by the same number i. Note that line i intersects line j iff i and j appear in reversed order in π. That is, the criterion for lines i and j to intersect is the same as for nodes i and j of the permutation graph to be adjacent. Therefore, an intersection graph of the lines of a permutation diagram is exactly the corresponding permutation graph.

Let D_1 and D_2 be subsets of V_n. (From now on, V_n denotes the set of lines of the permutation diagram and each member of V_n is called a *line*, with weight of line i equal to $w[i]$.) Then D_2 is said to *cover* D_1 if every line in $D_1 - D_2$ intersects some line in D_2. Our goal is to find a set of lines, say D, with minimum weight that covers the entire line set V_n of the permutation diagram. It is obvious that the set D then realizes a minimum-weight dominating set for G. For convenience, we first add two dummy nodes 0 and $n+1$, each with a weight 0, such that $\pi[0] = 0$ and $\pi[n+1] = n+1$, denoting the resulting graph by $G^+(\pi)$. Also, for any $j \geq 0$, V_j^+ denotes the set $\{0, 1, \ldots, j\}$. Note that any dominating set D^+ for G^+ directly realizes a dominating set for G by removing 0 and $n+1$ from D^+. Figure 1 shows the permutation diagram corresponding to $\pi = (2, 8, 6, 3, 1, 7, 4, 5)$ along with its weight function $w = (8, 3, 4, 1, 7, 1, 6, 12)$.

Any pair of lines i and j in V_{n+1}^+, $i \leq j$, is called an *ordered cross pair*, denoted by X_{ij}, if $i = j$ or i intersects (or crosses) j. For example, in Fig. 1, $(1, 2)$ and $(3, 3)$ are ordered cross pairs, while $(2, 3)$ and $(2, 1)$ are not. For any two ordered cross pairs X_{ij} and $X_{i'j'}$, X_{ij} is said to be *less* than $X_{i'j'}$, denoted by $X_{ij} < X_{i'j'}$, if (i) $j < j'$ or (ii) $j = j'$ and $i < i'$. For an ordered cross pair X_{ij}, we define $MWDS(X_{ij})$ to be a minimum-weight dominating set for V_j^+ such that $S_{ij} \subseteq MWDS(X_{ij})$, where

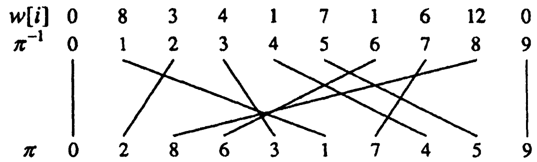

FIG. 1. *The permutation diagram for* $G^+(\pi)$.

$S_{ij} = \{i, j\}$. We first state a couple of results that appeared in [6].

THEOREM 2.1 (see [6]). *$MWDS(X_{(n+1)(n+1)})$ is a minimum-weight dominating set for G^+, and hence, $MWDS(X_{(n+1)(n+1)}) - \{0, n+1\}$ is a minimum-weight dominating set for G.*

THEOREM 2.2 (see [6]). *For each ordered cross pair $X_{ij}, j > 0$, there exists another cross pair $X_{i_bj_b}$, called back (X_{ij}), such that $X_{i_bj_b} < X_{ij}$ and $MWDS(X_{ij}) = MWDS(X_{i_bj_b}) + S_{ij}$.*

Observe that $back(X_{ij})$ is not unique in Theorem 2.2. That is, $back(X_{ij})$ is an arbitrary cross pair satisfying the given conditions. Throughout the paper, for the purpose of convenience, when a notation, such as $back(X_{ij})$, is introduced to indicate a single object, rather than a set, then an arbitrary one will be selected if more than one candidate is available. Theorem 2.2 leads to a natural algorithm for computing $MWDS(X_{(n+1)(n+1)})$ using the so-called dynamic programming technique similar to the one used in [6]. Once all $back(X_{ij})$'s are computed, $MWDS(X_{(n+1)(n+1)})$ is easily obtained by tracing through the relation *back*. That is, $MWDS(X_{(n+1)(n+1)}) = S_{i_{k+1}j_{k+1}} + S_{i_kj_k} + \cdots + S_{i_0j_0}$, where $X_{i_{k+1}j_{k+1}} = X_{(n+1)(n+1)}$, $X_{i_0j_0} = X_{00}$, and $back(X_{i_sj_s}) = X_{i_{s-1}j_{s-1}}$ for $s = k+1, k, \ldots, 1$. The algorithm in [6] consists of n stages and at the jth stage it finds an $MWDS(X_{ij})$ for each ordered cross pair X_{ij}, $i \leq j$. Each of these stages takes $O(m+n)$ steps, giving an overall time complexity of $O(n(m+n))$. The algorithm in this paper basically employs a similar technique but exploits some of the properties of permutation graphs to avoid duplicate computations so that the total time complexity is sharply reduced to $O(m+n)$.

3. The algorithm.

Before stating the algorithm, we first introduce a few definitions. We define four crossing lists, *TLCL* (*Top_Left Crossing List*), *TRCL* (*Top_Right Crossing List*), *BLCL* (*Bottom_Left Crossing List*), and *BRCL* (*Bottom_Right Crossing List*), that are used in computing $back(X_{ij})$. For each $i \in V^+_{n+1}$, $TLCL_i$ denotes the ordered list $(k_0, k_1, \ldots, k_r)$ such that each k_t, $0 \leq t < r$, crosses i and $k_0 < k_1 < \cdots < k_r = i$. That is, $TLCL_i$ is the list of the lines, maintained in the increasing order of their numbers, crossing i from the left side of i in the top channel of the permutation diagram to the right side of i in the bottom channel. Note that i itself is a member of the list. The rest of the lists are defined as follows.

$TRCL_i$ is the ordered list $(k_0, k_1, \ldots, k_r)$ such that each k_t, $0 < t \leq r$, crosses i and $i = k_0 < k_1 < \cdots < k_r$.

$BLCL_i$ is the ordered list $(k_0, k_1, \ldots, k_r)$ such that each k_t, $0 \leq t < r$, crosses i and $\pi^{-1}[k_0] < \pi^{-1}[k_1] < \cdots < \pi^{-1}[k_r] = \pi^{-1}[i]$.

$BRCL_i$ is the ordered list $(k_0, k_1, \ldots, k_r)$ such that each k_t, $0 < t \leq r$, crosses i and $\pi^{-1}[i] = \pi^{-1}[k_0] < \pi^{-1}[k_1] < \cdots < \pi^{-1}[k_r]$.

In Fig. 1, we have $TLCL_2 = (1,2)$, $TLCL_8 = (1,3,4,5,6,7,8)$, $TRCL_1 = (1,2,3,6,8)$, $TRCL_2 = (2)$, $BLCL_1 = (2,8,6,3,1)$, $BLCL_8 = (8)$, $BRCL_2 = (2,1)$, and $BRCL_8 = (8,6,3,1,7,4,5)$. Note that $TLCL_i$ and $BRCL_i$ contain the same set of lines in a different order. The same is true for $BLCL_i$ and $TRCL_i$. Lemma 4.1 describes an efficient method for computing the various crossing lists defined above.

We now concentrate on the computation of $back(X_{ij})$ along with $mw(X_{ij})$ for each X_{ij}, where $mw(X_{ij})$ denotes the weight of $MWDS(X_{ij})$. Let $X_{i_b j_b}$ denote a $back(X_{ij})$. As shown in the proof of Theorem 2.2 [6], $back(X_{ij})$ is an ordered cross pair with the smallest mw value among all the pairs that satisfy one of the following conditions:

(1) $i_b = i$ and $i < j_b < j$;

(2) $i_b < i$ and $j_b = j$; or

(3) $j_b < i$, $\pi^{-1}[j_b] < \pi^{-1}[j]$, and the set of lines between j_b and i is covered by $S_{i_b j_b} + S_{ij}$.

Note that i_b may intersect i or j or both. The three cases are shown pictorially in Fig. 2. For convenience, we let $iback(X_{ij})$, $jback(X_{ij})$, and $xback(X_{ij})$ indicate the $back(X_{ij})$ satisfying conditions (1), (2), and (3), respectively. For any X_{ij}, $back(X_{ij})$ is then one of $iback(X_{ij})$, $jback(X_{ij})$, and $xback(X_{ij})$, whichever results in the smallest $mw(X_{ij})$ value, i.e., the smallest among $W(MWDS(iback(X_{ij})) + S_{ij})$, $W(MWDS(jback(X_{ij})) + S_{ij})$, and $W(MWDS(xback(X_{ij})) + S_{ij})$. Note that at least one of the three different *backs* exists for each X_{ij} except for X_{00}. Figure 2 illustrates these different types of $back(X_{ij})$. For example, in Fig. 1, X_{56} and X_{57} are candidates for $iback(X_{58})$. Since $mw(X_{57}) = 17$ and $mw(X_{56}) = 11$, we let $iback(X_{58}) = X_{56}$. Among X_{48}, X_{38}, and X_{18}, which are candidates for $jback(X_{58})$, we pick X_{48} since $mw(X_{48}) = 16$, whereas $mw(X_{18}) = 20$ and $mw(X_{38}) = 19$. The candidates for $xback(X_{58})$ are X_{12} and X_{22}. Therefore, $xback(X_{58}) = X_{22}$, since $mw(X_{22}) = 3$ is smaller than $mw(X_{12}) = 11$. Thus in this case $back(X_{58}) = X_{22}$ because $xback(X_{58})$ results in the smallest $mw(X_{58})$. Note that there are no candidates for $iback(X_{36})$ and $jback(X_{11})$. The procedures for computing $iback(X_{ij})$ and $jback(X_{ij})$ are relatively simple and are discussed in Lemma 4.4. In the following, we show how to identify $xback(X_{ij})$.

We first introduce a few more definitions. For each X_{ij}, we define the *clique* of X_{ij}, denoted by $CLIQ(X_{ij})$, to be the set of lines, say k, satisfying $i \le k \le j$, $\pi^{-1}[j] \le \pi^{-1}[k] \le \pi^{-1}[i]$ and there is no line k' such that $k < k' < j$ and $\pi^{-1}[k] < \pi^{-1}[k'] < \pi^{-1}[i]$. That is, $CLIQ(X_{ij})$ is the set of lines between i and j, including i and j, that form a clique, and if two lines k and k', $k < k'$, are in two such different cliques, then we choose the clique that contains the line k', as illustrated in Fig. 3. For example, in Fig. 1, $CLIQ(X_{18}) = \{1, 3, 6, 8\}$, $CLIQ(X_{48}) = \{4, 7, 8\}$, $CLIQ(X_{13}) = \{1, 3\}$, and $CLIQ(X_{11}) = \{1\}$.

For each X_{ij}, we define a *minimum cover* of X_{ij}, denoted $mc(X_{ij})$, to be an ordered cross pair $X_{i_m j_m}$ such that $mw(X_{i_m j_m})$ is minimum over all pairs satisfying the following two conditions:

(1) $i \le j_m \le j$, $\pi^{-1}[j_m] \le \pi^{-1}[i]$, and

(2) $S_{i_m j_m}$ covers $CLIQ(X_{ij})$.

Note that the existence of $mc(X_{ij})$ for each X_{ij} is assured since for any $k \in CLIQ(X_{ij})$, X_{kk} satisfies (1) and (2) and, therefore, is a candidate for $mc(X_{ij})$. In Fig. 1, we have $mc(X_{18}) = X_{66}$ since $mw(X_{11}) = 8$, $mw(X_{12}) = 11$, $mw(X_{13}) = 12$, $mw(X_{16}) = 9$, $mw(X_{18}) = 20$, $mw(X_{33}) = 7$, $mw(X_{36}) = 8$, $mw(X_{38}) = 19$, $mw(X_{46}) = 5$, $mw(X_{48}) = 16$, $mw(X_{56}) = 11$, $mw(X_{58}) = 22$, $mw(X_{66}) = 4$, $mw(X_{68}) = 16$, $mw(X_{78}) = 21$, and $mw(X_{88}) = 15$. Similarly, $mc(X_{12}) = X_{22}$ and $mc(X_{57}) = X_{46}$.

For each X_{ij}, except X_{00}, let $V_{ij} = \{k \mid k < i, \pi^{-1}[k] < \pi^{-1}[j]\}$. That is, V_{ij} is

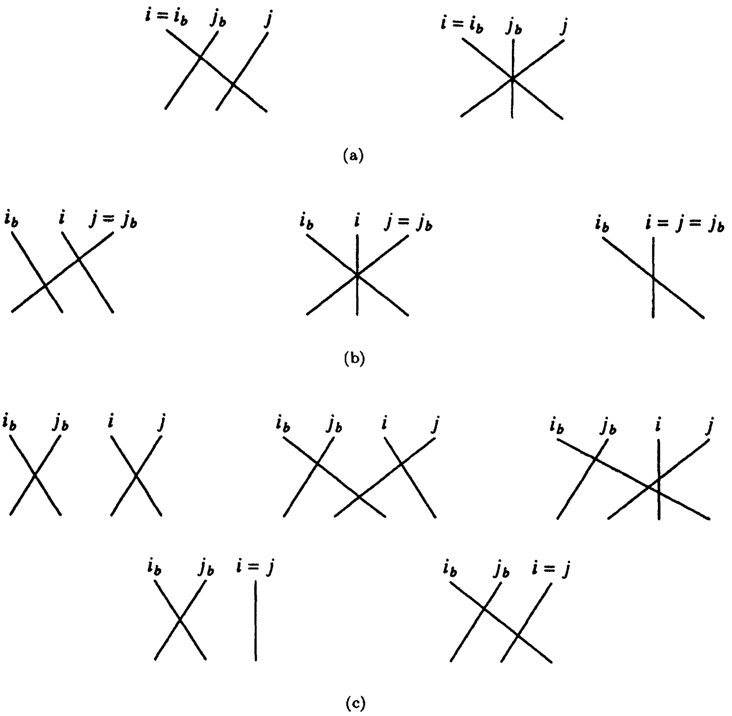

FIG. 2. *Illustration for* $iback(X_{ij})$, $jback(X_{ij})$, $xback(X_{ij})$. (a) $i_b = i$ *and* $i < j_b < j$; (b) $i_b < i$ *and* $j_b = j$; (c) $j_b < i$ *and* $\pi^{-1}[j_b] < \pi^{-1}[j]$.

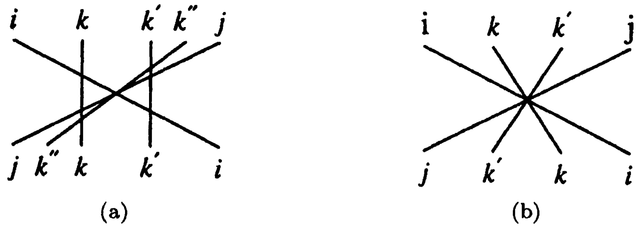

FIG. 3. *Examples of* $CLIQ(X_{ij})$. (a) $CLIQ(X_{ij}) = \{i, k', k'', j\}$; (b) $CLIQ(X_{ij}) = \{i, k, k', j\}$.

the set of lines less than i that do not intersect the line j. Then $limit(X_{ij})$ is the ordered cross pair, say $X_{i_l j_l}$, such that (i) $i_l, j_l \in V_{ij}$ and (ii) j_l is the largest number in V_{ij} and i_l is such that for all $k \in V_{ij}$, $\pi^{-1}[i_l] \geq \pi^{-1}[k]$. For example, in Fig. 1, $limit(X_{11}) = X_{00}$, $limit(X_{46}) = X_{22}$, $limit(X_{57}) = X_{13}$, and $limit(X_{99}) = X_{58}$. It is readily seen that for each X_{ij}, there is a unique $limit(X_{ij})$. As will be seen shortly, $limit(X_{ij})$ is useful in cutting down the amount of work needed to compute $xback(X_{ij})$. The computation of $limit(X_{ij})$ is discussed in Lemma 4.2.

We now return to the computation of $xback(X_{ij})$. By definition, $xback(X_{ij})$ is a cross pair, say $X_{i_b j_b}$, with the smallest *mw* value among the pairs that satisfies the following two conditions:

(1) $j_b < i$, $\pi^{-1}[j_b] < \pi^{-1}[j]$, and

(2) the set of lines k such that $j_b < k < i$ is covered by $S_{i_b j_b} + S_{ij}$.

A brute force method to find such a pair would be to check every pair that satisfies condition (1) to see whether it also satisfies condition (2). We, however, can put a limit in searching such pairs with the help of $limit(X_{ij})$.

THEOREM 3.1. *For any $X_{ij} \neq X_{00}$, let $X_{i_l j_l} = limit(X_{ij})$ and $X_{i_m j_m} = mc(X_{i_l j_l})$. Then $mw(xback(X_{ij})) = mw(X_{i_m j_m})$, if $W(MWDS(xback(X_{ij})) + S_{ij}) < W(MWDS(jback(X_{ij})) + S_{ij})$.*

Proof. Let $S_1 = \{X_{i'j'} | i_l \leq j' \leq j_l,\ \pi^{-1}[j'] \leq \pi^{-1}[i_l]$, and $S_{i'j'}$ covers $CLIQ(X_{i_l j_l})\}$ and $S_2 = \{X_{i'j'} | j' < i,\ \pi^{-1}[j'] < \pi^{-1}[j]$, and for any k such that $j' < k < i$, $\{k\}$ is covered by $S_{i'j'} + S_{ij}\}$. By definition, $X_{i_m j_m}$ and $xback(X_{ij})$ are the cross pairs in S_1 and S_2, respectively, with the smallest mw value. We show that $S_1 \subseteq S_2$ and the mw value of any cross pair in $S_2 - S_1$ is no less than the smallest mw value in S_1. First, prove $S_1 \subseteq S_2$. Let $X_{i'j'} \in S_1$. Then clearly $j' < i$ and $\pi^{-1}[j'] < \pi^{-1}[j]$ since $j_l < i$ and $\pi^{-1}[i_l] < \pi^{-1}[j]$. Next, let k be a line such that $j' < k < i$. If $j_l < k$, then S_{ij} covers $\{k\}$ by the definition of $limit(X_{ij})$. If $j' < k < j_l$ and $k \notin CLIQ(X_{i_l j_l})$, then we must have one of the following three cases:

(1) $\pi^{-1}[k] > \pi^{-1}[j]$,

(2) $\pi^{-1}[k] < \pi^{-1}[j_l]$, or

(3) there is a line $r \in CLIQ(X_{i_l j_l})$, such that $k < r$, and $\pi^{-1}[k] < \pi^{-1}[r]$.

In case (1), $\{k\}$ is covered by $\{j\}$, hence by S_{ij}. In case (2), it is covered by $\{i'\}$, hence by $S_{i'j'}$. In case (3), $\{r\}$ is covered by $S_{i'j'}$, so is $\{k\}$. Combining all these, we get $S_1 \subseteq S_2$.

Next, we show that the mw value of any cross pair in $S_2 - S_1$ is no less than the smallest mw value in S_1. Suppose it is not true, and let $X_{i'j'}$ be a cross pair with the smallest mw value in $S_2 - S_1$. That is, $mw(xback(X_{ij})) = mw(X_{i'j'})$. Since $X_{i'j'} \in S_2 - S_1$, we have $j' < i_l$, which implies $\pi^{-1}[i'] > \pi^{-1}[i_l]$ in order to cover $\{i_l\}$. This forces $X_{i'j}$ to be a candidate for $jback(X_{ij})$. Then $W(MWDS(jback(X_{ij}) + S_{ij})) \leq W(MWDS(X_{i'j'}) + S_{ij})) = W(MWDS(xback(X_{ij}) + S_{ij}))$. This contradicts the condition that $W(MWDS(xback(X_{ij}) + S_{ij})) < W(MWDS(jback(X_{ij}) + S_{ij}))$. □

The significance of this theorem is that instead of explicitly finding $xback(X_{ij})$ using its definition, we simply make use of $mc(limit(X_{ij}))$, which is already available as a result of the computation in the previous stages.

Now we show how to find $mc(X_{ij})$ for each X_{ij}. To help us identify such a pair, we use a line in $CLIQ(X_{ij})$ that divides $CLIQ(X_{ij})$ into two parts. This line, denoted by $cdiv(X_{ij})$, is defined as

$$cdiv(X_{ij}) = \begin{cases} i & \text{if } i = j, \\ \max\{CLIQ(X_{ij}) - \{j\}\} & \text{if } i \neq j. \end{cases}$$

Now consider the following two cases.

Case 1. $cdiv(X_{ij}) \neq i$. Let $cdiv(X_{ij}) = k$. Then it is not difficult to show that k divides $CLIQ(X_{ij})$ into two parts: $CLIQ(X_{ik})$ and $CLIQ(X_{kj})$. In Theorem 3.2, we show that $mc(X_{ij})$ is either $mc(X_{ik})$ or $mc(X_{kj})$, whichever has a smaller mw value.

Case 2. $cdiv(X_{ij}) = i$. Note that in this case, either $CLIQ(X_{ij}) = \{i\}$ if $i = j$ or $CLIQ(X_{ij}) = \{i, j\}$ if $i \neq j$. We compute $mc(X_{ij})$ from scratch. For convenience, let $mc2(X_{ij})$ denote $mc(X_{ij})$ when $|CLIQ(X_{ij})| \leq 2$. In other words, $mc2(X_{ij})$ is an ordered cross pair with the smallest mw value among all pairs, say $X_{i'j'}$, satisfying the following conditions:

(1) $cdiv(X_{ij}) = i$,

(2) $i \leq j' \leq j$, $\pi^{-1}[j'] \leq \pi^{-1}[i]$, and

(3) $S_{i'j'}$ covers $CLIQ(X_{ij})$;

Section 5 is devoted to computing all $mc2(X_{ij})$ efficiently.

THEOREM 3.2.

(a) *Suppose* $cdiv(X_{ij}) = k(\neq i)$. *Then* $mc(X_{ij}) = X_{i_m j_m} \in \{mc(X_{ik}), mc(X_{kj})\}$ *such that* $mw(X_{i_m j_m})$ *is a smaller of* $mw(mc(X_{ik}))$ *and* $mw(mc(X_{kj}))$.

(b) *Suppose* $cdiv(X_{ij}) = i$. *Then* $mc(X_{ij}) = mc2(X_{ij})$.

Proof. (a) Let

$C = \{X_{i'j'} \,|i \le j' \le j, \pi^{-1}[j'] \le \pi^{-1}[i]$, and $S_{i'j'}$ covers $CLIQ(X_{ij})\}$,

$C_1 = \{X_{i'j'} \,|i \le j' \le k, \pi^{-1}[j'] \le \pi^{-1}[i]$, and $S_{i'j'}$ covers $CLIQ(X_{ik})\}$, and

$C_2 = \{X_{i'j'} \,|k \le j' \le j, \pi^{-1}[j'] \le \pi^{-1}[k]$, and $S_{i'j'}$ covers $CLIQ(X_{kj})\}$.

Then it suffices to prove that $C = C_1 + C_2$. To prove $C_1 + C_2 \subseteq C$, first let $X_{i'j'} \in C_1$. Consider two cases: either (i) i' or j' is a member of $CLIQ(X_{ik})$, or (ii) neither of them is a member of $CLIQ(X_{ik})$. In (i), obviously $\{i'\}$ (or $\{j'\}$) covers $CLIQ(X_{ij})$. In (ii), since $j' < k$ and hence j' does not cross k, i' should cross k in such a way that $i' < k < j$ and $\pi^{-1}[j] < \pi^{-1}[k] < \pi^{-1}[i']$, which means that i' also crosses j. Therefore, $S_{i'j'}$ covers $CLIQ(X_{ij})$. In both cases, we have $X_{i'j'} \in C$. The other case, i.e., when $X_{i'j'} \in C_2$, can be proved similarly.

Now, to prove that $C \subseteq C_1 + C_2$, let $X_{i'j'} \in C$. Again consider two cases: (i) If i' or j' is a member of $CLIQ(X_{ij})$, then clearly $S_{i'j'}$ covers $CLIQ(X_{ij})$ and $CLIQ(X_{kj})$. Therefore, $X_{i'j'} \in C_1$ if $i \le j' \le k$, or $X_{i'j'} \in C_2$ if $k \le j' \le j$. (ii) If neither i' nor j' is a member of $CLIQ(X_{ij})$, then check two subcases: $k < j' < j$ or $i < j' < k$. If $k < j' < j$, then $\pi^{-1}[j'] < \pi^{-1}[j] < \pi^{-1}[k]$, which implies that j' intersects k but not j. This in turn implies that i' crosses j, hence, $S_{ij'}$ covers $CLIQ(X_{kj})$. Therefore, $X_{i'j'} \in C_2$. Suppose $i < j' < k$. Since j' is not a member of $CLIQ(X_{ij})$ and $\pi^{-1}[j'] < \pi^{-1}[i]$, we have $\pi^{-1}[j'] < \pi^{-1}[k]$, which implies that $\{k\}$ is to be covered by $\{i'\}$. Then $\pi^{-1}[k] < \pi^{-1}[i']$. Hence $CLIQ(X_{ik})$ is covered by $S_{i'j'}$.

(b) Part (b) of the theorem follows directly from the definition. □

Before closing this section, we outline the algorithm for computing $back(X_{ij})$ in Algorithm 3.1.

```

4. Subroutines. In this section, we show how to compute the four lists (*TLCL*, *TRCL*, *BLCL*, and *BRCL*) and basic functions such as *limit*, *cdiv*, *iback*, and *jback* efficiently.

LEMMA 4.1. *All $TLCL_j$'s, $TRCL_j$'s, $BLCL_j$'s, and $BRCL_j$'s can be computed in $O(m+n)$ time.*

Proof. To compute $TLCL_j$ for all $j \in V_{n+1}^{+}$, we inspect the given permutation $\pi = (\pi[1], \pi[2], \ldots, \pi[n+1])$ in its reverse order from $\pi[n+1]$ to $\pi[1]$. Let j be an element of the permutation in this order. We traverse a sorted list L, from the beginning, comparing each element of L with j until we insert j at the proper place in L, where L is maintained in the increasing order of its elements. Initially L is empty and $j = \pi[n+1]$. When j is inserted into L, the sequence $k_0, k_1, \ldots, k_{r-1}$ of elements in L that are less than j, along with j itself, forms $TLCL_j$, since $k_0 < k_1 < \cdots < k_{r-1} < j$ and $\pi^{-1}[k_0] > \pi^{-1}[k_1] > \cdots > \pi^{-1}[k_{r-1}] > \pi^{-1}[j]$. For example, let $\pi = (4\ 1\ 3\ 2\ 5)$. Initially L is empty. We first add 5 to L. In this case, no comparison is required and we have $TLCL_5 = (5)$. Next, add 2 to the front of 5 since 2 is less than 5, making $L = \{2, 5\}$. Since there is no element less than 2 in L at this time, we have $TLCL_2 = (2)$. For $j = 3$, put 3 between 2 and 5, making $L = \{2, 3, 5\}$, which gives (2, 3) as $TLCL_3$. For $j = 1$, add j to the beginning of L and let $TLCL_1 = (1)$. Finally for $j = 4$, we put j right after 3, making $L = \{1, 2, 3, 4, 5\}$, and get $TLCL_4 = (1, 2, 3, 4)$. Note that the number of comparisons made at the time of insertion of j into L is equal to the number of elements in $TLCL_j$. Thus, the time required in the above procedure is $\sum_{j=1}^{n+1} |TLCL_j| = O(m+n)$ steps, where $|TLCL_j|$ denotes the length of $TLCL_j$.

The remaining lists can be obtained in a similar way each with a time complexity of $O(m+n)$. □

LEMMA 4.2. *All limit (X_{ij})'s can be computed in time $O(m+n)$.*

Proof. Let $X_{i_l j_l} = limit(X_{ij})$, $limit(X_{ij}).i = i_l$, and $limit(X_{ij}).j = j_l$. We first compute $limit(X_{ij}).j$ for each $i \in TLCL_j$. For each j, $1 \leq j \leq n+1$, we consider $TLCL_j = (i_0, i_1, \ldots, i_r = j)$. Since line $i_0 - 1$ does not cross j, we have $limit(X_{i_0 j}).j = i_0 - 1$. Next, to compute $limit(X_{i_1 j}).j$, we compare i_0 and i_1. If their difference, $i_1 - i_0$, is only 1, then $limit(X_{i_1j}).j$ is again $i_0 - 1$, since there is no line between i_0 and i_1. If their difference is greater than 1, then $i_1 - 1$ should be $limit(X_{i_1j}).j$, because $i_1 - 1$ is the largest line that crosses neither i nor j. We continue the same computation for each $limit(X_{i_sj}).j$, $s = 2, \ldots, r$, setting $limit(X_{i_sj}).j$ to be $limit(X_{i_{s-1}j}).j$ if $i_s - i_{s-1} = 1$ and to $i_s - 1$ otherwise. The time required is exactly $m + n$ steps, since each element of $TLCL_j$ is inspected only once.

Next, we compute $limit(X_{ij}).i$ in a similar way. For each i, $1 \leq i \leq n+1$, we consider $BLCL_i = (j_0, j_1, \ldots, j_r = i)$. Let $k = \pi[\pi^{-1}[j_0] - 1]$. Since k does not cross i or j, we have $limit(X_{ij_0}).i = k$. To compute $limit(X_{ij_1}).i$, we compare $\pi^{-1}[j_0]$ and $\pi^{-1}[j_1]$. If their difference, $\pi^{-1}[j_1] - \pi^{-1}[j_0]$, is only 1, $limit(X_{ij_1}).i$ is again k, since $\pi^{-1}[k]$ is the largest among all $\pi^{-1}[k']$ such that $k' < i$ and $\pi^{-1}[k'] < \pi^{-1}[j_1]$. If their difference is greater than 1, then $\pi[\pi^{-1}[j_1] - 1]$ should be $limit(X_{ij_1}).i$. We continue the same computation for each $limit(X_{ij_s}).i$, $s = 2, \ldots, r$. Again the time required is exactly $m + n$, since each element of $BLCL_i$ is inspected only once. □

LEMMA 4.3. *All* $cdiv(X_{ij})$*'s can be computed in* $O(m+n)$ *time.*

Proof. For each $j \in V^+_{n+1}$, we traverse $TLCL_j = (i_0, i_1, \ldots, i_r = j)$ and $BRCL_j = (k_0 = j, k_1, \ldots, k_r)$ in their reverse order, from right to left. Obviously, $cdiv(X_{jj}) = j$. We first consider i_{r-1}, which is the second largest line in $TLCL_j$. For this i_{r-1}, we visit each member of $BRCL_j$ in its reverse order starting at k_r to identify every pair X_{k_sj}, $s = r, r-1, \ldots, 1$, whose $cdiv$ is i_{r-1}. It is straightforward to see that i_{r-1} is $cdiv$ for each pair X_{k_sj} such that k_s is a member of $BRCL_j$ satisfying $\pi^{-1}[k_s] \geq \pi^{-1}[i_{r-1}]$. Let k_t be the first member of $BRCL_j$, going from right to left, such that $\pi^{-1}[k_t] \leq \pi^{-1}[i_{r-1}]$. Since i_{r-1} cannot be $cdiv(X_{k_tj})$ any more, consider i_{r-2} next. Again, for this i_{r-2}, we traverse $BRCL_j$ again in reverse order starting from k_t and setting $cdiv(X_{k_tj})$ to i_{r-2} for each k_s in $BRCL_j$ such that $\pi^{-1}[k_s] \geq \pi^{-1}[i_{r-2}]$. We repeat the above procedure until we get $cdiv(X_{ij})$'s for all i's crossing j. As an example, consider Fig. 1. Let $j = 8$. Then $TLCL_8 = (1\ 3\ 4\ 5\ 6\ 7\ 8)$ and $BRCL_8 = (8\ 6\ 3\ 1\ 7\ 4\ 5)$. Then we set $cdiv(X_{88})$ to 8. Next, let 7 be $cdiv$ for X_{58}, X_{48}, and X_{78} since $\pi^{-1}[5] \geq \pi^{-1}[7]$, $\pi^{-1}[4] \geq \pi^{-1}[7]$, and $\pi^{-1}[7] \geq \pi^{-1}[7]$. Next, we consider 6 in $TLCL_8$ and traverse $BRCL_8$ starting at 1 from right to left and let 6 be $cdiv$ for X_{18}, X_{38}, and X_{68} for the same reason. This procedure takes $|TLCL_j| + |BRCL_j|$ steps for each j. Therefore, the time complexity for computing all $cdiv(X_{ij})$'s is $O(m+n)$. □

LEMMA 4.4. *All* $iback(X_{ij})$*'s and* $jback(X_{ij})$*'s can be computed in* $O(m+n)$ *time.*

Proof. We first show how to compute all $iback(X_{ij})$. Let $TRCL_i = \{i = j_0, \ldots, j_r\}$ with $j = j_t$ for some $t \in \{0, \ldots, r\}$. Note that $iback(X_{ij_0})$ $(= iback(X_{ii}))$ and $iback(X_{ij_1})$ are not defined.

Note that $iback(X_{ij_2}) = X_{ij_1}$ because X_{ij_1} is the only candidate. For $k = 3, \ldots, r$, $iback(X_{ij_k})$ is either $X_{ij_{k-1}}$ or $iback(X_{ij_{k-1}})$, whichever has a smaller mw value. The above operation is basically the prefix function on mw values of $X_{ij_1}, X_{ij_2}, \ldots$, and X_{ij_r}. Note that, in Algorithm 3.1, the $mw(X_{ij})$'s are computed in the increasing order of j. Since the total number of $iback(X_{ij})$'s is $\leq \sum_{i=1}^{n+1} |TRCL_i| \leq m+n$, the result follows.

Next, to compute all $jback(X_{ij})$, we perform a similar prefix computation using $TLCL_j$ instead of $TRCL_i$. □

5. Computing $mc2(X_{ij})$. According to its definition, $mc2(X_{ij})$ is to be computed only if $|CLIQ(X_{ij})| \leq 2$. If $|CLIQ(X_{ij})| = 1$, i.e., $i = j$, then $mc2(X_{ij}) = X_{jj}$ because $mw(X_{jj}) \leq mw(X_{i'j})$ for any cross pair $X_{i'j}$. In the following, therefore, we

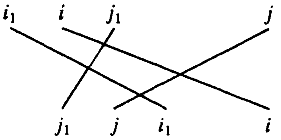

FIG. 4. *Illustration of* $base(X_{ij})$.

consider only the cross pairs X_{ij} such that $|CLIQ(X_{ij})| = 2$. We first introduce some notation that helps characterize all candidates for $mc2(X_{ij})$. To compute $mc2(X_{ij})$ when $|CLIQ(X_{ij})| = 2$, we need to consider all the ordered cross pairs $X_{i'j'}$ such that $i \leq j' \leq j$, $\pi^{-1}[j'] \leq \pi^{-1}[i]$, and $S_{i'j'}$ covers S_{ij} and then choose a pair for which the mw value is a minimum. Obviously, X_{ii} and X_{jj} are candidates for $mc2(X_{ij})$. Below we identify all candidates for $mc2(X_{ij})$ other than X_{ii} and X_{jj}.

5.1. Identifying candidates for $mc2(X_{ij})$. Let l be any line in V_{n+1}^{+} such that $|TRCL_l| \geq 2$. Define $j\_base[l]$ to be the second member of $TRCL_l$. Similarly, $i\_base[l]$ is the second member of $BRCL_l$, provided $|BRCL_l| \geq 2$. Now let X_{ij} be a cross pair such that $|CLIQ(X_{ij})| = 2$. Then $|TRCL_i| \geq 2$ and $|BRCL_j| \geq 2$. Let $i_1 = i\_base[j]$ and $j_1 = j\_base[i]$. Then it is easily observable that $i_1 \neq j_1$ and they cross each other as shown in Fig. 4. This ordered cross pair $X_{i_1 j_1}$ is called the *base pair* of X_{ij}, denoted by $base(X_{ij})$. It is obvious that such a base pair always exists for any given X_{ij} such that $|CLIQ(X_{ij})| = 2$ since X_{ij} itself may be its base pair.

Let $X_{i_1 j_1}$ be $base(X_{ij})$. Then let $TRCL_{i_1}[j_1, j] = (j_1, j_2, \dots, j_r = j)$ be the sublist of $TRCL_{i_1}$ consisting of all elements of $TRCL_{i_1}$ from j_1 up to j, preserving the order in $TRCL_{i_1}$. Further, for each such j_k, $1 \leq k \leq r$, in $TRCL_{i_1}[j_1, j]$, let $BRCL_{j_k}[i_1] = (i_{f_k(1)} = i_1, i_{f_k(2)}, \dots, i_{f_k(s_k)})$, be the sublist of $BRCL_{j_k}$ consisting of all elements from i_1 to the last member of $BRCL_{j_k}$, keeping the order intact. Define

$$\begin{aligned} C(X_{ij}) &= \{X_{i'j'} | X_{i_1 j_1} = base(X_{ij}) \text{ and } j' \in TRCL_{i_1}[j_1, j], i' \in BRCL_{j'}[i_1]\} \\ &= \{X_{i_{f_1(1)} j_1}, X_{i_{f_1(2)} j_1}, \dots, X_{i_{f_1(s_1)} j_1}, X_{i_{f_2(2)} j_2}, \dots, \\ &\qquad X_{i_{f_2(s_2)} j_2}, \dots, X_{i_{f_r(1)} j_r}, X_{i_{f_r(2)} j_r}, \dots, X_{i_{f_r(s_r)} j_r}\}. \end{aligned}$$

Then $C(X_{ij})$ consists of all candidates for $mc2(X_{ij})$ (other than X_{ii} and X_{jj}).

To choose $mc2(X_{ij})$ from $C(X_{ij})$ efficiently, we introduce an additional definition. Let $X_{i_1 j_1}$ be $base(X_{ij})$, and let $TRCL_{i_1}[j_1, j] = (j_1, j_2, \dots, j_r = j)$ and $BRCL_{j_k}[i_1] = (i_{f_k(1)} = i_1, i_{f_k(2)}, \dots, i_{f_k(s_k)})$ be the sublists defined above. For each k, $1 \leq k \leq r$, define $minv(X_{i_1 j_k})$ to be the minimum of $mw(X_{i_1 j_k})$, $mw(X_{i_{f_k(2)} j_k})$, $\dots$, and $mw(X_{i_{f_k(s_k)} j_k})$. Then to find $mc2(X_{ij})$ in $C(X_{ij})$, compare each of $minv(X_{i_1 j_1})$, $minv(X_{i_1 j_2}), \dots$, and $minv(X_{i_1 j_r})$, and pick a cross pair with the smallest $minv$ value. That is, for computing $mw(mc2(X_{ij}))$, we just make use of $minv(X_{i_1 j_k})$ values for all $j_k \in TRCL_{i_1}[j_1, j]$. It is not difficult to maintain these $minv$'s so that they may be available when we search for $mc2(X_{ij})$. After computing $mw(X_{ij})$'s, for all $i \in TLCL_j$ in Algorithm 3.1, apply, for example, the prefix computation on the mw values. To be specific, let $BRCL_j = (i_0 = j, i_1, \dots, i_r)$. Then $minv(X_{i_r j}) = mw(X_{i_r j})$, and for $s = r-1, r-2, \dots, 1$, $minv(X_{i_s j}) = \min\{mw(X_{i_s j}), minv(X_{i_{s+1} j})\}$. Obviously, for each j, it requires $|BRCL_j|$ time to compute all $minv(X_{ij})$'s, and thus the overall time to compute all $minv$'s is $\sum_{j=1}^{n} |BRCL_j| = O(m + n)$.

The use of $minv$ values considerably reduces the total number of comparisons needed in computing $mc2(X_{ij})$ for each X_{ij}. However, this reduction is not sufficient

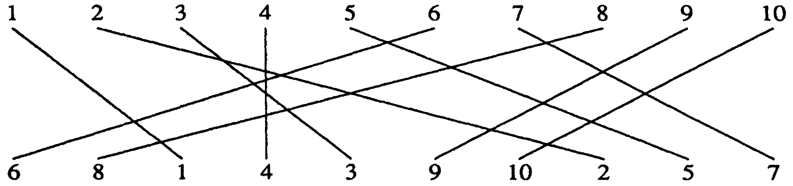

FIG. 5. *A sample graph for computing* $mc2(X_{ij})$.

to meet our goal since there are still potentially n values to be compared in computing each $mc2(X_{ij})$. Fortunately, $C(X_{ij})$ is well behaved, and it is possible to organize the computation of all $mc2(X_{ij})$'s in an orderly fashion to take advantage of the comparisons already made. To keep the total number of comparisons within desirable limits, we access each $minv(X_{ij})$ at most once during the entire run of our algorithm. The following observations are not hard to prove.

(1) $C(X_{ij'}) \subseteq C(X_{ij})$ if (i) $j' \leq j$ and (ii) $i\_base[j'] = i\_base[j]$.

(2) $C(X_{i'j}) \subseteq C(X_{ij})$ for $i \leq i'$.

The above properties suggest computing each $mw(mc2(X_{ij}))$ in increasing order of j and then in decreasing order of i for each $i \in TLCL_j$. Therefore, as we go from j' to j, $j' < j$, $mc2(X_{ij'})$'s are available for all $i \in TLCL_{j'}$ such that $|CLIQ(X_{ij'})| \leq 2$. Also, while at j, if $i' > i$, then $mc2(X_{i'j})$ is determined ahead of $mc2(X_{ij})$.

5.2. The algorithm for computing $mc2(X_{ij})$. Now we develop a formal procedure for all $mc2(X_{ij})$'s. At the jth stage, $0 \leq j \leq n+1$, visit each $i \in TLCL_j$ in reversed order starting at j. Note that we consider only i such that $|CLIQ(X_{ij})| = 2$. Let RS_TLCL_j denote the reversed sublist of $TLCL_j$ consisting of all such i's. Note that no two lines in RS_TLCL_j cross each other and i_base$[j]$ is also in RS_TLCL_j as the last member. Since $|CLIQ(X_{ij})| = 2$ only if $cdiv(X_{ij}) = i \neq j$, and since all $cdiv(X_{ij})$'s are known in advance, it is easy to determine whether $|CLIQ(X_{ij})| = 2$ in constant time. Hence, it takes $|TLCL_j|$ steps to compute RS_TLCL_j from $TLCL_j$. For example, in Fig. 5, $RS\_TLCL_8 = (7,5,4,1)$ and $RS\_TLCL_4 = (3)$. For each line j, let j_p be the largest line less than j such that $i\_base[j_p] = i\_base[j]$, if any exists. Note that j_p is the largest line for which $mc2(X_{ij_p})$ is available as a result of the j_pth stage. We can use $mc2(X_{ij_p})$ to compute $mc2(X_{ij})$ without revisiting the lines less than j_p. To compute all j_p's, scan $i\_base[j]$ for j from 1 to n, and append j to $list[i]$, which is empty initially, if $i\_base[j] = i$. For each i, let $list[i] = \{t_1, \ldots, t_k\}$. Then $j_p = t_{i-1}$ if $j = t_i$, $1 < i \leq k$, and let $j_p = -1$ if $j = t_1$. This procedure takes $O(n)$ time. Note that $|CLIQ(X_{ij_p})| = 2$, because, otherwise, we would have either $i\_base[j_p] \neq i\_base[j]$ or $|CLIQ(X_{ij})| \neq 2$. For each X_{ij}, where $i \in RS\_TLCL_j$, consider the following two cases for computing $mw(mc2(X_{ij}))$, hence $mc2(X_{ij})$.

Case 1. i is the first member of RS_TLCL_j. As usual, let $X_{i_1 j_1}$ be the base of X_{ij}. Then simply visit each member of $TRCL_{i_1}$ backward starting at j until we meet j_1 or j_p. Let $(j_t = j, j_{t-1}, \ldots, j_r)$ be the list of lines visited in this order. Further consider the following subcases.

Case 1.1. $j_r = j_1$. Then clearly, as shown in Fig. 6,

$$mw(mc2(X_{ij})) = \min\{minv(X_{i_1 j_t}, minv(X_{i_1 j_{t-1}}), \ldots, minv(X_{i_1 j1})\}.$$

For example, in Fig. 5, $mw(mc2(X_{79})) = \min\{minv(X_{29}), minv(X_{28})\}$ and $mw(mc2(X_{23})) = minv(X_{23})$.

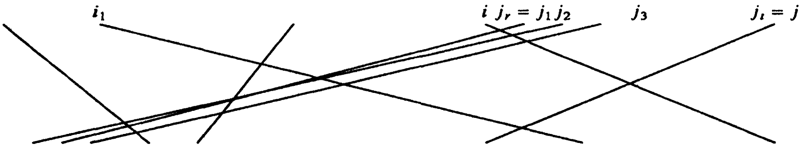

FIG. 6. *The illustration for subcase* 1.1.

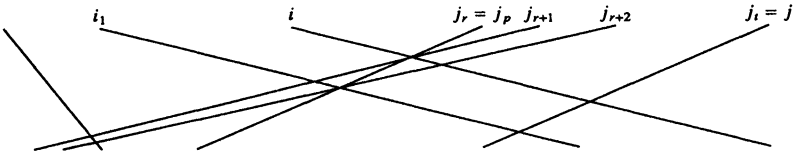

FIG. 7. *The illustration for subcase* 1.2.

Case 1.2. $j_r = j_p$. This implies that $mw(mc2(X_{ij_r}))$ is known as a result of the computation at the j_rth stage as illustrated in Fig. 7. Further, $C(X_{ij_r}) \subseteq C(X_{ij})$. Hence,

$$mw(mc2(X_{ij})) = \min\{minv(X_{i_1j_t}), minv(X_{i_1j_{t-1}}), \ldots, minv(X_{i_1j_{r+1}}), mw(mc2(X_{ij_r}))\}.$$

In Fig. 5, $mw(mc2(X_{7(10)})) = \min\{minv(X_{2(10)}), mw(mc2(X_{79}))\}$.

Case 2. i is not the first member in RS_TLCL_j. Let i' be the line that immediately precedes i in RS_TLCL_j. Then it is obvious that $C(X_{i'j}) \subseteq C(X_{ij})$ as mentioned earlier. As in Case 1, consider each member of $TRCL_{i_1}$ backward starting at j until we meet either j_1 or j_p. Again let $(j_t = j, j_{t-1}, \ldots, j_r)$ be the lines to be visited in this order. Again consider the following subcases.

Case 2.1. $j_r = j_1$. In this case, we do not actually examine all of the lines in $(j_t = j, j_{t-1}, \ldots, j_r)$ since some lines, say $(j_t = j, j_{t-1}, \ldots, j_s)$, $t \geq s \geq r$, were checked already when $mc2(X_{i'j})$ was computed at the i'th step of the jth stage. (Note that there exists at least one such line since j is one of the lines that was already computed.) In Fig. 8, only j_2 and j_1 will be examined because $j_t, j_{t-1}, \ldots, j_3$ were visited to obtain $mc2(X_{i'j})$. Hence, we compare $mw(mc2(X_{i'j}))$, $minv(X_{i_1j_{s-1}})$, $minv(X_{i_1j_{s-2}}), \ldots,$ and $minv(X_{i_1j_1})$ to pick a pair with the smallest value. In Fig. 5, $mw(mc2(X_{59})) = \min\{mw(mc2(X_{79})), minv(X_{26})\}$.

Case 2.2. $j_r = j_p$ and $i' > j_p$. Similar to subcase 2.1, let $(j_t = j, j_{t-1}, \ldots, j_s)$, $t \geq s \geq r$, be the lines already considered when $mc2(X_{i'j})$ was computed. Moreover, the lines $(j_p = j_r, j_{r-1}, \ldots, j_1)$ were already checked when $mc2(X_{ij_p})$ was computed at the ith step of the j_pth stage as shown in Fig. 9. So, simply compare $mw(mc2(X_{i'j}))$, $minv(X_{i_1j_{s-1}})$, $minv(X_{i_1j_{s-2}}), \ldots, minv(X_{i_1j_{r+1}})$, and $mw(mc2(X_{ij_r}))$ to pick a pair with the smallest value. Consider X_{58} in Fig. 5 as an example and verify that $mw(mc2(X_{58})) = \min\{mw(mc2(X_{56})), mw(mc2(X_{78}))\}$.

Case 2.3. $j_r = j_p$ and $i' < j_p$. It is not difficult to show that $mc2(X_{ij})$ is either $mc2(X_{i'j})$ or $mc2(X_{ij_r})$, whichever has a smaller mw value, since $C(X_{ij}) = C(X_{i'j}) + C(X_{ij_r})$. X_{48} in Fig. 5 is such an example. Recall that i_1 is the i-base line for both j and j_p. (See Fig. 10.)

This procedure is formalized in Algorithm 5.1.

Table 1 shows the computational relationship among all $mw(C(X_{ij}))$'s of our sample graph in Fig. 5 for $|CLIQ(X_{ij})| = 2$.

THEOREM 5.1. *All $mc2(X_{ij})$'s can be computed in $O(m + n)$ time.*

Proof. Since the correctness of our algorithm follows from the preceding discussion, we show its time complexity. As shown previously, all RS_TLCL_j's and j_p's can be obtained in $O(m + n)$ time and $O(n)$ time, respectively. All $minv(X_{ij})$'s can be obtained in $O(n+m)$ time using the prefix computation. It then suffices to show that each $minv(X_{ij})$ value is accessed at most once in calculating all $mc2(X_{ij})$'s in our algorithm that computes all $back(X_{ij})$'s. Let $minv(X_{i_1j'})$ be an arbitrary $minv$ value accessed in computing for some X_{ij} if any exists. Then $i\_base[j] = i_1$. We show that such X_{ij} is unique.

Let $K = (k_1, \ldots, k_s)$ be the sublist of $TRCL_{i_1}$ such that $i_1 < k_1 < \cdots < k_s$ and $|CLIQ(X_{i_1k_r})| = 2$ for $1 \leq r \leq s$. Let $H = (h_1, \ldots, h_t)$ be the sublist of $TLCL_{k_s}$ such that $i_1 = h_1 < \cdots < h_t < k_s$ and $|CLIQ(X_{h_rk_s})| = 2$ for each $r = 2, 3, \ldots, t$. Then it is readily seen that K and H are disjoint and no two lines in K (and H) intersect each other, as shown in Fig. 11. Let $L = (l_1, \ldots, l_{s+t})$ be the list obtained by merging

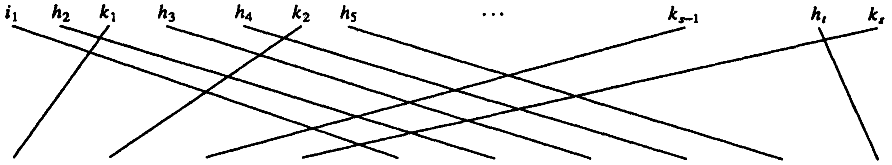

FIG. 11. *An illustration for K and H.*

K and H in increasing order. Now, try to position j' in L. If $j' = l_1 (= i_1)$, then $X_{i_1 j'}$ is used only in computing $mc2(X_{i_1 i_1})$. So, we assume that $j' > l_1$. Let l_r be the largest line smaller than j' in L. Then, we consider the following cases.

(1) $l_r = h_u$ and $l_{r+1} = k_v$ for some $1 \le u \le t$ and $1 \le v \le s$. Then $minv(X_{i_1 j'})$ is accessed only in computing $mc2(X_{h_u k_v})$. Hence X_{ij} is $X_{h_u k_v}$.

(2) $l_r = h_u$ and $l_{r+1} = h_{u+1}$ for some $1 \le u < t$. In this case, let k' be the smallest line in K such that $k' > h_{u+1}$. Then $minv(X_{i_1 j'})$ is accessed only in computing $mc2(X_{h_u k'})$. Hence X_{ij} is $X_{h_u k'}$.

(3) $l_r = k_v$ and $l_{r+1} = h_u$ for some $1 \le v \le s$ and $1 \le u \le t$. In this case, let k' be the smallest line in K such that $k' > h_u$, and let h' be the largest line in H such that $h' < k_v$. Then X_{ij} is $X_{h'k'}$.

(4) $l_r = k_v$ and $l_{r+1} = k_{v+1}$ for some $1 \le v < s$. Let h' be the largest line in H such that $h' < k_v$. Then X_{ij} is $X_{h' k_{v+1}}$.

(5) $l_r = l_{s+t}$. Then X_{ij} is $X_{l_{s+t} j'}$.

Clearly such X_{ij} is unique. Thus the number of $minv(X_{ij})$'s used in computing for all $mc2(X_{ij})$'s is $O(m+n)$. Since at most two previous computed $mc2(X_{ij})$ values are involved in computing a current $mc2(X_{ij})$ value, the total number of $mc2(X_{ij})$'s used in computing for all $mc2(X_{ij})$'s is limited to $O(m+n)$. Therefore, it takes $O(m+n)$ time to compute all $mc2(X_{ij})$'s. □

6. Summary.

We first review the dynamic strategy for computing $back(X_{ij})$ in Algorithm 3.1. The ordered lists ($TLCL_j$, $TRCL_j$, $BLCL_j$, and $BRCL_j$), $limit(X_{ij})$, and $cdiv(X_{ij})$ are computed during the initialization process. Their computational procedures are described in Lemmas 4.1, 4.2, and 4.3, respectively. At the jth stage, $j = 1, 2, \ldots, n+1$, our algorithm computes $mw(X_{ij})$ and $back(X_{ij})$ for each $i \in TLCL_j$ in increasing order. Each $mc(limit(X_{ij}))$ is available, and both $iback(X_{ij})$ and $jback(X_{ij})$ can be computed as described in Lemma 4.4. These functions are used to compute $back(X_{ij})$. Next in the same stage j, we compute $minv(X_{ij})$'s, $mc2(X_{ij})$'s, and $mc(X_{ij})$'s. All $minv(X_{ij})$'s are computed in reverse order of the list $BRCL_j$, and $mc2(X_{ij})$'s are computed for all i in reverse order of the list $TLCL_j$. The algorithm for computing $mc2(X_{ij})$ is described in Algorithm 5.1. Finally, $mc(X_{ij})$ are computed for all i in reverse order of the list $TLCL_j$. If $|CLIQ(X_{ij})| \le 2$, then $mc(X_{ij})$ is equivalent to one of $mc2(X_{ij})$, X_{ii} and X_{jj}, for which the mw value is a minimum. On the other hand, if $|CLIQ(X_{ij})| > 2$, then $mc(X_{ij})$ is either $mc(X_{ik})$ or $mc(X_{kj})$, whichever has a smaller mw value, where $k = cdiv(X_{ij})$. Now we are ready to state the following lemmas.

LEMMA 6.1. *All $mc(X_{ij})$'s can be found in $O(m+n)$ time.*

Proof. According to Theorem 3.1, if $cdiv(X_{ij}) = k (\ne i)$, then $mc(X_{ij}) = X_{i'j'} \in \{mc(X_{ik}), mc(X_{kj})\}$ such that $mw(X_{i'j'})$ is the smaller of $mw(mc(X_{ik}))$ and $mw(mc(X_{kj}))$. Otherwise, i.e., $cdiv(X_{ij}) = i$, $mc(X_{ij}) = mc2(X_{ij})$. Since all $cdiv(X_{ij})$'s can be found in $O(m+n)$ time (Lemma 4.3) and all $mc2(X_{ij})$'s can also be computed in $O(m+n)$ time (Theorem 5.1), it follows that all $mc(X_{ij})$'s can be found in $O(m+n)$ time. □

LEMMA 6.2. *All $back(X_{ij})$'s can be obtained in $O(m+n)$ time.*

Proof. For each X_{ij} we first identify $mc(limit(X_{ij}))$, which was computed at a previous stage. Then $back(X_{ij})$ is $iback(X_{ij})$, $jback(X_{ij})$, or $mc(limit(X_{ij}))$, whichever has the smallest value in $W(MWDS(iback(X_{ij}))+S_{ij})$, $W(MWDS(jback(X_{ij}))+S_{ij})$, or $W(MWDS(mc(limit(X_{ij}))) + S_{ij})$. The validity of this procedure is supported by Theorems 2.2 and 3.1. □

Note that once all $back(X_{ij})$'s are computed, a minimum-weight dominating set can be obtained by tracing back through the function *back*, which takes no more than $O(n)$ time. Thus we have the following main theorem.

THEOREM 6.3. *The minimum-weight dominating set problem for permutation graphs can be solved in $O(m+n)$ time.*

7. Conclusion. In this paper, we presented an algorithm for finding a minimum-weight dominating set in a permutation graph. The algorithm takes only $O(n+m)$ time, where n is the number of nodes and m is the number of edges in the graph. The algorithm basically uses the same approach as introduced in [6]. The improvement in time complexity is achieved as a result of identifying and removing some of the redundant computations. This is the best available algorithm to date for this problem.

Acknowledgments. The authors thank the anonymous referees for their comments that greatly helped improve the presentation of this paper. We also thank Glenn Manacher for bringing [7] to our attention.

GENERALIZED KRAFT'S INEQUALITY AND DISCRETE k-MODAL SEARCH*

ANMOL MATHUR† AND EDWARD M. REINGOLD‡

Abstract. A function $f : \Re \to \Re$ is *k-modal* if its kth derivative has a unique zero. We study the problem of finding the smallest possible interval containing the unique zero of the kth derivative of such a function, assuming that the function is evaluated only at integer points. We present optimal algorithms for the case when k is even and for $k = 3$ and near-optimal algorithms when $k \geq 5$ and odd. A novel generalization of Kraft's inequality is used to prove lower bounds on the number of function evaluations required. We show how our algorithms lead to an efficient divide-and-conquer algorithm to determine all turning points or zeros of a k-modal function. Unbounded k-modal search is introduced and some problems in extending previous approaches for unbounded searching to the k-modal case are discussed.

Key words. k-modal search, Kraft's inequality, k-modal functions, optimal algorithms, binary search, unimodal search, bimodal search, unbounded search, Fibonacci numbers

1. Introduction.

The problem of determining properties of an unknown function by evaluating it at scattered points arises in many different contexts. If the function is arbitrary, then this might require the evaluation of the function at all points in its domain. However, if the function is well behaved, it is possible to determine some parameters of the function from only a few evaluations. Shannon's sampling theorem in communication theory is a classic example of this problem. More recently, geometric probing has become an active area of research in computational geometry [20]; such probing aims to find some shape parameters of an object by probing it at the fewest possible points. In this paper we present a natural measure of the complexity of a function called the *modality* and demonstrate its utility in the design of efficient algorithms for finding certain parameters of the function.

A function $f : \Re \to \Re$ is *k-modal* if its kth derivative has a unique zero; such a function can have at most k local extrema. Although the use of local extrema in this definition suggests an implicit assumption about the continuity of f, the definition is easily extended to discrete functions $f : \{0, 1, \ldots, N\} \to \Re$. The analog of the kth derivative in the discrete case is $\Delta^k f$, defined recursively by

$$\Delta^k f = \Delta(\Delta^{k-1} f),$$
$$\Delta f(i) = f(i+1) - f(i).$$

With this in mind, we will use the term "kth derivative of f" to refer to the true kth derivative of f if f is sufficiently differentiable and to $\Delta^k f$ if f is discrete. A "zero" of a discrete function is an integer $i, 0 \leq i < N$ such that either

$$f(i) = 0$$

or

$$f(i) \cdot f(i+1) < 0.$$

We define a *turning point* of the discrete function f as an integer $i, 0 \leq i < N$, such that

$$\Delta f(i-1) \cdot \Delta f(i) < 0.$$

A discrete k-modal function can have at most k turning points (this follows from Lemma 2.2 below). It is important to note that a k-modal function can have fewer than k turning points (see Fig. 1). One major class of continuous k-modal functions is the set of polynomials of degree $k+1$. A discrete function that is obtained by restricting a continuous k-modal function to a set of points so that at least one point lies between any two adjacent roots of the continuous function is k-modal.

Throughout this paper, we assume that for a k-modal function f over the interval $[0, N)$, $\Delta^k f$ is increasing[1] and $f(0) = (-1)^{k+1}\infty$, $f(N) = (-1)^k\infty$. We define the *discrete k-modal search problem* as the determination of an interval $[i, i+k+1)$ containing the unique zero of the kth derivative of f by evaluating (probing) the function only at integer points in the range $[0, N)$. The smallest range to which the unique zero of the kth derivative of f can be localized is of size $k+1$ because at least $k+1$ values of f are required to compute a single value of $\Delta^k f$.

The problem of finding the zeros of continuous functions in one variable is closely related to its discrete counterpart in the case when only function evaluations are allowed [14], [19]. In order to approximate a zero of a continuous function $f : [0,1] \rightarrow \Re$ to an accuracy $\epsilon > 0$, we can locate the zero of the discrete function obtained by sampling the continuous function at $i\epsilon, 0 \leq i \leq 1/\epsilon$. Thus, the lower bounds and algorithms presented in this paper apply to continuous functions if the discretized function is k-modal.

The case $k = 0$ is the problem of finding the zero of a monotonic function, for which binary search is the optimal strategy. The case $k = 1$ corresponds to searching for the unique local maximum/minimum of a unimodal function. This problem was first studied by Kiefer [10], who gave an optimal algorithm for narrowing, in n probes, a unit interval containing the local extremum to an interval of length at most $1/F_{n+1} + \epsilon$, for any fixed $\epsilon > 0$, where F_i is the ith Fibonacci number defined by $F_0 = 0, F_1 = 1$, and $F_i = F_{i-1} + F_{i-2}$. Kiefer proved that this *Fibonacci search* is optimal in the sense that any algorithm using n probes that narrows the interval containing the local extremum to at most $1/F_{n+1}$ for some functions must fail to narrow the length of the interval to at most $1/F_{n+1} + \epsilon$ for other functions. Further work on variants of the unimodal search problem was done by Avriel and Wilde [2], Oliver and Wilde [15], and Witzgall [23]. Karp and Miranker [9] considered the unimodal searching problem under the assumption that several probes can be done in parallel. More recently, Goldstein and Reingold [6] studied the discrete unimodal search problem in which the probes are restricted to integer points. They use a variant of Kraft's inequality to prove a lower bound on the number of function evaluations required for the discrete unimodal search problem. We generalize their results.

Interest in discrete k-modal searching arises because of its applications in computational geometry, especially in algorithms for intersection of convex objects in two

[1] This does not entail any loss of generality because if $\Delta^k f$ is decreasing, then $\Delta^k(-f)$ is increasing. So, we can determine whether $\Delta^k f$ is increasing or decreasing by looking at the sign of $f(0)$ and, if it is decreasing, substitute $-f$ for f.

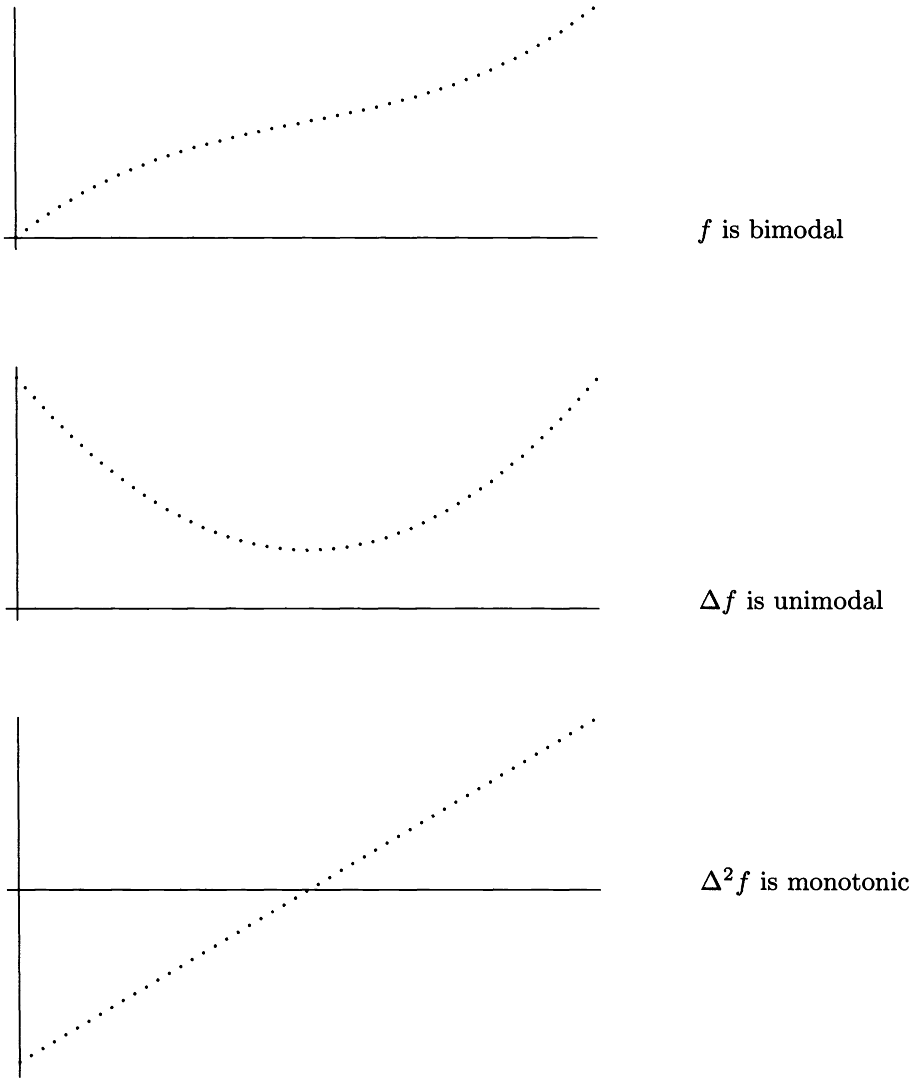

FIG. 1. *Example of a bimodal function. Notice that because $\Delta f > 0$, f has no turning points.*

and three dimensions [1], [4]. However, the case of k-modal searching for $k \geq 2$ has received little attention. Veroy [22] studied the problem of finding the extrema of a continuous, periodic bimodal function. Hyafil [7] studied the continuous k-modal search problem and proposed optimal algorithms for even k. He used the relationship between the complexity of finding the unique zero of a monotonic function with k asynchronous processors and that of $(k-1)$-modal searching with a single processor to prove lower bounds on the number of function evaluations required for k-modal search. This technique for proving lower bounds was first used by Kung [12]. In [13], Kung makes use of adversary arguments to prove lower bounds on the complexity of finding a zero of a continuous function. In contrast, we use characteristics of k-modal search trees to prove a generalization of the Kraft's inequality. The k-modal search algorithms and the algorithm for finding all the turning points of a discrete k-modal function have applications in one-dimensional optimization problems for which the objective function is not available in closed form and/or is time consuming to evaluate.

In this paper we extend the algorithms of [7] to discrete k-modal search and use a novel generalization of Kraft's inequality to give lower bounds on the number of function evaluations required for discrete k-modal search; a related, continuous generalization of Kraft's inequality was used by Karp [8] to derive lower bounds on the cost of some lopsided prefix-free codes. In the process of our work, some identities are proved for a natural generalization of the Fibonacci numbers. One consequence of our work is an improvement to an algorithm in [4] which uses bimodal searching ($k = 2$). We also present an algorithm to find all the local extrema of a k-modal function.

The organization of the rest of the paper is as follows: §2 discusses the representation of k-modal search algorithms as k-modal search trees and formulates a theorem that is used to prove lower bounds on the number of probes required for k-modal search. In §3 we prove the theorem establishing the lower bounds. Section 4 discusses algorithms for k-modal search and §5 describes how to use those algorithms to design an efficient algorithm for finding all the extrema of a k-modal function. Section 6 discusses unbounded k-modal search. Finally, in §7, we conclude with some open problems.

2. k-modal search trees and lower bounds.

All algorithms that use only function evaluations for k-modal searching maintain an *interval of uncertainty*, $I \subseteq [0, N)$, that is guaranteed to contain the unique zero of the kth derivative of the function. The algorithms begin with $I = [0, N)$ and use function evaluations to prune I until it becomes sufficiently small. These algorithms rely on the following lemmas.

LEMMA 2.1. *Given a k-modal function f, the knowledge of the function at fewer than $k + 1$ points* inside *the interval of uncertainty cannot reduce the length of the interval of uncertainty.*

Proof. It is easy to see that for a monotonic function, the interval of uncertainty cannot be shortened without making at least one probe. Since the kth derivative of a k-modal function f is monotonic and at least $k+1$ values of f are required to compute one value of the kth derivative of f, it follows that at least $k + 1$ values of f inside the interval of uncertainty are required to shorten it. □

LEMMA 2.2 (discrete Rolle's theorem). *Given a discrete function*

$$f : \{0, 1, \ldots, N\} \rightarrow \Re$$

having zeros at i and j, $i < j$, there is a k, $i \leq k \leq j$, such that Δf has a zero at k.

Proof. Assume without loss of generality that j is the first zero of f greater than i (otherwise one can replace j with the first zero greater than i in the subsequent argument). Since i is a zero of f, either $f(i) = 0$ or $f(i) \cdot f(i + 1) < 0$. Without loss of generality, assume that $f(i + 1) \geq 0$. If $f(i) = f(i + 1) = 0$, then $\Delta f(i) = 0$ and we are done. Otherwise, $f(i) < 0$ and $f(i + 1) > 0$, and then $\Delta f(i) > 0$. Since there is no other zero of f between i and j, $f(j) \geq 0$ and $f(j + 1) \leq 0$. Again, if $f(j) = f(j + 1) = 0$, then j is a zero of Δf and we are done; otherwise $\Delta f(j) < 0$. Hence, there must be some k, $i \leq k < j$ such that either $\Delta f(k) = 0$ or $\Delta f(k) > 0$ and $\Delta f(k + 1) < 0$. But such a k is a zero of Δf, thus proving the theorem. □

LEMMA 2.3. *Let $f : \{0, 1, \ldots, N\} \rightarrow \Re$ be a discrete function such that $\Delta^k f$ is increasing and $\Delta^k f(i) > 0$, for all $i \in \{0, 1, \ldots, N - k\}$. Then for every set $\{x_0, x_1, \ldots, x_k\}$ of $k + 1$ distinct values in $\{0, \ldots, N\}$,*

$$P(x_0, x_1, \ldots, x_k, f) > 0,$$

where

$$P(x_0, x_1, \ldots, x_k, f) = \sum_{i=0}^{k} \frac{f(x_i)}{\prod_{j \neq i}(x_j - x_i)}.$$

Proof. Consider the Lagrange interpolation formula [5] for the set of points $(x_i, f(x_i)), 0 \leq i \leq k$, given by $\sum_{i=0}^{k} f(x_i) \prod_{j \neq i} \frac{x - x_j}{x_i - x_j}$ and its error

$$E(x) = f(x) - \sum_{i=0}^{k} f(x_i) \prod_{j \neq i} \frac{x - x_j}{x_i - x_j}.$$

Since $E(x_i) = 0$, $0 \leq i \leq k$, by repeated application of Lemma 2.2, we can conclude that $\Delta^k E$ has a zero at some $m \in \{0, \ldots, N-k\}$. Furthermore, since Δ distributes over summation and $\Delta^k x^l = 0$, if $l < k$, we have

$$(1) \qquad \Delta^k f(x) = \Delta^k E(x) + k! P(x_0, x_1, \ldots, x_k, f).$$

By assumption, $\Delta^k f$ is positive at all points in $\{0, \ldots, N-k\}$. Also, since m is a zero of $\Delta^k E$, either $\Delta^k E(m) = 0$ or one of $\Delta^k E(m)$ or $\Delta^k E(m+1)$ is negative. Hence, from equation (1) we get that $P(x_0, x_1, \ldots, x_k, f) > 0$. □

LEMMA 2.4. *Given a k-modal function f and $k+3$ of its values*

$$f(x_0), f(x_1), \ldots, f(x_{k+2}),$$

with

$$x_0 < x_1 < \cdots < x_{k+1} < x_{k+2},$$

the interval of uncertainty can always be reduced to $[x_0, x_{k+1})$ or $[x_1, x_{k+2})$ irrespective of the choice of $x_1, \ldots, x_{k+2}$. Furthermore, in the worst case, the interval of uncertainty cannot be shortened by more than this amount.

Proof. Suppose the unique zero of $\Delta^k f$ lies in $[x_0, x_1)$. Then, $\Delta^k f$ is positive in $[x_1, N)$. So, using Lemma 2.3,

$$P(x_1, x_2, \ldots, x_{k+1}, f) > 0.$$

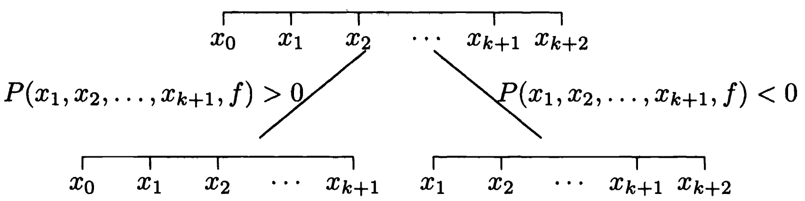
Thus, if

$$P(x_1, x_2, \ldots, x_{k+1}, f) \leq 0,$$

we can conclude that the unique zero of $\Delta^k f$ does not lie in $[x_0, x_1)$. By a symmetric argument, if $P(x_1, x_2, \ldots, x_{k+1}, f) \geq 0$, then the unique zero of $\Delta^k f$ does not lie in $[x_{k+1}, x_{k+2})$; see Fig. 2. If $P(x_1, x_2, \ldots, x_{k+1}, f) = 0$, then both $[x_0, x_1)$ and $[x_{k+1}, x_{k+2})$ can be pruned.

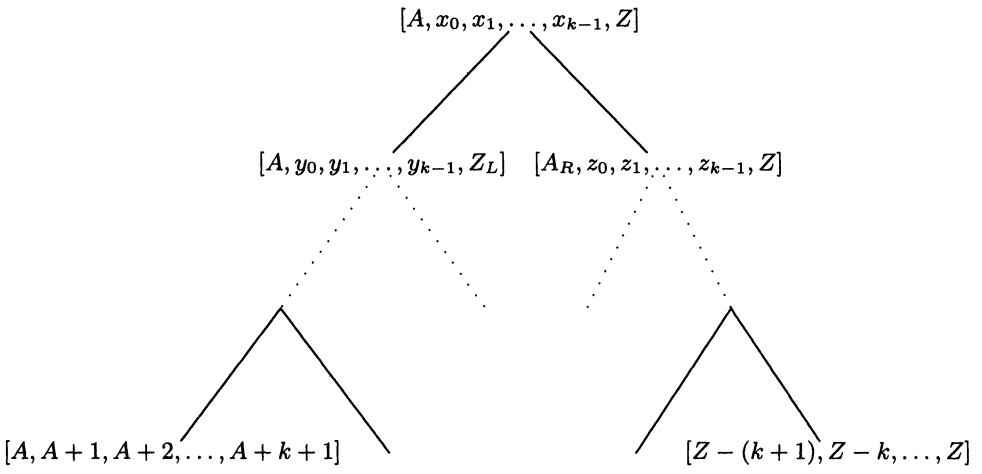
Given $k+3$ values of f such that $P(x_1, x_2, \ldots, x_{k+1}, f) \leq 0$, one can construct a function g which has the same values as f at the $k+3$ specified points but has the unique zero of its kth derivative anywhere in $[x_1, x_{k+2})$. Thus, no algorithm for discrete k-modal search can shorten the interval of uncertainty to be smaller than $[x_1, x_{k+1})$, given only the values of the function at $x_i, 0 \leq i \leq k+2$. A symmetric argument works for the case when the P function is nonnegative. □

Thus, the algorithms for k-modal search maintain an interval of uncertainty $I = [x_0, x_{k+1})$ in the form of an array of positions $[x_0, x_1, \ldots, x_k, x_{k+1}]$ at which



x_0 x_1 x_2 $\cdots$ x_{k+1} x_{k+2}
$P(x_1, x_2, \ldots, x_{k+1}, f) > 0$
$P(x_1, x_2, \ldots, x_{k+1}, f) < 0$
x_0 x_1 x_2 $\cdots$ x_{k+1}
x_1 x_2 $\cdots$ x_{k+1} x_{k+2}

FIG. 2. *Illustration of Lemma 4; if $P(x_1, x_2, \ldots, x_{k+1}, f) = 0$, then both the leftmost and rightmost segments can be discarded.*



$[A, x_0, x_1, \ldots, x_{k-1}, Z]$
$[A, y_0, y_1, \ldots, y_{k-1}, Z_L]$
$[A_R, z_0, z_1, \ldots, z_{k-1}, Z]$
$[A, A+1, A+2, \ldots, A+k+1]$
$[Z-(k+1), Z-k, \ldots, Z]$

FIG. 3. *A subtree of a k-modal search tree. The path from the root to the leftmost (rightmost) leaf is the left (right) spine.*

the function has been evaluated; at each step another probe is made inside I and either the leftmost or the rightmost segment is discarded, depending on the particular values of f at the $k+3$ points in the interval at which its values are known.

Lemmas 2.1 and 2.4 tell us that an algorithm that solves the discrete k-modal search problem by probing can be described by a k-modal search tree as shown in Fig. 3. Each node is an array of the form $[A, x_0, x_1, \ldots, x_{k-1}, Z]$ and represents the current interval of uncertainty $[A, Z)$ and the distribution of probes within it, with $A = x_{-1}$ and $Z = x_k$. The left (right) child of a node represents the new interval of uncertainty after the rightmost (leftmost) segment is discarded following a new probe. If the new probe is made at y, $x_i < y < x_{i+1}$, $-1 \leq i \leq k-1$, then the left child is $[A, y_0, y_1, \ldots, y_{k-1}, Z_L]$ with $A = y_{-1}$ and $Z_L = y_k$, where $y_j = x_j, -1 \leq j \leq i$, $y_{i+1} = y$, and $y_j = x_{j-1}, i+2 \leq j \leq k$. Similarly, if $[A_R, z_0, z_1, \ldots, z_{k-1}, Z]$ is the right child with $A_R = z_{-1}$ and $Z = z_k$, then $z_j = x_{j+1}, -1 \leq j \leq i-1$, $z_i = y$, and $z_j = x_j, i+1 \leq j \leq k$. The root of the tree is $[0, w_0, \ldots, w_{k-1}, N]$, where $w_0, w_1, \ldots, w_{k-1}$ are the initial k probes, and the leaves all have the form $[l, l+1, l+2, \ldots, l+k+1]$. The leftmost (rightmost) path in a k-modal search tree is referred to as the *left* (*right*) *spine*.

The *cost* of i in a given k-modal search tree, $c(i)$, is k plus the longest distance from the root to a leaf node containing the interval $[i, i+1)$. The k initial probes contribute the additive factor of k to the cost. $c(i)$ is the maximum number of probes required for k-modal search using the k-modal search algorithm corresponding to the given k-modal search tree, if the unique zero of the kth derivative of f is in the interval $[i, i+1]$.

We are now ready to state the main theorem that establishes the lower bounds; it is a generalization, to k-modal search trees, of Kraft's inequality [11] and the Fibonacci–Kraft inequality of [6].

THEOREM 2.5. *In a k-modal search tree over the range $[0, N)$,*

$$\sum_{i=0}^{N-1} \frac{1}{L_{c(i)+K}} \leq 1, \tag{2}$$

where

$$L_n = L_{n-1-\lfloor k/2 \rfloor} + L_{n-1-\lceil k/2 \rceil}, \tag{3}$$

and if k is even, then $L_i = 1$ for $0 \leq i \leq \lceil k/2 \rceil$, while if k is odd, then $L_0 = 0$ and $L_i = 1$ for $1 \leq i \leq \lceil k/2 \rceil$. In (2),

$$K = L^{-1}(k) + 1. \tag{4}$$

So, K is the smallest integer for which $L_{K-1} \geq k$.

COROLLARY 2.6 (see [11]). *For arbitrary binary trees* (*which correspond to* 0-*modal search trees*),

$$\sum_{i=0}^{N-1} \frac{1}{2^{c(i)}} \leq 1.$$

COROLLARY 2.7 (see [6]). *For a unimodal search tree over the range $[0, N)$,*

$$\sum_{i=0}^{N-1} \frac{1}{F_{c(i)+2}} \leq 1,$$

where F_i is the ith Fibonacci number.

The lower bound on the number of probes required is given by the following corollary.

COROLLARY 2.8. *In k-modal searching, in the worst case the minimum number of probes required to narrow the interval of uncertainty from $[0, N)$ to an interval of length $k+1$ is at least $L^{-1}(N) - K$. Thus, if $k = 2p$ is even, the minimum number of probes is at least $(p+1)\lg N - K$, and if $k = 2p+1$ is odd, then the minimum number of probes is at least $(\log_\gamma 2)\lg N - K$, where γ is the dominant root of $x^{p+2} - x - 1 = 0$.*

Proof. Let $h = \max_{0 \leq i < N} c(i)$. Theorem 2.5 implies that $N/L_{h+K} \leq 1$. Hence, $h \geq L^{-1}(N) - K$. The actual values of $L^{-1}(N)$ when k is even or odd follow from the definition of the sequence L. □

COROLLARY 2.9. *In binary* (0-*modal*) *search, the minimum number of probes required to narrow the interval of uncertainty from $[0, N)$ to an interval of length* 1 *is at least $\lceil \lg N \rceil$.*

COROLLARY 2.10 (see [6]). *In unimodal search, the minimum number of probes required to narrow the interval of uncertainty from $[0, N)$ to an interval of length* 2 *is at least $F^{-1}(N) - 2$, where $F^{-1}(N)$ is the smallest i such that $F_i \geq N$.*

COROLLARY 2.11. *In bimodal search, the minimum number of probes required to narrow the interval of uncertainty from $[0, N)$ to an interval of length* 3 *is at least* $2\lceil \lg N \rceil - 3$.

3. Proof of Theorem 2.5. In this section we prove Theorem 2.5, establishing the lower bound on the number of probes for k-modal search. The proof of the theorem is by induction on the height of the k-modal search tree. The proof for the case when k is even is much simpler since the recurrence relation in L_n is simple for this case. For odd k we must prove a stronger version of the generalized Kraft's inequality in Theorem 2.5, and the proof is more complicated. In both the cases, the proof makes use of the observation that the intervals of uncertainty at nodes that are not too far down the left and right spines overlap. This allows the sum in the generalized Kraft's inequality to be split into two sums that can be bounded by induction. The following lemma formalizes the crucial observation regarding overlap of intervals of uncertainty.

LEMMA 3.1. *Let $[A, Z)$ be the interval of uncertainty at the root of a k-modal search tree and let $[A, Z_L)$ and $[A_R, Z)$ be the intervals of uncertainty at the nodes at distance d_L and d_R along the left and right spines, respectively. If*

$$d_L + d_R \leq k + 2,$$

then

$$[A, Z_L) \cup [A_R, Z) = [A, Z)$$

and

$$Z_L - A_R \geq k + 2 - (d_L + d_R).$$

Proof. Let $x_0, x_1, \ldots, x_k$ be the $k + 1$ probes *inside* the interval of uncertainty $[A, Z)$ at the root of the k-modal search tree; these $k+1$ probes include the additional probe made just before one of the extreme segments is discarded. By Lemma 2.1, in one step down any path in a k-modal search tree at most one of the extreme segments can be discarded. Hence, after d_L steps down the left spine, at most d_L of the rightmost segments, out of the $k + 2$ initial segments, can be discarded. So, $Z_L \geq x_{k-d_L+1}$. Similarly, the left endpoint of the interval of uncertainty of the node d_R steps down the right spine must be at or to the left of x_{d_R-1}. If

$$d_L + d_R \leq k + 2,$$

then

$$d_R - 1 \leq k - d_L + 1.$$

Hence,

$$A_R \leq x_{d_R-1} \leq x_{k-d_L+1} \leq Z_L.$$

So,

$$[A, Z_L) \cup [A_R, Z) = [A, Z).$$

Furthermore,

$$\begin{aligned} Z_L - A_R &\geq x_{k-d_L+1} - x_{d_R-1} \\ &\geq k - d_L + 1 - (d_R - 1) \\ &= k + 2 - (d_L + d_R), \end{aligned}$$

as claimed. □

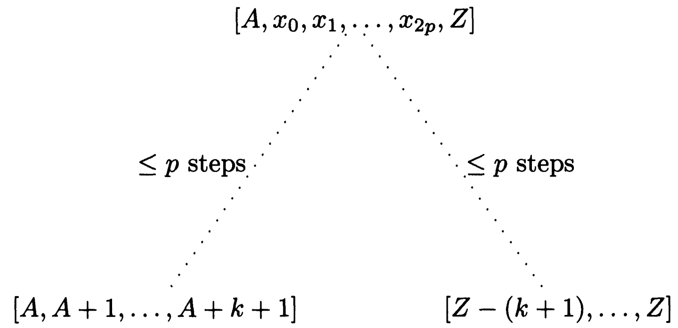


FIG. 4. *Base case for the inductive proof for even k.*

3.1. k even. We first note that for the case when $k = 2p$, the recurrence in equation (3) reduces to

$$L_n = 2L_{n-(p+1)},$$

with $L_i = 1$, $0 \leq i \leq p$, as the initial conditions. The solution to this recurrence is clearly

$$L_n = 2^{\lfloor \frac{n}{p+1} \rfloor}.$$

For the base case of the induction, the subtree has both the left and right spines of length at most p (see Fig. 4). Consider the extreme case when both the left and the right spines have length p. Let $[A, Z)$ be the interval of uncertainty at the root and let $x_0, x_1, \ldots, x_{2p}$ be the $2p+1$ probes *inside* the interval of uncertainty, including the probe made just before the first outermost interval is discarded. By Lemma 3.1, if $[A, Z_L)$ and $[A_R, Z)$ are the intervals of uncertainty at the leaves at the end of the left and right spines, respectively, then these two intervals overlap and $A_R - Z_L \geq 2p + 2 - 2p = 2$. Since both the intervals $[A, Z_L)$ and $[A_R, Z)$ correspond to leaves of the k-modal search tree, each has length $k+1$. So, the length of the interval $[A, Z)$ is at most $2(k+1) - 2 = 2k$. Also,

$$L_{k+L^{-1}(k)+1} \geq 2k.$$

Hence,

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \frac{2k}{L_{k+L^{-1}(k)+1}} \leq 1.$$

The theorem is thus true for all the base cases.

We now assume that the theorem is true for subtrees with height at most h, $h \geq p+1$. There are two cases for the induction step.

3.1.1. Case 1. Suppose that both left and right spines have length at least $p+1$. Here the situation is as shown in Fig. 5. Let $[A, Z)$ be the initial interval of uncertainty and let $x_0, x_1, \ldots, x_{2p}$ be the initial probes inside $[A, Z)$, including the probe made just before the first step down the tree. If $[A, Z_L)$ and $[A_R, Z)$ are the intervals of uncertainty after $p+1$ steps down the left and right spines, respectively, then by Lemma 3.1, $[A, Z_L)$ and $[A_R, Z)$ overlap. Hence, the subtrees T_L and T_R cover the

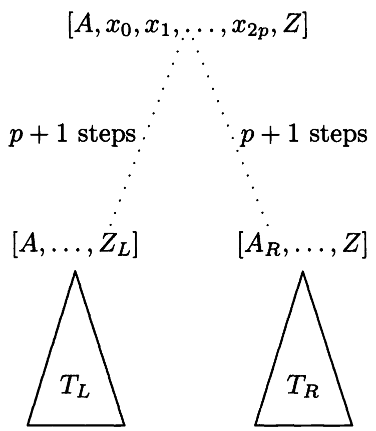

FIG. 5. *Case* 1 *of the induction for even* k.

entire range $[A, Z)$. Let c_L and c_R be the cost functions in T_L and T_R, respectively; then, using the induction hypothesis on T_L and T_R, we have

$$\text{sum in } T_L = \sum_{i=A}^{Z_L-1} \frac{1}{L_{c_L(i)+K}} \le 1$$

and

$$\text{sum in } T_R = \sum_{i=A_R}^{Z-1} \frac{1}{L_{c_R(i)+K}} \le 1.$$

Since $c(i) \ge \max\{c_L(i), c_R(i)\} + (p+1)$ and $L_{j+(p+1)} = 2L_j$, we have

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \le \frac{1}{2}(\text{sum in } T_L) + \frac{1}{2}(\text{sum in } T_R) \le 1.$$

This proves the theorem for Case 1.

3.1.2. Case 2. Suppose that one of the two spines has length less than $p+1$. Without loss of generality, assume that the left spine has length $l \le p$. Let T_R be the subtree rooted at the node at distance $p+1$ from the root along the right spine. By Lemma 3.1, it follows that the interval of uncertainty at the root of T_R, $[A_R, Z)$, and the one at the leaf at the end of the left spine, $[A, A+k+1)$, will overlap. In fact, if $[A, x_0, x_1, \ldots, x_{2p}, Z]$ is the distribution of probes in the interval of uncertainty at the root of the subtree, then $A+k+1 \ge x_{p+1}$ and $A_R \le x_p$. So, we can consider the term corresponding to the interval $[A+k, A+k+1)$ to be part of the sum over T_R. Thus,

$$\begin{aligned}\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} &\le \sum_{i=A}^{A+k-1} \frac{1}{L_{l+k+L^{-1}(k)+1}} + \sum_{i=A_R}^{Z-1} \frac{1}{L_{c_R(i)+p+1+K}} \\ &\le \frac{k}{2k} + \frac{1}{2} \\ &= 1,\end{aligned}$$

completing the proof of the theorem for even k.

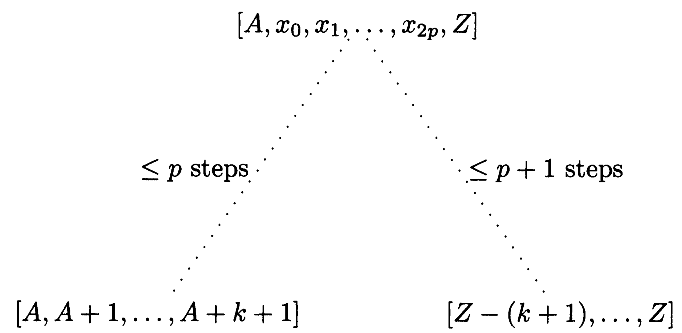

FIG. 6. *Base case for the inductive proof for odd k.*

3.2. k odd. Let $k = 2p+1$; we prove the following lemma, from which the theorem follows as a corollary.

LEMMA 3.2. *In a k-modal search tree, k odd, let $[A, x_0, x_1, \ldots, x_{k-1}, Z]$ be a node at distance l from the root and let q be a value in the range $A \leq q < Z$ having the least cost in the tree—that is, for all i, $A \leq i < Z$, $c(q) \leq c(i)$. Then*

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \frac{L_{c(q)+K-l}}{L_{c(q)+K}},$$

where L_n and K are defined by equations (3) *and* (4) *in Theorem* 2.5.

The following identity is used in the proof of Lemma 3.2 in the two subsections below. Its proof and that of some other identities describing the behavior of L_n when k is odd are given in the Appendix. For $i \geq 0$, $l > 0$, $j > 0$, if $i \equiv 2, 3, \ldots, p \pmod{p+1}$, then

$$(5) \qquad \frac{L_i}{L_{i+j}} = \frac{L_{i+l}}{L_{i+j+l}};$$

if $i \equiv 0$ or $1 \pmod{p+1}$ and $\lfloor \frac{i}{p+1} \rfloor$ is odd, then

$$(6) \qquad \frac{L_i}{L_{i+j}} > \frac{L_{i+l}}{L_{i+j+l}};$$

if $i \equiv 0$ or $1 \pmod{p+1}$ and $\lfloor \frac{i}{p+1} \rfloor$ is even, then

$$(7) \qquad \frac{L_i}{L_{i+j}} < \frac{L_{i+l}}{L_{i+j+l}}.$$

The proof of Lemma 3.2 is by induction on the height of the subtree. As in the proof of the theorem for even k, this proof uses Lemma 3.1 to infer that the intervals of uncertainty of the nodes at distance $p+1$ and $p+2$ down the left and right spines overlap and cover the entire interval of uncertainty at the root. This case, however, is much more complicated than for even k because the recurrence governing the lower bound does not have a simple, closed-form solution.

For the base case, the length of the left and right spines of the subtree are at most p and $p+1$ (see Fig. 6). Again, by Lemma 3.1, we know that the intervals of uncertainty at the leaves at the end of the left and right spine overlap and have at least two common segments. Hence, the length of the interval of uncertainty at the root is at most $2k$. So,

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \sum_{i=A}^{Z-1} \frac{1}{L_{c(q)+K}} \leq \frac{2k}{L_{c(q)+K}}.$$

Since $c(q) \geq l+k$, $L_{c(q)-l+K} \geq L_{k+L^{-1}(k)+1} \geq 2k$,

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \frac{L_{c(q)-l+K}}{L_{c(q)+K}}.$$

We now assume that the lemma is true for all subtrees of k-modal search trees of height at most h for any $h \geq p+1$.

For the induction step, we have a k-modal search tree in which both the spines are of length at least $p+1$. In the following discussion, we will assume that the interval of least cost, $[q, q+1)$, is contained in the subtree T_R rooted at a node at distance at most $p+2$ along the right spine. The case when $[q, q+1)$ lies in the left subtree is symmetric.

Let T_L and T_R be the subtrees rooted at distance $\min\{p+1, d_L\}$ and $\min\{p+2, d_R\}$ along the left and right spines, respectively, where d_L and d_R are the lengths of the left and right spines. From Lemma 3.1, we know that the intervals of uncertainty at the roots of T_L and T_R overlap.

3.2.1. Case 1. Suppose that the left and right spines have length at least $p+1$ and $p+2$, respectively; see Fig. 7. Let $[r, r+1)$ be the least-cost interval in T_L. By the induction hypothesis, we have

$$\text{sum in } T_L = \sum_{i=A}^{Z_L-1} \frac{1}{L_{c(i)+K}} \leq \frac{L_{c(r)-(l+p+1)+K}}{L_{c(r)+K}}$$

and

$$\text{sum in } T_R = \sum_{i=A_R}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}.$$

Now, if

$$\frac{L_{c(r)-(l+p+1)+K}}{L_{c(r)+K}} \leq \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}}, \tag{8}$$

then

$$\begin{aligned}
\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} &\leq (\text{sum in } T_L) + (\text{sum in } T_R) \\
&\leq \frac{L_{c(r)-(l+p+1)+K}}{L_{c(r)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}} \\
&\leq \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}} \\
&= \frac{L_{c(q)-(l+p+1)+K} + L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}} \\
&= \frac{L_{c(q)-l+K}}{L_{c(q)+K}}.
\end{aligned}$$

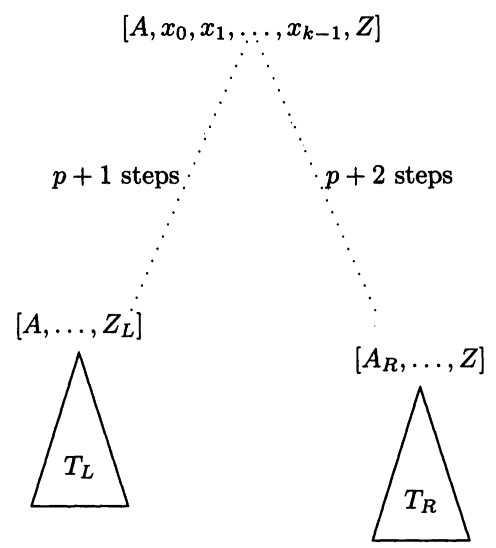

FIG. 7. *Induction when k is odd and no expansion of T_L is required.*

From (5) and (6), inequality (8) is true when $c(q) - (l + p + 1) + K \equiv 2, 3, \ldots, p \pmod{p+1}$ or when $c(q) - (l + p + 1) + K \equiv 0, 1 \pmod{p+1}$ and $\lfloor \frac{c(q)-(l+p+1)+K}{p+1} \rfloor$ is odd. If inequality (8) is not satisfied, then we have two subcases.

Case 1(a). Suppose the left and right spines of T_L have length at least $p+1$ and $p+2$, respectively. Let T_{LL} and T_{LR} be the subtrees at distance $p+1$ and $p+2$ along the left and right spine of T_L (see Fig. 8). Let $[s, s+1)$ and $[r, r+1)$ be the intervals of least cost in T_{LL} and T_{LR}, respectively. Then by the induction hypothesis,

$$\text{sum in } T_{LL} = \sum_{i=A}^{Z_{LL}-1} \frac{1}{L_{c(i)+K}} \le \frac{L_{c(s)-(l+2p+2)+K}}{L_{c(s)+K}},$$

$$\text{sum in } T_{LR} = \sum_{i=A_{LR}}^{Z_L-1} \frac{1}{L_{c(i)+K}} \le \frac{L_{c(r)-(l+2p+3)+K}}{L_{c(r)+K}},$$

and

$$\text{sum in } T_R = \sum_{i=A_R}^{Z-1} \frac{1}{L_{c(i)+K}} \le \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}.$$

Since inequality (8) is not satisfied,

$$a = \left\lfloor \frac{c(q) - (l + p + 1) + K}{p+1} \right\rfloor$$

is even. Hence,

$$\left\lfloor \frac{c(q) - (l + 2p + 2) + K}{p+1} \right\rfloor = \left\lfloor \frac{c(q) - (l + 2p + 3) + K}{p+1} \right\rfloor = a - 1$$

is odd. Thus, from inequality (6) it follows that

$$\frac{L_{c(s)-(l+2p+2)+K}}{L_{c(s)+K}} \le \frac{L_{c(q)-(l+2p+2)+K}}{L_{c(q)+K}}$$

and

$$\frac{L_{c(r)-(l+2p+3)+K}}{L_{c(r)+K}} \le \frac{L_{c(q)-(l+2p+3)+K}}{L_{c(q)+K}}.$$

Now, by Lemma 3.1,

$$\begin{aligned}\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} &\le (\text{sum in } T_{LL}) + (\text{sum in } T_{LR}) + (\text{sum in } T_R)\\ &\le \sum_{i=A}^{Z_{LL}-1} \frac{1}{L_{c(i)+K}} + \sum_{i=A_{LR}}^{Z_L-1} \frac{1}{L_{c(i)+K}} + \sum_{i=A_R}^{Z-1} \frac{1}{L_{c(i)+K}}\\ &\le \frac{L_{c(s)-(l+2p+2)+K}}{L_{c(s)+K}} + \frac{L_{c(r)-(l+2p+3)+K}}{L_{c(r)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}\\ &\le \frac{L_{c(q)-(l+2p+2)+K}}{L_{c(q)+K}} + \frac{L_{c(q)-(l+2p+3)+K}}{L_{c(q)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}\\ &= \frac{L_{c(q)-l+K}}{L_{c(q)+K}}.\end{aligned}$$

Case 1(b). Suppose that T_L is not big enough to be sufficiently expanded. Let $y = \min\{d_{LL}, p+1\}$ and $z = \min\{d_{LR}, p+2\}$, where d_{LL} and d_{LR} are the lengths of the left and right spines of T_L, respectively.

If $y \le p$ and $z \le p+1$, then by Lemma 3.1, the intervals $[A, Z_{LL})$ and $[A_{LR}, Z_L)$ overlap and $A_{LR} - Z_{LL} \ge 2$. Since both these intervals correspond to leaves in the k-modal search tree, their length is $k+1$. So, the length of $[A, Z_L)$ is at most $2(k+1)-2 = 2k$. Furthermore, since $c(q) \le c(i)$ for any i such that $[i, i+1) \subset [A, Z_L)$, we have

$$\text{sum in } T_L = \sum_{i=A}^{Z_L-1} \frac{1}{L_{c(i)+K}} \le \frac{2k}{L_{c(q)+K}}.$$

Since $c(q) \ge k+l+1$,

$$L_{c(q)-(l+p+1)+K} \ge L_{k+L^{-1}(k)+1} \ge 2k.$$

So,

$$\text{sum in } T_L \le \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}}.$$

By the induction hypothesis, we know that

$$\text{sum in } T_R \le \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}.$$

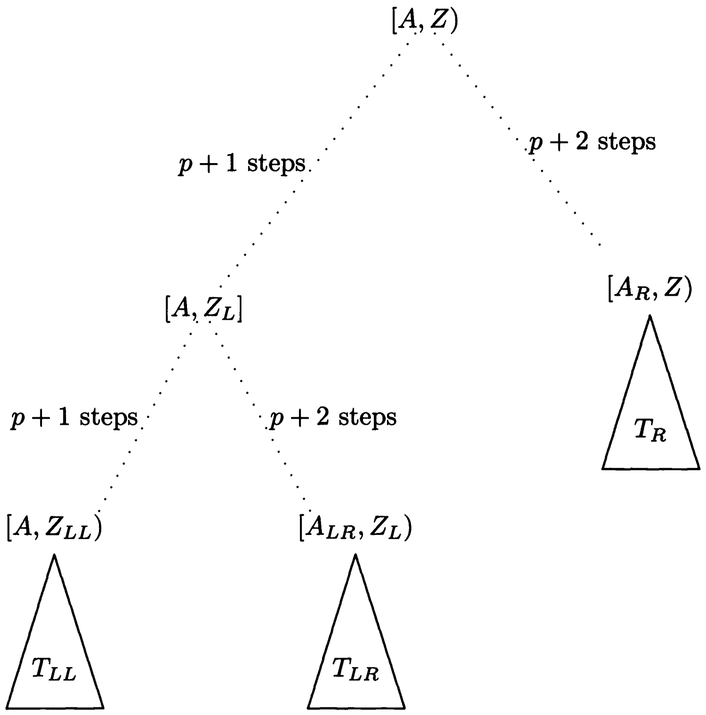

FIG. 8. *Subcase when T_L expands sufficiently.*

Hence,

$$\begin{aligned}\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} &= (\text{sum in } T_L) + (\text{sum in } T_R) \\ &\leq \frac{L_{c(q)-l+K}}{L_{c(q)+K}}.\end{aligned}$$

If $y = p+1$ and $z \leq p+1$, then by Lemma 3.1, we know that $A_{LR} - Z_{LL} \geq 1$. Furthermore, since the interval $[A_{LR}, Z_L)$ corresponds to a leaf, we have

$$\text{sum in } T_L \leq (\text{sum in } T_{LL}) + \sum_{i=Z_L-k}^{Z_L-1} \frac{1}{L_{c(i)+K}}. \tag{9}$$

By the induction hypothesis,

$$\text{sum in } T_{LL} \leq \frac{L_{c(s)-(l+2p+2)+K}}{L_{c(s)+K}}. \tag{10}$$

By the same argument as in Case 1(a),

$$\frac{L_{c(s)-(l+p+1)+K}}{L_{c(s)+K}} \leq \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}}.$$

Also, since $c(q) \leq c(i)$ for any i in the range $[A_{LR}, Z_L)$,

$$\sum_{i=Z_L-k}^{Z_L-1} \frac{1}{L_{c(i)+K}} \leq \frac{k}{L_{c(q)+K}}.$$

Since $c(q) \geq k + l + 1$,

$$L_{c(q)-(l+2p+3)+K} \geq L_{k-2p-2+L^{-1}(k)+1} = L_{L^{-1}(k)} = k.$$

So,

$$\sum_{i=Z_L-k}^{Z_L-1} \frac{1}{L_{c(i)+K}} \leq \frac{L_{c(q)-(l+2p+3)+K}}{L_{c(q)+K}}. \tag{11}$$

Thus by (9), (10), and (11),

$$\text{sum in } T_L \leq \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}},$$

and by the induction hypothesis,

$$\text{sum in } T_R \leq \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}},$$

yielding

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} = (\text{sum in } T_L) + (\text{sum in } T_R) \leq \frac{L_{c(q)-l+K}}{L_{c(q)+K}}$$

as desired.

The case when $y \leq p$ and $z = p + 2$ is identical to the above, *mutatis mutandis*, completing the proof of Lemma 3.2 for Case 1.

3.2.2. Case 2. Suppose that the spines of the k-modal search tree are not sufficiently long. Again, we consider two subcases.

Case 2(a). Assume that the left spine has length $y \leq p$ and the right spine has length at least $p+2$. Let T_R be the subtree rooted at the node at distance $p+2$ along the right spine (see Fig. 9). By Lemma 3.1, we know that

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \leq \sum_{i=A}^{A+k} \frac{1}{L_{c(i)+K}} + (\text{sum in } T_R).$$

By the induction hypothesis,

$$\text{sum in } T_R \leq \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}.$$

So,

$$\begin{aligned}\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} &\leq \sum_{i=A}^{A+k} \frac{1}{L_{c(i)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}} \\ &\leq \frac{k+1}{L_{c(q)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}.\end{aligned}$$

Since $c(q) \geq l + k + 1$,

$$L_{c(q)-(l+p+1)+K} \geq L_{k+L^{-1}(k)+1} \geq 2k \geq k+1.$$

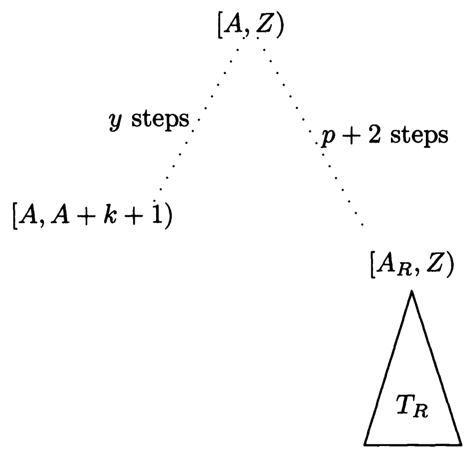

FIG. 9. *Induction when T_L does not expand sufficiently.*

Hence,

$$\sum_{i=A}^{Z-1} \frac{1}{L_{c(i)+K}} \le \frac{L_{c(q)-(l+p+1)+K}}{L_{c(q)+K}} + \frac{L_{c(q)-(l+p+2)+K}}{L_{c(q)+K}}$$
$$= \frac{L_{c(q)-l+K}}{L_{c(q)+K}}$$

as desired.

Case 2(b). Suppose the right spine has length $z \le p + 1$ and the left spine has length at least $p + 1$. This case is symmetric to Case 2(a). To show that the sum in T_L is sufficiently small, we use exactly the same arguments as in Case 1.

This completes the proof of Lemma 3.2, thus proving Theorem 2.5.

4. Algorithms for *k*-modal search. We first note that an algorithm for $(k-1)$-modal search can be used for k-modal searching because the derivative of a k-modal function f is the $(k-1)$-modal function Δf. Hence, we can replace each probe of Δf by the algorithm for $(k-1)$-modal searching by two probes at adjacent points, and use Δf as the result of the probe made by the algorithm for $(k-1)$-modal search. This gives an algorithm for k-modal searching that uses twice as many probes as the algorithm for $(k-1)$-modal searching. However, these naïve algorithms are not optimal. The key to designing optimal algorithms for k-modal searching is to find a probing strategy that insures that the k probes in the current interval of uncertainty divide that interval in such a way that both the outermost segments are "sufficiently large." Since this property must be satisfied recursively by the configurations that result after one of the outermost segments has been eliminated, it is necessary that the distribution of probes be "balanced" and the probing strategy must regenerate a distribution of probes similar to the starting distribution.

4.1. Optimal algorithms for even *k*. When $k = 2p$, the recurrence relation used in deriving the lower bound on the number of probes required is

$$L_n = 2L_{n-(p+1)},$$

with $L_i = 1$ for $0 \le i \le p$. The algorithm halves the length of the interval of uncertainty after $p + 1$ probes and is hence optimal with respect to the number of

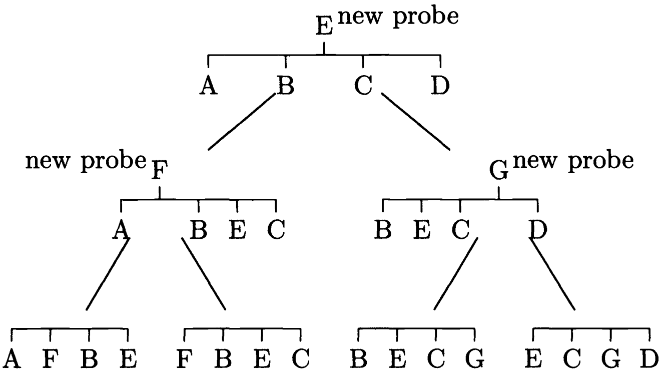

FIG. 10. *Part of the bimodal search tree generated by the optimal bimodal search algorithm.*

probes used. This algorithm is an extension of the discrete case of the algorithm proposed in [7].

Initially, the algorithm distributes the k probes uniformly over the interval $[0, N)$. Thus, the configuration of probes in the initial interval of uncertainty is of the form $[0, L_m, 2L_m, 3L_m, \ldots, 2pL_m, N]$, where m is chosen so that the rightmost segment has length at most L_m, $m = L^{-1}(N/(k+1))$. Now, the algorithm probes at the midpoint of the unique center segment—this is the $(p+1)$st segment from either end of the interval of uncertainty—dividing it into two segments of length $L_{m-(p+1)}$ each. Next, either the leftmost or the rightmost segment is discarded and a new probe is made at the midpoint of the segment adjacent to the center segment on the side *opposite* the side that lost a segment. The algorithm maintains a central "region of division" consisting of segments half as long as the segments on either side of this region. A new probe is always made at the midpoint of a segment adjacent to the "region of division" on the side opposite the side that lost a segment on the previous probe. This guarantees that the first p probes cause segments of length L_m to be discarded (except the first probe, which might result in the loss of the rightmost segment, which might have length less than L_m). After $p+1$ probes, the algorithm has a configuration of probes that divides the interval of uncertainty into segments of length $L_{m-(p+1)}$, except the rightmost segment, which can be shorter. Thus, after $p+1$ probes, the interval of uncertainty is halved and a configuration similar to the starting one is regenerated; this process is repeated until the interval of uncertainty is of length $k+1$. A part of a bimodal search tree generated by the above algorithm is shown in Fig. 10.

In the pseudocode of Algorithm 4.1, we use a binary search tree to store the pairs $(x, f(x))$ corresponding to probes in the current interval of uncertainty. The function *InsertPair* inserts a new pair $(x, f(x))$ into the binary search tree. *DeleteExtremeSegment* deletes the pair corresponding to the right or left endpoint of the interval of uncertainty. *FindSide* determines which of the two extreme segments in the current interval of uncertainty can be discarded by computing the sign of $P(x_0, x_1, \ldots, x_k, f)$, defined in the proof of Lemma 2.3 (see Fig. 2). Notice that our time complexity measure considers only function evaluations, ignoring the $O(\log k)$-time-per-tree operation.

4.2. Optimal algorithm for trimodal search. Goldstein and Reingold [6] presented an optimal algorithm for discrete unimodal ($k = 1$) search based on Kiefer's

ALGORITHM 1. *Optimal discrete k-modal search over the interval $[0, N)$.*

```
function ModalSearch(
    f: function(NonNegativeInteger): real; {k-modal function to be searched }
    k: NonNegativeInteger; {Modality of function f}
    low: NonNegativeInteger;
    high: PositiveInteger; {Interval [low, high) defines the domain of f}
    ): NonNegativeInteger; { Left endpoint of an interval of length $k+1$
                              containing the unique zero of $\Delta^k f$ }
{ Search over interval [low, high), $high - low \geq k+2$ }
procedure InsertPair(
    Fvalues: BinarySearchTree;
    x: NonNegativeInteger);
{Evaluates $f(x)$ and inserts the pair $(x, f(x))$ into a binary search tree indexed by x }
    ⋮
end;
procedure Search
    ⋮ { See Algorithm 4.1 }
end;
var
    i: NonNegativeInteger; { Left endpoint of interval containing the unique zero of $\Delta^k f$ }
    j, m: NonNegativeInteger;
    Fvalues: BinarySearchTree;
    p: NonNegativeInteger;

begin
    $p := \lfloor k/2 \rfloor$;
    $m := L^{-1}((high - low)/k + 1)$;
    for j = 1 to k do
        InsertPair(Fvalues, $low + jL_m$);
    i := low;
    Search(i, high, m);
    ModalSearch := i
end
```

Fibonacci search algorithm for the continuous version of unimodal search [10]. In this section, we give an optimal algorithm for trimodal search, modeled after Hyafil [7], and in the next section, we sketch a family of similar but not quite optimal algorithms for odd $k > 3$.

For trimodal searching, the recurrence relation governing the lower bound on the number of probes needed is

$$L_n = L_{n-2} + L_{n-3}. \tag{12}$$

It is easy to show that we also have

$$L_n = L_{n-1} + L_{n-5}. \tag{13}$$

For simplicity, assume that the initial length of the interval of uncertainty is L_n. Then, equations (12) and (13) can be used to generate an initial distribution of probes in

ALGORITHM 2. *Discrete k-modal search procedure.*

```
procedure Search(
    var i: NonNegativeInteger;{Upon entry, search has reached ...}
    j, m: NonNegativeInteger); { ...node $[i, i + L_m, i + 2L_m, \ldots, i + kL_m, j]$ }
procedure DeleteExtremeSegment(
    Fvalues: BinarySearchTree;
    side: (LEFT, RIGHT) );
{Deletes the pair $(x, f(x))$, corresponding to the left or the right
endpoint of the interval of uncertainty, from Fvalues }
    ⋮
end;
function FindSide( Fvalues: BinarySearchTree): (LEFT, RIGHT);
{This function determines the side that will lose its extreme segment by applying
Lemma 2.4, after $k + 1$ probes have been made}
    ⋮
end;
var
    left, right: NonNegativeInteger; {These delimit the left and right boundaries
                                      of the "region of division"}
    Side: (LEFT, RIGHT); {Flag indicating which side lost a segment as a result
                          of the last probe}
    num: NonNegativeInteger;
    NewProbe: NonNegativeInteger;
begin {Search}
  if $j - i \le k + 1$ then
    {$k$-modal search ends at interval $[i, i + k + 1)$}
  else begin
    left := right := $i + (p + 1)L_m$;
    Side := RIGHT;

    for num := 1 to $p + 1$ do begin
      if Side = LEFT then begin {Probe just beyond the right end of the
                                 "region of division"}
        NewProbe := right $+L_{m-(p+1)}$;
        right := right $+L_m$
        end
      else begin {Probe just to the left of the left end of the "region of division"}
        NewProbe := left $-L_{m-(p+1)}$;
        left := left $-L_m$
        end
      InsertPair(Fvalues, NewProbe);
      Side := FindSide(Fvalues);
      DeleteExtremeSegment(Fvalues, Side)
      end {of for loop}

    { Now we make the recursive calls }
    if Side = LEFT then begin
      i := left $+L_{m-(p+1)}$;
      Search(i, right, $m - (p + 1)$)
      end
    else begin
      i := left;
      Search(i, right $-L_{m-(p+1)}$, $m - (p + 1)$)
      end
    end {of else}
end
```

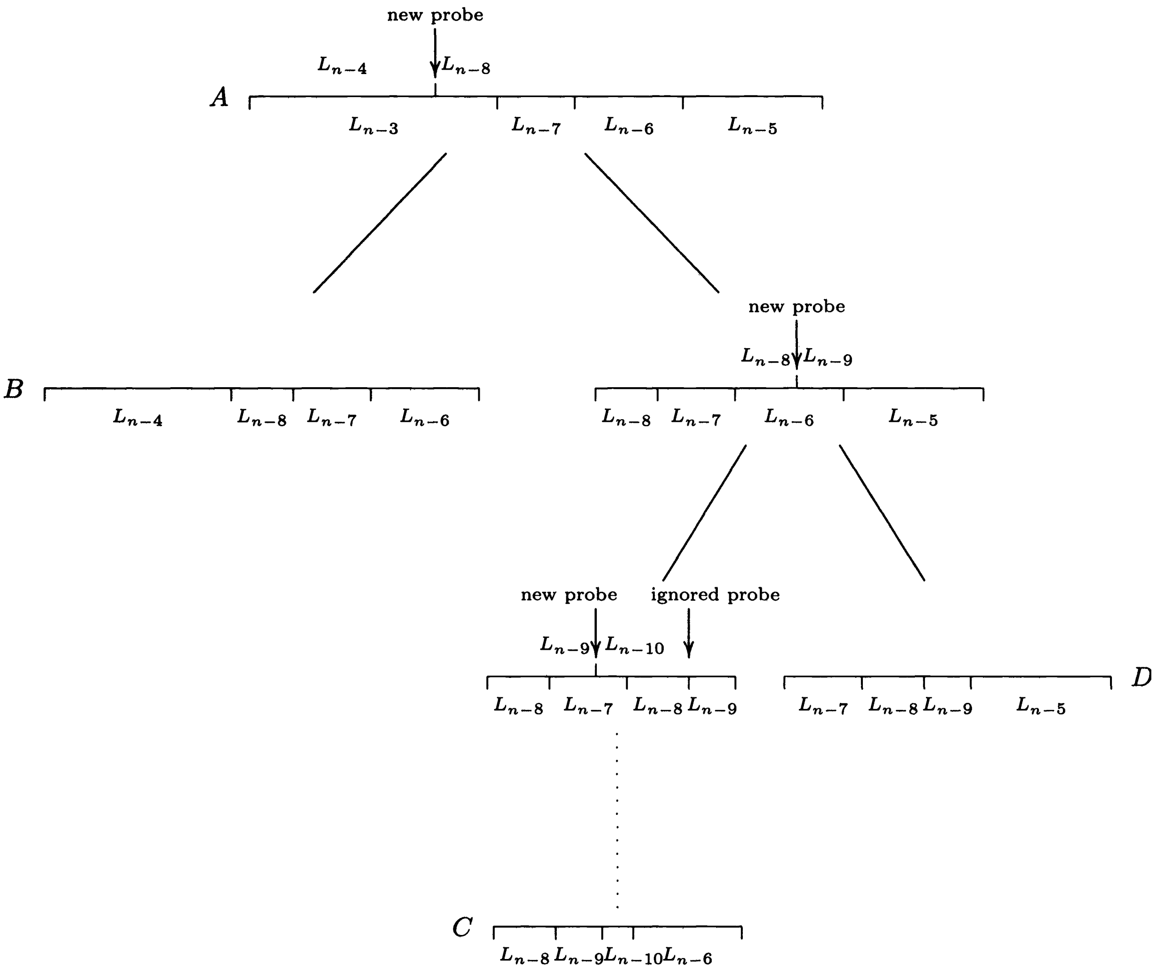

FIG. 11. *Pattern of probes in the optimal trimodal search algorithm. The root interval, labeled A, has length $L_n = L_{n-3} + L_{n-7} + L_{n-6} + L_{n-5}$; its left child, labeled B, has length $L_{n-1} = L_{n-4}+L_{n-8}+L_{n-7}+L_{n-6}$. The interval labeled C has length $L_{n-3} = L_{n-8}+L_{n-9}+L_{n-10}+L_{n-6}$. The interval labeled D has length $L_{n-2} = L_{n-7} + L_{n-8} + L_{n-9} + L_{n-5}$.*

which the segment lengths are, respectively, $L_{n-3}, L_{n-7}, L_{n-6}, L_{n-5}$. The subsequent pattern of probes in the optimal trimodal search algorithm is shown in the part of the trimodal search tree in Fig. 11. The distribution of probes at the leaves of this subtree is the same (up to symmetry) as the initial distribution of probes. This enables the recursive application of this probing strategy at these leaves. Furthermore, at leaf B the length of the interval of uncertainty is L_{n-1} after one probe, at leaf D the length of the interval of uncertainty is L_{n-2} after two probes, and at leaf C the length of the interval of uncertainty is L_{n-3} after three probes, insuring optimality. Notice that to regenerate a distribution of probes symmetric to the initial distribution of probes at leaf C, a "rearrangement probe" is made and an earlier probe is ignored.

4.3. Near-optimal algorithms for odd $k \geq 5$. Suppose $k = 2p + 1$, $p > 1$. For simplicity, assume that the length of the initial interval of uncertainty is L_n, where L_n is a member of the series defined by recurrence (3). To get the initial

ALGORITHM 3. *Algorithm for finding all local extrema of a k-modal function.*

```
var
    extrema: array of NonNegativeInteger; {stores the extrema found so far}
procedure FindAllExtrema(
    f: function(NonNegativeInteger): real;
    k: NonNegativeInteger; {Modality of function f}
    low: NonNegativeInteger;
    high: PositiveInteger); {f is k-modal in the range [low, high)}
procedure InsertExtremum(i: NonNegativeInteger);
{Inserts i in the array extrema, indicating an extremum in [i, i + k + 1)}
    ⋮
end;
var
    i: NonNegativeInteger;
begin
    i := ModalSearch(k, low, high, f);
    if k = 1 then
        InsertExtremum(i);
    else begin
        FindAllExtrema(f, k − 1, low, i + k + 1);
        FindAllExtrema(f, k − 1, i + 1, high)
        end
end
```

distribution of probes, we recursively divide the largest segment in the current set of segments into two parts, using recurrence (3), until there are $k+1$ segments. This results in an initial configuration of probes that has all segments with lengths in the set $\{L_{n-K_1}, L_{n-K_1+1}, \dots, L_{n-K_2}\}$, where K_1 and K_2 are constants depending on p. Now, the algorithm uses the same strategy as in the case when k is even; starting with one of the two center segments, a probe is made in a segment adjacent to the "region of division" on the side opposite the side that lost a segment as a result of the previous probe. Unfortunately, the nonuniqueness of the center segment (since $k+1$ is even) forces the algorithm to use, in the worst case, $p+2$ probes to shift the indices of the set of lengths of segments down by $p+1$. Thus, the algorithm is suboptimal, but as the value of k increases, its performance approaches the lower bound since the $\frac{p+1}{p+2} \to 1$ as $p \to \infty$. The proper choice of the distribution of segments of different lengths in the interval of uncertainty might hold the key to designing optimal algorithms for these cases.

5. Finding all extrema of a k-modal function.

We can use a k-modal search to obtain an efficient algorithm for finding all the local extrema (or zeros) of a k-modal function. The algorithm makes use of the following lemma.

LEMMA 5.1. *Let $f : \{0, \dots, N\} \to \Re$ be a k-modal function and let $[i, i+1)$ be the interval containing the unique zero of its kth derivative. Then the functions $f : \{0, \dots, i+k+1\} \to \Re$ and $f : \{i+1, \dots, N\} \to \Re$ are both $(k-1)$-modal.*

Proof. Since $[i, i+1)$ is the unique zero of $\Delta^k f$, Δ^{k-1} is necessarily unimodal. Assume without loss of generality that the part of $\Delta^{k-1} f$ to the left of $i+1$ is decreasing and the part to the right is increasing. We now note that $\Delta^{k-1} f$ in the range $[0, i+1)$ is determined by the values of f in the range $[0, i+k)$. Also, the values of $\Delta^{k-1}f$ in the range $[i+1, N-k-1)$ are determined by the values of f in the range $[i+1, N)$. Now, when splitting the original k-modal function f into the ranges $[0, i+k)$ and $[i+1, N)$, we will assume that $f(i+k) = -\infty$ for the function f over the range $[0, i+k)$ and $f(i+1) = \infty$ for the restriction of f to the range $[i+1, N)$. This then implies that both the restrictions of f defined above have a unique zero in their $(k-1)$st derivative and are hence $(k-1)$-modal. □

This lemma suggests a divide-and-conquer algorithm for finding all the local extrema (or zeros) of a k-modal function in which k-modal searching serves as the "divide" step. It is important to note that the number of local extrema of f need not be symmetrically distributed about the unique zero of the kth derivative of the k-modal function. In fact, there might be just one local extremum of f on one side and all the others (at most $k-1$) might lie on the other side.

A divide-and-conquer algorithm based on Lemma 5.1 is presented as Algorithm 3.

The k-modal searching algorithms discussed in §4 use at most $(\lceil k/2 \rceil + 1)\lg N$ probes for a k-modal function over the range $[0, N)$. The recurrence relation for the number of probes made in the worst case of Algorithm 4.3 is of the form

$$T(N,k) = \max_{0 \le i < N} \{T(i+k+1, k-1) + T(N-i-1, k-1)\} + (\lceil k/2 \rceil + 1)\lg N.$$

Furthermore, in this recurrence, the worst case arises when the division is perfectly balanced. Hence,

$$T(N,k) \le 2T(N/2, k-1) + (\lceil k/2 \rceil + 1)\lg N. \tag{14}$$

On unfolding this recurrence, we get

$$\begin{aligned} T(N,k) &\le \sum_{i=0}^{\min\{k,\lg N\}} (\lceil (k-i)/2 \rceil + 1)2^i \lg(N/2^i) \\ &< k \sum_{i=0}^{\min\{k,\lg N\}} 2^i \lg N \\ &= O(k2^{\min\{k,\lg N\}} \lg N). \end{aligned}$$

Thus the algorithm is better than the naïve sequential scan algorithm when $k < \lg N - 2\lg\lg N$. But, this algorithm does not make use of the probes made during k-modal searching while doing $(k-1)$-modal searching; hence, it should be possible to devise more efficient algorithms for finding all the local extrema of a k-modal function by reusing some of the probes made in k-modal search during the subsequent lower modal searches.

6. Unbounded k-modal search. In the unbounded discrete k-modal search problem, the search takes place over an infinite domain, the nonnegative integers. The problem of unbounded search was first introduced by Bentley and Yao [3]. Reingold and Shen [17] presented a hierarchy of successively better algorithms and corresponding lower bounds. Goldstein and Reingold [6] extended some of these ideas to unimodal searching.

6.1. Algorithms for unbounded discrete k-modal search. The infinite sequence of increasingly better algorithms for unbounded searching described for monotonic functions [17] and for unimodal functions [6] can be extended to k-modal searching. This follows from the observation that Lemma 2.4 gives us an efficient way of finding a finite interval containing the unique zero of the k-modal function by maintaining a set of $k+2$ probes and making probes at successive values of an Ackermann-like (rapidly growing) function. By computing the sign of the P function (see Lemma 2.4) for the last $k+1$ probes in the current set of probes, we can decide whether the zero lies in the interval spanned by the current set of probes. This strategy is used to mimic the top level search in [17] and [6]. The level-by-level search requires the definition of a hierarchy of Ackermann-like functions, $A_l(n)$, satisfying

$$A_l(n) = A_{l-1}(A_l(n-1)).$$

The function $A_1(n)$ needs to be chosen carefully so that the distribution of probes when the search reaches level $l = 1$ conforms to the distribution required by the finite k-modal search algorithm. The exact details of these Ackermann-like functions have been a stumbling block in our exploration of unbounded k-modal search.

6.2. Lower bounds for unbounded discrete k-modal search. The main tool used in generating lower bounds for unbounded discrete k-modal searching is the following infinite version of the generalized Kraft's inequality (2), which is a corollary of Theorem 2.5.

COROLLARY 6.1. *In an unbounded discrete k-modal search, if $c(i)$ is the number of probes used in the worst case when the unique zero of $\Delta^k f$ lies in $[i, i+1)$, then*

$$\sum_{i=0}^{\infty} \frac{1}{L_{c(i)+K}} \leq 1. \tag{15}$$

Proof. If not, then there must be some N for which

$$\sum_{i=0}^{N-1} \frac{1}{L_{c(i)+K}} > 1,$$

contradicting Theorem 2.5. □

As a direct consequence of Corollary 6.1, we have the following corollary that is used to prove lower bounds for unbounded discrete k-modal search.

COROLLARY 6.2. *Let $c(i)$ be the number of probes used in the worst case by an unbounded discrete k-modal search algorithm when the unique zero of $\Delta^k f$ occurs in the range $[i, i+1)$. If for some nondecreasing function d, the sum $\sum_{i=0}^{\infty} \frac{1}{L_{d(i)+K}}$ diverges, then $c(i) > d(i)$ for infinitely many i.*

Unfortunately, the algebra in trying to prove lower bounds using this approach gets too involved, at least for the definitions of the Ackermann-like functions that we examined.

7. Conclusions. One of the important problems related to k-modal searching is the the determination of the modality of a function. Although a linear scan can find all the turning points of the function, there does not seem to be an obvious linear-time algorithm for finding the modality of a function, when modality is defined as the largest derivative of the function having a unique zero. It would be interesting to find out if k-modal searching can be used to solve this problem.

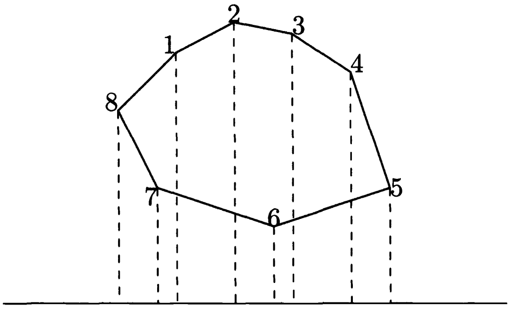

FIG. 12. *The distances of the vertices of a convex polygon from a line, when considered in order around the perimeter, yield a bimodal function.*

Bimodal search has been used in [4] to design algorithms for intersecting convex objects in two and three dimensions. These algorithms use the fact that the distances of the vertices of a convex polygon from a line yield a bimodal function (see Fig. 12). This raises the following question: given a polygon with a bounded number of concavities, do the distances of its vertices from a line yield a k-modal function? If so, can the algorithm for intersecting two-dimensional convex polygons be extended to an algorithm for intersecting nonconvex polygons with a bounded number of concavities by using k-modal search?

Using generalizations of Kraft's inequality to prove lower bounds seems to be applicable to several problems such that an algorithm for the problem can be mapped to a computation tree. A generalized Kraft's inequality then captures the minimum "degree of imbalance" that must be present in any computation tree solving the problem. In particular, the problem of discrete search in the presence of lies [16], [18], [21] might be a suitable candidate for a problem which can be attacked using this technique. It would also be interesting to see whether the lower-bound proof in this case suggests an optimal algorithm for discrete searching in the presence of lies, as was the case in k-modal searching.

Appendix: Some combinatorial identities. Here we give some identities describing the behavior of L_n when k is odd. Let $k = 2p+1$; then the recurrence relation defining the sequence L used in the theorem is

$$L_n = \begin{cases} 0 & \text{if } n = 0, \\ 1 & \text{if } 1 \le n \le p+1, \\ L_{n-(p+1)} + L_{n-(p+2)}, & \text{otherwise.} \end{cases}$$

When $p = 0$ this sequence is the Fibonacci sequence, so the identities we prove are generalizations of some well-known identities for the Fibonacci numbers.

PROPOSITION 7.1. *For $m \ge p+1$, $n \ge 0$,*

$$L_{m+n} = L_m L_{n+p+1} + L_{m-(p+1)} L_n.$$

Proof. We use induction on m and n. Assume that m is fixed. For the base case we have $n = 0$, so the proposition reduces to

$$L_m = L_m L_{p+1} + L_{m-(p+1)} L_0.$$

Since $L_{p+1} = 1$ and $L_0 = 0$, the proposition holds for the base case. Assume that the proposition holds for all $n \leq q$ and consider the case when $n = q + 1$:

$$L_{m+q+1} = L_{m+(q-p)} + L_{m+(q-p-1)}.$$

Applying the induction hypothesis to both of the terms on the right-hand side, we have

$$L_{m+q+1} = L_m L_{q+1} + L_{m-(p+1)} L_{q-p} + L_m L_q + L_{m-(p+1)} L_{q-p-1},$$

which, on collecting the common terms, reduces to

$$L_{m+q+1} = L_m L_{p+q+2} + L_{m-(p+1)} L_{q+1}.$$

This proves the proposition for the case $n = p + 1$, thus completing the proof by induction. A similar proof works when we assume n is fixed. □

PROPOSITION 7.2. *For $n \geq p+1$,*

$$L_{n+(p+1)} L_{n-(p+1)} - L_n^2 = \begin{cases} (-1)^{\lfloor \frac{n}{p+1} \rfloor} & \textit{if } n \equiv 0 \textit{ or } 1 \pmod{p+1}, \\ 0 & \textit{otherwise.} \end{cases}$$

Proof. The proof is by induction on n. For the base case, $n = p + 1$ and the identity is obvious. The induction step uses the following matrix identity, which is a consequence of Proposition 7.1:

$$\begin{bmatrix} L_{n+p+1} & L_n \\ L_n & L_{n-(p+1)} \end{bmatrix} = \begin{bmatrix} L_{2(p+1)} & L_{p+1} \\ L_{p+1} & 0 \end{bmatrix} \begin{bmatrix} L_n & L_{n-(p+1)} \\ L_{n-(p+1)} & L_{n-2(p+1)} \end{bmatrix}.$$

Taking determinants on both sides of this identity, we get

$$L_{n+p+1} L_{n-(p+1)} - L_n^2 = -L_{p+1}^2 (L_n L_{n-2(p+1)} - L_{n-(p+1)}^2).$$

Since $L_{p+1} = 1$ and by the induction hypothesis

$$L_n L_{n-2(p+1)} - L_{n-(p+1)}^2 = \begin{cases} (-1)^{\lfloor \frac{n-(p+1)}{p+1} \rfloor} & \text{if } n - (p+1) \equiv 0 \text{ or } 1 \pmod{p+1}, \\ 0 & \text{otherwise,} \end{cases}$$

we get the required identity. □

PROPOSITION 7.3. *For $m, n \geq p+1$,*

$$L_{n+m-(p+1)} L_n - L_{n-(p+1)} L_{m+n} = \begin{cases} L_m (-1)^{\lfloor \frac{n}{p+1} \rfloor + 1} & \textit{if } n \equiv 0 \textit{ or } 1 \pmod{p+1}, \\ 0 & \textit{otherwise.} \end{cases}$$

Proof. Using Proposition 7.1 to expand the terms on the left-hand side of the identity, we have

$$\begin{aligned} &L_{n+m-(p+1)} L_n - L_{n-(p+1)} L_{m+n} \\ &= L_n (L_m L_n + L_{m-(p+1)} L_{n-(p+1)}) - L_{n-(p+1)} (L_m L_{n+p+1} + L_{m-(p+1)} L_n) \\ &= L_m (L_n^2 - L_{n-(p+1)} L_{n+p+1}). \end{aligned}$$

Now, using Proposition 7.2, we get the required identity. □

PROPOSITION 7.4. *For $i \geq 0$, $l > 0$, $j > 0$, if $i \equiv 2, 3, \ldots, p \pmod{p+1}$, then*

$$\frac{L_i}{L_{i+j}} = \frac{L_{i+l}}{L_{i+j+l}};$$

if $i \equiv 0$ or $1 \pmod{p+1}$ and $\lfloor \frac{i}{p+1} \rfloor$ is odd, then

$$\frac{L_i}{L_{i+j}} > \frac{L_{i+l}}{L_{i+j+l}};$$

if $i \equiv 0$ or $1 \pmod{p+1}$ and $\lfloor \frac{i}{p+1} \rfloor$ is even, then

$$\frac{L_i}{L_{i+j}} < \frac{L_{i+l}}{L_{i+j+l}}.$$

Proof. These realtions can be written jointly as

$$L_i L_{i+j+l} <^? > L_{i+l} L_{i+j},$$

which on expansion, using Proposition 7.1, yields

$$L_i(L_l L_{i+j+p+1} + L_{l-(p+1)} L_{i+j}) <^? > L_{i+j}(L_l L_{i+p+1} + L_i L_{l-(p+1)}).$$

Simplifying, we have

$$L_i L_{i+j+p+1} <^? > L_{i+j} L_{i+p+1}$$

or

$$L_i L_{i+j+p+1} - L_{i+j} L_{i+p+1} <^? > 0.$$

Using Proposition 7.3 with $m = j$ and $n = i + p + 1$, we get

$$\left\{ \begin{array}{ll} L_j(-1)^{\lfloor \frac{i}{p+1} \rfloor + 1} & \text{if } i \equiv 0 \text{ or } 1 \pmod{p+1}, \\ 0 & \text{otherwise.} \end{array} \right\} <^? > 0.$$

This yields the required identities. □

AN ALGEBRAIC MODEL FOR COMBINATORIAL PROBLEMS*

RICHARD E. STEARNS† AND HARRY B. HUNT III†

Abstract. A new algebraic model, called the generalized satisfiability problem (GSP) model, is introduced for representing and solving combinatorial problems. The GSP model is an alternative to the common method in the literature of representing such problems as language-recognition problems. In the GSP model, a problem instance is represented by a set of variables together with a set of terms, and the computational objective is to find a certain sum of products of terms over a commutative semiring. The model is general enough to express all the standard problems about sets of clauses and generalized clauses, all nonserial optimization problems, and all {0,1}-linear programming problems. The model can also describe many graph problems, often in a very direct structure-preserving way. Two important properties of the model are the following:

1. In the GSP model, one can naturally discuss the structure of individual problem instances. The structure of a GSP instance is displayed in a "structure tree." The smaller the "weighted depth" or "channelwidth" of the structure tree for a GSP instance, the faster the instance can be solved by any one of several generic algorithms.
2. The GSP model extends easily so as to apply to hierarchically specified problems and enables solutions to instances of such problems to be found directly from the specification rather than from the (often exponentially) larger specified object.

Key words. GSP, structure tree, SAT, separator, tree decomposition, treewidth, bounded bandwidth, nonserial optimization, hierarchical specifications

AMS subject classifications. 68Q25, 90C27

1. Introduction.

It has proven very useful to model computational problems as language-recognition problems. Under this paradigm, a computational problem is expressed as the question "Does an input string belong to a specified language?" This approach enables the application of concepts from automata theory including the concepts of P, NP, NP-completeness etc., [8, 15, 10]. In this paper, we develop a different model for computational problems, an algebraic model we call the GSP model. GSP is an abbreviation of "generalized satisfiability problem." In this model, a computational problem is expressed as the question "given a set of variables and terms using these variables, what is the value of a certain sum of products on these terms?" We call this collection of variables and terms a "formula."

The advantage of representing a problem instance as a formula is that problem instances then have a combinatorial structure determined by which variables appear in which terms. Using an appropriate (nonunique) representation of this structure, a certain kind of "subproblem independence" is displayed in a manner that can be exploited by any of several algorithms to speed up the computation of a formula's value.

We call the data structure used to display formula structure a "structure tree." We give several algorithms which take a formula and structure tree as input and compute the sum-of-products "value" of the formula. In these algorithms, the order of operations and the flow of control are determined exclusively by the problem structure as displayed in the structure tree. The operations performed and values manipulated are determined exclusively by the meaning of the terms and specific "sum" and "product" operators which define the formula value. The algorithms are

† Department of Computer Science, State University of New York at Albany, Albany, NY 12222.

"generic" in the sense that they can be described with Pascal-like pseudocode using uninterpreted operators and functions.

The complexity of the generic algorithms can be expressed in terms of the numbers of each kind of operation performed. These numbers depend primarily on the tree's "weighted depth" or "channelwidth" as defined in §3. Some of these algorithms are exponential only in the weighted depth and others are exponential only in channelwidth. This can be a significant improvement over the generic brute-force method, which is exponential in the total number of variables. Although the weighted depth is never smaller than the channelwidth, the weighted-depth algorithms have an advantage in that they use only linear space. In contrast, the channelwidth methods use space exponential in channelwidth.

We also introduce a concept of hierarchically specified formulas whereby large formulas are constructed in a recursive manner from copies of smaller formulas. This mimics the way larger circuits are constructed from smaller circuits and large graphs are sometimes constructed using copies of smaller graphs. We show that the value of such formulas can be found using generic algorithms whose complexity depends only on the size and structure of the description. The formula description can be exponentially smaller than the formula it describes.

Sometimes there is an (often nonunique) assignment that can be associated with a formula's value—for example, the assignment which minimizes a certain sum or which satisfies a conjunction of clauses. In these cases, generic enhanced algorithms will produce an assignment along with a value. These problems include all those problems known as "nonserial optimization problems" (NOPs) as well as constrained versions of these problems. We note that all {0,1}-linear programming problems are included among the constrained NOPs.

As the name suggests, the GSP applications also include problems centered around the set of assignments which satisfy a set of Boolean-valued terms. Not only is satisfiability itself modeled, but so are the other questions often asked about such problems. Some of these questions are how many satisfying assignments does the formula have, is the number of satisfying assignments even or odd, what is the maximum number of terms which can be simultaneously satisfied, and what is the maximum number of ones in a satisfying assignment? From the GSP viewpoint, these questions are nearly trivial variations on the same problem. The structure of each problem instance is the same regardless of the question asked and the only difference is whether the terms are thought of as mapping into TRUE and FALSE or into other values appropriate to the question asked. We note that among the problems modeled are complete problems in the complexity classes NP, CoNP, #P [34], D^P [23], OPT-P [16], MAX SNP [24], MAX Π_1 [22], PSPACE [17], and #PSPACE [4].

We have also found that the GSP model can be applied easily to many graph problems and that it clearly does not apply to certain other graph problems. Exactly which graph problems should be considered as GSPs is a nonmathematical question. There are graph problems whose semantics can only be described awkwardly and artificially as GSPs and it is a matter of taste which of these problems should be called GSPs.

A major advantage of the GSP framework is that it partitions the algorithmic considerations into four orthogonal issues: how to model the problem as a GSP, how to analyze the structure of problem instances, which generic algorithm to use, and how to implement the algebraic operations. Any of these four issues can be studied in isolation and the results then applied to the full spectrum of GSP problems.

The GSP model together with structure trees unify several general themes that have been widely used in the literature. These themes include "separator theorems" [20, 11, 33], "planarity" [18, 9, 26, 36], "graph treewidth" [1, 3, 5, 28, 2], and "bounded bandwidth" [21]. From a separator-theorem viewpoint, a structure tree can be interpreted as a method of displaying separator sets for a problem and its recursively defined subproblems. From the viewpoint of tree decompositions, the structure tree is an alternative way of displaying the same information. The GSP viewpoint "unifies" these themes in the sense that many of the techniques, especially insights into structure, can now be applied automatically to a much broader class of problems.

Our generic algorithms can be thought of as exhaustive methods modified to exploit subproblem independence. This is to be expected because the GSP model is a very general model and we are investigating methods that apply universally to all GSPs. When the generic algorithms are specialized to a particular class of formulas, it may be possible to enhance and fine tune the algorithms to exploit the semantics of the particular problem. For example, certain branches of the computation can sometimes be seen as unnecessary and thereby circumvented or pruned. Nevertheless, the gains just from subproblem independence are often very significant and sufficient to obtain many of the complexity bounds on structured problems found in the literature.

This paper is organized into 12 sections. In §2, we introduce the ideas of a formula, a formula value, and a GSP. In §3, we define structure trees and associated concepts. This section also presents the key connections between structure trees and subproblem independence, the connections which make the generic algorithms work.

In §4, we present the generic algorithms and bound the number of algebraic operations they perform.

In §5, we sketch the relationship between two parts of the structure tree, the α and β functions. These relationships suggest two approaches to finding good structure trees, namely, find a good α and construct β or find a good β and construct α. They also establish a small upper bound on the number of nodes needed for a good structure tree.

In §6, we discuss the relationships between weighted depth and channelwidth, the key parameters which determine the usefulness of a structure tree. In §7, we discuss the problem of finding good structure trees, even for instances where nothing is known about the structure in advance. The methods discussed are based on applying hypergraph techniques to a "formula hypergraph" representing the combinatorial structure of a formula.

In §8, we extend the ideas to hierarchically specified formulas. A fundamental property is proven that the hierarchical definition can, from a value standpoint, be equivalently regarded as defining an object or as defining a sequence of functions. The implications for efficient calculation of the value are presented.

In §9, we characterize the situations where a GSP has an optimal assignment in addition to a value and show how the generic algorithms can be modified to find the assignment along with the value without more than a constant multiplier on the complexity. The case of optimal assignments corresponds precisely to NOPs [30].

In §10, we discuss the concept of a "constrained GSP," in which the formula value is determined by a constrained set of formulas. We show that this concept can be reinterpreted back into the original model.

In §11, we discuss applications to Boolean satisfiability problems and their variations. We show that, from the GSP viewpoint, satisfiability, counting solutions, maximizing the number of terms satisfied, and several other variants all have the same structure and are, in fact, identical in appearance. Thus any way of solving one of these problems through good structure will apply to all these problems.

In §12, we discuss briefly the application of GSPs to graph problems. We discuss and illustrate the thesis that the key step in applying the theory to graph problems is to pick a representation of the problem as a GSP so that the GSP inherits the structure of the input graph.

Sections 9–12 demonstrate that the GSP model applies to a broad range of problems. However, the range is much broader than we have space to discuss. Additionally, it should be noted that the ideas behind subproblem independence and structure trees have natural extensions beyond GSPs [25].

The appendix gives the various algorithms discussed in the text. These algorithms incorporate major general-purpose themes in common use: top-down backtracking, top-down backtracking with table look-up or memoization, and bottom-up nonserial dynamic programming. The point of the appendix is that, in the GSP context, these themes can be coded generically using uninterpreted operators.

2. The GSP model.

Here we present a series of definitions leading to the central concept of a GSP. The GSPs are computational problems where the solution is a single value obtainable by considering all assignments to some set of finite-domain input variables. The value sought is an element of a commutative semiring (rather than just TRUE or FALSE), the semiring **times** operator is used instead of the Boolean **and** operator, and the semiring **plus** instead of the Boolean **or**.

DEFINITION 2.1. *A* commutative semiring *is specified by a* 5*-tuple* $(S, +, \cdot, 0, 1)$, *where* S *is a set containing elements* 0 *and* $1, +$ *is a commutative associative binary operator on* S *with identity* 0, $\cdot$ *is a commutative associative operator on* S *with identity* 1, $\cdot$ *distributes over* $+$ *(i.e.,* $a \cdot (b + c) = a \cdot b + a \cdot c$*), and* $1 \cdot 0 = 0$.

The identity elements are mathematically necessary so that sums and products are well defined for empty sets, namely $\sum_{a \in \phi} a = 0$ and $\prod_{a \in \phi} a = 1$. The condition $1 \cdot 0 = 0$ is really the distributive law for empty sums, namely $1 \cdot \sum_{b \in \phi} b = \sum_{b \in \phi} 1 \cdot b$.

Note that the Boolean lattice $(\{\text{FALSE}, \text{TRUE}\}, \vee, \wedge, \text{FALSE}, \text{TRUE})$ is a commutative semiring. We refer to this semiring as the *Boolean semiring.*

DEFINITION 2.2. *Given a set of variables* V, *an* assignment on V *is a pairing in which each variable* v *from* V *is paired with a value in the domain of* v. *The set of assignments to* V *will be designated by the notation* $\Gamma(V)$. $\Gamma(\emptyset)$ *contains one assignment, namely the empty set of pairs. For any assignment* γ, *we denote the variables in* γ *by* $VAR(\gamma)$ *(i.e.,* $VAR(\gamma) = V$ *if and only if* $\gamma \in \Gamma(V)$*). If* γ_1 *and* γ_2 *are assignments such that* $VAR(\gamma_1) \cap VAR(\gamma_2) = \emptyset$, *we let* $\gamma_1 + \gamma_2$ *be the assignment in* $\Gamma(VAR(\gamma_1) \cup VAR(\gamma_2))$ *formed by taking the union of the two assignments.*

Conjunction normal form (CNF) formulas can be described as a set of clauses. More generally, as in [31], a generalized CNF formula is described by a set of terms which evaluate to a Boolean value. For GSPs, we use terms which evaluate to an element of a commutative semiring. Continuing the analogy with Boolean formulas, we refer to these terms as "predicates." On occasion, we will need other kinds of "terms," including terms which behave like macros in hierarchical specifications.

DEFINITION 2.3. *A* base symbol *"f" is a symbol which has an associated integer* k *called the* arity *of "f" and as associated vector of* k *domains* $D_1, \ldots, D_k$, *where each* D_i *is a finite set. A* term *for "f" is a string of the form "*$f(x_1, \ldots, x_k)$*," where the* x_i *are variables or constants and the type of* x_i *is the domain* D_i. *If "f" is the name of a function which maps* $D_1 \times \cdots \times D_k$ *into a set* S, *any term for "f" is also called an* S-term. *If* S *is the set of elements from a semiring* R, *monoid* R, *or other algebraic object* R, *an* S*-term will also be called an* R-term. *If* R *is a commutative semiring, an* R*-term will also be called an* R-predicate *or simply a* predicate *if* R *is* *understood.*

For any term $P =$ "$f(x_1, \ldots, x_k)$," $|P|$ is defined to be $k+1$ and is called the size of P. $VAR(P)$ is defined to be the set of variables on the list $x_1, \ldots, x_k$. If γ is an assignment such that $VAR(\gamma) \supset VAR(p)$ and p is an S-term for some set S, we define $p[\gamma]$ to be the set element $f(d_1, \ldots, d_k)$, where d_i is the value assigned to variable x_i by γ. If P is a set of terms, define $VAR(P) = \cup_{p \in P} VAR(p)$.

In practice, we treat any expression as a term or predicate provided the meaning is clear. Thus we write "$x \vee z \vee \overline{y}$" instead of "$f(x, z, y)$," where symbol "$f$" denotes the function f defined by $f(v_1, v_2, v_3) = v_1 \vee v_2 \vee \overline{v_3}$.

DEFINITION 2.4. *A* formula *F is a pair (V, P), where V is a set of variables and P is a set of terms such that $V \supset VAR(P)$. If P is a set of S-terms for some set S, F is also called an* S-formula; *if S is the set of elements of a semiring R, semigroup R, or other algebraic object R, F is also called an* R-formula. *If R is a commutative semiring, the* value *of F, denoted by $VALUE(F)$ is defined by*

$$VALUE(F) = \sum_{\gamma \in \Gamma(V)} \prod_{p \in P} p[\gamma].$$

The size *of F, written $|F|$, is defined to be $|V| + \sum_{p \in P} |P|$.*

The pair (V, P) is a "formula" in the same sense that a set of clauses is a CNF formula. In the case of clauses, it is understood that the clauses are to be connected by the "and" operator. For R-formulas, we understand that the terms are to be connected by the "$\cdot$" operator (i.e., think of $\prod_{p \in P} p$ as the full formula).

So far, we have placed no restrictions on the formulas to be considered. Even so, any R-formula has a value and, as we shall see, there are many generic insights that can be derived about finding values, even if the domains, functions, and semirings are uninterpreted. Indeed, this paper is mainly about such results. However, to model specific computational problems, the formulas considered must come from some specified domain.

DEFINITION 2.5. *A* problem domain *$\mathcal{D}$ is a set of R-formulas for some commutative semiring R. A formula in $\mathcal{D}$ is called a* problem instance. *The* GSP *for $\mathcal{D}$ is to take formulas F from $\mathcal{D}$ as input and produce $VALUE(F)$ as output.* □

CNF satisfiability is modeled by the GSP for the domain consisting of formulas constructed from Boolean predicates that can be described by clauses. It is easily verified that, for this domain, the value of a formula is TRUE if and only if the formula has a satisfying assignment.

Other questions about CNF formulas can be modeled simply by reinterpreting the functions defined by the clauses. To model the problem of counting the number of satisfying assignments, take the semiring of nonnegative integers $(N, +, \cdot, 0, 1)$ and let a clause have the integer value 0 when an assignment makes it false and integer value 1 when an assignment makes it true. A product is 1 when an assignment satisfies all clauses and 0 otherwise and so the sum of products equals the number of assignments.

Notice how V is a nontrivial consideration when counting solutions. For example, if $P = \{$"$\overline{x} \vee y$","$x \vee \overline{z}$"$\}$, then $F_1 = (\{x, y, z\}, P)$ has four solutions, whereas $F_2 = (\{w, x, y, z\}, P)$ has eight solutions.

Most of what we say about formulas has nothing to do with problem domains. For example, we can analyze a formula's structure and find its value without regard to which problem domain it was taken from. Every formula, in fact, belongs to many problem domains. Thus we often make reference to GSPs and formulas without mention of a problem domain.

One way to solve a GSP is to use Algorithm 1, given in the appendix. This program has an inner loop which computes products for individual assignments and an outer loop which sums these products. It is best described as the "brute-force method." The program is "generic" in the sense that it works independently of any particular semiring or problem domain. We can understand the complexity of this algorithm by counting operations. If each variable has a domain of size D, there are $|P| \cdot D^{|V|}$ "multiplications," $D^{|V|}$ "additions," and $D^{|V|}$ evaluations of each predicate. Assuming a unit cost for each "+" and "$\cdot$" operation and a cost k for evaluating k-ary functions, the above counts imply a $\Theta(|F| \cdot D^{|V|})$ time complexity.

When the semiring and symbol sets of the problem domain are both finite, the above cost assumptions are reasonable. Infinite semirings or symbol sets are not necessarily a problem since the set of values which arise while solving a given problem instance is finite—for example, if we are trying to count the number of solutions, the number of bits involved is at most $|F|$. In any case, we will be content to count operations. Issues concerning the representation of semirings, the complexity of performing semiring operations, or the complexity of evaluating functions are mostly outside the scope of this paper.

Although we require that all variable domains be finite, the number of the domains need not be finite. In particular, it is sometimes useful to allow formula variables to take on $|V|$ values. In such cases, we encounter running times such as $\Theta(|F| \cdot |V|^{|V|})$ or, equivalently, $\Theta(|F| \cdot 2^{|V| \cdot \log V})$.

3. Structure trees. Given a formula $F = (V, P)$, we would like to compute $VALUE(F)$ faster than by the exhaustive method of Algorithm 1. We do not know how to do this in general but we can do it better if we can associate the formula with a suitable "structure tree" as defined below. The structure tree can be thought of as an organization of the formula which displays subproblem independence. This independence can be exploited in several ways, as given in §4, to compute the value. In this section, we present the structure tree concept and certain algebraic equations which explain the correctness of the faster algorithms given in §4. When we use the term "ancestor" and "descendant," we consider any tree node to be an ancestor and a descendant of itself.

DEFINITION 3.1. *Given a formula $F = (V, P)$, define a* structure tree S for F *to be a triple (T, α, β), where*

1. *T is a rooted tree with node set N,*
2. *$\alpha : V \longrightarrow N$ gives the* variable association,
3. *$\beta : P \longrightarrow N$ gives the* predicate association,
4. *for all y in V and p in P, if $y \in VAR(p)$, then $\alpha(y)$ is an ancestor of $\beta(p)$ in T.*

There are several concepts pertaining to the nodes of the structure tree that are needed later. We present these in the next definition.

DEFINITION 3.2. *Let $F = (V, P)$ be a formula and $S = (T, \alpha, \beta)$ be a structure tree for F with node set N. For each node n, define the following:*

1. *$A(n) = \{y \in V \mid \alpha(y) = n\}$, the variables* associated *with n.*
2. *$B(n) = \{p \in P \mid \beta(p) = n\}$, the predicates* associated *with n.*
3. *$AD(n)$ is the union of the $A(n')$ such that n' is a descendant of n.*
4. *$BD(n)$ is the union of the $B(n')$ such that n' is a descendent of n.*
5. *y in V is a* branch variable *at node n if and only if $\alpha(y)$ is an ancestor of n. Let $BV(n)$ be be the set of branch variables at n.*
6. *y in V is a* channel variable *at node n if and only if y is a branch variable*

and either (i) $n = \alpha(y)$ *or* (ii) *there is a* p *in* P *such that* y *is in* $VAR(p)$ *and* $\beta(p)$ *is a descendant of* n. *Let* $CV(n)$ *be the set of channel variables at* n.

In (6), case (i) is implied by case (ii) whenever y appears in some predicate. Case (i) insures that every variable is a channel variable of at least one node, an assumption necessary for certain proofs.

Intuitively, the nodes $\alpha(y)$ and $\beta(p)$, where y is in $VAR(p)$, delineate the "scope" of variable y and $CV(n)$ is the set of variables whose values must be "channeled" through n to connect $\alpha(y)$ and $\beta(p)$.

Example. Figure 1 shows a structure tree for formula $(\{w, x, w, z\}, \{$"$f(x, y)$," "$f(x, z)$," "$f(x, w)$," "$f(v, w)$"$\})$. The figure shows the sets $A(n)$, $B(n)$, $BV(n)$, and $CV(n)$ for each node n. The functions α and β can be inferred from A and B (e.g., $\alpha(x) = b$ because $x \in A(b)$).

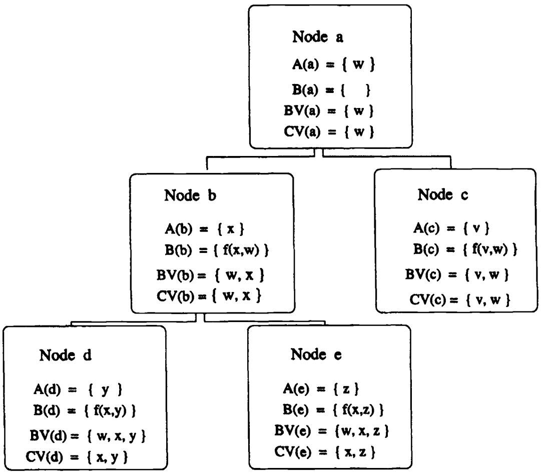

FIG. 1. *Structure tree for* $(\{w, x, y, z\}, \{f(x, w), f(x, y), f(x, z), f(v, w)\})$.

The algorithms described in the next section take a structure tree as part of their input and the complexities of these algorithms are characterized in terms of the parameters "weighted depth" and "channelwidth" defined as follows.

DEFINITION 3.3. *If* S *is a structure tree with node set* N, *we define* $WD(S)$, *the* weighted depth *of* S, *to be the maximum of* $\{|BV(n)| \mid for\, n \in N\}$. *We define* $CW(S)$ *to be the maximum of* $\{|CV(n)| \mid for\, n \in N\}$.

If F *is a formula, the minimum weighted depth over all structure trees for* F *is called the* weighted depth *of* F. *The minimum channelwidth over all structure trees for* F *is called the* channelwidth *of* F.

In the example, the weighted depth of (T, α, β) is 3 and the channelwidth is 2. There is another structure tree for F (with $\alpha(x)$ at the root) which also has weighted depth 3, but no structure tree has a smaller weighted depth. Therefore the weighted depth of the formula is 3. The channelwidth can never be less than the number of variables in a predicate so we know at once that channelwidth 2 cannot be improved upon.

Certain relationships among the concepts introduced above are needed to prove the correctness of various formulas and procedures given later. They are given by the following.

LEMMA 3.4. *Let* $F = (V, P)$ *be a formula,* $S = (T, \alpha, \beta)$ *a structure tree for* F, *and n a node of T. Then the following hold:*

1. $VAR(BD(n)) \subset CV(n) \cup AD(n)$,
2. $AD(n) \cap VAR(B(n)) \subset A(n)$, *and*
3. *for all children n' of n, $AD(n) \cap VAR(BD(n')) \subset A(n) \cup AD(n')$.*

Proof. These are all consequences of Definition 3.1(4). To prove (1), let x and p be such that $p \in BD(n)$ and $x \in VAR(p)$. Since $\alpha(x)$ must be above $\beta(p)$, $\alpha(x)$ is either above n or below n. In the case that $\alpha(x)$ is above, x will be in $CV(n)$ by definition. In the case that $\alpha(x)$ is below, x will be in $AD(n)$ by definition.

To prove (2), let x and p be such that $p \in B(n)$ and $x \in VAR(p)$. By definition, $\beta(p) = n$ so $\alpha(x)$ must be at or above n. If $\alpha(x) \in AD(n)$, $\alpha(x)$ also must be at n or below. Therefore, $\alpha(x) = n$.

To prove (3), let x and p be such that $p \in BD(n')$ and $x \in VAR(p)$. If x is also in $AD(n)$, then $\alpha(x)$ is in the subtree of T with root n and $\alpha(x)$ must be on the branch from n to $\beta(n)$, the branch going through n'. This implies that $\alpha(x)$ is at the root itself (i.e., $x \in A(n)$) or in the subtree with root n' (i.e., $x \in AD(n')$). □

So far, the concepts in this section are combinatorial concepts having nothing to do with the interpretation of the terms. That is, they depend only on memberships in the sets $VAR(p)$. This means that the structure of a formula, namely its structure trees, weighted depth, channelwidth, etc., is independent of the semantics of the formula. Hence the structural analysis of formulas (as in §7) can be carried out orthogonally to any consideration of the meaning of the formula.

Now we introduce concepts which require that the formulas be R-formulas for some semiring R. These concepts connect structure trees with formula evaluation.

DEFINITION 3.5. *Let $S = (T, \alpha, \beta)$ be a structure tree for formula $F = (V, P)$, let n be a node of T, and let γ be any assignment such that* (1) $VAR(\gamma) \cap AD(n) = \emptyset$ *and* (2) $VAR(\gamma) \cup AD(n) \supset VAR(BD(n))$. *Then let $E(n, \gamma)$ be the semiring member defined by*

$$E(n,\gamma) = \sum_{\gamma' \in \Gamma(AD(n))} \prod_{p \in BD(n)} p[\gamma + \gamma'].$$

The two conditions of the definition are necessary and sufficient for the expression to be well defined. Condition (1) is needed so that $VAR(\gamma') \cap VAR(\gamma) = \emptyset$, as required in Definition 2.2. Condition (2) is needed so that $VAR(\gamma + \gamma') \supset VAR(p)$ for all predicates p in the expression, as required in Definition 2.3. $VALUE(F)$ is identical to $E(r, \emptyset)$, where r is the root of the structure tree. $E(n, \gamma)$ can also be described as the value of subproblem $(AD(n), BD(n)[\gamma])$, where the notation $BD(n)[\gamma]$ represents the set of predicates obtained from $BD(n)$ by replacing variables from $VAR[\gamma]$ by their assigned values.

The formula in Definition 3.5 suggests an exhaustive method for computing $E(n, \gamma)$. The next result shows that $E(n, \gamma)$ can be computed from certain values associated with the children of n, values which can be viewed as solutions to subproblems. This key result is needed to prove the correctness of the generic algorithms in §4.

THEOREM 3.6. *If F, S, γ, and n are as defined in Definition* 3.5 *and node n has k children $n_1, \ldots, n_k$, then*

$$E(n,\gamma) = \sum_{\gamma' \in \Gamma(A(n))} \left(\prod_{p \in B(n)} p[\gamma + \gamma'] \right) \cdot \prod_{i=1}^{k} E(n_i, \gamma + \gamma').$$

Proof. We first prove that the $p[\gamma + \gamma']$ in the given expression are well defined. We know that $VAR(\gamma') = A(n) \subset AD(n)$ and so $VAR(\gamma') \cap VAR(\gamma) = \emptyset$ follows from condition (1) of Definition 3.5, and thus $\gamma + \gamma'$ is well defined. Because $B(n) \subset BD(n)$ and because of Lemma 3.4(2), condition (2) of Definition 3.5 implies $VAR(p) \subset VAR(\gamma + \gamma')$. Thus $p[\gamma + \gamma']$ is well defined.

Now consider if n_i and γ satisfy Definition 3.5. Because $AD(n_i) \subset AD(n)$ and $AD(n_i) \cap A(n) = \emptyset$, condition (1) for n_i and γ follows from condition (1) for n and γ. From Lemma 3.4(3), condition (2) for n and γ, and $BD(n_i) \subset BD(n)$, one can derive condition (2) for n' and γ.

Now that the right-hand side of the equation in the theorem has been shown to be well defined, we prove the equality by induction. If n has no children, $A(n) = AD(n)$, $B(n) = BD(n)$, and the equation is identical to Definition 3.5.

Finally, to prove the inductive step, substitute Definition 3.5 into both sides of the equation in the theorem. Applying the distributive and commutative laws to move products inside of sums, and using the two identities given below, the right-hand side can be transformed into the left-hand side. If V_1 and V_2 are disjoint sets of variables and P_1 and P_2 disjoint sets of predicates such that $V_i \supset VAR(P_i)$, the first identity is

$$\sum_{\gamma_1 \in \Gamma(V_1)} \sum_{\gamma_2 \in \Gamma(V_2)} \prod_{p \in P_1 \cup P_2} p[\gamma_1 + \gamma_2] = \sum_{\gamma \in \Gamma(V_1 \cup V_2)} \prod_{p \in P_1 \cup P_2} p[\gamma].$$

This identity holds because γ is in $\Gamma(V_1 \cup V_2)$ if and only if there are γ_1 in $\Gamma(V_1)$ and γ_2 in $\Gamma(V_2)$ such that $\gamma = \gamma_1 + \gamma_2$. For any γ_1 in $\Gamma(V_1)$ and γ_2 in $\Gamma(V_2)$, the second identity is

$$\left(\prod_{p \in P_1} p[\gamma_1]\right) \cdot \left(\prod_{p \in P_2} p[\gamma_2]\right) = \prod_{p \in P_1 \cup P_2} p[\gamma_1 + \gamma_2].$$

This identity holds because $p[\gamma_i] = p[\gamma_1 + \gamma_2]$ for all p in P_i, the value of p being independent of the values assigned to variables not in $VAR(p)$. □

Notice that the above proof makes use of each of the commutative, associative, and distributive properties of the binary operators. This explains why commutative semirings are the natural algebraic objects for the GSP model.

4. Algorithms based on structure trees. In this section, we discuss three algorithms (located in the appendix) for the GSP. Each algorithm requires that both a formula F and a structure tree for F be given as input. All three are "generic" in that they apply to all GSPs regardless of the problem domains. There are two main conclusions from this section. One is that structure trees are useful for organizing calculations for three general approaches, namely backtracking, backtracking with table look-up, and dynamic programming. The second is that weighted depth and channelwidth are the critical parameters in bounding the number of operations these algorithms perform.

The first algorithm is Algorithm 2. We refer to this algorithm as "generalized backtracking" since it evaluates particular partial assignments by considering all extensions and then "backs up" to try the next partial assignment. The key facts about this algorithm are as follows.

LEMMA 4.1. *When computation is initiated by calling $EVALUATE(r)$ from Algorithm 2, where r is the root of a structure tree for formula F, then the following hold for each node n:*

1. *When EVALUATE(n) is called, variables from $BV(n) - A(n)$ have an assignment γ_0.*
2. *EVALUATE(n) returns $E(n, \gamma_0)$.*
3. *EVALUATE(n) is called $|\Gamma(BV(n) - A(n))|$ times.*
4. *Summed over all calls, statements in the outer loop are executed $|\Gamma(BV(n))|$ times.*
5. *EVALUATE(r) returns $VALUE(F)$.*

Proof. Statement (1) is proved by induction starting from root r. $BV(r) = A(r)$ by definition so $BV(n) - A(n)$ is empty and trivially has an assignment. The assignment to $BV(n) - A(n)$ is extended by the "FOR statement" to an assignment to $BV(n)$ before the procedure is applied to child n' of n. But $BV(n)$ is $BV(n') - A(n')$ (this is immediate from Definition 3.2) and so (1) holds.

Statement (2) is now immediate because Algorithm 2 is a straightforward implementation of the formula in Theorem 3.6.

Whenever statement (3) is true, statement (4) must also be true since the outer loop is executed $|\Gamma(A(n))|$ time per call and multiplying the number of calls as given in statement (3) by $|\Gamma(A(n))|$ gives statement (4).

Statement (3) can now be proven by induction. It is true of the root r since *EVALUATE*(r) is called once and $BV(r) - A(r)$, being empty, has exactly one assignment. Now assume that statements (3) and hence (4) are true for node n and consider any child n' of n. *EVALUATE*(n') is called only from *EVALUATE*(n) and is done once each time the procedure goes through its outer loop. By statement (4), this happens $|\Gamma(BV(n))|$ times and $BV(n) = BV(n') - A(n')$. Thus statement (3) holds for n'.

Statement (5) is immediate since $E(r, \emptyset)$ is $VALUE(F)$ by Definition 3.5. □

From Lemma 4.1, we can bound the number of operations used to solve a GSP instance as follows.

THEOREM 4.2. *Let $F = (V, P)$ be a formula where each variable in V takes on at most D values. Let T be a structure tree for F having m nodes and weighted depth WD. If the procedure of Algorithm 2 is used with F and T, then*

1. *the number of "$\cdot$" operations is at most $(m + |P|) \cdot D^{WD}$;*
2. *the number of "+" operations is at most $m \cdot D^{WD}$;*
3. *each p in P is evaluated at most D^{WD} times.*

Proof. We consider part (3) first. A given predicate p is evaluated only when *EVALUATE* is called at node $\beta(p)$. The evaluation of p is done in the outer loop and so is done $|\Gamma(BV(n))|$ times by Lemma 4.1(4). This quantity is no greater than D^{WD}, and part (3) is proven.

The "$\cdot$" operation is performed once for each predicate evaluation and once for every procedure call (except the original call). From part (3), there are at most $|P| \cdot D^{WD}$ predicate evaluations and from Lemma 4.1(3), there are at most $m \cdot D^{WD}$ procedure calls.

The "+" operation is done once each time through the outer loop. By Lemma 4.1(4), this is at most D^{WD} per node, and hence part (2) is proven. □

In the next section, it is shown that, without changing WD, the structure tree T can be assumed to satisfy $m \leq 2 \cdot |V|$ and $m \leq 2 \cdot |P|$. Thus the bounds in parts (1) and (2) can be described as $3 \cdot |P| \cdot D^{WD}$ and $2 \cdot |V|^{WD}$ or $2 \cdot |P|^{\cdot WD}$. Under the unit-cost assumptions in §2, the time of the algorithm is $\Theta(|F| \cdot D^{WD})$, the largest contribution being the cost of evaluating predicates at k units per single k-ary function evaluation.

The space requirement is minimal. In addition to the space needed to store the structure tree, the procedure has a global variable for each variable in $|V|$, where each such variable must store a corresponding domain value, and two local variables x and y which must store any semiring elements generated by the procedure. Actually, only $O(WD)$ space is needed for variables since variables from different branches can share locations. We next consider Algorithm 3, the second of the three algorithms discussed in this section. It works similarly to Algorithm 2 except that tables are kept to remember the results of each procedure call and the tables are consulted at the beginning of any call to determine if the result the call can be read from a table rather than be recomputed. The key facts about this procedure are as follows.

LEMMA 4.3. *When computation is initiated by calling $EVALUATE(r)$ from Algorithm* 3, *where r is the root of a structure tree for formula F, then the following hold for each node n:*

1. *When $EVALUATE(n)$ is called, variables from $CV(n) - A(n)$ have an assignment γ_0;*
2. *$EVALUATE(n)$ returns $E(n, \gamma_0)$;*
3. *If n_0 is the parent of node n, then $EVALUATE(n)$ is called at most $|CV(n_0)|$ times;*
4. *$EVALUATE(r)$ returns $VALUE(F)$.*

Proof. To prove statement (1), observe that variables in $BV(n) - A(n)$ have assignments for the same reason as in Lemma 4.1(1). The result here is then immediate because $BV(n) \supset CV(n)$

To prove statement (2), first observe that γ_0 does meet the conditions imposed by Definition 3.5 because Definition 3.5(2) is implied by Lemma 3.4(1). Then observe that Algorithm 3 is a straightforward implementation of the formula in Theorem 3.6.

To prove statement (3), observe that $EVALUATE(n)$ is only called from inside $EVALUATE(n_0)$, and is only invoked at n for those calls at n_0 in which an assignment to $CV(n_0) - A(n_0)$ is seen for the first time. Those calls at n_0 which do invoke $EVALUATE(n)$ do so $|\Gamma(A(n_0))|$ times, once for each time through the variables loop. Multiplying the number of times the variables loop is used by the number of loop iterations gives $|\Gamma(CV(n_0))|$.

Statement (4) is immediate from statement (2) since $E(r, \emptyset)$ is $VALUE(F)$ by Definition 3.5. □

From Lemma 4.3, we can bound the number of operations used to solve a GSP instance via Algorithm 3.

THEOREM 4.4. *Let $F = (V, P)$ be a formula where each variable in V takes on at most D values. Let T be a structure tree for F having m nodes and channelwidth CW. If Algorithm* 3 *is used with F and T, then*

1. *the variable number of "$\cdot$" operations is at most $(m + |P|) \cdot D^{CW}$;*
2. *the number of "$+$" operations is at most $m \cdot D^{CW}$;*
3. *each p in P is evaluated at most D^{CW} times.*

Proof. This follows from Lemma 4.3 in the same way Theorem 4.2 follows from Lemma 4.1. □

Under the cost assumptions of the previous discussion, the time of the algorithm is $\Theta(|F| \cdot D^{CW})$. This is usually an improvement over the first algorithm since CW is never larger than WD. However, the space requirement now includes space fom m tables whose size could be as large as D^{CW}.

The third algorithm considered in this section is dynamic programming (Algorithm 4). The idea behind this algorithm is to work bottom-up in the structure tree, computing each table T_n (as defined above and in Algorithm 3) sometime after the tables for the children of n have been constructed. This algorithm also satisfies Theorem

4.4. We omit further analysis.

Backtracking with table look-up does hold a practical advantage over dynamic programming in that backtracking may leave some entries of the tables T_n uncomputed. On the other hand, dynamic programming can be organized to be more space efficient since tables can be discarded once the parent's table has been constructed. This is not a substantial difference from a complexity viewpoint.

5. Relationships between α and β. The relationship between α and β has implications for finding good structure trees and for bounding the number of nodes which must be considered by the generic algorithms. We omit proofs because they are easy and can be found in [32]. For ease of exposition, we assume that each variable of a formula appears in some predicate and that each predicate has at least one variable. Accommodating trivial variables and predicates is also discussed in [32].

Given a formula $F = (V, P)$, a rooted tree T, and a suitable α mapping V to tree nodes, a mapping β is easily constructed so that (T, α, β) is a structure tree for F. By "suitable," we mean that for each p in P there is a branch of T containing all $\alpha(y)$ for y in $VAR(p)$. This mapping β is defined by

$$\beta(p) = \text{ lowest node in } \{\alpha(x) \mid x \in VAR(p)\}.$$

In other words, $\beta(p)$ is placed as high in the tree as possible without violating Definition 3.1(4). This placement is optimal in that it gives the smallest channel variable sets. The pair (T, α) is called an *α-tree.* This concept opens an approach for finding structure trees, namely find a good α-tree and then construct the corresponding β. Given a formula $F = (V, P)$, an unrooted tree T, and an arbitrary β mapping P to tree nodes, a mapping α can be constructed, using any node as root, such that (T, α, β) is a structure tree for F. This α is defined by

$$\alpha(x) = \text{ lowest common ancestor of } \{\beta(p) \mid x \in VAR(p)\}.$$

In other words, $\alpha(x)$ is placed as low in the tree as possible without violating Definition 3.1(4). Again, this is optimal in that it gives the smallest branch-variable sets. The pair (T, β) is called a *β-tree.* This opens a second approach for finding structure trees, namely find a good β-tree and then construct the corresponding α. The mapping α constructed above has the property that a variable x is a channel variable at node n if and only if there are predicates p_1 and p_2 in P such that x is in $VAR(p_1) \cap VAR(p_2)$ and n is on a simple path between $\beta(p_1)$ and $\beta(p_2)$. This implies that channel variables can be defined by β alone and, therefore, channelwidth can be defined and computed directly from β just like weighted depth can be defined and computed directly from α.

Using the above ideas, one can modify a structure tree (in polynomial time) by moving various $\alpha(x)$ down the tree, moving various $\beta(p)$ up the tree, and deleting nodes n with only one child where $A(n)$ and $B(n)$ are empty. The result is a "compact" structure tree defined as follows.

DEFINITION 5.1. *Let $F = (V, P)$ be a formula in which every predicate has a variable and every variable belongs to some predicate. Let $S = (T, \alpha, \beta)$ be a structure tree for F. The structure tree is called* compact *if and only if the following conditions hold:*

1. *for v in V, $\alpha(v)$ is the lowest common ancestor of $\{\beta(p) \mid v \in VAR(p)\}$;*
2. *for p in P, $\beta(p)$ is the lowest node in $\{\alpha(v) \mid v \in VAR(p)\}$;*
3. *for nodes n in T, $A(n) = \emptyset$ or $B(n) = \emptyset$ implies n has at least two children.* □

The compact structure tree always has fewer nodes, smaller branch-variable sets, and smaller channel-variable sets than the original. Thus all the generic algorithms given here run more efficiently on compact trees. Compactness bounds the number of nodes as follows.

PROPOSITION 5.2. *If $S = (T, \alpha, \beta)$ is a compact structure tree for formula $F = (V, P)$ and N is the set of nodes of T, then $|N| \leq 2 \cdot |V|$ and $|N| \leq 2 \cdot |P|$.*

6. Relationship between weighted depth and channelwidth. There is a tradeoff between the algorithm based on weighted depth (Algorithm 2) and the algorithms based on channelwidth (Algorithms 3 and 4). The weighted-depth algorithm runs in linear space whereas the others use space exponential in channelwidth. However, the number of operations performed by the weighted-depth algorithm is exponential in the weighted depth whereas the others are exponential only in the channelwidth, which might be significantly smaller. Thus the relationship between weighted depth and channelwidth is of considerable interest.

Here we summarize the relationship without proof. By definition, a channel variable is also a branch variable so that, in any tree, the channelwidth is never more than the weighted depth. Also, it is easy to construct a formula and structure tree such that the structure tree has channelwidth 2 and arbitrary weighted depth. However, given a structure tree of good channelwidth, a tree of reasonably good weighted depth can be constructed easily as stated in the next theorem.

THEOREM 6.1. *Given a formula $F = (V, P)$ and a structure tree $S = (T, \alpha, \beta)$ for F with channelwidth CW, a structure tree $S' = (T', \alpha', \beta')$ for F can be constructed in polynomial time such that the weighted depth of S' is at most $CW \cdot (\log_2(|N|) + 1)$, where N is the set of nodes of T and also of T'.*

The theorem can be proven with a restructuring algorithm to construct T' from T given in [32]. It first changes the root of the tree to be one of the "middle nodes." (By middle node we mean a node with minimum maximum distance to any other node.) It then recursively applies this idea to the subtrees represented by each child of the new root r and edges from r are changed so that the roots of the restructured subtrees become the new children of r. The result is a new tree having the same node set as the original. The function β from the original structure tree is retained and a new α is computed using the principles of §5. Restructuring can also be achieved with a straightforward generalization of an algorithm from [6] so that weighted depth is $O(CW \cdot \log(|N|))$ and simultaneously channelwidth is O(CW). The new tree in this case has more nodes than the old.

7. Finding good structure trees. The algorithms described in §4 assume that a structure tree for the input formula is already known. It is therefore of considerable importance to understand the complexity of finding good structure trees since we would like to apply these techniques to situations where the structure tree is not given in advance. This includes situations where other structural information is known in advance.

As pointed out in §3, the concept of the structure tree for a formula is independent of the formula and depends only on a knowledge of which variables belong to which predicates. This information can be represented by a "formula hypergraph," defined as follows.

DEFINITION 7.1. *If $F = (V, P)$ is a formula, the* formula hypergraph *$HG(F)$ for F is the hypergraph (N, E), where N has one node n_v for each variable v in V, E has one edge e_p for each predicate p in P, and $n_v \in e_p$ if and only if $v \in VAR(p)$.*

The formula hypergraph provides links between the structure of formulas and previously studied structural concepts from graph and hypergraph theory. Some of these connections are as follow.

THEOREM 7.2. *Let $\mathcal{D}$ be a problem domain and let $\mathcal{H} = \{HG(F) \mid F \in \mathcal{D}\}$ be the set of hypergraphs for formulas in $\mathcal{D}$. Then the following hold:*

1. *If the hypergraphs in $\mathcal{H}$ have treewidth at most k, the formulas in $\mathcal{D}$ have channelwidth at most $k+1$.*
2. *If the hypergraphs in $\mathcal{H}$ are planar and each edge has at most m nodes, then each formula F in $\mathcal{D}$ has $O(\sqrt{|F|})$ weighted depth.*
3. *If the hypergraphs in $\mathcal{H}$ have bandwidth at most d and each edge has at most m nodes, then formulas in $\mathcal{D}$ have channelwidth at most $d \cdot m$.*
4. *If the hypergraphs in $\mathcal{H}$ satisfy a n^r recursive separator theorem* [19] *for $0 < r < 1$ and each edge has at most m nodes, then each formula F in $\mathcal{H}$ has weighted depth $O(n^r)$.*

Proof. Since we are not providing the definitions which appear elsewhere in the literature, we do not provide a proof. However, the results are almost immediate from the definitions. □

Theorem 7.2 together with the general theory make many insights available just by showing a problem can be modeled as a GSP. For example, it can be immediately confirmed that the planar version of such a problem can be solved in $2^{O(\sqrt{n})}$ operations and linear space (plus the polynomial time needed to find a structure tree of weighted depth $O(\sqrt{n})$ using planar separators).

We now discuss the problem of finding structure trees in the general situation. The methods discussed all start with the idea that the structure tree concept can be applied directly to hypergraphs using α to map nodes and β to map hyperedges and condition 4 of Definition 3.1 becoming "node v in edge p implies $\alpha(v)$ is above $\beta(e)$." The methods all find a structure tree for $HG(V, P)$ and then return the corresponding formula structure tree.

If $F = (V, P)$ is a formula and $V_0 \subset V$ and $P_0 \subset P$, we use the notation $[V_0, P_0]$ to represent the hypergraph with node set V_0 and edge set $\{VAR(p) \cap V_0 \mid p \in P_0\}$. Observe that $HG(V, P) = [V, P]$. It is easy to verify that, for any node n of a structure tree for $[V, P]$, the subtree with root n is a structure tree for $[AD(n), BD(n)]$. This enables a recursive approach to finding structure trees, namely the following:

1. Pick a set $V_0 \subset V$.
2. Construct a root node r.
3. Set $A(r) = V_0$ and $B(r) = \{p \in P \mid VAR(p) \subset V_0\}$.
4. Find the connected components of $[V - A(r), P - B(r)]$.
5. Construct a structure tree for each component and attach that tree to r.

The preferred choice of V_0 are sets which cause the graph to "separate" in step 4 into two or more connected components of substantial size. Under the right circumstances, a good choice of V_0 can be found by a "separator theorem" as in [20] or [11] and a structure tree built from recursive applications of the separator theorem. However, separator theorems do not have enough generality to explain all the circumstances where good separator trees arise. For example, recursive $O(n^r)$ separator theorems hold only for classes of graphs where the number of edges for graphs in the class is linear in the number of nodes (see Theorem 12 of [19]).

In [32], we incorporate exhaustive trials of all possible V_0 into the recursive approach. The result is an algorithm which takes graph (V, P) and integer d as input and, in $O(|F| \cdot |V|^d)$ time and polynomial space, determines if the given graph has a structure tree of weighted depth d and finds such a structure tree if one exists. Because this time bound is somewhat close to the $O(|F| \cdot D^d)$ operations, which suffice to solve a problem if a structure tree of weighted depth d is given, there are some interesting implications about exploiting structure even if no structure tree is given and no separator theorem applies.

Consider the implications of the above for SAT. If we allow time $|F|$ to evaluate a CNF formula F, SAT is solved by exhaustive search in $O(|F| \cdot 2^{|V|})$ time. In contrast, the above remarks imply the following result.

THEOREM 7.3. *SAT can be solved in* $O(WD \cdot |F| \cdot 2^{WD \cdot \log |V|})$ *time.*

Proof. Given F, apply the algorithm cited above repeatedly for $d = 1$, $d = 2$, ... until a separator tree is found. This happens when $d = WD$. Then apply Algorithm 2. Because Boolean operations can be performed in constant time, Theorem 4.2 implies the result. □

This last theorem shows that merely the *existence* of a good weighted-depth structure tree is sufficient to solve a SAT instance quicker than trying all cases, even though we are not given the structure tree as part of the input. With adjustments on the time bound for the domains and semirings involved, this idea applies to all GSPs.

Structure trees for hypergraphs have essentially the same information content as tree decompositions for hypergraphs. We now briefly explain this connection for readers familiar with tree decompositions (defined for graphs in [1]). A structure tree becomes a tree decomposition simply by taking $X(n) = CV(n)$ and viewing the tree as undirected. In the other direction, pick $\beta(p)$ to be one of the nodes such that $VAR(p)$ is in $X(n)$ and convert the resulting β-tree into a structure tree by the method of §5.

Because of the tight coupling of structure trees and tree decompositions, the tree-decomposition literature is quite useful for understanding structure trees. The intent of most papers on treewidth is to study graphs with bounded treewidth. The motivation for bounded treewidth is to obtain polynomial algorithms. (Bounded treewidth implies bounded channelwidth, which by Theorem 4.4 implies polynomial time when semiring operations are easy.) However, most of the results we have seen from the bounded-treewidth literature do generalize easily to hypergraphs and, except for conclusions about polynomial time, do not depend on the treewidth being of fixed size. We have already mentioned a procedure from [6] in §6. From [1], we infer that the problem of deciding if a formula has channelwidth less than some k is NP-complete, even if each predicate has only two variables. The literature has a succession of papers with procedures for finding tree decompositions (if any) for some given k. These procedures generalize without much difficulty to hypergraphs. The papers include [1, 27–29] and most recently [7]. The algorithms in [1] and [28] take space exponential in k (no problem when k is bounded). The algorithms in [29] and [27] are approximate in that they only find the best treewidth within a factor of 4. The approximation algorithm in [27] takes $O(27^{CW} \cdot CW \cdot |F|)$ time and polynomial space. The algorithm in [7] is exact and linear for fixed treewidth. However, its time is exponential in the cube of the treewidth. A treewidth algorithm explicitly for hypergraphs is given in [32]. It finds a structure tree of channelwidth k (if any) in $O(|F| \cdot |V|^{k \cdot \log |P|})$ time and uses only polynomial space. The algorithms imply that statements analogous to Theorem 7.3 can be made about channelwidth.

8. Hierarchically specified formulas. In this section we look at how formulas can be specified hierarchically using a sequence of templates. These templates can be visualized as macros which can be used to expand a given formula into a much larger formula, a formula which can be exponentially larger than the original. The good news is that the complexity of finding the value of this large formula depends only on the size and structure of the templates.

DEFINITION 8.1. *A* template *is a 4-tuple* $(``f", V, V', P)$ *where*

1. *"f" is the* defined symbol,
2. *V is an ordered set of variables called* parameters,
3. *V' is a set of variables with $V' \cap V = \emptyset$ called* local variables,
4. *P is a set of predicates with $V \cup V' \supset VAR(P)$.*

DEFINITION 8.2. *If $t = ``f(x_1, \ldots, x_k)"$ is a term and $M = (``f", V, V', P)$ is a template defining "f" with $VAR(t) \cap V =$ and $|V| = k$, then the* expansion of t by M *is the formula $(VAR(t) \cup V', P')$, where the predicates in P' are the predicates obtained from P by replacing occurrences of variables from V with the corresponding x_i. The same formula with variables in V' renamed will also be called an* expansion of t by M.

We always assume that when several expansions are involved, local variables are renamed for individual expansions so that they are different from the variables from any other expansion by the same or any other template.

DEFINITION 8.3. *Let Φ be a set of base symbols. A* hierarchical specification H *using Φ is a sequence $M_1, \ldots, M_k$ of templates $(``f_i", V_i, V_i', P_i)$ and a* base formula (V, P), *where the terms in P_i are $\Phi \cup \{f_1, \ldots, f_{i-1}\}$-terms and the terms in P are $\Phi \cup \{f_1, \ldots, f_k\}$-terms. The* formula specified *by H is the formula obtained from (V, P) by repeatedly expanding $\{f_1, \ldots, f_k\}$-terms until only Φ-terms remain.*

We want to discuss how obtaining structure trees for templates can be used to construct a structure tree for the expanded formula. We first need a structure tree concept for templates.

DEFINITION 8.4. *If $M = (``f", V, V', P)$ is a template, a* structure tree *for M is a triple $S = (T, \alpha, \beta)$, where S is a structure tree for formula $(V \cup V', P)$ and $V \subset A(r)$, where r is the root of T.*

THEOREM 8.5. *Let $M_1, ..., M_l, F_0$ be a hierarchical specification, T_0 a structure tree for formula F_0, and T_i for $1 \leq i \leq l$ a structure tree for template M_i. Let WD_i be the weighted depth and CW_i be the channelwidth of T_i for $0 \leq i \leq l$. Let F be the formula specified by the specification. Formula F has a structure tree with weighted depth no greater than $\sum_{i=0}^{l} WD_i$ and channelwidth no greater than $max\{CW_i \mid 0 \leq i \leq l\}$.*

Proof. We first describe how to construct a structure tree for a formula obtained from just one expansion. This will imply how a tree can be constructed from a series of expansions.

Let $F_0 = (V_0, P_0)$ be a formula, $M_1 = (``f", V_1, V_1', P_1)$ be a template, and $t = ``f(x_1, \ldots, x_k)"$ a term in P_0. Let $S_0 = (T_0, \alpha_0, \beta_0)$ be a structure tree for F_0 and $S_1 = (T_1, \alpha_1, \beta_1)$ be a structure tree for M_1. Let F be the result of expanding F_0 by t. With this notation, we now describe how to construct a structure tree (T, α, β) for F from the trees for F_0 and M_1.

The tree T is the tree obtained from T_0 and T_1 by making the root of T_1 be a child of node $\beta_0(t)$ in T_0. The variables of F are by definition $V_0 \cup V_1'$ and we define $\alpha(v) = \alpha_0(v)$ for v in V_0 and $\alpha(v) = \alpha_1(v)$ for v in V_1'. For terms p in $P_0 - \{t\}$, define $\beta(p) = \beta_0(p)$. If p is a predicate of F obtained by substitution for the parameters of some p_1 in P_1, define $\beta(p) = \beta_1(p_1)$.

To verify that the constructed tree is a structure tree, we must check condition (4) of Definition 3.1. Consider now a term p from P and a variable v in $VAR(p)$. If v in V_0 and p in P_0, $\alpha(v) = \alpha_0(v)$ is above $\beta(p) = \beta_0(v)$ because $\alpha_0(v)$ is above $\beta_0(v)$. If v in V_1' and p is obtained from p_1 in P_1 by substitution, $\alpha(v) = \alpha_1(v)$ is above $\beta(p) = \beta_1(p_1)$. Finally, consider v in V_0 and p obtained from p_1 in P_1. Since v is not in $VAR(p_i)$, v must be x_i for some i. Thus $\alpha(v) = \alpha_0(v)$ is above $\beta_0(t)$ and $\beta_0(t)$ is above the root of T_1 and hence above $\beta_1(p)$, so again (4) holds.

It is easy to verify that for node n of T originally from T_0, the channel variables are the same in both S and S_1. It is also easy to verify that the channel variables of a node n from T_1 is the set obtained from the original set of channel variables by replacing arguments with the corresponding x_i. In either case, the set of channel variables at a node is no larger than the original set.

Now consider the structure tree for the full expanded formula obtained by repeated use of the above construction. Since the channel variable sets never increase, the channelwidth of the constructed tree is no larger than any of the parts. Regarding weighted depth, any branch of the constructed tree consists of segments of at most one branch from each T_i. Thus the weighted depth of the branch is no more than the sum of the individual weighted depths. □

When the Φ-terms in Definition 8.3 are R-terms for commutative semiring R, then the hierarchical specification H describes a GSP. The weighted depth and channelwidth of the formula are bounded by Theorem 8.5 and any of the methods of §4 can be applied. However, the m and $|P|$ in Theorems 4.2 and 4.4 may be exponential in the size of the specification. Thus the number of operations can be exponential is specification size, even for bounded channelwidth. We now develop an alternative where the number of operations is bounded by the size and channelwidth of the templates. The improvements come from viewing templates as defining predicate symbols.

DEFINITION 8.6. *If $M = (\text{“}f\text{”}, V, V', P)$ is a template where the terms in P are all R-terms for some commutative semiring R, then M is also called an* R-template *and the function “f” from $\Gamma(V)$ to R defined by*

$$f(\gamma) = \sum_{\gamma' \in \Gamma(V')} \prod_{p \in P} p[\gamma + \gamma']$$

is called the predicate function defined by M.

This definition enables us to view a hierarchical specification as a sequence of function definitions. The next result says that the value implied from the “function” view equals the value implied by the “macro” view.

THEOREM 8.7. *Let Φ be a set of function names for functions into commutative semiring R. Let $M_1, \ldots, M_k, F_0$ be a hierarchical specification and F the formula described by the specification. Then each M_i is an R-template and F_0 is an R-formula. Furthermore,*

$$VALUE(F_0) = VALUE(F).$$

Proof. The terms of M_1 are all Φ-terms and hence they are R-terms and M_1 thus defines a function to R. This implies that the terms of T_2 are all R-terms and so on by induction. Finally, the terms of F_0 are all R-terms because they are constructed from Φ and the function symbols defined by the templates. All that remains to be shown is the claim about values.

We first consider the case where there is just one template $T_1 = (\text{“}f\text{”}, V_1, V_1', P_1)$ and formula $F_0 = (V_0, P_0)$ has one f-term, namely $t = \text{“}f(x_1, \ldots, x_k).\text{”}$ Let $F = (V_0 \cup V_1', (P_0 - \{t\}) \cup P_1')$ be the expansion of f_0 by t, where P_1' is the set P_1 with the x_i replacing the corresponding v_i from V_1. We want to show $VALUE(F_0) = VALUE(F)$. By definition,

$$VALUE(F_0) = \sum_{\gamma_0 \in \Gamma(V_0)} \left(\prod_{p \in P_0 - \{t\}} P[\gamma_0] \right) \cdot t[\gamma_0].$$

Consider $t[\gamma_0]$, which is "$f(x_1,\ldots,x_k)$"$[\gamma_0]$. The list $x_1,\ldots,x_k$ and γ_0 imply a corresponding assignment γ_0' in $\Gamma(V_1)$ where each v_i in V_1 is assigned the value assigned to x_i by γ_0. The value of $t[\gamma_0]$ is defined to be

$$\sum_{\gamma'\in\Gamma(V_1')}\prod_{p_1\in P_1} p_1[\gamma'+\gamma_0'].$$

Now $p_1[\gamma'+\gamma_0'] = p[\gamma'+\gamma_0]$, where p is the result of replacing v_i in P_1 by the corresponding x_i. Thus $t[\gamma_0]$ can be written as

$$\sum_{\gamma'\in\Gamma(V_1')}\prod_{p_1\in P_1'} P[\gamma'+\gamma_0'].$$

Thus $VALUE(F_0)$ is

$$\sum_{\gamma_0\in\Gamma(V_0)}\left(\prod_{p\in P_0-\{t\}} P[\gamma_0]\right)\cdot\sum_{\gamma'\in\Gamma(V_1')}\prod_{p\in P_1'} P[\gamma'+\gamma_0].$$

Applying the distributive law gives

$$\sum_{\gamma_0\in\Gamma(V_0)}\sum_{\gamma'\in\Gamma(V_1')}\prod_{p\in(P_0-\{t\})\cup P_1'} p[\gamma'+\gamma_0],$$

which is $VALUE(F)$.

Having proven the result when F is the result of just one expansion, the result follows by induction. □

By treating a hierarchical specification as a sequence of function definitions, we can obtain alternative algorithms for computing the value. The most straightforward approach is to make a table for the predicate function defined by the first template M_1, then a table for the predicate defined by M_2, etc., and finally compute the value of the formula F_0. If the template values are computed with the backtracking of Algorithm 2, the space will be exponential in the arity of the templates and the number of operations will depend on the templates' weighted depths. If computed with Algorithms 3 or 4, the space will be exponential in template channelwidth which could be substantially larger, but the number of operations will be smaller depending only on channelwidth. More precisely, this case can be stated formally as follows.

THEOREM 8.8. *Let $H = (M_1,\ldots,M_k,F_0)$ be a hierarchical specification where each variable takes on at most D values. Let $(T_1,\ldots,T_k,T_0)$ be structure trees for the templates and formula of H. Let CW be the maximal channelwidth of any of the structure trees T_i. Then the value of H can be found algebraically where the number of "$\cdot$" operations, the number of "$+$" operations, and the number of predicate evaluations are bounded by $2\cdot|H|\cdot D^{CW}$.*

Proof. The method of computing the value has already been described. Because template variables are all channel variables of the root, the tables giving a value for each assignment to template parameters is the projection of the root table computed in Algorithms 3 or 4. By using compact structure trees, we can insure by Proposition 5.2 that the number of nodes in all the structure trees is no more than twice the number of specification variables. The result follows from Theorem 4.4. □

The importance of this result is that the bound contains $|H|$ instead of $|F|$, where F is the formula obtained by expanding H, a formula which can be exponentially larger than H. Finally, these observations hold for the analogous problems over any finite algebraic structure, e.g., the problems in [12].

9. Optimization problems. In this section, we consider the circumstances in which the GSP model can be used to answer questions of the following form: "given a formula (V, P), find an assignment γ_0 in $\Gamma(V)$ which results in the best value for $\prod_{p \in P} p[\gamma_0]$." Intuitively, such a γ_0 is properly referred to as an "optimal assignment." In this section, we argue that the GSP concept applies precisely to those optimization problems where the question can also be posed as a question of the form "find an assignment γ_0 in $\Gamma(V)$ which minimizes $\sum_{p \in P} p[\Gamma_0]$," and we present a generic algorithm for solving such problems. Since problems of this form are known as NOPs [30], we can say that the GSP models all NOPs.

If the value of a formula is to be an "optimal" value associated with an "optimal assignment," then the optimal assignment must (at least) satisfy the following definition.

DEFINITION 9.1. *Given an R-formula $F = (V, P)$ for commutative semiring R, an* optimal assignment *for F is an assignment γ_0 in $\Gamma(V)$ such that*

$$VALUE(F) = \prod_{p \in P} p[\gamma_0].$$

This concept of "optimal assignment" seems unrelated to any concept of "best value," but the next two propositions show that such an assignment and the value it produces are, in fact, the solution to a minimization problem.

PROPOSITION 9.2. *Let $R = (S, +, \cdot, 0, 1)$ be a commutative semiring. Then every R-formula has an optimal assignment if and only if, for all a and b in S,*

$$a + b = a \text{ or } a + b = b.$$

Proof. If the condition on R holds, then for any $a_1, \ldots, a_n$ in S, $\sum a_i = a_k$ for some k, $1 \leq k \leq n$. Since $VALUE(F)$ is a sum of assignments to $\prod_{p \in P} p$, the sum must be equal to some $\prod_{p \in P} p[\gamma_0]$ and γ_0 is an optimal assignment.

If, for some a and b, $a + b \neq a$ and $a + b \neq b$, define $f : \{0, 1\} \to S$ by $f(0) = a$ and $f(1) = b$. Let $F = (\{x\}, \{\text{"}f(x)\text{"}\})$. $VALUE(F) = a + b$ and neither of the two assignments $x = 0$ or $x = 1$ is an optimal assignment. □

It should be noted that all formulas in a problem domain might have a solution even if $a \neq a + b \neq b$ for some a and b. This is because the problem domain might not include the formula F from the proof. Nevertheless, the proposition indicates special attention should be given to the condition "$a + b = a$ or $a + b = b$." This condition takes us immediately to commutative ordered monoids and nonserial optimization.

PROPOSITION 9.3. *If $R = (S, +, \cdot, 0, 1)$ is a commutative semiring in which $a + b = a$ or $a + b = b$ for all a, b in S, then the binary relation $\leq$ on S defined by*

$$a \leq b \Leftrightarrow a + b = a$$

is a total order on S. Furthermore,

$$a + b = \min(a, b)$$

and

$$a \leq c \, and \, b \leq d \, implies \, a \cdot b \leq c \cdot d.$$

Proof. The first claim is easily verified. The last claim is slightly tricky. Suppose $a = a + c$ and $b = b + d$. The condition on $+$ implies $x + x = x$ for all $x \in s$. Thus

$ab = ab+ab = (a+c)(b+d)+ab = (ab+cb)+(ab+ad)+cd = (a+c)b+a(b+d)+cd = ab+cd$. □

Because plus is really a minimization operator, we see that the value of the formula is actually the minimum value of $\prod_{p\in P} p[\gamma]$ over all possible assignments $\gamma \in \Gamma[V]$ and the optimal assignment is the assignment which achieves this minimum. Hence the appropriateness of the adjective "optimal."

A further change in notation puts this problem into standard nonserial dynamic optimization notation. In addition to changing "+" to "min," change "·" to "+," "0" to "∞" (the identity element for min), and "1" to "0" (the identity element for +). Thus $(S,+,\cdot,0,1)$ becomes $(S,\min,\cdot,\infty,1)$. With these changes in notation,

$$VALUE((V,P)) = \min_{\gamma\in\Gamma(V)} \sum_{p\in P} p[\gamma]$$

and an optimal assignment is a γ_0 in $\Gamma(V)$ which achieves the minimum.

To argue the converse that nonserial optimization can be modeled by a GSP, we first define nonserial optimization in a very general way.

DEFINITION 9.4. *An* ordered commutative monoid *is specified by a* 5*-tuple* $G = (S,+,0,\leq,\infty)$, *where* $+$ *is a commutative associative binary relation on* S *with identity* 0 *and* $\leq$ *is a total order on* S *such that* $a \leq \infty$ *for* a *in* S *and* $a \leq c$ *and* $b \leq d$ *implies* $a+b \leq c+d$. *If* $\mathcal{D}$ *is a set of G-formulas, the* NOP *for* $\mathcal{D}$ *is to take a formula* $F = (V,P)$ *from* $\mathcal{D}$ *and find both the minimum value of the set*

$$\left\{ \sum_{p\in P} p[\gamma] \mid \gamma \in \Gamma(V) \right\}$$

and an assignment γ_0 *for which the minimum is obtained.*

Sometimes an ordered monoid is defined without an ∞. The integers and rationals under addition are such monoids. However, an ordered monoid without ∞ can always have an ∞ appended and + extended so that $a+\infty = \infty+a = \infty$ for all a in $S\cup\{\infty\}$.

Proposition 9.3 can now be interpreted as saying that any optimization problem based on GSPs can also be interpreted as a NOP. The semiring + is interpreted as min and the · as monoid +. The next result says that the converse is true.

THEOREM 9.5. *For any ordered commutative monoid* G, *there is a commutative semiring* R *such that any G-formula* F *is an R-formula, the minimum value of G-formula* F *is* $VALUE(F)$, *and the optimal assignments for the G-formula are the same as the optimal assignments for the R-formula.*

Proof. Suppose $G = (S,+,0,\leq,\infty)$. Let R be $(S,\min,+,\infty,0)$. R is easily verified to be a commutative semiring. The distributive law, namely $a+\min(b,c) = \min(a+b,a+c)$, follows because $\min(b,c) = b$ implies $b \leq c$, which implies $a+b \leq a+c$, which implies $\min(a+b,a+c) = a+b$. Because G-terms map into S, they are also R-terms and hence G-formulas are S-formulas. The problem equivalence follows for reasons already discussed. □

We now consider how the generic algorithms can be modified to find an optimal assignment together with the value. Roughly speaking, the modifications are achieved by remembering the partial assignments which cause the best partial result to occur.

The modified version of Algorithm 2 is Algorithm 5. The modifications are designed so that when a call is completed, the global variables from $AD(n)$ have the assignment which (together with values assigned to $BV(n) - AD(n)$) gives the returned value. We have also switched from semiring notation in Algorithm 2 to ordered monoid notation. The performance of the algorithm is as follows.

THEOREM 9.6. *Let $F = (V, P)$ be a formula where each variable in V takes on at most D values. Let T be a structure tree for F having m nodes and weighted depth WD. If Algorithm 5 is applied to F and T, then*

1. *the number of "+" operations is at most $(m + |P|) \cdot D^{WD}$;*
2. *the number of* "min" *operations is at most $m \cdot D^{WD}$;*
3. *each p in P is evaluated at most D^{WD} times;*
4. *the number of "save a value" operations is at most $2 \cdot |V| \cdot m \cdot D^{WD}$.*

Proof. Except for (4), this is Theorem 4.2 translated to NOP notation. The saves only occur after a comparison or just prior to a return. Since up to $|V|$ values need to be saved, (2) implies (4). □

We note that Algorithm 5 becomes more efficient if we change "if $x \leq y$" to "if $x < y$." However, the programmer must then also take into account the possibility that the local variables may not contain any assignment if the value ∞ is returned. Other improvements to cut off unnecessary computations are possible but are beyond the scope of this presentation. The traditional method of solving NOPs is to use nonserial dynamic programming similar to Algorithm 4. However, our approach indicates that the full range of GSP techniques are available.

Because NOPs can be regarded as special GSPs, the methods of §8 define hierarchical NOP and tell us how to find their values efficiently. To print an optimal assignment could take time exponential in the size of the hierarchical specification simply because the number of variables may be exponential in this size. A reasonable alternative method of representing an assignment is to give an assignment of variables in the base formula together with a table for each template showing an optimal assignment of local variables for each assignment of parameter variables. From this information, the assignment to any particular variable in the expanded formula is easily computed. The appropriate tables can be computed by enhancing the algorithm of Theorem 8.8 with the techniques discussed earlier in this section.

10. Constrained GSPs.

The value of a GSP formula is, by definition, determined from a consideration of the set of all variable assignments. Here we consider situations where the value we want depends only on a subset of the assignments. We call these "constrained formulas" because the assignment subset is specified by a set of "constraints." However, instead of developing a separate theory for constrained GSPs, we show how constrained GSPs (CGSPs) are easily transformed back into ordinary unconstrained GSPs. This further illustrates the scope of the GSP model and makes the model easier to apply since it is often easy to see that a given problem can be posed as a CGSP.

DEFINITION 10.1. *If $R = (S, +, \cdot, 0, 1)$ is a commutative semiring and B is the Boolean semiring, then a* constrained R-formula *is given by a triple $C = (V, P, Q)$, where (V,P) is an R-formula and (V, Q) is a B-formula. The value of C, denoted by $VALUE(C)$, is defined by*

$$VALUE(C) = \sum_{\gamma \in \Gamma_0} \prod_{p \in P} p[\gamma],$$

where

$$\Gamma_0 = \{\gamma \in \Gamma(V) \mid q[\gamma] = \text{TRUE}\, \textit{for all}\, q \in Q\}.$$

If $\mathcal{D}$ is a set of constrained R-formulas, then the constrained GSP *(or CGSP) for $\mathcal{D}$ is to take a constrained formula from $\mathcal{D}$ and find its value.*

Note that if $\gamma_0 = \emptyset$, then the sum is on the empty set and $VALUE(C) = 0$.

The transformation from CGSP to GSP employs a very simple kind of term transformation achieved by mapping the term output into another set:

DEFINITION 10.2. *If r is a function from S_1 to S_2 and $p =$ "$f(x_1, \ldots, x_k)$" is an S_1-term, then we use the notation $r \circ p$ to mean an S_2-term equivalent to the expression "$r(f(x_1, \ldots, x_k))$". If Q_1 is a set of S_1-terms, we call the set $Q_2 = \{r \circ p \mid p \in Q_1\}$ a* reinterpretation *of Q_1* by *r and we write $Q_2 = r \circ Q_1$.*

THEOREM 10.3. *If (V, P, Q) is a constrained R-formula, Q has a reinterpretation $Q' = r \circ Q$ such that formula $(V, P \cup Q')$ is an R-formula having the same value.*

Proof. Let $R = (S, +, \cdot, 0, 1)$ be the commutative semiring for P. To get Q', use the reinterpretation r, where $r(\text{TRUE})$ is 1 and $r(\text{FALSE})$ is 0. Observe that $\sum_{t \in P \cup Q'} t[\gamma]$ is equal to $\sum_{p \in P} t[\gamma]$ whenever $q[\gamma] = 1$ for all q in Q' and is equal to 0 if $q[\gamma] = 0$ for some q in Q'. The result about values follows easily. □

Remark. Because Q and $r \circ Q$ have identical hypergraphs, Theorem 10.3 shows that it is the structure of P and Q combined (i.e., of $P \cup r \circ Q$) that must be considered in order to apply the generic algorithms to (V, P, Q). An important special case is the "linear case" where the predicates in P all have the form "$f_i(x_i)$." In this case, any structure tree (S, α, β) for (V, Q) is, for structural purposes, identical to a structure tree (S, α, β') for $(V, P \cup r \circ Q)$, where $\beta'(r \circ q) = \beta(q)$ and $\beta'(\text{"}f_i(x_i)\text{"}) = \alpha(x_i)$. The branch variables at each tree node are the same in both cases and so are the channel variables. Thus both cases have the same weighted depth and the same channelwidth.

By analogy, for an ordered commutative monoid G, we can define a "constrained G-formula" and hence a "constrained NOP" (CNOP).

COROLLARY 10.4. *If $G = (S, +, 0, \leq, \infty)$ is an ordered commutative monoid, any constrained G-formula F can be transformed into a GSP-formula F' such that*

1. *F and F' have the same value and same optimal assignments whenever the constraints are satisfiable;*
2. *the value of F' is ∞ and all assignments are optimal whenever the constraints are unsatisfiable.*

Remark. In the case where the G-terms of F have the form "$f_i(x_i)$", the structure of the problem is captured by the structure of the constraints for the same reason as in the previous remark. We call this the "linear objective function case."

We note that {0,1}-linear programs are a GSP with linear objective functions. The variable domains are $\{0, 1\}$, the linear constraints describe predicates, and the objective function terms are the single variable expressions $c_i v_i$.

11. Boolean satisfiability problems. By a "Boolean formula," we mean a B-formula where B is the Boolean semiring ($\{\text{TRUE}, \text{FALSE}\}$, $\vee$, $\wedge$, FALSE, TRUE). By a "Boolean satisfiability problem," we mean a GSP whose problem domain is some set of Boolean formulas. As observed in §2, the question "does a Boolean formula F have a satisfying assignment?" has answer "yes" if and only if $VALUE(F) = \text{TRUE}$. Thus SAT, 3SAT, and the problems from [31] are Boolean satisfiability problems. Satisfiability is one of several questions commonly asked questions.

DEFINITION 11.1. *We define the following problems for Boolean formulas F:*

- SATISFIABILITY. *Does F have a satisfying assignment?*
- COUNTING. *How many satisfying assignments does F have?*
- MAXIMIZATION. *What is the maximum number of predicates from F that can be simultaneously true?*
- PARITY. *Is the number of satisfying assignments odd or even?*
- UNIQUENESS. *Does F have a unique solution?*

TABLE 1
Semirings for Boolean formula questions.

PROBLEM	S	+	·	0	1
SATISFIABILITY	{T,F}	OR	AND	F	T
COUNTING	integers	+	·	0	1
MAXIMIZATION	naturals	max	+	0	0
PARITY	{0,1}	XOR	AND	0	1
UNIQUENESS	{0,1,2}	$\min(a+b,2)$	$\min(a\cdot b,2)$	0	1

Each of the defined problems can be expressed in a well-known way as a language-recognition problem, namely recognize the set of satisfiable formulas, recognize the set of pairs (F,k), where F has at least k satisfying assignments, etc. For CNF formulas, the corresponding language problems are known as SAT, #SAT, MAX SAT, PARITY SAT, and UNIQUE SAT and are complete for NP, #P [34], MAX-SNP [24], PARITY-P, and D^P [35]. The hierarchically specified versions of 3SAT and #3SAT are PSPACE- and #PSPACE-complete, respectively [13].

Recalling the concept of reinterpretation given in Definition 10.2, representations for each problem in Definition 11.1 are obtainable as follows.

PROPOSITION 11.2. *For each of the problems given in Definition* 11.1, *there is a commutative semiring* $(S,+,\cdot,0,1)$ (*given in Table* 1) *and a reinterpretation function* $r : \{\text{FALSE},\text{TRUE}\} \to S$ *such that the answer for Boolean formula* $F = (V,P)$ *is* $VALUE(V, r\circ P)$.

Proof. The semirings are given in Table 1 and, in each case, r maps FALSE to 0 and TRUE to 1. In the case of UNIQUENESS, think of "2" as "more than one." In this case, $VALUE(V,P)$ returns three possible answers, namely "no satisfying assignment," "one (unique) assignment," or "more than one assignment." For each problem, the assertion about $VALUE(V, r\circ P)$ is easy to verify. □

Because formulas (V,P) and $(V, r\circ P)$ have the same structure (i.e., they have identical formula hypergraphs), the problems from Definition 11.1 have equal complexity with regard to finding good structure trees and with regard to the number of operations performed by the generic algorithms. There may, however, be cost differences associated with performing the operations. For example, COUNTING can involve numbers with $|V|$ bits whereas SATISFIABILITY involves only Boolean values. In this same regard, care must be taken when extrapolating to a hierarchical specification H. For example, COUNTING then can involve numbers with $2^{|H|}$ bits.

Of the five problems from Definition 11.1, SATISFIABILITY and MAXIMIZATION are optimization problems, and hence optimal assignments can be computed along with the value. Although UNIQUENESS is not an optimization problem ($1+1 \neq 1$ contrary to Proposition 9.2), the uniquely satisfying assignment (if any) can be found by very similar methods.

Closely related to the above are problems of the form "find a satisfying assignment which minimizes $\sum_{x_i\in V} f_i(x_i)$." One of these problems is "find the satisfying assignment with the largest number of variables assigned TRUE," which is described by setting $f_i(\text{FALSE}) = 0$ and $f_i(\text{TRUE}) = 1$ for all i. This problem is MAXΠ_1-complete [22]. Another is "find the lexicographically smallest satisfying assignment," which is described by setting $f_i(F) = 0$ and $f_i(T) = 2^{|V|-i}$ for all i. This last problem is OPT-P-complete [16]. Both problems are constrained NOPs with a linear objective function and, as discussed in the remarks of §10, their structure is essentially just the structure of the constraints inherited from the original Boolean formula.

One implication of the fact that all problems in this section have identical structure is that Theorem 7.3 applies to all these problems, not just for SAT, after possible adjustments for the complexity of performing the corresponding semiring operations.

12. Graph problems. A fundamental question about graphs is the following: for which hard graph problems are highly structured input graphs easier to solve than the general case? A sufficient condition is provided by the GSP model: structured graphs are easier to solve when the semantics of the graph problem can be described by a GSP in such a way that the formula hypergraph inherits the structure of the graph. This inheritance is most direct and useful when the formula hypergraph and input (hyper)graph are identical. This happens if the GSP has variables corresponding to each node, predicates corresponding to each hyperedge, and each predicate has the variables which correspond to its hyperedge nodes. We call this the node-variable edge-predicate (NVEP) case.

A good example of NVEP is graph k coloring. To model this as a GSP, introduce a variable for each graph node and let the variables range over a set of k colors. For each graph edge (n_1, n_2), introduce a predicate "$f(v_1, v_2)$", where v_1 and v_2 are the variables corresponding to n_1 and n_2 and $f(v_1, v_2)$ is TRUE if and only if $v_1 \neq v_2$. Then the graph has a k coloring if and only if the value of the GSP is TRUE. This is an example of a Boolean satisfiability problem as discussed in the previous section.

The structure of a graph is also passed directly to a GSP when the problem semantics are described by NVEP constraints and a linear objective function to be maximized or minimized. (See the Remarks in §10.) A good example of this is minimum node cover for hypergraphs. There is an obvious representation where the node variables take on the value TRUE (for nodes included in cover) or FALSE (for nodes not included), there is a constraint $v_1 \vee \cdots \vee v_k$ for each hyperedge $\{x_1, \ldots, x_k\}$, and there is an objective term "$f(v)$" for each variable, where $f(\text{TRUE}) = 1$ and $f(\text{FALSE}) = 0$.

A simple extension of the NVEP case is to allow each predicate to contain an additional variable which is associated with the corresponding hyperedge. With minor adjustments to the structure tree, this extension can be accommodated with an increase of at most one in weighted depth and treewidth/channelwidth. This is essentially the edge condition composition (ECC) case of [5]. We say "essentially" because ECC is defined only for ordinary graphs, the definitions include conditions on certain monoids and the complexity of monoid operations, and the results are oriented toward bounded-treewidth graphs. However, the theme of [5] is the same as in this section, namely that graph structure can be exploited to solve a graph problem more quickly *provided the semantics of the graph problem has a suitable semantics*, and the proofs of [5] can be viewed as showing that the many graph problems considered are GSPs.

Some problems are more naturally represented with variables for each edge and predicates for each node, a case we call EVNP. For example, minimal edge cover is most naturally represented by EVNP constraints and a linear objective function. Here the structure of the graph is passed on but not so directly. (The formula hypergraph is actually the hypergraph dual of the input.) A structure tree for the graph can be converted to a structure tree for the formula, but the weighted depth and channelwidth can increase by a factor of k, where k is the size of the largest hyperedge. (k=2 for ordinary graphs.) This case relates to the local condition composition (LCC) case of [5] in the same way that NVEP relates to ECC. We omit further details.

The minimum edge-cover problem just discussed can also be represented (less naturally) as a NVEP problem. Let the variable for each node range over the set of edges for that node. For each hyperedge e, construct an integer-valued predicate which is one if any of the arguments are equal to edge e and is zero otherwise. For any assignment, the set of edges taken on by the node variables is an edge cover and the number of predicates with value 1 is the size of this edge cover. Thus the value of the formula under semiring $(N, \min, +, \infty, 0)$ is the minimum cover.

The last example illustrates the use of "instance-specific domains," in this case variables which take on edge names as values. With the use of instance-specific domains, even HAMILTONIAN CIRCUIT and TRAVELING SALESMAN can be described as GSPs [32]. From a computational viewpoint, the value of such representations diminishes as the domains become more contrived. It should also be noted that there are nonalgebraic ways of exploiting structure trees that may be computationally more appropriate. Thus whether certain graph problems should be called GSPs is really a matter of taste.

Some graph problems are known to be hard even when the graphs have a very simple structure. One such problem is BANDWIDTH (problem [GT40] from [10]) which is NP-complete even for trees (trees have channelwidth 2 and treewidth 1).

When the semantics of a graph problem are described as a GSP, we have found that the hierarchical methods of §8 frequently apply. This is the subject of another paper.

Appendix.

ALGORITHM 1. *Brute force.*

Input: Formula (V, P)
Variables: v in V, x for accumulating a sum, y for accumulating products
Output: $VALUE(V, P)$ $x \leftarrow 0$;

```
FOR $\gamma \in \Gamma(V)$ DO
BEGIN
$y \leftarrow 1$;
FOR $p \in P$ DO $y \leftarrow y \cdot [\gamma]$;
$x \leftarrow x + y$;
END;
OUTPUT ($x$)
```

ALGORITHM 2. *Generalized backtracking.*

Input parameter: n, a structure tree node for formula (V,P).
Global variables: v in V.
Local variables: x for accumulating a sum, y for accumulating products.
Assumptions: When called, global variables from $BV(n) - A(n)$ contain an assignment γ_0.
Value returned: $E(n, \gamma_0)$ from Definition 3.5. Returns $VALUE(V, P)$ when n is the root node.
Optimization: If ever $y = 0$, the program could skip to the next assignment α. A similar remark applies to other algorithms in this appendix.

```
    FUNCTION EVALUATE($n$)
$x$, $y$ are local variables.
$x \leftarrow 0$;
FOR $\gamma \in \Gamma(A(n))$ DO
BEGIN
$y \leftarrow 1$;
```

```
FOR $p \in B(n)$ DO $y \leftarrow y \cdot p[\gamma + \gamma_0]$;
FOR ALL CHILDREN $n'$ of $n$ DO $y \leftarrow y \cdot EVALUATE(n')$;
$x \leftarrow x + y$;
END;
RETURN(x);
```

ALGORITHM 3. *Backtracking with table lookups.*

Input parameter: n, a structure tree node for formula (V, P).

Global memory: variables v in V and, for each structure tree node m, a table T_m having an entry for each assignment γ in $\Gamma(CV(m))$. Table entries can be semiring elements or "undefined."

Local Variables: x for accumulating a sum, y for accumulating products.

Assumptions: When function is called, global variables from $CV(n) - A(n)$ contain an assignment γ_0. All table entries are initialized "undefined."

Value returned: $E(n, \gamma_0)$ from Definition 3.5. Returns $VALUE(V, P)$ when n is the root node.

```
FUNCTION $EVALUATE(n)$
$x$, $y$ are local variables.
IF $T_n(\gamma_0)$ = "undefined" THEN
BEGIN
$x \leftarrow 0$;
FOR $\gamma \in \Gamma(A(n))$ DO
BEGIN
$y \leftarrow 1$;
FOR $p \in B(n)$ DO $y \leftarrow y \cdot p[\gamma + \gamma_0]$;
FOR ALL CHILDREN $n'$ of $n$ DO $y \leftarrow y \cdot EVALUATE(n')$;
$x \leftarrow x + y$;
END;
$T_n(\gamma_0) \leftarrow x$;
END
RETURN $(T_n(\gamma_0))$
```

ALGORITHM 4. *Dynamic programming.*

Input: A structure tree for formula (V, P).

Memory: Variables x and y and, for each node m of the structure tree, a table T_m having one entry for each assignment in $\Gamma(CV(m) - A(m))$. The table entries are semiring elements.

Assumptions: Each table is initially considered "unconstructed" and is reclassified as "constructed" at the time indicated in the program.

Output: The table T_{root} for the root node has only one entry because $CV(root) - A(root) = \emptyset$ and thus on exit, this entry contains $VALUE(V, P)$.

```
WHILE not all $T_n$ are constructed DO
BEGIN
PICK $n$ such that
(1) $T_n$ is not constructed and
(2) $T'_n$ is constructed for all children of n;
FOR all $\gamma_0 \in \Gamma(CV(n) - A(n))$ DO
BEGIN
```

```
$x \leftarrow 0$;
For all $\gamma_1 \in \Gamma(A(n))$ DO
BEGIN
$y \leftarrow 1$;
FOR $p \in B(n)$ DO $y \leftarrow y \cdot p[\gamma_0 + \gamma_1]$;
For all children of $n'$ of $n$ DO $y \leftarrow y \cdot T_{n'}[\gamma_0 + \gamma_1$ projected to $CV(n') - A(n')]$;

                $x \leftarrow x + y$;
END;
$T_n[\gamma_0] \leftarrow x$
END;
{$T_n$ is now constructed};
END;
```

ALGORITHM 5. *Optimization using generalized backtracking.*

Input parameter: n, a structure tree node for formula (V,P).

Global variables: v in V.

Local variables: x for accumulating a maximum, y for accumulating sums, and v' for $v \in AD(n)$ for remembering the "best assignment for $AD(n)$ seen so far."

Assumptions: When called, global variables from $BV(n) - A(n)$ contain an assignment γ_0.

Value returned: $E(n, \gamma_0)$ from Definition 3.5. Additionally, the global variables $v \in AD(n)$ contain a corresponding assignment.

```
    FUNCTION $EVALUATE(n)$
$x$, $y$, $v'$ for $v \in AD(n)$ are local variables
$x \leftarrow \infty$;
For $\gamma \in \Gamma(A(n))$ DO
BEGIN
$y \leftarrow 0$;
FOR $p \in \beta(n)$ DO $y \leftarrow y + p[\gamma + \gamma_0]$
FOR ALL CHILDREN $n'$ of $n$ DO $y \leftarrow y + EVALUATE(n')$;
IF $y = x$ THEN {"IF $y < x$" is better}
BEGIN
$x \leftarrow y$;
FOR $v \in AD(n)$ DO $v' \leftarrow v$;
END;
END;
FOR $v \in AD(n)$ DO $v \leftarrow v'$;
RETURN $(x)$;
```

STRONGLY COMPETITIVE ALGORITHMS FOR PAGING WITH LOCALITY OF REFERENCE*

SANDY IRANI[†], ANNA R. KARLIN[‡], AND STEVEN PHILLIPS[§]

Abstract. What is the best paging algorithm if one has partial information about the possible sequences of page requests? We give a partial answer to this question by presenting the analysis of strongly competitive paging algorithms in the access graph model. This model restricts page requests so that they conform to a notion of locality of reference given by an arbitrary access graph.

We first consider optimal algorithms for undirected access graphs. Borodin et al. [*Proc. 23rd ACM Symposium on Theory of Computing*, 1991, pp. 249–259] define an algorithm, called FAR, and prove that it is within a logarithmic factor of the optimal online algorithm. We prove that FAR is in fact strongly competitive, i.e., within a constant factor of the optimum. For directed access graphs, we present an algorithm that is strongly competitive on *structured program graphs*—graphs that model a subset of the request sequences of structured programs.

1. Introduction.

Many computer systems have a two-level store of memory consisting of a small, fast memory and a large, slow memory. The abstraction of a large, fast, virtual memory is often implemented by dividing the slow memory into pages and keeping those pages that are likely to be referenced soon in the fast memory. A *page fault* occurs when a reference is made to a page that is not resident in fast memory. Handling a page fault is typically expensive since the page must be brought into fast memory. A *page-replacement strategy* specifies which page to replace on a page fault.

If the future sequence of page requests is known in advance, the optimal page replacement strategy is clear: replace the page whose next request is farthest in the future [1]. Unfortunately, the decision about which page to replace must usually be made *online*, without detailed information about future requests.

How can we analyze such an online algorithm? Straightforward worst-case analysis is useless; if arbitrary request sequences are allowed, then an adversary that always requests the last discarded page can force any paging algorithm to fault on each request. Average-case analysis is also problematic since it requires a statistical model of the sequence of requests. It is extremely difficult to devise a realistic model, since the pattern of accesses changes dynamically with time and with different applications. Nonetheless, several of the early analyses of paging algorithms were performed assuming a fixed probability distribution on the request sequences [6, 13, 1].

In order to get around these problems, the notion of *competitive analysis* was introduced by Sleator and Tarjan [12]. An online page-replacement strategy A is said to be *c-competitive* if there exists a constant β such that for every request sequence

σ,

$$A(\sigma) \leq c \cdot \mathrm{OPT}(\sigma) + \beta,$$

where $A(\sigma)$ is the cost (i.e., the number of faults) incurred by the algorithm A in processing the request sequence σ and $\mathrm{OPT}(\sigma)$ is the cost incurred by the optimal offline algorithm in processing σ. The *competitiveness* of A, denoted by c_A, is the infimum of c such that A is c-competitive.

Competitive analysis avoids the assumptions of probabilistic analysis, and has the power of differentiating between different paging algorithms. Sleator and Tarjan showed that no deterministic paging algorithm can achieve a competitiveness better than k, where k is the number of pages of fast memory. They also showed that some practical algorithms, such as first-in-first-out (FIFO) and least-recently-used (LRU), are k-competitive, and hence best possible in their model.

1.1. Locality of reference. The Sleator–Tarjan results conflict with practical experience on paging in at least two ways. First, FIFO and LRU have the same competitiveness, even though in practice LRU usually outperforms FIFO. Second, LRU usually incurs much less than k times the optimal number of faults, even though its competitiveness is k.

The reason for the practical success of LRU has long been known: most programs exhibit *locality of reference* [1, 4, 11]. This means that if a page is referenced, it is more likely to be referenced in the near future (temporal locality) and pages near it in memory are more likely to be referenced in the near future (spatial locality). Indeed, a two-level store is only useful if request sequences are *not* arbitrary.

Motivated by these observations, Borodin, Irani, Raghavan, and Schieber [2] proposed a technique for incorporating locality of reference into the traditional Sleator–Tarjan framework. Their notion of an *access graph* limits the set of request sequences the adversary is allowed to make.

An access graph $G = (V, E)$ for a program is a graph that has a vertex for each page that the program can reference. Locality of reference is imposed by the edge relation—the pages that can be referenced after a page p are just the neighbors of p in G or p itself. Thus a request sequence σ must be a walk on G. The specific walk that is generated is determined by the data given to the program. The definition of competitiveness remains the same as before, except for this restriction on the request sequences. Let $c_{A,k}(G)$ denote the competitiveness of an online algorithm A with k pages of fast memory on the access graph G. We denote by $c_k(G)$ the infimum (over online algorithms A with k pages of fast memory) of $c_{A,k}(G)$. Thus $c_k(G)$ is the best that any online algorithm can do. We say an algorithm A is *strongly competitive* if $c_{A,k}(G) = O(c_k(G))$.[1]

An access graph may be either directed or undirected. An undirected access graph might be a suitable model when the page reference patterns are governed by the data structures used by the program. For example, if a program performs operations on a tree data structure, and the mapping of the tree nodes to pages of virtual memory represents a contraction of a tree, then the appropriate access graph might be a tree. Alternatively, if we were to completely ignore data and focus only on the flow of control inherent in the structure of the program, a directed access graph might be a more suitable model.

[1] This terminology differs slightly from that of [7, 9], where strongly competitive was defined as achieving the competitive ratio $c_k(G)$.

Unfortunately, modeling access patterns is not as simple as these examples would suggest. See §4 for a discussion of the limitations of the model.

1.2. Summary of results. In this paper, we show that there are strongly competitive page replacement strategies in two important settings: (1) undirected access graphs and (2) directed access graphs representing the stream of instruction references made by a structured program.

1.2.1. Undirected access graphs. Borodin et al. proved that on any undirected access graph G, $c_{\mathrm{LRU},k}(G) \leq 2c_{\mathrm{FIFO},k}(G)$, and that LRU is often better than FIFO. However, on some graphs the competitiveness of both LRU and FIFO is much greater than $c_k(G)$. For example, it has been observed [8] that LRU and FIFO behave badly on loops just larger than k. This is substantiated by the following result in the access graph model: if G is the $(k+1)$-node cycle, then $c_k(G) = \lceil \log(k+1) \rceil$, while $c_{\mathrm{LRU},k} = k$. Thus LRU can be far from optimal among online algorithms.

We seek a *universal* algorithm, with a succinct description, whose competitiveness is close to $c_k(G)$ on *every* graph G. Importance is lent to this question by recent operating system research, in which facilities are provided for user-defined page replacement strategies [3, 10]. When these facilities are available, one must consider the following question: what is the best paging algorithm if one has partial information about the possible sequences of page requests? When the partial information is represented by an access graph, this question asks for a universal paging algorithm that is *strongly competitive.*

Borodin et al. describe a simple and natural algorithm called FAR, and prove that it achieves a competitiveness within $O(\log k)$ of $c_k(G)$for every graph G. They leave open the question of finding an algorithm with competitive ratio $O(c_k(G))$. Our main result for undirected access graphs is that FAR is optimal, within a constant factor, among online algorithms for paging with locality of reference.

THEOREM 1.1. *For any graph G and memory size k, the algorithm* FAR *is strongly competitive, i.e.,*

$$c_{\mathrm{FAR},k}(G) = O(c_k(G)).$$

The proof relies on a graph decomposition called a *vine decomposition* [2]. Borodin et al. show how to find a lower bound on $c_k(G)$ using a vine decomposition of G. We show that this lower bound is essentially optimal, by using the fault pattern of FAR to construct a vine decomposition of G.

1.2.2. Directed access graphs. In §3 we consider optimal algorithms for directed access graphs that represent a subset of the stream of instruction references made by a structured program. We use the notion of *structured program graphs* as in [2].

Structured program graphs (spg's) are defined recursively as follows: Every spg has a designated *start* node and a designated *stop* node. A single directed edge is an spg, where the node with outdegree 1 is the start node and the node with indegree 1 is the stop node. More complex spg's can be constructed by applying the following rules:

(i) Two spg's G_1 and G_2 can be combined to get a new spg, by identifying the start node of G_1 and the stop node of G_2 (serial composition).

(ii) Two spg's G_1 and G_2 can be combined to get a new spg, by identifying the stop nodes of G_1 and G_2 (branching statement).

(iii) A node v in an spg can be identified with a node u of a directed cycle to yield a new spg (loop).

Notice that there is no way to represent arbitrary "GOTO" statements. A significant limitation of this model is that the definition does not allow branching within loops.

Borodin et al. analyze a simple generalization of FAR, called 2FAR, that is optimal for spgs in which all strongly connected components have at most $k + 1$ nodes. We introduce a variant of 2FAR, called EVEN, and prove that it is strongly competitive for all spg's.

THEOREM 1.2. *The algorithm* EVEN *is strongly competitive on the class of structured program graphs. In other words, for any structured program graph G, $c_{k,\text{EVEN}}(G) = O(c_k(G))$.*

2. Undirected access graphs.

2.1. Background. We review some terminology and results on competitive paging. A sequence of page requests and the resulting behavior of a paging algorithm can be divided into *phases*. At the beginning of a phase, all pages are unmarked. When a page is *requested* (or *hit*) it is said to be *marked.* A phase ends just before the request to the $(k + 1)$st distinct node. At the end of a phase all nodes become unmarked again. We call the nodes requested in this phase but not in the previous phase *new* nodes. A node is said to be *evacuated* if it has been evicted from the fast memory during the phase. If a page is in the fast memory, we will say it is covered by a *server*.

The algorithm FAR is a *marking algorithm*. A marking algorithm is an algorithm that, on a fault, always evicts an *unmarked* page. The unmarked page that FAR chooses to evict is the page that is *furthest* (in the access graph) from the set of marked nodes.

We think of the sequence of page requests as being generated by an *adversary*, and say that the *cost* of the adversary is the cost of the offline algorithm on the request sequence.

PROPOSITION 2.1. (a) *If g_i new nodes are requested in the ith phase, then the cost of the adversary during the first i phases is at least $(\sum_{j=1}^{i} g_j)/2$, and at most $\sum_{j=1}^{i} g_j$.* (b) *If A is a marking algorithm then for any graph G, $c_{A,k}(G) \leq k$.*

The proof of part (a) is due to Fiat et al. [5], while part (b) is due to Karlin et al. [7].

A *vine decomposition* $\mathcal{V}(H) = (T, \mathcal{P})$ of any graph H is a tree T in H together with a set $\mathcal{P} = P_1, P_2, \ldots$ of pairwise edge disjoint simple paths in H (without loops), called *vines,* such that (i) the nodes of H are partitioned between T and the interior nodes of the P_i's; (ii) each endpoint of each path is a node in T. If a tree node is the endpoint of a vine, it is called an *anchor*. Let n_T be the number of leaves of T that are not anchors. The *value* of a path P, denoted $v(P)$, is defined to be $\lceil \log |P| \rceil$, where $|P|$ is the number of edges in P. The *value* of the vine decomposition $\mathcal{V}(H)$, denoted $v(\mathcal{V}(H))$ (or $v(\mathcal{V})$ for short), is

$$v(\mathcal{V}(H)) = \sum_i v(P_i) + n_T - 1.$$

Lastly, if C is a cycle on $k + g$ nodes, $1 \leq g \leq k$, then the *value* of C is $v(C) = \lfloor \log k - \log g \rfloor / 2$.

THEOREM 2.2. 1. *For any graph G and memory size k, let $\mathcal{V}$ be a vine decomposition on $k+1$ nodes in G. Then $c_k(G) \geq v(\mathcal{V})$.*

2. *Let G be a graph containing a cycle $\mathcal{C}$ on $k+g$ nodes, $1 \leq g \leq k$. Then $c_k(G) \geq v(\mathcal{C})$.*

Proof. The lower bounds are proved by describing an adversary who walks on the access graph, causing the online algorithm to fault a large number of times before the phase ends. This proves something a little stronger: that in *each phase*, the ratio of faults made by the online and offline algorithms is at least the stated lower bound.

The proof of part 1 is due to Borodin et al. [2]. For completeness we give an outline of the proof here. W.l.o.g. assume that G has $k+1$ nodes, so that the adversary incurs at most one fault per phase. An online algorithm A always leaves one node of G uncovered—this node is called the *hole*. The bound on $c_k(G)$ follows from noting that during a phase, the adversary can make A incur $v(\mathcal{V})$ faults. When A moves its hole to a new position following a fault, the adversary (and the request sequence) walks to that position, causing A to fault there. If the new location of the hole is a tree node, the adversary walks to the hole on a path that contains only marked nodes or internal tree nodes. If the new location of the hole is an interior node of a vine v, the adversary walks to the hole on a path that contains only marked nodes, internal tree nodes, anchors, and at most half the unmarked nodes on the vine v. The hole can be reached at least n_T times by requests to nonanchor leaves, and at least $v(P) = \lceil \log |P| \rceil$ times by requests to each vine P.

For part 2, assume w.l.o.g. that G is just a cycle $\mathcal{C}$ on $k+g$ nodes. There are g "holes" (nodes where the online algorithm A doesn't have a server) in G at any time. A phase starts with the adversary and A covering the same set of contiguous vertices. If A ever has a hole on a marked node, the adversary requests the path to the hole, passing only through marked nodes. The phase begins with the adversary issuing requests to all g of the uncovered nodes. At any point, the set of unmarked nodes forms a contiguous path. The adversary then repeats the following pattern: he requests all the nodes in whichever half of the path of unmarked nodes has more holes, causing the online algorithm to incur at least $g/2$ faults. When the pattern has been repeated $i = \lfloor \log k - \log g \rfloor$ times, the path of unmarked nodes has length $\lfloor k/2^i \rfloor < 2g$, and the adversary simply requests unmarked nodes till g remain, and the phase ends.

The adversary incurs only g faults during this process; at the start of the phase he vacates the g nodes that will remain unmarked at the end of the subsequence. Therefore the ratio between the number of faults incurred by the online algorithm and the adversary is $i/2 = \lfloor \log k - \log g \rfloor /2$. Since the situation at the end of this phase is the same as at the start, the adversary can repeat this behavior ad infinitum, hence $c_k(G) \geq \lfloor \log k - \log g \rfloor /2 = v(\mathcal{C})$. □

2.2. Proof of FAR's strong competitiveness. In this section we prove that FAR is a strongly competitive algorithm.

THEOREM 2.3. *For any undirected access graph G, $c_{\mathrm{FAR},k}(G) = O(c_k(G))$.*

For the entire proof, we restrict our attention to a single phase of the request sequence. Suppose that g new nodes are requested in the phase. By Proposition 2.1, the adversary incurs at least $g/2$ faults for this phase, amortized. The proof works by showing that there is a vine decomposition or large cycle whose value is at least c/g times the number of faults incurred by FAR in the phase, for some absolute constant c. The lower bound of Theorem 2.2 then implies that the number of faults incurred by FAR during the phase is $O(g \cdot c_k(G))$. Because this is true for all phases,

$c_{\mathrm{FAR},k}(G) = O(c_k(G))$.

We use the concept from [2] of *representatives* or *reps* for short. Each time FAR incurs a fault, it must vacate some node. Consider the sequence of nodes that are vacated during the phase: we divide this sequence into blocks of $g+1$ nodes that are vacated successively. The number of new nodes requested in the phase is g, so at any time during the phase, the number of nodes that have been evicted so far during the phase and are currently outside the fast memory is at most g. Therefore there is at least one node of each block that is marked before *any* node of the subsequent block is vacated by FAR. We pick such a node for each block and call it a *rep*.

Suppose that the number of reps for this phase is R. We need to construct a vine decomposition on $k+1$ nodes or a cycle whose value is $\Omega(R)$.

2.2.1. Preliminaries. Let G' be the directed subgraph of G containing every node that is marked during the phase, with a directed edge from u to v if the first request at v immediately follows a request at u. The graph G' is a directed tree, rooted at the first node requested during the phase, and a directed path from x to y in G' implies that x was marked before y.

The following definitions are fundamental to the rest of the proof.

DEFINITION 1. (i) *A node in G' is a* chain node *if it has degree* 2 *in G and both indegree and outdegree* 1 *in G'. Nodes that are not chain nodes are called* nonchain nodes. (ii) *A chain is a directed path in G' whose interior nodes are chain nodes, and whose endpoints are not chain nodes.*

There is a natural reason for not allowing a node whose degree is more than 2 in G to be a chain node in G'. The reason is that otherwise a chain might not be "self-contained" in the following sense: a chain node that had degree at least 3 in G could be close to a marked node outside the chain, but far from any marked node inside the chain. Excluding this case makes it possible to analyze chains in isolation.

We divide the reps into two types.

DEFINITION 2. *A rep is of type* 1 *if it is the last or one of the first five reps on a chain, or it is a nonchain node. Any other rep is of type* 2 *(i.e., any rep in the middle of a chain). Let R_1 and R_2 be the number of type-*1 *and type-*2 *reps, respectively.*

We have two constructions: The first is a vine decomposition which is a tree on $k+1$ nodes with $\Omega(R_1)$ leaves. The other construction is a vine decomposition $\mathcal{V}$ on $3k/2$ nodes whose vines have total value $\Omega(R_2)$. We use $\mathcal{V}$ to find a vine decomposition on $k+1$ nodes whose vines have total value $\Omega(R_2)$ or to find a large cycle whose value is $\Omega(R_2)$. Since one of R_1 and R_2 has value $\Omega(R)$, the two constructions will complete the proof of Theorem 2.3.

2.2.2. Constructing a vine decomposition with value $\Omega(R_1)$. We prove the following theorem.

THEOREM 2.4. *The graph G contains a subgraph on $k+1$ nodes which is a tree with $\Omega(R_1)$ leaves.*

Proof. Charge each type-1 rep that is on a chain to the far endpoint of the chain, and charge reps that aren't on chains to themselves. Each nonchain node is charged at most six times (because G' is a directed tree, so each node is the far endpoint of at most one chain). Hence the number of nonchain nodes is at least $R_1/6$. Now a nonchain node is either a leaf of G', the root of G', or has degree 3 or more in G. Let UG be the undirected version of the graph G'. Root the tree UG at the root of G'.

Case 1. At least half of the nonchain nodes in G' either

1. are leaves or the root in UG,
2. or have degree 3 or more in UG,

3. or have degree 2 in UG and a parent of degree 3 or more in UG.

If v satisfies condition 3, then its child in UG doesn't (and it has a child since it is not a leaf). And the first descendent of v that does not have degree 2 satisfies condition 1 or 2. Therefore if α nodes satisfy condition 3, then at least α nodes in the tree satisfy conditions 1 or 2. And so at least a quarter of the nonchain nodes in the tree satisfy conditions 1 or 2. Thus, at least $R_1/24 - 1$ nodes are leaves in UG or have degree 3 or more in UG.

The average degree of nodes in a tree is less than 2, since any tree with n nodes has $n-1$ edges. Therefore, at least half of the nodes not of degree 2 in UG are leaves, and UG is the desired tree.

Case 2. Otherwise, at least half of the nonchain nodes in G' have degree 3 or more in G, but degree 2 in UG and a parent of degree 2 in UG. Let S be a maximal set of vertices in UG that have degree 3 or more in G, degree 2 in UG, and whose parent in G' has degree 2 in UG and is not in S. It is easy to see that $|S| = \Omega(R_1)$. For each $v \in S$, let $a(v)$ be an arbitrary vertex that is a neighbor of u in G but not in UG.

For each $w \in G \setminus UG$, let $num(w) = |\{v | a(v) = w\}|$. For each such w, if $num(w)$ is 1 or 2, then add the node w to UG together with a single edge to one of the nodes $v \in UG$ such that $a(v) = w$. Thus w becomes a leaf of UG. Alternatively, if $num(w) \geq 3$, then add the node w to UG together with edges to all the nodes $v \in UG$ such that $a(v) = w$. For each of these nodes v, except for the one closest to the root of UG (breaking ties arbitrarily), sever the edge from v to its parent $p(v)$ in G'. Since $p(v)$ had degree 2 in UG, it becomes a leaf of UG, and UG remains a tree.

Since UG contains at most one new node for each node in S, at most $k/2$ nodes can be added to UG by this process. Finally, since at least $|S|/2$ leaves were added to UG, and $|S| = \Omega(R_1)$, UG has $\Omega(R_1)$ leaves.

We can then prune the tree until there are $k+1$ nodes, while keeping the number of leaves $\Omega(R_1)$. This can be done by first finding a node v whose removal from T results in components of size at most k. To find v, pick an arbitrary node u. Consider the tree rooted at u. If one of the children of u is the root of a subtree with more than k nodes, reset u to be that child. Keep resetting u until all the subtrees rooted at children of u have at most k nodes. Since the graph has at most $2k$ vertices, every time u is reset, the maximum number of nodes in a subtree rooted at a child of u decreases. Pick v to be the final u.

Gather the subtrees of v into groups as follows: consider each subtree and put it in the smallest numbered group possible so that no group has more than k nodes. There at most four groups, since the sum of the nodes in any two groups is more than k. One group must contain $\Omega(R_1)$ leaves of T. This group can be easily extended to a connected subgraph of T containing $k+1$ nodes, giving the desired tree. □

2.2.3. Constructing a vine decomposition with value $\Omega(R_2)$.

The first step towards finding a vine decomposition or cycle whose value is $\Omega(R_2)$ is to show that the separation between type-2 reps decreases exponentially along directed paths in G'.

DEFINITION 3. *For a chain node v, let $n(v)$ be the distance from v to the end of its chain.*

LEMMA 2.5. (i) *If v, w, and z are three consecutive reps on a chain, then $n(z) \leq n(v)/2$.*

(ii) *If y is the second-to-last rep on a chain in P and c is the third rep on a later chain in P, then $n(c) \leq n(y)$.*

(iii) *If P is a directed path in G', containing m type-2 reps, then $m \leq 2\lfloor \log l_1 \rfloor$, where l_1 is the length of the first chain in P containing a type-2 rep.*

Proof. Part (i) is proven as follows: Since v and w are consecutive reps on a chain, v is marked before w is evicted. Therefore, if w' is the last node on w's chain to be marked before w is evicted, then w' lies between v and w, and the unmarked portion of the chain extends from w' until the end of the chain at the time w is evicted. Note, however, that some of these nodes may not have servers on them. Since FAR evicts an unmarked node furthest from the set of marked nodes, if w is less than half the way from w' to the end of the chain, then every vertex between w and the midpoint must be a hole. Furthermore, none of them can be reps since any subsequent rep on the chain must be vacated after w is marked. Therefore, z must be beyond the midpoint of the chain from w' to the end, and so $n(z) \leq n(w')/2 \leq n(v)/2$.

For part (ii), suppose that z is the last rep on y's chain, and that a and b are the first two reps on c's chain (so the sequence of reps on chains in P is $\ldots, y, z, a, b, c, \ldots$). Since y is marked before z is evicted, z is at distance at most $n(y)$ from the set of marked nodes at the time it is evicted. Also, by part (i), $n(c) \leq n(a) - n(c)$. Now suppose that $n(c) > n(y)$. Then $n(a) - n(c) > n(y)$ also. But then the server at c is further from the set of marked nodes at the time z is evicted than z is, and would be vacated before z, so c cannot be a rep, a contradiction. So $n(c) \leq n(y)$.

For part (iii), let v_i, $1 \leq i \leq m$, be the sequence of type-2 reps on P. Let v_0 be the fifth type-1 rep on the first chain of P containing type-2 reps. By parts (i) and (ii) we have $n(v_{i+1}) \leq n(v_i)/2$ or $n(v_{i+2}) \leq n(v_i)/2$, for $0 \leq i \leq m-2$. Hence $n(v_m) \leq n(v_0)/2^{\lfloor \frac{m}{2} \rfloor}$. Since there are four type-1 reps on the first chain before v_0, we have by part (i) that $n(v_0) \leq l_1/4$. Therefore, $n(v_m) \leq l_1/(2^{\lfloor \frac{m}{2} \rfloor} + 2)$. Lastly, $n(v_m) \geq 1$, so $1 \leq l_1/(2^{\lfloor \frac{m}{2} \rfloor} + 2)$. Rearranging, we obtain $m \leq 2\lfloor \log l_1 \rfloor$. □

Because of this lemma, we know that the number of type-2 reps on any chain is logarithmic in the length of the chain. Therefore, if we could make all chains be vines in some vine decomposition, then the vine decomposition would have value $\Omega(R_2)$, and we'd be done. The problem is that in order to connect the vines, we may need to use some chains to construct the tree, leaving only a subset of the chains to become vines. The following procedure constructs a vine decomposition $\mathcal{V}$ (possibly containing a small number of additional nodes from outside G') for which the value of the chains that become vines is $\Omega(R_2)$.

The procedure keeps a contraction $\tilde{G}$ of G', where each edge of $\tilde{G}$ is part of a chain of G' that contains some type-2 reps.[2] It never contracts only part of a chain, so we can refer to a chain of G' that hasn't been contracted yet as a "chain of $\tilde{G}$" (though its endpoints in $\tilde{G}$ may be supernodes). The contraction $\tilde{G}$ is always a tree directed from the root, as contracting preserves this property.

The procedure repeatedly identifies a chain $\mathcal{C}$ of $\tilde{G}$ that will be a vine $\mathcal{V}$, and describes the path between the endpoints of $\mathcal{C}$ in the tree of $\mathcal{V}$. This path may contain some chains of $\tilde{G}$ (and hence G'), but we use Lemma 2.5 to show that $v(\mathcal{C})$ is at least a constant fraction of the number of type-2 reps on the path. The identified chain and the chains used in the path are then contracted, and the process continues.

[2] To *contract* an edge (u, v) in a graph means that u and v are merged into a *supernode*. Edges to and from u and v are replaced by edges to and from the supernode, with duplicates deleted. A contraction of a graph is obtained by repeatedly contracting edges.

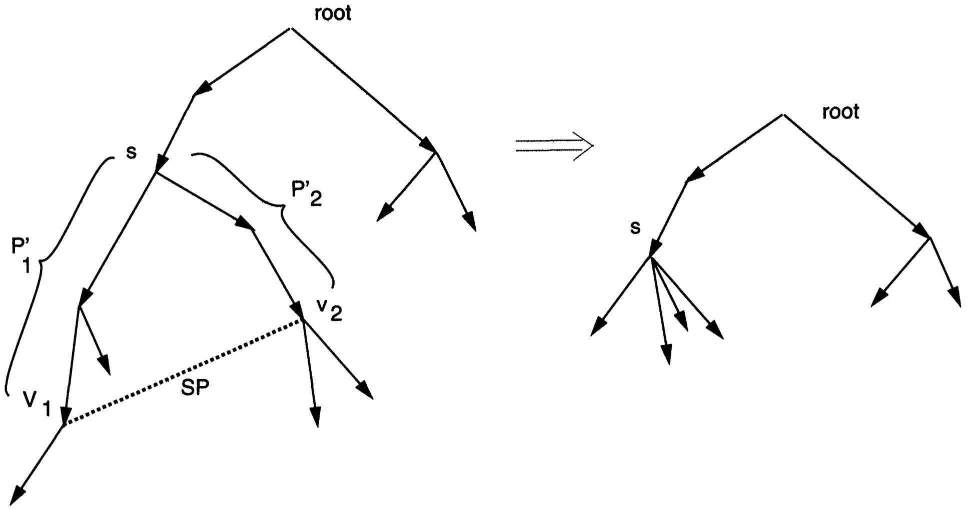

FIG. 1. *An iteration of the loop of* FindVineDecomp.

PROCEDURE FINDVINEDECOMP

Input: Undirected graph G, directed graph G' on nodes marked during the phase, and a record of FAR's faults during the phase.

Output: A vine decomposition $\mathcal{V}$ in G.

Initialization: First set $\tilde{G} = G'$. Then contract edges not in chains of G', and contract any chains that don't contain any type-2 reps. All edges so contracted are edges of the tree of $\mathcal{V}$. $\tilde{G}$ now consists of chains separated by (super)nodes.

Loop: Call the (super)node containing the first node marked in the phase *Root*. Repeat the following steps until *Root* is the only node in $\tilde{G}$.

1. Let v_1 and v_2 be two different (super)nodes in $\tilde{G}$. Let SP be the shortest path in G from any node contained in v_1 to any node contained in v_2 that doesn't use any edges of G' (if one exists). Choose v_1 and v_2 such that SP exists and $|SP|$ is minimal.

Let P_1 and P_2 be the directed paths in $\tilde{G}$ from *Root* to v_1 and v_2, respectively. Let s be the last supernode contained in both P_1 and P_2. Let P_1' be the portion of P_1 extending from s on, and similarly for P_2'. (See Figure 1. Edges in the picture correspond to chains in $\tilde{G}$.)

2. Now assume w.l.o.g. that P_1 has more type-2 reps than P_2. Let C be the first chain of P_1: C is identified as a vine of $\mathcal{V}$, and the edges in SP, P_1 (except for C), and P_2 are identified as edges in the tree of $\mathcal{V}$. In $\tilde{G}$ the paths P_1 and P_2 contracted (see Figure 1).

End FINDVINEDECOMP.

There must always be a pair of supernodes v_0 and v_1 for which SP exists, for the following reason. Let v be a leaf in $\tilde{G}$, and let C be the chain leading to v. If all paths from v to nodes marked earlier than those on C run through C, then there could be no more than one rep in C and v, by the definition of FAR—a contradiction.

The following lemma bounds the length of SP.

LEMMA 2.6. *In any iteration of the loop, the length of SP is at most $|C|/2$.*

Proof. The proof is similar to the proof of Lemma 2.5. Let x, y, and z be the last three reps (type 1 or 2) on the last chain of P_1. At the time y is evicted, x is marked, so at that time there must be some path Q of length at most $n(x) - n(y)$ from z, along the chain away from y, to earlier marked nodes (else z would be evicted before y). The path Q joins two different supernodes during this iteration of the loop and hence has a subpath that also joins two supernodes and has no edges of G'. Thus by minimality of $|SP|$ we have $|SP| \leq |Q| \leq n(x) - n(y)$.

Now from Lemma 2.5 we have $n(x) \leq |C|/2$, whence $|SP| \leq |C|/2$. □

LEMMA 2.7. *Procedure FindVineDecomp produces a vine decomposition $\mathcal{V}$ whose vines have value at least $R_2/4$, where R_2 is the number of reps of type 2. The number of nodes in $\mathcal{V} - G'$ is at most half the number of nodes in vines.*

Proof. Clearly the output of FindVineDecomp is a vine decomposition, $\mathcal{V}$. During each iteration through the loop, the number of (type-2) reps that become incorporated into a supernode is at most four times the value of the vine that is identified (this follows from Lemma 2.5, part (iii)). Hence the vines of $\mathcal{V}$ have value at least $R_2/4$.

The bound on the number of nodes of $\mathcal{V}$ follows from Lemma 2.6. □

Lastly we show how to use the vine decomposition $\mathcal{V}$ to construct either a large cycle or a vine decomposition on $k+1$ nodes, without losing much value.

THEOREM 2.8. *Either G contains a vine decomposition $\mathcal{V}'$ on $k+1$ nodes whose value is $\Omega(R_2)$, or a cycle on more than k nodes with value $\Omega(R_2)$.*

Proof. Let $\mathcal{V}$ be the vine decomposition given by procedure FindVineDecomp. We have two cases.

Case 1. $\mathcal{V}$ has a vine $\mathcal{C}$ with $r(\mathcal{C}) \geq R_2/16$. Suppose $\mathcal{C}$ has length l, and assume w.l.o.g. that $\mathcal{C}$ is contained in P_1. Let α be the length of the shortest cycle in G containing $\mathcal{C}$. If $\alpha \leq k+1$, the cycle can easily be extended to a vine decomposition with value at least $\log l$, while by Lemma 2.5, part (iii), $r(\mathcal{C}) = O(\log l)$, so $R_2 = O(\log l)$.

Otherwise $\alpha > k+1$. In addition, $\alpha \leq k(1+2^{-r(\mathcal{C})/4})$, since this is an upper bound on the length of the cycle containing SP, P_1, P_2, and some nodes inside supernodes (by Lemma 2.6). Hence by Theorem 2.2, part 2, the shortest cycle containing $\mathcal{C}$ has value at least $\lfloor r(\mathcal{C})/8 \rfloor = \Omega(R_2)$.

Case 2. No single vine $\mathcal{C}$ has $r(\mathcal{C}) \geq R_2/16$.

Let j be the number of nodes in vines. By Lemma 2.6, $\mathcal{V}$ has at most $k + j/2$ nodes, and by Lemma 2.7, $\mathcal{V}$ has value at least $R_2/4$. Delete the vines one by one, in decreasing order of length, till no more than $k+1$ nodes remain in $\mathcal{V}$. At most $j/2$ nodes are removed prior to the final deletion of vine $\tilde{v}$ that brings the number of remaining nodes below $k+1$. Since they are deleted in increasing order of ratio of value to number of nodes, the vine decomposition remaining before the deletion of $\tilde{v}$ has value at least $R_2/8$. The further deletion of $\tilde{v}$ leaves value at least $R_2/16$, since $\tilde{v}$ has value at most $R_2/16$. Lastly, we can easily extend the tree so that $\mathcal{V}$ has exactly $k+1$ nodes. □

2.2.4. Summary. We summarize the results of this section.

THEOREM 2.9. *For any graph G and memory size k, the algorithm* FAR *is strongly competitive, i.e.,*

$$c_{\mathrm{FAR},k}(G) = O(c_k(G)).$$

Proof. Let g be the number of new nodes requested in the current phase. By Proposition 2.1, the adversary incurs at least $g/2$ faults for this phase, amortized. Suppose that R is the number of reps for the phase; $2R$ is an upper bound on the competitive ratio of FAR for this phase. But $\Omega(R)$ is also a lower bound on $c_k(G)$. Indeed, either there are many type-1 reps, so we can find a tree with value $\Omega(R)$ using Theorem 2.4, or there are many type-2 reps, so we can use Theorem 2.8 to construct a vine decomposition on $k+1$ nodes or a cycle whose value is $\Omega(R)$. In either case, Theorem 2.2 gives $c_k(G) = \Omega(R)$. $\square$

3. Structured program graphs. The problem of devising competitive paging algorithms for directed access graphs is an important one. Unfortunately, in full generality this problem seems very difficult. There is, however, a restricted class of directed access graphs that is both important and tractable, which represents a subset of the stream of instruction references made by a structured program. We examine the class of *structured program graphs* (spg's) as defined in the introduction.

We assume that at run time, the paging algorithm knows the spg (the implications of this assumption are discussed in §4). The information that is not available until run time is the number of times a particular loop will be executed or the particular branch an execution path will take. In other words, it is unknown until run time exactly which path through the access graph will represent the access sequence for a particular execution. Fortunately, our analysis is worst-case over all paths through a particular access graph. The algorithm we introduce, called EVEN, is strongly competitive on all spg's. EVEN is a variation of an algorithm introduced in [2] called 2FAR.

Recall that spg's are recursively defined as follows: Every spg has a designated *start* node and a designated *stop* node. A single directed edge is an spg, where the node with outdegree 1 is the start node and the node with indegree 1 is the stop node. More complex spg's can be constructed by applying the following rules:

(i) Two spg's G_1 and G_2 can be combined to get a new spg by identifying the start node of G_1 and the stop node of G_2 (serial composition).

(ii) Two spg's G_1 and G_2 can be combined to get a new spg by identifying the start nodes and identifying the stop nodes of G_1 and G_2 (branching statement).

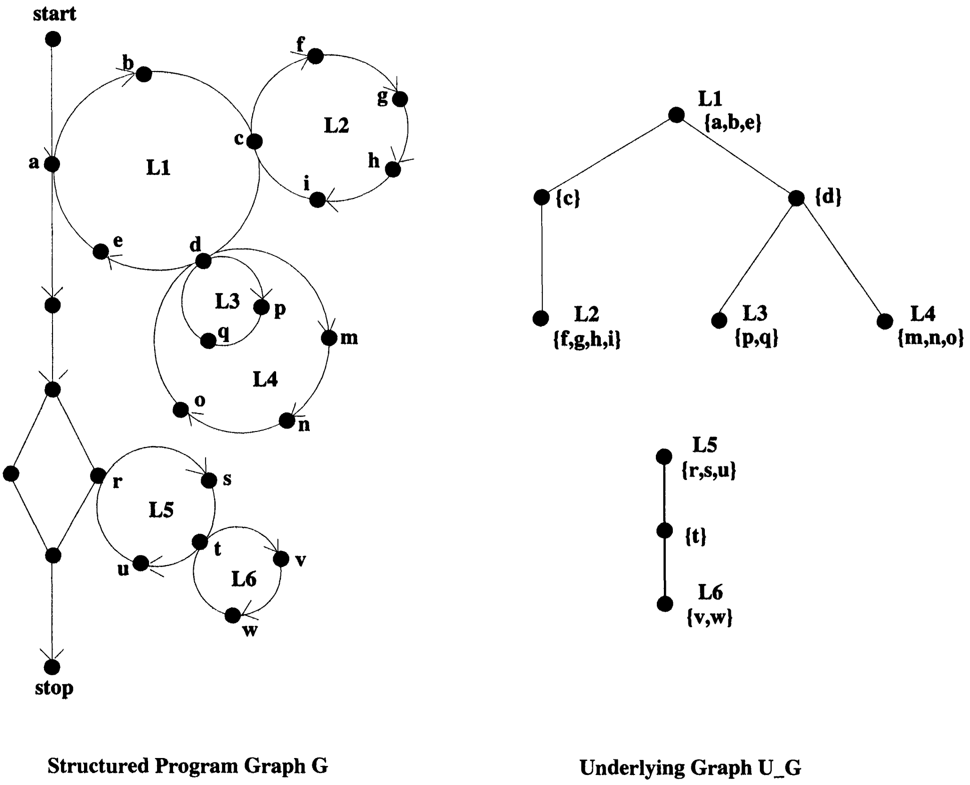
(iii) A node v in an spg can be identified with a node u of a directed cycle to yield a new spg (loop). We call v the *pivot* node for the cycle.

For each subgraph G' of an spg G (including the entire graph), we construct an undirected graph $U_{G'}$, called the underlying graph of G', that represents the relative embedding of the loops of G'. To distinguish between G' and U'_G, we call nodes in G' *nodes* and vertices in $U_{G'}$ *vertices.*

DEFINITION 4. *Let G' be a subgraph of an spg G. The* underlying graph $U_{G'}$ *of G' has one vertex for each loop l in G' (called a loop vertex), and one vertex for each pivot node in G' that is in at least two loops (called a pivot vertex). Each pivot vertex is adjacent to all the loop vertices corresponding to loops containing that pivot node. With each vertex u in $U_{G'}$, we associate a set of nodes of G', denoted $V(u)$: if u is a pivot vertex, then $V(u)$ is the corresponding pivot node. If u is a loop vertex corresponding to loop l, then $V(u)$ is the set of nonpivot nodes in l, and pivot nodes in l that are in only one loop.*

Figure 2 shows an example of an spg G and its underlying graph U_G. For each vertex v in the underlying graph, the nodes in $V(v)$ are shown in curly braces. Vertices in U_G with the name of a loop next to them are loop vertices; the remaining vertices are pivot vertices.

A strongly connected subgraph F of G is a subgraph such that for any two nodes w and v in F, there is a path from w to v and a path from v to w that only uses nodes and edges from F. Notice that if F is a strongly connected subgraph of an spg



Structured Program Graph G

Underlying Graph U_G

FIG. 2. *An spg and its underlying graph.*

G with more than one node and v is a vertex in F, then v is in a loop. In other words, $v \in V(u)$ for some $u \in U_G$.

LEMMA 3.1. *The underlying graph U_F of a strongly connected subgraph F of G is a tree. The underlying graph U_G of an spg G is a forest.*

Proof. By the construction rules for spg's, a strongly connected subgraph F of G consists of a connected set of cycles. Suppose that U_F contains a cycle. Since two loop nodes or two pivot nodes are never adjacent, every loop node contained in the cycle must be adjacent to two pivot nodes in the cycle. Among the loops represented in the cycle, let l be the last one added to the spg according to the construction rules above. Suppose that v and w are the two pivot nodes adjacent to l in the cycle. Since l was added last, a loop containing v and a loop containing w were already in the spg at the time l was added. But by the construction rule for loops, l can only be adjacent to one of them, which contradicts the existence of this cycle. Therefore U_F must be a tree.

Since U_G is the union of underlying graphs of maximal strongly connected subgraphs of G, and each of these is a tree, U_G must be a forest. □

3.1. A lower bound. A vertex in U_F is said to be a *peripheral vertex* if its removal does not disconnect U_F. If u is a peripheral vertex in U_F, $V(u)$ is said to be a *peripheral set* in F. The *size* of a peripheral set is its cardinality, $|V(u)|$. Note that if a node is in a peripheral set of F, then it is contained in only one loop in F. For any strongly connected graph F on $k + g$ nodes, define $l(F, g)$ to be the number of peripheral sets in F that have size at least g. Whenever the value of g is clear from context, we say that a peripheral set is *large* if it has size at least g, and we abbreviate $l(F, g)$ to $l(F)$.

We need the following preliminary lemmas.

LEMMA 3.2. *Let F be any $(k+g)$-node strongly connected subgraph of an spg. Let S be the set of peripheral sets in F. Then the following hold:*

1. *For any $s_1, s_2 \in S$, and for any nodes $x \in s_1$ and $y \in s_2$, there is a path in F from x to y that doesn't pass through any other peripheral set $s_3 \in S$, $s_3 \neq s_1, s_3 \neq s_2$.*
2. *For any y that is not in any peripheral set, and for any x, there is a path from x to y that doesn't contain nodes from any peripheral set (except perhaps for some nodes in s_1 such that $x \in s_1 \in S$).*

Proof. For the first part, consider the directed graph F' obtained from F by deleting, for each large peripheral set s_3 ($s_3 \neq s_1, s_3 \neq s_2$), all nodes in s_3. Since F' is still strongly connected, the desired path from x to y remains.

For the second part, consider the directed graph F' obtained from F by deleting, for each large peripheral set s ($s \neq s_1$ such that $x \in s_1$), all nodes in s. Since F' is still strongly connected, the desired path from x to y remains. □

The following theorem gives a lower bound on the competitive ratio achievable on an spg G. Let $\mathcal{H}_i(G)$ be the set of strongly connected subgraphs of G on i nodes. Let

$$comp(G) = \max_F \max\{(l(F)-1)/g, (H_{l(F)}-1)\},$$

where the maximum is taken over $F \in \mathcal{H}_{k+g}(G), k \geq g \geq 1$, and H_j is the jth harmonic number.

THEOREM 3.3. *If G is a structured program graph, then*

$$c_k(G) \geq comp(G).$$

Proof. Let F be any strongly connected subgraph of G on $k+g$ nodes, and let A be a paging algorithm. Let S be the set of large peripheral sets of F.

We now describe the adversary strategy. The adversary operates in phases (slightly different from the phases referred to elsewhere). We show that the adversary can force A to incur $g \cdot comp(G)$ faults in a phase while the adversary only incurs g faults in a phase. A phase starts with all of the adversary's holes on one set in S and the last request on a node in $\cup S$.

If the algorithm A ever maintains a hole on a node not contained in $\cup S$, or in a set in S that has already been requested in the phase, then the adversary requests a path to the hole without passing through any unrequested nodes in $\cup S$. Thus we can assume that all of A's holes are on unrequested nodes in $\cup S$. In this case, the adversary requests a path to the peripheral set in S with the most holes, such that the path followed doesn't hit any other peripheral sets in S. The phase ends when all but one of the large peripheral sets have been hit.

When the ith peripheral set is hit, A incurs at least $\lceil g/(|S|-i+1)\rceil$ faults. Therefore, the algorithm incurs at least

$$\begin{aligned}\lceil g/|S|\rceil + \lceil g/(|S|-1)\rceil + \cdots + \lceil g/2\rceil &\geq \max(g(H_{|S|}-1), |S|-1)\\ &\geq g \cdot comp(G)\end{aligned}$$

faults. Meanwhile, the adversary services the sequence by initially moving all g of its holes to the peripheral set that will not have been hit at the end of the phase and thus incurs at most g faults during the phase. □

3.2. The algorithm EVEN. We now explain the operation of EVEN on spg's. EVEN works in two modes. The first mode is when the set of nodes occupied by the servers and the present request are not contained in a strongly connected component. In this case, EVEN services a fault by using any server which is on a node that is not reachable from the current request. In the second mode, all the servers are in a strongly connected component and EVEN works as a marking algorithm. A new phase begins either when EVEN switches from mode 1 to mode 2 or when $k+1$ nodes have been marked in the previous phase (during the second mode). Roughly, EVEN attempts to vacate servers in peripheral node sets, and does so in a uniform way. A few definitions are necessary in order to rigorously describe the algorithm.

Let P be the set of nodes occupied by servers at the beginning of a phase. Let $\bar{P}$ be the smallest strongly connected subgraph that contains all of P.

Consider the underlying graph of $\bar{P}$, $U_{\bar{P}}$. Root $U_{\bar{P}}$ at the vertex whose node set contains the last request of the previous phase. This vertex is unique. As noted earlier, each vertex u in the underlying graph of $\bar{P}$, $U_{\bar{P}}$, corresponds to a node set in $\bar{P}$, $V(u)$. A node set is *empty* if it does not have any servers on it. A *limb* $L = (l_1, \ldots, l_r)$ in $U_{\bar{P}}$ is a simple path in $U_{\bar{P}}$ such that l_1 is a peripheral vertex (leaf of $U_{\bar{P}}$) and l_{i+1} is the parent of l_i for $1 \leq i < r$. The *limb set* $V(L)$ is the set of nodes corresponding to the vertices of the limb L (i.e., $\cup_{1 \leq i \leq r} V(l_i)$). EVEN keeps track of the limbs, making sure that each limb has servers only on the nodes in $V(l_r)$, i.e., all but the last vertex on the limb is empty. The vertex l_r (the endpoint of the limb that is furthest from the leaf) is called the *active vertex*, and $V(l_r)$ is called the *active set.*

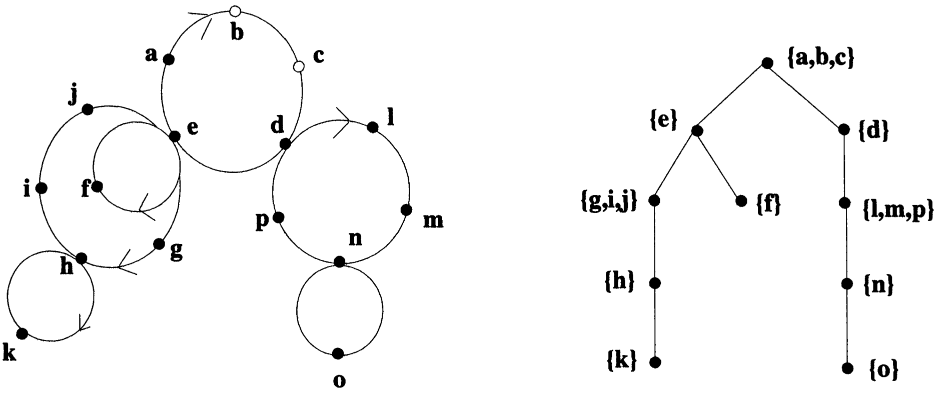
Limbs grow toward the root during the phase. At the beginning of a phase, each peripheral vertex is a limb. The peripheral set is the active set for that limb. Notice that because we chose $\bar{P}$ to be the minimum strongly connected subgraph that contains all nodes with servers, every peripheral set will contain at least one server. EVEN will always evacuate servers from the active set of some limb. A limb is said to *die* when any of the following conditions hold:

1. The active node set empties and some node in the node set of the parent vertex has been requested.
2. The active node set empties and the parent vertex has another child that is not yet in a dead limb.
3. A node in the active set is requested.

A *live* limb is one that has not died. The *value* of a limb L is the number of nodes in the limb set $V(L)$ that have been evacuated during the phase.

EVEN's policy for deciding which node to vacate when servicing a fault is determined as follows: Pick the live limb of minimum value. Evacuate any node in the node set of the active vertex. If the active vertex becomes empty then add the parent vertex to the limb (unless the limb dies for the reasons described above). The parent becomes the limb's active set. If there are no live limbs, then evacuate the unmarked node that is occupied by a server and is farthest from the current request.

Figure 3 shows an example of the operation of EVEN in mode 2. On the left side of the figure is the subgraph $\bar{P}$, and on the right side is the corresponding underlying graph $U_{\bar{P}}$. At the beginning of the phase all nodes are occupied by servers except for b and c, and the last request of the previous phase was at a. Initially there are three limbs, the peripheral vertices of the underlying graph: $\{k\}$, $\{f\}$, and $\{o\}$. The request to b results in the eviction of o, at which point, the parent vertex is added to the limb, resulting in the limb $(\{o\}, \{n\})$, with active vertex $\{n\}$. The request to c results in the eviction of f, at which point we observe that the parent of $\{f\}$ $(\{e\})$



Last Request of Previous Phase: a

Request Sequence: b,c,d,e,g,h,i,j,e,f,e,g,h,k,h,i,j,e,a,b,c,d,l,m,n,o

FIG. 3. *An example $\bar{P}$, $U_{\bar{P}}$, and request sequence.*

in the underlying graph has another child ($\{g, i, j\}$) that is not yet in a dead limb, and so by rule 2, the limb $\{f\}$ dies. At this point the two holes are at f and at o. Therefore, no further faults are incurred until the request to f, at which point k is evicted. The parent vertex of $\{k\}$ (h) has already been requested, and so by rule 1, the limb $\{k\}$ dies. The next fault is at the request to k, which results in the eviction of n, and the only remaining limb is extended to ($\{o\}, \{n\}, \{l, m, p\}$), with active set $\{l, m, p\}$. At this point, the two holes are at o and n. Finally, when l is requested, the limb dies by rule 3, since a node in the active set is requested.

In the next section, we bound the competitive ratio of EVEN.

3.3. The upper bound.

We will need the following three lemmas.

LEMMA 3.4. *Consider a phase of* EVEN. *If there are no live limbs, but there remain unmarked nodes that are occupied by servers, then all of the unmarked servers reside on the only simple path from the currently requested node to the first node that was requested in the phase.*

Proof. If no live limbs remain, then every loop with unmarked servers in $\bar{P}$ has a node that has been requested in the phase. Consider the set S of all nodes in $\bar{P}$ which have not been requested during the phase but are contained in cycles where some node has been requested. All unmarked servers reside on nodes in this set. Furthermore, since the set of requested nodes is contiguous, S forms a simple connected path in $U_{\bar{P}}$ from the most recently requested node to the first node requested in the phase. □

LEMMA 3.5. *At any point in a phase of* EVEN, *if there are l live limbs, the value of each limb is bounded above by $\lceil g/l \rceil$, where g is the number of new nodes requested in the phase.*

Proof. The values of any two live limbs differ by at most 1. Furthermore, the total number of evacuated nodes in live limbs at any time is at most g. The lemma follows. □

LEMMA 3.6. *Consider a phase of* EVEN *where $|\bar{P}| = k + g$. Let L be the set of limbs that grows in the phase. Then the limbs in L can be divided into two sets, L_1*

and L_2, and there is a strongly connected subgraph H of $\bar{P}$ of size $k+\alpha$, $1 \leq \alpha \leq g$, such that the following hold:

1. *Every peripheral set in H has size at least α.*
2. $|L_1| \leq 2l(H,\alpha)$.
3. *The total number of nodes contained in limbs in L_2 and evacuated during the phase is at most $2(g-\alpha)$.*

Proof. We trim $\bar{P}$ by repeatedly applying the following procedure: Let R be the subgraph of $\bar{P}$ that remains (initially $R = \bar{P}$). While R has $k+h$ nodes, but has peripheral sets of size less than h, apply the following rules: Pick a peripheral vertex r of U_R such that $V(r) < h$. Remove r from U_R and remove $V(r)$ from R. (Note that since every leaf of U_R is a loop vertex, R remains strongly connected.) If as a result of this operation there is a peripheral vertex v that is a pivot vertex, remove v from U_R and set $V(p(v))$ to be $V(p(v)) \cup V(v)$, where $p(v)$ is the parent of v in U_R. (Note that $p(v)$ is again a loop vertex.)

Call the resulting graph H. By the termination condition of the procedure, if H has $k+\alpha$ nodes, then every peripheral set has size at least α.

Figure 4 shows an example of the trimming operation. On top we see $\bar{P}$ and $U_{\bar{P}}$, with thick lines on the underlying graph representing the limbs. During the trimming process, loops a, b, c, and d are trimmed. The resulting underlying graph, U_H, is shown in the bottom left. Note that in the trimming process, limb l_4 was removed completely, whereas only part of limb l_2 was removed. Note that the intersection of l_2 with H does not contain a peripheral set of H.

Returning to the remaining two conditions of the lemma, if a limb in L has no intersection with H, then put it in L_2 and remove it from L. The total number of nodes in the limbs placed in L_2 so far is at most the total number of nodes removed from $\bar{P}$, which is in turn upper bounded by $g-\alpha$.

All remaining limbs in L intersect H. To account for these, create a limb tree as follows: Create a special root node. In addition, for each limb, create a node in the limb tree. Limb l is the parent of limb l' if the highest vertex in l' is the child of a vertex in l in the underlying graph $U_{\bar{P}}$. Any remaining limbs without parents take the root to be their parent. Note that any leaf in the limb tree corresponds to a limb l that contains a peripheral set in H. Other limbs may or may not contain peripheral sets of H. Figure 4 shows an example limb tree.

Let L' be the set of nodes in the limb tree whose parent has degree 2 (and is not the root). Then $|L'|$ is the number of degree-2 limb nodes in the tree. Therefore, there are at least $|L| - |L'|$ nondegree-2 limb nodes. But the average degree of nodes in a tree is less than two, and so at least $(|L| - |L'|)/2$ limbs in the tree are leaves and hence contain a peripheral set in H. We place the limbs in $L \setminus L'$ in L_1. Therefore, the total number of limbs in L_1 is at most $2l(H,\alpha)$ so far.

Consider a limb l in L'. Let $p(l)$ be the limb corresponding to the parent of l in the limb tree.

If $p(l)$ contains a peripheral set of H, add l to L_1. This limb can be amortized against the peripheral set belonging to $p(l)$. Note that $p(l)$ is not a leaf of the limb tree, and therefore is not charged against by L_1 limbs from $L \setminus L'$. ($p(l)$ may or may not end up in L_1 itself, depending on whether it is in L' or not.) Consequently, the total number of limbs in L_1 remains at most $2l(H,\alpha)$.

If $p(l)$ does not contain a peripheral set in H, then place l in L_2. We just have to prove that the number of evacuated nodes in $p(l) \cap \{\bar{P} \setminus H\}$, which we denote by S, upper bounds the number of evacuated nodes in l. (A node is said to be *evacuated*

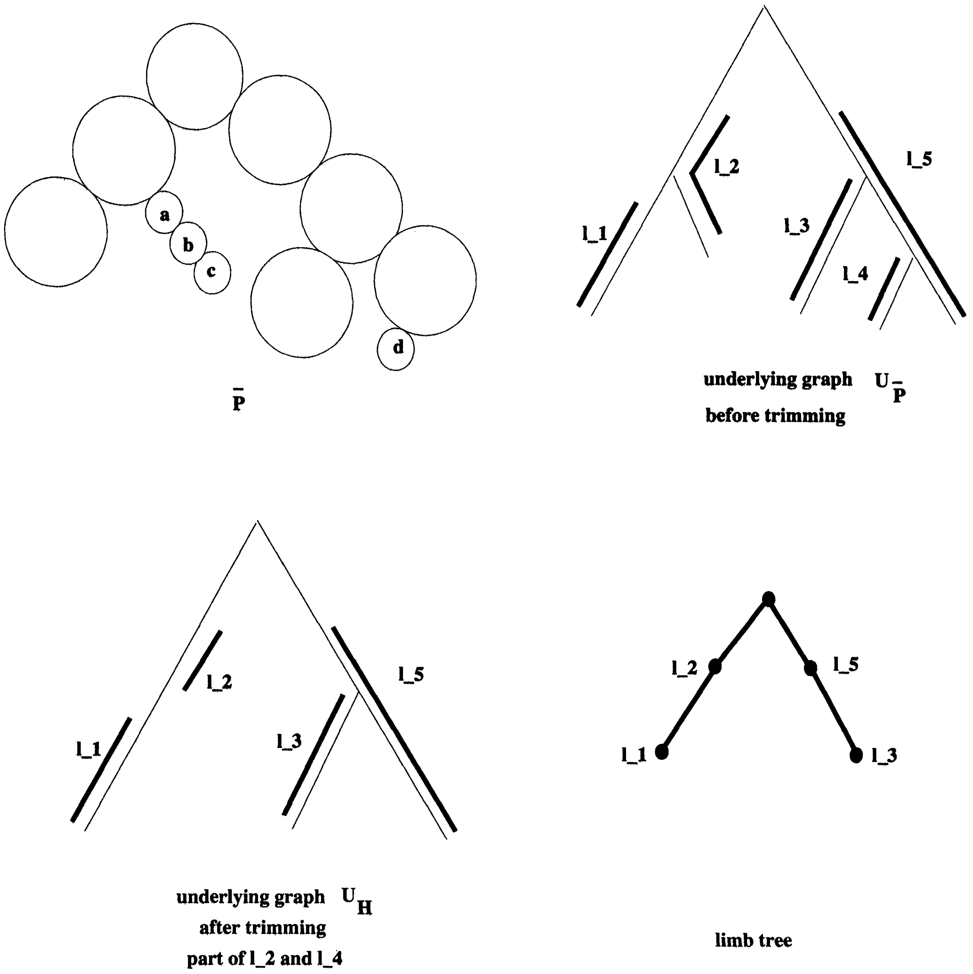


FIG. 4. *An example of the trimming process and limb tree.*

if it was evacuated some time in the phase). Since l is the only child of $p(l)$, we are amortizing against the set S only once.

Let t be the highest vertex in l. Let T be the parent of t and t' the only sibling of t in $U_{\bar{P}}$. Since the limb $p(l)$ has only one child in the limb tree and does not contain a peripheral set in H, t' and all of its descendants in $U_{\bar{P}}$ do not appear in U_H. That is, the set of nodes in $p(l)$ corresponding to t' and its descendants is exactly S. Recalling that the loop T is part of the limb $p(l)$ (otherwise $p(l)$ wouldn't be the parent of l in the limb tree), it must be that l died before $p(l)$ died. This means that t became empty before t' became empty and so the number of evacuated nodes in l is at most $|S|$. □

THEOREM 3.7. *The algorithm* EVEN *is strongly competitive on the class of structured program graphs. In other words, for any structured program graph G, $c_{k,\mathrm{EVEN}}(G) = O(comp(G))$.*

Proof. Consider an spg G. If EVEN incurs a fault on node v when in mode 1, then it is the first time that node v has been requested during the entire sequence. As a result, both EVEN and the optimal algorithm fault on the request to node v.

Thus, when EVEN is in mode 1, the number of faults that it incurs is equal to the number of faults the optimal algorithm incurs. We must now bound the number of faults incurred by EVEN in mode 2.

Let P' be the set of nodes requested in the phase before the previous phase. Let P be the set of nodes requested in the previous phase and let C be the set of nodes requested in the current phase. If the algorithm just switched from mode 1 to mode 2, then P is the set of nodes currently occupied by the servers, and P' are the k distinct nodes requested previous to the first request to any node in P.

Let g' be the number of new nodes requested in the last phase ($g' = |P - P'|$) and let g be the number of new nodes requested in this phase ($g = |C - P|$). If the number of faults EVEN incurs for an arbitrary phase is bounded by $O((g+g')c_k(G))$, then by Proposition 2.1, $c_{k,\text{EVEN}}(G) = O(c_k(G))$.

If $P' \cap C = \emptyset$, then $g' + g \geq k$. In this case, EVEN incurs $O(g' + g)$ faults during the phase, since no marking algorithm incurs more than k faults in a phase. If $P' \cap C \neq \emptyset$, then there is a strongly connected component containing P, contained in $C \cup P \cup P'$. Indeed, there is a directed path from the first node requested in C to a node x in $P' \cap C$. (This path contains at most g nodes outside P.) Since $x \in P'$, there is a path from x to the first node requested in the previous phase. (This path contains at most g' nodes outside P.) Finally, there is a path entirely inside P from the first node requested in the previous phase to the first node requested in the current phase. Therefore, if $\bar{P}$ is the smallest strongly connected subgraph containing P, $\bar{P}$ has at most $k + g + g'$ nodes.

Let L be the set of limbs in $\bar{P}$ that evolve in the phase. We now apply Lemma 3.6 to obtain a graph H of size $k + \alpha$ and a partition of L such that:

1. Every peripheral set in H has size at least α.
2. $|L_1| \leq 2l(H, \alpha)$.
3. The total number of nodes contained in limbs in L_2 that are evacuated during the phase is at most $2(g + g')$.

We can now show that the number of faults that EVEN incurs in the current phase is $O(g + g' + l(H) + gH_{l(H)})$. We count the number of faults by counting the number of nodes evacuated in $\bar{P}$. In fact, we only count the number of nodes in L that are evacuated. This is sufficient because Lemma 3.4 implies that there are at most $g + g'$ faults inbetween the time that the last limb dies and the end of the phase. As long as there are live limbs, all evacuated nodes are contained in limbs. Thus, the number of nodes that are not in any limb in L and are evacuated during the phase is at most $g + g'$.

We now bound the number of nodes in L that are evacuated. The number of nodes in L_2 evacuated in the phase is at most $2(g+g')$, by condition 3 in Lemma 3.6.

The number of evacuated nodes that are on limbs in L_1 is just the sum over all limbs in L_1 of the value of that limb when it dies. Consider the ith limb in L_1 that dies. By Lemma 3.5, the number of evacuated nodes on that limb is at most $\lceil g/(|L_1| - i + 1)\rceil$. Thus by condition 2 of Lemma 3.6, the total number of evacuated nodes in L_1 is at most

$$\sum_{j=1}^{2l(H)} \lceil (g/j) \rceil = O(l(H) + gH_{l(H)}).$$

We have shown that the number of faults that EVEN incurs in the current phase is $O(g + g' + l(H) + gH_{l(H)})$. Since $\alpha \leq g + g'$ and, by Theorem 3.3, $l(H)/\alpha + H_{l(H)} \leq$

$c_k(G)$, the number of faults EVEN incurs in the phase is

$$O(g+g'+l(H)+gH_{l(H)}) = O\left((g+g')\left(\frac{l(H)}{\alpha}+H_{l(H)}\right)\right) = O((g+g')c_k(G)). \qquad \square$$

4. Limitations of the model and open problems. There are four fundamental limitations to our work. The first is the fact that the model of structured program graphs that we use does not allow branching within loops.

The second limitation concerns our assumption that the paging algorithm knows the access graph. This is not realistic for several reasons. If the set of virtual pages accessed by a structured program and the data on those pages were static, life would be easy. In fact, the virtual pages associated with the data and instructions of a program typically fall into three categories.

(i) *Static.* At link time, program text (code) and global variables are assigned virtual addresses. These addresses remain fixed for the lifetime of the program.

(ii) *Heap.* Dynamically allocated data are assigned virtual addresses at runtime, when the memory is allocated. As long as these data are not deallocated, their virtual addresses remain fixed. However, once this storage is reclaimed, these virtual addresses can be allocated to other data. Consequently, the data on virtual pages associated to the heap may change many times over the lifetime of the program.

(iii) *Stack.* Variables local to procedures are assigned virtual addresses on the stack. Since the stack is growing and shrinking as the program runs, in accordance with the set of procedures being executed, a specific procedure's local variables may have several different virtual addresses over the runtime of the program.

Consequently, a given virtual address may store many different data items, and a given data item may reside in several different virtual addresses. This implies at the very least that one cannot directly associate program data with specific virtual pages.

Nonetheless, access graphs have well-defined semantics: an edge from virtual page p_1 to virtual page p_2 in an access graph means that at some point in the virtual address trace of the program, a reference to an address on p_2 immediately follows a reference to an address on p_1.

Since the access graph depends on the virtual address trace of the program, which in turn depends on the input data, it is a nontrivial problem to construct it. (In fact, in its most general form, the problem is undecidable since one must know if the program will halt in order to determine the access graph.) In practice, if one wishes the access graph to be accurate, one may need to execute or simulate the execution of the program.

This limitation raises several interesting open questions: Are there good approximations to the access graph that can be determined at compile time? Is there a strongly competitive algorithm that "learns" the access graph as more requests are seen? Also, are there good algorithms that only maintain a portion of the access graph, say, the subgraph generated by the pages in fast memory?

A third fundamental limitation of this model is that there is only a single pointer into the access graph at any time. For example, the spg's that we have studied only make sense in the context of the instructions of a program. Spg's do not adequately model both the instruction and the data references of a program. In order to model both, one would need at least two pointers into the access graph, one into a structured program portion of the graph, and another into an undirected or directed subgraph whose pages are storing program data. The request sequence would then consist of a walk on the graph, where the next request is always a neighbor of one of the two nodes pointed to. One could also imagine having more than two pointers, for example, if there were a collection of pointers into arrays, or other data structures in the program. It remains an interesting open question to generalize our results to the multiple-pointer case.

The last fundamental limitation of our work is that the competitive analysis we employ is worst-case. We optimize the worst-case ratio between our algorithm and the optimal offline, assuming that an adversary chooses the request sequence. Locality of reference is enforced by limiting the adversary's sequences to walks on the access graph. Nonetheless, walks on the access graph may bear little resemblance to the program address trace from which the access graph was generated. Therefore it is not obvious that optimizing the competitive ratio against such an adversary yields an algorithm that performs well in practice.

Recently, Karlin, Phillips, and Raghavan attempted to address this problem by studying paging algorithms for the case where the request sequence forms a Markov chain. The Markov chain incorporates locality of reference into the sequence, while eliminating the whole notion of an adversary.

The theoretical work on paging with access graphs could be complemented very well by experimental studies. It would be interesting to evaluate whether there are approximations to access graphs that model realistic page request sequences well. It would also be extremely interesting to evaluate how well the competitive algorithms described in this paper perform in practice.

Another interesting direction for research relates to granularity. In the introduction, we mentioned that an undirected access graph might be a suitable model for a program that performs operations on a tree data structure, as long as the mapping of the tree nodes to pages of virtual memory represents a contraction of the tree. Similarly, spg's are good models of the flow of control among individual program statements. However, once the instructions are assigned virtual addresses, the underlying access graph may not look anything like an spg, since many instructions are assigned to a single virtual page.

For a fixed page replacement strategy, different assignments of virtual addresses to data and procedure entry points can result in vastly different page-fault rates, since changing the layout changes the partition into pages. It would be very interesting to study techniques for laying out instructions and data in virtual memory, so that the partition into virtual pages results in a low page-fault rate.

Finally, dealing with the most general definition of structured program graphs remains open, as well as two questions from [2]:

Open Question 1. Design an algorithm that is strongly competitive on all structured program graphs (i.e., allow branching within loops).

Open Question 2. Show that for all G and k, $c_{\mathrm{LRU},k}(G) \leq c_{\mathrm{FIFO},k}(G)$.

Open Question 3. Is there a "universal" randomized algorithm that is close to optimal on every G? Is there a graph-theoretic lower bound on $c_k(G)$ for randomized algorithms against an oblivious adversary?

ON THE VALUE OF COORDINATION IN DISTRIBUTED DECISION MAKING*

SANDY IRANI† AND YUVAL RABANI‡

Abstract. We discuss settings where several "agents" combine efforts to solve problems. This is a well-known setting in distributed artificial intelligence. Our work addresses theoretical questions in this model which are motivated by the work of Deng and Papadimitriou [*Proc.* 12*th IFIPS Congress*, Madrid, 1992; *Proc. World Economic Congress*, Moscow, 1992]. We consider optimization problems, in particular load balancing and virtual circuit routing, in which the input is divided among the agents. An underlying directed graph, whose nodes are the agents, defines the constraints on the information each agent may have about the portion of the input held by other agents. The questions we discuss are as follows: Given a bound on the maximum out-degree in this graph, which is the best graph? What is the quality of the solution obtained as a function of the maximum out-degree?

Key words. analysis of algorithms, distributed computation, competitive analysis, load balancing, virtual circuit routing

AMS subject classifications. 68Q22, 68Q25

1. Introduction.

In recent years, there has been a great deal of research activity focused on analyzing algorithms which must compute using partial information about the problem to be solved. Much of this research effort has focused on *on-line* algorithms, where the limitation is due to temporal constraints: the input is arriving a piece at a time, and output must be produced before all the input arrives. The study of on-line algorithms is motivated by the fact that many problems which arise in a wide variety of settings are inherently on-line (i.e., one doesn't have the luxury of being able to collect all the information about an the instance of the problem before a partial answer must be produced). However, part of the reason for the recent interest in this area is the introduction of an appealing means of evaluating on-line algorithms called *competitive analysis* [18, 15]. The idea is to determine the quality of an on-line algorithm by comparing its performance to the performance of the optimal algorithm that can see the entire input in advance. Thus we measure what is lost by solving the problem on-line.

The work in this paper follows a model proposed by Deng and Papadimitriou [11] and further discussed by Papadimitriou and Yannakakis [17] who extend the use of competitive analysis to a more general setting than on-line algorithms. They discuss settings where several "agents" combine efforts to solve problems. The idea is that global information about a problem to be solved may be lacking due to spatial (or other) constraints. The framework suggested in [11] is to model specific constraints in the availability of information and study the solution quality that can be obtained under these information regimes. In [17], the information regime is determined by the input. Linear programming is considered, where each agent is responsible for a

variable or a set of variables and sees all constraints involving those variables.

We take a different approach that is suitable for the case where information is available at a price. Rather than analyzing particular constraint structures, we focus on the best constraint structure given a bound on the amount each agent communicates. We address the following questions. To what extent is it useful for the agents to communicate information about the piece of the input that each holds? What is the most effective pattern of communication? If some a priori information about the problem instance is known, how can this information be used to improve the solution quality?

1.1. The model. We consider optimization problems in the following context: A set of agents $A = \{a_0, a_1, \ldots, a_{n-1}\}$ are given an instance I of an optimization problem. Each agent is presented with a portion of the input: a_i gets input I_i, where $I = \cup_i I_i$. We assume that the objective function is not part of the input and is known to all agents.

A *strategy* S for the agents is a pair (G, D), where G is a directed graph and D is a set of algorithms, one for each agent. We refer to G as the *knowledge graph* because it represents the information available to each agent: a directed edge (a, b) in G means that agent a knows of the input portion given to agent b. Each agent's decisions are a function only of the input it knows: a set of algorithms D is *valid* for a knowledge graph G if the algorithm for each agent a_j is a function only of I_j and all I_k such that $(j, k) \in E$. If $S = (G, D)$ is a strategy, then D must be valid for G. In some cases, we refer to an undirected knowledge graph in which case an edge between agents a and b indicates that a and b know each other's input.

We denote by $\text{cost}_S(I)$ the value of the objective function for a strategy S on input I, and we denote by $\text{cost}(I)$ the value of the objective function for the optimal, global strategy on input I. A strategy S is *c-competitive* if for every I, $\text{cost}_S(I) - c \cdot \text{cost}(I)$ is bounded by a constant. The *competitive ratio* of S, denoted c_S, is the infimum over all c such that S is c-competitive.

If the knowledge graph is predetermined, then the goal is to devise the best algorithm with the given limitation in information. Thus, for a given knowledge graph G, we would like to choose the best set of algorithms D that are valid for that graph. The competitive ratio for a knowledge graph, denoted c_G, is the infimum of $c_{(G,D)}$ over algorithms D that are valid for G. On the other hand, if complete information is available (that is, any two agents can communicate) but at a cost, we would like to determine to what extent the solution can be improved with more information. Thus, we consider strategies that are constrained by limiting the maximum degree of a vertex in G. If G has maximum degree r, we call S an *r-strategy*. c_r is the infimum of c_S over all r-strategies. What pattern of communication and what algorithm are best for a given limitation in communication: for a given r, what r-strategy achieves c_r? To what extent is communication useful: how does c_r decrease as r increases? We study these general issues with respect to two specific problems: load balancing and virtual circuit routing.

Awerbuch et al. [3] study a problem very similar in flavor to the problems we consider here. They consider the number of steps necessary to broadcast a message in a fixed network. They show bounds on the number of steps necessary as a function of the radius of the network graph each vertex knows. Unlike our model, the processors do not get to choose the information they acquire. However, for the problems we consider, it is always optimal for the agents to communicate by grouping themselves into disjoint cliques and completely sharing information within a clique.

This model has several applications. We mention some of them here.

Parallel programming. It is now clear that realistic models of parallel computation must address communication overhead as well as processing time [1, 10, 12, 16, 19]. It seems easier to design and implement a parallel program where the parallel tasks are oblivious to each other as much as possible. Coordination between parallel tasks requires additional programming and increases communication overhead. Our work speaks to the tradeoff between the amount of coordination in a parallel program and the effectiveness of that program in solving specific problems. Particularly, the design of system services such as batch execution might benefit from this analysis.

High-speed network management. High-speed networks are expected to serve a large number of users bidding for a variety of services. The allocation of network resources by a centralized network manager becomes impractical under such conditions. As pointed out in [17], the multiple-agents model is suitable for discussing performance degradation due to the distributed nature of network management. Specifically, our results relate to the following questions: Network managers are requested to allocate virtual connecting paths between pairs of sites. Each virtual circuit consumes a fixed bandwidth. What is the required capacity of network links and switches to handle the expected traffic? How does this capacity change as a function of communication among network managers? What network structures support distributed management?

Large-scale planning. The question of cooperation among communicating problem solvers is considered fundamental in distributed AI, as it addresses planning problems in a large-scale system or organization that is faced with a rapidly changing environment. See [6] for a comprehensive collection of papers in the field. The AI approach tends to be either qualitative or experimental. Recent theoretical results [11, 17] as well as this work focus on quantitative analysis of such problems.

1.2. Outline of results. We consider the load-balancing problem discussed in [11]. Each agent gets a set of jobs to be executed, where the length of each job is known in advance. The agents redistribute the jobs among themselves. Their goal is to minimize the maximum load on an agent. The optimal strategy clearly divides the jobs evenly among all the agents, or as evenly as possible given the granularity of the job lengths.

Deng and Papadimitriou give a complete analysis of the problem of three agents scheduling jobs on two processors for all possible knowledge graphs. They also show that for an arbitrary number n of agents distributing jobs among themselves, when the agents do not communicate at all (i.e., the knowledge graph has no edges), then there is a way for each agent to redistribute its jobs that achieves a competitive ratio of $2\sqrt{n}$. Furthermore, for any deterministic strategy, there is a way of assigning n jobs of length 1 to the n agents such that some agent receives at least $\sqrt{n}$ jobs. Thus, if G has no edges, then $\sqrt{n} \leq c_G \leq 2\sqrt{n}$.

We generalize their results to show that for a fixed knowledge graph G, $\sqrt{\alpha(G)} \leq c_G \leq 2\sqrt{\phi(G)}$, where $\alpha(G)$ is the size of the maximum independent set of G and $\phi(G)$ is the size of the minimum clique cover in G. Thus, by choosing G to be a collection of disjoint $(r+1)$-cliques, $\sqrt{n/(r+1)} \leq c_r \leq 2\sqrt{n/(r+1)}$. The factor of two can be reduced when all the job lengths are identical.

As one might suspect, randomization is a very powerful tool in this setting. Deng and Papadimitriou show for the empty knowledge graph that if each agent sends each job to a random destination, then the competitive ratio is $\log n / \log\log n$. We show an asymptotically matching lower bound (also shown independently by Alon

[2]). Furthermore, we consider r-strategies for all r. We show tight bounds of $c_r \in \Theta(\log(n/r)/\log\log(n/r))$. The lower bound holds for any distribution of r-regular graphs, i.e., even when global information available to all agents is hidden from the adversary. For example, the lower bound holds even if the agents can organize themselves into random collections of disjoint $(r+1)$-cliques. The upper bound follows, as in the deterministic case, from an algorithm that gives $c_G = O\left(\log\phi(G)/\log\log\phi(G)\right)$ for all knowledge graphs G. The upper bound requires that agents which share their pieces of input can also toss common coins (but no global coins are needed).

We also consider questions that relate to virtual circuit routing. The problem is to route permutations in a network where each agent is responsible for selecting the route of a single input. The goal is to minimize the node or edge congestion. When no information is available to the agents besides their own destination assignment, this is the well-studied question of *oblivious* routing. If the paths for each input–output pair are precomputed by some central algorithm, we have the problem of *global* routing—also a very well-understood problem. We consider routing where the available information is in the spectrum between the oblivious and the global cases. Each agent (which represents a single input vertex in the network) knows its own destination and the destinations of some of the other agents and must decide on its path using the available information. The knowledge graph represents what information is available to which agents, and we determine the benefit obtained when each agent has degree at most r in the knowledge graph.

We consider N-node, degree-d networks with n input and n output nodes. We assume that the network is optimal for the required task, i.e., the agents may choose the structure of the network. For that reason, we do not give a competitive analysis but rather a worst-case analysis. We show an r-strategy for routing in a $\log n$-dimensional Beneš network [4, 20] with maximum edge congestion of $\sqrt{n/r}$. The lower bounds on oblivious routing of [7, 14] can be modified to show lower bounds of $(1/2d)\sqrt{n^2/(Nr)}$ on edge congestion and $(1/2)\sqrt{n^2/(Nr(d+1))} - (n/2Nr)$ on node congestion. We show a lower bound on node congestion of $\Omega\left(\log(n/r)/\log\log(n/r)\right)$ for randomized r-strategies. The lower bound follows the lower bound on oblivious single-port routing of Borodin et al. [9]. All of our bounds match the previously known bounds for $r = 1$ (oblivious routing) and $r = n$ (global routing).

2. Load balancing.

Each agent decides deterministically where to send its jobs based on the set of jobs it has and the set of jobs each of its neighbors in the knowledge graph has. Let $\phi(G)$ be the size of the minimum clique cover for a graph G and $\alpha(G)$ the size of the maximum independent set of G. We prove the following theorem.

THEOREM 1. *For every graph G, $\sqrt{\alpha(G)} \le c_G \le 2\sqrt{\phi(G)}$.*

Proof. Let S be an independent set. Let $|S| = s$. Give $n/\sqrt{s}$ jobs to each agent in S. After the jobs have been redistributed, some agent a will get $\sqrt{s}$ jobs. Pick a subset of at most $\sqrt{s}$ agents such that the total number of jobs given to agent a by agents in the subset is at least $\sqrt{s}$. Now instead, give $n/\sqrt{s}$ jobs only to agents in the subset. Since there are at most n jobs total, the optimal cost is one. Agent a still gets $\sqrt{s}$ jobs.

Let $\phi(G) = \Phi$. Partition the vertices into Φ cliques, $c_0, \ldots, c_{\Phi-1}$. A clique acts as one agent since all the agents know the inputs of the other agents in the clique. Fix an arbitrary ordering on the agents: $a_0, \ldots, a_{n-1}$. Let $m = n/\Phi$. Each clique c_i divides its tasks into at most n groups so as to minimize the maximum length of a group's tasks. Then it sorts the groups in decreasing order by length. Clique c_i sends the jobs in group k to agent $a_{\lfloor mi \rfloor + k \pmod{n}}$.

Fix some agent a_j. Let i_j be the number that satisfies $\lfloor m i_j \rfloor \leq j < \lfloor m(i_j+1) \rfloor$. Let t_i denote the number of jobs given to agent j from the clique $c_{i_j - i \pmod{\Phi}}$ (the clique that precedes clique i_j in the ordering by i). Fix some k such that $1 \leq k < \Phi$. We divide the work sent to agent a_j into two parts: $T_1 = \sum_{i=0}^{k-1} t_i$ and $T_2 = \sum_{i=k}^{\Phi-1} t_i$. The total job length sent to agent a_j is $T = T_1 + T_2 \leq 2\max\{T_1, T_2\}$. We can lower bound the cost to the optimal strategy by $\max_{0 \leq i < k} t_i$ because each clique divides its jobs into groups so that the maximum total length in any group is minimized. If $T_1 \geq T_2$,

$$\frac{T}{\max_{0 \leq i < k} t_i} \leq \frac{2T_1}{\max_{0 \leq i < k} t_i} \leq 2k.$$

Clique $c_{i_j - i \pmod{\Phi}}$ sends at least t_i jobs to agents $\lfloor (i_j - i)m \pmod{n} \rfloor, \ldots, \lfloor m i_j \rfloor$. Thus the total number of jobs originating at clique $c_{i_j - i \pmod{\Phi}}$ is at least $(\lfloor m i_j \rfloor - \lfloor m(i_j - i) \pmod{n} \rfloor + 1)t_i \geq m i t_i$. The total length of all the jobs in the system is at least $\sum_{i=k}^{\Phi-1} m i t_i \geq mk \sum_{i=k}^{\Phi-1} t_i$. Thus, the optimal solution sends jobs of total length at least

$$\frac{mk \sum_{i=k}^{\Phi-1} t_i}{n} = \frac{\sum_{i=k}^{\Phi-1} t_i}{\Phi/k} = \frac{kT_2}{\Phi}$$

to some agent. Thus, if $T_2 \geq T_1$, then

$$\frac{T}{kT_2/\Phi} \leq \frac{2T_2}{kT_2/\Phi} = 2\Phi/k.$$

Picking k to minimize the maximum of the two bounds $2\Phi/k$ and $2k$, we get $k = \sqrt{\Phi}$ which yields an upper bound of $2\sqrt{\Phi}$. □

COROLLARY 2. $\sqrt{n/(r+1)} \leq c_r \leq 2\sqrt{n/(r+1)}$.

Proof. The lower bound follows from the fact that any graph with maximum degree r has an independent set of size at least $n/(r+1)$ (the greedy algorithm finds such a set). For the upper bound, partition the set of agents into disjoint subsets of size $r+1$ each. The knowledge graph consists of $n/(r+1)$ complete graphs, one on each of the subsets. □

Remark. The upper bound can be improved to $\sqrt{2\Phi}$ when all the job lengths are the same. When the jobs lengths are not the same, it is an NP-hard problem to divide a set of jobs into at most n groups so as to minimize the maximum total length in any group. However, there is a polynomial-time approximation algorithm which comes within a factor of 4/3 of the optimal solution [13]. Thus, the above upper bound can be achieved by polynomial-time bounded agents with an extra factor of 4/3 in the ratio.

A natural question to ask is whether the upper or lower bound of Theorem 1 is tight. In order to answer this question, we need to examine a class of graphs whose maximum independent set and minimum clique cover differ. The distribution $\mathcal{G}(n, 1/2)$ is the distribution over all n-node undirected graphs where each pair of nodes is adjacent independently with probability 1/2. If G is drawn according to $\mathcal{G}(n, 1/2)$, then with high probability, $\phi(G) = \Omega(n/\log n)$ and $\alpha(G) = O(\log n)$ [5]. These facts combined with the following claim imply that the upper bound of Theorem 1 is not tight for the case when all job lengths are 1. We suspect that the lower bound is not tight either, that there are graphs G for which c_G lies strictly between $\sqrt{\alpha(G)}$ and $\sqrt{\phi(G)}$.

CLAIM. *If G is drawn at random from $\mathcal{G}(n, 1/2)$, then with high probability, $c_G = O(n^{1/3} \log n)$ when all job lengths are uniform.*

Proof. We can assume that no agent receives more than n jobs. If an agent receives x jobs, it can distribute $n\lfloor x/n \rfloor$ jobs evenly among the agents and it is left with the problem of distributing the remaining $x \bmod n$ jobs.

An *i-adversary* gives each agent either 0 jobs or x jobs, where $2^i \leq x < 2^{i+1}$. Suppose that for every $0 \leq i \leq \log n$, we can achieve a ratio of c against an i-adversary. Then we can achieve a ratio of $c(\log n + 1)$ against any adversary. Let the *i-agents* be those agents that start with y jobs such that $2^i \leq y < 2^{i+1}$. Each i-agent follows the strategy against the i-adversary with the following change. For every non-i-agent whose input it can "see," it assumes that that agent received 0 jobs. Let M_i be the number of jobs given to the agent who receives the maximum number of jobs from i-agents after the jobs have been redistributed. Let X_i be the total number of jobs given to i-agents by the adversary. Let $t = \log n$. The agent with the maximum number of jobs after redistribution has no more than $\sum_{i=0}^t M_i$ jobs. The optimal solution gives at least $\lceil (\sum_{i=0}^t X_i)/n \rceil$ jobs to some agent. We are guaranteed that $M_i / \lceil X_i/n \rceil \leq c$.

Since $\sum_{i=0}^t \lceil (X_i/n) \rceil \leq (t+1) \lceil (\sum_{i=0}^t X_i)/n \rceil$, we have that

$$\frac{\sum_{i=0}^t M_i}{\lceil \sum_{i=0}^t \frac{X_i}{n} \rceil} \leq \frac{(t+1)\sum_{i=0}^t M_i}{\sum_{i=0}^t \lceil \frac{X_i}{n} \rceil}$$

$$\leq (t+1) \cdot \max_i \left\{ \frac{M_i}{\lceil \frac{X_i}{n} \rceil} \right\} \leq c \cdot (\log n + 1).$$

Now for every $0 \leq i \leq \log n$, we show a strategy against an i-adversary. Then we show that with high probability, G has a certain property which ensures that each strategy achieves a ratio of $O(n^{1/3})$. Say that G has property A if for every subset of $8n^{1/3}$ nodes in G, the subgraph induced by that subset has more than $4n^{2/3}$ edges. We have the following lemma.

LEMMA 3. *When G is chosen according to $\mathcal{G}(n, 1/2)$, then*

$$\Pr[G \textit{ does not have property } A] \leq 2^{n^{1/3}(8 \log n - \frac{5}{3} n^{1/3})}.$$

Proof. Let $s = n^{1/3}$. Consider a fixed subset S of $8s$ vertices. What is the probability that there are at most $4s^2$ edges in the subgraph induced by S? There are at least $\binom{8s}{2} \geq 28s^2$ edge slots. Thus the expected number of edges is at least $14s^2$. Using Chernoff bounds, the probability that a fixed subset of $8s$ vertices induces a subgraph with no more than $4s^2$ edges is at most

$$e^{-(10s^2)^2/2 \cdot 28s^2} \leq 2^{-\frac{5}{3}s^2}.$$

Thus, the probability that there is a subset of size $8s$ vertices in the graph whose induced subgraph has fewer than $4s^2$ edges is at most

$$\binom{n}{8s} 2^{-\frac{5}{3}s^2} \leq n^{8n^{1/3}} 2^{-\frac{5}{3}n^{2/3}} \leq 2^{n^{1/3}(8 \log n - \frac{5}{3} n^{1/3})}. \qquad \square$$

Now we will show the strategy against an i-adversary. Our strategy gives the desired ratio if G has property A. Therefore, if property A holds, the strategies for all i give the desired ratio. Let $m = 2^{\lceil \log n \rceil}$. There will be n agents sending jobs and *m receivers.* The jobs sent to receiver j are sent to agent $j \pmod{n}$. An agent gets no more than twice the load of the most heavily loaded receiver. We will determine the ratio of the most heavily loaded receiver in the distributed solution to the most heavily loaded agent in the optimal solution. Let $X = 2^i$. Let x_j be the number of jobs that originate with agent j. Since we are playing against an i-adversary, $x_j = 0$ or $X \le x_j < 2X$ for all j.

If $X \ge n^{2/3}$, then agent j sends a job to receiver $k + j \bmod n$ for all $1 \le k \le x_j$. If some agent gets a jobs after redistribution, then there are at least aX jobs among all the agents. The optimal solution gives at least aX/n to some agent. This gives a ratio of at most n/X.

If $X \le n^{1/3}$, then each agent keeps all the jobs that it receives.

If $n^{1/3} \le X \le n^{2/3}$, then divide the receivers into m/X groups of X consecutive receivers. The agents are also divided into consecutive groups of X. There are only $\lceil n/X \rceil$ such groups and the last group may have fewer than X agents.

There are two cases.

Case 1. If an agent in group i gets jobs and is adjacent to no more than $n^{1/3}$ agents with jobs in its group, then it distributes its jobs evenly among the receivers in group i. In this case, an agent gives at most two jobs to each receiver.

Case 2. If an agent j is adjacent to at least $n^{1/3}$ agents with jobs in its group, it sends its jobs to receiver $(Xk + (j \bmod X)) \pmod{m}$ for $0 \le k < x_j$. In other words, each agent can be specified by the group to which it belongs (j div X) and its number within the group ($j \pmod{X}$). Starting with group 0 and cycling through the m/X groups of receivers, agent j gives its jobs to the receiver in each group which has the same number within its group.

Now consider a group of X agents with more than $8n^{1/3}$ agents that fall into Case 1. Pick $8n^{1/3}$ of them and call this set S. Every agent in S has fewer that $n^{1/3}$ edges to agents in S. That means that the subgraph induced by S has no more than $4n^{2/3}$ edges (since the sum of degrees is twice the number of edges); i.e., G does not have property A. Thus, by Lemma 3, with high probability G has the property that it is impossible to have more than $8n^{1/3}$ agents that fall into Case 1. For the remainder of the proof, we assume that this is the case. Using the fact that an i-agent from Case 1 gives at most two jobs to each agent in its group, we can conclude that the number of jobs given to an agent by i-agents from Case 1 is at most than $16n^{1/3}$.

So suppose that some receiver j gets l jobs from Case 2 agents. Receiver j only gets these jobs from agents whose number is congruent to $j \bmod X$. Each of these agents is in a different group and spreads its jobs as evenly as possible among the groups of receivers. Since each agent starts with at most $2X$ jobs and there are m/X groups, at most $\lceil 2X^2/m \rceil \le \max\{1, 4X^2/m\}$ jobs that end up with agent j come from the same group. Thus, there are at least $\min\{l, lm/4X^2\}$ groups where $n^{1/3}$ of the agents get jobs. Each such group has at least $Xn^{1/3}$ jobs. Therefore, the total number of jobs is at least $Xn^{1/3} \min\{l, lm/4X^2\}$, and the optimal solution gives at least $(X/n^{2/3}) \min\{l, lm/4X^2\}$ to some agent. Thus, the competitive ratio due to Case 2 is at most $\max\{n^{2/3}/X, 4X/n^{1/3}\}$. For $n^{1/3} \le X \le n^{2/3}$, the ratio is at most $4n^{1/3}$. □

We show the following upper bound on randomized strategies.

THEOREM 4. *For every knowledge graph G, there is a randomized load-balancing strategy whose competitive ratio is in $O(\log(\Phi)/\log\log(\Phi))$, where $\Phi = \phi(G)$.*

Proof. Let $m = \lceil n/\Phi \rceil$. Pick a clique cover of G of size Φ. We assume that the agents within a clique know the set of jobs assigned to the other agents in the clique as well as their random bits. Thus, each clique operates as a single agent. The agents will be divided into Φ sets of size m. Each agent will be indexed by a pair (i, j), where $0 \leq i \leq \Phi - 1$ and $0 \leq j \leq m - 1$. i indicates the set to which the agent belongs and j indicates the place within the set.

Each clique c_l divides its tasks into at most n sets such that the maximum length of a set's tasks is minimized. Then it sorts the sets in decreasing order of length. Each set will be indexed by a triplet (i, j, l) where $0 \leq i, l \leq \Phi - 1$ and $0 \leq j \leq m - 1$. The third index denotes the clique where the jobs originate. The first two indices identify the specific set at clique l. Let $s(i, j, l)$ be the total length of the jobs in set (i, j, l). They are sorted so that $s(i, j, l) \geq s(i', j', l)$ if $i < i'$ or if $i = i'$ and $j \leq j'$. For each $i \in \{0, \ldots, \Phi - 1\}$, clique c_l draws $k \in \{0, \ldots, \Phi - 1\}$ uniformly at random. Then for all $j \in \{0, \ldots, m - 1\}$, it sends all the jobs in set (i, j, l) to agent (k, j).

Denote the optimal cost for this instance by OPT. Denote the cost due to the distributed algorithm by the random variable D. We wish to show that $E[D] \in O((\log \Phi / \log \log \Phi)\text{OPT})$.

Consider a related problem: we have Φ agents. Agent l gets a set of Φ jobs of lengths $s(0, 0, l)$, $s(1, 0, l), \ldots, s(\Phi - 1, 0, l)$. (Some of these could be of length 0.) Let OPT' be the cost when the jobs are optimally distributed among the Φ agents. Let D' be the random variable denoting the cost of the distributed algorithm which sends each job to a random agent. The result of [11] gives that $E[D'] \in O((\log \Phi / \log \log \Phi)$ $\text{OPT}')$. Clearly, D and D' are identically distributed, so $E[D] = E[D']$. We show that $\text{OPT} \geq (1/3)\text{OPT}'$, which completes the proof.

Divide the jobs from the second problem into two sets:

$$T_1 = \sum_{l=0}^{\Phi-1} s(0, 0, l),$$

$$T_2 = \sum_{i=1}^{\Phi-1} \sum_{l=0}^{\Phi-1} s(i, 0, l).$$

Let $\text{MAX} = \max_{0 \leq l \leq \Phi-1} s(0, 0, l)$ Clearly, $\text{MAX} \geq T_1/\Phi$. We claim two facts.

1. $\text{OPT} \geq \max\{\text{MAX}, T_2/\Phi\}$;
2. $\text{OPT}' \leq \text{MAX} + (T_1 + T_2)/\Phi$.

The theorem follows from the two claims because

$$\text{OPT}' \leq 2\text{MAX} + \frac{T_2}{\Phi} \leq 3\text{OPT}.$$

To prove the first claim, observe that in the first problem each clique divides the jobs into sets so as to minimize the maximum length of the jobs in any set. So the length of the jobs in any set is a lower bound on the optimal solution. The second part of the "max" in claim 1 follows from

$$\text{OPT} \geq \frac{1}{n} \sum_{j=0}^{m-1} \sum_{i=0}^{\Phi-1} \sum_{l=0}^{\Phi-1} s(i, j, l).$$

Since for all $1 \leq i < m$, $\sum_{j=0}^{m-1} s(i, j, l) \geq m \cdot s(i + 1, 0, l)$,

$$\frac{1}{n} \sum_{j=0}^{m-1} \sum_{i=0}^{\Phi-1} \sum_{l=0}^{\Phi-1} s(i, j, l) \geq \frac{m}{n} \sum_{i=1}^{\Phi-1} \sum_{l=0}^{\Phi-1} s(i, 0, l)$$

$$\geq \frac{mT_2}{n} = \frac{T_2}{\Phi}.$$

To see the second claim, observe the discrepancy disc in the optimal solution. The discrepancy is the difference between the maximum load on an agent and the minimum load on an agent. Clearly, disc $\leq$ MAX. Since $(T_1 + T_2 + \Phi \cdot \text{disc})/\Phi$ is an upper bound on the optimal cost, the claim follows. □

COROLLARY 5. *There are randomized load balancing r-strategies for all n and r with a competitive ratio in $O(\log(n/r)/\log\log(n/r))$.*

Proof. Partition the set of agents into disjoint subsets of size $r+1$ each. The knowledge graph consists of $\lceil n/(r+1)\rceil$ complete graphs, one on each of the subsets. □

Corollary 5 is tight up to a constant factor, as the following theorem shows.

THEOREM 6. *If $\sqrt[4]{r(n)/n} \longrightarrow 0$ as $n \to \infty$, then for every sufficiently large n and for $r = r(n)$, the competitive ratio of every randomized load-balancing r-strategy on n agents is in $\Omega(\log(n/r)/\log\log(n/r))$.*

Remark. If $\sqrt[4]{r(n)/n} \geq \epsilon > 0$ for all n, then $(n/r(n)) \leq \epsilon^{-4}$. So, we get a lower bound of $\Omega(\log(n/r)/\log\log(n/r))$ for all $r < n$. Alon [2] has independently shown a lower bound of $\Omega(\log n/\log\log n)$ for the special case of an empty knowledge graph. This bound follows from our proof as well.

Proof. We need to consider only r-regular knowledge graphs (i.e., with *out-degree* r). Applying von Neumann's minimax principle (see [21, 8]), we show a probability distribution over inputs which beats every deterministic algorithm.

For the sake of completeness, we state and prove the exact claim that is needed (see [8, Lem. 7.2] for the original version).

LEMMA 7. *Let $\tilde{I}$ be a probability distribution over a finite sample space of inputs such that for every deterministic r-strategy S, $E_{\tilde{I}}[\text{cost}_S(\tilde{I}) - c\cdot\text{cost}(\tilde{I})] \geq 0$. Then for every randomized r-strategy $\tilde{S}$, there exists an input instance $I = I(\tilde{S})$ for which*

$$\frac{E_{\tilde{S}}[\text{cost}_{\tilde{S}}(I)]}{\text{cost}(I)} \geq c.$$

Proof. Fix $\tilde{S}$. $\tilde{S}$ is a probability distribution over deterministic strategies S_χ. Since for every χ, $E_{\tilde{I}}[\text{cost}_{S_\chi}(\tilde{I}) - c\cdot\text{cost}(\tilde{I})] \geq 0$, we have that $E_\chi[E_{\tilde{I}}[\text{cost}_{S_\chi}(\tilde{I}) - c\cdot\text{cost}(\tilde{I})]] \geq 0$. We may switch the order of integration since all expectations are finite. We get $E_{\tilde{I}}[E_\chi[\text{cost}_{S_\chi}(\tilde{I}) - c\cdot\text{cost}(\tilde{I})]] \geq 0$, or $E_{\tilde{I}}[\text{cost}_{\tilde{S}}(\tilde{I}) - c\cdot\text{cost}(\tilde{I})] \geq 0$. Therefore, there exists $I \in \tilde{I}$ for which $\text{cost}_{\tilde{S}}(I) - c\cdot\text{cost}(I) \geq 0$. □

The distribution we choose gives every agent d jobs independently with probability p and 0 jobs otherwise. We use $d = \sqrt[4]{r^3 n}$ and $(4/d) < p < (4e/d)$ so that $p(1-p)^r d = 4$. Notice that $d \in \omega(r) \cap o(n)$. The expected cost of the optimal algorithm is at most $8e$. Our goal is to show that the expected cost of any deterministic r-strategy is in $\Omega(\beta)$, where $\beta = \log(n/r)/\log\log(n/r)$.

Let $k = \log(d/r)/\log\log(d/r)$. By our choice of d, $k \geq \beta/4$. We need the following lemma.

LEMMA 8. *If $r(n) \in o(d(n))$ and if $Z = Z(n)$ is distributed according to the binomial distribution $B(4(r+1)/d, d/4(r+1))$, then for n large enough,*

$$\text{Prob}[Z \geq k] \geq \frac{r}{d}.$$

Proof. Let $\lambda = E[Z] = 1$. $\text{Prob}[Z = k]$ (which is a lower bound for $\text{Prob}[Z \geq k]$) can be estimated using the Poisson approximation to the binomial distribution. It gives

$$\mathrm{Prob}[Z=k] > p(k;\lambda)e^{-\frac{k^2}{d/4(r+1)-k}-\frac{\lambda^2}{d/4(r+1)-\lambda}},$$

where $p(k;\lambda)=e^{-\lambda}\lambda^k/k!$.

We can estimate $p(k;\lambda)$ for large k using Stirling's formula as follows:

$$p(k,1)=\frac{1}{e(k)!}\geq\frac{a}{\sqrt{k}}\left(\frac{e}{k}\right)^k$$

for some constant a.

Also, $e^{-\frac{k^2}{d/4(r+1)-k}-\frac{\lambda^2}{d/4(r+1)-\lambda}} \longrightarrow 1$ as $n\to\infty$, so for sufficiently large n this is lower bounded by $1/2$.

We have, for sufficiently large n,

$$\log\left(\frac{2\sqrt{k}}{a}\left(\frac{k}{e}\right)^k\right)\leq k\log k\leq\log\left(\frac{d}{r}\right). \quad \square$$

The condition that $\sqrt[4]{r(n)/n}\longrightarrow 0$ as $n\to\infty$, implies that $r(n)\in o(d(n))$.

We use Lemma 8 to bound a similar distribution. A vertex of G is said to be *chosen* if it gets jobs. A vertex is *isolated* if it is chosen and none of its neighbors are chosen.

LEMMA 9. *Let A be a subset of the vertices of G. To each vertex $v\in A$, assign an integer weight W_v between 1 and $k/8$ such that $\sum_{v\in A}W_v\geq d/4$. Let Y be the sum of the weights of the isolated vertices in A. Let Z be as in Lemma 8. Then for n sufficiently large,*

$$\mathrm{Prob}\left[Y\geq\frac{k}{2}\right]\geq\frac{1}{e^9}\mathrm{Prob}[Z\geq k].$$

Proof. Recall that $k=\log(d/r)/\log\log(d/r)$. Let $s=d/4$. We may assume that $\sum_{v\in A}W_v=s$; otherwise, we reduce weights and remove 0-weighted vertices from A until equality holds. For each vertex $v\in A$, we introduce W_v indicator variables. Each variable is set to 1 if its corresponding vertex is isolated and to 0 otherwise. Denote the indicator variables by $Y_1,\ldots,Y_s$. $Y=\sum Y_j$. For X a k-subset of $\{1,\ldots,s\}$, $V_Y(X)$ is the subset of vertices associated with $\{Y_i \mid i\in X\}$.

The proof proceeds in two steps. First, we relate the probability of the desired event in G to the probability of a similar event in a graph G_U, derived from G, where vertex weights are 1. Then we relate the probability of the desired event in G_U to the distribution of Z.

We form a graph G_U which is identical to G except that for every vertex $v\in A$, we have a set S_v of W_v nodes in G_U. If v and u are adjacent in G, then in G_U every vertex in S_u is adjacent to every vertex in S_v. Note that the degree in G_U is at most $kr/8$. Let $A_U=\cup_{v\in A}S_v$. Notice that $|A_U|=s$. Let U_i denote the indicator variable that is 1 if vertex i in A_U is isolated and 0 otherwise when each vertex of G_U is chosen independently of the others with probability p. Let $U=\sum U_j$.

Now consider a particular graph G_Z of s vertices consisting of disjoint $(r+1)$-cliques. Let $Z_1,\ldots,Z_s$ be the indicator variables which indicate for each vertex whether it is isolated when each vertex is chosen with probability p. Clearly, the distributions of Z from Lemma 8 and $\sum Z_j$ are identical.

We wish to show the following:

1. Prob$[Y \geq k/2] \geq$ Prob$[U \geq k]/e^4$.
2. Prob$[U \geq k] \geq$ Prob$[Z \geq k]/e^5$.

Proof of part 2. Define

$$S_U = E\left[\sum_{X \subset \{1,\ldots,s\}, |X|=k} \prod_{j \in X} U_j\right].$$

Similarly,

$$S_Z = E\left[\sum_{X \subset \{1,\ldots,s\}, |X|=k} \prod_{j \in X} Z_j\right].$$

Clearly, S_U is an upper bound on Prob$[U \geq k]$ and S_Z is an upper bound on Prob$[Z \geq k]$. First we prove that $S_U \geq S_Z/e^2$.

Examine a fixed k-set X of $\{1,\ldots,s\}$. When does $\prod_{j \in X} U_j = 1$? This happens when X forms an independent set, all the vertices in X are chosen, and all the vertices in the neighborhood set of X are not chosen. Notice that $|X| = k$ and the neighborhood set of X has at most $rk^2/8$ vertices. Thus if X forms an independent set, then $\prod_{j \in X} U_j = 1$ with probability at least $p^k(1-p)^{rk^2} \geq p^k/e \geq p^k(1-p)^{rk}/e$. (The first inequality follows from the fact that for sufficiently large n, $rk^2 \ll 1/p$. Since $(1-1/x)^{x-1} > e^{-1}$ for all $x \geq 2$, the inequality follows.)

Now let's look at the Z_j's. If X forms an independent set, then the neighborhood set of X has size rk (because the graph is composed of disjoint $(r+1)$-cliques). Thus, if X is an independent set, then $\prod_{j \in X} Z_j = 1$ with probability exactly $p^k(1-p)^{rk}$.

Therefore, we have to prove that the number of k-sets X that are independent sets in G_U is at least $1/e$ times the number of k-sets X that are independent sets in G_Z. We do this by picking X at random and showing that Prob[X is independent in G_U] $\geq e^{-1}$. We pick a random k-set vertex by vertex in G_U. Let v_i denote the ith vertex that is picked and V_i denote $\{v_1,\ldots,v_i\}$. The neighborhood set of V_i is denoted $N(V_i)$.

Thus, we have

$$\begin{aligned}
&\text{Prob}[V_k \text{ is independent}] \\
&= \prod_{j=1}^{k} \text{Prob}[v_j \notin N(V_{j-1}) \mid V_{j-1} \text{ is independent }] \\
&\geq \prod_{j=1}^{k}\left(1 - \frac{rk(j-1)}{8(s-j+1)}\right) \geq \prod_{j=1}^{k}\left(1 - \frac{2rk(j-1)}{8s}\right) \\
&\geq \left(1 - \frac{rk^2}{4s}\right)^k \geq e^{-1}.
\end{aligned}$$

The last inequality holds for sufficiently large n, since $k \ll d/rk^2$. Therefore, we conclude that $S_U \geq S_Z/e^2$.

We now complete the proof that Prob$[U \geq k] \geq$ Prob$[Z \geq k]/e^5$. Observe that

$$\text{Prob}[U \geq k] \geq S_U(1-p)^{s-k} \geq S_U/e^e \geq S_U/e^3.$$

The first inequality comes from the fact that the probability that there are exactly k isolated vertices in A is at least $S_U(1-p)^{s-k}$ (The lower bound is obtained by summing over all independent k-sets in G_U the probability that the k-set is isolated and all other vertices in A_U are not chosen). The second inequality uses the fact that $p < e/s$ and that for sufficiently large n, $k > e$, and thus $s-k < (s/e-1)e$. Therefore, to complete the proof of part 2,

$$\begin{aligned}\text{Prob}[U \geq k] &\geq \frac{1}{e^3}S_U \geq \frac{1}{e^5}S_Z\\ &\geq \frac{1}{e^5}\text{Prob}[Z \geq k].\end{aligned}$$

Proof of part 1. Let $\mathcal{I}$ be the set of independent sets in A of size at most $k/2$ whose weights sum to at least $k/2$. We want to relate the number of independent k-sets in A_U to the number of subsets in $\mathcal{I}$. To do that, we map every independent k-set X in A_U to an independent set in $\mathcal{I}$ as follows: if $|V_Y(X)| \geq k/2$, then map X to an arbitrary size-$k/2$ subset of $V_Y(X)$. Since the weight of a vertex is at least 1, the weight of the subset is at least $k/2$. If $|V_Y(X)| < k/2$, then map X to $V_Y(X)$. For any independent set $I \in \mathcal{I}$, there are at most $(k/8)^{k/2}\binom{s}{k/2}$ independent sets mapped to I: there are at most $(k/8)^{k/2}$ ways to pick the first $k/2$ vertices from the sets in G_U associated with the vertices of I and $\binom{s}{k/2}$ ways to pick the remaining vertices from A_U. Define

$$S_Y = \sum_{I \in \mathcal{I}} p^{|I|}(1-p)^{|N(I)|}.$$

We can lower bound S_Y by S_U/e as follows:

$$\begin{aligned}S_U &\leq \sum_{X \text{ indep., } |X|=k} p^k\\ &\leq \left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}\sum_{I\in\mathcal{I}}p^k\\ &\leq \left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}p^{k/2}\sum_{I\in\mathcal{I}}p^{k/2}\\ &\leq \left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}p^{k/2}\sum_{I\in\mathcal{I}}ep^{k/2}(1-p)^{kr/2}\\ &\leq \left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}p^{k/2}eS_Y.\end{aligned}$$

We show that

$$\left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}p^{k/2} \leq 1,$$

thus concluding that $S_Y \geq S_U/e$. Observe that p was chosen so that $p(1-p)^r = 4/d = 1/s$. So $p^{k/2} = (1/s)^{k/2}(1-p)^{-kr/2} \leq e(1/s)^{\frac{k}{2}}$ for sufficiently large n.

$$\left(\frac{k}{8}\right)^{k/2}\binom{s}{k/2}p^{k/2}$$

$$\leq \left(\frac{k}{8}\right)^{k/2} \frac{s^{k/2}}{(\frac{k}{2})!} es^{-k/2}$$
$$\leq \left(\frac{k}{8}\right)^{k/2} \left(\frac{2e}{k}\right)^{k/2} e \leq 1,$$

where the inequalities hold for sufficiently large n. In a similar manner to the proof of part 2,

$$\begin{aligned} \text{Prob}[Y \geq k/2] &\geq \frac{1}{e^3} S_Y \geq \frac{1}{e^4} S_U \\ &\geq \frac{1}{e^4}\text{Prob}[U \geq k]. \qquad \square \end{aligned}$$

This completes the proof of Lemma 9. We now proceed with the proof of Theorem 6.

Consider the following n by n bipartite graph H. There is an edge between a vertex x on the left and a vertex y on the right for every job that agent x sends to agent y when agent x is isolated. There is an edge from vertex x on the left to vertex x on the right for every job that x keeps when x is isolated. Note that the degree of a left node in H is exactly d. If a vertex is isolated, then it sends its jobs according to the edges in H. We examine the load due to isolated vertices only.

Our proof proceeds in three steps. First, we address two special cases: (i) there is a right vertex in H of degree at least βd; (ii) there are at least d left vertices in H that have an edge of multiplicity $\beta/32$ or more. Then, we prove the theorem for graphs H that do not fall into either of these categories.

LEMMA 10. *If H has a right vertex v of degree at least βd, then the expected number of jobs sent to v is at least* 4β.

Proof. Let $u_1, u_2, \ldots, u_k$ be the neighbors of v on the left. For $i = 1, 2, \ldots, k$, let W_i denote the multiplicity of the edge between u_i and v. $\sum W_i \geq \beta d$. Each of the u_i's is isolated with probability $p(1-p)^r$. Therefore, the expected number of jobs that v get is $p(1-p)^r \sum W_i \geq p(1-p)^r \beta d \geq 4\beta$. $\square$

LEMMA 11. *If there are at least d left vertices in H with an edge of multiplicity $\beta/32$ or more, then the expected maximum number of jobs an agent gets is at least $\beta/8e^3$.*

Proof. There is a set S of at least d vertices such that if any of them is isolated, some agent has a load of at least $\beta/32$. For $v \in S$, let E_v denote the event that v is isolated and the remaining vertices in S are not chosen. $\text{Prob}[E_v] \geq p(1-p)^{rk}(1-p)^{d/4e-1} \geq (4/de^3)$. (Recall that $p \leq 4e/d$ and for n sufficiently large $rk \ll 1/p$.) The probability that some vertex in S is isolated is at least $\sum_{v \in S} \text{Prob}[E_v] \geq 4/e^3$. Thus, the expected maximum load is at least $\beta/8e^3$. $\square$

We now consider the remaining case, where all right vertices in H have degree at most βd, and at most d left vertices in H have edges of multiplicity $\beta/32$ or more. Remove all the vertices on the left which have an edge of multiplicity at least $\beta/32$. There are at least $n - d$ left vertices remaining.

We need the following lemma.

LEMMA 12. *If the maximum degree of a right vertex in H is βd, then there exists a subgraph H' of H such that the following hold:*

1. *The number of right vertices in H' is at least d/r.*
2. *The degree of each right vertex in H' is at least $d/4$.*

3. *For every two distinct right vertices x and y in H', their neighborhood sets do not intersect.*

Proof. Let $c = 2\beta d^3/r(n-2d)$. Define a graph I whose vertices are a subset of the right vertices of H as follows. Remove all right vertices of degree less than $d/2$. Remove edges until each remaining right vertex has degree exactly $d/2$. Call the remaining graph H''. Connect two right vertices by an edge iff the size of the intersection of their neighborhood sets in H'' is at least c. The degree of any vertex in I is at most d^2/c. The number of right vertices in H that have degree at least $d/2$ is at least $(n-2d)/2\beta$ because the maximum degree is βd and the sum of degrees is $(n-d)d$. Therefore, there is an independent set of size at least $(n-2d)c/2\beta d^2 \geq d/r$ in I. Take a subset of size d/r of the independent set together with the neighborhood sets of these vertices in H'' and the connecting edges. What we get is a collection of d/r stars. Each right vertex is a root of one star and has degree $d/2$. Remove from this collection any left vertex that participates in more than one star. Since each right vertex removes from each other star at most c left vertices, the resulting stars are vertex disjoint and have minimum root degree of at least $d/2 - cd/r$ which is at least $d/4$ for sufficiently large n. □

The neighborhood sets of the right vertices of H' induce a collection of d/r disjoint sets of vertices in G. We call this collection of sets $\mathcal{A} = A_1, A_2, \ldots, A_{d/r}$. To each vertex v that belongs to such a set, we assign it a weight W_v which is equal to the multiplicity of its edge to its adjacent right vertex in H'. Since we have removed the vertices incident to edges of high multiplicity, the weight of any vertex is at most $\beta/32 \leq k/8$. Each set has a total weight of at least $d/4$. Let a_i be the sum of the weights of the isolated vertices in set A_i. We wish to show that the expected maximum over all a_i is in $\Omega(\beta)$.

For the remainder of the proof, "adjacency" refers to adjacency in the knowledge graph G. $N(X)$ denotes the neighborhood set of a set of vertices X. A subset X of vertices is isolated (not isolated/chosen/not chosen) if every vertex in the set is isolated (not isolated/chosen/not chosen). Let E_j denote the event $(a_1 < k/2) \wedge (a_2 < k/2) \wedge \cdots \wedge (a_j < k/2)$.

LEMMA 13. *Let* $1 \leq j \leq d/r$. *If* $\mathrm{Prob}[E_{j-1}] \geq 1 - (1/2e)$, *then*

$$\mathrm{Prob}[a_j \geq k/2 \mid E_{j-1}] \geq \frac{1}{2e^4}\mathrm{Prob}[a_j \geq k/2].$$

Proof. Let $A = A_1 \cup A_2 \cup \cdots \cup A_{j-1}$. Let $E = E_{j-1}$. For each vertex $v \in A_j$ we introduce W_v indicator variables as in the proof of Lemma 9. Let $Y_1, \ldots, Y_s$ be those variables. S_Y is defined as in Lemma 9. Using the arguments from the proof of Lemma 9, we have that $\mathrm{Prob}[a_j \geq k/2 \mid E] \geq E[S_Y \mid E]/e^3$. Also, $E[S_Y]$ is a trivial upper bound on $\mathrm{Prob}[a_j \geq k/2]$. Therefore, it is sufficient to prove that $E[S_Y \mid E] \geq E[S_Y]/2e$. Fix an arbitrary independent set $I \in \mathcal{I}$. We need to prove that $\mathrm{Prob}[I \text{ is isolated } \mid E] \geq \mathrm{Prob}[I \text{ is isolated}]/2e$.

The event that I is isolated happens if and only if I is chosen and $N(I)$ is not chosen. Therefore, $p^{|I|} \geq \mathrm{Prob}[I \text{ is isolated}]$. Also,

$$\begin{aligned}&\mathrm{Prob}[I \text{ is isolated } \mid E]\\ &= p^{|I|}\mathrm{Prob}[N(I) \text{ is not chosen } \mid E].\end{aligned}$$

Since

$$\begin{aligned}\mathrm{Prob}[N(I) \text{ is not chosen}] &= (1-p)^{|N(I)|}\\ &\geq (1-p)^{kr} \geq e^{-1},\end{aligned}$$

we have that

$$\begin{aligned}
&\text{Prob}[N(I) \text{ is not chosen } \mid E] \\
&\geq \text{Prob}[N(I) \text{ is not chosen } \wedge E] \\
&\geq \text{Prob}[N(I) \text{ is not chosen}] + \text{Prob}[E] - 1 \\
&\geq \frac{1}{2e}.
\end{aligned}$$

Putting these facts together, we get that

$$\text{Prob}[I \text{ is isolated } \mid E] \geq \frac{p^{|I|}}{2e} \geq \frac{\text{Prob}[I \text{ is isolated}]}{2e}. \qquad \square$$

We can now complete the proof of Theorem 6. The condition of Lemma 9 holds for sufficiently large n. If there exists j, $1 \leq j \leq d/r$, for which $\text{Prob}[E_j] < 1 - 1/2e$, then the expected maximum load is at least $k/4e \geq \beta/16e$. Otherwise, we may use Lemma 13 to get

$$\begin{aligned}
&\text{Prob}[\max a_j \geq k/2] \\
&= 1 - \text{Prob}[\forall j, a_j < k/2] \\
&= 1 - \prod_j \text{Prob}[a_j < k/2 \mid E_{j-1}] \\
&= 1 - \prod_j (1 - \text{Prob}[a_j \geq k/2 \mid E_{j-1}]) \\
&\geq 1 - \prod_j \left(1 - \frac{1}{2e^4}\text{Prob}[a_j \geq k/2]\right) \\
&\geq 1 - \prod_j \left(1 - \frac{1}{2e^{13}}\text{Prob}[Z \geq k/2]\right) \\
&\geq 1 - \left(1 - \frac{r}{2e^{13}d}\right)^{d/r} \geq 1 - e^{\frac{-1}{2e^{13}}},
\end{aligned}$$

where the last inequality holds for sufficiently large n. Therefore, $E[\max\{a_i\}] \geq (1-e^{-1/2e^{13}})(k/2) \geq (1-e^{-1/2e^{13}})(\beta/8) = \Omega(\beta)$. Recalling that the expected optimal cost is at most $8e$, the theorem follows. $\square$

3. Routing. We show $n(\log n + \log r)$-node networks with n input nodes where a maximum edge congestion of $\sqrt{n/r}$ can be guaranteed by a particular r-strategy. Theorem 16 proves this to be at the least nearly optimal.

THEOREM 14. *Divide all the input nodes into groups of r consecutive nodes. If each agent knows the destinations of the other input nodes in its group then we can route any $n \times n$ permutation on an $n(\log n + \log r)$-node network with maximum edge congestion $\sqrt{n/r}$.*

Proof. The network is derived from the Beněs network. We take the first $\log(n/r)/2$ levels of a $\log n$-dimensional Beněs network, then the middle $2 \log r$ levels of that network, then the next $\log(n/r)/2$ levels. As with global routing on a Beněs network, the bound on edge congestion is guaranteed even if there are two inputs for each source and two outputs for each destination. In the proof, we trace the selection of each path by describing the motion of a "packet" that moves along the path.

In every level, number each node from top to bottom $0, 1, \ldots, n-1$. The nodes in each level are divided into n/r groups of r nodes. The groups in the first level (the input level) determine the knowledge graph—each group is a clique in the knowledge graph.

For the first $\log(n/r)/2$ levels, each input picks the greedy path based on the first $\log(n/r)/2$ bits of the destination.

At this point, each packet reaches a place which differs with its input in only the first $\log(n/r)/2$ bits. There are n/r $\log r$-dimensional Beněs networks in the middle. The source nodes of each such subnetwork (i.e., the nodes at level $\log(n/r)/2+1$ of the whole network) receive packets from at most $\sqrt{n/r}$ different cliques. Furthermore, the place of each packet within its clique has not changed (that is, the place of each packet agrees with its source in the last $\log r$ bits). Thus, each node has at most two packets from each clique.

Now we will use the next $2\log r$ levels to route within each $r \times r$ network according to the last r bits of the destination (to be explained later).

Afterwards, the place of each packet corresponds with its destination in the first $\log(n/r)/2$ bits and the last $\log r$ bits. If the bits are numbered from left to right, then the place of a packet can only disagree with its destination in bits $\log n/r/2+1$ through $\log n/r$. Thus, there are at most $\sqrt{n/r}$ packets per node. Each packet then takes the greedy path to its destination. The congestion never exceeds $\sqrt{n/r}$ since at each successive level, the upper bound on the congestion decreases by a factor of two.

So far, everything specified about the paths can be determined by each source node without any extra information besides the destination of its own inputs.

We now have to explain how to do the routing in the middle $r \times r$ subnetworks. Now *source* and *destination* refer to the source and destination within the $r \times r$ network. We are guaranteed that for any such subnetwork, we only have $\sqrt{n/r}$ cliques routing simultaneously on that subnetwork. There are at most two packets per source from any single clique. There are at most $\sqrt{n/r}$ packets per destination from all cliques. Each clique determines the paths for all inputs in that clique so as to satisfy the conditions of Lemma 15 below. We then examine what happens when we have $\sqrt{n/r}$ cliques superimposed on the same $r \times r$ network.

In each level, number the nodes $0, 1, \ldots, r-1$ from top to bottom. Number levels from right to left so that the destination nodes are at level 1. For $j \in \{0, \ldots, 2^{\log r - k - 1} - 1\}$, define $S_i(j,k)$ to be the nodes in the ith level numbered $2^{\log r - k + 1}x + j$, for all $x \in \{0, 1, \ldots, 2^{k-1} - 1\}$. So, for any i, i' with $i > i'$ and any $k \geq i$, packets arriving at nodes in $S_i(j,k)$ can only reach level-i' nodes in $S_{i'}(j,k)$. In particular, packets arriving in $S_i(j,i)$ can only reach level-1 nodes in $S_1(j,i)$. We have the following lemma.

LEMMA 15. *Each clique can route the paths of its inputs so that the following hold:*

1. *In the first half of any particular $r \times r$ Beněs network, each edge carries at most one path.*

2. *In the second half of the network, the congestion along each edge coming into nodes in $S_i(j,i)$ from the previous level is the same (± 1).*

Proof. The proof is by induction on r. Consider the two $(r-1) \times (r-1)$ subnetworks in the middle. Suppose we manage to route the $r \times r$ problem so that each source sends one packet through the bottom network and one through the top network. And suppose that we manage to route the packets so that if a destination gets t packets, $t/2$ are routed through the bottom network and $t/2$ are routed through the top. (If t is not even, the number of packets routed through the top and the number routed through the bottom may differ by 1). Then we have managed to satisfy the constraints for the outer two level. By induction, we can satisfy the constraints for the inner levels.

Therefore, we just have to show that we can route the packets in that way. Make a bipartite graph—left vertices represent sources, right vertices represent destinations. An edge from a left vertex to a right vertex represents a path routed from that source to that destination. The degree of each vertex on the left is 2. The edges can be colored red and blue so that every vertex has half its edges red and half blue. The red edges represent paths through the upper subnetwork and the blue edges represent paths through the lower one. To see that the coloring of the edges can be done, split every vertex on the right with degree higher than 2 into vertices of degree 2 and at most one of degree 1. Now combine pairs of degree 1 vertices so that the graph is 2-regular. By Hall's theorem, the edges can be colored so that every vertex is incident to a red and a blue edge. When the vertices are recombined to get the original graph, if a vertex is incident to d edges, then at least $\lfloor d/2 \rfloor$ of the edges are colored with each color. □

We argue that if each clique can route its paths through each subnetwork so that conditions 1 and 2 are maintained, then the congestion is at most $\sqrt{n/r}$ even when we consider the congestion from all $\sqrt{n/r}$ cliques that are routing simultaneously on a particular subnetwork. In the first half of the network, each clique has only one path per edge. Thus, the total edge congestion is at most $\sqrt{n/r}$. In the second half of the network, paths that reach a node in $S_i(j,i)$ can only reach nodes in $S_1(j,i)$. If there are x paths coming into a node in $S_i(j,i)$, then property 2 guarantees that there are a total of $x2^{i-1}$ paths coming into all nodes in $S_i(j,i)$. These paths are all destined for nodes in $S_1(j,i)$. There can only be $2^{i-1}\sqrt{n/r}$ such paths because each destination gets only $\sqrt{n/r}$ paths from all cliques. Thus $x \leq \sqrt{n/r}$. □

THEOREM 16. *For every n-input, n-output, N-node, degree-d network, for every deterministic routing strategy with degree-r knowledge graph,*

1. *there exists a permutation for which the maximum congestion at a node is at least* $(1/2)\sqrt{n^2/Nr} - (n/2Nr)$;
2. *there exists a permutation for which the maximum congestion at an edge is at least* $(1/2d)\sqrt{n^2/Nr}$.

The proof is more or less a straightforward adaptation of the oblivious routing lower bounds of Borodin and Hopcroft [7] and Kaklamanis, Krizanc, and Tsantilas [14].

Proof: Part 1. Let S be an independent subset of size $n/2r$ in the knowledge graph. It has a neighbor set (in the knowledge graph) of size at most $n/2$. Fix the destinations of the sources in this neighbor set. We will ignore the congestion due to these paths. The algorithm for the inputs in S is now specified by a set of at least $n/2$ paths for each input—one to each remaining target.

Let $a = (1/2)\sqrt{n^2/(Nr(d+1))}$. We can assign to each of $t \geq (n/2) - da$ of the possible paths of an input node in S an internal node w such that each assigned w is assigned for at least a paths and at most $(d+1)a = (1/2)\sqrt{n^2/(Nr(d+1))}$ paths. The reason is as follows. Let $u \in S$. Repeat the following process. Find a node w that is an internal node of at least a paths from u. Mark it and assign w to a of these paths. Remove the paths and repeat till no such node can be found. Now, for each of the paths that have not been assigned a node, trace the path from its destination to its source, and assign it the first marked node that it encounters (excluding its source or destination) if there is one. A path does not get assigned a node either if its destination is a neighbor of u or if it passes through an unmarked neighbor of u. There are at most da such paths. The number of paths that get assigned any particular marked node w is at most the a paths that marked w plus any path that passed through an unmarked neighbor of w. There are at most da of the latter.

The number of distinct nodes w assigned for a fixed input in S is at least $(n/2 - da)/((d+1)a) \geq n/(2(d+1)a) - 1$. There are $n/2r$ nodes in S, so a total of $n^2/(4(d+1)ra) - (n/2r)$ nodes w are hit. Since there are N nodes in the network, there is a node w that is hit by at least $n^2/(4N(d+1)ra) - (n/2Nr) = (1/2)\sqrt{n^2/(Nr(d+1))} - (n/2Nr)$ paths from different input nodes. Each input node that hits w can choose from among at least $(1/2)\sqrt{n^2/Nr(d+1)}$ destinations that cause a hit on w, so there is a choice of distinct destinations for all input nodes that hit w.

Part 2. Let S be an independent set of size $t = n/2r$ in the knowledge graph. As in part 1, we fix the destinations of the sources in the neighborhood set of S and ignore the congestion due to the paths they choose. The destination of any source in S can be any of at least $n/2$ remaining output nodes in the network. An algorithm is specified by $nt/2$ paths. There are at least $t-1$ paths that end at any output node v (because v can also be a source node in S). Let $S(v)$ denote the set of edges in the network which have $k = \sqrt{n^2/Nr}/2d$ or more paths ending in v passing through them. Let $S^*(v)$ be the set of nodes incident to edges in $S(v)$. Note that $|S^*(v)| \leq 2|S(v)|$. Also, $v \in S^*(v)$. Thus,

$$|S - S^*(v)| \leq (k-1)d|S^*(v)|.$$

(For each source u not in $S^*(v)$, follow its path to v until it hits a node in $S^*(v)$. The last edge in this path has less than k paths in it.) This gives us that

$$t \leq kd|S^*(v)| \leq 2kd|S(v)|.$$

Thus $t/2kd \leq |S(v)|$. Summing over all $n/2$ destinations v,

$$\sum_{v \in V} |S(v)| \geq \frac{nt}{4kd}.$$

Since there are $Nd/2$ edges in the network, there is some edge e for which $e \in S(v)$ for at least

$$\frac{nt/4kd}{Nd/2} = k$$

different values of v.

Select e and $v_1, \ldots, v_k$ such that $e \in S(v_i)$ for $1 \leq i \leq k$. This means that we can find $u_1, \ldots, u_k$ such that $u_i \neq u_j$ for $i \neq j$ and the paths from u_i to v_i all pass through e. □

The following is a lower bound for randomized oblivious routing strategies. The lower bound holds when the knowledge graph is a set of fixed r-cliques.

THEOREM 17. *For every n-input, n-output, n-node, degree-d network, for every randomized routing strategy with a deterministic knowledge graph consisting of disjoint r-cliques, if $dr \leq n/2\log^4 n$, then there is a permutation for which the expected maximum congestion at a node is in $\Omega(\log(n/r)/\log\log(n/r))$.*

Proof. The proof follows a lower bound on randomized oblivious routing due to Borodin et al. [9]. We show a probability distribution over permutations that beats every deterministic routing strategy. Let $t = n/r$. There are t r-cliques in the knowledge graph. Each node will be numbered by a pair (i, j), where i represents the name of the clique the node is in and j represents the name of the node within the clique. $1 \leq i \leq t$ and $1 \leq j \leq r$. We pick one of $t!$ permutations uniformly at random. Each permutation is specified by a permutation over the cliques. If clique i is mapped to clique k, then (i, j) has to connect to (k, j) for all $1 \leq j \leq r$. Thus each node has to connect to one of t destinations. For some valid source–destination pairs (u, v), we assign a node (called $V(u, v)$) which is an internal node in the path from u to v. $V(C, D)$ denotes the multiset of nodes $V(u, v)$, where $u \in C$, $v \in D$, (u, v) is a valid source–destination pair, and $V(u, v)$ exists. $|V(C, D)|$ denotes the size of the set, counting multiplicity.

LEMMA 18. *Consider a clique C. The assignment can be picked so that the following hold:*

1. *A node w appears in at most $(d+1)\log t$ multisets $V(C, D)$.*
2. *If a node w appears in a multiset $V(C, D)$, then it appears in $V(C, D)$ for at least $\log t$ different cliques D.*
3. $\sum_D |V(C, D)| \geq n - dr\log t$.

Proof. Consider all the paths from a clique C to all the destination cliques D. There are a total of n paths. (For each source–destination pair of cliques, there are r paths and t destination cliques). Color each path so that the paths arriving at the same clique have the same color. This means that all the paths originating at a single source node have different colors. There are at most r paths colored with the same color. Now for each node that has at least $\log t$ paths of different colors going through it, mark the node and assign it $\log t$ paths of different colors. Then for each unassigned path, follow it from destination to source and assign it to the first marked node that it hits. A node will get at most $dr\log t$ paths of at most $d\log t$ colors this way. (This is because if a path gets assigned to a node, it came from an unmarked node. There are at most d unmarked nodes adjacent to a marked node. The paths that pass through an unmarked node have fewer than $\log t$ colors. There are at most r paths of a given color.)

How many paths don't get assigned? A path doesn't get assigned if it reaches its source node without hitting a marked node. There are r source nodes. How many make it back to a single source node u without getting assigned? If it doesn't get assigned, it passes through an unmarked neighbor of u just before it hits u. Call the neighbor v. All the paths going into u have different colors. If v is unmarked, than there are fewer than $\log t$ paths of different colors that pass through v. Thus there are fewer than $d\log t$ unassigned paths that reach u. □

In what follows, we denote by (C, D) the color of the r paths that lead from sources in C to destinations in D. Each of the t^2 combinations has a distinct color.

Now execute the following procedure. Find a node w that is hit by a single color (C, D) at least $\log t$ times. Remove all paths from C and repeat.

If at least $t/2$ such nodes are found, then we have the following situation: There is a sequence $C_1, C_2, \ldots, C_{t/2}$ of source cliques and a sequence $D_1, D_2, \ldots, D_{t/2}$ of destination cliques (not necessarily distinct) such that if D_i is assigned to C_i, there is a node that is $\log t$ congested. The probability that D_i is assigned to C_i is $1/t$. Conditioned upon D_1 not assigned to C_1, D_2 not assigned to $C_2, \ldots, D_{i-1}$ not assigned to C_{i-1}, the probability that D_i is assigned to C_i is still at least $1/2t$. Therefore, with probability at least $1-(1-1/2t)^{t/2} \geq 1-e^{-1/4}$, there is a $\log t$-congested node.

Otherwise, we have removed at most $t/2$ source cliques. The remaining source cliques have the property that no node is hit more than $\log t$ times by the same color. From now on, we consider only the remaining source cliques.

Let E_{Cw} denote the expected number of paths from sources in C that pass through w. The assignment of $V(C,D)$ has the property that $\sum_w \sum_C E_{Cw} \geq (n - dr\log t)/2$, where the second sum is taken over the remaining source cliques C.

Suppose that for all w, $\sum_C E_{Cw} \leq \log t$ (Otherwise, the lower bound on the expected congestion is established). Let $\delta = 1/8$. A node w is *good* if $\sum_C E_{Cw} \geq \delta$. The number of good nodes is at least $(n/2 - \delta n - dr \log t/2)/(\log t - \delta) \geq n/8 \log n$.

Fix a good node w. The assignment of $V(C,D)$ has the following property. For every clique C, either $E_{Cw} = 0$ or $\log t/t \leq E_{Cw} \leq ((d+1)\log^2 t)/t$. To see the upper bound, recall that none of the nodes are hit more than $\log t$ times by a single color $(C, \cdot)$. By claim 1 of Lemma 18, the upper bound follows. The lower bound follows from claim 2 of Lemma 18.

We want to lower bound the probability that h source cliques hit w for some $h < \log t$. Each hit corresponds to some clique C such that $E_{Cw} \geq \log t/t$. There are at least $\log t$ cliques D such that w is in $V(C,D)$. A hit by C removes one destination clique D from the list of possible destinations of other source cliques. Consider the conditional expectation of the number of paths from sources in C that pass through w, conditioned upon at least h other source cliques having hit w. By the above arguments, this conditional expectation is at least $1/t$. Notice further that if $w \in V(C,D)$, it may appear in $V(C,D)$ at most $\log t$ times (because of our assumption on the remaining source cliques). If D is assigned to C, we will count this as only one hit, so the expected number of hits on w is bounded below by $1/\log t \sum_C E_{Cw}$. Also, the probability of a hit due to source C is at most $(d+1)\log t/t$.

We use the following probabilistic lemma, due to Borodin et al. [9].

LEMMA 19 (Borodin et al.). *Let* $x_1, \ldots, x_k$ *be independent* $0/1$ *random variables. Let* $p_i = \text{Prob}[x_i = 1]$, $\sum p_i = \sigma$, *and* $a \leq p_i \leq b$. *Then, for any* $Y \leq \sigma/(2eb\log(b/a))$,

$$\text{Prob}\left[\sum x_i > Y\right] \geq \left(\frac{\sigma}{2e\log(b/a)Y}\right)^Y.$$

In our case, $\sigma = \delta/\log t = 1/8\log t$, $a = 1/t$, *and* $b = (d+1)\log t/t$.

According to the lemma, for n sufficiently large, the probability that node w is at least $Y = \log t/8 \log\log t$ congested is at least $1/\sqrt{t} \geq \log t/t$, provided that the condition on Y holds. It can be easily verified that for sufficiently large n, the condition that $dr \leq n/2\log^4 n$ implies the required condition on Y.

To summarize, we have shown that one of the following properties holds:

1. there is a sequence of (not necessarily distinct) nodes $x_1, x_2, \ldots, x_{t/2}$ such that with constant probability, at least one of them is at least $\log t$ congested; or
2. there is a node w whose expected congestion is at least $\log t$; or
3. there is a node w_1 that is at least $\log t/8\log\log t$ congested with probability at least $1/\sqrt{t} \geq \log t/t$.

If the first or second case holds, we are done. If the third case holds, we would like to construct a sequence of $t/\log t$ nodes $w_1, w_2, \ldots, w_{t/\log t}$ with the property that for every i, if $w_1, w_2, \dots, w_{i-1}$ are less than $\log t/\alpha \log\log t$ congested, then w_i is at least $\log t/\alpha \log\log t$ congested with probability at least $\log t/t$ for some constant α. We construct such a sequence by repeating the entire argument above at most $t/\log t$ times. If $w_1, w_2, \dots, w_i$, $i < t/\log t$, are less than $\log t/\log\log t$ congested, this constrains $t' = i \log t/\log\log t < t/\log\log t$ source cliques to their destination cliques. We remove these cliques and can thus repeat the above discussion setting $t := t'' = t - t'$ and assigning new values $V(u,v)$ for the remaining cliques. Notice that $t'' \geq t(1 - 1/\log\log t)$. We get one of the following properties:

1. there is a sequence of (not necessarily distinct) nodes $y_1, y_2, \dots, y_{t''/2}$ such that with constant probability, at least one of them is at least $\log t'' \geq \log t - 1$ congested; or
2. there is a node w' whose expected congestion is at least $\log t'' \geq \log t - 1$; or
3. there is a node w_{i+1} that is at least $\log t''/8 \log\log t'' \geq (\log t - 1)/8 \log\log t$ congested with probability at least $1/\sqrt{t''} \geq \log t/t$.

All the probabilities and expectations are conditioned upon the assignment of destination cliques to the t' constrained source cliques.

In the first case, recall that it followed from each of the y's being hit by $\log t''$ paths of one pair of source–destination cliques. If we remove the conditioning upon the assignment of destination cliques to the t'-constrained source cliques, this at most halves the probability of such a hit (because $t' < t/2$), so there would still be a constant probability for one of the y's to be at least $\log t - 1$ congested. In the second case, a similar argument shows that removing the condition at most halves the expected congestion at w' (using linearity of expectations). In the third case, we have constructed another node in the sequence $w_1, w_2, \dots, w_{t/\log t}$ and may proceed to constructing the next one. □

In the above proof, the permutation depends on the r-cliques. Assuming that $dr^3 \leq n/\log^3 n$, the lower bound in fact holds even when the agents can organize themselves into random r-cliques. The proof requires choosing uniformly at random an n-permutation of destinations rather than mapping cliques to cliques. We omit the proof.

4. Open problems.

We have given tight bounds, up to constant factors, for c_r, both in the deterministic and the randomized cases. It would be interesting to give better bounds for c_G in terms of other parameters of the graph G. Given G, what is the computational complexity of determining c_G? Our randomized upper bounds use shared coins. Can the same bounds be achieved with private coins? Our bounds for routing are far from being tight. Can one route deterministically on a high-degree network (where d is not a constant) achieving node or edge congestion close to the lower bounds given in Theorem 16? Does the randomized lower bound for node congestion hold for arbitrary knowledge graphs? Can a matching upper bound be achieved for large r?

Acknowledgments. We would like to thank the referees for their thorough reading and useful comments and suggestions. In particular, we would like to thank referee B for pointing out a flaw in our original proof of Lemma 9.

COMPLEXITY OF SUB-BUS MESH COMPUTATIONS*

ANNE CONDON†, RICHARD LADNER‡, JORDAN LAMPE§, AND RAKESH SINHA¶

Abstract. The time complexity of several fundamental problems on the sub-bus mesh parallel computer with p processors is investigated. The problems include computing the PARITY and MAJORITY of p bits, the SUM of p numbers of length $O(\log p)$, and the MINIMUM of p numbers. It is shown that in one dimension the time to compute any of these problems is $\Theta(\log p)$. In two dimensions the time to compute any of PARITY, MAJORITY, and SUM is $\Theta(\frac{\log p}{\log\log p})$. It was previously shown that the time to compute MINIMUM in two dimensions is $\Theta(\log\log p)$ [R. Miller et al., *IEEE Trans. Comput.*, 42 (1993), pp. 678–692; L. Valiant, *SIAM J. Comput.*, 4 (1975), pp. 348–355]

1. Introduction.

A sub-bus mesh computer is a single-instruction multiple-data (SIMD) two-dimensional array of processors, where processors can broadcast data vertically or horizontally on segmented busses. On a segmented bus, some of the processors on the bus are active while others are inactive. Each active processor can broadcast on the bus to all processors up to the next active processor. Thus, all the intervening inactive processors receive the data that has been broadcast. The sub-bus mesh computer architecture has been implemented on the commercially available MasPar MP-1 [5].

Typically, there are p processors in a $\sqrt{p}\times\sqrt{p}$ two-dimensional array, where $\sqrt{p}$ is a power of two. We will also consider one-dimensional meshes. For each of the problems we will consider, we assume there are p inputs, distributed one per processor.

The purpose of this paper is to present upper and lower bounds on the time to compute several fundamental functions including the PARITY and MAJORITY of p bits, the SUM of p numbers of length $O(\log p)$, and the MINIMUM of p numbers. Reisis and Prasanna Kumar appear to be the first to consider efficient algorithms for the sub-bus mesh architecture [26]. To our knowledge, this is the first paper to prove extensive results on the power and limitations of the sub-bus computer architecture.

1.1. Results.

There are simple algorithms for computing the Boolean OR and AND in constant time on a one- or two-dimensional sub-bus mesh computer [26].

Two other natural Boolean functions are PARITY and MAJORITY. We show that PARITY and MAJORITY are computable in time $\Theta(\log p)$ on a one-dimensional sub-bus mesh. The proofs of the lower bounds use a new technique for bounding the amount of information about the input that can be distributed on a one-dimensional mesh. The proof of the lower bound for MAJORITY can be used to show lower bounds for some other symmetric Boolean functions. We also consider the problem of computing the MINIMUM on a one-dimensional sub-bus mesh, and show that MINIMUM is computable in $\Theta(\log p)$ time. The lower bound for MINIMUM on the one-dimensional sub-bus mesh uses the same technique as the lower bound for PARITY.

We then show that PARITY and MAJORITY are computable in time $\Theta(\frac{\log p}{\log\log p})$ on a two-dimensional sub-bus mesh computer. The lower bounds follow from the fact that a concurrent-read/concurrent-write parallel random-access machine (CRCW PRAM) can simulate a sub-bus mesh computer to within a constant factor of the time and within a polynomial number of processors. Thus, the CRCW PRAM lower bounds on PARITY and MAJORITY [4] apply to the sub-bus mesh computer. The upper bounds follow from an algorithm for SUM, the sum of p numbers of length $O(\log p)$, which runs in time $O(\frac{\log p}{\log\log p})$. The SUM algorithm is nontrivial, using mixed radix arithmetic, the Chinese remainder theorem, and recursion to achieve the result. The obvious algorithm for SUM takes time $\Theta(\log p)$. The two-dimensional bound of $\Omega(\frac{\log p}{\log\log p})$ for SUM on the CRCW PRAM follows from the lower bound on PARITY.

1.2. Related results. The mesh or array parallel computer architecture has been investigated for a number of years, with numerous articles on its many variants [13, 17, 18, 22, 21, 26, 29]. The sub-bus mesh architecture was first investigated by Reisis and Prasanna Kumar [26], where they gave constant time algorithms for the OR of p bits and the MINIMUM of $\sqrt{p}$ numbers (all on one row), and an $O(\log p)$ algorithm for combining p data items with an associative operator. Two variants of the mesh computer are closely related to the sub-bus mesh. First, there is the full-bus mesh where processors can broadcast vertically or horizontally, but on a vertical (horizontal) broadcast at most one processor per column (row) can be active. The MPP of Goodyear and NASA is an example of a full-bus two-dimensional mesh computer [3]. Full-bus meshes are generally less powerful than sub-bus meshes. Both PARITY and MINIMUM require $\Omega(p^{\alpha})$ time for some $\alpha > 0$ on full-bus meshes [2, 25].

Second, there is the reconfigurable mesh, which allows the topology of the mesh to be changed by the executing program [18]. Several prototype, but no commercial, reconfigurable mesh computers have been built. PARITY can be computed in constant time on the reconfigurable, two-dimensional mesh [18]. Thus, our results demonstrate that the sub-bus mesh computer architecture is strictly more powerful than the full-bus mesh computer architecture, but strictly less powerful than the reconfigurable mesh computer. In other work on the PARITY function, MacKenzie [19] independently obtained a lower bound of $\Omega(\log p/k)$ for computing PARITY on a restricted $p \times k$ reconfigurable mesh model, which is exactly our one-dimensional sub-bus mesh model for $k = 1$. However, he did not extend this to other symmetric functions.

The SUM function has also been previously studied on the reconfigurable mesh. Nakano [23] and Nakano, Masuzawa, and Tokura [24] developed algorithms for SUM on the reconfigurable mesh that also use Chinese remaindering. Their results do not apply directly to the sub-bus mesh architecture. MINIMUM has also been previously studied on the two-dimensional reconfigurable mesh, and the techniques used can be applied directly to show that MINIMUM can be computed in $\Theta(\log\log p)$ time on the two-dimensional sub-bus mesh. From the work of Hao, MacKenzie, and Stout [12], a lower bound of $\Omega(\log\log p)$ is obtained for computing MINIMUM on a two-dimensional sub-bus mesh. Their proof is based on a PRAM simulation of the mesh model, and applies a result of Fich et al. [11] in which an equivalent lower bound is proved for the CRCW PRAM. However, this proof requires that the inputs be very large. Another lower bound of $\Omega(\log\log p)$ for computing MINIMUM on the two-dimensional sub-bus mesh follows from the general lower bound for the parallel comparison model of Valiant [31] and applies to comparison-based algorithms. A matching upper bound is due to Miller et al. [21], and is basically an implementation of the parallel MINIMUM algorithm of Valiant [31].

The PRAM is probably the most well-studied theoretical model of parallel computation. There are a number of variants of the PRAM, depending on whether reads or writes to the same memory location can be done concurrently. The variant most closely related to the sub-bus mesh is the CRCW PRAM (see [14] for an introduction to the PRAM model). In this version more than one processor can read or write the same memory location at the same time. A simultaneous write can be resolved in a number of ways. The ability of the sub-bus mesh to broadcast on segments of the bus is very much like a combination of a concurrent read and a concurrent write. Those processors that are actively broadcasting are executing a concurrent write while those that are inactive are executing a concurrent read. Indeed the sub-bus mesh can compute OR in constant time just as a CRCW PRAM can. We show that CRCW PRAM can simulate a sub-bus mesh computer to within a constant factor of the time. This simulation immediately implies that lower bounds for the CRCW PRAM are also lower bounds for a sub-bus mesh. Interestingly, some CRCW PRAM algorithms can be translated into sub-bus mesh algorithms. For example, the constant-time OR algorithm and Valiant's MINIMUM algorithm can be implemented on the sub-bus mesh. By contrast, some CRCW PRAM algorithms, such as the constant-time CRCW PRAM MINIMUM algorithm of Fich, Radge, and Wigderson [10], appear to be impossible to implement on the sub-bus mesh. More generally, the CRCW PRAM is strictly more powerful than the sub-bus mesh regardless of the number of dimensions. This is because problems like SORT require time $\Omega(p^\alpha)$ on mesh computers, but can be done in time $O(\log p)$ on a PRAM.

The sub-bus model is also incomparable with the exclusive read, exclusive write (EREW) PRAM model. To see this, note that computing the OR of p bits requires $\Omega(\log p)$ time on a CREW PRAM [9], whereas the sub-bus mesh can compute OR in constant time. By contrast, p integers can be sorted in $O(\log p)$ time on an EREW PRAM with p processors [1, 7, 16], but, by a simple bisection bandwidth argument, this task requires time $\Omega(p^\alpha)$ on mesh computers [30].

1.3. Organization of the paper.

In §2 we present our model of the sub-bus mesh computer. In §3 we prove our upper and lower bounds for the one-dimensional sub-bus mesh computer. In §4 we give two-dimensional algorithms for PARITY and SUM. In §5 we give our simulation of a two-dimensional sub-bus mesh by a CRCW PRAM, thereby yielding our two-dimensional lower bounds for PARITY, MAJORITY, and SUM. In §6 we present two-dimensional upper and lower bounds for MINIMUM. Finally, we have our conclusions in §7.

2. Sub-bus mesh computer model.

For the purposes of this paper we present a simple version of the sub-bus mesh computer architecture. Actual machines have a richer organization.

The sub-bus architecture can be easily explained for the one-dimensional mesh or linear array of processors. There are p processors, numbered consecutively 0 to $p-1$ on a circle. Processor 0 is the *front-end* which runs the parallel program. Each processor is a random-access machine (RAM) with its own memory which is referenced using *plural* variables. In addition, there are *singular* variables for which there is only one copy which is stored at the front-end processor. There is a special plural variable `PID` that always holds the processor's number. Processor operations include direct and indirect Boolean operations, arithmetic operations, shifts, and comparisons. In addition, the front-end can perform normal branching operations and issue *parallel instructions.*

A parallel instruction issued by the front-end has the form "**if** <*condition*> **then** <*statement*>." Each processor evaluates the condition, which can be any sequence of nonbranching operations on plural or singular data that evaluates to a Boolean value. If the condition is true then the processor is said to be *active*; otherwise it is said to be *inactive.* Only the active processors execute the statement part of the instruction.

There are two kinds of statements, *local operations* and *segmented broadcasts.* A local operation is just a typical nonbranching RAM operation executed on plural or singular data at each processor. A segmented broadcast has the form

`broadcast_`*direction*`[`*distance*`].`*plural variable* ← *plural variable.*

The *direction* can be either `left` or `right`. The variable *distance* must be singular. When an active processor i executes the instruction `broadcast_right[`d`].y` ← `x` then the location `y` at the processors $(i+1) \bmod p, (i+2) \bmod p, \ldots, (i+j) \bmod p$ receive the value stored in location `x` of processor i, where processors $(i+1) \bmod p, (i+2) \bmod p, \ldots, (i+j-1) \bmod p$ are inactive and either $j = d$ or $j < d$ and processor $(i+j) \bmod p$ is active. The segmented broadcast to the left is similar. In either case, the circle is partitioned into nonoverlapping segments. Each segment behaves like a sub-bus of the bus that includes all the processors. The MasPar MP-1 implements the segmented broadcast as `xnetc`. Table 1 describes the result of a segmented broadcast.

TABLE 1
*Demonstration of segmented broadcast. The * indicates that the value of* `y` *did not change because of the broadcast.*

	`broadcast_right[2].y ← x`							
PID	0	1	2	3	4	5	6	7
active	no	no	yes	yes	no	no	no	yes
x	a	b	c	d	e	f	g	h
y	h	h	*	c	d	d	*	*

In two dimensions there are also p processors, where p is a square number. The mesh processors are arranged in a $\sqrt{p} \times \sqrt{p}$ array. The coordinates of a mesh processor's number are stored in `PIDx` and `PIDy`. A mesh processor's number is stored in `PID` = `PIDy` * $\sqrt{p}$ + `PIDx`. The sub-busses go in four directions: `up`, `down`, `right`, and `left`. Processor (x, y) is immediately up from processor $(x, (y+1) \bmod \sqrt{p})$ and immediately to the left of processor $((x+1) \bmod \sqrt{p}, y)$. So vertical busses go up and down, while horizontal busses go right and left, all in a circular fashion. The front-end processor is processor $(0, 0)$.

2.1. Time of sub-bus mesh algorithms. For the purpose of analyzing our algorithms we consider time to be evaluated using the unit-cost RAM criterion where the values operated upon must have length $O(\log p)$. Each sequential operation by the front-end, each parallel operation used in evaluating the condition in a parallel instruction, and each statement of a parallel instruction costs 1 in our model. We do not charge for the broadcast of parallel instructions by the front-end to the mesh processors. We assume that cost is dominated by the cost of executing the parallel instruction.

As mentioned earlier, the RAM instructions include the usual direct and indirect Boolean operations, arithmetic operations, shifts, and comparison. In addition, we permit any fixed finite set of RAM instructions for our processors, provided each instruction can be implemented in uniform NC [8, 28], that is, each instruction can be built from $\log^{O(1)} p$ hardware and runs in time $\log^{O(1)} \log p$. The set of RAM operations is independent of p. Thus, the total hardware in the sub-bus mesh computer of p processors is $p \log^{O(1)} p$. The running time of $\log^{O(1)} \log p$ per RAM instruction is fast enough to be considered constant time in the mesh of processors.

For the purpose of proving our lower bounds we allow our model to be even more general. We do not restrict the length of the values operated on and do not restrict the RAM operations in any way. There is one exception. The two-dimensional lower bound for MINIMUM is done in the so-called "comparison model," where the only RAM operations allowed on input values are comparison, copy, and broadcast. Thus, with one exception, the lower bounds reflect the cost of computing functions due to the sub-bus mesh architecture, not any limitations on the individual processors. The two-dimensional lower bound for MINIMUM is still quite general, but is limited to the comparison model of the sub-bus mesh computer.

2.2. Examples of sub-bus mesh algorithms. Below we give two examples of sub-bus mesh algorithms, both of which will be building blocks in subsequent algorithms. Both examples can be found in the paper by Reisis and Prasanna Kumar [26]. In our terminology, if x is a plural variable then we indicate its value at processor i by $\mathtt{x}_i$ or at processor (i, j) by $\mathtt{x}_{i,j}$.

Our first program computes the OR in constant time.

```
CONSTANT-TIME-OR on a one-dimensional mesh
input: plural Boolean x
output: OR of all values $x_i$ in plural variable y
begin
  y ← false
  if x = true then
    broadcast_left[$p$].y ← true
end
```

In CONSTANT-TIME-OR, if any of the values $\mathtt{x}_i$ are true, then one or more of the processors will make sure to broadcast true into all processors' y's. However, if *none* of the $\mathtt{x}_i$ bits are true, then no processor will run the broadcast step, and so all the $\mathtt{y}_i$'s will remain false. Clearly, using DeMorgan's law, AND can also be computed in constant time.

Our second program computes the MINIMUM of $\sqrt{p}$ values in constant time on a two-dimensional $\sqrt{p} \times \sqrt{p}$ mesh.

```
CONSTANT-TIME-MINIMUM of $\sqrt{p}$ values on a two-dimensional mesh
input: plural integer/real variables $x_{0,0}, \ldots, x_{\sqrt{p}-1,0}$
output: MINIMUM value $x_{i,0}$ in plural variable y
other: plural Boolean t
```

```
begin
  if PIDy = 0 then
    broadcast_down[$\sqrt{p}-1$].x ← x
  if PIDx = PIDy then
    broadcast_left[$\sqrt{p}$].y ← x
  t ← x > y
  if t then
    broadcast_up[$\sqrt{p}-1$].t ← true
  if not t then
    broadcast_left[$\sqrt{p}$].y ← x
end
```

In CONSTANT-TIME-MINIMUM, the first two broadcasts have the effect of setting $x_{i,j} = x_{i,0}$ and $y_{i,j} = x_{j,0}$. The comparison $x_{i,j} > y_{i,j}$ is then equivalent to the comparison $x_{i,0} > x_{j,0}$. If such a comparison holds then $x_{i,0}$ is not the minimum. The statement "`if t then`..." computes, in one step, the "or" of the outcomes of these comparisons. Thus, after the broadcast up, if $t_{i,0} =$ `false` then $x_{i,0}$ is the minimum. This minimum is then broadcast to the first row of the mesh.

3. One-dimensional bounds.

In this section we give precise upper and lower bounds on the parallel time to compute PARITY, MAJORITY, SUM, and MINIMUM on the one-dimensional sub-bus mesh computer.

3.1. Upper bounds in one dimension.

As observed by Reisis and Prasanna Kumar [26], all our problems can be computed by a one-dimensional algorithm which works for any associative binary operator and runs in $O(\log p)$ time. Let $\oplus$ be any binary associative operation. The value REDUCE-$\oplus$(x) is $x_0 \oplus x_1 \oplus \cdots \oplus x_{p-1}$ stored in processor 0. The following algorithm simply computes the expression for REDUCE-$\oplus$(x) as a balanced binary tree.

```
REDUCE-⊕ on a one-dimensional mesh
input: plural variable x.
output: $y_0 = x_0 \oplus x_1 \oplus \ldots \oplus x_{p-1}$
other: plural variable z, singular integer i
begin
  y ← x
  i ← 1
  while i < $p$ do begin
    if PID mod i = 0 then
      broadcast_left[i].z ← y
    if PID mod 2i = 0 and PID + i < $p$ then
      y ← y ⊕ z
    i ← i * 2
  endwhile
end
```

Both SUM and MINIMUM can be expressed as REDUCE-$\oplus$ operations, where $\oplus$ is integer addition in the case of SUM and the minimum of two numbers in the case of MINIMUM. PARITY and MAJORITY are easily computable in constant time from SUM. Thus we have the following theorem.

THEOREM 3.1 (see [26]). *On a one-dimensional sub-bus mesh with p processors,* PARITY, MAJORITY, SUM, *and* MINIMUM *can be computed in time $O(\log p)$.*

3.2. Lower bounds in one dimension. Our lower bounds for the one-dimensional sub-bus mesh computer are based on the limited communication bandwidth of this architecture. Thus, in proving our lower bounds, we use a simplified model in which internal computations in a processor are "free" and only the time taken for communication is measured. It will be clear that any lower bound for this model applies also to the upper-bound model.

As before, there are p processors, numbered $0, 1, \dots, p-1$, connected by a circular sub-bus. The computation proceeds in rounds; we charge 1 time unit for a round. In each round of the computation, the processors first communicate and then perform arbitrary internal computation. The communication is controlled by the front-end, processor 0, just as in the upper-bound model described in §2. Once this is done, processors can do arbitrary internal computation that does not require communication. There is no bound on the length of values broadcast or computed by the processors.

An algorithm consists of both the algorithm that determines the sequence of communication instructions broadcast by processor 0, and the algorithms of processors $0, \dots, p-1$ that determine the internal computations at each round. Since processor 0 can read any information on the bus that passes in either direction between processor $p-1$ and processor 1, the communication instructions may depend on this information.

Let f be a function with domain D^p. We say algorithm A computes f if for all $(x_0, x_1, \dots, x_{p-1}) \in D^p$, if at the start of the algorithm each processor i has in its memory the value x_i, then at the end of the algorithm, every processor has in a special memory location the value $f(x_0, x_1, \dots x_{p-1})$. The tuple $(x_0, x_1, \dots, x_{p-1})$ is called the input. In all of the results of this section, we assume that $|D| \geq 2$.

Fix an input $\boldsymbol{x} = (x_0, x_1, \dots, x_{p-1})$. Processor k's *view* on input $\boldsymbol{x}$ at time t is a sequence $k, x_k, (1, v_1), (2, v_2), \dots, (t, v_t)$, where v_i is the value received by processor k at time i during the broadcast instruction. String v_i is a special symbol, say ϵ, if no value is received. We denote by $\text{View}_k(\boldsymbol{x}, t)$ the view of processor k at time t. For a fixed input $\boldsymbol{x}$, we say x_i is *unknown to* processor k at time t if $\text{View}_k(\boldsymbol{x}, t) = \text{View}_k(\boldsymbol{x}', t)$ for all $\boldsymbol{x}'$ that differs from $\boldsymbol{x}$ only at component i. Otherwise, we say x_i is known to processor k at time t.

Our main result is the following theorem.

THEOREM 3.2. *On a one-dimensional sub-bus mesh with p processors and for any algorithm A, there exists an input* $\boldsymbol{x}$ *such that for some* $i, 1 \leq i \leq p-1$, x_i *is unknown to processor* 0 *at time* $\log p - 1$.

This result is true, regardless of what function is being computed by A, as long as the domain size $|D| \geq 2$. Hence, the result immediately yields a lower bound of $\log p$ for the time to compute functions f with the property that for any $(x_0, x_1, \dots, x_{p-1}) \in D^p$ and any $i, 0 \leq i \leq p-1$, there is some $x'_i \in D$ such that

$$f(x_0, x_1, \dots, x_{i-1}, x_i, x_{i+1}, \dots, x_{p-1}) \neq f(x_0, x_1, \dots, x_{i-1}, x'_i, x_{i+1}, \dots, x_{p-1}).$$

Clearly PARITY is an example of such a function, where $D = \{0, 1\}$, and so Theorem 3.2 implies a lower bound of $\log p$ for PARITY. Also, the MINIMUM function over the integers is an example of such a function, so again Theorem 3.2 implies a lower bound of $\log p$ for computing MINIMUM.

We now describe informally the ideas in the proof of Theorem 3.2. Note that, for all inputs $\boldsymbol{x}$ and processors k, if $i \neq k$ then x_i is unknown to k at time 0. Consider a processor i at the first round. We consider two possibilities. The first is that i is inactive at round 1, regardless of its input value x_i. This is good since then, for any processor $k \neq i$, x_i is still unknown to processor k at time 1.

The other possibility is that i is "potentially active," that is, i is active on at least one possible value of its input. Then, unfortunately, at the end of round 1, x_i may be known to some, and possibly all, other processors. We can use this to our advantage, however, by setting i's input x_i to force i to be active. Then, the broadcast of processor i will block any other broadcast that might otherwise have sent information through i.

For the purpose of this informal discussion, suppose that at round 1 all processors are potentially active. Our strategy in this case will be to fix the values of alternate processors, in order to force them to be active. These fixed values determine a partial assignment $\alpha \in (D \cup \{*\})^p$, and partition the processors into *fixed* and *free* processors. On any input $\boldsymbol{x}$ consistent with the partial assignment α, the broadcasts of the fixed, active processors block the free processors from revealing any information about their values to too many processors.

In general, for any $t, 0 \leq t \leq \log p - 1$, we will define a partial assignment α that fixes the input at all but $\lfloor (p-1)/2^t \rfloor$ free processors. On any input $\boldsymbol{x}$ consistent with the partial assignment α, the input x_i of a free processor i will be known only to a set of contiguous processors containing i at time t.

We now state and prove the main lemma leading to the proof of Theorem 3.2.

LEMMA 3.3. *Fix an algorithm A. For any $t, 0 \leq t \leq \log p - 1$, there is a partial assignment α with at least $\lfloor (p-1)/2^t \rfloor$ free processors with the following property. On any input $\boldsymbol{x}$ consistent with α, the input x_i of a free processor i will be known only to a set of contiguous processors S_i containing i at time t, where $0 \notin S_i$. Moreover, for any two distinct free processors i and j, $S_i \cap S_j = 0$.*

Proof. The proof is by induction on t. The base case is when $t = 0$. In this case, since no communication has taken place, it is immediate that if α is the partial assignment that is not fixed anywhere, then all possible inputs $\boldsymbol{x}$ are consistent with α, all processors in the range $1, \ldots, p-1$ are free, and the value x_i of every processor i is known only to processors in the set $S_i = \{i\}$.

Suppose the lemma is true for $t - 1 \geq 0$, and let α be the partial assignment as in the statement of the lemma. Suppose that at round t, active processors broadcast to the right (the other case, when active processors broadcast to the left, is handled similarly).

We will define a partial assignment α' which extends α and satisfies the lemma for time t. To do this, we consider the free processors at time $t - 1$ in order from that with the largest index to that with the smallest index. (We consider processors in the opposite order in the case that the broadcast is to the left.) If free processors j, i occur consecutively in this ordering, with $j > i$, we say that j is i's *free neighbor to the right* at time $t - 1$.

For each of these processors i in turn, we will determine whether i remains free at round t, and if not, we will extend α to fix input value x_i. If i does remain free, we will define a corresponding set S'_i containing i, and will show that at time t, on any input $\boldsymbol{x}$ consistent with α', x_i is known only to processors in S'_i, that $0 \notin S'_i$, and that $S'_i \cap S'_j$ are disjoint, for free processors $i \neq j$.

Hence consider some processor i that is free at time $t - 1$. We say that S_i is *potentially active* if there is some input consistent with α such that some processor in S_i broadcasts at round t with that input. Otherwise S_i is said to be *inactive.*

If S_i is potentially active, then we define i to be free at round t if and only if the following conditions hold: (i) it is not the largest numbered free processor at time $t-1$, and (ii) processor i's free neighbor to the right at time $t-1$ is not free at time t. (Note that since i's free neighbor to the right has index $j > i$, and since we consider the free processors in order from the largest to the smallest, it is already determined whether j is free at time t.) The corresponding set S_i' is defined to be the smallest contiguous set containing S_i and S_j, where j is i's free neighbor to the right at time $t-1$. Otherwise, i is not free at time t and the value of x_i is fixed in α', to force some processor in S_i to be active at round t. It is important to note that since the processors in S_i do not know the values of x_j for the free processors $j \neq i$ at time $t-1$, then some assignment to the input x_i will force some processor in S_i to be active at round t regardless of any assignment to other inputs whose processors are free at time $t-1$.

If S_i inactive, then we define i to be free at round t and the corresponding set of processors S_i' to be equal to S_i. This completes the description of α' and the set S_i' for each free processor i.

We now argue that α' satisfies the lemma at time t. It is straightforward to see from the construction that for each free processor i at time t, $i \in S_i'$ and S_i' is a set of contiguous processors. Also, for any two distinct free processors, i and j, $S_i' \cap S_j' = 0$. This is because the S_i are contiguous, nonoverlapping sets, and each S_i' is either S_i or is formed by "collapsing" two neighboring sets S_i and S_j, where processor j is free at time $t-1$ but not at time t. Finally, using the fact that no set S_i contains processor 0, we show that no set S_i' contains processor 0. This is easy to see if S_i' equals S_i, since we know S_i does not contain processor 0. Otherwise, S_i' is the smallest contiguous set containing S_i and S_j, where j is i's free neighbor to the right at time $t-1$. Since $0 < i < j$, processor 0 cannot lie between the contiguous sets S_i and S_j. This, together with the fact that neither S_i nor S_j contain processor 0, implies that S_i' does not contain processor 0.

We next show that for any $\boldsymbol{x}$ consistent with α', if i is free at time t then x_i is known only to those processors in S_i'. First note that since processor 0 is not in S_i for any processor i that is free at time $t-1$, the instruction broadcast by 0 at time t does not reveal any information about the values of processors that are free at time $t-1$. Also, it is clear that if S_i is inactive at time t, for all $\boldsymbol{x}$ consistent with α', then x_i is still known only to those processors in S_i at time t.

Consider the other case, where S_i is potentially active at time t. Then i's free neighbor to the right at time $t-1$, say processor j, is free at time $t-1$ but not at time t. Moreover, by our construction of α', on any $\boldsymbol{x}$ consistent with α' there is a processor b in S_j that broadcasts at time t. Hence, on any input $\boldsymbol{x}$ consistent with α', any broadcast of a processor in set S_i reaches only processors in the segment between this active processor and processor b. The processors in this segment are contained in the smallest contiguous set containing both S_i and S_j. Hence, x_i is known only to processors in S_i' at time t.

To complete the proof, it remains to show that there are $\geq \lfloor (p-1)/2^t \rfloor$ free processors at time t. By the inductive hypothesis, there are $\geq \lfloor (p-1)/2^{t-1} \rfloor$ free processors at time $t-1$. If i and j are two neighboring free processors at time $t-1$, then at least one of these is still free at time t. To see this, suppose that $i < j$ and that j is not free at time t. Then either S_i is inactive at time t, in which case i is free at time t, or S_i is potentially active, in which case both conditions (i) and (ii) are satisfied, so again i is free at time t. Hence the number of free processors at time t is at least $\lfloor \lfloor (p-1)/2^{t-1} \rfloor /2 \rfloor = \lfloor (p-1)/2^t \rfloor$, as required. □

The proof of Theorem 3.2 now follows easily from Lemma 3.3. If $p \geq 2$ then $\lfloor (p-1)/2^{\log p - 1} \rfloor \geq 1$. Hence by the lemma, there is a partial assignment α that is not fixed at one free processor, say i, with the following property. On any input $\boldsymbol{x}$ consistent with α, at time $\log p - 1$, the input x_i will be known only to a set of processors S_i, where $0 \notin S_i$. Hence, x_i is unknown to processor 0 at time $\log p - 1$.

Lower bounds of $\log p$ time for PARITY and MINIMUM follow immediately from Theorem 3.2, as discussed after the statement of that theorem. The same lower bound must also hold for SUM, since PARITY can be computed from SUM without any communication. Thus, we have the following theorem.

THEOREM 3.4. *On a one-dimensional sub-bus mesh with p processors, the time to compute* PARITY, SUM, *and* MINIMUM *is at least* $\log p$.

In order to obtain lower bounds for MAJORITY and many other symmetric Boolean functions we need to modify Lemma 3.3. If α is a partial assignment, define α_0 to be the number of inputs fixed to 0 in α and α_1 to be the number of inputs fixed to 1 in α. We say a partial assignment α is *b-balanced* if $0 \leq \alpha_b - \alpha_{1-b} \leq 1$. That is, α is 1-balanced if the number of inputs assigned to 1 in α is equal to or one greater than the number of inputs assigned to 0 in α. Similarly, α is 0-balanced if the number of inputs assigned to 0 in α is equal to or one greater than the number of inputs assigned to 1 in α.

LEMMA 3.5. *Fix an algorithm A. For any bit b and for any* $t, 0 \leq t \leq \log_3 p - 1$, *there is a b-balanced partial assignment* α *with at least* $\lfloor (p-1)/3^t \rfloor$ *free processors with the following property. On any input* $\boldsymbol{x}$ *consistent with* α, *the input* x_i *of a free processor i will be known only to a set of contiguous processors* S_i *containing i at time t, where* $0 \notin S_i$. *Moreover, for any two distinct free processors i and j,* $S_i \cap S_j = 0$.

Proof. This proof is similar to that of Lemma 3.3. Assume we have a b-balanced partial assignment α at time $t-1$ and a number n of free processors with their associated segments satisfying the condition of the lemma. Assume also that at time t there is a broadcast to the right. As in the proof of Lemma 3.3, a segment is inactive if no processor in the segment would become active on any input consistent with α and is potentially active otherwise. As before, any processor i that is free at time $t-1$ and whose segment S_i is inactive remains free at time t. Assume the free processors at time $t-1$ are indexed by $i_1, i_2, \ldots, i_n$, where $i_j > i_{j+1}$ for $1 \leq j \leq n$. We consider these processors three at a time, largest index to smallest, to determine which potentially active processors remain free at time t and for those that do not remain free, what their inputs will be assigned to in the new b-balanced partial assignment α'. If n is divisible by 3 then this process will end simply. If not, there will be a remaining group of 1 or 2 that must be dealt with.

Assume that for $j \leq 3m$, it has already been determined whether i_j is free at time t and if not, what the assignment to x_{i_j} is in the assignment α'. We now consider the processors i_{3m+1}, i_{3m+2}, and i_{3m+3}, where $3m+3 \leq n$. There are four cases to consider, depending on how many of the segments $S_{i_{3m+1}}, S_{i_{3m+2}}, S_{i_{3m+3}}$ are potentially active. If none are potentially active then there is nothing to do. If exactly one, say $S_{i_{3m+k}}$, is potentially active, then set $x_{i_{3m+k}}$ to a value to make α' b-balanced. That is, if $\alpha'_0 = \alpha'_1$ then assign $x_{i_{3m+k}}$ to b, otherwise set it $1-b$. If exactly two of the segments are potentially active, then assign the input associated with one to 0 and the other to 1. Finally, if all three are potentially active then i_{3m+3} remains free, $x_{i_{3m+2}}$ is set so as force a processor in the segment $S_{i_{3m+2}}$ to be active, and then $x_{i_{3m+1}}$ is set to make α' b-balanced.

Once the groups of three have been processed there may be one or two remaining free processors. If exactly one of the segments in this remaining group is potentially active, then assign the input of that processor to a value to make the partial assignment b-balanced. If exactly two of the segments of the free processors in this remaining group are potentially active, then assign the two inputs of the free processors to opposite values.

At the end of this process, at least $\lfloor n/3 \rfloor$ of the processors are free. If i is free at time t and S_i is inactive, then $S_i' = S_i$. If i is free at time t and S_i is potentially active, then the corresponding set S_i' is defined to be the smallest contiguous set containing S_i and S_j, where j is i's free neighbor to the right at time $t-1$. This happens in the fourth case above when $i = i_{3m+3}$ and $j = i_{3m+2}$.

It should be clear that α' is a b-balanced partial assignment with at least $\lfloor (p-1)/3^t \rfloor$ unassigned inputs. Furthermore, for the same reasons as in the proof of Lemma 3.3, for any input $\boldsymbol{x}$ consistent with α', the input x_i of a free processor i will be known only to a set of contiguous processors S_i containing i at time t, where $0 \notin S_i$. Clearly, the segments at time t are disjoint. □

As a consequence of Lemma 3.5 we have the following theorem, which allows us to find a b-balanced input with a component unknown to processor 0 at a time slightly less than the maximum time to find just some input with a component unknown to processor 0, as in Theorem 3.2.

THEOREM 3.6. *On a one-dimensional sub-bus mesh with p processors and for any algorithm A and bit b, there exists a b-balanced input $\boldsymbol{x}$ such that for some $i, 1 \leq i < p-1$, x_i is set to b, but is unknown to processor* 0 *at time* $\log_3 p - 1$.

Proof. If $p \geq 2$ then $\lfloor (p-1)/3^{\log_3 p - 1} \rfloor \geq 1$. By Lemma 3.5, there is a $(1-b)$-balanced partial assignment α that is not fixed at a free processor i. Set $x_i = b$, then set the remaining unassigned inputs so as to make the input b-balanced. Since 0 is not a member of the segment S_i at time $\log_3 p - 1$, x_i is not known to processor 0. □

THEOREM 3.7. *On a one-dimensional sub-bus mesh with p processors, the time to compute* MAJORITY *is at least* $\log_3 p$.

Proof. Let A be any algorithm for MAJORITY. There are two cases to consider, depending on whether p is even or odd. If p is even then by Theorem 3.6 select a 0-balanced input $\boldsymbol{x}$ and an i such that $x_i = 0$ and x_i is not known to processor 0 at time $\log_3 p - 1$. Clearly, processor 0 cannot have computed the majority of the inputs by time $\log_3 p - 1$ since its computation would be identical for the input $\boldsymbol{x}$ and $\boldsymbol{x}'$, which is identical to input $\boldsymbol{x}$ except that $x_i' = 1$. The latter input has a majority of 1's while the former does not. If p is odd then select a 1-balanced input $\boldsymbol{x}$ and an i such that $x_i = 1$ and x_i is not known to processor 0 at time $\log_3 p - 1$. The remainder of the argument is similar to that above. □

For any symmetric Boolean function f on p inputs define $m(f)$ to be the k such that $\frac{p}{2} - k \geq 0$ is minimal and for some bit b the value of f on an input with exactly k inputs equal to b differs from the value of f on an input with $k+1$ inputs equal to b. For example, $m(\text{MAJORITY}) = m(\text{PARITY}) = \lfloor \frac{p}{2} \rfloor$ and $m(\text{OR}) = m(\text{AND}) = 0$.

COROLLARY 3.8. *On a one-dimensional sub-bus mesh with p processors, the time to compute any symmetric function f is at least* $\log_3(2m(f))$.

Proof. Let f be given. Let b be such that if $m(f)$ inputs have the value b then f has one value and if $m(f)+1$ inputs have the value b then f has another value. For simplicity consider the case in which $m(f)$ inputs equal 0 implies the value of f is 0 and $m(f)+1$ inputs equal 0 implies the value of f is 1. If exactly $p - 2m(f)$ inputs are set to 0 then the restricted function has $2m(f)$ inputs. By a proof identical to the proof of Theorem 3.7, any algorithm to compute the restricted function must take time $\log_3(2m(f))$. The argument for $b = 1$ is similar. □

Define THRESHOLD$_k$ to be the Boolean function that is 0 with k or fewer inputs set to 1 and 1 otherwise. Clearly, $m(\text{THRESHOLD}_k) = \min(k, p-k)$. Thus, we have the following corollary.

COROLLARY 3.9. *On a one-dimensional sub-bus mesh with p processors, the time to compute* THRESHOLD$_k$ *is at least* $\log_3(2\min(k, p-k))$.

4. Algorithms for PARITY and SUM.

In this section we present asymptotically optimal algorithms for PARITY and SUM on the two-dimensional sub-bus mesh computer. We start with the PARITY algorithm. It is the simpler of the two, and introduces some of the key ideas that are useful in the SUM algorithm.

4.1. PARITY algorithm.

We will introduce a series of problems in increasing order of difficulty. The algorithm for each problem will lead to the next one with some fresh tricks. This will help us concentrate on one idea at a time.

Each of the algorithms below can be executed on a submesh of the $\sqrt{p} \times \sqrt{p}$ mesh. By an *array* or *subarray* we mean a submesh of the full mesh which may be nonsquare and noncontiguous. In case it is noncontiguous, it is assumed that the processors between any two processors in the subarray are inactive so as not to interfere with communication between the processors in the subarray. Furthermore, any of the algorithms below can be executed in parallel on disjoint and properly aligned subarrays of the full $\sqrt{p} \times \sqrt{p}$ array. If the algorithm is executed on a $m \times n$ subarray, then we say processor (i, j) is the processor in the (i, j)th position (the ith column and jth row) of the subarray, where $0 \le i < m$ and $0 \le j < n$. Although it is not generally the case that processor (i, j) has its PIDx $= i$ and PIDy $= j$, it will always be the case that i, j, and dimensions of the subarray can be computed from the PID of the processor and other local data in constant time.

LEMMA 4.1. *On an $n \times 2^n$ array with each processor in the top row having an input bit, the parity of the input bits can be computed in constant time.*

Proof. There are 2^n possible inputs, so we will make row j of the array responsible for determining whether the input, thought of as an integer x with $0 \le x < 2^n - 1$, actually equals j. In particular, processor (i, j) determines if the input in processor $(i, 0)$ equals the ith bit of j. A downward broadcast of the input gives processor (i, j) knowledge of the input in processor $(i, 0)$. Then processor (i, j) compares the input of processor $(i, 0)$ with the ith bit of j. A constant time AND of the outcomes of these comparisons in all the rows in parallel tells processor $(0, j)$ whether the input, thought of as an n-bit number, equals j. This information can then be broadcast up to processor $(0, 0)$. Since $2^n \le \sqrt{p}$, we know $j \le \log p$ so that processor $(0, 0)$ can compute the sum of the bits in j in constant time, using the fact that computing the sum of the bits of an input is in uniform NC. The parity of the input bits is the parity of this sum. □

We saw that with exponentially many rows we can compute the parity in constant time. In general, if we have more than a constant number of rows, we can beat the straightforward $O(\log n)$ time algorithm.

LEMMA 4.2. *On an $n \times m$ array with each processor in the top row having an input bit, the parity of the input bits can be computed in time $O(\frac{\log n}{\log\log m})$.*

Proof. We can think of the $n \times m$ array as $\frac{n}{\log m}$ subarrays of dimension $\log m \times m$ placed side by side. As in the previous proof, we can compute the parity of groups of $\log m$ bits in constant time. This leaves $\frac{n}{\log m}$ partial results in the first row of an array of dimension $\frac{n}{\log m} \times m$. Repeating the process $\frac{\log n}{\log\log m}$ times we have the parity of all the n bits. □

So far we have been assuming that only the processors in the top row have inputs. Let us now consider the case where each processor has an input.

LEMMA 4.3. *On an $n \times m$ array with each processor having an input bit, the parity of the input bits can be computed in time $O(\log m + \frac{\log n}{\log\log m})$.*

Proof. First, in parallel, the processors within each column run the one-dimensional PARITY algorithm described in §3.1. This part takes time $O(\log m)$. At this point, we have partial results stored in the top row. From the previous lemma, the parity of these partial results can be computed in an additional $O(\frac{\log n}{\log\log m})$ steps. □

We are ready to give our PARITY algorithm.

THEOREM 4.4. *On a $\sqrt{p} \times \sqrt{p}$ mesh with each processor having an input bit,* PARITY *can be computed in time $O(\frac{\log p}{\log\log p})$.*

Proof. Think of the $\sqrt{p} \times \sqrt{p}$ mesh as $\frac{\sqrt{p}}{m}$ smaller arrays of dimension $\sqrt{p} \times m$, one on top of the other. Each of these arrays computes the parity of its input bits in parallel. By the previous lemma, this takes $O(\log m + \frac{\log\sqrt{p}}{\log\log m})$ time and leaves $\frac{\sqrt{p}}{m}$ partial results in the leftmost column. By Lemma 4.2 their parity can be computed in time $O(\frac{\log\sqrt{p}}{\log\log(\sqrt{p}/m)})$. Choosing $\log m = \frac{\log p}{\log\log p}$ we get a total running time of $O(\frac{\log p}{\log\log p})$. □

4.2. SUM algorithm. Computing PARITY is the same as computing the sum of the inputs modulo 2. Lemmas 4.1 and 4.2 can be generalized to compute the sum, modulo a small integer, of inputs on the top row. For all the problems below we assume that the inputs are nonnegative integers of length $O(\log p)$.

LEMMA 4.5. *If $\log Q \leq \sqrt{\log n}$ then on an $n \times n$ array with each processor having Q and with each processor in the top row having an input integer, the sum of the inputs modulo Q can be computed in time $O(\frac{\log n}{\log\log n})$.*

Proof. Let $m = \frac{\log n}{\log Q}$. Let us focus on an $m \times n$ subarray that has m inputs on the top row. There are $Q^m = n$ possibilities for the m inputs mod Q. For $0 \leq j < n$, think of j as an integer written in base Q. As in the computation of parity, processor (i, j) is responsible for determining if the ith input mod Q is equal to the ith Q-ary digit of j. Processor (i, j) learns of the input at $(i, 0)$ by a broadcast down from the first row. Then, processor $(0, j)$ learns from an AND on its row that the ith Q-ary digit of j is the ith input mod Q for all i such that $0 \leq i < m$. Processor $(0, j)$ then transmits j to processor $(0, 0)$ where the sum mod Q of the Q-ary digits of j is computed.

The original $n \times n$ array can be divided into $\frac{n}{m}$ subarrays of dimension $m \times n$ placed side by side where the algorithm above is performed in parallel. What remains are $\frac{n}{m}$ numbers in the top row. Iterate this process $O(\frac{\log n}{\log m}) = O(\frac{\log n}{\log\log n - \log\log Q})$ times to compute the sum of all the n integers modulo Q.

To complete the proof we must argue that computing the sum mod Q of the Q-ary digits of a number x is in uniform NC. We assume both Q and x are written in binary. First, since $\log Q \leq \sqrt{\log n}$ and $n \leq \sqrt{p}$, then the length of Q is $O(\sqrt{\log p})$. Second, $x \leq \sqrt{p}$, so that x is of length $O(\sqrt{\log p})$. Thus, the lengths of Q and x can be assumed to be bounded by the same number b, which we can assume is a power of two and of length $O(\sqrt{\log p})$. To find the sum mod Q of the Q-ary digits of x, write x as $x_0 + Q^{b/2}x_1$, by dividing x by $Q^{b/2}$. Recursively, find the a_0 and a_1 that are the sums mod Q of the Q-ary digits of x_0 and x_1, respectively. Then, $a = (a_0 + a_1) \bmod Q$ is the sum mod Q of the Q-ary digits of x. The necessary powers of Q, division by these powers, and sum are all in uniform NC. Since the number of levels of recursion is bounded by $\log_2 b$, then the result a can also be computed in uniform NC. □

By the Chinese remainder theorem we know that if we can compute the sum modulo sufficiently many small integers, we can compute the exact sum.

LEMMA 4.6. *If $6 \leq \log t \leq \sqrt{\log n}$ then on an $n \times tn$ array with each processor in the top row having an input integer such that the sum of these integers is less than*

2^t, *the sum of the inputs can be computed in time* $O(\frac{\log n}{\log\log n})$.

Proof. Think of the $n \times tn$ array as t subarrays, each of size $n \times n$, one on top of the other. Let M be the product of all primes less than t. If $t \geq 41$ then $M \geq 2^t$ [27, Cor. to Thm. 4, p. 70]. Hence, if the sum of the input integers is less than 2^t then it is enough to compute the sum modulo M. We already know how to compute the sum modulo small primes. Our plan is to let each $n \times n$ subarray compute the sum modulo a different prime and then apply the Chinese remainder algorithm to compute the sum modulo M.

To begin with, the processors in the top row broadcast the input values down the columns. The jth subarray decides whether j is a prime. This can be done in two stages. A number j is prime if and only if it is not divisible by any number between 1 and $\sqrt{j}$. In the first stage, assign $\sqrt{j}$ processors in the first row to check for each possible divisor. In the second stage, these processors compute an AND of their results. Only processors in the jth subarray for prime j participate in all subsequent steps. The jth subarray computes a_j, the sum of all the inputs modulo j. By Lemma 4.5, this can be done in $O(\frac{\log n}{\log\log n})$ time.

Next, in $O(\log t)$ steps, each processor in the jth subarray computes M, the product of all primes less than t, and $m_j = \frac{M}{j}$. The processors in the jth subarray compute $(a_j m_j)((m_j)^{-1} \bmod j)$. This can be done in constant time. The nontrivial part is computing $((m_j)^{-1} \bmod j)$. There are at most j possible values for the inverse. We assign j processors in (say) the first row of the jth subarray for each possible value of the inverse. In one step, each of these assigned processors can check whether it has the right value of the inverse. The processor corresponding to the right value of the inverse broadcasts this to all other processors. By the Chinese remainder theorem, the exact value of the sum is the summation of $(a_j m_j)((m_j)^{-1} \bmod j)$, which can be computed in $O(\log t)$ steps.

In total the computation can be done in $O(\log t + \frac{\log n}{\log\log n}) = O(\frac{\log n}{\log\log n})$ time. □

LEMMA 4.7. *If* $tw \leq m$ *and* $6 \leq \log t \leq \sqrt{\log w}$ *then on an* $n \times m$ *array with each processor in the top row having an input integer such that the sum of these integers is less than* 2^t, *the sum of the inputs can be computed in time* $O(\frac{\log n}{\log\log w})$.

Proof. Think of the $n \times m$ array as $\frac{n}{w}$ subarrays, each of dimension $w \times m$, side by side. Since $tw \leq m$, each $w \times m$ subarray can be thought of as containing a $w \times tw$ subarray at the top. Each $w \times tw$ subarray has its input on the top row. By Lemma 4.6, the sum of the inputs of all the $w \times tw$ subarrays can be computed in time $O(\frac{\log w}{\log\log w})$ leaving $\frac{n}{w}$ partial sums in the top row. This process is repeated $\frac{\log n}{\log w}$ times until the input is reduced to a single number. This reduction takes time $O(\frac{\log n}{\log\log w})$. □

We now consider the case where *each* processor has an input.

LEMMA 4.8. *If* $tw \leq m$ *and* $6 \leq \log t \leq \sqrt{\log w}$ *then on an* $n \times m$ *array with each processor having an input integer such that the sum of these integers is less than* 2^t, *the sum of the inputs can be computed in time* $O(\log m + \frac{\log n}{\log\log w})$.

Proof. The first step is simply to add the columns in parallel in time $O(\log m)$. We are now reduced to the problem in the previous lemma. Hence the total time is $O(\log m + \frac{\log n}{\log\log w})$. □

THEOREM 4.9. *On a* $\sqrt{p} \times \sqrt{p}$ *mesh with each processor having an input integer of length* $O(\log p)$, SUM *can be computed in time* $O(\frac{\log p}{\log\log p})$.

Proof. Choose $t = \log(p^k)$, where p^k is an upper bound on the sum of the input integers and $\log t \geq 6$. Let c be a constant, which depends only on k, such that $\log t \leq \sqrt{\frac{c \log p}{\log \log p}}$. Now, choose w such that $\log w = \frac{c \log p}{\log \log p}$. Let $m = tw$, so that t, w, and m satisfy the hypothesis of Lemma 4.8. Think of the $\sqrt{p} \times \sqrt{p}$ mesh as $\frac{\sqrt{p}}{m}$ arrays of dimension $\sqrt{p} \times m$ one on top of the other. By Lemma 4.8 the sum of these arrays can be computed in time $O(\log m + \frac{\log \sqrt{p}}{\log \log w})$, leaving $\frac{\sqrt{p}}{m}$ partial sums in the first column. We may now apply Lemma 4.7 to these inputs to find the full sum in an additional $O(\frac{\log \sqrt{p}}{\log \log w})$ time. The total time is then $O(\log m + \frac{\log \sqrt{p}}{\log \log w})$. Since $\log w = \frac{c \log p}{\log \log p}$ and $\log m = \log w + \log t = O(\frac{\log p}{\log \log p})$, the total time of the algorithm is $O(\frac{\log p}{\log \log p})$. □

It is interesting to note that if we assume that the individual processors can operate on integers of arbitrary length in constant time, then using the technique of Theorem 4.9, the sum of p integers of length $2^{O(\sqrt{\log p / \log \log p})}$ can be computed in time $O(\frac{\log p}{\log \log p})$.

Since MAJORITY can be computed from SUM in constant time we may now state the following theorem.

THEOREM 4.10. *On a two-dimensional sub-bus mesh with p processors,* PARITY, MAJORITY, *and* SUM *can be computed in time* $O(\frac{\log p}{\log \log p})$.

In the next section we will show these bounds are optimal.

5. Simulation of a sub-bus mesh by a CRCW PRAM. In this section, we prove a $\Omega(\frac{\log p}{\log \log p})$ lower bound for computing PARITY, MAJORITY, and SUM on the two-dimensional sub-bus mesh computer. To prove this, we show that any algorithm for the sub-bus model can be simulated by a CRCW PRAM algorithm with only a constant-factor loss in running time. We then apply lower-bound results for PARITY on the PRAM model. We begin this section by describing the PRAM results. Then we describe our lower-bound model and describe the simulation in detail.

Beame and Håstad [4] considered lower bounds for the following "ideal" CRCW PRAM model. There are $p(n)$ numbered processors that share $c(n)$ numbered memory cells, where $p(n)$ and $c(n)$ are polynomially bounded. There is no bound on the possible contents of a memory cell. Initially, the input bits $x_0, \ldots, x_{n-1}$ are stored in the first n memory cells and the remaining cells have value 0. Before each step t, a processor is in some state, say q. At the tth step, the processor may read the value v stored in some memory cell C. Based on C, v, and q, the processor moves to a new state q', and may write a value v' to some cell C'. There is no limit on the number of states of a processor nor on the resources needed to compute v' and C'. If several processors attempt to write into the same memory cell at the same step, the lowest numbered processor succeeds. This model is called the *priority* CRCW PRAM. Beame and Håstad [4] have shown that the time to compute any of PARITY, MAJORITY, and SUM on the ideal CRCW PRAM is $\Omega(\log n / \log \log n)$.

In our lower bound model of the two-dimensional sub-bus there are p processors, numbered $0, 1, \ldots, p-1$, connected in a $\sqrt{p} \times \sqrt{p}$ mesh as in the two-dimensional upper bound model. Processor 0 is the front-end. The computation proceeds in rounds costing one unit, and in each round, the processors first communicate and then perform arbitrary internal computation. The communication is done just as in the upper-bound model. Again, there is no bound on the size of values broadcast or computed. The main result of this section is the following theorem.

THEOREM 5.1. *Any problem that can be solved in time* $t(p)$ *on a two-dimensional* *sub-bus mesh computer with p processors can be solved in time $O(t(p))$ on a priority CRCW PRAM with $O(p^{3/2})$ processors.*

Proof. Let A be a $T(p)$-time algorithm for solving a problem on the two-dimensional sub-bus lower bound model. We describe an ideal CRCW PRAM that simulates A, such that each round of A takes $O(1)$ steps.

In the simulating PRAM, there are p processors, numbered $0, 1, \dots, p-1$, corresponding to the p processors of the sub-bus model. There are also auxiliary processors, whose computation will be described later.

There are two special memory cells, called Condition and Statement, used by processor 0 to communicate the instruction at each round. Also, corresponding to each processor $i, 0 \leq i \leq p-1$, there are the following special memory cells (we do not specify their exact addresses, but assume they are computable by processor i). Active(i) is used to denote at each round whether i is active. It is initialized to false at the beginning of each round. Send(i) is used to store the value broadcast by i, at each round, if i is active. Receive(i) is used to store the value, if any, received by i in each round. At the start of each round, processor i sets Active(i) to false and sets Receive(i) to some special value which is not in the range of possible values that can be broadcast by A.

We now describe the simulation of a single round of A. First, processor 0 writes the strings <*condition*> and <*statement*> in cells Condition and Statement, respectively. Each processor $i, 0 \leq i \leq p-1$ reads these cells and decides if it is active at this round. If so, i writes the value to be broadcast in Send(i) and sets Active(i) to true.

We next describe how each processor i determines the value it receives (if any) during the broadcast instruction. If i receives a value, it is from one of $\sqrt{p}$ processors on either the vertical or horizontal bus along which i is connected. Let these processors be numbered $i_1, \dots, i_{\sqrt{p}}$, where the ordering is such that if i_1 is active, then i_1 is the processor from which i receives a message; if i_1 is not active but i_2 is, then i_2 is the processor from which i receives a message, and so on, so that if i_k is active and none of $i_1, \dots, i_{k-1}$ are active, then i_k is the processor from which i receives a message. For example, if the direction of communication is up, then the sequence is $(i + \sqrt{p}) \bmod p, (i + 2\sqrt{p}) \bmod p, \dots, (i + \sqrt{p}\sqrt{p}) \bmod p$.

Each processor i has $\sqrt{p}$ auxiliary processors to help it compute the value it receives, if any. Let the auxiliary processors of i be numbered $n_i + 1, \dots, n_i + \sqrt{p}$, where $n_i = p + i\sqrt{p} - 1$. Each processor $n_i + k$ computes i_k; this can be done by reading <*statement*>, to determine the direction of communication. If processor i_k is active, that is, Active(i_k) is true, then processor $n_i + k$ reads the value Send(i_k) and writes it in Receive(i). Because of the ordering of the auxiliary processors, and the priority write conflict resolution assumption, the value written in Receive(i) is the value received by processor i at that round of A, in the sub-bus computation.

Once the cells Receive(i) have been computed, each processor $i, 0 \leq i \leq p-1$ completes the round by simulating the internal computation of the ith sub-bus processor. This completes the description of the simulation. It is clear that all the steps described can be done by the processors of the ideal CRCW PRAM, since they have unbounded resources with which to compute at each step, and an unbounded number of states that can be used to store the internal configurations of the processors of the sub-bus mesh computer. □

As a direct consequence of Theorem 5.1 we have the following theorem.

THEOREM 5.2. *On a two-dimensional sub-bus mesh with p processors, the time to compute* PARITY, MAJORITY, *and* SUM *is* $\Omega(\frac{\log p}{\log \log p})$.

6. MINIMUM. In this section we survey the two-dimensional complexity of MINIMUM in the comparison model of the sub-bus mesh. Previous work for the reconfigurable mesh shows that the time to compute MINIMUM on the two-dimensional mesh is $\Theta(\log\log p)$. For completeness, we include the algorithm, adapted to the sub-bus model.

THEOREM 6.1 (see [21, 31]). *In the comparison model of a two-dimensional sub-bus mesh computer with p processors, the time to compute* MINIMUM *is* $\Theta(\log\log p)$.

Proof. Recall that in the comparison model we assume the only operations allowed on input values are comparison, copy, and broadcast. With this restriction any sub-bus mesh algorithm for MINIMUM can be thought of as a "parallel comparison tree" as defined by Valiant [31]. In this model, any p comparisons of arbitrary input values can be made in one step. Depending on the outcome of these comparisons, one of 2^p branches to the next step can be made. Valiant showed that in the parallel comparison tree model with p processors, $\Omega(\log\log p)$ steps are necessary to determine the minimum of p inputs.

In the same paper Valiant [31], gave an algorithm for the minimum which runs in $O(\log\log p)$ time. The Valiant algorithm can be realized on the reconfigurable mesh computer as shown by Miller et al. [21]. In fact, their work also applies to the two-dimensional sub-bus mesh computer. In the Valiant algorithm, assume there are p processors, where $p = 2^{2^k}$ for some k. With one parallel comparison the number of possible minima to consider is reduced to $\frac{p}{2}$. Subsequently, if there are $\frac{p}{b}$ possible minima remaining, then in one parallel comparison this number can be reduced to $\frac{p}{b^2}$. This is done by dividing the $\frac{p}{b}$ numbers into $\frac{p}{b^2}$ groups of size b and using one parallel comparison to find the minimum of all the groups simultaneously. A group of size b requires b^2 processors to find the minimum in one parallel comparison. Thus, p processors are utilized to find the $\frac{p}{b^2}$ possible minima.

The Valiant algorithm can be realized on the two-dimensional sub-bus mesh computer. The basic building block is the MINIMUM algorithm described in §2.2, which in constant time finds the minimum of n values if they are in the first row of an $n \times n$ array of processors. In the two-dimensional algorithm, if there are $\frac{p}{b}$ values remaining (for $b \geq 2$) then there are $\frac{p}{b^2}$ subarrays of the $\sqrt{p} \times \sqrt{p}$ array, each of which is $b \times b$ with b inputs in the first row of the subarray. The leftmost corner of the subarrays appear at processors (ib, jb), where $0 \leq i, j < \frac{\sqrt{p}}{b}$. Using the basic building block, the $\frac{p}{b}$ possible minima can be reduced to $\frac{p}{b^2}$ possible minima in constant time. These possible minima are located at processors indexed (ib, jb), where $0 \leq i, j < \frac{\sqrt{p}}{b}$. By first broadcasting these values to the right, then selectively broadcasting these values up, we end up with $\frac{p}{b^2}$ remaining values in the first row of $\frac{p}{b^2}$ subarrays, each of size $\frac{p}{b^2} \times \frac{p}{b^2}$. The iterative version of this algorithm is given below.

```
MINIMUM of $p$ values on a two-dimensional mesh
input: plural number variable x
output: MINIMUM value $x_{i,j}$
other: plural number variable y, Boolean variable t, singular integer b
NOTE: We assume $p = 2^{2^k}$ for some $k$.
begin
  b ← 2
  broadcast_up[1].y ← x
  if y < x then
    x ← y
  repeat begin
```

```
        Step 1
        if PIDy mod b = 0 then
           broadcast_down[b-1].x ← x
        if PIDx mod b = PIDy mod b then begin
           y ← x
           broadcast_left[b-1].y ← y
        endif
        if PIDx mod b = 0 then
           broadcast_right[b-1].y ← y
        t ← (x > y)
        if t then
           broadcast_up [b-1].t ← true
        if not t then
           broadcast_left[b-1].x ← x
        Step 2
        if b = $p$ then
           return $x_{0,0}$
        if PIDy mod b = 0 then begin
           if PIDx mod b = 0 then
              broadcast_right[b-1].x ← x
           if PIDx mod b = (PIDy mod $b^2$) / b then
              broadcast_up[$b^2$-1].x ← x
        endif
        b ← $b^2$
     endrepeat
end
```

To explain the algorithm in more detail, at the beginning of step 1 there are possible minima in every processor along every bth row. Then step 1 does the constant time MINIMUM on each $b \times b$ block in parallel. Within each block, it distributes the b initial values into the variables x and y for each processor. Thus, the processor in position (i, j) in each block has the initial value of processor $(i, 0)$ in its x register and the initial value of processor $(j, 0)$ in its y register. A comparison of x and y is recorded in the Boolean value t. After broadcasting t up the only processor with the value false is the processor in position $(i, 0)$ which has the minimum for this block. So, that processor will broadcast its initial value x to processor $(0, 0)$ within the block.

In step 2 we have the situation where the processors (ib, jb) have possible minima, and we want to move them all to rows, so that the processors (i, jb^2) all have potential minima. This is accomplished in two substeps. First, broadcast the potential minima to the right. Second, selectively broadcast the minima up. That is, each potential minimum at processor $(ib + k, jb^2 + kb)$ for $0 \leq k < b$ is broadcast up.

In case p is not of the form 2^{2^k} for some k then the algorithm must be modified slightly. In the modified algorithm we will always maintain an active rectangular sub-mesh which is $\sqrt{p} \times q$, where $q \leq \sqrt{p}$ and b divides q evenly. In attempting step 2 it may happen that b^2 does not divide r evenly. If this is the case we set $q' = b^2 \lfloor q/b^2 \rfloor$ and use the upper $\sqrt{p} \times q'$ subarray. The blocks below this new rectangle can easily be merged into the blocks directly above them in constant time. Thus, in constant time we go from $b \times b$ blocks to $b^2 \times b^2$ blocks. This is sufficient to solve the problem in time $O(\log \log p)$. □

7. Conclusions. We have proved tight bounds (to within constant factors) on the time needed to compute several functions on the sub-bus mesh computer. For some of these problems, such as PARITY, MINIMUM, and SUM, the running times on a sub-bus mesh computer match (to within constant factors) the running times on a general PRAM. Moreover, machines based on the sub-bus mesh architecture are commercially available [5]. For these reasons, we believe that the sub-bus mesh architecture deserves further study.

Our algorithms for PARITY and SUM are probably not practical for any reasonable size p for two reasons. First the speed-up by a factor of $O(\log \log p)$ has too large a constant factor to be significant. Second, it is doubtful that hardware designers would want to implement the new NC functions required by the algorithm. It is possible to remove the second factor inhibiting practicality by adding preprocessing phases to the algorithms. A preprocessing phase uses only standard arithmetic/Boolean operations to compute values that depend only on the processor PIDs and the structure of the algorithm and which, in the original algorithm, would be computed as results of NC functions. Using preprocessing, many more values would be computed than are actually used in the algorithm, since during the preprocessing it is not known exactly which values will be needed later on. The necessary preprocessing for the two algorithms PARITY and SUM is complicated, but can be accomplished within the $O(\frac{\log p}{\log \log p})$ time bound.

We have implemented the $O(\log \log p)$ MINIMUM algorithm on a 1,024 processor MasPar MP-1. The constant factor in front of the $\log \log p$ forces the algorithm to run more slowly than the standard $O(\log p)$ algorithm. However, we believe that the ideas in the $O(\log \log p)$ MINIMUM algorithm have the potential to be used in a competitive practical algorithm for finding the minimum on commercially available meshes with more than 1,024 processors.

Several open questions are suggested by our results. Are there simpler $O(\frac{\log p}{\log \log p})$ algorithms for PARITY or SUM on the two-dimensional sub-bus mesh that may be competitive on real machines? Is it possible to improve the lower bound for MAJORITY on a one-dimensional mesh from $\log_3 p$ to $\log_2 p$? Can our lower bound for PARITY on the two-dimensional sub-bus mesh can be simplified, or improved by a constant factor, using the mesh model directly rather than translating results from the PRAM model?

Acknowledgments. We thank Eric Bach, David Barrington, and Paul Beame for several useful discussions and suggestions. We thank Tosten Suel and Phil MacKenzie for providing us with several references to previous work on the reconfigurable mesh. We thank the anonymous referees for useful suggestions and for pointing out a seminal reference to the sub-bus mesh architecture.

PATHWIDTH, BANDWIDTH, AND COMPLETION PROBLEMS TO PROPER INTERVAL GRAPHS WITH SMALL CLIQUES*

HAIM KAPLAN† AND RON SHAMIR‡

Abstract. We study two related problems motivated by molecular biology.

- Given a graph G and a constant k, does there exist a supergraph G' of G that is a unit interval graph and has clique size at most k?
- Given a graph G and a proper k-coloring c of G, does there exist a supergraph G' of G that is properly colored by c and is a unit interval graph?

We show that those problems are polynomial for fixed k. On the other hand, we prove that the first problem is equivalent to deciding if the bandwidth of G is at most $k-1$. Hence, it is NP-hard and $W[t]$-hard for all t. We also show that the second problem is $W[1]$-hard. This implies that for fixed k, both of the problems are unlikely to have an $O(n^\alpha)$ algorithm, where α is a constant independent of k.

A central tool in our study is a new graph-theoretic parameter closely related to pathwidth. An unexpected useful consequence is the equivalence of this parameter to the bandwidth of the graph.

Key words. design and analysis of algorithms, parameterized complexity, interval graphs, bandwidth, pathwidth

1. Introduction.

This paper studies the following graph-theoretic questions.

- *Problem* A. Given a graph G and a constant k, does there exist a supergraph G' of G that is a unit interval graph and has clique size at most k?
- *Problem* C. Given a graph G and a proper k-coloring c of G, does there exist a supergraph G' of G that is properly colored by c and is a unit interval graph?

A related problem that generalizes both of these problems is the following.

- *Problem* B. Given two graphs G and G^2 such that $G \subseteq G^2$, is there a unit interval graph G' such that $G \subseteq G' \subseteq G^2$ and G' has clique size at most k?

Those questions arise as abstractions of practical problems in molecular biology, as will be explained later. They are NP-complete, but we show that they are all polynomial when the parameter k is fixed. We prove that Problem A is equivalent to the BANDWIDTH problem. In particular, this equivalence together with a recent result of Bodlaender, Fellows, and Hallet [4] imply that Problems A and B are hard for the parameterized complexity class $W[t]$ for all t. We prove here that Problem C is $W[1]$-hard. This implies that none of the problems is likely to have an algorithm with time complexity bounded by $f(k)n^\alpha$ for any constant α.

Problem B may be viewed as a *sandwich problem*, since G' must be "sandwiched" between G and G^2. Sandwich problems were introduced in [22] and studied further in [20]. Problem B was shown to be NP-hard for the case where $k = |V|$ (i.e., without any restriction on the clique size) in [21]. The NP-hardness results here are stronger since they apply to Problem C, a restriction of Problem B in which the forbidden edges are those between like-colored endpoints.

Let A', B', and C' be analogous to Problems A, B, and C, respectively, with the only change that the supergraph G' is required to be interval instead of unit interval. Problem A' is equivalent to asking if the *pathwidth* of G is at most $k - 1$, and it arises in various guises (and under different names) in numerous areas (cf. [33]). It is NP-hard [2, 24, 28, 35] but linearly solvable for fixed k [3, 30]. Problem C' (and hence also B') was shown to be NP-hard when $k = |V|$ independently in [21] and [13]. Fellows, Hallet, and Wareham [13] also showed that the Problem C' is hard for $W[1]$ and that it is not finite state for bounded pathwidth or treewidth and, hence, not polynomially solvable by conventional algorithmic techniques. Recently, Bodlaender, Fellows, and Hallet [4] strengthened these results by proving that Problem C' is hard for $W[t]$ for all t. Note that the known results on Problems A' and C' do not directly imply analogous results for Problems A and C or vice versa. For example, as we show here, the parametric complexities of Problems A' and A are qualitatively very different.

The three problems that we study here arise in molecular biology. In order to study a genome, several copies of it are cut or broken down, and some of the resulting shorter segments (called *clones*) are preserved for further analysis. Depending on the technique used, the preserved clones may have variable length, or they may all have essentially the same length. In the process of producing the clones, all information about their relative position along the DNA chain is lost. The goal of *physical mapping* of DNA is to reconstruct that order, based on experimental data on the overlaps between pairs of clones [8, 26, 36]. Hence, the graph with vertices corresponding to clones and edges corresponding to overlapping pairs of clones should be an interval graph if clone lengths vary or a proper interval graph if all clones have the same length. Both types of graphs can be recognized in linear time [7, 10, 32].

In practice, information on overlap is never perfect. There are several ways to model this imperfection: If one assumes that all the errors in the data are false nonoverlaps (*false negatives*) and wishes to minimize their number, one gets the *interval graph completion problem* [17, Prob. GT35; 27], that is, minimize the number of edges whose addition to the graph will form an interval graph. If one assumes that all errors are erroneous overlaps (*false positives*), the *interval graph deletion problem* comes up [18]. If some pairs of clones are definite overlaps, some are definite nonoverlaps, and the rest are unknown, then one gets the *interval sandwich problem* [22]. All three problems are NP-hard, for interval and proper interval graphs. Hence, the question arises if introduction of additional biological constraints can make any of the problems tractable.

An important feature of real biological data is that the "width" of the map is consistently very small; the largest number of mutually overlapping clones is typically between 5 and 15, compared with a total number of clones in the thousands [31, 37]. Our study here focuses on the tractability of the models above in this special situation. More formally, do the problems remain NP-hard when the clique size of the proper interval graph is assumed to be bounded by a small constant? Hence, the model in Problem A bounds the width of the map and assumes false negatives only. Problem B allows a finer partition of the overlap information (into sure, unsure, and forbidden overlaps) while again bounding the map width. In Problem C, the set of clones consists of k disjoint subsets, with each subset originating from the dissection of a single copy of the genome. This implies that within each subset all clones are disjoint. Equivalently, the vertices corresponding to such a subset may all be assigned the same color. Admittedly, these models are crude, but they provide a starting point by allowing rigorous analysis. We believe that this line of research may eventually lead also to practical, tractable models, especially in view of the positive results given here for the fixed parameter cases.

The rest of the paper is organized as follows. In §2 we give formal definitions and background. In §3 we give two characterizations of proper pathwidth, a new graph-theoretic parameter introduced here, and in particular prove that proper pathwidth equals bandwidth. This result may be of independent interest, and we expect that it will be useful elsewhere. It implies immediately the NP-completeness of Problem A, its polynomiality for fixed k, and its $W[t]$-hardness for all t. Section 4 expands the equivalence to sandwich instances. Section 5 then exploits this equivalence to obtain a polynomial algorithm for Problem B (and hence C) when k is fixed. Section 6 contains a proof that the parameterized version of Problem C is hard for $W[1]$. Section 7 contains some concluding remarks.

2. Preliminaries.

In this section we give definitions and background and state without proof some well-known facts about notions that we will need in the sequel. For other graph-theoretical definitions see, e.g., [19].

2.1. Basic definitions.

All graphs are assumed to be undirected, simple, and finite. A graph $G = (V, E)$ is a *supergraph* of the graph $G' = (V', E')$ if $V = V'$ and $E \supseteq E'$. For a subset $W \subseteq V$, the subgraph of G *induced by* W is (W, E_W), where $E_W = \{(u, v) \in E \mid u, v \in W\}$. A *clique* in a graph $G = (V, E)$ is a set $C \subseteq V$ such that the subgraph induced by C is complete. A clique is *maximal* if it is not properly contained in any other clique in the graph. The *clique size* of G, denoted $\omega(G)$, is the maximum cardinality of a clique in G. An *independent set* in G is a set of vertices no two of which are adjacent. A *k-coloring* of graph $G = (V, E)$ is a function $c : V \to \{1, \ldots, k\}$ such that $c(u) \neq c(v)$ if $(u, v) \in E$. A supergraph G of G' *respects* the k-coloring c of G' if c is also a k-coloring for G.

2.2. Interval and proper interval graphs.

Let $S = (U, <)$ be a linear order. For every $u, w \in U$ such that $u \leq w$, the set $[u, w] = \{v \in U \mid u \leq v \leq w\}$ is called an *interval*. The most commonly used example involves intervals on the real line, but we shall refer also to intervals on finite, linearly ordered sets. A graph $G = (V, E)$ is an *interval graph* if one can associate with each vertex v an interval $I(v)$ such that two intervals intersect if and only if their vertices are adjacent. The set of intervals $\Sigma = \{I(v)\}_{v \in V}$ is called an (interval) *representation* for G, and G is called the *intersection graph* of Σ. A graph is a *proper interval graph* if it has an interval representation in which no interval is properly contained in another. A graph is a *unit interval graph* if it is an interval graph that has a representation on the real line in which all the intervals have equal length. Roberts has shown that these two definitions coincide as follows.

THEOREM 2.1. (See [38].) *A graph is unit interval if and only if it is proper interval.* □

The proof of the following lemma is straightforward and hence omitted.

LEMMA 2.2. *Every interval graph (and every proper interval graph) has an interval (resp., proper interval) representation on the real line in which all endpoints are distinct, and the left endpoints are assigned to the integers* $1, 2, \ldots, |V|$. □

We shall call such a representation *canonical.*

2.3. Pathwidth and proper pathwidth.

A *path decomposition* of a given graph $G = (V, E)$, is a sequence of subsets of V, $X = (X_1, \ldots, X_l)$ such that the following hold:

(1) $V = \cup_i X_i$.

(2) For each edge $(u, v) \in E$, there exists some $i \in \{1, \ldots, l\}$ so that both u and v belong to X_i.

(3) For each $v \in V$ there exist some $s(v), e(v) \in \{1, \ldots, l\}$ so that $s(v) \leq e(v)$, and $v \in X_j$ if and only if $j \in \{s(v), s(v)+1, \ldots, e(v)\}$.

The *width* of X is defined by $pw_X(G) = \max\{|X_i| \mid i = 1, \ldots, l\} - 1$. The *pathwidth* of G, denoted $pw(G)$, is the minimum value of $pw_X(G)$ over all path decompositions; i.e., $pw(G) = \min\{pw_X(G) \mid X$ is a path decomposition of $G\}$. The notion of pathwidth was originally introduced by Robertson and Seymour in [39].

LEMMA 2.3. (See, e.g., [6].) *For any path decomposition $X = (X_1, \ldots, X_l)$ of a graph G, every clique in G must be contained in some X_i.* □

The PATHWIDTH problem is to decide for a given graph G and a given integer k if $pw(G) \leq k$. Equivalent problems arise in various areas, including VLSI layout, processor management, node searching, and vertex separation (see the excellent survey of Möhring on pathwidth and the relations among these problems [33]). PATHWIDTH is NP-complete on arbitrary graphs [2, 28] and even for chordal graphs [24] and (using the equivalence to node search [29]) for planar graphs with vertex degrees at most three [35]. On the other hand, it is polynomial when k is fixed. The results of Robertson and Seymour [39] imply nonconstructively that an $O(n^2)$ algorithm exists for fixed k [14, 15]. The recent results of Bodlaender [3] yield a linear algorithm for PATHWIDTH for every fixed k [30, Chap. 11]. The notions of pathwidth and interval graphs are related by the following well-known observation.

LEMMA 2.4. (Cf. [33].) *For every graph G, the pathwidth of G is one less than the least clique size of any interval supergraph of G.* □

We introduce here the notion of a *proper path decomposition* of G; it is as a path decomposition X that satisfies (1)–(3) and also

(4) For every $u, v \in V$, $\{s(u), s(u)+1, \ldots, e(u)\} \not\subset \{s(v), s(v)+1, \ldots, e(v)\}$.

(As usual, $\subset$ denotes strict containment.) The *proper pathwidth* of G, denoted $ppw(G)$, is the minimum value of $pw_X(G)$ over all proper path decompositions of G; namely, $ppw(G) = \min\{pw_X(G) \mid X$ is a proper path decomposition of $G\}$.

Clearly, $pw(G) \leq ppw(G)$, but note that $pw(G)$ and $ppw(G)$ can differ dramatically: for the star graph with $2n+1$ vertices, $G = K_{1,2n}$, $pw(G) = 1$ but $ppw(G) = n$. An easy way to see the last equality is to the characterizations we shall provide in the next section.

2.4. Bandwidth. Another measure of graph width that we shall use is bandwidth; that is, for $G = (V, E)$ with $|V| = n$, a linear *layout* of the graph is a 1–1 function $L : V \rightarrow \{1, \ldots, n\}$. The *bandwidth of* L is $bw_L(G) = \max_{(u,v) \in E}\{|L(u) - L(v)|\}$. The *bandwidth* of G is the minimum bandwidth over all layouts of G; namely, $bw(G) = \min\{bw_L(G) \mid L$ is a layout of $G\}$. The BANDWIDTH problem is to decide for a given graph G and integer k, if $bw(G) \leq k$. This problem has been studied intensely because of its application to sparse matrix algebra [9]. It is known to be NP-complete even for binary trees [16] and for caterpillars with hair length at most three [34]. On the other hand, it is solvable in $O(n^k)$ for arbitrary k [23] and in linear time for $k = 2$ [16].

2.5. Sandwich problems. Given two graphs $G^1 = (V, E^1)$ and $G^2 = (V, E^2)$ such that G^2 is a supergraph of G^1, a graph $G = (V, E)$ is called a *sandwich* for this pair if $E^1 \subseteq E \subseteq E^2$. ($G$ must be "sandwiched" between G^1 and G^2, hence the name.) Let E^3 be the set of all edges in the complete graph with vertex set V that are not in E^2. We assume that a *sandwich instance* S is actually represented by the triplet (V, E^1, E^3). For a family $\mathcal{F}$ of graphs, the $\mathcal{F}$-SANDWICH problem is to decide for a given instance if there exists a sandwich graph $G \in \mathcal{F}$. For example, in the *proper interval sandwich* problem the set $\mathcal{F}$ is the set of all proper interval graphs.

Sandwich problems model flexibility (or ambiguity) of the problem data, where the edges of $E^2 - E^1$ are not known for sure to be included or excluded from the graph. Sandwich problems were introduced in [22] and studied later in [5, 13, 20, 21]. Their applications include matrix algebra, evolutionary tree construction, and temporal reasoning. Physical mapping of DNA motivated our study here of the following problem.

PROPER INTERVAL SANDWICH WITH BOUNDED CLIQUE SIZE (BPIS):
INPUT: A sandwich instance $S = (V, E^1, E^3)$ and an integer k.
QUESTION: Does there exist a sandwich G for S that is proper interval graph with $\omega(G) \le k$?

The proper interval sandwich problem (with no restriction on the clique size) was shown to be NP-complete in [21]. BPIS includes it as a special case by setting $k = |V|$. Hence, BPIS is NP-complete. In §5 we give an $O(f(k) \times |V|^{k-1})$ algorithm for BPIS, where $f(k)$ is a term that varies only with k. Thus, fixing k, one can determine if there exists a proper interval sandwich G with $\omega(G) \le k$ in polynomial time.

We shall also study the following special case of BPIS.

COLORED PROPER INTERVAL GRAPH COMPLETION (CPIC):
INPUT: A graph $G = (V, E)$ and a k-coloring c of G.
QUESTION: Does there exist a proper interval supergraph of G that respects c?

Note that CPIC is a restriction of BPIS: Given a graph $G = (V, E)$ with a k-coloring c, build the sandwich instance $S = (V, E, E^3)$ where $E^3 = \{(u, v) \mid u, v \in V, c(u) = c(v)\}$. Clearly, every supergraph of G which respects the coloring c is a sandwich graph for S that has clique size at most k, and vice versa.

In order to the describe this algorithm we need to extend the definition of graph bandwidth to sandwich instances as follows: Let $S = (V, E^1, E^3)$ be a sandwich instance. As before, a *layout* L of S is a one-to-one function from V onto $\{1, \ldots, n\}$. The *bandwidth of* L is $bw_L(S) = \max_{(u,v)\in E^1}\{|L(u) - L(v)|\}$. A layout L of a sandwich instance S is a *legal layout* if for every $(u, v) \in E^3$ there is no $(x, y) \in E^1$ such that $L(x) \le L(u) < L(v) \le L(y)$. The *bandwidth* of S is the minimum bandwidth over all legal layouts of G. Namely, $bw(S) = \min\{bw_L(S) \mid L \text{ is a legal layout of } S\}$. If S has no legal layout define $bw(S) = \infty$.

Remark 2.5. When $E^3 = \emptyset$, every layout of S is legal and $bw(S) = bw(G^1)$.

2.6. Parameterized complexity. Recently, Downey and Fellows initiated a systematic analysis of the complexity of parameterized decision problems [1, 11, 12]. An instance of a *parameterized decision problem* Π is a pair (x, k) where k is the parameter and x is the input other than the parameter, with $|x| = n$. The interest is usually in parameterized problems that are NP-complete but have polynomial complexity when the parameter k is fixed. This is the situation for CLIQUE, PATHWIDTH, BANDWIDTH, and many other problems. However, the dependence of the complexity on k may vary drastically. For some problems (like PATHWIDTH), algorithms of complexity $f(k)n^{\alpha}$ are known (for some constant α), while for others (like CLIQUE) the best known algorithms require $f(k)n^{g(k)}$ steps. Hence, for fixed k the complexity of the former is polynomial, and in some cases linear, independent of k, while in the latter the degree of the polynomial depends on k. A parameterized problem is called *fixed parameter tractable* if it belongs to the former family; i.e., it is solvable in time complexity $O(f(k)poly(n))$, where f is an arbitrary function of

k only and *poly* is a polynomial in n only, independent of k. The class of all fixed parameter tractable parameterized decision problems is denoted FPT. For example, PATHWIDTH and VERTEX COVER are NP-hard for variable k, but both are in FPT.

Downey and Fellows defined an appropriate notion of reduction for parameterized problems as follows: Let Π_1 and Π_2 be two parameterized decision problems. A *parameterized reduction* from Π_1 to Π_2 is an algorithm that, given an instance (x, k) for Π_1, decides if the answer is "Yes" in $O(f(k)poly(n))$ time, using an oracle for Π_2 on instances with parameter value no greater than $g(k)$, where *poly* is a polynomial in n only and f and g are arbitrary functions of k only. Thus, if Π_1 parametrically reduces to Π_2 and $\Pi_2 \in$ FPT, so is Π_1.

Parameterized decision problems are classified with respect to the W-hierarchy. To introduce it we need some definitions. A *mixed boolean decision circuit* is a boolean circuit with a single output and two types of gates: (1) *small gates:* AND, OR gates with fan-in two and NOT gates; and (2) *large gates:* AND and OR gates with unrestricted fan-in. The *weft* of a circuit C is the maximum number of large gates on an input–output path in C. The *depth* of C is the maximum number of gates (small or large) on an input-output path in C. Let F be a family of mixed boolean decision circuits. The yes-instances of the *parameterized problem associated with* F, denoted by Π_F, are $\{(C, k) \mid C \in F$ accepts an input vector with k ones$\}$. The class $W[t]$ consists of those parameterized decision problems that parametrically reduce to Π_F, where F is a family of mixed boolean decision circuits of bounded depth and weft at most t. This family of classes of parameterized decision problems satisfies FPT $\subseteq W[1] \subseteq W[2] \subseteq \cdots$ and is called the *W-hierarchy.* All containments are conjectured to be proper [11].

A problem Π is *$W[s]$-hard* if every problem in $W[s]$ has a parameterized reduction to Π. If Π is both in $W[s]$ and *$W[s]$-hard*, then Π is *$W[s]$-complete.* Thus, each problem that is hard for $W[s]$ for some $s \geq 1$ is conjectured not to have an algorithm with complexity bound $f(k)n^\alpha$. For example, DOMINATING SET is $W[2]$-complete [11], and BANDWIDTH was recently shown to be $W[t]$-hard for all t [4]. We shall use the latter result in §3. INDEPENDENT SET was shown to be $W[1]$-complete [1]. In §6 we give a parameterized complexity reduction from INDEPENDENT SET to CPIC. Hence, if CPIC has an $f(k)n^\alpha$ algorithm, then so does INDEPENDENT SET, and every other problem in $W[1]$, which is considered unlikely.

3. Characterizations of proper pathwidth.

In this section we show two equivalent characterizations of proper pathwidth. The following observation is analogous to Lemma 2.4.

LEMMA 3.1. *For every graph G, the proper pathwidth of G is one less than the least clique size of any proper interval supergraph of G.*

Proof. Suppose $X = (X_1, \ldots, X_l)$ is a proper path decomposition of G and $pw_X(G) = ppw(G) = k$. On the linear order $1 < 2 < \cdots < l$, let $I(v)$ be the interval $[s(v), e(v)]$. Then $\{I(v)\}_{v \in V}$ is a representation of an interval graph G'. G' is proper since no interval is strictly contained in the other, by property (4) in the definition of a proper path decomposition. G' is a supergraph of G, by property (2). Since X is also a path decomposition of G', Lemma 2.3 implies that every clique in G' must be contained in some X_i. Hence, $\omega(G') \leq k + 1$.

Conversely, suppose $k+1$ is the least clique size of any proper interval supergraph of G. Let $\{I(v)\}_{v \in V}$ be a proper interval representation of such a supergraph $G' = (V, E')$ with $\omega(G') = k+1$, in which all endpoints are distinct, and $I(v) = [l(v), r(v)]$. Order the $2n$ endpoints from left to right as $p_1, \ldots, p_{2n}$. Define $X_i = \{v \in V \mid p_i \in$

$I(v)\}$ for $i = 1, \ldots, 2n$. (Here and throughout $n = |V|$.) We claim that $(X_1, \ldots, X_{2n})$ is a proper path decomposition of G. Checking the four requirements from a proper path decomposition one can observe that (1) is immediate. (2) follows since $E \subseteq E'$, and if $(u, v) \in E'$ and $l(u) < l(v)$, then $l(v) \in I(v) \cap I(u)$. In other words, every edge in E' is represented in some X_i. Since G' is a proper interval graph, it follows that $s(v) = l(v)$ and $e(v) = r(v)$ satisfy (3) and (4). Since the clique size of G' is $k + 1$, each point p_i can meet at most $k + 1$ intervals in the representation. Hence, $\max_i |X_i| \leq k + 1$, so $ppw(G) \leq k$. □

We turn now to the proof of the main theorem in this section. It is actually a special case of a theorem about sandwich instances that will be proved in the next section (see Remark 4.3). However, since this theorem is of independent interest and its proof is simpler and more intuitive, we include its proof below.

THEOREM 3.2. *The bandwidth of a graph equals its proper pathwidth.*

Proof. For the graph $G = (V, E)$ with $ppw(G) = k$, by Lemma 3.1 there exists a supergraph $G' = (V, E')$ of G that is proper interval with clique size $k + 1$. Let $\{I(v)\}_{v \in V}$ be a canonical representation for G', where $I(v) = [l(v), r(v)]$. Define a layout L on G by $L(u) = l(u)$ for all $u \in V$. Suppose $L(u) - L(v) > k$ for some $(u, v) \in E$, where $L(v) = i$. Then $\{L^{-1}(i), \ldots, L^{-1}(i + k + 1)\}$ form a clique of size $k + 2$ in G', a contradiction. Hence, $bw(G) \leq bw_L(G) \leq ppw(G)$.

Conversely, let L be a layout of G so that $bw_L(G) = bw(G) = k$. Form a set of equal-length intervals on the real line $\{I(v)\}_{v \in V}$ where $I(v) = [L(v), L(v) + k]$. Let $G' = (V, E')$ be the intersection graph of that set of intervals. Clearly $E' \supseteq E$ since if $(u, v) \in E$, then $|L(u) - L(v)| \leq k$, so $I(u) \cap I(v) \neq \emptyset$. Since the maximum clique size for G' is at most $k + 1$, using Lemma 3.1, $ppw(G) \leq k$. Hence, $bw(G) \geq ppw(G)$. □

This interesting—and somewhat surprising—equivalence between bandwidth and proper pathwidth allows us to draw several immediate conclusions from the results on bandwidth.

COROLLARY 3.3.

A. *Finding the proper pathwidth is NP-hard, even for binary trees and for caterpillars with hair length at most three.*

B. *Problem* A *can be solved in $O(f(k)n^{k-1})$ time and, in particular, is polynomial when k is fixed.*

C. *Deciding whether the proper pathwidth of a graph is not greater than two can be done in linear time.*

D. *The parametric version of Problem* A *is $W[t]$-hard for every $t > 0$.*

E. *Problem* B *is NP-complete and its parametric version is $W[t]$-hard for every $t > 0$.* □

These results follow immediately from known results on bandwidth, using Theorem 3.2. Result A follows from [16, 34], B follows from [23], C from [16], and D from [4]. Result E follows since Problem B is a generalization of Problem A and thus at least as hard.

4. The bandwidth of a sandwich instance. We saw that one can embed a graph in a proper interval graph G' with $\omega(G') \leq k$ if and only if $bw(G) \leq k$. The question that we consider now is what happens when we cannot use every edge when forming the embedding and we have forbidden edges. In other words, we ask for a characterization of those sandwich instances that have a proper interval sandwich G' with $\omega(G') \leq k$. To state this characterization, we already generalized the notion of bandwidth to sandwich instances in §2 and we use it in the following theorem.

THEOREM 4.1. *Let $S = (V, E^1, E^3)$ be a sandwich instance. There is a proper interval sandwich $\tilde{G}$ in S with $\omega(\tilde{G}) \leq k+1$ if and only if $bw(S) \leq k$.*

Proof. Suppose $bw(S) \leq k$, and let L be a legal layout of S for which $bw_L(S) \leq k$. Let $|V| = n$ and $\epsilon = \frac{1}{n}$. For every vertex $v \in V$ in increasing order of $L(v)$ define recursively an interval $I(v) = [l(v), r(v)]$ as follows.

1. If $L(v) = 1$ define $I(v) = [1, r(v)]$ where $r(v) = \max(\{L(w) \mid (v,w) \in E^1\}) + \epsilon$.
2. Suppose $L(v) = p$, and $I(v)$ has already been defined for every vertex v with $L(v) < p$. Define $I(v) = [p, r(v)]$ where $r(v) = \max(\{L(z) \mid (v,z) \in E^1\} \cup \{r(L^{-1}(p-1))\}) + \epsilon$.

In particular, $L(v) = l(v)$ for every $v \in V$. One can easily prove by induction on p that all the endpoints of the intervals are distinct, and for every two vertices $v, w \in V$, if $L(v) < L(w)$, then $l(v) < l(w)$ and $r(v) < r(w)$. Thus, the intersection graph $\tilde{G} = (V, \tilde{E})$ defined by these n intervals is a proper interval graph. The following observation can easily be proved by induction on the left endpoints of the intervals.

OBSERVATION 4.2. *Let $I(v) = [l(v), r(v)]$ and let $w = L^{-1}(\lfloor r(v) \rfloor)$. There is a vertex u with $L(u) \leq L(v)$ such that $(u, w) \in E^1$.* □

We now prove that $\tilde{G}$ is a sandwich graph for S: By the construction of the intervals, $E^1 \subseteq \tilde{E}$. Suppose $E^3 \cap \tilde{E} \neq \emptyset$. Let (x, y) be an edge in $E^3 \cap \tilde{E}$. Without loss of generality assume that $l(x) < l(y)$ (so $L(x) < L(y)$). Since $(x, y) \in \tilde{E}$, it follows that $r(x) > l(y)$. Let $w = L^{-1}(\lfloor r(x) \rfloor)$. According to Observation 4.2 there is an edge $(u, w) \in E^1$, and u satisfies that $L(u) \leq L(x)$. This contradicts the assumption that L is legal since $(x, y) \in E^3$, $(u, w) \in E^1$, and $L(u) \leq L(x) < L(y) \leq L(w)$.

Suppose that $\tilde{G}$ has a clique C with more than $k+1$ vertices. Let x and y be the vertices in C with minimum and maximum values, respectively, under the layout L. Since $|C| > k+1$, $L(y) - L(x) > k$. $(x, y) \in \tilde{G}$ implies that $r(x) > L(y) = l(y)$, so according to Observation 4.2 there is an edge $(u, w) \in E^1$ where $L(u) \leq L(x)$ and $L(w) = \lfloor r(x) \rfloor \geq L(y)$, and that is a contradiction to the assumption that $bw_L(S) \leq k$.

To prove the converse, assume that there is a proper interval sandwich $\tilde{G} = (V, \tilde{E})$ for S with $\omega(\tilde{G}) \leq k+1$. Let $\{I(v)\}_{v \in V}$ be a canonical proper interval representation of $\tilde{G}$ where $I(v) = [l(v), r(v)]$. Define a layout L of S by $L(v) = l(v)$ for all $v \in$V. We claim first that L is a legal layout. Suppose on the contrary that there is an edge $(x, y) \in E^3$ and an edge $(u, v) \in E^1$ such that $L(u) \leq L(x) < L(y) \leq L(v)$. $\tilde{G}$ is a sandwich graph for S, so (u, v) must belong to $\tilde{E}$ and thus $l(v) < r(u)$. Since $\tilde{G}$ is proper interval, the left endpoints must appear in the same order as the right endpoints in the realization, namely $r(u) \leq r(x) < r(y) \leq r(v)$. Hence, all four intervals intersect at $l(v)$ and thus $\{u, x, y, v\}$ induce a clique in $\tilde{G}$. In particular, $(x, y) \in \tilde{E}$, a contradiction.

Finally, we show that $bw_L(S) \leq k$. Suppose, on the contrary that $bw_L(S) > k$. Let (u, v) be an E^1-edge such that $L(u) - L(v) > k$. Let $C = \{x \mid L(v) \leq L(x) \leq L(u)\}$. Note that $|C| > k+1$. $\tilde{G}$ is a sandwich graph for S, so $(u, v) \in \tilde{E}$. Arguments similar to the ones in the previous paragraph imply that C induces a clique in $\tilde{G}$, contradicting the assumption that $\omega(\tilde{G}) \leq k+1$. □

Remark 4.3. One can obtain Theorem 3.2 as a corollary to the theorem above by applying Theorem 4.1 to the sandwich instance $S = (V, E, \emptyset)$. In that case, every supergraph of G is a sandwich graph for S, so Theorem 3.2 follows by Remark 2.5.

5. A polynomial algorithm for fixed *k*. In this section we show that deciding if a given sandwich instance S admits a proper interval sandwich graph with clique size at most k can be done in $O(f(k)n^{k-1})$ steps. Hence, Problems B and C are polynomial when k is fixed. Our algorithm is based on the equivalence established in the previous sections with the bandwidth problem. For fixed k, Saxe [40] gave an $O(n^{k+1})$ algorithm that determines if the bandwidth of an n-vertex graph is at most k. Gurari and Sudborough [23] reduced its complexity to $O(n^k)$. We generalize that algorithm to the problem of deciding if the bandwidth of a sandwich instance is at most k. We assume without loss of generality that in the input S each vertex is incident on at most $2k$ E^1-edges and that $G^1 = (V, E^1)$ is connected.

We need the following definitions. Let $S = (V, E^1, E^3)$ be a sandwich instance. A *partial layout* of S is a 1–1 mapping from some nonempty $V' \subseteq V$ to $\{1, \ldots, |V'|\}$. V' is called the *domain* of L and denoted $D(L)$. In this section we shall use the term *layout* for a partial layout and *complete layout* for a layout L with $D(L) = V$. The *bandwidth* of L is $bw_L(S) = \max\{|L(u) - L(v)| \mid (u,v) \in E^1, u, v \in D(L)\}$. If $e = (x,y) \in E^1$, $x \in D(L)$ and $y \notin D(L)$, then e is called a *dangling edge* in L. The set of all dangling edges in L will be denoted $d(L)$. A vertex in the domain of L is called *active* if it is incident on a dangling edge. Let $r = \min(\{i \mid L^{-1}(i) \text{ is active}\})$. The sequence $(L^{-1}(r), L^{-1}(r+1), \ldots, L^{-1}(|D(L)|))$ is called the *active region* of L and denoted $R(L)$. Note that the dangling edges of L are exactly the edges in the cut $(D(L), V - D(L))$ in G^1. The connectivity assumption guarantees that $d(L) = \emptyset$ if and only if the layout is complete.

A layout L is called *legal* if the following requirements hold.

1. For each E^3-edge with $u, v \in D(L)$ there is no $(x,y) \in E^1$ such that $x, y \in D(L)$ and $L(x) \le L(u) < L(v) \le L(y)$.

2. No E^3-edge has both endpoints in $R(L)$.

A layout L' *augments* the layout L if $D(L) \subseteq D(L')$ and $L'(u) = L(u)$ for all $u \in D(L)$. L can be augmented to a complete legal layout L' with $bw_{L'}(S) \le k$ only if (1) L is legal, (2) $bw_L(S) \le k$, and (3) $|R(L)| \le k$. We thus restrict the algorithm to construct only layouts in Λ_k where

$$\Lambda_k = \{L \mid L \text{ is a legal layout such that } bw_L(S) \le k \text{ and } |R(L)| \le k\}.$$

For $L_1, L_2 \in \Lambda_k$, define $L_1 \approx L_2$ if $R(L_1) = R(L_2)$ and $d(L_1) = d(L_2)$. $\approx$ is an equivalence relation that partitions Λ_k into *classes*. For such a class C with $L \in C$, $R(C) = R(L)$ and $d(C) = d(L)$ are uniquely defined. Moreover, the assumption that G^1 is connected implies that equivalent layouts have identical domains, so $D(C)$ is also well defined for every class C. We call the pair $\Sigma(C) = (R(C), d(C))$ the *signature* of the class C, and we call a signature *valid* if a class with that signature exists. Given a sandwich instance S and integer k, $bw(S) \le k$ if and only if there is a class C in Λ_k such that $\Sigma(C) = (\emptyset, \emptyset)$. This class contains all the legal layouts in Λ_k.

5.1. The algorithm. The algorithm is based on the dynamic programming technique. It generates systematically all classes in Λ_k, until the search is exhausted or a class corresponding to a complete legal layout with bandwidth at most k is found. It is based on the following observation.

OBSERVATION 5.1. *Let $X = (x_1, \ldots, x_l)$, $l \le k$, and let $\hat{d} \subseteq E^1$ be a set of edges, each incident on one vertex from X. There is a class C' in Λ_k with $\Sigma(C') = (X, \hat{d})$ and $|D(C')| > 1$ if and only if for every $1 \le i \le l-1$, $(x_i, x_l) \notin E^3$ and there exists a class C in Λ_k such that $R(C) = (z_1, \ldots, z_j, x_1, \ldots, x_{l-1}), 0 \le j \le k - l + 1$, and*

$$d(C) = \hat{d} + \{(x_l, y) \in E^1 \mid y \in R(C)\} - \{(x_l, y) \in E^1 \mid (x_l, y) \in \hat{d}\}.$$

Proof. Suppose a class C' with $|D(C')| > 1$ exists, and let $L' \in C'$. Since L' is legal, for every $1 \le i \le l-1$, $(x_i, x_l) \notin E^3$. Since C' is in Λ_k, $bw_{L'}(S) \le k$. Clearly $L'(x_l) = |D(L')|$. Let L be a layout with $D(L) = D(L') - \{x_l\}$ such that L' augments

L. It is easy to see that L is legal and $bw_L(S) \leq k$. Thus, the class to which L belongs will be the required class C. The proof of the converse is similar. □

Under the conditions of the observation we shall say that C' *extends* C. Hence, the observation says that a nonsingleton class exists if and only if it extends another class.

Let $V = \{v_1, \ldots, v_n\}$. The algorithm starts by initializing a queue Q to contain n classes $C_1, \ldots, C_n$ where $R(C_i) = \{v_i\}$ and $d(C_i)$ contains all the E^1-edges incident on v_i. In each iteration a class is removed from Q and every class in Λ_k that extends it and was not treated before is generated and added to Q. This process ends in one of two possible ways.

1. If $bw(S) \leq k$, then the class C whose active region is empty (and then, by the connectivity of G^1, $D(C) = V$) is generated in some stage of the algorithm. When this happens the algorithm stops with a positive answer.
2. If $bw(S) > k$, then the algorithm will stop with a negative answer when its queue becomes empty.

A prototype of the algorithm is depicted in Figure 1.

```
ALGORITHM BANDWIDTH($S, k$);

/* $S = (V, E^1, E^3)$ is a sandwich instance */
/* initialization */
for each $v \in V$ :
        1. Create an equivalence class $C$
        with $R(C) = \{v\}$ and $d(C) = \{(v, y) \mid (v, y) \in E^1\}$.
        2. Mark $C$ and add it to the queue $Q$.
begin
        while $Q \neq \emptyset$ do :
        /* iteration */
        begin
                    3. Remove $C$ from $Q$.
                    4. Let $T$ be the set of classes in $\Lambda_k$ that extend $C$.
                    5. for each $C' \in T$ do :
                         5.1 if $R(C') = \emptyset$ output "$bw(S) \leq k$" and stop.
                         5.2 if $C'$ is unmarked mark $C'$ and add it to $Q$.
        end
        4. Output "$bw(S) > k$" and stop.
end
```

FIG. 1. *An algorithm for determining if a sandwich instance has bandwidth at most k.*

Let us explain how the set of all classes that extend C (denoted T in step 4 of the algorithm of Figure 1) can be generated. Distinguish the following two cases.

(A) If $|R(C)| = k$ there is at most one class C' that extends C. If $R(C) = (x_1, \ldots, x_k)$, such C' can exist only if exactly one dangling edge, say (x_1, y), is incident on x_1. In that case, C' must have $R(C') = (x_i, \ldots, x_k, y)$, where x_i is the first vertex in $R(C)$ that is connected by a dangling edge to a vertex other than y, and $d(C') = d(C) - \{(x_j, y) \mid (x_j, y) \in d(C)\} + \{(y, z) \in E^1 \mid z \notin D(C)\}$. Class C' exists if and only if y is not connected by an E^3-edge to any vertex in the set $\{x_2, \ldots, x_k\}$.

(B) If $|R(C)| = l < k$, up to $|V - D(C)|$ classes may extend C: Let $R(C) = (x_1, \ldots, x_l)$ and let $y \in V - D(C)$. Suppose x_i, $1 \leq i \leq l$, is the first vertex in $R(C)$ that is connected to a vertex other than y by a dangling edge. Then, if y is not connected by an E^3-edge to any vertex in $\{x_j | 1 \leq j \leq l\}$, the class C' with $R(C') =$

$(x_i, \ldots, x_l, y)$ and $d(C') = d(C) - \{(x_j, y) \mid (x_j, y) \in d(C)\} + \{(y, z) \mid z \notin D(C)\}$ exists and extends C.

5.2. Implementation. We describe an implementation of the algorithm that runs in time and space complexity $O(f(k)n^k)$. A class C in Λ_k will be represented by its signature $\Sigma(C)$. We assume that the E^3 edges are recorded in a vertex–vertex incidence matrix, so that the existence of an E^3 edge between two given vertices can be checked in constant time. Constructing an incidence matrix from a representation of E^3 by adjacency lists takes $O(n^2)$ time and space, so for $k \geq 2$ such a stage would not increase the worst case bounds of the algorithm. (The case $k = 1$ is trivial since $bw(S) = 1$ if and only if the graph G^1 is a path.)

LEMMA 5.2. *Given a class C and a vertex $y \notin D(C)$, one can verify whether there exists a class C' with $D(C') = D(C) \cup \{y\}$ in constant time assuming k is fixed. If C' exists, its signature can also be constructed in constant time.*

Proof. Since $|R(C)| \leq k$, verifying that y is not connected by an E^3 edge to any vertex in the active region takes constant time. To compute $\Sigma(C')$ given $\Sigma(C)$, one must copy each vertex from the region of C starting from the first vertex that is connected by a dangling edge to a vertex other than y. For each such vertex, E^1-edges that connect it to y should be removed from the new list of dangling edges. Since $|d(C)|$ is bounded from above by a function of k, this stage takes constant time. Vertex y should be added as the last vertex in the region. The set of new dangling edges, $\{(y, z) \mid z \notin D(C)\}$, can be constructed in constant time even though $D(C)$ is not represented explicitly since $\{(y, z) \mid z \notin D(C)\} = \{(y, z) \mid z \notin R(C)\}$. This construction takes constant time since the number of E^1-edges incident on y is at most $2k$. □

Let us now analyze the overall complexity of the algorithm for fixed k. Recall that in G^1 all the degrees are bounded by $2k$. Hence, for every active region R the number of possible sets of dangling edges with active region R is bounded by a constant. Therefore, the number of classes with active region of size k is $O(n^k)$, and the number of classes whose active region is smaller than k is $O(n^{k-1})$.

The algorithm inserts into the queue only classes that are new, i.e., previously unmarked. In order to do that without an increase in the time complexity one can maintain an array of all possible class candidates and their status as marked or unmarked, using $O(n^k)$ space. The marks enable the algorithm to encounter a class only once.

For a class with an active region of size k, there is only one possible class that extends it and by Lemma 5.2 a constant time is needed to check whether this class exists and if so to generate it. For a class with a smaller active region, there are up to n possible extensions. All the vertices in $V - D(C)$ are candidates for extension of C, but $D(C)$ is not maintained explicitly. To find that set, note that after deleting all dangling edges from $G^1 = (V, E^1)$, one obtains a disconnected graph $\tilde{G}^1$ in which $D(C)$ and $V - D(C)$ must be disconnected. The vertices in $V - D(C)$ constitute exactly these connected components of $\tilde{G}^1$ that do not contain an active vertex. Enumerating all candidates for extension can be done by depth first search of the appropriate components in $\tilde{G}^1$ in $O(n)$ steps [41], since $|E^1| = O(n)$. Checking each candidate and adding it to Q if it actually exists can be done in a constant time by Lemma 5.2. Thus, we obtain that the overall time complexity of the algorithm is $O(n^k)$ using no more than $O(n^k)$ space. The following theorem summarizes our findings.

THEOREM 5.3. *Given a sandwich instance S the algorithm determines whether $bw(S) \leq k$ in $O(f(k)n^k)$ time and space.* □

Together with Theorem 4.1 we obtain the following corollary.

COROLLARY 5.4. *Problem* B (*and hence also Problem* C) *can be solved in* $O(f(k)n^{k-1})$ *time and space and, in particular, in polynomial time and space when k is fixed.* □

By maintaining a representative layout with every class generated by the algorithm, one can obtain a complete legal layout with bandwidth not greater than k when the algorithm halts with a positive answer. The cost is an increase by a factor of n in the space complexity of the algorithm. The proof of the "if" part of Theorem 4.1 demonstrates how to obtain from that layout a unit interval sandwich graph in $O(n)$ time.

6. Colored proper interval graph completion is $W[1]$-hard. In this section we prove the following theorem.

THEOREM 6.1. *The Colored Proper Interval Graph Completion Problem is hard for* $W[1]$.

To prove Theorem 6.1 we describe a parameterized reduction from INDEPENDENT SET. Given a graph $G = (V, F)$ and an integer k as inputs to INDEPENDENT SET, we build a graph $G' = (V', F')$ colored using only $f(k) = 8k + 7$ colors. The graph G' is built such that it has a unit interval supergraph that respects the same coloring if and only if G has a size k independent set. Assume that $V = \{1, \ldots, n\}$ and $F = \{e_1, \ldots, e_m\}$. For convenience, we assume that the edge $e_t = (i, j)$ is denoted such that $i < j$.

6.1. Constructing G'. Let us first give an overview of the construction (see Figure 2): It consists of a *platform*—a long chain in which certain vertices are replaced by cliques, with subblocks corresponding to edges, and of k *floating paths*—each one is a long chain corresponding to a vertex in the independent set. Each path also consists of subblocks corresponding to edges. The platform and the floating paths are all connected at their endpoints, which forces their intervals to overlap in the representation of any unit interval graph completion. An additional decision component called *arrow* is connected to each edge-subblock in the platform. It is designed so that it prevents the complete placement of the k floating paths on top of the platform if and only if the graph does not contain an independent set of size k.

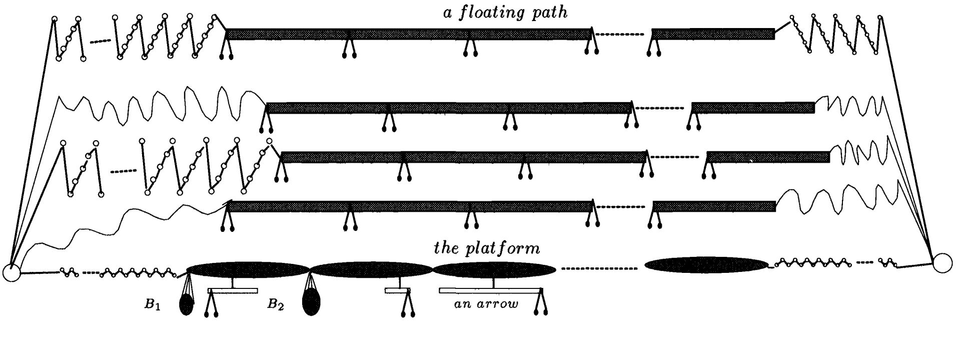

FIG. 2. *The graph G'.*

To describe these components we introduce the following definitions. Let $G^1 = (V^1, E^1)$ and $G^2 = (V^2, E^2)$ be two colored graphs. A colored graph G is a *concatenation* of G^1 and G^2 if it can be constructed by taking their union and identifying pairs of vertices, where in each pair one vertex is from V^1, the other from V^2, and their colors are identical. The concatenation is completely specified by these pairs of vertices. We shall occasionally omit listing the pairs in a concatenation when they are clear from the context. A graph G is a *concatenation* of $G_1, \dots, G_s$ if one can construct it by concatenating a graph H with G_s where H is a concatenation of $G_1, \dots, G_{s-1}$. If G is a concatenation of the colored graphs $H_1, \dots, H_s$, we denote by $H_j(G)$ the copy of H_j in G. If X is a set of vertices in a graph G, then $X(G)$ will denote the subgraph induced by X in G. For x a vertex in H and H' some copy of H, $x(H')$ will denote the vertex x in the copy H' of H. Greek letters will denote colors, small Latin letters will denote vertices, and capital Latin letters will usually denote graphs.

6.1.1. The floating paths. We first construct k isomorphic but differently colored floating paths. Each path consists of left and right ends and a middle part. Figure 3 gives an overview of the structure of such a path.

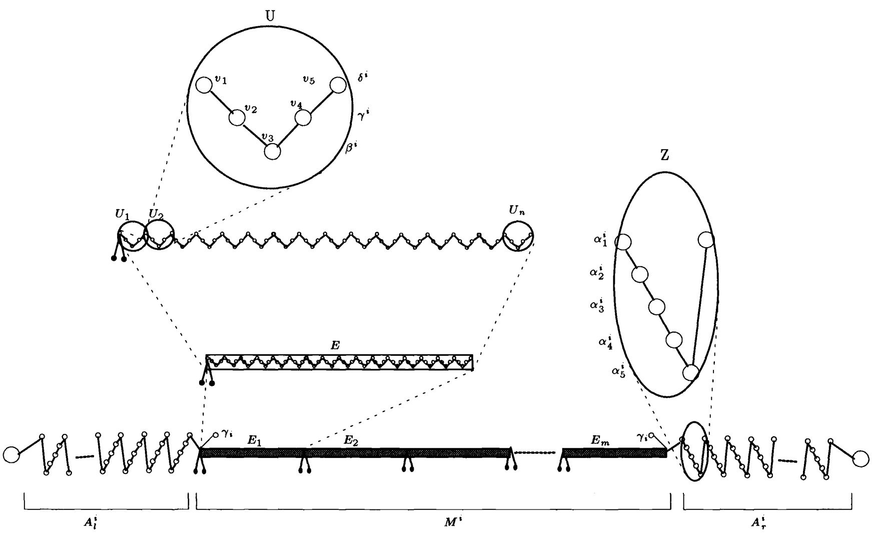

FIG. 3. *The structure of the floating path P^i.*

First we describe the construction of the middle part, which is denoted M. This part will overlap with the middle part of the platform in a representation of any unit interval completion. Let U denote a path with five vertices: $v_1, v_2, \dots, v_5$. Color it such that $c(v_1) = c(v_5) = \delta$, $c(v_3) = \beta$, $c(v_2) = c(v_4) = \gamma$. Take n copies of this colored U path denoted $U_1, U_2, \dots, U_n$ and *concatenate* them by identifying $v_5(U_j)$ with $v_1(U_{j+1})$ for every j, $1 \leq j \leq n-1$. Denote the resulting path E. Now, take m copies of E denoted $E_1, \dots, E_m$ and concatenate them by identifying $v_5(U_n(E_j))$ with $v_1(U_1(E_{j+1}))$ for $1 \leq j \leq m-1$. This resulting graph is the middle part M. Equivalently, one can think about M as a concatenation of nm copies of U or as a path of $4nm+1$ vertices colored periodically $\delta, \gamma, \beta, \gamma, \delta, \gamma, \dots$.

Next we describe the right and left ends of a floating path. These identical parts actually let the path "float" on the platform; i.e., using them we gain some flexibility in the starting position of M relative to the platform. Let Z denote a path on six vertices denoted $z_1, \dots, z_6$. Color it such that $c(z_1) = c(z_6) = \alpha_1$, $c(z_i) = \alpha_i, 2 \leq i \leq 5$.

Concatenate n copies of Z denoted $Z_1, \ldots, Z_n$ by identifying $z_6(Z_j)$ with $z_1(Z_{j+1})$ for every $1 \leq j \leq n-1$. Call the resulting graph A.

Complete a construction of a path P as follows. Take two copies of A, A_l, and A_r (we shall call these the *Left Accordion* and the *Right Accordion*, respectively) and one copy of M. Connect $z_1(Z_1(A_l))$ by an edge to $v_1(U_1(E_1))$ and connect $z_1(Z_1(A_r))$ by an edge to $v_5(U_n(E_m))$.

Each of the k floating paths denoted $P^1, \ldots, P^k$ is isomorphic to the path P above, where in P^i a private set of colors $\alpha_1^i, \alpha_2^i, \ldots, \alpha_5^i, \delta^i, \gamma^i, \beta^i$ replaces $\alpha_1, \alpha_2, \ldots, \alpha_5, \delta, \gamma, \beta$, respectively. Denote the subpaths of P^i as the corresponding subpaths of P with the additional superscript i (e.g., M^i, E_j^i).

On each P^i hang vertices colored ξ as follows: two such vertices are connected to $v_1(U_1(E_j^i))$ for every $1 \leq j \leq m$. We shall call them the *cherries* of E_j^i. Also, connect two vertices colored γ^i one to $v_1(U_1(E_1^i))$ and the other to $v_5(U_n(E_m^i))$.

6.1.2. The platform. Similar to a floating path, the platform also consists of three parts: a middle part similar to the M part of a floating path and two flanking end parts. Certain vertices in the paths are replaced by cliques in the platform, the end parts are shorter, and colored to allow little flexibility in any unit interval representation. The structure of the platform is depicted in Figure 4.

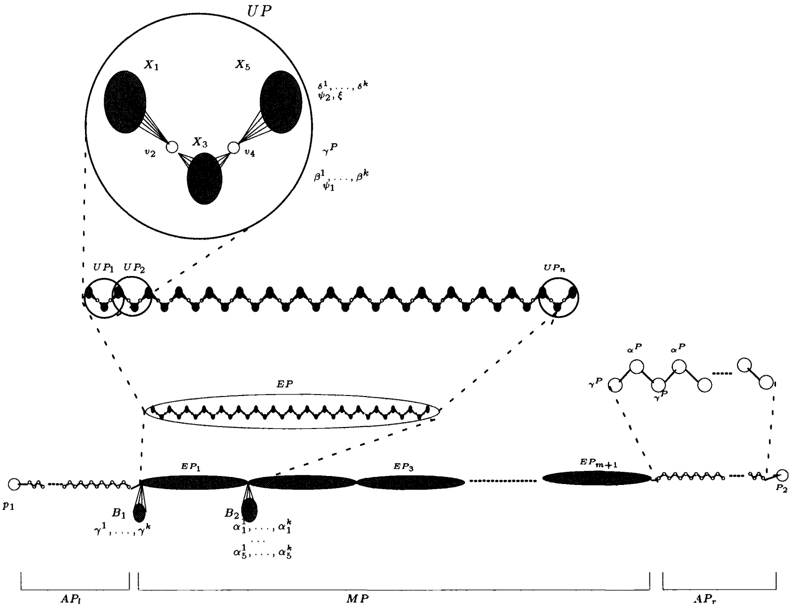

FIG. 4. *The structure of the platform.*

The main component of the platform is the graph UP that can be constructed from the path U as follows. Replace v_3 with a clique X_3 on $k+1$ vertices, and replace v_1 and v_5 with cliques X_1, X_5, respectively, each containing $k+2$ vertices. Connect each vertex of X_3 to v_2 and v_4, each vertex of X_1 to v_2, and each vertex of X_5 to v_4.

Color UP as follows: $c(v_2) = c(v_4) = \gamma^P$. X_3 is colored such that it contains one vertex colored β^i for every $1 \leq i \leq k$ and a vertex colored ψ_1. X_1 and X_5 are colored such that they contain one vertex colored δ^i for every $1 \leq i \leq k$, a vertex colored ψ_2, and a vertex colored ξ.

To construct the middle part of the platform, first take n copies of UP denoted $UP_1, \ldots, UP_n$ and concatenate them by identifying vertices colored identically in $X_5(UP_j)$ and $X_1(UP_{j+1})$ for every $1 \leq j \leq n-1$. Denote the resulting graph EP. Next, take $m+1$ copies of EP, denoted $EP_1, \ldots, EP_{m+1}$, and concatenate them by identifying like-colored vertices in $X_5(UP_n(EP_j))$ and $X_1(UP_1(EP_{j+1}))$ for every $1 \leq j \leq m$. Denote the resulting concatenation MP. One can also refer to MP as a concatenation of $n(m+1)$ copies of UP obtained by identifying vertices colored identically in $X_5(UP_j)$ and $X_1(UP_{j+1})$ for every $1 \leq j \leq n(m+1)-1$.

To define the flanking ends of the platform, let AP be a path with $n-1$ vertices $z_1^p, \ldots, z_{n-1}^p$, colored such that $c(z_i^p) = \gamma^p$ if i is odd and $c(z_i^p) = \alpha^p$ for i even. (As we shall see later, this coloring forces such a path to "spread out" with no additional overlap in any representation.) Take MP and two copies of AP, AP_l, and AP_r (which will be called the *Left end* and the *Right end* of the platform). Connect $z_1^p(AP_l)$ to all vertices of $X_1(UP_1(EP_1))$ and connect all vertices of $X_5(UP_n(EP_{m+1}))$ to $z_1^p(AP_r)$. The construction of the platform is now complete.

6.1.3. The arrows. An additional graph called an arrow that is "almost a path" is generated for each edge in the original graph G. Each arrow is connected to a certain clique in the subpath of the platform corresponding to its edge. The arrow (and, in particular, two special vertices at one of its ends) is designed to force the independence of the vertices that the t floating paths will define. Figure 5 demonstrates the details of this part in the construction.

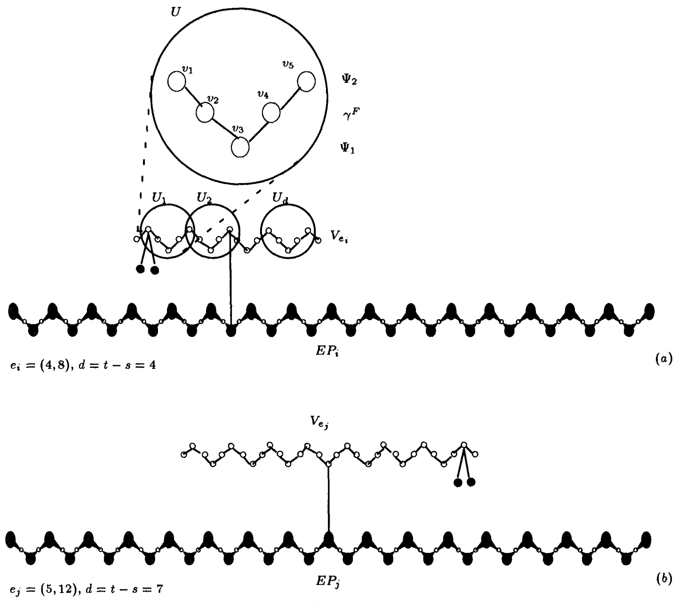

FIG. 5. *An arrow and its location on the platform:* (a) $d = t - s$ *is even,* $s \notin K$; (b) $d = t - s$ *is odd,* $s \in K$, $t \notin K$.

For each edge $e = (s,t) \in F$ construct an *arrow* V_e as follows. Set $d = t - s$; and let $U_1, \ldots, U_d$ be d copies of a path U colored such that $c(v_1) = c(v_5) = \psi_2$, $c(v_3) = \psi_1$, and $c(v_2) = c(v_4) = \gamma^F$. Concatenate them by identifying $v_5(U_j)$ with $v_1(U_{j+1})$ for every $1 \leq j \leq d-1$. Call $v_1(U_1(V_e))$ the *head* of the arrow and call $v_5(U_d(V_e))$ the *tail* of the arrow. Connect two vertices colored ξ to the head, call them the *cherries* of the arrow V_e. Connect one vertex colored γ^F to the head of the path and connect another such vertex to the tail. Let $m(V_e)$ be the middle vertex of the arrow, i.e., $m(V_e) = v_5(U_{\frac{d}{2}}(V_e))$ if d is even and $m(V_e) = v_3(U_{\frac{d+1}{2}}(V_e))$ if d is odd. Note that $c(m(V_e)) = \psi_2$ if d is even, and otherwise $c(m(V_e)) = \psi_1$.

For each edge e_j connect $m(V_{e_j})$ to all the vertices of $X_3(UP_{\frac{t+s}{2}}(EP_j))$ if d is even (note that there is no vertex colored ψ_2 in $X_3(UP_{\frac{t+s}{2}}(EP_j))$) and to all the vertices of $X_5(UP_{\frac{t+s-1}{2}}(EP_j))$ if d is odd (note that there is no vertex colored ψ_1 in $X_5(UP_{\frac{t+s-1}{2}}(EP_j))$.

6.1.4. Completing the construction. To complete the construction of G' take two more cliques B_1 and B_2: B_1 contains k vertices colored with the k colors $\gamma^i, 1 \leq i \leq k$; and B_2 contains $5k$ vertices colored α^i_j, $1 \leq j \leq 5$, $1 \leq i \leq k$. Connect every vertex of B_1 with every vertex of $X_1(UP_1(EP_1))$ and every vertex of B_2 with every vertex of $X_1(UP_1(EP_2))$. The role of these two cliques is to force the representation of each middle part in a floating path to start in between their representations in any unit interval graph completion.

Finally, to connect the k floating paths and the platform, introduce two vertices p_1, p_2 colored θ^p. Connect $z_6(Z_n(A^i_l))$, $1 \leq i \leq k$, and $z^p_{n-1}(AP_l)$ to p_1, and connect $z_6(Z_n(A^i_r))$, $1 \leq i \leq k$, and $z^p_{n-1}(AP_r)$ to p_2.

The overall structure of G' is drawn schematically in Figure 2.

6.2. Validity of the construction. The construction described is clearly polynomial. We will now prove that G' can be turned to a unit interval graph by adding edges that respect its coloring if and only if G has a size k independent set.

6.2.1. $\Leftarrow$ (if). First suppose that G has a size k independent set K. We shall show how to represent each vertex in G' by a closed unit interval on the real line such that the following two requirements hold.

1. Intervals that correspond to vertices with the same color do not overlap.
2. Intervals that correspond to adjacent vertices in G' do overlap.

The intersection graph defined by this representation of the intervals will be the required properly colored unit interval supergraph of G'.

For every vertex $x \in V'$, $I(x)$ will denote the interval that corresponds to it. If this unit interval is placed between c and $c+1$ on the real line denote it by $I(x) = [l(x), r(x)] = [c, c+1]$. For the two intervals I_1 and I_2, define that $I_1 < I_2$ if and only if $r(I_1) < l(I_2)$. For I an interval and b a point on the real line, define $I < b$ $(b < I)$ if and only if $r(I) < b$ $(b < l(I))$.

In every copy of a U path or UP graph in our construction $c(v_2) = c(v_4)$. Thus, in any representation that fulfills the requirements above $I(v_2) \cap I(v_4) = \emptyset$. A representation of a U path or a UP graph is called *right-oriented* if and only if $I(v_2) < I(v_4)$ and otherwise it is *left-oriented.* We shall occasionally say that "a graph is right-oriented" for short when we actually mean that its representation is right oriented.

Let Y be a UP graph on the platform and fix a right-oriented representation for Y. With respect to this representation define two points on the real line, $Right(Y)$ and $Left(Y)$, as $Right(Y) = \min(\cap_{x \in X_5(Y)} I(x))$ and $Left(Y) = \max(\cap_{x \in X_1(Y)} I(x))$. Note that since $X_5(Y)$ and $X_1(Y)$ are cliques, $\cap_{x \in X_5(Y)} I(x) \neq \emptyset$ and $\cap_{x \in X_1(Y)} I(x) \neq \emptyset$, and thus $Right(Y)$ and $Left(Y)$ are well defined. Say that a unit interval I *is in* Y and denote it $I \lhd Y$ if and only if $Left(Y) < I < Right(Y)$. For a vertex x in G', x *is in* Y if and only if $I(x) \lhd Y$. Denote it $x \lhd Y$.

6.2.1.1. Placing the platform. The whole representation will occupy the interval [0, 4nm + 6n]. First assign $I(p_1) \mapsto [0, 1]$. For every vertex v on the platform whose distance (length of shortest path) from p_1 is d assign $I(v) = [d, d+1]$. Thus, the intervals of the vertices in the Left end are assigned to the right of the interval $I(p_1)$; then, further to the right, the intervals of the vertices in MP are placed; and finally, the intervals corresponding to the vertices in the Right end of the platform are placed. In particular, $I(p_2) = [4nm + 6n - 1, 4nm + 6n]$. Interval $I(p_2)$ will be the rightmost interval of the representation. Note that all the intervals corresponding to the vertices in one of the cliques X_1,X_3, or X_5 in any of the UP graphs on the platform are assigned to the same position. Also note that the representation of all the UP graphs on the platform is right-oriented.

Remark 6.2. Let Y be a UP graph on the platform. Obviously $Right(Y) - Left(Y) = 3$. Moreover, for every vertex $x \in X_5(Y) \cup \{v_4(Y)\}$, $Right(Y) \in I(x)$ and for every vertex $x \in X_1(Y) \cup \{v_2(Y)\}$, $Left(Y) \in I(x)$. Since there is no vertex colored ξ in X_3 but there is one in X_1 and X_5, the maximum number of other vertices colored ξ that can be placed in each UP graph on the platform is two.

6.2.1.2. Placing the cliques B_1 and B_2. Assign the vertices of B_1 to the same position as the vertices of $X_1(UP_1(EP_1))$. The vertices of B_2 are assigned to the same position as the vertices of $X_1(UP_1(EP_2))$.

6.2.1.3. Placing the arrows. Let $e_j = (s,t)$ be an edge in G, $d = t - s$, and let V_{e_j} be the corresponding arrow. Assign $m(V_{e_j})$ to the same position as that of the clique on the platform to which it is connected.

Since K is an independent set, it cannot contain both s and t. If $s \notin K$ place the arrow such that the representation of each U path on the arrow is right-oriented and $v_1(U_i(V_{e_j})) \lhd UP_{s+i-1}(EP_j)$ for every $1 \leq i \leq d$. The two cherries of V_{e_j} that are connected to its head are placed in $UP_s(EP_j)$ (see Figure 5(a)). If $s \in K$ then place the arrow such that the representation of each U path is left-oriented and $v_1(U_i(V_{e_j})) \lhd UP_{t-i+1}(EP_j)$ for every $1 \leq i \leq d$. In the latter case the two cherries are placed in $UP_t(EP_j)$ (see Figure 5(b)).

One should note that the cherries of the arrow of (s,t) are placed in $UP_s(EP_j)$ if $s \notin K$ and in $UP_t(EP_j)$ otherwise. Thus, $UP_i(EP_j)$ does not contain vertices colored ξ originating from an arrow, for every $1 \leq j \leq m$ and $i \in K$.

6.2.1.4. Placing the floating paths. Let $K = \{i_1, \ldots, i_k\}$. The j-th floating path, P^j, will correspond to i_j. First M^j is placed and then the left and right accordions A^j_l and A^j_r are placed as follows.

Each U path in P^j is placed such that its representation is right-oriented and $v_1(U_l(M^j)) \lhd UP_{i_j+l-1}(MP)$ for $1 \leq l \leq n \times m$. Thus, the whole representation of M^j spreads from $UP_{i_j}(EP_1)$ to $UP_{i_j}(EP_{m+1})$ on the platform. Recall that to each $v_1(U_1(E^j_s))$, $1 \leq s \leq m$, two cherries are connected. These cherries are placed together with $v_1(U_1(E^j_s))$ in $UP_{i_j}(EP_s)$.

This placement can be carried out without violating requirement 1 above since in each of the UP graphs, X_3 does not contain a vertex colored γ^j and X_1, X_5 do not contain vertices colored β^j. One also must check that in each UP graph no more than two vertices colored ξ are placed. This is indeed the situation since for every $1 \leq j \leq m$ the arrows insert vertices colored ξ only to $UP_l(EP_j)$ for indices $l \notin K$. On the other hand, the floating paths insert vertices colored ξ to $UP_l(EP_j)$ for every $l \in K$ and $1 \leq j \leq m$. Since all the other vertices in the arrows have colors that do not appear in P^j, property 1 is satisfied.

The left accordion A^j_l should be placed between $I(p_1)$ and $I(v_1(U_1(M^j)))$. According to the placement of the paths, $n+1 < l(I(v_1(U_1(M^j)))) < 5n-1$. Analyzing the coloring of A^j_l one can verify that for each number x such that $n+1 < x < 5n-1$

a representation of A_l^j that spreads out on an interval whose length is x can be constructed. Such a representation can be placed between $I(p_1)$ and $I(v_1(U_1(M^j)))$ since there is no other vertex colored α_i^j, $1 \leq i \leq 5$, placed there. A representation of the right accordion can similarly be constructed and placed between $I(v_5(U_{n\times m}(M^j)))$ and $I(p_2)$.

The intervals that correspond to the two vertices colored γ^j connected to $v_1(U_1(E_1^j))$ and $v_5(U_1(E_m^j))$ are placed with $I(v_1(U_1(E_1^j)))$ and $I(v_5(U_1(E_m^j)))$ in $UP_{i_j}(EP_1)$ and $UP_{i_j}(EP_{m+1})$, respectively.

6.2.2. ⇒ (only if). Suppose G' has a unit interval supergraph G'' that respects the coloring of G'. Our goal now is to prove that under these conditions there exists an independent set of size k in G. We actually show that the structure and coloring of G' force every representation of G'' to look very similar to the one we built in the previous part of the proof.

Let $\{I(x)\}_{x\in V'}$ be a representation of G'' by closed unit intervals. Since $c(p_1) = c(p_2) = \theta^p$, $I(p_1) \cap I(p_2) = \emptyset$. One can assume without loss of generality that $I(p_1) < I(p_2)$ (otherwise just reverse the entire representation).

The platform contains paths from p_1 to p_2 in which every second vertex is colored γ^P. Every such path starts with AP_l, ends with AP_r, and in between contains all the vertices colored γ^P in MP, a representative from $X_1(UP_i(MP))$ and $X_3(UP_i(MP))$, for each i, $1 \leq i \leq n(m+1)$, and a representative from $X_5(UP_{n(m+1)}(MP))$. Since every second vertex on such a path is colored γ^P, its representation cannot "fold back" and all the intervals of the vertices colored γ^P must be disjoint and appear (from left to right) in the same order as they appear in the path. This immediately implies that the representation of each UP graph on the platform is right-oriented.

Let X and Y be two right-oriented UP graphs or two identically colored right-oriented U paths. We say that X is *to the left of* Y or, equivalently, Y is *to the right of* X if and only if $I(v_4(X)) < I(v_2(Y))$. Denote this situation by $X \prec Y$ or $Y \succ X$. (We use a different notation here since the sets of intervals corresponding to X and Y may overlap.) The existence of a path between p_1 and p_2 on which every second vertex is colored γ^P implies that there must exist a linear order between the UP graphs in the platform, i.e., $UP_j(MP) \prec UP_{j+1}(MP)$ for every $1 \leq j \leq n(m+1)-1$.

Let $b_1 = \max(\cap_{x\in B_1 \cup X_1(UP_1(EP_1))} I(x))$ and $b_2 = \min(\cap_{x\in B_2 \cup X_1(UP_1(EP_2))} I(x))$. Note that the assumption $I(p_1) < I(p_2)$ implies $I(p_1) < b_1 < b_2 < I(p_2)$.

LEMMA 6.3. *$b_1 < I(v_1(U_1(M^i))) < b_2$ for every $1 \leq i \leq k$.*

Proof. First we prove that $b_1 < I(v_1(U_1(M^i)))$ for every $1 \leq i \leq k$. Fix i. Clearly $b_1 \notin I(v_1(U_1(M^i)))$, since $X_1(UP_1(EP_1))$ contains a vertex y colored δ^i, the same color of $v_1(U_1(M^i))$, such that $b_1 \in I(y)$. Suppose on the contrary that $I(v_1(U_1(M^i))) < b_1$. Recall that B_1 contains a vertex z colored γ^i such that $b_1 \in I(z)$. Since every second vertex on M^i is colored γ^i, the whole representation of M^i will spread out to the left of b_1. In particular, $I(v_5(U_{n\times m}(M^i))) < b_1$. This implies that the representation of the right accordion A_r^i should intersect b_2. That is a contradiction since it means that two intervals of vertices colored α_j^i for some $1 \leq j \leq 5$ overlap in b_2.

One can similarly show the other inequality for every i. First, note that $b_2 \notin I(v_1(U_1(M^i)))$ since $X_1(UP_1(EP_2))$ contains a vertex z with the same color as $v_1(U_1(M^i))$ such that $b_2 \in I(z)$. Assume on the contrary that $b_2 < I(v_1(U_1(M^i)))$. Thus, $I(p_1) < b_2 < I(v_1(U_1(M^i)))$ and the representation of the left accordion A_l^i intersects b_2, a contradiction. □

LEMMA 6.4.

(a) *$U_j(M^i)$ is right-oriented for every $1 \leq j \leq nm$ and $1 \leq i \leq k$.*

(b) *$U_j(M^i) \prec U_{j+1}(M^i)$ for every $1 \le j \le nm-1$ and $1 \le i \le k$.*

Proof. Fix i. Since in M^i every second vertex is colored γ^i, its representation cannot "fold back." Thus, either all the U paths on P^i are right-oriented and satisfy $U_j(M^i) \prec U_{j+1}(M^i)$, $1 \le j \le nm-1$, or they are all left-oriented and satisfy $U_{j+1}(M^i) \prec U_j(M^i)$, $1 \le j \le nm-1$.

Suppose the second possibility occurs. Together with Lemma 6.3 this implies that the whole representation of M^i is to the left of b_2. In particular, $I(v_5(U_{nm}(M^i))) < b_2$ which means that the representation of the right accordion A^i_r intersects b_2 and that is a contradiction. □

Remark 6.5. Each vertex in M^i (including the first and the last) that is not colored γ^i has two adjacent vertices that are colored γ^i. This forces the endpoints of the intervals in each U path in M^i to satisfy $l(I(v_1)) < l(I(v_2)) < l(I(v_3)) < l(I(v_4)) < l(I(v_5))$. Similarly the placement of the intervals corresponding to vertices in a UP graph on the platform must be such that $l(I(x_1)) < l(I(v_2)) < l(I(x_3)) < l(I(v_4)) < l(I(x_5))$ for every $x_1 \in X_1$, $x_3 \in X_3$, $x_5 \in X_5$.

So far we proved that the representation of each M^j starts, at its left end, in some $UP_{i_j}(EP_1)$ (i.e., $v_1(U_1(M^j)) \lhd UP_{i_j}(EP_1)$) for some $1 \le i_j \le n$ and spreads to the right. Recall that to each $v_1(U_1(E^j_s)$, $1 \le j \le k$, $1 \le s \le m$, two cherries colored ξ are connected. The intervals corresponding to them must be placed in the same UP graph as $v_1(U_1(E^j_s))$ itself, since there are vertices colored ξ in X_1 and X_5 of every UP graph.

Three vertices colored ξ cannot be placed in the same UP graph. Thus, for every $j_1 \ne j_2$, M^{j_1} and M^{j_2} must start in different UP graphs. We obtain that the starting positions of M^j, $1 \le j \le k$, in EP_1 on the platform define a set of k distinct vertices $K = \{i_1, \dots, i_k\}$ in G. We shall prove that K is an independent set.

In the following lemma we analyze further the structure of a floating path's representation and prove that it must be intertwined in the platform in a very specific manner.

LEMMA 6.6. *If $v_1(U_j(M^i)) \lhd UP_s(MP)$, then $v_1(U_{j+1}(M^i)) \lhd UP_{s+1}(MP)$ for every $1 \le j \le nm-1$ and $1 \le s \le n(m+1)-1$.*

Proof. Suppose that $v_1(U_j(M^i)) \lhd UP_s(MP)$. According to Lemma 6.4, $v_1(U_{j+1}(M^i))$ cannot be in $UP_l(MP)$ for some $l < s$. Suppose the claim is false. There are two possibilities for failure.

(1) $v_1(U_{j+1}(M^i)) \lhd UP_s(MP)$. This implies, according to Remark 6.5 and Lemma 6.4, that $v_3(U_j(M^i))$, which is colored β^i, must also be in $UP_s(MP)$. Let z be the vertex colored β^i in $X_3(UP_s(MP))$. Clearly $I(z) \cap I(v_3(U_j(M^i))) = \emptyset$. Assume that $I(z) < I(v_3(U_j(M^i))) < Right(UP_s(MP))$. Since $Right(UP_s(MP)) - r(z) \le |I(v_4(UP_s(MP)))| = 1$, this assumption leads to a contradiction. Assuming that $Left(UP_s(MP)) < I(v_3(U_j(M^i))) < I(z)$, since $l(z) - Left(UP_s(MP)) \le |I(v_2(U_j(M^i)))| = 1$, this also implies a contradiction. Thus $v_1(U_{j+1}(M^i))$ cannot be also in $UP_s(MP)$.

(2) $Right(UP_{s+1}(MP)) < I(v_1(U_{j+1}(M^i)))$. Let x and y be the vertices colored γ^i in $X_1(UP_{s+1}(MP))$ and $X_5(UP_{s+1}(MP))$, respectively. Since we assumed that $v_1(U_j(M^i)) \lhd UP_s(MP)$, the order of the intervals in the representation is $I(v_1(U_j(M^i))) < I(x) < I(y) < I(v_1(U_{j+1}(M^i)))$. Let z be the vertex colored β^i in $X_3(UP_{s+1}(MP))$. According to Remark 6.5 $l(x) < l(z) < r(z) < r(y)$, one gets that $z \lhd U_j(M^i)$. Consider now the interval $I(v_3(U_j(M^i)))$. Since $c(v_3(U_j(M^i))) = c(z)$, $I(z) \cap I(v_3(U_j(M^i))) = \emptyset$. The two possibilities $I(z) < I(v_3(U_j(M^i)))$ and $I(v_3(U_j(M^i))) < I(z)$ will both lead to a contradiction since $l(I(v_1(U_{j+1}(M^i)))) - r(I(v_3(U_{j+1}(M^i))))$ and $l(I(v_3(U_j(M^i)))) - r(I(v_1(U_j(M^i))))$ cannot be greater than

one. □

The immediate conclusion from this lemma and the discussion preceding it is that if M^j starts in $UP_{i_j}(EP_1)$, then $v_1(U_1(E_l^j)) \lhd UP_{i_j}(EP_l)$ for every $1 \leq l \leq m$. Thus, for every l, $1 \leq l \leq m$, $UP_{i_j}(EP_l)$ contains two cherries of P^j.

In order to prove that K is an independent set we should now check how the arrows are placed in our representation. Let V_{e_j} be an arrow corresponding to the edge $e_j = (s,t)$ and again let $d = t-s$. Recall that if d is even $v_5(U_{\frac{d}{2}}(V_{e_j})) = v_1(U_{\frac{d}{2}+1}(V_{e_j}))$ is connected to the vertices of $X_3(UP_{\frac{t+s}{2}}(EP_j))$. Thus, $v_1(U_{\frac{d}{2}+1}(V_{e_j})) \lhd UP_{\frac{t+s}{2}}(EP_j)$ and the representation of $U_{\frac{d}{2}+1}(V_{e_j})$ is either right-oriented or left-oriented. If d is odd, then $v_1(U_{\frac{d+1}{2}}(V_{e_j})) \lhd UP_{\frac{t+s-1}{2}}(EP_j)$ if the representation of $U_{\frac{d+1}{2}}(V_{e_j})$ is right-oriented, otherwise $v_1(U_{\frac{d+1}{2}}(V_{e_j})) \lhd UP_{\frac{t+s+1}{2}}(EP_j)$.

Analogously to Lemma 6.4 the following lemma holds with respect to the arrows.

LEMMA 6.7. *For every arrow V_e where $e = (s,t)$, all $U_j(V_e)$, $1 \leq j \leq t-s$, have the same orientation. Moreover, if the $U_j(V_e)$ are all right-oriented, then $U_j(V_e) \prec U_{j+1}(V_e)$ for every $1 \leq j < t-s$; otherwise, $U_{j+1}(V_e) \prec U_j^i(V_e)$ for every $1 \leq j < t-s$.* □

Let V_e be an arrow corresponding to the edge $e = (s,t)$. Define V_e to be *right-oriented* (*left-oriented*) if $U_j(V_e)$ is right-oriented (left-oriented) for every $1 \leq j \leq t-s$.

The arrows also must be intertwined in the platform, and the following lemma can be proved analogously to Lemma 6.6.

LEMMA 6.8. *Let V_{e_j} be an arrow corresponding to the edge $e_j = (s,t)$. If V_{e_j} is right-oriented, then $v_1(U_i(V_{e_j})) \lhd UP_{s+i-1}(EP_j)$ for every $1 \leq i \leq t-s$; and if V_{e_j} is left-oriented, then $v_1(U_i(V_{e_j})) \lhd UP_{t-i+1}(EP_j)$ for every $1 \leq i \leq t-s$.* □

Now suppose on the contrary that K is not an independent set, i.e., there is an edge $e_j = (i_s, i_t)$ where $i_s, i_t \in K$. In the discussion following Lemma 6.6 we already noted that each of $UP_{i_s}(EP_j)$ and $UP_{i_t}(EP_j)$ contains cherries originating in the floating paths P^s and P^t. But from Lemma 6.8 it follows that the two cherries connected to the arrow V_{e_j} must be placed together either in $UP_{i_s}(EP_j)$ or in $UP_{i_t}(EP_j)$. Since one cannot place more than two vertices colored ξ in any UP graph, we get a contradiction. Hence, K is an independent set of size k in G, and the proof is complete.

Since the parameterized reduction of Theorem 6.1 is actually a Karp reduction, we can also conclude with the following corollary.

COROLLARY 6.9. *The Colored Unit Interval Graph Completion Problem is NP-complete.* □

7. Concluding remarks.

In this paper we studied proper interval graph completion problems with small clique size. The problems arise in physical mapping of DNA. We showed that the Proper Interval Sandwich Problem with fixed bound k on the clique size is polynomial. On the other hand, we showed that a restriction of the problem, namely, the Colored Unit Interval Graph Completion Problem, with k viewed as a parameter is $W[1]$-hard and, hence, does not have an $O(f(k)n^\alpha)$ algorithm unless all problems in $W[1]$ (including, for example, INDEPENDENT SET) have one. This result also implies the NP-completeness of the problem.

Regarding the Proper Interval Graph Completion Problem With Minimum Clique Size, we showed that the problem is equivalent to BANDWIDTH and also to the new parameter *proper pathwidth*, which was defined here. This unexpected equivalence may be useful to other problems, since it allows one to apply tools from interval graph theory to bandwidth problems and vice versa. In fact, it has already proved its usefulness in our results here. It implied, using previous results on BANDWIDTH, that the problem when k is fixed is polynomial but $W[t]$-hard for all t in its parameterized version. This last hardness result is somewhat surprising since the analogous problem with interval graphs replacing proper interval graphs is known to be *linear* for fixed k and, in particular, fixed parameter tractable.

The algorithms presented here for fixed k are still impractical for the range of k required in the physical mapping problem. However, our results demonstrate that incorporating more biological restrictions into the model may cause the complexity to decrease. An interesting line of research is to introduce further realistic restrictions that will lead to efficient practical algorithms for physical mapping.

Acknowledgments. We thank Mike Fellows and Andrzej Proskurowski for their helpful comments on an early version of this manuscript. We also thank two anonymous referees for their careful remarks and suggestions.
